
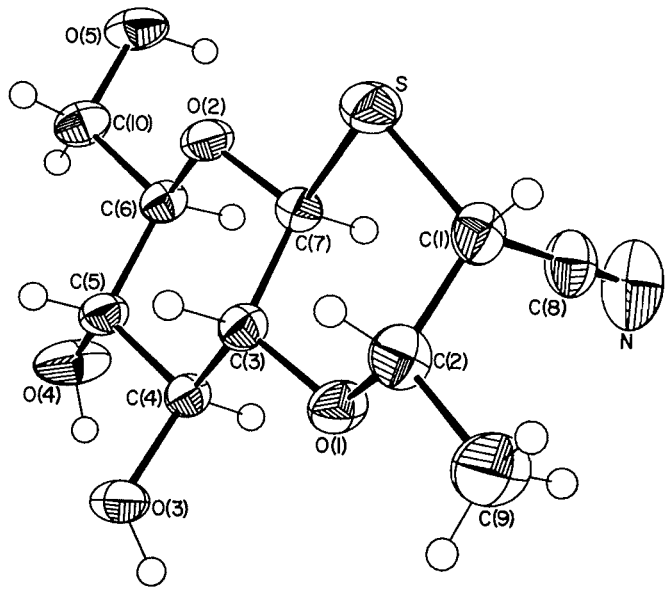

FIG. 1. ORTEP perspective drawing of merosinigrin showing the atomic numbering scheme. Thermal ellipsoids are drawn at the 50% probability level and H atoms are included as spheres of radius 0.1 Å. H atoms are labelled according to the atom to which they are bonded; thus H(1) is bonded to C(1), etc.

three such bonds are found: O(3)—H(3)O . . . O(2) (at 1 + x, y, z), O(3) . . . O(2) = 2.810(4) Å, and H(3)O . . . O(2) = 2.03 Å; O(4)—H(4)O . . . O(5) (at 1 + x, y, z), O(4) . . . O(5) = 2.736(4) Å, and H(4)O . . . O(5) = 1.90 Å; O(5)—H(5)O . . . O(3) (at 1 − x, y, 1 − z), O(5) . . . O(3) = 2.728(4) Å, and H(5)O . . . O(3) = 1..83 Å.

The molecular structure consists of two fused 6-membered rings, each in a chair conformation. The chirality at C(1) and C(2) is *R* and *S*, respectively, relative to the known chirality of the β-D-glucopyranose ring. The cyano function adopts an axial disposition and, as there was evidence for C—H exchange at C(1) without epimerization (1), we conclude that this orientation is thermodynamically preferred and constitutes an example of the anomeric effect. So far as we are aware, merosinigrin provides the first illustration of this effect in a cyanothiane system, although it is well established for a variety of thianes carrying other polar substituents (8).

BRIAN R. JAMES, DAVID DOLPHIN, T. W. LEUNG, FREDERICK W. B. EINSTEIN, and ANTHONY C. WILLIS. Can. J. Chem. **62**, 1238 (1984).

Some ruthenium(III) complexes Ru(porp)(L)X and [Ru(porp)L_2]X, (porp = dianion of octaethylporphyrin (OEP) or tetraphenylporphyrin (TPP); L = PPh_3, P"Bu_3; X = Br, Cl) have been prepared from the precursor complexes Ru(porp)L_2 or Ru(porp)(CO)L using as oxidant the halogens, or air in the presence of the hydrogen halides. The X = PF_6 salts can be made using $Et_3O^+PF_6^-$ as oxidant. Ruthenium(II) porphyrin π-cation radical intermediates have sometimes been detected. The X-ray crystal structure of Ru(OEP)(PPh_3)Br, the first reported for a ruthenium(III) porphyrin, reveals that metal is displaced 0.049 Å from the plane of the pyrrole N atoms towards the phosphine. The Ru(OEP)(py)Br and [Ru(OEP)(py)CH_3CN]PF_6 complexes have been synthesized from Ru(OEP)(CO)py. The ruthenium(III) complexes are low-spin as shown by magnetic and esr data. Optical and ^1H nmr data, the latter showing large paramagnetic shifts, are also presented.

BRIAN R. JAMES, DAVID DOLPHIN, T. W. LEUNG, FREDERICK W. B. EINSTEIN et ANTHONY C. WILLIS. Can. J. Chem. **62**, 1238 (1984).

On a préparé quelques complexes du ruthénium(III), soit le Ru(porp)(L)X et le [Ru(porp)L_2]X, (porp = le dianion de l'octaéthylporphyrine (OEP) ou de la tétraphénylporphyrine (TPP); L = PPh_3, p"Bu_3; X = Br, Cl), à partir des complexes précurseurs Ru(porp)L_2 ou Ru(porp)(CO)L et en utilisant comme oxydants soit les halogènes soit l'air en présence d'halogénures d'hydrogène. On peut préparer les sels du type X = PF_6 en utilisant le $Et_3O^+PF_6^-$ comme oxydant. On a quelquefois décelé des radicaux cations ruthénium(II) porphyrines comme intermédiaires. La structure cristalline du Ru(OEP)(PPh_3)Br, la première structure rapportée pour un complexe de ruthénium(III) prophyrine, révèle que la phosphine attire le métal qui est déplacé de 0,049 Å par rapport aux atomes d'azote du plan du pyrrole. On a synthétisé les complexes de Ru(OEP)(py)Br et de [Ru(OEP)(py)CH_3CN]PF_6 à partir du Ru(OEP)(CO)py. Le spin des complexes de ruthénium(III) est faible comme le révèlent les données magnétiques et de la rpe. On présente également les données optiques ainsi que de la rmn du ^1H qui montrent de grands déplacements paramagnétiques.

[Traduit par le journal]

Introduction

Interest in the chemistry of ruthenium porphyrin systems continues to grow. Certain ruthenium(II) complexes in solution show reactivity towards small gas molecules such as O_2, CO, and N_2 (1–3), and have been shown to have catalytic activity in oxidation and decarbonylation reactions (4, 5). Ruthenium(III) systems can catalytically utilize iodosylbenzene as an oxidant for saturated and unsaturated hydrocarbons, and isolated oxo-ruthenium(IV) porphyrin cation radical intermediates appear to be good models for the active enzymatic species utilized during cytochrome P450 oxidations (6, 7).

Our continuing developments in the synthetic area of ruthenium porphyrin chemistry (8, 9) are reported in this paper, which describes the synthesis and characterization of some neutral and ionic ruthenium(III) complexes, including the X-ray structure of Ru(OEP)(PPh_3)Br,[2] which has been used as a precursor for oxo-ruthenium(IV) species (7).

Experimental

The materials, methods, and instrumentation used have been largely described in earlier papers (8, 9). The complexes Ru(OEP)(CO)EtOH (8), Ru(TPP)(CO)EtOH (10), Ru(OEP)(CO)py (11), and Ru(porp)L_2: porp = OEP, TPP; L = PPh_3, P"Bu_3 (8, 9), were synthesized according to the literature procedures. No special precautions were taken generally to exclude trace water, although the CH_2Cl_2 was distilled from calcium hydride (8).

Conductivity measurements were performed in CH_3NO_2 solution. Evans' method (12) was used to determine the magnetic susceptibility of Ru(TPP)(PPh_3)Br (in CH_2Cl_2); other susceptibilities were measured on a Faraday balance (13). Diamagnetic corrections for the porphyrin were taken from the literature (14, 15), and otherwise calculated using Pascal's constants (16, 17). The ^1H nmr spectra were recorded on a Varian XL-100 operating in the FT-mode. The esr spectra were recorded in frozen toluene at 77 K on a Varian E-3.

Preparation of complexes

The yields obtained in the synthetic procedures described below, which were carried out under Ar unless noted otherwise, were usually in the 60–80% range. The uv/visible spectra of the isolated complexes are given in Table 1.

Bromo(octaethylporphinato)(triphenylphosphine)ruthenium(III)

To 500 mg of Ru(OEP)(PPh_3)$_2$ (0.43 mmol) dissolved in 75 mL of CH_2Cl_2 was added dropwise 10 mL of Br_2 (0.2 g, 1.2 mmol) in CH_2Cl_2. After stirring the solution for 1 h, the solvent was removed and the residue redissolved in 3 mL CH_2Cl_2 prior to chromatography on silica gel (1 cm × 10 cm, 5% H_2O). A red band was eluted with CH_2Cl_2/MeOH (1:1 v/v) to yield a solid, which was redissolved in 5 mL of CH_2Cl_2 and reprecipitated as purple-red crystals by addition of 30 mL hexane. A non-eluted green band remained on the top of the column.

An alternative synthetic procedure is to use, instead of the Br_2 solu-

TABLE 1. Optical spectral data for some ruthenium(III) porphyrin complexes in CH_2Cl_2 solution

Complex	λ_{max} (nm) (log ϵ)
Ru(OEP)(PPh_3)Br	510(4.05), 405(4.86), 360sh(4.50)
Ru(OEP)(PPh_3)Cl	510(3.97), 403(4.90)
$[Ru(OEP)(PPh_3)_2]^+PF_6^-$	520br(4.15), 393(4.98)
$[Ru(OEP)(PPh_3)_2]^+PF_6^-$ [a]	520(4.08), 410(4.80), 370sh(4.60)
Ru(TPP)(PPh_3)Br	525(4.03), 413(5.10), 345(4.47)
$[Ru(OEP)(P''Bu_3)_2]^+Br^-$ [b]	515(4.00), 412(4.69), 363(4.76)
Ru(OEP)($P''Bu_3$)Br [b]	510(4.00), 408(4.92), 360(4.67)
Ru(OEP)($P''Bu_3$)Cl	510(3.97), 403(4.90)
Ru(OEP)(py)Br	535sh(4.10), 506(4.15), 397(4.95)
$[Ru(OEP)(py)CH_3CN]^+PF_6^-$	525br(4.12), 395(4.86)

[a] Spectrum obtained in the presence of excess PPh_3.
[b] The data agree well with our earlier work (8).

tion, a saturated CH_2Cl_2 solution of HBr and carry out the reaction in air; the work-up procedure is unchanged. Electron spin resonance $g_\perp$ = 2.28, $g_\parallel$ = 1.98; μ = 2.0 BM; nmr[3] δ_{TMS} ($CDCl_3$): +2.7 (3H, *p*-H), +0.5 (24H, CH_3), −8.8 (8H, CH_2), −9.9 (4H, meso-H), −14.6 (12H, *o*- and *m*-H), −18.5 (8H, CH_2); ms *m/e*: 896 (100), Ru(OEP)PPh_3^+; 715, 713 (20), Ru(OEP)Br^+; 634 (100), Ru(OEP)$^+$. *Anal.* calcd. for $C_{54}H_{59}N_4BrPRu$: C 66.45, H 6.09, N 5.74, P 3.17; found: C 65.81, H 6.49, N 5.49, P 2.98.

Crystals for X-ray work were obtained by slowly evaporating a 1:1 CH_2Cl_2/hexane solution over a few days, and contained a solvent hexane molecule.

Chloro(octaethylporphinato)(triphenylphosphine)ruthenium(III)

The complex was prepared by the procedure described above for the bromo analogue except that saturated solutions of Cl_2 or HCl were used; esr $g_\perp$ = 2.30, $g_\parallel$ = 1.98; μ = 2.1 BM; nmr[3] δ_{TMS} ($CDCl_3$): +2.4 (3H, *p*-H), +0.5 (24H, CH_3), −8.9 (8H, CH_2), −9.9 (4H, meso-H), −14.6 (12H, *o*- and *m*-H), −18.3 (8H, CH_2); ms *m/e*: 896 (100), Ru(OEP)PPh_3^+; 634 (90) Ru(OEP)$^+$; 448 (80), Ru(OEP)-$(PPh_3)^{2+}$. *Anal.* calcd. for $C_{54}H_{59}N_4ClPRu$: C 69.62, H 6.38, N 6.01, P 3.32; found: C 69.40, H 6.91, N 5.51, P 3.17.

(Octaethylporphinato)bis(triphenylphosphine)ruthenium(III) hexafluorophosphate

To 300 mg of Ru(OEP)(PPh_3)$_2$ (0.26 mmol) dissolved in 50 mL of CH_2Cl_2 was added 0.1 g $Et_3O^+PF_6^-$ (0.40 mmol) together with a few drops of H_2O. After stirring for 30 min, the solution was evaporated and the resulting residue redissolved in 10 mL CH_2Cl_2. Addition of 50 mL of hexane allowed for crystallization of the product. Infrared $\nu(PF_6)$: 560, 840 cm^{-1}; Λ = 135 mho cm^2 mol^{-1}. *Anal.* calcd. for $C_{74}H_{72}N_4P_3F_6Ru$: C 66.35, H 5.72, N 4.30; found: C 65.53, H 5.76, N 4.20.

Bromo(tetraphenylporphinato)(triphenylphosphine)ruthenium(III)

This complex was prepared from Ru(TPP)(PPh_3)$_2$ by the Br_2 or HBr procedure described above for the OEP analogue; μ = 1.9 BM; ms *m/e*: 1056 (1), Ru(TPP)(PPh_3)Br^+; 976 (100), Ru(TPP)(PPh_3)$^+$; 795, 793 (15), Ru(TPP)Br^+; 714(60), Ru(TPP)$^+$. *Anal.* calcd. for $C_{62}H_{43}N_4PBrRu\cdot\frac{1}{2}CH_2Cl_2$: C 68.34, H 4.04, N 5.10; found: C 68.21, H 3.96, N 5.25.

*(Octaethylporphinato)bis(tri-*n*-butylphosphine)ruthenium(III) tribromide (or bromide)*

To 500 mg of Ru(OEP)($P''Bu_3$)$_2$ (0.48 mmol) dissolved in 75 mL hexane was added dropwise 5 mL of Br_2 (0.2 g, 1.2 mmol) in hexane. The microcrystalline product that separated was filtered, washed with pentane, and dried *in vacuo*. Electron spin resonance $g_\perp$ = 2.34, $g_\parallel$ = 1.98; Λ = 110 mho cm^2 mol^{-1}. *Anal.* calcd. for $C_{60}H_{98}N_4P_2Br_3Ru$: C 56.38, H 7.72, N 4.38, Br 18.77; found: C 55.86, H 7.72, N 4.46, Br 18.7. A saturated solution of HBr in hexane could be used aerobically in lieu of the Br_2 solution, in which case the complex was isolated as the bromide salt, [Ru(OEP)($P''Bu_3$)$_2$]Br, that has been prepared previously from the bis(phosphine) precursor using CH_2Cl_2 solutions of Br_2 (8).

*Bromo(octaethylporphinato)(tri-*n*-butylphosphine)ruthenium(III)*

This complex may be synthesized via Br_2 oxidation of the isolated Ru(OEP)(CO)$P''Bu_3$ complex as described earlier (8), or via the same precursor formed *in situ* as described here.

To 500 mg of Ru(OEP)(CO)EtOH (0.71 mmol) dissolved in 30 mL CH_2Cl_2 was added dropwise a solution of $P''Bu_3$ (0.5 mL phosphine in 20 mL CH_2Cl_2), until the Soret absorption indicated complete formation of Ru(OEP)(CO)$P''Bu_3$ (the 393-nm band of the ethanol precursor is replaced by one at 408 nm). A solution of Br_2 (0.1 g, 0.6 mmol in 10 mL CH_2Cl_2) was then added dropwise. The reaction solution turned green initially but soon became red. After 15 min of stirring, the solvent was removed to give a residue that was redissolved in 5 mL of CH_2Cl_2; addition of 25 mL hexane deposited crystals of the product in quantitative yield. Electron spin resonance $g_\perp$ = 2.31, $g_\parallel$ = 1.98; μ = 2.3 BM; Λ = 4.0 mho cm^2 mol^{-1}; ms *m/e*: 916 (20), Ru(OEP)($P''Bu_3$)Br^+; 836 (100), Ru(OEP)($P''Bu_3$)$^+$; 715, 713 (5), Ru(OEP)Br^+; 634 (30), Ru(OEP)$^+$. *Anal.* calcd. for $C_{48}H_{71}N_4BrPRu$: C 62.93, H 7.81, N 6.12; found: C 62.33, H 7.91, N 6.30.

*Chloro(octaethylporphinato)(tri-*n*-butylphosphine)ruthenium(III)*

This complex was prepared in quantitative yield by the *in situ* method described above for the bromo analogue, but using for the oxidation a saturated solution of Cl_2 in CH_2Cl_2. Mass spectra *m/e*: 870 (10), Ru(OEP)($P''Bu_3$)Cl^+; 836 (100), Ru(OEP)($P''Bu_3$)$^+$; 634 (20), Ru(OEP)$^+$. *Anal.* calcd. for $C_{48}H_{71}N_4ClPRu\cdot\frac{1}{2}CH_2Cl_2$: C 63.73, H 7.95, N 6.13; found: C 64.46, H 8.09, N 5.84.

Bromo(octaethylporphinato)(pyridine)ruthenium(III)

A solution of the Ru(OEP)(CO)py complex (500 mg, 0.67 mmol in 10 mL CH_3CN and 200 mL toluene) was irradiated in a Hanovia apparatus for 4 h (a medium pressure 450-W mercury vapour bulb); the optical spectrum then showed complete absence of the carbonyl-pyridine species (18) and new absorption maxima at 530, 497, and 406 nm attributable to Ru(OEP)(py)(CH_3CN) (11). Solvent was removed under vacuum, and the resulting solid was dissolved in 25 mL CH_3CN and oxidized by adding dropwise 5 mL of CH_3CN containing 0.1 g Br_2 (0.6 mmol). After stirring for 30 min, the solution was evaporated to dryness and the resulting solid redissolved in 5 mL of CH_2Cl_2 prior to addition of 30 mL of hexane. The product crystallized out. Mass spectra *m/e*: 715, 713 (20), Ru(OEP)Br^+; 634 (100), Ru(OEP)$^+$. *Anal.* calcd. for $C_{41}H_{49}N_5BrRu$: C 62.11, H 6.23, N 8.83; found: C 61.68, H 5.94, N 8.60.

Acetonitrile(octaethylporphinato)(pyridine)ruthenium(III) hexafluorophosphate

To 200 mg of Ru(OEP)(py)Br (0.25 mmol) dissolved in 30 mL of CH_3CN was added 0.1 g $AgPF_6$ (0.40 mmol) as a suspension in 5 mL CH_3CN. After stirring for 15 min, the solution was evaporated to dryness, and 3 mL of CH_2Cl_2 was then added to the residue. After filtering off the AgBr, 15 mL hexane was added to the filtrate in order to effect crystallization of the product. μ = 2.3 BM; Λ = 120 mho cm^2 mol^{-1}; ir: $\nu(PF_6)$: 560, 840 cm^{-1}; ν(CN) not observed. *Anal.* calcd. for $C_{43}H_{52}N_2F_6PRu$: C 57.45, H 5.83, N 9.35; found: C 57.13, H 5.72, N 8.69.

X-Ray crystallographic analysis

Crystals of Ru(OEP)(PPh_3)Br·solvate were obtained as very thin needles. A section 0.104 × 0.678 × 0.054 mm was cut from one of the thickest needles and mounted on a glass fibre with its longest dimension approximately parallel to the fibre axis. X-ray photographs (CuKα radiation) revealed Laue $2/m$ symmetry and systematic extinctions $0k0$: $k = 2n + 1$, $h0l$: $l = 2n + 1$, uniquely determining the space group as $P2_1/c$.

The crystal was transferred to a Picker FACS-I four-circle auto-

[3] The paramagnetic convention is used; signals downfield from Me_4Si are referred to as negative and those upfield as positive.

For personal use only.

mated diffractometer employing graphite-crystal monochromatized MoKα radiation. Accurate cell dimensions were obtained by a least-squares analysis of the setting angles of 18 reflections ($16.5° < 2\theta < 21.9°$), widely separated in reciprocal space, which were accurately centered on the detector.

Crystal data:

$C_{54}H_{59}N_4BrPRu(C_6H_{14})$ fw = 1062.26

Monoclinic, $P2_1/c$, $a = 13.037(3)$, $b = 15.372(3)$, $c = 29.577(7)$ Å, $\beta = 115.19(2)°$, $V = 5363.7$ Å^3, $Z = 4$, $D_o = 1.32$, $D_c = 1.315$ g cm^{-3}, μ(MoKα) = 10.9 cm^{-1}, λ(MoKα$_1$) = 0.7093 Å.

The intensities of unique set of data (*hkl* and $\bar{h}kl$) were collected for $3° \leq 2\theta \leq 40°$ using a $\theta-2\theta$ scan running at 2° min^{-1}. The scan width was 1.6° plus a correction for $\alpha_1-\alpha_2$ dispersion. Stationary-crystal stationary-detector background counts were taken for 0.25 × scan time on each side of every scan to determine the intensity and the associated standard deviation.[4] A total of 5042 reflections were measured of which 2536, with $I > 2.3\ \sigma(I)$, were regarded as observed and used in structure solution and refinement. Two standards were measured after every 80 reflections. They showed a 6% decrease in intensity over the length of data collection, so data were scaled accordingly. ψ-scans of two axial reflections showed only small variations in intensity as the crystal was rotated. This had been anticipated as the crystal cross-section was small and μ was also small. Consequently, no absorption correction was applied to the data.

The structure was solved by heavy-atom methods and refined by block-diagonal least-squares. The coordinates of the Ru and Br atoms were determined from a Patterson synthesis. Successive refinement and difference Fourier syntheses led to the location of all atoms of the OEP and PPh_3 groups. Those H atoms which could be located geometrically were included in subsequent refinement at their calculated positions, but their parameters were not refined.[5] Refinement with anisotropic temperature factors for Ru, Br, and P (others isotropic) converged to $R = 0.10$.[6] A difference map at this stage revealed eight peaks which were not attached to the Ru(OEP)(PPh_3)Br molecule. These were assigned as C atoms and included in refinement with variable occupancies: some gave reduced occupancies, others retained values of about 1.0. The occupancies of these atoms were then fixed at appropriate values for subsequent refinement. Their identities could not be unambiguously determined but, taking into account which solvents were used in the preparation and recrystallization, reasonable assignments can be made. Five of them, along with their inversion images, constitute a ten-numbered "molecule" with terminal members having occupancies of about 0.5. We believe that this arises from disordered packing of *n*-hexane molecules in this region of the unit cell which, on average, gives an inversion centre at (0,0,0). The remaining unidentified atoms are connected to their symmetry-related images to produce a six-membered chain which, once again, is thought to be *n*-hexane, though some of the bond lengths and angles do not fit this model very well. Poor packing of solvate molecules within the unit cells of porphyrins is not unusual (19, 20). All features in a difference map were <0.9(1) eÅ^{-3}, the five largest being near the Ru and Br atoms. There was little evidence that introducing anisotropic temperature factors for the C and N atoms would substantially improve the agreement, so refinement was terminated at this stage. Final $R = 0.076$, $R_w = 0.077$ for 292 variables. Shift-to-error ratios in the final cycle of least-squares ≤ 0.04.

Refinement was by block-diagonal least-squares, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = [(\sigma(F))^2 + 0.0004\ F^2]^{-1}$. Neutral-atom scattering factors with anomalous dispersion corrections (21) were used throughout. Computer programs (22) were run on a PDP-8e computer.

Final positional and thermal parameters are listed in Table 2. Anisotropic thermal parameters for Ru, Br and P, H atom coordinates, selected least-squares planes, and structure factor listings have been deposited.[7] Figure 1 shows the numbering scheme of the porphyrin atoms and the averaged geometry assuming that the halves of all of the pyrrole rings are equivalent.[8]

Bond lengths and angles are given in Table 3. Figure 2 shows the molecular structure of the complex, and Fig. 3 shows a stereoscopic packing drawing.

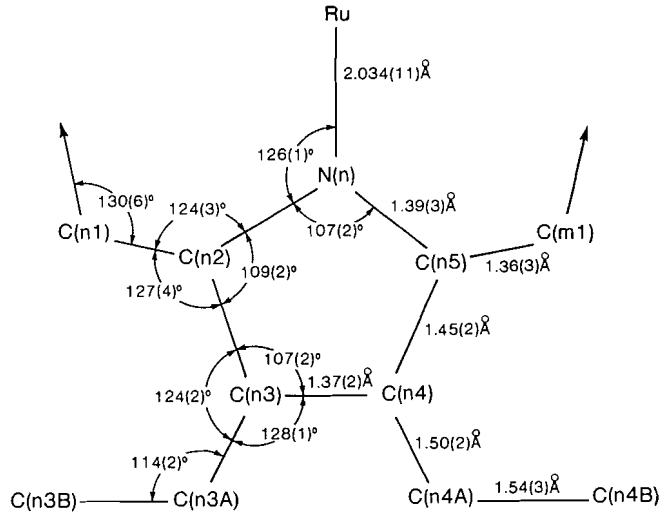

FIG. 1. Atom-labelling scheme for the pyrrole rings and averaged geometry.

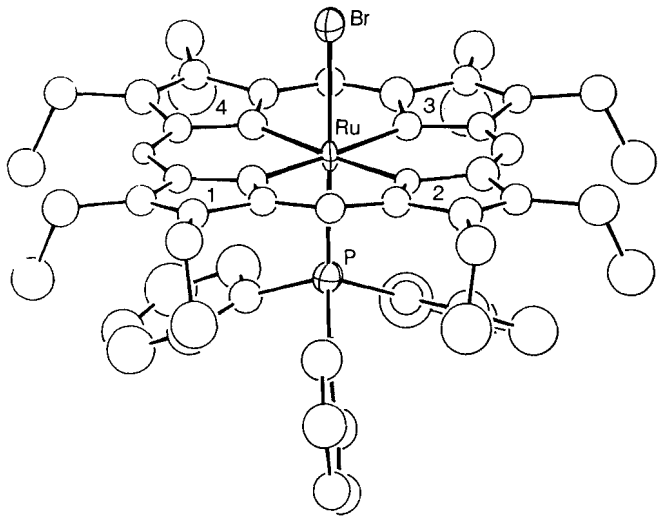

FIG. 2. Molecular structure of Ru(OEP)(PPh_3)Br showing numbering of pyrrole rings. Thermal ellipsoids enclose 50% probability levels. Hydrogen atoms have been deleted for clarity.

Results and discussion

Syntheses and characterization of the complexes

The ruthenium(III) complexes Ru(porp)(PPh_3)X (porp = OEP, TPP; X = Br, Cl) are readily synthesized by oxidation of the ruthenium(II) precursors Ru(porp)(PPh_3)$_2$ using the appro-

[4] $I = S - 2(B_1 + B_2)$; $\sigma(I) = (S + 4(B_1 + B_2))^{1/2}$ where S = count during scan, B = background count.

[5] H isotropic temperature factors were derived from those of the C atoms to which they were attached.

[6] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $R_w = (\Sigma_w(|F_o| - |F_c|)^2/\Sigma_w|F_o|^2)^{1/2}$.

[7] Complete set of data can be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0S2.

[8] The esd's are derived from the formula $S = (\Sigma_m(X_m - \bar{X})^2/(m - 1))^{1/2}$.

likely $[Ru^{II}(OEP)^{+\bullet}(CO)P^nBu_3]^+$. Loss of carbon monoxide from such Ru(II) cation radical species appears to trigger the intramolecular electron transfer (IMET) to generate Ru(III) (8, 26); subsequent coordination of phosphine or bromide would generate the bromo(phosphine) product. The O_2 oxidation of $Ru(MpIX)Im_2$ to give $[Ru(MpIX)Im_2]^+$ has been shown earlier to occur via an outer-sphere process, and initial electron transfer to the dioxygen from the porphyrin periphery to give a Ru(II) porphyrin cation radical species was suggested (27); the excess imidazole present in the solution presumably acts as a proton source (see above).

Br_2 oxidation of Ru(OEP)(CO)py does not generate cation radical species (26), and thus formation of Ru(OEP)(py)Br requires a photochemical decarbonylation procedure prior to the oxidation step. The bromide can be removed using silver salts in CH_3CN to generate the corresponding cationic complex containing the coordinated nitrile.

Attempts to oxidize $Ru(TPP)(P^nBu_3)_2$ with X_2 or O_2/HX resulted in the formation of impure green compounds: the colour, coupled with a quite sharp esr signal at $g = 2.00$, strongly suggests the present of cation radical species containing the $[Ru^{II}(TPP)^{+\bullet}]$ moiety (8). The reason for the contrasting behaviour of the $Ru(TPP)(PPh_3)_2$ complex, which yields Ru(TPP)(PPh$_3$)X (see above), is not immediately clear but, if the oxidations proceed via an outer-sphere mechanism, then plausible intermediates are $[Ru^{II}(TPP)^{+\bullet}(PR_3)_2]^+X^-$ species, and whether subsequent IMET occurs must depend at least partly on the nature of the axial ligands. A more basic phosphine would be expected to stabilize Ru(III) relative to Ru(II) (8, 28) and thus a key feature may be the entrance of X^- into the coordination sphere of the metal with displacement of a phosphine; this would be easier with the PPh_3 system, on both electronic and steric grounds. The successful generation of $[Ru(OEP)(P^nBu_3)_2]^+$ from $Ru(OEP)(P^nBu_3)_2$ may result from the stronger basicity of OEP compared to TPP (29). The Br_2 oxidation of $Ru(TPP)(CO)P^nBu_3$, formed *in situ* from the ethanol adduct, gave an unidentified green compound, that again suggests that the $[Ru^{II}(porp)^{+\bullet} \rightarrow Ru^{III}(porp)]$ process occurs less readily with TPP systems.

The six-coordinate ruthenium(III) products have magnetic susceptibilities in the range of 1.9–2.3 BM, confirming the expected one unpaired electron in low-spin d^5 systems. The frozen solution esr spectra (Fig. 4) show a broad signal centred at about $g = 2.3$ and a weaker but sharper signal at $g = 1.98$; these are typical of low-spin d^5 Ru(III) complexes in tetragonally-distorted octahedral structures (5, 30) and are assigned to $g_\perp$ and $g_\parallel$, respectively. The ^1H nmr signals noted in the experimental section for the Ru(OEP)(PPh$_3$)X complexes (X = Br, Cl) were generally broad and coupling constants were not obtained; the assignments are based on the relative intensities and those reported for the porphyrin ring with the paramagnetic $[Ru(OEP)]_2$ complex (31). The two different axial ligands induce an anisochrony of the methylene protons within OEP, and the large chemical shift difference between the diastereotopic protons (~10 ppm) originates from differential π-spin density transfer from the porphyrin system to each of the protons (31). The porphyrin meso protons appear as a relatively sharp singlet, little shifted from that in six-coordinate diamagnetic $Ru^{II}(OEP)$ complexes (9, 32). Proton nmr signals for the other Ru(III) complexes were too broad and weak to

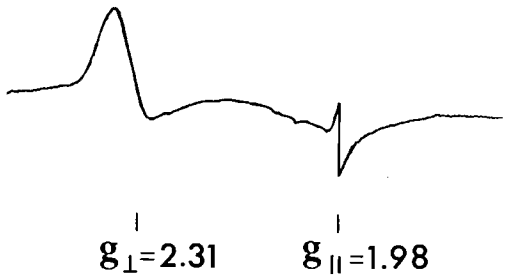

FIG. 4. Frozen solution esr spectrum of Ru(OEP)(P"Bu_3)Br in toluene at 77 K.

analyze satisfactorily.

The optical spectra (Table 1) show in each case a single absorption maximum in the 500–550 nm region, and two more intense maxima of comparable magnitude in the 360–415 nm Soret region. The log ϵ values of the Soret bands are in the 4.5–5.0 range, and are at least 0.3 lower than that of the major Soret band of six-coordinate ruthenium(II) porphyrin complexes; this coupled with the two-peak maxima of the latter makes it simple to distinguish qualitatively the presence of the two oxidation states. Figure 5 of ref. 8 shows spectra of the $[Ru(OEP)(P"Bu_3)_2]^+$ and $Ru(OEP)(P"Bu_3)_2$ species and these are representative of all the six-coordinate complexes. The spectrum of the $[Ru(OEP)(PPh_3)_2]^+$ cation changes on the addition of excess phosphine, implying dissociation of a phosphine ligand (26); that recorded in the presence of excess phosphine is attributed to the six-coordinate complex, and agrees with one measured earlier on a species formed *in situ* by adding excess PPh_3 to $[Ru^{II}(OEP)^{+\bullet}(CO)]^+$ (8).

Structure description of Ru(OEP)(PPh_3)Br·solvate

This is the first time that the structure of a Ru(III) porphyrin has been reported.[9] The Ru atom is approximately octahedrally coordinated by the four pyrrole N atoms of the porphyrin, the P atom of the PPh_3 group, and the Br atom, and is displaced 0.049(1) Å from the plane of the pyrrole N atoms in the direction of the P atom.

The Ru—N distances range from 2.025 (12) to 2.047 (13) Å. In general, Ru(III) is expected to show shorter bond lengths than Ru(II) (34) on account of contraction of electron density with increasing charge. However, comparison of high or low-spin six-coordinate Fe^{II} and Fe^{III} species shows that the magnitude of the effect is reduced in porphyrin complexes (35). Ru—N (equatorial) bond lengths in Ru(II) porphyrins have been reported for $Ru(OEP)(PPh_3)_2$ (ranging from 2.044(3) to 2.057(3) Å) (9), $Ru(OEP)py_2$ (from 2.032(6) to 2.050(5) Å) (36), Ru(TPP)(CO)py (from 2.036(6) to 2.058(6) Å) (37), Ru(TPP)(CO)EtOH (2.048(5) and 2.051(5) Å) (10), and $Ru(TPP)(Ph_2PCH_2PPh_2)_2$ (2.038(8) and 2.045(8) Å) (19). Numerically, the average of the Ru—N bonds in the present structure is shorter than for the Ru(II) complexes, but the esd's are too large to call the difference statistically significant. The porphyrin core shows a small degree of doming (N(n) atoms average 0.07 Å displacement from the porphyrin least-squares plane; C(n1), C(n2), C(n3) average −0.01 Å; C(n3), C(n4) average −0.04 Å; where P is on the positive side of the plane) with the terminal C atoms of the ethyl groups directed in a ++, ++, ++, ++ manner (38) towards the phosphine. The Ru atom is displaced 0.127(2) Å from the porphyrin least-squares plane and 0.049(2) Å from the N_4 plane. The average geometry of the pyrrole rings is shown in Fig. 1 and, within its precision, is in agreement with values previously reported for OEP metalloporphyrins (9, 38, 39).

The Ru—P distance of 2.412(5) Å is at the high end of the range of 2.2–2.4 Å normally found for Ru—P bonds (9, 19, 40). A close contact between phenyl group C(71)—C(76) and part of the porphyrin (C(21) . . . H(76) = 2.44 Å) causes the P atom to be deflected away from this side of the molecule, so that angles P—Ru—N (3 and 4) are less than 90° even though the Ru atom is on the same side of the N_4 plane as the P atom. This contact also causes angle Ru—P—C(71) to be considerably larger than those to C(51) and C(61), and for C(21) to be pushed out of the plane of the porphyrin.

The Ru—Br bond is 2.552(2) Å, which is typical for terminal bromines coordinated at ruthenium (41).

Concluding remarks

Some procedures have been established for the synthesis of ruthenium(III) porphyrin complexes from ruthenium(II) precursors. The oxidations can be effected using Br_2 or Cl_2, or the corresponding hydrogen halides in the presence of air, or the $Et_3O^+PF_6^-$ salt if non halide-containing complexes are required. The primary synthetic routes into ruthenium porphyrin chemistry generally involve Ru(porp)(CO)L (L = EtOH) precursors. If L = a tertiary phosphine, the oxidations to Ru(III) occur with concomitant loss of CO via intermediate porphyrin π-cation radical species; with L = py, a photodecarbonylation is required prior to the oxidation step in order to effect good conversion to Ru(III) products. In general, OEP systems react cleanly, giving high yields of red/purple Ru(III) complexes, while TPP products are often contaminated with green cation radical species.

The first structure of a ruthenium(III) porphyrin complex, $Ru(OEP)(PPh_3)Br$, is reported, and such species generally are important as precursors to models for heme proteins (especially cytochrome P450).

Orientation et dynamique moléculaire de sondes paramagnétiques en phase lamellaire dibutylephosphate de sodium/eau

C. CHACHATY

Département de Physico-Chimie, Centre d'Etudes Nucléaires de Saclay, 91191 Gif-sur-Yvette Cedex, France

Reçu le 24 mai 1983[1]

C. CHACHATY. Can. J. Chem. **62**, 1246 (1984).

Les solutions aqueuses de dibutylephosphate de sodium (NaDBP) en concentrations de 3 à 4 mol L^{-1} forment, entre 280 et 340 K, une phase cristalline liquide lamellaire. On étudie par rpe l'orientation et la dynamique moléculaire dans cette phase, de sondes paramagnétiques telles que l'ion vanadyle et les radicaux nitroxydes, tempoamine, tempone et tempobutanamide.

L'ion VO^{2+} forme, avec le groupe phosphate, un complexe dont l'axe magnétique z est orienté en moyenne selon la normale au plan lamellaire. La mobilité moléculaire à l'interface entre les couches d'eau et de DBP^- est donnée par le temps de corrélation de nutation de l'axe z que l'on déduit de la largeur totale du spectre par la relation empirique $\tau_R = a[1 - (A_\parallel/A_{ZZ})]^b$. Les paramètres $a = 2{,}95 \times 10^{-11}$ s et $b = -1{,}42$ sont déterminés par des mesures en fonction de la viscosité, des largeurs de raies et de l'anisotropie du couplage hyperfin de VO^{2+}

La tempoamine et la tempone se localisent dans les domaines polaires de la mésophase avec une réorientation rapide autour de la direction N—O orientée en moyenne selon le directeur de la phase lamellaire. L'anisotropie de réorientation de ces radicaux est attribuable selon les cas à la formation de liaisions hydrogène avec les groupes phosphates ou les molécules d'eau interstitielles. On établit quelques corrélations entre la rpe de ces sondes paramagnétiques et la rmn de ^2H et ^{31}P des molécules de substrat.

C. CHACHATY. Can. J. Chem. **62**, 1246 (1984).

Aqueous solutions of sodium dibutylphosphate (NaDBP) give rise to lamellar liquid crystalline phase between 280 and 340 K for NaDBP concentrations ranging from 3 to 4 mol L^{-1}. The orientation and dynamic behaviour of several paramagnetic probes such as the vanadyl ion, tempoamine, tempone and tempobutanamide dissolved in this phase have been investigated by esr.

The vanadyl ion binds to the phosphate group, forming a complex, the z magnetic axis of which is on the average perpendicular to the lamellar plane. The molecular mobility at the H_2O/DBP^- interface is given by the reorientation correlation time of the z axis, which is derived from the total width of the spectrum, using the empirical relation $\tau_R = a[1 - (A_\parallel/A_{ZZ})]^b$. The parameters $a = 2.95 \times 10^{-11}$ s and $b = -1.42$ are obtained from the viscosity dependence of the esr line widths and of the anisotropic hyperfine couplings.

The tempone and tempoamine are localized in the polar domains of the mesophase, reorienting rapidly about the N—O direction which is, on the average, parallel to the director of the lamellar plane. The anisotropic motion of these radicals is assigned to hydrogen bonding which occurs, according to the cases, with water molecules or phosphate groups. Some correlations are established between the esr of spin probes and ^2H and ^{31}P nmr experiments on substrate molecules.

I. Introduction

L'étude par résonance magnétique de solutions aqueuses micellaires de dibutylephosphate de sodium (NaDBP) nous a conduits à mettre récemment en évidence la formation de cristaux liquides lyotropes pour des concentrations élevées en NaDBP (1). L'évolution avec la température et la concentration en NDBP de l'anisotropie de déplacement chimique de ^{31}P ou du couplage quadrupolaire de deutérium de l'eau, ainsi que l'observation au microscope polarisant, ont permis de délimiter le domaine d'existence d'une phase lamellaire (Fig. 1). Cette phase, caractérisée par diffraction de rayons X, consiste en une alternance de doubles couches hydrocarbonées et de domaines polaires contenant les groupes phosphates et l'eau interstitielle, d'épaisseurs respectives $8{,}5 < D_1 < 9{,}8$ et $9{,}2 > D_2 > 7{,}1$ selon la teneur en eau (Fig. 2).

Nous nous sommes proposés d'étudier par résonance magnétique nucléaire (rmn) et par résonance paramagnétique électronique (rpe) l'orientation et la dynamique des molécules de substrat ou de sondes paramagnétiques dissoutes dans ce milieu. Nous nous limiterons ici aux principaux résultats de l'étude par rpe, ceux de la rmn, dont l'interprétation est en cours, ayant fait l'objet d'une publication préliminaire (2).

Les sondes paramagnétiques intervenant dans ce travail ont été choisies en fonction de leurs dimensions moléculaires, inférieures ou comparables à celles de NaDBP et de leur aptitude à s'associer à des degrés divers avec les molécules de substrat. Ainsi l'ion vanadyle forme un complexe de coordination avec l'anion DBP^- alors que les nitroxydes mentionnés au Tableau 1 sont susceptibles soit de s'incorporer dans la couche hydrocarbonée (tempobutanamide), soit de former des liaisons hydrogène avec les constituants polaires de la mésophase (tempone et tempoamine). Les radicaux nitroxydes et à un moindre degré l'ion VO^{2+} sont souvent utilisés pour l'étude par rpe de cristaux liquides thermotropes ou de membranes phospholipidiques (3). Il n'existe par contre que peu d'exemples d'études analogues sur des mésophases lyotropes formées à partir de petites molécules amphiphiles où, comme dans le cas présent, on tente d'établir des corrélations entre la réorientation de ces sondes mesurée par rpe et celle des molécules de substrat déduites d'expériences de résonance et de relaxation nucléaires.

II. Conditions expérimentales

L'acide dibutyle phosphorique (OSI, France) a été purifié par dissolution dans l'eau alcaline pour éliminer le tributylephosphate insoluble dans ce milieu. L'acide dibutylephosphorique était séparé de l'acide monophosphorique par acidification de la solution aqueuse et extraction au tétrachlorure de carbone, suivie d'une distillation sous pression réduite pour éliminer le solvant. La pureté de l'acide dibutylephosphorique, supérieure à 98% était contrôlée par rmn de ^1H, ^{13}C et ^{31}P.

La phase cristalline liquide était formée soit par addition progressive d'une solution concentrée $NaOH/H_2O$ à l'acide di-

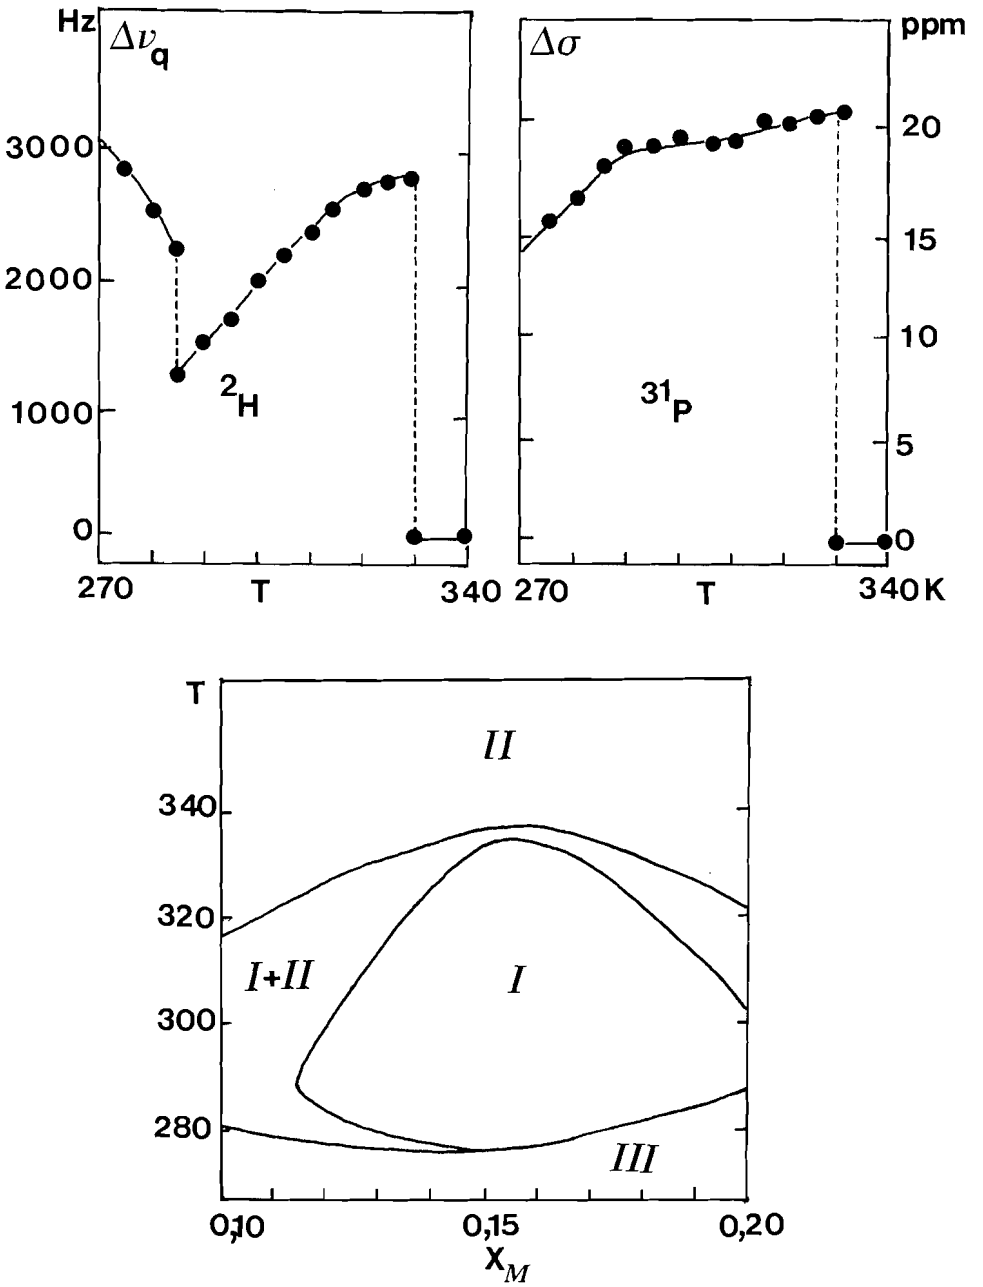

FIG. 1. Variation avec la température de l'écart quadrupolaire de ^{2}H et de l'anisotropie de déplacement chimique $\Delta\sigma = |\sigma_\parallel - \sigma_\perp|$ de ^{31}P dans le système NaDBP/H_2O pour une fraction molaire X_M = 0,165 de NaDBP. Diagrammes de phases: I, phase lamellaire; II, liquide isotrope; III, gel ou solide hétérogène (coagel).

butylephosphorique, soit par dissolution de NaDBP dans H_2O. La solution visqueuse était homogénéisée par chauffage à 50–60°C pendant plusieurs heures. Les radicaux 2,2,6,6-tétraméthyl-4-pipéridinone-1-oxyl (tempone) et 4-amino-2,2,6,6-tétraméthylpipéridine-1-oxyl (tempoamine) ainsi que le sulfate de vanadyle proviennent d'Aldrich Chemical. La tempobutanamide a été synthétisée par action du chlorure d'acide correspondant sur la 2,2,6,6-tétraméthylpipéridine-1-oxyl-4-ol et purifiée par chromatographie.

Les expériences de rpe ont été effectuées sur un spectromètre Varian E9 à une fréquence de 9,15 GHz et avec une modulation de 100 KHz. L'échantillon était placé dans un système à température variable V 257. Dans la plupart des expériences nous avons utilisé une cellule rectangulaire de section interne 3,5 × 0,5 mm (Wilmad WG 808) que l'on orientait par rapport au champ magnétique.

Le champ magnétique étant calibré à l'aide d'un magnétomètre Varian F8, les facteurs g étaient mesurés par rapport à une référence externe de DPPH (système Varian Fieldial Mark II) dont le g effectif, compte tenu de sa position par rapport à la cavité, est de 2,00375 ± 0,00005.

III. Paramètres d'ordre et largeurs des raies

Paramètres d'ordre

L'orientation moléculaire par rapport au directeur de la mésophase est définie par les paramètres d'ordre S_{ii} qui ont pour expression (4, 5):

$$[1] \quad S_{ii} = \frac{1}{2}\langle 3\cos^2\theta'_i(t) - 1\rangle$$

$\theta'_i(t)$ étant l'angle dépendant du temps entre un axe i du système de référence moléculaire et le directeur de la mésophase. Le système de référence choisi étant celui des axes principaux

*Mesuré en phase isotrope.

x, y et z, communes aux tenseurs de couplage hyperfin **A** et au tenseur **g**, désignés tous deux par **T**, la réorientation moléculaire autour du directeur nous donne (4, 5):

$$[2] \quad T_{\|} - T_{\perp} = S_{11}T_{xx} + S_{22}T_{yy} + S_{33}T_{zz}$$

Pour les radicaux nitroxydes, l'axe z coïncide avec celui de l'orbitale de l'électron non apparié, centrée sur l'azote et l'axe x est aligné à quelques degrés près selon la liaison N—O (6). Dans le cas de l'ion VO^{2+} l'axe z est orienté selon la liaison V—O et les axes x et y sont pratiquement équivalents. Les valeurs principales de ces tenseurs, indiquées dans le tableau 1, ont été déterminées par simulation des spectres de rpe en ma-

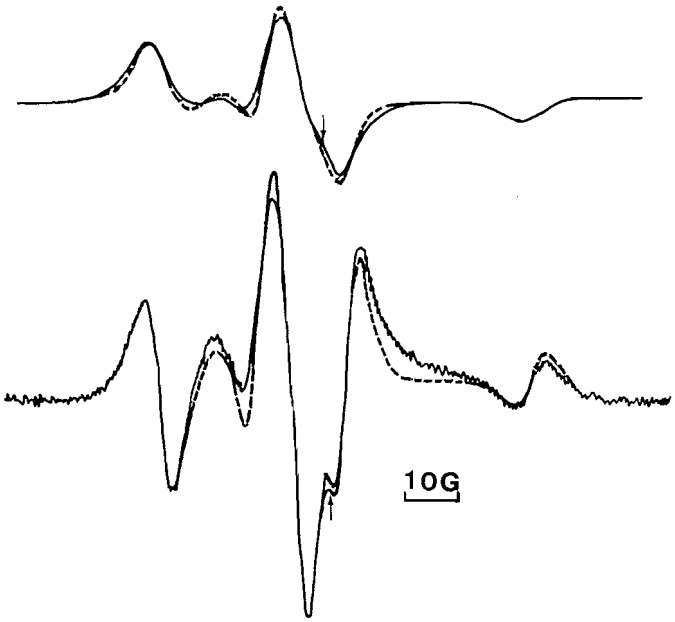

FIG. 3. Détermination des valeurs principales des tenseurs **A** et **g** du radical tempobutanamide par simulation des dérivées première et seconde du spectre rpe en milieu rigide; (—) spectres expérimentaux; (- - -) spectres calculés avec les paramètres du Tableau 1. Les flèches verticales correspondent à $g = 2{,}00375$.

trice rigide NaDBP/H_2O à $T < 120$ K. Alors que les tenseurs **A** de ces sondes paramagnétiques et le tenseur **g** de VO^{2+} peuvent être considérés comme axiaux autour de z, le tenseur **g** des nitroxydes dévie notablement de la symétrie axiale.

Dans nos conditions expérimentales, la résolution limitée de la dérivée première d'absorption des spectres de nitroxydes en milieu rigide ne donne que g_{zz} et $\frac{1}{2}(g_{xx} + g_{yy})$. La position des singularités de la dérivée seconde dépend par contre beaucoup plus fortement de l'asymétrie du tenseur **g**, définie par $\Delta g = (g_{xx} - g_{yy})/(g_{zz} - g_0)$ avec $g_0 = \frac{1}{3}(g_{xx} + g_{yy} + g_{zz})$. Nous avons donc déterminé les valeurs principales de **g** à partir de la dérivée seconde des spectres de rpe en vérifiant cette mesure par simulation des spectres (Fig. 3). Les valeurs de Δg obtenues sont respectivement de $-0{,}75$, $-0{,}92$ et -1 pour la tempobutylamide, la tempone et la tempoamine, en bon accord avec les valeurs que l'on calcule d'après les données de la littérature (voir par ex. les références 7, 8).

La mesure des paramètres d'ordre a été effectuée à partir de la position des singularités associées aux valeurs principales des tenseurs **A** et **g** en écrivant la relation [2] sous la forme:

$$[3] \quad \frac{T_{\parallel} - T_{\perp}}{T_{zz} - \frac{1}{2}(T_{xx} + T_{yy})} = S_{33} + \frac{1}{2}\frac{(T_{xx} - T_{yy})(S_{11} - S_{22})}{T_{zz} - \frac{1}{2}(T_{xx} + T_{yy})}$$

Comme $A_{xx} \cong A_{yy}$, S_{33} est donné directement par mesure de l'écart hyperfin alors que S_{11} et S_{22} sont obtenus à partir de l'anisotropie de **g**. Cette mesure n'est valable que si la réorientation moléculaire est rapide par rapport à $\Delta A/h$ et à $\Delta g \beta B_0/h$ (9), ΔA et Δg représentant l'anisotropie des tenseurs **A** et **g** et B_0 le champ magnétique directeur.

Largeurs de raies

Dans le domaine des movements rapides spécifié plus haut, les largeurs de raies liées au temps de relaxation électronique T_2, permettent de déterminer les temps de corrélation de réorientation moléculaires par une expression de la forme (10):

$$[4] \quad T_2^{-1} = \gamma_0 \Delta B(m_I) = a + bm_I + cm_I^2$$

$\gamma_0 = g_0 \beta/\hbar$ est le rapport gyromagnétique de l'électron, m_I le nombre quantique nucléaire et $\Delta B(m_I)$ la demi-largeur de raie à mi-hauteur d'une lorentzienne (élargissement homogène).

Pour un couplage hyperfin exprimé en gauss, les constantes a, b et c ont pour expressions (10):

$$[5] \quad a = \frac{1}{6} B_0^2 \hbar^2 \beta_e^2 \sum_{K=-2}^{2} (-1)^K F_g^{(K)} F_g^{(-K)} G_1^{(K)}(\omega) + \frac{1}{12} I(I+1) \gamma_e^2 \sum_{K=-2}^{2} (-1)^K F_A^{(K)} F_A^{(-K)} G_2^{(K)}(\omega)$$

$$b = \frac{1}{6} B_0 \hbar^{-1} \beta_e \sum_{K=-2}^{2} [(-1)^K (F_A^{(K)} F_g^{(-K)} + F_A^{(-K)} F_g^{(K)})] G_1^{(K)}(\omega)$$

$$c = \frac{1}{6} \gamma_e^2 \sum_{K=-2}^{2} (-1)^K F_A^{(K)} F_A^{(-K)} \left[G_1^{(K)}(\omega) - \frac{1}{2} G_2^{(K)}(\omega) \right]$$

$G_1^{(K)}(\omega)$ et $G_2^{(K)}(\omega)$ sont des combinaisons linéaires des densités spectrales $J(\omega)$ qui seront explicitées plus loin

$$[6] \quad \begin{aligned} G_1^{(K)}(\omega) &= 4J_0^{(K)}(0) + 3J_1^{(K)}(\omega_S) \\ G_2^{(K)}(\omega) &= J_0^{(K)}(\omega_S) + 3J_1^{(K)}(\omega_A) + 6J_2^{(K)}(\omega_S) \end{aligned}$$

avec $\omega_S = \gamma_0 B_0$, $\omega_A \cong \gamma_0 A_0$, A_0 étant la constante de couplage hyperfin de contact.

$F_T^{(K)}$ avec $K = 0, \pm 1, \pm 2$ désigne l'une des composantes des tenseurs **A** ou **g** en base sphérique:

$$[7] \quad \begin{aligned} F_T^{(0)} &= \sqrt{\frac{2}{3}} \left(T_{zz} - \frac{1}{2}(T_{xx} + T_{yy}) \right) \\ F_T^{(\pm 1)} &= 0 \\ F_T^{(\pm 2)} &= \frac{1}{2}(T_{xx} - T_{yy}) \end{aligned}$$

Dans le cas d'une réorientation autour d'un axe moléculaire Δ_M, ces composantes deviennent:

$$[8] \quad F'^{(K')} = \sum_{K=-2}^{2} D_{K'K}^{(2)}(0, \beta, \gamma) F^{(K)}$$

$D_{K'K}^{(2)}$ désignant la matrice de Wigner d'ordre 2.

Les densités spectrales de la relation [6] sont de la forme (11, 12):

$$[9] \quad J_M^K(\omega, \Theta) = J' + J'' P_2(\cos\Theta) + J''' P_4(\cos\Theta)$$

$P_2(\cos\Theta)$ et $P_4(\cos\Theta)$ désignent les polynômes de Legendre d'ordre 2 et 4, θ étant l'angle entre B_0 et Δ_L (Fig. 4). J', J'' et J''' sont des combinaisons linéaires des densités spectrales correspondant à $\Theta = 0$, et qui ont pour expression générale (11, 13):

$$[10] \quad J_M^K(\omega, 0) = \bar{d}_{KM}^2 \frac{\tau_K}{1 + \omega^2 \tau_K^2}$$

avec K ou $M = 0, \pm 1, \pm 2$.

Les temps de corrélation τ_0, τ_1, τ_2 sont liés aux coefficients de diffusion rotationnelle $D_{\parallel}$ et $D_{\perp}$, par la relation (14, 15):

$$[11] \quad \tau_K^{-1} = C[6D_{\perp} + (D_{\parallel} - D_{\perp})K^2]$$

où C est un coefficient dépendant du modèle de mouvement (diffusion Brownienne ou réorientation par sauts). Ceci nous donne:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

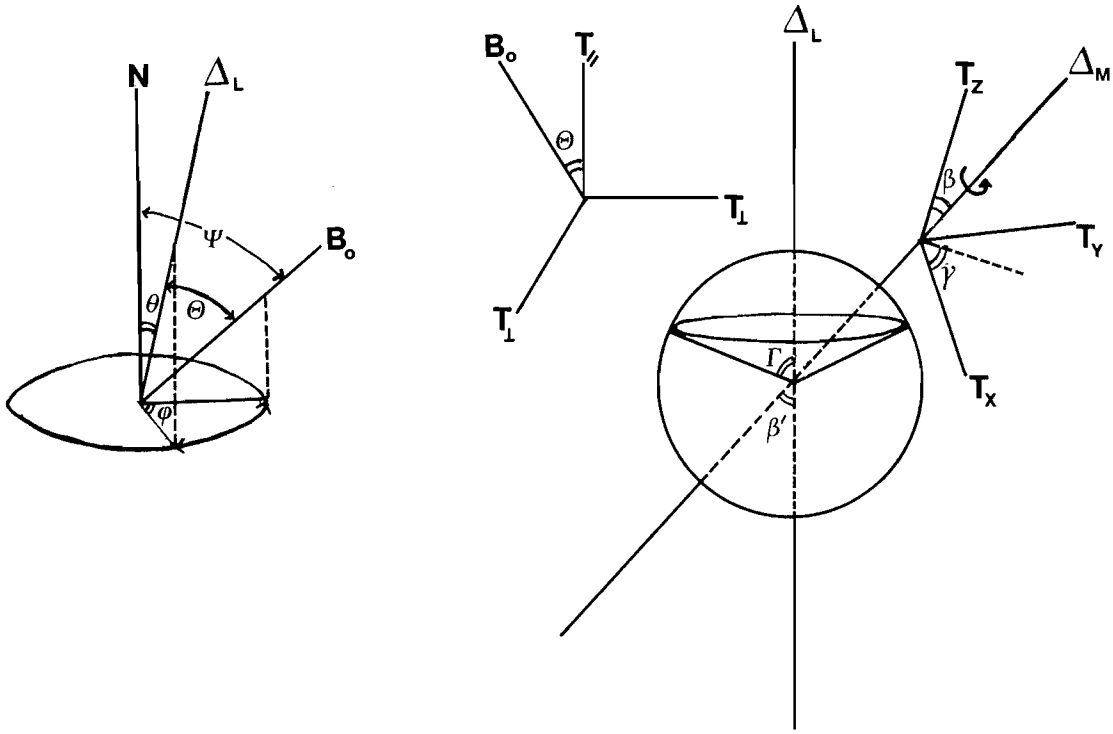

FIG. 4. Définition des angles et des axes. *N*: axe de référence de l'échantillon, généralement normal au plan de la cellule rectangulaire ou au plan moyen de la phase lamellaire orientée; Δ_L: directeur local; Δ_M: axe de rotation moléculaire préférential; **T**: tenseurs **A** ou **g**. Ces tenseurs sont moyennés par réorientation autour de Δ_M et Δ_L.

$$[12]\quad \tau_1 = \frac{6\tau_0}{5 + (D_\parallel/D_\perp)}, \qquad \tau_2 = \frac{6\tau_0}{2 + 4(D_\parallel/D_\perp)}$$

τ_0, que l'on désignera également par τ_R correspond au mouvement de nutation de l'axe moléculaire Δ_M autour du directeur Δ_L. Dans la relation [10] $\bar{d}^2_{KM}$ est le carré moyen d'un élément de la matrice de rotation entre les axes moléculaires et un système de référence fixe. L'expression de $\bar{d}^2_{KM}$ en fonction des paramètres d'ordre P_2 (cos β') = $\frac{1}{2}\langle 3\cos^2\beta' - 1\rangle$ et $\bar{P}_4$ (cos β') = $\frac{1}{8}\langle 35\cos^4\beta' - 30\cos^2\beta' + 3\rangle$ est donné dans les références 11 ou 13, pour un modèle de réorientation par sauts, β' étant l'angle dépendant du temps entre Δ_M et Δ_L (Fig. 4). $\bar{P}_2$ (cos β') est donné par l'écart hyperfin des raies de résonance:

$$[13]\quad \frac{A_\parallel - A_\perp}{A_{zz} - \frac{1}{2}(A_{xx} + A_{yy})} = \frac{1}{2}\bar{P}_2(\cos\beta')[3\cos^2\beta - 1] = S_{33}$$

où β désigne l'angle entre Δ_M et l'axe z du tenseur de couplage hyperfin.

La relation entre $\bar{P}_2$ (cos β') et $\bar{P}_4$ (cos β') dépend du modèle de réorientation proposé. Dans le cas présent $\bar{P}_4$ (cos β') a été déduit de $\bar{P}_2$ (cos β') mesuré expérimentalement en admettant que l'axe moléculaire Δ_M effectue un mouvement aléatoire de nutation à l'intérieur d'un cône centré sur Δ_L (Fig. 4) (16) ou que ce mouvement dépend d'un potentiel de la forme $U(\beta')/kT = -\lambda\sin^2\beta'$ (17). Une étude en cours sur la dépendance angulaire de la relaxation de ^{31}P dans le système NaDBP/H_2O montre que ce second modèle rend le mieux compte des résultats expérimentaux, de sorte que nous l'avons également adopté pour le calcul des largeurs de raies des radicaux nitroxydes.

Du fait de la distribution statique d'orientation des directeurs Δ_L des domaines formant la phase cristalline liquide, il est généralement nécessaire de confirmer la détermination des paramètres d'ordre S_{ii} et des largeurs de raies par simulation des spectres de rpe. Dans ce but nous avons écrit un programme APL qui permet de calculer ces spectres en fonction des paramètres cités plus haut, pour une forme de raie gaussienne ou lorentzienne selon que l'on se trouve dans les conditions de mouvements lents (VO^{2+}) ou rapides (nitroxydes). Pour une forme de raie lorentzienne par exemple, la dérivée première d'absorption a pour expression (18)

$$[14]\quad F(B) = -\frac{2}{\pi}\sum_{m_I=-1}^{+1}\int_0^{2\pi}\int_0^{\pi} \times \frac{G(\phi)\,G(\theta)\,P(\theta,\phi)\,\Delta B(B - B_R)\sin\theta\,d\phi\,d\theta}{(\Delta B^2 + (B - B_R)^2)^2}$$

B est le champ magnétique variable, ΔB la demi-largeur de raie à mi-hauteur, θ l'angle entre le directeur local Δ_L et l'axe référence N, ϕ l'angle entre la projection de B_0 sur un plan perpendiculaire à N et la projection de Δ_L sur ce plan (Fig. 4). B_R et $P(\theta,\phi)$ désignent respectivement le champ magnétique de résonance et la probabilité de transition. $G(\theta)$ et $G(\phi)$ représentent les fonctions de distribution statique du directeur Δ_L centrées sur θ_0 ou ϕ_0, assimilées à une gaussienne (16):

$$[15]\quad G(u) = \frac{1}{\Delta u_m\sqrt{2\pi}}\exp\left[-\frac{1}{2}\left(\frac{u - u_0}{\Delta u_m}\right)^2\right]$$

Pour une orientation donnée de Δ_L, qui est l'axe de symétrie des tenseurs **A** et **g** moyennés par la réorientation moléculaire autour du directeur, le champ magnétique de résonance B_R a pour expression (18):

$$[16]\quad B_R = \frac{h\nu_0/\beta - [(A_\parallel g_\parallel)^2\cos^2\Theta + (A_\perp^2 g_\perp^2)\sin^2\Theta]^{1/2} m_I}{(g_\parallel^2\cos^2\Theta + g_\perp^2\sin^2\Theta)^{1/2}} + B'_R$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

avec Θ = arc cos (cos θ cos ψ + sin θ cos ϕ sin ψ), ν_0 étant la fréquence du spectromètre et B'_R le terme du second ordre dont on trouvera l'expression dans la réf. 18.

Le temps de calcul des spectres a été considérablement réduit en replaçant l'intégration sur θ et ϕ de l'équation [14] par une simple intégration sur Θ (Fig. 4):

$$[17]\quad F(B) = -\frac{2}{\pi}\sum_{m_I=-1}^{+1}\int_0^{\pi/2}\frac{G(\Theta)P(\Theta)\Delta B(B-B_R)}{(\Delta B^2-(B-B_R)^2)^2}\,d\Theta$$

$P(\Theta)$ est la probabilité de transition (19):

$$[18]\quad P(\Theta) = \frac{1}{2}g_\perp^2\left\{1+\frac{g_\parallel^2}{g_\parallel^2\cos^2\Theta+g_\perp^2\sin^2\Theta}\right\}$$

$G(\Theta)$ est la distribution de probabilités de l'angle Θ calculée numériquement à partir de l'expression:

$$[19]\quad G(\Theta) = \mathcal{N}\frac{G(\phi)G(\theta)\sin\theta\,\Delta\Theta}{\Theta(\theta+\Delta\theta,\phi+\Delta\phi)-\Theta(\theta,\phi)}$$

$\Delta\Theta$, $\Delta\theta$ et $\Delta\phi$ étant des pas angulaires constants et $\mathcal{N}$ un facteur de normalisation. Le nombre de points d'intégration sur Θ est réduit par troncature de $G(\Theta)$ et cette fonction peut être utilisée dans des calculs successifs.

La dépendance angulaire de ΔH intervient dans les relations [14] et [17]. Elle est soit ajustée empiriquement sous la forme:

$$[20]\quad \Delta B = (\Delta B_\parallel^2\cos^2\Theta + \Delta B_\perp^2\sin^2\Theta)^{1/2}$$

soit calculée en fonction des paramètres d'ordre et des temps de corrélation τ_K. Dans ce second cas, on tient compte de l'élargissement inhomogène par une largeur de raie additionnelle:

$$[21]\quad \Delta B' = \Delta B_1 + \Delta B_2\cos^2\Theta$$

ΔB_1 et ΔB_2 sont des paramètres ajustables qui correspondent respectivement aux parties scalaire et dipolaire du couplage hyperfin non résolu des protons. Pour une orientation donnée, la largeur pic à pic de la dérivée d'une raie d'absorption dans l'approximation d'une forme lorentzienne est donc:

$$[22]\quad \Delta B_{pp} = \frac{2}{\sqrt{3}}[(\gamma_0 T_2)^{-1} + \Delta B')]$$

T_2 étant calculé à partir des relations [4]–[12].

Dans le cas des nitroxydes étudiés ici, le second terme de la relation [21] est négligeable étant donné le faible couplage dipolaire des protons, moyenné à zéro par la réorientation moléculaire rapide. La simulation des spectres nous a donné les valeurs optimales $\Delta B' = 0{,}3 \pm 0{,}05$ G pour la tempone et $\Delta B' = 0{,}9 \pm 0{,}1$ G pour la tempoamine et la tempobutanamide. Ces valeurs sont voisines de la demi-largeur à mi-hauteur:

$$[23]\quad \sigma = 0{,}59\left(\sum_i n_i a_{H_i}^2\right)^{1/2}$$

de l'enveloppe de la structure hyperfine des protons assimilés à une gaussienne. Les constantes de couplage hyperfin a_H des protons de la tempone (20) et de la tempoamine (21) donnent en effet respectivement $\Delta B' \cong \sigma = 0{,}225$ G et 0,83 G.

Pour certaines simulations, la contribution de la structure hyperfine non résolue a été introduite par convolution gaussienne des spectres. Cette procédure ne donne pas de différences notables avec l'utilisation de la relation [22].

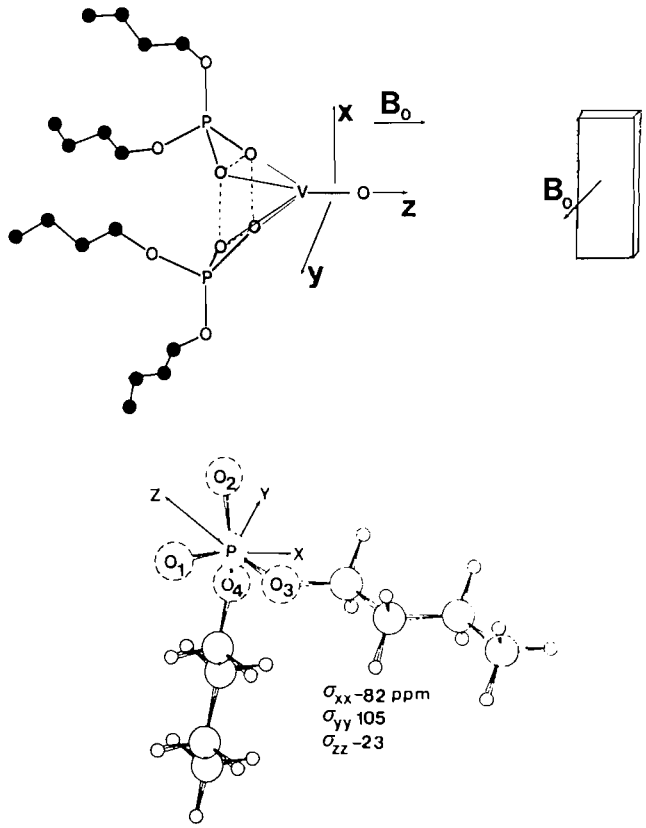

FIG. 5. Orientation des axes principaux des tenseurs **A** et **g** de VO^{2+} pour $\psi = 0$, $\theta_0 = 0$, x et y étant équivalents. Tenseur de déplacement chimique σ de ^{31}P.

IV. Résultats et discussion

Ion vanadyle

L'étude par rmn de la complexation de VO^{2+} par DBP^- en milieu micellaire indique la formation d'un complexe bidentate avec deux molécules de monomère (1) représenté sur la figure 5. Dans la phase lamellaire ce complexe donnera une orientation moyenne de l'axe V—O perpendiculaire aux doubles couches de DBP^-. Le spectre rpe de VO^{2+} apportera donc des informations sur la distribution d'orientation du directeur et la mobilité moléculaire à l'interface DBP^-/H_2O.

Les amplitudes des singularités du spectre de VO^{2+} correspondant aux orientations de l'axe de symétrie et du plan principal des tenseurs **g** et **A** parallèles à B_0, varient par rotation de la cellule rectangulaire. On observe que les singularités parallèles, correspondant à $T_\parallel$, ont une amplitude maximale ou minimale selon que B_0 est perpendiculaire ou parallèle au plan de la cellule, alors que les singularités perpendiculaires varient en sens inverse (Fig. 6). Cette dépendance angulaire indique que les doubles couches de la phase lamellaire s'orientent préférentiellement dans le plan de la cellule. On observe parfois un comportement inverse, qui correspond à une orientation aléatoire de Δ_L dans le plan de la cellule. L'apparition de l'un ou l'autre type d'orientation depend d'une manière critique du traitement thermique de l'échantillon. La transition entre la phase lamellaire et la phase III par refroidissement à $T < 280$ K entraîne la disparition de l'effet d'orientation, que l'on retrouve par recuit prolongé de l'échantillon entre 300 et 330 K.

De la symétrie quasi-axiale et de l'orientation des tenseurs magnétiques de VO^{2+}, il résulte que la relaxation électronique de cet ion ne dépend au premier ordre que du seul temps de

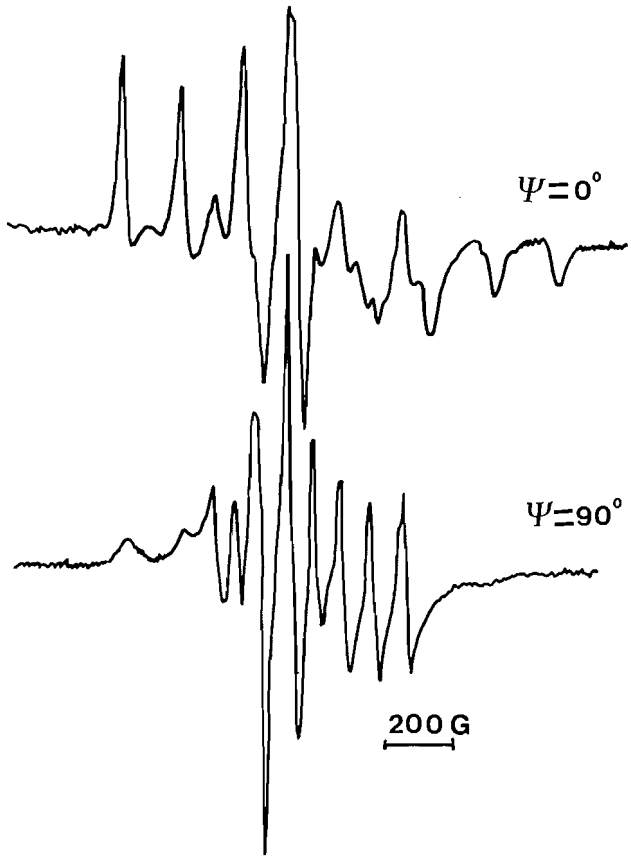

FIG. 6. Spectres de l'ions VO^{2+} en phase lamellaire NaDBP/H_2O, $X_M = 0{,}13$ pour les orientations perpendiculaires ($\psi = 0°$) et parallèle ($\psi = 90°$) de la cellule par rapport à B_0. Ces spectres indiquent que l'axe V—O s'oriente préférentiellement selon la normale au plan de la cellule ($\theta_0 = 0$).

corrélation $\tau_R = \tau_0$ de nutation de l'axe V—O autour du directeur local Δ_L de la phase lamellaire. La rpe de VO^{2+} en solutions de viscosité variable (1) indique que la détermination de τ_R par des mesures de largeurs de raies (éq. [4]) ne s'applique que pour $\tau_R < 3 \times 10^{-10}$ s, étant donné la grandeur de l'anisotropie du couplage hyperfin ($A_\parallel - A_\perp \simeq 3{,}5 \times 10^8$ Hz). La comparaison des spectres de VO^{2+} dans la mésophase NaDBP/H_2O avec des systèmes analogues (22) ou des spectres théoriques (23, 24) montre que l'échelle de temps des mouvements de réorientation se situe entre 10^{-8} et 10^{-9} s.

Dans ces conditions, la largeur totale $\Delta A = 7\,A_\parallel$ du spectre de VO^{2+}, mesurée entre les pics extrêmes sur un échantillon polyorienté, dépend du temps de corrélation τ_R (23) et donne un paramètre d'ordre $0{,}7 < S^*_{33} < 1$ supérieur au paramètre d'ordre $S_{33} = \bar{P}_2$ (cos β′) donnant l'orientation moyenne de V—O autour de Δ_L. La distinction entre S_{33} et S^*_{33}, que McConnell désigne respectivement par "ensemble-average order parameter" et "frequency-amplitude order parameter" est discutée dans la réf. 9. L'anisotropie de déplacement chimique du phosphore donne $S_{33} \simeq 0{,}5$ à 0,65 selon la fraction molaire de NaDBP; on peut admettre des valeurs assez proches de celles-ci pour l'ion VO^{2+} lié aux groupes phosphates.

En milieu isotrope, τ_R peut être évalué par la relation empirique (14, 23):

$$[24] \quad \tau_R = \alpha\,(1 - S)^\beta$$

valable pour $0{,}8 < S = A_\parallel/A_{ZZ} < 1$, α et β étant des constantes

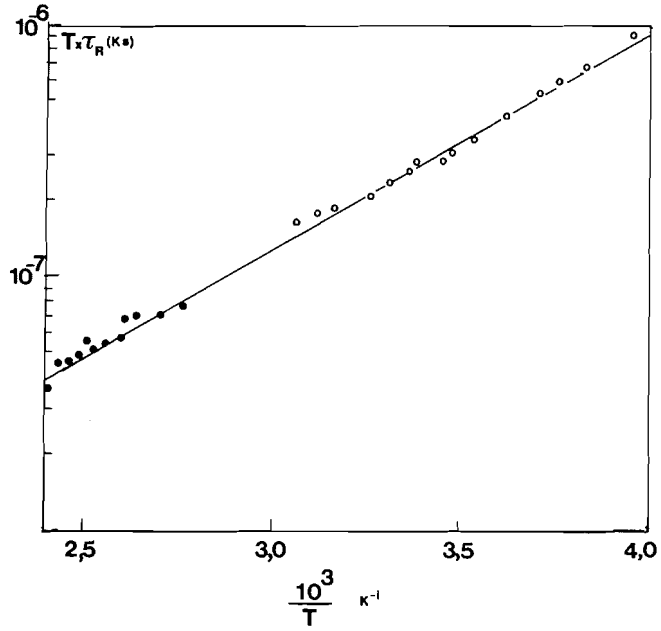

FIG. 7. Détermination des paramètres α et β de la relation $\tau_R = \alpha\,(1 - A_\parallel/A_{ZZ})^\beta$ à partir du spectre rpe de $VO(AA)_2$ dans l'acide dibutylphosphorique. (●) $T \times \tau_R$ est donné par la dépendance des largeurs de raies en fonction de m_I, pour $\tau_R < 3 \times 10^{-10}$ s (relation [4]). (○) $T \times \tau_R$ est calculé à partir des rapports $A_\parallel/A_{ZZ}$ pour $\alpha = 2{,}95 \times 10^{-11}$ s et $\beta = -1{,}42$.

dépendant du modèle de réorientation (14). L'application de cette relation à un milieu anisotrope a été effectué par Polnaszek *et al.* (25) dans le cas de radicaux nitroxydes, en tenant compte de la contribution, dans un certain domaine, de la décroissance de S_{33} avec la température. Dans le cas présent, on ne note pas de discontinuité dans la variation de S entre 280 et 350 K malgré les transitions de phase III → I et I → II (Fig. 1), cette dernière annulant S_{33}. On peut donc admettre que la décroissance de S avec la température ne dépend que de τ_R. Des valeurs de α et β ont été données par Bruno *et al.* (23) pour un modèle de diffusion Brownienne, en fonction de la largeur de raie résiduelle $\Delta B'$ ($\alpha = 1{,}02 \times 10^{-11}$ s, $\beta = -1{,}97$ et $\alpha = 1{,}38 \times 10^{-11}$ s, $\beta = -1{,}84$ pour $\Delta B' = 1$ G ou 7,5 G). Il nous a paru préférable de déterminer ces deux paramètres en mesurant la variation avec la température de S pour l'acétylacétonate de vanadyle ($VO(AA)_2$) dans l'acide dibutylephosphorique (HDBP).

La relation de Stokes–Einstein, avec une viscosité variant exponentiellement avec $1/T$ (voir par exemple, la réf. 26), nous donne:

$$[25] \quad \tau_R = \frac{V}{kT}\,\eta_0 \exp\left(\frac{E}{kT}\right)$$

où V est le volume moléculaire et η la viscosité du solvant. A des températures supérieures à 360 K pour lesquelles $\tau_R < 3 \times 10^{-10}$ s, ce temps de corrélation est obtenu par la dépendance des largeurs de raies avec m_I (éq. [4]). Ayant vérifié que log ($\tau_R \times T$) varie linéairement avec $1/T$, avec une énergie d'activation de $3{,}9 \pm 0{,}2$ kcal mol^{-1}, l'extrapolation de cette fonction dans le domaine des mouvements lents ($128 < T < 320$ K) permet de calculer τ_R. En mesurant le rapport S dans ce domaine, on obtient $\alpha = (2{,}95 \pm 0{,}03) \times 10^{-11}$ s et $\beta = -1{,}42 \pm 0{,}02$, par les moindres carrés (Fig. 7).

La variation de τ_R avec la température pour des fractions molaires de NaDBP $X_M = 0{,}13$ et $X_M = 0{,}165$ est donnée par

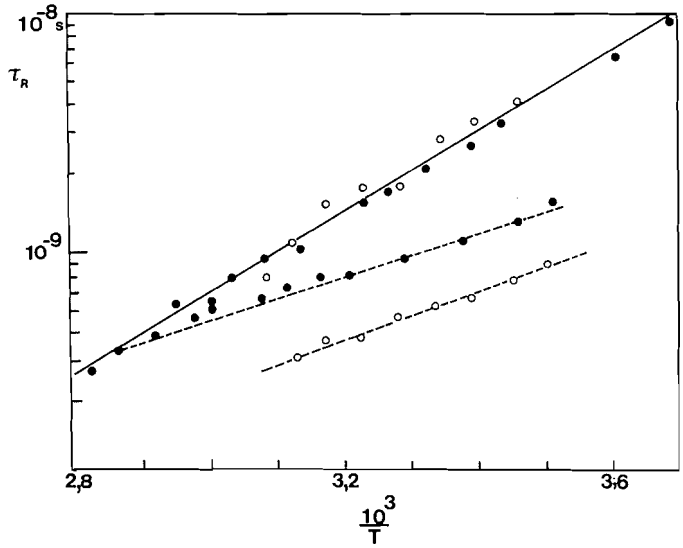

FIG. 8. Temps de corrélation de nutation de l'axe z des tenseurs **A** et **g** de VO^{2+} et du tenseur σ de ^{31}P autour du directeur Δ_L perpendiculaire à la phase lamellaire, déterminés par la largeur totale du spectre de VO^{2+} (●) ou par relaxation longitudinale de ^{31}P (○). (—) X_M = 0,165; (- - -) X_M = 0,13.

la figure 8. Le temps de corrélation τ_R déterminé par la rpe de VO^{2+} a été comparé à celui fourni par la relaxation nucléaire longitudinale de ^{31}P, qui donne la mobilité des groupes phosphate à l'interface entre les domaines polaires et non polaires de la mésophase, les axes z des tenseurs magnétiques de VO^{2+} et du tenseur de déplacement chimique de ^{31}P étant orientés perpendiculairement au plan lamellaire. La relaxation de ^{31}P comporte une contribution de l'anisotropie de déplacement chimique (ADC) et de l'interaction dipolaire avec les protons voisins (DIP), qui ont pour expressions respectives:

$$[26] \quad (T_1^{-1})_{ADC} = \omega_p^2 \sum_{K=-2}^{2} F^{(K)} F^{(-K)} J_{1K}(\omega_p)$$

avec:

$$[27] \quad F_\sigma^{(0)} = \sqrt{\frac{2}{3}}\left[\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy})\right]$$

$$F_\sigma^{(\pm 1)} = 0$$

$$F_\sigma^{(\pm 2)} = \frac{1}{2}(\sigma_{xx} - \sigma_{yy})$$

σ_{ii} étant les valeurs principales du tenseur de déplacement chimique de ^{31}P données dans la figure 5, et:

$$[28] \quad (T_1^{-1})_{DIP} = \frac{1}{3} \sum_{K=-2}^{2} F_D^{(K)} F_D^{(-K)} [J_{0K}(\omega_H - \omega_p) + 3J_{1K}(\omega_p) + 6J_{2K}(\omega_H + \omega_p)]$$

avec:

$$[29] \quad F_D^{(0)} = \sqrt{\frac{3}{2}}\gamma_p \gamma_H \hbar\, r_{PH}^{-3}, \qquad F_D^{(\pm 1)} = F_D^{(\pm 2)} = 0$$

r_{PH} étant la distance effective proton–phosphore évaluée à 2,3 Å d'après la relaxation de ^{31}P en milieu micellaire (1). Les densités spectrales sont données par les relations [9] et [10]. On remarque sur la figure 8 que pour la plus forte de ces concentrations, qui correspond à peu près à la rigidité maximum de la phase lamellaire, ces deux méthodes sont en accord et nous donnent $\tau_R = (2,4 \pm 0,2) \times 10^{-9} \exp[4200\,(1/T - 1/300)]$ s soit $E_0 = 8,3 \pm 0,3$ kcal mol^{-1}. τ_R se situe donc dans une échelle de temps de 10^{-9} à 3×10^{-9} s, comparable à celle observée par rpe de VO^{2+} (22) ou de radicaux nitroxydes (4) dans d'autres mésophases lyotropes, qui correspondrait à un mouvement moléculaire coopératif entraînant une déformation de l'interface entre les domaines polaires et non polaires (22) et donc à une fluctuation d'orientation du directeur de la phase lamellaire.

A plus faible concentration en NaDBP (X_M = 0,13), la relaxation nucléaire de ^{31}P et la rpe de VO^{2+} donnent respectivement $\tau_R = (5,5 + 0,5) \times 10^{-10} \exp[2500\,(1/T - 1/300)]$ s et $(1,0 \pm 0,1) \times 10^{-9} \exp[2200\,(1/T - 1/300)]$ s soient $E_0 = 5,0 \pm 0,3$ kcal mol^{-1} et $E_0 = 4,3 \pm 0,3$ kcal mol^{-1}. Cette différence d'un facteur deux entre ces déterminations de τ_R est interprétable par un accroissement de la liberté de réorientation avec la teneur en eau. En effet, la réorientation moléculaire autour de l'axe z intervient dans la relaxation de ^{31}P mais non dans le spectre rpe de l'ion VO^{2+} dont les tenseurs magnétiques sont axiaux selon cette direction. Ce point doit être vérifié par une étude en cours sur l'effet de la concentration sur la relaxation de ^{31}P et la largeur totale du spectre rpe du complexe VO^{2+}/NaDBP dans tout le domaine d'existence de la phase lamellaire.

Radicaux nitroxydes

En phase lamellaire NaDBP/H_2O, les constantes de couplage des radicaux nitroxydes sont de 14,9, 15,9 et 15,85 G respectivement pour la tempone, la tempoamine et la tempobutanamide. Pour ces mêmes radicaux a_N est de 13 G en milieu apolaire et de 16 G (tempone) ou de 17 G (tempoamine) en solution aqueuse. Le groupe nitroxyle de ces sondes paramagnétiques est donc localisé dans les domaines polaires de la mésophase.

L'anisotropie du couplage hyperfin de l'azote qui, en phase lamellaire, croît dans l'ordre tempobutanamide, tempone, tempoamine, ainsi que l'anisotropie de **g** permettent de déterminer les paramètres d'ordre S_{ii}. Cette mesure, généralement effectuée en cellule rectangulaire, est réalisée en orientant la cellule parallèlement puis perpendiculairement au champ magnétique et vérifiée par simulation des spectres selon ces deux orientations.

La tempobutanamide possède une chaîne de longueur comparable à celle du dibutylephosphate et susceptible de s'incorporer dans des doubles couches hydrocarbonées de la phase lamellaire. Son spectre présente une faible variation d'écart hyperfin et un déplacement de la raie centrale par rotation de l'échantillon entre les angles $\psi = 0°$ et $\psi = 90°$ qui nous donnent $A_\parallel - A_\perp = 1,4 \pm 0,2$ G, $g_\parallel - g_\perp = -3,14 \times 10^{-4}$ et donc $S_{33} = 5 \times 10^{-2}$, $S_{22} = -1,2 \times 10^{-2}$ et $S_{11} = -3,8 \times 10^{-2}$, sans variation notable avec la température. La simulation des spectres de la tempobutanamide (Fig. 9) indique une réorientation quasi-isotrope. Etant donné la faible anisotropie du couplage hyperfin, les temps de corrélation τ_R dont la variation avec la température est donnée dans la figure 10, ont été déterminés à partir des largeurs de raies mesurées directement sur les spectres comme en phase isotrope. Le comportement de la tempobutanamide, très voisin de celui que l'on observe en phase liquide isotrope, suggère une forte perturbation de l'ordre local de la mésophase, ce qui nous a conduit à étudier plus en détail d'orientation et la dynamique de la tempoamine et de la tempone dont les dimensions sont inférieures à celles des molécules de NaDBP.

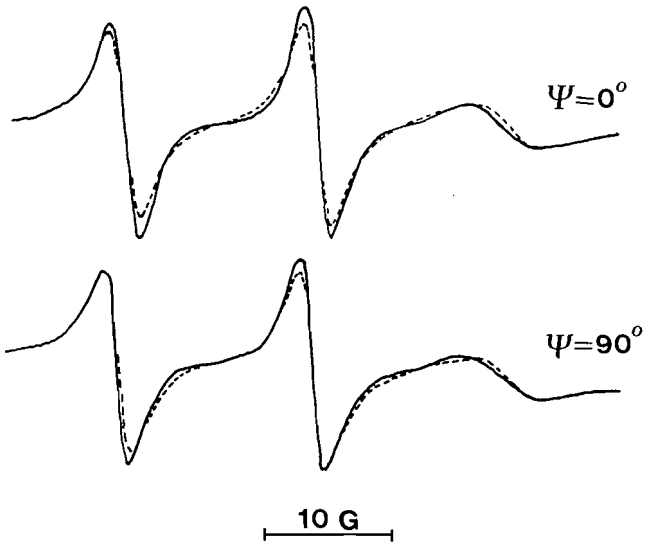

FIG. 9. Tempobutanamide en phase lamellaire (T = 300 K, X_M = 0,13). Les spectres en pointillés sont simulés avec les paramètres: S_{11} = −0,0125, S_{22} = −0,0385, S_{33} = 0,051, τ_R = 1,5 × 10^{-9} s, $\Delta B'$ = 0,8 G.

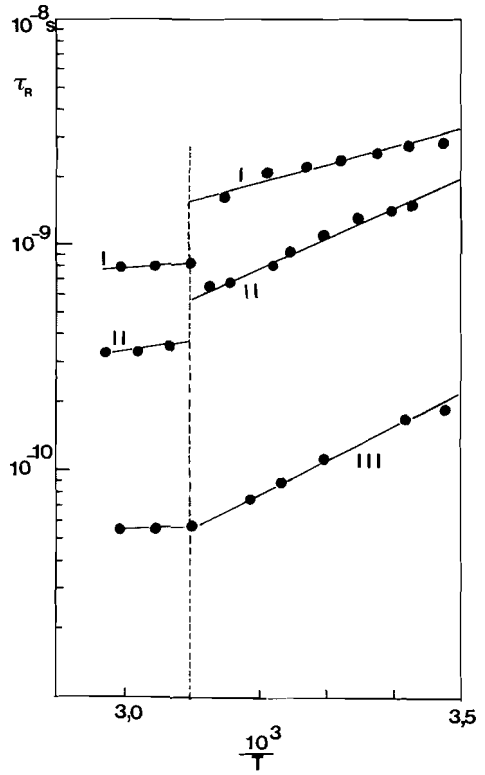

FIG. 10. Dépendance avec la température de $\tau_0 = \tau_R$: (I) tempoamine, (II) tempobutanamide, (III) tempone en solution dans NaDBP/H_2O, X_M = 0,13. Le trait pointillé correspond à la transition entre les phases lamellaire et isotrope. Les facteurs préexponentiels et les énergies d'activation sont donnés dans le Tableau 2.

Les spectres de la tempoamine polyorientée ou partiellement orientée (Fig. 11) ont été enregistrés immédiatement après la transition III → I (280 K) puis après recuit de l'échantillon jusqu'à 320 K, quelques degrés au-dessus de la transition I → II (~325 K). Les spectres correspondant aux orientations ψ = 0° et ψ = 90° de la cellule rectangulaire montrent que la tempo-

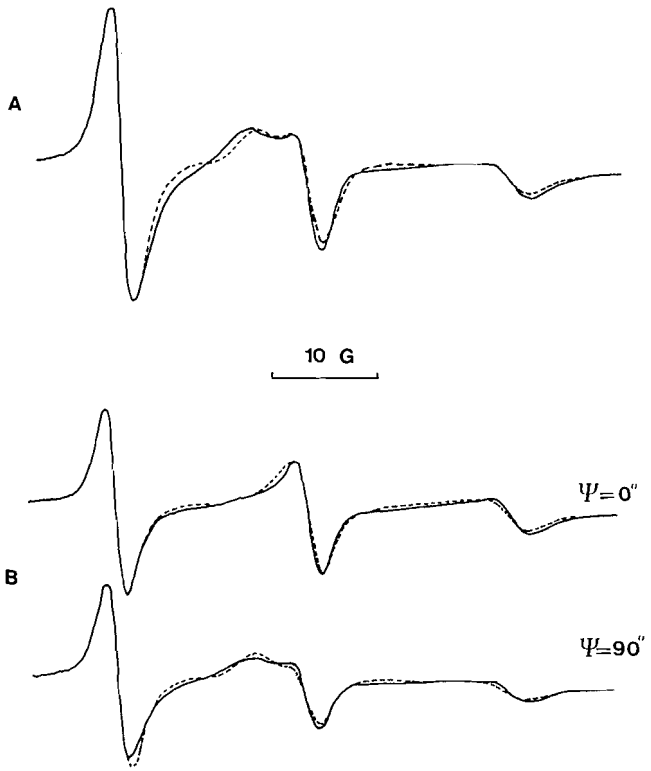

FIG. 11. Spectres de la tempoamine en phase lamellaire X_M = 0,13 à 290 K, avant réchauffement à la transition lamellaire → isotrope. A: Orientation aléatoire des radicaux; B: radicaux partiellement orientés dans le plan de la cellule rectangulaire ($\Delta\theta_m$ = 40°, θ_0 = 90°). (—) Spectres expérimentaux; (- - -) spectres calculés avec: τ_0 = 2,5 × 10^{-9} s; τ_2 = 5 × 10^{-10} s; S_{11} = 0,73; S_{22} = −0,46; S_{33} = −0,27. L'élargissement inhomogène est introduit par convolution gaussienne du spectre avec $\Delta B'$ = 0,8 G.

amine se réoriente préférentiellement autour de l'axe N—O• ($A_\parallel$ = 10,7 G, $A_\perp$ = 18,4 G, $g_\parallel$ = 2,0085, $g_\perp$ = 2,005) et que le directeur Δ_L est orienté en moyenne parallèlement au plan de la cellule. La simulation de ces spectres indique en outre que la distribution angulaire statique de Δ_L peut être représentée par une gaussienne de largeur 40° centrée sur θ_0 = 90°.

Après réchauffement de l'échantillon au-delà de la transition entre la phase lamellaire et la phase isotrope, puis refroidissement lent dans le champ magnétique, on observe un alignement de l'axe N—O de la tempoamine selon l'axe de l'échantillon. La rotation de l'échantillon autour de cet axe n'entraîne qu'une faible différence entre les spectres enregistrés selon les orientations ψ = 0 et ψ = 90°, dont on peut rendre compte par une distribution étroite d'orientation de Δ_L autour des angles ϕ_0 = 90° et θ_0 = 90° (Fig. 12). Ce comportement que l'on observe également par rmn de ^2H et ^{31}P (2) correspond à une orientation de Δ_L perpendiculaire au champ magnétique.

Pour une orientation perpendiculaire de la cellule par rapport à B_0 (ψ = 0), le spectre rpe de la tempoamine est pratiquement symétrique par rapport à la ligne de base (Fig. 12). L'ecart hyperfin de ce spectre et le facteur g de la raie centrale qui varient de 18,3 G à 18,1 G et de 2,0053 à 2,0051 entre 295 K et 325 K (Tableau 2) donnent les valeurs moyennes de paramètres d'ordre S_{11} = 0,6, S_{22} = −0,35, S_{33} = −0,25.

Dans l'hypothèse d'une réorientation axiale, S_{33} est donné par la relation [13]. On montre facilement que les autres paramètres d'ordre peuvent s'écrire:

TABLEAU 2. Paramètres d'ordre et temps de corrélation de réorientation des radicaux nitroxydes en phase lamellaire NaDPB/H_2O (X_M = 0,13)

		T (K)				
	Paramètre	288	294	303	313	322

Temps de corrélation: $\tau_R = (\tau_R)_{300} \exp\left[\frac{E}{R}\left(\frac{1}{T} - \frac{1}{300}\right)\right]$

Tempoamine: $(\tau_R)_{300} = 2{,}35 \times 10^{-9}$ s, $E = 3{,}75$ kcal mol^{-1}

T(K)	288	292	296	301	306	316
$D_\parallel/D_\perp$	6	8	9	10	11	9

Tempone: $(\tau_R)_{300} = 1{,}1 \times 10^{-10}$ s, $E = 5{,}9$ kcal mol^{-1}, $\frac{D_\parallel}{D_\perp} = 2{,}5 \pm 0{,}5$

Tempobutanamide: $(\tau_R)_{300} = 1{,}15 \times 10^{-9}$ s, $E = 5{,}6$ kcal mol^{-1}, $\frac{D_\parallel}{D_\perp} = 1$

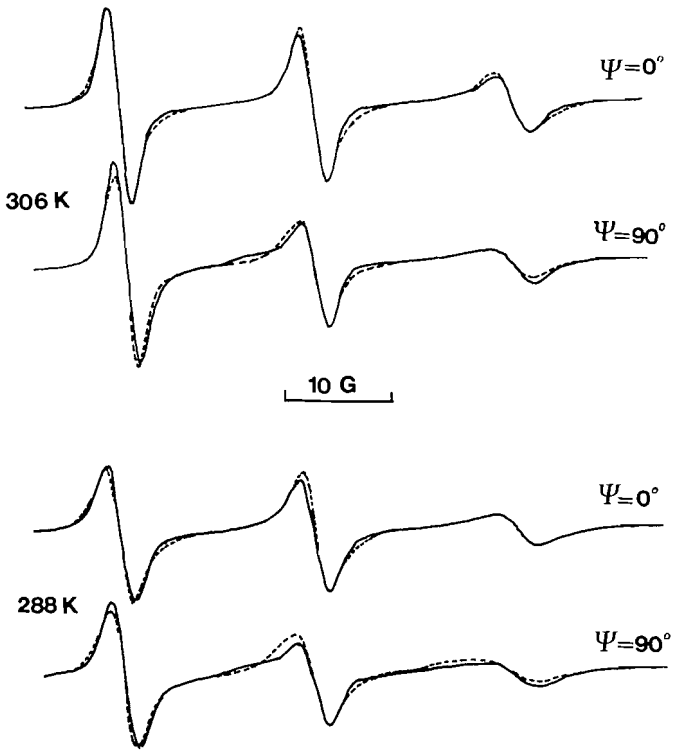

FIG. 12. Spectres de la tempoamine orientée par refroidissement de l'échantillon dans le champ magnétique, à partir de la phase isotrope (X_M = 0,13). (—) Spectres expérimentaux; (- - -) spectres calculés à partir des paramètres du Tableau 2. Le spectre correspondant à ψ = 90° est calculé pour une distribution gaussienne d'orientations de Δ_L avec $\Delta\theta_m$ = 10°, θ_0 = 90°, $\Delta\phi_m$ = 25°, ϕ_0 = 90° (éq. [15]). La distribution des angles ϕ n'a pas d'influence sur les spectres correspondant à ψ = 0° alors que la distribution des angles θ contribue à l'élargissement inhomogène des raies.

$$S_{11} = \frac{1}{2}\bar{P}_2(\cos\beta')\,[3\sin^2\beta\cos^2\gamma - 1] \quad [30]$$

$$S_{22} = \frac{1}{2}\bar{P}_2(\cos\beta')\,[3\sin^2\beta\sin^2\gamma - 1]$$

où γ désigne l'angle azimuthal de Δ_M dans le système d'axes moléculaires x, y, z (Fig. 4), ici égal à zéro, étant donné la symétrie du radical tempoamine. L'angle β entre Δ_M et l'axe z des tenseurs **A** et **g** est alors donné par la relation:

$$[31]\quad \beta = \arccos\left[\frac{1}{\sqrt{3}}\left(\frac{\rho+3}{\rho+1}\right)^{1/2}\right]$$

que l'on déduit des équations [13] et [30] en prenant $\rho = (S_{11} - S_{22})/S_{33}$. On obtient ainsi $\beta \simeq 72°$ soit une déviation de 18° entre les axes x et Δ_M, avec $\bar{P}_2(\cos\beta') \simeq 0{,}7$. Il est peu probable qu'une telle déviation corresponde à la réalité, d'une part parce que la rpe et la cristallographie des nitroxydes étudiés ici indiquent que l'angle entre l'axe x et l'axe de moindre inertie (direction N—O') ne dépasse pas 10° (6), d'autre part parce que le meilleur accord entre les largeurs de raies calculées et observées est realisée pour β = 90° et $\bar{P}_2(\cos\beta') = 0{,}6$. Il n'est pas exclu que la différence entre cette valeur effective de l'angle β et celle donnée par la relation [31] résulte de ce que le tenseur de diffusion moleculaire n'est pas parfaitement axial, comme nous l'avons admis en prenant pour simplifier les calculs de largeurs de raies, $D_\parallel = D_{xx}$, $D_\perp = \frac{1}{2}(D_{yy} + D_{zz})$.

La dynamique de réorientation de la tempoamine a été déterminée à partir des largeurs de raies mesurées sur les spectres symétriques obtenus pour l'orientation ψ = 0 de l'échantillon par rapport au champ magnétique (Fig. 12). Pour cela on a utilisé un programme qui recherche par la méthode des moindres carrés le meilleur accord entre les largeurs de raies et celles calculées à partir des relations [4]–[13] en prenant comme

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

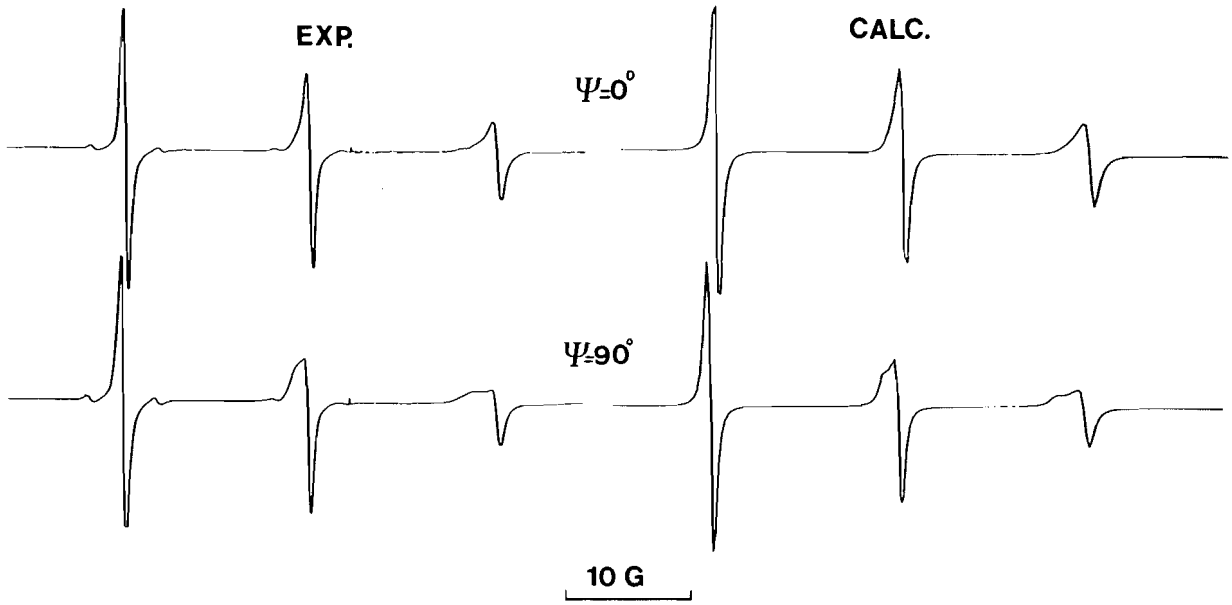

FIG. 13. Spectres de la tempone à 300 K (X_M = 0,13). Les paramètres utilisés pour la simulation de ces spectres sont donnés dans le Tableau 2, avec une distribution gaussienne d'orientations de Δ_L de largeur $\Delta\theta_m$ = 25° autour de θ_0 = 90° et une largeur inhomogène de raie de 0,3 G.

paramètres ajustables τ_0, τ_2 et donc $D_\parallel/D_\perp$, ainsi que la largeur inhomogène de raie $\Delta B'$ (eq. [22] que l'on trouve comprise entre 0,8 et 1 G. La validité de cette méthode a été vérifiée par simulation des spectres, pour une forme Lorentzienne de raie (Fig. 12). Dans tout le domaine de température étudié, on observe que $\tau_2 \ll \tau_0$, ce qui indique une réorientation rapide autour de l'axe Δ_M. Le rapport $D_\parallel/D_\perp$ varie de 5 à 11 entre 295 K et 325 K (phase lamellaire) et diminue à 3 en milieu isotrope. Que l'on envisage une réorientation par sauts ou une diffusion brownienne, ce rapport est beaucoup plus élevé que celui auquel on peut s'attendre d'après les dimensions moléculaires de la tempoamine, comparables à celles de la tempone que nous verrons plus loin. L'association par liaison hydrogène de la tempoamine avec les groupes phosphates du NaDBP est suggérée par la valeur quasi équivalente du paramètre $\bar{P}_2$ (cos β′) que l'on obtient par rpe (Tableau 2) et par rmn du phosphore. On note également sur la figure 10 que τ_R est du même ordre de grandeur que le temps de corrélation du mouvement de nutation de l'axe z du groupe phosphate (Fig. 8) avec $E_0 \simeq 3.75$ kcal mol^{-1} pour la tempoamine et $E_0 \simeq 4.3$ kcal mol^{-1} pour ce groupe.

Des expériences similaires ont été effectuées sur la tempone dissoute en phase lamellaire. Les spectres obtenus pour les orientations $\psi = 0$ et $\psi = 90°$ de la cellule rectangulaire (Fig. 13) ont été interprétés comme pour la tempoamine par une orientation de N—O en moyenne parallèle au plan de la cellule avec une distribution angulaire de largeur ~25° autour de θ_0 = 90°. Les positions des singularités du spectre correspondant à $\psi = 90°$ donnent en moyenne $S_{11} = 0,14$, $S_{22} = -0,10$ et $S_{33} = -0,04$. Les relations [13] et [31] nous donnent $\beta = 67°$ et $\bar{P}_2$ (cos β′) ≅ 0,15, cependant ici encore les amplitudes relatives et les largeurs de raies calculées concordent mieux avec l'expérience pour $\beta = 90°$.

La dynamique de réorientation de la tempone en phase lamellaire a été étudiée en déterminant τ_0 et $D_\parallel/D_\perp$ par comparaison des amplitudes relatives de raies I_0/I_{+1} et I_{-1}/I_{+1} du spectre expérimental obtenu pour $\psi = 0$, avec celles calculées en fonction de ces deux paramètres, pour une distribution gaussienne d'orientations de Δ_L de largeur 25° autour de $\theta_0 = 90°$. En phase lamellaire, le rapport $D_\parallel/D_\perp = 2,5 \pm 0,5$ est nettement supérieur à la valeur de 1,36 calculée à partir des dimensions moléculaires de la tempone $d_{x'}$ = 4,2 Å selon la direction N—O, $d_{z'}$ = 2,7 Å dans le plan de symétrie moléculaire et $d_{y'}$ = 3 Å (7). En phase isotrope on obtient par contre $D_\parallel/D_\perp \simeq 1$ avec $\tau_0 \cong \tau_2 = 6 \times 10^{-11}$ s à 330 K. En phase lamellaire $\tau_0 = \tau_R$ est inférieur d'un facteur 10 environ à celui de la tempoamine (Fig. 10) et comparable à celui des molécules d'eau interstitielles mesuré par relaxation de ^{2}H et ^{17}O ($8 \times 10^{-11} < \tau_R < 2,5 \times 10^{-10}$ pour $320 > T > 300$ K) (2). On note également que les paramètres d'ordre S_{ii} augmentent en valeur absolue avec la température. Ce phénomène, pour lequel nous n'avons pas trouvé jusqu'à présent d'interprétation satisfaisante, est également observé pour le deutérium (Fig. 1) et l'oxygène 17 de l'eau (2). Ces deux faits nous suggèrent que l'anisotropie de réorientation de la tempone en phase lamellaire résulte de la formation de liaisons hydrogènes entre les molécules d'eau et les oxygènes des groupes nitroxyle et carbonyl qui définissent l'orientation de l'axe de rotation moléculaire Δ_M.

V. Conclusion

Ce travail, mené en parallèle avec des expériences de résonance nucléaire, constitue une première partie d'une étude sur la dynamique et l'orientation moléculaire dans les phases cristallines liquides provenant de solutions aqueuses concentrées d'alkylphosphates.

Le spectre rpe de l'ion vanadyle, lié au groupe phosphate, permet de mesurer, en complément de la relaxation de ^{31}P, la mobilité moléculaire à l'interface des domaines polaire et non polaire de la mésophase.

La tempobutanamide effectue un mouvement de réorientation quasi-isotrope avec un paramètre d'ordre moléculaire $\bar{P}_2$ (cos β′) ≅ 0 en raison soit de rotations internes multiples, soit d'une désorganisation du réseau bidimensionnel de la mésophase due à la dimension de ces sondes, comparable à celles de dibutylphosphate.

La tempone et la tempoamine sont localisées dans les couches polaires de la mésophase et se réorientent préféren-

For personal use only.

tiellement autour de la liaison N—O dont l'orientation moyenne est parallèle au directeur de la phase lamellaire. Bien que ces deux sondes aient des dimensions moléculaires comparables, les temps de corrélation de réorientation et le paramètre d'ordre $\bar{P}_2$ (cos β') sont beaucoup plus importants pour la tempoamine que pour la tempone. Il est probable que la tempoamine forme à la fois des liaisons hydrogène avec l'eau et avec les oxygènes d'un groupe phosphate alors que la tempone ne se lie qu'aux molécules d'eau. Ces interactions paraissent seules susceptibles d'expliquer la forte anisotropie de réorientation de ces deux radicaux nitroxydes en phase lamellaire.

Quadrupolar interactions in amines as determined by ^{1}H nuclear magnetic resonance: mono- and dimethylamines[1]

JAMES D. HALLIDAY, PATRICK E. BINDNER, and SHAHSULTAN PADAMSHI

Physical Chemistry Branch, Atomic Energy of Canada Limited, Research Company, Chalk River Nuclear Laboratories, Chalk River, Ont., Canada K0J 1J0

Received December 13, 1983

JAMES D. HALLIDAY, PATRICK E. BINDNER, and SHAHSULTAN PADAMSHI. Can. J. Chem. **62**, 1258 (1984).

Nitrogen-14 quadrupole interactions have been observed in the nonexchanging amino proton ^{1}H nmr spectra of rigorously purified liquid mono- and dimethylamines over the temperature range −82°C to +81°C. The proton lineshapes have been analyzed to yield ^{14}N spin-lifetimes (τ) as a function of temperature. Activation energies and correlation times for molecular reorientation in the liquids have been calculated from these data and the results compared with those from ^{14}N nmr measurements.

JAMES D. HALLIDAY, PATRICK E. BINDNER et SHAHSULTAN PADAMSHI. Can. J. Chem. **62**, 1258 (1984).

L'examen des spectres rmn du ^{1}H de mono- et de diméthylamines liquides rigoureusement purifiées, à des températures allant de −82°C à +81°C, a permis d'observer les interactions quadrupolaires de l'azote-14 avec les protons aminés qui ne peuvent pas s'échanger. On a analysé la forme des raies des protons afin d'obtenir les temps de vie des spin du ^{14}N en fonction de la température. Utilisant ces données, on a calculé les énergies d'activation et les temps de corrélation des réorientations moléculaires dans les liquides et on a comparé les résultats avec ceux obtenus à partir d'autres mesures de rmn du ^{14}N.

[Traduit par le journal]

Introduction

Analysis of the proton lineshapes (1, 2) for molecules in which the proton is spin-coupled to a ^{14}N nucleus represents an alternate way of obtaining data on ^{14}N quadrupole interactions in the liquid phase. The temperature dependence of the ^{14}N spin-lifetimes (τ) leads to activation energies and correlation times for molecular dynamical processes (3) in the liquids. Comparison of data from both ^{1}H and ^{14}N nmr spectra of the methyl substituted ammonias had not been possible previously because of loss of ^{14}N—H spin coupling owing to rapid amino proton exchange, even in distilled samples (4). We have succeeded in obtaining anhydrous, amino proton exchange free methylamine (5) and dimethylamine and have analyzed the temperature dependence of the amino proton line shapes. A comparison is made between these data and the ^{14}N nmr studies by Atkins, Loewenstein, and co-workers (6, 7).

Experimental

Anhydrous dimethylamine (Eastman) was prepared by a technique similar to that previously reported for the preparation of anhydrous methylamine (5). A glass apparatus (Fig. 1), which allowed keeping the solution under vacuum at all times, contained 8 Wilmad 528 (5-mm) nmr tubes and 2 reservoirs A, B. After evacuation of the system a saturated solution of cesium dimethylamide in dimethylamine under vacuum was added and the vessel was sealed with a J. Young Co. Ltd. valve, C. The very reactive cesium dimethylamide solution was allowed to contact the walls of the apparatus for 24 h to remove any traces of adventitious water. Hydrogen gas was pumped off after freezing the solution with liquid nitrogen and, upon thawing, the amide solution was poured into reservoir A, the amine cryodistilled back into B using liquid nitrogen, and the vessel rinsed with this distillate. This procedure for washing all of the amide solution into A was repeated 15 times or until no amide uv absorbance was detected in the attached optical cells. A sample was then distilled into an nmr tube and sealed off. Repeated rinsings followed until there was no difference in the amino and methyl group proton nmr spectra in successive nmr tube samples.

Anhydrous trimethylamine was also prepared in an attempt to measure quadrupole effects through H—C—^{14}N coupling. Since there are no amino protons to exchange, purification was simplified. The amine was allowed to contact a potassium mirror in a glass flask with a J. Young Co. Ltd. valve for at least 24 h to remove any residual water. It was then cryodistilled into a 5-mm nmr tube and sealed off.

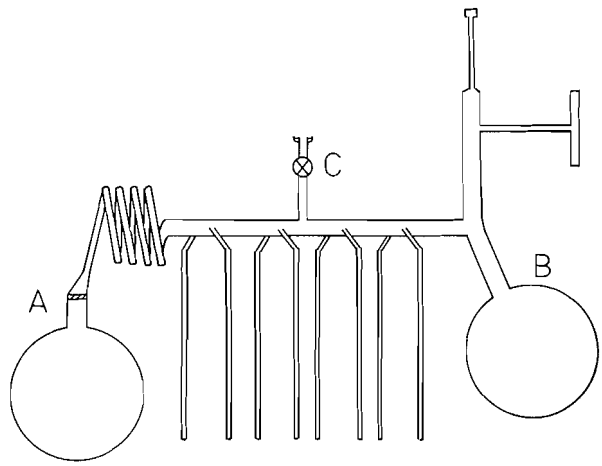

FIG. 1. Schematic of apparatus used for the preparation of anhydrous dimethylamine nmr samples.

The nmr spectra (^{1}H) were obtained with a Bruker HX90 spectrometer (90 MHz, 2.114 T) equipped with a Bruker B-ST100/700 variable temperature controller (±0.5°C) and Nicolet 1174 signal averager.

Results

The data presented in this paper for ^{14}N spin-lifetimes in dimethylamine, methylamine, and ammonia have been obtained from current research ($(CH_3)_2NH$), previous research (CH_3NH_2 (5)), and the literature (NH_3 (8)). The previously obtained ^{14}N spin-lifetime data for ammonia (8) and methylamine (5) were originally used to allow calculation of the base-catalyzed exchange kinetics in the $NH_3/\bar{N}H_2$ and $CH_3NH_2/CH_3\bar{N}H$ systems. The ^{14}N spin-lifetimes' relevance to the determination of ^{14}N quadrupolar parameters was not addressed in these papers.

For the anhydrous dimethylamine case a typical amino pro-

ton nmr spectrum is shown in Fig. 2, along with the simulated spectrum calculated using the procedure of Sack (1) and Pople (2), described below. These amino resonances are broader than those measured for methylamine (5), indicating an increased asymmetry in the electric field gradient at the ^{14}N nucleus with increased methyl group substitution on the nitrogen nucleus. Since amino proton exchange has been suppressed by the purification technique (the methyl groups show sharp multiplets through coupling with the non-exchanging amino proton(s)), the lineshape observed is due solely to coupling with both the ^{14}N nucleus and the protons on the methyl groups. This coupling is included in the theoretical calculation of the spectra.

Lineshape simulation for a proton spin-coupled to a ^{14}N nucleus

The amino proton nmr spectra were analyzed for ^{14}N spin-lifetimes using a lineshape function developed by Sack (1) and Pople (2) and modified with a linewidth parameter by Kintzinger *et al.* (9).

The lineshape is given by eq. [1]

$$[1]\quad I(\nu) \propto R(\mathbf{W}\cdot\mathbf{A}^{-1}\cdot\mathbf{1})$$

where R denotes "real part of", $\mathbf{W}$ is a vector containing the probabilities of the spin states in the ^{14}N, and $\mathbf{A}$ is a lineshape matrix given by eq. [2]

$$[2]\quad \mathbf{A} = \begin{bmatrix} \beta_1 & \frac{1}{\tau} & \frac{2}{\tau} \\ \frac{1}{\tau} & \beta_2 & \frac{1}{\tau} \\ \frac{2}{\tau} & \frac{1}{\tau} & \beta_3 \end{bmatrix}$$

The diagonal elements of $\mathbf{A}$ are defined by eqs. [3]–[5]

$$[3]\quad \beta_1 = i2\pi(\nu_0 - \nu + J_{^{14}NH}) - 3/\tau - 1/T_2$$

$$[4]\quad \beta_2 = i2\pi(\nu_0 - \nu) - 2/\tau - 1/T_2$$

$$[5]\quad \beta_3 = i2\pi(\nu_0 - \nu - J_{^{14}NH}) - 3/\tau - 1/T_2$$

where τ is the ^{14}N spin-lifetime, $1/T_2$ is the linewidth parameter, and $\mathbf{1}$ is the unit matrix.

The following procedure was used to simulate the amino proton spectra for dimethylamine.

1. The H^{14}NCH coupling constant was determined by comparison of the experimental methyl spectrum of this tightly coupled system with simulated spectra calculated with the Quantum Chemistry Program Exchange (QCPE) computer program DNMR3 (10).

2. The ^{14}N—H coupling constant was determined through

[a]Reference 15.
[b]Reference 16.

the experimentally observable ^{15}N—H coupling constant. For dimethylamine the ^{15}NH natural abundance (0.37%) spectrum is visible as a small septet on either side of the broad ^{14}N—H line (Fig. 2A). The magnitudes of the ^{14}NH and ^{15}NH coupling constants are theoretically related through the gyromagnetic ratios for the two nuclei, so that

$$J_{^{14}NH} = -\frac{\gamma_{^{14}N}}{\gamma_{^{15}N}} \cdot J_{^{15}NH}$$

The coupling constants are given in Table 1.

3. The QCPE computer program LAOCN-4A (11) was used to simulate the amino proton spectra in the absence of quadrupolar effects.

4. The above coupling constants and the Sack (1) equation were used to expand each spectral line in step 3, then the envelope of all the lines was obtained by summation for comparison with the experimental spectra.

The calculated spin-lifetimes, τ, are shown in Fig. 3 as a function of temperature. Our previous data for methylamine (5) and the data of Swift *et al.* for ammonia (8) are also included to show the complete series.

An attempt was also made to observe ^{14}N quadrupole effects in trimethylamine through changes in the methyl resonance ^1H spectra. However, as with methylamine and dimethylamine, no vicinal coupling could be measured. This H—C—^{14}N coupling ($J_{HC^{14}N} \leq 0.5$ Hz) has only been measured in very symmetrical compounds ($(CH_3)_4\overset{+}{N}$) where the electric field gradient at the nitrogen nucleus is zero by symmetry or very weak (12).

Discussion

Molecular dynamical parameters that may be derived from the ^{14}N spin-lifetimes shown in Fig. 3 are the molecular reorientation correlation time for isotropic tumbling (τ_q) and the activation energy for molecular reorientation.

1. *Correlation times, τ_q*

The ^{14}N spin-lifetimes are directly related to ^{14}N spin-lattice relaxation times, T_1, by $T_1 = \tau/5$ (13). The correlation time τ_q may be calculated from eq. [6]

$$[6] \quad 1/T_1 = \frac{3}{8}\left(1 + \frac{b^2}{3}\right)(e^2qQ/\hbar)^2\tau_q$$

where $e^2qQ/h = \chi$, the quadrupole coupling constant (MHz) and b is the asymmetry parameter of the electric field gradient. The calculated τ_q (25°C) are given in Table 2, with literature values for χ and b (15) and the ^{14}N T_1 (25°C) determined from the ^{14}N spin-lifetimes measured. The ammonia value of 2.08×10^{-13} s is in good agreement with data from Atkins *et al.* (6) who found τ_q for NH_3 of 1.8×10^{-13} s and τ_q for ND_3 of 2.3×10^{-13} s from ^{14}N data. We may compare these experimentally determined τ_q with a simple theoretical value, τ_c, based on the assumption of a liquid composed of hard spheres with radius A and viscosity η.

$$[7] \quad \tau_c = 4\Pi\eta A^3/kT \qquad \text{(ref. 14)}$$

A may be estimated from the molar volume, V_m (3), assuming hexagonal closepacked spheres: $A = (0.74\ V_m/(4\pi N_0/3))^{1/3}$ where N_0 is Avogadro's number. The values of τ_c (25°C), η, and A are also given in Table 2.

Our data for τ_q are significantly shorter than the values of τ_c estimated from a simple hard sphere model. Similar disagreements have also been noted in other studies (3) with the hard sphere model giving consistently longer estimates of τ_c than experimental values.

2. *Activation energies*

The Arrhenius activation energies for molecular reorientation in ammonia, methylamine, and dimethylamine may be obtained from the slope of the temperature dependence of the ^{14}N spin-lifetimes (τ) in a ln τ vs. $1/T$ plot (Fig. 3). The activation energies calculated from the ^1H nmr data are given in Table 3, along with data obtained from the literature for ^{14}N nmr relaxation time measurements.

The two methods agree within the experimental error limits for ammonia and dimethylamine but the activation energy of methylamine from the ^1H data is less than that reported from the ^{14}N data (8.8 kJ mol^{-1} vs. 11.6 kJ mol^{-1}). It is unlikely that this can be attributed to any residual amino proton exchange in the system because the amino proton coupling to the methyl group

TABLE 3. Comparison of E_a from ^1H and ^{14}N nuclear magnetic resonance measurements

Compound	E_a (^1H) (kJ mol^{-1})	E_a (^{14}N) (kJ mol^{-1})
NH_3	7.59±0.23	7.87±0.21[a]
ND_3	—	7.87±0.25[a]
CH_3NH_2	8.82±0.10	—
CH_3ND_2	—	11.63±0.59[b]
$(CH_3)_2NH$	13.82±0.25	—
$(CH_3)_2ND$	—	13.39±0.42[b]
$(CH_3)_3N$	—	5.02±0.17[b]

[a]Reference 6.
[b]Reference 7.

protons was well resolved even at the highest temperature. Calculation of the ^{14}N spin lifetimes from the ^{14}N data (7) shows that at 60°C the value is comparable to that obtained from the ^1H spectra but at −73°C the value is lower.

The accounts for the higher activation energy from the ^{14}N data. Thus any interaction with the protons that would increase with decreasing temperature might be the source of this difference. Increased molecular association through hydrogen bonding in the methylamine at reduced temperatures fulfills the requirements stated and it is conceivable that this could influence the ^1H nmr spectra such that it would lead to slightly differing values for the calculated τ.

In conclusion, we have shown that ^1H nmr measurements on protons spin-coupled to ^{14}N in carefully purified simple aliphatic amines can provide data on the quadrupolar interactions within the molecules that are in reasonable agreement with ^{14}N nmr studies (6, 7). Slight differences may be accounted for through hydrogen bonding effects.

Analytic results for finite systems of ringed flory polymers

JOHN L. SPOUGE

Theoretical Division, University of California, Los Alamos National Laboratory, Los Alamos, NM 87545 USA

Received August 29, 1983

JOHN L. SPOUGE. Can. J. Chem. **62**, 1262 (1984).

We examine Flory's RA_f model of polymerization for a finite closed system of N monomers. Monomers have f functional groups of type A. Random stepwise reaction between A's, regardless of ring formation, bonds the monomers together.

We give exact statistics for the resulting polymer distribution and verify the results of the Falk and Thomas computer simulation. As $N \rightarrow \infty$, Flory's modification of the Stockmayer distribution gives the distribution of finite polymers, and cyclization is confined to the gel.

Similar results hold for Flory's A_gRB_{f-g} model.

JOHN L. SPOUGE. Can. J. Chem. **62**, 1262 (1984).

Nous examinons le modèle de polymérisation RA_f de Flory pour un système formé de N monomères. Les monomères ont f groupes fonctionnels de type A. Une réaction aléatoire par étapes entre des groupes A, sans égard à la formation de cycles, relie ensemble les monomères.

Nous donnons des statistiques exactes relatives à la distribution du polymère qui en résulte et nous vérifions les résultats de la simulation par ordinateur de Falk et de Thomas. Lorsque $N \rightarrow \infty$, la modification apportée par Flory à la distribution de Stockmayer permet de déterminer la distribution des polymères finis et la cyclisation est confinée au gel.

On obtient des résultats analogues avec le modèle A_gRB_{f-g} de Flory.

[Traduit par le journal]

Introduction

Flory's RA_f model (1) serves as a paradigm of chemical polymerization. In this model, each monomeric unit has f functional groups of type A. Stepwise reaction between A's bonds the units together, forming polymers.

Let α be the proportion of A's which have reacted at a given time. Assuming that the A's react independently with probability α, and that *intramolecular reaction does not occur*, Flory (2) showed that an infinite polymer (gel) formed only for $f \geqq 3$ and that gelation took place at

$$[1] \quad \alpha_c = (f - 1)^{-1}$$

If the initial monomers have concentration 1, Stockmayer (3) showed that when the extent of reaction is α, the n-mer concentration is

$$[2] \quad x_n = \frac{w_n}{n!} \frac{\alpha^{n-1}(1 - \alpha)^{fn-2n+2}}{f^{n-1}}$$

where

$$[3] \quad w_n = \frac{f^n(fn - n)!}{(fn - 2n + 2)!}$$

is the number of ways of constructing one polymer from n units under classical statistics (i.e., all A's, though chemically identical, are distinguishable). Exclusion of intramolecular reaction ensures that only branched-chain polymers form.

Although Stockmayer's derivation indicated that eq. [2] was valid only for $\alpha < \alpha_c$, Flory (4) held that eq. [2] was valid for all α. Flory himself (ref. 4, p. 192) says: "in deducing these distribution equations it was merely necessary to assume, or rather to make the approximation, that no intramoleclular reactions occur *within finite species*" (italics his).

Whiteway *et al.* (5) challenged the restriction of intramolecular reaction to the gel as logically inconsistent, sparking a debate (6–8) which was settled by the Falk and Thomas (9) computer simulation.

In their "Rings Allowed Model", Falk and Thomas took a finite, closed system of N monomers. They paired the fN functional groups stepwise at random while keeping track of polymer sizes n and bond numbers b (i.e., $b = n - 1$ for ringless polymers). As $N \rightarrow \infty$, they found that the limiting distribution of finite polymers approached eq. [2] for all α; asymptotically, rings did not occur for $\alpha < \alpha_c$ and were "limited to infinite polymers" for $\alpha > \alpha_c$, thereby vindicating Flory's assumptions. Donoghue (10) also confirmed Flory's gel predictions by simulation.

In their "Rings Forbidden Model", Falk and Thomas performed a similar simulation but excluded intramolecular reactions and derived results consistent with Stockmayer's formulas. Ziff and Stell (11) later confirmed analytically that in the Stockmayer model, the gel reacts neither with the sol nor itself; whereas in Flory's model, it reacts with both.

Donoghue and Gibbs (12–14) gave asymptotics for the Stockmayer model; this paper gives asymptotics for the Flory Model, which is the "Rings Allowed Model" of Falk and Thomas. Our results confirm the conclusions drawn by Falk and Thomas.

Polymer distribution and cyclization

Consider a closed system of N RA_f monomers in which B bonds join $2B$ of the fN functional groups. If the functional groups are distinguishable, there are

$$[4] \quad \Omega_{NB} = \frac{(fN)!}{(fN - 2B)!\, 2^B B!}$$

ways this can occur. Equation [4], first given by Harris (15), is proved as follows. Label the A's $1, 2, \ldots, fN$ and choose $2B$ of them. Permute the chosen A's $(2B!)$ and bond the A's in the 1st, 3rd, 5th, ... positions to the A's following them. This overestimates Ω_{NB} by a factor of $2^B B!$ since order within bonded pairs is immaterial (2^B), as is the order of the bonded pairs themselves $(B!)$.

The proportion of reacted A's is

$$[5] \quad \alpha = \frac{2B}{fN}$$

Let m_{nb} be the number of n-mers containing b bonds, and let $\Omega_{NB}(m_{nb})$ be the number of realizations of the system which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

produce m_{nb} b-bonded n-mers. Clearly

$$[6] \quad \Omega_{NB} = \sum_{(m_{nb})} \Omega_{NB}(m_{nb})$$

the sum being over $m_{nb} = 0, 1, 2, \ldots$.

The expected number of b-bonded n-mers, averaged over the Ω_{NB} system states, is

$$[7] \quad E_{NB}(m_{nb}) = \frac{\Sigma m_{nb}\Omega_{NB}(m_{nb})}{\Omega_{NB}}$$

(We abbreviate E_{NB} to E in future and sums are over $m_{nb} = 0, 1, 2 \ldots$ unless otherwise stated.)

But

$$[8] \quad \sum m_{nb}\Omega_{NB}(m_{nb}) = \frac{N!}{(N-n)!n!} w_{nb}\Omega_{N-n,B-b}$$

where w_{nb} is the number of ways of bonding n units into a b-bonded n-mer. (w_n of eq. [3] is now $w_{n,n-1}$.)

Proof: The number of ways of bonding the system to produce m_{nb} b-bonded n-mers ($\Omega(m_{nb})$) and then painting one of the m_{nb} b-bonded n-mers black (m_{nb}) is equal to the number of ways of painting n of the initial N units black, combining them into a black b-bonded n-mer (w_{nb}) and then forming $B - b$ bonds among the remaining $N - n$ units. In each case the system has a total of N units, B bonds, and one black b-bonded n-mer.

The expected concentration of b-bonded n-mers in the system, normalized so that the initial monomeric concentration is 1, is

$$[9] \quad x_{nb} = \frac{E(m_{nb})}{N}$$

Although we have no closed form of w_{nb} except when $b = n - 1$ ($w_{n,n-1}$ is the w_n of eq. [3]), eqs. [4] [7], [8], and [9] yield an exact expression for x_{nb}. Repeated use of the inequality $1 \geqq (1 - a)(1 - b) \geqq 1 - (a + b)$ yields

$$[10] \quad \frac{K!}{(K-k)!} = K^k\left(1 - \frac{1}{K}\right)\left(1 - \frac{2}{K}\right)\ldots\left(1 - \frac{k-1}{K}\right)$$
$$= K^k\left[1 + O\left(\frac{k^2}{K}\right)\right]$$

Hence,

$$[11] \quad x_{nb} = \frac{w_{nb}}{n!}\frac{\alpha^b(1-\alpha)^{fn-2b}}{f^b} N^{(n-1)-b}\left[1 + O\left(\frac{n^2}{N}\right)\right]$$

When $b = n - 1$ (ringless polymer), eq. [11] is in asymptotic agreement with eq. [2]. There are no ringed polymers ($b > n - 1$) of finite size in the limit as $N \to \infty$.

Analogously to eq. [8], we may prove

$$[12] \quad \sum m_{nb}(m_{nb} - 1)\Omega_{NB}(m_{nb}) = \frac{N!}{(N-2n)!n!n!} \times w_{nb}^2\Omega_{N-2n,B-2b}$$

by blackening two b-bonded n-mers in the system. Following the logic of eqs. [7]–[11], we find

$$[13] \quad \mathrm{var}\left(\frac{m_{nb}}{N}\right) = \frac{E^2(m_{nb}) - E^2(m_{nb})}{N^2} = O\left(\frac{n^2}{N}\right)$$

so that the concentration of b-bonded n-mers is asymptotically the same for almost all realizations of the system.

Falk and Thomas also examined the system cyclization

$$[14] \quad C = \frac{B - \sum_{(nb)}(n-1)m_{nb}}{N}$$

which gives the number of bonds per unit in excess of those required for ringless polymers. ((nb) denotes a sum over $n = 1, 2, 3, \ldots$, and $b = n - 1, n, n + 1, \ldots$.)

Units are conserved,

$$[15] \quad N = \sum_{(nb)} nm_{nb}$$

so the expected cyclization is

$$[16] \quad \bar{C} = E(C) = \frac{f\alpha}{2} - 1 + \sum_{(nb)} x_{nb}$$

If the last term is asymptotically equal to the total concentration of polymers in the Flory model, then use of eq. [13] of Ziff and Stell (11) gives

$$[17] \quad \bar{C} = \begin{cases} 0 & \alpha < \alpha_c \\ \dfrac{f\alpha}{2} - 1 + \dfrac{1}{2}[f(1-\alpha)\zeta^{f-1} - (f-2)\zeta^f] & \alpha > \alpha_c \end{cases}$$

where ζ is the only positive root of

$$[18] \quad \zeta + \zeta^2 + \cdots + \zeta^{f-2} = \frac{1-\alpha}{\alpha}$$

Equations [17] and [18] agree with the Falk and Thomas simulation. Proof rests on verification of the hypothesis following eq. [16].

Equations [9] and [15] show

$$[19] \quad \sum_{(nb)} nx_{nb} = 1 \qquad x_{nb} \geqq 0$$

and we note that

$$[20] \quad w_{nb} \leqq w_{n,b-1}(fn)^2 \leqq \cdots \leqq w_{n,n-1}(fn)^{2[b-(n-1)]}$$

since the number of ways of building a b-bonded n-mer is less than the number of ways of building a $(b - 1)$-bonded n-mer and then bonding two more groups together. Inequality [20], though unnecessarily weak, is all we require.

Let $0 < \epsilon < \frac{1}{2}$ and let (n_ϵ) denote a sum over all $n \leqq N^{1/2-\epsilon}$. Then we can bound the total concentration of ringed polymers of size $\leqq N^{1/2-\epsilon}$:

$$[21] \quad \sum_{(n_\epsilon)}\sum_{b \geqq n} x_{nb} \leqq \sum_{(n_\epsilon)} x_{n,n-1}\sum_{b \geqq n} O\left(\frac{n^2}{N}\right)^{b-(n-1)}$$
$$\leqq \sum_{(n_\epsilon)} x_{n,n-1}O(n)O\left(\frac{n^2}{N}\right) \leqq O(N^{-2\epsilon})$$

Note eqs. [11] and [20]. The inner sum has $O(n)$ terms, since an n-mer has at most $\frac{1}{2}fn$ bonds. Equation [19] completes the proof.

If $\sim(n_\epsilon)$ denotes a sum over all $n > N^{1/2-\epsilon}$, then

$$[22] \quad \sum_{\sim(n_\epsilon)}\sum_{b \geqq n-1} x_{nb} \leqq N^{-1/2+\epsilon}\sum_{\sim(n_\epsilon)}\sum_{b \geqq n-1} nx_{nb} \leqq N^{-1/2+\epsilon}$$

If $\epsilon = 1/6$, then eqs. [11], [21], and [22] show the total polymer concentration deviates from the Flory value by $O(N^{-1/3})$, thereby proving eq. [17] (except when the error term from eq. [11], $O(\Sigma n^2 x_{nb})$, diverges for the Flory distribution at $\alpha = \alpha_c$).

Using the novel techniques of Whittle (16), section 6, a tortuous derivation which I omit yields

$$[23] \quad \sum_{(nb)} n^2 x_{nb} \sim N(1 - \zeta^f)^2 \qquad \alpha > \alpha_c$$

where ζ is given by eq. [18]. This result is consistent with a "gel" containing $N(1 - \zeta^f)$ units as predicted by the Flory model.

The A_gRB_{f-g} model

This model, also introduced by Flory (1), is like the RA_f model except that monomers have g A groups and $f - g$ B groups. Only A—B bonds form. Spouge (17) gives the principal results for the model.

As before, random stepwise reaction between A's and B's produces B bonds between N units. If α is the proportion of reacted A groups and β the proportion of reacted B groups, then

$$[24] \quad r = \frac{B}{N} = g\alpha = (f - g)\beta$$

The number of ways of forming B bonds between N monomers is

$$[25] \quad \Omega_{NB} = \frac{(gN)!}{(gN - B)!} \frac{[(f - g)N]!}{[(f - g)N - B]!} \frac{1}{B!}$$

The logic of eqs. [6] – [11] gives

$$[26] \quad x_{nb} = \frac{w_{nb}}{n!} \frac{(1 - \alpha)^{gn-b}(1 - \beta)^{(f-g)n-b} r^b}{g^b(f - g)^b} \times N^{(n-1)-b}\left[1 + O\left(\frac{n^2}{N}\right)\right]$$

where w_{nb} is the number of ways of building a b-bonded n-mer from A_gRB_{f-g} units. This agrees with previous results.

Further results for the A_gRB_{f-g} model are similar to those for the RA_f model.

Discussion

This paper shows that Flory's exclusion of the intramolecular reaction in finite polymers, but not in the gel, is logically consistent. If intramolecular reaction is not specifically favored, it is negligible except in the gel because any sol molecule contains an infinitesimal proportion of the functional groups available for reaction. This fact, long known and now proven, has spurred the development of models which specifically incorporate intramolecular reaction (18, 19).

Donoghue's (14) analysis of gel statistics in the Stockmayer model is more precise than is presently possible for the Flory model. Mathematical techniques for handling the divergent generating functions introduced by rings are few and require exploration. Whittle (16) gives some techniques for handling such functions. The Flory RA_f model is the special case $H(x) = (1 + x)^f$ of his paper as been shown by Spouge (20).

Effects of solvent structure on electron reactivity and radiolysis yields: 2-propanol/water mixed solvents[1]

JOANNA CYGLER[2] AND GORDON R. FREEMAN
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 23, 1984

JOANNA CYGLER and GORDON R. FREEMAN. Can. J. Chem. **62**, 1265 (1984).

Reaction of solvated electrons with nitrobenzene, N, is nearly diffusion controlled in both pure solvents; $k_N \sim 10^{10}$ dm^3/mol s. The value of k_N is approximately proportional to the inverse viscosity η^{-1} in the pure solvents, and in the mixed solvents at different temperatures. However, on going from zero to 74 mol% water at the same temperature k_N is independent of the 40% increase of η. Electron diffusion in the mixed solvents is not a simple function of fluidity.

Reaction with the inefficient scavengers tryptophane ($k_S \sim 10^9$ dm^3/mol s) and phenol ($k_S \sim 10^7$–10^8 dm^3/mol s) correlates inversely with the electron optical absorption energy. The latter is related to the trap depth in the solvent; electrons in deeper traps have less tendency to react with molecules of low electron affinity.

Addition of 3 mol% 2-PrOH to water at 296 K increases the value of $G\epsilon_{max}$ by 16%, although the value in pure 2-PrOH is three-fold smaller than that in pure water. The increase is attributed to an increase in the free ion yield, caused by an increase in the product of the electron thermalization range and the microscopic dielectric constant of the fluid between the ion and electron, averaged over the time that they exist as a correlated pair. Addition of a small amount of alcohol to water increases the orderliness of the water structure.

JOANNA CYGLER et GORDON R. FREEMAN. Can. J. Chem. **62**, 1265 (1984).

La réaction des électrons solvatés avec le nitrobenzène, N, est une réaction qui est à toutes fins pratiques contrôlée par la diffusion dans les deux solvants à l'état pur; $k_N \sim 10^{10}$ dm^3/mol s. La valeur de k_N est approximativement proportionnelle à l'inverse de la viscosité η^{-1} dans les solvants purs et dans les solvants mixtes à différentes températures. Cependant, si on opère à une température constante et que l'on fait varier la quantité d'eau de zéro jusqu'à 74 mol% d'eau, la valeur de k_N ne varie pas malgré une augmentation de 40% de la valeur de η. La diffusion des électrons dans les solvants mixtes n'est pas une fonction simple de la fluidité.

La réaction avec des pièges inefficaces comme le tryptophane ($k \sim 10^9$ dm^3/mol s) et le phénol ($k \sim 10^7$–10^8 dm^3/mol s) est en corrélation inverse avec l'énergie d'absorption optique de l'électron. Cette énergie est reliée à la profondeur du piège dans le solvant; les électrons localisés dans les pièges les plus profonds ont moins tendance à réagir avec les molécules qui ont une petite affinité électronique.

L'addition de 3 mol% de PrOH-2 à l'eau à 296 K augmente la valeur de $G\epsilon_{max}$ de 16% bien que la valeur dans le PrOH à l'état pur soit 3 fois plus faible que dans l'eau pure. On attribue l'augmentation à une augmentation du rendement en ion libre provoquée par une augmentation du produit du domaine de la thermalisation de l'électron et de la constante diélectrique microscopique du fluide entre l'ion et l'électron pondéré par rapport au temps où ils existent sous forme de paire d'ions. L'addition de petites quantités d'alcool à l'eau augmente l'ordre de la structure de l'eau.

Introduction

Solutions of hydroxy-compounds in water show many interesting abnormalities and for that reason have been the subject of intensive studies in many fields. Especially interesting are monohydric alcohol–water mixtures, because they deviate greatly from ideal behaviour.

In spite of many studies of various properties of alcohol–water mixtures, for example excess thermodynamic functions (1–9), viscosities (1–3, 10–13), acoustics (13), and dielectric relaxation (1, 14, 15), the nature and structure of these systems is little understood. The peculiar behaviour can be qualitatively attributed to the polar/non-polar bifunctional nature of alcohol molecules, which, depending on the composition of the mixture, can enhance or diminish the amount of orderliness in the intermolecular structure of the liquid.

In this laboratory, various aspects of electron behaviour in hydroxylic solvents have been studied (16–24). Recently (22, 23) it was found that the optical absorption spectra of solvated electrons in alcohol–water mixtures display a strong composition dependence, which was attributed to changes in solvent structure. One might therefore expect to find changes in electron reaction rate constants. The aim of the present work was to determine the reactivity of solvated electrons with different types of scavengers in 2-propanol/water mixtures of various composition.

Experimental

Materials

Spectral grade (99+%) 2-propanol, nitrobenzene (99%), L-tryptophane (99%), and phenol (99+%) were obtained from Aldrich Co. Reagent grade sodium borohydride was obtained from Fisher Scientific Co.

The 2-propanol (2-PrOH) was stored over freshly activated (200°C) molecular sieves 4A for one week and then fractionally distilled. Sodium borohydride (2 g/L) and a new portion of freshly activated molecular sieves were added to the distillation flask. The distillate was carefully protected from moisture by a tube filled with molecular sieves and silica gel. The distillation was performed under UHP argon (Liquid Carbonic Co.) atmosphere. The middle 50% of the alcohol was collected and stored under UHP argon in a flask equipped with a syphon system. Argon pressure was used to transfer alcohol from the storage flask without contaminating the rest of it with air.

The purity of 2-PrOH treated in the above way was checked by uv spectrophotometry. The spectrum was completely structureless at wavelengths down to 220 nm. The water content as measured by the Karl-Fischer method (25) was 0.2 mol%.

The water was always freshly, triply distilled from acidic dichromate, basic permanganate, and no added reagent, under nitrogen

[1] Financially assisted by the Natural Sciences and Engineering Research Council of Canada.

[2] On leave from the Institute of Radiation Chemistry, Technical University of Łódź, Poland.

(Commercial grade, Liquid Carbonic Co.) atmosphere. Nitrobenzene was purified by simple distillation and stored under UHP argon.

Phenol and tryptophane were used as received.

Techniques

Mixtures of 2-PrOH and water were prepared by volume measurement. Stock solutions of scavengers were prepared in volumetric flasks. Nitrobenzene was injected by a microliter syringe. Tryptophane and phenol solutions were prepared by weight. The actual solutions for measurements, made from properly diluted stock solutions, were poured into Spectrosil cells (10 mm optical path) and bubbled with UHP argon at ~15 cm^3/min through long stainless steel needles for ~45 min before sealing the cells (17).

The concentration of scavenger was determined after bubbling, by spectrophotometric measurements at 258 nm (nitrobenzene), 273 nm (phenol), or 281 nm (tryptophane). Solutions of phenol and sometimes of tryptophane had to be diluted in order to measure their concentrations. In such cases the concentration measurements were performed after the pulse radiolysis experiments were completed.

The methods of irradiation, dosimetry, and optical measurements were similar to those described earlier (19, 26). The 100 ns pulses of 1.9 MeV electrons delivered a dose of 2–3 × 10^{16} eV/g. The temperature was controlled to within ±0.5°C. The optical measurements were performed at the absorption maximum of the solvated electron band at each temperature, on the basis of the results obtained by Leu (22, 23).

Results and discussion

A. Yields of solvated electrons

The values of $G\epsilon_{max}$ were measured at the end of the pulse for various compositions of 2-PrOH/H_2O mixture in the absence of scavenger, at 296 K. The results are shown in Fig. 1. Since the decay of e^-_s under the conditions of our experiments was first order, all electrons observed were free-ion solvated electrons. The densities of solutions used in $G\epsilon_{max}$ calculations were taken from Roux and co-workers (8).

The value of $G\epsilon_{max}$ in pure water agrees to within 2% with those reported earlier (23, 27). For pure 2-PrOH, using ϵ_{max} = 1.3 × 10^4 M^{-1} cm^{-1} (28) we obtain $G(e^-_s)$ = 1.2; this agrees with the value 1.2 ± 0.2 obtained from scavenging studies (16).

In the mixtures with low alcohol content, $G\epsilon_{max}$ is very sensitive to composition. Small addition of alcohol to water causes quite a dramatic increase of $G\epsilon_{max}$ values. The value reaches a sharp maximum for ~3 mol% of 2-PrOH. With further increase of the alcohol content the $G\epsilon_{max}$ values decrease. Similar dependence of $G\epsilon_{max}$ on the composition of water alcohol mixtures has been observed by Leu and Jha (23*b*) in methanol, ethanol, and 1-propanol. The initial increase of $G\epsilon_{max}$ values correlates with a small increase of the energy of the peak of the e^-_s spectrum, $E_{\epsilon max}$, for small amounts of alcohol in water (22). The maximum in the plot of $G\epsilon_{max}$ against mixture composition is the most pronounced for 1-PrOH, and so is the increase of $E_{\epsilon max}$. This behaviour can be discussed in terms of solvent structure changes. There are experimental evidences that the addition of a small amount of monohydric alcohol changes the structure of liquid water. No complete model of water structure yet exists. A group of oversimplified models, each able to explain certain properties of water, known under the common name of "mixture models" (29–31), are generally used. Some of them assume that liquid water consists of two different types of species: hydrogen bonded molecules which form 3-dimensional clusters, similar to those proposed for ice V, and free non-bonded molecules. Interstitial models, which are a special class of mixture models, assume that non-bonded water molecules occupy cavities between bonded clusters (30, 31).

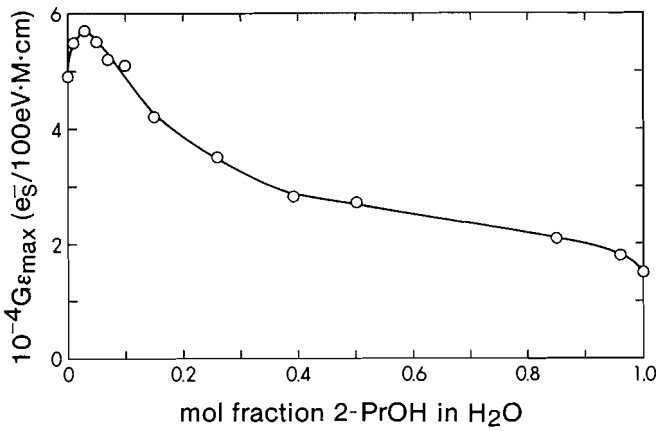

FIG. 1. Composition dependence of $G\epsilon_{max}$ for free-ion solvated electrons in 2-PrOH/H_2O mixtures, at the end of a 100 ns pulse, 296 K.

In contrast to pure water, monohydric alcohols do not form a 3-dimensional structure. They form linear polymers which exist in equilibrium with non-bonded molecules (1). The association of alcohols tends to decrease with increasing molecular weight and in the sequence primary, secondary, tertiary. Addition of a small amount of alcohol to water leads at first to enhancement of water structure. This is confirmed by such experimental facts as the composition dependence of thermodynamic functions of mixing (1, 2, 4, 6), partial molar volumes and expansibilities (5, 7–9, 32), structural contribution to the temperature of maximum density (TMD) of alcohol–water mixtures (33, 34), mutual diffusion coefficients (35–37), and sound absorption and velocity (13).

Excess entropy of mixing is negative and decreases rapidly for small alcohol concentrations in water, reaching a minimum around 20 mol% of alcohol (1, 2).

Partial molar volumes display a sharp minimum and partial molar expansibilities a maximum in the low concentration range (2–7 mol%) of alcohol (5, 7–9, 32).

There is a maximum for the structural contribution to the temperature of maximum density in aqueous solutions of alcohols between 2 and 4 mol% of alcohol (33, 34).

Especially interesting is the behaviour of viscosity, η, and related parameters for aqueous alcohol solutions. Addition of a small amount of alcohol to water rapidly increases the viscosity of the mixture, which reaches a maximum around 20 mol% of alcohol (1–3, 10, 11, 13) (Fig. 2). The derivative curve $\Delta\eta/\Delta x_2$, where x_2 is the mole fraction of alcohol, has a sharp maximum for a few mol% of ethanol in water (2, 3). This behaviour is believed to be typical for the structure stabilization processes. Also, as was shown by Ueberreiter (32), the so-called structure temperatures of mixtures of water with various alcohols have a maximum in the range of 0–20 mol% of alcohol. In a similar concentration range the mutual diffusion coefficients have a minimum in alcohol–water solutions (35–37). All the above facts can be qualitatively explained on the basis of the Samoilov interstitial model (30), as formulated by Franks (31) (who introduced such terms as hydrophobic and hydrophilic solvation), indicating stabilization of the water structure. Alcohol molecules fill the cavities between ice-like clusters, stabilizing their structure. The power of stabilization increases with the size of the hydrophobic alkyl group. This is

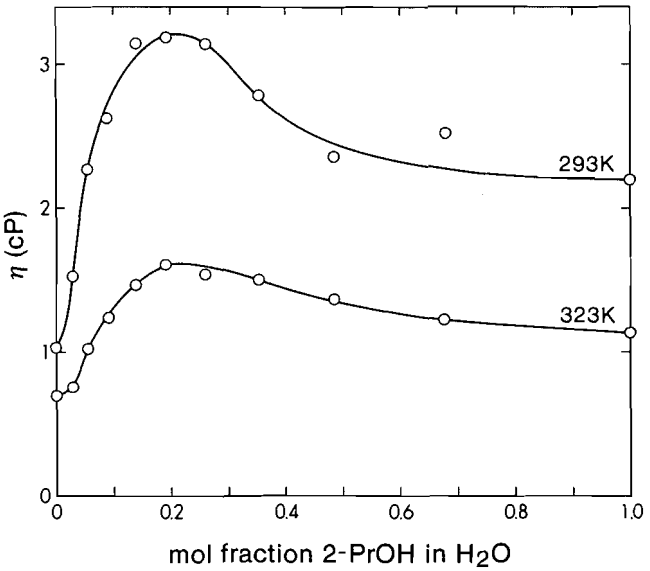

FIG. 2. Composition dependence of shear viscosity in 2-PrOH/H_2O mixtures. Data from ref. 13.

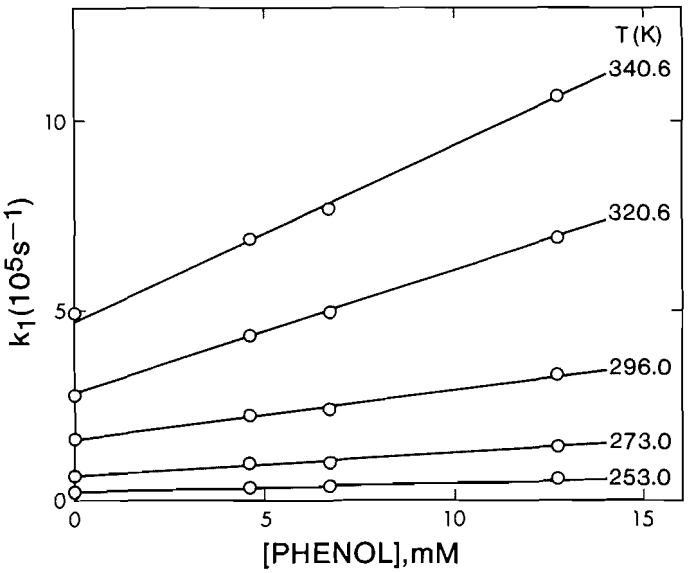

FIG. 3. First order rate constants, k_1, of the reaction of solvated electrons with phenol in 61 mol% H_2O/2-PrOH at various temperatures.

confirmed by the facts that the longer the alkyl group of the alcohol, the higher is the structure temperature (32), and at the same time the minimum of the mutual diffusion coefficient curve is shifted towards smaller alcohol concentrations (37). Further increase of alcohol content decreases the structure temperature, which finally reaches zero, and increases the mutual diffusion coefficient. Water–alcohol mixtures become normal, "free" liquids ($T_0 = 0$) sooner when the alkyl group is the smaller. The mutual diffusion coefficient after passing through a minimum increases with further increase of alcohol concentration faster when the alkyl group is the shorter. Thus the structure-making power of an alcohol increases with the size of its hydrophobic group.

The behaviour of $G\epsilon_{max}$ values of solvated electrons as a function of 2-PrOH content in the mixture (Fig. 1) follows a pattern similar to those discussed above. It is assumed that the addition of 3 mol% of alcohol to water would negligibly alter the value of ϵ_{max}, so the increase in the structuredness of the fluid apparently increases the free ion yield. A larger free ion yield implies a larger value of the product of the distance between the geminate electron and ion, and the dielectric constant of the fluid between them. This can be accomplished in two ways which are not mutually exclusive: *1*, the increased order in the structure might increase the thermalization range of the electron (23*b*); *2*, the new structure might contain more favorably oriented electron-localization sites that result in a higher time-averaged dielectric constant between the electron and its geminate cation during their lifetime as a correlated pair.

It has been suggested that the increase of $G(e^-_s)$ upon addition of 1 *M* (2 mol%) of an alcohol to water is due to the inhibition of the spur reaction [1] by [2] (38–41).

[1] $[e^-_s + \dot{O}H \rightarrow OH^-_s]$

[2] $[\dot{O}H + RCH_2OH \rightarrow H_2O + R\dot{C}HOH]$

However, the assumption that reaction [3] does not occur is unwarranted (see discussion in ref. 23*b*).

[3] $[e^-_s + R\dot{C}HOH \rightarrow RCHOH^-_s]$

Furthermore, the rate of decay of e^-_s in water containing alcohol would be lower than that in pure water because of the much greater viscosity of the former, with consequently lower diffusion coefficients (23*b*).

B. Reaction rates of e^-_s with scavengers in 2-PrOH/H_2O

For the kinetics studies the following mol% H_2O were chosen: 100, 99, 74, 61, 15, 8, 0.

Second order rate constants k_2 of solvated electrons with three scavengers of different reactivities were measured at temperatures between the freezing point of the mixture and 360 K. The scavengers were nitrobenzene ($k^{298}_{2,H_2O} \approx 10^{10}$ dm^3/mol s), tryptophane ($k^{298}_{2,H_2O} \approx 10^8$ dm^3/mol s), and phenol ($k^{298}_{2,H_2O} \approx 10^7$ dm^3/mol s). First order decay constants, k_1, of e^-_s were measured for several different concentrations of each scavenger at a given temperature. The second order rate constant k_2 was obtained from the slope of the plot of k_1 against the scavenger concentration.

Typical plots of k_1 are shown in Fig. 3.

The Arrhenius plot of k_2 values obtained from the data in Fig. 3 is presented in Fig. 4. The parameters of the Arrhenius equation $k_2 = A_2 \exp(-E_2/kT)$ are listed in Table 1. The table also contains values of k_2 at 298 K. The k_2 values in pure water and 2-PrOH are in satisfactory agreement with the data reported earlier (20, 21, 42, 43).

The reaction of nitrobenzene with e^-_s is two times faster in pure water than in 2-PrOH, which correlates inversely with the viscosities of these solvents (13). This reaction is nearly diffusion controlled (18). Figure 5 shows the plot of k_2 against η in the mixtures at two temperatures. The value of k_2 changes approximately as $\eta^{-1.0}$ over a four-fold range in the unmixed solvents and in a given mixed solvent as a function of temperature. However, on going from zero to 74 mol% water at 298 K, k_N is nearly independent of the 1.4-fold increase of η. There is therefore a large difference between the temperature and composition effects, even for the nearly diffusion-controlled reaction. It was reported earlier that in a series of normal aliphatic alcohols (21) and glycols (24) at 298 K the rate constant for nitrobenzene reacting with e^-_s follows the relation $k_2 \propto \eta^{-0.6}$. Neither water nor 2-PrOH fitted this correlation. The

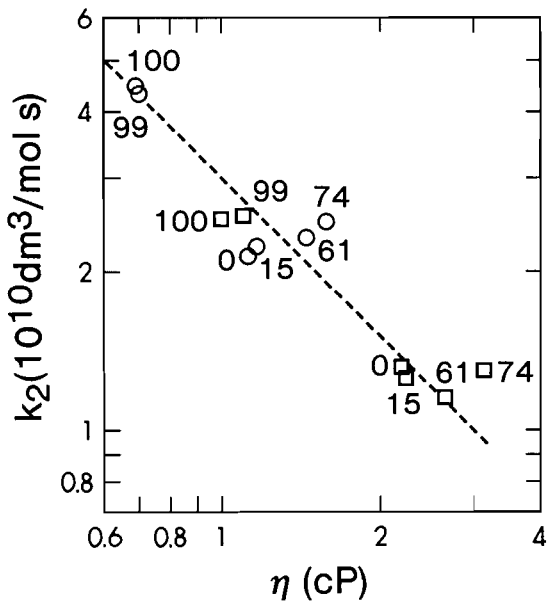

FIG. 5. Viscosity dependence of rate constant k_2 of the reaction of solvated electrons with nitrobenzene. □, 293 K; ○, 323 K. Numbers indicate mol% water; ---, slope = −1.0.

results indicate a complex dependence of e^-_s diffusion coefficient upon solvent structure; its independent measurement is in order.

The rate constants of e^-_s reacting with tryptophane and phenol are smaller than those with nitrobenzene by one and two orders of magnitude, respectively. For tryptophane the rate constant increases with the increase of alcohol concentration in the mixture, regardless of the complex changes in viscosity shown in Fig. 2. The value of k_2 is 4.7 times greater in 92 mol% 2-PrOH than in pure water, while $(\eta_{92\%}/\eta_{H_2O})^{-1} = 0.46$. This is in agreement with the previous reports of Afanassiev and Freeman (20, 21). They proposed that for less efficient scavengers the reaction rate is determined by the e^-_s trap depth rather than the viscosity. The deeper the trap, the more difficult it is for an electron to jump up to a scavenger molecule, which results in a lower rate constant k_2. The energy E_r half way up the red side of the e^-_s optical absorption band was chosen as the measure of trap depth. The energy E_r is connected with $E_{\epsilon max}$ at the maximum of the absorption band, by the relation

$$[1] \quad E_r = E_{\epsilon max} - W_r$$

where W_r is the portion of the width at half height that is on the red side of $E_{\epsilon max}$ (26).

Phenol is the least efficient of these e^-_s scavengers. The value of its k_2 is an order of magnitude greater in pure 2-PrOH than in water. In the water-rich mixtures the value of k_2 for phenol is highest for 1 mol% 2-PrOH. This is the region of rapid increases in η, $d\eta/dx$, and $G\epsilon_{max}$. As discussed in the previous paragraph, in this concentration range of alcohol there are structure-making effects. They apparently assist the capture of the electron by the aromatic molecule. This conclusion is supported by the smaller value of the activation energy (Table 1).

In alcohol-rich solutions, an increase of 2-PrOH concen-

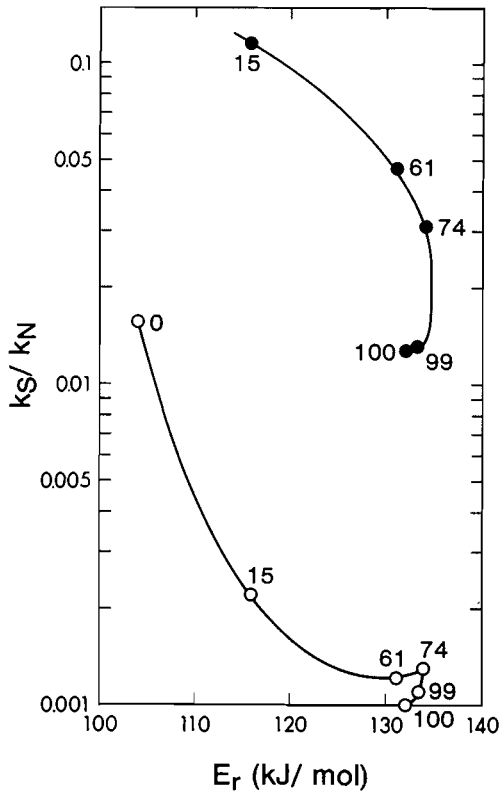

FIG. 6. Effect of electron solvation energy, represented by E_r, on the normalized rate constant of electron reaction with scavenger S, represented by k_S/k_N, at 298 K. The rate constant k_N for nitrobenzene is used to normalize the others for diffusion effects. S: tryptophane ●, phenol ○. Numbers indicate mol% water.

tration is followed by an increase of k_2 for phenol, up to the value 2.0×10^8 dm^3/mol s in pure 2-PrOH. The activation energy and entropy have minima at between 15 and 8 mol% water. The minima cannot be explained on the basis of changes in E_r, which decreases monotonically in this concentration range (22, 23). However, between 0 and 10 mol% of water in 2-PrOH there is a sharp decrease of W_b, the portion of the width at half height on the blue side of $E_{\epsilon max}$ (22). The quantity $E_b = E_{\epsilon max} + W_b$ has a minimum at 10 mol% water (22, 23). This is a characteristic feature for 2-PrOH/H_2O solutions and was not found in mixtures of primary or tertiary alcohols with water. In the secondary alcohol 2-PrOH, the high energy side of the band is relatively broad and is rapidly reduced in width by the addition of a small amount of water. This is probably attributable to changes in the electron solvation sites.

The peculiar solvent effects on the electron reaction efficiencies with tryptophane and phenol are illustrated by normalizing the latter to the nearly diffusion-controlled rate with nitrobenzene. The ratio k_S/k_N is plotted against E_r in Fig. 6; N is nitrobenzene and S is the other scavenger. There is a general decrease of k_S/k_N with increasing E_r as found in other systems. However, the interpretation of the shapes in the water-rich solutions awaits further investigation.

The crystal and molecular structure of *endo*-7-hydroxy-2,4-dioxa-3-oxobicyclo[3.3.1]nonane

WINNIE WONG-NG[1] AND STANLEY C. NYBURG

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received September 16, 1983

WINNIE WONG-NG and STANLEY C. NYBURG. Can. J. Chem. **62**, 1271 (1984).

The crystal and molecular structure of the title compound are described. Crystals are orthorhombic, space group $Pna2_1$, a = 10.977(3), b = 6.489(2), c = 9.811(2) Å, Z = four molecules per cell. Atom C(4), to which the hydroxyl group is attached, appears to have been moved outwards (away from hydroxyl). This resembles similar movements in *chair–chair* bicyclo[3.3.1]nonanes where intramolecular repulsion is thought to be responsible. In the present molecule, however, the more likely cause is the presence of an intermolecular hydrogen bond.

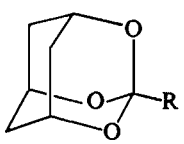
WINNIE WONG-NG et STANLEY C. NYBURG. Can. J. Chem. **62**, 1271 (1984).

On décrit les structures cristalline et moléculaire du composé mentionné dans le titre. Les cristaux sont orthorhombiques, groupe d'espace $Pna2_1$, a = 10,977(3), b = 6,489(2), c = 9,811(2) Å, Z = 4 molécules par unité. L'atome C(4), auquel le groupe hydroxyle est attaché, semble être déplacé vers l'extérieur (s'éloigne de l'hydroxyle). Ceci ressemble à des déplacements semblables dans les bicyclo[3.3.1]nonanes *chaise–chaise* où l'on croit que la répulsion intramoléculaire en est responsable. Dans la présente molécule, il semble toutefois que ce déplacement soit dû à la présence d'une liaison hydrogène intramoléculaire.

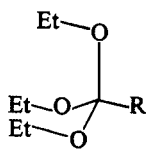
[Traduit par le journal]

Introduction

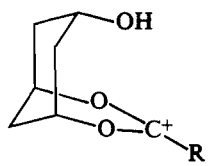
It is known that 2,4,10-trioxaadamantanes, **1**, hydrolyse much more slowly than the corresponding acyclic *ortho*-esters **2** (1, 2). It is thought that hydrolysis of **1** is governed by a rate-determining decomposition of the intermediate oxocarbonium ion, **3**, which is known to be formed very quickly



1

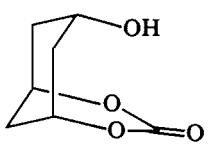


2



3

when sulfuric acid is added to the ester (3). The carbonate corresponding to **1** (i.e. with R = oxygen) has recently been prepared and is also slow to hydrolyse. An analog **4** of the putative intermediate has also been prepared and, since its molecular structure is of some interest, its crystal structure is the subject of this paper.



4

Experimental

Crystals of the title compound were colorless and in the form of triangular plates. One such crystal, 0.32 × 0.11 mm thick, was used for X-ray analysis mounted normal to the goniometer axis.

After preliminary photographic examination, intensity data were collected on an automated Picker four-circle diffractometer using Ni-filtered CuKα radiation and pulse height discrimination. Data were collected in θ–2θ scan mode at 2° min^{-1} with a scan width of 2°. A standard reflection remeasured every 40 reflections showed the crystal to be stable.

A total of 701 reflections was recorded in the range sin θ ≤ 0.89. Of these, 110 had (scan − Σb) < $2\sigma(I)$ and were considered insignificant on the basis $\sigma(I)$ = (scan + Σb)$^{1/2}$ where Σb is the total background count. Unit cell dimensions were obtained by least squares from the θ, φ, and χ settings of 12 reflections. Systematic absences were $0kl$ for $k + l$ odd, $h0l$ for h odd. Crystal data are as follows:

$C_7H_{10}O_4$ fw = 158.16

Orthorhombic, $Pna2_1$ or $Pnam$ (former confirmed by structure analysis); a = 10.977(3), b = 6.489(2), c = 9.811(2) Å, V = 698.8(3) Å^3. D_c (for Z = 4), 1.50 Mg m^{-3}; 22°C; λ(CuKα) = 1.5418 Å; μ(CuKα) = 10.7 cm^{-1}.

Structure solution and refinement

The structure was solved using MULTAN 80 (4). E statistics indicated an acentric structure, i.e. space group $Pna2_1$ rather than $Pnam$. Ten phase sets were generated for the 230 reflections with $E > 1$. The phase set with the highest combined figure of merit gave a stereochemically feasible structure. Full-matrix anisotropic least-squares refinement was carried out on the non-hydrogen atoms using XFLS3 (5). All hydrogen atoms were revealed on the ΔF map on which the largest spurious peak was 0.25 e Å^{-3}. Except for H(O1) whose position was taken from the map, all hydrogen atoms had d_{C-H} set to 1.0 Å and were kept in fixed calculated positions. They were given the same anisotropic temperature factors as the atoms to which they were attached. The scattering factors used were those of Cromer and Mann (6), without correction for anomalous dispersion. No absorption corrections were applied. $\sigma(F_o)$ was taken as $[\{\sigma(I)/Lp\}^2 + 0.02F_o^4]^{1/2}/2F_o$ where Lp is the Lorentz-polarization factor. Isotropic extinction corrections were applied according to Coppens and Hamilton (7), ($\bar{T}$ = 0.04 cm, G_{iso}^0 = 0.185). The penultimate value of R fell from 0.056 to 0.044. Tables of anisotropic temperature factors and phased F values have been deposited.

Fractional atomic co-ordinates are given in Table 1. Table 2(*a*) lists bond lengths and intermolecular distances and Table 2(*b*) the bond angles. Table 3 gives the least-squares planes. An ORTEP (8) plot of the molecule giving the atomic numbering scheme is shown in Fig. 1. Figure 2 shows the packing of the molecules within one unit cell.

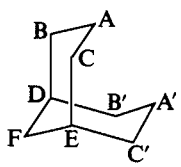
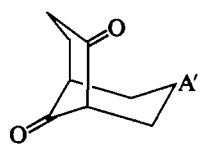
Discussion

In *chair–chair* bicyclo[3.3.1]nonanes, **5**, the existence of a repulsive strain between rings can be inferred from the distances of atoms A, A′, and F from the mean planes BCDE and B′C′DE, respectively. In the absence of strain it is assumed that these distances would be about 0.73 Å. Thus, in a derivative with CH_3 at D and CH_2R at E, X-ray structure analysis (9) shows that A and A′ lie 0.51 and 0.45 Å from their appropriate mean planes whereas F lies 0.71 and 0.72 Å from them. This implies a repulsive strain between the rings. Similar effects are found in other *chair–chair* bicyclo[3.3.1]nonanes (10, 11[2]). The repulsive strain in all three molecules is caused, presumably, not only by interactions between the carbon atoms at



5



6

A and A′ (unstrained distance ca. 2.52 Å, that usually found ca. 3.05 Å) but also by the opposing methylene hydrogen atoms which are close together (ca. 2.05 Å) in these molecules. Further evidence of this type can be adduced from the crystal structure analysis of a *chair–boat* bicyclo[3.3.1]nonane, **6** (12). This structure would be expected to be free from intramolecular strain and indeed, the carbon atom at A′ is found to be 0.70 Å from its appropriate plane as would be expected in an unstrained molecule.

[2] The extensively substituted molecule of ref. 11 is erroneously said to have the *boat–boat* conformation. It is actually *chair–chair* and we calculate the displacements of the atoms from their appropriate planes as: A, 0.56; A′, 0.50; and F, 0.65 and 0.74 Å.

O(2)—C(6)—C(5)	110.5(5)
C(1)—C(6)—C(5)	114.0(5)
O(2)—C(7)—O(3)	117.6(5)
O(2)—C(7)—O(4)	120.4(5)
O(3)—C(7)—O(4)	122.0(6)

The geometry of the molecule studied here would, at first sight, seem to imply the presence of the same kind of repulsive intermolecular interaction as shown by *chair–chair* bicyclo[3.3.1]nonanes. The atom at position A, C(4), is only 0.514(6) Å from the mean plane of C(2), C(3), C(5), and C(6) whereas C(1) is 0.729(7) Å from this plane (Table 3, plane *1*). Atom O(1) is about equidistant from O(2), O(4), and O(7) at 2.99, 2.99, and 2.93 Å, respectively, but there is no indication of a repulsive interaction here. If the C(2), O(4), C(7), O(2), C(6) system be considered in two halves hinged about O(2)...O(4) (Table 3, planes *2* and *3*), there is a small angle

TABLE 3. Best least-squares planes, $AX + BY + CZ = D$ where X, Y, Z are real orthogonal coordinates (in Å)

Atoms defining the best least-squares plane	Plane coefficients Displacements of atoms from plane (Å)
Plane *1* C(2)C(3)C(5)C(6)	$A = -0.255(5)$, $B = 0.252(4)$, $C = -0.933(8)$, $D = -8.407(4)$ C(1), −0.729(7); C(2), −0.009(8); C(3), 0.007(7); C(4), 0.514(6); C(5), −0.008(7); C(6), 0.009(7)
Plane *2* O(2)O(3)O(4)C(7)	$A = 0.811(6)$, $B = 0.073(3)$, $C = -0.579(5)$, $D = -2.518(2)$ O(2), 0.000(5); O(3), 0.001(5); O(4), 0.000(5); C(7), −0.002(6)

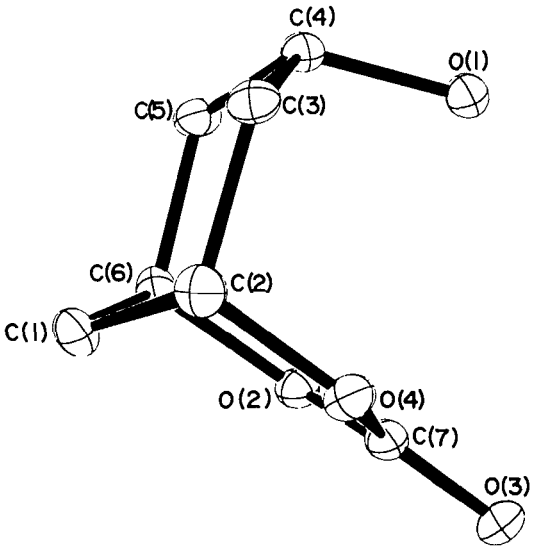

FIG. 1. ORTEP plot of molecule showing atom numbering scheme and 50% probability ellipsoids.

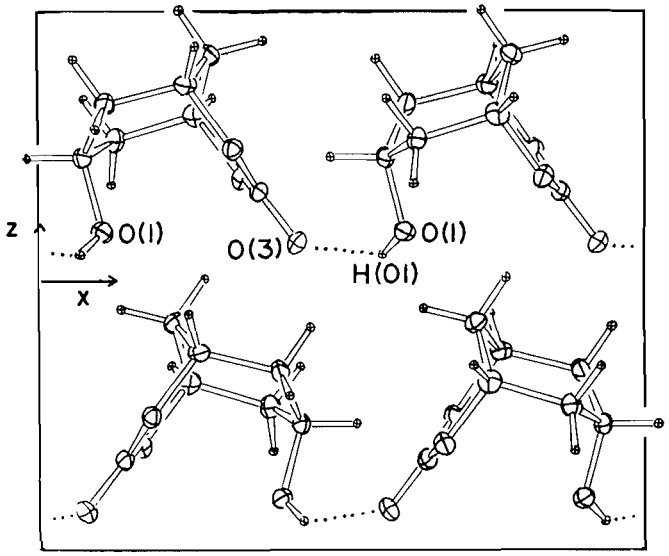

FIG. 2. Content of one unit cell in *y*-projection.

between the planes, 0.7(4)°. This is too small to be significant but, in any case, is such as to bring O(3) slightly closer to, rather than slightly further from, O(1). Thus repulsive intramolecular interaction of the type postulated for *chair–chair* bicyclo[3.3.1]nonanes seems to be absent although it should be recognised that the 2,4-dioxa-3-oxo system is probably very resistant to out-of-plane deformation.

A possible alternative reason for O(1) being further from O(3) than might have been expected is the presence of a O(1)—H(O1)...O(3) intermolecular hydrogen bond (Fig. 2) with O(1)—H(O1), 0.93 Å, H(O1)...O(3), 2.178(4) Å and the O(1)—H(O1)...O(3) angle, 119.8°. Such a bond could cause a movement of O(1) away from O(3) of the same molecule.

Successful refinement shows the crystal to belong to space group $Pna2_1$ and not to *Pnam*. Commonly this choice arises because the true structure is a slightly distorted version of a possible *Pnam* structure. This is not the case here, however. If the structure were *Pnam* the four molecules per cell would need to have either mirror planes or centers of symmetry. The molecules have, in fact, pseudo mirror planes but these planes are not oriented even approximately as required by *Pnam*. This can be seen in Fig. 2, where, if the structure were *Pnam* there would be mirror planes of symmetry at $z = 1/4, 3/4$.

The non-hydrogen atoms of the molecule show significant departures from m (C_s) symmetry. In particular, bonds O(2)—C(7) and O(4)—C(7) are 1.357(8) and 1.304 Å, respectively. Differences in chemically equivalent interbond angles are also present: O(2)—C(7)—O(3), 117.6°, O(4)—C(7)—O(3), 111.9°, O(1)—C(4)—C(3), 108.2°. Hydrogen bonded atom H(O1) lies 0.62 Å from the mean midplane of the molecule. It is difficult to see, however, how a hydrogen bond could be the cause of such marked asymmetry in C—O bond lengths and in O—C—O interbond angles.

Surface photochemistry: the amide Photo-Fries rearrangement[1]

MAGDY M. ABDEL-MALIK AND PAUL DE MAYO

Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 2, 1983

MAGDY M. ABDEL-MALIK and PAUL DE MAYO. Can. J. Chem. **62**, 1275 (1984).

The Photo-Fries rearrangement of eight anilides on the surface of dry silica gel has been examined. The rearrangement occurs quite cleanly, giving somewhat more of the *para* isomer than that obtained in methanolic solution. A test for intermolecularity on the silica gel surface showed that, as in solution, the radical pair intermediates do not separate. This contrasts with the behaviour of a previously reported dibenzyl ketone derivative.

MAGDY M. ABDEL-MALIK et PAUL DE MAYO. Can. J. Chem. **62**, 1275 (1984).

On a étudié la transposition de photo-Fries de huit anilides, à la surface de gel de silica sec. La transposition se produit d'une façon assez propre; dans ce cas, il se forme plus d'isomère *para* qu'en solution méthanolique. La détermination de l'intermolécularité à la surface du gel de silica a démontré que, comme en solution, la paire de radicaux intermédiaires ne se sépare pas. Ceci est en opposition avec le comportement rapporté antérieurement pour un dérivé de la dibenzylcétone.

Introduction

Several years ago Anderson and Reese (1) observed that catechol monoacetate in ethanolic solution rearranged upon irradiation. Since then the reaction has been studied at length (2) and interest in this, the Photo-Fries rearrangement, continues. The mechanism established is that of Kobsa (3): homolysis to give a radical pair which recombines efficiently in the solvent cage (cf. *inter alia* ref. 4). The scope of the reaction has been greatly extended (5) and now encompasses amides (6–9).

Some time ago the possibility that a silica gel surface might act as a restraining agent on radical pairs generated thereon was examined. The concept was tested on the Photo-Fries rearrangement of esters (10) and found to be successful and led to the further study of excited species on silica gel surfaces (11, 12).

The reasons for studying the possibility of carrying out the amide Photo-Fries on dry silica gel were two-fold. Firstly, the quantum yield of the rearrangement, especially in polar solvents, was low (6*b*, 8). This was interpreted as an indication of rapid radical recombination in the solvent cage without significant molecular movement. The homolysis was attributed (6*b*) to predissociation (Scheme 1). Since at that time it had been reported (13) that radicals derived from azoisobutyronitrile photolysis were anchored on the surface of a silica gel slurry via the nitrogen, it seemed possible that such bonding might delay recombination and allow the radicals to rotate. However, these earlier findings have since been shown to be in error (11*b*). Secondly, it was hoped that the proportion of *ortho* to *para* reaction (Scheme 1) might be usefully altered by adsorption. During the completion of this work the use of β-cyclodextrin, to achieve the same end, was reported (9).

Results and discussions

The photolyses of compounds **1***a*–**1***h* was examined. Their physical properties are recorded in Table 1 (Experimental section), the results being presented in Table 2. The reproducibility may be assessed by the results for **1***a*. Also contained in Table 2 are the results of photolyses in methanolic solution, a solvent approximating silica gel in polarity (14).

The experiments performed on silica gel appeared cleaner than those in solution and though the conversions were lower,

the yields based on unrecovered material were somewhat higher. There was also a decrease in aniline formation and other unidentified by-products, presumably, in part, because of the lack of a good hydrogen donor to reduce the radicals. Surprisingly, considering that these results suggest restraint on the movement on the radical pair, the reactions on silica gel vis-a-vis those in solution favoured the formation of the *para*-substituted ketone. This is particularly noteworthy in the case of benzanilide (**1***e*) where the *o/p* ratio changes by a factor of two. Other examples tended in the same direction, but were not so marked. We consider that the gel surface may permit more time for rotation, as compared with recombination times, or, less likely, the time to diffuse away, than does the solvent. However, in view of the large changes in behaviour recorded in solution accompanying polarity change in the solvent attribution of such changes to an adsorption phenomenon can only be tentative.

The Photo-Fries rearrangement has been shown to be "intramolecular" for amides in solution (6*d*, 7). We have demonstrated that the same situation holds for the surface reaction. Irradiation on the dry gel surface of a mixture of **1***c* and **1***i* did not reveal the formation of any products (cross-products) of intermolecular reaction: the only ketones produced were **2***c* and **2***i*. This is in contrast to the photolysis on silica gel of the dibenzyl ketone **5** (11) which gave the dibenzyls from both intra- and intermolecular combination.

This dichotomy in behaviour is to be attributed to the very probable photolysis of the amide via the singlet and that of the ketone via the triplet (15). The amide photolysis resembles

5

more that of the ester **6** (11*a*), the multiplicity of whose fission is not known. Related compounds have, however, been shown by Givens (16) to photolyse via the singlet. The "intramolecular" nature of the rearrangement on the silica gel may be construed as evidence in favour of a singlet reaction under these conditions. The singlet process has been well-established in solution by Shizuka and his collaborators (6*b*).

6

Experimental

Melting points are uncorrected and were measured on a Reichert hot stage; nmr spectra were obtained on a Varian XL-100 MHz; mass spectra on a MAT 311A. A Varian model 3700 gas chromatograph connected to a Hewlett-Packard 3390A integrator was used for gc analysis. In all cases the injector and flame ionization detector were set at 220°C. Two columns were used for analysis: column A was 10% OV 101 Chromosorb W; column B was carbowax 20M on chromosorb W (HP; 80–100 mesh).

Materials

Merck silica gel 60, 230–400 mesh was used in the flash chromatography. All the starting materials were prepared as described in the literature and recrystallized until there was no further improvement in

the melting point (see Table 2). The irradiation products reported in Table 2 were isolated from preparative scale experiments in solution and the flash chromatography technique was used in the separation process. The isolated compounds were sublimed and then crystallized. Chromatography was unsuccessful for the isolation of 3,5-dimethyl-4-aminobenzophenone (**3***h*). The latter compound was synthesized from 2,6-dimethylbenzanilide, benzoyl chloride, and anhydrous zinc chloride for 24 h at 220–240°C (17). The structure of this compound followed from spectral data and precise mass (*m/e*, 225.11527; calcd. 225.11535). The nmr data, mp (Table 2) and precise mass (*m/e* 211.09959; calcd. 211.09970) found for **2***f* were in accord with the structure of 3-methyl-2-aminobenzophenone. 3,5-Dimethyl-4-aminoacetophenone (**3***d*) had *m/e* (%) 163 (M^+ $C_9H_{13}ON$(45)) 148 (100 M − CH_3) and 120 (38 M − —CO—CH_3) (precise mass *m/e* 163.0999, calcd. 163.0997).

Irradiations

General procedure

A Rayonet reactor equipped with 254.7 nm lamps was used for photolysis of solutions and for silica gel experiments.

(A) Photolysis of solutions: The methanolic solutions of the esters were contained in quartz tubes which were degassed by purging with dry nitrogen for 15–20 min. A quartz immersion well was used as a cooling system to keep the temperature 18–20°C in the irradiation (24 h) of acetanilide derivatives (3.0×10^{-2} *M*). Air circulation was used to control the temperature at 20–25°C in the irradiation (48 h) of benzanilide derivatives (1.0×10^{-2} *M*).

(B) Photolysis of samples of silica gel: The Rayonet reactor was placed on its side and the sample cell was rotated in the centre of the reactor using a rotary evaporator motor and was air cooled to keep the internal temperature in the range of 20–25°C. The samples were irradiated for the same length of time as the solutions. The concentrations for the acetanilide group were 9.97×10^{-5} mol/g and for the benzanilide group were 5.46×10^{-5} mol/g.

Preparation of silica gel samples

For silica gel sample preparation the apparatus illustrated in Fig. 1 was used. The cell itself was of quartz joined by a graded seal to Pyrex. The silica gel (5 g) was placed in the cell. With stopcocks A and C open to the pump and B and D closed the gel was heated at 200°C (1 mm Hg) overnight. After cooling C was closed, the sample placed in F, and the system reevacuated; C was then opened and the sample transferred. The same procedure was used to distil dry methylene chloride via B into the cell. The amount of methylene dichloride was enough to cover the gel: the slurry was sonicated for 10 min. The receiver attached to B was then cooled and the solvent distilled from the cell. Finally, with B closed and A opened to the pump, the gel was degassed at 1 mm Hg (133.32 Pascals) for ~5 h. The system was then disconnected from the vacuum, the cell cooled in liquid nitrogen, and the flame sealed at E.

Sample analysis

The silica gel was extracted with methanol, the methanol removed by distillation, and the residue containing some silica gel extracted with chloroform to constant weight. The acetanilide group products were analysed by nmr using about 4-methoxybenzophenone as a calibrating compound and using the acetyl signals as probes. Anilines were estimated by glc analysis after prior quantitative sublimation: the same calibrating compound was used. *o*-Toluidine was analyzed on column A as was 2,6-dimethylaniline. Column B was used for aniline and *p*-toluidine.

In all the benzanilide analyses column A was used with tetracosane as reference (temperature 80–220°C).

Mixed experiment

(a) Silica gel: 66 mg of an equimolecular mixture of *p*-methylacetaniline and *p*-chloropropionylanilide were adsorbed onto 5 g silica gel as previously described, and irradiated in the usual way. The analysis showed the presence of two new peaks. Isolation by chromatography gave unreacted starting materials together with 5-methyl-2-aminoacetophenone and 5-chloro-2-aminopropiophenone. Authentic samples were prepared by separate irradiation in methanol. Traces of *p*-toluidine and *p*-chloroaniline were observed. The conversions of *p*-methylacetanilide and *p*-chloropropionylanilide were 35 and 47%, respectively.

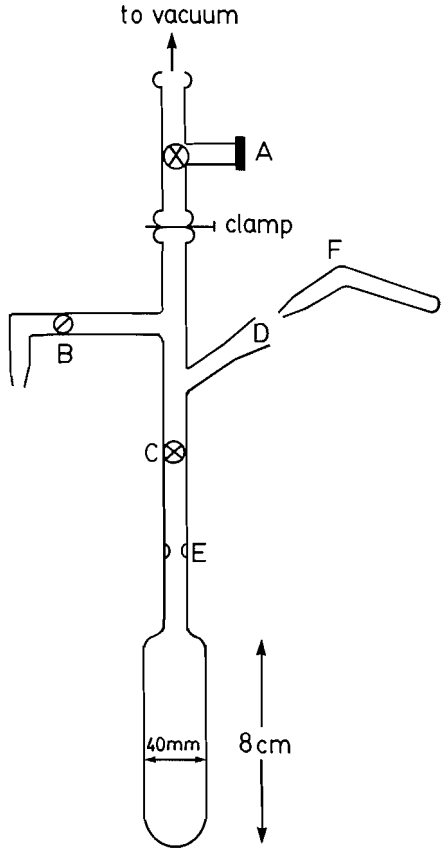

FIG. 1. Apparatus for the preparation of silica gel samples (see text).

(b) Methanol solution: a similar mixture of amides dissolved in 25 mL methanol was irradiated. Up to ~50% conversion glc analysis showed the presence of the same four components as found on silica gel.

Surface photochemistry: the effect of surface modification on the photophysics of naphthalene and pyrene adsorbed on silica gel[1]

RICHARD K. BAUER, PAUL DE MAYO, LALGUDI V. NATARAJAN, AND WILLIAM R. WARE
Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 5, 1983

RICHARD K. BAUER, PAUL DE MAYO, LALGUDI V. NATARAJAN, and WILLIAM R. WARE. Can. J. Chem. **62**, 1279 (1984).

The influence of heat treatment and of added coadsorbates on the surface photophysics of pyrene and naphthalene adsorbed on silica gel is reported. When the silica gel surface is partially dehydroxylated, the distribution of pyrene or naphthalene is inhomogeneous, as indicated by multiexponential fluorescence decay and broad emission spectra. Addition of polar coadsorbates renders the surface more homogeneous with singlet lifetimes approaching solution values. The pretreatment and addition of coadsorbates, in the case of pyrene, also influence the relative importance of dynamic excimer formation vis-a-vis ground state association.

RICHARD K. BAUER, PAUL DE MAYO, LALGUDI V. NATARAJAN et WILLIAM R. WARE. Can. J. Chem. **62**, 1279 (1984).

On a examiné l'influence, sur la photophysique du pyrène et du naphtalène adsorbé sur du gel de silice, des substances coadsorbées ainsi que celle du traitement de la surface par la chaleur. Lorsque la surface du gel de silice est partiellement déshydroxylée, la distribution du pyrène ou du naphtalène n'est pas homogène comme l'indiquent la désintégration de fluorescence multiexponentielle et le spectre d'émission qui est élargi. L'addition de produits de coadsorption polaires rend la surface plus homogène avec des temps de vie du singulet qui s'approchent des valeurs observées en solution. Le traitement préalable et l'addition de produits de coadsorption, dans le cas du pyrène, influencent également l'importance relative de la formation de l'excimère dynamique par rapport à l'association dans l'état fondamental.

Introduction

In recent years there has been considerable interest in the photophysics and photochemistry of molecules adsorbed on oxide surfaces such as alumina and silica gel. The purpose of these investigations has been two-fold: to observe how the surface interactions may modify the behaviour of the excited molecules, and to use photochemistry as a tool to probe the substrate surface. Amongst the techniques employed that of fluorescent spectroscopy has so far been used most intensively both on silica gel (1–5), alumina (6–13), and porous glass (14).

The surface of silica gel consists of siloxane bridges between atoms of tetracovalent silicon. The terminal oxygen functions — the silanols — have been shown by infrared studies to be geminal, vicinal, or isolated (15–23). These functions, in an amorphous framework, serve to render the silica gel surface inhomogeneous. The binding of molecules with π-systems or with lone pair electrons is largely by hydrogen bonding to the silanols or to physically adsorbed water molecules. As a consequence of the varied silanol environment the emission of aromatic hydrocarbons adsorbed on "active" surfaces is characterized by broader emission and excitation spectra, and also by a multi-exponential decay of usually shorter mean decay time. This is in contrast to that observed in solution where the spectra are well resolved and the lifetimes are much higher.

Since heat treatment of silica gel modifies the number and nature of the surface silanols, it is to be expected that the fluorescence behaviour will also be changed. Heat treatment of silica gel first induces loss of the physically adsorbed water molecules and, subsequently, dehydroxylation of the silanol groups. The number of hydroxyl groups on the silica gel surface depends strongly on the temperature of pretreatment of the samples studied (15–24). Measurements performed by Fripiat and Uytterhoeven (21), amongst others, indicate that the amount of free water rapidly decreases with increasing temperature and, for temperatures higher than about 250°C, it is reduced to nil. The number of silanol groups decreases more slowly; starting at ~6 OH/100 Å^2, it is reduced to ~2 OH/100 Å^2 at 500°C and to ~1 OH/100 Å^2 at 800°C. Up to 450°C the dehydroxylation process can be reversed by exposing the silica gel to water vapour, for higher temperatures this process is slow. If the heating is taken to ~700°C, or higher, only isolated OH groups remain on the surface (21, 23). Fripiat and Uytterhoeven's (21) findings have been recently supported by nmr studies (24) in which, additionally, the proportion of geminal-hydroxyl sites to single hydroxyl sites, previously the subject of much debate, was determined. In the temperature range 500–700°C, the surface concentration of geminal-hydroxyl sites remains roughly constant, but the ability to regenerate silanols by exposure to water vapour decreases suddenly. Therefore, heating the surface of SiO_2 to temperatures higher than 500°C followed by rehydration changes the proportion of isolated to geminal-hydroxyl sites. At higher temperatures (700–900°C), all geminal and vicinal OH groups are removed from the surface and only siloxane and isolated silanols remain.

Heat treatment of silica gel, with and without subsequent partial or complete hydration, thus offered the possiblity of surface modification, with attendant increase in homogeneity; a process that promised to be revealed by emission studies. We report here the results of such studies both of dehydrated silica gel and of silica subsequently modified by the addition of water and various alcohols.

Experimental section

Materials

Silica gel (Merck 60, 35–75 mesh) was used as adsorbent. Pyrene (Aldrich, 99+%) was purified by recrystallization from ethanol and vacuum sublimation. Naphthalene was zone refined. Cyclohexane (Fisher Scientific) spectroanalysed grade contained 56 μg/mL water (Karl Fischer). Cyclohexane passed through fresh silica gel column contained 26 μg/mL water. The water content was lowered to 2 μg/mL by distillation over P_2O_5 and storage on molecular sieves (4 Å). For most of the experiments, cyclohexane dried with a silica gel column was used. Methanol and 1-decanol were spectroanalyzed grades. The silica gel surface area (560 m^2/g) was determined by the

[1] Publication 315 from the Photochemistry Unit.

method of Hoffman *et al.* (25). Monolayer coverages for naphthalene and pyrene were taken very roughly as 100 mg/g silica gel.

Photophysical studies

1. Preparation of samples: The different methods of silica gel treatment for the sample preparation are summarized as follows: (*a*) heating in vacuum at 800°C for 4 h, undried cyclohexane was used for dissolving the hydrocarbon; (*b*) heating in air at 800°C for 4 h, undried cyclohexane was used for dissolving the hydrocarbon; (*c*) heating in vacuum at 700°C for 4 h, undried cyclohexane was used for dissolving the hydrocarbon; (*d*) heating in vacuum at 700°C for 4 h; (*e*) heating in vacuum at 600°C for 4 h; (*f*) heating in air at 600°C for 4 h; (*g*) heating in the presence of dry O_2 at 600°C for 4 h; (*h*) heating in the presence of dry N_2 at 600°C for 4 h; (*i*) heating in vacuum at 600°C for 4 h followed by exposure to air for 1 h; and (*j*) heating in vacuum at 500°C for 4 h.

In general, the silica gel (2 g) was heated in vacuum for 4 h at the desired temperature and then cooled down to room temperature in vacuum. This heating period was selected because Sindorf and Maciel (24) reported that under such conditions 90% dehydration occurred. The deaerated (freeze–thaw method) naphthalene or pyrene solution (2 mL/g SiO_2) was then added to the cooled silica gel (20°C) in vacuum. The cyclohexane was then evaporated and the remaining adsorbate-covered silica gel evacuated to 2E-5 Torr for 30 min. For most of the experiments a measured volume of deaerated water, methanol, hexanol, or decanol was then transferred, in vacuum, on to the silica gel. If necessary, heating of the apparatus with a hot air gun to about 70°C was employed. After transfer of the additive, pumping was terminated. During the transfer, the silica gel was shaken to ensure an even distribution of the additive. The amount of water introduced in the cyclohexane (dried on a silica gel column) was about 50 μg/g SiO_2, equal to 2.8×10^{-6} mol/g SiO_2, a quantity much less than the lowest amount of water deliberately added. After preparation of the sample of pyrene or naphthalene on silica gel it was transferred to a quartz cuvette (1 mm) in vacuum, sealed, and tumbled 1 h to achieve an even distribution of adsorbed molecules (3).

2. Fluorescence decay measurements: Fluorescence decay was measured with a Photochemical Research Associates (PRA) System 3000 Nanosecond Spectrofluorometer. Detailed description of the experimental techniques is given elsewhere (1–4). The decays were not single exponential, and it was necessary to use a two component decay with four parameters, according to eq. [1] (26, 27).

$$[1] \quad I_F(t) = A_1[\exp(-\lambda_1 t)] + A_2[\exp(-\lambda_2 t)]$$

The average lifetime was calculated from eq. [2].

$$[2] \quad \bar{\tau} = \frac{A_1\tau_1^2 + A_2\tau_2^2}{A_1\tau_1 + A_2\tau_2}$$

The average decay times τ are reproducible to within ±5% for multiple samples of the same experiment.

Relative quantum yields were calculated from eqs. [3] and [4]

$$[3] \quad \phi_1 = A_1\tau_1/(A_1\tau_1 + A_2\tau_2)$$

$$[4] \quad \phi_2 = A_2\tau_2/(A_1\tau_1 + A_2\tau_2)$$

For example, the percentage of the short decay component (τ_2) was calculated as $\phi_2 \times 100$.

The steady state emission and excitation spectra were measured on a Perkin-Elmer 650-40 computer-controlled fluorescence spectrophotometer (1–4).

Results

Influence of surface preparation on the photophysics of naphthalene

For naphthalene adsorbed on silica gel the pretreatment consisted in the gel's being heated at different temperatures in different gases or in vacuum. The highest temperature used was 800°C. In Fig. 1 are presented emission spectra, obtained with

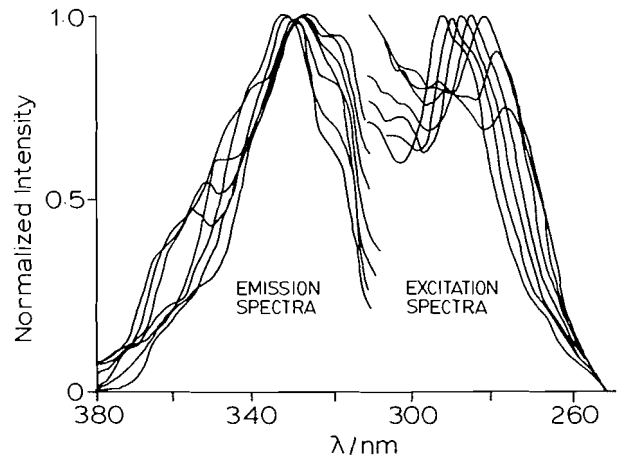

FIG. 1. Excitation and emission spectra of naphthalene adsorbed on silica gel. The silica gel was heated in vacuum for 4 h at 800°C (Preparation (*a*)). Naphthalene coverage was 0.2 mg/g SiO_2. As the excitation was varied from 270 to 300 nm, emission varied from 332 to 350 nm.

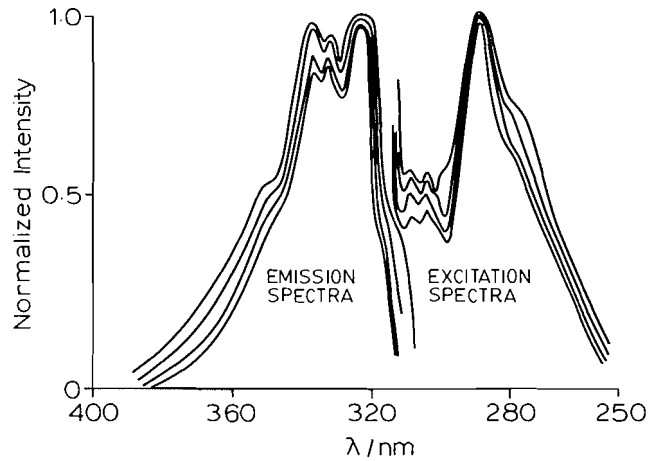

FIG. 2. Excitation and emission spectra of naphthalene adsorbed on silica gel with different emission and excitation wavelengths. The silica gel was heated for 4 h in open air at 800°C (Preparation (*b*)). Napthalene coverage was 0.2 mg/g SiO_2. Excitation varied from 270 to 300 nm, emission varied from 332 to 350 nm.

different excitation wavelengths, together with excitation spectra, monitored at different emission wavelengths, of naphthalene adsorbed on SiO_2 pretreated at 800°C. The sets of different spectra must arise because the heat treatment has rendered the surface very inhomogeneous and the naphthalene molecules find themselves in many different environments. There is a systematic shift of the excitation spectra with emission wavelength. The observed increase of the excitation spectral intensity above 300 nm is to be attributed to strong scattering. The decay of the emission is strongly nonexponential with a highly shortened mean decay time of only 6.67 ns and a 67% (ϕ_2) contribution from the short component.

These characteristics of the surface changed if the sample was heated at the same temperature but exposed to air (Fig. 2). Although these spectra also show some dependence on excitation or viewing wavelengths, they indicate a much more homogeneous surface. The decay approaches more closely a single exponential. The observed mean decay time was 49.1 ns with only 12.8% contribution from the shorter component (Fig.

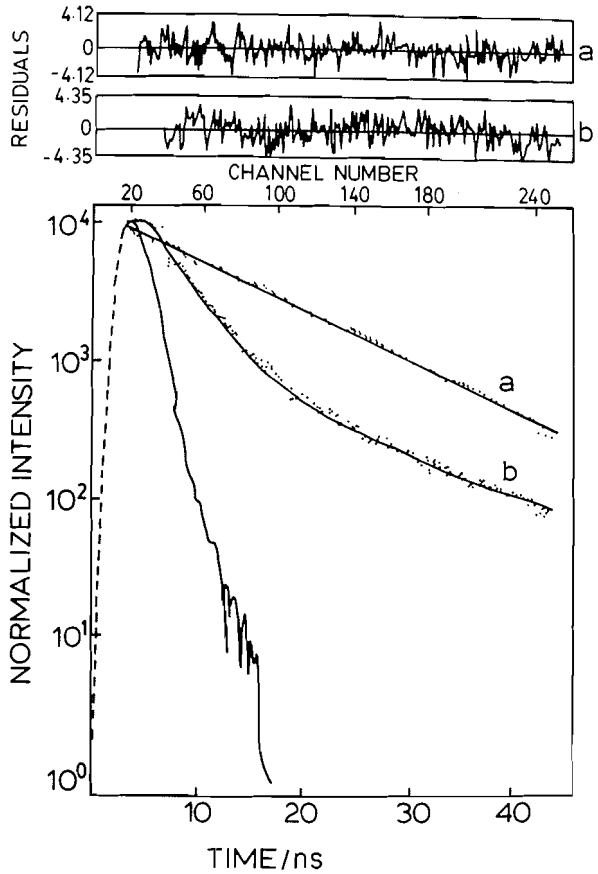

FIG. 3. The decay of naphthalene fluorescence. Emission wavelength is 333 nm: (*a*) silica gel was heated in open air for 4 h at 800°C (Preparation (*b*)); (*b*) silica gel was heated in vacuum for 4 h at 800°C (Preparation (*a*)).

3). Lowering the temperature in the sample preparation to 700°C and 600°C with exposure to air results in differences between the emission spectra with different excitation wavelengths becoming almost negligible. For the sample heated to 600°C, the decay approaches a single exponential with only 8.5% contribution from the shorter component.

The vibronic structure of the naphthalene fluorescence also depended on whether the SiO_2 was heated in vacuum or in air. In vacuum the fine structure of the adsorbed naphthalene fluorescence almost disappeared (Fig. 4*a*). The ratio of the intensity of the first maximum to the intensity of the first minimum, I/I_{min} indicated in Fig. 4 may serve as a measure of the vibronic structure.

To determine why heating in air improved the homogeneity of the silica gel surface a series of samples was prepared for which the silica gel was heated to 600°C in vacuum, in dried oxygen, in dried nitrogen, and in dried air. The emission spectra of these samples were very similar and showed low vibronic resolution and pronounced non-exponentiality of the decay with low mean decay time of 40 ns. If the sample was heated in vacuum, cooled, and then exposed to the open air for 1 h, the vibronic resolution increased and the decay time lengthened to 45 ns.

These observations suggested that the spectral behaviour of adsorbed naphthalene depends on the amount of water adsorbed during exposure to air. To verify this, a set of samples was prepared for which the silica gel was heated to 700°C in vacuum and, prior to naphthalene adsorption, a measured

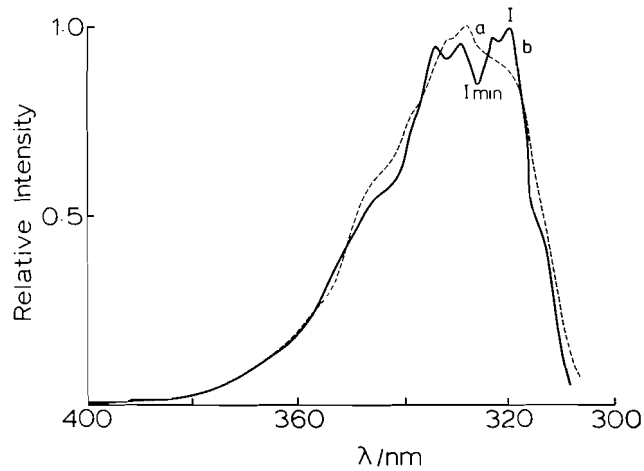

FIG. 4. Emission spectra of naphthalene: (*a*) silica gel heated to 700°C in vacuum for 4 h (Preparation (*c*)); (*b*) silica gel heated at 700°C in vacuum for 4 h (Preparation (*c*)). Water, 5.5×10^{-4} mol/g SiO_2, was added. The excitation wavelength was 285 nm.

amount of water was added. The deaerated water was transferred in vacuum from an additional side arm in the closed vacuum system. The amount of water added ranged from 2.8×10^{-5} to 1.14×10^{-3} mol/g SiO_2. As can be seen (Fig. 4*b*), the addition of water strongly influenced the SiO_2 surface. The most pronounced vibronic structure is present in the sample with 5.5×10^{-4} mol/g SiO_2 of water added. The longest decay time of 50 ns ($\bar{\tau}$) and the smallest contribution from the short decay component (8.5%) were observed for a sample with 2.8×10^{-4} mol/g SiO_2 of water.

Effect of surface modification on the photophysics of pyrene

Since pyrene has been suggested as an indicator of the polarity of its environment in solution (28, 29), measurements of the influence of water on the silica gel surface were made with adsorbed pyrene. As observed with naphthalene, the mean decay time increased with increasing amounts of water and the decay itself approached a single exponential with the contribution from the short component dropping from 45% for the dry sample (700°C) to 8% for the sample with 4.2×10^{-4} mol/g of added water. The data are summarised in Table 1. It can be seen that the higher the temperature, the shorter the mean lifetime of the pyrene and the more pronounced the effect of adding water on the decay time. The emission spectra of pyrene adsorbed on silica gel with different amounts of water added are shown in Fig. 5. The vibronic structure depends very strongly on the water content which causes an increase in the second band as well as the intensity ratio I_0/I_2. It is particularly striking that if the water content is 4.2×10^{-4} mol/g SiO_2, the decay time changes from 66.6 ns to 312 for a heating treatment of 700°C. The emission spectral area as well as the intensity ratio I_0/I_2 are most affected by the addition of water after the highest temperature heat treatment.

The question arose whether the behaviour of water was unique in this respect or whether other polar molecules would similarly influence the silica gel surface. Methanol was selected as a possible candidate, and the results are presented in Table 2. The amount of methanol adsorbed was varied from 3.75×10^{-5} mol/g SiO_2 to 7.5×10^{-4} mol/g SiO_2 for low pyrene concentrations. The influence of MeOH on the emission spectrum and the decay time is more pronounced (Table 2) than that of water. For instance, the decay time for one sample with

[b] Pyrene coverage is 0.05 mg/g SiO_2.
[c] Silica gel preparation is as (*e*) in the Experimental section.
[d] Silica gel preparation is as (*d*) in the Experimental section.
[e] Pyrene coverage is 0.5 mg/g SiO_2.
[f] The experimental conditions are as (*c*) in the Experimental section.
[g] Area ratio is calculated from integrated area of the emission spectrum from 360 to 460 nm.

methanol coadsorbed becomes as long as 383 ns with only 2.8% intensity contributed by the short component. This is to be compared with the decay time of pyrene in MeOH and in cyclohexane which are 370 and 430 ns, respectively. The I_0/I_2 ratio also is reduced from 1.75 to 1.14. This is to be compared with the value of 1.35 (29) for MeOH solution.

n-Decanol was also used as a coadsorbate. At the same molar concentration the binding from hydrogen bonding would be expected to be similar to that of methanol, but the hydrophobic tail might interact with, and perhaps cover, the hydrophobic siloxane functions, thus reducing pyrene–siloxane interactions. There might also be steric interference with the approach of pyrene to non-bonded silanols. In the event, *n*-decanol resolved the emission spectrum and increased the decay time more efficiently than MeOH or water at the same concentration (Fig. 6 and Table 3). The intensity ratios I_0/I_2 also changed more rapidly.

In the experiments described so far, the pyrene coverage was ~0.05%. We have previously reported for higher coverages (~1%) the observation of excimer-like emission (1, 3, 4) from pyrene. It has been shown that, with other treatments of the surface and with glycerol or decanol additives, there was evidence for both ground state association and dynamic excimer formation. We, therefore, increased the pyrene coverage in the present experiments under more controlled conditions to observe the effect of surface modification by adding water, methanol, hexanol, and decanol. As seen in Fig. 7, and Tables 1, 2, and 3, with increasing water or MeOH there is an increase of excimer-like emission. This is also seen in the ratio I_{470}/I_{392} where I_{470} refers to the excimer intensity. Thus methanol produces a more significant effect on excimer intensity than does water. The excitation spectra (MeOH at 1.2×10^{-3} mol/g SiO_2) corresponding to excimer emission and monomer emission are different. That corresponding to the 470 nm emission is red-shifted as compared to that at 393 nm (Fig. 8), suggesting the occurrence of ground state bimolecular association. On the other hand, at the same concentration of *n*-decanol the two excitation spectra are almost identical (Fig. 9). Further, the *n*-decanol curve for excimer emission has a pre-exponential term A_2 which is *negative*, with values of A_2 and A_1 which are numerically almost equal (Table 3). For methanol the values of A_2 and A_1 are both positive. In the former situation, therefore, kinetic excimer formation is dominant whereas ground state association predominates in the latter (4, 30).

To confirm that there was a relationship between the contribution of the hydrophobic moiety, i.e., the carbon chain, and dynamic excimer formation, an intermediate length alcohol, *n*-hexanol, was investigated (1.10×10^{-3} mol/g SiO_2) at ~1% pyrene coverage, a large excimer growth was seen and $A_2/A_1 = -0.65$, indicative of dynamic excimer formation. The excitation spectra for 470 nm emission and 393 nm emission,

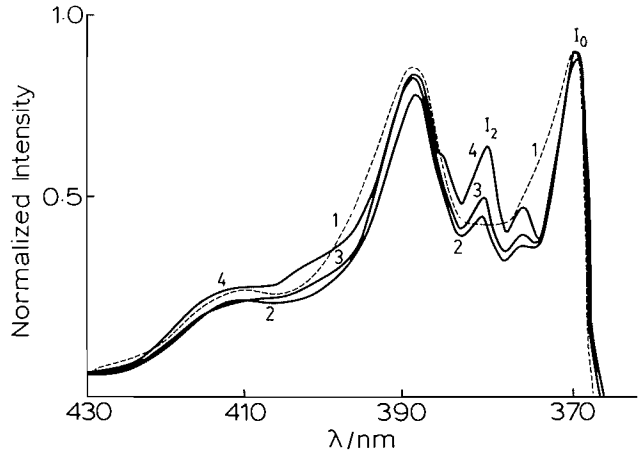

FIG. 5. Effect of addition of water on the emission spectra of pyrene coverage is 0.05 mg/g SiO_2. Silica gel was heated in vacuum to 700°C for 4 h (Preparation (*d*)). though not identical, were more similar than those observed for methanol (Fig. 10). Ground state association is also indicated. As with pyrene at low coverage, the additives resolve the emission spectra and also increase the monomer decay times (Tables 2, 3). Similarly, for the higher coverage of pyrene with increasing additives the monomer decay approaches a single exponential with a low contribution from the short-lived component.

Discussion

The experimental fluorescence decay data have been analyzed in terms of a four-parameter model, i.e., a two component decay. While direct comparison with this same model for solution excimer behavior appears to provide insight into the behavior of pyrene on silica gel, it must be understood that no exact physical significance is intended to be associated with the derived parameters. A six-parameter model would not seem appropriate and this type of system is too complex to permit the sort of analysis that might lead to quantitative interpretation of the parameters of the double experimental model employed here. This model has therefore been used to systematize the experimental data and form the basis of the discussion of the behavior of pyrene on the surface.

The experimental results with naphthalene and pyrene show that heating of the silica gel in vacuum to 500–700°C causes the adsorbed hydrocarbons to have broad and structureless fluorescence spectra with low quantum efficiency and substantially non-exponential decay. The addition of coadsorbed polar molecules such as water, methanol, hexanol, or decanol on the surface results in an increase in quantum efficiency, higher resolution of vibronic structure, and a large increase in decay time which approaches a single exponential. Furthermore, with increasing amounts of additives, the ratio of the vibronic bands, I_0/I_2, decreases. If this behaviour can indeed be compared with

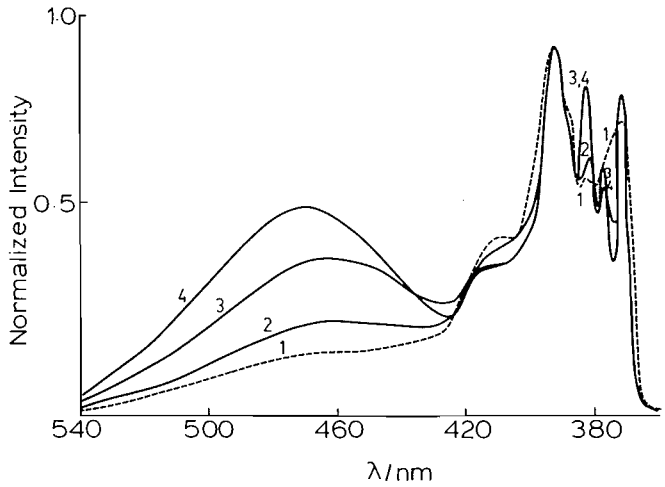

FIG. 7. Effect of methanol addition on the excimer-like emission of pyrene adsorbed on silica gel heated in vacuum at 700°C (Preparation (*d*)). Pyrene coverage is 1 mg/g SiO_2. The excitation wavelength was 347 nm. (*1*), 0 MeOH; (*2*), 3.75×10^{-5}; (*3*), 5×10^{-4}; (*4*), 1.3×10^{-3}, methanol concentrations are in mol/g SiO_2.

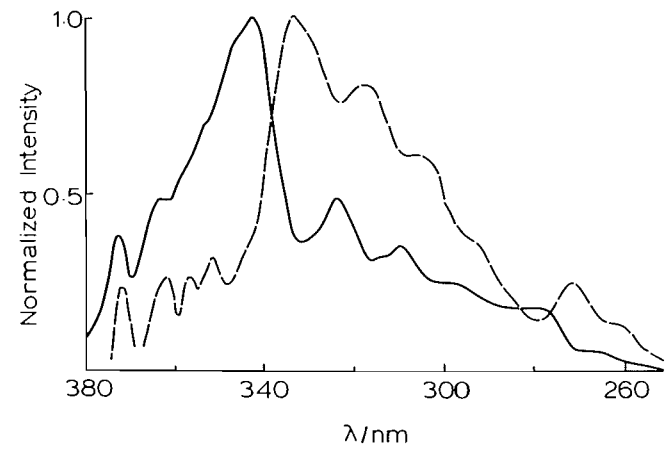

FIG. 8. Excitation spectra of emission of pyrene adsorbed on silica gel heated in vacuum at 700°C (Preparation (*d*)) and 1.3×10^{-3} mol/g SiO_2 of methanol added. Pyrene coverage was 1 mg/g SiO_2. Emission 470 nm (—), emission 393 nm (- - -).

that observed in solution (28, 29), it indicates a change in the polarity of the surface.

It is well established, theoretically (31) and experimentally (32–34), that the binding of adsorbed molecules, including aromatic hydrocarbons, takes place by hydrogen bonding to the silanol functions. Furthermore, of the various environments in which the silanol function may find itself, it is what is isolated, freely vibrating, and not hydrogen bonded to another silanol or to water, that is the most effective in binding (35–37). In the present instance, because of the dimension of the adsorbed naphthalene and pyrene, even when the dehydration of the surface is taken to about ~2 silanols/100 Å^2 (21), there must be more than one hydrogen bond per molecule. Because of the relatively small number of binding sites, their strength, and their nonuniform distribution there are, apparently two consequences.

First, the various molecules will be in a variety of local environments. The consequences are that there will be a family of similar, but not identical, emitting species, resulting in a complex decay, here expressed as the sum of two exponential.

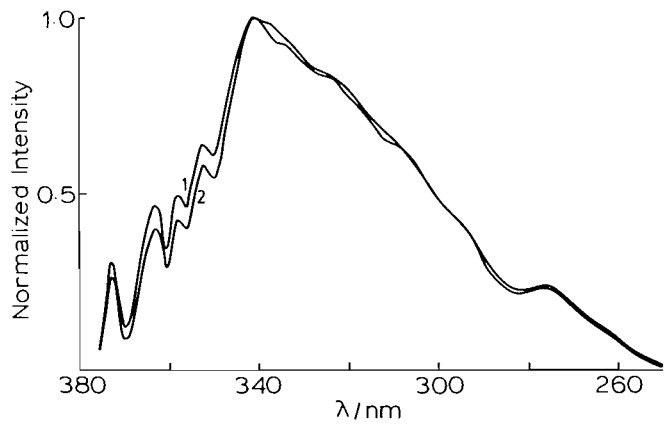

FIG. 9. Excitation spectra of pyrene adsorbed on silica gel. Silica gel heated in vacuum to 700°C (Preparation (*d*)) and 1.3×10^{-3} mol/g SiO_2 of 1-decanol added. Pyrene coverage is 1 mg/g SiO_2. (*1*), Emission at 470 nm; (*2*) emission at 393 nm.

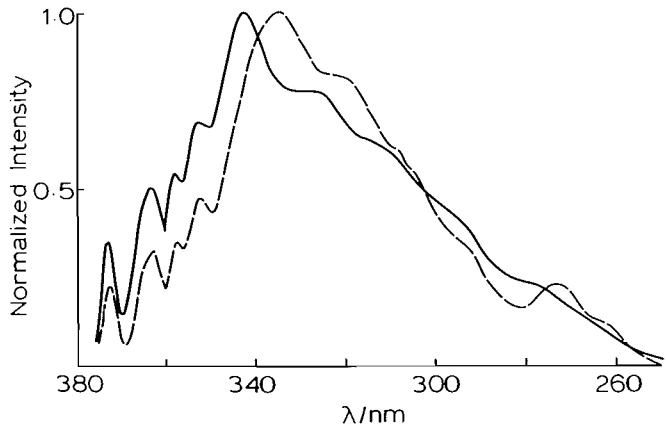

FIG. 10. Excitation spectra of emission of pyrene adsorbed on silica gel. Silica gel heated to 700°C in vacuum (Preparation (*d*)). 1-Hexanol, 1.3×10^{-3} mol/g SiO_2, was added. Pyrene coverage was 1 mg/g SiO_2; — emission 470 nm, - - - emission 393 nm.

Their emission spectra will likewise not be identical. A second consequence is that the low coverage and sparsely, isolated silanol population render hydrocarbon motion limited and the proximity of two pyrene molecules less likely; dynamic excimer formation is not observed. At higher pyrene concentration (1), with comparatively few sites available, the chances of static ground state association becomes higher and the existence of such complexes has been reported (1).

The remaining silanol functions make for a polar local environment, more so, perhaps, than when dissipated by hydrogen bonding to adjacent silanols or water. This polarity could, according to recent work (28, 29), be reflected in the I_0/I_2 ratio of the peak in the pyrene emission spectrum. Indeed, the ratio is found to be in the range 1.7–1.8. Since the I_0/I_2 ratio of pyrene in water is reported to be 1.85 (38), this might be interpreted as an argument for a high polarity in the immediate vicinity of the pyrene molecule. However, it is not immediately clear why the addition of water should *decrease* the ratio to ~1.44 when water itself is more polar than the isolated silanol. The striking increase of resolution of vibrational structure of the emission spectra and the increase of decay times for the increasing amounts of water added must be rationalized by an interaction of water with the surface. Water not only binds to the isolated silanol groups through hydrogen bonding but also

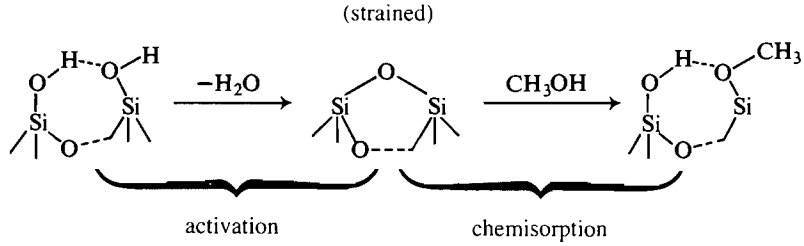

SCHEME 1

hydrolyses strained siloxane bonds formed by heating, thereby increasing the number of vicinal hydroxyl groups. Probably the first effect precedes the second, since rehydration is slow with drastically dehydrated silica gel and since the water has little to which it can anchor because the siloxane bonds are known to be hydrophobic (35). Iler (39) and others (40) have suggested that the rate-limiting step may instead involve the association of molecular water with uncondensed silanol functions. We are presently unable to decide the extent to which both contribute; in either case, the strongly interactive isolated silanol is removed (24) and this may be responsible for the I_0/I_2 decrease. Alternatively, the suggested use (29) of I_0/I_2 may not extend to silica gel surfaces: protonic solvents also are aberrant on this "Py scale" which appears to be insensitive to hydrogen bonding (29).

For the same molar concentration per gram of SiO_2, methanol as the coadsorbing additive is more efficient than water in resolving the vibrational structure of pyrene emission and also increasing the decay time. This decay times, as high as 383 ns with only ~2% contribution from the short decay component, were observed for methanol concentrations of 7.5×10^{-4} mol/g SiO_2. This value compares with that of 370 ns observed in methanol and 430 ns in cyclohexane. The surface is now much more homogeneous than that obtained by the addition of water, and approximates a two-dimensional system as described by Dacey (41).

As in the case of water, it has been shown, by infrared studies (22) of methanol adsorption on silica gel activated by heating between 200–950°C, that the formation of two species occurs on the surface. The first is methanol, hydrogen bonded to isolated silanol groups (physical adsorption), and the other involves the formation of Si—O—CH_3 bonds (chemisorbed methanol). The latter is a consequence of reaction with strained, easily-breakable siloxane linkages, as shown in Scheme 1. Evidence of interaction of CH_3OH with siloxane groups is provided by the observation that methanol adsorption increases with increase of preheat treatment of silica gel. Both surface methylation and the physical adsorption through hydrogen bonding renders the surface more uniform, in a polar sense, to pyrene and, in fact, the environment of the pyrene could approximate that of methanolic solution as hydration with water approximates aqueous solution.

On a molar basis 1-decanol is even more effective in inducing spectral resolution in pyrene than is methanol or water, presumably in part because of its greater cross-section. Here, in addition, adsorption can probably occur to the siloxanes without perturbing the silanols, as has been reported for octadecanol (42).

Excimer formation

Excimer-like emission has already been reported at higher pyrene coverages (1, 4). With increasing amounts of additives the excimer-like intensity at 470 nm increased. With methanol (1.3×10^{-3} mol/g) ground state bimolecular association was indicated by the difference in excitation spectra (4) at 393 nm (monomer) and at 470 nm (dimer). The excimer-like emission is to be attributed to the excitation of preformed pairs of pyrene molecules. The absence of any negative pre-exponential term A_2 (30) (Table 2) also implies the absence of predominant dynamic excimer formation which in turn would indicate that the mobility of pyrene is restricted. On the other hand, for 1-decanol predominant dynamic excimer formation is indicated by the negative value of A_2 (Table 3) and the value of ratio of A_2/A_1 (−0.85). Also the excitation spectra for 393 nm and 470 nm emission are now almost identical (Fig. 9). The presence of the 1-decanol has not only rendered the environment of the pyrene molecules more uniform but has increased the diffusion rate. 1-Hexanol also resolves the monomer emission and evidence is seen of some dynamic excimer formation ($A_2/A_1 = -0.65$). The excitation spectra at 393 nm and 470 nm were not quite as similar as with 1-decanol: it is concluded that both ground state association and dynamic excimer formation are important in this case.

Presumably the surface now resembles that of an alkylated silica gel, approaching what may be achieved by silylation. On such a surface a hydrocarbon will be more generally but more weakly bound, and hence have a lower activation energy for motion: diffusion will thus be facilitated.

In an earlier publication, we reported that 1-adamantanol as a coadsorber behaved differently from 1-decanol (4). The emission spectrum of pyrene in the presence of 1-adamantanol was diffuse and the decay was multiexponential with a short mean decay time. No dynamic excimer formation was observed. The area of cross-section is, however, roughly equal to that of 1-hexanol which, as described, behaves differently. This difference must be attributed to the different shapes of these two molecules. 1-Hexanol should be able to interact with all isolated silanols, but 1-adamantanol may not; it should be recollected that ca. 99% of the silica gel surface is on the *inside* of the granules. Furthermore, the rigidity of the adamantanol framework and its hydrophobicity may render many of the isolated silanols inaccessible if a consequence of bonding would entail close interaction of the cycloalkyl residue with a second silanol; an interaction that would be avoided by the flexible 1-hexanol by coiling. Finally, it may well be that the hydroxyl function may be too hindered to react chemically with strained siloxanes, as do at least water and methanol, i.e., chemisorption may be impossible.

Conclusions

When the silica gel is dry, the distribution of pyrene or naphthalene is inhomogeneous and the surface yields a broader emission spectrum and multiexponential decay; the polarity of the surface also is high. When the dried surface is saturated with polar additives, the surface becomes homogeneous, as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

seen by the highly resolved emission spectra and the near single exponential decay. The singlet lifetime of pyrene approaches that observed in solution. In this context the behaviour of the surface may be best described as approaching that of a two-dimensional gas or liquid (41). The effectiveness of the additive alcohol in rendering the "surface" more homogeneous increases with chain length and presumably signals interaction with the siloxane framework (42).

Interactions de l'ion Ag^+ avec la glutarimide

JOHANNE PERRON ET ANDRÉ L. BEAUCHAMP[1]

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Reçu le 1 décembre 1983

JOHANNE PERRON et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **62**, 1287 (1984).

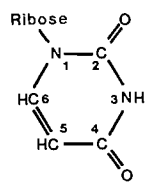
Le composé 1:1 de l'ion Ag^+ avec la glutarimide a été étudié par diffraction des rayons X, par spectroscopie infrarouge et par rmn ^1H et ^{13}C. Les cristaux sont monoclinques, $C2/c$, a = 13,497(3) Å, b = 9,503(2) Å, c = 9,600(4) Å, β = 92,30(3)°, Z = 4 molecules par maille. La structure a été affinée au moyen de 1086 réflexions MoK$\bar{\alpha}$ d'intensité significative jusqu'à un facteur R de 0,027. La moitié des atomes d'argent est linéairement coordonnée aux atomes d'azote de deux coordinats glutarimides déprotonés, tandis que l'autre moitié est entourée d'un tétraèdre déformé de quatre oxygènes carbonyles appartenant à deux ensembles $[Glu-Ag-Glu]^-$ adjacents. Les groupes $[Glu-Ag-Glu]^-$ réunis par l'atome Ag à coordination tétraédrique forment des chaînes infinies selon l'axe c. La complexation produit plusieurs changements dans le spectre infrarouge de la glutarimide. Ils peuvent être reliés à la disparition du vibrateur N—H et à la modification des indices de liaison dans la portion —C(O)—N—C(O)— du coordinat. Les spectres rmn montrent que la glutarimide coordonnée conserve un miroir lorsque le composé d'argent est dissous dans DMSO. Ceci laisse supposer que les atomes Ag liés à l'oxygène sont largement dissociés en solution, ce qui laisse les ions linéaires $[Glu-Ag-Glu]^-$ comme espèce complexe prédominante.

JOHANNE PERRON and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **62**, 1287 (1984).

The 1:1 complex formed between Ag^+ ions and glutarimide was investigated by X-ray diffraction, infrared spectroscopy, and ^1H and ^{13}C nmr. The crystals are monoclinic, $C2/c$, a = 13.497(3) Å, b = 9.503(2) Å, c = 9.600(4) Å, β = 92.30(3)°, Z = 4 molecules per cell. The structure was refined on 1086 nonzero MoK$\bar{\alpha}$ reflections to R = 0.027. One half of the Ag atoms are linearly coordinated to the N atoms of two deprotonated glutarimide ligands, whereas the other half are surrounded by an approximate tetrahedron of four carbonyl oxygens belonging to two adjacent $[Glu-Ag-Glu]^-$ units. The $[Glu-Ag-Glu]^-$ groups are joined by tetrahedrally coordinated Ag atoms into infinite chains along the c axis. Complexation introduces a number of changes in the infrared spectrum of glutarimide. They can be related to the disappearance of the N—H vibrator and the change of bond orders in the —C(O)—N—C(O)— portion of the ligand. The nmr spectra show that coordinated glutarimide retains a mirror plane when the Ag complex is dissolved in DMSO. This suggests that the O-bonded Ag atoms dissociate to a large extent in solution, leaving the linear $[Glu-Ag-Glu]^-$ ions as the major glutarimide complex species.

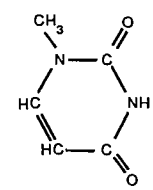
Introduction

Dans le but de préciser la nature des interactions de l'ion Ag^+ avec les acides nucléiques (1), les réactions de cet ion avec différents composés modèles ont été etudiées dans notre laboratoire. Nous avons montré que l'uridine (**1**) forme avec l'ion



1

Ag^+ en milieu aqueux des espèces de stoechiométries 2:1 et 2:2. Toutefois, la structure de ces espèces n'a pu être déterminée sur des échantillons solides à cause de leur grande solubilité et de l'instabilité de leurs solutions saturées. Avec la méthyl-1 thymine (HMT, **2**), un composé de formule



2

$Ag[Ag(MT)_2]$ a été préparé (2). La moitié des atomes d'argent dans ce composé est linéairement reliée à l'atome N(3) déprotoné de la thymine pour créer des motifs $[MT-Ag-MT]^-$, alors que l'autre moitié est entourée d'un tétraèdre déformé constitué de fonctions carbonyles appartenant à deux ensembles $[MT-Ag-MT]^-$ voisins dans le cristal. Des solides de type $M'[MT-Ag-MT]$ (où $M' = Na^+, K^+$) ont été obtenus, mais sous une forme qui ne se prête pas à un travail cristallographique (3). Nous nous sommes donc tournés vers les imides cycliques, qui renferment un ensemble —C(O)—N(H)—C(O)— semblable à celui de l'uracile et de la thymine. L'étude du système Ag^+–succinimide (**3**) par plusieurs méthodes a effectivement montré l'existence de deux sortes d'ions Ag^+ (4, 5) comme pour les dérivés de l'uracile. Le présent article décrit les résultats obtenus avec la glutarimide (HGlu, **4**), qui possède un cycle à six atomes la rapprochant de l'uracile et la thymine.

Partie expérimentale

Instruments et réactifs

Les spectres infrarouges ont été obtenus à l'aide d'un spectrophotomètre Beckman 4250 au moyen de pastilles de KBr ou d'émulsions dans le Nujol ou l'hexachlorobutadiène. La précision des nombres d'onde est de ± 5 cm^{-1} entre 4000 et 2000 cm^{-1} et ± 3 cm^{-1} entre 2000 et 500 cm^{-1}.

Les spectres rmn ont été enregistrés au moyen d'un appareil Bruker modèle WH-90 pour les spectres ^{1}H et modèle WH-80 (en opérant à 20,11 MHz) pour les spectres ^{13}C. Le solvant utilisé pour les deux noyaux était le DMSO-d_6 Silanor (Merck, Sharp et Dohme Canada) d'une pureté isotopique de 99,5% et contenant 1% de tétraméthylsilane comme référence interne.

La glutarimide (Aldrich Chemicals) a été utilisée sans autre purification.

Préparation du composés Ag–glutarimide

Ce composé est connu depuis longtemps (6). Nous l'avons préparé sous forme de fines aiguilles à partir d'un mélange de glutarimide, de $AgNO_3$ et de NaOH selon des rapports 1:1:1. Les cristaux utilisés pour les études aux rayons X ont été obtenus lors de tentatives de préparation de $Li[Ag(Glu)_2]$ et $Na[Ag(Glu)_2]$, qui n'ont pas pu être isolés. A une solution de 0,70 g (6 mmol) de glutarimide et 0,43 g (2,5 mmol) de $AgNO_3$ dans 20 mL d'eau à la température ambiante, on ajoute goutte à goutte une solution de 5 mmol d'hydroxyde (0,22 g, $LiOH.H_2O$ ou 0,20 g NaOH). Après addition de la moitié de l'hydroxyde, un précipité blanc apparaît, puis se redissout lorsqu'on poursuit l'addition. Par évaporation à l'abri de la lumière, on isole des cristaux incolores prismatiques de composition AgGlu.

Données cristallographiques

$C_{10}H_{12}Ag_2N_2O_4$ m = 439,95

Monoclinique, $C2/c$, a = 13,497(3), b = 9,503(2), c = 9,600(4) Å, β = 92,30(3)°, V = 1230,3 Å^3, Z = 4, D_o = 2,32(2) g cm^{-3}, D_c = 2,374 g cm^{-3}, λ(MoK$\bar{\alpha}$) = 0,71069 Å (monochromateur de graphite), T = 298(3) K, dimensions du cristal: 0,066 mm × 0,081 mm × 0,188 mm, μ(MoKα) = 31,6 cm^{-1}, transmission = 0,71–0,82.

Mesures d'intensité et résolution de la structure

Les groupes spatiaux Cc et $C2/c$ sont compatibles avec les extinctions systématiques. La structure a été interprétée selon le groupe centrosymétrique $C2/c$ et ce choix a été ultérieurement confirmé par le succès de l'affinement. La détermination précise des constantes réticulaires et les mesures d'intensités ont été faites au moyen d'un diffractomètre Enraf–Nonius CAD4, selon la méthode décrite antérieurement (7). Un ensemble de 1086 taches hkl et $hk\bar{l}$ dans une sphère limitée par $2\theta \leq 50°$ a été mesuré et 750 d'entre elles ($I > 3\sigma(I)$), corrigées pour l'absorption, ont été retenues pour la résolution.

La structure a été résolue par la méthode de l'atome lourd et affinée par moindres carrés sur $|F_o|$ en inversant la totalité de matrice. Les positions atomiques ont été affinées pour tous les atomes, y compris ceux d'hydrogène. Les facteurs d'agitation thermique affinés étaient isotropes pour l'hydrogène, anisotropes pour les autres atomes. Le fond continu sur la carte de Fourier différence finale était inférieur à $\pm 0,28$ e/Å^3. Les facteurs d'accord sont R = 0,027 et R_w = 0,033.

Les coordonnées atomiques sont réunies au tableau 1. Les facteurs d'agitation thermique et le tableau des facteurs de structure sont déposés en archive.[2]

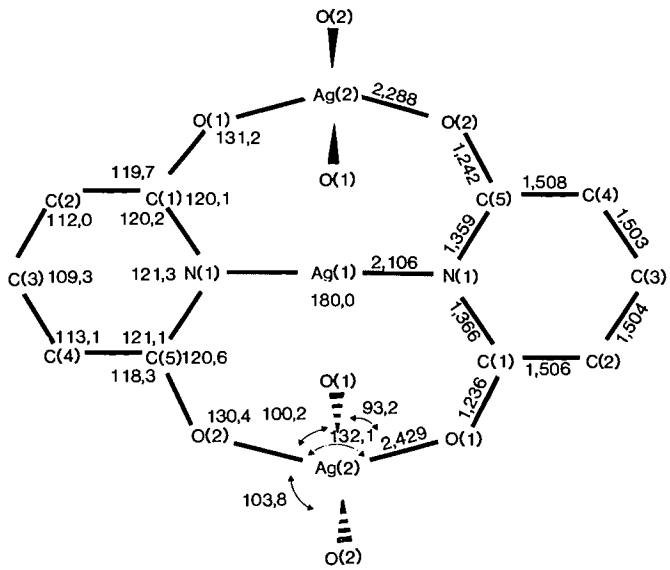

FIG. 1. Schéma du motif moléculaire avec les distances interatomiques et les angles de liaisons. Les atomes d'hydrogène ne sont pas représentés. Les écarts-types sont: 0,004–0,005 Å, Ag—O(N); 0,007–0,009 Å, autres; 0,2°, angles autour de Ag; 0,4–0,5°, autres. L'angle N—Ag—N est rigoureusement égal à 180° par symétrie.

Résultats et discussion

Description de la structure

Les trois sites potentiels de coordination, soit O(1), O(2) et N(1), sont pleinement utilisés (Fig. 1). Le composé contient deux atomes d'argent non équivalents. L'atome Ag(1) occupe un centre de symétrie cristallographique. Il se trouve donc linéairement coordonné (180° par symétrie) à l'atome d'azote de deux molécules de glutarimide déprotonée. La longueur des liens Ag(1)—N(1) (2,106(5) Å) est légèrement supérieure à celles de composés analogues avec la méthylthymine (2,081(4) Å) (2) et de la succinimide (2,079(5) Å) (4). Les deux coordinats de l'ensemble [Glu–Ag–Glu]$^-$ sont à peu près coplanaires, de sorte que chacun des côtés de cet ensemble peut jouer le rôle de chélatant grâce à une paire de groupes carbonyles. De fait, chaque ensemble [Glu–Ag–Glu]$^-$ est lié à deux atomes Ag(2) distincts dans le cristal. Réciproquement, chaque atome Ag(2) est entouré de deux paires d'oxygènes carbonyles appartenant à deux ensembles [Glu–Ag–Glu]$^-$, qui lui assurent un environnement à peu près tétraédrique (Fig. 1). Les distances Ag(2)—O (2,429(4) et 2,288(4) Å) sont un peu plus courtes que celles obtenues avec la méthylthymine (2,512(4) et 2,333(4) Å). L'écart entre les distances Ag(2)—O(1) et

[2] Les facteurs de structure, les facteurs d'agitation thermique, les calculs de plans moyens, ainsi que les distances et angles impliquant les atomes d'hydrogène peuvent être obtenus en s'adressant au Dépôt de Données Non-publiées, ICIST, Conseil National de Recherches du Canada, Ottawa, Ont., Canada K1A 0S2.

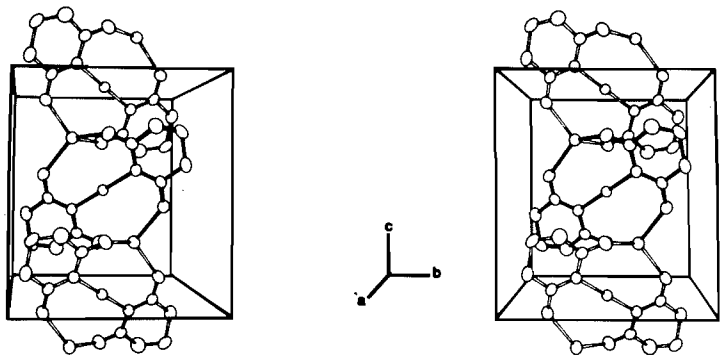

FIG. 2. Vue stéréo de l'enchaînement moléculaire le long de l'axe *c*. Le motif en traits pleins correspond à celui de la figure 1.

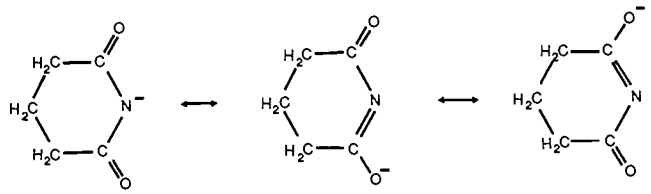
Ag(2)—O(2) semble lié essentiellement à des conditions de rangement moléculaire, puisque O(1) et O(2) sont chimiquement équivalents.

Les liaisons C—N (moy. 1,363, σ = 0,007 Å) sont plus courtes et les liaisons C=O (moy. 1,239, σ = 0,007 Å) sont plus longues que dans la glutarimide même (moy. 1,382 et 1,215 Å, σ = 0,003 Å, respectivement) (8). Ces variations sont en accord avec une contribution accrue des formes limites **5***b* et **5***c* dans l'anion (**5**). La coordination de l'argent aux



5a 5b 5c

5

atomes d'oxygène favorise encore davantage ces formes limites, tandis que la coordination sur l'azote tend à en diminuer l'importance, bien qu'à un degré moindre que ne le ferait l'hydrogène dans la glutarimide neutre. La distribution électronique dans l'anion de glutarimide complexé est donc intermédiaire entre celle de l'anion libre et celle de la forme neutre protonée. Ces changements se répercutent également sur les angles de liaisons: l'angle C(1)—N(1)—C(5) diminue de 5,6° et les angles N(1)—C—C voisins augmentent de ~3,5° par rapport à ceux de la glutarimide (8). Un effet analogue a été noté pour la succinimide (4) et se rencontre couramment pour les purines (9). Notons que ces changements angulaires dans le cycle ne provoquent pas de changement notable des angles N—C—O et que seuls les angles C—C—O sont modifiés.

La glutarimide conserve dans le complexe la conformation observée pour la molécule neutre (8). Les atomes N(1), C(1), C(2), C(4) et C(5) définissent un ensemble à peu près plan. Les écarts des atomes à ce plan sont significatifs (6,5σ), mais assez faibles ($\leq$0,040(6) Å). Le groupe méthylène C(3), le plus éloigné de l'azote, se trouve à 0,633(6) Å de ce plan et confère à la glutarimide une conformation "enveloppe". L'oxygène carbonyle O(1) n'est qu'à 0,034(4) Å de ce plan, tandis que O(2) s'en écarte davantage (0,168(5) Å), dans la direction de l'argent auquel il est lié.

L'empilement moléculaire est représenté à la figure 2. Le cristal est constitué d'ensembles $[Glu-Ag-Glu]^-$ linéaires et à peu près plans, reliés entre eux par des atomes Ag(2) de manière à constituer des colonnes infinies orientées selon l'arête *c* de la maille. De telles colonnes traversent la face *ab* au centre et à chacun des coins. Entre les colonnes, il n'existe que des contacts de van der Waals normaux.

Spectroscopie infrarouge

Les spectres infrarouges de la glutarimide en solution dans le chloroforme et l'acétonitrile ont été discutés par Thompson *et al.* (10). L'influence de la concentration sur les régions spectrales ν(N—H) et ν(C=O) a permis de conclure à un équilibre entre le monomère et un dimère lié par ponts hydrogène dans ces solvants. Le spectre rapporté au tableau 2 a été obtenu sur le solide. De manière générale, il diffère peu de celui des solutions, et les régions ν(N—H) et ν(C=O) sont semblables à celles de la forme associée en solution. Ceci est attribuable au fait que les vibrateurs N—H et C=O se trouvent dans des conditions analogues dans le solide et dans le dimère en solution. En effet, les molécules de glutarimide dans le cristal sont associées en rubans au moyen de liaisons N—H . . . O impliquant l'une des fonctions carbonyles et laissant l'autre libre (8). Les attributions proposées au tableau 2 ont été faites par comparaison avec les résultats de Thompson *et al.* (10).

Comme le complexe d'argent renferme la forme anionique de la glutarimide, les bandes dues au lien N—H doivent disparaître du spectre. C'est bien le cas de la bande ν(NH) dédoublée à 3195 et 3095 cm^{-1}. L'absorption résiduelle à 3150 cm^{-1} est probablement due à une harmonique de la vibration ν(C=O) observée à 1582 cm^{-1}, puisque ce même mode apparaissant à 1665 cm^{-1} dans la glutarimide semble également produire une harmonique à 3375 cm^{-1}. La bande large située à 835 cm^{-1} est attribuée à la déformation N—H hors-plan, par comparaison avec la position et la forme de la bande analogue de la succinimide à 823 cm^{-1} (4, 11). Dans le complexe Ag–glutarimide, il ne reste dans cette région que deux absorptions faibles à 853 et 869 cm^{-1}, que Thompson *et al.* (10) attribuent à des mouvements ν(CC) et δ(CCH). Quant à la déformation N—H dans le plan, elle semble se coupler à d'autres mouvements, pour contribuer aux bandes situées vers 1330 et 1055 cm^{-1}. La région 1330 cm^{-1} est trop compliquée pour qu'on puisse clairement identifier des changements dans le composé d'argent, mais le déplacement de la bande à 1061 cm^{-1} vers 969 cm^{-1} semble relié à la déprotonation du coordinat dans le complexe.

Les résultats cristallographiques indiquent que la redistribution des électrons dans le coordinat complexé entraîne une diminution de l'indice de la liaison C=O et une augmentation de celui de la liaison C—N. Le spectre infrarouge appuie cette conclusion. Les modes carbonyles se déplacent depuis 1720 et 1670 cm^{-1}, vers 1625 et 1580 cm^{-1}, respectivement, lors de la complexation. L'accroissement de l'indice de liaison C—N se

répercute sur le doublet 1277/1260 cm^{-1}, qui donne une bande à 1303 cm^{-1}. Un déplacement semblable sur la bande située à 1193 cm^{-1} dans la succinimide a été proposé comme un indice de déprotonation de l'imide (4). Certains autres déplacements sont également notés; par exemple, les bandes à 763 et 673 cm^{-1} passent respectivement à 778 cm^{-1} et 682 cm^{-1} dans le composé d'argent.

Spectroscopie de résonance magnétique nucléaire ^1H et ^{13}C

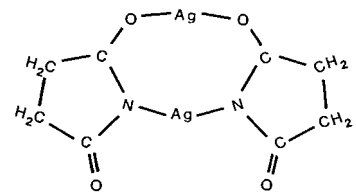
Les spectres de la glutarimide et de son complexe d'argent ont été étudiés dans le DMSO-d_6. Les pics du spectre ^{13}C ont été attribués par Hasan (12). Le spectre ^1H est interprété au moyen de la multiplicité et l'intégration des pics. Les valeurs des déplacements chimiques sont données au tableau 3. L'ensemble des modifications observées lors de la complexation est semblable à ceux qu'on retrouve pour les complexes de la phtalimide et la succinimide (4).

Dans le spectre ^1H, on retrouve à champ faible (10,58 ppm) la résonance du proton N—H qui disparaît comme prévu lors de la complexation. Les deux spectres (coordinat et complexe) présentent un triplet correspondant aux quatre protons en α du carbonyle. Un multiplet plus blindé, intégrant pour deux protons, est dû aux protons en β du carbonyle. Le triplet à 2,45 ppm et le multiplet à 1,83 ppm de HGlu apparaissent à 2,36 et 1,77 ppm respectivement dans le complexe. Ce blindage est relié à l'accroissement de densité électronique introduit dans le cycle par la substitution du proton par l'argent moins électro-attracteur.

Dans le spectre ^{13}C, le signal C=O apparaît à champ très faible (173,75 ppm) pour le ligand et à champ plus bas pour le complexe (181,14 ppm, $\Delta\delta = +7{,}39$ ppm). Ce déplacement également relié à la poussée des électrons vers le cycle, résulte de la hausse de polarité du lien C=O lors de la complexation (4, 13). Les carbones en α et en β des carbonyles subissent également un blindage, mais à un degré moindre ($\Delta\delta = +0{,}74$ ppm et $\Delta\delta = +1{,}91$ ppm respectivement).

Discussion

La structure cristalline du complexe de la glutarimide et celle du composé analogue de la méthyl-1 thymine présentent plusieurs points communs. Dans les deux cas, la moitié des atomes d'argent est linéairement reliée aux atomes d'azote de deux coordinats déprotonés, tandis que l'autre moitié est entourée de deux paires de fonctions carbonyles provenant de deux ensembles $[L-Ag-L]^-$ différents. Cette ressemblance tient au fait que le segment —C(O)—N—C(O)— adopte la même répartition spatiale dans les deux cas. En effet, si l'on excepte le groupe méthylène en position 4, la glutarimide possède comme la thymine un cycle à peu près plan et ce cyle possède six atomes. Il s'ensuit que la séparation O . . . O est la même des deux côtés de l'ensemble $[L-Ag-L]^-$ (Fig. 1) et que cette séparation est juste suffisante pour donner une interaction bidentate chélatante avec un autre atome d'argent. Cette géométrie particulière permet de construire des chaînes infinies très stables, dans lesquelles chaque ensemble $[L-Ag-L]^-$ interagit des deux côtés avec des atomes Ag(2) et chaque atome Ag(2) interagit avec deux anions complexes. Par contre, pour un cycle à 5 atomes comme celui de la succinimide, les angles internes plus petits placeraient les groupes carbonyles à une distance plus grande l'un de l'autre dans l'espèce linéaire $[Suc-Ag-Suc]^-$. Pour donner une interaction bidentate avec un premier atome d'argent, une paire de carbonyles doit se rapprocher l'un de l'autre (**6**), ce qui rend impossible une



6

seconde interaction bidentate chélatante par l'autre paire de groupes carbonyles du même anion complexe, comme nous l'avons précédemment observé (4). La conformité particulière pour le cas des cycles à six atomes semble donc conduire à une stabilisation accrue des solides $Ag[AgL_2]$, qui par leur plus faible solubilité empêchent d'obtenir des sels comme $Li[AgL_2]$ et $Na[AgL_2]$, qui sont isolables avec la succinimide (4).

Les chaînes infinies présentes dans le cristal doivent se rompre pour permettre au composé d'entrer en solution dans le DMSO. Les spectres rmn ^1H et ^{13}C montrent que le miroir passant par l'azote et le groupe méthylène en position 4 de la glutarimide est conservé dans le complexe présent en solution. A cause de la stabilité du lien Ag—N indiquée par la courte distance interatomique et l'obtention d'ensembles linéaires N—Ag—N dans les composés de ce genre (2, 4), il est fort

TABLEAU 3. Spectres de résonance magnétique nucléaire ^1H et ^{13}C de la glutarimide et du complexe d'argent

	^1H			^{13}C		
	NH	$(CH_2)(\alpha)$	$(CH_2)(\beta)$	C=O	C(α)	C(β)
HGlu	10,58	2,45	1,83	173,75	31,35	17,56
$Ag[AgGlu_2]$		2,36	1,77	181,14	32,09	19,47

probable que l'ion linéaire $[Glu-Ag-Glu]^-$ persiste en solution. Une interaction additionnelle avec d'autres ions Ag^+, qui ne pourrait se faire qu'avec une seule paire de groupes carbonyles à la fois, serait incompatible avec l'équivalence des deux moitiés du coordinat indiquée par la rmn, à moins que cet atome d'argent s'échange rapidement d'une paire de carbonyles à l'autre. Une explication également plausible serait une

$$Ag[AgGlu_2] \xrightarrow{DMSO} [Ag(DMSO)_n]^+ + [AgGlu_2]^-$$

dissociation du complexe dans le DMSO, pour donner une cation Ag^+ solvaté par DMSO et l'anion $[Glu-Ag-Glu]^-$ aperçu dans le solide.

Effect of substituents in the formation of diacetanilides[1]

NAGARAJ R. AYYANGAR AND KUMAR V. SRINIVASAN
National Chemical Laboratory, Pune 411 008, India

Received October 18, 1983

NAGARAJ R. AYYANGAR and KUMAR V. SRINIVASAN. Can. J. Chem. **62**, 1292 (1984).

A number of diacetanilides, including some which have not been reported so far, have been synthesized from the corresponding monoacetyl derivatives and characterized by spectral and elemental analyses. A tlc/fid method for the quantitative estimation of the relative amounts of mono- and diacetyl derivatives has been standardized. Linear correlation of the extent of diacetylation with Hammett σ-values of substituents and basicity constants of monoacetyl derivatives has been established. A plausible mechanism for the diacetylation reaction based on experimental observations has been suggested. An explanation for the anomalous behaviour of acetanilides containing electron-withdrawing substituents in the *ortho* position has been put forth.

NAGARAJ R. AYYANGAR et KUMAR V. SRINIVASAN. Can. J. Chem. **62**, 1292 (1984).

Utilisant les dérivés monoacétylés correspondants comme produits de départ, on a synthétisé un certain nombre de diacétanilides (dont quelques-uns qui n'avaient pas été rapportés jusqu'à maintenant) qui ont été caractérisés par des analyses spectrales et élémentaires. On a standardisé une méthode ccm/fid permettant d'évaluer quantitativement les proportions relatives de dérivés mono- et diacétylés. On a établi des corrélations linéaires entre les pourcentages de diacétylation et, d'une part, les valeurs de Hammett des substituants et, d'autre part, avec les constantes de basicité des dérivés monoacétylés. On suggère une mécanisme plausible pour la réaction de diacétylation qui tient compte des observations expérimentales. On propose aussi une explication pour le comportement anormal des acétanilides portant des substitutants électroaffinitaires en positions *ortho*.

Introduction

N,N-Diacetylamines play a key role as intermediates in acetyl transfer reactions in biochemical synthesis (1–5). Some of the diacetylamines have insecticidal (6, 7), flea-repellant (8), anti-ulcer and anti-secretory (9, 10), flame proofing (11), and immunostimulant and immunoregulatory (12) properties. Conformational (13, 14), thermodynamic (15), and mass spectrometric (16) studies of the diacetylamines have been reported. The methods of preparation of the diacetylamines involve the reaction of amines with acetylating agents such as acetyl chloride, acetic anhydride, and ketene and enol esters in presence of catalysts such as pyridine, sulphuric acid, and sodium acetate (17–22). An improved method for diacetylation of primary amines by acetic anhydride uses cupric acetate and magnesium as catalyst (5). The latter removes acetic acid from the reaction by forming insoluble magnesium acetate. It was observed that the presence of a positive or negative substituent in the *ortho* position to an amino group of a primary arylamine facilitated the formation of diacetyl derivative (18, 19) at the expense of monoacetyl derivative. If the primary arylamines with chloro, bromo, or nitro substituents in the *ortho* position are acetylated under monoacetylation conditions the formation of monoacetyl derivative has been retarded. This has been atrributed to the *ortho* effect which reduces the basicity of the nitrogen atom, the driving force for the monoacetylation reaction (23).

The diacetyl compounds thus have recently been attracting considerable interest. The detailed course of the diacetylation reaction is discussed in the present communication. Acetylation of aromatic amines results in the initial formation of monoacetanilides which undergo further acetylation to diacetanilides. Monoacetyl derivatives of anilines with suitable substituents in the *ortho*, *meta*, and *para* positions have been used as starting materials in our study.

[1]NCL Communication No. 3292.

Results

Diacetylation of the corresponding monoacetyl derivatives was carried out under identical conditions using an excess of acetic anhydride. The relative amounts of the mono- and diacetyl derivatives in the reaction mixtures were estimated by thin-layer chromatographic (tlc) procedure with flame ionization detection (fid) of the eluted fractions. Acetic anhydride and acetic acid present in the reaction mixture did not intefere in the estimations. Under our experimental conditions, the reaction was not reversible. Further confirmation of the irreversibility of the reaction was obtained by refluxing diacetanilide with 10% molar excess of Analytical Reagent (AR) grade glacial acetic acid for 4.0 h. The tlc/fid analysis indicated no formation of monoacetyl derivative. Material balance for the formation of diacetanilides from the corresponding monoacetyl derivatives could be established within ±1%.

The basicity constants (pK_{BH^+}) of the monoacetyl derivatives, Hammett σ-values (24) of substituents, yield of diacetyl derivatives, and R_f values are recorded in Table 1. We found that the extent of formation of diacetanilides had a linear correlation with Hammett σ-values of substituents (Fig. 1) and pK_{BH^+} of the monoacetanilides (Fig. 2). For the *p*-nitro substituent, σ^- and not the σ value was found to give a better correlation (Fig. 1).

Discussion

Since the acetylation reaction is electrophilic in nature, it is important to consider the basicities of the monacetanilides used. Substituted acetanilides are very weak bases (Table 1). They lack adequate spectral differences in their acid and base forms and have insufficient solubility for potentiometric titrations. The experimental determination of their basicity constants is difficult. As such, the available literature on experimental pK_{BH^+} values of acetanolides is scarce. The pK_{BH^+} values of most of the acetanilides used in the present study (Table 1) are experimental values reported in the literature (25,

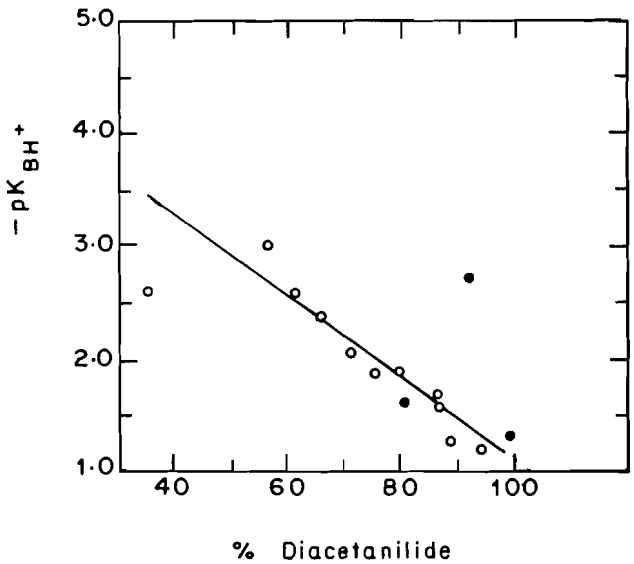

FIG. 2. Variation of % diacetanilide formation with pK_{BH^+} of acetanilide; ○: *meta* and *para*-substituted; ●: *ortho*-substituted acetanilide.

26). For compounds **15**, **16**, and **18** the interim pK_{BH^+} values have been predicted from the regression equation (27) derived from linear correlation of pK_{BH^+} values with Hammett σ-values of substituents. Acetanilides can become either O- or N-protonated in acid media. The known evidence is strongly in favour of predominant O-protonation on the basis of (a) uv spectral changes observed on protonation of the acetanilides (b) the greater electronegativity of the oxygen atom, and (c) resonance stabilization of the O-protonated species by the unshared electron pair on the nitrogen atom (26). Recently, the data obtained from the study of nitrogen proton resonances of primary amides were shown to be consistent with the assumption of N-protonation as the major pathway for proton exchange for primary amides (28).

Our experimental evidence is in favour of higher basicity for the oxygen as compared to the nitrogen, as is clear from the following discussion. A plausible mechanism for the formation of diacetanilides from the monoacetyl derivatives is shown in Scheme 1. While suggesting the mechanism, the following experimental observations have been taken into account, viz.: (a) the *ortho* substituents in acetanilides have facilitated the diacetyl derivative formation, particularly for *ortho* disubstituted acetanilides where quantitative conversions to the diacetanilides have been observed, irrespective of whether the *ortho* substituents are electron withdrawing or electron repelling (Table 1); (b) linear correlations such as those indi-

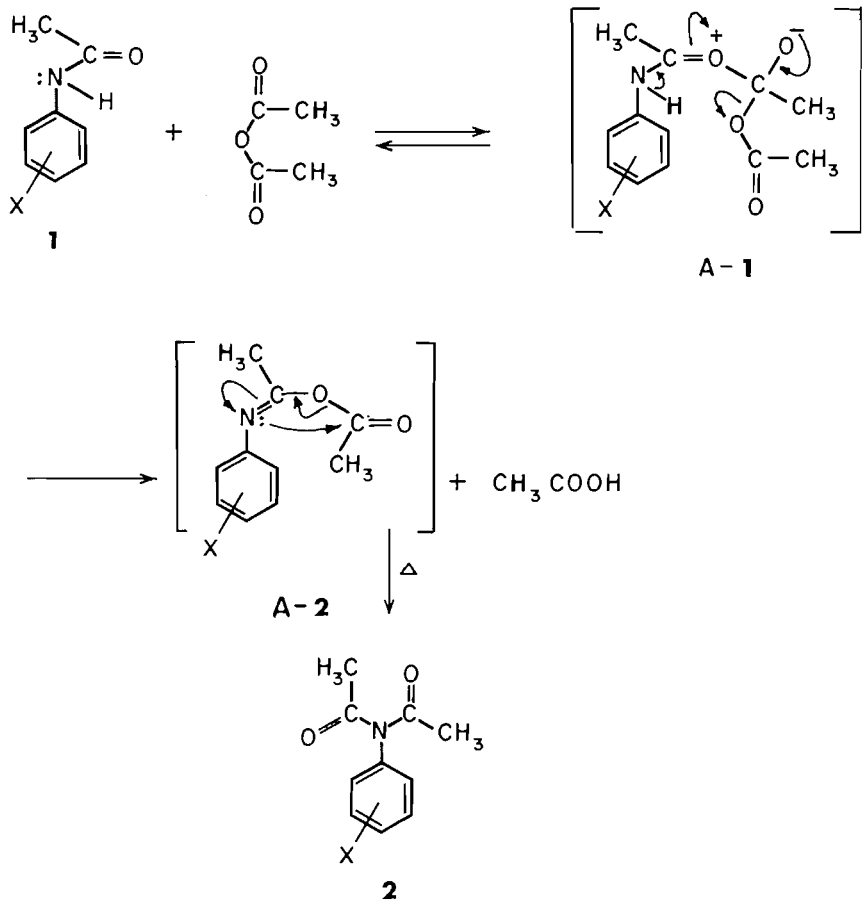

SCHEME 1

cated in Figs. 1 and 2. Hence the initial electrophilic reaction of the carbonyl carbonium ion of acetic anhydride is on the more basic carbonyl oxygen of the acetanilide to form the intermediate complex A-1. The positive charge on the oxygen is then stabilized by the electron drift from the nitrogen atom, forming the intermediate A-2 with the liberation of acetic acid. The formation of the diacetyl derivative then takes place via the acid catalysed rearrangement of the intermediate A-2 at the high temperature of the reaction. Attack on amide nitrogen would not be favoured, since such substituents decrease the basicity of the amide nitrogen either by intramolecular hydrogen bonding or, where this is disrupted by solvent effects, by their strong electron-withdrawing inductive effects. This would result in a lower yield of diacetyl derivative, which is contrary to the experimental results obtained (Table 1). It is apparent that the extent of diacetanilide formation would be governed by the electron density of the nitrogen atom in the intermediate A-2. In analysing the effect of substituents, the comparisons have been made with the unsubstituted acetanilide. The deviations in % yields of substituted diacetanilides from that of the unsubstituted diacetanilide are recorded in Table 2.

Effect of substituents at the meta *and* para *positions*

The substituents at the *meta* and *para* positions would enhance or decrease the basicity of nitrogen by the inductive, hyperconjugation, and resonance effects. The conformational studies of the monoacetanilides (29, 30) as well as our experimental results (Table 2) are in agreement with the above considerations. It may be noted that the *meta* isomer forms a relatively lesser amount of the diacetyl derivative than the *para* isomer, since only the inductive effect comes into play with the *meta* substituent.

TABLE 2. Deviation of % yield of substituted diacetanilides from unsubstituted diacetanilide

Compound no.	Substituent	Deviation* %
2	4-Br	−6.9
3	4-Cl	−11.4
4	3-Cl	−15.9
8	4-NO_2	−51.5
9	3-NO_2	−30.8
11	4-CH_3	+2.1
12	3-CH_3	−0.04
13	2-CH_3	−5.8
15	2-CH_3,5-NO_2	+4.8
16	4-CH_3,3-NO_2	−20.7
17	4-OCH_3	+7.5
18	2-OCH_3,5-NO_2	−25.7

*negative: decrease in yield; positive: increase in yield.

Effect of substituents at the ortho *position*

Due to steric considerations, the —C=N linkage in the intermediate A-2 is no longer in the same plane as the π-electron cloud of the benzene ring for any significant resonance interaction. Hence it is the inductive and steric effects which would predominantly determine the extent of diacetylation. Thus the actual amount of diacetanilide formed by acet-*o*-toluidide is less than that of acetanilide, due to steric hin-

drance (Table 2). However, the presence of alkyl groups at both *ortho* positions has increased the basicity of nitrogen to such an extent that quantitative conversions to the diacetanilides were observed (Table 1). The presence of a nitro group in the *para* position to the methyl group in compound 15 enhances the electron-donating ability of the methyl group, which results in increased diacetanilide formation (Table 2). The surprisingly lowered yield of diacetyl derivative exhibited by 2-methoxy-5-nitro acetanilide suggests that the steric *ortho* effect has taken a secondary place and the major contribution seems to have come from the inductive effect of the *meta* nitro substituent (Fig. 1). Substituents such as nitro and chloro groups exert their electron-withdrawing inductive effects via σ-bonds, localizing the π-electrons of the —C=N linkage on the nitrogen which is no longer in conjugation with the benzene ring. The enhanced nitrogen basicity in such cases has resulted in nearly quantitative conversions to the diacetyl derivatives.

In conclusion, the formation of a monoacetyl derivative may proceed via an arylamine acetate intermediate complex, decomposing to the monoacetyl derivative and acetic acid. The stability of the complex is governed by the substituents present. The diacetylation, which is a subsequent acetylation of the monoacetyl derivative, must involve the more basic amide oxygen as the initial reaction site, forming the amidine intermediate, which rearranges to the diacetanilide. The experimental results, as discussed above, strongly favour O-protonation concepts for acetamides and related substances in acid medium. Furthermore, the tlc/fid method of estimation, described above, serves as a useful quality control test for some commercially important acetyl derivatives such as acetanilide, paracetamol, and phenacetin, which are important drug intermediates. It is quite apparent that the formation of a diacetanilide during the manufacturing process which employs acetylation as a major unit process cannot be overlooked.

Experimental

Melting points were recorded in capillary tubes. Infrared spectra were recorded on a Perkin–Elmer 221 spectrophotometer, proton nmr spectra on a Varian T-60 spectrometer using TMS as internal standard, mass spectra were recorded on a CEC-21-110-B mass spectrometer, and tlc/fid estimations were carried out on an Iatroscan Th-10 tlc/fid analyser (Newman-Howells Assoc. Ltd., U.K.) connected to a two-pen flat-bed type strip chart recorder VP-6621A (National, Japan).

Preparation of monoacetyl derivatives

A mixture of the aniline (100 mmol), pyridine (100 mmol), and acetic anhydride (110 mmol) was stirred and heated in a boiling water bath for 2 h. The monoacetyl derivatives were isolated by drowning in water, filtered, washed well with water, and purified by several recrystallizations, using dilute ethanol as solvent. The acetanilides (**1**) prepared (melting points in parentheses) are as follows. 4-bromo (168°C); 4-chloro (178°C); 3-chloro (72°C); 2-chloro (87°C); 2,6-dichloro (190°C); 2,4,6-trichloro (207°C); 4-nitro (207°C); 3-nitro (155°C); 2-nitro (94°C); 4-methyl (148°C); 3-methyl (65°C); 2-methyl (110°C); 2,6-dimethyl (178°C); 2-methyl,5-nitro (152°C); 4-methyl,3-nitro (144°C); 4-methoxy (132°C); 2-methoxy-5-nitro (178°C); 2,6-diethyl (136°C). Commercial acetanilide was recrystallized twice from boiling water (mp 113°C).

Preparation of diacetyl derivatives

A mixture of the monoacetyl derivative (70 mmol) and acetic anhydride (40 mL) was refluxed for 4 h. Excess acetic anhydride and acetic acid formed in the reaction were removed by distillation at 95°C under reduced pressure. The following work-up procedures were adopted depending upon whether the residue after removal of the solvents is a solid or liquid at room temperature.

(a) *Diacetyl derivative (solid)*

The residual solid is boiled with petroleum ether (bp 40–60°C) (100 mL) for a few minutes and filtered hot. The filtrate is concentrated to 70 mL and allowed to cool. The sparingly soluble monoacetyl derivative crystallized out, and was filtered off. Further concentration of the filtrate yielded the diacetyl derivative in its pure form. The procedure was repeated if traces of the monoacetyl derivative still remained, as judged by tlc.

(b) *Diacetyl derivative (liquid)*

The residual oily liquid was subjected to fractional distillation under reduced pressure when the diacetyl derivatives distilled out as colourless liquids.

The following known diacetanilides were synthesized (their spectral and elemental analysis are in agreement with their constitutions; their purities checked by tlc/fid): (**1**) diacetanilide, mp 36°C (lit. (5) mp 36°C); (**2**) 4-bromo-, mp 74°C (lit. (18) mp 74.5°C); (**3**) 4-chloro, mp 65°C (lit (5) mp 65°C); (**5**) 2-chloro, bp 136°C/5 Torr (lit. (31) bp 136°C/5 Torr); (**7**) 2,4,6-trichloro, mp 81°C (lit. (32) mp 81–82°C); (**8**) 4-nitro, mp 135°C (lit (33) mp 135°C); (**10**) 2-nitro, mp 94°C (lit. (34) mp 94°C); (**11**) 4-methyl, mp 45°C (lit. (34) mp 45°C); (**12**) 3-methyl, bp 165°C/16 Torr (lit. (35) bp 164–168°C/16 Torr); (**13**) 2-methyl, bp 152°C/20 Torr (lit. (19) bp 153°C/20 Torr); (**15**) 2-methyl,5-nitro, mp 81°C (lit. (36) mp 81–83°C); (**16**) 4-methyl,3-nitro, mp 77°C (lit. (37) mp 77–78°C); and (**17**) 4-methoxy, mp 60°C (lit. (35) mp 60°C).

The following new diacetyl derivatives, so far not reported in literature, have been synthesized.

(**4**) 3-Chloro, bp 151–152°C/5 Torr; ir (Nujol): 1720 (C=O), 1585, 1470, 1410, 1360, 1285, 1200, 1090, 1070, 950, and 920 cm^{-1}; ^1H nmr (CCl_4) δ: 2.2 (s, 6H, $COCH_3$) and 6.9–7.6 (m, 4H, Ar-H); ms *m/e*: 211 (M^+), 213, 172, 171, 170 ($M^+ + 1 - CH_2{=}C{=}O$), 169, 129, 128, 127 (base) ($M^+ + 2 - 2$ ($CH_2{=}C{=}O$)), 111, and 99. *Anal.* calcd. for $C_{10}H_{10}ClNO_2$: C 56.7, H 4.7, N 6.6, Cl 16.7; found: C 56.5, H 4.4, N 6.6, Cl 16.5.

(**6**) 2,6-Dichloro, mp 63–64°C; ir (Nujol): 1720 (C=O), 1570, 1450, 1350, 1290, 1235, 1040, 1020, and 950 cm^{-1}; ^1H nmr (CCl_4) δ: 2.3 (s, 6H, $COCH_3$) and 7.1–7.5 (m, 4H, Ar-H); ms *m/e*: 246 (M^+), 244, 205 ($M^+ + 1 - CH_2{=}C{=}O$), 203, 186, 168, 165, 162, 161 (base,) 147, 145, and 135. *Anal.* calcd. for $C_{10}H_9Cl_2NO_2$: C 48.8, H 3.7, N 5.7, Cl 28.8; found: C 49.2, H 3.9, N 6.1, Cl 28.8.

(**9**) 3-Nitro, mp 64°C; ir (Nujol): 1740, 1710, 1540, 1470, 1380, 1360, 1250, 1170, 1095, 1038, and 950 cm^{-1}; ^1H nmr (CCl_4) δ: 2.6 (s, 6H, $COCH_3$) and 7.5–8.4 (m, 4H, Ar-H); ms *m/e*: 222 (M^+), 182, 181 ($M^+ + 1 - CH_2{=}C{=}O$), 180, 165, 164, 163, 139, 138 ($M^+ + 2 - 2$ ($CH_2{=}C{=}O$)) (base), 133, 108, and 92. *Anal.* calcd. for $C_{10}H_{10}N_2O_4$: C 54.0, H 4.5, N 12.6; found: C 53.8, H 4.9, N 12.8.

(**14**) 2,6-Dimethyl, bp 111–112°C/5 Torr; ir (Nujol): 1715 (C=O), 1600, 1475, 1360, 1275, 1180, 1160, 1010, and 942 cm^{-1}; ^1H nmr (CCl_4) δ: 2.1 (s, 6H, CH_3), 2.2 (s, 6H, $COCH_3$), and 7.2 (s, 3H, Ar-H); ms *m/e*: 205 (M^+), 204 (base), 164 ($M^+ + 1 - CH_2{=}C{=}O$), 163, 121 ($M^+ - 2$ ($CH_2{=}C{=}O$)), 120, 106, and 91. *Anal.* calcd. for $C_{12}H_{15}NO_2$: C 70.6, H 7.3, N 6.8; found: C 70.9, H 7.3, N 7.0.

(**18**) 2-Methoxy,5-nitro, mp 109–110°C; ir (Nujol): 1710 (C=O) 1590, 1530, 1495, 1370, 1250, 1210, 1100, 1035, and 970 cm^{-1}; ^1H nmr (CCl_4) δ: 2.2 (s, 6H, $COCH_3$), 2.9 (s, 3H, OCH_3), and 7.0 (s, 3H, Ar-H); ms *m/e*: 252 (M^+), 211 ($M^+ + 1 - CH_2{=}C{=}O$), 210 (base), 169 ($M^+ + 1 - 2$ ($CH_2{=}C{=}O$)), 168, 167, 153, 151, 150, 138, 122, 121, and 91. *Anal.* calcd. for $C_{11}H_{12}N_2O_5$: C 52.3, H 4.8, N 11.1; found: C 52.0, H 4.9, N 11.5.

(**19**) 2,6-Diethyl, mp 47–48°C; ir (Nujol): 1708 (C=O), 1455, 1365, 1280, 1247, 1190, 1018, and 950 cm^{-1}; ^1H nmr (CCl_4) δ: 1.2 (t, 6H, CH_3), 2.2 (s, 6H, $COCH_3$), 2.4 (q, 4H, CH_2), and 7.3 (s, 3H, Ar-H); ms *m/e*: 233 (M^+), 190 ($M^+ - 1 - CH_2{=}C{=}O$), 189 (base), 188, 175, 173, 148 ($M^+ - 1 - 2$ ($CH_2{=}C{=}O$)), 147, 133, 131, 120, 117, and 91. *Anal.* calcd. for $C_{14}H_{19}NO_2$: C 72.1, H 8.1, N 6.5; found: C 72.3, H 8.2, N 6.5.

Diacetylation experiments

The nineteen mono-, di-, and trisubstituted monoacetyl derivatives were diacetylated in cylindrical tubes (6.5 cm × 2.5 cm id,) fitted with reflux condensers and calcium chloride guard tubes through ground glass joints, with an excess of acetic anhydride, at reflux temperature, in a single oil bath, under identical conditions. The oil bath was heated on a hot plate and the heating rate was controlled by a dimmerstat. To 7 mmol of the monoacetyl derivative in each tube was added 4 mL of acetic anhydride. The reaction was carried out under reflux for 4 h. The tubes were cooled to ambient temperature and the contents were diluted to 25 mL with acetone (AR) in standard volumetric flasks.

Thin-layer chromatographic flame ionization detection estimations

The relative amounts of the mono- and diacetyl derivatives in the reaction mixtures were determined by a tlc/fid instrument making use of a thin-layer chromatographic (tlc) procedure with flame ionization detection (fid) of the eluted fractions.

Standard solutions

Approximately 180-200 mg of the pure mono- and diacetyl derivatives were accurately weighed, dissolved, and diluted to 10 mL with acetone (AR) in standard volumetric flasks.

Solvents

A mixture of AR grade chloroform and acetone, in the proportion of 94:6 by volume, was used for development.

Procedure

The samples (diluted reaction mixtures) were spotted in volumes of 1 μL each with a fine microliter syringe on the Chromarods. The Chromarod is a silica rod 0.9 mm in diameter and 150 mm long, having a sintered uniform coating of active adsorbent mixed with glass powder with a mean thickness of 75 μm. The spotted rods were dried at 40°C for 15 min in a thermostatically controlled oven. The rods were then eluted with chloroform–acetone (94:6) in the development tank, over a distance of 10 cm. After the development, the rods were dried in the thermostatically controlled oven at 40°C to dry off the solvents. Quantitative detection of the separated components was obtained by passing the Chromarods through the flame ionizaton detector of the instrument and the chromatograms were recorded. Standard solutions of the pure mono- and diacetyl derivatives were spotted and eluted under identical conditions. The response factors were calculated from the areas under the recorded peaks, which are directly proportional to the concentrations of the corresponding components on the rod from which the estimations were done. The areas were directly read off the chart by measuring the height of the appropriate step on the integral trace. Each estimation was a mean of at least four consecutive spottings and elutions.

Lown and Chen have used a stock solution of concentration 8×10^{-2} *M* for both the quinones. Although daunorubicin hydrochloride is soluble in water, it is somewhat difficult to solubilize it to the extent of 8×10^{-2} *M*. In the case of quinizarin, an equivalent solubility in water is impossible. In the course of our pulse radiolysis (work to be published) and epr studies (1) on quinizarin, we have used the chemical from Aldrich (as have the above authors) as well as from Sigma. A triply recrystallized sample of quinizarin showed a solubility in water of a few micromoles per litre only. The compound is more soluble in hot water, but precipitates again on cooling. It has a rather low solubility even in alcohol and aqueous micellar solutions of different detergents (cetyl trimethyl ammonium bromide, CTAB; triton X-100, TX 100, and sodium lauryl sulphate, SLS), in which similar compounds like juglone, naphthazarin, etc. are found to be much more soluble. For this reason, we had to use a solvent system comprising 5 *M* isopropanol and 1 *M* acetone. Even then the maximum solubility attained was just better than 10^{-4} *M*. A 2-sulphonate derivative of quinizarin was also synthesized to overcome this solubility problem. We could obtain a solubility of ca. 10^{-3} *M* in water. It therefore appears that the authors might have used some isomeric form of quinizarin, which is more soluble in water and which may give rise to a radical equivalent to that obtained from quinizarin on reduction. A few examples of such indirect radical formation methods have been given by Russell and Neugebauer (2). The ir, nmr, and ms analyses of the quinizarin sample used by Lown and Chen will be welcome. Our sample proved to be genuine quinizarin on these analyses.

Lown and Chen report that they recorded their spectra with "free access to atmospheric oxygen". In the course of our pulse radiolysis work (3) involving adriamycin and related compounds and our epr work involving the same compounds, we found that the corresponding semiquinones are very susceptible to the presence of a trace quantity of oxygen. We could not observe an epr signal on irradiation of aerated quinone solutions. The signals in deaerated systems disappeared instantly on opening the epr tubes to air. We can explain this from consideration of the one-electron reduction potential (E_7^1) of the couples, e.g. adriamycin/adriamycin semiquinone (3) and $O_2/O_2^{\cdot -}$ (4), viz., −328 mV and −155 mV respectively, at pH 7. The reaction [1] was seen to go to virtual completion to the right with rate constants of 3.5×10^8 M^{-1} s^{-1} (k_f) and 4.1×10^5 M^{-1} s^{-1} (k_b) respectively.

$$[1] \quad {}^{+}HAdH_2^{\cdot -} + O_2 \underset{k_b}{\overset{k_f}{\rightleftharpoons}} {}^{+}HAdH_2 + O_2^{\cdot -}$$

Following Kalyanaraman *et al.* (5), the half-life of the daunorubicin radicals in aerated solutions can be estimated as ca. <7.5 μs only. Surprisingly, Rao *et al.* (6) have themselves stated, "In contrast, the reduced form of daunorubicin is air sensitive and solutions of it are completely reoxidized extremely rapidly".

The corresponding E_7^1 value for the quinizarin system is around −270 mV in the mixed solvent system used and the reaction [1] goes to the right for this system as well as for quinizarin 2-sulphonate in water. All these semiquinones thus spontaneously reduce O_2 to $O_2^{\cdot -}$ at pH 7.4 and it is, therefore, highly unlikely that they can be observed in epr under the condition of "free access to atmospheric oxygen". At atmospheric pressure and 25°C, there will be ca. 2.65×10^{-4} *M* O_2 present in the system, sufficient to drive reaction [1] to the right. On the other hand, a few quinones having an E_7^1 value close to that of the $O_2/O_2^{\cdot -}$ system (4), such as naphthazarin (E_7^1 = −109 mV (7)) and juglone ($E_7^1 \approx -95$ mV, unpublished data), can be reduced to the corresponding semiquinone by excess reductant in the presence of a trace quantity of oxygen, due to establishment of equilibrium of the type of [1]. This equilibrium is totally shifted to the right in the case of daunorubicin, adriamycin, and quinizarin.

The statement about past work as given by Lown and Chen (their refs. 7, 18, and 19) is slightly erroneous. While an epr spectrum in aqueous solution has been attributed to the daunorubicin semiquinone (8–10), a somewhat different spectrum in 50% aqueous DMSO has been attributed to the daunorubicinone semiquinone (10). The epr spectrum was obtained in aqueous solution by Sinha and Chignell (9) using borohydride as reductant, but in the absence of oxygen, and adding the reductant in 5 small installments over a period of 25 min. We obtained well-resolved epr spectra for most of the semiquinones we studied (1). The semiquinones were generated by different techniques like pulsed irradiation with electrons of an aqueous deaerated solution at appropriate pH and containing excess formate (3, 7), photolysis in the presence of isopropanol, and photolysis in aqueous micellar solutions of CTAB, TX 100, and SLS. We failed, however, to obtain any well-resolved epr signal from adriamycin in aqueous solution, either by any of the above three methods or by borohydride reduction, even at the highest sensitivity of our epr spectrometer (Varian model E9). We obtained a well-resolved electrolytically generated epr signal in DMSO or DMF. In aqueous solution, the epr spectra of other semiquinones including quinizarin(1) and adriamycinone were well resolved. Reduction with borohydride was complicated. A very weak unresolved epr signal was obtained from adriamycin. The uv–visible absorption spectrum of a solution containing

[1] Author to whom correspondence may be addressed.

adriamycin and excess borohydride showed that the spectrum changed with time and not to that of the semiquinone. Kalyanaraman *et al.* (5) also showed a progressive change in the epr spectrum of daunorubicin semiquinone. Since daunorubicin and adriamycin have essentially comparable chemical structure as far as epr is concerned and both have different structural sites in the molecule capable of undergoing reduction, it is quite likely that these two quinones undergo borohydride reduction of a more complex nature.

The spectra shown by Lown and Chen (Figs. 2 and 3) are not very different from our spectra of adriamycin semiquinone in DMSO and quinizarin semiquinone in water (1), respectively. Exact comparison is, however, difficult. The chemical structures of the radicals shown in these figures appear to be incorrect; since the pK_a values of the semiquinone radicals are 2.9 (adriamycin and daunorubicin) (3) and 3.3 (quinizarin), the form of the semiquinones at pH 7.4 will be almost exclusively zwitterionic for the former (3) and anionic for the latter. Also, the strong intramolecular hydrogen bonding in the semiquinone has not been taken into consideration at all. Such H-bonding causes the second —OH to ionize at a pH nearly 11 units higher than that for the first —OH (3, 7). The zwitterionic or anionic structure and the strong intramolecular H-bonding naturally affect the electron density at different positions, and consequently affect the epr spectrum. This raises a further question regarding the authenticity of a computer simulation. It should also be pointed out that any quantitative theoretical analysis is impossible unless these structural features are taken into consideration. The one-electron LCAO–MO calculations shown by Lown and Chen are also bound to be only approximate, and not quantitative as claimed, due to the same reasons.

The statement by Lown and Chen that no deuterium effect was observed for quinizarin semiquinone is questionable. The splitting definitely changes in D_2O for quinizarin and similar hydroxyquinones (1, 11, 12). Adams *et al.* (13) and Vincow and Fraenkel (14) (ref. 23 in Lown's paper) do not support Lown and Chen, since neither paper gives spectra and their reported splittings are different from those given by Lown and Chen.

Lastly, we believe that reduction with excess borohydride does not result in the pure semiquinone alone, but that further reduction takes place, leading probably to other products and to the rupture of the O–sugar ring, thus forming daunorubicinone and adriamycinone semiquinones, responsible for the well-resolved epr spectra hitherto reported in the borohydride reduction of these compounds. This hypothesis was supported earlier by Kalyanaraman *et al.* (5) and, further, by the fact that we obtained a well-resolved spectrum in an aqueous solution of adriamycinone, but not from adriamycin or daunorubicin. This point obviously merits further work in future.

Reply to comments: Electron paramagnetic resonance characterization and conformation of daunorubicin semiquinone intermediate implicated in anthracycline metabolism, cardiotoxicity, and anticancer action

J. W. LOWN
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 25, 1983

For personal use only.

Because of the widespread clinical utility of the anthracyclines in the treatment of human malignancies (1–3) and because of the severe limitations imposed on their use by the cardiotoxicity they display (5, 6), recent work in this area has focused on their mechanism of action and on the molecular origin of the cardiotoxicity. Recent evidence links the latter effect to the in vivo redox behaviour of the anthracyclines in leading, *inter alia*, to lipid peroxidation in cardiac tissue (6–8). An analysis of the structural features in the anthracyclines which control their in vivo redox activity has permitted a twentyfold reduction in cardiotoxicity with no sacrifice in antileukemic efficacy (9). As a result of these investigations, there has been considerable interest in the detection and characterization of the free radicals to which these drugs give rise, including the corresponding semiquinones which are obligatory intermediates in the generation of reactive oxygen species.

While it is much more convenient experimentally to generate, stabilize, and study these semiquinones under nonphysiological conditions as Mukherjee suggests, e.g. by pulse radiolysis or generation in DMSO or isopropyl alcohol and acetone or photolysis in micellar suspensions of CTAB, TX100, or SLS or by electrolysis, these conditions do not relate to the in vivo situation (2–4, 6). For this reason and as described in our paper (10), we were at pains to generate and study anthracycline semiquinones under conditions that more closely correspond to physiological (e.g. in which epr signals are evident from cell cultures treated with anthracyclines (6, 11)). An additional reason for selecting aqueous conditions over an organic solvent was the evident sensitivity of the hyperfine couplings of the semiquinone to medium effects (12). Therefore it was considered that any attempt to deduce stereochemical information from the epr spectrum of the semiquinone (of interest because of its suggested role as a site-specific radical (6)) should deal with the unperturbed species. Therefore we employed dilute aqueous solutions at pH 7.2 in the presence of mild reducing agents. As anticipated, this use of aqueous conditions necessarily required considerable sacrifice in stability of the radicals and made their detection by epr extremely difficult, for example, because of the dielectric loss. The epr spectrum of the daunorubicin semiquinone was in fact obtained, although with considerable difficulty, since, as in the corresponding generation by NADPH–hepatic microsomal system by Sato *et al.* (11), the weak epr signals appeared only after the dissolved oxygen was consumed. Our experimental conditions were therefore very similar to those reported by Kalyanaraman *et al.* (13) for the generation of daunomycinone semiquinone in aqueous solution using borohydride as reductant. Mukherjee is evidently unable to repeat their experiment. In contrast, his statement "On the other hand quinones . . . can be reduced to the corresponding semiquinone by excess of reductant without rigorous exclusion of air" is in fact in accord with the conditions we employed. The extended discussion in the Comment to prove that semiquinones react with oxygen merely emphasizes the obvious. Moreover, we do not claim that "stoichiometric one-electron reduction" is taking place. Since our experiments were not designed to quantify the amounts of radical species or measure rates of reactions, the concentrations of the dilute aqueous solutions were selected so as to give detectable epr spectra. The quinizarin used was pure by spectroscopic criteria using ir, ^{1}H nmr, and ms and gave rise to an epr spectrum closely similar to that reported by Vincow and Fraenkel (14) and others (15) produced by mild reduction in aqueous solutions.

The fact that our aqueous solution conditions give rise to the epr spectrum of daunorubicin semiquinone has been supported recently by Kleyer and Koch (16), who generated it by mild reduction at ca. 10^{-4} *M* and state "The (epr) signal was assigned to the semiquinone of daunomycin based upon the *g*-value and splitting constants which are similar to those determined by Lown and co-workers in aqueous medium. The signal is significantly different from that observed for semiquinone **9** (7-deoxydaunomycinone) in methanol". This is contrary to Mukherjee's speculation on the identity of these species. The fact that the semiquinone of the parent antibiotic may be generated cleanly by these mild reducing conditions, albeit in low concentration, is also confirmed by Kleyer and Koch (16) in that "No additional paramagnetic species were observed". These authors also provide evidence that daunorubicin semiquinone does not eliminate the sugar moiety, contrary to Mukherjee's contention.

We have already dealt with the question of the form of the semiquinones in aqueous solution as it relates to the pK_a values of the phenolic OH groups (p. 3214 of paper) (10). We point out that the pK_a values of the phenolic OH groups anticipated to be in the region of 3 to 4 will result in the semiquinones being in anionic forms (and this implies a zwitterionic form for daunorubicin semiquinone). The good match of the experimental epr spectrum and the computer simulation shown in our Fig. 3 and reported independently by Vincow and Fraenkel (14) is in accord with the view that hyperfine coupling from the exchangeable OH protons is negligible or disappears in the line width, in contrast to the situation when DMSO is used as a solvent (12).

Finally, other workers have documented evidence that treatment of daunorubicin with borohydride does not effect glycosidic cleavage (17), contrary to Mukherjee's speculations.

Kinetic and thermodynamic control of pseudobase formation from C-3 substituted 1-methylquinolinium cations

JOHN W. BUNTING AND NORMAN P. FITZGERALD
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received November 3, 1983

JOHN W. BUNTING and NORMAN P. FITZGERALD. Can. J. Chem. **62**, 1301 (1984).

The kinetic and thermodynamic control of pseudobase formation from 3-W-1-methylquinolinium cations has been studied for a variety of substituents (W). Spectral data indicate that, in both aqueous and methanolic solution, the C-2 pseudobases predominate at equilibrium for W = H and Br, while the C-4 pseudobases are the thermodynamically preferred species for W = $CONH_2$, CO_2CH_3, CN, and NO_2. Stopped-flow studies indicate that in all cases the C-2 pseudobases are the kinetically-controlled products upon basification of the aqueous solutions of these cations. Equilibrium constants (pK_{R+}) have been measured for pseudobase formation at both C-2 and C-4 for each W in all cases where they are experimentally accessible. Substituent effects upon pK^2_{R+} correlate with σ_m for W, while pK^4_{R+} depends upon σ_p^-. These substituent effects allow the prediction of pK^2_{R+} = 15.4 and pK^4_{R+} = 17.4 for the 1-methylquinolinium cation. Rates of C-2 to C-4 pseudobase equilibration have been measured in all cases where the latter species is thermodynamically more stable. These kinetic data allow the evaluation of rate constants for C-4 pseudobase equilibration with each cation. In all cases except W = CN, C-2 pseudobase formation is complete within the mixing time of the stopped-flow instrument.

JOHN W. BUNTING et NORMAN P. FITZGERALD. Can. J. Chem. **62**, 1301 (1984).

On a étudié le contrôle cinétique et thermodynamique de la formation de pseudobases à partir de cations W-3 méthyl-1 quinolinium portant plusieurs substituants W. Les données spectrales indiquent que, tant en solution aqueuse que méthanolique, les pseudobases en C-2 prédominent à l'équilibre lorsque W = H ou Br alors que les pseudobases en C-4 sont les espèces thermodynamiquement préférées lorsque W = $CONH_2$, CO_2CH_3, CN et NO_2. Des études par flux stoppé indiquent que, dans tous les cas, les pseudobases en C-2 sont les produits de contrôle cinétique lorsque les solutions aqueuses de ces cations sont rendues basiques. On a mesuré les constantes d'équilibre (pK_{R+}) pour la formation de pseudobases tant en C-2 qu'en C-4 pour tous les substituants W dans tous les cas où ceci était expérimentalement possible. On a pu établir une corrélation entre les effets des substituants sur les pK^2_{R+} et les σ_m des W; les valeurs de pK^4_{R+} dépendent de σ_p^-. Ces effets de substituants permettent de prédire des valeurs de pK^2_{R+} = 15,4 et pK^4_{R+} = 17,4 pour le cation méthyl-1 quinolinium.

Dans tous les cas où les dernières sont les espèces thermodynamiquement les plus stables, on a mesuré les vitesses d'équilibration des pseudobases C-2 en C-4. Ces données cinétiques permettent d'évaluer les constantes de vitesse pour l'équilibration de chaque pseudobase C-4 avec son cation. Dans tous les cas, excepté lorsque W = CN, la formation de la pseudobase en C-2 est complète en dedans du temps de mélange dans l'appareil à flux stoppé.

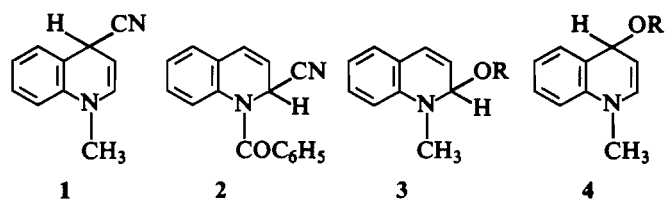
Quinolinium cations are well known to be susceptible to nucleophilic addition at either C-2 or C-4 to give 1,2-dihydro- and 1,4-dihydro-quinolines, respectively (1–4). Thus, whereas cyanide ion addition to the 1-methylquinolinium cation occurs at C-4 to give **1** (5, 6), the Reissert compound **2** is isolated from mixtures of quinoline and benzoyl chloride in the presence of cyanide ion and is presumably formed by addition of cyanide ion at C-2 of the 1-benzoylquinolinium cation (7). For neither **1** nor **2** is it clear whether these are the products of kinetic or thermodynamic control.

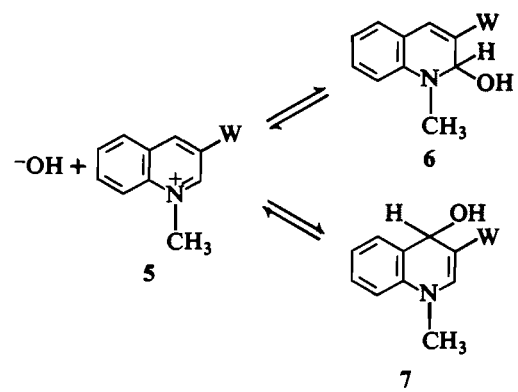
Methoxide ion addition to the 1-methylquinolinium cation in methanol gives the C-2 adduct (**3**: R = CH_3) (8). By analogy to this latter observation, it is generally assumed that pseudobase formation in aqueous solution would give the C-2 adduct



1 **2** **3** **4**

(**3**: R = H) as the thermodynamically most stable pseudobase rather than the isomeric C-4 adduct (**4**: R = H). This assumption is supported by the observation that 2-quinolones are obtained upon oxidation of quinolinium cations in aqueous base (9), although the possibility that this latter observation reflects a kinetic preference in oxidations of the C-2 and C-4 pseudobases rather than the relative thermodynamic stabilities of these pseudobases has never been satisfactorily addressed.

In a kinetic study (10) of hydroxide ion addition to the 1-methyl-3-nitroquinolinium cation (**5**: W = NO_2), it was found that whereas the C-2 pseudobase (**6**: W = NO_2) is the kinetically controlled product, the thermodynamically more stable pseudobase is the C-4 hydroxide adduct (**7**: W = NO_2). If the above assumption that the thermodynamically preferred



5 **6** **7**

pseudobase of the 1-methylquinolinium cation is **3**: R = H is correct, it is then required that the presence of the 3-nitro substituent in this ring system should have a pronounced effect upon the relative thermodynamic stabilities of the 1,2-dihydro- and 1,4-dihydro-quinoline isomers. This in turn raises the question of whether the nitro group is unique in this regard, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

also whether different pseudobases are obtained in kinetically and thermodynamically controlled additions of hydroxide ion (and also in other nucleophilic additions) to other C-3 substituted quinolinium cations. Analogous studies on nucleophilic addition to pyridinium cations have been reported; in this system the preferred products of kinetic and thermodynamic control seem to be quite dependent on both the substituents on the pyridinium ring and also the nature of the attacking nucleophile (11).

We now wish to report a detailed kinetic and equilibrium study of pseudobase formation for a variety of C-3 substituted 1-methylquinolinium cations (**5**) in aqueous solution. It becomes clear that the influence of the nitro substituent upon kinetic and thermodynamic control of pseudobase formation is typical of all C-3 substituents that are electron-withdrawing via a resonance effect ("σ_p^- substituents"). However, linear free energy relationships allow a prediction that the C-2 pseudobase of the 1-methylquinolinium cation is both the kinetically and thermodynamically preferred species.

Experimental

3-Bromoquinoline, 3-quinolinecarbonitrile, and 3-quinolinecarboxylic acid were commercial products (Aldrich Chemical Co.).

3-Quinolinecarboxamide

3-Quinolinecarbonitrile (5.6 g) and Amberlite IRA 400 ion exchange resin (10 g) were refluxed in a mixture of water (35 mL) and acetonitrile (20 mL) for 2 h. After cooling and filtration, the solvent was removed on the rotary evaporator and the amide product was recrystallized from water; mp 190–192°C (lit. (12) mp 193–194°C).

Methyl 3-quinolinecarboxylate

An anhydrous methanolic solution (50 mL) of 3-quinolinecarboxylic acid (1 g) was saturated with dry hydrogen chloride, and kept for 72 h. After neutralization with sodium carbonate, the solid sodium chloride was filtered off and the solvent was removed on the rotary evaporator. The ester product was recrystallized from hexane in 45% yield; mp 70–72°C (lit. (13) mp 73–74°C).

1-Methylquinolinium salts

The appropriate 3-W-quinoline was either stirred with excess methyl bromide in acetone in a Fisher pressure bottle or refluxed with methyl iodide in ethanol. After several recrystallizations from ethanol, these salts were characterized by ^{1}Hmr spectroscopy in D_2O and halide ion titration by the Vollhard method.

Determination of pK_{R+}

Equilibrium pK^E_{R+} values were determined spectrophotometrically by the general method of Albert and Serjeant (14) in aqueous buffers of ionic strength 0.1 at 25°C on the Varian Cary 210 spectrophotometer. Buffer solutions were prepared by addition of hydrochloric acid to aqueous solutions of either K_2HPO_4, $(HOCH_2)_3CNH_2$, $Na_2B_4O_7$ or Na_2CO_3, or from standard solutions of KOH adjusted to ionic strength 0.1 with KCl.

pK_{R+} values of unstable species were similarly measured from instantaneous absorbances after mixing neutral aqueous solutions of the quinolinium cations with appropriate buffers on the Durrum–Gibson stopped-flow spectrophotometer. Reported pK_{R+} values are averages of at least eight different values obtained from solutions buffered in the range pH = $pK_{R+} \pm 1$.

Kinetic studies

All kinetic data were obtained by mixing neutral aqueous solutions of the quinolinium cations with appropriate buffers to give final ionic strength 0.1 in the stopped-flow spectrophotometer at 25°C. Absorbance vs. time curves at an appropriate wavelength were digitized (118 data points), and the data were collected and fitted to first-order rate equations with the Tekronix 4051 minicomputer. Individual rate constants for pseudobase formation (k_f) and decomposition (k_d) were evaluated from the observed pseudo-first-order rate constants for cation–pseudobase equilibration by the standard algebraic methods described previously (10, 15).

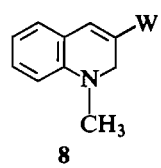
[c] Approximate value due to rapid ester hydrolysis in aqueous base (see text).
[d] For the ethyl ester (19).

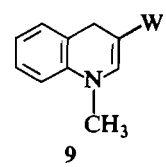
Results

The 3-W-1-methylquinolinium cations **5**: W = Br, $CONH_2$, CO_2CH_3, CN, and NO_2 all display reversible pH-dependent electronic absorption spectra in aqueous solution. The C-3 unsubstituted cation displays a pH-independent electronic absorption spectrum, indicating that within the accessible pH range (pH < 14) there is no significant pseudobase formation. In very basic aqueous solutions this latter cation is known to undergo an irreversible disproportionation reaction (9).

Hydroxide ion attack may occur at either the C-2 or C-4 position of the cations **5** to give the pseudobases **6** or **7** respectively. The longest wavelength absorption maximum in the spectrum of the pseudobase derived from each **5** is indicated in Table 1 along with analogous data for the corresponding methoxide adducts in methanol and the corresponding 3-W-1-methyl-1,2-dihydroquinolines (**8**) and 3-W-1-methyl-1,4-dihydroquinolines (**9**). In all cases the 1,2-dihydroquinoline derivatives (**8**) absorb at significantly longer wavelengths than their 1,4-dihydroquinoline isomers (**9**). None of the pseudobases derived from **5**: W = $CONH_2$, CO_2CH_3, or CN show absorption maxima in the vicinity of 400 nm, as appear in the spectra of the corresponding 1,2-dihydroquinolines (**8**),



8



9

and this effectively rules out the C-2 adducts (**6**) as being the predominant pseudobase species in these cases. In fact, these pseudobases, like the methoxide adducts, absorb at approximately 30 nm shorter wavelength than do the corresponding 1,4-dihydroquinoline derivatives (**9**).

The 3-bromo derivative is the only case in Table 1 for which the C-2 adduct (**6**) can reasonably be proposed as the predominant aqueous pseudobase species. It should be noted that in all cases the absorption maxima for the hydroxide adducts in water are very similar to those for the methoxide adducts in meth-

[c]Slowly exchanges with solvent deuterium without any other spectral change.
[d]OCH_3 signal slowly exchanges with OCD_3.

anolic solution. The methoxide adduct of the parent 1-methylquinolinium cation has been conclusively shown (8) to be **3**: R = CH_3, and the close similarity of the spectral data for W = H and Br in Table 1 confirms the 1,2-dihydroquinoline character for the pseudobase derived from **5**: W = Br.

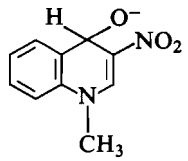
The above structural interpretations of pseudobase structure are further supported by the ^{1}Hmr spectral data for the trideuteriomethoxide adducts of **5** (Table 2). The H(2)—H(3) coupling constant was of particular importance in the unambiguous assignment (8) of the spectrum of the trideuteriomethoxide adduct of **5**: W = H to the C-2 adduct (**3**: R = CD_3). Analogous coupling constant data are not applicable to the C-3 substituted species of the current study; however, all spectra in Table 2 can be assigned by reference to the known **3**: R = CD_3 and suitable related spectra in the literature. The spectrum of the trideuteriomethoxide adduct of **5**: W = Br is almost identical to that of **3**: R = CD_3, lacking only the signal for H(3) at δ 5.66 ppm. In particular, the signal for H(2) slowly disappears due to base-catalyzed exchange of this proton with solvent deuterium, as is also observed for **3**: R = CD_3, and the chemical shifts for the N-methyl protons differ by only 0.04 ppm for W = H and Br. Thus the identity of the trideuteriomethoxide adduct of **5**: W = Br as the C-2 adduct seems secure.

The chemical shifts of the N-methyl protons for W = $CONH_2$, CO_2CH_3, and CN in Table 2 all lie 0.4 ppm downfield of the N-methyl protons for W = H and Br. This observation is particularly significant, because it is firmly established (21) that, independent of the nature of W, the chemical shifts of the N-methyl protons of the 1,4-dihydroquinolines **9** are uniformly 0.3–0.4 ppm downfield of the corresponding signals in the 1,2-dihydroquinolines **8**. Thus this shift implies that the trideuteriomethoxide adducts of **5**: W = $CONH_2$, CO_2CH_3, and CN are the C-4 adducts rather than the C-2 adducts as deduced above for W = H and Br. The remainder of the chemical shift data in Table 2 are not sufficiently distinctive to allow further interpretation. However, this assignment seems secure in the light of the data in Table 1 and the identification of the isomeric C-2 and C-4 hydroxide adducts in the stopped-flow experiments discussed below.

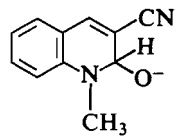
All spectral data for hydroxide and methoxide adducts discussed above refer to stable species that are present in equilibrated basic solutions of the cations **5**. However, rapid mixing of neutral aqueous solutions of these cations with aqueous base in the stopped-flow spectrophotometer allows the observation of an intermediate which is rapidly converted to the stable pseudobase species of Table 1. Since the exact details of the spectral observations on the stopped-flow time scale differ in detail for each W, it is preferable to now discuss each C-3 substituted 1-methylquinolinium cation individually.

5: W = NO_2

In an earlier investigation (10), the C-2 adduct (**6**: W = NO_2; pK^2_{R+} = 9.16) was shown to be formed in times less than the mixing time in the stopped-flow spectrophotometer; however, this species rapidly rearranges to **7**: W = NO_2 as the thermodynamically more stable product (pK^4_{R+} = 6.82). In more basic aqueous solutions, this pseudobase undergoes a deprotonation to generate the corresponding alkoxide ion (**10**) with pK_{RO^-} = 13.0 (8).



10



11

5: W = CN

The pH dependence of the electronic absorption spectrum of this cation indicates the presence of two different acid–base equilibria in aqueous solutions. In dilute base, the species having λ_{max} = 304 nm in Table 1, and identified above as the C-4 pseudobase **7**: W = CN, is in equilibrium with **5**: W = CN, and pK^E_{R+} = 9.02 ± 0.06 has been evaluated. This species in turn is in equilibrium in more basic solutions (pK_a = 13.40 ± 0.05) with a conjugate base having λ_{max} = 388 nm. This bathochromic shift of 84 nm between dilute and concentrated base is far greater than can be rationalized in terms of simple alkoxide ion formation upon deprotonation of **7**: W = CN, and suggests that this pK_a = 13.40 is associated with an extensive electronic reorganization within the molecule. In view of the similarity of the spectrum of this conjugate base to that of the 1,2-dihydroquinolines in Table 1, we suggest that the alkoxide ion (**11**) of the C-2 pseudobase **6**: W = CN is the thermodynamically most stable species in the vicinity of pH 14.

When neutral aqueous solutions of the cation **5**: W = CN are mixed with basic buffer solutions in the stopped-flow spectrophotometer, the absorbance changes at constant wavelength indicate the occurrence of two rapid reactions. This phenomenon is illustrated in Fig. 1 for pH 10.16 at 420 nm, which is a wavelength at which neither **5** nor the equilibrium pseudobase species (**7**) significantly absorbs. The initial rapid reaction generates a species which absorbs relatively strongly at this wavelength, but this species subsequently decomposes in a slower reaction to give the observed equilibrium species. Since we do not have access to a scanning stopped-flow instrument, we have not determined the complete spectrum of this intermediate species; however, repetitive runs at several wavelengths indicate λ_{max} in the vicinity of 400 nm. This observation is consistent with this intermediate being a 3-cyano-1,2-dihydroquinoline derivative (Table 1), and suggests that the C-2 pseudobase (**6**: W = CN) is the kinetically controlled species in these solutions, while the C-4 pseudobase (**7**: W = CN) is the thermodynamically more stable product. This result is exactly analogous to that previously reported for the corresponding 3-nitroquinoline derivative (10). The pH dependence of the maximum absorbance at 420 nm was found to be consistent with a pK_a value of 10.10 ± 0.04, and we assign this as the pK^2_{R+} value for formation of the C-2 pseudobase of **5**: W = CN.

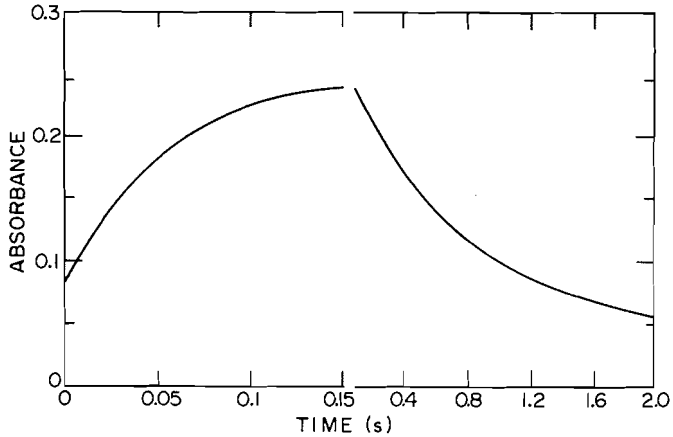


FIG. 1. Time dependence of the absorbance at 420 nm upon mixing a neutral aqueous solution of the 3-cyano-1-methylquinolinium cation with aqueous buffer of pH 10.16.

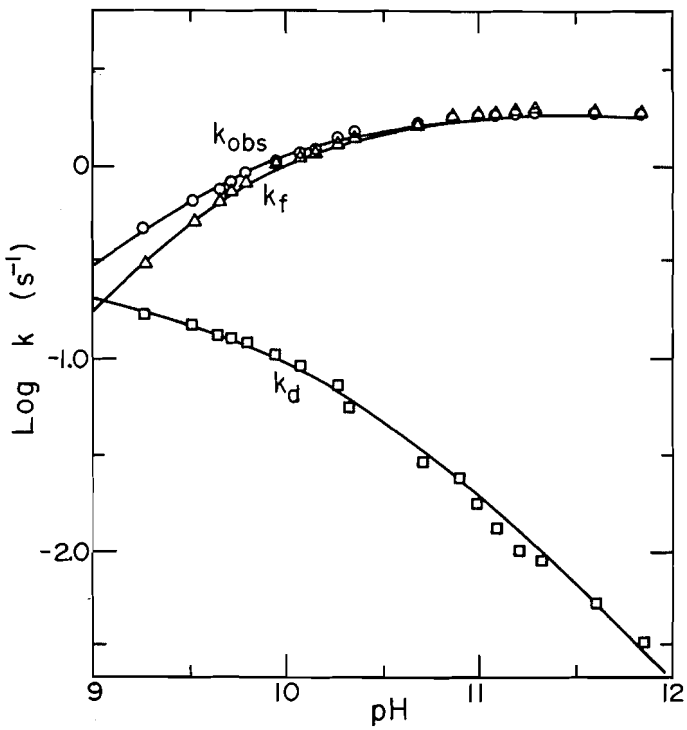

FIG. 2. The pH dependence of k_{obs}, k_f, and k_d for the equilibration of the C-2 and C-4 pseudobases of the 3-cyano-1-methylquinolinium cation.

Both the fast and slow reactions in Fig. 1 proved to be kinetically first order in the quinolinium cation. For the fast reaction, pseudo-first-order rate constants (k_{fast}) were evaluated at a number of pH values in the range pH 10–11. At pH < 10 the absorbance change becomes too small to allow accurate evaluation of these rate constants, while for pH > 11 this reaction becomes too rapid to allow investigation by the stopped-flow technique. These rate constants represent the rate of equilibration of **5** and **6**, and may be used to evaluate the individual forward (k_f for formation of **6**) and reverse (k_d for reversion of **6** to **5**) rate constants in the usual way (15). In this pH range, k_f proved to be linear in [$^-$OH], allowing the second-order rate constant for hydroxide ion attack at C-2 of **5**: W = CN to be evaluated as 7.8 (±0.7) × 10^5 M^{-1} s^{-1}, while k_d = 98 ± 8 s^{-1} was pH independent.

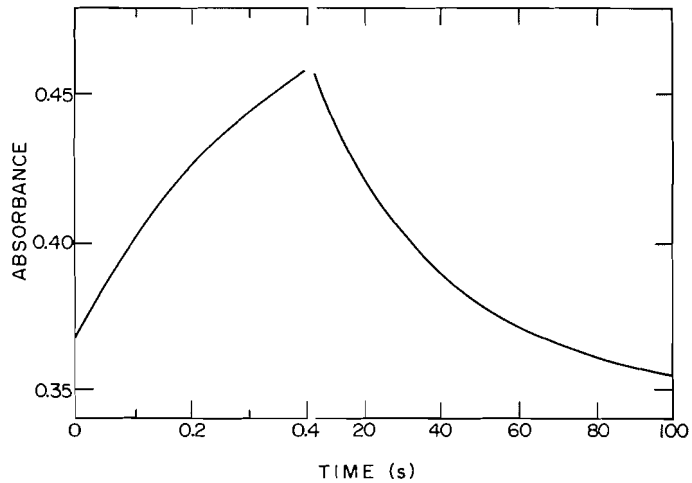

FIG. 3. Time dependence of the absorbance at 315 nm upon mixing a neutral aqueous solution of the 3-methoxycarbonyl-1-methylquinolinium cation with aqueous buffer of pH 10.96.

The pseudo-first-order rate constant (k_{obs}) for the slower reaction involving a decrease in absorbance at 420 nm was evaluated over the range pH 9–12. This pH dependence is displayed in Fig. 2. The individual rate constants for formation (k_f) and decomposition (k_d) of the C-4 pseudobase (**7**) can be calculated from k_{obs} as previously described (10) for the 3-nitroquinolinium cation. The pH profiles for k_f and k_d are also included in Fig. 2, and allow the evaluation of k^4_{OH} = 1.55 (±0.07) × 10^4 M^{-1} s^{-1} for hydroxide ion attack at C-4 of **5**: W = CN and k_2 = 0.16 ± 0.1 s^{-1} for the microscopic reverse of this process.

The greater thermodynamic stability displayed by the C-4 pseudobase over its C-2 isomer for W = CN is consistent with the recent observation of Roberts *et al.* (21) that 3-cyano-1,4-dihydro-1-methylquinoline (**9**: W = CN) has significantly greater thermodynamic stability than its 1,2-dihydro isomer (**8**: W = CN).

5: *W = CO_2CH_3*

This methyl ester is rapidly hydrolyzed in aqueous base and consequently the equilibrium of this quinolinium cation with its pseudobase is not maintained. When neutral aqueous solutions of **5**: W = CO_2CH_3 are mixed with basic buffer solutions (pH > 11.5), a species absorbing in the vicinity of 400 nm is formed within the mixing time of the stopped-flow instrument. Thus in this case the increase in absorbance due to the formation of the C-2 adduct is much faster than that observed for **5**: W = CN (Fig. 1). The pH dependence of the initial absorbance at 420 nm immediately after mixing allows the evaluation of pK^2_{R+} = 12.39 ± 0.03 for C-2 pseudobase formation from this cation.

The subsequent decrease in absorbance at 420 nm consists of a fast phase and a slower phase. This phenomenon is more obvious if this reaction is observed at 315 nm, in which case the fast reaction produces an increase in absorbance while the slower reaction results in a decrease in absorbance (Fig. 3). The pH dependence of the maximum absorbance attained at 315 nm is consistent with a pK_a = 11.25 ± 0.06, and we assign this as the pK^E_{R+} value for formation of the equilibrium pseudobase (predominantly **7**) from **5**: W = CO_2CH_3. This increase in absorbance at 315 nm is kinetically first order in quinolinium cation. Pseudo-first-order rate constants (k_{obs}) were evaluated over the range pH 11–13. The pH dependence of k_{obs} is similar

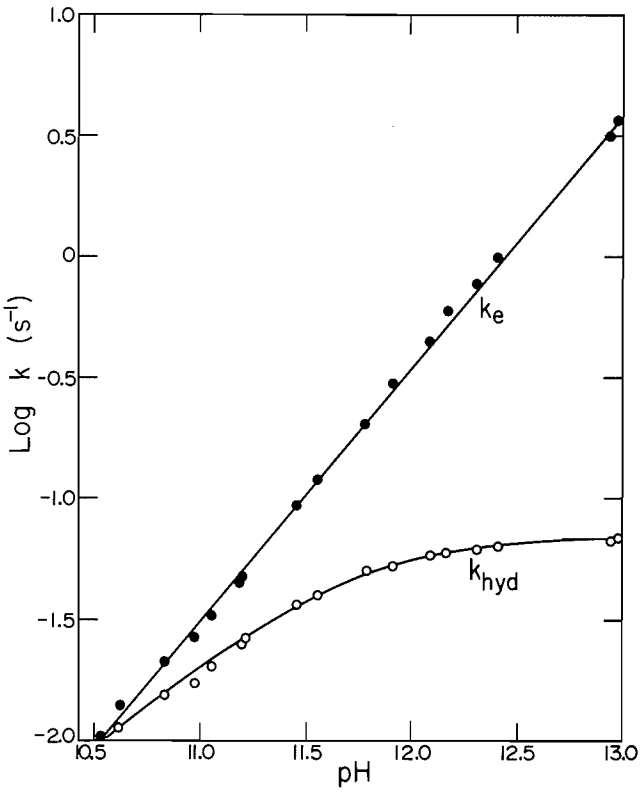

FIG. 4. The pH dependence of k_{hyd} and k_e for **5**: W = CO_2CH_3.

to that shown in Fig. 2, and after separation of k_f and k_d, k^4_{OH} = 1.04 (±0.08) × 10^3 M^{-1} s^{-1} for hydroxide ion attack at C-4 of **5**: W = CO_2CH_3 and k_2 = 1.9 ± 0.1 s^{-1} for pseudobase decomposition to the cation were evaluated.

The slow reaction seen in Fig. 3 is also kinetically first order in total quinoline species present. The pseudo-first-order rate constant (k_{hyd}) for this process was determined over the range pH 10.5–12.5 and is displayed in Fig. 4. As discussed below, we believe this reaction to be the hydrolysis of the methyl ester.

5: W = $CONH_2$

pK^E_{R+} = 12.09 ± 0.03 was calculated for the equilibrated pseudobase species from the pH dependence of the absorbance at 315 nm of basic aqueous solutions of this cation. Further very slow spectral changes were noted to occur in basic solutions containing equilibrated mixtures of the cation and pseudobase; however, this phenomenon was not investigated further.

A species absorbing in the vicinity of 400 nm is formed in basic solutions within the mixing time of the stopped-flow instrument. We assign this as the C-2 pseudobase, and have measured pK^2_{R+} = 12.83 ± 0.03 from the pH dependence of this initial absorbance. This absorbance decreases in a reaction that is kinetically first order in quinolinium cation. Pseudo-first-order rate constants were evaluated over the region pH 12.4–13.5, and allow the calculation of k^4_{OH} = 450 ± 10 M^{-1} s^{-1} and k_2 = 5.5 ± 0.2 s^{-1} for C-4 pseudobase formation and decomposition respectively.

5: W = Br

From equilibrated aqueous solutions of this cation, pK^E_{R+} = 12.34 ± 0.02 was obtained, and is assigned to C-2 pseudobase formation as discussed above. Cation–pseudobase equilibration at every pH is complete within the mixing time of the stopped-flow spectrophotometer, and no transitory species absorbing in the vicinity of 400 nm is apparent.

Discussion

All rate and equilibrium constants obtained for cation–pseudobase equilibration for the quinolinium cations **5** are collected in Table 3. In all cases hydroxide ion attack at C-2 to give **6** is much faster than attack at C-4, and for all W except cyano this C-2 attack is too rapid to allow measurement by stopped-flow methods. This much faster rate of attack at C-2 than at C-4 ensures that the pK_{R+} value measured for the transitory species present immediately upon mixing is a pure pK_{R+} for C-2 pseudobase formation. For all W except bromo this kinetically controlled C-2 pseudobase species is subsequently converted into its thermodynamically more stable C-4 isomer, and in each of these cases the equilibrium pK_{R+} (pK^E_{R+}) is lower than that of the kinetic product. In general, we may define this equilibrium pK_{R+} by:

$$[1] \quad K^E_{R+} = \frac{[H^+]([\mathbf{6}] + [\mathbf{7}])}{[\mathbf{5}]}$$

$$[2] \quad = \frac{[H^+][\mathbf{6}](1 + [\mathbf{7}]/[\mathbf{6}])}{[\mathbf{5}]} = K^2_{R+}(1 + [\mathbf{7}]/[\mathbf{6}])$$

$$[3] \quad = \frac{[H^+][\mathbf{7}](1 + [\mathbf{6}]/[\mathbf{7}])}{[\mathbf{5}]} = K^4_{R+}(1 + [\mathbf{6}]/[\mathbf{7}])$$

Thus the equilibrium ratio of pseudobases ([**7**]/[**6**]) can be evaluated from eq. [2] for W = $CONH_2$, CO_2CH_3, CN, and NO_2, and is included in Table 3. Provided this ratio is much larger than 1, pK^E_{R+} will be equal to pK^4_{R+}; if this is not the case, this ratio can be used to calculate pK^4_{R+} from eq. [3]. Of these four substituents, only in the case of W = $CONH_2$ is this ratio small enough to cause a significant difference between pK^E_{R+} and pK^4_{R+} (Table 3).

The substituent dependences of pK^2_{R+}, pK^4_{R+}, and k^4_{OH} in Table 3 have been considered in terms of various forms of the Hammett σ constants. For pK^2_{R+}, by far the best fit is obtained by making use of *meta* substituent constants (eq. [4]); attempted fits using σ_p (corr. coeff. = 0.948) or σ_p^- (corr. coeff. = 0.860) are much less statistically significant.

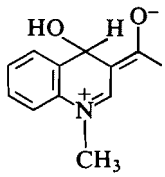
$$[4] \quad pK^2_{R+} = -8.9\ (\pm 0.1)\ \sigma_m + 15.4\ (\pm 0.4) \qquad \text{(corr. coeff. = 0.985)}$$

This dependence of pK^2_{R+} upon σ_m suggests that the electronic interactions of C-3 substituents with the positively charged nitrogen atom are the predominant influences in determining the substituent dependence of pK^2_{R+}.

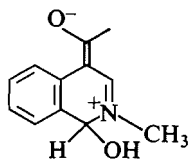
For pK^4_{R+}, the best fit is with σ_p^- (eq. [5]), rather than σ_p (corr. coeff. = 0.990) or σ_m (corr. coeff. = 0.993).

$$[5] \quad pK^4_{R+} = -8.4\ (\pm 0.3)\ \sigma_p^- + 17.4\ (\pm 0.3) \qquad \text{(corr. coeff. = 0.999)}$$

This correlation with σ_p^- can be rationalized in terms of the importance of resonance contributors such as **12** in the stabilization of the enamine unit of these C-4 pseudobases. A close correlation of pK_{R+} with σ_p^- was also found (22) for pseudobase formation from C-4 substituted isoquinolinium cations in which analogous resonance stabilization of the enamine moiety is present (e.g. **13**). Interestingly, the ρ = −8.8 ± 0.4 for pK_{R+} in these latter C-4 substituted isoquinolinium cations is identical within experimental error to ρ = −8.4 ± 0.3 for pK^4_{R+} for these C-3 substituted quinolinium cations.



12



13

Equation [4] allows the prediction of pK^2_{R+} = 15.4 ± 0.4 for the parent 1-methylquinolinium cation, which is somewhat smaller than the value of 16.5 previously predicted (8) from substituent effects upon pK_{R+} for ring substituted 1-cyanoquinolinium cations (23). Equation [5] indicates that pK^4_{R+} for this ion is 17.4 ± 0.3, and so it seems clear that the C-2 pseudobase of the 1-methylquinolinium cation has significantly greater thermodynamic stability than the isomeric C-4 pseudobase. Similarly, eq. [5] predicts the C-4 pseudobase of the 3-bromo derivative to be less stable than the experimentally observed C-2 isomer. These quantitative correlations of substituent effects are entirely consistent with the assigned thermodynamic stabilities made above for various W substituents in **6** and **7** on the basis of spectral considerations.

Equations [4] and [5] allow the prediction of the relative thermodynamic stabilities for any **5** for which the appropriate substituent constants are available. It is clear that, in general, substituents which are strongly electron withdrawing by resonance (σ_p^- substituents) favour formation of the C-4 pseudobase, while weakly electron-withdrawing or electron-releasing substituents will favour the preferential formation of the C-2 pseudobase. Combination of eqs. [2]–[5] gives eq. [6] which allows the prediction of the equilibrium ratio of the C-4 and C-2 pseudobases of **5** for any W for which the appropriate substituent constants are available.

$$[6] \quad \log ([\mathbf{7}]/[\mathbf{6}]) = -8.9\ \sigma_m + 8.4\ \sigma_p^- - 2.0$$

The substituent dependence of k^4_{OH} for hydroxide ion attack at C-4 may be correlated with either σ_m, σ_p, or σ_p^- as shown by eqs. [7], [7*a*], and [7*b*].

$$[7] \quad \log k^4_{OH} = 5.5\ (\pm 0.3)\ \sigma_m + 1.2\ (\pm 0.1) \qquad \text{(corr. coeff. = 0.998)}$$

$$[7a] \quad \log k^4_{OH} = 3.9\ (\pm 0.2)\ \sigma_p^- + 0.2\ (\pm 0.2) \qquad \text{(corr. coeff. = 0.997)}$$

$$[7b] \quad \log k^4_{OH} = 5.8\ (\pm 0.4)\ \sigma_p + 0.5\ (\pm 0.2) \qquad \text{(corr. coeff. = 0.996)}$$

The marginally better correlation with σ_m (eq. [7]) and the lack of a clear preference for σ_p^- indicates that, as expected, resonance stabilization involving W is less important in the transition state for hydroxide ion attack at C-4 than it is in the product (**7**) itself. Combination of eqs. [5] and [7*a*] gives eq. [8].

$$[8] \quad \log k^4_{OH} = -0.46\ pK^4_{R+} + 8.3$$

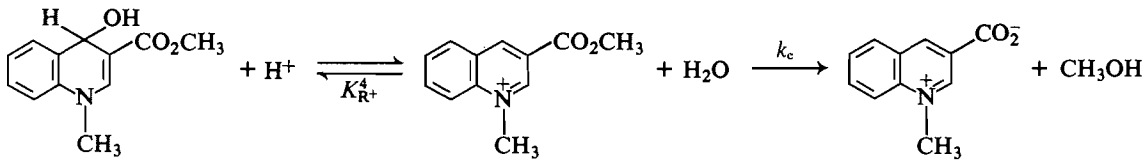
Equation [8] may be compared with eq. [9] deduced previously (24) for C-2 pseudobase formation from a variety of substituted quinolinium cations.

$$[9] \quad \log k^2_{OH} = -0.45\ pK^2_{R+} + 10.0$$

Application of eq. [9] to C-2 pseudobase formation from **5**: W = CN, predicts $k^2_{OH} = 3 \times 10^5\ M^{-1}\ s^{-1}$, which is in reasonable agreement with the experimental value in Table 3 for this reaction. The application of eq. [9] in this case suggests that, in general, steric effects from C-3 substituents are far less important than electronic effects, a result which is also confirmed by the reasonable correlations obtained in eqs. [4]–[7] where steric effects are ignored. Equations [8] and [9] may also be used to predict second-order rate constants of $1000\ M^{-1}\ s^{-1}$ and $2\ M^{-1}\ s^{-1}$ for hydroxide ion attack at C-2 and C-4, respectively, in the parent 1-methylquinolinium cation.

The similar slopes of the linear relationships in eqs. [8] and [9] are consistent with the general observation that Bronsted values for such reactions are usually close to 0.5 (25, 26). These relationships also indicate that, for a quinolinium cation having C-2 and C-4 pseudobases of equal thermodynamic stabilities, the rate of hydroxide ion attack at C-2 will be 50-fold greater than at C-4. This factor of 50 represents the difference in intrinsic reactivities (27) of hydroxide ion at C-2 and C-4 of quinolinium cations. An alternative interpretation of eqs. [8] and [9] suggests that k^4_{OH} will only be greater than k^2_{OH} when pK^4_{R+} is more than 3.8 units smaller than pK^2_{R+}. This pK_{R+} is not approached for any case in Table 3 and, consequently, in all cases the C-2 pseudobase is the kinetically controlled species, even in those cases in which the C-4 pseudobase is of greater thermodynamic stability.

Pseudobase formation by the 10-methylacridinium cation (eq. [10]) is formally analogous to pseudobase formation at C-4 of these 1-methylquinolinium cations. It is therefore of interest



14

SCHEME 1

to test the applicability of eq. [8] to this case. For the 10-methylacridinium cation, $pK_{R+} = 10.01$ (15), and in this case eq. [8] predicts $k_{OH} = 5000\ M^{-1}\ s^{-1}$, which is almost exactly tenfold greater than the experimentally observed value of $550\ M^{-1}\ s^{-1}$ (15).

[10] 
The slow reaction displayed in Fig. 3 can be rationalized as being ester hydrolysis. Since ester hydrolysis in the cation **5**: W = CO_2CH_3 should be much faster than in either of the corresponding pseudobases **6** or **7**, we formulate this hydrolysis as in Scheme 1, which starts from the thermodynamically more stable C-4 pseudobase.

Using this scheme,

$$d[\mathbf{14}]/dt = k_{hyd}([\mathbf{6}] + [\mathbf{5}])$$
$$= k_{hyd}(1 + K^4_{R+}/[H^+])[\mathbf{5}]$$
$$= k_c[\mathbf{5}]$$

Thus,

[11] $$k_c = k_{hyd}(1 + K^4_{R+}/[H^+])$$

Values of k_c calculated in this way from the experimentally determined k_{hyd} are included in Fig. 4, and indicate that log k_c is linear in pH, and of slope 1. This is consistent with k_c representing the base-catalyzed hydrolysis of **5**: W = CO_2CH_3, with the second-order rate constant of $39 \pm 2\ M^{-1}\ s^{-1}$ for this process. This value is in reasonable agreement with $58\ M^{-1}\ s^{-1}$ for the second-order rate constant for the base-catalyzed hydrolysis of the analogous ester **15** derived from nicotinic acid (28), and lends further credence to this analysis.

Deshielding γ−*gauche* effects in ^{13}C magnetic resonance: a comparison of the conformational behaviour of the acetyl group in cyclohexane and 5-substituted-1,3-dioxane systems

G. W. BUCHANAN, S. H. PREUSSER, and V. L. WEBB

Ottawa−Carleton Institute for Research and Graduate Studies in Chemistry, Dept. of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received December 23, 1983

G. W. BUCHANAN, S. H. PREUSSER, and V. L. WEBB. Can. J. Chem. **62**, 1308 (1984).

Low temperature (173 K) ^{13}C spectra of acetylcyclohexane, 1-acetyl-1-methylcyclohexane, and 5-acetyl-5-methyl-1,3-dioxane are reported. Data permit the first direct measurement of $-\Delta G^0$ for the acetyl group bonded to cyclohexane. The value obtained, 1.02 ± 0.05 kcal/mol in $CS_2-CD_2Cl_2$ solution, is considerably lower than that determined by equilibration methods. Factors contributing to observed axial−equatorial carbonyl carbon chemical shift differences for substituted cyclohexanes and 1,3-dioxanes are discussed.

G. W. BUCHANAN, S. H. PREUSSER et V. L. WEBB. Can. J. Chem. **62**, 1308 (1984).

Opérant à basse température (173 K), on a examiné les spectres rmn du ^{13}C de l'acétylcyclohexane, de l'acétyl-1 méthyl-1 cyclohexane et de l'acétyl-5 méthyl-5 dioxanne-1,3. Les données ont permis de faire la première mesure directe du $-\Delta G^0$ du groupe acétyle lié à un cyclohexane. La valeur obtenue, 1,02 ± 0,05 kcal/mol pour une solution dans le $CS_2-CD_2Cl_2$, est considérablement plus faible que celle déterminée par des méthodes d'équilibration. On discute des facteurs contribuant aux différences de déplacements chimiques des carbones des carbonyles axiaux et équatoriaux observées dans les cyclohexanes et dioxannes-1,3 substitués.

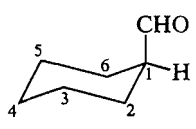
Introduction

Carbon-13 nmr spectroscopy is now a well-established technique in stereochemical analysis (1). In particular, γ-effects (below) have been utilized,

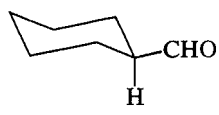
the best known cases being the upfield or shielding γ−*gauche* interactions (1).

Furthermore, the γ-*anti* effect is now well documented and it is clear that one must consider the electronegativity of the atoms (2, 3) involved as well as the degree of substitution (4) on the terminal carbon in assessing the influence of γ−*anti* groups on ^{13}C chemical shifts.

Recently (5) we reported an example in which the axial formyl carbon of cyclohexane carboxaldehyde (A) was *deshielded* relative to its equatorial counterpart in (E) by ca. 1 ppm. This is the first example of a *deshielding* γ−*gauche*



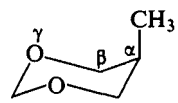
(A)



(E)

effect in a ring system lacking heteroatoms. It was rationalized via the known fact that in the preferred conformation of (A) the formyl proton does not sterically interfere with the *syn*-axial protons on C-3 and C-5 since the C=O tends to eclipse the C_1-C_6 or C_1-C_2 bond.

For heterocyclic systems such as 1,3-dioxanes (6) it is known that an axial 5-CH_3 group, for example, is deshielded relative to its equatorial counterparts, a result attributed to the removal of the *syn*-axial hydrogens from the γ positions (below).



In an attempt to explore the scope and origin of deshielded axial carbonyl carbons we present a comparison of γ−*gauche* effects in some substituted cyclohexane and 1,3-dioxane molecules. ^{13}C spectra of acetylcyclohexane, 1-acetyl-1-methylcyclohexane, and 5-acetyl-5-methyl-1,3-dioxane, recorded at temperatures where ring immersion is slow on the nmr timescale, are reported.

The influence of solvent on chemical shifts and conformational equilibria has been explored and the data permit the first nmr determination of $-\Delta G^0$ for the acetyl group bonded to cyclohexane.

Results and discussion

(a) *Acetylcyclohexanes*

^{13}C chemical shifts for acetylcyclohexane **1** at 293 K in two solvent media and for individual conformers **1***A* and **1***B* at 173 K are presented in Table 1. Resonance assignments at 293 K were made on the basis of off-resonance ^1H decoupling, APT (7) experiments, and well-established trends of acyl group substitution (8). Distinction between resonances for C-3,5 and C-4 was made on the basis of relative intensity measurements in the nOe suppressed spectrum. The present assignments are consistent with earlier data of Pehk and Lippmaa (9) for **1** in Et_2O solution, except for interchange of C-4 and C-3,5 assignments.

At 173 K, in $CS_2-CD_2Cl_2$ solvent, three new resonances, attributed to **1***A*, appear which were not present at 293 or 203 K, each having relative intensity of ca. 5% of the intensity of corresponding carbons for **1***B*. From intensity data, the equilibrium constant for the process below was determined to be 19.4.

TABLE 1. ^{13}C chemical shifts of acetylcyclohexane conformers ($\delta_c \pm 0.01$)

Compound	Solvent	C-1	C-2,6	C-3,5	C-4	C=O	CH_3
1†	$CD_2Cl_2-CS_2$	51.30	28.75	26.10	26.41	209.58	27.50

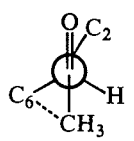
1A ***1B***

Using $-\Delta G^0 = RT \ln K_{eq}$, this translates into a value of 1.02 ± 0.05 kcal/mol for the conformational free energy of the acetyl group. This is, to our knowledge, the first nmr determination of this parameter. Previous results from equilibration measurements (10) yielded a value of 1.52 ± 0.02 kcal/mol for $-\Delta G^0_{COCH_3}$, so that it is clear that the direct determination yields a considerably lower effective "size" for the acetyl group than do equilibration data obtained for MeOH solutions. The acetyl group is, however, somewhat "larger" than the formyl group for which, in these laboratories, both ^{13}C and ^1H nmr (5, 11) give $-\Delta G^0$ values of ca. 0.84 kcal/mol. Another estimate for $-\Delta G^0_{C-H}$ in CD_2Cl_2 solution is 0.96 kcal/mol (12), also from low temperature ^{13}C nmr.

It is interesting to note that the carbonyl carbon of ***1A*** is *shielded* relative to ***1B*** by ca. 0.5 ppm. This is in contrast to results for formylcyclohexane in which the axial carbonyl was deshielded relative to its equatorial counterpart (5).

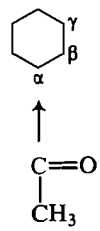
It was argued (5) that the known high preference for a conformation in which the C=O bond eclipses the $C_1 \cdots C_6$ (or $C_1 \cdots C_2$) bond was responsible for the deshielded axial formyl carbon resonance. In the axial acetyl case, however, such a conformation (below) would be considerably less favoured, due to the presence of an additional *gauche* interaction between the acetyl methyl and C_2 or C_6 of the ring.



Unfortunately this argument canot be extended further since at present there are no experimental data available regarding preferred conformations about the $C_1-\overset{O}{\overset{\|}{C}}$ bond of axial acetyl functions bonded to cyclohexane.

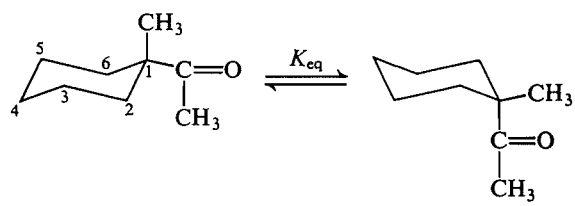
For the toluene-d_8 solution of **1**, the axial carbonyl is again shielded relative to its equatorial counterpart, in this instance by 0.83 ppm. The equilibrium ***1A*** ⇌ ***1B*** appears to be more biased toward ***1B*** in this solvent, giving $-\Delta G^0 = 1.21 \pm 0.05$ kcal/mol as the conformational free energy of the acetyl function.

The upfield "γ" shift in the axial conformer is also apparent in the C-3,5 resonance for ***1A***, which is at $\delta_c = 25.30$ vs. 26.11 for C-3,5 of ***1B***, in $CD_2Cl_2-CS_2$ solvent. Using our shift of 27.27 ppm for cyclohexane at 173 K in $CD_2Cl_2-CS_2$, one can obtain the following α,β, and γ shift parameters for acetyl group substitution:



$\alpha_{eq} = +23.78$, $\beta_{ax} = -0.13$, $\beta_{eq} = +1.22$, $\gamma_{ax} = -1.97$, and $\gamma_{eq} = -1.16$.

Since the conformational equilibrium ***1A*** ⇌ ***1B*** is highly biased, we have included in this work a study of a less biased model compound which will allow one to augment the data re $-\Delta G^0$ for the acetyl group, and the apparent solvent dependence of this parameter. To this end, 1-acetyl-1-methylcyclohexane **2** was prepared and examined by ^{13}C nmr at 173 K. Results are given in Table 2 for the equilibrium ***2A*** ⇌ ***2B*** shown below.



2A ***2B***

Spectral assignments in the CH_3 region at 173 K were greatly aided by the *J*-modulated spin echo or APT (7) method, since methyl resonances are negative while CH_2's are positive under the conditions used (*vide infra*).

It is known that the axial CH_3 group of methylcyclohexane is shielded by ca. 6 ppm relative to its equatorial counterpart (13, 14). An even greater difference is noted for conformer ***2A*** where the $*CH_3-C_1$ resonance appears 9.19 ppm upfield of that present in the more abundant conformer ***2B***, in $CD_2Cl_2-CS_2$ solution. In toluene-d_8 solution the difference is somewhat smaller (7.74 ppm).

Also, in accord with results for ***1A*** and ***1B***, the axial carbonyl function of ***2B*** is again shielded by ca. 0.5 ppm relative

†At 293.0 ± 2.0 K.
‡n.o. ≡ not observable.

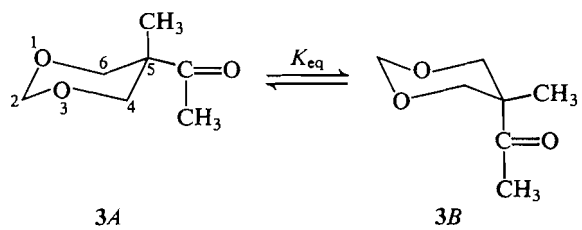
to its counterpart in an equatorial acetyl moiety in **2***A* for both solvent media.

From relative intensities determined in the nOe suppressed spectra, the average value of K_{eq} for the process **2***A* ⇌ **2***B* is 6.9 in CD_2Cl_2–CS_2 solvent and 5.6 in toluene-d_8. Using the currently accepted (14) value of 1.75 ± 0.06 kcal/mol for $-\Delta G^0_{CH_3}$, and assuming additivity, one obtains values of 1.09 ± 0.05 and 1.16 ± 0.05 kcal/mol for $-\Delta G^0_{CCH_3}$ (=O) in CS_2–CD_2Cl_2 and toluene-d_8 solutions respectively. These results are within 0.1 kcal/mol of those determined directly from **1***A* ⇌ **1***B*, indicating that the assumption of additivity of conformational free energies of 1,1-disubstituted cyclohexanes is valid to at least the first approximation for the present materials. In past work there are reports of successful application of additivity assumptions (15) as well as cases where significant deviations from additivity have arisen (16) in 1,1-disubstituted compounds.

(b) *5-Acetyl-5-methyl-1,3-dioxane* **3**

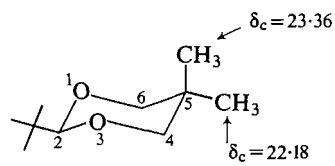
^{13}C chemical shifts for **3** at 293 K in two solvent media and for individual conformers **3***A* and **3***B* at 173 K are listed in Table 3. Room temperature shifts are in accord with those recently reported for **3** in $CDCl_3$ solution (17).



3*A* **3***B*

From previous low temperature ^1H work (17), K_{eq} for the above process was determined to be 8.1 in CS_2 solution at 183 K. ^{13}C spectra at 173 K (nOe suppressed) yield, from relative intensity data, K_{eq} values of 8.3 and 8.9 for CD_2Cl_2–CS_2 and C_7D_8 solutions respectively.

It is of interest to compare the *CH_3—C_5 and the carbonyl shifts of **3***A* and **3***B* with those of **2***A* and **2***B*, since there are no *syn*-axial hydrogens in **3** relative to an axial C-5 substituent. In **3***A* and **3***B*, the axial CH_3 becomes *deshielded* relative to its equatorial counterpart by 1.14 ppm in CD_2Cl_2–CS_2 solution and by 1.59 ppm in C_7D_8. This is in contrast to the highly shielded axial CH_3 observed in **2***A* vs. **2***B*. The present difference in CH_3 shifts in 1,3-dioxanes is very similar to that reported earlier (6) for methyl groups of 2-tert-butyl-5,5-dimethyl-1,3-dioxane (below), in CS_2 solution.



Regarding the carbonyl resonances, the *axial* carbonyl in **3***B* is deshielded by 0.91 ppm relative to its equatorial counterpart in **3***A* for the CD_2Cl_2–CS_2 solution. This appears to reflect the general trend of deshielded axial carbons when potentially *syn*-axial hydrogens are removed from the γ–*gauche* positions.

In the aromatic solvent toluene-d_8, however, this effect is reversed. The axial carbonyl resonance of **3***B* is now *shielded* by 0.40 ppm relative to its equatorial counterpart in **3***A*. This presumably reflects the existence of subtle intermolecular ring current effects of the aromatic solvent on the solute in the preferred collision complex. Thus it is clear that influences of aromatic solvent–solute complex geometry can reverse "normal" stereochemical substituent effects in carbonyl-

For personal use only.

containing solute molecules.

To conclude, we have demonstrated that the conformational free energy of the acetyl group bonded to cyclohexane as determined directly by ^{13}C nmr is substantially lower than that previously determined by equilibration measurements (10). Also the deshielding γ–*gauche* effect on carbonyl carbon resonances appears to be dependent upon several factors, including the conformation about the ring – carbonyl carbon bond and the presence or absence of an aromatic solvent, at least in 1,3-dioxanes.

Experimental

(a) *Materials*

Acetylcyclohexane was obtained from Fluka A. G. and distilled before use. Synthesis of 5-acetyl-5-methyl-1,3-dioxane was performed according to procedures described in the literature (18, 19). Preparation of 1-acetyl-1-methylcyclohexane also followed published methods (20).

(b) *Spectra*

The ^{13}C nmr spectra were obtained at 50.3 MHz using a Varian XL-200 spectrometer. Sample concentrations were 1.0 *M* in 1:1 CD_2Cl_2–CS_2 or in C_7D_8 containing 5% TMS in 10-mm o.d. tubes. For the nOe suppressed spectra, the ^1H decoupler was gated off during the delay between observed pulses. Other conditions were as follows: sweep width = 12 000 Hz, number of data points = 32 000, acquisition time = 1.3 s, pulse width = 7.0 μs (45°), and repetition rate = 3.0 s. Typically, 1000 accumulations were required for the 173 K spectra. For the *J*-modulated spin echo (APT) (7) experiments, D2 was set at 7.0×10^{-3} s.

Nuclear magnetic resonance studies of the acid–base chemistry of amino acids and peptides. IV. Mixed disulfides of cysteine, penicillamine, and glutathione

YVON THERIAULT, BRUCE V. CHEESMAN, ALAN P. ARNOLD, AND DALLAS L. RABENSTEIN[1]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received December 13, 1983

YVON THERIAULT, BRUCE V. CHEESMAN, ALAN P. ARNOLD, and DALLAS L. RABENSTEIN. Can. J. Chem. **62**, 1312 (1984).

The acid–base chemistry of the ammonium groups of penicillamine–glutathione mixed disulfide and cysteine–glutathione mixed disulfide has been characterized by ^{13}C nmr and that for the ammonium groups of penicillamine–cysteine mixed disulfide by ^{1}H nmr. The mixed disulfides were formed by thiol/disulfide exchange. Chemical shift titration data were obtained simultaneously for the mixed disulfides, the thiols, and the symmetrical disulfides in the mixture. Since the fractional titration of individual ammonium groups can be obtained directly from chemical shift data, it was not necessary to isolate the mixed disulfides. The chemical shift data indicate that the two ammonium groups of each of the mixed disulfides are titrated over the same pH range, with the acidity of the ammonium group of the penicillamine and cysteine parts of the penicillamine–glutathione and cysteine–glutathione mixed disulfides 4.4 and 3.9 times as acidic as those of the glutathione part. In the penicillamine–cysteine mixed disulfide, the penicillamine ammonium group is 1.7 times as acidic as that of the cysteine part. Macroscopic and microscopic acid dissociation constants are reported for each of the mixed disulfides. The advantages of nmr as a method for characterizing the acid–base chemistry of mixed disulfides are discussed.

YVON THERIAULT, BRUCE V. CHEESMAN, ALAN P. ARNOLD et DALLAS L. RABENSTEIN. Can. J. Chem. **62**, 1312 (1984).

On a caractérisé la chimie acide–base des groupes ammonium des disulfures mixtes pénicillamine–glutathion et cystéine–glutathion en faisant appel à la rmn du ^{13}C et celle des groupes ammonium du disulfure mixte pénicillamine–cystéine par la rmn du ^{1}H. Les disulfures mixtes ont été obtenus via un échange thiol/disulfure. On a obtenu simultanément les données de titrage du déplacement chimique pour les disulfures mixtes, les thiols et les disulfures symétriques du mélange. Il n'est pas nécessaire d'isoler les disulfures mixtes puisqu'on peut obtenir directement le titrage fractionnel des groupes ammonium individuels à partir des données de déplacement chimique. Ces données indiquent que les deux groupes ammonium de chaque disulfure sont titrés dans le même domaine de pH. Les acidités des groupes ammonium des portions pénicillamine et cystéine des disulfures mixtes pénicillamine–glutathion et cystéine–glutathion sont respectivement 4,4 et 3,9 fois plus élevées que celle de la partie glutathion. Dans le disulfure mixte pénicillamine–cystéine l'acidité du groupe ammonium de la pénicillamine est de 1,7 fois plus élevée que celle de la cystéine. On rapporte les constantes macroscopique et microscopique de dissociation acide pour chaque disulfure mixte. On discute des avantages de la rmn en tant que méthode de caractérisation de la chimie acide–base des disulfures mixtes.

Introduction

Thiols are oxidized by disulfides in two steps:

[1] $RSH + R'SSR' \rightleftarrows RSSR' + R'SH$

[2] $RSH + RSSR' \rightleftarrows RSSR + R'SH$

Oxidation of RSH to RSSR occurs via the stable mixed disulfide RSSR'. Oxidation of thiols by disulfides is important in the biological chemistry of thiols (1, 2), and numerous mixed disulfides have been identified in biological systems, including cysteine–homocysteine mixed disulfide in human plasma (3–5), cysteine–penicillamine mixed disulfide in human urine (6), cysteine–glutathione mixed disulfide in liver homogenate (7) and calf lens (8), and glutathione – coenzyme A mixed disulfide in rat (9) and bovine (10) liver.

Although the acid–base chemistry of many thiols and disulfides has been characterized, there are no reports on the acid–base chemistry of mixed disulfides. Their acid–base chemistry is of interest because the kinetics and equilibria of the thiol/disulfide exchange reactions described by eqs. [1] and [2] depend on the protonation states of the species involved. As part of a study of the kinetics and equilibria of thiol/disulfide exchange reactions of biological molecules, we have characterized the acid–base chemistry of penicillamine–glutathione mixed disulfide (PSSG, **1**), cysteine–glutathione mixed disulfide (CSSG, **2**), and penicillamine–cysteine mixed disulfide (PSSC, **3**).

[1] Author to whom correspondence should be addressed.

The acid–base chemistry of **1**–**3** was characterized by using the pH dependence of the chemical shifts of selected resonances in their ^{1}H or ^{13}C nuclear magnetic resonance (nmr) spectra. Since chemical shifts give directly the fractional protonation of the various acidic groups (11), it is not necessary that the solution being titrated contain pure mixed disulfide. Nuclear magnetic resonance spectra were obtained for **1**–**3** in mixtures prepared by reacting the appropriate thiols and disulfides. In this way, chemical shift titration data were obtained simultaneously for the thiols and symmetrical disulfides as well as for the mixed disulfides.

Experimental

D-Penicillamine, glutathione, glutathione disulfide, and D,L-cysteine were obtained from Sigma Chemical Co., D,L-cystine from ICN Pharmaceuticals, and D-penicillamine disulfide from Aldrich Chemical Co. The thiols and disulfides were used as received.

The pH measurements were made at 25°C with a Fisher Accumet pH meter equipped with a standard glass electrode and a fiber-tipped, saturated calomel reference electrode. The pH meter was calibrated with standard solutions having nominal pH values of 4.00, 7.00, and 10.00 at 25°C. The exact pH value of each standard solution was established, and periodically checked, by comparison with freshly prepared NBS pH standard solutions.

The ^{1}H nmr spectra were measured at 200 MHz and 25°C on a Bruker WH-200 nmr spectrometer operating in the pulse/Fourier transform mode. All nmr spectra were obtained on aqueous solutions. To avoid the dynamic range problem, the water resonance was reduced in intensity by saturation with a decoupler pulse applied at the water resonance frequency for 2 s prior to the observation pulse (12).

The spectrometer was run in the unlocked mode since the magnet shows no detectable drift over the time required to obtain a spectrum. The ^1H chemical shifts were measured relative to the methyl resonance of *tert*-butanol (TBA), which was added to the solution at a concentration of ~0.01 *M*. The chemical shifts are reported relative to the methyl resonance of sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS); the resonance for TBA is 1.2397 ppm to high frequency from that of DSS.

The ^{13}C nmr spectra were measured at 90.56 MHz on a Bruker WM-360 nmr spectrometer operating in the pulse/Fourier transform mode. For ^{13}C measurements on **1**, the solvent was doubly distilled H_2O; for ^{13}C measurements on **2**, the solvent was a mixture of 10% D_2O/90% H_2O. The sample temperature was maintained at 25°C by collecting free induction decays under conditions of inverse gated decoupling (nOe suppressed) to minimize heating of the sample and by blowing chilled air over the sample tube in the probe. The ^{13}C chemical shifts were measured relative to internal dioxane, but are reported relative to tetramethylsilane (TMS). The resonance for dioxane is at 67.40 ppm to high frequency from TMS.

Solutions were prepared in water which had been purified by distilling it twice and then passing it through a Barnstead D8902 Ultrapure mixed bed ion-exchange resin. KCl (0.4 *M*) was added for ionic strength control. The solvent mixture was deoxygenated by bubbling with argon or nitrogen before the addition of thiol to minimize oxidation by dissolved oxygen. The appropriate thiol/disulfide pair was then added and allowed to react according to eqs. [1] and [2] to form the desired mixed disulfide. The thiol was added in four portions, the pH adjusted to near 8, and the solution allowed to react for 13 to 24 h after each addition. The solution was bubbled with oxygen between additions to oxidize the thiols to disulfides. This procedure resulted in more mixed disulfide than is present at equilibrium in a solution prepared from the same total amounts of thiol and disulfide. The total concentrations of penicillamine (PSH) and glutathione disulfide (GSSG) added in the preparation of PSSG were 0.20 *M* and 0.078 *M* respectively. In the preparation of CSSG, the total added concentrations were 0.21 *M* and 0.078 *M* for cysteine (Cys) and GSSG. For PSSC, the added concentrations of PSH and CSSC were 0.03 *M* and 0.09 *M*. Insoluble CSSC was removed by filtration from solutions of CSSG and PSSC.[2]

Samples for nmr measurement were prepared by adjusting the pH of the final solutions to the low pH end of the pH range of interest with concentrated acid, and then withdrawing samples at closely spaced pH intervals as the pH was increased by the addition of concentrated base.

Acid dissociation constants were evaluated from the chemical shift data as mixed activity–concentration constants (activity of hydrogen ion[3] – concentration of acid and its conjugate base). The weighted nonlinear least-squares curve fitting program KINET (14) was used to evaluate the macroscopic acid dissociation constants from the chemical shift data.

Results

Penicillamine–glutathione mixed disulfide

Spectrum C in Fig. 1 is the ^{13}C nmr spectrum of the solution prepared by reacting PSH with GSSG.[4] Also shown in Fig. 1 are ^{13}C spectra for PSH, PSSP, GSH, and GSSG at the same pH. Resonance 0 is for dioxane; resonances 1–4 are for the C_α, C_β, CH_3, and CH_3 carbons respectively of PSH; resonances 5–8 are for the same carbons of PSSP; resonances 19–24 are for the Cys-C_α, Glu-C_α, Gly-C_α, Glu-C_γ, Glu-C_β, and Cys-C_β carbons of GSH; and resonances 25–30 are for the Glu-C_α, Cys-C_α, Gly-C_α, Cys-C_β, Glu-C_γ, and Glu-C_β carbons of GSSG. The extra resonances (9–18) in spectrum C are for PSSG. Resonances 9–12, 14, and 16 were assigned to specific carbons of PSSG on the basis of their chemical shifts and the changes in their chemical shifts when the ammonium groups were titrated. The resonances at 55.18, 44.29, 32.39, and 27.12 ppm were assigned to the Glu-C_α, Gly-C_α, Glu-C_γ, and Glu-C_β carbons, respectively, of all three species (GSH, GSSG, and PSSG) on the basis of (*i*) the chemical shifts observed for GSH and GSSG alone, (*ii*) the expected similarity of the chemical shifts of these carbons in all three species, since they are far removed from the thiol or disulfide groups, and (*iii*) the intensities of the resonances.

To characterize the acid–base chemistry of the ammonium groups of PSSG, ^{13}C spectra were measured as a function of pH over the pH range 4–12 for the solution used to obtain spec-

[2] CSSC has a solubility of 2.8×10^{-4} *M* at pH 6.95 and 25°C (13).

[3] Activity of hydrogen ion as approximated by $10^{-(\text{pH meter reading})}$.

[4] The carbonyl region is not shown in Fig. 1.

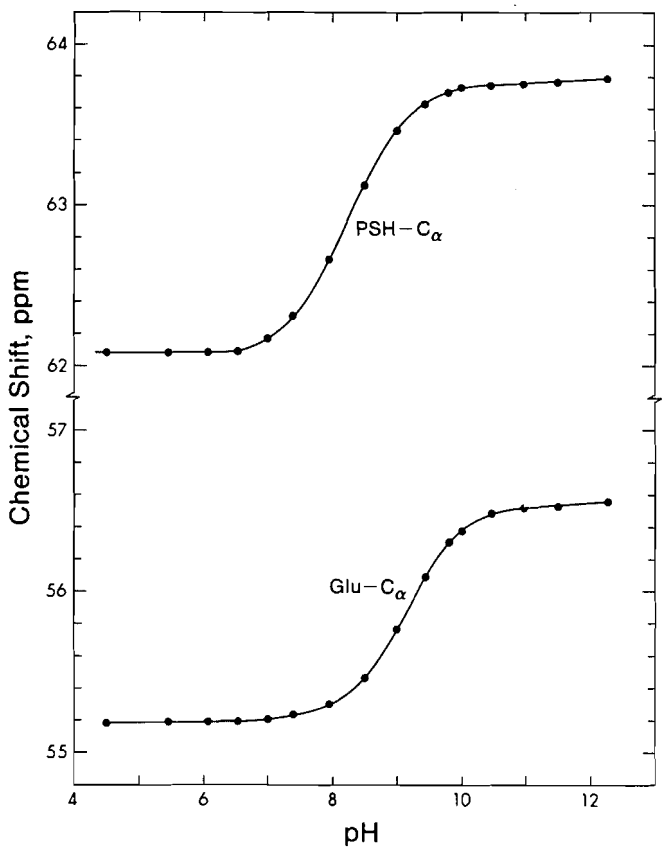

FIG. 2. pH dependence of the chemical shifts of the penicillamine and glutamyl α carbons of PSSG.

trum C. Chemical shift titration data for the PSH-C_α and Glu-C_α carbons of PSSG are presented in Fig. 2. Because there are 11 bonds separating the PSH-C_α carbon from the glutamyl ammonium group in PSSG, changes in the chemical shift of the PSH-C_α resonance can be assumed to be due only to changes in the protonation state of the penicillamine ammonium group (15). Likewise, changes in the chemical shift of the resonance for the Glu-C_α carbon can be assumed to be due only to changes in the protonation rate of the glutamyl ammonium group. Thus, the chemical shift data in Fig. 2 indicate that the two ammonium groups of PSSG are titrated over the same pH range, as described by the titration scheme for PSSG in Fig. 3.

At low pH, PSSG has 5 titratable protons. As the pH is increased, the three carboxylic acid groups are titrated first; K_1–K_3 are the macroscopic acid dissociation constants for their titration. Then, over the pH range studied in this work, the two ammonium groups are titrated; k_{1234}, k_{1235}, k_{12345}, and k_{12354} are the microscopic constants for their dissociation. The specific species to which a given microconstant refers is indicated by its subscript; the last number in the subscript denotes the group dissociating in that step, while the preceding numbers denote groups titrated in preceding steps. The three carboxylic acid groups are labelled 1–3, and the PSH and Glu ammonium groups are labelled 4 and 5 respectively. The microconstants for the ammonium groups are related to the macroconstants K_4 and K_5:

$$[3] \quad K_4 = k_{1234} + k_{1235}$$

$$[4] \quad K_5 = \frac{k_{12345}k_{12354}}{k_{12345} + k_{12354}}$$

Both the macroconstants and the microconstants for the ammonium groups were evaluated from the chemical shift data in Fig. 2. First, the macroconstants were evaluated by the procedure described previously (11). In this procedure, the fractional titration of each of the two ammonium groups is calculated from the chemical shift data using eq. [5].

$$[5] \quad f_d = \frac{\delta_{obs} - \delta_p}{\delta_d - \delta_p}$$

where f_d is the fractional deprotonation, δ_{obs} the observed chemical shift at the particular pH, and δ_p and δ_d the chemical shifts at low and high pH where the ammonium groups are completely protonated and deprotonated, respectively. The fractional deprotonation curves for groups 4 and 5 are shown in Fig. 4. The average number of titratable ammonium protons per molecule, $\bar{p}$, is then calculated as a function of pH from the fractional titration data.

$$[6] \quad \bar{p} = 2 - f_{4,d} - f_{5,d}$$

where $f_{4,d}$ and $f_{5,d}$ represent the fractional deprotonation of groups 4 and 5. The $\bar{p}$ values vs. pH data are also shown in Fig. 4.

In terms of the protonated species in the macroscopic titration sequence, $\bar{p}$ is given by

$$[7] \quad \bar{p} = \frac{2[H_2A] + [HA]}{[H_2A] + [HA] + [A]}$$

which leads to

$$[8] \quad \bar{p} = \frac{2a_H^2 + K_4a_H}{a_H^2 + a_HK_4 + K_4K_5}$$

Values were obtained for K_4 and K_5 by curve fitting the $\bar{p}$ vs. pH data in Fig. 4 to eq. [8]. The results are given in Table 1. The solid curve through the $\bar{p}$ vs. pH data in Fig. 4 is the theoretical curve predicted by eq. [8] for the values listed in Table 1 for K_4 and K_5.

Microconstants were calculated from the macroconstants by calculating with eq. [9] the ratio of the concentrations of species **2** and **3** (Fig. 3), which is equal to the ratios k_{1234}/k_{1235} and k_{12354}/k_{12345}

$$[9] \quad \frac{[\mathbf{2}]}{[\mathbf{3}]} = \frac{f_{4,d} - \alpha_2}{f_{5,d} - \alpha_2}$$

where α_2 is the fractional concentration of species **4**. α_2 was calculated from the macroconstants using eq. [10].

$$[10] \quad \alpha_2 = \frac{K_4K_5}{a_H^2 + a_HK_4 + K_4K_5}$$

The average value obtained for the ratio from data at 8 pH values is 4.38 with a standard deviation of 0.53. The microconstants listed in Table 1 for PSSG were calculated from this ratio and the macroconstants using eqs. [3] and [4].

Macroconstants for the ammonium and thiol groups of GSH and PSH and the two ammonium groups of GSSG and PSSP were also calculated from ^{13}C chemical shift data obtained simultaneously with that for PSSG. The results are given in Table 1. Microconstants for GSSG and PSSP were calculated directly from the macroconstants since the two ammonium groups in each molecule are identical. The microconstants listed for the ammonium groups of PSH and GSH were taken from the literature.

TABLE 1. Macroscopic and microscopic acid dissociation constants for thiols, symmetrical disulfides, and mixed disulfides[a,b,c]

Molecule	Acid group	Acid dissociation constant	pK	Molecule	Acid group	Acid dissociation constant	pK
Penicillamine–glutathione mixed disulfide	$NH_3^+ + NH_3^+$	K_4[d]	8.13 ± 0.02	Glutathione	$NH_3^+ + SH$	K_3	8.67 ± 0.03
	$NH_3^+ + NH_3^+$	K_5[d]	9.24 ± 0.01		$NH_3^+ + SH$	K_4	9.44 ± 0.03
	NH_3^+ (PS)[e]	k_{1234}[f]	8.22 ± 0.06		NH_3^+	k_{124}[h]	9.14[h]
	NH_3^+ (GS)[e]	k_{1235}[f]	8.66 ± 0.06	Penicillamine	$NH_3^+ + SH$	K_2	8.04 ± 0.04
	NH_3^+ (GS)	k_{12345}[f]	9.15 ± 0.06		$NH_3^+ + SH$	K_3	10.64 ± 0.03
	NH_3^+ (PS)	k_{12354}[f]	8.51 ± 0.06		NH_3^+	k_{12}[i]	8.7[j]
Cysteine–glutathione mixed disulfide	$NH_3^+ + NH_3^+$	K_4	8.55 ± 0.02	Cysteine	NH_3^+	k_{12}[i]	8.86[k]
	$NH_3^+ + NH_3^+$	K_5	9.30 ± 0.02	Glutathione disulfide	$NH_3^+ + NH_3^+$	K_5	8.73 ± 0.05
	NH_3^+ (CS)[e]	k_{1234}[f]	8.61 ± 0.04		$NH_3^+ + NH_3^+$	K_6	9.49 ± 0.04
	NH_3^+ (GS)	k_{1235}[f]	9.19 ± 0.04		NH_3^+	k_{12345}[l]	9.03 ± 0.05
	NH_3^+ (GS)	k_{12345}[f]	9.23 ± 0.04		NH_3^+	k_{123456}[l]	9.19 ± 0.04
	NH_3^+ (CS)	k_{12354}[f]	8.65 ± 0.04	Penicillamine disulfide	$NH_3^+ + NH_3^+$	K_3	7.76 ± 0.02
Penicillamine–cysteine mixed disulfide	$NH_3^+ + NH_3^+$	K_3	8.04 ± 0.01		$NH_3^+ + NH_3^+$	K_4	8.71 ± 0.02
	$NH_3^+ + NH_3^+$	K_4	8.93 ± 0.01		NH_3^+	k_{123}[m]	8.06 ± 0.02
	NH_3^+ (PS)[e]	k_{123}[g]	8.24 ± 0.02		NH_3^+	k_{1234}[m]	8.41 ± 0.02
	NH_3^+ (CS)	k_{124}[g]	8.47 ± 0.02	Cysteine disulfide (cystine)	$NH_3^+ + NH_3^+$	K_3	7.95[n]
	NH_3^+ (CS)	k_{1234}[g]	8.73 ± 0.02		$NH_3^+ + NH_3^+$	K_4	8.95[n]
	NH_3^+ (PS)	k_{1243}[g]	8.50 + 0.02		NH_3^+	k_{123}[m]	8.25
					NH_3^+	k_{1234}[m]	8.65

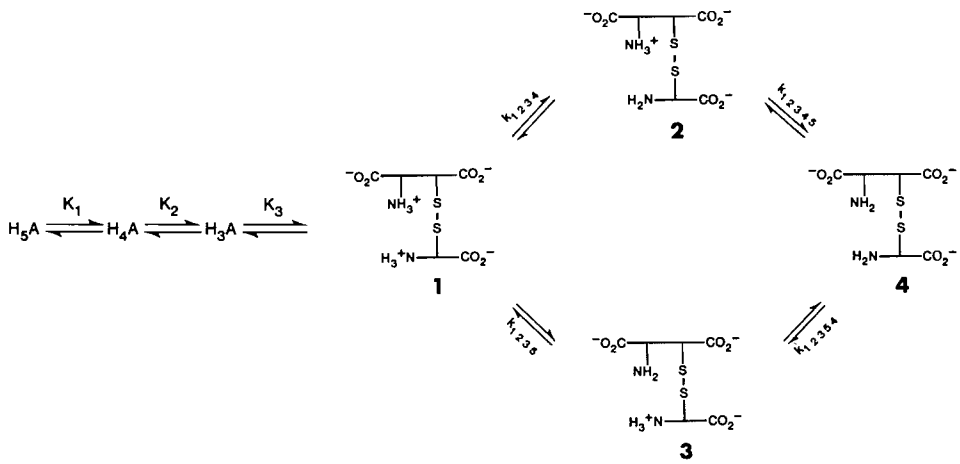

FIG. 3. The microscopic acid dissociation scheme for the ammonium groups of PSSG and CSSG.

Cysteine–glutathione mixed disulfide

The ^{13}C nmr spectra were obtained as a function of pH for the final solution of CSSG prepared by reacting CSH with GSSG. Macroscopic and microscopic constants for the two ammonium groups of CSSG were evaluated from the pH dependence of the chemical shifts of the resonances for the Glu-C_α and Cys-C_α (CS part) carbons using the procedures described above. The results are given in Table 1. The fractional titration and $\bar{p}$ data are presented in Fig. 5. The value obtained for the ratio [**2**]/[**3**] (eq. [9]) from data at 9 pH values was 3.89 ± 0.31.

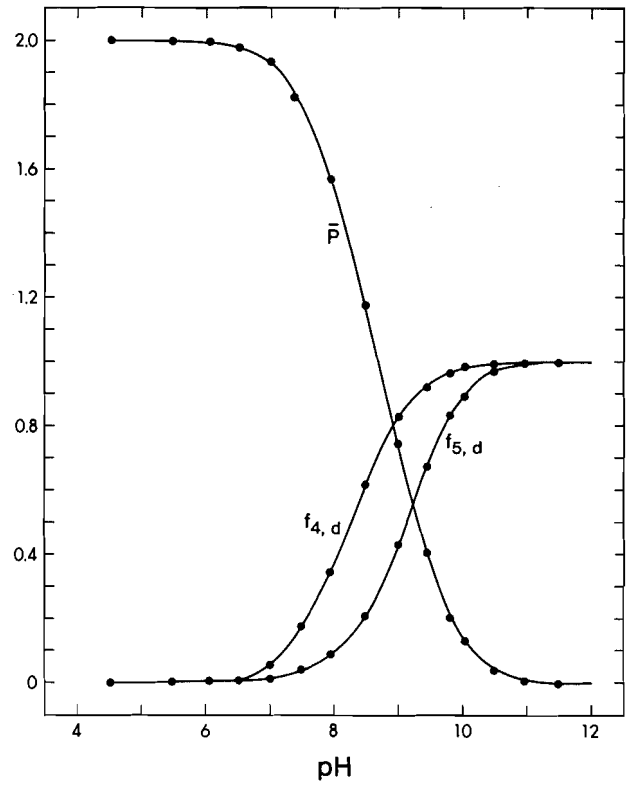

FIG. 4. The pH dependence of the fractional titration of the penicillamine ($f_{4,d}$) and glutamyl ($f_{5,d}$) ammonium groups of PSSG and the average number of ammonium protons per molecule ($\bar{p}$). The smooth curve through the $\bar{p}$ data is the theoretical curve predicted by the macroconstants in Table 1.

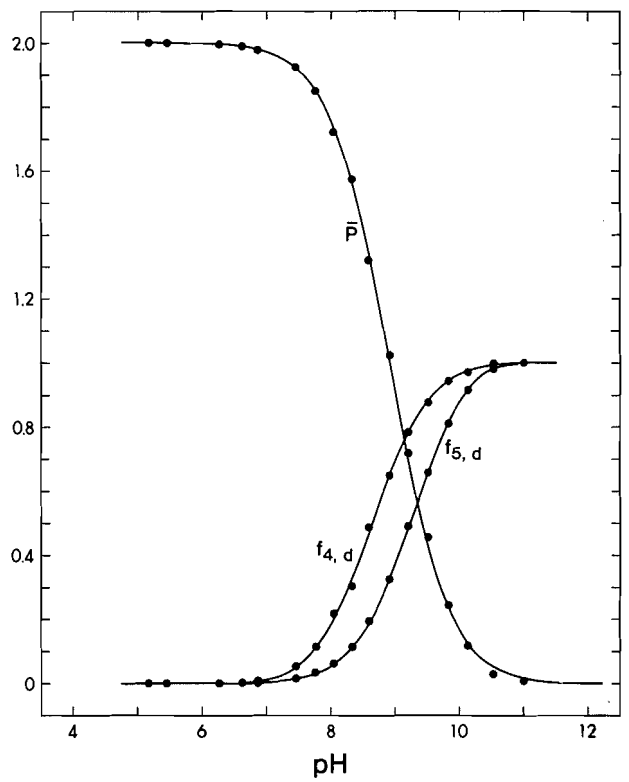

FIG. 5. The pH dependence of the fractional titration of the cysteine ($f_{4,d}$) and glutamyl ($f_{5,d}$) ammonium groups of CSSG and the average number of ammonium groups per molecule ($\bar{p}$). The smooth curve through the $\bar{p}$ data is the theoretical curve predicted by the macroconstants in Table 1.

Penicillamine–cysteine mixed disulfide

The acid–base chemistry of the two ammonium groups of PSSC was characterized using the pH dependence of the chemical shifts of the resonances for the C_α protons of the PSH and Cys parts of the molecule. Although the resonance for the C_α proton of the Cys part is in the same region as that for CSH and CSSC, there was no interference because CSH had been oxidized and CSSC is relatively insoluble. Since the C_α proton of the PSH part of PSSC is seven bonds removed from the ammonium group of the Cys part, changes in its chemical shift over the pH range 4–12 are assumed to be due only to titration of the PSH ammonium group. Likewise, changes in the chemical shift of the C_α proton of the Cys part are assumed to be due to titration of its ammonium group.

Fractional titration of each of the 2 ammonium groups was calculated as a function of pH from the chemical shift data. The ammonium groups of the PSH and Cys parts are labelled 3 and 4 respectively. $\bar{p}$ was then calculated as a function of pH. The fractional titration and $\bar{p}$ data are shown as a function of pH in Fig. 6. K_3 and K_4 were obtained from the $\bar{p}$ vs. pH data over the pH range 4–12, and microscopic constants were calculated from the macroconstants as described above. The results are listed in Table 1. The value obtained for the ratio [**2**]/[**3**] (eq. [9]) from data at 21 pH values was 1.70 ± 0.05.

Discussion

The nmr chemical shift data for PSSG, CSSG, and PSSC indicate that the two ammonium groups in each mixed disulfide are similar in acidity. Thus, the monoprotonated form of each molecule exists as a mixture of two protonation isomers. For PSSG, the ratio of the isomers, [**2**]/[**3**], is 4.4. For CSSG, the ratio is 3.9. For PSSC, the ratio of the concentration of the PSH protonated species to that of the Cys protonated species is 1.7. This ratio is independent of pH, as indicated by the species distribution diagram for PSSG in Fig. 7.

The ammonium groups of the PSH and Cys parts of PSSG and CSSG, respectively, are more acidic than are the ammonium groups of the GSH part. This is as would be predicted by the relative acidities of the ammonium groups of PSSP, CSSC, and GSSG (Table 1). However, even though the two ammonium groups in PSSG and in CSSG are separated by twelve bonds, their acidity does depend on the actual molecule and thus it is not possible to predict their acidities from acid dissociation constants for related molecules. For example, pk_{1234} = 8.22 for PSSG while pk_{123} = 8.06 for PSSP and pk_{123} = 8.24 for PSSC. For Cys, pk_{1234} = 8.61 for CSSG while pk_{123} = 8.25 for CSSC and pk_{124} = 8.47 for PSSC. Further evidence for interaction of the two ammonium groups in a given molecule is provided by the large differences between the two microconstants for a particular group. For example, if the two ammonium groups dissociate independently of each other, successive macroconstants will differ by a factor of 4 and the two microconstants for a particular ammonium group will be equal. The dependence of the acidity of one ammonium group on the protonation state of the other ammonium group is approximately the same for PSSP, GSSG, PSSC, and PSSG ($\Delta pk \sim$ 0.3–0.4), and zero within experimental error for CSSG.

One trend suggested by the results in Table 1 is that oxidation increases the acidity of ammonium groups close to the sulfur. For example, pk_{12} is 8.7 for PSH whereas pk_{123} is 8.06

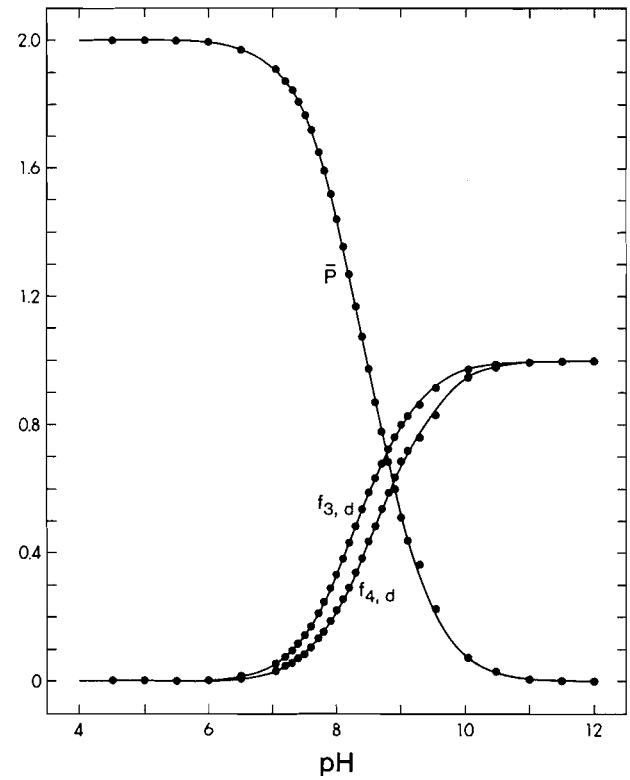

FIG. 6. The pH dependence of the fractional titration of the penicillamine ($f_{3,d}$) and cysteine ($f_{4,d}$) ammonium groups of PSSC and the average number of ammonium groups per molecule ($\bar{p}$). The smooth curve through the $\bar{p}$ data is the theoretical curve predicted by the macroconstants in Table 1.

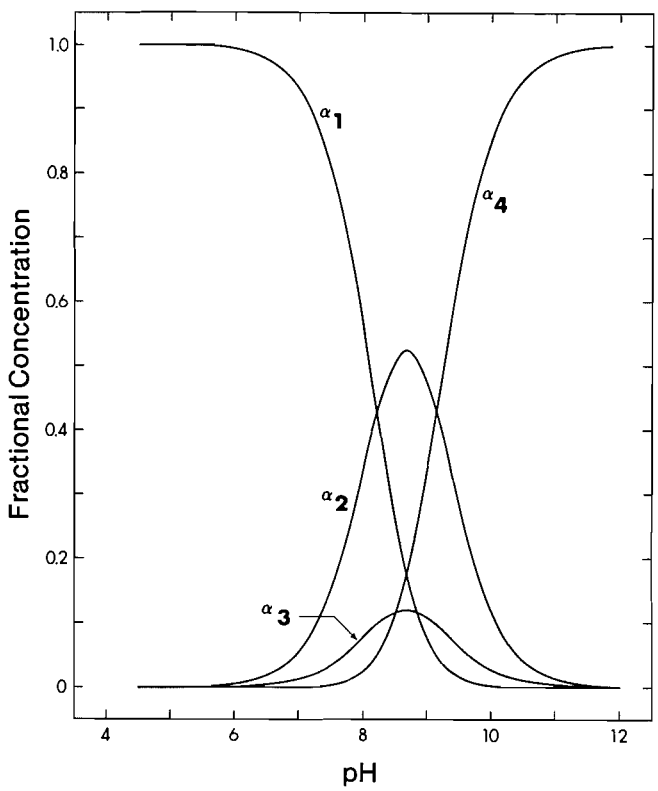

FIG. 7. pH dependence of the distribution of PSSG among its various ammonium protonated forms. α represents the fractional concentration of the species indicated by the subscript. The species are identified in Fig. 3.

for PSSP, pk_{1234} is 8.22 for PSSG, and pk_{123} is 8.24 for PSSC. Similarly, pk_{12} for Cys is 8.86, while pk_{123} is 8.14 for CSSC, pk_{1234} is 8.65 for CSSG, and pk_{123} is 8.24 for PSSC. In contrast, changes in the acidity of the ammonium group of GSH upon oxidation of the more distant thiol group are much less and show no apparent trend.

There are no values available for comparison with those reported in Table 1 for PSSG, CSSG, and PSSC. However, the values reported for PSSP, GSSG, GSH, and PSH agree well with literature values (16–20). The absence of literature values for the mixed disulfides may be due to the fact that methods generally used to measure acid dissociation constants require pure compounds. However, this is not a requirement for the nmr method since the ratio of protonated to deprotonated forms is obtained directly from chemical shift data. Thus, the nmr method is ideally suited to the characterization of the acid–base chemistry of mixed disulfides; the mixed disulfides can be formed from the appropriate thiols and disulfides by thiol/disulfide exchange, and their acid–base chemistry characterized using chemical shift data obtained from nmr measurements on the resulting mixture. Another advantage of the nmr method is that it provides information about both the macroscopic and the microscopic acid–base chemistry.

Aromatic sulphonates and the hydrolysis of 2-(*p*-nitrophenoxy)tetrahydropyran

STELLA O'LEARY

Pulp and Paper Research Institute of Canada, 570 St. John's Boulevard, Pointe Claire, P.Q., Canada H9R 3J9

Received May 10, 1983[1]

STELLA O'LEARY. Can. J. Chem. **62**, 1320 (1984).

The rate of hydrolyis of 2-(*p*-nitrophenoxy)tetrahydropyran was measured in a variety of buffers in water at 30°C. At low ionic strength (μ = 0.05), 3,6-disulphonaphthoxyacetic acid catalysed the reaction. The second-order rate constant was 20 times faster than predicted from pK_a. At high ionic strength ($\mu \doteq 0.5$), plots of k_{obs} vs. total buffer concentration for both 3,6-disulphonaphthoxyacetic acid and 6,8-disulphonaphthyoxyacetic acid go through a maximum. Polyacrylic acid catalysed the reaction. The results are discussed in terms of aggregation and salt effects.

STELLA O'LEARY. Can. J. Chem. **62**, 1320 (1984).

Opérant à 30°C et dans une variété de tampons, on a mesuré les vitesses d'hydrolyse du (*p*-nitrophénoxy)-2 tétrahydropyranne. A des forces ioniques faibles (μ = 0,05), l'acide disulfo-3,6 naphtoxyacétique catalyse la réaction. La constante de vitesse du second ordre est 20 fois plus rapide que la vitesse prédite en se basant sur le pK_a. A des forces ioniques plus élevées (μ = 0,5), les courbes des k_{obs} vs. les concentrations totales de tampon passent par un maximum tant pour l'acide disulfo-3,6 naphtoxyacétique que pour l'acide disulfo-6,8 naphtoxyacétique. L'acide polyacrylique catalyse la réaction. On discute des résultats en termes d'aggrégats et d'effets de sel.

[Traduit par le journal]

Introduction

In addition to the hydronium ion catalysis normally observed in acetal hydrolysis the hydrolysis of 2-(*p*-nitrophenoxy)-tetrahydropyran (PNPTHP) in water and mixtures of dioxane–water is characterized by general acid catalysis and a pH-independent unimolecular decomposition above pH 4 (1, 2).

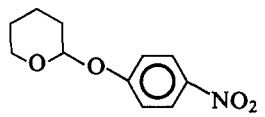
This observation has been attributed by Fife to two factors: (1) the decrease in basicity relative to other acetals, due to the electron-withdrawing nature of the *p*-nitrophenoxy group, and (2) a carbonium ion which is not especially destabilized compared with, for example, one derived from a sugar.

p-Nitrophenylglycosides are not subject to general acid catalysis because the electron-withdrawing effect of the hydroxyl groups on the glycone destabilizes the carbonium ion sufficiently to cause the C—O bond cleavage to remain rate determining (3–5).

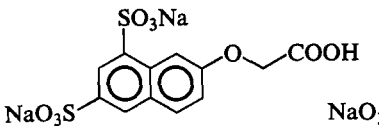
In the catalysis of glycoside hydrolysis by enzymes, such as lysozyme, the cellulases, and amylases, it is probable – and for lysozyme, at least, there is strong supporting evidence – that the reaction is also general acid catalysed (6, 7). This poses the question of which features of enzyme structure are responsible.

In the case of lysozome, an important factor appears to be stabilization of the incipient carbonium ion by a neighbouring carboxylate anion (6–8). A second factor, strain in the substrate ground state caused by binding to the enzyme, may also be important (9, 10). In the amylase case, it is becoming obvious from X-ray crystallographic data that substrate strain must be a significant feature of catalysis (11). There are no data at present on the three-dimensional structure or active-site geometry of a cellulase.

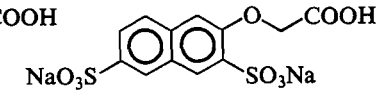
The ultimate goal of the present work is to find a catalyst for the hydrolysis of cellulose which would be functional at higher pH than concentrated mineral acids. To this end, model studies of glycoside hydrolysis were initiated and this report contains the first results of this work. PNPTHP was chosen as a model substrate as it is closely related in structure to the phenyl glycosides but is much easier to hydrolyse because it lacks the electron-withdrawing hydroxyl groups on the pyran ring. Its hydrolysis is subject to general acid catalysis, as is enzyme-catalysed hydrolysis of glycosides.



PNPTHP



6,8-SNOA



3,6-SNOA

The sulphonaphthoxyacetic acids (6,8-SNOA and 3,6-SNOA) were chosen as catalysts because they bear a structural resemblance to the direct dyes which bind to cellulose, they are water soluble, and they have a carboxylic acid group which will be protonated at a higher pH than the sulphonate anions, thus enabling the molecules to act as general acid catalysts. It was hoped that the sulphonate anions at positions 8 and 3 respectively might be suitably positioned to offer some electrostatic stabilization of the incipient carbonium ions. Examination of CPK space-filling models shows that the necessary contacts are possible.

Experimental

Substrate and catalysts

PNPTHP was prepared by the method of Fife and Jao (1). The oil obtained on evaporation of solvent gave pale yellow crystals after column chromatography.

6,8-Disulphonaphthoxyacetic acid (6,8-SNOA) and 3,6-disulphonaphthoxyacetic acid (3,6-SNOA) were prepared as follows: the appropriate naphthol disulphonic acid, di-salt (Eastman Kodak Co.), was recrystallized twice from hot water with charcoal treatment. One equivalent of purified naphthol and two equivalents of monochloroacetic acid were refluxed together in 10% NaOH for 1.25 h. The solution was allowed to cool, then acidified, and the product collected by filtration. This material was then recrystallized from hot water. In both cases the di-sodium salt was obtained (rather than the tri-acid form), because titration with NaOH took just one equivalent of base.

6,8-SNOA: white crystals; nmr (DMSO): 4.8 (s, 2H), 7.1–8.5 (complex, 5H). *Anal.* calc. for $C_{12}H_8O_9S_2Na_2 \cdot 4\ H_2O$: C 30.13, H 3.37, S 13.40; found: C 29.58, H 3.19, S 13.48.

3,6-SNOA: white solid; nmr (D_2O): 5.1 (s, 2H), 7.2–8.8 (complex, 5H). *Anal.* calc. for $C_{12}H_8O_9S_2Na_2 \cdot 1\ H_2O$: C 33.96, H 2.37, S 15.11; found: C 34.41, H 2.21, S 14.43.

Polyacrylic acid (PAA) (Aldrich Chemical Company) was obtained as a 65% solution in water, average mol wt. 2000, and used without further purification. Naphthoxyacetic acid (NOA) (Aldrich Chemical Company) was recrystallized twice from hot acetone to give sparkling white crystals. Phenoxyacetic acid (POA) (Anachemia Chemicals Ltd.) was used without further purification.

Kinetics

Rates of hydrolysis were measured spectrophotometrically by following the increase in absorbance due to *p*-nitrophenol release in a Gilford Model 250 spectrophotometer equipped with a Gilford 6050 chart recorder. The temperature was maintained at 30.0 ± 0.1°C by a Haake Model FE constant temperature circulator. The wavelengths used were 330 nm for acetic acid buffer, 340 nm for formic, chloroacetic, and polyacrylic acid buffers, and 355 nm for NOA, POA, 6,8-SNOA, and 3,6-SNOA buffers.

Buffers were prepared in distilled, deionized water. Where indicated, constant ionic strength was maintained by addition of NaCl. The NOA, 6,8-SNOA, and 3,6-SNOA buffers were sensitive to light and were stored, wrapped in foil, in the refrigerator.

Reaction was initiated by adding 10 μL of substrate ($3.2 \times 10^{-2}\ M$ in CH_3CN) to 3 mL of buffer solution, by means of a 10-μL Hamilton microsyringe. The cuvette was then capped and inverted several times. Infinity points were taken after ten half-lives. Reactions were plotted (log (O.D. − O.D.$_\infty$) vs. *t*) for three half-lives and good first-order kinetics were obtained. Most rate constants are the average of at least three runs, with a mean deviation of 5%. The pH of each solution was measured after reaction was complete. Deviations were never more than 0.03 from the original value.

pH

Buffers were prepared, pH measurements made, and potentiometric titrations carried out on a Radiometer Titrator TT2 or an Orion Research Model 601A/ digital Ionalyser pH metre, standardized with aqueous buffers (Fisher Scientific Company).

Results

Common buffers

The rate of hydrolysis of PNPTHP in water at 30°C, μ = 0.5 was measured in acetic, formic, chloroacetic, polyacrylic, NOA, 6,8-SNOA, and 3,6-SNOA buffers. Acetic, formic, and chloroacetic acids acted as general acid catalysts, i.e. the rate increased linearly with total buffer concentration and the slope of the line was inversely dependent on pH (Fig. 1). The second-order rate constants are given in Table 1 and are essentially the same as those observed by Armas *et al.* (13). A Bronsted plot of these data is linear with a slope of −0.43. Some experiments at low salt (μ = 0.05) were also done with acetic and formic acids at pH 3.7 and 2.8 respectively. The formic acid results are identical to those obtained at μ = 0.5. The rate constants for acetic acid at μ = 0.05 are slightly faster.

Polyacrylic acid (PAA)

The polyacrylic acid had an average chain length of 28. An average pK_a was estimated from potentiometric titration to be 5.8. A plot of k_{obs} vs. total buffer concentration at pH 4.7 shows a clear departure from second-order kinetics with a plateau reached at 0.5 *M* buffer (Fig. 2).

Sulphonaphthoxyacetic acid (SNOA)

The pK_a of both sulphonaphthoxyacetic acids was determined by potentiometric titration to be 3.4. Plots of k_{obs} vs. total buffer concentration are also non-linear for these compounds at high ionic strength but here the rate goes through a maximum (Fig. 3). The rates were measured at two different values of pH. The rates of hydrolysis were greater at low pH and the maxima were more pronounced. The rate of hydrolysis was also measured in SNOA buffers ($1 \times 10^{-3}\ M$) in 50% (v/v) dioxane–water at 50°C, μ = 0.5. The rate was much slower than in water, but essentially the same for both compounds ($5.0 \times 10^{-5}\ s^{-1}$).

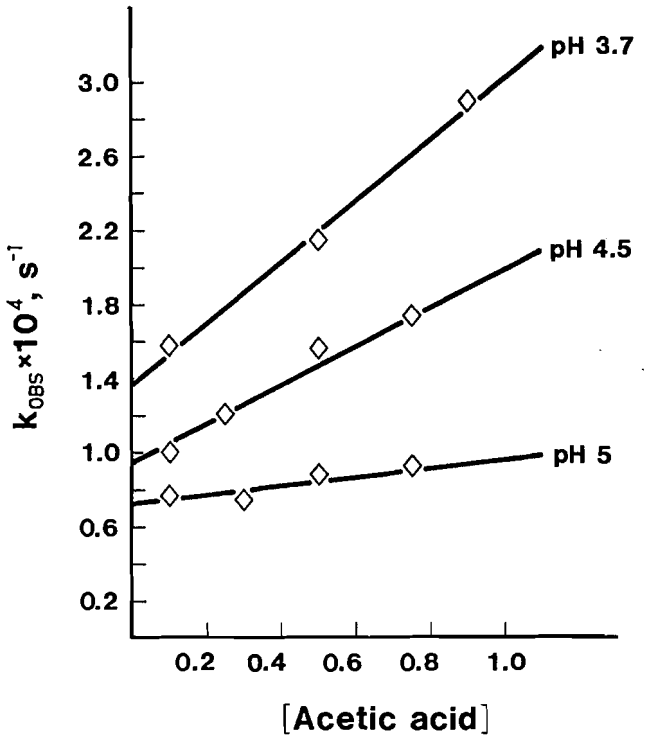

FIG. 1. $k_{obs} \times 10^4\ s^{-1}$ vs. total acetic acid concentration (*M*) at various pH values. *T* = 30 ± 0.1°C, μ = 0.5, [PNPTHP] = $1.0 \times 10^{-4}\ M$.

TABLE 1. Second-order rate constants for general acid catalysis of 2-PNPTHP hydrolysis at 30°C in water, μ = 0.5

Acid	$k_2 \times 10^4$ (L mol^{-1} s^{-1})	pK_a
Acetic	2.0	4.75
Formic	3.5	3.75
Chloroacetic	15.3	2.85

To determine the effect of ionic strength on this reaction, 3,6-SNOA-catalysed hydrolysis was carried out at pH 2.8, both in the absence of added salt and at μ = 0.05 and at pH 3.1, μ = 0.05. Under these low-salt conditions, the rate increased linearly with buffer concentration: the slopes were 2.01×10^{-2} and 1.58×10^{-2} L mol^{-1} s^{-1} respectively (Fig. 4) at pH 2.8, and 1.06×10^{-2} L mol^{-1} s^{-1} at pH 3.1.

Naphthoxyacetic acid (NOA)

Hydrolysis rates with naphthoxyacetic acid were measured in 10% EtOH–water owing to the sparing solubility of this compound in water (Fig. 3). The pK_a in this solvent was determined by potentiometric titration to be 3.7.

Phenoxyacetic acid (POA)

The rate of hydrolysis of PNPTHP at 30°C, μ = 0.05 in

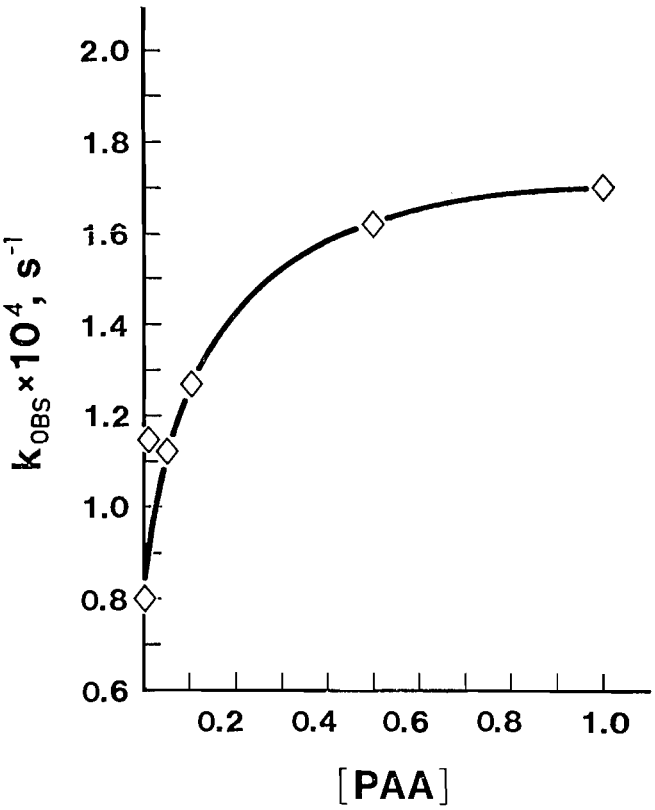

FIG. 2. $k_{obs} \times 10^4\ s^{-1}$ vs. total polyacrylic acid concentration (M). pH = 4.7, T = 30 ± 0.1°C, μ = 0.5, [PNPTHP] = 1×10^{-4} M.

aqueous phenoxyacetic acid was determined at four different values of pH around the pK_a, which is 3.1 for this compound. The second-order rate constant was determined to be 2.33×10^{-3} L mol^{-1} s^{-1} (Fig. 6).

Background hydrolysis

The rate of hydrolysis in water at 30°C, μ = 0.5 was obtained over the pH range 2.8 to 5 by extrapolation to zero buffer concentration of plots of observed rate constants versus buffer concentration (Fig. 5). In accordance with the observations at 50°C of Fife and Brod (2), the rate is strongly dependent on pH below pH 4 and becomes less so in less acidic solutions. The background rates at μ = 0.05 were determined in a similar manner. The values for μ = 0.5 are all slightly higher than for μ = 0.05.

Discussion

It is obvious from the results in Figs. 3 and 4 that ionic strength is important in the hydrolysis of PNPTHP in aromatic sulphonaphthoxyacetic acid buffers. It appears that the aromatic sulphonates are aggregating in the high salt solutions, where the presence of large amounts of sodium ions can stabilize the close proximity of sulphonate anions. At low ionic strength, the tendency of large aromatic compounds to aggregate in aqueous solution is offset by the negative electrostatic interactions of the anions. It is of course well known that high salt concentrations generally lower the rate of micellar-catalysed reactions and also the critical micelle concentration of surfactants (12).

The hydrolysis of PNPTHP in micellar solutions has been studied previously in the pH range 1–3 with no added salt (13). The second-order rate constant for reaction with H^+ was measured and found to be very sensitive to surfactant structure (all the surfactants were long-chain alkyl sulphonates). The second-order rate constants went through a maximum.

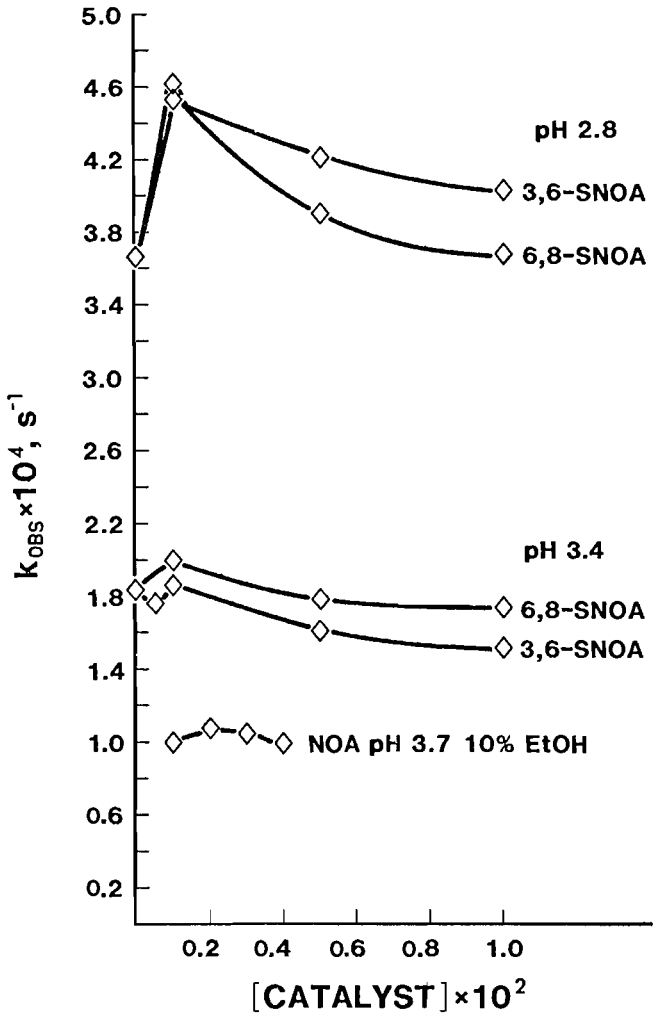

FIG. 3. $k_{obs} \times 10^4\ s^{-1}$ vs. total catalyst concentration $\times 10^2$ (M) for 3,6-SNOA, 6,8-SNOA, and NOA. T = 30 ± 0.1°C, μ = 0.5, [PNPTHP] = 1×10^{-4} M.

The rates of hydrolysis of *p*-nitrobenzaldehyde dialkyl acetals in long-chain sulphonic acid micelles with no added salt have also been measured (14). In this case the second-order rate constants reach a plateau once all the substrate has been bound to the micelle. In both these cases reaction is catalysed in the presence of anionic micelles.

In the case of the aromatic sulphonate 3,6-SNOA, the reaction is second order at μ = 0.05 and also with no added salt. The second-order rate constants are 1.58×10^{-2} and 2.01×10^{-2} L mol^{-1} s^{-1} respectively. This means that the 3,6-SNOA-catalysed reaction is 23 times faster than predicted by its pK_a (8.33×10^{-4} L mol^{-1} s^{-1}) (Fig. 6). There are two factors which are probably contributing to this enhanced catalytic effect: (1) stabilization of the incipient carbonium ion by the sulphonate anion at position 3 of the naphthyl ring, and (2) hydrophobic binding between catalyst and substrate. Examination of CPK space-filling models shows possible contacts between the naphthyl ring of the catalyst and either the pyran or phenyl rings of the substrate, while maintaining good contact between the sulphonate anion and the incipient carbonium ion (Fig. 7). Estimating the relative magnitude of the two effects is

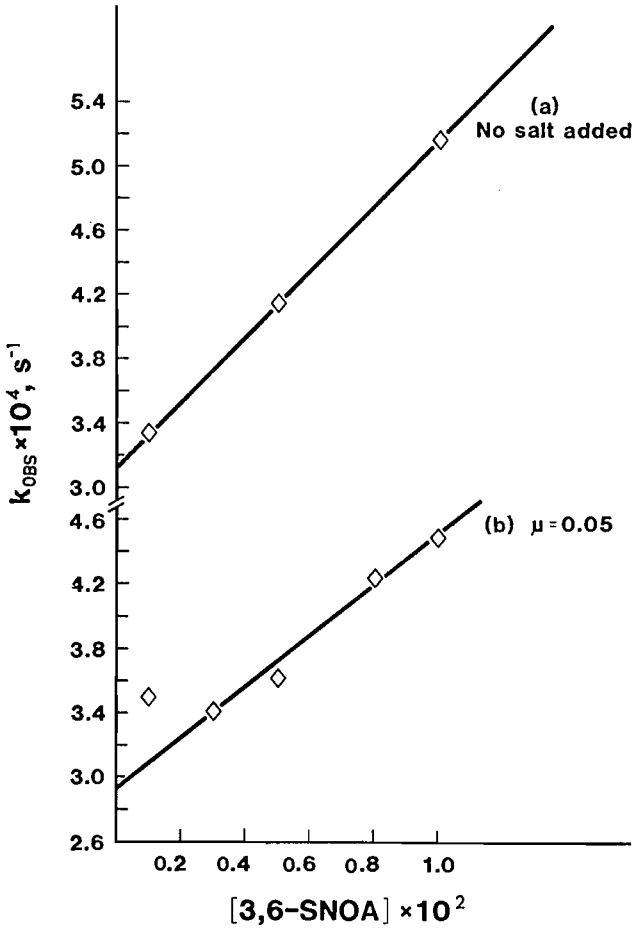

FIG. 4. $k_{obs} \times 10^4$ s^{-1} vs. total 3,6-SNOA concentration $\times 10^2$ (M). pH = 2.8, T = 30.0 ± 0.1°C, [PNPTHP] = 1×10^{-4} M. (a) No added salt, (b) μ = 0.05.

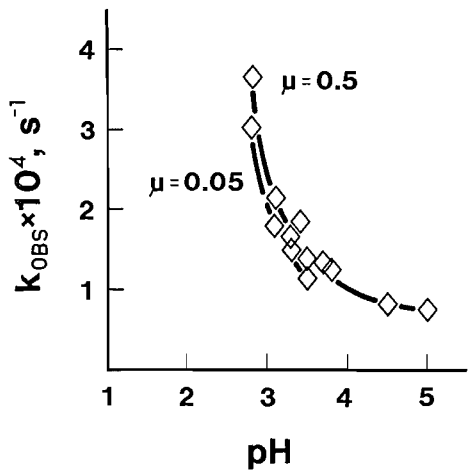

FIG. 5. $k_{obs} \times 10^4$ s^{-1} vs. pH for background hydrolysis of PNPTHP (1×10^{-4} M). T = 30 ± 0.1°C, μ = 0.5 and 0.05.

rather tricky: hydrophobic effects alone might be responsible for a rate enhancement of about ten-fold (15) while a 1:1 electrostatic effect could give a fifteen-fold enhancement (16). The results reported in the present work are of the same order of magnitude. Moreover, they apparently represent true second-order kinetics as opposed to micellar reaction.

To factor out the relative contributions of hydrophobic and

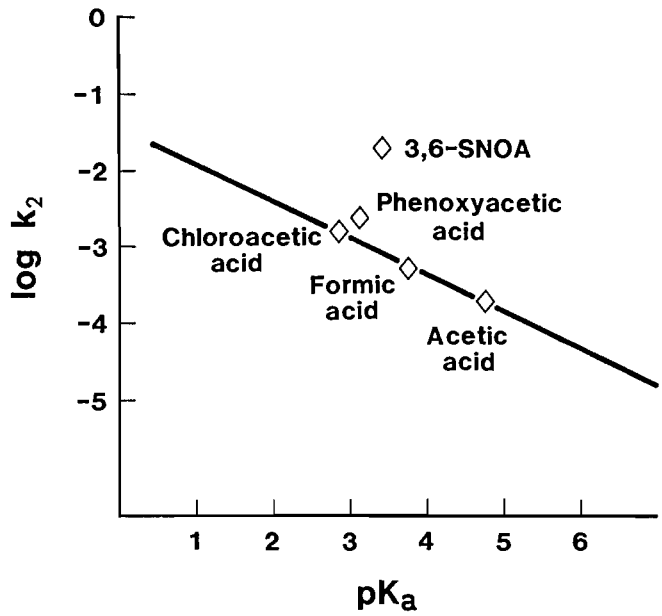

FIG. 6. Bronsted plot (log k_2 vs. pK_a) for chloracetic, formic, acetic, and phenoxyacetic acids and 3,6-SNOA.

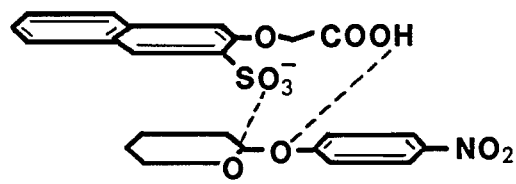

FIG. 7. Possible hydrophobic contact between naphthyl ring of catalyst and pyran ring of substrate. Dashed lines indicate possible contact between sulphonate anion and incipient oxocarbonium ion, and between carboxylic acid group and oxygen atom of leaving group.

electrostatic effects, suitable control experiments must be done. It is not possible to compare the sulphonaphthoxyacetic acids directly with naphthoxyacetic acid over the same range of concentration because of the very sparing solubility of the latter compound in water or in 10% ethanol water (4×10^{-3} M seems to be the upper limit on solubility in 10% ethanol–water.) A truer comparison would probably be with 6-sulpho-2-naphthoxyacetic acid or phenoxyacetic acid. Both compounds would be more water soluble and examination of CPK models shows that the carboxylic and sulphonate groups of the former cannot interact simultaneously with PNPTHP.

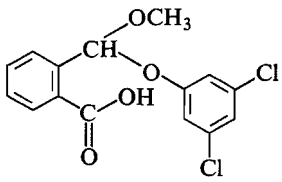
The rates of hydrolysis in phenoxyacetic acid buffers were measured at μ = 0.05, T = 30°C, at several different total buffer concentrations and pH values. The true second-order rate constant was determined to be 2.33×10^{-3} L mol^{-1} s^{-1}. This is twice the value expected from the Bronsted plot for a simple carboxylic acid of pK_a 3.1. The enhancement is probably small enough to be attributable to experimental error but is also consistent with the sort of enhancement which might be expected for hydrophobic binding involving only one phenyl group (16).

If the twofold enhancement is really due to hydrophobic binding, then there remains a 10-fold enhancement to be explained by electrostatic stabilization of the incipient carbonium ion by the catalyst sulphonate anion. This is of the same order of magnitude as that observed by Guthrie and Ueda in an ester hydrolysis where the negatively-charged ester was electro-

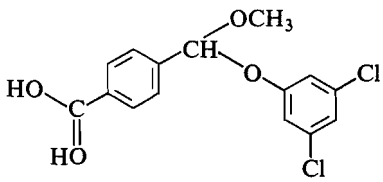
statically bound to the positively-charged catalyst (16).

If the twofold rate enhancement observed for phenoxyacetic acid is indeed due to experimental error, then the full 23-fold enhancement should be attributable to electrostatic stabilization. It seems fair to say that a ten-to-twenty-fold rate enhancement due to intermolecular electrostatic stabilization has been observed in this system.

This compares not unfavourably with Fife's observation of a 100-fold enhancement due to electrostatic stabilization in acetal hydrolysis in an intramolecular system (8), the phthalaldehydic acid system.



Phthalaldehydic acid methyl 3,5-dichlorophenyl acetal



Terephthalaldehydic acid methyl 3,5-dichlorophenyl acetal

Fife has observed (8) that anion stabilization of a developing carbonium ion should be capable of generating significant rate enhancements, but only in reactions where there is a relatively large amount of C—O bond breaking in the transition state. This is the case for the phthalaldehydic acid acetal (8) and is also the case for PNPTHP (1). The present observation of electrostatic stabilization of acetal hydrolysis in PNPTHP seems to bear out the theory. It is also the first example of electrostatic stabilization of acetal hydrolysis where the reaction has been shown to be truly second order.

The basis for comparison used here is the Bronsted plot, which actually represents hydrolysis at $\mu = 0.5$, while the 3,6-SNOA values were measured at $\mu = 0.05$. Some experiments were done with formic and acetic acids at $\mu = 0.05$ and the results are very similar to the $\mu = 0.5$ values. If there is a strong effect of ionic strength upon the simple carboxylic acid-catalysed reaction, one would expect it to be in the direction of increasing reaction rates with increasing salt concentration. Therefore, the value of 8.33×10^{-4} L mol^{-1} s^{-1}, for a simple carboxylic acid of pK_a 3.4, probably represents an upper limit. The background hydrolysis rates at $\mu = 0.05$ are all slightly lower than the corresponding rates at $\mu = 0.5$ (Fig. 5).

The polyacrylic acid has a catalytic effect on the rate of hydrolysis, which reaches a plateau at 0.5 *M*. This probably indicates the formation of micelles or aggregates. The pH was such that the polyacrylic acid was essentially protonated and the concentrations at the upper end of the range were very high (1 *M*).

Radical addition, decomposition, and isomerization reactions in the pyrolysis of ethane and ethylene

ALLAN L. MACKENZIE,[1] PHILIP D. PACEY,[2] AND JAYANTHA H. WIMALASENA[3]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

ALLAN L. MACKENZIE, PHILIP D. PACEY, and JAYANTHA H. WIMALASENA. Can. J. Chem. **62**, 1325 (1984).

Pure C_2H_6, pure C_2H_4, and a mixture of these have been pyrolyzed at 892 to 905 K and 23 to 250 Torr in a flow reactor system. Rates of formation of CH_4, C_3H_6, and 1-C_4H_8 were consistent with a mechanism involving the following radical addition, decomposition, and isomerization reactions:

[A] $C_2H_5 + C_2H_4 \rightleftharpoons 1\text{-}C_4H_9 \rightarrow 1\text{-}C_4H_8 + H$

[B] $C_2H_5 + C_2H_4 \rightleftharpoons 1\text{-}C_4H_9 \rightarrow 2\text{-}C_4H_9 \rightarrow C_3H_6 + CH_3$

[C] $CH_3 + C_2H_4 \rightleftharpoons 1\text{-}C_3H_7 \rightarrow C_3H_6 + H$

In pure C_2H_6 pyrolysis, some CH_4 and C_3H_6 also appeared to be formed by the decomposition of the product, n-C_4H_{10}. It was found that $k_A = 5.2\ (\pm 0.6) \times 10^4$ L mol^{-1} s^{-1} at 902 K and $k_B = 2.3\ (\pm 0.2) \times 10^4$ L mol^{-1} s^{-1} at 898 K. Arrhenius parameters for k_A were calculated from data in the literature. Process [C] was measured relative to the abstraction.

[15] $CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$

It was found that $k_C/k_{15} = 1.7\ (\pm 0.7)$ at 896 K.

ALLAN L. MACKENZIE, PHILIP D. PACEY et JAYANTHA H. WIMALASENA. Can. J. Chem. **62**, 1325 (1984).

Utilisant un appareil à écoulement et opérant à des températures allant de 892 à 905 K et à des pressions allant de 23 à 250 Torr, on a effectué la pyrolyse du C_2H_6 et du C_2H_4 à l'état pur ainsi que d'un mélange de ces deux composés. Les vitesses de formation du CH_4, du C_3H_6 et du C_4H_8 sont en accord avec un mécanisme qui implique une addition radicalaire et des réactions de décomposition et d'isomérisation

[A] $C_2H_5 + C_2H_4 \rightleftharpoons 1\text{-}C_4H_9 \rightarrow 1\text{-}C_4H_8 + H$

[B] $C_2H_5 + C_2H_4 \rightleftharpoons 1\text{-}C_4H_9 \rightarrow 2\text{-}C_4H_9 \rightarrow C_3H_6 + CH_3$

[C] $CH_3 + C_2H_4 \rightleftharpoons 1\text{-}C_3H_7 \rightarrow C_3H_6 + H$

Lors de la pyrolyse du C_2H_6 à l'état pur, il semble aussi se former du CH_4 et du C_3H_6 par décomposition du produit, le n-C_4H_{10}. On a trouvé que $k_A = 5{,}2\ (\pm 0{,}6) \times 10^4$ L mol^{-1} s^{-1} à 902 K et $k_B = 2{,}3\ (\pm 0{,}2) \times 10^4$ L mol^{-1} s^{-1} à 898 K. On a calculé les paramètres d'Arrhénius pour le k_A à partir de données trouvés dans la littérature. On a mesuré la vitesse de la réaction C par rapport à celle de l'abstraction

[15] $CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$

On a trouvé que $k_c/k_{15} = 1{,}7\ (\pm 0{,}7)$ à 896 K.

[Traduit par le journal]

Introduction

Most laboratory studies of alkane pyrolysis have focussed on the early, primary reactions. In industrial pyrolysis, in contrast, conversions are large, and reactions of the product olefins become important (1, 2). The subject of this article is the addition of methyl and ethyl radicals to ethylene, and the subsequent decomposition and isomerization reactions of the adduct radicals. Conversions have been kept small to avoid complications, but the results should be valid at greater conversions.

The major primary reactions in the pyrolysis of ethane are as follows (3–5):

[1] $C_2H_6 \rightarrow 2CH_3$

[2] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

[3] $C_2H_5 \rightarrow C_2H_4 + H$

[4] $H + C_2H_6 \rightarrow H_2 + C_2H_5$

[5a] $2C_2H_5 \rightarrow C_4H_{10}$

[5b] $2C_2H_5 \rightarrow C_2H_4 + C_2H_6$

Lin and Back (4) showed that the ethylene produced may participate in the following sequence:

[6,−6] $C_2H_5 + C_2H_4 \rightleftharpoons 1\text{-}C_4H_9$

[7] $1\text{-}C_4H_9 \rightarrow 1\text{-}C_4H_8 + H$

These may be considered as a combined process:

[A] $C_2H_5 + C_2H_4 \rightarrow 1\text{-}C_4H_8 + H$

The rate of reaction [3] is much greater than that of reaction [5b]. Making the steady-state assumption, the concentrations of products as a function of time may be obtained as Taylor series. The leading terms in some of these are

$$[C_2H_4] = k_3[C_2H_5]_0 t + \ldots$$

$$[C_4H_{10}] = k_{5a}[C_2H_5]_0^2 t + \ldots$$

$$[1\text{-}C_4H_8] = (1/2)\, k_A k_3 [C_2H_5]_0^2 t^2 + \ldots$$

Hence the subscript 0 indicates a radical concentration after the steady state is established, but before secondary reactions sig-

For personal use only.

nificantly affect this concentration. These three equations may be combined to give

$$[8] \qquad k_A k_{5a}^{-1/2} = 2[1\text{-}C_4H_8][C_2H_4]^{-1}[C_4H_{10}]^{-1/2}t^{-1/2} + \ldots$$

In the copyrolysis of ethane and ethylene, the leading term for $[C_2H_4]$ becomes the initial concentration and a similar procedure leads to the following equation:

$$[9] \qquad k_A k_{5a}^{-1/2} = [1\text{-}C_4H_8][C_2H_4]^{-1}[C_4H_{10}]^{-1/2}t^{-1/2} + \ldots$$

The copyrolysis may also be used to study the process

$$[B] \qquad C_2H_5 + C_2H_4 \rightarrow C_3H_6 + CH_3$$

This is believed (4, 5) to consist of reactions [6] and [−6], followed by

$$[10] \qquad 1\text{-}C_4H_9 \rightarrow 2\text{-}C_4H_9$$

$$[11] \qquad 2\text{-}C_4H_9 \rightarrow C_3H_6 + CH_3$$

Steady-state treatment leads to

$$[12] \qquad k_B k_{5a}^{-1/2} = [C_3H_6][C_2H_4]^{-1}[C_4H_{10}]^{-1/2}t^{-1/2} + \ldots$$

In the pyrolysis of pure ethylene, it would be difficult to use reaction [5*a*] as a reference, as butane yields are very small (6−8). An alternative is

$$[12] \qquad C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$$

which is the major source of ethane in this system. A similar procedure leads to

$$[14] \qquad k_A k_{13}^{-1} = [1\text{-}C_4H_8][C_2H_6]^{-1}$$

In ethylene pyrolysis, methyl radicals formed by process [B] may react as follows (5, 6):

$$[15] \qquad CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$$

$$[16,-16] \qquad CH_3 + C_2H_4 \rightleftharpoons 1\text{-}C_3H_7$$

$$[17] \qquad 1\text{-}C_3H_7 \rightarrow C_3H_6 + H$$

The latter two reactions may be considered as the process:

$$[C] \qquad CH_3 + C_2H_4 \rightarrow C_3H_6 + H$$

The following relationships are predicted to apply:

$$[18] \qquad k_B k_{13}^{-1} = (1/2)([CH_4] + [C_3H_6])[C_2H_6]^{-1}$$

$$[19] \qquad k_B k_{15}(k_{15} + k_C)^{-1}k_{13}^{-1} = [CH_4][C_2H_6]^{-1}$$

The present article describes experimental tests of equations [8], [9], [12], [14], [18], and [19].

Experimental

The flow system and the purification of reagents have been described elsewhere (8, 9). A 1 m, 10% NaOH on alumina (100/120 mesh) column, operated at 296 K, was used for gas chromatographic analysis of CH_4, C_2H_6, and C_3H_6 from C_2H_4 pyrolysis. A 0.75 m silica gel (100/120 mesh, acid washed) column at 323 K was used for analysis of CH_4, C_2H_6, and C_4H_8 from C_2H_4 pyrolysis. The other analyses were performed with a 4.75 m, 10% squalane on Chromosorb P (NAW 100/120 mesh) column at 273 K.

Results

Experiments[4] have been performed at reactor temperatures from 892 to 905 K and with residence times from 0.3 to 51 s and conversions of 8% or less.

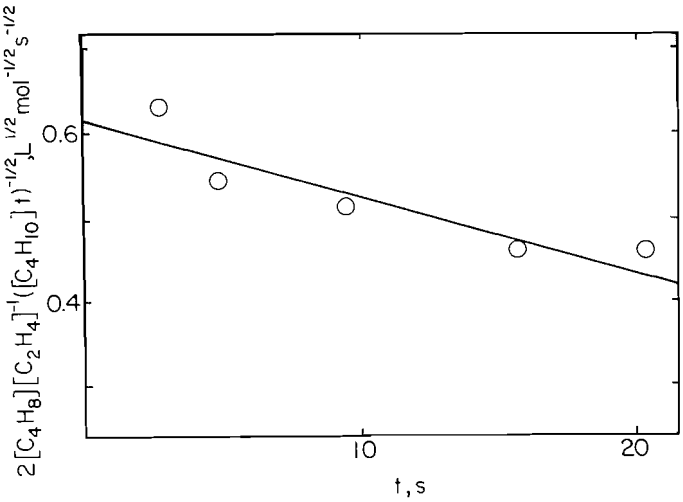

FIG. 1. The quotient of produet yields in eq. [8], as a function of reactor residence time for experiments at 200 Torr and 902 K in an 8 mm internal diameter reactor: ○, experimental points; —, least-squares straight line.

Pure ethane

Yields of C_2H_4, 1-C_4H_8, and *n*-C_4H_{10} have been measured in the pyrolysis of pure ethane and the quotient of yields appearing in eq. [8] has been calculated. Results of experiments at 902 K and 200 Torr are shown in Fig. 1. It can be seen that the quotient declines slightly with increasing residence time because of higher terms in eq. [8]. The value of $k_A k_{5a}^{-1/2}$ has been taken as the intercept. From $k_{5a} = 9 \times 10^9$ L mol^{-1} s^{-1}, determined in related experiments (9, 10), values of k_A have been calculated from intercepts at this and other pressures. The results are listed in Table 1.

Ethane−ethylene mixtures

Mixtures of 75 mol% C_2H_6 with 25% C_2H_4 have been pyrolyzed at two pressures. Yields of C_3H_6, 1-C_4H_8, and C_4H_{10} have been measured. The right-hand sides of eqs. [9] and [12] have been calculated and extrapolated to find the intercepts, $k_A k_{5a}^{-1/2}$ and $k_B k_{5a}^{-1/2}$, as in Fig. 1. The resulting values of k_A and k_B are listed in Table 2.

Pure ethylene

Pure C_2H_4 has been pyrolyzed. Various combinations of CH_4, C_2H_6, C_3H_6, and 1-C_4H_8 yields were measured with the different chromatographic columns. The quotients of product

yields in eqs. [14], [18], and [19] were found to be independent of reaction time, within experimental uncertainty. For this reason the quotients were not extrapolated to initial values; instead, simple averages were taken. The value of k_{13} was taken as 8×10^4 L mol^{-1} s^{-1}, from related experiments (8). Values of k_A, k_B, and the quotient in eq. [19] are listed in Table 3.

Discussion

The rate parameters in the tables are independent of pressure, within experimental uncertainty. The parameters are also independent of the feedstock, especially when the variations in temperature are taken into account. These facts confirm that the mechanisms assumed are reasonable and that the chosen literature values of k_{5a} and k_{13} (8–10) are consistent.

Process [A]

Lin and Back (4) have measured the rate of formation of C_4H_8 in C_2H_6 pyrolysis at 824 to 893 K. If eq. [8] is applied to their data, one finds $\log_{10} k_A$ (L mol^{-1} s^{-1}) = 8.1(±0.5) − 57 (±8) kJ mol^{-1}/2.3RT. At 900 K, this gives $k_A = 6.4 \times 10^4$ L mol^{-1} s^{-1}, in satisfactory agreement with the average of the present results, 5.2(±0.6) × 10^4 L mol^{-1} s^{-1}.

The ratio $[C_4H_8]/[C_2H_6]$ has been measured in C_2H_4 pyrolysis at much lower temperatures and was found to increase with pressure (6, 7). The following expressions may be calculated from the data at 773 K (6) and 787 K (7), respectively: $[C_4H_8]/[C_2H_6]$ = 0.75(±0.11) + 3.8(±0.4) × 10^{-3} Torr^{-1} P or 0.57 (±0.17) + 2.4(±0.9) × 10^{-3} Torr^{-1} P. The pressure-dependent term appears to be caused by an alternative source of C_4H_8, a source for which there is an extra C_2H_4 molecule in the critical complex. This source could involve the transfer of H from C_4H_9 to C_2H_4, as suggested in ref. 11, or the isomerization of 1-C_6H_{13} and subsequent decomposition of 3-C_6H_{13}, as suggested in ref. 6. These processes are expected to have lower activation energies than process [A] and would make a negligible contribution under the conditions of the present work. The pressure-independent terms above, 0.75 and 0.57, are similar to the value from the present work, 0.58, indicating that process [A] and reaction [13] must have activation energies which differ by 12 kJ mol^{-1} or less.

If reaction [6] is assumed to be at or near equilibrium, then $k_A = K_6 k_7$, where K_6 is the equilibrium constant. Calculating K_6 from thermochemistry (12), one finds $\log_{10} k_7$ (s^{-1}) = 13.4(±0.5) − 149(±8) kJ mol^{-1}/2.3RT and at 900 K, $k_7 = 5.4 \times 10^4$ s^{-1}. This is almost two orders of magnitude less than the predicted value of k_{-6} (12), confirming the validity of the equilibrium assumption just used. The Arrhenius parameters are similar to values of 13.8 and 159 kJ mol^{-1} recommended in ref. 12 for the related reaction, [17].

Process [B]

Arrhenius parameters for process [B] have previously been reported from studies of the pyrolysis of pure C_2H_6 (4, 5). These parameters lead to values of k_B at 900 K about twice as great as the values in Tables 2 and 3. In the present work, it has been confirmed that C_3H_6 yields from pure C_2H_6 pyrolysis are greater than predicted using the values of k_B in Tables 2 and 3. It has also been found that the chordal rate of formation of butane, $[C_4H_{10}]/t$, declines with time at about the same rate as $[C_3H_6]/t$ increases. Propylene is a major product of the chain decomposition of butane. This suggests that much of the C_3H_6 formed from pure C_2H_6 at these temperatures comes from the decomposition of C_4H_{10}, as well as from process [B]. Equations [12] and [18], used to calculate the values in Tables 2 and 3, depend on initial rates, and would not be affected by decomposition of C_4H_{10} formed.

At lower temperatures, the main source of C_3H_6 in pure and mixed C_2H_6 and C_2H_4 is believed (3, 4, 6, 13, 14) to be the process consisting of reactions [6], [−6], and

[20] 1-C_4H_9 + C_2H_4 → 1-C_6H_{13}

[21] 1-C_6H_{13} → 2-C_6H_{13}

[22] 2-C_6H_{13} → C_3H_6 + C_3H_7

This sequence will be referred to as process [D]. In the pyrolysis of ethylene at 773 and 803 K (6, 15), the ratio $([C_3H_6] + [CH_4])[C_2H_6]^{-1}$ was found to be proportional to $[C_2H_4]$ within experimental uncertainty. In Table 3, this ratio is found to be independent of $[C_2H_4]$ at 896 K. Such behavior suggests that process [D] is dominant at the lower temperatures and process [B] at the upper temperature. Lin and Back (4) estimated experimentally that the difference in activation energies for these processes is about 155 kJ mol^{-1}. This difference is sufficient to explain the observed change in the dependence on $[C_2H_4]$ between 773 and 896 K.

The average value of k_B from the tables is 2.3(±0.2) × 10^4 L mol^{-1} s^{-1}. The ratio of the rate of isomerization [10] to decomposition [7] of the 1-butyl radical is found to be 0.44(±0.06). This may be compared with a value of 0.2 (±0.1) for deuterated ethyl radicals (16).

Reaction [15] and process [C]

The values in the final column in Table 3 are more scattered than the others because of the difficulty in measuring the small CH_4 peaks. Taking k_B/k_{13} from the present work, one finds $k_C/k_{15} = 1.7$ (±0.7). This may be compared with the analogous ratio for the ethyl radical, $k_A/k_{13} = 0.58$ (± 0.01). For methyl, the addition–decomposition process is favoured over abstraction; the reverse is true for ethyl. The CH_3 addition reaction, [16], is about 14 kJ mol^{-1} more exothermic than the C_2H_5

For personal use only.

addition, [6] (12). Since these reactions are believed to be in equilibrium and the subsequent decompositions should have similar rates, all of this exothermicity difference should be reflected in the rates. Reaction [15] is also more exothermic than reaction [13], but only part of this difference should be reflected in the activation energies of the forward reactions, part in the activation energies of the reverse processes.

Theoretical study on dinitrogen complexes. Relation between facility of protonation and difference of electronic structures of d^6 and d^8 complexes

KENZI HORI[1] AND TOKIO YAMABE[2]

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto, Japan 606

Received June 30, 1983[3]

KENZI HORI and TOKIO YAMABE. Can. J. Chem. **62**, 1329 (1984).

Electronic structures of different *d* configurations have been studied in relation to the facility of protonation to dinitrogen ligand in Cr(0) and Co(I) complexes. The d^6 Cr complex has much better MO's for protonation than the d^8 Co complex. This difference largely affects the protonation energies and the reduction of nitrogen molecule in these complexes.

KENZI HORI et TOKIO YAMABE. Can. J. Chem. **62**, 1329 (1984).

On a étudié les structures électroniques de différentes configurations *d* en relation avec la facilité de protonation du ligand diazoté de complexes Cr(0) et Co(I). Le complexe d^6 du Cr possède des OM beaucoup plus propices à la protonation que celles du complexe d^8 du Co. Cette différence affecte grandement les énergies de protonation et la réduction de la molécule d'azote dans ces complexes.

Introduction

Reduction of molecular dinitrogen by transition metal complexes has been a major goal since the first dinitrogen complex $Ru(NH_3)_5(N_2)^{2+}$, was synthesized (1). Subsequently, many dinitrogen complexes have been synthesized with a wide range of transition metals (2). For Mo and W complexes, the dinitrogen ligand can be reduced to NH_3(3). It is known that two Mo atoms are included at the active site of nitrogenase. Therefore, Mo with d^6 configuration is considered a key factor for the reduction of the dinitrogen ligand.

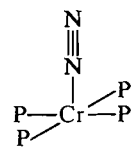
In order to reduce the dinitrogen ligand, it is necessary to form protonated species. Neither these compounds nor reduction products have ever been obtained from mononuclear complexes without Mo and W being the central metal. On the other hand, both protonated species and reduction products were obtained by treating d^6 Mo(0) and W(0) complexes in solution with HCl or H_2SO_4 as acids (4). The reduction of the dinitrogen ligand requires the existence of a d^6 metal. Therefore, one of the most important themes of dinitrogen complex chemistry is to answer the question, "Why Mo or W?".

Electrophilic attack of a proton on dinitrogen complexes involves both the highest occupied molecular orbital (HOMO) and a lone pair orbital of the N_2 ligand, (n_N), and they control the position and/or direction in forming the N—H bond. In d^6 complexes, these electronic features will be considerably different from those in d^8 or d^{10} systems. It is important to compare these properties in d^6 nitrogen complexes with those in different *d*-configurations.

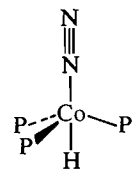
In this paper, electronic structures of a d^6 Cr complex, $Cr(PH_3)_4(N_2)$ and a d^8 complex, $CoH(PH_3)_3(N_2)$, are examined and the relation between the *d*-configuration and the facility of protonation is investigated using *ab initio* MO calculations.

Method of calculations

The MO calculations were carried out with the GAUSSIAN-76 program (5). The basic sets of Cr and Co, given by Roos *et al.* (6), are contracted to [5*s*2*p*2*d*], and *p*-type orbitals of 1G are added to the basis set (7). The basis sets used for the central metals seem rather small, but even such small basis sets may be acceptable for describing such qualitative features as orbital patterns. For the ligands, STO-3G minimal basis sets internal to the program were adopted. The geometries of the Cr and Co complexes are shown as structures **1** and **2**. They have C_4 and C_{3v} symmetries, respectively (8).



1



2

A five-coordinated Cr complex is adopted for the model of Mo or W analogues because of the simplicity of calculations. Since the orbital nature may be different between complexes with and without the sixth dinitrogen ligand, $Cr(PH_3)_4(N_2)_2$ with the optimized Cr—N and N—N bond lengths were also calculated and examined. The geometries of the M—N_2 moiety were optimized as functions of the M—N and N—N bond lengths by energy minimization (8); this is because they are unknown in the Cr complex. Moreover, natures of the moiety probably have more influence on protonation process since protons electrophilically attack on the dinitrogen ligand. On the other hand, other parts of dinitrogen complexes do not participate in the reduction of dinitrogen ligands. Therefore, Cr—P(2.53 Å), Co—P (2.18 Å), and Co—H (1.60 Å) lengths are fixed in all calculations.[4]

Results and discussion

Co—N and N—N bond lengths in $CoH(PPh_3)_3(N_2)$ observed by Davis *et al.* (9) are 1.829 and 1.123 Å, respectively. The optimized values of these lengths are 2.061 and 1.134 Å, respectively. While the calculated N—N length is very close to the observed value, the calculated Co—N length is slightly larger than the observed value. The small basis sets used here may cause a slight overestimation of the M—N bond length.

Those in the Cr complexes are calculated to be 1.774 and 1.162 Å, respectively.

As mentioned above, MO's involved in protonation will be largely different in d^6 and d^8 complexes. HOMO and n_N of dinitrogen complexes are closely related to the MO's and are represented in Fig. 1. The HOMO of Cr complex is d_π (Fig. 1*a*) with a large p_x coefficient of the terminal nitrogen atom (N_T) while that of Co is the MO which has a large contribution of a hydride ligand as shown in Fig. 1*b*. Orbital energies are −0.033 and −0.159 au, respectively. While the Co complex has a d_π orbital similar to that of the Cr complex, it is mainly constructed from the d_{xz} orbital of Co plus a small contribution from the p_x orbital of N_T. The lone-pair nature in n_N of the Co complex is larger than that of Cr as is illustrated in Fig. 1*c* and 1*d*. However, the first orbital is much lower than the second one, and the orbital energies of Co and Cr complexes are calculated to be −0.569 and −0.378 au, respectively. It means that the d^6 Cr complex has an electronic structure for protonation more preferable than that of the d^8 Co complex. In other words, the Cr complex has a stronger Lewis basicity, the ability to donate its own electron density, than that of the Co complex. These electronic features strongly influence the magnitude of the protonation energies.

At this point, it is necessary to compare the MO properties in the five- and six-coordinated Cr complexes. The calculated results show that $Cr(PH_4)_4(N_2)_2$ also has d_π and n_N orbitals similar to those of the coordinatively unsaturated model. The orbital energies of the former are calculated to be −0.064 and −0.447 au, respectively. They are lower by 0.031 and 0.009 au, respectively, in comparison with those calculated for the five-coordinated complex. However, they are still higher than the corresponding MO's of the Co complex (−0.159 and −0.569 au) for HOMO and n_N, respectively. Therefore, it is possible to compare their qualitative nature in dinitrogen complexes by using the simple model adopted here.

Protonation energies were calculated on the assumption that the geometry of the metal moieties, $CoH(PH_3)_3(N_2)$ and $Cr(PH_3)_4(N_2)$, are taken to be the same as those of their parent complexes. In the Co complex, the NNH angle and the N—H length are 180.0° and 1.05 Å, respectively. In Cr complex they are 120.0° and 1.05 Å, respectively. In order to estimate protonation energies more correctly, 4-31G basis sets were adopted for the N_2 moieties. The energies for Co and Cr complexes are calculated to be 300.5 and 147.2 kcal/mol. This trend is consistent with that expected by the difference of MO's calculated. The protonation energy for the Co complex is similar to that calculated for a nitrogen molecule (123.0 kcal/mol) although N_2H^+ has not been observed in the usual solvents. On the other hand, the protonation energy of the Cr complex is larger than that of NH_3 (225.4 kcal/mol), which forms NH_4^+ in aqueous solution. The protonated species have been regarded as intermediates on the way of reduction. The existence of these compounds in solution requires larger protonation energy than the solvent. It is therefore necessary to gain a protonation energy as large as that calculated for the Cr complex to form stable intermediates.

It has never been reported that the nitrogen molecule in $Ru(NH_3)_5(N_2)^{2+}$ is reduced to NH_3 or N_2H_4 although the complex has the same d^6 configuration as Cr(0) and Mo(0) complexes. The energy levels of d electrons in the divalent Ru complex is much lower than those in the latter, and therefore the Ru complex has poorer Lewis basicity than the latter. The strong Lewis basicity with the Cr complex largely influences the reduction of the dinitrogen ligand.

On the other hand, it is known that dinitrogen ligand in Mo and W complexes can be reduced to NH_3 and N_2H_2 while in other d^8 or d^{10} complexes these reduction products have never been obtained. These experimental results are also attributed to the difference in Lewis basicity originating from their electronic structures of the latter complexes. Although the central metal as model adopted here is different from those in Mo and W complexes, these metals all have d^6 electron configuration. Therefore the characteristic MO feature in the d^6 complexes largely affects the possibility of the reduction of the nitrogen molecule in transition metal complexes.

Alkyne isomerization reagents: mixed alkali metal amides[1]

SUZANNE R. ABRAMS

Plant Biotechnology Institute, National Research Council of Canada, Saskatoon, Sask., Canada S7N 0W9

Received January 4, 1984

SUZANNE R. ABRAMS. Can. J. Chem. **62**, 1333 (1984).

Addition of sodium and potassium alkoxides, particularly potassium *tert*-butoxide, to the lithium salts of either 1,2-diaminoethane or 1,3-diaminopropane afford alkyne isomerization reagents that effect triple bond migration to the end of a methylene chain under milder conditions and in higher yield than do previously reported reagents.

SUZANNE R. ABRAMS. Can. J. Chem. **62**, 1333 (1984).

L'addition d'alcoolates de sodium ou de potassium, particulièrement le *tert*-butylate de potassium, à des sels de lithium de diamino-1,2 éthane ou de diamino-1,3 propane fournit des réactifs permettant d'effectuer l'isomérisation de la triple liaison d'alcynes vers l'extrémité de la chaîne méthylène en utilisant des conditions expérimentales beaucoup plus douces et avec de meilleurs rendements que ceux rapportés antérieurement avec d'autres réactifs.

In connection with other studies of triple bond migration in long chain compounds, we required an alkyne isomerization reagent (1, 2) that could be prepared free of impurities. It was suspected that side reactions were taking place during preparation of the reagent, the sodium salt of 1,3-diaminopropane, from sodium hydride and 1,3-diaminopropane, as the reaction produced a brown solution. We now report the preparation and use of a new, cleaner reagent which causes triple bonds to be isomerized to the terminus of a long chain rapidly and under mild conditions. This system is much more amenable to larger scale preparations of terminal alkynes and alkynols.

Lithium metal reacts with 1,3-diaminopropane to give a white suspension of the alkali metal amide in the colourless diamine (3, 4). Reaction of sodium or potassium hydride with 1,3-diaminopropane affords brown reaction mixtures. While the last two are very effective isomerization reagents, rearrangements with the lithium amide proceed slowly. We anticipated that addition of sodium or potassium salts to the preformed lithium reagent might effect exchange of the cation and afford a clean, colourless, potent isomerization reagent.

To study the progress of rearrangement reactions we employed a model system we have used previously (3), the isomerization of 2- to 9-decyn-1-ol with n-decanol as internal standard. Figure 1 shows the rate of formation of the terminal isomer using $LiNH(CH_2)_3NH_2$ alone (6.5 equivalents of reagent 2.0 *M* in 1,3-diaminopropane at 70°C). In an hour 9-decyn-1-ol comprises 91% of the total decyn-1-ol mixture, but the yield based upon the internal standard is only 52%. Addition of one equivalent of potassium carbonate to the preformed lithium reagent, which did not appear to dissolve in the medium, or of potassium chloride, which did dissolve, gave no change in the rate or in the yield. When one equivalent of potassium *tert*-butoxide was employed, a yellow reagent was obtained that gave marked improvement in the rate of the reaction (99% 9-decyn-1-ol in 15 min) and a yield of 65%. Isomerization of 2-decyn-1-ol with potassium *tert*-butoxide alone in 1,3-diaminopropane gave no terminal isomer. Increasing the ratio of potassium *tert*-butoxide to 2-decyn-1-ol to 4:1 and decreasing the temperature of the reaction to ambient led to a pale lemon-yellow reagent that gave vastly improved results (Fig. 2).

A variety of other potassium and sodium alkoxides were tested using the conditions optimized with potassium *tert*-butoxide. Table 1 summarizes the results obtained. It is interesting to observe that in the sodium series, the methoxide derived reagent is superior to the ethoxide and the isopropoxide, while in the potassium series *tert*-butoxide gives the best results. This apparent reversal in reactivity is most likely due to the greater solubility of potassium *tert*-butoxide in the diamine.

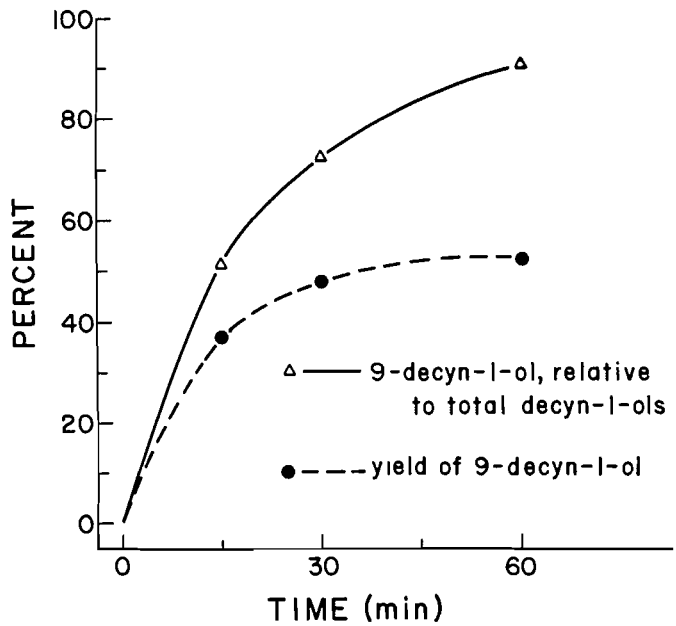

FIG. 1. Isomerization of 2- to 9-decyn-1-ol (1.0 equivalent) using $LiNH(CH_2)_3NH_2$ (6.5 equivalents), 2.0 *M* in 1,3-diaminopropane, at 70°C

Addition of potassium *tert*-butoxide to the colourless lithium salt of 1,2-diaminoethane resulted in rapid development of an intense purple colour which faded after about 5 min affording a brown solution. Wotiz *et al.* (5) have observed similar coloration in the reaction of strong bases with vicinal diamines. They postulated the intermediacy of pyrazine type radical species. Although by-products are obviously being formed in the current case, the reagent produced is very effective, affording 99% 9-decyn-1-ol in 93% yield in 15 min at room temperature, using the same ratios of alkoxide, diamine, and substrate.

The new mixed systems are particularly useful for preparative purposes. Both 1,2-diaminoethane and 1,3-diaminopropane work well. Reactions may be scaled up easily and the

reagents are relatively inexpensive. Crude products are entirely free of mineral oil, which is advantageous in the synthesis of hydrocarbons. Table 2 summarizes results obtained for acetylene isomerizations of a variety of substrates, and both diamines. Yields are of pure products. Reaction conditions required to effect complete isomerization of the triple bond along a 24-carbon chain have been reduced from overnight at 80°C with a yield of 47% (2) to 2 h at room temperature with a yield of chromatographed 23-tetracosyn-1-ol of 82%. An isomerization reaction of 7-tetracosyn-1-ol to 23-tetracosyn-1-ol is described in full.

TABLE 2. Isomerization of alkynes and alkynols with lithium alkyl amides and added potassium *tert*-butoxide[a]

Starting material	Product	Reaction conditions/time (h)	Yield (%)
2-Decyn-1-ol	9-Decyn-1-ol	1,3-Diaminopropane 0.5	76

[a]Using 6.5 equivalents $LiNH(CH_2)_3NH_2$, 4.0 equivalents KO*t*Bu, 1.0 equivalent substrate, room temperature.

Experimental

Decyn-1-ol/decanol mixtures were analyzed as described previously (6). Proton nmr spectra were obtained on a Varian EM 390 spectrometer, with deuterochloroform as solvent and internal tetramethylsilane as reference. Melting points are uncorrected.

23-Tetracosyn-1-ol

Under a slight positive pressure of dry nitrogen, 1,3-diaminopropane (10.0 mL, previously distilled from BaO and stored over 4 Å sieves) was added to lithium (140 mg, 20 mmol, washed free of mineral oil with hexane). The mixture was heated and stirred at 70°C for approximately 2 h until the blue colour had discharged, and a milky white suspension of the lithium salt was obtained. The mixture was cooled to room temperature and potassium *tert*-butoxide (1.3 g, 12 mmol) was added all at once, affording a pale yellow solution. After stirring for 15 min addition of 7-tetracosyn-1-ol (2) (1.05 g, 3.0 mmol) in one portion resulted in the reaction mixture turning orange with suspended white solid. Stirring was continued for a further 2.0 h and the mixture poured into water. The product was extracted with $CHCl_3$ (4×). The combined organic phases were washed successively with water, and dilute HCl and NaCl solution, the dried over Na_2SO_4. The solution was filtered and the solvent evaporated to yield 1.0 g white solid. The product was chromatographed over silicic acid (100 g), eluting with 50% ether/50% hexane, to give 23-tetracosyn-1-ol (860 mg, 82%), mp (CH_3OH) 76–77°C (lit. (2) mp 77–78°C); ^1H nmr: 3.65 (t, J = 6 Hz, 2H), 2.20 (m, 4H), 1.90 (t, J = 2.5 Hz, 1H), and 1.2–1.9 (m, 4H).

Further studies on the synthesis of symmetrical anhydrides and 2,4-disubstituted-5(4*H*)-oxazolones from *N*-alkoxycarbonylamino acids using soluble carbodiimide

ALENKA PAQUET,[1] FRANCIS M. F. CHEN, AND N. LEO BENOITON

Department of Biochemistry, University of Ottawa Health Sciences, Ottawa, Ont., Canada K1H 8M5

Received November 28, 1983

ALENKA PAQUET, FRANCIS M. F. CHEN, and N. LEO BENOITON. Can. J. Chem. **62**, 1335 (1984).

Pure symmetrical anhydrides of *N*-alkoxycarbonyl (ROCO)-valine, for R = ethyl, *tert*-butyl, trichloroethyl, *p*-nitrobenzyl, *p*-methoxybenzyl, and 9-fluorenylmethyl, and *N*-ethoxycarbonylaminoisobutyric acid have been prepared using 0.5 equivalents of *N*-ethyl-*N'*-(3-dimethylaminopropyl)carbodiimide hydrochloride in dichloromethane followed by removal of side-products by washing with aqueous solutions. When an excess of carbodiimide was used, 2-alkoxy-5(4*H*)-oxazolone was also generated, except when R = trichloroethyl. High yields of pure 5(4*H*)-oxazolone were obtained when R = ethyl. The 2-(9-fluorenylmethyloxy)-5(4*H*)-oxazolone gradually underwent a β-elimination during manipulation or storage.

ALENKA PAQUET, FRANCIS M. F. CHEN et N. LEO BENOITON. Can. J. Chem. **62**, 1335 (1984).

On a préparé les anhydrides symétriques purs de la *N*-alkoxycarbonyl (ROCO)-valine (où R = éthyl, *tert*-butyl, trichloroéthyl, *p*-nitrobenzyl, *p*-méthoxybenzyl et fluorènyl-9 méthyl) et de l'acide *N*-éthoxycarbonyl aminoisobutyrique en utilisant 0.5 équivalents de chlorhydrate de *N*-éthyl, *N'*-(diméthylamino-3 propyl)carbodiimide dans le dichlorométhane et en enlevant ensuite les produits secondaires par lavage avec des solutions aqueuses. Lorsqu'on utilise un excès de carbodiimide, il y a aussi formation de l'alkoxy-2 (4*H*)-oxazolone-5 (sauf lorsque R = trichloroéthyl). On a obtenu de bons rendements de la (4*H*)-oxazolone-5 lorsque R = éthyl. La (fluorènyl-9 méthyloxy)-2 (4*H*)-oxazolone-5 subit lentement une élimination au cours des manipulations ou de l'entreposage.

[Traduit par le journal]

The solid phase method of peptide synthesis according to Merrifield (1) involves the carbodiimide-mediated reaction of an *N*-alkoxycarbonylamino acid (**1**) with the amino group of a polymer-supported peptide chain. The activated intermediates undergoing aminolysis are the *O*-acylisourea (**2**) which is formed initially, the symmetrical anhydride (**3**) produced by the reaction of **2** with **1**, and in some cases the 2-alkoxy-5(4*H*)-oxazolone (**4**) generated by cyclization of **2**(2) or the reaction of carbodiimide with **3**(3) (see refs. 4 and 5 for reviews). In the modified version, the symmetrical anyhrides are preformed by reaction of **1** with 0.5 equiv. of dicyclohexylcarbodiimide and used without isolation after removal of the dialkylurea by filtration (see ref. 4).

Purified anhydrides **3** ($R^1 = (CH_3)_3C$) are available from the acid salt and phosgene (6). Their use to eliminate side-reactions has been recommended (7). Our realization that $(Boc\text{-}Val)_2O$[2] was resistant to aqueous washes (8) led us to develop a simple procedure for preparing anhydrides **3** using a soluble carbodiimide. Reaction of **1** with 0.5 equiv. of EDC in dichloromethane followed by washing the solution with aqueous acid and sodium hydrogen carbonate gave excellent yields of **3** ($R^1 = (CH_3)_3C$ and $C_6H_5CH_2$) except for derivatives of valine and isoleucine (9). It transpired that in the latter cases a second neutral product, the 2-alkoxy-5(4*H*)-oxazolone (**4**), was also formed, in 20% yield (2). Further study revealed that by increasing the amount of EDC to 1.5 equiv., more 5(4*H*)-oxazolone than anhydride was produced by the reaction. Pure compounds **4***a* were obtained from the mother liquors after

precipitation of the anhydrides using light petroleum (2). Our discovery of the implication of these novel 2-alkoxy-5(4*H*)-oxazolones in some carbodiimide-mediated reactions has prompted us to examine the general applicability of the method used for their preparation. Implicit in this study was the assessment of the method of preparing the corresponding symmetrical anhydrides. The results are described in this communication.

Valine bearing various urethane-type protectors was reacted with 0.5 equiv of EDC in dichloromethane. Removal of the water-soluble components by a mild aqueous acid and alkali wash provided the pure symmetrical anhydrides of *N*-ethoxycarbonyl-, *N*-trichloroethoxycarbonyl-, *N*-*p*-nitrobenzyloxycarbonyl-, and *N*-9-fluorenylmethyloxycarbonyl-L-valine in 79–87% yields (Table 1). A lower yield (68%), paralleling the lower yields previously obtained for the *tert*-butoxycarbonyl and benzyloxycarbonyl derivatives (9), was obtained for the *p*-methoxybenzyloxycarbonyl derivative. This poorer synthetic efficiency was due to the formation of the 5(4*H*)-oxazolone (**4***e*) as second product, and some release of the alkoxy group yielding *p*-methoxybenzyloxy alcohol. Generation of the alcohol implies concomitant formation of the *N*-carboxyanhydride which would have been destroyed by the aqueous washes. Formation of the 5(4*H*)-oxazolone (**4***g*), which was readily removed by precipitation of the anhydride with ether, also accounted for the lower yield (68%) in the preparation of *N*-ethoxycarbonylaminoisobutyric anhydride (**3***g*) (Table 1). The success with the derivatives of valine and aminoisobutyric acid in this work, combined with the previous work where unhindered residues gave high yields of **3** for R^1 = $(CH_3)_3C$ and $C_6H_5CH_2$(9), demonstrates that this method of preparing symmetrical anydrides is of general applicability. Since the original report (9), it has been used by others to prepare anhydrides of 9-fluorenylmethyloxycarbonylamino acids (10). The analogous reaction of *N*-acylamino acids and protected peptide acids with EDC gives the 2,4-dialkyl-5(4*H*)-oxazolone instead of the anhydride (11, 12, 5). Isolated anhydrides have been used in solid phase synthesis (10) and for synthesis in solution in aqueous dimethylformamide (13).

Reaction of acids **1***b–g* with 1.5 equiv. of EDC followed by removal of water-soluble components by an acid and alkali wash gave a mixture of anhydrides **3** and 5(4*H*)-oxazolones **4** in all cases except for Tec-Val-OH (**1***c*). The presence of the 5(4*H*)-oxazolone in the mixtures, as well as the proportions of the two products, could be established by ^{1}H nmr spectroscopy by virtue of the two characteristic differences previously identified between **3***a* and **4***a*, namely, the upfield shift in δ of the methyleneoxy protons of **4** relative to **3**, and the change in character of the C^α proton. In valine derivatives in particular where R^2 = $(CH_3)_2CH$, the C^α (R^3) proton multiplet in **1** or **3** becomes a sharp doublet in **4** due to removal of the —NH proton. These differences in nmr spectra are tabulated in Table 2. An additional feature of the spectra is the change in the two side-chain methyl group doublets in **3***a–f* which coalesce into a triplet in the corresponding cyclic structures **4***a–f*.

The complete absence (<1%) of oxazolone in the neutral product obtained from Tec-Val-OH was confirmed by reacting it with methylamine. Equimolar amounts of Tec-Val-NHCH$_3$ and Tec-Val-OH were generated, indicating that it was exclusively the anhydride. Aminolysis of an oxazolone produces no acid (<1%) from this reaction (5, 12). Its presence in a mixture makes the amide-to-acid ratio >1.

Among the substrates examined, the ethoxycarbonyl derivatives responded uniquely to the presence of excess EDC. The amount of anhydride formed was greatly diminished (8% yield), and eight times as much oxazolone was produced. Complete removal of the anhydride by precipitation with light petro-

leum allowed subsequent recovery of the 2-ethoxy-5(4*H*)-oxazolones **4***b* and **4***g* from the mother liquors in 62–68% yield. These were stable at −5°C at least for several days.

On the other hand, excess EDC had only a minor effect on the generation of anhydride from Mbc-Val-OH. Most of it (74% yield) could be removed by precipitation with light petroleum. 5(4*H*)-Oxazolone was present in the mother liquor, but its manipulation resulted in partial decomposition as evidenced by the liberation of *p*-methoxybenzyl alcohol.

An excess of EDC produced roughly equal amounts of anhydride and 5(4*H*)-oxazolone from the remaining substrates, Nbc-Val-OH and Fmc-Val-OH. Neither oxazolone could be purified by precipitating out the anhydride with light petroleum. Pure stable 2-*p*-nitrobenzyloxy-5(4*H*)-oxazolone **4***d* was finally obtained, albeit in low yield, by extraction into the hexane. The oxazolone from Fmc-Val-OH was destroyed by aqueous sodium hydrogen carbonate, producing 9-fluorenylmethyl alcohol. Most of the compound survived contact with water, and oxazolone **4***f*, free of anhydride, was obtained by extraction of an aqueous suspension of the mixture with light petroleum. It contained ≈15% of dibenzofulvene (**5**), and gradually decomposed on standing or in solution in deuterochloroform, producing more of the fulvene but no alcohol. The dibenzofulvene results from a β-elimination, the usual mechanism implicated in Fmc–NH cleavage (14) and is attributed to an auto-catalyzed β-elimination, namely the action of the basic secondary nitrogen atom of one molecule of 5(4*H*)-oxazolone on a second molecule. The instability exhibited by **4***f*, the oxazolone from Fmc-Val-OH, contrasts with the relative stability of the oxazolone from Boc-Val-OH (2).

In this and the previous work (2), only Tec-Val-OH amongst the N-alkoxycarbonylamino acids **1** failed to give rise to the 2-alkoxy-5(4*H*)-oxazolone in the presence of EDC. The reaction is therefore a general one for this type of derivative, except for those containing an unusually strong electron-withdrawing alkoxy group. It also pertains to derivatives of residues which are not β-methyl substituted (e.g. Ala, Leu) (2), though considerably less 5(4*H*)-oxazolone was present in the final reaction mixtures. In line with accepted notions on carbodiimide reactions, the immediate precursor of the oxazolone is considered to be the *O*-acylisourea (**2**) (ref. 2; see also ref. 5). Some oxazolone may arise from attack of the carbodiimide on the anhydride (3), but this is a slow reaction, and indications are that this can be at best a minor source for the oxazolone. The first and only other source identified for compounds **4** is the action of triethylamine on the acids **1** previously treated with chloride-forming reagents (15, 16). Examples have been restricted to a few benzyloxycarbonylamino acid derivatives.

Experimental

General

EDC (17) was purchased from Sigma Chemical Co. St. Louis. Light petroleum refers to the 30–60°C fraction, from Baker (Canlab). Magnesium sulfate was used for drying solutions. Solvents were removed at room temperature using a rotary evaporator. Melting points were taken by the capillary method and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 polarimeter using a 1-dm tube. Proton nmr spectra were recorded with a Varian T60 spectrometer. Chemical shifts are given in ppm relative to tetramethylsilane as internal standard for solutions in deuterochloroform. Elemental analyses were carried out by Mr. G. Morris of the Microanalytical Services of Agriculture Canada. Tec-Val-OH and Fmc-Val-OH were prepared using the corresponding succinimidyl carbonates (18). Mbc-Val-OH was obtained using the acyl azide (19).

N-Ethoxycarbonylamino acids

These were prepared using ethyl chloroformate according to the method used to prepare *N*-benzyloxycarbonylphenylalanine (20). Eoc-Val-OH(**1***b*), 90% yield, $[\alpha]_D^{24}$ −0.1° (*c* 1.0 ethanol). *Anal.* calcd. for $C_8H_{15}NO_4$: C 50.78, H 7.99, N 7.34; found: C 50.66, H 8.00, N 7.42. Eoc-Aib-OH (**1***g*), 48% yield, mp 81–83°C. *Anal.* calcd. for $C_7H_{13}NO_4$: C 47.99, H 7.48, N 7.99; found: C 47.72, H 7.24, N 8.03.

p-*Nitrobenzyloxycarbonyl-L-valine* (**1**d)

This compound was obtained in 71% yield using the chloroformate (21) and in 88% yield using the succinimidyl carbonate (18), mp 75–76°C $[\alpha]_D^{24}$ +4.8° (*c* 2.0 ethanol). *Anal.* calcd. for $C_{13}H_{16}N_2O_6$: C 52.70, H 5.44, N 9.45; found: C 52.76, H 5.85, N 9.03.

Symmetrical anhydrides (3)

These were prepared according to a published procedure (9) except that the solvent was not replaced by ethyl acetate (5) for work-up. A solution of the acid (**1**) (1mmol) and soluble carbodiimide EDC (0.5 mmol) in dichloromethane (20 mL) was stirred at 23°C for 2 h. The solution was washed successively with cold aqueous citric acid, sodium chloride, sodium bicarbonate, and sodium chloride, dried, and the solvent was removed by evaporation at 0°C. Physical data of the products appear in Tables 1 and 2. Only the *p*-methoxycarbonyl derivative **3***e* was difficult to crystallize. The crude product contained (nmr) 10–15% of 5(4*H*)-oxazolone **4***e* and some *p*-methoxybenzyl alcohol. The nmr spectra of anhydrides **3** were identical with those of the parent acids **1** except in the acid proton region (see Table 2).

2,4-Disubstituted-5(4H)-oxazolones (**4**)

These were prepared as described previously using an excess of EDC (2) but without the addition of $Et_3N \cdot HCl$. A solution of protected acid **1** (2 mmol) in CH_2Cl_2(20 mL) was added dropwise over 20 min to a stirred solution of EDC (3 mmol) in CH_2Cl_2(100 mL). After 30 min, the mixture was washed with cold 10% aqueous citric acid (20 mL), saturated aqueous $NaHCO_3$ (20 mL), and water (20 mL), and dried. The solvent was removed, light petroleum was added, and the mixture was left at −5°C. Products were isolated as described below. Pertinent nmr data appear in Table 2.

(S)-*2-Ethoxy-4-isopropyl-5(4*H*)-oxazolone* (**4**b)

Eoc-Val-OH (3 mmol) was reacted with EDC and the mixture was manipulated as described above. The mixture was filtered after 3 h of cooling to give 43.4 mg (8% yield) of $(Eoc\text{-}Val)_2O$. Evaporation of the mother liquor gave **4***b* as an oil (0.32 g; 62% yield), $[\alpha]_D^{24}$ − 51.1° (*c* 1.0, $CHCl_3$). *Anal.* calcd. for $C_8H_{13}NO_3$: C 56.12, H 7.65, N 8.17; found: C 55.77, H 7.59, N 8.38.

*Attempted preparation of 2-trichloroethoxy-5-isopropyl-5(4*H*)-oxazolone* (**4**c)

Tec-Val-OH (**1***c*) (2 mmol) was reacted with EDC and the mixture was manipulated as described above. Filtration after 5 h of cooling gave 0.38 g (66.6% yield) of $(Tec\text{-}Val)_2O$. Evaporation of the mother liquor gave a residue whose nmr spectrum corresponded to that of the anhydride. In a second experiment the product, after removal of the CH_2Cl_2, was mixed with an excess of CH_3NH_2 in anhydrous ether. The mixture was filtered to give $Tec\text{-}Val\text{-}O^- \cdot {}^+NH_3CH_3$. The mother liquor was evaporated to give Tec-Val-$NHCH_3$, mp 128–129°C, $[\alpha]_D^{25}$ −11.7° (*c* 0.67, $CHCl_3$). *Anal.* calcd. for $C_9H_{15}Cl_3N_2O_3$: C 35.37, H 4.94, N 9.16; found: C 35.27, H 5.16, N 9.04. The molar ratio of methylamine salt to methylamide was 1.03. This demonstrates that the mixture had not contained a significant amount of 5(4*H*)-oxazolone (see ref. 5).

(S)-*2-p-Nitrobenzyloxy-4-isopropyl-5(4*H*)-oxazolone* (**4**d)

Nbc-Val-OH (**1***d*) (2 mmol) was reacted with EDC and the mixture was manipulated as described above. The residue after removal of the CH_2Cl_2 contained anhydride and 5(4*H*)-oxazolone in a 1:1 ratio. Separation by light petroleum extraction was inefficient. Pure **4***d* was obtained in low yield by extraction into hexane and evaporation of the solvent. *Anal.* calcd. for $C_{13}H_{14}N_2O_5$: C 56.11, H 5.07; found: C 56.03, H 5.28.

Attempted preparation of 2-p-*methoxybenzyloxy-4-isopropyl-5(4*H*)-oxazolone (4e)*

Mbc-Val-OH (**1***e*) (5.19 mmol) was reacted with EDC and the mixture was manipulated as described above. Filtration after 5 h of cooling gave 0.40 g (74%) of (Mbc-Val)$_2$O. The filtrate contained some 5(4*H*)-oxazolone (**4***e*) but it could not be purified without some decomposition, with the concomitant liberation of *p*-methoxybenzyl alcohol.

(S)-*2-(9-Fluorenylmethyloxy)-4-isopropyl-5(4*H*)-oxazolone (4f)*

Fmc-Val-OH (**1***f*) (2 mmol) was reacted with EDC as described above. After 30 min, the solvent was removed and the residue was partitioned between cold light petroleum and water. The mixture was separated and the organic phase was washed twice with water. The solution was dried, and the solvent was removed to give 0.36 g (≈50%) of **4***f*; nmr δ: 4.08 (d, C^{α}—H), containing 15% of dibenzofulvene, nmr δ: 6.0 (s, H_2C=). The 5(4*H*)-oxazolone is completely decomposed after standing 16 h at 23°C, and is rapidly destroyed by aqueous $NaHCO_3$. A solution in $CDCl_3$ at 23°C decreased in concentration by 15% in 24 h, with the concomitant formation of dibenzofulvene. Variation of the synthetic reaction conditions had no significant effect on the outcome of the reaction.

*2-Ethoxy-4,4-dimethyl-5-(4*H*)-oxazolone (4g)*

Eoc-Aib-OH (1 mmol) was reacted with EDC as described above. Cooling the residue under light petroleum gave solid anhydride (0.08 mmol), followed by 0.10 g (68%) of **4***g*, semi-solid, after evaporation of the solvent. *Anal.* calcd. for $C_7H_{11}NO_3$: C 53.49, H 7.05, N 8.90; found: C 53.70, H 7.15, N 8.94.

J. C. SCAIANO, LAURA C. STEWART, P. LIVANT, and A. W. MAJORS. Can. J. Chem. **62**, 1339 (1984).

Absolute rate constants for the reactions of *tert*-butoxyl and triplet benzophenone, with a series of di-*tert*-amines have been obtained via laser flash photolysis. These diamines have in common the feature that the nitrogen centers are in the backbone of an aliphatic eight-membered ring at positions 1 and 5. A modest rate enhancement is observed, particularly for **1** in its H-abstraction reaction with *tert*-butoxyl, which may be explained by the operation of a stereoelectronic effect. From the absorption maxima of the radical cations of these diamines (produced quenching acetophenone triplets), information concerning the conformations of the eight-membered rings may be inferred. It is concluded that these radical-cations are stabilized by relatively strong through-space bonding interactions between the two nitrogen centers.

J. C. SCAIANO, LAURA C. STEWART, P. LIVANT et A. W. MAJORS. Can. J. Chem. **62**, 1339 (1984).

Faisant appel à la photolyse flash au laser, on a obtenu les constantes de vitesse absolues des réactions du *tert*-butoxyle et du triplet de la benzophénone avec diverses amines di-tertiaires. Toutes ces diamines sont caractérisées par le fait que les centres azotés sont situés en positions 1 et 5 d'un cycle aliphatique à huit chaînons. En particulier lors de la réaction d'abstraction d'hydrogène du composé **1** par le *tert*-butoxyle, on observe une légère augmentation de la vitesse de réaction que l'on peut expliquer par un effet stéréoélectronique. On peut déduire des informations relatives aux conformations des cycles à huit chaînons à partir des absorptions maximales des cations radicaux de ces diamines (produits par le piégeage des triplets de l'acétophénone). On en conclut que ces cations radicaux sont stabilisés par des interactions de liaison à travers l'espace qui sont relativement fortes et qui impliquent les deux azotes.

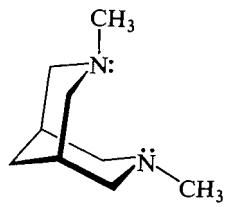
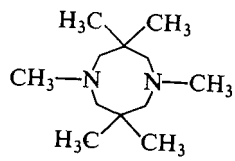
Introduction

The study of medium-ring (so-called mesocyclic) systems has provided chemists with a number of surprising results. In particular, heteroatom-substituted eight-membered rings are peculiar. 1,5-Dithiacyclooctane shows appreciable S−S interaction as evidenced by a splitting of 0.43 eV in its photoelectron (PE) spectrum (1). 1,4-Dithiacycloheptane, 1,5-dithiacyclononane, and 1,6-dithiacyclodecane each shows negligible S−S interaction (<0.1 eV), indicating that in the eight-membered case the conformation has the two sulfurs in close proximity. Also, electrochemical oxidation of these same bis-sulfides (2) occurs in the range 0.34−0.75 V (1,5-dithiacyclooctane is the most easily oxidized) as compared with normal sulfides 0.66−1.32 V. These oxidation potentials reflect the properties of the radical cations: that is, S----$S^{+}\cdot$ interaction is greatest in the 1,5-dithiacyclooctane radical cation. Other aspects of the peculiar eight-membered ring have been reviewed by Anet (3).

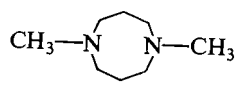
Bicyclic mesocycle-containing systems are also fascinating. The 3,7-diheteroatom bicyclo[3.3.1] skeleton may be thought of as a 1,5-diheteroatom cyclooctane with the addition of a one-carbon bridge across 3, 7. Here the commonly encountered chair−chair conformation (with respect to the bicyclic skeleton) is actually an example of the rare boat−boat form of an eight-membered ring. Recent PES study of 3,7-dimethyl-3,7-diazabicyclo[3.3.1]nonane (4) **1** showed that in the gas-phase the compound adopted the chair−chair form, probably with some flattening of the wings. We have examined the reactions of **1**−**3** with alkoxy radicals and ketone triplets, leading to the corresponding α-aminoalkyl radicals or radical cations.



1



2



3

Since the conformation of **1** is known with fair certainty, the behaviour of **1** serves to model a system in which transannular interaction in the ground state is large. The behaviour of **2** and **3** may then be compared to **1**, as well as with representative monoamines. A comparison of kinetic and spectroscopic parameters determined using laser photolysis techniques allows the evaluation of the importance of geometry on the behaviour of these substrates and the resulting radical-cations.

Particularly relevant to our study is the recent report by Lewis *et al.* (5) of cooperative effects in the exciplex interactions of stilbenes with mono and diamines; in the case of the former, exciplex quenching can be achieved by increasing concentration of amines. In the case of diamines the effects are strongly dependent upon conformational factors, in particular, the ability of the two nitrogen centers to approach enough for a considerable interaction to develop. Steric effects have been shown to play an important role. Grellman and Suckow had

also observed an example of exciplex quenching by amines (6).

In a recent study of proton affinities and ionization energies of bicyclic amines and diamines, Alder *et al.* (7) have shown that the stabilization of the diamine radical-cations by interaction with the second nitrogen center can exceed 11 kcal/mol.

Experimental

Compounds were either commercial samples or were prepared by literature procedures or slight modifications thereof, viz. **1**, **2**, and **3** (8). Purity was checked by gas chromatography.

Laser flash photolysis experiments were performed using a Molectron UV-24 nitrogen laser (337.1 nm, ~8 ns, up to 10 mJ/pulse) for excitation. A Tektronix R-7912 transient digitizer initially captures the signals, which are then transferred to a PDP-11/23 computer that also controls the experiment and provides suitable processing, storage and hardcopy facilities. Further details can be found elsewhere (9).

Results

Hydrogen abstraction by tert-*butoxyl*

Photodecomposition of di-*tert*-butyl peroxide in the presence of amines in a 1:2 (v/v) mixture of benzene and peroxide leads to hydrogen abstraction from the amine by *tert*-butoxyl, reactions [1] and [2].

$$[1]\quad Bu'OOBu' \xrightarrow{h\nu} 2Bu'O\cdot$$

$$[2]\quad Bu'O\cdot + RCH_2NR_2' \xrightarrow{k_A} Bu'OH + \dot{R}CHNR_2'$$

It has been established that the transient absorption signals from radicals of the type $\dot{R}CHNR_2'$ are, while detectable, relatively weak and not convenient for kinetic studies of this type (10–12). We have preferred to use a "probe technique", that we have described earlier (13), and used widely for *tert*-butoxyl (11, 13–16) and other radicals (17). Briefly, a second substrate, capable of generating strong, easily detectable signals is added to the system, so as to make the monitoring of the kinetic signals straightforward. It is well established that diphenylmethanol is a very convenient choice (13–16); reaction with *tert*-butoxyl yields the easily detectable diphenylhydroxymethyl radical:

$$[3]\quad Bu'O\cdot + Ph_2CHOH \xrightarrow{k_p} Bu'OH + Ph_2\dot{C}OH$$

The experimental pseudo-first order rate constant, associated with the build-up of the signal due to $Ph_2\dot{C}OH$ is given by:

$$[4]\quad k_{exp} = k_d + k_p[Ph_2CHOH] + k_A[Amine]$$

where k_d represents all first, or pseudo-first, order modes of *tert*-butoxyl decay (such as β-scission or abstraction from the solvent). At constant diphenylmethanol eq. [4] reduces to eq. [5].

$$[5]\quad k_{exp} = k_0 + k_A[Amine]$$

Diphenylmethanol was typically kept constant at around 0.1 *M*, while the amine concentrations were changed. Figure 1 shows a representative plot used to determine k_A. Values for k_A are listed in Table 1.

The absorption spectra of the α-aminoalkyl radicals derived from **1**, **2**, and **3** can be detected during flash photolysis. Figure 2 shows the spectra for the radicals from **1** and **2**. They are nearly identical, and they strongly resemble the spectrum of $\cdot CH_2N(CH_3)_2$ (10, 11). The spectrum of the α-aminoalkyl radical derived from **1** decays with clean second-order kinetics when monitored at 370 nm, having a decay constant:

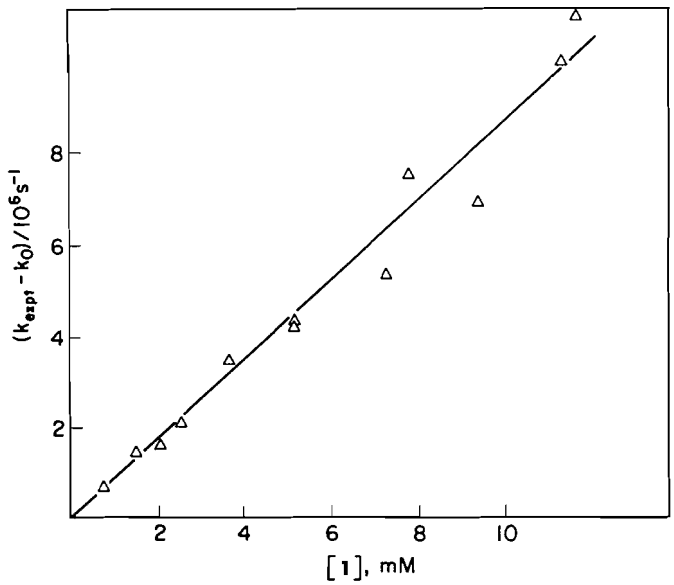

FIG. 1. Determination of k_A for **1** according to eq. [5], using 0.1 *M* diphenylmethanol as a probe.

TABLE 1. Kinetic parameters at 300 K[a]

Substrate	k_A ($Bu'O\cdot$)[b]	k_q[c]
Triethylamine	1.8×10^8	4.1×10^9
DABCO[d]	2.8×10^7	3.1×10^9
1	8.7×10^8	5.9×10^9
2	5.9×10^8	5.4×10^9
3	6.1×10^8	6.3×10^9

[a]All values in units of M^{-1} s^{-1}.
[b]1:2 benzene:di-*tert*-butyl peroxide solvent.
[c]For benzophenone in benzene.
[d]1,4-Diazabicyclo[2.2.2]octane.

$$2k_t/\epsilon = 1.25 \times 10^6 \text{ cm s}^{-1}$$

which compares well with the corresponding value for $\cdot CH_2N(CH_3)_2$. Here ε is the extinction coefficient for the corresponding α-aminoalkyl radical at the monitoring wavelength.

Quenching of benzophenone triplets

The quenching of benzophenone triplets by amines **1**–**3** was examined in benzene at 300 K. The signals were monitored at 540 nm where both benzophenone triplet and the ketyl radical derived from it absorb. The absorbance of the latter is weaker than the former at this wavelength. In the presence of amine, a fast decay (quenching of triplet by H-abstraction from amine) followed by a slow decay (subsequent reactions of the radicals produced in the quenching step) is observed. The ratio of optical density after and before triplet decay is a measure of the yield of ketyl radical. Using triethylamine as an actinometer (18), it can be estimated that at least 80% of the quenching takes place via formation of ketyl radicals (i.e. by H-abstraction from the amine), reactions [6] and [7].

$$[6]\quad Ph_2CO \xrightarrow{h\nu} {}^{1}Ph_2CO^* \xrightarrow{ISC} {}^{3}Ph_2CO^*$$

$$[7]\quad {}^{3}Ph_2CO^* + RCH_2NR_2' \rightarrow Ph_2\dot{C}OH + \dot{R}CHNR_2'$$

The slope of plots of the reciprocal triplet lifetime (τ_T^{-1}) vs. amine concentrations is the quenching rate constant, k_q; these are listed in Table 1.

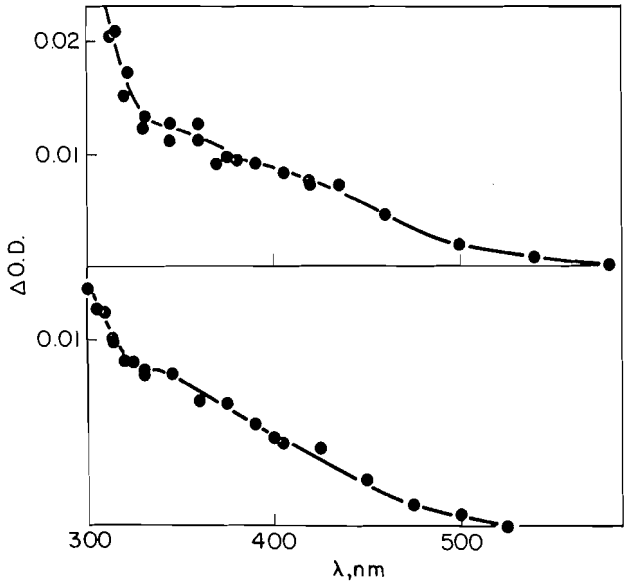

FIG. 2. Spectra of the α-aminoalkyl radicals produced by reaction of *tert*-butoxyl with **1** (top) and **2** (bottom).

Hydrogen abstraction from **1**–**3** by benzophenone triplet is roughly an order of magnitude faster than these abstractions by *tert*-butoxyl. We note that while the products of reaction in benzene reflect hydrogen abstraction, the process may involve charge transfer interactions and, indeed, the radical ions may be the expected products in polar media.

Quenching of acetophenone triplets

In polar solvents, in this case acetonitrile:water 4:1 (v/v), excited acetophenone undergoes single-electron transfer with an amine to give the acetophenone radical-anion and the amine radical-cation, both of which can be observed on the time scale of the present experiments.

[8] $PhCOCH_3 \xrightarrow{h\nu} \rightarrow PhCOCH_3^*$

[9] $PhCOCH_3^* + R_3N \xrightarrow{k_q} [PhCOCH_3]^{-\cdot} + R_3N^{+\cdot}$

For $R_3N = Et_3N$ we observe a transient maximum at ~445 nm, which we assign to the ketone radical-anion. The signals due to the amine radical-cation are expected to be very weak in this spectral region and easily monitored only in the uv region. To our initial surprise, we found that when the substrate was any of the mesocyclic diamines used in this work there were strong, readily observable signals in the visible region, in addition to those expected from the ketone radical-anion (*vide supra*). The new signals can be deconvoluted by subtracting those of the ketone radical-anion and show maxima in the 480–590 nm region, depending on the substrate (**1**–**3**). These signals are not due to the ketyl radical, $PhC(OH)CH_3$, which is known to absorb at 415 nm (19) and whose spectrum was also recorded in our laboratory by photoreduction of acetophenone by 1-phenylethanol. The new signals in the 480–590 nm region are attributed to the corresponding diamine radical-cations.

After investing considerable effort into deconvoluting the signals mentioned above, we discovered that a rather simple experimental trick allowed the straightforward separation of the spectra. The introduction of a trace of oxygen (≤1% O_2 in the gas phase above the solution) into the diamine–acetophenone system leads to rapid reaction of the acetophenone radical-anion with oxygen, leaving an unadulterated spectrum of the diamine radical-cation. The spectra obtained using the O_2-injection method are shown in Fig. 3 and the absorption maxima are recorded in Table 2. Triethylamine radical cation exhibits an absorption maximum at λ ≤ 350 nm under these conditions. The cyclic diamines show an extremely large shift to longer wavelengths.

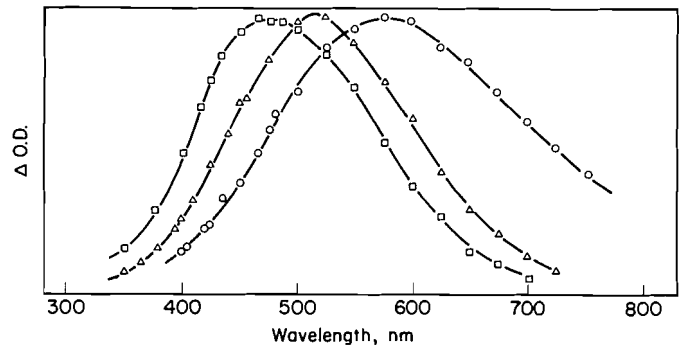

FIG. 3. Transient spectra of the radical cations from **1** (△), **2** (○), and **3** (□) produced by reaction of acetophenone triplets in 1:4 water–acetonitrile using the oxygen injection technique (see text).

TABLE 2. Spectroscopic data for the various diamines examined

Amines	λ_{max}, nm[a]	IP_1, eV	IP_2, eV	Δ_{NN}, eV
1	520	7.84	8.35	0.51
2	584	7.35	8.05	0.70
3	480	8.02	8.02	≤0.2

[a]Transient absorption of radical cation in 1:4 water:acetonitrile at 300 K.

Discussion

Kinetics

Our kinetic results have been summarized in Table 1. The very low value for 1,4-diazabicyclo[2.2.2]octane (DABCO) has been explained in terms of a stereoelectronic effect (11). The value for triethylamine was chosen as a point of reference because essentially free rotation about the C—N bonds would average the stereoelectronic effect in this case. Rate constants for hydrogen abstraction from **1**, **2**, and **3** are all substantially higher than for triethylamine. To some extent this difference must reflect an increase in the reaction path degeneracy (i.e. two amine centers rather than one); however, the value of k_A is in all cases over twice that for the monoamine, generally displaying a modest rate enhancement. The effect is more marked for **1**, and suggests that one of the two non-equivalent hydrogens of each —CH_2— is held (at least part of the time) in a conformation favorable to H-abstraction. From molecular mechanics calculations (*vide infra*) we find the dihedral angles shown below (Newman projection down an N—CH_2 bond of **1**).

The anti hydrogen is the likely candidate for abstraction, since the developing *p*-orbital would be in a good position to overlap with the nitrogen lone pair. The anti hydrogen would not be as effective in this regard as a hydrogen which eclipses the lone pair. Because of this, and because six of the fourteen α-hydrogens of **1** are N—CH_3 hydrogens for which no stereoelectronic effect is to be expected, the rate enhancement is modest.

The effect observed in the case of benzophenone triplets is very small; in fact, smaller than the increase in reaction path degeneracy. This is hardly surprising since these processes approach diffusion control, and for a diffusion controlled process one would not expect to observe any effect (i.e., the "chemistry" no longer determines the kinetic behaviour).

Spectroscopy

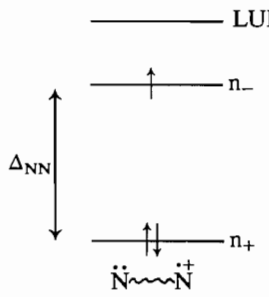
The spectra in Fig. 3 are the first reported that unequivocally show that radical-cations from diamines with suitable geometry involve considerable interaction between the two nitrogen centers.

In a study relevant to the discussion presented herein Halpern (20) attributed a shift in the fluorescence maximum from 282 nm for trimethylamine to 365 nm for *N,N,N′,N′*-tetramethyl-1,3-propanediamine to internal excimer formation in the diamine case.

More recently, Lewis *et al.* (5) studied the quenching of stilbene singlet by mono- and diamines. Their results led them to conclude that the positive charge on the nitrogen in these exciplex-mediated reactions could be stabilized by a second nitrogen center in inter- or intramolecular interactions which effectively amount to a through-space (and perhaps relatively loose) three electron bond. In the present case, the molecular orbitals formed by symmetric (n_+) and antisymmetric (n_-) combination of the nitrogen "lone pair" orbitals will be split to an extent dependent on the strength of the nitrogen−nitrogen interaction (which we will call Δ_{NN}). Presumably, in the radical cation the n_+ is doubly occupied and the n_- is singly occupied, to a first approximation. The stronger the nitrogen−nitrogen interaction is, the higher in energy the n_- orbital moves, and the lower in energy and longer in wavelength the excitation process from the n_- HOMO becomes.

Thus the absorption spectrum of the radical cation provides information about Δ_{NN} and about the proximity of the two nitrogens, if it is assumed Δ_{NN} is a through-space interaction, and that the observed visible absorption band corresponds to excitation of the n_- electron to the LUMO.[3]

From the results in Table 2, $\mathbf{2}\cdot^+$ has the two nitrogens in closest proximity, in $\mathbf{1}\cdot^+$ they are less intimate, and in $\mathbf{3}\cdot^+$ the N—N distance is largest. All three exhibit *some* N−N interaction since on formation of the radical cation the electron is donated to ketone triplet from an antibonding (n_-) orbital, leaving a N—N "bond" of bond order 0.5 where no bond existed before.



It is not surprising that $\mathbf{1}\cdot^+$ would manifest a significant nitrogen−nitrogen interaction, since the proximity of the heteroatoms is fairly rigidly fixed by the bicyclic skeleton. It is surprising, however, that the (presumably) more flexible monocyclic systems would manifest a significant nitrogen−nitrogen interaction. To rationalize these results, molecular mechanics calculations (21) were performed which were designed to probe whether the change in geometry from two pyramidal nitrogens to one pyramidal and one trigonal nitrogen *in itself* engenders a shortening of the N—N distance. That is, disregarding partial bond formation and charge−dipole interactions, does the alteration of one nitrogen from pyramidal to flat have the effect of drawing the two nitrogens together? Suffice it to say that molecular mechanics calculations showed a plethora of ring conformations energetically accessible to **2** and **3** and their respective radical cations, and the details of these calculations as well as a variable temperature nmr study of **2** will be reported shortly. In the context of the present discussion it is fair to conclude that in **1**−**3** the loss of a single electron (*a*) leads to a reduction in strain energy (3.5−7.5 kcal/mol) and (*b*) has almost no effect on the N—N distance (contraction by only 1% at most). Therefore, the two nitrogens are not thrown together upon ionization by the steric demands of the ring. They may or may not be thrown together by formation of a partial bond ("3-electron σ-bond" (7)) between them. Assuming for the moment no dramatic change in geometry upon loss of a single electron, one may infer something about the geometry of the radical cations (and hence about their λ_{max} values) from any technique which sheds light on the geometry of the parent diamines.

As mentioned in the Introduction, Δ_{NN} is available for **1** from examination of the doublet separation of the lone pair ionization band in the photoelectron spectrum, viz. Δ_{NN} = 0.51 eV (4). We have obtained the photoelectron spectrum of **2** and **3** and we find Δ_{NN} = 0.70 eV and Δ_{NN} = ≤0.2 eV (one band), respectively. These results are consistent with an ordering of N—N interactions as **2** > **1** >**3**, which is exactly the ordering of λ_{max} for the radical cations. Therefore, either the N−N interaction in the radical cation is dictated by the steric demands of the ring, and the λ_{max} values *should* mirror the Δ_{NN}'s found from photoelectron spectroscopy of the parent amines, or the N−N interaction in the radical cation is dictated mainly by the three-electron σ-bond between nitrogens and the agreement with PES results on the parent diamines is fortuitous. Probably both effects are at work. At any rate, the discovery of a nonrigid system showing such remarkable cooperative effects in *both* the ground state and the radical cation is of interest.

Received November 8, 1983

BRENDA M. LOUIE and ALAN STORR. Can. J. Chem. **62**, 1344 (1984).

The reaction of the symmetrical bidentate chelating pyrazolyl gallate ligands $[Me_2Ga(N_2C_3HR_2)_2]^-$ (where R = H or Me) with the rhenium dimer molecule $[Re(CO)_4Cl]_2$ are described. In addition, the novel unsymmetrical bidentate chelating pyrazolyl gallate ligands $[Me_2Ga(N_2C_3HR_2)(OH)]^-$ are introduced and their reactivities towards the $[Re(CO)_4Cl]_2$ molecule detailed. Substitution reactions of the tetracarbonyl rhenium species produced by the above reactions are described, and possible conformations for the various complexes are suggested on the basis of ^1H nmr and ir results.

BRENDA M. LOUIE et ALAN STORR. Can. J. Chem. **62**, 1344 (1984).

On décrit la réaction de ligands chélatants bidentates symétriques, les gallates de pyrazolyle $[Me_2Ga(N_2C_3HR_2)_2]^-$ (où R = H ou Me), avec la molécule dimère de rhénium $[Re(CO)_4Cl]_2$. De plus, on introduit de nouveaux ligands chélatants bidentates qui ne sont pas symétriques, les gallates de pyrazolyle $[Me_2Ga(N_2C_3HR_2)(OH)]^-$, et on détaille leurs réactivités vis-à-vis la molécule de $[Re(CO)_4Cl]_2$. On décrit les réactions de substitution des espèces rhénium tétracarbonyle produites par les réactions décrites ci-dessus et, en se basant sur des spectres ir et de rmn du ^1H, on suggère des conformations possibles pour les divers complexes.

Introduction

The syntheses of the bidentate chelating ligands $[Me_2Ga(N_2C_3HR_2)_2]^-$ (where R = H or Me), and their complexation to divalent transition metal ions have been detailed previously (1–4). In addition, a number of allylic Ni and Pd complexes containing these ligands have also been reported (5). Recently Mn, Mo, and W carbonyl derivatives incorporating the ligand where R = H have been described (6). The present account details the reactions of $[Re(CO)_4Cl]_2$ with the above symmetrical ligands. The syntheses of the novel unsymmetrical ligands $[Me_2Ga(N_2C_3HR_2)(OH)]^-$ (where R = H or Me) and their reactivity towards the above Re dimer are also described.

Experimental

Starting materials

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and stored in the dry box following distillation. Benzene and methylene chloride were treated in a similar manner after refluxing over molten potassium and P_2O_5 respectively. Pyrazole (Aldrich) and PPh_3 (MCB) were used as supplied. $[Re(CO)_4Cl]_2$ was prepared from $Re_2(CO)_{10}$ (Strem) and Cl_2 (Matheson) as described in the literature (7). The symmetric bidentate gallium ligands $Na^+[Me_2Ga(N_2C_3HR_2)]^-$ (R = H or Me) were prepared as described previously (4) and used as THF solutions. $[Me_2Ga(OH)]_4$ was prepared from Me_3Ga(4) by a literature method (8). Analytical and ir data for the complexes described below are given in Table 1. ^1H nmr data are given in Table 2.

Preparation of $[Me_2Ga(N_2C_3H_3)_2]Re(CO)_4$

To a solution of $[Re(CO)_4Cl]_2$ (1.000 g, 1.498 mmol) dissolved in 50 mL THF two molar equivalents of $Na^+[Me_2Ga(N_2C_3H_3)_2]^-$ in 25 mL of the same solvent were added and the resultant mixture was stirred overnight. The THF was then removed *in vacuo* and the remaining off-white residue extracted with benzene and filtered. Evaporation of benzene resulted in a sticky, air-sensitive pale yellow solid. Residual solvents were removed by drying this solid at ~45°C *in vacuo* for several days. Yield ~60–70%.

Preparation of $[Me_2Ga(N_2C_3HR_2)_2]Re(CO)_3X$ [R = H or Me; X = PPh_3 or $N_2C_3H_4$]

For these reactions the $[Me_2Ga(N_2C_3HR_2)_2]Re(CO)_4$ (R = H or Me) complexes were not isolated but were prepared in THF solution as described above. Assuming a 100% yield, one molar equivalent of X dissolved in 25 mL THF was added and the resultant solution stirred for 12 h. The solvent was subsequently removed *in vacuo* and the remaining residue extracted with benzene and filtered. The complexes where R = H were air-stable white powders or colourless prisms. Yields ~90–100%. When R = Me the products could only be solidified after extended drying *in vacuo*. Impurities of X, $[Me_2Ga(N_2C_5H_7)]_2$ and $Re_2(CO)_{10}$ were sublimed out of these reaction mixtures. Although the products were moderately air stable as solids they quickly decomposed in solution on exposure to air. Yields ~30–35%.

Preparation of the ligands $Na^+[Me_2Ga(N_2C_3HR_2)(OH)]^-$ (R = H or Me)

In a typical preparation $[Me_2Ga(OH)]_4$ (0.905 g, 1.938 mmol) and $Na^+(N_2C_3H_3)^-$ (0.698 g, 7.755 mmol), both dissolved in 30 mL THF, were combined and the mixture stirred overnight. The clear, colourless solution was diluted with THF to 250.0 mL in a volumetric flask and aliquots were withdrawn for use in the following reactions.

Preparation of $[Me_2Ga(N_2C_3HR_2)(OH)]Re(CO)_3X$ (R = H or Me; X = CO or PPh_3)

These complexes were prepared using a similar procedure to that described above for the analogous compounds containing the $[Me_2Ga(N_2C_3H_3)_2]^-$ ligand. When X = CO, the hydroxo products were extracted with CH_2Cl_2, due to insolubility in benzene. The compounds were isolated as air-sensitive, off-white powders. Yields ~50–60%.

Spectra and analysis

Mass spectra were recorded on a Varian MAT CH4 mass spectrometer operating at 70 eV. Infrared spectra were recorded on a Perkin Elmer 598 spectrometer and ^1H nmr spectra were obtained on either a Bruker WP-80 or a Varian XL-100 spectrometer using FT techniques. Elemental analyses were performed by Mr. P. Borda of the U.B.C. Microanalytical Laboratory.

Results and discussion

The dimethylbis(1-pyrazolyl)gallate ligand, $[Me_2Ga(N_2C_3H_3)_2]^-$, reacted with $[Re(CO)_4Cl]_2$ to form an unstable tetracarbonyl complex with the gallate ligand occupying *cis* positions in the octahedral molecule. The monomeric nature of the product was confirmed by mass spectral analysis. A weak parent ion signal due to the ion $[Me_2Ga(N_2C_3H_3)_2]Re(CO)_4^+$ (=

P^+) was observed with a relative intensity of ~2.5% of the most intense signal which corresponded to the ion, P − CO − Me^+. Intense signals were also observed for ions resulting from the successive loss of four CO groups from either the P^+ or P − Me^+ ions. In addition to the expected signals arising from the tetracarbonyl species the mass spectrum also contained weak signals due to ions arising from the complex [MeGa$(N_2C_3H_3)_3$]$Re(CO)_3$. The appearance of this minor product was not entirely unexpected as similar results have been observed in analogous systems. Thus, when the dihydrobis(1-pyrazolyl)-borate ligand, $[H_2B(N_2C_3H_3)_2]^-$, was reacted with the pentacarbonyls, $M(CO)_5Br$ (where M = Mn or Re), at room temperature no tetracarbonyl complex formed. Instead the compounds $[H_2B(N_2C_3H_3)_2]M(CO)_3(N_2C_3H_4)$ were isolated in low yields

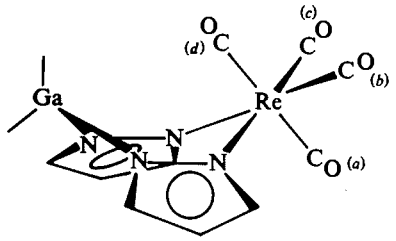

FIG. 1. Proposed conformation of the tetracarbonyl complex $[Me_2Ga(N_2C_3H_3)_2]Re(CO)_4$.

together with the corresponding decacarbonyl, $M_2(CO)_{10}$. Furthermore, when the above Mn borate complex was refluxed in THF for 24 h an internal condensation reaction took place, resulting in the compound $[HB(N_2C_3H_3)_3]Mn(CO)_3$ (9). In addition when the gallate ligand, $[Me_2Ga(N_2C_3H_3)_2]^-$, was stirred with $Mn(CO)_5Br$ in THF, with no added pyrazole present, the complex $[Me_2Ga(N_2C_3H_3)_2]Mn(CO)_3(N_2C_3H_4)$ was isolated in low yield (6). Again, in this reaction, no evidence of the expected tetracarbonyl species was observed.

The introduction of methyl groups at the 3- and 5-positions of the pyrazolyl rings of the gallate ligand led to a rhenium tetracarbonyl complex of much lower stability. In fact, although spectral evidence for the desired complex was observed, attempts at isolating a pure sample of $[Me_2Ga(N_2C_5H_7)_2]Re(CO)_4$ were unsuccessful. Repeated contamination of the product with the known stable dimer $[Me_2Ga(N_2C_5H_7)]_2$ (3) indicate that the complex was disproportionating.

It is well known that transition metal complexes containing the bis(1-pyrazolyl)gallate or -borate ligands generally adopt a boat conformation for the central M—(N—N)$_2$—M′, (where M = transition metal, M′ = B or Ga) six-membered ring. This situation is dictated by a combination of steric and electronic factors (3, 10). Such a conformation in the complex $[Me_2Ga(N_2C_3H_3)_2]Re(CO)_4$ places the two gallium methyl groups in inequivalent environments (Fig. 1) and leads to two singlets for the $GaMe_2$ group in the ^1H nmr spectrum of the compound (Table 2). On reaction of the tetracarbonyl complexes $[Me_2Ga(N_2C_3HR_2)_2]Re(CO)_4$ (R = H or Me), with PPh_3 or pyrazole, $N_2C_3H_4$, monosubstituted tricarbonyl products were formed. The ^1H nmr spectra (Table 2) of the products from these reactions clearly indicated that the position of substitution must be at position (*a*) or (*d*) of Fig. 1 since the two bridging pyrazolyl groups gave only one set of signals. The solution ir spectra of these tricarbonyl products (Table 1) each contained three strong bands in the carbonyl stretching region, a pattern indicative of facial coordination of the three CO groups (11) and strongly supportive of substitution at either position (*a*) or (*d*) in the original syntheses. This pattern of substitution would also be predicted on *trans*-effect arguments — the CO group *trans* to another CO group would be expected to be more labile than one opposite to a pyrazolyl group. A recent X-ray structure determination of the complex $[Me_2Ga(N_2C_3H_3)_2]Mn(CO)_3(N_2C_3H_4)$ shows definitively this type of arrangement, with the pyrazole ligand occupying the (*a*) position in the molecule (6). Molecular models indicate that this would be the sterically favored position of substitution since bulky substituents in the (*d*) position may clash with the pseudo axial methyl group on the gallium atom.

The ^1H nmr spectrum of the complex $[Me_2Ga(N_2C_3H_3)_2]Re(CO)_3(N_2C_3H_4)$ is shown in Fig. 2*a* and an expanded view of

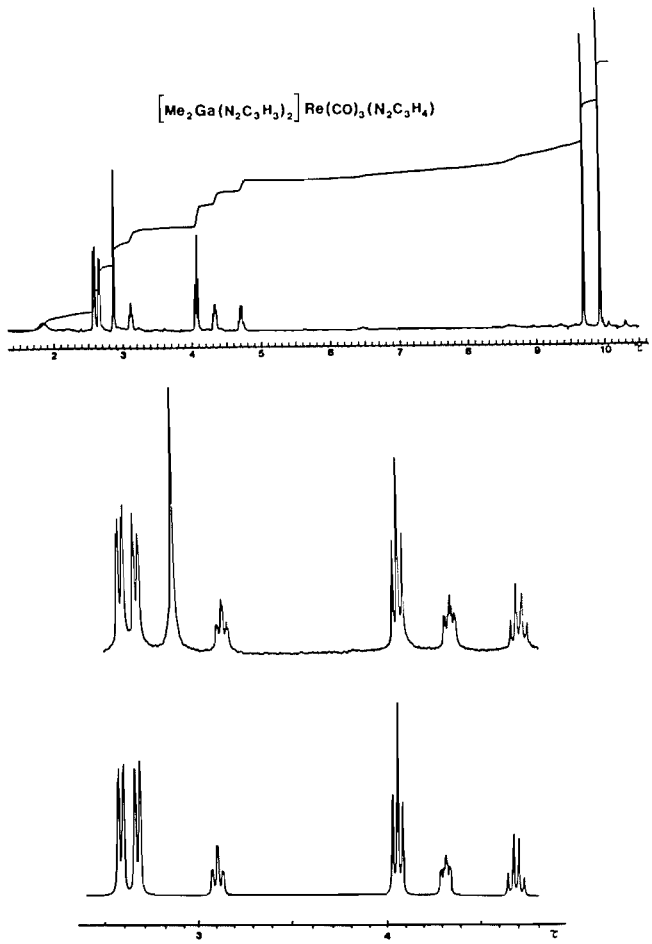

FIG. 2. (top) Room temperature 100 MHz ^1H nmr of $[Me_2Ga(N_2C_3H_3)_2]Re(CO)_3N_2C_3H_4$ in C_6D_6 solution. (middle) Expanded pyrazolyl proton region of above spectrum. (bottom) Computer simulated spectrum of pyrazolyl proton region of spectrum (top) using coupling constants given in Table 3.

the "pyrazolyl proton" region of the spectrum is shown in Fig. 2*b*. The latter clearly shows small cross-ring couplings in addition to the normal J_{HCCH} couplings usually observed in the ^1H nmr spectra of pyrazolyl complexes. A computer-simulated spectrum (Fig. 2*c*) based on the parameters given in Table 3 fits very closely to the experimental spectrum.

The complexes $[Me_2Ga(N_2C_3HR_2)_2]Re(CO)_3X$ (where R = Me; X = PPh_3 or $N_2C_3H_4$) were less stable than the corresponding complexes where R = H, and could only be isolated in low yields. Steric effects could be an important factor contributing to this observed instability, especially with the bulky PPh_3 ligand. The reaction of $[Me_2Ga(N_2C_5H_7)_2]Re(CO)_4$ with $N_2C_3H_4$ resulted in a solid which analyzed correctly for the expected product $[Me_2Ga(N_2C_5H_7)_2]Re(CO)_3(N_2C_3H_4)$. The mass spectrum showed a parent ion signal and a pattern of signals predictable from the expected fragmentation of the molecular ion. In addition, ir data indicated a facially coordinated tricarbonyl complex although the two lower frequency bands were broader than normal and the 1902 cm^{-1} vibration displayed a shoulder at 1908 cm^{-1}. The ^1H nmr spectrum of the complex was not easily interpretable, containing many more signals than expected. Thus the product should display two Ga—Me signals and one NH signal. However, the $GaMe_2$ region of the room temperature spectrum showed four sharp signals at 9.11, 9.18, 9.64, and 9.73 τ. In addition two NH

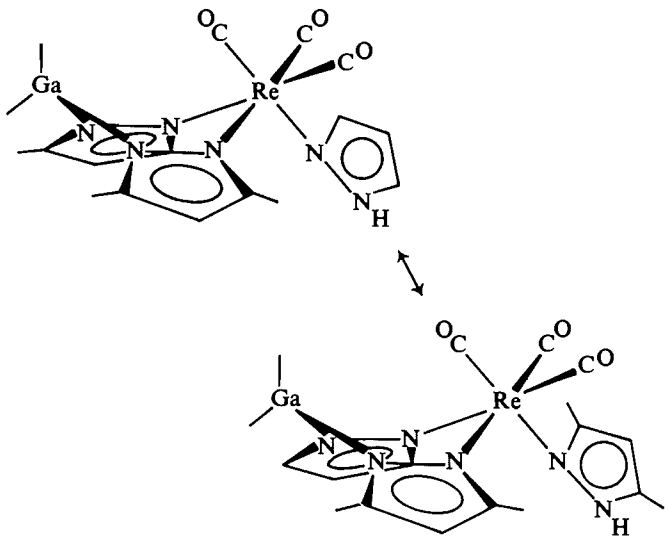
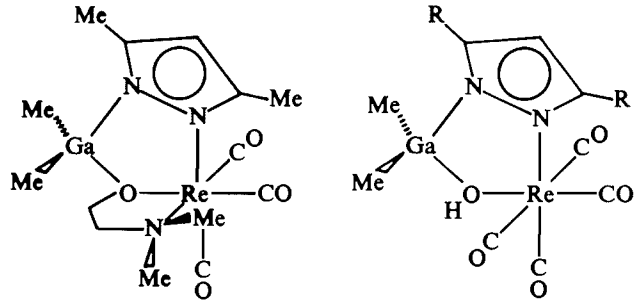
signals at 1.53 and 2.14 τ and complicated patterns in the pz—^{4}H and pz—Me regions of the spectrum were observed. The main signals could be assigned to the following molecular arrangements:



To explain the ^{1}H nmr and ir results it is proposed that the complex $[Me_2Ga(N_2C_5H_7)_2]Re(CO)_3(N_2C_3H_4)$ is fluxional in solution and that the fluxional process leads to an exchange between the terminal "pyrazole" and the bridging "pyrazolyl" rings. A possible mechanism for the proposed exchange is illustrated below:



(*a*) (*b*)

FIG. 3. (*a*) Conformation of five-membered [—Ga(—N—N—)-Re—O—] ring in the complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$-$Re(CO)_3$. (*b*) Proposed conformation of five-membered [—Ga-(—N—N—)Re—O—] rings in the complexes $[Me_2Ga(N_2C_3HR_2)$-$(OH)]Re(CO)_4$.

In this scheme the terminal pyrazole group is shown in the (*d*) position of Fig. 1, an arrangement which may be preferred for this ligand or could arise via a simple Ga—$(N—N)_2$—Re boat flip if this group started out in the (*a*) position. A hydrogen switch then alternates the pyrazole and 3,5-dimethyl pyrazole groups as the terminal ligand. A similar mechanism has been proposed previously to explain the solution behaviour of the anionic species $\{[Me_2Ga(N_2C_3H_3)_2]_2M(CO)_3(N_2C_3H_4)\}^-$, (where M = Mo or W). Thus the ^{1}H nmr spectra of these two species displayed but one set of signals for both the terminal pyrazole and bridging pyrazolyl groups (6). Additional support for the proposed mechanism of the fluxional process comes with the formation of the complex $[MeGa(N_2C_5H_7)_2(N_2C_3H_3)]$-$Re(CO)_3$ upon heating a C_6D_6 solution of the compound $[Me_2Ga(N_2C_5H_7)_2]Re(CO)_3(N_2C_3H_4)$ at ~70°C. In the fluxional process described it can be seen that the "mobile" hydrogen is brought within close range of a methyl group on the gallium atom, making a methane elimination reaction feasible (cf. ref. 9).

The novel unsymmetrical bidentate chelating gallate ligands $[Me_2Ga(N_2C_3HR_2)(OH)]^-$ (where R = H or Me) have been prepared via bridge cleavage reactions of the weakly associated tetrameric $(Me_2GaOH)_4$ molecule (12) with the appropriate sodium pyrazolide. The ligands reacted with the dimer $[Re-(CO)_4Cl]_2$ to give the tetracarbonyl species $[Me_2Ga(N_2C_3HR_2)$-$(OH)]Re(CO)_4$. Both complexes, like the tetracarbonyls described above, have one CO group which is very labile and easily replaced by a PPh_3 ligand.

The geometry of the five-membered ring formed by the ligand at the Re centre is of interest. An X-ray structure of the complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Re(CO)_3$ (13) shows a facial coordination of the tridentate gallate ligand but more importantly a near planarity for the [—Ga—(N—N)—Re—O—] five-membered ring (Fig. 3*a*). It seems likely that the present bidentate ligand could be coordinated in a similar manner (Fig. 3*b*). Such a planar geometry, of course,

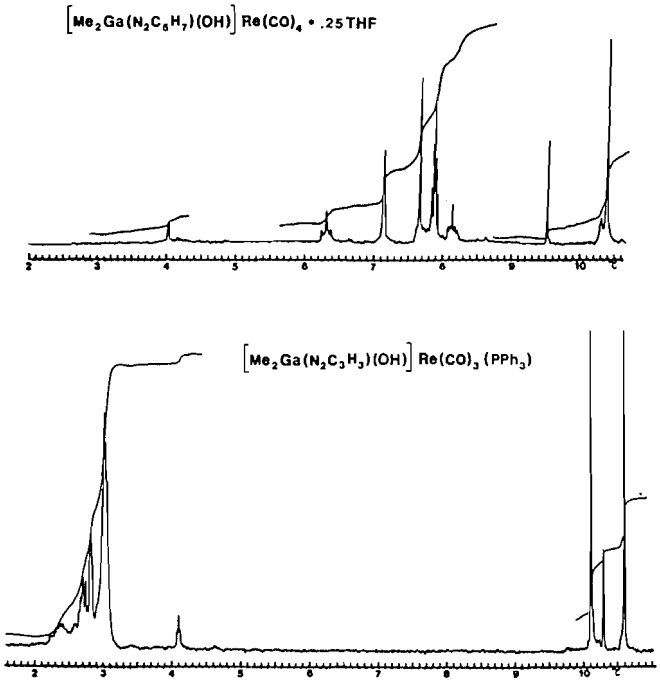

FIG. 4. Room temperature 100 MHz ^{1}H nmr of (top) $[Me_2Ga(N_2C_5H_7)(OH)]Re(CO)_4 \cdot 0.25THF$ in d_6-acetone, (bottom) $[Me_2Ga(N_2C_3H_3)(OH)]Re(CO)_3(PPh_3)$ in C_6D_6.

makes the two methyl groups on the gallium atom structurally equivalent, and this is consistent with the singlet observed for the $GaMe_2$ protons in the ^{1}H nmr spectrum of the complex $[Me_2Ga(N_2C_5H_7)(OH)]Re(CO)_4$ (Fig. 4*a*). Substitution of a PPh_3 group for a CO group leads to non-equivalence of the two Ga—Me groups (Fig. 4*b*) and consequently must be occurring at a position mutually *cis* to both donor atoms of the chelating gallate ligand. Facial coordination of the three remaining CO groups is also indicated by the three strong ν_{CO} stretching vibrations in the ir spectra (11) of the substituted products.

The mass spectra of the complexes $[Me_2Ga(N_2C_3HR_2)(OH)]Re(CO)_3(PPh_3)$ displayed predictable sets of signals. When R = H the monomer parent ion, P^+, signal was observed, with the most intense signal arising from the $P - CO^+$ ion. When R = Me no parent ion signal was observed but major signals attributable to the ions $P - Me^+$ (10%), $P - CO^+$ (20%), and $P - Me - PPh_3^+$ (100%) dominated the spectrum.

The present $[Me_2Ga(N_2C_3HR_2)(OH)]^-$ bidentate ligands have only one related system in the literature and that is the tridentate ligand $[MeGa(N_2C_5H_7)_2(OH)]^-$ which appeared serendipitously in some products from reactions involving the symmetrical tridentate ligand $[MeGa(N_2C_5H_7)_3]^-$ (14).

Our investigations are expanding to include other related unsymmetric bidentate ligands with the oxygen donor functionality of the present systems being replaced by —SR or $—PR_2$ groupings.

Theory of ^{13}C and ^{1}H paramagnetic shifts in uranocene. Does it indicate *f* orbital covalency?

BRUCE R. MCGARVEY
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received October 6, 1983

BRUCE R. MCGARVEY. Can. J. Chem. **62**, 1349 (1984).

The paramagnetic shift resulting from *f* orbital covalency for lanthanide fluorides has been successfully treated theoretically in earlier studies. This theoretical method has been modified to calculate the paramagnetic shift for ^{13}C and ^{1}H in uranocenes. It is shown that the very large anisotropy in the magnetic moment makes the treatments in the literature incorrect. The so-called "contact shift" in ^{13}C is in reality three terms: (*1*) a dipolar contribution from spin in the carbon p_z orbital, (*2*) a dipolar contribution from spin in the nearest neighbor carbon p_z orbitals, and (*3*) an induced Fermi contact term. Contribution (*1*) is the largest. For ^{1}H there are contributions from the direct dipolar interaction of spin in the nearest carbon p_z orbital and the induced Fermi contact term. Both terms are nearly equal in magnitude. The theory, however, predicts a much smaller magnitude and the incorrect sign for the shift as measured experimentally. The measured shift must, therefore, result from a polarization mechanism in which exchange interactions between the *f* electrons and electrons in filled orbitals cause spin delocalization into the ligand σ orbitals. It is argued that this polarization mechanism operates primarily through the overlap of the outer 6*s* and 6*p* orbitals of the uranium atom with the σ orbitals of the ligand making the observed nmr shifts insensitive to the nature of the bonding between the ligand and the uranium atom. We conclude, therefore, that the question of how much *f* orbitals are involved in covalent bonds between uranium and the ligands in uranocene cannot be answered by measuring the paramagnetic shift in ^{13}C or ^{1}H.

BRUCE R. MCGARVEY. Can. J. Chem. **62**, 1349 (1984).

Dans des études antérieures, on avait traité d'un point de vue théorique et avec succès des déplacements paramagnétiques résultant de la covalence de l'orbitale *f* des fluorures de lanthanides. On a modifié cette méthode théorique pour calculer les déplacements paramagnétiques du ^{13}C et du ^{1}H dans des uranocènes. On montre que, dû à la très grande anisotropie du moment magnétique, tous les traitements rapportés dans la littérature sont incorrects. Tout ce qu'on appelle "déplacement de contact" en rmn du ^{13}C recouvre en réalité trois termes: (*1*) une contribution dipolaire du spin dans l'orbitale p_z du carbone, (*2*) une contribution dipolaire de la part du spin dans les orbitales p_z du carbone voisin le plus près et (*3*) un terme de contact de Fermi induit. La contribution (*1*) est la plus importante. Dans le cas du ^{1}H, on observe des contributions provenant d'une interaction dipolaire directe du spin dans l'orbitale p_z du carbone le plus près ainsi que le terme de contact de Fermi induit. L'importance de chacun de ces deux termes est à peu près du même ordre de grandeur. La théorie, cependant, prédit un ordre de grandeur beaucoup plus faible et un signe incorrect pour le déplacement tel qu'il est mesuré expérimentalement. Les déplacements mesurés doivent, dans ce cas, provenir d'un mécanisme de polarisation dans lequel les interactions d'échange entre les électrons *f* et les électrons des orbitales saturées provoquent une délocalisation de spin vers les orbitales du ligand. On prétend que ce mécanisme de polarisation opère principalement par l'intermédiaire du recouvrement des orbitales périphériques 6*s* et 6*p* de l'atome d'uranium avec les orbitales du ligand rendant ainsi les déplacements chimiques observés en rmn insensibles à la nature de la liaison entre le ligand et l'atome d'uranium. Nous concluons alors que la réponse à la question relative à l'importance de la participation des orbitales *f* dans la liaison covalente entre l'uranium et les ligands dans l'uranocène ne peut être obtenue par une mesure du déplacement paramagnétique du ^{13}C ou du ^{1}H.

[Traduit par le journal]

Introduction

In earlier studies (1) we have developed a model for calculating the paramagnetic shift arising from a covalent interaction between *f* orbitals of a rare earth ion and the *s* and *p* orbitals of the ligand atom. This model was successfully applied in a series of studies of ^{19}F nmr in lanthanide fluoride solids (2–9). These studies revealed that the covalent interaction was large enough to dominate the paramagnetic shift for lanthanides in the second half of the series. The shift in the first half appeared to be dominated by the spin polarization mechanism of Watson and Freeman (10). No comparable analysis of shifts in actinide complexes appears to have been done.

A large number of organometallic actinide compounds have been made and their nmr spectra studied in solution. Much of this nmr work has been reviewed by Fischer (11) and by Luke and Streitweser (12). In those cases in which the pseudo-contact shift could be reliably estimated, it was found that when the pseudo-contact shift was subtracted from the experimental shift that a sizeable shift, which has generally been called the contact shift, remained. The existence of this contact shift has been cited as evidence of covalency between the actinide and the ligand but it is rarely clearly stated which orbitals of the actinide are involved, although it seems to be generally assumed that the π orbitals of the ligands are where the transferred spin resides. The sign of the shifts, however, suggests that the shifts are determined mainly by the polarization transfer mechanism which involves the σ electrons of the ligand rather than the π electrons.

Our earlier studies on the lanthanides have shown that when the orbital momentum and spin–orbit interaction are not quenched by the crystal field (as is the case in the lanthanides and actinides), then unpaired electrons in *p* orbitals on the ligand atoms can make as great or greater a contribution to the isotropic shift as the *s* electrons do through the Fermi contact shift. The sign of this contribution depends on the nature of the ground and excited states of the complex in question. Thus the treatment of the shift as just a contact shift, using equations that were derived for the transition metal complexes, is very suspect.

We have decided that it would be of some interest to extend our theory to the actinide complexes to see what sort of shifts are predicted when the spin is transferred to the ligand through *f* orbital covalency. We have chosen to study the uranocene molecule, $U(C_8H_8)_2$. The high symmetry of this molecule

makes it a good candidate for theoretical study and the extensive number of nmr studies of it and its derivatives gives us something with which to compare our calculations.

What is the ground state of uranocene?

U(IV) has an f^2 configuration with the lowest state being $^3H_4$. The point symmetry group of $U(C_8H_8)_2$ is either D_{8h} or D_{8d} and since it will make no difference in the calculations we will assume the former for convenience. The eight-fold symmetry results in a crystal field with no spherical harmonics with $M > 0$ and, therefore, the $^3H_4$ state is split by the crystal field into five states which are:

$$|J,M_J\rangle = |4,\pm4\rangle;\ |4,\pm3\rangle;\ |4,\pm2\rangle;\ |4,\pm1\rangle;\ |4,0\rangle$$

There is no agreement in the literature as to which of these five states is the ground state. The $|4,\pm4\rangle$, $|4,\pm3\rangle$, and $|4,0\rangle$ states have all been suggested as the ground state in uranocene.

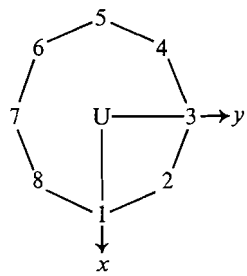
Karracker (13) predicted $|4,\pm4\rangle$ ground state based on theoretical considerations. This was confirmed by Hayes and Edelstein (14) in their analysis of the magnetic susceptibility of powders of uranocene, neptunocene, and plutonocene. Amberger *et al.* (15) fitted their susceptibility data to a model in which the ground state was $|4,0\rangle$ with the $|4,\pm1\rangle$ state only 17 cm^{-1} above it. Dallinger *et al.* (16) found with Raman studies that the first excited state was at 466 cm^{-1} and differed from the ground state by $\Delta M_J = \pm1$. They proposed a ground state of $|4,\pm4\rangle$ with the first excited state being $|4,\pm3\rangle$ by fitting the theoretical susceptibility against the experimental susceptibility versus temperature plot. They obtained a slightly poorer fit when the two states were reversed.

Fischer (11) has estimated $(\mu_\parallel^2 - \mu_\perp^2)$ to be 8.8 Bohr magnetons from pseudo-contact shift studies and claims this requires a $|4,\pm3\rangle$ ground state with the first excited state being $|4,\pm2\rangle$. Luke and Streitweiser (12) have also estimated the pseudo-contact shift and obtain a value of $(\mu_\parallel^2 - \mu_\perp^2) = 12.5$ Bohr magnetons which we estimate would best fit a ground state of $|4,\pm3\rangle$ with the first excited state being $|4,\pm4\rangle$. Hayes and Edelstein (14) also predicted a $|4,\pm3\rangle$ ground state on the basis of Wolfsberg–Helmholtz MO computations.

The present evidence suggests three possibilities: $|4,\pm4\rangle$ is ground state with $|4,\pm3\rangle$ at 466 cm^{-1} or $|4,\pm3\rangle$ is ground state with either $|4,\pm4\rangle$ or $|4,\pm2\rangle$ at 466 cm^{-1}. We will do our calculations for all three possibilities.

Molecular orbitals of $U(C_8H_8)_2$

For D_{8h} the MO's for the p_z orbitals of COT (cyclooctatetraene) will be given using the numbering system for individual carbon atoms as shown below.



The lower ring has atom number 9 under 1, 10 under 2, etc. Since the f orbitals belong to the A_{2u}, E_{1u}, E_{2u}, and E_{3u} irreducible representations, we give in eq. [1] only the π MO's belonging to those representations.

$$\phi(A_{2u}) = \frac{1}{4}[p_z^1 + p_z^2 + p_z^3 + p_z^4 + p_z^5 + p_z^6 + p_z^7 + p_z^8 + p_z^9 + p_z^{10} + p_z^{11} + p_z^{12} + p_z^{13} + p_z^{14} + p_z^{15} + p_z^{16}]$$

$$\phi(E_{1u})[x(5z^2 - r^2)] = \frac{1}{4}[\sqrt{2}p_z^1 + p_z^2 - p_z^4 - \sqrt{2}p_z^5 - p_z^6 + p_z^8 - \sqrt{2}p_z^9 - p_z^{10} + p_z^{12} + \sqrt{2}p_z^{13} + p_z^{14} - p_z^{16}]$$

$$\phi(E_{1u})[y(5z^2 - r^2)] = \frac{1}{4}[p_z^2 + \sqrt{2}p_z^3 + p_z^4 - p_z^6 - \sqrt{2}p_z^7 - p_z^8 - p_z^{10} - \sqrt{2}p_z^{11} - p_z^{12} + p_z^{14} + \sqrt{2}p_z^{15} + p_z^{16}]$$

[1]
$$\phi(E_{2u})[z(x^2 - y^2)] = \frac{1}{\sqrt{8}}[p_z^1 - p_z^3 + p_z^5 - p_z^7 + p_z^9 - p_z^{11} + p_z^{13} - p_z^{15}]$$

$$\phi(E_{2u})[zxy] = \frac{1}{\sqrt{8}}[p_z^2 - p_z^4 + p_z^6 - p_z^8 + p_z^{10} - p_z^{12} + p_z^{14} - p_z^{16}]$$

$$\phi(E_{3u})[x(x^2 - 3y^2)] = \frac{1}{4}[\sqrt{2}p_z^1 - p_z^2 + p_z^4 - \sqrt{2}p_z^5 + p_z^6 - p_z^8 - \sqrt{2}p_z^9 + p_z^{10} - p_z^{12} + \sqrt{2}p_z^{13} - p_z^{14} + p_z^{16}]$$

$$\phi(E_{3u})[y(3x^2 - y^2)] = \frac{1}{4}[p_z^2 - \sqrt{2}p_z^3 + p_z^4 - p_z^6 + \sqrt{2}p_z^7 - p_z^8 - p_z^{10} + \sqrt{2}p_z^{11} - p_z^{12} + p_z^{14} - \sqrt{2}p_z^{15} + p_z^{16}]$$

The appropriate atomic orbitals for the $|4,4\rangle$, $|4,3\rangle$, and $|4,2\rangle$ states of the f^2 configuration are given in eq. [2] below.

$$|4,4\rangle = \frac{1}{\sqrt{5\cdot6\cdot11}}\{3\sqrt{3}(f_3^+f_1^- + f_3^-f_1^+) - 3\sqrt{30}f_3^-f_2^- - \sqrt{2}f_2^+f_1^+ - 2f_3^+f_0^+\}$$

[2]
$$|4,3\rangle = \frac{1}{4\sqrt{3\cdot5\cdot11}}\{-24\sqrt{3}f_3^-f_1^- + 8\sqrt{2}(f_2^-f_1^+ + f_2^+f_1^-) + 16(f_3^+f_0^- + f_3^-f_0^+) - 4\sqrt{6}f_2^+f_0^+ - 4\sqrt{3}f_3^+f_{-1}^+\}$$

$$|4,2\rangle = \frac{1}{\sqrt{5\cdot6\cdot7\cdot11}}\{-14\sqrt{2}f_2^-f_1^- - 28f_3^-f_0^- + 7\sqrt{6}(f_2^+f_0^- + f_2^-f_0^+) + 7\sqrt{3}(f_3^+f_{-1}^- + f_3^-f_{-1}^+) - 2\sqrt{15}f_1^+f_0^+ - 9\sqrt{2}f_2^+f_{-1}^+ - \sqrt{30}f_3^+f_{-2}^+\}$$

The f orbitals are combinations of real functions that match the above π orbitals in symmetry. We therefore combine the π orbitals in an analogous fashion to give the complex functions listed in eq. [3] below.

$$[3]\quad \begin{array}{ll} f_0 = |z(5z^2 - 3r^2)\rangle & \phi_0 = \phi(A_{2u}) \\ f_{\pm1} = \frac{1}{\sqrt{2}}[\mp|x(5z^2 - r^2)\rangle - i|y(5z^2 - r^2)\rangle] & \phi_{\pm1} = \frac{1}{\sqrt{2}}\{\mp\phi(E_{1u})[x(5z^2 - r^2)] - i\phi(E_{1u})[y(5z^2 - r^2)]\} \\ f_{\pm2} = \frac{1}{\sqrt{2}}[|z(x^2 - y^2)\rangle \pm i|xyz\rangle] & \phi_{\pm2} = \frac{1}{\sqrt{2}}\{\phi(E_{2u})[z(x^2 - y^2)] \pm i\phi(E_{2u})[xyz]\} \\ f_{\pm3} = \frac{1}{\sqrt{2}}[\mp|x(x^2 - 3y^2)\rangle - i|y(3x^2 - y^2)\rangle] & \phi_{\pm3} = \frac{1}{\sqrt{2}}\{\mp\phi(E_{3u})[x(x^2 - 3y^2)] - i\phi(E_{3u})[y(3x^2 - y^2)]\} \end{array}$$

We now combine the metal f orbital and the π ligand orbitals to get the complex MO's listed in eq. [4].

$$[4]\quad \begin{array}{l} F_0 = N_0 f_0 - b_0\phi_0 \\ F_{\pm1} = N_1 f_{\pm1} - b_1\phi_{\pm1} \\ F_{\pm2} = N_2 f_{\pm2} - b_2\phi_{\pm2} \\ F_{\pm3} = N_3 f_{\pm3} - b_3\phi_{\pm3} \end{array}$$

We now replace the f orbitals in eq. [2] with the F functions of eq. [4]. It is these functions that will be used to calculate the contribution of covalent bonding between f orbitals and the π orbitals of COT to the paramagnetic shift. In practice we will calculate the shift for atom 1 and will need to worry only about the p_z^1, p_z^2, and p_z^8 terms in the above MO's.

Calculation of paramagnetic shift for ^{13}C

The calculation of the paramagnetic shift is a straightforward but tedious procedure using the theory of Kurland and McGarvey (17). If there is only one excited state to include in the calculation, the equation for the shift takes on the following form:

$$\left(\frac{\Delta H}{H}\right)_{i=(x,y,z)} = \frac{1}{qkT}\left[\langle 4,3|\mu_i|4,3\rangle\langle 4,3|\frac{A_{Ni}}{g_N\mu_N}|4,3\rangle + \langle 4,4|\mu_i|4,4\rangle\langle 4,4|\frac{A_{Ni}}{g_N\mu_N}|4,4\rangle\, e^{-\Delta/kT} + \frac{kT}{\Delta} \times (1 - e^{-\Delta/kT})\langle 4,4|\mu_i|4,3\rangle\langle 4,3|\frac{A_{Ni}}{g_N\mu_N}|4,4\rangle\right]$$

$$[5]\quad q = 2(1 + e^{-\Delta/kT})$$

$$\mu_i = -g_J\mu_e J_i$$

$$\frac{A_{Ni}}{g_N\mu_N} = \frac{8}{3}\pi g_e\mu_e \sum_j \delta(r_j)(s_i)_j + g_e\mu_e \sum_j [(3s_j\cdot r_j)(r_i)_j - r_j^2(s_i)_j]r_j^{-5} + 2\mu_e \sum_i r_j^{-3}(l_i)_j$$

where we have assumed the ground state to be $|4,\pm3\rangle$ and the excited state to be $|4,\pm4\rangle$, Δ is the energy difference between the two states, and the other symbols have their usual meanings. To obtain the result when $|4,\pm4\rangle$ is the ground state and $|4,\pm3\rangle$ the excited state, we simply make Δ negative in value and to obtain the shift when the excited state is $|4,\pm2\rangle$, we simply replace $|4,\pm4\rangle$ by $|4,\pm2\rangle$ in the above equation.

The matrix elements of eq. [5] are given in the Appendix along with the steps needed in their computation. The calculation was done for carbon nucleus 1 and contributions from unpaired spin on neighboring atoms 2 and 8 have been included. The A_{2p} term comes from p_z^1 and the R^{-3} term comes from p_z^2 and p_z^8. The Fermi contact term Q has contributions from all three atoms and is estimated by standard methods (18).

Using the matrix elements in the Appendix and eq. [5], the shift is calculated for the x, y, and z principal directions and the results are given in eq. [6]. Please note that the shift for both x and y must be calculated because the local symmetry around the carbon nucleus is not axial, even though the molecule itself has axial symmetry. The equations given in eq. [6] are for the case when the ground state is $|4,\pm3\rangle$ and the nearest excited state is $|4,\pm4\rangle$.

$$\left(\frac{\Delta H}{H}\right)_z = \frac{\mu_e}{3300kT(1 + e^{-\Delta/kT})}\left[\frac{A_{2p}}{g_N\mu_N} - \frac{g_e\mu_e}{R^3} + \frac{Q}{2g_N\mu_N}\right]\{9[35b_3^2 - 2b_2^2 + 35b_1^2 - 2b_0^2] + 4[133b_3^2 + 134b_2^2 - b_1^2 - 2b_0^2]e^{-\Delta/kT}\}$$

$$[6]\quad \left(\frac{\Delta H}{H}\right)_{x,y} = \frac{\mu_e(1 - e^{-\Delta/kT})}{6600\Delta(1 + e^{-\Delta/kT})}\left\{\left[-\frac{A_{2p}}{g_N\mu_N} + C_{x,y}\frac{g_e\mu_e}{R^3} + \frac{Q}{g_N\mu_N}\right][62b_3^2 + 4b_2^2 + 58b_1^2 + 8b_0^2] + D_{x,y}\left[-\frac{A_{2p}}{g_N\mu_N} + \frac{Q}{g_N\mu_N}\right] \times [9b_1^2 - 12\sqrt{30}b_2b_0 + 12\sqrt{15}b_3b_1]\right\} \qquad C_x = -1.1213;\ C_y = 3.1213;\ D_x = -1;\ D_y = +1$$

The average value for the shift is given in eq. [7].

$$[7]\quad \left(\frac{\Delta H}{H}\right)_{ave} = \frac{\mu_e}{1100kT(1 + e^{-\Delta/kT})}\left\{\left[\frac{A_{2p}}{g_N\mu_N} + \frac{Q}{2g_N\mu_N} - \frac{g_e\mu_e}{R^3}\right][(35b_3^2 - 2b_2^2 + 35b_1^2 - 2b_0^2) + \frac{4}{9}e^{-\Delta/kT}(133b_3^2 + 134b_2^2 - b_1^2 - 2b_0^2)] + \frac{1}{9}\left[-\frac{A_{2p}}{g_N\mu_N} + \frac{Q}{g_N\mu_N} + \frac{g_e\mu_e}{R^3}\right]\left(\frac{kT}{\Delta}\right)(1 - e^{-\Delta/kT})(62b_3^2 + 4b_2^2 + 58b_1^2 + 8b_0^2)\right\}$$

The corresponding equation when the excited state is $|4,\pm2\rangle$ is as follows:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

$$[8]\quad \left(\frac{\Delta H}{H}\right)_{ave} = \frac{\mu_e}{1100kT(1 + e^{-\Delta/kT})}\left\{\left[\frac{A_{2p}}{g_N\mu_N} + \frac{Q}{2g_N\mu_N} - \frac{g_e\mu_e}{R^3}\right][(35b_3^2 - 2b_2^2 + 35b_1^2 - 2b_0^2) + \frac{1}{63}e^{-\Delta/kT}(377b_3^2 + 100b_2^2 + 85b_1^2 + 362b_0^2)] + \frac{7}{9}\left[-\frac{A_{2p}}{g_N\mu_N} + \frac{Q}{g_N\mu_N} + \frac{g_e\mu_e}{R^3}\right]\left(\frac{kT}{\Delta}\right)(1 - e^{-\Delta/kT})(19b_3^2 + 14b_2^2 + 11b_1^2 + 22b_0^2)\right\}$$

Please note that because the orbital momentum and spin–orbit coupling are not quenched, the dipolar terms of A_{2p} and R^{-3} are not averaged out and therefore make a major contribution to what many people refer to as the "contact shift".

Calculation of paramagnetic shift for ^{1}H

The ^{1}H shift resulting from spin in the p_z orbital of the neighboring carbon atom is readily calculated from the present equations. We simply drop out the A_{2p} and R^{-3} terms and replace $Q/g_N\mu_N$ by $(Q/g_N\mu_N - g_e\mu_eR^{-3})$ in the z shift equation, by $(Q/g_N\mu_N + 2g_e\mu_eR^{-3})$ in the x term, and by $(Q/g_N\mu_N - g_e\mu_eR^{-3})$ in the y term. The Q now is the appropriate hyperfine term for ^{1}H in aromatic radicals and the R^{-3} term is the dipolar contribution from the spin in the carbon p_z orbital which does not average out to zero when the angular momentum is not quenched. The resulting shift equation for the case of a $|4,\pm3\rangle$ ground state with the first excited state of $|4,\pm4\rangle$ is as follows:

$$[9]\quad \left(\frac{\Delta H}{H}\right)_{ave} = \frac{\mu_e}{2200kT(1 + e^{-\Delta/kT})}\left\{\left[\frac{Q}{g_N\mu_N} - \frac{g_e\mu_e}{R^3}\right][(35b_3^2 - 2b_2^2 + 35b_1^2 - 2b_0^2) + \frac{4}{9}e^{-\Delta/kT}(133b_3^2 + 134b_2^2 - b_1^2 - 2b_0^2) + \frac{1}{9}\left[\frac{2Q}{g_N\mu_N} + \frac{g_e\mu_e}{R^3}\right]\left(\frac{kT}{\Delta}\right)(1 - e^{-\Delta/kT})(62b_3^2 + 4b_2^2 + 58b_1^2 + 8b_0^2) - \left[\frac{g_e\mu_e}{R^3}\right]\left(\frac{kT}{\Delta}\right)(1 - e^{-\Delta/kT})(3b_1^2 - 4\sqrt{30}b_2b_0 - 4\sqrt{15}b_3b_1)\right\}$$

and for the excited state of $|4,\pm2\rangle$ the equation becomes

$$[10]\quad \left(\frac{\Delta H}{H}\right)_{ave} = \frac{\mu_e}{2200kT(1 + e^{-\Delta/kT})}\left\{\left[\frac{Q}{g_N\mu_N} - \frac{g_e\mu_e}{R^3}\right][35b_3^2 - 2b_2^2 + 35b_1^2 - 2b_0^2) + \frac{1}{63}e^{-\Delta/kT}(377b_3^2 + 100b_2^2 + 85b_1^2 + 362b_0^2)] + \frac{7}{9}\left[\frac{2Q}{g_N\mu_N} + \frac{g_e\mu_e}{R^3}\right]\left(\frac{kT}{\Delta}\right)(1 - e^{-\Delta/kT})(19b_3^2 + 14b_2^2 + 11b_1^2 + 22b_0^2) + \frac{2}{9}\left[\frac{g_e\mu_e}{R^3}\right]\left(\frac{kT}{\Delta}\right) \times (1 - e^{-\Delta/kT})(81b_1^2 + 4\sqrt{30}b_2b_0 - 4\sqrt{15}b_1b_3)\right\}$$

Comparison with experiment

We can now attempt to calculate numerical values to compare with experimental values. The following values were used for the parameters in the equations:

$A_{2p}(^{13}C) = 90.8$ MHz

$Q(^{13}C) = 21.83$ MHz

$g_e\mu_eg_N\mu_NR^{-3}(^{13}C) = 7.39$ MHz

$Q(^1H) = -75.6$ MHz

$g_e\mu_eg_N\mu_NR^{-3}(^1H) = 78.97$ MHz

To obtain estimates of the magnitude and sign of the shifts predicted by these equations, we need to make assumptions concerning the values of the four b parameters. One reasonable assumption would be to assume that only the topmost filled π orbital in the COT ion would be involved in covalent bonding with the f orbitals. This would assume that $b_0 = b_1 = b_3 = 0$, since the E_{2u} is the topmost filled level. Another possible assumption is to make all π orbitals equally involved in bonding, which would assume that $b = b_0 = b_1 = b_2 = b_3$. The results of making these two assumptions for three different arrangements of states are given in Table 1.

The values in Table 1 should be compared to what most experimentalists have called the contact shift, that is, the isotropic shift from which the pseudo-contact shift has been subtracted. Fischer (11) reports the following values for these shifts:

$(\Delta H/H)_{con}(^{13}C) = -140.8$ ppm

$(\Delta H/H)_{con}(^1H) = 38.1$ ppm

Luke and Streitweiser (12) report for ^{1}H a value of 34.2 ppm. A comparison of the experimental values with the table entries quickly reveals that the theory will not account for the experimental results, since it would require in most cases that b^2 or b_2^2 be negative or, in one case where the signs agree, it would require an unreasonably large value of b_2^2. We must therefore conclude that the major contribution to the contact shift in uranocene comes from spin transfer mechanisms other than the one investigated here.

It must not be concluded from the above arguments that f orbital covalency is unimportant in uranocene, because in the most likely cases examined, that is for a $|4,\pm3\rangle$ ground state with only b_2 different from zero, the predicted contribution to the shift is quite small for reasonable values of b_2^2 and would be difficult to detect. Thus we have shown the existence of a sizeable contact shift in uranocene and its derivatives is not an indication of covalency, at least in the f orbitals, and any changes in the shift do not necessarily indicate changes in covalency.

Polarization mechanism of spin transfer

The polarization mechanism of spin transfer is more difficult to handle in a theoretical or semi-theoretical manner. In principle, exchange interactions between the unpaired spins in the f orbitals induce a small uncoupling (or polarization) of paired spins in filled orbitals of the system. This is in general small,

TABLE 1. Paramagnetic shifts (ppm)

Ground state	$\|4,\pm3\rangle$	$\|4,\pm3\rangle$	$\|4,\pm4\rangle$
Excited state	$\|4,\pm4\rangle$	$\|4,\pm2\rangle$	$\|4,\pm3\rangle$
	$b_0 = b_1 = b_3 = 0$		
$(\Delta H/H)_{ave}(^{13}C)$	$67.5b_2^2$	$-74.3b_2^2$	$964.8b_2^2$
$(\Delta H/H)_{ave}(^{1}H)$	$-16.7b_2^2$	$-0.68b_2^2$	$-198.1b_2^2$
	$b = b_0 = b_1 = b_2 = b_3$		
$(\Delta H/H)_{ave}(^{13}C)$	$1210b^2$	$971.7b^2$	$2078b^2$
$(\Delta H/H)_{ave}(^{1}H)$	$-245.3b^2$	$-270.8b^2$	$-1282b^2$

but if the filled orbital involves an *s* orbital of the atom in question, the Fermi contact term will be large enough to produce a measureable effect. Quite a few filled orbitals could make a contribution to this effect and this makes interpretation of such shifts very difficult.

A simple model was used to interpret and predict the polarization component of the nmr shift in lanthanide fluorides (2–9) which can be applied to uranocene. This will at least allow us to compare the magnitude of the effect between the lanthanides and the actinides. In this model, it was assumed that the matrix elements of A_{Ni} were proportional to the matrix elements of S_i. That is

$$[11]\quad \langle 4M|A_{Nz}|4M\rangle = K_{\parallel}\langle 4M|S_z|4M\rangle$$
$$\langle 4M|A_{Nx}|4M\rangle = K_{\perp}\langle 4M|S_x|4M\rangle$$

Using this formalism and assuming a ground state of $|4,\pm3\rangle$ and first excited state of $|4,\pm4\rangle$, we obtain for the average shift

$$[12]\quad (\Delta H/H)_{ave} = -[g_J(g_J - 1)\mu_e/3kTg_N\mu_N(1 + e^{-\Delta/kT})] \times [(9 + 4e^{-\Delta/kT})K_{\parallel} + 14(1 - e^{-\Delta/kT})(kT/\Delta)K_{\perp}]$$

If we assume $K_{\parallel} = K_{\perp} = K$ and if we assume that the entire ^{13}C shift in uranocene is due to the polarization mechanism, we calculate a K value of -0.899 MHz from eq. [12]. This is, surprisingly, close to the value estimated by Edelstein *et al.* (19) who assumed a $|4,\pm4\rangle$ ground state with no contributing excited states. $K_{ave} = -1.82$ MHz for ^{19}F—Gd^{3+} and -2.23 MHz for ^{19}F—Eu^{2+}. Since K is a hyperfine constant and is proportional to g_N, we must scale these numbers by the ratio of g_N's before comparing them. $K = -0.899$ MHz would become -3.36 MHz for a ^{19}F nucleus. Thus the polarization of spin in the carbon atom adjacent to the U^{4+} is only slightly larger than that of the fluorine ion adjacent to Gd^{3+} or Eu^{2+}.

Can we determine which filled orbitals in the molecule make the major contributions to spin transfer by polarization? Streitweiser *et al.* (20) have proposed that it is the filled bonding orbitals which involve *f* and *d* orbitals of uranium combined with π orbitals of the COT anion. We consider this to be unlikely for two reasons. First, these orbitals will have only a small admixture of the *f* and *d* orbitals so that the exchange integrals with the *f* electrons will be small (and therefore the spin polarization will be small) and this coupled with the fact that these MO's do not have any direct admixture of carbon *s* orbitals makes it highly unlikely that polarization of these orbitals can account for the measured nmr shift. The magnitude of K estimated earlier would require a polarization of the spin of better than 10% in the π orbitals if this were the only source of the nmr shift. Second, these orbitals would contribute only by a double polarization which would yield a shift of opposite sign to that observed. A more likely source is the polarization of the outer 6*s* and 6*p* electrons in the uranium. Overlap of these electrons with the σ bonding electrons of the COT anion will result in a renormalization of the two sets of orbitals which will (10), in turn, result in a polarization of the 2*s* and 2*p* orbitals of the carbon atom. If this is the case, we would expect the nmr shift to be related more to overlap of the outer electrons in the metal and ligand atoms (which is a function of the bond distance) than to the nature of the bonding interactions. If this is the case, we would expect the nmr shift of ^{13}C to be similar for any carbon attached directly to the uranium atom. This appears to be borne out in the limited data available on ^{13}C shifts.

In eq. [12], K is divided by g_N so that we can infer from the fact that the magnitude of the ^{1}H shift in uranocene is less than one third that of the ^{13}C shift that the polarization of the spin near the ^{1}H nucleus is less than one third of that near the ^{13}C nucleus. This is reasonable since the polarization must be transmitted through the C—H bond which also causes the reversal in sign of the polarization. Again we would expect the ^{1}H shift to be influenced only slightly by bonding changes, if the spin polarization is transmitted primarily by overlap between the outer electrons of the uranium and carbon atoms. It has been commented on several times (11, 12) that the "contact" shift in $(C_5H_5)_3UX$ compounds varies only slightly with X. Further, the "contact" shift in $U(C_8H_8)_2$ is not much different than that observed in $U(C_5H_5)_4$.

Conclusions

There are several conclusions to be drawn from this work. The theoretical approach used in the work has been successfully applied to the lanthanide system, where it showed that covalency involving the *f* orbitals played a major role in determining the paramagnetic shift for the ions in the second half of the series. Thus we have every expectation that the present calculations should give a good estimate of the sign and magnitude of the shift from *f* orbital covalency in uranocene. The failure of the calculations to explain the sign and magnitude of the observed shifts must, therefore, indicate that either there is little covalency or (more likely) the ground state is $|4,\pm3\rangle$ with covalency involving primarily the E_{2u} π MO of COT, since this was shown to lead to very small paramagnetic shifts.

The paramagnetic shift must be determined mostly by the polarization mechanism of spin transfer. It appears that this mechanism operates mainly through the overlap of the outer 6*s* and 6*p* orbitals of uranium with the σ bonding orbitals of the carbon atom. Therefore, the nmr shift in these complexes is not very sensitive to the nature of the bonding between the ligand and the uranium atom.

Another important, but less obvious, conclusion is the importance of terms other than the Fermi contact term in determining the sign and magnitude of the isotropic shift in actinide complexes. The A_{2p} term was larger than the Q term in the ^{13}C

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

computations and the R^{-3} term was just as large as the Q term in the ^1H case. Thus these calculations point out that it is unreasonable to characterize the isotropic shift as a contact shift in the actinide systems and even more unreasonable to consider the shift as a measure of the esr Q parameter for unpaired electrons in the π system.

Appendix

Calculation of the $\langle 4M|\mu_i|4M'\rangle$ matrix elements in eq. [5] is straightforward. We take $g_J = 4/5$ and $J_i = L_i + S_i$. If we further assume that only the central orbital part of the MO contributes to L_i, we obtain the matrix elements

$$\langle 44|\mu_z|44\rangle = -(4\mu_e/165)[123N_3^2 + 68N_2^2 + 7N_1^2 - 66] \approx -(16/5)\mu_e$$

$$\langle 43|\mu_z|43\rangle = -(\mu_e/15)[39N_3^2 + 4N_2^2 + 11N_1^2 - 18] \approx -(12/5)\mu_e$$

$$\langle 42|\mu_z|42\rangle = -(2\mu_e/1155)[831N_3^2 + 556N_2^2 - N_1^2 - 462] \approx -(8/5)\mu_e$$

[A1] $$\langle 44|\mu_x|43\rangle = -(\sqrt{2}\mu_e/55)[7N_3N_2 + 45N_2N_1 + 14N_1N_0 - 22] \approx -(4\sqrt{2}/5)\mu_e$$

$$\langle 44|\mu_y|43\rangle = -i\langle 44|\mu_x|43\rangle$$

$$\langle 43|\mu_x|42\rangle = -(\mu_e/55\sqrt{14})[149N_3N_2 + 15N_2N_1 + 298N_1N_0 - 154] \approx -(2\sqrt{14}/5)\mu_e$$

$$\langle 43|\mu_y|42\rangle = -i\langle 43|\mu_x|42\rangle$$

The final values in the above equations are obtained by assuming $N_3 = N_2 = N_1 = N_0 \approx 1$, which should be a reasonable assumption for f orbitals.

The calculation of the $\langle 4M|A_{Ni}/g_N\mu_N|4M'\rangle$ matrix elements is more laborious. We first consider the A_{Nz} terms. Since these terms are centered on the ligand nucleus, we consider only the ϕ_m terms in the MO's. Since these have only p_z orbitals, we can ignore the orbital momentum part of A_{Nz} in eq. [5]. In fact, the only portion of the A_{Nz} operator that makes a contribution is the s_z terms, so that we write

[A2] $$A_z's_z = \sum_j [(8/3)\pi g_e\mu_e\delta(r_j) + g_e\mu_e(3\cos^2\theta_j - 1)r_j^{-3}]s_{zj}$$

The $\langle 4M|A_{Nz}/g_N\mu_N|4M'\rangle$ matrix elements then take the general form

[A3] $$\langle 4M|A_{Nz}/g_N\mu_N|4M'\rangle = A(MM')\sum_{m=0}^{3} a(MM'm)b_m^2 \times \langle\phi_m|A_z'|\phi_m\rangle$$

where the coefficients for appropriate MM' values are as follows:

MM'	$A(MM')$	$a(MM'0)$	$a(MM'1)$	$a(MM'2)$	$a(MM'3)$
44	1/330	2	1	−134	−133
33	1/110	2	−35	2	−35
22	1/2310	−362	−85	−100	−377

It is quickly established that all the $\langle\phi_m|A_z'|\phi_m\rangle$ are identical, so that calculation of one will suffice. Since our nucleus of interest is carbon nucleus 1, we assume only it and its nearest neighbours, nuclei 2 and 8, will make a contribution. Thus we can write

[A4] $$\langle\phi_m|A_z'|\phi_m\rangle \approx 16^{-1}[\langle p_z^1|A_z'|p_z^1\rangle + \langle p_z^2|A_z'|p_z^2\rangle + \langle p_z^8|A_z'|p_z^8\rangle]$$

The dipolar (second term in eq. [A2]) term in A_z' gives contributions from all three nuclei. For nucleus 1 we obtain

[A5] $$\langle p_z^1|A_z'|p_z^1\rangle = (4/5)g_e\mu_e\langle r^{-3}\rangle = 2A_{2p}/g_N\mu_N$$

For nuclei 2 and 8 we use the point dipole form of A_z', which is $g_e\mu_e(3\cos^2\Omega - 1)R^{-3}$. R is the distance between nucleus 1 and nucleus 2 or 8 and Ω is the angle between this direction vector and the z axis. Since $\Omega = 90°$, we get

[A6] $$\langle p_z^2|A_z'|p_z^2\rangle = \langle p_z^8|A_z'|p_z^8\rangle = -g_e\mu_eR^{-3}$$

The Fermi contact term (first term in eq. [A2]) would give zero for the MO's in eq. [1]. However, we know from free radical studies of such aromatic rings that polarization of filled bonding σ orbitals produces a hyperfine interaction proportional to the density of spin in the p_z orbital on the nucleus in question plus the density in the nearest neighbours. Since the hyperfine interaction of a spin in ϕ_m is calculated for the z direction by $\langle\phi_m|A_z'|\phi_m\rangle$ and the fraction of spin on any nucleus is 16^{-1} for each ϕ_m orbital, we can write for eq. [A4] the following:

[A7] $$\langle\phi_m|A_z'|\phi_m\rangle = [2A_{2p} - 2g_e\mu_eg_N\mu_NR^{-3} + Q]/16g_N\mu_N$$

where $Q/16$ is the Fermi contact part of the hyperfine interaction constant for a free radical with unpaired spin in a ϕ_m orbital. Q can be estimated by procedures given in ref. 18.

A similar procedure is adopted for the $A_{Nx}/g_N\mu_N$ and $A_{Ny}/g_N\mu_N$ terms. The general form for the matrix elements is

[A8] $$\langle 4M|A_{Nx,y}/g_N\mu_N|4M'\rangle = (+1, -i)B(MM') \times \sum_{m=0}^{3} b(MM'm)b_m^2\langle\phi_m|A_{x,y}'|\phi_m\rangle + (+1, +i)C(MM') \times \langle\phi_1|A_{x,y}'|\phi_{-1}\rangle[c(MM'1)b_1^2 + c(MM'2)b_2b_0 + c(MM'3)b_3b_1]$$

the coefficients in eq. [A8] are as follows:

MM'	$B(MM')$	$b(MM'0)$	$b(MM'1)$	$b(MM'2)$	$b(MM'3)$
43	$\sqrt{2}/330$	−4	−29	−2	−21
32	$\sqrt{14}/660$	22	11	14	19

	$C(MM')$	$c(MM'1)$	$c(MM'2)$	$c(MM'3)$
43	$1/110\sqrt{2}$	3	$-4\sqrt{30}$	$4\sqrt{15}$
32	$1/2640\sqrt{14}$	−81	$-4\sqrt{30}$	$-4\sqrt{15}$

In an analogous fashion to that used for the $A_{N_z}/g_N\mu_N$ terms we find

[A9] $$\langle\phi_m|A_x'|\phi_m\rangle = [-A_{2p} - 1.1213 g_e\mu_e g_N\mu_N R^{-3} + Q]/16 g_N\mu_N$$

[A10] $$\langle\phi_m|A_y'|\phi_m\rangle = [-A_{2p} + 3.1213 g_e\mu_e g_N\mu_N R^{-3} + Q]/16 g_N\mu_N$$

The cross terms are:

[A11] $$\langle\phi_1|A_{x,y}'|\phi_{-1}\rangle = [A_{2p} - Q]/16 g_N\mu_N$$

These cross terms disappear when we compute the average nmr shift.

Simple lower and upper bounds for isomerization energies

PAUL G. MEZEY
Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received August 30, 1983

PAUL G. MEZEY. Can. J. Chem. **62**, 1356 (1984).

Lower and upper bounds for the energies of various isomers can be obtained by a simple inspection of the nuclear charges. The bounds are quantum-mechanically rigorous, and are strictly applicable only to specific nuclear geometries and require only back-of-the-envelope type calculations.

PAUL G. MEZEY. Can. J. Chem. **62**, 1356 (1984).

On peut évaluer facilement les limites inférieures et supérieures des énergies de divers isomères en se basant sur une inspection simple des charges nucléaires. Les limites sont rigoureuses sur la base de la mécanique quantique, elles peuvent s'appliquer d'une façon stricte uniquement pour des géométries nucléaires spécifiques et peuvent être déterminées par des calculs simples pouvant se faire sur le dos d'une enveloppe.

Most chemists believe that even approximate quantum chemical calculations of isomerization energies of molecules require time-consuming computations with complex computer programs. Yet, rigorous (although rather loose) upper and lower bounds of some isomerization energies can be obained by simple back-of-an-envelope type calculations, if energy values for some other isomers and/or for some other isoelectronic species are known.

Consider a general molecule M of w nuclei of nuclear charges $z_1, z_2, \ldots z_w$, and of arbitrary geometry. Let us assume that an isomeric molecule, ISOM, can be obtained from M by a permutation of the nuclei otherwise having the same geometry, implying in general that at least one of the isomers has a distorted geometry, as compared to its equilibrium nuclear arrangement. Consider a third molecule, that is isoelectronic with M and ISOM, and contains the same total number of protons, i.e. the sum of nuclear charges is the same. We shall consider first the simplest case and take this third molecule as a single atom, UA (united atom), containing all the protons of M.

Let us assume that all these molecules are in their electronic ground states, or all of them are in the lowest state of a given electronic manifold (e.g. lowest triplet or lowest doublet state, etc.). Then, M, ISOM, and UA fulfill the conditions for a corollary (1) of a quantum chemical theorem on the abstract nuclear charge space (2) and we can write that

$$[1] \quad (1 - \alpha)E_e\,(\mathrm{UA}) + \alpha E_e(\mathrm{M}) \leq E_e\,(\mathrm{ISOM})$$

Here E_e stands for the electronic energy of the given electronic state, and number α fulfills the following constraints:

$$[2] \quad 0 \leq \alpha \leq 1$$

$$[3] \quad \alpha z_i(\mathrm{M}) \leq z_i\,(\mathrm{ISOM}) \qquad i = 1, 2, \ldots, w$$

(The theorem states that all open sets of the level set topology set up by the electronic energy functional on an abstract nuclear charge space are convex. The proof and some related results are given elsewhere (1–5).) For example, α can be chosen as the minimum ratio of nuclear charge pairs:

$$[4] \quad \alpha = \min_i \{z_i\,(\mathrm{ISOM})/z_i(\mathrm{M})\}$$

Let us interchange now the roles of the two isomers M and ISOM, then we obtain

$$[5] \quad (1 - \alpha')\,E_e(\mathrm{UA}) + \alpha' E_e(\mathrm{ISOM}) \leq E_e(\mathrm{M})$$

with

$$[6] \quad \alpha' = \min_i \{z_i(\mathrm{M})/z_i(\mathrm{ISOM})\}$$

where α' is not in general the same as α. However, if only two nuclei are interchanged in the isomerization, then necessarily $\alpha = \alpha'$ for the minimum ratios.

Combining inequalities [1] and [5] we obtain

$$[7] \quad (1 - \alpha)E_e(\mathrm{UA}) + \alpha E_e(\mathrm{M}) \leq E_e(\mathrm{ISOM}) \leq (1/\alpha')E_e(\mathrm{M}) + (1 - 1/\alpha')E_e(\mathrm{UA})$$

That is, we have obtained both an upper and a lower bound for the electronic energy of isomer ISOM. If energy values for molecule M and for the single atom UA are available, then all that is needed for the evaluation of upper and lower energy bounds for isomer ISOM is a trivial calculation of α and α'. The above is a rigorous quantum chemical result within the non-relativistic Born–Oppenheimer approximation. It is also valid for less accurate electronic energies, e.g. it is valid at the Hartree–Fock limit, or for energies obtained in any finite basis set calculations, if the *same* finite basis set is used for all the species to which the theorem is applied.

Although the result is rigorous and always valid, the actual lower and upper bounds are in general very loose bounds (however, significant improvements are possible, *vide infra*). Apart from their extreme simplicity, they have little practical value in their above form, although they are of some theoretical interest in setting energy bounds for extensive domains of multidimensional potential energy surfaces. In practice their use is suggested only for very rough guidelines or for a quick test to guard against gross errors in more elaborate quantum chemical calculations, which may easily require a million times more numerical operations. It should also be pointed out that total energy changes are generally accompanied by much larger (often by several orders of magnitude larger) changes in the electronic energy. Hence, bounds which would appear very loose for total energies can be quite consistent with the scale of electronic energy variations.

It is of some interest that the relation is valid for any distorted geometry, even for the extreme case of dissociated fragments, as long as the *same* distortion is applied to both isomers.

The looseness of the above energy bounds stems from the involvement of the united atom UA in the relation, since

E_c(UA) is much below the energies of the isomers. Even if the coefficient $(1 - \alpha)$ of E_c(UA) is a small number (the smallest with the largest α value permitted by relation [3]), the $(1 - \alpha)E_c$(UA) term renders the bounds loose. On the other hand, the relations are the simplest to apply if UA is involved, and numerical values for E_c(UA) are readily available.

Much tighter and more useful energy bounds can be obtained if the set of molecules involved does not include UA. The same general relation of ref. 1 can be applied to M, ISOM, and a sequence of isoelectronic and isoprotonic molecules $M_1, \ldots, M_{n-1}$ of the same geometry, if for a sequence of numbers $\alpha_1, \ldots, \alpha_{n-1}, \alpha_n$ the following conditions apply:

[8] $\alpha_j \geq 0$

$j = 1, \ldots, n$

[9] $\sum_{j=1}^{n} \alpha_j = 1$

[10] $\sum_{j=1}^{n} \alpha_j z_i(M_j) = z_i(\text{ISOM})$

for every $i = 1, \ldots, w$

where the M_n = M notation is used. Then from the general result of ref. 1 the following inequality is obtained for isomers M, ISOM, and molecules M_j:

[11] $\alpha_1 E_c(M_1) + \ldots + \alpha_{n-1} E_c(M_{n-1}) + \alpha_n E_c(M) \leq E_c$ (ISOM)

The above relation gives much tighter energy bounds. Although its use is somewhat less convenient than relations [3] and [7], involving well known E_c(UA) values, nevertheless, suitable $E_c(M_j)$ values are often available. Relation [11] is the simplest if $n = 2$, i.e. if only one molecule, in addition to isomer M, is involved on the left hand side.

In the following we shall show examples for the application of relations [3], [7], as well as [11].

To illustrate the application of inequalities [7] take, for example, the ground electronic states of isomers HOCN and HNCO at a common geometry. Their nuclear charges are (1, 8, 6, 7) and (1, 7, 6, 8), respectively, with a sum of 22, hence UA = Ti, titanium. Following a simple inspection of these nuclear charges we can conclude that

[12] $\alpha = \alpha' = 7/8$

fulfills conditions [4] and [6]. Substitution into inequality [7] gives

[13] $(1/8)E_c(\text{Ti}) + (7/8)E_c(\text{HOCN}) \leq E_c(\text{HNCO}) \leq (8/7)E_c(\text{HOCN}) - (1/7)E_c(\text{Ti})$

that is, lower and upper bounds are obtained for the electronic energy of isomer HNCO. We may test relation [13] against the available numerical data. Considering the Hartree–Fock limits throughout, the value reported (6) for titanium is $E_{HF}(\text{Ti}) = -848.406$ atomic units (au), whereas on the basis of *ab initio* studies (7), values close to the Hartree–Fock limits for the *electronic energies* of HOCN and HNCO can be estimated as −225.127 au and −226.406 au, respectively. Substitution into relation [13] gives

$$-303.037 \text{ au} \leq -226.406 \text{ au} \leq -136.087 \text{ au}$$

that is, both bounds are valid with very wide margins. Whereas the actual numbers may change if the molecular geometries are distorted, inequalities [13] give valid bounds for isomer HNCO for any *distorted geometry*, as long as the same distortion is applied to both HOCN and HNCO, e.g., the same relation [13] is applicable to dissociated fragment pairs HO + CN and HN + CO, or to corresponding points along dissociation pathways.

In order to illustrate the application of relation [11] and to obtain tighter bounds for the above isomers, consider molecule M_1 = fluoroacethylene, HCCF. Choosing $\alpha_1 = \alpha_2 = 0.5$, for isomers HOCN (= M_2 = M) and HNCO (= ISOM), relations [8] and [9] are evidently valid, as well as all four relations of type [10]:

[14] $0.5 \times 1 + 0.5 \times 1 = 1$

[15] $0.5 \times 6 + 0.5 \times 8 = 7$

[16] $0.5 \times 6 + 0.5 \times 6 = 6$

[17] $0.5 \times 9 + 0.5 \times 7 = 8$

Consequently, for *any* common geometry the relation

[18] $0.5\ E_c(\text{HCCF}) + 0.5\ E_c(\text{HOCN}) \leq E_c(\text{HNCO})$

is necessarily valid, if all these species are in the lowest electronic state of a given type. For a typical nuclear arrangement the obtained energy bound is about two orders of magnitude tighter than that calculated using relation [1].

One important feature of the loose [7] and, especially, of the tighter [11] bounds is the fact that they can be applied easily to very large molecular systems, for which even semiempirical quantum chemical calculations are impractical or impossible. Such applications to large zeolite cluster models will be reported shortly (8).

The general results [1], [7], and [11] are given for the electronic energies. If total energies are of interest, then the corresponding total energy relations can be obtained by adding the respective nuclear repulsion terms E_n to the electronic energies E_c, $E_t = E_c + E_n$. Knowing the nuclear charges, E_n can be calculated by elementary application of Coulomb's law.

Ortho-disubstituted aromatics with bulky substituents are distorted so that the substituents are above and below the approximate plane of the aromatic system. This introduces chirality which was observed by proton resonance spectroscopy with and without the use of a chiral shift reagent. The more nearly planar naphthalene systems invert their chiral configurations more rapidly. Crystals of 1,2-benzenediacetic acid, α,α,α′,α′-tetramethyldimethyl ester are monoclinic, space group $A2/a$ with a = 10.665(3), b = 8.467(2), c = 17.198(4) Å and β = 105.94(2)°. The torsion angle between the 1,2 substituents is 12.1°. Crystals of 2,3-naphthalene diacetic acid, α,α,α′,α′-tetramethyldimethyl ester are also monoclinic, space group $P2_1/c$ with a = 9.0992(14), b = 18.849(3), c = 11.319(2) Å and β = 113.88(1)°. The analogous torsion angle in this case is 8.9°.

L. Ross C. Barclay, Sydney Brownstein, Eric J. Gabe et F. L. Lee. Can. J. Chem. **62**, 1358 (1984).

Les composés aromatiques portant deux substituants encombrants dans les positions *ortho* sont déformés d'une façon telle que les substituants sont situés au-dessus et au-dessous du plan approximatif du système aromatique. Ceci introduit une chiralité que l'on a observé par rmn du proton, avec ou sans utilisation d'un réactif chiral de déplacement. Les systèmes naphtaléniques, qui sont plus proches de la planéité, intervertissent leurs configurations chirales plus rapidement. Les cristaux de l'ester diméthylique de l'acide benzène bis(diméthylacétique)-1,2 sont monocliniques et appartiennent au groupe d'espace $A2/a$ avec a = 10,665(3), b = 8,467(2), c = 17,198(4) Å et β = 105,94(2)°. L'angle de torsion entre les substituants 1 et 2 est de 12,1°. Les cristaux de l'ester diméthylique de l'acide naphtalène bis(diméthylacétique)-2,3 sont également monocliniques et appartiennent au groupe d'espace $P2_1/c$ avec a = 9,0992(14), b = 18,849(3), c = 11,319(2) Å et β = 113,88(1)°. Dans ce cas, l'angle de torsion est de 8,9°.

[Traduit par le journal]

Introduction

Ortho-disubstituted aromatics which have bulky substituents are likely to experience severe steric strain. For *ortho* di-*t*-butylbenzene the strain energy has been found to be 22.3 ± 0.5 kcal/mol (1). The steric strain in 1,2,4,5-tetra-*t*-butylbenzene is relieved by angular distortions of up to 10° in the benzene ring and by stretching of the exocyclic bonds, from a normal value of 1.53 Å (2) to 1.57 Å, but without sacrificing the planarity of the benzene ring nor of the carbon atoms attached directly to it (3). Similarly in 1,3,6,8-tetra-*t*-butylnaphthalene the aromatic carbon – quaternary carbon bond length is stretched from 1.53 Å for the non-hindered *t*-butyl group to 1.56 Å for the hindered one (4).

If an aromatic ring has two *ortho*-substituents which are bent above and below its plane the molecule is potentially chiral. An example is the stereo pair stick diagram of 1,2-benzenediacetic acid, α,α,α′,α′-tetramethyldimethyl ester (**2**), which is reproduced in Fig. 3. This chirality would be lost if there were rapid exchange of the position of the above-plane and below-plane groups via a planar intermediate. Such exchange most probably accounts for earlier unsuccessful attempts to chemically resolve α,α,α′,α′-tetramethyl-1,2-benzene diacetic acid (5). The barrier to flipping between equivalent non-planar states of 1,8-di-*t*-butylnaphthalene was found to be 24 kcal/mol (6).

It is well known that the protons of a methylene group adjacent to a chiral centre display magnetic non-equivalence (7). It has also been frequently observed that the resonance signals of chiral molecules can be split into those of their *d* and *l* diastereomers on complexing with chiral shift reagents (8). This study attempts to determine if there are some *ortho* substituted benzenes and naphthalenes where the substituents are bent out of the plane of the aromatic ring and also the rate of averaging via a planar intermediate. High resolution proton resonance spectroscopy and single crystal X-ray diffraction techniques have been employed to study the problem, in both solution and the solid state.

Experimental

β,β′-Dihydroxy-*o*-di-*t*-butylbenzene (**1**), 1,2-benzenediacetic acid, α,α,α′,α′-tetramethyldimethyl ester (**2**), β,β′-dihydroxy-2,3-di-*t*-butylnaphthalene (**3**) and 2,3-naphthalenediacetic acid α,α,α′,α′-tetramethyldimethyl ester (**4**) were available from previous studies (5, 9). Proton resonance spectra were obtained in the Fourier Transform mode at an operating frequency of 100 MHz on a hybrid Varian XL-100 Nicolet 1010 apparatus.

X-ray intensity data for the compounds **2** and **4** were measured on a Picker 4-circle automatic diffractometer using graphite monochromatised MoKα radiation with θ/2θ scan methods and line profile analysis (10). The unit cell constants were obtained by least-squares refinement of the setting angles of reflections with 2θ > 40° and 45°, respectively, (λ(MoKα$_1$) = 0.70932 Å). The relevant experimental details are given in Table 1. The intensities were corrected for Lorentz and polarization effects, using measured values for direct beam polarization (11). Absorption corrections were not considered to be justified because the effects are small.

Both structures were solved by the application of MULTAN (12). After several cycles of refinement with isotropic temperature factors, the hydrogen atoms were located in a difference map. The structures were refined further by full-matrix least-squares with anisotropic tem-

perature factors for the non-hydrogen atoms. Counting statistics weights were used throughout ($w = 1/\sigma^2(F_o)$). Intensity statistics on **2** clearly indicated the space group $A2/a$. Subsequent refinement in Aa and $A2/a$ confirmed this. The final R values are given in Table 1. Scattering factors for neutral atoms were taken from International tables for X-ray crystallography (1974). The final positional and equivalent isotropic temperature factors are given in Tables 2 and 3. Tables of thermal parameters and structure factors are deposited as supplementary material.[4] All calculations were performed using the NRC PDP8-E system of programs (13), adapted for a VAX11/780 computer.

[4] Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and discussion

Proton magnetic resonance studies

The spectrum of **1** in $CDCl_3$ at room temperature shows two sharp lines of equal intensity for the methylene hydrogens. These are considerably broadened and only partially resolved at 55°C, with the spectral changes normally found in a two-site exchange situation. The chemical shift values are listed in Table 4. This non-equivalence, which is partly averaged at higher temperature, may be due to the chiral nature of the molecules because of displacement of the substituents above and below the plane of the aromatic ring or may arise from the presence of a dimer in the solution. With the addition of a chiral shift reagent, europium tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato], ($Eu(hfc)_3$), the methylene signals are broadened and shifted but the non-equivalence remains at 0°C. It is no longer observable at room temperature. The effect of a shift reagent suggests that the non-equivalence is not due to dimer formation. The dimer, if present, would be dissociated by the shift reagent and non-equivalence would never be observed. A potential problem in ascribing the two lines to magnetic non-equivalence due to an adjacent chiral centre is the lack of observed proton–proton spin-coupling.

If the observed non-equivalence is due to dimer formation it should be accentuated in a less polar solvent than $CDCl_3$. Therefore the studies were repeated in CS_2 and the results are also listed in Table 4. Separate lines from the CH_2 protons were not observed with or without $Eu(hfc)_3$ in CS_2 solution. It is therefore likely that dimer formation is not the cause of the observed non-equivalence in $CDCl_3$ solution. The changes in chemical shift and their temperature dependence suggest that aggregation may possibly be occurring in CS_2.

It is reasonable to suppose that a correspondingly substituted naphthalene would have similar aggregation in solution as **1**. It is also possible that the ease of distortion of the aromatic ring, and hence the barrier to rapid inversion about the plane of the aromatic ring, may be different for the benzene and naphthalene analogues. The same proton resonance measurements were also made on **3** and the results included in Table 4. Only at 0°C in $CDCl_3$ and with $Eu(hfc)_3$ is splitting observed. The results in Tables 4 and 5, which frequently show splitting of the methyl signals for the benzene derivatives, but rarely for the naphthalene derivatives, are interpreted in terms of averaging

[a] B_{eq} is the arithmetic mean of the principal axes of the thermal ellipsoid.

of the magnetic non-equivalence being easier for the naphthalene than the corresponding benzene compound. It has been established that line broadening from shift reagents at low temperatures precludes their use for accurate kinetic studies below about 40°C (14). Therefore only qualitative conclusions can be presented.

Since the data on the —CH_2OH compounds are slightly equivocal a similar series of measurements were made on compounds **2** and **4** where the substituent is —$COOCH_3$. The binding of this group to the shift reagent should be weaker than for the CH_2OH group and there should be little tendency for

[a] There is evidence from a DISPA plot (15) that these are two unresolved lines.

dimerization in solution. The results are listed in Table 5. There is no evidence for non-equivalence of the methyl groups in **2** or **4** in the absence of shift reagent. When Eu(hfc)$_3$ is added to the solutions a splitting of the methyl groups at low temperature is observed with **2** but not with **4**.

From all of these observations we may conclude that all the compounds studied are chiral in solution. This lack of symmetry is removed by motional averaging which has a lower energy barrier in the case of the naphthalene compounds than the benzene compounds.

X-ray crystal structure studies

Bond lengths and angles for compounds **2** and **4** are shown in Figs. 1 and 2, respectively. It should be noted that the thermal parameters of H11, H41, H61, and H91 are exceptionally small. This may be an artifact of the refinement but we

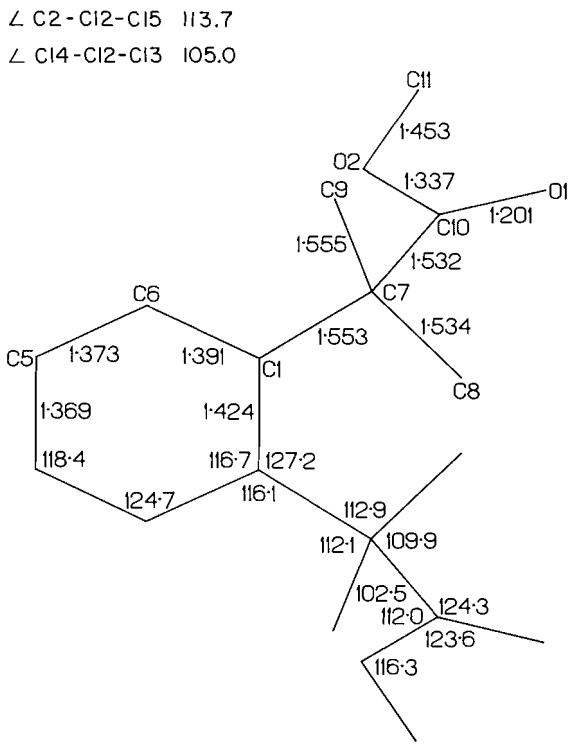

FIG. 1. Bond lengths and angles for **2**.

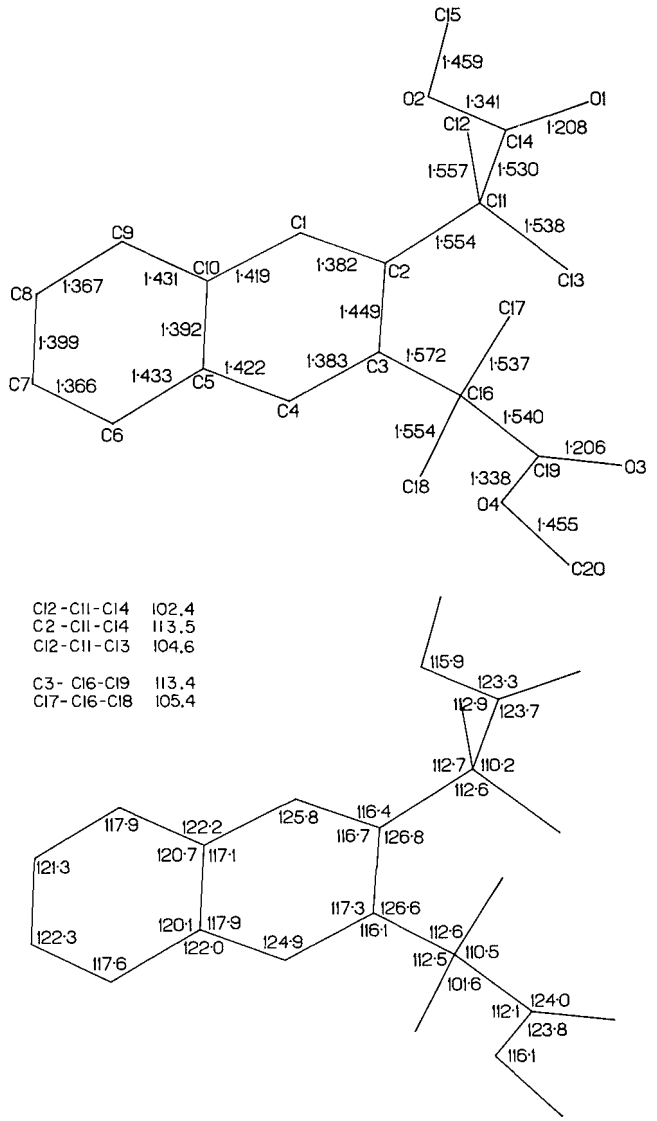

FIG. 2. Bond lengths and angles for **4**.

can offer no satisfactory explanation. Lists of structure factors and anisotropic thermal parameters are also lodged with the Depository of Unpublished Data.[4]

The molecule of **2** uses a crystallographic two-fold axis, but as this is a symmetry operator of the first kind it is still possible for the molecule to possess "handedness" (chirality). In fact the molecules of **2** and **4** both show such handedness because of the out-of-plane distortions of the $—(CH_3)_2COOCH_3$ group. In **2** this distortion produces a 12.1° torsion angle between the two substituents on atoms C_1 and C_2, and in **4** the torsion angle is 8.9°. It should be emphasized that because the space groups of **2** and **4** are both centrosymmetric, left- and right-handed molecules exist in both crystals. The chirality of **2** is clearly illustrated by the stereo pair representation of Fig. 3.

The benzene ring of **2** is distorted so that atoms C_1 and C_2 are −0.032 and +0.032 Å from the plane and C_5 and C_4 are +0.019 and −0.019 Å out-of-plane. The substituents atoms C_7 and C_{12} are −0.203 and +0.203 Å, respectively from the plane. There is less distortion of the unsubstituted aromatic ring of **4** (C_5 to C_{10}) than for the benzene ring of **2** with C_5, C_8, and C_9 0.013, 0.004, and 0.001 Å above the plane and C_6, C_7, and C_{10} 0.008, 0.001, and 0.010 Å below the plane. The substituted aromatic ring of **4** is also very nearly planar with C_3 and C_{10} at +0.024 and +0.020 Å, respectively, and C_1, C_2, C_4, and C_5 at −0.003, −0.019, −0.008, and −0.015 Å. However, there is a dihedral angle of 2.83° between the planes of the two rings. The substituent atoms C_{11} and C_{16} of **4** are at −0.132 and +0.161 Å from the plane of the substituted benzene ring. Therefore, one may say that there are greater deviations from planarity in **2** than in **4**. The lengths of the exocyclic carbon–carbon bonds are similar in both **2** and **4** and also similar to those found for other hindered *t*-butyl substituted aromatic compounds (3, 4). The aromatic carbon–carbon bonds of the ring atoms attached to the bulky substituents, C1—C2 in **2**, and C2—C3 in **4**, are also significantly lengthened.

Since the bulk of the *ortho*-substituents is the same for the benzene and napthalene compounds but the structures of the napthalene compounds were found to be more nearly planar, it follows that there is a greater steric strain energy in the naphthalene series. We can assume that the steric strain for the substituent groups to pass each other in the transition state for moving from above to below the plane of the aromatic ring is the same for the benzene and naphthalene compounds since the relevant bond lengths and angles for the two are similar. This implies that the difference in energy between the ground state and the planar transition state for exchange of substituent positions relative to the aromatic ring will be less for the naphthalene compounds than the corresponding benzene compounds. Such a result is in fact inferred from the proton resonance observations. Therefore the structural results obtained for the solids are consistent with the proton magnetic resonance results in solution.

Structural studies of organoboron compounds. XX.[1] (Salicylaldoximato-*O*,*N*)diphenylboron

WOLFGANG KLIEGEL

Institut für Pharmazeutische Chemie, der Technischen Universität Braunschweig, 3300 Braunschweig, Beethovenstraße 55, Bundesrepublik Deutschland

AND

STEVEN J. RETTIG AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received November 9, 1983

WOLFGANG KLIEGEL, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **62**, 1363 (1984).

Crystals of (salicylaldoximato-*O*,*N*)diphenylboron are triclinic, a = 10.125(2), b = 10.797(1), c = 14.760(2) Å, α = 89.05(1), β = 86.98(1), γ = 83.18(1)°, Z = 4, space group $P\bar{1}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.040 and R_w = 0.048 for 4145 reflections with $I \geq 3\sigma(I)$. The structure consists of two crystallographically independent, but essentially identical, molecules linked by strong O—H···O hydrogen bonds to form continuous spirals along the a axis. The Ph_2B moiety is chelated by the phenolic oxygen and oxime nitrogen atoms of the ligand resulting in the formation of a non-planar six-membered chelate ring. Important libration-corrected mean bond lengths are O—B = 1.516(1), N—B = 1.609(2), and C—B = 1.613(2) Å.

WOLFGANG KLIEGEL, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **62**, 1363 (1984).

Les cristaux de (salicylaldoximato-*O*,*N*)diphénylbore sont tricliniques; a = 10,125(2), b = 10,797(1), c = 14,760(2) Å, α = 89,05(1), β = 86,98(1), γ = 83,18(1)°, Z = 4, groupe d'espace $P\bar{1}$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,040 et de R_w = 0,048 pour 4145 réflexions avec $I \geq 3\sigma(I)$. La structure consiste en deux molécules qui sont cristallographiquement indépendantes, mais essentiellement identiques, et qui sont liées par de fortes liaisons hydrogènes O—H···O formant ainsi une spirale continue le long de l'axe a. L'unité Ph_2B est chélatée par l'oxygène phénolique et par l'azote de l'oxime du ligand; il en résulte la formation d'un chélate cyclique à six chaînons qui n'est pas plan. Les longueurs de liaison importantes, corrigées pour la libration, sont: O—B = 1,516(1), N—B = 1,609(2) et C—B = 1,613(2) Å.

[Traduit par le journal]

Introduction

Spectroscopic data and chemical behavior of different boron chelates of salicylaldoxime support the assumption that they contain six-membered heterocyclic rings with intramolecular N→B coordination (1). This structure was already suggested for the diphenylboron chelate **4** by Umland and Schleyerbach (2) who first reported the synthesis of this compound from salicylaldoxime (**1**) and diphenylborinic acid anhydride. The chelate structure **4** would derive from the (*E*)-form of salicylaldoxime (**1**), which has been verified by X-ray crystallographic analysis (3) and which is also represented in several metal chelates of salicylaldoxime (4–8). Nevertheless, the seven-membered isomeric chelate structure **5**, which could result from a configurational change of (*E*)-salicylaldoxime to the (*Z*)-isomer under the influence of the Lewis-acid borinic acid reagent during the synthesis, could not be excluded unambiguously by chemical or spectroscopic means (1). Moreover, the seven-membered ring system of **5** has been verified in various boron chelates of salicylaldehydnitrones **7** (9).

An X-ray crystallographic study was undertaken to decide between the two structures **4** with N→B coordination and **5** with O→B coordination. To avoid thermal stress which can cause the transformation of the diphenylboron chelate into the pentacyclic dimer **6** of a monophenylboron derivative of salicylaldoxime (1, 10), the compound was recrystallized from methanol/acetonitrile or methanol/water under mild conditions.

Experimental

(Salicylaldoximato-O,N)diphenylboron (3-hydroxy-2,2-diphenyl-1-oxa-3-azonia-2-borata-1,2-dihydronaphthalene) (4)

The compound was synthesized from salicylaldoxime and oxybis(diphenylborane) by the literature method (2). Melting point 157°C; lit. (2) 157°C. Crystals suitable for X-ray analysis were obtained by slow evaporation of a methanol/water solution. A crystal bounded by the six faces (followed by their distances in mm from a common origin): ±(0 1 1), 0.163, ±(0 1 −1), 0.256, ±(1 0 0), 0.313 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 40−45°) measured on a diffractometer with Mo-Kα Radiation (λ(Kα$_1$) = 0.70930, λ(Kα$_2$) = 0.71359 Å). Crystal data at 22°C are:

$C_{19}H_{16}BNO_2$ fw = 301.15

Triclinic, a = 10.125(2), b = 10.797(1), c = 14.760(2) Å, α = 89.05(1), β = 86.98(1), γ = 83.18(1)°, V = 1599.8(4) Å^3, Z = 4, ρ_c = 1.250 gcm^{-3}, F(000) = 632, μ(Mo-Kα) = 0.75 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2, reduced cell) from structure analysis.

Intensities were measured with graphite-monochromated Mo-Kα radiation on an Enraf-Nonius CAD4-F diffractometer. An ω−2θ scan at 1.44−10.06° min^{-1} over a range of (0.65 + 0.35 tan θ) deg in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 2.5%. Of the 7310 independent reflections measured and processed,[2] 4145 (57%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods in the centrosymmetric space group $P\bar{1}$ (strongly indicated by the E-statistics), the coordinates of all non-hydrogen atoms being determined from an E-map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to R = 0.080, a difference map gave

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

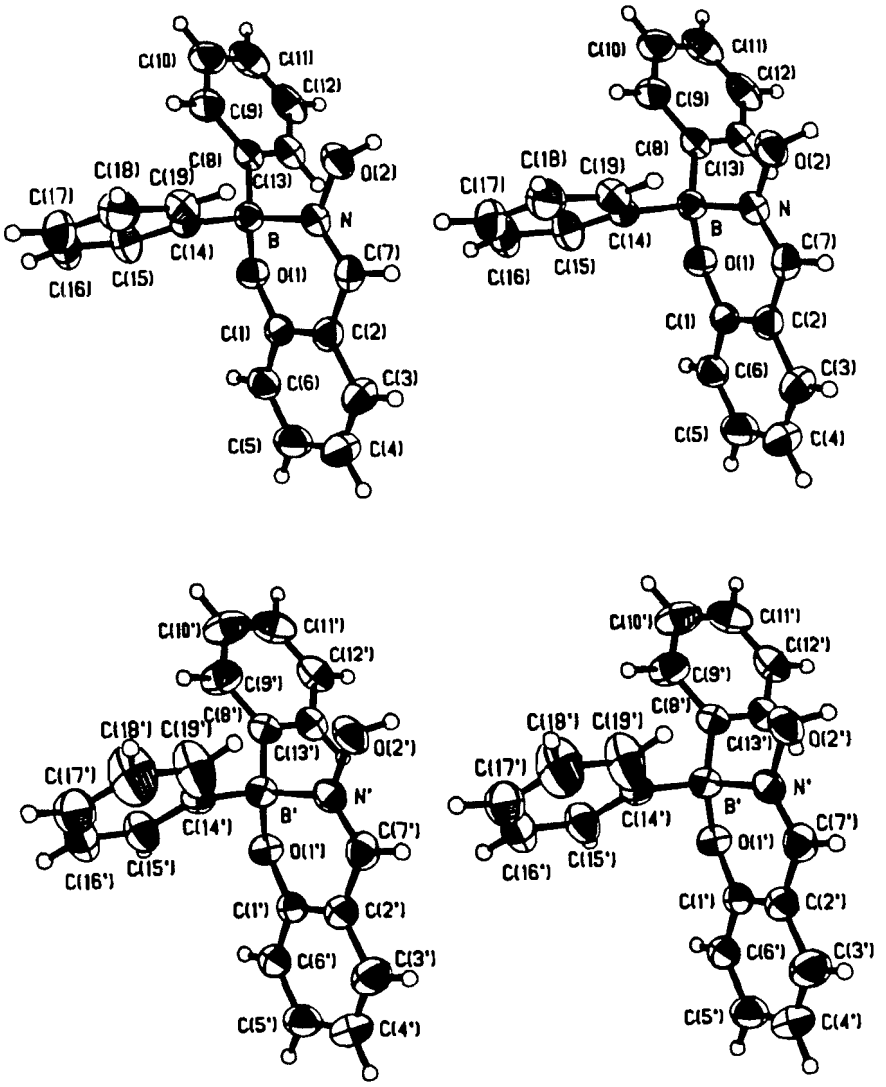

FIG. 1. Stereoscopic views of two independent (salicylaldoximato-*O*,*N*)diphenylboron molecules. 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

the positions of all hydrogen atoms which were refined with isotropic thermal parameters in subsequent least-squares cycles. The scattering factors of ref. 11 were used for non-hydrogen atoms and those of ref. 12 for hydrogen atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of refinement. Unobserved reflections were not included in the refinement. Convergence was reached at $R = 0.040$ and $R_w = 0.048$ for 4145 reflections with $I \geq 3\sigma(I)$. For all 7310 reflections $R = 0.088$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.05 and 0.68σ, respectively. The maximum parameter shift was associated with the *y* coordinate of H(18′). The mean error in an observation of unit weight was 1.851. A final difference map was essentially featureless, residual densities ranging from -0.24 to $+0.157$ e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 5,[3] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (13). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0010 Å^2. Analyses of the two independent molecules indicated significant independent motion of the phenyl rings. The 7-atom BPh and 11-atom groups consisting of the fused-ring system plus O(2) were separately analysed (rms ΔU_{ij} = 0.0014–0.0025 Å^2). The appropriate bond distances have been corrected for libration (13, 14), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 3. Intra-annular torsion angles defining the conformations of the six-membered chelate rings are listed in Table 4. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 6–8) are included as supplementary material. Corrected bond lengths (esd's taken as equal to those associated with the uncorrected values) are employed in the discussion.[4]

[3]The structure factor table, Table 5 (anisotropic thermal parameters) and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[4]All bond lengths referred to in the discussion except those for compound **8** have been corrected for libration.

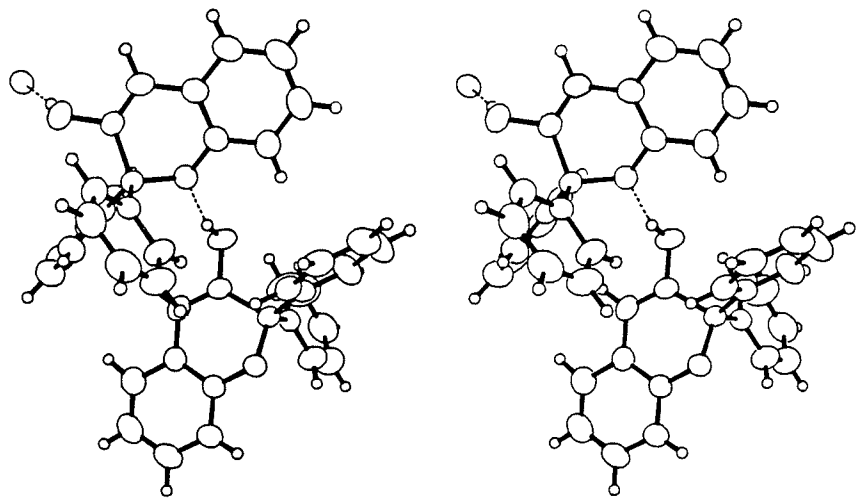

FIG. 2. Stereoscopic view of the asymmetric unit showing the spatial relationship between the two independent molecules. Hydrogen bonds are represented by broken lines.

Results and discussion

The X-ray analysis confirms the six-membered chelate structure **4** containing an intramolecular N→B interaction. The structure is thus consistent with that found earlier for **6** (10), to which **4** is transformed upon heating.

The crystal structure of **4** consists of discrete molecules linked by strong O—H···O hydrogen bonds (O(2)—H(O2)···O(1′) ($1 + x, y, z$), O···O = 2.737(3), H···O = 1.80(3) Å, O—H···O = 167(2)°; O(2′)—H(O2′)···O(1), O···O = 2.699(2), H···O = 1.82(2) Å, O—H···O = 161(2)°) to form continuous spirals along the *a* axis. The two crystallographically independent molecules are related to one another by a pseudo-twofold screw axis along *a*; coordinates of unprimed atoms are approximately given by the operation ($1/2 + x, 1/2 - y, 1/2 - z$) on the coordinates of the corresponding primed atoms. The spatial disposition of the two molecules and the intermolecular H-bonding are shown in Fig. 2. There are short C—H···O contacts between chains (C(18′)—H(18′)···O(2′) ($1 - x, 1 - y, 1 - z$), C···O = 3.453(2), H···O = 2.54(3) Å, C—H···O = 152(2)°). There are also a pair of close intermolecular H···H contacts between phenyl rings on adjacent molecules along the chain (H(13)···H(15′) ($1 + x, y, z$) = 2.35(3) and H(13′)···H(15) = 2.25(3) Å).

The two independent molecules of the asymmetric unit have

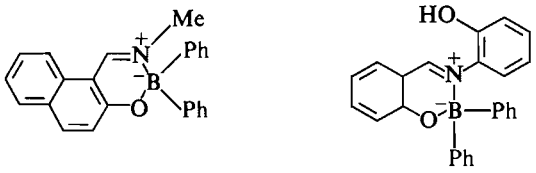
nearly identical structures (Fig. 1). In each molecule there is a short intramolecular C—H···O contact (C(19)—H(19)···O(2), C···O = 3.246(2) and 3.137(3), H···O = 2.57(2) and 2.46(3) Å, C—H···O = 125(1) and 127(2)°). Corresponding bond lengths and angles in the two molecules are presented side-by-side in Tables 2 and 3 for ease of comparison. Mean[5] bond lengths will be employed in subsequent discussion.

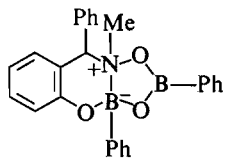
[5]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

The significantly non-planar C_3BNO chelate rings have conformations which may be described as either B-envelopes or half-chairs with B and O atoms displaced in opposite directions from the approximate plane formed by the four other ring atoms, very similar to those in **6** (10), **9** (15), and in the related molecule (salicylaldehydato)diphenylboron (16). The chelate ring in the *N*-aryl derivative **9**, however, deviates more from planarity than those in **4** as indicated by the torsion angles compared in Table 4. In the square-planar metal complexes bis(salicylaldoximato)M(II) (where M = Ni (4, 5), Cu (6), and Pd (7)), the chelate rings were found to be nearly planar although a conformation similar to that found here was reported for the compound bis(5-chlorosalicylaldoximato)copper(II) (8). The six independent aromatic rings are either planar within experimental error or nearly so, the maximum deviation of any atom from the respective C_6 mean plane being 0.0090(23) Å for C(4).

Bond lengths in **4** are very similar to the values reported for the free ligand **1** itself (3), the "chelated" proton in **1** being replaced by the diphenylborenium cation in **4**. The N—B distance of 1.609(2) Å is similar to the longer of two N(sp^2)—B bonds in **6** (1.602(2) Å) and that in the related Schiff-base complex **8** (17) (uncorrected value of 1.601(4) Å), but is significantly shorter than the distance of 1.638(5) Å in the *N*-aryl



8 9



10

derivative **9** (15). The O—B distance in **4** (1.516(1) Å) is significantly longer than the distance between the phenolic oxygen and boron in **6** (mean 1.481(7) Å) or in the tricyclic compound **10** (18) (1.445(2) Å), slightly longer than in **8** (1.506(3) Å, uncorrected), or in (salicylaldehydato)diphenylboron (1.500(4) Å) (16). An even longer bond of this type has been observed in the Ph_2B chelate **9** (O—B = 1.524(5) Å). The C=N and N—O bonds of the oxime moiety in **4** are essentially the same as those in the free oxime **1** and are similar to values reported for various oximes and derivatives thereof (19–21). The geometry of the B-substituted phenyl rings is as expected (22) and the mean B—C distance of 1.613(2) Å is normal.

KAKALI CHATTERJEE, SANTANU LAHA, SANKAR CHAKRAVORTI, TAPAN GANGULY, and SUKHENDU B. BANERJEE. Can. J. Chem. **62**, 1369 (1984).

Fluorescence spectra of 1,2,3,4-tetrahydroquinoline (THQ) in binary and ternary mixtures in nonpolar and hydrogen bonding solvents at different temperatures are investigated. A probable case of partial protonation of THQ at 300 K due to hydrogen bonding in the excited state with ethanol is reported. At 77 K, there is no significant hydrogen bonding interaction between these molecules. Interaction between the n-orbital of triethylamine (TEA) and the π-electron system of excited THQ results in the formation of a CT-type complex which causes slow quenching of the fluorescence of THQ at 300 K. This quenching is not observed at 77 K because restriction of molecular orientation at 77 K prevents the formation of such complex. In pyridine, the fluorescence is strongly quenched both at room temperature and at 77 K. This has been attributed to π-electronic delocalization interaction between the fluorescer THQ and the nonfluorescing quencher pyridine. Possibility of conformational change is suggested. Rate constants associated with suitable reaction scheme for depletion of excited state are estimated. It is indicated that the quenching of fluorescence may be largely diffusion controlled.

KAKALI CHATTERJEE, SANTANU LAHA, SANKAR CHAKRAVORTI, TAPAN GANGULY et SUKHENDU B. BANERJEE. Can. J. Chem. **62**, 1369 (1984).

Les spectres de fluorescence de la tétrahydroquinone-1,2,3,4 (THQ) ont été examinés à différentes températures et dans des mélanges binaires et tertiaires de solvants non-polaires et de solvants exerçant des biens hydrogène. On remarque que le THQ dans son état excité subit une liaison hydrogène avec l'éthanol ce qui vraisemblablement provoque la protonation partielle du THQ à 300 K. Par contre on ne retrouve aucun lien hydrogène entre ces deux même substances à 77 K. A 300 K, l'intéraction entre l'orbitale n de la triéthylamine (TEA) et les π électrons du THQ excité provoque la formation d'un complexe de transfert de charge qui entraîne une extinction de la fluorescence du THQ. Cet effet n'est cependant pas observé à 77 K ce qui s'explique par la restriction imposée sur l'orientation moléculaire qui empêche la formation d'un tel complexe. Dans la pyridine, la fluorescence est fortement diminuée aussi bien à la température ambiante qu'à 77 K. On attribue cet effet a l'interaction des systèmes d'électrons délocalisés présents; on soupçonne de plus un changement de conformation. Les vitesses de réaction pour la dépopulation des états excités été mesurées. En conclusion, il semble que l'extinction de la fluorescence soit largement controlée par diffusion.

[Traduit par le journal]

Introduction

Effect of solvent–solute interaction, including hydrogen-bonding, on the fluorescence and phosphorescence spectra of molecules in solution has been extensively studied (1–14). Specifically hydrogen bonding interactions bring about many changes in the spectra such as spectral shift, intensification of spectra, as well as quenching of fluorescence in specific solvents. Hydrogen bonding abilities of molecules are usually different in the ground and excited electronic states. A number of organic molecules form stronger hydrogen bonds in the excited states (7, 12). A few extreme cases of strong hydrogen bonding in the excited state leading to protonation (15) or deprotonation (16) of molecules in donor or acceptor solvent, as the case may be, are known. As regards the phenomenon of fluorescence quenching due to hydrogen bonding, possible reaction schemes providing routes for nonradiative energy loss have been described (17–23), but a clear interpretation of the phenomenon is lacking.

Hydrogen bonding in 1,2,3,4-tetrahydroquinoline (THQ) molecule, a bicyclic secondary amine, in the ground state was studied by ultraviolet and infrared absorption spectroscopy (24). In this molecule, the N—H group is in the alicyclic-like ring 2 (Fig. 1(*a*)) and according to Booth (25), the molecule is a mixture of rapidly inverting half-chair structure with equal proportions of axial and equatorial conformations. It was suggested (24) that intermolecular hydrogen bond with dioxane brought about conformational change favourable for large participation of nitrogen lone pair in the π-electronic system of the benzene-like ring. The purpose of this work was to study hydrogen bonding properties of THQ in the excited state. Probable reaction schemes for depletion of excited state and changes in the position and intensity of fluorescence bands of the molecule due to hydrogen bonding reactions in different solvents at 300 and 77 K are described in this paper.

Experimental

Pure 1,2,3,4-tetrahydroquinoline (THQ) supplied by Fluka, Switzerland was used after distillation under reduced pressure. Solvents cyclohexane (CH), methylcyclohexane (MCH), dioxane, and ethanol (EtOH) were of spectroscopic grade and solvents triethyl amine (TEA), pyridine, and acetonitrile, obtained from E. Merck, were repeatedly distilled under vacuum before use and were tested for the absence of any fluorescence. At room temperature, CH or MCH was the "inert" solvent while at 77 K, MCH was used to obtain a glassy matrix. The fluorescence and excitation spectra were recorded with a Perkin-Elmer model MPF 44A fluorescence spectrophotometer provided with corrected spectra unit and the absorption spectra with a Shimadzu UV-VIS spectrophotometer model 210A. The fluorescence quantum yield of THQ in CH was measured from the corrected area under fluorescence curve relative to that of phenanthrene (26) in identical condition and the fluorescence life time τ was determined therefrom (27).

Results and discussion

In a previous paper (24) it was reported that spectral changes characteristic of H-bonding in the ground state such as change in N—H stretching frequency, red-shift and intensification of absorption bands, were observed in the ir and uv absorption

spectra of THQ in CH solution in the presence of dioxane. In this work it is found that hydrogen bonding between excited THQ and dioxane is stronger as is evident from larger fluorescence spectral shift compared to shift of excitation spectrum due to hydrogen bonding (Table 1). When EtOH is used in place of dioxane a small red shift and a small change in intensity of ultraviolet absorption bands are observed as the concentration of EtOH is increased in steps (Fig. 1(*a*)). The infrared spectrum does not provide any conclusive evidence of formation of hydrogen bond between THQ in the ground state and EtOH. Therefore it is not possible to assess the contribution of such bond in effecting the changes of the absorption spectra relative to other factors like dispersion or electrostatic forces, especially when it is remembered that secondary amines are weak H-bonding agents. It is interesting to find that the fluorescence spectrum of THQ in CH or in MCH is strongly influenced by the presence of EtOH and a very large shift of about 1468 cm^{-1} of the fluorescence band occurs (Table 1). One tempting possible interpretation is that THQ forms strong hydrogen bond with EtOH in the excited state, though only weak bond, if any, is formed in the ground state of THQ. To test if hydrogen bonding is in any way responsible for the fluorescence spectral shift, the fluorescence spectrum was recorded when EtOH was replaced by acetonitrile, a non-hydrogen bonding solvent having a higher dielectric constant ($\epsilon \sim 38$) than EtOH ($\epsilon \sim 25$). It can be seen from Fig. 1(*c*) and Table 1 that only a small red shift of 203 cm^{-1} is produced with acetonitrile. This possibly gives indirect support to the supposition that the large red shift of the fluorescence band in EtOH−THQ−CH system is to be ascribed to strong hydrogen bonding between excited THQ and EtOH. The strong hydrogen bond is indicative of the amine acting as a proton acceptor (28) to EtOH. It seems, however, that the red shift is too large to be accounted for by simple H-bonding. Protonated tetrahydroquinolium ion in aqueous acid solution emits fluorescence near 26 946 cm^{-1} (Fig. 1(*b*)) which is shifted towards red from the fluorescence of "free" THQ by about 3425 cm^{-1}. The corresponding band in EtOH—CH or EtOH—MCH is at 28 803 cm^{-1} showing a red shift of 1468 cm^{-1}. It may be speculated that though an actual protolytic reaction should be disregarded in ethanol, the strong H-bonding of the excited THQ molecule with EtOH, which acts as a proton donor, may lead to partial protonation of THQ, to which the large red shift may be attributed. These results refer to measurement of fluorescence spectra at 300 K. Interestingly, there is no such remarkably large red shift of the fluorescence band of THQ in EtOH—MCH glass matrix at 77 K. The red shift is only about 366 cm^{-1}, comparable with the excitation red shift of about 334 cm^{-1} (Table 1), showing that at 77 K, there is no significant hydrogen bonding interaction between EtOH and THQ in the excited state, in contrast to what was observed at 300 K. The same is true for THQ in dioxane and MCH at 77 K. It may thus be generally concluded that in the viscous media at the low temperature, there is no increase in H-bond strength between

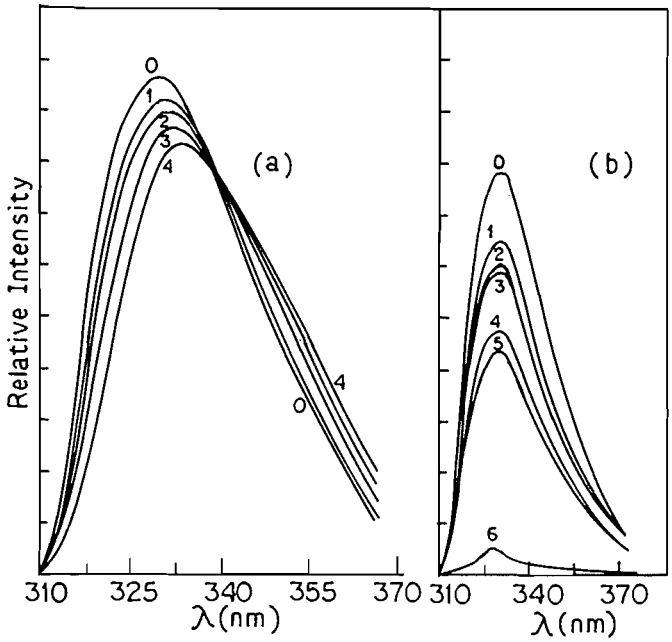

FIG. 2. (*a*) Fluorescence spectra of THQ (2.60×10^{-4} *M* L^{-1} in CH) at 300 K (excitation wavelength = 290 nm). Concentration (*M* L^{-1}) of TEA in *0*, 0; *1*, 0.05; *2*, 0.089; *3*, 0.22; *4*, 0.45. (*b*) Fluorescence spectra of THQ (5.2×10^{-4} *M* L^{-1} in CH) at 300 K (excitation wavelength is 290 nm). Concentration (*M* L^{-1}) of pyridine in *0*, 0; *1*, 3.75×10^{-4}; *2*, 1.25×10^{-3}; *3*, 3.6×10^{-3}; *4*, 7.25×10^{-3}; *5*, 1.25×10^{-2}; *6*, 9×10^{-1}.

excited THQ and hydrogen bonding solvents EtOH and dioxane behaving either as proton donor or acceptor relative to the bond strength in the ground state.

The ground state equilibrium constant, K_g, calculated from absorption measurement is given in Table 1. From the changes of the fluorescence spectra of THQ at 300 K in dioxane or EtOH in CH solution, the equilibrium constant, K_e, in the first excited singlet state is calculated utilising the frequently used equation (15),

$$[1] \quad \frac{1 - f_0/f}{Q} = -K_e + K_e\alpha(f_0/f)$$

where f_0 and f represent relative fluorescence intensities of THQ in CH without and with the H-bonding solvent whose concentration is Q, respectively, and α is the ratio of the fluorescence yield of H-bonded and free THQ molecules. Equation [1] holds under the condition that the extinction coefficients of free and H-bonded THQ molecules are equal at the wavelength of an exciting light. For the THQ–EtOH–CH system the excitation wavelength chosen is 290 nm, which corresponds to the isosbestic point in the absorption curves of this system reproduced in Fig. 1(*a*). Fluorescence intensities f_0 and f's are measured at 346 nm which corresponds to wavelength of the fluorescence spectrum due to hydrogen bonded THQ in EtOH (Fig. 1(*b*)). In the case of the THQ–dioxane–CH system, the excitation wavelength is chosen at 310 nm near which difference between the extinction coefficients (ϵ) of free and bonded species is very small (24).

A linear plot is obtained by taking $(1 - f_0/f)/[Q]$ as ordinate and (f_0/f) as abscissa. From the intercept and slope of the graph α and K_e are calculated. The calculated values are included in Table 1, from which it is seen that K_e values are larger than K_g values.

More pronounced changes in fluorescence are produced by TEA and particularly by pyridine, when they are used as H-bonding solvents. In TEA, at 300 K, the fluorescence intensity falls off very slowly and the band shifts towards longer wavelength (Fig. 2(*a*)) as the concentration of TEA is increased in steps in the binary mixture of THQ in CH. In the case of pyridine, however, the fluorescence intensity falls off more rapidly (Fig. 2(*b*)) without any appreciable shift of the fluorescence bands. It is to be noted that in the concentration range in which the changes in the fluorescence spectrum are produced by TEA or pyridine, no noticeable change in the absorption spectrum is observed with the same solvents. In other words, the changes in the fluorescence spectrum of THQ in CH by H-bonding interaction with TEA or pyridine arise at much lower concentration of these solvents than that producing any changes of consequence in the absorption spectra. Fluorescence quenching by hydrogen bonding interaction of THQ with pyridine, which has conjugate π-electron system, may occur due to CT interaction between the π-electron systems of the fluorescer THQ and proton acceptor pyridine (1–4, 6, 17, 29). It is also possible that when THQ enters into H-bonding with pyridine there is a change of conformation of the molecule, favourable for π-electron delocalization via the H-bond between the fluorescer THQ and the non-fluorescing pyridine. The quenching by TEA may be ascribed to the interaction between n-orbital of TEA and π-electron system of excited THQ molecule (13, 30).

The following reaction scheme describing the situation may be examined:

$$\mathrm{DH} + \mathrm{A} \underset{K_g}{\rightleftharpoons} \mathrm{DH} \cdots\cdots \mathrm{A}$$

$$\mathrm{DH} \rightarrow \mathrm{DH}^*$$

$$\mathrm{DH}^* + \mathrm{A} \underset{K_2}{\overset{K_1}{\rightleftharpoons}} (\mathrm{D}^{\delta+}\text{—}\mathrm{H} \cdots\cdots \mathrm{A}^{\delta-})^*$$

$$K_f \quad K_i \qquad K_{f'} \quad K_{i'}$$

$$\mathrm{DH} + h\nu_f \quad \mathrm{DH} \qquad \mathrm{DH} + h\nu_{f'} \quad \mathrm{DH}$$

where

$$\tau = 1/(K_i + K_f), \qquad \tau' = 1/(K_{i'} + K_{f'})$$

K_1 = bimolecular rate constant of H-bonding reaction, K_2 = unimolecular rate constant of dissociation of H-bond, $K_{f'}$ = rate constant associated with possible transfer of electronic excitation to nonfluorescent acceptor A.

When no H-bonded complex worth noting is formed in the ground state, Mataga *et al.* (6) used for calculating the rate constants K_1 and K_2, the equations

$$[2] \quad \frac{f/f_0 - 1}{[Q]} = \frac{\alpha\tau K_1}{1 + K_2\tau'} - \frac{\tau K_1}{1 + K_2\tau'}(f/f_0)$$

and

$$[3] \quad f_0/f = 1 + K_1\tau[Q]$$

where τ is the fluorescence decay time in the absence of a quencher. Equation [3] is nothing but the simple Stern–Volmer equation valid for notable quenching and is applicable in the case of pyridine. Equation [2] may be used for the quencher TEA in which no notable quenching takes place. By plotting f_0/f versus quencher pyridine concentration, τK_1 is estimated from the slope of the curve and from the measured

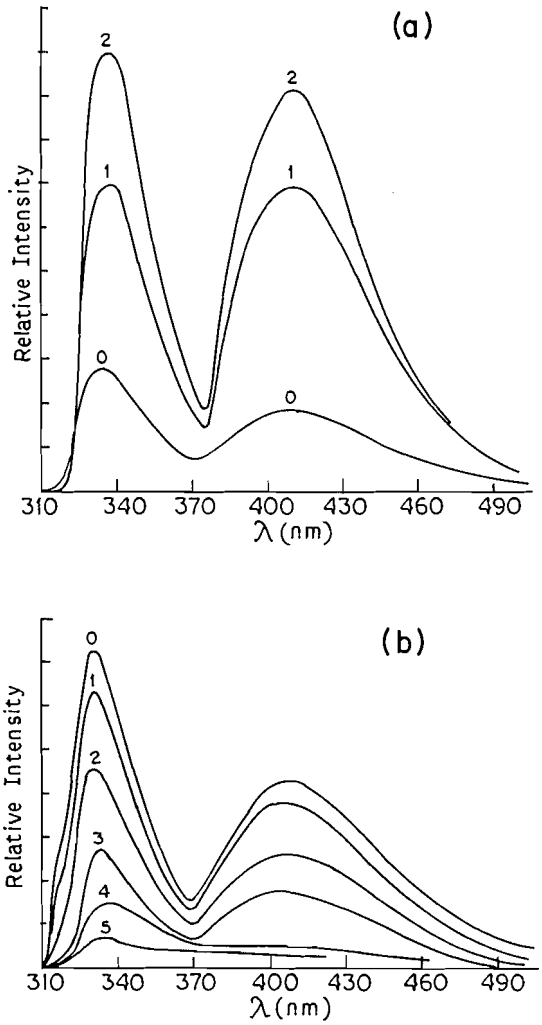

FIG. 3. (*a*) Fluorescence spectra of THQ (5.2×10^{-4} *M* L^{-1} in MCH) at 77 K (excitation wavelength is 290 nm). Concentration (*M* L^{-1}) of TEA in *0*, 0; *1*, 4.2×10^{-2}; *2*, 1.4×10^{-1}. (*b*) Fluorescence spectra of THQ (5.2×10^{-4} *M* L^{-1} in MCH) at 77 K (excitation wavelength is 290 nm). *0*, $C_{Pyridine} = 0$, *1*, $C_{Pyridine} = 3.75 \times 10^{-4}$ *M* L^{-1}, *2*, $C_{Pyridine} = 1.25 \times 10^{-3}$ *M* L^{-1}, *3*, $C_{Pyridine} = 3.6 \times 10^{-3}$ *M* L^{-1}, *4*, $C_{Pyridine} = 7.25 \times 10^{-3}$ *M* L^{-1}, *5*, $C_{Pyridine} = 1.25 \times 10^{-2}$ *M* L^{-1}.

value of $\tau = 2.37 \times 10^{-8}$ s. K_1 has been evaluated for the system THQ–pyridine–CH to be 0.3×10^{10} which is comparable with the diffusion-controlled rate constant, $K_d = 8RT/3000\eta = 0.6 \times 10^{10}$, indicating that the quenching of fluorescence of the THQ–CH system by pyridine is largely diffusion controlled.

Going back to the reaction scheme shown above it can be said that in the case of TEA, both $K_{f'}$ and $K_{i'}$ have competitive role even at high concentration of TEA whereas in the case of pyridine where remarkable quenching occurs without significant shift, $K_{i'}$ dominates over $K_{f'}$. In other words, at 300 K the excited hydrogen-bonded complex is rather stable in the case of TEA whereas in the case of pyridine immediate nonradiative degradation of electronic excitation energy takes place.

At 77 K, intensity of fluorescence due to THQ in TEA–MCH does not diminish. It is possible that in the rigid matrix at the low temperature, molecular orientation during the lifetime of the excited molecule which may be necessary for formation of CT-complex according to previous authors (13, 31), is restricted. Actually at 77 K, the emitted fluorescence is intensified as the concentration of TEA is increased (Fig. 3(*a*)). At the present stage, it is difficult to offer any definite interpretation of this observation. In pyridine–MCH, on the other hand, the fluorescence as well as the phosphorescence of THQ is strongly quenched even at 77 K (Fig. 3(*b*)). This indicates that the process of nonradiative transfer of energy to the nonfluorescing pyridine molecule through π-electronic delocalization via hydrogen bond between THQ and pyridine is efficiently operative at the low temperature.

Received November 1, 1983

JOHN A. STONE, WILLIAM M. SPLINTER, and DENA E. SPLINTER. Can. J. Chem. **62**, 1373 (1984).

The reactions of $CH_3ClCH_3^+$ (**I**) and $CH_3ClCH_2Cl^+$ (**II**) with a range of bases have been studied in a high pressure ion source. Reactant ion monitoring has been used to obtain the relative reactivities. Transfer of CH_3^+ from **I** and CH_2Cl^+ from **II** are the only reactions observed with N- and O-containing bases. Following addition of CH_2Cl^+ from **II**, the lower alkyl aromatics (ArH) yield either $ArHCH_2Cl^+$ or the benzyl ions $ArCH_2^+$ and $ArCHCl^+$ while CH_3^+ transfer leads only to $ArHCH_3^+$. The reactivities of the alkyl aromatics increase with increasing exothermicity (benzene → mesitylene) and there is an increasingly negative temperature coefficient of reactivity in the same order.

JOHN A. STONE, WILLIAM M. SPLINTER et DENA E. SPLINTER. Can. J. Chem. **62**, 1373 (1984).

On a étudié les réactions du $CH_3ClCH_3^+$ (**I**) et du $CH_3ClCH_2Cl^+$ (**II**) avec un certain nombre de bases dans une source d'ions à haute pression. On a utilisé la technique de l'enregistrement de l'ion qui réagit pour obtenir les réactivités relatives. Les seules réactions observées avec les bases contenant de l'azote ou de l'oxygène sont celles du transfert de CH_3^+ à partir de **I** et de CH_2Cl^+ à partir du composé **II**. Après l'addition de CH_2Cl^+ à partir du composé **II**, les dérivés aromatiques alkylés inférieurs (ArH) conduisent soit au $ArHCH_2Cl^+$ ou aux ions benzyliques $ArCH_2^+$ et $ArCHCl^+$; par ailleurs, le transfert de CH_3^+ conduit uniquement à l'ion $ArHCH_3^+$. La réactivité des composés aromatiques alkylés augmente avec l'exothermicité (benzène → mésityléne) et le coefficient de température évolue vers des valeurs de plus en plus négatives lorsqu'on procède dans le même ordre.

[Traduit par le journal]

Introduction

Dialkylchloronium ions are good and selective alkylating agents in the liquid and gaseous phases (1–4). For example, $CH_3ClCH_3^+$ transfers a methyl cation to alkyl aromatics (ArR) in the gas phase with a reaction efficiency which increases with increasing exothermicity of reaction [1]

[1] $CH_3ClCH_3^+ + ArR \rightarrow CH_3Cl + ArRCH_3^+$

We used the technique of Reactant Ion Monitoring (RIM) (2, 5) to determine the relative rates of these reactions in the high pressure ion source of a mass spectrometer and found the relative reactivity of ArR to increase in the order toluene < xylenes < mesitylene. Neither benzene nor fluorobenzene was observed to react but in a subsequent publication Sen Sharma and Kebarle (3) showed that benzene does indeed react, but very slowly ($k \sim 10^{-12}$ cm^3 molecule^{-1} s^{-1} at 298 K).

In our RIM study $CH_3ClCH_3^+$ was generated by argon resonance photoionization of CH_3Cl in an approximately 50/50 He/CH_3Cl mixture at about 1 Torr total pressure.

[2] $CH_3Cl \xrightarrow{h\nu} CH_3Cl^+ + e$

[3] $CH_3Cl^+ + CH_3Cl \rightarrow CH_3ClH^+ + CH_2Cl$

[4] $CH_3ClH^+ + CH_3Cl \rightarrow CH_3ClCH_3^+ + HCl$

The advantage of this photoionization is that no fragmentation of the molecular ion occurs and therefore only one reactant ion is present but a big disadvantage is that the ion intensity is small and consequently the signal-to-noise ratio is poor. The photoionization study was also limited to ambient temperature since the ion current from the field free high pressure ion source employed decreased significantly with increasing temperature. Increased ion current is obtainable using electron impact ionization but at the expense of having more than one reagent ion. We report on the use of such ionization in this paper.

The electron impact initiated ion chemistry of methyl chloride is well documented (6–9). CH_3Cl^+, CH_2Cl^+, and CH_3^+ are the major primary ions and these in CH_3Cl at 1 Torr lead to only two ions of significance at long times viz the two chloronium ions $CH_3ClCH_3^+$ and $CH_3ClCH_2Cl^+$. The former ion arises from CH_3Cl^+ by reactions [3] and [4]. CH_2Cl^+ was found to be unreactive towards CH_3Cl in low pressure experiments (6–8) but $CH_3ClCH_2Cl^+$ was observed at pressures of CH_3Cl greater than 0.4 Torr and it was suggested that it was formed in the following sequence (9).

[5] $CH_3^+ + CH_3Cl \rightarrow CH_2Cl^+ + CH_4$

[6*a*] $CH_2Cl^+ + CH_3Cl \rightarrow CH_3ClH^+ + CHCl$

[6*b*] $\xrightarrow{M} CH_3ClCH_2Cl^+$

Our objective in this work was to confirm and extend our studies of the CH_3^+ transfer reactions of $CH_3ClCH_3^+$ with aromatics and also to study reactions with N- and O-containing bases. We have also studied CH_2Cl^+ transfer from $CH_3ClCH_2Cl^+$ to the same series of bases. Pulsed electron beam, high pressure mass spectrometry (10, 11) has been used to observe the temporal sequences of ion molecule reactions in some of these systems.

Experimental

The field free ion source and the quadrupole ion detection system have been described (2, 11). RIM experiments were carried out in the manner which has been described in detail (2, 5) and will therefore only be briefly described.

CH_3Cl from a reservoir at atmospheric pressure and the helium carrier gas eluting from a gas chromatograph are mixed prior to entry into the ion source which operates at pressures from 0.5 to 1.2 mm Hg. The CH_3Cl/He pressure ratio is usually in the range 0.1 to 1, 500 eV electrons provide continuous ionization and the signal due to the ion of interest, $CH_3ClCH_3^+$ or $CH_3ClCH_2Cl^+$, is continuously monitored. The steady signal is decreased when a reactive compound elutes from the chromatograph, the decrease in signal providing a measure of its reactivity. The monitored ion current and the chromatograph flame ionization detector trace are displayed on a two pen strip chart recorder running at 5 in. min^{-1}. The monitored ion current appears like an inverted gc trace (2). The relative reactivity R_A/R_B of two compounds, A and B, with a given reactant ion is (5)

$$\frac{R_A}{R_B} = \frac{\ln\left(1 - \frac{\Delta I_A}{I^0}\right)}{\ln\left(1 - \frac{\Delta I_B}{I^0}\right)} \frac{W_{(1/2)B} C_B}{W_{(1/2)A} C_A}$$

where I^0 is the ion current in the absence of reactive eluent, ΔI_A and ΔI_B are the measured maximum decreases in I^0 when A and B are eluting, $W_{1/2}$ is the (inverted) peak width at half height and C_A and C_B are the concentrations of A and B in the sample injected into the chromatograph. The latter concentrations are checked by the gc flame ionization detector (FID).

The increased signal-to-noise ratios obtained with the electron impact source enable decreases in ion signal of less than 5% to be measured with good precision (±5%). The majority of the signal is nullified by a bucking potential and the residue is amplified using the range switch of the strip chart recorder. The gc and ms "peaks" were gaussian and of the same width but the heights varied with sensitivity to FID and RIM.

All samples injected into the isothermally operated gas chromatograph contained up to four compounds of interest, each at a concentration of about 0.15 *M* in a suitable solvent, either *n*-hexane or dodecane. A 0.1 to 0.5 μL injection was used and the split at the column exit was such that about 5% of the eluent entered the ion source. The temperature range over which the ion source could be operated was from 75°C (determined by the heating effect of the electron emitting filament) to 230°C (obtained by the use of cartridge heaters embedded in the source block).

The kinetics of some of the systems were observed qualitatively by pulsing the electron beam using a blocking pulse on the beam defining plate (10). Samples of the required composition were made up in a heated oven and bled slowly into the ion source. Normalized ion currents were obtained as functions of time in the usual manner. Because it was necessary to cover a fairly wide mass range, a satisfactory determination of mass discrimination in the whole system could not be made and only order of magnitude estimates of rate constants are given.

Results and discussion

Relative reaction rates were obtained under ion source conditions where $CH_3ClCH_3^+$ and $CH_3ClCH_2Cl^+$ were the only ions of significance in the spectrum in the absence of chromatographic eluent. Initial ionization of CH_3Cl in the CH_3Cl/He mixture was either by direct electron impact, which yields mainly CH_3Cl^+ with lesser amounts of CH_3^+ and CH_2Cl^+, or by charge transfer from He^+. The latter reaction is ~300 kcal mol^{-1} exothermic and will lead to more fragmentation. The yields of $CH_3ClCH_3^+$ and $CH_3ClCH_2Cl^+$ were in the ratio of 2:1. No solvation of these ions by CH_3Cl was observed.

Products of the reactions of $CH_3ClCH_3^+$ and $CH_3ClCH_2Cl^+$

The ionic products formed by the reactions of $CH_3ClCH_3^+$ and $CH_3ClCH_2Cl^+$ with neutral, M, were identified by averaging repetitive mass spectral scans taken as M eluted from the gas chromatograph. The concentration of M was adjusted so that only the halonium ions reacted and not their precursors. The appearance of MH^+ was taken to signify reaction with precursor CH_3ClH^+ although, as described later, MH^+ can arise from other sources. The products were identified under conditions such that they constituted no more than 5% of total ionization. The mass spectral patterns of these product ions were not exactly reproducible (±10%) under these conditions but the absence of a product ion, i.e. less than 0.1% total ionization, could be determined. The results are summarized in Table 1.

Only four product ions are of significance. These have formulae represented by MCH_3^+, MCH^+, MCH_2Cl^+, and $MCCl^+$. $CH_3ClCH_3^+$ yields the arenium ion (**I**) with aromatics by transfer of CH_3^+ (reaction [1]) (2, 3) and $CH_3ClCH_2Cl^+$ could presumably transfer CH_3^+ or CH_2Cl^+ to yield either **I** or **II**

TABLE 1. Product ion yields from the reactions of $CH_3ClCH_3^+$ and $CH_3ClCH_2Cl^+$ with neutrals M, yields are expressed as % of total products (351 K)

M	Yield			
	MCH^+	MCH_3^+	MCl^+	MCH_2Cl^+
Benzene	28	4	17	52

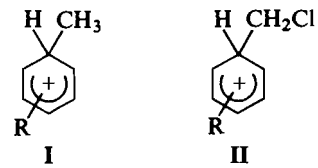
[7a] $CH_3ClCH_2Cl^+ + M \longrightarrow CH_3Cl + MCH_2Cl^+$

[7b] $\longrightarrow CH_2Cl_2 + MCH_3^+$



I **II**

Sen Sharma and Kebarle (3, 12) have shown that in an asymmetrical dialkyl chloronium ion, RClR′, the more weakly bonded alkyl group is the one yielding the more stable cation. Theoretical studies are in agreement (13). For example, with CH_3ClR, the dissociation energy for removal of R^+, $D(CH_3Cl—R^+)$, decreases in the order $CH_3^+ > C_2H_5^+ > i\text{-}C_3H_7^+ > t\text{-}C_4H_9^+$. We therefore expect CH_2Cl^+ to be much more weakly bound than CH_3^+ in $CH_3ClCH_2Cl^+$ and that reaction [7*a*] will predominate over [7*b*]. The relative yields of MCH_3^+ and MCH_2Cl^+ are consistent with this assumption although it cannot be proved by RIM studies.

The modes of formation of MCH^+ and of $MCCl^+$ were investigated further by substituting CH_4 for He as buffer gas. In $CH_4/CH_3Cl/C_6H_6$ (20/1/0.01), essentially no $CH_3ClCH_2Cl^+$ was formed and neither $C_7H_7^+$ $(MCH)^+$ nor $C_7H_6Cl^+$ $(MCCl^+)$ were observed. MCH^+, in addition to $MCCl^+$, therefore arises only from $CH_3ClCH_2Cl^+$. With perdeuterated benzene, MCH^+ and $MCCl^+$ became $C_7D_5H_2^+$ and $C_7D_5HCl^+$, respectively. With toluene-d_8 the ions were $C_8D_7H_2^+$ and $C_8D_7HCl^+$. Therefore, arenium ion (**II**) can either be collisionally stabilized to yield MCH_2Cl^+ or lose H_2 or HCl forming $MCCl^+$ and MCH^+, respectively. These are both benzyl ions since in their formation one H is lost from the aromatic ring, for example, following the addition of CH_2Cl^+ to C_6D_6 [8*a*] or [8*b*] may occur.

[8a] 
[8b] 
Further confirmation that $C_7H_7^+$ in $C_6H_6/He/CH_3Cl$ is the benzyl cation was furnished by the observation of an ion at m/e 169 which shifted to m/e = 180 when C_6D_6 was used. The intensity of the ion decreased with increase of temperature. Following the work of Ausloos (14) and Sen Sharma and Kebarle (15) we suggest that this ion results from the reaction of the benzyl cation with benzene.

[9] 
Icr studies have shown that following the addition of both CH_2Cl^+ (16) and CH_2F^+ (17) to benzene at low pressure ($<10^{-3}$ Torr), there is exclusive loss of HCl or HF and no stabilized $C_7H_8Cl^+$ or $C_7H_8F^+$ is observed. This can be attributed to the high exothermicity of reactions [10] and [11].

[10] $CH_2F^+ + C_6H_6 \rightarrow [C_7H_8F^+] \rightarrow C_6H_5CH_2^+ + HF$
$\Delta H^\circ = -71$ kcal mol^{-1}

[11] $CH_2Cl^+ + C_6H_6 \rightarrow [C_7H_8Cl^+] \rightarrow C_6H_5CH_2^+ + HCl$
$\Delta H^\circ = -56$ kcal mol^{-1}

Speranza and Pepe (4) do observe both $C_6H_5CH_2F$ and $C_6H_5CH_2Cl$ as neutral products ascribed to the removal of protons from the collisionally stabilized arenium ions produced in γ-irradiated $CH_3X/C_6H_6/NH_3$ (X = F, Cl) gaseous mixtures at pressures ranging from 100 to 760 Torr. The present results show that CH_3Cl^+ ions will not be present as suggested at the high CH_3Cl concentrations used but rather the reacting ions will be $CH_3ClCH_2Cl^+$. Reaction [7a] is less exothermic than reaction [11] by the $CH_3Cl-CH_2Cl^+$ binding energy. Collisional stabilization is still required for the appearance of $C_6H_5CH_2Cl$ but the energy to be removed is now decreased by ~30 kcal mol^{-1} (see later).

With the exception of $C_6H_5NO_2$ there is no H_2 or HCl loss from **II** for the N and O bases for which addition will occur at the heteroatom. As noted previously (2), addition to $C_6H_5NO_2$ must be mainly at O since the molecule does not fit the previously determined correlation for aromatics of increasing reactivity with decreasing ionization potential. This location has been confirmed as we find no D^+ transfer to added $(CH_3)_3N$ as would occur if arenium ions **I** or **II** were formed. For example D^+ transfer was observed with mesitylene-d_{12}.

For compounds in Table 1 the loss of H_2 and HCl from **II** is significant only from the lower alkyl aromatics, benzene, toluene, and ethylbenzene, and the importance of these losses decreases with increasing length of the alkyl chain. This demonstrates the increased stabilization of the positive charge in the arenium ion with increased polarizability of the alkyl group.

The xylenes and mesitylene show essentially no H_2 or HCl loss in keeping with the high stability of arenium ions with more than one methyl substituent (18). It is also to be noted that the relative ion yield from the addition of CH_2Cl^+ ($(MCH_2Cl^+ + MCH^+)/MCH_3^+$) decreases as the number of methyl substituents increases. The preponderance of MCH_3^+ with mesitylene is as for the N and O bases.

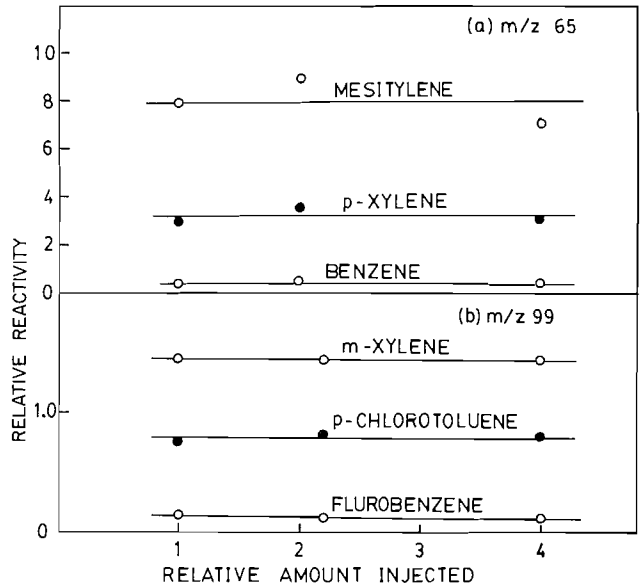


FIG. 1. Relative reactivities (toluene = 1.0) of neutrals towards (*a*) $CH_3ClCH_3^+$ (*m/z* 65) and (*b*) $CH_3ClCH_2Cl^+$ (*m/z* 99). Volumes injected into chromatograph were 0.1 to 0.4 μL dodecane containing neutrals at approximately 0.15 *M*.

If relative product yields are taken as indicative of reaction rates, and with the knowledge that $CH_3ClCH_3^+$ predominates by a factor of two in the ion source plasma, it can be seen that the rate of reaction of $CH_3ClCH_3^+$ with the N and O bases is greater than that of $CH_3ClCH_2Cl^+$ while the reverse is true for the lower alkyl aromatics. For the latter compounds there is a trend towards greater relative reactivity of $CH_3ClCH_3^+$ as the number of alkyl substituents increases.

Relative rates of reaction by RIM

For RIM to succeed in giving reliable relative rate data the amount of reactive neutral M must be sufficient to give a measurable decrease in ion signal (ΔI) but not excessive so that precursors of the monitored ion also react. The latter condition is presumed to be shown when new product ions appear and/or when the relative rate of reaction changes with increasing concentration of M. Figure 1 shows that the relative rates of reaction do not change when the concentration of M is changed by a factor of five for neutrals of widely differing reactivities. $\Delta I/I^\circ$ is less than 4% at the high end of the concentration range employed.

The relative reactivities of a series of nucleophiles with both $CH_3ClCH_3^+$ and $CH_3ClCH_2Cl^+$ are shown in Table 2, all values being given with reference to reactivity towards toluene. It was apparent from the concentrations of M required to give the same relative decrease $\Delta I/I_0$ for each of the two monitored ions that $CH_3ClCH_2Cl^+$ reacts considerably faster with the less reactive compounds than does $CH_3ClCH_3^+$. Table 2 also shows that there is a much larger range of reactivity with $CH_3ClCH_3^+$ than with $CH_3ClCH_2Cl^+$, a factor of 100 vs. a factor of 20. However, the order of reactivities is essentially identical, fluorobenzene being the least reactive and cyclohexanone, nitrobenzene, and 2-chloropyridine being the most reactive. In fact,

TABLE 2. The relative reactivities of neutrals with $CH_3ClCH_3^+$ (m/z 65) and $CH_3ClCH_2Cl^+$ (m/z 99) (351 K)

Neutral	m/e 65	m/e 99
Fluorobenzene	0.19 (0.0)[a]	0.14

[a] Reference 2.
[b] Reference 3.
[c] Not determined.

with the exception of dihydropyran, all the N- and O-containing bases are much more reactive with both ions than are all the alkylbenzenes except mesitylene. A similar observation has been made by Sen Sharma and Kebarle (3) for the reaction of $CH_3ClCH_3^+$ with a much more limited range of compounds. The significantly higher reactivity of 2-chloropyridine compared with the more basic pyridine suggests that electrophilic attack on this compound may be occurring at Cl as well as at N.

The alkyl aromatics show a wide range of reactivity with both halonium ions. The order of increasing reactivity is the same as we found previously for $CH_3ClCH_3^+$ with a much more limited set of compounds (2). The relative reactivities do not compare too well, however, with these previous values (Table 2) and neither does the value of 0.11 for benzene (calculated using Fig. 10 of ref. 3) compare well with the value of 0.34 found in this study. The range of reactivities of the alkyl aromatics in this study is less than that in ref. 2. The results for benzene in Table 2 are not consistent with the product yields in Table 1 which show little reactivity with $CH_3ClCH_3^+$ when judged by the yield of $C_6H_6CH_3^+$. This will be discussed later.

We noted previously (2) that the reactivity of M towards $CH_3ClCH_3^+$ increases with decreasing ionization potential and hence with increasing proton affinity (P.A.). P.A. is in general directly proportional to methyl cation affinity (MCA) for similar compounds (13) and so the rates of reaction of these aromatics increase with increasing MCA. This is also the direction of increasing exothermicity of reaction [1] (Table 3). There is insufficient information available to calculate the exothermicity of CH_2Cl^+ transfer (reaction [7*a*]) but as a rough estimate all reaction exothermicities will be increased compared with those for $CH_3ClCH_3^+$ by the difference in binding energies to CH_3Cl of the group transferred, i.e., $D(CH_3Cl—CH_3^+) - D(CH_3Cl—CH_2Cl^+)$ which is ~30 kcal mol^{-1}.

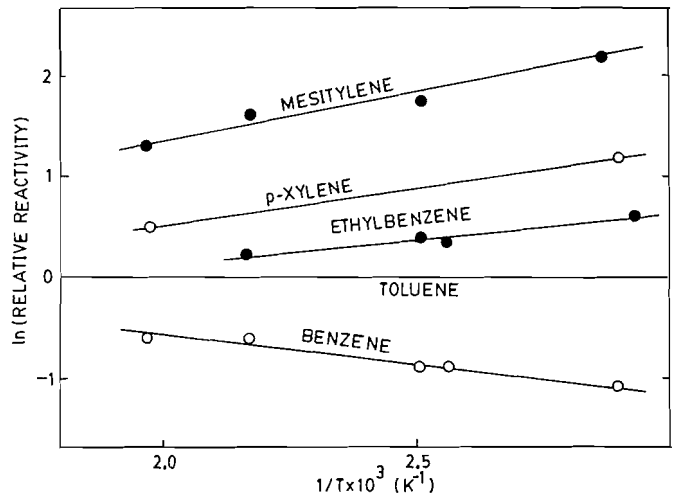

FIG. 2. Relative reactivities of neutrals towards $CH_3ClCH_3^+$ as functions of temperature.

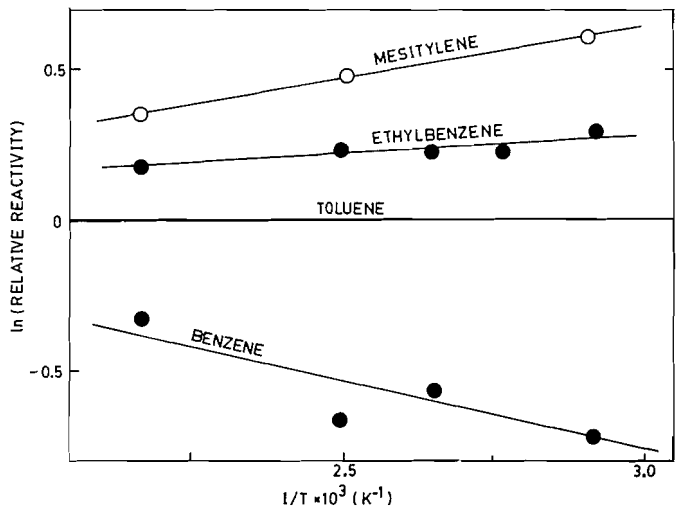

FIG. 3. Relative reactivities of neutrals towards $CH_3ClCH_2Cl^+$ as functions of temperature.

All the reactions are very exothermic but the large variation in reaction rates shows that for the slower reactions the collisional efficiency ($k_{reaction}/k_{collision}$) must be low.

The effect of temperature on relative reactivities

Although RIM has been employed to obtain data on numerous reagent ions there is no record of it having been used to measure relative reactivities at other than a fixed temperature. A problem arises since only relative reactivities are measured and if all reactant neutrals have the same temperature coefficient for reaction with the monitored ion then the relative reactivities will be independent of temperature.

Each of the alkyl aromatics examined showed a change of relative reactivity towards both halonium ions as the temperature was changed over the range 70–230°C (Figs. 2 and 3). No significance can be placed on the fact that benzene shows a temperature dependence of the opposite sign to the other

TABLE 3. The thermochemistry of the reaction $CH_3ClCH_3^+ + B \rightarrow BCH_3^+ + CH_3Cl$[a, b]

B	$\Delta H_f^0(B)$	$PA(BCH_3)$[c]	$\Delta H_f^0(BCH_3^+)$[d]	$\Delta H_f^0(BCH_3—H)$[e]	$\Delta H^0_{reaction}$[f]

aromatics since all rates are relative to those of toluene whose reactivity is arbitrarily assigned a zero temperature coefficient. The result is, however, consistent with the finding of Sen Sharma and Kebarle (3) that the rate constant for the reaction of benzene with $CH_3ClCH_3^+$ has a positive temperature coefficient whereas the analogous reactions involving toluene and isopropyl benzene have negative coefficients. It is gratifying that RIM can demonstrate temperature dependences of reaction rates, albeit only in favourable cases.

The increasingly negative temperature dependence of relative reactivity of the alkyl aromatics with increasing exothermicity of reaction has not been noted before. There is no obvious explanation for this observation which we are investigating further.

Pulsed electron beam studies

RIM provides a measure of the relative reactivity of M towards the long lived ions in the ion source plasma but it can give no absolute rate constants, nor can it show the sequence of ions in a reaction. Such information is provided by pulsed electron beam, high pressure mass spectrometry. Due to the unknown mass discrimination in the instrument used, the reaction sequence is obtainable but only rough estimates of reaction rate constants can be made.

The results for pure CH_3Cl alone with no M present are shown in Fig. 4. Only the two chloronium ions are of significance during the time of observation and at long times $CH_3ClCH_3^+$ is dominant. A first order decay of $CH_3ClCH_2Cl^+$ therefore leads to $CH_3ClCH_3^+$, presumably with CH_2Cl_2 as the neutral product. The rate constant for this displacement reaction is $\sim 10^{-13}$ molecule cm^{-3} s^{-1}.

[12] $CH_3Cl + CH_3ClCH_2Cl^+ \rightarrow CH_3ClCH_3^+ + CH_2Cl_2$

An estimate of the enthalpy of formation of $CH_3ClCH_2Cl^+$ can be obtained if it is assumed that for this reaction $\Delta G^0 \approx \Delta H^0$, i.e., $\Delta S^0 = 0$. This approximation should be reasonable given the similar nature of CH_3Cl and CH_2Cl_2. For reaction [12] to be observed $\Delta H^0 \leq 0$ and using the dissociation energy $D(CH_3Cl—CH_3^+) = +64$ kcal mol^{-1} (13), $\Delta H_f^0(CH_3ClCH_3^+) = +175.9$ kcal mol^{-1}, $\Delta H_f^0(CH_3ClCH_2Cl^+) \leq +173$ kcal mol^{-1} and $D(CH_3Cl—CH_2Cl^+) \leq +36$ kcal mol^{-1}. This latter value is far less than $D(CH_3Cl—CH_3^+) = 64$ kcal mol^{-1} and closer to $D(CH_3Cl—C_2H_5^+) = 31$ kcal mol^{-1} (12). The switching reaction [12] will have an effect on the RIM experimental results. Since for the less reactive compounds, $CH_3ClCH_2Cl^+$ reacts faster than $CH_3ClCH_3^+$ then even when reaction with the latter is very slow as for example with benzene, a faster reaction with $CH_3ClCH_2Cl^+$ can lead to an enhanced reduction in

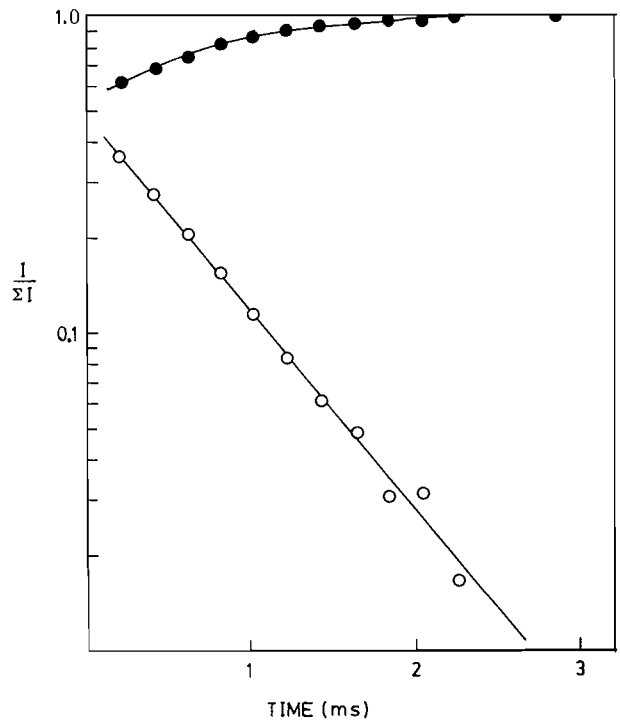

FIG. 4. The temporal variations of normalized ion yields in pure CH_3Cl at 0.90 Torr and 444 K. ●, $CH_3ClCH_3^+$, ○, $CH_3ClCH_2Cl^+$. The rate constant for the disappearance of $CH_3ClCH_2Cl^+$ is approximately 10^{-13} cm^3 $molecule^{-1}$ s^{-1}.

the monitored $CH_3ClCH_3^+$ ion. The errors in the RIM relative rates are expected to be the greatest for the least reactive compounds and become proportionately smaller for the more reactive ones when less neutral is required for a measurable decrease in monitored ion current. This explains why the rate of reaction relative to toluene for $CH_3ClCH_3^+$ obtained by RIM is higher for benzene than we found previously (2) and than was found by Sen Sharma and Kebarle (3). It is disturbing, however, that the relative rates of reaction did not show a variation with the amount of material added (Figs. 2 and 3) which should signal a problem due to a slow disappearance of one of the monitored ions. It is to be noted that this complication does not affect the validity of the RIM results for $CH_3ClCH_2Cl^+$.

Figure 5 shows the strictly pseudo first order decays of $CH_3ClCH_3^+$ and $CH_3ClCH_2Cl^+$ in the presence of mesitylene and confirms the qualitative RIM observation of the greater reactivity of the former ion. It is noted that the maximum yields

The first order rate constants are: $CH_3ClCH_3^+$, approximately 1×10^{-10} cm^3 molecule^{-1} s^{-1}; $CH_3ClC_2H_5^+$, approximately 1.2×10^{-10} cm^3 molecule^{-1} s^{-1}; $CH_3ClCH_2Cl^+$, approximately 7×10^{-10} cm^3 molecule^{-1} s^{-1}.

of the adducts $C_9H_{12}CH_3^+$ and $C_9H_{12}CH_2Cl^+$ are very close to the initial yields of the respective halonium ion precursors. In this system reaction [12] is of little consequence because of the high reactivity of the mesitylene.

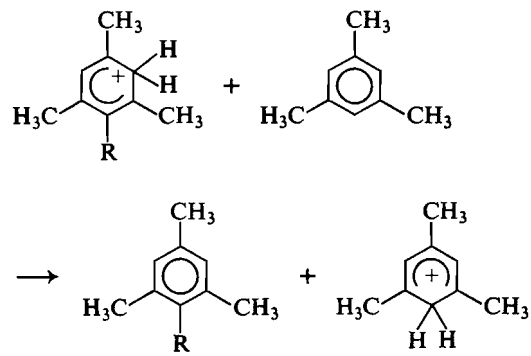
When CH_4 rather than He was used as a buffer gas, three halonium ions were formed, viz. $CH_3ClCH_3^+$, $CH_3ClCH_2Cl^+$, and $CH_3ClC_2H_5^+$. Their decays were always pseudo first order and their rates of reaction with the lower alkylbenzenes increase in the order $CH_3ClCH_3^+ < CH_3ClC_2H_5^+ < CH_3ClCH_2Cl^+$. The example of *o*-xylene is shown in Fig. 6. All the reaction products result from the displacement of CH_3Cl by the *o*-xylene.

[13] $CH_3ClR^+ + C_8H_{10} \rightarrow CH_3Cl + C_8H_{10}R^+$

The more weakly bonded $CH_3ClC_2H_5^+$ reacts a little more rapidly than $CH_3ClCH_3^+$ and we may assume that since $CH_3ClCH_2Cl^+$ reacts even more rapidly that the binding energy $D(CH_3Cl—CH_2Cl^+)$ is probably less than $D(CH_3Cl—C_2H_5^+)$ = 31 kcal mol^{-1} (12).

With the more reactive mesitylene (Fig. 7) $CH_3ClCH_3^+$ actually reacts more rapidly than does $CH_3ClC_2H_5^+$ and entropy rather than energy factors must now be important in the transition state. Protonated *o*-xylene and mesitylene (MH^+) are formed at long reaction times (Figs. 6 and 7) and obviously do not arise from the reaction of M with the early but unobserved ion CH_3ClH^+. The major precursor ion of MH^+ in both systems is MCH_2Cl^+ although with mesitylene both MCH_3^+ and $MC_2H_5^+$ also contribute as shown by the slow decline of their relative yields at long reaction times. The proton transfer reaction in the mesitylene system is shown in reaction [14], it being assumed that the initially formed *ipso*-substituted ions rearrange rapidly by H^+ migration.

[14]



The relative rates of reaction [14] increase with R in the order $C_2H_5 < CH_3 \ll CH_2Cl^+$, which is as expected since it is the reverse of the order of the stabilizing effect of R on a protonated benzene ring. The proton affinities of both 1,3,4,5-tetramethylbenzene and 1,3,5-trimethyl-4-ethylbenzene will be greater than that of mesitylene, so that for R = CH_3 or C_2H_5 reaction [13] is slightly endothermic and the rate of reaction should be low (19), as is observed. The much more rapid reaction for R = CH_2Cl shows the destabilization caused by the inductive effect of a Cl substituent on CH_3 and for this group reaction [14] may be thermoneutral or even slightly exothermic.

Conclusions

The ion–molecule chemistry initiated by dialkylchloronium ions has many interesting facets. The very wide range of reactivities with aromatic compounds is unusual, as is the negative temperature coefficient of reactivity for a bimolecular displacement reaction. The products of the alkylation reaction depend

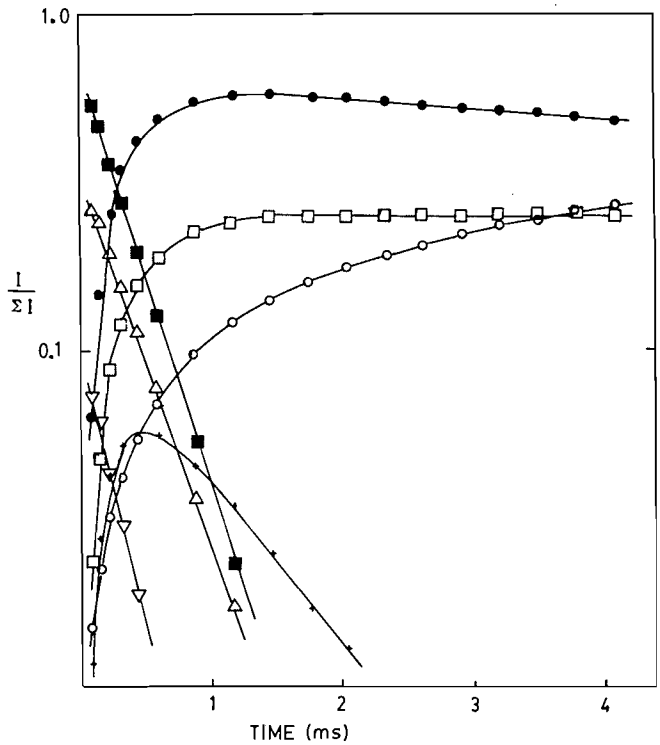


FIG. 7. The temporal variations of normalized ion yields. CH_4, 0.60 Torr; CH_3Cl, 0.20 Torr; mesitylene, 1.6×10^{-4} Torr; 345 K. ■, $CH_3ClCH_3^+$; △, $CH_3ClC_2H_5^+$; ▽, $CH_3ClCH_2Cl^+$; ●, mesitylene·CH_3^+; □, mesitylene·$C_2H_5^+$; +, mesitylene·CH_2Cl^+; ○, mesitylene·H^+. The first order rate constants are: $CH_3ClCH_3^+$, approximately 7×10^{-10} cm^3 molecule^{-1} s^{-1}; $CH_3ClC_2H_5^+$, approximately 5×10^{-1} cm^3 molecule^{-1} s^{-1}; $CH_3ClCH_2Cl^+$, approximately 1×10^{-9} cm^3 molecule^{-1} s^{-1}.

not only on the exothermicity of the reaction but also on the stabilization of the initially formed adduct ion afforded by substituents in the aromatic ring. The qualities of the halonium ions as alkylating agents are due to the moderating influence of CH_3Cl on the alkyl cation. The alkylmethyl halonium ions may be regarded as alkyl ions solvated by CH_3Cl. This solvation lowers the reactivity of the bare ion (20) and decreases the exothermicity of the alkylation reaction. Alkylation may then proceed with less likelihood of decomposition of the ion–neutral adduct.

Reactant ion monitoring has been shown to be a useful technique for obtaining the relative reactivities of neutrals with ions but it is obvious that the reaction sequences for all ions in the ion source plasma should be determined to ensure that the chosen reactant ions are in fact unreactive except towards these neutrals. This is not an easy task at the best of times but for slow reactions it is impossible to accomplish without time resolution as in pulsed high pressure mass spectrometry and ion cyclotron resonance spectrometry or spatial resolution as in the flowing afterglow. RIM can provide useful information on relative reaction rates and we have demonstrated that under certain conditions, one can observe the effects of temperature on reaction rates. In our estimation the technique is well suited to survey type experiments when many compounds can be quickly screened for reaction with a single ion. The best values for relative reaction rates will be obtained for fast reactions as has been well demonstrated (5).

The chemical reactions initiated by multiphoton absorption in gaseous ethanol were studied in the pressure range of 0.1 to 10 Torr under irradiation of a focused TEA CO_2 laser. The predominant reaction is a unimolecular elimination: $C_2H_5OH \rightarrow C_2H_4 + H_2O$, which is particularly important at low pressures and lower laser intensities. This process has not been previously identified in pyrolysis studies. At higher pressures and higher laser intensities, H_2, CO, and CH_4 also become important reaction products which are claimed to originate from a higher energy channel. Several arguments are provided to show that the increasing yield of CO and CH_4 at higher levels of excitation of the ethanol molecule are not consistent with a radical mechanism.

SERGIO ROBERTO DE ANDRADE LEITE, PAULO CELSO ISOLANI et JOSÉ MANUEL RIVEROS. Can. J. Chem. **62**, 1380 (1984).

Opérant à des pressions allant de 0,1 à 10 Torr et à l'aide d'une irradiation provenant d'un laser focalisé TEA à CO_2, on a étudié les réactions chimiques initiées par des absorptions multiphotons dans l'éthanol gazeux. La réaction principale consiste en une élimination unimoléculaire: $C_2H_5OH \rightarrow C_2H_4 + H_2O$, qui est particulièrement importante à de faibles pressions et à de faibles intensités du laser. On n'avait pas identifié ce processus antérieurement lors d'études de pyrolyse. Lorsqu'on utilise de plus fortes pressions et un laser à plus haute puissance, la formation de H_2, CO et CH_4, comme produits de la réaction, devient importante et l'on croit que ces produits sont formés par le biais d'une voie impliquant un niveau d'énergie plus élevé. On apporte plusieurs arguments pour montrer que les augmentations de rendement en CO et en CH_4, lorsqu'on opère à des niveaux d'excitation de la molécule d'éthanol qui sont plus élevés, ne sont pas en accord avec un mécanisme radicalaire.

Introduction

Chemical reactions initiated by multiphoton excitation in the infrared region have generated a great deal of interest in recent years (1–3). At low pressures, where the excitation occurs under collision-free conditions, the resulting processes can be adequately described as unimolecular reactions for which statistical rate theories may be applied (4–7). Considerable development has also been achieved in the different theoretical aspects of vibrational multiphoton excitation. While many questions are still at large, the approach advanced by Quack (8–11) provides a valuable framework towards the understanding of the basic role of the different variables in the collisionless experiment.

Reactions induced by multiphoton excitation at higher pressures, and in the collision regime, are not always subject to simple interpretations. Much effort has been dedicated to distinguish between true laser-induced processes and conventional pyrolysis (12). In some cases, experiments under these conditions can be used to an advantage as an interesting methodology for bimolecular chemical reactions in the gas phase (13–16).

The present interest in the basic aspects of the gas phase chemistry of ethanol, a promising fuel and chemical feedstock, has led us to investigate the behavior of ethanol under multiphoton excitation from a CO_2 laser. Furthermore, ethanol represents an interesting case because several primary processes may be envisioned as a result of ir multiphoton absorption,

[1] $C_2H_5OH + nh\nu \rightarrow C_2H_4 + H_2O$

[2] $\rightarrow CH_3CHO + H_2$

[3] $\rightarrow H_2CO + CH_4$

[4] $\rightarrow \cdot CH_3 + \cdot CH_2OH$

Other bond fission channels could also be considered in principle, although of higher endothermicity.

[5] $C_2H_5OH \rightarrow \cdot C_2H_5 + \cdot OH$ $\quad \Delta H^0 = 92$ kcal mol^{-1}

[6] $\rightarrow C_2H_5O\cdot + \cdot H$ $\quad \Delta H^0 = 104$ kcal mol^{-1}

[7] $\rightarrow CH_3\dot{C}HOH + \cdot H$ $\quad \Delta H^0 \approx 90$ kcal mol^{-1}

There are no pertinent data on the activation energies for the first three processes in the absence of a catalyst. For reaction [4], it can be safely assumed that $E_a \sim 82$ kcal mol^{-1}, the estimated carbon–carbon bond energy.[4] The pyrolysis of ethanol at temperatures around 600°C and in the pressure range of 50 to 350 Torr has been claimed to be a homogeneous free-radical reaction initiated by process [4] (18). The main products in the early stages of the reaction are H_2 (53%), CO (11%), CH_4 (16%), and CH_3CHO (20%). At 300 Torr, addition of 1 Torr of NO results in a ten-fold inhibition, lending support to a free-radical mechanism. Later studies (19) also conclude that H_2 and CH_3CHO are the main products at these temperatures although the initiation process is proposed to be dissociation of a carbon–hydrogen bond (20).

The chemistry of ethanol under multiphoton excitation from a pulsed HF laser has been previously investigated (21). A distinct variation of product yield has been observed as a function of pressure in the range of 0.04 to 43.6 Torr. At 1 Torr, the quantum yield for C_2H_4 is an order of magnitude larger than that of C_2H_6, and two orders of magnitude larger than that of CH_4. At 40 Torr, the quantum yield of C_2H_4 is nine times larger than that of C_2H_6, but only three times larger than that of CH_4. While process [1] is apparently the main channel at low pressure, processes [1], [2], and [4] are claimed to be involved at higher pressures. Another related study revealed that ethanol pumped by a CO_2 laser at pressures of 1 Torr or less, in the presence of 2-propanol and HBr, decomposes unimolecularly

by process [1] in a non-thermal reaction (22). A very brief and recent report (23) establishes C_2H_4 and H_2 as the main products at 1 Torr, and claims formation of CH_4 via a non-radical mechanism, namely process [3].

Ethanol displays a wide absorption band in the 9.6 μm region involving three fundamental modes: 1089 cm^{-1} (C—O asym stretch), 1062 cm^{-1} (CH_3 rocking), and 1033 cm^{-1} (CH_3 rocking) (24, 25). Considerable overlap among these bands, even at low pressures, allows for pumping by many lines of the CO_2 laser.

The present study reports the chemistry resulting from multiphoton excitation of ethanol in the 9.6 μm region and in the pressure range of 0.1 to 10 Torr. The product distribution suggests a multiplicity of mechanisms related apparently to differences in the final level of excitation of the C_2H_5OH molecule. Process [1] is shown to be the most important reaction under these conditions, unlike the pyrolytic studies which reveal ethylene in minor quantities.

Experimental section

Irradiations were carried out with a multimode line tunable TEA CO_2 laser (Tachisto, Model 215G). Typical operating conditions resulted in pulses made up of a 50 ns spike (FWHM), containing about 65% of the energy, and a 1 μs tail.[5] Laser energies were monitored with a Coherent Radiation pyroelectric detector.

Samples were handled in a grease-free glass vacuum line. The irradiation cells were made of glass, 22 cm in length and 2 cm inside diameter, and provided with NaCl windows. The laser beam was focused by a 25 cm focal length CdTe lens onto a spot located 15 cm behind the entrance window. No reaction was observed with an unfocused beam. There was no luminescence visible to the naked eye at the windows, at the walls, or at the focal point for neat ethanol with the described geometry at pressures as high as 15 Torr. The pressure inside the cell was continuously monitored by a capacitance manometer (MKS Baratron) attached directly to the system.

Irradiated samples were analyzed qualitatively by ir spectroscopy. Quantitative yields were determined by gas phase chromatography using thermal conductivity detection. The sensitivity of the detector was calibrated with known quantities of the appropriate compound. Analysis was usually carried out after 100 to 200 pulses, corresponding typically to less than 15% decomposition of ethanol. Product yields obtained as average values of samples irradiated under similar experimental conditions displayed a reproducibility better than 10%. The deviations were likely due to fluctuations in laser power and in the number of hot spots.

While several laser lines were tested for efficiency in promoting reactions in ethanol, the most thorough experiments were performed with the P(20) line at 1046.85 cm^{-1}. The nature and relative abundance of products originating from irradiation with the P(20), and the R(20) line at 1078.58 cm^{-1}, showed no significant differences. The system failed to yield any reaction when pumped with the P(20) line of the 10.6 μm band at 944.21 cm^{-1}.

Results

The net efficiency of ethanol decomposition under infrared multiphoton excitation was initially established by measuring the pressure increase as a function of the number of pulses. The behavior of neat ethanol in the 0.5 to 10 Torr pressure range is displayed in Fig. 1. These experiments were run under low product conversion conditions to avoid sizable contribution from chemical reactions of the products themselves. The data are reported as the normalized pressure increment per pulse,

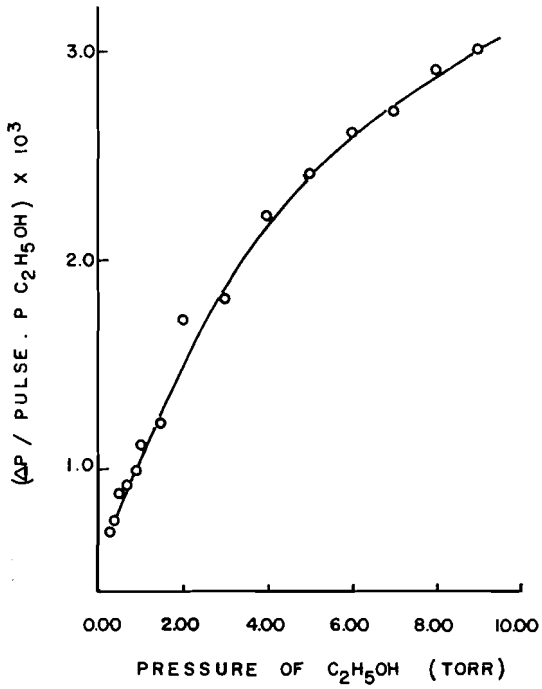

FIG. 1. Total normalized yield of ethanol decomposition, measured as the pressure increment per laser pulse, as a function of ethanol pressure. Laser energy = 1 J.

and were obtained from the number of pulses required to increase the initial pressure by 10%. Below 0.5 Torr, there is a marked increase in efficiency which has not been investigated in detail.

Analysis of the products revealed detectable quantities of H_2, C_2H_4, CO, CH_4, C_2H_2, and C_2H_6. Acetaldehyde was observed only in trace quantities by gc. No attempt was made to measure the amount of water vapor produced in these processes.

Figure 2 shows the normalized yield for different products as a function of pressure after 200 laser shots at 1 J of energy. It is noticeable that the rise in yield per pulse plotted in Fig. 1 can be correlated with the increasing production of CH_4 and CO as a function of pressure. On the other hand, while the amount of C_2H_4 decreases slowly in the pressure range, the sum of C_2H_4 plus C_2H_2 (presumably formed from hot ethylene) remains essentially constant in this interval. A single measurement carried out at 6 Torr reveals that the yield of H_2, at this pressure, is 6% less than C_2H_4.

Dilution of ethanol with argon as a buffer gas also resulted initially in a sizable enhancement of the yield per pulse as a function of buffer gas pressure. The data shown in Fig. 3. were again obtained by following the behavior of the total pressure of the system during the number of laser shots necessary to produce a 10% variation in the initial pressure of C_2H_5OH. Analysis of the products by gc showed that the rising net efficiency of decomposition was due to more efficient formation of CH_4 and CO.

The possible participation of free-radical mechanisms in the laser-initiated decomposition of ethanol was probed with known scavenging agents. The net yield per laser pulse of ethanol in the presence of NO was plotted in Fig. 4, for the case where the partial pressure of C_2H_5OH was maintained at 1 Torr. The laser energy was kept at 1 J, and the procedure adopted was similar to the previous cases. At 10 Torr of total pressure, an equimolar mixture of C_2H_5OH and NO after 200 laser shots

[5]The pulse shapes were measured with a photon drag detector at the M.I.T. Regional Laser Center.

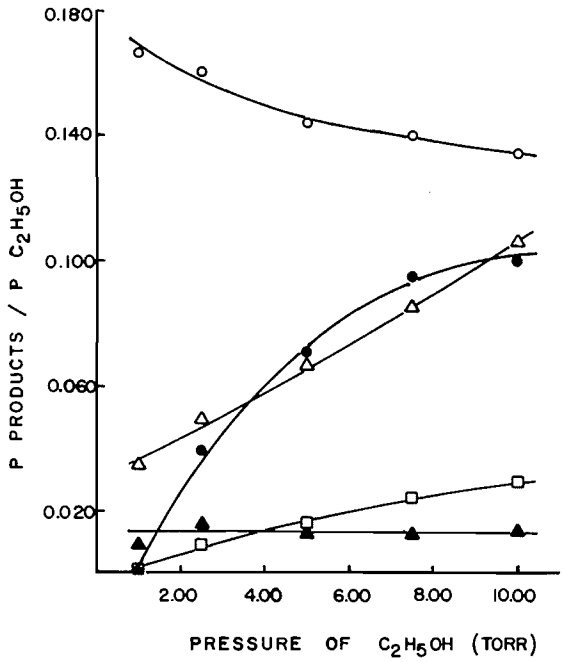

FIG. 2. Individual normalized product yields after 200 laser shots as a function of ethanol pressure. ○, Ethylene; ●, methane; □, acetylene; ▲, ethane; △, carbon monoxide. Laser energy = 1 J.

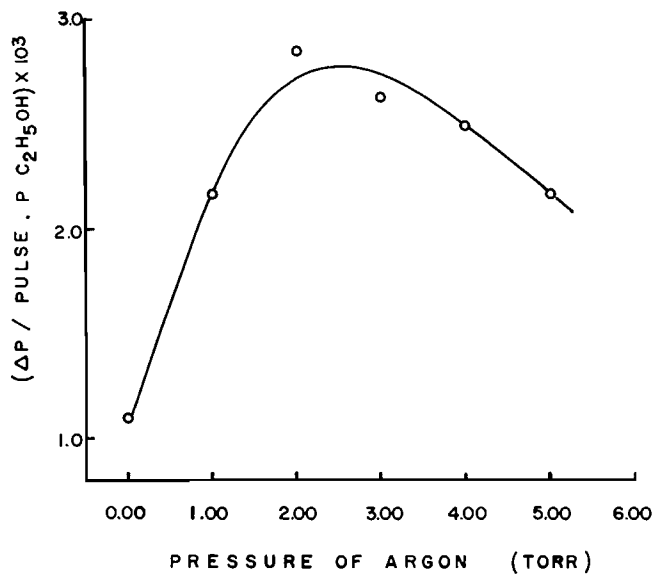

FIG. 3. Total normalized yield of ethanol decomposition (pressure increment per laser pulse) at 2 Torr of C_2H_5OH as a function of argon pressure. Laser energy = 1 J.

produces about 20% less ethylene than neat C_2H_5OH. The effect on CH_4, CO, and C_2H_6 was even less pronounced. Even at high NO-to-C_2H_5OH ratios, the overall inhibition remained small and products like HCN were not detected by ir or gc. Experiments carried out in the presence of propylene displayed no significant inhibition.

Irradiation of C_2H_5OH in the presence of O_2 gave rise to pale blue luminescence in the focal region which became weak after the initial 50 to 100 pulses. Quantitative product yields after 250 pulses showed no significant variations except for the formation of small quantities of CO_2.

The use of shorter laser pulse widths, obtained by reducing

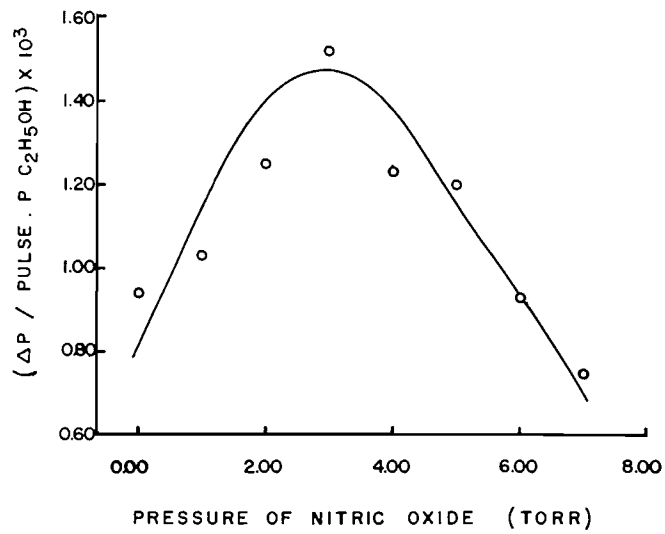

FIG. 4. Total normalized yield of ethanol decomposition (pressure increment per laser pulse) at 1 Torr of C_2H_5OH as a function of NO pressure. Laser energy = 1 J.

the nitrogen in the flow mixture of the laser, and at constant laser energy, enhances significantly the ease of ethanol decomposition per laser shot. Table 1 shows that this enhancement is due again to significant changes in the product distribution which favors CH_4 and CO at the higher laser intensities.

The relative product distribution is also affected by variation of the laser energy between 0.4 and 1.2 J. Relevant data for neat ethanol at 10 Torr appears in Table 2. These experiments are of somewhat more complex interpretation because both, intensity and fluence, are varying in each case. Nevertheless, it is clear that CH_4 and CO become increasingly important at higher fluences and higher intensities, while the ratio (C_2H_4/C_2H_6) remains essentially unchanged.

The kinetics of the decomposition of ethanol, as followed by the ir absorption spectrum of ethanol, shows that the decomposition processes are first order with respect to ethanol approximately during the first 50 pulses.

Finally, the absorption processes in ethanol under the experimental conditions have been found to obey a Beer–Lambert relationship in the pressure range and even above 20 Torr. Because of the focused geometry, it is not possible to obtain a meaningful absorption coefficient from these measurements.

Discussion

Chemical reactions induced by multiphoton excitation under focused conditions, and in the pressure range where this study was carried out, usually involve more than one mechanism because of the large fluence at the focal point. Thus, high local heating, energy pooling, and radical–radical processes may become important in these situations.

The dramatic change in product distribution observed in ethanol under multiphoton excitation over a relatively narrow pressure range (Fig. 2) suggests that several mechanisms are intervening in the overall chemistry. Furthermore, there are strong indications that the final level of excitation of ethanol in these processes are both pressure and intensity dependent. Several systems have been previously investigated in which reaction channels of different activation energies and frequency factors can be shown to compete under MPE conditions (26, 27). Such experiments have been advocated as sensitive probes

TABLE 1. Product yields (in Torr) as a function of laser pulse width after 200 shots, laser energy = 0.5 J, pressure of C_2H_5OH = 5 Torr

	Yield				
Pulse*	CO	CH_4	C_2H_4	C_2H_2	C_2H_6
Long (~1.7 μs)	0.075	0.053	0.334	0.005	0.043
Short (~1.2 μs)	0.145	0.096	0.353	0.017	0.052

*The actual pulse width is uncertain in these experiments because the response time of the pre-amplifier used for the measurements is not better than 300 ns.

TABLE 2. Product yields (in Torr) as a function of laser energy after 200 shots; pressure of C_2H_5OH = 10 Torr

	Yield				
Energy (J)	CO	CH_4	C_2H_4	C_2H_2	C_2H_6
0.4	0.235	0.200	0.420	0.029	0.039
0.7	0.660	0.665	1.02	0.142	0.080
1.0	1.05	1.05	1.36	0.253	0.130

of internal energy and its distribution within the molecule. A precise interpretation of the different reaction channels in ethanol is, however, obscured by the fact that the primary dissociation processes have not been characterized kinetically.

Ethylene is clearly the dominant product at the lower pressures and lower laser intensities for ethanol. This fact strongly argues in favor of process [1] as the lowest energy pathway even though no quantitative measurements have been carried out for the other reaction product, namely, H_2O. This observation is similar to that reported for ethanol at low pressures pumped by either an HF or CO_2 laser (21, 23), but distinct from the low temperature pyrolysis (18).

Reaction [1], which has not been identified as a unimolecular decomposition in thermal experiments, can be viewed as a four-center elimination of H_2O. This mechanism is analogous to HX elimination in alkyl halides and in $(CH_3)_3COH$ (28). A careful comparison with the available data for these systems allows us to place an estimate of 65 kcal mol^{-1} for the activation energy of reaction [1] and a frequency factor in the range of 10^{13} s^{-1}.

The appearance of acetylene among our products is common to many multiphoton experiments under focused geometry, and characteristic of high local temperature. Thus, the formation of C_2H_2 can be rationalized in terms of decomposition of "hot" ethylene molecules, or by further laser pumping of ethylene itself (29).

The presence of other products clearly establishes that reaction [1] is not the only channel. In particular, the relative amounts of CO and CH_4 do not follow a well-defined stoichiometry at the lower pressures. The growth of CO and CH_4 as a function of pressure (as well as that of C_2H_2) must be associated with either higher energy processes, or as a result of thermal chemistry. The fact that this effect is noticeable not only in neat ethanol, but in varying degrees in mixtures with Ar, NO, and O_2 indicates that a general energy transfer mechanism must be responsible for this behavior. Rotational hole filling due to collisions during the laser pulse can be an effective mechanism that allows for more efficient pumping through the discrete ladder (30, 31), and may be more important in a given pressure range than V−V or V−T deactivating collisions of highly excited species. A second possibility which could explain the increase of the "thermal" products, CH_4 and CO, as a function of pressure is the achievement of a common temperature among the different degrees of freedom.

The fact that CO and CH_4 are also favored at higher laser intensities (shorter pulses) supports our contention that these products originate from a higher energy pathway than reaction [1]. Pulse-duration effects have been demonstrated for a number of systems (32, 33) and illustrate that the ultimate energy content of the molecule can be dictated by peak power as a consequence of competition in the continuum between optical pumping and dissociation. This is particularly true in cases of high fluences typical of focused experiments.

The above considerations enable us to conclude that rotational hole filling, higher intensity and fluence are all responsible for a higher final excitation level of the ethanol molecule.

The actual mechanism by which CO and CH_4 are formed is a matter of some conjecture. The observation that CO and CH_4 result apparently from a higher energy channel could be interpreted as the result of free radical reactions initiated by a bond scission process like [4]. This step may be expected to have a high A factor (~10^{16} s^{-1}) and a high activation energy (~82 kcal mol^{-1}) and could account for its increasing participation in the overall mechanism at a final higher energy content of the excited C_2H_5OH. The presence of free radicals can be inferred from the appearance of ethane among the products, and the detection of the CH species (34). Yet, three experimental observations cast some doubts as to whether process [4] can be solely responsible for the increasing yield of CH_4 and CO at higher pressures: (*i*) the lack of any significant inhibition by NO; (*ii*) the small product changes observed when ethanol is pumped in mixtures with O_2; and (*iii*) the fact that the amount of C_2H_6 remains essentially constant in the pressure range where CH_4 and CO grow rapidly, and with increasing fluence and intensity.

It is thus apparent that either process, [2] or [3], or both, are also likely to be involved in the formation of CH_4, CO, and H_2. The fact that only trace quantities of CH_3CHO are detected, and no CH_2O could be interpreted as indicative of thermal decomposition of either aldehyde within the same laser pulse, or by intense local heating, or by large internal energy deposition in the product leading to facile decomposition. The pyrolysis of acetaldehyde is in itself a free-radical process initiated by the step

$$CH_3CHO^* \rightarrow \cdot CH_3 + \cdot CHO$$

which demands 79 kcal mol^{-1} of activation energy (35). Direct pumping of CH_3CHO,[6] or destruction by the laser pulse (36) are nevertheless very inefficient processes. On the other hand, a large fraction of the exit barrier energy has been shown to be converted into internal energy in four-center type elimination reactions (5). The other possibility is to consider process [3] followed by thermal decomposition of H_2CO

$$C_2H_5OH \rightarrow CH_4 + CH_2O$$

$$CH_2O^* \rightarrow CO + H_2$$

a mechanism reminiscent of that proposed in the multiphoton excitation of CH_3OH (37). A comparison of activation energies and A factors is not straightforward in these cases to account for

pronounced changes in mechanisms.

We believe that our present data cannot unequivocally distinguish between the several possibilities advocated for the higher energy channel. Yet, the results clearly establish some distinct differences with high pressure thermal chemistry. Thus, in our pressure range, process [1] can be identified as a true laser-induced process.

Our present work reinforces the idea that ethanol is indeed a case which displays a rich chemistry under vibrational MPE. It is also our belief that these results warrant further exploration, both on the conventional pyrolysis and on the primary dissociation processes of ethanol.

A. K. CHENG, ASHIM K. GHOSH, and J. B. STOTHERS. Can. J. Chem. **62**, 1385 (1984).

The effect of strongly basic conditions (*t*-BuO$^-$/*t*-BuOH/185°C) on the *exo* and *endo* isomers of 7,7-dimethyltricyclo[3.2.1.0^{2,4}]octan-6-one has been examined. While the *exo* isomer is stable, the *endo* isomer readily rearranges to 4,4-dimethyltricyclo[3.3.0.0^{2,8}]octan-3-one (**6**) which subsequently undergoes reduction of the three-membered ring. The initial transformation is one of very few examples of γ-enolate rearrangement. Experiments in *tert*-butyl alcohol-O-d_1 were carried out to establish the several sites of deuterium incorporation in the initial ketones and in **6** using ^{2}Hmr. These results reveal the stereochemistry of γ-enolate formation and cleavage as well as the stereoselectivities and relative rates of the exchange processes.

A. K. CHENG, ASHIM K. GHOSH et J. B. STOTHERS. Can. J. Chem. **62**, 1385 (1984).

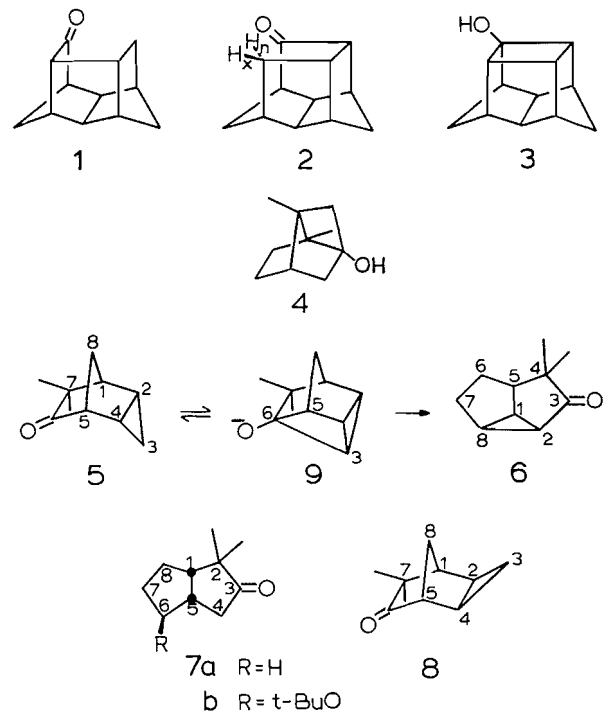
On a étudié l'effet de conditions fortement basiques (*t*-BuO$^-$/*t*-BuOH/185°C) sur les isomères *exo* et *endo* de la diméthyl-7,7 tricyclo[3.2.1.0^{2,4}] octanone-6. Alors que l'isomère *exo* est stable, l'isomère *endo* se transpose facilement en diméthyl-4,4 tricyclo[3.3.0.0^{2,8}] octanone-3 (**6**) qui subit une réduction subséquente pour donner un cycle à trois chaînons. La transformation initiale correspond à un des rares exemples de transposition d'un énolate γ. On a effectué des expériences dans l'alcool *tert*-butylique O-d_1 afin de pouvoir déterminer, grâce à la rmn du ^{2}H, quels sont les divers sites d'incorporation du deutérium dans le produit (**6**) et dans les cétones initiales. Ces résultats permettent de déterminer la stéréochimie de la formation et du clivage de l'énolate γ ainsi que les stéréosélectivités et les vitesses relatives des processus d'échanges.

[Traduit par le journal]

Introduction

Following the original discovery that, under strongly basic conditions, a ketonic carbonyl group can activate proton abstraction from carbons more than one bond removed (1), many examples involving both acyclic and polycyclic monoketones have been described (2). Most of these cases concern β-enolization, i.e., proton abstraction from β-carbons. Very few examples of γ-enolization have been encountered and, heretofore, only one has been found to lead to skeletal rearrangement, namely, the isomerization of half-cage ketone **1** to **2** (3). The formation of γ-enolates has been inferred from the observation of H/D exchange at C-8, the *syn*-methyl carbon, of camphor (4), at C-6 and -7 in 3,3-dimethylbicyclo[3.3.0]octan-2-one (5), and at the *endo*-6-methyl carbon of 3,3,6,6-tetramethyl[2.2.1]heptan-2-one (6). The conversion of *sym*-tetramethyldiphenylacetone to 2-isopropyl benzoic acid (7) can be viewed formally as rearrangement through a γ-enolate, but specific activation of proton abstraction from the phenyl ring by the carbonyl group seems unlikely and the process cannot be taken as a true example of γ-enolization within the usual frame of reference. For each of the systems exhibiting γ-enolization the γ-carbon is either held relatively close to the carbonyl carbon by skeletal restraints as in **1** or may closely approach the carbonyl group in certain conformations.

The observations of β- and γ-enolization in a variety of systems stirred interest in the reverse process, the protonation of the homoenolic species or homoketonization. Such studies not only provide supporting evidence for the existence of proposed intermediates but also give information on the stereochemistry of the process. One of the early studies of β-enolate ketonization involved the treatment of 1-acetoxynortricyclene



with various bases in deuterated media (8). In all cases, *exo*-6-deuterionorcamphor was the major product (>95%), showing that inversion of configuration is strongly favored. Subsequently, examinations of several other β-enolates have demonstrated that β-enolate cleavages tend to be highly stereoselective, generally proceeding with inversion although a number of highly strained polycyclic systems exhibit retention of configuration (2). Homoketonization of several γ-enolates has also received attention. An early example was the finding that base-catalyzed homoketonization of the bird-cage alcohol **3** gave the same mixture of **1** and **2** as that obtained by the treatment of **1** in strong base (3); thus, the alkoxide of **3** is

undoubtedly the γ-enolate formed from **1**. Furthermore, homoketonization of **3** in *t*-BuO^-/*t*-BuOD gave **2**-d_x having H_n largely replaced with deuterium while only traces replaced H_x (9). These data established that the cleavage of **3** proceeded with 95 ± 3% retention of configuration. Examinations of several other substituted cyclobutanols have also revealed high stereoselectivities favoring retention (2). Strong evidence to support the formation of a cyclic γ-enolate in camphor, as had been proposed to account for H/D exchange at the *syn*-methyl carbon (4), has been provided by the preparation of **4**, homoketonization of which, in a deuterated medium, gave 8-deuteriocamphor exclusively (10).

Our interest in remote enolization has led to the examination of other ketones which appear to be potentially capable of rearrangement through γ-enolates. A study of the 7,7-dimethyltricyclo[3.2.1.$0^{2,4}$]octan-6-ones has revealed a new example of such rearrangement. Although the *exo* isomer is stable under the usual reaction conditions (*t*-BuO^-/*t*-BuOH, 185°C), the *endo* isomer **5** is smoothly transformed to 4,4-dimethyltricyclo[3.3.0.$0^{2,8}$]octan-3-one (**6**). Experiments in *tert*-butyl alcohol-O-d_1 showed that all three compounds undergo multiple site H/D exchange. From ^{2}Hmr spectra, the location and stereochemistry of the exchange processes were established. In this paper we wish to describe the results of these experiments, a preliminary report of which has appeared (11).

Results and discussion

Homoenolization experiments

Following our usual procedures (12), the *endo*-tricyclic ketone **5** (13) was dissolved in anhydrous *t*-BuO^-/*t*-BuOH (1.27 *M*) to furnish a solution 0.26 *M* in **5**. Aliquots of this solution were transferred to glass tubes under nitrogen, sealed under vacuum, and heated to 185°C for varying periods of time. The neutral product (>80% yields) from each tube was isolated by pentane extraction and analyzed by gas–liquid chromatography (glc). Over the course of 100 h, glc revealed the smooth disappearance of starting material **5** and the appearance of three new components. The major new component **6** in the earlier samples was found to reach a maximum concentration (~60%) in ca. 50 h but its relative concentration decreased progressively thereafter. The amounts of the second and third new components **7***a* and *b* increased smoothly with increasing reaction time such that the ratio of these three materials was ca. 2:2:1 after 100 h. The distribution of components in the neutral fraction as a function of time is given in Table 1A. Three minor components constituting <5% of the product in the longest runs were not investigated. Samples of **6**, **7***a*, and **7***b* were readily obtained by preparative glc and each gave rise to strong carbonyl absorption in the infrared, showing these to be ketones.

Ketone **6** (1713 cm^{-1}, $CHCl_3$) exhibited a ^{1}Hmr spectrum having prominent methyl singlets (δ, $CDCl_3$) at 0.85 and 1.10 with the following multiplets: 2.66 (bq, 1H), 2.43 (bt, 1H), 1.35 (m, 1H), and complex absorption 1.6–2.1 (5H). Its ^{13}Cmr spectrum contained ten signals (δ_c, $CDCl_3$): CH_3, 17.0, 28.7; CH_2, 25.2, 35.6; CH, 30.8, 34.0, 36.0, 50.4; C, 51.3; and C=O, 219.5. A precise mass measurement showed the molecular formula to be $C_{10}H_{14}O$ which in conjunction with the nmr data is consistent with the tricyclic structure **6**. Since the parent ketone had been described (14), a sample was prepared following the literature procedure and dimethylated using the $NaNH_2/CH_3I$ method (15). The resulting product was identical to **6**, thereby confirming the assigned structure.

TABLE 1. Composition[a] of the neutral product obtained under homoenolization conditions (*t*-BuO^-/*t*-BuOH at 185°C)

[a]Determined as % of the total by glc using a 6% FFAP column.

The second ketonic product **7***a* (1730 cm^{-1}, $CHCl_3$) was found to have the molecular formula $C_{10}H_{16}O$ by precise mass measurement. Its proton spectrum also contained two methyl singlets (1.03, 1.08) with multiplets centred at 2.70 (2H), 2.25 (1H), 2.04 (1H), and complex absorption 0.9–1.9 (6H). The ^{13}C spectrum consisted of ten signals (δ_c, $CDCl_3$): CH_3, 19.8, 26.9; CH_2, 25.8, 28.6, 32.8, 43.1; CH, 35.1, 54.2; C, 49.4; and C=O, 223.6. These data suggested the bicyclic structure **7***a*. This conclusion was confirmed by reduction of **6** with potassium in alcohol followed by oxidation of the resulting alcohols which furnished the identical ketone.

The third ketonic product has a molecular formula of $C_{14}H_{24}O_2$, by precise mass measurement. In addition to its strong carbonyl absorption at 1740 cm^{-1} in the infrared, there was strong absorption at 1130 cm^{-1} indicative of an ethereal oxygen–carbon stretching mode. The proton spectrum contained three methyl singlets at δ 1.00, 1.05, and 1.20 in the ratio 1:1:3, a multiplet (3.80, 1H), and complex absorption, 1.30–3.30 (8H). Its ^{13}C spectrum had twelve signals: CH_3, 19.2, 26.5, 28.6 (rel. int. 1:1:3); CH_2, 27.1, 36.0, 40.7; CH, 44.0, 52.3, 80.2; —C— 49.4, 73.4; and C=O, 222.8. On the basis of these data, structure **7***b* was assigned to this ketone.

To establish that **7***a* and *b* are generated from **6**, samples of the latter, prepared as described above, were subjected to the usual homoenolization conditions. It was found that **6** was slowly converted to a mixture of **7***a* and *b* as anticipated; Table 1B includes the neutral product composition as a function of time.

Under the reaction conditions employed for the rearrangement of **5**, the isomeric *exo*-tricyclooctanone **8** was found to be stable (>80% recovery) with no evidence for the formation of rearranged products in the neutral fraction by glc analysis even after >110 h at 185°C.

With the structure of **6** confirmed by independent synthesis, the transformation of **5** → **6** must involve proton abstraction from C-3 leading to the intermediate γ-enolate **9** (or its equivalent), which could then suffer cleavage of the original C-5,-6 bond to generate **6** or return to starting material. From the experiments with **6** alone there was no evidence for the formation of **5**, indicating that the cleavage **9** → **6** is irreversible. From the H/D exchange studies described later, this conclusion was confirmed.

The conversion of **6** → **7** requires a reducing agent but we have been unable to detect an oxidized product. With lithium

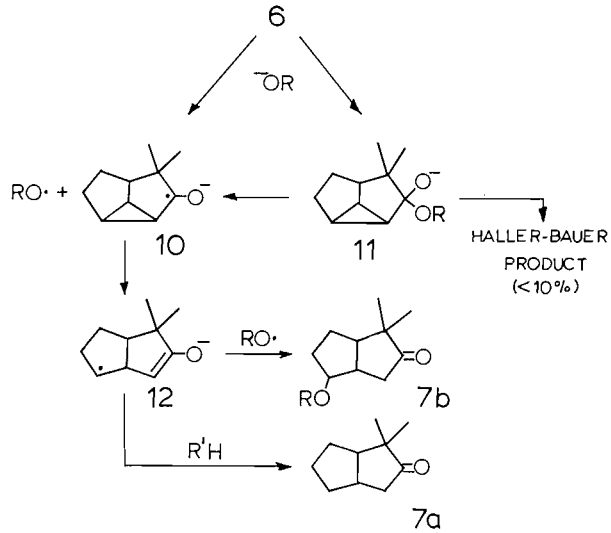

SCHEME 1

aluminium hydride, **6** was reduced in high yield to a 3:2 mixture of the corresponding epimeric alcohols in which the three-membered ring is intact. This was established by oxidation of the alcohol mixture with $K_2Cr_2O_7/H_2SO_4$ in ether to furnish **6** in high yield. As noted above, **6** is readily reduced with potassium metal in *tert*-butyl alcohol to a 2:1 mixture of bicyclic alcohols which upon oxidation gave **7***a* in high yield. Treatment of **6** with *t*-BuO^-/*t*-BuOH at reflux gave no reaction even after 135 h. Thus, the formation of **7***b* by a Michael addition of *t*-BuO^- to **6** seems unlikely. We suggest that the transformation of **6** to **7** occurs by electron transfer from the *tert*-butoxide anion, either directly to form **10** or by homolysis of the addition product **11** formed by reaction of *t*-BuO^- at the carbonyl group of **6** (see Scheme 1). Haller–Bauer cleavage of **11** to form an ester almost undoubtedly occurs, but this cannot be a major pathway since the acid fraction from the homoenolization of **5** constitutes less than 10% of the total product after the longest reaction times. The acidic product was not characterized in this work. Ketyl **10** can open to form **12** which subsequently gains a hydrogen atom from solvent to give **7***a* or reacts with *tert*-butoxide radical, formed in the direct generation of **10** from **6**, to furnish **7***b*. Evidence of electron transfer from *t*-BuO^- has been reported by other workers (16).

H/D Exchange experiments

To determine the regio- and stereoselectivity of proton abstraction in **5** under the strongly basic conditions, its homoenolization was examined in a deuterated medium. After treatment of **5** in *t*-BuO^-/*t*-BuOD at 185°C, samples of **5**-d_x and **6**-d_x were isolated by preparative glc and their ^{2}Hmr spectra were recorded. For **5**-d_x from a 6-h run the spectrum contained four signals, as illustrated in Fig. 1B, the assignments for which were obtained by comparison with the ^{1}Hmr spectrum (Fig. 1A). In the latter, prominent singlets at 0.985 and 1.103 arise from the two methyl groups and these were correlated with the methyl ^{13}C signals at 25.4 and 19.5 ppm (13), respectively, by selective decoupling; thus, it follows that the higher field signal (0.985) arises from the *exo*-methyl group since the less shielded carbon is *exo* (13). The lowest field multiplet at 2.67 was readily ascribed to the bridgehead H-5 while the pattern at 2.18–2.40 (3H) could be attributed to H-1 and the 8-methylene protons. The latter give rise to an AB pattern, J_{AB} = 9.5 Hz, further split by additional smaller coupling interactions; the higher field portion, δ 2.22, is coupled to H-5, J = 1.2 Hz, and to H-1, at 2.35, with J = 2.2 Hz and could be assigned to the *anti*-8 proton. Double irradiation at 2.67 (H-5) revealed $J_{5,anti\text{-}8}$ and reduced the multiplet at 1.83 to a doublet of triplets (J = 3.3, 8.5 Hz), thereby identifying the H-4 absorption, $J_{4,5}$ = 4.5 Hz. An analogous change in the multiplet at 1.57 occurred upon double irradiation at 2.35; thus, H-2 absorbs at 1.57. Since the 3-methylene absorption was obscured by the strong methyl signals, shift reagent studies were required to complete the spectral analysis.

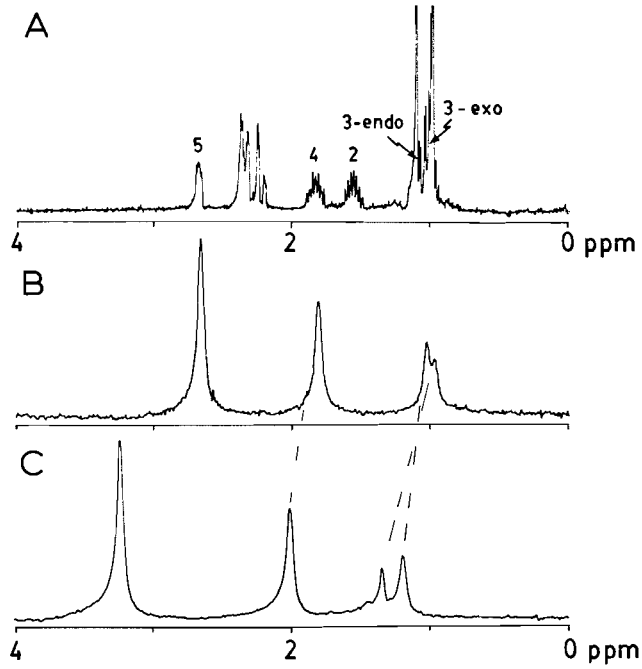

FIG. 1. Nuclear magnetic resonance spectra of **5**. (A) 200 MHz ^{1}H spectrum of **5** in $CDCl_3$; (B) 30.7 MHz ^{2}H spectrum of **5**-d_x in $CHCl_3$; (C) ^{2}H spectrum of **5**-d_x in $CHCl_3$ containing 0.06 equiv. of Eu(fod)$_3$.

Upon the addition of Eu(fod)$_3$, the lowest field signal exhibited the largest shift as expected for the α-bridgehead proton. The shift difference, ν_{AB}, for the 8-methylene protons doubled in the presence of 0.07 equiv. of Eu(fod)$_3$ confirming that the higher field portion of the "AB" system is due to the *anti*-8 proton. In the high field region of the spectrum, the methyl signals shifted smoothly to lower field revealing an eight-line pattern attributable to the *exo*-3 proton. Double irradiation of the *syn*-8 proton absorption reduced this pattern to an apparent quartet by eliminating a splitting of 2.2 Hz which must be the long range coupling interaction between the *exo*-3 and *syn*-8 protons. A five-line multiplet was barely discernible in the high field region and was ascribed to the *endo*-3 proton but the pattern was partially obscured by the lower field methyl signal. Consequently, the spectrum was also examined after the addition of Pr(fod)$_3$, in which case the two multiplets for the 3-protons were clearly resolved. All of the assignments for the individual multiplets were confirmed by the appropriate decoupling experiments and the ^{2}Hmr spectrum could now be interpreted. The four signals (Fig. 1B) establish that exchange occurred at C-5, C-4, the *exo*-methyl, and the *exo*-3 positions. The latter assignments were confirmed by examination of the effect of added Eu(fod)$_3$ (Fig. 1C). Mass spectrometric analysis of this sample showed it to contain 1.83 atoms ^{2}H per molecule and integration of the ^{2}H spectrum (Fig. 1C) indicated the deuterium distribution to be 0.28 (*exo*-3-^{2}H), 0.55 (4-^{2}H), 0.82

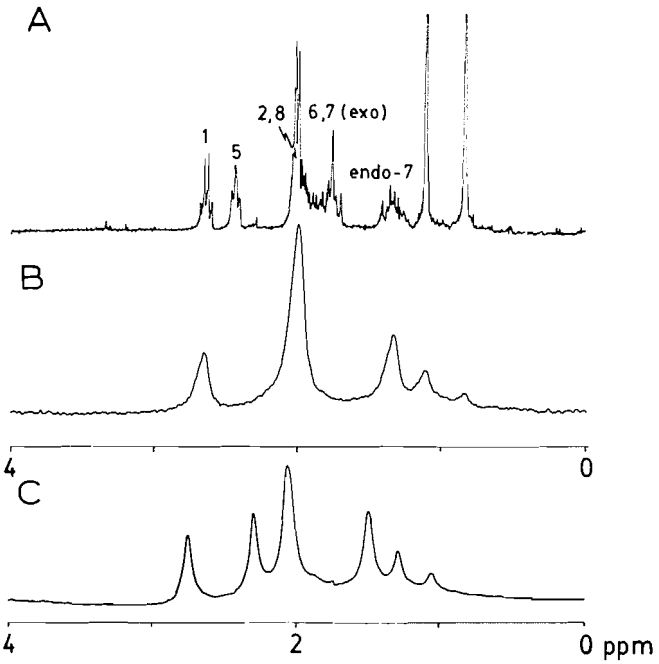

FIG. 2. Nuclear magnetic resonance spectra of **6**. (A) ^{1}H spectrum (200 MHz) of **6** in $CDCl_3$; (B) 30.7 MHz ^{2}H spectrum of **6**-d_x (in $CHCl_3$) generated from **5** after 18 h in *t*-BuO^-/*t*-BuOD at 185°C; (C) ^{2}H spectrum of **6**-d_x in $CHCl_3$ containing 0.05 equiv. of $Eu(fod)_3$.

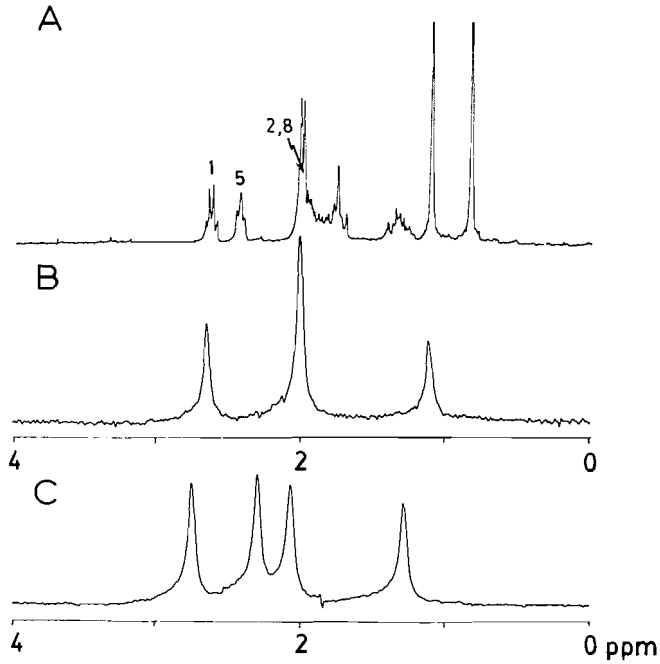

FIG. 3. Nuclear magnetic resonance spectra of **6**. (A) 200 MHz ^{1}H spectrum of **6** in $CDCl_3$; (B) 30.7 MHz ^{2}H spectrum of **6**-d_x (in $CHCl_3$) after 31 h in *t*-BuO^-/*t*-BuOD at 185°C; (C) ^{2}H spectrum of **6**-d_x in $CHCl_3$ containing 0.05 equiv. of $Eu(fod)_3$.

(5-^{2}H), and 0.18 (*exo*-Me) atoms ^{2}H.

The rearrangement product **6**-d_x isolated from a 18-h reaction exhibited the ^{2}Hmr spectrum illustrated in Fig. 2B; the ^{1}H spectrum of **6** is shown in Fig. 2A. Of the two methyl singlets in the latter spectrum, that at δ 1.10 was correlated with the less shielded of the two ^{13}C methyl signals (δ_c, 28.7) by selective decoupling; thus these signals were assigned to the *exo*-methyl group and those at δ 0.85 and δ_c 17.0 to the *endo*-methyl. The broadened "quartet", a doublet of triplets with longer range couplings, at δ 2.66 could be assigned to H-1, and the broadened "triplet" at δ 2.43 to H-5. The multiplet at δ 1.35 was assigned to the *endo*-7-H on the basis of its higher shielding relative to the other skeletal protons, attributable to its orientation with respect to the carbonyl group, i.e. lying above the plane of the carbonyl bond in the shielding cone. The complex absorption in the region 1.7–2.1 integrated for five protons, accounting for the remaining skeletal protons. Upon the addition of increasing amounts of $Eu(fod)_3$, a doublet of doublets was shifted out of this pattern and exhibited the greatest sensitivity to added shift reagent (1.5 ppm/0.2 equiv. of $Eu(fod)_3$), thereby identifying it as the H-2 absorption. With 0.06 equiv. of $Eu(fod)_3$ the H-1 absorption was shifted to δ 2.81, the H-5 pattern to 2.60, the *endo*-7 multiple to 1.63, and the H-2 multiplet to 2.43. Spin-decoupling experiments confirmed these assignments from the following results. Irradiation at δ 1.63 had little effect on the three low field multiplets, while irradiation at 2.43 (H-2) eliminated a 5-Hz coupling in the 2.81 (H-1) pattern with little effect on the 2.60 multiplet. Decoupling at δ 2.60 (H-5) collapsed the 2.81 (H-1) pattern to a triplet, while decoupling at 2.81 changed the absorptions at 2.60 (H-5) and 2.43 (H-2) to doublets. Finally, irradiation at δ 2.15 produced a doublet at 2.43 (H-2) and a triplet at 2.81 (H-1) without affecting the 2.60 (H-5) pattern, thus H-8 absorbs at 2.15.

From Fig. 2B it is apparent that **6**-d_x contains deuterium at several sites including the 1-, *endo*-7-, and both methyl positions. In the presence of shift reagent a clear signal emerged from the large band at δ 2.0 (Fig. 2B) whose sensitivity to added $Eu(fod)_3$ identified it as a 2-deuteron; with 0.05 equiv. of $Eu(fod)_3$ the resulting shift dispersion is shown in Fig. 3C. Unfortunately, additional shift reagent failed to resolve the largest peak although it was consistently broader than the other signals. It was tentatively concluded that this is the absorption of two nearly equivalent ^{2}H nuclei. Mass spectrometric analysis showed this sample to contain 3.55 atoms ^{2}H/molecule. Integration of the ^{2}H spectrum indicated the distribution to be 0.25 and 0.09 atoms ^{2}H at the *exo*- and *endo*-methyl sites, respectively, 0.45 at C-1, and 0.69 at the *endo*-7- and 2-positions, while the absorption at 2.1 ppm represented 1.38 atoms ^{2}H, confirming that deuterium is at two nearly equivalent sites which are presumably the 8- and *exo*-7-positions.

Deuterium incorporation in **6** results from exchange in **5** before conversion to **6** *and* from exchange after its formation. To examine the latter processes separately, samples of **6** were treated with *t*-BuO^-/*t*-BuOD at 185°C. The ^{2}H spectra of the recovered **6**-d_x samples differed significantly from those for **6**-d_x generated from **5** described above, as illustrated in Fig. 3B for a sample isolated after 31 h at 185°C in deuterated base. Upon the addition of 0.05 equiv. of $Eu(fod)_3$ the absorption initially at 2.0 ppm was clearly resolved into two components, δ 2.30 and 2.08, assignable to deuterium at C-2 and -8, respectively. This sample contained 2.71 atoms ^{2}H/molecule by mass spectrometric analysis and the distribution was found to be 0.59, 0.75, 0.78, and 0.59 atoms ^{2}H at C-1, -2, -8, and the *exo*-methyl site, respectively. There was no detectable deuterium at the *endo*-methyl site even with the somewhat longer reaction time which was chosen to test for such exchange.

With these results one can now consider the various exchange processes in these compounds. For **5**, exchange proceeds at four sites, with that at C-4 and -5 presumably activated

by the inductive effect of the carbonyl group. Preferential exchange at the *exo*-methyl group has been observed in several polycyclic systems (2) and evidence supporting the intermediacy of a cyclopropoxide in this process has been presented for a number of bicyclic ketones (17). Exchange at C-3 is stereospecific with deuterium only in the *exo* orientation. This is indicative of the reversible formation of **9**, opening with *inversion* to return to **5**. Since all other γ-homoketonizations for which the stereochemistry has been examined proceed with *retention* of configuration, the cleavage of **9** → **5** with inversion is the first such example. The rearrangement of the deuterated **5** to **6** will produce **6**-d_x bearing deuterium at C-2, -7 and -8, and the *endo*-methyl carbon, because the relative orientation of the methyl group is reversed upon conversion of **5** → **6**. Since bridgehead exchange occurs at C-5 in **5** before rearrangement and this carbon picks up deuterium upon the opening of **9** → **6**, both the *exo* and *endo*-7 sites in **6** will be partially deuterated regardless of the stereochemistry of the ring opening; thus we have no information on the stereoselectivity of the cleavage. For **6**-d_x obtained directly from **6** only four ^{2}H signals were apparent after 31 h (Fig. 3C). No deuterium was found at the *endo*-methyl or at C-7! The absence of ^{2}H at C-7 established that the cleavage of **9** → **6** is unidirectional. Since only hydrogens bonded to the *exo*-methyl and cyclopropyl carbons undergo exchange, **6** does not undergo γ-enolization. For **6**-d_x generated from **5** in the deuterated medium (Figs. 2B, C) the signals for ^{2}H at C-7 and the *endo*-methyl group must arise from exchange *before* the formation of **6** while those for ^{2}H at C-1 and the *exo*-methyl group represent exchange *after* its formation. Thus, **6** exhibits the usual preferential *exo*-methyl exchange.

Although **8**, the *exo* isomer of **5**, was found to be stable under the conditions for rearrangement of **5**, this does not preclude the occurrence of H/D exchange. Consequently samples of **8** were treated with *t*-BuO$^-$/*t*-BuOD at 185°C for various times. After 18 h, samples were found to contain 2.27 atoms ^{2}H/molecule by mass spectrometry and ^{2}Hmr revealed five sites of exchange for which the ^{2}H distribution was determined by integration. The ^{2}Hmr signals and ^{2}H content were as follows: δ 2.58 (0.83), 1.37 (0.13), 1.05 (0.05), 0.92 (0.83), and 0.43 (0.43). The ^{1}Hmr spectrum of **8** exhibited methyl singlets at δ 1.055 and 1.160 which, by correlation with the ^{13}C spectrum, could be assigned to the *exo*- and *endo*-methyl hydrogens, respectively. Thus, **8** undergoes slow exchange preferentially at the *exo*-methyl site, as expected. In addition, the ^{1}H spectrum contained broadened singlets at δ 2.185 and 2.575, assignable to the bridgehead protons at C-1 and -5, respectively, broadened doublets at 1.210 and 1.375 (the C-8 protons), a "quartet" at 0.43 (one of the 3-protons), with multiplets centred at 1.30 (1H) and 0.95 (2H). From these data, it was deduced that exchange occurred at C-3, -5, -8, and the *exo*-methyl, as well as at one other site.

Confirmation that deuterium was present at C-3, -4, and -5 was provided by examination of the ^{13}C spectrum of this sample, which could be compared with the spectrum of **8** described previously (13). In the spectrum of **8**-d_x, strong singlets were apparent for C-1 (δ 44.0), C-7 (48.3), and the methyl carbons (20.9 and 23.9) while all other absorptions exhibited the typical effects of deuterium substitution at sites adjacent to the individual carbons. It can be noted that the deuterium content at the *exo*-methyl and C-8 sites was too low to be clearly detectable in the spectrum of this 17-mg sample. The strongly attenuated singlet for C-8 at δ 22.0 was accompanied by a prominent singlet 0.095 ppm towards higher field, constituting good evidence for ^{2}H at C-5 since two-bond ^{2}H isotope effects on ^{13}C shieldings are typically 0.1 ppm (18). The expected singlet at δ 13.4 for C-2 was also strongly attenuated and accompanied by two signals at 0.115 and 0.205 ppm higher field, indicative of one *and* two β-deuterons, thereby revealing ^{2}H uptake at C-3 and -4. The absorption pattern for C-3 was more complex. In addition to the expected weak singlet at δ 5.3 and an isotope-shifted component at 0.115 ppm higher field, there were two 1:1:1 triplets, each with J_{CD} = 24 Hz, the centres of which were separated by 0.115 ppm; the central peak of the less shielded triplet was 0.285 ppm upfield from the δ 5.3 signal for C-3. The isotope-shifted singlet indicates the presence of ^{2}H at C-4 while the triplets arise from those molecules bearing deuterium on C-3, with and without ^{2}H at C-4. While the integrated intensities of these patterns for C-2, -3, and -8 were comparable to those for C-1 and -7, the intensity of the absorption for C-4 was decreased by ca. 80%, providing additional evidence for ^{2}H exchange at this site. For those species bearing a 4-deuteron, the C-4 absorption will be a triplet and these signals will be relatively weak because of the substantially reduced Overhauser effect. Furthermore, additional deuterium at C-3 and/or C-5 will exert isotope effects. Consequently it was not surprising that the triplet patterns were not discernible in this spectrum. The absorption consisted of the expected signal at δ 9.8 together with isotope-shifted components at 0.100 and 0.185 ppm higher field, indicative of ^{2}H at C-3 and -5. Finally, C-5 gave rise to a two-line pattern whose total intensity was comparable to that for C-4; the expected singlet at δ 48.9 was accompanied by a signal at 0.105 ppm higher field, consistent with ^{2}H uptake at C-4 and -8.

While the foregoing data established that ^{2}H exchange occurred at C-3, -4, -5, -8, and the *exo*-methyl sites in **8**-d_x, additional information was required to determine the stereochemistry of exchange at the methylene groups (C-3 and -8). To this end, the effect of shift reagent on the ^{1}H spectrum of **8** was examined. In the presence of 0.54 equiv. of Eu(fod)$_3$, multiplets for each of the eight skeletal protons were separately resolved, permitting complete assignments. The broadened singlets initially at δ 2.185 and 2.575 shifted 1.45 and 3.73 ppm downfield, confirming their assignments to H-1 and -5, respectively. The 8-methylene protons initially absorbing at δ 1.210 and 1.375 as broadened doublets, $J \sim 12$ Hz, shifted 1.55 and 2.35 ppm, thereby identifying these patterns as the *anti* and *syn* signals, respectively. A pair of multiplets, appearing as ill-defined triplets, was clearly resolved in the shifted spectrum; these patterns initially near δ 0.95 and 1.30 exhibited similar shifts of ca. 1.8 ppm and could be assigned to H-4 and -2. The two remaining multiplets, the 1:3:3:1 "quartet" at δ 0.43 and a 1:2:2:2:1 "quintet", initially partially obscured near 0.95, were found to shift 0.78 and 1.05 ppm, respectively; these arise from the 3-protons. Since the "quartet" was least sensitive to added shift reagent, it was assigned to H-3 *cis* to the vicinal cyclopropyl methine protons, H-2 and -4. The four-line pattern, with spacings of 6.6 Hz, is that expected for a proton with comparable coupling to three nonequivalent neighbors. The quintet with spacings of 3.3 Hz can arise from a proton coupled to three neighbors for which one coupling constant is twice as large as the other two; thus, the spacings indicate that J = 6.6 and 3.3 Hz. Since it is well known that $J_{cis} > J_{trans}$ for vicinal coupling in cyclopropyl rings (19), the observed quartet and quintet patterns for the 3-protons *cis* and *trans*, respectively, to H-2 and -4 confirm the assignments. Additional

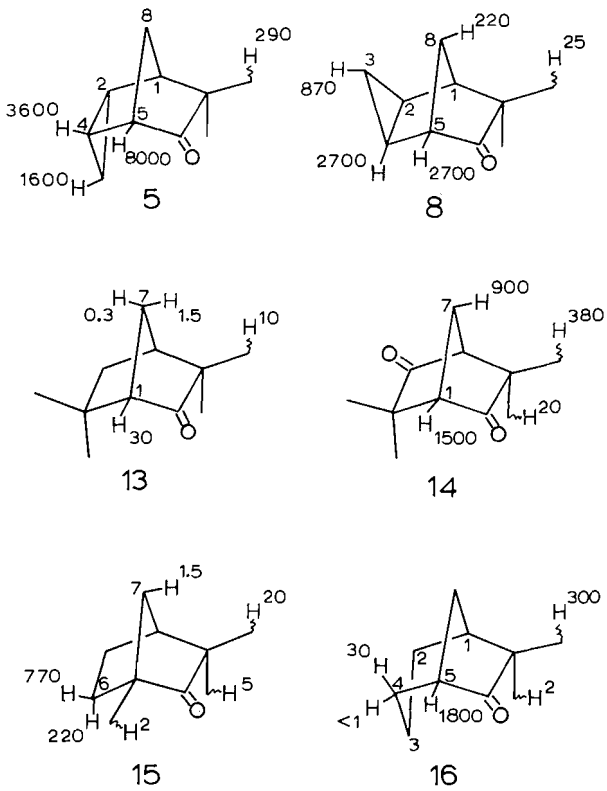

FIG. 4. Deuterium exchange rates ($k \times 10^8\ s^{-1}$) at the various sites in **5**, **8**, and **13**–**16** by β- and γ-enolization at 185°C in *t*-BuO^-/*t*-BuOD.

confirmation of all of these assignments was obtained from a series of spin decoupling experiments. Thus, deuterium exchange at the 3- and 8-methylene sites in **8** is highly stereoselective with observable ^2H found only at the *cis* and *syn* orientations, respectively.

Approximate first-order rate constants for exchange at the various sites in **5** and **8** were extracted from the deuterium incorporation data and these are given in Fig. 4 together with published data for the closely related systems **13** (6), **14** (6), **15** (12), and **16** (20). In our earlier study (12) of fenchone (**15**) exchange at C-7 was not detected but, in a more recent examination, Werstiuk *et al.* (6) found that slow exchange indeed occurs with a distinct preference for the *syn* over the *anti* site even though it would appear that the *anti* hydrogen is the less hindered. However, the rate of *syn* exchange was found to be the same as that in **13** for which the *syn*- and *anti*-7 hydrogens are in similar steric environments but exhibit a *syn*/*anti* preference of 5:1. Much faster exchange at C-7 was found for diketone **14**, apparently attributable to an activating effect of the second carbonyl group (21). On the other hand, only *syn* exchange occurs at C-8 in **8** and at a rate >100 times that for both **13** and **15**, while the same process in **5**, if it occurs, must proceed at a rate comparable to that for **13** and **15**, since no deuterium was observed at C-8 in **5** which rearranges with a rate constant of ca. $2 \times 10^{-5}\ s^{-1}$. While the stereospecificity of the exchange at C-8 in **8** could be attributed to steric hindrance, the increased reactivity for the process is difficult to explain. There is also a marked increase in reactivity for exchange at the 5-bridgehead carbon in both **5** and **8** relative to **13**; both **5** and **8** undergo exchange at C-5 at rates greater than those exhibited by **14** and **16** at the corresponding bridgeheads. It appears that the inductive effect of the carbonyl group in **5** and **8** is enhanced, thereby increasing the acidity of the hydrogens at both C-4 and -5. While it is well known that cyclopropyl hydrogens are more acidic than their alicyclic counterparts, the lack of exchange at C-2 in each of these systems shows that the carbonyl group exerts a significant effect. Furthermore, the rate of exchange at C-4 in both **5** and **8** is distinctly faster than that at C-3, although the latter presumably bears the more acidic hydrogen. The stereospecificity at C-3 can be ascribed to steric factors since the hydrogen exhibiting exchange is much less hindered in each case. Finally it may be noted that, while methyl exchange occurs with the usual *exo*-preference, the rates for **5** and **8** differ by a factor of 10, with that for **5** comparable to the rate found for the [3.2.1] analog **16**. Clearly, rather subtle factors govern the reactivity of exchange in these compounds and additional data are required before definitive interpretations can be put forward.

In the case of **6**, deuterium exchange at the *exo*-methyl carbon appears to proceed with $k \sim 1.2 \times 10^{-6}\ s^{-1}$ at 185°C, which is comparable to the rate of methyl exchange in 2,2,5,5-tetramethylcyclopentanone (20). Exchange of the skeletal hydrogens, however, is too fast at 185°C to give meaningful rate data and, consequently, a series of runs was carried out at 170°C to obtain the following rate constants: 45, 20, and 10 $\times 10^{-6}\ s^{-1}$ for the 1-, 2-, and 8- positions, respectively. These exchange rates are considerably greater than those found for the systems in Fig. 4 because the inductive effect of the α-carbonyl group can be expected to enhance the acidity of these cyclopropyl hydrogens.

At the present time, examination of some closely related systems is in progress, not only as an extension of our search for rearrangements proceeding via γ-enolization but also to investigate similar exchange processes in other polycyclic systems containing three-membered rings, as an aid to the understanding of the enhanced reactivities found for ketones **5** and **8**.

Experimental

General

The preparations of **5** and **8** have been described (13) and the general procedures for the rearrangement and exchange experiments, reported previously (12), were followed. To a solution of the base, prepared *in situ* by dissolving potassium metal in dry *tert*-butyl alcohol under a nitrogen atmosphere, was added the ketone to give a solution containing ketone – *t*-BuO^-/*t*-BuOH in a molar ratio of 1:4:40. Aliquots were placed in glass tubes which were sealed after degassing and heated at an appropriate temperature for various times. For the exchange experiments, *tert*-butyl alcohol-O-d_1 (99% deuterated and <0.005 *M* in water) was used. After cooling, the ketonic products were isolated by pentane extraction and the product mixtures analyzed by gas–liquid chromatography (glc). Preparative glc using either a 6% FFAP or 10% Carbowax on Chromosorb W column were employed to isolate samples of each ketone.

Nuclear magnetic resonance spectra:

The ^1H, ^2H, and ^{13}Cmr spectra were recorded using a Varian XL-200 spectrometer in the Fourier transform mode utilizing, for ^1H and ^{13}C, the ^2H signal of the $CDCl_3$ solvent as a lock; the ^2H spectra were obtained in $CHCl_3$ solution without lock since the field drift is negligible over the few hours required to obtain satisfactory S:N levels. The effect of Eu(fod)$_3$, as shift reagent, was utilized to increase the shift dispersion in both the ^1H and ^2H spectra to permit unambiguous assignments for specific nuclei; ^1H assignments, confirmed through a series of spin decoupling experiments, gave definitive ^2H assignments since ^1H and ^2H shieldings are essentially identical. Integration of the dispersed ^2H spectra indicated the extent of ^2H incorporation at the various sites undergoing exchange, while the total ^2H content was

determined by mass spectrometry with a Varian MAT-311A instrument.

4,4-Dimethyltricyclo[3.3.0.0^{2,8}]octan-3-one (6)

Tricyclo[3.3.0.0^{2,8}]octan-3-one was prepared from 2-cyclopenten-1-acetyl chloride in 83% yield using the sequence described by Monti *et al.* (14), and exhibited the same ir (ν_{max} (film): 1720 cm^{-1}) and ^{1}Hmr spectra as those reported. Its ^{13}Cmr spectrum contained the following signals: δ_c ($CDCl_3$): 219.4 (C=O), 24.7, 41.0, 47.0 ($3CH_2$'s), 30.7, 36.3, 37.6 and 38.9 (4CH's). Dimethylation using sodamide and methyl iodide (15) furnished **6** in 65% yield, isolated by preparative glc (FFAP); ir ($CHCl_3$): 1713 cm^{-1}; ^{1}Hmr (described in text); ^{13}Cmr ($CDCl_3$), δ_c: 219.5 (C=O), 51.3 (C-4), 50.4 (C-5), 25.2 (C-6), 35.6 (C-7), 33.9 (C-8), 30.8 (C-2), 36.0 (C-1), 28.7 (*exo*-Me), and 17.0 (*endo*-Me). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1044.

Reduction of 6

(a) A solution of **6** (200 mg) in ether (5 mL) was added dropwise to a refluxing suspension of lithium aluminium hydride (27 mg) in ether (20 mL) under a nitrogen atmosphere and the mixture refluxed for 3 h. After cooling and the dropwise addition of water (20 mL), the product was isolated by ether extraction to afford a mixture of two alcohols (175 mg, 86% yield) in a ratio of ca. 3:2; ^{1}Hmr ($CDCl_3$) δ: 4.07 (d, $J \sim 5.5$ Hz, 1H), 3.50 (bs, 1H), 0.86 (S, 3H, Me), 0.98 (s, 3H, Me); ^{13}Cmr ($CDCl_3$) δ_c (major component): 78.5 (CHOH), 52.2 (quat C), 53.6, 30.1, 30.0, 26.0 (CH's), 33.0, 24.1 (CH_2's), 21.6, 22.9 (CH_3's); minor component: 83.2 (CHOH), 49.6 (quat C), 54.3, 33.3, 33.2, 32.0 (CH's), 30.7, 25.6 (CH_2's), 19.2, 27.7 (CH_3's). Oxidation of this mixture (125 mg) with sodium dichromate/H_2SO_4 in ether according to Brown *et al.* (22) gave a single ketonic product (100 mg, 80% yield) which was identical in all respects with **6**.

(b) Ketone **6** (250 mg) was dissolved in *tert*-butyl alcohol (20 mL) and the solution heated to reflux. Metallic potassium (1 g) was added to the solution and refluxing was continued until the potassium completely dissolved. After the addition of water (50 mL), the product was extracted with pentane (3 × 20 mL) and the combined extracts washed thoroughly with water (8 × 20 mL) before drying over anhydrous $MgSO_4$. Evaporation of the solvent gave a clear oil (140 mg, 55% yield) which was shown by ^{1}H and ^{13}Cmr to be a 2:1 mixture of two alcohols; ^{1}Hmr ($CDCl_3$) δ: 3.79 (dd, $J \sim 7$, 9.5 Hz), 3.71 (dd, $J \sim 6$, 6.5 Hz), 0.97 (s, CH_3), 0.955 (s, CH_3), 0.89 (s, $2CH_3$'s); ^{13}Cmr ($CDCl_3$) δ_c (major component): 8.30 (CHOH), 43.5 (quat C), 53.1, 39.5 (CH's), 39.8, 34.7, 28.2, 28.0 (CH_2's), 29.0, 18.0 (CH_3's); minor component: 79.1 (CHOH), 43.0 (quat C), 53.3, 37.0 (CH's), 39.6, 35.5, 29.3, 27.6 (CH_2's), 22.7, 22.5 (CH_3's). Oxidation of this mixture of alcohols (80 mg) gave a single ketonic product identical with the second ketone produced by rearrangement of **5** and characterized as 2,2-dimethyl-*cis*-bicyclo[3.3.0]octan-3-one (**7***a*) on the basis of the following data: ir ($CHCl_3$): 1730 cm^{-1}; ^{1}Hmr (described in the text); ^{13}Cmr ($CDCl_3$) δ_c: 223.6 (C=O), 54.3 (C-1), 49.4 (C-2), 43.1 (C-4), 35.2 (C-5), 32.9 (C-6), 25.8 (C-7), 28.6 (C-8), 26.9 (*exo*-Me), and 19.9 (*endo*-Me); *m/e* (relative intensity): 152 (28), 110 (63), 95 (35), 82 (54), 81 (75), 79 (35), 69 (35), 67 (100), 54 (48). *Exact Mass* calcd. for $C_{10}H_{16}O$: 152.1206; found: 152.1200.

2,2-Dimethyl-exo-*6*-tert-*butoxy*-cis-*bicyclo[3.3.0]octan-3-one* (7b)

The third ketonic component from the rearrangement of **5** was assigned structure **7***b* on the basis of the following data: ir ($CHCl_3$): 1130, 1740 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.00 (s, 3H, CH_3), 1.05 (s, 3H, CH_3), 1.20 (s, 9H, CH_3), 3.80 (m, 1H, —CHO—), 1.30–3.0 (complex absorption, 8H); ^{13}Cmr ($CDCl_3$) δ_c: 222.8 (C=O), 52.3 (C-1), 49.4 (C-2), 40.7 (C-4), 44.0 (C-5), 80.2 (C-6), 36.0 (C-7), 27.1 (C-8), 26.5 (*exo*-Me), 19.2 (*endo*-Me), 28.6 and 73.4 (Me and quat C of *tert*-butyl). *Exact Mass* calcd. for $C_{14}H_{24}O_2$: 224.1764; found: 224.1770.

Condensation of cyclic and acyclic imines with phthalide anions. Synthesis of protoberberines and substituted 3,4-dihydro-2-methyl-1(2*H*)-isoquinolones[1]

RICHARD MARSDEN AND DAVID B. MACLEAN[2]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 1, 1984

RICHARD MARSDEN and DAVID B. MACLEAN. Can. J. Chem. **62**, 1392 (1984).

3,4-Dihydroisoquinolines react with anions derived from phthalides and 3-methylphthalides in tetrahydrofuran yielding 13-hydroxy-8-oxotetrahydroprotoberberines and 13-hydroxy-13-methyl-8-oxotetrahydroprotoberberines, respectively. Only one of two possible diastereomers is formed. The lactams may be reduced to the corresponding protoberberines with lithium aluminium hydride. The reaction of the acyclic imine, 3,4-dimethoxybenzylideneméthylamine, with anions derived from phthalide, 3-phenylphthalide, and 5,6-dimethoxyphthalide, has been investigated. In all cases separable mixtures of diastereomeric substituted 3,4-dihydro-1(2*H*)-isoquinolones were formed.

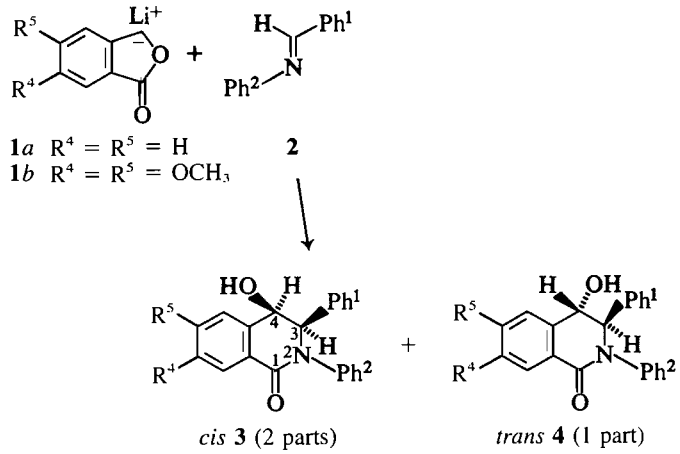
RICHARD MARSDEN et DAVID B. MACLEAN. Can. J. Chem. **62**, 1392 (1984).

Les dihydro-3,4 isoquinoléines, dans le tétrahydrofuranne, réagissent avec les anions provenant des phthalides et des méthyl-3 phthalides pour conduire respectivement aux hydroxy-13 oxo-8 tétrahydroprotoberbérines et aux hydroxy-13 méthyl-13 oxo-8 tétrahydroprotoberbérines. Il ne se forme qu'un seul des deux diastéréoisomères. On peut réduire les lactames en protoberbérines correspondantes en faisant appel à l'hydrure double de lithium et d'aluminium. On a étudié la réaction de l'imine acyclique, diméthoxy-3,4 benzylidèneméthylamine, avec les anions provenant du phthalide, du phènyl-3 phthalide et du diméthoxy-5,6 phthalide. Dans tous les cas, il se forme des mélanges, que l'on peut séparer, des diastéréoisomères des dihydro-3,4 (2*H*)-isoquinolones-1 substituées.

[Traduit par le journal]

The reaction of imines with phthalide anions derived from phthalides and lithium diisopropylamide (LDA) was reported in a preliminary communication in 1980 by Dodsworth *et al.* (1). A more complete account of their work leading to the formation of various diarylisoquinolones has recently appeared (2). In the interim we reported our initial studies on the reaction of phthalide anions with 3,4-dihydroisoquinolines, a reaction that leads in one step to the protoberberine ring system (3). Here we give a full account of our initial work, and its extension to the synthesis of 13-methylprotoberberines. We also report the preparation of several 2-methyl-3-phenyl-4-hydroxy-3,4-dihydro-1(2*H*)-isoquinolones and a pair of 2-methyl-3,4-diphenyl-4-hydroxy-3,4-dihydro-1(2*H*)-isoquinolones.

Dodsworth *et al.* (2) showed that the anions of phthalide (**1***a*) and 5,6-dimethoxyphthalide (**1***b*) react with a variety of diaryl imines **2** to form 3,4-dihydro-1(2*H*)-isoquinolones substituted at C-2 and C-3 by the aryl groups present in imine **2** and at C-4 by an OH group. (The generation of two new chiral centres leads to the formation of racemic diastereomers as shown in Scheme 1.) This reaction very likely proceeds by initial attack of phthalide anion at the carbon atom of the carbon–nitrogen double bond with transfer of charge to nitrogen. The negatively charged nitrogen then attacks the phthalide carbonyl carbon to form a tetrahedral intermediate which opens to form the isoquinolone. Dodsworth *et al.* found that the formation of the *cis* isomer **3** was favored over the *trans* **4** in a ratio of ca. 2:1, and that the isomers may be differentiated on the basis of their coupling constants in their ^{1}H nmr spectra. The *cis* isomer **3** shows J = 6.0–6.6 Hz and the *trans* isomer **4**, J = 2.0–2.2 Hz, with the coupling constants reflecting a dihedral angle of ca. 55° in the *cis* isomer and ca. 90° in the *trans* isomer. Examination of Dreiding models showed that these dihedral angles are reasonable in minimizing steric interactions. Cushman *et al.* (4) had observed coupling constants of the same order for a related group of *cis*- and *trans*-3,4-disubstituted-



SCHEME 1

3,4-dihydro-1(2*H*)-isoquinolones. Elimination reactions carried out on the mesylates of **3** and **4** supported the stereochemical assignment.

We have found that 3,4-dihydroisoquinolines **5** (cyclic imines) react readily with phthalide anions **1**, to form 13-hydroxy-8-oxotetrahydroprotoberberines **6** in a single step, as shown in Scheme 2. Three such compounds have been prepared in yields ranging from 60–68%. The lactams underwent reduction with $LiAlH_4$ in THF to the corresponding 13-hydroxytetrahydroprotoberberines **7** in yields of 75–85%. Only one of the two possible racemic diastereomers has been isolated in the condensation so that the reaction is highly stereoselective in contrast to the reaction with acyclic imines (1, 2). Compounds **6***b* (5), **7***b* (5, 6), and **7***c* (epiophiocarpine) (6–10) are described in the literature; the physical properties recorded for these compounds correspond to those of the substances prepared here. In particular, the ^{1}H and ^{13}C nmr spectra of **7***c* and the ^{1}H nmr spectrum of **7***b* are in accord with our observations. The coupling constants between the hydrogens at C-13 and C-14 in the bases **7** are in keeping with a *trans* relationship between them; for **7***a*, $J_{13,14}$ = 8.4 Hz, for **7***b*, $J_{13,14}$ = 8.1 Hz,

and for **7c**, $J_{13,14} = 8.4$ Hz. The same configuration may be assigned to **6a**, **6b**, and **6c** since one would not expect hydride reduction to alter the relative configuration of the two relevant hydrogens. The hydrogens at C-13 and C-14 in the lactams **6** had very similar chemical shifts and it was not possible to draw conclusions about their stereochemistry from their ^1H nmr spectra. However, in the 13-acetyl derivative of **6c** the signals for H-13 and H-14 are well separated, appearing, respectively, at δ 5.81 and δ 4.68 with $J = 10.1$ Hz, in accord with a *trans* configuration of the two hydrogen atoms.

Only two 13-hydroxyprotoberberines have been found in nature, namely ophiocarpine (**11**) and 13-hydroxystylopine (**12**), which has the same configuration as ophiocarpine. The compounds prepared here are diastereomeric with the naturally occurring compounds. The conversion of 13-hydroxyprotoberberines to tetrahydroprotoberberines has been reported previously (6, 11, 13) so that this synthesis provides another and convenient route to this class of alkaloids. Other synthetic approaches to this group of alkaloids may be found in several reviews (11, 14–16).

This method of synthesis has now been applied to the preparation of 13-methyltetrahydroprotoberberines. For this purpose 3-methylphthalide **8a** and 6,7-methylenedioxy-3-methylphthalide **8b** were investigated as starting materials in place of the phthalides examined previously. The former was prepared according to the method of Bray *et al.* (17) and the latter by an adaptation of the method developed by Hung *et al.* (18) for the conversion of benzyl alcohols to phthalides as illustrated in Scheme 3. Both 3-methylphthalides, **8a** and **8b**, formed anions with LDA and reacted readily with 6,7-dimethoxy-3,4-dihydroisoquinoline **5a** to form the expected adducts **9a** and **9b**. Again the reaction was stereoselective and led to the formation of only one of the two possible diastereomers as shown in Scheme 4. The assignment of stereochemistry to **10**, the hydride reduction product of **9b**,

SCHEME 4

and by implication to **9a** and **9b**, is based on ^1H nmr studies and on analogy to the nmr spectra of 13-hydroxy- and 13-methyltetrahydroprotoberberines. The signal at H-1 in ophiocarpine appears at δ 6.77 and in epiophiocarpine **7c** at δ 7.39. The signal of H-1 in **10** appears at δ 7.47, indicating that this proton is deshielded just as in the case of epiophiocarpine and that the OH group is pseudoequatorial. A comparison of the C-methyl signal of **10** with those of 13-methyltetrahydroprotoberberines (19) is also revealing. Thus the methyl group of cavidine, in which the C-methyl is pseudoaxial in ring C, resonates at δ 0.98 while in the epimeric compound, thalictrifoline (Scheme 5), the C-methyl group resonates at δ 1.48. In **10** the C-methyl group resonates at δ 1.23, suggesting that it is pseudoaxial. It would be expected to be deshielded relative to cavidine because of the geminal OH group. Further support for this stereochemistry comes from comparison of the C-methyl signals of **9b** and **10**. In the lactam **9b** the C-methyl group resonates at δ 1.10, above that of **10**, presumably because it lies in the shielding cone of the carbonyl group.

Dehydration of **9b** with *p*-toluenesulfonic acid yielded **11**, a compound previously prepared by Ninomiya *et al.* (20). The physical properties of **11** corresponded closely with those reported by the earlier workers and there can be no doubt about their identity even though a direct comparison was not made. Ninomiya *et al.* have reported the reduction of **11** to

SCHEME 6

(±)-cavidine (20) and have quoted another source (21), not available to us, that (±)-cavidine may be converted to (±)-thalictrifoline (epimeric with cavidine at C-13). The reactions are outlined in Scheme 5. The reaction of 3-methylphthalide anions with 3,4-dihydroisoquinolines therefore provides a new route to the diastereomeric 13-methyltetrahydroprotoberberines.

We next investigated the reaction of 3,4-dimethoxybenzylidenemethylamine **12** with lithium phthalide **1***a* ($R^1 = R^2 = R^3 = H$) and lithium 5,6-dimethoxyphthalide **1***b* ($R^1 = R^2 = OCH_3$; $R^3 = H$) to determine whether imines derived from methylamine would be suitable substrates in this reaction (Scheme 6). We found in the reaction of **1***b* with **12** that the *cis* **13** and *trans* **14** isomer were formed but that the overall yield of 40% was less than with the cyclic imine. The *cis* isomer was isolated as an amorphous solid but yielded a crystalline acetate **15**. Both **13** and **14** gave typical ^1H nmr spectra as described by Dodsworth *et al.* (2) and it was on this basis that the stereochemical assignments were made. Somewhat improved yields were obtained when anhydrous $ZnCl_2$ was added to the solution of lithium anion before addition of the imine; the combined yield of *cis* and *trans* isomers was 50%. Apparently exchange of Li for Zn reduced the basicity of the anion so that addition competed more effectively with proton abstraction. In a second experiment using Li phthalide **1***a* and $ZnCl_2$ both isomers were again formed in a combined yield of 57% and in a ratio of *cis*/*trans* ≈ 2:1, as in the first experiment with $ZnCl_2$. The *cis* isomer is designated **16**, the *trans* isomer, **17**.

Finally we examined the feasibility of preparing 3,4-diphenylisoquinolones by using 3-phenylphthalide **1***d* ($R^4 = R^5 = H$; $R^6 = C_6H_5$) as starting material. The reaction with 3,4-dimethoxybenzylidenemethylamine proceeded normally, yielding a mixture of the *R**,*R** **18** (57%) and *R**,*S** **19** (9%) isomers that correspond, respectively, to the *cis* and *trans* isomers examined earlier with phenyl replacing H at C-4. The stereochemical assignments are not secure in the case of **18** and **19**, being based on the chemical shift of only one signal in the nmr, namely, the hydrogen at C-3. In all the isoquinolones examined in this study, the signal for H-3 in the *cis* isomer resonated at lower field than the corresponding proton in the *trans* isomer. For **18** and **19**[3] the values are 4.64 in **18** (*cis* *R**,*R**) and 4.53 in **19** (*trans*, *R**,*S**). The isomer formed in higher yield and the less polar isomer (based on tlc) in all cases has been the *cis* isomer and the assignment of stereochemistry to **18** and **19** conforms with this pattern.

Further support for the stereochemical assignment comes from an examination of the ^{13}C nmr spectra of **13**, **14**, **16**, **17**, **18**, and **19** recorded in Table 1. The signals for C-3 and C-4 in the *cis* isomers **13** and **16**, whose stereochemistry is evident from their ^1H nmr spectra, are shielded by 2–3 ppm relative to

[3] *cis*-Isomer refers to the situation where the hydrogen at C-3 is *cis* to the phenyl at C-4, and *trans* isomer to the situation where H-3 and the phenyl at C-4 are *trans*.

† Several overlapping signals.

(a) Acyclic, *E*-imine (b) Acyclic or cyclic, *Z*-imine

FIG. 1. Proposed orientation of the reactants leading to the *cis* isomer (a), and *trans* isomer (b).

their respective *trans* isomers **14** and **17**. The same is true for the pair **18** and **19**; the C-3 and C-4 signals are shielded by ca. 1.5 ppm in **18** relative to **19**. A small but consistent shielding of the N—CH_3 signal in the three *cis* isomers is observed, whereas the opposite effect is found for the carbonyl carbon. All the data are consistent with **18** having the *R*,R** and **19** the *R*,S** relative configuration.

It is apparent that the reaction with acyclic imines is not nearly as stereoselective as the reaction with the cyclic imines. Moreover, the *cis* isomer is favored in the acyclic series by a factor of 2:1 whereas the *trans* isomer would appear to be the sole reaction product in the case of the cyclic imines studied. The explanation advanced by Dodsworth *et al.* (2) to account for the preferred formation of *cis* isomers in the acyclic series will not serve for the cyclic systems; an alternative explanation is offered below.

Acyclic imines exist almost exclusively in the *E* configuration (22, 23) while the cyclic imines studied here can exist only in a *Z* configuration. Isomerism is possible in the acyclic system in the presence of a nucleophile and some *Z* isomer may be present in the reaction system and react as such. The explanation of Dodsworth *et al.* that the favored transition state is one in which the phenyl group of the imine places itself remote from the phthalide phenyl is a satisfactory explanation for the stereochemical preference found for the *cis* isomer for reaction with acyclic imines. However, it fails for the cyclic imines studied because they give solely *trans* products.

A model that reconciles the behaviour of acyclic and cyclic systems is illustrated in Fig. 1. The essential feature of the model is that the lone pair of the nitrogen atom and the two oxygen atoms of the phthalide ring become coordinated with lithium. The fourth ligand may be the C-atom at C-3 of another lithium phthalide or a solvent molecule. Such a model would require that acyclic imines react in the *E* configuration and orient themselves with respect to the phthalide as in Fig. 1(a) to form the *cis* isomers, and react in the *Z* configuration as in Fig. 1(b) to form the *trans* isomers. Cyclic imines are constrained by their structures to the *Z* configuration. Experiments to test this proposal will be undertaken.

Experimental

Apparatus, materials, and methods

Unless otherwise stated, the ^1H nmr spectra were continuous wave, run at 90 MHz on a Varian EM 390 spectrometer. The samples were dissolved in $CDCl_3$ using tetramethylsilane (TMS) as the internal standard. Chemical shifts, quoted as δ values, were measured in relation to TMS. The symbols s, singlet, d, doublet, t, triplet, q, quartet, and m, multiplet are used in reporting spectra. The Fourier transform spectra were run on either a Bruker WP80 (80 MHz) or WM250 (250 MHz) spectrometer. The ^{13}C nmr spectra were run at 62.9 MHz on a Brucker WM250 FT spectrometer at 22.7°C, or at 20.115 MHz on a Bruker WP80.

Mass spectra were recorded on a V.G. Micromass 7070 F mass spectrometer at 70 eV. Infrared spectra were recorded on a Perkin–Elmer 283 spectrometer in $CHCl_3$ solution. Melting points were determined using a Gallenkamp apparatus and are uncorrected. The microanalyses were performed by the Guelph Chemical Laboratories Ltd., Guelph, Ontario.

Thin layer chromatography (tlc) was performed using Polygram Sil G/UV_{254} plates. Flash column chromatography (24) was employed using Kieselgel 60 (230–400 mesh).

All reactions involving lithiation steps were carried out in flame-dried apparatus under a blanket of argon, using septa and syringes for transfer of reagents. Diisopropylamine was refluxed over calcium hydride and distilled onto molecular sieves (4 Å). THF was dried by distillation from Na/benzophenone under a nitrogen atmosphere just prior to use. Anhydrous $ZnCl_2$ was obtained by heating a sample above its melting point for 5 min, cooling under vacuum, and storage under vacuum. Other solid reagents were stored over P_2O_5 under vacuum.

The following compounds were prepared by standard methods and gave satisfactory physical data: meconin (18), *m*-meconin (25), 3-phenylphthalide (26), and 6,7-dimethoxy-3,4-dihydroisoquinoline (27).

Preparation of 6,7-methylenedioxy-3,4-dihydroisoquinoline

(a) *3,4-Methylenedioxy-β-nitrostyrene*

To a solution of piperonal (15 g, 0.1 mol) in glacial acetic acid (150 mL) were added nitromethane (10.2 g, 0.17 mol) and ammonium acetate (20 g), and the mixture heated on a steam bath for 6 h. The resulting dark red solution was poured onto crushed ice (350 g) and allowed to stand for 2 h. The yellow precipitate was filtered, washed with water, and crystallized from ethanol as yellow needles (15.3 g, 79.3%), mp 159–160°C (lit. (28, 29) mp 161°C); ^1H nmr δ: 6.10 (2H, s, —OCH_2O—), 6.91 (1H, d, J = 8.0 Hz, ArC-5H), 7.04 (1H, d, J = 2.0 Hz, ArC-2H), 7.13 (1H, dd, J = 8.0 Hz and 2.0 Hz, ArC-6H), 7.51 (1H, d, J = 13.5 Hz, vinyl-H), 7.99 (1H, d, J = 13.5 Hz, vinyl-H).

(b) *Homopiperonylamine*

A solution of 3,4-methylenedioxy-β-nitrostyrene (9.6 g, 50 mmol) in dry THF (200 mL) was added dropwise to a stirred slurry of $LiAlH_4$ (6 g, 150 mmol) in refluxing THF (300 mL) over a period of 3 h, and refluxing continued for another 5 h. The mixture was cooled in an ice bath and excess $LiAlH_4$ decomposed by careful addition of water (6 mL), 15% NaOH (6 mL), and water (18 mL), in that order. Ether (500 mL) was added and the inorganic material removed by filtration. Evaporation of the filtrate to dryness gave a brown oil which was distilled under vacuum to give a colourless oil (5.9 g, 72%), bp 75–80°C/0.05 Torr (1 Torr = 133.32 Pa), hydrochloride mp

206–207°C (lit. (30) mp 208–210°C); ^{1}H nmr δ: 1.15 (2H, broad s, exchanges with D_2O, —NH_2), 2.55–3.05 (4H, m, —CH_2CH_2—), 5.90 (2H, s, —OCH_2O—), 6.5–6.8 (3H, m, Ar-H).

(c) *Homopiperonyl formamide*

Homopiperonylamine (5.8 g, 35 mmol) and formic acid (2.4 g of a 90% aqueous solution, 47 mmol) were heated under reflux for 20 h. Bulb-to-bulb distillation at 0.13 Torr gave a fraction at 150–170°C (air bath temperature) which solidified on cooling (5.9 g, 87%). Crystallization from ether–acetone gave white crystals, mp 59–61°C (lit. (31) mp 60–62°C); ^{1}H nmr δ: 2.6–2.9 (2H, m, benzylic), 3.3–3.7 (2H, m, CH_2N—), 5.91 (2H, s, —OCH_2O—), 6.5–6.9 (3H, m, Ar-H), 8.19 (1H, broad s, CHO).

(d) *6,7-Methylenedioxy-3,4-dihydroisoquinoline (norhydrastinine)*

This compound was prepared from homopiperonyl formamide according to the method of Slemon *et al.* (31) in 42% yield.

3-Methylphthalide ***8****a*

Prepared according to the procedure of Bray *et al.* (17) in 70% yield, this compound exhibited a red coloration which persisted after two distillations. Its ^{1}H nmr spectrum, however, contained no extraneous peaks, and the material was used in subsequent steps without further purification; ir ($CHCl_3$) ν_{max}: 1760 cm^{-1} (γ-lactone); ^{1}H nmr δ: 1.65 (3H, d, J = 7.0 Hz, —CH_3), 5.58 (1H, q, J = 7.0 Hz, benzylic), 7.4–8.1 (4H, m, aromatic).

α-Methyl-3,4-methylenedioxybenzyl alcohol

A solution of piperonal (10.5 g, 70 mmol) in dry ether (100 mL) was added dropwise over 1 h to a solution of CH_3MgI (77 mmol, made from 1.9 g Mg and 10.95 g CH_3I) in dry ether (100 mL) at room temperature. After stirring a further 2 h the mixture was quenched in an ice-cold solution of NH_4Cl. Standard extraction procedure using ether gave a pale yellow oil (10.3 g, 88.6%) which was used without further purification; ^{1}H nmr δ: 1.42 (3H, d, J = 7.0 Hz, —CH_3), 2.20 (1H, broad s, exchanges with D_2O, —OH), 4.78 (1H, q, J = 7.0 Hz, benzylic), 5.90 (2H, s, —OCH_2O—), 6.78 (2H, broad s, aromatic), 6.89 (1H, broad s, aromatic).

3-Methyl-6,7-methylenedioxyphthalide ***8****b*

The method described here utilizes the demonstrated synthesis of phthalides from benzyl alcohols by Hung *et al.* (18). α-Methyl-3,4-methylenedioxybenzyl alcohol (2.49 g, 15 mmol) was dissolved in dry THF (75 mL) under argon at room temperature and treated dropwise with n-BuLi (20 mL of a 1.65 *M* solution in hexane, 33 mmol, 2.2 equiv.) over 15 min, cooling if necessary to maintain ambient temperature. The turbid, dark orange solution was stirred another 45 min and treated with gaseous CO_2 for 1 h, and subsequently with HCl (85 mL of a 10% solution). After stirring for 0.5 h, the upper organic layer was separated and kept. The lower aqueous layer was extracted with CH_2Cl_2, the extract combined with the aforementioned organic layer, dried (Na_2SO_4), and evaporated, yielding a yellow solid. Flash chromatography (silica, eluting with CH_2Cl_2–hexane, 80:20) gave a solid which crystallized from methanol as white needles (1.11 g, 38.5%), mp 143–145°C; ir ($CHCl_3$) ν_{max}: 1765 cm^{-1} (γ-lactone); ^{1}H nmr δ: 1.59 (3H, d, J = 6.0 Hz, —CH_3), 5.48 (1H, q, J = 6.0 Hz, benzylic), 6.16 (2H, s, —OCH_2O—), 6.83 and 7.08 (2H, ABq, J = 8.0 Hz, aromatic). *Mol. Wt.* calcd. for $C_{10}H_8O_4$: 192.042; found (hrms): 192.042.

3,4-Dimethoxybenzylidenemethylamine ***12***

Methylamine (12.1 g of a 15.4% w/w solution in benzene (32), equivalent to 1.86 g CH_3NH_2, 60 mmol) was added to a solution of 3,4-dimethoxybenzaldehyde (6.64 g, 40 mmol) in benzene and the whole heated under reflux in a Dean–Stark apparatus (a balloon was attached to the condensor to minimize loss of CH_3NH_2) for 3 h. A further portion of methylamine solution (4 g, 20 mmol) was added to the cooled mixture and refluxing continued for 2 h. This was repeated, after which a test sample examined by ^{1}H nmr showed quantitative conversion to the imine. The solution was evaporated to dryness to give a cream colored solid in quantitative yield; ^{1}H nmr δ: 3.50 (3H, d, J = 2.0 Hz, —NCH_3), 3.90 (3H, s, —OCH_3), 3.93 (3H, s, —OCH_3), 6.88 (1H, d, J = 8.0 Hz, Ar-5H), 7.15 (1H, dd, J = 8.0 Hz and 2.0 Hz, Ar-6H), 7.42 (1H, d, J = 2.0 Hz, Ar-2H), 8.21 (1H, m, CH=N).

General procedure for reaction of phthalides ***1****a*, ***1****b, and* ***1****c with dihydroisoquinolines* ***5***

A solution of the appropriate phthalide in dry THF (ca. 2 mL per mmol) was added dropwise to a solution of lithium diisopropylamide (LDA, 1.1 equiv.) at −70°C (LDA was prepared by addition of a solution of 1.65 *M* nBuLi in n-hexane to an equivalent amount of diisopropylamine in dry THF at −10°C (ca. 5 mL per mmol)). The yellow or orange anion thus prepared was stirred for 15 min, the temperature raised to −40°C, and the solution treated with a solution of the dihydroisoquinoline in dry THF (2 mL per mmol). After stirring for 1 h at −40°C, the mixture was allowed to warm to room temperature and stirred overnight. The THF was then evaporated, water added, and the contents extracted with chloroform, dried (Na_2SO_4), and evaporated to dryness to give the crude products.

trans-*13-Hydroxy-2,3-dimethoxy-8-oxotetrahydroprotoberberine* ***6****a*

Generation of the anion from phthalide (***1****a*, 0.2 g, 1.5 mmol) gave a suspension at −70°C, which dissolved to give a clear orange solution at −40°C. Addition of 6,7-dimethoxy-3,4-dihydroisoquinoline (0.287 g, 1.5 mmol) and work-up gave a yellow foam. Flash chromatography (silica, eluting with $CHCl_3$ + 1.5% MeOH) gave ***6****a* as a creamy crystalline powder (295 mg, 60.5%), mp 180–181°C (EtOH – pet. ether 30–60°C); ir ($CHCl_3$) ν_{max}: 1645 cm^{-1}; ^{1}H nmr (250 MHz) δ: 2.7–3.0 (3H, m, C-5 H's and C-6 H, ax.), 3.86 (3H, s, —OCH_3), 3.88 (3H, s, —OCH_3), 4.6–4.7 (2H, distorted s, C-13 and C-14 H's), 4.9–5.0 (1H, m, C-6 H, eq.), 6.72 (1H, s, C-4 H), 6.98 (1H, s, C-1 H), 7.43 (1H, t, J = 7.7 Hz, C-10 or C-11 H), 7.57 (1H, t, J = 7.7 Hz, C-11 or C-10 H), 7.68 (1H, d, J = 7.7 Hz, C-12 H), 8.06 (1H, d, J = 7.7 Hz, C-9 H); C-9, C-10, C-11, and C-12 H signals also show *meta* coupling (ca. 1Hz); ^{13}C nmr δ: 30.6 (C-5), 39.8 (C-6), 56.5, 56.6 (OMe), 62.0 (C-14), 72.1 (C-13), 112.4, 112.7, 124.2, 128.4, 128.7, 132.7 (ArCH); 124.9, 128.0, 129.4, 141.5, 147.9, 148.9 (ArC), 164.6 (C=O). ms, m/z (%): 325 (8) M$^+$, 192 (100), 134 (10). *Anal.* calcd. for $C_{19}H_{19}NO_4$: C 70.15, H 5.85, N 4.31%; found: C 70.26, H 5.68, N 4.47%.

trans-*13-Hydroxy-2,3-dimethoxytetrahydroprotoberberine* ***7****a*

A solution of lactam ***6****a* (65 mg, 0.2 mmol) in dry THF (20 mL) was added to a slurry of $LiAlH_4$ (150 mg, 4 mmol) in dry THF (30 mL) under argon, and the whole heated under reflux for 8 h. Water (1 mL) was carefully added to the cooled mixture, which was then filtered and the filtrand washed with $CHCl_3$. The filtrate was dried (Na_2SO_4) and evaporated to dryness to give ***7****a* as a pale yellow solid (46 mg, 74%), mp 162–164°C (from CH_2Cl_2 – pet. ether 30–60°C); ir ($CHCl_3$) ν_{max}: 2850–2750 cm^{-1} (Bohlmann bands); ^{1}H nmr (250 MHz) δ: 2.65–2.8 (2H, m, C-5 H's), 3.0–3.22 (2H, m, C-6 H's), 3.55 (1H, d, J = 8.4 Hz, C-14 H), 3.90 (2H, s, C-8 H's), 3.91 (6H, s, 2 × —OCH_3), 4.78 (1H, d, J = 8.4 Hz, C-13 H), 6.65 (1H, s, C-4 H), 7.11 (1H, d, J = 7.0 Hz, C-9 H), 7.2–7.35 (2H, m, C-10 and C-11 H's), 7.57 (2H, broad s, C-1 and C-12 H's), ms, m/z (%): 311 (4) M$^+$, 192 (100), 120 (22). *Mol. Wt.* calcd. for $C_{19}H_{21}NO_3$: 311.150; found (hrms): 311.152.

trans-*13-Hydroxy-2,3,10,11-tetramethoxy-8-oxotetrahydroprotoberberine* ***6****b*

Addition of 6,7-dimethoxy-3,4-dihydroisoquinoline (0.57 g, 3 mmol) to the yellow-orange anion of *m*-meconin (0.582 g, 3 mmol) and work-up gave a yellow oil. Flash chromatography (silica, applying the oil to the column in EtOAc–CH_2Cl_2, 1:1, then eluting with EtOAc) yielded ***6****b* as a white powder (0.79 g, 68.4%), mp 208–210°C (EtOH – pet. ether 30–60°C) (lit. (5) mp 210–212°C); ir ($CHCl_3$) ν_{max}: 1640 cm^{-1}; ^{1}H nmr (250 MHz) δ: 2.7–3.0 (3H, m, C-5 H's and C-6 H, ax.), 3.87 (3H, s, —OCH_3), 3.88 (3H, s, —OCH_3), 3.94 (3H, s, —OCH_3), 3.97 (3H, s, —OCH_3), 4.5–4.7 (2H, m, C-13 and C-14 H's), 4.85–4.95 (1H, m, C-6 H, eq.), 6.73 (1H, s, C-4 H), 6.98 (1H, s, C-1 H), 7.17 (1H, s, C-12 H), 7.58 (1H, s, C-9 H); ms, m/z (%): 385 (3) M$^+$, 194 (8), 192 (100); ^{13}C nmr δ: 30.2 (C-5), 39.4

*(13*S**,14*R**)-13-Hydroxy-13-methyl-2,3-dimethoxy-8-oxotetrahydroprotoberberine* **9**a

Addition of 6,7-dimethoxy-3,4-dihydroisoquinoline (0.382 g, 2 mmol) to the orange anion of 3-methylphthalide (0.296 g, 2 mmol) and work-up gave a white solid. Crystallization from $CHCl_3$ gave **9***a* as a white powder (0.4 g, 59%). An additional sample (90 mg, 13%) was obtained by recrystallizing the evaporated mother liquor from EtOH, and a final sample (100 mg, 15%) was obtained by flash chromatography of the second mother liquor (silica, applying the sample onto the column in warm $CHCl_3$, and eluting with $CHCl_3$ + 2.5% MeOH) to give a total yield of 0.59 g, 87%, mp 226–228°C; ir ($CHCl_3$) ν_{max}: 1640 cm^{-1}; ^1H nmr (250 MHz) δ: 1.13 (3H, s, —CH_3), 2.7–3.0 (3H, m, C-5 H's and C-6 H, ax.), 3.86 (3H, s, —OCH_3), 3.90 (3H, s, —OCH_3), 4.92 (1H, s, C-14 H), 4.95–5.05 (1H, m, C-6 H, eq.), 6.73 (1H, s, C-4 H), 7.03 (1H, s, C-1 H), 7.41 (1H, t, J = 7.7 Hz, C-10 or C-11 H), 7.56 (1H, t, J = 7.7 Hz, C-11 or C-10 H), 7.69 (1H, d, J = 7.7 Hz, C-12 H), 8.08 (1H, d, J = 7.7 Hz, C-9 H); C-10, C-11, C-12, and C-13 signals also show *meta* coupling (ca. 1 Hz); ^{13}C nmr δ: 23.9 (C—CH_3), 29.8 (C-5), 39.3 (C-6), 56.2, 56.4 (OCH_3), 64.2 (C-14), 74.4 (C-13), 112.1, 112.4, 123.2, 128.1, 128.7, 132.7 (ArCH), 123.2, 127.1, 130.6, 146.1, 147.7, 148.8 (ArC), 164.3 (C-8); ms, m/z (%): 339 (3) M^+, 192 (100), 148 (10). *Anal.* calcd. for $C_{20}H_{21}NO_4$: C 70.80, H 6.19, N 4.13%: found: C 70.41, H 6.43, N 4.09%.

*(13*S**,14*R**)-13-Hydroxy-13-methyl-2,3-dimethoxy-9,10-methylenedioxy-8-oxotetrahydroprotoberberine* **9**b

Addition of 6,7-dimethoxy-3,4-dihydroisoquinoline (0.573 g, 3 mmol) to the orange anion of 3-methyl-6,7-methylenedioxyphthalide (0.576 g, 3 mmol) and work-up gave a yellow foam. Flash chromatography (silica, eluting with $CHCl_3$ + 2.5% MeOH) yielded **9***b* as a white powder (920 mg, 80%), mp 281–284°C (dec.) (EtOH): ir ($CHCl_3$) ν_{max}: 1645 cm^{-1}; ^1H nmr (250 MHz) δ: 1.10 (3H, s, —CH_3), 2.65–2.9 (3H, m, C-5 H's and C-6 H, ax.), 3.86 (3H, s, —OCH_3), 3.90 (3H, s, —OCH_3), 4.83 (1H, s, C-14 H), 4.95–5.05 (1H, m, C-6 H, eq.), 6.07 and 6.18 (2H, 2 × d, J = 1.2 Hz, nonequivalent —OCH_2O—), 6.72 (1H, s, C-4 H), 6.94 (1H, d, J = 8.1 Hz, C-11 H), 6.99 (1H, s, C-1 H), 7.15 (1H, d, J = 8.1 Hz, C-12 H); ^{13}C nmr δ: 24.0 (C—CH_3), 29.6 (C-5), 38.6 (C-6), 56.2, 56.3 (2 × OCH_3), 64.2 (C-14), 74.4 (C-13), 102.6 (OCH_2O), 111.4, 111.9, 112.3, 116.1 (ArCH), 123.0, 130.5, 139.4, 147.5, 148.0, 148.6 (ArC), 162.0 (C-8); ms, m/z (%): 383 (4) M^+, 192 (100). *Anal.* calcd. for $C_{21}H_{21}NO_6$: C 65.80, H 5.48, N 3.66%; found: C 65.66, H 5.64, N 3.72%.

*(13*S**,14*R**)-13-Hydroxy-13-methyl-2,3-dimethoxy-9,10-methylenedioxytetrahydroprotoberberine* ***10***

Reduction of lactam **9***b* (100 mg, 0.27 mmol) with $LiAlH_4$ (205 mg, 5.4 mmol) gave **10** as white blocks with a faint pink tinge (76 mg, 78.9%), mp 162–164°C with darkening (EtOH); ir ($CHCl_3$) ν_{max}: 2840–2750 cm^{-1} (Bohlmann bands); ^1H nmr (250 MHz) δ: 1.23 (3H, s, —CH_3), 2.5–2.7 (2H, m, C-5 H's), 3.0–3.15 (2H, m, C-6 H's), 3.65 (1H, d, J = 15.2 Hz, C-8 H), 3.69 (1H, s, C-14 H), 3.85 (3H, s, —OCH_3), 3.87 (3H, s, —OCH_3), 4.0 (1H, d, J = 15.2 Hz, C-8 H), 5.94 and 5.97 (2H, 2 × d, J = 1.3 Hz, nonequivalent —OCH_2O—), 6.60 (1H, s, C-4 H), 6.77 (1H, d, J = 8.2 Hz, C-11 H), 7.11 (1H, d, J = 8.2 Hz, C-12 H), 7.47 (1H, s, C-1 H); ms, m/z (%): 369 (1) M^+, 351 (2), 192 (100), 178 (6), 163 (25). *Anal.* calcd. for $C_{21}H_{23}NO_5$: C 68.29, H 6.23, N 3.79%; found: C 68.55, H 6.21, N 3.69%.

13,14-Didehydro-2,3-dimethoxy-13-methyl-9,10-methylenedioxyberbine-8-one ***11***

Lactam **9***b* (65 mg) in benzene was heated under reflux in a Dean–Stark apparatus for 3 h with *p*-toluenesulfonic acid (20 mg). Evaporation of the benzene gave a yellow solid which was crystallized twice from EtOH, yielding a white powder (48 mg, 77.5%) which adopted a greenish tinge on standing, mp 250–252°C (lit. (20) mp 243–245°C); ir ($CHCl_3$) ν_{max}: 1640 cm^{-1}; ^1H nmr δ: 2.54 (3H, s, —CH_3), 2.83 (2H, t, J = 6.0 Hz, C-5 H's), 3.92 (3H, s, —OCH_3), 3.95 (3H, s, —OCH_3), 4.19 (2H, t, J = 6.0 Hz, C-6 H's), 6.21 (2H, s, —OCH_2O—), 6.79 (1H, s, C-4 H), 7.10 (1H, s, C-1 H), 7.22 (2H, s, (collapsed AB quartet), C-11 and C-12 H's).

cis- *And* trans-*6,7-dimethoxy-3-(3,4-dimethoxyphenyl)-4-hydroxy-2-methyl-3,4-dihydro-1(2*H*)-isoquinolones* ***13*** *and* ***14***

(a) *without* $ZnCl_2$

Addition of a solution of 3,4-dimethoxybenzylidenemethylamine **12** (0.269 g, 1.5 mmol) in dry THF to the anion of *m*-meconin (0.291 g, 1.5 mmol) and work-up, in the manner described earlier, gave a yellow foam. Flash chromatography (silica, eluting with $CHCl_3$ + 1% MeOH) gave the following two components: (*i*) *cis* isomer **13** (169 mg, 30.2%), amorphous solid, R_f 0.25 (silica, EtOAc); ir ($CHCl_3$) ν_{max}: 1640 cm^{-1}; ^1H nmr δ: 3.07 (3H, s, —NCH_3), 3.67 (3H, s, —OCH_3), 3.80 (3H, s, —OCH_3), 3.87 (3H, s, —OCH_3), 3.93 (3H, s, —OCH_3), 4.65 (1H, d, J = 6.0 Hz, C-3 H), 5.3–5.6 (1H, m (on addition of D_2O sharpens to a doublet, J = 6.0 Hz), C-4 H), 6.5–6.85 (3H, m, protons of the 3-phenyl substituent), 7.0 (1H, s, C-5 H), 7.70

Synthetic approaches to β-lactam antibiotics: a stereocontrolled synthesis of *trans* 3-(*S*)-amino-4-(*S*)-ethyl-2-oxo-1-azetidine[1]

STEPHEN HANESSIAN AND SOUMYA P. SAHOO
Department of Chemistry, Université de Montréal, Montréal, P.Q., Canada H3C 3V1

Received January 30, 1984

STEPHEN HANESSIAN and SOUMYA P. SAHOO. Can. J. Chem. **62**, 1400 (1984).

A synthesis of the title compound, an immediate precursor of the biologically active 4-ethyl monobactam, from 2-amino-2-deoxy-D-glucose is described. The strategy allows for the synthesis of a variety of β-substituted α-amino acids, which are otherwise difficultly accessible.

STEPHEN HANESSIAN et SOUMYA P. SAHOO. Can. J. Chem. **62**, 1400 (1984).

La synthèse d'un précurseur de l'antibiotique 4-ethyl monobactame, à partir du 2-amino-2-deoxy-D-glucose est décrite. La stratégie suivie permet la synthèse d'un nombre d'acide α-aminés contenant un substituant sur la position β, et qui sont difficilement accessibles par d'autres voies.

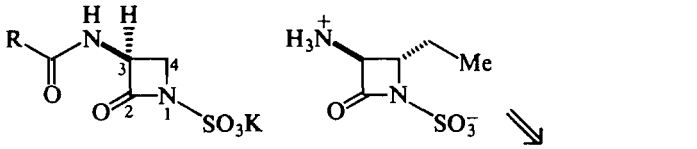
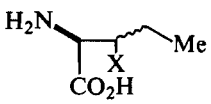
Since the discovery of the monobactams, a family of monocyclic β-lactam antibiotics produced by various gram-negative bacteria (1), extensive studies have been devoted to the synthesis of the parent structure **1** (2) as well as its analogs (3). These intense efforts have been rewarded by the emergence of aztreonam, a *trans* 3-(*S*)-amino-4-(*S*)-methyl-2-oxo-1-azetidinesulfonic acid substituted with a heterocyclic moiety at N-3, as a clinical candidate. Related structures with a *cis*-substitution pattern are also known (4). A noteworthy feature



1 **2**



3, X = OH
4, X = NH_2

of the 4-substituted monobactams is their higher intrinsic antibacterial activity and resistance to β-lactamases as manifested, for example, by the N-acyl derivative of a racemic structure corresponding to expression **2** (3). Since the structures of the naturally-occurring monobactams do not lend themselves to chemical modification at the C-4 position, recourse has been made to totally synthetic and semi-synthetic routes in order to probe into aspects of structure–activity relationships (3, 5). As with any synthetic program with a biological objective, the quest for enantiomerically pure targets becomes a matter of concern.

Compared to the structurally more impressive bicyclic β-lactam antibiotics, the synthesis of the monobactams as exemplified by the optically pure title compound may appear to present a trivial exercise (for some recent syntheses of 4-substituted azetidinones, see for example ref. 6). Indeed, a simple retrosynthetic analysis of the target reveals logical progeny from a 2-amino-3 hydroxy pentanoic acid (L-ethylserine) **3**, or a 2,3-diaminopentanoic acid **4** as potential chirons (7). These, however, are not readily available amino acids in optically pure form, hence the reason why the title compound was prepared and tested as a racemic mixture (3, 5). The prospects of azetidinone formation in the β-hydroxy-α-amino acid series must be dealt with with some caution because of the propensity for elimination, racemization, and intramolecular reactions (see for example, ref. 8). We have recently found an expedient solution to this problem in the facile 3-step transformation of N-[(benzyloxy)carbonyl]-L-serine *p*-methoxyphenylamide into 3-(*S*)-1-amino-2-oxo-1-azetidine, the parent monobactam structure corresponding to **1** (9).

In this paper, we describe a general synthetic protocol for the stereocontrolled access to optically active 2-amino-3-hydroxy acids with a specific application to the total synthesis of the title monobactam precursor **2**. The strategy utilizes 2-amino-2-deoxy-D-glucose as a chiral template in which, quite fortuitously, the sense of chirality of the amine-bearing carbon atom is convergent with C-3 in the target. Stereocontrolled attack by an ethyl Grignard on the aldehyde function of **6** which is readily available from **5** (10) was expected to occur in an anticipated sense to give a high preponderance of the desired material (Scheme 1). Adjustment of functionality and manipulation of expendable appendages would thus lead to the intended target. These chemical events were experimentally realized.

Acetonation of **5** gave the crystalline diacetonide derivative (98%), mp 54–56°C; $[\alpha]_D$ − 28.2° ($CHCl_3$). Conversion to the aldehyde **6** followed by treatment with methylmagnesium chloride led to a nearly quantitative yield of a 4:1 mixture of isomers **7** and **8** which were readily separated by preparative hplc.[2,3] Hydrolysis of the acetal functions in the major isomer **7** (syrup, $[\alpha]_D$ 0 ± 1° ($CHCl_3$), MH^+ 410), followed by oxidative cleavage (11) gave N-Cbz L-threonine **11**, characterized as the crystalline *p*-methoxybenzamide derivative **12**, mp 165–167°C; $[\alpha]_D$ −63.2° ($CHCl_3$), identical with an authentic sample. Thus, nucleophilic attack on the aldehyde took place

in the anticipated manner, and it was expected that bulkier Grignard reagents would increase the stereoselectivity even more. Thus, treatment of **6** with ethylmagnesium bromide gave a 9:1 mixture of isomers **9** and **10**, in almost quantitative yield, which were easily separated by flash column chromatography. The major component **9**, $[\alpha]_D$ +9.2° ($CHCl_3$), MH^+ 424, was mesylated to **13** (syrup, ~quant.) and the potential amino group was introduced by an inversion process to give the azide **14** as a syrup (80%); $[\alpha]_D$ +2° ($CHCl_3$). Oxidative cleavage then gave the β-azido acid **15** (syrup, 60%)[4] which was reduced and subjected to a variety of ring closure procedures.[5] We

[4] The corresponding methyl ester showed $[\alpha]_D$ +22.2° ($CHCl_3$); MH^+ 307.

[5] A variety of methods, including various carbodiimide-related cyclizations, led to decomposition or unidentified products. Methods for azetidinone formation of 3,4-disubstituted systems, from the corresponding β-amino acids, are not widely known, see ref. 9.

found a minor modification of the Ohno method (12) to be the most effective, particularly at higher dilutions than originally reported. With this proviso, it was possible to obtain the target β-lactam **16** in 50% yield (2 steps), $[\alpha]_D$ −34.3° (MeOH); ir ($CHCl_3$): 1770 cm^{-1} (β-lactam); 1750 cm^{-1} (Cbz); ^1H nmr (400 MHz, $CDCl_3$), ppm: 4.37, H-3 (dd, $J_{3,4}$ = 1.8 Hz; $J_{3,NH}$ = 8.25 Hz); 3.5, H-4 (ddd, $J_{4,3}$ = 1.8 Hz, $J_{4,4''}$ = 6.5 Hz, $J_{4,4''}$ = 6.7 Hz); etc; MH^+ 249. Compound **16** (racemic form) has been previously transformed into the corresponding N-sulfonic acid and the latter further elaborated into biologically active N-acyl derivatives (3, 5).

The presently described route to optically active β-hydroxy amino acids can nicely converge with the Squibb process (2, 5) or related ones (8) which rely on a Mitsunobu reaction (13) in the β-lactam ring-forming step. Our methodology also provides access to rare amino acids. For example, reaction of **6** with phenylmagnesium bromide gave the corresponding carbinol as the preponderant, if not exclusive, product having the expected stereochemistry. Oxidative degradation would lead to 2-(*R*)-amino-3-(*R*)-hydroxyphenyl propionic acid (phenylserine) which is commercially available in racemic form (for some recent reviews on the asymmetric synthesis of amino acids, see ref. 14).

Finally, it should be noted that even though the C-4—C-6 segment of the original amino sugar is sacrificed en route to the target β-lactam, its inherent functional and stereochemical features have served their intended useful purpose, firstly, to provide the chiral framework that secured the high degree of stereoselection in the Grignard reaction and, secondly, to act as a latent carboxyl group of the target amino acid. In view of the very low cost of this amino sugar and the obvious advantages of the strategy, the planned "burning off" of essentially half the original molecule may be tolerable.

Acknowledgments

We wish to acknowledge generous financial support from NSERCC and Le Ministère de l'éducation du Québec, as well as from Sandoz (Vienna). We also thank Dr. P. M. Tan for high resolution nmr spectra and Mr. M. Evans for mass spectra.

A stereoselective synthesis of digitoxin. On cardioactive steroids. XIII[1]

THOMAS Y. R. TSAI, HAOLUN JIN, AND KAREL WIESNER[2]

Natural Products Research Centre, University of New Brunswick, Fredericton, N. B., Canada E3B 6E2

Received February 15, 1984

THOMAS Y. R. TSAI, HAOLUN JIN, and KAREL WIESNER. Can. J. Chem. **62**, 1403 (1984).

The first highly stereoselective synthesis of digitoxin is described. The furyl derivative of digitoxigenin was coupled with one unit of digitoxose using our previously described acid catalyzed method. For the second and third glycosylation a new method involving ethyl thioglycosides and 1,3-participation by a *p*-methoxy benzoate group was developed. As the final step after deprotection of the triglycoside, the 17-furyl group in the steroid aglycone was converted to a butenolide by our oxidative method.

THOMAS Y. R. TSAI, HAOLUN JIN et KAREL WIESNER. Can. J. Chem. **62**, 1403 (1984).

On décrit la première synthèse très stéréosélective de la digitoxine. On a couplé le dérivé furyle de la digitoxigénine avec une unité de digitoxose en faisant appel à la méthode acido-catalysée que nous avons décrite antérieurement. Afin de réaliser les deuxième et troisième glycosylations, on a développé une nouvelle méthode impliquant les thioglycosides d'éthyle et une participation-1,3 d'un groupement *p*-méthoxy benzoate. Dans la dernière étape, qui suit la déprotection du triglycoside, on utilise notre méthode oxydative pour transformer, en buténolide, le groupement furyle en position 17 de l'aglycone stéroidique.

Digitoxin (**16**), first in the form of crude Digitalis extracts, later as a pure crystalline glycoside, has been used in medicine for 200 years. Even today, in spite of the deadly toxicity of natural Digitalis glycosides, these compounds belong among the ten most prescribed drugs. Our interest in the total synthesis of digitoxin started when it became desirable to attach the natural digitoxin glycosidic side chain to our totally synthetic relatively nontoxic cardenolide and bufadienolide analogues in order to prolong their duration of action and modify some other of their pharmacologic parameters.

The reaon why digitoxin, in spite of its importance, resisted previous attempts at total synthesis was the nonexistence of a highly stereoselective β-glycosylation method for 2-deoxy sugars in general and digitoxose in particular. We have partly remedied this situation in a previous communication of this series (2) in which we have shown that a 1,3-participation of a urethane group can control the stereochemistry of the acid catalyzed glycosylation of a digitoxose derivative.[3]

The starting material for the present synthesis was the protected glycoside **6** (mp 151−153°C; $[\alpha]_D$ −7.68; ^{1}Hmr ($CDCl_3$) δ: 8.03, 6.98 (d, J = 10 Hz, 2H each, 4 aromatic H), 7.34, 7.23, 6.49 (br s, 1H each, furan), 5.56 (br s, 1H, 3′-H), 4.93 (d, J = 10 Hz, 1H, 1′-H), 4.08 (br s, 1H, 3-H), 3.90 (s, 3H, —OCH_3), 1.35 (d, J = 6 Hz, 3H, 6′-CH_3), 0.92 (s, 3H, 19-CH_3), 0.71 (s, 3H, 18-CH_3)) which we have prepared by the previously described stereoselective method (2) followed by a simple modification of the protecting groups as portrayed in the formulae **1**−**6**.

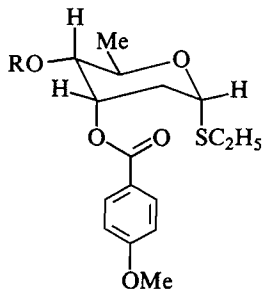
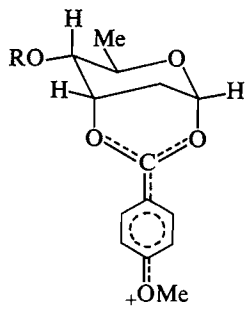
It soon became clear that it is not possible to continue the synthesis by the same method. With glycosidic bonds present, both in starting material and product, cleavage predominated over glycosylation and the higher glycosides were obtained only in traces. In order to deal with the second and third stage of the synthesis, we have prepared by simple acid catalyzed glycosylation (anhydrous CH_2Cl_2 *p*-toluenesulfonic acid) the ethyl α-thioglycosides **7** and **8** and the corresponding β-glycosides (4(*a*)).[4] Treatment of **6** in CH_2Cl_2 at 20°C for 40 h with 4 mol of the α-thioglycoside **7**, 4 mol of $HgCl_2$, and



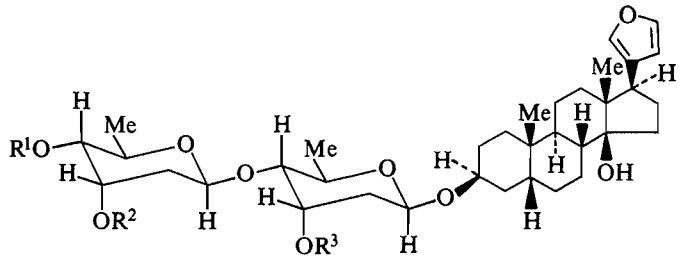
7 R = O_2N—C(=O)—, mp = 94–95°C; $[\alpha]_D$ = +214.12

8 R = MeO—C(=O)—, mp = 104–105°C; $[\alpha]_D$ = +266.51



9

an excess of $CdCO_3$ yielded the oily product **10** besides starting material. Compound **10** was obtained in a yield of 60% on the basis of starting material not recovered (^{1}Hmr ($CDCl_3$) δ: 8.19, 8.03, 7.96, 6.99 (m, 12H in all, 12 aromatic H), 7.34, 7.22, 6.48 (br s, 1H each, furan), 5.76, 5.68 (br s, 1H each, 3′- and 3″-H), 5.06 (d, J = 10 Hz, 1H, 1″-H), 4.86 (m, $W_{1/2}$ = 20 Hz, 2H, 1′- and 4″-H), 4.05 (br s, 1H, 3-H), 3.92, 3.90 (s, 3H each, OCH_3 × 2), 3.52 (dd, J = 4, 10 Hz, 1H, 4′-H), 1.35, 1.16 (d, J = 6 Hz, 3H each, 6′- and 6″-CH_3), 0.91 (s, 3H, 19-CH_3), 0.70 (s, 3H, 18-CH_3)). A trace of a product containing an α-glycosidic linkage was found in some runs and separated. The use of the corresponding β-thioglycoside gave the identical result. For this reason the more easily available α-glycosides **7** and **8** were employed throughout the synthesis. We believe that the species **9** plays a part in the glycosylation reaction. In none of the systems tried have we observed a displacement of the thioglycosidic bond without participation and with inversion of configuration as described by Ferrier *et al.* (5). Ammonolysis of **10** in methanol yielded 90% of an equilibrium mixture of **11** and **12** in a ratio 3.5:1. Compound



10 R^1 = O_2N—C(=O)—, R^2 = R^3 = MeO—C(=O)—

11 R^1 = H, R^2 = R^3 = MeO—C(=O)—

12 R^2 = H, R^1 = R^3 = MeO—C(=O)—

13 R^1 = R^2 = R^3 = H

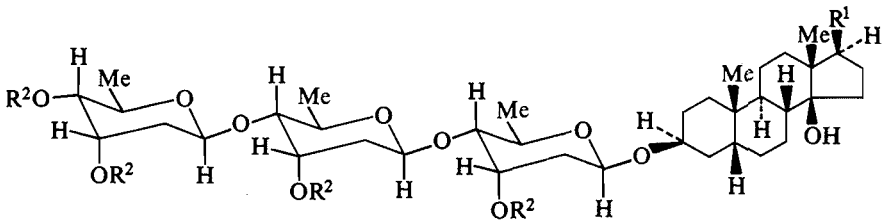
12 could be reequilibrated to yield the same product in the identical ratio. Both products **11** and **12** remained oily. (**11**: ^{1}Hmr ($CDCl_3$) δ: 8.03, 6.98 (m, 4H each, aromatic H), 5.64, 5.45 (br s, 1H each, 3′- and 3″-H), 4.88 (m, $W_{1/2}$ = 20 Hz, 2H, 1′- and 1″-H), 4.03 (br s, 1H, 3-H), 3.90, 3.89 (s, 3H each, OCH_3 × 2), 3.47 (m, 2H, 4′- and 4″-H); **12**: ^{1}Hmr ($CDCl_3$) δ: 8.02, 6.96 (m, 4H each, aromatic H), 5.63 (br s, 1H, 3′-H), 5.00, 4.85 (d, J = 10 Hz, 1H each, 1′- and 1″-H), 4.68 (dd, J = 4, 10 Hz, 1H, 4″-H), 4.29 (br s, 1H, 3″-H), 3.89, 3.87 (s, 3H each, OCH_3 × 2), 3.47 (dd, J = 4, 10 Hz, 1H, 4′-H).) Reduction of compound **11** with $LiAlH_4$ yielded **13** ($[\alpha]_D$ +4.15; mp 185–187°C; ^{1}Hmr ($CDCl_3$) δ: 7.33, 7.23, 6.49 (br s, 1H each, furan), 4.91 (m, $W_{1/2}$ = 20 Hz, 2H, 1′- and 1″-H), 4.27, 4.15, 4.05 (br s, 1H each, 3-, 3′-, and 3″-H), 3.28 (m, $W_{1/2}$ = 20 Hz, 2H, 4′- and 4″-H), 1.29, 1.23 (d, J = 6 Hz, 3H each, 6′- and 6″-CH_3), 0.91 (s, 3H, 19-CH_3), 0.69 (s, 3H, 18-CH_3)) identical with a product obtained by partial hydrolysis (two-phase system *p*-toluenesulfonic acid in H_2O/CH_2Cl_2) of the naturally derived compound **15** (2).

Coupling of the protected glycoside **11** with the thioglycoside **8** under identical conditions as in the step **6** → **10** yielded 58% of the protected glycoside **14** identical with the same derivative obtained by treatment of naturally derived **15** (2) with *p*-methoxybenzoylchloride and pyridine ($[\alpha]_D$ +112.92; mp 159–161°C; ^{1}Hmr ($CDCl_3$) **20** δ: 8.05, 7.98, 7.80, 6.98, 6.81 (m, 16H in all, aromatic H), 7.33, 7.22, 6.48 (br s, 1H each, furan), 5.67, 5.59 (br s, 2H and 1H, 3′-, 3″-, and 3‴-H), 4.96, 4.82 (d, J = 10 Hz, and m, $W_{1/2}$ = 20 Hz, 4H in all, 1′-, 1″-, 1‴-, and 4‴-H), 3.90, 3.89, 3.81 (s, 12H in all, OCH_3 × 4), 3.41 (m, 2H, 4′- and 4″-H), 1.26, 1.21, 1.14 (d, J = 6 Hz, 3H each, 6′-, 6″-, and 6‴-CH_3), 0.90 (s, 3H, 19-CH_3), 0.70 (s, 3H, 18-CH_3)). No product containing an α-glycosidic linkage was found. Finally, $LiAlH_4$ reduction of **14** gave 87% of compound **15**, identical by mixture mp and all spectral and chromatographic criteria with the same material described in our previous communication (2). The oxidative conversion of the furyl derivative **15** to either digitoxin (**16**) or isodigitoxin (**17**)[5] can be found in the same publication (2).

It remains to be mentioned that (for reasons which we shall discuss in a full publication) the thioglycoside method is only mildly stereoselective when used in the first step of the syn-

[4]For the preparation of ethyl thioglycosides by glycosylation with a Lewis acid, see ref. 4 (*b*).

[5]We have now found that **17** (mp 149–150°C) contains ether of crystallization. After vigorous drying at elevated temperature *in vacuo*, **17** melts at 214–216°C.



14 $R^2 = MeO-C_6H_4-CO-$, $R^1 =$

15 $R^2 = H$, $R^1 =$

16 $R^2 = H$, $R^1 =$

17 $R^2 = H$, $R^1 =$

thesis and consequently we have preferred to prepare compound **6** by our acid catalyzed method (2).

The chemistry of thujone. X.[1] Thujone as a chiral synthon for the preparation of sesquiterpenes. Synthesis of (+)-α-eudesmol and (−)-α-selinene

JAMES P. KUTNEY AND ASHOK K. SINGH

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received January 25, 1984

JAMES P. KUTNEY and ASHOK K. SINGH. Can. J. Chem. **62**, 1407 (1984).

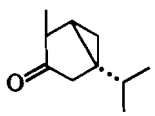
Efficient synthetic routes to the chiral sesquiterpenes (+)-α-eudesmol (**7**) and (−)-α-selinene (**9**) from a thujone-derived intermediate (**2**) are described.

JAMES P. KUTNEY et ASHOK K. SINGH. Can. J. Chem. **62**, 1407 (1984).

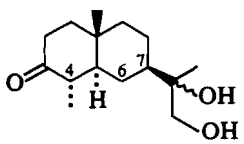
On décrit des méthodes efficaces de synthèse des sesquiterpènes chiraux (+)-α-eudesmol (**7**) et (−)-α-selinène (**9**) à partir de l'intermédiaire (**2**) dérivé de la thujone.

[Traduit par le journal]

In a recent series of papers (2–4) we have described the preparation of the natural chiral sesquiterpenes (+)-β-cyperone (2), (+)-carissone (3), and β-elemol (4) of the eudesmane series by appropriate transformations of the chiral synthon thujone (**1**)[2] as the starting material.



1



2

In these studies the thujone derived keto-diols (general structure **2**) became important intermediates, as for example, in the syntheses of β-elemol (4) and (+)-carissone (3). On the basis of these successful conversions it was possible to assign the absolute configuration in **2** at the chiral centres C-7, C-5, and C-10, as shown, thereby allowing these intermediates to be utilized in further syntheses of naturally occurring sesquiterpenes. In this publication we wish to describe a highly stereoselective synthesis of (+)-α-eudesmol (**7**) and (−)-α-selinene (**9**), proceeding through the intermediate **2**.

The synthetic route to (+)-α-eudesmol (**7**) is outlined in Scheme 1 and our experiments with respect to this study are discussed first.

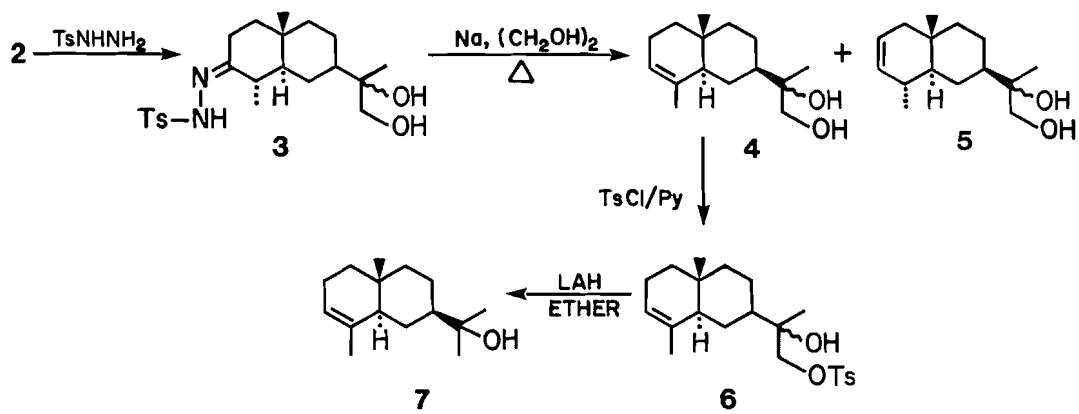
The mixture of known ketodiols **2**, prepared as previously described (4), was converted quantitatively into an inseparable mixture of isomeric tosylhydrazones **3** by treatment with tosylhydrazine and BF_3 in benzene. Since the subsequent steps in the synthesis eliminate the chirality at C-11, separation into the pure isomers was not essential at this time.

The hydrazones **3** were then converted to the corresponding isomeric hydroxyalkenes **4** and **5** using the Bamford–Stevens procedure (for a review of this reaction, see ref. 5). The major components were readily separated by chromatography over silver nitrate impregnated silica gel and it was thus shown that **4** constitutes 70% of the original mixture while **5** is present in 30%.

Treatment of **4** with tosylchloride in pyridine afforded **6**, which was readily reduced by LAH in ether to (+)-α-eudesmol (**7**). The latter compound proved to be identical in every respect with the natural (+)-α-eudesmol (6) (see Experimental).

On the other hand, oxidation of **4** with $NaIO_4$ in aqueous methanol provided the chiral ketone **8** (Scheme 2) in 79% yield. This intermediate could be considered for the synthesis of (−)-α-selinene (**9**) as summarized in Scheme 2.

In our initial studies with **8** we proceeded to react the latter under normal Wittig reaction conditions, that is, methyl triphenylphosphonium bromide, sodium hydride, and dimethyl sulfoxide (7). Unfortunately the conversion of **8** to **9**, under



SCHEME 1

[1] For part IX, see ref. 1.

[2] Thujone is the major component (ca. 80%) of the steam distillate from the slash (waste) of Western red cedar.

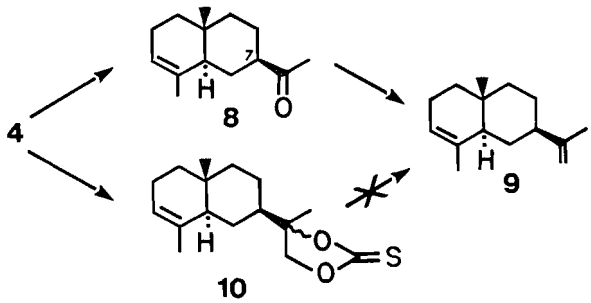

SCHEME 2

these conditions, proceeded in only 3% yield. We then turned to the use of a crystalline form of the Wittig reagent as developed by Schlosser and Schaub (8). To our delight a marked improvement was achieved and a 69% yield of **9** was realized.

It is interesting to consider the possibility of epimerization at the chiral centre C-7 in **8** during the basic conditions employed in the Wittig reaction, thereby altering the stereochemistry at this position in the resultant product **9**. Firstly it must be noted that the absolute stereochemistry at C-7, as shown in **8**, is established from our earlier studies relating to the synthesis of (+)-carissone and from nmr spectroscopy (nine-line resonance, tt, $J_{aa} = 12$; $J_{ae} = 4$ Hz centered at 2.40 ppm for the axial C-7 proton). When **8** was treated under the conditions utilized in the Wittig olefination process ($NaNH_2$ in THF, room temperature, 40 min) the starting material was recovered. It is therefore clear that the stereochemical assignment as illustrated for (−)-α-selinene (**9**) is secure.

Finally the alternative pathway 4 → 10 → 9 as outlined in Scheme 2 was also considered. However, although the thiocarbonate **10** could be prepared, its conversion to **9** met with failure and this sequence was therefore abandoned.

In conclusion, it is clear that thujone can indeed serve as an efficient chiral synthon for these types of sesquiterpenes. In a subsequent publication we will demonstrate the further utility of this compound in an efficient synthesis of optically active sesquiterpene lactones.

Experimental

Melting points were determined on a Reichert hot stage apparatus and are uncorrected. Ultraviolet spectra were recorded on a Cary 15 spectrophotometer in methanol solution. Infrared spectra were measured on a Perkin–Elmer 710 spectrophotometer using chloroform as solvent. The ^{1}Hmr spectra were recorded on Bruker WH-400, Bruker WP-80, Varian XL-100, or Nicolet–Oxford H-270 instruments. Deuteriochloroform was used as the solvent with TMS as internal standard. Low resolution mass spectra were determined on either an AEI-MS-902 or an Atlas CH-4B spectrometer. High resolution mass measurements were made on an AEI-MS-50 spectrometer. Optical rotations were recorded on a Perkin–Elmer 141 polarimeter using a cell with a path length of 10 cm. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. Column chromatography utilized Merck silica gel 60 (70–230 mesh). Preparative and thin layer chromatography utilized Merck silica gel GF_{254}. Petroleum ether refers to the fraction with boiling range 30–60°C.

Hydrazones 3

To a solution of hydroxyketone **2** (369 mg) and *p*-toluene sulfonyl hydrazide (271 mg) in benzene (50 mL) was added a drop of boron trifluoride etherate. The solution was stirred under argon at ambient temperature for 4 h. The resulting mixture was evaporated under reduced pressure, diluted with water (10 mL), extracted with THF–ether (100 mL, 1:1 v/v), and dried ($MgSO_4$). The solvent was removed under reduced pressure giving hydrazones **3** (598 mg, 98%), which were crystallized from ether–THF – pet. ether; mp 98–100°C; ir ν_{max}: 3488, 1600, 1378, 1173 cm^{-1}; uv λ_{max}: 225 (ε 13 288), 274 (988) nm; ^{1}Hmr δ: 0.89 (3H, s), 0.93 (1H, m), 0.99, 1.00 (3H, s, two sets), 1.03, 1.13 (3H, d, J = 6 Hz, two sets), 1.16–1.36 (2H, m), 1.38–1.75 (5H, m, including 1.48 (1H, bs, D_2O exchangeable)), 1.78–2.38 (6H, m, including 2.07 (1H, bs, D_2O exchangeable)), 2.43, 2.44 (3H, s, two sets), 2.56 (1H, m), 3.44 (1H, m), 3.58 (1H, m), 3.75 (1H, bs), 7.30, 7.36 (2H, d, J = 8 Hz, two sets), 7.80, 7.85 (2H, d, J = 8 Hz, two sets); ms *m/e*: 422 (M^+), 391, 278, 266. High resolution molecular weight determination, calcd. for $C_{22}H_{34}N_2O_4S$: 422.2239; found: 422.2248. *Anal.* calcd. for $C_{22}H_{34}N_2O_4S$: C 62.56, H 8.06, N 6.63; found: 62.29, H 7.96, N 6.30.

Diols 4 and 5

The tosyl hydrazones **3** (545 mg) in ethylene glycol (22 mL) containing dissolved sodium metal (568 mg) were heated at 155–165°C in an oil bath for 30 min under argon. The mixture was cooled, diluted with 20 mL water, and extracted with methylene chloride (2 × 100 mL). The organic extracts were dried ($MgSO_4$), concentrated, and the residue was chromatographed on silica gel impregnated with silver nitrate. Elution with petroleum ether – ethyl acetate (1:1 v/v) provided diols **4** (117.8 mg, 38%) and **5** (50.5 mg, 17%) as viscous oils. The physical properties of **4** are as follows: ir ν_{max} (neat): 3338 cm^{-1}; ^{1}Hmr δ: 0.78 (3H, s), 0.96 (1H, m), 1.14, 1.16 (3H, s, two sets), 1.17–1.58 (8H, m, including 1.58 (1H, bs, D_2O exchangeable)), 1.60, 1.63 (3H, s, two sets), 1.73 (1H, m), 1.84–1.92 (2H, m, including 1.90 (1H, bs, D_2O exchangeable)), 1.97 (1H, m), 2.09 (1H, m), 3.43, 3.45 (1H, d, J = 12 Hz, two sets), 3.58, 3.61 (1H, d, J = 12 Hz, two sets), 5.32 (1H, bs); ms *m/e*: 238 (M^+), 220, 205, 207, 189, 163. High resolution molecular weight determination, calcd. for $C_{15}H_{26}O_2$: 238.1923; found: 238.1938. *Anal.* calcd. for $C_{15}H_{26}O_2$: C 75.63, H 10.92; found: C 75.38, H 10.91. And for **5**, ir ν_{max} (neat): 3373 cm^{-1}; ^{1}Hmr δ: 0.83 (3H, s), 0.88 (1H, m), 0.97, 0.99 (3H, d, J = 6 Hz, two sets), 1.13, 1.14 (3H, s, two sets), 1.15–1.42 (2H, m), 1.45–1.60 (4H, m, including 1.55 (1H, s, D_2O exchangeable)), 1.64 (1H, dt, J = 12, 6 Hz), 1.68–1.85 (4H, m, including 1.83 (1H, bs, D_2O exchangeable)), 1.88 (1H, dt, J = 12, 6 Hz), 3.44, 3.45 (1H, d, J = 12 Hz, two sets), 3.57, 3.60 (1H, d, J = 12 Hz, two sets), 5.43 (1H, m), 5.54 (1H, m); ms *m/e*: 238 (M^+), 220, 207, 189. High resolution molecular weight determination, calcd. for $C_{15}H_{26}O_2$: 238.1933; found: 238.1923. *Anal.* calcd. for $C_{15}H_{26}O_2$: C 75.63, H 10.92; found: C 75.39, H 11.17.

Tosylates 6

To a well-stirred solution of diols **4** (45 mg) in 2 mL of pyridine was added, portion-wise, *p*-toluenesulphonyl chloride (108 mg). After 40 h at ambient temperature, the mixture was diluted with water (5 mL) and thoroughly extracted with ether (2 × 50 mL). The combined extracts were washed with water and saturated brine and dried ($MgSO_4$). The crude residue, after evaporation of the solvent *in vacuo*, was chromatographed on silica gel (40 g). Elution with ether – petroleum ether (3:7 v/v) afforded tosylates **6** (63.4 mg, 86%) as a viscous oil; ir ν_{max} (neat): 3512, 1598, 1453, 1353, 1183 cm^{-1}; uv λ_{max}: 222 (ε 12 418), 250 (2 179), 272 (871) nm; ^{1}Hmr δ: 0.74 (3H, s), 0.95 (1H, m), 1.12, 1.15 (3H, s, two sets), 1.24–1.53 (7H, m), 1.55, 1.58 (3H, s, two sets), 1.66 (1H, m), 1.79 (1H, s, D_2O exchangeable), 1.84 (1H, m), 1.95 (1H, m), 2.08 (1H, m), 2.46 (3H, s), 3.90, 3.91 (1H, d, J = 10 Hz, two sets), 3.97, 4.01 (1H, d, J = 10 Hz, two sets), 5.31 (1H, bs), 7.36 (2H, d, J = 8 Hz), 7.81 (2H, d, J = 8 Hz); ms *m/e*: 392 (M^+), 374, 359, 229, 220. High resolution molecular weight determination, calcd. for $C_{22}H_{32}O_4S$: 392.2021; found: 392.2013. *Anal.* calcd. for $C_{22}H_{32}O_4S$: C 67.35, H 8.16; found: C 66.95, H 8.41.

(+)-α-Eudesmol 7

A solution of tosylates **6** (100 mg) in ether (5 mL) was added to a stirred suspension of lithium aluminium hydride (50 mg) in dry ether (10 mL) and the mixture refluxed for 2 h. The cooled mixture was

decomposed with ice water, extracted with ether, and dried ($MgSO_4$). The solvent was distilled under reduced pressure to give an oil which solidified on standing. Recrystallization from petroleum ether afforded (+)-α-eudesmol **7** (49.5 mg, 86%); mp 74–75°C; $[\alpha]_D$ +28.6° (*c* 1.05, $CHCl_3$) (lit. (6) mp 74–75°C, $[\alpha]_D$ +28.5° (*c* 1.2, $CHCl_3$)); ir ν_{max}: 3575 cm^{-1}; ^{1}Hmr δ: 0.78 (3H, s), 0.98 (1H, m), 1.04–1.20 (2H, m), 1.21 (3H, s), 1.22 (3H, s), 1.26–1.51 (6H, m), 1.53 (1H, bs, D_2O exchangeable), 1.63 (3H, s), 1.88 (1H, dd, J = 10, 2Hz), 1.96 (1H, m), 2.10 (1H, m), 5.33 (1H, bs); ms *m/e*: 222 (M^+), 204, 189. High resolution molecular weight determination, calcd. for $C_{15}H_{26}O$: 222.1984; found: 222.1974. *Anal.* calcd. for $C_{15}H_{26}O$: C 81.08, H 11.71; found: C 81.16, H 11.56.

Ketone 8

To a solution of diols **7** (80 mg) in methanol (3.5 mL) and water (0.7 mL) was added $NaIO_4$ (233 mg). The resulting mixture was stirred at room temperature for 30 min. After the successive addition of a saturated solution of NaCl (7 mL) and sodium thiosulphate (7 mL), the product was extracted with ether–THF (100 mL, 1:1 v/v) and dried over $MgSO_4$. Solvent was removed and the residue chromatographed on silica gel (15 g), then eluted with ether – petroleum ether (0.3:9.7, v/v) to give as an oil **8** (55 mg, 79%); $[\alpha]_D$ −19.1° (*c* 0.44, $CHCl_3$); ir ν_{max} (neat): 1708 cm^{-1}; ^{1}Hmr δ: 0.81 (3H, s), 1.17–1.38 (4H, m), 1.52 (1H, dt, J = 12, 4 Hz), 1.63 (3H, s), 1.64–1.78 (2H, m), 1.88–1.96 (2H, m), 2.00 (1H, m), 2.09 (1H, m), 2.17 (3H, s), 2.40 (1H, tt, J = 12, 4 Hz, 9 lines), 5.35 (1H, bs); ms *m/e*: 206 (M^+), 191, 163. High resolution molecular weight determination, calcd. for $C_{14}H_{22}O$: 206.1671; found: 206.1662. *Anal.* calcd. for $C_{14}H_{22}O$: C 81.55, H 10.68; found: C 81.47, H 10.79.

(−)-α-Selinene 9

Ketone **8** (30 mg) in THF (2 mL) was added to a mixture of methyl triphenylphosphonium bromide (1 g) and THF (8 mL) which had been stirred for 40 min at room temperature. After the mixture had been stirred for an additional 40 min, the excess of reagent decomposes with cold water. The reaction mixture was extracted with petroleum ether and dried over $MgSO_4$. Evaporation of the solvent and purification by preparative layer chromatography with petroleum ether gave pure **9** as an oil, yield 20.6 mg (69%): $[\alpha]_D$ −12.9° (*c* 0.21, $CHCl_3$) (lit. (9) $[\alpha]_D$ −14.5° ($CHCl_3$, 1%)); ir ν_{max} (neat): 1641, 1440, 1375, 890 cm^{-1}; ^{1}Hmr δ: 0.81 (3H, s), 1.12–1.27 (2H, m), 1.30–1.38 (2H, m), 1.46 (1H, dt, J = 12, 4 Hz), 1.51–1.59 (2H, m), 1.61 (3H, s), 1.75 (3H, s), 1.78 (1H, m), 1.88–2.01 (3H, m), 2.10 (1H, m), 4.69 (1H, s), 4.72 (1H, s), 5.81 (1H, bs); ms *m/e*: 204 (M^+), 189, 175. High resolution molecular weight determination, calcd. for $C_{15}H_{24}$: 204.1878; found: 204.1878. *Anal.* calcd. for $C_{15}H_{24}$: C 88.24, H 11.76; found: C 88.25, H 11.88.

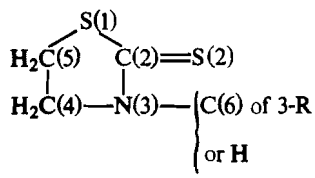
X-ray crystallographic determinations of 3-phenyl- and 3-cyclohexyl-thiazolidine-2-thiones are reported as a method for finding the origin of the discrepancy between ^{13}C and *R*-(Lambert) methods of determining the puckering in the ring. It is found that in the solid state, the puckering angles are 23.2° and 7.5° for the 3-phenyl and 3-cyclohexyl derivatives, respectively. The comparison of intramolecular and intermolecular distances for both compounds strongly suggests that these values are a fair representation of what is going on in solution. Therefore it is deduced that the puckering angle in these systems is probably better obtained by the ^{13}C nmr shift approach than by the *R*-Lambert method (in agreement with the most recent Lambert results). Both thiazolidine-2-thiones display a common property – S(1)C(2)S(2)N(3) lie in the same plane. N substitution is, however, different; all of the atoms of either the N-phenyl or of the N-cyclohexyl substituent are not in the S(1)C(2)S(2)N(3) plane. Only the C(6) atom of the N-cyclohexyl group is in the plane and the C(6) atom of the N-phenyl moiety is 0.12 Å out of this plane.

OLIVIER NUZZO, MARCEL PIERROT, ANDRÉ BALDY, MICHEL CHANON et FRANÇOISE CHANON. Can. J. Chem. **62**, 1410 (1984).

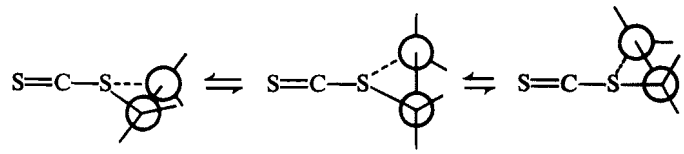
On rapporte les données cristallographiques pour la phényl-3 et la cyclohexyl-3 thiazolidinethiones-2 afin de trouver l'origine de la divergence des résultats quant au plissement du cycle apportés par la méthode du *R* de Lambert et la méthode de l'effet γ en rmn ^{13}C. On trouve qu'à l'état solide les angles de torsion de la liaison C—C sont 23,2° et 7,5° respectivement pour les dérivés phényl-3 et cyclohexyl-3. La comparaison des distances intra et intermoléculaires pour ces deux dérivés suggère fortement que les valeurs précédentes donnent une bonne approximation de l'état en solution. On en conclut que l'angle de torsion dans ces systèmes se rapproche plus de celui déduit par l'approche rmn ^{13}C que celui donné par la méthode du *R* (en accord avec les résultats les plus récents de Lambert). Les deux thiazolidinethiones-2 ont une propriété commune: S(1)C(2)S(2)N(3) sont dans le même plan. La localisation de la liaison N-substituant est cependant différente: seul l'atome C(6) du groupe N-cyclohexyl est dans le plan tandis que l'atome C(6) du groupe N-phényl est hors du plan (0, 12 Å).

Introduction

The aim of this paper is to obtain further information concerning the conformational modifications of the 1,3-thiazolidine-2-thione ring which we studied previously (1*a*, 1*b*) by ^1H and ^{13}C nmr. Kubiak and Glowink (2*a*) recently reported on the X-ray analysis of tetrakis(1,3-thiazolidine-2-thione)palladium(II) dichloride 1,3-thiazolidine-2-thione (1:2), while Raper and Oughtred (2*b*) gave the crystal structure of 1,3-thiazolidine-2-thione. In the present paper we will deal with the comparison of results from nmr and X-ray crystallography of N-substituted thiazolidine-2-thiones:



Spectroscopic studies suggested that in the solution: (1) the S(1)C(2)S(2)N(3) (C(6) or H) fragment for compounds with 3-R = H, Me, Et, iPr, *t*Bu is planar (3); (2) the five-membered ring is puckered, with a C(4)C(5) torsional angle φ whose value was evaluated. The application of Lambert's *R*-value equation (4) to differently substituted alkylthiazolidine-2-thiones provides an average value of 40°, whereas an upper limit of 25° is deduced from ^{13}C-γ effects in *cis*-4,5-dimethylthiazolidine-2-thione (1*a*); (3) the set of stable conformations was described by the equilibrium (1*a*):



C(5) out-of-plane envelope | C(4)C(5) out-of-plane half-chair | C(4) out-of-plane envelope

We showed that transannular interactions are negligible for this system; vicinal constraints and van der Waals requirements of the substituents control this conformational equilibrium.

To gain a deeper insight into the origin of the discrepancy in torsional angles obtained by the two approaches we report here on the X-ray crystallographic results of 3-phenylthiazolidine-2-thione (**1**) and 3-cyclohexylthiazolidine-2-thione (**2**).

Experimental

The compounds were prepared as previously reported (5) and crystals were obtained by slow evaporation at room temperature of benzene–cyclohexane solutions.

Space group and cell parameters were obtained from preliminary X-ray photographs. Crystals were mounted on a CAD-4 Enraf–Nonius diffractometer equipped with a graphite monochromator [MoK_α λ = 0.7107 Å]. Unit cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections. Intensities were

* See Table 1 (footnote).

measured using an $\omega-2\theta$ scan of 0.91° to 10.06° min^{-1} over a range of (1.0 + 0.35 tan θ) degrees in ω. The intensities of three check reflections measured every 5000 s throughout the data collection remained constant to within 2%. Crystal data at 20°C are:

3-Phenylthiazolidine-2-thione (1)

$C_9H_9S_2N$ fw: 195.2

Orthorhombic, a = 11.777 (3); b = 10.346 (3); c = 7.668 (2) Å; V = 934 Å^3; Z = 4; ρ_{obs} = 1.40 (2); ρ_{calc} = 1.39; $F(000)$ = 408; μ = 0.5 cm^{-1}. Space group: $Pna2_1$; 2071 reflections ($2\theta_{max}$ = 60°) measured on a crystal ca 0.4 × 0.4 × 0.5 mm; 1571 symmetry-related reflections were averaged (agreement factor on I = 0.01) and finally 1268 with $I > 3\sigma(I)$ were kept for structure determination.

3-Cyclohexylthiazolidine-2-thione (2)

$C_9H_{15}S_2N$ fw: 201.2

Orthorhombic, a = 10.276 (5); b = 10.916 (5); c = 18.81 (1) Å; V = 2110 Å^3; Z = 8; ρ_{obs} = 1.27 (3); ρ_{calc} = 1.27; $F(000)$ = 864; μ = 0.5 cm^{-1}. Space group: $Pbca$; crystal size: 0.4 × 0.25 × 1.0 mm; 1721 reflections measured ($2\theta_{max}$ = 50°) from which 1144 independent reflections with $I > 3\sigma(I)$ were kept for structure determination.

Determination of the structures

All computations were performed on a PDP 11/44 using the SDP software package (6). After data reduction, an absorption correction (7) was made for the N-cyclohexyl compound (**2**) in view of the anisotropic shape of the crystal. The structures were solved by direct methods (MULTAN (8)). After full matrix refinement of all non-hydrogen atoms with anisotropic thermal parameters, difference Fourier maps gave the positions of the hydrogen atoms. Subsequent least-squares cycles including the refinement of the positional parameters for the hydrogen atoms were performed and the refinements converged with R = 0.027 for 3-phenylthiazolidine-2-thione and with R = 0.042 for 3-cyclohexylthiazolidine-2-thione. ($R = \Sigma(\|F_o| - |F_c\|)/\Sigma|F_o|$ where F_o and F_c are the observed and calculated structure factor amplitudes. The function minimized in all least-squares calculations was $\Sigma w(|F_o| - |F_c|)^2$ where w = 1 for all reflections with $I > 3\sigma(I)$. Final positional and thermal parameters are presented in Tables 1 and 2.[3]

Discussion

Compound 1

This set of crystallographic data (Fig. 1a) shows that the thiazolidine-2-thione ring in **1** displays a twist form, with C(4) and C(5), respectively, displaced from the S(1)C(2)S(2)N(3) plane by 0.193 Å and −0.176 Å. The C(4)—C(5) torsional angle ϕ is 23.2°, in agreement with the value provided by the ^{13}C nmr study, in contrast with the information provided by the R-approach (1*a*).

The S(2)—C(6) intramolecular distance (3.14 Å, Fig. 1a) is shorter than the 3.44 Å limiting value given by R.F. Bryan *et al.* (9). So, steric interactions between thione sulfur S(2) and the phenyl ring control the ring conformation. Steric strain is relieved in two ways. First, the phenyl ring is rotated 80.7° with respect to the plane through S(1)C(2)N(3)S(2) (Figs. 2a and 3a). A value of 58° had been estimated for the rings of the more conjugated 1-phenyl-4-Δ-imidazoline-2-thione (10). Second, C(6) is 0.127 Å out of the mean plane of the five-membered ring (Fig. 2b). It appears that the phenyl ring, in such a conformation, does not induce any specific torsion in the C-4—C(5) fragment. Therefore the measured torsional angle ϕ

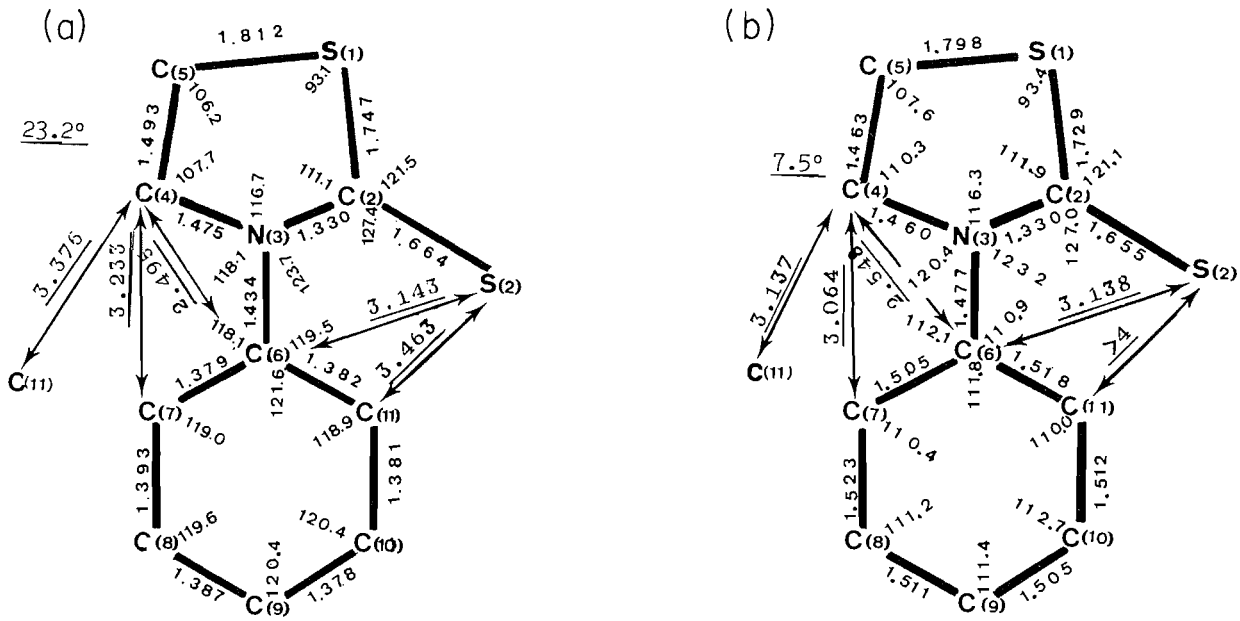

FIG. 1. Bond lengths (Å), intramolecular distances (Å), angles (°), and torsional angles, ϕ (°); (a) 3-phenylthiazolidine-2-thione (**1**); (b) 3-cyclohexylthiazolidine-2-thione (**2**).

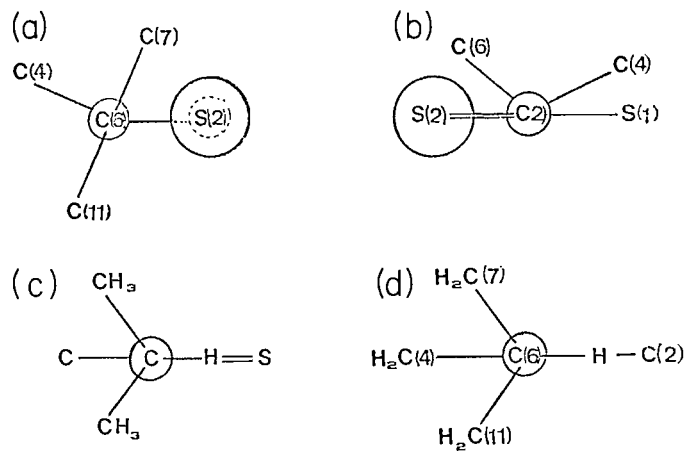

FIG. 2. Newman projections; (a) 3-phenylthiazolidine-2-thione (**1**), projection along C(6)—N(3); (b) 3-phenylthiazolidine-2-thione (**1**), projection along C(2)—N(3); (c) 3-isopropyl-4-Δ-thiazoline-2-thione, projection along $(CH_3)_2HC$—N bond (13); (d) 3-cyclohexylthiazolidine-2-thione (**2**), projection along C(6)—N(3).

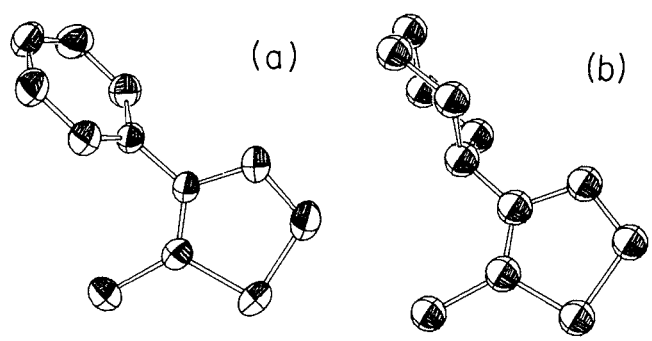

FIG. 3. View of the molecules; thermal ellipsoids are drawn at 50% probability level; (a) 3-phenylthiazolidine-2-thione (**1**); (b) 3-cyclohexylthiazolidine-2-thione (**2**).

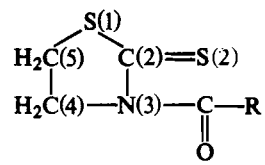
(23.2°) is probably a good approximation to the one expected for an N-unsubstituted ring. This contrasts with the case of:



3 R = *p*-bromophenyl (9)
4 R = $(CH_2)_4$—C—thiazolidine-2-thione (11)
O

Presumably because of potential lone-pair repulsions between S(2) and O, the observed conformation has these two atoms *trans* to each other. Then the C═O group induces a distorsion around the C(4)—C(5) bond because of the van der Waals repulsions with the C(4)H_2 fragment (ϕ_3 = 33° for **3**; ϕ_4 = 34.3° for **4**).

Compound 2

The crystallographic data (Fig. 1b) show that the five-membered ring is nearly planar. C(4) and C(5) distances from the S(1)C(2)S(2)N(3)C(6) plane are respectively −0.059 Å and +0.057 Å. The conformation is a very flat C(4)C(5) out-of-plane half-chair with a C(4)—C(5) torsional angle ϕ of 7.5°. The geometries of the **1** and **2** five-membered rings are in sharp contrast (Fig. 1). This set of values suggests that C(4) and C(5) gain partial sp^2 character when passing from 3-R = phenyl to 3-R = cyclohexyl, as observed in the 2-phenyliminothiazolidine ring (12). The cyclohexyl ring is a perfect chair conformation (Figs. 1b and 3b) with the C(6) and C(9) atoms out of the six-membered ring mean plane [VI][4] respectively by −0.664 Å and +0.640 Å; C(6) is in the best plane of the thiazolidine-2-thione ring [V].[4] The two rings [V] and [VI] are

[4] [VI] is the C(7)C(8)C(10)C(11) plane; [V] is the S(1)C(2)S(2)N(3) plane.

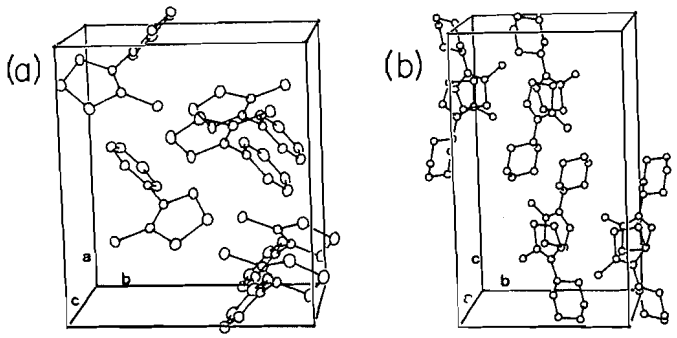


FIG. 4. View of the packing arrangement. (a) Viewed along *c* (**1**); (b) viewed along *a* (**2**).

nearly perpendicular: 91.8° (Figs. 1b and 3b) with the cyclohexyl ring being displaced towards C(4). A similar kind of preferential conformation has been found for 3-isopropyl-4-methyl-4-Δthiazoline-2-thione (13) and for 1-isopropyl-4-Δ-imidazoline-2-thione (10) (Fig. 2c).

Therefore, in **2**, no important steric interactions between the [VI] ring and S(2) exist, so S(6) can stay in plane [V]; the S(2)—C(6) distance is 3.138 Å, similar to case **1**, 3.143 Å. But van der Waals strain between $C(7)H_2$, $C(11)H_2$, and $C(4)H_2$ (Fig. 2d) prevents C(4) from moving away from the C(6)N(3)C(2) plane; thus the five-membered ring displays a far smaller torsional angle. In this case, too, steric hindrance between the thione sulfur S(2) and the substituent ring controls the conformation.

The intermolecular distances (depository material) are more numerous and shorter in **1** than in **2**, but none are less than the sums of the van der Waals radii given by N.L. Allinger (14). Then it seems that the "packing effect" is less pronounced in the 3-cyclohexylthiazolidine-2-thione case than in the 3-phenyl one. By comparison, the intramolecular distances are smaller (Figs. 1), so we can conclude that ring conformation is controlled mainly by intramolecular steric effects.

Crystal cohesion in **1** arises from overlap of the phenyl ring with the thione sulfur (Fig. 4a), and in **2** it lies in inverse superposition of two five-membered rings while six-membered chair rings fit together with other molecules (Fig. 4b).

Conclusions

It appears that the thiazolidine-2-thione ring is very flexible and can easily adopt different conformations. This can be explained by intramolecular steric effects between the N-substituent and the thione sulfur. As indicated by J. B. Lambert (4*d*), the torsional angle is overestimated by a considerable amount using the *R*-value method for a five-membered ring. Further work is in progress, aiming at delineating systematically the issue of solid state versus solution conformational data of this heterocyclic, conformationally-mobile system (15, 16).

The ultraviolet absorption spectrum of oxalic acid vapor[1]

R. A. BACK

Division of Chemistry, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R6

Received July 7, 1983[2]

R. A. BACK. Can. J. Chem. **62**, 1414 (1984).

The ultraviolet absorption spectrum of oxalic acid vapor has been studied for the first time. Low-resolution spectra show a moderately weak (ϵ_{max} = 25 M^{-1} cm^{-1} at 277 nm) banded absorption system beginning at about 310 nm and extending to 250 nm where a stronger absorption begins. Medium-resolution spectra show a complex vibrational fine-structure at wavelengths above about 287 nm, with many sharp line-like R-branch heads, each corresponding to a different vibrational transition. A vibrational analysis was completed for $^{12}C_2O_4H_2$, $^{12}C_2O_4D_2$, and $^{13}C_2O_4H_2$, and electronic origins were estimated to be at 31903.2, 31970.2, and 31949.4 cm^{-1}, respectively (about 313 nm). Strong features were assigned to progressions in ν_2' and ν_3', the C=O and C—O stretching vibrations, with prominent sequences in ν_{10}, the C—C torsional vibration, running to the blue, implying that $\nu_{10}' > \nu_{10}''$.

This absorption system has been assigned to the first excited singlet state, designated $\tilde{A}$, corresponding to a $\pi^* \leftarrow n_+$, $^1A_u \leftarrow {}^1A_g$ transition of planar *trans*-oxalic acid. High-resolution spectra of several bands show rotational fine-structure, and a partial analysis was carried out on the 2_0^1 and $2_0^1 10_1^1$ bands of $^{12}C_2O_4H_2$, based on apparently-simple diverging P-branches.

R. A. BACK. Can. J. Chem. **62**, 1414 (1984).

On a étudié pour la première fois le spectre d'absorption ultraviolet de la vapeur d'acide oxalique. Les spectres à basse résolution montrent la présence d'un système de bandes d'absorption (ϵ_{max} = 25 M^{-1} cm^{-1} à 277 nm) qui sont modérément faibles, qui commencent à 310 nm et qui s'étendent jusqu'à 250 nm alors que commencent une absorption plus forte. Les spectres à moyenne résolution montrent une structure fine vibrationnelle complexe à des longueurs d'onde commençant à environ 287 nm, avec plusieurs têtes de branche R, qui donne l'apparance de raies étraites, chacune correspondant à une transition vibrationnelle différente. On a effectué une analyse vibrationnelle pour les composés suivants: $^{12}C_2O_4H_2$, $^{12}C_2O_4D_2$, $^{13}C_2O_4H_2$ et on a évalué que leurs origines électroniques sont respectivement à 31903,2, 31970,2 et 31949,4 cm^{-1} (environ 313 nm). On a attribué les fortes caractéristiques aux progressions dans ν_2' et ν_3', les vibrations d'élongations de C=O et de C—O, avec des bandes fortes dans ν_{10}, la vibration de torsion C—C, allant jusqu'au bleu et impliquant que $\nu_{10}' > \nu_{10}''$.

On a attribué ce système d'absorption au premier état singulet excité que l'on désigne par $\tilde{A}$ et qui correspond à une transition $\pi^* \leftarrow n_+$, $^1A_u \leftarrow {}^1A_g$ de l'acide oxalique *trans* qui est planaire. Les spectres à haute résolution de plusieurs bandes montrent une structure fine rotationnelle et on a effectué une analyse partielle des bandes 2_0^1 et $2_0^1 10_1^1$ du $^{12}C_2O_4H_2$ qui est basée sur les branches P divergentes apparemment simples.

[Traduit par le journal]

Introduction

Oxalic acid in solution shows a weak absorption beginning about 300 nm with a maximum around 260 nm, which has been attributed to a $\pi^* \leftarrow n_+$ transition, the lowest excited singlet state (1). A phosphorescence excitation spectrum in the same region, measured in frozen EPA solution at 77 K, showed broad vibrational features which were thought to be a progression in a carbonyl stretching mode (1).

No corresponding vapor-phase spectrum of oxalic acid has been reported, probably because of its low volatility and ease of thermal decomposition. Oxalic acid is of interest through its close structural similarity to glyoxal and biacetyl, both of which have been the subjects of intense spectroscopic, photophysical, and photochemical investigation. The present study was undertaken in conjunction with photochemical experiments in this laboratory (2).

Experimental

Oxalic acid vapor and White-cell mirror surfaces proved to be mutually destructive at the temperatures required, and all spectra finally reported were obtained using a single-pass quartz cell about 4 m long and 25 mm in diameter, heated to 130 to 140°C. Oxalic acid vapor was supplied from a sidearm containing the solid anhydrous acid held at a somewhat lower temperature, giving vapor pressures of 1 to 3 Torr. Oxalic acid decomposes appreciably at these temperatures, so the vapor was pumped away and replenished frequently to avoid loss and accumulation of products. Some absorption bands of formic acid, a major decomposition product, were observed below 250 nm. All the other reported products, H_2O, CO, CO_2, and H_2, are transparent above 200 nm.

Anhydrous oxalic acid of 99% purity was obtained from Aldrich. Oxalic acid-d_2 and mixtures of oxalic acid-h_2, -*hd*, and -d_2 were obtained by mixing with D_2O or appropriate H_2O-D_2O mixtures and then removing water by prolonged pumping at room temperature. Oxalic acid-*c*-13 with 90 atom% *c*-13 was purchased from Merck, Sharp and Dohme of Canada Ltd.

Low-resolution spectra were obtained with a Heath modular double-beam spectrophotometer modified to take 4 m absorption cells. Medium-resolution spectra were photographed using an Eagle 6.6 m spectrograph with a grating with 600 lines/mm used in the 2nd order, to give a dispersion of 1.2 Å/mm. High-resolution spectra were obtained with an Ebert 7.3 m spectrograph, with a grating of 300 lines/mm, in the 20th order, for a dispersion of about 0.096 Å/mm.

Results

The low-resolution spectrum in Fig. 1 shows a moderately weak absorption, typical of a $\pi^* \leftarrow n_+$ transition, beginning about 310 nm, with ϵ_{max} of about 25 M^{-1} cm^{-1} at 277 nm, and broad vibrational features. There is some indication of vibrational fine structure at long wavelengths, confirmed in the medium resolution spectra in Fig. 2, and at still higher resolution (Fig. 3) rotational fine structure is evident. A much stronger absorption begins at about 252 nm, with sharp vibrational features superimposed (Fig. 1) which are due to formic acid.

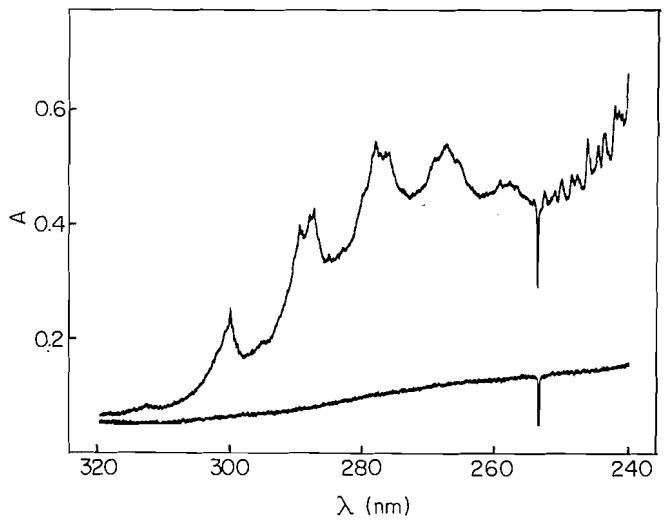

FIG. 1. Low-resolution spectrum of oxalic acid vapor.

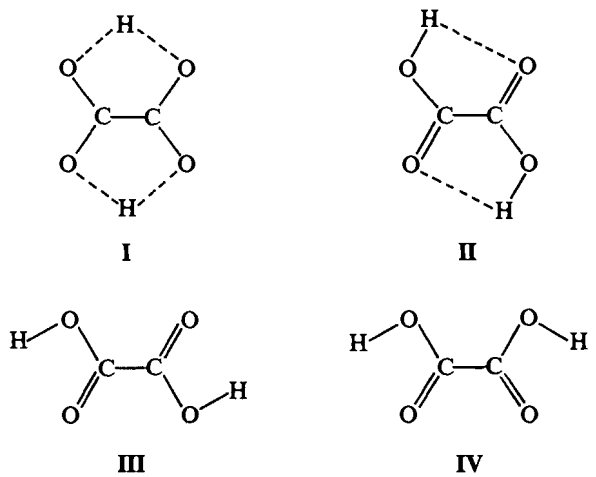
Discussion

Before analysing the observed spectra, the molecular structure of oxalic acid must be considered. Electron diffraction studies (3, 4) showed a planar carbon–oxygen skeleton for the oxalic acid monomer, and four structures are possible:



Structures **I** and **II** have strong internal hydrogen bonding, with **I** being a resonance hybrid of the two possible forms of **II**. Electron diffraction showed two distinctly different C—O bond lengths, with the carbonyl groups in a *trans* configuration (3, 4), apparently ruling out structures **I** and **IV**, and this is supported by infrared and Raman observations of reasonably normal O—H and C=O stretching frequencies (4–7). Shibata and Kimura (3) also argued that the skeletal planarity implied the hydrogen bonded structure **II**, and the same "chelated" structure was supported by Pava and Stafford (5) on the basis of O—H, O—D, and C=O stretching frequencies observed in the vapor-phase infrared spectrum of oxalic acid and oxalic acid-d_2. Glyoxal, however, has a planar structure without the benefit of chelation (8), and similar forces to those that hinder rotation about the C—C bond in glyoxal should be operative in oxalic acid. The infrared evidence for chelation has also been criticized by Stace and Oralratmanee (7), who concluded that no clear decision could be made between structures **II** and **III**. Formic acid monomer has been shown (9) to be planar, with *cis*

and *trans* isomers and a barrier to rotation around the C—O single bond of 10–15 kcal/mol and a corresponding torsional vibration frequency of 640 cm^{-1}. The *cis* isomer is the more stable one, and by analogy structure **III** should perhaps be more stable than **II** unless the latter is sufficiently stabilized by hydrogen bonding. The planarity of formic acid suggests that the hydrogen atoms of oxalic acid should also lie in the plane of the C—O skeleton. With regard to structure **IV**, both *cis* and *trans* isomers of glyoxal are known to exist, with the *trans* form much more abundant (10). In the following analysis, an initial working assumption will be made that structure **II** is responsible for the observed spectra.

Vibrational analysis

The frequencies of the 18 fundamental vibrational modes of the ground state of the planar *trans* isomer of oxalic acid listed in Table 1, are not all well established.. Some frequencies shown are from infrared and Raman spectra, while others are estimated, and assignments have been aided by comparison with known frequencies of *trans*-glyoxal and formic acid. The numbering and the assignments shown are appropriate to both structures **II** and **III** if the effects of hydrogen bonding are minimal; for structure **II** with strong hydrogen bonds, the numbering and descriptions of several of the vibrations would be altered (7).

The low-resolution spectra of both $C_2O_4H_2$ and $C_2O_4D_2$ (Fig. 1) show obvious strong progressions of bands with average frequency intervals of 1377 and 1370 cm^{-1}, respectively (Table 2). There appears to be a second, weaker progression in the same frequency lying about 500 cm^{-1} to the blue. By analogy with glyoxal and other $\pi^* \leftarrow n$ spectra, it is reasonable to assign these progressions to excitation of the symmetric carbonyl stretching mode, ν_2', in the upper state, with the weaker progression probably corresponding to excitation of one quantum of an in-plane vibration such as ν_5' or ν_6'. The medium-resolution photographic spectra in Fig. 2, however, reveal a much more complex vibrational structure in these apparently simple bands. The bands centred around 300 nm, corresponding to the first strong band in Fig. 1, are the strongest features of these spectra. Much weaker bands lying to the red around 313 nm in all three isotopic species also show fine structure; the next strong bands to the blue, around 290 nm, show some structure but are becoming diffuse, while all spectra at shorter wavelengths are completely diffuse.

Prominent in each spectrum in Fig. 2 are many sharp line-like features. From high-resolution spectra it will be seen later that these are composite R-branch heads, and each corresponds to a different vibronic transition. Frequencies of these branch-heads are listed in Tables 3–5, together with vibrational assignments. Capital letters are used to designate those features in Fig. 2 corresponding to the electronic origin band and to bands involving excitation of the symmetric vibrational modes, ν_2' to ν_7'. Small-case letters designate bands involving the low-frequency modes, ν_{10} and ν_{18} (mostly hot bands). Numerical subscripts indicate members of ν_{10} sequence bands, while a few unassigned features are labelled X. In the following vibrational analysis, it is convenient to use these easily measured sharp features to calculate frequency differences, rather than using true band origins which can only be determined accurately for a few bands with resolved rotational structure. In the latter, the band origins lie typically 5 or 6 wave numbers to the red of the

R-branch heads, and little error should be introduced by using the latter to estimate frequency differences.

The electronic origin

Location of the band corresponding to the electronic origin of the present band system requires some discussion. An obvious choice at first glance is the strong feature marked J_0 in Fig. 2, close to the first strong maximum in the low-resolution spectra (Fig. 1). This raises a problem, however, in assigning the much weaker system of bands, labelled A, around 313 nm. The intensity of the latter seems about right for a ν_2' hot band, but the observed frequency difference of 1359 cm^{-1} for $J_0 - A_0$ for $^{12}C_2O_4H_2$ is much too low for ν_2'', and is in fact more appropriate for ν_2', the excited-state frequency. A ν_3'' hot band is perhaps a possibility, as this vibration also appears to be active in the transition, but again the frequency difference is appreciably below the Raman frequency of 1423 cm^{-1} reported for ν_3''. Another possibility is that the bands at 313 nm are due to weak absorption by the *cis* isomer of oxalic acid, present in low concentration; in the analogous glyoxal spectrum, weak absorption by the *cis* isomer appears 1467 cm^{-1} to the red of that of *trans*-glyoxal (10). A telling argument against this possibility is the general similarity of the *A* and *J* bands (Fig. 2) and more particularly the sequence-band intervals (Tables 3–5) which are very similar. By contrast, in glyoxal, intervals in the corresponding sequences in the torsional vibration differ by a factor of two in the *cis* and *trans* isomers (10). Finally, the observed isotope shifts offer the most convincing evidence in the identification of the electronic origin. Deuterium isotope shifts of +58 and +67 cm^{-1} for J_0 and A_0, respectively are both compatible with expected zero-point energy differences. The carbon-13 isotope shift of only +1.32 cm^{-1} for J_0 is, however, much too small, while the shift of 46 cm^{-1} for A_0 appears reasonable. The analogous isotope shift in *trans*-glyoxal (8) is +14 cm^{-1}, but oxalic acid has considerably more vibrational modes involving the carbon atoms which change frequency in the transition. All things considered, it must be concluded that the band, A_0, despite its relative weakness, corresponds to the electronic origin of the present system. It will be seen that subsequent detailed analysis of the spectrum supports this conclusion. It is also assumed in the analysis that all the bands observed are due to the *trans* isomer of oxalic acid.

Noting again that the frequencies shown in Tables 3–5 are for R-branch head maxima, and assuming that for the A_0 bands these lie the same distance to the blue of the band origin as in J_0 for $^{12}C_2O_4H_2$ (see below, Table 10), the true electronic origins for $^{12}C_2O_4H_2$. $^{12}C_2O_4D_2$, and $^{13}C_2O_4H_2$ are estimated to be at 31903.2, 31970.2, and 31949.4 cm^{-1}, respectively. The chief uncertainty in these values lies in the assumed separation of the R-head maxima from the origins; the A_0 bands themselves were too weak to photograph in high resolution.

Sequence bands and hot bands involving ν_{10}, the C—C torsional vibration

Many of the features listed in Tables 3–5 can be grouped into obvious regular sequences, running with decreasing intensity to the blue, with intervals between members of 40–45 cm^{-1} in $^{12}C_2O_4H_2$, and $^{13}C_2O_4H_2$ and 35–40 cm^{-1} in $^{12}C_2O_4D_2$. There seems little doubt that these sequence bands can be assigned to transitions from thermally populated levels of ν_{10}'', the torsional vibration around the C—C bond. Microdensitometer measurements indicate a decrease of between 20 and 40% between adjacent members, which from the Boltzmann factor corresponds to an energy difference of between 60 and 150 cm^{-1}, assuming constant transition probability. From Table 1 it is clear that ν_{10}'' is the only vibrational mode at all likely to have such a low frequency. The $\pi^* \leftarrow n_+$ spectrum of glyoxal shows similar sequence bands involving the corresponding C—C torsion vibration (8), lending support to the present assignment. As in glyoxal, the sequences de-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

crease in intensity towards the blue, implying that $\nu'_{10} > \nu''_{10}$. Intervals between sequence members are listed in Tables 3–5, and show considerable variation, both within single sequences and between sequences. Several sequences are very regular (J_0 to J_6 in $^{12}C_2O_4H_2$, for example) while others are less so; the A-sequence in $^{12}C_2O_4H_2$ shows a very small interval between A_3 and A_4, while the J-sequence in $^{12}C_2O_4D_2$ has a large interval between J_1 and J_2.

In addition to the $\Delta V_{10} = 0$ sequence bands, a few weak bands have been assigned to simple hot bands corresponding to ($V'_{10} = 0$, $V'_{10} = 1$) transitions. The features labelled C_0 in $^{13}C_2O_4H_2$ and $^{12}C_2O_4D_2$ lie 89 and 84 cm^{-1} to the red of the origin band. These values for ν''_{10} can be combined with sequence interval values of about 43 and 39 cm^{-1} (from $A_1 - A_0$) to give values of 132 and 123 cm^{-1}, respectively, for ν'_{10}. Stronger hot bands, j_0 and n_0, were observed with all three isotopic species to the red of the strong features I_0 and J_0, giving values of ν''_{10} close to those from c_0 (above), with the ^{12}C and ^{13}C isotopic species almost the same, as expected for a torsional vibration about the C—C axis. Several other ν''_{10} hot bands, f_0, j_1, n_1, and r_0 were assigned in one or the other of the isotopic oxalic acids.

Hot bands and sequences involving ν_{18}, the asymmetric O=C—O rocking mode

A single weak feature in the $^{13}C_2O_4H_2$ spectrum lying 279 cm^{-1} to the red of the origin band, A_0, has been assigned to a simple hot band of ν''_{18}, for which a Raman frequency of 306 cm^{-1} has been reported (7) for $^{12}C_2O_4H_2$. Similar bands were found lying to the red of strong features such as I_0 and J_0 in all three spectra, and have also been assigned to ν''_{18} hot bands, listed in Table 6. Also evident in all three spectra are a few short sequences with intervals between 50 and 60 cm^{-1}, usually with one or two members, occasionally three, and these we have attributed to $\Delta V_{18} = 0$ sequences, also listed in Table 6. These sequences run with decreasing intensity to the red, indicating, as might be expected that $\nu''_{18} > \nu'_{18}$. Taking values of ν''_{18} of 287, 279, and 243 cm^{-1} for $^{12}C_2O_4H_2$, $^{13}C_2O_4H_2$, and $^{12}C_2O_4D_2$, respectively, and values for the corresponding ν_{18} sequence intervals (Table 6) of 55, 54, and 51 cm^{-1}, values of ν'_{18} = 232, 225, and 192 cm^{-1} can be estimated for the three isotopic species.

Excitation of the symmetric vibrations, ν'_2 to ν'_7

In Fig. 4 is an energy-level plot and vibrational assignments for the three isotopic oxalic acids showing the sharp features from Fig. 2 which remain when all hot bands and sequence bands involving ν_{10} and ν_{18} are removed. The strongest feature, J_0, is assigned to the carbonyl stretching vibration, $V'_2 = 1$, with W_0 corresponding to the second member of the progression. The low-resolution spectrum in Fig. 1 indicates that the progression continues to at least $V'_2 = 5$, with perhaps maximum intensity at $V'_2 = 3$, but no sharp features are evident beyond W_0, $V'_2 = 2$. ν'_2 exhibits a slight negative anharmonicity in all three isotopic species.

The next strongest features in the spectrum, I_0 and T_0, are assigned to a progression in ν'_3, and again it is evident from the low-resolution spectrum that these progressions continue to shorter wavelengths; in fact the broad maxima at low resolution are composites of ν'_2 and ν'_3, overlaid and broadened by the complex sequences and hot bands discussed above, rather far from simple carbonyl stretching progressions.

Bands labelled E_0 in all three spectra are assigned to excitation of one quantum of ν'_4. A number of rather weak bands are assigned to excitations of ν'_5, ν'_6, and ν'_7; these are mostly combination bands, especially combinations with the strong ν'_2 and ν'_3 bands, J_0 and I_0. In Table 7 are listed all the vibrational frequencies derived from the present spectrum. Several features may be noted. Values of ν'_2 are markedly reduced from the ground-state value (1800), as usually found in $\pi^* \leftarrow$ n transitions of carbonyl compounds; less usual is the slight negative anharmonicity in ν'_2. The torsional frequency, ν_{10}, as noted earlier, is increased in the excited state, as in glyoxal (8), but both the frequency and the change in frequency are less than in the latter, probably reflecting the repulsion between the oxygen atoms in planar oxalic acid not present in *trans*-glyoxal. The value of ν'_5, approximately described as a C—C stretching vibration, is *decreased* in the excited state, despite the increase in ν'_{10} and the probable decrease in the C—C bond length (see below). The explanation is probably that ν_5 is very far from a pure C—C stretching vibration, so that any increase in the C—C force constant is more than outweighed by decreases in the other force constants involved. Glyoxal shows a similar decrease in the "C—C stretching" vibration in the excited state (8). The isotope effects in Table 7 are compatible with the approximate descriptions of the vibrations, noting again that several of these, notably ν_4 to ν_7, are probably very mixed in character (7). An exception is the value of ν'_7 for $^{12}C_2O_4D_2$, which is much too low for any normal isotope effect, although there seems no alternative assignment for the feature K_0 in Fig. 2 on which it is based.

Rotational analysis

High-resolution spectra of a number of the bands showed rotational fine structure. This was most clearly evident in the bands labelled J_0 and J_1 in the medium-resolution spectrum of $^{12}C_2O_4H_2$ (Fig. 2) which we have assigned to 2^1_0 and $2^1_0 10^1_1$ vibronic transitions respectively; the high-resolution spectra are shown in Fig. 3. Each band shows sharp features in what appears to be a diverging P-branch, a band origin marked by a sharp onset of absorption, and what appears to be a very strong R-branch head which corresponds to one of the sharp features noted in the medium-resolution spectra. Two much weaker R-branch heads, assigned to $3^1_0 10^3_3$ and $3^1_0 10^4_4$ vibronic transitions, can also be distinguished.

There have been two electron-diffraction determinations of the structure of oxalic acid in the gas phase, both of which favored structure **II**, as discussed earlier (3, 4). Using the structural parameters from the more recent work of Nahlovska *et al.* (4), (r(C—C) = 1.548 Å, r(C=O) = 1.208 Å, r(C—O) = 1.339 Å, r(O—H) = 1.056 Å, ∠C—C=O = 123.1°, ∠O=C—O = 125.0°, and ∠C—O—H = 104.4°) moments of inertia and rotational constants were calculated for structure **II** (Table 8). Stace and Oralratmanee (7) have argued that structure **III** cannot be ruled out, so rotational parameters were also calculated for structrure **III**, assuming the same bond lengths and angles, but with the O—H bonds rotated through 180°, and are shown in parentheses in Table 8. In both structures, the molecule is a strongly asymmetric top, with the c-axis, the axis of symmetry, perpendicular to the molecular plane, and closer to a prolate rather than an oblate symmetric top (κ negative).

Excited-state rotational constants were also calculated, using two models, and are shown in Table 9. In model 1, the C=O bond length was increased to 1.258 Å and the C—C bond length decreased to 1.480 Å, the same percentage changes observed in the first excited singlet state of glyoxal (8). Other

bond lengths and angles, which changed little in glyoxal, were left unchanged. In model 2, the C—C bond length was reduced by only half as much, to 1.514 Å, and a small increase was made in the C—O bond length to 1.346 Å, the same percentage change as in the C—H bond in glyoxal. Other bond lengths and angles were the same as in model 1. The smaller decreases in the C—C bond length is to take into account increased repulsion between the carbonyl and hydroxyl oxygen atoms in oxalic acid, relative to glyoxal, which is borne out by the longer C—C bond in the ground state (1.548 vs. 1.51 Å in

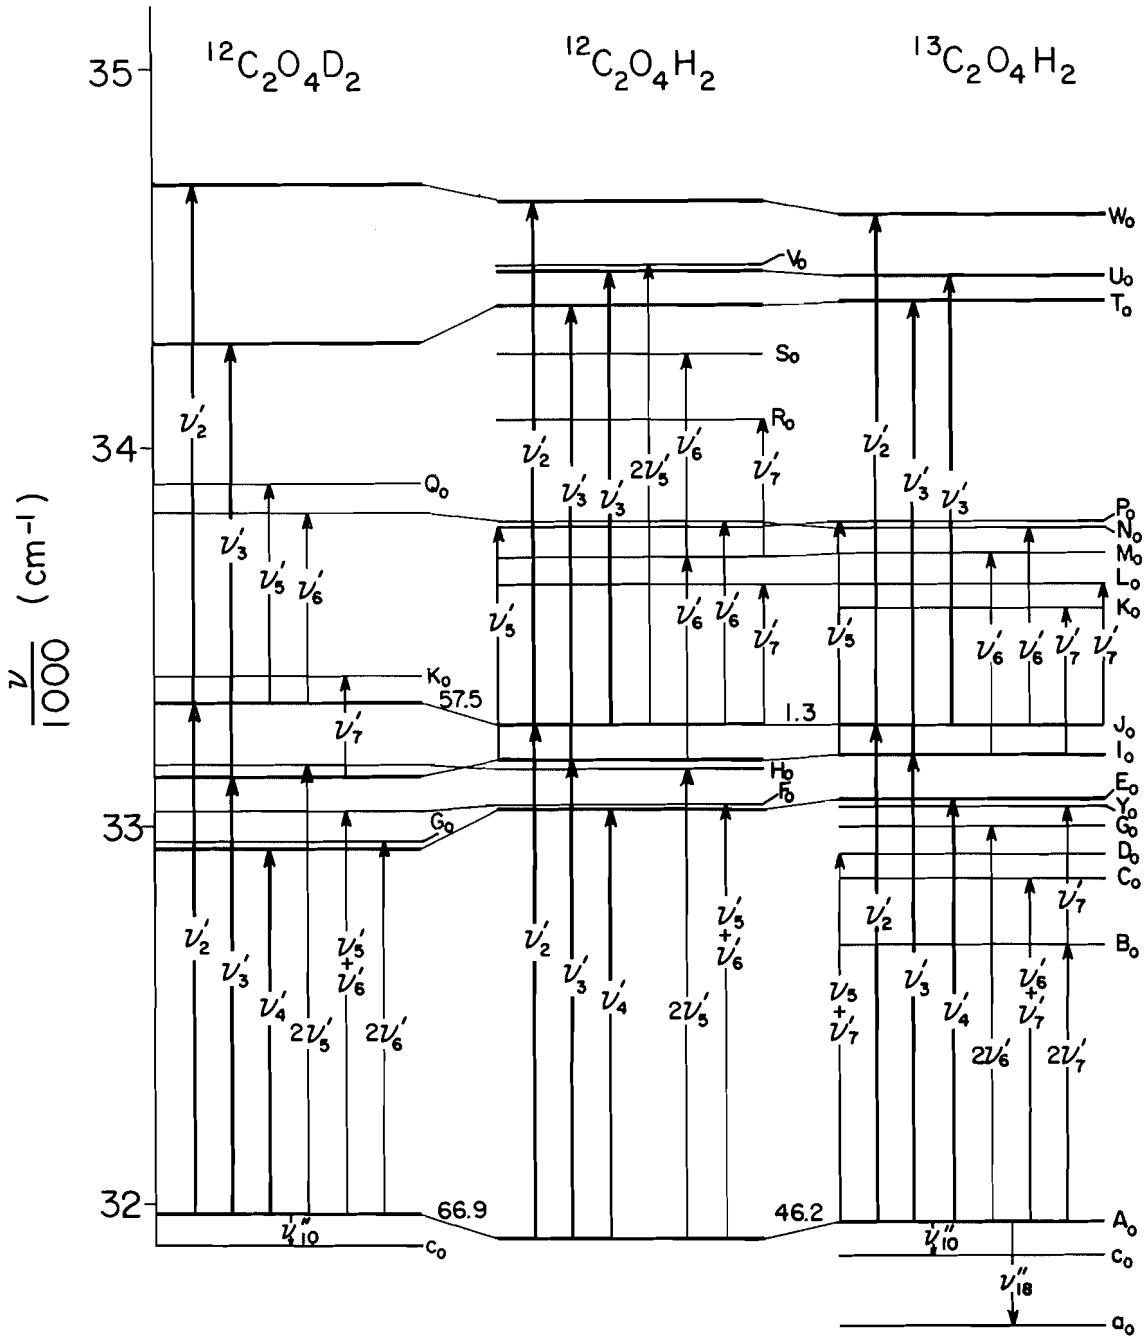

FIG. 4. Vibrational energy levels of the $\tilde{A}$ state of oxalic acid, oxalic acid-d_2, and oxalic acid-$^{13}C_2$, based on the R-branch heads in Fig. 2. For simplicity, sequence bands and other hot bands involving ν_{10} and ν_{18} have been omitted except those to the red of the origin.

glyoxal), by the lower torsional frequency in the ground state (89 vs. 127 cm^{-1} in glyoxal), and by the much smaller increase in the torsional frequency in the first excited state (89 to 132 vs. 127 to 232 cm^{-1} in glyoxal). The molecule in both models of the excited state, for both structures, remains a strongly asymmetric top, with structure **III** definitely closer to prolate; structure **II** is almost midway between prolate and oblate, with κ close to zero (Table 8).

Both planar structures **II** and **III** belong to point-group C_{2h}, and the first excited singlet state, π^*-n_+, is expected to correspond to a $^1A_u - ^1A_g$ transition (1). The two bands in Fig. 3, 2_0^1 and $2_0^1 10_1^1$, will be $^1A_u - ^1A_g$ and $^1A_g - ^1A_u$ vibronic transitions, respectively, with the transition moment parallel to the *c*-axis, perpendicular to the plane of the molecule (11).

Analysis of the rotational structure in Fig. 2 presents some difficulty. Standing out most clearly are the sharp features in the "P-branches" for "*J*" between about 10 and 40, which show an apparently simple regular structure, and the strong "R-branch" heads. Positions of these features were measured from a photographic print to an accuracy of ± 0.02 cm^{-1} and are listed in Tables 10 and 11. Regular rotational features can arise in the spectra of strongly asymmetric tops in a variety of ways (11, 12). In particular, Hollas (12) has discussed the "low-*K*, high-*J*" approximation in which a *prolate* asymmetric top behaves like an *oblate* symmetric top, with the regular features in the spectrum corresponding to coincident band

heads rather than simple rotational lines. If the present spectrum of oxalic acid is treated this way, with the transition moment perpendicular to the plane of the molecule, parallel to the *c*-axis, a type-*C* band is expected for an $A_u - A_g$ transition, and the quadratic coefficient for a regular diverging series of features should equal ΔC. The facts, however, do not support this interpretation of the spectrum. The band contour is that of an *A*-type band; the quadratic coefficient is much larger than

reasonably might be expected for ΔC, and there is no alternation in intensity as might be expected from the presence of two hydrogen atoms in the molecule (cf. Fig. 6.111, p. 426 of ref. 12).

Curiously, if the data in Tables 10 and 11 are analysed as if they correspond to simple P-branches of parallel (type-*A*) bands of an *oblate* nearly-symmetric top, reasonable rotational constants are obtained. Frequencies of such a P-branch should be given approximately by the equation

$$[1]\quad \nu(J,K) = \nu_0 - J(\tilde{B}'' + \tilde{B}') - J^2(\tilde{B}'' - \tilde{B}') - K^2(C'' - C') + K^2(\tilde{B}'' - \tilde{B}')$$

in which $\tilde{B} = \frac{1}{2}(A + B)$.

In Fig. 5 are shown plots of $(\nu_0 - \nu)/J$ against J, which from eq. [1], neglecting the K^2 terms for low K and high J, should give straight lines, with intercepts of $\tilde{B}'' + \tilde{B}'$ and slopes of $\tilde{B}'' - \tilde{B}'$, and values of $\tilde{B}''$ and $\tilde{B}'$ obtained this way are shown in Table 9. These plots were also used to fix the J-numbering since an increase or decrease in the numbering by one led to pronounced curvature in both plots. Similarly, it can be shown that the R-branch head will occur at $J = (3\tilde{B}' - \tilde{B}'')/2(\tilde{B}'' - \tilde{B}')$. Using the values of $\tilde{B}'$ and $\tilde{B}''$ obtained from the P-branch data, the positions of the R-branch heads are calculated to be at $\nu - \nu_0 = 6.91$ and 6.13 cm^{-1} for

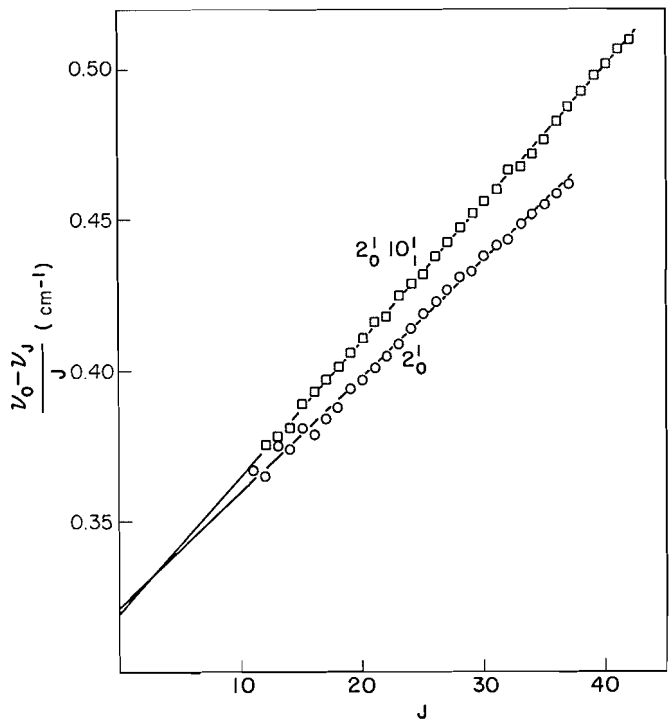

FIG. 5. Plots of $(\nu_0 - \nu_J)/J$ vs. J for the P-branches of the 2_0^1 and $2_0^1 10_1^1$ bands of $^{12}C_2O_4H_2$, used to obtain estimates of $\tilde{B}''$ and $\tilde{B}'$.

the 2_0^1 and $2_0^1 10_t^1$ bands respectively, which may be compared with measurements from the spectra of 6.65 and 5.58 (Fig. 3). The calculated positions of the R-branch heads are extremely sensitive to the value taken for ν_0, and the agreement with the observed positions, which are also not sharply defined, is probably as good as can be expected.

In Table 9, mean rotational parameters from the foregoing analysis are compared with calculated values taken from Table 8. The agreement with the absolute values of $\tilde{B}$ is reasonable for both excited-state models, but the measured $\Delta\tilde{B}$ values are compatible only with model 2, in which the C—C bond length was decreased half as much as in glyoxal (discussed earlier). Uncertainties in the analysis and the calculations preclude any choice between structures **II** and **III**. There is a real and appreciable difference in $\Delta\tilde{B}$ between the two bands in Fig. 3, which is in fact reflected throughout the medium resolution spectrum (Fig. 2) in which the R-head of the first sequence band is always noticeably sharper than the sequence origin. The larger $\Delta\tilde{B}$ in the sequence bands presumably reflects inertial defects associated with the out-of-plane torsional motion.

It is not clear why such a simple rotational analysis should apparently be applicable to the sharp features in Fig. 3. One possibility is that they correspond to a single ($K_a'' = 0$, $K_a' = 0$) sub-band of a parallel transition, and that all other sub-bands for $K_a' > 0$ are weakened and broadened by predissociation, as is observed, for example, in the $\tilde{B}-\tilde{X}$ system of diimide (13). There is certainly diffuse absorption underlying the sharp features in Fig. 3, and weak diffuse Q-branches are also evident as expected for $K_a' > 0$ (cf. Fig. 110, p. 262, ref. 11); diffuse absorption could also contribute to the strong R-branch heads. The molecule should certainly be predissociated in the excited state, with yields of photolysis close to unity throughout the whole absorption system, independent of pressure, and fluorescence extremely weak (2).

It is also not clear why the sharp features in Fig. 3 should resemble a type-*A* rather than a type-*C* band, as shown by the lack of a strong Q-branch and the fit of the data to $\tilde{B} = \frac{1}{2}(A + B)$ and not to $\tilde{B} = \frac{1}{2}(B + C)$ (Tables 8 and 9). Proper understanding of this rotational structure must await measurement of a band less overlapped by sequence bands and diffuse absorption, perhaps the (0,0) band at reduced temperatures, to which contour analysis could be applied. The low vapour pressure and weak absorption makes this experimentally difficult.

Acknowledgements

I am grateful to Mr. M. Barnett and Mr. J. M. Parsons for assistance in photographing and measuring the spectra, and to Dr. D. A. Ramsay for helpful discussions. I am also grateful to one of the referees for pointing out several errors, and problems in the original rotational analysis.

An FT-ir study of *cis*- and *trans*-dichlorodiammineplatinum(II) bound to inosine-5′-monophosphate

H. A. TAJMIR-RIAHI AND T. THEOPHANIDES

Département de Chimie, Université de Montréal, Montreal (Qué.), Canada H3C 3V1

Received November 2, 1983

H. A. TAJMIR-RIAHI and T. THEOPHANIDES. Can. J. Chem. **62**, 1429 (1984).

Inosine-5′-monophosphate disodium salt (5′-IMPNa$_2$) reacts with *cis*-dichlorodiammineplatinum(II) (*cis*-DDP) and its *trans*-isomer (*trans*-DDP) to give complexes of the type *cis*- and *trans*-Pt(NH$_3$)$_2$(IMPNa$_2$)$_n$Cl$_2$.xH$_2$O, n = 1 or 2 and Pt(IMPNa$_2$)$_n$Cl$_2$.xH$_2$O, where n = 1, 2, or 3 and x = 0–6. In the 1:2 platinum complexes the nucleotide binds only to the N$_7$-atom of the purine ring system, while in the 1:1 metal complexes there is indication for Pt–carbonyl interaction (bridging or chelation) in addition to the N$_7$-bonding at neutral pH values with *cis*-DDP.

Solution FT-ir studies (H$_2$O and D$_2$O) showed that the 1:1 species formed with *cis*-DDP at neutral pH's behaved differently from those with *trans*-DDP. The carbonyl stretching vibration of the free base at 1685 cm^{-1} (H$_2$O) and 1670 cm^{-1} (D$_2$O) exhibited marked spectral changes in intensity, shifting, and shape upon complexation, whereas the reaction with the *trans*-isomer produced only slight perturbations in the above region.

H. A. TAJMIR-RIAHI et T. THEOPHANIDES. Can. J. Chem. **62**, 1429 (1984).

Le sel de l'inosine-5′-monophosphate (5′-IMPNa$_2$) réagit avec le *cis*-dichlorodiammineplatine(II), (*cis*-DDP) et son isomère-*trans* (*trans*-DDP) et forme des complexes de type *cis*- et *trans*-Pt(NH$_3$)$_2$(IMPNa$_2$)$_n$Cl$_2$.xH$_2$O et Pt(IMPNa$_2$)$_n$-Cl$_2$.xH$_2$O, où n = 1, 2 ou 3 et x = 0–6. Dans ces complexes 1:2, le nucléotide est fixé au platine par l'azote N$_7$ de l'anneau purique, tandis que dans les complexes 1:1 avec le *cis*-DDP et à pH neutre le nucléotide est fixé au platine par l'azote N$_7$ et le carbonyle C$_6$=O (liaison pontée ou chelatée).

Des études spectroscopiques ir-TF en solution (H$_2$O et D$_2$O) montrent que l'espèce 1:1 formée avec le *cis*-DDP à pH neutre se comporte différemment du complexe formé avec le *trans*-DDP. La fréquence de valence de la liaison carbonyle de la base libre à 1685 cm^{-1}(H$_2$O) et à 1670 cm^{-1} (D$_2$O) montre des modifications importantes en intensité, déplacement, et forme de la bande, lorsque il se forme le complex *cis*-DDP, au contraire l'isomère *trans* ne produit que de très faibles perturbations à cette bande.

[Traduit par le journal]

Introduction

Since the discovery of the antitumor activity of *cis*-DDP and other related platinum compounds (1), which seem to bind DNA in tumor cells (2), several attempts have been made (2–7) to explain the mechanism of action of *cis*-DDP *in vitro* and *in vivo*. The N$_7$-bonding of mononucleotides (GMP, IMP, and AMP) to the *cis*-DDP and other metals has been reported both in solid state and in solutions (8). However, the possibility of a direct metal–carbonyl interaction, in addition to N$_7$-bonding, has been the subject of a long controversy (8, 9). It has been suggested (2) that the effectiveness of the platinum antitumor agent is based on the interaction of the drug with the guanine bases at N$_7$ in the GC pairs (7, 10, 11) in nucleic acids and also on the interaction with the O$_6$ of the carbonyl group of guanine (12, 13). Such an interaction could lead to deprotonation of N$_1$ of the guanine residue and eventually lead to a mispairing of guanine with thymine and finally cause the cell death (2, 13*c*). Several attempts have been made (12–14) to demonstrate the direct metal–carbonyl coordination in addition to the N$_7$-bonding; however, no crystallographic evidence could be obtained. Recently, the structural analysis of a series of platinum blue compounds containing DNA components (uracil and thymine derivatives) showed (15–17) direct metal–carbonyl bonding as well as Pt–nitrogen interaction (bridging). Bau *et al.* have recently analysed (18) the crystal structure of Cu$_4$(5′-IMPH$_{-1}$)$_2$(*o*-phen)$_4$(H$_2$O)$_4^{2+}$ in which two of the Cu(II) cations show N$_7$—O$_6$ bonding (bridging) while the two other Cu(II) ions show N$_1$- and phosphate bonding.

More recent spectroscopic studies (19, 20) showed that platinum(II) could interact with a guanosine residue and lead to the formation of a direct metal–carbonyl bonding, if the reaction was performed under basic conditions (pH = 9–10). These studies are concerned with the tautomeric conversion of a keto-imine (A) to an enol-imine (B) form, in acidic and basic solutions, respectively. On the basis of the above observations it was concluded that the deprotonation of the B form at basic pH values in the presence of platinum or other metal cations could lead to the formation of a negatively charged oxygen atom at O_6^- which would give a chelated metal–nucleobase compound linked to the metal via the N$_7$-atom and the carbonyl oxygen atom of the guanine residue at O$_6$. Most recently, it has been shown theoretically (21) that if a monomer complex in 1:1 ratio is formed between Pt(NH$_3$)$_2$Cl$_2$ and a guanine residue of DNA, the most stable bonds formed would be those of N$_7$—Pt—O$_6$ chelation.

The marked similarities of 5′-IMP coordination chemistry to that of guanosine-5′-monophosphate (5′-GMP), prompted us to study the interaction between 5′-IMPNa$_2$ and *cis*- and *trans*-DDP at neutral pH's. The present solution infrared study shows that there is a metal–carbonyl interaction in the case of 1:1 complexes in addition to the Pt—N$_7$ bond only with the *cis*-DDP and not with the *trans*-DDP.

In the present work the different behaviour of *cis*- and *trans*-interaction towards 5′-IMPNa$_2$ in solution and in several solid isolated platinum(II)–nucleotide complexes is described. Furthermore, a correlation between the spectral changes and the coordination sites used by the mononucleotide, with possible assignments of the ir vibrational frequencies is given. The

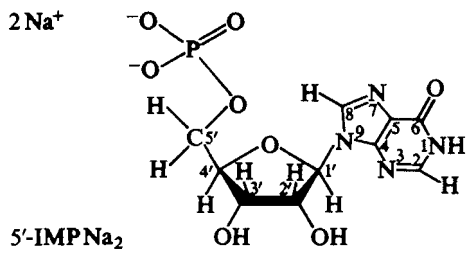
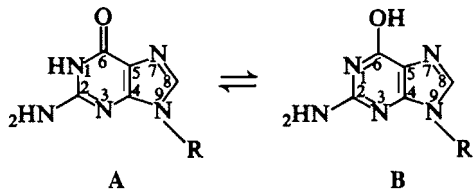
structure of 5′-IMPNa$_2$ with the numbering of the atoms is illustrated below.





Experimental

Materials

5′-IMP in acid and sodium salt forms were purchased from Sigma Chemical Company. D_2O (99.8) was from Cambridge Isotope Laboratories. K_2PtCl_4 was from Johnson Matthey Chemicals, and it was converted to *cis*- and *trans*-DDP by published methods (22, 23) and purified as reported (24). All the other chemicals were reagent grade and used as supplied.

Preparation of the stock solutions

Solutions of the platinum compounds were prepared by mixing the *cis*- and *trans*-DDP with an IMPNa$_2$ solution in H_2O or D_2O to give a 1 : 1 ratio (0.05 mol) and were kept in the dark with constant shaking for a period of 8 days. The pH (pD) of the solutions was adjusted to 7.0 ± 0.2 with 0.1 *N* NaOH (NaOD) or $HClO_4$ ($DClO_4$). The solution pH values were measured every day before and after recording the spectra with a Fisher Accumet Model 630 pH meter, and for D_2O solutions the meter reading was corrected as described in the literature (25).

Synthesis of the platinum compounds

The Pt(II) compounds with 5′-IMPNa$_2$ were prepared by the addition of stoichiometric amounts of K_2PtCl_4 or *cis*- and *trans*-DDP to the solution of the mononucleotide in 200 mL water, in the presence of appropriate amounts of NaCl at room temperature and at pH = 7. The solutions were kept in the dark for one week and then the amount of water was reduced to 50 mL under low pressure at 50°C. Ethanol (50 mL) was then used to precipitate the compound. This was washed with ethanol several times, then dried over $CaCl_2$ and analyzed to show a composition of $[Pt(IMPNa_2)_n]Cl_2.xH_2O$, where n = 1, 2, or 3 and x = 4−6. The *cis*- or *trans*-DDP give compounds of the formula $[Pt(NH_3)_2(IMPNa_2)_n]Cl_2.xH_2O$, where n = 1 or 2 and x = 0−2. The compounds and hygroscopic, soluble in water or acidic solutions, but not in common organic solvents. They show high values of molar conductivity Λ_M (400−80 Ω^{-1} cm^2 mol^{-1}) at 25°C in water solutions. This is mainly due to the presence of Na^+ ions (26) associated with the 5′-IMPNa$_2$, preventing us to draw a conclusion on the ionic nature of these compounds. The analytical data are given in Table 1.

FT-ir spectra

Infrared spectra have been recorded on a DIGILAB FTS-15C/D Fourier Transform Infrared Interferometer equipped with a wide range HgCdTe detector (Infrared Associates, New Brunswick, NJ), a KBr Beam Splitter and a Globar source.

A sealed BaF_2 cell (International Crystal Laboratories) with a nominal path length of 0.0124 cm was used (for solutions) and the instrument was purged with nitrogen.

Normally 500 to 1000 interferograms of 2048 points were recorded with an optical velocity of 1.2 cm s^{-1} and a maximum optical retardation of 0.25 cm, co-added and Fourier transformed with four levels of zero filling for a spectral resolution of 4 cm^{-1}.

The interferograms of the D_2O solutions were apodized with a triangular function while water liquid and vapor was subtracted from the absorbance spectra of the aqueous solutions, then the resulting spectrum was smoothed using a Lorentzian function $F(X) = 1/1 + X^2/CVF^2$ where X is the distance of the point being weighted (in points) from the current point and CVF is the convolution factor, "CVF = 1" approximately. This is a common procedure which affects, however the resolution by a factor of 2, which corresponds to an effective resolution of 8.

Conductance measurements

The molar conductivities of the Pt−IMP compounds were measured on a conductoscope, E365B Metrohm.

Elemental analysis

The Pt(II) content has been determined by atomic absorption. C, H, and N were analysed by Schwarzkopf Microanalytical Laboratory (USA). The halide was determined as silver halide.

Results and discussion

Interaction of cis- *and* trans-*$Pt(NH_3)_2Cl_2$ and 5′-IMPNa$_2$ in solution*

Figure 1 shows the recorded FT-ir spectra of the *cis*- and *trans*-DDP with 5′-IMPNa$_2$ for the 1 : 1 ratio in H_2O at 27°C and pH = 7, after 1 day, 5 days, and 8 days. Figure 2 shows the corresponding reactions in D_2O solutions under similar conditions. The strong and broad absorption band at 1685 cm^{-1} in water solutions related mainly to the C_6=O stretching vibration (27, 28) of the free 5′-IMPNa$_2$, exhibited considerable intensity changes (shifting and splitting) between day *1* and day *5* and finally shifted to a lower frequency near 1635 cm^{-1} between days *5* and *8* upon *cis*-DDP complexation. For the *trans* isomer a small shift of that band towards higher frequencies ($\Delta\bar{\nu}$ = 5 cm^{-1}) was observed (Fig. 1). Similar trends were observed for the C_6=O stretching vibration at 1670 cm^{-1} in D_2O solutions upon interaction with *cis*- and *trans*-DDP. The shifting of the carbonyl stretching vibration towards a lower frequency ($\Delta\bar{\nu}$ = 50 cm^{-1}) with the *cis*-DDP, and that there was no change upon reaction with the *trans*-DDP is clearly a positive indication of an interaction of the *cis*-DDP with the carbonyl group (bridging or chelation). It is worth noting that the solid state complexes isolated from the above aqueous solutions after standing for a period of *8* days by precipitation with ethanol showed similar spectral changes in the carbonyl stretching region (Fig. 3). The carbonyl stretching frequency of 5′-IMPNa$_2$ at 1675 cm^{-1} shifted to a lower frequency at 1622 cm^{-1} in the spectrum of the structurally known (18) $[Cu_4(IMP_{-H})_2(o\text{-phen})_4(H_2O)_4^{2+}]^{2+}$, where a bridging Cu—$N_7O_6$—Cu has been observed. This carbonyl band shifted towards a higher frequency at 1680 cm^{-1} in the spectrum of the known (29) $[Cu(IMP)(dpa)(H_2O)]_2$ compound, where there is no Cu−purine interaction, the copper being linked only to the phosphates. The infrared study of the structurally known $[Cu(IMP).H_2O]_n$ (30) showed that the carbonyl stretching vibration of the free nucleotide at about 1680 cm^{-1} appeared at 1690 cm^{-1} upon base metalation and this is characteristic of an uncomplexed carbonyl group, metal-bonding is through the N_7- and the phosphate oxygen atoms here. A similar trend was found in the ir spectra of the structurally characterized (12, 31) $[cis\text{-}Pt(NH_3)_2(IMP)_2]^{2+}$, where the Pt-bonding is through the

N_7-atom in both purine rings. The spectral changes occurred for the carbonyl group of the 5′-$IMPNa_2$ in different coordination environments are given in Table 2. Recently, Lippert *et al.* have reported (15) an X-ray structural and infrared analysis of several metal–methylthyminato complexes of *cis*-DDP and Ag^+ that showed direct metal–carbonyl bonding. It was shown that the C=O stretching vibration of the free nucleobase at 1660 cm^{-1} exhibited shifting towards lower frequencies upon direct Pt(II) or Ag–carbonyl interaction, whereas when the carbonyl did not interact with the metal there was no considerable perturbation of this vibrational frequency (15). Similar behaviour was observed in an infrared study (32) of a series of methylthymine compounds with CH_3Hg^+ and Ag^+ cations. The direct coordination of the Ag – carbonyl oxygen atom caused splitting and shifting of the C=O stretching vibration of the free base to a lower frequency in the Ag–methylthymine compound, while N_3-coordination of the CH_3Hg^+ moiety did not alter the position of the carbonyl absorption band considerably. It has been also suggested (19) that deprotonation of N_1^- of the guanine nucleobase moiety under basic conditions in the presence of the $Pt(en)^{2+}$ cation could lead to the formation of N_7—Pt—O_6 chelation. The N_7—Pt—O_6 interaction was also proposed (33) in the guanosine reaction with $PtenCl_2$ from nmr spectra of the $[Pt(en)(Guo)]^{2+}$ complexes. It is interesting to note that the solution studies of *cis*- and *trans*-DDP with 5′-$GMPNa_2$ at neutral conditions showed similar shifting and splitting of the C_6=O stretching frequency from 1690 cm^{-1} to about 1600 cm^{-1} upon *cis*-complexation, whereas the *trans*-DDP interaction produced no alteration in this frequency (34).

The distinct spectral similarities in the carbonyl region of the [*cis*-$Pt(NH_3)_2(IMP)]Cl_2$ and that of the structurally known $[Cu_4(IMP)_2(o\text{-phen})_4(H_2O)_4^{2+}]$ (Table 2) are indicative of a bridging platinum–IMP compound via the oxygen atom of the carbonyl group and the N_7-atom of the imidazol ring with a possible dimer formula, $[Pt_2(IMP)_2(NH_3)_4(H_2O)]^{2+}$. This is under investigation in our laboratory and attempts are being made to obtain single crystals of this material for X-ray analysis. The spectral similarities of the [*trans*-$Pt(NH_3)_2(IMP)_2]Cl_2$ to that of the structurally known (12, 31) N_7-bonded [*cis*-$Pt(NH_3)_2(IMP)_2]^{2+}$ compound (see Table 2) indicate that only N_7-bonding with platinum exists in the *trans*-IMP compound.

The absorption bands at about 1595, 1560, and 1535 cm^{-1} in the spectrum of the free base assigned to the skeletal vibrations (27, 28) of the ring system showed marked intensity changes upon *cis*-interaction (Fig. 1), whereas with the *trans*-isomer only the imidazole band at 1535 cm^{-1} exhibited changes indi-

cating an N_7-bonding (Fig. 1). Since the C_6=O and the C=C stretching vibrations of the ring system are strongly coupled, it seems that upon carbonyl coordination the double bond stretching region is strongly affected as a consequence of uncoupling and delocalization of the π electrons in the heterocyclic ring and the exocyclic C_6=O group.

Solid-state platinum–IMP complexes

Structural analysis of $[Pt(NH_3)_2(IMPNa_2)_2]^{2+}$ shows (12, 31) that the Pt(II) ion is bonded to the N_7-atoms of both purine rings and to two NH_3 groups in a square plane arrangement. Furthermore, the coordination polyhedron around each Na^+ ion is completed by the sugar OH groups and water molecules. The carbonyl and the phosphate groups are hydrogen bonded to metal-coordinated H_2O molecules. In this work the FT-ir spectra of 5′-IMPNa$_2$ and its defined platinum compounds have been recorded and compared with that of the structurally known $[Pt(NH_3)_2(IMP)_2]^{2+}$. This comparison has allowed the observation of the characteristic features of each structural type of compound obtained here and the establishment of a correlation between the spectral changes and the binding sites used by the 5′-IMPNa$_2$ molecule. The results obtained are discussed for the two different regions, namely, 3700–2700 cm^{-1} and 1800–400 cm^{-1}. In the region 3700–2700 cm^{-1} the asymmetric and symmetric stretching vibration (27, 28) of NH, OH, H_2O, CH, and CH_2 groups of the free base are observed and showed no appreciable changes upon metalation. The rearrangement of the strong hydrogen bonding network of the free nucleotide (36) in the crystal structure of the platinum compound (12, 31) caused small shifts of the bands to higher frequencies. The main features of the spectra of the solid compounds with possible assignment are given in Table 3.

Drastic spectral changes occurred in the 1800–400 cm^{-1} region of the spectra upon complexation. A strong and broad absorption band at 1680 cm^{-1} of the free 5′-IMPNa$_2$ molecule, mainly related (27, 28) to the C_6=O stretching frequency, showed considerable intensity changes and shifted towards lower frequencies in the spectra of the 1:1 *cis*-$[Pt(NH_3)_2(IMP)]Cl_2$ and K[P(IMP)Cl$_3$] complexes (Figs. 3, 4 and Table 3). The shift of the carbonyl stretching frequency to lower frequencies ($\Delta\bar{\nu}$ = −35 cm^{-1}) in the spectra of these compounds is indicative of metal–carbonyl interaction. Similar observations have been made by Bau *et al.* (18) in the spectra of $[Cu_4(IMP)_2(o\text{-phen})_4(H_2O)_4]^{2+}$, where the Cu(II) ion binds to N_7 and O_6 of two IMP molecules (Table 2). On the other hand, the carbonyl stretching vibration of the free ligand at 1680 cm^{-1} shifted towards higher frequencies at about 1690 cm^{-1} in the spectra of all the other platinum–IMP complexes studied here (Figs. 3, 4, and Table 3). Similar high shifts have been observed for the structurally analysed (12, 31) *cis*-$[Pt(NH_3)_2(IMP)_2]^{2+}$ compound, where the platinum coordination takes place only through the N_7-atom of the imidazol ring (Table 2).

Three other absorption bands with medium intensities at about 1590, 1550, and 1520 cm^{-1} assignable mainly to the skeletal C_4—N_3, C_4—C_5, and C_4—N_9 stretching vibrations,

respectively (27, 28), exhibited major intensity changes upon metal complex formation (Figs. 3, 4, and Table 3). The changes observed in these vibrational frequencies are mainly due to the N_7- and/or O_6 bonding, where both coordination sites (N_7- and O_6) are involved. The perturbation of the above vibrations is much stronger (Figs. 1–3) in the case of *cis*-$[Pt(NH_3)_2(IMP)]Cl_2$ and $K[Pt(IMP)Cl_3]$ than in the other complexes.

The absorption band with medium intensity at 1480 cm^{-1} mainly related to the C_8—N_7 stretching and C_8—H bending vibrations (35) shifted to a higher frequency in the spectra of the complexes. The shift of this band ($\Delta\bar{\nu}$ = 5–20 cm^{-1}) towards higher frequencies is consistent with the C=N^+ frequency. Since it has been found (38) that the C=N^+ groups have in general higher frequencies than the parent C=N groups, therefore, it seems that metalation (39) or protonation (40) of the C=N group slightly increases this vibrational frequency.

The other absorption bands at about 1380, 1346, 1333, 1260, and 1217 cm^{-1} have been attributed mainly to the purine ring vibrational frequencies (27, 41). They showed marked spectral changes (intensity changes and shifting) upon N_7-metalation (Table 3). These absorption bands are assigned to the N_7—C_8, C_8—N_9, C_5—N_7 stretchings and C_8—H bending vibrations. An absorption band with medium intensity at 688 cm^{-1} assigned to the ring breathing mode (27) appeared at a higher frequency in the spectra of the complexes (Table 3). Similar behaviour was observed for this absorption frequency in a series of N_7-metalated 5′-GMP complexes and is characteristic of N_7-bonding (35).

Phosphate vibrational frequencies

The vibrational frequencies of mononucleotides together with their metal-complexes have been discussed earlier (35). The ir spectra of 5′-$IMPNa_2$ show five absorption bands in the region 1100–400 cm^{-1} assignable to the phosphate group PO_3^{2-} vibrational frequencies (42): 1072 cm^{-1} (broad and strong) assigned to the PO_3^{2-} degenerate stretching; 976 cm^{-1} (strong) assigned to PO_3^{2-} symmetric stretching; 825 cm^{-1} (medium intensity) assigned to the ribose–phosphate stretching, and two other absorption bands at about 525–550 and 420–480 cm^{-1} assigned to the symmetric and degenerate deformation modes of the PO_3^{2-} group, respectively (Table 3).

The two absorption bands at 1072 and 976 cm^{-1} are sensitive to a direct metal–phosphate coordination. The FT-ir spectra of the structurally known (30, 43) $[Cu(IMP).H_2O]_n$ and $[Zn(IMP).H_2O]_n$ containing direct metal–phosphate bonding, showed shifting and splitting of these two bands, whereas the infrared spectra of the corresponding Co(II) and Ni(II) complexes (35) containing an indirect metal–phosphate interaction, through coordinated water molecules (44) exhibited no considerable changes in these vibrational frequencies.

The infrared spectra of all platinum complexes studied here showed no changes in the bands at 1072 and 976 cm^{-1} (Figs. 3, 4, and Table 3), indicating no direct metal–phosphate coordination for these Pt–IMP complexes.

Sugar vibrational frequencies

The sugar vibrational frequencies appeared as broad and strong bands at about 3600–2700 cm^{-1} (27, 42), the ribose ring also contains several sharp and fine absorption bands, in the region 1400–400 cm^{-1} that are mainly overlapped by the strong and broad absorption bands of the phosphate group and that of the base bands. The band at 1117 cm^{-1} assigned to the C—O stretching of the ribose ring (42) showed no major changes in the spectra of the platinum complexes (Table 3) which indicates no direct metal–sugar interaction. The other absorption bands at about 900–700 cm^{-1} assigned to the ribose–phosphate stretching vibrations (45) exhibited some intensity changes and shifting (Table 3) upon ligand metalation. The slight changes observed may be due to the conformational changes around the ribose–phosphate bond (46, 47) or to conformational changes of the sugar ring due to the direct or indirect metal–phosphate interaction.

Conclusion

Based on the comparison of spectroscopic changes from structurally known *cis*-$[Pt(NH_3)_2(IMP)_2]^{2+}$ and other Cu–IMP derivatives and the platinum compounds synthesized here, the following concluding remarks can be made: (*a*) The interaction between *cis*-DDP and 5′-$IMPNa_2$ in aqueous solutions leads to the formation of N_7–O_6 complexes with most probably N_7–O_6 bridging. The *trans*-isomer interaction gave complexes with an N_7–metal linkage only. (*b*) The other platinum–IMP complexes isolated as solids in this work show N_7-bonding. Only the 1:1 *cis*-$[Pt(NH_3)_2(IMP)]Cl_2$ and $K[Pt(IMP)Cl_3]$ complexes have shown N_7—O_6 bonding (bridging or chelation) as is concluded from ir spectral analysis. (*c*) No direct metal–phosphate complexes both in solution or in the solid state were obtained in this study.

The retroaldol reaction of cinnamaldehyde

J. PETER GUTHRIE,[1] KEVIN J. COOPER, JOHN COSSAR, BRIAN A. DAWSON, AND KATHLEEN F. TAYLOR
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received November 15, 1983

J. PETER GUTHRIE, KEVIN J. COOPER, JOHN COSSAR, BRIAN A. DAWSON, and KATHLEEN F. TAYLOR. Can. J. Chem. **62**, 1441 (1984).

Rate and equilibrium constants have been measured for the hydration and retroaldol reactions of cinnamaldehyde. The equilibrium constant for the 1,4-addition of water to cinnamaldehyde is 4.42×10^{-3}. The rate constants for hydroxide catalyzed reaction, extrapolated to zero hydroxide concentration (to correct for the addition of hydroxide to the aldol carbonyl), are: $k_{12}^0 = 2.20 \times 10^{-3} M^{-1} s^{-1}$; $k_{21}^0 = 0.456 M^{-1} s^{-1}$; and $k_{23}^0 = 9.08 \times 10^{-2} M^{-1} s^{-1}$. The rate of the formation reaction was measured by adding small amounts of acetaldehyde to alkaline solutions of benzaldehyde: $k_{32}^0 = 0.63 M^{-1} s^{-1}$ and $K_{overall} = 1480 M^{-1}$. The course of the synthetically useful reaction of acetaldehyde with benzaldehyde is discussed in the light of these results.

J. PETER GUTHRIE, KEVIN J. COOPER, JOHN COSSAR, BRIAN A. DAWSON et KATHLEEN F. TAYLOR. Can. J. Chem. **62**,1441 (1984).

On a mesuré les constantes de vitesse et d'équilibre des réactions d'hydratation et rétroaldolique du cinnamaldéhyde. La constante d'équilibre de l'addition-1,4 de l'eau sur le cinnamaldéhyde est de $4,42 \times 10^{-3}$. Les constantes de vitesse pour la réaction catalysée par l'hydroxyde, extrapolées à une concentration d'hydroxyde égale à zéro (pour corriger l'addition de l'hydroxyde sur le carbonyle de l'aldol), sont de $k_{12}^0 = 2,02 \times 10^{-3} M^{-1} s^{-1}$; $k_{21}^0 = 0,456 M^{-1} s^{-1}$; et $k_{23}^0 = 9,08 \times 10^{-2} M^{-1} s^{-1}$. On a mesuré la vitesse de la réaction de formation en ajoutant de petites quantités d'acétaldéhyde à des solutions alcalines de benzaldéhyde: $k_{32}^0 = 0,63 M^{-1} s^{-1}$ and $K_{global} = 1480 M^{-1}$. A la lumière de ces résultats, on discute du déroulement de la réaction de l'acétaldéhyde avec le benzaldéhyde qui présente de l'intéret comme réaction de synthèse.

Introduction

We have reported a study (1) of the equilibrium constants for aldol condensation reactions. Since we consider it important to have a reliable set of rate and equilibrium constants for a set of simple aldol reactions and need such data for an examination of rate–equilibrium correlations for the aldol reaction, we have undertaken the investigation of the kinetics of various aldol reactions, studying them in the reverse sense to avoid the difficulties of side reactions which plague the kinetics of aldol reactions in the forward sense. The case of cinnamaldehyde is of interest because it is cited as a textbook example of thermodynamic control in the aldol reaction (2), yet has not been studied kinetically. Meyers and Durandatta (3) have reported a method for preparing the aldol corresponding to cinnamaldehyde, i.e. 3-hydroxy-3-phenylpropanal. This compound proved essential to the investigation, because the equilibrium constant for dehydration to cinnamaldehyde is quite large and cannot be measured directly by studying the hydration of cinnamaldehyde, yet must be known to sort out the kinetics.

Results and discussion

The retroaldol reaction of cinnamaldehyde can be followed spectrophotometrically; when cinnamaldehyde, as a solution in acetonitrile, is injected into aqueous sodium hydroxide solution there is a smooth disappearance of the absorbance at 285 nm, which follows a simple first-order rate law; see Fig. 1. Thus one can see no sign of the two stages which are believed to be essential for this reaction; eq. [1]

$$[1]\quad \mathrm{Ph{-}CH{=}CH{-}CHO} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} \mathrm{Ph{-}CHOH{-}CH_2{-}CHO}$$

$$\mathrm{Ph{-}CHOH{-}CH_2{-}CHO} \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} \mathrm{Ph{-}CHO + CH_3{-}CHO}$$

The two phases of the reaction are quite apparent when the aldol, 3-phenyl-3-hydroxy-2-butanal, is injected into aqueous sodium hydroxide solution; the absorbance at 285 nm first rises and then, about 1000 times more slowly, falls again; see Fig. 2. The rate of the slow fall in absorbance is essentially identical

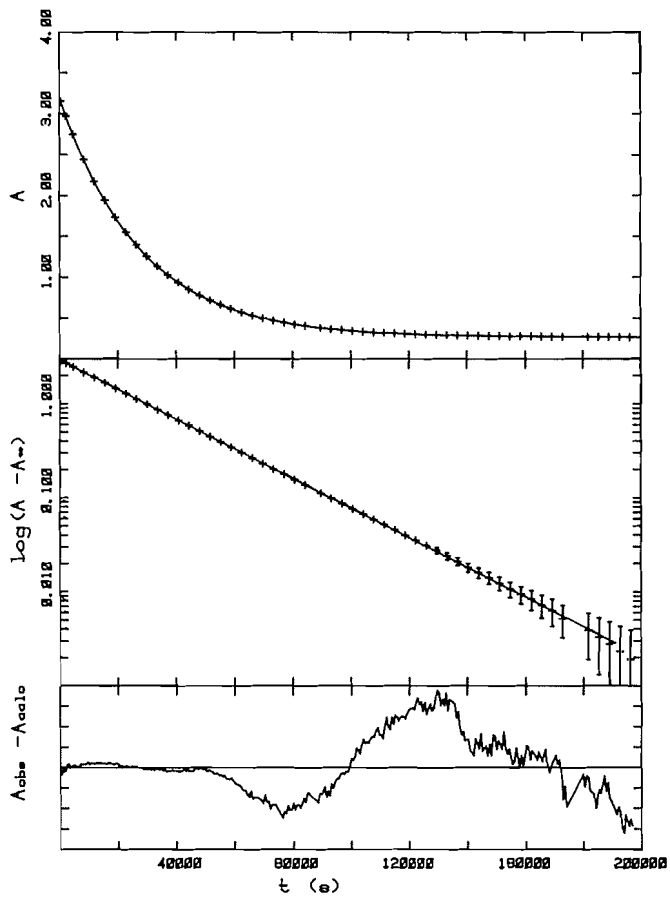

FIG. 1. Absorbance vs. time for the reaction of $7.82 \times 10^{-5} M$ cinnamaldehyde in 0.1 *N* NaOH. Followed at 285 nm, using 10-cm cells.

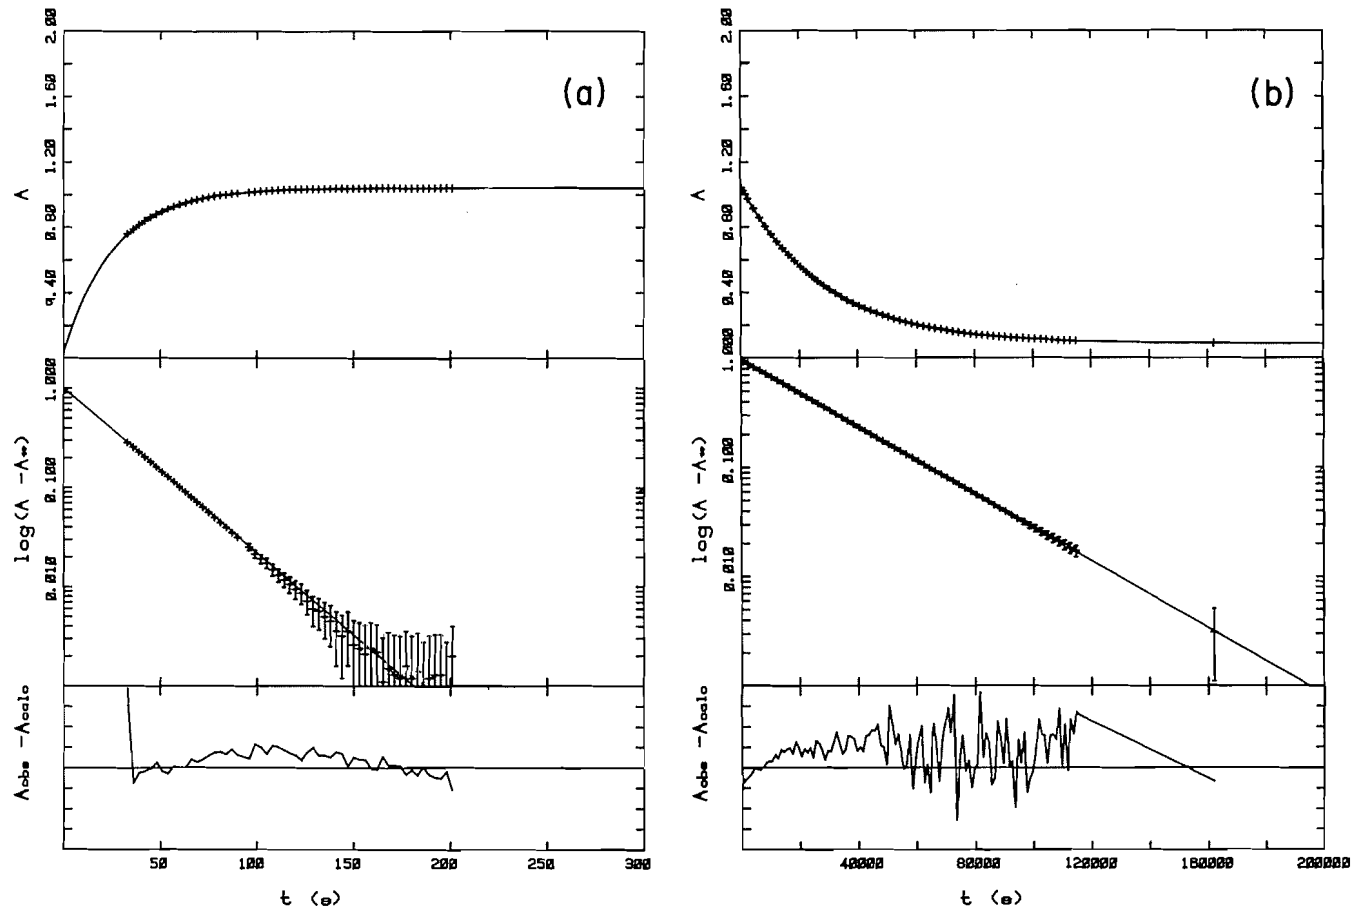

FIG. 2. Absorbance vs. time for the reaction of 5.33×10^{-6} *M* 3-hydroxy-3-phenylpropanal in 0.1 *N* NaOH. (a) Initial phase, appearance of cinnamaldehyde. (b) Final phase, disappearance of cinnamaldehyde. Followed at 285 nm, using 10-cm cells.

to the rate of disappearance of the absorbance of cinnamaldehyde when the latter is used to initiate reaction. Analysis of the two-phase kinetic data permits evaluation of the rate constants. For the system of interest, where a low concentration of aldol product undergoes retroaldol cleavage, the rate of the second-order aldol formation process, described by k_{32}, is negligible. A rigorous solution of the kinetics equations is possible following the procedure described in Moore and Pearson (4), but to an excellent approximation the two stages of the reaction can be treated independently. For the fast reaction,

$$A = A_\infty + \alpha \exp(-\lambda_2 t)$$

and for the slow reaction,

$$A = A_\infty + \beta \exp(-\lambda_3 t)$$

where: $-\alpha \cong C_2^0 k_{21} \epsilon_1/\lambda_2$; $\beta \cong C_1^0 \epsilon_1$ starting from cinnamaldehyde; $\beta \cong C_2^0 k_{21} \epsilon_1/\lambda_2$ starting from the aldol; $\lambda_2 \cong k_{21} + k_{23}$; $\lambda_3 \cong k_{12}/(1 + k_{21}/k_{23})$; ϵ_1 = extinction coefficient for cinnamaldehyde; and C_i^0 = initial concentration of cinnamaldehyde ($i = 1$) or aldol ($i = 2$). Then:

$$k_{21} = |\alpha|\lambda_2/C_2^0\epsilon_1$$

$$k_{23} = \lambda_2 - k_{21}$$

$$k_{12} = \lambda_3(1 + k_{21}/k_{23})$$

Table 1 shows the results of applying this analysis to the experimental data for cinnamaldehyde and the corresponding aldol. The individual rate constants show the expected first-order dependence upon the hydroxide concentration, but there is clearly a decrease in k'_{21} and k'_{23}[2] as the hydroxide concentration increases; see Fig. 3. This phenomenon has been observed for crotonaldehyde, and is attributed to ionization of the carbonyl hydrate, or equivalently to addition of hydroxide to the aldehyde carbonyl, leading to a lower concentration of the kinetically significant form of the aldol. Since both k'_{21} and k'_{23} respond to hydroxide concentration in the same way, it is best to fit $\lambda_2/[OH^-]$ to the equation:

$$[3] \quad \lambda_2/[OH^-] = (\lambda_2^0/[OH^-])/(1 + a[OH^-])$$

Similar equations apply to k'_{21} and k'_{23}, but propagation of errors leads to greater scatter, and the effect is close to the limits of detection for k'_{23}. We calculated values for k_{21}^0 and k_{23}^0 from the individual values of k'_{21} and k'_{23}, and then averaged them. Table 2 shows the second-order rate constants for the individual steps evaluated in this work, extrapolated to zero hydroxide concentration.

The value of a which we obtained was 4.66 ± 1.17; it is easily shown that $a = K_a/K_w\,(1 + 1/K_{hydration})$. The hydration constant may be estimated, using the linear free energy

[2] We use the following notation for rate constants: k_{ij} are the rate constants obtained from the analysis described at a given value of $[OH^-]$; $k'_{ij} = k_{ij}/[OH^-]$ are the apparent second-order (third-order for k_{32}) rate constants; and k_{ij}^0 are the second- or third-order rate constants corrected for hydrate ionization to zero hydroxide ion concentration. All rate constants refer to species at covalent hydration equilibrium.

relation[3] of Greenzaid *et al.* (5) as 3.52 ± 1.4 (error based on the errors reported by Greenzaid *et al.* for their parameters). This calculation required a σ* value for Ph—CH(OH)—CH_2, which we estimate as σ* ($PhCH_2CH_2$) + σ* ($HOCH_2CH_2$) − σ* (CH_3CH_2), using values of σ* from Perrin *et al.* (3), and estimating σ* ($HOCH_2CH_2$) as 0.4σ* ($HOCH_2$) (3). K_a for the hydrate can be calculated (7) as 13.16. These values lead to a predicted value of $a = 5.4$, in excellent agreement with the value which was obtained.

In order to determine the overall equilibrium constant for cinnamaldehyde formation we measured kinetics of the reaction of benzaldehyde and acetaldehyde in aqueous alkali. It is necessary to use excess benzaldehyde and low, limiting quantities of acetaldehyde in order to keep the acetaldehyde concentration low enough to preclude formation of crotonaldehyde. This condition can be satisfied because of the very favorable overall equilibrium constant for the condensation of acetaldehyde with benzaldehyde. Kinetics were carried out with 0.1 *N* NaOH and varying concentrations of benzaldehyde. In each case the acetaldehyde was ca. 1/10 the benzaldehyde concentration, low enough to ensure pseudo first-order kinetics, high enough to give a useful absorbance change superimposed on the background absorption of benzaldehyde. Although the background absorbance was small enough for the two lower concentrations of benzaldehyde to permit the reaction to be followed at 285 nm, for the highest concentration of benzaldehyde, 3.03×10^{-3} *M*, it was necessary to follow the reaction at 310 nm. A solution of benzaldehyde in 0.1 *N* NaOH showed no absorbance change over times comparable to those for the kinetics runs.

The observed rate of reaction is the rate of approach to equilibrium and includes both forward and reverse reaction, as is shown in eq. [2]

$$[2] \quad k_{obs} = k_{rev} + k_{fwd}\,[PhCHO]$$

Figure 4 shows that the points measured starting with cinnamaldehyde fall at the intercept of a line fitting the runs for approach to equilibrium, as they must by our interpretation. The best line through the points is $k_{obs} = (3.58 \pm 0.03) \times 10^{-5} + (0.0452 \pm 0.00402)$[PhCHO], corresponding to an overall apparent equilibrium constant of 1263 ± 113 M^{-1}.

The rate constant in the forward direction can be expressed in terms of the rate constants of eq. [1] as $k_{fwd} = k_{32}k_{21}/(k_{21} + k_{23})$. Using values of k^0_{23} and k^0_{21} from Table 2 we obtain $k'_{32} = 0.56 \pm 0.05\ M^{-2}\ s^{-1}$.

As we discussed above for the reverse reactions, we must consider the effect of hydroxide addition to the starting materials for the condensation, in order to extract the true third-order rate constants for the hydroxide catalyzed reaction at zero hy-

[3] For RR'C=O + $H_2O \rightleftharpoons$ RR'C(OH)$_2$, $\log K_{hydration} = 1.70\Sigma\sigma^* + 2.03\Delta - 2.81$, where Δ = number of aldehydic protons and $K_{hydration}$ is dimensionless, i.e. activity of water = 1 (5).

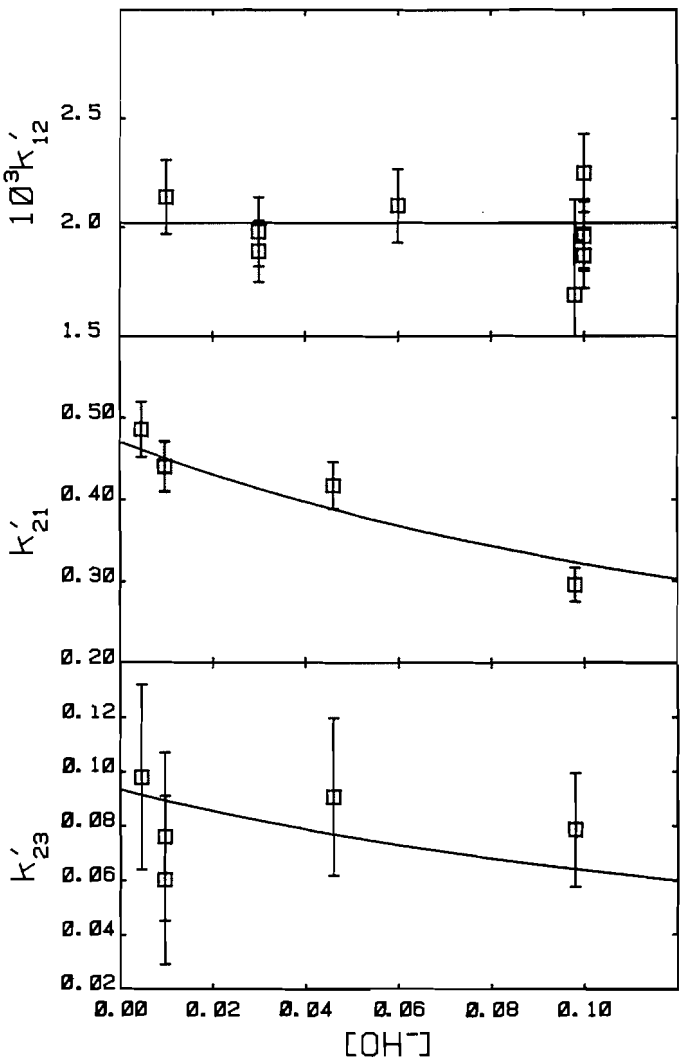

FIG. 3. Dependence of apparent second-order rate constants upon $[OH^-]$. Lines for k'_{21} and k'_{23} calculated using equations of the form of [3] with $a = 4.66$. The line for k'_{12} represents the weighted average value.

droxide concentration. It may be shown that the correction takes the form:

$$k'_{fwd} = k^0_{fwd}/(1 + b[OH^-])\,(1 + c[OH^-])$$

where b and c are analogous to a, defined above for the ketol, but refer to acetaldehyde and benzaldehyde respectively. From the literature values for the pK_a of acetaldehyde hydrate (13.48, ref. 8) and for the hydration constant for acetaldehyde (1.06, ref. 9) we can calculate that b is 1.48; from the equilibrium constant for addition of hydroxide to benzaldehyde (0.18, ref. 10) and the knowledge that hydration is negligible (10), we can calculate that c is 0.18. For 0.1 N NaOH these values lead to a net correction of $k'_{fwd} = k^0_{fwd}/1.17$. Thus $k^0_{32} = 0.65 \pm 0.06$. A similar correction must be made to $K_{overall}$, leading to $K^0_{overall} = 1480 \pm 133\ M^{-1}$.

We have previously reported equilibrium constants for the aldol condensation leading to cinnamaldehyde, and for the dehydration step (1). For the dehydration, our value, based on thermodynamic calculations using disproportionation reactions, was 424 ($\Delta G^0 = -3.59 \pm 1.63$); from the kinetics measured in this work the equilibrium constant is 226 ± 17 ($\Delta G^0 = -3.21 \pm 0.04$), in satisfactory agreement. For the

TABLE 2. Rate constants at zero hydroxide concentration for the retro-aldol reaction of cinnamaldehyde[a]

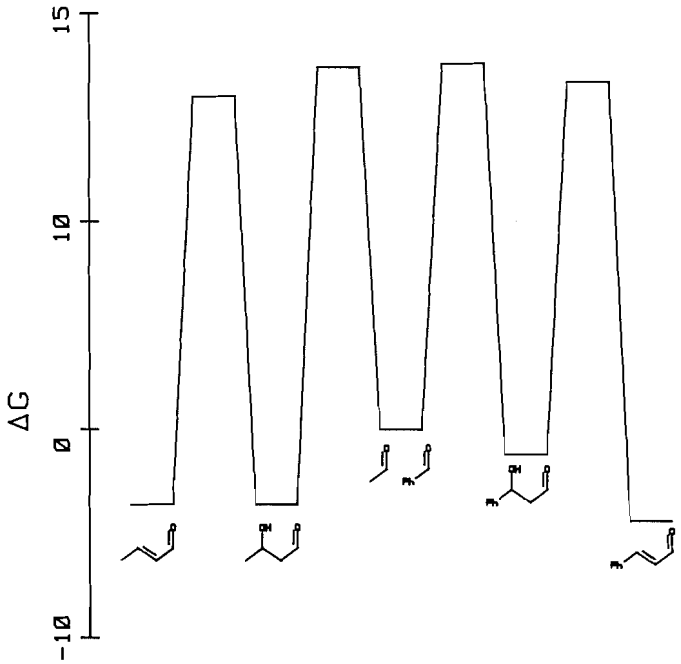

FIG. 5. Reaction coordinate diagram for the system starting with acetaldehyde plus benzaldehyde. Free energies of activation were calculated from the rate constants in Table 2 and ref. 11.

reactions to estimate thermochemical quantities gives useful approximate values.

It is instructive to draw a reaction coordinate diagram for the condensation of acetaldehyde with benzaldehyde, now that the rate constants are available from this and earlier work (11). Figure 5 shows such a diagram, and makes it clear that 3-hydroxybutanal and 2-butenal will indeed accumulate in the early stages of a reaction, but will be replaced by the more slowly formed but more stable cinnamaldehyde at long times. This picture is of course oversimplified, in that it ignores the possible further aldol reactions of 3-hydroxybutanal and 2-butenal which would be expected to be competitive with the simple condensations.

In terms of this simple picture, we can calculate that for initial concentrations of [acetaldehyde] = [benzaldehyde] = 0.01 *M*, the final concentration of cinnamaldehyde will be 0.00684 *M*, with 0.00085 *M* each of 3-hydroxybutanal and crotonaldehyde, so that the yield is 68% and r = [cinnamaldehyde]/([acetaldol] + [crotonaldehyde]) = 4.03. The predicted yield of cinnamaldehyde and the predicted value of r both increase at higher concentrations: 84%, $r = 7$ at 0.1 *M* reactants; 90%, $r = 9$ at 1 *M* reactants. This is likely to prove illusory because of the increasing rate of polymerization to be expected at higher concentrations of acetaldehyde; polymerization was neglected in these simple calculations, as were the effects of solubility.

Experimental

Materials

Cinnamaldehyde was redistilled in vacuum before use.

3-Hydroxy-3-phenylpropanal

This was prepared following the procedure reported by Meyers *et al.* (3); their procedure, involving reaction of the lithium salt of 2-methyl-2-thiazoline with benzaldehyde, led to a product with the nmr spectrum expected (3) for 2-(2-hydroxy-2-phenylethyl)-2-thiazoline, as did the aluminum amalgam reduction of this material to give 2-(2-hydroxy-2-phenylethyl)-1,3-thiazolidine. When mercuric ion catalyzed hydrolysis was attempted we did not obtain a material with the nmr spectrum reported (3), but rather an oil, which gave a solid on addition of n-pentane to an ether solution. The solid was recrystallized from $CHCl_3$; mp 115–117°C (dec.). The 2,4-dinitrophenylhydrazone of this solid was prepared and recrystallized from ethanol/ethyl acetate; mp 250–251°C (lit. (12) mp for cinnamaldehyde 2,4-DNP 252°C). A solution of 2-(2-hydroxy-2-phenylethyl)-1,3-thiazolidine, (0.5 g) in acetonitrile (ca. 15 mL) was added over 5 min to a solution of $HgCl_2$ in 80% acetonitrile–water (10 mL) at 0°C. After stirring 10 min, water (15 mL) was added, and the white precipitate filtered off. The filtrate was extracted using 1:1 ether–pentane (4 × 25 mL), the extracts were dried (Na_2SO_4), and the solvent evaporated to leave a pale yellow oil (0.25 g). The nmr spectra ($CDCl_3$) of this oil were consistent with 3-hydroxy-3-phenylpropanal; ^1H, δ: 9.6 (t, 1H), 7.2 (s, 5H), 5.1 (t, 1H), 3.4 (s, 1H), 2.7 (d of t, 2H); ^{13}C, δ: 202.0 (CHO), 142.8, 128.6, 127.8, 125.6 (Ph), 68.9, 52.1 (CH(OH), CH_2).

The sample was dissolved in a few milliliters of ether, and an equal volume of petroleum ether was added. The bright yellow precipitate was filtered off, and the clear, essentially colorless solution was cooled with Dry Ice; fluffy white crystals formed and were filtered off, but melted below 0°C on warming. This material was used for kinetics.

Methods

The procedure for kinetics was as previously described (13, 14). The reactions were followed at 285 nm, except for the formation experiment at highest benzaldehyde concentration. For this experiment the adsorption due to benzaldehyde at 285 nm was too high to permit the reaction to be followed, so it was followed at 310 nm.

The final solutions from retroaldol kinetics experiments had absorbances appropriate to the anticipated products. This will be illustrated for the 7th entry in Table 1. The initial and final absorbances (based on the least-squares parameters) were 3.20 and 0.267 respectively. The corresponding apparent extinction coefficients were 2.4×10^4 and 2.0×10^3. The extinction coefficient for cinnamaldehyde at 285 nm is 2.3×10^4 (12); that for benzaldehyde at 285 nm is 1.5×10^3, (this work). From the overall equilibrium constant of 1480 M^{-1} we can calculate that 2.65×10^{-7} *M* cinnamaldehyde would be present at equilibrium, along with 1.31×10^{-5} *M* benzaldehyde (and 1.31×10^{-5} *M* acetone, which would make a negligible contribution to the absorbance). The calculated apparent extinction coefficient is 1.96×10^3. The agreement is satisfactory, confirming that the reactions are well behaved.

ipso Nitration. XXIV.[1] Nitration of 2-methylphenols. Formation and rearrangement of 6-methyl-6-nitrocyclohexa-2,4-dienones

GORDON G. CROSS, ALFRED FISCHER, GEORGE N. HENDERSON, AND TREVOR A. SMYTH
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received January 17, 1984

GORDON G. CROSS, ALFRED FISCHER, GEORGE N. HENDERSON, and TREVOR A. SMYTH. Can. J. Chem. **62**, 1446 (1984).

Nitration of *o*-cresol and some mono-, di-, and trimethyl derivatives in acetic anhydride at −60°C gives 6-methyl-6-nitrocyclohexa-2,4-dienones. The dienones are more labile than the isomeric 4-methyl-4-nitrocyclohexa-2,5-dienones and, if the 2-position of the dienone is not blocked, undergo regiospecific rearrangement to 6-nitro-*o*-cresols. 2,3,6-Trimethyl- and 2,3,5,6-tetramethylphenol also give a 2,5-dienone with nitro attached to a secondary carbon.

GORDON G. CROSS, ALFRED FISCHER, GEORGE N. HENDERSON et TREVOR A. SMYTH. Can. J. Chem. **62**, 1446 (1984).

La nitration, dans l'anhydride acétique et à −60°C, de l'*ortho*-crésol et de quelques-uns de ses dérivés mono-, di- et tri-méthylés conduit à des méthyl-6 nitro-6 cyclohexadiène-2,4 ones. Ces dièmones sont plus labiles que les méthyl-4 nitro-4 cyclohexadiène-2,5 ones isomères et, si la position 2 de la dièmone n'est pas bloquée, elles subissent une transposition régiospécifique conduisant aux nitro-6 *o*-crésols. Les triméthyl-2,3,6 et tétraméthyl-2,3,5,6 phénols conduisent aussi à des diène-2,5 ones dans lesquelles le groupe nitro est attaché à un carbone secondaire.

Introduction

Nitration of 2,4,6 trisubstituted phenols often gives nitrodienones (2, 3). Normally the 2,5-dienone is formed, although formation of a 2,4-dienone has been reported (4). Nitration of *p*-methylphenyl acetate gives 4-methyl-4-nitrocyclohexa-2,5-dienone, and other 4-alkylphenyl acetates give the corresponding dienones (5–7). *p*-Cresol behaves similarly. In this report we describe the formation of 6-methyl-6-nitrocyclohexa-2,4-dienones by nitration of *o*-cresol and some of its derivatives.[2]

Results and discussion

Nitration of *o*-cresol (**1***a*) with nitric acid in acetic anhydride at temperatures from −40°C to −78°C gave a mixture of dienone **2***a*, 6-nitro-*o*-cresol (**4***a*), and 4-nitro-*o*-cresol (**5***a*) (Scheme 1). The amount of dienone obtained increased with decrease in temperature. At −78°C the ratio of the products **2***a*/**4***b*/**5***b* was 67:19:14, at −60°C 62:22:16, and at −50°C 56:23:21. *o*-Cresol was also nitrated in [$^2H_6$]acetic anhydride, so that the ^1H nmr spectrum of the methyl region could be determined. Dideuterio-*o*-cresol **1***b* was nitrated to form the corresponding dienone **2***b*. Dienone **2***a* isomerized slowly ($t_{1/2}$ ≈ 7 h) in the reaction mixture at −40°C and survived for only a few minutes when the temperature was raised to −20°C. 6-Nitro-*o*-cresol (**4***a*) was formed, regiospecifically. Addition of the reaction mixture at −60°C to fourteen times its volume of ether at −60°C, followed by careful addition of excess ice-cold 30% aqueous ammonia to the resulting solution and further work-up at low temperature (< −20°C), gave a mixture of **2***a* and nitrocresols. Pure dienone **2***a* can be obtained by passing an ethereal solution of the dienone and nitrophenols through a column of alumina at −78°C.[3] The isolated dienone also isomerized regiospecifically to **4***a*. When the reaction mixture was quenched at −60°C and work-up was carried out at 0°C a mixture of the nitrophenols **4***a* (85%) and **5***a* (15%) was obtained, but no dienone. Under these conditions the dienone isomerized to **4***a* during the work-up process.

Identification of the dienones, all of which were labile and some, including **2***a*, at temperatures as low as −40°C, was by ^1H nmr spectroscopy. The ^{13}C nmr spectra were also obtained for several of the compounds and these confirmed the structural assignments. Dienone **2***a* had ^1H nmr peaks in acetic anhydride at δ 6.17 (d, 1), 6.6 (m, 2), 7.31 (8 lines, 1) ppm. These were assigned as follows. The spectrum of the deuterated dienone **2***b* showed that peaks at δ 7.31 and 6.60 ppm arise from the 3- and 5-protons. The peak at δ 6.17 ppm in the spectrum of **2***a*, which exhibits a simple 10-Hz coupling, must be the 2H, since the 4-H would exhibit strong couplings to the two adjacent protons, and the 4-H, together with the 3-H, must be responsible for the complex absorption at δ 6.6 ppm. Confirmation of the correctness of these assignments was provided by the close correspondence of the computer simulated spectrum to the observed spectrum. The methyl protons in **2***a* were observed in [$^2H_6$]acetic anhydride at δ 1.74 ppm and, for the isolated dienone dissoved in [^2H]chloroform, at δ 1.84 ppm. These absorptions are above the range of aromatic methyl protons and are characteristic of methyl *ipso* to nitro. In the ^{13}C nmr spectra of **2***a* the tetrahedral and carbonyl carbon atoms have characteristic absorptions at δ 91.3 and 192.5 ppm respectively.

Nitration of 2,3-dimethylphenol (**1***c*) in acetic anhydride at −60°C gave 5,6-dimethyl-6-nitrocyclohexa-2,4-dienone (**2***c*) (52%) and the 4-nitro- and 6-nitrophenols **5***c* (24%) and **4***c* (24%), respectively. The dienone decomposed when the temperature of the reaction mixture was raised, although some was still present after 25 min at 0°C indicating that dienone **2***c* is more stable than **2***a*. Regioselective formation of the 6-nitrophenol **4***c* was indicated by the fact that, after neutralization of excess nitric acid with triethylamine and warming the reaction mixture to ambient temperature, this isomer constituted 75% of the product **4***c* and **5***c* although in the nitration mixture **4***c* and **5***c* were originally present in equal amount.

Nitration of 2,4-dimethylphenol (**1***d*) in acetic anhydride at −60°C gave two dienones in approximately equal amounts. Since both dienones exhibited the 10-Hz coupling characteristic of vicinal vinyl protons they were assigned as 4,6-dimethyl-6-nitrocyclohexa-2,4-dienone (**2***d*) and 2,4-dimethyl-6-nitrocyclohexa-2,5-dienone (**3***d*). The third possible isomer, 2,4-dimethyl-6-nitrocyclohexa-2,4-dienone, does not have vicinal vinyl protons. After 60 min at −60°C all of the substrate had been nitrated and the ratio of the products **2***d*/**3***d*/**4***d* was

SCHEME 1

38:44:18. Dienone **2***d* disappeared after 20 min at −40°C. Dienone **3***d* survived to 0°C. The assignments are in accord with the observation that 2,5-dienones are more stable than 2,4-dienones. The peaks of 2,4-dimethyl-6-nitrophenol (**4***d*) increased as the dienones disappeared and **4***d* was the only species observed when the reaction mixture, after 90 min at −60°C, was treated with triethylamine (to remove excess nitric acid) before warming to ambient temperature. When the reaction mixture was warmed without destroying the excess nitric acid, the 2,4-dimethyl-6-nitrophenol was further nitrated to 2,4-dimethyl-4,6-dinitrocyclohexa-2,5-dienone or 4,6-dimethyl-2,6-dinitrocyclohexa-2,4-dienone (^{1}H nmr δ 7.07(s) and 7.82(s) ppm).

Nitration of 2,5-dimethylphenol in acetic anhydride at −40°C gave variable results. In some experiments yields of the dienone **2***e* were in excess of 90% but in others only 60% **2***e* was obtained together with **4***e* and **5***e*. At −20°C the dienone slowly isomerized, regioselectively, to the 6-nitrophenol **4***e*. Neutralization of excess nitric acid with trimethylamine followed by warming to ambient temperature gave a mixture of **4***e* (66%) and **5***e* (34%). Careful quenching of the reaction mixture at −65°C and work-up at low temperature gave a product which, when extracted into [^{2}H]chloroform, was **2***e* (80%) and **4***e* (20%) (the 4-nitrophenol **5***e* is rather insoluble in chloroform). When this solution was warmed to ambient temperature, the dienone isomerized to the 6-nitrophenol **4***e*.

Nitration of 2,6-dimethylphenol in acetic anhydride at −60°C gave 2,6-dimethyl-6-nitrocyclohexa-2,4-dienone (**2***f*) and 2,6-dimethyl-4-nitrophenol (**5***f*). Much of the nitrophenol precipitated and was filtered off at −78°C. The filtrate contained a mixture of **2***f* (80%) and **5***f* (20%). When the temperature was raised to −20°C the nitrophenol began to disappear and was replaced by a species with a broad singlet at δ 7.74 ppm, assigned as 2,6-dimethyl-4,6-dinitrocyclohexa-2,4-dienone. At 0°C no nitrophenol remained. At ambient temperature both dienones disappeared and were replaced by a species assigned as 2-methyl-4-nitro-6-nitromethylphenol. Careful neutralization of the reaction mixture at −65°C with aqueous ammonia and work-up at low temperature gave, after dissolution of the product in [^{2}H]chloroform at −60°C, a solution of dienone **2***f*. The nitrophenol was insoluble in chloroform at this temperature. The dienone isomerized to the nitrophenol **5***f* on warming this solution to ambient temperature. When the reaction mixture was worked up by pouring the solution into a mixture of ether and aqueous ammonia at 0°C, a mixture of **5***f* (66%) and 2,6-dimethyl-*p*-benzoquinone (34%) was obtained.

Nitration of 2,3,5-trimethylphenol at −60°C gave, after 17 min, the dienone **2***g* (77%) and the nitrophenols **4***g* and **5***g* (23%). After 35 min at −60°C the peaks of the nitrophenols had disappeared, presumably as a result of crystallization, as yellow crystals had formed. On warming to 0°C a broad singlet appeared at δ 6.42 ppm, assigned as either 2,6-dinitro-3,5,6-trimethylcyclohexa-2,4-dienone or its 4,6-dinitro isomer. Careful neutralization of the reaction mixture with aqueous ammonia at −65°C and work-up at low temperature gave a mixture of the dienone **2***g* (70%) and the nitrophenols **4***g* (8%) and **5***g* (22%). The dienone rapidly isomerized regiospecifically to **4***g* at ambient temperature, and over 24 h at −20°C, in [^{2}H]chloroform. When the reaction mixture was worked up by pouring into a mixture of ether and ammonia at −60°C and the mixture then warmed to 0°C, a mixture of **2***g* (15%), **4***g* (57%), and **5***g* (28%) was obtained.

Nitration of 2,3,6-trimethylphenol in acetic anhydride at −60°C gave three intermediate dienones. The species which had broad singlets at δ 5.85 and 6.90 ppm and which isomerized quantitatively to **5***h* is assigned the 2,5-dienone structure **3***h* on the basis of the nmr spectrum (the highest field proton is attached to the tetrahedral carbon) and the relative stability (dienones with nitro attached to a secondary carbon are not expected to be stable because of the facile tautomerization to the nitrophenol). The dienone with the broadened doublets at δ 6.24 and 7.05 ppm (J = 7 Hz) is assigned as **2***h* and that which had a singlet with fine splitting at 6.44 ppm is assigned as **2***i*. These assignments follow from the observation that in the ^{1}H nmr spectra of 2,4-dienones the 3-H is at lowest field and the 4-H and 5-H absorb at similar positions at higher field. Furthermore, the 7-Hz coupling identifies the **2***h* structure. The **2***i* structure would exhibit a 10-Hz coupling. The initial ratio of **3***h*/**2***h*/**2***i* at −60°C was 30:32:38. When the temperature was raised to −40°C, **3***h* disappeared over 45 min and an equal amount of **5***h* was formed. The dienones **2***h* and **2***i* survived for 30 min when the reaction mixture was warmed to ambient temperature. Neutralization of excess nitric acid by the addition of triethylamine to the reaction mixture at −60°C, followed by warming to ambient temperature, gave the nitrophenol **5***h* as the sole product. Careful neutralization of the reaction mixture at −60°C with aqueous ammonia and work-up at low temperature gave a 60:40 mixture of **2***h* and **2***i* which was dissolved in [^{2}H]chloroform–[^{2}H$_3$]acetonitrile. The dienones isomerized to the nitrophenol **5***h* at ambient temperature and some 2,3,5-trimethylbenzoquinone was also formed in the nmr sample.

Nitration of 2,4,6-trimethylphenol in acetic anhydride at

−60°C gave a mixture of the 2,4- and 2,5-dienones **2***i* and **3***j*. Both dienones survived when the reaction mixture was warmed to ambient temperature but **2***j* isomerized to **3***j* over 30 min at that temperature. Careful quenching and work-up of the reaction mixture at low temperature gave a mixture of the two dienones. In [$^2H_6$]acetone at ambient temperature **2***j* isomerized to **3***j* over 2 h and **3***j* isomerized to 2,6-dimethyl-4-nitromethylphenol over 3 days. The isomerization of **3***j* to 2,6-dimethyl-4-nitromethylphenol has been reported previously (9). Pure **3***j* was obtained by crystallization of the crude dienone from ether.

Nitration of 2,3,5,6-tetramethylphenol (**1***k*) in acetic anhydride at −60°C gave two dienones. A species (22%) which exhibited a broad singlet at δ 5.77 ppm and which disappeared when the temperature was raised to −40°C is assigned as **3***k*. The species (78%) which exhibited a broad singlet at δ 6.20 ppm and which survived until the temperature was raised to ambient temperature is assigned as **2***k*.

Prior to the present work the only 2,4-dienone that had been obtained by nitration of phenol was 2,6-di-*tert*-butyl-4-chloro-6-nitrocyclohexa-2,4-dienone from nitration of 2,6-di-*tert*-butyl-4-chlorophenol (4). Ershov and Zlobina also studied the nitration of 2,4,6-trialkylphenols, but obtained only the 2,5-dienones (10). Earlier the corresponding 2,5-dienones had been obtained on nitration of 2,6-di-*tert*-butyl-4-methylphenol (11) and 2,4,6-tri-*tert*-butylphenol (12). Ershov *et al.* also studied the nitration of 2,6-dialkylphenols, but did not observe the formation of dienones (13). However, they deduced from kinetics studies that a transient intermediate was formed in the nitration of a 2,6-dialkylphenol and they assigned this intermediate the 2,5-dienone structure (14). Our results show that formation of the 2,4-dienone occurs readily and extensively in even the simplest substituted phenol (*o*-cresol) and that mesitol, which is known to form a 2,5-dienone (10), also forms a previously undetected 2,4-dienone. The *ortho*-methyl substituent appears to exert a directing effect to the *ipso* position, and particularly so in comparison with unsubstituted positions. *ipso* Nitration occurs to an extent of more than 60% in *o*-cresol, whereas nitration at the unsubstituted 6 position is around 20% and at the 4 position even less. Nitration of phenol and, presumably, the methylphenols is complicated by nitrous acid catalysis which affects the isomer distribution. If nitration via nitrosation is important under our conditions (which would likely require concentrations of nitrous acid $> 10^{-3}$ mol dm^{-3} (15)) it must exhibit a preference for *ipso* attack. The *para* position is more reactive when it is itself substituted – a *para*-methyl group directs to its own *ipso* position – as indicated by the fact that the 2,5-dienone is formed to about the same extent as the 2,4-dienone when 2,4-dimethylphenol is nitrated. Formation of the 2,4-dienones at a rate competitive with 2,5-dienones reflects transition state control. The 2,5-dienone is thermodynamically more stable than the 2,4-dienone, as is shown by the fact that in the case of the dienones from mesitol the 2,4-dienone isomerizes to the 2,5-dienone. The 2,4-dienones are more labile than the 2,5-dienones: the dienone from *p*-cresol survives at ambient temperature, whereas that from *o*-cresol starts to rearomatize at −40°C. In the cases of those 2,4-dienones which have an unsubstituted 2 position, the rearomatization process is regioselective with the nitro group migrating to the 2 position and not the 4 position: the 6-nitrophenol is formed. It was proposed previously that the oxygen function played a role in this process, forming a phenyl nitrate intermediate (8, 16). However, more recently we have observed examples of 1,5 sigmatropic migration of the nitro group in 6-nitrocyclohexa-2,4-dienes (17) and it seems likely that a similar process could be operative in the case of the 2,4-dienones.

Nitration of 2,3,6-trimethylphenol and of 2,3,5,6-tetramethylphenol gave in each case a transient dienone, assigned as the 2,5-dienone, in addition to the expected 2,4-dienones. These 2,5-dienones have the nitro group attached to a secondary carbon and result from addition of the nitronium ion at an unsubstituted nuclear position. They are more labile than the dienones formed by addition of the nitronium ion *ipso* to a methyl group, because of the extremely facile prototropic tautomerization to the nitrophenol. Such a dienone is a likely intermediate in the nitration of a phenol at an unsubstituted position since, in the precursor hydroxynitrocyclohexadienyl cation, deprotonation at oxygen, to give the dienone, should be more rapid than deprotonation at carbon, to give the nitrophenol. However, for most such dienones the reverse protonation at the carbonyl oxygen and eventual deprotonation at carbon is sufficiently rapid for the dienone not to be detectable. In the cases of the dienones **3***h* and **3***k* it is likely that steric hindrance slows up the prototropic processes to an extent such that the dienone lifetime moves into the observable range.

Experimental

The ^{1}H nmr spectra at 90 and 250 MHz were determined using Perkin–Elmer R32 and Bruker WM250 spectrometers, respectively. The latter instrument was also used for ^{13}C nmr determination at 62.9 MHz. Mass spectra were obtained on a Hitachi Perkin–Elmer RMU7 spectrometer. Combined gas chromatography and mass spectrometry was carried out on a Finnigan 3300 system. Gas chromatography was carried out on a Varian 3700 gas chromatograph using a 25-m fused silica SE30 capillary column. *o*-Cresol, 2,3-dimethylphenol, 2,4-dimethylphenol, 2,3,5-trimethylphenol, 2,3,6-trimethylphenol, 2,4,6-trimethylphenol, 2,6-dimethyl-4-nitrophenol, and 2-methyl-4-nitroaniline were from Aldrich. 2,3,4,6-Tetramethylphenol was from Tokyo Kasei. 2,6-Dimethylphenol was from Eastman Kodak. 2,5-Dimethyl-4-nitroaniline was from Pfaltz and Bauer Inc.

4,6-[$^2H_2$]-*o*-Cresol was prepared by adding with stirring PBr_3 (4 cm^3) and *o*-cresol (5.4 g) to D_2O (50 g) under an argon atmosphere (18). The mixture was heated under reflux for 4 h, cooled, and extracted with ether (4 × 50 cm^3). The combined ethereal extract was washed with water, aqueous sodium bicarbonate, and water, dried ($MgSO_4$), and distilled. The 4,6-[$^2H_2$]-*o*-cresol (4.34 g) had bp 190–191°C, ^{1}H nmr ($CDCl_3$) δ: 2.19 (s, 3, C*H*$_3$), 5.41 (s, 1, O*H*), 7.02 (s, 1, 3-*H*), 7.07 (s, 1, 5-H) ppm.

4-Nitro-*o*-cresol (**5***a*) was prepared by diazotization of 2-methyl-4-nitroaniline followed by hydrolysis in boiling aqueous sulfuric acid, following the procedure for *m*-nitrophenol (19). The product was crystallized from methylene chloride – pentane, sublimed (60–100°C, 35 Pa), and the sublimate decolorized with charcoal and recrystallized from methylene chloride to give **5***a*, mp 97–98°C (lit. (20) mp 94.6–95°C); ^{1}H nmr ($CDCl_3$/$(CD_3)_2CO$) δ: 2.27 (s, 3, C*H*$_3$), 6.92 (d, 1, $J_{5,6}$ = 8 Hz, 6-*H*), 7.95 (dd, 1, $J_{5,6}$ = 8 Hz, $J_{3,5}$ = 3 Hz, 5-*H*), 8.02 (d, 1, $J_{3,5}$ = 3 Hz, 3-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ$_c$: 15.8 (*C*H$_3$), 115.0 (*C*-6), 123.8 (*C*-5), 125.6 (*C*-2), 127.0 (*C*-3), 141.0 (*C*-4), 160.4 (*C*-1) ppm; ms (70 eV) *m*/*e* (relative intensity): 153.043 (100, M_r $^{12}C_7{}^1H_7{}^{14}N^{16}O_3$: 153.043), 137 (10), 123 (23), 107 (14), 95 (15), 81 (10), 79 (16), 78 (11), 77 (52).

2,5-Dimethyl-4-nitrophenol (**5***e*) was prepared by diazotization of 2,5-dimethyl-4-nitroaniline followed by hydrolysis of the diazonium salt (19). After recrystallization from ethanol–water **5***e* had mp 124–125°C (lit. (21) mp 117–119°C); ^{1}H nmr ($CDCl_3$/$(CD_3)_2CO$) δ: 2.23 (s, 3, 2-C*H*$_3$), 2.52 (s, 3, 5-C*H*$_3$), 6.73 (s, 1, 6-*H*), 7.92 (s, 1, 3-*H*), 8.25 (br, s, 1, O*H*) ppm; ^{13}C nmr ($CDCl_3$) δ$_c$: 15.2 (2-*C*H$_3$), 21.2 (5-*C*H$_3$), 118.3 (*C*-6), 123.0 (*C*-2), 128.5 (*C*-3), 135.0 (*C*-5),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

141.4 (*C*-4), 158.5 (*C*-1); ms (70 eV) *m/e* (relative intensity): 168 (12), 167.061 (97, M_r $^{12}C_8{}^1H_9{}^{14}N^{16}O_3$: 167.058), 151 (18), 150 (100), 122 (22), 120 (12), 95 (18), 94 (15), 91 (37), 78 (10), 77 (53).

Nitration of o-*cresols*

A solution of nitric acid (15 mmol) in acetic anhydride (4.3 cm^3) at −60°C was added with stirring to a solution of the phenol (5 mmol) in acetic anhydride (9.9 cm^3) at −60°C. A sample of the reaction mixture was transferred to a nmr tube using a precooled pipette stored under argon and the progress of the reaction monitored at −60°C for 60 min and then at 20°C temperature intervals. After 1–2 h the remaining nitric acid in the bulk reaction mixture was neutralized by the addition of excess triethylamine (25 mmol) previously cooled to −60°C and the solution subsequently warmed to ambient temperature. The nitrodienones isomerized to nitrocresols on this treatment and the mononitrocresol(s) were then characterized by ^{1}H nmr. Alternatively, the reaction mixture was poured into a mixture of 30% aqueous ammonia (30 cm^3) and ether (50 cm^3) at −60°C. The resulting mixture was warmed to 0°C, the ether layer separated, the aqueous layer extracted with ether (3 × 50 cm^3), and the combined ethereal extracts washed with brine, dried, and the ether evaporated to yield the mononitrocresol(s).

In order to obtain the ^{13}C nmr spectrum of the nitrodienone it was necessary to remove the acetic anhydride without decomposing the dienone. A mixture of the nitrodienone and nitrocresol(s) was prepared in acetic anhydride at −60°C as described above, but on twice the scale. The solution was poured into ether (400 cm^3) at −60°C and ice-cold 30% aqueous ammonia was added to the stirred solution, a little at a time, so that the temperature did not rise above −60°C. The ethereal layer was decanted off and rapidly washed with brine (2 × 400 cm^3) at −20°C. The ether solution was dried ($MgSO_4$) at −78°C and the ether evaporated at −40°C. The solid residue was swirled with $CDCl_3$ (3 cm^3) at −60°C and the ^{1}H and ^{13}C nmr spectra of the solution determined at that temperature. Finally the solution was warmed to ambient temperature so that the product of isomerization of the nitrodienone could be determined. 4-Methyl-4-nitrocyclohexa-2,5-dienones were more stable than the 2,4-dienones and could be worked up at 0°C.

Prior to the development of the technique for isolation of the dienones, some of the nitration reactions were studied in [$^2H_6$]acetic anhydride in order to determine the ^{1}H nmr shifts of the dienone methyls.

Characterization of nitration products

o-*Cresol* (*1*a)

6-Methyl-6-nitrocyclohexa-2,4-dienone (**2***a*) had ^{1}H nmr (Ac_2O, $(CD_3CO)_2O$) δ: 1.74 (s, 3, CH_3) 6.17 (d, 1, 2-*H*), 6.58 (4-*H*), 6.60 (5-*H*), 7.31 (8 lines, 1, 3-*H*) ppm, $J_{2,3}$ = 9.9, $J_{3,4}$ = 6.7, $J_{3,5}$ = 0.8, $J_{4,5}$ = 9.8 Hz; ($CDCl_3$) δ: 1.84 (s, 3), 6.26 (d, 1, *J* = 10 Hz), 6.54 (2), 7.27 (1) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 23.1 (CH_3), 91.3 (*C*-6), 124.2 and 124.8 (*C*-4 and *C*-2), 136.5 (*C*-5), 142.5 (*C*-3), 192.5 (*C*-1) ppm. 6-Nitro-*o*-cresol (**4***a*) was isolated from the residue obtained on work-up of the nitration mixture. Sublimation (55°C, 1.3 kPa), followed by recrystallization from ether–pentane, gave **4***a*, mp 69–70°C (lit. (22) mp 70°C); ^{1}H nmr ($CDCl_3$) δ: 2.30 (s, 3, CH_3), 6.85 (t, 1, $J_{3,4}$ = 8 Hz, $J_{4,5}$ = 8 Hz, 4-*H*), 7.44 (d, 1, $J_{3,4}$ = 8 Hz, 3-*H*), 7.95 (d, 1, $J_{4,5}$ = 8 Hz, 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 15.7 (CH_3), 119.2 and 122.6 (*C*-4 and *C*-5), 129.5 (*C*-2), 133.4 (*C*-6), 138.1 (*C*-3), 153.7 (*C*-1) ppm; ms (70 eV) *m/e* (relative intensity): 153.042 (100, M_r $^{12}C_7{}^1H_7{}^{14}N^{16}O_3$: 153.043), 137 (24), 123 (33), 111 (26), 109 (28), 107 (24), 105 (22), 97 (41), 95 (40), 91 (26), 85 (22), 83 (34), 82 (20), 81 (38), 79 (27), 77 (65). The minor isomer **5***a* was characterized by comparison of the ^{1}H nmr peaks attributed to the isomer in the mixture with those of the authentic compound.

*4,6-Dideuterio-*o*-cresol* (*1*b)

2,4-Dideuterio-6-methyl-6-nitrocyclohexa-2,4-dienone (**2***b*) had ^{1}H nmr (Ac_2O) δ: 6.60 (s, 5-*H*), 7.30 (s, 3-*H*) ppm; 4-deuterio-6-nitro-*o*-cresol (**4***b*) had δ: 7.54 (s, 3-*H*) and 7.95 (s, 5-*H*) ppm and 6-deuterio-4-nitro-*o*-cresol (**5***b*) had δ: 7.98 (s, 5-*H*), 8.02 (s, 3-*H*) ppm.

2,3-Dimethylphenol (*1*c)

5,6-Dimethyl-6-nitrocyclohexa-2,4-dienone (**2***c*) had ^{1}H nmr (Ac_2O) δ: 6.09 (d, 1, 2-*H*), 6.33 (br d, 1, 4-*H*), 7.26 (dd, 1, 3-*H*) ppm, $J_{2,3}$ = 10.0, $J_{3,4}$ = 6.2, $J_{4,5\text{-}CH_3}$ = 1.1 Hz. 2,3-Dimethyl-6-nitrophenol (**4***c*) and 2,3-dimethyl-4-nitrophenol were isolated from the residue obtained on work-up of the nitration mixture. Sublimation (50°C, 7 Pa), followed by recrystallization of the sublimate from ethanol–water, gave **4***c*, mp 48–49°C (lit. (23) mp 48.5–49°C); ^{1}H nmr ($CDCl_3$) δ: 2.20 (s, 3, 2-CH_3), 2.30 (s, 3, 3-CH_3), 6.75 (d, 1, $J_{4,5}$ = 9 Hz, 4-*H*), and 7.83 (d, 1, $J_{4,5}$ = 9 Hz, 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 11.3 (2-CH_3), 20.5 (3-CH_3), 121.2 and 121.4 (*C*-4 and *C*-5), 126.8 (*C*-2), 131.5 (*C*-6), 147.5 (*C*-3), 153.2 (*C*-1) ppm; ms (70 eV) *m/e* (relative intensity): 167.061 (100, M_r $^{12}C_8{}^1H_9{}^{14}N^{16}O_3$: 167.058), 150 (18), 121 (18), 120 (10), 92 (11), 91 (33), 77 (26). The material which did not sublimate was triturated with ether, the ether solution was washed with brine, the ether was evaporated, and the residue was crystallized from ether–pentane. Recrystallization from ethanol–water gave **5***c*, mp 126–127°C (lit. (24) mp 123–125°C); ^{1}H nmr ($CDCl_3$/$(CD_3)_2CO$) δ: 2.20 (s, 3, 2-CH_3), 2.40 (s, 3, 3-CH_3), 6.79 (d, 1, $J_{5,6}$ = 9 Hz, 6-*H*), 7.65 (d, 1, $J_{5,6}$ = 9 Hz, 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 12.0 (2-CH_3), 16.1 (3-CH_3), 112.5 (*C*-6), 123.9 (*C*-5), 124.9 (*C*-2), 134.3 (*C*-3), 144.3 (*C*-4), 157.2 (*C*-1) ppm; ms (70 eV) *m/e* (relative intensity): 167.057 (100, M_r $^{12}C_8{}^1H_9{}^{14}N^{16}O_3$: 167.058), 150 (99), 122 (14), 120 (10), 104 (14), 95 (19), 94 (22), 91 (40), 79 (10), 78 (12), 77 (60).

2,4-Dimethylphenol (*1*d)

4,6-Dimethyl-6-nitrocyclohexa-2,4-dienone (**2***d*) had ^{1}H nmr (Ac_2O) δ: 6.16 (d, 1, 2-*H*), 6.25 (br s, 1, 5-*H*), 7.19 (d, 1, 3-*H*) ppm, $J_{2,3}$ = 10 Hz, $J_{2,5}$ = 0.5 Hz, $J_{3,5}$ = 1 Hz, $J_{5,4\text{-}CH_3}$ = 1.5 Hz. 2,4-Dimethyl-4-nitrocyclohexa-2,5-dienone (**3***d*) had δ: 6.37 (d, 1, 6-*H*), 6.96 (br, 1, 3-*H*), 7.18 (dd, 1, 5-*H*), $J_{3,2\text{-}CH_3}$ = 1.4 Hz, $J_{3,5}$ = 3.2 Hz, $J_{5,6}$ = 10 Hz. 2,4-Dimethyl-6-nitrophenol (**4***d*) had ^{1}H nmr (Ac_2O) δ: 7.35 (s, 3-*H*), 7.70 (s, 5-*H*) ppm. Work-up of the nitration mixture after quenching at −60°C gave a brown oil. Crystallization from ethanol–water gave yellow-brown crystals, mp 68–70°C. This material was dissolved in hot pentane, then filtered, which removed the brown colour as a gummy material. The filtrate was evaporated and the residue crystallized from ethanol–water to give **4***d*, mp 70–71°C (lit. (25) mp 72°C); ^{1}H nmr ($CDCl_3$) δ: 2.26 (s, 6, 2-CH_3 and 4-CH_3), 7.26 (s, 1, 3-*H*), 7.73 (s, 1, 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 15.6 (2-CH_3), 20.2 (4-CH_3), 121.8 (*C*-5), 128.9 and 129.0 (*C*-2 and *C*-4), 133.1 (*C*-6), 139.4 (*C*-3), 151.7 (*C*-1) ppm; ms (70 eV) *m/e* (relative intensity); 167.057 (99 M_r $^{12}C_8{}^1H_9{}^{14}N^{16}O_3$: 167.058), 137 (10), 121 (10), 119 (10), 111 (12), 109 (13), 97 (17), 95 (18), 93 (12), 91 (30), 86 (100), 85 (12), 83 (15), 81 (18), 77 (24).

2,5-Dimethylphenol (*1*e)

3,6-Dimethyl-6-nitrocyclohexa-2,4-dienone (**2***e*) had ^{1}H nmr (Ac_2O, $(CD_3CO)_2O$) δ: 1.71 (s, 6-CH_3), 6.01 (s, 1, 2-H), 6.46 (d, 1, 4-*H*), 6.61 (d, 1, 5-*H*) ppm, $J_{4,5}$ = 9.7 Hz (the 3-CH_3 peak is obscured by peak(s) of other components); ($CDCl_3$) δ: 1.80 (s, 3, 6-CH_3), 2.20 (s, 3, 3-CH_3), 6.09 (s, 1, 2-*H*), 6.45 (s, 2, 4-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 23.1 (6-CH_3), 23.6 (3-CH_3), 90.1 (*C*-6), 121.8 (*C*-2), 128.0 (*C*-4), 135.3 (*C*-5), 156.1 (*C*-3), 191.9 (*C*-1) ppm. 2,5-Dimethyl-6-nitrophenol (**4***e*) was obtained when the $CDCl_3$ solution of dienone **2***e* was warmed to ambient temperature. Recrystallization of the residue from ethanol–water gave **4***e*, mp 34°C (lit. (26) mp 34–34.5°C); ^{1}H nmr ($CDCl_3$) δ: 2.23 (s, 3, 2-CH_3), 2.51 (s, 3, 5-CH_3), 6.69 (d, 1, $J_{3,4}$ = 8 Hz, 4-*H*), 7.22 (d, 1, $J_{3,4}$ = 8 Hz, 3-*H*), and 10.60 (s, 1, O*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 15.7 (2-CH_3), 22.2 (5-CH_3), 122.9 (*C*-4), 126.6 (*C*-2), 133.8 (*C*-5), 134.9 (*C*-6), 135.9 (*C*-3), 153.6 (*C*-1) ppm; ms (70 eV) *m/e* (relative intensity): 168 (10), 167.063 (94, M_r $^{13}C_8{}^1H_9{}^{14}N^{16}O_3$: 167.058), 150 (42), 120 (43), 106 (11), 97 (12), 95 (27), 94 (11), 93 (13), 92 (28), 91 (45), 83 (13), 81 (12), 78 (11), 77 (36). The presence of the minor isomer **5***e* in the product from nitration was demonstrated by comparison of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

the ^{1}H nmr and glc retention time with those of an authentic sample of **5***e*.

*2,6-Dimethylphenol (**1**f)*

2,6-Dimethyl-6-nitrocyclohexa-2,4-dienone (**2***f*) had ^{1}H nmr (Ac_2O) δ: 6.47 (apparent d, 2, 4-*H* and 5-*H*), 7.09 (m, 1, 3-H) ppm, $J_{3,4}$ = 6, $J_{3,5}$ = 1, $J_{3,2\text{-}CH_3}$ = 1.5, $J_{4,5}$ = 10 Hz; ($CDCl_3$) δ: 1.82 (s, 3, (6-CH_3), 2.00 (s, 3, 2-CH_3), 6.37 and 6.50 (m, 2, 4-*H* and 5-*H*), 7.04 (br d, 1, 3-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 15.8 (2-CH_3), 23.2 (6-CH_3), 91.3 (*C*-6), 124.7 (*C*-4), 133.0 (*C*-2), 134.1 (*C*-5), 138.9 (*C*-3), 193.4 (*C*-1) ppm. On warming the $CDCl_3$ solution of the dienone to ambient temperature, 2,6-dimethyl-4-nitrophenol (**5***f*) was formed. Crystallization from ethanol–water gave **5***f*, mp 172–174°C (lit. (27) mp 170.5–170.6°C); ^{1}H nmr ($CDCl_3$/$(CD_3)_2CO$) δ: 2.30 (s, 6, 2- and 6-CH_3), 7.87 (s, 2, 3- and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 15.9 (2- and 6-CH_3), 123.8 (*C*-2 and *C*-6), 124.5 (*C*-3 and *C*-5), 140.9 (*C*-4), 157.9 (*C*-1) ppm; ms (70 eV) *m/e* (relative intensity): 167.059 (100, M_r $^{12}C_8{}^1H_9{}^{14}N^{16}O_3$: 167.058), 137 (19), 91 (41), and 77 (56). The identity was confirmed by comparison of the glc retention time with that of an authentic sample. 2,6-Dimethyl-*p*-benzoquinone, obtained with **5***f* when the nitration mixture was quenched with ammonia and worked up, had ^{1}H nmr ($CDCl_3$) δ: 1.96 (s, 6) and 6.50 (s, 2) ppm and identical retention time on glc with that of the authentic quinone.

*2,3,5-Trimethylphenol (**1**g)*

3,5,6-Trimethyl-6-nitrocyclohexa-2,4-dienone (**2***g*) had ^{1}H nmr (Ac_2O) δ: 5.97 (s, 1, 2-*H*), 6.26 (s, 1, 4-*H*) ppm; ($CDCl_3$) δ: 1.78 (s, 3, 6-CH_3), 1.94 (s, 3, 5-CH_3), 2.15 (s, 3, 3-CH_3), 5.98 (br s, 1, 2-*H*), 6.18 (br s, 1, 4-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 18.0 (5-CH_3), 23.1 (6-CH_3), 23.8 (3-CH_3), 94.5 (*C*-6), 119.1 (*C*-2), 125.2 (*C*-4), 145.0 (*C*-5), 158.1 (*C*-3), 194.4 (*C*-1) ppm. Crystallization from ether–pentane of the mixture of nitrophenols **4***g* (74%) and **5***g* (26%), obtained on work-up of the nitration mixture after all of the dienone **2***g* had isomerized, gave **4***g*, mp 80–81°C (lit. (28) mp 78–79°C); ^{1}H nmr ($CDCl_3$) δ: 2.16 (s, 3, 2-CH_3), 2.24 (s, 3, 3-CH_3), 2.50 (s, 3, 5-CH_3), 6.60 (s, 1, 4-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 11.7 (2-CH_3), 20.5 (3-CH_3), 22.4 (5-CH_3), 124.5 (*C*-2), 125.2 (*C*-4), 133.2 (*C*-5 and *C*-6), 145.4 (*C*-3), 153.9 (*C*-1) ppm; ms (70 eV) *m/e* (relative intensity): 181.073 (100 M_r $^{12}C_9{}^1H_{11}{}^{14}N^{16}O_3$: 181.074), 164 (61), 163 (14), 134 (23), 106 (13), 91 (21), 77 (11); ms (methane C.I.) 182 (*M* + 1), 210 (*M* + 29), 222 (*M* + 41). The minor product **5***g* was not isolated. It had ^{1}H nmr (in a mixture with **4***g*) δ: 2.14 (s), 6.49 (s) ppm. It could be separated from **4***g* by gas chromatography, and a methane C.I. mass spectrum was obtained which showed peaks at *m/e* 182 (*M* + 1) and 210 (*M* + 29).

*2,3,6-Trimethylphenol (**1**h)*

2,3,6-Trimethyl-4-nitrocyclohexa-2,5-dienone (**3***h*) had ^{1}H nmr (Ac_2O) δ: 5.85 (br s, 1, 4-*H*), 6.90 (br s, 1, 5-*H*) ppm; 2,3,6-trimethyl-6-nitrocyclohexa-2,4-dienone (**2***i*) had ^{1}H nmr (Ac_2O) δ: 6.44 (s, 4-*H* and 5-*H*) ppm; ($CDCl_3$–CD_3CN) δ: 1.73 (s, 3, 6-CH_3), 1.89 (s, 3, 2-CH_3), 2.13 (s, 3, 3-CH_3), 6.37 (s, 2, 4-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$–CD_3CN) δ_c: 11.0 (2-CH_3), 21.2 (3-CH_3), 23.2 (6-CH_3), 90.7 (*C*-6), 128.5 or 129.8 (*C*-2), 129.8 (*C*-4), 132.6 (*C*-5), 150.0 (*C*-3), 192.5 (*C*-1) ppm; 2,5,6-trimethyl-6-nitrocyclohexa-2,4-dienone (**2***h*) had ^{1}H nmr (Ac_2O) δ: 6.24 (br d, 4-*H*), 7.05 (br d, 3-*H*) ppm, $J_{3,4}$ = 6.9 Hz; ($CDCl_3$–CD_3CN) δ: 1.73 (s, 3, 6-CH_3), 1.89 (s, 6, 2-CH_3 and 5-CH_3), 6.19 (br d, 1, 4-*H*), 6.98 (br d, 1, 3-*H*) ppm, $J_{3,4}$ = 6.9 Hz; ^{13}C nmr ($CDCl_3$–CD_3CN) δ_c: 15.4 (2-CH_3), 17.9 (5-CH_3), 23.3 (6-CH_3), 96.0 (*C*-6), 121.5 (*C*-4), 129.8 or 128.5 (*C*-2), 140.5 (*C*-3), 143.5 (*C*-5), 195.4 (*C*-1) ppm. The ^{13}C nmr peaks of the mixture of dienones were assigned on the basis of the relative amounts of the isomers present, the peak heights, the splitting pattern in a gated experiment, and the calculated shifts based on the methyl substituent effects in the other dienones. 2,3,6-Trimethyl-4-nitrophenol (**5***h*) was formed when the solution of dienones **2***h* and **2***i* in $CDCl_3$–CD_3CN was warmed to ambient temperature. After recrystallization from methylene chloride **5***h* had mp 97–98°C; ^{1}H nmr ($CDCl_3$) δ: 2.35 (s, 3, 2- or 6-CH_3), 2.38 (s, 3, 6- or 2-CH_3), 2.53 (s, 3, 3-CH_3), 5.56 (br s, 1, O*H*), 7.70 (s, 1, 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 12.3 (2-CH_3), 15.6 and 16.0 (3-CH_3 and 6-CH_3) 120.7 (*C*-6), 123.7 (*C*-2), 124.6 (*C*-5), 131.5 (*C*-3), 143.9 (*C*-4), 155.6 (*C*-1); ms (70 eV) *m/e* (relative intensity): 181.074 (61, M_r $^{12}C_9{}^1H_{11}{}^{14}N^{16}O_3$: 181.074), 165 (12), 164 (76), 136 (23), 134 (10), 122 (10), 115 (10), 109 (32), 108 (25), 107 (17), 105 (18), 95 (12), 94 (15), 93 (20), 92 (17), 91 (100), 81 (26), 79 (46), 78 (14), 77 (50). Some 2,3,5-trimethyl-*p*-benzoquinone (δ: 1.96 (s, 6), 2.04 (s, 3), 6.55 (s, 1) ppm) was formed in one sample on exposure to air.

*2,4,6-Trimethylphenol (**1**j)*

2,4,6-Trimethyl-6-nitrocyclohexa-2,4-dienone (**2***j*) had ^{1}H nmr (Ac_2O) δ: 6.12 (br s, 5-*H*), 6.94 (br s, 3-*H*) ppm; ($(CD_3)_2CO$) δ: 1.68 (s, 3, 6-CH_3), 1.89 (s, 3, CH_3), 1.97 (s, 3, CH_3), 6.16 (br s, 1, 5-*H*), 6.97 (br s, 1, 3-*H*) ppm; 2,4,6-trimethyl-4-nitrocyclohexa-2,5-dienone (**3***j*) had ^{1}H nmr (Ac_2O) δ: 6.94 (s) ppm; ($(CD_3)_2CO$) δ: 1.89 (s, 9), 6.97 (s, 2) ppm; ($CDCl_3$) δ: 1.86 (s, 3, 4-CH_3), 1.94 (s, 6, 2-CH_3 and 6-CH_3), 6.84 (s, 2, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 16.2 (2-CH_3 and 6-CH_3), 26.1 (4-CH_3), 84.7 (*C*-4), 137.1 (*C*-2 and *C*-6), 138.2 (*C*-3 and *C*-5), 185.3 (*C*-1) ppm. 2,6-Dimethyl-4--nitromethylphenol obtained on isomerization of dienone **3***j* had ir (film): 3480 (OH), 1558 (NO_2) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.19 (s, 6, 2- and 6-CH_3), 5.24 (s, 2, CH_2NO_2), 7.01 (s, 2, 3- and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 15.8 (2-CH_3 and 6-CH_3), 79.8 (CH_2–NO_2), 121.4 (*C*-4), 124.1 (*C*-2 and *C*-6), 130.4 (*C*-3 and *C*-5), 153.8 (*C*-1) ppm.

Comparison of methods for determination of boron in heavy water moderator

L. W. GREEN,[1] E. C. DAVEY, J. GULENS, T. H. LONGHURST, AND J. P. MISLAN
Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited Research Company, Chalk River, Ont., Canada K0J 1J0

Received December 14, 1983

L. W. GREEN, E. C. DAVEY, J. GULENS, T. H. LONGHURST, and J. P. MISLAN. Can. J. Chem. **62**, 1452 (1984).

Five analysis methods were compared for the determination of boron in heavy water moderator: isotope dilution mass spectrometry, spectrophotometry, neutron activation, inductively coupled plasma – atomic emission spectrometry, and ion selective electrode potentiometry. Ten samples were analysed by each method; the results showed close agreement between all of the methods. Only mass spectrometry achieved the required precision (<1% rsd) for samples taken during initial reactor operation, but all of the methods achieved sufficient precision (<10% rsd) for samples taken during normal operation. For samples for which the ^{10}B concentration must be determined, only mass spectrometry and neutron activation are applicable.

L. W. GREEN, E. C. DAVEY, J. GULENS, T. H. LONGHURST et J. P. MISLAN. Can. J. Chem. **62**, 1452 (1984).

On a comparé cinq méthodes d'analyse pour la détermination du bore dans des modérateurs à l'eau lourde: la spectrométrie de masse par dilution isotopique, la spectrophotométrie, l'activation neutronique, la spectrométrie d'émission atomique par plasmas induits par radiofréquence et la potentiométrie à l'aide d'électrodes spécifiques à certains ions. On a analysé dix échantillons par chacune des méthodes. Seule la spectrométrie de masse a permis d'obtenir la précision requise (coefficient de variation plus petit que 1%) pour des échantillons prélevés au cours de l'opération initiale du réacteur, mais toutes les méthodes donnent une précision suffisante (coefficient de variation plus petit que 10%) pour des échantillons obtenus durant le cours normal des opérations. Si on doit déterminer les concentrations en ^{10}B dans les échantillons, seules la spectrométrie de masse et l'activation neutronique peuvent être utilisées.

Introduction

Boron, in the form of boric acid, is added to the heavy water moderator of CANDU™ power reactors to compensate for excess reactivity that exists during initial operation conditions and to serve as a readily removable reactivity shim during long term operation (1). It is also used during reactor commissioning to calibrate the reactivity worth of control devices such as the liquid zone control system, mechanical control absorbers, and adjuster rod adsorbers. The mass 10 isotope of boron is well suited for these purposes because its thermal neutron capture cross section is large (3.81×10^{-21} cm^2) and varies linearly with the inverse of neutron velocity over a wide velocity range.

For calibration of the reactivity devices and for many of the reactivity assessments during normal operation, an uncertainty of less than 1 part in 1000 in the neutron balance (uncertainty ≤1 mk) is required. This corresponds to a precision of ±0.03 μg/g (2 s) for ^{10}B or, in the case of isotopically natural boron, ±0.12 μg/g for total boron. The ^{10}B concentration is ~1.5 μg/g during initial operation and decreases to ~0.15 μg/g during normal operation, thus relative uncertainties of ≤2% (2 s) for the initial operation samples and of ≤20% for the normal operation samples are required for an analysis method. A method that can detect the ^{10}B isotope is preferable, but since frequently the boron isotopic composition is known or can be inferred, determination of total boron concentration is sufficient.

Currently at the generating stations, spectrophotometric methods (2, 3) are used for total boron determinations and a neutron activation method (1*a*) is used for ^{10}B determinations. Additionally, samples are periodically analysed by isotope dilution mass spectrometry (IDMS), to verify both the boron isotopic composition and total concentration.

Stewart (8) has reviewed the status of moderator boron analysis up to 1977, but since then some newer methods have been applied. The purpose of this work was to assess the accuracy, precision, and suitability of both old and new methods for the determination of boron in heavy water moderator. Five methods were investigated: spectrophotometry (chromotropic acid), neutron activation (NA), IDMS, inductively coupled plasma atomic emission spectroscopy (ICP-AES), and ion selective electrode (ISE) potentiometry (fluoroborate electrode). Ten moderator samples were distributed to each participant and each sample was analysed in duplicate or triplicate.

[1] To whom all correspondence should be addressed.

Experimental

Sampling

Five samples of heavy water moderator were obtained at the sampling stations of each of the Wolsung and Point Lepreau nuclear generating plants during their Phase B commissioning periods. Samples were collected and stored in leakproof polyethylene bottles (CANLAB series B7504) that had been rinsed with moderator prior to sample collection. Spectrophotometric and, for the Wolsung samples, neutron activation analyses were completed at the generating stations. For the other methods, samples were sent to the Chalk River Nuclear Laboratories, subdivided, and distributed to the various participants. The above described CANLAB bottles were used for sample subdivision; these were leached in 1 *M* Na_2CO_3, rinsed with deionized water and dried before use. Contact of the samples with glassware was avoided.

Methods

Isotope dilution mass spectrometry

The National Bureau of Standards (NBS) recommended procedure for mass spectrometry of boron was used (4). Accurately weighed aliquots of sample (~5 g) and spike (NBS SRM 952 solution) were mixed with sodium carbonate solution, evaporated to dryness under nitrogen flow at ~35°C, dissolved and mixed in 0.5 mL of deionized water, re-evaporated to dryness, and dissolved in 30 μL of deionized water. Approximately 5 μL of this solution was deposited and dried on a tantalum centre filament. The $Na_2BO_2^+$ ions were measured at masses 88 and 89. The NBS boron standard SRM 951 (10/11 atomic ratio = 0.2473) was used to standardize this and all other methods.

Special care was taken to avoid boron contamination. Solutions were stored and handled in plastic containers that had been leached overnight in 1 *M* Na_2CO_3 solution and rinsed with deionized water. High purity Aristar (BDH Chemicals Ltd., Poole, Eng.) sodium carbonate was used in sample preparation; sufficient Na_2CO_3 was added

TABLE 1. Determined concentrations and isotopic composition of boron in heavy water moderator

to each sample to yield an approximately equimolar sodium and boron content. Deionized light water was used for all dissolutions and dilutions.

Spectrophotometry

The chromotropic acid procedure described by Kuemmel and Mellon (2) was used. Absorbance measurements were recorded on a Perkin-Elmer Coleman 55 spectrophotometer at 360 nm. Samples were closely bracketed by standards to avoid calibration errors due to non-linearity. A disodium chromotropate stock solution was prepared fresh each week and stored in the dark to avoid photodecomposition. Furthermore, once samples were mixed with reagents exposure to light was minimized.

Neutron activation

The Boron-10 Analyser and methodology described by Davey (1*a*) were used. Samples and standards were diluted with light water to the 0.1 to 0.5 μg/g ^{10}B range, and evaporated on aluminum planchets in five successive 0.2 mL quantities in an oven at 95°C. For the Point Lepreau samples, the planchets were roughened by sandblasting to achieve satisfactory surface wetting; this was not necessary for the Wolsung planchets. The planchets were exposed to a thermal neutron flux of 1×10^9 neutrons m^{-2} s^{-1} derived from a heavy water moderated ^{252}Cf source, and the 1.47 MeV α particles from the ^{10}B (n, α) ^7Li reaction were simultaneously counted. The mass spectrometrically determined isotopic composition was used to compute the total [B] from the determined [^{10}B].

Inductively coupled plasma atomic emission spectroscopy

The procedure was similar to that reported for a D.C. argon plasma spectrometer (5). Samples were directly aspirated into the plasma and boron I emission was monitored at 249.68 nm. The plasma emission spectrometer consisted of a Jobin-Yvon 38P Spectrometer, a Plasmatherm 2.5 kW, 27.12 MHz source and a hybrid nebulizer torch consisting of an Instruments SA concentric nebulizer, a Perkin-Elmer spray chamber, and a Plasmatherm quartz torch. Typical instrumental conditions were: incident power, 1.3 kW; reflected power, 5 W; coolant flow-rate, 13 L min^{-1}; auxiliary flow rate, 1.4 L min^{-1}; and sample uptake, 0.9 mL min^{-1}. For calibration, standards were prepared in reactor grade 99.7% D_2O. Resolution was insufficient to separate the emission lines of the two boron isotopes.

Ion selective electrode potentiometry

Boric acid was converted to the fluoroborate anion and analysed by the method described by Gulens and Leeson (6). Due to the limited volume of sample available for analysis, the samples were diluted ten-fold with 94.5% D_2O prior to the conversion step. The fluoroborate sensing module was stored between use in a heavy water solution containing 5 μg B/g as BF_4^-.

Results and discussion

Preliminary results showed that significant biases were obtained with the neutron activation method for the Point Lepreau measurements when the planchets were not roughened and with the ICP-AES method when the deuterium concentration of the heavy water used for preparation of standards did not match that of the samples. For example, the neutron activation results for the Point Lepreau samples were ~40% low when unroughened planchets were used; this was likely due to poor surface wetting and loss of H_3BO_3 during the drying step. The ICP-AES results for all the samples were 10% low when standards were prepared in 94.8% D_2O; reactor grade deuterium content is 99.8%. These low results were attributed to a viscosity effect.

The final results of the interlaboratory comparison are listed in Table 1. The estimated precision of each method is included; relative standard deviations were determined from six or more replicate analyses on typical samples. As expected, the IDMS method demonstrated much higher precision than the others. Because of its higher precision and proven reliability over many years, the IDMS method was chosen as a reference method against which the others were compared; the mean IDMS values for each sample were used as the population mean or "true" values in t-tests (7).

The results in Table 1 show consistent good agreement between each method and the reference method, and the given t-test values indicate that there were not any systematic differences in the methods. There is one large deviant, the spectrophotometric result for sample W3.

Of the methods investigated, only IDMS achieved the high level of precision required for reactivity assessment during initial reactor operation, but all of the methods were suitable for reactivity assessment during normal operation. The ICP-AES method proved to be the most convenient method; it was ~3 times faster than the others and had minimal operational difficulties. The results in Table 1 show that the precision and accuracy of this method were better than those of the others, except for IDMS. The IDMS and NA methods have the advantage of capability of ^{10}B determination; the spectrophotometric and potentiometric methods have the advantages of low cost and portability.

Received October 31, 1983

J. M. CAMPELO, A. GARCIA, J. M. GUTIERREZ, D. LUNA, and J. M. MARINAS. Can. J. Chem. **62**, 1455 (1984).

Cyclohexene skeletal isomerization, in a microcatalytic pulse reactor, was investigated using Al_2O_3 and $AlPO_4-Al_2O_3$ as catalysts. Apparent rate constants and apparent activation energies were calculated according to the kinetic model of Bassett–Habgood. Selectivity studies concluded that 1-MCP and 3-MCP were competitive products with a first-order kinetics. The rate constants as well as the selectivity at 1-MCP increase with an increase in the number and strength of stronger acid sites, measured by means of the irreversible adsorption of aniline in cyclohexane, at 298 K, using a spectrophotometric method. The parallel reaction pathway, proposed for $AlPO_4$ catalysts, agrees with both the observed rates and selectivities using Al_2O_3 and $AlPO_4-Al_2O_3$ catalysts.

J. M. CAMPELO, A. GARCIA, J. M. GUTIERREZ, D. LUNA et J. M. MARINAS. Can. J. Chem. **62**, 1455 (1984).

Utilisant le Al_2O_3 et le $AlPO_4-Al_2O_3$ comme catalyseurs, on a étudié l'isomérisation du squelette du cyclohexène dans un réacteur microanalytique pulsé. On a calculé les constantes apparentes de vitesse et les énergies apparentes d'activation en utilisant le modèle cinétique de Bassett et Habgood. Des études de sélectivité ont permis de conclure que les 1-MCP et 3-MCP sont des produits compétitifs avec une cinétique du premier ordre. Les constantes de vitesse ainsi que la sélectivité en faveur du 1-MCP augmentent avec une augmentation du nombre de sites acides et de l'acidité de ces sites tels que mesurés grâce à l'adsorbtion irréversible de l'aniline dans le cyclohexane, à 298 K, en faisant appel à une méthode spectrophotométrique. Le modèle réactionnel parallèle, proposé pour les catalyseurs de $AlPO_4$, correspond aussi bien aux vitesses qu'aux sélectivités observées lors de l'utilisation des catalyseurs Al_2O_3 et $AlPO_4-Al_2O_3$.

Introduction

In a previous study, we have shown that the precipitation agent of the $AlPO_4$ catalysts exerts a strong effect on the acid properties as well as on the catalytic activity for the skeletal isomerization of cyclohexene (1). Thus, the $AlPO_4$ obtained by precipitation with propylene oxide has the greatest number of acid sites of high strength, when titrated vs. aniline, exhibiting the highest isomerization activity and selectivity to 1-methylcyclopentene, which, together with 3-methylcyclopentene, are the isomerization products. These products are obtained by parallel reactions according to a carbocationic mechanism with rearrangement of intermediates.

The present paper deals with the study of surface acidity and catalytic activity in the cyclohexene skeletal isomerization on $AlPO_4-Al_2O_3$ catalysts obtained by precipitation with ethylene or propylene oxide. This study also includes the Al_2O_3 catalyst that constitutes the $AlPO_4-Al_2O_3$ systems.

As in a previous work, the cyclohexene skeletal isomerization has been carried out in a microcatalytic pulse reactor according to the Bassett–Habgood model (2) developed for first-order processes where the surface reaction is the rate-determining step.

Experimental

Catalysts

The Al_2O_3 (AL) was obtained by precipitation with aqueous ammonia from an aqueous solution of aluminum nitrate.

The $AlPO_4-Al_2O_3$ (75:25 wt.%) systems were obtained by adding aluminum hydroxide, obtained as in the AL case, in a reaction medium where the precipitation of $AlPO_4$, from $AlCl_3.6H_2O$ and H_3PO_4 (85 wt.%) aqueous solutions, has been initiated by addition of ethylene (BA) or propylene (BPA) oxide. The total precipitation of $AlPO_4$ is then carried out by addition of ammonium hydroxide solution. The pH value at the precipitation "end-point" was 6.1 in both cases.

The three samples received the same thermal treatment, namely, drying at 393 K for 24 h and calcination at 923 K for 3 h in a muffle furnace.

The detailed description of the syntheses has been described previously (3, 4).

Physico-chemical properties

The physico-chemical properties of the catalysts have already been researched. Thus, the surface area was determined by the BET method (5) and the porosity detection was carried out by means of the Lecloux method (6) using n_3 due to the monolayer value. Pore size analysis was made using the "corrected modelless" method for mesopores (7).

The surface acidity was determined by titration with cyclohexylamine, pyridine, and aniline from cyclohexane solutions (spectroscopic grade, Merck) at 298 K using a spectrophotometric method previously described (1, 8, 9).

Apparatus and procedure

The CH isomerization was carried out in a microcatalytic pulse reactor according to a method described elsewhere (1). However, in this work we have maintained a constant catalyst loading of 150 mg ($\leq$0.7 mm), except for the BA sample that exhibits the highest activity.

CH was obtained from Merck and was used after purifying it by a column of alumina previously calcined at 573 K for 3 h.

The reaction products are analyzed by glc as previously reported (1), using a 3-m stainless steel column of 2-mm diameter, filled with 5% squalane on Chromosorb G AW-DMCS 80/100.

Results and discussion

Textural and surface acid properties

The adsorption isotherm is type II of Brunauer's classification for $AlPO_4-Al_2O_3$ catalysts, while it is type IV for Al_2O_3, and pronounced hysteresis loops are shown for the three samples. By application of the "corrected modelless" method for mesopore analysis, the cylindrical model could fit the criteria of corrected analysis. The textural properties thus obtained, surface area, pore volume, and main pore radius, are presented in Table 1.

TABLE 1. Textural properties and surface acidity of $AlPO_4-Al_2O_3$ and Al_2O_3 catalysts

Catalysts	S ($m^2\ g^{-1}$)	V ($mL\ g^{-1}$)	r (nm)	CY (pK_a = 10.6) $x_m \cdot 10^6$	CY (pK_a = 10.6) $b \cdot 10^{-4}$	PY (pK_a = 5.3) $x_m \cdot 10^6$	PY (pK_a = 5.3) $b \cdot 10^{-4}$	AN (pK_a = 4.6) $x_m \cdot 10^6$	AN (pK_a = 4.6) $b \cdot 10^{-4}$
AL	151	0.31	2.0	172	5.7	77	8.6	6	15.1
BA	263	0.53	3.0	620	5.1	300	12.4	60	194.1
BPA	237	0.70	2.5	684	5.7	385	11.4	35	29.3

As regards the surface acid properties, the chemical interaction adsorbate–surface can be accomplished by applying the linear transformed Langmuir adsorption isotherm [1]

$$[1]\quad C/x = 1/bx_m + C/x_m$$

as in the $AlPO_4$ case.

The monolayer coverage, x_m, which corresponds to the theoretical amount of base adsorbed by 1.0 g of solid systems if all sites are covered, must be assumed as a measure of the acid sites corresponding to specific pK_a of the base.

Since the linearization of the Langmuir isotherm assumes uniformity of sites, besides x_m, we can also use the b constant which depends on the interaction strength of the base with the acid site, i.e. the site strength. These b values displayed a greater experimental error since they are obtained from the intercept at the origin.

Thus the reproducibility of the titration method has been checked experimentally and the measurements were repeated 2–3 times. The relative error was about 6% for x_m values, while the b values were reproducible to within about 15%.

The surface distribution of x_m and b values is presented in Table 1. As can be seen, the irreversible adsorption of the base, x_m, agrees with its specific pK_a; thus, the sequence obtained in all cases is CY > PY > AN. Therefore, the difference between the x_m values for CY and the other bases (PY or AN) is a measure of the number of weaker acid sites.

The $AlPO_4-Al_2O_3$ system obtained by precipitation with propylene oxide (BPA) shows the highest number of acid sites with respect to CY and PY, while the number of strong acid sites are lower than the BA sample. On the other hand, the alumina AL only exhibits acidity vs. CY and PY with a very low number of acid sites.

With respect to the strength of acid sites measured by the constant b, the BA sample is the one which shows the highest value, ahead of PY and AN, especially in the latter case.

Thus, from a general point of view, the present results show that the precipitation agent of the $AlPO_4-Al_2O_3$ system exerts an influence on the number and strength of acid sites, as in the $AlPO_4$ catalysts, the system obtained with ethylene oxide being the one which possesses the highest strength of acid sites.

Catalytic activity

As in the previous study of the CH skeletal isomerization on $AlPO_4$ catalysts, the reaction rate is free from transport influences, and the isomerization was maintained at low conversion levels (<8%). Also, 1-MCP and 3-MCP are the only isomerization products detected due to the short contact time of the reaction. For sample AL, only 1-MCP was obtained.

The isomerization activity, expressed by the total conversion to 1- and 3-MCP, is adjusted to the Bassett–Habgood equation [2] (2), as can be seen in Fig. 1.

$$[2]\quad \ln (1/1 - X) = RT \cdot kK\ (W/Q)$$

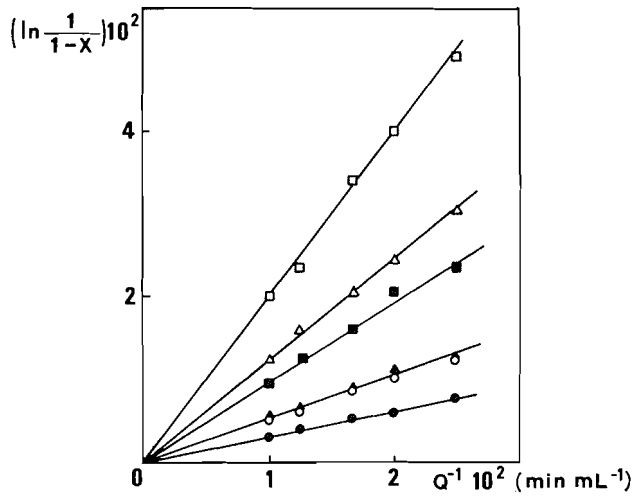

FIG. 1. Test of first-order rate law for cyclohexene isomerization. BA 151 mg (○) 573 K; (△) 623 K; (□) 673 K. BPA 149 mg (●) 573 K; (▲) 623 K; (■) 673 K.

TABLE 2. Apparent rate constant and apparent activation energies for CH isomerization on Al_2O_3 and $AlPO_4-Al_2O_3$

Catalyst	T (K)	$kK \times 10^6$ (mol $atm^{-1}\ g^{-1}\ s^{-1}$)	E_a (kJ mol^{-1})
A	573	0.22±0.02	
	623	0.26±0.02	21.2±1.9
	673	0.37±0.03	
BA	573	1.20±0.08	
	623	2.67±0.19	44.3±4.0
	673	4.06±0.28	
BPA	573	0.73±0.05	
	623	0.94±0.07	36.2±3.3
	673	1.96±0.14	

Thus, the skeletal isomerization of CH is a first-order kinetic process, the rate of surface reaction being the rate-determining step.

The apparent rate constants, kK, at a fixed temperature, from the plots ln $(1/1 - X)$ vs. $1/Q$, and the apparent activation energy, E_a, from ln [ln $(1/1 - X)$] vs. $1/T$, were obtained in each case and are collected in Table 2.

As can be seen from the data in Table 2, the catalytic activity of alumina AL is very low as corresponds to the small number and strength of its acid sites. On the other hand, the BA catalyst exhibits higher activity than the BPA sample, as a consequence of its larger number of stronger acid sites.

Taking into account the previous results (1), the sites responsible for the CH skeletal isomerization seem to be those

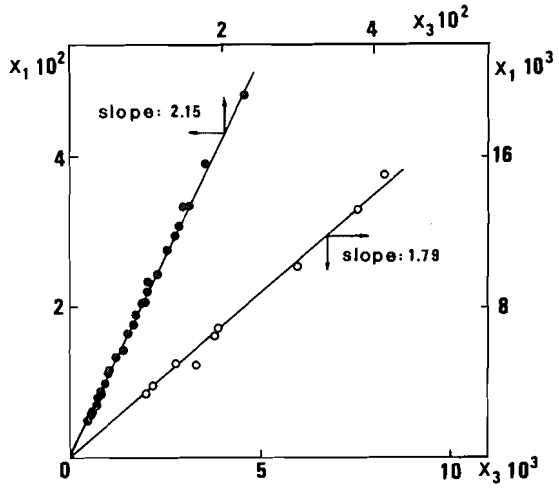

FIG. 2. Selectivity factors: X_1 vs. X_3 on BA (●) and BPA (○) catalysts. (Data at every temperature.)

titrated vs. AN through the x_m and b values working simultaneously.

On the other hand, the concentration of 1-MCP was always higher than 3-MCP for BA and BPA samples, and these isomerization products are competitors, with a first-order kinetics, since the application of the Wheeler criterion (10) on the kinetic selectivity factor, σ, leads to a straight line, as can be seen in Fig. 2 where the plots of X_1 vs. X_3 appear.

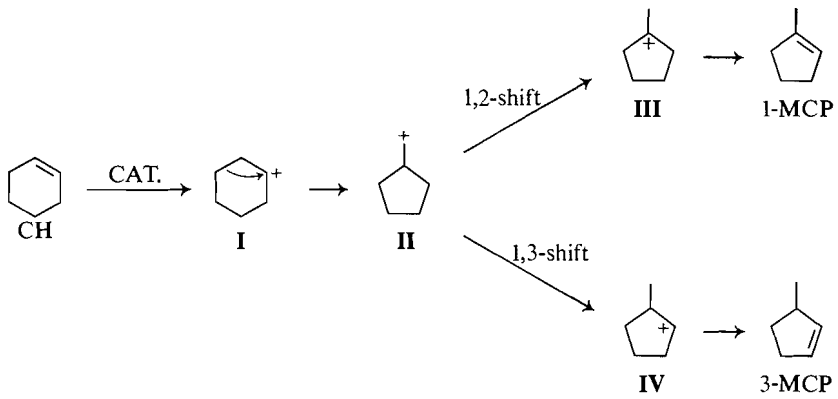
[3] $\sigma = K_1/K_3 = X_1/X_3$

A least-squares regression analysis and a "t-test" of significance, performed on the regression coefficients, show the accuracy of fit of the data, in all experimental conditions, in the straight lines of Fig. 2.

As Fig. 2 contains points at the three temperatures, the apparent activation energies for 1- and 3-MCP formation are identical for each catalyst. Besides, the selectivity to 1-MCP for the BA sample is larger than for the BPA sample, as corresponds to its higher acid strength (high values of x_m and b vs. AN).

Thus, as in the previous study on the CH skeletal isomerization for $AlPO_4$ catalysts, the different σ values for each catalyst are due to different A_1/A_3 ratios, since for each catalyst the formation of 1- and 3-MCP has identical apparent activation energies. So, both isomerization products are obtained by a carbocationic mechanism (11–14) with a rearrangement of intermediates, across parallel reactions, as has been shown previously (1).

For an AL sample, the 1,3-hydride shift that changes the tertiary carbenium ion I into a secondary ion (IV) is not as easy as corresponds to its low surface acidity. So, the 3-MCP formation on an AL catalyst is difficult and thus is not observed in the present experimental conditions.



Conclusions

The present results, together with those previously obtained (1), show that the stronger acid sites are necessary for the CH skeletal isomerization to 1- and 3-MCP on $AlPO_4$, Al_2O_3, and $AlPO_4$–Al_2O_3 catalysts, and that the apparent rate constant, kK, and the selectivity at 1-MCP increase with an increase in the number (x_m) and strength (b) of stronger acid sites (vs. AN), both acting simultaneously.

The previously proposed mechanism, through intermediates with a more or less developed carbocationic character, agrees with these experimental results.

Nomenclature

A: preexponential factor of Arrhenius equation
AN: aniline (λ_{max}: 232 nm)
b: Langmuir's constant (L mol^{-1})
C: concentration of titrating agent in solution, at equilibrium with the adsorbate on the surface acid sites (mol L^{-1})
CH: cyclohexene
CY: cyclohexylamine (λ_{max}: 225 nm)
E_a: apparent activation energy (kJ mol^{-1})
k: rate constant of the surface process (s^{-1})
K: adsorption constant of the CH on the catalyst (mol atm^{-1} g^{-1})
MCP: methylcyclopentene
PY: pyridine (λ_{max}: 252 nm)
Q: flow rate of the carrier gas (mL s^{-1})
r: main pore radius (nm)
S: surface area (BET method, m^2 g^{-1})
T: reaction temperature (K)
V: pore volume (mL g^{-1})
W: catalyst weight (mg)
x: amount of titrating agent adsorbed on the acid sites (mol g^{-1})
x_m: monolayer coverage; the theoretical amount of titrating agent that may be chemically adsorbed by 1.0 g of solid system (mol g^{-1})
X: molar fractionary conversion
σ: kinetic selectivity factor
λ: wavelength of the maximum absorption (nm)
Subscripts: 1: 1-MCP; 3: 3-MCP

Effects of solvents on a model of rhodopsin consisting of a conjugated imine and substituted acetic acids

MARTINE BISSONNETTE, HOA LE THANH, AND DANIEL VOCELLE[1]

Département de chimie, Université du Québec à Montréal, Montréal (Qué.), Canada H3C 3P8

Received December 22, 1983

MARTINE BISSONNETTE, HOA LE THANH, and DANIEL VOCELLE. Can. J. Chem. **62**, 1459 (1984).

A model system of rhodopsin consisting of a dienylidene Schiff base and different halogeno acids has been studied in two solvents, chloroform and methanol, by uv and 400-MHz nmr spectroscopies. The uv results indicate that in chloroform, a nonpolar solvent, monohalogenoacetic acids can protonate the Schiff base only partially, while nmr data show that the aldimine hydrogen is slightly affected by acids and that the acidic proton is moving rapidly between the donor and the acceptor. In methanol, data indicate a leveling effect. In relation with rhodopsin, our results imply that, depending on the environment surrounding the chromophore, the state of protonation of the Schiff base could be strongly affected. Finally, our model shows experimental evidence that Nakanishi's external point charge could be operating in visual pigments.

MARTINE BISSONNETTE, HOA LE THANH et DANIEL VOCELLE. Can. J. Chem. **62**, 1459 (1984).

Un modèle de la rhodopsine comprenant une base de Schiff diénylidène et différents acides halogénés a été étudié dans le chloroforme et le méthanol par les spectroscopies ultraviolette et résonance magnétique nucléaire (400 MHz). Les résultats dans l'uv indiquent que dans un solvant non polaire comme le chloroforme, les acides acétiques monohalogénés peuvent protoner la base de Schiff que partiellement tandis que la rmn montre que l'hydrogène de l'aldimine n'est que peu affecté par la présence d'acides et que le proton acide se déplace rapidement entre le donneur et l'accepteur. Dans le méthanol, les données indiquent la présence d'un effet équalisateur dû au solvant. Extrapolés à la rhodopsine, nos résultats impliquent que l'état de protonation du chromophore peut être affecté grandement par le milieu environnant la base de Schiff. Finalement, notre modèle présente quelques données expérimentales tendant à montrer l'existence d'une charge externe près du chromophore telle que préconisée par Nakanishi.

Introduction

The electronic spectrum of rhodopsin, the visual pigment responsible for vision, is of fundamental importance in the study of the molecular mechanism of vision (1). Bovine rhodopsin absorbs at 500 nm while the hydrochloride salt of retinylidene butylamine absorbs at 440 in methanol (2). The 60-nm difference between rhodopsin and the model has been termed the "opsin shift" by Nakanishi *et al.* (3) and it represents the red shift of the chromophore due to the effects of the protein environment. This opsin shift has been ascribed by Nakanishi to an external point charge located near the 11-*cis* double bond of retinal. This widely accepted theory is presented in Fig. 1.

More recently, Mordechai and Nakanishi (4) have devised a polyene iminium system where the effect of a carboxylate anion in close proximity to the polyenic group could be evaluated. Again, the external point charges were shown to be contributors to the spectroscopic characteristics of the model system. Other factors were shown to be important also: the distance between the minimum nitrogen and the counteranion (an effect already described by Blatz and co-workers (5)) and solvent polarity.

In a recent note (6), we have proposed a model where (1) the protonating species was a carboxylic acid; (2) the presence of polar groups (halogen, cyano, etc.) could serve as an external point charge; (3) solvent effects could also be measured. *trans-trans*-2,4-Heptadienylidene *tert*-butyl amine (**1**) was used as a model of retinal since, according to Nakanishi *et al.* (3), this fragment of the chromophore is where the interactions occur. Figure 2 shows our model, which should be compared to Nakanishi's external point charge model.

In that note it was said that in chloroform certain acids like trifluoroacetic acid (TFA), propiolic acid, and cyanoacetic acid (CAA) in a 1:1 molar ratio with **1** gave ultraviolet (uv) spectra which indicated the presence of an equilibrium between a protonated and an unprotonated imine. Proton magnetic resonance data indicated that this was not so simple. In fact, it was not possible to relate the deshielding of the hydrogens located on the double bonds with the percentage of protonation evaluated by the uv method. It was concluded that more data were necessary in order to understand completely the behavior of the Schiff base in the presence of acids.

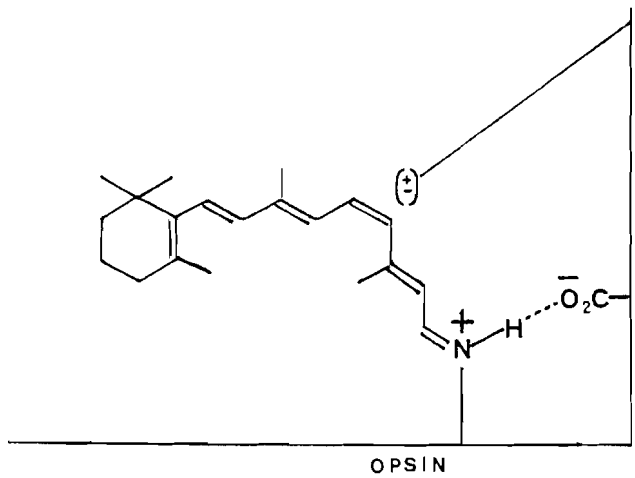

FIG. 1. Nakanishi's external point charge model of rhodopsin.

In the present paper, we are presenting results obtained by the use of five more acids, by varying the ratio of acids toward imine **1** and by extending our study not only in chloroform but also in methanol.

Materials and methods

Synthesis of *trans-trans*-2,4-heptadienylidene *tert*-butylamine (**1**) was made according to the procedure of Kosower and Sorensen (7). This imine is rather unstable to oxygen, light, and heat so that a freshly distilled sample is required. Proton magnetic resonance (^{1}H nmr) was used to check its purity. All acids and solvents were thoroughly dried,

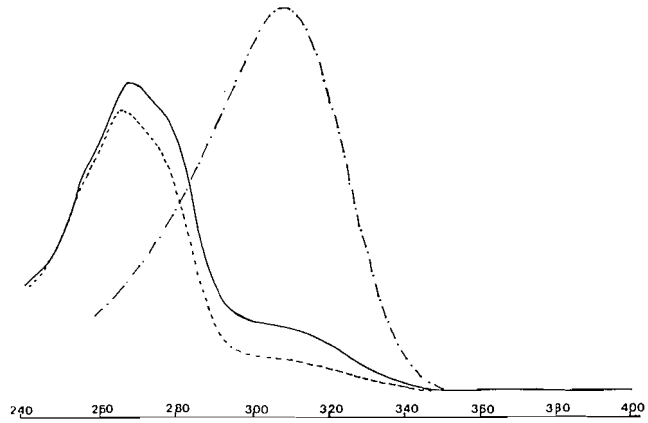

FIG. 3. Ultraviolet spectra of **1** in $CHCl_3$ in a 1:1 molar concentration with (- - -) CH_2ICO_2H; (–) CH_2FCO_2H; (–○–) $CHCl_2CO_2H$.

since protonated Schiff bases are readily hydrolysed. Chloroform was passed on a column of basic alumina in order to remove traces of hydrogen chloride. Under such conditions, spectra of **1** in $CHCl_3$ did not show any significant band in the 300-nm region. Special attention was given to prevent hydrolysis, which was kept minimal. Solutions were prepared in 10^{-4} *M* concentrations for uv studies and 10^{-2} *M* concentrations for nmr. The uv spectra were recorded on a Cary 17 and the nmr studies were done on a Bruker WH 400/DS (400 MHz) spectrometer.

Results

(a) *Ultraviolet studies*

In $CHCl_3$

Ultraviolet spectra of the Schiff base **1** mixed with different halogenated acetic acids in chloroform are shown in Figs. 3, 4, and 5.

Figures 3 to 5 indicate that monohalogenoacetic acids, in a 1:1 molar ratio with the Schiff base **1**, give spectra composed of two bands: one at 267 nm, the other at 310 nm. The 267-nm band represents the unperturbed imine band, while the 310-nm band is due to the protonated imine (6). This new band represents approximately 20% protonation. Since in high excess of the acid, the 310-nm band only is present, it is possible to measure the molar adsorptivity ϵ of the protonated imine in such conditions; thus, the Schiff base **1** in the presence of excess monochloroacetic acid has an ϵ of around 26 000 L mol^{-1} cm^{-1} at 310 nm. By measuring the ϵ at that wavelength it is possible to evaluate the proportion of the 310-nm band; it represents about 22% for the mixture of **1** with monochloroacetic acid and 17% for **1** with monobromacetic acid. Table 1 gives the percentage of protonation of **1** with a series of acids.

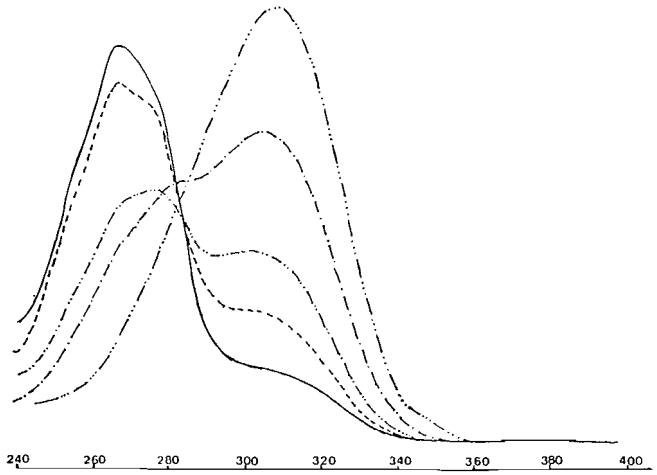

FIG. 4. Ultraviolet spectra of **1** in $CHCl_3$ with varying concentrations of CH_2ClCO_2H: (–) 1:1 (- - -) 1:2; (–···–) 1:4; (–·–) 1:10; (–···–) 1:50 molar ratio.

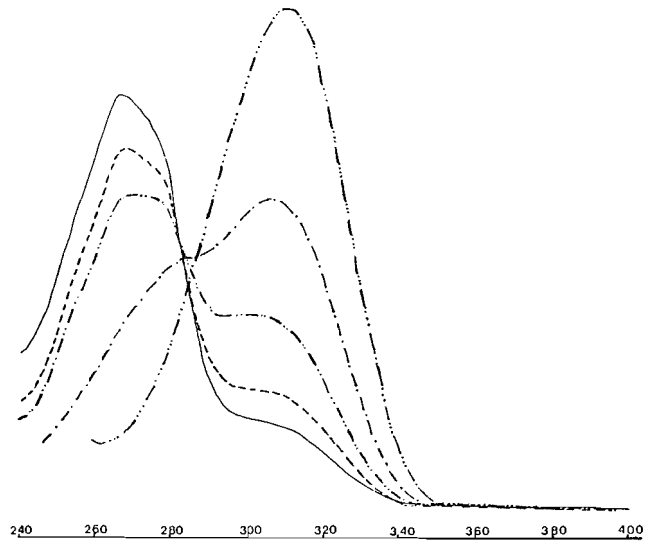

FIG. 5. Ultraviolet spectra of **1** in $CHCl_3$ with varying concentrations of CH_2BrCO_2H: (–) 1:1 (- - -) 1:2; (–···–) 1:4; (–·–) 1:10; (–···–) 1:50 molar ratio.

All the acids which gave a two-band system were mixed with the Schiff base **1** in high excess (1:100). In all cases except propionic acid, only the band at 310 nm resulted, the 267-nm band being completely absent. With propionic acid which afforded no protonation (the 310-nm band being barely present) in a 1:1 molar ratio, no red shift could be observed when a high excess of acid was used. In contrast, 3-nitropropanoic acid, with a pK_a in water of 3.7, was able to completely shift the 267-nm band to 310 nm when a high excess was used.

The effects toward the imine of varying the concentrations of the acids were studied particularly for both monochloro and monobromoacetic acids (Figs. 4 and 5). These spectra show that by increasing the amount of the acid compared to the Schiff base the 310-nm band increases while the 267-nm band decreases. The shape of the 267-nm band is also altered in the process; a growing shoulder appears around 280 nm. It could be due to the presence of the increasing 310-nm band, since the spectrum of unprotonated **1** shows a large and asymmetric band with a shoulder in that region. Other interpretations are possible, such as the presence of some Rydberg bands superimposed

Only one band is present with a max at 307 nm. All the other acids give superimposable spectra to the one of Fig. 6.

(b) *Nuclear magnetic resonance (nmr) studies*

In $CDCl_3$

The same acids mixed with **1** were studied in $CDCl_3$ by using a 400-MHz instrument. Figure 7(a) shows the actual spectrum of the heptadienylidene Schiff base while Fig. 7(b) shows the spectrum of **1** mixed with TCA in equimolar concentration. Identification of each set of peaks was possible by using a double resonance technique.

Table 2 presents the data for each ethylenic hydrogen of **1** taken at its peak center.

Table 3 shows the deshielding effect caused by the carboxylic acids on all of these hydrogens.

The numbers represent the difference in ppm between the value for a hydrogen of **1** in $CDCl_3$ compared with the value of that same hydrogen when an acid is present. It is important to note that H_7 is a doublet even in the presence of the carboxylic acids. This is unexpected, since protonation of the nitrogen of the imine of **1** should give four peaks of equal intensities (a double doublet), proton exchange with $CDCl_3$ not being possible. In contrast, HCl gives such a quartet. Using TCA in varying concentrations with the Schiff base **1**, it was found that for a molar ratio of 1:3 the desired quartet appeared (Fig. 8).

No correlation was found between the deshielding values of the ethylenic hydrogens (Table 3) and the pK_a of the acids measured in water (since the pK_as are not known in chloroform). Also, no correlation was found between the percentages of protonation as measured by uv and the deshielding values of Table 3.

In CD_3OD

Table 4 presents the results of the same study as previously described, but this time in deuterated methanol.

From Table 4 it is possible to note a slight variation in the chemical shifts of the ethylenic hydrogens. The contrast between these results in CD_3OD and those in $CDCl_3$ (Table 2) is striking; however, it was expected in the light of the uv results obtained.

Discussion

From comparing the results presented above in chloroform and in methanol one conclusion can readily be drawn: there is a leveling effect occurring in methanol. Blatz and co-workers (5) have previously proposed such an effect in their uv study of *N*-retinylidene *n*-butylamine (NRBA) in the presence of very strong acids like HCl, H_2SO_4, etc.. Since they could not observe any variation in the λ_{max} of NRBA with different acids, they invoked solvation of protonated NRBA by methanol. They called this non-variation of the λ_{max} in methanol the leveling

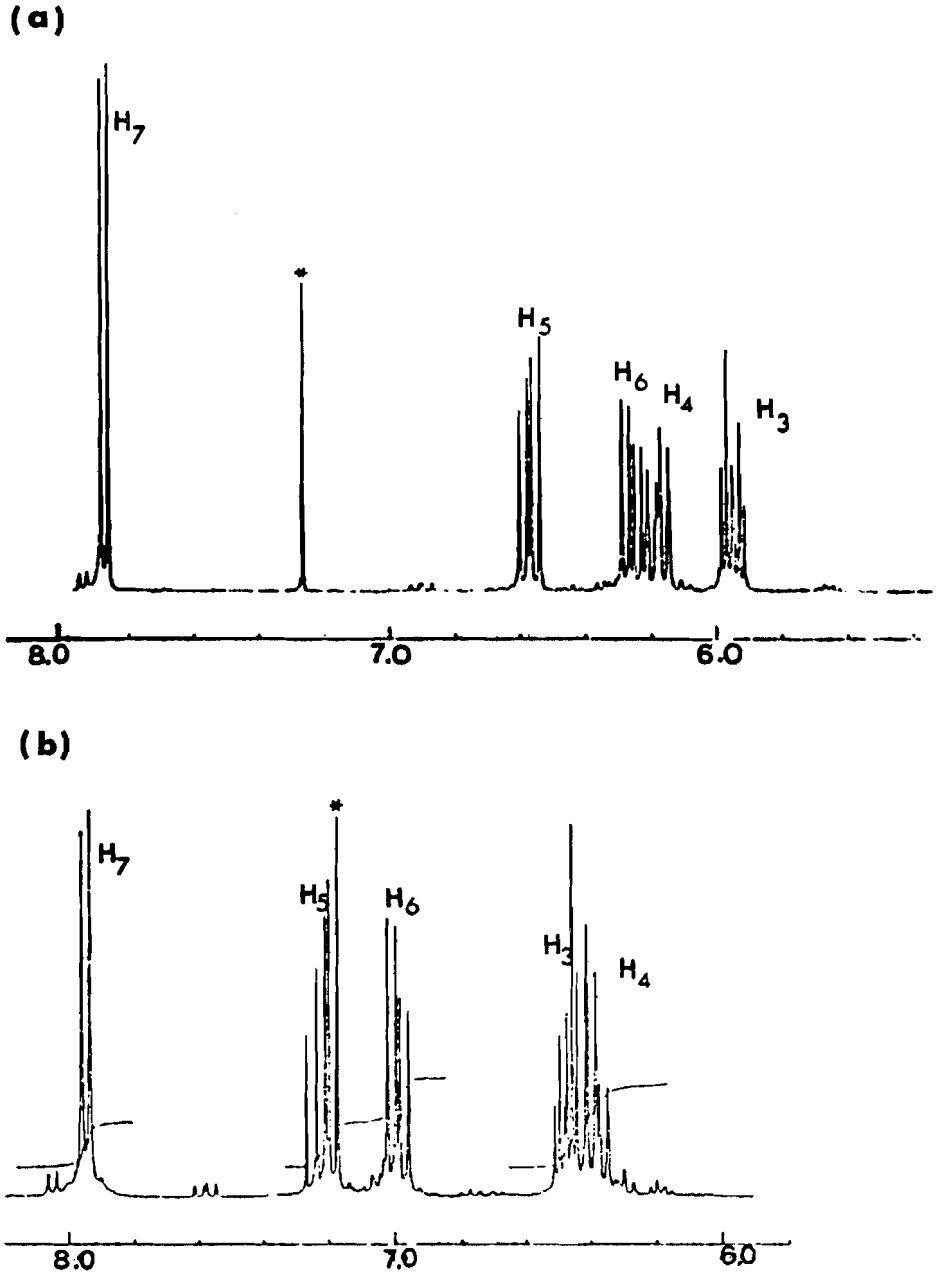

FIG. 7. 400-MHz ^{1}H nmr in $CDCl_3$ (a) of 2,4-*trans*-*trans*-heptadienylidene *tert*-butylamine (**1**) showing the ethylenic protons H_3 to H_7 and (b) of a mixture of **1** with trichloroacetic acid in a 1:1 molar ratio.

effect of methanol. The same kinds of results were obtained in our study in methanol. Both uv and nmr data show no variation, whatever the acids used. Comparing H_6 values obtained in $CDCl_3$ and in CD_3OD, it is possible to note a strong deshielding value in $CDCl_3$ but only a small one in CD_3OD. This could be explained by the fact that, in $CDCl_3$, the carbonyl group of the counteranion affects H_6, while in CD_3OD only a small effect is expected since the solvent replaces the counteranion. The similarity of the results in deuterated methanol and the small deshielding effect on H_6, combined with the nonvariation of the uv spectra, support the hypothesis that a leveling effect is operating in methanol.

It is interesting also to note that H_3 and H_5 are strongly deshielded by acids both in $CDCl_3$ and in CD_3OD, the deshielding being bigger in CD_3OD than in $CDCl_3$. This represents the effect of protonation of the Schiff base by the different acids through resonance.

A most important aspect of our study of **1** by ^{1}H nmr is the impact of the acids on H_7 (that is —C*H*=N—). In deuterated chloroform H_7 is only slightly shifted by the presence of acids (less than 0.1 ppm), while in CD_3OD the deshielding reaches nearly 0.5 ppm. This effect on H_7 through the use of different solvents might explain the controversy surrounding the ^{13}C nmr results of rhodopsin (9). Since nmr data for H_7 reflect the fundamental state of the imine bond, there must exist a relation between nmr characteristics of the imine proton (RC*H*=N—) and the ^{13}C of the carbon bearing the imine linkage (R*C*H=N—). Our results indicate that in a nonpolar solvent the aldimine proton (H_7) is very slightly affected by acids, while in a more polar solvent the effect is much greater. The ^{13}C nmr should indicate the same thing for the aldimine carbon. Extended to rhodopsin, our reasoning means that, depending

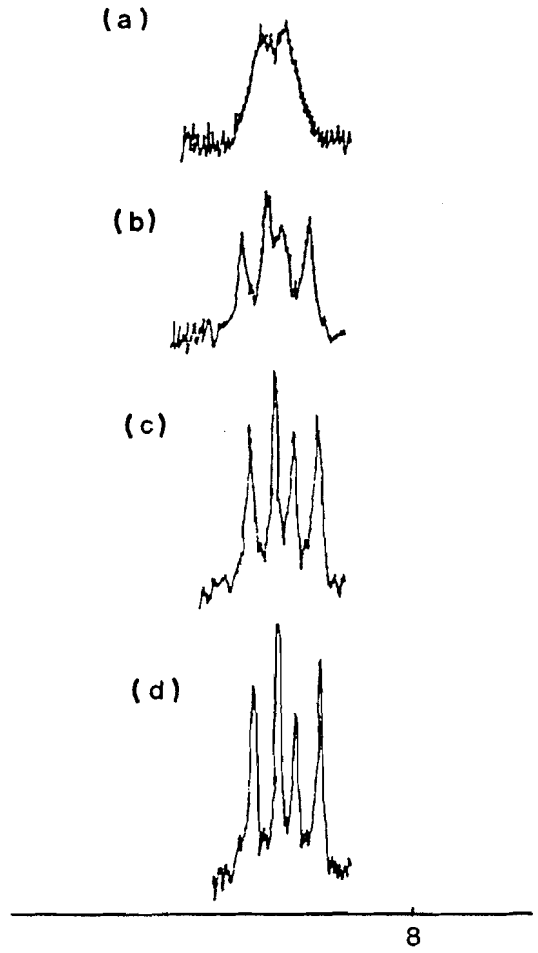

FIG. 8. ^1H nuclear magnetic resonance of **1** with trichloroacetic acid in $CDCl_3$. (a) 1:2; (b) 1:3; (c) 1:4; (d) 1:5 molar ratio. Exceptionally, these spectra were obtained on a Varian EM360L.

on the milieu in which rhodopsin is studied, ^{13}C nmr could indicate protonation or no protonation. Especially important is the use of detergents in extraction of visual pigments: depending on their characteristics, different answers could be obtained. Thus, the nature of detergents has been judged crucial in *in vitro* regeneration of visual pigments (10), and photoconversion of bathorhodopsin to rhodopsin and isorhodopsin is strongly influenced by detergents (11). If no effect of detergents on the state of protonation of rhodopsin has been seen as yet, such an effect has been invoked by Lam and Packer (12) for bacteriorhodopsin.

In chloroform (or $CDCl_3$), uv and nmr data are particularly interesting. Only HCl, TCA, and dichloroacetic acid (DAA) are able to completely shift the 267-nm band to 310 nm. It will be noted that λ_{max} for all three acids is the same; this is somewhat surprising since Blatz (5) noted a variation in the λ_{max} of NRBA in the presence of strong acids in nonpolar solvents. With all the other acids, only a partial shift occurred. For these acids, it is possible to explain the results by establishing the following equilibrium, eq. [1]:

[1] $$RCH{=}N{-}R' + R''CO_2H \rightleftharpoons \left[RCH{=}\overset{+}{N}(H){-}R'\right]\bar{O}_2CR''$$

For the monohalogeno acids, the mixture observed by uv

* In a 1:1 molar ratio.

consists of approximately 80% of the imine (λ_{max} 267) and 20% of the salt (λ_{max} 310). In the presence of a large concentration of acids the equilibrium is shifted to the right as expected. Accordingly, the percentage of the salt increases with the proportion of acid so that at a ratio of 1:50 the imine has completely disappeared. As was said before, there is no correlation between the percentage of the salt and the pK_a of the acid measured in water (6). Considering that in chloroform carboxylic acids are very weak acids and that their difference in acidity could be considered negligible, it is possible to rationalize our results by invoking the ability of the polar groups (Cl, Br, I, F) to stabilize one of the resonance forms of the protonated Schiff base, eq. [2].

[2] $$C_2H_5CH{=}CH{-}\overset{+}{C}H{-}CH{=}CH{-}N(H){-}R \quad X{-}CH_2{-}COO^- \longleftrightarrow C_2H_5\overset{+}{C}H{-}CH{=}CH{-}CH{=}CH{-}N(H){-}R \quad X{-}CH_2{-}\bar{C}OO$$

That this could be true is seen by looking at the nmr results. Table 3 shows a pronounced deshielding on H_5 and H_3. It is worth mentioning that propionic acid (no polar group present) has a slight effect on H_3 and H_5 while 3-nitropropanoic acid induces a strong deshielding (6). With halogens, chlorine has the greatest stabilizing effect (especially di- and trichloro). This interpretation of our results is consistent with the external point charge advocated by Nakanishi.

Finally, the fact that H_7 in $CDCl_3$ appears as a doublet in the nmr spectra must be fully discussed. It has been shown (Fig. 8) that, by varying the concentration of TCA, a quartet could be obtained like the one seen for HCl. A quartet is expected for a system such as $=C(H){-}C(H){=}N{-}$. Since, with TCA and DAA, the uv spectra show full protonation, to observe such a quartet is to be expected. As Fig. 7(b) shows, a doublet is present when equimolar concentrations are used. From these results it must be concluded that, in $CDCl_3$, the proton is wandering between the acceptor and the donor, eq. [3].

[3] 
When high concentrations of acid are used, the proton resides a longer time with the nitrogen and a quartet ensues. In a 1:1 molar ratio, the proton is moving rapidly between the nitrogen and the oxygen of the carboxylate anion so that it is as though it were not there; a doublet is the result. This means that protonation and hydrogen bridging (13) become undistinguisable. When extrapolated to rhodopsin, our interpretation of our results means that not only the solvents or detergents are important, but that the spectroscopic techniques used could lead to conflicting conclusions.

Acknowledgments

The authors are grateful to the Laboratoire régional de RMN à haut champ (Mr. Phan Viet Minh Tan) of the University of Montreal for gathering all the 400-MHz nmr spectra. We owe many thanks also to Professor Camille Sandorfy of the University of Montreal for helpful discussions and, finally, to the National Research Council for financial support through grant A0943.

Marcus theory and the existence or non-existence of transition states in gas phase deprotonation of carbon acids

SAUL WOLFE
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received October 19, 1983

SAUL WOLFE. Can. J. Chem. **62**, 1465 (1984).

At the 3-21G (3-21G*) computational level, the intrinsic barriers associated with proton transfer between XCH_2^- and CH_3X have been found to be essentially constant (ca. 10 kcal/mol) for X = H, F, SH, Cl. According to the Marcus rate-equilibrium treatment of proton transfer reactions, this result means that transition states should not exist for gas phase reactions $HO^- + CH_3X \rightleftarrows H_2O + XCH_2^-$, when the energy change exceeds 20 kcal/mol. This prediction has been confirmed for two cases (X = H, F) in which the energy change is less than 20 kcal/mol, and two cases (X = SH, Cl) in which the energy change is greater than 20 kcal/mol.

SAUL WOLFE. Can. J. Chem. **62**, 1465 (1984).

Faisant appel à des calculs au niveau 3-21G (3-21G*), on a trouvé que les barrières intrinsèques associées au transfert de proton entre le XCH_2^- et le CH_3X sont essentiellement constantes (soit environ 10 kcal/mol) pour X = H, F, SH, Cl. D'après le traitement vitesse-équilibre fait par Marcus des réactions de transfert de proton, ce résultat signifie qu'il ne devrait pas y avoir d'états de transition pour les réactions en phase gazeuse du $HO^- + CH_3X \rightleftarrows H_2O + XCH_2^-$, lorsque la variation d'énergie dépasse 20 kcal/mol. Cette prédiction est confirmée dans deux cas (X = H, F) pour lesquels les variations d'énergie sont inférieures à 20 kcal/mol et dans deux cas (C = SH, Cl) dans lesquels la variation d'énergie est supérieure à 20 kcal/mol.
[Traduit par le journal]

There is an extensive literature on rate-equilibrium relationships associated with electron transfer, atom transfer, proton transfer, and alkyl transfer reactions of the type A—B + C → A + B—C (1). To account for deviations from Brönsted behaviour that are observed when A and C are allowed to vary greatly, a number of equations have been derived that relate $\Delta E^{\ddagger}$, the energy barrier of the reaction, not only to ΔE, the overall energy change, but also to $\Delta E_0^{\ddagger}$, an intrinsic kinetic quantity. Most commonly, $\Delta E_0^{\ddagger}$ has been taken as the average of the barriers associated with the identity reactions A—B + A → A + B—A and C—B + C → C + B—C. Although the mathematical forms of these equations differ, and different physical models have been employed to obtain them, Murdoch has shown (2) that they can be generalized to [1], where g_1 and g_2 are functions that govern the relative importance of the kinetic and thermodynamic contributions to the overall barrier.

$$[1] \quad \Delta E^{\ddagger} = \Delta E(1 + g_1) + \tfrac{1}{2}\Delta E_0^{\ddagger}(1 - g_2)$$

A particularly successful variant of eq. [1] is the Marcus eq. [2] (3), in which $g_1 = \Delta E/4\Delta E_0^{\ddagger}$, and $g_2 = (\Delta E/4\Delta E_0^{\ddagger})^2$. The derivation of eq. [2] assumes a single stationary point between the reactants (A—B + C) and the products (A + B—C), which can be either an energy maximum (transition state) or an energy minimum (stable intermediate) (4).

$$[2] \quad \Delta E^{\ddagger} = \Delta E_0^{\ddagger} + \tfrac{1}{2}\Delta E + (\Delta E)^2/16\Delta E_0^{\ddagger}$$

Gas phase transfer reactions create problems for the application of the Marcus treatment, because the reaction coordinate may contain additional stationary points. In particular, for alkyl transfer reactions (B = alkyl), both experiment (5) and theory (6) suggest that, when C is an anion, reactant (A—B···C) and product (A···B—C) ion–molecule complexes are present. In Fig. 1, which illustrates such behaviour, eq. [2] refers only to the central portion, from A—B···C to A···B—C, and its application requires the characterization of all three stationary points. This is a difficult experimental problem when many combinations of A and C are to be studied. A computational

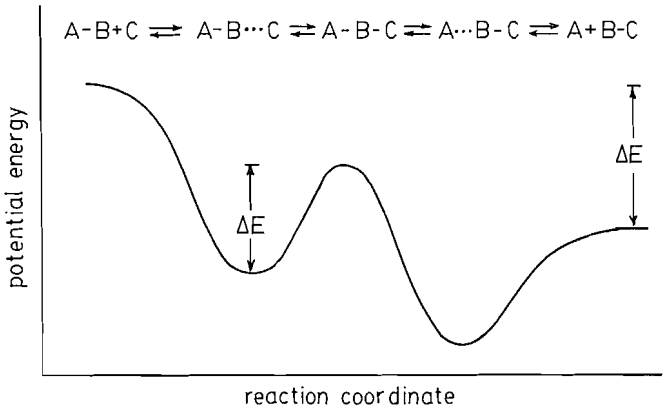

FIG. 1. Typical gas phase reaction coordinate for an exothermic gas phase transfer reaction AB + C → A + BC when C is an anion.

test of eq. [2] is also feasible, and has recently been performed, for the S_N2 reaction, for twenty combinations of A and C. Excellent agreement with the Marcus equation was observed (7).

A useful consequence of the applicability of the Marcus treatment is that this treatment predicts no stationary points to exist between reactants and products when $|\Delta E| \geq 4\Delta E_0^{\ddagger}$. This condition appears to apply also to gas phase reactions; for example, at the 4-31G computational level, the reaction $F^- + CH_3Cl \rightarrow FCH_3 + Cl^-$ proceeds with $\Delta E = -59.2$ kcal/mol, and $\Delta E_0^{\ddagger}$ is 8.6 kcal/mol. No transition state should, therefore, exist for this reaction at this computational level, and none could be found (8).

This result is relevant to a problem of interest in this laboratory, viz., the kinetic acidities of the diastereotopic methyl protons of compounds CH_3X (X = sulfide, sulfoxide, sulfone, and sulfonium) in reaction [3] (9). At the 3-21G* level (10), the calculated $-\Delta E$ for these reactions range from 23.4 kcal/mol

$$[3] \quad HO^- + CH_3X \rightarrow H_2O + {}^-CH_2X$$

for X = sulfide to 181.1 kcal/mol for X = sulfonium. For

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

transition states to exist in these reactions, $\Delta E_0^{\ddagger}$ would have to exceed 5.85 kcal/mol in the case of X = sulfide and 45.28 kcal/mol in the case of X = sulfonium. The processes that define $\Delta E_0^{\ddagger}$ in these cases are summarized by eqs. [4] and [5], where $\Delta E_0^{\ddagger} = \frac{1}{2}(\Delta E_{OO}^{\ddagger} + \Delta E_{CC}^{\ddagger})$, and the intrinsic barriers $\Delta E_{OO}^{\ddagger} = E_2 - E_1$ and $\Delta E_{CC}^{\ddagger} = E_4 - E_3$.

[4] $HO^- + HOH \rightleftarrows [HO\cdots HOH]^- \rightleftarrows [HO{-}H{-}OH]^- \rightleftarrows [HOH\cdots OH]^- \rightleftarrows HOH + OH^-$
1 **2** **1**

[5] $XCH_2^- + CH_3X \rightleftarrows [XCH_2\cdots HCH_2X]^- \rightleftarrows [XCH_2{-}H{-}CH_2X]^- \rightleftarrows [XCH_2H\cdots CH_2X]^- \rightleftarrows XCH_3 + CH_2X^-$
3 **4** **3**

There has been recent interest in the magnitude of $\Delta E_{OO}^{\ddagger}$, in connection with studies of anionic hydrogen bonds (11). With full geometry optimization of **1** and **2**, the barrier is calculated to be 0.21, 1.03, and 0.77 kcal/mol, at the 4-31G, 6-31G*, and 6-31G** levels, respectively. As will be seen below, no barrier is found at the 3-21G* level.[1] This means that the deprotonation reaction $HO^- + CH_3X$ (X = sulfide) will have no transition state if $\Delta E_{CC}^{\ddagger}$ (X = SR) < 11.7 kcal/mol (i.e., $-\Delta E/2$); the deprotonation reaction $HO^- + CH_3X$ (X = sulfonium) will have no transition state if $\Delta E_{CC}^{\ddagger}$ (X = $^+SR_2$) < 90.6 kcal/mol. Since the strategy to be adopted for a computational investigation of reaction [3] for various X would depend upon the presence or absence of transition states in such reactions, the magnitudes of the previously unknown $\Delta E_{CC}^{\ddagger}$, and the manner in which these depend on X had to be established.

The purposes of the present work are, therefore, as follows: (*1*) to calculate $\Delta E_{CC}^{\ddagger}$ at the 3-21G* level for the series X = H, F, SH, Cl; (*2*) where the magnitudes of $\Delta E_{CC}^{\ddagger}$ and ΔE for reaction [3] indicate that a transition state should exist, to find this transition state and the reactant and product ion–molecule complexes; (*3*) where no transition state is predicted to exist, to check that no transition state can be found. All computations were performed on a Perkin–Elmer 3251 computer, using GAUSSIAN 80 (13), with full optimization of the structures.

Results and discussion

Tables 1 and 2 list, respectively, the total energies and selected geometrical parameters of the species required for the application of the Marcus treatment. The various ΔE of interest, based on the data of Table 1, are summarized in Table 3. These are as follows: ΔE_{st}, the stabilizing effect of X upon XCH_2^-, from the isodesmic reaction [6], ΔE_w and ΔE_b (see Fig. 2), $\Delta E_{CC}^{\ddagger}$, $\Delta E_0^{\ddagger}$, $4\Delta E_0^{\ddagger}$, and ΔE for reaction [3].

[6] $CH_3^- + XCH_3 \rightarrow CH_4 + XCH_2^-$

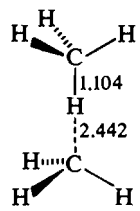
Comparison of neutral (XCH_3) and anionic (XCH_2^-) structures

Computations on XCH_3 and XCH_2^- systems have been performed recently by Pross *et al.* (14) and by Schleyer (15). The trends observed in those comprehensive studies are reproduced in the present, more limited, work. Although, based on Schleyer's calculations with a triply split valence basis set (15), ΔE_{st} is overestimated at the 3-21G* level, it is clear that each of X = F, SH, Cl stabilizes XCH_2^- relative to X = H.

The stabilization associated with X = SH is of a different nature than that associated with X = F, Cl, since the C—X bond length of XCH_2^- is significantly shorter for X = SH, and is significantly longer for X = F, Cl, than the C—X bond length of CH_3X. In the spirit of the discussion in refs. 14 and 15, the HOMO of $HSCH_2^-$ is stabilized by the $n_C - \sigma_{SH}^*$ orbital interaction, a π-accepting (hyperconjugative) mechanism. This mechanism is not available in FCH_2^- and $ClCH_2^-$, which are stabilized by σ-electron withdrawal. The HOMO's of these latter anions are dominated by the $n_C - n_X$ destabilizing orbital interaction; this destabilization is relieved by an increase in the C—X bond length, and a decrease in the energy of n_C, which corresponds to greater pyramidalization of the carbanion. In the case of $ClCH_2^-$, the increase in the C—Cl bond length (0.41 Å), and the increased pyramidalization ($\angle HCCl$ = 91.7°, compared to $\angle HCS$ = 112.0° in $HSCH_2^-$) are so large that this anion should be regarded as a carbene solvated by Cl^-. A similar conclusion has been reached concerning the antiperiplanar conformation of $^-CH_2{-}SH_2^+$ (16).

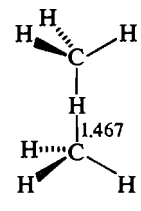
Effect of X upon ΔE_w, ΔE_b, and $\Delta E_{CC}^{\ddagger}$

All of the **3** and **4** species were constrained to the staggered (antiperiplanar) conformations shown in Table 2. This choice was checked for X = H: the eclipsed structures **5** and **6** are



5

$E = -79.231664$



6

$E = -79.216153$

marginally less stable than the staggered structures, and the calculated $\Delta E_{CC}^{\ddagger}$ (9.73 kcal/mol) is 0.09 kcal/mol higher (17).

The most significant finding is that the intrinsic barriers $\Delta E_{CC}^{\ddagger}$ do not appear to depend on X. This results from a cancellation of the energetic effects of X upon the ion–molecule complexes **3** and the transition structures **4**; both species are stabilized to the same extent by X ≠ H. In the general reaction $XCH_2^- + HCH_2X \rightleftarrows$ **3** or **4**, an increase in the stability of XCH_2^- must lead to a *decrease* in the reactivity of this anion towards the proton donor, which is counter-balanced by an *increase* in the reactivity of XCH_3 towards the proton acceptor.

Consequences of the relationship between ΔE and $4\Delta E_0^{\ddagger}$

From the last two columns of Table 3, and the Marcus condition for the existence or non-existence of a transition state, it follows that reactions [7] and [8] should have transition states, but [9] and [10] should not.

[7] $HO^- + CH_4 \rightarrow H_2O + CH_3^-$

[1]The 3-21G (12) and 3-21G* basis sets are the same for atoms of the first row. In the 3-21G* basis set, a set of six *d*-type functions is added to second row atoms.

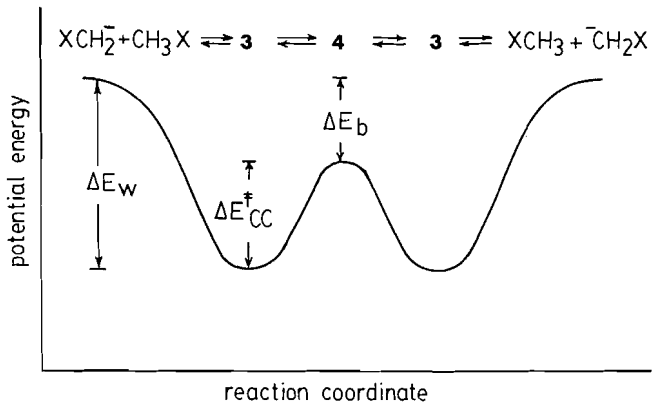

FIG. 2. Reaction coordinate associated with the intrinsic barrier $\Delta E^{\ddagger}_{CC}$, and definitions of the quantities ΔE_w and ΔE_b.

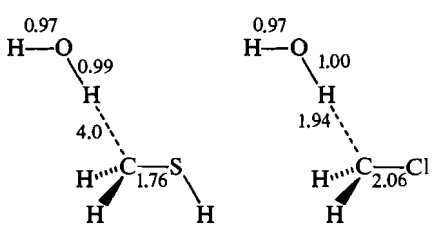
[8] $HO^- + FCH_3 \rightarrow H_2O + FCH_2^-$

[9] $HO^- + HSCH_3 \rightarrow H_2O + HSCH_2^-$

[10] $HO^- + ClCH_3 \rightarrow H_2O + ClCH_2^-$

The attack of HO^- upon the antiperiplanar methyl proton of CH_3SH was examined, but the search for a transition structure was terminated when this search had reached **7**, i.e., H_2O + $^-CH_2SH$, separated by 4 Å. Clearly reaction [9] proceeds directly to product, with no transition state, as predicted by the Marcus treatment. An analogous structure (**8**) was obtained for reaction [10].



7 8

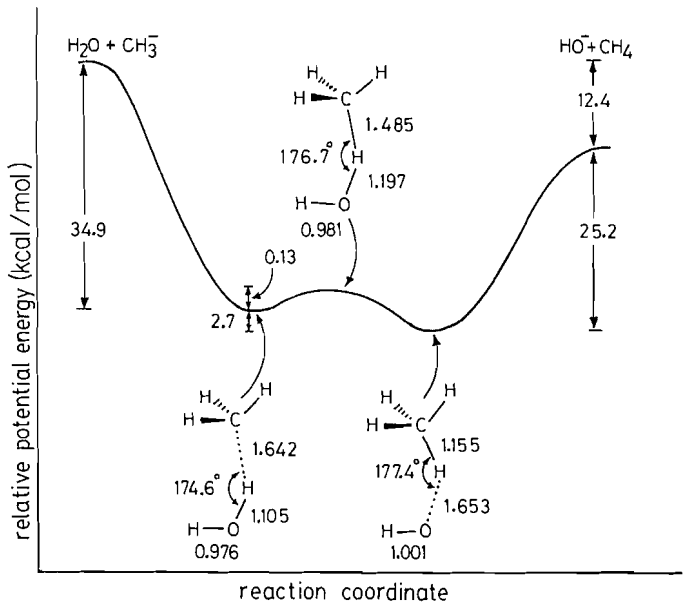


FIG. 3. Calculated gas phase reaction coordinate for the exothermic reaction $H_2O + CH_3^- \rightarrow HO^- + CH_4$, and the relative energies and structures of the stationary points on this reaction coordinate.

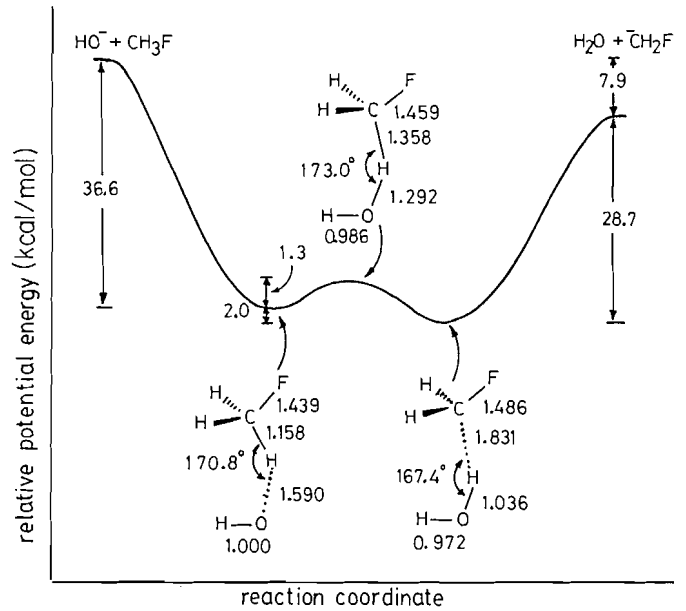

FIG. 4. Calculated gas phase reaction coordinate for the exothermic reaction $HO^- + CH_3F \rightarrow H_2O + {}^-CH_2F$, and the relative energies and structures of the stationary points on this reaction coordinate.

On the other hand, as summarized in Figs. 3 and 4, reactant and product ion−molecule complexes and transition structures do exist for reactions [7] and [8]. It will be noted that the applicability of the Marcus treatment does not depend on the direction of the reaction, since [7] is endothermic, while [8] is exothermic.

When stationary points are found for a series of related reactions, the Bell−Evans−Polanyi−Leffler−Hammond effect states (18) that *the more exothermic the reaction, the more closely the transition structure resembles the higher energy*

reactants. The data just presented for reactions [7] and [8] allow a first test of this principle for gas phase proton transfer from carbon acids. Since [7] is more exothermic (in the exothermic direction) than [8], it is expected that the transition structure of [7] should resemble its higher energy reactant $[HO—H\cdots CH_3]^-$ more than the transition structure of [8] resembles its higher energy reactant $[HO\cdots H—CH_2F]^-$. An examination of the change in the HO—H bond lengths between the reactants and the transition structures for the two reactions reveals that, in [7], this bond lengthens by 8.4%, but in [8] this bond shortens by 18.8%. A more comprehensive study of the relationship between the geometries of the stationary points and the energetics of proton transfer from carbon acids is in progress.

Summary and conclusions

The concept of a reaction coordinate is an essential feature of the transition state theory of chemical reactions. If the reaction coordinate is defined as the minimum energy reaction path from reactants to products, it is clear that the reaction coordinate constitutes only a small region of a more complex energy hypersurface. The topologies of such hypersurfaces have been the subject of much recent work (19), and the many problems associated with the computational characterization of their "critical" (20) or stationary points have been pointed out (21). It is, therefore, useful to know prior to a computational search that the supposed structure of interest actually exists. That the existence or non-existence of transition structures can be predicted in advance is a facet of the Marcus approach that does not appear to have been exploited previously. As seen in the present work, the reliability of this aspect of Marcus theory will greatly facilitate future theoretical investigations of reaction coordinates and rate-equilibrium relationships.

Stereoelectronic effects and the kinetic acidities of diastereotopic hydrogens

SAUL WOLFE, ALBERT STOLOW, AND LAWRENCE A. LAJOHN
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received October 19, 1983

SAUL WOLFE, ALBERT STOLOW, and LAWRENCE A. LAJOHN. Can. J. Chem. **62**, 1470 (1984).

A general qualitative treatment is proposed which accounts for the relative reactivities of diastereotopic hydrogens adjacent to a heteroatom in proton transfer, hydride transfer, and hydrogen atom transfer reactions. This treatment focuses on the structures of the reactive intermediates formed in such reactions, which can be predicted or understood in terms of qualitative molecular orbital arguments, and on the manner in which these intermediates will undergo readdition of H^+, H^-, or $H\cdot$. The procedure has been tested, for the specific case of proton transfer reactions, by a direct computational approach to the energy differences between diastereomeric transition states of reactions $HO^- + CH_3X \rightarrow H_2O + {}^-CH_2X$ (X = sulfide, sulfoxide, sulfone, sulfonium). The computations support the qualitative treatment, and are in all cases in near quantitative agreement with the extensive experimental data concerning the diastereotopic selectivities exhibited in these systems.

SAUL WOLFE, ALBERT STOLOW et LAWRENCE A. LAJOHN. Can. J. Chem. **62**, 1470 (1984).

On propose une méthode qualitative générale qui tient compte des réactivités relatives des hydrogènes diastéréotopiques adjacents à un hétéroatome lors de réactions de transfert de protons, d'hydrures ou d'atomes d'hydrogène. Cette méthode met l'accent à la fois sur la structure des intermédiaires réactifs formés au cours de telles réactions, qui peuvent être prévus ou compris en termes d'arguments qualitatifs d'orbitales moléculaires, et sur la façon dont ces intermédiaires peuvent subir une nouvelle addition de H^+, H^- ou $H\cdot$. On a vérifié cette méthode, dans le cas spécifique de réactions de transfert de proton, par une technique de calculs directs des différences d'énergie entre les états de transition diastéréoisomères des réactions: $HO^- + CH_3X \rightarrow H_2O + {}^-CH_2X$ (X = sulfure, sulfoxyde, sulfone, sulfonium). Les calculs sont en accord avec l'approche qualitative et, dans tous les cas, ils sont aussi en accord quasi-quantitatif avec les données expérimentales extensives relatives aux sélectivités diastéréotopiques observées dans ces systèmes.

Introduction

Heterotopic selectivity in a reversible non-enzymatic reaction was first recorded experimentally by Rauk *et al.* in 1965 (ref. 1, see ref. 2 for a recent discussion of terminology), with the observation that the diastereotopic methylene protons of benzyl methyl sulfoxide have different kinetic acidities. In 0.25 *M* NaOD–D_2O at 15°C, the ratio of the rate constants for hydrogen-deuterium exchange of these protons is 16.7. This observation was quickly confirmed (3), and extended to the hydrogen exchange behaviour of other sulfoxides (4), sulfones (5), and sulfonium salts (6), and to demonstrations that α-lithiated dithianes (7), sulfoxides (8), and sulfonium salts (9) are generated and/or quenched with significant selectivity.

Although diastereotopic selectivity in reversible and irreversible proton transfer reactions of sulfur-containing species is thus well established experimentally, a completely satisfactory analysis of the phenomenon has been difficult to achieve, because the magnitude and, in some cases, even the direction of the effect can be changed by a change in the experimental conditions. For example, the magnitude and direction of the selectivity in the hydrogen–deuterium exchange of sulfoxides depend upon the solvent (3*b*, 4*i*); and the magnitude and direction of the selectivity in the formation and quenching of α-lithiosulfoxides depend upon the presence, absence, and nature of added lithium salts (8*j*, *k*).

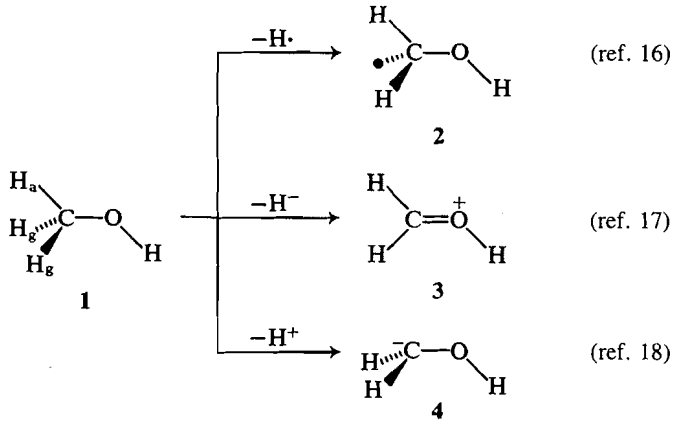
Selectivity in carbon–hydrogen bond breaking processes is not restricted to proton transfer reactions, or to sulfur-containing systems; hydride (10) and hydrogen atom transfer reactions (11) of diastereotopic hydrogens also exhibit selectivity.

One of the objectives of the present work is to suggest a qualitative treatment that can be applied generally to the prediction of the relative reactivities of diastereotopic hydrogens when solvation and related factors can be ignored. A second objective is to check these qualitative predictions quantitatively for proton transfer reactions by direct calculation of the energies of diastereomeric transition states associated with proton abstraction adjacent to sulfide, sulfoxide, sulfone, and sulfonium moieties. A third objective is to provide detailed comparisons between theory and experiment, where such comparisons can be justified.

A qualitative treatment of diastereotopic selectivity

The methyl hydrogens of methanol are diastereotopic. In the staggered conformation **1**, one of these hydrogens (H_a) is antiperiplanar to the O—H bond, and the other two (H_g) are *gauche*. The diastereotopic relationship between H_a and H_g is reflected in certain ground state properties of the molecule: C—H_g is ca. 0.006 Å longer than C—H_a (12), and the C—H_g stretching force constant is lower by ca. 0.1 mdyn/Å (13). On the basis of this difference in stretching force constants it has been calculated, by two quite different procedures (14, 15), that D(C—H_g), the bond dissociation energy of C—H_g, is 5 kcal/mol lower than D(C—H_a) (95 versus 100 kcal/mol). The lower of these numbers corresponds to the experimental D(C—H) of methanol.

How do these differences in the properties of the diastereotopic hydrogens translate into differences in reactivity? As shown in Scheme 1, removal of $H\cdot$, H^-, and H^+ from the carbon atom of methanol leads, respectively, to $HOCH_2\cdot$, $HOCH_2^+$, and $HOCH_2^-$. The structures of these reactive intermediates are known (16–18), and are shown in **2**–**4**. In each case, the factors responsible for the adoption of these structures are also known: for example, the structure of **2** can be understood in terms of the pyramidalizing effect of a heteroatom on an adjacent radical centre (19), coupled with the stabilization resulting from a two-orbital three-electron interaction (20); an α-heteroatom-stabilized carbocation adopts a planar structure such as **3** in order to maximize charge transfer from the higher energy non-bonding orbital on the heteroatom to the unoccu-



SCHEME 1

pied acceptor orbital at the cationic centre (17); and an α-heteroatom-stabilized carbanion adopts a conformation (e.g., **4**) that maximizes charge transfer from the non-bonding orbital on carbon to a σ* or π* orbital of the activating moiety (21).

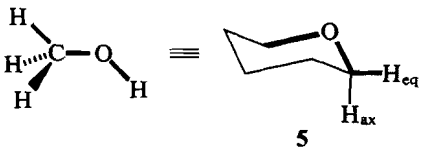
Inspection of the radical **2** suggests that it is formed from **1** by the loss of H_g, i.e., H_g of **1** is more reactive than H_a. Since this is the result expected on the basis of the difference in bond dissociation energies, there appears to be a relationship between the structure of the reactive intermediate **2** and the radical reactivities of the diastereotopic hydrogens of methanol. Two assumptions are necessary to support such a relationship, viz., (*i*) the transition state for the process **1** → **2** must be product-like; (*ii*) the readdition of hydrogen to a non-planar centre must proceed with retention of configuration, the microscopic reverse of the abstraction process.

Rapid progress in the development of gradient optimization techniques (22, 23) is beginning to lead to theoretical studies aimed at the direct computation of the geometries and energies of transition structures. A recent application of such procedures to the S_N2 reaction (24) led to striking support for the principle (25) that *the transition state resembles the product in an endothermic reaction*. Since the reactions depicted in Scheme 1 are strongly endothermic, it follows that their transition states resemble the species **2**–**4**, in accord with assumption (*i*). Assumption (*ii*) is related to the arguments by Fraser *et al.* (4*i*), Fava and co-workers (6*c*), and King and du Manoir (8*h*) that stereoselectivity can be observed in hydrogen exchange reactions only if the more reactive of two diastereotopic hydrogens is removed and replaced with retention of configuration.

The direction of addition of H^- to **3** is well-known (26): addition will proceed, with an O—C—H^- angle of ca. 110°, from the plane perpendicular to the plane of the cation. Clearly, the H^- that adds to **3** becomes H_g of methanol. This allows the prediction that hydride abstraction from **1** will exhibit a kinetic preference for C—H_g.

In the case of the addition of H^+ to the non-planar carbanion **4**, this proton will become H_a. Consequently, proton abstraction from **1** should exhibit a kinetic preference for C—H_a.

If the skeleton of methanol is incorporated into that of tetrahydropyran (**5**), it is seen that H_g of **1** corresponds to the axial



5

hydrogen adjacent to oxygen, and H_a of **1** corresponds to the equatorial hydrogen. It follows that hydrogen and hydride abstraction adjacent to oxygen will exhibit a kinetic preference for an axial site, but proton abstraction will exhibit a kinetic preference for an equatorial site. All three of these predictions are in accord with the available experimental data on radical (11), hydride (10), and proton (27) abstraction adjacent to oxygen.

The argument just presented has focused solely on the stereoelectronic effect of the heteroatom, and has ignored the possibly countervailing influences of the solvent, the nature of the abstracting agent, and the remainder of the substrate molecule. For example, axial approach of the abstracting species would be deterred by 1,3-diaxial interactions that are absent in an equatorial approach. This effect is seen in reactions of trityl cation (28): although tetrahydrofuran and diethyl ether undergo hydride abstraction readily, the corresponding reaction with tetrahydropyran is too slow to measure.

In addition, although the argument has focused for simplicity on stereoelectronic effects and the reactivities of diastereotopic hydrogens adjacent to ether oxygen, the approach is general and should be applicable to any system for which the structures of the reactive intermediates are known or can be predicted. An example of such a system is the series of carbanions resulting from the reaction $HO^- + CH_3X \rightarrow H_2O + {}^-CH_2X$ (X = SR, SOR, SO_2R, SR_2^+). Since the structures of these carbanions are known and understood (29, 30), it should be possible to predict the relative kinetic acidities of diastereotopic hydrogens adjacent to each of these sulfur-containing moieties. As will be seen, these predictions are in every case consistent with experiment. This comparison is discussed below, in conjunction with a more rigorous theoretical analysis of the problem that is based on a computational treatment of the diastereomeric transition states associated with the above series of reactions.

A quantitative treatment of diastereotopic selectivity

A number of conceptual and technical problems had first to be overcome, viz.:

(*1*) To what kind of experimental information can computations be compared, as a test of the validity of these computations? The extensive research on H/D exchange of the diastereotopic methylene protons of benzyl methyl sulfoxide (1, 3*b*) suggests the nature of the required comparison. The selectivities observed in this reaction, and in the exchange of conformationally constrained sulfoxides (4*c*, *e*, *i*) are strongly solvent dependent because of effects associated with ion-pairing and internal return. However, in an important study, Fraser has shown (31) that these complicating effects are unimportant in water solvent. This result implies that kinetic data for water solvent do reflect the difference in the kinetic acidities of diastereotopic protons. Therefore, theoretically computed selectivities could reasonably be compared to experimental selectivities determined in water. Where such data were not available, but trends in water and methanol had been found to be the same, data from the latter solvent were employed for the comparison;

(*2*) What choice of R represents the best compromise between meaningful results and computational practicality? Based on the recent study of ${}^-CH_2X$ (X = SH, SMe, SHO, SOMe, SO_2H, SO_2Me, $^+SH_2$, $^+SMe_2$) (29, 30), systems with R = H and R = Me exhibit the same trends in their structures and proton affinities. Therefore, R = H was selected for the present study. The 3-21G* basis set (32) was employed, since this basis set has been found (29, 30) to reproduce accurately

For personal use only.

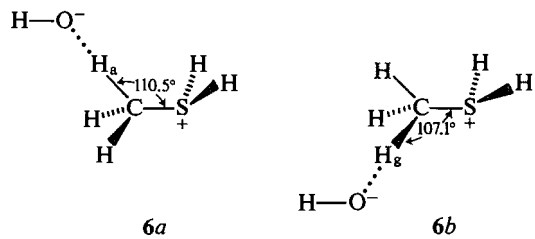
the structural effects in these sulfur-containing systems;

(*3*) With R = H, how can a transition structure for proton abstraction from carbon be described, to the exclusion of transition structures for other competing processes? For example, the reaction $HO^- + CH_3SH_2^+$ may proceed by proton abstraction from carbon (to yield the ylide CH_2SH_2), by proton abstraction from sulfur (to yield CH_3SH), or by S_N2 displacement on carbon (to yield CH_3OH). Only the first of these processes was of interest but, with R = H, deprotonation at sulfur is energetically preferred.

After extensive experimentation, the following protocol was adopted. As exemplified in **6***a*, HO^- was allowed to approach H_a, the hydrogen of $CH_3SH_2^+$ that is antiperiplanar to the sulfur lone pair, along the extension of the C—H_a bond ($\angle$C—H_a—O = 180°), and the S—C—H_a bond angle and H_a—C—S—H dihedral angle were held to their values in $CH_3SH_2^+$. For the deprotonation of H_g, HO^- approached along the extension of the C—H_g bond, with the S—C—H_g and H_g—C—S—H angles maintained as in $CH_3SH_2^+$ (**6***b*);



6*a* **6***b*

(*4*) Do these calculated reactions have transition states? This question can be posed as a result of insights gained from the application of the Marcus rate-equilibrium treatment (33) to gas phase proton transfer reactions (34). As discussed in detail elsewhere (34), it was clear at the outset that, in the gas phase, all of the reactions $HO^- + CH_3X$ (X = sulfide, sulfoxide, sulfone, sulfonium) would proceed directly to product. It was, therefore, necessary to assume that the reaction surface differs in the regions of H_a and H_g, and the dynamics of the attack of HO^- upon these hydrogens was followed, from a distance of 3 Å to a distance of 1.5 Å. All geometrical parameters of the resulting supermolecule were optimized at each distance, with the exception of those noted above. As will be seen, this procedure led to acceptable results.

After the present work was essentially complete, somewhat analogous theoretical treatments of the ene reaction of singlet oxygen (35) and the deprotonation of acetaldehyde (36) were reported.

The calculations were performed with the programme GAUSSIAN 80 (37), using the 3-21G* basis set. With the exceptions noted, all geometrical parameters were optimized in every case, using the appropriate gradient procedure.

Results and discussion

$HO^- + CH_3SH_2^+ \rightarrow H_2O + CH_2SH_2$

The structures of the reactant and product are shown in **7** and **8** (30). The reaction leads to a 0.2 Å decrease in the C—S bond length, and the carbon centre of the ylide **8** is planar, with the HCH plane bisecting the HSH plane. The non-bonding orbital on the ylide carbon is perpendicular to the HCH plane. The postulate that the reverse reaction **8** → **7** proceeds by proton transfer to the carbon non-bonding orbital of **8** leads to the prediction that this proton becomes H_g of the reactant, i.e., H_g of **7** has the higher kinetic acidity.

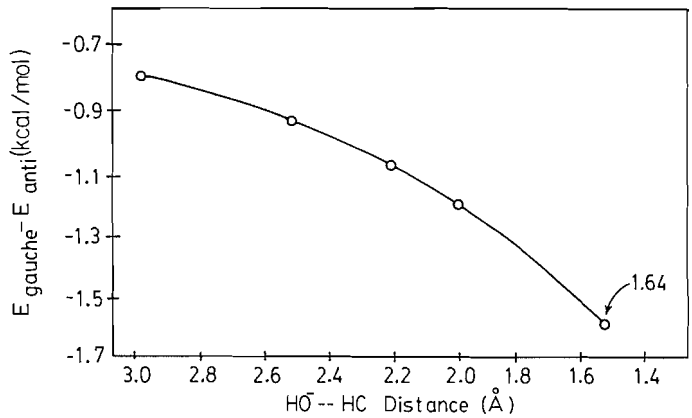


FIG. 1. A plot showing the difference in the energies of **6***b* and **6***a* as the HO⁻---HC distance is decreased from 3 Å to 1.5 Å.

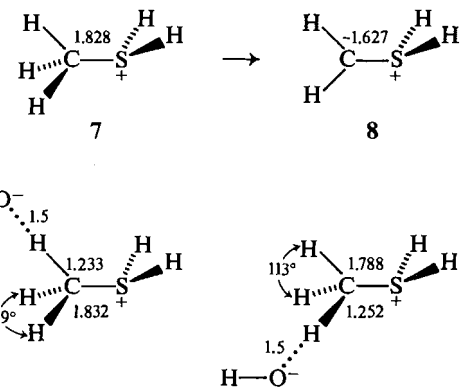
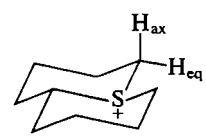
The structures corresponding to attack of HO^- upon C—H_g and C—H_a are shown in **9** and **10**, for an HO . . . H distance of 1.5 Å. At this distance, the C—S bond length of **9** is 0.045 Å shorter than that of the reactant; in addition, C—H_g has lengthened from 1.079 to 1.252 Å, and the other two methyl hydrogens now form an HCH angle of 113°, an increase from the tetrahedral angles in **7**. On the other hand, in **10**, the C—S bond length is unchanged from that of **7**, although C—H_a has lengthened from 1.077 to 1.233 Å. The total energy of **9** is lower, by 1.64 kcal/mol, and, as seen in Fig. 1, the energy



E = −511.04198 (1.64 kcal/mol) E = −511.04460 (0.0)



11

difference between the diastereomeric structures increases progressively to this value of 1.64 kcal/mol as the HO . . . H distance is decreased from 3.0 to 1.5 Å. Based on the equation $k_g/k_a = \exp(1640/RT)$, the selectivity is calculated to be k_g/k_a = 12 at 60°C, or one order of magnitude.

The relevant experimental data are those of Fava, for the conformationally constrained compound **11**, in NaOD–D_2O at 60°C (38). The equatorial (H_{eq}) and axial (H_{ax}) protons of this compound correspond, respectively, to H_g and H_a of **7**. The experimental result is k_{eq}/k_{ax} = 35, and is consistent with (*i*) a one order of magnitude greater kinetic acidity of k_{eq}; (*ii*) some reduction of k_{ax} associated with interactions between OD^- and

the 1,3-diaxial hydrogens of the sulfur-containing ring; (*iii*) selective reprotonation of a planar ylide (9*c*) from the equatorial direction.

Based on this first comparison, the theoretical approach to the problem appears to be adequate, and the notion that stereoselectivity in the deprotonation step can be predicted from a knowledge of the structure of the product is supported.

$HO^- + CH_3SHO \rightarrow H_2O + {}^-CH_2SHO$

Structures **12** and **13** are Newman projections of the reactant and the product (30). The bond lengths are, in **12**, C—S = 1.794 Å, S—O = 1.490 Å; in **13**, C—S = 1.675 Å, S—O = 1.523 Å. Proceeding as above, HO^- was positioned 1.5 Å from the extensions of C—H_1, C—H_2, and C—H_3, and the geometries and energies of the resulting diastereomeric species were calculated. The resulting relative energies (kcal/mol) and bond lengths (Å) are, for attack on H_1, 0.0; C—S = 1.760, S—O = 1.511; for attack on H_2, 7.3; C—S = 1.766, S—O = 1.504; for attack on H_3, 9.2; C—S = 1.783, S—O = 1.502. The calculated relative reactivities at 30°C are $H_1:H_2:H_3 = 4.3 \times 10^6:23:1$. At 84.5°C, the calculated relative reactivities are $H_1:H_2:H_3 = 4.5 \times 10^5:15:1$, or $k_1 \gg k_2 > k_3$.

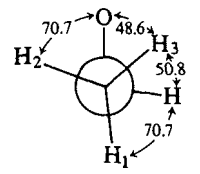
The relevant experimental data are those of Katritzky, for sulfoxides **14** and **15**, in methanol at 84.5° (4*e*), and those of Fraser, for sulfoxide **16**, in methanol at 30° (4*i*). The latter workers have recalculated Katritzky's rate constants, and these corrected values are employed here. Katritzky has provided some data for the exchange of **14** and **15** in water solvent at 90°; although these are not extensive, they indicate that the same ordering of relative reactivities is observed in water and in methanol.

As seen in **12**, the dihedral angles in the model sulfoxide of the present work are not ethane-like, because the angles at sulfur are not tetrahedral. The calculated relative reactivities are, therefore, not precisely comparable to those of the experimental systems whose dihedral angles are not known with certainty, but it is clear that the calculations predict highest reactivity for a hydrogen opposite the sulfinyl oxygen, and lowest reactivity for a hydrogen that lies near the axis of the sulfur lone pair.

Because of the rigidity of **16**, the dihedral angles reported for it from measurements on Dreiding models are probably more certain; these are reproduced in **17** and **18**. Of the four hydrogens H_1'—H_4' shown in these two structures, H_1' is opposite the sulfinyl oxygen, but closer to the axis of the sulfur lone pair than is H_1 of **12**; H_2' corresponds to H_2 of **12**, but is closer to the sulfinyl oxygen; H_3' corresponds very closely to H_3 of **12**; H_4' has no counterpart in **12**.

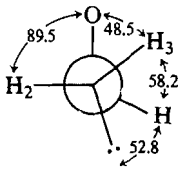
The experimental relative reactivities are $H_1':H_2':H_3':H_4' = 250:6.7:1.0:0.03$ at 30°C, or $k_1' \gg k_2' > k_3'$. The theoretical results are in agreement with this trend. If the difference in the dihedral angles of **12** and **16** is taken into account, the agreement improves: the least reactive hydrogens of **16** are H_3' and H_4', whose C—H bonds lie closest to the axis of the sulfur lone pair. The ratio $H_2'/H_4' = 200$, for hydrogens that otherwise lie in the same region of the molecule, also reflects the substantial retardation associated with increased eclipsing of a C—H bond with the axis of the sulfur lone pair. Since an analogous effect is seen when H_1' is compared to H_1, the experimental relative reactivity of H_1' could be lower than that calculated for H_1 by a factor of at least 10^2, as has been found.

Turning to Katritzky's data for compounds **14** and **15**, the relative reactivities in methanol solvent at 84.5°, as recalculated by Fraser, are $H_1':H_2':H_3' = 10:2:1$, or $k_1' > k_2' > k_3'$. The differences are much smaller than those observed for the rigid sulfoxide **16**, but the trend remains in agreement with that given by the theoretical calculations.



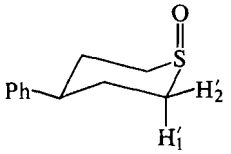
12

$\angle SCH_1 = 109.35°$
$\angle SCH_2 = 108.75°$
$\angle SCH_3 = 110.40°$

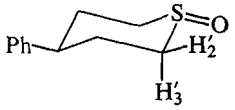


13

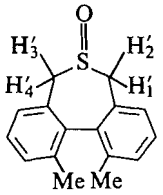
$E = -584.96103$ (0.0 kcal/mol)
$E = -584.94944$ (7.3)
$E = -584.94644$ (9.2)



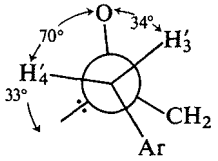
14



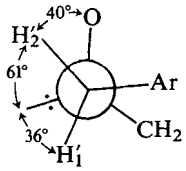
15



16



17



18

In the model reaction **12** → **13**, only one sulfinylcarbanion is formed. Attempts to optimize fully the structures of the carbanions corresponding to removal of H_2 and H_3 of **12** resulted in rotation to **13**. This kind of conformational change cannot occur in the cyclic structures **14**–**16**, and the formation of three carbanions can be envisaged with these cyclic structures. To simulate the effect of such conformational constraint in the deprotonation of **12**, H_1, H_2, and H_3 were removed, and the C—S and S—O bond lengths of the resulting anions were optimized, but C—S rotation was not permitted to occur. Relative to the stable structure **13**, the resulting energies were **12** − H_1, 6.6; **12** − H_2, 16.5; **12** − H_3, 17.2 kcal/mol.

It is clear that there is a one-to-one relationship between diastereotopic selectivity in the deprotonation of a sulfoxide and the relative stability of the resulting carbanion. In terms of the principal thesis of the present work, the notion that stereoselectivity in the deprotonation step can be predicted from a knowledge of the structure of the product is again supported.

Finally, it should be noted that allowing for the slight differences in dihedral angles already discussed, Fraser's interpretation (4*i*) of the origin of the diastereotopic selectivity in the exchange of benzyl methyl sulfoxide in water is strongly supported by the present calculations.

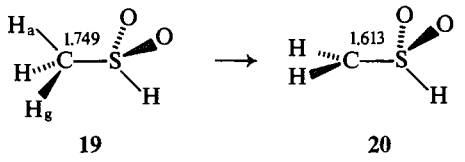
$HO^- + CH_3SHO_2 \rightarrow H_2O + {}^-CH_2SHO_2$

The structures of the reactant and product are shown in **19**

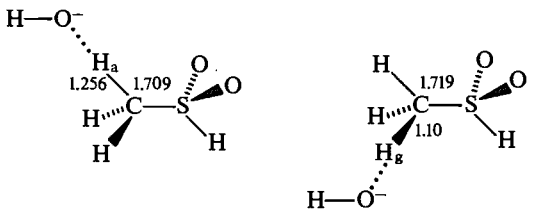
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

and **20** (30). Deprotonation leads to a 0.136 Å shortening of the C—S bond, and the carbon centre of the anion **20** is planar. The non-bonding orbital on this carbon atom lies in the same plane as the S—H bond. Inspection of **20** leads to the prediction that H_a of **19** has the higher kinetic acidity.

The structures corresponding to attack of HO^- upon H_a and H_g of **19** are shown in **21** and **22**, for an HO . . . H distance of 1.5 Å; **21** is lower in energy by 0.265 kcal/mol. The calculated selectivity is $k_a/k_g = 1.5$ between 30–80°C.

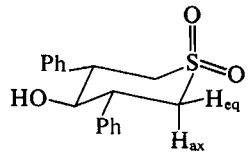


19 **20**

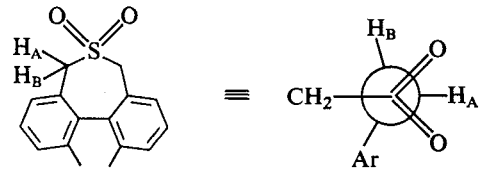


21 **22**

$\angle SCH_a = 108.3°$ $\angle SCH_g = 110.1°$
$E = -659.41185$ (0.0) $E = -659.41143$ (0.265)



23



24

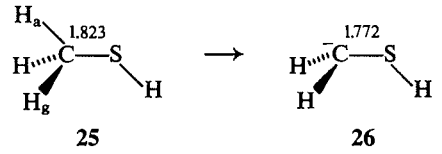
The experimental data are again from Katritzky (5*b*), for compound **23** at 36°C, and Fraser (5*a*), for compound **24** at 80°C. In **23**, H_{eq} corresponds to H_a of **19**; in **24**, H_A corresponds to H_a of **19**. The experimental selectivities are $k_{eq}/k_{ax} = 1.6$ for **23**, and $k_A/k_B = 3$ for **24**. Although the agreement between theory and experiment seems remarkable in this case, this must be fortuitous. In the case of sulfone **23** the medium for the exchange was DMSO–D_2O–OD^-; for **24** the medium was *t*BuOD–PhO^-. Ion-pairing effects can be expected to be important in such media, rendering the significance of the comparison between experimental and theoretical selectivities suspect.

Nevertheless, the calculations support the prediction, based on the structure of the α-sulfonylcarbanion, that diastereotopic selectivity in the deprotonation of **19** favors H_a.

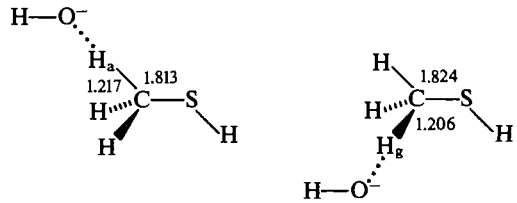
$$HO^- + CH_3SH \rightarrow H_2O + {}^-CH_2SH$$

The structures of the reactant and product are shown in **25** and **26** (29). The anion **26** has a non-planar configuration at carbon, and the non-bonding orbital on carbon lies in the S—H plane. Inspection of this structure allows the prediction that H_a of **25** has the higher kinetic acidity.

The structures corresponding to attack of HO^- upon H_a and H_g of **25** are shown in **27** and **28**, for an HO . . . H distance of

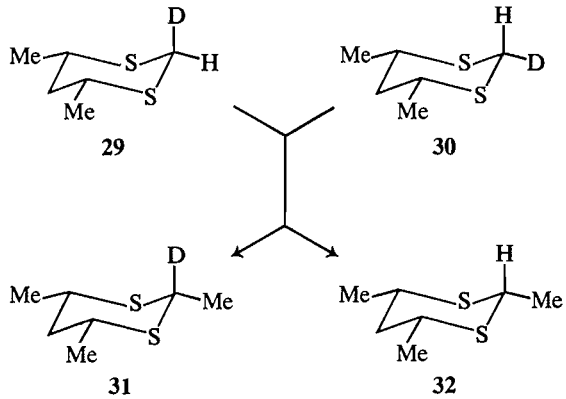


25 **26**



27 **28**

$\angle SCH_a = 106.8°$ $\angle SCH_g = 111.3°$
$E = -510.56730$ (0.0) $E = -510.56554$ (1.11)



29 **30**

31 **32**

1.5 Å; **27** is lower in energy by 1.11 kcal/mol. The calculated selectivity is $k_a/k_g = 9.1$ at −20°C.

Experimental work on hydrogen exchange in thianes has not been reported. Hydrogen–tritium exchange in 1,3-dithianes has been studied (39), but the experiments were conducted in *t*-butanol solvent, and the relative reactivities of the diastereotopic C2 protons were not determined explicitly. The most relevant experimental data appear to be those of Eliel (7), for the reaction of the diastereomeric anancomeric dithianes **29** and **30**, in the temperature range −20 to −25°C with, successively, butyllithium and methyl iodide in tetrahydrofuran solvent. These reactions lead to a mixture of **31** and **32**. Because of the nature of these experiments, application of the Curtin equations (40) to the mass spectral information leads directly to k_e/k_a, the ratio of the kinetic acidities towards butyllithium. This was found to be 8.6, compared to the theoretical value of 9.1 for the stereoelectronic effect of one sulfur atom.

Summary and conclusions

The present work has demonstrated two connections: a quantitative connection between theoretical diastereotopic selectivities based on a transition state approach to the problem, and selectivities observed experimentally for a variety of sulfur-containing systems; and a qualitative connection between these theoretical selectivities and the structures of the reactive intermediates.

The latter connection may be of particular interest to experimentalists, because qualitative molecular orbital arguments that deal with the structures of reactive intermediates such as **2**–**4** and the reactive intermediates of the present work are well developed (41), and are becoming more common as the concepts of charge transfer and stabilizing orbital interactions become more familiar.

Comment: Infrared absorption and resonance Raman scattering of photochromic triphenylformazans

HUBERT LANGBEIN AND ULRICH-WALTER GRUMMT
Sektion Chemie, Friedrich-Schiller-Universität Jena, 6900 Jena (G.D.R.)

(Ref. Can. J. Chem. **61**, 809 (1983))
Received February 9, 1984

In a very interesting paper by Lewis and Sandorfy (1), the existence of four isomers **A**, **B**, **C**, **D** of unsubstituted triphenylformazan (2–4) was called in question because only two of them, **A** and **D**, could be detected by means of vibrational spectroscopy.

It is obvious from our kinetic data obtained from flash photolysis (3) that the lifetime of **B** is too short as to allow detection by a nontime-resolved spectroscopic method. At room temperature the concentration of **B** is negligibly small in any photostationary state.

The experimental conditions used by Lewis and Sandorfy when preparing the yellow nonchelate form **D** also exclude the presence of appreciable concentrations of **C** in the photostationary states because of the following reasons. The effective wavelength applied for generating **D** for the ir-measurements was 546 nm (medium pressure mercury arc in combination with a 475 nm cut-off filter). This wavelength generates a photostationary state $\mathbf{D} \underset{h\nu}{\overset{h\nu}{\rightleftarrows}} \mathbf{C}$ which is nearly quantitatively shifted to the left side since $\epsilon_\lambda^{\mathbf{D}} < \epsilon_\lambda^{\mathbf{C}}$ for $\lambda > 470$ nm (2) and $\Phi_{\mathbf{C}\rightarrow\mathbf{D}} > \Phi_{\mathbf{D}\rightarrow\mathbf{C}}$. The same applies for continuous irradiation with the laser line $\lambda' = 488$ nm which was used for recording the resonance Raman spectra. We calculate a conversion ratio of $C_{\mathbf{C}}/C_{\mathbf{D}} < 0.1$ in the photostationary state for that wavelength. Furthermore, because CCl_4 upon irradiation is highly prone to trace contamination by hydrochloric acid and the thermal transformations of the formazan isomers are known to be extremely sensitive to acid catalysis, this photostationary state is expected to be even farther shifted to the left due to a reduced lifetime of **C** in CCl_4.

Thus the experimental results presented by Lewis and Sandorfy do not contradict our findings, particularly they do not allow one to doubt the existence of four isomers for which unequivocal evidence has been given under different experimental conditions.

Some investigations of the chemistry of tellurium chloride pentafluoride, its reaction with caesium fluoride, and the preparation of *cis* and *trans* methoxytellurium(VI) chloride tetrafluoride, $(CH_3O)TeClF_4$

LAWRENCE J. LAWLOR AND JACK PASSMORE[1]

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received October 19, 1983

LAWRENCE J. LAWLOR and JACK PASSMORE. Can. J. Chem. **62**, 1477 (1984).

The reaction of $TeClF_5$ with CH_3OH, and CH_3OSiMe_3, leads to a mixture of *cis*- and *trans*-$(CH_3O)TeClF_4$ in a ratio of 1:6, as well as some unidentified Te(IV) product. The vibrational spectrum of the 1:6 mixture of *cis*- and *trans*-$(CH_3O)TeClF_4$ was accounted for on the basis of the predominant pseudo-C_{4v} *trans* isomer. $TeClF_5$ is unreactive towards anhydrous HF, SbF_5, $AlCl_3$, SO_2, F_2, and ClF at room temperature. Over the temperature range 70−250°C it thermally decomposes to TeF_6, TeF_4, and Cl_2. It slowly reacts with CsF to form $CsTeF_5$, TeF_6, Cl_2, and small amounts of ClF, and with $HNMe_2$ it is also reduced to form $TeF_4 \cdot HNMe_2$.

LAWRENCE J. LAWLOR et JACK PASSMORE. Can. J. Chem. **62**, 1477 (1984).

La réaction du $TeClF_5$ avec le CH_3OH et le CH_3OSiMe_3 conduit à un mélange de $(CH_3O)TeClF_4$ *cis* et *trans* dans un rapport de 1:6 en plus de quelques produits de Te(IV) non identifiés. On a expliqué le spectre de vibration du mélange en se basant sur la présence prédominante de l'isomère *trans* de symétrie pseudo C_{4v}. Le $TeClF_5$ est inerte vis-à-vis du HF, du SbF_5, du $AlCl_3$, du SO_2, du F_2 et du ClF anhydres, à la température ambiante. Dans l'intervalle de température allant de 70 à 250°C, il se décompose thermiquement en TeF_6, TeF_4 et Cl_2. Il réagit lentement avec le CsF pour former le $CsTeF_5$, le Cl_2 et de petites quantités de ClF. Le $HNMe_2$ le réduit également avec formation de $TeF_4 \cdot HNMe_2$.

Introduction

Tellurium chloride pentafluoride was first prepared in low yield by the reaction of elemental fluorine with tellurium tetrachloride (1). Large amounts of tellurium hexafluoride and chlorine were also produced from which the product was not separated. Nevertheless, $TeClF_5$ was reported to be reduced by olefins and phosphorus trifluoride (1). A convenient high yield synthesis of pure tellurium chloride pentafluoride has been developed in this laboratory (2, 3), making an exploration of its chemistry possible.

It is well known that sulphur hexafluoride is extremely inert chemically, especially towards nucleophiles, and that its low reactivity is mainly due to kinetic rather than thermodynamic factors (4). Sulphur chloride pentafluoride, on the other hand, has an extensive chemistry (4−10). The reactivity of the hexafluorides of group six increase as the group is descended, and tellurium hexafluoride can directly form a variety of substituted derivatives (11−14). It also forms compounds in which the coordination number of tellurium appears to have increased to 7 or 8. For example, it reacts with NMe_3 to form $2NMe_3 \cdot TeF_6$ (15) and with caesium and rubidium fluorides to form the corresponding salts of TeF_7^- and TeF_8^{2-} (16). It was therefore envisaged that tellurium chloride pentafluoride would be more reactive than either tellurium hexafluoride or sulphur chloride pentafluoride. Reactions of tellurium chloride pentafluoride with a variety of reagents are reported below. In the course of these investigations, *cis*- and *trans*-$(MeO)TeClF_4$ were prepared and characterised (17). Very recently Seppelt and coworker have reported some photochemical reactions of tellurium chloride pentafluoride in which the chlorine atom has been replaced by some other groups (18, 19).

Experimental

Except when stated, apparatus, reagents, and techniques are the same as those previously described (2, 20, 21).

Volatile reactive fluorides were manipulated in a Monel vacuum line and reactive solids in a Vacuum Atmospheres Dri-Box equipped with a Dri-Train. Infrared spectra of gaseous materials were obtained by using a stainless steel cell equipped with AgCl windows. F.E.P. reaction vessels (volume ca. 10 mL) were constructed from $\frac{1}{2}$ in od tubing and connected to the metal vacuum line via a Whitey 1KS4 valve and stainless steel $\frac{1}{4}$ in. Swagelok fitting. High pressure reactions were carried out in Monel vessels (volume ca. 50 mL) or a Parr bomb (volume ca. 45 mL). Pyrex vessels (volume ca. 30 mL) equipped with 1KS4 Whitey valves were also used as reaction vessels.

^{19}F nmr chemical shifts are quoted relative to CCl_3F with positive chemical shifts corresponding to high shielding. ^1H nmr chemical shifts are relative to Me_4Si. Raman spectra were obtained by the 5145 Å exciting line of a 2W Argon Ion Spectra Physics Laser. The slit width was 4 cm^{-1}. $CH_3OTeClF_4$ samples, for which Raman spectra were obtained, were contained in sealed thin walled F.E.P. tubing.

Mass spectra were obtained using a Varian V-5900 I.C.R. spectrometer operating at 70 eV. Quantitative elemental analyses were performed by Alfred Bernhardt Mikroanalytisches Laboratorium, West Germany or Butterworth Laboratories Ltd., Great Britain.

The purity of starting materials was routinely established by X-ray powder photography or infrared or Raman spectroscopy. Literature methods were used to prepare $TeClF_5$ (2, 3), $CsTeF_5$ (22), and TeF_4 (23, 24). Me_3SiCl (Petrarch) and C_6F_6 were used without further purification. Me_3SiOMe (ICN-K and K Pharmaceuticals) and anhydrous methanol were stored over molecular sieve (3 Å) before use. Dimethyl amine (Matheson) was dried by repeated distillation from molecular sieves (3 Å) over which it was stored. CsF (Ozark-Mahoning) was heated at 150°C *in vacuo* for 12 h, then ground prior to reaction. SbF_5 (Ozark-Mahoning) was purified by vacuum distillation at room temperature. Anhydrous HF (Matheson) was dried over K_2NiF_6. Fluorine was stored over NaF. SO_2 (Matheson) was evacuated at −196°C to remove oxygen and dried over CaH_2 before use.

Thermal stability of $TeClF_5$

$TeClF_5$ (0.90 g) was heated in a well fluorinated Monel Parr bomb at 70°C for 20 days. The product (0.90 g) was $TeClF_5$ containing a trace of TeF_6 (ir) which was reheated at 110°C for 2 months. The product (0.90 g) contained $TeClF_5$, TeF_6, and a trace of SiF_4 (ir). The mixture was heated at 180°C for 20 days and the products (0.86 g) identified (ir) as $TeClF_5$, TeF_6, traces of SiF_4, and the presence of

TABLE 1. Some reactions and attempted reactions of $TeClF_5$

Reaction[a]	Conditions and comments	Products
1. $TeClF_5$ (2.05) F_2 (9.21)	Monel vessel (50 mL) 10 days, rt	$TeClF_5$ + trace TeF_6 (ir)[b]
$TeClF_5$ (5.81) F_2 (23.2)	Parr bomb (45 mL) 3 days, 165°C	$TeClF_5$:TeF_6 ratio ca. 1:5 (^{19}F nmr)
2. $TeClF_5$ (2.62) ClF (6.61)	Monel vessel 14 days, rt	$TeClF_5$ trace TeF_6 (ir)
3. $TeClF_5$ (1.60) Anhydrous HF (24.0)	Well passivated F.E.P. vessel (10 mL) 2 phases present	$TeClF_5$, HF (^{19}F nmr)
4. $TeClF_5$ (2.18) SO_2 (3.88)	Pyrex vessel (30 mL) $TeClF_5$ dissolves in SO_2	$TeClF_5$, SO_2 traces SiF_4 (ir)
5. $TeClF_5$ (3.91) $AlCl_3$ (4.27)	Pyrex vessel (*a*) overnight rt, (*b*) overnight 45°C	Volatiles, $TeClF_5$, (*a*) trace SiF_4 (ir), (*b*) as above
6. $TeClF_5$ (4.03) SbF_5 (4.66)	Pyrex vessel equipped with a Rotoflo valve and a side arm containing a capillary. $TeClF_5$ dissolved in SbF_5	SbF_5, $TeClF_5$ (Raman of material poured into capillary side arm)
7. $TeClF_5$ (5.22) Solid KOH (5.54)	F.E.P. vessel. Reaction with bubbling left 7 days	Volatiles (0.3 g) TeF_6, $TeClF_5$, Cl_2 (ir, Raman) Solid (1.32 g) white powder, $KTeF_5$ + lines in the Raman spectrum at 750, 689, and 670 cm^{-1}
8. $TeClF_5$ (6.62) Me_3SiCl (6.27)	Pyrex vessel (*a*) Warmed to rt giving a milky white solution (*b*) Rt for 2 days, quantity of white solid increased with time, liquid became yellow	(*a*) Volatiles contained Me_3SiF and $TeClF_5$ (ir) (*b*) Volatiles (1.90 g) Me_3SiF, $TeClF_5$ and SiF_4 (ir, Raman). Solid (0.43 g) $TeCl_4$ (Raman, X-ray powder diffraction photography)
9. $TeClF_5$ (2.81) Me_4Si (3.09)	F.E.P. vessel (*a*) Overnight rt (*b*) 8 h, ca. 75°C	(*a*) $TeClF_5$, Me_4Si (ir) (*b*) $TeClF_5$, Me_4Si (ir, ^{19}F nmr)
10. TeF_6 (8.53) Me_3SiCl (13.4)	Pyrex vessel 8 h, 75°C	TeF_6, Me_3SiCl (ir, ^{19}F nmr)
11. $TeClF_5$ (2.28) H_2 (11.16)	Quartz vessel uv radiation (*a*) 4 h, sides of vessel covered with a white solid (*b*) Overnight	(*a*) Volatiles contain SiF_4, $TeClF_5$ + trace TeF_6 (*b*) Volatiles SiF_4. Solid. Unidentified broad peaks in Raman spectrum at 680, 500, 435, and 280 cm^{-1}

[a]Amounts of reactant are given in mmoles in parentheses.
[b]Method of identification, in the table and elsewhere in the text, is given in parentheses.

chlorine was implied by its physical properties. In another experiment, $TeClF_5$ was heated at 250°C in a Monel vessel overnight giving TeF_6, $TeClF_5$, and solid TeF_4 (ir).

Attempted reactions of $TeClF_5$ with F_2, ClF, HF, SO_2, $AlCl_3$, SbF_5, solid KOH, Me_3SiCl, Me_4Si, and H_2 under uv radiation are listed in Table 1.

Reaction of $TeClF_5$ with CsF

In a typical reaction $TeClF_5$ (8.53 mmol) was condensed onto CsF (4.11 mmol) in a glass vessel and the mixture stirred at rt. After 15 days the volatile products contained $TeClF_5$, TeF_6, and SiF_4 (ir) and the physical properties of the mixture suggested the presence of chlorine. After 30 days the volatile products (1.3584 g), TeF_6, $TeClF_5$, SiF_4, and Cl_2 (ir, Raman, and ^{19}F nmr) were removed, leaving a solid (1.4065 g) which was shown to contain $CsTeF_5$ (Raman) and CsF (X-ray powder photography). The volatile reaction products were held at −78°C and a portion of these products condensed onto sulphur dioxide. The presence of SO_2ClF (ir) in this material infers the presence of ClF in the volatile product of the reaction of CsF and $TeClF_5$. A number of similar reactions carried out under different conditions are given in Table 2.

Reaction of $CsTeF_5$ with ClF

Chlorine monofluoride (7.52 mmol) was condensed onto $CsTeF_5$ (5.85 mmol) in a Monel vessel and left at rt for 3 days. The volatiles (0.5083 g) contained TeF_6, Cl_2, and a trace of $TeClF_5$ (ir, Raman, ^{19}F nmr). The Raman spectrum of the solid product (1.80 g) showed it to contain $CsTeF_5$ (25) and $CsClF_2$ (26).

Reaction of $TeClF_5$ with dimethyl amine ($HNMe_2$)

In a typical reaction SO_2 (5.03 mmol) was condensed onto $TeClF_5$ (5.91 mmol) in a F.E.P. vessel. $HNMe_2$ (5.56 mmol) was added in two aliquots. After each addition the reaction vessel was held at −22°C, 0°C and rt for 30, 15, and 15 min, respectively. A white solid was observed at −22°C and at 0°C, but the product changed to a clear liquid on warming to rt. The final product consisted of a clear layer of viscous material below a slightly yellow non-viscous liquid. The more volatile phase contained SO_2ClF and Cl_2 (ir, Raman, ^{19}F nmr). The viscous product was identified as $TeF_4 \cdot HNMe_2$ by comparing its infrared spectrum to that of $TeF_4 \cdot HNMe_2$ prepared by the reaction of TeF_4 with $HNMe_2$. The ^{19}F nmr spectrum of the product in SO_2 consisted of one intense peak at 42.4 ppm (40.8 ppm for $TeF_4 \cdot HNMe_2$ in acetonitrile prepared from TeF_4). A peak attributable to a ^{125}Te—F coupling was not observed. Table 3 lists other similar reactions.

Reactions of $TeClF_5$ with CH_3OH

$TeClF_5$ (9.4 mmol) and CH_3OH (8.44 mmol) were consecutively condensed on Na_2CO_3 (3.9 mmol) in an F.E.P. vessel and held at 0°C and rt for 10 h and 3 days, respectively. Two volatile components were condensed out of the reaction mixture. A more volatile yellow

[b]Numbers in parentheses represent the relative intensity of the ion.

liquid (0.59 g) contained SiF_4, $TeClF_5$, and TeF_6 (ir). A less volatile clear liquid (0.56 g) was identified as a mixture of *cis*- and *trans*-$(CH_3O)TeClF_4$ (ir, Raman, ^{19}F nmr). The weight of remaining solid was 1.47 g greater than that of Na_2CO_3 reactant.

Reaction of $TeClF_5$ with Me_3SiOCH_3

Me_3SiOMe (4.76 mmol) was condensed onto $TeClF_5$ (4.99 mmol) in an F.E.P. vessel in three aliquots. After each addition the mixture was held at 0°C for 20 min with stirring. A white solid formed and disappeared on warming to rt for 0.5 h prior to the addition of the next aliquot. The product volatile at −78°C (0.6431 g) contained $TeClF_5$ and Me_3SiF (ir). The remaining volatile liquid contained $CH_3OTeClF_5$ and a trace of Me_3SiF (ir). The trace of Me_3SiF was removed by subjecting the mixture, held at −45°C, to a dynamic vacuum for 10 min. The $CH_3OTeClF_4$ (4.20 mmol) was condensed out of the vessel, leaving a trace of a clear involatile liquid. The results of some similar reactions are given in Table 4.

Anal. calcd. for $CH_3OTeClF_4$: Te 47.08, F 28.04, Cl 13.08, C 4.43, H 1.11; found: Te 46.67, F 27.71, Cl 12.91, C 4.71, H 1.35. The mass spectrum of $CH_3OTeClF_4$ is given in Table 5.

Results and discussion

Preparation of cis- *and* trans-*$CH_3OTeClF_4$*

cis- and *trans*-$(CH_3O)TeClF_4$ were prepared by the reaction of $TeClF_5$ with CH_3OH in the presence of Na_2CO_3, and with $MeOSiMe_3$ at room temperature according to reactions [10] and [11].

[10] $TeClF_5 + CH_3OH \rightarrow CH_3OTeClF_4 + HF$

[11] $TeClF_5 + CH_3OSiMe_3 \rightarrow CH_3OTeClF_4 + Me_3SiF$

The hydrogen fluoride generated in reaction [10] was neutralised by the Na_2CO_3 present. In both reactions some uncharacterised Te(IV) containing involatile liquid was also produced that had peaks in the Raman spectrum in the methyl stretching region (3000–2800 cm^{-1}) and in the TeF, TeO stretching region (700–500 cm^{-1}). The nature of the oxidised product was not established.

The reaction of TeF_6 and methyl alcohol in the presence of NaF led to CH_3OTeF_5, and with Na_2CO_3 to predominately *cis*-$(CH_3O)_2TeF_4$ (14). As far as we are aware there are no reports of reactions of methyl alcohol with $SClF_5$.

Characterisation of cis- *and* trans-*$CH_3OTeClF_4$*

The elemental analyses and mass spectrum (Table 5) were consistent with the formation of $CH_3OTeClF_4$. The proton and fluorine nmr data are listed in Table 6 with the fluorine chemical shifts estimated by the method of Dean and Evans (27) with adjustable parameters determined from the reported chemical shifts of $TeClF_5$ (1) and CH_3OTeF_5 (14). The spectrum of *cis*-$CH_3OTeClF_4$ was simulated by the computer program LAME (28). The crude values of the coupling constants together with the line positions were given as input to the program which refined the values to give a good fit in very few iterations. The ratio of *cis*-to-*trans* isomer was estimated to be ca. 1:6. Consistently the ratio of *cis*-to-*trans* $HOTeClF_4$ given on hydrolysis of $TeClF_5$ was 1:4 (17). In addition the reaction of $SClF_5$ with R_2NSiMe_3 (R = CH_3) led to only *trans*-R_2NSClF_4 (9). Random replacement of fluorine atoms would lead to a three-fold predominance of the *cis* isomer. It is possible that the *trans* isomer is the thermodynamically favoured product. A tellurium chlorofluoride of the type *trans*-$RTeClF_4$ (R = C_2F_5 (29–31)) has been prepared, but as far as we are aware this is the first report of a *cis*-chlorofluoride of composition $RTeClF_4$.

Vibrational spectra of trans-$CH_3OTeClF_4$

The vibration spectrum of $CH_3OTeClF_4$ is given in Figs. 1 and 2 and the frequencies are listed in Table 7 with tentative assignments made on the basis of C_{4v} *trans*-$CH_3OTeClF_4$. The major features of the spectrum can be accounted for in this way, although it is known that ca. 15% is in fact the *cis* isomer. Presumably the weaker spectrum of the *cis* isomer has absorp-

[a]Frequencies are in cm^{-1}.

tions at similar frequencies to that of the *trans* isomer, and these are hidden under the *trans* isomer peaks. The vibrations of the CH_3 group have been assigned by comparison with CH_3X (X = Br, Cl, F, I, OH) (32–34). The intense infrared band at 1012 cm^{-1} has been assigned to the CO stretching frequency by comparison with CH_3OH (33). The rest of the spectrum was assigned by comparison with the spectrum of $TeClF_5$ (35), $OTeF_5^-$ (36), and *trans*-$C_2F_5TeClF_4$ (29–31) (Table 8). It is assumed that *trans*-$CH_3OTeClF_4$ has C_{4v} symmetry. Two Raman bands at 692 and 583 cm^{-1} are e and b_2 modes, respectively, but are found to be polarised. This implies that the pseudo-C_{4v} symmetry in *trans*-$CH_3OTeClF_4$ is reduced by the presence of the bent $TeOCH_3$ entity.

General thermal and chemical stability of $TeClF_5$

Tellurium chloride pentafluoride appears to be stable indefinitely at room temperature. Over the temperature range 70–250°C it thermally decomposes to TeF_6, TeF_4, and Cl_2. Sulphur chloride pentafluoride is reported (5) to decompose at 400°C to SF_6, SF_4, and Cl_2.

Tellurium chloride pentafluoride like TeF_6 and $SClF_5$ does not react at room temperature with the strong acid, anhydrous hydrogen fluoride, or the strong Lewis acids antimony pentafluoride and aluminium trichloride. It is also unreactive towards the strong oxidising agents chlorine monofluoride and fluorine under ambient conditions. At 165°C TeF_6 was formed in the reaction of fluorine and $TeClF_5$. It does not react with the potential reducing agents sulphur dioxide or elemental mercury (2) at room temperature; however, it is reduced by PF_3 and olefins (1). In photochemical reactions of $SClF_5$ with olefins, addition of Cl and SF_5 occurs across the double bond (7, 8). There is no reaction of $TeClF_5$ with hydrogen, but under uv radiation reduction occurs. Not surprisingly, no evidence was obtained for Te_2F_{10} (c.f. S_2F_{10} (5)). Tellurium chloride pentafluoride is slowly hydrolysed by water at room temperature, leading to the formation of *cis*- and *trans*-$HOTeClF_4$ (c.f. *cis*- and *trans*-$(CH_3O)TeClF_5$ below), other $(HO)_xTeClF_{5-x}$ (17) species, $(HO)_xTeF_{6-x}$ ($m = 1 \rightarrow 4$) (11, 13, 37), and some tellurium(IV)-containing product (17, 28). Tellurium hexafluoride is also slowly hydrolysed under similar conditions (11), but no reaction occurs with sulphur chloride pentafluoride.

Reactions of $TeClF_5$ with CsF, KOH, and $HNMe_2$

Caesium fluoride reacts slowly at room temperature with $TeClF_5$. The products $CsTeF_5$, TeF_6, and Cl_2 were identified, and the presence of ClF was inferred as a product, as the gaseous products reacted with SO_2 to form SO_2ClF. In an attempt to establish a possible route for this reaction, $CsTeF_5$ was reacted with ClF leading to $CsClF_2$, TeF_6, and Cl_2.

The inhomogeneous reaction of $TeClF_5$ with solid KOH led to products that included $KTeF_5$, TeF_6, and Cl_2. Reduction to a tellurium(IV) product was also observed in the reaction of $TeClF_5$ and $HNMe_2$ which proceeded essentially quantitatively according to eq. [9].

[9] $TeClF_5 + HNMe_2 \rightarrow TeF_4 \cdot HNMe_2 + \text{"ClF"}$

The chlorine monofluoride was not observed directly, but in a reaction in which sulphur dioxide was present, SO_2ClF was detected. The analogous reaction of NMe_3 and TeF_6 led to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

stable $2NMe_3 \cdot TeF_6$ (15). Some reduction of tellurium(VI) to tellurium(IV) was also observed in the reactions of $TeClF_5$ with H_2O (17), MeOH, and $MeOSiMe_3$.

Reaction of $TeClF_5$ and TeF_6 with Me_3SiCl

Tellurium chloride pentafluoride reacts at room temperature with Me_3SiCl to form $TeCl_4$, Cl_2, Me_3SiF. Presumably $TeCl_2F_4$ is formed initially, which itself, or the decomposition product TeF_4, reacts preferentially with Me_3SiCl leading to the observed products. Tellurium hexafluoride did not react with Me_3SiCl under similar conditions. This implies that reactions of $TeClF_5$ of this sort involve the positive chlorine of $TeClF_5$. An analogous reaction of $SClF_5$ led to SCl_2, Cl_2, and $(CH_3)_3SiF$ (38).

Acknowledgments

We wish to thank Dr. T. B. McMahon for the mass spectrum of $CH_3OTeClF_4$, E. K. Richardson and Dr. R. Kaiser for the ^{19}F nmr spectra, and the Natural Sciences and Engineering Research Council of Canada for financial support and for a scholarship (L.J.L.).

Oxidation of 1-butene by nitrous oxide over manganese(III) and related transition metal oxides

ROBERT A. ROSS[1] AND CRAIG FAIRBRIDGE[2]

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received October 13, 1983

ROBERT A. ROSS and CRAIG FAIRBRIDGE. Can. J. Chem. **62**, 1483 (1984).

The oxidation of 1-butene by nitrous oxide over manganese(III) oxide was studied in a continuous flow system from 573 to 673 K. Kinetic parameters were derived from the exponential relationship: $r = ka\,P_{N_2O}^{0.5}P_{C_4H_8}^{0.4}$ over reactant partial pressure ranges, $0.30 < P_{N_2O} < 2.60$ kPa and $0.43 < P_{C_4H_8} < 8.27$ kPa. The reaction mechanism proposed involves a complex sequence of steps which include surface radical reactions. On the basis of a comparison of specific reaction rates, the catalytic activity series for the reaction over a number of transition metal oxides was: $CuO > Fe_2O_3 > NiO > Mn_2O_3 > Cr_2O_3 > TiO_2 > Sc_2O_3 > SnO > ZnO > V_2O_5 > Al_2O_3$.

ROBERT A. ROSS et CRAIG FAIRBRIDGE. Can. J. Chem. **62**, 1483 (1984).

On a étudié l'oxydation du butène-1 par l'oxyde de manganèse(III) dans un système à écoulement continu entre 573 et 673 K. On a déduit les paramètres cinétiques à partir de la relation exponentielle: $r = ka\,P_{N_2O}^{0.5}P_{C_4H_8}^{0.4}$ à des pressions partielles des réactifs allant de $0{,}30 < P_{N_2O} < 2{,}60$ kPa et de $0{,}43 < P_{C_4H_8} < 8{,}27$ kPa. Le mécanisme réactionnel proposé fait intervenir une suite complexe d'étapes qui comprend des réactions radicalaires de surface. En se basant sur une comparaison de vitesses spécifiques de réactions, on a pu établir la série suivante pour les activités catalytiques d'un grand nombre d'oxydes de métaux de transition vis-à-vis de la réaction: $CuO > Fe_2O_3 > NiO > Mn_2O_3 > Cr_2O_3 > TiO_2 > Sc_2O_3 > SnO > ZnO > V_2O_5 > Al_2O_3$.

Introduction

The catalytic performance of manganese oxides in several redox reactions involving hydrocarbons with oxygen or nitrogen oxides has been reported recently. The work has included the oxidation of ethane by nitric oxide over unsupported manganese(III) oxide (1) and the oxidation of 1-butene and ethane by oxygen over manganese(III) oxide supported on carbon fibres (2). The results of these experiments pointed to complex surface mechanisms with rate-controlling steps most probably associated with the interactions of species within the adsorbed layer.

In the present investigation an attempt has been made to evaluate the kinetics of the catalysis of 1-butene by nitrous oxide over manganese(III) oxide. Measurements of reaction rates were supplemented by structural analysis. A general comparison of the catalytic activities in the reaction of metal oxides of the first transition series has also been carried out.

Experimental

A Hewlett-Packard Research Chromatograph Model 5754 B was used for in-line product analysis from the glass flow system and quartz reactor (3) with high-purity helium as a carrier gas and columns packed with Poropak Q, 120–300 mesh. A Beckman NO/NO_x analyzer, Model 951, was placed in series with the gas chromatograph.

Experimental reaction rates were recorded at steady catalyst activity and at less than 15% hydrocarbon conversions. Effects of space velocity, catalyst mass, and particle size were evaluated in the usual way (4) to determine conditions which minimized heat and mass transfer effects. As a result, kinetic measurements were conducted on manganese(III) oxide with a total gas flow rate of 350 mL min^{-1} (NTP) on 1 g catalyst samples having <37 μm maximum diameter and surface area 15.5 $m^2\,g^{-1}$.

Catalysts were examined by low-temperature gas adsorption (krypton, BET, 77 K, $\sigma = 19.5$ Å^2), X-ray and chemical analysis. Infrared spectra were recorded on a Beckman IR-12 spectrophotometer using 0.5 wt% KBr pellets. The catalyst surfaces were examined by scanning electron microscopy, Cambridge Stereoscan 600, and X-ray photoelectron spectroscopy, Vacuum Generator ESCA-3.

α-Manganese(III) oxide was prepared and analyzed as previously described (1, 5). Scandium(III) oxide (99.9% pure), zinc(II) oxide (99.99%), chromium(III) oxide (99%), iron(III) oxide (99.99%), vanadium (V) oxide (99.9%), and tin(II) oxide (99.99%) were obtained from Alfa Inorganics Limited. Copper(II) oxide (99%) and nickel(II) oxide (99.99%) were obtained from BDH Chemicals Limited. Aluminum(III) oxide (99.9%) and titanium(IV) oxide (99%) were purchased from Baker Chemical Company. All oxides were heated in air at 773 K for 10 h and stored in desiccators prior to activation in the experiments.

Carbon dioxide, 99.5%, nitrogen, 99.99%, and helium, 99.99%, were obtained from Canadian Liquid Air Limited, and nitrous oxide, 99.9%, from Liquid Carbonic Limited.

Results

Reaction rate measurements on manganese(III) oxide

The rate of the catalytic reaction, measured as the rate of nitrogen or carbon dioxide production, decreased slightly for the first hour of reaction at 673 K and remained constant thereafter for a minimum of 24 h. The conversion of 1-butene at this temperature amounted to 15% with only nitrogen, carbon dioxide, and water as the products of reaction.

Rate-order measurements based on the rates of nitrogen, r_1, and carbon dioxide, r_2, production were determined when the systems had achieved a steady state after pretreatment with 2.66 kPa nitrous oxide and 2.66 kPa 1-butene for 3 h at 623 K.

With the partial pressure of the hydrocarbon maintained at 3.05 kPa, the effects of from 0.30 to 4.93 kPa nitrous oxide on the experimental rates were observed, Fig. 1. The rate order with respect to nitrous oxide was 0.5 for partial pressures <2.60 kPa. At higher pressures, the rate of reaction increased with increasing nitrous oxide partial pressure.

The partial pressure of 1-butene was altered from 0.43 to 8.27 kPa while nitrous oxide partial pressure was held constant at 2.49 kPa. The rate order was 0.4 with respect to 1-butene, Fig. 1. The partial pressures of nitrous oxide and 1-butene were

TABLE 1. Reaction rate constants for the oxidation of 1-butene by nitrous oxide over manganese(III) oxide

Temperature (K)	$k_1 \times 10^{-5}$ (nitrogen)	$k_2 \times 10^{-5}$ (carbon dioxide)
673	46.7	35.5
663	35.4	24.6
653	28.8	18.1
643	21.4	12.6
633	14.2	8.46
623	8.90	5.70
613	6.76	3.92
603	4.60	2.60
593	3.08	1.71
583	1.97	1.11
573	1.30	0.711

maintained at 2.48 and 2.58 kPa, respectively, and that of carbon dioxide was adjusted from 0.62 to 8.33 kPa. This had no effect on the rate r_1, and the reaction was zero order with respect to CO_2. Variations in the partial pressure of water vapour from 0.09 to 2.10 kPa with nitrous oxide (2.48 kPa) and 1-butene (2.58 kPa) partial pressure held constant had no effect on the rate.

Based on these results, the rate of reaction was expressed by:

$$[1] \quad r_1 = k_1 P_{N_2O}^{0.5} P_{C_4H_8}^{0.4}$$

and

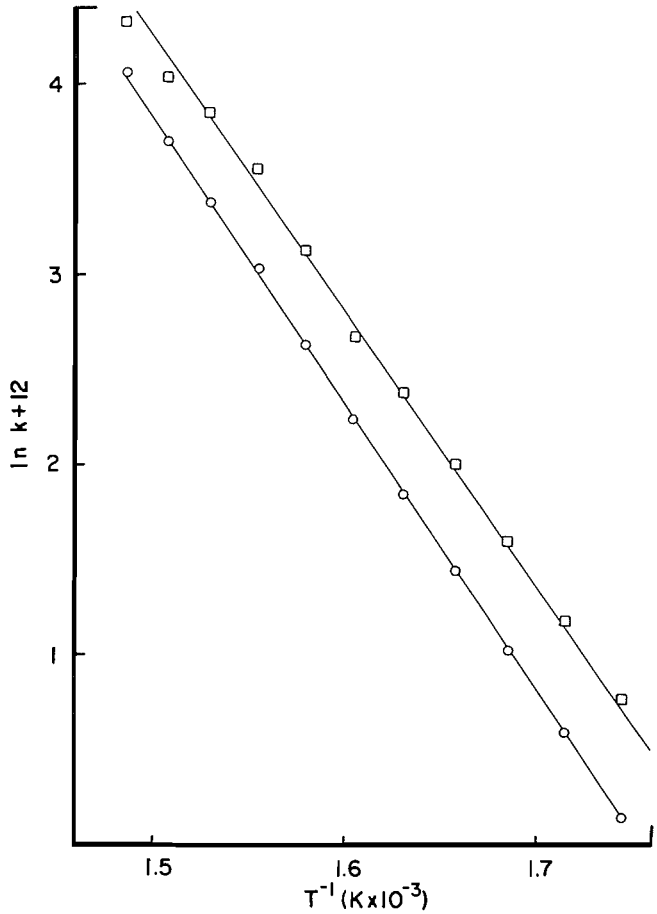

FIG. 2. Arrhenius plots for the N_2O/C_4H_8 reaction over Mn_2O_3; □, k_1, ○, k_2.

$$[2] \quad r_2 = k_2 P_{N_2O}^{0.5} P_{C_4H_8}^{0.4}$$

where $0.30 < P_{N_2O} < 2.60$ kPa.

The effects of temperature on catalyst activity were determined after the oxide had been conditioned in 2.23 kPa nitrous oxide and 2.78 kPa 1-butene at 673 K for 3 h. Reaction rate constants were calculated at 10 K intervals from 673 to 573 K, Table 1, using the integrated form of eqs. [1] and [2]. When plotted in the Arrhenius fashion, these data gave apparent activation energies of 117 ± 4 and 126 ± 4 kJ mol^{-1} and pre-exponential factors 6.09×10^5 and 1.94 $mol^{0.1}$ $L^{-0.1}$ m^{-2} s^{-1} for the nitrogen and carbon dioxide rates, respectively, Fig. 2.

Effects of reaction conditions on catalyst properties

The catalyst surface area was 15.5 m^2 g^{-1} after reaction in all cases. Chemical analysis gave 69.0 wt% manganese (theory 69.59%) and X-ray diffraction showed only *d*-spacings corresponding to γ-Mn_2O_3 — 2.48, 2.74, 3.08, 1.54, 1.56, 1.81, and 2.06 Å.

The infrared spectrum of the catalysts after reaction resembled those observed previously for catalysts in the N_2O/C_2H_6 and O_2/C_2H_6 reactions (6) with bands at 615, 490, 425, and 350 cm^{-1}. Under the scanning electron microscope the used catalyst particles showed somewhat round edges with a high degree of surface roughness similar to the reported condition of manganese(III) oxide prior to catalysis (7).

X-ray photoelectron spectra were corrected for charging by reference to the C(1*s*) line at 285.0 eV. The Mn, $2p_{3/2}$, spec-

Catalyst	Surface area ($m^2\ g^{-1}$)	Experimental rates (mol $m^{-2}\ s^{-1}$) r_1	r_2
CuO	4.1	6.82×10^{-6}	3.28×10^{-6}
Fe_2O_3	6.0	1.58×10^{-6}	9.10×10^{-7}
NiO	2.5	6.72×10^{-7}	3.19×10^{-7}
Mn_2O_3	15.5	2.20×10^{-7}	9.74×10^{-8}
Cr_2O_3	3.1	4.85×10^{-8}	—
TiO_2	9.0	2.48×10^{-8}	—
Sc_2O_3	2.3	1.41×10^{-8}	—
SnO	9.0	1.36×10^{-8}	—
ZnO	11.7	1.04×10^{-8}	—
V_2O_5	6.1	8.77×10^{-9}	—
Al_2O_3	2.8	7.68×10^{-9}	—

trum gave a binding energy of 642.0 eV in all used samples, while for unreacted manganese(III) oxide the value was 640.7 eV. The O(1*s*), binding energy was 528.7 eV before reaction; after reaction two binding energy values of 530.0 and 533.0 eV were observed. No N(1*s*) spectra were observed.

Related oxides

A number of metal oxides — Sc_2O_3, TiO_2, V_2O_5, Cr_2O_3, Mn_2O_3, Fe_2O_3, Al_2O_3, NiO, CuO, ZnO, and SnO — were evaluated as possible catalysts for the nitrous oxide/1-butene reaction. The catalytic reaction generally produced nitrogen, carbon dioxide, and water in measureable quantities at temperatures >623 K.

The catalytic activity of each oxide was assessed by determining the rates of nitrogen and carbon dioxide formation at 673 K. As in previous studies, 1 g catalyst samples were used and the total gas flow rate was 350 mL min^{-1}. The catalysts were pretreated with nitrous oxide and 1-butene, both at 2.66 kPa partial pressure for 12 h at 673 K. Each reactant was passed separately over the catalyst to ensure that no reaction occurred until both were present.

Surface areas were determined after reaction and are presented in Table 2 along with the experimental rate data.

Discussion

Various relationships based on Langmuir–Hinshelwood kinetics (8, 9) were tested for the N_2O/C_4H_8 reaction over manganese(III) oxide on the basis of statistical criteria (10, 11). The equation which gave the best correlation for all of the rate order data was adopted. It is not possible to uniquely determine the mechanism of a reaction from such an equation but a mechanism which has a theoretical basis and is consistent with the form of the expression can be postulated.

The relationship was:

$$[2]\quad r = \frac{kaP_{N_2O}^{0.5}bP_{C_4H_8}^{0.5}}{(1 + aP_{N_2O}^{0.5} + bP_{C_4H_8}^{0.5})^2} \times (P_{N_2O}P_{C_4H_8})$$

As shown in Fig. 3, plots of $P^{0.5}$ versus $(P^{1.5}/r)^{0.5}$ were linear. The form of the equation suggests that an irreversible bimolecular reaction occurs between adsorbed reactants where each species is adsorbed on two surface sites (12). Further steps will involve the interaction of nitrous oxide and 1-butene, as indicated by the $(P_{N_2O}P_{C_4H_8})$ term, suggesting a complex overall surface process.

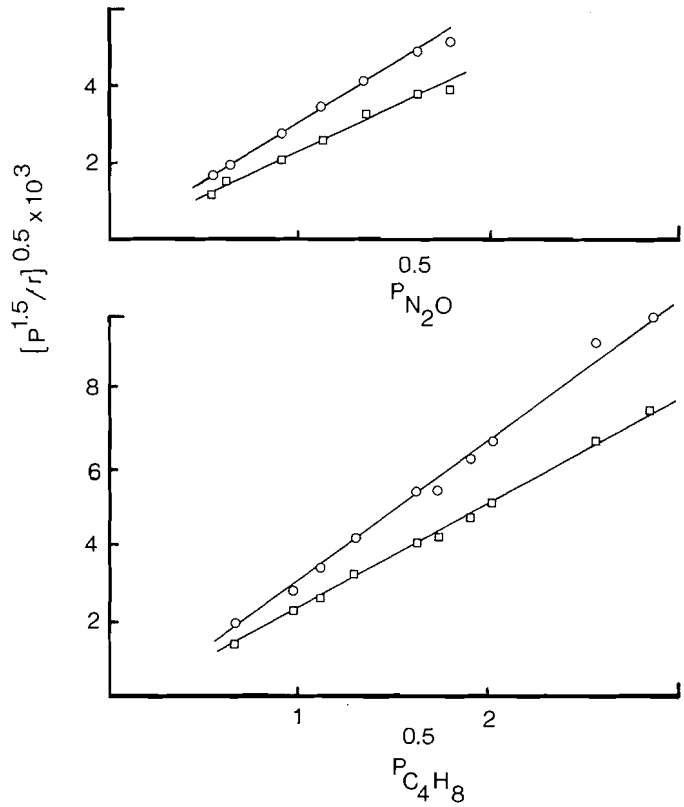

FIG. 3. Reduced plots of the Langmuir–Hinshelwood expression (2) for the N_2O/C_4H_8 reaction at 628 K over Mn_2O_3; □, r_1, ○, r_2.

$$[3]\quad C_4H_8(g) \leftrightarrow C_4H_{8(ads)}$$

$$[4]\quad N_2O + [O] + C_4H_{8(ads)} \rightarrow C_4H_{7(ads)} + [OOH] + N_2$$

$$[5]\quad C_4H_8 + S + [OOH] \rightarrow C_4H_{7(ads)} + [O] + H_2O$$

S is a surface site and [O] and [OOH] are, respectively, surface oxygen and hydroperoxide species. Further reactions are represented by:

$$[6]\quad 2C_4H_{7(ads)} + 23N_2O \rightarrow 8CO_2 + 7H_2O + 23N_2$$

The apparent activation energy was very close to that found for the nitrous oxide/ethane reaction on a similar catalyst (6).

The deviation from 0.5 order in nitrous oxide at partial pressures above 2.60 kPa indicates that the rate of reaction increases with P_{N_2O}. In these conditions, the conversion of N_2O becomes greater than 15% and heat and mass transfer effects become important. A pseudo steady state condition may be achieved with respect to 1-butene adsorption. The rate limiting step becomes eq. [6] with adsorption and reaction of N_2O subject to transport limitations.

The initial step in the oxidation of 1-butene over bismuth molybdate was also believed to involve C—H bond rupture as in eq. [4] (13, 14) while the decomposition of nitrous oxide over similar manganese oxide catalysts gave activation energies of 118 (15) and 146 (10) kJ mol^{-1}. The formation of peroxides from nitrous oxide as proposed in eq. [4] has been noted (15). Equation [6] summarizes a complex series of steps which may include surface radical reactions (17).

X-ray photoelectron spectroscopy indicated that two surface oxygen species were present from the evidence of two O(1*s*) binding energy values. The lower value was close to that expected for chemisorbed oxygen in metal oxides and the higher value was characteristic of that associated with the presence of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

molecular oxygen species (18). In the complete oxidation of hydrocarbons, oxygen is activated and adsorbed on the catalyst surface as O^- and O_2^- species (18, 19) which lead to the formation of epoxy or peroxy intermediates.

A catalytic activity series for this redox reaction over the transition metal oxides may be proposed on the basis of a comparison of reaction rates, thus giving an overall sequence of reactivity in decreasing order:

$$CuO > Fe_2O_3 > NiO > Mn_2O_3 > Cr_2O_3 > TiO_2 > Sc_2O_3 > SnO > ZnO > V_2O_5 > Al_2O_3$$

Close examination of Table 2 reveals that the difference in r_1 between titanium (IV) oxide and aluminum(III) oxide is of the same order of magnitude as that between each of the first five oxides in the series. Together with the low value of r_1 and the fact that r_2 could not be measured for these oxides, this suggests that the position of the last six members of the series are not as unequivocally determined as the first five.

The series is similar to those generally observed for catalytic oxidation reactions (20, 21), with the exception of the position of iron(III) oxide. It resembles those found for the nitric oxide/carbon dioxide reaction (22), the nitrous oxide/carbon dioxide reaction (23), and the decomposition of nitric (24) and nitrous (25) oxides.

Possible relationships between the rate of the reaction at 673 K and various properties of the oxides were examined.

Heats of oxygen desorption, q, have been related to catalytic activity for a number of reactions over transition metal oxides and reasonable correlations have been found between q and the activation energy of oxygen isotopic exchange (26) and the metal/oxygen bond energy in oxidation reactions (20, 21). The following expected activity series on these bases would be:

$$Co_3O_4 > CuO > NiO > MnO_2 > Cr_2O_3 > Fe_2O_3 > V_2O_5 > ZnO > TiO_2$$

Oxygen desorption was thought to occur in the rate-limiting step of the decomposition of nitric (27) and nitrous oxides (25). The heat of desorption was influenced by the oxide stoichiometry (26) where q usually increased with the removal of surface oxygen, except for chromium(III) and iron(III) oxides.

However, it has been shown that surface oxygen does not occupy a continuous distribution of states on the oxide, but rather that mobile oxygen may be present on discrete surface states (28). Quantitative correlations between catalytic activity and oxygen mobility imply a knowledge of the oxygen states involved, and these may change with surface location, temperature, time, and reagent concentrations. A shift to higher states might therefore cause large distortions of the general activity series.

No clear correlation was discernible between the catalytic reaction rate and the metal/oxygen bond length or the charge/radius ratio with respect to the cation (29).

Plots of ln A against the apparent activation energy for the present and previous data (1, 2, 6) showed a linear trend in which a change in value of one of the Arrhenius parameters for the reaction was offset by a corresponding change in the other. A number of theoretical models have been proposed to explain this compensation effect, and these have been summarized recently (30).

If the present data are converted to the units used by Galwey (30), then

$$[7] \quad \log A = B = eE$$

and e becomes 0.1042. A value very close to that found in the oxidation reactions of propene and acetylene over various oxides (30). This observation suggests that the general form of the rate-limiting step is similar in these related reactions.

Quenching of the singlet and triplet state of benzene in condensed phase

H. A. KHWAJA, G. P. SEMELUK, AND I. UNGER

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received October 5, 1983

H. A. KHWAJA, G. P. SEMELUK, and I. UNGER. Can. J. Chem. **62**, 1487 (1984).

Quenching of the fluorescence of benzene by halocarbons in methanol, ethanol, acetonitrile, and cyclohexane has been investigated. It proceeds via a reversible exciplex intermediate formed between excited singlet benzene and ground state halocarbon. Quenching is controlled by the polarity of the medium. Excited singlet benzene interacts with acetonitrile solvent and a longer wavelength emission due to this complex is observed.

The effect of CCl_4, CH_3CN, $CHCl_3$, and CH_3CCl_3 on the triplet and singlet excited states of benzene in a methylcyclohexane–isopentane mixture at 77 K has been examined. Carbon tetrachloride and acetonitrile are far more effective quenchers than either $CHCl_3$ or CH_3CCl_3. In the case of the latter pair enhanced intersystem crossover competes with complex formation.

H. A. KHWAJA, G. P. SEMELUK et I. UNGER. Can. J. Chem. **62**, 1487 (1984).

On a étudié le piégeage de la fluorescence du benzène par les halocarbones dans le méthanol, l'éthanol, l'acétronitrile et le cyclohexane. Il se produit via un exciplex intermédiaire réversible qui se forme entre le benzène singulet excité et l'état fondamental de l'halocarbone. Le piégeage est controlé par la polarité du milieu. Le benzène à l'état singulet excité interagit avec l'acétonitrile et on observe que la longueur d'onde de l'émission est plus élevée à cause de ce complexe.

On a étudié l'effet du CCl_4, du CH_3CN, du $CHCl_3$ et du CH_3CCl_3 sur les états triplet et singulet excités du benzène dans un mélange de méthylcyclohexane/isopentane à 77 K. Le tétrachlorure de carbone et l'acétonitrile sont des pièges beaucoup plus efficaces que le $CHCl_3$ ou le CH_3CCl_3. Dans le cas de cette dernière paire, une augmentation dans les échanges entre systèmes est en compétition avec la formation de complexe.

[Traduit par le journal]

Introduction

Exciplex formation between excited singlet or triplet state species and ground state partners of a different chemical nature has been demonstrated to be a key pathway in fluorescence and phosphorescence quenching (1–3). Some exciplexes exhibit fluorescence which is characterized by a red-shift with respect to the uncomplexed excited monomeric state, a lack of vibronic structure, and different decay characteristics. Nonemissive exciplexes have also been shown to exist (2–6). In such cases, indirect evidence is obtained for the intermediacy of exciplexes. Typical examples are the quenching of aromatic hydrocarbons and carbonyl excited states by aromatic compounds (7), olefins (8), and amines (9). In most of these systems the interposition of exciplexes is supported by a dependence of the quenching rate constant on both the ionization potential of the donor and the electron affinity or the reduction potential of the acceptor.

Since exciplexes possess total or partial charge-transfer nature, the rate of these processes should increase when the dielectric constant and the polarizability of the solvent increase (10–12), and this dependence should reflect the degree of charge transfer. A number of experimental (13, 14) and theoretical studies (15, 16) have confirmed this view. The decrease in exciplex emission in polar solvents appears to be due to ionic dissociation of the exciplex to free solvated radical ions (17).

Halocarbons, and CCl_4 in particular, have been shown to be efficient fluorescence quenchers for a number of molecules (18–21). It has also been shown that polar solvents increase this quenching (22, 23). In a previous publication we reported on the fluorescence quenching of benzene vapour by a number of halocarbons (6). We report here on the effect of solvent polarity on this reaction in liquid phase and on the rates of quenching by CCl_4, CH_3CN, $CHCl_3$, and CH_3CCl_3 in solid phase.

Experimental

Materials

Benzene (spectrograde 99.9%) was obtained from Fischer Scientific Company and was used without any further purification. CCl_4 and CH_2Cl_2 were GC spectrophotometric quality obtained from the J. T. Baker Chemical Company. CH_3CCl_3 (analytical reagent grade 99.5) was obtained from BDH Chemicals Ltd. These halogenated methanes were further purified by gas–liquid chromatography using a Hewlett-Packard Model 7620 A chromatograph attached to a 579 A collecting unit, with He as the carrier gas; detection was by flame ionization. The chromatographic procedure gave a purity of >99.9% for each of the materials. $CFCl_3$ was commercially available from Matheson Company (>99%) and was used as received.

The sources of the solvents were as follows: hexane, Sigma Chemical Company; ethanol, Consolidated Alcohols Ltd.; methanol and acetonitrile, BDH Chemicals Ltd.; methyl cyclohexane and isopentane, Matheson, Coleman and Bell. The solvents were used as received. Blank runs were made with solvent alone which showed no fluorescence emission at the maximum sensitivity of the instrument, in the spectral region of interest.

Apparatus and procedures

Absorption spectra were obtained with a Perkin-Elmer 402 spectrophotometer. Fluorescence spectra were recorded with a modified Aminco-Bowman spectrophotofluorometer (SPF). Most details of the apparatus and data collection and processing have been given previously (6, 24).

All quenching experiments were carried out in deoxygenated solution at room temperature with λ_{ex} = 254 nm. Samples were degassed prior to use by the freeze–pump–thaw method with a minimum of three cycles at better than 5×10^{-6} Torr. Sample cells (1 cm × 1 cm) were made of quartz and had a side arm made of Pyrex tubing to facilitate the freeze–pump–thaw procedure.

Preparation of samples involved adding an aliquot of stock solution of benzene to each sample along with the required quantity of quencher and diluting to volume with solvent. The benzene concentration used was chosen such that it would be approximately 20% absorbing in a 1 cm cell at 254 nm; a 2×10^{-3} *M* solution was found to be satisfactory. The quencher concentrations were in the 2×10^{-3} *M* to 8×10^{-3} *M* range. At λ_{ex} 254 nm and the concentrations used in this study, CCl_4 has an extinction coefficient of $\simeq$0.14 L mol^{-1} cm^{-1}. Thus absorption due to C_6H_6 is $\simeq$200 times greater than that due to CCl_4 and k_q's should not be negligibly affected by absorption of the latter.

Fluorescence yields are based on that of C_6H_6 being 0.06, 0.04, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

0.029 in hexane, ethanol, and methanol, respectively, at λ_{ex} = 254 nm (25).

The solid phase studies were carried out in a 1:1 methylcyclohexane, isopentane mixture at 77 K. The cells were 2 mm cylindrical quartz tubes; these were placed in a quartz microdewar flask whose bottom was in the shape of a finger transparent to uv light. Dry warm N_2 was circulated around the Dewar to prevent condensation on the outside of the Dewar and to reduce ice formation within the liquid nitrogen in the Dewar. An Aminco-Kiers rotating shutter operating at a chopping rate of 50 Hz was used to isolate and record phosphorescence spectra. All solutions were outgassed several times and hermetically selaed *in vacuo* prior to usage. The benzene concentration was 2×10^{-3} *M* while quencher concentrations ranged from 0 to 0.5 *M*.

Results and discussion

Liquid phase

The effect of CCl_4, CH_3CCl_3, and CH_2Cl_2, and $CFCl_3$ on the fluorescence intensities of solutions of C_6H_6 in hexane was examined. In each case quenching obeys a Stern–Volmer relationship. Figure 1 shows plots of Φ_f^0/Φ_f versus the concentration of quencher, where Φ_f^0 and Φ_f refer to fluorescence yields of C_6H_6 in the absence and presence of quencher, respectively. The least-squares fit of the data to a straight line was obtained in all cases by excluding the Stern–Volmer intercept (0,1) from the calculation as a more stringent test of how closely the best fit line extrapolates to an intercept of 1. The effect of CCl_4 on the excited singlet state of C_6H_6 was also examined in CH_3CN, C_2H_5OH, and CH_3OH. The results in C_2H_5OH and CH_3OH are summarized in Fig. 2. Bimolecular quenching rate constants, k_q, were derived from the slope of Stern–Volmer plots and the singlet fluorescence lifetimes τ of C_6H_6. Values for τ were obtained from the literature, for conditions similar to those used in this study. The data are given in Table 1.

Halocarbons efficiently quench C_6H_6 fluorescence in hexane with k_q's ranging from 3.4×10^8 L mol^{-1} s^{-1} for the C_6H_6–$CFCl_3$ system to 6.7×10^9 L mol^{-1} s^{-1} for the C_6H_6–CCl_4 pair. Quenching is more efficient by about two orders of magnitude in aromatic–halocarbon systems than in aliphatic ketone – halocarbon systems (18).

In the absence of a distinct exciplex emission quenching cannot automatically be ascribed to the formation of a charge transfer complex. Other quenching mechanisms need to be ruled out and typical exciplex behaviour such as a linear dependence of ln k_q vs. EA (electron affinity of acceptor) or ID_D (ionization potential of donor) must be established (28). In the present instance, singlet–singlet energy transfer between C_6H_6 and halocarbons can be ruled out since the fluorescence spectrum of C_6H_6 does not overlap with the absorption spectrum of any of the halocarbons. Quenching due to the enhancement of nonradiative processes is unlikely. No evidence was observed for photochemical reaction subsequent to excitation nor was there any evidence for ground state complex formation, the absorption spectrum of C_6H_6 remaining unchanged on addition of each of the halocarbons.

There is a reasonably good linear correlation between ln k_q and EA (see Fig. 3). This, coupled with gas phase studies on the same systems (6) and improbability of other quenching paths, supports a charge-transfer complex as being responsible for the quenching of the C_6H_6 fluorescence. Finally, k_q is sensitive to solvent polarity which is typical of charge transfer exciplexes (29). A slope of 3.3 eV^{-1} is obtained from Fig. 3, a value similar to that obtained by us (6, 30) for the quenching of singlet aromatics by chloromethanes in the vapour phase. The magnitude of the gradient is much less than $1/RT \simeq 39$ eV^{-1}, the value expected for a full electron transfer from excited aromatic to quencher.

Solvent viscosity has been postulated to have an effect on the rate of formation and dissociation of exciplexes (31). Though not extensive, our study indicates that solvent viscosity does not play an important role in exciplex formation in the C_6H_6–halocarbon systems. On the other hand, solvent polarity clearly does enhance quenching and a mechanism consistent with the results is given below as reactions [1] to [6]

[1] $D + h\nu \xrightarrow{I_a} {}^1D^*$

[2] ${}^1D^* \xrightarrow{k_1} D + h\nu_f$

[3] ${}^1D^* \xrightarrow{k_2} D$ or ${}^3D^*$

[4] ${}^1D^* + Q \underset{k_4}{\overset{k_3}{\rightleftharpoons}} {}^1(D\cdots Q)^*$

[5] ${}^1(D\cdots Q)^* \xrightarrow{k_5} D + Q$

[6] ${}^1(D\cdots Q)^* \xrightarrow{k_6} D^{\cdot+} + Q^{\cdot-}$

where D and Q are the ground state benzene and halocarbon molecules, respectively, an asterisk indicates the electronically excited state, and the prefixed superscript is the multiplicity of the electronic state.

Employing the usual steady-state treatment we obtain eq. [7].

[7] $\Phi_f^0/\Phi_f = 1 + K_{sv}[Q]$

The Stern–Volmer constant K_{sv} is given by eq. [8].

[8] $K_{sv} = k_q\tau$

The lifetime of the excited singlet benzene, τ, is $(k_1 + k_2)^{-1}$ and the measured quenching rate constant, k_q, is given by eq. [9].

[9] $k_q = \left[\dfrac{k_3(k_5 + k_6)}{k_4 + k_5 + k_6}\right]$

In nonpolar solvents k_6 is zero; in polar solvents it has a non-zero value which increases with increasing dielectric constant of the solvent. As k_6 increases, the numerator in eq. [9] increases more rapidly than the denominator; thus k_q would be expected to increase with increasing solvent polarity which is consistent with experimental observation.

Studies in CH_3CN solvent showed that a complex is formed between it and excited singlet C_6H_6. In addition to the normal fluorescence band of C_6H_6 centered around 276 nm, two new structureless bands were observed with maxima at ~355 and 405 nm. These data do not warrant any further conclusions at this time.

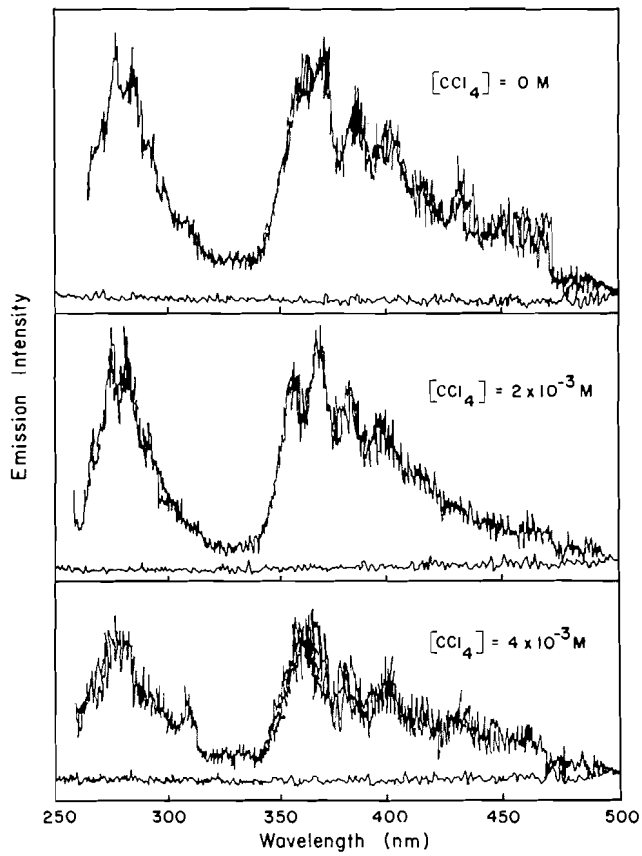

FIG. 4. Fluorescence and phosphorescence emission spectra of benzene perturbed by CCl_4 in MCH/ISPT at 77 K ($[C_6H_6] = 2 \times 10^{-3}$ M, λ_{ex} = 254 nm).

Solid phase

Quenching of C_6H_6 fluorescence and phosphorescence in solid phase by CCl_4, CH_3CN, $CHCl_3$, and CH_3CCl_3 is depicted in Figs. 4 to 7. Our experimental setup for solid phase studies

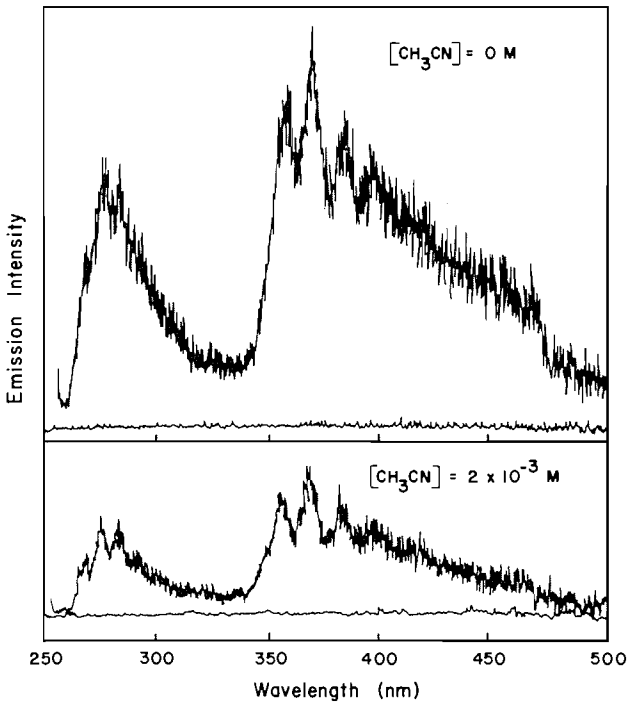

FIG. 5. Fluorescence and phosphorescence emission spectra of benzene perturbed by CH_3CN in 3 MP at 77 K ($[C_6H_6] = 2 \times 10^{-3}$ M, $\lambda_{ex} = 254$ nm).

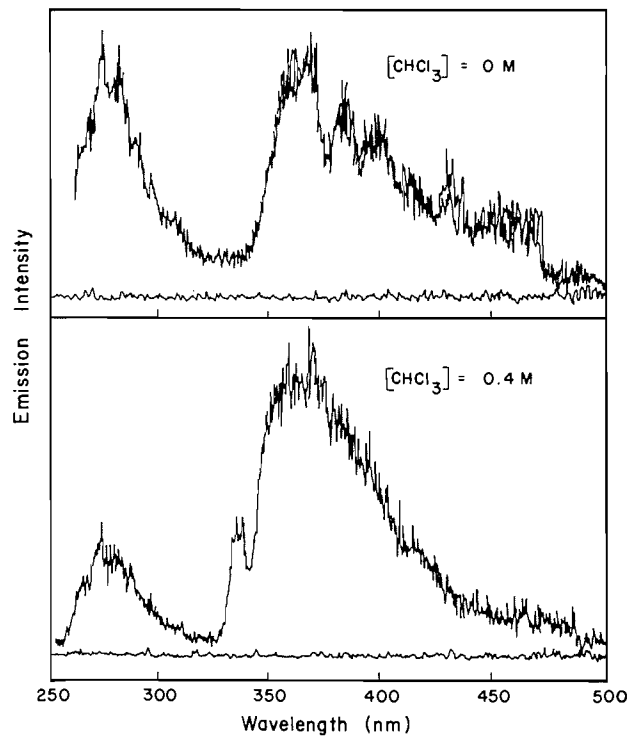

FIG. 6. Fluorescence and phosphorescence emission spectra of benzene perturbed by $CHCl_3$ in MCH/ISPT at 77 K ($[C_6H_6] = 2 \times 10^{-3}$ M, $\lambda_{ex} = 254$ nm).

did not allow for the determination of amount of light absorbed; consequently, we were not able to determine quantum yields. However, care was taken to ensure that the amount of light absorbed would be approximately the same for each of the glassy matrix solutions. Thus, Figs. 4–7 are expected to present a reasonable comparison picture of the effect of these quenchers since the same experimental setup when used for vapour and liquid phase studies showed very little variation in absorbed light intensity from run to run.

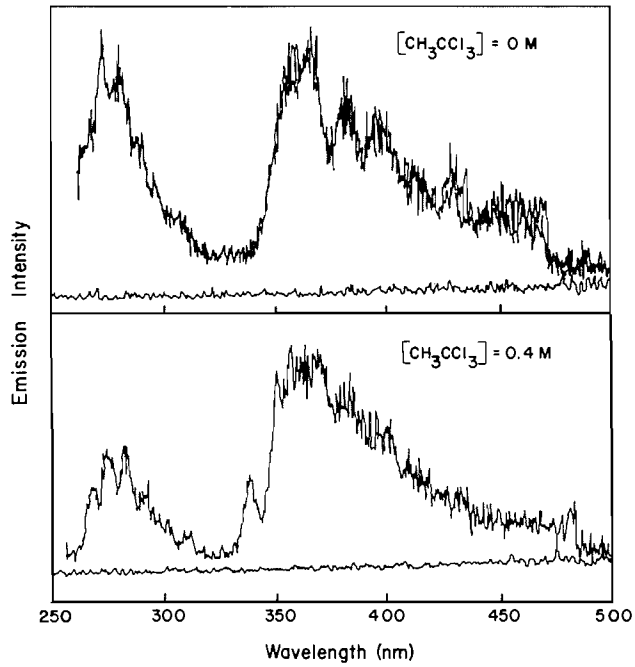

FIG. 7. Fluorescence and phosphorescence emission spectra of benzene perturbed by CH_3CCl_3 in MCH/ISPT at 77 K ($[C_6H_6] = 2 \times 10^{-3}$ M, $\lambda_{ex} = 254$ nm).

Inspection of Figs. 4 and 5 shows that CCl_4 and CH_3CN are comparable and efficient quenchers of the emission of C_6H_6 excited at 254 nm. The phosphorescence emission is quenched to the same extent as the fluorescence and this indicates that CCl_4 and CH_3CN have little effect on the triplet state of C_6H_6 with the decrease in its production being due to a decrease in singlet state population. Inspection of Figs. 6 and 7 shows that $CHCl_3$ and CH_3CCl_3 are also comparable quenchers but far less effective than CCl_4 and CH_3CN. It takes 4×10^{-1} M of $CHCl_3$ or CH_3CCl_3 to give approximately the same amount of fluorescence quenching as that produced by 4×10^{-4} M CCl_4. At these high concentrations of $CHCl_3$ and CH_3CCl_3 the enhanced intersystem crossover apparently competes with fluorescence quenching and a relative increase in phosphorescence is observed (see Figs. 6 and 7). Clearly, halocarbons can promote two reactions viz., reactions [10] and [11].

$$[10] \quad {}^1D^* + Q \xrightarrow{k_{10}} (D\cdots Q)^*$$

$$[11] \quad {}^1D^* + Q \xrightarrow{k_{11}} {}^3D^* + Q$$

For CCl_4 (and probably CH_3CN) $k_{10} \gg k_{11}$ whereas for $CHCl_3$ and CH_3CCl_3, k_{10} must be of the same order of magnitude as k_{11}.

Photoréactivité des complexes nitriles – cuivre (I) et (II). II. Système cyanure d'allyle – cuivre (I) et (II)

MICHÈLE BOLTE ET JACQUES LEMAIRE

Laboratoire de Photochimie, E.R.A. N° 929, Université de Clermont II, B.P. 45, 63170 Aubière, France

Reçu le 6 décembre, 1982[1]

MICHÈLE BOLTE et JACQUES LEMAIRE. Can. J. Chem. **62**, 1492 (1984).

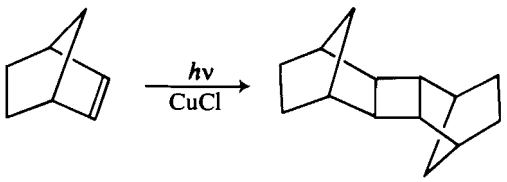
La complexation du cuivre(I) avec le cyanure d'allyle se fait par transfert de charge entre le métal et le groupement nitrile. Elle induit la transformation du cyanure d'allyle en crotonitrile (isomère α,β insaturé). Le cuivre(II) se fixe également sur l'azote du nitrile par un transfert de charge —C≡N → Cu^{II}. La photoréactivité des complexes avec le cuivre(II) montre que le ligand complexé se comporte comme un nitrile α,β insaturé.

MICHÈLE BOLTE and JACQUES LEMAIRE. Can. J. Chem. **62**, 1492 (1984).

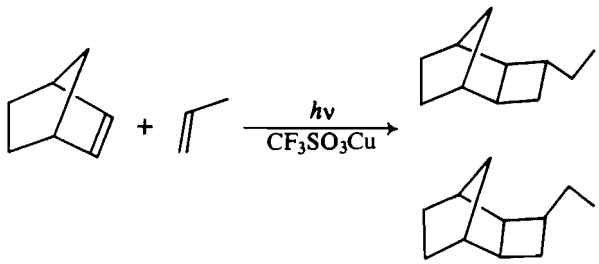
Through complexation with copper I, the allyl cyanide ligand has been shown to be converted in the dark into *cis* + *trans* crotonitrile. The photoreactivity of allyl cyanide – copper II complexes provides evidence that the ligand behaves like an α,β unsaturated nitrile. In both cases, the copper atom is bonded with the nitrogen atom of the allyl cyanide by charge transfer from the ligand to the metal (LMCT).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

La photoréactivité des complexes de cuivre(I) et (II) a connu un développement important durant ces dernières années. Notamment, l'aptitude du cuivre I à se fixer sur les doubles liaisons éthyléniques a permis la synthèse photochimique de nombreux dérivés cyclobutaniques (1, 2). L'emploi de CuCl comme catalyseur a été décrit pour la dimérisation de molécules à cycle tendu telles que le norbornène ou le bicyclopentadiène (1). L'utilisation du triflate de cuivre CF_3SO_3Cu a permis l'obtention de dérivés cyclobutaniques à partir de composés à double liaison extracyclique (3):



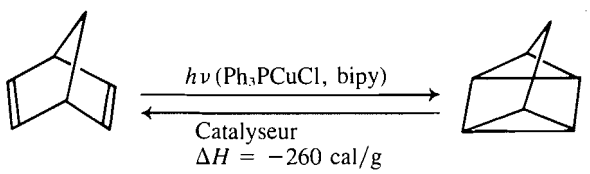
(ref. 1)



(ref. 3)

Par ailleurs, la photo-isomérisation du norbornadiène en quadricyclane, catalysée par un sel de cuivre I est un système envisagé pour la récupération de l'énergie solaire (4).

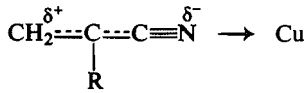
En ce qui concerne le cuivre(II), de nombreux systèmes contenant des protéines complexes ou des macrocycles polyazotés ont été étudiés (5, 6). Gagné *et al.* ont décrit un



(ref. 4)

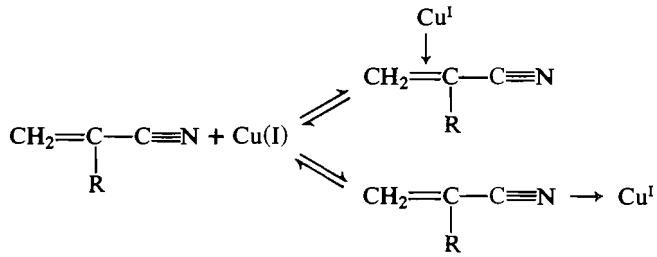
complexe Cu^{II} – macrocycle tétraazoté qui peut fixer photochimiquement un cinquième ligand sur le cuivre (CO, CH_3CN ou la 1-méthyl imidazole) (7).

Dans un précédent mémoire, nous avons décrit la photoréactivité des complexes du cuivre(I) et (II) avec différents nitriles saturés ou α,β insaturés (8). La position en α,β de la double liaison dans les complexes cuivre–nitrile insaturés semble être un facteur déterminant de la photoréactivité de ces complexes. Ainsi, nous avons pu établir que la délocalisation existant dans le ligand facilite le transfert de charge —C≡N → Cu du ligand vers le cuivre:



R = H ou CH_3

Dans le cas du cuivre(I), cette délocalisation favorise la formation des complexes dans lequels le métal est lié à la double liaison ou au groupement nitrile; l'association avec la double liaison reste cependant minoritaire.



R = H ou CH_3

Les photoréactivités associées à ces deux types de complexation sont différentes. La complexation du cuivre sur la double liaison induit sélectivement la photodimérisation cyclobutanique du ligand. La complexation avec le groupement nitrile augmente le rendement quantique d'isomérisation *trans*→*cis*: ainsi le crotonitrile CH_3—CH=CH—C≡N pour lequel les valeurs des rendements quantiques d'isomérisation $\phi^0_{t\to c}$ et $\phi^0_{c\to t}$ sont multipliées par un facteur trois lors de l'irradiation en présence de CuCl (9). Il en est de même pour le cinnamonitrile C_6H_5—CH=CH—C≡N dont le rendement $\phi^0_{t\to c}$ augmente de 0,28 (sans CuCl) à 0,42 (avec CuCl) (10). De plus, dans les deux cas, l'isomérisation de nitrile est assistée par le complexe

		2279 mf ν(C≡N complexé)

R—CH=CH—C≡N—Cu^{I} (effet catalytique du cuivre(I)).

L'étude des systèmes nitriles–cuivre(II) a montré que la présence d'une double liaison conjuguée avec le groupement nitrile augmente aussi le rendement quantique de réduction du cuivre(II) (8).

Il apparaissait donc que la position de la double liaison en α,β du groupement nitrile était un facteur déterminant de la photoréactivité des complexes nitriles–cuivre. Afin de vérifier cette conclusion, nous avons entrepris l'étude de système cuivre – nitrile β,γ insaturé, soit:

CH_2=CH—CH_2—C≡N, CuCl
et CH_2=CH—CH_2—C≡N, $CuCl_2$

Résultats expérimentaux

Dans les systèmes étudiés, le nitrile sert de ligand avec le cuivre et de solvant pour le complexe formé. Les spectres d'absorption que nous décrivons correspondent aux transitions supplémentaires inhérentes à la formation d'un complexe entre le métal et le ligand.

(a) Système CH_2=CH—CH_2—C≡N, CuCl

CuCl est très soluble dans le cyanure d'allyle, on peut obtenir des solutions de concentration en CuCl égale à 0,5 *M*. Lorsqu'on dissout du chlorure cuivreux dans le nitrile, on note une augmentation importante de densité optique entre 250 et 320 nm sans qu'il soit possible de déterminer un maximum d'absorption.

Le spectre Raman de ces solutions permet de mettre en évidence un transition supplémentaire à 2279 cm^{-1} (Tableau 1). On ne note, par ailleurs, aucune autre modification du spectre.

Nous observons à l'obscurité, la transposition lente du cyanure d'allyle en son isomère α,β insaturé, le crotonitrile:

$$CH_2{=}CH{-}CH_2{-}C{\equiv}N \xrightarrow[\theta = 20°C]{\Delta,\ CuCl} \underset{\substack{(cis\ +\ trans)\\ 50\%\quad 50\%}}{CH_3{-}CH{=}CH{-}C{\equiv}N}$$

Cette réaction d'ordre apparent 1 se fait avec une constante de vitesse $k = 5{,}7 \times 10^{-5}$ mn^{-1} calculée sur l'apparition des crotonitriles. La transposition en crotonitrile est catalysée par CuCl; l'emploi d'une solution, par exemple de concentration égale à 0,1 *M* en CuCl permet de transformer 20% du cyanure d'allyle pris à l'état pur, soit 2,4 mol.

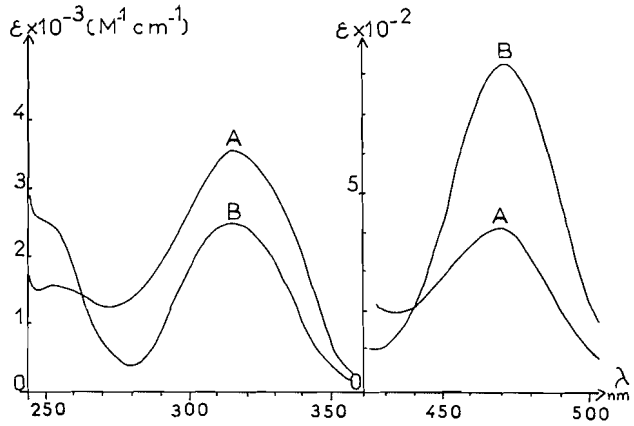

FIG. 1. Spectres d'absorption de $CuCl_2$ dans le cyanure d'allyle.

TABLEAU 2. Spectres d'absorption de $CuCl_2$ dans le cyanure d'allyle

A $c > 10^{-3}$ *M*		B $c < 5 \times 10^{-4}$ *M*	
λ_{max} (nm)	ϵ_{max} (M^{-1} cm^{-1})	λ_{max} (nm)	ϵ_{max} (M^{-1} cm^{-1})
256	1550	250	2700
312	3450	315	2650
468	410	470	815

Nous n'avons pas observé d'accélération du phénomène par excitation photochimique à 254 nm.

(b) *Systèmes CH_2=CH—CH_2—C≡N—$CuCl_2$*

$CuCl_2$ est relativement peu soluble dans le cyanure d'allyle. La concentration en sel de cuivre est généralement comprise entre 5×10^{-3} *M* et 2×10^{-4} *M*. Dans ces conditions, on obtient des spectres d'absorption comportant deux transitions en uv et une dans le visible (Fig. 1). Selon la concentration en $CuCl_2$, on observe deux spectres différents correspondant à des complexes que nous désignerons par "A" et "B"; le complexe "A" apparaît à des concentrations en $CuCl_2$ supérieures à 10^{-3} *M*; le complexe "B" est observé quand la concentration en $CuCl_2$ devient inférieure à 5×10^{-4} *M*. La dilution d'une solution contenant le complexe "A" entraîne l'apparition rapide du complexe "B". Les solutions concentrées évoluent dans le temps: on observe une modification spectrale lente conduisant au spectre obtenu en solution diluée. Cependant, on peut conserver le complexe "A" quelques jours sans modification notable de son spectre d'absorption. Le tableau 2 regroupe les caractéristiques spectrales des spectres d'absorption observés dans les différents domaines de concentration de $CuCl_2$.

L'addition de LiCl (Cl/Cu ~ 3) à la solution concentrée de $CuCl_2$ dans le cyanure d'allyle entraîne une modification du spectre d'absorption et notamment une très forte augmentation de la transition à 468 nm ($\epsilon_{max} = 1200\,M^{-1}\,cm^{-1}$). Une addition supplémentaire de LiCl (Cl/Cu ~ 8) ne modifie que très légèrement le spectre, on voit apparaître un épaulement à environ 405 nm (Fig. 2).

Nous avons irradié le complexe "A" en lumière monochromatique de longueur d'onde 254, 313 et 491,6 nm correspondant à chacune des transitions du complexe. Quelle que soit la longueur d'onde utilisée, on observe le même phénomène en deux étapes: la transformation de "A" en "B" durant laquelle le faisceau des courbes correspondantes présente deux points isobestiques à 263 et 440 nm (Fig. 3); puis la disparition de la

TABLEAU 3. Rendements quantiques de transformation A→B et de disparition

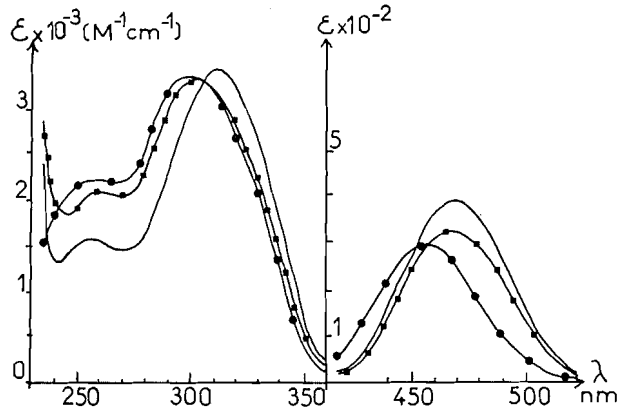

FIG. 6. Complexes nitrile–$CuCl_2$ (A) avec CH_3CN (-●-●-), CH_2=CH—CN (-■-■-) et CH_2=CH—CH_2—CN (———).

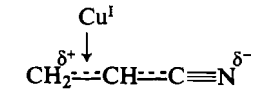
présente aucun signal en rpe. Par irradiation de ce complexe, il apparaît de nouveau un signal à quatre raies qui disparaît en fin de photoréaction. Cette étude a été également réalisée avec le système $CuCl_2$–CH_3CN pour lequel nous obtenons des résultats tout à fait analogues.

Discussion

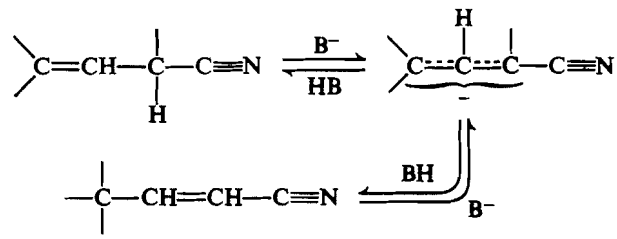
A. *Système cyanure d'allyle – cuivre(I)*

L'étude en spectroscopie Raman montre que le cuivre(I) se fixe uniquement sur le groupement nitrile. En effet, dans un précédent mémoire (11), il a été établi que l'augmentation de fréquence du mode ν(C≡N) correspond à une complexation du cuivre(I) avec le ligand, de type —C≡N → Cu(I).

La complexation avec la double liaison observée avec les nitriles α,β insaturés est donc directement liée à la conjugaison présente dans la molécule et à l'appauvrissement en électrons qui en résulte:

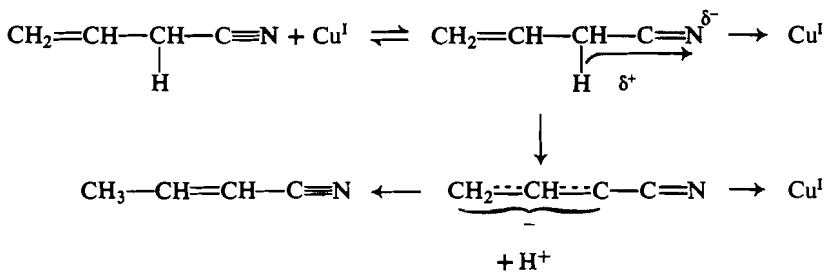


La transposition du cyanure d'allyle en crotonitrile à l'obscurité, est analogue à celle décrite par Mialhe et Vessière (12) pour les composés allyliques en présence d'une base:



B = diéthylamine

Dans notre cas, en l'absence de base, l'hydrogène placé en α du groupement nitrile est rendu plus labile par la complexation avec le cuivre, ce qui favorise la migration de la double liaison:



La stéréochimie du carbanion formé ne favorise aucun isomère en particulier, les crotonitriles *cis* et *trans* se forment en quantités équivalentes. Il n'apparaît aucune modification notable de ce processus par excitation photochimique.

L'étude photochimique des systèmes crotonitrile (*cis* ou *trans*) – Cu^I (9) a montré que le phénomène majoritaire est la désactivation par isomérisation *trans* ⇌ *cis* du ligand. L'état photostationnaire obtenu contient les deux isomères en égales proportions. Par ailleurs, la photodimérisation cyclobutanique observée avec le complexe crotonitrile *cis* – Cu^I est un phénomène extrêmement minoritaire qu'il est donc impossible de mettre en évidence à partir du cyanure d'allyle.

B. *Systèmes cyanure d'allyle – cuivre(II)*

Comme le montre la figure 6, les spectres d'absorption des complexes "A" et "B" sont analogues à ceux obtenus avec un ligand saturé (acétonitrile); la fixation du métal se fait exclusivement sur l'azote du groupement nitrile (8) (caractère de donneur σ de ce groupement).

L'absorption à 470 nm dans le visible est caractéristique d'un complexe tétracoordoné du cuivre(II) (13). Sykora *et al.* indiquent effectivement que la mise en solution de $CuCl_2$ ($c_{CuCl_2} \sim 10^{-3}$ *M*) dans l'acétonitrile correspond à l'apparition de différents complexes $CuCl(CH_3CN)_3^+$ (17%), $CuCl_3(CH_3CN)^-$ (26%) et $CuCl_2(CH_3CN)_2$ (52%) Cu^{2+} (4%). Ils indiquent également la présence d'un signal rpe qui disparaît par irradiation. L'addition d'ions Cl^- à cette solution entraîne la formation de $CuCl_3^-$ (96% pour un rapport $Cu^{2+}/Cl^- = 1/3$) puis celle de $CuCl_4^{2-}$ (λ_{max} = 404 nm) obtenu presque pur pour un rapport $Cu^{2+}/Cl^- = 1/8$.

La mise en solution de $CuCl_2$ dans le cyanure d'allyle provoque en proportions vraisemblablement différentes, la formation des complexes mentionnées ci-dessus. L'addition d'ions Cl^- à cette solution favorise la formation de $CuCl_3^-$; par contre, une addition supplémentaire d'ions Cl^- ne permet l'obtention de $CuCl_4^{2-}$ qu'en très faible quantité (épaulement à 404 nm).

Le signal symétrique observé en rpe à g = 2,136 pour une solution concentrée du $CuCl_2$ dans le cyanure d'allyle avec et sans LiCl est attribué au complexe $CuCl_3RCN^-$. La disparition de ce signal provisoire thermiquement ou photochimiquement correspond à la transformation A → B mise en évidence par spectroscopie d'absorption. L'absence de signal rpe pour le complexe "B" alors que l'absorption dans le visible est maximum indique la présence de cuivre(II) fortement solvaté par les

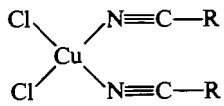
molécules de nitriles. Par ailleurs, la réapparition d'un signal rpe différent du précédent, observée en poursuivant l'irradiation, montre que le complexe "B" est effectivement un complexe de cuivre(II). L'hypothèse d'une structure dimère pourrait expliquer la disparition du signal rpe soit par liaison directe métal–métal, soit par super-échange par l'intermédiaire du ligand. Cependant cette hypothèse est en contradiction avec l'obtention du complexe "B" par dilution et son existence dans un domaine de concentration inférieure à 5×10^{-4} *M*. Le cuivre(II) se trouve donc fortement solvaté par les molécules de nitriles et il y a couplage entre les électrons du cuivre(II) paramagnétique et les électrons du ligand. Ce même phénomène a été observé avec les complexes chrome(III) – acides aminés pour lesquels l'addition en quantités croissantes d'acide aminé à une solution aqueuse de chrome(III) entraîne la disparition progressive du signal rpe (14).

L'ensemble de ces résultats nous conduit à décrire le complexe "B" présent en solution diluée comme une entité neutre tétracoordonnée autour du cuivre:



Le complexe "A" est, comme nous l'avons déjà indiqué, un mélange instable de différentes espèces dont $CuCl^+$, $CuCl_3^-$ et $CuCl_2$. Par dilution, activation thermique ou photochimique, on observe la transformation de ces différents complexes en une seule entité, le complexe neutre solvaté "B".

Par excitation dans chacune des trois bandes de transfert de charge du complexe "B", on observe la destruction du complexe (réapparition du signal du cuivre(II) en rpe) et photoréduction du cuivre(II) en cuivre(I).

En ce qui concerne la cinétique de photoréduction, les valeurs des rendements quantiques (Tableau 3) sont élevées, de l'ordre de celles obtenues avec les nitriles α,β insaturés; elles sont bien supérieures à celles observées avec l'acétonitrile. Elles ne varient que relativement peu avec la longueur d'onde d'excitation.

Cette similitude de comportement avec les nitriles α,β insaturés, indique que le cyanure d'allyle complexé avec le cuivre possède à l'état excité une conjugaison importante qui favorise le transfert de charge du ligand vers le cuivre(II) et donc la réduction du Cu^{II} en Cu^{I}. Cependant, en l'état actuel de nos connaissances, il n'est pas possible de préciser si le cyanure d'allyle complexé se comporte déjà à l'état fondamental comme un ligand α,β insaturé. Nous n'avons pas observé, à l'obscurité, de transposition en crotonitrile induite par le cuivre(II). Il convient toutefois de noter que les concentrations de cuivre(II) mises en jeu sont nettement inférieures à celles observées pour le cuivre(I) et que la mise en évidence d'une telle transposition peut s'avérer plus difficile. Il s'est avéré également impossible d'identifier les photoproduits d'oxydation du cyanure d'allyle.

Conclusion

Les résultats obtenus pour le système cyanure d'allyle – Cu^{I} montrent que, lorsque la double liaison n'est pas conjuguée avec le groupement nitrile, on n'observe pas de complexation du cuivre(I) sur la double liaison. La seule complexation mise en évidence est une liaison par transfert de charge entre le groupement nitrile et le cuivre, quelle que soit la valence du cuivre, (I) ou (II).

Avec le cuivre(I), cette complexation favorise la migration de la double liaison et entraîne la transposition du cyanure d'allyle en son isomère α,β insaturé, le crotonitrile (*cis* et *trans*). La liaison $—C\equiv N \rightarrow Cu^{II}$ observée avec le cuivre divalent induit une photoréactivité analogue à celle d'un complexe $CuCl_2$ – nitrile α,β insaturé.

Partie expérimentale

Le cyanure d'allyle (Merck) est distillé afin d'éliminer les impuretés qu'il contient. Ainsi distillé, il ne peut être conservé que quelques semaines à l'obscurité. Le liquide se teinte ensuite progressivement en jaune et l'impureté qu'il contient empêche toute complexation avec le cuivre.

Les spectres d'absorption uv–visible ont été enregistrés sur un appareil Cary 118CX. les crotonitriles *cis* et *trans* ont été analysés par chromatographie en phase gazeuse sur un appareil Carlo Erba Fractovap 2101 équipé d'une colonne Carbowax 20M. Les mélanges réactionnels sont mis en solution dans l'acétonitrile et analysés sur une colonne dont la température est fixée à 100°C.

Les spectres Raman ont été faits sur un spectromètre Jobin Yvon, modèle Ramanor HG 28 équipé de deux réseaux holographiques concaves. La raie d'excitation 514,5 nm est celle d'un laser à argon ionisé Spectraphysics Modèle 164.

Les spectres de rpe ont été faits sur un appareil ER 200D Brucker. Les solutions dégazées à l'argon, sont placées dans des cellules plates (épaisseur 0,1 mm). Les conditions de travail sont les suivantes: fréquence 9,52 MHz, modulation de champ 400 kHz, modulation d'amplitude 4 G, puissance 56 mW.

La manipulation de sels et complexes de cuivre(I) est faite uniquement en boîte à gants sous atmosphère d'azote sec. Les solutions de $CuCl_2$ sont préparées à l'air mais elles sont dégazées puis irradiées sous vide. Les dégazages sont faits par des cycles de congélation–décongélation dans l'azote liquide (trois cycles).

Les irradiations à 254 nm des solutions de CuCl dans le nitrile ont été faites dans un réacteur en quartz cylindrique entouré de six tubes à vapeur de mercure basse pression ($I_0 \simeq 3 \times 10^{16}$ photons/cm^3 s). Les actinométries sont faites avec l'oxalate d'uranyle. Les irradiations à 313 nm et 491,6 nm sont faites en faisceau parallèle avec une lampe à vapeur de mercure moyenne pression équipée d'un monochromateur Bausch et Lomb "haute intensité". Les solutions de $CuCl_2$ sont irradiées dans des cellules cylindriques de 1 cm de rayon et de 1 cm ou 1 mm de longueur. Les actinométries sont faites avec le ferrioxalate de potassium (0,006 *M* ou 0,15 *M*).

Discreteness-of-charge effects in electrode kinetics. III. The electroreduction of aquopentamminochromium(III) cation in the presence of specifically adsorbed iodide anions

W. RONALD FAWCETT[1] AND KVETA MARKUŠOVÁ[2]

Guelph–Waterloo Centre for Graduate Work in Chemistry (Guelph Campus), Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received December 5, 1983

W. RONALD FAWCETT and KVETA MARKUŠOVÁ. Can. J. Chem. **62**, 1497 (1984).

The kinetics of electroreduction of the aquopentamminochromium(III) cation have been studied at a Hg electrode in acidified aqueous solutions of NaI + $NaClO_4$ with an ionic strength of 0.25 *M*. The rate of reaction increased with increase in iodide concentration due to the accelerating effect of this anion when it is adsorbed on the electrode. Analysis of the double layer effect indicates that the rate acceleration is greater than that predicted by the Frumkin theory chiefly because the reaction site is closer to the electrode than to the outer Helmholtz plane.

W. RONALD FAWCETT et KVETA MARKUŠOVÁ. Can. J. Chem. **62**, 1497 (1984).

Opérant dans des solutions aqueuses acidifiées de NaI + $NaClO_4$ et à une force ionique de 0,25 *M*, on a étudié la cinétique de l'électroréduction du cation aquopentamminochrome(III) à une électrode de Hg. Dû à l'effet accélérant de l'iodure lorsqu'il est adsorbé sur l'électrode, la vitesse de la réaction augmente avec une augmentation de la concentration en iodure. L'analyse de l'effet de double couche indique que l'augmentation de la vitesse est plus grande que celle que l'on pourrait prédire en se basant sur la théorie de Frumkin; ceci est principalement dû au fait que le site réactionnel est plus près de l'électrode que le plan extérieur de Helmholtz.

Introduction

In a previous paper of this series (1), double layer effects on the electroreduction of hexamminocobalt(III) cation were examined in mixed electrolyte solutions of constant ionic strength containing nitrate and fluoride anions. Analysis of these effects proved to be rather complex for two reasons. Firstly, the reaction occurs at potentials close to the point of zero charge (p.z.c.) where the ionic composition of the double layer changes most rapidly. Secondly, the reactant has some tendency to ion pair especially with the F^- anion so that it is possible that the average charge on the reactant changes with composition of the base electrolyte. Analysis of double layer effects on the reduction of Cr(III) ions is expected to be somewhat simpler since these species are reduced at more negative potentials at which the predominant ions in the double layer are cations in the absence of anionic adsorption. The double layer effect is then classified as Type I (2) and is the simplest possible from the point of view that attractive ion–ion interactions in the vicinity of the reaction site can be neglected.

The reactant chosen for the present study, namely, $Cr(NH_3)_5OH_2^{3+}$ was investigated previously by Anson *et al.* (3), and Weaver and Satterberg (4) in solutions of high ionic strength. These authors found that the experimental transfer coefficients for reduction of this cation and hexamminochromium(III) were significantly greater than that for the reduction of hexaquochromium(III). In addition, the increase in the logarithm of the rate of reduction at constant potential due to the adsorption of a fixed amount of iodide anion at the electrode was at least twice as large in the case of the ammino-complex. In discussing these results, it was suggested (4) that the reaction site for the ammino-complex is closer to the electrode than that for the aquo-complex. As a result, changes in the potential at the reaction site due to anion adsorption have a much larger effect on the reaction rate.

The purpose of the present study was to examine the effect of adsorbed iodide ion on the reduction of $Cr(NH_3)_5OH_2^{3+}$ in more detail with quantitative estimation of the change in the potential drop across the diffuse layer, ϕ^d. Due to the fact that deficiencies in the Gouy–Chapman theory used to calculate ϕ^d are expected to become more important as the ionic strength increases, the experiments reported here were carried out at a lower ionic strength.

Experimental

The kinetic data were obtained by d.c. polarography using a dropping mercury electrode with a flow rate of 0.26 mg s^{-1} and droptime of 2 s. The depolarizer obtained from Dr. R. J. Balahura was purified by recrystallization; the chromium content was confirmed analytically and the nature of the ligands spectroscopically. At a concentration of 0.5 m*M*, the polarographic waves exhibited a maximum which became more pronounced as the concentration of iodide in the solution increased. In order to eliminate polarographic maxima, the depolarizer concentration was kept low (0.133 m*M*) and higher iodide concentrations avoided. The solutions were kept at a low pH to prevent hydrolysis of the depolarizer by maintaining a $HClO_4$ concentration of 0.01 *M*. The diffusion coefficient of $Cr(NH_3)_5OH_2^{3+}$ in solutions with an ionic strengh of 0.25 *M* was 6.72×10^{-6} cm s^{-1}. The salts used as base electrolytes, namely, $NaClO_4$ and NaI were purified and dried according to procedures described earlier (5, 6). The concentration of $NaClO_4$ + NaI was 0.24 *M*. The rate constant was calculated from the ratio of the observed current to its diffusion limited value using Koutecký's theory including correction for electrode sphericity (7). The reference electrode was a calomel system with a 4.16 *M* NaCl solution, and the counter electrode a Pt cylinder. All experiments were carried out at 25°C.

The potential drop across the diffuse layer, ϕ^d was estimated with consideration of the contribution of the reactant and product to the ionic strength as described earlier (1). The double layer data used were those obtained earlier for the system xM NaI + $(0.25 - x)M$ NaF (6). Accordingly, it was assumed that the ClO_4^- anion is not adsorbed in the potential region where kinetic data were obtained, and that its role in the double layer is the same as that of the F^- anion.

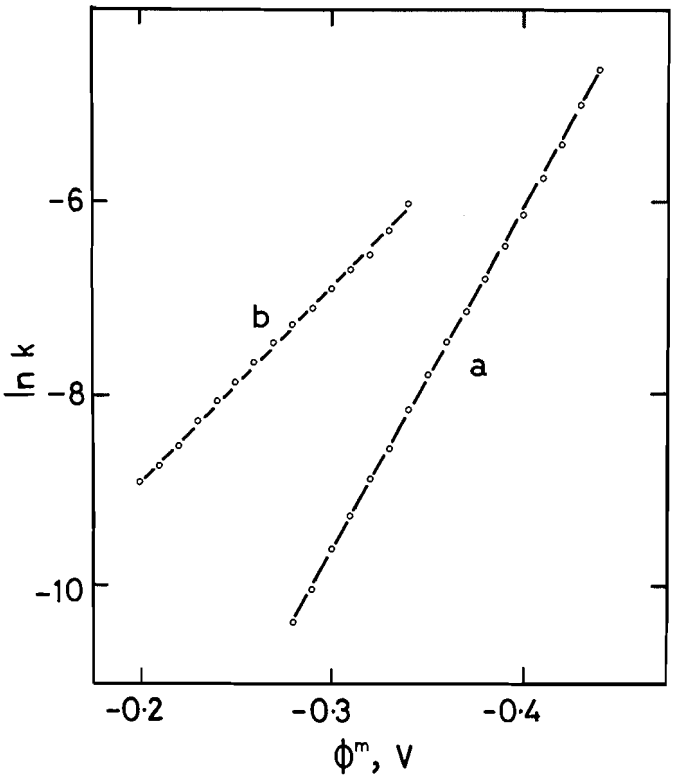

FIG. 1. Plots of the logarithm of the rate constant for reduction of $Cr(NH_3)_5H_2O^{3+}$ at mercury against electrode potential on the rational scale in solutions of (*a*) 0.24 *M* $NaClO_4$ + 0.01 *M* $HClO_4$ and (*b*) 0.04 *M* NaI + 0.20 *M* $NaClO_4$ + 0.01 *M* $HClO_4$.

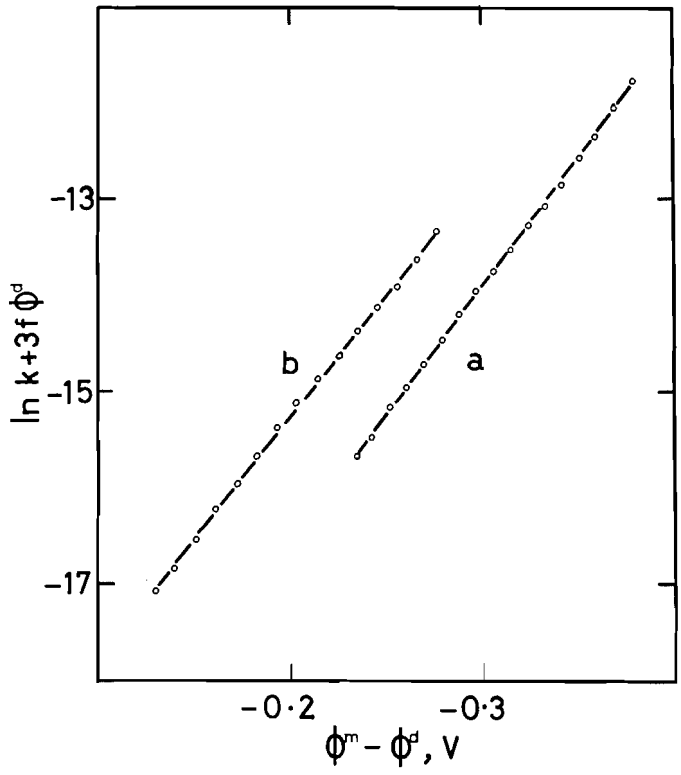

FIG. 2. Plots of the logarithm of the corrected rate constant, ln k + $3f\phi^d$ for reduction of $Cr(NH_3)_5H_2O^{3+}$ at mercury against the potential drop across the inner layer, $\phi^m - \phi^d$ in solutions of (*a*) 0.24 *M* $NaClO_4$ + 0.01 *M* $HClO_4$ and (*b*) 0.04 *M* NaI + 0.20 *M* $NaClO_4$ + 0.01 *M* $HClO_4$.

Results

Kinetic data were obtained in six different electrolyte solutions of composition xM NaI + $(0.24 - x)M$ $NaClO_4$ + 0.01 *M* $HClO_4$ where x = 0, 0.0063, 0.01, 0.016, 0.025, and 0.04 *M*. Data obtained in solutions where x = 0 and 0.04 *M* are shown in Fig. 1. As expected, the rate constant increases with increase in I^- concentration at constant electrode potential. The acceleration is attributed to the shift in the potential drop across the diffuse layer in the negative direction with increase in the extent of I^- ion adsorption, and the corresponding increase in the rate of reduction of the positively charged reactant. The experimental transfer coefficient α_{ex} obtained in the electrolyte with no I^- anion (x = 0) was 0.91. This value can be compared with values of 0.72 obtained by Anson *et al.* (3) in 1 *M* $NaClO_4$ + 0.01 *M* $HClO_4$, and 0.73 obtained by Weaver and Satterberg (4) in the same electrolyte. Since the double layer effect is reduced with increase in ionic strength, its influence on α_{ex} is smaller in the data obtained earlier (3, 4). If one corrects for the double layer effect assuming that the reaction site is on the outer Helmholtz plane (o.H.p.), then one can obtain the apparent transfer coefficient α_a, which is given by

$$[1] \quad \alpha_a = \frac{\alpha_{ex} - z(d\phi^d/d\phi^m)}{1 - (d\phi^d/d\phi^m)}$$

where z is the charge on the reactant, and $d\phi^d/d\phi^m$, the change in ϕ^d with electrode potential, ϕ^m. For the present base electrolyte, ignoring possible specific adsorption of ClO_4^- anion, $d\phi^d/d\phi^m$ = 0.098. It follows that α_a = 0.68 when z is assumed to be 3. Weaver and Satterberg (4) estimated that $d\phi^d/d\phi^m$ is in the range 0.055 to 0.085 in 1 *M* $NaClO_4$ but apparently did not consider the influence of the highly charged reactant and product on ϕ^d and $d\phi^d/d\phi^m$. Choosing the lower limit (0.055), the value of α_a estimated from their data is 0.59. Both values are greater than the result expected for a reaction occurring on the o.H.p., namely, 0.5, and support the conclusion reached earlier that the reaction site for the ammino-complexes of Cr(III) and Co(III) is in the inner layer (3, 4, 8). In the absence of discreteness-of-charge effects, attractive ion–ion interactions and surface coverage effects, the true or intrinsic transfer coefficient α can be calculated from the apparent value using the equation

$$[2] \quad \alpha = (\alpha_a - \lambda z)/(1 - \lambda)$$

where λ is a dimensionless fraction determined by the distance between the reaction plane (r.p.) and o.H.p., and the dielectric permittivity of the medium between these planes. If it is assumed that α is 0.5, then λ equals 0.072, indicating that the potential at the reaction site is 7.2% more negative than the average potential on the o.H.p. It follows that a very small shift in the potential at the reaction site has a large effect on the rate of reaction and apparent transfer coefficient in the case of highly charged reactants.

Corrected Tafel plots (c.T.p.) for the present data are shown in Fig. 2 for the case that the charge on the reactant is assumed to be 3+. Neglecting discreteness-of-charge effects, the corrected rate of reaction is given by

$$[3] \quad \ln k + zf\phi^d = \ln k_0 - \alpha_a f(\phi^m - \phi^d)$$

where k is the rate constant for the reduction reaction, and k_0, its value when both ϕ^m and ϕ^d are zero, that is, at the p.z.c. in an electrolyte which does not specifically adsorb. It is clear

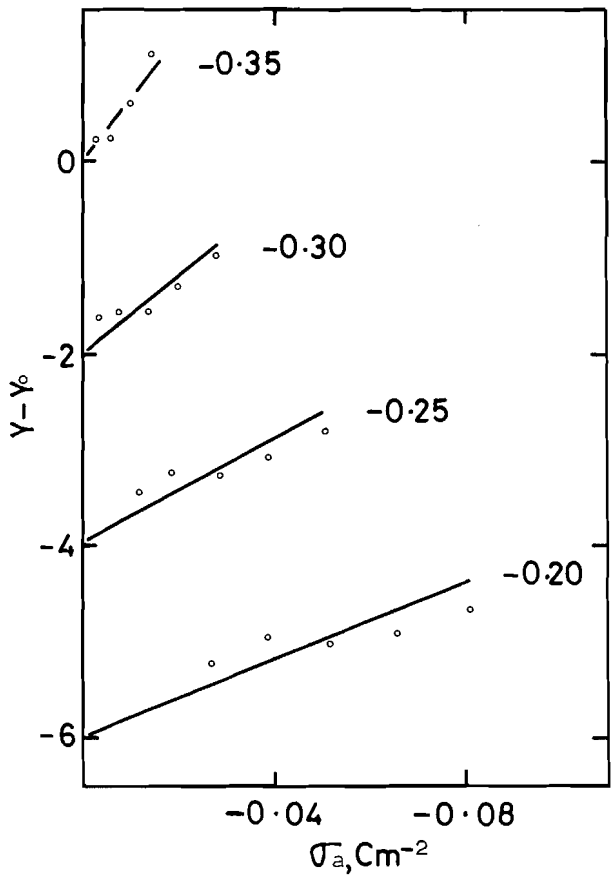

FIG. 3. Plots of the logarithm of the corrected rate constant, $y = \ln k + 3f\phi^d$ for reduction of $Cr(NH_3)_5OH_2^{3+}$ at mercury in mixed $NaClO_4$–NaI solution with respect to that in $NaClO_4$, y_0 against adsorbed charged density due to iodide anions, σ_a for constant potential drop across the inner layer, $\phi^m - \phi^d$. The value of $\phi^m - \phi^d$ in volts is indicated adjacent to each curve. The ordinate scale is correct for the data at −0.35 V whereas the data at −0.30, −0.25, and −0.20 V have been shifted down by 2, 4, and 6 units, respectively.

from the c.T.p. that the classical theory is not able to account for the accelerating effect of the adsorbed I^- anions, the corrected rate constant being higher in the system 0.04 *M* NaI + 0.20 *M* $NaClO_4$ with respect to the value in 0.24 *M* $NaClO_4$ by a factor of 4. As expected, the value of the apparent transfer coefficient calculated from the slope of the c.T.p. obtained in the absence of I^- ion is the same (0.68) as that found on the basis of eq. [1]. Values of α_a for data obtained in the presence of I^- ion are somewhat lower (~0.58), suggesting that the classical analysis is not valid for these systems. If one assumes that ion pairs are involved in the electrode reaction, as was done earlier in analyzing data for the reduction of $Co(NH_3)_6^{3+}$, and sets $z = 2$ in the c.T.p., then the separation between the c.T.p. for the systems considered in Figs. 1 and 2 would be significantly larger. This fact is an indirect support for the assumption that ion pairs are not involved in the present electrode reaction, and that the charge should be set equal to 3+ in constructing the c.T.p. It should be noted that the classical technique for determining z (9, 10) using kinetic data obtained in solutions of varying composition cannot be applied to the present system since the Frumkin equation (eq. [3]) does not correctly describe the double layer effect. Furthermore, an alternate method (11) which makes use of data obtained at a fixed electrolyte composition, for instance, 0.24 *M* $NaClO_4$ in the present case, is also not applicable because ϕ^d is approximately a linear function of ϕ^m in the potential range of interest.

The change in the corrected rate constant, $y = \ln k + zf\phi^d$ with adsorbed I^- anion charge density at constant $\phi^m - \phi^d$ is illustrated in Fig. 3 from which it is apparent that the extent by which a fixed amount of adsorbed I^- anion influences y is a function of $\phi^m - \phi^d$. At the most negative potentials the influence is greatest, and it decreases steadily as $\phi^m - \phi^d$ becomes more positive. A similar trend was found for the effect of adsorbed I^- on the corrected rate of reduction of tetrathionate anion (12). In assessing the variation in y with adsorbed charge density, σ_a it should be remembered that according to the Frumkin model of double layer effects, y should be independent of solution composition, and therefore, σ_a, when the effect of the latter is considered in estimating ϕ^d. It is clear that the Frumkin model is not able to describe the present results, and in fact, only accounts for ~50% of the variation in ln k with solution composition illustrated in Fig. 1.

The variation in y with σ_a may be attributed to the dependence of the local potential at the reaction site on the extent of iodide adsorption, and attractive ion–ion interactions between the reacting cation and the adsorbed anions. On the basis of the theory presented earlier (2), the change in y with respect to its value in the absence of adsorbed anions, y_0 is given by

$$[4] \quad y - y_0 = \frac{(\alpha - z)f(1 - \lambda)(1 - g)}{K_2}\sigma_a - \frac{a_{\neq}\sigma_a}{RT}$$

where g is a dimensionless parameter related to the degree that repulsive interactions between adsorbent anions are screened by their electrostatic environment, K_2, the integral capacity of the region between the inner Helmholtz plane (i.H.p.) and the o.H.p., and $a_{\neq}$, the parameter accounting for interaction between the reacting cation and adsorbed anions in the activated state. According to the exclusion disc model for discreteness-of-charge effects (13), the parameter g is close to unity. When it is exactly one, the local potential ψ^r is given by (2)

$$[5] \quad \psi^r = \phi^d + \lambda(\phi^m - \phi^d)$$

that is, by the same expression that applies in the absence of specific adsorption. This means that the change in the local potential in the inner layer with position is independent of the value of σ_a provided that the local dielectric permittivity and thus λ are also independent of σ_a. When $g = 1$, the contribution of the first term on the r.h.s. of eq. [4] is zero. In most cases, g is not exactly one, and in the case of iodide adsorption for the conditions of the present experiment, it is less than one (6, 12). In fact, since $(\alpha - z)$ is negative, the first term leads to an increase in the corrected rate of reaction with increase in the extent of iodide adsorption. The second term, which accounts for attractive interactions between the reacting cation and adsorbed anions, also depends on σ_a and is positive. This implies that the interaction parameter $a_{\neq}$ is positive. On the basis of models developed to estimate $a_{\neq}$ (14, 15), this parameter changes with the dielectric properties of the medium in the vicinity of the reaction site, and therefore, is expected to change with electrode potential.

In order to assess the relative contributions of the two effects discussed above, the parameters characterizing iodide adsorption at Hg from the NaI–NaF system are required. On the basis of the data obtained earlier (6), $K_2 = 0.662$ Fm^{-2} and $g = 0.86$ at $\phi^m - \phi^d = -0.2$ V. From the value of α_a for the present system (0.68), $(\alpha - z)(1 - \lambda)$ is equal to −2.32. It follows that $(\alpha - z)f(1 - \lambda)(1 - g)/K_2$ is equal to −19.1 m^2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

C^{-1} at −0.2 V. As $\phi^m - \phi^d$ is made more negative, both the capacity K_2 and the parameter g decrease somewhat. As a result $(\alpha - z)f(1 - \lambda)(1 - g)/K_2$ increases. From the plots in Fig. 3, $dy/d\sigma_a$ varies from -20 m^2 C^{-1} at −0.20 V to -50 m^2 C^{-1} at −0.35 V. These results indicate that the observed variation in the corrected rate of reaction with σ_a can be attributed entirely to the discreteness-of-charge effect; in other words, the role of possible attractive interactions between the adsorbed anions and the reacting cation expressed through the term $a_{\neq}\sigma_a/RT$ is quite negligible.

Discussion

In agreement with results obtained earlier in solutions of higher ionic strength (3, 4), the present data show clearly that the effect of adsorbed iodide on the kinetics of reduction of $Cr(NH_3)_5OH_2^{3+}$ is considerably greater than that predicted by the Gouy–Chapman model. Furthermore, as discussed in the earlier work (3, 4), this observation can be attributed chiefly to the fact that the reaction site for this complex ion is in the inner layer, presumably between the i.H.p. and o.H.p. Thus, as the potential at the reaction site becomes more negative, the rate of reduction of this highly charged cationic reactant is significantly accelerated. In the context of the analysis of the double effect used here, it is interesting to estimate the extent to which discreteness-of-charge effects are important in determining the magnitude of the observed acceleration. On the basis of the model presented earlier (2), the difference between the local potential at the reaction site ψ^r and the average potential on the o.H.p., ϕ^d is given by

$$[6] \quad \psi^r - \phi^d = \lambda(\phi^m - \phi^d) + \frac{(1 - \lambda)(1 - g)\sigma_a}{K_2}$$

When λ is defined as K_i/K_{rd} where K_i is the integral capacity of the inner layer and K_{rd}, the integral capacity of the region between the r.p. and the o.H.p., the above expression is valid for any reaction site in the inner layer. The extent to which specific adsorption modifies this potential difference at constant potential drop across the inner layer is given by

$$[7] \quad \Psi_d = \left[\frac{\partial(\psi^r - \phi^d)}{\partial\sigma_a}\right]_{\phi^m - \phi^d} = \frac{(1 - \lambda)(1 - g)}{K_2}$$

Using the double layer parameters for the NaI–NaF system and assuming $\lambda = 0.1$, this coefficient is equal to 0.19 m^2 F^{-1} at $\phi^m - \phi^d = -0.2$ V, and 0.29 m^2 F^{-1} at $\phi^m - \phi^d = -0.3$ V. Thus, it increases with change in $\phi^m - \phi^d$ in the negative direction, and as a result, the observed change in the corrected rate constant also increases (Fig. 3). When the reaction site is closer to the electrode, λ is larger, and Ψ_d decreases, reflecting the fact that the screening of attractive interactions between the reactant and the adsorbed anions becomes more effective the closer the reaction site is to the electrode. It is also interesting to note that if g is greater than unity, as is true in the case of nitrate adsorption (16), Ψ_d is negative, and one should observe that the corrected rate of reaction y decreases with increase in σ_a at constant $\phi^m - \phi^d$. Under these circumstances, the local potential is somewhat more positive than the value given by eq. [5], and deceleration of the reduction of a cation would be observed with increase in adsorbed anionic charge density. If the discreteness-of-charge effect is ignored, then the difference between the average potential on the r.p., ϕ^r and that on the o.H.p. for reaction sites between the i.H.p. and o.H.p. is given by (2)

$$[8] \quad \phi^r - \phi^d = \lambda(\phi^m - \phi^d) + \frac{\lambda\sigma_a}{K_1}$$

where K_1 is the integral capacity of the region between the electrode and the i.H.p. The extent to which specific adsorption modifies this potential difference is given by

$$[9] \quad \Psi_a = \left[\frac{\partial(\phi^r - \phi^d)}{\partial\sigma_a}\right]_{\phi^m - \phi^d} = \frac{\lambda}{K_1}$$

Assuming $\lambda = 0.1$, Ψ_a is equal to 0.24 m^2 F^{-1} at $\phi^m - \phi^d = -0.2$ V, and 0.25 m^2 F^{-1} at −0.3 V. First of all, it is immediately apparent that the coefficients Ψ_a and Ψ_d are approximately equal at the most positive value of $\phi^m - \phi^d$, and that they are of the same order of magnitude for the chosen value of λ. This result is not surprising considering the fact that the discreteness-of-charge effect is not expected to play an important role when λ is small and the reaction site is close to the o.H.p. On the other hand, Ψ_a changes negligibly with $\phi^m - \phi^d$ so that one could not account for the observed variations in $dy/d\sigma_a$ (Fig. 3) on the basis of a model which ignored discreteness-of-charge. Furthermore, as the reaction site is moved closer to the electrode, Ψ_a increases whereas Ψ_d decreases. In addition, for a given reaction site in the inner layer, one should always observe acceleration of the reduction of a cation independent of the nature of the adsorbed anion. In conclusion, although the present data do not provide unequivocal evidence for the importance of discreteness-of-charge effects, they can be rationalized in all details on the basis of the discreteness-of-charge model.

Because of the relative simplicity of the double layer effect for the present system, it was possible to conclude that attractive interaction between the reactant and adsorbed anions do not constitute an important contribution to the observed acceleration of the reaction rate in the presence of iodide ions. This result is expected when shielding of the reactant from the adsorbed anions is strong, as predicted by the theory of discreteness-of-charge effects (2, 13–15). Furthermore, $Cr(NH_3)_5OH_2^{3+}$ has been shown by Anson (3) and Weaver (4) to be an outer sphere reactant (17), that is, a reactant which does not interact strongly with the electrode. It follows that the reaction site for $Cr(NH_3)_5OH_2^{3+}$ is expected to be further away from the electrode than the i.H.p., and on the basis of the evidence presented above, between the i.H.p. and o.H.p.

There has been considerable discussion in the literature (8, 18, 19) relating to the question of whether kinetic data can be used to demonstrate failure of the Gouy–Chapman–Stern model of the potential distribution in the double layer. There is no doubt that the diffuse layer model is seriously defective in solutions involving multivalent ions (20, 21). Calculations by Henderson and Blum (22) suggest that $d\phi^d/d\phi^m$ is somewhat less than the value predicted by Gouy–Chapman theory in 1–1 electrolytes when more realistic models are used for the diffuse layer. In this case, the estimate of α_a made above is low. It follows that one cannot use defects in the Gouy–Chapman model to argue that the reaction site is on the o.H.p. Furthermore, it should be kept in mind that the Gouy–Chapman model was used to obtain the adsorbed charge densities (6) employed in the analysis of the present kinetic data. In this sense, any systematic error in the values of σ_a will also be present in the kinetic analysis. If the increase in y with σ_a reported in Fig. 3 is attributed to an error in ϕ^d, then $|\phi^d|$ is underestimated by 10 mV for a change in y by one logarithmic unit. Given that $d\phi^d/d\sigma_a = 0.28$ m^2 F^{-1}, the corresponding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

error in the estimate of σ_a would be 0.036 C m^{-2}. It is difficult to imagine that σ_a would be in error by this amount especially considering the facts that the data were obtained at constant ionic strength, and that values of σ_a are being used for constant $\phi^m - \phi^d$. Thus, it is concluded that a better model of the diffuse layer would change the kinetic parameters but would not change qualitatively the conclusions made above regarding the nature of the double layer effect.

In conclusion, it would be interesting to examine the double layer effect for the present reactant or a related species in the presence of an adsorbed anion such as nitrate for which the screening parameter g is greater than one. Such an experiment would provide unequivocal evidence of the discreteness-of-charge effect. Experiments with this goal in mind are currently in progress.

Ab initio SCF + CI calculation of rotational energy barriers in CH_2—X—CH_2 species

F. VOLATRON

Laboratoire de Chimie Théorique (CNRS-UA 506), Bâtiment 490, Université de Paris-Sud, 91405 Orsay Cédex — France

Received October 19, 1983

F. VOLATRON. Can. J. Chem. **62**, 1502 (1984).

The rotational energy barriers in CH_2—X—CH_2 species (X = NH, O, CH_2) are calculated by means of *ab initio* SCF + CI calculations. With the most sophisticated CI calculations, they are found to be equal to 36.1, 20.6, and 1.1 kcal/mol for X = NH, O, and CH_2, respectively. These values are briefly discussed with respect to the valence bond analysis of the wave function.

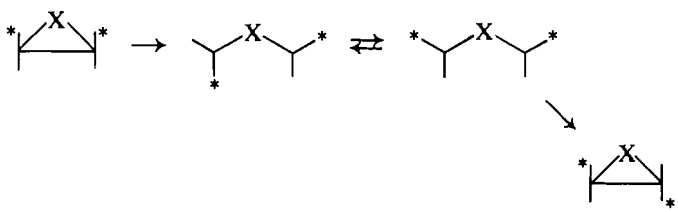
F. VOLATRON. Can. J. Chem. **62**, 1502 (1984).

Faisant appel à des calculs *ab initio* en champ autocohérent + CI, on a calculé les barrières d'énergie rotationnelle dans les espèces CH_2—X—CH_2 (X = NH, O, CH_2). Avec les calculs CI les plus sophistiqués, on trouve qu'elles sont égales à 36,1, 20,6 et 1,1 kcal/mol respectivement pour X = NH, O et CH_2. On discute brièvement de ces valeurs par rapport à l'analyse des liaisons de valence des fonctions d'ondes.

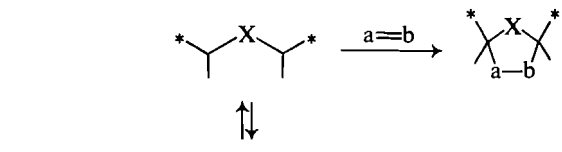
[Traduit par le journal]

Introduction

1,3-Dipoles of CH_2—X—CH_2 type (X = NH, O) are generated by ring opening of a three-membered ring (see ref. 1 for X = NH, ref. 2 for X = O). They are intermediates along the reaction path for the *cis–trans* isomerization reaction (3) (Scheme 1) and can be trapped by a dipolarophile (a = b) to give a five-membered cycloadduct (1, 2) (Scheme 2).



SCHEME 1. Reaction pathway for *cis–trans* isomerization of three-membered rings.



SCHEME 2. Formation of cycloadduct by trapping 1,3-dipole intermediate.

In the latter, if cycloaddition with a = b is fast relative to isomerization process, the stereochemistry of the cycloadduct reveals the initial opening mode of the three-membered ring (see ref. 4(*a*) for X = NH, ref. 4(*b*) for X = O). In both kinds of experiments, the rotation in the planar CH_2—X—CH_2 species is a crucial factor for mechanism analysis: (*i*) in the *cis–trans* isomerization, this step controls the formation of the reaction product; (*ii*) in reactions involving a dipolarophile, the rapid *cis–trans* isomerization of planar intermediate can lead to a loss of stereoselectivity in the final cycloadduct. Such a loss of stereoselectivity has been already observed in the case of substituted oxiranes (5) (X = O) and it could result from a rather low rotational energy barrier in the intermediate carbonyl ylide species (6).

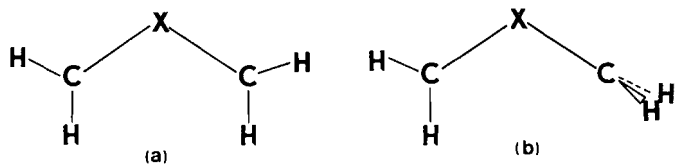


FIG. 1. Geometrical definition of EE and EF structures.

The aim of this paper is the study of barriers of rotation in such species (CH_2—X—CH_2 with X = O and X = NH) by means of *ab initio* calculations. In order to understand the role of increasing electronegativity of the central X atom, we also studied the extreme case in which X = CH_2, corresponding to the trimethylene diradical.

Two structures have been studied for each species: the edge-to-edge (EE) structure in which both CH_2 groups lie in the ∠CXC plane (Fig. 1*a*) and the edge-to-face (EF) structure in which a CH_2 group is orthogonal to that plane (Fig. 1*b*). The rotational energy barrier is assumed to be the energy difference between EE and EF structures.

Method of calculation

As shown in a previous paper (7*a*, for theoretical calculations on the photochemical properties of such intermediates, see ref. 7*b*), a proper description of both EE and EF structures needs an open shell SCF calculation followed, at least, by a (3 × 3) configuration interaction (CI) involving the three singlet configurations built from the two frontier molecular orbitals. These structures have been optimized at the STO3G (8) + (3 × 3) CI level with the GAUSSIAN 70 (9) program using the Nesbet (10) restricted hamiltonian for open shell systems. Then these optimized structures have been recomputed at the 4-31G (11) + extended CI level with the MONSTERGAUSS (12) program using the Davidson's (13) triplet open shell hamiltonian which ensures a more rapid convergence of the CI procedure. For extended CI calculations, we used the CIPSI (14) algorithm whose main features are the following: from SCF calculation, a few number of determinants are selected (*S*-space), the diagonalization of the associated hamiltonian matrix leading to the zeroth order wave function and energy. All the determinants built by single and double excitation from the determinants belonging to the *S*-space are treated by a second order perturbation leading to the calculation of the perturbation coefficient. If this coefficient is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

greater than an arbitrarily fixed threshold (τ), the corresponding determinant is included in the *S*-space. This iterative procedure is completed when all the perturbation coefficients are lower than the threshold. This process allows (*i*) a rigourous selection of the determinants belonging to the zeroth order multideterminantal wave function and (*ii*) to calculate by perturbation the contribution of other excited configurations to the correlation energy. We performed these CI calculations at three distinct levels: (*1*) *S* is limited to the determinants built from the frontier orbitals. Then diagonalization in *S*-space is equivalent to the (3 × 3) CI. This type of calculation will be referred as S_{min}; (*2*) the threshold (τ) is fixed at 0.03; and (*3*) the threshold (τ) is fixed at 0.02.

For each calculation, we report the variational diagonalization energy in the *S*-space, the total energy including perturbational contributions, and the norm (*N*) of perturbational correction of the variational zeroth order wave function.

Results

(A) Wave function analysis

(1) EF structure

The geometrical parameters for the three EF structures are depicted in Fig. 2.

• *Calculation with* S_{min}

For X = CH_2 and X = O, the optimized structures are symmetrical with respect to the ∠CXC plane. The two frontier orbitals — non-bonding *n* orbital carried by C_3 and π^*_{cx} orbital (7) — are orthogonal and the zeroth order wave function of the singlet ground state is described by the $^1n\pi^*$ configuration.

For X = NH, the situation is more complicated since geometrical optimization leads to an out-of-plane motion of the central hydrogen atom (H_N) which destroys the symmetry plane. Therefore, the zeroth order wave function of the singlet ground state is a mixing of the three singlet configurations built on the frontier orbitals:

$$\psi^0 = 0.760^1n\pi^* + 0.384\pi^{*2} - 0.525n^2$$

• *Extension of* S*-space*

The extension of the *S*-space has been performed as described above. We found no determinant with coefficient greater than 0.03. This shows that the configurations involved in the limited (3 × 3) CI are by far the most important for the description of EF structure. When lowering the threshold to 0.02, the *S* dimension grows to 7, 8 , and 10 for X = NH, O, and CH_2, respectively. The zeroth order wave function is only slightly perturbed by the new determinants (mainly representing correlation effects in the terminal methylene groups):

$$\psi^0_{NH} = 0.758^1n\pi^* + 0.383\pi^{*2} - 0.527n^2 + \ldots$$

$$\psi^0_{O} = 0.998^1n\pi^* + \ldots$$

$$\psi^0_{CH_2} = 0.998^1n\pi^* + \ldots$$

The accuracy of this zeroth order wave function can be tested by calculating the norm (*N*) of perturbation correction (Table 1). The values reported in Table 1 show that the norm of the perturbation correction is almost independent of the *S*-space dimension, thus confirming that the zeroth order wave function corresponding to S_{min} is already a rather good approximation of the total wave function.

(2) EE structure

Geometrical parameters for optimized EE structures are depicted in Fig. 3. Note that, for X = NH, the H_N atom lies in the CNC plane in order to allow an allyl-like resonance stabilization in the π system.

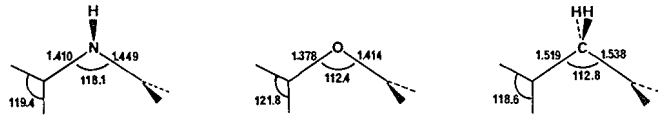

FIG. 2. Geometrical parameters for the three EF structures. The CH_2 groups are assumed trigonal. Out-of-plane bending of central hydrogen atom in CH_2—NH—CH_2 is 38.3°.

TABLE 1. Norm of perturbation correction (*N*) depending on the *S*-space dimension (EF structures)

	N		
X	S_{min}	τ = 0.03	τ = 0.02
NH	0.105	0.105	0.104
O	0.104	0.104	0.103
CH_2	0.098	0.098	0.098

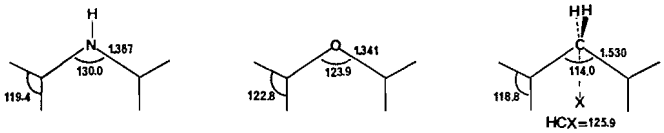

FIG. 3. Geometrical parameters for the three EE structures. The CH_2 groups are assumed trigonal.

• *Calculation with* S_{min}

Simple Hückel calculations on the π system of planar CH_2—X—CH_2 species show that an increasing electronegativity of the central group (X = NH, O, CH_2) leads to a reduction of the energy gap between the frontier molecular orbitals π_2 and π_3. Therefore, the energy gap between the ground configuration $[\pi_2^2]$ and the first doubly excited configuration $[\pi_3^2]$ being smaller, the mixing of these configurations should increase. This tendency is confirmed by the expression of the zeroth order wave functions:

$$\psi^0_{NH} = 0.914\pi_2^2 - 0.404\pi_3^2$$

$$\psi^0_{O} = 0.872\pi_2^2 - 0.489\pi_3^2$$

$$\psi^0_{CH_2} = 0.731\pi_2^2 - 0.683\pi_3^2$$

In the latter, one can note that the coefficients of π_2^2 and π_3^2 are almost equal because trimethylene species is almost a "pure" diradical with a singlet ground state wave function approximately given by (15):

$$\psi^0 = \frac{1}{\sqrt{2}}(\pi_2^2 - \pi_3^2)$$

• *Extension of* S*-space*

Consider first the EE structure for X = CH_2. As we have just seen, this structure can be mainly described by the diradical structure:

One electron is localized on each terminal carbon and a pair of electrons in the central π_{CH_2} orbital. The predominance of this valence bond structure can be interpreted by recognizing the

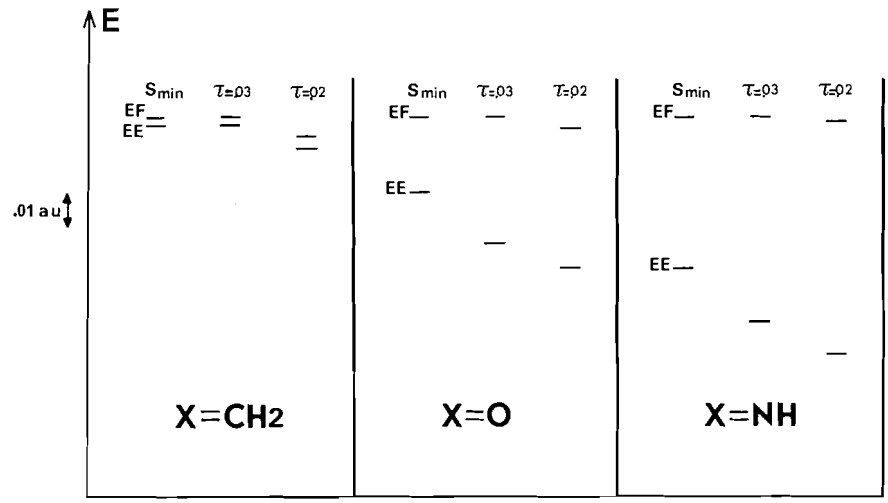

FIG. 4. Evolution of EE and EF energies with increasing S-space size. In each case, the energy of EF structure, calculated at the S_{min} CI level, is arbitrarily taken as origin. The absolute energies are −132.7780, −152.5644, and −116.8610 au for X = NH, O and CH_2, respectively.

large energy difference between the $2p$ and the π_{CH_2} orbitals.

In this description, the two unpaired electrons are rather well correlated by a CI limited to the S_{min} space. In other words, this electronic correlation problem is almost identical to a two electrons problem in which a (3 × 3) CI gives the proper correlation energy. Then, extension of the CI is only useful for correlating the two electrons localized in the π_{CH_2} orbital. Indeed, only eight determinants are needed in the S-space when the threshold is fixed to 0.02.

On the contrary, when X = NH, the central lone pair interacts more strongly with the carbon $2p$ orbitals and new valence bond structures contribute to the description of the ground state (16):

These structures represent the classical zwitterionic forms:

Now, an important part of the wave function localizes two electrons in the same $2p$ orbital of terminal carbon. So CI expansion is useful not only to correlate the two electrons in the central lone pair, but also to correlate the electron pair localized in the $2p$ orbital of terminal atoms. This is illustrated by an increase of S-space to 26 determinants when the threshold is 0.02. For X = O, we get an intermediate dimension of 20 determinants for S. In Table 2 are reported the norm of perturbation correction N computed for each type of calculation.

The results illustrate our preceeding discussion: for X = CH_2, the high diradical character ensures a rather good description even at a limited S-space dimension (N = 0.096). The increase of the CI size does not improve noticeably the accuracy of the wave function. On the contrary, for X = NH, the limited CI gives a more approximate wave function (N = 0.118), a result which can be notably improved (N = 0.104) by an increase of the S-space dimension. An intermediate result is found for X = O since the diradical character of carbonyl ylide is intermediate between those of azomethine ylide (X = NH) and trimethylene (X = CH_2) (17).

TABLE 2. Norm of perturbation correction (N) depending on the S-space dimension (EE structures)

	N		
X	S_{min}	τ = 0.03	τ = 0.02
NH	0.118	0.108	0.104
O	0.115	0.107	0.103
CH_2	0.096	0.096	0.095

TABLE 3. Calculated rotational barriers at various level of CI (perturbative terms are not taken into account)

	Barrier (kcal/mol)		
X	S_{min}	τ = 0.03	τ = 0.02
NH	24.9	33.8	38.3
O	12.7	20.7	23.3
CH_2	1.4	1.4	2.0

(B) Rotational energy barriers

(1) Variational zeroth order energy

In the preceeding section, it has been shown that EF structures are rather well described at the SCF + S_{min} CI level while EE structures are more sensitive to CI extension. As a consequence, an increase of the rotational barrier with the CI size is expected. Furthermore, the rotational energy barrier increase should be more and more important going from X = CH_2 to X = O and X = NH. Both these tendencies are confirmed by calculation of zeroth order energies with various sizes of S-space (Fig. 4). The computed energy barriers are reported in Table 3.

Although the results given by a limited CI (S_{min}) leads to an energy barrier order in agreement with that computed with more extended CI calculations, they are not very good from a quantitative point of view, since these values are at least 50% lower than the most sophisticated ones. Note that the increase of the barrier with the size of the CI has been already reported by Yamaguchi (18) on study of methylene peroxide CH_2OO.

TABLE 4. Rotational barriers taking into account the perturbation terms in correlation energy

X	Barrier (kcal/mol) S_{min}	$\tau = 0.03$	$\tau = 0.02$
NH	36.7	35.2	36.1
O	22.7	21.2	20.6
CH_2	1.0	1.0	1.1

(2) Influence of perturbation terms

In Table 4 are reported the rotational barriers taking into account the part of correlation energy computed by perturbation treatment.

First, one can note a small dependence of the computed rotational barrier with the various size of *S*-space, the maximum variation being 10%. Furthermore, the computed barriers are close to those found using the zeroth order energies at our highest level of CI.

Discussion

The calculated values are not directly comparable to experimental data only available for highly substituted species: for the (*exo,exo*)-1-cyano, 1,3-diphenylcarbonyl ylide HΦC—O—CΦCN, the rotational barrier is found in the range of 12−16 kcal/mol, and for the (*exo,exo*)-1,3-dimethyldicarboxylate

(N_4-methoxyphenyl) azomethine ylide (CHR—N—CHR with R = —$COOCH_3$) this barrier is 22.0 kcal/mol (1*c*). Computed energy barriers are systematically higher than the experimental ones. Note, however, that the ratio between theoretical (unsubstituted molecules) and experimental (substituted molecules) values is nearly 1.5 both for X = O (carbonyl ylide) and X = NH (azomethine ylide).

This trend shows the strong connection between rotational energy barrier and diradical character of the CH_2—X—CH_2 intermediate: as the weight of the diradical structure increase, the rotational energy barrier decreases. It can be related to the weakening of the π bonding between X and C, arising from the decreasing participation in the wave function of VB structures such as:

Going from X = NH to X = O and X = CH_2, the allyl-like resonance in the four π electron system decreases, making it easier to rotate around C—X bond.

Finally, our results show that calculations which include the perturbation terms lead to rather stable values for the energy barrier (Table 4) whatever the extension of *S*-space from S_{min}.

Examination of the molecular properties of D-fructose and L-sorbose by *ab initio* LCAO-MO calculations

WALTER A. SZAREK, SIRKKA-LIISA KORPPI-TOMMOLA, OLIVIER R. MARTIN, AND VEDENE H. SMITH, JR.
Carbohydrate Research Institute and Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received September 29, 1983

WALTER A. SZAREK, SIRKKA-LIISA KORPPI-TOMMOLA, OLIVIER R. MARTIN, and VEDENE H. SMITH, JR. Can. J. Chem. **62**, 1506 (1984).

Ab initio SCF LCAO-MO calculations at the STO-3G level have been performed on β-D-fructopyranose (**1**) and α-L-sorbopyranose (**2**) using crystallographic data as the geometrical input. Molecular properties of **1** and **2** are discussed in terms of orbital energies, total energy. ionization potentials, Mulliken population analysis, and electrostatic potentials, with a particular emphasis on the possible consequences of these features as regards the sweet taste of these two ketoses. No correlation was found, for example, with the electrostatic, point-charge distribution since the calculated hydrogen-bonding abilities would lead to the prediction of **2** being sweeter than **1**. On the other hand, non-bonded overlap populations between oxygen and hydroxyl-hydrogen atoms reveal the presence of intramolecular interactions, which may have a determinant influence on the taste of these molecules and which could explain why D-fructose is much sweeter than its epimer at C-5, namely, L-sorbose.

WALTER A. SZAREK, SIRKKA-LIISA KORPPI-TOMMOLA, OLIVIER R. MARTIN et VEDENE H. SMITH, JR. Can. J. Chem. **62**, 1506 (1984).

Des calculs *ab initio* d'orbitales moléculaires (SFC LCAO) ont été réalisés au niveau STO-3G pour le β-D-fructopyranose (**1**) et l'α-L-sorbopyranose (**2**) en utilisant les dimensions cristallographiques comme données géométriques. Les propriétés moléculaires des composés **1** et **2** telles que les énergies orbitalaires, l'énergie totale, les potentiels d'ionisation, l'analyse des populations de Mulliken, et les potentiels électrostatiques, sont discutées en mettant l'accent sur les conséquences possibles de ces caractéristiques sur la douceur de ces deux céto-sucres. Par exemple il n'existe pas de relation avec la distribution de charges électriques ponctuelles: prises comme mesure de l'aptitude à former des liaisons hydrogène, elles prédiraient en effet que **2** est plus doux que **1**. En revanche, les populations de recouvrement non-liant entre atomes d'oxygène et d'hydrogène de groupe hydroxyle révèlent la présence d'interactions intramoléculaires qui pourraient avoir une influence déterminante sur la saveur de ces composés, et expliquer pourquoi le D-fructose est beaucoup plus doux que son épimère en C-5, le L-sorbose.

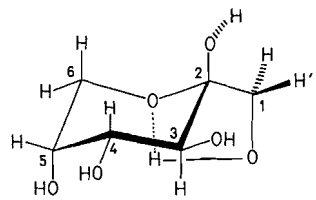
Introduction

As part of a study (1) of molecular properties of D-fructose and L-sorbose, having as the ultimate goal the determination of some effects responsible for the high sweet taste of D-fructose and for the surprizing difference of sweetness between these two ketoses, *ab initio* quantum mechanical calculations on β-D-fructopyranose (**1**) and α-L-sorbopyranose (**2**) have been performed, and we report and discuss, in this article, the results of these investigations in terms of orbital energies, ionization potentials, Mulliken population analysis, and electrostatic potentials.

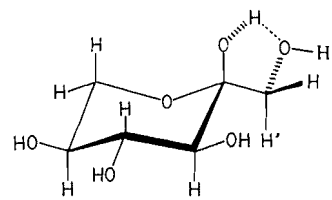
Very few studies have been reported in which *ab initio* calculations have been used to investigate structural features of an entire sugar molecule. In the course of their studies on the properties of the components of nucleic acids, Berthod and Pullman (2) performed *ab initio* computations on ribose using Clementi's minimal basis set (3) of Gaussian functions and crystallographic data as the geometrical input. The two anomers of D-glucopyranose as well as a disaccharide (β-maltose) have been studied by means of *ab initio* calculations at the minimal basis-set level by Rasmussen and co-workers (4); the molecular geometry used had been optimized by a purely classical method previously developed by them (empirical force-field method) (5).

Method

Owing to the large size (24 atoms, 96 electrons), on the scale of *ab initio* calculations, of D-fructose and L-sorbose, our study has been limited to only one conformer of each ketose in its pyranoid form. The conformers chosen are those found by neutron diffraction to be the preferred ones in the crystalline state: β-D-fructopyranose (**1**) in the $^2C_5$ (D) conformation with the CH_2OH group adopting a *gauche/gauche* orientation (6), and α-L-sorbopyranose (**2**) in the $^2C_5$ (L) conformation with the CH_2OH group in a *gauche/trans* disposition (7). The precise geometrical input was taken from crystallographic data (6–8). The torsion angles for α-L-sorbopyranose, which have not been reported, were evaluated using a BASIC computer program designed to calculate interatomic distances and bond angles as well as torsion angles from fractional atomic coordinates (9) (Table 1). Furthermore, the neutron diffraction study of **2** (7) revealed a very short (0.917 Å) bond length for the O-1—H bond, a result attributed to the increased thermal motion of the disordered CH_2OH group (0.625 *gauche/trans*, 0.375 *gauche/gauche* orientation). Because this artificially shortened bond length would affect the results of the Mulliken population analysis (10), the standard bond length (0.96 Å) was, therefore, adopted for the O-1—H bond of **2**.



1



2

The STO-3G minimal basis set (11) was used and the *ab initio* SCF-LCAO computations were peformed by means of the Gaussian 76 system of programs (12).

Results and discussion

Orbital energies

In order of increasing energy, the first six orbitals (from

[a]Calculated from fractional atomic coordinates of **2** (7); $H' = H_{pro\text{-}R}$.

−20.260 to −20.242 hartrees for **1**, −20.263 to −20.231 hartrees for **2**) of the 48 occupied molecular orbitals of each of **1** and **2** are almost pure 1*s* atomic orbitals of the oxygen atoms (contribution ~99.4%). The second set of six orbitals (−11.149 to −11.091 hartrees for **1**, −11.150 to −11.094 hartrees for **2**) is comprised of almost pure 1*s* atomic orbitals of carbon. The energy levels of the core orbitals are represented schematically in Fig. 1. The lowest-lying O(1*s*) orbital in **1** belongs to O-3 whereas in **2** it belongs to O-6; Rasmussen's calculations (4) on hexopyranoses have revealed that the lowest-lying O(1*s*) orbital is that of the ring oxygen and, in this respect, β-D-fructopyranose (**1**) seems to be an exception. In both **1** and **2**, the lowest-lying C(1*s*) orbital, which is the C(1*s*) orbital having the largest bonding energy, belongs to the anomeric carbon, C-2. The binding-energy difference ("chemical shift") between the binding-energy of the C-2 (1*s*) orbitals and the average of the other C(1*s*) orbitals is almost the same in **1** (1.35 eV) as in **2** (1.37 eV).

The following group of six orbitals, which are preponderantly constituted by 2*s* atomic orbitals of oxygen, extends in energy from −1.357 to −1.26 hartrees, and the final main group of 30 orbitals from −1.011 to −0.311 hartree for **1**, and from −1.004 to −0.306 hartree for **2**. Inspection of the Mulliken overlap population matrix reveals that the highest-occupied molecular orbital (HOMO) of both **1** and **2** has primary contributions from the lone pairs of the hydroxyl group at C-3 and of the ring oxygen atom (see Table 2). The energy of the lowest-unoccupied molecular orbital (LUMO) is 0.470 hartree for **1** and 0.480 hartree for **2**.

As shown in Table 2, the ionization potentials, calculated according to Koopmans' theorem (13) (vertical potentials), are ~8.4 eV for **1** and **2**. The only experimental values available for correlation are those measured for D-ribose (14); these values are somewhat larger than those calculated for **1** and **2**. However, it has been shown (15) that small basis sets, such as STO-3G, seem to underestimate the orbital energies and a correction of 1.85 eV is needed to match the results of larger basis-set calculations, and experimental values. If such a correction is applied to the orbital energies of **1** and **2**, the energies of the first and second HOMO (Table 2) fall in the same range as those observed for D-ribose.

Total energies and dipole moments

The total energy calculated for β-D-fructopyranose is −674.417 hartrees and for α-L-sorbopyranose −674.428 hartrees. The energy difference between the two molecules is 0.011 hartree (6.9 kcal/mol), α-L-sorbopyranose being the more stable. Thus, these *ab initio* values give an energy difference of the right sign. However, as determined from the conformational free energies (2.30 kcal/mol for the all-equatorial *sorbo* isomer, 2.85 kcal/mol for the *fructo* isomer) (16), the energy difference between the two ketoses which are epimeric at C-5 is expected to be of the order of 0.5 kcal/mol, a value equivalent to the energy contribution of a 1,3-*syn*-diaxial interaction present in β-D-fructopyranose. In view of the fact that *ab initio* energy differences constitute only a small fraction of the total energies, the qualitative agreement is noteworthy.

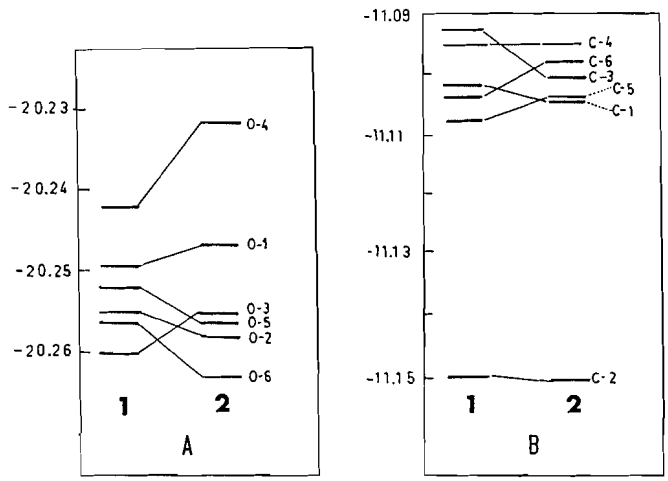

FIG. 1. Core energies (hartree) of **1** and **2**. (*A*) Almost pure O(1*s*) orbitals; (*B*) almost pure *C*(1*s*) orbitals.

The dipole moments have been calculated to be 2.03 and 3.03 debye units for **1** and **2**, respectively.

Mulliken population analysis

The net atomic charges (Q) derived by Mulliken population analysis for **1** and **2** are listed in Table 3.

As expected (4), the atoms can be separated into classes according to the elements to which they are bonded. Thus, the anomeric carbon atom carries the most positive charge, the methylene carbon atoms (C-1 and C-6) are almost neutral, and the methine carbon atoms bear an average charge of +0.059 e in **1** and +0.067 e in **2**. Correlation of the Q_C values with the experimental ^{13}C chemical shifts of **1** and **2** (Table 4) revealed

TABLE 2. Description of the HOMO's of **1** and **2** and ionization potentials

	Molecular orbital	Eigenvalue (hartree)	Ionization potential (eV)[a]	MO coefficients
1	ϵ_{48}	−0.311	8.46	−0.389 (O-3, $2p_y$) −0.358 (O-6, $2p_y$)
	ϵ_{47}	−0.327	8.90	−0.495 (O-6, $2p_x$) 0.395 (O-5, $2p_z$) 0.314 (O-3, $2p_z$) −0.302 (O-6, $2p_y$)
2	ϵ_{48}	−0.306	8.33	0.487 (O-3, $2p_x$) −0.424 (O-6, $2p_x$)
	ϵ_{47}	−0.322	8.76	−0.438 (O-4, $2p_z$) 0.430 (O-5, $2p_x$) −0.426 (O-6, $2p_x$)

[a]1 hartree = 27.210 eV.

a linear relationship; linear regression analysis of the data gave the following expression (correlation coefficient $r = 0.9917$):

[1] $Q_C = 0.0070\delta(^{13}C) - 0.4386$

This result is consistent with the statement (19) that *ab initio* STO-3G Mulliken charges can be used to calculate ^{13}C chemical shifts or vice versa, the linear relationship between these parameters being valid, however, only in sets of similar molecules. Equation [1] suggests a downfield shift with increasing positive character of carbon, a trend exhibited by situations in which both $2s$ and $2p$ populations vary, whereas typical sp^3 carbons follow the inverse trend (see ref. 19). Interestingly, the 1,3-*syn*-diaxial interaction between HO-5 and H-3, which is responsible for the upfield shift of C-3 in **1** with respect to the chemical shift of C-3 in **2**, is clearly reproduced by the present *ab initio* calculations: the C-3—H bond of **1** is polarized, as shown by the comparison of the atomic charges on C-3 (0.049 e) and H (C-3) (0.081 e) in **1** with the corresponding charges in **2** (0.066 and 0.050 e, respectively) in which the interaction is absent. This through-space interaction is also revealed by the Mulliken overlap population, $\zeta_{O\text{-}5,H(C\text{-}3)}$ (156.7 au for **1**, 0.0 for **2**).

Equation [1] was used to estimate the net atomic charges Q_C in 5-deoxy-β-D-*threo*-hexulopyranose (18), a close analog of **1** and **2** and a compound having great significance in a study of the sweetness of these sugars. The results are reported in Table 4. The change of charge density at C-5 on deoxygenation is 0.266 e toward a negative charge; this effect is slightly larger than that occasioned by deoxygenation at C-2 (β-D-arabinopyranose → 2-deoxy-β-D-*erythro*-pentopyranose) (0.158 e) as determined from CNDO/2 charges (20).

Using the net atomic charges at the oxygen and hydrogen atoms as a measure of their basicity and acidity, respectively, the following, decreasing sequence of acidities of the hydrogen atoms can be derived from the data in Table 3:

(**1**): H(O-4) > H(O-1) > H(O-3) = H(O-5) > H(O-2)

(**2**): H(O-4) > H(O-2) > H(O-1) > H(O-5) > H(O-3)

The basicities of the oxygen atoms decrease in the following order:

(**1**): O-4 > O-2 > O-5 > O-1 > O-3 > O-6

(**2**): O-4 > O-1 > O-2 > O-5 > O-3 > O-6

Thus, in both **1** and **2**, the hydroxyl group at C-4 seems to exhibit the highest values. In order to establish if this feature is merely a result of the short covalent-bond length of the O-4—H bond (0.948 Å in **1**, 0.941 Å in **2**), *ab initio* MO calculations at the STO-3G level using the Gaussian 80 system of programs (21) were performed on the same molecular conformations of **1** and **2** but with the standard bond length (0.96 Å) for all of the O—H bonds. The results are listed also in Table 3. The modified order of basicities of the oxygen atoms is the following:

(**1**): O-2 > O-4 > O-5 > O-1 > O-3 > O-6

(**2**): O-1 > O-4 > O-2 > O-5 > O-3 > O-6

The acidities of the hydroxyl groups are in the following sequence:

(**1**): H(O-1) > H(O-4) > H(O-3) = H(O-5) > H(O-2)

(**2**): H(O-2) > H(O-4) > H(O-1) > H(O-3) > H(O-5)

Thus, the hydroxyl group at C-4 retains its strong acidic and basic nature. However, the strongest hydrogen-bond donor in **1** is now the HO-1 group and the strongest hydrogen-bond acceptor the anomeric hydroxyl group; the weak acidity of the latter, usually considered to be the most acidic hydroxyl group in carbohydrate molecules, is noteworthy. In **2** the normal order is restored with the HO-2 group being the strongest hydrogen-bond donor and the HO-1 group the strongest hydrogen-bond acceptor. These results are in sharp contrast with the hydrogen-bonding abilities determined from the infrared and Raman spectra of **1** and **2** (22). In particular, the HO-4 group was shown to be involved in the weakest hydrogen bonds in crystalline **1** and **2**, and the HO-2 group to participate in the strongest hydrogen bonds in **1**. These discrepancies are attributable at least partly to the completely different conditions under which these properties were determined; the present theoretical calculations were performed on isolated molecules and took into consideration only intramolecular interactions, whereas intermolecular hydrogen bondings are the most important in the solid state.

According to Shallenberger's theory (23), sweet taste is thought to occur through hydrogen bonding between a topologically well-defined AH,B site on the sweet molecule and a complementary B,AH site on the receptor of the tongue, and the intensity of the sweetness response depends on the strength of such bonding. The principal saporous unit of β-D-fructopyranose has been assigned (24) to the HO-2 (AH) and HO-1 (B) groups. On the basis of the relative hydrogen bonding abilities of HO-1 and 2 of **1** and **2**, our theoretical investigations would lead to the prediction that L-sorbose is sweeter than D-fructose. This result is in obvious disagreement with the actual taste experience (sweetness ratio **1**/**2**: 64 (25), 115 (26)), and shows that the sweetness of D-fructose is not related primarily to the electronic point-charge distribution in the molecule.

In the present study, Mulliken population analysis was used to gain some theoretical information on the existence of intramolecular hydrogen bonding in **1** and **2**. The non-bonded overlap populations between oxygen and hydroxyl-hydrogen atoms, $\zeta_{O,H}$ (see Table 5), thus reveal that the only intramolecular interaction in **1** is a hydrogen bond between the ring oxygen (O-6) and the HO-1 proton (see structures **1** and **2**); this interaction has been shown by neutron diffraction analysis (6) to be present in the crystalline state. The absence of a hydrogen

[a]Data from Gaussian 80 calculations using the stardard OH bond length.

bond between the axial HO-5 group and O-6, once invoked (27) to be responsible for the high sweet taste of D-fructose and later shown (18) to be irrelevant by studies on "5-deoxyfructose" (5-deoxy-D-*threo*-hexulose), is noteworthy. In **2**, the main hydrogen bond occurs between O-1 and the anomeric hydroxyl proton (HO-2). As anticipated, the overlap populations are much smaller than those involved in covalent bonding (for example, $\zeta_{O\text{-}1,H} = 0.262$ in **1**).

As the Raman spectroscopic studies (28) of aqueous solutions of D-fructose as well as the recent study (29) of Bock and Lemieux on the molecular conformation of sucrose in dimethylsulfoxide appear to indicate, intramolecular hydrogen bonds present in the crystalline state of a sugar exist also in solution; these interactions might have a profound influence on the taste of **1** and **2**. Thus, the rotation of the hydroxymethyl group in **1** is inhibited by the O-6 . . . H(O-1) hydrogen bond, and the anomeric hydroxyl as well as O-1 are free to interact with the sweet taste receptor. On the other hand, the corresponding sites are internally hydrogen bonded in **2**, with HO-2 acting as a hydrogen donor; this interaction might prevent efficient binding of **2** with the receptor and might be one of the reasons why L-sorbose is much less sweet than D-fructose.

Molecular electrostatic potentials

The molecular electrostatic potentials around the oxygen atoms of **1** and **2** were calculated from the present STO-3G wave functions (from Gaussian 76 calculations) by the method of Peeters and Sana (30); maps of the potentials around O-1 and O-2 of **1** and **2** are shown in Fig. 2. Noteworthy is the crowded potential around O-1 of **2**, a feature attributable to the existence of a hydrogen bond between this atom and H(O-2). In the case of **1**, however, the map shows the regular isopotential contours around the O-1 nucleus. The calculated potentials (Table 6) are generally stronger in **2** than in **1**, and the order of minima follows the following sequence:

(**1**): O-4 > O-2 > O-3 > O-1 > O-5 > O-6

(**2**): O-4 > O-3 > O-2 > O-1 > O-5 > O-6

This order would correspond to an order of reactivity of the oxygen atoms toward an electrophilic reagent, and, for example, the O-4 atom would be predicted to be the most attractive site for protonation in both molecules. However, a lack of experimental data prevents any correlation with the actual reactivities of the hydroxyl groups of the keto-hexopyranoses.

Conclusion

The work described in this article represents the first attempt

to correlate results of quantum mechanical calculations on carbohydrate molecules with their sweetness. The *ab initio* study of β-D-fructopyranose (**1**) and its epimer at C-5, α-L-sorbopyranose (**2**), does not reveal any prominent difference in the electronic properties of the atoms presumed to be involved in their saporous unit, which might be related to the high sweet taste of **1** and the markedly lower sweetness of **2**. However, Mulliken population analysis suggests some intramolecular interactions, such as hydrogen bonding between HO-1 and O-6 in **1**, and between HO-2 and O-1 in **2**, which might play an important role as regards the taste of these molecules.

Interestingly, the HO-4 function seems to be the most reactive of the secondary hydroxyl groups of **1** and **2**, a finding, the experimental confirmation of which, would be a worthy undertaking.

Raman and infrared spectra of polycrystalline samples of four structurally related sugars, namely D-fructose, L-sorbose, 5-deoxy-D-*threo*-hexulose (5-deoxy-D-fructose), and D-arabinose are reported. Three regions of the spectrum have been studied: the OH stretching region 3650–3100 cm^{-1}, the CH stretching region 3000–2800 cm^{-1}, and the "fingerprint" region 1600–200 cm^{-1}. Raman spectra in the region 200–10 cm^{-1} have also been recorded. Bands in the OH stretching region have been correlated with the O—H . . . O distances obtained from recent neutron diffraction studies. The results are discussed in relation to hydrogen bonding and relative sweetness of these sugars.

Detailed assignments are given for the bands in the CH stretching region, and it is shown that the spectra are very sensitive to small structural changes in the molecule. Spectra are presented for the "fingerprint" region and some characteristic "group" frequencies are noted for ketohexoses and aldopentoses.

WALTER A. SZAREK, SIRKKA-LIISA KORPPI-TOMMOLA, HERBERT F. SHURVELL, VEDENE H. SMITH, JR. et OLIVIER R. MARTIN. Can. J. Chem. **62**, 1512 (1984).

Nous rapportons les spectres Raman et infrarouge d'échantillons polycristallins de quatre sucres de structure apparentée, le D-fructose, le L-sorbose, le désoxy-5-D-*threo*-hexulose et le D-arabinose. Trois régions du spectre ont été étudiées: la région du stretching OH, 3650–3100 cm^{-1}, la région du stretching CH, 3000–2800 cm^{-1}, et la région du "fingerprint", 1600–200 cm^{-1}. Les spectres Raman ont également été enregistrés dans la région 200–10 cm^{-1}. Les bandes dans la région du stretching OH ont été mises en corrélation avec les distances O—H . . . O tirées d'études récentes par diffraction de neutrons. Les résultats sont discutés en rapport avec les liaisons hydrogène et la douceur relative de ces sucres.

Nous donnons les attributions détaillées des bandes de la région du stretching CH, et montrons que les spectres sont très sensibles à des changements de structure mineurs dans la molécule. La région du "fingerprint" des spectres est représentée et quelques fréquences caractéristiques de "groupes" sont relevées pour les cétohexoses et les aldopentoses.

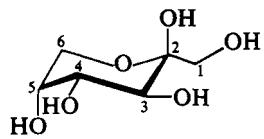
Introduction

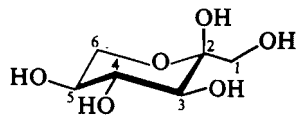
The objective of the present work was to study the relationship between the vibrational spectra and the structures of four sugars, namely D-fructose, L-sorbose, 5-deoxy-D-*threo*-hexulose (5-deoxy-D-fructose), and D-arabinose, in order to evaluate some aspects of the current theories of the origin of sweetness of sugars.

D-Fructose (**I**) is a well-known member of the family of ketoses. It occurs widely in nature and is known to be the sweetest of the naturally occurring sugars. Shallenberger's hypothesis (1) of sweetness suggests that it is induced by the existence of a suitable AH,B system, where A and B are each electronegative atoms in a particular geometric disposition and H is an acidic proton. According to this model, a molecule exhibits sweet taste by hydrogen bonding with the complementary AH,B system on the receptor site.

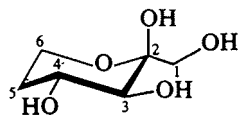
The only isomer of D-fructose isolated so far in crystalline form is β-D-fructopyranose. It has been suggested (2) that the unit giving rise to sweetness is the anomeric hydroxyl group (the AH moiety) and O-1 (the B moiety); this proposal is supported by the lower degree of sweetness of β-D-arabinopyranose (**IV**) and of 2,6-anhydro-D-mannitol, two structural analogs of β-D-fructopyranose (**I**) which lack the hydroxymethyl and the 2-hydroxyl group, respectively. Surprizingly, the epimer at C-5 of **I**, namely α-L-sorbopyranose (**II**), which contains the same AH,B unit, was found (3) to exhibit a markedly lower sweetness than **I** (sweetness order: **I** > **IV** > **II**), a result which suggested that the hydroxyl group at C-5 in these molecules might play an important role in their sweetness. However, this possibility was found (4) not to be the case in our separate study involving 5-deoxy-D-*threo*-hexulose



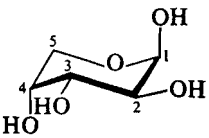
D-Fructose
(**I**)



L-Sorbose
(**II**)



5-Deoxy-D-*threo*-hexulose
(**III**)



D-Arabinose
(**IV**)

(**III**). Compound **III** was shown to be nearly as sweet as β-D-fructopyranose.

It has been suggested (3) that differences in intensity of sweetness amongst sugars can be attributed to differences in the nature of the hydrogen bonding of the molecules. Information on hydrogen bonding can be obtained from the positions and widths of OH stretching bands in the vibrational spectra. These bands have been studied, therefore, in the infrared and Raman spectra of D-fructose, L-sorbose, 5-deoxy-D-*threo*-hexulose, and D-arabinose. Recently, O—H . . . O distances in **I**, **II**, and **IV** have been obtained from neutron diffraction studies (5–9), and the existence of possible correlations between the OH stretching frequencies and the O—H . . . O distances in these molecules has been examined.

Two other regions of the vibrational spectra should provide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

structural information on sugar molecules. The CH stretching modes of the various methylene and methine groups in the molecules are expected to give bands between 3000 and 2800 cm^{-1}, and the "fingerprint" region between 1600 and 300 cm^{-1} often contains characteristic group frequencies. These two regions of the spectra of **I–IV** have been examined also in the present work.

Raman spectra of aqueous solutions of D-fructose have been reported recently (10–12). Several publications have reported (13–23) infrared spectra of various monosaccharides, and a complete normal coordinate calculation has been performed for α- and β-D-glucose (24, 25). However, the relationship between the frequencies of stretching modes of hydrogen-bonded OH groups and the O—H . . . O distances has not been studied previously for D-fructose, L-sorbose, and D-arabinose. Also, we are not aware of any detailed assignments of bands in the CH stretching region of these molecules.

Experimental

Commercial samples of D-fructose, L-sorbose, and D-arabinose were recrystallized from water–methanol. The sample of 5-deoxy-β-D-*threo*-hexulose was synthesized in this laboratory previously (4).

Infrared spectra were recorded on Perkin-Elmer models 598 and 180 spectrophotometers. The spectra were recorded from KBr pellets. Frequencies in the region 4000–3100 cm^{-1} are believed to be correct to within ±10 cm^{-1} in those cases where the bands are very broad. Wavenumbers of the sharp bands in the region 4000–2800 cm^{-1} are believed to be correct to within ±2 cm^{-1}.

Room-temperature Raman spectra were recorded on a Jarrell-Ash 25-305 spectrophotometer. To obtain Raman spectra at reduced temperatures the powdered polycrystalline samples were tamped into a small hole in a copper finger attached to a liquid nitrogen-cooled low-temperature cell; these spectra were recorded using a Jarrell-Ash 25-100 monochromator and a photon counting system. The spectra were excited by the 514.5 nm line of Spectra-Physics model 164 argon ion lasers operating at powers between 200 and 600 mW. The instruments were calibrated using atomic emission lines from neon lamps; wavenumbers reported are believed to be accurate to within ±5 cm^{-1} above 3100 cm^{-1}, and ±1 cm^{-1} in the regions from 3100 cm^{-1} to 2700 cm^{-1} and from 1600 cm^{-1} to 10 cm^{-1}.

Results and discussion

The molecules **I–IV** are structurally close analogs, which exist preponderantly in the $^2C_5$ (or $^1C_4$) conformation. The Raman and infrared spectra were obtained from these molecules in their crystalline state. The crystallographic parameters were obtained for **I** and **II** from neutron diffraction studies (5, 6), and for **IV** from an X-ray investigation (7) performed on β-DL-arabinopyranose and from neutron diffraction studies (8, 9) performed on β-L-arabinopyranose. The X-ray study (7) revealed that both *arabino* enantiomers adopt the same hydrogen-bond structure in the crystal lattice.

Figure 1 shows Raman and infrared spectra in the OH stretching region of **I–IV**. The Raman bands are all very weak in this region, but serve to confirm the positions of many features of the strong infrared bands. Figure 2 shows the Raman and infrared spectra in the CH stretching region. In this case the Raman lines are strong and sharp. Figure 3 shows the "fingerprint" and the very low frequency region (1600–10 cm^{-1}) of the Raman spectra of **I–IV**. The three regions of the vibrational spectra are discussed separately.

The OH stretching region

β-D-*Fructopyranose (I)*

The hydrogen-bond structure of **I**, with the bonds being

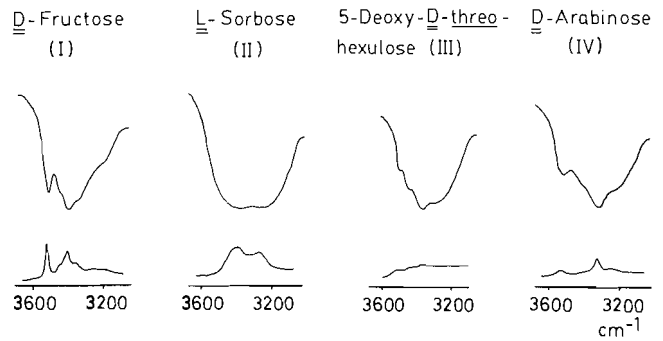


FIG. 1. Raman (lower trace) and infrared (upper trace) spectra in the OH stretching region of **I–IV** recorded at room temperature.

classified according to Jeffrey and Takagi's (26) statistical analysis, as well as the assignments of the OH stretching frequencies, are reported in Table 1. As shown by the crystallographic analysis of **I** (5), the anomeric HO-2 group is bound in an infinite chain with a very short hydrogen bond of length 1.750 Å, a value which indicates strong hydrogen bonding. The HO-1 and HO-3 groups act both as donors and acceptors in the infinite-chain structure, their hydrogen-bond lengths being, however, longer (1.965 and 1.977 Å, respectively) than that of HO-2; in addition, each of these hydroxyl groups participates in an asymmetric, bifurcated hydrogen-bond system (26) involving the ring oxygen atom, a type of interaction which has been shown (27) to be energetically comparable to, or even more favorable (by 1–2 kcal/mol) than, a normal, linear hydrogen bond. The HO-5 group is part of the infinite-chain structure and, being both a donor and an acceptor, forms strong hydrogen bonds. However, these bonds are not as strong as those formed by HO-2 (on the basis of hydrogen-bond lengths), or by HO-1 and HO-3, which are involved in bifurcated bonding. Finally, the HO-4 group belongs to the class of finite-chain, donor-type only, hydroxyls, which were shown (26) to form weaker hydrogen bonds.

On the basis of these evaluations, the following decreasing order of strengths of the hydrogen bonds formed by the hydroxyl groups in **I** can be proposed.

HO-2 > HO-1 > HO-3 > HO-5 > HO-4

Frequencies in the Raman and infrared spectra have been

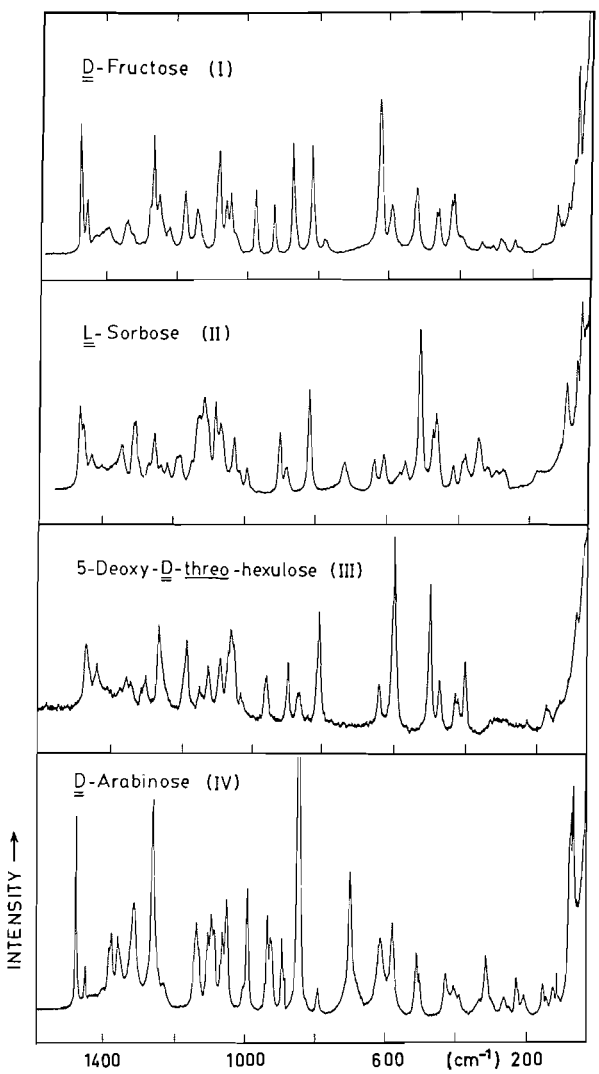

FIG. 3. Partial Raman spectra of **I**–**IV**.

assigned on the basis of the tenet that the strongest hydrogen bonding gives rise to the lowest frequency OH stretching mode. The Raman frequencies of Table 1 were obtained from spectra recorded at 77 K. Bands are often sharper and better resolved at low temperature; in the present case the broad band observed at 3415 cm^{-1} in the room-temperature spectrum of **I** (see Fig. 1) is observed as a triplet having maxima at 3395, 3365, and 3305 cm^{-1} in the low-temperature spectrum. These bands are all shifted to lower frequencies at 77 K. This shift is a characteristic feature of hydrogen-bonded hydroxyl groups (18–21).

According to the order of hydrogen-bonding strengths of the hydroxyl groups, the four bands observed in the low-temperature Raman spectrum of **I** are assigned as follows: the sharp band at 3500 cm^{-1} (3525 cm^{-1} at room temperature) to the weakly bound O-4—H, the band at 3395 cm^{-1} (3415 cm^{-1} at room temperature) to O-5—H, and the bands at 3365 cm^{-1} and at 3305 cm^{-1} to O-3—H and O-1—H, respectively, both being involved in bifurcated bonding. It is proposed that the low-frequency infrared shoulder at 3190 cm^{-1} arises from the ν(OH) mode of the strongly hydrogen-bonded HO-2 group.

α-L-*Sorbopyranose (II)*

The classification of the hydroxyl groups in **II** is presented in Table 1, together with the assignments of the OH stretching bands.

According to crystallographic data (6), the HO-2 and HO-5 groups of **II** form an infinite-chain system of hydrogen bonding and are thus strongly bonded, with distances of 1.882 Å (O-2—H . . . O-5) and 1.953 Å (O-5—H . . . O-2). The rather long distance between O-5—H and O-2 is attributable to the fact that O-5—H is participating also in a weak interaction with O-3 (2.582 Å); the hydrogen-bonding pattern of HO-5 is an example of an asymmetric, bifurcated interaction (26) with distances being close to the average experimental values (1.95 and 2.50 Å). The HO-3 group is involved in a complex hydrogen-bond structure; in addition to having a very short (1.746 Å) and strong bond to O-4, this group serves also as a double acceptor of the O-1—H and O-5—H hydroxyls. The HO-1 in both of the possible conformers of the hydroxymethyl

TABLE 2. Correlation of the ν(OH) frequencies of **I**, **II**, and **IV** with the O—H and H . . . O bond lengths

Compound	ν(OH) (cm^{-1})	O—H (Å)	H . . . O (Å)	Comments
I	(3170)[a]	0.979	1.750	Long O—H
II	3180	0.974	1.746	short H . . . O
IV	(3210)[a]	0.979	1.735	distances
II	3272	0.969	1.882	
II	3272	0.962	1.953[c]	Intermediate
IV	(3300)[a]	0.974	1.801	O—H and
I	3305	0.972	1.965[c]	H . . . O
II	3360	0.917[b]	1.867	distances
II	3360	0.932[b]	2.151[c]	
I	3365	0.964	1.977[c]	
I	3395	0.963	1.964	
IV	(3380)[a]	0.952	1.820	
II	3420	0.941	1.932	Short O—H
I	3500	0.948	2.065	long H . . . O
IV	3535	0.920	2.201	distances

[a] Low-temperature frequency estimated from observed, room-temperature Raman frequency.
[b] Shortened because of increased thermal motion (5).
[c] Lengthened because of the bifurcated bond (27).

group is at the origin of a finite-chain structure. In the *gauche/trans* conformer (62.5%), the O-1A—H hydroxyl acts as a donor only with a medium-strong bond to O-3 of length 1.867 Å. In the *gauche/gauche* conformer, the O-1B—H group forms a symmetrical, bifurcated hydrogen bond with O-3 and O-4 in which the H . . . O distances (2.151 Å to O-3, 2.209 Å to O-4) are very close to the optimal value of 2.2 Å (26). As in the case of the asymmetric type, this type of bonding was found (27) to be at least as stable as a normal, linear bond. Thus, the hydrogen-bonding ability of the HO-1 group can be considered to be independent of the conformation of the hydroxymethyl group. The HO-4 group can be classified in the group of the finite-chain, medium strongly bonding hydroxyls.

The above discussion suggests the following order of hydrogen-bonding capacity of the hydroxyl groups in **II**.

HO-3 > HO-2 > HO-5 > HO-1 > HO-4

In the room-temperature Raman and infrared spectra of **II** (see Fig. 1), broad bands having two maxima at 3410 cm^{-1} and 3260 cm^{-1} are observed. At 77 K the Raman spectrum shows four distinct bands having frequencies 3420, 3360, 3272, and 3180 cm^{-1}. The following assignments are suggested for these frequencies. The band at 3180 cm^{-1} arises from the O-3—H mode. The absorption at 3272 cm^{-1} is attributable to both O-2—H and O-5—H modes. The band at 3360 cm^{-1} is attributable to the O-1—H mode and that at 3420 cm^{-1} to the stretching mode of the HO-4 group.

5-Deoxy-β-D-threo-*hexulopyranose (III)*

Because no crystallographic data are available for this molecule, its O—H stretching frequencies are discussed in relation to the assignments made for **I**, **II**, and **IV**.

The room temperature Raman spectrum of **III** (see Fig. 1) showed very weak features, and no frequencies could be obtained. In contrast, four bands were observed in the room temperature infrared spectrum; these are a medium–strong shoulder at 3500 cm^{-1}, a shoulder at 3440 cm^{-1}, a band at 3360 cm^{-1}, which is the strongest feature of the spectrum, and a broad band centered at 3250 cm^{-1}. On the basis of the data of Table 2, two of the four hydroxyl groups of **III** would be expected to exhibit very short O—H bond lengths and to form hydrogen bonds of long distances. Moreover, these hydroxyls are probably of the donor-type only, and are linked to the finite-chain system or form a single link. The bands at 3500 cm^{-1} and 3440 cm^{-1} are attributed to these two hydroxyls. The band at 3360 cm^{-1} suggests the presence of a hydroxyl group which is medium-strongly bonded in a hydrogen-bonding network and which has an O—H bond of average length; this hydroxyl may be part of the infinite-chain structure and would belong to the class of donor–acceptor hydroxyls. Finally, **III** exhibits a strongly bonded hydroxyl similar to O-2—H in **I**, O-3—H in **II**, and O-2—H in **IV** (for detailed parameters, see Table 1); the band at 3250 cm^{-1} is attributed to this hydroxyl.

β-D-*Arabinopyranose (IV)*

This molecule has only four distinct hydrogen bonds and exhibits no secondary interaction such as the bifurcated bonding observed in the crystal structures of **I** and **II**. Therefore, its OH stretching region should be particularly amenable to analysis using the relationship between the OH stretching frequencies and the hydrogen-bond strengths. Table 1 lists the hydroxyl groups of **IV** in increasing order of hydrogen-bond lengths.

The room-temperature spectra in the OH stretching region of D-arabinose are shown in Fig. 1. The observed bands were assigned according to the hydrogen-bond lengths of the OH groups as follows: the band at 3230 cm^{-1} to the most strongly bonded hydroxyl, O-2—H, the band at 3320 cm^{-1} to O-3—H, the band at 3400 cm^{-1} to the anomeric hydroxyl, and the high frequency band at 3535 cm^{-1} to the weakly bound O-4—H. These assignments are included in Table 1.

Correlation of the ν(OH) frequencies with crystallographic data

Table 2 lists the ν(OH) frequencies observed in the low-temperature Raman spectra of **I** and **II**, and the low-temperature Raman frequencies for **IV** estimated from observed room-temperature frequencies. The corresponding O—H and H . . . O bond lengths are included in this table. It should be noted that low-temperature frequencies are approximately 20 cm^{-1} lower than those obtained from room-temperature spectra. Inspection of bond lengths and frequencies reveals two regions in which the observed frequencies clearly show an inverse correlation with the O—H bond lengths and a direct correlation with the H . . . O bond lengths.

In the region below 3250 cm^{-1} appear the bands of those hydroxyls which clearly have longer than average O—H bond lengths (0.968 Å in carbohydrates, see ref. 8) and a very short hydrogen-bond length (average value for **I**, **II**, and **IV**, 1.745 Å). In the region above 3400 cm^{-1} are the bands of those hydroxyls having O—H distances considerably shorter than the average, and having very long H . . . O bond lengths (~2.0 Å). In the middle-frequency region, 3400–3250 cm^{-1}, there is a wider distribution of the values for both the covalent- and hydrogen-bond lengths.

Correlation of OH stretching modes with sweetness

In previous studies (3, 28) a high-frequency band, which appears in the infrared spectra of some sugar molecules, has been empirically correlated to their sweetness. This band was observed in the present study at 3525 cm^{-1} for **I**, at 3535 cm^{-1} for **IV**, and at 3500 cm^{-1} for **III**. The frequencies were obtained from the room-temperature Raman spectra. The corresponding band was not observed for **II**. In the case of **I**, the

band was assigned to stretching of the weakly bonded HO-4 group, and, in **IV**, to HO-4 (which corresponds to HO-5 in a ketohexose). In the case of **II**, the HO-4 group was also found to be the most weakly bonded hydroxyl, but its band appeared at a lower frequency, namely, 3420 cm^{-1}. The HO-4 group of ketohexoses has not been correlated with the sweetness of these sugars, and it is suggested that the high-frequency band is merely a result of the molecular parameters, such as O—H bond lengths and hydrogen-bond structure, that a particular molecule exhibits.

Since the interaction with the receptor site occurs presumably through hydrogen bonding, those hydroxyls which are strong hydrogen-bond donors and which have their ν(OH) bands at low frequencies might be expected to be of particular relevance. In **I**, such a hydroxyl is the anomeric HO-2 group, which has been identified as the proton-donor moiety of the AH,B saporous unit, while in **II**, such a hydroxyl is the HO-3 hydroxyl. The stretching frequencies of these two hydroxyls are at 3200 cm^{-1} and below. The anomeric hydroxyl of **II** thus would appear to exhibit a weaker hydrogen-bonding capacity than does the anomeric hydroxyl of **I**, a feature which may be of significance in the fact that **II** is considerably less sweet than **I**.

The CH stretching region

The room-temperature Raman and infrared spectra of **I**–**IV** in the region 3100–2800 cm^{-1} are shown in Fig. 2.

Compounds **I** and **II** both have seven fundamental CH stretching modes, while **IV** has six, and **III** eight. However, because of the inherent width of some lines and the consequent overlap, not all of these CH stretching fundamentals are observed in the spectra recorded at room temperature. In contrast, in the low-temperature Raman spectra, seven lines are observed for each of **I** and **II** and six for **IV**. The observed frequencies and assignments are listed in Table 3 for these three molecules. Assignments for **III** are given in Table 4 and are discussed separately. It should be mentioned that some of the weaker bands in the spectra in the CH stretching region might possibly be due to overtones or combinations of CH_2 deformation modes in Fermi resonance with CH stretching modes.

There are some striking differences in the spectra of **III** compared to those of the other three molecules. Firstly, the high-frequency bands at ~3000 cm^{-1}, which are present in the spectra of the latter compounds, are not observed in the spectra of **III**. Secondly, the CH stretching bands of **III** seem to be broader and more overlapped than those of the other three sugars. Therefore, it was decided to compare the CH stretching frequencies of **I**, **II**, and **IV**, and, on the basis of proposed assignments, to analyze then the CH stretching fundamentals of **III**.

The major difference in the spectra of **I** and **II** compared to that of **IV** is that the two bands at 3014 cm^{-1} and 2895 cm^{-1} in **I**, and at 3006 cm^{-1} and 2899 cm^{-1} in **II**, are not present in the spectrum of **IV**. This feature is attributable to the difference in the molecular structure at the anomeric centre: **I** and **II** each have a hydroxymethyl group at the anomeric carbon, whereas in **IV**, this group is replaced by a hydrogen atom. Thus, it appears that the two bands arise from the two CH stretching modes of the hydroxymethyl group. The band at 3014 cm^{-1} in **I** (3006 cm^{-1} in **II**) is assigned to the antisymmetric $\nu_a(CH_2)$ mode, and the band at 2895 cm^{-1} in **I** (2899 cm^{-1} in **II**) to the symmetric $\nu_s(CH_2)$ mode. In the case of ethanol, the antisymmetric and symmetric CH_2 stretching modes of the hydroxymethyl group are observed at 2953 cm^{-1} and at 2900 cm^{-1}, respectively (29).

The three molecules **I**, **II**, and **IV** each have a ring-methylene group in a similar molecular environment. Thus, it is expected that the bands of the two CH stretching modes arising from this group should appear at approximately the same frequencies. Each of these compounds exhibits a high-frequency band having medium-strong intensity. The frequencies of these bands are the following: 2987 cm^{-1} for **I**, 2988 cm^{-1} for **II**, and 3000 cm^{-1} for **IV**. On the basis of the present assignment of the $\nu_a(CH_2)$ mode of the hydroxymethyl group, each of these bands is identified as an antisymmetric CH_2 stretching mode of the ring-methylene group. The corresponding symmetric $\nu_s(CH_2)$ modes are observed at 2936 cm^{-1} for **I**, 2935 cm^{-1} for **II**, and 2938 cm^{-1} for **IV**. The frequencies of these ring-methylene stretching modes are higher than those observed for related compounds, namely, 1,4-dioxane (30) and simple tetrahydropyran derivatives (31). Also, the present as-

signment is not in agreement with that of Mathlouthi and Luu (10), who assigned a band at 2988 cm^{-1} to the ν(CH) mode of a methine group and bands at 2946 and 2908 cm^{-1} to $\nu_a(CH_2)$ and $\nu_s(CH_2)$, respectively. However, it is felt that the present assignment is reasonable on the basis of the total assignment of the CH stretching modes of the three molecules.

A medium-strong band which appears at 2967 cm^{-1} in the spectrum of **IV** is not present in the spectra of **I** and **II**. This band is identified as the anomeric ν(CH) mode. As noted above, in the cases of **I** and **II**, the anomeric CH group is replaced by the hydroxymethyl group.

There are three more bands to identify, namely, those arising from the stretching vibrations of the methine groups, at C-3, C-4, and C-5 in **I** and **II**, or at C-2, C-3, and C-4 in **IV**. Compounds **I** and **IV** each have two axial hydrogen atoms and one equatorial hydrogen atom at these respective positions, whereas compound **II** has the hydrogens at C-3, C-4, and C-5 in the axial orientation. The Raman bands which arise from these methine groups are believed to be the following: in **I**, 2962 cm^{-1} (medium-strong), 2956 cm^{-1} (sharp shoulder), and 2918 cm^{-1} (medium-strong); in **IV**, 2961 cm^{-1} (shoulder), 2957 cm^{-1} (medium-strong), and 2930 cm^{-1} (weak shoulder on the intense band at 2938 cm^{-1}); in **II**, 2961 cm^{-1} (medium-strong), 2948 cm^{-1} and 2917 cm^{-1} (shoulders on the intense band at 2936 cm^{-1}). Assignments of these bands have been made on the basis of the similarities or differences in molecular environment.

The relative intensities of these three methine fundamentals appear to be comparable in magnitude from molecule to molecule, except in the case of the bands of **IV** at 2961 cm^{-1} and 2957 cm^{-1}, the intensity ratio of which is opposite to that of the corresponding bands of **I** or **II**; the relative intensities may be disturbed by possible combination bands or overtones in this region.

The above results indicate that the spectra are very sensitive, even to small structural changes. Thus, the shift in the frequency of the $\nu_a(CH_2)$ band of the hydroxymethyl group in **I** (3014 cm^{-1}) and in **II** (3006 cm^{-1}) may be attributable to the difference in conformation of this group. In **I**, the group adopts a *gauche/gauche* conformation (5), whereas in **II**, it is predominantly in a *gauche/trans* conformation (6). The other structural difference between these two molecules is the configuration at C-5; the band of the C-5—H group of **I** was observed at a higher frequency than that of the corresponding group of **II**. Analogous behavior has been observed for the NH stretching vibrations of piperidine (32).

5-Deoxy-D-threo-*hexulose (**III**)*

This deoxy sugar contains three methylene groups. A total of six bands should arise from these groups; in addition, two bands from the ring-methine stretching modes should be observed. The room-temperature Raman spectrum reveals that the CH stretching fundamentals are situated in a very narrow spectral region, a feature which causes an overlap of the bands. The frequency region 3000–2700 cm^{-1} is dominated by two intense bands, namely, those at 2950 cm^{-1} and 2914 cm^{-1}. By analogy with the assignments for **I**, **II**, and **IV**, these two bands are assigned to the symmetric $\nu(CH_2)$ stretching modes of **III**. The two symmetric vibrations of the ring-methylene groups are assumed to coincide and to give rise to the band at 2950 cm^{-1}, and the band at 2914 cm^{-1} is assigned to $\nu_s(CH_2)$ of the hydroxymethyl group. The corresponding frequencies for **I** are 2938 and 2900 cm^{-1}, respectively.

[a] v = very, s = strong, m = medium, w = weak, sh = shoulder.
[b] d = doublet, t = triplet.
[c] Some assignments are given in the Results and discussion section.
[d] Frequencies below 300 cm^{-1} are accurate to within ±4 cm^{-1}.

The high-frequency shoulders at 2979 and 2969 cm^{-1} on the Raman band at 2950 cm^{-1} are assigned to the antisymmetric CH_2 stretching modes. Again, the ring-methylene modes are assumed to be degenerate and to give rise to a single band at 2979 cm^{-1}; $\nu_a(CH_2)$ of the hydroxymethyl group is observed at 2969 cm^{-1}.

Finally, the band at 2930 cm^{-1} is attributed to the stretching fundamental of C-3—H or C-4—H. The other methine fundamental may be overlapped by the intense $\nu_s(CH_2)$ bands. The assignments are summarized in Table 4.

Frequencies below 1600 cm^{-1}

It has been shown (24, 25) that most of the normal modes of vibrations of carbohydrate molecules in this region are highly coupled and hence very difficult to identify. Consequently, the following discussion of the Raman frequencies of **I**–**IV** is concerned only with the bands which are common to all of these molecules and with the intense bands which can be regarded as being characteristic for ketohexoses or for aldopentoses. The Raman frequencies of these four molecules are given in Table 5 and the spectra shown in Fig. 3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

Each of the four molecules exhibits the characteristic CH_2 deformation band (24, 25, 33–35) in the 1475–1450 cm^{-1} region. In the case of **I**, **II**, or **IV**, two bands are observed in this region, whereas **III** shows only one intense band at 1468 cm^{-1}. The band at ~1260 cm^{-1} is common to the spectra of all four molecules. In the case of an aqueous solution of D-fructose (10), the corresponding band has been assigned to the CH_2 twisting mode, and, in the cases of crystalline D-glucose and related molecules, the band has been identified as a highly coupled mode of the hydroxymethyl group (24, 25, 36).

A sharp, intense band is observed at 1175 cm^{-1} in the spectrum of **I** and at 1186 cm^{-1} in that of **III**. In the spectrum of **II** the corresponding band appears as a doublet having frequencies 1192 cm^{-1} and 1187 cm^{-1}, and in the spectrum of **IV**, which has no hydroxymethyl group, the band is absent. It is proposed that this band is associated with C—O stretching and H—C—O bending modes of the hydroxymethyl group, and that the two conformations of the hydroxymethyl group in **II** give rise to two separate bands.

Another type of absorption, which appears in the spectra of the three ketohexoses but is not observed in the spectrum of the aldopentose, is observed as an intense band at 817 cm^{-1} in the spectra of **I** and **II**, and at 813 cm^{-1} in the spectrum of **III**. It seems reasonable to attribute this absorption also to a vibration of the hydroxymethyl group. The absorption probably involves CC and CO stretching modes, which usually give rise to bands in this region (37, 38).

The spectrum of **IV** exhibits a very intense band at 841 cm^{-1}; this type of absorption was not observed in the spectra of the three ketohexoses. This absorption is characteristic of all aldose sugars which contain an equatorial hydrogen at the anomeric carbon atom (24, 39, 40).

In the region below 800 cm^{-1} both the frequency and the intensity patterns appear to be characteristic of each individual molecule; thus, the bands corresponding to a common vibrational mode are difficult to identify. For example, the strongest band in this region in the case of **I** is found at 626 cm^{-1}, whereas in the cases of **II**–**IV**, the strongest bands are observed at 509 cm^{-1}, 609 cm^{-1}, and 698 cm^{-1}, respectively.

Several weak bands are observed in the region between 300 and 100 cm^{-1} in the Raman spectra of all four molecules. These may be associated with low-frequency ring-deformation modes such as ring twisting and puckering. The strong Raman bands below 100 cm^{-1} are probably associated with lattice modes of the crystals.

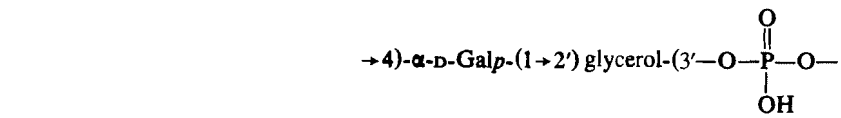
Received December 13, 1983

FRANCIS MICHON, RENÉ ROY, HAROLD J. JENNINGS, and FRASER E. ASHTON. Can. J. Chem. **62**, 1519 (1984).

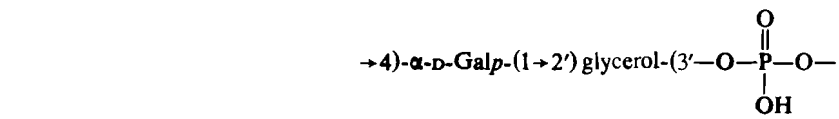
The capsular polysaccharide from newly isolated *Neisseria meningitidis* group H elaborates a structurally unique polysaccharide which is the group specific antigen. The polysaccharide contains D-galactose, glycerol, and phosphate in the molar ratio of 1:1:1 and is composed of the following basic repeating unit:



The polysaccharide contains *O*-acetyl groups, in the molar ratio of 0.8:1.0 with D-galactose, which are essential to the formation of the major group specific determinant based on serological experiments described. Although all the *O*-acetyl groups are located on D-galactopyranosyl residues, the substitution pattern is complex, 60% of the residues being substituted at *O*-3 and 20% at *O*-2.

FRANCIS MICHON, RENÉ ROY, HAROLD J. JENNINGS et FRASER E. ASHTON. Can. J. Chem. **62**, 1519 (1984).

Le polysaccharide capsulaire recémment isolé de la bactérie *Neisseria meningitidis* Groupe H possède une structure unique qui est de plus l'antigène spécifique du groupe. Le polysaccharide contient des residus de D-galactose, glycérol et phosphate sous un rapport de 1:1:1 et il est constitué de l'unité répétitive de base suivante:



Le polysaccharide contient des groupes *O*-acétyles, dans un rapport molaire de 0,8:1,0 avec le D-galactose, qui sont essentiels pour l'expression de l'immunospécificité du groupe, résultats basés sur les expériences sérologiques décrites. Bien que tous les groupes *O*-acetylés soient localisés sur les résidus D-galactopyrannosyles, le schéma de substitution est complexe: 60% des residus sont substitués en *O*-3 et 20% en *O*-2.

[Traduit par le journal]

Introduction

Neisseria meningitidis is a Gram-negative organism that has been classified serologically (1, 2) into groups A, B, C, D, 29E, W135, X, Y, Z, and newly isolated group L (3). Except for group D, each group produces a unique, capsular polysaccharide that is the antigen responsible for group specificity (1–3). The structures of all these capsular polysaccharides have been determined (2, 4). In 1981 Ding *et al.* (5) described three new serogroups, isolated in China, and designated them groups H, I, and K. As a continuation of our structural studies on the meningococcal polysaccharides we now report the structure of the group H polysaccharide. Preliminary serological studies and the identification of galactose, glycerol, and phosphate as components of the H polysaccharide have recently been reported.[2]

Experimental

Materials

The *Neisseria meningitidis* strain 1890 (H) was obtained from Dr. Shao-qing Ding, National Institute for the Control of Pharmaceutical and Biological Products, Beijing, China and was grown in a chemically defined medium (NCDM) (6). The capsular polysaccharide was isolated and purified as previously described (6), using an initial Cetavlon precipitation to obtain the crude polysaccharide. It had $[\alpha]_D$ +119° (*c*, 0.33 in water). D,L-α-Glycerophosphate was obtained from Sigma Chemical Co., St. Louis, MO, and crystalline floridoside was obtained from Dr. J. S. Craigie, National Research Council Canada, Atlantic Research Laboratory, Halifax, N.S. and was isolated from the common red alga *Chondus crispus*.

Analytical methods

Phosphorus was determined by the method of Chen *et al.* (7). Solutions were concentrated below 50°C under diminished pressure in a rotary evaporator. Periodate oxidation of the de-*O*-acetylated H polysaccharide (10 mg) was performed using 0.05 *M* sodium metaperiodate (10 mL) and the oxidation was allowed to continue for 72 h at room temperature in the dark.

Instrumental methods

Optical rotations were determined on a Perkin–Elmer 243 instrument with 1-dm semi-micro cells at 23 ± 1°C.

Gas–liquid chromatography (gc) was performed on a Hewlett–Packard 5710A instrument equipped with a flame ionization detector and a model 3380A electronic integrator. Glass columns (2 mm × 180 mm) were used with the following packings and programs: (A) 3% SP2340 on 80–100 mesh Supelcoport, from 180°C (delay 2 min) to 240°C at 4°C/min; (B) 3% OV17 on 80–100 mesh Chromosorb W,

from 180°C (delay 2 min) to 270°C at 6°C/min. Combined gas–liquid chromatography – mass spectrometry (gc–ms) was carried out on a Hewlett–Packard 5985B instrument using the above columns and an ionization potential of 70 eV. Chemical ionization (CI) spectra were obtained using methane as the vector gas.

The ^{13}C nmr spectra were recorded in 10-mm tubes at 25°C on a Varian CFT 20 instrument operating at 20 MHz in the Fourier transform mode with complete proton decoupling. Chemical shifts are reported in parts per million (ppm) downfield from external tetramethylsilane, and the ^{2}H resonance of deuterium oxide was used as the field-frequency lock signal. Polysaccharides and oligosaccharides were examined as solutions in deuterium oxide (30–100 mg/mL).

The ^{1}H nmr spectra were recorded at 80°C with a Varian 400-MHz spectrometer (Regional High Resolution N.M.R. Laboratory, University of Montreal, Quebec) in the pulsed Fourier transform mode. The polysaccharides (3–5 mg) were twice lyophilized from 99.7% D_2O and examined in 99.96% D_2O solution. The apparent first order coupling constants (Hz) were measured directly, and the chemical shifts (δ) are expressed relative to external sodium 2,2-dimethyl-2-silapentane-5-sulfonate. The HOD signal was removed from the spectra by saturation and some of the protons were assigned by selective homonuclear irradiation.

Glycose analysis

Complete acid hydrolyses of the polysaccharides and oligosaccharides were carried out with either 2 *M* trifluoroacetic acid for 8 h at 100°C, or 0.5 *M* trifluoroacetic acid for 16 h at 100°C. The component sugars were detected as their alditol acetates (8) by gc–ms analysis using column A.

Dephosphorylation of the H polysaccharide

The polysaccharide (15 mg) was dissolved in 48% hydrofluoric acid (1 mL) and left for 72 h at 5°C in a Teflon flask. The hydrofluoric acid was then neutralized using Dowex-1 (OH^-) ion-exchange resin (60 mL). The products of dephosphorylation were purified by passage through a Sephadex G-50 column (1.5 cm × 90 cm) using a 0.02 *M* pyridinium acetate buffer (pH 5.4) as eluant and a Waters R403 differential refractometer for monitoring the components.

De-O-acetylation of the H polysaccharide

Complete de-*O*-acetylation of the H polysaccharide was carried out at 25°C for 16 h using either 0.1 *M* sodium hydroxide or 0.02 *M* ammonium hydroxide. The solutions were neutralized with acetic acid (1 *M*) and the de-*O*-acetylated polysaccharide was purified by passage of the neutralized solution through a Sephadex G50 gel-filtration column; it had $[\alpha]_D$ +115° (*c*, 0.29 in water). Partial de-*O*-acetylation was achieved by absorbing the H polysaccharide onto Dowex-1 (OH^-) anion-exchange resin for 1 h and then eluting it from the resin using 0.6 *M* sodium chloride solution. The partially de-*O*-acetylated polysaccharide was obtained by lyophilization of the dialysed sodium chloride eluate.

Methylation analysis

The de-*O*-acetylated H polysaccharide and its oligosaccharide component were methylated with methyl iodide in the presence of methyl sulfinyl anion according to the method of Hakomori (9). The methylated products were recovered by passage of the reaction mixtures through a column of Sephadex LH20 column (30 cm × 1 cm) using chloroform as eluant. The eluted products were detected on thin layer chromatography plates by 10% sulfuric acid in ethanol. The permethylated products were hydrolysed using 0.5 *M* trifluroacetic acid for 16 h at 100°C and the methylated sugars were reduced with sodium borohydride, acetylated with pyridine – acetic anhydride (1:1 v/v) for 1 h at 100°C, and analysed by gc–ms (10) using column B. The permethylated oligosaccharide component of the H polysaccharide was also analysed directly by the above procedure.

Immunodiffusion

Double radial immunodiffusion was performed in 1.0% agarose gels in PBS containing 2% polyethylene glycol (mol. wt. 6000) at 25°C.

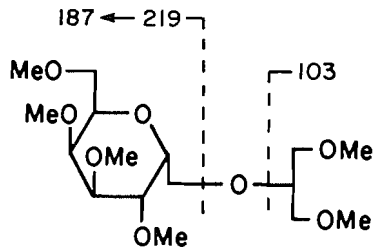

FIG. 1. Methylated oligosaccharide obtained from the H polysaccharide with some primary fragments.

Antisera to the H polysaccharide

Antisera to the H polysaccharide were prepared by injecting whole group H organisms in rabbits as previously described (11).

Quantitative microprecipitin experiments

Quantitative microprecipitin experiments were carried out by the method of Kabat and Mayer (12) using 0.1 mL of antiserum (diluted 5 times in PBS at pH 7.0) and 0.1 mL of antigen solution containing from 5 to 100 μg of polysaccharide. Precipitates were dissolved in 0.1 mL of 0.1 *M* sodium hydroxide and the protein content was determined by the method of Lowry *et al.* (13).

Results and discussion

Isolation and characterization of 2′-O-α-D-galactopyranosylglycerol

Dephosphorylation of the H polysaccharide using 48% aqueous hydrogen fluoride yielded only one chromatographically pure disaccharide component. Hydrolysis of the disaccharide yielded D-galactose and glycerol as determined by gc–ms, the D-configuration being assigned to the galactose residue by virtue of the high positive rotation of the original disaccharide.

Methylation of the disaccharide and subsequent gc–ms analysis of the permethylated compound gave a fragmentation pattern in its mass spectrum consistent with pure 2′-*O*-2,3,4,6-tetra-*O*-methyl-α-D-galactopyranosyl-1′,3′-di-*O*-methylglycerol (Fig. 1). The following fragments are listed using the terminology of Kochetkov and Chizov (14). Primary ions (of the A series) characteristic of the terminal non-reducing hexosyl residue were *m/e* 219 (aA_1), 187 (aA_2), and 155 (aA_3); those of the glycerol moiety were *m/e* 103 (bA_1) and 163 (abJ_1). Expected secondary ions also appeared at *m/e* 101, 88, 71, 59, and 45. The gc–ms analysis in the chemical ionization (CI) mode also gave fragments consistent with the structure. A base peak at *m/e* 187, peaks at 219 (44), peak $(M + H)^+$ at 339, *M* at 338, and $(M - H)^+$ at 337, together with other ions generated by the subsequent loss of methanol from $(M + H)^+$ at *m/e* 305, 273, and 241 (14). The abJ_1 ion at *m/e* 163 was also a dominant feature (11.7%) in the CI spectrum. Hydrolysis of the permethylated compound yielded 2,3,4,6-tetra-*O*-methyl-D-galactopyranose and 1,3-di-*O*-methylglycerol, as indicated by gc–ms, which is also consistent with the above structure.

The ^{13}C nmr spectrum of the disaccharide is also consistent with the above structural evidence and the chemical shifts and assignments of the nine carbon signals are listed in Table 1. The fact that three free hydroxymethyl signals (at 61.6, 62.3, and 62.6 ppm) appear in the spectrum indicates that both hydroxymethyl groups of the glycerol moiety must be unsubstituted, thus implying that linkage occurs at C-2′ (79.9 ppm). Except for the highly characteristic galactopyranosyl anomeric signal (C-1) at 99.3 ppm, most of the other carbons of the galactopyranosyl residue can be readily assigned by

[e,f]Tentative assignments.

comparison with previous assignments made on α-D-galactopyranose (15). One minor deviation from the above coincidence of signals was that the C-5 signal of the disaccharide was displayed downfield by 0.9 ppm compared to the C-5 signal of α-D-galactopyranose (15). This displacement can be attributed to the nature of the aglycone as no similar displacement occurs in the C-5 signal of methyl α-D-galactopyranoside (15). Assignments for the 2′-*O*-α-D-galactopyranosylglycerol differ from those assigned by Norton *et al.* (16) who reversed the assignments of C-2 and C-3.

The above evidence indicated that the disaccharide was 2′-*O*-α-D-galactopyranosylglycerol (floridoside) which has been isolated crystalline from the *Rhodophyceae* (17). Crystallization of our preparation of the disaccharide was induced in ethanol by seeding the solution with authentic crystalline floridoside. The crystals had $[\alpha]_D$ +159° (*c*, 0.38 in H_2O) (lit. (17) $[\alpha]_D$ +162° (*c*, 1.0 in H_2O)) and mp 129.5°−130.5°C undepressed on admixture with authentic floridoside.

Structure of the H polysaccharide

Chemical analyses indicate that the H polysaccharide contains phosphate in a molar ratio of 1:1 with D-galactose. Therefore the simple nine resonance ^{13}C nmr spectrum of the de-*O*-acetylated H polysaccharide (Fig. 2) is only consistent with it having a repeating unit of 2′-*O*-α-D-galactopyranosylglycerol-phosphate. To complete the structure of the H polysaccharide it was necessary to assign the position of the phosphate diester linkages joining the disaccharide repeating units and the *O*-acetyl substituents. The presence of *O*-acetyl substituents in the native H polysaccharide was indicated by characteristic methyl (—$COCH_3$) signals at 21.6 and 21.9 ppm (18, 19) in its ^{13}C nmr spectrum (Table 1).

Because the glycerol residue of the disaccharide repeating unit is linked at C-2′, the phosphate diester must be linked to one of its remaining two primary hydroxymethyl groups. This is consistent with the ^{13}C nmr spectrum of the de-*O*-acetylated H polysaccharide which exhibits two signals with chemical shifts characteristic of free primary hydromethyl groups (18, 19), which at 62.0 and 62.4 ppm could be assigned to C-6 and C-1′ respectively. The ^{13}C chemical shifts of the native and de-*O*-acetylated H polysaccharide are listed in Table 1 together with $^{13}C—^{31}P$ coupling constants. The signal at 65.8 ppm can be assigned to the phosphate-linked hydroxymethyl group at C-3′ by virtue of its characteristic chemical shift (18, 19) and the fact that it is a doublet due to two-bond $^{13}C—^{31}P$ coupling, $^2J_{C\text{-}3',P}$ = 5.1 Hz.

The linkage of the phosphate diester to the galactopyranosyl residue must be assigned to C-4 from an analysis of the ^{13}C nmr spectrum of the de-*O*-acetylated H polysaccharide. Neither the C-1 nor C-2 signals of the galactopyranosyl residue of the H polysaccharide are significantly displaced in comparison with the signals of C-1 and C-2 in the disaccharide repeating unit (Table 1), thus indicating the lack of a substituent at C-2 (α effect) or C-3 (β effect) (18, 19). This analysis is entirely consistent with the results of the Smith degradation of the de-*O*-acetylated H polysaccharide. The periodate oxidized polysaccharide was reduced with sodium borohydride, dephosphorylated with aqueous hydrogen fluoride, and hydrolysed with 2 *M* trifluoroacetic acid for 6 h at 100°C. This analysis yielded glycerol, threitol, and galactitol in the ratio of 0.8:1.0:1.0 as determined by gc−ms analysis. The presence of threitol confirms that C-4 is indeed the site of the phosphate diester linkage, as it could only be formed from C-6, C-5, C-4, and C-3 of the α-D-galactopyranosyl residue. The detection of equimolar amounts of threitol and galactitol indicates that only half the α-D-galactopyranosyl residues of the de-*O*-acetylated H polysaccharide were oxidized despite using an excess of oxidant over a protracted period of time. One possible explanation is that the stability of some of the galactopyranosyl residues could be due to hydrogen bonding between the phosphate anion and their 3-OH groups. The stability of apparently periodate-sensitive sugar residues in other charged polysaccharides has also been attributed to a similar type of hydrogen bonding (20). The low estimation of glycerol in the foregoing analysis can be attributed to the volatility of glycerol triacetate in the evaporation procedures used. Thus the de-*O*-acetylated H polysaccharide can be represented by the repeating unit depicted in Fig. 2.

To complete the structure of the native H polysaccharide it was now necessary to locate its *O*-acetyl substituents. That all the *O*-acetyl groups were situated on the galactopyranosyl residues could be ascertained from the fact that C-1′ of the glycerol residue was shown to be unsubstituted by ^{13}C nmr. The C-1′ signal had an identical chemical shift in the ^{13}C nmr spectra of both the native and de-*O*-acetylated H polysaccharides. The detection of two methyl (—$COCH_3$) signals in the ^{13}C nmr spectrum of the H polysaccharide (Fig. 3) and the complexity of the spectrum in comparison with that of the

de-*O*-acetylated H polysaccharide is only consistent with a complex *O*-acetyl substitution pattern. In addition to signals that can be assigned to unsubstituted galactopyranosyl residues, other signals can be assigned on the assumption that other galactopyranosyl residues are substituted with *O*-acetyl groups either at *O*-2 or *O*-3 (Table 1).

This complex substitution pattern, shown in Fig. 4, was readily resolved using high resolution 400-MHz ^1H nmr spectroscopy. The assignments of some signals pertinent to this analysis are listed in Table 2 together with their chemical shifts and coupling constants. The ^1H nmr spectrum of the H polysaccharide exhibits three anomeric doublets at δ 5.19, 5.25, and 5.32 in the ratio of 1:1:3, representative of unsubstituted galactopyranosyl residues, galactopyranosyl residues substituted at *O*-2, and galactopyranosyl residues substituted at *O*-3, respectively. Thus only 80% of the galactopyranosyl residues are substituted with *O*-acetyl groups, which is also consistent with the intensity ratio of anomeric (1H) and *O*-acetyl (3H) protons in the ^1H nmr spectrum being 1:2.5. Two doublet of doublets at δ 5.08 and 5.01 in the intensity ratio of 2:1 can be assigned to H_3 and H_2 of the galactopyranosyl residues substituted at *O*-3 and *O*-2, respectively, by *O*-acetyl groups. The

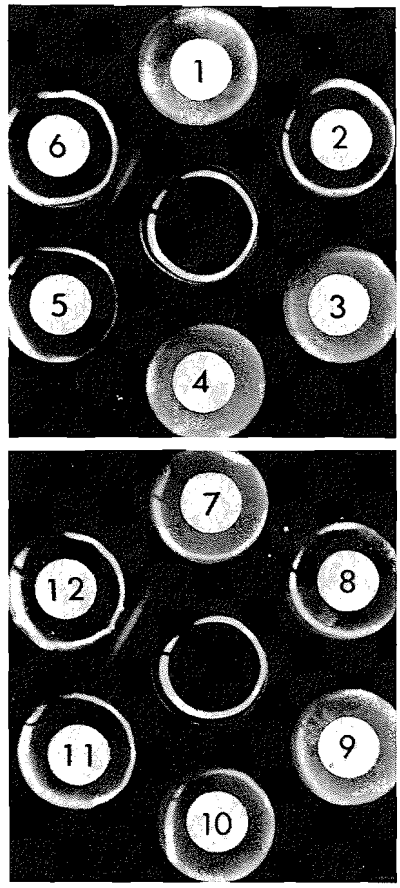

FIG. 5. Double diffusion in agar of meningococcal grouping sera gainst purified capsular polysaccharide of *N. meningitidis* group of H. Central wells contain the H polysaccharide; peripheral wells 6 and 12 contain anti-group H serum; remaining wells (1 to 5 and 7−11) contain A, B, C, X, Y, Z, 29E, W135, I, and K grouping sera respectively.

aforementioned assignment is also corroborated by an analysis of the complex H-4 signal in the ^1H nmr of the H polysaccharide. The signal is composed of three doublet of doublets at δ 4.66, 4.63, and 4.55 in an intensity ratio of 3:1:1 and an overall intensity ratio of 1:1 with the anomeric protons. The doublet of doublets at δ 4.55 is present in the ^1H nmr of the de-*O*-acetylated H polysaccharide (Table 2) and can therefore be assigned to H-4 of the unsubstituted galactopyranosyl residues, while the doublet of doublets at δ 4.63 can be assigned, by virtue of its intensity, to galactopyranosyl residues substituted by *O*-acetyl groups at *O*-2, and the doublet of doublets at δ 4.66 to the same residues substituted at *O*-3. The above assignment is also compatible with the presence of two methyl signals at δ 2.17 and 2.20 in the intensity ratio of 3.1:1.0, which can be attributed to the two *O*-acetyl groups of the differently substituted galactopyranosyl residues.

Using ^1H nmr spectroscopy, the distribution of *O*-acetyl groups in the partially de-*O*-acetylated H polysaccharide could also be determined. From the intensities of the anomeric proton signals mentioned previously (Table 2) one could deduce that 65% of the galactopyranosyl residues are unsubstituted, 25% are substituted by *O*-acetyl at *O*-3, and 10% are substituted by *O*-acetyl at *O*-2.

The H polysaccharide was demonstrated to be group specific in immunodiffusion experiments shown in Fig. 5. In these experiments the H polysaccharide gave a precipitin line only

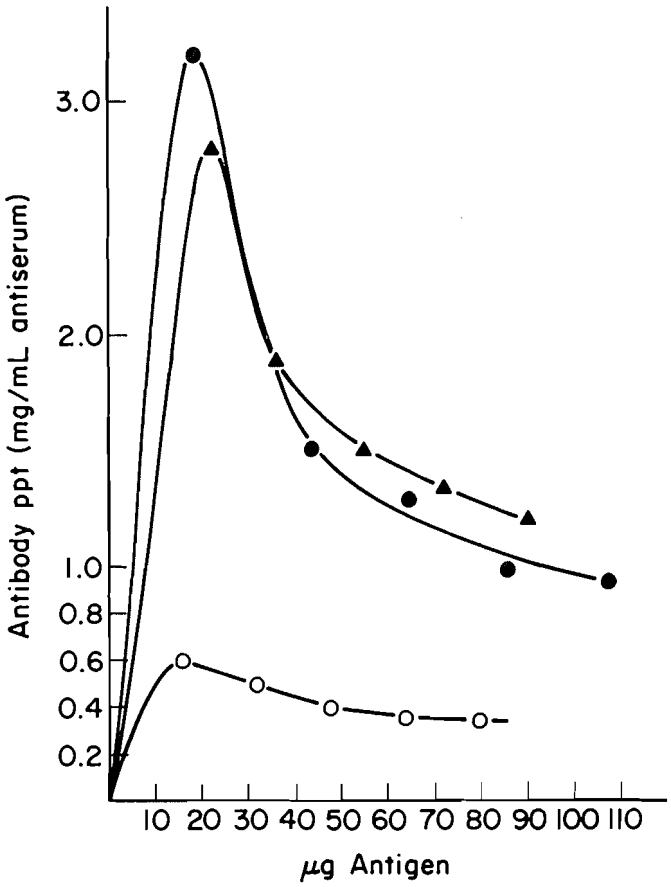

FIG. 6. Quantitative precipitin curves of the H polysaccharide ●—●, the partially de-*O*-acetylated H polysaccharide ▲—▲, and the de-*O*-acetylated H polysaccharide ○—○.

with an antiserum made to its homologous organisms and not to the antisera raised to all the other known meningococcal serogroups.

Quantitative serological experiments using the native and modified H polysaccharide with the aforementioned group H specific antiserum are shown in Fig. 6. These experiments demonstrate that some of the *O*-acetyl groups are essential to the formation of the group-specific determinant. While the native H polysaccharide precipitated 3.2 mg of antibody from 1 mL of antiserum, the de-*O*-acetylated H polysaccharide precipitated less than one fifth of this amount. It is interesting to note that removal of more than half of the *O*-acetyl substituents from the H polysaccharide barely affected its ability to precipitate the maximum amount of antibody. Because only 10% of galactopyranosyl residues substituted at *O*-2 remain in this partially de-*O*-acetylated H polysaccharide, it is perhaps indicative of the more populous 3-*O*-acetyl group being immunodominant.

R. A. BACK, D. K. EVANS, and H. M. ADAMS. Can. J. Chem. **62**, 1525 (1984).

Studies of the multiphoton absorption (MPA) and decomposition (MPD) of cyclobutanone have been extended to short pulses (10 and 40 ns fwhm) and low pressures (0.01 − 1.3 kPa) spanning conditions from essentially no gas kinetic collisions during the laser pulse to a collisional regime. MPA results are modelled by a rotational hole-filling model with a system relaxation time of 0.07 (kPa ns)$^{-1}$ and no dependence on laser intensity is observed. By contrast, decomposition appears to be more efficient using a 10 ns pulse than one of 40 ns. Results are reported for both major and minor products and a mechanism for MPD consistent with these results is discussed.

R. A. BACK, D. K. EVANS et H. M. ADAMS. Can. J. Chem. **62**, 1525 (1984).

On a étendu les études d'absorption et de décomposition multiphoton (AMP et DMP) de la cyclobutanone de façon à inclure de courtes pulsations (10 et 40 ns fwhm) et de faibles pressions (0,01 − 1,3 kPa) et à couvrir des conditions allant esentiellement de l'absence de collisions cinétiques en phase gazeuse pendant l'impulsion du laser jusqu'à un régime impliquant des collisions. On représent les résultats de l'AMP par un modèle rotationel de remplissage de cavité avec un temps de relaxation du système de 0,07 (kPa ns)$^{-1}$ et on n'a observé aucune relation avec l'intensité du laser. La décomposition au contraire semble être plus efficace lorqu'on utilise une impulsion de 10 ns au lieu de 40 ns. On rapporte les résultats relatifs aux produits principaux et secondaires et on discute d'un mécanisme de la DMP qui est en accord avec les résultats.

[Traduit par le journal]

Introduction

The multiphoton absorption and decomposition in cyclobutanone have been studied in several laboratories (1−5). This work has been done with conventional CO_2 lasers with relatively long pulses (≥ 1 μs) and mostly at fairly high pressures, up to several kPa, and therefore in the "collisional" regime, where both absorption and decomposition may be strongly modified by collisions. Cyclobutanone is interesting because it decomposes fairly easily, exhibiting two clean unimolecular decomposition paths,

[1] cyclobutanone → C_2H_4 + H_2CCO

[2] cyclopropane + CO

with relative rates and activation energies well defined from thermal reaction studies (6). Other higher-energy channels, less well defined, yield propylene, acetylene, and other hydrocarbons. Measurement of product ratios from these several channels should yield information about the energy of molecules decomposing in the multiphoton process.

The present paper describes the extension of the studies of multiphoton absorption and decomposition in cyclobutanone into the collision-free regime, using the Chalk River variable pulse CO_2 laser and the single pulse photoacoustic absorption technique developed at CRNL. Using 10 and 40 ns fwhm pulses, we have made absorption measurements with an average of between 0.3 and 4.5 gas-kinetic collisions per molecule during the pulse, and decomposition experiments with between 0.01 to 4.5 collisions per molecule during the pulse (7). Measurements under these conditions should clarify the role of collisions both in absorption and decomposition.

Experimental

All irradiations were performed using the prototype variable pulse CO_2 laser system built by Lumonics Inc. (8).

The laser was tuned to the 9P(20) line at 1046.9 cm^{-1} with temporally smooth pulses of 10 or 40 ns fwhm. The energy contrast ratio was kept to at least 10 by use of saturable absorbers. Pulse energy to the samples was varied by use of calibrated CaF_2 absorbers.

The multiphoton absorption measurements were made using the single-pulse photoacoustic technique (9). A typical photoacoustic measurement involves recording pulse energy and microphone voltage for about 1000 laser pulses. Calibration factors to convert microphone voltage to absorbed energy were determined by a conventional transmission experiment at relatively low fluences (0.01 − 0.1 J/cm^2) using an arrangement similar to that of ref. 10 with the absorption cross-section corrected for the radial profile of the beam and for attenuation along the cell (10). The temporal dependence of absorption was measured by using two photon drag detectors and comparing the pulse shape of a 40 ns pulse before and after passage through a 46 cm cell containing 1.333 kPa of cyclobutanone. Calibration measurements were made at cyclobutanone pressures of 0.333, 0.667, 1.000, and 1.333 kPa using the 10 ns pulse and photoacoustic measurements were made at these pressures for both 10 and 40 ns pulses, corresponding to an average of 0.3 to 4.5 collisions during the pulse (7).

Multiphoton decomposition experiments were performed in Pyrex cells 46 cm long, 2.5 cm in diameter and fitted with greaseless valves and NaCl windows mounted at 7° to the cell axis to prevent back reflections causing self-oscillation of the amplifier section of the laser system. BaF_2 lenses of 50 or 100 cm focal length were used. Fluences are given by the laser pulse energy divided by the area of the beam waist. For the 1.6, 2.2, and 3.5 J/cm^2 studies the 100 cm lens was used; however, at higher fluences the short pulse damaged the cell windows, so fluence dependence studies were done using a 50 cm focal length lens. Cyclobutanone pressures from 0.013 − 1.333 kPa were used in the decomposition studies.

Products were analysed with a gas chromatograph using a phenyl isocyanate column and flame ionization detection. Relative yields are more precise than the absolute determinations.

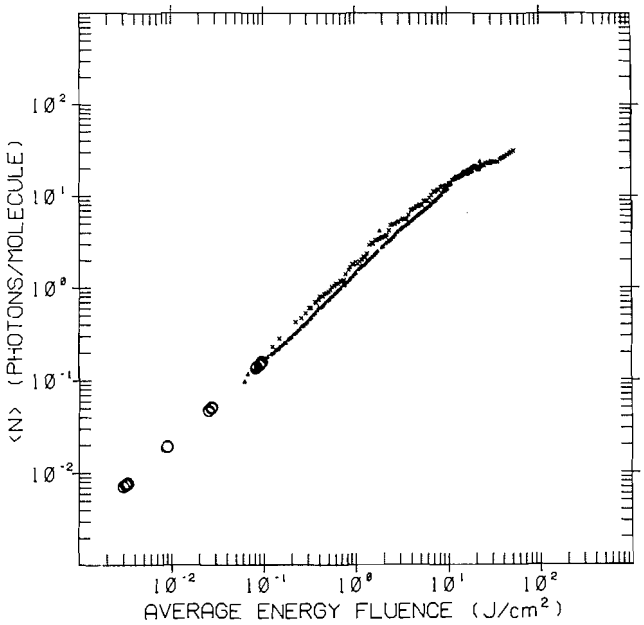

FIG. 1. The intensity dependence of multiphoton absorption by cyclobutanone. Calibration results (○) for 1.333 kPa and a 10 ns fwhm pulse and calibrated photoacoustic results for 1.333 kPa, 10 ns (△) and 0.333 kPa, 40 ns (×) are shown. At the same pressure times pulse width there is no intensity dependence observed.

Results and discussion

Multiphoton absorption

The multiphoton absorptions measured in these experiments show very little dependence on laser fluence or intensity. This can be seen in Fig. 1 where the calibrated values of $\langle n \rangle$, the average number of photons absorbed per molecule, are plotted in log−log form against fluence for a 10 ns pulse at 1.333 kPa and a 40 ns pulse at 0.333 kPa pressure of cyclobutanone.

Also shown in Fig. 1 (○) are the values of $\langle n \rangle$ determined by the transmission experiment. The photoacoustic measurements are calibrated by ensuring that there is an overlap of the $\langle n \rangle$ values from calibration and microphone measurements. (In Fig. 1, each of the points in each cluster of calibration results is an average of 100 laser pulses for a total of 2000 pulses to obtain a calibration factor for each pressure.)

The product of pulse width and pressure is constant in these two experiments, so there is the same number of collisions during the pulse. Although the laser intensity is four times higher in the shorter pulse, the differences in the two plots are within the uncertainty of the photoacoustic measurement. The slopes are close to unity except at high fluence, implying cross-sections independent of fluence. Table 1 summarizes measurements of $\langle n \rangle$ and cross-sections obtained from such measurements. The photoacoustic data used to compare with calibration results were restricted to fluences ≤ 2 J/cm^2 because at higher fluences the assumptions inherent in the photoacoustic measurement no longer hold. In particular, as decomposition becomes appreciable, energy is lost (the reaction is endothermic), so that the rise in temperature, and hence the rise in pressure measured by the microphone, is reduced. This probably explains why the lines in Fig. 1 curve downward at high fluence.

In Fig. 2 we have plotted $\langle n \rangle$ at fluences of 0.5 and 1.0 J/cm^2 against the product of pressure and pulse width, which is proportional to the number of collisions during the pulse. The curves drawn are calculated on the assumption that rotational relaxation by collisions is responsible for the rise in $\langle n \rangle$ with increasing values (pressure × pulse width, $p\tau$). If only a fraction of the molecules is initially in an appropriate rotational state to absorb radiation, and this is replenished by a first-order process, the system can be described by the equation

$$\frac{\langle n \rangle(p\tau) - \langle n \rangle_\infty}{\langle n \rangle_0 - \langle n \rangle_\infty} = \exp\,[-kp\tau]$$

where $\langle n \rangle_0$ and $\langle n \rangle_\infty$ are low-pressure and high-pressure limits respectively, p is pressure and τ is the fwhm of the pulse. The data at each of the two fluences can be fitted with a common value of $k = 0.07$ (kPa ns)$^{-1}$ for the two curves (11). This is a composite rate constant corresponding to the several collisions required to bring a molecule into a resonant rotational level, and is not directly comparable with the value of 0.225 in the same units reported by Starov *et al.* (3) for a single relaxing collision. The ratio of these values, 3.2, should in fact correspond to the average number of collisions required to bring all the molecules into resonance with the laser radiation. The ratio $\langle n \rangle_0/\langle n \rangle_\infty$ had a value of 0.25 at both fluences, which may be interpreted as the fraction of molecules initially capable of absorbing laser radiation, and may be compared with a value of 0.3 chosen by Starov *et al.* (3) to fit their model to their observations.

In another study of cyclobutanone, Harrison and co-workers (2) measured a value of $\langle n \rangle$ of 3 or 4 at a fluence of 0.67 J/cm^2 at a laser frequency of 1073 cm^{-1}, *independent* of pressure from 0.04 to 2.7 kPa. The pulse length from their conventional CO_2 laser was not clearly reported, but was probably long enough to place their measurements, even at the lowest pressure, in the plateau region of Fig. 2. Thus there is no conflict between our results and theirs when the pulse length as well as pressure is considered.

Finally, our photon drag measurements showed that absorption was uniform throughout the 40 ns pulse at 1.333 kPa, the lowest pressure permitting quantitative measurement; at 0.667 kPa, the absorption also appeared uniform within the accuracy of the observations. Thus no net depletion of absorbing species could be observed during the pulse.

Multiphoton decomposition

Decomposition products were those observed previously; ethylene was the major product measured, with cyclopropane

TABLE 1. The least squares fits of the number of photons per molecule ($\langle n \rangle$) and cross section (σ) to laser fluence (E)* for the form $\log \langle n \rangle = a + b \log E$ and $\log \sigma = c + d \log E$

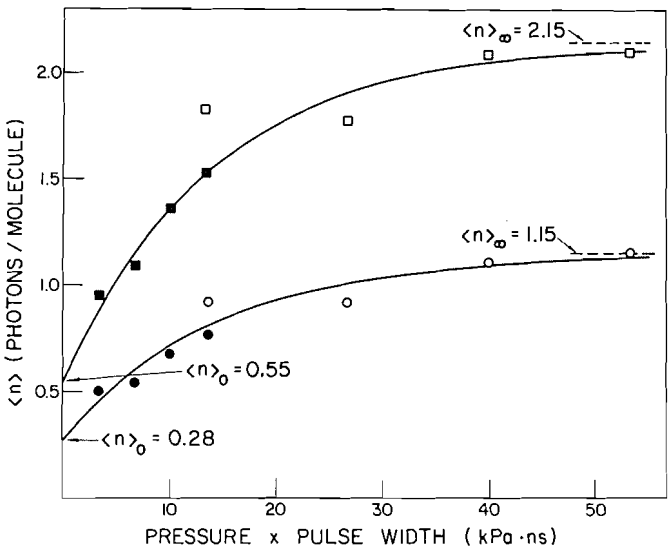

FIG. 2. The pressure dependence of multiphoton absorption by cyclobutanone at fixed laser fluences (○, ● — 0.5 J/cm^2 and □, ■ — 1.0 J/cm^2, filled symbols for 10 ns pulses, open for 40 ns pulses). The curves are a first order relaxation model which is discussed in the text.

between 3 and 7% of the ethylene and propylene between 1 and 60% of the cyclopropane. At higher fluences, significant yields of methane, ethane, acetylene, and traces of other C_3 and C_4 hydrocarbons were observed. Ketene and CO, which presumably were formed in conjunction with ethylene and cyclopropane in reactions [1] and [2], were not measured. In Fig. 3 is shown a log−log plot of P, the probability of decomposition per pulse for a molecule in the central cylindrical portion of the irradiation zone (12), as a function of the fluence at the centre (corrected for attenuation) for pressures of cyclobutanone of 0.333 and 1.333 kPa, pulse length of 10 and 40 ns fwhm, and using both the 50 and 100 cm focal length lenses. It was assumed in calculating P that the observed decomposition occurred entirely in the central reaction zone. Each experiment consisted of a sequence of between 50 and 1000 pulses with the laser operating at 2 Hz. The extent of decomposition in an experiment (based on the total cell contents, not just the gas in the beam) varied from less than 1% to about 40%, and a first-order correction for the depletion of the cyclobutanone during the experiment was applied in calculating P. The corrected values showed no significant variation with percent decomposition. Values of P for 1.333 kPa were consistently higher than those at 0.333 kPa, but within the experimental scatter, there does not appear to be a dependence of P on the pulse width or the focal length of the lens. At fluences greater than about 5 J/cm^2, values of P exceed unity, clearly implying that extensive decomposition was occurring outside the central cylindrical zone.

A series of experiments was done at three incident fluences, similar to those used in earlier studies (1−4) (about 1.7, 2.3, and 3.6 J/cm^2) using pulse lengths of both 10 and 40 ns and four pressures of cyclobutanone. The products measured, product ratios, percent of sample decomposed, and P are given in Table 2. For all pressures with the 40 ns pulse, P was proportional to (fluence)$^{2.8}$. About the same dependence was found for the 10 ns pulse at a pressure of 1.333 kPa cyclobutanone; however, with decreasing pressure the fluence dependence became stronger.

From these experiments, we have interpolated the values of

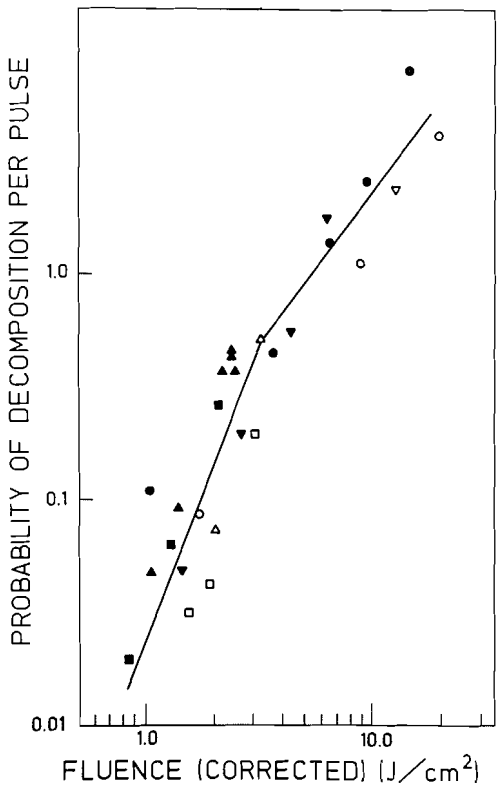

FIG. 3. Probability of decomposition in the central cylindrical region vs. laser fluence for two focal lengths and pressures. □, ■ — 40 ns, 100 cm focal length; ○, ● — 40 ns, 50 cm focal length; △, ▲ — 10 ns, 100 cm focal length; ▽, ▼ — 10 ns, 50 cm focal length; filled symbols — 1.333 kPa, open symbols — 0.333 kPa.

P for a fluence of 2 J/cm^2 for each pulse width and pressure and these are plotted in Fig. 4 against $p\tau$ in log−log form. The decomposition will be enhanced with increasing $p\tau$ as additional molecules become resonant with the laser radiation. If the decomposition process were unmodified by collision, the increase in P with increasing $p\tau$ should be no more than linearly proportional to the increase in absorption (Fig. 2) but, in fact, the increase evident in Fig. 4 is much larger than this. Furthermore, plotting P against $p\tau$ fails to bring the data for the two pulse widths into coincidence as it did for the absorption measurements (Fig. 2), with the values of P for the 10 ns pulse lying about a factor of 5 too high to give a single continuous curve. Since the MPA experiments (see Fig. 1) show that the energy absorbed is nearly the same for the two pulse widths, it appears that at this fluence this energy is used much more efficiently when delivered in a shorter time.

In Fig. 5, values of the two product ratios C_3H_6/C_2H_4 and propylene/C_3H_6 (where C_3H_6 = cyclopropane plus propylene) are plotted against corrected central fluence for a number of pressures using 10 ns pulses. At higher fluences, and higher conversions, the C_3H_6/C_2H_4 ratio was found to increase with increasing conversion. Product ratios obtained at 15% or less conversion were found to be independent of conversion and only such experimental results are plotted in Fig. 5. A similar plot for the 40 ns results shows that the product ratios lie about 10% below those for the shorter pulse. The experimental scatter is such that this difference is not definitely established; however, ratios from previous experiments with a conventional long-pulse CO_2 laser were appreciably lower again, continuing the trend to lower ratios with increasing pulse length. FIG. 4. Probability of decomposition in the cylindrical region, P, vs. pressure times pulse width at 2 J/cm^2. □ — 10 ns pulse, ○ — 40 ns pulse. The dotted line is the results for 10 ns divided by five.

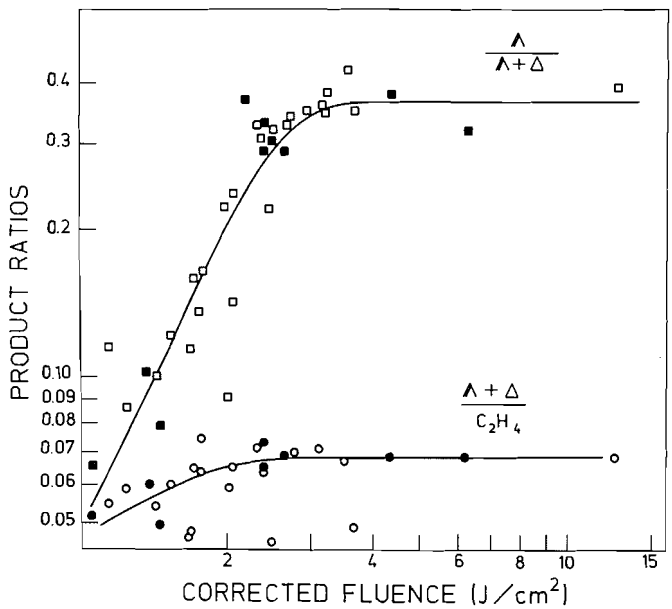

FIG. 5. The ratio of C_3H_6 (total) to C_2H_4 (○, ●) and of propylene to total C_3H_6 (□, ■) vs. fluence corrected for absorption losses at a variety of pressures.

product ratios have little dependence on fluence in the present experiments, with no variation above 3 J/cm^2. This behaviour probably reflects extensive decomposition outside the central focal zone at high fluence, the same effect that caused P to rise above unity in Fig. 3, with consequent reduction in the effective average fluence for the decomposition. With the 10 ns pulse there is no significant variation in the product ratios with pressure; however, with the 40 ns pulse, the product ratios decrease as pressure decreases below about 0.67 kPa.

The propylene/C_3H_6 ratio for irradiation with a 40 ns pulse shows a greater fluence dependence at low fluence than the C_3H_6/C_2H_4 ratio but like the latter it levels out at high fluence,

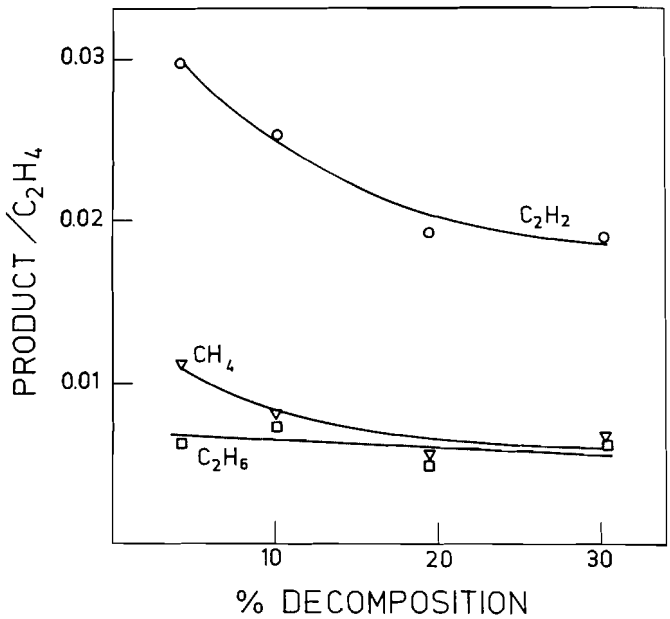

FIG. 6. The ratios of each of C_2H_2, CH_4, and C_2H_6 to C_2H_4 as a function of sample conversion at 1.333 kPa using a 10 ns pulse focussed to 2.30 ± 0.15 J/cm^2 (corrected) with a 100 cm focal length lens.

probably for the same reason.

Acetylene, methane, and ethane have been reported before as minor products but were not measured systematically. They became measurable in the present experiments only at fluences above 2 J/cm^2. All three are products of the thermal (13) and infrared laser-induced (14) decomposition of ethylene, which suggests that they might be of secondary origin in the present system. Figure 6 shows the dependence of those products, relative to ethylene, on conversion for a typical series of experiments and it is clear that the accumulation of ethylene (or other products) with increasing number of pulses does not enhance the relative yields of C_2H_2, CH_4, or C_2H_6 which in fact appear to decline at higher conversions. The possibility remains that they are derived from secondary decomposition of ethylene within a single pulse, since in the reaction zone, conversion after a single pulse was about 40% in these experiments. The C_2H_2/C_2H_4 at all pressures tends to be higher for the 10 ns pulse than for the 40 ns pulse. This suggests that the more efficient conversion of energy to reaction with the shorter pulse noted earlier might correspond to the absorbed energy having a different distribution such that a larger fraction are excited to higher levels. These would decompose more efficiently and at higher energies, thus favouring high energy channels. These arguments are only valid if the C_2H_2 is a primary photochemical product. A similar trend was observed for CH_4 and C_2H_6 but there was larger scatter in the results.

The mechanism of multiphoton decomposition

The present results offer somewhat conflicting evidence about the mechanism of decomposition. The higher probability of decomposition in the shorter pulse after allowing for differences in absorption (Fig. 4) implies a competition between pumping by the laser radiation and collisional deactivation at least during the 40 ns pulse, with decomposition occurring during or shortly after the pulse. For such a decomposition, however, P should decrease with increasing pressure as the absorbed energy is shared among more molecules, whereas in

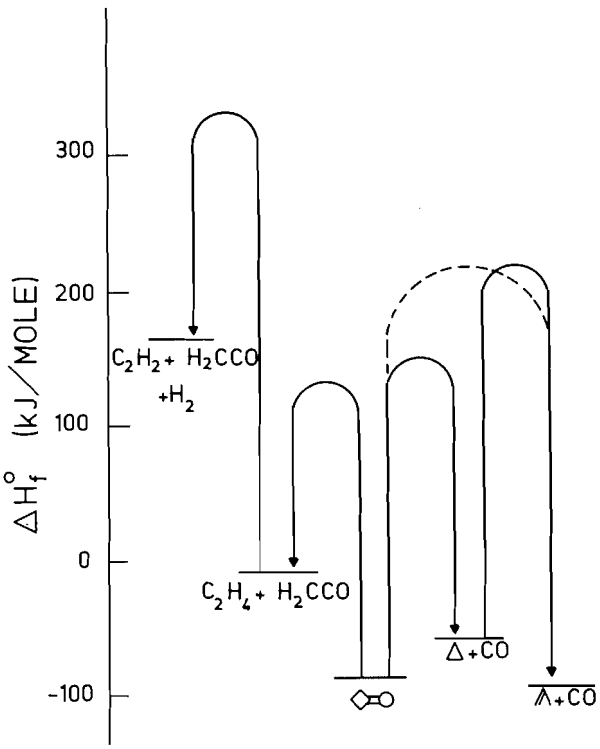

FIG. 7. The energy relations in cyclobutanone decomposition based on heats of formation from Benson and O'Neal (18).

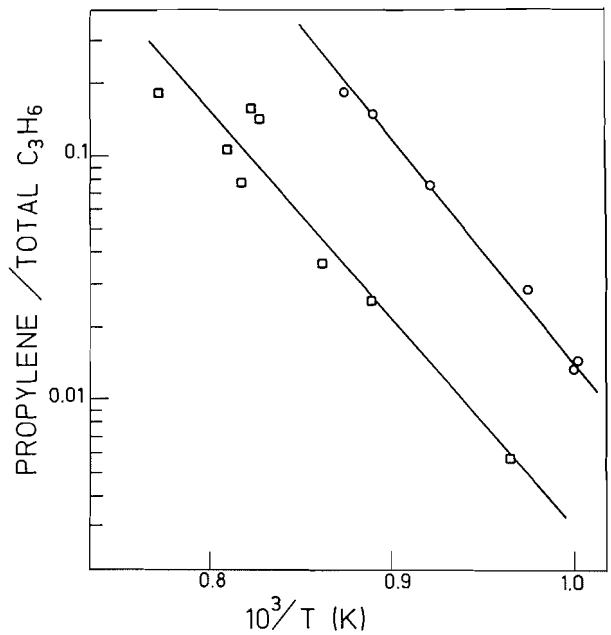

FIG. 8. The fraction of propylene to total C_3H_6 vs. a temperature derived from the two main channel ratios. For 0.333 kPa the slope of the line leads to $E_a \approx 175$ kJ/mol and for 1.333 kPa, $E_a \approx 160$ kJ/mol. Results for 0.667 and 1.000 kPa give lines with similar slopes.

fact an increase in P was observed. These observations may be reconciled if the decomposition were a sum of two processes; the first a fast, almost collision-free decomposition in which collisions deactivate excited molecules, reducing P, and the second a slower decomposition of the collisionally equilibrated hot gas remaining after the pulse. Probability of decomposition in the first process will decrease as pressure increases and intensity may affect channel ratios, while that for the second, P increases with increasing pressure as has often been observed with longer pulses (15–17) and will depend only on fluence. This dual mechanism is rather similar to that suggested in a previous study of cyclobutanone at lower pressures (4). The C_3H_6/C_2H_4 and propylene/total C_3H_6 ratios appear to reflect a similar behaviour, as they are somewhat higher with the shorter pulse, but do not decline with increasing pressure. Unfortunately, uncertainties in the true reaction volume and the effective fluence, caused by attenuation effects and reaction occurring outside the central focal zone, as discussed earlier, prevent any quantitative test of the suggested mechanism.

It has been suggested that in the thermal decomposition of cyclobutanone, propylene comes from the isomerization of vibrationally excited cyclopropane formed in reaction [2] and not from secondary decomposition of thermalized cyclopropane. Previous multiphoton decomposition studies and the present results support this conclusion. The energies of the several decomposition processes are shown in Fig. 7 using information from Benson and O'Neal (18). In Fig. 8, we have plotted, in Arrhenius form, the fraction of total C_3H_6 converted to propylene for the 40 ns results. The temperature in these plots has been calculated from the observed relative rates of reactions [1] and [2] using the equation

$$[3] \quad R_1/R_2 = (3.60/2.34) \exp [6000/RT]$$

Equation [3] should give a measure of the effective temperature of the decomposing cyclobutanone molecules if they are internally relaxed after excitation so that a unimolecular thermal decomposition description is appropriate. The plot in Fig. 8 yields an "activation energy" of about 165 kJ/mol. A similar calculation using the 10 ns results (which are more scattered) gives an "activation energy" of about 130 kJ/mol. If all the energy in the transition state (Fig. 7) were available to the cyclopropane produced in the primary decomposition, one would expect to require an additional energy of about 60 kJ/mol to form propylene. If none were available, 274 kJ/mol would be needed to form propylene from cyclopropane in the hot gas following the laser pulse. The observed intermediate value suggests that some energy is carried over from the first step but not the maximum available.

The minor products, C_2H_2, C_2H_6, and CH_4 probably come from H-atom cracking reactions in the hot gas following the pulse, similar to those in the high-temperature decomposition of ethylene.

Stereocontrolled routes to *cis*-hydroxyamino sugars. Part VI. A synthesis of garosamine[1]

HENRY W. PAULS[2,3] AND BERT FRASER-REID[3]

Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received October 14, 1983

HENRY W. PAULS and BERT FRASER-REID. Can. J. Chem. **62**, 1532 (1984).

The exocyclic olefin, **5**, obtained from the known epoxy uloside, methyl 2,3-anhydro-β-D-*erythro*-pentopyranosid-4-ulose, **3**, reacts with ammonia or methylamine to give the 3-amino-3-deoxy or 3-methylamino-3-deoxy derivatives respectively. The benzamide, **8***c*, obtained from the former, reacts with iodonium ion to give an oxazoline in which the *cis* relationship between the tertiary alcohol and the 3-amino group of garosamine is secured. Deiodination is followed by a one-pot *N*-methylation and reduction. A hydrolysis gives methyl α-L-garosamimide **2**. In a second route, the urethane, **16***c*, reacts with iodonium ion to give an oxazolidone **17***a*. This reaction establishes the *cis*-hydroxyamino moiety and circumvents the *N*-methylation/reduction steps. Deiodination followed by deprotection yields methyl α-L-garosaminide **2**. Both routes require eight steps from **3** with overall yields of 14% and 11%, respectively.

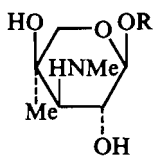
HENRY W. PAULS et BERT FRASER-REID. Can. J. Chem. **62**, 1532 (1984).

L'oléfine exocyclique, **5**, qui est obtenue de l'époxy uloside connu, anhydro-2,3 β-D-*érythro*-pentopyrannoside ulose-4 de méthyle, **3**, réagit avec l'ammoniac ou la méthylamine pour donner, suivant le cas, soit le dérivé amino-3 déoxy-3 ou méthylamino-3 déoxy-3. Le benzamide **8***c*, obtenu à partir du premier de ces dérivés, réagit avec l'ion iodonium pour donner une oxazoline dans laquelle on a fixé, entre l'alcool tertiaire et le groupe amino-3, la relation *cis* qui existe dans la garosamine. Après l'élimination de l'iode, on effectue, dans le même ballon, une *N*-méthylation suivie d'une réduction. Une hydrolyse conduit à la α-L-garosamimide de méthyle, **2**. Dans une deuxième voie de synthèse, on fait réagir l'uréthane **16***c* avec l'ion iodonium pour obtenir une oxazolidone **17***a*. Cette réaction permet d'établir la relation *cis* de la portion amino-alcool et évite les étapes de *N*-méthylation/réduction. L'élimination de l'iode, suivie d'une déprotection, conduit au produit **2**. Chacune des voies requiert huit étapes à partir du produit **3** et leurs rendements respectifs sont de 14% et 11%.

[Traduit par le journal]

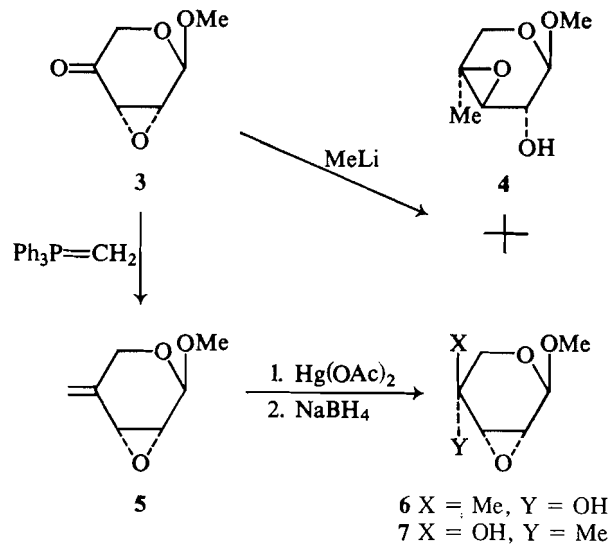
Introduction

The *C*-gentamycins are the principle components of an antibiotic complex produced by *Micromonospora purpurea* NRRL 2953 and *Micromonospora echinospora* NRRL 2985 under anaerobic conditions (1). Widespread clinical use has established them as major broad-spectrum antibiotics, and the advent of semi-synthetic methods has raised the possibility of obtaining novel, more potent modifications (2). A common, essential subunit of all three is the amino sugar garosamine, **1**, which occurs also in a number of other potent aminocyclitol antibiotics, sisomycin (3), G-52 (4), and XK-62-2 (5). Accordingly, a reliable synthetic route to **1** has been of interest for some time, and was the reason for our entry into the area of amino sugar synthesis (6–10).[4]



1 R = H
2 R = Me

Two structural features, the tertiary alcohol and the *cis*-hydroxyamino moiety, had posed challenges for earlier syn-



SCHEME 1

thesis of garosamine (11, 12). The first of these by zu Reckendorf and Bishop (11), served to establish the correct structure of **1**; but major problems were encountered which caused low yields. The synthesis of the Schering group led by Wright (12) employed a clever solution to the problematic tertiary alcohol. However, this did not constitute a general solution to *cis*-hydroxyamino features.

From these publications (11, 12) it is apparent that the tertiary alcohol is a major obstacle, and some early exploratory investigations in our group convinced us that there would be no easy solutions. Thus the known epoxy uloside **3** seemed to be a plausible intermediate. Paulsen and Eberstein had shown that methyllithium addition to **3** gave virtually equal amounts of **4** and **6** (13). We decided to examine the hydration of the exo-

cyclic olefin **5**, which could be obtained cleanly by a Wittig reaction of **3**. However, the yield of **5** was variable because of the high volatility of the material. We had hoped that, in keeping with our studies on frontalin (14), hydration of the double bond would lead to the desired lyxoside **7**. Unfortunately, the single product obtained from oxymercuration–demercuration of **5** proved to be the riboside **6**.

With regard to the second problem, the *cis*-hydroxyamino moiety, we were interested in developing a general methodology for this structural feature. Winstein *et al.* had achieved the halolactonization of simple allylic amides to afford oxazolines (5). Application of this methodology to **8***b* would not only establish the *cis*-hydroxyamino component, but would simultaneously secure the troublesome tetiary hydroxyl group. In this and the accompanying manuscript (16) we give full details of some of our results.

Results and discussion

EE = —$CH(OC_2H_5)CH_3$

SCHEME 2

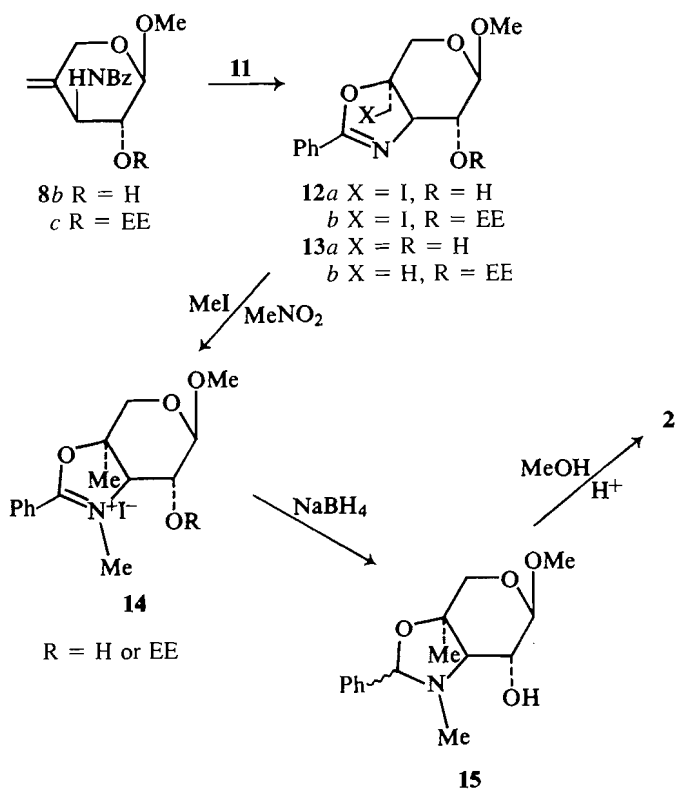
Route I

The appropriate precursor would be the amine **8***a*, obtainable by S_N2 attack at the allylic position of **5**. Azidolysis was examined initially, and some pertinent data relating to this are summarized in Scheme 2. At low temperatures, a clean S_N2 reaction occurred at the allylic site, C-3, to give the azido alcohol **9**, there being only traces of the S_N2' product **10**, barely detectable by tlc. With refluxing aqueous ethanol, compound **10** was the sole product after 4 h. The latter could be obtained alternatively by heating **9** in ethanol, or by allowing **9** to stand at room temperature for 24 h.

The sigmatropic rearrangement to the thermodynamically more stable **10** detracted from **9** as an intermediate and hence ammonolysis was examined. The best procedure was to saturate an ice-cold ethanol solution of the epoxide **5**, contained in a pressure vessel, with the amine, seal and place the vessel in an oil bath, and gradually raise the temperature to 80°C. Under these conditions, the primary amine **8***a* was obtained in 97% yield.

The benzamide **8***b* was prepared, but in contrast to Winstein's case (5), no reaction could be induced with *N*-bromosuccinimide. Typical iodolactonization conditions (I_2/KI/H_2O/THF) were also unsuccessful.

Iodonium dicollidine perchlorate (17) **11** was adopted, since in our experience this salt is a reliable source of iodonium ions (18). Indeed, treatment of the benzamides **8***b* or **8***c* with the salt in chloroform (Scheme 3) yielded the iodo-oxazolines **12***a* or **12***b* respectively, which were smoothly deiodinated by treatment with tri-n-butyltin hydride to **13***a* and **13***b* respectively.

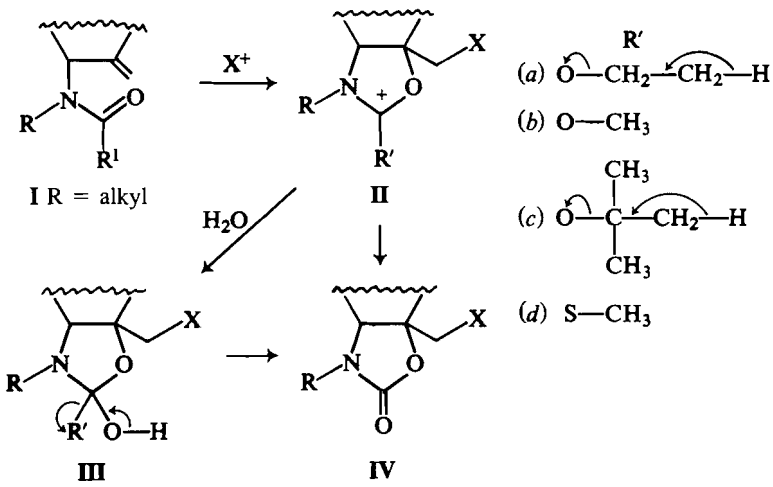


SCHEME 3

Since *cis*-fusion is expected for 6/5 heterocyclic systems (19) the product was expected to establish the desired orientation at C-4 stereospecifically.

Quaternization of the nitrogen of **13***b* required heating with methyl iodide in nitromethane for 48 h (tlc). The resulting salt, presumably **14**, was reduced directly with sodium borohydride in methanol. During these two steps, the C-2 protecting group was lost, giving **15** as the product. Strangely, the unprotected alcohol **13***a* could not be *N*-methylated under identical conditions.

Hydrolysis of the oxazolidine **15** was achieved with methanol and hydrogen chloride and the resulting material had infrared and ^{1}H nmr spectra identical with those of an authentic sample of methyl α-L-garosaminide **2** (*vide infra*).



SCHEME 4

Mechanistic considerations

In spite of the success of the above route, some economy of steps was desired. An intermediate such as **I** (Scheme 4, R = Me) was preferable since the extra steps of *N*-methylation and reduction would be circumvented. The urethane group emerged as the nitrogen substituent of choice since the corresponding cationic intermediate, **II**, is stablized by three heteroatoms, and should react further to give cyclic urethane **IV** (i.e. a 2-oxazolidone).

It is appropriate to comment on the possible modes of decomposition of the carbocation intermediates in Scheme 4. These species ought to react readily with traces of water to give **III**, which should eject an alcohol to give the cyclic urethane **IV**. This mode of decomposition should not be greatly affected by the nature of the substitutent R′. However, subsequent to our preliminary report, Parker and O'Fee (20) found that methyl urethanes, for example **II***b*, gave little, if any, oxazolidone, whereas *tert*-butyl analogs, for example **II***c*, reacted very smoothly. The results with **II***a* and **II***c* are accommodated by the alternate mode of decomposition depicted in Scheme 4, in which ethylene and isobutylene, respectively, are ejected. This is more satisfying than involvement of **III**, since our work was carried out under rigorously anhydrous conditions.

The foregoing notwithstanding, it should be noted that Knapp and Patel have obtained excellent results from bromocyclization of methylurethanes and methylthiourethanes, such as **II***b* and **II***d* respectively (21).

Route 2

The *N*-methyl amino alcohol **16***a*, prepared in a manner similar to **8***a*, was treated with ethyl chloroformate, followed by ethyl vinyl ether, to yield **16***c*. Reaction of **16***c* with the iodonium salt, **11**, afforded the desired product **17***a* in 82% yield. Deiodination was effected by hydrogenolysis over palladium, and subsequent hydrolysis with pyridinium *p*-toluenesulfonate led to oxazolidone **17***c* as a crystalline substance. This material was alternatively prepared by treating urethane **18** (obtained from authentic methyl α-L-garosaminide[4]) with sodium hydride in dimethyl formamide. The two samples had identical physical constants. Hydrolysis of **17***c* with potassium hydroxide gave the previously described garosamide **2**.

Summary

The syntheses described above are reasonably successful in terms of economy of steps and overall yield. The oxazoline route yields methyl α-L-garosaminide **2** from the known epoxy uloside **3** in 8 steps with 14% overall yield. The overall yield of **2** from **3** for the oxazolidone route (Scheme 5) is 11% in 8 steps. Further use of the oxy-amination procedure is reported in the accompanying paper (16).

Experimental

General methods

Melting points were determined in capillary tubes in a Buchi model SMP-20 melting point apparatus, and are uncorrected. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., 500 York Road, Guelph, Ont., N1H 3J4. Nuclear magnetic resonance (^{1}H nmr) spectra were determined in deuteriochloroform containing 1% tetramethylsilane (TMS) as internal standard with a Perkin– Elmer R-12B (60 MHz) or, when specifically stated, with a Varian HR-220 spectrometer. Coupling constants were obtained by measuring the spacings of spectra judged to be first order. Infrared (ir) spectra were determined on a Beckman model IR-10 spectrometer using 0.1-mm sodium chloride cells and chloroform as solvent for solids, or sodium chloride plates for thin film smears. Low resolution mass spectra were determined on a Varian MAT CH7 mass spectrometer. High resolution mass spectra (hrms) were determined on a VG 7070F.

Optical rotations were measured on a Carl Zeiss model LEP nür 370740 Lichtelektrisches Präzisionspolarimeter at 23°C.

The progress of all reactions was monitored by thin layer chromatography (tlc) which was performed on 1.3 cm × 6.6 cm aluminum sheets precoated with silica gel 60 (HF-245, E. Merck) to a thickness of 0.25 mm. The following solvent systems were used to develop the plates: (A) ethyl acetate – petroleum ether (30–60°C), (1:1); (B) diethyl ether – methylene chloride (1:19); (C) ethyl acetate. The chromatograms were viewed under an ultraviolet light, sprayed with concentrated sulfuric acid, and heated to a temperature greater than 100°C under a hot air gun. For column chromatography E. Merck Kieselgel 60 (230–400 mesh A.S.T.M.) was used. The columns were eluted under pressure.

*Methyl 2,3-anhydro-4-*C*-methylene-β-*D*-*erythro*-pentopyranoside (**5**)*

To a stirred mixture of (methyl) triphenylphosonium bromide (6.50 g, 18.2 mmol) and 50 mL dry DME under argon was added 2.2 molar n-butyllithium in hexane (6.04 mL, 13.3 mmol). The resulting suspension was stirred for 15 min, placed in an ice bath, and stirred an additional 15 min. The ketone, **3** (10) (1.74 g, 12.1 mmol), dissolved in 15 mL dry dimethoxyethane, was added dropwise. After the addition was complete the resulting mixture was stirred for 5 min, then quenched with wet diethyl ether (300 mL). The resulting slurry was filtered through Celite and washed several times with diethyl ether. The filtrate was evaporated under reduced pressure at room temperature and the residue was chromatographed with solvent system B. Epoxy olefin **5**, the only carbohydrate product, was isolated as a mobile oil (0.88 g, 51.3%); R_f 0.51 (solvent B); $[\alpha]_D^{23}$ −123.7° (*c* 1.0, chloroform); ir ν_{max}: 1450 (terminal alkene C—H bend) cm^{-1}; ^{1}H nmr δ: 3.15 (dd, 1, $J_{2,3}$ = 3.5 Hz, H-3), 3.4 (s, 3, —OCH_3), 3.62 (d, 1, H-3), 4.07–4.18 (complex ABq, 2, H-5, H-5′), 4.92 (bs, 1, H-1), 5.20–5.35 (dm, 2, =CH_2).

*Methyl 2,3-anhydro-4-*C*-methyl-β-*D*-*ribopyranoside (**6**)*

Epoxy olefin **5** (0.197 g, 1.39 mmol) was dissolved in 5 mL THF and 6 mL water, to which was added mercuric acetate (0.493 g, 1.56 mmol). The mixture was stirred at room temperature until the starting material had disappeared – typically 10 h. At this time 3.5 mL of 3 *M* aqueous sodium hydroxide and 2 mL of freshly prepared aqueous sodium borohydride (0.5 *M*, 1.0 mmol) in 3 *M* sodium hydroxide were added in quick succession. The resulting mixture was extracted 3 times with methylene chloride. The organic layers were combined, filtered to remove suspended mercury, dried over sodium sulfate, and evaporated. The sole product **6** (0.176 g, 79%) was obtained as a white solid. Recrystallization from chloroform/hexane yielded white crystals which showed mp 99–101°C; $[\alpha]_D^{23}$ −72° (*c* 1.1, chloroform). The literature (13) reports mp 103°C; $[\alpha]_D^{23}$ −79°.

*Methyl 3-azido-3,4-dideoxy-4-*C*-methylene-α-*L*-threo-pentopyranoside, (**9**)*

The starting material **5** (0.10 g, 0.70 mmol) was dissolved in 4 mL of a 3:1 ethanol/water mixture, sodium azide (0.14 g, 2.1 mmol) was added, and the mixture was stirred at room temperature. After 30 min, tlc indicated that the epoxy olefin had been consumed and replaced by **9** with trace amounts of **10**, showing R_f 0.47 and 0.32 respectively in solvent A. The reaction mixture was poured into ice water and the aqueous layer was extracted three times with methylene chloride. The combined organic washings were dried over sodium sulfate and evaporated to yield 0.92 g of a white solid (71%). The crude product exhibited the following physical data; ir ν_{max}: 3300–3500 (OH), 2120 (N_3), 1625 (C=C) cm^{-1}; ^{1}H nmr δ: 3.1 (bs, 1, OH), 3.30–4.47 (m, 5, H-1, H-2, H-3, H-5, H-5′), 3.50 (s, 3, —OCH_3), 5.15–5.30 (dm, 2, =CH_2).

*Methyl 4-*C*-azidomethyl-3,4-dideoxy-β-*D*-*glycero*-pent-3-enopyranoside (**10**)*

(a) Epoxy olefin **5** (1.0 g, 7.04 mmol) was dissolved in 25 mL of ethanol, to which was added 7.5 mL water, sodium azide (0.52 g, 8.1 mmol), and ammonium chloride (0.53 g, 9.8 mmol). The mixture was refluxed with stirring for 4 h, at which time tlc revealed **10** as the only product. The solvent was evaporated and the residue was partitioned between water and methylene chloride. The aqueous layer was separated and washed once more with methylene chloride, then the organic layers were combined, dried, and evaporated. Product **10** was obtained as a pale brown syrup (0.88 g, 67.5%); $[\alpha]_D^{23}$ −175.1° (*c* 0.6, chloroform); ir ν_{max}: 3440–3460 (OH), 2100 (N_3) cm^{-1}; ^{1}H nmr δ: 2.8 (bs, 1, —OH), 3.53 (s, 3, —OCH_3), 3.8 (s, 2, H-4a, H-4b), 3.9 (m, 1, H-2), 4.13 (s, 2, H-5, H-5′), 4.6 (d, 1, $J_{1,2}$ = 2.5 Hz, H-1), 5.9 (bs, 1, H-3); *m/e*: 143 ($M^+ - N_3$), 125 ($M^+ - N_3 - H_2O$), 94 ($M^+ - N_3 - H_2O$ – OMe).

(b) Azide **9**, upon standing at room temperature for about 24 h, or when refluxed in ethanol/water for 4 h, was converted into azide **10**.

*Methyl 3-amino-3,4-dideoxy-4-*C*-methylene-α-*L*-threo-pentapyranoside (**8***a*)*

The epoxy olefin **5** (0.389 g, 2.74 mmol) was dissolved in absolute ethanol (20 mL) and placed in a pressure vessel. The vessel was cooled in an ice bath and the solution saturated with a stream of ammonia. The pressure vessel was sealed, placed in an oil bath, and heated to 80°C. After 30 min the vessel was removed, cooled to room temperature, and the solvent was removed on a rotary evaporator. A brown solid, **8***a* (0.42 g, 96.8%), was obtained, which was suitable for subsequent manipulations. After two recrystallizations from ethanol white crystals of **8***a* were obtained with the following physical constants: mp 170.0–170.5°C; $[\alpha]_D^{23}$ −65.5° (*c* 0.7, chloroform); ir ν_{max}: 3400–3600 (NH and OH) cm^{-1}; ^{1}H nmr δ: 3.54 (s, 3, OCH_3), 3.90–4.32 (m, 3, H-1, H-5, H-5′), 5.10 (dm, 2, =CH_2). *Anal.* calcd. for $C_7H_{13}O_3N$: C 52.82, H 8.23, N 8.80; found: C 53.13, H 8.51, N 8.69.

*Methyl 3-benzamido-3,4-dideoxy-4-*C*-methylene-α-*L*-threo-pentopyranoside (**8***b*)*

The allylic amine **8***a* (0.360 g, 2.26 mmol) was dissolved in 20 mL dry chloroform. To this was added sodium bicarbonate (0.190 g, 2.26 mmol) and benzoyl chloride (0.30 mL, 2.6 mmol). After stirring for 1 h at room temperature, 20 mL of water was added, and the mixture was stirred another 15 min. The mixture was poured into a separatory funnel and the organic layer was removed. The aqueous layer was saturated with sodium chloride and extracted twice more with methylene chloride. The organic layers were combined, dried, and evaporated to dryness to give a white solid **8***b* (0.494 g, 83%) which, after recrystallization from ethanol, gave the following data: mp 202–203°C; $[\alpha]_D^{23}$ −131.3° (*c* 1.6, chloroform); ir ν_{max}: 1660 (C=O stretch) cm^{-1}; ^{1}H nmr (220 MHz) δ: 2.62 (d, 1, $J_{2,3}$ = 8 Hz, H-3), 3.50 (s, 3, —OCH_3), 3.65 (m, 1, —OH), 4.10 (ABq, 2, $J_{5,5'}$ = 13.5 Hz, H-5, H-5′), 4.60 (d, 1, $J_{1,2}$ = 4 Hz, H-1), 4.8 (dd, 1, H-2), 5.23 (d, 2, =CH_2), 7.42 (m, 3, *meta* and *para* phenyl protons), 7.75 (m, 2, *ortho* phenyl protons). *Anal.* calcd. for $C_{14}H_{17}O_5N$: C 63.87, H 6.51, N 5.32; found: C 64.10, H 6.55, N 5.25.

*2′-Phenyl-(methyl 3,4-dideoxy-4-*C*-iodomethyl-α-*L*-arabinopyranosido)-[3,4:4′,5′]-Δ$^{2'}$-oxazoline (**12***a*)*

Compound **8***b* (0.128 g, 0.49 mmol) was dissolved in 20 mL

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

chloroform to which was added iodonium dicollidine perchlorate **11** (17) (0.342 g, 0.735 mmol). The solution was stirred at room temperature in the dark for 4 h. Diethyl ether (100 mL) was added and the unreacted reagent was removed by filtration. The filtrate was evaporated and the residue was redissolved in methylene chloride. The methylene chloride phase was washed with 10% sodium thiosulfate, 5% hydrochloric acid, and, finally, water. The aqueous layers were washed successively with two fresh aliquots of methylene chloride. The organic layers were combined, dried over sodium sulfate, and evaporated. The crude syrup obtained was chromatographed on silica gel with solvent A to yield product **12***a* as a foam (0.147 g, 93%); R_f 0.33 (Solvent A); ir ν_{max}: 1730 (oxazoline C=N stretch), 3400 (OH) cm^{-1}; ^1H nmr δ: 3.48 (s, 3, $-OCH_3$), 3.52 (s, 2, $-CH_2I$), 4.54 (d, 1, $J_{1,2}$ = 5 Hz, H-1), 7.48 (m, 3, *meta* and *para* phenyl protons), 7.95 (m, 2, *ortho* phenyl protons). *Exact Mass* calcd. for $M^+ - OCH_3$: 357.9942; found (hrms): 357.9940; calculated for $M^+ - I$: 262.1079; found (hrms): 262.1078.

*2'-Phenyl-(methyl 3,4-dideoxy-4-*C*-methyl-α-L-arabinopyranosido)-[3,4:4',5']-Δ$^{2'}$-oxazoline (**13**a)*

Iodide **12***a* (0.347 g, 0.89 mmol) was dissolved in 20 mL reagent benzene to which was added tri-n-butyltin hydride (0.30 mL, 0.10 mmol). The reaction mixture was heated to reflux for 4 h, at which time the benzene was removed by evaporation. The resultant residue was partitioned between hexane and acetonitrile. The acetonitrile layer was washed twice more with hexane, then evaporated to give product **13***a* (0.155 g, 66%), which after one recrystallization from ethyl acetate had the following physical data: mp 208–209°C; $[\alpha]_D^{23}$ −0.6° (*c* 1.3, chloroform); ^1H nmr δ: 1.40 (s, 3, $-CCH_3$), 3.54 (s, 3, $-OCH_3$), 3.87 (ABq, 2, $J_{5,5'}$ = 11 Hz, H-5, H-5'), 4.49 (d, 1, $J_{1,2}$ = 5 Hz, H-1), 4.05 (bs, 1, —OH), 7.55 (m, 3, *meta* and *para* phenyl protons), 8.10 (m, 2, *ortho* phenyl protons). Satisfactory elemental analysis of **13***a* could not be obtained.[5]

*Methyl 3-benzamido-3,4-dideoxy-2-*O*-α-ethoxyethyl-4-*C*-methylene-α-L-*threo*-pentopyranoside (**8**c)*

The starting material **8***b* (0.116 g, 0.44 mmol) was dissolved in dry methylene chloride (40 mL) to which was added ethyl vinyl ether (0.12 mL, 1.2 mmol) and pyridinium *p*-toluenesulfonate (0.30 g, 0.13 mmol). The solution was stirred at room temperature and the reaction progress was followed by tlc. Upon completion, typically 4 h, the reaction mixture was poured into an equal volume of brine, shaken, and separated. The aqueous layer was washed twice with methylene chloride. The organic layers were combined, dried over sodium sulfate, and evaporated to yield impure **8***c*. After chromatography, in solvent A, the product **8***c* was obtained as a white solid (0.156 g, quantitative yield); it showed mp 154–155°C; R_f 0.30 (solvent A); ir ν_{max}: 1730 (amide C=O stretch) cm^{-1}; ^1H nmr δ: 1.05–1.5 (m, 6, $-OCH(CH_2)OCH_2CH_3$), 3.54 (s, 3, $-OCH_3$), 5.1 (m, 2, $=CH_2$), 7.30–8.0 (m, 5, phenyl protons). *Anal.* calcd. for $C_{18}H_{25}O_5N$: C 64.46, H 7.51, N 4.18; found: C 64.14, H 7.47, N 4.11.

*2'-Phenyl-(methyl 3,4-dideoxy-2-*O*-α-ethoxyethyl-4-*C*-iodomethyl-α-L-arabinopyranosido)-[3,4:4',5']-Δ$^{2'}$-oxazoline (**12**b)*

Compound **8***b* (0.047 g, 0.14 mmol) was treated with iodonium dicollidine perchlorate **11** (0.098 g, 0.21 mmol) as described for **12***a* above. The crude product was chromatographed with solvent A to yield compound **12***b* as an amber syrup (0.077 g, quantitative yield); R_f 0.5 (solvent A); ir ν_{max}: 1665 (oxazoline C=N stretch) cm^{-1}; ^1H nmr δ: 1.05–1.55 (m, 6, $-OCH(CH_3)OCH_2CH_3$), 3.50 (s, OCH_3), 3.65 (bs, 2, $-CH_2I$), 4.6 (m, 1, H-1), 4.95 (m, 1, $-OCH(CH_3)OCH_2CH_3$), 7.55 (m, 3, *meta* and *para* phenyl protons), 8.0 (m, 2, *ortho* phenyl protons).

[5]Compound **13***a* was hydrolysed on standing to give the crystalline amide **19**, mp 222–223°C. *Anal.* calcd. for $C_{14}H_{19}O_5N$: C 59.72, H 6.67, N 4.70; found: C 59.66, H 6.83, N 4.81.

*2'-Phenyl-(methyl 3,4-dideoxy-2-*O*-α-ethoxyethyl-4-*C*-methyl-α-L-arabinopyranosido)-[3,4:4,4'5')-Δ$^{2'}$-oxazoline (**13**b)*

Iodide **12***b* (0.214 g, 0.48 mmol) was dissolved in 20 mL reagent benzene to which was added tri-n-butyltin hydride (0.15 mL, 0.50 mmol). The reaction was heated to reflux for 4 h in the presence of AIBN (1–2 mg). The benzene was removed by rotary evaporation and the resultant residue was chromatographed using solvent A. Product **13***b* was isolated as a syrup (0.127 g, 83%); it showed R_f 0.5 (solvent A); ir ν_{max}: 1645 (oxazoline C=stretch) cm^{-1}; ^1H nmr δ: 1.0–1.45 (m, 6, $-OCH(CH_3)OCH_2CH_3$), 1.45 (s, 3, $-C(CH_3)$), 3.36 (s, 3, $-OCH_3$), 4.60 (two d, 1, H-1), 4.90 (two q, 1, $-OCH(CH_3)CH_2CH_3$).

*3'-*N*-Methyl-2'-phenyl-(methyl 3,4-dideoxy-4-*C*-methyl-α-L-arabinopyranosido)-[3,4:4',5')-oxazolidine (**15**)*

The starting material **13***b* (0.395 g, 1.18 mmol) was dissolved in nitromethane (10 mL) to which was added methyl iodide (0.20 mL, 2.36 mmol). The reaction flask was fitted with a reflux condenser and heated with stirring at 70–80°C for 24 h. At this time more methyl iodide was added (0.20 mL, 2.36 mmol), and the reaction mixture was heated an additional 24 h. Analysis by tlc indicated the replacement of starting material by a new, uv active spot at the base line. Solvent and remaining reagent were removed under reduced pressure to yield a syrupy residue, presumably **14**.

The residue was redissolved in absolute methanol (15 mL) and the solution was cooled in an ice bath. To this was added sodium borohydride (0.045 g, 1.18 mmol) and the mixture was stirred for 1 h at 5°C, with the exclusion of moisture. At this time tlc indicated that the base line material had been replaced by a more mobile compound having R_f 0.58 (solvent A). The reaction vessel was allowed to warm to room temperature and, after slow addition of small amounts of water, the contents were partitioned between equal volumes of water and methylene chloride. The layers were separated and the aqueous layer was extracted twice more with methylene chloride. The organic layers were combined, dried over sodium sulfate, and evaporated. Chromatography of the residue (solvent A) yielded solid oxazolidine **15** (0.201 g, 61.5%). Recrystallization from ethyl acetate gave pure **15** which showed mp 101.5–102.5°C; $[\alpha]_D^{23}$ −3.3° (*c* 0.6, chloroform); ir ν_{max}: 3300–3650 (OH stretch) cm^{-1}; ^1H nmr δ: 1.43 (s, 3, $-CCH_3$), 2.34 (s, 3, $-NCH_3$), 2.60 (d, 1, $J_{2,3}$ = 5 Hz, H-3), 3.10 (bs, 1, —OH), 3.31–4.10 (m, 3, H-2, H-5, H-5'), 3.43 (s, 3, $-OCH_3$), 4.58 (d, 1, $J_{1,2}$ = 4 Hz), 4.90 (s, 1, benzylidine-methine), 7.40–7.70 (m, 5, aromatic protons). *Anal.* calcd. for $C_{15}H_{21}O_4H$: C 64.50, H 7.58, N 5.01; found: C 64.75, H 7.95, N 5.41.

*Methyl 3,4-dideoxy-3-(*N*-ethoxycarbonyl-*N*-methylamino)-4-*C*-methylene-α-L-*threo*-pentopyranoside (**16**b)*

The epoxy olefin **5** (0.77 g, 5.4 mmol) was dissolved in absolute ethanol (30 mL) and placed in a pressure vessel. The vessel was cooled in an ice bath and gaseous methylamine was bubbled through the ethanol solution for 15 min. The vessel was then sealed, placed in an oil bath, and heated to 80°C. After 30 min the vessel was removed, cooled to room temperature, and the contents concentrated. The product, obtained as a heavy brown oil, was dissolved in 10 mL of chloroform. To this was added sodium bicarbonate (0.361 g, 2.2 mmol) and ethyl chloroformate (0.39 mL, 2.5 mmol). After stirring for 15 min, saturated sodium bicarbonate solution (20 mL) was added and the mixture was stirred for an additional 15 min. The aqueous and organic layers were separated and the aqueous phase was washed three times with methylene chloride. The organic layers were combined, dried, and evaporated to dryness. The product **16***b* was obtained as a beige solid (0.287 g, 55%) which, upon recrystallization from ethanol, gave the following physical data: mp 132.5–133°C; $[\alpha]_D^{23}$ −63.3° (*c* 1.0, chloroform); ir ν_{max}: 1695 (urethane C=O stretch), 3300–3600 (OH stretch) cm^{-1}; ^1H nmr δ: 1.25 (t, 2, $-OCH_2CH_3$), 2.89 (s, 3,

For personal use only.

—NHCH_3), 3.58 (s, 3, —OCH_3), 4.9 (bd, 3, =CH_2, H-1); *m/e*: 245 (M^+), 227 ($M^+ - H_2O$), 214 (M^+ − OMe), 185 ($M^+ - C_2O_2H_4$). *Anal.* calcd. for $C_{11}H_{19}O_5N$: C 53.87, H 7.81, N 5.71; found: C 53.88, H 8.05, N 5.68.

*Methyl 3,4-dideoxy-3-(*N*-ethoxycarbonyl-*N*-methyl amino)-2-O-ethoxyethyl-4-C-methylene-α-*L*-*threo*-pentopyranoside (**16***c*)*

Urethane **16***b* (0.082 g, 0.33 mmol) was treated with ethyl vinyl ether in a similar manner as used in the preparation of **8***c*. The crude syrup obtained was chromatographed on silica gel using solvent A. Compound **16***c* (0.092 g, 86%) was obtained as a thick oil; R_f 0.52 (solvent A); ir ν_{max}: 1690 (urethane C=O stretch) cm^{-1}; ^1H nmr δ: 1.0−1.5 (m, 9, —$OCH(CH_3)OCH_2CH_3$, —OCH_2CH_3), 2.78, 2.81 (two s, 3, —NCH_3), 3.5 (two, s, 3, —OCH_3), 4.93 (bd, 4, =CH_2, H-1, —$OCH(CH_3)OCH_2CH_3$).

*3′-*N*-Methyl-2′-oxo-(methyl 3,4-dideoxy-2-O-α-ethoxyethyl-4-C-iodomethyl-α-*L*-arabinopyranosido)-[4,4:4′5′]-oxazolidone (**17**a)*

The starting material **16***c* (0.162 g, 0.051 mmol) was dissolved in chloroform, to which was added one equivalent of iodonium dicollidine perchlorate (0.202 g, 0.051 mmol). The resulting solution was stirred in the dark for five days, a fresh equivalent of iodonium dicollidine perchlorate being added per 24 h of reaction time. The reaction mixture was worked up by addition of diethyl ether. Unreacted reagent was filtered off and the filtrate was concentrated under vacuum. The residue was dissolved in methylene chloride and washed with 10% sodium thiosulfate, then 5% hydrochloric acid and, finally, water. The aqueous layers were washed successively with two fresh aliquots of methylene chloride. The organic layers were combined, dried over sodium sulfate, and evaporated to dryness to yield **17***a* (0.174 g, 82%); it showed R_f 0.46 (solvent A); ir ν_{max}: 1740 (urethane C=O stretch) cm^{-1}; ^1H nmr δ: 1.20−1.40 (m, 6, —$OCH(CH_3)OCH_2CH_3$), 2.84, 2.93 (two s, 3, —NCH_3), 3.38, 3.40 (two s, 3, —OCH_3), 3.51, 3.54 (two s, 2, —CH_2I), 4.58, 4.69 (two d, 1, H-1), 4.86 (d, 1, —$OCH(CH_3)OCH_2CH_3$).

*3-*N*-Methyl-2′-oxo-(methyl 3,4-dideoxy-2-O-ethoxyethyl-4-C-methyl-α-*L*-arabinopyranosido)-[3,4:4′,5′]-oxazolidone (**17**b)*

Compound **17***a* (0.238 g) was placed in a Parr hydrogenation flask, then dissolved in methanol/water, 9:1 (20 mL). One pellet of potassium hydroxide and 10% palladium on carbon (50 mg) were added. The mixture was shaken under 20 atm of hydrogen for 24 h (1 atm = 101.3 kPa). The reaction mixture was filtered and the filtrate was partitioned between water and methylene chloride. The organic layer was separated and washed with 5% hydrochloric acid followed by water. The aqueous layers were washed successively with two portions of methylene chloride. The combined organic layers were dried over sodium sulfate and evaporated to yield **17***b* (0.162 g, 76.8%); ir ν_{max}: 1750 (urethane C=O stretch) cm^{-1}; ^1H nmr δ: 1.1−1.45 (m, 6, —$OCH(CH_3)OCH_2CH_3$), 1.51 (s, 3, —$C(CH_3)$—), 2.92, 2.98 (two s, 3, —$N(CH_3)$—), 3.4 (s, 3, —OCH_3), 4.60, 4.72 (two d, 1, H-1), 4.90 (two q, 1, —$OCH(CH_3OCH_2CH_3)$).

*3-*N*-Methyl-2′-oxo-(methyl 3,4-dideoxy-4-C-methyl-α-*L*-arabinopyranosido)-[3,4:4′,5′]-oxazolidone (**17**c)*

(a) Starting material **17***b* (0.162 g, 0.561 mmol) was dissolved in ethanol (10 mL) to which was added pyridinium *p*-toluene sulfonate (22) (0.017 g, 0.056 mmol). The solution was warmed on a steam bath until all the starting material had reacted. The ethanol was evaporated and the residue was taken up in methylene chloride (40 mL) and brine (15 mL). The layers were separated and the aqueous portion was washed twice more with methylene chloride. The organic layers were dried and evaporated to yield solid **17***c* (0.112 g, 92.1%). Recrystallization from ethyl acetate, followed by chloroform and hexane, yielded the following physical constants: mp 136−137°C; $[\alpha]_D^{23}$ −44.3° (*c* 0.5 chloroform); ir ν_{max}: 1750 (C=O stretch) cm^{-1}; ^1H nmr (220 MHz) δ: 1.48 (s, 3, —CCH_3), 3.03 (s, 4, —NCH_3, —OH), 3.40 (d, 1, $J_{2,3}$ = 6 Hz), 3.50 (s, 3, —OCH_3), 3.75 (m, 1, H-2), 3.81 (ABq, 2, $J_{5,5'}$ = 12.5 Hz, H-5, H-5′), 4.39 (d, 1, $J_{1,2}$ = 5.5 Hz). *Anal.* calcd. for $C_9H_{15}O_5N$: C 49.76, H 6.96, N 6.45; found: C 49.66, H 6.84, N 6.33.

(b) Compound **18** (0.240 g, 0.738 mmol), derived from authentic methyl α-*L*-garosaminide (12), was dissolved in dry DMF (15 mL) and cooled in an ice bath. A small amount of 50% sodium hydride dispersion in oil (0.040 g, 0.833 mmol) was washed three times with petroleum ether (bp 30−60°C) and added to the reaction vessel. The mixture was stirred at 0°C with exclusion of moisture until tlc indicated that compound **18**, R_f 0.45 (Solvent C), had been replaced by a new, more polar product. The flask contents were partitioned between water, added slowly, and methylene chloride. The organic layer was separated, dried, and evaporated to yield a white solid (0.112 g, 70%). The material was recrystallized from ethyl acetate, followed by chloroform and hexane, to give oxazolidone **17***c* of part (a); it showed a mixture mp 134.5−136°C.

*Methyl α-*L*-garosaminide (**2**)*

(a) The starting material **15** (0.111 g, 0.398 mmol) was dissolved in absolute methanol (30 mL) to which was added methanolic hydrochloric acid (13.5%, 5 mL). The solution was stirred at room temperature, with exclusion of moisture, for 24 h, at which time tlc (solvent A) indicated the replacement of **15** by a new material at the base line. The methanol was removed under vacuum and the resulting residue was partitioned between 5% hydrochloric acid (40 mL) and methylene chloride (40 mL). The aqueous layer was separated, neutralized with 5% sodium hydroxide, and evaporated to dryness. The solid obtained was extracted three times with hot ethyl acetate. The ethyl acetate was evaporated to yield amorphous, solid methyl α-garosaminide **2** (0.054 g, 70.1%). This material refused recrystallization from ethanol, but its nmr, ir, and tlc behavior matched that of the authentic sample (12).

(b) The starting oxazolidone **17***c* (0.112 g, 0.516 mmol) was added to 15% KOH (20 mL) and the reaction vessel was fitted with a condenser. The mixture was heated to 50−60°C for 6 h, at which time tlc (solvent A) indicated the replacement of **17***c* by a new material at the base line. The solution was acidified with 10% sulfuric acid and washed once with methylene chloride. The aqueous layer was neutralized with 5% sodium hydroxide and then evaporated to dryness. The solid remaining was extracted three times with hot ethyl acetate, which was removed under vacuum to yield **2** (0.067 g, 72%) as a thick syrup. The physical constants were identical with those of the material described in part (a).

Acknowledgements

We are grateful to NSERC for support of this work by means of an operating grant, and a PRAI grant.[4] In connection with the latter we express our thanks to Bristol Laboratories, Candiac, Quebec, particularly Drs. Marcel Menard and Ivo Monkovic, for helpful discussions. We also thank Dr. J. J. Wright of Schering Corporation for generous samples of **2** and **18**.

Stereocontrolled routes to *cis*-hydroxyamino sugars. Part VII.[1] A synthesis of holacosamine[2]

MICHAEL GEORGES,[3] D. MACKAY, AND BERT FRASER-REID[4]
Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received October 14, 1983

MICHAEL GEORGES, D. MACKAY, and BERT FRASER-REID. Can. J. Chem. **62**, 1539 (1984).

Methyl 4,6-di-*O*-*p*-toluenesulfonyl-α-D-*threo*-hex-2-enopyranoside **4***b* reacts with methylamine at room temperature to displace the allylic sulfonate only, and the ethyl urethane of the resulting 4-*N*-methylamino sugar is cyclized with iodonium ion to give the 2-iodo-oxazolidinone, **13**. This substance, upon treatment with sodium iodide in acetone, gives the 2,6-diiodide **14***a*. Deiodination, followed by base hydrolysis, gives the *cis*-hydroxyamino precursor, which upon *N*-acetylation and *O*-methylation affords the previously known holacosaminide **1***b*.

MICHAEL GEORGES, D. MACKAY et BERT FRASER-REID. Can. J. Chem. **62**, 1539 (1984).

Le di-*O*-*p*-toluènesulfonyl-4,6 α-D-*thréo*-hexèno-2 pyrannoside de méthyle (**4***b*) réagit avec la méthylamine à la température ambiante pour déplacer uniquement le sulfonate allylique; l'éthyl uréthane du sucre *N*-méthylamino-4 qui en résulte se cyclise avec l'ion iodonium pour donner l'iodo-2 oxazolidinone (**13**). Cette substance, sous l'action de l'iodure de sodium dans l'acétone, conduit au dérivé diiodo-2,6 (**14***a*). L'élimination de l'iode, suivie d'une hydrolyse alcaline, conduit au précurseur amino-alcool-*cis* qui, par *N*-acétylation et *O*-méthylation, fournit l'holacosaminide déjà connu, **1***b*.

[Traduit par le journal]

In the accompanying paper (1) we gave full details of a new synthesis of garosamine in which the troublesome *cis*-hydroxyamino moiety and the tertiary hydroxyl group were established simultaneously by means of iodonium ion-induced cyclization of an allylic amide, for example **I**–**III**, Scheme 1. A secondary feature of this crucial process of the introduction of the iodine atom which opens the way for several additional transformations, of which reductive deiodination is one of the more obvious. Thus, a ready route to polydeoxyamino sugars is suggested, and in order to develop this chemistry we looked at the trideoxyamino sugar, holacosamine **1***a*. In this paper we give full details of this study, which was reported previously in preliminary form (2).

Holacosamine, **1***a* (Scheme 3), was first obtained from the amino glycosteroids, holacurtin, **2***a*, and holarosine, **2***b*, isolated from the leaves of *Holarrhena curtisii* which is a native plant of Malaysia (3). The sugar was subsequently isolated from the corticosteroid, mitiphylline, extracted from the leaves of *Holarrhena mitis* from Sri Lanka (4). These compounds have cardiotonic activity, and there is also some interest in them as anti-cancer drugs in view of the discovery that some glycosteroids have significant inhibitory activity against human carcinoma of the nasopharynx (5). An early synthesis of holacosamine was reported by Gero and co-workers (6), but the number of epimerizations needed to establish the proper stereorelationships, the harsh conditions for most of these reactions, and their low yield illustrate the problems associated with even such a relatively simple *cis*-hydroxyamino sugar.

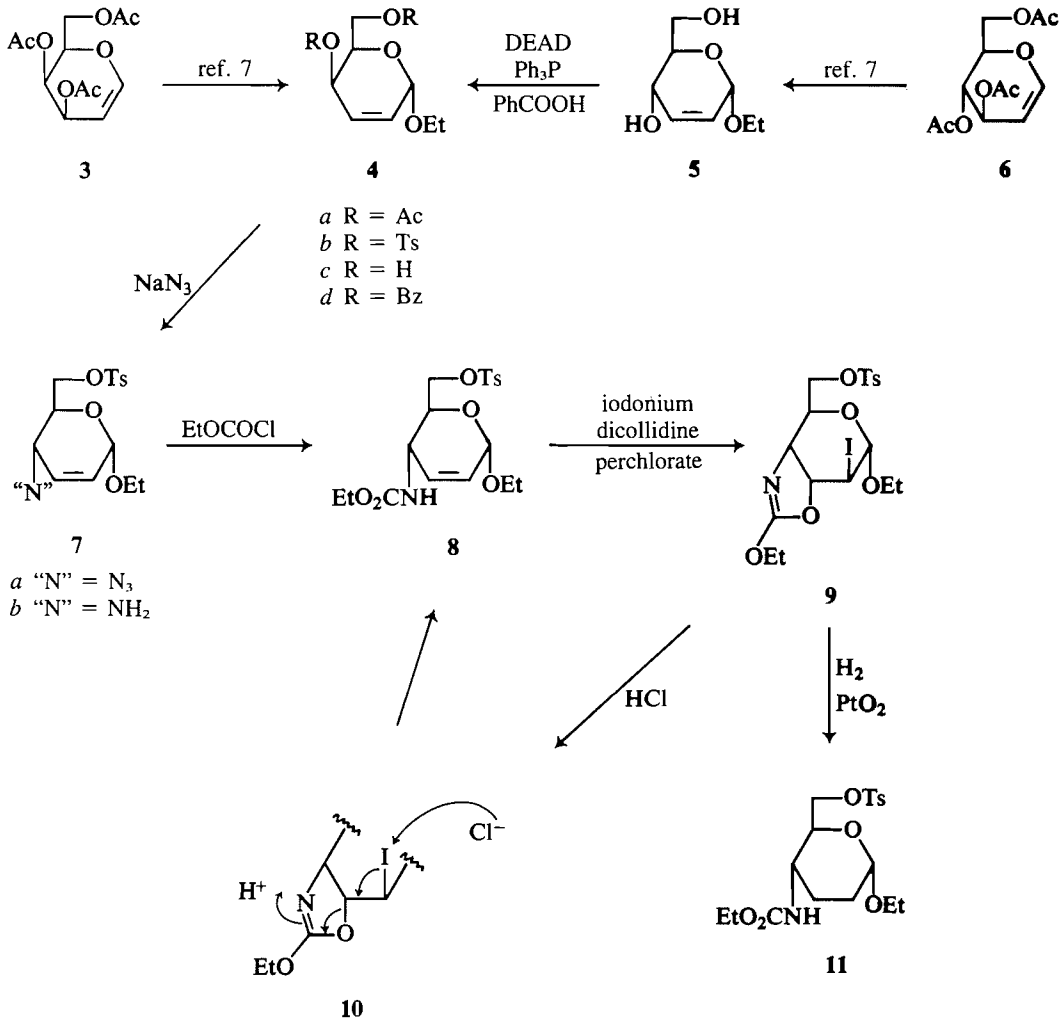
Application of the process depicted in **I** → **II** → **III**, Scheme 1, would require the unsaturated amino sugar **7** whose preparation from the *threo*-hex-2-eno-pyranoside **4***b* is apparent. Although the corresponding diacetate **4***a* is obtainable in one step from "triacetyl galactal" by the Ferrier rearrangement (7), considerations of economy and efficiency make the three-step sequence beginning with commercially available "triacetyl glucal", **6**, more attractive (7). As was the case in Gero's synthesis (6), we faced a double inversion sequence to establish the C-4 nitrogen in **7**. However, since our reactions would be occurring at an allylic site, much milder conditions would be required.



SCHEME 2

Reaction of the diol **5** under the Mitsunobu conditions (8), as modified by Galynker and Still (9), allowed for direct conversion into the disulfonate **4***b*. Although this modification (9) saves two steps in the sequence, the necessity of using five equivalents of diethyl azodicarboxylate per hydroxyl group did not make it very practical for large scale preparations and conventional sulfonation was therefore preferred. Accordingly, **5** was converted into the dibenzoate **4***d* by the Mitsunobu reaction (8), and the latter was converted into the disulfonate **4***b* via diol **4***c*. Reaction of **4***b* with sodium azide in dimethyl sulfoxide at room temperature displaced only the allylic sulfonate, and the structure of the product **7***a* was apparent from the value $J_{3,4}$ = 1 Hz. The azide was reduced to the amine **7***b* with lithium aluminium hydride in ether at −25°C. Treatment of the derived urethane, **8**, with iodonium dicollidine perchlorate (10) in methylene chloride gave the oxazoline **9**, instead of an oxazolidinone as in the garosamine synthesis (1).

Very surprisingly, hydrolysis of **9** with 0.5 *N* hydrochloric acid at room temperature for 1.5 h regenerated the allylic urethane **8**. We rationalized that this course of reaction was triggered by protonation of the nitrogen with the eventual collapse depicted in **10**. Removal of the C-2 iodine should, therefore, prevent this process, but reductive deiodination of **9** proved remarkably difficult. Hydrogenolysis did not occur with palladium as catalyst, and with platinum, two products in the ratio 7:1 were obtained, the major of which proved to be **11**. Compound **11** is probably formed by a homolytic fragmentation comparable to the heterolytic process depicted in **10**, followed by hydrogenation of the double bond.

4b **12** *a* X = H; *b* X = CO_2Et

13 Y = OTs; X = I
14 *a* X = Y = I; *b* X = Y = H

15 *a* X = R = H; R′ = Et; *b* X = Ac; R = H; R′ = Et

1 *a* X = Ac; R = Me; R′ = H; *b* X = Ac; R = Me; R′ = Et

SCHEME 3

The difficulties experienced with **9** contrasted with the smooth process in the garosamine case (1), and suggested that at least part of our problem might be due to the fact that our intermediate **9** was a 2-ethoxy oxazolidine instead of an oxazolidinone. The presence of a C-4 *N*-methyl substituent, ultimately required at C-4 of **1**, would preclude the formation of such a 2-ethoxy oxazolidine, and so the ammonolysis of **4***b* was examined. The pressure vessel method used in our earlier work (1) led to decomposition, but use of dimethyl sulfoxide saturated with methylamine at room temperature afforded a 71% yield of **12***a*. Reaction of the derived urethane **12***b* with iodonium dicollidine perchlorate (10) at room temperature did give the desired oxazolidone **13**, but a second, unstable product obtained in 25% yield vitiated this result. The structure of the latter material was not determined, but patient experimentation showed that its formation could be avoided by adding the iodonium salt in small portions to **12***b* in refluxing dioxane.

When **13** was heated in refluxing acetone containing sodium iodide, the diiodourethane **14***a* was obtained and this was reduced with tri-*n*-butyltin hydride in refluxing benzene to afford the trideoxy sugar **14***b*. Hydrolysis of the oxazolidone with 5% potassium hydroxide proceeded smoothly to yield the *cis* vicinal hydroxyamine, **15***a*. *N*-Acetylation of the latter followed by *O*-methylation of the product, **15***b*, yielded *N*-acetyl holacosamine **1***b*. An attempt to procure an authentic sample of holacosamine from Gero (6) was unsuccessful. However, the synthetic sample of **1***b* gave compatible 400 MHz ^{1}H nmr and ir spectra, as well as microanalytical data (see Experimental).

Experimental

General methods

Melting points were determined in capillary tubes in a Buchi Model 510 and are uncorrected. Elemental analyses were performed by Guelph Chemical Labs, Guelph, Ontario and by Dr. F. Kasler, Department of Chemistry, University of Maryland. The ^{1}H nmr spectra were determined in deuteriochloroform with internal tetramethylsilane as the standard, unless otherwise stated, on one of the following spectrometers: Varian T-60, Bruker WP-80, or Bruker WH-400. Coupling constants were measured directly from the spectra or calculated from the peak listings. The ir spectra were determined on either a Beckman IR-10 or a Perkin–Elmer 298 spectrometer. Neat samples were smeared on sodium chloride plates and solutions were placed in sodium chloride cells. Low resoltuion ms were run on a Hitachi/Perkin–Elmer RMH-2. Optical rotations were determined on a Perkin–Elmer 241 polarimeter.

Thin layer chromatography (tlc) was performed using aluminum plates precoated with silica gel (HF-254, 0.2 mm thickness) containing a fluorescent indicator (E. Merck, CAT. 5539). The chromatograms were viewed under a uv light (254 nm), sprayed with concentrated sulfuric acid, and heated until charring occurred.

Column chromatography was carried out using silica gel (E. Merck 70–230 mesh A.S.T.M. or 230–500 mesh A.S.T.M.).

*Ethyl 2,3-dideoxy-α-D-*threo*-hex-2-enopyranoside, 4*c

To a solution of **5** (11) (1.74 g, 10 mmol) triphenylphosphine (5.76 g, 22 mmol), and benzoic acid (2.68 g, 22 mmol) in dry tetrahydrofuran (50 mL) at 23°C under argon was added, over a period of 5 min, diethyl azodicarboxylate (3.82 g, 22 mmol). The reaction mixture was stirred for 30 min, after which time the solvent was removed *in vacuo*. The resulting oily mixture was purified by medium pressure chromatography on silica gel (30:70 diethyl ether – petroleum ether 30–60°C, R_f 0.57) to afford 3.31 g (85%) of the known (12) **4***d* dibenzoate as a colourless oil; ir ($CHCl_3$) ν_{max}: 2910, 1715 (benzoate), 1614, 1600, 1310–1160, 1110–950 cm^{-1}; ^{1}H nmr (80 MHz) δ: 1.23 (t, 3H, OCH_2CH_3), 3.39–4.06 (m, 2H, OCH_2CH_3), 4.42–4.78 (m, 3H, H5, H6, H6), 5.17 (d, J = 3 Hz, 1H, H1), 5.38 (bd, J = 5.3 Hz, 1H, H4), 6.09 (dd, J = 3, 10 Hz, 1H, H2), 6.31 (dd, J = 5.1, 10 Hz, 1H, H3), 7.30–7.60 (m, 6H, aromatic), 7.94–8.13 (m, 4H, aromatic).

To a solution of **4***d* (4.36 g, 11mmol) in methanol (50 mL) at 23°C was added a catalytic amount of sodium methoxide (100 mg). The reaction mixture was stirred for 2 h, after which time the solvent was removed *in vacuo*. The resulting mixture was chromatographed on silica gel (7:93 methanol – methylene chloride, R_f 0.32) to afford 1.51 g (75%) of an oil that crystallized upon standing. Recrystallization from methylene chloride – hexane afforded the known diol **4***c* as a crystalline material, mp 75–76°C (lit. (11) mp 76–77°C).

*Ethyl 2,3-dideoxy-4,6-di-*O*-p-toluenesulfonyl-α-D-*threo*-hex-2-enopyranoside, 4*b

To a solution of **4***c* (4.00 g, 23 mmol) in dry pyridine (30 mL) cooled to −40°C, *p*-toluenesulfonyl chloride (8.70 g, 46 mmol) and dry pyridine (20 mL) were added over 20 min. After 48 h at 0°C the reaction mixture was poured into ice water, carefully neutralized with 1 *N* HCl, and extracted with methylene chloride (1 × 75, 2 × 25 mL). The methylene chloride fractions were combined, washed with a saturated aqueous sodium chloride solution, dried over sodium sulfate, and concentrated *in vacuo* to yield an oil. Medium pressure chromatography on silica gel (2:98 methanol – methylene chloride) followed by recrystallization (ether–hexane) afforded 9.52 g (86%) of pure **4***b* mp 78–79°C; R_f 0.36 (methylene chloride); $[\alpha]_D^{23}$ −11.3° (*c* 0.7, in $CHCl_3$); ir ν_{max} ($CHCl_3$): 2920, 1594 (C=C), 1464 (SO_2), 1168 (SO_2), 1097, 1000, 972 cm^{-1}; ^{1}H nmr (80 MHz) δ: 1.20 (t, 3H, OCH_2CH_3), 2.48 (s, 6H, tosyl CH_3), 3.25, 4.00 (m, 2H, OCH_2CH_3), 4.12 (2d, J = 2, 2.5, 6 Hz, 2H, H6, H6), 4.31 (ddd, J = 2.5, 6 Hz, 1H, H5), 4.67 (dd, J = 2.5, 5 Hz, 1H, H4), 4.97 (d, J = 2.5 Hz, 1H, H1), 5.82 (dd, J = 5, 10 Hz, 1H, H3), 6.03 (dd, J = 2.5, 10 Hz, 1H, H2), 7.33 (d, 4H, aromatic), 7.78 (d, 4H, aromatic). *Anal.* calcd. for $C_{22}H_{26}O_8S_2$: C 54.76, H 5.43; found: C 54.90, H 5.17.

*Ethyl 4-azido-2,3,4-trideoxy-6-*O*-p-toluenesulfonyl-α-D-*erythro*-hex-2-enopyranoside, 7*a

To a solution of **4***b* (12.7 g, 26 mmol) in dry dimethyl sulfoxide

(20 mL) under argon at 23°C was added sodium azide (2.40 g, 37 mmol). The reaction mixture was stirred for 45 min, poured into 100 mL of ice water, and extracted with ethyl acetate (1 × 100, 1 × 30 mL). The ethyl acetate fractions were combined, washed with a saturated aqueous sodium chloride solution, dried over sodium sulfate, and concentrated *in vacuo* to afford 7.20 g (77%) of **7***a* as a colourless oil; R_f 0.69 (methylene chloride); ir ν_{max} ($CHCl_3$): 2900, 2100 (N_3), 1585 (tosylate), 1430, 1350, 1270, 1220, 1155, 1100, 1084, 990, 955, 910 cm^{-1}; ^1H nmr (80 MHz) δ: 1.19 (t, 3H, OCH_2CH_3), 2.46 (s, 3H, ϕCH_3), 3.30–3.95 (m, 4H, OCH_2CH_3, H4, H5), 4.25 (bs, 2H, H6, H6), 4.95 (s, 1H, H1), 5.93 (s, 2H, H2, H3), 7.35 (bd, 2H, aromatic), 7.82 (bd, aromatic); *m/e*: 325 ($M^+ - N_2$).

*Ethyl 4-amino-2,3,4-trideoxy-6-*O-p-*toluenesulfonyl-α-D-*erythro-*hex-2-enopyranoside,* **7**b

To a suspension of lithium aluminum hydride (380 mg, 10 mmol) in dry ether (150 mL) at −25°C under an atmosphere of argon was added, over 10 min, **7***a* (7.20 g, 20 mmol) in dry ether (50 mL). The reaction mixture was stirred for 20 min. The excess lithium aluminum hydride was destroyed by the slow addition of sodium sulfate decahydrate. The resulting precipitate was removed by filtration. The filtrate was concentrated *in vacuo* to afford 6.00 g (90%) of **7***b* as a clear oil; R_f 0.52 (110:90 methanol − methylene chloride); ir ν_{max} ($CHCl_3$): 3410, 3320 (amine), 2985, 2900, 1600 (tosylate, amine), 1455, 1320, 1120, 975, 970 cm^{-1}; ^1H nmr (80 MHz) δ: 1.19 (dt, 3H, OCH_2CH_3), 1.39 (s, 2H, NH_2), 2.45 (s, 3H, CH_3), 3.21–3.87 (m, 4H, OCH_2CH_3, H4, H5), 4.26 (d, 2H, H6, H6), 4.87 (bs, 1H, H1), 5.66–5.77 (m, 2H, H2, H3), 7.32 (bd, 4H, aromatic), 7.71 (bd, 4H, aromatic); *m/e*: 283 (($M^+ + 1$)-OC_2H_5), 282 ($M^+ - OC_2H_5$).

*Ethyl 2,3,4-trideoxy-4-*N-*ethoxycarbonylamino-6-*O-p-*toluenesulfonyl-α-D-*erythro-*hex-2-enopyranoside,* **8**

To a solution of **7***b* (790 mg, 2.4 mmol) and triethylamine (0.42 mL, 3 mmol) in dry methylene chloride (15 mL) at 0°C under argon was added, over 5 min, ethyl chloroformate (0.25 mL, 2.6 mmol) in dry methylene chloride (3 mL). The mixture was stirred for 30 min and then methanol (~0.5 mL) was added to destroy any remaining ethyl chloroformate. The reaction mixture was washed with water, dried over sodium sulfate, and concentrated *in vacuo*. Purification by medium pressure chromatography on silica gel (2:3 diethyl ether − methylene chloride, R_f 0.82) afforded 828 mg (86%) of **8** as a colourless oil; ir ν_{max} ($CHCl_3$): 3440 (NH), 2900, 1725 (urethane), 1610, 1590, 1375, 1310, 1185, 1108, 1005, 985 cm^{-1}; ^1H nmr (80 MHz) δ: 1.21 (dt, 6H, OCH_2CH_3), $CO_2CH_2CH_3$), 2.45 (s, 3H, CH_3), 3.38–4.70 (m, 9H, OCH_2CH_3, $CO_2CH_2CH_3$, H4, H5, H6, H6, NH), 4.94 (s, 1H, H1), 5.77 (s, 2H, Hs, H3), 7.32 (d, 2H, aromatic), 7.80 (d, 2H, aromatic); *m/e*: 355 (($M^+ + 1$)-OC_2H_5), 354 ($M^+ - OC_2H_5$).

*2′-Ethoxy (ethyl 2,4-dideoxy-2-iodo-6-*O-p-*toluenesulfonyl-α-D-altropyranosido)-[3,4:5′,4′]-Δ²-oxazoline,* **9**

A solution of **8** (399 mg, 1 mmol) and iodonium dicollidine perchlorate (10) (702 mg, 1.5 mmol) in dry methylene chloride (7 mL) was stirred under argon at 23°C in the dark. After 6 h an additional 350 mg (0.75 mmol) of iodonium dicollidine perchlorate were added and the reaction was allowed to continue for 18 h. The reaction mixture was poured into diethyl ether (25 mL) and filtered. The filtrate was concentrated *in vacuo* to yield a reddish coloured oil. Purification by medium pressure chromatography on silica gel (10:90 diethyl ether − methylene chloride) followed by recrystallization (diethyl ether − hexane) afforded 320 mg (61%) of **9**; R_f 0.76 (3:7 diethyl ether − methylene chloride); ir ν_{max} ($CHCl_3$): 2900, 1658 (C=N), 1595, 1362, 1324, 1170, 1100, 990, 915 cm^{-1}; ^1H nmr (80 MHz) δ: 1.08–1.40 (m, 6H, 2(OCH_2CH_3)), 2.45 (s, 3H, ϕCH_3), 3.48–4.34 (m, 10 H, C2, C3, C5, C6, C6, 2(OCH_2CH_3)), 5.13 (d, 1H, H1), 7.26–7.38 (bd, 2H, aromatic), 7.73–7.86 (bd, 2H, aromatic); *m/e*: 526 ($M^+ + 1$), 525 (M^+).

*Ethyl 4-*N-*ethoxycarbonylamino-2,3,4-trideoxy-6-*O-p-*toluenesulfonyl-α-D-*erythro-*hexopyranoside,* **11**

Product **9** (120 mg, 0.20 mmol) in methanol (10 mL) and triethylamine (0.25 mL) was hydrogenated over platinum oxide (10 mg). After 2 h the reaction mixture was filtered through a bed of Celite. The filtrate was evaporated to dryness *in vacuo*. Purification by medium pressure chromatography (30:70 diethyl ether − chloroform, R_f 0.65) followed by recrystallization (methylene chloride − hexane) afforded 35 mg (38%) of **11** as crystals, mp 116–117°C; ir ν_{max}: 3418 (NH), 1710 (urethane), 1600, 1450 (tosylate), 1290, 1117, 973, 951 cm^{-1}; ^1H nmr (80 MHz) δ: 1.21 (dt, 6H, OCH_2CH_3, $CO_2CH_2CH_3$), 1.60 (s, 1H, NH), 1.68–1.86 (m, 4H, H2, H2, H3, H3), 2.43 (s, 3H, ϕCH_3), 3.22–4.57 (m, 9H, H4, H5, H6, H6, OCH_2CH_3, $CO_2CH_2CH_3$), 4.77 (bs, 1H, H1), 7.36 (2bs, 2H, aromatic), 7.79 (2bs, 2H, aromatic). *Anal.* calcd. for $C_{18}H_{27}N\,O_7S$: C 53.86, H 6.73, N 3.49; found: C 54.20, H 7.05, N 3.30.

*Ethyl 2,3,4-trideoxy-4-*N-*methylamino-6-*O-p-*toluenesulfonyl-α-D-*erythro-*hex-2-enopyranoside,* **12**a

To a solution of dry dimethyl sulfoxide saturated with methylamine (1 mL) was added **4***b* (110 mg, 0.2 mmol). The reaction mixture was allowed to stand at room temperature for 1.5 h, during which time the colour changed from light yellow to wine red. The reaction mixture was diluted with 3 mL of ice water and extracted with ethyl acetate (3 × 5 mL). The ethyl acetate fractions were combined, washed with a saturated aqueous sodium chloride solution, dried, and concentrated *in vacuo* to afford an orange-red oil. Purification by medium pressure chromatography on silica gel (8:92 methanol − methylene chloride, R_f 0.50) afforded 55 mg (71%) of **12***a* as a colourless oil: $[\alpha]_D^{23}$ +160.5° (*c* 1.1, in $CHCl_3$) ir ν_{max}: ($CHCl_3$) 3680 (NH), 3460 (NH), 2880, 2480, 1598 (C=C), 1425, 1355 (S[=O]$_2$), 1100, 995, 925 cm^{-1}; ^1H nmr (80 MHz) δ: 1.00 (s, 1H, NH), 1.22 (t, 3H, OCH_2CH_3), 1.38 (s, 3H, ϕCH_3), 1.48 (s, 3H, NCH_3), 2.48 (bd, 1H, H4), 3.34–3.95 (m, 3H, OCH_2CH_3, H5), 4.28–4.48 (m, 2H, H6, H6), 4.94 (bs, 1H H1), 5.88 (dt, J = 2 Hz, 10 Hz, 1H, H3), 6.08 (bd, J = 10 Hz, 1H, H2), 7.35 (2bs, 2H, aromatic), 7.83 (2s, 2H aromatic); *m/e*: 297 (($M^+ + 1$)-OC_2H_5), 296 ($M^+ - OC_2H_5$).

*Ethyl 2,3,4-trideoxy-4-*N-*ethoxycarbonyl-*N-*methylamino)-6-*O-p-*toluenesulfonyl-α-D-*erythro-*hex-2-enopyranoside,* **12**b

To a solution of **12***a* (1.90 g, 5.6 mmol) and triethylamine (606 mg, 6 mmol) in dry methylene chloride (35 mL) under argon at 0°C was added, over 5 min, ethyl chloroformate (0.57 mL, 6 mmol) in dry methylene chloride (10 mL). The reaction mixture was stirred for 2 h, quenched with 1 mL of methanol, washed with a saturated aqueous sodium chloride solution, dried over sodium sulfate, and concentrated *in vacuo*. Purification by medium pressure chromatography on silica gel (3:97 methanol − methylene chloride, R_f 0.73) afforded 1.80 g (79%) of **12***b* as a colourless oil: $[\alpha]_D^{23}$ +34.3° (*c* 1.1, in $CHCl_3$); ir ν_{max} ($CHCl_3$): 2887, 1680 (urethane), 1593, 1357, 1291, 1127, 959 cm^{-1}; ^1H nmr (80 MHz) δ: 1.25 (dt, 6H, OCH_2CH_3, $CO_2CH_2CH_3$), 2.46 (s, 3H, ϕCH_3), 2.75 (s, 3H, NCH_3), 3.37–3.88 (m, 2H, H4, H5), 3.88–4.31 (m, 6H, H6, H6, OCH_2CH_3, $CO_2CH_2CH_3$), 4.95 (bs, 1H, H1), 6.70 (bd, J = 10.6 Hz, 1H, H3), 6.93 (dt, J = 2.4, 10.6 Hz, 1H, H2); *m/e*: 370 (($M^+ + 2$]-OC_2H_5), 369 (($M^+ + 1$)-OC_2H_5), 368 (M^+-OC_2H_5).

*3′-*N-*methyl-2′-oxo-(ethyl 2,4-dideoxy-2-iodo-6-*O-p-*toluenesulfonyl-α-D-altropyranosido)-[3,4:5[,4′]-oxazolidone,* **13**

To a solution of **12***b* (1.20 g, 2.5 mmol) in 15 mL of refluxing dioxane under argon was added iodonium dicollidine perchlorate (1.75 g, 3.7 mmol). After 15 min a second addition of iodonium dicollidine perchlorate (0.88 g, 1,9 mmol) was made, followed by a third addition (0.88 g, 1.9 mmol) 15 min later. The reaction mixture was refluxed another 10 min, then cooled and concentrated *in vacuo*. The resulting dark oil was diluted with 75 mL of methylene chloride, washed with ice-cold 0.5 *N* hydrochloric acid, 0.5 *M* sodium thiosulfate, saturated aqueous sodium chloride, dried over sodium sulfate, and concentrated *in vacuo*. Further purification by medium pressure chromatography (diethyl ether, R_f 0.43) afforded 1.03 g (72%) of **13** as a colourless oil; $[\alpha]_D^{23}$ −2.9° (*c* 0.3, in $CHCl_3$); ir ν_{max} ($CHCl_3$): 2900, 1760 (urethane), 1590, 1600 (C=C tosylate), 1460 (tosylate), 1435 (R_2NCH_3), 1100, 995 cm^{-1}; ^1H nmr (80 MHz) δ: 1.19 (t, 3H, OCH_2CH_3), 2.48 (s, 3H, ϕCH_3), 2.85 (s, 3H, NCH_3), 3.29–4.38 (m, 7H, H2, H4, H5, H6, H6, OCH_2CH_3), 4.73 (dd, J = 8.0, 9.3 Hz, 1H,

H3), 5.12 (d, J = 6.0 Hz, 1H, H1), 7.30 (d, 2H aromatic), 7.82 (d, 2H, aromatic); *m/e*: 479 (M^+).

*3'-N-Methyl-2'-oxo-(ethyl 2,4,6-trideoxy-2,6-diiodo-α-D-altropyranosido)-[3,4:5',4]-oxazolidone, **14**a*

A solution of **13** (400 mg, 0.8 mmol) and sodium iodide (180 mg, 1.2 mmol) in dry acetone (10 mL) was refluxed for 6 h. The reaction mixture was cooled and concentrated *in vacuo*. The residue was diluted with methylene chloride (25 mL), washed with a saturated aqueous sodium chloride solution, dried over sodium sulfate, and concentrated again *in vacuo* to give a clear oil. Purification by medium pressure chromatography on silica gel (diethyl ether) followed by recrystallization (methylene chloride − hexane) afforded 280 mg (76%) of **14***a* as crystals, mp 109−110°C; R_f 0.53 (diethyl ether); $[\alpha]_D^{23}$ +7.5° (*c* 1, in $CHCl_3$); ir ν_{max} ($CHCl_3$): 3510 (carbonyl overtone), 2900, 1755 (urethane), 1590, 1421, 1373, 1348, 1125, 1098, 992, 955 cm^{-1}; ^1H nmr (400 MHz) δ: 1.24 (t, 3H, OCH_2CH_3), 2.92 (s, 3H, NCH_3), 3.29 (dd, J = 6.9, 11.2 Hz, 1H, H6), 3.52 (dd, J = 2.3, 11.2 Hz, 1H, H6), 3.58 (m, 1H, $OCH\,CH_3$), 3.78 (m, $J_{4,5}$ = 16.6 Hz, H4, H5), 3.95 (m, 1H, $OCH\,CH_3$), 4.08 (dd, J = 6.1, 9.4 Hz, 1H, H2), 4.76 (dd, J = 9.4, 8.0 Hz, 1H, H3), 5.20 (d, J = 6.1 Hz, 1H, H1). *Anal.* calcd. for $C_{10}H_{15}NO_4I_2$: C 25.71, H 3.24, N 3.00, I 54.34; found: C 25.75, H 3.30, N 3.00, I 54.92.

*3'-N-Methyl-2'-oxo-(ethyl 2,4,6-trideoxy-α-D-*ribo-hexapyranosido)-[3,4:5',4']-oxazolidone, ***14**a*

To a solution of **14***b* (250 mg, 0.5 mmol) in dry benzene (10 mL) under argon was added tri-*n*-butyltin hydride (0.4 mL, 1.5 mmol) and a catalytic amount of benzoyl peroxide. The reaction mixture was refluxed for 30 min, cooled, and concentrated *in vacuo*. The resulting oil was dissolved in acetonitrile (25 mL) and washed with hexane (1 × 15, 1 × 5 mL). The acetonitrile layer was concentrated *in vacuo* to afford an oil that crystallized upon standing. Recrystallization from methylene chloride − hexane afforded 70 mg (59%) of **14***b* as crystals, mp 67−68°C; R_f 0.35 (diethyl ether); $[\alpha]_D^{23}$ +107.1° (*c* 0.5, in $CHCl_3$); ν_{max} ($CHCl_3$): 3485 (carbonyl overtone), 2895, 1747 (urethane), 1595, 1425, 1373, 1105, 1045, 1005 cm^{-1}; ^1H nmr (80 MHz) δ: 1.25 (t, 3H, OCH_2C_3), 1.37 (d, J = 6.3 Hz, 3H, CH_3), 1.71−2.48 (m, 2H, H3, H2), 2.90 (s, 3H, NCH_3), 3.27−4.13 (m, 4H, H5, OCH_2CH_3), 4.42−4.94 (m, 2H, H1, H3). *Anal.* calcd. for $C_{10}H_{17}NO_4$: C 55.81, H 7.92, N 6.51; found: C 56.10, H 8.12, N 6.77.

*Ethyl-4-(N-methylacetamido)-2,4,6-trideoxy-α-D-*ribo-*hexopyranoside, **15**b*

A solution of **14***b* (175 mg, 0.8 mmol) in 5 mL of 5% potassium hydroxide was refluxed for 30 min. The reaction mixture was cooled and concentrated *in vacuo*. The resulting oily material was extracted with hot ethyl acetate (3 × 5 mL). The ethyl acetate fractions were combined and concentrated *in vacuo* to afford 110 mg (71%) of crude **15***a* as a clear oil; ^1H nmr (80 MHz) δ: 1.08−1.44 (m, 6H, OCH_2CH_3, CH_3), 1.80−2.33 (m, 4H, H2, H2, OH, NH), 2.45 (s, 3H, NCH_3), 3.30−4.18 (m, OCH_2CH_3, H3, H4), 4.90 (bd, 1H, H1).

To a solution of impure **15***a* (55 mg, 0.3 mmol) in dry methanol (2 mL) at 23°C under argon was added 0.25 mL of acetic anhydride. After 24 h the solvents were removed *in vacuo* to give an oil. Purification by medium pressure chromatography on silica gel (5:95 methanol − methylene chloride, R_f 0.38) afforded 55 mg (82%) of **15***b* as a colourless oil; $[\alpha]_D^{23}$ +194° (*c* 1.1, in $CHCl_3$); ir ν_{max} ($CHCl_3$): 3500 (OH), 3400, 1620 (amide), 1380, 1310, 950 cm^{-1}; ^1H nmr (80 MHz) δ: 1.10−1.30 (m, 6H, OCH_2CH_3, C—CH_3), 1197−2.23 (m, 6H, H2, OH, CH_3CO), 3.08 (d, 3H, NCH_3), 3.22−4.54 (m, 6H, OCH_2CH_3, H3, H4, H5), 4.96 (bs, 1H, H1); *m/e*: 232 (M^+ +1), 231 M^+.

*Ethyl-4-(N-methylacetamido)-3-O-methyl-2,4,6-trideoxy-α-D-*ribo-hexopyranoside, ***1**b*

To a suspension of sodium hydride (prewashed with hexane) (20 mg, 50% oil dispersion, 0.4 mmol) in dry tetrahydrofuran (3 mL) at 23°C under argon was added **15***b* (55 mg, 0.2 mmol) in dry tetrahydrofuran (2 mL). Tetra-*n*-butylammonium iodide (10 mg) was added, followed 10 min later by the addition of methyl iodide (1 mL). The reaction mixture was stirred for 2 h, quenched with sodium sulfate decahydrate, and filtered. The filtrate was concentrated *in vacuo* and then diluted with 5 mL of a saturated aqueous sodium chloride solution. The aqueous solution was extracted with diethyl ether (3 × 5 mL). The diethyl ether fractions were combined, washed with water, dried over sodium sulfate, and concentrated *in vacuo* to give an oil that crystallized upon standing. Recrystallization from hexane afforded 46 mg (79%) of **1***b* as granular crystals, mp 83−84°C; $[\alpha]_D^{23}$ +29.6° (*c* 0.6, in $CHCl_3$); R_f 0.31 (2:98 methanol − diethyl ether); ir ν_{max}: ($CHCl_3$) 3396, 1623 (amide), 1380, 1316, 943 cm^{-1}; ^1H nmr (400 Mhz, $CDCl_3$) δ: 1.17−1.84 (m, 6H, OCH_2CH_3, CH_3), 1.81 (dt, J = 4.1, 14.4 Hz, H2), 2.11 (d, 3H, $COCH_3$), 2.16 (2dd, J = 1.0, 14.2 Hz), 2.76 (d, 3H, NCH_3), 3.33 (d, 3H, OCH_3), 3.38−3.76 (m, 3H, H4, OCH_2CH_3), 4.22−4.32 (m, 2H, H3, H5), 4.80 (d, J = 4.2, 1H, H1). *Anal.* calcd. for $C_{12}H_{23}NO_4$: C 58.78, H 9.93, N 5.71; found: C 58.84, H 9.50, N 5.92.

TAKAKAZU YAMAMOTO and YASUHIRO SEKINE. Can. J. Chem. **62**, 1544 (1984).

The reaction of thiophenol (PhSH) with metallic copper affords CuSPh and H_2 through Cu-catalyzed dehydrogenative coupling of PhSH to PhSSPh and ensuing addition of PhSSPh to Cu. Condensation between thiophenols (ArSH) and aryl iodides or bromides (Ar'X) in the presence of Cu affords diaryl sulfides (ArSAr') in good or moderate yields (ArSH + Ar'X + Cu → ArSAr' + CuX + $1/2H_2$). Use of alkyl iodides (RI), instead of Ar'X, affords alkyl aryl sulfides (ArSR) in good yields. These condensations are considered to proceed mainly through (1) copper-catalyzed dehydrogenative coupling of ArSH to ArSSAr with evolution of H_2, (2) addition of ArSSAr to Cu giving CuSAr, and (3) coupling of CuSAr with Ar'X giving ArSAr' and CuX; temperature dependence of products, time course of the reaction, the reaction of PhSSPh with Cu, and the reaction of Ar'X with CuSPh support this view. Use of copper oxides (Cu_2O and CuO), instead of Cu, also affords diaryl sulfides in good or moderate yields.

TAKAKAZU YAMAMOTO et YASUHIRO SEKINE. Can. J. Chem. **62**, 1544 (1984).

Le thiophénol (PhSH) réagit avec le cuivre métallique en donnant du CuSPh et du H_2; cette réaction se produit via un couplage déshydrogénant, catalysé par le cuivre, du PhSH en PhSSPh qui s'additionne ensuite sur le Cu. La condensation des thiophénols (ArSH) avec les iodures ou les bromures aryliques (Ar'X) en présence de cuivre fournit les sulfures de diaryles (ArSAr') avec des rendements qui varient de bons à modérés (ArSH + Ar'X + Cu → ArSAr' + CuX + $1/2H_2$). L'utilisation d'iodures d'alkyles (RI), au lieu de Ar'X, permet d'obtenir des sulfures d'alkyles et d'aryles (ArSR) avec de bons rendements. On considère que ces condensations se font principalement par: (1) l'intermédiaire du couplage déshydrogénant, catalysé par le cuivre, de ArSH en ArSSAr avec dégagement d'hydrogène, (2) l'addition de ArSSAr sur le cuivre pour donner le CuSAr et (3) le couplage de CuSAr avec Ar'X qui donne le ArSAr' et le CuX; l'effet de la température sur la nature des produits, l'influence du temps sur le cours de la réaction, la réaction de PhSSPh avec le Cu et la réaction de Ar'X avec le CuSPh confirment cette hypothèse. L'utilisation d'oxydes de cuivre (Cu_2O et CuO), au lieu de Cu, permet également d'obtenir les sulfures de diaryles avec des rendements allant de bons à modérés.

[Traduit par le journal]

Introduction

Previously we reported effective Ullman type condensation of active hydrogen compounds, RZH (Z = N, O, C), with aryl halides, ArX, using metallic copper as a reactant (1).

[1] RZH + ArX + Cu → RZAr + CuX

The condensation was assumed to proceed through formation of intermediate CuZR and ensuing attack of ArX on CuZR. However, in the case of the active hydrogen compounds tested in our previous paper, isolation of the supposed CuZR was not feasible. Recently, we have found that a similar condensation proceeds when thiophenol is employed as the active hydrogen compound and in this case the supposed intermediate CuSPh is isolable.

The purpose of the present study is twofold: to apply the condensation reaction expressed by eq. [1] to thiophenols (ArSH), and to reveal the process giving the intermediate CuSPh.

Results and discussion

Reaction of PhSH with Cu

We first examined the reaction of thiophenol, PhSH, with Cu in the absence of ArX. As shown in Table 1, the reaction of PhSH with Cu above 150°C gives CuSPh, PhSSPh, and H_2. Table 1 includes reactions of diphenyl disulfide, PhSSPh, with Cu. Formation of CuSPh by reaction of PhSH with cuprous oxide (Cu_2O) is known (2), but formation of CuSPh by the reaction of PhSH and Cu has not been reported. CuSPh seems to be formed through direct reaction of PhSH with Cu (eq. [2]) or by an indirect route via PhSSPh (eqs. [3] and [4]).

[2] 2Cu + 2PhSH → 2CuSPh + H_2

[3] 2PhSH → PhSSPh + H_2

[4] 2Cu + PhSSPh → 2CuSPh

Occurrence of the reaction [4] was supposed by several researchers (3–5), and it is now unequivocally established as shown in Nos. 5–8 in Table 1.

At the moment, we do not have evidence to prove or disprove the direction reaction route to form CuSPh (eq. [2]). However, as for the indirect route via PhSSPh, the reaction definitely proceeds, since PhSSPh is formed in the reaction of PhSH with Cu (Nos. 1–4); we prefer the indirect route as the main reaction route. The dehydrogenative coupling of PhSH (eq. [3]) is evidently catalyzed by Cu, since heating of PhSH without Cu afforded considerably less PhSSPh. Partial formation of PhSPh at temperatures higher than 180°C is considered to be due to thermal degradation of CuSPh.

Condensation between ArSH and Ar'X

Based on the results obtained above, we analyzed the condensation of PhSH with PhBr or TolX (Tol = *p*-tolyl; X = Br, I) using metallic copper as a reactant. Figure 1 shows the temperature dependence of the products. From the results shown in Fig. 1 the following conclusions can be drawn.

1. Cu-catalyzed dehydrogenation of PhSH affords PhSSPh as the initial product. The presence of the aryl halide may assist this catalytic reaction.

2. PhSSPh reacts with Cu to afford an intermediate species,

TABLE 1. Formation of CuSPh by reactions of Cu with PhSH and PhSSPh[a]

No.	Reactant (mmol)	Cu (mmol)	Temp. (°C)	CuSPh[b] (mmol)	Other products (mmol)		
					PhSSPh	PhSPh	H_2
1	PhSH (10)	30	150	1.7	0.4	0	Small amount
2	PhSH (10)	30	180	2.1	1.4	0.1	2.0
3	PhSH (10)	30	210	3.2	2.0	0.3	2.4
4	PhSH (10)	30	240	1.7	0.7	0.6	4.0
5	PhSSPh (5)	30	150	4.9	—	0	0
6	PhSSPh (5)	30	180	5.3	—	0.3	0
7	PhSSPh (5)	30	210	5.9	—	0.4	0
8	PhSSPh (5)	30	240	5.5	—	0.9	0

[a]Reaction time = 6 h; under N_2.
[b]Based on powder X-ray pattern, increase in weight, and acidolysis of the copper product (see Experimental).

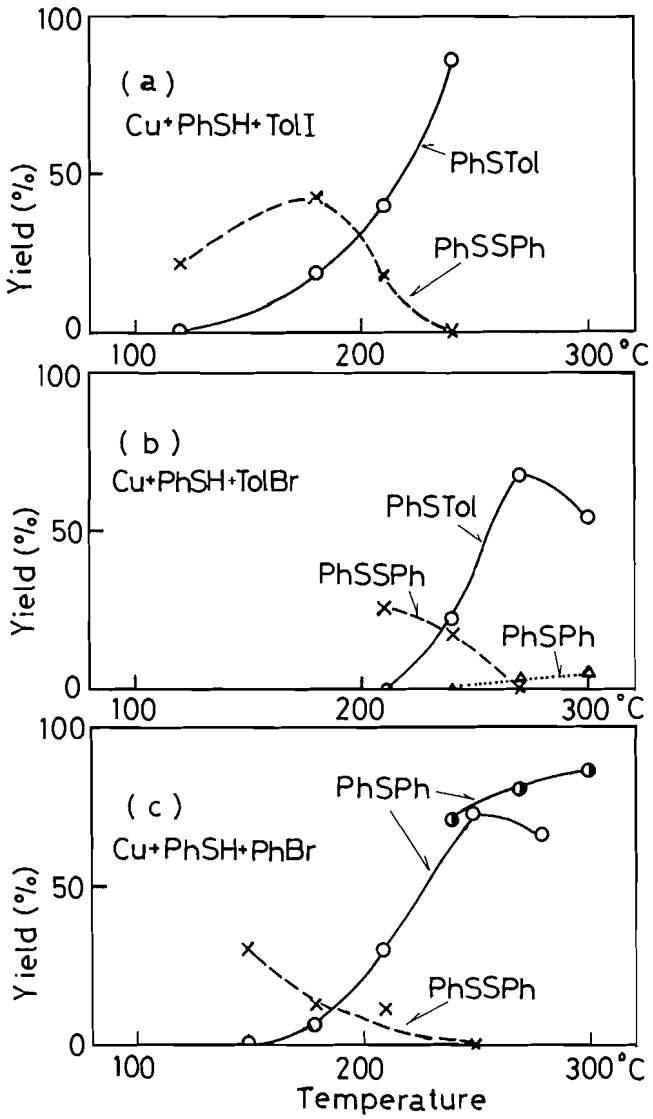

FIG. 1. Temperature dependence of yields of products in the condensation reaction of PhSH with aryl halide (Ar'X) using Cu as a reactant, under N_2 for 6 h; Cu/PhSH = 3.0. ○ (or ◑) and × show yields of PhSAr' and PhSSPh (based on PhSH), respectively. (a) Ar'X = TolI (1 mol/mol of PhSH). (b) Ar'X = TolBr (1 mol/mol of PhSH); △ shows a yield of PhSPh. (c) Ar'X = PhBr (1 mol/mol of PhSH for ○ and ×; 2 mol/mol of PhSH for ◑). Evolution of a considerable amount of H_2 was confirmed in experiments shown in Fig. 1(c).

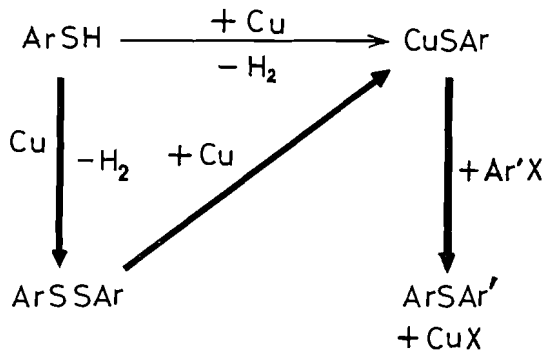

SCHEME 1

CuSPh, which further reacts with PhBr and TolX to give PhSPh and PhSTol, respectively. As discussed above, a direct reaction of PhSH with Cu also may afford the intermediate CuSPh; this situation is visualized in Scheme 1.

3. At higher temperatures (above about 250°C), degradation of CuSPh occurs to give PhSPh even in the reaction using TolX as the reactant. Thermolysis of CuSPh becomes rapid at about 250°C to give Cu_2S and PhSPh as revealed by TGA, glc, and powder X-ray diffraction pattern.

4. TolI has higher reactivity than TolBr, in agreement with the known trend that aryl iodides have higher reactivity than aryl bromides (1, 6).

In relation to Scheme 1, that CuSPh affords aryl phenyl sulfide by the reaction with aryl halides was demonstrated by Adams (1, 7) and here in Table 2, which shows no correlation between the Hammett's σ-value and reactivity of aryl bromide. Time dependence of the product of the reaction of Cu with the mixture of PhSH and PhBr (Table 3) also supports conclusions Nos. 1 and 2. Campbell reported preparation of diaryl sulfides by reactions of diaryl disulfides (e.g., PhSSPh) with mixtures of Cu and aryl halides in dimethylacetamide (3), and he assumed the addition of diaryl disulfides to Cu giving the arylthiolatocoppers. We investigated similar reactions by using no solvent and obtained diaryl sulfides from diaryl disulfides, aryl bromides or iodides, and Cu in good yields.

Table 4 shows results of condensation of thiophenols with aryl halides using Cu as a reactant. As shown in Table 4, the condensation of aryl iodides with thiophenols proceeds smoothly at 240°C to give the corresponding diaryl sulfides in good yields. The condensation of aryl bromides with thiophenols requires considerably higher temperature; it gives the

diaryl sulfides in good or moderate yields in cases of Runs 6, 7, 8, 11, 12, and 13, but the yield of sulfide is sometimes low, as shown in Runs 9, 10, and 14. Aryl chlorides show only low reactivities for the condensation reaction.

Use of Cu_2O or CuO, instead of Cu, in the condensation reaction also affords the corresponding diaryl sulfides as shown in Fig. 2. In the case of Cu_2O, the condensation most probably proceeds through a known facile reaction of PhSH with Cu_2O to give CuSPh (2), which, as described above, reacts with aryl halide. When CuO is employed, an oxidation product of PhSH, PhSSPh, is formed in about 50% yield per PhSH at relatively

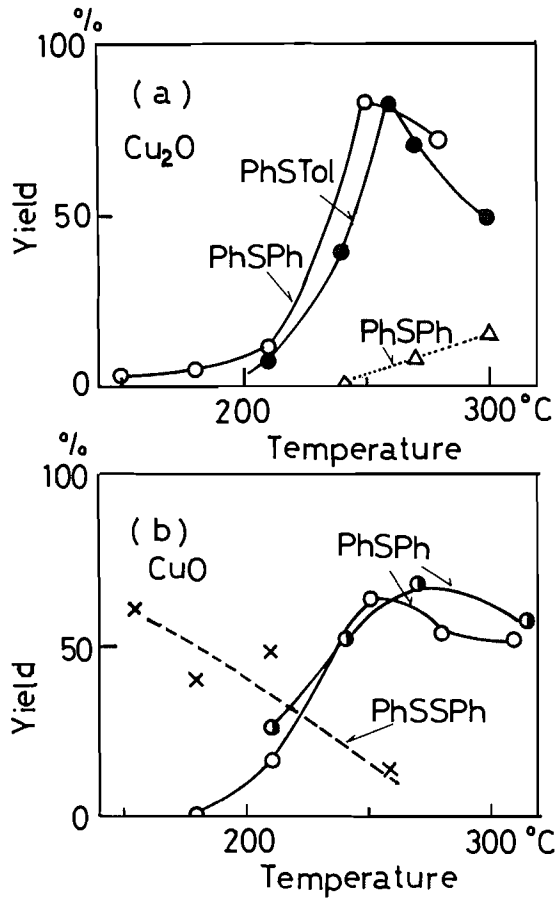

FIG. 2. Condensation using copper oxides. (a) Cu_2O = 15 mmol, PhSH = 10 mmol, PhBr = 10 mmol for ○. Cu_2O = 15 mmol, PhSH = 10 mmol, TolBr = 10 mmol for ●. △ represents yield of PhSPh in the condensation between PhSH and TolBr. (b) CuO = 30 mmol, PhSH = 10 mmol, PhBr = 10 mmol (○) or 20 mmol (◑). X shows yield of PhSSPh (PhBr = 10 mmol).

low temperatures. PhSSPh seems to be consumed in a further reaction with a mixture of aryl halide and CuO to give the diaryl disulfide. Use of alkyl iodides (RI) instead of aryl halides in the condensation reaction with thiophenols using Cu as a reactant affords alkyl aryl sulfides (ArSR) as shown in Figs. 3 and 4. The yield profile obtained at 120°C using n-alkyl iodides (Fig. 3) agrees with an order of reactivities of alkyl iodides in S_N2-type reactions (8), suggesting that the reaction proceeds through S_N2-type nucleophilic attack of CuSPh on alkyl iodide.

Experimental

Materials

Cu was prepared by reducing Cu^{2+} with Zn (9) in a Schlenk tube under an atmosphere of N_2 and stored under N_2 to avoid oxidation. Cu_2O, thiophenols, and organic halides were used as purchased from Tokyo Kasei or Wako Co. Ltd.

Analysis

Analyses of H_2, diaryl sulfides, diaryl disulfides, and other volatile organic products were carried out by gas chromatography with a Shimadzu GC-3BT gas chromatograph (carrier = He; column = SDC-550 or SSE-30 on SiO_2 purchased from Gas-chro Kogyo Co. Ltd.) using appropriate compounds (Ph−Ph, $PhCH_2Ph$, or $PhCH_2CH_2Ph$ in most cases) as internal standards. Thermogravimetric analyses were made with a Shimadzu thermoanalyzer DT-30. The ir and nmr spectra were recorded on a Hitachi 295 spectrometer and JEOL PS-100 spectrometer, respectively. Microanalyses of C, H, and

N were performed with a Yanagimoto CHN Autocorder MT-2, and those of S with a Yazawa sulfur analyzer. Powder X-ray diffraction patterns were obtained with a Phillips PS-1051 (amount of sample: ca. 50 mg).

Reactions of Cu and PhSH and PhSSPh (cf. Table 1, No. 2)

A mixture of Cu (1.91 g, 30 mmol) and PhSH (1.1 g, 10 mmol) was heated in a 100-cm^3 stainless steel autoclave (Type VS-1, purchased from Taiatsu Glass Co., Ltd.) under an atmosphere of N_2. After 6 h, the reaction mixture was cooled to room temperature. Gas chromatographic analysis of the gas phase showed evolution of 2.0 mmol of H_2. Organic materials were extracted by diethyl ether and glc analysis of the extract showed formation of 1.4 mmol of PhSSPh and 0.1 mmol of PhSPh. Weighing the remaining solid showed an increase in weight of 190 mg, corresponding to conversion of 1.7 mmol of Cu to CuSPh. Powder X-ray diffraction pattern (X-ray sources: CuK_α) of the remaining solid showed only diffraction bands assigned to Cu (at $2\theta = 43.4°$ and 50.5°) and CuSPh (at $2\theta = 7.2°$, 10.2°, and 16.2°). Authentic CuSPh was prepared according to the literature (2). Acidolysis of the solid with concentrated HCl released 1.7 mmol of PhSH. In a separate experiment we confirmed that CuSPh (2) released PhSH quantitatively on acidolysis with HCl. Other results in Table 1 were obtained analogously.

Reaction of CuSPh with aryl halide (cf. Table 2)

A mixture of CuSPh (1.73 g, 10 mmol) and TolBr (1.71 g, 10 mmol) was heated in an autoclave at 270°C for 6 h under N_2. Gas–liquid chromatographic analysis showed formation of 6.8 mmol of PhSTol and 1.4 mmol of PhSPh. A similar reaction with TolCl gave 0.8 mmol of PhSTol and 4.2 mmol of PhSPh.

No. 1 in Table 2: A mixture of CuSPh (0.173 g, 1 mmol), PhBr (1.05 cm^3, 10 mmol), and p-$NO_2C_6H_4Br$ (2.01 g, 10 mmol) was heated in an autoclave at 240°C for 6 h. The glc analysis showed formation of 0.204 mmol of p-$NO_2C_6H_4SPh$ and 0.206 mmol of PhSPh. Other reactions listed in Table 2 were carried out analogously.

Condensation of thiophenols with aryl and alkyl halides using metallic copper as the reactant

No. 1 in Table 4: A mixture of Cu (1.9 g, 30 mmol), PhSH (1.1 g, 10 mmol), and PhI (1.1 cm^3, 10 mmol) in an autoclave was heated at 240°C for 6 h under N_2. The glc analysis showed formation of 8.7 mmol of PhSPh and 0.7 mmol of PhSSPh. Other condensations were carried out analogously.

Synthèses de dioxolannes α-iodés

CHRISTOPHE DAUBIÉ, CATHY BACQUET-EINHORN ET DANIEL LELANDAIS[1]

Laboratoire de Chimie Organique Structurale, Bâtiment F 7ème étage, E.R.A. 557, 4 Place Jussieu, 75230 Paris Cedex 05, France

Reçu le 3 octobre 1983

CHRISTOPHE DAUBIÉ, CATHY BACQUET-EINHORN et DANIEL LELANDAIS. Can. J. Chem. **62**, 1548 (1984).

Trois méthodes de préparation de cétals cycliques iodés sont décrites. La iodation directe des cétals par le chlorure d'iode dans l'éther conduit à des composés monoiodés avec de bons rendements. La réaction s'effectue avec une grande sélectivité quand l'un des carbones α est tertiaire.

CHRISTOPHE DAUBIÉ, CATHY BACQUET-EINHORN, and DANIEL LELANDAIS. Can. J. Chem. **62**, 1548 (1984).

Three methods of iodination of cyclic ketals are described. Direct iodination by monoiodine chloride in ether leads to very good yields in monoiodo compounds. A high selectivity is obtained when one of the α-carbon atoms is tertiary.

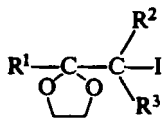
Dans le cadre de recherches effectuées au laboratoire sur les dérivés cétalisés de composés carbonylés (1) nous nous sommes intéressés à la synthèse de cétals cycliques α-iodés du type



Si de tels cétals α-bromés ont déjà été décrits (2), il n'en est pas de même pour leurs analogues α-iodés. A notre connaissance seuls Goosen et McLeland (3) signalent l'obtention d'acétals cycliques α-iodés sans d'ailleurs décrire ces composés. Pourtant ce type de produits peut présenter un intérêt soit dans l'utilisation de l'iode comme marqueur, soit en synthèse. Par ailleurs ils ont déjà fourni par réduction électrochimique des γ-bisdioxolannes que nous décrirons par ailleurs.[2]

Pour préparer les cétals α-iodés nous avons tout d'abord fait appel à deux méthodes dérivées de réactions classiques, puis avons mis au point une méthode originale de iodation directe de cétals cycliques par le chlorure d'iode. Cette réaction s'est révélée simple, rapide et efficace dans la très grande majorité des cas étudiés.

Les résultats obtenus selon les trois voies sont décrits dans les tableaux 1 à 3.

Première méthode

Elle est dérivée de celle proposée par Garbisch (4) pour la synthèse directe de cétals α-bromés à partir de cétones cycliques: la cétone en solution dans l'éthylèneglycol est traitée par l'iode.

Dans notre cas, si le résultat est assez satisfaisant avec la cyclohexanone, il n'en a pas été de même avec les cétones acycliques; des composés diiodés sont obtenus si la température de réaction est un peu élevée ou du cétal non halogéné lorsqu'elle est trop basse.

En fait la manipulation est délicate à mener: d'une part il est difficile de contrôler correctement l'introduction d'iode; d'autre part, la réaction devant être initiée thermiquement, son évolution devient délicate à maîtriser par la suite.

Les rendements indiqués dans le tableau 1 sont les meilleurs que nous ayons obtenus lors de différents essais. Leur modicité et les excellents résultats obtenus sans problème avec le chlorure d'iode nous ont amenés à ne pas approfondir, dans l'immédiat, l'étude de cette méthode.

TABLEAU 1. Synthèse de dioxolannes α-iodés par iodation de cétones dans l'éthylène glycol

N°	Cétone de départ	Produit obtenu	Rdt (%)
A_2			7 41
A_9			75
A_{10}			20

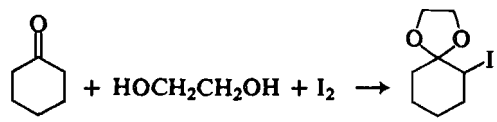


SCHÉMA 1

Notons toutefois que, lorsque deux sites d'attaque sont possibles, la réaction conduit à l'halogénure secondaire de façon prépondérante (essai A_2).

Deuxième méthode

Elle fait appel à la synthèse de cétones α-iodées par échange iode–chlore ou iode–brome au moyen de l'iodure de potassium à partir de cétones α-chlorées ou α-bromées (5, 6) suivie de leur cétalisation (7).

La première difficulté rencontrée est, dans ce cas, l'obtention des cétones α-iodées. Nous avons pu isoler les cétones α-bromées indiquées dans le tableau 2 dont la plupart n'avaient pas été entièrement décrites jusqu'ici (essais B_2, B_3, B_4, B_6, B_8, B_9). Cependant ces produits sont relativement instables et doivent être cétalisés immédiatement après leur préparation pour obtenir des rendements corrects.

Même dans ces conditions, la cétalisation s'effectue de telle sorte qu'une perte d'iode intervient durant la réaction et que les rendements chutent dès que l'on veut former un iodure secondaire.

Cette méthode reste néanmoins intéressante dans la mesure où la bromation régiosélective des cétones est bien connue (8).

SCHÉMA 2

Il sera possible de préparer ainsi des cétals iodés différents de ceux obtenus par iodation directe par le chlorure d'iode.

Troisième méthode

Il s'agit du traitement direct des cétals cycliques (obtenus le plus souvent à partir des cétones selon la méthode de Salmi (7)) par le chlorure d'iode.

Si l'étude de la littérature montre l'intérêt croissant porté à cet halogénure mixte il est surtout utilisé pour l'iodation de composés aromatiques ou comme catalyseur de diverses réactions de chloration. Nous citerons cependant son emploi dans des études cinétiques d'halogénation de cétones (9) et surtout son intervention dans deux réactions intéressant directement (10) ou indirectement (3) des acétals. Comme nous l'avons signalé plus haut, l'une de ces réactions (3) conduit à l'obtention de petites quantités d'acétals α-iodés; cependant l'approche des auteurs est différente de celle adoptée ici.

Dans notre cas la position α des cétals cycliques s'est révélée très réactive vis à vis du chlorure d'iode. De tous les solvants utilisés, l'éther a conduit à la plus haute sélectivité, les produits monoiodés étant formés avec un rendement quasiment quantitatif (voir tableau 3).

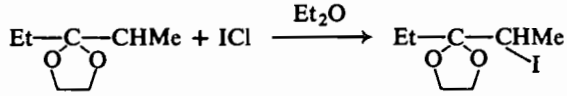

SCHÉMA 3

Les essais C_2 et C_{18} montrent la formation prépondérante d'un iodure secondaire par rapport à l'iodure primaire comme nous l'avions noté pour la première méthode.

En outre, lorsque l'un des carbones α du dioxolanne de départ est tertiaire, la réaction fournit un composé iodé sur l'autre carbone de façon totalement régiosélective (essais C_{13}, C_{17}, C_{19}). En fait la formation d'un iodure tertiaire n'a été observée en aucun cas (voir C_{20}).

Le mécanisme des réactions d'halogénation a été étudié dans le cas des chlorations et des bromations et il sort de l'objet de cet article de discuter celui de la réaction présentée ici.

Il nous semble cependant que quelques résultats observés trouvent leur source dans l'importance des effets stériques lors de cette iodation. C'est le cas, pensons nous, pour l'essai C_{15} où l'encombrement du cycle cétalique est accru, ainsi que pour l'essai C_{12} où ce sont cette fois les radicaux R^1 et R^2 qui augmentent la gêne stérique. Il est remarquable dans ce dernier cas que la réaction s'effectue avec d'excellents rendements si R^2 est un méthyle (essai C_6) au lieu d'un éthyle.

Conclusion

Les différentes méthodes décrites ici nous ont conduit à l'obtention d'un nombre important de cétals cycliques α-iodés qui sont des produits nouveaux.

Les deux premières méthodes peuvent avoir souvent leur utilité. C'est en particulier le cas pour la seconde qui profite des

connaissances acquises pour la bromation ou la chloration régiosélective des cétones et peut conduire ainsi à des produits que la troisième méthode ne permet pas d'atteindre (essai B_7 par exemple).

Pourtant cette troisième méthode se révèle la plus rentable, d'abord à cause des très bons rendements et de la simplicité de sa mise en oeuvre, mais aussi à cause de l'iodation quasi-totalement régiosélective observée dans certains cas.

Partie expérimentale

Les spectres rmn ont été effectués sur un appareil Bruker 80 WP en solution dans le deutérochloroforme avec pour référence interne l'hexaméthyldisiloxane.

Les échantillons pour analyse ont été séparés par chromatographie en phase vapeur sur une colonne SE 30 de 3 mètres de long.

Synthèse de cétals α-iodés selon la 1^e^ méthode

La réaction est conduite sous azote avec une agitation magnétique.

Une solution de 0,1 mol de cétone dans 60 mL d'éthylèneglycol est portée à 60°C. Quelques gouttes d'une solution de 0,1 mol d'iode dans l'éther sont alors ajoutées. Quand le milieu réactionnel est décoloré, la température est amenée à 30°C, et le reste de la solution d'iode est introduit goutte à goutte. A la fin de l'addition, l'agitation est maintenue pendant deux heures. Le milieu est alors neutralisé par du carbonate de sodium, puis dilué par 50 mL de pentane et 50 mL d'eau. Après trois extractions par 50 mL d'éther et séchage sur carbonate de sodium, la phase organique est évaporée à température ambiante. Le résidu est distillé.

Synthèse de cétals α-iodés selon la 2e méthode

Suivant le type de cétones bromées désiré (bromation sur le carbone le moins substitué, le plus substitué, ou bromation d'une cétone cyclique) quatre méthodes de synthèses ont été utilisées (6, 8). Les cétones iodées correspondantes, obtenues selon le mode opératoire de Modaraï et Khosdel (5), sont traitées suivant le méthode de Salmi (7).

Exemple: synthèse du iodométhyl-2 propyl-2 dioxolanne-1,3: une solution de 0,1 mol de bromo-1 pentanone-2 (6) dans 50 mL d'éthanol est portée à reflux deux heures en présence de 0,12 mol d'iodure de potassium. Après refroidissement du milieu réactionnel, la solution filtrée est évaporée à froid. La cétone iodée brute est ajoutée à une solution de 100 mL de benzène contenant 0,12 mol d'éthylèneglycol et quelques milligrammes d'APTS. L'élimination totale de l'eau est observée après 12 heures de reflux. La solution benzénique est lavée deux fois avec une solution de potasse $N/10$. La phase organique décolorée est alors séchée sur carbonate de sodium et évaporée à froid. Le résidu est distillé $E_{0,1}$ = 80°C; Rdt = 62%.

Cétones iodées

Iodo-1 propanone-2: δ = 3,7 (s, 2H), 2,3 (s, 3H).

Iodo-2 cyclohexanone: δ = 4,8 (m, 1H), 3,8 à 1,5 (m, 8H).

Iodo-3 butanone-2: δ = 4,5 (q, 1H) 2,3 (s, 3H), 1,8 (d, 3H).

Iodo-3 pentanone-2: δ = 4,3 (t, 1H), 2,3 (s, 3H), 1,9 (d, 2H), 1,0 (t, 3H).

Iodo-3 octanone-2: δ = 4,4 (t, 1H), 2,3 (s, 3H), 2,2 à 1,5 (m, 2H), 1,5 à 0,7 (m, 9H).

Iodo-3 méthyl-4 pentanone-2: δ = 4,3 (d, 1H), 2,6 à 2,0 (m, 2H), 2,3 (s, 3H), 1,0 (m, 6H).

Iodo-1 diméthyl-3,3 butanone-2: δ = 3,7 (s, 2H), 1,0 (s, 9H).

Iodo-1 pentanone-2: δ = 3,7 (s, 2H), 2,8 (t, 2H), 2,0 à 1,1 (m, 2H), 0,9 (t, 3H).

Dioxa-1,4 iodo-6 spiro[4,5] décane; A_9: voir première méthode.

Synthèse de cétals α-iodés selon la 3e méthode

Les dioxolannes des cétones ont été préparés selon Salmi (7). La réaction d'iodation est conduite sous azote avec agitation magnétique.

Une solution de 0,02 mol de dioxolanne dans 10 mL d'éther anhydre est rapidement ajoutée à une solution de 0,024 mol de chlorure d'iode dans 40 mL d'éther anhydre refroidie par un bain de glace. L'évolution de la réaction est suivie par chromatographie en phase gazeuse.

Quand tout le dioxolanne de départ a disparu le milieu réactionnel est traité par une solution de potasse jusqu'à décoloration. Le mélange obtenu est extrait quatre fois par 20 mL d'éther, séché sur carbonate de sodium puis évaporé à température ambiante. Le résidu est distillé.

Dioxolannes α-iodés

Nouvelle synthèse électrochimique de γ-bisdioxolannes symétriques et dissymétriques

CHRISTOPHE DAUBIÉ, CATHY BACQUET-EINHORN ET DANIEL LELANDAIS[1]

Laboratoire de Chimie Organique Structurale, Bâtiment F, 4 Place Jussieu, 75230 Paris Cedex 05, France

Reçu le 12 août 1983

CHRISTOPHE DAUBIÉ, CATHY BACQUET-EINHORN et DANIEL LELANDAIS. Can. J. Chem. **62**, 1552 (1984).

La réduction électrochimique de dioxolannes α-iodés permet de préparer une série de γ-bisdioxolannes symétriques et dissymétriques.

CHRISTOPHE DAUBIÉ, CATHY BACQUET-EINHORN, and DANIEL LELANDAIS. Can. J. Chem. **62**, 1552 (1984).

The electrochemical reduction of α-iodinated dioxolanes leads to the preparation of a series of symmetrical and non-symmetrical γ-bisdioxolanes.

[Journal translation]

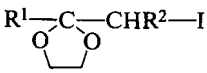
Nous avons récemment mis au point une nouvelle méthode de préparation de cétals α-iodés (1) du type



avec R^2 = H ou radical, et il nous a semblé intéressant d'étudier le comportement électrochimique de ces composés.

En effet, les iodures d'alkyle RI étant connus pour fournir un radical R· par réduction électrochimique, nous pouvions espérer dans notre cas aboutir, par dimérisation du radical intermédiaire, à des γ-bisdioxolannes qui ont déjà été l'objet de notre attention (2, 3).

Par ailleurs, l'obtention par réduction électrochimique, du dioxolanne de la cyclopropanone à partir du 2,2 bis(chlorométhyl)-1,3 dioxolanne (4) et la réactivité plus grande des dérivés iodés par rapport aux analogues chlorés confortaient cet espoir.

En fait les essais d'électrolyse menés dans des conditions analogues ou voisines (utilisation d'une concentration supérieure en dérivé halogéné destinée à favoriser la dimérisation) de celles décrites par Van Tilborg *et al.* (4) ne nous ont conduits qu'à de faibles quantités de dimère. A côté du cétal déshalogéné (80%) la réaction fournit un mélange complexe de produits (probablement issus de l'ouverture du cycle cétalique et de diverses dégradations).

Les essais d'électrolyse dans les conditions classiques ayant échoué, nous avons observé que la réaction espérée se produisait avec de bons rendements en dimère (Tableau 1) et des rendements moyens en courant en conduisant l'électrolyse de la façon suivante: (*i*) cellule à compartiment unique; (*ii*) anode en platine et cathode en platine portée à un potentiel pouvant atteindre −5 V par rapport à l'électrode de référence au calomel; (*iii*) milieu méthanolique anhydre 1 *M* en dioxolanne α-iodé et 1 *M* en potasse.

Les conditions opératoires extrêmes utilisées nous amènent, sans vouloir discuter du mécanisme, à faire quelques remarques:

1. L'électrolyse conduite en cellule à compartiments séparés – dont seul le compartiment cathodique reçoit le substrat – libère le dimère avec des rendements qui ne sont pas supérieurs à ceux observés en compartiment unique, tout en compliquant le montage.

2. L'utilisation d'une quantité équimolaire de potasse est indispensable, le substrat n'étant modifié que proportionnellement à la quantité de potasse ajoutée. L'électrolyse s'accompagne d'ailleurs d'une forte précipitation d'iodure de potassium.

3. Les dérivés bromés sont retrouvés intacts dans les mêmes conditions d'électrolyse.

4. Si les réactions électrochimiques classiques ont permis d'obtenir un peu (5%) des dimères attendus, nous avons pu observer qu'il en était de même lors de diverses réactions de type Wurtz utilisant le sodium (5). Mais les rendements sont très faibles là encore et le produit principal est le dioxolanne déshalogéné.

La méthode proposée ici semble donc satisfaisante. Elle présente cependant des limitations: en effet les acétals α-iodés ouverts fournissent essentiellement des produits de dégradation tandis que les dioxannes-1,3 α-iodés, homologues supérieurs des dioxolannes utilisés, ne conduisent qu'au dioxanne déshalogéné. Par contre, cette électrolyse s'est révélée une synthèse rentable de γ-bisdioxolannes dissymétriques.

Ces produits sont obtenus en utilisant une méthode bien connue pour d'autres dimérisations radicalaires mixtes, la réaction de Kolbe en particulier (3): le cétal α-iodé le plus précieux est introduit de façon controlée durant l'électrolyse d'un excès du composé le plus accessible.

En conclusion, on peut remarquer que, si pour certains γ-bisdioxolannes (**1, 2**) les rendements sont légèrement inférieurs à ceux que nous avions obtenus par oxydation anodique d'acides β-cétaliques (2), la méthode reste compétitive vu l'accès très aisé aux produits de départ. En outre, contrairement à la réaction précédemment décrite, elle permet l'accès à des γ-bisdioxolannes substitués sur les carbones centraux, ce qui accroit considérablement la quantité de squelettes carbonés susceptibles d'être atteints par cette voie.

Enfin, sans préjuger des applications nouvelles issues d'un déblocage sélectif des cétals, en cours d'étude au laboratoire, ces γ-bisdioxolannes mènent par déblocage total à des γ-dicétones dont l'intérêt comme synthons n'est plus à démontrer.

Partie expérimentale

Les spectres rmn ont été effectués sur un appareil Brucker 80WP en solution dans le deutérochloroforme avec pour référence interne l'hexaméthyldisiloxane.

I. *Préparation des dioxolannes α-iodés*

Ils ont été synthétisés de deux façons différentes: soit par une réaction d'échange brome–iode sur la cétone bromée selon la réf. 6 suivie de la préparation du dioxolanne selon Salmi (7), composés **1**, **3–7**; soit par iodation directe des dioxolannes de cétones selon la réf. 1, composés **2** et **8**.

II. *Obtention des bisdioxolannes*

1. *Conditions d'électrolyse: mode opératoire général*

L'appareil utilisé est un potentiostat Tacussel PRT 40-5X qui permet d'imposer un potentiel fixe à la cathode. Les mesures coulométriques ont été faites à l'aide d'un intégrateur Tacussel IG5-LN monté en série sur le circuit. L'intensité du courant est vérifiée par un ampèremètre monté sur le circuit de l'anode. La cellule d'électrolyse est constituée par une cuve de verre entourée d'une jaquette permettant de maintenir une circulation d'eau de refroidissement. L'anode est une lame de platine de 3 cm^2 et la cathode une lame de platine de 9 cm^2.

Cas de γ-bisdioxolannes symétriques

Dans la cellule non divisée une solution de 0,02 mol de dioxolanne α-iodé dans 20 mL de méthanol anhydre est introduite. L'électrolyse est effectuée sous agitation magnétique et la tension imposée est comprise entre −2,5 et −5 V par rapport à l'électrode de référence au calomel, la réaction commence dès que l'on ajoute quelques pastilles de potasse. L'addition de potasse doit se faire progressivement pour éviter une trop forte intensité de courant. L'électrolyse est arrêtée après passage de 3 F/mol substrat. Le mélange réactionnel est évapo-

For personal use only.

ré sous pression réduite, le résidu est repris par 100 mL d'un mélange 1 : 1 d'éther et de chloroforme. Le précipité jaune obtenu est filtré. Le filtrat est séché au carbonate de sodium puis évaporé.

Cas de γ-bisdioxolannes dissymétriques

Dans la cellule, une solution de 0,02 mol du dioxolanne α-iodé le plus accessible est mis en solution dans 20 mL de méthanol anhydre. L'électrolyse est démarrée dans les mêmes conditions que ci-dessus mais une solution de 0,01 mol du dioxolanne α-iodé le plus précieux dans 10 mL de méthanol est ajoutée goutte à goutte de telle sorte que toute la solution soit versée après passage de 0,01 F. La potasse est ajoutée dès l'introduction du produit le plus précieux et progressivement tout au long de l'électrolyse de manière à maintenir une intensité de courant constante. La réaction est ensuite menée comme précédemment.

Discussion on ^{13}C nuclear magnetic resonance spectra of structurally rigid cyclonucleosides. Violation of Karplus relationship between $^{3}J_{C,H}$ and dihedral angles

JUN UZAWA AND KENTARO ANZAI[1]

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351, Japan

Received January 25, 1983

JUN UZAWA and KENTARO ANZAI. Can. J. Chem. **62**, 1555 (1984).

Using structurally rigid cyclonucleoside derivatives of adenosine, the effect of the oxygen functional groups on the vicinal coupling constants between carbon and hydrogen in ^{13}C nmr was investigated.

JUN UZAWA et KENTARO ANZAI. Can. J. Chem. **62**, 1555 (1984).

Faisant appel à des dérivés cyclonucléosides de l'adénosine structuralement rigides, on a étudié l'effet des groupements fonctionnels oxygénés sur les constantes de couplage vicinales entre les carbones et les hydrogènes, dans les spectres rmn du ^{13}C.

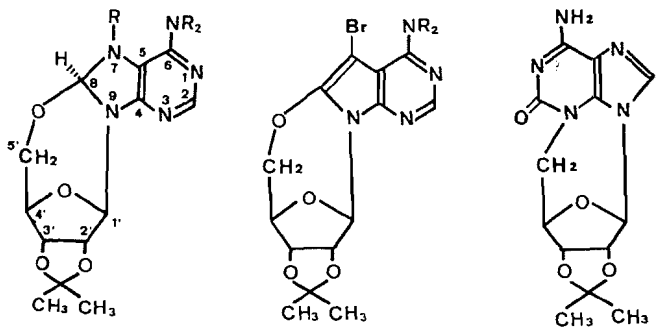
Deviation from the Karplus relationship (1–3) between dihedral angles and vicinal coupling constants in ^{1}H nmr and ^{13}C nmr has attracted the attention of organic chemists. In 1965 Booth (4) reported that the proton-proton vicinal coupling constant in a structure —CH—CH(R)—, where R is an oxygen or nitrogen functional group, was influenced by the electronegativity of the hetero atom as well as its orientation in the molecule.

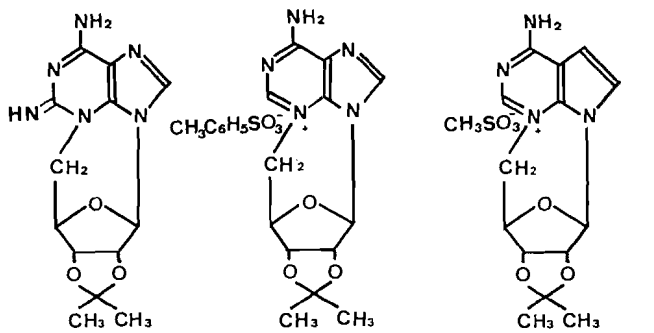
Schwarcz and Perlin (5) also observed the orientational effect of oxygen functional groups upon vicinal coupling constants between carbon and hydrogen using ^{13}C-enriched carbohydrate derivatives. Their findings were: when a compound has a partial structure ^{13}C—C—C(O)—H, where the ^{13}C—C and C—O bonds are located in a *trans* relationship, the vicinal coupling constant between carbon and hydrogen is smaller than that of the compound having a *cis* structure. Thus, their data showed that when the dihedral angle between the ^{13}C—C and C—H bonds is 60° the coupling constant is no longer observed, for the case of "*trans*" compounds only.

Delbaere *et al.* (6) were interested in "anomalous" vicinal coupling constants between carbon and hydrogen when they studied the cyclonucleoside derivatives of uracil, and gave an explanation for the deviation from the Karplus curve based on the bond electron density obtained by X-ray diffraction analysis.

Synthesis of the adenosine cyclonucleoside **1** from 2′,3′-*O*-isopropylidene adenosine and phenyl chloroformate was reported in a previous paper (7), where the configurational assignment at C8 was not yet accomplished. For the structural determination of **1**, long-range selective proton-decoupling (lspd) (8–11) was quite useful to extract $^{3}J_{C,H}$ from broadening peaks in ^{13}C nmr. Thus structural assignment of **1** as a 8,5′-*O*-cyclonucleoside of adenosine rather than a 2,5′-*O*-cyclonucleoside congener was possible using lspd, in spite of the uselessness of the conventional ^{13}C nmr and ^{1}H nmr spectra: i.e. the broadening peaks of a doublet at δ 98.0 ($^{1}J_{C,H}$ = 188.0 Hz), which showed the presence of a sp^{3}-carbon in the base moiety of the product, were sharpened in a triple resonance spectrum (Fig. 1) obtained by weak irradiation at H-1′ and H-5′



1 R = $COOC_6H_5$ **2** **3**



4 **5** **6**

($^{3}J_{C8,H\text{-}1'}$ = 4.9 Hz, $^{3}J_{C8,H\text{-}5'a}$ = 9.8 Hz, $^{3}J_{C8,H\text{-}5'b}$ = 4.9 Hz), thus excluding a structural assignment of the product as a 2,5′-*O*-cycloadenosine derivative.

The configuration at C8 of **1** was determined to be *R* by nOe difference spectra, which disclosed the proximity of H-8 to H-1′ (7% nOe) as well as H-5′ to H-8 (18% nOe), and gave grounds for believing that the N9—C1′—O(4′)—C4′—C5′—O(5′)—C8 seven-membered ring exists as a pseudo-

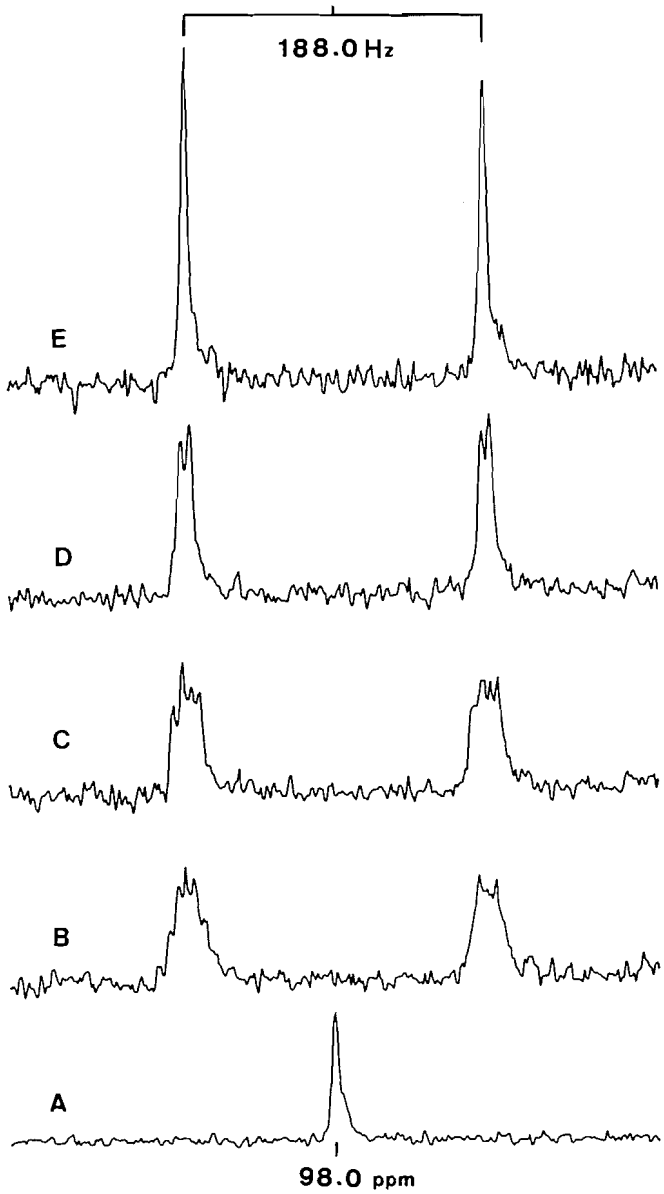

FIG. 1. Long-range selective ^1H decoupling spectra at 98.0 ppm of **1**. **A**, proton noise decoupling; **B**, gated decoupling with nOe; **C**, irradiation at H-1′; the splittings are 9.8 Hz and 4.9 Hz ($^3J_{C8,H\text{-}5'}$); **D**, irradiation at H-5′; the splitting is 4.9 Hz ($^3J_{C8,H\text{-}1'}$); **E**, irradiation at H-1′ and H-5′ simultaneously. The spectra were recorded on a JEOL FX-400 FT nmr spectrometer at 100.7 MHz. Experimental conditions; repetition, 1.8 s × 5000; data points, 32 K; spectral width, 16 kHz; power level for ^1H irradiation ($\gamma H_2/2\pi$), 100 Hz; concentration, 80 mg in 1 mL $CDCl_3$.

chair conformer as depicted in Fig. 2.[2]

Collection of $^3J_{C,H}$ in ^{13}C nmr of **1** (Table 1) led to findings that there are cases where the Karplus relationship between vicinal coupling constants and dihedral angles is not evident: e.g. coupling was not observed between C4 and H-1′, though the dihedral angle of this structurally rigid compound was measured to be 35° and a $^3J_{C,H}$ value around 3 Hz was expected based on the Karplus curve (3).

[a] Reference 17.

Investigation of $^3J_{C,H}$ in other structurally rigid cyclonucleosides **2** through **6** (Table 1), which were mainly prepared in this laboratory (12–17), resulted in finding that the orientational effect of oxygen functional groups on $^3J_{C,H}$ is also similar to that observed by Schwarcz and Perlin (5) in the study on glycoside derivatives.

The chemical shifts of compounds **1** through **6** in ^{13}C nmr (Table 2)[3,4] are worth comment before entering the present theme. The polarity of the atoms located near the observed nuclei seemed to influence the chemical shift: e.g. a δ_{C5} value in **1** is 18.4 ppm lower than the corresponding δ value in **2**, being consistent with the shielding effect of N7 in **1**. Similarly, a δ_{C5} value in **5** is 14.8 ppm lower than the corresponding δ value in **6**. The $\delta_{C5'}$ values in **1** through **6** reflect a stronger polar effect of oxygen than that of nitrogen, the increase of polarity by affording charge on nitrogen, and the difference of polarity between sp^2 and sp^3 carbons. Chemical shifts of carbons on the furanose ring as well as those of the isopropylidene group are quite similar through these compounds with an exception that $\delta_{C1'}$ in **2** is 4–5 ppm higher than the other $\delta_{C1'}$ values, and the reason is not evident.

Inspection of these $^3J_{C,H}$ values of compounds **1** through **6** (Table 1),[4] which were determined unequivocally by lspd,

[2] On the contrary, if a molecular model is constructed as having *S*-configuration at C8, H-2′ and H-8 are found to be in close proximity, and the lack of nOe between these two protons also serves as another evidence for *R*-configuration.

[3] Assignment of the peaks was confirmatively done through studies on lspd, selective decoupling, and $^1J_{C,H}$.

[4] The numbering of the 7-deazaadenosine derivatives **2** and **6** is given here in a similar way to that of the adenosine derivatives for the reader's convenience.

C8-H1'	4.9	6.8	≤ 2.0

FIG. 3. The Newman projection of adenosine cyclonucleoside derivatives **1** to **6** through the C1′—N9 bond.

reveals that $^{3}J_{C4,H\text{-}1'}$ and $^{3}J_{C8,H\text{-}1'}$ of these adenosine cyclonucleosides are under the influence of the orientational effect of oxygen functional groups on $^{3}J_{C,H}$, and the Newman projection through C1′ and N9 as depicted in Fig. 3 will be helpful in illustrating this effect.

In conclusion, we add further proof that an oxygen atom located at a *trans* position to the observed carbon nucleus has the effect of decreasing $^{3}J_{C,H}$ and in consideration of this, lspd serves a useful purpose in the structural determination of cyclonucleosides.

1,5-Acyclic stereoselection. The stereocontrolled synthesis of optically active vitamin E fourteen-carbon side chain alcohol[1]

GERVAIS BÉRUBÉ[2] AND PIERRE DESLONGCHAMPS

Laboratoire de Synthèse Organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received March 22, 1984

GERVAIS BÉRUBÉ and PIERRE DESLONGCHAMPS. Can. J. Chem. **62**, 1558 (1984).

The Diels–Alder product **3** was first transformed into the symmetrical nine-membered cyclic carbonate **8**. Reaction of **8** with *l*-(−)-α-methylbenzylamine (**12**) yielded a mixture of optically active diastereoisomeric urethanes **9***a* (**9**, R = H, R′ = $C_6H_5CHCH_3NHCO$—) and **9***b* (**9**, R = $C_6H_5CHCH_3NHCO$—, R′ = H) which were separated and respectively converted into **11***a* and **11***b*. Compounds **11***a* and **11***b* were then transformed respectively into the optically active side chain alcohol **2** (R = H) of vitamine E (**1**).

GERVAIS BÉRUBÉ et PIERRE DESLONGCHAMPS. Can. J. Chem. **62**, 1558 (1984).

Le produit de Diels–Alder **3** fut transformé en carbonate symétrique cyclique à neuf membres **8**. La réaction de **8** avec la *l*-(−)-α-méthylbenzylamine a donné les uréthanes diastéréoisomériques optiquement actifs **9***a* (**9**, R = H, R′ = $C_6H_5CHCH_3$-NHCO—) et **9***b* (**9**, R = $C_6H_5CHCH_3NHCO$—, R′ = H) qui furent séparés et respectivement transformés en composés **11***a* et **11***b*. Ces derniers ont conduit par la suite à la chaîne latérale de la vitamine E, i.e. l'alcool **2** (R = H) optiquement actif.

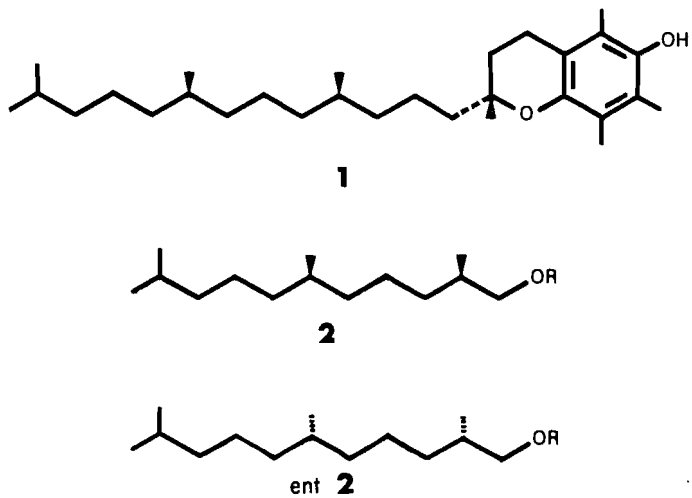
The stereocontrolled synthesis of substituted aliphatic chains containing chiral centers, i.e. acyclic stereoselection, is presently an active field of research (1). For instance, several groups have reported (2, 3) various ways of constructing the 1,5-dimethylated aliphatic chain which is found in vitamin E (**1**) (Scheme 1) and in several other natural products like vitamin **K**, phytol, and insect pheromones (pine saw fly (4) and tsetse fly (5)).

In this communication, we wish to report a new strategy for the synthesis of the optically active side chain alcohol **2** (R = H) which has been converted into vitamin E (2).

The Diels–Alder product **3** (mp 94–95°C) which is readily available (6) from the addition of maleic anhydride to *trans,trans*-2,4-hexadiene, was chosen as starting material (Scheme 2). Esterification of **3** (CH_3OH, HCl, 95% yield) gave the *cis*-dimethylester **4**[3] (mp 49–50°C) which was converted ($CHBr_3$, NaOH, $(C_2H_5)_3NCH_2C_6H_5Cl$, 0° → 25°C, 65% yield) (7) into the dibromocyclopropane derivative **5** (mp 114–115°C). Basic hydrolysis (NaOH, H_2O–dioxane–CH_3OH, 99% yield) of **5** gave the corresponding dicarboxylic acid which upon bis-decarboxylation ($Pb(OAc)_4$, pyridine, 65°C, 84% yield) (8) yielded the cyclic olefin **6**. Cleavage of **6** ((a) O_3, CH_3OH, CH_2Cl_2, −78°C (9) and (b) $LiBH_4$, 0°C, 96% yield) gave the *meso*-dibromocyclopropyldiol **7** (mp 126–127°C).

Compound **7** was then converted ((a) dihydropyran, *p*-TsOH, C_6H_6, 84% yield, (b) CH_3Li, ether, −35°C, 96% yield (10)) into the allene derivative **10** (R = R′ = THP). Catalytic reduction (H_2, PtO_2, CH_3OH, 99% yield) and hydrolysis (*p*-TsOH, CH_3OH, 89%) of **10** (R = R′ = THP) gave *meso*-2,6-dimethylheptan-1,7-diol **11** (R = R′ = H) (3*f*).

A toluene solution of phosgene was slowly added (with a syringe pump) during a period of 10 h to a mixture of *meso*-dibromocyclopropyldiol **7**, triethylamine, and dichloromethane, to yield the nine-membered cyclic carbonate **8** (mp 96–98°C) in 80% yield (11). The lithiated derivative of *l*-(−)-α-methylbenzylamine (**12**) (*n*-BuLi, ether) was then reacted with the symmetrical cyclic carbonate **8** (THF, −78°C, 30 min, 86% yield) to yield a mixture (~1:1 ratio) of optically active diastereoisomeric urethanes **9***a* (**9**, R = H and R′ = Ur = $C_6H_5CHCH_3NHCO$—) and **9***b* (**9**, R = Ur = $C_6H_5CHCH_3$-NHCO— and R′ = H) which were separated by hplc (12). Treatment of optically active urethane **9***a* with methyllithium (ether, −35°C, 99% yield) (10) gave the corresponding allene **10***a* which on catalytic reduction (H_2, PtO_2, CH_3OH, 98% yield) furnished the optically active urethane **11***a*. Similarly, **9***b* yielded the optically active urethane **11***b* via **10***b*.



SCHEME 1

Each diastereoisomer (**11***a* and **11***b*) was then respectively converted into optically active **2** (R = H), i.e. 2*R*,6*R*,2,6,10-trimethylundecan-1-ol. The conversion **11***a* (**11**, R = H, R′ = Ur) → **2** (R = H) was carried out in the following manner: (a) *p*-TsCl, $(C_2H_5)_3N$, CH_2Cl_2, 0° → 25°C, 99% yield in tosylate **11** (R = Ts, R′ = Ur), (b) $SiHCl_3$, $(C_2H_5)_3N$, C_6H_6, 25°C (13), 76% yield in tosylate alcohol **11** (R = Ts, R′ = H; $[\alpha]_D$ +8.07° (*c* 3.025 in $CHCl_3$), (c) dihydropyran, pyridinium *p*-toluenesulfonate (PPTS), CH_2Cl_2 (14), 94% yield in THP derivative **11**

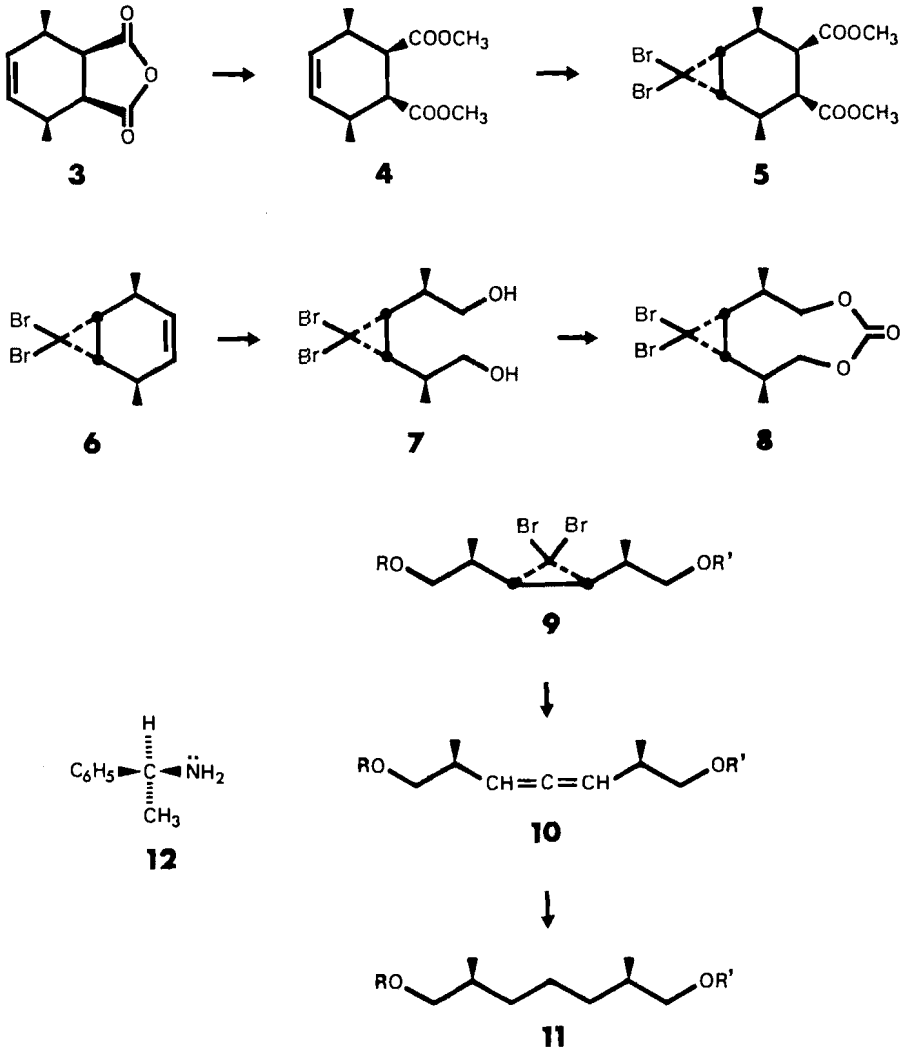

SCHEME 2

(R = Ts, R′ = tetrahydropyran), (d) $(CH_3)_2CHCH_2CH_2MgBr$, Li_2CuCl_4, THF, −78° → 25°C (15; for preparation of the reagent, see ref. 15*b*), 60% yield in **2** (R = THP), and (e) CH_3OH, PPTS, (14), 99% yield in **2** (R = H). The transformation **11***b* (**11**, R = Ur, R′ = H) → **2** (R = H) was realized via the following steps: (a) *tert*-butyldimethylsilyl (TBDMS) chloride, imidazole, THF, 25°C (16), 96% yield in **11** (R = Ur, R′ = TBDMS), (b) $SiHCl_3$, $(C_2H_5)_3N$, C_6H_6, 25°C (13), 84% yield in **11** (R = H, R′ = TBDMS), (c) *p*-TsCl, $(C_2H_5)_3N$, CH_2Cl_2, 0° → 25°C, 90% yield in **11** (R = Ts, R′ = TBDMS), (d) $(CH_3)_2CHCH_2CH_2MgBr$, Li_2CuCl_4, THF, 0° → 25°C (15), 65% yield in **2** (R = TBDMS), and (e) $(n\text{-}Bu)_4NF$, THF, 25°C (16), 68% yield in **2** (R = H).

The diastereoisomer **11***b* (**11**, R = Ur, R′ = H) was also transformed into the enantiomer of **2** (R = H) (ent-**2**) (17), i.e. 2*S*,6*S*,2,6,10-trimethylundecan-1-ol, in the following way: (a) *p*-TsCl, $(C_2H_5)_3N$, CH_2Cl_2, 0° → 25°C, 86% yield in **11** (R = Ur, R′ = Ts), (b) $SiHCl_3$, $(C_2H_5)_3N$, C_6H_6, 25°C (13), 87% yield in **11** (R = H, R′ = Ts; $[\alpha]_D$ −8.05° (*c* 3.3 in $CHCl_3$), (c) *tert*-butyldimethylsilyl chloride, imidazole, THF, 25°C (16), 88% yield in **11** (R = TBDMS, R′ = Ts), (d) $(CH_3)_2CHCH_2CH_2MgBr$, Li_2CuCl_4, THF, 0° → 25°C (15), 66% yield in ent-**2** (R = TBDMS), and (e) $n(Bu)_4NF$, THF, 25°C (16), 83% yield in ent-**2** (R = H).

The samples of 2*R*,6*R*,2,6,10-trimethylundecan-1-ol (**2**, R = H, $[\alpha]_D$ + 8.6° (*c* 2.07, hexane) obtained and that of its enantiomer (ent-**2**, R = H, $[\alpha]_D$ −8.17° (*c* 2.09, hexane) (lit. (2, 3) $[\alpha]_D$ 8.6 ± 0.6°) were shown to be enantiomerically pure by analysis (250 MHz ^1H nmr) of their corresponding Mosher's ester derivative (O-methylmandelate) (18).

The principal elements of the above synthetic strategy can be summarized as follows: (a) The readily available symmetrical Diels–Alder product **3** ensures a complete control of the relative stereochemistry of the two methyl groups. (b) Appropriate functional group modifications and insertion of a methylene group (cyclopropane and allene formation and catalytic reduction) allow the mutation from a 1,4 to a 1,5-acyclic stereoselection process. (c) The symmetrical properties of **3** permit the formation of the nine-membered cyclic carbonate **8**. (d) Reaction of the symmetrical carbonate **8** with optically active *l*-(−)-α-methylbenzylamine gave a mixture of two optically active diastereoisomers which can be separated and converted into the desired optically active fourteen-carbon side chain alcohol **2**. This last operation ensures a complete control of the absolute configuration without loss of enantiomeric materials (12).

Work is now in progress to produce more complex substituted aliphatic chains starting from compounds **9** and **10**.

Nuclear magnetic resonance study of fluorine exchange in the $PhPF_4-PhPF_5^-$ system

CHENGRUI WANG[1] AND ALEXANDER F. JANZEN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 13, 1983

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

CHENGRUI WANG and ALEXANDER F. JANZEN. Can. J. Chem. **62**, 1563 (1984).

Intermolecular fluorine exchange in the $PhPF_4-PhPF_5^-$ system has been studied by ^{31}P nmr spectroscopy. The anion $PhPF_5^-$ was prepared *in situ* from $PhPF_4$ and KF in 18-crown-6, or from $PhPF_4$ and SiF_5^-. Exchange was found to be first-order in $PhPF_4$, first-order in $PhPF_5^-$, and slowed down by donor solvents such as acetonitrile, in support of a mechanism involving a fluorine-bridged intermediate. Experimental difficulties are probably due to HF impurities.

CHENGRUI WANG et ALEXANDER F. JANZEN. Can. J. Chem. **62**, 1563 (1984).

Utilisant la rmn du ^{31}P, on a étudié l'échange intermoléculaire du fluor dans le système $PhPF_4-PhPF_5^-$. On a préparé l'anion $PhPF_5^-$ *in situ* à partir du $PhPF_4$ et du KF dans l'éther 18-couronne-6 ou à partir du $PhPF_4$ et du SiF_5^-. On a trouvé que l'échange est du premier ordre en $PhPF_4$, du premier ordre en $PhPF_5^-$ et ralenti par les solvants donneurs comme l'acétonitrile; ceci est en accord avec un mécanisme impliquant un intermédiaire avec une fluor ponté. Les difficultés expérimentales sont probablement dues à la présence d'impuretés dans le HF.

Axial–equatorial fluorine exchange in phenyltrifluorophosphorane, $PhPF_3H$, is a unimolecular process with $\Delta G_{298} = 13.3 \pm 0.5$ kcal/mol. Addition of a base such as pyridine (or triethylamine) leads to intermolecular fluorine exchange with $\Delta G_{298} = 7 \pm 2$ kcal/mol. The intermolecular process is solvent-dependent and appears to involve slow reaction with base to produce $PhPF_4H^-$, followed by rapid fluorine transfer between five- and six-coordinate species, $PhPF_3H$ and $PhPF_4H^-$, via a fluorine-bridged intermediate (1). In order to establish whether a similar mechanism is responsible for intermolecular fluorine exchange in phenyltetrafluorophosphorane, $PhPF_4$, (2) we decided to carry out a ^{31}P nmr study of exchange in the $PhPF_4-PhPF_5^-$ system.

The $PhPF_5^-$ anion was prepared in two ways: either by addition of KF in 18-crown-6 to $PhPF_4$ or by addition of SiF_5^- to $PhPF_4$.

[1] $PhPF_4 + KF \text{ (in 18-crown-6)} \rightarrow K(18\text{-crown-6})^+PhPF_5^-$

[2] $PhPF_4 + Pr_4N^+SiF_5^- \rightarrow Pr_4N^+PhPF_5^- + SiF_4$

Intermolecular fluorine exchange was initiated by adding small amounts of F^- or $PhPF_5^-$ to an excess of $PhPF_4$, and the rate of exchange was studied by means of $^{31}P\{^1H\}$ nmr spectroscopy. Unlike $PhPF_3H$ (1), intramolecular exchange in $PhPF_4$ could not be slowed down, even at −110°C, therefore axial–equatorial exchange of ligands was always faster than intermolecular fluorine exchange.

If fluorine exchange in $PhPF_4-PhPF_5^-$ is a simple bimolecular process, then one should find that $a = b = 1$ in eq. [3].

$$[3] \quad \tau^{-1} = \frac{1}{4}k[PhPF_4]^{a-1}[PhPF_5^-]^b$$

A plot of $\ln \tau^{-1}$ vs. $\ln [PhPF_5^-]$ is shown in Fig. 1 and the slopes are 1.05 in toluene and 1.19 in acetonitrile, which we interpret as unity. As seen in Fig. 1, exchange is slower in acetonitrile than in toluene, in agreement with a similar effect found in the $PhPF_3H-PhPF_4H^-$ system (1) and attributed to coordination of the donor solvent to the phosphorane, thus preventing the formation of a fluorine-bridged intermediate.

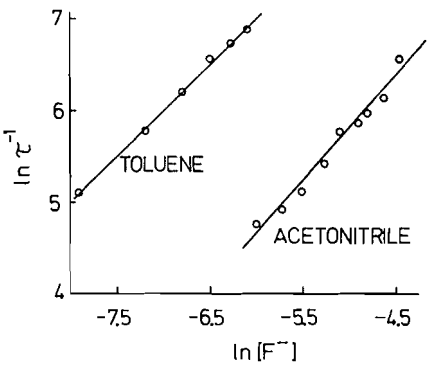

FIG. 1. Plot of $\ln \tau^{-1}$ vs. $[F^-]$ in toluene and acetonitrile solutions at 34°C and $[PhPF_4] = 0.4$ *M*. Note: $[F^-] = [PhPF_5^-]$

Experimental difficulties were encountered during studies of exchange as a function of temperature and $PhPF_4$ concentration. We attribute these difficulties to the presence of impurities which were detected in several ways: firstly, most $PhPF_4-PhPF_5^-$ samples contained varying amounts of the hydrolysis product $PhP(O)F_2$ (2, 5), detected by ^{31}P nmr. No other phosphorus-containing impurity could be detected. Secondly, plots of $\ln \tau^{-1}$ vs. $\ln [PhPF_4]$, as well as activation energy plots,

[4] $PhPF_4 + H_2O \rightarrow PhP(O)F_2 + 2HF$

did not give consistent results. ^{31}P nmr examination showed that $PhPF_4$ was free of impurities after one distillation; therefore, the most likely source of moisture was 18-crown-6 (used to solubilize KF) or $Pr_4N^+PhPF_5^-$. Water is completely removed as a result of eq. [4], and $PhP(O)F_2$ always gave sharp nonexchange-broadened lines, therefore, these species do not interfere with exchange in the $PhPF_4-PhPF_5^-$ system.

Our view is that HF is responsible for experimental difficulties, probably due to the equilibrium of eq. [5].

[5] $PhPF_5^- + HF \rightleftarrows PhPF_4 + FHF^-$

The problem of HF and H_2O impurities also arose in the $PhPF_3H-PhPF_4H^-$ study (1), but there it was solved by ensuring that samples contained a slight excess of $PhPF_2$ so that any HF would react to give $PhPF_3H$ while H_2O was removed

[1]Visiting scientist. Permanent address: Department of Chemistry, Wuhan University, Wuhan, China.

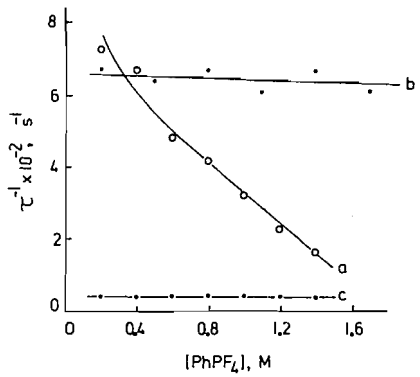

FIG. 2. Plot of τ^{-1} vs. $[PhPF_4]$ at 34°C. (*a*) $[F^-] = 8.6 \times 10^{-4}$ *M* in toluene. (*b*) $[F^-] = 6.5 \times 10^{-4}$ *M* in benzene. Note: $[F^-] = [PhPF_5^-]$ (*c*) $[PhPF_5^-] = 5.6 \times 10^{-4}$ *M* in benzene.

as PhP(O)HF. Such *in situ* removal of common impurities was not achieved in this study.

The study of exchange as a function of $PhPF_4$ concentration was repeated several times. Line (*a*) in Fig. 2, showing a decrease in rate with increasing $PhPF_4$ concentration, is a result which we ascribe to the effect of impurities. On two occasions, however, careful studies showed the rate to be independent of $PhPF_4$ concentration, as seen in lines (*b*) and (*c*). If the rate of fluorine exchange is indeed independent of $PhPF_4$ concentration ($a = 1$ in eq. [3]), and if the order is one with respect to $PhPF_5^-$ concentration, as shown in Fig. 1, then the most reasonable mechanism of exchange is a bimolecular process involving five- and six-coordinate phosphorus species and a fluorine-bridged intermediate. Such a mechanism is entirely consistent with that proposed for the $PhPF_3H-PhPF_4H^-$ system (1) and for related exchange in silicon fluorides (3).

[6] 
Experimental

Acetonitrile was distilled from P_2O_5 and stored over 4A molecular sieve. Toluene was distilled and stored over 4A molecular sieve. Potassium fluoride (Fisher) was dried at 100°C under vacuum for 48 h, and 18-crown-6 (Aldrich) was dried over P_2O_5 (4). $C_6H_5PF_4$ was prepared by the method of Schmutzler (5) and the fraction bp 131.5–133°C stored at 0°C prior to use. Solutions of KF in 18-crown-6 in a 1:1 molar ratio were added to $PhPF_4$ in acetonitrile or toluene in a nitrogen-filled dry box. $(n\text{-}C_3H_7)_4NSiF_5$ was prepared as described previously (6, 7).

$C_6H_5PF_4$ (4.8 g) was syringed onto $(n\text{-}C_3H_7)_4NF$ (5.4 g) (7, 8) in 50 mL acetonitrile in a nitrogen-filled dry box. Evaporation of the solvent gave crystalline $(n\text{-}C_3H_7)_4NPhPF_5$ (1.7 g), which was filtered, dried over P_2O_5 and under vacuum and identified by ^{31}P and ^{19}F nmr (2, 9).

Nuclear magnetic resonance spectra

The proton-decoupled ^{31}P nmr spectra were obtained on a Bruker WH-90 spectrometer at 36.44 MHz. Line-shape calculations were performed on an Amdahl 470-V7 computer with the IBM Fortran H (extended) compiler using a modified version of the program EXCHSYS (10, 11). The exchange probability matrix is identical to that required for the ^1H nmr study of fluorine exchange in $CH_3SiF_4^-$ (7, 11).

The far-infrared spectra and the ring inversion vibrations of a series of methylenecyclohexanes

HAL WIESER, TRACY L. SMITHSON, NAN IBRAHIM, AND PETER J. KRUEGER
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received December 2, 1983

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

HAL WIESER, TRACY L. SMITHSON, NAN IBRAHIM, and PETER J. KRUEGER. Can. J. Chem. **62**, 1565 (1984).

The far-infrared spectra in the region of 50 to 400 cm^{-1} are reported for the vapours of methylenecyclohexane and the related compounds 4-methylenetetrahydro-4*H*-pyran, 4-methylenetetrahydro-4*H*-thiopyran and 3-methylenetetrahydro-4*H*-pyran. The absorptions are assigned to the three out-of-plane deformations of the six-membered rings. The observed series of Q branches are ascribed to combination sequences involving the three modes. The lowest wavenumber sequence in each compound is believed to arise from a vibration which if completely executed would take the chair conformation to its equivalent via an inversion through the planar form. With the use of a one-dimensional Hamiltonian incorporating a quadratic-quartic double minimum potential function, barriers to planarity for the rings are estimated. The similarities between these compounds and the corresponding ketones are discussed.

HAL WIESER, TRACY L. SMITHSON, NAN IBRAHIM et PETER J. KRUEGER. Can. J. Chem. **62**, 1565 (1984).

On rapporte les spectres infrarouges lointains, dans la région allant de 50 à 400 cm, des vapeurs du méthylènecyclohexane et de composés apparentés, les méthylène-4 tétrahydro 4*H*-pyranne, méthylène-4 tétrahydro 4*H*-thiopyranne et méthylène-3 tétrahydro 4*H*-pyranne. On a attribué les absorptions aux trois déformations hors du plan des cycles à 6 chaînons. On a attribué les séries de branches Q observées à des séries de combinaisons qui font intervenir les trois modes. On pense que la série de combinaisons apparaissant aux plus faibles longueurs d'onde, dans le cas de chacun des composés, provient d'une vibration qui, si elle était complètement exécutée, transformerait la conformation chaise en son équivalent par l'intermédiaire d'une inversion en passant par la forme planaire. On a évalué les barrières à la planéité du cycle en utilisant un Hamiltonien unidimensionel incorporant une fonction de potentiel quadratique-quartique à double minima. On discute des ressemblances entre ces composés et les cétones correspondantes.

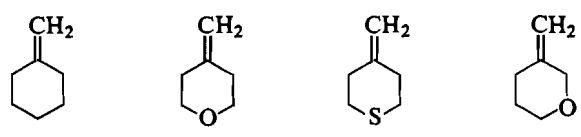
Introduction

We have recently had the opportunity of comparing the far-infrared spectra of conjugated and non-conjugated cyclohexenones (1) with those of the corresponding methylenecyclohexenes (2). These spectra reflected appreciable differences in the effect of the keto and vinyl groups on the out-of-plane deformation modes of the cyclohexene ring. In the conjugated compounds the magnitude of the barrier to inversion through the molecular plane depends to some degree on the extent of conjugation, the barrier being larger for the ketone (3640 vs. 2110 cm^{-1}). For the non-conjugated ketone the spectra indicated a bent ground state conformer with a relatively low barrier of 464 cm^{-1} to planar inversion. The non-conjugated methylene compound appears to exist in four equivalent bend-twist ground state conformations which can interconvert via either a twist barrier of 1476 cm^{-1} or a bend barrier of 2215 cm^{-1}, the planar structure being 3641 cm^{-1} above the ground state.

We have investigated recently also the inversion vibrations of a series of heteroatom substituted cyclohexanones as they are observed in the far-infrared spectra (3). The lowest wavenumber mode we visualized as a vibration which if completely executed would lead to the chair–chair inversion through the planar form. The observed sequences of absorptions suggest a barrier to planarity of 2940 cm^{-1} for the parent compound and diminishing barriers for the oxygen-substituted analogs, depending on the position and number of the oxygen atoms. It was of interest to us to determine to what extent the inversion modes are affected when the keto group is replaced by the vinyl group.

Cyclohexanone and methylenecylohexane are similar in several respects. Both exist in a chair conformation in the ground state (4, 5). The ketone is slightly flattened at the C=O end as determined experimentally and by molecular mechanics calculations (6). A similar effect can probably be expected also for the methylene compound, although corresponding data are not available. The free energy barriers for the chair–chair interconversion ($\Delta G^{\#}$) via one of the flexible conformations have been reported from low temperature proton nmr measurements as 17 and 35 kJ/mol (5, 7) (4.0 and 8.4 kcal/mol, or 1400 and 2940 cm^{-1}), respectively, for cyclohexanone and methylenecyclohexane. For the latter the corresponding calculated strain energy barrier is quoted as 34 kJ/mol (8.1 kcal/mol) (8). The various boat and twist-boat conformations are said to be of similar energy and about 12 kJ/mol (4) or, respectively, 20 to 24 kJ/mol (8, 9) less stable than the chair conformation (1000, or 1660 to 2000 cm^{-1}). In both compounds the process of inversion is likely to start with a torsion about the C—C bonds adjacent to the carbonyl or vinyl groups.

In the following we report the vapour phase far-infrared spectra of methylenecyclohexane (**I**) and the related compounds 4-methylenetetrahydro-4*H*-pyran (**II**), 4-methylenetetrahydro-4*H*-thiopyran (**III**), and 3-methylenetetrahydro-4-*H*-pyran (**IV**):



I **II** **III** **IV**

The spectra are characterized by the sequences of absorptions typical of anharmonic, large amplitude vibrations. These are assigned as far as is possible in terms of the three out-of-plane ring deformations, and barriers to planarity are suggested.

TABLE 1. Comparison of the ring inversion vibrations (in cm^{-1}) of methylenecyclohexanes and cyclohexanones

	Compound	$\nu_1(A')$	$\nu_2(A'')$	$\nu_3(A')$
I	Methylenecyclohexane	123.58	202.37	303.74
	Cyclohexanone	92.39	181.51	307.62
II	4-Methylenetetrahydro-4*H*-pyran	127.31	211.06	327.84
	Tetrahydro-4*H*-pyran-4-one	97.16	184.44	336.87
III	4-Methylenetetrahydro-4*H*-thiopyran	106.83	204	251.37
	Tetrahydro-4*H*-thiopyran-4-one	77.48	186.2	253.6
IV	3-Methylenetetrahydro-4*H*-pyran	126.35	215.06	321.17
	Tetrahydro-4*H*-pyran-3-one	90.48	186.43	336.64

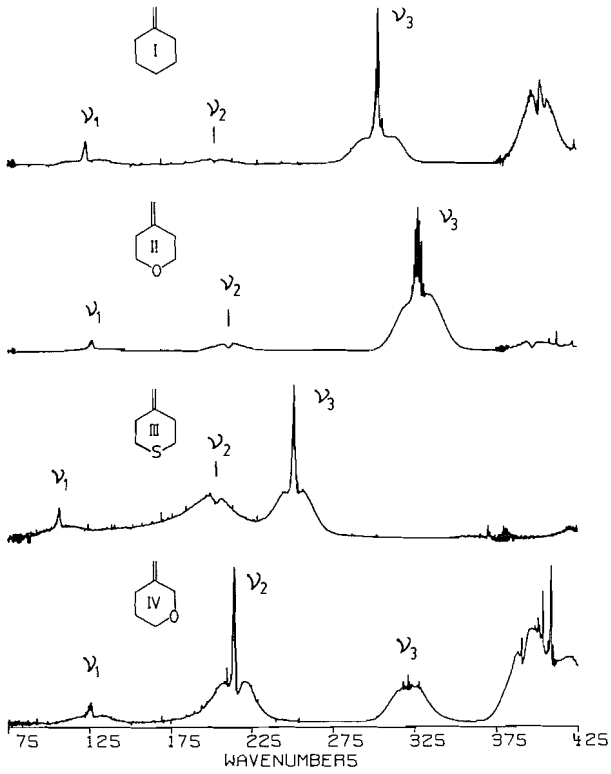


FIG. 1. Survey spectra of methylenecyclohexane and related compounds: 18 m path, reduced vapour pressures, 0.24 cm^{-1} resolution, 6 μm Mylar beamsplitter, 400 cm^{-1} Mylar (for **I** to **III**) or polyethylene (for **IV**) cut-on filter on bolometer, 400 scans.

Experimental

Methylenecyclohexane was purchased from K & K Laboratories and dried by means of refluxing over benzophenone and sodium followed by distillation. The remaining compounds were made from the corresponding ketones by means of the Wittig reaction (10) using triphenylphosphorous methylide. The ketone analogs of **II** and **III** originated from Aldrich Chemicals. The synthesis of the ketone precursor for **IV** was described previously (3). The yields after purification by preparative gc (**II** and **IV**) and distillation (**III**) were 15, 44, and 10% for **II** to **IV**, respectively. The final purity as determined by gc was at least 99% for **II** and **III**, and 85% for **IV**. The contaminant in the last mentioned was *n*-octane, apparently a by-product of the reaction with a very similar boiling point. The far-infrared spectra show no trace of this impurity.

The spectra were obtained with a Nicolet 8000 Fourier Transform Interferometer with optical paths of either 18.75 m in a 20 m Wilks multipass cell, or 45 m in a 60 m optically matched long path cell manufactured by Nicolet. The vapour pressures were adjusted to give reasonable absorbancies in the region of interest. The resolution was set at 0.07, 0.12, or 0.24 cm^{-1} with boxcar apodization. The interferograms were transformed with at least two times zero filling. Either a globar or a mercury arc was used as the light source in conjunction with a 400 or 250 cm^{-1} cut-on filter, respectively, on an Infrared Laboratories liquid helium cooled bolometer as detector operating at 4.2 K, and the appropriate Mylar beamsplitter. The mirror velocity was adjusted as required to achieve a good signal-to-noise ratio. Between 200 and 400 scans were accumulated as necessary. Calibrated against standard water absorptions the reported peak positions are believed to be accurate to at least 0.03 cm^{-1}.

Results

In the C_s symmetry point group of the molecules **I**, **II**, and **III**, the three out-of-plane deformation modes belong to $2A' + A''$. For cyclohexanone we conveniently described the two A' modes, in increasing energy, as out-of-phase (ν_1) and in-phase (ν_3) combinations of a simultaneous though not necessarily equal folding about the C2—C6 and C3—C5 axes, and the A'' mode (ν_2) as a twisting of the middle part of the chair (3). These descriptions we realize are at best approximate. They are, however, based upon extensive earlier force field calculations (11), are consistent with the vapour phase contours, the apparent band intensities, intensity changes upon oxygen substitution, and resemble the corresponding deformation coordinates suggested for cyclohexane (12, 13).

The three absorptions of the methylene compounds are shown in the survey spectra in Fig. 1. The skeletal deformations of the vinyl group, placed in other molecules near 350 and 420 cm^{-1} (14), are not assigned specifically and will not be discussed. The positions of the ring deformation modes are compared in Table 1 for the two series. As in the ketones, the ν_1 and ν_3 fundamentals in the methylene compounds show the expected C contours. As also observed for the ketones, the ν_2 mode exhibits the B contour anticipated for **I**, **II**, and **III**, whereas for **IV** the absorption takes on an A−C character and dominates the spectrum, indicating a comparatively larger dipole moment change in the twist mode. The relative intensities of ν_1 and ν_3 are reversed in the two series, that of the latter being greater for the methylenecyclohexanes. We interpret this as indicating that it is the vinyl or the carbonyl end which undergoes the larger displacement for ν_1, and the opposite end for ν_3. The positions of the fundamentals point to the same conclusions. The ν_1 absorption is shifted to higher wavenumbers by a significant amount for the methylene compounds, while ν_3 stays nearly the same. The ν_2 fundamental evidently is also shifted to higher energy as would be expected if the vibration involved partly a torsion about the C1—C2 and C1—C6 bonds.

If some interaction between the skeletal modes does take place, we would expect to find evidence to this effect primarily

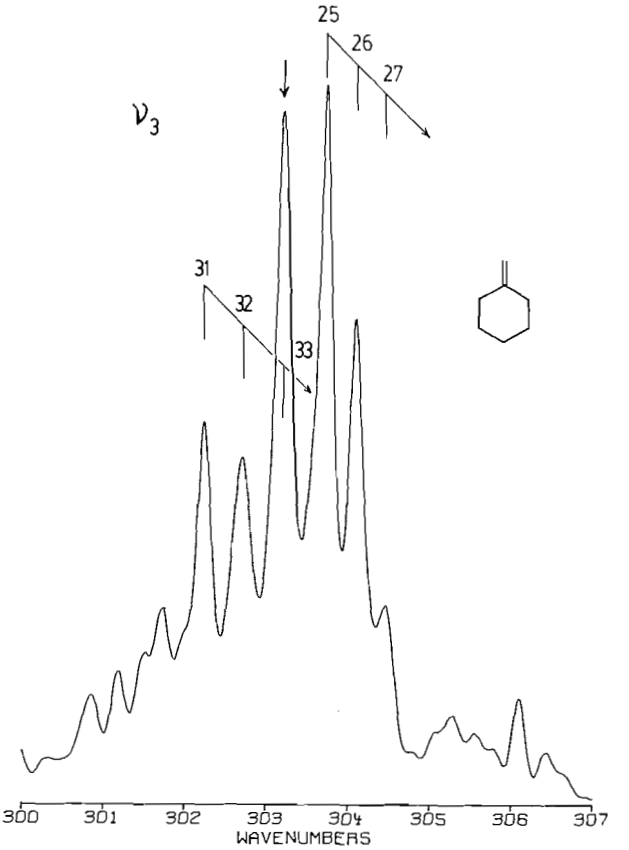

FIG. 3. Expansion of ν_3 band of methylenecyclohexane: 18 m path, reduced vapour pressure, 0.24 cm^{-1} resolution, 6 μm Mylar beamsplitter, 400 cm^{-1} Mylar cut-on filter, 200 scans.

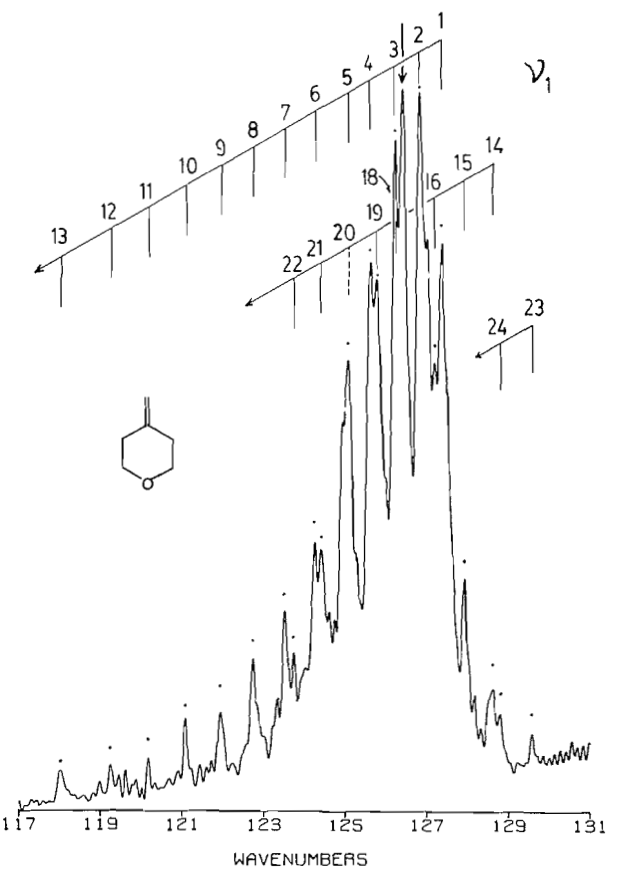

FIG. 4. Expansion of ν_1 band of 4-methylenetetrahydro-4*H*-pyran: 18 m path, reduced vapour pressure, 0.12 cm^{-1} resolution, 12 μm Mylar beamsplitter, 250 cm^{-1} cut-on filter, 400 scans.

for ν_1 and ν_3 in **I**, **II**, and **III**, and for all three modes in **IV**, as we observed for the ketones. All the corresponding absorptions in Fig. 1 show the characteristic sequences. They are expanded in Figs. 2 to 10. The ν_1/ν_3 sequences of all four compounds and the ν_1/ν_2 sequences of **IV** can be assigned as combination series, as summarized in the common energy level scheme drawn in Fig. 11. The peak positions are given in Tables 2 to 4. The peak numbers listed in these tables correspond to the labelled absorptions in the figures and the numbered transitions in the energy level diagram.

For the ketones we were able to model the ν_1 spacings successfully with a one-dimensional double minimum potential function. We suggested that this function can be thought of as representing a section through the four-dimensional potential energy surface (i.e. the potential in the three ring deformations) along the ν_1 coordinate at zero displacement of the other two. The height of the central barrier should then provide an estimate for the barrier to the chair−chair inversion through the planar structure. From Table 2 it is evident that for all four methylene compounds the one-dimensional quadratic-quartic potential successfully reproduces the transitions in the ground state of all other modes. All the energy levels shown are described properly without truncation errors by the set of basis functions used. Moreover, the potential constants, given in terms of the dimensionless coordinate, are well determined by the data, so that we are confident that the extrapolation to the barrier top does not introduce an error in the barrier height of more than 10%. The inversion sequences in the first excited state of ν_3 for **I**, **II**, and **III**, and ν_2 for **IV** yield estimates for

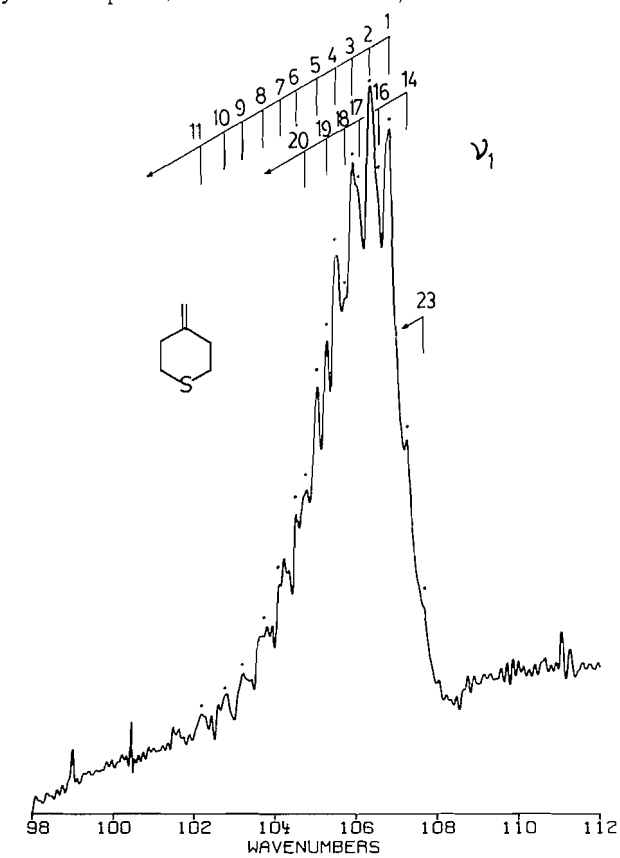

FIG. 6. Expansion of ν_1 band of 4-methylenetetrahydro-4*H*-thiopyran: 18 m path, saturated vapour pressure, 0.12 cm^{-1} resolution, 12 μm Mylar beamsplitter, 250 cm^{-1} cut-on filter, 200 scans.

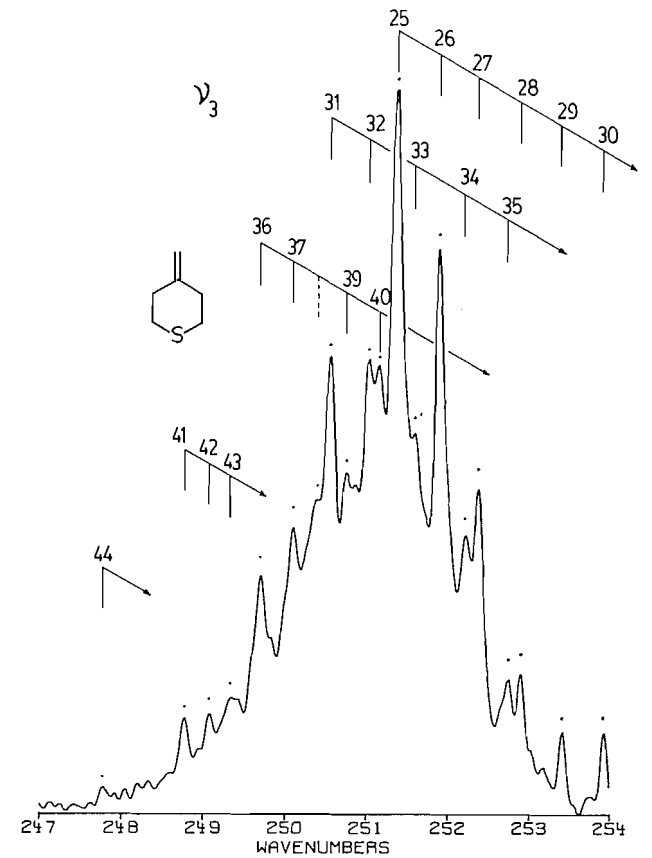

FIG. 7. Expansion of ν_3 band of 4-methylenetetrahydro-4*H*-thiopyran: 18 m path, saturated vapour pressure, 0.12 cm^{-1} resolution, 6 μm Mylar beamsplitter, 400 cm^{-1} Mylar cut-on filter, 300 scans.

the effective excited state potential constants. These, together with the barriers deduced from them, are given in Table 3.

Discussion

The location of the lowest members of the ν_1 sequences in the ground state and in the first excited state of ν_3 in all cases are assured by the combination principle. For **III**, in particular, the first five transitions in ν_1, which may appear uncertain as a result of the closeness of the series, are confirmed by the clearly assignable ν_3 sequence (cf. Figs. 6 and 7). There are several additional prominent Q branches left unassigned for **I** and **II** that cannot be part of the ν_1/ν_3 combination series (for example in Figs. 3, 4, and 5, marked with an arrow). These we believe are ν_1 transitions in various excited states of ν_2. They cannot be confirmed since the B contours of the twist mode are not resolved and no sum or difference bands are observed. For **IV**, however, where the twist band dominates, ν_1/ν_2 sequences are clearly evident (see Fig. 9).

Ideally a proper theoretical analysis for modelling the observed transitions should use an appropriate three-dimensional Hamiltonian allowing for coupling and anharmonic corrections in both the kinetic and potential energy parts. The feasibility of using such a three-dimensional analysis for ring deformations has recently been demonstrated. For 1,3-disilacyclobutane a Hamiltonian was employed which in principle is similar to that indicated in footnote *e* of Table 2, except that it is extended to include appropriate potential terms in the three coordinates as well as a kinetic energy expansion for the puckering coordinate (16). In that particular case, only the puckering mode displayed a double minimum character while the other two modes were

treated as harmonic, and the authors could take advantage of the relatively infrequent luxury of having available a wealth of combination data. More appropriate for our present case is the kind of treatment demonstrated recently with cyclohexane (17) and *p*-dioxane (18). For neither of these two molecules are the transitions sufficiently well-known experimentally to permit the evaluation of the potential parameters best fitting the observed positions, although the author states that in principle the method does not preclude a fitting procedure. For the methylenecyclohexanes and the ketone analogues we chose not to pursue such computations at this time. Notwithstanding the amount of information we do have, the set of data obviously is not complete. We have tried earlier to reproduce the ν_1 and ν_3 transitions of the ketone analogue of **II** in a two-dimensional way, albeit with a constant coordinate-independent reduced mass (3). The results were not encouraging and we accepted perforce the one-dimensional method as currently the only reasonable way of extracting the limited barrier information from the data.

At first glance it is remarkable that the one-dimensional Hamitonian with the quadratic-quartic potential function is capable of reproducing the spacings for ν_1 quite as successfully. Perhaps this success is not too surprising, however, when one considers that since the chair is the ground state conformation ν_1 must be the dominant mode, and up to a relatively high energy the other two modes correspond to anharmonic deformations in the chair's deep potential well. The spectra show the slowly diminishing sequence for ν_1 characteristic of a double minimum situation with a high barrier, while the diminishing sequences of ν_3 (and of ν_2 in the case of **IV**) are caused by the anharmonic potential environment. In order to evaluate quantitatively the extent to which the three modes are coupled, of course, would require some sort of three-dimensional analysis. For coupled they must be, at least to some extent, since the ν_1 sequences in the excited states of ν_2 and ν_3 are shifted from the

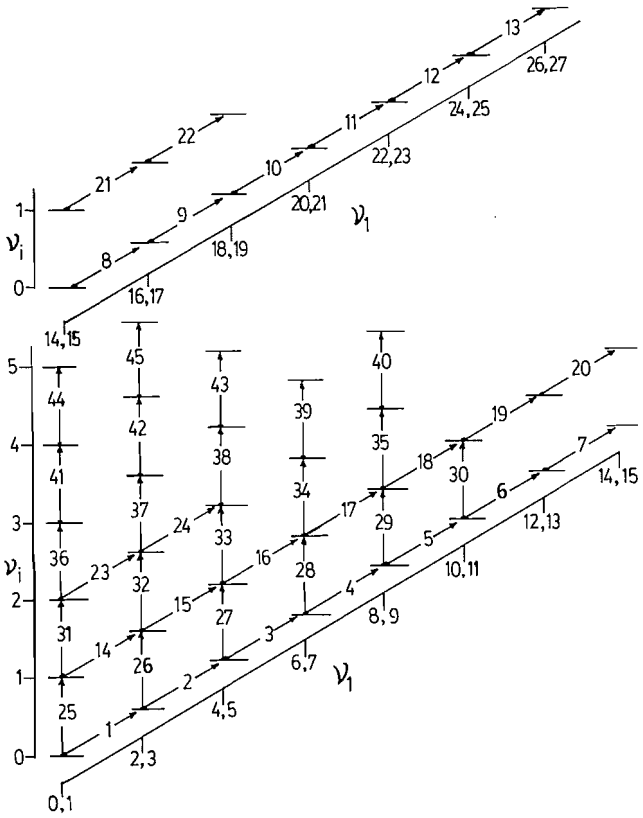

FIG. 11. Energy level diagram showing combination transitions between ν_1 and ν_i, $i = 2$ or 3. Numbered transitions correspond to the peaks labelled in Figs. 2 to 10 and in Tables 2 to 4.

ν_1 fundamental position (to lower wavenumbers for the former and to higher for the latter), and the effective potential constants for ν_1 are different in the excited states of ν_2 (**IV** only) and of ν_3 (**I**, **II**, and **III**) than those of the ground state. The question as to how the barrier to planarity which is estimated here one-dimensionally would be affected by a multidimensional approach, unfortunately cannot be answered. Neither does the present analysis provide any information about the relative stabilities of the conformers involved or the barriers to interconversion between them. Specifically this means that the inversion barriers derived from nmr measurements cannot be verified by the infrared data since these two methods determine different barriers on the potential surface.

It is noteworthy to observe the trend of negative to positive to negative deviations between the calculated and observed ν_1 transitions in Table 2. This kind of trend, as noted by Malloy (19), can result from neglecting the subtle contribution made to the anharmonicity by the kinetic energy. When we attempted to include in the fitting process a kinetic term of the form $g^{(2)}pq^2p$, q the dimensionless coordinate, p its conjugate momentum, and $g^{(2)}$ the coefficient of q^2 in the expansion of the reduced mass in terms of the deformation coordinate used as a fitting parameter, the deviations were reduced only marginally with the trend remaining, even if $g^{(2)}$ was optimized to yield the best fitting potential constants. In contrast, remarkable improvements in the fit have been demonstrated by just such a procedure in several other instances (19, 20). While anharmonic contributions from the kinetic energy may well play a role also in the present cases, they evidently are difficult to quantify. Judging by the experience made by others (e.g. 19, 21), we believe that the estimated barriers to planarity are not likely to be influenced significantly by neglecting such contributions.

[a]Peak numbers correspond to labelled peak positions in Figs. 2 to 10, and numbered transitions in Fig. 11.
[b]Peak numbers 14′ and 23′ in Fig. 8.

Accepting the deduced values for the barriers to planarity as reasonable estimates, some interesting trends are revealed. The barriers diminish with oxygen substitution. The same trend was observed for the ketones, for which the comparative values for the analogues of **I**, **II**, and **IV** are 2940, 2772, and 1068 cm^{-1}, respectively (3). An oxygen atom in the position β to the exocyclic double bond (either C=C or C=O) evidently reduces the barrier more effectively than an oxygen in the γ position. The difference between the cyclohexanones and the methylene analogues reflects the established fact that torsion about a C—C bond adjacent to a carbonyl group is easier than when adjacent to a vinyl group.

Apart from different relative intensities reflecting differences in the dipole moment change with the coordinates, the far-infrared absorptions of the methylenecylohexanes are very similar to those of their ketone counterparts. In appears, therefore, that replacing the carbonyl group with the vinyl group does not affect dramatically the dynamics of the deformations of the cyclohexane ring.

Determination of CNDO/2 dipole moment derivatives from interpolating polynomials

ALLAN WILLIAM TARR AND BRYAN ROGER HENRY
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received October 10, 1983

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

ALLAN WILLIAM TARR and BRYAN ROGER HENRY. Can. J. Chem. **62**, 1573 (1984).

A numerical differentiation technique is presented from which dipole moment derivatives are estimated from sets of CNDO/2 calculated dipole moment values. The dipole moment values are evaluated over a range of molecular geometries, which are obtained by distorting the molecule along CH-stretching local coordinates. The technique effectively fits the dipole moment values to an interpolating polynomial, but the utilization of difference tables and lozenge diagrams makes the explicit determination of the polynomial unnecessary.

First, second, and third order pure derivatives, and second order mixed derivatives, are estimated for methane and ethane. Several testing procedures for the numerical technique are discussed. On this basis, the accuracy of these derivatives is judged to be very good.

ALLAN WILLIAM TARR et BRYAN ROGER HENRY. Can. J. Chem. **62**, 1573 (1984).

On présente une technique de différenciation numérique qui permet d'évaluer les dérivées du moment dipolaire à partir d'un ensemble de valeurs de moments dipolaires calculés par CNDO/2. On a évalué les moments dipolaires dans un domaine de géométries moléculaires que l'on obtient en déformant la molécule le long de coordonnées locales d'élongation du C—H. La technique permet effectivement d'établir une corrélation avec les valeurs du moment dipolaire jusqu'à un polynome d'interpolation; toutefois l'utilisation de tables de différence et de diagrammes de lozange rend inutile la détermination explicite du polynome.

On a évalué, pour le méthane et pour l'éthane, les dérivées pures des premier, deuxième et troisième ordres et les dérivées mixtes du deuxième ordre. On discute de plusieurs méthodes de vérification de la technique numérique. Dans ces conditions, on estime que la précision de ces dérivées est très bonne.

Introduction

The local mode model has proven to be very useful in understanding the high energy, XH-stretching overtone spectra of a wide variety of molecules (1). Although the general patterns of the overtone bands can be rationalized within this model, quantitative prediction of relative local mode intensities remains a major problem. Of central importance in understanding these intensities is the dependence of the electric dipole moment, μ, on local coordinates. The dipole moment can be expanded in a Taylor series in local coordinates, q_i

$$[1] \quad \boldsymbol{\mu} = \boldsymbol{\mu}^0 + \sum_i \boldsymbol{\mu}_i q_i + \left(\frac{1}{2}\right) \sum_{i,j} \boldsymbol{\mu}_{ij} q_i q_j + \ldots$$

where $\boldsymbol{\mu}^0$ is the electric dipole moment of a molecule at the average geometry of the vibrational ground state, and $\boldsymbol{\mu}_i = (\partial\boldsymbol{\mu}/\partial q_i)_0$ and $\boldsymbol{\mu}_{ij} = (\partial^2\boldsymbol{\mu}/\partial q_j \partial q_i)_0$ represent the derivatives of the dipole moment function, which are evaluated at the average geometry. The purpose of the present paper is to present a convenient method to obtain these dipole moment derivatives and to illustrate the application of the method to methane and ethane.

CNDO molecular orbital theory (2*a*) has been used extensively to calculate first order derivatives of the electric dipole moment (3–8). The general procedure is to distort the molecule from its equilibrium geometry along some symmetry coordinate (3–6, 8), or to move a specific atom along a Cartesian coordinate (7). The dipole moments of the molecule at several distorted geometries are calculated, and the first derivative is often obtained from the assumption that the dipole moment is linear in the distorting coordinate. Occasionally nonlinear dipole moment functions have been assumed. In one investigation of ethane, twenty values of the distorted geometry dipole moments have been fitted with a least squares procedure to a quadratic function of the Cartesian nuclear displacement (7).

Molecular orbital calculations have also been used to calculate dipole moment derivatives with respect to local coordinates (9–12). Burberry and Albrecht have determined the first and second order derivatives of the dipole moment functions of benzene and ground ($X^2\pi$) state CH radical with respect to the CH-stretching local coordinates (9). A one dimensional dipole moment function was assumed in both cases. The dipole moments of distorted geometries of benzene were determined from CNDO/S (13) calculations and were fitted to a quintic power series in the displacement. The published (14) *ab initio*, extended CI dipole moments of the CH radical, at a variety of bond lengths, were also fitted to a power series. Tamagake *et al.* have published a series of papers (10–12) in which they have calculated $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_{11}$ for several molecules. They used *ab initio* calculations with 4-31 G (15) and 6-31 G* (16) basis sets to determine dipole moments at distorted geometries. In all cases a one dimensional dipole moment function was assumed and the dipole moments were fitted to a quadratic function in displacement. In fitting their model to experimental overtone intensities, they found an indication that $\boldsymbol{\mu}_{111}$ should not be neglected in the case of chloroform (11), and that the mixed second derivative, $\boldsymbol{\mu}_{12}$, was important in the case of 1,1-dichloroethane (12).

The numerical technique that we present in this paper effectively fits the dipole moment values to a one dimensional interpolating polynomial of high degree. However, through the use of forward difference tables and lozenge diagrams, we are able to avoid the explicit determination of the interpolating polynomial. The technique allows a straightforward determination of $\boldsymbol{\mu}_1$, $\boldsymbol{\mu}_{11}$, $\boldsymbol{\mu}_{12}$, and $\boldsymbol{\mu}_{111}$ in an efficient fashion.

Theory

1. Outline

In the calculation of dipole moments, the average geometry

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

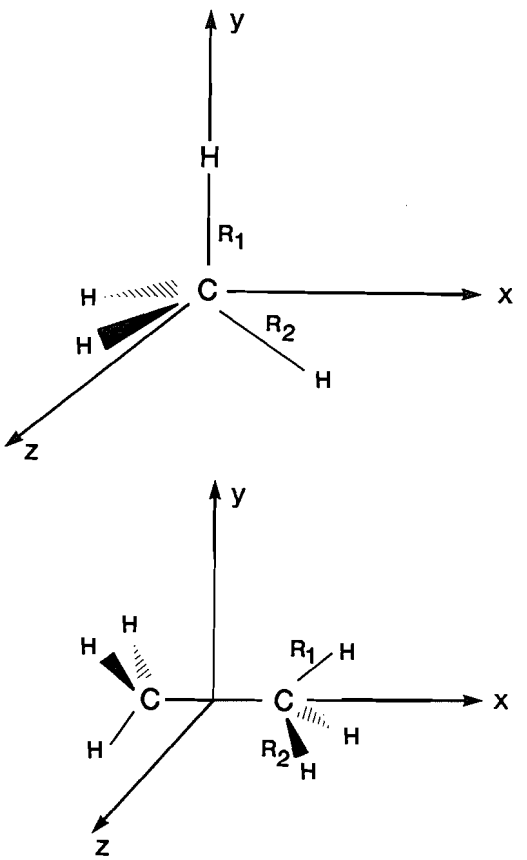

FIG. 1. Spectroscopic structures for (*a*) methane: r^0_{CH} = 1.09397 Å (22), ∠HCH = 109.47° and (*b*) ethane (23): r^0_{CH} = 1.108 Å, r^0_{CC} = 1.536 Å, ∠HCH = 108.8°, ∠CCH = 110.1°.

of the vibrational ground state of the molecule of interest is held rigid, except for the two CH bonds R_1 and R_2 (see Fig. 1). Each of these bond lengths is varied independently in a stepwise fashion. A constant stepsize of h = 0.05 Å is used for both R_1 and R_2. Trials with other stepsizes indicated that this value was the optimum one for this work (*vide infra*).

The dipole moments of the distorted molecules are calculated from the CNDO/2 program INDOFPT (17). There are several reasons why CNDO/2 is used to obtain these values. Dipole moments from CNDO/2 calculations have been found to be generally reliable, especially for hydrocarbons (2). In some instances, CNDO/2 calculations have been more successful at predicting ir intensities than *ab initio* calculations (6). In a parallel study,[1] we have compared dipole moments calculated for dichloromethane from CNDO/2, INDO (2*a*), and STO-3G (18) molecular orbital theories. The CNDO/2 and INDO calculations used the INDOFPT program (17), while the STO-3G calculation used GAUSSIAN 70 (19). The CNDO/2 calculation gave a value for the dipole moment only 3% higher than the experimental value of 1.60 ± 0.03 D (20). Values for the INDO and STO-3G calculations were approximately 7% and 40% too high, respectively.

Thus, CNDO/2 dipole moments are calculated as R_1 and R_2 are varied uniformly and independently. Bond independence is a good approximation for the molecules considered in this work. The valence electron densities of the atoms of methane, which are not involved in the R_1 stretch, vary by less than 0.25% over the full range of the R_1 stretch. Changes of a similar magnitude are observed for ethane, except for the hydrogen atom *trans* to the R_1 bond. The valence electron density at this atom decreases by 0.5% over the full extension of the R_1 bond.

In order to obtain the derivatives simply and accurately, the calculations require that for a specific R_2 value, the dipole moment must be evaluated at an odd number of R_1 values, and vice versa. It is convenient to organize the dipole moments, $\boldsymbol{\mu}(R_1, R_2)$, as a square grid, where each grid element contains the three Cartesian components of the dipole moment. The geometry distortions are performed such that the central element of the grid is $\boldsymbol{\mu}(R_1^0, R_2^0)$, where R_1^0 and R_2^0 refer to the average bond length, r_{CH}^0.

In the next section, we present a numerical technique which allows the approximation of derivatives of one dimensional functions. This technique can be used straightforwardly to estimate the pure derivatives of the dipole moment, $\boldsymbol{\mu}_1$, $\boldsymbol{\mu}_{11}$, and $\boldsymbol{\mu}_{111}$, e.g.

$$[2] \quad \boldsymbol{\mu}_1 = (\mathrm{d}\boldsymbol{\mu}(R_1, R_2^0)/\mathrm{d}R_1)_{R_1 = R_1^0}$$

where R_2 is held fixed at R_2^0. To evaluate $\boldsymbol{\mu}_{12}$, the foregoing procedure is repeated for all the selected values of R_2 to obtain a set of $\boldsymbol{\mu}_1$ values as a function of R_2. Thus the problem is reduced to one dimension, and $\boldsymbol{\mu}_{12}$ can be estimated from

$$[3] \quad \boldsymbol{\mu}_{12} = (\mathrm{d}/\mathrm{d}R_2[(\mathrm{d}\boldsymbol{\mu}(R_1, \bar{R}_2)/\mathrm{d}R_1)_{R_1 = R_1^0}])_{R_2 = R_2^0}$$

where the bar on R_2 denotes the parametric dependence of $\boldsymbol{\mu}_1$.

2. *Numerical differentiation*

Numerical derivatives can be obtained through the use of one dimensional interpolating polynomials of high degree (21). Any particular row or column of the dipole moment grid contains dipole moment values which are effectively a function of only one CH bond length. For generality, denote the set of CH bond lengths and the corresponding dipole moments as $\{x_i, f(x_i)\}$. The following constraints are imposed on the data set to increase the ease of calculation and accuracy of the result. The x_i values are evenly spaced, i.e., $x_{i+1} = x_i + h$ and are odd in number, n. The point at which the derivatives are evaluated x_0, is set to be the central point in the range of x_i values.

The technique effectively fits the n data points to a polynomial of degree $(n - 1)$.

$$[4] \quad P_{n-1}(x_i) = f(x_i)$$

This interpolating polynomial is used as an approximation to the continuous function, i.e.,

$$[5] \quad P_{n-1}(x) \simeq f(x)$$

Numerical approximations of the derivatives of $f(x)$ are obtained by analytic differentiation of $P_{n-1}(x)$. Although $P_{n-1}(x)$ can be determined explicitly, the following technique does not require it.

The numerical technique can be derived through the use of symbolic operator algebra. With a constant stepsize, h, it is possible to introduce an integral index, s, where $s = (x_i - x_0)/h$. A forward difference operator, Δ, can be defined

$$[6] \quad \Delta f_s = f_{s+1} - f_s$$

in which we have used the more concise notation $f_s \equiv f(x_s)$. The forward difference operator is linear. Thus higher order difference operators can be defined by

$$[7] \quad \Delta^j f_s = \Delta^{j-1} f_{s+1} - \Delta^{j-1} f_s$$

[1] B. R. Henry, O. S. Mortensen, A. W. Tarr, and K. Ahmed. Unpublished work.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

The calculated fifferences are conveniently tabulated in a (forward) difference table, e.g.,

f_s	Δf_s	$\Delta^2 f_s$	$\Delta^3 f_s$	$\Delta^4 f_s$
f_{-2}				
	Δf_{-2}			
f_{-1}		$\Delta^2 f_{-2}$		
	Δf_{-1}		$\Delta^3 f_{-2}$	
f_0		$\Delta^2 f_{-1}$		$\Delta^4 f_{-2}$
	Δf_0		$\Delta^3 f_{-1}$	
f_1		$\Delta^2 f_0$		
	Δf_1			
f_2				

[8]

and the interpolating polynomial can be written in terms of these forward differences (21). Two frequently used formulae are the Newton–Gregory forward formula

$$[9] \quad P_{n-1}(x) = \sum_{j=0}^{(1/2)(n-1)} \binom{s}{j} \Delta^j f_0$$

and the Newton–Gregory backward formula

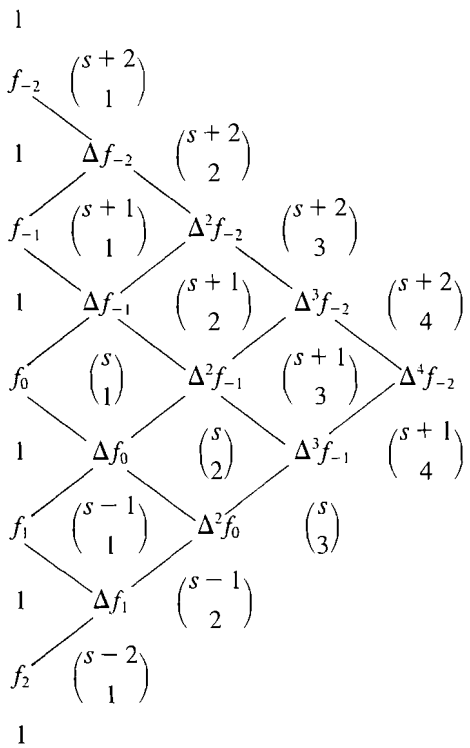
$$[10] \quad P_{n-1}(x) = \sum_{j=0}^{(1/2)(n-1)} \binom{s+j-1}{j} \Delta^j f_{-j}$$

where

$$\binom{s}{j} = [s(s-1)(s-2)\ldots(s-j+1)]/j!$$

$$\binom{s}{0} = 1 \text{ and } \Delta^0 f_0 = f_0$$

Since x_0 has been constrained to lie at the center of the range of x values, eqs. [9] and [10] use only half of the available data. However, the coefficients of the differences in eqs. [9] and [10] can be modified to allow an interpolating polynomial to be fitted to all the available data points (21). For example, the difference table of eq. [8] is associated with the following lozenge diagram for an interpolating polynomial



[11]

The modified Newton–Gregory forward formula can be obtained from the lozenge diagram by summing the differences along the top diagonal, with each difference multiplied by the coefficient directly above, i.e.,

$$P_4(x) = \sum_{j=0}^{4} \binom{s+2}{j} \Delta^j f_{-2}$$

The utility of the lozenge diagram, and the accompanying difference table, lies in the property that any path starting at the left and ending at the right (in this example at $\Delta^4 f_{-2}$) will generate the same interpolating polynomial, as long as a few simple rules are obeyed (21).

Lozenge diagrams can be generated from which the values of the derivatives of the interpolating polynomial may be obtained. Small lozenge diagrams for $(dP_{n-1}/dx)_{x_0}$ and $(d^2P_{n-1}/dx^2)_{x_0}$ are available in numerical analysis texts (ref. 21, for example). However, to our knowledge, lozenge diagrams for $(d^3P_{n-1}/dx^3)_{x_0}$ and large diagrams for the lower order derivatives are not available in the literature. We have calculated lozenge diagrams, capable of accepting thirteen data points, for the first, second, and third order derivatives. These results are presented in Figs. 2–4.

The lozenge diagrams are extended (or created) as follows. If the derivatives are evaluated at $x = x_0$, then $s = 0$ and the differential operator, D, can be defined as (21)

$$[12] \quad Df_0 = (1/h) \ln (1 + \Delta) f_0$$

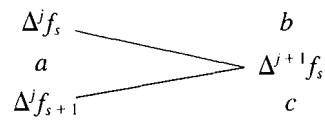
where 1 and Δ are the unit and forward difference operators, respectively. Similarly, higher order differential operators are defined as

$$[13] \quad D^k f_0 = (1/h)^k \ln^k (1 + \Delta) f_0$$

Expansion of the differential operator in terms of the Maclaurin expansion for $\ln (1 + \Delta)$ gives

$$[14] \quad hDf_0 = \sum_{j=1}^{\infty} (-1)^{j+1} (1/j) \Delta^j f_0$$

Equation [14] generates the row of coefficients above the diagonal $\Delta^j f_0$ row in the D^1 lozenge diagram (Fig. 2) from the Newton–Gregory forward formula. The remaining coefficients can be calculated from another property of the lozenge diagram, namely, that the coefficients in a lozenge diagram behave as an upside down, backwards difference table, i.e.,



$$\Delta^{j+1} f_s = \Delta^j f_{s+1} - \Delta^j f_s$$

whereas $a = b - c$.

The coefficients above the $\Delta^j f_0$ row in the D^2 lozenge diagram (Fig. 3) are calculated by squaring the Maclaurin expansion for $\ln (1 + \Delta)$.

$$[15] \quad h^2 D^2 f_0 = [\Delta^2 - \Delta^3 + (11/12)\Delta^4 - (5/6)\Delta^5 + (137/180)\Delta^6 - (7/10)\Delta^7 + (363/560)\Delta^8 - (761/1260)\Delta^9 + (7129/12600)\Delta^{10} - (671/1260)\Delta^{11} + (83711/166320)\Delta^{12} + \ldots] f_0$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

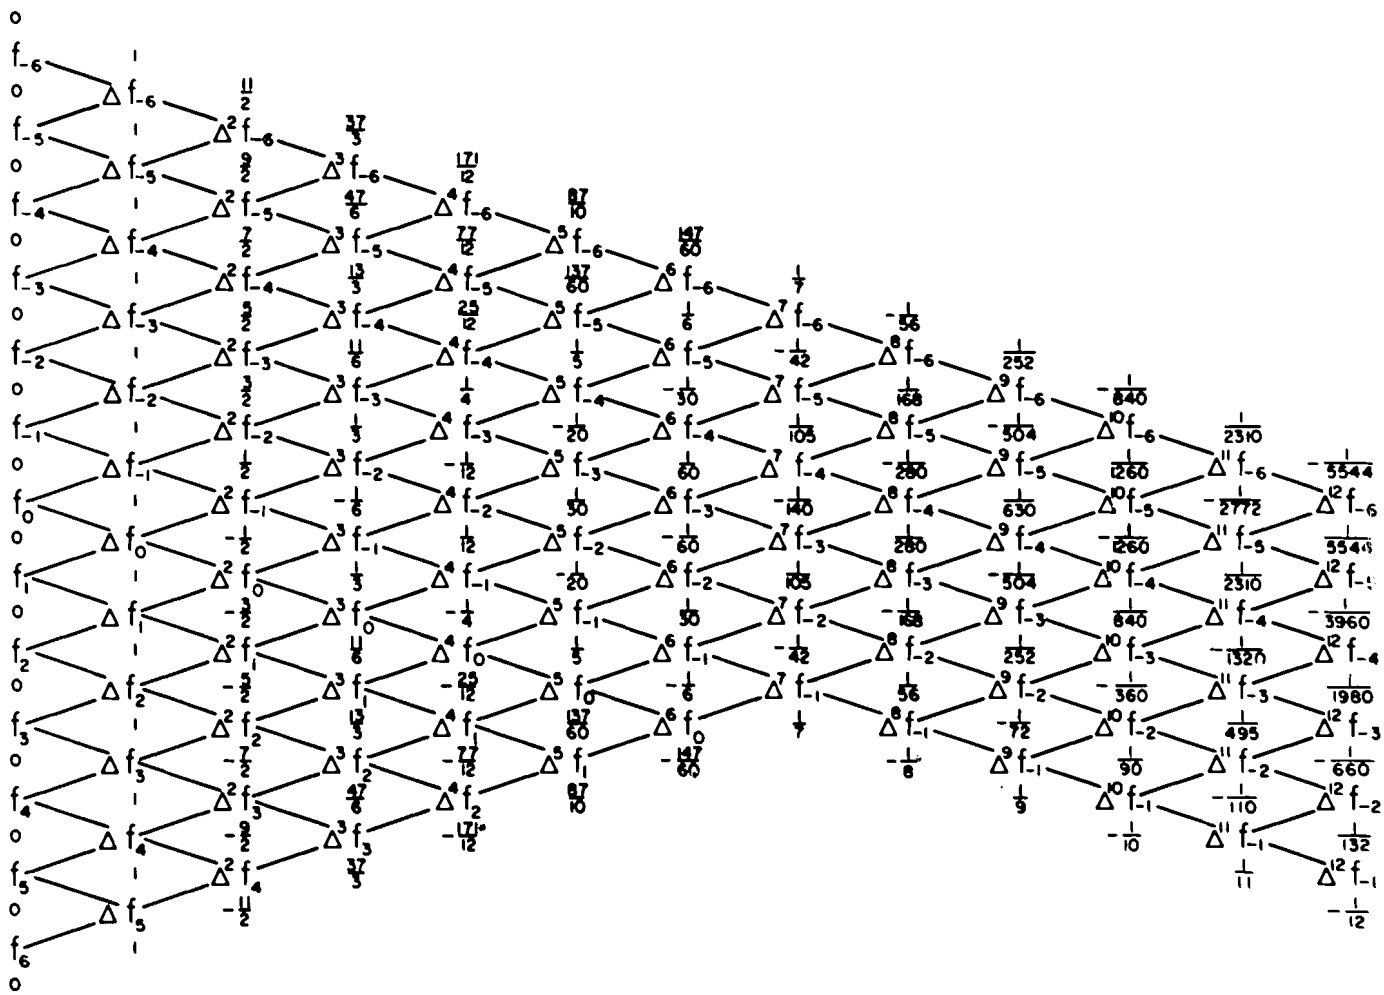


FIG. 2. Lozenge diagram for first order derivatives (hDf_s).

Similarly, the lozenge diagram in Fig. 4 was produced starting with the coefficients from

$$[16]\quad h^3D^3f_0 = [\Delta^3 - (3/2)\Delta^4 + (7/4)\Delta^5 - (15/8)\Delta^6 + (29/15)\Delta^7 - (469/240)\Delta^8 + (29531/15120)\Delta^9 - (1303/672)\Delta^{10} + (16103/8400)\Delta^{11} - (190553/100800)\Delta^{12} + \ldots]f_0$$

The derivative values are calculated from the lozenge diagrams and difference tables in a manner similar to that used to obtain the interpolating polynomial.

Results

The molecular geometry and coordinate system that we used in the calculation of the dipole moment derivatives of methane are shown in Fig. 1*a*. The equilibrium bond length, r_{CH}^0, was taken from an analysis by Herranz and Stoicheff of the high resolution spectrum of the ν_3 Raman band of methane (22). The Cartesian components of the dipole moment were calculated at nine R_1 values (R_1 = 0.89397 (0.05) 1.29397 Å with R_2 = 1.09397 Å). The Cartesian components of $\boldsymbol{\mu}_1$, $\boldsymbol{\mu}_{11}$, and $\boldsymbol{\mu}_{111}$ were estimated with the numerical procedure of the last section, and are given in Table 1. The relatively large number of R_1 values is required in order to obtain reasonable estimates of $\boldsymbol{\mu}_{111}$.

The Cartesian components of $\boldsymbol{\mu}_{12}$ were estimated from a 9 × 9 grid of dipole moment values, i.e., R_1, R_2 = 0.89397 (0.05) 1.29397 Å. The components of $\boldsymbol{\mu}_{12}$ were estimated numerically and are also given in Table 1.

TABLE 1. Local coordinate dipole moment derivatives of methane[a]

Derivatives[b]	*x*	*y*	*z*
$\boldsymbol{\mu}_1$[c] (D Å^{-1})	0	−0.5437	0
$\boldsymbol{\mu}_{11}$[c] (D Å^{-2})	0	−1.06	0
$\boldsymbol{\mu}_{12}$[d] (D Å^{-2})	0.859	0.059	0
$\boldsymbol{\mu}_{111}$[c] (D Å^{-3})	0	1.1	0

[a] The number of significant figures indicates the estimated accuracy of the derivatives of the CNDO/2 calculated dipole moment function and is not intended to imply that the derivatives of the actual dipole moment function are this well known.
[b] All derivatives were evaluated at R_1 = R_2 = 1.09397 Å.
[c] Nine data points were used (R_1 = 0.89397 (0.05) 1.29397 Å, R_2 = 1.09397 Å).
[d] 9 × 9 data point were used (R_1, R_2 = 0.89397 (0.05) 1.29397 Å).

The molecular geometry and coordinate system that we used for the ethane molecule are shown in Fig. 1*b*. The geometry was taken from an analysis by Lafferty and Plyler (23) of the rotational fine structure of the ir (ν_2 + ν_6) combination band of ethane, and from studies of the rotational fine structure of the

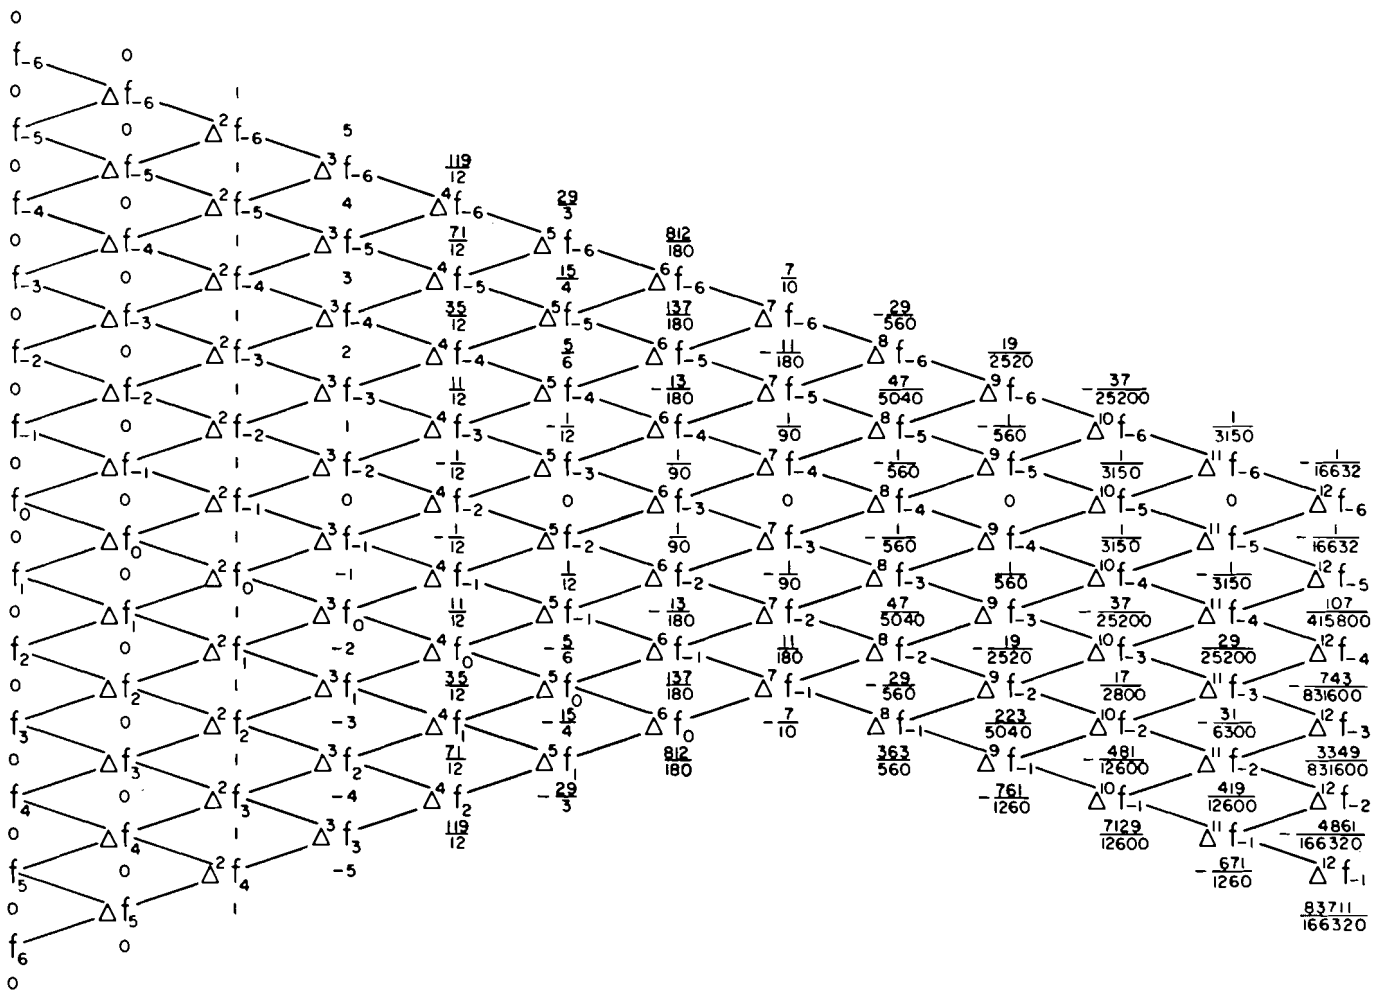

FIG. 3. Lozenge diagram for second order derivatives ($h^2D^2f_s$).

Raman ν_{11} band of ethane (24) and the ir ($\nu_2 + \nu_6$) combination band of perdeuteroethane (25). The molecule was held fixed in its low energy, staggered conformation.

The components of $\boldsymbol{\mu}_1$, $\boldsymbol{\mu}_{11}$, and $\boldsymbol{\mu}_{111}$ were estimated from the dipole moment components calculated at nine R_1 values (R_1 = 0.908 (0.05) 1.308 Å with R_2 = 1.108 Å). As in methane, a 9 × 9 grid (R_1, R_2 = 0.908 (0.05) 1.308 Å) of dipole moments was used to estimate the components of $\boldsymbol{\mu}_{12}$. The dipole moments in the upper right triangular portion of the grid, including the principal diagonal, were calculated directly. The remaining dipole moments were calculated from the transformation matrix.

$$[17]\quad \begin{bmatrix} \mu_x(a,\,b) \\ \mu_y(a,\,b) \\ \mu_z(a,\,b) \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos 120^\circ & \sin 120^\circ \\ 0 & \sin 120^\circ & -\cos 120^\circ \end{bmatrix} \begin{bmatrix} \mu_x(b,\,a) \\ \mu_y(b,\,a) \\ \mu_z(b,\,a) \end{bmatrix}$$

The components of the dipole moment derivatives are given in Table 2.

TABLE 2. Local coordinate dipole moment derivatives of ethane[a]

Derivatives[b]	x	y	z
$\boldsymbol{\mu}_1$[c] (D Å^{-1})	−0.3659	−0.7353	0
$\boldsymbol{\mu}_{11}$[c] (D Å^{-2})	−0.939	−1.39	0
$\boldsymbol{\mu}_{12}$[d] (D Å^{-2})	0.127	0.044	0.079
$\boldsymbol{\mu}_{111}$[c] (D Å^{-3})	0.05	0.35	0

[a] See footnote *a* of Table 1.
[b] All derivatives were evaluated at $R_1 = R_2$ = 1.108 Å.
[c] Nine data points were used (R_1 = 0.908 (0.05) 1.308 Å, R_2 = 1.108 Å).
[d] 9 × 9 data points were used (R_1, R_2 = 0.908 (0.05) 1.308 Å).

Discussion

The results of Tables 1 and 2 can be compared to other results from the literature only in a very limited sense. What other results do exist relate primarily to $\boldsymbol{\mu}_1$. Newton and Person have reported atomic polar tensors calculated from experimental ir intensities of methane (6). They reported two polar tensors due to the uncertainty in the signs of the dipole moment derivatives with respect to normal coordinates. The two values of $\boldsymbol{\mu}_1$, contained in these tensors, are -0.667 ± 0.038 D Å^{-1} and -0.52 ± 0.13 D Å^{-1}, with the former value corresponding to the preferred sign combination. The same authors also reported hydrogen polar tensors derived from CNDO/2 calculations and from the *ab initio* calculations of Meyer and Pulay (26). These tensors give $\boldsymbol{\mu}_1$ values of -0.542 D Å^{-1} and -0.845 D Å^{-1}, respectively. Kornblum has made several calculations of the values of $\boldsymbol{\mu}_1$ for the CH_n (n = 1–4) series using a STO-3G basis set (27). The preferred calculation for methane

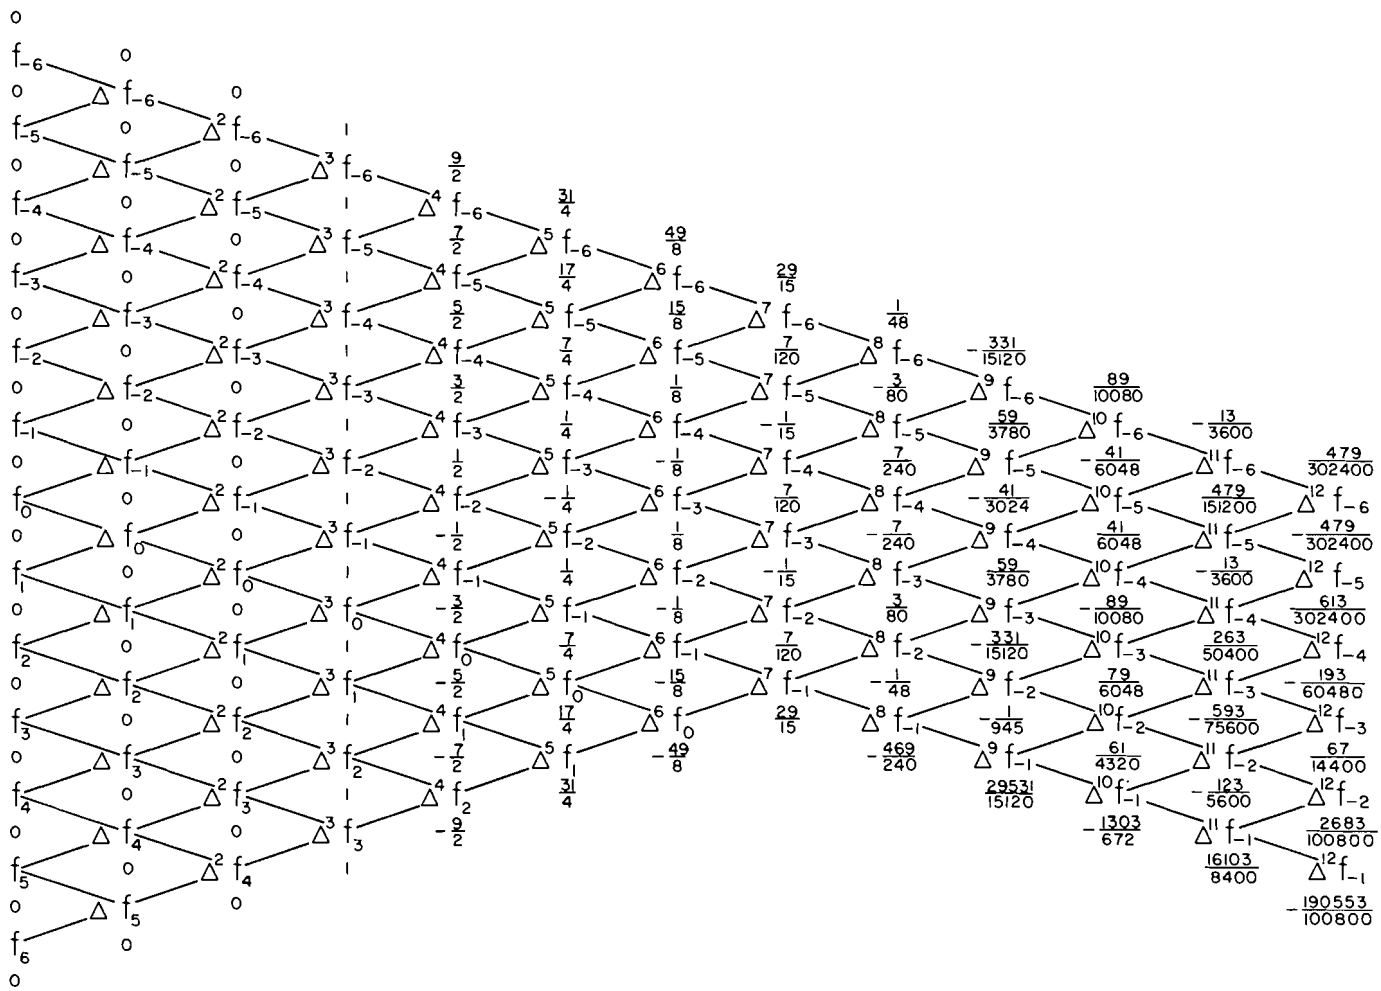

FIG. 4. Lozenge diagram for third order derivatives ($h^3D^3f_x$).

gave $\boldsymbol{\mu}_1 = -0.444$ D Å^{-1}. Tamagake *et al.* calculated values of $\boldsymbol{\mu}_1 = -0.85$ D Å^{-1} and $\boldsymbol{\mu}_{11} = -1.30$ D Å^{-2} from their 4-31G calculations on methane (10). It is not surprising that these results are in moderately good agreement with each other and with the results of Table 1. The differences primarily reflect the relative accuracy of the input data, i.e., the dipole moments, and not differences in the theoretical techniques used to obtain the dipole moment derivatives. It is this latter theme, particularly as it relates to higher order dipole moment derivatives, that is the principal concern of this work.

Thus we have evaluated our procedure using a number of internal tests. The *y*-components of the pure derivatives of the dipole moment of methane were calculated with differing numbers of dipole moment values. The results of this "convergence" test are given in Table 3. Table 3 demonstrates that an increase in the number of data points past nine has no significant effect on the values of $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_{11}$. The value of $\boldsymbol{\mu}_{111}$ changes slightly due to round-off errors (*vide infra*). Therefore, additional values bracketing the central set of nine values do not significantly alter the form of the calculated dipole moment function at r_{CH}^0. The "convergence" of $\boldsymbol{\mu}_{12}$ was not calculated but is expected to be similar to that of $\boldsymbol{\mu}_{11}$.

The "convergence" observed in Table 3 does not guarantee the accuracy of the numerical procedure. Round-off errors due to truncation of the computer generated dipole moment values can markedly affect the values of the higher order derivatives. The round-off effects become serious when the stepsize is small enough that the truncation error is comparable to $\boldsymbol{\mu}(x + h) - \boldsymbol{\mu}(x)$.

TABLE 3. Convergence test for methane

Number of data points	$(\mu_1)_y^a$ (D Å^{-1})	$(\mu_{11})_y^a$ (D Å^{-2})	$(\mu_{111})_y^a$ (D Å^{-3})
3	−0.5432	−1.0560	—
5	−0.5436	−1.0557	1.0800
7	−0.5437	−1.0556	1.1100
9	−0.5437	−1.0556	1.1497
11	−0.5437	−1.0556	1.1844
13	−0.5437	−1.0556	1.2148

[a] All derivatives were evaluated at $R_1 = R_2 = 1.09397$ Å.

In order to determine the appropriate stepsize, and to obtain an estimate of the truncation errors, we used an analytically compact, two dimensional exponential test function, $f(x, y) = 0.036 \exp(x + y)$. The pre-exponential factor was chosen such that the $f(x, y)$ surface around (1, 1) would roughly mimic the *y*-component of the distorted geometry dipole moments of dichloromethane. Specifically, the pre-exponential factor was calculated to meet the condition that $f(1 + h, 1) - f(1, 1) = \mu_y(R_1^0 + h, R_2^0) - \mu_y(R_1^0, R_2^0)$, for $h = 0.005$ Å. Although the value of $f(1, 1) = 0.266$ did not reproduce the magnitude of the equilibrium geometry dipole moment of dichloromethane, 1.65 D, the gradients of the $\mu_y(R_1, R_2)$ and $f(x, y)$ surfaces were

similar over the regions considered when the stepsize was 0.05 Å. Thus the $f(x, y)$ test function was a good imitation of the y component of the $\mu(R_1, R_2)$ function even though the two functions were shifted from one another by a constant value. The shift constant was of no consequence in the evaluation of the numerical differentiation procedure.

Errors in numerical differentiation were obtained by comparison of the analytical and numerical derivatives of the test function. The test function values used to obtain the numerical derivatives were truncated, with rounding, to the same degree as the computer generated dipole moment values. Large errors in f_{111} resulted when the technique was tested with nine points and a stepsize of 0.005 Å. The effect of round-off error was reduced by an increase in the stepsize. With a stepsize of 0.05 Å, the values of the numerical derivatives differed by 0.01%, 3%, and 12% from the analytical values of f_1, f_{11}, and f_{111}, respectively. The mixed second derivative was not calculated with this stepsize since previous testing with $h = 0.02$ Å had shown that the quality of f_{11} and f_{12} were similar (9% and 4% low, respectively, as compared to the analytical derivatives).

An alternative to increasing the stepsize to minimize the effects of round-off error would have been a modification of the INDOFPT program to allow the generation of more precise dipole moment values. This option was not undertaken even though, in theory, the mapping of the dipole moment function would be somewhat better with a smaller stepsize. Such a modification is clearly not justified given the accuracy of the CNDO/2 calculation.

The test function was also used to investigate the type of convergence illustrated in Table 3, as the number of data points is increased. Round-off errors in a difference table increase in magnitude toward the right side of the table. Thus, as the number of data points increases, the difference table becomes larger and the round-off errors in the rightmost portion of the table increase. Therefore, round-off errors impose an effective upper limit on the number of points that can be used to estimate meaningful values of the derivatives. Calculations with the test function showed that the discrepancy between analytical and numerical derivatives increases very slowly, with increasing number of points, for f_1 and f_{11}, and by about 2% for each additional pair of points for f_{111}. A decrease in the number of data points decreases the effects of round-off errors but also decreases the accuracy of the mapping of the function. In the present work, the appropriate trade-off between these two factors was found to occur at nine points.

As we have already noted for methane (Table 3), the round-off errors do not significantly affect μ_1 and μ_{11} when up to thirteen dipole moment values are used. Similar results are obtained for ethane. The values of μ_{111} given in Tables 1 and 2 change in their least significant digit. Thus, for thirteen data points, $(\mu_{111})_y$ changes by 0.1 D Å^{-3} and 0.02 D Å^{-3} for methane and ethane, respectively.

On the basis of these tests, we conclude that numerical differentiation with interpolating polynomials gives very good estimates of theoretical dipole moment derivatives, up to at least the second order derivatives. The numerical third order derivatives, although subject to larger errors, are considered to be good estimates as well. One other observation supports this conclusion. In our calculation of the local coordinate dipole moment derivatives of dichloromethane,[1] the Cartesian coordinate system was chosen so that the z-axis bisected the Cl—C—Cl angle and the z-axis lay in the H—C—H plane. Therefore, by symmetry, $(\mu_{12})_y = 0$. The numerical value that we calculated using 9×9 data points and a stepsize of 0.05 Å was -5×10^{-7} D Å^{-2}, which provides another indication of the level of accuracy of the numerical technique.

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

DAVID M. MCKINNON, K. ANN DUNCAN, and LESLEY M. MILLAR. Can. J. Chem. **62**, 1580 (1984).

Several 3-aminothiophene-2-carboxylic ester derivatives are made by reaction of potassium 3-ethoxy-3-oxopropanoate with isothiazolium salts or by reaction with 2-ethoxy-2-oxoethylidenedimethylsulfurane. In the latter case deaminated products are also isolated. These products are consistent with initial nucleophilic attack on the sulfur atom of the isothiazolium salt. In one case a pyrrole derivative is formed by a novel rearrangement of an intermediate aziridine derivative. Some further derivatives of 3-benzylaminobenzo[*b*]thiophene are described.

DAVID M. MCKINNON, K. ANN DUNCAN et LESLEY M. MILLAR. Can. J. Chem. **62**, 1580 (1984).

On a préparé plusieurs esters de l'acide amino-3 thiophène carboxylique-2 en faisant réagir l'éthoxy-3 oxo-3 propanoate de potassium avec des sels d'isothizaolium ou avec l'éthoxy-2 oxo-2 éthylidènediméthyl-sulfuranne. Dans ce dernier cas, on a également isolé des produits de désamination. Ces produits correspondent à une attaque nucléophile initiale sur l'atome de soufre du sel d'isothiazolium. Dans un cas, il se forme un dérivé du pyrrole selon une nouvelle transposition d'un dérivé aziridine intermédiaire. On décrit quelques autres dérivés de le benzylamino-3 benzo[*b*]thiophène.

Introduction

Nucleophilic attack by some stable carbanions at the ring sulfur atom of both monocyclic isothiazolium salts **1** and 1,2-benzisothiazolium salts has been demonstrated (1, 2). The final isolated products are frequently thiophene or benzo[*b*]thiophene derivatives respectively, formed by recyclization of initial reaction products. For example, the reaction of phenacylidenedimethylsulfurane with 2,5-diphenylisothiazolium perchlorate (**1***a*) afforded 3-anilino-2-benzoyl-5-phenylthiophene. An alternative approach to this type of compound used sodium benzoylacetate, behaving as a potential phenacyl ion, reacting with 2,5-diphenyl-3-methylthioisothiazolium perchlorate (**1***b*). In this case the final aromatization is effected by loss of a group that was originally on the isothiazolium ring. In view of the potential of aminothiophenecarboxylic acids in the synthesis of fused thiophene heterocycles, analogous to the preparation of fused heterocycles from anthranilic acid derivatives, we have investigated their preparation by methods analogous to these.

Results and discussion

Since we have earlier demonstrated that in these reactions sodium benzoylacetate functions as a potential phenacyl ion, accordingly, in this work, we used potassium 3-ethoxy-3-oxopropanoate as a source of the anion of ethyl acetate. Thus, when it was treated with 2-benzyl-3-methylthio-1,2-benzisothiazolium perchlorate (**1***c*), ethyl 3-benzylaminobenzo[*b*]thiophene-2-carboxylate (**2***b*) was obtained in high yield. This reaction likely proceeds by initial attack of the anion on the ring sulfur atom, forming an acyclic intermediate which then recyclizes, forming the thiophene by loss of methanethiol (Scheme 1, X = SCH_3). Likewise 2-methyl-3-methylthio-1,2-benzisothiazolium perchlorate (**1***d*) gave ethyl 3-methylaminobenzo[*b*]thiophene-2-carboxylate (**2***c*).

Treatment of monocyclic isothiazolium salts **1***e*,*g* similarly successfully gave the thiophene-2-carboxylic ester **3***b* in moderate yield. In these cases the final aromatization is by loss of an amine function, as these compounds lack alkylthio leaving groups in suitable positions. For the compound **1***h*, the thiophene derivative **3***c* was obtained along with methyl 3-methylamino-2-phenyldithiopropenoate (**4**). Had attack of the nucleophile occurred at carbon-5 of the salt, methanethiol would likely have been eliminated to provide a reductant, as is known for some 2,1-benzisothiazolium cation reactions (3).

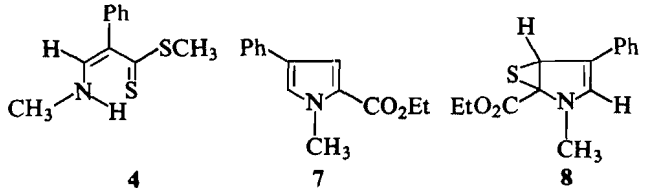
Indeed, treatment of the salt **1***h* with sodium methanethiolate did provide the aminodithioester **4** in good yield. However, we have not been able to isolate any reaction product arising from nucleophilic attack at carbon.

Another possible approach to the desired amino esters would be by using the anion of ethyl acetate stabilized as an ylid. Accodingly, 2-ethoxy-2-oxoethylidenedimethylsulfurane was treated with the five monocyclic isothiazolium salts **1***a*, *e*–*h*, and in each case we obtained the expected 3-aminothiophene-2-carboxylic ester derivatives **2***a*, *d*–*g*, i.e. products consistent with initial attack of the ylid at ring sulfur (Scheme 2). However, the intermediate **5** could form the ester **2** in several ways. One possible pathway is via an aziridine **6** (Scheme 2, path a) as suggested (4) by analogy with the known formation of aziridines from imines and sulfur ylids (5). Nevertheless, we consider that another pathway, involving a β-elimination, is more likely, especially for the formation of unsaturated esters of type **2** (Scheme 2, path b). This is discussed below.

In three cases, **1***a*, *e*, and *f* the aminoesters **2** were accompanied by products which did not contain an amino function, i.e. **3***a*, *b*, and *c* respectively. Likewise **1***h* also gave **3***c* (the nitrogen atom and substituent are lost in the reaction). One possibility is that there is some reduction stage in the reaction, involving loss of the sulfonium moiety, so that eventual aromatization ocurs by loss of amine. This reduction may be by the ethanol solvent or by a nucleophilic displacement on the exocyclic sulfur atom. Various stabilized carbanions or equivalent are known to be displaceable from the corresponding sulfides (6–8). Another possibility is that there may be bond formation between the sulfur and nitrogen atoms, producing a four-membered ring or transition state analogous to the intermediates of Wittig reactions, with final elimination of an azasulfonium ylid (Scheme 2, path c). Although the occurrence of "σ-tetravalent" sulfur in the four-membered ring is not impossible (9), there do not appear to be any earlier literature reports of a reaction such as path c, and it may represent an unusual reaction product of sulfonium ylids.

When the isothiazolium salt **1***g* was treated with ylid, the pyrrole derivative **7** was obtained as a minor product. A possible source for its formation would be the episulfide **8**, since it is known that these readily extrude sulfur, especially when aromatic structures are produced (10). The episulfide itself could be formed from the aziridine **6** by a number of possible rearrangement mechanisms. Although we have shown one ionic mechanism (Scheme 3), there are in fact a number of methods, involving other ionic mechanisms or pericyclic reactions, whereby the conversion might be effected. The pyrrole **7** has not been previously synthesized. Its structure was proved by hydrolysis and decarboxylation to the known 1-methyl-3-phenylpyrrole. While isothiazolium salts have been used in the preparation of other heterocyclic systems, these reactions have usually involved retention of the sulfur atom. This reaction therefore is of a new type, where the nitrogen atom is retained instead, and it may have potential in the synthesis of pyrrole derivatives.

Another plausible mechanism for the formation of the aziridines **6** would be from a carbene **9**, produced by α-elimination from the sulfonium ylid, such as are known (11).



4 **7** **8**

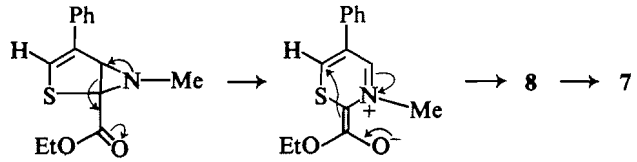

SCHEME 3

mediate. Since there appears to be little reason why any such aziridine should not convert to the corresponding pyrrole, and yet pyrrole products were not obtained from the isothiazolium salts **1***a*, *e*, *f*, we favor the β-elimination pathway (Scheme 2, path b) for these. Possibly in these cases the nitrogen atom, bearing an aryl substituent, would be less nucleophilic and less able to displace dimethyl sulfide to form the aziridine. However, in one case, **1***h*, which is an *N*-methylisothiazolium salt, no pyrrole was obtained. Other factors may therefore be implicated.

The reaction of 2,3-dimethylisothiazolium perchlorate (**1***i*) with the ylid gave a number of products which we have been unable to identify.

We attempted to produce aminothiophenecarboxylic esters using a nitrogen ylid, the anion of *N*-(2-methoxy-2-oxoethyl)-pyridinium bromide, and treatment with the isothiazolium salt (**1***f*) gave methyl 3-anilino-5-methylthio-4-phenylthiophene-2-carboxylate (**2***h*). The yield of this, however, was lower than the ester formed using the sulfonium ylid.

Since N-substituted anthranilic acids serve as synthetic precursors of isatoic anhydrides and thence 2,1-benzisothiazoles (12, 13), we attempted comparable conversions of the amino-acid **10***a*, produced by basic hydrolysis of the ester **2***b*, in an attempt to prepare thieno[3,2-*c*]isothiazole derivative. The acid **10***a* only gave the urethane **10***b* on treatment with ethyl chloroformate. The acid contains structural elements resembling anthranilic acids and thiophene-2-carboxylic acids, both of which decarboxylate readily. Treatment of **2***b* directly gave the ester **10***c*, and thionation of the amide **10***d*, prepared from the ester **2***b* and pyrrolidine, gave a complex mixture from which no thioamides, possible precursors of isothiazoles, could be isolated.

Although the nitrogen atom in compound **10***d* would be expected to have sp^2 hybridization, due to its attachment both to a thiophene ring and a carbonyl group, the neighboring benzylic protons were evident as two doublets, indicating their non-equivalency. It thus appears that steric constraints force the nitrogen atom into an sp^3 hybridization, rendering the benzylic protons diastereotopic. Rapid inversion at nitrogen is also precluded by steric hindrance.

Experimental

The ^{1}H nmr spectra were obtained in deuteriochloroform solution using tetramethylsilane as an internal standard, on a Varian model E.M. 360 spectrometer. Mass spectra were obtained on a Finnigan model 1015 spectrometer, and thick-layer chromatography (tlc) was performed on "Camag" silica gel type D.S.F.5 supplied by Terochem laboratories. Where necessary, solutions were dried over anhydrous magnesium sulfate.

*Reactions of isothiazolium salts (**1**) with potassium 3-ethoxy-3-oxopropanoate*

To the isothiazolium salt (~1 mmol) in anhydrous ethanol (10 mL) was added potassium 2-ethoxy-2-oxopropanoate (1.5 mmol) and the mixture heated gently until complete reaction (~5 min). The solutions were diluted with water and extracted with chloroform. The dried evaporated extracts were thick oils which were purified by chromatography using benzene or chloroform as eluents, depending on the polarity of products. In some cases the products crystallized on standing. For the product **2***b* no chromatography was necessary and it was crystallized from ethanol. Results are summarized in Table 1.

*Reactions of isothiazolium salts (**1**) with 2-ethoxy-2-oxoethylidene-dimethylsulfurane*

2-Ethoxy-2-oxoethyldimethylsulfonium bromide (1.5 mmol) in ethanol (10 mL) was treated with sodium ethoxide (1.5 mmol) and to the solution was added the isothiazolium salt (1 mmol). The mixtures were warmed until homogeneous and the solutions were worked up as above. Results are summarized in Table 2. In general, although both thiophenecarboxylic esters (**3**) and aminothiophenecarboxylic esters (**2**) chromatographed at similar R_f values, satisfactory separation was obtained by varying the eluents.

*Reaction of 2,4-diphenyl-3-methylthioisothiazolium perchlorate with N-(2-methoxy-2-oxoethyl)pyridinium bromide to form **2**h*

To a solution of sodium (46 mg) dissolved in ethanol (10 mL) was added the pyridinium salt (232 mg, 1.0 mmol) and the mixture swirled until homogeneous. Then the isothiazolium salt (384 mg, 1.0 mmol) was added, and the mixture warmed until homogeneous. Work-up by the procedures used above for sulfonium ylids gave the ester as an oil which crystallized on standing. It was finally recrystallized from ethanol as pale yellow needles, mp 158°C (19%).

The nmr spectrum, δ: 2.47 (3H, s, S—CH_3), 3.71 (3H, s, CO_2Me), 6.5–7.4 (10H, m, aromatic), 8.45 (broad N—H). The mass spectrum: M^+ 355, M calcd. 355. *Anal.* calcd. for $C_{19}H_{17}NO_2S_2$: C 64.23, H 4.79, N 3.94, S 18.03; found: C 64.41, H 4.82, N 3.81, S 18.22.

*Reduction of 2-methyl-5-methylthio-4-phenylisothiazolium perchlorate (**1**h) by methanethiol to methyl 3-methylamino-2-phenyldithiopropenoate (**4**)*

The salt **1***h* (1.0 mmol) was added to a sodium methanethiolate solution (prepared by passing excess methanethiol into a solution of sodium ethoxide) and the mixture warmed until homogeneous, then diluted with water. The dried chloroform extract gave yellow needles on evaporation. Recrystallization from hexane gave **4** as long yellow needles (60%). The product was identical (mixture mp, R_f, to that isolated above). The nmr spectrum, δ: 2.5 (3H, s, S—CH_3), 3.1–3.2 (3H, d, N—CH_3), 6.8–7.1 (1H, s, vinyl), and 7.2–7.5 (5H, m, aromatic).

*3-Benzylaminobenzo[b]thiophene-2-carboxylic acid (**10**a)*

The ester **2***b* (1 g, 3.02 mmol) in ethanol (10 mL) was treated with 20% aqueous sodium hydroxide solution (5 mL) and refluxed 3 h. The solvent was evaporated and the residue in water (10 mL) was adjusted to pH 4 with concentrated hydrochloric acid. The amino acid precipitated as a pale yellow powder, mp 125–126°C (94%), which was collected and dried. This was sufficiently pure for further reactions without recrystallization. The mass spectrum: M^+ 283, M calcd.: 283. *Anal.* calcd. for $C_{10}H_{13}NO_2S$: C 67.84, H 4.59, N 4.95, S 11.31; found: C 67.66, H 4.81, N 4.63, S 11.52.

*Ethyl N-benzyl-N-(3-benzo[b]thienyl)carbamate (**10**b)*

The acid **10***a* (0.707 g, 2.5 mmol) in ethyl chloroformate (10 mL) was refluxed 3 h. Evaporation of the solution yielded a viscous oil which crystallized on standing under cyclohexane. The material was recrystallized from cyclohexane as colorless needles, mp 76–78°C (85%). The nmr spectrum, δ: 1.15 and 4.20 (—CH_2—CH_3), 4.90 2H, s, CH_2—Ph), 6.99 (1H, s, the thiophene), 7.15–7.95 (9H, m, aromatic). *Anal.* calcd. for $C_{18}H_{17}NO_2S$: C 69.45, H 5.47, N 4.50, S 10.29; found: C 69.28, H 5.20, N 4.69, S 10.51.

*Reactions of ethyl 3-benzylaminobenzo[b]thiophene-2-carboxylate (**2**b) with pyrrolidine to form N-pyrrolidinyl-3-benzylamino-benzo[b]thiophene-2-carboxamide (**10**c)*

The ester **2***b* (1 g, 3.2 mmol) in pyrrolidine (10 mL) was heated in a closed vessel at 130°C for 16 h. Evaporation of the solution gave a semicrystalline oil which was crystallized from methanol as colorless

The effect of α-cyclodextrin upon the kinetics of aqueous bromination of anisole

OSWALD S. TEE[1] AND JANICE M. BENNETT[2]

Department of Chemistry, Concordia University, 1455 de Maisonneuve Ouest, Montréal, P.Q., Canada H3G 1M8

Received September 26, 1983

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

OSWALD S. TEE and JANICE M BENNETT. Can. J. Chem. **62**, 1585 (1984).

α-Cyclodextrin (cyclohexaamylose) (CD) reduces the rate of bromination of anisole and *p*-methylanisole in aqueous KBr solutions (0.05−0.1 *M*). This retardation is largely due to the formation of a CD − tribromide ion complex and, to a lesser extent, to the encapsulation of bromine and of the anisole substrate. For *p*-methylanisole no other effects seem to be important. However, for anisole a pathway involving free (or complexed) anisole and complexed (or free) bromine seems to be operative. The intermediacy of a ternary complex (CD−anisole−Br_2) cannot be ruled out. Both equilibrium and kinetic measurements indicate that the dissociation constant of the CD−Br_3^- complex is ~2 × 10^{-4} *M*.

OSWALD S. TEE et JANICE M BENNETT. Can. J. Chem. **62**, 1585 (1984).

L'α-cyclodextrine (cyclohexaamylose) (CD) réduit la vitesse de bromation de l'anisole et du *p*-méthylanisole dans des solutions aqueuses de KBr (0,05 à 0,1 *M*). Ce ralentissement est dû en grande partie à la formation d'un complexe CD − ion tribromure et, à un moindre degré, à l'encapsulation du brome et du substrat anisole. Il ne semble pas y avoir d'autres effets importants dans le cas du *p*-méthylanisole. Cependant, dans le cas de l'anisole, un mécanisme impliquant de l'anisole libre (ou complexé) et du brome complexé (ou libre) semble avoir une certaine importance. On ne peut écarter la participation d'un complexe ternaire intermédiaire (CD−anisole−Br_2). Des mesures d'équilibre et de cinétique indiquent que la constante de dissociation du complexe de CD−Br_3^- est d'environ 2 × 10^{-4} *M*.

Cyclodextrins are toroidal-shaped molecules, composed of several glucose units, with a hydrophobic cavity (1). They form inclusion complexes with a wide variety of organic substrates (1, 2). Most studies of their ability to influence reactivity have focussed upon "model enzyme studies" (3) and, in particular, on their ability to catalyze hydrolytic reactions (1, 3−5). Much less attention has been spent on their possible effect on other classes of reaction (1, 2, 4). Notable exceptions are studies of the influence of cyclodextrins on intermolecular (6) and intramolecular Diels−Alder reactions (7), on the Reimer−Tiemann reaction (8), and on the chlorination of anisole by hypochlorous acid (9).

In the last case, the classic study of Breslow and Campbell (9), it was found that α-cyclodextrin[3] significantly raises the *para/ortho* product ratio. This effect has two origins: *o*-chlorination is suppressed due to complexation of the anisole, and *p*-chlorination is enhanced due to a process involving a hypochlorite ester of the cyclodextrin encapsulating anisole (9).

Following on from earlier work on pyridones (10), we are now studying the bromination of phenols (11). It seemed reasonable that cyclodextrins might exert significant effects on the normal course of these reactions since various phenols (and their anions) form inclusion complexes (1). Preliminary kinetic experiments with *p*-nitrophenol and phenol suggested that the situation was far more complex than anticipated. Therefore we have studied the bromination of anisole in the presence of α-cyclodextrin[3] in some detail to minimize the complexities which might be involved with an ionizable phenol.

Results and discussion

We have monitored the kinetics of bromination of anisole in aqueous solution as a function of the concentrations of anisole, α-cyclodextrin, bromide ion, and hydrogen ion using the stopped-flow method. Some experiments were also carried out with *p*-methylanisole. Before discussing these results, we first consider the various equilibria involving several species in solution and which are relevant to analysis of the kinetics.

Equilibria

For reasons given elsewhere (12), bromination reactions in aqueous solution are conveniently studied when the medium contains an excess of bromide ion. In the present work we have used [KBr] = 0.05−0.10 *M*. Therefore, the first equilibrium which must be considered is that forming tribromide ion (eq. [1]). In general, the presence of this equilibrium is easily

$$[1] \quad Br_3^- \rightleftharpoons Br^- + Br_2$$

$$K = \frac{[Br^-][Br_2]}{[Br_3^-]} = 0.0562\ M \ (13)$$

corrected for (12, 14), the fraction of free bromine given by[4]

$$[2] \quad f_B = \frac{[Br_2]}{[Br_2]_t} = \frac{K}{(K + [Br^-])}$$

However, in the present case there are added complications. It turns out that *all three species* involved in eq. [1] form complexes with α-cyclodextrin (CD) in aqueous solution and these must be accounted for.

Wojcik and Rohrbach determined the dissociation constant (K_I) of the complex between CD and bromide ion[4,5] (15). The high value indicates relatively weak binding and in many instances the complexation might be ignored. This is not the case

[1]Author to whom correspondence should be addressed.

[3]α-Cyclodextrin (cyclohexaamylose) has six glucose units joined 1,4 in its torus. Its cavity is about 7Å deep and 4.5 Å across (1).

[4]On concentration brackets a subscript "t" indicates the total concentration, a subscript "c" indicates the concentration of a species complexed with CD.

[5]The reversed square brackets are used to symbolize the cyclodextrin encapsulating the species shown between them.

For personal use only.

[3] $]Br^-[\rightleftharpoons Br^- + CD$

$$K_I = \frac{[Br^-][CD]}{[Br^-]_c} = 0.286\ M \quad (15)$$

here; at the high concentrations of bromide ion used, the effect of equilibrium [3] upon the concentration of CD must be included. The available CD is given by:[4]

[4] $$[CD] = \frac{K_I[CD]_t}{(K_I + [Br^-])}$$

Bromine forms a stronger complex with α-cyclodextrin (eq. [5]) (9). However, under our conditions this complexation does not affect the concentration of CD appreciably since

[5] $]Br_2[\rightleftharpoons Br_2 + CD$

$$K_B = \frac{[Br_2][CD]}{[Br_2]_c} = 2.1 \times 10^{-3}\ M \quad (9)$$

$[Br_2] \leq 50\ \mu M$. However, it does contribute somewhat to the reduction of the free bromine concentration (*vide infra*).

Our initial kinetics experiments suggested the formation of a CD complex having a dissociation constant about $10^{-4}\ M$. This is too low for either bromine or anisole (9). Therefore, we carried out a uv spectral study of the effect of adding α-cyclodextrin to aqueous solutions containing bromide ion, bromine, and tribromide ion. Qualitatively, we observe an increase in the Br_3^- absorption maximum at 266 nm and a slight shift to longer wavelengths, suggesting complexation of tribromide ion and an apparent shift in the Br_3^-/Br_2 equilibrium (eq. [1]). Consistent with this we note that formation of Br_3^- is more favorable in less polar media (15). Quantitative measurements at two wavelengths (see Experimental) gave an average dissociation constant $K_T = 1.7 \pm 0.2 \times 10^{-4}\ M$ for the complex between tribromide ion and α-cyclodextrin complex. This low value indicates 10-fold stronger binding than that of

[6] $]Br_3^-[\rightleftharpoons Br_3^- + CD$

$$K_T = \frac{[Br_3^-][CD]}{[Br_3^-]_c} = 1.7 \times 10^{-4}\ M$$

of bromine (see eq. [5]), and it means that under our kinetic conditions equilibrium [6] will be of more significance than [5] in determining the free bromine concentration (see later).

The free anisole (An) concentration is governed by the constant K_A, previously determined by Breslow and Campbell (9). For *p*-methylanisole the value of K_A is 0.015 *M* (9).

[7] $]An[\rightleftharpoons An + CD$

$$K_A = \frac{[An][CD]}{[An]_c} = 3.7 \times 10^{-3}\ M \quad (9)$$

Except at the lowest CD concentrations used, we have $[CD] \gg [An]_t$ and so the fraction of free anisole is given by eq. [8].

[8] $$f_A = \frac{[An]}{[An]_t} = \frac{K_A}{(K_A + [CD])}$$

From the above discussion it is apparent that analysis of the bromination kinetics requires appropriate consideration of *five* equilibria: [1], [3], [5], [6], and [7]. Complexation of bromide ion ([3]) intrudes by reducing available cyclodextrin and can be corrected for by eq. [4]. Similarly, the encapsulation of anisole [7] can be accounted for by eq. [8]. The three remaining equilibria affect the concentration of free bromine and must be considered together.

The total bromine is given by[4]

$$[Br_2]_t = [Br_2] + [Br_3^-] + [Br_2]_c + [Br_3^-]_c$$

Therefore, the fraction of free bromine is given by eq. [9]. At zero CD this expression simplifies to eq. [2], as is appropriate.

[9] $$f_B = \frac{KK_BK_T}{(K_BK_T(K + [Br^-]) + [CD](KK_T + K_B[Br^-]))}$$

At the highest bromide ion concentration used (0.1 *M*), $K_B[Br^-] = 2.1 \times 10^{-4}\ M^2$, whereas $KK_T = 9.6 \times 10^{-6}\ M^2$ and so a simplified version of eq. [9] was also used: eq. [10]. This corresponds to the situation where the formation and complexation of Br_3^- are the major factors which reduce the free bromine concentration.

[10] $$f_B = \frac{KK_T}{(K_T(K + [Br^-]) + [Br^-][CD])}$$

Kinetics

The aqueous bromination of various anisoles has been studied by Aaron and Dubois (16). For anisole in 0.1 *M* NaBr + 1 m*M* $HClO_4$ at 25°C they obtained a second-order rate constant, $k_2^{obs} = 37\,000\ M^{-1}\ s^{-1}$. Under slightly different conditions (0.1 *M* KBr + 10 m*M* HCl) we obtain essentially the same value: $36\,400\ M^{-1}\ s^{-1}$. In each case the reported value is derived from the apparent rate constant (k_2^{app}) by correcting for the fraction of free bromine (eq. [2]) in the equilibrium [1]. For the reaction

$$An + Br_2 \xrightarrow{k_2}$$

$$\text{rate} = k_2^{app}[An][Br_2]_t = k_2[An][Br_2]$$

and so

$$k_2^{app} = k_2 f_B$$

Hence we take $k_2^{obs} = k_2^{app}/f_B$. This approach ignores any reaction via tribromide ion, which is reasonable since k_2^{obs} remains constant ($36\,400$, $34\,600$, $35\,100\ M^{-1}\ s^{-1}$) at the bromide concentrations (0.1, 0.075, 0.05 *M*) used.

We have also measured the kinetics of bromination of *p*-methylanisole and again find good agreement between our results and those of Aaron and Dubois (16) under comparable conditions.

We now consider the effect on adding α-cyclodextrin upon the kinetics of bromination of anisole and of *p*-methylanisole. These two substrates present slightly different pictures. In the case of anisole it appears that there are two bromination pathways, whereas for *p*-methylanisole only one is important. For simplicity of presentation the latter case will be dealt with first, even though it was in fact studied last.

Table 1 shows the effect of added CD[6] upon the measured values of k_2^{app} for *p*-methylanisole at two different bromide ion concentrations. In both cases k_2^{app} is substantially reduced in a manner consistent with the complexation of Br_3^-, Br_2, and the anisole, although the effect of the first of these is dominant.

If the reaction only involves *free* bromine reacting with the *free* anisole then k_2^{app} is simply governed by the fractions of these species.

[11] $$k_2^{app} = k_2 f_A f_B$$

where $f_A = [An]/[An]_t$ and $f_B = [Br_2]/[Br_2]_t$. Since both f_A and f_B depend upon the CD concentration (eqs. [8] and [9]), the form of k_2^{app} in eq. [11] is complex. However, analysis of the data can be facilitated by defining a corrected rate constant

	1.0	1210	7.75
	2.0	678	13.0
	5.0	251	29.9

[a]At 25°C, pH = 2.08 (HCl), total I = 0.11 *M*. Each rate constant is derived from a pseudo-first-order rate constant which is the average of 3–5 runs. Values of k_2^{corr} have been corrected for substrate complexation (see eq. [12]) using the corrected [CD] (eq. [4]).
[b]With 0.05 *M* NaCl to maintain I.

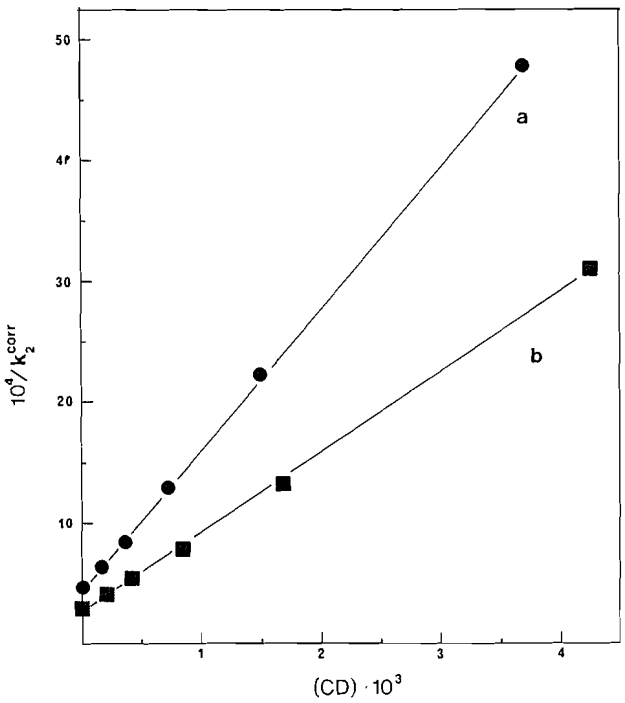

FIG. 1. Rate data for the bromination of *p*-methylanisole, plotted according to eq. [13]. Data from Table 1: (a) 0.10 *M* KBr; (b) 0.05 *M* KBr.[6]

(k_2^{corr}) which allows for the effect of complexation of the anisole, which in the present case is fairly small:

$$[12] \quad k_2^{corr} = k_2^{app}/f_A = k_2 f_B$$

The fraction f_A is taken from eq. [8]. The form of eq. [12] is still non-linear, but its reciprocal, eq. [13], is linear in the concentration of CD,[6] the fraction f_B being obtained from eq. [10].

[6]In the tables the CD concentration is that added, i.e. $[CD]_t$. In data analysis and for plots we use the value obtained after correction for the effect of Br^- (eq. [4]).

TABLE 2. Constants from fitting and direct measurements for *p*-methylanisole bromination[a]

$$[13] \quad 1/k_2^{corr} = 1/k_2 f_B = \frac{(K + [Br^-])}{k_2 K} + \frac{[Br^-][CD]}{k_2 K K_T}$$

Figure 1 shows two plots[6] of the data for *p*-methylanisole corresponding to eq. [13]. They are quite linear ($r > 0.999$) and from their slopes and intercepts one can extract reasonable values of k_2 and K_T (Table 2).

From the above we conclude that α-cyclodextrin significantly reduces the rate of bromination of *p*-methylanisole due to the complexation of tribromide ion and, to a lesser extent, of bromine and the substrate itself. The only important bromination pathway is that involving free substrate and free bromine. Attempts to analyse the data in terms of two pathways, as in the case of anisole (below), led to nonsensical results, such as negative rate constants.

Table 3 presents the data obtained for anisole as a function of CD concentration[6] and at three different bromide concentrations. These data are presented graphically in Fig. 2, as plots

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

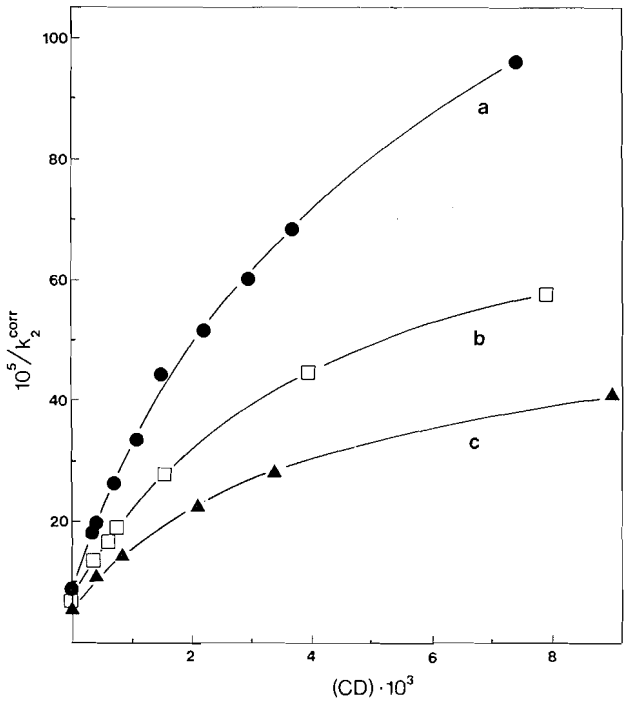

FIG. 2. Rate data for the bromination of anisole. Data from Table 3: (a) 0.10 *M* KBr; (b) 0.075 *M* KBr; (c) 0.05 *M* KBr.[6]

of $1/k_2^{corr}$ versus [CD]. Unlike the linear plots for *p*-methylanisole in Fig. 1, these plots are decidedly curved, the reason being that at higher CD concentrations k_2^{app} is larger than anticipated. As [CD] is raised from 0 to 0.01 *M*,[7] the value of k_2^{app} decreases by a factor of 38. This decrease is *smaller* than the factor of 90 which should arise due to the complexation with CD of Br_2, Br_3^-, and anisole. In other words, there appears to be a second bromination pathway which becomes important as the concentration of CD is raised.

There are various possibilities for a second process, but our results are consistent with either complexed bromine reacting with free anisole, or free bromine attacking complexed anisole. A variety of experiments were carried out to eliminate other possibilities.

At high CD concentration (0.02 *M*) the pseudo-first-order rate constants (k_1^{obs}) for bromine disappearance (see Experimental) increase monotonically with anisole concentration, showing that the transition state for the second process contains anisole. This eliminates the possibility of rate-limiting dissociation of the CD–bromine or CD – tribromide ion complexes.

Experiments were also carried out at various pHs in the range of 0–5. Both in the presence and absence of CD (0.01 *M*) the respective values of k_2^{app} remain constant. These results militate against any process involving HOBr or a hypobromite ester of the cyclodextrin (cf. ref. 9), since the formation of these from bromine is pH dependent (see eq. [14]) (17).

$$[14]\quad Br_2 + ROH \rightleftharpoons ROBr + H^+ + Br^-$$

Likewise, the experiments carried out at three different bromide concentrations are inconsistent with the involvement of

[7]Initial experiments were carried to higher CD concentrations, but then one encounters deviations due to CD affecting the Br^- concentration (eq. [3]).

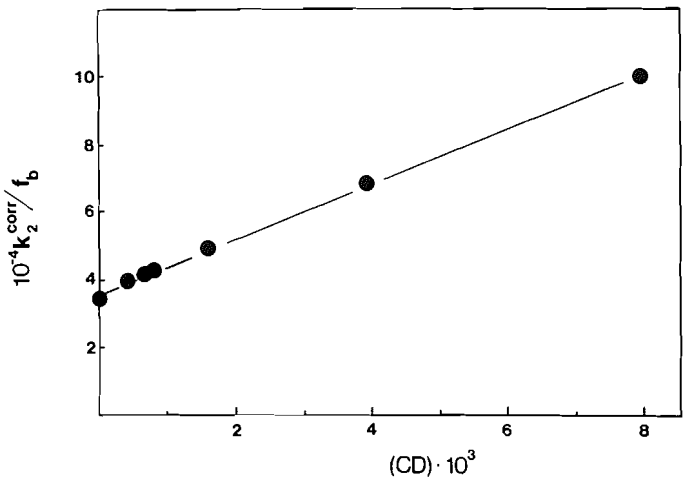

FIG. 3. Rate data for the bromination of anisole, plotted according to eq. [17]. [KBr] = 0.075 *M*.[6]

tribromide ion in the second process. They are, however, compatible with the attack of free (or complexed) bromine on complexed (or free) anisole, as we now show.

If the second process involves free bromine and complexed anisole

$$[15]\quad]An[+ Br_2 \xrightarrow{k_2'}$$

then the overall rate constant will be a weighted sum due to the two contributing pathways,

$$[16]\quad k_2^{app} = (k_2 f_A + k_2'(1 - f_A))f_B$$

where f_A is the fraction of free anisole (eq. [8]), $(1 - f_A)$ the fraction of the anisole–CD complex, and f_B is the fraction of free bromine (eq. [9] or [10]). Rearrangement of eq. [16] leads to

$$\frac{k_2^{app}}{f_A f_B} = k_2 + k_2' \frac{(1 - f_A)}{f_A}$$

which is the same as

$$[17]\quad \frac{k_2^{corr}}{f_B} = k_2 + k_2' \frac{[CD]}{K_A}$$

since $k_2^{corr} = k_2^{app}/f_A$. Figure 3 shows a plot based on eq. [17]. The data for all three bromide ion concentrations (0.1, 0.075, 0.05 *M*) show comparable linearity (r = 0.9950, 0.9980, 0.9975). The values of k_2 and k_2' obtained from the least-squares slopes and intercepts are collected in Table 4.

The data may also be analyzed by a Lineweaver–Burk type of equation (1, 9), to obtain values of k_2' and K_T. Using f_B from eq. [10], the appropriate equation for k_2^{corr} is

$$[18]\quad k_2^{corr} = \frac{(k_2 K_A + k_2'[CD])KK_T}{K_A(KK_T + K_T[Br^-] + [Br^-][CD])}$$

and the apparent rate constant in the absence of CD is defined by

$$[19]\quad k_2^u = k_2 K/(K + [Br^-])$$

From these two equations considerable manipulation leads to the Lineweaver–Burk form shown below.

$$[20]\quad \frac{1}{k_2^{corr} - k_2^u} = \frac{K_A K_T(K + [Br^-])}{[CD](k_2' KK_T - k_2^u K_A[Br^-])} + \frac{K_A[Br^-]}{(k_2' KK_T - k_2^u K_A[Br^-])}$$

[d]Assumed to be the measured value of 1.7×10^{-4} M.

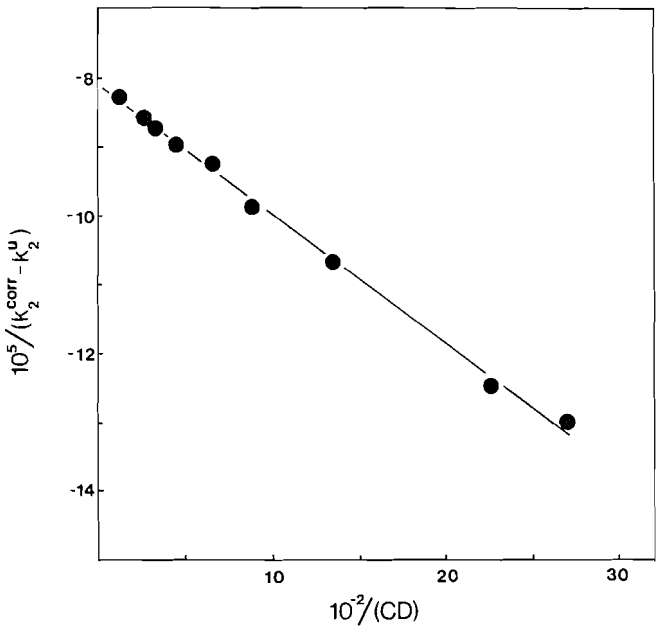

FIG. 4. Rate data for the bromination of anisole, plotted according to the Lineweaver–Burk form, eq. [20]. [KBr] = 0.1 M.[6]

Figure 4 shows a plot corresponding to this equation. The plots for all three values of $[Br^-]$ (0.1, 0.075, 0.05 M) are quite linear (r = 0.9974, 0.9999, 0.9997). From the slopes and intercepts were obtained the values of k_2' and K_T presented in Table 4.

We have also applied non-linear fitting techniques (18) to the equation appropriate to the curved plots shown in Fig. 2. The reciprocal form of k_2^{corr}, using f_B from eq. [9], is

$$[21] \quad \frac{1}{k_2^{corr}} = \frac{K_A(K_B K_T(K + [Br^-]) + [CD](KK_T + K_B[Br^-]))}{(k_2 K_A + k_2'[CD])KK_B K_T}$$

Fitting this equation with k_2 and k_2' as the disposable parameters gives the values in Table 4, and calculated curves which fit the experimental data well[8] (Fig. 2).

The values of the constants given by the three treatments show reasonable consistency and agreement[9] with those from direct measurement, where available (Table 4). They support the hypothesis that free bromine attacks encapsulated anisole (eq. [15]), but they are inconsistent with the second bromination pathway involving Br_3^-. If such a process was involved, the value of k_2' would vary in proportion to $[Br^-]$.

The second pathway might also involve free anisole and encapsulated bromine:

$$[22] \quad An +]Br_2[\xrightarrow{k_2''}$$

since this is kinetically indistinguishable from the process [15]. This is clearly seen in eq. [23], which is appropriate for the process [22], and which has the same mathematical form as eq. [17].

$$[23] \quad \frac{k_2^{corr}}{f_B} = k_2 + k_2'' \frac{[CD]}{K_B}$$

Thus to obtain estimates of k_2'' one can take the values of k_2' from Table 4 and multiply them by the factor K_B/K_A.

Assuming that the process [15] is involved, the data in Table 4 suggest that free anisole is slightly more reactive than encapsulated anisole towards free bromine ($k_2 \sim 37\,000$, $k_2' \sim 32\,000\ M^{-1}\ s^{-1}$). On the other hand, if the second process is that depicted in eq. [22], the data indicate that free bromine is about twice as reactive as the bromine–CD toward free anisole ($k_2 \sim 37\,000$, $k_2'' \sim 18\,000\ M^{-1}\ s^{-1}$).

Initially we had hoped to be able to differentiate between the processes [15] and [22] by studying *p*-methylanisole (PMA) as substrate. The conclusion that PMA has no second pathway might indicate that anisole employs the k_2' process (]An[+ Br_2 →). In encapsulated PMA the reactive *ortho* positions should be buried and unavailable for reaction (9), and so no k_2' process would be observed[10] (Scheme 1).

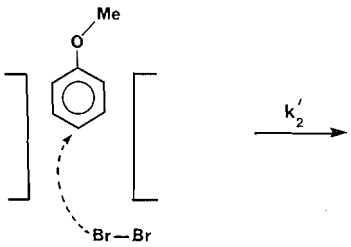
However, a similar steric argument might be used to invoke the k_2'' process (An +]Br_2[→) for anisole. The lack of reactivity of PMA[10] might simply reflect that its *ortho* positions cannot penetrate the CD cavity far enough to react with encapsulated bromine (Scheme 2).

In a similar way, we cannot rule out the involvement of a discrete ternary complex (CD–anisole–Br_2) (Scheme 3). Evidence for the intermediacy of such a complex in the α-cyclo-

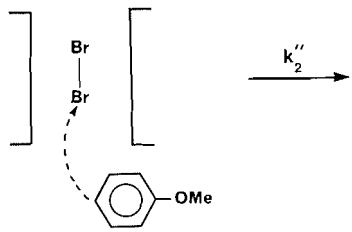
[8]For example, for the data at $[Br^-]$ = 0.1 M the average deviation of the points is 2.4%.

[9]The agreement between the values obtained using eqs. [17] and [21] is very good. The agreement with the values of k_2' from the Lineweaver–Burk treatment (eq. [20]) is much poorer. This is not too surprising, since this treatment put heavy emphasis on the rate constant (k_2^u) at [CD] = 0, and this value gave us problems due to solubility problems (see Experimental). Moreover, the point at [CD] = 0 consistently shows the largest deviation (~10%) in the other treatments. Given that our data analysis employs various constants from various sources, we feel that the overall agreement inTable 2 and Table 4 is quite satisfactory.

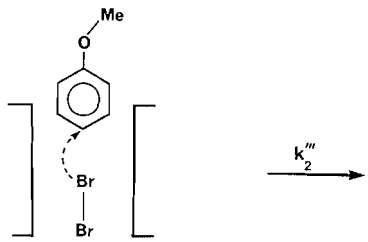
[10]In principle, the inability to detect a k_2' process for PMA might simply be due to its weaker binding to CD (see above). To put this into perspective, one has to estimate what value of k_2' would be detectable under our conditions. Assuming we could detect a 20% contribution from a second process at [CD] = 0.005 M, we conclude that for PMA $k_2' < 3900\ M^{-1}\ s^{-1}$. Likewise for the alternative process we estimate $k_2'' < 550\ M^{-1}\ s^{-1}$. Both of these values are significantly lower than k_2 for PMA (~6500 $M^{-1}\ s^{-1}$).



SCHEME 1



SCHEME 2



SCHEME 3

dextrin mediated Riemer-Tiemann reaction has been put forward (8). In a ternary complex involving PMA the approach of Br_2 to the *ortho* positions would again be blocked (Scheme 3).

Experimental

Anisole (Chemalog) was distilled before use. *p*-Methylanisole (Aldrich) and α-cyclodextrin hydrate (Aldrich) were used as received. Other reagents were of the analytical grade. Potassium bromide was kept in a drying oven at 110–120°C when not in use.

The anisole substrates are poorly soluble in water. Initial experiments showed poor reproducibility which was traced to this problem. For the results reported here, a stock solution of the anisole in methanol (0.05 *M*) was used and diluted with the desired aqueous medium. Immediately before use substrate solutions were shaken vigorously for several minutes. Use of a stock solution in ethanol gave odd results at low CD concentrations. This was probably due to the encapsulation of EtOH by CD (19). The solubility problems diminish with increasing CD concentration due to CD–anisole complex formation (9).

Bromine solutions were made by dilution of a small volume of a stock solution (0.1 *M* in 0.1 *M* aqueous KBr) with the desired medium. This stock solution was made by weighing a few drops of liquid bromine into 10 mL of 0.1 *M* KBr and diluting with 0.1 *M* KBr to arrive at a 0.1 *M* concentration.

Kinetic measurements normally used a substrate concentration of 5×10^{-4} *M* and a bromine concentration of 5×10^{-5} *M* (both values are after mixing in the stopped-flow). Equilibrium measurements (see below) employed bromine solutions of 10^{-4} *M* and 10^{-3} *M* for the experiments at 265 nm and 385 nm, respectively.

Most of the kinetic experiments were carried out at pH 2.08 (0.01 *M* HCl + 0.1 *M* electrolyte). The total ionic strength was maintained at 0.11 *M*, from 0.1 *M* (KBr + NaCl) + 0.01 *M* (HCl or buffer). Unlike Br^-, Cl^- apparently does not form a complex with CD (15). Experiments at pH > 2 used Perrin's (I = 0.01 *M*) buffers (20).

Kinetic methods

Rates were measured as bromine disappearance at 265 nm (Br_3^- band) using the stopped-flow apparatus (21) and acquisition system (22) described earlier. With an excess of substrate, ten-fold or more, good first-order behaviour was observed for >90% reaction; least-squares analysis of ln $(A - A_\infty)$ vs. t showed good linearity (r > 0.999). Pseudo-first-order rate constants (k_1^{obs}) were converted to apparent second-order rate constants (k_2^{app}) by division by the factor $([S] - [Br_2]_0)$ (23).

Bromine reacts with α-cyclodextrin over a period of about an hour. Accordingly, bromine was not brought into contact with CD until mixed in the stopped-flow apparatus. One drive syringe contained substrate and CD in the appropriate medium, the other contained bromine in the medium. This approach should not distort the results since the rate constants for the formation of CD inclusion compounds approach diffusion-controlled (1). Moreover, initial experiments where CD was present in both syringes gave similar results.

Equilibrium measurements

The dissociation constant K_T for the CD–Br_3^- complex was measured spectrophotometrically (9, 24). Absorbance values at two wavelengths were analyzed using the equation:

$$[24] \quad \frac{[Br_2]_t}{(A - A_0)} = \frac{K_T}{\beta\Delta\epsilon[CD]} + \frac{1}{\Delta\epsilon}$$

This is the same as the Benesi–Hildebrand equation (9, 24), except that it contains the factor β, which is the fraction of Br_3^- in the equilibrium [1]. It is given by:

$$\beta = [Br_3^-]/[Br_2]_t = [Br^-]/(K + [Br^-])$$

We used a medium containing 0.01 *M* KBr (+ 0.09 *M* NaCl), so that β = 0.151. At zero [CD] the Br_3^- band (265 nm) is small. As [CD] increases this band increases dramatically as more and more bromine becomes converted to Br_3^- and encapsulated. Even at 385 nm (bromine band) one sees an increase in absorption because the extinction coefficient of Br_3^- is greater than that of Br_2 (17).

Separate experiments at 265 nm (pH 3) and at 385 nm (pH 2) gave plots of $1/(A - A_0)$ vs. $1/[CD]_t$ showing good linearity (r = 0.9936 and 0.9998). From their slopes and intercepts (and β) we obtained $K_T = 1.58 \times 10^{-4}$ and 1.95×10^{-4} *M*, respectively. Correcting these for the free CD concentration (eq. [4]) and averaging the results gives $K_T = 1.7 \pm 0.2 \times 10^{-4}$ *M*.

Long-range $^{13}C,^{1}H$ and $^{13}C,^{19}F$ coupling constants as indicators of the conformational properties of 4-fluoroanisole, 2,3,5,6-tetrafluoroanisole, and pentafluoroanisole

Received October 28, 1983

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

TED SCHAEFER, REINO LAATIKAINEN, TIMOTHY A. WILDMAN, JAMES PEELING, GLENN H. PENNER, JAMES BALEJA, and KIRK MARAT. Can. J. Chem. **62**, 1592 (1984).

Long-range spin–spin coupling constants over six bonds between ^{13}C nuclei in the methyl group and ring protons or ^{19}F nuclei in the *para* position are reported for 4-fluoroanisole, 2,3,5,6-tetrafluoroanisole, and pentafluoroanisole in solution. The couplings are $\sigma-\pi$ electron mediated, as indicated by INDO MO FPT computations and by measurements on anisole, 2,6-dibromoanisole, 2,6-dichloroanisole, 2,6-dibromo-4-fluoroanisole, and 2,6-dibromo-4-methylanisole. On the basis of the measured coupling magnitudes and a hindered rotor model, it is concluded that the barrier to internal rotation about the C_{sp^2}—O bond in 4-fluoroanisole lies near 6 kcal/mol, is nearly zero in the tetrafluoroanisole, and is somewhat less than 1 kcal/mol in the pentafluoroanisole. In the latter, the preferred conformation is that in which the methoxy group lies in a plane perpendicular to the pentafluorophenyl plane. Some inconclusive dynamic nmr experiments on anisole, including $T_{1\rho}$ measurements, are briefly discussed.

TED SCHAEFER, REINO LAATIKAINEN, TIMOTHY A. WILDMAN, JAMES PEELING, GLENN H. PENNER, JAMES BALEJA et KIRK MARAT. Can. J. Chem. **62**, 1592 (1984).

On rapporte les constantes de couplage à longue distance à travers six liaisons entre le noyau ^{13}C du groupe méthyle et les protons du cycle ou les noyaux ^{19}F en position *para* du fluoro-4 anisole, du tétrafluoro-2,3,5,6 anisole et du pentafluoroanisole en solution. Les couplages sont transmis par les électrons $\sigma-\pi$ comme l'indiquent des calculs d'OM INDO FPT et des mesures sur l'anisole et sur les dibromo-2,6, dichloro-2,6, dibromo-2,6 fluoro-4 et dibromo-2,6 méthyl-4 anisoles. En se basant sur l'intensité des couplages mesurés et sur un modèle rotatif encombré, on conclut que la barrière à la rotation interne autour de la liaison C_{sp^2}—O dans le fluoro-4 anisole est voisine de 6 kcal/mol alors qu'elle est voisine de zéro dans le cas du tétrafluoroanisole et quelque peu inférieure à 1 kcal/mol dans le cas du pentafluoroanisole. Dans ce dernier cas, la conformation préférée est celle où le groupe méthoxy se situe dans un plan perpendiculaire à celui du pentafluorophényle. On discute brièvement de certaines expériences de rmn dynamique sur l'anisole, y compris des mesures de $T_{1\rho}$, qui ne permettent toutefois pas de tirer de conclusions.

Introduction

Various physical techniques (1–8) indicate[4] coplanar heavy atoms in the preferred conformation of anisole and imply that the barrier to internal rotation about the C_{sp^2}—O bond is strongly state dependent, and that in solution it lies between about 1.5 and 6 kcal/mol (1 cal ≡ 4.184 J). In some treatments, notably those applied to the torsional mode corresponding to oscillation about the C_{sp^2}—O bond (10, 11), a twofold hindering potential is assumed. It is also usually assumed that $2p-\pi$ conjugation accounts for the preferred planarity and that repulsion between the methyl group and the *ortho* C—H bonds perhaps introduces a fourfold component (7) to the rotational potential (the rotational barrier in phenol is twofold (12)).

The most recent calculations on anisole (7, 9) at the STO 3G MO and 4-31 G MO levels of theory imply a very shallow local minimum, if present at all, in the perpendicular conformation, but that a fourfold component does exist. The magnitude of internal barrier to rotation about the C_{sp^2}—O bond is computed (7) as 1.9 kcal/mol, to be compared with a molecular mechanics result of 1.9 kcal/mol (8). In solution this barrier must be substantially higher, as implied by the torsional data and by our coupling data below. In the solid the barrier magnitude is about 11.5 kcal/mol (1).

A technique not yet applied to this problem is the *J* method (13), in which a long-range nuclear spin–spin coupling with a known conformational dependence is related to the hindering potential and other parameters. This method has had some success in defining the low-energy conformation and the twofold internal potential of sidechains in benzene derivatives, for example in such compounds as ethylbenzene (14) and thiophenol (15, 16) derivatives. Such studies utilized couplings over four and six bonds between sidechain protons and ring protons or fluorine nuclei. More recently (17), the couplings over five bonds between sidechain protons and ring *para* carbon nuclei, as well as over six bonds between β carbon nuclei and *para* ring protons have been examined and found to be useful in the *J* method.

Now, in anisole and its derivatives suitable coupling constants would involve a ^{13}C nucleus in the methyl group, the methyl protons displaying no long-range couplings to *para* protons or fluorine nuclei. A series of experiments on anisole and its derivatives in this laboratory have yielded numerous coupling data for ^{1}H, ^{19}F, and ^{13}C nuclei. These results have not been entirely explicable for anisole, where the fourfold component of the barrier to rotation about the C_{sp^2}—O bond adds an additional complication. However, for the title compounds a reasonable explanation of these data is possible. The coupling

[a] Enriched to 95% α-^{13}C, 200 mg in 2.5 mL of a solvent consisting of 30 v/v% C_6D_{12} in CS_2.

[b] Enriched as above, approximately 5 mol% in acetone-d_6; both samples run at 315 K in an attempt to reduce spin-lattice relaxation rates of α-^{13}C. Diethylether as solvent did not appear to alter the long-range couplings.

[c] Samples were 50 v/v% in benzene-d_6, 0.637 Hz being $^7J_p^{C,H}$.

[d] Samples were 50 v/v% in acetone-d_6.

[e] Samples were 11 mol% in acetone-d_6.

[f] Numbers in parentheses are estimated errors in the last one or two significant figures for these parameters obtained from first-order splitting patterns; in 2,5-dichloro-, 3,5-dichloro-, and 2,3,5-dichloroanisoles no evidence for couplings to *ortho* or *para* protons larger than those in the table could be found.

[g] The value of 0.331 Hz is equal to $^6J_p^{C,H}$ and was indistinguishable in magnitude from $^5J_m^{C,F}$. The ^{13}C nmr spectrum was acquired with the INEPT pulse sequence.

mechanisms for $^6J_p^{C,H}$ and $^6J_p^{C,F}$ are investigated and the observed numbers are used to show that the barrier in 4-fluoroanisole must indeed be rather large, that it is very small or zero in the tetrafluoroanisole, and that in the pentafluoroanisole the preferred conformation is perpendicular.

Experimental

Materials

Anisole-α-^{13}C was prepared by the standard method (18) in which methyl iodide containing 95 at.% ^{13}C (Merck, Sharp and Dohme) was added to a mixture of zone-refined phenol (Aldrich) and anhydrous K_2CO_3 in acetone. The product was identified by ^{1}H nmr and mass spectrometry. The 2,6-dichloro- and 2,6-dibromoanisoles came from Aldrich, as did the 4-methyl-2,6-dibromophenol used to prepare the corresponding anisole derivative using unenriched methyl iodide. The 4-fluoroanisole and the pentafluoroanisole were purchased from Aldrich, while 2,3,5,6-tetrafluoroanisole was a PCR, Inc. product.

The 2,6-dibromo-4-fluoroanisole was synthesized as follows: 8.96 g of 4-fluorophenol (Pfaltz and Bauer, 0.08 mol) were dissolved in 60 mL CS_2 containing 10 mL ether in a 250-mL round bottom flask, and 25.6 g of Br_2 (0.082 mol, ca. 8.5 mL) in 20 mL CS_2 were added dropwise at room temperature over a 0.5-h period. The mixture was stirred for 1 day and then refluxed for 3 h, reduced in volume by rotary evaporation under reduced pressure, taken up in ether, washed twice with water, dried over $MgSO_4$, and rotary-evaporated to yield 17.28 g of a crystalline solid (80%). Spectral data confirmed product identity. This 2,6-dibromo-4-fluorophenol was methylated as above (18) and the anisole derivative was submitted to mass spectral and ^{1}H nmr analysis.

Spectral data

The spectral data employed in this paper were mainly accumulated on a WH90 FT nmr spectrometer at a probe temperature maintained at 305 K, unless otherwise stated. The ^{13}C nmr spectra of the anisole derivatives were acquired using the INEPT (19) pulse sequence. A typical experiment had a 12-μs P_{90} pulse for carbon, a 43-μs P_{90} pulse for protons, $1/4J$ = 1.8 ms, and a 5-s equilibrium delay time. A spectral width of about 400 Hz and up to 1000 scans were employed. The ^{13}C nmr spectra of the fluorine derivatives were also acquired under conditions of broadband ^{1}H decoupling. The solvents and concentrations are indicated in Table 1. Variable temperature experiments were performed using the temperature controller, previously calibrated with a thermocouple.

Molecular orbital calculations

These were carried out on an Amdahl 470/V8 computer system and employed the INDO MO FPT programs (20, 21). The geometry of anisole was that recently described in another connection (22), in which the C_2C_1O angle is given by 120° + 5.0 cos θ and the COC angle by 112° + 3.0° |cos θ|. Here θ is the angle of twist about the C_{sp^2}—O bond, zero corresponding to a heavy-atom coplanar geometry. Similar calculations on 4-fluoroanisole employed a standard geometry (23). Some computations were performed in which certain off-diagonal Fock matrix elements were forced to vanish, in the manner of Barfield (24), thereby providing indications of coupling pathways.

Results and discussion

Conformational dependence of $^6J_p^{C,H}$ and $^6J_p^{C,F}$.

In anisole, $^6J_p^{C,H}$ could not be observed, as illustrated in Fig. 1, and is clearly <0.05 Hz. In the presence of two *ortho* chlorine or bromine substituents the coupling becomes 0.603(5) and 0.625(7) Hz, respectively. In 4-methyl-2,6-dibromoanisole, $^7J_p^{C,H}$ is 0.637(20) Hz. In the presence of two sizeable *ortho* substituents, X-ray diffraction data indicate a perpendicular conformation of the methoxy group (25–27). For a σ–π mechanism, in which the coupling is transmitted via the π orbitals of the benzene ring, it is expected that $^6J_p^{C,H} = -^7J_p^{C,H}$ (13, 28) in the dibromoanisole and its 4-methyl derivative. The signs of these two couplings are unknown. However, our INDO MO FPT computations in Table 2 clearly show that $^6J_p^{C,H}$ is negative and that it has a $\sin^2\theta$ dependence as expected for a σ–π mechanism. In particular, a calculational series in

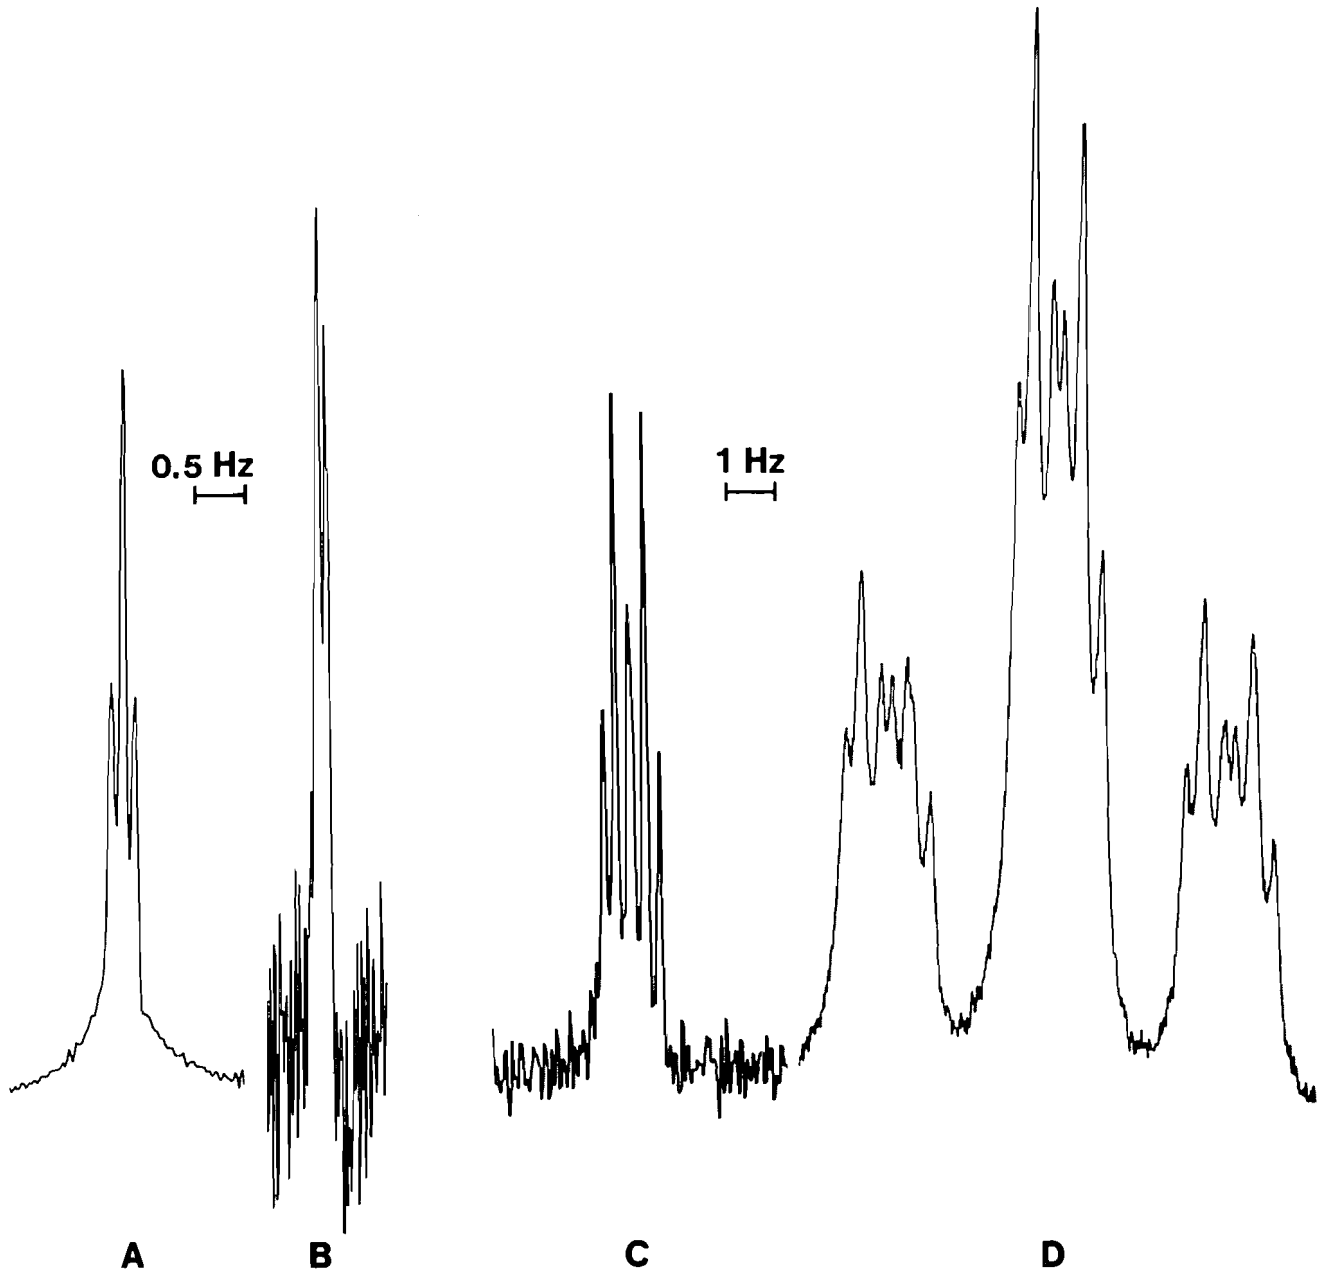

FIG. 1. In A is shown one of the multiplets of the ^{13}C nmr spectrum of the methyl group of anisole-α-^{13}C as a 2 to 4 mol% solution in CS_2 containing 30 v/v% C_6D_{12}. The spectrum was accumulated with 1020 scans using the INEPT pulse sequence on a WH90 spectrometer and a probe temperature of 315 K. The triplet arises from coupling to the *meta* protons five bonds removed and the splitting is just less than 0.12 Hz. The triplet can be reproduced by simulation of a six-spin system, with the ^1H nmr parameters taken from a full analysis of the ^1H spectrum, a linewidth at half height of 0.05 Hz for ^{13}C, and a coupling of 0.03 Hz to the *para* proton. In B is shown the ^{13}C nmr spectrum of the methyl group of 4-fluoroanisole as a 50 vol% solution in acetone-d_6 under conditions of ^1H decoupling. The splitting is very near 0.08 Hz, as determined from repeated experiments. Very similar spectra were obtained for a benzene-d_6 solution, all spectra being accumulated at 305 K and acquisition times of 41 s. In C one of the multiplets in the ^{13}C nmr spectrum of the methyl group of 2,6-dichloroanisole is shown for a 50 vol% solution in benzene-d_6; 648 scans were used with the INEPT sequences. The large "doublet" splitting is 0.60 Hz and the smaller splitting is 0.26 Hz. Part D displays the ^{13}C nmr spectrum of the methyl group of a 50 vol% solution of pentafluoroanisole in acetone-d_6 at 305 K. The protons are being decoupled. The coupling over six bonds to ^{19}F is 0.96 Hz; 1424 scans were accumulated into 32K of memory.

which the twist of the methyl group about the C_{sp^3}—O is correlated with the rotation about the C_{sp^2}—O bond, as in column *B* of Table 2, yields eq. [1].

$$[1] \quad {}^6J_p^{C,H}\,(\text{Hz}) = -0.01 - 0.626 \sin^2\theta$$

This equation reproduces the numbers in column *B* to within 0.01 Hz and also happens to agree rather closely with the magnitudes of ${}^6J_p^{C,H}$ in 2,6-dibromoanisole and of ${}^7J_p^{C,H}$ in the 4-methyl-2,6-dibromoanisole. In conjunction, the experimental and theoretical data presented here appear to warrant the conclusion that ${}^6J_p^{C,H}$ is a σ−π coupling with a simple conformational dependence. Furthermore, in column *C* of Table 2 the σ−π path at the site of the methoxy group has been interrupted by setting the relevant off-diagonal Fock matrix elements equal to zero for all SCF cycles, resulting in a marked reduction in the magnitude of the calculated coupling and there-

[a] The geometry is described in the text and was the same as that used in a satisfactory calculation of ${}^5J_o^{H,CH_3}$ (22).

[b] θ is the angle of twist about the C_{sp^2}—O bond, zero corresponding to a planar form.

[c] No twisting of CH_3 about its O—C bond, being staggered about the *ortho* C—H bond for θ = 0.

[d] The methyl group twists so as to keep two H—H_{ortho} distances equal (correlated motion).

[e] All Fock matrix elements involving oxygen p_z, methyl carbon p_z, and methyl hydrogen 1*s* orbitals are kept at zero.

fore qualitative support of the conclusion above.

Calculations on 2-fluoroanisole, not reproduced here, suggest that ${}^6J_p^{C,H}$ changes by 0.01 Hz, at most, in the presence of the *ortho* fluorine substituent, implying that intrinsic ring substituent perturbations of this coupling are small or negligible. Consequently, ${}^6J_{90}^{C,H}$ in anisole and its derivatives will be taken as 0.63 ± 0.01 Hz in magnitude. Of course, the methoxy group in the 2,6-dibromo derivative is not *rigidly* held at θ = 90°. However, if the barrier to internal rotation in this molecule is greater than about 6 kcal/mol, then the quoted value for ${}^6J_{90}^{C,H}$ is acceptable.

Turning to ${}^6J_p^{C,H}$, INDO MO FPT calculations substantiate its $\sin^2\theta$ dependence in 4-fluoroanisole but estimate its maximum value as only 0.7 Hz. For 2,6-dibromo-4-fluoroanisole the observed value is 1.476(20) Hz. An underestimate of the magnitude of ${}^6J_p^{F,H}$ in 4-fluorotoluene is also found (28*b*). The methyl group replacement technique (25) is inapplicable as a test of the σ−π mechanism but, in line with the computations for ${}^6J_p^{F,H}$ and ${}^6J_p^{C,F}$, the latter will also be taken as a σ−π coupling. The presence of a small contribution to ${}^6J_p^{C,F}$ from a mechanism other than σ−π cannot be ruled out, nor can an intrinsic ring substituent perturbation of its magnitude. Yet the discussion below is self-consistent if these assumptions are made, namely that ${}^6J_p^{C,F} = 1.48\ \langle\sin^2\theta\rangle$, where $\langle\sin^2\theta\rangle$ is the expectation value of $\sin^2\theta$ for the hindered motion.

Conformational deductions

(i) 4-Fluoroanisole

On the assumption that ${}^6J_p^{C,F}$ is a σ−π coupling, its magnitude being 0.085 ± 0.005 Hz, one has $\langle\sin^2\theta\rangle$ as (0.085 ± 0.005)/(1.476 ± 0.020) = 0.058 ± 0.005, where the error estimate depends on the measurement errors only. For a *twofold* barrier, tables of $\langle\sin^2\theta\rangle$ as a function of temperature, reduced moment of inertia, and the barrier are available (29). In the present instance they yield the barrier as 5.6 ± 0.5 kcal/mol. If harmonic oscillator instead of free rotor functions are used as a basis, the barrier becomes 5.2 ± 0.5 kcal/mol.

The torsional modes for liquid 4-fluoroanisole gave 6.1 kcal/mol (error not given (11)), assuming a harmonic oscillator model and a twofold barrier. If, as indicated by molecular orbital calculations, the fourfold component is a significant part of the barrier in anisole and therefore no doubt also for 4-fluoroanisole, then the present results are only an approximation to the true barrier. According to the torsional frequencies, the barrier is markedly state dependent, being only about 3 kcal/mol in the gas phase. Microwave spectra confirm the preferred planar conformation of 4-fluoroanisole (30) and place a lower limit of 1.1 kcal/mol on the barrier in the gas phase and are not compatible with a perpendicular conformer of appreciable stability.

The coupling data were measured in acetone-d_6 solution and confirm the rather high barrier found from the torsional data in the liquid. The dipole moment of anisole calculated by STO 3G (9) increases by 0.15 D on going to the perpendicular conformer, from 1.18 to 1.33 D. The experimental value is 1.30 ± 0.03 D (31). Consequently a polar solvent should stabilize the perpendicular form (32), contrary to experiment.

It seems unequivocal that the barrier to rotation about the C_{sp^2}—O bond in 4-fluoroanisole is substantial. Whatever the true shape of the barrier, a small value would entail a much larger ${}^6J_p^{C,F}$ than the observed value of <0.1 Hz.

(ii) 2,3,5,6-Tetrafluoroanisole

${}^6J_p^{C,H}$ is 0.331(8) Hz and, as before, $\langle\sin^2\theta\rangle$ is (0.331 ± 0.008)/(0.630 ± 0.010) or 0.525 ± 0.020, where the ${}^6J_{90}^{C,H}$ is taken as discussed above. If the O—CH_3 bond lay rigidly in a plane perpendicular to the benzene plane, then $\langle\sin^2\theta\rangle$ would equal unity and would vanish if this bond were fixed in the molecular plane. Free rotation about the C_{sp^2}—O bond entails a value of 0.5 for $\langle\sin^2\theta\rangle$. Consequently, a value of 0.525 suggests a very small barrier of 0.1 ± 0.1 kcal/mol (from $\langle\sin^2\theta\rangle$ versus twofold barrier tables) with a slightly preferred perpendicular conformation. Whether the latter is indeed of lower energy depends rather crucially on the true value of ${}^6J_{90}^{C,H}$. The safe conclusion, whether or not there exists a fourfold component, is that the internal barrier is effectively zero.

Support for this conclusion can be adduced in three ways. First, the high resolution nmr spectra of 2,3,5,6-tetrafluoroanisole partially oriented in a nematic phase were consistent with either essentially free rotation or interconversion between 2^{n+1} equivalent positions (n = 1,2,3,...) of the methoxy group (33). This result can be taken as support for the conclusions reached above on the basis of ${}^6J_p^{CH}$. Second, if a 4-fluoro substituent reduces the $2p\ldots\pi$ conjugation of the methoxy group, pentafluoroanisole might well display an unmistakable preference for the perpendicular conformation. This aspect is discussed in the next section. Third, confirmatory evidence might be sought in the temperature dependence of ${}^5J_o^{F,CH_3}$, as can be seen in the following way.

${}^5J_o^{F,CH_3}$ is a proximate (34) coupling, as shown in unpublished work in this laboratory. Its value is +0.2 to +0.3 Hz when the methoxy group is oriented in the plane of the ring with the methyl group lying *trans* to an *ortho* C—F bond. As the methyl group approaches this C—F bond it becomes rather larger than +3 Hz. For a 4.7 mol% solution of the tetrafluoroanisole in acetone-d_6, ${}^5J_o^{F,CH_3}$ increases from 1.30 Hz at 305 K to 1.45 Hz at 192 K. Because this coupling is largest when the methyl group approaches the *ortho* C—F bond most closely, this small increase of about 10^{-3} Hz/deg implies that the perpendicular conformer is not the stable conformer. However, it is conceivable that a decrease in temperature stabilizes the planar or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

a near planar conformation as the density of the polar solution increases. Note that the planar conformation of 4-fluoroanisole is apparently strongly stabilized in solution.

(iii) Pentafluoroanisole

The value of $\langle \sin^2 \theta \rangle$ is $(0.963 \pm 0.023)/(1.476 \pm 0.020)$ or 0.652 ± 0.025. It seems definite that the low-energy conformation is perpendicular. In terms of a twofold barrier, its magnitude is therefore $0.7_8 \pm 0.1_4$ kcal/mol as obtained from tables of $\langle \sin^2 \theta \rangle$ as a function of the barrier, the temperature, and the reduced moment of inertia. The torsional frequencies in the gas phase yield a twofold barrier of 0.86 kcal/mol, but do not assign the low-energy confromation, nor do photoelectron data (35). The chemical shift of ^{13}C-4 indicates a nonplanar conformation (36). Because a *para* fluorine substituent reduces the conjugative barrier in *N*-methylaniline (37) and thiophenol (15, 16), the present result is reasonable in comparison to 2,3,5,6-tetrafluoroanisole. Parenthetically, a *para* amino substituent in thiophenol induces a perpendicular low-energy conformation of the sulfhydryl group in thiophenol (16).

Additional evidence for a perpendicular conformer in pentafluoroanisole comes from the temperature dependence of $^5J_o^{F,CH_3}$. For a 5 mol% solution in acetone-d_6, this coupling *decreases* from 1.085(2) Hz at 305 K to 1.003(8) Hz at 180 K. For the reasons discussed in the previous section, this decrease is consistent with a preferred perpendicular conformer whose amplitude of oscillation about the C_{sp^2}—O bond decreases as the temperature of the sample drops.

(iv) Concerning the barrier magnitude

The large decrease in the barrier to rotation about the C_{sp^2}—O bond in the presence of the two *ortho* C—F bonds is probably a composite of steric and conjugative interactions. That two *ortho* C—F bonds can raise a barrier by steric forces is clear from 2,6-difluoroethylbenzene (38). In this molecule the twofold barrier is most likely mainly steric and is 4 to 5 kcal/mol higher than in ethylbenzene itself. Of course, in the ethylbenzene the stable conformer is perpendicular, so that the barrier increases as the *ortho* C—F bonds introduce increased repulsion with the methyl group in a planar conformer during the rotation about the C_{sp^2}—C_{sp^3} bond. In the anisole derivatives, the planar conformation is destabilized relative to the nonconjugative perpendicular conformer by the steric repulsions between the C—F bonds and the methyl group. As well, because fluorine is a π donor, the *ortho* C—F bonds will decrease the double bond character of the C_{sp^2}—O bond and therefore cause a further destabilization of the conjugative ground state. The net result is a nearly zero internal barrier in the tetrafluoroanisole. Addition of a *para* fluorine substituent to the latter further decreases the $2p-\pi$ conjugation of the methoxy group, leading to a perpendicular ground state in pentafluoroanisole. Of course, the coupling data in Table 1 and X-ray structure analysis show that *ortho* substituents larger than fluorine, such as chlorine or bromine, cause very stable perpendicular conformers in anisole.

(v) Remarks on the barrier in anisole

The discussion in previous paragraphs implies a higher barrier in anisole than in 4-fluoroanisole. The torsional data for the two liquids do not support this implication, giving 6.05 and 6.10 kcal/mol for the former and latter, respectively (11). The coupling data in Table 1 indicate a substantial barrier for anisole. In fact, a classical averaging procedure gave the result that V_2 is 6.0 kcal/mol and V_4 is very nearly zero if $^6J_p^{C,H}$ is as large as 0.036 Hz in magnitude and $^6J_{90}^{C,H}$ is -0.640 Hz with a strict $\sin^2 \theta$ dependence. The ^{13}C nmr spectrum of the methyl group in Fig. 1 suggests that $^6J_p^{C,H}$ can hardly be larger than 0.036 in magnitude. Therefore our coupling data for anisole and 4-fluoroanisole are consistent with a higher barrier in the former, the barrier in the latter being estimated above as 5.6 ± 0.5 kcal/mol.

However, a barrier as high as 6 kcal/mol should have led to a positive DNMR result using ^{13}C nmr spectra. Yet, for a dimethyl ether solution at 120 K not even a relative broadening of the C-2 and C-6 peaks was observable, and similarly for the 3,5-dichloro derivative. On the basis of known substituent effects on ^{13}C shifts (39, 40), the difference in chemical shifts between C-2 and C-6 in planar anisole at slow exchange can be hardly less than 6 ppm. It is then a simple matter to show that the free energy of activation for rotation about the C_{sp^2}—O bond must be less than 4.7 kcal/mol.

If the small $^6J_p^{C,H}$ for anisole is to be consistent with this result, the potential barrier cannot be purely twofold. The potential must increase rather rapidly as the methoxy group leaves the ring plane if $^6J_p^{C,H}$ is to be as small as observed. A rapid rise in potential can be provided by a substantial fourfold component. A coupling of -0.030 Hz can be fit with V_2 and V_4 values of 2.7 ± 0.9 and 2.2 ± 0.5 kcal/mol, respectively, yielding a maximum in the hindering potential of 3.8 kcal/mol. This number, while consistent with the DNMR result, is inconsistent with the torsional data in solution. It is noteworthy, however, that in the gas phase (1) the methoxy torsion frequency can be reproduced exactly by a V_2 of 4.8 kcal/mol and a minor contribution from V_4. Even if, as suggested (1), the V_4 component becomes more important in solution, the evidence for an increased magnitude of the barrier in solution suggests the inadequacy of the fit to the coupling data. Of course, the -0.03 Hz is only an estimate of $^6J_p^{C,H}$. It may actually be smaller in magnitude (see Fig. 1).

Because $T_{1\rho}$ measurements can give estimates of site exchange rates rather higher than those obtainable from lineshapes, an attempt to resolve the unsatisfactory situation described above involved $T_{1\rho}$ measurements (41, 42). The result of an extensive set of measurements was that the free energy of activation is less than 4.4 kcal/mol on the assumption that the shift difference between C-2 and C-6 is 6 ppm, again a negative result. Attempts at measuring this chemical shift difference in solid anisole in another laboratory have been unsuccessful so far. In the solid state, this shift is 6.0 ppm for an ethylphenyl ether derivative (43).

Because our DNMR and $T_{1\rho}$ measurements did not give positive results, they are not described here in detail.

As far as coupling constants are concerned, the anisole barrier problem remains unsatisfactory. In future, other couplings, including ^{13}C,^{13}C interactions, will be studied. Perhaps a temperature dependence of some couplings will be found and may allow a fit to a two-term potential function.

On the spin trapping of cyanatyl (·NCO) radicals by nitrosodurene

DETLEF REHOREK[1] AND EDWARD G. JANZEN[2]

Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received October 5, 1983

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

DETLEF REHOREK and EDWARD G. JANZEN. Can. J. Chem. **62**, 1598 (1984).

Spin trapping experiments with cyanatyl radicals and nitrosodurene show that the triazene-1,3-dioxyl radical described earlier has the structure as indicated for **I**.

DETLEF REHOREK et EDWARD G. JANZEN. Can. J. Chem. **62**, 1598 (1984).

Des expériences de piégeage de spin impliquant les radicaux cyanatyles et le nitrosodurène ont permis de démontrer que le radical triazènedioxyle-1,3 décrit antérieurement doit être représenté par la structure **I**.

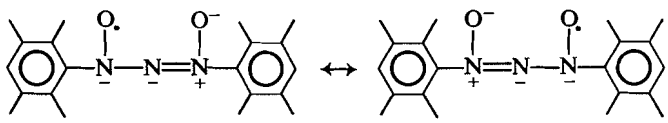
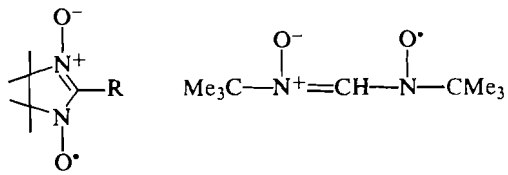
It has been shown that azidyl radicals (N_3·) may be trapped by nitrones to give persistent spin adducts which are easily detected by electron spin resonance (esr) at room temperature in liquid solution (1–4).

Nitrosodurene, however, gives a persistent aminoxyl (nitroxide) which appears to be the result of double spin trapping. Since hyperfine splitting due to three nitrogen nuclei, with two being magnetically equivalent, was detected, the spectrum was tentatively assigned to the triazene-1,3-dioxyl, **I**, (5):

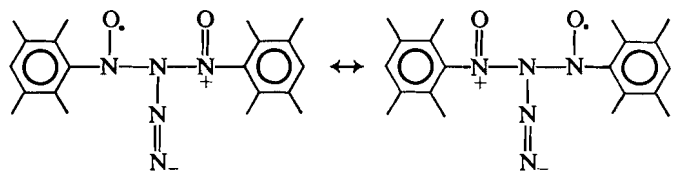


I

which is isoelectronic with the well-known seven π-electron nitronyl nitroxides (6, 7):



An alternate structure (**II**) with a pendant N_2 group which might have been formed by the addition of N_3· radicals to the nitrosodurene dimer, similar to the previously reported (8) reaction of iminyl radicals, has also been considered:



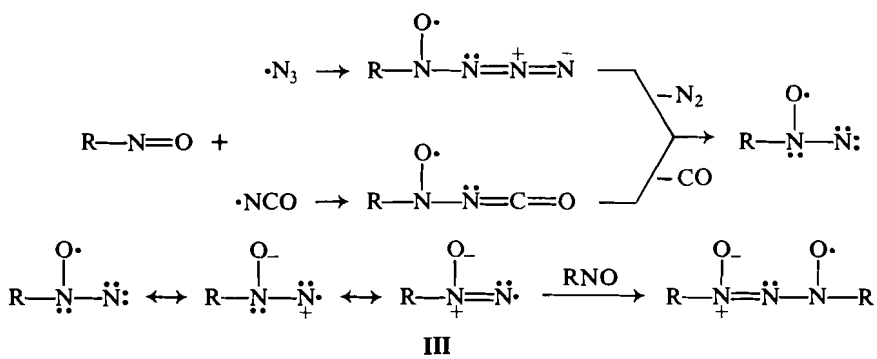
II

Although experiments with ^{15}N-labelled azide (9) confirmed the presence of two equivalent nitrogens originating from the nitrosodurene structure, **II** could not be ruled out. Since cyanatyl radicals (OCN·) are isoelectronic with azidyl radicals, a similar behaviour of these radicals towards nitrosodurene might be expected.

The esr spectra of the aminoxyls recorded during spin trapping of azidyl and cyanatyl radicals by nitrosodurene[3] together with the computer simulation are shown in Fig. 1. The hyperfine coupling constants measured from these spectra are identical within experimental error (±0.05 G). Moreover, no secondary splitting was observed with the azide spin adduct of perdeuteronitrosodurene (as might be expected from the pendant N_2 group). These findings strongly suggest that the spectrum in Fig. 1 is due to structure **I** and not **II**.

Similar results were obtained with pentamethylnitrosobenzene, whereas nitrosomesitylene gave measurable spectra with azidyl radicals only (see Table 1).

The mechanism of formation of **I** is of interest. The following route suggests itself:



III

[1]On sabbatical leave from Sektion Chemie der Karl Marx Universität, Leipzig, DDR.

[2]Author to whom correspondence should be addressed.

[3]The pseudohalide radicals were generated by photolysis (330 nm < λ < 500 nm) of the CT complex formed between CBr_4 and tetrabutylammonium pseudohalide in dichloromethane. The nitrosoaromatics were synthesized according to the literature (10).

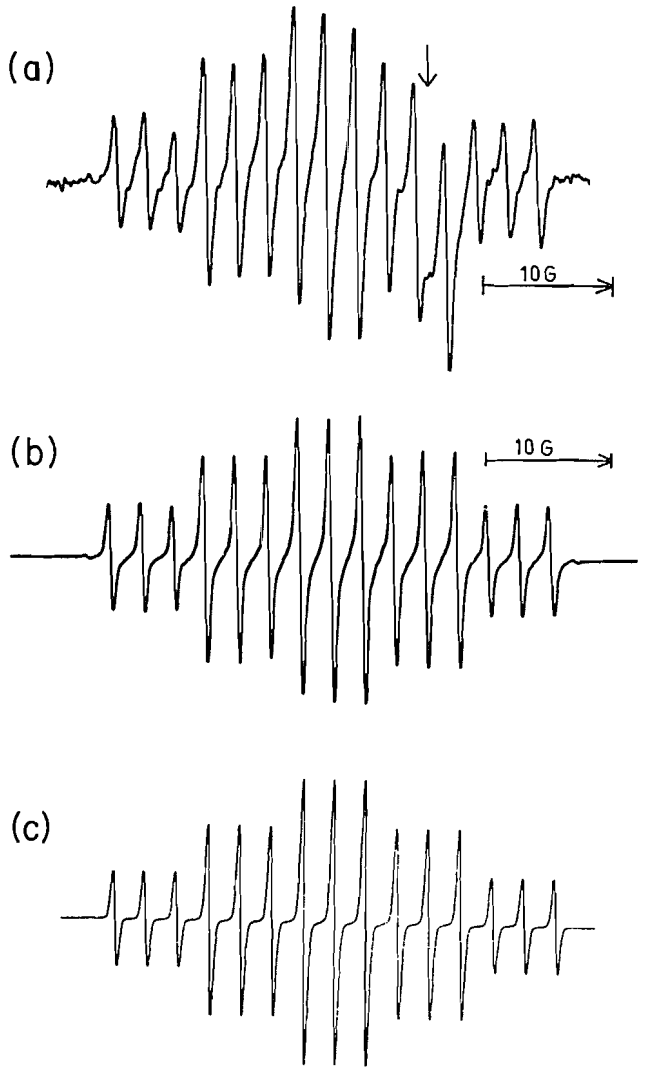


FIG. 1. The esr spectrum of bis-duryltriazene-1,3-dioxyl obtained from (a) ·NCO radicals (arrow indicates F-centre infused quartz cell); (b) $\cdot N_3$ radicals; (c) computer simulation.

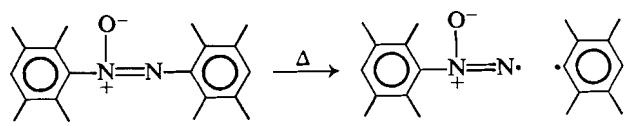
III would appear to be one of the radicals expected from thermal decomposition of "azoxydurene":



It should be noted that the signal intensity of the aminoxyls formed by spin trapping of cyanatyl radicals by nitrosodurene is much less than for azidyl radicals (about 100× less). In order to obtain sufficient esr intensity, spin trap concentrations above 0.01 *M* were needed. In contrast, both azidyl and cyanatyl radicals appear to be easily trapped by nitrones (1–4, 11).

No persistent spin adducts were obtained with thiocyanatyl and selenocyanatyl radicals and nitrosodurene.

In conclusion, the assignment of the structure of the aminoxyl obtained from nitrosodurene and azidyl radicals (**I**) has been confirmed. Nitrosodurene or nitrones can be used as detectors of azidyl radicals although nitrones are better spin traps for the detection of cyanatyl radicals.

TABLE 1. Electron spin resonance hyperfine splitting constants of diaryltriazene-1,3-dioxyls[a]

Spin trap	Radical trapped	a_N^1	a_N^2
Nitrosodurene	$\cdot N_3$	7.21 (2 N)	2.38 (1 N)
Nitrosodurene	·NCO	7.23 (2 N)	2.40 (1 N)

Received November 17, 1983

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

CHIU-MING WONG, AI-QIAO MI, JIALI REN, WASIMUL HAQUE, HING-YAT LAM, and KIRK MARAT. Can. J. Chem. **62**, 1600 (1984).

The title compound, a new heteroanthracyclinone was synthesized in five steps starting with 5,8-dimethoxy-2-acetyltetralin (**15**). Reaction of 2,2′-dithiosalicylic acid (**16**) with the tetralin **15** in concentrated sulfuric acid gave the tetracyclic thioxanthones **17** and **18**. Conversion of **18** to **24** by demethylation and realkylation followed by oxidation and acid hydrolysis gave the title compound **27**.

CHIU-MING WONG, AI-QIAO MI, JIALI REN, WASIMUL HAQUE, HING-YAT LAM et KIRK MARAT. Can. J. Chem. **62**, 1600 (1984).

On a synthétisé le composé mentionné dans le titre, une nouvelle hétéroanthracyclinone, en cinq étapes en utilisant la diméthoxy-5,8 acétyl-2 tétraline (**15**) comme produit de départ. La réaction de l'acide dithio-2,2′ salicylique (**16**) avec la tétraline **15** dans l'acide sulfurique concentré conduit aux thioxanthones tétracycliques **17** et **18**. La transformation de **18** en **24** par le biais d'une déméthylation et d'une réalkylation suivie d'une oxydation et d'une hydrolyse acide conduit au composé **27** mentionné dans le titre.

[Traduit par le journal]

Introduction

For the last decade, attempts to improve the therapeutic effect of the first generation anthracycline antitumor antibiotics, namely daunomycin (**1**) and adriamycin (**2**), have been rewarded with encouraging results. New anthracyclines and their derivatives, of both natural and synthetic origin, such as aclacinomycin A (**3**), 4-demethoxydaunomycin (**4**), 4-demethoxy-11-deoxydaunomycin (**5**), 11-deoxydaunomycin (**6**), and 4′-deoxydaunomycin (**7**) and many others were shown to be much more potent or slightly less toxic than the first generation antitumor anthracyclines (1). However, cardiotoxicity remains the critical side effect which severely restricts the dosages and excludes the possibility of using these drugs for long term maintenance purposes.

According to structure–activity relationship studies, the antineoplastic properties of anthracyclines could be rationalized by at least four different mechanisms. They are: intercalative binding to DNA double helix (2); superoxide formation causing DNA and chromosome cleavage (3); quinone methide formation and alkylation (4); interaction with cell membranes and possibly lipid peroxidation (5). The superoxide formation is likely to be the cause of cardiotoxicity due to the relatively low level of superoxide dismutase in the heart cells.

In our continuous effort to search for anthracycline analogues with reduced cardiotoxicity, we have proposed heteroanthracyclines for structure–activity relationship and cardiotoxicity studies and, recently, we reported the synthesis and biological activity of 4-demethoxyxanthodaunomycinone (**8**) (6). The low activity of **8** against MCF-7 human mammary cancer cells as compared to daunomycinone (**9**), which has no activity, could be an indication that a quinone methide inter-

mediate similar to **10** (7) is a contributing factor to cytoxicity. A similar intermediate in the case of anthracyclines is still a postulate and has not been isolated or proven to exist. Nevertheless, the activity of **8** could mean that daunomycin goes through a bioreductive process to the hydroquinone intermediate **11** before it can easily form the quinone methide **12** and its cytotoxicity becomes discernible. The availability of 4-demethoxythioxanthodaunomycinone (**27**) opens the avenue further for studies of the possible quinone methide intermediate and the relationship between the quinone moiety of anthracyclines and cardiotoxicity. Furthermore, it could also serve as a precursor for the corresponding sulfone and sulfoxide analogues of anthracyclines. Although direct chemical conversion of **27** and its derivatives to the corresponding sulfoxide and sulfone has not yet been achieved, they have been synthesized in a more elaborate process and will be reported later.

Results and discussion

The starting material, 3-acetyl-4-(2,5-dimethoxyphenyl)-butanal (**13**) (8), was easily converted to 1-chloro-5,8-dimethoxy-3-acetyltetralin (**14**) in a hydrogen chloride saturated dichloromethane solution at −40°C. Hydrogenolysis of **14** in ethanol in the presence of palladium on charcoal gave an overall yield of more than 75% of 5,8-dimethoxy-2-acetyltetralin (**15**). The tetracyclic skeletons **17** and **18** were conveniently assembled by condensing 2,2′-dithiosalicylic acid (**16**) with the tetralin **15** (9) in concentrated sulfuric acid in 58% yield. This process offers a route to the tetracyclic aglycone skeletons which is shorter and easier than the tedious process reported earlier in the xanthone series (6). The two isomers separated by column chromatography on silica were characterized by routine spectroscopy and elemental analyses and finally dipole moments (10, 11), which provided the only simple means to differentiate **17** from **18**. The first isomer (**17**) collected from the column has a calculated dipole moment of 3.2 D and an experimental value of 3.5 D; the second isomer (**18**) from the column has a calculated value of 4.7 D and an experimental value of 4.9 D.

Oxidation of **18** by molecular oxygen in *N,N*-dimethylformamide, *tert*-butyl alcohol, and trimethyl phosphite (12) gave directly a 3:1 mixture of the *cis*-diol **19** and the *trans*-diol **20** in 50% yield. The *cis*-geometry of **19** and the *trans*-geometry of **20** of the C_7—OH and C_9—OH together with the D-ring conformations of these two isomers could be established by detailed analysis of their high field ^{1}Hmr spectra, infrared spectra, and the formation of derivative **22**.

The high field ^{1}Hmr spectrum of **19** (Figs. 1(a) and 1(b)) shows that the C_7—H_e appearing as an octet at 5.28 ppm is coupled to C_7—OH, C_8—H_a, and C_8—H_e with J_{7c7OH} = 8.5 Hz, J_{7c8a} = 4.7 Hz, and J_{7e8e} = 2.5 Hz. The C_9—OH appears as a singlet at 4.554 ppm while the C_7—OH appears as a doublet at 4.268 ppm with J_{7OH7e} = 8.5 Hz which collapsed to a singlet when the C_7—H_e at 5.28 ppm was irradiated. The C_{10}—H_e appearing as doublet of a doublet at 3.195 ppm is geminally coupled to C_{10}—H_a with J_{10e10a} = 17.3 Hz and it is further coupled to C_8—H_e with J_{10e8e} = 1.9 Hz. The C_{10}—H_a appears only as a doublet with J_{10a10e} = 17.3 Hz at 3.06 ppm. The C_8—H_e at 2.30 ppm shows up as two triplets which are in fact doublet of a doublet of a doublet with J_{8a8e} = 14 Hz, J_{7e8e}

For personal use only.

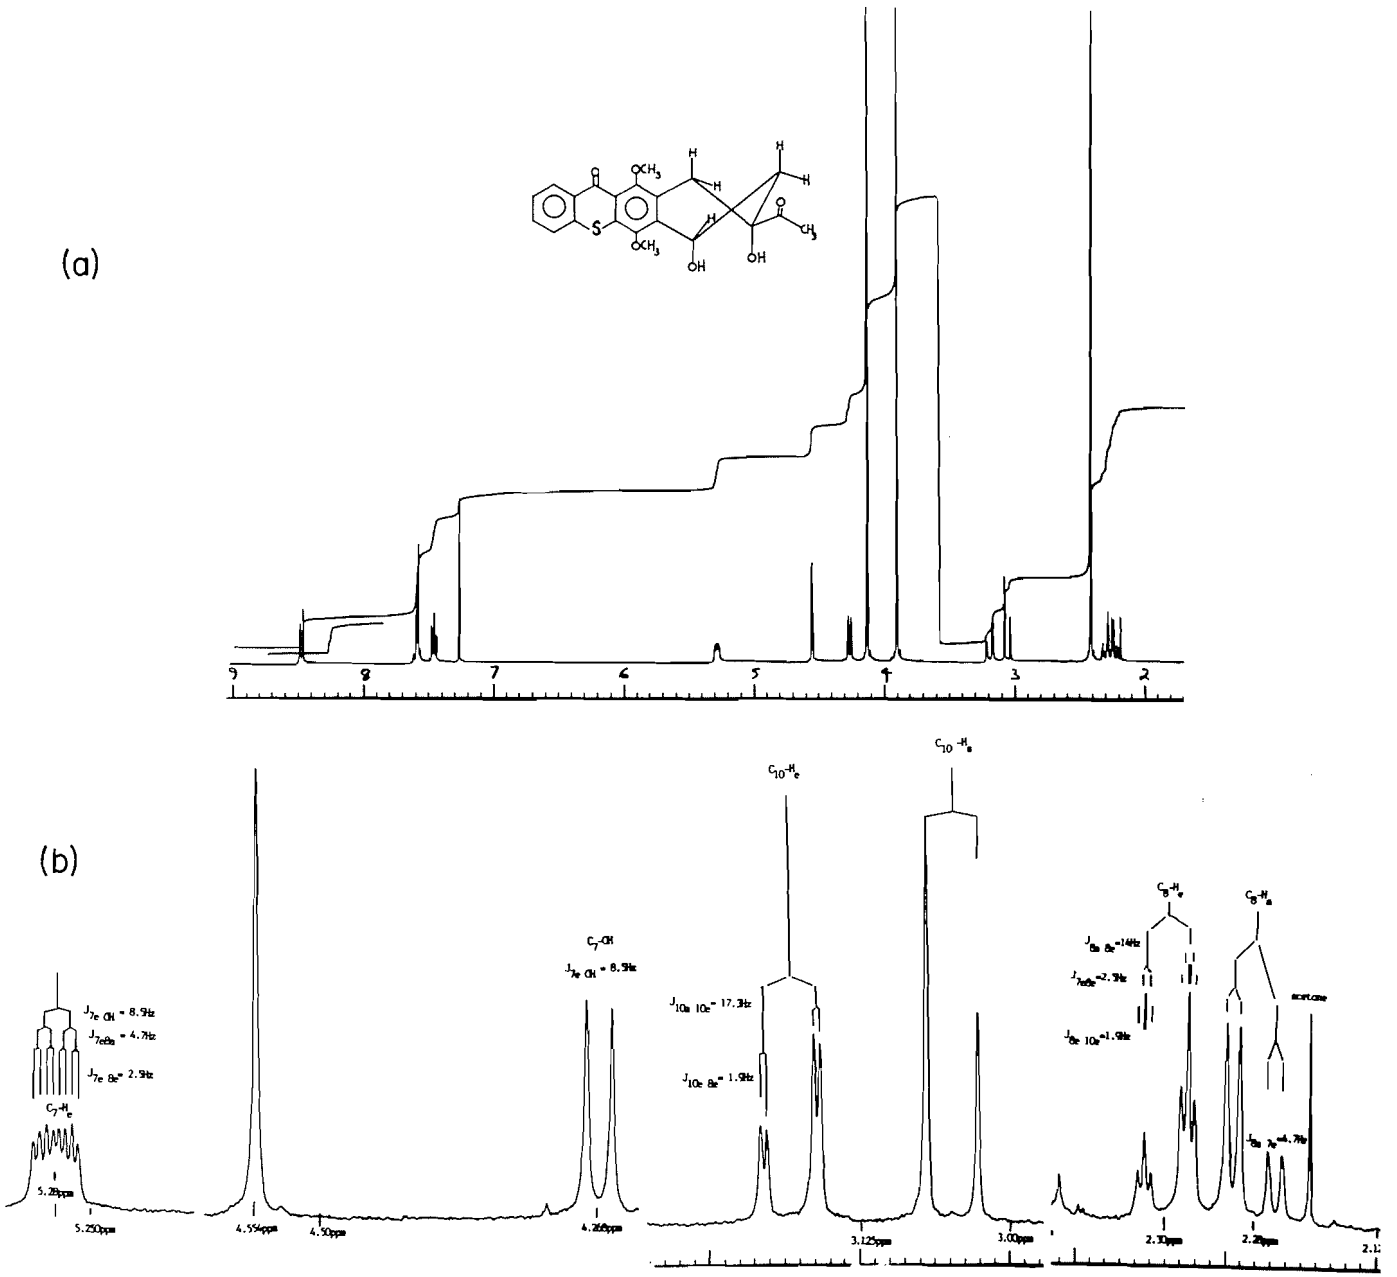

FIG. 1. (a) Bruker WH-400 ^{1}Hmr spectrum of **19**. (b) Expanded area between 5.3 and 2.1 ppm.

= 2.5 Hz, and J_{8e10e} = 1.9 Hz. The C_8—H_a appearing at 2.228 ppm is a doublet of a doublet with J_{8a8e} = 14.0 Hz, J_{8a7e} = 4.7 Hz. The infrared spectrum of **19** shows a relatively broad absorption peak at 3450 cm^{-1} while in the case of **20** two absorption peaks at 3600 cm^{-1} and 3560 cm^{-1} are present, indicating that both the C_7—OH and C_9—OH are hydrogen-bonded. This information agrees well with the D-ring conformation of **19** shown in Fig. 1(a) instead of the other possible conformation where the C_7—OH and C_9—OH are both equatorial.

The high field ^{1}Hmr spectrum of **20** shows that it exists in a slow equilibrium with the hemiketal **21**. When the C_6—OCH_3 and C_{11}—OCH_3 are replaced by other groups such as benzyloxy or methoxymethylenoxy groups, the ^{1}Hmr spectra become too complicated, or the compounds become too unstable to be thoroughly purified for detailed analyses. Only in the case of **20** can all the peaks be clearly identified, along with those of **21** (Figs. 2(a) and 2(b)). The C_7—H_e of **21** appearing as a doublet at 5.40 ppm with J_{7e8e} = 6.0 Hz is a good indication of the [3.2.1]bicyclo-hemiketal structure where the H_{7e}—C_7—C_8—H_{8a} dihedral angle is close to 90° with $J_{7e8a} \simeq 0$. The C_{10}—H_e of **21** appears at 3.323 ppm as doublet of a doublet with J_{10e10a} = 17.8 Hz and J_{10e8e} = 2.0 Hz. The C_{10}—H_a appears at 3.195 ppm as a doublet with J_{10a10e} = 17.8 Hz. Signals due to the C_9—OH and the C_{13}—OH, which disappear after deuterium exchange with deuterated methanol, appear as singlets at 3.105 ppm and 2.805 ppm respectively. The relatively high field shift of the C_{13}—OH in comparison with other hydroxy protons of **20**, **21**, and **22** could be the result of diamagnetic shielding of ring C and is in agreement with the assignment of the stereochemistry at C_{13}. The C_8—H_e appears as an octet at 2.675 ppm with J_{8e8a} = 11.0 Hz, J_{8e7e} = 2.0 Hz. The C_8—H_a, appearing at higher field than all the other C_8—H's of both **20** and **21** at 2.0 ppm as a doublet with J_{8a8e} = 11.0 Hz, is also due

For personal use only.

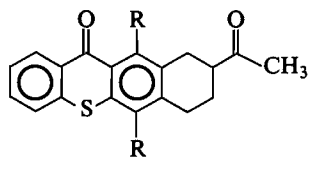
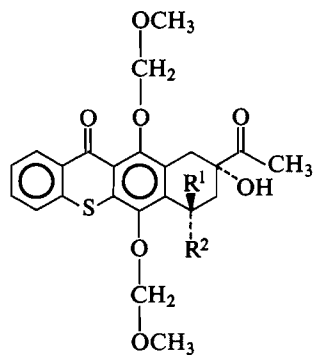
to the diamagnetic shielding of ring C of **21**.

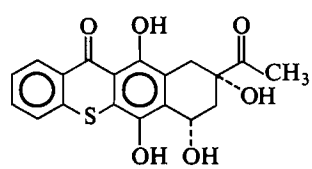
The D-ring protons of **20** can also be easily identified. The C_7—H_a at 5.425 ppm is coupled to C_8—H_a, C_8—H_e, and C_7—OH with J_{7a8a} = 9.0 Hz, J_{7a8e} = 6.5 Hz, and J_{7aOH} = 1.5 Hz. The C_7—OH doublet at 4.15 ppm with J_{7OH7a} = 1.5 Hz and the C_9—OH at 3.855 ppm exchanged with deuterated methanol. The C_{10}—H_a appears at 3.185 ppm as a doublet with J_{10a10e} = 16.7 Hz, while the C_{10}—H_e appears as doublet of a doublet at 2.960 ppm with J_{10e10a} = 16.7 Hz and J_{10e8e} = 2.3 Hz. The C_8—H_e appearing at 2.320 ppm as an octet is coupled to C_8—H_a, C_7—H_a, and C_{10}—H_e with J_{8e8a} = 13 Hz, J_{8e7a} = 6.5 Hz, and J_{8e10e} = 2.3 Hz. The C_8—H_a appearing at 2.190 ppm as a quartet is coupled to C_8—H_e and C_7—H_a with J_{8a8e} = 13 Hz and J_{8a7a} = 9.0 Hz. The four methoxy groups of **20** and **21** show up as four singlets between 3.88 and 4.08 ppm while the acetyl group of **20** appears at 2.43 ppm and the C_{13}—CH_3 of **21** appears at 1.40 ppm. The *trans*-geometry of **20** was further established when it was converted completely into **22**. The ^{1}Hmr spectrum of **22** shows only a clean doublet for H_{7e} with J_{7e8e} = 6 Hz, in addition to a new peak at 3.35 ppm for the C_{13}—OCH_3. The peaks at 5.425 ppm (Fig. 2(b)) belonging to the C_7—H_a, together with all other peaks assigned to **20**, completely disappear. The infrared spectum of **20** shows a weak absorption at 1710 cm^{-1} which disappears after **20** is converted to **22**. While conversion of the *trans*-isomer **20** to the *cis*-isomer **19** can easily be achieved by aqueous trifluoroacetic acid, demethylation of **19** to the desired product **27** by various processes failed. It is obvious that a protecting group much less stable than a methyl group is necessary. The isomer **18** was demethylated by hot sulfuric acid to give the phenol **23** which was realkylated by chloromethyl methyl ether to form **24**. Oxidation of **24** by molecular oxygen as before gave a mixture of



23 R = OH
24 R = OCH_2OCH_3



25 R^1 = H, R^2 = OH
26 R^1 = OH, R^2 = H



27

the *cis*-diol **25** and the *trans*-diol **26**. However, attempts to effect a clean separation of **25** from **26** under various chromatography conditions failed. Separation of **25** from **26** by preparative thin-layer chromatography on neutral alumina invariably gave only the *cis*-diol **25**, the structure of which was firmly established by detailed analysis of its high field ^{1}Hmr spectrum (Figs. 3(b) and 3(c)). The C_7—H_e at 5.328 ppm is a poorly resolved octet with J_{7e7OH} = 5.0 Hz, J_{7e8a} = 4.0 Hz, and J_{7e8e} = 3.0 Hz. The two latter coupling constants reveal that the C_7—H_{7e} bond bisects the H_{8a}—C_8—H_{8e} angle almost equally while, in the case of compound **19**, the coupling constants J_{7e8a} = 4.7 Hz and J_{7e8e} = 2.5 Hz correspond to the H_{7e}—C_7—C_8—H_{8a} and H_{7e}—C_7—C_8—H_{8e} dihedral angles of about 45° and 65°. This difference could be rationalized if, in the case of **19**, the C_7—OH proton hydrogen-bonds with the C_9—OH oxygen and, in the case of **25**, the C_7—OH proton hydrogen-bonds with the C_{16}—OCH_3 oxygen. The C_{15}—H_aH_b show up as an AB quartet at 5.281 ppm with J_{15a15b} = 6.0 Hz and $\Delta\delta_{ab}$ = 0.165 ppm. The C_{16}—H_aH_b appear as an AB quartet at 5.146 ppm with J_{16a16b} = 6.6 Hz and $\Delta\delta_{ab}$ = 0.034 ppm. The C_9—OH appears at 5.092 ppm as a singlet and the C_7—OH appears as a doublet at 4.931 ppm with J_{7OH7e} = 5.0 Hz. The C_{10}—H_aH_e appear at 3.290 as an AB quartet with J_{10a10e} = 18 Hz and $\Delta\delta_{ab}$ = 0.22 ppm. The C_{10}—H_e is further coupled to C_8—H_e with J_{10e8e} = 2.0 Hz while the C_{10}—H_a appears only as a doublet. The C_8—H_aH_b appear as an AB quartet at 2.210 ppm with J_{8a8e} = 14 Hz. The C_8—H_e is further coupled to C_7—H_e and C_{10}—H_e with J_{8e7e} = 4.5 Hz and J_{8e10e} = 2.0 Hz, while the C_8—H_a is further coupled to C_7—H_e with J_{8a7e} = 4.0 Hz, in agreement with the assigned structure.

Hydrolysis of **25** in acetone in the presence of dilute hydrochloric acid gave the desired product, 4-demethoxythioxanthodaunomycinone (**27**). The ^{1}Hmr spectrum (Fig. 4) reveals a very low field one-proton singlet at 13.98 ppm, typical of the strongly chelated proton of C_{11}—OH. The non-chelated phenolic C_6—OH appears at 6.95 ppm as a singlet. The C_7—H_e at 5.10 ppm shows up as an octet with J_{7e7OH} = 12.0 Hz, J_{7e8a} = 5.5 Hz, and J_{7e8e} = 2.7 Hz. The C_9—OH at 4.13 ppm is a singlet and the C_7—OH at 3.95 ppm is a doublet with J_{7OH7e} = 12 Hz. This relatively large coupling constant is possible if the dihedral angle of H_{7e}—C_7—O—H is close to 180°, as shown in Fig. 4. Both C_{10}—H_2 and C_8—H_2 are broad singlets at 3.02 ppm and 2.34 ppm respectively and the acetyl group appears as a sharp three-proton singlet at 2.40 ppm.

Experimental

All melting points were recorded on a Fischer–Johns apparatus and were uncorrected. Nuclear magnetic resonance spectra were recorded on a Bruker WH-90 or a Bruker WH-400 using tetramethylsilane as internal standard. Infrared spectra were recorded on a Perkin–Elmer 710 infracord and dipole moments were taken on a DM01 Kahl dipolometer. Mass spectra were recorded on a Finnigan 1015 or an A.E.I. MS-50. Elemental analyses were performed by Geller laboratories.

Preparation of 5,8-dimethoxy-2-acetyltetralin (15)

To a methylene chloride solution (150 mL) saturated with anhydrous hydrogen chloride at −30°C was added 3-acetyl-4-(2,5-dimethoxyphenyl)-butanal (**13**) (15 g) and the solution was stirred for a period of 20 min, evaporated to dryness under reduced pressure at room temperature to give the easily polymerized chlorotetralin **14**, possibly as mixture of *cis*- and *trans*-isomers which, without purification, was then hydrogenolysed in ethanol (200 mL) in the presence of Pd/C (5%) (1.5 g) under atmospheric pressure for a period of 4 h. The ethanol solution, after removal of the catalyst by filtration, was evaporated to dryness under reduced pressure to give a colorless syrupy residue which crystallized upon addition of ether. The crystalline product (7.7 g) is identical to the 5,8-dimethoxy-2-acetyltetralin (**15**) prepared previously (8).

Preparation of 7,8,9,10-tetrahydrobenzo[b]-8-acetyl-6,11-dimethoxythioxanthen-12-one (17) and 7,8,9,10-tetrahydrobenzo[b]-9-acetyl-6,11-dimethoxythioxanthen-12-one (18)

To an ice-cooled stirred concentrated sulfuric acid solution (250 mL) of 2,2′-dithiosalicyclic acid (**16**) (15 g) was added 5,8-dimethoxy-2-acetyltetralin (**15**) (5 g). The solution was stirred for a period of

6 h at room temperature and then poured into ice-water (1.5 L) and extracted exhaustively with ethyl acetate (4 × 300 mL). The combined extracts, washed with water, sodium bicarbonate solution, and dried over anhydrous magnesium sulfate, were evaporated to dryness under reduced pressure to give an orange solid residue (6.2 g) which was a mixture of mainly **17** and **18** together with a small amount of corresponding demethylated compounds. This crude product was then dissolved in acetone (200 mL) to which was added finely pulverized potassium carbonate (10 g) and methyl iodide (10 mL). The solution was stirred at 40°C for a period of 16 h, cooled, filtered, and evaporated to dryness to give a semi-solid residue which was purified by pressurized column chromatography on silica (250 g E.M. Silica Gel 60, 230 mesh) to give the crystalline products **17** (2.3 g) and **18** (2.1 g).

The first isomer **17** was purified by recrystallization from chloroform and ether, mp 142–144°C; ir (cm^{-1}): 1710 (acetyl), 1640 (phenone); ^{1}Hmr (δ ppm): 8.48 (m, 1H, C_4—H), 7.32–7.61 (m, 3H, C_1—H, C_2—H, C_3—H), 3.91 (s, 3H, OCH_3), 2.15–1.55 (m, 2H, C_8—H_2); *Mol. Wt.* (ms) calcd. for $C_{21}H_{20}O_4S$: 368.1084; found: 368.1087; dipole moment calcd.: 3.2 D; found: 3.5 D. *Anal.* calcd. for $C_{21}H_{20}O_4S$: C 68.46, H 5.43; found: 68.47, H 5.49.

The second isomer **18** was further purified by recrystallization from chloroform–ether, mp 160–162°C; ir (cm^{-1}): 1710 (acetyl), 1640 (phenone); ^{1}Hmr (δ ppm): 8.44 (m, 1H, C_1—H), 7.33–7.62 (m, 3H, C_2—H, C_3—H, C_4—H), 3.92 (s, 3H, OCH_3), 3.80 (s, 3H, OCH_3), 2.70–3.44 (m, 5H, C_7—H_2, C_9—H, C_{10}—H_2), 2.08–2.35 (m, 2H, C_8—H_2), 2.30 (s, 3H, $COCH_3$); *Mol. Wt.* (ms) calcd. for $C_{21}H_{20}O_4S$: 368.1084; found: 368.1088; dipole moment calcd.: 4.7 D; found: 4.9 D.

*Preparation of 7,8,9,10-tetrahydrobenzo[*b*]-6,11-dimethoxy-7,9-*cis*-dihydroxy-9-acetylthioxanthen-12-one (**19**) and 7,8,9,10-tetrahydrobenzo[*b*]-6,11-dimethoxy-7,9-*trans*-dihydroxy-9-acetylthioxanthen-12-one (**20**)*

The thioxanthone **18** (200 mg) was added to *N,N*-dimethylformamide (30 mL) containing *tert*-butyl alcohol (1.5 mL). The solution was warmed in a hot water bath to dissolve the thioxanthone, cooled in a Dry Ice bath at −30°C and then was added to freshly distilled trimethyl phosphite (0.5 mL) and potassium *tert*-butoxide (200 mg). Dry oxygen was introduced into the solution through a gas dispersion tube for a period of 1 h, keeping the cold bath temperature between −20°C and −30°C. Cold dilute hydrochloric acid was added dropwise until the dark brown colour of the solution disappeared. Water (150 mL) was added and the aqueous solution was extracted with ethyl acetate (3 × 150 mL). The combined ethyl acetate solution was dried over magnesium sulfate, evaporated to dryness under reduced pressure, and the residue was subjected to thick-layer chromatography over silica.

The less polar *cis*-isomer (**19**) (85 mg) was further purified by recrystallization from chloroform–ether, mp 205–208°C; ir (cm^{-1}): 3450 (*cis*-C_7—OH and C_9—OH), 1710 (acetyl), 1640 (phenone); *Mol. Wt.* (high resolution ms) calcd. for $C_{21}H_{20}O_6S$: 400.0981; found: 400.0986; ^{1}Hmr, see Figs. 1(a) and 1(b).

The more polar *trans*-isomer (**20**) (30 mg) was further purified by recrystallization from chloroform–acetone, mp 102–106°C; ir (cm^{-1}): 3600 (OH), 3560 (OH), 1715 (weak, $COCH_3$), 1645 (phenone); ^{1}Hmr, see Figs. 2(a) and 2(b).

*Preparation of ketal **22***

The *trans*-isomer **20** (160 mg) was added to benzene (60 mL) containing freshly distilled 2,2-dimethoxypropane (500 mg) and anhydrous *p*-toluenesulfonic acid (26 mg). The solution was stirred at room temperature under anhydrous condition for 24 h, washed with saturated sodium carbonate solution, dried over magnesium sulfate, and evaporated to dryness under reduced pressure. The solid residue (161 mg) was recrystallized from methylene chloride – ether, mp 123–124°C; ir (cm^{-1}): 3550 (OH), 1645 (phenone), 1590 (aromatic); ^{1}Hmr (δ ppm): 8.49 (dd of d, 1H, C_1—H, $J_{1,2}$ = 8 Hz, $J_{1,3}$ = 1.4 Hz, $J_{1,4}$ = 1.0 Hz), 7.35–7.62 (m, 3H, C_2—H, C_3—H, C_4—H), 5.31 (d, 1H, C_7—H_e, J_{7e8e} = 6.0 Hz, J_{7e8a} = 0), 3.94 (s, 3H, OCH_3), 3.92 (s, 3H, OCH_3), 3.35 (s, 3H, C_{13}—OCH_3), 3.38 (dd, 1H, C_{10}—H_e, J_{10e10a} = 20 Hz, J_{10e8e} = 1.5 Hz), 3.23 (s, 1H, C_9—OH), 3.09 (d, 1H, C_{10}—H_a, J_{10a10e} = 20 Hz), 2.64 (dd of d, 1H, C_8—H_e, J_{8e8a} = 11 Hz, J_{8e7e} = 6 Hz, J_{8e7e} = 1.5 Hz), 1.92 (d, 1H, C_8—H_a, J_{8a8e} = 11 Hz, J_{8a7e} = 0), 1.24 (s, 3H, C_{13}—CH_3); *Mol. Wt.* (high resolution ms) calcd. for $C_{22}H_{22}O_6S$: 414.1137; found: 414.1137.

*Preparation of **23***

The thioxanthone **18** (2 g) in sulfuric acid solution (80%) (200 mL) was heated with stirring in a 100°C oil-bath for 14 h. The solution was diluted with water (800 mL), extracted exhaustively with ethyl acetate (4 × 300 mL), and after routine work-up gave a dark brown solid residue which was purified by fast filtration over silica and recrystallization from acetone–ether, mp 253–254°C; ir (cm^{-1}) (Nujol: 3300 (broad, phenols), 1700 (acetyl), 1620 (chelated phenone), 1590 (aromatic); ^{1}Hmr (δ ppm): 12.1 (s, 1H, C_{11}—OH), 8.30 (dd of d, 1H, C_1—H, $J_{1,2}$ = 7 Hz, $J_{1,3}$ = 1.5 Hz, $J_{1,4}$ = 1.5 Hz), 7.30–7.80 (m, 3H, C_2—H, C_3—H, C_4—H), 5.22 (s, 1H, C_6—OH), 2.55–3.22 (m, 5H, C_7—H_2, C_9—H, C_{10}—H_2), 2.06–2.30 (m, 2H, C_8—H_2), 2.28 (s, 3H, $COCH_3$); *Mol. Wt.* (high resolution ms) calcd. for $C_{19}H_{16}O_4S$: 340.0769; found: 340.0771. *Anal.* calcd. for $C_{19}H_{16}O_4S$: C 67.04, H 4.74; found: C 67.10, H 4.77.

Preparation of ***24***

To anhydrous acetone (100 mL) containing pulverized and freshly baked potassium carbonate (5 g) was added the thioxanthone **23** (450 mg). To the dark orange solution heated in a 80°C oil bath under nitrogen was injected chloromethyl methyl ether (2.5 mL) which was dried by passing freshly distilled chloromethyl methyl ether through grade 1 neutral alumina. The acetone solution was heated under reflux for 7 h, cooled, filtered, and evaporated to dryness under reduced pressure. The residue was dissolved in methylene chloride, filtered to remove the residual potassium carbonate, and evaporated to dryness to give a syrupy residue which crystallized upon addition of ether and was recrystallized from methylene chloride – ether (360 mg), mp 126–128°C; ir (cm^{-1}): 1710 (acetyl), 1640 (phenone), 1595 and 1580 (aromatic); ^{1}Hmr (δ ppm): 8.43 (dd of d, 1H, C_1—H, $J_{1,2}$ = 7.5 Hz, $J_{1,3}$ = 1.5 Hz, $J_{1,4}$ = 1.5 Hz), 7.30–7.60 (m, 3H, C_2—H, C_3—H, C_4—H), 5.17 (s, 2H, —O—CH_2—O—), 5.11 (s, 2H, —O—CH_2—O—), 3.72 (s, 3H, OCH_3), 3.60 (s, 3H, OCH_3), 2.50–3.55 (m, 5H, C_7—H_2, C_9—H, C_{10}—H_2), 2.0–2.34 (m, 2H, C_8—H_2), 2.28 (s, 3H, $COCH_3$); *Mol. Wt.* (high resolution ms) calcd. for $C_{23}H_{24}O_6S$: 428.1294; found: 428.1293.

Preparation of ***25***

The methoxymethyl ether **24** (200 mg) was dissolved in anhydrous *N,N*-dimethylformamide (30 mL) and *tert*-butyl alcohol (1.5 mL). To the gently stirred solution kept in a cold bath of −30°C was added potassium *tert*-butoxide (200 mg) and anhydrous trimethyl phosphite (0.5 mL). Dry oxygen was introduced through a gas dispersion tube into the solution for 1 h, keeping the cold bath temperature between −20°C and −30°C. The solution was acidified to pH 8–9 by adding, dropwise, cold dilute hydrochloric acid, then was diluted with water and extracted exhaustively by chloroform. The extract, washed with water and dried over anhydrous magnesium sulfate, was evaporated to thorough dryness under reduced pressure to give a brown residue. Thin-layer chromatography of the residue over silica gave a major fraction (138 mg) which was shown by ^{1}Hmr to be a mixture of mainly **25** and possibly **26**. Further purification of this fraction by thin-layer chromatography over neutral alumina gave only the *cis*-isomer **25** (80 mg) which was further purified by recrystallization from methylene chloride – ether, mp 135–137°C; ^{1}Hmr (δ ppm): 8.425 (dd, 1H, C_1—H, $J_{1,2}$ = 8 Hz, $J_{1,3}$ = 1.1 Hz), 7.58 (m, 2H, C_3—H, C_4—H), 7.45 (dd of d, 1H, C_2—H, $J_{2,1}$ = 8 Hz, $J_{2,3}$ = 7 Hz, $J_{2,4}$ = 1.6 Hz), 5.281 (q, 2H, C_{15}—H_aH_b, J_{15a15b} = 6 Hz, Δδ = 0.165 ppm), 5.328 (dd of d, 1H, C_7—H_e, J_{7e7OH} = 5.0 Hz, J_{7e8a} = 4.0 Hz, J_{7e8e} = 3.0 Hz), 5.146 (q, 2H, C_{16}—H_aH_b, J_{16a16b} = 6.6 Hz, Δδ = 0.034 ppm), 5.092 (s, 1H, C_9—OH), 4.931 (d, 1H, C_7—OH, J_{7OH7e} = 5.0 Hz), 3.756 (s, 3H, OCH_3), 3.390 (dd, 1H, C_{10}—H_e, J_{10e10a} = 18 Hz, J_{10e8e} = 2.0 Hz), 3.170 (d, 1H, C_{10}—H_a, J_{10a10e} = 18.0 Hz), 2.416 (s, 3H, $COCH_3$), 2.240 (dd of d, 1H, C_8—H_e, J_{8e8a} = 14.0 Hz, J_{8e7e} = 3.0 Hz, J_{8e10e} = 2.0 Hz), 2.09 (dd, 1H, C_8—H_a, J_{8a8e} = 14.0 Hz, J_{8a7e} = 4.0 Hz); see Figs. 3(b) and 3(c); *Mol. Wt.* (high resolution ms) calcd. for $C_{23}H_{24}O_8S$: 460.1202; found: 460.1193.

*Preparation of 4-dimethoxythioxanthodaunomycinone (****27****)*

The *cis*-isomer **25** (65 mg) was added to acetone (15 mL) containing dilute hydrochloric acid (2 mL (5%). The acetone solution was stirred at room temperature for a period of 16 h, concentrated by removing most of the acetone under reduced pressure, diluted with water (20 mL), and extracted with ethyl acetate (4 × 30 mL). The combined ethyl acetate extracts were dried over magnesium sulfate and evaporated to dryness under reduced pressure to give a light yellow crystalline product (45 mg) which was recrystallized from acetone–ether, mp 190–192°C; ir (cm^{-1}): 3450 (*cis*-C_7—OH, C_9—OH), 1710 (acetyl), 1620, 1600 (chelated phenone), 1585 (aromatic); ^{1}Hmr (δ ppm): 14.0 (s, 1H, C_{11}—OH), 8.60 (dd of d, 1H, C_1—H, $J_{1,2}$ = 8 Hz, $J_{1,3}$ = 1.4 Hz, $J_{1,4}$ = 1.2 Hz), 7.38–7.68 (m, 3H, C_2—H, C_3—H, C_4—H), 6.95 (s, 1H, C_6—OH), 5.10 (dd of d, 1H, C_7—H_e, J_{7e7OH} = 12 Hz, J_{7e8e} = 5 Hz, J_{7e8a} = 2 Hz), 4.13 (s, s, 1H, C_9—OH), 3.95 (d, 1H, C_7—OH, J_{7OH7e} = 12 Hz), 3.02 (broad s, 2H, C_{10}—H_2), 2.40 (s, 3H, $COCH_3$), 2.34 (broad s, 2H, C_8—H_2); see Fig. 4.

A change in rate-determining step in the hydrolysis of cyclic ketals

ROBERT A. MCCLELLAND AND N. ESTHER SEAMAN
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received October 12, 1983

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

ROBERT A. MCCLELLAND and N. ESTHER SEAMAN. Can. J. Chem. **62**, 1608 (1984).

A kinetic study is reported of the hydrolysis of 2-methoxy-2-phenyltetrahydrofuran and 2-ethoxy-2-phenyltetrahydrofuran. At pH >6 the rate-determining step involves H^+-catalyzed formation of the oxocarbocation, this reaction occurring with cleavage of the exocyclic alkoxy group to produce a cyclic cation. Between pH 5 and pH 6 a change-over occurs and at pH <5, the rate-determining step in product formation is breakdown of the cyclic hemiketal intermediate, 2-hydroxy-2-phenyltetrahydrofuran. The changeover occurs because the H^+-catalyzed breakdown of this intermediate is a slower process than the H^+-catalyzed oxocarbocation-forming step. Hydroxide ion catalysis makes the hemiketal decomposition faster at higher pH. Analogous cyclic ortho esters (2-alkoxy-1,3-dioxolanes) show this same change in rate-determining step between high pH and low pH, while acyclic acetals, ketals, and ortho esters generally have the oxocarbocation-forming stage rate determining at all acidities. It is concluded that the structural features inherent in the cyclic systems are responsible for the difference. In particular, the oxocarbocation-forming stage involves exocyclic bond cleavage, giving it an entropic advantage over the hemiketal or hemiorthoester breakdown which is endocyclic.

ROBERT A. MCCLELLAND et N. ESTHER SEAMAN. Can. J. Chem. **62**, 1608 (1984).

On rapporte une étude cinétique de l'hydrolyse du méthoxy-2 phényl-2 tétrahydrofuranne et de l'éthoxy-2 phényl-2 tétrahydrofuranne. A un pH > 6, l'étape déterminante fait intervenir la formation d'un oxocarbocation qui est catalysée par H^+ et qui implique un clivage du groupe alkoxy exocyclique afin de produire un cation cyclique. A des pH compris entre 5 et 6, il se produit une transition dans le mécanisme de la réaction; à un pH inférieur à 5, l'étape déterminante est la rupture de l'hémicétal cyclique intermédiaire, l'hydroxy-2 phényl-2 tétrahydrofuranne. La transition dans le mécanisme réactionnel se produit parce que la rupture de cet intermédiaire, catalysée par H^+, est un processus plus lent que l'étape de formation de l'oxocarbocation, catalysée par H^+. La catalyse par l'ion hydroxyde fait que la décomposition de l'hémicétal se fait de plus en plus rapidement à mesure que l'on augmente le pH. Dans le cas des ortho esters cycliques analogues (alkoxy-2 dioxolannes-1,3), on observe le même type de transition entre les étapes déterminantes lorsqu'on passe des pH faibles aux pH plus élevés; par ailleurs, quel que soit le pH, la formation de l'oxocarbocation est généralement l'étape déterminante lors de l'hydrolyse des acétals acycliques, des cétals et des ortho esters. On en conclut que les caractéristiques structurales inhérentes aux systèmes cycliques sont responsables de la différence. En particulier, la formation de l'oxocarbocation qui implique le clivage de la liaison exocyclique possède un avantage entropique sur les ruptures impliquées lors de l'hydrolyse des hémicétal ou ortho ester qui sont endocycliques.

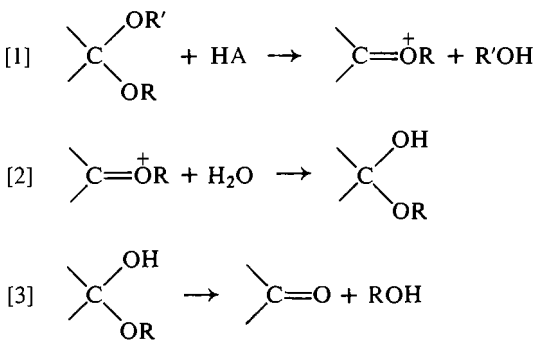
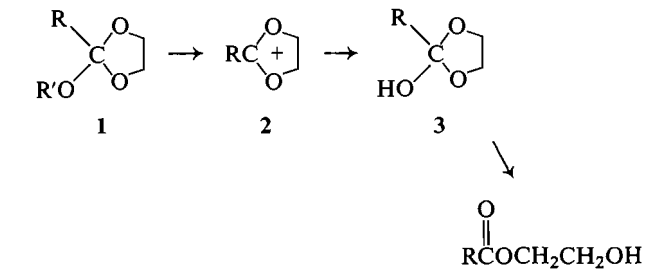
A three-stage reaction mechanism is now commonly accepted (1) for the hydrolysis of acetals and ortho esters: (*i*) generation, usually in an acid-catalyzed reaction, of an oxocarbocation; (*ii*) hydration of this cation to a hemiacetal or hemiorthoester; and (*iii*) breakdown of this intermediate to products. The first reaction stage is normally the rate-



determining step, and a considerable body of information is now available for this process. Within the last ten years, however, a number of acetal derivatives (2–10) and ortho acid derivatives (10–22) have been found where a later stage is rate limiting or partially rate limiting under some conditions, and the oxocarbocation intermediate or the hemiacetal/hemiorthoester intermediate is observed as a transient intermediate. These studies not only conclusively establish the existence of these intermediates, they also supply kinetic and mechanistic information for the later stages.

Cyclic ortho esters such as **1** (2-alkyl or aryl-2-alkoxy-1,3-dioxolanes) have proved to be particularly noteworthy in this respect (11, 15). The first reaction stage involves loss of the exocyclic alkoxy group, and in acids this process is found to



occur considerably more rapidly than the third reaction stage, the ring opening of the cyclic hemiorthoester **3**. This intermediate therefore accumulates during the hydrolysis, and the kinetics which are based on appearance of product refer directly to the kinetics of the third stage, the hemiorthoester decomposition. Acyclic ortho esters, with one exception (21), do not show this behavior, the dialkoxycarbocation-forming stage being rate determining at all acidities. The cyclic ortho esters must open a ring in the third stage, and the change in rate-determining step appears to be associated with an inherent difficulty of this process.

The oxocarbocation-forming stage is rate limiting (or mainly rate limiting (7, 8)) at all acidities with simple acyclic acetals and ketals. We considered if a change in behavior could be observed by incorporating the structural features inherent in the cyclic ortho ester **1** at this level of oxidation. We have, therefore, prepared ketal analogs and report here that they do undergo a similar change in the slow step.

Results and analysis

2-Methoxy-2-phenyltetrahydrofuran (**4**) and its 2-ethoxy derivative (**5**) were prepared by the reaction of alcoxide with the oxocarbocation (**6**), prepared as its borofluorate salt by treatment of 4-chlorobutyrophenone with silver borofluorate (23).

5, R = Et

Hydrolysis in aqueous solution produces 4-hydroxybutyrophenone (**7**) and, presumably, ROH. The hydroxyketone exists predominantly in this form. We estimate that the concentration at equilibrium of the cyclic hemiketal **8** is less than 0.1%. This figure is arrived at through the observation that the ultraviolet (uv) spectrum of **7** in 1.0 *M* NaOH is quantitatively identical to the spectrum recorded at pH 7. The hemiketal hydroxyl group, because of the adjacent oxygen, is considerably more acidic

than the hydroxyl of a simple alcohol, pK_a values for simple aldehyde hydrates and hemiacetals being in the range 12−12.5 (24−27). If there were a significant amount of the neutral hemiketal in equilibrium with the hydroxyketone, that equilibrium would shift in concentrated base because of the hemiketal ionization (see refs. 27−29 for systems where this occurs). This would show up as a decrease in uv absorbance due to the disappearance of the PhCO— chromophore (27). In quantitative terms, we define (28) K_a(app) as [**9**][H$^+$]/[**7**] and set pK_a(app) > 15, since no hemiacetal anion is observed even at pH 14. K_a(app) is equal to $K_{eq} \cdot K_a$, and if p$K_a \approx 12$, $K_{eq} < 0.001$.

The hydrolysis of the ketals **6** and **5** can proceed with cleavage, initially, of either the exocyclic or endocyclic C—O bond, and we propose that the former is occurring as it does with the

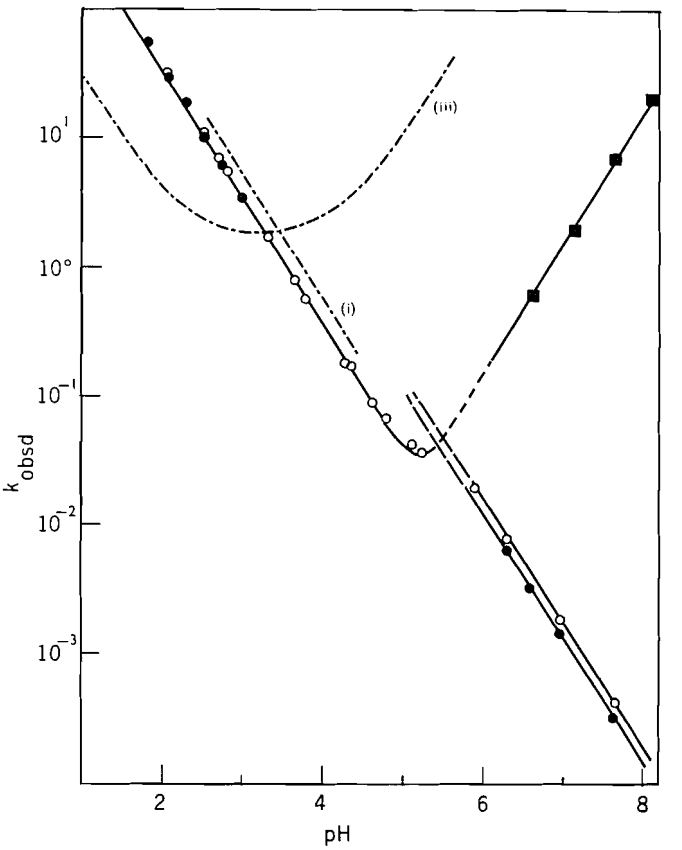

FIG. 1. Observed first-order rate constants (25°C, ionic strength = 0.1) as a function of pH. (○) 2-Methoxy-2-phenyltetrahydrofuran. (●) 2-Ethoxy-2-phenyltetrahydrofuran. (■) Stopped-flow trapping experiments with 2-ethoxy-2-phenyltetrahydrofuran. (....) 2-Methoxy-2-phenyl-1,3-dioxolane, from ref. 14. Stage (i): $k_{obsd} = 5.4 \times 10^3$ [H$^+$]. Stage (iii): $k_{obsd} = 3.0 \times 10^2$ [H$^+$] + 1.5 + 10^{10} [OH$^-$].

analogous ortho ester **1**. One piece of evidence is that the ketals in 100% H_2SO_4 produce methanol or ethanol and the oxocarbocation **6**. This cation is stable in 100% H_2SO_4 and its structure is verified by nmr comparison with the cation obtained from the chloroketone (23) (eq. [5]). The cleavage could be different in the aqueous solutions where the kinetic experiments have been conducted. However, the kinetic parameters themselves provide strong support for initial exocyclic cleavage.

Kinetic studies were conducted at constant pH and buffer concentration, using 10^{-4} *M* solutions of ketal and following the appearance of the product ketone using uv spectroscopy. In phosphate buffers of pH 6−8, the observed first-order rate constants obey the relationship $k_{obsd} = k_1^H[H^+]$ (Fig. 1), with $k_1^H = (1.35 \pm 0.08) \times 10^4\ M^{-1}\ s^{-1}$ for R = Me and $(1.65 \pm 0.04) \times 10^4\ M^{-1}\ s^{-1}$ for R = Et. Buffer catalysis is not observed, although this aspect was not investigated in detail. In HCl solutions, first-order rate constants obtained with the two ketals were identical, within experimental error (Fig. 1), obeying the relationship $k_{obsd} = k_3^H[H^+]$ with $k_3^H = (3.7 \pm 0.1) \times 10^3\ M^{-1}\ s^{-1}$.

This behavior is similar to that observed with the cyclic ortho esters **1**, and points to a change in the slow step in the overall hydrolysis between the phosphate buffers and HCl solutions. The changeover occurs because k_1^H, the rate constant for acid-catalyzed formation of the hemiketal, is greater than k_3^H, the rate constant for its acid-catalyzed decomposition. In con-

[7] 
sequence, the hemiketal forms in acid solutions more rapidly than it goes on to ketone product, and it therefore accumulates as a transient intermediate during the hydrolysis. Since rate constants are based on product formation, they refer directly to the hemiketal decomposition, and k_3^H is provided by the acid kinetics. It can be noted that the acid rates are independent of the nature of the exocyclic alkoxy group, since that group is not present in the kinetically important step. This observation also provides further indication that the exocyclic group is lost in the initial reaction stage.

Hemiacetals, hemiketals, and hemiorthoesters have other pathways available for their decomposition, a pH-independent reaction (k_3^0 of eq. [7]) and an hydroxide ion catalyzed reaction (k_3^{OH}). The occurrence of these means that at high pH the oxocarbocation-forming stage, which is only acid catalyzed, must become the slow step. The changeover is depicted in Fig. 1 for a typical cyclic ortho ester, 2-methoxy-2-phenyl-1,3-dioxolane, where, because of relatively large k_3^0 and k_3^{OH} rate constants, changeover occurs near pH 3.5. With the ketals of this study, first-order rate constants measured in dilute formate and acetate buffers remain on the line extrapolated from HCl solutions even at pH 5 (Fig. 1), indicative that hemiketal decomposition is remaining rate limiting. The changeover occurs abruptly at this point and, by pH 5.8, the first-order rate constants join the high pH lines associated with a rate-determining first stage. The region between pH 5.2 and 5.5 is characterized by marked curvature in the first-order kinetic plots. This behavior is observed near the crossover point in any system which has this type of changeover, and is associated with the first-order rate constants for formation and decomposition having very similar magnitudes (14). Curved first-order kinetic plots should be obtained in all acid solutions, and the statement that stage three is the slow stage in these solutions is not exactly valid. It is true that the rate difference is rather small. However, a system of consecutive irreversible first-order reactions can be shown to have reasonable first-order kinetics in product formation in such a case, with the observed rate constant equal to the slower of the two first-order rate constants (17).

The abruptness of the changeover makes the determination of k_3^0 and k_3^{OH} difficult, and in fact it is impossible to determine which of the two processes is becoming important around pH 5 so that the hemiketal decomposition becomes more rapid than formation. The following trapping experiment, however, provides this information, as well as furnishing additional proof that hemiketal is present as a transient intermediate in acid solutions. This approach was described initially by Jensen and Lenz (7), where it was used to establish the presence of small quantities of benzaldehyde hemiacetals during hydrolysis of benzaldehyde acetals. Reacting acid solutions of these acetals were rapidly treated with excess hydroxide. This quenches any further reaction of the acetal itself, since acid is required to convert this species to the oxocarbocation and thus initiate the overall hydrolysis. However, any hemiacetal which is present as a transient intermediate is rapidly converted to the product benzaldehyde, because of the OH^--catalyzed pathway of decomposition available to such species. This was observed by Jensen and Lenz as a burst in absorbance accompanying the hydroxide quench. In our version of this experiment (8) the quenching was carried out on a stopped-flow spectrophotometer, with the pH after the quench being such that the actual conversion of hemiacetal to benzaldehyde could be monitored. This has the added benefit of providing kinetic information for this process as it occurs in the quenched solution.

In the present case the ketal **5** was added to dilute pH 5.0 buffer, and this solution rapidly placed in one syringe of a stopped-flow apparatus where it was mixed with buffers containing excess phosphate such that the pH after mixing was 7–8. A significant increase in absorbance is observed in the mixed solution, associated with the conversion to product of the hemiketal which had accumulated in the pH 5 solution. The hemiketal, of course, reacts at pH 5 as well, so that subsequent firings result in smaller absorbance changes until no change is observed at all. This experiment conclusively establishes that hemiketal is being formed as a transient intermediate in acid solutions. The rates obtained after mixing provide kinetic data for the decomposition in the high pH solutions. The following relationship is obeyed (Fig. 1): $k_{obsd} = k_3^{OH}[OH^-]$, with $k_3^{OH} = 1.4 \times 10^7\ M^{-1}\ s^{-1}$. (Buffer catalysis, probably representing general base catalysis (8), is also observed, but this point was not investigated in detail.)

Extrapolation of this rate to pH 5–5.5 reveals that it is the inception of the hydroxide ion catalyzed reaction that results in the change in slow step at this pH (Fig. 1). The rate–pH profile for hemiketal breakdown consists only of $[H^+]$-catalyzed and $[OH^-]$-catalyzed regions, with the pH-independent reaction not being able to compete at any acidity. An upper limit of $0.01\ s^{-1}$ can be set on k_2^0, based on the consideration that a value greater than this would have resulted in an observable contribution to the overall rate at pH 5.0.

Discussion

The question as to whether the third reaction stage can become rate limiting in the hydrolysis of an acetal, ketal, or ortho ester revolves around a comparison of the hydronium ion catalytic coefficients k_3^H and k_1^H. As summarized in Table 1, acyclic systems generally have $k_3^H > k_1^H$, and in such a case the first stage, formation of the oxocarbocation, must be rate determining at all acidities. Although k_3^H is sufficiently close to k_1^H with both the acetal and ketal that there is a small amount of hemiacetal/hemiketal build-up in acid solutions (7, 8), it now appears as if incorporation into a cyclic system can result in the opposite situation, $k_3^H < k_1^H$. This has now been observed with a number of cyclic ortho esters (12–14, 17, 33), and, in this study, with a cyclic ketal, and, as discussed recently by Kresge and co-workers, the effect must therefore be associated with the presence of the ring. In these cases, although oxocarbocation formation is rate limiting at high pH, a changeover occurs and breakdown of the hemiketal or hemiorthoester becomes rate limiting in acids.

We can consider why there is a difference between acyclic and cyclic systems. It is probably fair to say that the acid-catalyzed third stage, involving cleavage of a carbon–oxygen bond in a species such as HO—C—OR, is inherently going to be more rapid than the analogous cleavage when only alkoxyl

groups are present (RO—C—OR). This seems reasonable since there should be an additional hydrogen-bonding stabilization in the developing cation in the former case ($HO{=}\overset{+}{C}$) or, in the mechanism which we prefer (20), simultaneous removal of the hydroxyl proton to assist bond breaking. We feel that it is this factor which makes $k_3^H > k_1^H$ in the acyclic systems. This same factor must, of course, also be in operation in the cyclic species, so that here there must be some additional factor responsible for the turnaround. The major difference with the cyclic system is that the third reaction stage involves cleavage of an endocyclic bond or ring opening, while the first stage involves exocyclic cleavage or the production of two species from one. This results in an entropic disadvantage to the ring opening, which we feel is the major cause behind the third stage becoming slower than the first. Support for this suggestion comes in the general observation (34) that hydrolysis reactions of 1,3-dioxolanes and 1,3-dioxanes, cyclic acetals, and ketals, where a ring must open in the first stage, are significantly slower than reactions of acyclic analogs. The difference in reactivity, moreover, appears mainly in the entropy of activation.

The k_1^H values also deserve comment. The approximately 100-fold difference in k_1^H observed between cyclic and acyclic orthobenzoates has been explained (35, 36) in terms of a steric inhibition of resonance in the dialkoxycarbocation **10** derived from the former. The aromatic ring in **10** is forced out of coplanarity with the π system associated with the charge. In the cyclic cation **11**, full planarity is possible because the methylene carbons are tied back in the ring. The observation of a similar, albeit smaller (approximately 10-fold), difference between cyclic and acyclic phenyl ketones implies that a similar effect is in operation even here. That is, there is some steric inhibition to resonance in the oxocarbocation **12** derived from an acetophenone ketal, and the π systems are not completely coplanar.

Experimental

Materials

Starting ketals were prepared by a modification of the method of Ward and Sherman (23). 4-Chlorobutyrophenone (0.01 mol) was slowly added to a stirred suspension of silver borofluorate (0.01 mol) in anhydrous ether (50 mL) cooled in an ice bath. After 30 min stirring at room temperature, the precipitate, which had formed from a mixture of the borofluorate salt of **6** and silver chloride, was filtered in an anhydrous environment (glove bag), washed with dry ether, and then added to a stirred solution containing an excess quantity of sodium methoxide in anhydrous methanol or ethoxide in ethanol. The silver chloride was then removed by filtration, the majority of the alcohol removed on a rotary evaporator, and a mixture of ether (100 mL) and water (100 mL) added. The ether layer was separated, washed with dilute aqueous sodium bicarbonate, and dried with sodium carbonate. After filtration, the ether was removed and the ketal obtained by distillation. Samples were stored over a small amount of anhydrous Na_2SO_3. *2-Methoxy-2-phenyltetrahydrofuran* (**4**) had bp 70°C/0.1 Torr (1 Torr = 133.32 Pa); nmr δ: 7.1–7.5 (m, 5H), 4.0 (complex

Hydrolysis mechanisms for acylhydrazines in aqueous sulfuric acid, determined using the excess acidity method[1,2]

ROBIN A. COX AND KEITH YATES

Department of Chemistry, University of Toronto, 80 St. George St., Toronto, Ont., Canada M5S 1A1

Received December 7, 1983

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

ROBIN A. COX and KEITH YATES. Can. J. Chem. **62**, 1613 (1984).

The excess acidity method has been applied to hydrolysis rate data for some acyl- and benzoylhydrazines, obtained as a function of medium composition in aqueous sulfuric acid mixtures. Two hydrolysis mechanisms are indicated, both involving a second proton transfer to monoprotonated substrate. In the first mechanism this transfer is to oxygen, which is the rate-determining step in dilute acid, followed by attack of a water molecule in an A-2 hydrolysis, which is rate determining in more concentrated acid. Bisulfate ion becomes the nucleophile at high acidity. The second mechanism, found at higher acid concentrations, involves rate-determining nitrogen protonation, probably concerted with C—N bond rupture, to give an acylium ion, for those substrates capable of forming one.

ROBIN A. COX et KEITH YATES. Can. J. Chem. **62**, 1613 (1984).

On a appliqué la méthode de l'acidité en excès aux données, obtenues en fonction de la composition du milieu dans des mélanges d'acide sulfurique aqueux, de vitesses d'hydrolyse de certaines acyl- et benzoyl-hydrazines. On identifie deux mécanismes d'hydrolyse impliquant tous deux un deuxième transfert de proton au substrat monoprotoné. Dans le premier mécanisme, ce transfert, qui se fait vers l'oxygène, est l'étape déterminante en milieu acide dilué et il est suivi par une attaque d'une molécule d'eau dans une hydrolyse de type A-2 qui devient l'étape déterminante en milieu acide plus concentré. A des acidités élevées, l'ion bisulfate devient le nucléophile. Le deuxieme mécanisme, observé à des concentrations d'acide encore plus élevées, fait intervenir la protonation de l'azote dans l'étape déterminante et cette protonation se produit probablement d'une façon concertée avec la rupture de la liaison C—N pour donner un ion acyllium avec les substrats susceptibles d'en former.

Introduction

Recently, the excess acidity method, developed as a tool for the investigation of reaction mechanisms in strong acid media (1), was applied to rate data obtained for the hydrolysis of benzamides (2) and related compounds in sulfuric acid (3). It was found that nucleophilic attack upon oxygen-protonated amide was rate limiting, and that, as the acidity increased, the nucleophile changed from three water molecules acting in concert, in dilute acid, to one water molecule, to one bisulfate ion at high acidities (3).

It is of interest to see how far this mechanism extends to other amidic substrates, and in this paper the hydrolyses of some acyl- and benzoylhydrazines are studied. These compounds are protonated in the pH-range, as shown in reaction [1], on the amine nitrogen (4, 5), and the resulting positive

[1] 
charge should alter the properties of the amide part of the molecule considerably in acidic media. Previous work on these substrates includes that of Edward *et al.*, on acetylhydrazine in HCl (6), of Mashim and Ikeda, on formylhydrazine in $HClO_4$ and H_2SO_4 (4), of Mashima *et al.*, on a number of acylhydrazines in H_2SO_4 (7), of Zarakhani *et al.*, on benzoylhydrazine in H_2SO_4 (8), and of Jagdale and Nimbalkar, on some substituted benzoylhydrazines in H_2SO_4, $HClO_4$, and HCl (9). The consensus of their conclusions is that most compounds hydrolyze by an A-2 mechanism, and that some may switch to an A-1 mechanism at high acidity.

Kinetic analysis

The excess acidity method, applied to reaction kinetics, consists of deriving rate equations based on reasonable reaction mechanisms, and determining which of them best applies to the process under consideration (1). Several examples of the method in use are now available (1, 3, 10–12). For the acylhydrazine hydrolyses under consideration here, a reasonable possibility is that given in Scheme 1, which is based on the normal amide hydrolysis mechanism (3). Monoprotonated substrate SH^+ is protonated again, on the carbonyl oxygen; insofar as the substrate is already positively charged, the possibility that this second protonation is rate determining must be considered. Diprotonated SH_2^{2+} then undergoes nucleophilic attack; one water molecule is shown as the nucleophile in Scheme 1, but several water molecules or a bisulfate ion may be involved (3, 10–12). If the second protonation is fast this second stage will probably be the slow step. Subsequent tautomerization and loss of hydrazine lead to the observed benzoic acid product (6–9).

Scheme 1, k_0 slow

[2] $$k_\psi C_{SH^+} = k_0 a_{SH} + a_{H^+}/f_\ddagger = k_0 C_{SH^+} C_{H^+} (f_{SH^+} f_{H^+}/f_\ddagger)$$

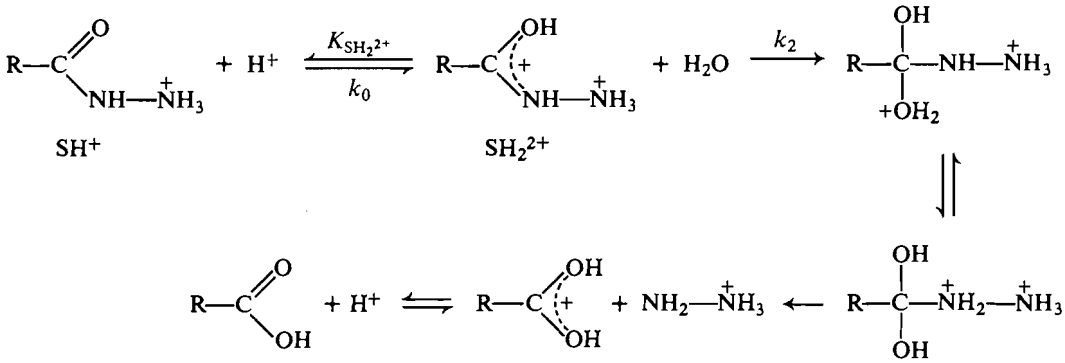
[3] $$\log (f_{SH^+} f_{H^+}/f_\ddagger) = m_0^\ddagger \log (f_{SH^+} f_{H^+}/f_{SH_2^{2+}}) = m_0^\ddagger m^* X$$

[4] $$\log k_\psi - \log C_{H^+} = \log k_0 + m_0^\ddagger m^* X$$

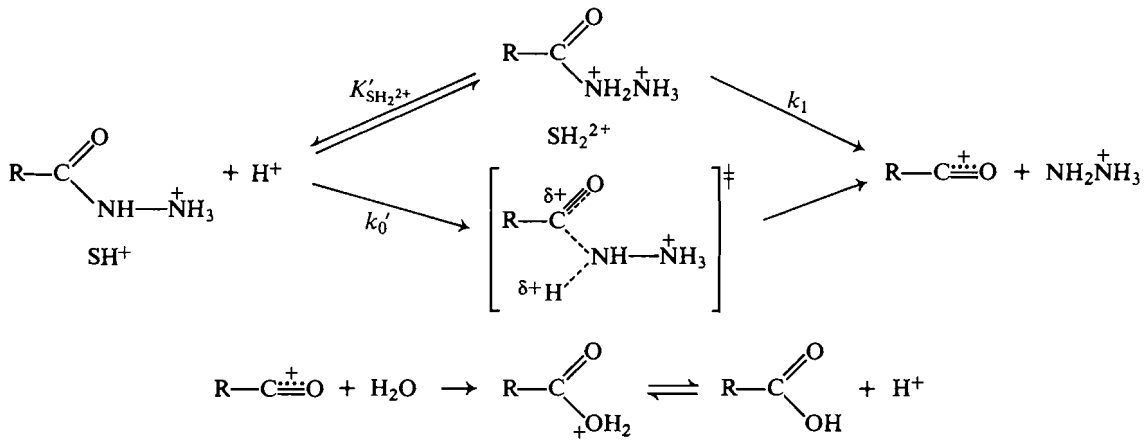
Using the terminology of Scheme 1, eq. [2] is obtained in the usual way (1); k_ψ is the observed pseudo-first-order rate constant, a is activity, C molar concentration, and f molar activity coefficient. Activity coefficient ratios such as those in eqs. [2] and [3] have been shown to be linear in one another (1, 13), and the slope parameters $m^\ddagger$ (subscript 0 for A-S_E2 processes, 1 for

[1]Mechanistic studies in strong acids IX. Part VIII is ref. 12.

[2]Presented in part at the 66th Chemical Conference of the Chemical Institute of Canada, Calgary, Alberta, June 1983, No. OR21-3.



SCHEME 1



SCHEME 2

A-1, and 2 for A-2 reactions, subscripts on k similarly) and m^* are defined as in eq. [3]. $X = \log (f_{B^*} f_{H^+}/f_{B^*H^+})$ for a standard base B*; values of X and $\log C_{H^+}$ in H_2SO_4 (13), $HClO_4$ (13), and HCl (14) are available. Suitable manipulation of eqs. [2] and [3] produces eq. [4], for the rate-determining proton transfer to oxygen shown in Scheme 1. Regarding the slope parameters, $m_o^{\ddagger} < 1$ for an A-S_E2 proton transfer (1), probably about 0.5 (12), and m^* for carbonyl oxygen protonation is 0.6 or less (13). Thus a total slope against X of 0.3 or less would be expected for eq. [4].

Scheme 1, k_2 *slow*

$$k_\psi C_{SH^+} = k_2 a_{H_2O} a_{SH_2^{2+}}/f_\ddagger$$

$$K_{SH_2^{2+}} = a_{SH^+} a_{H^+}/a_{SH_2^{2+}}$$

$$k_\psi = (k_2/K_{SH_2^{2+}}) a_{H_2O} C_{H^+} (f_{SH^+} f_{H^+}/f_\ddagger)$$

[5] $$\log k_\psi - \log C_{H^+} - \log a_{H_2O} = \log (k_2/K_{SH_2^{2+}}) + m_2^{\ddagger} m^* X$$

[6] $$\log k_\psi - \log C_{H^+} - \log C_{HSO_4^-} = \log (k_2'/K_{SH_2^{2+}}) + m_2^{\ddagger\prime} m^* X$$

If the k_2 step is rate determining in Scheme 1, eq. [5] can be derived, as shown above, for the case in which the nucleophile is one water molecule. If several are involved, eq. [5] is modified by multiplying the $\log a_{H_2O}$ term by two, three, etc. (11, 12), and if the nucleophile is bisulfate, eq. [6] results. (Bisulfate activities are unavailable, but the error involved in using the concentration should be small (3, 10).) For A-2 reactions $m_2^{\ddagger} \simeq 1$ (1, 12), thus an overall slope against X of 0.6 or less should result for eqs. [5] and [6].

By analogy with ester hydrolysis (11, 12), another possible mechanism for acylhydrazines would be acylium ion formation at low water activity, as shown in Scheme 2. Here either pre-equilibrium nitrogen protonation, followed by carbon–nitrogen bond breaking, can occur, the upper A-1 process in Scheme 2, or slow nitrogen protonation, which may or may not be concerted with C—N bond rupture, may result, the lower A-S_E2 process of Scheme 2.

Scheme 2, k_1 *slow*

$$k_\psi C_{SH^+} = k_1 a_{SH_2^{2+}}/f_\ddagger = (k_1/K'_{SH_2^{2+}}) C_{SH^+} C_{H^+} (f_{SH^+} f_{H^+}/f_\ddagger)$$

[7] $$\log k_\psi - \log C_{H^+} = \log (k_1/K'_{SH_2^{2+}}) + m_1^{\ddagger} m^* X$$

Equation [7] can be derived for A-1 acylium ion formation. For A-1 processes $m_1^{\ddagger} > 1$, probably about 2–3 (1), and m^* for nitrogen protonation $\simeq 1$ (13), so an overall slope of 2–3 should be obtained.

Scheme 2, k_0' *slow*

$$k_\psi C_{SH^+} = k_0' a_{SH^+} a_{H^+}/f_\ddagger$$

[8] $$\log k_\psi - \log C_{H^+} = \log k_0' + m_0^{\ddagger\prime} m^* X$$

In this case an overall slope against X of about 0.5 would be reasonable, so eqs. [7] and [8] should be distinguishable by their slopes.

In deriving the above equations it has been assumed that the substrate is fully monoprotonated but essentially not diprotonated under the acidic reaction conditions. Since monoprotonation occurs in the range pH 2 to pH 3.5 (4, 5), the former assumption is reasonable. Brignell *et al.* (15) found that

the first and second protonation in a series of substituted phenylhydrazines were separated by at least ten H_0 units, so the latter assumption is reasonable too.

Results

Graphs of log observed rate constant against acidity (as X) for formyl- and acetylhydrazine (7) are given in Fig. 1; the other acylhydrazines behave similarly. Overall, the rate profiles resemble those for ester rather than amide hydrolysis (compare Fig. 1 with ethyl benzoate, Fig. 1 in ref. 12, for instance), and the reactions are fast compared to those of normal amides (2, 3). The formylhydrazine data are plotted according to eqs. [4] and [5] in Fig. 2. A change in rate-determining step is clearly indicated. Equation [4], the k_0 pathway in Scheme 1, is followed at acidities below about 75% H_2SO_4, and eq. [5], k_2 in Scheme 1 rate-determining, above this acidity. The slopes are in accord with the expectations noted above. The acetylhydrazine results, see Fig. 3, are similar, except that the change in rate-determining step occurs at lower acidity, about 60% H_2SO_4. At about 82% H_2SO_4 another mechanism takes over, with log k_ψ − log C_{H^+} again linear against X in this region. This is assigned to the k_0' pathway of

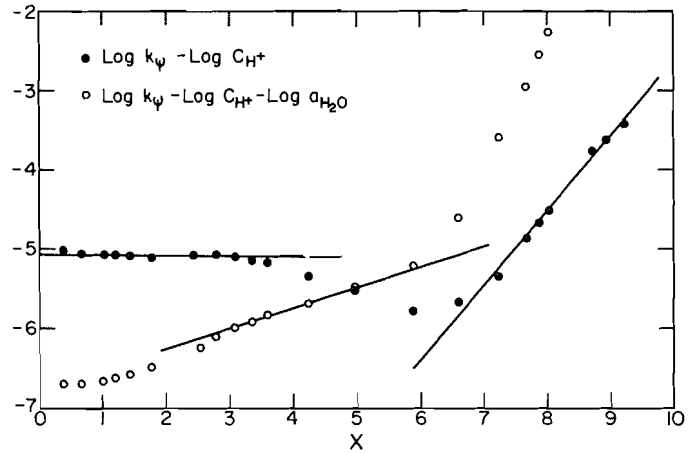

FIG. 3. Hydrolysis rate constants for acetylhydrazine at 25°C, plotted according to eqs. [4] and [8] (filled circles), and eq. [5] (open circles), showing the change of mechanism, Scheme 1 to Scheme 2.

Scheme 2, on the basis of the observed less-than-unit slope. The two mechanisms were separated, on the assumption that $k_\psi = k_{A\text{-}2} + k_{A\text{-}1}$, using the same computer program as before (3, 11, 12).

The slope and intercept values for all the acylhydrazines in the study are given in Tables 1 and 2. These include the compounds studied by Mashima *et al.* (7) at 25 and 55°C, and some results for benzoylhydrazine by Zarakhani *et al.* (8), extrapolated to 25°C as before (3, 12). Scheme 1 was followed by all the compounds examined (results in Table 1), with the nucleophile being one water molecule. In this case, the k_0 step is rate determining in the acidity region where three water molecules were involved in benzamide hydrolysis (3), so a three-water-molecule mechanism is not observed here.

Some of the compounds switch to a Scheme 2 mechanism, and the slope and intercept data of eq. [8] for these are collected in Table 2. Formylhydrazine and chloroacetylhydrazine at 55°C do not hydrolyze by Scheme 2, but at higher acidities bisulfate ion takes over as a nucleophile from water in the Scheme 1 hydrolysis. The results of fitting the data for these two compounds to eq. [6] are also shown in Table 2. For formylhydrazine at 25°C this mechanism was represented by only one data point, and details could not be obtained.

For benzoylhydrazine, one deviant point on the high acidity side was also observed; it was impossible to tell whether this represented a switch to a Scheme 2 mechanism or not, although this seems likely. Activation parameters were obtained; for k_2 these were $\Delta H^\ddagger = 21.43 \pm 0.45$ kcal/mol, and $\Delta S^\ddagger = -28.6 \pm 1.5$ eu, and for k_0, 21.02 ± 0.33 and −21.0 ± 1.1. The same data could be fitted to either eq. [4] or eq. [5] for this compound, and so both sets of results are given here and in Table 2.

Jagdale and Nimbalkar (9) studied benzoylhydrazine at 90°C, together with its *m*- and *p*-methoxy derivatives. Their results for the parent compound are in fair agreement with those of Zarakhani's group (8). Equation [5] (k_2) fits the data considerably better than eq. [4] (k_0), and gives slopes of 0.350 ± 0.008, 0.341 ± 0.008, and 0.381 ± 0.025, and intercepts of −4.768 ± 0.006, −4.591 ± 0.006, and −4.672 ± 0.020 for the *p*-OCH_3, *m*-OCH_3, and parent compounds, respectively.

All values of X, log C_{H^+}, log a_{H_2O} and log $C_{HSO_4^-}$ used were obtained from the sources previously cited, and temperature-corrected as necessary as described before (3, 10−13).

[a]In a hypothetical ideal medium containing 1 M bisulfate ion.

Discussion

The excess acidity method is capable of revealing mechanistic features which other methods of analyzing kinetic data in strong acids cannot (1, 3, 12). Here the change in rate-determining step in Scheme 1 is clearly indicated by the change in the rate equation followed, eq. [4] to eq. [5], see Figs. 2 and 3. Also, the change in nucleophile in some cases, from water to bisulfate, can be seen. Mashima *et al.* (7) analyzed the same data in terms of the Bunnett–Olsen (16) and Bunnett w-parameter (17) mechanistic criteria; these showed the change in mechanism from Scheme 1 to Scheme 2, assigned as A-2 and A-1 without further specification (7). These methods proved to be ambiguous, however, in the Scheme 1 region, giving curved plots or multiple linearity, and did not show the change in rate-determining step. In the Scheme 2 acidity region the distinction between A-1 and A-S_E2 acylium ion formation, made in this work, was not apparent.

As noted above, at least for the acylhydrazines hydrolysis is faster than it is for equivalent amides (3); the extra positive charge in the substrate causes the second protonation to be difficult, as would be expected, but when SH_2^{2+} is formed it reacts very quickly. Evidently the strongly electron-withdrawing $^+NH_3$ group makes the carbon centre much more electrophilic. For instance, in Scheme 1 deprotonation of SH_2^{2+} back to SH^+ has to be slower than nucleophilic attack on it by H_2O, in order for the k_0 step to be rate determining, as it is in the low acidity region. SH_2^{2+} is resonance-stabilized, which means that the internal electron pair on the amide nitrogen is competing for the second positive charge with the external electron pairs on solvating water molecules. This effect evidently slows deprotonation enough, and the $^+NH_3$ group accelerates nucleophilic attack by water enough, to make the protonation step rate determining. At low acidities, C_{H^+} is low and protonation is rate limiting. As the acidity increases, C_{H^+} increases and a_{H_2O} decreases, and nucleophilic attack becomes the slow step.

Both mechanisms involve slow proton transfer, at least at some acidities. Slow protonation is quite common at carbon (18), and it has been observed at sulfur in strong acids (12), but rate-determining oxygen or nitrogen protonation is seen less often. Here it can be observed because the second protonation of a positively charged species is involved. In the Scheme 2 process there is no way of deciding from the data whether or not C—N bond rupture is concerted with proton transfer, but this process has precedent in the Wallach rearrangement of azoxy compounds in strong acids (19), where a symmetrical dicationic intermediate is formed by concerted proton transfer to oxygen, N—O bond cleavage, and participation of a nitrogen lone pair (20). It seems reasonable here too.

Formyl- and chloroacetylhydrazine do not react by Scheme 2. Acylium ions which are stabilized by electron-donating alkyl groups can evidently form more easily than those which have only H, or electron-withdrawing $ClCH_2$. Formylhydrazine hydrolyzes faster than the other compounds by Scheme 1. Benzoylhydrazine reacts much more slowly. Presumably this is because of the absence of stabilizing alkyl groups in the former case, and in the latter because the charge can be delocalized into the aromatic ring, reducing the susceptibility of the carbon to nucleophilic attack. Steric factors do not seem important; increasing the length of the alkyl chain makes little difference

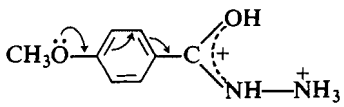
For personal use only.

to the rates (Table 1).

As mentioned, the benzoylhydrazine data can be fitted to either eq. [4] or eq. [5]. One data set gives a better statistical fit with eq. [4] (8), and the other with eq. [5] (9). On the basis of the activation parameters, a $\Delta S^{\ddagger}$ of -28 eu for k_2 seems much more likely than one of -21 for k_0, and so the former is tentatively assigned the rate-determining step in this case. Benzamides are more difficult to protonate than acetamides by up to one pK unit (21), but this fact may not affect the *rate* of proton transfer. Once SH_2^{2+} is formed it is resonance-stabilized, as mentioned, and thus less reactive. Thus it is not unreasonable that nucleophilic attack should be rate limiting at all acidities for these compounds.

The methoxy-substituted benzoylhydrazines studied by Jagdale and Nimbalkar (9) react in the order m-OCH_3 > H > p-OCH_3. This order is as expected, and can be rationalized by considering that inductive electron withdrawal of OCH_3, which



is activating to nucleophilic attack, is counteracted by mesomeric electron donation, as shown, which is deactivating, in the *para* but not the *meta* position.

Normal amides do not usually hydrolyze by forming acylium ions; the only cases of this observed so far involve β-lactams (3) and some acetanilides (22). Presumably this is because nitrogen protonation as in Scheme 2 produces a neutral NH_3 leaving group in the amide case, compared to the positive $^{+}NH_3$—NH_2 leaving group involved here, which must be much better in acidic media. Apart from this, acylhydrazines react in much the same way as normal amides do, see Scheme 1, when account is taken of the fact that they contain an extra positive charge.

A spin-lattice relaxation study of the molecular reorientation of 2-methylindole as a function of viscosity and complex formation

KENNETH J. FRIESEN AND BARRY J. BLACKBURN

Department of Chemistry, University of Winnipeg, Winnipeg, Man., Canada R3B 2E9

Received February 2, 1984

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

KENNETH J. FRIESEN and BARRY J. BLACKBURN. Can. J. Chem. **62**, 1618 (1984).

The viscosity (η) dependence of the ^{13}C spin-lattice relaxation time (T_1) of C-3 of 2-methylindole was investigated by changing the temperature (T) and by changing the solvent system. The observed η/T dependence of the effective reorientation correlation time (calculated from T_1) is compared with those derived from theory based on hydrodynamic rotation with "stick" and with "slip" boundary conditions. This data implies that the reorientation of 2-methylindole obeys a near-slip condition in 1,2-dichloroethane. The ^{13}C T_1 of C-3 of 2-methylindole was also determined as a function of the fraction complexed with 1,3,5-trinitrobenzene (TNB) at 35°C in 1,2-dichloroethane. The observed T_1, in this case, depends on the rates of reorientation of the molecule in the free and the bound states, the rate of association of the molecules, the rate of dissociation of the complex, as well as increases in viscosity brought about by increases in the concentration of TNB. Analysis of the data, by application of the Anderson–Fryer formulation, gives a rate of reorientation in the bound state of 55 ns^{-1} at 35°C and 0.69 cP as compared to a value of 150 ns^{-1} in the free state under the same conditions.

KENNETH J. FRIESEN et BARRY J. BLACKBURN. Can. J. Chem. **62**, 1618 (1984).

Faisant varier la température (T) et le système de solvant, on a étudié l'effet de la viscosité (η) sur le temps de relaxation spin-réseau (T_1) du ^{13}C du carbone en position 3 du méthyl-2 indole. La valeur observée pour la dépendance η/T du temps de corrélation effectif de la réorientation (calculée à partir de T_1) a été comparée aux valeurs que l'on peut dériver en se basant sur une rotation hydrodynamique dans des conditions où les limites sont fixées par des "tiges" et des "lamelles". Ces donnés impliquent que, dans le dichloro-1,2 éthane, la réorientation du méthyl-2 indole obéit à une condition quasilamelaire. Opérant à 35°C, dans le dichloro-1,2 éthane, on a également déterminé la valeur T_1 du ^{13}C pour le carbone en position 3 du méthyl-2 indole en fonction de la fraction complexée avec le trinitro-1,3,5 benzène (TNB). Dans ce cas, la valeur observée pour T_1 dépend des vitesses de réorientation de la molécule dans les états libre et lié, de la vitesse d'association des molécules, de la vitesse de dissociation du complexe ainsi que des augmentations de viscosité, dues aux augmentations de concentration dans le TNB. L'analyse des données, à l'aide de la formulation de Anderson–Fryer, conduit à une vitesse de réorientation de l'état lié de 55 ns^{-1}, à 35°C et 0,69 cP, qui se compare à une valeur de 150 ns^{-1} pour l'état libre dans les mêmes conditions.

[Traduit par le journal]

Introduction

The calculations of Hu and Zwanzig (1) on rotational friction coefficients of spheroids under two sets of boundary conditions, combined with Woessner's theory (2), have proved useful in the study of molecular reorientation by nuclear magnetic relaxation methods. A good example of this, which includes a theoretical discussion, is a study (3) of the hydrodynamical rotation of triphenylene. A review article in this area, giving theoretical developments as well as experimental studies, has appeared recently (4).

Anderson and Fryer (5) have given expressions relating nuclear relaxation times to the rates of reorientation and chemical exchange of a molecule in the free and complexed state and applied them to proton relaxation data. Brevard and Lehn (6) have adapted these equations to study the molecular dynamics of complex formation by deuterium quadrupolar relaxation. A recent review (7) summarizes the latter two articles and discusses related studies.

In this paper, the effects of viscosity and complex formation with 1,3,5-trinitrobenzene on the carbon-13 spin-lattice relaxation times for C-3 of 2-methylindole-(methyl,3-$^{13}C_2$) are evaluated in light of the above-mentioned theories to give information about the molecular reorientation. Some of this data was presented earlier in a preliminary communication (8) which pointed out the usefulness of carbon-13 spin-lattice relaxation times as a probe for the study of electron donor–acceptor complexes.

Experimental

1,3,5-Trinitrobenzene and 1,2-dichloroethane were purified and 2-methylindole-(methyl,3-$^{13}C_2$) synthesized by previously reported methods (8). 1,1,2,2,-Tetrachloroethane was washed with concentrated sulfuric acid, then water, and then dried and distilled.

Solutions, prepared by weight, were transferred into 8-mm nmr tubes, degassed on a high vacuum gas line at least four times by the freeze–pump–thaw technique, and then sealed. All solutions utilizing 1,2-dichloroethane as either a pure or mixed solvent contained sufficient 1,2-dichloroethane-d_4 to provide a deuterium lock. The sample of 2-methylindole in pure 1,1,2,2,-tetrachloroethane was degassed by bubbling dry nitrogen through for about 3 min. A coaxial tube containing D_2O was added to this sample to provide the lock nucleus.

Viscosities were determined with an Ostwald viscometer and density bottle at 35°C using unenriched 2-methylindole.

Proton-decoupled ^{13}C nmr spectra were obtained on a Varian CFT-20 spectrometer. Spin-lattice relaxation times, T_1's, for C-3 of 2-methylindole-(methyl,3-$^{13}C_2$) were determined by the inversion–recovery pulse sequence ($d-180°-t_i-90°$), where t_i is a variable time, and the pulse delay, $d \geq 7T_1$. For each T_1 determination, 10–12 t_i values were used. A total of 40–50 transients was sufficient to obtain signal-to-noise > 75:1. The free induction decays were weighted to broaden the lines, otherwise seen as a doublet due to $^{13}C—^{13}C$ coupling, in order to facilitate phasing. The T_1 values, determined with semilogarithmic plots, had a precision better than 4%. Nuclear Overhauser enhancement, nOe, factors were measured using the gated proton decoupler technique with $d \geq 7T_1$.

The probe temperature, measured with a thermometer immersed in 1,2-dichloroethane and set to the same depth as the sample being studied, was maintained with a Varian CFT-20 Variable Temperature Accessory using precooled nitrogen where necessary.

was determined by changing the temperature as well as by changing the solvent system used.

Since nOe factors for C-3 of 2-methylindole are within experimental error of the full nOe over the entire viscosity range studied, it is assumed that this carbon is relaxed solely by the dipolar interaction with its bonded proton. In the region of motional narrowing and under conditions of complete proton decoupling the dipolar ^{13}C relaxation rate, $1/T_1$, of a carbon nucleus containing one bonded proton is related (9) to the effective molecular correlation time, τ_c, according to

$$[1] \quad 1/T_1 = \hbar^2\gamma_C^2\gamma_H^2 r^{-6}\tau_c$$

where $2\pi\hbar$ is Planck's constant, γ_C and γ_H are the magnetogyric ratios of ^{13}C and ^1H nuclei, and r is the C—H bond length.

Table 1 summarizes the T_1 data for C-3 of 2-methylindole as a function of temperature. The effective molecular correlation times were calculated from the T_1 data by eq. [1] using $r = 1.08$ Å for the required C—H bond length in 2-methylindole (10). The viscosities of 1,2-dichloroethane as a function of temperature, also given in Table 1, were obtained from the literature (11*a*); it was assumed that the small amount of 2-methylindole (0.10 molal) and the use of 50% 1,2-dichloroethane-d_4 would not significantly affect these solvent values. A least-squares fit of the data to (3, 4, 12)

$$[2] \quad \tau_c = C\,\eta/T + b$$

where η is the viscosity, T is the temperature in K, and b is the intercept, gives the experimental η/T dependence of τ_c as C_{exp} = 3.46 ns K/cP, with a correlation coefficient of 0.995.

Variation of the viscosity was also accomplished by using different mixtures of 1,2-dichloroethane and 1,1,2,2-tetrachloroethane as the solvent. 1,1,2,2-Tetrachloroethane was chosen since its dielectric constant (ϵ = 7.83 at 25°C) (11*b*) matched that of 1,2-dichloroethane (ϵ = 10.13 at 25°C) (11*b*) fairly well, it provided a sufficient range in viscosity, and because of a reasonable structural similarity to 1,2-dichloroethane. The changes in the solvent, other than viscosity, should therefore not be great on mixing this component with 1,2-dichloroethane. The T_1's of C-3 of 2-methylindole at 35°C as a function of solvent mixture are given in Table 2; also given in this table are the experimentally determined viscosities and the correlation times calculated by eq. [1]. These correlation times show a η/T dependence (according to eq. [2]) of C_{exp} = 3.96 ns K/cP, with a correlation coefficient of 0.996.

The use of a hydrodynamical model in a study of this type is common (4, 13). In order to apply such a model of molecular reorientation to the rotational behaviour of 2-methylindole in solution, an approximation of the molecular geometry is necessary. A space-filling model suggests that 2-methylindole may be approximated by an oblate spheroid. Using the van der Waals radius of carbon, 1.7 Å, as an approximation (3, 14) of the semi-minor axis, c, and the sum of the van der Waals volume increments of all the atoms in this molecule (15), 126.8 Å^3, as an approximation of the molecular volume, V, the semi-major axis, a, is calculated to be 4.22 Å. This value of a is regarded as a lower limit, as using $V = 4\pi a^2 c/3$ to calculate a implicitly assumes unfilled spaces between peripheral atoms as part of the volume. A scale diagram of 2-methylindole was drawn using the bond lengths and angles of L-tryptophan hydrochloride (16) determined by X-ray crystallography. If van der Waals radii of the outer atoms are included (3), this diagram suggests that 5.55 Å is the maximum radius that would be swept out by rotation in the plane of the molecule; therefore a = 5.55 Å was taken as an upper limit. We consider the average of these two limits, 4.9 Å, to be a reasonable approximation.

Molecular reorientation was considered under two different boundary conditions. Under "stick" boundary conditions, which assumes that the solvent sticks to the surface of and therefore rotates with the solute, the viscosity-dependent term in eq. [2] can be theoretically calculated for a spheroid (2, 3) by

$$[3] \quad \tau_{stick} = \frac{\zeta_1}{24\,kT} + \frac{3\zeta_1}{8\,kT[1 + (2\zeta_1/\zeta_3)]}$$

where T is the temperature, k is the Boltzmann constant, and ζ_1 and ζ_3 are rotational friction coefficients ($\zeta_1 = \zeta_2$ for a spheroid) which are calculated from the geometry of the spheroid and the viscosity. The equations for ζ_1 and ζ_3 and a discussion relevant to them are given in ref. 3. Substitution for the rotational friction coefficients and rearranging gives τ_{stick} proportional to η/T and the proportionality constant can be calculated from the geometry of the molecule. Using a = 4.9 Å and c = 1.7 Å yields a η/T dependence, C_{stick}, of 19.7 ns K/cP. (For a = 4.22 Å and c = 1.7 Å, C_{stick} = 13.2 ns K/cP.)

Under slip boundary conditions the solvent is considered to slip by the surface of the rotating molecule and resistive forces are due only to the displacement of fluid as the body rotates. For rotation *of* the symmetry axis of spheroids, Hu and Zwanzig (1) have calculated the ratio ζ_{slip}/ζ_1 as a function of the ratio of the lengths of the semiaxes. The rotational friction coefficient corresponding to ζ_3 will be zero since rotation *about* the

[e] The fraction of 2-methylindole complexed.

symmetry axis of an oblate spheroid does not displace any fluid. Under this condition the right hand side of eq. [3] is dominated by the first term so that the viscosity-dependent term in eq. [2] can be calculated for the slip condition by

$$[4] \quad \tau_{slip} = \frac{R\zeta_1}{24\ kT}$$

where R is the ratio ζ_{slip}/ζ_1 obtained from the work of Hu and Zwanzig (1). Substituting and rearranging gives τ_{slip} proportional to η/T. Using a = 4.9 Å and c = 1.7 Å yields a η/T dependence, C_{slip}, of 2.13 ns K/cP. (For a = 4.22 Å and c = 1.7 Å, C_{slip} = 1.16 ns K/cP.)

Comparison of the experimentally determined η/T dependence of the effective molecular correlation time with the results of the slip and stick treatments (see Table 3) implies that the molecular reorientation of 2-methylindole much more nearly approximates slip conditions than stick conditions. The slip boundary condition will disturb less solvent and will therefore show a smaller viscosity dependence and faster rate of reorientation. The stick boundary condition predicts too much friction to rotation for the case at hand and therefore shows a viscosity dependence that is too high. In spite of the difficulty in defining the geometry due to the lack of symmetry in 2-methylindole, the model does provide a qualitative picture of the reorientation of 2-methylindole in 1,2-dichloroethane. The solvent is not expected to interact strongly with 2-methylindole since it will not hydrogen bond to the solute. Therefore the amount of "stick" is expected to be minimal, which is in agreement with observations.

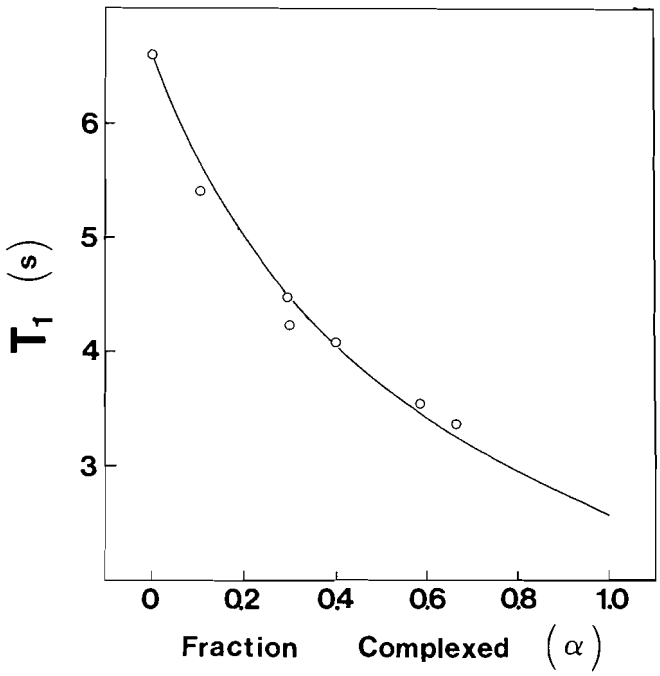

FIG. 1. The dependence of T_1 (corrected for the effects of viscosity) of C-3 of 2-methylindole on the fraction complexed, showing the experimental points and the theoretical curve providing the best fit.

Effect of complex formation

The experimental dependence of T_1 of C-3 of 2-methylindole on the fraction complexed (see Table 4) was determined by measuring the relaxation time as a function of the concentration of 1,3,5-trinitrobenzene (TNB) while keeping the concentration of 2-methylindole essentially constant. The fraction complexed, α, was calculated from the initial concentrations and an equilibrium constant of 1.3 kg solvent mol^{-1}, assuming 1:1 complex formation only (see ref. 8). (The equilibrium constant was obtained by standard methods (17) from the chemical shift changes, of C-2 and the methyl carbon of 2-methylindole, which result from complex formation with TNB.) Figure 1 shows the observed T_1, corrected to account for the changes in viscosity as TNB is added, as a function of the fraction complexed. The reference viscosity chosen is that of the solution containing no TNB.

Since nOe factors for all solutions are within experimental error of the full nOe, relaxation of C-3 is dominated by dipolar interaction with the directly attached proton. The dipolar spin-lattice relaxation time of a nucleus undergoing exchange between the free and complexed state will depend on the rates of reorientation of the free molecule (k_1) and the complex (k_2), as well as the rate of association (k_3) of the molecules and the rate of dissociation (k_4) of the complex. Utilizing the equations of Anderson and Fryer (5), the ^{13}C dipolar relaxation rate, $1/T_1$, can be written as a function of these rate constants and the fraction complexed. In the region of motional narrowing and under conditions of complete proton decoupling

$$[5] \quad 1/T_1 = B[(Q_+/\lambda_+) + (Q_-/\lambda_-)]$$

where $B = \hbar^2\gamma_C^2\gamma_H^2 r^{-6}$ and Q_+, Q_-, λ_+, and λ_- are complex functions of k_1, k_2, k_3, k_4, and the fraction complexed which are given in the work of Anderson and Fryer (5). (As pointed out by Brevard and Lehn (6) a minus sign should replace the plus sign in the brackets of the Q_+ and Q_- expressions.) Using this relationship, T_1 can be calculated as a function of the fraction

[b, c] Spin-lattice relaxation times for C-3 of 2-methylindole-(methyl,3)-$^{13}C_2$ in the free and complexed state respectively.

complexed for a given set of rate constants.

This T_1 expression can be reduced to an equation containing two unknowns. In the region of motional narrowing and under conditions of complete proton decoupling, T_1 is related to the effective molecular correlation time for reorientational motion by eq. [1]. Therefore, the T_1 of C-3 of 2-methylindole in the solution containing no TNB was used to calculate the rate of reorientation of free 2-methylindole as $k_1 = (\tau_c)^{-1}$ (6). By using the equilibrium constant of 1.3 kg solvent mol^{-1}, determined as described above, a substitution can be made for k_3, since $K = k_3/k_4$.

The computer program of Brevard and Lehn (6, private communication with J. M. Lehn), based on the deuterium quadrupolar relaxation version of eq. [5], was modified for ^{13}C dipolar relaxation and to take into account the effects of viscosity on the experimental T_1's. This program was used to generate a series of theoretical curves of T_1 as a function of the fraction complexed. For each k_2 (rate of reorientation of the complex) tested, k_4 (rate of dissociation of the complex) was varied such that k_4/k_2 covered the range from 10^{-5} to 10^4. Best fits with the experimental data are given by k_2 of 55 ± 5 ns^{-1}. The theoretical curve best fitting the experimental points is shown in Fig. 1.

The results, summarized in Table 5, show that the overall rotational motion of 2-methylindole decreases considerably due to complex formation ($k_1/k_2 \sim 3$). The rates of formation and dissociation of the complex, k_3 and k_4, are slower than the rates of reorientation of 2-methylindole in the free, k_1, and bound state, k_2. The lifetime of the complex, $(k_4)^{-1}$, is therefore longer than the correlation time for rotational motion of the complex, $(k_2)^{-1}$. This implies that the complex experiences considerable rotational motion prior to dissociation. Thus, by the classification of ref. 7, this is a true complex and not merely a collision complex.

In the limiting case for slow exchange relative to the rates of molecular reorientation in the free and complexed environments (k_3, $k_4 \ll k_1$, k_2), eq. [5] simplifies to (5)

$$[6] \quad 1/T_1 = (1 - \alpha)/T_D + \alpha/T_{AD}$$

where T_D and T_{AD} represent the dipolar spin-lattice relaxation times of the free and complexed molecules respectively. A simplification in eq. [5] also occurs (5) in the limiting case for fast exchange relative to the rates of reorientation (k_3, $k_4 \gg k_1$, k_2). The results in Table 5 show that the system under investigation is best defined as having an intermediate rate of exchange relative to k_1 and k_2.

Our previous treatment of the 2-methylindole/TNB system (8), which assumed slow exchange relative to k_1 and k_2, gave $T_{AD} = 3.0$ s. The difference between this value and T_{AD} of 2.4 s obtained here may be attributed to this assumption.

A trihydroxy acyclonucleoside series[1]

KELVIN K. OGILVIE,[2] NGHE NGUYEN-BA, AND RAYMOND G. HAMILTON
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received December 8, 1983

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

KELVIN K. OGILVIE, NGHE NGUYEN-BA, and RAYMOND G. HAMILTON. Can. J. Chem. **62**, 1622 (1984).

An acyclonucleoside structure (**Z**) has been developed which possesses three hydroxymethyl groups attached to the carbon which is analogous to the 4′-carbon of natural nucleosides. The presence of the third hydroxymethyl group significantly reduces activity against herpesviruses as compared to the dihydroxymethyl (BIOLF-62) and monohydroxymethyl (acyclovir) models.

KELVIN K. OGILVIE, NGHE NGUYEN-BA et RAYMOND G. HAMILTON. Can. J. Chem. **62**, 1622 (1984).

On a développé une structure acyclonucléoside (**Z**) comportant un carbone portant trois groupes hydroxyméthyles qui est analogue au carbone 4′ des nucléosides naturels. Si on la compare aux modèles dihydroxyméthylés (BIOLF-62) et monohydroxyméthylés (acyclovir), on note que la présence d'un troisième groupe hydroxymèthyle réduit d'une façon importante l'activité contre les virus herpès.

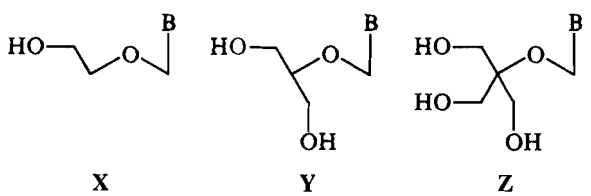
Introduction

Nucleoside analogues represent an important group of biologically active molecules (1). We have developed an analogue structure **Y** (2–6, the "glycerosides"), members of which have shown pronounced antiviral activity (5, 7–12). As part of our overall program to determine the limits on structural changes to the side chain with regard to optimal biological activity, we have introduced specific changes at the 3′-position. One such structural change involves the introduction of an additional hydroxymethyl group at the 3′-position (analogous to the 4′-position of natural nucelosides). In this report we wish to describe the synthesis of compound **Z** where B = adenine, cytosine, guanine, 6-chloropurine, and thymine. When B = guanine, the series **X**, **Y**, and **Z** represent a progression of hydroxymethyl modification at the 4′-position. The order of activity against herpesviruses is **Y** > **X** ≫ **Z** where **X** is acyclovir (1, 13).



X **Y** **Z**

Discussion and results

The key intermediate in the synthesis is compound **5**. The route to compound **5** is outlined in Scheme 1. The starting material, 1,3-dibenzyloxy-2-propanol (**1**), is readily available (5) and is easily oxidized to the ketone **2** using *N*-chlorosuccinimide and dimethyl sulfide (14). Other common oxidizing agents such as pyridinium chlorochromate, pyridinium dichromate, and Jones reagent were less successful. Compound **2** was smoothly converted into the epoxide **3** in high yield using trimethylsulfoxonium iodide (15). Sodium hydride was very effective in this reaction provided that rigorously anhydrous conditions were maintained; otherwise a number of by-products formed. However, *n*-butyllithium gave good yields consistently. The epoxide ring of **3** was opened by the attack of benzylate anion at the least hindered site to produce the desired 1,3-dibenzyloxy-2-benzyloxymethyl-2-propanol (**4**).

In preparing the glyceroside series **Y** we had activated the intermediate alcohol by conversion to the chloromethyl ether. This conversion requires formaldehyde under strongly acidic conditions (HCl). When applied to **4**, a product was obtained which was quite unstable because of the adjacent tertiary carbon system. To avoid the acidic conditions we attempted the synthesis of the thiomethyl ether system **5**. The alcohol **4** was smoothly converted to the stable product **5** using acetic anhydride in DMSO (16). The thiomethyl ether system is readily activated by iodine, allowing nucleophilic attack at the methylene position. As a result, compound **5** was coupled to purines and pyrimidines using the silylated base procedure (3, 17–19) to produce the desired compounds of general structure **Z** as outlined in Scheme 2.

As usual, the guanine derivative (**12**) was produced in the lowest yield. However, the process was unexpectedly easy to carry out. The N-7 isomer is produced in significant quantity along with the N-9 isomer. Fortunately, in the method used (beginning with *N*-acetylguanine), the N-7 isomer crystallizes from solution after removal of the *N*-acetyl group from the direct condensation product. This greatly facilitates an otherwise tedious separation process. This route to the guanine derivative was prompted by a similar and earlier success in the synthesis of the guanine derivative of **Y** (BIOLF-62).[3]

The route chosen to the adenine derivative **9** involved 6-chloropurine in the condensation step. Using the conditions described (48 h condensation time), very little of the N-7 isomer is present at the end of the reaction. The chlorine at position 6 is readily displaced by ammonia to give the adenine derivative **9**.

All of the compounds were identified by their spectral characteristics. In this regard the ^{13}C chemical shift data (Table 1) and the uv data (Table 2) are most useful. These identifications are confirmed by comparison of these results to those from the series **Y** compounds (3–6).

The compounds described in this report have been subjected to testing against herpesviruses. Only the guanine derivative **12** had an ED-50 of less than 100 μg/mL with HSV-1. The ED-50

value of **12** at 54 μg/mL is substantially below that of BIOLF-62 (**Y**, B = guanine) where the ED-50 vs. HSV-1 is 0.2 μg/mL.

Experimental

General methods

Products from preparative scale reactions were isolated by column chromatography using Merck silica gel 60 (230–400 mesh) packed in glass columns (15 g of silica per gram of crude material). Thin-layer chromatographic data (R_f values) are recorded from Merck Kieselgel 60F254 analytical sheets. Solvent A consists of isopropyl alcohol – concentrated ammonium hydroxide – water (7:1:2). Purine bases were purchased from Sigma Chemical Co. Ultraviolet spectra were recorded on a Cary 17 spectrometer. Nuclear magnetic resonance spectra were recorded using a Bruker WH-90, a Varian XL-200, and a Varian T60A spectrometer.

1,3-Dibenzyloxyacetone (2)

N-chlorosuccinimide (43 g) was suspended in 500 mL of toluene (Spectrograde) and the mixture was cooled in an ice bath. Dimethyl sulfide (35 mL) was added and a white precipitate formed immediately. The mixture was then cooled to −25°C in a dry ice – carbon tetrachloride bath. 1,3-Dibenzyloxy-2-propanol (60 g) in toluene (50 mL) was added to the mixture via syringe through a serum cap. The mixture was kept under nitrogen for 2 h, whereupon triethylamine (45 mL) was added and the cooling bath was removed. After a further 25 min the solution was collected by filtration. The residue was washed with ether (500 mL). The filtrate and washings were combined, neutralized with 5% aqueous HCl, washed with saturated sodium chloride

SCHEME 2

TABLE 2. Ultraviolet spectral data of acyclonucleosides

Compound	Base ring	λ_{max}, nm (ε) pH 1	pH 7	pH 14
6	Cytosine	276(10 000)	267(6 600)	267(7 200)
7	Thymine	265(11 500)	265(11 300)	264(9 200)
8	6-Chloropurine	263(7 400)	264(8 400)	264(6 900)
9	Adenine	257(12 400)	258(12 600)	258(12 500)
12	Guanine	254(11 800)	250(12 300)	254(11 300)
		274(8 200)	270(8 900)	266(10 900)
13	Guanine	250(9 500)	240(6 800)	282(7 700)
		268(7 500)	284(7 700)	

in water and with water, and finally dried over magnesium sulfate. The solvents were removed at reduced pressure (liquid nitrogen trap for dimethyl sulfide) and the resulting oil was distilled in a Kugelrohr apparatus. The product (50 g, 83%) was obtained in the fraction boiling at 140–155°C (0.05 Torr) (1 Torr = 133.32 Pa). Normal high vacuum distillation was not satisfactory as the product decomposes at high temperature. The ^{1}Hmr spectrum ($CDCl_3$ + TMS) showed signals at δ (ppm) of 4.16 (s, 4H, —C(=O)—CH_2—O—), 4.50 (s, 4H, —$CH_2\phi$), and 7.23 (s, 10H, ϕ). This material was used directly in the subsequent experiment.

2,2-Dibenzyloxymethylethylene oxide (3)

Trimethylsulfoxonium iodide (25.3 g, 0.115 mol) was dissolved in dry DMSO (350 mL). *n*-Butyllithium (66 mL, 1.65 *M* in hexane) was added via syringe to the mixture kept under nitrogen. The mixture was stirred for 25 min and then cooled to room temperature, at which point compound **2** (26.7 g, 0.098 mol) in DMSO (10 mL) was added via syringe. The mixture was stirred for a further 45 min and then poured into 1 L of cold water. The product was extracted into ether (3 × 300 mL). The organic layer was washed with saturated NaCl solution and dried over magnesium sulfate. Solvents were removed at reduced pressure and the residue was distilled in a Kugelrohr apparatus. The product (bp 120–135°C/0.05 Torr) was obtained in 82% yield (23 g). The ^{1}Hmr spectrum ($CDCl_3$ + TMS) showed signals at δ (ppm) of 2.66 (s, 2H, CH_2), 3.80 (4H, —CH_2—), 4.50 (s, 4H, —$CH_2\phi$), and 7.20 (s, 10H, ϕ).

1,3-Dibenzyloxy-2-benzyloxymethyl-2-propanol (4)

To benzyl alcohol (150 mL) in a three-neck flask (500 mL) was added sodium hydride (2.4 g, 0.1 mol obtained by washing 4 g of 60% sodium hydride dispersion in oil with hexane) in portions under a nitrogen atmosphere. The resulting mixture was stirred for 1 h. Compound **3** (22.5 g, 0.08 mol) in benzyl alcohol (20 mL) was added via syringe. The reaction mixture was heated at 90–95°C for 18 h. After cooling to room temperature, the mixture was poured into 500 mL of cold water and the solution was neutralized with 5% aqueous HCl. The product was extracted into ether (2 × 300 mL) and the combined extracts were washed with water and saturated NaCl solution. After drying over magnesium sulfate the solvent was removed to leave an oil which was distilled in a Kugelrohr apparatus. The fraction boiling at 190–210°C (0.1 Torr) contained the desired product (26.7 g, 86%). The ^{1}Hmr spectrum ($CDCl_3$ + TMS) showed signals of δ (ppm) of 2.80 (s, 1H, —OH), 3.53 (s, 6H, —CH_2O—), 4.46 (s, 6H, —$CH_2\phi$), and 7.20 (s, 15H, ϕ). This material was used directly in the subsequent experiment.

The methylthiomethyl ether 5

Compound **4** (28 g) was dissolved in 100 mL of dry DMSO (100 mL) followed by the addition of acetic anhydride (100 mL). The solution was stirred at room temperature for 48 h. The solvents were removed at reduced pressure and the residue was dissolved in 300 mL of ether. After washing with water and saturated NaCl solution, the ether solution was dried over magnesium sulfate and again concentrated to an oil at reduced pressure. The product (27.3 g, 84%) was collected in the fraction boiling at 190–210°C (0.1 Torr) on distillation in a Kugelrohr apparatus. The ^{1}Hmr spectrum ($CDCl_3$ + TMS) showed signals at δ (ppm) of 2.20 (s, 3H, —SCH_3), 3.70 (s, 6H, —CH_2O), 4.53 (s, 3H, —$CH_2\phi$), 4.83 (s, 2H, —CH_2S—), and 7.30 (s, 15H, ϕ). The product **5** was stable on standing and was used directly in the condensation reactions described below.

Standard procedure for the condensation of 5 with purines and pyrimidines. Reaction condition 1

The purine or pyrimidine base (10 mmol) was heated at reflux in HMDS (50 mL) to which ammonium sulfate (200 mg) had been added. Reflux was continued until the solution became clear (30 min for 6-chloropurine; 3 h for cytosine and thymine; 18 h for *N*-acetylguanine). At this point the excess HMDS was removed by distillation at reduced pressure. Atmospheric pressure was restored using nitrogen and the solid residue was dissolved in 75 mL of freshly distilled THF. Compound **5** (4.52 g, 10 mmol) dissolved in dry THF (15 mL) is added, followed by 5 g of oven activated molecular sieves (type 4A). Iodine (2.54 g) was added and the solution was stirred at room temperature for 48 h. (A nitrogen atmosphere was maintained at all times. For the *N*-acetylguanine reaction, the solution was stirred at room temperature for 24 h, followed by heating at a gentle reflux for 6 h.) Sodium sulfite solution (150 mL, 5% aqueous) was added and the resulting solution was extracted with methylene chloride (3 × 200 mL). The combined extracts were washed with saturated NaCl solution and water and then dried over magnesium sulfate. The solvent was removed at reduced pressure and the residue was flash-chromatographed on silica gel. The specific solvents for each base and the properties of the product are described below.

Standard procedure for the removal of the benzyl groups. Reaction condition 2

The product (2 g) from reaction condition 1 (the tribenzyl product) was dissolved in methylene chloride (50 mL) and the solution was coolled to −78°C. A 1 *N* solution of BCl_3 in methylene chloride (23 mL) was added via syringe and under a nitrogen atmosphere. The mixture was stirred at −78°C for 3 h. A solution of methanol and methylene chloride (1:1, 50 mL) was added and the cooling bath was removed. The clear solution was neutralized with triethylamine or sodium bicarbonate and stirred for an additional 35 min. The solvent was removed at reduced pressure, water (20 mL) was added, and again the solvent was removed at reduced pressure. This process was repeated three times, followed by the evaporation of absolute ethanol (30 mL). At this point variations in the work-up occurred. The remaining procedures are described for the individual compounds listed below.

1-[[1,3-Dihydroxy-2-(hydroxymethyl)-2-propoxy]methyl]cytosine 6

Reaction condition 1 (from cytosine)

The product was isolated by flash chromatography using chloroform – ethyl acetate – ethanol (4:5:1) as eluant. The yield of the

tribenzylated product was 3.5 g (58%). The product had an R_f of 0.31 in chloroform–methanol (9:1). The ^{1}Hmr spectrum ($CDCl_3$ + TMS) showed signals at δ (ppm) of 3.66 (s, 6H, —CH_2O—), 4.50 (2, 6H, —$CH_2\phi$), 5.40 (s, 2H, —NCH_2O—), 5.73 (d, 1H, J = 6 Hz, H-5), 7.30 (s, total 16H, 15 from φ and H-6 buried under aromatic H's).

Reaction condition 2

The above product was treated as described in the general procedure. The residue so obtained was extracted with chloroform (30 mL) under stirring and the solution was filtered through Celite. The Celite was washed twice with chloroform (2 × 20 mL) which removed the triethylamine hydrochloride. The Celite was then washed with 150 mL of hot methanol. The methanol solution was concentrated at reduced pressure and the residue was crystallized from methanol–ether to give the desired product **6** (72%, mp 198–200°C, R_f in solvent A of 0.53). The ^{1}Hmr spectrum (DMSO-d_6 + TMS) showed signals at δ (ppm) of 3.50 (s, 6H, —CH_2—OH), 5.23 (s, 2H, —NCH_2O—), 5.80 (d, 1H, H-5, $J_{5,6}$ = 6 Hz), 7.73 (d, 1H, H-6, $J_{5,6}$ = 6 Hz), and 7.73 (broad, 2H, —NH_2). The ^{13}C chemical shifts are recorded in Table 1. The uv characteristics are collected in Table 2. *Anal.* calcd. for $C_9H_{15}N_3O_5 \cdot 1/2H_2O$: C 42.52, H 6.29, N 16.53; found: C 42.62, H 6.15, N 16.62.

1-[[1,3-Dihydroxy-2-(hydroxymethyl)-2-propoxy]methyl]thymine 7

Reaction condition 1 (from thymine)

The tribenzyl product was recovered as an oil in 74% yield from flash chromatography using ethyl acetate – hexane (1:1) as eluant. The ^{1}Hmr spectrum ($CDCl_3$ + TMS) showed signals at δ (ppm) of 1.70 (s, 3H, —CH_3), 3.63 (s, 6H, —CH_2O—), 4.46 (s, 6H, —$CH_2\phi$), 5.30 (s, 2H, —NCH_2O—), 7.10 (m, 1H, H-6), and 7.20 (s, 15H, φ). The compound had λ_{max} of 263 nm in methanol. This intermediate was subjected directly to the general reaction condition 2.

Reaction condition 2

The residue was stirred with 30 mL of hot methanol and filtered. Silica gel (5 g) was added and the resulting slurry was concentrated in a rotary evaporator and the silica was dried under high vacuum overnight. This silica was placed on top of a prepared silica gel column which was then eluted with methylene chloride – methanol (4:1). The desired product **7** was obtained in 70% yield (mp 165–167°C). The product had an R_f of 0.48 in methylene chloride – methanol (4:1). The ^{1}Hmr spectrum (DMSO-d_6 + TMS) showed signals at δ (ppm) of 1.80 (s, 3H, —CH_3), 3.55 (s, 6H, —CH_2O—), 4.50 (broad, 3H, —OH), 5.23 (s, 2H, —NCH_2O—), and 7.53 (s, 1H, H-6). The ^{13}C spectral properties and the uv data are collected in Tables 1 and 2, respectively. *Anal.* calcd. for $C_{10}H_{16}N_2O_5$: C 46.16, H 6.19, N 10.76; found: C 46.00, H 6.08, N 10.71.

9[[1,3-Dihydroxy-2-(hydroxymethyl)-2-propoxy]methyl]-6-chloropurine 8

Reaction condition 1 (from 6-chloropurine)

The residue was flash chromatographed on silica gel using ethyl acetate – hexane (1:1). The tribenzyl product was obtained as an oil in 55% yield with R_f of 0.38 in the eluting solvent. The uv spectrum (methanol) showed λ_{max} at 263 nm. The ^{1}Hmr spectrum ($CDCl_3$ + TMS) showed signals at δ (ppm) of 3.63 (s, 6H, —CH_2O—), 4.43 (s, 6H, —$OCH_2\phi$), 5.90 (s, 2H, —NCH_2O—), 7.20 (s, 15H), 8.20 (s, 1H, H-2), and 8.66 (s, 1H, H-8).

A trace amount of another product, assumed to be the N-7 isomer, was also obtained. This material had R_f 0.22 in the eluting solvent and a λ_{max} of 267 nm in methanol. The ^{1}Hmr spectrum of this product ($CDCl_3$ + TMS) showed signals at δ (ppm) of 3.70 (s, 6H, —CH_2O—), 4.40 (s, 6H, —$OCH_2\phi$), 6.0 (s, 2H, —NCH_2O—), 7.30 (s, 15H, φ), 8.30 (s, 1H, H-2), and 8.80 (s, 1H, H-8).

Reaction condition 2

The residue (obtained by starting with the desired N-9 product from reaction condition 1) was extracted with warm methanol. The solution was filtered and treated with 5 g of silica gel as described for compound **7**. The column was eluted with methylene chloride – methanol (4:1). The desired product **8** was crystallized from methanol–ether in 65% yield (mp 158–160°C) and had R_f of 0.58 in the eluting solvent. The ^{1}Hmr spectrum (DMSO-d_6 + TMS) showed signals at δ (ppm) of 3.66 (s, 6H, —CH_2OH), 4.66 (t, 3H, —OH), 6.00 (s, 2H, —NCH_2O—), 8.83 (s, 1H, H-2), and 8.86 (s, 1H, H-8). The ^{13}C spectral data and the uv data are collected in Tables 1 and 2 respectively. *Anal.* calcd. for $C_{10}H_{13}ClN_4O_4 \cdot 1/2H_2O$: C 40.34, H 4.74, N 18.82; found: C 40.72, H 4.38, N 18.60.

9-[[1,3-Dihydroxy-2-(hydroxymethyl)-2-propoxy]methyl]adenine 9

The N-9 product of reaction condition 1 from the 6-chloropurine condensation was heated in a steel bomb at 125°C for 17 h in saturated (at 0°C) methanolic ammonia (15 mL/g of starting material). The bomb was cooled to room temperature, the solvents were evaporated, and the product obtained by chromatography on silica gel using methylene chloride – methanol (9:1) as eluant. The product was obtained in 88% yield and had λ_{max} (methanol) at 257 nm and an R_f of 0.68 in the eluting solvent. The ^{1}Hmr spectrum ($CDCl_3$ + TMS) showed signals at δ (ppm) of 3.70 (s, 6H, —CH_2O—), 4.40 (s, 6H, —$OCH_2\phi$), 5.80 (s, 2H, —NCH_2O—), 6.20 (b, 2H, —NH_2), 7.30 (s, 15H, φ), 8.0 (s, 1H, H-2), and 8.30 (s, 1H, H-8).

This material was subjected to reaction condition 2 and the product was obtained by silica gel chromatography using methylene chloride – methanol (4:1). The product **9** (76%) had mp 206–209°C and an R_f of 0.17 in the eluting solvent. The ^{1}Hmr spectrum (DMSO-d_6 + TMS) showed signals at δ (ppm) of (bs, 6H, —CH_2OH), 5.80 (s, 2H, —NCH_2O—), 7.40 (b, 2H, —NH_2), 8.20 (s, 1H, H-2), and 8.30 (s, 1H, H-8). The ^{13}C spectral data and the uv data are collected in Tables 1 and 2 respectively. *Anal.* calcd. for $C_{10}H_{15}N_5O_4 \cdot 1/2H_2O$: C 43.16, H 5.79, N 25.17; found: C 43.41, H 5.81, N 25.26.

*9-[[1,3-Dihydroxy-2-(hydroxymethyl)-2-propoxy]methyl]guanine (**11**) and 7-[[1,3-dihydroxy-2-(hydroxymethyl)-2-propoxy]-methyl]guanine (**12**)*

Reaction condition 1

The starting material in this condensation was *N*-acetylguanine. The residue from reaction condition 1 was flash-chromatographed on silica gel using chloroform – ethyl acetate – ethanol (4:5:1). An oil was obtained (43%) which according to ^{1}Hmr was a mixture of the N-9 and N-7 isomers (3:2).

The mixture was dissolved in dry methanol (50 mL) and this solution was added to methanol (100 mL) containing sodium (500 mg). This solution was heated at reflux for 3 h. After cooling to room temperature the solution was carefully neutralized using glacial acetic acid. White crystals formed during the neutralization and these were collected by filtration and found to be the pure N-7 isomer (**11**) in 9% overall yield (mp 215–218°C). The filtrate was concentrated and chromatographed on silica gel using methylene chloride – methanol (9:1). The N-9 isomer (**10**) was obtained in 15% overall yield (mp 185°C (dec.)).

The ^{1}Hmr spectrum of N-9 isomer **10** (DMSO-d_6 + TMS) showed signals at δ (ppm) of 3.6 (s, 6H, —CH_2O—), 4.53 (s, 6H, —$CH_2\phi$), 5.60 (s, 2H, —NCH_2O—), 6.46 (b, 2H, —NH_2), 7.3 (s, 15H, φ), 7.66 (s, 1H, H-8), and 9.14 (b, 1H, H-1). The ^{1}Hmr spectrum of the N-9 isomer (**11**) under the same conditions showed signals at δ (ppm) of 3.63 (s, 6H, —CH_2O—), 4.53 (s, 6H, —$CH_2\phi$), 5.86 (s, 2H, —NCH_2O—), 6.23 (b, 2H, —NH_2), 7.33 (s, 15H, φ), and 7.96 (s, 1H, H-8).

*Reaction condition 2 on **10***

The N-9 isomer from above (**10**) was subjected to the standard conditions. The residue obtained crystallized from 95% ethanol to give pure **12** in 77% yield (mp >300°C). The R_f in solvent A on tlc was 0.51. The ^{1}Hmr spectrum of **12** (DMSO-d_6 + TMS) showed signals at δ (ppm) of 3.60 (s, 6H, —CH_2OH), 5.63 (s, 2H, —NCH_2O—), 6.53 (b, 2H, —NH_2), 7.90 (s, 1H, H-8), and 10.80 (b, 1H, H-1). The ^{13}C and uv data are collected in Tables 1 and 2 respectively. *Anal.* calcd. for $C_{10}H_{15}N_5O_5$: C 42.10, H 5.26, N 24.56; found: C 41.89, H 5.19, N 24.83.

*Reaction condition 2 on **11***

The N-7 isomer from above (**11**) was subjected to the standard

conditions. The dry white residue from the reaction was treated with chloroform and filtered through Celite. The Celite was washed with chloroform (2 × 20 mL). The Celite was then poured into 200 mL of water which was brought to the boiling point and filtered. The filtrate was lyophilized to yield a white powder (78% yield, R_f on tlc in solvent A of 0.53). The ^{1}Hmr spectrum of **13** in (DMSO-d_6 + TMS) showed signals at δ (ppm) of 3.50 (s, 6H, —CH_2OH), 5.70 (s, 2H, —NCH_2O—), 6.40 (b, 2H, —NH_2), and 8.10 (s, 1H, H-8). The ^{13}C and uv data are collected in Tables 1 and 2 respectively. *Anal.* calcd. for $C_{10}H_{15}N_5O_5$: C 42.10, H 5.26, N 24.56; found: C 42.39, H 5.40, N 24.67.

In an extension of Wallach rearrangement studies into the phenylazoxypyridine series, an investigation of 4-, 3-, and 2-phenylazoxypyridines, the *N*-oxides, and methiodides is reported. Oxidation of 4- and 3-phenylazopyridine with peracetic acid gives rise to the α and β phenylazoxypyridine-*N*-oxides, contrary to previous literature reports on the obtention solely of the α isomers. 2-Phenylazopyridine, however, yields only the 2-(phenyl-α-azoxy)pyridine-*N*-oxide. These results are rationalized on the basis of field, resonance, and steric effects. An unprecedented reactivity difference has been observed in the reactions of the α,β isomers of phenylazoxypyridines under conditions of the Wallach rearrangement. This reactivity difference permits the isolation of the α-azoxy isomers from the α,β mixtures. Unequivocal confirmation of the structures has been obtained from X-ray crystal structure determinations of two representative compounds in this series, viz. 4-(phenyl-β-azoxy)-pyridine-*N*-oxide (**11**) and 4-(phenyl-α-azoxy)pyridinium methiodide (**12**), which itself was formed by deoxygenation of 4-(phenyl-α-azoxy)pyridine-*N*-oxide, followed by methylation with methyl iodide. The crystal structure of **11** was solved by direct methods and refined by block-diagonal least squares to $R = 0.041$ for 2479 observed reflections. The asymmetric unit contains two independent molecules, both of which are planar. The structure of **12** was determined by the heavy-atom method and refined by full-matrix least squares to $R = 0.043$ for 1718 observed reflections. The molecules are not planar, the pyridine ring being rotated by 36.5° from the phenylazoxy plane. Evidence is presented for the existence of intramolecular C—H···O and C—H···N bonds in crystal structures of *trans*-azoxyarenes. The carbon atoms involved in these hydrogen bonds are *ortho* to the azoxy group and can act as proton donors as a result of the inductive effect of the adjacent nitrogen.

Dans le but de poursuivre les études sur la transposition de Wallach dans la série des phénylazoxypyridines, on rapporte une étude réalisée sur les phénylazoxy-4, phénylazoxy-3 et phénylazoxy-2 pyridines, et leurs *N*-oxydes et les iodométhylates. L'oxydation des phénylazo-4 et phénylazo-3 pyridines par l'acide peracétique conduit aux α ainsi qu'aux β *N*-oxydes de phénylazoxypyridines; ce résultat diffère de ce qui a été rapporté antérieurement, à savoir qu'on avait alors obtenu uniquement l'isomère α. Cependant, la phénylazo-2 pyridine donne uniquement le *N*-oxyde de la (phényl-α azoxy)-2 pyridine. On rationalise ces résultats en se basant sur les effets du champ, de résonance, et les effets stériques. On a observé une différence de réactivité inhabituelle au cours de la réaction des isomères α et β des phénylazoxypyridines dans les conditions de la transposition de Wallach. Cette différence de réactivité permet d'isoler l'isomère α azoxy d'un mélange contenant les isomères α et β. On a confirmé les structures d'une manière univoque en se basant sur la détermination des structures cristallines, par diffraction de rayons-X, de deux composés représentatifs de la série, à savoir: le *N*-oxyde de (phényl-β azoxy)-4 pyridine (**11**) et l'iodométhylate de (phényl-α azoxy)-4 pyridinium (**12**); ce dernier composé se forme d'ailleurs lui-même par une désoxygénation du *N*-oxyde de la (phényl-α azoxy)-4 pyridine suivie d'une méthylation par l'iodure de méthyle. On a résolu la structure cristalline du composé **11** par des méthodes directes et on l'a affinée par la méthode des moindres carrés (approximation diagonale) jusqu'à une valeur de $R = 0{,}041$ pour 2479 réflexions observées. L'unité asymétrique contient deux molécules indépendantes qui sont planes. On a déterminé la structure du composé **12** par la méthode de l'atome lourd et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à une valeur de $R = 0{,}043$ pour 1718 réflexions observées. Les molécules ne sont pas planes; le cycle de la pyridine est décalé de 36,5° par rapport au plan du groupe phénylazoxy. On présente des données suggérant l'existence de liaisons intramoléculaires C—H···O et C—H···N dans les structures cristallines des azoxyarènes-*trans*. Les atomes de carbones impliqués dans ces liaisons hydrogènes sont en *ortho* du groupe azoxy et peuvent agir comme donneurs de protons en raison de l'effet inductif de l'atome d'azote adjacent.

Introduction

As an extension of our studies (1–4) of the acid-catalyzed Wallach rearrangement of azoxybenzene to *p*-hydroxyazobenzene (eq. [1]), and related processes, we have undertaken an investigation of the phenylazoxypyridine series. These systems would constitute the first incursion of Wallach rear-

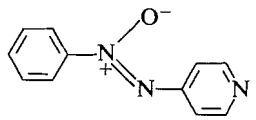
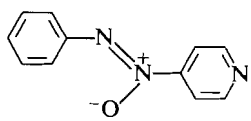
rangement studies into the heterocyclic series and, as well, would provide a critical test of previously proposed mechanisms (5–16) for this process, for example concerning formation of the key intermediates **3** and **4**.

Another point of interest in the phenylazoxypyridine series relates to the difference in reactivities that one might expect for α and β isomers, for example 4-(phenyl-α-azoxy)pyridine **5** and 4-(phenyl-β-azoxy)pyridine **6**.



5



6

At the outset of our work there was no study extant which reported the formation of a β phenylazoxypyridine. The oxidation of 4-phenylazopyridine with peracetic acid was reported (17) to give rise only to the 4-(phenyl-α-azoxy)pyridine-*N*-oxide, none of the isomeric β product being obtained. Similarly, only 3-(phenyl-α-azoxy)pyridine-*N*-oxide and 2-(phenyl-α-azoxy)pyridine-*N*-oxide were reported as formed in related reactions (18–20). These results are somewhat surprising since the oxidation of unsymmetrical azobenzene derivatives generally gives rise to a mixture of the isomeric α- and β-azoxybenzenes in a ratio of ca. 1:1 (21–24), except when a bulky substituent is present on one ring in which case one azoxy isomer is obtained predominantly (25).

In the present work we have found, however, that the peracetic acid oxidation of 4- and 3-phenylazopyridine gives rise to both α- and β-azoxy *N*-oxides, though only the α isomer is formed in the case of 2-phenylazopyridine. The characterization of these compounds and their structure determination forms the substance of the present paper.

Results and discussion

Synthetic strategy

The following synthetic strategy was devised in order to facilitate the efficient synthesis of the desired families of compounds, that is the α/β 4-, 3-, and 2-phenylazoxypyridines, the *N*-oxides, and methiodides.

1. The mixture of α,β phenylazoxypyridine-*N*-oxides obtained in the peracetic oxidation of the phenylazopyridines was separated into its constituents by hplc. Prior to use of the hplc method, repeated crystallization from ethanol or use of column chromatography proved to be unsuccessful as methods of separation.

2. The resulting α and β phenylazoxypyridine-*N*-oxides were separately deoxygenated (phosphorus trichloride) to yield the parent phenylazoxypyridines.

3. Methylation of the latter (methyl iodide) gave the respective methiodides in straightforward manner.

The physical properties of the families of compounds thus obtained, together with the elemental analyses, are given in Tables 1 and 2.

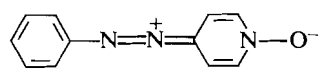
The uv absorption data of the various azoxy compounds synthesized in this work are included in Table 1. The absorption maxima ($\pi-\pi^*$) show only slight bathochromic or hypsochromic shifts with respect to azoxybenzene (λ_{max} 323 nm in EtOH). This is not surprising since these compounds can be classified as even, heteroconjugated systems (26) and introduction of a heteroatom into the axoxybenzene π system does not alter significantly the lowest $\pi-\pi^*$ transition. Further discussion of the uv characteristics has been given elsewhere (27).

The nmr characteristics of the families of compounds together with a full interpretation will be described in a future paper. The structural assignments based on the nmr results are in complete agreement with the assignments given in this paper as a result of the X-ray structure determinations (*vide infra*) and other considerations.

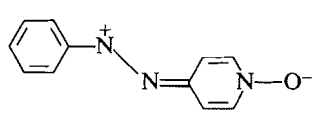
Orientation in oxidation

In the oxidation of phenylazopyridines by peracid, the site of the attack will be determined by the relative electron densities at the various nitrogen centres since the peroxide function acts as an electrophilic reagent (28). It is hence expected that when more than one site of attack is possible, the position of attack in peracid oxidation will follow the same order as found in protonation (29, 30). This expectation should probably hold even though the former process is governed by kinetic considerations and the latter by thermodynamic. One would then predict that mono-oxidation will occur on the pyridine nitrogen as the basicity of this center (pK_a 4.4 (27)) is much greater than that of the azo function (pK_a −5.1 (27)). In fact, oxidation of 4-phenylazopyridine by perbenzoic acid (17) or *m*-chloroperbenzoic acid (present work) under mild conditions occurs almost exclusively on the pyridine function to yield 4-phenylazopyridine-*N*-oxide.

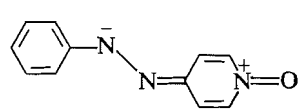
Further oxidation of 4-phenylazopyridine-*N*-oxide should occur on the azo nitrogen with the greatest electron density, and this is expected to be the nitrogen adjacent to the benzene ring. The azo nitrogen adjacent to the heterocyclic ring will be depleted of electron density as a result of a field effect between this center and the N^+-O^- dipole. There could also be the possibility of a partial positive charge on this nitrogen as indicated by structure **7***a*. The nitrogen adjacent to the benzene ring could take on either partial positive charge as indicated in **7***b*, or partial negative charge as in **7***c*. Crystal structure results presented subsequently on an azoxy analogue (**11**) suggest that contribution by **7***c* should be the more likely.



7*a*



7*b*



7*c*

Whereas the above considerations refer to initial state effects, one can invoke also a transition state effect which would lead to the result of preferential attack by electrophilic oxygen on the nitrogen removed from the heterocyclic ring. Thus, to the extent that the transition state structure resembles the product in its electronic configuration, there will be partial delocalization of charge as shown by **8***a* ↔ **8***b*. This type of delocalization is not possible if the nitrogen adjacent to the

heterocyclic ring undergoes attack by electrophilic oxygen.

The direct field effect will increase in importance as one proceeds to 3-phenyl- and to 2-phenylazopyridine-*N*-oxides. The resonance effect, on the other hand, will operate in the latter case but not in the former. In addition to the field and resonance effects, a steric effect may also operate due to interaction between the approaching peracid molecule, especially with the more sterically demanding perbenzoic or *m*-chloroperbenzoic acids, and the protonated/solvated *N*-oxide function. This steric factor is clearly expected to be greatest in the case of the reaction of 2-phenylazopyridine-*N*-oxide, and this should serve to further decrease the availability towards oxygenation of the nitrogen site adjacent to the heterocyclic ring.

Our observations are in qualitative agreement with the above considerations, since both the 4- and 3-phenylazopyridines, on oxidation with peracetic acid, have been found to give rise predominantly to the α-phenylazoxypyridine-*N*-oxides. That oxidation occurs sequentially is indicated by the fact that the respective phenylazopyridine-*N*-oxides have been isolated in small yield in these reactions. On the other hand, the latter compounds are the major products when oxidation is performed with *m*-chloroperbenzoic acid. Reaction of 2-phenylazopyridine with peracetic acid gave rise only to 2-(phenyl-α-azoxy)-2-pyridine-*N*-oxide, indicating that in this case a combination of field and steric effects prevails, resulting in complete exclusion of the β isomer (30).

Reactivity differences of isomers in Wallach rearrangement: a novel method of isomer separation

A preliminary study has revealed an apparently unprecedented difference in the reactivities of α and β 4-phenylazoxypyridine-*N*-oxides under Wallach rearrangement conditions. In fact, under conditions that the β isomer reacted readily (95–100% H_2SO_4), to yield 4-(*p'*-hydroxyphenylazo)pyridine-*N*-oxide, no detectable rearrangement could be observed for the α isomer (31).

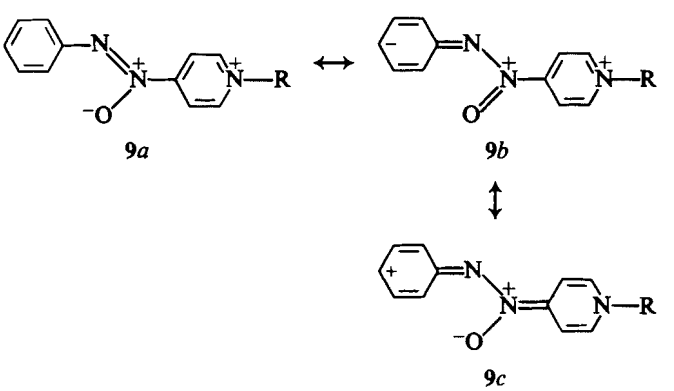
This observation could be utilized in the present work to separate the pure α isomers from the α,β mixtures in the case of 4- and 3-phenylazoxypyridines and their *N*-oxides. In practice, the α,β azoxy mixture was allowed to react in the acid medium until rearrangement of the β isomer was essentially complete (≥95%) and the unreacted α-azoxy isomer was isolated following work-up (see Experimental). The rearrangement products, i.e. 4(3)-(*p'*-hydroxyphenylazo)pyridines and *N*-oxides, could readily be separated by their solubility in aqueous base through formation of the azophenolate salt, leaving the unreacted α-azoxy compound in the organic phase. In each case, the α isomer thus obtained had properties identical to that of the compound obtained by hplc separation of the α,β mixture in the peracetic acid oxidation. Since α,β azoxy isomers are generally difficult to separate by normal procedures (23–25), the present method for obtaining one isomer in pure form is noteworthy, though based on serendipitous circumstances.

Structural considerations in phenylazoxypyridine series

Structural identification of the phenylazoxypyridine isomers in the work of Colonna, Risaliti, and Pentimalli (17–20) was based on the classical method first devised by Angeli (32). The principle of this method is that the $N^+—O^-$ dipole of the azoxy function "protects" the phenyl ring adjacent to $N^+—O^-$ from electrophilic attack, e.g. in bromination or nitration (33). Moreover, the pyridine ring would itself be deactivated, relative to a phenyl ring, towards electrophilic attack (34, 35).

The reaction sequence thus used by Colonna *et al.* (17) to assign the structure is shown in Scheme 1, which uses the oxidation of 3-phenylazopyridine for illustration. The finding that the product from the peracid oxidation did not undergo bromination was used as the main evidence for assignment of structure as the α isomer.

However, caution is required when applying the classical method to the present systems. Considering the possible resonance structures **9***a*, **9***b*, and **9***c*, to the extent that **9***b* would be contributing, the benzene ring would be activated towards electrophilic attack; however, contribution by **9***c* would result in deactivation. It seems reasonable that **9***c* would indeed be an important contributor, in which case compound **9** could be unreactive towards electrophilic substitution, even though it is the β isomer. This would cause the classical method to be inconclusive as a way of differentiating between α and β isomers in the phenylazoxypyridine series.



9*a* **9***b* **9***c*

One can contrast this situation and the one that obtains with 4-β-nitroazoxybenzene, which does undergo electrophilic sub-

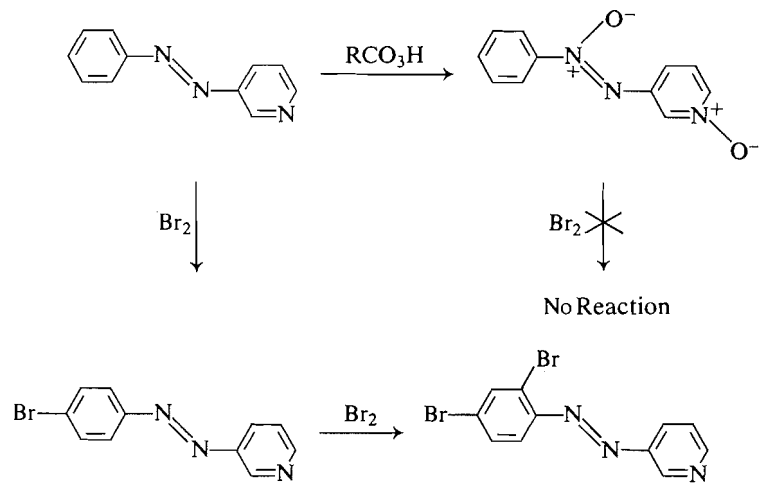
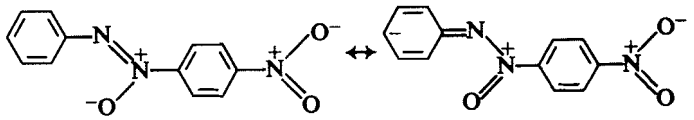
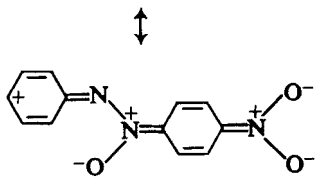


SCHEME 1

stitution. Of the analogous resonance structures **10***a*, **10***b*, and **10***c*, one would expect that contribution by **10***b* would outweigh that by **10***c*. In **10***c* the barrier to rotation about the C_4—NO_2 bond should be low, contrasting with **9***c* where the positive nitrogen pole forms part of the π-system of the hetero ring. Bromination of **10** is hence expected to occur at the benzene ring. Thus analogy between the pyridine and nitro functionalities is of limited utility in predicting reactivities of the present series of compounds.

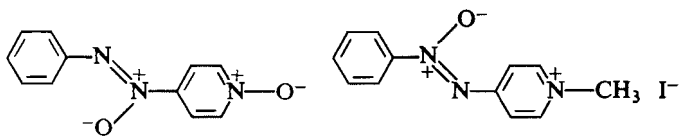


10*a* **10***b*



10*c*

Unequivocal structure proof in the present system can be obtained from X-ray structure determinations. This aspect of the work is described in detail in the following section, but the main conclusion can be drawn here. Structure analysis was effected for two representative compounds which could be obtained in satisfactory crystalline form, viz. 4-(phenyl-β-azoxy)pyridine-*N*-oxide (**11**) and 4-(phenyl-α-azoxy)pyridinium methiodide (**12**), the latter being obtained by deoxygenation of the corresponding *N*-oxide, followed by methylation with methyl iodide. Since the α and β phenylazoxypyridine-*N*-oxides are the precursors of the α and β phenylazoxypyridines, as well as of the corresponding pyridinium methiodides, it follows that the X-ray structure analyses provide sufficient basis for correlating the structures of the various compounds investigated in this work.



11 **12**

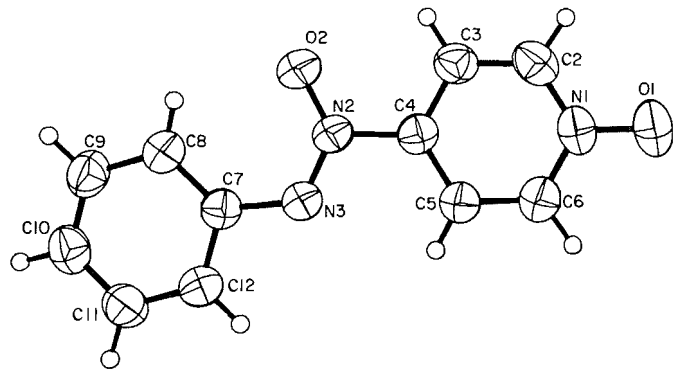


FIG. 1. The numbering system in **11**.

Results of X-ray analyses

The final atomic parameters in **11** and in **12** are listed in Tables 3 and 4, respectively. Figures 1 and 2 show the atomic numbering system in the two molecules.

The bond lengths and bond angles in **11** (mols A and B) are listed in Table 5. Since the distances appeared somewhat shorter than expected, we applied to them corrections for thermal vibration (36). The average correction was 0.007 Å (2σ) and the largest one 0.011 Å. The agreement between equivalent bond lengths in the two independent molecules A and B is excellent, both for the uncorrected and the corrected values: the average difference is 0.004 Å and the largest one 0.008 Å. Consequently, we feel justified in averaging these values, and in the subsequent discussion of this structure we will be referring to averaged corrected bond lengths. These bond lengths are also given in Table 5.

Both molecules are almost planar: the dihedral angles between six-membered rings are 5.6 and 3.6° for molecules A and B, respectively. All molecules pack in the crystal with their long axes almost parallel to *c* (Fig. 3). We note some stacking of the aromatic rings as well as some dipole–dipole interactions between adjacent N → O groups. The order of packing is −A−A−B−B− and the stacking distances between the A−A and B−B pairs are 3.14 and 3.30 Å, respectively.

The bond lengths and bond angles in **12** are listed in Table 6. Their estimated standard deviations are 2–3 times larger than in **11** owing to the presence of the heavy iodide ion. The molecules are not planar, the pyridine ring being rotated by

about 37° from the phenylazoxy group. The packing of the molecules in the crystal is shown in Fig. 4. Phenyl rings and azoxy groups are stacked parallel to each other at a distance of 3.48 Å, giving rise to considerable overlap.

Discussion of crystal structures

Bond lengths

No crystal structure of a phenylazoxypyridine has yet been reported in the literature, but derivatives of azobenzene and azoxybenzene have been studied. Among the latter are several *trans* (37–40) and one *cis* isomer (41) (structures **13**–**17**). Some of the authors have compiled geometrical details of the azoxy group in previously determined structures and attempted to interpret them (40, 41). Such attempts have been generally unsuccessful owing to the low precision or low accuracy of some of the structure determinations. In particular, the two earliest studies, those of *p*-azoxyanisole (37) and ethyl *p*-

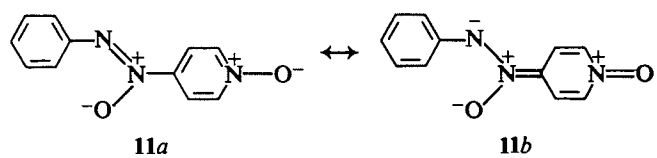
azoxybenzoate (38), produced results which were incompatible with subsequent X-ray analyses: the C—N(O) bonds were unusually long (1.496, 1.570 Å) while the N(O)=N bonds were unusually short (1.218, 1.155 Å). However, a critical reading of these publications reveals several disturbing details: the *R* values (9.1 and 9.3%) were rather high, considering that the data had been collected on a diffractometer; in the *p*-azoxyanisole structure the final difference Fourier map showed two extraneous peaks, indicating the possibility of disorder; in both structures there were atoms with unusually high and (or) low temperature parameters, but no corrections were made for thermal vibration. In view of these facts, we feel justified in ignoring the distances found in these two structure analyses.



11*a* **11***b*

The bond lengths in the azoxy group (Table 7) can now be interpreted on the basis of substitution and electron delocalization. The N=N bond lengths (1.26–1.28 Å) are intermediate between those found in azobenzenes (1.23–1.25 Å) and those in diazoxy compounds (1.31–1.32 Å) in which both nitrogen atoms carry an oxygen (42). Similarly, the C—N(O) bond length in azoxy groups is 1.44–1.47 Å while the C—N bonds are in the 1.41–1.43 Å range, both in azo- (43) and in azoxybenzenes (39–41). No N—O bonds deviate significantly from the average observed value of 1.266 Å.

The bond lengths in **11** indicate a significant contribution of a quinonoid resonance form to the structure. This is borne out by a comparison of the bond lengths in the pyridine *N*-oxide moiety with the results of the highly precise, low-temperature (30 K) X-ray analysis of *p*-nitropyridine *N*-oxide (44). With the exception of the somewhat short N(1)—C(2) value of 1.357 Å, all bond lengths in the two structures agree within 0.007 Å (2σ). In both structures the C—C bonds parallel to the molecular axis are significantly shorter than the other C—C ring bonds. In *p*-nitropyridine *N*-oxide (**18**) there will be similar charge delocalization, with contribution by the resonance form **18***b*.

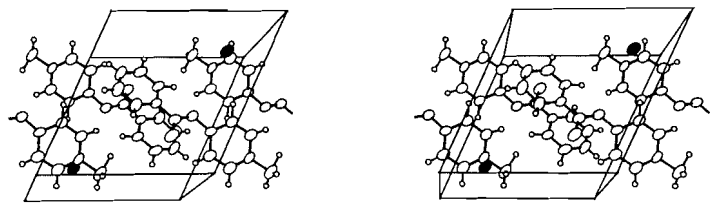

FIG. 4. Packing diagram of **12**. The directions of the axes are a ⊙, b →, c ↑. The iodide ion is shaded.

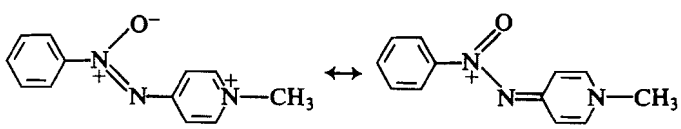
The bond lengths in the phenyl ring also differ from normal values. Near the substituted atom the bonds are longer than usual, but further away from it they are significantly shorter. This is a clear indication of the inductive effect of the substituent which causes the σ electrons to be displaced away from the substituted carbon atom (45).

A quinonoid resonance form might at first sight be expected to contribute to the structure of **12** as well. However, in view of the rotation of the pyridine ring from the phenylazoxy group (see above), that contribution cannot be very large. This can be attributed to the fact that structure **12***b* does not contain the



12*a* **12***b*

stabilizing features associated with the quinonoid moiety of **11***b* or **18***b*, namely delocalization of the negative charge onto two electronegative atoms (O, N in **11***b*; O, O in **18***b*). Although the lower precision of the results obtained with **12** precludes a rigorous analysis, we can state that the observed bond lengths agree qualitatively with expected values.

C—H···O and C—H···N bonds

In their discussion of the structure of *p*-azoxyanisole, Krigbaum *et al.* (37) noted the short distances (2.27 and 2.31 Å) between the oxygen atom of the azoxy group and the hydrogen atoms H_B and H_C, respectively (Fig. 5). Nevertheless, they found "little evidence for the existence of hydrogen bonds" between these atoms. Other authors (39, 40) have not commented on short H···O distances. There is no doubt, however, that intramolecular C—H···O and C—H···N bonds are common features in molecules in which two aromatic rings are attached to a *trans* azoxy group. In a recent review of 113 crystal structures determined by neutron diffraction, Taylor and Kennard (46) cite 59 (C—)H···O contacts ≤2.400 Å, i.e. at least 0.3 Å shorter than the sum of the van der Waals radii of hydrogen and oxygen, as well as 11 (C—)H···N contacts with H···N distances in the range of 2.522–2.721 Å. In intramolecular hydrogen bonds the C—H···O angles were in the range 90.7–155.7°. These results, and the conclusions based on them, are highly significant since hydrogen atom coordinates obtained from neutron diffraction studies are ~10 times more precise than those obtained from X-ray analyses. On the other hand, it has been shown (47) that very reliable information about the geometry of a hydrogen bond can be obtained even from an X-ray analysis if one extends an observed O—H bond length to the real distance known from neutron diffraction (0.97 Å). Using corrected values of 1.09 Å for C(ar)—H bonds (48), we calculated H···O and H···N distances as well as C—H···O and C—H···N angles in our structures, as well as in previously determined crystal structures of azoxybenzenes.

[a]See Fig. 5 for definitions. All C(ar)—H bonds normalized to 1.09 Å.
[b]Averages of molecules A and B after corrections for thermal vibration.

The results, listed in Table 7, show that the distances and angles are in very good agreement with those found by Taylor and Kennard (46). It will be noted that all protons participating in these intramolecular hydrogen bonds are bonded to carbon atoms which are *ortho* to the azoxy group. We should also point out that we found *intermolecular* C—H···O bonds involving *ortho* carbon atoms in *cis*-azobenzene dioxide (42) and in *cis*-4-(phenyl-α-azoxy)toluene (41). The electron density at these carbon atoms is decreased owing to the inductive effect of the adjacent nitrogen (see above) which enhances their ability to act as proton donors. Thus, it was found (46) that in *p*-nitropyridine *N*-oxide a carbon atom *ortho* to the nitro group participates in a fairly strong hydrogen bond (H···O 2.145 Å). Another C—H···O bond found in that structure involves a carbon atom *ortho* to the positively charged ring nitrogen. Such carbons are especially likely to form C—H···X bonds (46), and in the crystal structure of **11** we observe that in each independent molecule C(6) donates its proton to O(1) in another molecule. The H···O distances are 2.34 and 2.13 Å and the C—H···O angles are 173 and 165°, respectively.

Bond angles and torsion angles

The geometry of *trans*-azoxyarenes reveals various distortions of bond angles which are necessary in order to avoid excessively short nonbonded interatomic contacts. An indication of the crowding is the H···O and H···N distances in the intramolecular hydrogen bonds. Of the 59 (C—)H···O contacts listed by Taylor and Kennard (46), 56 are longer than the $H_C \cdots O$ distance of 2.14 Å in **11** (Table 7) and about half are longer than 2.33 Å, the $H_B \cdots O$ distance. Moreover, none of the (C—)H···N distances listed there is as short as the $H_A \cdots N$ distances in Table 7. An inspection of the bond angles in Table 7 enables us to formulate several observations about *trans*-azoxyarenes. The sums (α + γ) and (β + δ) are approximately 236° each, but the former is usually somewhat larger, reflecting the fact that the van der Waals radius of N is slightly larger than that of O. Since in all cases the aromatic ring attached to N(O) is more or less in the plane of the azoxy group, these sums have to be balanced in order to prevent either N or O from being too close to one of the *ortho* hydrogen atoms. The $H_C \cdots O$ distance

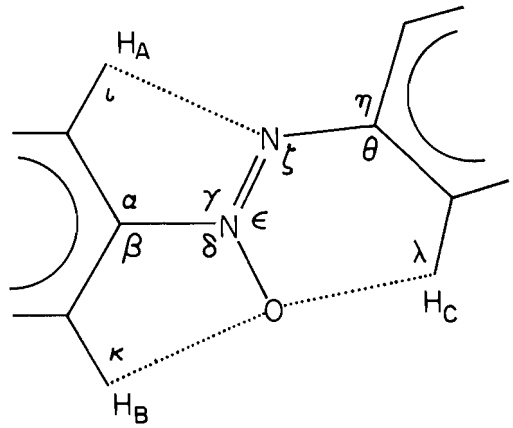

FIG. 5. Geometry of azoxyarenes.

would be prohibitively short if not for a rotation of the aromatic ring about the N—C bond (0–36.5°, Table 8) and for an increase of ϵ vs. γ and θ vs. η. Table 8 shows that in most structures the two aromatic rings are not coplanar; this is probably attributable to the fact that rotation about a bond is energetically more favourable than distortion of a bond angle. The exact planarity of **14** probably reflects a higher contribution of the quinonoid structure which results from a delocalization of electrons to the carbonyl oxygen of the ester group.

It is well known that bond angles in aromatic rings are affected by ring substitution. These distortions, caused by withdrawal or release of π and (or) σ electrons, have been compiled for various substituents (49) but not for an azoxy group. We note, however, that in the phenyl ring of **11** the deviations from 6/*mmm* symmetry agree qualitatively with those calculated for an N=NR substituent. In the structure of **12** the angular distortions are larger and fairly similar to those caused by an NO_2 substituent. We can also derive the distortion effect of an N(O)=N(C_6H_5) substituent by subtracting the known corrections due to an NO_2 group (49*b*) from the angles found in *p*-nitropyridine *N*-oxide (44). This gives us the angles in unsubstituted pyridine *N*-oxide, and the difference between

16	3.1	179.8	10.0

them and the angles in the pyridine ring in **11** yields the following corrections for N(O)=N(C_6H_5): +1.3, −1.0, +0.3, and +0.4° for the *ipso*, *ortho*, *meta*, and *para* atoms, respectively. The correlation between the first two values is exactly as calculated by Domenicano and Murray-Rust (49*a*).

One of the most interesting differences between the crystal structures of the α- and β-azoxy isomers is that whereas in the β compound **11** the pyridine ring and the benzene ring are practically coplanar, in the α compound **12** the two rings deviate appreciably from coplanarity (see Table 8). It was noted also that the bond lengths found in **11** were indicative of significant contribution by the quinonoid resonance forms **11***b*. It follows on inspection of the structure **11***b* that the negative charge on the azo nitrogen will be further delocalized over the benzene ring, implying coplanarity between the latter and the pyridine ring, as found experimentally. However, in the case of **12**, contribution via the quinonoid form **12***b* was not considered to be important. The deviation from coplanarity of the two rings in the case of **12** would then result from the short N···H and O···H contacts, which appear to be characteristic of *trans*-azoxyarenes in general (Table 7 and Fig. 5).

Experimental

Melting points were determined on a Fisher–Johns block and are uncorrected. The uv spectra were taken on a Beckman DU-8 spectrophotometer. Column chromatography was carried out using basic alumina (Sigma). The hplc separations were performed using silica gel columns (Merck) fitted to a fluid metering pump, pulse dampener (FMI), uv detector, and fractionator (Gilson).

Aminopyridines (Aldrich) were used as received. 30% H_2O_2 was procured from Mallinckrodt. Nitrosobenzene was prepared by the method of Vogel (50), kept in a dry box, and sublimed before use.

Phenylazopyridines

The 4-, 3-, and 2-phenylazopyridines were prepared by condensation of nitrosobenzene with 4-, 3-, and 2-aminopyridine, respectively, according to the procedure of Brown and Grammeman (51) and purified by column chromatography with benzene as eluent. Recrystallization from hexane yielded 4-phenylazopyridine, mp 97–98°C (lit. (19) mp 98–99°C); 3-phenylazopyridine, mp 51–52°C (lit. (19) mp 53–54°C); and 2-phenylazopyridine, mp 32–34°C (lit. (19) mp 32°C).

m-*Chloroperbenzoic acid oxidation of phenylazopyridines*

Oxidation of 4-, 3-, and 2-phenylazopyridine by the method of Badger and Lewis (52) using *m*-chloroperbenzoic acid yielded the 4-, 3-, and 2-phenylazopyridine-*N*-oxides. The reaction products were purified by column chromatography eluting with ethyl acetate/methylene chloride, and recrystallized from hexane yielding 4-phenylazopyridine-*N*-oxide, mp 149–150°C (lit. (19) mp 150°C); 3-phenylazopyridine-*N*-oxide, mp 86–88°C (lit. (19) mp 87–88°C); and 2-phenylazopyridine-*N*-oxide, mp 108–109°C (lit. (19) mp 109–110°C).

Peracetic acid oxidation of phenylazopyridines

2-Phenylazopyridine, on reaction with H_2O_2/glacial acetic acid following the method of Colonna, Risaliti, and Pentimalli (17–19), gave, after column chromatography and recrystallization from ethanol, yellow crystals of 2-(phenyl-α-azoxy)pyridine-*N*-oxide, mp 136–137°C (lit. (19) mp 137–138°C), and a small quantity of 2-phenylazopyridine-*N*-oxide.

Oxidation of 4- and 3-phenylazopyridines yielded small amounts of phenylazopyridine-*N*-oxides and mixtures of the α and β phenylazoxypyridine-*N*-oxides. The latter were separated by hplc using toluene/ethyl acetate/methanol (4:2:1) as the eluent solvent mixture and monitoring the separation by tlc. The α,β mixture of 4-phenylazoxypyridine-*N*-oxides (3.00 g) yielded 1.50 g of pure 4-(phenyl-α-azoxy)pyridine-*N*-oxide, mp 144–145°C (lit. (19) mp 142°C), and 0.85 g of pure 4-(phenyl-β-azoxy)pyridine-*N*-oxide, mp 146–147°C. Similarly, 5.50 g of the α,β mixture of 3-phenylazoxypyridine-*N*-oxides yielded 3.14 g of pure 3-(phenyl-α-azoxy)pyridine-*N*-oxide, mp 124–126°C (lit. (19) mp 85–87°C), and 1.05 g of pure 3-(phenyl-β-azoxy)pyridine-*N*-oxide, mp 134–135°C. Based on the recovered yields, the product ratios in the oxidation are calculated as: 4-phenylazoxypyridine-*N*-oxide, α/β ≃ 2:1; 3-phenylazoxypyridine-*N*-oxide, α/β ≃ 3:1.

Phenylazoxypyridines

The 4-, 3-, and 2-phenylazoxypyridine-*N*-oxides obtained as above were selectively deoxygenated on the *N*-oxide function with phosphorus trichloride according to the procedure of Pentimalli (19). The products, recrystallized from petroleum ether, had the mp values: 4-(phenyl-α-azoxy)pyridine, 87–88°C (lit. (19) mp 80°C); 4-(phenyl-β-azoxy)pyridine, 67–68°C; 3-(phenyl-α-azoxy)pyridine, 64–65°C (lit. (19) mp 59–61°C); 3-(phenyl-β-azoxy)pyridine, 80–81°C; 2-(phenyl-α-azoxy)pyridine, 30–31°C (lit. (19) mp 30–31°C).

Phenylazoxypyridinium methiodides

Methylation of the phenylazoxypyridines with methyl iodide yielded the pyridinium methiodides. As one example of the procedure, a solution of 2-(phenyl-α-azoxy)pyridine (1.80 g) in 30 mL ethanol was heated under reflux with 5.0 g methyl iodide for 5 h. The red crystals obtained on cooling were recrystallized from ethanol to yield 1.85 g of 2-(phenyl-α-azoxy)pyridinium methiodide, mp 185–187°C.

Phenylazopyridinium methiodides

These were obtained in 86–93% yield by methylation of the phenylazopyridines as described above. The characteristics of the products and analytical data are given in Table 2.

Isolation of α isomers from Wallach rearrangement of α,β azoxy mixtures

The isolation of 3-(phenyl-α-azoxy)pyridine following reaction of the mixture of α,β isomers in 99.5% H_2SO_4 is described as a representative example. The sample used was obtained by deoxygenation (PCl_3) of an α,β mixture of 3-phenylazoxypyridine-*N*-oxides resulting from the peracetic acid oxidation of 3-phenylazopyridine and originated prior to use of the hplc method for isomer separation.

The α,β mixture of 3-phenylazoxypyridines (0.070 g) was dissolved in 300 mL of preheated (50°C) 99.47% H_2SO_4 in a round-bottom flask, which was wrapped in aluminum foil and placed in a thermostatted bath at 50°C. After 20 min, corresponding to >95% reaction for the β isomer, the solution was cooled to 0°C, diluted 10-fold with water while keeping the temperature below 5°C, and transferred to a liquid–liquid extractor containing 400 mL of methyl-

ene chloride. After extraction had proceeded for 20 h, the CH_2Cl_2 solution was concentrated to 100 mL and extracted with 1 *N* NaOH in a separatory funnel. The basic extract was carefully neutralized with 1 *N* HCl which caused the hydroxyazo product to precipitate. The solid material was filtered and recrystallized from ethanol, yielding 3-(*p'*-hydroxyphenylazo)pyridine, mp 220–221°C. The CH_2Cl_2 solution from the extraction was dried ($MgSO_4$), evaporated to dryness, and the residue dissolved in 20 mL of methanol/ethyl acetate/toluene (1:2:4). Development on a preparative tlc plate and recrystallization of the product thus obtained from petroleum ether yielded the 3-(phenyl-α-azoxy)pyridine, mp 64–65°C.

X-ray analysis of ***11***

Crystals are yellowish in color and the one chosen for data collection was a rectangular parallelopiped with dimensions 0.075 × 0.17 × 0.5 mm. All X-ray measurements were carried out on a CAD-4 diffractometer. Systematic absences indicated the space group to be $P2_1/c$. The unit cell dimensions were obtained from a least-squares refinement of the angular settings of 24 reflections with 2θ values between 80° and 90°. The volume and the density indicated that there are two molecules per asymmetric unit.

$C_{11}H_9N_3O_2$ mw = 215.2

Monoclinic, space group $P2_1/c$, a = 14.984(1), b = 5.627(1), c = 25.484(1) Å, β = 109.93(1)°, Z = 8, D_m = 1.41, D_c = 1.415 g cm^{-3} (21°C), CuKα$_1$, λ = 1.54051, CuKα$_2$, λ = 1.54433 Å, F(000) = 896, V = 2019.8 Å^3, μ = 8.5 cm^{-1}.

The density was measured by flotation in a mixture of bromobenzene and chlorobenzene.

A total of 4136 unique reflections (2θ < 150°) was measured (ω–2θ scan) with Ni-filtered CuKα radiation. Three standard reflections were monitored at regular intervals; their intensities did not show any systematic changes. Of the measured reflections, 2484 had intensities greater than 2σ(I) and were considered observed. The structure was solved by direct methods with the aid of the program MULTAN (55) and refined by block-diagonal least squares. Sixteen hydrogens were located on a difference map and the remaining two from stereochemical considerations. Hydrogen parameters were refined isotropically while those for nonhydrogen atoms were refined using anisotropic thermal parameters. All C—H bonds were in the range 0.92–0.97 Å. The quantity minimized in the refinements was $w(|F_o| - |F_c|)^2$ where $w = [(12/|F_o|) \sin\theta]^{1/2}$ for $|F_o| < 12$ and $w = [(|F_o|/12) \sin\theta]^{1/2}$ for $|F_o| > 12$.

During the final stages of the refinement it was noticed that five reflections (400, 410, 112, 211, and 217) were seriously affected by extinction and they were given zero weights in the least-squares calculations. The final R and R_w are 0.041 and 0.045 for the 2479 reflections used in the least-squares refinement. All scattering factors were taken from ref. 56 and all calculations, apart from MULTAN 78 (55), were carried out with programs written by Ahmed *et al.* (57). Lists of anisotropic temperature parameters and of observed and calculated structure factors are available.[3]

X-ray analysis of ***12***

Red prisms were obtained from ethanol solution. They belong to the triclinic space group $P\bar{1}$. The crystal data are as follows:

$[C_{12}H_{12}N_3O]^+ I^-$ fw = 313.14

$P\bar{1}$, a = 7.477(1), b = 9.939(1), c = 10.073(1) Å, α = 65.39(1), β = 70.38(1), γ = 79.92(1)°, V = 640.51 Å^3, Z = 2, D_c = 1.62 g cm^{-3}, λ(CuKα) = 1.54178 Å, μ(CuKα) = 198.7 cm^{-1}.

A crystal with dimensions 0.11 × 0.26 × 0.28 mm was used for data collection. A total of 1756 independent reflections with 2θ < 128° were measured on a Syntex $P2_1$ diffractometer, using Ni-filtered CuKα radiation. The ω/2θ scan technique was employed with the scan width Δ(2θ) = (1.6 + 0.28 tan θ)° and the scan speed varying in the range 2.0 to 10.0°/min. Three reflections were monitored every 60 reflections and were used for appropriate scaling. Of the measured reflections, 1718 were above the threshold of 2.5σ(I_{net}). The intensities were corrected for Lorentz and polarization factors. An absorption correction was calculated analytically and first checked on several reflections, randomly distributed in the reciprocal space, for which the intensities were measured over the full range of ψ angles (every 10°). After applying the correction, the intensities of these reflections were scattered by less than 5% from their mean values. The absorption correction for all measured data varied in the range 0.047 to 0.252.

The position of the iodine atom was derived from a Patterson map. The Fourier map, calculated with phases from the iodine atom, revealed all nonhydrogen atoms. The structure was refined by the full-matrix least-squares procedure with first isotropic and later anisotropic temperature factors. All hydrogen atoms were located on a difference map and were included in the refinement with isotropic temperature factors. Three reflections with low θ angles and large $|F_o|$ were affected by extinction and were given zero weight in the refinement. The weighting scheme $w^{-1} = \sigma^2_{stat}(F) + k^2F_o^2$, with k = 0.0035, was used in the last few cycles of refinement. At convergence the residual indices were: R = 0.0432 and R_w = 0.0614. The average parameter shift in the last cycle of the refinement was 0.08 and the maximum was 0.42.

All scattering factors were taken from ref. 56 and all calculations were performed with the program SHELX (58). Lists of anisotropic temperature parameters and of observed and calculated structure factors are available.[3]

[3]These lists may be obtained at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Received December 16, 1983

This paper is dedicated to Professor G. E. Dunn on the occasion of his 65th birthday

MAKIKO SUGIURA, HELMUT BEIERBECK, GEORGE KOTOVYCH, and PATRICE C. BÉLANGER. Can. J. Chem. **62**, 1640 (1984).

The conformational analysis of LTD_4 in D_2O was carried out based on the analysis of vicinal proton–proton coupling constants, nonselective proton longitudinal relaxation times, and nuclear Overhauser effect data. The H6—C6 to C12 region of the molecule is *transoid*, the predominant rotamer about C5—C6 is *gauche*, and two rotamers can be used to describe the rotation about C12—C13. There are three rotamers that can be used to describe the rotation about the C21—C22 bond of cysteine. Finally, chelation between an Yb^{3+}, shift reagents and LTD_4 was not observed.

MAKIKO SUGIURA, HELMUT BEIERBECK, GEORGE KOTOVYCH et PATRICE C. BÉLANGER. Can. J. Chem. **62**, 1640 (1984).

Faisant appel à une analyse des constantes de couplage proton–proton vicinales, des temps de relaxation longitudinaux non-sélectifs des protons et de données d'effet Overhauser nucléaire, on a réalisé une analyse conformationnelle du LTD_4 dans le D_2O. La région H6—C6 à C12 de la molécule est *transoide*, le rotamère prédominant autour de la liaison C5—C6 est *gauche* et deux rotamères peuvent être utilisés pour décrire la rotation autour de la liaison C12—C13. On peut utiliser trois rotamères pour décrire la rotation autour de la liaison C21—C22 de la cystèine. Finalement, on n'a pas pu observé de chélation entre le Yb^{3+}, un réactif de contact, et le LTD_4.

Introduction

The metabolism of arachidonic acid involves its oxygenation via two enzymic systems. Cyclooxygenase transforms arachidonic acid into the prostaglandins, the thromboxanes, and prostacyclin, and lipoxygenases give rise to a new class of eicosanoids, the leukotrienes. In this metabolic process, 5-lipoxygenase oxidizes arachidonic acid to form 5(*S*)-hydroperoxy-6*E*-8,11,14*Z*-eicosatetraenoic acid (5-HPETE), which is then converted to 5*S*-5,6-epoxy(7*Z*,9*Z*,11*E*,14*E*)-eicosatetraenoic acid, leukotriene A_4 (LTA_4) (1, 2).

Leukotriene A_4 may be further metabolized by two enzymic pathways or may be chemically hydrolysed by a non-enzymic pathway. The first enzymic pathway (2, 3) involves insertion of H_2O to produce leukotriene B_4 ((5*S*,12*R*)-5,12-dihydroxy-(6*Z*,8*E*,10*E*,14*Z*)-eicosatetraenoic acid) (LTB_4). Two other 5,12-dihydroxyeicosatetraenoic acids can also be produced by the nonenzymic hydrolysis of leukotriene A_4. In this case, the double bonds in the triene structure are all *trans* and the hydroxyl groups have the configuration 5*S*,12*S* or 5*S*,12*R*. A fourth 5,12-dihydroxyeicosatetraenoic acid may be produced by a dual lipoxygenase attack and in this case the triene structure has the configuration *trans, cis, trans* and the hydroxyl groups are 5*S*,12*S*.

Leukotriene B_4 is a potent stimulator of the movement of leucocytes in vitro and can also induce vascular permeability changes. The role of LTB_4 as a mediator of leucocyte function has recently been reviewed (4).

The second enzymic pathway involves conjugation with glutathione to produce leukotriene C_4 (LTC_4) ((5*S*)-hydroxy-(6*R*)-*S*-glutathionyl-7,9-*trans*-11,14-*cis*-eicosatetraenoic acid) which is then metabolized to form leukotrienes D_4 (Fig. 1) and E_4 (5, 6). These compounds collectively account for the biological activity known as Slow Reacting Substance of Anaphylaxis (SRS-A). These leukotrienes possess potent biological properties and can contract certain smooth muscle preparations, constrict coronary and cerebral arteries, and may induce changes in vascular permeability and mucous production. They may therefore be important mediators of human diseases such as bronchial asthma. This research has now been well reviewed (7–11). The geometrical assignments of the double bonds of the different leukotrienes as well as the stereochemical assignments have been made possible by total syntheses and subsequent comparison of synthetic and natural products (12–20).

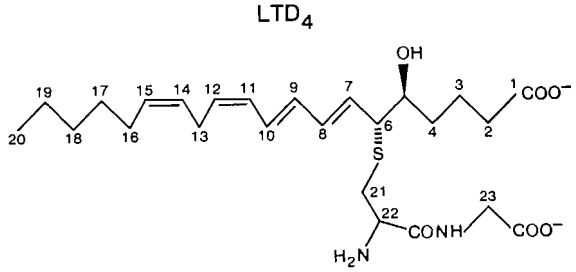

FIG. 1. The structure of LTD_4.

In the present study, our objective is to obtain the possible conformations of LTD_4 in aqueous solution. The determination of such a conformation is very important as it could be used in the design of analogs of LTD_4. It could also lead to a better understanding of the structure–activity relationships (21, 22) and of the interaction of LTD_4 with its specific receptor. Some nmr studies have been reported on derivatives of leukotrienes (23–26) and the deprotected LTD_4 in methanol solution (26), but only LTB_4 has been studied in an aqueous system (27). The

[1] This is paper No. 12 in a series of high-field nmr studies on the eicosanoids.

[a] Assumed value in the computer analysis.

small amount of material available and its stability are responsible for the scarcity of these important studies, and the nature of these derivatives makes it nearly impossible to obtain crystals suitable for X-ray analysis. Hence we have carried out an extensive proton nmr investigation of LTD_4 in aqueous solution. The experiments involve a pH-dependent study of the chemical shifts, proton longitudinal nonselective relaxation time measurements, nuclear Overhauser enhancements, and an analysis of the coupling constants. These data were combined with conformational studies of model compounds and, in this manner, the preferred conformations for LTD_4 are evaluated.

Experimental

The potassium salt of LTD_4 was synthesized by Merck–Frosst Canada, Inc., Pointe Claire, Quebec, Canada (28). The nmr measurements were carried out in D_2O (100%, Aldrich), which was vacuum distilled. The leukotriene was received as a solution in water, which was removed under vacuum. D_2O was then added, the samples were degassed, and then pumped to dryness twice. In this way the residual HDO peak was minimized. Fresh 100% D_2O was then added (0.4 mL) and the solutions were degassed four times using the freeze–pump–thaw technique and then sealed. All glassware was cleaned extensively, including a nitric acid wash, to eliminate paramagnetic impurities.

The proton magnetic resonance measurements were carried out in the Fourier transform mode using the Bruker WH-400/DS nmr spectrometer and the Aspect 2000 Data System, utilizing 16K of data memory for the nOe and the relaxation time measurements. Up to 64 K of memory were used in evaluating the chemical shifts and coupling constants. The deuterium resonance of the solvent D_2O was used as the lock signal. The proton longitudinal nonselective relaxation times (T_1^{NS}) were obtained using the (180°–τ–90°–t) two-pulse sequence. Usually about 10 τ values were included in the analysis of the data, based on the initial slope of a plot of ln ($M_\infty - M_\tau$) vs. τ.

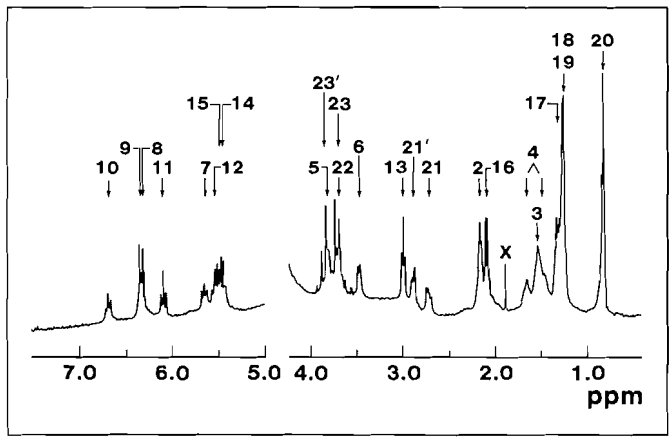

FIG. 2. The general spectrum of LTD_4 in aqueous solution (pH ~8).

These *M* values were obtained from the measurement of the sum of the peak heights of a multiplet corresponding to a given proton, and for some protons peak areas were measured by weighing out the peaks. As well, two M_∞ values were measured for maximum accuracy. The relaxation times were obtained from a computer analysis of the data using a least-squares program.

The steady-state nOe difference experiments were carried out following procedures described previously (29). Saturation power levels were determined by measuring the minimum power necessary to completely suppress a given multiplet. The reported nOe's are the average values for two or three experiments. Subspectral analyses were carried out with the Bruker PANIC program.

For the pH studies, phosphate and borax buffer solutions were prepared in D_2O at pH's of 6 to 9. The buffer concentrations were ~0.005 *M*. About 70 μg LTD_4 was then added to 0.4 mL of buffer solution, and the concentration of LTD_4 in each solution was about 3.5×10^{-4} *M*. Duplicate buffer solutions were prepared with a trace of DSS to be used as a reference. After the spectrum was obtained on LTD_4, the reference sample was placed in the probe, the lock signal adjusted to the same spectral reference, and in this way the chemical shifts were calibrated. Shifts at eight pH values were determined to confirm that at pH ~9 only one predominant species is present in solution. At pH ~9.0 the NH_2 group is deprotonated.

The chemical shifts reported in Table 1 are with respect to external DSS.

Results

The assignment of the proton multiplets was carried out following standard decoupling techniques and these are shown in Fig. 2. The chemical shifts and coupling constants are listed in Table 1 and two examples of the computer fit to the data are shown in Fig. 3. Comparing our chemical shifts in Table 1 with those previously reported in CD_3OD (26), a solvent effect on the shifts is observed.

To check for aggregation, chemical shifts were measured, at pH ~8, on ~3×10^{-3} *M* and ~3.6×10^{-4} *M* solutions with good agreement in the first-order chemical shifts. Hence the relaxation time data in Table 2 and the nOe data in Table 3 were obtained under conditions where intermolecular association is not present. In the case of prostaglandin $F_{2\alpha}$ (30), hydrophobic interactions were not present at concentrations below 0.02 *M* and this is also apparent with prostacyclin and its analogs (31). Consequently, the present studies are carried out at a concentration where aggregation is minimal. As well, the pK_a for the cysteine amino group is determined to be ~7.5 and the NH_2 group is not protonated for all of the data reported in the tables for aqueous solutions at a pH ~9.

[a] The fit to the data was obtained using a correlation time of 0.33 ns.
[b] Values of T_1's were determined simultaneously because of multiplet overlap.

In Table 1, the chemical shifts for protons H-2 to H-4, and H-17 to H-20 are reported to first order, whereas the remainder of the chemical shifts, and the coupling constants, were determined from a computer fit to the data. Several simulations were carried out, namely (a) decoupling H-6 and fitting the spectra for H-7 to H-11; (b) decoupling H-16 and fitting H-11 to H-15; (c) decoupling H-8 and fitting the spectra for H-5 to H-7; (d) decoupling H-13 and fitting H-11 to H-16, and (e) fitting the amino acid proton spectra.

The approach that was chosen to elucidate the possible conformations of LTD_4 in solution is based on the Karplus analysis of the coupling constants combined with proton nuclear Overhauser effect (nOe) measurements and proton nonselective relaxation time measurements (T_1^{NS}). The application of the Karplus equation to conformational analysis has been well documented (32, 33). The proton nOe and relaxation time measurements were carried out since these data are extremely sensitive to the interproton distances (34, 35). For proton–proton intramolecular dipolar relaxation, the spin-lattice transition probabilities are W_0^{ij}, W_1^{ij}, and W_2^{ij}, respectively, for zero-, single-, and double quantum transitions involving the nuclear spins i and j. These are given as follows:

$$[1] \quad W_0^{ij} = \frac{1}{10}\gamma^4\hbar^2\tau_c/r_{ij}^6$$

$$[2] \quad W_1^{ij} = \frac{3}{20}\gamma^4\hbar^2\tau_c/(1 + \omega^2\tau_c^2)\,r_{ij}^6$$

$$[3] \quad W_2^{ij} = \frac{6}{10}\gamma^4\hbar^2\tau_c/(1 + 4\omega^2\tau_c^2)\,r_{ij}^6$$

The relaxation rates are defined as

$$[4] \quad \sigma_{ij} = W_2^{ij} - W_0^{ij}$$

$$[5] \quad \rho_{ij} = W_0^{ij} + 2W_1^{ij} + W_2^{ij}$$

where σ_{ij} is the cross-relaxation term and ρ_{ij} is the direct relaxation term for a proton pair. The interproton distance is r_{ij}, ω is the Larmor frequency, and τ_c is the correlation time for molecular reorientation. The magnetogyric ratio is γ and $\hbar$ is Planck's constant h divided by 2π.

The nuclear Overhauser effect (nOe) is an excellent probe of molecular conformation because it depends on the interproton distance r_{ij}^6. It is defined as the fractional enhancement of nucleus d on saturating nucleus s ($f_d(s)$) and comprises a term (first) for *direct* interactions and one (second) for *indirect* interactions (35–37).

$$[6] \quad f_d(s) = \sum_s N_s\sigma_{ds}/R_d - \sum_{n\neq d,s} N_n\sigma_{dn}f_n(s)/R_d$$

where N_i is the number of equivalent nuclei i. The total direct relaxation rate is R_d:

$$[7] \quad R_d = \sum_n N_n\rho_{dn} + p^*$$

The nonselective relaxation time is T_1^{NS} and is defined as:

$$[8] \quad T_1^{NS} = \frac{1}{R_d + S_d}, \text{ where } S_d = \sum_n N_n\sigma_{dn}$$

On the basis of these equations, a computer program was written which optimizes the nOe and the T_1^{NS} data for a given conformation. The optimum value of τ_c is thus obtained. Several possible conformations are used as input, based on the Karplus analysis of the coupling constants. The internuclear distances are estimated from Dreiding models. This approach has now been successfully applied to the study of leukotriene B_4 (27).

The molecular modeling was carried out in the following manner for LTD_4 in aqueous solution at pH ~9.0. Carbon atoms C1 to C6 and C15 to C20 are *trans*, as expected. The triene portion of the molecule from C6 to C12 is also *trans* (24, 26, 27), and the present study supports this conclusion. The coupling constants observed for olefinic protons across a connecting single bond are J(H6—H7) = 10.1 Hz, J(H8—H9) = 10.4 Hz, J(H10—H11) = 11.2 Hz. The coupling constants indicate that the olefinic protons about interconnecting single bonds are *transoid*.

To estimate the possible rotamers about C4—C5, coupling

H-11						8% (7.2%)		
H-13					7.7% (7.6%)	7.4% (5.1%)		11.0%

[a]These data were optimized using a correlation time of 0.33 ns. Values in brackets represent the calculated nOe's.

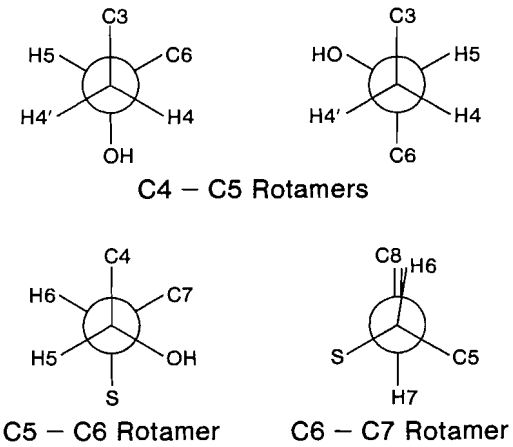

FIG. 4. The possible rotamers about C4—C5, C5—C6, and C6—C7.

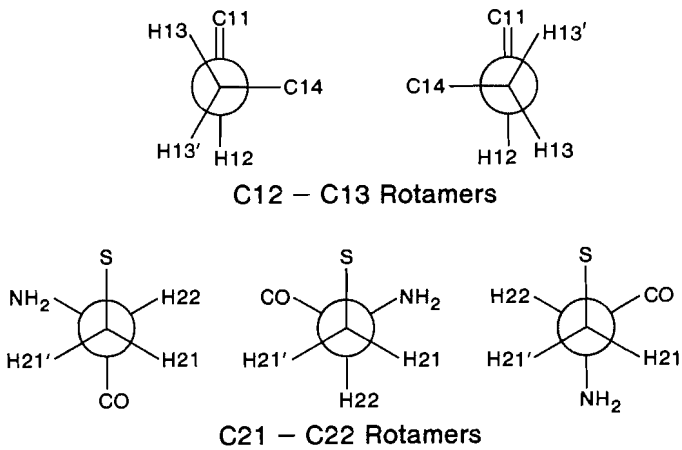

FIG. 5. The possible rotamers about C12—C13, and C21—C22.

constants *J*(H4—H5) are required, but could not be evaluated from the spectra. The two rotamers used in the present analysis (Fig. 4) are the same as were evaluated for LTB_4 where the coupling constants could be measured *J*(H4—H5) = 6.3 Hz (27). The C4—C5—C6—C7 dihedral angle is 60°, in agreement with *J*(H5—H6) of 4.1 Hz (Fig. 4) (26). A value of 4.1 Hz may indicate the presence of a *transoid* conformer, but the predominant conformer is still *gauche*.

The H6—C6—C7—H7 dihedral angle is chosen as 180° because the coupling constant is 10.1 Hz and this leads to a *trans* orientation between the methine protons at C6 and C7 (26). As well, for rotational isomerism about sp^2–sp^3 carbon–carbon single bonds, the preferred conformation (Fig. 4) is the one where the C—H bond at the sp^3 center eclipses the C=C double bond (38–40), and this places H6 and H7 in a *trans* orientation.

In considering the rotamers about C12—C13 (Fig. 5) the preferred rotamers again are expected to be the ones where CH(13) and CH(13′) eclipse the C11=C12 double bond. However, this leads to a steric interaction between H-10 and H-13 (or H-13′) because of the extra *cis* double bond substitution, and the calculated T_1^{NS} for H10 is too short. In the present analysis, two preferred rotamers are used, as shown in Fig. 5 with the C11—C14 bonds perpendicular. In this way, the stabilization due to the eclipsed conformation is still present, but is decreased by the H10—H13 interaction. This gives a more reasonable fit to the T_1^{NS} data. The H12—H13 and H12—H13′ dihedral angles are then equal to 150° and 30°. A coupling constant *J*(H12—H13) of ~9 Hz is expected and a coupling of 8.5 Hz is observed. Finally, even though the data are not sufficient to prove the presence of these two rotamers about C13—C14 and C15—C16, the above analysis can be extended to rotation about these bonds. In considering the amino acid substituent, the choice of the C5—C6—S—C21 dihedral angle and the C6—S—C21—C22 dihedral angle does not affect the nmr data, especially since an nOe is not observed between H6 and H21. Hence in considering the rotation about C6 and S, C5 was placed *trans* to C21, and for rotation about S—C21, C6 was placed *trans* to C22.

To calculate the rotamers associated with the amino acid cysteinyl glycine side chain, a pH dependence of coupling constants for this dipeptide was carried out[3] following the procedure of Fujiwara *et al.* (41). It was found that at pH 9.27, the populations of the three rotamers are about 0.25, 0.33, and 0.42. In rotamer 1, the sulphur is *trans* to CO, whereas in rotamer 2 the sulphur is *trans* to the NH_2 group and in rotamer three the sulphur is *trans* to H22 (Fig. 5). The coupling constants at this pH are 7.2 and 5.4 Hz for *J*(H21—H22) and *J*(H21—H22′). For LTD_4 the coupling constants are 7.1 Hz and 5.4 Hz, indicating a distribution of rotamers about the C21—C22 bond in LTD_4 similar to that for free cysteinyl glycine.

In analyzing the T_1 and nOe data by themselves, several

[3] P. C. Bélanger, unpublished data.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

models were tried and, because of the large number of possible rotamers, it was impossible to determine the allowed conformations. However, with the aid of the Karplus analysis of the coupling constants, the T_1^{NS} and nOe data can be used to confirm the possible conformations. A fit to the T_1^{NS} (Table 2) and nOe data (Table 3) was obtained for the above mentioned conformations. The reorientational correlation time τ_c for the C—H vectors for the planar C6 to C12 portion of the molecule is taken to be isotropic, in agreement with the data for prostacyclin (31) and prostaglandin $F_{2\alpha}$ (30). The optimized fit to the nOe data is achieved with $\tau_c = 0.33 \pm 0.05$ ns (95% confidence limits). This correlation time was then used to obtain the best fit to the T_1^{NS} data, which are not very sensitive to a change in the correlation time.

Because of the availability of potential metal ion ligands at C5(OH), S, C=O groups, and COO^-, it was thought that chelation with a metal ion may be observed. However, on adding up to 40% $YbCl_3$, a shift reagent, no chemical shifts were observed.

Discussion

One of the important conclusions of the present study is based on the coupling constants and confirms the observation (26) that H6—C6 to C12 is *transoid*. The coupling constants presented in Table 1 are the first to be published on unprotected LTD_4 in aqueous solution. The *transoid* conformation is supported by the fit to the T_1 data and the nOe data for the region of the molecule that can be represented by a single isotropic correlation time. A comparison of the data indicates that the calculated and experimental values are within 10% of each other.

Because the LTD_4 molecule is flexible, an analysis of all of the available parameters must be undertaken in order to evaluate the preferred conformations for LTD_4. This includes an analysis of the coupling constants, the T_1^{NS}, and the nOe data. Using this combined approach, the conformational analysis of a complex molecule such as LTD_4 is possible. The predominant rotamer about C5—C6 has C4 and C7 *gauche*. Secondly, H6 and H7 are *trans*, and there are two rotamers about C12—C13. As nOe's were not observed between H21 and H-6, conclusions cannot be drawn about the C5—C6—S—C21 and C6—S—C21—C22 dihedral angles. Finally, the conformers at pH 9 for the C21—C22 bond of cysteine in LTD_4 are calculated by comparing the H21—H22 coupling constants with the model compound cysteine-glycine, and three rotamers are predicted.

Substituent effects on rates of formation of methoxy-substituted carbonyl ylides from 2-aryl-2-methoxy- and 5-aryl-2-methoxy-Δ^3-1,3,4-oxadiazolines

MICHEL BÉKHAZI, PETER J. SMITH,[1] AND JOHN WARKENTIN
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 2, 1983

This paper is dedicated to Professor Gerald E. Dunn on the occasion of his 65th birthday

MICHEL BÉKHAZI, PETER J. SMITH, and JOHN WARKENTIN. Can. J. Chem. **62**, 1646 (1984).

2-Aryl-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazolines (**4**) and 5-aryl-2-methoxy-2,5-dimethyl-Δ^3-1,3,4-oxadiazolines (**5**) were synthesized. Compounds **4** decompose in solution with first order kinetics. Rate constants are correlated with Hammett substituent constants (σ^-) with $\rho(49.2°C) = 0.74$ and 0.89 for CCl_4 and CD_3OD, respectively. The final products from **4** indicate that thermolysis involves the cleavage of both C—N bonds, to form N_2 and, initially, a carbonyl ylide. Compounds **5**, which were obtained as mixtures of *cis/trans* isomers containing several impurities, and which therefore gave poorer kinetic data, decomposed in $CDCl_3$ solution with $\rho(45°C) \simeq 1.1$. Carbonyl ylide intermediates, similar to those from the closely-related compounds **4**, were assumed on the basis of analogy and on the basis of partial identification of products. The effects of *para* substituents in the aryl groups of **4** and **5** show that the transition states have greater electron density at C-2 of **4** and at C-5 of **5** than do the starting materials. In spite of the increase in electron density at C-2 of **4**, the transition state must be less polar, overall, than the ground state because rate constants for thermolysis of **4** in methanol are smaller than those for CCl_4 solvent. A plausible explanation for the substituent effects and the solvent effects is that the loss of N_2 is concerted, with a transition state resembling more closely a spin paired 1,3-diradical than a 1,3-dipole. Alternative stepwise mechanisms, in which C2—N3 bond scission of **4** and C5—N4 bond scission of **5** are the rate-determining steps, leading to 1,5-diradical intermediates, can not be excluded on the basis of the evidence.

MICHEL BÉKHAZI, PETER J. SMITH et JOHN WARKENTIN. Can. J. Chem. **62**, 1646 (1984).

On a synthétisé les aryl-2 méthoxy-2 diméthyl-5,5 Δ^3 oxadiazolines-1,3,4 (**4**) et aryl-5 méthoxy-2 diméthyl-2,5 Δ^3 oxadiazolines-1,3,4 (**5**). Les composés **4** se décomposent en solution avec une cinétique d'ordre un. On a relié les constantes de vitesse aux constantes de substitution de Hammet (σ^-) et les valeurs de ρ à 49,2°C sont respectivement 0,74 et 0,89 pour le CCl_4 et le CD_3OD. Les produits finals obtenus à partir du composé **4** indiquent que la thermolyse implique le clivage des deux liaisons C—N pour former du N_2 et, initialement, un ylure de carbonyle. Les composés **5**, que l'on obtient sous la forme de mélanges d'isomères *cis/trans* contenant plusieurs impuretés et qui par conséquent donnent de mauvaises donnés cinétiques, se décomposent en solution dans le $CDCl_3$ et la valeur de ρ à 45°C est égale à 1,1. En se basant sur l'analogie des réactions et sur une identification partielle des produits, on fait l'hypothèse qu'il existe aussi dans ces cas des ylures de carbonyle intermédiaires semblables à ceux observés dans le cas des composés **4** qui leur sont très voisins. Les effets des substituants en position *para* des groupes aryles des composés **4** et **5** montrent que, par rapport aux produits de départ, les états de transition ont une plus grande densité électronique en C-2 dans les composés **4** et en C-5 dans les composés **5**. En dépit d'une augmentation de la densité électronique en C-2, dans les composés **4**, l'état de transition doit être, dans l'ensemble, moins polaire que l'état fondamental puisque les constantes de vitesse de la thermolyse des composés **4** dans le méthanol sont plus faibles que celles dans le CCl_4. Une perte de N_2 concertée, avec un état de transition ressemblant de très près à un diradical-1,3 de spin pairé plutôt qu'à un dipole, constitue une explication plausible des effets de substituant et de solvant. Les preuves obtenues n'excluent pas la possibilité d'un mécanisme par étapes dans lequel la scission de la liaison C2—N3 des composés **4** et de la liaison C5—N4 des composés **5** constituerait l'étape déterminante et conduirait à la formation de diradicaux-1,5 intermédiaires.

Introduction

Cycloaddition and cycloreversion reactions have had a very large impact on several areas of chemistry, including synthesis and both the theoretical and the experimental aspects of mechanism.[2] In general, cycloadditions are used to prepare stable end products while cycloreversions are of greatest interest as routes to reactive intermediates, such as diradicals, carbenes, and ylides. Mechanistic interest in both classes of reactions has centered around the question of the timing of the bond-forming or bond-breaking processes that are involved. In principle, mechanistic information can be obtained by studying either a cycloaddition or its reverse, because the transition state must be the same for either direction of the reaction. In practice, there are many cases where only one choice is available. Cycloadditions to N_2, for example, do not occur readily, although the reverse process, cycloelimination of N_2, is a well-known and much studied reaction (8–10).

Although many studies of the mechanisms of extrusion of nitrogen from cyclic compounds have been reported, there is continued activity and interest in the area because of the apparent variety of mechanisms that are applicable. That variety can be illustrated with the 1-pyrazoline system for which, depending on the substituents, an ion pair mechanism (11), eq. [1], and a range of diradicaloid mechanisms have been proposed. The latter family includes planar 1,3-diradicals (12–16), nonplanar 1,3-diradicals (or π-cyclopropanes) (17), and 1,5-diradicals of the alkyl diazenyl type (18–20). Finally, it has been pointed out that, for monocyclic 1,3-dialkyl pyrazolines at least, it may not be possible to describe the cycloelimination of N_2 (and the subsequent chemistry, if there

[2] The literature on these subjects is very extensive. For review articles on cycloadditions and cycloreversions see refs. 1–7 and 8–10, respectively. The list is not exhaustive and some of the review articles deal also with additional material that does not fit into either category. Moreover, the separation of reviews into those on cycloaddition and those on cycloreversion is somewhat arbitrary in a few instances because of overlap of the topics.

are discreet steps) with conventional mechanistic terminology (21).

Mechanisms of thermolysis of Δ^3-1,3,4-oxadiazolines (oxy analogues of pyrazolines) have not been studied extensively. Small solvent effects and small aryl substituent effects on the rate constants for thermolysis of **1** were interpreted in terms of concerted extrusion of N_2 (22), leading to a carbonyl ylide (eq. [2]). Although dipolar contributors to **2** suggest that the

[2] 
1 **2**

benzylic carbon ought to become negative at the transition state for concerted decomposition, aryl substituent effects were correlated with σ^+ constants with $\rho^+ = -0.50$, suggesting development of positive charge there. Stepwise scission of the C—N bonds in the thermolysis of **3** (eq. [3]) was proposed (23), in part to account for the presence of oxirane among the reaction products from **3***a* but not among those from **3***b*. Although

[3] 
3 *a* R = C_6H_5
b R = CH_3

that mechanism could account for some additional features, such as very low yields of cycloadduct from thermolysis of compounds like **3***b* in the presence of neat acrylonitrile, it has been pointed out (10) that the rate factor (k_{3a}/k_{3b}) is smaller than might be expected for a stepwise mechanism. Moreover, it has been found subsequently that both trialkylacetoxy- (24) and trialkylalkoxy-substituted carbonyl ylides (25, 26) can fragment to carbenes and carbonyl compounds more rapidly (27) than they can close to oxiranes. An intramolecular 1,4-hydrogen shift is also fast relative to oxirane formation, in some systems. On the other hand, an aryl substituent at the ylide carbon which bears the alkoxy group slows or stops both ylide fragmentation and intramolecular H-transfer (27). Those results, summarized in Scheme 1, can be interpreted in terms of ylide chemistry alone without invoking a diazenyl diradical intermediate (23) as the precursor of that ylide. However, in view of recent evidence for stepwise homolysis of a number of unsymmetric (28) and symmetric (29, 30) acyclic azo compounds, it would be premature to dismiss the diazenyl diradical mechanism of oxadiazoline thermolysis entirely at this time.

In view of the considerable potential of carbonyl ylides, not only as intermediates for cycloadditions but also as sources of carbenes (24–27), we began studies aimed at elucidating the mechanisms of ylide formation from oxadiazolines and of intramolecular and intermolecular ylide reactions.[3] We report here some substituent effects and solvent effects on rate constants for unimolecular thermolysis of oxadiazolines **4** and **5**.
