
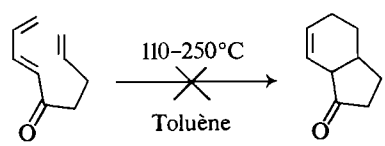
1 R = $SiMe_3$, $SnMe_3$

Le diène **2***e* (R = $SnMe_3$) est un diène particulièrement intéressant car c'est un précurseur d'un anion butadiènyl-1,3 de stéréochimie *E* (17):

Ce diène n'a pu être obtenu jusqu'à présent qu'avec de faibles rendements (même par thermolyse à 600°C) en raison de la fragilité des liaisons allyliques C—Sn.

Les cétones diéniques **2**(*l*–*n*) sont obtenues chimiquement et stéréoisomériquement pures après chromatographie sur colonne de silice. (La stéréochimie *E* est facilement déterminée par le couplage *trans* (J = 15–17 Hz) observé entre le proton vinylique situé en α du carbonyle et le proton vinylique voisin.) Cependant dans le produit brut de thermolyse, la spectrométrie de masse couplée à la chromatographie en phase vapeur montre la présence d'une faible quantité (3 à 6%) d'un isomère. Dans le cas de la nonadiène-6,8 one-5 **2***m*, cet isomère minoritaire a été séparé et purifié. Le spectre de rmn ^1H montre qu'il s'agit de l'isomère *Z* (couplage *cis* J = 10 Hz entre le proton vinylique en α du carbonyle et le proton vinylique voisin). La cétone triénique **2***n* semblait être un synthon intéressant pour la préparation d'hydrindanones par réaction de Diels–Alder intramoléculaire. Cependant la cyclisation n'a pu être effectuée ni en phase vapeur ni par chauffage en tube scellé en solution dans le toluène. Jusqu'à 150°C la cétone **2***n* est récupérée inchangée; à 250°C seuls des polymères sont formés:



(d) *Synthèse du dodécadiène-9,11 yl-1 acétate* (E)

Le lépidoptère *Diparopsis castanea* est un fléau majeur des plantations de coton du sud-ouest de l'Afrique. Nesbitt *et al.* (18) ont montré que la phéromone sexuelle la plus efficace produite par le femelle de cet insecte est le dodécadiène-9,11 yl-1 acétate **12** de stéréochimie *E*. La méthode décrite ci-dessus a été appliquée à une synthèse simple et efficace de cette phéromone sexuelle **12** selon le schéma suivant (pour les synthèses antérieures voir la référence 19):

[4] On pourrait aussi invoquer un processus de rupture radicalaire et de recombinaison de la liaison C—$SnMe_3$; cependant une recombinaison efficace paraît difficile dans les conditions de la réaction (pression de 10^{-2} Torr; 1 Torr = 133.3 Pa).

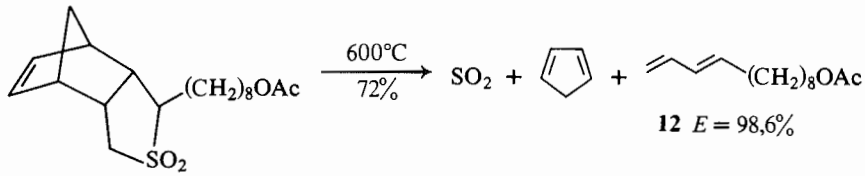
10



11 **12** $E = 98{,}6\%$

L'anion de sulfone **4** réagit facilement avec l'éther tétrahydropyrannylique de l'iodo-8 octanol (20) pour donner la sulfone alkylée **10** sous forme d'un seul isomère. La régénération de l'alcool par l'acide *p*-toluènesulfonique suivie d'une acétylation par le chlorure d'acétyle en présence de triéthylamine conduit à l'acétate **11** avec un excellent rendement. La thermolyse à 600°C de **11**[5] fournit directement la phéromone **12**.

Une analyse de l'acétate **12** obtenu par chromatographie gazeuse sur phase nématique[6] montre que la pureté stéréoisomérique de cette phéromone est de 98,6%. La stéréosélectivité observée ainsi que le rendement (~40–45% à partir de la sulfone **4**) font de cette méthode une des plus efficaces pour l'obtention de cette phéromone sexuelle d'insecte.

Partie expérimentale

Les spectres de rmn ont été enregistrés avec un spectromètre Perkin–Elmer R-12A (60 MHz) ou/et un spectromètre Perkin–Elmer R-32 (90 MHz). Le tétraméthylsilane est utilisé comme référence interne et la position des pics est donnée dans l'échelle δ (en ppm) (δ = 0 pour le TMS).

Les spectres infrarouges ont été enregistrés avec un spectrophotomètre Perkin–Elmer 682. Les positions des bandes d'absorption caractéristiques sont données en cm^{-1}.

Les spectres de masse ont été enregistrés avec un spectromètre GC/MS Hewlett-Packard 5992A ou un spectromètre GC/MS Ribermag R10-10 (colonne capillaire CPSIL 5 de 25 m). Les intensités relatives sont indiquées entre parenthèses, le chiffre 100 étant attribué au pic de base.

Thia-4 tricyclo[5.2.1.$0^{2,6}$] décène-8 **9**

Dans un tricol de 100 mL muni d'un thermomètre, d'un réfrigérant et d'une agitation mécanique on place 77,5 g (0.25 mol) de dimésylate **8** (11) dissout dans 250 mL de toluène, 108 g (0,45 mol) de Na_2S9H_2O dissout dans 250 mL d'eau et 10,1 g (0,025 mol) d'aliquat 336. Le mélange réactionnel est violemment agité à 90°C pendant 6 h. Après refroidissement, la phase organique est décantée et la phase aqueuse extraite 2 fois avec 100 mL d'éther. Les phases organiques sont séchées sur $MgSO_4$, le solvant est éliminé au rotavapor et le résidu donne par distillation 30,5 g (81%) de sulfure **9**; Eb/0,05 Torr 54–55°C; rmn (CCl_4) δ: 6,4 (m, 2H); 3,4 (m, 2H), 3,0 (s élargi, 4H), 2,6 (m, 2H), 2,0 (m, 2H) ppm. Masse: 152 (M^+, 49), 86 (78), 85 (100), 66 (74).

Dioxo-4,4 thia-4 tricyclo[5.2.1.$0^{2,6}$] décène-8 **4**

Dans un tricol de 2000 mL muni d'un thermomètre, d'une agitation mécanique et d'une ampoule à brome on place 30,4 g (0,2 mol) de sulfure **9** dissout dans 750 mL de méthanol. La solution est refroidie à −20°C et on ajoute lentement une solution de 184 g (0,6 mol de $KHSO_5$) d'oxone dans 750 mL d'eau de façon à ce que la température ne dépasse pas −10°C. On agite pendant 15 h à −20°C après addition puis reprend par 1000 mL d'eau. Après 3 extractions avec 300 mL de chlorure de méthylène, les phases organiques sont séchées et le solvant éliminé au rotavapor. On obtient 36,7 g (98%) de sulfone **4** de pureté supérieure à 95% (rmn). Après chromatographie sur colonne de silice (éluant: CH_2Cl_2 90, acétate d'éthyle 10) on obtient 31 g de sulfone **4** pure + 4 g de sulfone **4** contenant quelques pour cent d'un produit provenant d'une époxydation de la double liaison.

Sulfone **4**. *F* 129°C; ir ($CDCl_3$): 3060 (f), 1310 (F), 1150 (F); rmn ($CDCl_3$) δ: 6,3 (s élargi, 2H), 3,05 (m, 4H), 2,3 (m, 4H), 1,6 (m, 2H) ppm. Masse: 184 (M^+, 0,3), 66 (100). *Anal.* calc. pour $C_9H_{12}O_2S$: C 58,67, H 6,56, S 17,40; trouvé: C 58,82, H 6,68, S 17,24.

Méthode générale de préparation des sulfones **5**

Dans un bicol de 25 mL muni de bouchons à jupe rabattable et maintenu sous atmosphère d'azote, on place 920 mg (5 mmol) de sulfone **4** en solution dans 10 mL de THF anhydre. On refroidit la solution à −78°C (acétone–Carboglace) et on ajoute lentement au moyen d'une seringue 5 mmol d'une solution de nBuLi dans l'hexane. On agite pendant 15 min puis ajoute 6 mmol de l'électrophile par l'intermédiaire d'une seringue. Après 1/2 h d'agitation à −78°C, on laisse le mélange réactionnel revenir à température ambiante, hydrolyse par addition de 10 mL H_2O et extrait 3 fois avec 10 mL d'éther. La phase organique séchée est évaporée au rotavapor et le résidu est purifié par chromatographie sur colonne de silice (éluant: hexane 70, acétate d'éthyle 30). Les sulfones **5** ainsi préparées ont les caractéristiques suivantes.

5*a*: ir ($CDCl_3$): 3040 (f), 1300 (F), 1140 (F); rmn ($CDCl_3$) δ: 6,3 (m, 2H), 3,05 (s élargi, 3H), 2,3 (m, 4H), 1,7 (m, 2H), 1,35 (d, J = 7 Hz, 3H) ppm. Masse: 198 (M^+: 1,4), 66 (100).

5*b*: ir ($CDCl_3$): 3060 (f), 1300 (F), 1130 (F); rmn ($CDCl_3$) δ: 6,2 (m, 2H), 3 (m, 3H), 2,3 (m, 4H), 1,4 (m, 12H), 0.9 (t déformé, 3H) ppm. Masse: 254 (M^+: 0,4), 66 (100).

5*c*: ir ($CDCl_3$): 3040 (m), 1640 (f); rmn ($CDCl_3$) δ: 6,3 (m, 2H), 5,25 (m, 3H), 3 (m, 3H), 2,5 (m, 4H), 1,2–1,9 (m, 4H) ppm. Masse: 224 (M^+: 0,2), 66 (100).

5*d*: *F* 131°C; ir ($CDCl_3$): 3040 (f), 1310 (F), 1220 (F), 1130 (F); rmn ($CDCl_3$) δ: 6,25 (s élargi, 2H), 2,95 (m, 3H), 2,1 (m, 4H), 1,7 (m, 2H), 0,3 (s, 9H) ppm. Masse: 256 (M^+: 0,9), 241 (28), 73 (71), 66 (100). *Anal.* calc. pour $C_{12}H_{20}O_2SSi$: C 56,20, H 7,86, S 12,50; trouvé: C 56,24, H 7,96, S 12,47.

[5] A cette température la conversion de **11** n'est que de 95%. Mais à 650°C, où la conversion de **11** est totale, le rendement en diène **12** est limité par une décomposition partielle de l'acétate avec élimination d'acide acétique.

[6] Cette analyse a été effectuée au Tropical Products Institute à Londres dans le laboratoire du Docteur D. R. Hall que nous remercions pour son aimable assistance.

Masse: 135 (18), 66 (100). *Anal.* calc. pour $C_{14}H_{18}O_3S$: C 63,13, H 6,81, S 12,04; trouvé: C 63,40, H 6,87, S 11,98.

*Thermolyse des sulfones **4**: méthode générale d'obtention des diènes **2***

Des échantillons de 200 mg à 1 g de sulfones **5** sont évaporés sous 0,01 Torr dans un tube en mullite horizontal (diamètre intérieur 10 mm) chauffé à 650°C sur une longueur de 10 cm (14). Les produits formés sont recueillis à la sortie du four sur la paroi froide d'un Dewar rempli d'azote liquide. Les diènes formés sont isolés de deux manières différentes selon leur volatilité: les diènes volatils (à l'exception de **2***a*) sont distillés directement à température ambiante sous 10^{-2} Torr dans un piège refroidi à −78°C, le cyclopentadiène n'étant pas piégé dans ces conditions. Les diènes moins volatils sont isolés par lavage du Dewar avec 20 mL d'éther et élimination de l'éther et du cyclopentadiène au rotavapor puis purifiés par chromatographie sur silice.

Le pentadiène-1,3 **2***a*, obtenu sous forme d'un mélange avec le cyclopentadiène, a été identifié par comparaison de son spectre de rmn avec celui d'un échantillon authentique. Les caractéristiques des autres diènes sont les suivantes.

Nonadiène-1,3 **2***b*: rmn ^1H ($CDCl_3$) δ: 4,8–6,6 (m, 5H), 2,1 (m, 2H), 1,35 (m, 6H), 0,95 (t déformé, 3H) ppm. rmn ^{13}C ($CDCl_3$) δ: 137,6; 135,7; 131,2; 114,7; 32,7; 31,7; 29,1; 22,7; 14,2. Masse: 124 (M^+: 19), 67 (68), 54 (100).

Heptatriène-1,3,6 **2***c*: rmn ^1H ($CDCl_3$) δ: 5,5–6,5 (m, 5H), 4,9–5,25 (m, 3H), 2,3 (m, 2H) ppm; rmn ^{13}C ($CDCl_3$) δ: 137,3, 136,5, 132,5, 132,2, 115,8, 115,6, 35,8. Masse: 94 (M^+: 22), 79 (100).

Triméthylsilyl-1 butadiène-1,3 **2***d*: Les spectres de rmn ^1H et ir sont en accord avec ceux déjà décrits (21); rmn ^{13}C ($CDCl_3$) δ: 146,2, 141,1, 137,2, 119,6, −1,1.

Triméthylstannyl-1 butadiène-1,3 **2***e*: ir (film): 3100 (m), 3020 (f), 1570 (F); rmn ^1H ($CDCl_3$) δ: 5,2–7,2 (5H), 0,4 (s, 9H) ppm; rmn ^{13}C ($CDCl_3$) δ: 147,2, 140,1, 135,4, 116,6, −9.6. Masse (avec ^{120}Sn): 218 (M^+: 1,3), 203 (100), 165 (14).

Pentadiène-2,4 oate d'éthyle **2***f*: ir (film): 1720 (FF), 1650 (F), 1610 (F); rmn ^1H ($CDCl_3$) δ: 7,3 (m, 1H), 6,3–6,6 (m, 1H), 3,95 (d, J = 15 Hz, 1H), 5,4–5,7 (m, 2H), 4,25 (q, J = 7 Hz, 2H), 1,3 (t, J = 7 Hz, 3H) ppm; rmn ^{13}C ($CDCl_3$) δ: 144,8, 135, 125,6, 122,5, 60,5, 14,3.

Méthyl-5 octadiène-1,3 ol-4 **2***g*: ir (film): 3400 (F), 3100 (m), 1610 (F); rmn ^1H ($CDCl_3$) δ: 4,9–6,5 (m, 5H), 1,4–1,7 (m, 5H), 1,2 (s, 3H), 0,95 (t déformé, 3H) ppm; rmn ^{13}C ($CDCl_3$) δ: 141,2, 136,9, 128,6, 116,9, 73,1, 45,03, 28,1, 17,4, 14,7. Masse: 140 (M^+: 1,6), 97 (43), 43 (100).

Cyclohexyl-1 pentadiène-2,4 ol-1 **2***h*: ir (film): 3400 (F), 3100 (m), 1610 (F); rmn ^1H ($CDCl_3$) δ: 5–6,6 (massif, 5H), 2,05 (s, 1H), 1,6 (m, 10H) ppm; rmn ^{13}C ($CDCl_3$) δ: 144, 139, 130, 119, 73, 39, 26, 23.

Heptadiène-4,6 ol-3 **2***i*: ir (film): 3400 (F), 3100 (m), 1610 (F); rmn ^1H ($CDCl_3$) δ: 4,9–6,6 (m, 5H), 3,95 (m, 1H), 3,14 (s, 1H), 1,45 (m, 2H), 0,9 (t, J = 7 Hz, 3H) ppm. rmn ^{13}C ($CDCl_3$) δ: 136,6, 131,3, 117,5, 74,0, 30,3, 9,8. Masse: 112 (M^+: 7), 83 (79), 57 (100), 55 (68).

Nonadiène-1,3 ol-5 **2***j*: ir (film): 3400 (F), 3100 (f), 1610 (F); rmn ^1H ($CDCl_3$) δ: 5–6,5 (m, 5H), 4,15 (m, 1H), 2,12 (s, 1H), 1,38 (m, 6H), 0,89 (t déformé, 3H) ppm; rmn ^{13}C ($CDCl_3$) δ: 136,9, 136,6, 131,2, 117,6, 72,7, 37,1, 27,7, 22,8, 14,1. Masse: 86 (70), 84 (100).

Méthyl-5 hexadiène-1,3 **2***k*: rmn ^1H ($CDCl_3$) δ: 6,42 (2dd, J = 10,5 Hz, 17 Hz, 10,5 Hz, 1H), 6,11 (dd, J = 15 Hz, 10,5, 1H), 5,75 (dd, J = 15 Hz, 7 Hz, 1H), 5,14 (dd, J = 2 Hz, 17 Hz, 1H), 5,00 (dd, J = 2 Hz, 10,5 Hz, 1H), 2,23 (septuplet, J = 4,5 Hz, 1H), 0,83 (d, J = 4,5 Hz, 6H) ppm. Masse: 96 (M^+: 34), 81 (100), 53 (36).

Hexadiène-3,5 one-2 **2***l*: ir ($CDCl_3$): 3100 (f), 3040 (f), 1690 (m), 1670 (F), 1630 (m), 1595 (F); rmn ^1H ($CDCl_3$) δ: 7,12 (dd, J = 17 Hz, 10 Hz, 1H), 6,5 (m, 1H), 6,16 (d, J = 17 Hz, 1H), 5,4–5,8 (m, 2H), 2,23 (s, 3H) ppm; rmn ^{13}C ($CDCl_3$) δ: 198,5, 143,5, 135,5, 131,5, 126,3, 27,4. Masse: 96 (M^+: 26), 95 (23), 81 (19), 53 (100), 43 (50).

Nonadiène-6,8 one-5 **2***m*: ir (film): 3100 (f), 3040 (f), 1690 (F), 1670 (F), 1625 (F), 1595 (F); rmn ^1H ($CDCl_3$) δ: 7,2 (dd, J = 17 Hz, 10 Hz, 1H), 6,55 (m, 1H), 6,22 (d, J = 17 Hz, 1H), 5,5–5,8 (m, 2H), 2,6 (t, J = 8 Hz, 2H), 1,2–1,8 (massif, 4H), 0,93 (t, J = 6 Hz, 3H) ppm; rmn ^{13}C ($CDCl_3$) δ: 201, 142,5, 135,6, 130,6, 126,3, 40,5, 26,6, 22,6, 14,02. Masse: 138 (M^+: 2,2), 96 (24), 81 (66), 53 (100).

Nonatriène-1,3,8 one-5 **2***n*: ir (film): 3080 (m), 3040 (f), 1690 (F), 1670 (F), 1620 (F), 1590 (F); rmn ^1H ($CDCl_3$) δ: 7,08 (dd, J = 17 Hz, 10 Hz, 1H), 6,5 (m, 1H), 6,12 (d, J = 17 Hz, 1H), 5,4–5,9 (massif, 3H), 5,0 (m, 2H), 2,25–2,70 (m, 4H) ppm. Masse: 136 (M^+: 3), 94 (14), 81 (100), 53 (60).

*Préparation de la sulfone **10***

Dans un bicol muni d'une ampoule à brome et d'une entrée d'azote, on place 1,38 g (7,5 mmol) de sulfone **4** dissout dans 30 mL de THF anhydre. On ajoute lentement à la solution refroidie à −78°C 4,8 mL de nBuLi 1,55 *M* en solution dans l'hexane (7,5 mmol). On laisse agiter 10 min puis on ajoute 2,72 g (8 mmol) de l'éther tétrahydropyrannylique de l'iodo-8 octanol (20). On laisse agiter 1 h 30 à −78°C puis laisse revenir à température ambiante. On ajoute alors 80 mL d'eau + 50 mL d'éther, décante, extrait la phase aqueuse 2 fois avec 35 mL d'éther, sèche la phase éthérée sur $MgSO_4$ puis élimine les solvants au rotavapor. Le résidu (3,20 g) est chromatographié sur silicagel (éluant: hexane 75, acétate d'éthyle 25). On obtient par ordre d'élution: la sulfone dialkylée (630 mg), la sulfone **10** (1,87 g, 63%), la sulfone **4** de départ (175 mg).

*Sulfone **10***: ir ($CDCl_3$): 3070 (f), 1300 (F), 1140 (F); rmn ($CDCl_3$) δ: 6,19 (m, 2H), 4,55 (s élargi, 1H), 3,1–4,1 (m, 4H), 2,8–3,1 (m, 3H), 1,3–2,7 (massifs, 26H) ppm.

*Préparation de la sulfone **11***

Un mélange de 1,78 g (4,5 mmol) de sulfone **10**, 25 mL de méth-

anol, 1,2 mL d'eau et 40 mg d'acide paratoluène sulfonique est agité à 40°C pendant 2 h (disparition totale de **10**). Après évaporation du méthanol, le résidu est repris par 10 mL H_2O et extrait 3 fois avec 10 mL d'éther. La phase éthérée est séchée puis l'éther éliminé au rotavapor. On obtient 1,34 g d'alcool qui sont dissout dans 15 mL de CH_2Cl_2 anhydre. On ajoute à la solution en agitant 630 mg de triéthylamine puis 504 mg de chlorure d'acétyle. La réaction es terminée en 15 min (ccm). Après addition de 15 mL d'eau, décantation et extraction avec 2 fois 10 mL de CH_2Cl_2, les phases organiques sont séchées sur $MgSO_4$ puis le solvant éliminé au rotavapor. On obtient ainsi 1,42 g (90%) d';acétate **11**: ir ($CDCl_3$): 3070 (f), 1735 (F), 1300 (F), 1140 (F); rmn ($CDCl_3$) δ: 6,25 (m, 2H), 4,08 (t, J = 7 Hz, 2H), 1,2–3,4 (massifs, 26H avec 1 singulet à 2,07 ppm) ppm.

Dodécadiène-9,11 yl-1 acétate ***12***

La sulfone **11** (531 mg, 1,5 mmol) est thermolysée à 600°C (durée 1 h) et le produit de thermolyse est piégé sur la paroi d'un Dewar refroidie à −196°C. Après réchauffement à température ambiante, la paroi du Dewar est rincée avec 10 mL d'acétone, l'acétone évaporée et le résidu est chromatographié (30 g silice, éluant: hexane 90, éther 10). On obtient 242 mg (72%) d'acétate diénique **12** dont les caractéristiques spectrales (ir, rmn, masse) sont identiques à celles déjà rapportées (22). Sa pureté stéréoisomérique a été déterminée par chromatographie en phase vapeur sur cristaux liquides. Colonne en verre de 1,8 m × 2 mm de diamètre intérieur remplie de Gazchrom Q enrobé de 5% de (*p*-méthoxycinnamyloxy)-4 méthoxy-4′ azobenzène; température programmée à 4°/min à partir de 110°C. L'échantillon ainsi analysé contient au moins 98,5% d'isomère *E*.

Structure-reactivity correlation in inclusion complexes: deoxycholic acid di-*tert*-butyl thioketone

K. PADMANABHAN, K. VENKATESAN, AND V. RAMAMURTHY

Department of Organic Chemistry, Indian Institute of Science, Bangalore 560 012, India

Received January 12, 1984

This paper is dedicated to Professor Paul de Mayo on the occasion of his 60th birthday

K. PADMANABHAN, K. VENKATESAN, and V. RAMAMURTHY. Can. J. Chem. **62**, 2025 (1984).

Ultraviolet irradiation of crystalline molecular inclusion complexes of deoxycholic acid with di-*tert*-butyl thioketone results in no reaction. The structure of the above complex has been determined via X-ray diffraction. The absence of expected photoreactions, namely, photoreduction and photooxidation, is rationalized on the basis of the X-ray structure analysis of the complex.

K. PADMANABHAN, K. VENKATESAN et V. RAMAMURTHY. Can. J. Chem. **62**, 2025 (1984).

Lors de l'irradiation, par de la lumière uv, de complexes cristallins d'inclusion moléculaire d'acide déoxycholique en présence de la di-*tert*-butyl thiocétone il ne se produit aucune réaction. Faisant appel à la diffraction des rayons-X, on a déterminé la structure du complexe décrit plus haut. C'est en se basant sur une analyse de la structure du complexe, telle que déterminée par diffraction des rayons-X, que l'on rationalise le fait que les photoréactions attendues, soit une photoréduction et une photo-oxydation, ne se produisent pas.

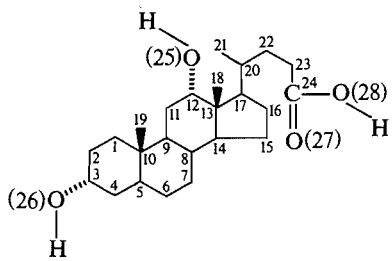
The control and modification of reactivity through incorporation of molecules into organized assemblies, functionalized polymers, and interfacial sites remain an area of considerable interest (1). Molecular inclusion complexes can serve as matrices for the performance of clean stereo and regiospecific reactions. The advantages of utilization of inclusion complexes (2) and host-controlled guest reactions (3) have been demonstrated quite recently. In this regard, we have initiated a programme utilizing thioketones as the guest molecules and deoxycholic acid (DCA, **1**) as the host with the view to bring about selective



1, DCA

functionalization of the host molecules or to achieve selectivity in the unimolecular photoprocesses of the guest thioketones. In our attempt to obtain crystals of complexes of DCA with thioketones **2**–**8**, only **2**–**4** gave good crystals with DCA. Photochemical and crystallographic results obtained with the inclusion complex of DCA and di-*tert*-butyl thioketone (**2**) are presented here.

Light red-coloured single crystals of the inclusion complex of DCA and **2** were powdered and irradiated using a low pressure mercury arc lamp. The progress of the photolysis was followed by the variation in the mp and the ir and ^{1}H-nmr spectra. Surprisingly, no change was observed even after 50 days of continuous exposure to uv radiation. Oxidation of **2** to the corresponding ketone and sulfine is a well-established reaction in solution (4). Further, facile photoreduction from S_2 of di-*tert*-butyl thioketone is known (5). Therefore the absence of the above reactions of **2** in the DCA matrix is unexpected. A systematic crystallographic study of the inclusion complex was thus undertaken in order to understand the non-reactivity of the

complex in terms of the three-dimensional arrangement.

Figure 1 shows the three-dimensional packing arrangement of the DCA–**2** complex in a unit cell. As mentioned in the Experimental section there are two guest molecules in the crystal lattice. The space group being $P_{2_12_12}$, it was expected that the molecular symmetry of the guest molecule would be a two-fold axis, the C=S bond being coincident with the crystallographic two-fold axis. However, it was found from a careful analysis of the crystal structure that the guest molecule exhibited an orientational disorder, as shown in Fig. 2, with the disordered arrangement exhibiting a two-fold axis of symmetry.

The two halves of the bilayer are related by a 2_1 axis at $b = 1/4$ and are parallel to the a axis. The bilayers are stacked along the b direction and are related by the two-fold rotation axis. The DCA molecules in the bilayer are held together by a helical system of intermolecular hydrogen bonds about the c-axis. (O(26)—H···O(27): 2.755(14) Å; O(28)—H···O(25): 2.644(10) Å; O(25)—H···O(26): 2.705(10) Å.) The

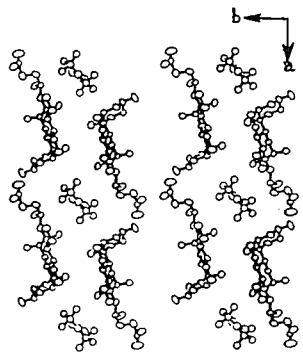

FIG. 1. Packing arangement of deoxycholic acid di-*tert*-butyl thioketone complex.

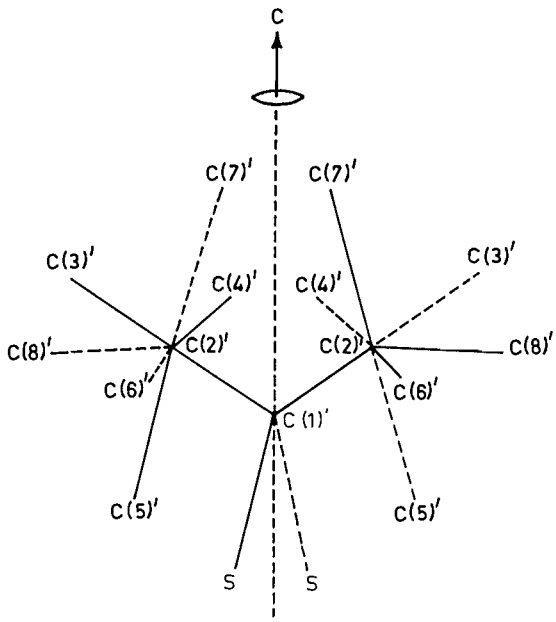

FIG. 2. Projection on the *XOZ* plane showing the two position of the disordered guest di-*tert*-butyl thioketone molecule (related by a two-fold axis).

overall packing of the DCA molecules in our crystal is the same as in DCA–camphor complex (2:1) (6*a*) which also crystallizes in $P_{2_12_12}$ with a = 27.353(3), b = 13.814(2), c = 7.233(1) Å. In both these complexes, the DCA channel walls are directly opposite, the molecules being related by the two-fold rotation axis. It may be noted again that the packing in the DCA:acetic acid complex (6*b*) is similar to the structure discussed in this paper. However, as the DCA:acetic acid complex crystallizes in $P_{2_12_12_1}$ with a = 25.55, b = 13.81, c = 7.109 Å, the opposite walls of DCA channel are staggered. Between the hydrophobic surfaces of adjacent DCA bilayers there are channels with cross sectional area of 4 × 7 Å^2 centered on the two-fold axis, and the void in the channel is sufficient to accommodate the guest thioketones. The interaction between the host and guest molecules is mainly of the van der Waals type.

The absence of an intermolecular addition reaction between the guest **2** and the host **1** is most unexpected for the reason that the thiocarbonyl chromophore has been established to undergo inter and intramolecular hydrogen abstraction reactions from both S_2 ($\pi\pi^*$) and T_1 ($n\pi^*$) states (7). Further, intermolecular topochemical photoaddition of aliphatic and aromatic ketones

TABLE 1. Intermolecular contacts (<5 Å) of importance for reactivity between host and guest atoms

(*a*) S(thione)···H(steroid) contacts (Å)

Atom pair	Distance	Atom pair	Distance
S···H(3)	4.92	S···1H(16)	3.60
S···1H(4)	4.49	S···1H(18)	4.22

to deoxycholic acid in the crystalline phase is known (2). However, the absence of such reactions in the present system may be rationalized on the basis of unfavourable intermolecular contacts in the crystal. Distances between the carbon and sulfur atoms of the thiocarbonyl chromophore and the host hydrogens (<5 Å) and those between the thiocarbonyl carbon and the steroid carbon (<5 Å) are listed in Table 1. Initial hydrogen abstraction by the thiocarbonyl chromophore can occur either by carbon or by sulfur. However, none of the hydrogens of DCA are within the sum of the van der Waals radii of hydrogen and either the carbon or sulfur of the thiocarbonyl group. Therefore, the first requirement for efficient hydrogen abstraction in the crystalline medium, namely, that the atoms involved are to be within the sum of the van der Waals radii (8) is not obeyed. However, violations especially in DCA–ketone complexes are known (2). In the ketone complexes investigated (2), the distance between O′(ketone) and H(steroid) range from 2.9 to 3.9 Å. Based on these results, one could expect thiocarbonyl sulfur to abstract any one of the following hydrogens: H(5), 1H(16), H(20), 1H(22), or 2H(22). But the distance between the steroid carbon and C′(thione) is too large to allow the resulting diradicals from the hydrogen abstraction to interact and form a C—C σ bond. The distance C(16)···C(1)′ alone is less than 5 Å, but even this is too large to allow the resulting diradicals from the abstraction of 1H(16) by sulfur to interact and eventually form the C(16)—C(1)′ bond. Thus in our case, hydrogen abstraction by sulfur and eventual carbon–carbon bond formation is not expected as all C′(thioketone) and C(steroid) distances are beyond these limits. Similarly, hydrogen abstraction by thiocarbonyl carbon may not occur due to the large distance between the reactive atoms as seen in Table 1.

The possible occurrence of photooxidation of the guest molecule in these crystals was also considered. It has been established that the photooxidation (to the corresponding carbonyls)

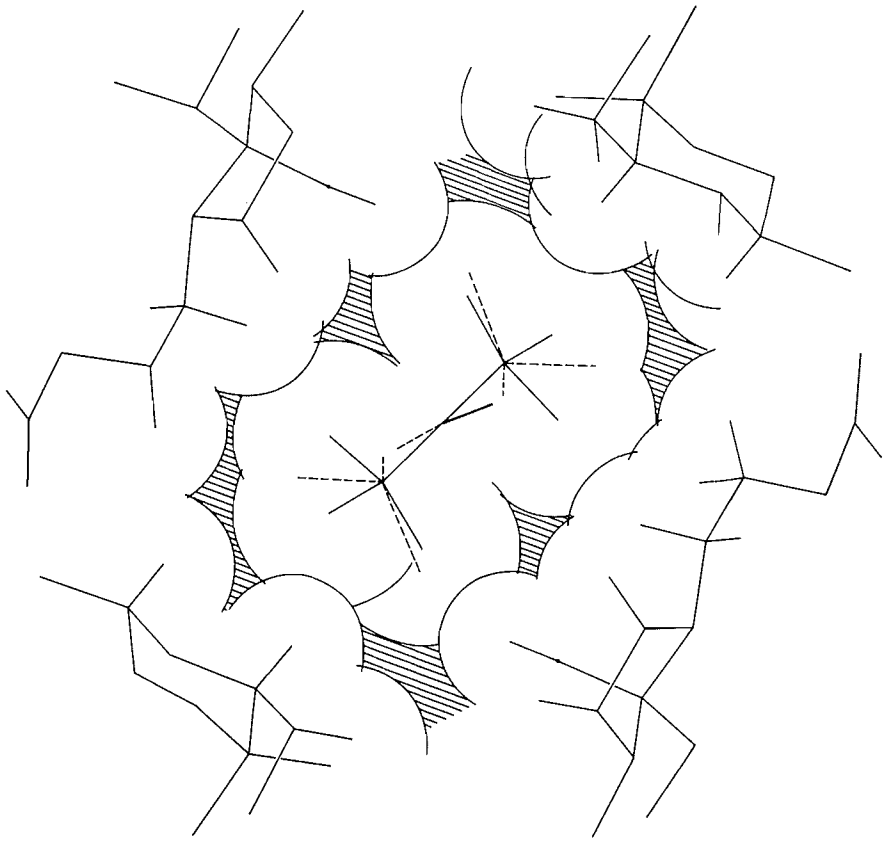

FIG. 3. Projection of the crystal packing down the *c*-axis showing a cross-section of the channel.

of a few thioketones occurs in the solid state if the molecular packing is such that there is enough void for the oxygen molecule to diffuse into the crystal lattice (9). It has been reported from our laboratory that di-*tert*-butyl thioketone is readily oxidized in solution to the corresponding ketone and *S*-oxides upon exposure to uv/visible light (4). In this connection, the inertness of **2** in the DCA matrix is quite remarkable. The modification of the reactivity of **2** by the DCA matrix can be understood on the basis of the X-ray crystal structure. the projection of the crystal packing down the channel axis (*c* axis) is shown in Fig. 3. It is quite obvious from this figure that, with the guest molecule occupying the void, there is no space for the molecular oxygen to diffuse into the crystal to effect oxidation of the guest molecules. At the most there can only be surface oxidation.

In conclusion, the absence of expected reactions of di-*tert*-butyl thioketone in the deoxycholic acid matrix has been understood on the basis of the molecular arrangement in the crystals.

Experimental

Di-*tert*-butyl thioketone was prepared by the reported procedure (10). Deoxycholic acid (Sigma) was used as received. Single crystals of the inclusion complex of DCA with di-*tert*-butyl thioketone were grown by slow evaporation of methanol from an ice cold solution containing a 2:1 molecular ratio of DCA and thione. The above crystals were light red and did not have a sharp melting point (mp 135–155°C). Formation of the inclusion complex was identified by its spectral properties both in solution and the solid state. An ethanol solution of these well grown crystals had the following spectral characteristics indicating the inclusion of the thione. uv (EtOH) λ_{max}: 536; 237 nm; ^{1}H nmr ($CDCl_3$): δ1.1 (s, 18H) in addition to DCA hydrogen signals. Confirmatory evidence for the inclusion of the thioketone in DCA came from the solid state ir and solid state ^{13}C-nmr spectra: ir (KBr): 1115 cm^{-1} (C=S); ^{13}C-nmr: δ 275.0 (C=S), 54.1 C(*t*Bu), 33.1 $(CH_3)_3$ in addition to the DCA carbon signals.

Photolysis

Powdered single crystals of the complex were irradiated using a low pressure mercury arc lamp (254 nm) in a petri dish. Samples were turned around periodically to provide uniform exposure. The progress of the irradiation was monitored by the variation in mp, ^{1}H-nmr and ir spectra. However, no change was observed even after 50 days of irradiation.

X-ray structural analysis

Unit cell dimensions were determined from the least-squares analysis of diffractometer measurements for 20 centered reflections: a = 13.933(1), b = 27.294(3), c = 7.285(2) Å, V = 2770.3 Å^3, Z = 4 ($C_{24}H_{40}O_4 \cdot \frac{1}{2}C_9H_{18}S$) and d = 1.130 g cm^{-3} (floatation in aqueous KI).

Intensity data were collected on an Enraf-Nonius CAD-4 diffractometer using monochromated MoKα radiation (λ = 0.71073 Å) in $\omega/2\theta$ scan mode for a crystal of dimensions 0.06 × 0.25 × 0.44 mm^3. A total of 2830 reflections were collected, out of which 1364 were considered significant $|F_o| \geq 3\sigma(|F_o|)$. Lorentz and polarization corrections were applied but the absorption correction was not considered important (μ = 0.75 cm^{-1}). The structure was solved by the direct methods program "MULTAN-80" (11). From the E map with 300 reflections ($E \geq 1.331$), 26 out of 28 non-hydrogen atoms of the host molecule were identified. The remaining two atoms were fixed after a Karle recycling (12) operation using these 26 atoms.

A difference electron density map calculated at this stage showed clearly that the guest molecule is disordered, with the two orientations of the molecule related by the two-fold axis on which the atom C(1)′ lies (Fig. 2). The difference map calculated at R = 0.132 revealed further disorder for the *tert*-butyl methyl groups corresponding to hindered rotation about the C(1)′—C(2)′$(CH_3)_3$ bond. The full-matrix least-squares refinement (SHELX 76) (13) of the positional and anisotropic thermal parameters of 28 non-hydrogen atoms of the DCA

molecule and the positional and isotropic thermal parameters of 40 hydrogens (kept fixed in the penultimate cycles) of the DCA and the positional and isotropic termperature factors of the non-hydrogen atoms of di-*tert*-butyl thioketone with an occupancy value of 0.5 using the weighting scheme $w = 1/\sigma^2(|F|) + 0.0058\,|F|^2$ has led to a final R-value of 0.101 for the significant reflections. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$.[1]

Photochemistry of methyl(hydrido)diplatinum(II) complexes, including examples of C—H and C—C bond formation by intramolecular reductive elimination[1]

KAZI A. AZAM, ROSS H. HILL, AND RICHARD J. PUDDEPHATT[2]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 16, 1984

This paper is dedicated to Professor Paul de Mayo on the occasion of his 60th birthday

KAZI A. AZAM, ROSS H. HILL, and RICHARD J. PUDDEPHATT. Can. J. Chem. **62**, 2029 (1984).

Photolyses of the complex cations $[Pt_2H(\mu\text{-}H)Me(\mu\text{-}dppm)_2]^+$, $[Pt_2(\mu\text{-}H)Me_2(\mu\text{-}dppm)_2]^+$, and $[Pt_2Me_3(\mu\text{-}dppm)_2]^+$ lead to reductive elimination of H_2, CH_4, and C_2H_6, respectively. However, photolysis of $[Pt_2Me_3(\mu\text{-}dppm)_2]^+$ in pyridine gives $[PtMe_2(dppm)]$ and $[PtMe(C_5H_5N)(dppm)]^+$. The reductive eliminations of CH_4 and C_2H_6 are shown to be primarily intramolecular reactions by isotopic labelling. Quantum yields are reported and the mechanisms of reaction discussed.

KAZI A. AZAM, ROSS H. HILL et RICHARD J. PUDDEPHATT. Can. J. Chem. **62**, 2029 (1984).

Les photolyses des complexes cationiques $[Pt_2H(\mu\text{-}H)Me(\mu\text{-}dppm)_2]^+$, $[Pt_2(\mu\text{-}H)Me_2(\mu\text{-}dppm)_2]^+$ et $[Pt_2Me_3(\mu\text{-}dppm)_2]^+$ conduisent respectivement à des éliminations réductrices de H_2, CH_4 et C_2H_6. Toutefois, la photolyse de $[Pt_2Me_3(\mu\text{-}dppm)_2]^+$ dans la pyridine fournit du $[PtMe_2(dppm)]$ et du $[PtMe(C_5H_5N)(dppm)]^+$. Faisant appel à des marquages isotopiques, on démontre que les éliminations réductrices de CH_4 et C_2H_6 sont principalement des réactions intramoléculaires. On rapporte les rendements quantiques et on discute des mécanismes réactionnels.

Introduction

In previous papers we have reported the synthesis and reactions of the complexes ions $[Pt_2H_nMe_{3-n}(\mu\text{-}dppm)_2]^+$, n = 0–3, dppm = $Ph_2PCH_2PPh_2$, **1**–**4** (1–6).

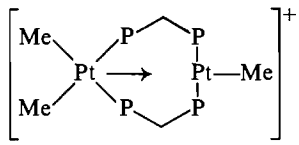
3, X = Y = Me



4

The thermal and photochemical reductive elimination of H_2 from complex **1** was been well studied (3, 7–13) but the properties of **2**–**4** have not been investigated in detail. Complex **2** undergoes reductive elimination of methane on treatment with the alkyne $CF_3C{\equiv}CCF_3$, but hydrogen is eliminated on reaction with tertiary phosphines (5, 6). Complex **3** undergoes reductive elimination of methane on reaction with $CF_3C{\equiv}CCF_3$, but reacts only very slowly with phosphines (4, 6), while **4** is stable to thermal reductive elimination (2). All complexes **1**–**4** have been shown to be photosensitive, but only for **1** has the reaction been studied in detail (reaction [1], L = C_5H_5N, MeCN, or tetrahydrofuran) (7–9).

[1] $1 + L \xrightarrow{h\nu}$  $+ H_2$

5*a*, L = C_5H_5N
5*b*, L = MeCN

The photochemical reactions of **2**–**4** are of considerable interest because, potentially, they can lead to binuclear coupling of C—H or C—C bonds and such reductive eliminations (or the reverse oxidative additions) are significant in catalysis involving formation or activation of alkanes at transition metal centres (14–20). There have been no detailed studies of photochemical reductive eliminations leading to C—H or C—C bond formation even in mononuclear systems, and there are only a few qualitative reports of such reactions (4, 14, 21–25). This article reports a study of the photochemistry of complexes **2**–**4**, with particular emphasis on **3** and **4** which can give reductive elimination of methane and ethane, respectively. A preliminary account of parts of this work has been published (26).

Results

Photochemistry of the methyl(hydrido)diplatinum complexes 2 and 3

Photolysis of complexes **2** and **3** in pyridine or acetonitrile solution occurred according to eqs. [2] and [3], giving in each case the methyldiplatinum(II) complex.

[2] 
6*a*, S = C_5H_5N
6*b*, S = MeCN
6*c*, S = Me_2CO

[3] 
The gaseous products, H_2 or CH_4, were detected using gas chromatography. In reaction [3] no ethane was detected, while in reaction [2] only a trace of the alternative product methane was detected. The complexes **6***a* and **6***b* were formed without

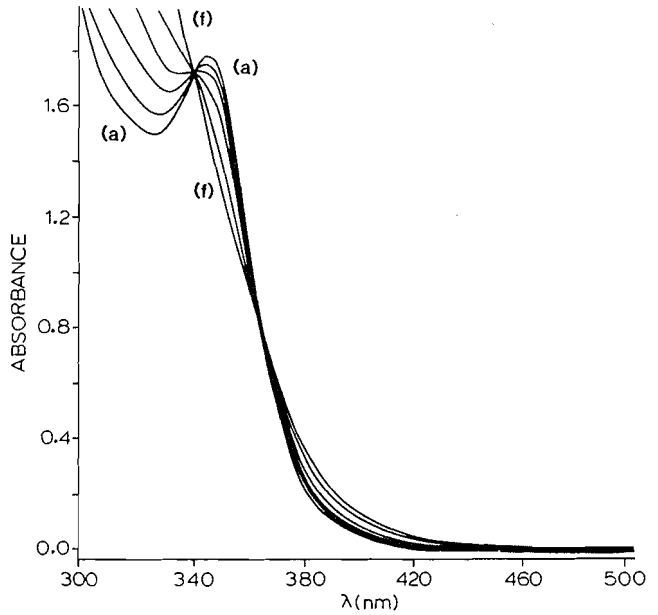

FIG. 1. Changes in the uv–visible absorption spectrum on irradiation of **2** in MeCN, with the following numbers of Einsteins of incident light (362 ± 7 nm): (*a*) 0, (*b*) 4.0×10^{-7}, (*c*) 8.0×10^{-7}, (*d*) 14.4×10^{-7}, (*e*) 26.4×10^{-7}, (*f*) extended irradiation.

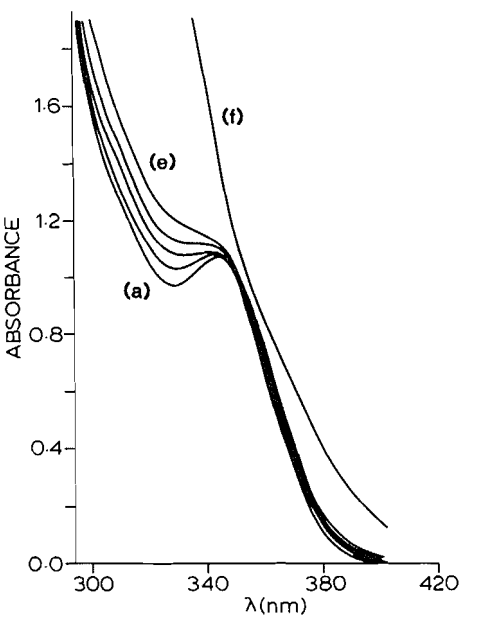

FIG. 2. Changes in the uv–visible absorption spectrum on irradiation of **3** in MeCN, with the following numbers of Einsteins of incident light (362 ± 7 nm): (*a*) 0, (*b*) 3.6×10^{-7}, (*c*) 6.0×10^{-7}, (*d*) 8.4×10^{-7}, (*e*) 11.2×10^{-7}, (*f*) extended irradiation.

detectable impurities (^{1}H and ^{31}P nmr spectra) of the alternative products **5***a* and **5***b*, respectively, indicating that the reactions are very selective.

Complex **6***a*, as the $[SbF_6]^-$ salt, is a yellow solid, which is stable in air at room temperature. It was characterized by elemental analysis and by the ^{1}H and $^{31}P\{^1H\}$ nmr spectra. The spectra are very characteristic and the parameters (Experimental section) are very similar to those for other methyldiplatinum(I) complexes $[Pt_2MeL(\mu\text{-dppm})_2]^+$, with L = tertiary phosphine, which have been discussed in detail elsewhere (5, 27). Complexes **6***b* and **6***c*, with the weakly co-ordinated MeCN or Me_2CO ligands, were not sufficiently stable to be isolated but were positively characterized by comparison of the ^{1}H nmr data with those for **6***a*, and by conversion to **6***a* on addition of pyridine.

Reaction [2] involving reductive elimination of H_2 is analogous to reaction [1] studied previously (7–9), but reaction [3] is of a new and significant type and so a labelling experiment was carried out to determine if reductive elimination of methane is an intramolecular or intermolecular process. A mixture of $[Pt_2(\mu\text{-H})Me_2(\mu\text{-dppm})_2][PF_6]$ and $[Pt_2(\mu\text{-D})(CD_3)_2(\mu\text{-dppm})_2][PF_6]$ gave CH_4 and CD_4, with only traces of CH_3D or CD_3H, on photolysis. It is thus proved that intramolecular reduction elimination occurs. When photolysis was not complete, the yield of CH_4 was greater than that of CD_4. This suggests that, as in the photolysis of **1**, there is a significant primary isotope effect on the rate of reaction (9).

Quantum yields for photolysis of **2** or **3** in pyridine or acetonitrile were determined by irradiation of rigorously degassed solutions in quartz cuvettes with 362 ± 7 nm light from a Jasco Spectroirradiator, previously calibrated using ferrioxalate actinometry. Typical sets of uv–visible absorption spectra obtained during irradiation of **2** and **3** are shown in Figs. 1 and 2. For photolysis of **2** good isosbestic points were observed (Fig. 1) but for photolysis of **3** there were no crossover points in the uv–visible spectra (Fig. 2). In each case, the extent of reaction was determined by monitoring the optical density at suitable points, and good linear plots of quanta absorbed by **2** or **3** vs. extent of conversion were then obtained. From these data, the quantum yields were determined and their values are given in Table 1.

TABLE 1. Quantum yields (362 ± 7 nm) for photolysis of diplatinum complexes

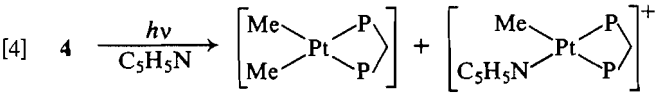
Complex	Quantum yield[a] py	MeCN	Reference
$[Pt_2H_2(\mu\text{-H})(\mu\text{-dppm})_2][PF_6]$	0.57	0.81[b]	9
$[Pt_2H(\mu\text{-H})Me(\mu\text{-dppm})_2][SbF_6]$	0.21	0.37	This work
$[Pt_2(\mu\text{-H})Me_2(\mu\text{-dppm})_2][PF_6]$	0.30	0.34	This work
$[Pt_2Me_3(\mu\text{-dppm})_2][PF_6]$[c]	0.6	0.1	This work

[a]In all cases, these are Φ for photodecomposition of reagent.
[b]Geoffroy *et al.* quote Φ = 0.62 for photolysis using 366 nm light (7).
[c]Φ = 0.6 in C_6H_6, 1.2 ± 0.3 in acetone, 2.0 ± 0.1 in CH_2Cl_2.

It can be seen from Table 1 that the quantum yields for photolysis of **1**–**3** are all high, with Φ for **1** > **2** ≈ **3**, and the quantum yields are in all cases slightly higher in acetonitrile than in pyridine.

Photochemistry of the trimethyldiplatinum(II) complex, 4

Photolysis of complex **4** in pyridine gave no gas evolution, and monitoring by ^{1}H and $^{31}P\{^1H\}$ nmr indicated that the products were mononuclear complexes as shown in reaction [4].



These complexes could not be separated, but were positively identified by the ^{1}H and $^{31}P\{^1H\}$ nmr spectra. $[PtMe_2(dppm)]$ is a known complex and was characterized by comparison of the nmr parameters with those for an authentic sample (28, 29). A sample containing the cation $[PtMe(C_5H_5N)(dppm)]^+$ was pre-

pared independently by reaction of [PtClMe(dppm)] with 1 mol-equiv. of silver nitrate followed by excess pyridine. The ^1H and $^{31}P\{^1H\}$ nmr spectra, which are very characteristic (Experimental section), were identical with those of the second photolysis product of reaction [4].

Extended photolysis of the above mixture did lead to some ethane formation and an uncharacterized symmetrical diplatinum complex was also formed. The quantum yield of the primary photochemical reaction of reaction [4] was high (Table 1) but the secondary photolysis was very inefficient and has not been studied in detail.

Photolysis of **4** in acetonitrile occurred cleanly in the initial stages to give ethane and complex **6***b*, identified by its ^1H and $^{31}P\{^1H\}$ nmr and uv–visible absorption spectra. However, the quantum yield was low (Table 1), and, as a result, further photolysis of product **6***b* became competitive in the later stages and the isosbestic points were lost. This reaction gave the first indication of a photochemical reductive elimination with C—C bond formation, and so the photolysis was studied in several other solvents.

Efficient reductive elimination of ethane occurred on photolysis of **4** in benzene, acetone, or dichloromethane as solvents. In benzene, the product of photolysis was very insoluble and precipitated during photolysis so that an accurate quantum yield could not be obtained. In acetone, the primary products were C_2H_6 and complex **6***c* and the stoichiometry was clean until the late stages, when photolysis of **6***c* became a problem. In this reaction 1.0 ± 0.1 mol of ethane was formed for each mol of **4** decomposed and the quantum yield (362 ± 7 nm) was 1.2 ± 0.3. The large uncertainty in the quantum yield arose due to problems with the secondary photolysis of **6***c*. The quantum yield is within experimental error of 1.0, and is an order of magnitude greater than that in acetonitrile solvent.

In dichloromethane solution, the stoichiometry of reaction was different and only 0.5 mol of C_2H_6 was formed for each mole of **4** decomposed (reaction [5]).

$$[5]\quad 2[Pt_2Me_3(\mu\text{-dppm})_2]^+ \xrightarrow[CH_2Cl_2]{h\nu} 2[Pt_2Me_2(\mu\text{-Cl})(\mu\text{-dppm})_2]^+ + C_2H_6$$

The product **7** has been characterized previously (29) and was isolated in quantitative yield. It is clear that a chlorine atom abstraction from solvent dichloromethane occurs during this reaction. The quantum yield for disappearance of **4** was 2.0 ± 0.1.

Because this clean photochemical C—C coupling reaction has no precedents, attempts were made to determine if the elimination is an intramolecular process. Photolysis of an equimolar amount of $[Pt_2Me_3(\mu\text{-dppm})_2][PF_6]$ and $[Pt_2(CD_3)_3(\mu\text{-dppm})_2][PF_6]$ in CH_2Cl_2 or acetone gave a product ratio of C_2D_6:CH_3CD_3 of 1:0.4 and 1:1.0, respectively (C_2H_6 yields could not be determined accurately due to high background at m/e 30, under the conditions used, with analysis by mass spectrometry). An intramolecular reaction should give C_2D_6:CH_3CD_3 = 1:0, while an intermolecular coupling reaction should give a ratio of 1:2. The experiment thus proves that at least 50% of the reaction occurs by intramolecular coupling in acetone and at least 80% in dichloromethane.

An effort was made to determine which two methyl groups in **4** were eliminated. However, an attempt to synthesize the unsymmetrical labelled complex ion $[(CD_3)_2Pt(\mu\text{-dppm})_2Pt\text{-}CH_3]^+$ by reaction of $[Pt(CD_3)_2(dppm)]$ with [PtClMe(dppm)] gave a sample of **4** in which complete scrambling of CD_3 and CH_3 groups had occurred, as determined by ^1H nmr spectroscopy. Thus it was not possible to solve this important problem. We suspect that the alkyl-for-alkyl exchange reactions which lead to this scrambling, and which have also been observed in other diplatinum complexes (30), may also account for the apparent intermolecular component of the reductive elimination reaction noted above.

Discussion

The photolyses of the family of complex cations, **1**–**3**, in each case leads to an overall binuclear reductive elimination in which the formal oxidation state of each platinum centre decreases from +II to +I. The reactions are very selective. Thus complex **2** gives hydrogen rather than CH_4 and complex **3** gives CH_4 rather than C_2H_6, and so it can be concluded that bond formation is favoured in the sequence H—H > CH_3—H > CH_3—CH_3 in these complexes. However, it should be noted that, in **1**–**3**, hydride occupies the bridging position and, since it is possible that the reaction always involve loss of the bridging ligand, only for **2** is there positive evidence that H—H bond formation is preferred rather than CH_3—H bond formation. The same selectivity is observed in thermal reductive eliminations induced by tertiary phosphine ligands (4, 5, 27), but hexafluorobut-2-yne induces selective reductive elimination of methane from **2** (6). In the thermal reactions, the rates of reaction follow the sequence **1** > **2** ≫ **3** (4, 13, 27), but there are only small differences in the rates of the photochemical reactions (Table 1). In particular, the quantum yields for photolysis of **2** (which gives H_2) and **3** (which gives CH_4) are very similar.

It has been proved that the reductive eliminations from **1** and **3** are intramolecular, but the detailed mechanisms of reaction cannot be determined unequivocally. For photolysis of **1**, a mechanism involving reductive elimination of H_2 from a single metal centre was proposed (9), but a subsequent study of the thermal reductive elimination suggested a true binuclear reductive elimination in which hydride ligands coupled across two platinum centres (13). The results from the present study can be interpreted in terms of either mechanism (see refs. 13, 18, 30, 32–35 for related discussions of mechanisms in binuclear and cluster complexes), but the primary photochemical step in all cases is probably the cleavage of the $Pt_2(\mu\text{-H})$ linkage by excitation of an electron to a σ^*(PtPt) orbital (9, 31).

The photochemically-induced reductive elimination of ethane from **4** appears to be a unique reaction. Photolysis of alkyl transition metal complexes usually gives homolysis of the M—C bond to give alkyl radicals (36, 37), though β-elimination, isomerization, loss of other ligands with no reaction of the M—R bond, and other reactions can also occur (22–25, 38–40). Photolysis of mononuclear alkyl platinum(II) or alkylplatinum(IV) complexes leads primarily to the formation of alkyl radicals (41–43), though reductive elimination may be oberved with platina(IV)cycloalkanes (22, 23, 44, 45). There are two properties of **4** which might lead to its unique reactivity. Firstly, the primary photochemical process almost certainly will involve cleavage of the Pt—Pt bond by excitation of an electron to the σ^*(PtPt) orbital, and this excited state is not possible with mononuclear complexes. However, it is not obvious why this excited state should cause reductive elimination from the dimethylplatinum centre (46). Secondly, since **4** is binuclear, new mechanisms, such as a coupling of methyl groups across two platinum centres, become available. The experimental data cannot distinguish between these

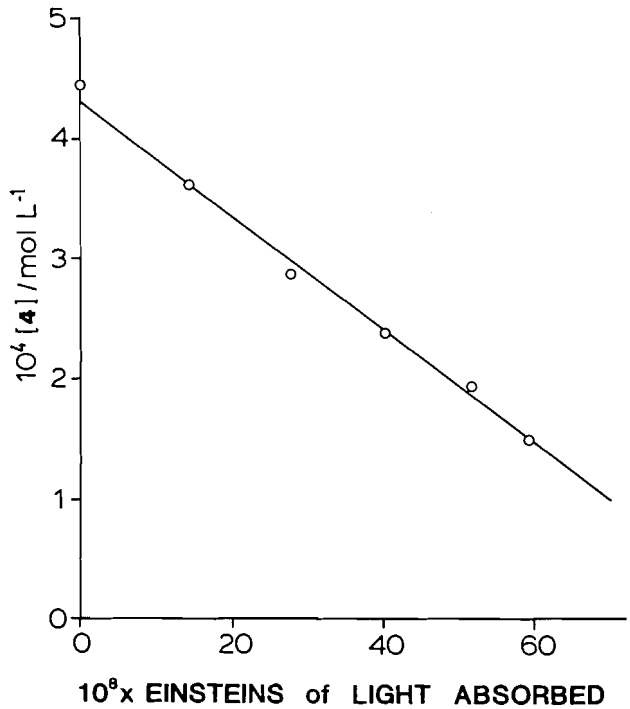

FIG. 3. Plot of concentration of **4** (mol L^{-1}) vs. light (362 ± 7 nm) absorbed by **4** (E), showing that the quantum yield is independent of concentration of **4**.

possibilities.

We have shown that the reductive elimination of ethane is at least partially intramolecular by a labelling experiment, and we believe that this reaction is almost entirely intramolecular. In order to give the observed quantum yields (Table 1) for an intermolecular elimination, the lifetime of the excited state would need to exceed 10^{-5} s to allow complete quenching by a second molecule of **4** (assuming $k_q \sim 10^{10}$ s^{-1} and ~99% efficiency of quenching) at the concentrations used. Few lifetimes of organometallic excited states have been measured but most such lifetimes are $<10^{-6}$ s at 298 K (47). In addition, an intermolecular process should give a concentration-dependent quantum yield which was not observed (Fig. 3).

Finally, a comment is needed on the solvent dependence of the quantum yields and reaction products. The good donor pyridine can presumably co-ordinate to the monomethylplatinum centre of **4** after photochemical cleavage of the PtPt bond, and cleavage of the dimer to mononuclear fragments (reaction [4]) follows. In the poor donor solvent acetone, the excited state gives intramolecular loss of C_2H_6 with a quantum yield of ~1. The lower quantum yield in acetonitrile may be explained if this is a good enough ligand for platinum to co-ordinate reversibly and hence deactivate the excited state but not good enough to cause breakdown to mononuclear fragments. Finally, in dichloromethane intramolecular loss of ethane from **4** gives $[Pt_2Me(\mu\text{-dppm})_2]^+$, which must then accept a methyl group from a second molecule of **4** in a rapid thermal reaction and abstraction of Cl radicals from CH_2Cl_2 solvent gives the observed product (reaction [5]). The true quantum yield for the reductive elimination is therefore 1.0.

Experimental

^1H and $^{31}P\{^1H\}$ nmr spectra were recorded using Varian XL100 or XL200 NMR spectrometers, and chemical shifts are quoted with respect to TMS or trimethylphosphate, respectively. Gas analysis (H_2, CH_4, and C_2H_6) was carried out by injection of a standard volume of gas formed in the photochemical reaction into a Varian Series 1400 gas chromatograph. Calibration was carried out by injection of known volumes of the pure gases into the reaction vessel containing only solvent, then allowing to equilibrate and sampling as above. The columns used were 6′ × 1/8″ packed with Molecular Sieve 5A or Porapak Q.

[Pt(CD$_3$)$_2$(dppm)]

A solution of CD_3Li (24 mL, 1.7 *M*), freshly prepared from Li and CD_3I in ether, was added dropwise to a suspension of $[PtCl_2(dppm)]$ (1.52 g) in ether (30 mL) cooled to 0°C. The solution was allowed to warm to room temperature. After 1 h, the mixture was hydrolysed with cold saturated aqueous NH_4Cl solution (5 mL). The layers were separated, and the aqueous layer was further extracted with CH_2Cl_2. The organic extracts were dried over $MgSO_4$ and evaporated to yield the product (0.62 g).

[Pt$_2$(CD$_3$)$_3$(μ-dppm)$_2$][PF$_6$]

A mixture of $[Pt(CD_3)_2(dppm)]$ (0.19 g) and $[PtCl_2(dppm)]$ (0.066 g) in methanol (15 mL) was heated under reflux for 1 h. $[NH_4][PF_6]$ (0.12 g) was then added, heating was continued for 5 min, the solution was cooled, and water was added dropwise to precipitate the product as a yellow solid. This was purified by precipitation from CH_2Cl_2 solution by slow addition of hexane, and was identified by the ^1H and $^{31}P\{^1H\}$ nmr spectra (2).

[Pt$_2$(μ-D)(CD$_3$)$_2$(μ-dppm)$_2$][PF$_6$]

This was prepared by the literature method for the synthesis of **3** (4), but using $[Pt(CD_3)_3(\mu\text{-dppm})_2][PF_6]$ (0.09 g), $NH_4[PF_6]$ (0.06 g) in CH_3OD (10 mL) with $Na[BD_4]$ (0.1 g) in CH_3OD (3 mL). The yield was 0.06 g (70%) and the complex was characterised by the ^1H and $^{31}P\{^1H\}$ nmr spectra (4).

[Pt$_2$Me(C$_5$H$_5$N)(μ-dppm)$_2$][SbF$_6$]

A solution of $[Pt_2H(\mu\text{-H})Me(\mu\text{-dppm})_2][SbF_6]$ (0.05 g) in dry pyridine (20 mL) was deoxygenated by passing nitrogen through the solution for 45 min. The reaction vessel was a flat-sided Pyrex flask, with a sidearm fitted with a 1 mm quartz cuvette to allow monitoring of the reaction by uv–visible absorption spectroscopy. The solution was irradiated for 2h, using a medium pressure Hg lamp 12 cm from the sample and using a water filter, after which no further change in absorption spectrum occurred. A sample of the gas phase was analysed by gc, and showed hydrogen and a trace of methane to be present. The solvent was then removed under high vacuum to give the product as a yellow solid in quantitative yield. *Anal.* calcd. for $C_{56}H_{52}NF_6P_4Pt_2Sb$: C 45.2, H 3.5; found: C 44.7, H 3.6. ^{1}Hmr (C_5D_5N)δ: 0.53[*m*, ^2J(PtH) 72.5, ^3J(PH) 11, *Me*Pt], 5.29[*m*, CH_2P_2]. ^{31}Pmr (C_5D_5N)δ: 8.4[*m*, $^1J(PtP^A)$ 2930], −4.7[*m*, $^1J(PtP^B)$ 2850, $^2J(P^AP^B)$ 37.5, $^3J(P^AP^{B'})$ 57.5].

This same product was formed by the similar photolysis of $[Pt_2(\mu\text{-H})Me_2(\mu\text{-dppm})_2][SbF_6]$ (0.03 g) in pyridine (5 mL), but in this case the only gaseous product was CH_4. The product was identified by the ^1H and $^{31}P\{^1H\}$ nmr spectra.

[Pt$_2$Me(Me$_2$CO)(μ-dppm)$_2$][PF$_6$]

A solution of $[Pt_2Me_3(\mu\text{-dppm})_2][PF_6]$ (0.05 g, 3.9×10^{-5} mol) in dry acetone (5 mL), in an apparatus with a sidearm fitted with a 1 mm quartz cuvette, was degassed by several freeze–pump–thaw cycles and then photolysed using a 150 W xenon lamp with water and Corning 0-52 filters. The reaction was monitored by uv–visible spectroscopy, and when complete the gaseous phase was analysed by gc. Ethane ($4.0 \pm 0.2 \times 10^{-5}$ mol) was the only gas formed.

The product was isolated as a yellow solid by evaporation of the solvent under high vacuum, and was identified by the ^1H nmr spectrum in $(CD_3)_2CO$ [δ: 0.29, ^2J(PtH)70, ^3J(PH)7.5, *Me*Pt] and by conversion to $[Pt_2Me(C_5H_5N)(\mu\text{-dppm})][PF_6]$ on addition of pyridine. The acetone complex decomposed over a period of several hours to an unidentified product having δ 0.24 [*m*, ^2J(PtH)82, ^3J(PH)7].

This product **6***c*, as the SbF_6^- salt, was also prepared by similar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

photolysis of a degassed solution of $[Pt_2H(\mu\text{-}H)Me(\mu\text{-}dppm)_2][SbF_6]$ (0.10 g) in $(CD_3)_2CO$ (0.7 mL) and was identified as above.

$[Pt_2Me(CD_3CN)(\mu\text{-}dppm)_2][SbF_6]$

This was obtained and identified by photolysis of $[Pt_2H(\mu\text{-}H)Me(\mu\text{-}dppm)_2][SbF_6]$ in CD_3CN as described above. ^{1}Hmr (CD_3CN)δ: 0.80[m, ^2J(PtH)60, ^3J(PH)6.5 Hz]. This complex was stable in CD_3CN solution in the absence of oxygen, but decomposed on evaporation of the solvent. The same product was formed by similar photolysis of $[Pt_2(\mu\text{-}H)Me_2(\mu\text{-}dppm)_2][SbF_6]$ or, as the PF_6^- salt, by photolysis of $[Pt_2Me_3(\mu\text{-}dppm)_2][PF_6]$.

Photolysis of $[Pt_2Me_3(\mu\text{-}dppm)_2][PF_6]$ in CD_2Cl_2

$[Pt_2Me_3(\mu\text{-}dppm)_2][PF_6]$ (0.0843 g) was dissolved in CD_2Cl_2 (1 mL) in a 5 mm nmr tube. The solution was then degassed, flame sealed, and then irradiated using a 150 W xenon lamp source filtered through Corning 0-52 and H_2O filters. Photolysis was continued for 30 min. The ^{1}H and ^{31}P{^{1}H} nmr spectra showed the product to be $[Pt_2Me_2(\mu\text{-}Cl)(\mu\text{-}dppm)_2][PF_6]$ (29).

The nmr tube was then opened and the gas product analysed by gc. The gases C_2H_6, CH_4, and C_2H_4 were observed in a ratio of 1:0.08:0.02. The absolute yield of C_2H_6 was 45% mol/mol **4** decomposed.

$[PtMe(C_5H_5N)(dppm)][NO_3]$

A solution of $AgNO_3$ (0.060 g) in methanol (12 mL) was added dropwise to a solution of [PtClMe(dppm)] (0.20 g) (29) in CH_2Cl_2 (50 mL). The mixture was then filtered to remove AgCl and pyridine (0.5 mL) was added. After 10 min, the solvent was evaporated under vacuum to give the product. This was characterised by the nmr spectra in C_5D_5N. ^{31}Pmr, δ: −26.6[*m*, $^2J(P^AP^B)$38, $^1J(PtP^A)$-3388, P^A *trans* to C_5H_5N], −42.3[*m*, $^2J(P^AP^B)$38, $^1J(PtP^B)$1270, P^B *trans* to Me]. ^{1}Hmr, δ: 1.02 [*m*, $^3J(P^BH)$8, $^3J(P^AH)$3, ^2J(PtH)61, *Me*Pt]. These assignments were confirmed by selective ^{31}P decoupling experiments.

When the photolysis of $[Pt_2Me_3(\mu\text{-}dppm)_2][PF_6]$ was carried out in C_5D_5N with monitoring by ^{1}H and ^{31}P{^{1}H} nmr, an equimolar mixture of [$PtMe_2$(dppm)] (29) and $[PtMe(C_5D_5N)(dppm)]^+$ was formed. The parameters for the latter complex were identical with those of the sample prepared above.

Quantum yield determinations

Irradiations were performed with a Jasco CRM-FA Spectro-irradiator equipped with a counter. The light flux and counter were calibrated by using ferrioxalate actinometry at 362 ± 7 nm.

In a typical experiment, a solution of $[Pt_2Me_3(\mu\text{-}dppm)_2][PF_6]$ in CH_2Cl_2 (4.0 mL, 4.45×10^{-4} *M*) was degassed by three freeze−pump−thaw cycles, each time pumping to a residual pressure of 5×10^{-5} mbar at 77 K. The solution was then flame sealed in a 1 cm quartz cuvette. The reaction was monitored by following the change in optical density at 440 nm. The data were then analysed by calculating the concentration of $[Pt_2Me_3(\mu\text{-}dppm)_2]^+$ after each irradiation. From this an average concentration over each irradiation interval, and hence the percent light absorbed was calculated. Linear plots of $[Pt_2Me_3(\mu\text{-}dppm)_2]^+$ concentration vs. quanta of light absorbed by $[Pt_2Me_3(\mu\text{-}dppm)_2]^+$ were obtained (correlation coefficient > 0.99). The quantum yields were then calculated from the slopes of these lines.

The quantum yield measurement in benzene was complicated by precipitation of a white microcrystalline material after ~40% reaction at which stage an isosbestic point at 360 nm was lost. The final absorption was estimated and the quantum yield calculated as 0.6. The error due to this estimation is difficult to assess.

Proof of intramolecular reaction

A mixture of $[Pt_2(\mu\text{-}D)(CD_3)_2(\mu\text{-}dppm)_2][PF_6]$ (0.025 g) and $[Pt_2(\mu\text{-}H)(CH_3)_2(\mu\text{-}dppm)_2][PF_6]$ (0.025 g) in pyridine (5 mL) was degassed and photolysed to partial conversion. The gaseous products were analysed using a Varian MAT 311A mass spectrometer. For comparison, photolysis of the pure labelled materials were also carried out and the gases analysed in the same way. The above system gave $CD_4:CD_3H:CH_3D:CH_4$ = 1:0.04:0.02:1.6.

Experiments using $[Pt_2(CD_3)_3(\mu\text{-}dppm)_2][PF_6]$ and $[Pt_2(CH_3)_3(\mu\text{-}dppm)_2][PF_6]$ were carried out in a similar way.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada for financial support and Professor P. de Mayo for access to the Jasco Spectroirradiator used in the quantum yield determinations and for valuable discussions.

Stereospecific *trans*-elimination of 2-alkoxy- and 2-cycloalkoxytropones to alkenes and cycloalkenes[1]

HITOSHI TAKESHITA AND HIROAKI MAMETSUKA

Research Institute of Industrial Science, 86, Kyushu University, Sakamoto, Kasuga, Fukuoka 816, Japan

Received February 2, 1984

This paper is dedicated to Professor Paul de Mayo on the occasion of his 60th birthday

HITOSHI TAKESHITA and HIROAKI MAMETSUKA. Can. J. Chem. **62**, 2035 (1984).

The title compounds undergo thermal fragmentation to tropolones and alkenes and cycloalkenes. Product distribution and kinetic analyses of specifically labelled deuterio compounds establish the process to be a concerted $[s8\pi + a2\sigma + s2\sigma]$ electrocyclic reaction.

HITOSHI TAKESHITA et HIROAKI MAMETSUKA. Can. J. Chem. **62**, 2035 (1984).

Les composés mentionnés dans le titre subissent une fragmentation thermique conduisant à des tropolones, à des alcènes et à des cycloalcènes. Faisant appel à des analyses de la cinétique et de la distribution de produits marqués spécifiquement par du deutérium, on a établi que le processus est une réaction électrocyclique concertée du type $[s8\pi + a2\sigma + s2\sigma]$.

Introduction

Recently, we have observed terminal diene formation by heating 2-(2-alkenyloxy)tropones (1), and on this basis have explained the low yields in the previous syntheses of nootkatin from hinokitiol (2) and procerin from β-dolabrin (3). We now wish to report a new thermal reaction of troponoid ethers, namely the electrocyclic fragmentation of 2-alkoxytropones to alkenes.

Results and discussion

When 2-(cyclopentyloxy)tropone (**1***d*) (4) was heated in DMSO at 180°C in a sealed tube for 2 h, in the hope of obtaining cyclopentanone (5), unexpected formation of cyclopentene (**2***d*) and tropolone (**3**) occurred as shown by nmr spectroscopy. This contrasted with our earlier work; i.e., heating of 2-isopropoxytropone (**4***a*) in that solvent gave acetone (**5***a*) and **3**, and prompted us to investigate similar reactions with other alkoxy- and cycloalkoxytropones. The treatment of alkoxytropones (**4**) indeed formed mixtures of alkenes (**6**) and alkanones (**5**); heating 2-(2-butyloxy)tropone (**4***b*) in DMSO at 180°C for 30 min gave *Z*- and *E*-2-butenes (*Z*-**6***b* and *E*-**6***b*, 1:1) and 2-butanone (**5***b*). Similar treatment of 2-(3-pentyloxy)tropone (**4***c*) gave *Z*- and *E*-2-pentenes (*Z*-**6***c* and *E*-**6***c*, 1:2) and 3-pentanone (**5***c*). Conversely, all the cycloalkoxytropones examined, including 2-(cyclododecyloxy)tropone (**1***h*), a macrocyclic derivative, gave only the corresponding cycloalkenes (**2**) in good yields.

Heating, as above, of the cyclooctyl phenyl ether (**7**) had no effect and, therefore, the presence of an adjacent carbonyl group is essential for the elimination to occur.

The ethers (**8***d*, **8***g*, **9***d*, and **9***g*) derived from hinokitiol (4-isopropyltropolone, **10**) gave products similar to those from ethers of **3**; this suggests the generality of this elimination in tropolonyl ethers.

To provide information about mechanism, several deuterium-labelling experiments were carried out using appropriately labelled **1***g*, which could be prepared from **3** and deuterated cyclooctanols (**11**). The first feature observed was that the mass spectrometric and ^1H and ^{13}C nmr analyses of the purified **3** generated by heating 2-(*Z*-2-deuteriocyclooctyloxy)tropone (*Z*-D-**1***g*), 2-(*E*-2-deuteriocyclooctyloxy)tropone (*E*-D-**1***g*), and 2-(2,2,8,8-tetradeuteriocyclooctyloxy)tropone (D_4-**1***g*) in decalin showed it to contain no deuterium. In this solvent, the hydrogen exchange of the aromatic ring of **3** does not occur, although substantial exchange was observed in dimethyl-d_6 sulfoxide. Thus, a possible $[2\pi + 2\sigma + 2\sigma]$ process may be rejected. In addition, the mass spectrometric analysis of the deuteriodibromocyclooctanes, **12***a* obtained from thermolysis of *E*-D-**1***g* in decalin and **12***b* obtained from *Z*-D−**1***g* in decalin, showed the process to be a *trans*-elimination; i.e., according to mass spectral analysis of deuterium distributions, **12***a* contains the deuterium-free **12**, while **12***b* retains all the deuterium, as shown in Fig. 1.

The ^{13}C nmr spectrum of **12***b* showed signals attributable to a mixture of *E*-3-deuterio (*E*-D-**12**) and *Z*-3-deuterio (*Z*-D-**12**) derivatives together with 1-deuterio **12** (1-D-**12**) in a ratio of 1:1:2, while the ^{13}C nmr of **12***a* showed signals attributable to *E*-D-**12** and *Z*-D-**12** derivatives and the deuterium-free **12** in a ratio of 1:1:1.[2]

TABLE 3. Thermolysis of 2-cycloalkoxytropones in decalin at 180°C

Reactants	Time (h)	Products	Yields (%)
1*d*	4	Cyclopentene (**2***d*)	70[a]

8*g*	3	Cyclooctene (**2***g*)	95[b]
8*d*	4	Cyclopentene (**2***d*)	95[b]
9*g*	3	Cyclooctene (**2***g*)	95[b]

[a] Determined after isolation as dibromo derivatives.
[b] Determined by nmr spectrometry.

These isotopic distributions led to the conclusion that H-abstraction is twice as fast as D-abstraction. Indeed, this has been verified by measurement of reaction rates for the thermol-

[2] Locations of the deuterium in the compounds were conveniently determined by the gated decoupling ^{13}C nmr spectra (irradiation time = 2 s, pulse interval = 90 s) δ: 30.7 (t, J = 19 Hz) and 31.7 (t, J = 19 Hz) for *E*- or *Z*-D-**12** and 61.1 (t, J = 24 Hz) for 1-D-**12**.

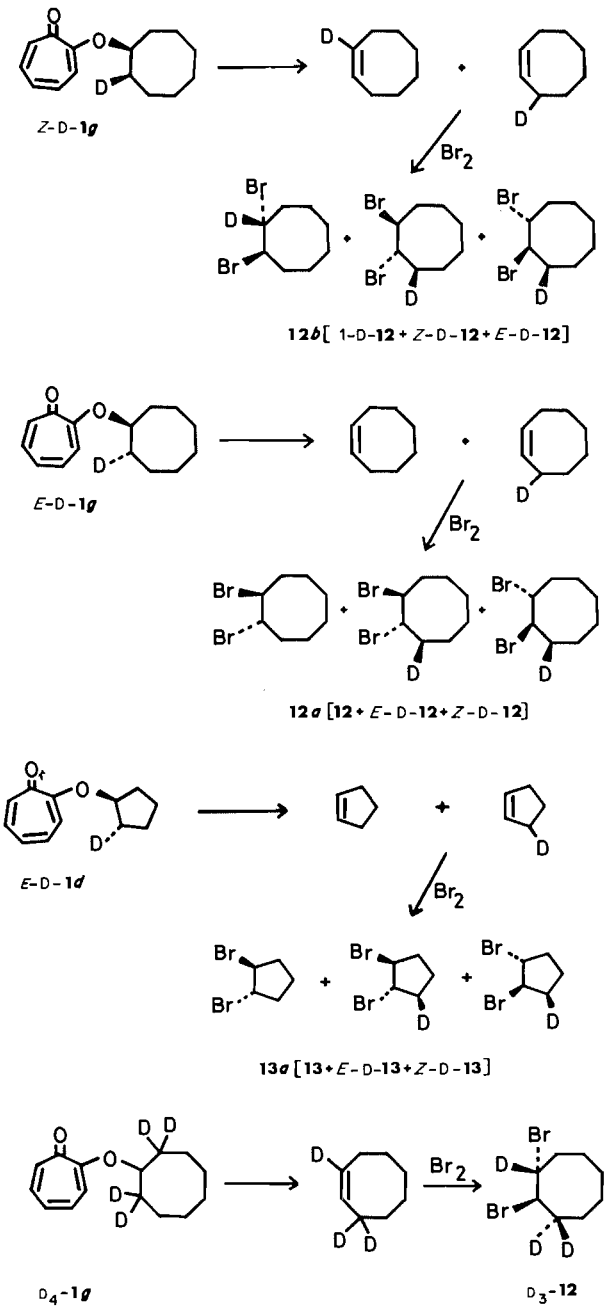
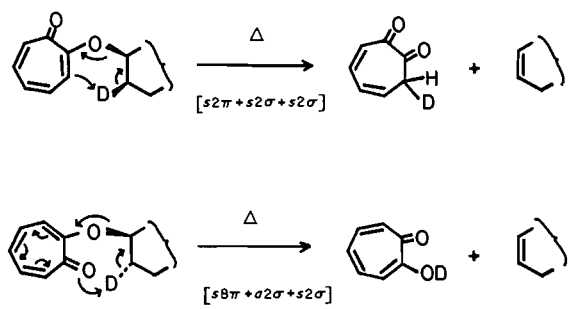


SCHEME 2

ysis of tetradeuterio and deuterium-free *g* to be k_H(453.7 K) = 3.2×10^{-5} s^{-1} and k_D(453.7 K) = 1.3×10^{-5} s^{-1}; thus, the relative rate was calculated as 1:2.5, a reasonable value for a primary isotope effect. The isotopic composition, which is crucial for the rate analysis, of the brominated thermolysates 1,3,3-trideuterio **12** (D_3-**12**) was $d_3:d_2:d_1:d_0$ = 95:4:1:0. Therefore, these two observations (*i*) the stereospecific *trans*-elimination and the recognition of this primary isotope effect, and (*ii*) a rate-determining nature for the C—H(D) bond-breaking step, have proven the reaction to be concerted. Furthermore, the exclusive formation of the trideuterio derivative from D_4-**1***g* ruled out a possible transannular hydrogen shift; this may be regarded as additional evidence for the electrocyclic mechanism.

In addition to the stereospecific feature, *trans*-elimination, a kinetic study provided supporting evidence; i.e., the rates of



SCHEME 3

the reaction of **1***g* at various temperatures have been measured; in addition to k(453.7 K), the following rate constants k(447.2 K) = 1.6×10^{-5} s^{-1}, k(441.2 K) = 1.1×10^{-5} s^{-1}, k(435.2 K) = 6.3×10^{-6} s^{-1}, and k(426.2 K) = 2.6×10^{-6} s^{-1}, led us to obtain E_a = +140 kJ mol^{-1}, and $\Delta S^{\neq}$ = −21 J mol^{-1} K^{-1} at 180.5°C. This negative $\Delta S^{\neq}$ value was in the range of those observed for typical electrocyclic reactions, Cope rearrangement (6–8). Should the twelve-electron system be the concerted process, there should be an *antara* mode, which is in accord with the observed *trans* relationship; thus, the elimination may be designated as the [$s8\pi + a2\sigma + s2\sigma$] process.

Because formation of *trans*-cyclooctene is known, it might be suggested that the olefin (*cis*-**2***g*) isolated from **1***g* is the thermodynamically stable secondary product formed via the all-*supra* mode. However, this is unlikely since (*i*) assumption of primary formation of *trans*-**2***g* with the observed deuterium distributions via a thermally-forbidden [$s8\pi + a2\sigma + s2\sigma$] reaction requires a folded conformation of **1***g* having severe I-strain, and (*ii*) it is difficult to explain the unreactivity of the unstrained conformer of **1***g*. Nevertheless, this possibility can be eliminated by looking at a deuterated cyclopentyl ether. When *E*-D-**1***d* in decalin was refluxed at 180°C with the nitrogen stream, the volatile product collected as the dibromides (**13***a*) was found to contain the deuterium-free **13**, *E*-D-**13**, and *Z*-D-**13** in the ratio of 1:1:1. Consequently, no ambiguity has been left on this point.

The thermal *cis*-elimination of alkyl carboxylates to alkenes and carboxylic acids, which may be designated as the [$s2\pi + s2\sigma + s2\sigma$] process, generally needs more severe conditions: 1,3-di(acetoxymethyl)cyclohexane yielded 1,3-bis-methylenecyclohexane by heating at 555°C (9) and 4-(2-acetoxyethyl)-imidazole could be converted to 4-vinylimidazole at 500°C (10). The mildness of the pyrolysis of tropolonyl ethers, together with the reversal of the usual selectivity of the acid-induced dehydration of alcohols, makes this simple procedure valuable as a new method in organic syntheses for preparing or masking alkenes.

Experimental

The elemental analyses were performed by Miss M. Yamaguchi, this Institute. The nmr spectra were measured by an FX 100 Model spectrometer, JEOL, in $CDCl_3$ solutions unless otherwise stated, and the chemical shifts expressed in δ units were those from the internal $SiMe_4$. The mass spectra were measured by an 01SG Model spectrometer, JEOL.

*General procedure for preparation of 2-alkoxy- (**4**) and 2-cycloalkoxytropones (**1**) (ref. 11)*

A mixture of alkanol or cycloalkanol (**11**, ca. 2.3 mmol), *N*,*N*′-dicyclohexylcarbodiimide (DCC, 2.2 mmol), and CuCl (10 mg) in benzene (1 mL) was kept under a N_2 atmosphere with stirring for

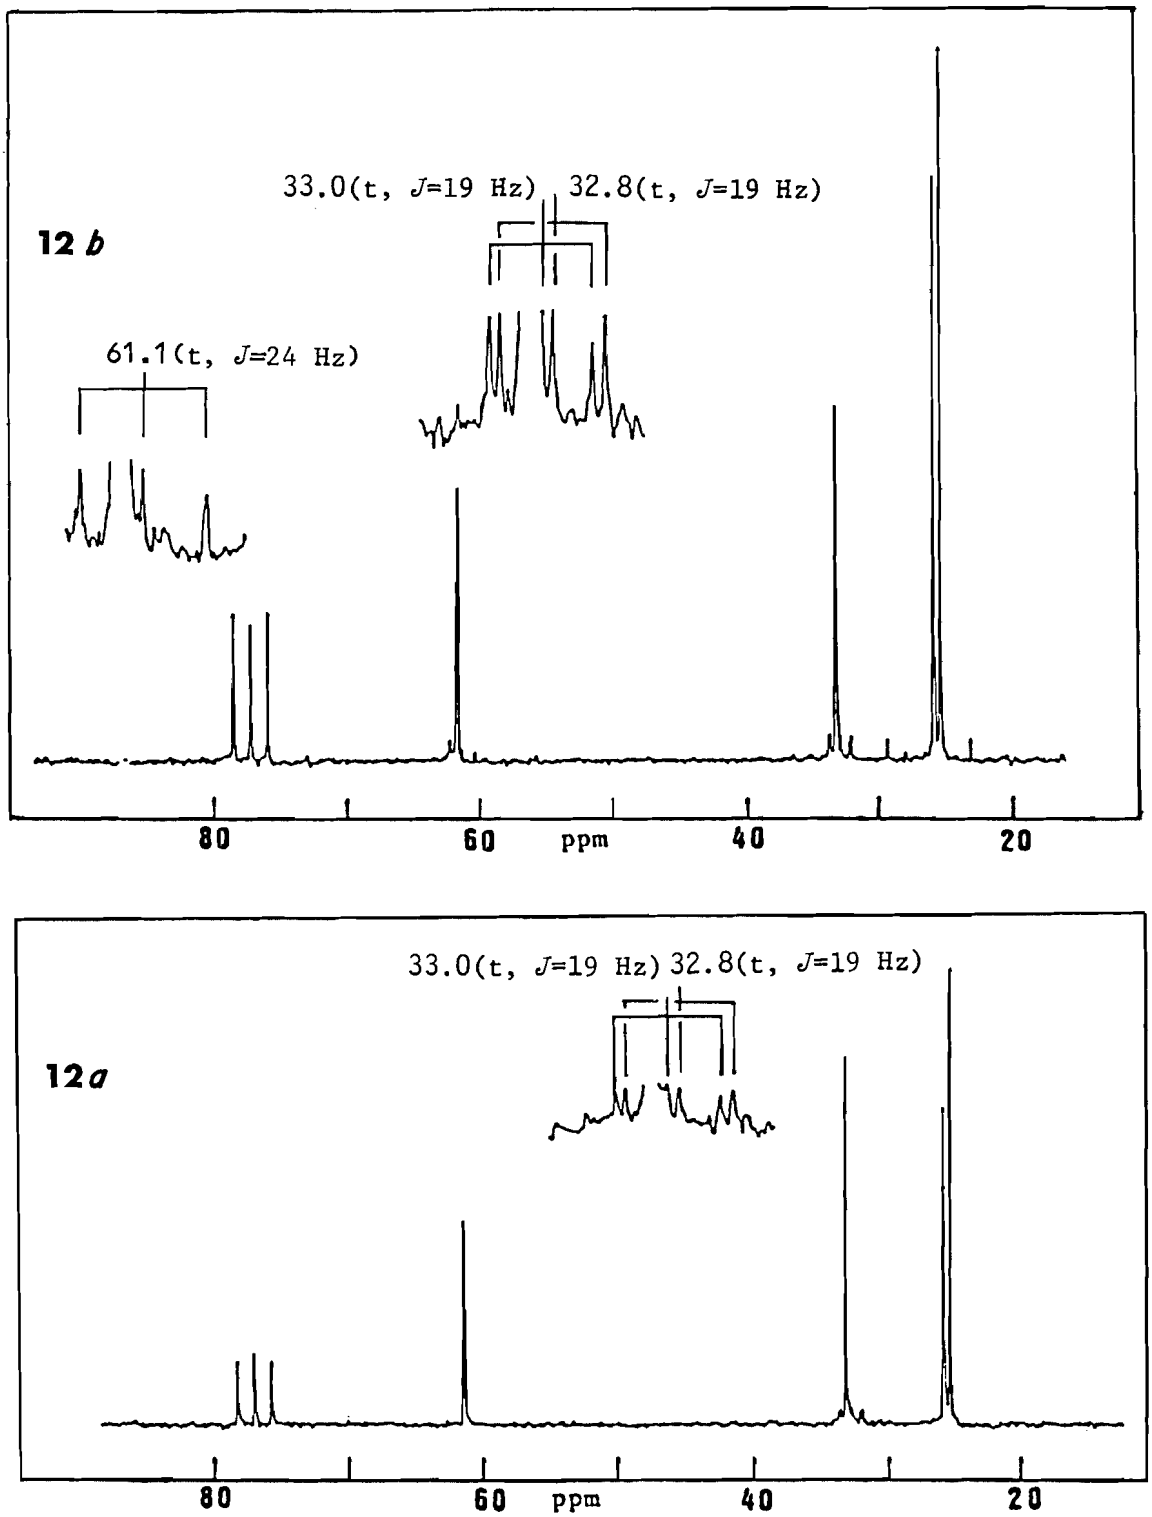

FIG. 1. The ^{13}C nmr spectra (expanded in part) of **12***a* and **12***b*.

10 to 24 h at 55°C depending on the progress of the reaction (tlc). A benzene solution (1 mL) of **3** or **10** (ca. 2.0 mmol) was added to the mixture, and heating at 80°C continued for another 24 h. After cooling, ethyl acetate (2 mL) was added to the mixture, and the resultant *N,N'*-dicyclohexylurea filtered. The organic layer was diluted with ether, and washed with aqueous KOH to remove the unreacted **3** or **10**. A residual oil obtained by distillation of ether *in vacuo* was chromatographed on a silica gel column; fractions eluted with benzene – ethyl acetate (9:1 to 8:2) afforded the desired **4** and **1**. The yields of the ethers were satisfactory in most cases. Characterizations of the ethers are summarized in Tables 1 and 2.[3]

[3] The ^1H nmr spectra of these alkoxy and cycloalkoxytropones are similar, and we wish to record the spectrum of **9***g* as representative: δ: 1.21 (6H, d, J = 7 Hz), 1.3–2.1 (14H, m), 2.75 (1H, sept, J = 7 Hz), 4.50 (1H, m), 6.57 (1H, dd, J = 9.5, 1.5 Hz), 6.72 (1H, dt, J = 11, 1.5 Hz), 6.95 (1H, dd, J = 11, 9.5 Hz), and 7.11 (1H, d, J = 1.5 Hz).

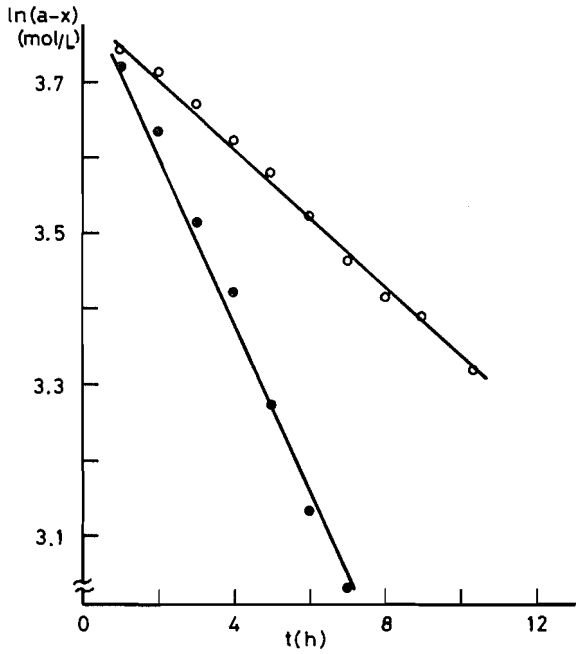

FIG. 2. The reaction rates for **1***g* (●) and D-**1***g* (○) at 180.5°C.

*Thermolysis of 2-(cyclopentyloxy)tropone (**1**d) in DMSO*

An anhydrous DMSO solution (0.5 mL) of **1***d* (45 mg) was heated at 180°C in a sealed tube for 8 h. Liberation of **3** was confirmed by $FeCl_3$ coloration, but absence of dimethyl sulfide eliminated the occurrence of the oxidation. The mixture was diluted with H_2O, and bubbled with a N_2 stream to collect the volatile material into a $CDCl_3$ solution. The nmr spectrum confirmed the formation of **2***d*.

*Thermolysis of 2-(2-butyloxy)tropone (**4**b) in DMSO*

An anhydrous DMSO solution (0.5 mL) of **4***b* (45 mg) was heated in a top-sealed glass ampule at 180°C for 8 h. Liberation of **3** was recognized ($FeCl_3$). After opening the vessel, the mixture was bubbled with a N_2 stream and volatile material was collected into a $CDCl_3$ solution. The nmr spectrum showed a formation of *Z*-**6***b* (δ: 1.50 (6H, d, J = 6 Hz) and 5.28 (2H, m)); *E*-**6***b* (δ: 1.53 (6H, d, J = 6 Hz) and 5.35 (2H, m)[4]); and **5***b* in 5%, 7%, and 7% yields, respectively.[5]

*Thermolysis of 2-(3-pentyloxy)tropone (**4**c) in DMSO*

An anhydrous DMSO solution (0.5 mL) of **4***c* (45 mg) was heated in a sealed glass ampule at 180°C for 8 h. The volatile material in the reaction mixture was similarly collected into a $CDCl_3$ solution with a N_2 stream. Its nmr spectrum showed a formation of *Z*-**6***c* (δ(C): 12.3, 14.1, 20.1, 122.8, and 132.3), 4%; *E*-**6***c* (δ(C): 13.9, 17.8, 25.5, 123.4, and 133.0),[6] 8%; and **5***c*, 20%.

*Thermolysis of **4**c in dioxane-d_8*

A dioxane-d_8 solution (0.3 mL) of **4***c* (45 mg) was heated at 180°C in a top-sealed nmr tube for 20 h. The ^{13}C nmr spectrometry revealed a formation of only *E*- and *Z*-**6***c* in a 1:2 ratio.

*Thermolysis of 2-cycloalkoxytropones (**1**, **8**, or **9**) in decalin. General procedure*

A decalin solution (0.5 mL) of **1**, **8**, or **9** (ca. 50–70 mg, 0.2 to 0.3 mmol) was sealed in a glass ampule, and heated at 180°C for 2 to 8 h. After cooling, the mixture was diluted with CCl_4 and extracted with 2 *N* KOH to recover **3** or **10**. The organic layer was washed with H_2O and dried on $MgSO_4$. Bromination of the CCl_4 solution at 0°C for 2 h, distillation of the solvent *in vacuo*, and purification through a silica gel column gave dibromoalkanes. The results of the thermolysis can be found in Table 2.

*Preparation of 2-(2-E-deuteriocyclooctyloxy)tropone (E-D-**1**g)*

To an anhydrous THF solution (50 mL) of $LiAlD_4$ (600 mg, 15 mmol), 1,2-epoxycyclooctane (3.6 g, 28 mmol) in THF (50 mL) was added drop by drop at 0°C. After 1 h, the mixture was refluxed for 17 h, and treated with ice and 1 *N* NaOH. An ether extract of the mixture was dried on $MgSO_4$, and removal of the solvent left an oil, 3.1 g, which was purified by distillation *in vacuo* (bath temperature 80–88°C/6 Torr (1 Torr = 133.3 Pa)) to give *E*-D-**11**, 2.05 g, 57%.

Similarly to deuterio-free **11**, *E*-D-**11** (967 mg, 7.5 mmol) and **3** (810 mg, 6.6 mmol) were condensed by DCC (1.51 g, 6.6 mmol) and CuCl (15 mg) to give *E*-D-**1***g*, 871 mg (75%) (δ: 1.3–2.0 (13H, m), 4.50 (1H, m), and 6.6–7.2 (5H, m); δ(C): 23.2, 23.3, 25.7, 26.8 (2C), 31.3 (t, $J_{C\text{-}D}$ = 19.6 Hz), 31.6, 79.5, 115.3, 127.5, 132.7, 136.1, 136.7, 164.0, and 181.0; *m/e*: 232 (5), 233 (100), 234 (22); d_0:d_1 = 5:95).

*Preparation of 2-(2-Z-deuteriocyclooctyloxy)tropone (Z-D-**1**g)*

To an anhydrous THF solution (25 mL) of $NaBD_4$ (1.08 g, 26 mmol) and **2***g* (3.85 g, 35 mmol), BF_3 etherate (2.4 mL, 20 mmol) in THF (10 mL) was added dropwise under the N_2 atmosphere, and kept at 20–25°C for 2 h with stirring. The mixtue was then diluted with H_2O, basified with 3 *N* NaOH (7.5 mL), and oxidized with 30% H_2O_2 (7.5 mmol) at 50°C for 75 min. After cooling, the solution was fractionated with aqueous NaCl and ether, then dried over $MgSO_4$ and heated to remove the solvent. A colorless oily residue, 3.2 g, was distilled *in vacuo* (bath temperature 80–88°C/6 Torr) to give a colorless liquid, *Z*-D-**11**, 2.3 g, 51%.

Similarly, from *Z*-D-**11** (983 mg, 7.6 mmol), **3** (806 mg, 6.6 mmol), DCC (1.54 g, 6.6 mmol), and CuCl (15 mg), *Z*-D-**11** was obtained as colorless needles, 917 mg (89%) (δ: 1.3–2.0 (13H, m), 4.50 (1H, m), and 6.6–7.2 (5H, m); δ(C): 23.2, 23.3, 25.8, 26.8 (2C), 31.4 (t, $J_{C\text{-}D}$ = 18.5 Hz), 31.7, 79.6, 115.4, 127.5, 132.7, 136.1, 136.7, 164.0, and 181.0; *m/e*: 232 (14), 233 (100), 234 (25); d_0:d_1 = 12:88).

*Preparation of 2-(2,2,8,8-tetradeuteriocyclooctyloxy)tropone (D_4-**1**g)*

Cyclooctanone (2.5 g, 20 mmol) was treated wih a mixture of dioxane (1.5 mL) and D_2O (6 mL) with K_2CO_3 (60 mg) at 145°C in a sealed tube for 46 h. From the mixture, the solvent was removed *in vacuo*, and the residue was fractionated with ether and H_2O. Ether extracts afforded a colorless oily deuteriocyclooctanone, 2.4 g, which was then dissolved in methanol (25 mL) and reduced with $NaBH_4$ (700 mg, 19 mmol) at 0°C to colorless oily D_4-**11**, 1.55 g, 59%.

As above, D_4-**11** (660 mg, 5 mmol) was treated with **3** (660 mg, 5.4 mmol), DCC (1 g, 5 mmol), and CuCl (10 mg) to give colorless crystalline D_4-**1***g*, 538 mg, 53% (δ: 1.4–2.0 (10H, m), 4.53 (1H, br s), and 6.6–7.2 (5H, m); δ(C): 23.1 (2C), 25.7, 26.7 (2C), 31.3 (2C, m), 79.4, 115.3, 127.5, 132.7, 136.1, 136.6, 163.9, and 181.0; *m/e*: 234 (2), 235 (4), 235 (100), 237 (26); d_2:d_3:d_4 = 2:3:95).

*Preparation of 2-(2-E-deuteriocyclopentyloxy)tropone (E-D-**1**d)*

To a mixture of benzene and 2-*E*-D-cyclopentanol (710 mg), prepared from **2***d* by MCPBA oxidation and following $LiAlD_4$ reduction, DCC (1.375 g) and CuCl (20 mg) were added and kept at 55°C for 21 h. Then **3** (1.040 g) was added and kept at 80°C for a further 5 h. The product, *E*-D-**1***d*, obtained in 86.5%, was characterized by the nmr (δ: 1.4–2.1 (7H, m), 4.80 (1H, qm, J = 6 Hz), and 6.6–7.3 (5H, m); δ(C): 24.1, 24.2, 32.3 (t, J = 19.5 Hz), 32.6, 80.7, 114.6, 127.3, 132.8, 136.1, 136.5, 164.3, and 180.7) and mass spectrum (*m/e*: 191 and 190 (M^+); d_1:d_0 = 98:2).

Thermolysis of E-D-**1**g *in decalin*

E-D-**1***g* (151 mg, 0.7 mmol) in decalin (1 mL) was heated at 180°C

[4] In the literature (12) are reported ^1H nmr values measured for neat liquid: δ: 1.54 (6H, d, J = 7 Hz) and 5.37 (2H, m) for *Z*-**6***b* and δ: 1.58 (6H, d, J = 6 Hz) for *E*-**6***b*.

[5] Low yields after the work-up are due to the volatility of the products. The nmr spectrometry of the whole mixture indeed disclosed no signals other than for the described rpoducts.

[6] The ^1H nmr spectra of *E*-**6***c* and *Z*-**6***c* are mutually indistinguishable. These ^{13}C nmr values were obtained by determination with the authentic samples prepared independently.

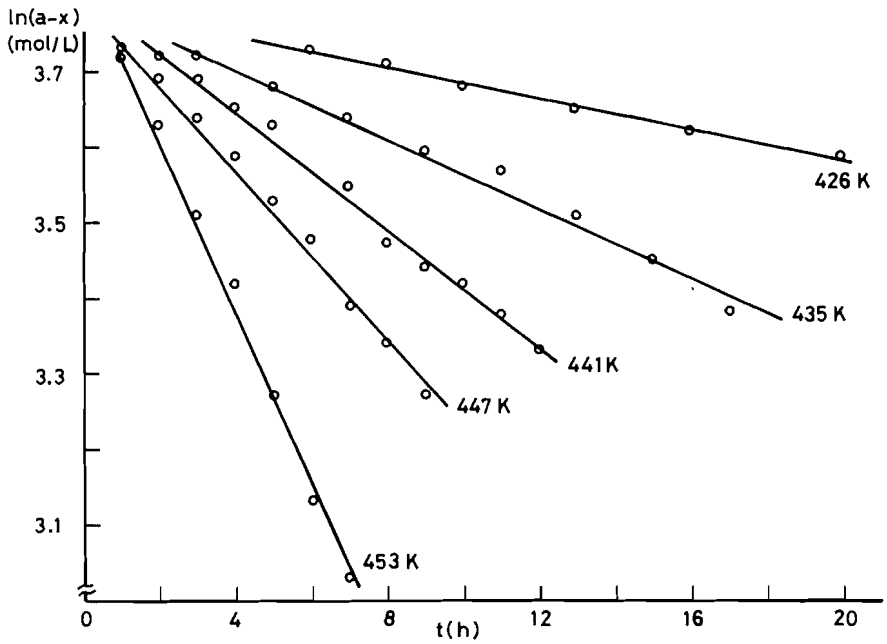

FIG. 3. The reaction rates for **1***g* at various temperatures.

for 14 h. The mixture was then diluted with CCl_4 and washed with 3 *N* KOH. The organic layer was treated with Br_2 in CCl_4, and the solvent was removed by distillation *in vacuo*. The residue was chromatographed on a silica gel column to give a colorless oil, **12***a*, 145 mg (77%).

Thermolysis of Z-D-**1***g in decalin*

Similarly, Z-D-**1***g* (209 mg, 0.96 mmol) in decalin (1 mL) was heated at 180°C for 14 h. After similar work-up, the thermolysates were characterized as the dibromide, a colorless oil, **12***b*, 190 mg (73%).

Thermolysis of D_4-**1***g in decalin*

Similarly, D_4-**1***g* (90 mg, 0.41 mmol) in decalin (0.5 mL) was heated at 180°C for 14 h. After the bromination as above, the deuterio **2***d* was obtained as a colorless liquid, 82 mg (73%), whose mass spectrum showed it to be solely the trideuterio derivative.

Thermolysis of E-*D*-**1***d in decalin*

E-D-**1***d* (322 mg) in decalin (5 mL) was refluxed for 14 h with a continuous bubbling of the N_2 stream to collect a volatile thermolysate into a cold Br_2-containing CCl_4 solution. Subsequently, the solution was evaporated *in vacuo* to leave a colorless oil, **13***a*, 90 mg (24%). The ^{13}C nmr (δ(C): 21.0 (C-4 of d_0) and 21.1 (C-4 of d_1) with a ratio of 2:1, 33.6 (t, J = 20 Hz, C-3 of d_1)[7] and 33.9 (C-3 bearing no *d*), and 57.2 (C-1 and C-2 of d_0) and 57.3 (C-1 and C-2 of d_1) with a ratio of 1:2) indicated the product to be a mixture of the deuterium-free **13**, *E*-D-**13**, and Z-D-**13** in a ratio of 1:1:1.

Kinetic experiments of deuterated 2-(cyclooctyloxy)tropones

Dioxane-d_8 solutions (0.3 mL) containing the deuterio **1***g* (ca. 35 mg) were placed in top-sealed nmr tubes, and heated on a constant temperature bath for appropriate periods. The reaction was monitored by ^1H nmr spectrometry in respect to signals at δ 4.5 due to the carbinyl proton of **1***g* and δ 5.7 due to the resultant olefinic protons of **2***g*.

Preparation of cyclooctyl phenyl ether (7) and its attempted thermolysis

A mixture of **11** (610 mg, 4.7 mmol), DCC (1.1 g, 5.5 mmol), and CuCl (10 mg) was heated at 55°C for 22 h under the N_2 atmosphere. To the mixture, phenol (580 mg, 6.2 mmol) was added, and heated again at 100°C for 23 h. A work-up in the usual manner gave 210 mg (19%) of **7**, a colorless liquid (δ: 1.2–2.0 (14H, m), 4.28 (1H, m), 6.87 (3H, m), and 7.23 (2H, m); δ(C): 23.2 (2C), 25.8, 27.1 (2C), 31.7 (2C), 77.6, 115.9 (2C), 120.2, 129.3 (2C), and 157.7. *Anal.* calcd. for $C_{14}H_{20}O$: C 82.30, H 9.87; found: C 82.35, H 9.60).

A dioxane-d_8 solution (0.3 mL) containing **7** (50 mg) was placed in a top-sealed nmr tube and heated at 180°C for 28 h. The nmr spectrum revealed no reaction. Removal of the solvent by evaporation left 45 mg of the starting **7**.

[7] In the case of **13**, the δ of C-3 was the same for both *E*- and Z-D-**13**.

Received January 26, 1984

This paper is dedicated to Professor Paul de Mayo on the occasion of his 60th birthday

HARUO SHIZUKA and EHICHI KIMURA. Can. J. Chem. **62**, 2041 (1984).

Acid–base properties in the triplet state of aromatic ketones in H_2O-CH_3CN (4:1) mixtures have been studied by means of nanosecond laser flash photolysis. The acidity constants $pK_a(T)$ in the triplet state were determined by the $T_n \leftarrow T_1$ absorbance titration curve, the Ware plot, and the Rayner–Wyatt plot. Good agreement among them shows that the acid–base equilibrium in the T_1 state of aromatic ketones is established during the triplet lifetime. A linear relation between $pK_a(T)$ and the Taft σ^* values was obtained for phenyl alkyl ketones.

HARUO SHIZUKA et EHICHI KIMURA. Can. J. Chem. **62**, 2041 (1984).

Opérant dans des mélanges H_2O-CH_3CN (4:1) et faisant appel à la photolyse flash au laser à l'échelle de la nanoseconde, on a étudié les propriétés acide–base dans l'état triplet de cétones aromatiques. On a déterminé les constantes d'acidité, $pK_a(T)$, dans l'état triplet en se basant sur les courbes de titration d'absorbance $T_n \leftarrow T_1$, sur les courbes de Ware et sur les courbes de Rayner–Watt. L'existence d'une bonne concordance entre les diverses valeurs démontre que l'équilibre acide–base dans l'état T_1 des cétones aromatiques s'établit au cours de la durée de vie du triplet. Dans le cas des phényl alkyl cétones, on a obtenu une corrélation linéaire entre les $pK_a(T)$ et les valeurs σ^* de Taft.

Introduction

Proton transfer reactions in the excited states of aromatic compounds are elementary processes not only in photochemistry but also in biochemistry. The acid–base properties of aromatic compounds in the excited state are closely related to the corresponding electronic structure, which is considerably different from that in the ground state.

Since the original work of Förster (1950) (1) and Weller (1952) (2) showing that the acidity constant pK_a^* in the excited state is markedly different from that in the ground state, a number of studies on pK_a^* have been reported (3–9). It is known that the pK_a^* values can be estimated by means of the Förster cycle (1–3, 10), the fluorescence titration curve (2, 3), and the $T_n \leftarrow T_1$ absorbance titration curve (11). These methods involve the assumptions that proton transfer in the excited state is very fast and that the acid–base equilibrium may be attained during the lifetime of the excited state. Establishment of prototropic equilibrium in the excited singlet state has been reported in the cases of 2-naphthol-6,8-disulfonate (12), 2-naphthol (13), and 1-isoquinoline (14).

However, the prototropic equilibrium in the S_1 state of aromatic compounds having an electron-donating group (e.g., an amino or hydroxy group), where protonation or dissociation occurs, is not to be the case. Proton-induced fluorescence quenching takes place effectively due to electrophilic protonation at a carbon atom of the aromatic ring in the S_1 state of such species, leading to hydrogen exchange (or isotope exchange) (15). Electron migration from the electron donating substituent to the aromatic ring (i.e., intramolecular charge transfer) occurs in the S_1 state in polar media, and the CT state is responsible for the proton-induced quenching (15, 16). In fact, it has been shown that the proton-induced quenching is competitive with proton transfer reactions in the excited state of neutral naphthylamines (that is, the simple acid–base equilibrium cannot be established in the excited state of aromatic amines) and dynamic analyses taking into account the proton-induced quenching are, therefore, needed in order to obtain the correct pK_a^* values (17). The dynamic analyses by means of nanosecond time-resolved spectroscopy with fluorimetry were applied to the other aromatic amines (18–20) and naphthols (13). The Stuttgart group (21) has supported our method to determine the pK_a^* values of naphthylamines. Similar experiments for excited naphthols have been reported by Harris and Selinger (22).

As for the triplet state, a laser study of the prototropic equilibrium of triplet benzophenone has been reported by Rayner and Wyatt (23). Recently, the acid–base equilibrium in the triplet acridinium ion has been investigated by Nishida *et al.* (24). Establishment of the prototropic equilibrium in the triplet state of phenyl alkyl ketones has not yet been given. A study of the acid–base equilibrium in the triplet state of aromatic ketones was needed in the course of our investigation of proton-transfer reactions in the excited state of aromatic compounds. In addition, the variation of acid–base properties in the triplet state of aromatic ketones as a function of their electronic structures was of interest. This paper reports an examination of the acid–base properties in the T_1 state of aromatic ketones studied by means of nanosecond laser flash photolysis. The $pK_a(T)$ values were determined by the $T_n \leftarrow T_1$ absorbance titration curve (11), the Ware plot (25), and the Rayner–Wyatt plot (23).

Experimental

Materials

Benzophenone, acetophenone, propiophenone, and benzyl phenyl ketone were G.R. grade products from Tokyo Kasei. Benzophenone was purified by repeated recrystallization from H_2O–EtOH mixtures. Sulfuric acid (97%, Wako), D_2SO_4 (96–98%, isotope purity 99%, Merck), and D_2O (99.7% Merck) were used. Distilled water and acetonitrile (G.R. grade, Wako) were used as a H_2O-CH_3CN mixture (4:1 in volume). The concentrations of benzophenone and the other ketones were 3×10^{-3} *M* and ca. 1×10^{-2} *M*, respectively. The pH values of samples were recorded with a pH meter (Corning M-125). The samples were thoroughly degassed by freeze–pump–thaw cycles on a high vacuum line. All experiments were carried out at 20°C.

[1] This paper was supported by a Scientific Research Grant-in-Aid from the Ministry of Education of Japan (No. 58470001).

Absorption spectra were recorded of the ketones at the high acidities used; no changes were observed indicating that they are stable with respect to ground state condensation reactions.

Laser flash photolysis

Nanosecond laser flash photolysis at 347 nm was carried out using a Q-switched ruby laser (JEOL JLS-R34A, 23-ns half-width). The output energy of the 347 nm pulse was recorded digitally on a peak-hold meter calibrated with a thermopile (TRG Model 107) and a pulse generator (Anritsu MG 411B). The output energy for excitation was attenuated to less than 15 mJ/pulse by glass plates in order to avoid triplet–triplet annihilation. The transient absorbances for a series of experiments at different acidities were corrected to the same laser intensity. A xenon flash (~600-μs half-width) from a stroboscope (Sunpack Model 107) was used as an analytic flash for the detection of the transients. The monitoring light was passed through a grating monochrometer (Hitachi Model 139) and was analyzed by a detection system consisting of a photomultiplier tube (HTV R636) and a 200 MHz oscilloscope (Iwatsu SS-6200). The triplet transients of benzophenone, acetophenone, propiophenone, and benzyl phenyl ketone were monitored at 525, 370, 360, and 350 nm, respectively.

Photochemical isotope-exchange reaction

The photochemical isotope-exchange reactions were carried out with 2×10^{-2} *M* acetophenone (or propiophenone) in D_2O–CH_3CN (4:1) with $[D_2SO_4] = 0.05$ *M*. A medium-pressure mercury lamp with an interference glass filter was used as the 313-nm radiation source. The isotope-exchange reaction in the dark was also performed at room temperature as a blank test. Actinometry was carried out with a ferric oxalate solution (26, 27). After a definite irradiation, the sample solution was neutralized wih sodium carbonate solution. The sample was then extracted with benzene several times, followed by evaporation under reduced pressure. The resulting residue was purified by passing it through a silica gel column with benzene as a developing solvent. The H–D isotope-exchange positions of acetophenone or propiophenone were determined by means of ^1H nmr spectroscopy (Varian EM-360 60 MHz) and quantitative analyses of the exchange reaction were carried out by means of mass spectroscopy (JEOL JMS6).

Results and discussion

Nanosecond laser flash photolyses of aromatic ketones

The transient absorption spectra of aromatic ketones at the delay time 200 ns after the pulse, in the absence of protons, are shown in Fig. 1 (28).

It is well known that triplet formation or decay through intersystem crossing of carbonyl compounds is very rapid, according to El-Sayed's rule (29). For benzophenone (BP), a strong absorption band with a maximum at 525 nm was observed just after pulsing, which decayed by first-order kinetics with the decay rate $(\tau_0)^{-1} = 2.3_8 \times 10^5\ s^{-1}$. This band corresponds to that of the $T_n \leftarrow T_1$ absorption in water (30). The absorption bands at longer wavelengths (600 nm), which decayed very slowly in comparison with the decay rate of the $T_n \leftarrow T_1$ band at 525 nm, may be due to those of the ketyl radical (545 nm) and the radical anion (600 nm) (31). These long-lived transients are also produced by flash photolysis of BP in water (30, 32). Fortunately, the triplet lifetime τ_0 was relatively short, and its decay rate could be measured at 525 nm without interference from the longer-lived transients (28).

Laser flash photolysis of a 5 *M* H_2SO_4 solution of benzophenone produced a weak transient with $\lambda_{max} = 505$ nm. The transient spectrum with a lifetime of 17 ns was similar to that observed by conventional flash photolysis (33) as shown in Fig. 2. The transient spectrum is, therefore, believed to be protonated benzophenone triplet. This transient absorption was weak, and the decay rate of benzophenone triplet could be measured at 525 nm. The $T_n \leftarrow T_1$ absorption of acetophenone (34) and the other phenyl alkyl ketones are also shown in Fig. 1. The decay rate of the triplet state of aromatic ketones were monitored at 370 nm (acetophenone), 360 nm (propiophenone), and 350 nm (benzyl phenyl ketone), where the $T_n \leftarrow T_1$ absorption of the corresponding protonated ketone was very weak as shown in Fig. 2. There was no ketyl radical (or anion radical) formation in laser flash photolysis of phenyl alkyl ketones in neutral H_2O–CH_3CN (4:1), in contrast to that of BP. This is due to the fact that the lowest triplet state of the phenyl alkyl ketones is not $^3(n,\pi^*)$ but $^3(\pi,\pi^*)$ in polar media (34, 35), whereas the lowest triplet state of BP is $^3(n,\pi^*)$.

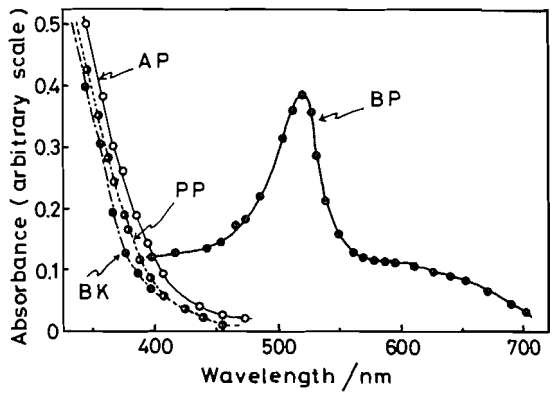

FIG. 1. Transient absorption spectra of benzophenone (BP) acetophenone (AP), propiophenone (PP), and benzyl phenyl ketone (BK) in H_2O–CH_3CN (4:1) mixtures at 200 ns after pulsing at room temperature. The spectra were taken from ref. 28, except for BK.

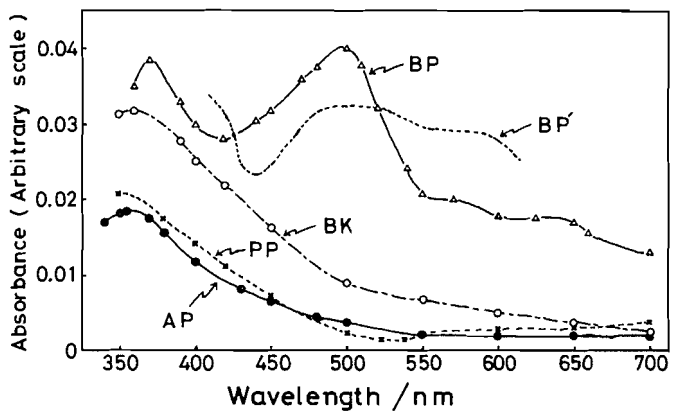

FIG. 2. Transient absorption spectra of aromatic ketones in H_2O–CH_3CN (4:1) mixtures in the presence of 5M H_2SO_4 just after pulsing at 20°C, where BP′ denotes the transient observed by conventional flash photolysis (33).

It is known that the triplet lifetime of BP depends upon its concentration (self-quenching) (30). However, if the same concentration of the ketone is used throughout the experiments with and without acids, this problem may be excluded. There is little or no quenching of triplet ketones by the counter anion SO_4^{2-} under the experimental conditions (28).

Triplet–Triplet absorbance titration curve

The $T_n \leftarrow T_1$ absorbance titration curves of benzophenone (BP), acetophenone (AP), propiophenone (PP), and benzyl phenyl ketone (BK) at various acidities are shown in Fig. 3 (a)–(d), respectively. The absorbance was the value of the initial absorbance. From the midpoint of the titration curve

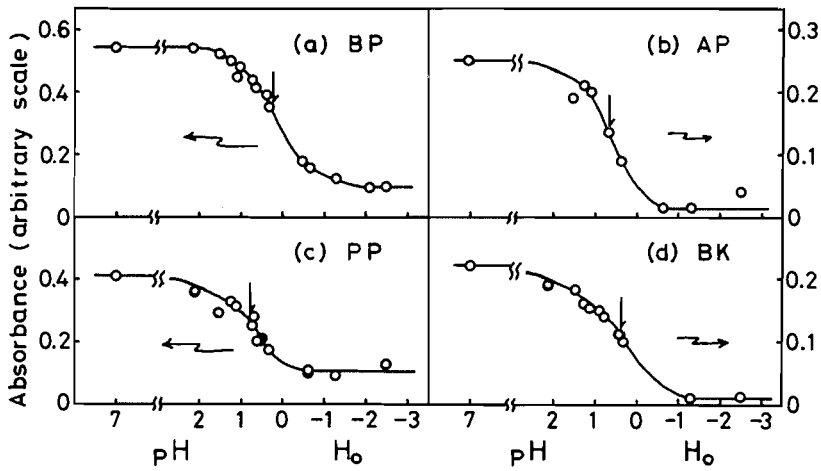

FIG. 3. The $T_n \leftarrow T_1$ titration curves of aromatic ketones in H_2O–CH_3CN (4:1) at 20°C.

(11), the acidity constant $pK_a(T)$ of the triplet state of aromatic ketones can be simply determined to be 0.20 ± 0.02 (BP), 0.63 ± 0.07 (AP), 0.75 ± 0.05 (PP), and 0.35 ± 0.05 (BK).

Kinetic analyses: Ware and Rayner–Wyatt plots

The oscillogram trace of the $T_n \leftarrow T_1$ absorption of each of the aromatic ketones showed a single exponential decay with and without protons. The observed triplet lifetimes τ of BP, AP, PP, and BK are listed in Table 1. The τ values decreased quickly with increasing proton concentration. The acid–base reaction in the triplet state of aromatic ketones (^3A) can be accounted for by the scheme in reaction [1]:

[1]
$$\begin{array}{ccccc} {}^1A & \xrightarrow{k_{isc}} & {}^3A + H^+ & \underset{k_2}{\overset{k_1}{\rightleftharpoons}} & {}^3A^+H \\ \uparrow h\nu & & \downarrow (\tau_0)^{-1} & & \downarrow (\tau_0')^{-1} \\ A & & + H^+ & \underset{k_2^0}{\overset{k_1^0}{\rightleftharpoons}} & A^+H \end{array}$$

where τ_0 and τ_0' denote the lifetimes of ^3A (in the absence of protons) and $^3A^+H$ respectively, k_1 and k_2 the protonation and dissociation rate constants in the triplet state, respectively, and A^+H protonated aromatic ketones. At the highest acidities used the ground state ketones are unprotonated (6). If we assume that the rates of the proton transfer reactions ($k_1[H^+]$ and k_2) in the triplet state are very fast in comparison with the triplet decay rates ($(\tau_0)^{-1}$ and $(\tau_0')^{-1}$), respectively (that is, an acid–base equilibrium is established within the triplet lifetime), the following equations proposed by Ware (25) and Rayner–Wyatt (23) may be applied to the present system. The Ware equation reads

$$[2] \quad \{\tau^{-1} - \tau_0^{-1}\}^{-1} = \{(\tau_0')^{-1} - \tau_0^{-1}\}^{-1}\left\{1 + \frac{K_a}{[H^+]}\right\}$$

The Rayner–Wyatt equation reads

$$[3] \quad \frac{1}{[H^+]}\{\tau^{-1} - \tau_0^{-1}\} = \frac{(\tau_0')^{-1}}{K_a} - \frac{\tau^{-1}}{K_a}$$

where τ denotes the observed triplet lifetime and K_a the equilibrium constant in the triplet state, which is equal to k_2/k_1. Both equations are derived on the assumptions that $k_1[H^+] \gg \tau_0^{-1}$ and $k_2 \gg (\tau_0')^{-1}$, as described above. In fact, if eq. [4] (23) is substituted into eq. [3] one can derive the Ware equation (eq. [2]).

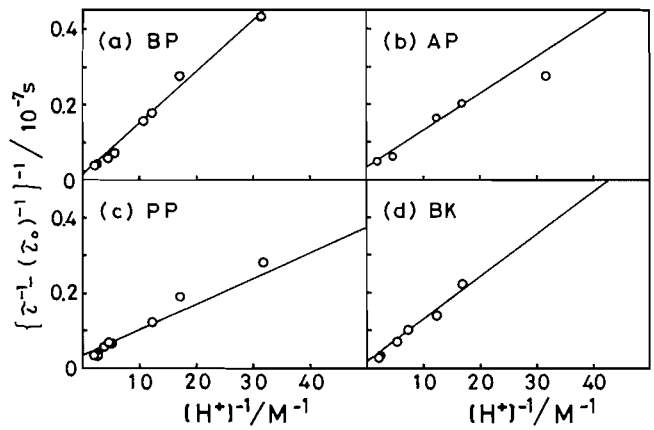

FIG. 4. The Ware plot of aromatic ketones. For details see text.

$$[4] \quad \tau^{-1} = \frac{k_1[H^+]}{k_2 + k_1[H^+]}(\tau_0')^{-1} + \frac{k_2}{k_2 + k_1[H^+]}\tau_0^{-1}$$

The Rayner–Wyatt equation is very sensitive to the τ value which appears on both sides in eq. [3]. The Ware equation is sensitive to $[H^+]$, since the difference between τ^{-1} and τ_0^{-1} becomes small at lower concentrations of protons. The Ware plot of $(\tau^{-1} - \tau_0^{-1})^{-1}$ as a function of $[H^+]^{-1}$ is shown in Fig. 4, and a straight line is obtained, demonstrating that the experimental results agree with eq. [2]. From the slope and intercept, the K_a value can be determined. The $pK_a(T)$ values of aromatic ketones obtained by the Ware plot are 0.13 ± 0.02 (BP), 0.60 ± 0.10 (AP), 0.70 ± 0.10 (PP), and 0.30 ± 0.05 (BK). These data are listed in Table 2.

The Rayner–Wyatt plot of $(\tau^{-1} - \tau_0^{-1})[H^+]^{-1}$ vs. τ^{-1} is depicted in Fig. 5. Although the deviation from linearity in the case of PP (*c*) and simple scatter in the cases of BP (*a*) and AP (*b*) exist in Fig. 5, the experimental results are approximately fitted to eq. [3], except for BK. From Rayner–Wyatt plot, the $pK_a(T)$ values are estimated to be 0.1 ± 0.1 (BP), 0.60 ± 0.15 (AP), and 0.78 ± 0.20 (PP). For BK, the laser flash experiments were repeated four times independently. However, similar results were obtained as shown in Fig. 5(*d*). The reason why no slope was obtained in the case of BK is unknown at the present time. Judging from the Ware and Rayner–Wyatt plots, in Figs. 4 and 5, the former is obviously superior to the latter in yielding the K_a values, though both eqs. [2] and [3] are essentially the same.

[a] Arbitrary scale.
[b] $\tau = \tau_0$ at pH = 7.0.
[c] Transient absorption is too weak for kinetic analysis.

It is noteworthy that the $pK_a(T)$ values determined by the $T_n \leftarrow T_1$ absorbance titration curve are in good agreement with those by the kinetic analyses (Ware and Rayner–Wyatt plots) as shown in Table 2. This means that for aromatic ketones the acid–base equilibrium in the T_1 state is attained during its lifetime. Equation [2], which is derived on the assumptions that

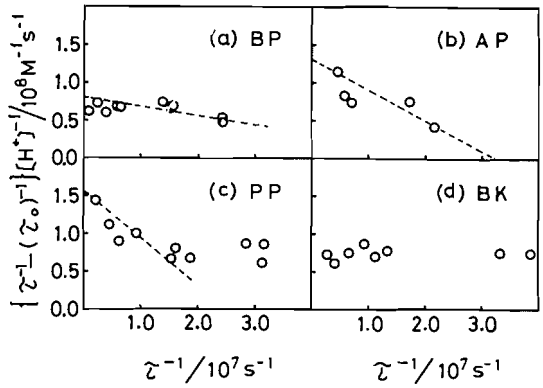

FIG. 5. The Rayner–Wyatt plot of aromatic ketones. See text.

$k_1[H^+] \gg \tau_0^{-1}$ and $k_2 \gg (\tau_0')^{-1}$, fairly holds in the present system. The establishment of prototropic equilibria in the triplet states of BP (23) and acridine (24) has been reported. Therefore it can be said that the prototropic equilibrium in the T_1 state of aromatic compounds is generally accomplished during the excited-state lifetime. The establishment is due to the fact that the forbidden $T_1 \rightarrow S_0$ decay is slow compared with the rate of proton transfer reaction.

Isotope-exchange reactions in the T_1 *state and proton-induced quenching*

It has been reported that the triplet state of acetone is quenched by water and the quenching is caused by the hydrogen (or isotope) exchange reaction in the triplet state (36). In the present work, a similar isotope-exchange reaction was observed. For example, the isotope-exchange reaction occurred effectively in the triplet state of AP (or PP) as shown in eq. [5] (or eq. [6]):

[5] 
[6] 
These reactions were detected by nmr and ms methods. The isotope-exchanged position (the methyl or methylene group adjacent to the carbonyl group) of AP or PP was determined by nmr spectroscopy (AP: methyl protons 2.59 ppm; PP: methylene protons 2.70–3.07 ppm). For BP having no methyl or methylene group, no isotope-exchange reaction in the T_1 state was observed under the experimental conditions. The reaction quantum yield for AP was ca. 0.2 in D_2O:CH_3CN (4:1) in the presence of 0.05 *M* D_2SO_4 at 313 nm. The value was determined by ms measurements at m/e = 120 and m/e = 121, calibrating naturally abundant ^{13}C in acetophenone. Unfortunately, the quantitative work for the photochemical isotope-exchange reaction was very difficult since it took place in the dark, even at room temperature. The isotope-exchange reaction of AP may proceed via enol formation (reaction [7]).

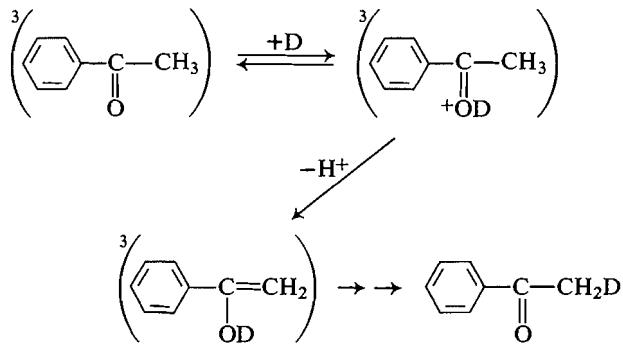
[7]



The radiationless decay due to deuterium (or proton) exchange does not exceed the proton dissociation rate k_2 in eq. [1], whereas the radiationless decay due to isotope (or proton) exchange is competitive with the protonation rate in the excited singlet state of aromatic compounds (15, 17–22).

There may be two reasons why the proton-induced quenching is not so effective in the triplet state. First, the excited state properties reflect the rates of the proton-induced quenching; the ionic reaction is dominant in the S_1 state and in contrast little or no proton-induced quenching in the T_1 state occurs (15). For 2-naphthylammonium ion, the proton transfer reaction occurs effectively in the S_1 state while the hydrogen atom transfer from triplet naphthylammonium ion to the ground aromatic ketones takes place (37). This is another example of the triplet state being more favourable for the radical reaction rather than the ionic reaction. Secondly, the prototropic position in an excited molecule is important for proton-induced quenching (15). When the prototropic reaction takes place at the electron-donating substituent (amino or hydroxy group) of aromatic compounds, proton-induced quenching occurs effectively by electrophilic attack at one of the carbon atoms of the aromatic ring (13, 15, 18–20). That is, effective proton-induced quenching is caused in the case that the electrophilic protonation occurs at a different position from that of the prototropic reaction. However, when the prototropic position (e.g., the oxygen atom of carbonyl group) having a relatively high charge density produced by intramolecular charge transfer is just the same as that of the electrophilic attack by protons, there is little or no proton-induced quenching and only the pK_a value may increase significantly in the excited state. The prototropic feature in the T_1 state of aromatic ketones is of the latter case, as discussed later.

Relationship between $pK_a(T)$ *and Taft* σ* *values*

Substituents attached to aromatic ketones may affect the basic properties in the triplet state, leading to a change in the $pK_a(T)$ values. We examined, therefore, the plot of $pK_a(T)$ as a function of Taft σ* values (38), as shown in Fig. 6. The plot suggests that there is a linear relation between $pK_a(T)$ and σ* values, except for BP. The σ-electron donating power of the alkyl group (R) increases the $pK_a(T)$ value; the +I effect of the group is in the order $CH_2CH_3 > CH_3 > CH_2Ph$. From Fig. 6, eq. [8] is obtained:

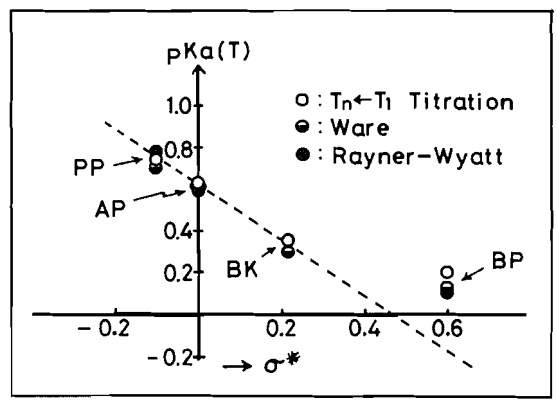


FIG. 6. The relation between $pK_a(T)$ and Taft σ* values.

[8] $pK_a(T) = \rho^*\sigma^* + pK_a(T)_0$

where the slope $\rho^* = -1.33$ and $pK_a(T)_0$ denotes the $pK_a(T)$ value of AP (0.60). The +I effect of R increases the charge density (i.e., basicity) at the oxygen atom of the carbonyl group, resulting in an increase of the $pK_a(T)$ value. For BP, a positive deviation from the line can be seen in Fig. 6. The $pK_a(T)$ of BP has a greater value than that (−0.2) expected from its σ* value. This fact cannot be explained by the difference in the T_1 character between $^3(n,\pi^*)$ (BP) and $^3(\pi,\pi^*)$ (phenyl alkyl ketones) in polar media. The electron density at the carbonyl group in the $^3(n,\pi^*)$ state should be smaller than that in the $^3(\pi,\pi^*)$ state, since the $^3(n,\pi^*)$ state involves back charge-transfer (from the carbonyl group to the phenyl ring). Actually the $^3(n,\pi^*)$ and $^3(\pi,\pi^*)$ states are perturbed by one another since the energy separation between them is very small in polar media (as discussed previously (28)). The reason why the basicity in the T_1 state of BP is relatively high may be due to a positive mesomeric effect (+M) from the phenyl group. That is, the $pK_a(T)$ value of BP becomes large compared to that estimated from eq. [8]. Electron migration from the phenyl group to the carbonyl group may occur in the T_1 state of BP resulting in an increase in the charge density at the carbonyl

For personal use only.

group in ^{3}BP. The electronic structure in the T_1 state of BP in polar media has an intramolecular CT structure to some extent.

The experimental value (0.20 ± 0.1) of $pK_a(T)$ of BP obtained in a 20% acetonitrile solution is close to that (0.5 ± 0.3) in a 20% ethanol solution reported by Rayner and Wyatt (23). The $pK_a(T)$ value of BP in aqueous solution is known to be 1.5 ± 0.2 (23). The solvent effect on $pK_a(T)$ may be caused by the intramolecular CT character in ^{3}BP, which is dominant in aqueous solution compared to that in mixtures. The pK_a values in the T_1 state of aromatic ketones having an electron-withdrawing group (carbonyl group) are greatly increased in comparison with those in the ground state (BP: $pK_a(S_0) = -5.7$ (39); AP: $pK_a(S_0) = -6.1$ (6)).

The determination of $pK_a(T)$ value of BP by means of the Förster cycle is more difficult than by laser flash photolysis because the measurement of the correct value of $pK_a(S_0)$ in the ground state of BP is not easy. The $pK_a(S_0)$ value of BP is negatively large ($-6.09 \sim -6.25$ on the H_0 scale (40); -5.70 on the H_B scale (39)). At higher concentrations of H_2SO_4, the $pK_a(S_0)$ value depends upon the H_0 or H_B scale as discussed by Rayner and Wyatt (23). A similar situation may exist for other aromatic ketones. Therefore, it can be said that the determination of $pK_a(T)$ values of aromatic ketones by means of the $T_n \leftarrow T_1$ absorbance titration method (11) has the advantage of greater simplicity. The kinetic analysis by the Ware plot (25) is also available for the determination of $pK_a(T)$ values.

Conclusion

The results reported are consistent with the scheme shown in reaction [1] and allow the following conclusions to be drawn: (*1*) The $pK_a(T)$ values determined by the $T_n \leftarrow T_1$ absorbance titration curve, the Ware plot, and the Rayner–Wyatt plot show the same values within experimental errors. (*2*) The acid–base equilibrium in the triplet state of aromatic ketones is established during the lifetime of triplet aromatic ketones. The triplet lifetime is long enough to produce the prototropic equilibrium. (*3*) A linear relation between $pK_a(T)$ and the Taft σ^* values is obtained, except for benzophenone. (*4*) Proton-induced quenching in the T_1 state is small compared to the rates of proton transfer reactions.

Photoirradiation of anthracene in benzene in the presence of oxygen gave predominantly a photodimer of anthracene, and very little oxidation product. Similar irradiation of anthracene in bromobenzene, however, produced 9,10-anthraquinone in high yield. The yield of anthraquinone increased in the presence of a heavy-atom solvent such as bromobenzene, *p*-dibromobenzene, 1,3,5-tribromobenzene, 1-bromopropane, and dibromomethane in proportion to the sum of squares of the spin–orbit coupling parameter ζ of the solvent molecule. This relationship indicates an external heavy-atom effect on the photooxidation of anthracene. The mechanistic investigations suggest the involvement of singlet oxygen, anthracene peroxide, and a radical intermediate in the formation of anthraquinone.

NAOKI TOSHIMA, TOSHIHIKO SUGANO et HIDEFUMI HIRAI. Can. J. Chem. **62**, 2047 (1984).

La photoirradiation de l'anthracène dans le benzène, en présence d'oxygène, conduit principalement au photodimère de l'anthracène et à très peu de produits d'oxydation. Toutefois, une irradiation analogue de l'anthracène dans le bromobenzène conduit à l'anthraquinone-9,10 avec un rendement élevé. Le rendement en anthraquinone augmente lorsqu'on opère la réaction dans des solvants comme le bromobenzène, le *p*-dibromobenzène, le tribromo-1,3,5-benzène, le bromo-1 propane et le dibromométhane qui portent des atomes lourds; d'un point de vue quantitatif, le rendement en anthraquinone est proportionnel à la somme du carré du paramètre de couplage spin–orbite (ζ) de la molécule de solvant. Cette relation suggère l'existence d'un effet extérieur des atomes lourds sur la photoxydation de l'anthracène. Les recherches sur le mécanisme réactionnel suggèrent l'implication d'oxygène singulet, de peroxyde d'anthracène et d'un intermédiaire radicalaire dans la formation de l'anthraquinone.

Introduction

Heavy-atom enhanced $S_1 \rightarrow T_1$ intersystem crossing has proven quite useful in synthetic and mechanistic photochemistry. The heavy-atom effect is synthetically useful for increasing quantum yield, product yield, and product selectivity. For example, Cowan and Drisko (1–3) have detected an increase in the yield of *trans*-photodimer due to a heavy-atom effect in photodimerization of acenaphthylene. We have found that heavy-atom solvents are effective for accelerating the photoaddition (4) and photoreduction (5) of *N*-acetyldiphenylketimine in spite of the molecule having a carbonyl group.

Photodimerization of anthracene is known as one of the oldest organic photoreactions. Fluorescence of anthracene can be quenched by the addition of a heavy-atom solvent, which has been explained in terms of a heavy-atom effect (6, 7). Since the photodimerization of anthracene and its derivatives proceeds through a singlet excimer (8), the photodimerization should be quenched by a heavy-atom effect. The same heavy-atom effect has been also discovered in photoreactions in micelles recently. Thus, the heavy-atom effect of the bromide counter-ions of cetyltrimethylammonium micelles reduces the photodimerization quantum yield (9) as well as the fluorescence quantum yield (10) of 9-methylanthracene.

In this paper we present confirmation of the decrease of photodimerization yields of anthracene by the addition of heavy-atom solvents such as bromobenzenes, and then extend the effect to the reaction of anthracene and its derivatives through triplet states with a resulting increase in their photooxidation yields.

Experimental

Chemicals

Commercial anthracene of an extra pure grade was purified by recrystallization from benzene and chloroform. Commercial anthracene derivatives of an extra pure grade were used as received. Benzene was purified by distillation through a Vigreux column from sodium metal. Bromobenzene was distilled before use. Other solvents were used as received. Commercial pure solvents (Luminasol) for fluorescence spectra were used for the fluorescence measurements. Anthracene peroxide was prepared according to the method of Foote (11) by using methylene blue as a sensitizer and a tungsten–halogen lamp as a light source.

Instruments

Photoirradiations were carried out in Pyrex tubes fixed in a Rikōkagaku irradiation apparatus of a merry-go-round type using an Eikōsha 500 W high pressure mercury lamp. The rotating Pyrex tubes were held in a constant temperature water bath with a turntable device, which also rotated around the lamp housed in a water-cooled quartz immersion well. A Rikōkagaku 300 W tungsten–halogen lamp was used as a light source for the preparation of anthracene peroxide. Reaction products were analyzed with a Tōyōsōda HPLC apparatus equipped with an LS-410K reverse column by using a mixed solvent of water and methanol (1:9) as a carrier. Fluorescence and phosphorescence spectra were measured with a Hitachi MPF-4 fluorescence spectrometer. Ultraviolet and visibile spectra were recorded with a Hitachi 340 recording spectrophotometer. Infrared spectra were measured with a JASCO A-3 spectrometer. A Hitachi M-52 mass spectrometer was used for mass spectrum analyses. Nuclear magnetic resonance spectra were observed with a JEOL JNM-PS-100 spectrometer.

Photodimerization of anthracene

A solution of anthracene (3 mmol dm^{-3}) in a mixed solvent of benzene and bromobenzenes in a Pyrex tube was degassed in three successive freeze–pump–thaw cycles, and then irradiated under argon with a 500 W high pressure mercury lamp in a 30°C water bath for 60 min through Pyrex glass ($\lambda_{max} > 300$ nm). The conversion yield (%) of anthracene was measured by hplc using dibenzyl as an internal standard.

Photooxidation of anthracene and its derivatives

The same solution of anthracene used for photodimerization was

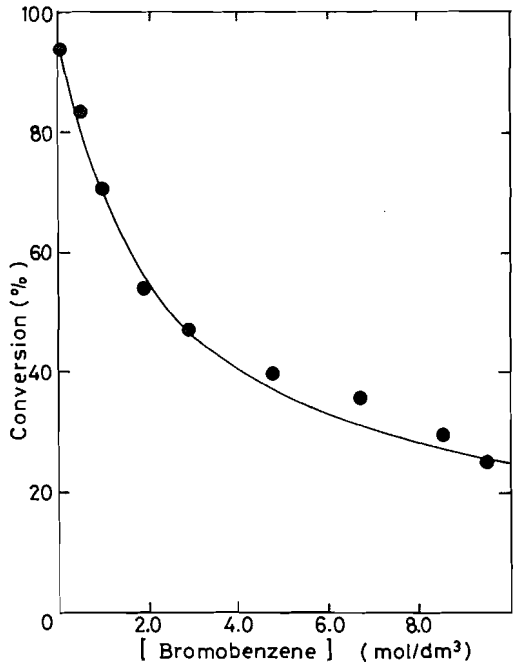

FIG. 1. Dependence of the photodimerization rate of anthracene upon the concentration of bromobenzene on irradiation of 3 mmol dm^{-3} anthracene in benzene under argon at 30°C for 60 min.

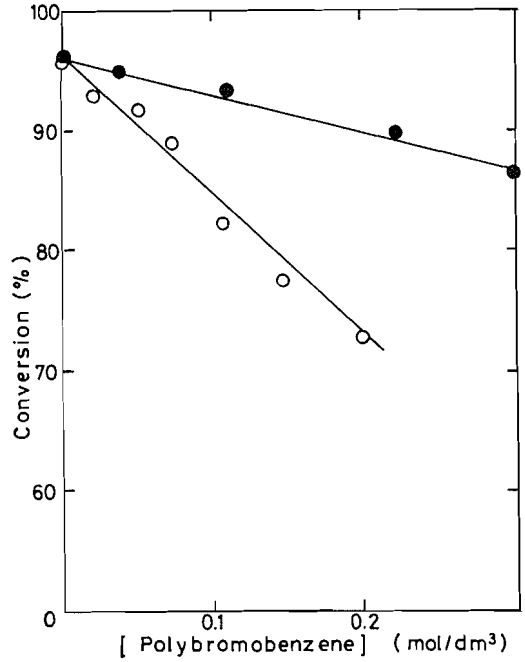

FIG. 2. Dependence of the photodimerization rate of anthracene upon the concentration of *p*-dibromobenzene (●) and 1,3,5-tribromobenzene (○) under the same conditions as Fig. 1.

oxygenated by passing a stream of oxygen through it for 2 min. Photoirradiation of the solution was carried out in the same way as that for photodimerization, but under oxygen, for 60 min or 120 min. The product was isolated by preparative thin layer chromatography using chloroform as the developing solvent. The isolated yellow crystalline compound was identified as 9,10-anthraquinone by comparing the uv, ir, and nmr spectra with those of the authentic sample. The product yields were determined by measuring the peak area of the hplc traces using dibenzyl as an internal standard.

Similar conditions were also employed in the presence of the additives described in the Discussion section.

Results

Effect of bromobenzenes on photodimerization of anthracene

Irradiation of anthracene (3 mmol dm^{-3}) in benzene in the absence of oxygen produced the photodimer of anthracene as a precipitate. Addition of bromobenzene to the solution decreased the conversion of anthracene as shown in Fig. 1. The presence of about 3 mol dm^{-3} of bromobenzene reduced the conversion to half, but the effect of further addition of bromobenzene, however, was less marked (see Fig. 1). Similar reduction of the conversion rate was observed by the addition of smaller amounts of *p*-dibromobenzene or 1,3,5-tribromobenzene as shown in Fig. 2. The bromobenzenes were recovered from these photoreactions without change.

Effect of bromo compounds on photooxidation of anthracene

Irradiation of a dilute solution of anthracene (3 mmol dm^{-3}) in benzene under oxygen still gave the photodimer of anthracene and a small amount of 9,10-anthraquinone. Addition of bromobenzene to the solution decreased the yield of the photodimer and increased the yield of anthraquinone. The effect of the concentration of bromobenzene on the yield of anthraquinone is shown in Fig. 3. The yield of anthraquinone increased with the increase of the concentration of bromobenzene until about 4 mol dm^{-3}, then started to decrease slowly. This trend was observed whether the irradiation time was 60 min or

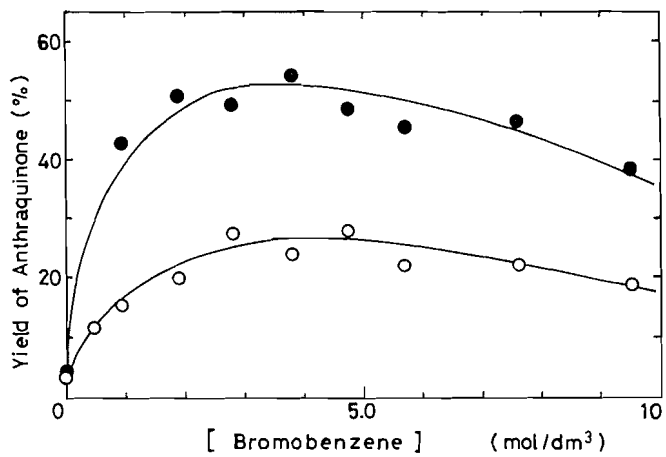

FIG. 3. Effect of the concentration of bromobenzene upon the yield of 9,10-anthraquinone on irradiation of 3 mmol dm^{-3} anthracene in benzene under oxygen at 60°C for 30 min (○) or 120 min (●).

120 min. When other bromocompounds were used instead of bromobenzene, similar increases in the yields of anthraquinone were observed as shown in Fig. 4. The effect of the concentration of bromo compounds depends on the number of bromine atoms per molecule, i.e., the effect increases in the order of bromobenzene, *p*-dibromobenzene, and 1,3,5-tribromobenzene. No products other than anthraquinone and the photodimer were detected in these photoreactions.

Chlorobenzene, iodomethane, and nitrobenzene were used as co-solvents instead of bromo compounds in the photoreaction. Chlorobenzene showed a small effect on the yield of anthraquinone. In the case of iodomethane, most of the photoenergy was consumed in the cleavage of the C—I bond and the anthraquinone yield increased modestly. No effect was detected by addition of nitrobenzene.

[b]The quantum yield of the intersystem crossing (ϕ_{isc}) and the triplet energy (E_T) were taken form ref. 25.

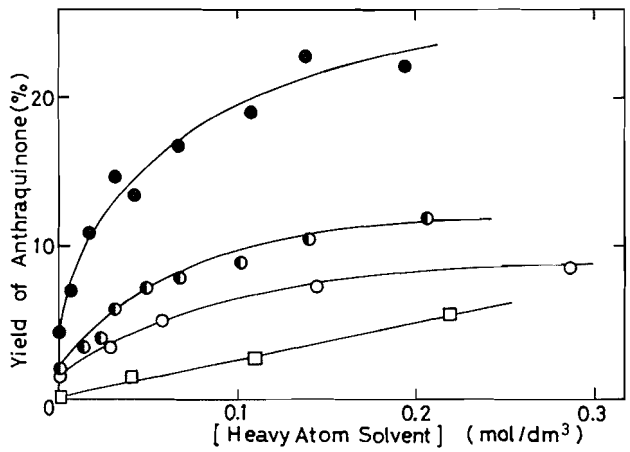

FIG. 4. Effect of the concentrations of 1,3,5-tribromobenzene (●), *p*-dibromobenzene (◐), dibromomethane (○), and 1-bromopropane (□) upon the yield of 9,10-anthraquinone on irradiation of 3 mmol dm^{-3} anthracene in benzene under oxygen at 30°C for 60 min.

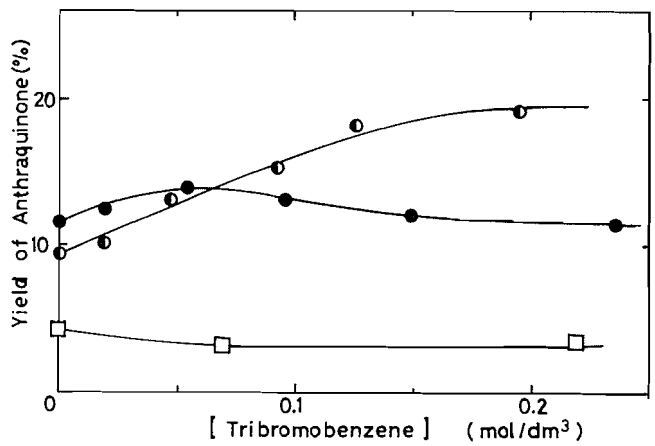

FIG. 5. Effect of the concentration of tribromobenzene upon the yield of 9,10-anthraquinone on irradiation of 3 mmol dm^{-3} 9-methylanthracene (◐), 9,10-dimethylanthracene (●), and 9-phenylanthracene (□) in benzene under oxygen for 60 min.

Photooxidation of anthracene derivatives in the presence of tribromobenzene

The effect of tribromobenzene on the photooxidation was examined for 9- and 9,10-substituted anthracene. Dependence of anthraquinone yield on the concentration of tribromobenzene is illustrated in Fig. 5 for 9-methylanthracene, 9,10-dimethylanthracene, and 9-phenylanthracene. In the irradiation of 9-methylanthracene, addition of tribromobenzene increased the yield of anthraquinone. By way of contrast, little effect of the addition of tribromobenzene was observed in the case of 9,10-dimethylanthracene and 9-phenylanthracene. Other products detected were methane, identified by ir and mass spectra of the gaseous product in the photooxidation of 9,10-dimethylanthracene, and 9-phenylanthrone, identified by ir spectra in the photooxidation of 9-phenylanthracene.

Photooxidation of chloro- or bromo-substituted anthracene was carried out in the absence and presence of 1,3,5-tribromobenzene. The results of other substituted anthracenes mentioned above are summarized in Table 1. Effects of the presence of tribromobenzene (TBB) are indicated by the ratio of the yields of anthraquinone in the presence and absence of TBB (ϕ/ϕ^0).

Effect of additives on the photooxidation of anthracene

A benzene solution of anthracene was irradiated in oxygen with the addition of benzil using a VY-42 filter ($\lambda > 400$ nm), also producing anthraquinone, although no light was absorbed by anthracene. In contrast, the addition of piperylene to a benzene–bromobenzene (3.81 mol dm^{-3}) solution of anthracene (3 mmol dm^{-3}) quenched the photooxidation of anthracene under oxygen, as shown in Fig. 6. These results indicate the contribution of the excited triplet state of anthracene to the photooxidation (see Discussion section).

Anthraquinone was also obtained in moderate yield by the irradiation of anthracene with a VY-42 filter under oxygen in the presence of rose bengal or methylene blue instead of bromo compounds. In contrast, addition of tetramethylethylene (2,3-dimethyl-2-butene, 3 to 40 mmol dm^{-3}) to benzene–bromobenzene or benzene–dibromobenzene solution of anthracene rapidly decreased the yield of anthraquinone when irradiated in oxygen. Reduction of mixtures of the photoproducts with sodium borohydride gave 2,3-dimethylbut-3-en-2-ol, which was identified by comparing the mass spectrum of the corresponding peak in the gas chromatograph of the products with that of the authentic sample prepared separately. Addition of

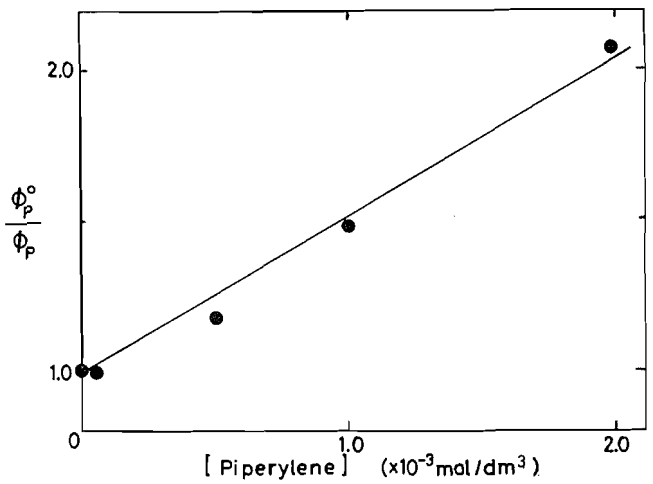

FIG. 6. Stern–Volmer plot for the quenching of 9,10-anthraquinone yield by piperylene (1,3-pentadiene) on irradiation of 3 mmol dm^{-3} anthracene in benzene with addition of 3.81 mol dm^{-3} bromobenzene under oxygen at 30°C for 60 min.

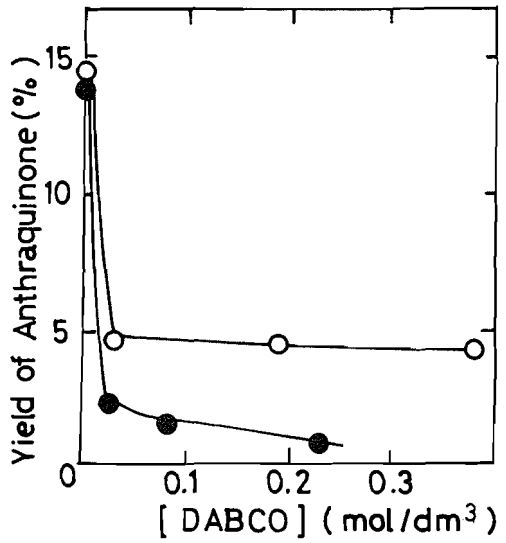

FIG. 7. Effect of the concentration of 1,4-diazabicyclo[2.2.2]-octane (DABCO) upon the yield of 9,10-anthraquinone on irradiation under oxygen for 60 min of 3 mmol dm^{-3} anthracene (○) in benzene with addition of 1.9 mol dm^{-3} bromobenzene, and of 3 mmol dm^{-3} 9-methylanthracene (●) in benzene with addition of 0.11 mol dm^{-3} 1,3,5-tribromobenzene.

1,4-diazabicyclo[2.2.2]octane (DABCO) to a solution of anthracene in bromobenzene, or 9-methylanthracene in tribromobenzene caused a large decrease in the yield of anthraquinone on irradiation as shown in Fig. 7. The inhibiting effect of DABCO on the formation of anthraquinone was also observed in other anthracene derivatives as summarized in Table 2. These results suggest the contribution of singlet oxygen in the photooxidation of anthracene in the presence of a heavy-atom solvent (see Discussion section).

Effect of *p*-hydroquinone as a radical scavenger was examined. Since hydroquinone is not soluble in benzene, mixed benzene–methanol (6:4) instead of benzene was used as a solvent in the photooxidation of anthracene. Irradiation of anthracene in benzene–methanol with the addition of *p*-dibromobenzene (0.13 mol dm^{-3}) under oxygen for 60 min gave anthraquinone in 15.3% yield. By way of contrast, the presence of hydroquinone (6 mmol dm^{-3}) inhibited the formation of anthraquinone and reduced the yield to 0.69%.

TABLE 2. Effect of 1,4-diazabicyclo[2.2.2]octane (DABCO) upon the anthraquinone yield in the photooxidation of anthracene derivatives[a]

Anthracene		Yield of anthraquinone (%)	
9-Substituent	10-Substituent	Without DABCO	With DABCO[b]

Me	H	16.8	2.4
Me	Me	12.8	0.42
Ph	H	4.05	0.56
Cl	Cl[c]	28.1	0.42
Br	H[c]	41.1	5.45
Br	Br[c]	36.5	2.72

[a]The benzene solutions were irradiated under oxygen at 30°C for 60 min in the presence of bromobenzene (1.9 mol dm^{-3}).
[b][DABCO] = 0.027 mol dm^{-3}.
[c]Irradiations were carried out without bromobenzene in these cases.

Reactions of anthracene peroxide

The reactions of singlet oxygen and anthracene derivatives are known to produce anthracene peroxide derivatives (12–15). In the present photooxidation of anthracene it seemed possible that anthracene peroxide might exist as an intermediate in the formation of anthraquinone from anthracene. Attempts to isolate anthracene peroxide, however, failed even at low temperature.

Heating the endoperoxide of 9,10-diphenylanthracene has been reported to produce anthracene and singlet oxygen (16, 17). Heating a dilute solution of anthracene peroxide gave isomerized products, plus anthracene and anthraquinone in minor amounts (18). The reactions of anthracene peroxide were examined under the same conditions employed in the photooxidation of anthracene in the present investigations. When a benzene solution of anthracene peroxide was first kept at 30°C under oxygen for 60 min, no change was detected. However, photoirradiation of anthracene peroxide in benzene under oxygen in a Pyrex tube gave anthraquinone in about 15% yield. Addition of tribromobenzene (0.1 mol dm^{-3}) to this system decreased the yield of anthraquinone to about 10%. The same results were obtained in the case of 9,10-dimethylanthracene peroxide.

Discussion

Heavy-atom effect in the photoreaction of anthracene

It is well known that anthracene readily dimerizes on irradiation, producing the photodimer. A 3 mol dm^{-3} benzene solution of anthracene produced the dimer in 94% yield on irradiation with 500 W high-pressure mercury lamp for 60 min. Addition of bromobenzene to this system reduced the yield of the photodimer as shown in Fig. 1. The effect of bromobenzene can be explained in terms of an external heavy-atom effect. The singlet excited state of anthracene gives the photodimer via an excimer which is formed from singlet excited anthracene and ground state anthracene (8). A solvent molecule containing one or more heavy-atom can promote a forbidden singlet–triplet transition in an aromatic molecule by an external heavy-atom effect. Therefore, the bromobenzene-induced reduction in the yield of anthracene photodimer should be proportional to the quenching effect of bromobenzene upon the fluorescence of anthracene. This relationship has been confirmed by experi-

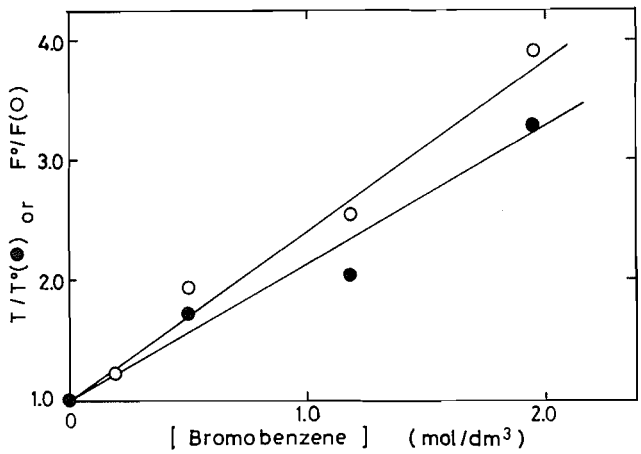

FIG. 8. Stern–Volmer plots for the quenching of anthracene fluorescence by bromobenzene (F^0/F, ○), and for the quenching of 35% anthracene conversion in time (T/T^0, ●). See text for detail.

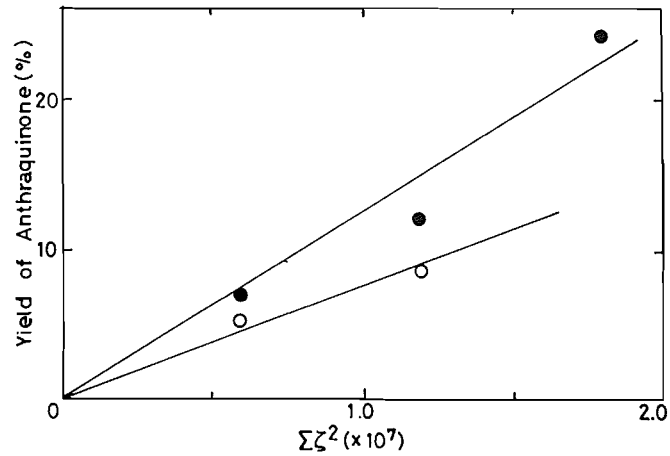

FIG. 9. Relationships between the 9,10-anthraquinone yields and the sum of the square of the spin–orbit coupling parameter (ζ) of heavy-atom solvents. Data were taken from Figs. 1 and 2 at 0.2 mol dm^{-3} concentration of each heavy-atom solvent. See text for detail.

ments with 0.1 mmol dm^{-3} anthracene in benzene. The black circles in Fig. 8 show the ratio of the time for 35% photoconversion of anthracene in the presence of the prescribed amount of bromobenzene to that in the absence of bromobenzene. The open circles indicate a Stern–Volmer plot for the quenching of anthracene fluorescence by bromobenzene. The slopes in the two plots are nearly the same. This consistency supports the idea that the bromobenzene-derived reduction in the photodimer yield and the fluorescence quenching have the same origin, namely, the external heavy-atom effect. Larger effects were observed with dibromobenzene and tribromobenzene (Fig. 2).

The heavy-atom effect in the photooxidation of anthracene and its derivatives

The photolysis products from air-saturated anthracene solutions are known to be strongly dependent on the anthracene concentration and the type of solvent used (8, 19, 20). The important effect of solvent has been demonstrated by Aspler *et al.* Thus, in isooctane, photolysis of a dilute solution of anthracene gives a high yield of the photodimer, whereas in Freon 113, roughly equimolar yields of endoperoxide, anthraquinone, and anthracene dimer are formed (20).

The present results concerning the effect of bromo compounds suggest that the photooxidation proceeds through a triplet excited state of anthracene, the formation of which is promoted by an external heavy-atom effect. This suggestion is supported by the plot of the anthraquinone yields in the presence of a 0.2 mol dm^{-3} brominated solvent against the square of the spin–orbit coupling parameters of the solvent molecules as shown in Fig. 9 (21). Here, the spin–orbit coupling parameter was estimated by summing up the spin–orbit coupling parameter(s) of the heavy atom(s) (bromine) present in the solvent molecule. The linear relationships indicate that the heavy-atom effect plays an important role in the reaction and implicates the triplet state of anthracene. Two lines in Fig. 9 show the relationship in the series of aromatic solvents (black circles: bromobenzene, *p*-dibromobenzene, and 1,3,5-tribromobenzene) and that in aliphatic solvents (open circles: 1-bromopropane and dibromomethane). The difference between the two lines can be explained in terms of the charge-transfer interaction between anthracene and the aromatic solvents. The small effects of chlorobenzene and nitrobenzene can be understood in the same way. The yield of anthraquinone decreased when the concentration of bromobenzene was increased beyond 4 mol dm^{-3} (Fig. 3). Similar reasoning may be used to explain the photodimerization results of acenaphthylene in the presence of iodoethane (22). Thus, highly concentrated bromobenzene could be effective for enhancing intersystem crossing from the triplet excited state to the singlet ground state whereas diluted bromobenzene is effective for enhancing intersystem crossing from the singlet excited state to the triplet excited state.

The above considerations indicate that although photoirradiation of anthracene in usual solvents predominantly gives the photodimer and does not produce anthraquinone under oxygen, the presence of a heavy-atom solvent inhibits the photodimerization by promoting the intersystem crossing, resulting in the formation of anthraquinone on irradiation under oxygen.

In a series of 9- or 9,10-substituted anthracenes, the increases of the anthraquinone yields by the addition of tribromobenzene (ϕ/ϕ^0), the reported quantum yields of the intersystem crossing (ϕ_{isc}), the triplet energies (E_T), and the probabilities of photodimerization have been reported in Table 1. The increase (ϕ/ϕ^0) is not directly related to either ϕ_{isc} or to E_T, but rather appears to be connected to the probability of photodimerization. Thus, the derivative which can dimerize on irradiation also gives the increase in the anthraquinone yield ($\phi/\phi^0 > 1$), as shown in Table 1. This result agrees with the proposal that the presence of a heavy-atom solvent inhibits photodimerization by promoting intersystem crossing, resulting in an increase in the anthraquinone yield upon irradiation under oxygen. Considerably higher yields of anthraquinone in the photooxidation of 9- or 9,10-halosubstituted anthracenes in the absence of tribromobenzene might be partially due to the internal heavy-atom effect.

Photooxidation mechanism

It has been proposed (20, 23) that anthracene photooxidation proceeds via oxygen quenching of the triplet excited state of anthracene molecules and reaction of the resulting singlet oxygen with an anthracene molecule in its ground state. An alternative possibility has been suggested involving electron transfer from triplet anthracene to an oxygen molecule (24).

In the present photooxidation, the presence of the triplet intermediate is supported by the sensitization by benzil, a sensitizer, and the quenching effect of piperylene, a triplet

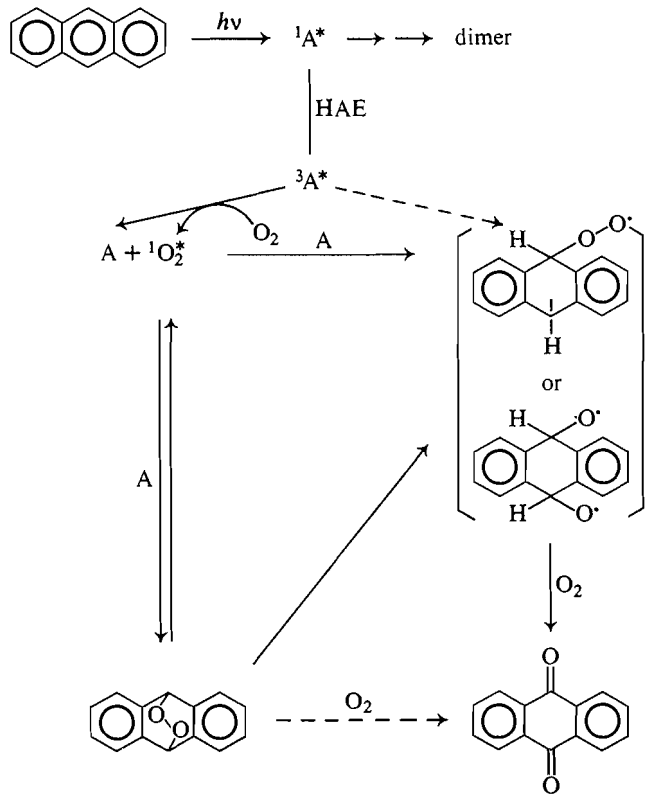

SCHEME 1. Proposed paths for the photooxidation of anthracene (A) in the presence of heavy-atom solvents.

quencher, as well as the heavy atom effect. The quenching of the excited state of anthracene by piperylene is surprising since the triplet energy of piperylene is 59.2 kcal mol^{-1} for the *trans*-isomer or 58.3 kcal mol^{-1} for the *cis*-isomer (25), and anthracene has a first excited triplet energy of 42.0 kcal mol^{-1}. However, the quenching by piperylene may possibly occur from the second excited triplet state (T_2) of anthracene (74.5 kcal mol^{-1}), because the T_2 state of anthracene is known to have a long enough lifetime for energy transfer (26–28).

Photooxidation takes place mostly through the singlet excited state of oxygen (29), and the excitation of oxygen molecules from their triplet ground state ($^3O_2$) to the excited singlet state ($^1O_2^*$) is known to take place by energy transfer from the triplet excited state of anthracene and other aromatic molecules (30). The involvement of the singlet oxygen in the present system was examined by the addition of tetramethylethylene (TME) and DABCO, both singlet oxygen quenchers (31, 32). These results indicate that at least part of the present photooxidation of anthracene in the presence of a heavy-atom solvent involves the singlet oxygen.[1]

There are two possible paths in the reaction of singlet oxygen with anthracene to form anthraquinone. One path involves anthracene peroxide (20, 23), although it could not be isolated from the reaction mixtures in this work.

The other possible path involves a photoperoxidation process where the singlet excited oxygen molecule interacts with the ground state aromatic hydrocarbon (^1M) to form the peroxide $MO_2\cdot$ (33). Inhibition of anthraquinone formation by hydroquinone, a radical scavenger, suggests the involvement of a radical intermediate in the present photooxidation. Hydroquinone also acted partially as an inhibitor in the formation of anthraquinone during the irradiation of anthracene peroxide. Therefore, it cannot be decided whether the radical intermediate is produced directly or via anthracene peroxide.

In summary, the most probable paths of photooxidation of anthracene in the presence of a heavy-atom solvent are shown in Scheme 1. An anthracene molecule absorbs the light leading to a singlet excited state and then to a triplet state. The efficiency of the latter process is enhanced by an external heavy-atom effect. Interaction of triplet excited anthracene with an oxygen molecule in the ground state produces singlet excited oxygen. Reaction of singlet excited oxygen with anthracene in the ground state forms the peroxide radical intermediate, either directly or through anthracene peroxide, which then yields anthraquinone.

[1]A referee has suggested the involvement of an electron transfer step from triplet anthracene to an oxygen molecule (24). According to this mechanism, anthracene radical cation, a product of the above electron transfer, should be quenched by TME or DABCO through electron transfer.

Synthèse de méso-α,γ bis(diamino-2,6 phényl) porphyrines

ALEXANDRA LECAS-NAWROCKA, JACQUES LEVISALLES, CLAIRE MARIACHER, ZAFIARISOA RENKO ET ERIC ROSE[1]

Laboratoire de Chimie Organique (UA 408), Université Pierre et Marie Curie, 4 Place Jussieu, 75230 Paris, Cedex 05, France

Reçu le 17 janvier 1984

Cet article est dédié au Professeur Paul de Mayo à l'occasion de son 60e anniversaire

ALEXANDRA LECAS-NAWROCKA, JACQUES LEVISALLES, CLAIRE MARIACHER, ZAFIARISOA RENKO et ERIC ROSE. Can. J. Chem. **62**, 2054 (1984).

Les synthèses de méso-α,γ bis(diamino-2,6 phényl) octaalkyl-porphyrines ont été réalisées à partir de diacétamido-2,6 phényl bis(benzyloxycarbonyl-2′ dialkyl-3′,4′ pyrryl-5′) méthanes. La synthèse de telles porphyrines à double piquet permet la fonctionnalisation des quatre groupes amino de manière à protéger les deux faces de la porphyrine.

ALEXANDRA LECAS-NAWROCKA, JACQUES LEVISALLES, CLAIRE MARIACHER, ZAFIARISOA RENKO, and ERIC ROSE. Can. J. Chem. **62**, 2054 (1984).

The syntheses of α,γ-meso-bis(2,6 diaminophenyl) octaalkyl-porphyrins are described starting from 2,6-diacetamidophenyl-bis(2′-benzyloxycarbonyl, 3′,4′-dialkyl, 5′-pyrryl) methanes. The synthesis of such double-picket-fence porphyrins enables the four amino groups to function in such a way as to protect both faces of these porphyrins.

La recherche de modèles de l'hémoglobine a conduit divers groupes à synthétiser des porphyrines à piquets (1) ou des porphyrines à anses (2). Les porphyrines à anses déjà synthétisées ne comportent qu'une seule anse, ou deux anses indépendantes (une sur chaque face du squelette porphyrinique). Cet arrangement confère à ces molécules une mobilité conformationnelle notablement supérieure à celle de l'hémoglobine, donc en fait des modèles imparfaits. S'il était possible de coupler mécaniquement le mouvement des deux anses, la mobilité conformationnelle devrait être diminuée, et les modèles ainsi synthétisés devraient être meilleurs. Ce couplage mécanique peut en principe être obtenu en greffant les deux anses sur des groupes phényles, fixés sur des positions *méso* opposées (α et γ) du squelette porphyrinique et disubstitués en positions 2 et 6, par des groupements fonctionnels permettant la greffe (3).

La préparation de porphyrines méso (α,γ) disubstituées par des groupes phényles 2,6 disubstitués fait l'objet du présent mémoire.

Résultats

Trois pyrroles ont été employés dans la réaction de synthèse: le diméthyl-3,4 pyrrole carboxylate de benzyle **1***c*, à cause de la simplicité de sa préparation, est un candidat évident, mais les octaméthyl porphyrines sont notoirement insolubles, ce qui peut poser des problèmes pour le greffage des anses. C'est pourquoi les butyl-3 méthyl-4 pyrrole carboxylates d'éthyle **1***a* et de benzyle **1***b* ont été également préparés avec l'espoir que les tétraméthyl-tétrabutyl-porphyrines obtenues auraient des solubilités satisfaisantes.

Les pyrroles **1***a* et **1***b* sont synthétisés par la méthode employée pour le pyrrole **1***d* (4). L'éthoxycarbonyl-2 diméthyl-3,5 butyl-4 pyrrole **2***a* est préparé selon la méthode de Kleinspehn (5) par condensation de l'oximinomalonate de diéthyle (6) sur l'acétyl-3 heptanone-2 (7).

La transestérification (5) de l'ester éthylique **2***a* livre l'ester benzylique **2***b*. Le pyrrole **2***b* est transformé en pyrrole **1***a* selon la méthode de McDonald *et al.* (8): l'oxydation du pyrrole **2***b* par 3 équivalents de chlorure de sulfuryle, suivie d'un traitement à l'éthanol conduit au diester **2***c* dont l'hydrogénolyse fournit l'acide **2***d*. La décarboxylation de l'acide **2***d* selon la méthode de Battersby *et al.* (9) conduit au pyrrole **1***a* qui est transestérifié en pyrrole **1***b*. Le rendement global du pyrrole **1***b* à partir du malonate d'éthyle est de 18%.

La réactivité du pyrrole **1***b* a été testée sur le diéthoxy-3,3 propionate d'éthyle selon le mode opératoire classique (10) en présence de *p*-TsOH. Le dipyrrylméthane correspondant **3***a* se forme avec un rendement de 70%.

Dans les conditions habituelles (EtOH, HCl) (10) utilisées lors de la condensation d'un pyrrole avec un aldéhyde, les pyrroles **1***a* et **1***b* ne réagissent pas en présence de dinitro-2,6 benzaldéhyde, mais sont récupérés intacts. Lorsque la condensation est effectuée en présence de *p*-TsOH, les produits qui se

forment ne sont pas des phényl-dipyrrylméthanes. Leurs structures **4** et **5** et leur mode de formation sont décrits dans le mémoire suivant (11).

En revanche, lorsque la condensation est effectuée en présence de quantités catalytiques de CF_3CO_3H dans le benzène, les dipyrrylméthanes attendus **6***a* et **6***b* sont obtenus à côté de faibles quantités des produits **4** et **5**. Le choix des conditions expérimentales est assez limité, car le dipyrrylméthane **6***a* est obtenu avec un rendement de 63% si l'on opère dans le benzène à température ordinaire, de 34% si l'on opère au reflux du benzène pendant 1 h, et de 8% si l'on opère dans le chloroforme.

Si on emploie le diacétamido-2,6 benzaldéhyde (12)[2] dans le benzène, en présence de *p*-TsOH, les pyrroles **1***c* et **1***b* conduisent respectivement aux dipyrrylméthanes **6***c* et **6***d*. Ce passage par le diacétamido benzaldéhyde est rendu nécessaire par le fait que l'hydrolyse (acide ou basique) du dipyrrylméthane **6***b* ne conduit qu'à des polymères, que l'hydrogénolyse de **6***b* conduit apparement au diacide **6***e*, mais que celui-ci n'est pas transformable en porphyrine et que la réduction des groupes NO_2 ne conduit à aucun produit renfermant le squelette du dipyrrylméthane.

L'hydrogénolyse des dipyrrylméthanes **3***a*, **6***c* et **6***d* conduit aux diacides **3***b*, **6***f* et **6***q* respectivement.

Afin de vérifier que les groupes n-butyles ne gênent pas la formation de porphyrines, le diacide **3***b* a été traité par $HC(OEt)_3$ et CCl_3CO_2H ou CF_3CO_2H, ce qui conduit après déshydrogénation par la dichlorodicyanoquinone (DDQ), à la porphyrine **7***a*. De même les diacides **6***f* et **6***g* conduisent respectivement aux porphyrines **7***c* et **7***b*.

La désacétylation de **7***c* en **7***d* et la transformation en dérivé triméthylacetylé de **7***d* en **7***e* ont également pu être effectuées.

En conclusion, la synthèse de porphyrines méso-disubstituées en α et γ par des groupes phényles *ortho* disubstitués est possible. La synthèse et les propriétés des porphyrines à deux anses couplées, qui en dérivent, seront décrites dans des mémoires ultérieurs.

Partie expérimentale

Les spectres rmn ont été enregistrés sur un appareil JEOL C 60 HL (60 MHz). Les spectres d'absorption ir ont été enregistrés sur un spectrophotomètre Beckman 4240. Les spectres uv sont réalisés avec un appareil Beckman DK 2A. Les spectres de masse ont été réalisés sur un appareil Crantos MS 30 MS 50. Les spectres de rmn ^{13}C et

[2] La synthèse du diacétamido-2,6 benzaldéhyde a été réalisée au laboratoire par une autre méthode qui sera décrite dans une autre publication.

certains spectres rmn ^1H ont été effectués sur un appareil JEOL FX 90Q. Les microanalyses ont été effectuées au service de microanalyse de l'Université Pierre et Marie Curie.

Lorsque la méthode d'isolement des produits réactionnels comporte une dilution éventuelle du milieu par l'eau, une extraction par solvant organique par l'eau et éventuellement une solution diluée d'acide ou de bicarbonate, un séchage sur Na_2SO_4 et l'évaporation du solvant, l'expression "traitement habituel" sera utilisée.

La chromatographie sur gel de silice se fait avec un éluant qui consiste en un mélange en quantité variable d'éther de pétrole (EP) (fraction Eb = 35–60°C) et d'éther (Et_2O).

1. *Synthèse de pyrroles*

Ethoxycarbonyl-2 diméthyl-3,5 butyl-4 pyrrole **2**a

L'acétyl-3 heptanone-2 (1 mol, 156 g) dans l'acide acétique (716 mL) est chauffée à 80°C avec agitation. On y additionne dans un premier temps le mélange de zinc (3,3 mol, 218 g) et d'acétate de sodium (3,1 mol, 260 g) puis durant 40 min une solution d'oximino malonate de diéthyle (191 g) dans le mélange acide acétique (376 g), eau (155 mL). Le milieu réactionnel est maintenu encore 20 min entre 95 et 105°C, puis versé dans un mélange eau–glace. Le pyrrole **2***a* est recristallisé dans l'éthanol et obtenu sous forme d'un solide blanc nacré; *m* = 155 g, Rdt 70%; *F* = 102°C; *M*, $C_{13}H_{21}NO_2$ = 223; ir ($CHCl_3$): 3460, 1670 cm^{-1}; rmn (CCl_4): 0,9–2,5 (m, 10H), 2,2 (s large, 8H), 4,2 (q, *J* = 6,5 Hz, 2H); rmn ^{13}C ($CDCl_3$): 162,20 (C=O), 129,99, 126,92, 122,21, 116,76 (C pyrroliques), 59,49 (CO_2CH_2), 33,09, 23,73, 22,45, 14,53, 13,93, 11,25, 10,63 (nBu, 2 pyrroles Me, CO_2—CH_3); sm (*M* = 223): pics à 223, 180, 134.

Benzyloxycarbonyl-2 diméthyl-3,5 butyl-4 pyrrole **2**b

Le pyrrole **2***a* (89 g, 0,4 mol) en solution dans l'alcool benzylique (300 mL) contenant du sodium (5 g) est chauffé vers 80°C sous une pression de 15 Torr (1 Torr = 133.3 Pa) durant 4 h. L'éthanol formé est distillé, puis sous pression de 2 Torr l'alcool benzylique est distillé. Après extraction de façon habituelle, le pyrrole **2***b* est recristallisé dans l'hexane; *m* = 72 g, Rdt 67%; *F* = 75–76°C *M*, $C_{18}H_{23}NO_2$ = 285; ir (CCl_4): 3430, 1675 cm^{-1}; rmn (CCl_4): 0,9–1,5 (m, 7H), 2,1 (s, 3H), 2,2 (s, 3H), 2–2,4 (m, 2H), 5,1 (s, 2H), 7,1 (s large, 5H), 10,0 (s, 1H). *Anal.* calc.: C 75,76, H 8,12, N 4,91; tr.: C 75,62, H 8,26, N 5,01.

Benzyloxycarbonyl-2 méthyl-3 butyl-4 éthoxycarbonyl-5 pyrrole **2**c

A une solution de pyrrole **2***b* (0,23 mol) dans l'éther anhydre (500 mL) est ajouté le chlorure du sulfuryle (89 g, 0,66 mol). Le mélange est agité 18 h en maintenant la température entre 10 et 15°C. L'éther est évaporé, puis on ajoute sous la hotte goutte à goutte l'éthanol (325 mL) puis l'eau (455 mL). Le milieu réactionnel est traité de la façon habituelle comprenant en plus un lavage avec une solution de bisulfite de sodium. Le pyrrole **2***c* est recristallisé dans l'hexane; *m* = 67 g, Rdt 85%; *F* = 74°C; *M*, $C_{20}H_{25}NO_4$ = 343; ir (CCl_4): 3430, 1712, 1700

Ethoxycarbonyl-2 butyl-3 méthyl-4 carboxyl-5 pyrrole **2**d

Le pyrrole **2***c* (10 g, 0,03 mol) est mis en solution dans le THF anhydre (100 mL) contenant du palladium sur charbon à 10% (100 mg) et une goutte de triéthylamine. Le ballon est relié à un système de burettes contenant de l'hydrogène. Une forte agitation est maintenue. Il y a absorption de 500 mL d'H_2. Le mélange réactionnel est filtré à chaud sur Célite. Après évaporation est obtenu un solide blanc insoluble dans H_2O, C_6H_6, CH_2Cl_2, $CHCl_3$, CH_3COCH_3, m = 5,1 g, Rdt 70%; F = 216°C; M, $C_{13}H_{19}NO_4$ = 253; ir (KBr): 3210, 1695, 1660 cm^{-1}; rmn (DMSO): 0,9–1,5 (m, 10H), 2,2 (s, 3H), 2,6 (m, 2H), 4,2 (q, J = 7 Hz, 2H), 5,8 (m, 1H): s'échange avec D_2O; 11,5 (s, 1H): s'échange avec D_2O; sm (M = 253): pics à 253, 210, 192, 182, 138, 120. *Anal.* calc.: C 61,64, H 7,56, N 5,53; tr.: C 61,47, H 7,81, N 5,63.

Ethoxycarbonyl-2 butyl-3 méthyl-4 iodo-5 pyrrole **2**e

Le mélange bicarbonate de sodium (32×10^{-3} mol, 2,7 g) dans l'eau (11,3 mL) et le dichloro-1,2 éthane (13,2 mL) est chauffé à 50°C. On y ajoute successivement le pyrrole **2***d* (2,1 g, 9×10^{-3} mol), puis durant 5 min la solution d'iodure de sodium (3,5 g, 23×10^{-3} mol) et d'iode (2,8 g, 11×10^{-3} mol) dans l'eau (11,3 mL). Le reflux est maintenu 1 h, puis une solution saturée de thiosulfate est additionnée, la solution est traitée de façon habituelle. Le pyrrole obtenu est recristallisé dans l'hexane: il se présente sous forme de cristaux blancs rosés; m = 2,6 g, Rdt 85%; F = 103°C; M, $C_{12}H_{18}NO_2I$ = 335; ir (KBr): 3280, 1670 cm^{-1}; ($CHCl_3$): 3260, 1705, 1680 cm^{-1}; rmn ($CDCl_3$): 0,9–1,8 (s, 10H), 2,0 (s, 3H), 2,7 (m, 2H), 4,4 (q, J = 7 Hz, 2H), 9,5 (m, 1H); rmn ^{13}C ($CDCl_3$): 161,06 (C=O), 131,95, 127,8, 125,61, 123,40 (C pyrroliques), 60,32 (CO_2CH_2), 32,91, 25,52, 22,69, 14,50, 14,00, 11,98 (nBu, CO_2—CH_2—CH_3, pyrrole —CH_3); sm (M = 335): pics à 335, 293, 264, 246, 220. *Anal.* calc.: C 43,00, H 5,41, N 4,18, I 37,86; tr.: C 42,66, H 5,63, N 4,49, I 37,47.

Ethoxycarbonyl-2 butyl-3 méthyl-4 pyrrole **1**a

A une solution du pyrrole précédent **2***e* (41 g, 0,13 mol) dans l'éthanol bouillant est additionné goutte à goutte tout d'abord l'iodure de sodium (31,1 g, 0,21 mol) dans l'eau (250 mL), puis l'acide chlorhydrique (0,19 mol), le reflux est maintenu 1 h. Après addition d'une solution de bisulfite de sodium à 37% (55 mL, soit 0,2 mol $NaHSO_3$) le milieu réactionnel est refroidi doucement, puis extrait de la façon habituelle (CH_2Cl_2). Le pyrrole recristallisé dans l'hexane est obtenu sous forme de cristaux blancs rosés; m = 24 g, Rdt 88%; F = 46°C; M, $C_{12}H_{19}NO_2$ = 209; ir ($CHCl_3$): 3470, 1665 large (épaulement 1720 et 1655) cm^{-1}; rmn ($CDCl_3$): 0,8–1,6 (m, 10H), 1,9 (s, 3H), 2,5–3,0 (m, 2H), 4,2 (q, J = 7 Hz, 2H), 6,5 (d, 1H), 9,3 (m, 1H); sm (M = 209): pics à 94, 138, 166, 167, 180. *Anal.* calc.: C 68,86, H 9,15, N 6,69; tr.: C 68,86, H 9,07, N 6,88.

Benzyloxycarbonyl-2 butyl-3 méthyl-4 pyrrole **1**b

On opère par transestérification de la même façon que précédemment lors de la formation de **2***b*. Le pyrrole **1***b* se présente sous la forme d'un solide blanc qui est recristallisé dans l'hexane; m = 5,2 g, Rdt 70%; F = 64–65°C; M, $C_{17}H_{21}NO_2$ = 271; ir ($CDCl_3$): 3465, 1700, 1680 cm^{-1}; uv (EtOH): 205 (35 000), 275 (17 000); rmn ($CDCl_3$): 0,8–1,5 (m, 7H), 1,9 (s, 3H), 2,5–2,9 (m, 2H), 5,1 (s, 2H), 6,4 (d, J = 3 Hz, 1H), 7,2 (s, 5H), 9,3 (s large, 1H); rmn ^{13}C ($CDCl_3$): 161,42 (C=O), 136,51, 132,28, 120,21, 118,66 (C pyrroliques), 128,53, 128,23, 128,11 et 120,78 (Ar), 65,75 (CO_2CH_2), 33,12, 24,84, 22,81, 13,99 et 9,88 (n-Bu, pyrrole —Me); (C_6D_6): 161,64 (C=O), 137,03, 132,26, 119,89 et 119,03 (C pyrroliques), 128,54, 128,15 et 121,24 (Ar), 65,82 (CO_2CH_2), 33,58, 25,23, 23,09, 14,18 et 9,98 (n-Bu et pyrrole —Me); sm (M = 271): pics à 91, 138, 180, 229. *Anal.* calc.: C 75,25, N 7,80, N 5,16; tr.: C 75.03, H 7,79, N 5,08.

2. *Synthèse de dipyrrylméthanes*

Bis(benzyloxycarbonyl-5, butyl-4, méthyl-3, pyrryl-2)-3,3 propionate d'éthyle **3**a

A une solution de pyrrole **1***b* (15×10^{-4} mol, 0,136 g) dans le benzène (1,5 mL) est ajouté l'acide paratoluène sulfonique (2 mg). La solution est portée à reflux sous azote et on y ajoute le diéthoxypropionate d'éthyle (9×10^{-4} mol, 0,171 g). Le reflux est maintenu 24 h sous azote. Après traitement habituel et filtration sur colonne de silice, une huile jaune est obtenue (0,11 g); Rdt = 70%; ir ($CHCl_3$): 3450, 3360, 1685 (large) cm^{-1}; rmn (CCl_4): 0,8–1,5 (m, 17H), 2,0 (s, 6H), 2,4–2,8 (m, 4H), 3,1 (d, J = 8 Hz, 2H), 3,8 (q, J = 7 Hz, 2H), 4,7 (t, J = 8 Hz, 1H), 5,1 (s, 4H), 7,1 (s, 10H), 10,2 (s large, 2H); rmn ($CDCl_3$): 0,7–1,4 (m, 17H), 1,90 (s, 6H), 2,62 (m, 4H),

For personal use only.

3,06 (d, J = 8 Hz, 2H), 4,00 (q, J = 7 Hz, 2H), 4,70 (t, J = 8 Hz, 1H), 5,20 (s, 4H), 7,25 (s, 10H), 9,60 (s, 2H). De la même manière est obtenu le bis(éthoxycarbonyl-5, butyl-4, méthyl-3 pyrryl-2)-3,3 propionate d'éthyle **3***c*. Rdt 70%; M, $C_{29}H_{44}N_2O_6$ = 516. *Anal.* calc.: C 67,35, H 8,51, N 5,42; tr.: C 67,31, H 8,52, N 5,59.

Bis(carboxy-5, butyl-4, méthyl-3, pyrryl-2)-3,3 propionate d'éthyle **3**b

Une solution de dipyrrylméthane **3***a* ($1,7 \times 10^{-4}$ mol, 0,11 g) dans le THF (3 mL) contenant du palladium sur charbon à 10% (10 mg) et une goutte de triéthylamine est mise en contact d'hydrogène pendant 4 h sous forte agitation. Le contenu du ballon est filtré sur Célite, lavé au THF et le solvant évaporé sous vide à température ambiante. Le solide jaune clair obtenu (0,08 g) est utilisé tel quel pour la synthèse de la porphyrine **7***a*; ir ($CHCl_3$): 3330, 3250, 1728, 1665 cm^{-1}; rmn (CCl_4): 0,8–1,5 (m, 17H), 2,00 (s, 3H), 2,03 (s, 3H), 2,4–2,8 (m, 4H), 3,16 (d, J = 8 Hz, 2H), 3,80 (q, J = 7 Hz, 2H), 4,73 (t, J = 8 Hz, 1H), 5,13 (s, 4H), 7,10 (s, 10H), 10,20 (s large, 2H).

Dinitro-2,6 phényl-bis(méthyl-3', butyl-4', éthoxycarbonyl-5', pyrryl-2') méthane **6**a

Dans un ballon surmonté d'un Dean–Stark le pyrrole **1***a* (5×10^{-4} mol, 0,105 g) et le dinitro-2,6 benzaldéhyde ($2,7 \times 10^{-4}$ mol, 0,053 g) sont mis en solution dans le toluène contenant l'acide trifluorométhane sulfonique (1×10^{-4} mol). Le mélange est porté à reflux 2 h sous azote. Après traitement habituel comprenant en plus un lavage avec une solution de bisulfite de sodium pour éliminer l'aldéhyde n'ayant pas réagi et un traitement au noir animal dans le THF, les différents constituants sont séparés par chromatographie sur silice. Un premier produit **4***a* (11) (5 mg) moins polaire que le pyrrole de départ est élué avec le mélange éther–EP (20:80).[3] Ce produit a été obtenu dans une autre réaction (11). Le dipyrrylméthane **6***a* (60 mg) est alors élué avec un mélange éther–EP (35:65), Rdt 40%, huile rouge, M, $C_{31}H_{40}N_4O_8$ = 596. Deux autres produits **4***b* et **5***a* caractérisés par ailleurs (11) sont alors élués: 10 mg **4***b* avec un mélange éther–EP (60:40); puis 10 mg **5***a* avec un mélange éther–EP (65:35). **6***a*, ir ($CHCl_3$): 3440, 1700–1680, 1500, 1360 cm^{-1}; rmn ($CDCl_3$): 0,8–1,6 (m, 20H), 1,76 (s, 6H), 2,5–2,9 (m, 4H), 4,23 (q, J = 7 Hz, 4H), 6,16 (s, 1H), 7,5–7,9 (m, 3H), 8,8 (s large, 2H).

Dinitro-2,6 phényl bis(méthyl-3', butyl-4', benzyloxycarbonyl-5', pyrryl-2) méthane **6**b

Dans un ballon surmonté d'un Dean–Stark, le mélange constitué du pyrrole **1***b* ($9,68 \times 10^{-3}$ mol), de dinitro-2,6 benzaldéhyde ($4,84 \times 10^{-3}$ mol) et d'acide trifluorométhane sulfonique (2×10^{-3} mol) dans le benzène (10 mL) est laissé avec agitation 1 h à température ambiante, puis porté à reflux 10 min. En traitant comme précédemment 15 mg de **4***c* (11), 1,2 g de **6***b* (Rdt = 34%) et 0,25 g de **5***b* (11) sont obtenus.

En effectuant la réaction à température ordinaire le mélange constitué du pyrrole **1***b* (30×10^{-3} mol, 8,1 g), de dinitro-2,6 benzaldéhyde (15×10^{-3} mol) et d'acide trifluorométhane sulfonique (6×10^{-3} mol) dans le benzène (30 mL) est agité 3 h; après traitement habituel, une chromatographie sur colonne de silice fournit les quatre produits suivants: l'élution avec le mélange éther–EP (10:90)[3] fournit le pyrrole de départ **1***b* (0,8 g), puis le produit **4***c*, caractérisé par ailleurs (11) (0,1 g) avec le mélange éther–EP (40:60), puis le dipyrrylméthane **6***b* (6,2 g, Rdt 57%, F déc. = 58°C, M, $C_{41}H_{44}N_4O_8$ = 720) avec le mélange éther–EP (45:55), puis le produit **5***b* (1,4 g) caractérisé par ailleurs (11) avec le mélange éther–EP (50:50). **6***b*, ir ($CHCl_3$): 3420, 1700–1680, 1540, 1355 cm^{-1}; uv (EtOH): 280 (31 900), 240 (31 500), 209 (74 600); rmn ($CDCl_3$): 0,8–1,6 (m, 14H), 1,8 (s, 6H), 2,5–2,9 (m, 4H), 5,1 (s, 4H), 6,2 (s, 1H), 7,9 (m, 13H), 9,1 (s large, 2H). *Anal.* calc.: C 68,33, H 6,15, N 7,77; tr.: C 68,26, H 5,93, N 7,98.

De la même manière est obtenu le dipyrrylméthane **6***i* à partir du pyrrole **1***c* et du dinitro-2,6 benzaldéhyde. **6***i*,Rdt 70%; F = 166–167°C; M, $C_{35}H_{32}N_4O_8$ = 636. ir ($CHCl_3$): 3440, 1690, 1540, 1360 cm^{-1}; rmn ^1H ($CDCl_3$): 1,7 (s, 6H), 2,2 (s, 6H), 5,2 (s, 4H), 6,2 (s, 1H), 7,2–7,8 (m, 13H), 8,8 (s large, 2H). *Anal.* calc.: C 66,02, H 5,06, N 8,80; tr.: C 66,28, H 5,06, N 8,96.

Diamino-2,6 phényl bis(méthyl-3', butyl-4', carboxy-5', pyrryl-2) méthane **6**h

Le dipyrrylméthane **6***b* (3×10^{-3} mol, 2,16 g) en solution dans le THF (75 mL) est introduit dans le THF (20 mL) contenant la triéthylamine (6 gouttes) et le palladium sur charbon à 10% (0,3 g). Le ballon est relié à un système de burettes contenant de l'hydrogène, en 10 h il y a absorption de 24×10^{-3} mol d'hydrogène.

Le contenu du ballon est filtré sur Célite, lavé au THF, on opère sous atmosphère d'azote dans une boîte à gants du fait de l'instabilité du diacide botenu. Le solvant est évaporé sous vide à température ordinaire et l'on obtient une huile jaune, m = 1,5 g (composé instable que l'on utilise tel quel et que l'on suppose être **6***h*); ir ($CHCl_3$): 3440, large bande 3000, 1660 cm^{-1}; rmn (DMSO): 0,8–1,5 (m, 14H), 1,63 (s, 6H), 2,4–2,7 (m, 4H), 4,5 (s large (s'échange avec D_2O), 1H), 5,8 (s, 1H), 6,7–7,4 (m, 3H), 9,8 et 10,0 (deux massifs qui s'échangent avec D_2O).

3. *Synthèse de porphyrines*

Bis(éthoxycarbonyl)-5,15 tétrabutyl-2,8,12,18 tétraméthyl-3,7,13,17 porphyrine **7**a

Le mélange constitué de diacide **3***b* (0,1 mmol), d'acide trichloroacétique (0,23 mL d'une solution 5,2 M CCl_3COOH/CH_2Cl_2 soit 0,12 mol) et d'orthoformiate de triméthyle (0,8 mmol) est porté à reflux 18 h. Du DDQ[3] (0,1 mmol) est alors ajouté et le reflux est continué 90 min. La solution est lavée avec une solution de bicarbonate à 20%, puis à l'eau, séchée puis évaporée. Après filtration sur colonne de silice, la porphyrine **7***a* éluée au CH_2Cl_2 est obtenue (2 mg) (Rdt 2,6%), M, $C_{48}H_{66}N_4O_4$ = 762; uv (CH_2Cl_2 + 1 goutte $N(Et)_3$): bande de Soret 408 et bandes I, II, III, IV à 630, 577, 545, 510 nm; (CH_2Cl_2 + 1 goutte HCl): bande de Soret 435 et bandes ép 537, 570 et 620 nm; ir ($CHCl_3$): 1720 (large) cm^{-1}; rmn ($CDCl_3$): 10,07 (s, 2H), 5,91 (s, 4H), 4,40 (q, J = 8 Hz, 4H), 4,00 (t, J = 8 Hz, 8H), 3,40 (s, 12H), 1,8–1,1 (m, 28H); sm: 762.

Bis(diacétamido-2,6 phényl)-5,15 tétrabutyl-2,8,12,18 tétraméthyl-3,7,13,17 porphyrine **7**b

Dans un ballon surmonté d'un Dean–Stark, le pyrrole **1***b* (0,3 mmol, 81,6 mg) et le diacétamido-2,6 benzaldéhyde (12) (0,15 mmol, 33 mg) sont mis en solution dans le benzène en présence d'acide paratoluène sulfonique (2 mg). Le mélange est porté à reflux pendant 48 h sous azote. Après traitement habituel, l'huile obtenue est chromatographiée sur silice. Le dipyrrylméthane **6***d* est élué avec le mélange acétone–éther (15:85) (Rdt 60%). Le dipyrrylméthane **6***d* (22 mg) est traité en solution dans le THF (5 mL) et la triéthylamine (1 goutte) en présence de Pd/C sous hydrogène pendant 100 min. Après filtration et évaporation du solvent, le produit obtenu **6***g* utilisé sans autre purification (produit instable) est dissout dans CH_2Cl_2 (15 mL), puis traité avec CCl_3CO_2H (1 mmol, 163 mg) et $HC(OMe)_3$ (0,15 mmol, 16 mg). La solution est agitée 4 jours puis traitée au DDQ. Après traitement habituel, le brut est chromatographié sur colonne de silice, la porphyrine **7***b* est éluée au chloroforme: m = 4 mg, Rdt 10%.

Diacétamido-2,6 benzaldéhyde (12): M, $C_{11}H_{12}N_2O_3$ = 220; ir ($CHCl_3$): 1700, 1670, 1617, 1597 cm^{-1}; (KBr): 3300–3285, 1700, 1685, 1645, 1620, 1600 cm^{-1}; rmn ($CDCl_3$): 9,86 (s, 1H), 7,53 (m, 3H), 2,15 (s, 6H); rmn (Me_2CO): 10,3 (s large s'échange avec D_2O), 9,8 (s, 1H), 7,6 (m, 3H), 2,06 (s, 6H); sm: 220, 192 (—CO), 177 (—CH_3), 150 (—CH_2CO), 108 (—CH_2CO). *Anal.* calc.: C 59,99, H 5,49, N 12,72; tr.: C 60,32, H 5,79, N 12,93.

Dipyrrylméthane **6**d: $F \approx$ 149°C; M, $C_{45}H_{52}N_4O_6$ = 744; ir ($CHCl_3$): 1710, 1645 cm^{-1}; rmn ($CDCl_3$): 9,27 (s large, 1H), 7,28 (m, 13H), 6,70 (s large, 2H), 5,17 (s, 4H), 2,69 (m, 4H), 1,74 (s, 6H), 1,30 (m, 14H). *Anal.* calc.: C 72,55, H 7,04, N 7,52; tr.: C 72,79, H 7,20, N 7,78.

Porphyrine **7**b: M, $C_{60}H_{74}N_8O_4$ = 970; ir ($CHCl_3$): 1695 (large) cm^{-1}; uv (CH_2Cl_2): 405, 504, 531, 567, 617; ($CHCl_3$): 407, 505, 537, 568, 618; uv ($CHCl_3$ + HCl): ép 400–451, ép 540–583, 629; rmn ($CDCl_3$): 10,4 (s, 2H), 8,5 (m, 4H), 7,9 (m, 2H), 6,3 (s, 4H), 4,0 (m,

[3] DDQ: dichloro, dicyano, parabenzoquinone; EP: éther de pétrole fraction Eb = 35–60°C; *p*-TsOH: acide paratoluène sulfonique.

8H), 2,6 (s, 12H), 1,2 (s, 12H); sm: 970.

Bis(diacétamido-2,6 phényl)-5,15 octaméthyl-2,3,7,8,12,13,17,18 porphyrine 7c

Dans un ballon surmonté d'un Dean–Stark, le pyrrole **1***c*[3] (10 mmol) et le diacétamido-2,6 benzaldéhyde (5,5 mmol) sont mis en solution dans le benzène en présence de quantité catalytique de *p*-TsOH. Le mélange est porté à reflux sous azote pendant 17 h. Après traitement habituel, l'huile obtenue est chromatographiée sur colonne de silice. Le dipyrrylméthane **6***c* est élué avec le mélange acétone–éther (15:85) (3,9 mmol; Rdt 78%), F = 128°C; M, $C_{39}H_{40}N_4O_6$ = 660; ir (KBr): 3450, 1710, 1645 cm^{-1}; rmn ($CDCl_3$): 9,47 (s, 2H, NH), 7,66 (s, 13H, ArH), 5,73 (s, 1H, CH-Pyr), 5,20 (s, 4H, CH_2Ar), 2,25 (s, 6H, $COCH_3$), 1,83 (s, 6H, Me), 1,75 (s, 6H, Me). *Anal.* calc.: C 70,88, H 6,10, N 8,48; tr.: C 70,53, H 6,17, N 8,43.

Le dipyrrylméthane **6***c* (1 mmol) est dissout dans le THF (30 mL) en présence de NEt_3 (3 gouttes) et de Pd/C sous pression atmosphérique d'H_2 jusqu'à ce que la quantité d'H_2 devant être absorbée corresponde à 2 mmol (44,8 mL). Après filtration et évaporation du solvant, le produit obtenu **6***f* est dissout sans autre purification dans CH_2Cl_2 sec. A cette solution est ajouté CCl_3CO_2H (1,89 g) dissout dans 25 mL de CH_2Cl_2 puis $HC(OMe)_3$ (0,9 mL) à l'abri de la lumière, à température ambiante. La solution est agitée pendant 4 jours, puis traitée au DDQ[3] (220 mg) pendant 2 jours. Après traitement habituel, le brut est filtré sur colonne de silice: la tétraacétamido-porphyrine **7***c* est éluée avec le mélange CH_2Cl_2/acétone (85:15) (88 mg; Rdt 11%; M, $C_{48}H_{50}N_8O_4$ = 802); uv ($CHCl_3$): 401, 504, 538, 571, 624; ir ($CHCl_3$): 1690–1670 cm^{-1}; rmn ($CDCl_3$): 10,4 (s, 2H meso), 8,5 (d, J = 8 Hz, 2H, ArH), 7,9 (t, J = 9 Hz, 2H, ArH), 6,4 (s large, 2H, NH), 3,6 (s, 12H, CH_3), 2,6 (s, 12H, CH_3), 1,20 (s, 12H, $COCH_3$); ($CDCl_3$ + CF_3CO_2H): 9,37 (s, 2H meso), 8,2 et 8,0 (ArH); Me (3,3); Me (2,45); NHAC (1,35); sm m/e: 802.

Bis(dipivalamido-2,6 phényl)-5,15 octamethyl-2,3,7,8,12,13,17,18 porphyrine 7e

L'hydrolyse de la porphyrine **7***c* par HCl 6 *N* (13) sous azote, à l'abri de la lumière à reflux pendant 2 h fournit une solution verte qui est traitée par NaOH 10%. Le précipité rouge **7***d* formé est filtré, puis lavé à l'eau (Rdt 94%), M, $C_{40}H_{42}N_8$ = 634; uv (CH_2Cl_2): 408, 506, 538, 571, 625; rmn (CF_3CO_2D): 8,35 (m, ArH), 3,5 (s, Me), 2,7 (s, Me). La tétraamino-porphyrine **7***d* dissoute dans une solution de CH_2Cl_2 et de CF_3CO_2H est traitée à température ordinaire pendant 8 h avec un excès de chlorure de pivaloyle dissout dans du chlorure de méthylène et de la pyridine (13). La réaction fournit après lavage à l'eau une huile qui est chromatographiée sur colonne de silice. L'éluant 50% Et_2O/EP livre la tétrapivalamido porphyrine **7***e* qui est recristallisée dans le mélange éther–cyclohexane; Rdt 60% (solide rouge violet); M, $C_{60}H_{74}N_8O_4$ = 970; uv (CH_2Cl_2): 405, 505, 537, 572, 637; ir (KBr): 3430, 1690 cm^{-1}; ($CHCl_3$): 3425, 1690 cm^{-1}; rmn ($CDCl_3$): 10,22 (s, CH meso), 8,48 (d, J = 8 Hz, 4H, ArH), 7,81 (t, J = 8 Hz, 2H, ArH), 6,83 (s, 4H, NH), 3,5 (s, 12H, CH_3), 2,55 (s, 12H, CH_3), 0,04 (s, 36H, *t*Bu); sm m/e: 970.

Reçu le 17 janvier 1984

Cet article est dédié au Professeur Paul de Mayo à l'occasion de son 60e anniversaire

ALEXANDRA LECAS-NAWROCKA, JACQUES LEVISALLES, CLAIRE MARIACHER et ERIC ROSE. Can. J. Chem. **62**, 2059 (1984).

La condensation du dinitro-2,6 benzaldéhyde et d'un pyrrole ne conduit pas à un dipyrrylméthane, mais à des produits résultant soit d'un doublement des molécules de pyrrole de départ, soit de réactions d'oxydo-réduction de l'intermédiaire **9** correspondant à un début de condensation entre une molécule de pyrrole et une molécule d'aldéhyde. Les groupes nitro du dinitro-2,6 benzaldéhyde jouent un rôle important dans ces réactions inattendues.

ALEXANDRA LECAS-NAWROCKA, JACQUES LEVISALLES, CLAIRE MARIACHER, and ERIC ROSE. Can. J. Chem. **62**, 2059 (1984).

The condensation between 2,6-dinitrobenzaldehyde and a pyrrole does not afford a dipyrrylmethane but products which result from a duplication of the starting pyrrole or from oxydo-reduction reactions of the pyrryl-arylcarbinol **9** which arise from the condensation between one molecule of pyrrole and one molecule of aldehyde. The nitro groups of the benzaldehyde play a crucial role in these reactions.

Il est bien connu que la condensation d'un aldéhyde avec un pyrrole dans le rapport 1:2 conduit à un dipyrrylméthane, précurseur de porphyrines (1, 2) (éq. [1]). Le présent mémoire décrit le cours anormal de la condensation du dinitro-2,6 benzaldéhyde avec les pyrroles **1***a* et **1***b*, qui a été observé dans le cadre des études de porphyrines du laboratoire (3, 4).

[1] 
1*a* R = Et
b R = $CH_2C_6H_5$

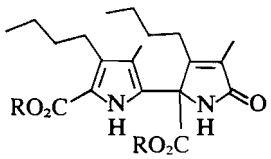
Au lieu des dipyrrylméthanes attendus, on observe la formation des trois produits **2***a*, **3***a* et **4***a* à partir de **1***a*, et de deux produits **2***b* et **4***b* à partir de **1***b* (éq. [2]). Les structures de ces composés résultent des observations spectroscopiques suivantes.

[2] 
1*a* R = Et
b R = $CH_2C_6H_5$

2*a* R = Et
b R = $CH_2C_6H_5$

3*a* R = Et

+



4*a* R = Et
b R = CH_2Ph

Composés 2 et 3

Les spectres de rmn ^1H des composés **2** et **3** montrent qu'il n'y a qu'un seul motif pyrrolique par motif dinitrobenzénique (tableau 1). Le composés **3***a* possède deux protons de plus que le composé **2***a* (ce que confirment les spectres de masse), et l'un de ces protons est échangeable par traitement par D_2O, mais le reste du spectre de rmn est très semblable à celui de **2***a*. Les protons arèniques des composés **2***a*, **2***b* et **3***a* présentent des signaux caractéristiques dont l'empreinte est analogue à celle des protons arèniques du dinitro-2,6 benzaldéhyde.

Les fréquences d'élongation observées dans les spectres ir pour les vibrateurs NH, CO et NO sont rassemblées dans le tableau 1. Les bandes à 1710−1720 cm^{-1} peuvent être attribuées aux groupes carbonyles libres des alcoxycarbonyl-2 pyrroles, et les bandes à 1690−1685 cm^{-1} aux mêmes groupes liés par pont hydrogène au groupe NH pyrrolique (5−7). Quant aux groupes carbonyles cétoniques, on peut leur attribuer les bandes situées entre 1650 et 1590 cm^{-1}, par analogie avec celle que le benzoyl-2 triméthyl-3,4,5 pyrrole présente à 1608 cm^{-1} (8). Outre les bandes NH vers 3450−3280 cm^{-1} on notera dans le tableau 1 la bande présentée par **3***a* vers 3500 cm^{-1}, probablement due au groupe OH. Enfin la présence de groupe NO est visible dans les spectres ir vers 1530−1540 cm^{-1} (tableau 1) et dans les spectres de masse (perte de 30 unités de masse = NO) (9).

Composés 4

Les spectres de rmn montrent l'absence de groupement dinitrophényle (notamment pour **4***a* où il n'y a aucun signal au delà de 4,2 ppm). En revanche, l'existence de deux singulets (1,76 et 1,88 ppm pour **4***a*, 1,80 et 1,86 ppm pour **4***b*) révèle la présence de deux groupes méthyles *différents*, de même que l'existence de deux quadruplets presque superposés pour **4***a* (—COO—CH_2—CH_3) et de deux singulets pour **4***b* (—COO—CH_2—C_6H_5) révèle la présence de deux groupes

SCHÉMA 1

esters *différents* (tableau 1). Ces données suggèrent la superposition dans **4** de deux motifs différents dérivés de **1**.

Dans la région des fréquences d'élongation des vibrateurs C=O, les spectres ir présentent de larges bandes centrées vers 1700 cm^{-1} pour **4***a* et 1710 cm^{-1} pour **4***b*. Par analogie avec les fréquences observées pour les composés modèles **5** (10), **6** (11), **7** (12) et **8** (13), qui sont de l'ordre de 1680 cm^{-1} pour le groupe CONH et de 1740 cm^{-1} pour le groupe ester de **5**, et par analogie avec les fréquences observées pour les fonctions esters de **1***a* (1700, 1675, 1655 cm^{-1}) et de **1***b* (1700, 1680, 1655 cm^{-1}) on peut considérer que les larges bandes observées pour **4***a* et **4***b* résultent du recouvrement des bandes dûes aux groupes amide conjugué, ester conjugué et ester non conjugué.

Enfin dans les spectres de masse la perte du groupe ester non conjugué—CO_2R donne lieu à un pic intense (m/e = 359 = M—$CO_2CH_2CH_3$ pour **4***a*, m/e = 421 = M − $CO_2CH_2C_6H_5$ pour **4***b*), accompagné d'un autre pic à m/e = 313, correspondant à M − CO_2R − ROH, et commun aux spectres de masse de **4***a* et de **4***b*.

L'ensemble des données précédentes est en accord avec les structures de benzoyl-pyrroles substitués pour **2** et **3** et de pyrryl-pyrrolidones pour **4**.

Discussion

Le tableau 2 donne les rendements en produits **2**, **3** et **4** obtenus lors des essais de préparation des dipyrrylméthanes, en présence d'acide *p*-toluène sulfonique (TsOH). On voit que le rapport **2** + **3**/**4** varie de 1,7 à 3,2. On notera que par rapport au composé primaire attendu de la condensation, l'alcool **9**, les composés **2** et **3** sont plus oxydés d'un côté (l'alcool est devenu cétone), moins oxydés de l'autre (les groupes NO_2 sont devenus NO ou NHOH). Cette anomalie s'explique aisément par le comportement photochimique de l'alcool *ortho*-nitrobenzylique et de l'aldéhyde *ortho*-nitrobenzoïque qui se transforment en aldéhyde et en acide *ortho*-nitrosobenzoïque respectivement (14). En présence de lumière l'alcool **9** peut donner la cétone **10**, qui peut être réduite en composé **2** ou **3** si un réducteur est présent dans le milieu (schéma 1).

La présence d'un réducteur dans le milieu est plausible. Il est

TABLEAU 2. Rendements des produits obtenus lors de la condensation du pyrrole **1***a* ou **1***b* avec le dinitro-2,6 benzaldéhyde DNB

			Composé					
Pyrrole	1/DNB	Solvant	**2***a*	**3***a*	**4***a*	**2***b*	**4***b*	Catalyseur

1*a*	1/0,55	Toluène	27	11	18			*p*TsOH (a)*
1*a*	1/0,55	Toluène	0	16	13			*p*TsOH (b)
1*b*	1/1,8	Benzène				36	20	*p*TsOH (a)
1*b*	1/1,8	Xylène				40	24	*p*TsOH (a)
1*b*	1/1,8	Xylène				39	12	*p*TsOH (a)

*(a) Quantité catalytique; (b) *p*TsOH/pyrrole **1***a* = 2.

en effet bien connu qu'en milieu acide, un pyrrole tel que **1** peut se condenser sur lui-même pour donner une pyrryl-pyrroline (1) telle que **11** qui peut se transformer en composé **4**, en présence des oxydants que sont les groupes NO_2 de la cétone **10** et du dinitro-2,6 benzaldéhyde. On sait par exemple que le nitrobenzène peut oxyder photochimiquement l'isopropanol en donnant la phénylhydroxylamine en l'absence d'oxygène, ou le nitrosobenzène en présence d'oxygène (les arylhydroxylamines s'oxydent spontanément en nitrosoarènes en présence d'air) (15, 16). Comme la formation de la pyrroline **11** en milieu acide est réversible, c'est son oxydation par les groupes NO_2 de la cétone **10** ou du dinitrobenzaldéhyde, qui provoque la formation irreversible du composé **4**. Ceci peut être vérifié par le traitement des pyrroles **1**, qui, placés dans les conditions de la formation de **4**, mais *sans* aldéhyde, sont récupérés inchangés après 48 h, même en présence d'air, ou de nitrobenzène, alors que l'autoxydation à 50°C du *N*-méthyl pyrrole et du triméthyl-2,3,4 pyrrole conduit respectivement aux composés **12** (17) et **13** (18).

On peut se demander pourquoi un tel comportement n'a pas été observé avec l'*ortho*-nitrobenzaldéhyde. Il est vraisemblable que ce dernier, moins encombré que le dinitro-2,6 benzaldéhyde, réagit rapidement avec une deuxième molécule de pyrrole pour conduire au dipyrrylméthane; en revanche le dini-

12 13

trobenzaldéhyde, très encombré, donne l'alcool **9** qui, trop encombré pour se condenser une deuxième fois, subit les réactions photochimiques secondaires conduisant à **2**, **3** et **4**.

En conclusion, les essais de synthèse de dipyrrylméthane, infructueux à partir du dinitro-2,6 benzaldéhyde, mettent en évidence les produits qui résultent d'un début de condensation et qui par leur nature oxydante facilitent la formation de produits de doublement des molécules de pyrrole de départ.

Partie expérimentale

L'action du pyrrole **1***a* ou **1***b* à reflux pendant 24 h ou plus en présence d'un demi équivalent de dinitro-2,6 benzaldéhyde et d'acide chlorhydrique en quantité catalytique dans l'éthanol ne conduit à aucun produit nouveau. Les produits de départ sont récupérés.

Dans un ballon surmonté d'un Dean–Stark le pyrrole **1***a* ou **1***b* et le dinitro-2,6 benzaldéhyde DNB sont mis en solution dans le solvant (tableau 2) en présence de quantité catalytique d'acide *para*-toluène sulfonique *p*-TsOH. Le mélange est porté à reflux 48 h. Après "traitement habituel" (3) comportant en plus un lavage avec une solution de bisulfite de sodium pour éliminer l'aldéhyde qui n'a pas réagi, les différents prduits sont chromatographiés sur colonne de silice. Les rendements en produits formés sont donnés au tableau 2.

Dans le cas du pyrrole **1***a*, la chromatographie sur colonne de silice fournit un premier produit **2***a* légèrement moins polaire que le pyrrole de départ **1***a* qui est élué avec le mélange éther – éther de pétrole EP 20:80, puis un deuxième produit **3***a* plus polaire que le pyrrole de départ **1***a* élué avec un mélange éther–EP 60:40 et enfin un troisième produit **4***a* élué avec un mélange éther–EP 65:35.

Dans le cas du pyrrole **1***b*, les produits **2***b* et **4***b* sont élués avec les mélanges Et_2O–EP 40:60 et 50:50.

Cet article est dédié au Professeur Paul de Mayo à l'occasion de son 60e anniversaire

HENRI DESHAYES et JEAN-PIERRE PETE. Can. J. Chem. **62**, 2063 (1984).

Lorsqu'on traite un ester carboxylique (R—C(=O)—OR') par une solution de sodium dans l'hexaméthylphosphortriamide (HMPA), on observe essentiellement la formation de l'acide carboxylique, d'un mélange de l'alcool R'OH et de l'alcane R'H correspondant. La proportion d'alcane est très importante pour les esters d'alcools encombrés et diminue lorsque l'encombrement au niveau du groupe carboxyle baisse. Le taux d'alcane augmente aussi en présence de *tert*-butanol. La discussion de ces résultats et leur comparaison avec la réduction des esters dans les amines primaires indiquent que l'alcane provient essentiellement de la décomposition d'un radical anion solvaté ou non alors que l'alcool résulte de processus bimoléculaires de décomposition de l'ester. L'acide carboxylique est dû à la fois à une réaction de fragmentation du radical anion et à des réactions bimoléculaires.

HENRI DESHAYES and JEAN-PIERRE PETE. Can. J. Chem. **62**, 2063 (1984).

Carboxylic acids, alcohols (R'OH), and alkanes (R'H) are the main products of the reduction of carboxylic esters (RCO_2R') by sodium in hexamethylphosphoric triamide (HMPA). Alkanes are preferentially formed from the carboxylic esters of hindered alcohols. The alkane content, however, is lowered when there is less steric hindrance on the carboxylic group, and increased when *tert*-butanol is introduced into the reaction mixture. The reduction of esters in HMPA has been compared to the reduction in alkylamines. The alkane is produced mainly by the decomposition of a radical anion intermediate which can be solvated by HMPA. The alcohol is the result of several possible bimolecular nucleophilic reactions; however, unimolecular and bimolecular processes are involved in the production of the carboxylic acid.

Depuis l'observation à la fin du siècle dernier de la réduction des amides par l'amalgame de sodium en solution aqueuse et depuis la mise en évidence par Bouveault et Blanc de la transformation des esters en alcools par action réductrice du sodium dans les alcools éthylique ou amylique anhydre (1), de nombreux travaux ont été consacrés à l'action des métaux sur les dérivés d'acide et plus particulièrement sur les esters carboxyliques (2). Ainsi, il a pu être montré qu'en solvant protique, la réaction de Bouveault et Blanc présentait une grande généralité et un certain intérêt pour la transformation de la fonction acide en fonction alcool. En solvant aprotique par contre, une nouvelle réaction réductrice nommée condensation acyloïne est observée préférentiellement (3). Bien que l'intérêt synthétique de ces réductions ait été rapidement exploré, l'étude mécanistique et la caractérisation d'intermédiaires n'est intervenue que beaucoup plus tard (4). Si la formation intermédiaire d'un radical anion par action du sodium sur un ester carboxylique ne fait aucun doute, les processus de formation des produits de réaction à partir de cet intermédiaire sont encore mal connus.

Ainsi, le mécanisme de la condensation acyloïne a pu être récemment remis en question (5); de même, l'isolement d'acides carboxyliques par action des métaux alcalins sur les esters carboxyliques dans l'ammoniac liquide (6)[2] ou dans l'hexaméthylphosphortriamide (HMPA) (7) a conduit divers auteurs à proposer une nouvelle voie de décomposition (éq. [1]) pour le radical anion qui ferait intervenir la réduction du groupe alcoxy de l'ester.

[1] 
Cependant, si la formation d'hydrocarbures était bien observée au cours de la réduction d'esters benzyliques (7), il n'existait pas d'exemple clair d'une telle réduction en absence de groupes allyliques ou benzyliques, au moment où nous avons entrepris notre étude.[3]

Par ailleurs, au cours de travaux sur la photolyse, des esters carboxyliques dans un mélange HMPA–eau, il a été proposé qu'un complexe de transfert de charge pouvait être responsable de la réduction des groupes alcoxy d'esters carboxyliques (9) (éq. [2]). Il était donc envisageable si le mécanisme proposé

[2] 
[1] Auteur à qui toute correspondance doit être adressée.

[2] La formation d'acide pourrait, dans ce cas, résulter aussi d'une attaque nucléophile d'amidure sur le groupe méthyle de l'ester.

[3] Il en est de même au cours des réductions cathodiques; la réduction du groupe alcoxy de l'ester n'est observée que pour des dérivés d'alcools benzyliques ou allyliques. cf. réf. 8.

[a] On arrête la réaction 5 min après la fin de l'addition de l'ester (cf. partie expérimentale).
[b] Déterminé par cpv.
[c] Le même isomère est obtenu à partir des deux épimères avec un rendement de 85% environ après recristallisation.

pour la réaction photochimique était fondé, de rendre préparative la réduction du groupe alcoxy d'esters carboxyliques par action du sodium ou d'autres métaux alcalins dans le HMPA en présence d'un donneur de protons.[4] Le HMPA, bon solvant des métaux alcalins et du sodium en particulier (11), donne des solutions bleues paramagnétiques caractéristiques de la présence d'électrons solvatés dans le milieu (11, 12) et douées d'un fort pouvoir réducteur. Le potentiel développé entre une électrode saturée au calomel (SCE) en contact électrique avec une solution de Na-HMPA et mesuré à 28°C est de −2,96 V (13), alors que des valeurs de −2,2 et −2,3 V (vs. SCE) ont été décrites pour des solutions de sodium dans l'ammoniac liquide à −33°C (14).

La réduction des alcools en hydrocarbures par action du sodium dissous dans le HMPA sur les esters carboxyliques correspondants est une réaction efficace; nous rapportons dans ce mémoire la généralité de la réaction, ses limites et nous comparons nos résultats avec ceux décrits récemment pour l'action sur les esters des métaux alcalins dissous dans l'éthylamine et la *tert*-butylamine (15).

Résultats

1. *Aspect préparatif*

Lorsqu'on ajoute une solution diluée d'ester dans l'éther – *t*-BuOH (1 : 1) à une suspension de sodium dans le HMPA à une vitesse telle que le milieu restement constamment coloré, les résultats de la réduction observée (tableau 1) peuvent être résumés dans l'éq. [3]:

[3]

$$R'H + R'OH + RCO_2H + RCH_2OH$$

Dans les réactions utilisées, les alcools primaires, secondaires ou tertiaires sont transformés en hydrocarbures par réduction des acétates correspondants. Les rendements en alcanes augmentent avec l'encombrement au niveau du groupe alcoxy et la réduction devient même quantitative lorsque l'on soumet au sodium-HMPA les esters d'alcools tertiaires. On

[4] Une partie de ce travail a fait l'objet d'une note préliminaire (10).

TABLEAU 2. Influence de la nature du groupe carboxyle sur la réduction d'esters de cholestanyle

note qu'une quantité notable d'alcool est obtenue dans le mélange réactionnel lorsqu'on réduit dans le mélange HMPA – *tert*-butanol des esters d'alcools primaires et secondaires.

La nature de l'ester carboxylique influe également sur le cours de la réaction sans en modifier la généralité. Le tableau 2 montre que l'augmentation de l'encombrement au niveau du groupe carboxyle a aussi pour effet d'augmenter la part du processus de réduction, puisque la production d'alcool, très majoritaire dans le cas des formiates, est fortement diminuée pour les autres esters de cholestanyle. Cependant, l'effet d'encombrement est plus limité que lors du passage des dérivés d'alcools primaires à des dérivés d'alcools tertiaires puisque le passage de l'acétate au pivalate et au méthyl-1 cyclohexène carboxylate de cholestanyle n'améliore plus le rendement de la désoxygénation.

Une des applications intéressantes de la réaction de photoréduction du groupe alcoxy d'esters concernait la préparation de déoxysucres. Nous avons essayé d'obtenir ces mêmes déoxysucres par action du sodium dans le HMPA. Malheureusement, la libération d'alcool s'est révélée plus efficace et nous n'avons pu isoler le dérivé désoxy attendu par traitement par le sodium de l'acétate suivant:

[4] 
Les raisons de l'échec de cette réaction de réduction par le sodium dans le HMPA ne sont pas connues. Nous pouvons toutefois remarquer que la présence des deux groupes acétonides dans la molécule peut modifier la chélation aussi bien du cation sodium que du *tert*-butanol. Le même échec est rencontré lorsque la réduction est conduite en absence de *tert*-butanol.

[b] Non dosé.

présence de HMPA ayant montré la nécessité de la présence d'un agent protique dans le milieu, nous avons examiné si la réduction de ces esters en alcanes par action du sodium dans le HMPA était sensible à la présence de protons. Nous avons, pour cela, effectué la réaction de réduction d'esters en absence de source de protons et comparé les résultats à ceux de témoins réalisés en présence de *tert*-butanol (tableau 3).

La présence de *tert*-butanol dans le milieu favorise la formation d'alcanes aux dépens de la formation d'alcools dans le cas des esters peu encombrés d'alcools primaires ou secondaires. Dans le cas d'esters encombrés, la présence de protons dans le milieu ne semble pas améliorer sensiblement le rendement en produit de réduction du groupe alcoxy.

(b) *Nature des intermédiaires réactionnels*

L'examen des essais 9 et 10 ou 11 et 12 décrits dans le tableau 1 montre que le même hydrocarbure est obtenu au cours de la réduction de deux esters épimères.

Afin de déterminer la nature de l'intermédiaire commun qui rend compte de la formation de l'épimère le plus stable au cours de la réaction, nous avons procédé à deux séries d'expériences permettant de déterminer si un radical $R^{\cdot}$ était ou non sur le chemin réactionnel.

Le remplacement du *tert*-butanol par un alcool deutérié (R—OD) permet de deutérier les carbanions suceptibles de se former dans le milieu. Le dosage de la teneur en deutérium dans les hydrocarbures isolés indique dans quelle mesure l'arrachement d'hydrogène au HMPA par un radical intermédiaire est susceptible d'entrer en compétition avec la protonation d'un anion par l'alcool deutérié.

Le tableau 4 fait apparaître que la nature du donneur de protons influe considérablement sur la proportion des produits obtenus puisque le méthanol plus acide que le *tert*-butanol favorise la libération de cholestanol. D'autre part, le dosage du deutérium dans le cholestane isolé montre dans chaque cas une incorporation importante de deutérium. Un intermédiaire carbanionique est donc sur le chemin privilégié qui conduit à l'alcane. Cependant, la teneur en deutérium inférieure à l'unité indique qu'une partie de l'alcane pourrait provenir d'un intermédiaire radicalaire après arrachement d'un atome d'hydrogène au solvant. La réduction d'un ester de cyclopropylcarbinyle est susceptible de nous apprendre si l'intermédiaire formé initialement par rupture de la liaison C—O du groupe alcoxy possède une structure radicalaire ou anionique. En effet, il a pu être montré dans l'action de radicaux anions dans le glyme sur le chloro-6β cyclo-3α, 5α-cholestane que le radical

[5] 
intermédiaire conduisait à 25°C à un dérivé du cholestène-5, alors que l'anion du système cyclopropylcarbinyle conduisait, de préférence, aux dérivés cyclopropaniques (16). La forte proportion de cholestène-5 observé semble indiquer qu'un radical intermédiaire est initialement formé lorsque la rupture C—O du groupe alcoxy intervient.

+40	—	51	46	
+60	*t*-BuOH	18	69	

(c) *Influence des conditions réactionnelles*

Les divers produits observés, lorsqu'on fait réagir un métal sur un ester, résultent de processus compétitifs au niveau du radical anion initialement peuplé. Nous avons donc cherché à déterminer l'influence de la température, de la durée de réaction et de la nature du métal sur le cours de la réduction de l'acétate de cholestanyle en cholestane. Bien que la réduction des esters par les métaux dans les amines primaires soit sensible à la température, nous n'avons pu mettre en évidence une augmentation conséquente du taux d'alcane lorsqu'il y a augmentation de la température, surtout lorsque la réaction est réalisée en présence de *tert*-butanol.

La vitesse d'addition de l'ester dans la solution d'électrons solvatés à 25°C étant effectuée de manière à éviter que la couleur bleue ne disparaisse au cours de l'addition, nous avons procédé à l'isolement des produits de réaction dès la fin de l'introduction de l'ester dans le milieu réducteur. Le rendement en alcane isolé est alors optimum. Ceci nous permet de conclure que la transformation du radical anion intermédiaire est rapide à température ambiante.

Le pouvoir réducteur élevé des solutions de sodium dans le HMPA permet la réduction des liaisons multiples (11) y compris les liaisons éthyléniques (17). Il est néanmoins possible de contrôler le cours de la réduction d'un ester insaturé en contrôlant le temps de contact de l'ester avec la solution réductrice. Ainsi, nous pouvons orienter la réduction de l'acétate de cholestéryle vers la formation de dérivés du cholestène-5 ou du 5α-cholestane.

[6] 
5 min 68% 29%

24 h 28% 64%

L'étude de l'influence de la nature du métal sur la réduction est rendue difficile par la grande instabilité des solutions de lithium et de potassium dans le HMPA (7). Il a en effet été montré que les solutions de métal alcalin-HMPA voient rapidement leur conductibilité baisser pour le lithium ou le potassium, contrairement au cas des solutions de sodium pour lesquelles la conductibilité reste constante durant des périodes assez longues (18). La baisse de conductibilité semblerait liée à une décomposition du HMPA.

Un essai de réduction d'acétate de cholestanyle par une solution de Li-HMPA conduit à une formation prépondérante d'alcool (cholestanol 81%, cholestane 9%). Nous constatons en outre que la dissolution du lithium dans le HMPA est bien plus rapide que celle du sodium et que l'hydrolyse du brut de réduction par Li-HMPA conduit à la formation de produits gazeux à odeur de phosphine. De plus, la libération d'ions diméthylamidure susceptibles de réagir sur les esters (7) a déjà été notée. Des travaux récents ayant montré que des esters encombrés pouvaient être réduits sélectivement par le lithium dans une amine primaire (15, 19, 20), nous avons comparé le cours de la réduction de l'acétate de cholestanyle pris comme modèle d'un acétate d'alcool secondaire dans différents milieux et nous avons rassemblé les résultats dans le tableau 6.

Ces divers essais montrent d'une part que le taux d'alcane est plus élevé lorsque le HMPA est utilisé comme solvant, d'autre part que la présence de *tert*-butanol dans le milieu accroît la formation d'alcane aux dépens de la réduction en alcool, aussi bien dans l'éthylamine que dans le HMPA.

L'introduction d'une solution de sodium-HMPA préalablement titrée (13) à une solution d'ester dans un mélange HMPA–éther permet de déterminer le nombre d'électrons nécessaires à la réduction. On constate en effet, et à la précision des déterminations près (tableau 7), qu'en absence de *tert*-butanol, il y a consommation de moins de deux équivalents de sodium et donc de moins de deux électrons par mole d'ester au moment où la solution maintient une couleur bleue persistante. Un tel résultat est donc en accord à la fois avec la formation rapide du radical anion dérivé de l'ester et avec la non compétitivité d'autres processus de réduction en absence de *tert*-butanol.

En présence de *tert*-butanol, on observe non seulement que plusieurs équivalents "électrons solvatés" sont nécessaires avant l'observation du maintien d'une couleur bleue persistante, mais aussi une grande instabilité de ces colutions colorées même pour un nombre d'équivalents très supérieur à 2. Des processus de réduction successifs semblent devoir être retenus dans la mesure où nous avons vérifié que le *tert*-butanol ne décolore pratiquement pas la solution de sodium dans le HMPA.

Les proportions d'alcane et d'alcool obtenus au cours de ces expériences de titrage sont conformes aux résultats préparatifs décrits dans les tableaux 3 et 7. On vérifie ainsi qu'il y a davantage de produits de réduction en présence de *t*-BuOH et qu'il y a dans chaque cas formation d'une quantité importante d'alcool.

Discussion

La réduction des esters carboxyliques, par les métaux dissous, conduit à un mélange d'alcanes, d'alcools et d'acide carboxylique. Le degré de substitution du groupe alcoxy de l'ester, la nature du dérivé acide, les conditions de réaction et, plus particulièrement, la nature du milieu réactionnel, influencent les rendements respectifs dans les divers produits. Dans tous les milieux cependant, on peut considérer que la première étape réalise la fixation d'un électron sur l'ester et fournit un radical anion d'où découleront les divers produits de réaction.

L'alcane issu de la réduction du groupe alcoxy et les alcools peuvent, a priori, découler d'une décomposition du radical

SCHÉMA 1

anion selon les divers processus regroupés dans le schéma 1.

En milieu dilué, on peut négliger, dans le HMPA, la duplication du radical anion conduisant aux α-cétols et considérer que la décomposition de cette espèce [A] va dépendre essentiellement des conditions du milieu: présence ou non de protons, solvatation spécifique des cations, température . . .

La grande stabilité de l'anion carboxylate permet la fragmentation selon la voie (*1*). Le radical R$^{\bullet}$ ainsi formé, par arrachement d'un atome d'hydrogène au HMPA ou capture d'un électron puis d'un proton, fournit l'alcane observé. Une telle décomposition unimoléculaire est sensible à la variation de contraintes stériques. Le passage d'un ester d'alcool primaire à un ester d'alcool tertiaire provoque une augmentation considérable de l'encombrement. Il est probable que les contraintes stériques sont modifiées au niveau du radical anion qui tend à adopter une structure tétraédrique aplatie (24). La relaxation stérique sera donc d'autant plus importante que le radical anion [A] sera encombré. Il en résulte que plus l'encombrement est important, plus la vitesse de fragmentation est élevée, et moins les réactions parasites ont la possibilité d'apparaître. On observe effectivement que l'encombrement au niveau des groupes alcoxy ou groupe carboxy (10, 22) augmente la proportion d'alcane.

Le rôle du *tert*-butanol est sans doute complexe. On peut cependant considérer qu'il est capable de solvater le radical anion [A] dans le HMPA, voie (*2*), augmenter ainsi les contraintes stériques à ce niveau et accélérer sa décomposition. En effet, il est connu que les alcools sont susceptibles de solvater

les radicaux anions dans le HMPA et de provoquer ainsi une modification notable du spectre rpe de cet intermédiaire (25). De plus, nous avons pu montrer que la libération d'acide carboxylique à partir d'un radical  est possible lors de la photolyse des esters dans le HMPA, bien que celle-ci soit sans doute moins favorable que la fragmentation de [A] en ion carboxylate correspondant.

Le radical anion peut aussi fournir l'alcool $R'O^-$ selon divers processus. La décomposition unimoléculaire de [A] en radical acyle et $R'O^-$, voie (*3*), semble devoir être exclue. En effet, des calculs *ab initio* effectués sur le radical anion dérivé du formiate de méthyle indiquent que la fragmentation en radical méthyle et anion formiate est, de loin, plus favorable que la fragmentation en radical acyle et anion méthylate (ΔE = 263 kJ) (26). La capture d'un second électron par le radical anion ne semble pas possible, ni dans le HMPA, ni dans une amine en présence d'éthers couronnes. En effet, la répulsion électronique au niveau du dianion ainsi formé est trop importante et les processus compétitifs sont prépondérants. C'est ainsi que l'alcool RCH_2OH attendu après la capture d'un second électron n'est pas observé, ou reste un produit trés minoritaire aussi bien dans le HMPA que dans un mélange de *tert*-butylamine et de tétrahydrofuranne en présence d'éther couronne (cf. réfs. 22, 23, tableau 2, entrées 1–5 et 12). La réduction du radical anion devient possible si l'anion reste lié au cation métallique ou, éventuellement, de manière concertée avec la fixation d'un proton (21, 22) dans les conditions de Bouveault et Blanc. L'absence d'un taux élevé de réduction en présence de *tert*-butanol indique que la protonation concertée avec la fixation d'un second électron par le radical anion est sans doute considérablement ralentie pour des raisons stériques.

La formation d'alcool R'OH peut résulter également d'un déplacement de $R'O^-$ dans l'ester par une base présente dans le milieu. La mise en évidence d'amides au cours de réductions par le lithium dans l'éthylamine (22) ou le lithium dans le HMPA (7), montrent que le lithium est capable de produire dans ces deux milieux des ions amidures susceptibles de libérer $R'O^-$ de l'ester correspondant. Cependant, les solutions de sodium dans le HMPA sont stables sur de longues périodes dans nos conditions de réduction et ne conduisent donc pas à la formation d'amides.

Les pK_a relatifs des amines primaires et secondaires ($41 < pK_a < 44$) sont plus élevés que ceux du *tert*-butanol (pK_a = 32,2) (27). En présence d'un large excès de *tert*-butanol, nous pouvons considérer que les ions amidures ou diméthyl amidures sont entièrement et rapidement neutralisés, aussi bien dans les amines primaires que dans le HMPA. La formation d'alcool R'OH par action d'un ion amidure sur l'ester devrait donc être totalement inhibée par le *tert*-butanol, dès lors que la décomposition de ce même ester par le *tert*-butylate de potassium, et selon le processus de Bouveault et Blanc, est exclue. Or, il n'en est rien! Le tableau 6, entrées 6 et 7, montre qu'en présence d'un grand excès de *tert*-butanol, on obtient une augmentation de 10% du rendement en cholestane et une diminution de 10% de l'alcool correspondant.

Une autre base, l'hydroxyde de sodium, aurait pu résulter de la présence d'une certaine quantité d'eau dans le HMPA utilisé. Nous pouvons exclure cette possibilité pour plusieurs raisons: (a) la coloration bleue caractéristique de la présence d'électrons solvatés dans le milieu, est obtenue dès que l'on ajoute du sodium au HMPA anhydre utilisé, sans qu'aucun dégagement gazeux puisse être detecté; (b) pour une même quantité de solvant HMPA–ether, la proportion d'alcool, si celui-ci résultait au moins en partie d'une saponification de l'ester, devrait diminuer lorsque la quantité d'ester introduit est elle-même augmentée. Lorsqu'on réduit, dans la même quantité de solvant 0,232 mmol ou 0,88 mmol d'acétoxy-3β cholestane, on obtient la même proportion de cholestane et de cholestanol.

Une *trans* estérification de l'ester par le *tert*-butanol ou le *tert*-butoxyde de sodium est peu probable en raison de l'encombrement de l'ion *tert*-butoxyde et de la rapidité des réductions. Une *trans* estérification ayant été détectée lors de la réduction des esters dans les amines primaires (22) mais pas dans nos conditions de réduction, nous avons aussi examiné le rôle du cholestanol sur la réduction de l'heptanoate de méthyle par le sodium dans le HMPA. Contrairement aux résultats obtenus dans les amines, nous n'avons pu détecter que des traces (~1%) de cholestane provenant de l'heptanoate de cholestanyle intermédiairement formé par *trans* estérification. Le milieu réactionnel étant très basique, la formation d'énolate suivie d'une condensation de Claisen, pouvait être responsable d'une partie de l'alcool R'OH libéré. Un tel processus a effectivement été détecté lors d'une addition d'une solution d'électrons solvatés dans une solution d'ester (addition inverse). Cependant, la quantité d'acétylacétoxy-3β cholestane (10%) à partir d'acétoxy-3β cholestane reste très faible tout comme la proportion de produits issus de la condensation acyloïne.

Lors de la réduction des esters dans les différents milieux, on peut considérer que la formation d'une molécule d'alcane fournit nécessairement un équivalent d'acide carboxylique. Cependant, le rendement en RCO_2H est bien supérieur à celui de R'H (tableau 8). Ce rendement sensiblement égal à la somme des rendements en R'H et R'OH est voisin de 100%. Il existe donc une ou plusieurs voies susceptibles de conduire à la fois à RCO_2H et R'OH.[5] La discussion précédente met en évidence que, dans le HMPA, ni l'anion diméthylamidure ou l'ion hydroxyle, ni l'ion *tert*-butoxyde ou l'ion énolate, ne peuvent être considérés comme responsables de la formation d'une quantité importante d'alcool. Une autre observation méritant d'être soulignée est que, pour 1 à 1,8 équivalent de sodium introduit dans une solution d'acétate de cholestanyle dans le HMPA, on ne récupère pas d'ester non transformé d'une part, et la proportion de cholestane et de cholestanol (25:75) est équivalente à celle obtenue en présence d'un grand excès de réducteur d'autre part.

Le tableau 8 montre que le même problème de la formation simultanée d'alcool (R'OH) et d'acide carboxylique (RCO_2H) est rencontré dans des milieux extrêmement différents. Une interprétation commune pourrait impliquer, quel que soit le milieu, la formation d'intermédiaires semblables et suffisamment instables pour être hydrolysés rapidement au moment de l'isolement. Une telle possibilité représentée dans le schéma 2 mérite d'être considérée. L'addition nucléophile de radicaux anions sur des dérivés carbonylés a déja été envisagée pour rendre compte de la réaction de dismutation de Cannizzaro et de certaines anomalies rencontrées dans la réaction de condensation acyloïne (5). Cette addition de [A] sur une molécule d'ester fournirait [B] susceptible de se fragmenter en R'· et [C]

[5] Le processus de Bouveault et Blanc conduisant à la fois à R'OH et RCH_2OH est négligeable dans les exemples retenus. Dans les résultats obtenus par Barrett *et al.* (réf. 22), la formation de *tert*-butyl amidure intervient peu ou pas dans le milieu réactionnel de même que la réaction de Bouveault et Blanc.

TABLEAU 8. Rôle des conditions sur la formation simultanée d'alcool et d'acide carboxylique

Ester R—C(=O)—OR′	Conditions	°C	RCO_2H	RCH_2OH	R′OH	R′H	Réf.
Adamantane-1 carboxy-3β cholestane-5α	K-*t*-$BuNH_2$ – THF (30:10) 18-crown 6	46	96	2	57	43	22
		20	86		43	53	22

[a] Ce travail.

TABLEAU 9. Influence de la concentration en acétoxy-3β 5α-cholestane sur la proportion cholestane/cholestanol en présence de sodium dans le HMPA

Acétoxy-3β 5α-cholestane	Conditions	Cholestane (%)	Cholestanol (%)
$2{,}5 \times 10^{-3}\ M\ L^{-1}$	HMPA	43	54
$2{,}4 \times 10^{-2}\ M\ L^{-1}$	HMPA	35	58
$1{,}2 \times 10^{-3}\ M\ L^{-1}$	HMPA – *t*-BuOH (20:1)	64	33
$7{,}7 \times 10^{-2}\ M\ L^{-1}$	HMPA – *t*-BuOH (20:6)	69	20

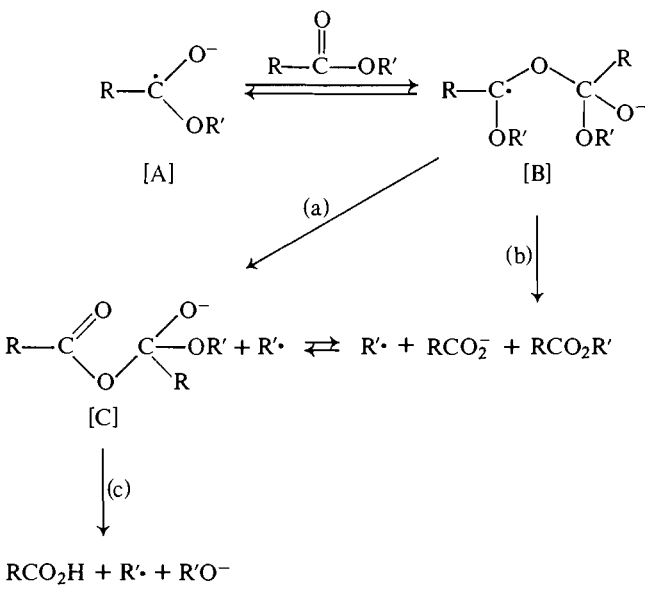

SCHÉMA 2

selon la voie (a) ou en R′·, RCO_2R' et RCO_2^- selon la voie (b).

Si l'addition du radical anion sur une molécule d'ester intervient, l'alcane peut provenir, en partie, de la fragmentation de l'intermédiaire [B] selon les voies (a) et (b) du schéma 2. De même, la formation d'alcool pourrait résulter de la fragmentation, soit dans le milieu réactionnel, soit au moment de l'isolement d'un intermédiaire tel que [C] formé au cours de la réaction. Le bilan de cette suite de réactions indique qu'une molécule d'alcane, une molécule d'alcool et deux molécules d'acide carboxylique sont susceptibles d'être produites pour chaque électron piégé par l'ester. Tous les autres processus bimoléculaires envisagés précédemment conduiraient à une molécule d'alcool et une molécule d'un dérivé d'acide suffisamment stable dans le milieu pour être isolé. En fait, nous constatons (essai 9, tableau 2) que le rapport acide carboxylique – alcane est supérieur à l'unité. La quantité d'alcool formé devrait dépendre de la concentration et nous avons testé l'influence de la concentration sur le cours de la réaction dans le HMPA. L'alcool, qui résulte uniquement d'une réaction bimoléculaire, devrait voir son rendement diminuer alors que l'alcane, qui provient surtout d'une fragmentation intramoléculaire, devrait voir son rendement augmenter pour une diminution de la concentration. Or, les résultats du tableau 9 indiquent que la dilution du milieu ne modifie pas sensiblement la proportion d'alcool et d'alcane, et qu'un dérivé du HMPA pourrait être impliqué dans la formation à la fois d'alcool et d'acide.

En conclusion, la réduction des esters par le sodium dans le HMPA est une réaction générale qui est d'autant plus efficace que les esters sont encombrés. Le rendement en alcane, à partir d'un ester donné, augmente en présence du *tert*-butanol qui peut à la fois neutraliser le diméthylamidure de lithium susceptible de se former et accroître, par solvatation, l'encombrement au niveau du radical intermédiaire.

De même, l'utilisation d'une faible concentration en ester carboxylique permet d'éviter la réaction bimoléculaire de condensation acyloïne et favorise la formation d'alcane. L'alcane provient essentiellement de la fragmentation du radical anion formé après capture d'un électron par l'ester. La formation d'alcool est due à plusieurs réactions bimoléculaires compétitives impliquant le diméthylamidure, la *tert*-butylate de sodium et, éventuellement, un dérivé du HMPA comme nucléophile.

TABLEAU 10. Réduction d'esters en présence de *tert*-butanol monodeutérié[a]

Ester	R″OD	Rendement RH (%) (RD)	M^+	$M^+ + 1$	$M^+ + 2$	Teneur en deutérium	R′OH
Acétoxy-3β 5α-cholestane	*t*-BuOH	69	100	31	3,4	0	20
	t-BuOD	68	100	760	23,7	0,87	29
	CH_3OD	21	100	590	193	0,83	74
Méthyl-1 cyclo hexanecarboxy-3β 5α-cholestane	*t*-BuOD	87	100	180	40	0,60	
Acétoxy-3β 5α-cholestane[b]	*t*-BuOD	42	100	185	60	0,65	58
	t-BuOH	40	100	350	100	0,76	50

[a]La technique opératoire est la même que dans le cas général.
[b]Addition inverse.

Partie expérimentale

Les spectres ir ont été enregistrés sur un appareil Philips SP2000, rmn sur Varian A60. Les points de fusion sont déterminés sur banc Kofler.

Produits de départ

Formoxy-3β 5α-cholestane préparé par action de l'acide formique à 98% sur le cholestanol-3β en présence de quantité catalytique d'acide perchlorique (28).

Acétoxy-6β cyclo-3α, 5α-cholestane obtenu par traitement du tosyloxy-3β cholestène-5 par l'acétate de potassium anhydre dans l'acide acétique (29).

Dans les autres cas: les esters sont obtenus par action du chlorure d'acide sur l'alcool dans le HMPA (30). Le HMPA a été séché plusieurs jours sur CaH_2 puis distillé sur CaH_2. Les points de fusion et analyses sont donnés dans le tableau 11.

Identification des produits

Les produits ont été identifiés par chromatographie sur couche mince, point de fusion, spectroscopie ir et rmn.

Réduction par le sodium

Une solution d'ester (1 g) dans un mélange éther – *t*-BuOH (1:1) (5 mL) est ajoutée à une solution de sodium (1 g) dans un mélange solvant (10 mL) – éther (5 mL) à une vitesse telle que la solution bleue obtenue ne se décolore pas quand l'addition est terminée, l'excès de sodium est éliminé. La solution versée dans l'éthanol est ensuite hydrolysée.

Méthode générale décrite pour la réduction d'ester carboxylique par la solution Na-HMPT

Du sodium finement divisé (1 g) est introduit dans le HMPA (10 cm^3). A la solution bleue, une solution d'acétoxy-3β cholestane (0,760 g) dans un mélange d'éther (10 cm^3) et de *tert*-butanol (3 cm^3), est ajoutée goutte à goutte à une vitesse telle que la solution n'est jamais décolorée. Dix minutes après la fin de l'addition, l'excès de sodium est filtré puis la solution est hydrolysée en milieu acide et extraite à l'éther (3 × 50 cm^3). Une chromatographie sur silice permet de séparer le cholestane (recristallisé dans l'acétone, 454 mg, 69%) et le cholestanol-3β (134 mg, 20%).

Réduction d'esters carboxyliques par la solution Li-ethylamine

Du lithium finement divisé (0,106 g) est introduit dans l'éthylamine (10cm^3). A la solution bleue, on ajoute goutte à goutte un mélange d'acétoxy-3β cholestane (0,098 g) avec du *tert*-butanol (2 cm^3) et de l'éthylamine (5 cm^3), de façon à éviter la décoloration. Ce mélange est alors laissé 1 h à reflux de l'éthylamine, puis l'éthylamine est distillée. Une hydrolyse acide puis extraction avec de l'éther et une chromatographie sur silice permettent d'isoler le cholestane (9 mg, 10%) et le cholestanol-3β (68 mg, 77%).

Réduction de l'acétoxy-3β cholestène-5

Dans une solution bleue de HMPA (10 cm^3) sodium (0,5 g), est ajouté goutte à goutte l'acétoxy-3β cholestène-5 (100 mg) en solution dans l'éther (5 cm^3) et le *tert*-butanol (2 cm^3). Cette addition dure 5 min en évitant la décoloration de la solution. Le sodium restant est immédiatement filtré, la solution hydrolysée en milieu acide puis extraite à l'éther (3 × 50 cm^3). Une chromatographie sur colonne de silice permet de séparer le cholestène-5 (59 mg, 68%) du cholestérol (26 mg, 29%). Le cholestène-5 est contrôlé par ccm sur silice imprégnée de $AgNO_3$ puis par rmn.

Si le temps de contact est de 24 h, le cholestane pur est isolé (58 mg, 64%) ainsi que le 5α-cholestanol-3β (21 mg, 28%). Le cholestane a été contrôlé par ccm sur silice imprégnée de $AgNO_3$ et par rmn, le cholestanol par rmn.

Dosage d'une solution de HMPA-Na

La solution bleue obtenue à partir de sodium (2 g) en suspension dans le HMPA (40 cm^3) est versée à l'aide d'une microburette dans une solution (1 cm^3) de n-butanol 0,214 *M* dans l'éther jusqu'à persistance de la coloration bleue (1,68 cm^3 versé; c = 0,119 *M*).

Réduction de l'acétoxy-3β 5α-cholestane par la solution de HMPA-Na 0,119 M

La solution bleue de HMPA-Na 0,119 *M* est versée goutte à goutte dans l'acétoxy-3β 5α-cholestane (81 mg) mis en solution dans l'éther (10 cm^3) jusqu'à persistance de la coloration (1,54 cm^3). Après hydrolyse, extraction et chromatographie, le cholestane (21 mg, 30%) et le cholestanol (51 mg, 70%) sont isolés.

Action de la solution bleue de HMPA-Na sur le tert*-butanol*

Une solution bleue de HMPA-Na (c = 0,0366 *M*) est ajoutée goutte à goutte au *tert*-butanol (191 mg) dilué dans l'éther (10 cm^3) jusqu'à persistance de la coloration. La persistance de la couleur bleue est obtenue après que 0,524 cm^3 de solution ait été ajoutée.

Réduction de l'acétoxy-3β 5α-cholestane pur par la solution bleue de HMPA-Na

Une solution bleue de HMPA-Na (4,13 cm^3, c = 0,049 *M*) est ajoutée rapidement sur l'acétoxy-3β 5α-cholestane pur (152 mg, 3,45 × 10^{-4} mol). Le mélange obtenu est laissé 10 min à la température ambiante puis hydrolysé en milieu acide. Une chromatographie sur silice permet d'isoler le cholestane (58 mg, 44%), l'acétylacétoxy-3β 5α-cholestane (17 mg, 10%) et le cholestanol-3β (54 mg, 39%).

Action de $NaNH_2$ sur l'acétoxy-3β 5α-cholestane en milieu HMPA

De l'amidure de sodium (253 mg) est mis en suspension dans le HMPA (10 cm^3) puis l'acétoxy-3β 5α-cholestane (552 mg) est mis en présence de ce mélange pendant 30 min. On ajoute alors rapidement de l'alcool puis de l'acide chlorhydrique 3 *M* avant d'extraire à l'éther. La chromatographie sur silice permet d'isoler de l'ester non transformé (477 mg, 86%) et le 5α-cholestanol-3β (75 mg, 14%).

Action de $NaNH_2$ sur l'ester en milieu HMPA-Na

De l'amidure de sodium (325 mg) est mis en suspension dans le HMPA (10 cm^3) en présence de sodium (solution bleue). L'acétoxy-

TABLEAU 11. Caractérisation des esters d'alkyle

Ester	F (°C)	Analyse Trouvé C	Analyse Trouvé H	Analyse Calculé C	Analyse Calculé H
Acétate de triméthyl-3β,4,4 5α-cholestanyle-3	128–129	80,88	11,65	81,28	11,94
Pivalate de 5α-cholestanyle-3β	160–161	81,34	11,77	81,28	11,94
Cyclohexane carboxylate de 5α-cholestanyle-3β	158–159	81,79	11,73	81,86	11,72
Heptanoate de 5α-cholestanyle-3β	78–79	81,29	11,90	81,53	12,68
Méthyl-1 cyclohexane carboxylate de 5α-cholestanyle-3β	136–137	81,46	11,80	81,97	11,80

Ester	F (°C)	F (litt.)	Réf.
Acétate de 5α-cholestanyle-3β	107	91–111	31
Acétate de cholesten-5 yl-3β	114	111–116	32
Acétate de diméthyl-4,4 5α-cholestanyl-3β	138	138–139	33
Benzoate de 5α-cholestanyl-3β	131	136–137	34
Phényl-2 acétate de 5α-cholestanyl-3β	90	91–92	35
Acétate de méthyl-3β 5α-cholestanyl-3α	87	—	36
Acétate de méthyl-3α 5α-cholestanyl-3β	114	—	36

3β 5α-cholestane (567 mg) en solution dans l'éther est ajouté et laissé en présence de cette solution pendant 30 min. Après élimination du sodium, hydrolyse et chromatographie sur silice, le cholestane est isolé (152 mg, 31%) ainsi que le cholestanol-3β (309 mg, 60%) et l'acétoxy-3β 5α-cholestane non transformé (12 mg, 2%).

Action de $NaNH_2$ sur l'ester en milieu HMPA en présence de tert-*butanol*

De l'amidure de sodium (150 mg) est mis en suspension dans le HMPA (10 cm^3) puis de l'acétoxy-3β 5α-cholestane (860 mg) en solution dans un mélange éther – *tert*-butanol (9:1) (10 cm^3) pendant 30 min. On ajoute alors de l'alcool puis de l'acide chlorhydrique 3 *M* avant d'extraire à l'éther. La chromatographie sur silice permet de séparer de l'ester (150 mg, 22%) et du cholestanol-3β (423 mg, 69%).

Action de $NaNH_2$ sur l'ester en milieu HMPA-Na en présence de tert-*butanol*

De l'amidure de sodium (330 mg) est mis en suspension dans la solution bleue HMPA-Na. L'acétoxy-3β 5α-cholestane (703 mg) en solution dans un mélange éther – *tert*-butanol (9:1) (10 cm^3) est alors additionné et laissé à la température ambiante pendant 30 min. Après traitement identique au précédent, le cholestane (317 mg, 52%), le cholestanol-3β (280 mg, 44%) et l'ester de départ (4 mg, 0,5%) sont isolés.

Reactions of 2,2-dibromocyclopropyl carboxylic acids with methyllithium

LEIV K. SYDNES[1] AND SØLVI SKARE
Department of Chemistry, University of Tromsø, P.O. Box 953, N-9001 Tromsø, Norway

Received Janaury 3, 1984

This paper is dedicated to Professor Paul de Mayo on the occasion of his 60th birthday

LEIV K. SYDNES and SØLVI SKARE. Can. J. Chem. **62**, 2073 (1984).

For reactions of 2,2-dibromocyclopropyl carboxylic acids with methyllithium, the course of reaction depends mainly on the position of the carboxyl group. When the COOH group is directly attached to the *gem*-dibromocyclopropane ring MeLi generally attacks the *gem*-dibromo moiety and gives the corresponding monobromocyclopropane as the principal product. When the reaction is performed above −80°C the monobromides are formed stereospecifically in the *trans* configuration. The highest yields, as high as 80−90%, are obtained at 0°C. When the carboxyl group is not directly attached to the cyclopropane ring most of the MeLi is consumed in an acid−base reaction with the COOH group.

LEIV K. SYDNES et SØLVI SKARE. Can. J. Chem. **62**, 2073 (1984).

L'orientation de la réaction dépend principalement de la position du groupe carboxylique. Lorsque le groupe COOH est attaché directement au cycle *gem*-dibromocyclopropane, le MeLi attaque généralement la portion *gem*-dibromo et conduit principalement au produit monobromocyclopropane correspondant. Lorsqu'on effectue la réaction à des températures supérieures à −80°C, les monobromures se forment stéréospécifiquement en configuration *trans*. C'est à 0°C que l'on obtient les rendements les plus élevés, qui peuvent aller jusqu'à 80−90%. Lorsque le groupe carboxyle n'est pas attaché directement au cyclopropane, la majorité du MeLi est utilisé dans une réaction acide−base avec le groupe COOH.

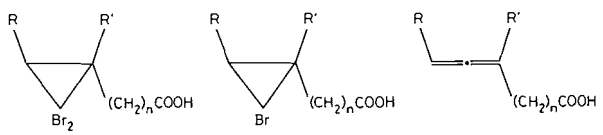
Introduction

Reactions of *gem*-dibromocyclopropanes with methyllithium generally occur with initial lithium−bromine exchange, resulting in formation of the corresponding bromolithio derivatives (**1**, **2**). The subsequent reaction of such derivatives is significantly influenced by the nature of the substituents attached to the ring. When the substituents are nonpolar, like alkyl and aryl groups, the organometallic intermediates usually collapse by elimination of lithium bromide to yield allene and (or) bicyclobutane derivatives (**1**−**10**). On the other hand, a variety of polar groups, e.g. the carbonyl, alkoxy, and silyloxy moieties, may stabilize the lithio-bromocyclopropane by intramolecular coordination and thus prevent LiBr elimination (**9**−**13**). In such cases the major product is generally the corresponding monobromocyclopropane, which is formed by hydrolysis of the lithium derivative during aqueous work-up.

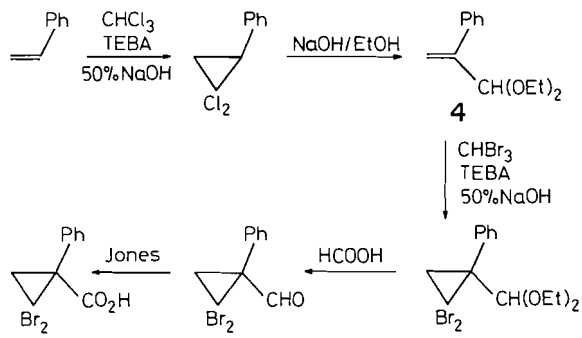
An exception to this general pattern is 2,2-dibromo-1-methylcyclopropanecarboxylic acid (**1***b*). When this compound was treated with methyllithium at 0°C, a stereospecific formation of *trans*-2-bromo-1-methylcyclopropanecarboxylic acid (**2***b*) was observed (14). According to Stein and Morton



1 **2** **3**

a R = R′ = H, *n* = 0
b R = H, R = CH_3, *n* = 0
c R = R′ = CH_3, *n* = 0
d R = H, R′ = Ph, *n* = 0
e R = H, R′ = CH_3, *n* = 1

this product resulted from an intramolecular quenching of a cyclopropyl anion *prior to* hydrolysis (14). It is thus conceivable that a COOH group attached to a *gem*-dibromocyclopropane can function as a general directing group and act as a vehicle for stereoselective preparation of a variety of monobromocyclopropanes. It was therefore of interest to study the reactions between methyllithium and various *gem*-dibromocyclopropanecarboxylic acids; the results of this investigation are reported here.



SCHEME 1

Results and discussion

Most of the acids employed were prepared in good yields by literature procedures. 2,2-Dibromo-1-phenylcyclopropanecarboxylic acid (**1***d*), however, was obtained from styrene as outlined in Scheme 1. The low overall yield (23%) results from inefficient addition of dibromocarbene to the carbon−carbon double bond of atropaldehyde diethylacetal (**4**); this is not surprising since dichlorocarbene addition to similar acetals is fairly ineffective (15). 2-(2,2-Dibromo-1-methylcyclopropyl)-ethanoic acid (**1***e*) was prepared by Jones oxidation of the corresponding primary alcohol, which was obtained by dibromocarbene addition to 3-methyl-3-buten-1-ol under phase-transfer conditions.The cyclopropyl alcohol formed in the latter reaction was contaminated with a minor product tentatively identified as 2,2-dibromo-1-methyl-1-(2-dibromomethoxyethyl)cyclopropane (**5**) on the basis of analogy with earlier work (16); **5** is probably produced by dibromocarbene insertion into the O—H bond (Scheme 2) (16).

The *gem*-dibromocyclopropane acids were reacted with

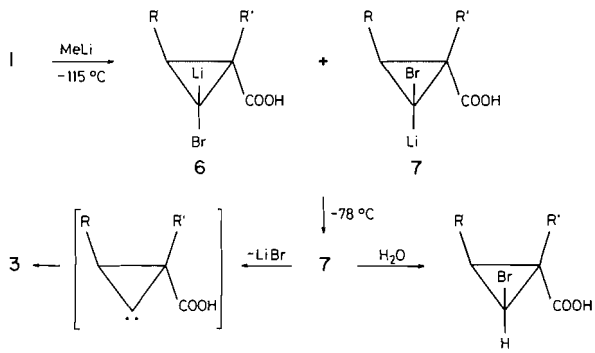

SCHEME 3

methyllithium at −115 to 25°C using, in most cases, 1.2 molar equivalents of the lithium reagent. The reaction mixtures were analyzed by gas−liquid chromatography (glc) before the products were isolated by distillation or column chromatography and identified by spectroscopic means. Most of the results are summarized in Table 1, which reveals several interesting features.

With the exception of **1***e*, the acids generally react to give the corresponding monobromocyclopropanes **2** as the main products. When the reactions were carried out below −80°C the monobromides were formed as isomeric mixtures. However, above −80°C the monobromo derivatives were formed as single isomers with the bromine and carboxyl groups *trans* to each other. The stereochemistry is assigned by ^{1}H nmr spectroscopy on the basis of two assumptions. Firstly, it is assumed that in a cyclopropane ring the *cis* coupling constant is larger than the *trans*, which is in accordance with calculations as well as experimental data (17). Secondly, the assumption is that for a pair of isomers the hydrogen atom geminal to the bromine atom gives rise to signals at a lower field for the *trans* than for the *cis* isomer, because of the anisotropy of the carbonyl group (12, 13, 17).

Treatment of acid **1***e* with methyllithium, on the other hand, gave no monobromocyclopropane at all; the predominant product was 3-methyl-3,4-pentadienoic acid (**3***e*) which was isolated in low yield when the reaction was carried out above −5°C. An allene, 2-methyl-2,3-pentadienoic acid (**3***c*), was also formed when **1***c* was treated with MeLi at and above 0°C, but in this case the monobromide was the major product.

The products isolated can be accounted for as outlined in Scheme 3. The first step involves an exchange of bromine with lithium, which has been reported to be a faster reaction than proton abstraction from the carboxyl and hydroxyl groups of various bromosubstituted acids and alcohols (14, 18−20). The organolithium intermediate is not formed stereospecifically since reactions performed at −115°C result in formation of mixtures of isomeric monobromocyclopropane acids. Consequently, at −115°C the stereoisomeric organolithium derivatives **6** and **7** equilibriate very slowly. However, at −78°C and above, the only isomer present is **7**, which is the more

stable due to lithium−oxygen coordination. Stabilization of organolithium intermediates by adjacent oxygen functions has been extensively reported in the literature (9, 11−13). The final products result from two competing reactions following the formation of the lithio-bromocyclopropanes, viz. quenching of the cyclopropyl anion and allene formation via a cyclopropylidene intermediate. When the carboxyl group is directly attached to the ring, the former alternative is generally the predominant reaction; α-elimination of lithium bromide and subsequent allene production are only observed when steric interactions increase the internal energy of **7** and render opening of the ring a more favourable process.

The amount of recovered starting material depends, in addition to the relative amount of methyllithium employed, mainly on two factors. More important is obviously the position of the carboxyl group relative to the *gem*-dibromocyclopropane ring. When the COOH group is directly attached to the ring, as in **1***a*−**1***d*, the dibromo moiety and the carboxyl group will mutually interact; this is convincingly borne out by comparing the pK_a values of the acids with those of similar cyclopropane-

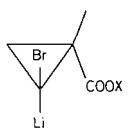
1*b*/DTC	48:52	36:59	12

carboxylic acids (Table 2) (21–23). As a result of this interaction the bromine atoms become more positive and compounds **1***a*–**1***d* are therefore more prone to undergo lithium–bromine exchange than proton abstraction from the carboxyl group when treated with MeLi. On the other hand, in **1***e* such interactions are impossible, and proton abstraction is therefore the predominant reaction when this compound is treated with methyllithium; consequently, most of the acid is recovered unchanged during the work-up.

The reaction temperature also influences considerably the amount of recovered starting material. At and below −70°C the irreversible consumption of acid is generally very low, primarily because most of the methyllithium is consumed in reaction with the carboxyl group. When the temperature increases, however, the relative importance of the lithium–bromine exchange reaction increases and reaches, for no obvious reason, its maximum at 0°C. The attack on the *gem*-dibromo moiety is therefore a more temperature sensitive process than the abstraction of a proton from the carboxyl group.

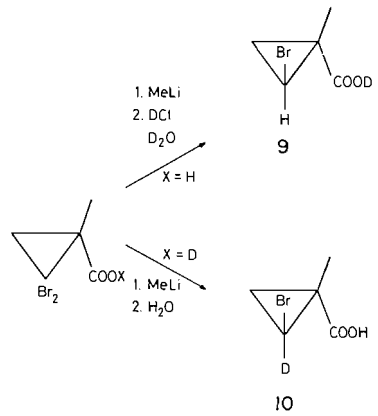
If the rationale above correctly describes the course of reaction between methyllithium and acids **1***a*–**1***e*, then 2,2-dibromo-1-methylcyclopropanecarboxylic acid (**1***b*) should be more reactive toward MeLi than either acid **1***e* or alkyl-substituted *gem*-dibromocyclopropanes. Experimentally, this was found to be the case; when acid **1***b* was mixed with **1***e* and 1,1-dibromo-2,2,3-trimethylcyclopropane and treated with MeLi, **1***b* was selectively attacked by the lithium reagent. This is borne out by a decrease in the relative amount of **1***b* in the mixtures and by a simultaneous formation of *trans*-**2***b* as the main reaction product (Table 3).

From acids **1***a*–**1***d* the monobromocyclopropanes are formed by an acid–base reaction between the lithiocyclopropyl moiety and a proton source. From experiments performed with deuterated reactants at 0°C (Scheme 4) Stein and Morton concluded that the proton was supplied by the carboxyl group in an intramolecular process. This conclusion would have been correct if the lithium intermediates corresponding to **6** and **7** both had been present at 0°C. This is, however, not the case; the only cyclopropyl lithium derivative present at this temperature is **8**, which will yield the *trans* monobromides **9**

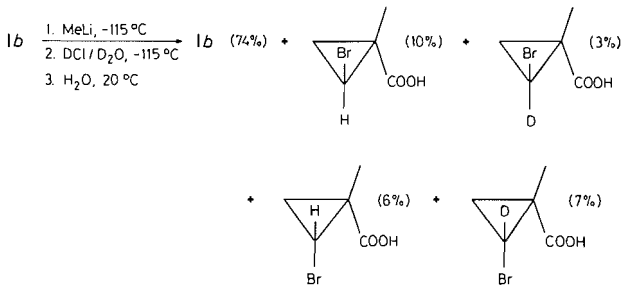


8

and **10** as the only products whether **8** is quenched intramolecularly or intermolecularly. In order to shed more light on this problem, acid **1***b* was treated with MeLi at −115°C and subsequently hydrolyzed, first with DCl/D_2O and then with H_2O. By comparing glc and ^1H nmr analyses of the reaction

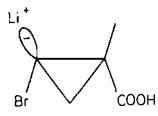


SCHEME 4



SCHEME 5

mixture the results summarized in Scheme 5 emerge. Most striking is the fact that *trans*-**2***b* and a second product which from the similarity of its ^1H nmr signals is almost certainly the *cis* isomer, were both formed as a mixture of 2-bromo-1-methylcyclopropanecarboxylic acid and 2-bromo-1-methylcyclopropanecarboxylic-2-*d* acid. This clearly shows that the cyclopropyl anions abstract protons both prior to *and* during the hydrolysis and, consequently, that the organolithium intermediates live long enough to permit intermolecular quenching. In fact, studies of models of the *anti* cyclopropyl anion **11** clearly indicate that only intermolecular quenching is conceivable for this and other intermediates with the same configuration.



11

From the results outlined above it is evident that one can influence the course of reaction by employing a salt of the acids instead of the acids themselves. Such salts, prepared quantitatively by treating the acids with 1 equivalent of sodium hydride, were therefore treated with methyllithium in the usual way. When the reaction mixtures were worked up it turned out that the reduced loss of methyllithium did not increase the yield of *trans*-2-bromocyclopropanecarboxylic acids but rather the yield of other products. Typical examples are shown in Scheme 6: 2-acetyl-1,1-dibromo-2-methylcyclopropane was formed as a minor product from the sodium salt of **1***b* at 0°C (24), whereas the yield of allene **3***c* tripled when sodium 2,2-dibromo-1,3-dimethylcyclopropanecarboxylate was reacted under the same conditions. Consequently, the sodium salts react less selec-

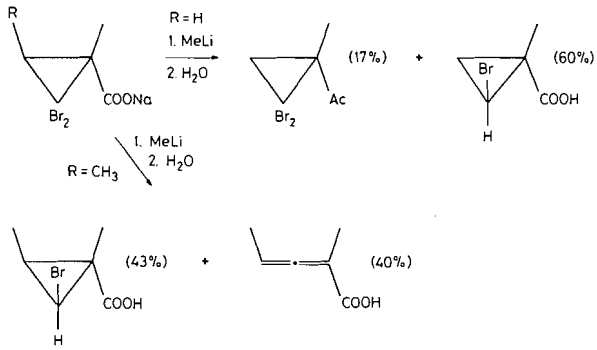

SCHEME 6

tively with methyllithium than the corresponding acids, but it is interesting to note that the monobromocyclopropanecarboxylic acids are formed exclusively in the *trans* configuration, i.e from cyclopropyllithium intermediates in which lithium coordinates with the sodium carboxylate moiety.

Experimental

Gas chromatographic analyses were carried out on a Varian 3700 gas chromatograph equipped with thermal conductivity and flame ionization detectors. The columns were 2 m long and were packed with 3% OV17 on Chromosorb W-HP, 80/100. The ir spectra were recorded on a Shimadzu IR 420 spectrophotometer. The nmr spectra were obtained on JEOL PMX 60 SI and JEOL FX 90Q spectrometers, using tetramethylsilane as internal standard. Mass spectra were run on a Micromass 7070 H spectrometer, operated in the EI mode with an ionization potential of 70 eV. Boiling points and melting points are uncorrected. Melting points were determined on a Mettler FP61 apparatus. Elemental analyses were performed by Ilse Betz Microanalytical Laboratory, Kronach, West Germany. A PHM 62 pH-meter with a Radiometer SK2401 C glass electrode was used to determine the pK_a values of carboxylic acids.

Preparation of starting materials

2,2-Dibromocyclopropanecarboxylic acid (**1***b*), 2,2-dibromo-1-methylcyclopropanecarboxylic acid (**1***b*), and 2,2-dibromo-1,3-dimethylcyclopropanecarboxylic acid (**1***c*) were prepared as described in the literature (13, 25).

2,2-Dibromo-1-phenylcyclopropanecarboxylic acid (**1***d*) was made in the following way. Dibromocarbene, from bromoform (43.0 g, 0.17 mol) and 50% aqueous NaOH (10.0 g, 0.225 mol), was added to atropaldehyde diethylacetal (**4**) (15.0 g, 0.07 mol) under phase-transfer conditions using TEBA (0.50 g, 0.002 mol) as catalyst (26, 27) to give 2,2-dibromo-1-phenylcyclopropanecarbaldehyde diethylacetal (10.6 g, 40%), bp 122–125°C/0.2 Torr (1 Torr = 133.3 Pa); ir (film): 1602, 1500, 1450, 1370, 1300, 1240, 1200–1000, 695 cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$) δ: 1.13 (3H, t, *J* 7 Hz), 1.22 (3H, t, *J* 7 Hz), 2.10 (2H, s), 3.57 (2H, q, *J* 7 Hz), 3.65 (2H, q, *J* 7 Hz), 4.49 (1H, s), 7.34 (5H, br s) ppm; the compound isolated was not pure enough for elemental analysis. A solution of the cyclopropanecarbaldehyde diethylacetal (4.6 g, 0.012 mol) in 80% formic acid (50 mL) was then refluxed for 3 h; after extraction (diethyl ether), washing (aqueous $NaHCO_3$), and drying ($MgSO_4$), work-up in the usual way left a residue which was essentially pure 2,2-dibromo-1-phenylcyclopropanecarbaldehyde (3.4 g, 97%) (25). Jones oxidation (17) of this aldehyde (3.4 g, 0.012 mol) gave 2,2-dibromo-1-phenylcyclopropanecarboxylic acid (**1***d*) (3.5 g, 97%), mp 121–122°C (from water) (lit. (25) mp 118–120°C (sublimed)).

2-(2,2-Dibromo-1-methylcyclopropyl)ethanoic acid (**1***e*) was prepared as follows. Dibromocarbene, from bromoform (116.0 g, 0.46 mol) and 50% aqueous NaOH (56.0 g, 0.70 mol), was added to 3-methyl-3-buten-1-ol (20.0 g, 0.23 mol) in the presence of TEBA (0.70 g, 0.003 mol) (27) to give 2-(2,2-dibromo-1-methylcyclopropyl)ethanol (34.3 g, 58%) by distillation, bp 95–98°C/0.2 Torr; ir (film): 3300, 1730, 1460, 1390, 1180, 1050, 700 cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$) δ: 1.41 (3H, s), 1.44 (1H, d, *J* 8 Hz), 1.52 (1H, d, *J* 8 Hz), 1.90 (1H, br s), 1.95 (2H, 2t, *J* 7 Hz), 3.87 (2H, 2t, *J* 7 Hz), 4.38 (weak signal, t, *J* 7.5 Hz), 8.07 (weak signal, s) ppm; the compound gave no molecular ion in ms and was not obtained pure enough for elemental analysis; the ir absorption at 1730 cm^{-1} and the nmr signals at 4.38 and 8.07 ppm are tentatively ascribed to cyclopropane **5**. Jones oxidation (17) of the dibromocyclopropylethanol (34.0 g, 0.13 mol) afforded acid **1***e* (18.0 g, 51%) by recrystallization from water, mp 94–96°C; ir (CCl_4): 3500–2300, 1710, 1410, 1260, 1220, 1115, 1020, 695 cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$) δ: 1.52 (3H, s), 1.54 (1H, d, *J* 8 Hz), 1.59 (1H, d, *J* 8 Hz), 2.78 (2H, s), 9.66 (1H, s) ppm; ^{13}C nmr (22.5 MHz, $CDCl_3$) δ: 23.1 (CCH_3), 26.9(CCH_3), 34.4 (CH_2), 36.8 (Br*C*Br), 43.0 (CH_2COOH), 176.9(CH_2COOH) ppm; ms *m/e*: 215(8), 213(14), 211(7), 193(19), 191(19), 151(27), 149(29), 133(12), 131(11), 111(100), 82(73), 81(28), 80(77), 79(29). *Anal.* calcd. for $C_6H_8Br_2O_2$: C 26.50, H 2.94; found: C 26.09, H 3.25.

Treatment of gem*-dibromocyclopropyl acids with methyllithium; general procedure*

The reaction was carried out under pure nitrogen.

An etheral solution (1.4 *M*) of MeLi, containing lithium bromide, was added dropwise to a stirred solution of acid in dry ether (15 mL ether/10 mmol acid) at and above −78°C and in a 11:3:6 mixture of tetrahydrofuran, ether, and petroleum ether (5 mL/mmol acid) at −115°C. The mixture was stirred for another 1.5 h at bath temperature and was then hydrolyzed with 1.0 *M* HCl and extracted with ether. The combined organic fractions were dried ($MgSO_4$). Evaporation of ether left a residue which was analyzed by glc prior to purification by distillation or recrystallization.

Reactions of **1**a

The acid was treated with MeLi (1.2 equivalents) at temperatures from −115 to 25°C. The glc (column temperature 60–180°C, 6°/min) and ^1H nmr analyses gave the results included in Table 1.

The products formed at −115°C were, according to ^1H nmr spectra of the reaction mixture, the *cis* and *trans* isomers of 2-bromocyclopropanecarboxylic acid (**2***a*) (23, 29).

At and above −78°C the only product formed was *trans*-**2***a*, bp 105°C/1.5 Torr; mp 64.5–65°C (sublimed); ir (film): 3600–2200, 1700, 1440, 1260, 1215, 1020, 945 cm^{-1}; ^1H nmr (60 MHz, $CDCl_3$) δ: 1.15–2.30 (3H, very complex m), 3.20–3.55 (1H, m), 9.65 (1H, br s).

When the reaction was carried out at −78, 0, and 25°C with 0.98 g (4.0 mmol) of **1***a*, *trans*-**2***a* was isolated by sublimation in 20, 90, and 30% yield, respectively.

Reactions of **1**b

The acid was reacted with MeLi (1.2 equivalents) at temperatures from −115 to 25°C; The glc analyses (column temperature 80–180°C, 10°/min) gave the results compiled in Table 1.

When the acid (2.58 g, 0.010 mol) was treated with MeLi at −115°C a 1:1 mixture (0.35 g, 20%) of the *trans* and (evidently) *cis* isomers of 2-bromo-1-methylcyclopropanecarboxylic acid (**2***b*) was formed, bp 64–65°C/10 Torr; ir (film): 3500–2500, 1690, 1460, 1405, 1310, 1185, 1040, 690 cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$) δ: 0.92–1.99 (2H, m, *cis* and *trans*), 1.40 and 1.47 (3H, 2s, due to *cis* and *trans*, respectively), 3.05 and 3.57 (1H, 2dd, due to *cis* and *trans*, respectively, *J* 6 and 7.5 Hz), 10.75 (1H, s).

When reacted at −78 and 0°C, *trans*-**2***b* was the only product formed. The boiling point and spectroscopic data were in accordance with literature data (14). At −78°C 2.58 g (10 mmol) of **1***b* gave 0.54 g (30%) of *trans*-**2***b* by distillation. At 0°C 2.28 g (8.8 mmol) of **1***b* afforded 1.21 g (81%) of the same product by distillation.

When the acid (1.29 g, 5 mmol) was reacted at 25°C, 0.31 g (35%) of *trans*-**2***b* was isolated by Kugelrohr distillation. In addition, glc analyses (column temperature 80–180°C, 10°/min) showed that 5 additional products had been formed in approximately 5% yield; these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

products were not identified.

Reactions of **1**c

This acid was reacted with MeLi (1.2 equivalents) at temperatures ranging from −78 to 25°C. The glc analyses (column temperature 80−180°C, 10°/min) of the reaction mixture prior to work-up gave the results presented in Table 1.

At −78°C, treatment of 1.36 g (5.0 mmol) of **1***c* gave a reaction mixture from which 0.14 g (15%) of the *trans* isomer of 2-bromo-1,3-dimethylcyclopropanecarboxylic acid (**2***c*) was isolated by Kugelrohr distillation at 90°C/0.5 Torr. The product crystallized during the distillation, mp 98−99°C; ir (CCl_4): 3400−2400, 1690, 1420, 1290, 1180, 600 cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$) δ: 1.12 (3H, d, *J* 6.5 Hz), 1.27 (3H, s), 1.55−1.94 (1H, m), 3.73 (1H, d, *J* 8 Hz), 12.28 (1H, s) ppm; ^{13}C nmr (22.5 MHz, $CDCl_3$) δ: 10.00 ($CHCH_3$), 10.54 (CCH_3), 24.78 (CH_3CH), 25.76 (CCH_3), 36.51 (*H*C*B*r), 180.33 (*C*OOH) ppm; ms *m/e*: 194(2, M^+), 192(2, M^+), 179(2), 177(2), 149(2), 113(100), 95(31), 82(6), 80(6), 67(66). *Anal.* calcd. for $C_6H_9BrO_2$: C 37.34, H 4.66; found: C 37.27, H 5.13.

When **1***c* (2.72 g, 10 mmol) was treated with MeLi at 0°C distillation afforded *trans*-**2***c* (0.56 g, 29%), bp 94°C/0.4 Torr, and 2-methyl-2,3-pentadienoic acid (**3***c*) (0.15 g, 13%), bp 85°C/0.4 Torr (lit. (28) bp 74°C/0.03 Torr).

When **1***c* (2.72 g, 10 mmol) reacted with MeLi at 25°C, the yield of isolated *trans*-**2***c* and **3***c* dropped to 25% and 12%, respectively.

Reactions of **1**d

Reactions between this acid and MeLi (1.2 equivalents) were performed at temperatures ranging from −78°C to 25°C. The glc analyses (column temperature 100−200°C, 20°/min) of the reaction mixture, after quenching with water but prior to work-up, gave the results given in Table 1.

Reactions on a preparative scale were only performed at 0 and 25°C. At 0°C acid **1***d* (3.20 g, 10 mmol) gave *trans*-2-bromo-1-phenylcyclopropanecarboxylic acid (*trans*-**2***d*), which was isolated in 70% yield (1.69 g) when recrystallized from water, mp 136.5−137.5°C; ir (CCl_4): 3350−2200, 1690, 1420, 1300, 1180, 1055, 695, 650, 600 cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$) δ: 1.75 (2H, t, *J* 6 Hz), 2.24 (2H, dd, *J* 6 and 8 Hz), 3.80 (2H, dd, *J* 6 and 8 Hz), 7.33 (5H, br s), 11.60 (1H, br s) ppm; ^{13}C nmr (22.5 MHz, $CDCl_3$) δ: 24.87 (H*C*H), 27.76 (H*C*Br), 34.16 (*C*Ph), 128.10 (*C*H), 128.20 (*C*), 131.45 (*C*H), 134.24 (*C*), 178.37 (*C*OOH) ppm; ms *m/e*: 242(9, M^+), 240(9, M^+), 224(0.5), 222(0.5), 197(0.5), 195(0.6), 161(6), 160(7), 133(20), 117(13), 116(20), 115(100), 103(21), 91(8). *Anal.* calcd. for $C_{10}H_9BrO_2$: C 49.83%, H 3.73; found: C 50.19%, H 3.45%.

When the same reaction was carried out at 25°C the isolated yield of *trans*-**2***d* dropped to 58%.

Reactions of **1**e

The acid was treated with 1.2 equivalents of MeLi at temperatures between −115 and 25°C. The glc analyses (column temperature 80−180°C, 10°/min) gave the results compiled in Table 1. Three products, formed in 6 and 4% yield at 0 and 25°C, respectively, could not be identified although there are indications that one of the compounds is 3-(2,2-dibromo-1-methylcyclopropyl)-2-propanone.

The reactions performed at −115 and −78°C gave no product except recovered starting material.

When the acid (2.70 g, 10 mmol) was reacted with MeLi at 0°C, a product believed to be 3-methyl-3,4-pentadienoic acid (**3***e*) (0.09 g, 8%) was obtained by distillation, bp 100°C/0.5 Torr; ir (film): 3500−2500, 1970, 1740, 850 cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$) δ: 1.79 (3H, t, *J* 3.2 Hz), 3.03 (2H, t, *J* 2.3 Hz), 4.70 (2H, m), 10.05 (1H, s); the compound was not obtained pure enough for elemental analysis.

An identical reaction carried out at 25°C gave **3***e* in 6% yield.

pK_a *measurements*

The measurements were carried out by titration of aqueous solutions (25.0 mL) of the acids with 0.100 *M* aqueous NaOH. The pK_a values were determined graphically from plots of pH as a function of added base. The results are presented in Table 2.

Reactions of methyllithium with **1**b/**1**e *and* **1**b/*1,1-dibromo-2,2,3-trimethylcyclopropane mixtures*

Both reactions were performed in the following way. An etheral solution (5 mL), containing approximately 1.00 mmol of each acid, was stirred at 0°C and treated with 1.0 mL of a 1.0 *M* etheral solution of MeLi. The reaction was quenched and worked up in the usual way after 40 min. The composition of the reaction mixture was determined by glc (column temperature 80−180°C, 10°/min). The results are summarized in Table 3.

Treatment of **1**b *with MeLi and DCl/*D_2O *at −115°C*

Acid **1***b* (0.51 g, 2.0 mmol), dissolved in a dry mixture (10 mL) of THF, ether, and petroleum ether, was stirred at −115°C and treated with 2.0 mL of a 1.2 *M* solution of MeLi. The mixture was kept at bath temperature for 30 min and was then hydrolyzed at the same temperature with DCl/D_2O (5 mL, 2.0 *M*). The hydrolysate was allowed to reach room temperature before 20 mL H_2O was added. The reaction mixture was then worked up in the usual way and analyzed. The glc analysis (column temperature 60−180°C, 8°/min) indicated that a 1.0:1.0 mixture of the *cis* and *trans* isomers of deuterated and nondeuterated **2***b* had been formed in 26% yield. The ^1H nmr (90 MHz, $CDCl_3$) analysis showed, by comparing the integral of the double doublet at 3.57 ppm (*H*CBr due to *trans*-**2***b*), the double doublet at 3.05 ppm (*H*CBr due to *cis*-**2***b*), and the doublet at 2.44 ppm (*H*CH due to **1***b*), that the reaction mixture contained 16% of nondeuterated **2***b* in a *trans*/*cis* ratio of 5.0:3.0.

Preparation of etheral solutions of sodium salts of 2,2-dibromocyclopropanecarboxylic acids

The sodium salts were prepared by treating a 0.20 *M* etheral solution of the acids at 0°C with an equivalent amount of sodium hydride, which was obtained from a NaH dispersion by removing the mineral oil with pentane. The mixture was stirred for 45 min at ambient temperature to complete the reaction.

Hydrolysis and adjustment of pH to 1 followed by standard work-up gave recovered acids in quantitative yields (30).

Reactions of the sodium salts of **1**b *and* **1**c *with methyllithium*

The reactions were carried out according to the general procedure for treatment of the corresponding acids with methyllithium. A 20% excess of MeLi was used. The glc analyses of the reaction mixtures (column temperature 80−180°C, 10°/min) gave the results presented in Scheme 6.

When the sodium salt of **1***b* was reacted with 1.2 equivalents of MeLi, 2-acetyl-1,1-dibromo-2-methylcyclopropane was isolated in 15% yield, bp 33°C/0.2 Torr (lit. (31) bp 38°C/0.6).

This article is dedicated to Professor Paul de Mayo on the occasion of his 60th birthday

PANAYIOTIS ANASTASIS, ISABEL FREER, CHRISTOPHER GILMORE, HUGH MACKIE, KARL OVERTON, DOUGLAS PICKEN, and STEPHEN SWANSON. Can. J. Chem. **62**, 2079 (1984).

Experiments with intact callus cultures of *Andrographis paniculata* and a derived cell-free system have established that: (1) the biosynthesised γ-bisabolene has the *Z*-configuration **6**; (2) the biosynthetic intermediate is a 6-*trans*-**13** and not a 6-*cis*-**15** farnesyl pyrophosphate; (3) in paniculide B **17**, and probably also in γ-bisabolene **14**, the ring carbon derived from C-2 of mevalonate is *anti* to the side chain; (4) mevalonolactone and *trans,trans*-farnesyl pyrophosphate are incorporated into γ-bisabolene without hydrogen loss respectively from C-5 and C-1; cyclisation to the bisabolenyl cation therefore does not involve prior *trans* to *cis* isomerisation of the terminal double bond of farnesol by a redox mechanism; (5) taken together with our previous findings, it is established that *Andrographis* cultures contain two independently functioning enzymes: (*i*) a *trans,trans*- to *cis,trans*-farnesol isomerase, and (*ii*) a *trans,trans*-farnesyl pyrophosphate isomerase-cyclase. The absolute configuration of paniculide B has been established by an X-ray crystallographic analysis of its bis-*p*-bromobenzoate.

PANAYIOTIS ANASTASIS, ISABEL FREER, CHRISTOPHER GILMORE, HUGH MACKIE, KARL OVERTON, DOUGLAS PICKEN et STEPHEN SWANSON. Can. J. Chem. **62**, 2079 (1984).

En se basant sur des expériences réalisées avec des cultures intactes de *Andrographis paniculata* ainsi qu'avec un système dérivé sans cellules, on a établi que: (1) le γ-bisabolène biosynthétisé possède la configuration *Z*, **6**; (2) l'intermédiaire biosynthétique est un pyrophosphate de farnésyle *trans*-6 (**13**) et non pas *cis*-6 (**15**); (3) le carbone cyclique de la paniculide B (**17**) ainsi que celui du γ-bisabolène (**14**), dérivée de C-2 de la mévalonate, est *anti* par rapport à la chaîne latérale; (4) la mévalonolactone et le pyrophosphate de farnésyle-*trans,trans* sont incorporés dans le γ-bisabolène sans perte d'hydrogène respectivement des positions C-5 et C-1; la cyclisation conduisant au cation bisabolènyle n'implique vraisemblablement pas une isomérisation préliminaire, *trans* en *cis* de la double liaison terminale du farnésol par un mécanisme rédox; (5) si l'on considère ces résultats avec ceux que nous avons obtenus antérieurement, on peut considérer qu'il a été établi que les cultures d'*Andrographis* contiennent deux systèmes indépendants d'enzymes qui sont opérationnels: (*i*) une isomérase *trans,trans* à *cis,trans* du farnésol et (*ii*) une isomérase-cyclase du pyrophosphate du farnésyle *trans,trans*. On a établi la configuration absolue de la paniculide B en se basant sur la diffraction par les rayons-X de son bis-*p*-bromobenzoate.

[Traduit par le journal]

At a notional level, γ-bisabolene (or cations derived from it) are early intermediates in the biosynthesis of a whole range of sesquiterpenoids that manifest remarkable structural variety (1). The stratagems that Nature uses to construct the carbon skeleton of γ-bisabolene therefore merit detailed attention.

The two basic questions to be addressed are: (*i*) is γ-bisabolene formed by cyclisation of 2-*trans*,6-*trans* (*trans,trans*)- **2** or 2-*trans*,6-*cis* (*trans,cis*)-farnesyl pyrophosphate **3**, and (*ii*) how is the terminal *trans* double bond of farnesyl pyrophosphate cyclised to a cyclohexenyl cation?

We have studied both problems using callus cultures of *Andrographis paniculata*. When grown in suspension in presence of oxygen and light, these cultures produce the sesquiterpene lactones, paniculides A **7**, B **8**, and C **9**, which we have described previously (2). The structure of paniculide A has recently been confirmed by total synthesis (3) and that of paniculide B by X-ray analysis (this paper) which also confirms the absolute configuration. A cell-free system obtained from the callus cultures, grown under anaerobic conditions, accumulates γ-bisabolene **6** as well as *trans,trans*-**10** and *cis,trans*-farnesol **11** (5). A plausible biosynthetic relationship between these substances that is fully supported by the sequel is indicated in Scheme 1.

We deal first with the question "Is γ-bisabolene formed by cyclisation of *trans,trans*-**2** or *trans,cis*-farnesyl pyrophosphate **3**?". The question was formulated by Ruzicka in 1962 (6), but had not been subjected to experimental scrutiny prior to our studies (7). In essence, Ruzicka's analysis leads to the conclusion that *Z*-γ-bisabolene **14** could be formed from *cis,trans*-farnesyl pyrophosphate **13** or *E*-γ-bisabolene **16** from *cis,cis*-farnesyl pyrophosphate **15** directly (Scheme 2). Alternatively, a cross-over pathway via bridged cations could lead from **13** to **16** or from **15** to **14**. The *cis*-allylic pyrophosphates (**13** = **4** or **15** = **5**) were tacitly assumed to be the substrates required for cyclisation without any suggestion as to how they might be formed from the (presumably) initially biosynthesised *trans*-allylic pyrophosphates (**2** or **3**) (see below). We decided that a choice between the several alternatives posed by Ruzicka's analysis might be made by devising experiments to answer the following questions: (*i*) in γ-bisabolene, is the ring carbon atom derived from C-2 of mevalonate **12** *anti* (as **14**) or *syn* (as **16**) to the side chain; (*ii*) is natural γ-bisabolene the *Z*-**14** or *E*-isomer **16**; (*iii*) is *cis,trans*-**13** or *cis,cis*-farnesyl pyrophosphate **15** the intermediate to γ-bisabolene?

An answer to question (*i*) can in principle be obtained by examining the ^{13}C nmr spectrum of γ-bisabolene (**14** or **16**)

produced by incubating [2-^{13}C]mevalonate with the cell-free system from *Andrographis* cultures. It would be difficult to make a distinction between the alternative labelling patterns as in **14** or **16** ^{13}C nmr. If, however, one assumes the reasonable direct biosynthetic relationship between **14** and **17** on the one hand and between **16** and **18** on the other, then the experimental problem is immediately simplified, since a distinction in the ^{13}C nmr spectrum between C-9 and C-11 in paniculide B (**17** or **18**) is vastly simpler than it is in γ-bisabolene. The experiment was further simplified by using not [2-^{13}C]mevalonate but [1,2-$^{13}C_2$]acetate as the labelled precursor. It is well known (8) that carbon atoms derived from C-2 of mevalonate will then appear as enriched singlets, whereas those derived from C-3, C-3′, C-4, and C-5 of mevalonate appear as triplets (natural abundance singlet + doublet from vicinally doubly labelled molecules). The natural abundance ^{13}C nmr spectrum of paniculide B **8** was assigned from chemical shift data and off-resonance decoupling experiments and by examining the spectrum of paniculide B enriched from [1-^{13}C]acetate. Table 1 and Fig. 1 record the ^{13}C nmr spectrum of paniculide B enriched from [1,2-$^{13}C_2$]acetate. It is immediately evident that the signals corresponding to C-1, C-5, and *C-9* (deriving from C-2 of mevalonate) are *singlets*, but that the signal for *C-11* is a triplet. *It follows that in paniculide B (as 17) and therefore probably*

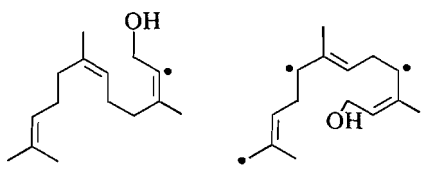
*also in γ-bisabolene (as **14**) the ring carbon atom derived from C-2 of mevalonic acid is* anti *to the side chain.*

(*ii*) The conclusion in (*i*) above implies, on the simplest basis, that natural γ-bisabolene is the *Z*-**14** rather than the *E*-isomer **16**. However, the point had not at the time been established for any sample of γ-bisabolene of natural provenance and therefore required experimental support. This was obtained in the following way. *Z*- and *E*-γ-bisabolenes had recently been synthesised (9) and their configurations established by X-ray analysis (9) of an intermediate in the synthesis. γ-Bisabolene, biosynthesised from [2-^{14}C]mevalonate by the *Andrographis* cell-free system, was purified by preparative tlc after adding carrier and then co-injected with the synthetic *Z*/*E*-γ-bisabolene mixture (kindly made available by Dr. D.J. Faulkner, La Jolla) on a gas–liquid chromatograph equipped with radioactivity detector (see Experimental). Radioactivity appeared in the peak corresponding to *Z*-γ-bisabolene **14** (*I* = 1500) but not in that corresponding to *E*-γ-bisabolene **16** (*I* = 1515). *Natural γ-bisabolene biosynthesised by* Andrographis *cultures is therefore the Z-isomer **14**.* It is interesting to note that Faulkner and co-workers (9) subsequently identified γ-bisabolene from plant sources (Oil of Myrrh and Oil of Lime) as the Z-isomer, but a sample from a species of seaweed (Laurencia) as the *E*-isomer.

(*iii*) A decision as to whether *cis,trans*-**13** or *cis,cis*-farnesyl pyrophosphate **15** is the intermediate was reached as follows: [2-^{14}C]*cis,cis*-farnesol **19** was prepared by lithium aluminium hydride reduction of the Wittig reaction product from neryl acetone with ^{14}C-labelled diethylmethoxycarbonyl methylphosphonate, itself prepared by Michaelis–Arbuzov reaction



19 **20**

of triethyl phosphite with methyl [2-^{14}C]bromoacetate (10). [4,8,12-$^{14}C_3$]*cis,trans*-farnesol **20** was prepared biosynthetically from [2-^{14}C]mevalonate, using the cell-free system from *Andrographis* cultures (5*a*). Each of the labelled farnesols[2] was incubated with the *Andrographis* cell-free system and the bisabolene fractions isolated by preparative tlc after addition of carrier. Each was converted into crystalline trihydrochloride and crystallised to constant activity. Incorporation from [2-^{14}C]*cis,cis*-farnesol was 0.02%, while from [4,8,12-$^{14}C_3$]*cis,trans*-farnesol it was 1.2%. *Thus,* cis,trans- *and not* cis,cis-*farnesyl pyrophosphate is the intermediate to Z-γ-bisabolene biosynthesised by* Andrographis *cultures.*

We now turn to the second question: "How is the terminal *trans* double bond of farnesyl pyrophosphate cyclised to a cyclohexenyl cation?" (11). As noted above, the point was glossed over in Ruzicka's analysis of the possible modes of formation of γ-bisabolenes from farnesyl pyrophosphates. Yet the problem posed by this particular cyclisation is a general one that arises in the formation of six-membered rings from allylic pyrophosphates throughout terpene biosynthesis: a terminal *cis* double bond is required in the acyclic precursor to avoid formation of a *trans*-cyclohexene. Cane has provided a penetrating discussion of the problem (12, see also ref. 1*c*), which has three possible solutions: (*i*) condensation of geranyl- and isopentenyl-pyrophosphate to form *cis,trans*-farnesol directly; (*ii*) isomerisation of initially formed *trans,trans*-farnesol to *cis,trans*-farnesol by a redox mechanism; (*iii*) isomerisation of *trans,trans*- to *cis,trans*-farnesyl pyrophosphate via nerolidyl pyrophosphate.

We had previously found that the cell-free system from *Andrographis* cultures formed *trans,trans*- and *cis,trans*-farnesols with total loss of tritium from (3*RS*)-[2-^{14}C, (4*S*)-$^3H_1$]mevalonate and total retention from the (4*R*)-isomer (5*a*). At the time this strongly suggested to us that *cis,trans*-farnesyl pyrophosphate was not formed directly. This supposition indeed turns out to be correct, as demonstrated by the experiments reported below. Recent reports (13) of *Z*-double bond formation in plant polyprenols with loss of the (4*S*)-hydrogen of mevalonate would have made the prediction less secure. We had also found previously (5*a*) that the *Andrographis* cell-free preparation contains a redox system that isomerises *trans,trans*- to *cis,trans*-farnesol with loss of 1-H_{si} and *cis,trans*- to *trans,trans*-farnesol with loss of 1-H_{re}. It was tempting to suppose that this same enzyme mediates the required *trans,trans*- to *cis,trans*-farnesol isomerisation in preparation for cyclisation to γ-bisabolene. However, it should be noted that intervention of such a redox system requires pyrophosphate hydrolysis and rephosphorylation prior to cyclisation, an uneconomical diversion of the metabolic pathway that turns out to be unnecessary. In any event, a clear experimental distinction is available between, on the one hand, *trans,cis*-isomerisation at the alcochol level and, on the other, *trans,cis*-isomerisation via nerolidyl pyrophosphate **24**: *the*

[2]The cell-free system evidently contains the necessary phosphokinases to transform the free alcohols into their pyrophosphates, since the evidence reported below clearly indicates that pyrophosphate rather than free alcohol is cyclised to γ-bisabolene.

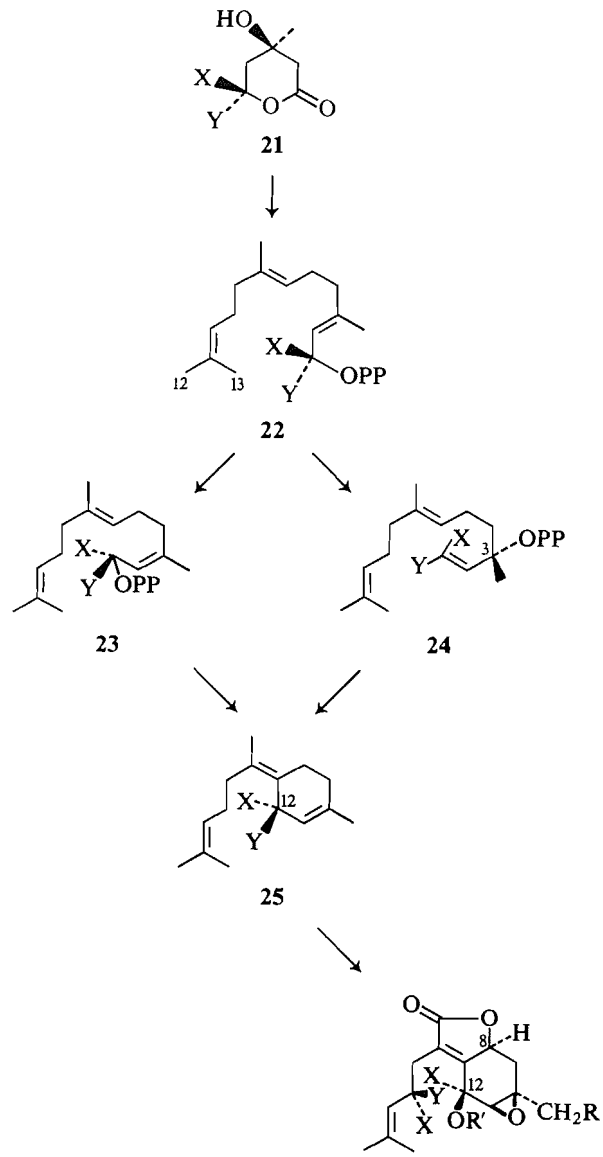
former must result in loss of one hydrogen from C-1 of farnesol; the latter does not.

Accordingly, *trans,trans*-[1-$^3H_2$, 12,13-$^{14}C_2$]farnesyl pyrophosphate (14) (**22**; X = Y = ^3H; $^3H/^{14}C$ of diphenyl urethane crystallised to constant activity 3.26 ± 0.07) was incubated with the 75 000 g supernatant from *Andrographis* cultures. Labelled γ-bisabolene was recovered after addition of carrier, separated by preparative tlc, converted to trihydrochloride, and crystallised to constant isotopic ratio ($^3H/^{14}C$ 3.44 ± 0.28). The total retention of tritium label here observed parallels recent results concerning the in vivo formation of trichodiene from *trans,trans*-[1-$^3H_2$, 12,13-$^{14}C_2$]farnesyl pyrophosphate by a cell-free preparation from *Trichothecium roseum* (14) and of coccinol from [5-$^3H_2$, 2-^{14}C]mevalonate by whole cells of *Fusidium coccineum* (15). In both cases the initial cyclisation of *trans,trans*-farnesyl pyrophosphate to the γ-bisabolenyl cation occurs with complete retention of the tritium label. Analogous results in the monoterpene series have recently been reported by Croteau and co-workers (16, 17).

The incorporation of *both* C-1 hydrogen atoms of *trans,trans*-farnesyl pyrophosphate into γ-bisabolene is at variance with our previous findings (5*b*, 7) that one-sixth of the tritium activity was apparently lost when the same cell-free system converted [5-$^3H_2$, 2-^{14}C]mevalonate into γ-bisabolene. These misleading results may be attributable to the low, albeit consistent, counts obtained in these experiments; furthermore, the apparent loss of one in six tritium atoms corresponds to an error of only 2.78% per labelled site. This discrepancy has now been resolved beyond doubt and further insight gained into the detailed mechanism of the cyclisation by the following additional experiments with (5*S*)- and (5*R*)-[5-^{3}H]mevalonates.

A doubly labelled specimen obtained by mixing (3*R*, 5*R*)-[5-^{3}H]- (18) (**21**; X = ^1H, Y = ^3H) and (3*RS*)-[2-^{14}C]mevalonolactones ($^3H/^{14}C$ for the recrystallised diphenylmethylamides 1.05 ± 0.02) was incubated as the potassium salt with the cell-free system. The γ-bisabolene (incorporation 0.1%), recovered as before, had (as the crystalline trihydrochloride) a $^3H/^{14}C$ ratio of 2.09 ± 0.03 (only (3*R*)-mevalonate metabolised), corresponding to 99.7% tritium retention. Similar incubation of (3*R*,5*S*)-[5-^{3}H]- (19) (**21**; X = ^3H, Y = ^1H) + (3*RS*)-[2-^{14}C]mevalonates ($^3H/^{14}C$ 7.01) gave recovered γ-bisabolene (incoporation 0.18%) whose trihydrochloride had a constant $^3H/^{14}C$ ratio of 13.49, corresponding to 96.3% retention of tritium. *Clearly, then, both hydrogens at C-5 of mevalonate, which become the C-1 hydrogens of farnesol, are retained on incorporation into γ-bisabolene. trans,cis*-Isomerisation of the terminal double bond in farnesol cannot, therefore, involve a redox system at the alcohol level and so most probably proceeds at the pyrophosphate level via the tertiary nerolidyl pyrophosphate **24**, by a mechanism previously discussed by Arigoni and others (20). Whether such a mechanism operates here can be further checked by establishing the configuration of the hydrogens at C-12 in γ-bisabolene **25**. Again, this is more easily done in practice by examining the stereochemistry at C-12 of the derived paniculides A **26**, B **27**, and C **28**. Thus, the specimen of (3*R*,5*S*)-[5-^{3}H]- (**21**; X = ^3H, Y = ^1H) + (3*RS*)-[2-^{14}C]mevalonates above was incubated with callus tissue, grown in suspension for 21 days after transfer from solid medium, and the paniculides A, B, and C were harvested after six days, purified by preparative tlc, and crystallised to constant isotopic ratio (for paniculides A and B). Obtained in this way, paniculide A (**26**; X = ^3H, Y = ^1H) had a $^3H/^{14}C$ atomic ratio of 1.92^3:3, paniculide B (**27**; X = ^3H, Y = ^1H) had a ratio of 1.16^3:3, and paniculide C (**28**; X = ^3H, Y = ^1H) had a ratio 0.93^3:3. Oxidation of the biosynthesised paniculide B wth manganese dioxide afforded paniculide C ($^3H/^{14}C$ atomic ratio 1.01^3:3). The shortfall of tritium label in paniculide B ($^3H/^{14}C$ 1.16^3:3 instead of 2:3) is unexplained, but consistent. Thus, with [5-$^3H_2$, 2-^{14}C]mevalonate as precursor, the biosynthesised paniculide B (**27**; X = Y = ^3H) had $^3H/^{14}C$ 2.38:^{3}:3 (instead of 3:3) and the paniculide C (**28**; X = Y = ^3H) obtained from it with MnO_2 had $^3H/^{14}C$ 2.06^3:3.



26 R = R′ = H
27 R = OH; R′ = H
28 R = OH; 12-one
29 R = $OCOC_6H_4Br$; R′ = COC_6H_4Br
30 R = $OCOC_6H_4Br$; R′ = H

SCHEME 3

As illustrated in Scheme 3, (3*R*,5*S*)-[5-^{3}H]mevalonate (**21**; X = ^3H, Y = ^1H)[4] will lead (21) to *trans,trans*-(1*S*)-[1,5,9-$^3H_3$]farnesyl pyrophosphate (**22**; X = ^3H, Y = ^1H).[4]

[3] Both hydrogens at C-8 of γ-bisabolene are apparently lost on lactone formation.

[4] Only the isotopic labels relevant to the discussion are shown in Scheme 3.

This will isomerise, without hydrogen loss, to *cis,trans*-(1*R*)-[1,5,9-$^3H_3$]farnesyl pyrophosphate (**23**; X = ^{3}H, Y = ^{1}H).[4] Epimerisation at C-1 is a predictable consequence of the isomerisation mechanism (20*a*).

Cyclisation with inversion at C-1 then affords (12*S*)-[4,8,12-$^3H_3$]-γ-bisabolene (**25**; X = ^{3}H, Y = ^{1}H).[4] Alternatively, the nerolidyl pyrophosphate (**24**; X = ^{3}H, Y = ^{1}H)[4] (or its C-3 epimer with ^{3}H and ^{1}H interchanged), which is an intermediate in the above *cis,trans*-isomersation, cyclises by an *anti*-S_N1' process to the *same* (12*S*)-[4,8,12-$^3H_3$]-γ-bisabolene (**25**; X = ^{3}H, Y = ^{1}H).[4] There are indeed several recorded examples of the in vivo formation of six-membered rings by (formal) *anti*-S_N1' displacement of allylic pyrophosphates by a suitably located double bond (12). The distinction made above between S_N displacement of the primary pyrophosphate **23** and S_N1' displacement of the tertiary pyrophosphate **24** is convenient as a heuristic device but probably not meaningful, since the biosynthetic intermediate will approximate to the delocalised ion pair accessible from **22**, **23**, or **24**. In this connection it is relevant to recall that in our earlier experiments [4,8,12-$^{14}C_3$]*cis,trans*-farnesol **20** was efficiently (1.2%) incorporated into γ-bisabolene.

Hydroxylation at C-12 of the γ-bisabolene (**25**; X = ^{3}H, Y = ^{1}H) should lead, with expected retention (22), to paniculides A (**26**; X = ^{3}H, Y = ^{1}H) and B (**27**; X = ^{3}H, Y = ^{1}H), having the (12*S*)-configuration as shown, and in which tritium is retained. Tritium was indeed retained (see above) and the predicted absolute configuration (as **27**) of natural paniculide B, previously inferred (2) from the circular dichroism of the corresponding ketone, has been confirmed by an X-ray structure determination of its bis-*p*-bromobenzoate **29**.

The results of the single-crystal X-ray analysis are summarised in Table 2, which lists the coordinates of the non-hydrogen atoms with their equivalent isotropic temperature factors. Other material has been deposited in the Depository of Unpublished Data.[5] A perspective drawing of the molecule is given in Fig. 2. This analysis was primarily concerned with the establishment of the absolute configuration, and this has been achieved with a confidence level well in excess of 99.5%. The structure itself has, crystallographically, no unusual or unexpected features.

Our experiments demonstrate that the *Andrographis* cell-free system contains two independent enzymes: (*i*) a farnesol *trans,cis*-isomerase that operates by stereospecific hydrogen removal from C-1 in either direction and (*ii*) a *trans,trans*-farnesyl pyrophosphate isomerase-cyclase that transforms its substrate into γ-bisabolene without hydrogen loss from C-1.

TABLE 2. Fractional atomic coordinates and equivalent isotropic temperature factors (Å^2) for the non-hydrogen atoms in paniculide B bis-*p*-bromobenzoate. The equivalent isotropic temperature factor is defined as $(U_{11} + U_{22} + U_{33})/3$. The standard deviations in the last significant digits are in parentheses

Experimental

Radioactivity was determined by liquid scintillation counting in a Philips model PW-4530 liquid-scintillation analyser, with 2,5-diphenyloxazole (5 g/L) and 1,4-bis-(5-phenyloxazol-2-yl)benzene (0.1 g/L) in toluene as scintillant. Counting efficiencies were typically 90% for ^{14}C alone and 75% and 32% respectively for ^{14}C and ^{3}H in experiments using both nuclides. Corrections for counting efficiency and quenching were automatically computed, using a channels-ratio mode of operation with ^{137}Cs as external standard. Chromatograms were scanned for radioactive components using a Panax thin layer scanner RTLS 1A. Radiogas–liquid chromatography was performed on a Pye 104/Panax Radiogas detector system operated in either the ^{14}C only or ^{3}H mode. Counting efficiencies were ~40% for ^{3}H and 90% for ^{14}C. Analytical glc was performed on a Perkin–Elmer F11 gas chromatograph with a flame ionisation detector using nitrogen as carrier gas.

The ^{1}H nmr spectra were recorded at 60 MHz on a Varian spectrometer. The ^{13}C nmr spectra were obtained on a Varian XL 100 spectrometer at 25.2 MHz operated in the Fourier transform mode using deuterium internal lock. All chemical shifts are reported as parts per million downfield of internal tetramethylsilane reference. Mass spectra were recorded on EMI MS 12 spectrometer. High speed centrifugation was carried out in a MSE High Speed 25 centrifuge.

Culture techniques

Procedures for establishing and maintaining stock cultures of *A. paniculata* have been described (23). Hypocotyl isolates were grown as callus cultures on a modified White's medium (24), solidified with 0.7% agar (Oxoid No. 3) and containing Fe-EDTA as the iron source. Callus cultures were grown on agar for 21 days after subculture and then inoculated into liquid medium (composition as solid medium

[5] The structure factor table, a table of hydrogen atom coordinates, a table of anisotropic thermal parameters, a table of bond lengths and angles, and a table of torsion angles are available from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

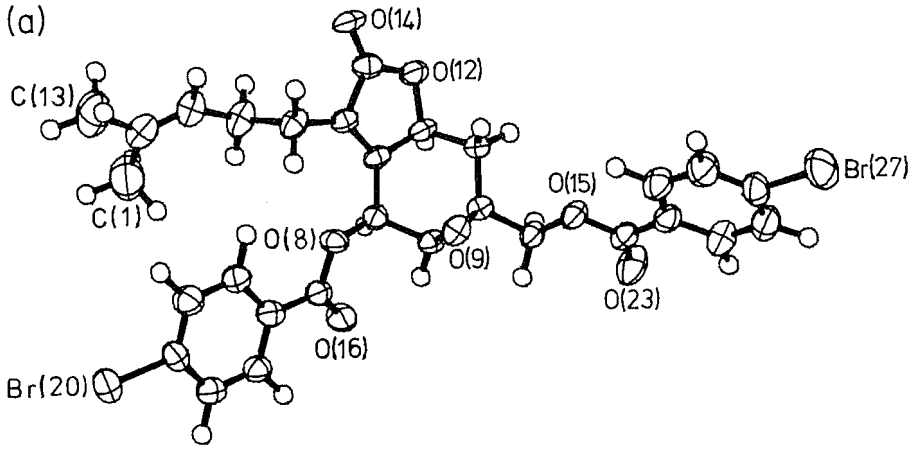

FIG. 2. (a) A perspective view of paniculide B bis-*p*-bromobenzoate. The ellipsoids are 50% ellipsoids; the hydrogen atoms have been drawn with an arbitary radius of 0.15 Å. For clarity, only the Br, O, and terminal methyl atoms have been labelled.

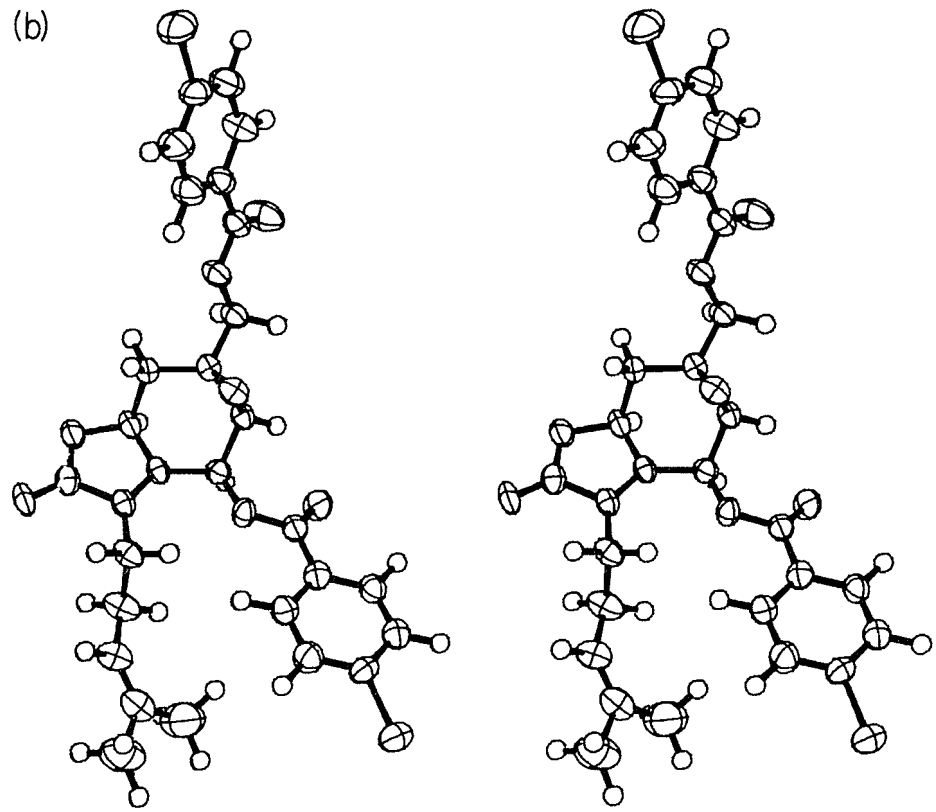

FIG. 2. (b) A stereo view of paniculide B bis-*p*-bromobenzoate. The ellipsoids are 50% ellipsoids; the hydrogen atoms have been given an arbitary radius of 0.15 Å.

without agar; 0.5 g fresh callus/100 mL medium) contained in 250-mL modified Erlenmeyer flasks having four vertical glass ridges running up the inside of each flask to aid agitation. Flasks were kept on a horizontal rotary shaker (140 rev/min) for 21 days at 25 ± 1°C with illumination (approx. 3200 lx).

Preparation of cell-free extracts

Hypocotyl tissues that had grown in suspension culture for 21 days were collected by filtration and homogenized in a precooled tissue homogenizer (Kontes Glass Co., Vineland, N.J., U.S.A.) for 2 min at 0°C in sodium phosphate buffer (0.1 *M*, pH 7.6; 1 mL buffer per g of fresh cells) containing sucrose (0.35 *M*), GSH (5 m*M*), nicotinamide (5 m*M*), and soluble polyvinylpyrrolidone (mol. wt. 24 500; 1%, w/v). The homogenate was centrifuged at 75 000 g/min for 1 h at 4°C and the supernatant used direct for incubation.

Biosynthesis of paniculide B ***17*** *from [1,2-$^{13}C_2$]acetate*

A filter-sterilized solution of [1,2-$^{13}C_2$]acetate (Merck and Co. Inc., Rahway, N.J.; 150.8 mg, 91.7 at.%) was administered to cultures of *A. paniculata* (15 flasks, 2.55 g dry callus tissue), that had been grown in suspension for 21 days following transfer from solid medium. After a further 10 days' growth, the tissue was removed by filtration and the medium was concentrated *in vacuo* at below 40°C to one-quarter its original volume. The concentrate was extracted three times with an equal volume of ethyl acetate. Drying of the combined extracts over anhydrous Na_2SO_4 and solvent removal *in vacuo* afforded a residue from which pure paniculide B (117 mg; mp 145–146°C) was isolated by preparative tlc over silica gel ($CHCl_3$–CH_3OH, 94:6 v/v) and

crystallisation from chloroform. The ^{13}C nmr spectrum of the paniculide B obtained in this experiment is reproduced in Fig. 1. Table 1 records the observed chemical shifts (δ) and coupling constants ($^1J(^{13}C—^{13}C)$).

Biosynthesis of paniculide B from [1-^{13}C]acetate

[1-^{13}C]Acetate (Merck; 149.7 mg, 90.0 at.%) incubated in the same manner and on the same scale afforded paniculide B (86.5 mg; mp 144–146°C). The ^{13}C nmr spectrum of this material showed enhancement (approx. 150%) of the signals corresponding to C-2, C-4, C-6, C-8, C-10, and C-12.

*Incorporation of 3*RS-*[2-^{14}C]mevalonate **12** into γ-bisabolene; comparison of the product with synthetic* Z- *and* E-γ-bisabolene

(3*RS*)-[2-^{14}C]Mevalonic acid lactone (radiochemical Centre, Amersham; 5 μCi, 0.28 μmol) was converted into its K-salt by treating it with KOH–H_2O (1 *M*, 100 μL) at 37°C for 1 h. The solution was neutralized with NaH_2PO_4 (1 *M*, 100 μL) and incubated at 27°C for 16 h with the cell-free system (3 mL) containing NADH (0.5 m*M*), NADPH (0.5 m*M*), ATP (1 m*M*), and NaF (1 m*M*) (final volume 4 mL) in a 15-mL Warburg flask. The flask was evacuated and filled with Ar six times before mixing substrate and medium. The incubation was terminated by adding ice-cold EtOH (8 mL) and the suspension kept at 0°C for 30 min more. Denatured protein was removed by centrifugation (17 000 rpm, 30 min) and the supernatant extracted with hexane (3 × 10 mL). The combined extracts were dried over anhydrous Na_2SO_4, concentrated *in vacuo* to a small volume, carrier bisabolene (200 μg, commerical mixture) added, and the mixture subjected to preparative tlc (Merck Kieselgel G, 20 × 20 cm; ethyl acetate – hexane, 1:3, v/v). Radio scanning showed activity in the bands corresponding to farnesol (R_f 0.23) and γ-bisabolene (R_f 0.8); incorporations were approximately 1.2% and 0.4% respectively.

The γ-bisabolene recovered from the plate with hexane was examined by radio-glc (1% SE 30 at 110°C) on a Pye 104/Panax Radiogas detector system operating in the "^{14}C only" mode. Co-injection of an aliquot of the γ-bisabolene fraction, purified as above, with a mixture of synthetic Z- and E-γ-bisabolene (9) (kindly furnished by Dr. D.J. Faulkner, La Jolla) demonstrated that Z-γ-bisabolene (I = 1500) was labelled but that E-γ-bisabolene (I = 1515) was not.

*Biosynthesis of [4,8,12-$^{14}C_3$]*cis,trans-*farnesol **20***

[4,8,12-$^{14}C_3$]*cis,trans*-Farnesol was biosynthesised from 3*RS*-[2-^{14}C]mevalonate (50 μCi) as the potassium salt, by the cell-free preparation from *Andrographis* callus tissues, by the method previously described (5*a*).

*Synthesis of [2-^{14}C]*cis,cis-*farnesol **19** (ref. 10)*

Nerylacetone (Z-6,10-dimethyl-2-keto-5,9-diene) was obtained from a mixture containing the E- and Z-isomers by preparative glc on 5% SE 30 at 135°C. The Z-isomer has a retention index of 1340, the E-isomer has I = 1380.

Triethylphosphite (15 mg, 0.09 mmol) was heated at 120–130°C for 5 h with [2-^{14}C]methyl bromoacetate (Radiochemical Centre, Amersham; 50 μCi, 12 mg, 0.08 mmol) under an air condenser. Volatile material was then removed by very gentle heating of the resulting [^{14}C]diethylphosphonoacetate *in vacuo*. The residue (15 mg, 0.076 mmol) was dissolved in dry tetrahydrofuran (25 μL) and added slowly to a stirred suspension of sodium hydride (7.3 mg, 50% dispersion, 0.155 mmol) in the same solvent (200 μL) under nitrogen. Stirring was continued at room temperature for a further 45 min before addition of a solution of nerylacetone (14.8 mg, 0.076 mmol) in tetrahydrofuran (25 μL). After stirring for a further two days at room temperature, water (1 mL) was added, and the mixture extracted with ether (3 × 5 mL). The dried solution was then evaporated to ~5 mL and added over a period of 30 min to a stirred suspension of lithium aluminium hydride (7.5 mg, 0.156 mmol) in dry ether (1 mL) at 0°C. The reaction mixture was stirred 30 min more and then saturated aqueous NH_4Cl solution (5 mL) was cautiously added, followed by water (10 mL). The organic layer was separated, and the aqueous layer extracted with ether (3 × 5 mL). Farnesol was purified by preparative tlc over silica (ethyl acetate – hexane, 1:3, v/v) and *cis,cis*-farnesol was separated from the *trans,cis*-isomer by preparative tlc over silver nitrate – silica (ethyl acetate – acetic acid, 499:1, v/v). Analytical glc on 1% SE 30 at 150°C showed that the material was >95% *cis,cis*-isomer. The radiochemical yield of [2-^{14}C]*cis,cis*-farnesol **19** was 9%.

*Incorporation of [4,8,12-$^{14}C_3$]*cis,trans-*farnesol **20** and [2-^{14}C]-*cis,cis-*farnesol **19** into γ-bisabolene by Andrographis cell-free system*

[4,8,12-$^{14}C_3$]*cis,trans*-Farnesol (6.2 × 10^5 dpm), prepared as above from 3*RS*-[2-^{14}C]mevalonate by the *Andrographis* cell-free system, was ultrasonically dispersed in 0.2 mL sodium phosphate buffer (0.1 *M*, pH 7.6) with Tween 80 (1 mg). The suspension was incubated anaerobically overnight with the cell-free system and added co-factors and then worked up as previously described. Carrier γ-bisabolene (1 mg, commercial material) was added before preparative tlc. The radioactive γ-bisabolene which was isolated was dissolved in dry ether (2 mL) and the crystalline trihydrochloride derivative was prepared by passing dry hydrogen chloride gas through the solution for 15 min at 0°C. The solution was then allowed to stand at room temperature overnight before addition of carrier bisabolene trihydrochloride (6 mg). The ether was then evaporated and the solid residue was recrystallised from a small quantity of methanol. After five recrystallisations, the specific acitivity was constant at 1062 dpm/mg. This represents an incorporation of 1.2%.

In a parallel experiment, [2-^{14}C]*cis,cis*-farnesol (7.7 × 10^5 dpm), prepared as above, was incubated with the cell-free system under identical conditions. After the second recrystallisation, the bisabolene trihydrochloride obtained in the experiment was found to have a very low level of ^{14}C activity, representing an incorporation of 0.02%.

Incorporation of trans,trans*[1-$^3H_2$, 12,13-$^{14}C_2$]farnesyl pyrophosphate (**22**; X = Y = ^3H) into γ-bisabolene*

trans,trans--[1-$^3H_2$, 12,13-$^{14}C_2$]Farnesyl pyrophosphate (14*a*, *b*) (2.63 μmol, 2.43 μCi, ^{14}C μmol^{-1}; $^3H/^{14}C$ of diphenyl urethane crystallised to constant activity 3.26 ± 0.07, atomic ratio 2:2) was incubated with the 75 000 g supernatant (3 mL; 7.5 mg protein) from *Andrographis* cultures. The incubation was terminated after 17 h by adding ethanol and then kept at 0°C for 30 min. The denatured protein was removed by centrifugation and the supernatant extracted with hexane (3 × 10 mL). Labelled γ-bisabolene was recovered from the extract after adding carrier bisabolene (9 mg, regenerated from the trihydrochloride, mp 78–79°C, with Li_2CO_3–LiBr in DMF at 100°C; 2 major peaks (after HCl/MeOH–$CHCl_3$ treatment at 20°C) ratio 3:2 on OV-1 at 100°C) by preparative tlc (ethyl acetate – hexane, 1:3, R_f 0.8, incorporation 0.23%) and converted into the trihydrochloride (dissolution in dry ether, HCl gas for 1 h at 0°C). This was mixed with carrier (18 mg, mp 78–80°C) and crystallised (3×) from methanol to constant isotopic ratio ($^3H/^{14}C$ 3.44 ± 0.28). The crystalline hydrochloride (mp 78–80°C) from the combined mother liquors had $^3H/^{14}C$ 3.61 ± 0.10.

*Incorporation of (3*R,5R*)-[5-^3H]- (ref. 18) + (3*RS*)-[2-^{14}C]-mevalonolactones into γ-bisabolene*

The compounds in the title were mixed ($^3H/^{14}C$ 1.08 ± 0.02; atomic ratio 1:1) and a portion was converted into the diphenylmethylamide (4), which after three crystallisations from benzene–hexane had mp 98–99°C, $^3H/^{14}C$ 1.05 ± 0.02. The doubly labelled lactone (3 μCi ^{14}C) was converted to the K-salt and then incubated with the cell-free system (4 mL) and added co-factors and the γ-bisabolene recovered (incorporation 0.1%), derivatised, and the trihydrochloride crystallised to constant ratio as above: $^3H/^{14}C$ 2.09 ± 0.03 (only (3*R*)-mevalonolactone metabolised); atomic ratio 2.99:3, corresponding to 99.7% retention of tritium label.

*Incorporation of (3*R,5S*)-[5-^3H]- (ref. 19) + (3*RS*)-[2-^{14}C]-mevalonolactones into γ-bisabolene and paniculides*

The mixture of (3*R*,5*S*)-[5-^3H]- + (3*RS*)-[2-^{14}C]mevalonate (K-salts; 0.6 μCi ^{14}C, $^3H/^{14}C$ 7.01; atomic ratio 1:1) was divided into two equal portions. One was incubated with the cell-free system as for the (3*R*,5*R*)-isomer above. The recovered γ-bisabolene (incorporation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

0.18%) afforded the trihydrochloride of constant isotope ratio $^3H/^{14}C$ 13.49, atomic ratio 2.89:3, corresponding to 96.3% retention of the tritium label.

The other portion was incubated with callus tissue (dry weight 5.0 g) grown in suspension for 21 days following transfer from solid agar, and the paniculides A **26**, B **27**, and C **28** were harvested after 6 days by solvent extraction and purified by preparative tlc (5% MeOH–$CHCl_3$) (see above). Crystallisation to constant isotopic ratio afforded paniculide A **26**, mp 118–120°C, $^3H/^{14}C$ 1.92:3, incorporation of ^{14}C 0.05%; paniculide B **27**, mp 146–148°C, $^3H/^{14}C$ 1.16:3, incorporation of ^{14}C 2.26%; paniculide C **28** (oil), purified by preparative tlc (5% MeOH–$CHCl_3$) $^3H/^{14}C$ 0.93:3, incorporation of ^{14}C 0.15%. Oxidation of one half of the above paniculide B with MnO_2 in benzene afforded the oily paniculide C which, after purification by preparative tlc, had ^1H nmr and mass spectra identical with those of the natural material, and $^3H/^{14}C$ 1.01:3.

*Formation of the mono- **30** and bis-*p*-bromobenzoate **29** of paniculide B*

To paniculide B (200 mg; 0.71 mmol) dissolved in dry THF (20 mL) containing 4-dimethylaminopyridine (2 crystals) was added *p*-bromobenzoylchloride (250 mg; 1.14 mmol) and then dry triethylamine (1 mL) under Ar. The resulting cloudy solution was heated under reflux for 2 h, cooled, poured into ice-water (200 mL), and extracted with ethyl acetate (3 × 25 mL). Evaporation of the washed and dried ($MgSO_4$) organic extracts afforded a solid residue (365 mg) consisting of two major compounds (tlc). Chromatography over silica gel (ethyl acetate – chloroform mixtures, 4:1 to 1:1) afforded first the *bis*-p-*bromobenzoate* **29**, 120 mg, mp 142–143°C (from chloroform – light petroleum); ir ν_{max} (KBr disc): 1760, 1727, 1694, 1591 and 1485 cm^{-1}; nmr δ ($CDCl_3$): 1.43 and 1.58 (3H, each, br s's), 1.75–2.55 (4H, m), 2.87 (2H, dd, J = 17, 9 Hz), 3.65 (1H, d, J = 3 Hz), 4.42 (2H, q, J = 22 Hz), 4.88 (2H, m), 6.52 (1H, br s), 7.52–8.12 (8H, m). *Anal.* calcd. for $C_{29}H_{26}Br_2O_7$: C 53.9, H 4.0, Br 24.75%; found: C 53.6, H 4.05, Br 24.6; and then the *mono*-p-*bromobenzoate* **30** 122 mg, mp 178–180°C (from ethyl acetate – hexane); ir ν_{max} (KBr disc): 3500, 1763, 1730, 1705, 1590 and 1485 cm^{-1}; nmr δ ($CHCl_3$): 1.57 and 1.73 (3H each, br s's), 1.80–2.63 (5H, m), 2.80 (2H, dd, J = 18, 9 Hz), 3.52 (1H, d, J = 3 Hz), 4.38 (2H, q), 4.60–5.35 (3H, m), 7.56, and 7.87 (4H). *Anal.* calcd. for $C_{22}H_{23}O_6Br$: C 57.0, H 4.95, Br 17.25%; M^+ 462.0672; found: C 57.0, H 4.7, Br 17.2; M^+ 462.0687.

X-ray crystallography studies

A crystal ca. 0.13 × 0.25 × 0.54 mm was used. Unit cell parameters were determined from 25 reflections having θ > 12° mounted on an Enraf–Nonius CAD-4 diffractometer with MoKα radiation (λ = 0.71069 Å). Crystal data are:

$C_{29}H_{26}Br_2O_7$ fw = 646.3

Monoclinic, $P2_1$, a = 14.326(6), b = 4.826(2), c = 19.974(9) Å, β = 102.27(3)°, V = 1349.4 $Å^3$, ρ_c = 1.59 g cm^{-3}, Z = 2, $F(000)$ = 652, μ(MoKα) = 29.94 cm^{-1}. Data collection was carried out at room temperature (16 ± 3°C). An ω–2θ scan was used with an ω scan width of 0.66 ± 0.3 tan θ degrees in ω and a maximum ω scan speed of 10° min^{-1}. The maximum scan time was 180 s with the background counted for one quarter of the scan time at each end of the scan. Two standard reflections were measured every 2 h, and the orientation checked every 200 measured reflections. Only minor variations were noted. The quadrant having h 0–17, k 0–5, and l −24–24 was measured with a θ limit of 26 degrees. Of the 3285 reflections measured, 2101 had $I > 2.0\sigma(I)$ and were classified as observed. The data were corrected for absorption via an analytical method. The maximum and minimum transmission factors were 0.65 and 0.30 respectively.

The structure was solved by direct methods (25) and completed via weighted Fourier methods. The hydrogen atoms were included in their calculated positions; the orientation of hydrogen atoms on the terminal methyl atoms was derived from peaks on a difference electron density map. The hydrogen atoms were given a single, overall isotropic temperature factor; all other atoms had individual anisotropic thermal parameters. The scattering factors from the International Tables for X-ray Crystallography were used (26). The function minimised was $\Sigma\omega\Delta^2$ where $\omega = (\sigma^2|F_o| + 0.0008|F_o|^2)^{-1}$. Refinement converged at R = 0.041, R_w = 0.044.

At this point anomalous scattering factors were introduced for the first time, and a structure factor calculation performed, without scale factor refinement, for each enantiomeric form of the molecule. The weighted R-factors were 0.0522 and 0.0552 respectively, giving an R-factor ratio of 1.057 (27), thus establishing the preferred enantiomer with a confidence level in excess of 99.5%. The final R factor was 0.039 (R_w = 0.042). The corresponding factors for the enantiomer were 0.044 and 0.047. The final difference map had no features larger than 0.58 e $Å^{-3}$. The maximum parameter shifts in the final cycle of refinement were 0.3σ. Full-matrix refinement was used throughout the analysis.

Dihydrothiophenes.10. The preparation and Diels–Alder reactions of some sulfur and phosphorus-substituted dienophiles and 2-aza-substituted 1,3-dienes[1]

JOHN M. MCINTOSH AND LILIANNA Z. PILLON
Department of Chemistry, University of Windsor, Windsor, Ont., Canada, N9B 3P4

Received January 6, 1984

JOHN M. MCINTOSH and LILIANNA Z. PILLON. Can. J. Chem. **62**, 2089 (1984).

The use of 3-carboxylated 2,5-dihydrothiophenes as the dienophilic component of the Diels–Alder reaction has been investigated. The yields are generally quite low. The formation of conjugated dienes that are aminated at an interior position of the conjugated chain by formation and thermal decomposition of 3-acetamido-2,5-dihydrothiophenes appears to be a viable route to these useful compounds. One example of the Diels–Alder reaction of 2-carboxylated diethyl vinylphosphonates is reported.

JOHN M. MCINTOSH et LILIANNA Z. PILLON. Can. J. Chem. **62**, 2089 (1984).

On a évalué les possibilités d'utiliser les dihydro-2,5 thiophènes portant des groupes carboxyliques en position 3 comme dièns dans des réactions de Diels–Alder. Les rendements sont généralement assez bas. Il semble que la formation de dièns conjugués et aminés sur une position intérieure de la chaîne conjugée par la formation et par la décomposition thermique d'acétamido-3 dihydro-2,5 thiophènes est une route viable pour obtenir ces composés utiles. On rapporte un exemple de réaction de Diels–Alder de diéthyl vinyl phosphonates carboxylés en position 2.

[Traduit par le journal]

In recent years, we have developed a remarkably facile approach to the preparation of 2,5-dihydrothiophenes and noted their use as sources of regiospecifically generated conjugated dienes and other useful derivatives (1). In this report we draw attention to the use of certain of these compounds as sources of the dienophilic component of the Diels–Alder reaction and to the preparation and use of some interesting nitrogen-substituted dienes and one unusual phosphorus-substituted dienophile.

The possibility of using the same molecular type as the source of either the diene or dienophilic component of the Diels–Alder reaction is predicated on the different properties of two easily interconverted forms of sulfur (Scheme 1). Compounds **1**, easily assembled from 2-mercaptoaldehydes or ketones and vinyl phosphonium salts (X = H) (1*a*–1*d*) or vinyl phosphonates (X = *E*lectron-*W*ithdrawing *G*roup) (1*e*–1*f*) are oxidized to **2** with peracid in quantitative yield. Mild thermal decomposition of **2** affords dienes in a regiospecific and stereospecific manner. These in turn provide substituted cyclohexenes on reaction with dienophiles. The limitations to the predictability of regio- and stereoselectivity in such processes are well known. On the other hand, **1** (X = EWG) are potential dienophiles. Annelation of a cyclohexene ring via a Diels–Alder reaction followed by desulfurization should provide regiospecifically and stereospecifically substituted cyclohexenes. Such a process was exploited by Stork and Stotter (2) in an intriguing apporach to the *trans*-C/D ring fusion of steroids. Stork's work has appeared only as a communication and no yields were stated. To further expand the knowledge in this area, we have briefly investigated some additional examples of this reaction.

Reaction of **1***a* (R = R′ = H, X = COOMe) (1*e*) or **1***b* (R = H, R′ = Ph, X = COOMe) (1*e*) with either butadiene or isoprene at 180°C led to the formation of the Diels–Alder products in only modest yields (Scheme 1). Attempts to improve the yields and (or) reduce the severity of the reaction conditions by employing catalysis ($AlCl_3$, $SnCl_4$) failed. Extensive polymerization of the diene was the major result of such modifications. While both the gc and the ^1H nmr of **3**–**6** indicated the presence of only one isomer, the ^{13}C nmr of **4** clearly indicated the presence of **4***a* and **4***b* in a 3:2 ratio. Compounds **5** and **6** showed only one set of signals in their ^{13}C nmr spectra. It is clear from these results that, while the approach appears viable, practical application in synthesis must await a significant improvement in yields.

An attractive addition to the use of **1** in synthesis is represented by **8**. Such compounds should lead to dienes and thence to cyclohexenes which possess a regiospecifically-generated enamine-type functionality which, in turn, could be alkylated, reduced, or hydrolyzed. Formation of 1,3-dienamines or dienamides in which the nitrogen atom is at the end of the conjugated chain is straightforward, and such compounds have been used extensively in Diels–Alder reactions by Oppolzer *et al.* (3). However, generation of such systems which possess the nitrogen function at an interior position is a problem fraught with difficulties. Perhaps the most useful method is the thermal rearrangement of trichloroacetimidates pioneered by Overman *et al.* (4). However, even this method affords 2-substituted diene systems only when the 1-substituted isomers cannot form (4*c*). Evidence is available that compounds **8** function efficiently in Diels–Alder reactions with reactive dienophiles (4*a*). In 1979, Field (5) reported the serendipitous formation of two examples of **8** from the cyclization in refluxing acetic anhydride of the condensation products of 2-haloketones and *N*-acetylcysteine (**7**) (Scheme 2). Detailed below are our observations on some of the limitations to Field's method and the efficacy of the conversion of **8** to aminated dienes.

Reaction of 2-chlorocyclohexanone (**9**) or chloroacetone (**15**) with **7** followed by treatment with acetic anhydride afforded **11** (5) and **17** in 52 and 50% yields respectively. The reasons for the incorporation of the extra acetyl unit in **17** is obscure at this time. A minor by-product (**19**) was also isolated from the chloroacetone reaction. Oxidation of **11** and **17** with MCPBA gave **12** and **18** in quantitative yields. Heating these compounds in refluxing toluene in the presence of maleic anhydride, followed by hydrolysis in the case of **12**, gave the products **14** and **20** in 42 and 70% yields, respectively.

When haloketone **21** was alkylated with **7**, **22** was formed. Acetic anhydride treatment of **22** led mainly to decomposition products. From this mixture a compound to which we assign

5 R′ = R″ = H R = Ph (55%)
6 R″ = H R = Ph R′ = Me (29%)

SCHEME 1

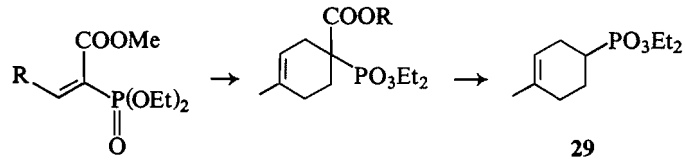
the structure **23** could be isolated. We have been unable to effect the double elimination reaction required to form the desired substitution dihydrothiophene under either acidic or basic conditions.

Inter alia it should be noted that an exactly analogous result was obtained using *N*-acetylhomocysteine (generated *in situ* from the commercially available acetylated thiolactone of homocysteine). In this way **15** or **21** afforded **24** or **26** respectively. Again we have been unable to effect the decarboxylative elimination of **26** and the reason for the formation of the diacetylated derivative **24** is unclear. Oxidation of **24** afforded **25** in 45% overall yield.

It seems apparent from these results and those of Field that, in the absence of steric congestion around the carbonyl group, acceptable yields of 3-acetamido-2,5-dihydrothiophenes can be realized and that sulfone formation and decomposition lead to a viable synthesis of conjugated dienes that are regiospecifically aminated at an interior position.

Several phosphonate-type dienophiles have been used in Diels–Alder reactions (6). The nmr of the crude product from reaction of diethyl vinylphosphonate with isoprene indicated the formation of a mixture of isomeric products in a 4:1 ratio (6*c*). Vinyl phosphonates bearing a 2-carboalkoxy group might be expected to be more reactive dienophiles than their unsubstituted analogs and orientational specificity might also be expected to be more pronounced. Since we had available some of the vinylphosphonates **27**, we decided to examine an example of their Diels–Alder reactions. When **27***a* was treated with isoprene, a product which was homogeneous to all tests used (including ^{13}C nmr) was obtained in 95% yield, to which we assign the structure **28**. Hydrolysis and decarboxylation of **28** gave phosphonate **29**. Unfortunately phosphonate **27***b* could not be induced to undergo Diels–Alder addition with isoprene or butadiene.

It is well known that phosphonates like **29** will not undergo olefination reactions (7). However, the corresponding phosphonamides do (8). Therefore, we made several attempts to prepare the bis(dimethylamide) derivative of **27***a* or **27***b* by



27*a* R = H **28***a* R = Me
27*b* R = Ph **28***b* R = H

29

methods analogous to those used for the preparation of **27**. As of this time, these efforts have been uniformly unsuccessful. However, in the experimental section, we report a simplified preparation of the useful (8) methylphosphonic acid bis(dimethylamide) **30** which avoids the necessity of using gaseous dimethyl amine.

Experimental

Infrared spectra were run on a Beckman IR-12 instrument as neat liquids or in $CHCl_3$ unless otherwise noted. The ^1H nmr spectra were usually run at 60 MHz in $CDCl_3$ solution and ^{13}C nmr spectra were run in the same solvent at 22.64 MHz in the FT mode using a flip angle of 45°. The nmr spectra are reported in ppm relative to TMS as internal standard. Mass spectra were run on a Varian MAT CH-5 DF instrument equipped with electron impact (EI), field ionization (FI), and field desorption (FD) sources. Gas chromatographic analyses were performed using 20% SE-30 on Chromosorb W columns. Preparative tlc was performed using 2 mm thick plates of silica gel GF (Analtech). Solvents were removed at reduced pressure and the drying agent was anhydrous $MgSO_4$. Microanalyses were done by Guelph Microanalytical Laboratories and Canadian Microanalytical Services, Vancouver, B.C.

General procedure for the Diels–Alder reactions of **1**a *and* **1**b

A solution of **1***a* or **1***b* (2 mmol), hydroquinone (0.01 g), and either butadiene or isoprene (20 mmol) in 5 mL of xylene was heated (sealed tube) at 180°C for 20 h. The cooled solution was concentrated and the product was separated from the hydrocarbon polymer using thick layer chromatography (1:9 ether/petroleum ether). The physical data on the products follows. Addition of catalytic amounts of $AlCl_3$ or $SnCl_4$ reduced the yields considerably.

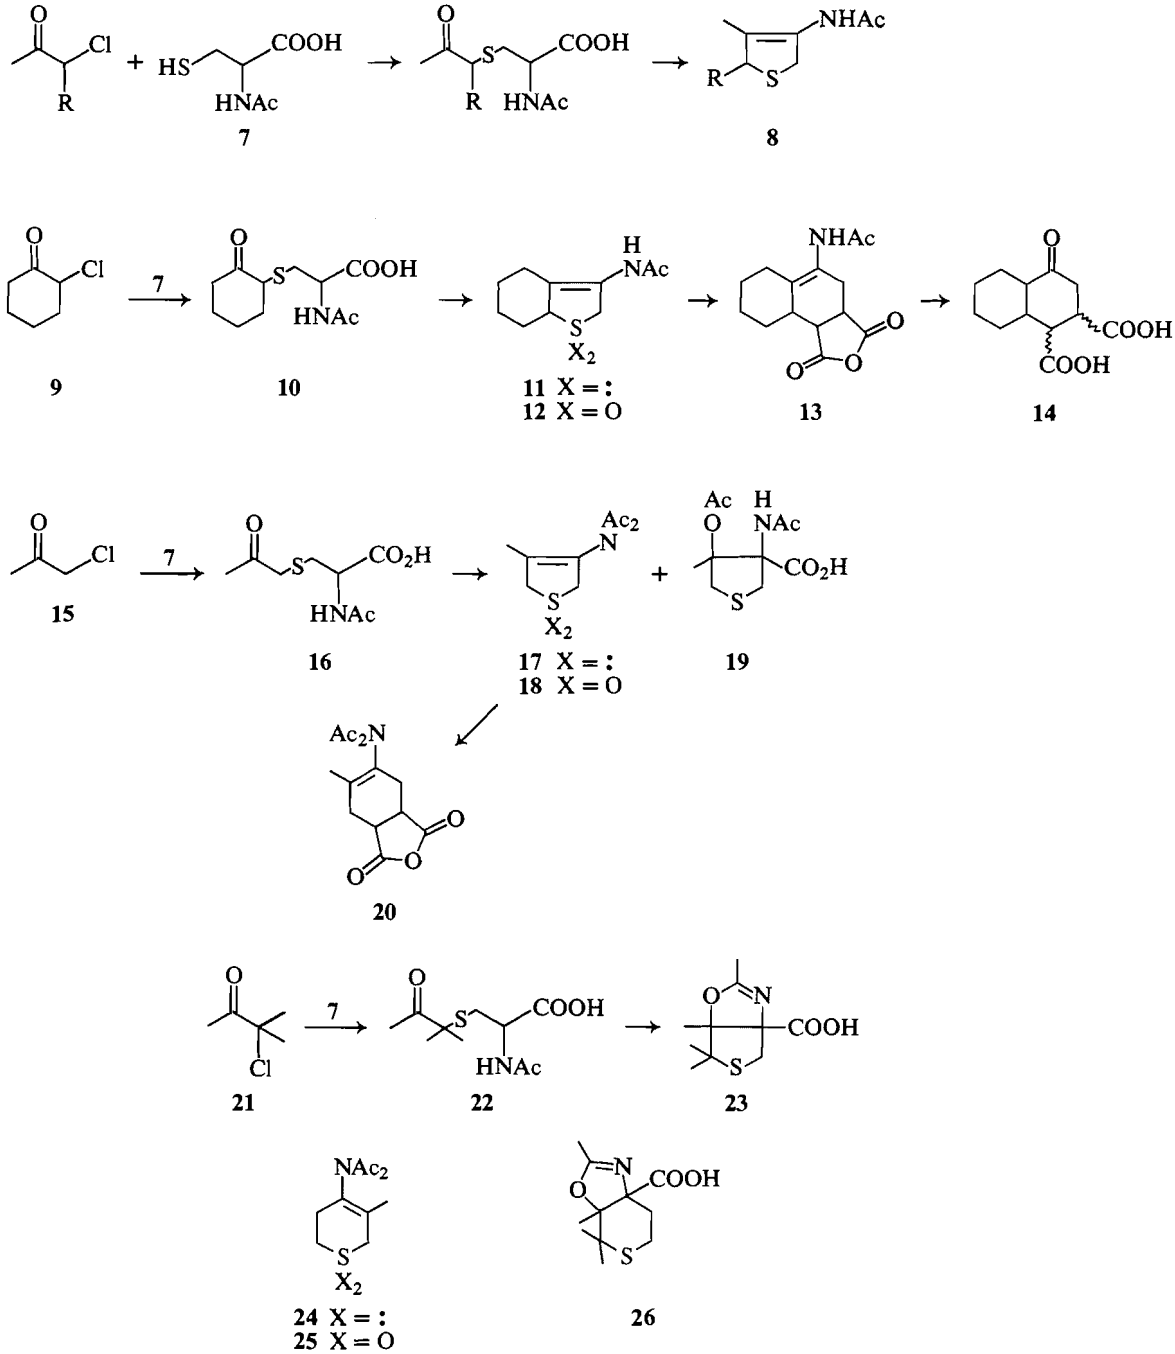

SCHEME 2

Compound 3: colorless oil, 159 mg (38%); ir ($CHCl_3$): 1710, 1640, 1180 cm^{-1}; ^1H nmr: 5.6 (bs, 2H), 3.7 (s, 3H), 3.3–1.95 (m, 9H). *Anal.* calcd. ($C_{10}H_{14}O_2S$): C 60.61, H 7.06; found' C 60.85, H 7.10.

*Compounds 4*a *and 4*b: yellowish oil, 68 mg, (16%); ir ($CHCl_3$): 1730, 1615, 1225 cm^{-1}; ^1H nmr: 5.3 (bs, 1H), 3.75 (s, 3H), 3.35–1.90 (m, 9H), 1.65 (s, 3H): ^{13}C nmr: 175.3, 175.2, 134.8, 131.0, 130.4, 124.2, 53.9, 53.1, 52.1, 42.3, 41.6, 39.5, 39.2, 38.7, 35.2, 32.7, 30.8, 28.6, 26.5, 26.2. *Anal.* calcd. ($C_{11}H_{16}O_2S$): C 62.27, H 7.54; found: C 62.62, H 7.13.

Compound 5: colorless oil, 300 mg (55%); ir ($CHCl_3$): 1720, 1650, 1590, 1520, 1490, 1210 cm^{-1}; ^1H nmr: 7.4 (m, 5H), 5.65 (bs, 2H), 4.31 (s, 1H), 3.65–2.0 (m, 10H); ^{13}C nmr: 172.6, 141.1, 129.1, 127.7, 127.5, 124.9, 123.9, 60.9, 59.2, 51.4, 39.3, 35.1, 30.3, 26.1; *m/z* (FI) = 274 (M^+), 183, 138, 135, 91. *Anal.* calcd. ($C_{16}H_{18}O_2S$): C 70.08, H 6.57; found: C 70.43, H 6.57.

Compound 6: colorless oil, 160 mg (29%); ir ($CHCl_3$): 3020, 1720, 1640, 1595, 1580, 1490, 1200 cm^{-1}; ^1H nmr: 7.3 (m, 5H), 5.20 (bs, 1H), 4.23 (s, 1H), 3.55–1.6 (m, 13H); ^{13}C nmr: 172.7, 141.2, 131.8, 130.1, 129.1, 127.7, 127.5, 60.6, 59.2, 51.4, 39.8, 38.8, 35.2, 30.7, 26.3. *Anal.* calcd. ($C_{17}H_{20}O_2S$): C 70.84, H 6.93; found: C 70.40, H 7.14.

Alkylation of N-*acetylcysteine*

The alkylations of **7** with 2-haloketones were carried out by the method reported by Field (5). The following products were obtained.

N-*acetyl*-S-*(2-oxocyclohexyl)cysteine* ***(10)***, 60%, mp 117–120°C (lit. (5) 124–128°C).

N-*acetyl*-S-*acetonylcysteine* ***(16)***, 68%, yellowish oil; ir (neat): 3600–2600, 1720, 1650, 1565, 1425, 1380, 1250 cm^{-1}; ^1H nmr (DMSO): 8.15 (bd, 1H), 4.40 (nm, 1H), 3.45 (s, 2H), 2.82 (m, 2H), 2.20 (s, 3H), 1.85 (s, 3H); *m/z* (FI) = 219 (M^+), 201, 165, 159.

N-*acetyl*-S-*(1,1-dimethylacetonyl)cysteine* ***(21)***, white crystals

(74%), mp 131–133°C; ir (KBr): 3300–2600, 1715, 1695, 1620, 1545, 1460, 1380, 1260 cm^{-1}; ^1H nmr (DMSO): 8.3 (bd, 1H), 4.32 (m, 1H), 2.52 (m, 2H), 2.20 (s, 3H), 1.85 (s, 3H), 1.35 (s, 6H); ^{13}C nmr (DMSO): 205.3, 171.6, 169.2, 52.2, 51.8, 30.3, 23.9, 23.6, 22.2; *m/z* (FI) = 247 (M^+), 248, 202. *Anal.* calcd. ($C_{10}H_{17}NO_4S$): C 48.59, H 6.87; found: C 48.45, H 6.63.

Alkylations of N-*acetylhomocysteine*

These were carried out in the same way as the alkylations of **7**, except that the solvent was 2-propanol and the starting material was *N*-acetylhomocysteine thiolactone. The following products were obtained.

N-*acetyl*-S-*acetonylhomocysteine* (84%), yellowish oil; ir (neat): 3500–2500, 1710, 1660, 1605, 1555, 1440, 1325, 1300, 1240 cm^{-1}; ^1H nmr (DMSO): 8.05 (bd, 1H), 4.30 (m, 1H), 3.52 (s, 2H), 2.25 (s, 3H), 1.85 (s, 3H), 2.4–1.7 (m, 4H); ^{13}C nmr (DMSO): 203.8, 173.1, 169.4, 58.1, 50.8, 41.3. 30.7, 27.8, 22.2. *Anal.* calcd. ($C_9H_{15}NO_4S$): C 46.36, H 6.43; N 6.00; found: C 46.56, H 6.80, N 6.02.

N-*acetyl*-S-*(1,1-dimethylacetonyl)homocysteine (22)*: 50%, mp 151–152°C (from EtOAc); ir (KBr): 3600–3200, 1710, 1655, 1560, 1450, 1385, 1245 cm^{-1}; ^1H nmr (DMSO): 8.15 (bd, 1H), 4.25 (m, 1H), 2.4–1.55 (m, 4H), 2.25 (s, 3H), 1.80 (s, 3H), 1.35 (s, 3H); ^{13}C nmr (DMSO): 205.5, 173.1, 169.5, 52.4, 51.0, 31.0, 25.3, 24.1, 23.7, 22.4; *m/z* (FI) = 261 (M^+), 218, 156, 143. *Anal.* calcd. ($C_{11}H_{19}NO_4S$): C 50.58, H 7.27; found: C 50.31, H 7.04.

Cyclizations of S-*alkylated cysteine and homocysteine*

The cyclizations were carried out essentially using Field's procedure (5). The following procedure is representative. Compound **22** (1.48 g, 6 mmol) was mixed with 1.3 mL of acetic anhydride and stirred at 130–135°C for 5 h. The cooled mixture was diluted with 5 mL of water which caused **23** to precipitate as a heavy yellow oil which was separated. An analytical sample of **23** was purified using preparative tlc (ether). In this way the following products were isolated.

From **10**, after heating 1 h, amide **11**, yellow solid (52%), mp 135–138°C (lit. (5) 139–144°C) was obtained.

From **16**, after heating for 1 h, was obtained a mixture of a yellow oil and white crystals which were separated by filtration. The filtrate (amide **17**) was not purified but converted directly to sulfone **18** (*vide infra*). The residue gave, after recrystallization from EtOH, acid **19**, white crystals (15%), mp 211–213°C; ir (KBr): 3400–2600, 1760, 1740, 1660, 1570, 1260 cm^{-1}; ^1H nmr (DMSO): 8.05 (s, 1H), 3.6–2.9 (m, 4H), 2.05 (s, 3H), 1.91 (s, 3H), 1.53 (s, 3H); ^{13}C nmr (DMSO): 169.9, 169,6, 169,4, 87,1, 71.4, 36.1, 32.7, 25.5, 21.8, 18.9; *m/z* (FI) = 261 (M^+), 157, 60. *Anal.* calcd. ($C_{10}H_{15}NO_5S$): C 45.99, H 5.74, N 5.36; found: C 45.65, H 5.77, N 5.49.

From **22**, acid **23**, yellow oil (25%); ir ($CHCl_3$): 3600–2700, 2990, 1715, 1465, 1440, 1375, 1270, 1110 cm^{-1}; ^1H nmr ($CDCl_3$): 2.35 (s, 3H), 2.31 (dd, 2H, J = 2, 2 Hz), 1.50 (s, 6H), 1.45 (s, 3H); *m/z* (FI) = 229 (M^+), 227, 185. *Anal.* calcd. ($C_{10}H_{15}NO_3S$): C 52.42, H 6.53; found: C 52.92, H 6.53. Heating **23** with NaH in toluene or with 10% aqueous HCl failed to produce any dihydrothiophene.

From *N*-acetyl-*S*-acetonylhomocysteine, after heating for 1 h, was obtained amide **24**, which was not purified, but oxidized directly to sulfone **25**.

From *N*-acetyl-*S*-(1,1-dimethylacetonyl)homocysteine, after heating for 5 h, acid **26**, yellow oil (35%); ir ($CHCl_3$): 3500–2500, 1720, 1670, 1605, 1575, 1440, 1375, 1270 cm^{-1}; ^1H nmr ($CDCl_3$): 2.65–2.05 (m, 4H), 2.35 (s, 3H), 2.30 (s, 3H), 1.45 (s, 6H); *m/z* (FI) = 243 (M^+), 199, 185, 159. *Anal.* calcd. $C_{11}H_{17}NO_3S$): C 54.33, H 6.99; found: C 54.24, H 6.82.

Oxidations of sulfides to sulfones

The previously reported procedure (1*b*) was followed. Products obtained were as follows.

From **11**, sulfone **12**, yellowish crystals (68%), mp 157–159°C; ir ($CHCl_3$): 3420, 1700, 1670, 1500, 1310, 1115 cm^{-1}; ^1H nmr ($CDCl_3$): 7.58 (bs, 1H), 4.20–3.55 (m, 3H), 2.35 (s, 3H), 2.30–1.00 (m, 8H); *m/z* (FI) = 229 (M^+), 165. *Anal.* calcd. ($C_{10}H_{15}NO_3S$): C 52.40, H 6.55, N 6.11; found: C 51.96, H 6.36, N 6.31.

From **17**, sulfone **18**, white crystals (42%), mp 151–152°C; ir ($CHCl_3$): 1720, 1330, 1260, 1130, 1010 cm^{-1}; ^1H nmr ($CDCl_3$): 3.9 (bs, 4H), 2.40 (s, 6H), 1.75 (s, 3H); ^{13}C nmr (DMSO): 171.4, 135.0, 128.6, 59.3, 55.6, 25.3, 13.2; *m/z* (FI) = 231 (M^+), 188. *Anal.* calcd. ($C_9H_{13}NO_4S$): C 46.76, H 5.62, N 6.06; found: C 46.38, H 5.82, N 6.52.

From **24**, sulfone **25**, white crystals (45%), mp 181–182°C; ir ($CHCl_3$): 1710, 1580, 1420, 1370, 1325, 1295 cm^{-1}; ^1H nmr ($CDCl_3$): 3.65 (s, 2H), 3.35–2.50 (m, 4H), 2.35 (s, 6H), 1.60 (s, 3H); ^{13}C nmr ($CDCl_3$): 171.9, 151.7, 127.8, 67.1, 53.7, 47.3, 29.1, 25.5; *m/z* (FI) = 245 (M^+), 202, 186. *Anal.* calcd. ($C_{10}H_{15}NO_4S$): C 48.99, H 6.12, N 5.71; found: C 48.94, H 6.48, N 5.89.

Diels–Alder reactions of **12** *and* **18**

To a solution of sulfone **15** or **18** (0.01 mol) in 50 mL of xylene was added 0.01 mol of maleic anhydride and a small amount of hydroquinone. The reaction was heated at reflux overnight under a nitrogen atmosphere. The solution was cooled and the crystalline product was isolated by filtration. Since **13** was very prone to hydrolysis, it was converted to **14** before analysis. Data on the products follows.

Compound **13**, yellow crystals (62%), mp 213–215°C; ir ($CHCl_3$): 3280, 1860, 1780, 1675, 1660, 1550, 1455, 1375 cm^{-1}; ^1H nmr (DMSO): 8.95 (bs, 1H), 4.0–3.15 (m, 5H), 2.35–1.00 (m, 11H); ^{13}C nmr (DMSO): 173.3, 135.6, 110.2, 67.5, 45.4, 43.0, 42.4, 40.8, 39.9, 38.7, 31.5, 29.5, 26.3; *m/z* (FI) = 263 (M^+), 261, 245, 222, 197.

Hydrolysis to **14** was achieved by refluxing **13** (1.5 g, 6 mmol) with 40 mL of 15% HCl overnight. Filtration of the cooled mixture gave **14**, white crystals (54%), mp 111–113°C; ir (KBr): 3200–2600, 1715, 1700, 1445, 1345, 1250 cm^{-1}; ^1H nmr (DMSO): 3.15–2.81 (m, 3H), 2.35–0.8 (m, 11H); ^{13}C nmr (DMSO): 182.2, 181.3, 173.1, 47.7, 45.3, 43.2, 42.3, 36.7, 31.1, 25.4, 25.1, 24.8. *Anal.* calcd. ($C_{12}H_{16}O_5 \cdot H_2O$): C 55.87, H 6.97; found: C 56.06, H 7.22.

Compound **20**, white crystals (70%), mp 162–163°C; ir ($CHCl_3$): 1860, 1790, 1720, 1445, 1430, 1375, 1270 cm^{-1}; ^1H nmr ($CDCl_3$): 3.52 (m, 2H), 2.63 (m, 4H), 2.30 (s, 6H), 1.71 (s, 3H); ^{13}C nmr ($CDCl_3$): 178.6, 178.2, 172.8, 172.5, 132.6, 128.8, 40.2, 39.8, 31.2, 29.6, 28.8, 26.7, 25.7; *m/z* (FI) = 265 (M^+), 223, 183. *Anal.* calcd. ($C_{13}H_{15}NO_5$): C 58.86, H 5.66, N 5.28; found: C 58.52, H 5.56, N 5.68.

*Methyl 4-methyl-1-(diethylphosphono)-3-cyclohexenecarboxyate (28*a*)*

A mixture of **27** (1*e*) (0.22 g, 1 mmol), 0.1 g (1.5 mmol) of isoprene, and a small quantity of hydroquinone was dissolved in 25 mL of toluene and heated at reflux for 3 h. Evaporation and tlc purification (ether) gave **28***a* as a yellow oil (0.27 g, 95%); ir ($CHCl_3$): 1730, 1650, 1460, 1380, 1270 cm^{-1}; ^1H nmr ($CDCl_3$): 5.32 (bs, 1H); 4.15 (qq, 4H, J = 7, 7 Hz), 3.71 (s, 3H), 2.85–1.80 (m, 6H), 1.65 (s, 3H), 1.35 (t, 6H, J = 7 Hz); ^{13}C nmr ($CDCl_3$): 171.2, 133.3, 118.7 (J_{P-C} = 13 Hz), 63.1, 62.8, 52.5, 47.8 (J_{P-C} = 134 Hz), 28.4, 27.4 (J_{P-C} = 13 Hz), 25.8, 23.5, 16.6. *Anal.* calcd. ($C_{13}H_{23}PO_5$): C 53.82, H 7.92; found: C 53.86, H 7.66.

*4-Methyl-1-(diethylphosphono)-3-cyclohexenecarboxylate (28*b*)*

To a solution of 0.05 g (1.25 mmol) of NaOH in 5 mL of absolute ethanol was added 0.28 g (1 mmol) of **28***a*. The mixture was refluxed for 3 h and the solvent was removed. The residue was dissolved in water, acidified, and extracted with ether. The ether extracts were dried and evaporated to yield **28***b*, white crystals (0.24 g, 90%), mp 134–135°C; ir ($CHCl_3$): 3500–2700, 1740, 1670, 1475, 1415, 1280, 1210 cm^{-1}; ^1H nmr ($CDCl_3$): 10.25 (bs, 1H), 5.25 (bs, 1H), 4.10 (qq, 4H, J = 7, 7 Hz), 2.7–1.85 (m, 6H), 1.6 (s, 3H), 1.33 (tt, 6H, J = 7, 7 Hz); ^{13}C nmr ($CDCl_3$) (100 MHz): 172.7, 133.5, 118.1 (J_{P-C} = 14 Hz), 63.5 (J_{P-C} = 7.5 Hz), 63.4 (J_{P-C} = 6.2 Hz), 47.5 (J_{P-C} = 133 Hz), 28.2, 26.8 (J_{P-C} = 12.5 Hz), 25.3, 23.4, 16.4. *Anal.* calcd. ($C_{12}H_{21}PO_5$): C 52.20, H 7.60; found: C 52.16, H 7.57.

Diethyl 4-methyl-3-cyclohexen-1-ylphosphonate (29)

Acid **28***b* (2.7 g, 10 mmol) was heated at 200°C for 30 min at normal pressure. The reaction mixture was cooled and purified using

preparative tlc (ether) to give **29**, yellowish oil (1.59 g, 70%); ir ($CHCl_3$): 3000, 1660, 1460, 1390, 1270, 1050 cm^{-1}; ^1H nmr ($CDCl_3$): 5.35 (bs, 1H), 4.15 (qq, 4H, J = 6, 6 Hz), 3.50 (m, 1H), 2.72–1.85 (m, 6H), 1.59 (s, 3H), 1.25 (tt, 6H, J = 6, 6 Hz). *Anal.* calcd. ($C_{11}H_{21}PO_3$): C 56.93, H 9.04; found: C 57.09, H 9.23.

*Improved preparation of methylphosphonic acid bis(dimethylamide) **30***

To a cooled suspension of 32.6 g (0.4 mol) of dimethylamine hydrochloride in 125 mL of ether was added 32 g of 50% aqueous NaOH and the mixture was stirred vigorously overnight under nitrogen. The layers were separated, the ether layer dried for 15 min over $MgSO_4$, cooled to 0°C and 10 g (0.075 mol) of methylphosphonic acid dichloride (Aldrich) was added. The mixture was stirred at 0°C for 1 h and at ambient temperature for 3 h. The reaction mixture was filtered, the filtrate evaporated, and the residue distilled to give 9.6 g (85%) of methylphosphonic acid bis(dimethylamide), bp 85–88°C (2.5 Torr (1 Torr = 133.3 Pa)) (lit. (9) bp 138°C (32 Torr)).

Complexes of tungsten(VI) with thiomalic acid studied by ^1H and ^{13}C nuclear magnetic resonance spectroscopy

M. MADALENA CALDEIRA AND VICTOR M. S. GIL
Department of Chemistry, University of Coimbra, 3000 Coimbra, Portugal

Received September 27, 1983[1]

M. MADALENA CALDEIRA and VICTOR M. S. GIL. Can. J. Chem. **62**, 2094 (1984).

Proton and carbon-13 nmr evidence is presented on the number, stoichiometry, geometry, and stability of the complexes which form when sodium tungstate and (D,L)-thiomalic acid are mixed in aqueous solution at pH values in the range 2–7. In particular, three (or four) complexes are detected having a 1:2 composition (metal–ligand), as well as a less stable complex which seems to be a 1:1 species. Preliminary data are also given on the exchange of bound ligand in these complexes.

M. MADALENA CALDEIRA et VICTOR M. S. GIL. Can. J. Chem. **62**, 2094 (1984).

Faisant appel à la rmn du ^1H et du ^{13}C, on a étudié le nombre, la stoichiométrie, la géométrie et la stabilité des complexes qui se forment lorsqu'on mélange du tungstate de sodium et de l'acide (D,L)-thiomalique en solutions aqueuses, à des pH allant de 2 à 7. En particulier, on a pu détecter trois (ou quatre) complexes de composition 1:2 (métal–ligand) ainsi qu'un autre complexe moins stable qui semble être une espèce 1:1. On présente aussi des données préliminaires sur l'échange des ligands qui sont liés dans ces complexes.

Introduction

Complexes of tungsten(VI) with hydroxycarboxylic acids and complexes of other transition metals with thiomalic acid have been studied since about 1900, using various techniques. In more recent years, there has been a renewed interest in the metal complexes of thiomalic acid, partly because of their relevance in medicine, biology, and industry. Also, complexes of W(VI) with ligands containing oxygen, nitrogen, or sulphur have drawn increased attention, especially in view of their importance in studies of enzymatic activity.

The only study of the the W(VI) – thiomalic acid system of which we are aware is a preliminary work done in our laboratory some years ago (1). This was carried out in aqueous solution at pH ≅ 3 using visible spectroscopy and 100-MHz proton nmr. Evidence for 1:2 (metal–ligand) complexation was found and a discussion on the conformation of the bound ligand was presented.

The work now reported is a more thorough investigation of this system using 200- and 300-MHz proton nmr as well as ^{13}C nmr spectroscopy, with extension to pH values up to 7 and to more dilute solutions.

The approach is essentially the same as that used in previous papers of ours (2). Information on the number of complexes formed, their relative stabilities, and their structures is obtained; also, preliminary evidence is given on ligand exchange phenomena.

Experimental

Analytical grade sodium tungstate and commercially available (D,L)-thiomalic acid were used (unavailability of the optically active forms and failure in attempts to resolve the racemic mixture preclude us from also using one of the optical isomers, at this stage). In order to reduce the intensity of the OH nmr signal, the former was dried at 120°C, the latter was lyophilized from a solution in deuterium oxide, and D_2O solutions were used throughout. The concentrations of the tungstate solutions were established by weight and the acid solutions were standardized by potentiometry. The pH was adjusted by addition of solutions of DCl and NaOD; the pH* values quoted are the direct pH-meter readings (room temperature) after standardization with aqueous (H_2O) buffers. Whenever necessary, the ionic strength was kept approximately constant by making the solutions 1 *M* in KNO_3. In order to minimize air oxidation of the thiomalic acid, N_2 was run through the solutions during preparation and the nmr tubes were sealed under nitrogen atmosphere. The ^1H spectra were obtained on Varian XL-200 and Bruker CXP-300 spectrometers. The ^{13}C spectra were recorded on the Varian XL-200 instrument (50.3 MHz for ^{13}C) using gated decoupling techniques with suppression of the nuclear Overhauser effect; in this manner, temperature fluctuations were reduced to ca. ±1°C. Typically, spectral widths of 10 000 Hz, acquisition times of 1.5 s, pulse delays of 8–12 s, and 2000 pulses were used.

Results and discussion

1. *Spectral parameters and stoichiometry of complexes*

Figure 1(A) shows the 300-MHz proton nmr spectrum of a 0.017 *M*:0.033 *M* (metal–ligand) solution of sodium tungstate and (D,L)-thiomalic acid in D_2O (pH* 5.5, temperature 278 K). Six ABX spectra can be identified (although the AB subspectra are in part superposed) corresponding to the methylene and methyne protons of bound (five spectra) and free ligand: CO_2H—CH(SH)—CH_2—CO_2H. No further spectra are observed for higher concentrations (up to 2 *M*) for other metal–ligand ratios (4:1 to 1:4 was the range covered) and other pH values; the range of pH studied was 2–7. Free ligand is always detected and its relative concentration increases with dilution; for pH above ca. 7 almost all ligand occurs as free species for dilute solutions. For pH < 2, the signals become very broad, presumably due to extensive polymerization.

The presence of a small amount of the disulphide due to partial oxidation of thiomalic acid is also revealed by the spectra (Fig. 1(A)). It increases with time but can be greatly diminished by running N_2 through the solutions and keeping them under an atmosphere of N_2. As a matter of fact, without these precautions, practically all free and bound thiomalic acid is oxidized to the disulphide in about 3–4 months time, all spectral evidence for complexation with W(VI) having disappeared by then.

The fact that different spectra are observed for ligand molecules in different situations means that, at room and low temperatures, these are undergoing exchange processes that are slow in the nmr time scale. Most proton nmr spectra were obtained not at room temperature but at 278 K to ensure both sharper signals and smaller interference of the residual OH

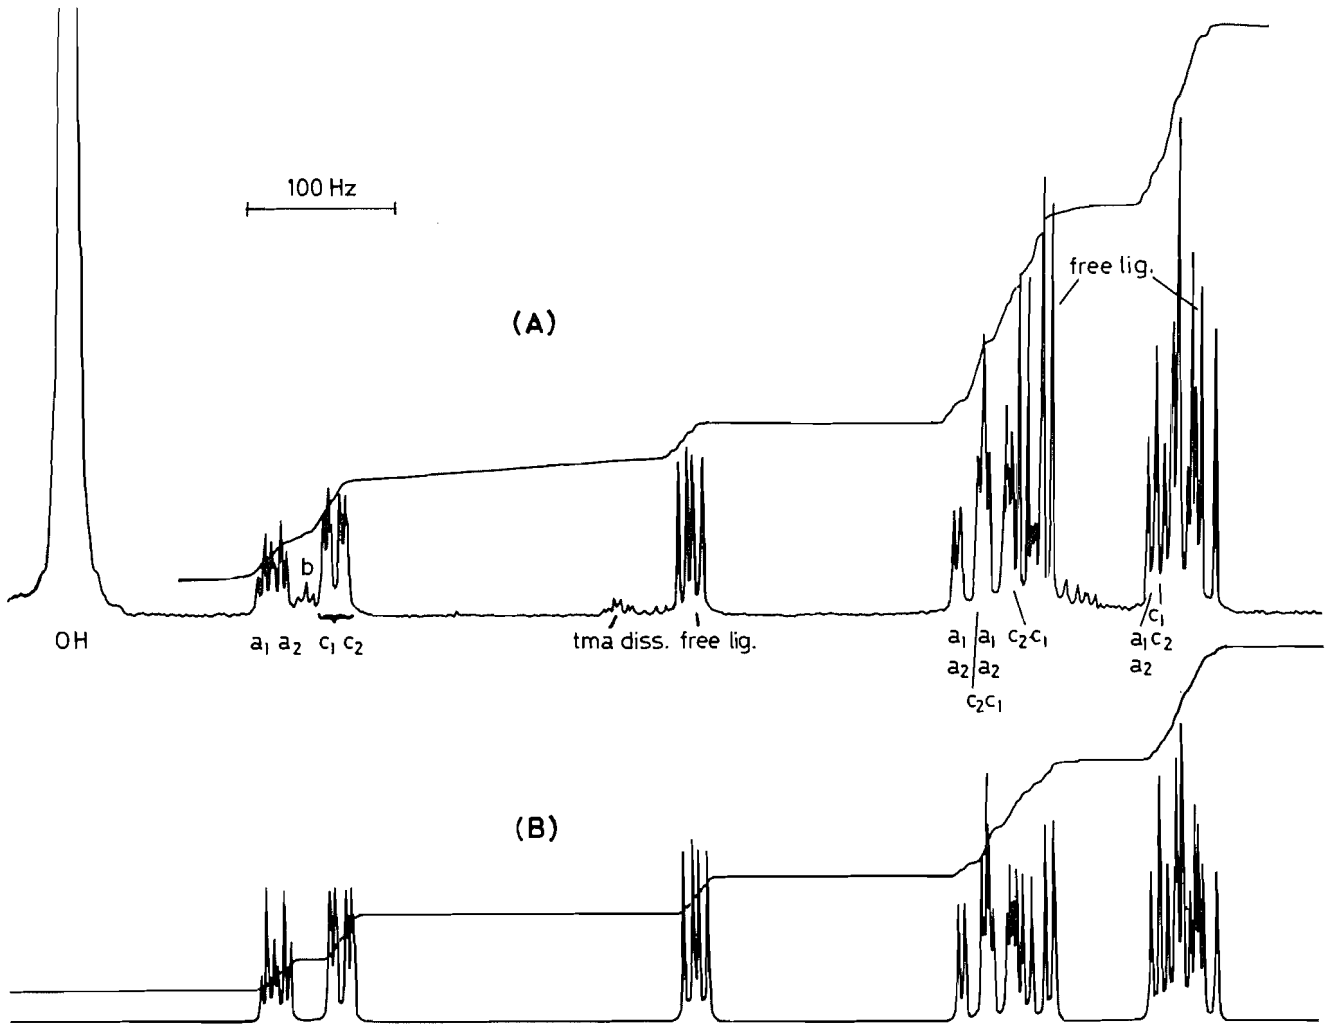

FIG. 1. Observed (A) and simulated (B) (only a_1, a_2, c_1, c_2, and free ligand) 300-MHz proton nmr spectrum of a 0.017 M:0.033 M (metal−ligand) solution of sodium tungstate and (D,L)-thiomalic acid in D_2O, at pH* 5.5 and at 278 K.

signal; however, since no noticeable changes in the position and intensities of the various signals were observed, the results can be taken as valid for room temperature. Some preliminary high temperature results are also presented below.

Whereas the weak X-spectrum denoted by b in Fig. 1(A) can be directly assigned to a less abundant complex, the close X-multiplets a_1 and a_2 and c_1 and c_2 can either be due to distinct complexes or else to a smaller number of complexes possessing two (or more) magnetically nonequivalent ligand molecules.

The assignment of the a_1 and a_2 X-peaks in Fig. 1(A) was done by comparison with the corresponding signals at different spectrometer frequencies (100 and 200 MHz) in conjunction with the analysis of the AB subspectra. The A and B signals were assigned on the basis of intensity considerations and proton spin decoupling experiments.

It is noted that, whereas the AB signals of thiomalic acid undergo only a small low-field shift upon complexation (0−0.15 ppm), the X peaks are much more shifted: 0.7−0.9 ppm to low field. The various chemical shifts relative to free ligand in the same conditions were obtained from ABX analysis of the spectra and are shown in Table 1 for three typical pH values. The results for free thiomalic acid agree with those of ref. 3, except in the case of $\nu_B - \nu_A$ for pH $\cong$ 3 which is given as 0.27 ppm in that paper. The remaining spectral parameters are also given in the table. We have assumed that the relative position of the A and B resonances is retained on complexation, the only hypothesis which is fully supported by the whole set of results (see below). For complex b only ν_X and the sum $J_{AX} + J_{BX}$ could be obtained.

Figure 1(B) shows the simulated spectrum corresponding to bound ligands a_1, a_2, c_1, and c_2 present as well as free ligand, with concentrations given by the integrated X-multiplets. The differences observed in the AB part when comparing the real and the simulated spectra are due to superposed spectra arising from the remaining species, namely complex b and the thiomalic acid disulphide.

The existence of five types of magnetically nonequivalent bound ligand molecules contrasts with the observation of only two ^{13}C sets of signals due to complexation. One reason is that complex b is practically absent for higher concentrations, as is proved by the proton nmr spectrum in the same conditions. Figure 2 shows the ^{13}C 50.3-MHz proton decoupled spectrum of a 0.25 M:0.50 M (metal−ligand) solution of WO_4^{2-} and (D,L)-thiomalic acid in H_2O (with 20% D_2O), pH 4.7, obtained at room temperature. Three sets of peaks are observed, one due to free ligand and the other two to bound ligand. These two are likely to correspond to the close a_1,a_2 and c_1,c_2 proton spectra, respectively. This hypothesis is supported by the relative in-

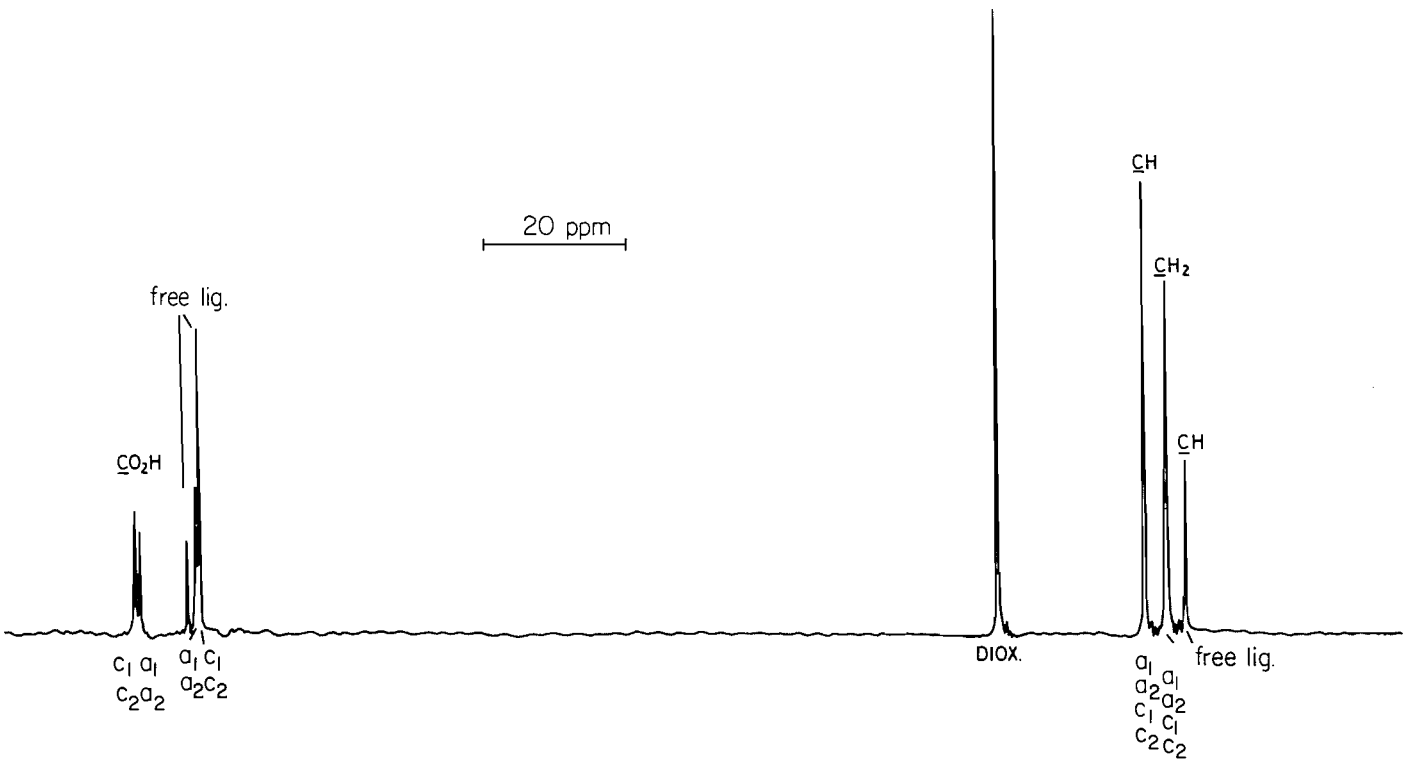

FIG. 2. 50.3-MHz ^{13}C proton decoupled spectrum of a 0.25 M:0.50 M solution of sodium tungstate and (D,L)-thiomalic acid in H_2O/D_2O (pH 4.7, 296 K).

tensities of the ^{13}C signals as compared to the ^1H spectra. The chemical shifts of free ligand relative to dioxane (see also ref. 4) and those of bound ligand relative to free thiomalic acid in the same conditions are given in Table 2. The assignment of the carboxyl signals of each complex has been made on the basis of the observation that only one is appreciably shifted by the formation of complex (shift to low field) and assuming that this corresponds to the carboxyl group next to the sulfhydryl group; since S is also involved in complexation (see below), this assumption means chelation with formation of 5-membered rings. It is noted that the ordering of the C(H) and C(H_2) signals changes on complexation.

From the relative intensities of the X signals in the proton nmr spectra, the amount of bound ligand a_1, a_2, b, $c_1 + c_2$ (due to broadening effects in some solutions, the c_1 and c_2 signals could not always be integrated separately) was determined as a function of metal−ligand molar ratio. The Job's plots thus obtained are given in Fig. 3, for a total concentration of metal + ligand of 0.050 M and pH* 5.0 throughout; the ionic strength was kept approximately constant from solution to solution by

TABLE 2. ^{13}C chemical shifts (in ppm) for WO_4^{2-} + thiomalic acid (0.25 *M*:0.50 *M*; pH 4.7; temperature 296 K)

	HO_2C —	CH(SH) —	CH_2 —	CO_2H
Free ligand (relative to dioxane)	114.4	−26.2	−24.0	112.8
a_1,a_2 (relative to free ligand)	6.4	5.6	0.0	0.4
c_1,c_2 (relative to free ligand)	7.2	5.6	0.4	0.0

making them 1 *M* in KNO_3. For more concentrated conditions (total concentration of metal + ligand = 1.0 *M*, pH* 5.0) the maxima at the 1:2 ratio are again well defined for the ligands *a* and *c*; however, as already mentioned, complex *b* is not detected in those conditions.

In view of the neat maximum at 1:2 for $c_1 + c_2$, and because the intensity ratio for c_1 and c_2 always remains practically constant whenever separate signals can be detected, we conclude that both bound ligands c_1 and c_2 show maximal concentration for a metal−ligand molar ratio of 1:2.

In spite of the limitations of Job's method when there is more than one complex, Fig. 3 is a firm indication that the complexes with spectra a_1, a_2, c_1, and c_2 in Fig. 1 are 1:2 (metal−ligand) species. As for the much less abundant complex *b*, the occurrence of a (less well-defined) maximum at the molar ratio 1:1 can only be taken as a hint of its stoichiometry; this is because there is always a large excess of the other complexes present and, in such circumstances, a maximum in a Job's plot is not necessarily a proof of a certain stoichiometry. We note that evidence for a 1:1 and two 1:2 complexes has previously been found by us for the system tungstate − malic acid (8).

The different intensities of the a_1 and a_2 signals show that they do not arise from two (slightly magnetically nonequivalent) ligand molecules in a 1:2 complex. The same is true of the c_1 and c_2 peaks. The hypothesis of a_1 and c_2 (less intense signals) belonging to one 1:2 complex and, simultaneously, a_2 and c_1 to another can also be ruled out, because then the total intensity of $a_1 + a_2$ should be equal to that of $c_1 + c_2$; this is not the case. Careful analysis of the intensities in those few cases when c_1 and c_2 could be resolved shows that the only hypothesis left is that of a_2 and c_2 corresponding to one 1:2 complex.

2. *The geometry of the complexes*

The large low-field shifts of the methyne proton (X) and of the S-bonded carbon nucleus of thiomalic acid upon complexation indicate that the sulfhydryl group is involved in complexation to W(VI). This is in line with the fact that the disulphide does not complex and with evidence from solid state studies in related complexes (5).

The large low-field shift of one of the carboxyl ^{13}C nuclei of the bound ligands a_1, a_2, c_1, c_2, which we have attributed to the carboxyl group next to SH, is consistent with chelation through the formation of 5-membered rings, as is the case with complexes of malic acid[2] and of α-mercaptocarboxylic acids studied in the solid state (5).

Support for this conclusion comes also from the fact that

[2]The hypothesis of formation of 6-membered rings in complexes of thiomalic acid with Mo(VI) and of malic acid with Mo(VI) and W(VI), considered for some of the complexes in our previous studies (2, 8, 9), must be revised in view of this and other data (5).

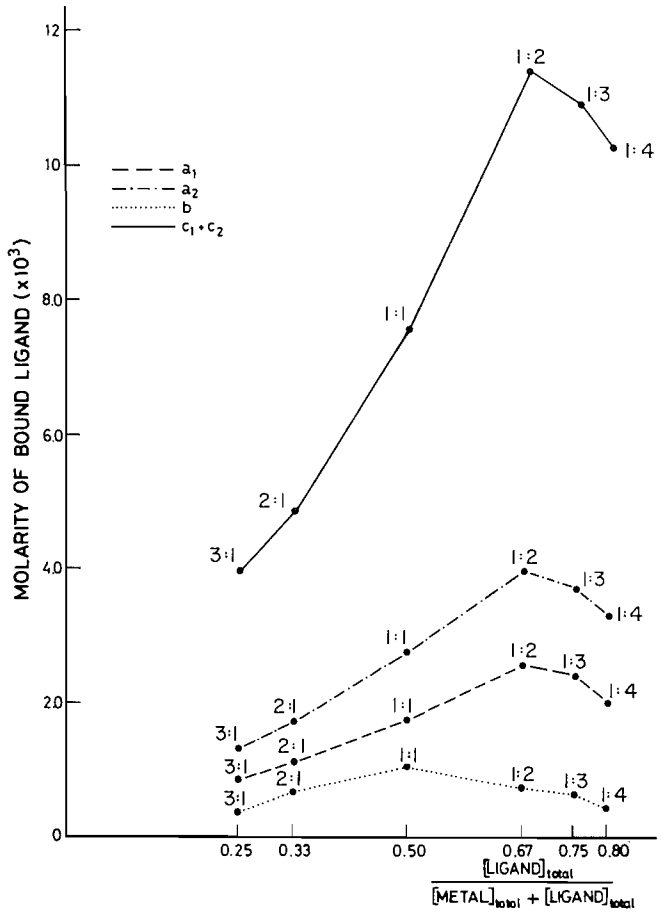

FIG. 3. Job's curves based on proton nmr spectral intensitites. Total concentration of complexing species: 0.050 *M* (solvent D_2O, pH* 5.0, 278 K).

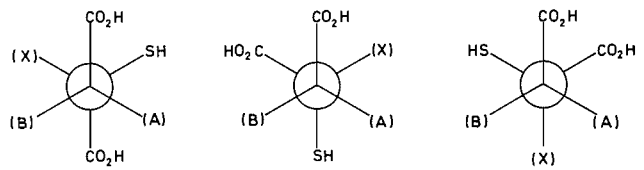
2-mercaptopropionic acid (thiolactic acid), CH_3—CH(SH)—CO_2H, undergoes similar shifts on complexation with W(VI), whereas complexation with the 3-mercapto isomer, CH_2(SH)—CH_2—CO_2H, is almost nonexistent. In fact, the ^1H and ^{13}C nmr spectra of a solution of 3-mercaptopropionic acid are practically not affected by the presence of WO_4^{2-}. On the contrary, important changes occur in the case of the 2-mercapto isomer. For a 1:2 (metal−ligand) solution, at pH* 7, two CH patterns in the proton spectrum occur 0.797 and 0.677 ppm to low field of the corresponding signal of free ligand and having different intensities; the ^{13}C shift for the same group is 4.4 ppm, also to low field relative to free ligand, and those for the carboxyl group are 6.8 ppm and 7.6 ppm (two types of bound ligand). These and other preliminary results point to the presence of two 1:2 complexes.

Further evidence for the involvement of sulfhydryl and carboxyl groups in chelation arises also from Raman spectroscopy. In particular, the band at 1870 cm^{-1} due to the stretching vibration of the deuterated sulfhydryl group markedly decreases in intensity upon complexation, which is indicative of ionization of this group as a result of bonding to the metal; simultaneously, the band at ca. 1200 cm^{-1} becomes stronger, suggesting an enhanced contribution of the C—O stretching vibration upon complexation (6).

The H—H vicinal coupling constants observed for bound ligands *a* and *c* are of similar magnitude. This shows that the conformation of the ligand is approximately the same in all the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

1:2 complexes. More precisely, with the $—CH_2—CO_2H$ moiety still rotating around the central C—C axis, we conclude that the potential energy functions for internal rotation most likely have similar features in those complexes. For about pH 5 and above, comparison with the J_{AX} and J_{BX} values for the free ligand in the same conditions shows that the most stable conformation of the acid for these pH values (3, 4), which is conformation **I** below, is further stabilized relative to the others on complexation. The pronounced decrease of J_{AX} for the 1:2 complexes on going from pH 5 to pH 3, accompanied by only a slight change of J_{BX} in ligands c_1, c_2 and no change in a_1, a_2 suggests that conformation **I** loses stability (especially in favour of **III**), as is the case with the free ligand itself (3, 4). However, contrary to free thiomalic acid at this low pH, conformation **I** is still the most stable in the complexes ($J_{AX} > J_{BX}$).

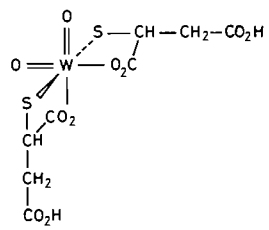


I **II** **III**

Regarding complex *b*, only $J_{AX} + J_{BX}$ could be obtained from the spectrum. The small value for this sum (ca. 8 Hz) suggests that the main conformation of the ligand now is **III**. This is in accordance with a terdentate function of the ligand in this presumably 1:1 complex.

The tungstyl group $—WO_2$ in the 1:2 complexes is expected to have *cis* configuration (5). The occurrence of two Raman bands observed at 930 cm^{-1} and 880 cm^{-1} (room temperature, pH 4, various metal−ligand molar ratios) supports this hypothesis (6, 7).

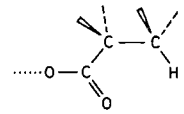
Thus, one possible structure for a 1:2 complex is



where the S atoms are *trans* to each other (and are assumed nonprotonated). Other possibilities do of course exist. In addition, the use of racemic thiomalic acid increases the number of isomers. Depending on the configuration at the tungsten centre and on the optically active forms of acid involved being the same or not, 12 magnetically nonequivalent 1:2 complexes can in principle form, four of which would have C_2 symmetry (with two magnetically equivalent ligands). The use of one of the optical isomers of thiomalic acid as ligand would reduce the number of possible complexes and would help to clarify the characterization of this system. Unfortunately, difficulties related to the resolution of (D,L)-thiomalic acid force us to postpone such a study.

On the basis of molecular models, it is found that the CH group of bound ligand lies either almost parallel to one of the W=O bonds or away. This may be the main reason for the observation of the two groups of X signals a_1,a_2 and c_1,c_2. The former would then be associated with a parallel orientation for which the CH proton shielding constant is decreased by the magnetic anisotropy and the electric field effects of the W=O group.

It is also found that when the bound ligand adopts the most stable conformation − conformation **I** − proton B of CH_2 (which is then *trans* to the S atom) lies approximately in the plane of the bonded carboxyl group and parallel to the C=O axis



thus experiencing a deshielding effect due to the C=O group. This is in accordance with the shift of proton B to low field relative to proton A on complexation; for instance, for pH* 5.5, $\nu_B - \nu_A$ is 0.360 for free ligand, 0.441 for bound ligands a_1, a_2, and 0.396 and 0.403 for ligands c_1 and c_2. This chemical shift decreases as pH changes from 5 to 3, in agreement with a decrease of the contribution of conformation **I**.

3. *The effect of pH and the stability of the complexes*

The effect of pH on the concentrations of bound ligands a_1, a_2, *b*, and $c_1 + c_2$ is shown in Fig. 4 for various metal−ligand molar ratios. The behaviour of the curves is quite similar, with maxima occurring for pH* in the region 4−4.5 for *b* and $c_1 + c_2$ and in the region 3−4 for a_1, a_2. The results, especially for a_1 and a_2, enable us to rule out the hypothesis of the corresponding complexes differing just on the degree of ligand protonation.

The complexes of W(VI) with thiomalic acid are found to be less stable than the complexes between W(VI) and malic acid; in fact, in the first case free ligand is detected by nmr even for a 4:1 metal−ligand molar ratio, whereas the same only happens for 1:*n* ratios of metal and malic acid with $n \geqq 1.5$ (8). The difference is especially marked for complex *b*, which is always less abundant than the 1:2 complexes.

The fact that separate ^1H nmr signals are observed for bound and free ligand in the various complexes naturally prompted us to make an estimate of their formation constants from the spectral intensities. It must, however, be recognized that we are dealing with a very complex system in which the metal oxoions are involved in various polymerization equilibria depending on concentration, pH, and ionic strength (10) besides being involved in complexation equilibria. This can lead to errors. Additional uncertainties arise from the fact that the ionizations of thiomalic acid (the microscopic constants of which we are determining in a separate study) are affected by complexation, especially in the case of the SH group; also, we are using D_2O and not H_2O solutions. Therefore, the conditions for which any determination is done can be very critical.

We have performed calculations at pH* 4.0, for 2:1 (0.033 *M*:0.017 *M*; 0.050 *M*:0.025 *M*), 1:1 (0.017 *M*:0.017 *M*; 0.025 *M*:0.025 *M*), 1:2 (0.017 *M*:0.033 *M*; 0.025 *M*:0.050 *M*), and 1:3 (0.017 *M*:0.050 *M*) solutions; the ionic strength was held approximately constant with 1 *M* KNO_3. For these conditions, the main species of W(VI) present is believed to be the polyanion $W_{12}O_{39}^{6-}$ (10). On the other hand, from the published values (11) of pK_1 (3.1) and pK_2 (4.6) for aqueous solution at 298 K, we conclude that the main species of thiomalic acid (here represented by D_3Y) present at pH* 4.0 is D_2Y^- (one carboxyl group ionized). Thus the main equilibrium for 1:2 complexation at this pH* is

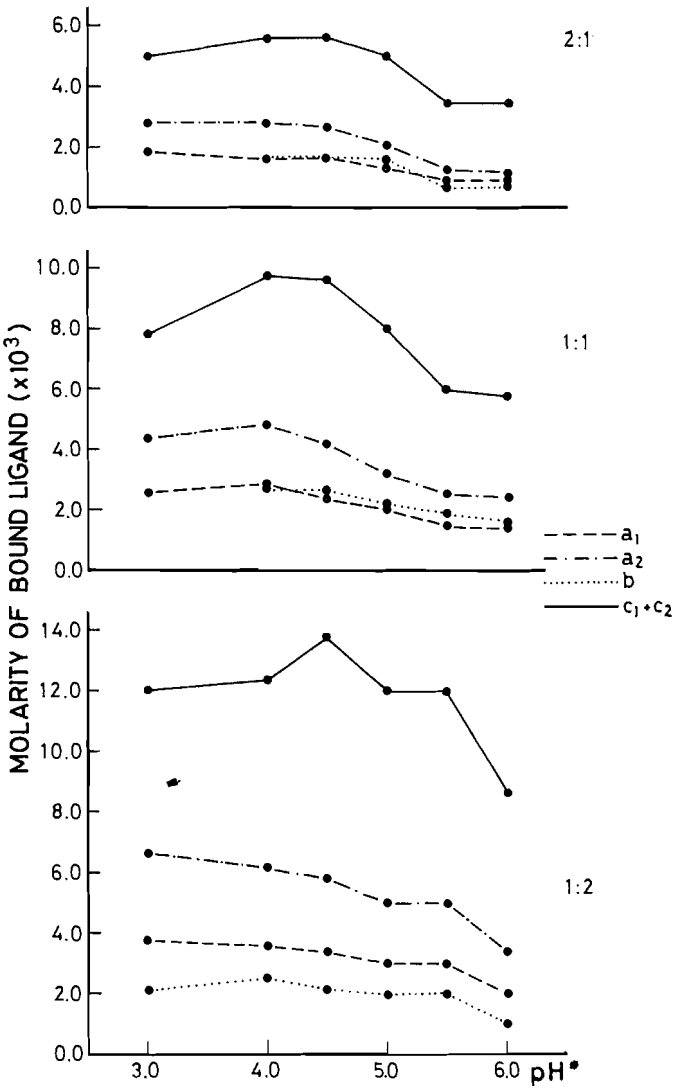

FIG. 4. Effect of pH on concentration of bound ligands for various metal–ligand molar ratios (0.033 *M*:0.017 *M*; 0.025 *M*:0.025 *M*; 0.017 *M*:0.033 *M*).

$$W_{12}O_{39}^{6-} + 24D_2Y^- + 6D^+ \rightleftarrows 12WO_2(DY)_2^{2-} + 15D_2O$$

use being made of the previous conclusion that the sulfhydryl group is ionized in the complexes.

From the concentrations of free and bound ligand obtained from the spectral intensities for each solution, and ignoring other equilibria, we obtained pK values of formation for the 1:2 complexes, according to the equation above, which range from −47.5 to −49 in the case of a 1:2 a_1 complex, and from −50 to −51.5 for a 1:2 a_2 complex; the corresponding values for c_1 and c_2 complexes are lower by about −1 to −2 relative to a_2 and a_1, respectively. If a_2 corresponds to just one of the ligands in a 1:2 complex, the other ligand being responsible for c_2, then the calculated pK value for such a complex is from −54 to −55.

In spite of the limited dispersion of values obtained, they should be taken with caution. We note, in particular, that if the free ligand is only 70% in the form D_2Y^-, then all pK values go up by almost 4 units.

Similar determinations at lower pH* values, at which the dominant form of thiomalic acid is D_3Y, were not feasible, owing to excessive broadening of the nmr signals. On the other hand, identical calculations at higher pH* values become increasingly unwarranted because of the presence of various polymerization equilibria of WO_4^{2-} (10).

4. *Ligand exchange*

The proton nmr spectrum shown in Fig. 1 was obtained at 278 K. At room and higher temperatures some of the signals due to the complexes become broader and eventually coalesce into groups of smaller numbers of lines. This is an indication of ligand exchange at these temperatures. As the chemical shifts between the A protons for the various complexes are different from those for B or X protons, coalescence of the corresponding signals occurs at different temperatures.

Thus, for a 1:2 solution at pH* 5.0, the A signals due to bound ligands a_1,a_2 and c_1,c_2 are only 0.019 ppm apart and coalesce into one group of four lines at 294 K. This points to a rate of ligand exchange for these complexes of about 8 s^{-1} at room temperature.

The B signals, which have an internal chemical shift of ca. 0.060 ppm, only coalesce at 315 K; at this temperature the rate of ligand exchange will then be about 26 s^{-1}.

The X multiples due to a_1,a_2 and c_1,c_2, which are 0.15 ppm apart, turn into a broad peak at ca. 333 K; the rate of ligand exchange will then be about 65 s^{-1}.

From these preliminary rates of ligand exchange obtained for the 1:2 complexes, a value of about 40 kJ mol^{-1} is estimated for the corresponding free energy of activation. A more complete study is in progress.

Conclusions

When thiomalic acid and sodium tungstate are mixed in aqueous solution, at pH ranging from 2 to 7, four (or five) complexes form, especially at pH 3–4.5, as follows.

(*a*) Three (or four) are comparatively strong and they have a 1:2 (metal–ligand) stoichiometry; the ligand acts as bidentate, involving the (deprotonated) sulfhydryl group and the (ionized) adjacent carboxyl group, the two carboxyl groups being approximately *trans* to each other; ligand exchange is slow at room temperature (rate about 8 s^{-1}) with a free energy of activation of the order of 40 kJ mol^{-1}; evidence exists for the presence of a *cis* tungstyl group in these complexes.

(*b*) One weaker complex, less well characterized, is probably of 1:1 stoichiometry; the bound ligand has a conformation where the sulfhydryl group and the adjacent carboxyl group are both approximately *gauche* to the other carboxyl group, a conformation which is appropriate to a tridentate function of the ligand.

(*c*) By ignoring secondary equilibria, a crude nmr estimation was made of the formation constants of the 1:2 complexes, but the results must be taken with caution owing to the great complexity of the system. Nevertheless, clear evidence exists for weaker complexes of W(VI) with thiomalic acid than with malic acid.

Pyrones. X.[1] Lateropyrone, a new antibiotic from the fungus *Fusarium lateritium* Nees

GORDON WILLIAM BUSHNELL, YUN-LONG LI,[2] AND GERALD ARTHUR POULTON
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received February 7, 1984

GORDON WILLIAM BUSHNELL, YUN-LONG LI, and GERALD ARTHUR POULTON. Can. J. Chem. **62**, 2101 (1984).

Lateropyrone, 5-hydroxy-9-methoxy-2-methyl-4*H*,6*H*-pyrano[3,4-*g*]-1-benzopyran-4,6-dione-8-carboxylic acid, **1**, has been isolated from cultures of the fungus *Fusarium lateritium* Nees, and shown to have inhibitory activity against the growth of a gram-positive bacterium and a yeast. A crystal structure of the dimethyl derivative of lateropyrone, **2**, was determined. The crystals are monoclinic, space group $P2_1/c$, with a = 9.663(4), b = 22.317(9), c = 7.747(5) Å, β = 113.03(4)°, D_c = 1.496 g cm^{-3}, V = 1538(1) Å^3, T = 25°C, $C_{17}H_{14}O_8$. The structure was refined to R = 0.0543 by least squares using 2100 observed, independent reflections measured on a 4-circle diffractometer, to obtain 241 parameters. The linearly fused tricyclic ring system is only approximately planar. In- and out-of-plane distortions are rationalized in terms of molecular overcrowding.

GORDON WILLIAM BUSHNELL, YUN-LONG LI et GERALD ARTHUR POULTON. Can. J. Chem. **62**, 2101 (1984).

On a isolé la latéropyrone, l'acide hydroxy-5 méthoxy-9 méthyl-2 4*H*,6*H*-pyranno[3,4-*g*] benzopyranne-1 dione-4,6 carboxylique-8, **1**, de cultures du champignon *Fusarium lateritium* Nees et on montre qu'elle a une activité inhibitrice vis-à-vis la croissance d'une bactérie gramme-positive et d'une levure. On a déterminé la structure cristalline du dérivé diméthylé, **2**, de la latéropyrone. Les cristaux sont monocliniques et appartiennent au groupe d'espace $P2_1/c$ avec a = 9,663(4), b = 22,317(9), c = 7,747(5) Å, β = 113,03(4)°, D_c = 1,496 g cm^{-3}, V = 1538(1) Å^3, T = 25°C, $C_{17}H_{14}O_8$. On a affiné la structure par la méthode des moindres carrés jusqu'à une valeur de R = 0,0543 pour 2100 réflexions indépendantes observées et mesurées à l'aide d'un diffractomètre à 4 cercles pour obtenir 241 paramètres. Le système tricyclique condensé linéaire n'est qu'approximativement planaire. On rationalise les distortions dans le plan et hors du plan en fonction d'un encombrement moléculaire.

The *Fusaria* fungi are well known as contaminants in cereal grains (1), as the causative agents of stem and branch cankers in trees (2), and as an insect pathogen (3). Many investigations of the metabolites of *Fusaria* species have been carried out, with toxins causing fusariotoxicoses in animals (4, 5), and metabolites possessing insecticidal activity (3) or antibiotic activity (6, 7) having been identified. A recent review has appeared (8).

Fusarium lateritium Nees has been isolated[3] from *Tsuga heterophylla* (Raf.) Sarg. trees suffering from dieback, and produces visible quantities of crystals when cultured on malt extract at room temperature. Extraction of the culture plates with dichloromethane allowed the isolation of a crystalline metabolite which showed significant antimicrobial activity; this communication details the structural elucidation of this metabolite, hereafter called lateropyrone. The identical metabolite was also isolated from an unidentified contaminant fungus.

Results and discussion

Lateropyrone has the molecular formula $C_{15}H_{10}O_8$, as indicated by accurate mass measurement, and contains a carboxylic acid function (deuterium exchangeable signal at 14.7 ppm, ir absorption at 3200−2500 and 1750 cm^{-1}) and a hydrogen-bonded phenol (deuterium exchangeable signal at 10.4 ppm, ir absorption at 3450 cm^{-1}). The presence of these functional groups was confirmed by pK* measurements,[4] which gave values of 6.70 ± 0.05 (acid) and 10.9 ± 0.2 (phenol), and by the formation of a monoacetate (acid peak at 14.68 ppm, ir absorption at 3100−2300, 1750 cm^{-1}, acetate at 2.44 ppm, carbonyl absorption at 1727 cm^{-1}) and a dimethyl ether methyl ester (three 3H singlets at 4.08, 3.99, and 3.97 ppm). The latter compound was chosen for X-ray analysis, as suitable crystals of the natural product could not be obtained.

Figure 1 is an ORTEP drawing of this derivative, giving the atomic labelling scheme, and a display of the thermal motion ellipsoids scaled to enclose 50% probability. The fractional atomic coordinates are presented in Table 1 together with isotropic temperature parameters derived from the deposited anisotropic temperature parameters. The interatomic distances are given in Table 2. The central ring is aromatic and the mean bond length is 1.398 Å, but the rings on either side are of the α- and γ-pyrone types and are not aromatic. The olefinic double bonds are similar, but not identical in length, as they are situated differently with respect to the oxygen atoms and the aromatic ring. Considering the error limits, the C—O single bonds in the pyrone rings are of the same length, as are the exocyclic C—C bonds, and all three CH_3—O bonds. However, the carbonyl bond C(1)=O(1) is longer than the other two in the structure. The difference of 0.031(4) Å is significant and may possibly be ascribed to the close intramolecular approach of H(132) to O(1) of 2.43(1) Å (the sum of the van der Waals radii = 2.60 Å) in contrast to the other oxygen atoms of carbonyl groups whose shorter contacts with hydrogen atoms are greater than 2.585 Å. Such a lengthening of a carbonyl bond may be regarded as a very weak hydrogen bonding. In comparison, hydrogen bonding in 2,6-dimethyl-γ-pyrone·HBr·H_2O lengthens the carbonyl group to 1.32 Å (11). The central aromatic ring has normal bond lengths. The positions of the double bonds in the pyrone rings are indicated by C—C lengths in the 1.32−1.35 Å range, by the detection of H(2), and by the approximate planarity of O(10), C(9), C(91), C(8), O(8), and C(7).

The bond angles are given in Table 3 and the mean plane and

torsion angles in Table 4. The most striking feature is the lateral displacement of O(1) and O(11) away from the O(13) methoxy group. The angles bout C(13) are very close to 120° because the steric repulsion, which we shall discuss further, between O(13) and O(1),O(11) comes from both sides. The bond angles around the ethylenic bonds in the α- and γ-pyrone rings are remarkably similar to each other. The angles at the methoxy oxygen atoms on the ring system are essentially identical, with a mean value of 115.6°. The conformation of the methoxy groups on ring systems of this kind is of some interest. In *p*-dimethoxybenzene (12) the MeO groups are approximately in-plane and *trans* for electronic reasons. For the bikaverin molecule **5**, in which there is little possibility of the methoxy groups being crowded, the conformation is again approximately planar (13). On the other hand, the methoxy group in avicennin **6** is crowded by two adjacent ethylenic hydrogen atoms, and adopts a conformation with the C—O—C plane approximately perpendicular to the ring system (14). In the title compound the O(13) methoxy group is inescapably restricted in its rotation by O(1) and O(11), and the O(8) methoxy group is confined by H(6) and also by O(92) in the observed conformation of the methyl ester. The methoxy groups project on opposite sides of the molecular plane.

The weighted least-squares plane and torsion angle results are given in Table 4. The least-squares plane of the central aromatic ring was chosen as the best reference plane. The molecule is significantly non-planar, and even the six atoms of the central ring do not form a planar set. The non-planarity is

*The coordinate system used has *x* along *a*, *y* along *b*, and *z* along *c**. $\chi^2 = \sum_i (P_i^2/\sigma^2(P_i))$, the summation being over all atoms in the plane.

largely a consequence of overcrowding between the peripheral C—O bonds, which in an idealized molecule of this kind would be parallel and about 2 × 1.4 × cos 30° = 2.4 Å apart. As the van der Waals radius of oxygen is 1.4 Å (15), the molecule is deformed. The deformation can be analyzed into in-plane and out-of-plane components. The former have been dealt with in discussing the bond angles. For the ester group, out-of-plane deformation is particularly easy, and O(92) is more out-of-plane than O(8), and in the opposite direction. The set of atoms C(9), C(91), O(91), O(92) maintains planarity (χ^2 = 5.5), and is at 11.6° to the plane of the aromatic ring. On the other side of the molecule O(1) and O(11) move out of the plane in opposite directions. O(13) is −0.100(2) from the plane in the same direction as O(1), whereas C(131) is at +1.126(3) Å on the same side as O(11). The torsion angle for this MeO group shows that it is 11.7° away from orthogonality with the aromatic ring, in the direction to be expected from the O(1),O(11) out-of-plane distortions. The twisting of the molecule, arising from the overcrowding of O(1), O(13), and O(11), is transmitted to the aromatic ring (through C(1) to C(14), and through C(11) to C(12)) and largely accounts for its non-planarity.

In seeking analogous structural effects, bikaverin **5** is the closest natural product whose crystal structure is available (14). It contains four linearly fused six-membered rings, in the order aromatic, γ-pyrone, hydroquinone, quinone. An hydroxyl group therefore lies between, and parallel to, two ketone groups. Unfortunately for the comparison, this hydroxyl group is not methylated and can hydrogen bond with one of the adjacent O atoms, thus countering the repulsive effect on that side. We cannot say with certainty on which side this occurs, since the hydrogen atoms were not found in this structure. However, the adjacent quinone oxygen has a slight lengthening of the C=O bond 1.25(2) Å combined with a closing of the external angle at C facing the OH group (117.8(15)°), suggesting that the H-bonding occurs here. The adjacent oxygen atom on the other side (γ-pyrone), has a C=O bond length of 1.22(2) Å, an external angle facing OH of 123.7(15)°, and out-of-plane distortion of 0.17(1) Å suggesting repulsion, and so reinforcing the assignment already given. Thus bikaverin does provide an example of overcrowding between adjacent oxygen atoms along the edge of a linearly fused system.

Similar structural effects have been observed further afield in

the Russion crystallographic work on 1,8-dihaloanthraquinones (hal = Cl and I) (16, 17). This work confirms that out-of-plane deformations do occur in response to overcrowding of this kind. The dichloro compound distorts to put the central ring in the boat form, whereas the diiodo compound distorts the quinone ring into shallow chair form. Surprisingly, the dichloro compound shows the greater deviation from planarity. The steric repulsion between chlorine and oxygen atoms thus placed in a linear tricyclic system is also well exemplified by a pair of crystal structures in which central γ-pyrone and pyran rings respectively are flanked by 1,2,4-trichlorobenzene rings (18). The Cl---Cl distances (between 1,8 type positions) are 5.61 Å, 5.28 Å, and 4.26 or 4.37 Å as the intervening group is ketone, methylene, and ether. When the central ring is γ-pyrone, the out-of-plane distortions show the molecule to be twisted. The van der Waals radius for Cl is 1.80 Å (15), so that it is to be expected that the overcrowding effects will be greater for these halo compounds than for ours.

With the structure **2** confirmed for the dimethyl derivative of lateropyrone, the natural product is either the 5-methoxy-9-hydroxy compound **3** or the 5-hydroxy-9-methoxy compound **1**; we prefer the latter choice, as **3** is a β-ketoacid and, as such, should be susceptible to decarboxylation. Lateropyrone is therefore assigned the structure 5-hydroxy-9-methoxy-2-methyl-4*H*,6*H*-pyrano[3,4-*g*]-1-benzopyran-4,6-dione-8-carboxylic acid, **1**.

Lateropyrone shows significant inhibitory activity towards the growth of the gram-positive bacterium *S. aureus* and the yeast *C. albicans*, but did not affect the gram-negative bacterium *E. coli*. The dimethyl derivative **2** showed no effect on all three test organisms.

Experimental

General

Melting points were determined on a Kofler hot stage and are uncorrected. Proton nmr spectra were determined on a Perkin–Elmer R32 spectrometer at 90 MHz or on a Bruker WM250 spectrometer at 250 MHz with reference to TMS. Infrared spectra were obtained on a Perkin–Elmer 283 spectrometer, and ultraviolet spectra on the Beckman DU-8 spectrophotometer. Microanalyses were conducted by Canadian Microanalytical Service Ltd., Vancouver, Canada. Accurate mass measurements were kindly provided by the University of British Columbia Mass Spectrometry Centre using the Kratos MS-50 instrument.

Cultures

F. lateritium was cultured on 3% malt extract (DIFCO) in Petri dishes at room temperature in the dark for 5 weeks. Test organisms were obtained from the Department of Biochemistry and Microbiology, and were grown on 3% malt extract (DIFCO) at 37°C; filter paper discs of compounds to be tested and of standard antibiotics were placed on the surface of the agar and covered with a coating of soft agar. Test organisms used were *Escherichia coli* W3110, *Staphylococcus aureus* 3538P, and *Candida albicans* 10231. Antibiotic activity was monitored by the inhibition of growth of the microorganism after approximately 24 h.

Extraction

Mycelium and agar from 40 dishes were extracted by stirring with dichloromethane at room temperature (3 × 800 mL). The crude extract was concentrated, and the product recrystallized from acetone–dichloromethane (5:1). Lateropyrone (50 mg) was isolated as pale yellow needles, mp 257–259°C.

Lateropyrone 1

Showed ν_{max} (KBr): 3450, 3200–2500 (br), 1750, 1650, 1610 cm^{-1}; λ_{max} (CH_2Cl_2): 370 (log ε = 4.16), 351 (4.16), 282 (4.19), 272 (4.15), and 244 nm (4.23); ^{1}Hmr (CD_2Cl_2): 14.7 (1H, s, COOH, D_2O exchangeable), 10.4 (1H, s, OH, D_2O exchangeable), 7.44 (1H, s, 10-H), 6.26 (1H, s, 3-H), 4.01 (3H, s, OMe), 2.45 (3H, s, 2-Me); ms, *m/z* (relative intensity): 318.0369 (M^+, 19, calculated for $C_{15}H_{10}O_8$: 318.0376), 231 (6), 230 (21), 203 (14), 202 (100), 175 (16), 174 (33), 134 (16). *Anal.* calcd. for $C_{15}H_{10}O_8$: C 56.61, H 3.17%; found: C 56.36, H 2.88%.

Lateropyrone dimethyl derivative 2

Lateropyrone (100 mg) in dichloromethane (110 mL) was added to excess ethereal diazomethane at room temperature. After 2 h, a few drops of acetic acid were added, and the resulting solution washed (water, saturated aqueous NaCl). The combined aqueous layers were extracted with dichloromethane (2 × 30 mL). The organic phases were dried and evaporated, and the residue chromatographed on silica gel; elution with dichloromethane–acetone (92:8) gave the crude product, which was recrystallized from dichloromethane–acetone to yield colourless needles of the dimethyl ether, 45 mg (41%), mp 250–252°C; ν_{max} (KBr): 1745, 1718, 1650, 1600 cm^{-1}; λ_{max} (CH_2Cl_2): 320 (4.06), 292 (4.16), 276 (4.29), 234 nm (4.04); ^{1}Hmr ($CDCl_3$): 7.59 (1H, s, 10-H), 6.14 (1H, s, 3-H), 4.08 (3H, s, OMe), 3.99 (3H, s, OMe), 3.97 (3H, s, OMe), 2.37 (3H, s, Me); ^{13}Cmr, see Table 5; ms, *m/z* (relative intensity): 346 (M^+, 39), 328 (60), 275 (100), 243 (94), 216 (40), 188 (90), 158 (39), 117 (30). *Anal.* calcd. for $C_{17}H_{14}O_8$: C 58.96, H 4.08%; found: C 58.71, H 3.97%.

Lateropyrone acetate 4

Lateropyrone (30 mg) in acetic anhydride (30 mL) was treated with 70% perchloric acid (3 drops) and left until dissolution was complete. Ice was added and the mixture boiled to decompose excess anhydride. The solution was extracted with dichloromethane, the extracts dried and evaporated. The residue was triturated with water, and the resulting acetate recrystallized from dichloromethane–hexane, mp 271–273°C; ν_{max} (KBr): 3100–2300 (br), 1770, 1750, 1727, 1650, 1610 cm^{-1}; λ_{max} (CH_2Cl_2): 352 (4.02), 328 (4.16), 313 (4.04), and 274 nm (4.43); ^{1}Hmr ($CDCl_3$): 14.68 (1H, s, COOH), 6.96 (1H, s, 10-H), 6.24 (1H, s, 3-H), 3.91 (3H, s, OMe), 2.44 (6H, s, 2-Me and OAc); ms, *m/z* (relative intensity): 360 (M^+, 2), 318 (74), 259 (56), 202 (100), 174 (37), and 134 (28).

Microbiological screening

	Lateropyrone **1**	Dimethyl derivative **2**	Ampicillin
E. coli W3110	×	×	√
S. aureus 3538P	√	×	√
C. albicans 10231	√	×	×

X-ray

The colourless needle-shaped crystal was mounted on a glass fibre in the direction of its greatest length, and photographed using Weissenberg and precession cameras with CuK_α radiation. The symmetry was found to be monoclinic and an approximate unit cell was established. The crystal was then transferred to a Picker 4-circle diffractometer using MoK_α radiation and automated with a PDP-11/10 computer, on which all further work was done. The unit cell was refined by least squares from 12 pairs of reflections (at ±2θ) in the range 2θ = 11–39°. The crystal data are:

$C_{17}H_{14}O_8$ Mol. wt. 346.29

Space group $P2_1/c$ (No. 14), a = 9.663(4), b = 22.317(9), c = 7.747(5) Å, β = 113.03(4)°, V = 1538(1) Å^3, T = 25°C, Z = 4 molecules per cell, D_{meas} = 1.477 g cm^{-3} (flotation in CCl_4/*m*-xylene), D_{calc} = 1.496 g cm^{-3}, λ = 0.71069 Å, μ = 1.299 cm^{-1}, needle length 0.98 mm, cross section 0.086 × 0.090 mm, no absorption correction applied. Intensity measurements were done for 1 quadrant ($k,l \geq 0$) in the range 2θ = 0–50°, using a stepped scan of 120 steps of 0.01° in 2θ counting for 0.40 s per step. Background counting was for 24 s at each end of the scan. A set of standards 300;

*In all cases, the numbering used conforms to that used for the same carbons as in the lateropyrone nucleus.
†Assignments may be reversed.
‡Assignments may be reversed.

0,10,0; 002 were measured before each batch of 50 reflections. 3222 measurements consisting of 195 standards and 3027 reflections were obtained. Lorentz and polarisation corrections were applied and equivalent measurements were averaged to obtain a final file with 2177 entries. 611 reflections having $I < 2.5\sigma(I)$ were suppressed in the subsequent calculations.

Structure solution and refinement

The programs used were SHELX-76 by G. M. Sheldrick (26), and ORTEP (27). The atomic scattering factors were those given in the SHELX-76 program (26, 28). The structure was solved using direct methods, and refined by standard Fourier synthesis techniques and by least squares minimizing $\Sigma w\Delta^2$ (where w is a weight derived from the counting statistics, $w = 1/(\sigma^2(F) + 0.001F^2)$, and $\Delta = ||F_o| - |F_c||$). Initially carbon atomic scattering factors were used for all the ring atoms. O(4) and O(10) were identified as the oxygen atoms by abnormally low temperature parameters and by the clear detection of hydrogen atoms H(2) and H(6). The hydrogen atoms of the methoxy and ester groups were placed at their calculated positions (C—H = 1.08 Å). The hydrogen atoms of the C(31) methyl group were first calculated, and then the group as a whole was refined as a rigid body. The hydrogen atoms were treated as isotropic scatterers, and the heavier atoms were allowed the freedom of anisotropic thermal motion. U_{iso} was refined for those hydrogen atoms whose positional coordinates were refined. The hydrogen atoms fixed at calculated positions were assigned U_{iso} values of 0.05 Å^2. H(2) and H(6) were relatively well determined. The final residuals were $R = 0.0543$, $R_g = \sqrt{(\Sigma w\Delta^2/\Sigma wF_o^2)} = 0.0835$. The convergence was good with the final maximum (shift/esd) = 0.10. The final difference map had no important features, maximum 0.27 e Å^{-3}, minimum -0.33 e Å^{-3}. The number of measurements, 2100, was sufficient to determine the 241 parameters well. Supplementary Tables containing hydrogen atom parameters, anisotropic thermal parameters, bond angles involving hydrogen atoms, selected intermolecular distances, and observed and calculated structure amplitudes have been deposited.[5]

Synthesis of ^{18}F-labelled 2-fluoroethyl-nitrosoureas[1]

SIMIN FARROKHZAD, MIRKO DIKSIC,[2] LUCAS Y. YAMAMOTO, AND WILLIAM FEINDEL
Montreal Neurological Institute and Department of Neurology and Neurosurgery, McGill University, Montreal, P.Q., Canada H3A 2B4

Received January 25, 1984

SIMIN FARROKHZAD, MIRKO DIKSIC, LUCAS Y. YAMAMOTO, and WILLIAM FEINDEL. Can. J. Chem. **62**, 2107 (1984).

^{18}F-labelled 1,3-bis-(2-fluoroethyl) nitrosourea (^{18}F-BFNU) (**9**) and 1-(2-chloroethyl)-3-(2-fluoroethyl) nitrosourea (^{18}F-CFNU) (isomeric mixture, **11**,**12**) were synthesized by nucleophilic attack of ^{18}F-labelled tetra-n-butylammonium fluoride on the aziridine ring of 1,3-substituted ureas. Diethyleneurea (DEU) (**5**), 1-(2-fluoroethyl)-3-ethyleneurea (FEU) (**7**), and 1-(2-chloroethyl)-3-ethyleneurea (CEU) (**14**) were used as starting materials in the synthesis. Nitrosation of ^{18}F-labelled 1,3-bis-(2-fluoroethyl) urea (^{18}F-BFU) (**6**) produced ^{18}F-BFNU with a radiochemical yield of 5–10%. Nitrosation of ^{18}F-labelled 1-(2-chloroethyl)-3-(2-fluoroethyl) urea (^{18}F-CFU) (**15**) gave ^{18}F-CFNU as a mixture of two isomers. Geometrical isomers of CFNU were separated by hplc, and the radiochemical yield of the two isomers ranged from 8% to 15%, with a radiochemical purity exceeding 96%. Syntheses, which took about 60 min, yielded products with specific activity of 680 mCi/mmol when n-$Bu_4N^+F^-$ was used, or 300 mCi/mmol when HF was used to complete the opening of the aziridine ring.

SIMIN FARROKHZAD, MIRKO DIKSIC, LUCAS Y. YAMAMOTO et WILLIAM FEINDEL. Can. J. Chem. **62**, 2107 (1984).

On a réalisé la synthèse des bis(fluoro-2 éthyl)-1,3 (^{18}F-BFNU) (**9**) et (chloro-2 éthyl)-1 (fluoro-2 éthyl)-3 (^{18}F-CFNU) (mélange d'isomères, **11**,**12**) nitrosourées marquées au ^{18}F en faisant appel à une attaque nucléophile du fluorure de tétra n-butylammonium, marqué au ^{18}F, sur le cycle aziridine d'urées substituées en 1,3. On a utilisé les diéthylène (DEU), (**5**), (fluoro-2 éthyl)-1 éthylène-3 (FEU), (**7**) et (chloro-2 éthyl)-1 éthylène-3 urées (CEU), (**14**) comme produits de départ pour ces synthèses. La nitrosation de la bis(fluoro-2 éthyl)-1,3 urée marquée au ^{18}F (^{18}F-BFU), (**6**) conduit au ^{18}F-BFNU avec un rendement radiochimique de 5 à 10%. La nitrosation de la (chloro-2'éthyl)-1 (fluoro-2 éthyl)-3 urée marqué au ^{18}F (^{18}F-CFU), (**15**) conduit au ^{18}F-CFNU sous forme de mélange de deux isomères. On a séparé les isomères géométriques du CFNU par clhp et le rendement radiochimique des deux isomères varie de 8 à 15% alors que leur pureté radiochimique dépasse 96%. Les synthèses, qui prennent environ 60 min, fournissent des produits dont l'activité spécifique est respectivement de 680 ou 300 mCi/mmol suivant que l'on utilise du n-$Bu_4N^+F^-$ ou du HF pour compléter l'ouverture de l'aziridine.

[Traduit par le journal]

Introduction

Nitrosoureas such as 3-cyclohexyl-1-(2-chloroethyl)-1-nitrosourea (CCNU), 1,3-bis-(2-chloroethyl) nitrosourea (BCNU), and 3-(4-methylcyclohexyl)-1-(2-chloroethyl)-1-nitrosourea (MeCCNU) are used to treat patients with malignant brain tumors, including brain gliomas (1–4). Even after numerous studies, however, the pharmacokinetics and mode of action of these drugs remain unknown (5–7). The distribution of these 2-chloroethylnitrosoureas and their breakdown products is of particular importance if we are to understand their oncologenic activity.

The Sloan–Kettering group labelled several nitrosoureas with ^{13}N (8) and then studied their in vivo decomposition and the radioactivity tissue distribution after intravenous injection (9). In an attempt to determine the in vivo distribution of BCNU we recently labelled BCNU with ^{11}C in the carbonyl group (10) and with ^{13}N in the nitroso group (11), and studied their metabolic decomposition. We also studied their behaviour in human brain tumors using positron emission tomography (PET) (28) and in the animal brain tumor model by tissue sampling (29).

However, since it was difficult to evaluate the complete pharmacokinetics of BCNU using only these two compounds (^{13}N- and ^{11}C-labelled BCNU), we synthesized the analog of BCNU, 1,3-bis-(2-fluoroethyl)nitrosourea (BFNU) (**9**), and 1-(2-chloroethyl)-3-(2-fluoroethyl) nitrosourea (CFNU) (isomers **11** and **12**), both labelled with positron-emitting fluorine-18. Because of the longer half-life of fluorine-18 ($t_{1/2}$ = 110 min) as compared to the other positron emitting radionuclides (^{11}C $t_{1/2}$ = 20 min and ^{13}N $t_{1/2}$ = 10 min), we believed it would be more convenient to study the decomposition of these BCNU analogs into 2-haloethyldiazonium hydroxide and 2-haloethylisocyanate, and try to correlate the results with the decomposition of BCNU into 2-chloroethyldiazonium hydroxide and 2-chloroethylisocyanate (12, 13). The mixture of ^{18}F-CFNU isomers is particularly interesting, since one part of each molecule is identical with BCNU, and the other with BFNU. Since the nitroso group is present on different sides of the CFNU molecule, after decomposition it would give two different fragments carrying the ^{18}F-label, therefore providing information about both fragments of nitrosourea molecules. By using labelled fluorine attached to the ethylene group, we might also obtain information on the interstrand crosslinking of related nitrosoureas with DNA (14, 15). Since these BCNU analogs themselves have antitumor properties (16, 17) their pharmacokinetics is also of interest to us.

This report describes the synthesis of ^{18}F-labelled 1,3-bis-(2-fluoroethyl) nitrosourea (**9**) (Fig. 2) and 1-(2-chloroethyl)-3-(2-fluoroethyl) nitrosourea (geometrical isomers **11** and **12**) (Fig. 3) via nucleophilic attack of fluoride on the aziridine ring of 1,3-substituted ureas as well as through heterogenous exchange of chloride with fluoride. The synthesis described here represents a new approach to the preparation of these nitrosoureas. Since the synthesis for "cold" material described in the literature does not allow introduction of an ^{18}F-label into the molecule (16), a new technique was definitely needed.

Materials and methods

Research purity chemicals used in this work were obtained from regular suppliers. Dimethyl sulfoxide (DMSO) was dried by distillation over calcium hydride and stored over 4 Å molecular sieves

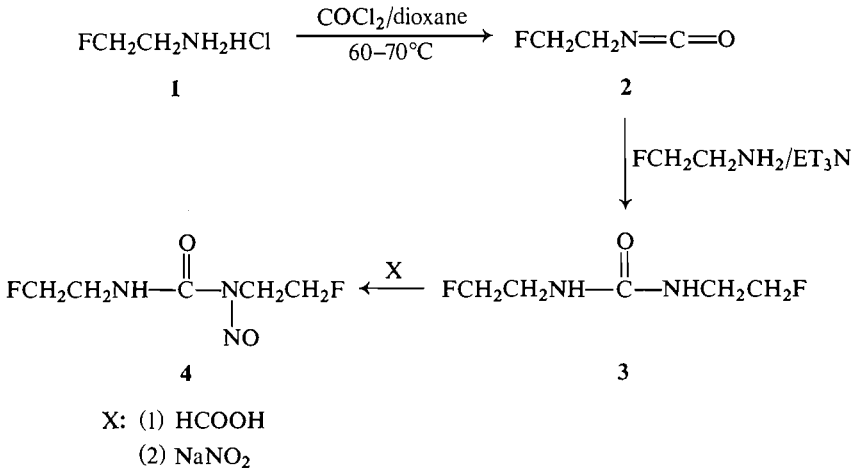

FIG. 1. Synthesis of unlabelled 1,3-bis-(2-fluoroethyl) nitrosourea (BFNU) (**4**).

activated at 110°C. Melting points were determined in a conventional melting apparatus and are reported uncorrected.

The infrared spectra (ir) were recorded in chloroform or film (oil) on a Perkin–Elmer 297 spectrophotometer. Proton nuclear magnetic resonance spectra (^{1}H nmr) were obtained in acetone-d_6 or chloroform-d on a Varian XL-200 or a Varian-60A spectrometer at 200 MHz and 60 MHz respectively, using tetramethylsilane as an internal standard. The ^{19}F nmr spectra were recorded on a Bruker WP-80SY spectrometer at 75.386 MHz. These spectra were also obtained in chloroform-d by using trichlorotrifluoroethane (with a chemical shift of −82.204 ppm) as an external standard. The notation used for the identification of nmr spectra is: s = singlet, d = doublet, t = triplet, dt = doublet of triplet, m = multiplet, dm = doublet of multiplets, bs = broad singlet. Mass spectra (ms) were determined on an HP 5980A mass spectrometer at 70 eV.

Thin-layer chromatograms (tlc) and thin-layer radiochromatograms (tlrc) were developed on hard layer silica gel plates with a fluorescent indicator (254 nm) by using appropriate solvent mixtures. A chloroform–acetone mixture was used for ureas, and an ether–hexane mixture for nitrosoureas. Ureas were detected by examining plates under ultraviolet light after spraying them with sodium nitrite and formic acid (99%), and then heating to 90°C (18). The nitrosoureas were visualized by spraying with Griess reagent,[3] which is specific for nitroso compounds. The hplc separations were performed on a Partisil-10 PAC-column.[4] The silica gel (mesh 40–140)[5] was used for flash chromatography instead of 230–400 mesh used in the original method (19). In the work-up procedures for various syntheses, unless otherwise noted, the solvents were removed with a rotary evaporator under reduced pressure (0.3 Torr; 1 Torr = 133.3 Pa) at a bath temperature of 80°C.

1,3-Diethyleneurea prepared by a procedure described in the literature (20) from ethylenimine (aziridine) (21) and phosgene in the presence of triethylamine was identified by nmr, ir, and ms spectroscopy; ir (Nujol), ν: 1680 (C=O), 1350, 1255, (C—N) cm^{-1}; ^{1}H nmr ($CDCl_3$), δ: 2.01 (s, 8H) ppm; ms, *m/e* (relative intensity); 112 (2.8, M^+), 70 (23.1).

The specific activity of the final radiopharmaceuticals was determined by measuring the radioactivity in an isotope calibrator and dividing it by the absolute amount of BFNU. The absolute amount of BFNU was measured by hplc, by comparing the responses of the uv detector at λ = 236 nm to standards of known concentration and BFNU samples. In the synthesis where no HF was added, the specific activity of ^{18}F-F_2 was measured as described earlier (23).

Since the data published on proton nmr is inadequate and no data has been published on fluorine nmr, we have provided this information for the ureas and nitrosoureas described here.

(a) *Synthesis of 2-fluoroethylisocyanate (2) (Fig. 1)*

A suspension of 2-fluoroethylamine hydrochloride (**1**) (400 mg, 4 mmol) in 15 mL dioxane was heated to 60°C, and phosgene gas was slowly bubbled through the suspension for 15 min. (A similiar procedure was reported for the synthesis of 2-chloroethylisocyanate (22).) The reaction mixture was stirred at 65°C for an additional 30 min. The excess of phosgene was removed by flushing it with nitrogen, and unreacted fluoroethylamine hydrochloride was filtered off. The 2-fluoroethylisocyanate was used without further purification in the subsequent step. The presence of isocyanate was confirmed by ir (ν: 2275 cm^{-1}) as well as by the reaction performed in the subsequent step.

(b) *Synthesis of 1-(2-fluoroethyl)-3-ethylene urea (FEU) (7)*

A solution of aziridine (344 mg, 8 mmol) in dioxane (1 mL) containing triethylamine (2.1 g, 21 mmol) was added dropwise to a stirred solution of 2-fluoroethylisocyanate (**2**) in dioxane, prepared as described above, and kept in a 0°C bath for 20 min. The insoluble white precipitate of triethylammonium hydrochloride was filtered off. (Since 2-fluoroethylisocyanate from the previous step was not purified, the HCl produced in this step precipitated as triethyleneammonium hydrochloride.) After evaporation of the solvent, a mixture of FEU (**7**) and 1-(2-fluoroethyl)-3-(2-chloroethyl) urea (CFU) (**8**) in a ratio of 9:1 was obtained as a colorless oil. This was used without further purification for the preparation of BFU (**3**). The ^{1}H nmr ($CDCl_3$) of FEU (**7**), δ: 2.13 (s, 4H, aziridine group), 3.47 (dm, 2H, —CH_2—NH, $^3J_{HF}$ = 27.6 Hz), 4.47 (dt, 2H, —CH_2—F, $^2J_{HF}$ = 47.6 Hz, $^3J_{HH}$ = 4.8 Hz), 6.74 (bs, 1H, N—H) ppm; ms, *m/e* (relative intensity); 132 (0.5, M^+), 113 (0.8), 99 (1.8), 90 (4.7).

(c) *Synthesis of 1-(2-chloroethyl)-3-(2-fluoroethyl) urea (CFU) (8)*

2-Chloroethylisocyanate (**13**) (211 mg, 2 mmol) in dioxane (0.5 mL) was added dropwise to a mixture of 2-fluoroethylamine hydrochloride (**1**) (199 mg, 2 mmol) and triethylamine (303 mg, 3 mmol) in dioxane (4 mL), and kept in a 0°C bath. The reaction mixture was stirred at 50–60°C for 30 min, then at room temperature for an additional 3 h. After removal of triethylamine hydrochloride by filtration and evaporation of the solvent under reduced pressure, pale yellow crystals were obtained, which were recrystallized from chloroform–hexane (1:12) in a 50% yield; mp 94–95°C (lit. (16) mp 94–96°C); ^{1}H nmr ($CDCl_3$), δ: 3.51 (m, 6H, —CH_2 groups), 4.45 (dt, 2H, —CH_2F, $^2J_{HF}$ = 47.6 Hz, $^3J_{HH}$ = 4.7 Hz), 5.89 (bs, 2H, for

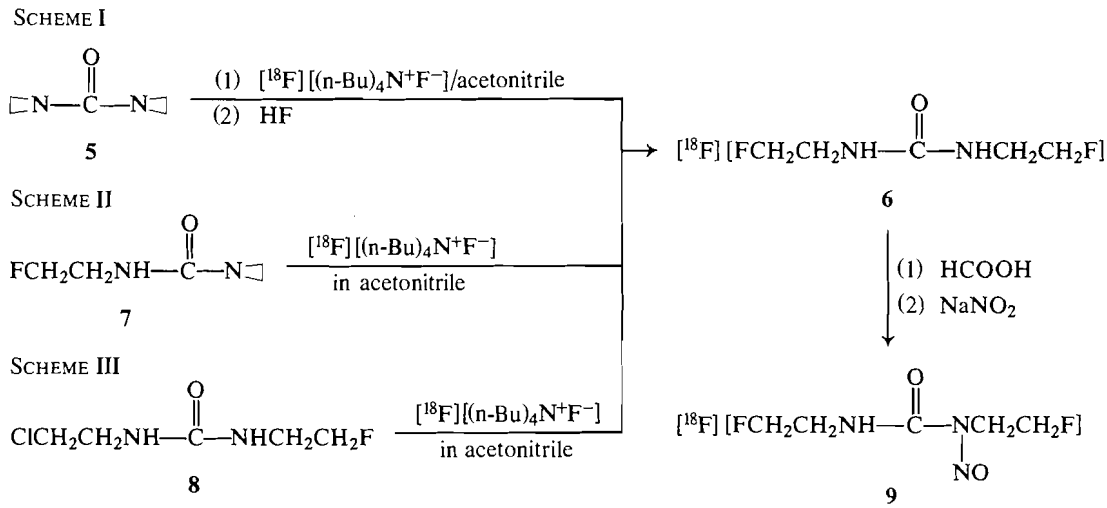

FIG. 2. Synthesis of ^{18}F-labelled 1,3-bis-(2-fluoroethyl) urea (^{18}F-BFU) (**6**) and ^{18}F-labelled 1,3-bis-(2-fluoroethyl) nitrosourea (^{18}F-BFNU) (**9**).

two NH groups) ppm; ms, *m/e* (relative intensity); 169 (0.5, M^+), 136 (0.3), 133 (0.9), 106 (1.3), 63 (22.4).

(d) *Synthesis of ^{18}F-BFU (6) (Fig. 2)*

^{18}F-F_2 was produced through a (d, α) reaction on ^{20}Ne in a nickel target containing a mixture of 0.5% F_2 in research purity neon (23). At the end of the irradiation, gas was bubbled through the reaction mixture, which contained tetra-n-butylammonium hydroxide (19.6 mg, 0.07 mmol) in water (6 mL) where F_2 reacted with water and /(or) hydroxide anion and water yielding $[^{18}F]F^-$. Evaporation of the solvent under reduced pressure (0.3 Torr) at 60°C gave a white solid residue that was dried by using acetonitrile (3 mL) (twice) and benzene (3 mL). The dry ^{18}F-labelled tetra-n-butylammonium fluoride was then dissolved in acetonitrile (2 mL) and added to DEU (**5**), FEU (**7**), or CFU (**8**) (0.1–0.2 mmol) in the presence of catalytic amounts of 18-crown-6 ether, a compound known to influence the nucleophilic activity of fluoride (24). The reaction vial was closed and heated in an oil bath at 145°C for 20 min. Evaporation of the solvent under reduced pressure gave white crystals that were treated with chloroform and washed with a potassium fluoride solution (0.1 *M*) and water. After drying the chloroform layer with sodium sulphate it was evaporated to dryness under reduced pressure.

When DEU (**5**) was used as the aziridine-containing compound, after evaporation of chloroform it was stirred with 0.5 mL HF (14 *M*) for 6 min to complete the opening of the aziridine ring. Partial opening of the aziridine ring was confirmed by tlc. After removing the acid solution, a sample of the product was examined by thin-layer radiochromatography (silica gel, solvent acetone–chloroform (1:2)). The major radioactivity present in the reaction mixture had the same R_f value (0.45) as that of authentic BFU (**3**). The product was used without further purification in the subsequent step. The yield of BFNU was not changed when nucleophilic substitution was made in acetonitrile without any crown ether, but by-products were detected on tlc. This complicated the purification of ^{18}F-BFNU.

(e) *Synthesis of BFU (3) (Fig. 1)*

Unlabelled BFU (**3**) (Fig. 1) was prepared from 2-fluoroethylisocyanate (**2**) as follows: to a stirred solution of 2-fluoroethylisocyanate (**2**) (prepared as described earlier) and 2-fluoroethylamine hydrochloride (**1**) in dioxane kept at 0°C, 8 mL of water and 2 mL of triethylamine were added dropwise. The reaction mixture was maintained at room temperature for 1 h. Triethylamine hydrochloride formed during the reaction was removed by filtration. After evaporation of the solvent under reduced pressure, the colorless oil was purified by flash chromatography (chloroform–acetone, 4:1). The white solid residue was then further purified by recrystallization from ethanol. The yield of BFU (**3**) as white needles was 200 mg (65%), mp 139–141°C (lit. (16) mp 141°C). The product was identified by ^{1}H nmr and ms spectroscopy; ^{1}H nmr (acetone-d_6), δ: 3.42 (dm, 4H, CH_2—NH, $^3J_{HF}$ = 26.61 Hz), 4.43 (dt, 4H, CH_2F, $^2J_{HF}$ = 47.66 Hz, $^3J_{HH}$ = 5.1 Hz) ppm; ms, *m/e* (relative intensity): 152 (14.6, M^+), 119 (24.6), 86 (4.7), 47 (100).

Unlabelled BFU was also prepared from DEU (**5**) by the method described earlier for preparing ^{18}F-labelled BFU (**6**). For this synthesis we used DEU (**5**) (55 mg, 0.5 mmol), dry tetra-n-butylammonium fluoride (379 mg, 1.2 mmol), and a catalytic amount of 18-crown-6 ether in acetonitrile (1.5 mL). The product was identified by ^{1}H nmr. Thin-layer chromatography on silica gel in acetone–chloroform (1:2) as a developing solvent gave R_f 0.45. The ^{1}H nmr spectra and the R_f value of the product were identical with those of a sample prepared from 2-fluoroethylamine hydrochloride (**1**) and 2-fluoroethylisocyanate (**2**). The product was used without further purification in the nitrosation reaction.

(f) *Synthesis of ^{18}F-BFNU (9) (Fig. 2)*

^{18}F-BFU (**6**) prepared in a previous reaction was dissolved in 99% formic acid (1 mL) at 0°C. Sodium nitrite (69 mg, 1 mmol) dissolved in water (0.2 mL) was added dropwise to this solution and stirred for 5 min. The final product (BFNU) (**9**) was extracted with chloroform, and the chloroform layer washed with water and dried over sodium sulphate. The ^{18}F-BFNU was purified by hplc using an ether–hexane mixture (1:1) as the solvent on a Partisil-10 PAC-column. ^{18}F-BFNU was eluted after 4 min, with an elution volume of 8 mL. The R_f 0.6 of ^{18}F-labelled BFNU, using tlc on silica gel with ether–hexane (7:3), was identical to the BFNU (**4**) sample prepared from 2-fluoroethylamine hydrochloride (**1**), as explained later in this paper. Both values were identical to those of an authentic sample of BFNU. The synthesis time was about 40 min after the end of the fluorine collection, and the radiochemical yield for the total synthesis of BFNU was between 5% and 10%.

The unlabelled BFNU (**4**) (Fig. 1) was prepared as follows: a solution of sodium nitrite (69 mg, 1 mmol) in water (0.2 mL) was added dropwise to a cold (0°C) stirred solution of BFU (**3**) (16 mg, 0.5 mmol) in 99% formic acid (1.5 mL) (16). The reaction was stirred at 0°C for 40 min. The work-up procedure was the same as that described for ^{18}F-BFNU. Evaporation of the solvent yielded BFNU, which was purified by hplc (ether–hexane, 1:1). Yield 63 mg (70%), mp 30–34°C (lit. (16) mp 30–34°C); ir (film), *v*: 1725 (C=O) and 1532 (C—NH) cm^{-1}; ^{1}H nmr ($CDCl_3$), δ: 3.82 (dm, 2H, CH_2F—CH_2—NH, $^3J_{HF}$ = 27.37 Hz), 4.21 (dm, 2H, —CH_2—N—NO, $^3J_{HF}$ = 22.7 Hz, $^3J_{HH}$ = 5.11 Hz), 4.43 (d of semi t, 2H, CH_2F—CH_2—N—NO—, $^2J_{HF}$ = 46.85 Hz, $^3J_{HH}$ = 5.10 Hz), 4.63 (dt, 2H, CH_2F—CH_2—NH, $^2J_{HF}$ = 47.12 Hz, $^3J_{HH}$ = 4.8 Hz)

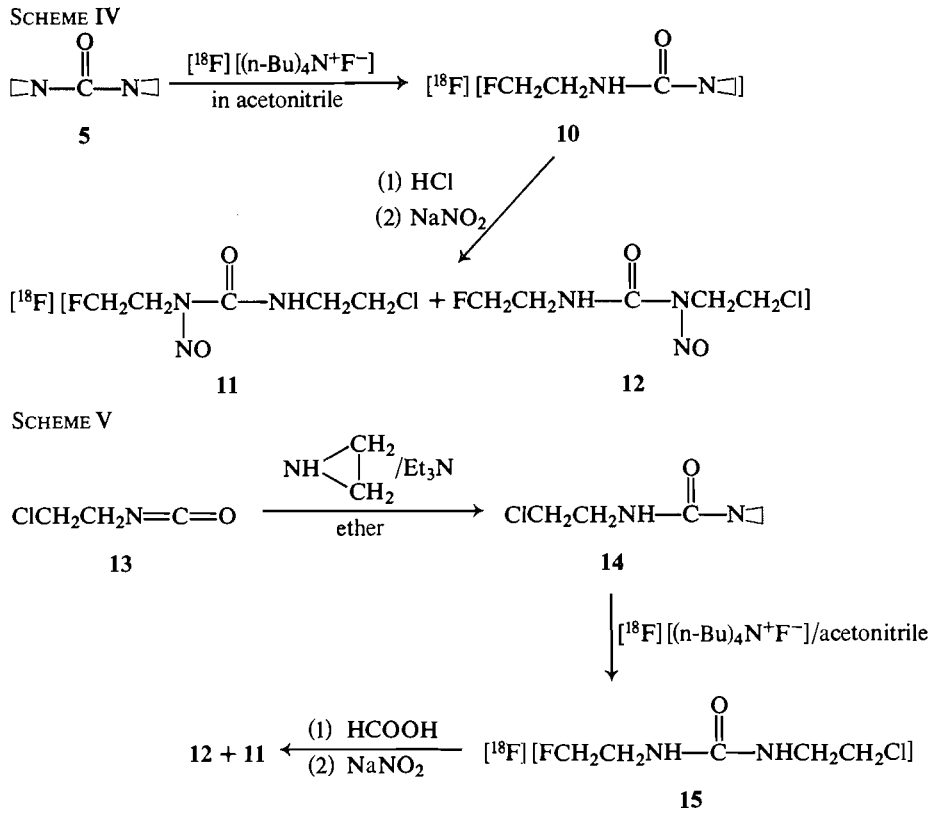

FIG. 3. Synthesis of ^{18}F-labelled 1-(2-chloroethyl)-3-(2-fluoroethyl) nitrosoureas (^{18}F-CFNU) (isomer mixtures **11** and **12**).

ppm; ^{19}F nmr ($CDCl_3$), ϕ: −230.47 (s, 1F, FCH_2CH_2NH), ϕ: −230.65 (s, 1F, F—CH_2CH_2—N—NO) ppm.

(g) *Synthesis of ^{18}F-CFNU mixtures (**11** and **12**), from DEU (**5**)*

Anhydrous ^{18}F-labelled tetra-n-butylammonium fluoride was prepared as described earlier and dissolved in 2 mL dry acetonitrile. After DEU (**5**) (11 mg, 0.1 mmol) and a crystal of crown-ether were added, the vial was closed and heated to 100°C for 15 min. Evaporation of the solvent under reduced pressure (60°C, 0.3 Torr) left a solid residue, which was dissolved in hydrochloric acid (12 *M*). The mixture was stirred at room temperature for 5 min. Sodium nitrite (69 mg, 1 mmol) was added to this solution at 0°C and stirred for an additional 5 min. The final product was extracted with chloroform, and the chloroform layer was washed with water and dried over sodium sulfate. After removing the chloroform under reduced pressure, the residue was redissolved in ether (0.4 mL) and injected on hplc (solvent: ether–hexane (1:9), column: Partisil 10-PAC). An elution volume of about 32 mL was obtained for isomer **11**. The 3:1 ratio between **11** and **12** was established by hplc for these two isomers by means of ^{18}F-labelled compounds using radioactivity and uv detectors. However, from ^{1}H nmr the 2:1 ratio for isomers **11** and **12** was obtained; tlrc R_f values of purified isomers, obtained on silica gel in ether–hexane (2:3) as a solvent, were 0.30 for **11** and 0.29 for **12**. The radiochemical yield for isomer **11** ranged from 10% to 15%, and for isomer **12** was 4%–8%.

(h) *Synthesis of CEU (**14**) (Fig. 3)*

To a stirred solution of 2-chloroethylisocyanate (**13**) (1.0 g, 10 mmol) in ether (3 mL) was added dropwise a solution of aziridine (473 mg, 11 mmol) in ether (2 mL). The mixture was kept in a 0°C bath for 30 min. Evaporation of the solvent under reduced pressure gave an 82% yield of CEU (**14**), which was used without further purification in the subsequent step; ^{1}H nmr (acetone-d_6), δ: 3.1 (s, 4H, aziridine group), 3.5 (m, 4H, —CH_2—CH_2—), 6.1 (bs, 1H, —N—H) ppm.

(i) *Synthesis of ^{18}F-CFNU (isomers mixture) from CEU (**14**)*

Dry ^{18}F-labelled tetra-n-butylammonium fluoride prepared as described earlier in this paper was added to CEU (**14**) (14.9 mg, 0.1 mmol) and a crystal of crown ether dissolved in acetonitrile (2 mL). The reaction was carried out in a closed vial at 120°C for 15 min. After removing the solvent under reduced pressure, the residue was dissolved in 99% formic acid (1 mL). A solution of sodium nitrite (69 mg, 1 mmol) in water (0.2 mL) was added to this mixture at 0°C and stirred for 5 min. The procedure, purification of the final product (CFNU isomer mixtures **11** and **12**), and the radiochemical yield of isomers were the same as described for preparation of ^{18}F-CFNU in paragraph (g). An example of hplc radiochromatogram of ^{18}F-CFNU isomers mixture is shown in Fig. 4.

Results and discussion

For the first time, a nucleophilic attack of ^{18}F-labelled tetra-n-butylammonium fluoride on an aziridine ring (Scheme I and II, Fig. 2), or nucleophilic displacement of chloride in CFU (**8**, Scheme III, Fig. 2) in acetonitrile (an aprotic solvent), has been used in the synthesis of ^{18}F-labelled ureas/nitrosoureas. The reactions reported here were done in the presence of 18-crown-6 ether (24). In the experiments reported here the use of crown ether did not significantly increase the yield in any of the reactions. However, it should be noted that absence of crown ether resulted in side products in the synthesis of ^{18}F-BFU, complicating purification of ^{18}F-BFNU. Since the nucleophilic substitution investigated in this work was done on ureas and $(n\text{-}Bu)_4N^+F^-$ was used, our observations on the usefulness of crown ether in the nucleophilic reactions may not be conclusive. All three reactions (Fig. 2) examined in this work had approximately the same radiochemical yield, purification procedure, and complexity of synthesis. Because of the HF used in the synthesis, ^{18}F-BFNU derived from DEU (**5**) (Scheme I, Fig. 2) had the lowest specific activity. However, if a high specific activity is not required, this is the method of choice, since the starting material has great shelf stability and

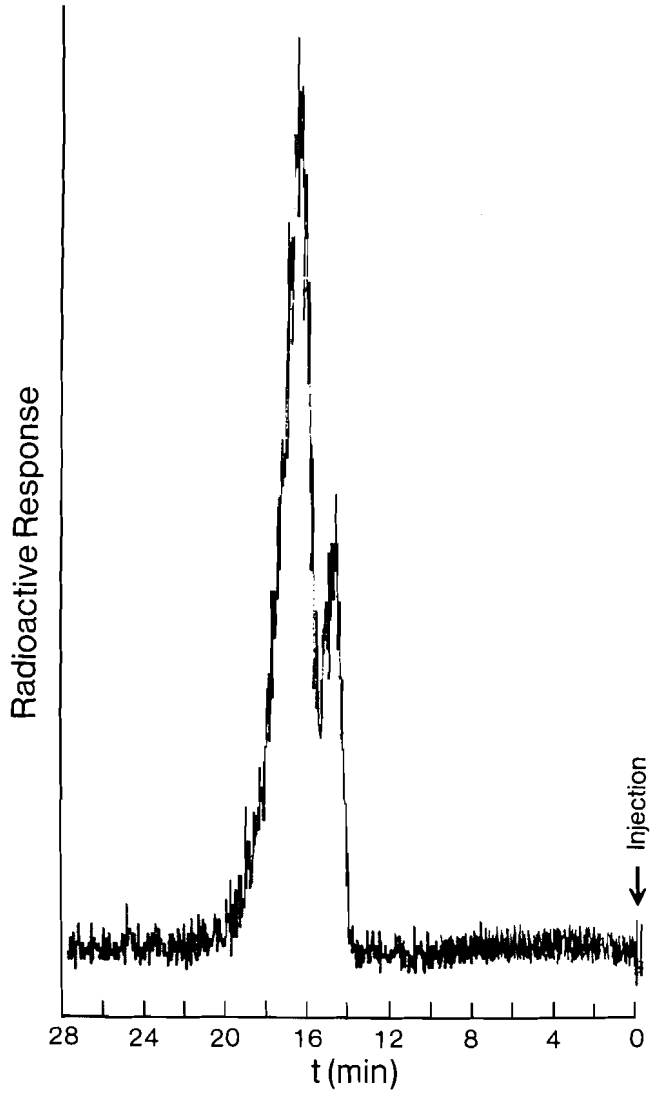

FIG. 4. The hplc chromatogram of ^{18}F-labelled 1-(2-chloroethyl)-3-(2-fluoroethyl) nitrosourea (^{18}F-CFNU) (isomers **11** and **12**) on a Partisil 10-PAC column with ether–hexane (1:9) as solvent.

the radiochemical yield is always slightly higher than that of the other two syntheses.

The synthesis of BFU (**3**) as described in the literature (16) uses a reaction of 2-fluoroethylamine hydrochloride with 3-(2-fluoroethyl)-1-methyl-1-nitrosourea in water in the presence of 50% aqueous sodium hydroxide. The nitrosation with solid sodium nitrite in hydrochloric acid gave BFNU in an overall chemical yield of about 33% (16). Although this reaction has a higher chemical yield than the one we used, it cannot be used in the synthesis of an ^{18}F-labelled compound because it does not allow introduction of the ^{18}F-label into the molecule of BFU.

Radiochemical yields are marginally better in the syntheses of CFU/CFNU (Schemes IV and V, Fig. 3) than in the synthesis of ^{18}F-BFU/BFNU. The only difference between the two syntheses (CFU/CFNU and BFU/BFNU) is the presence of chlorine in the compound used for introduction of ^{18}F into the molecule, which indicates that fluoride opens the aziridine ring more easily when chlorine is already present in the molecule (comparison of Scheme II, Fig. 2 and Scheme V, Fig. 3). It also seems that the introduction of chloride into compound **10** (Scheme IV, Fig. 3) results in a better yield than does nucleophilic opening of the aziridine ring with fluoride (Scheme II, Fig. 2).

The ^{1}H and ^{19}F nmr spectra of alkylureas had narrow line widths; it was therefore relatively easy to explain and identify the chemical shifts as well as to obtain all the coupling constants. However, the introduction of the nitroso group complicates both types of spectra with many coupling constants. It is only through computer simulation[6] that chemical shifts have been explained and coupling constants deduced for all nitrosoureas. This complexity is probably one of the reasons why the nmr spectra of BFNU have not been described in the literature. The methylene group adjacent to fluorine on the nitroso side resonates at a higher field than does the same group on the NH side. The geminal H—F coupling constant on the side of the nitroso group is slightly lower than on the NH side, indicating the influence of the electron-withdrawing nitroso group. The influence of the nitroso group is clearly evident in the magnitude of the vicinal H—F coupling constants (see Materials and methods), where the constant on the side of the nitroso group is smaller. It was possible to simulate ^{1}H- and ^{18}F-spectra by computer,[6] with identical coupling constants and chemical shifts. Infrared spectroscopy of BFNU in Nujol oil shows absorption at 1725 cm^{-1}, for C=O stretch. This agrees with results reported earlier (16). Mass spectra gave M^+ with the relative intensity of 0.1%.

The ^{1}H and ^{19}F nmr spectra of CFU were also identifiable because they contained those resonances found in the spectra of BCU and BFU. The nmr spectra of the mixture of nitroso isomers **11** and **12** are complex, because they contain all resonances of BCNU and BFNU. Fortunately there was little overlap of the peaks, allowing us to identify corresponding chemical shifts and coupling constants. Chemical shifts and coupling constants for the part of the molecule identical to that of BCNU are given in ref. 25, and those for the part of the molecule identical to that of BFNU are given in this paper. From ^{1}H and ^{19}F nmr spectra we concluded that neither side of the CFNU molecule, respective to the carbonyl group, influences the chemical shift and coupling constants on the other side. Both geminal and vicinal coupling constants for all nitrosoureas described here agree well with the published values for such constants (26).

The ratio between isomers **11** and **12** is different when determined from hplc chromatograms and ^{1}H nmr spectra. Reasons for this discrepancy might be found in the complexity of the ^{1}H nmr spectra as well as in the partial separation obtained by hplc. Our ratio for isomers **11** and **12** differs from the 1:1 ratio reported by Johnston *et al.* (16), who did not describe how they measured this ratio. However, they nitrosated in concentrated hydrochloric acid with solid sodium nitrite, which might influence the ratio of the two isomers.

^{18}F-labelled CFNU isomers, when used in in vivo studies, could give us valuable information about the fate of the decomposition fragments. One side of the molecule might behave like the BCNU molecule, while the other side would carry the ^{18}F-label and behave as BFNU, giving us information about both drugs. The latter fragment might be easier to follow than the same fragment carrying the ^{11}C-label, which is partially lost through the formation of carbamic acid (17). Using ^{18}F-labelled

[6] Computer simulation of the nmr spectra was done by Professor L.D. Colebrooke, Chemistry Department, Concordia University, Montreal, Quebec.

CFNU isomers we should also be able to correlate the amounts of 2-fluoroethanol, 2-fluoroethylamine, and part of the compound decomposing through the isocyanate, and to compare these with the fragments obtained during decomposition of ^{11}C-labelled BCNU, the compound synthesized (10) and used by us in in vivo studies (28, 29).

Conclusion

This paper describes for the first time the synthesis of ^{18}F-labelled BFNU and CFNU, analogs of the chemotherapeutic drug BCNU. Although both syntheses give a rather low yield, a 60-min irradiation with a small medical cyclotron can produce enough ^{18}F-labelled radiopharmaceutical for a human PET study.

These BCNU analogs will be used to study the in vivo pharmacokinetics, and the results obtained with these analogs will be compared to those obtained for BCNU. The yield of the synthesis is around 10%, taking the amount of ^{18}F-F_2 as 100%. Except in the synthesis with HF, where the specific activity was 300 mCi/mmol, the specific activity of nitrosoureas was 680 mCi/mmol, the same as that of ^{18}F-F_2 determined by titration (23).

Acknowledgements

This investigation was supported in part by the National Cancer Institute of Canada, the Medical Research Council of Canada, a Killam Scholarship to Dr. Mirko Diksic, and the Cone Memorial Research Fund of the Montreal Neurological Institute. We are specially grateful to Dr. Victoria Lees for editing several versions of this manuscript. We thank Mr. Stephen Irwin for operation of the medical cyclotron and Mr. Dean Jolly, radiochemist, for his assistance in one stage of the work reported here. The Faculty for Graduate Studies and Research, McGill University, provided financial support toward the purchase of an hplc system.

Heterogeneous permanganate oxidations. 4. The oxidation of sulfides and selenides[1]

N. A. Noureldin, W. B. McConnell, and Donald G. Lee
Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received October 3, 1983

N. A. Noureldin, W. B. McConnell, and Donald G. Lee. Can. J. Chem. **62**, 2113 (1984).

The heterogeneous oxidation of sulfides and selenides by copper(II) permanganate octahydrate or a mixture of potassium permanganate and copper(II) sulfate pentahydrate has been studied. Conditions under which quantitative conversions of the sulfides and selenides to the corresponding sulfones and selenones take place have been determined and an attempt has been made to visualize a mechanism for the reaction.

N. A. Noureldin, W. B. McConnell et Donald G. Lee. Can. J. Chem. **62**, 2113 (1984).

On a étudié l'oxydation hétérogène de sulfures et de sélénures par l'octahydrate du permanganate de cuivre(II) ou par un mélange de permanganate de potassium et du pentahydrate du sulfate de cuivre(II). On a déterminé les conditions qui permettent de transformer quantitativement les sulfures et les sélénures en sulfones et en sélénones et on a essayé de visualiser une mécanisme pour la réaction.

Introduction

The use of heterogeneous reagents in organic synthesis has dramatically increased during the last decade. It has been found that a large number of substitution, elimination, addition, oxidation, and reduction reactions can be achieved by use of insoluble or polymer supported reagents (1, 2). For example, recent publications have described the heterogeneous oxidation of organic compounds by chromyl chloride chemisorbed on silica/alumina (3), pyridinium chlorochromate or dichromate on molecular sieve (4), chromium trioxide on graphite, Celite, or silica gel (5), alumina or silica supported sodium metaperiodate (6), clay supported iron(III) nitrate (7), silver carbonate on Celite (8), polymer supported iodate, periodate, pyridinium dichromate, or hypochlorite (9), and permanganate on a variety of solid supports including molecular sieve (10), alumina (11), silica (12), or bentonite (13).

It has also been observed that permanganate can be used effectively as a heterogeneous oxidant in nonaqueous solvents if it is associated with a hydrated metal cation. For example, copper(II) permanganate octahydrate is an excellent oxidant (14), as are sodium, zinc, and magnesium permanganates (15). Mixtures of potassium permanganate and copper sulfate pentahydrate (16) or other hydrated salts[2] also serve as good, inexpensive heterogeneous oxidants. One of the functions of these added supports is to provide moisture to the system; when the reagents and solvents are carefully dried, reaction takes place very slowly, if at all (17).

The use of permanganate as a heterogeneous oxidant in organic solvents such as hexane or methylene chloride dramatically modifies its selectivity. Whereas it readily attacks carbon–carbon double bonds when used homogeneously (18), permanganate reacts very slowly with alkenes under the conditions described above (15). This property has led to its use as an oxidant for unsaturated alcohols (13, 14).

In a recent mechanism study it was found that although alkenes are not oxidized heterogeneously by permanganate their presence inhibits the oxidation of alcohols (19), presumably by the formation of π-complexes at the reactive sites on the reagent (eq. [1]). Furthermore, the evidence indicates that the oxidation of allylic alcohols is initiated by complexation of the double bond followed by a rearrangement in which

[1] 
the alcohol oxygen also becomes a ligand of the central manganese atom (eq. [2]).

It has also been briefly mentioned in the literature that sulfides can be oxidized heterogeneously to the corresponding sulfones (14, 15). In this paper we wish to describe more fully the oxidation of sulfides and attempt to expose the synthetic potential of the reaction as well as to expand our understanding of the reaction mechanism.

[2] 
Experimental

Materials

Commercial methylene chloride was found to contain impurities which interfered with the reaction. Purification was achieved by treatment with potassium permanganate (along with a small amount of phase transfer agent) for 24 h, followed by distillation. *n*-Hexane (BDH) was used without further purification except that it was treated with sodium metal when anhydrous conditions were required. Hydrated copper permanganate and potassium permanganate were obtained from the Carus Chemical Co. Copper sulfate pentahydrate was obtained from the Fisher Scientific Co. These reagents were dried over phosphorus pentoxide at 0.1 Torr (1 Torr = 133.3 Pa) before use in those experiments requiring anhydrous conditions. The sulfides were obtained commercially and purified by distillation before use. Diphenyl selenide (K&K) was purified by distillation, followed by column chromatography on silica gel using hexane–ether (20:1) as the eluant.

[1] For part 3 of this series see ref. 19.
[2] C. F. Sebastian. Unpublished results.

Yields were calculated as isolated and (or) from gas chromatograms after application of predetermined response factors. Diethylene glycol or Apiezon L on Chromosorb W were used as column packings.

*Oxidation of di-*n*-butyl sulfide*

A mixture of potassium permanganate (1.0 g) and copper sulfate pentahydrate (0.5 g) was added to di-*n*-butyl sulfide (0.36 g, 2.5 mmol), dissolved in 20 mL of *n*-hexane. The reaction mixture was stirred under reflux for 25 h, cooled to room temperature, diluted by addition of 20 mL of ether, and then stirred for another 10 min. This mixture was filtered through Celite and concentrated by flash evaporation. After partial removal of the solvent a sample was withdrawn and injected into the gas chromatograph. Only one product (with a retention time identical to that of authentic di-*n*-butyl sulfone) was detected. Evaporation to dryness gave a solid product (0.43 g, 2.4 mmol, 96%), mp 43–45°C (lit. (20) mp 46°C).

When the experiment was repeated under identical conditions except for the addition of cyclohexene (0.2 g, 2.4 mmol) to the initial mixture the yield was reduced to 7%. When the reaction was completed under anhydrous conditions the yield was reduced to 22%.

Oxidation of diphenyl selenide

A mixture of potassium permanganate (3 g) and copper sulfate pentahydrate (1 g) was added to freshly purified diphenyl selenide (0.5 g, 2.4 mmol), dissolved in 20 mL of *n*-hexane. The reaction mixture was refluxed for 22 h and then filtered through Celite, the inorganic residue being washed thoroughly with ether. The combined filtrates were dried and concentrated, slowly, using a rotary evaporator to give crude diphenyl selenone (0.32 g, 1.2 mmol, 56%) mp 147–149°C. Recrystallization from cold ether gave 0.25 g (0.94 mmol, 44%) of colorless crystals, mp 154–155°C (lit. (21) mp 154.9°C). The inorganic residue was washed with dilute hydrochloric acid and the filtrate, extracted with ether, was in turn washed with water until neutral. After drying, the solvent was evaporated to give 0.16 g of a semi-solid, colorless product with a sharp odour. When analyzed by tlc this residue exhibited several unidentified spots.

Oxidation of pentamethylene sulfide (tetrahydrothiopyran)

Copper permanganate octahydrate (2.0 g) was added to a stirred solution of pentamethylene sulfide (0.25 g, 2.5 mmol) in 15 mL of hexane. The reaction mixture was stirred at room temperature for 1 h and filtered through Celite. The inorganic residue was washed with ether (3 × 10 mL) and the combined organic layers were dried over anhydrous magnesium sulfate, filtered, and evaporated, leaving very pure pentamethylene sulfone (0.31 g, 2.31 mmol, 94%), mp 101.0–101.5°C (lit. (22) mp 98–99°C).

Results and discussion

Alkyl and aryl sulfides and selenides are very easily converted into the corresponding sulfones or selenones when treated with either copper(II) permanganate octahydrate or a mixture of potassium permanganate and copper(II) sulfate pentahydrate. The yields obtained for a number of representative sulfides are summarized in Table 1.

Since it is known that the oxidation of alcohols is inhibited by the complexation of alkenes on the surface of the heterogeneous oxidant (16, 19), it was of interest to also examine their effect on the oxidation of sulfides. The possibility existed that sulfides would compete more effectively with alkenes for attachment at the active sites on the oxidant. However, the experimental results demonstrated that the oxidation of sulfides is also inhibited by the presence of an alkene in the solution. It may therefore be concluded that the equilibrium depicted in eq. [3] must lie to the left. The formation of π-complexes with d^0 transition metals has been described by Sharpless *et al.* (23).

The mode of transfer of oxygen from the oxidant to the substrate, while open to considerable speculation, may be visualized as proceeding by way of the mechanism outlined in

[3] 
Scheme 1. Following the suggestion of Sharpless *et al.* (23), it is assumed that the reaction will be initiated by formation of a coordinate covalent bond between the sulfur and the manganese (step a). The sulfur would thereby acquire a partial positive charge and thus be attracted to an oppositely charged oxygen ligand leading to the formation of a new bond (step b). The intermediate, **1**, is directly analogous to the metallocyclooxetanes, **3**, that are formed during the oxidation of alkenes by permanganate (eq. [4]), the major difference being that a three- rather than a four-membered ring is formed (24, 25). Conversion of **1** into **2** involves migration of the sulfur from manganese to an oxo group, a transformation which is analogous to the migration of carbon from manganese to oxygen during the oxidation of alkenes (step d, eq. [4]). The

[4] 
intermediate **2** is similar to the one which has been proposed by Block to occur during the oxidation of sulfoxides by permanganate (26). It would also be stabilized by the presence of a spectator oxo which has been shown to have a major influence on the course of oxidations by transition metal oxides (24).

This mechanism envisages the conversion of sulfides directly into sulfones without formation of intermediate sulfoxides. Although traces of compounds with retention times identical to those of the corresponding sulfoxides were occasionally noted during analysis of the products by glc, it is not clear if they are intermediates or by-products. However, it was noted that sulfoxides are also readily oxidized under these conditions and it is possible that they could be formed as intermediates and rapidly converted into sulfones, thus preventing their accumulation in the final products. In such a case the reaction could be considered to proceed by way of path c in Scheme 1.

Although the oxidation of selenides was less completely studied, it was found that they are also easily converted into the corresponding selenones, presumably by way of a similar reaction mechanism. The major product obtained from diphenyl selenide was the corresponding selenone. The oxidation of phenyl methyl selenide under these conditions produced a foul smelling product mixture that appeared to be quite toxic.[3] Be-

[3] The products obtained from the oxidation of methyl phenyl selenide had an offensive odour that caused violent retching.

Di-*n*-butyl sulfoxide	[a]	Di-*n*-butyl sulfone (100)
Diphenyl selenide	[b]	Diphenyl selenone (50)[h]
Methyl phenyl selenide	[b]	Unidentified (toxic)

[a] Substrate (2.5 mmol) was dissolved in 15 mL of *n*-hexane and stirred over 2.5 g of $Cu(MnO_4)_2 \cdot 8H_2O$ for 1.0 h at room temperature.

[b] Substrate (2.5 mmol) was dissolved in 20 mL of methylene chloride over 1.0 g of $KMnO_4$ and 0.5 g $CuSO_4 \cdot 5H_2O$ and refluxed for 25 h.

[c] Substrate (2.5 mmol) was dissolved in 20 mL of *n*-hexane over 1.0 g of $KMnO_4$ and 0.5 g $CuSO_4 \cdot 5H_2O$ and refluxed for 25 h.

[d] As in *c* with anhydrous conditions maintained.

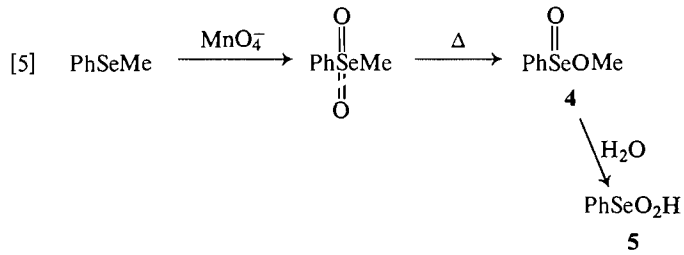
[e] As in *b* with 2.5 mmol of cyclohexene added.

[f] As in *c* with 2.5 mmol of cyclohexene added.

[g] Unless otherwise indicated, yields were determined by glc.

[h] Isolated yield.

cause the analytical facilities available to us are not equipped to handle toxic substances we were unable to thoroughly characterize this product. However, three compounds were detected by use of thin layer chromatography. These may have been formed by partial rearrangement of the expected product, phenyl methyl selenone, to the corresponding ester, methyl benzeneselenonate (**4**), followed by incomplete hydrolysis to benzeneselenonic acid (**5**) as in eq. [5]. Such rearrangement and hydrolysis reactions have previously been observed for these compounds.[4]



Finally, it should be noted that this procedure for the oxidation of sulfides and selenides is of potential value in organic synthesis. The reaction is fairly selective and, since it is heterogeneous, the isolation of products is easily achieved by filtration and flash evaporation of the solvent.

Electrogenerated luminescence in the Kolbe reactions of pyruvic and phenylglyoxylic acids

J. DE LA FUENTE, E. A. LISSI, AND R. ROZAS
Departamento de Química, Facultad de Ciencias, USACH, Santiago, Chile

Received October 11, 1983

J. DE LA FUENTE, E. A. LISSI, and R. ROZAS. Can. J. Chem. **62**, 2117 (1984).

The Kolbe reaction of pyruvic and phenylglyoxylic acids in acetonitrile takes place with high yields of biacetyl and benzil, respectively. Electroluminescence is produced during the electrolysis. This luminescence can be attributed to phosphorescence following the generation of excited triplets of the α-diketones in the acyl radical recombination. The efficiencies of the triplet production, relative to ground state formation, were evaluated to be of the order of 8×10^{-3} and 10^{-4} for the recombination leading to benzil and biacetyl, respectively.

J. DE LA FUENTE, E. A. LISSI et R. ROZAS. Can. J. Chem. **62**, 2117 (1984).

Les réactions de Kolbe, dans l'acétonitrile, des acides pyruvique et phénylglyoxylique conduisent respectivement aux biacétyle et au benzile, avec d'excellents rendements. Il se produit de l'électroluminescence au cours de l'électrolyse. On peut attribuer cette luminescence à une phosphorescence qui suit la génération des triplets excités des α-dicétones lors de la recombinaison des radicaux acyles. On a évalué que les efficacités de production de triplets, relatives à la formation de l'état fondamental, sont de l'ordre de 8×10^{-3} et 10^{-4} pour les recombinaisons conduisant respectivement au benzile et au biacétyle.
[Traduit par le journal]

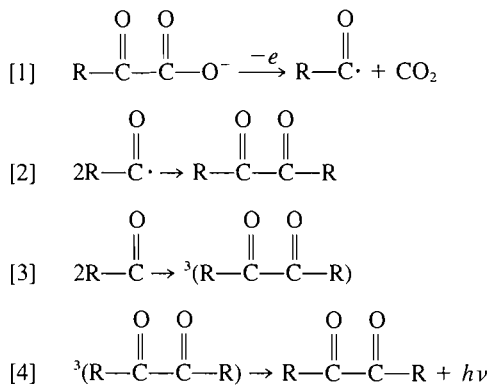
The electrogeneration of ion-radicals leads frequently to luminescence (1, 2). On the other hand, there are no reported data on luminescence arising from the recombination of neutral free radicals. The probability of excited state formation in the recombination of free radicals has been evaluated for several radicals pairs (3). These calculations show that this probability is relatively high for those recombinations whose exothermicity is larger than the energies of the product excited states. This situation is found, for example, in the recombination of acyl radicals. In the present work we report results obtained in the electrogeneration of acyl free radicals by the Kolbe reaction. In this process, an electroluminescence that can be interpreted in terms of the following reaction scheme is observed:



Experimental

Pyruvic acid (PA) and triethylamine were Fluka products. They were purified by distillation. Acetonitrile (Aldrich gold label) was employed as received. Phenylglyoxylic acid (PhGA) was prepared from mandelic acid (Fluka) (4). The melting point of the product obtained was 64−65°C.

$Ru(bpy)_3(ClO_4)_2$ was prepared by melting $RuCl_3$ with 3 equiv. of 2,2′-dipyridyl. The product obtained was dissolved in ethanol:water (1:1) and reduced on a Pt electrode at −0.85 V vs. sce. The reduced product was treated with an excess of $NaClO_4$ in a perchloric acid solution at pH = 4. The resulting complex was characterized by cyclic voltammetry and by its emission spectrum (5).

The electrochemical equipment employed comprised a Princeton Applied Research model 173 Potentiostat, a model 175 Universal Programmer, and a model 179 Integrator. The electrochemical cell designed for this work is shown in Fig. 1. The anodic and cathodic compartments were separated by a glass frit. The anode was made of Pt grill, with a geometric area of 4.5 cm^2. An sce was employed as reference. A Pyrex glass flat window was placed in front of the anode and near the front window of an EMI 9502-S photomultiplier. The photocurrent was measured with a KEITHLEY 414 A picoammeter. Glass filters and absorbing solutions were placed between the cell and the photomultiplier in order to characterize the emitted spectra. The reactions were carried out under nitrogen in a temperature-controlled bath at 20 ± 1°C.

The electrochemical reaction was made either potentiostatic or galvanostatic. The potentiostatic electrolysis was carried out between 2.0 and 2.3 V vs. sce. The galvanostatic experiments were carried out in the same range of potentials. All measurements were carried out employing a 10% solution of tetrabutylammonium bisulphate in the cathodic compartment.

The number of electrons transferred in the electrochemical oxidations (n) was determined by coulometry at 30 mV more positive than the peak determined by cyclic voltammetry (see Fig. 2).

Detection and determination of the α-diketones produced during the electrolysis were done by gas−liquid chromatography, thin layer chromatography, and fluorescence spectroscopy. The emission yield was evaluated employing the electro-oxidation of $Ru(bpy)_3^{2+}$ in the presence of $C_2O_4^{2-}$ as reference. For this reaction an electroluminescence efficiency of 2% has been reported (6).

Integrated emission spectra were obtained employing solutions of picric acid or potassium dichromate of different concentrations. The cut-off of the filter was assumed to be at the wavelength at which the absorbance of the solution was 0.5. The spectra obtained in the electroreactions were compared to those obtained from benzil and biacetyl triplets. These triplets were generated by decomposing dioxetane in the presence of biacetyl or benzil in acetonitrile solution. The dioxetane was kindly supplied by Dr. E. Bechara, University of Sao Paulo, Brazil.

Luminescence measurements were carried out in a Hitachi-Perkin Elmer 204-S spectrofluorimeter. 2,5-Dimethyl-2,4-hexadiene (Aldrich) and anthracene (Hopkins and Williams, sublimed) were employed as selective triplet quenchers in the electroluminescence experiments and in the luminescence measurements. Sodium pyruvate (Merck), triethylamine (Fluka, bidistilled), and pyruvic acid (Aldrich) were employed in the luminescence quenching experiments. Biacetyl triplet lifetimes were measured in a Perkin-Elmer LS-5 spectrofluorimeter.

Results

Electrochemical processes

The Kolbe electro-oxidation of aliphatic α-ketoacids has been previously studied in aqueous and methanolic solutions (7, 8). As a result of the nucleophilic media the dimers comprise less than 20% of the observed products. In our work several experimental conditions were tested in order to improve the yield of the α-diketones. The highest electrochemical yields

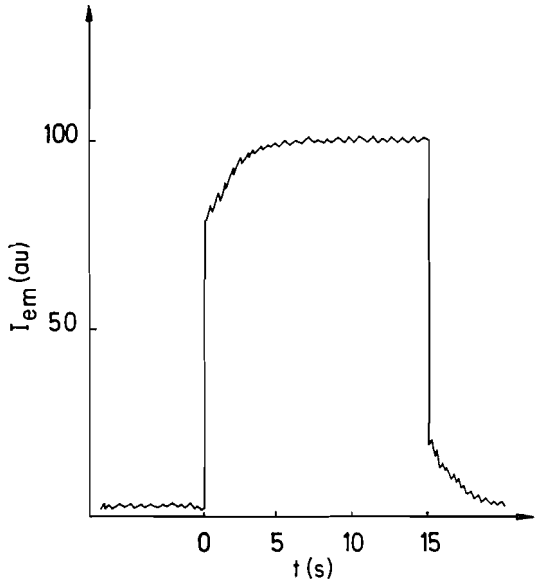

FIG. 3. Measured luminescence from a pyruvic acid solution as a function of time in a galvanostatic step.

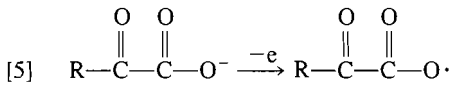
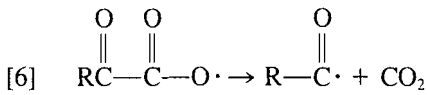
were obtained with the α-ketoacids partially (25%) neutralized with triethylamine in acetonitrile solution (75% yield of biacetyl and more than 90% yield of benzil).

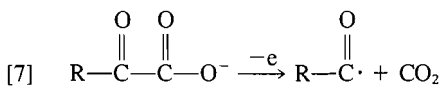
The fact that no other products than biacetyl and benzil were observed by glc and tlc at low α-ketoacids conversion, as well as the large electrochemical yields already mentioned, indicate that the electro-oxidation can be described by



followed almost quantitatively by



This conclusion is in agreement with the known instability of these types of radicals (9). Nevertheless, the possibility that decarboxylation is concerted with the electron transfer step is also compatible with the present results (10):



The number of electrons transferred per acid molecule reacted obtained by coulometry were 0.91 and 0.95 for PA and PhGA, respectively. All the results are then in agreement with a single electrochemical process that can be represented by reaction [1], followed mainly by the dimerization of the electrogenerated acyl radicals.

Electroluminescence

During the electrolysis a significant luminescence is observed (signal-to-noise ratio from 20 to 200). The luminescence observed as a function of time is shown in Fig. 3 for a galvanostatic pulsed electrolysis. The steady state electroluminescence is reached approximately 7 s after applying the current. The luminescence drops to the background level immediately after turning-off the applied current. Similar behaviours were observed with PA and PhGA. The delay time to

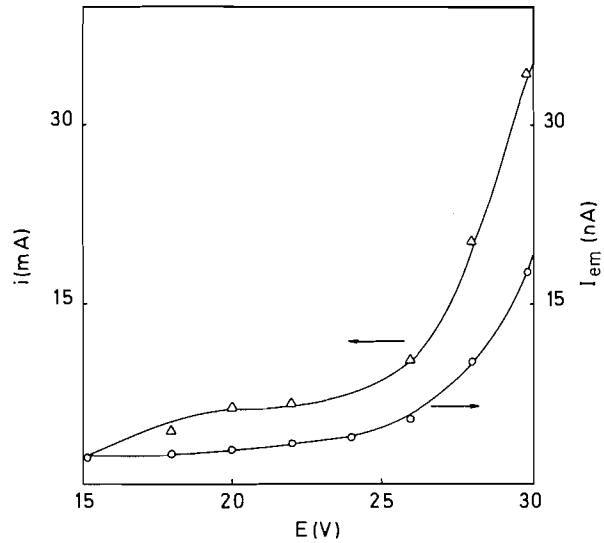

FIG. 4. Current intensity and luminescence intensity as a function of applied potential in the electrolysis of pyruvic acid (E in V against sce). △, current intensity; ○, luminescence intensity.

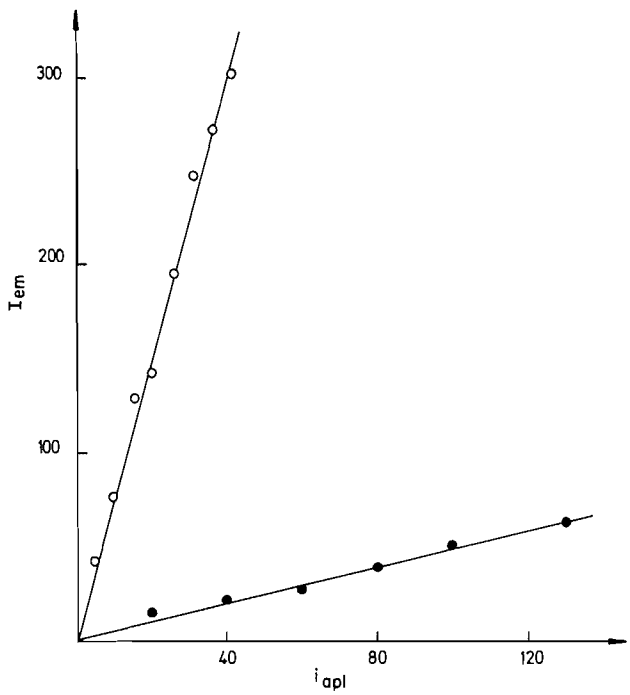

FIG. 5. Luminescence intensity as a function of applied current intensity; ●, pyruvic acid, 0.1 M; ○, phenylglyoxylic acid, 0.05 M.

reach the steady state emission is not due to the necessity of product accumulation since addition of biacetyl or benzil do not change either the delay time or the steady state emission intensity observed. The delay time could be related to the time required to deplete traces of oxygen in the surroundings of the anode. In fact, it was observed that oxygen is an efficient luminescence quencher.

Figure 4 shows the current intensity and luminescence intensity (in the plateau region) as a function of the operating potentials in the Kolbe region. Figure 5 shows the relationship between applied current and measured intensities in the steady state region in galvanostatic experiments. A linear relationship between current and light intensity is observed for PA and

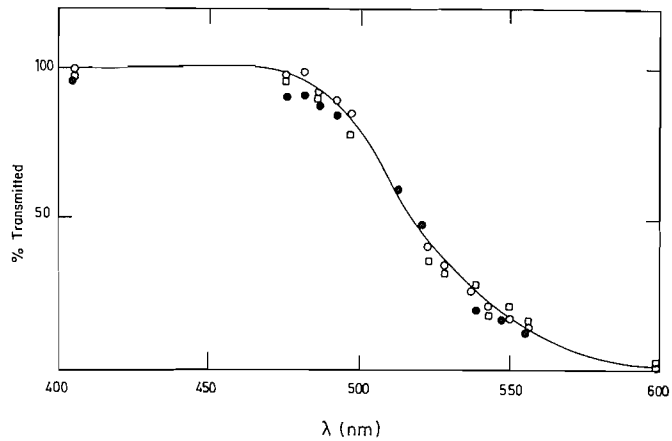

FIG. 6. Integrated spectra in the electrolysis of pyruvic acid; □, electrolysis of pyruvic acid; ●, electrolysis of pyruvic acid in the presence of 10^{-4} M 2,5-dimethyl-2,4-hexadiene; ○, spectra obtained in the pyrolysis of tetramethyldioxetane in the presence of 5×10^{-2} M biacetyl.

FIG. 7. PhGA. The slopes of these plots are 0.47 and 7.65 nA of photocurrent per mA of applied current for PA and PhGA, respectively. Change in the substrate concentration between 5×10^{-2} and 0.1 M does not modify significantly the luminescence efficiency. With the same experimental set up, the $Ru(bpy)_3^{2+}/C_2O_4^{2-}$ system gives 1.2×10^4 nA of photocurrent per mA of applied current.

The integrated emission spectra obtained in the electrolysis of PA and PhGA are given in Figs. 6 and 7. These spectra were obtained employing cut-off filters since the signal-to-noise ratio was not enough to allow the use of a monochromator. In these figures are also included the results obtained when biacetyl and benzil triplets were directly sensitized by dioxetane thermolysis at 60°C in the presence of the corresponding diketones.

Addition of anthracene or 2,5-dimethyl-2,4-hexadiene decreases the electroluminescence intensity without affecting the current intensity. The ratio between the measured intensity in the presence of 2,5-dimethyl-2,4-hexadiene and that measured in the absence of additive are given in Figs. 8 and 9. In these figures are also included data obtained in the quenching of

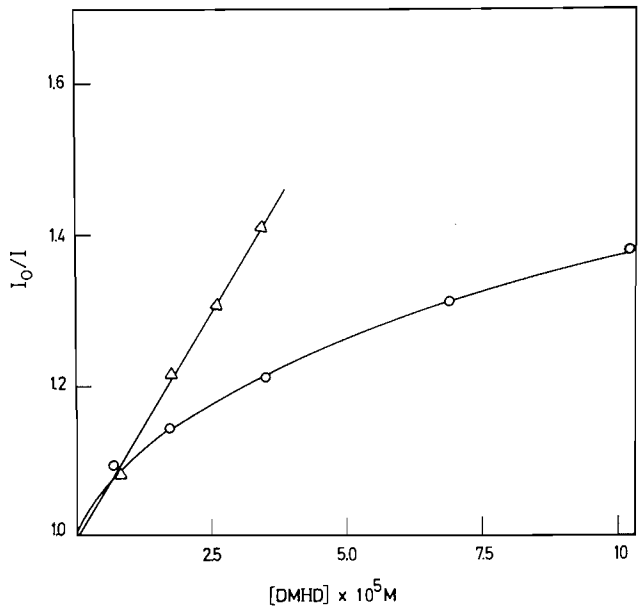

FIG. 8. Quenching of the luminescence produced in the electrolysis of pyruvic acid by 2,4-dimethyl-2,4-hexadiene; ○, electroluminescence; △, quenching of biacetyl phosphorescence in the same medium (irradiation wavelength 410 nm).

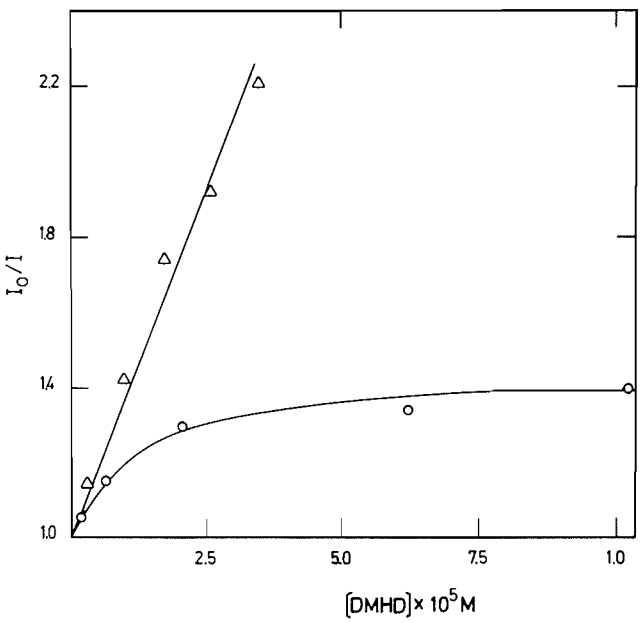

FIG. 9. Quenching of the luminescence produced in the electrolysis of phenylglyoxylic acid by 2,5-dimethyl-2,4-hexadiene; ○, electroluminescence; △, quenching of benzil phosphorescence in the same medium (irradiation wavelength 440 nm).

biacetyl and benzil phosphorescence. These data were obtained by irradiating benzil and biacetyl at 440 and 410 nm, respectively, in the reaction media employed in the electroluminescence experiments.

Biacetyl phosphorescence yields in the electrolysis mixture were determined by relating the phosphorescence yield in the working solution to that measured in benzene. This latter value was obtained from the triplet lifetime (7.5×10^{-4} s) and the phosphorescence rate constant (1×10^2 s (11)). By this procedure, a value of 2.1×10^{-3} was obtained for the phosphorescence yield of biacetyl in 10^{-1} *M* pyruvic acid partially

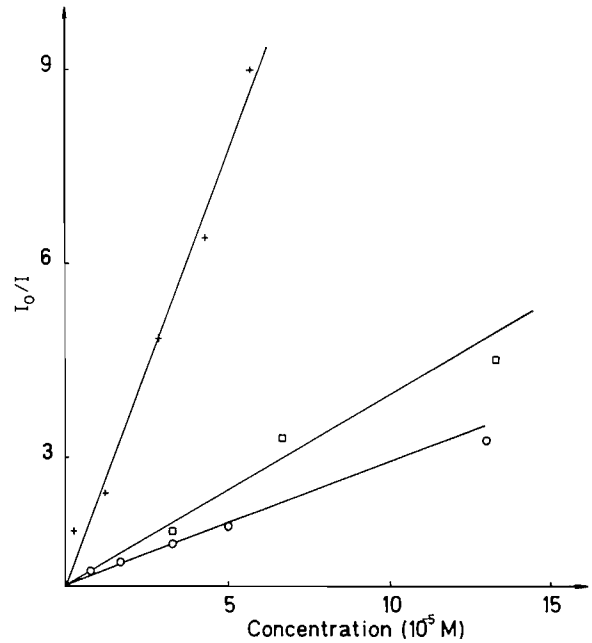

FIG. 10. Quenching of biacetyl phosphorescence by the components of the anodic solution; +, triethylamine; □, pyruvate anion (solvent acetonitrile plus 20% of water) added as sodium pyruvate; ○, pyruvic acid (concentrations has to be multiplied by 10^3); irradiation wavelength, 410 nm.

neutralized with triethylamine. A similar value was obtained by a comparison of the phosphorescence yield in this solvent and the fluorescence yield in benzene (12, 13).

Benzil phosphorescence yields in the working mixture were evaluated by relating the phosphorescence yield to the fluorescence yield measured in benzene (12). From this procedure, a value of 5×10^{-4} was obtained for the phosphorescence yield in 5×10^{-2} *M* phenylglyoxylic acid partially neutralized by triethylamine. The low phosphorescence yields measured in the working solutions are due to quenching of the excited carbonyl triplets by the parent acid, the acid anion, and the free triethylamine. Figure 10 shows the data obtained measuring the biacetyl phosphorescence yield as a function of added triethylamine, pyruvic acid, and the pyruvate anion (added as sodium salt). These data show that the quenching capacity of the additives follows the order amine > pyruvate ⩾ pyruvic acid. Figure 11 shows the Stern–Volmer plot obtained when a mixture of pyruvic acid and triethylamine (4:1) is added to biacetyl up to the concentrations employed in the electrolysis. The downward curvature observed is compatible with the partial neutralization of the pyruvic acid and the larger quenching capacity of the amine (whose free fraction decreases when the added concentration increases). Similar results were obtained by measuring the benzil phosphorescence yield as a function of the added concentration of partially neutralized phenylglyoxylic acid.

Discussion

The results given in Figs. 6 and 7 would indicate that most of the observed luminescence can be assigned to biacetyl and benzil phosphorescence. This phosphorescence imply direct triplet production since the sequence

[8] $2R-\overset{O}{\overset{\|}{C}}\cdot \rightarrow {}^1(R-\overset{O}{\overset{\|}{C}}-\overset{O}{\overset{\|}{C}}-R)$

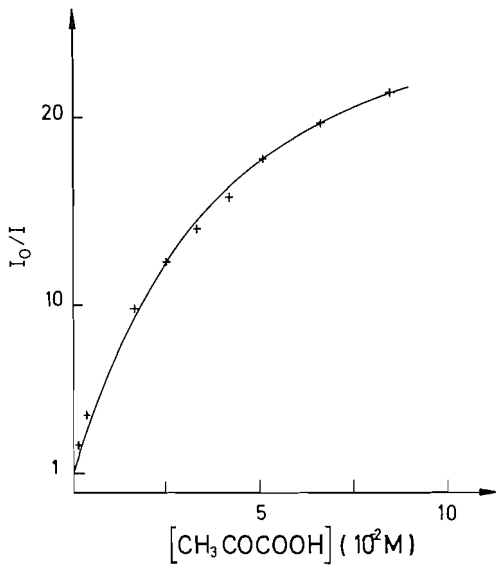

FIG. 11. Quenching of biacetyl phosphorescence by addition of a mixture of pyruvic acid and triethylamine (4:1); irradiation wavelength, 410 nm.

[9] $$^1(R{-}\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}{-}R) \rightarrow {}^3(R{-}\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}{-}R)$$

followed by triplet emission, would lead mainly to biacetyl fluorescence due to significant triplet quenching in the reaction media employed.

Significant emission from biacetyl and benzil triplets is also in agreement with the quenching effect of oxygen, anthracene, and 2,5-dimethyl-2,4-hexadiene. Furthermore, it is interesting to note that anthracene is more effective than 2,5-dimethyl-2,4-hexadiene (as observed in the quenching of diketone triplets) and that the initial slopes are similar in the luminescence quenching and electroluminescence quenching experiments. Nevertheless, the data given in Figs. 8 and 9 show that Stern–Volmer type plots obtained employing 2,5-dimethyl-2,4-hexadiene as quencher present a strong downward curvature (a similar behaviour was observed with anthracene).

This behaviour could be due to the presence of more than an emitting species, or to different triplet lifetimes in different reaction zones. In order to test the first possibility, we have measured the emitted light distribution in the absence and in the presence of 2,5-dimethyl-2,4-hexadiene. These data have been included in Figs. 6 and 7 and show that the presence of the quencher do not significantly modify the spectral distribution of the electroluminescence. We consider then that the most likely explanation of the curvature in the Stern–Volmer plots is a shorter lifetime of the triplet in the neighbourhood of the electrodes as a consequence of electrode deactivation and/or impurity quenching.

The possibility of having a gradient in excited biacetyl lifetimes in the neighbourhood of the electrode, as well as the decreased concentration of the anion that could take place in their surroundings, could explain the apparent contradiction observed between the data of Fig. 10 (that shows a dependence in phosphorescence yield with salt concentration in the working region) and the stated independence of the measured photocurrent per mA of applied current with the substrate concentration. Nevertheless, it must be noted that the reproducibility of the electroluminescence measurements is rather low (±15%) and that the range of working concentrations that can be employed is small. This, together with the rather small slope of the Stern–Volmer plot obtained in the quenching experiments at large salt concentrations (see Fig. 11), makes it difficult to quantitatively compare both sets of data.

We consider then that all the experimental results are compatible with and suggestive of a reaction scheme such as that comprising reactions [1] and [4]. The triplet yield in the electrolysis can be obtained from the electroluminescence yield and the phosphorescence yield measured when the diketone is directly excited in the same reaction medium. The electroluminescence yield was obtained employing $Ru(bpy)_3^{2+}/C_2O_4^{2-}$ as reference (6). This method has the advantage that, since both electroprocesses take place on the same electrode, all geometrical factors cancel out. On the other hand, it has the disadvantage that it is necessary to introduce a correction for spectral sensitivity of the detection system. The electroluminescence yield will be given by

[10] $$\phi_{ECL} = f(I/I_{ref})(\phi_{ECL})_{ref}$$

where I and I_{ref} are the photocurrents of the sample and the reference reaction per mA of applied current, $(\phi_{ECL})_{ref}$ is the number of photons emitted by transferred electron in the reference reaction, and f is the factor that takes into account differences in the photomultiplier response. Taking $(\phi_{ECL})_{ref}$ as 0.02 Einstein/Faraday (6), we obtain yields of 1.3×10^{-7} and 2.1×10^{-6} Einstein/Faraday for the electrolysis of PA and PhGA, respectively.

Triplet yields can be obtained from

[11] $$\phi_T = \phi_{ECL}/\phi_{Ph}$$

where ϕ_{Ph} is the phosphorescence efficiency of a triplet under the conditions employed. These values were estimated as 2.7×10^{-3} and 5×10^{-4} for PA and PhGA in the luminescence experiments. If these values are considered to apply to the triplets produced in the electrochemical process, we obtain ϕ_T of 6.2×10^{-5} and 4×10^{-3} for PA and PhGA, respectively.

These values are bound to be large errors, mainly due to the difficulty in evaluating the phosphorescence efficiency of the electrogenerated triplet. They must then be considered only as an indication of the order of magnitude of the triplet yield.

Combining these values with the biacetyl and benzil electrochemical yields, we obtain

[12] $$(k_3/k_2)_{biacetyl} \approx 10^{-4}$$

and

[13] $$(k_3/k_2)_{benzil} \approx 8 \times 10^{-3}$$

The excited recombination of acetyl radical has been proposed as a possible source of the chemiluminescence observed in the thermal reaction between ethylhyponitrite and acetaldehyde (14). Abuin and Lissi (3) have estimated, from thermochemical considerations and the rate of triplet photocleavage, a rate constant of $3 \times 10^3\ M^{-1}\ s^{-1}$ for the recombination of acetyl radicals leading to the excited biacetyl triplet. Furthermore, from the luminescence observed in the photolysis of 3,3-dimethyl-2-butanone they concluded that $k(CH_3COCOCH_3)^3/k(CH_3COCOCH_3)$ must be lower than 2×10^{-3}. This estimation is in agreement with the presently reported value. Furthermore, if a diffusion controlled rate is assumed for the $CH_3CO\cdot$ radical recombination ($5 \times 10^9\ M^{-1}\ s^{-1}$), we conclude from the present data that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

$$k(CH_3COCOCH_3)^3 \approx 5 \times 10^5\ M^{-1}\ s^{-1}$$

This value, although considerably larger than that estimated by Abuin and Lissi (3), seems reasonable if it is considered that the energy barrier imposed on the triplet state decomposition of biacetyl is, at least in the gas phase, nearly equal to the endothermicity of the process (15).

The possibility of luminescence emission in the recombination of PhCO radicals has been considered by Huggenberger *et al.* (16) and Abuin and Lissi (3). The former authors concluded that less than 3% of the recombination leads to the excited triplet. Abuin and Lissi estimated that the fraction of triplet could be as large as 0.05, a value bound to large errors (3). The value found in the present work is then not incompatible with these previous estimates. Benzoyl recombination is a diffusionally controlled process (16) and its rate constant can be taken as $5 \times 10^9\ M^{-1}$ in acetonitrile. This leads to $k_3 \approx 4 \times 10^7\ M^{-1}\ s^{-1}$. For the benzil triplet photocleavage at room temperature, a value of $\sim 3 \times 10^3$ has been obtained in dodecane by extrapolation of high temperature data (17), leading to a ΔG^0 of ≈ 6.5 kcal/mol for benzoyl radicals formation from the excited benzil triplet. This value, although larger than that evaluated from thermochemical methods, is inside the indetermination of the estimates (16).

Conclusions

In the present work it is shown that the Kolbe reaction of pyruvic and phenylglyoxylic acids can be carried out with high yields in acetonitrile solution. The luminescence observed in the electrolysis can be related to the formation of the excited α-diketone in the combination of the corresponding acyl radicals. The data provide the first experimental values of the efficiency of these processes.

Studies of the initial steps in the polymerization of C_2N_2 induced by Xe^+

ASIT BARAN RAKSIT AND DIETHARD KURT BOHME
Department of Chemistry and Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received December 12, 1983

ASIT BARAN RAKSIT and DIETHARD KURT BOHME. Can. J. Chem. **62**, 2123 (1984).

A Selected-Ion Flow Tube (SIFT) apparatus has been used to produce Xe^+ by electron impact and to study its reactions with C_2N_2. The $^2P_{3/2}$ and $^2P_{1/2}$ spin states of Xe^+ were observed to react differently: by C_2N_2 addition to form $Xe^+ \cdot C_2N_2$ and by charge transfer to form $C_2N_2^+$, respectively. Further ion–molecule reactions with C_2N_2 were observed to establish polymeric ions of the type $(C_2N_2)_x^+$. The results indicate that the simple charge transfer model may be sufficient to account for the rate enhancement observed in the radiolytic polymerization of C_2N_2/Xe mixtures.

ASIT BARAN RAKSIT et DIETHARD KURT BOHME. Can. J. Chem. **62**, 2123 (1984).

On a utilisé un tube à écoulement sélecteur d'ions (TESI) pour produire des ions Xe^+ par impact électronique et pour étudier leurs réactions avec le C_2N_2. On a observé que les états de spin $^2P_{3/2}$ et $^2P_{1/2}$ du Xe^+ réagissent différemment alors qu'ils donnent respectivement une addition du C_2N_2 pour former l'ion $Xe^+ \cdot C_2N_2$ et un transfert de charge qui conduit à l'ion $C_2N_2^+$. On a observé que d'autres réactions ion–molécule avec le C_2N_2 conduisent à des ions polymères de type $(C_2N_2)_x^+$. Les résultats indiquent que le modèle simple de transfert de charge peut être suffisant pour expliquer l'augmentation de la vitesse réaction observée lors de la polymérisation par radiolyse de mélanges de C_2N_2/Xe.

[Traduit par le journal]

Introduction

The rate of radiolytic polymerization of C_2N_2 is known to be enhanced by noble gases approximately in proportion to the stopping power of the noble gas (1). This increase in rate has been explained in terms of an initial charge transfer reaction involving the rare gas ion for those noble gases which have a higher ionization energy than C_2N_2 (2). Xenon has been viewed as an exception because of its relatively low ionization energy and it has been argued that the simple charge transfer theory cannot explain the observations with xenon additive (3). An alternative mechanism has been proposed in which a complex of the type $[XeC_2N_2]^+$ is invoked as an intermediate in a sequence of steps [1] to [3]

$$[1] \quad Xe \rightarrow Xe^+ + e^-$$

$$[2] \quad Xe^+ + C_2N_2 \rightarrow [XeC_2N_2^*]^+$$

$$[3] \quad [XeC_2N_2^*]^+ + C_2N_2 \rightarrow (C_nN_m)^+ + \cdot C_pN_q + Xe$$

where n and m equal 1 to 4 but n is not necessarily equal to m, $p = 4 - n$ and $q = 4 - m$ (1, 3). Neutral cyanogen can continue to react with the ionic species produced in step [3] to form polymeric ions which ultimately can lead to neutral products by ion–ion or ion–electron recombination. The addition complex $[XeC_2N_2]^+$ has actually been observed with a mass spectrometer to be formed in a 3.5:1 mixture of cyanogen and xenon at a total pressure of 1 Torr (1). Its observation has provided support for this mechanism which has become known as the "cluster theory".

We report here laboratory measurements directed towards elucidating the nature and kinetics of the initial steps in the Xe^+-induced polymerization of C_2N_2. The reaction of Xe^+ with C_2N_2 is studied in complete "isolation" in helium carrier gas at room temperature. The primary ionic products are identified along with ionic products from ensuing secondary reactions. The results provide evidence for the direct formation of the adduct $Xe^+ \cdot C_2N_2$ from Xe^+ and C_2N_2 but they also suggest that the simple charge transfer model may be entirely adequate to account for the Xe/C_2N_2 radiolysis results.

Experimental

The measurements were performed with the Selected-Ion Flow Tube (SIFT) apparatus in the Ion Chemistry Laboratory (4, 5). For the measurements reported here the instrument was fitted with an axial electron impact ionizer (Extranuclear, Model 041-3). Xe^+ and He^+ were derived from their parent gases at an electron energy of ca. 26 eV and an ion injection energy of ca. 13 V. Helium was used as the carrier gas in all experiments. The cyanogen was of a commercial grade (Matheson, 98.5% minimum by volume in the liquid phase). Separate measurements using H_3^+ as a chemical ionization reagent indicated a purity for the gas of more than 99%. All measurements were made at an ambient temperature of 296 ± 2 K.

Results and discussion

Figure 1 displays observations recorded with the addition of cyanogen into the reaction region of the SIFT apparatus in which the m/z 129 isotope of Xe^+ was established as the dominant ion. The loss curve for Xe^+ shows initial curvature followed by only a gradual decay. There is a sharp concomitant growth and decay in $C_2N_2^+$ and further reactions with C_2N_2 to form polymeric ions of the type $(C_2N_2)_x^+$. Also the cluster ion $Xe^+ \cdot C_2N_2$ is observed to be formed as a product ion.

Overall the observations shown in Fig. 1 show a complicated behaviour. However, the behaviour may be understood if one recognizes the existence of the spin states of Xe^+ with configurations $^2P_{3/2}$ (lowest energy) and $^2P_{1/2}$ formed initially by electron impact, and if one allows for a possible difference in the reactivity of these two spin states (6). A difference in reactivity can be expected simply from a consideration of energetics. The recombination energies of $Xe^+(^2P_{3/2}) = 12.13$ eV and $Xe^+(^2P_{1/2}) = 13.44$ eV are such that charge transfer with C_2N_2, IE = 13.374 ± 0.008 eV (7), is endothermic for the $^2P_{3/2}$ state and slightly exothermic for the $^2P_{1/2}$ state.

The decay of Xe^+ shown in Fig. 1 contains contributions from both Xe^+ spin states and may be analysed in the manner described by Adams *et al.* for the analogous reactions of the spin states of Xe^+ with CH_4 (6). The decay in Xe^+ at small C_2N_2 additions may be attributed to reaction of the 1/2 spin state. The sharp rise in $C_2N_2^+$ at these additions indicates that this state reacts by charge transfer and Fig. 1 shows that $C_2N_2^+$ reacts further with C_2N_2 by addition to form $(C_2N_2)_2^+$ and then $(C_2N_2)_3^+$. Small amounts of $C_3N_3^+$ appear to be produced in a biomolecular reaction of $(C_2N_2)_2^+$ with C_2N_2. The much more gradual decay in Xe^+ at higher C_2N_2 additions may be attribut-

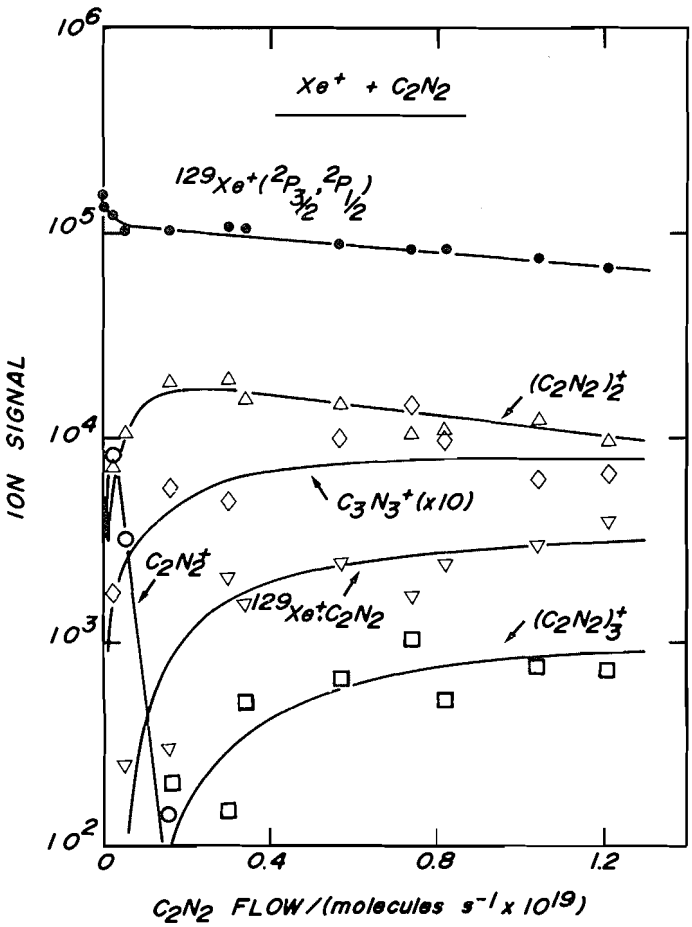

FIG. 1. The observed variation in ion signals for the addition of cyanogen into the reaction region where $^{129}Xe^+$ has been established by injection upstream into helium buffer gas. P = 0.296 Torr, $\bar{v}$ = 7.2 × 10^3 cm s^{-1}, L = 46 cm, T = 295 K. No correction has been made for mass discrimination in the mass spectrometer.

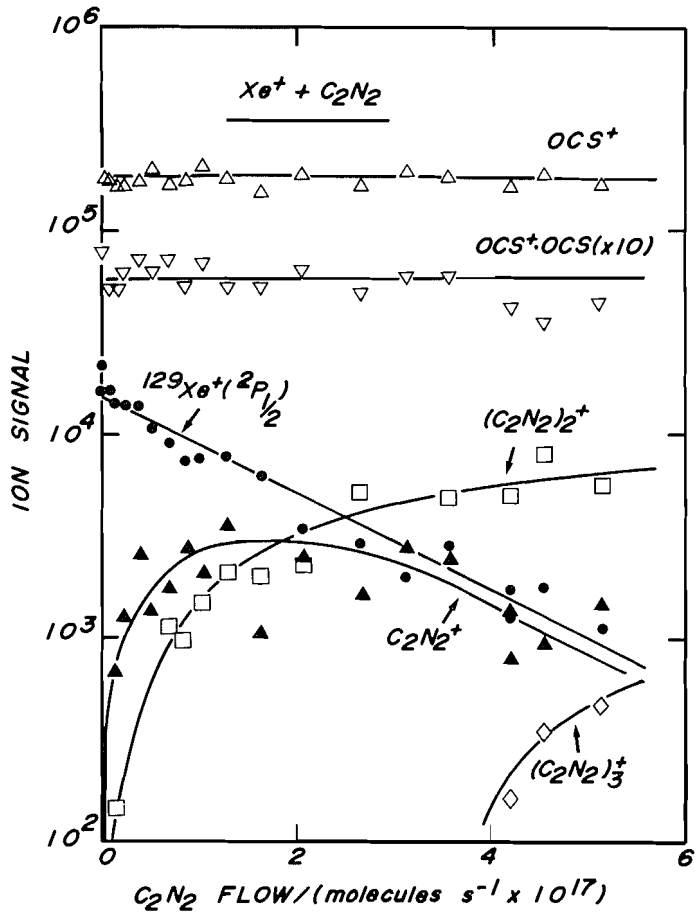

FIG. 2. The observed variation in ion signals for the addition of cyanogen into the reaction region where the 1/2 spin state of Xe^+ has been established by injection of Xe^+ and addition of 6 × 10^{17} molecules s^{-1} of OCS "filter gas" upstream into helium buffer gas. P = 0.298 Torr, $\bar{v}$ = 7.1 × 10^3 cm s^{-1}, L = 46 cm, T = 295 K. No correction has been made for mass discrimination in the mass spectrometer.

ed to the reaction of the 3/2 spin state and it is matched by the appearance of $Xe^+ \cdot C_2N_2$ due presumably to the thermolecular reaction [4]. The slope of this decay corresponds to an effective second-order rate constant of 4 × 10^{-12} cm^3 $molecule^{-1}$ s^{-1}

[4] $Xe^+(^2P_{3/2}) + C_2N_2 + He \rightarrow Xe^+(^2P_{3/2}) \cdot C_2N_2 + He$

at a helium density of 9.7 × 10^{15} atoms cm^{-3} or a third-order rate constant of 4 × 10^{-28} cm^6 $molecule^{-2}$ s^{-1}. The $Xe^+(^2P_{3/2}) \cdot C_2N_2$ may add a second C_2N_2 molecule but there was no evidence for measurable amounts of $Xe^+ \cdot (C_2N_2)_2$ up to the largest flow of C_2N_2 indicated in Fig. 1. A bimolecular reaction between $Xe^+(^2P_{3/2}) \cdot C_2N_2$ and C_2N_2 is much less likely. Certainly charge transfer to produce $C_2N_2^+$ is endothermic. Also formation of $(C_2N_2)_2^+$ is exothermic only if the difference in the ionization energies of C_2N_2 and Xe (1.24 eV) is exceeded by the relative binding energies of $C_2N_2^+$ and Xe^+ (which are not known). However, the occurrence or non-occurrence of such a reaction cannot be resolved with the data in Fig. 1. The loss of $Xe^+(^2P_{3/2}) \cdot C_2N_2$ may be determined by its slow rate of formation and any $(C_2N_2)_2^+$ which might be produced is indistinguishable from the $(C_2N_2)_2^+$ produced concomitantly in large amounts from the reaction sequence initiated by the charge transfer reaction with the 1/2 spin state of Xe^+.

The 1/2 and 3/2 spin states are expected to be produced in the ion source in the ratio of 1 to 2 from statistical considerations (6). The initial reduction in the Xe^+ signal is about 25% which is sufficiently close to the statistical weight prediction (≈33%) that we may conclude that collisional quenching is not a significant loss process for the 1/2 spin state (6). This was corroborated with additional experiments in which OCS was added as a "filter gas" to study separately the reaction of the 1/2 spin state of Xe^+. Adams *et al.* (6) have shown that OCS reacts about 40 times more rapidly with the 3/2 spin state than with the 1/2 spin state. We have reproduced this result in our SIFT apparatus and added OCS upstream in a separate study of the reaction of Xe^+ with C_2N_2. Figure 2 shows observations made under these conditions. OCS^+ and $OCS^+ \cdot OCS$ are the primary and secondary products, respectively, of the charge transfer reaction of the 3/2 spin state of Xe^+ with OCS. With addition of C_2N_2 the remaining Xe^+, which is now predominantly in the 1/2 spin state, decays rapidly with a rate constant of 6.5 × 10^{-10} cm^3 $molecule^{-1}$ s^{-1}. The primary charge transfer product, $C_2N_2^+$, appears and, as before, adds C_2N_2 in two sequential reactions. The Xe^+ decay is not strongly curved so that collisional quenching by C_2N_2 to form the much less reactive 3/2 spin state is not proceeding efficiently. Also $Xe^+ \cdot C_2N_2$ is observed *not* to be present in the product spectrum under these operating conditions from which we may conclude that the 1/2 spin state reacts predominantly by charge transfer.

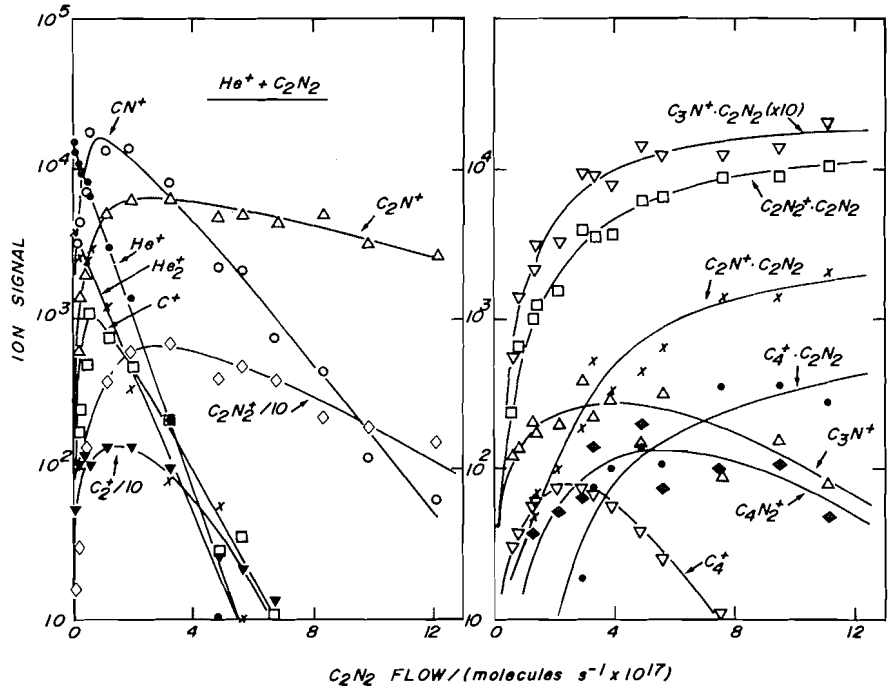

FIG. 3. The observed variation in ion signals for the addition of cyanogen into the reaction region where He^+ and He_2^+ have been established by injection of He^+ upstream into helium buffer gas. $P = 0.335$ Torr, $\bar{v} = 7.4 \times 10^3$ cm s^{-1}, $L = 46$ cm, $T = 297$ K. Left diagram: reactant ions and possible primary ions. Right diagram: secondary product ions.

To contrast the behaviour of Xe^+ towards C_2N_2 with that of another rare gas ion we have included in Fig. 3 results obtained for the reaction of He^+ which has a recombination energy of 24.6 eV which is well above the ionization energy of C_2N_2. Since helium was used as the buffer gas He_2^+ was established in the reaction region by reaction [5]. Both He^+ and He_2^+

[5] $He^+ + He + He \rightarrow He_2^+ + He$

appear to react rapidly with C_2N_2 primarily by dissociative charge transfer. The decay in the He^+ signal corresponds to a rate constant of 1.6×10^{-9} cm^3 molecule^{-1} s^{-1}. The decay in the He_2^+ is influenced in part by the depletion of the He^+ ion in the reaction region. The ions CN^+, C_2N^+, C_2^+, and C^+ were observed to be the principal primary product ions. There was no evidence for the formation of the cluster ion $He^+ \cdot C_2N_2$. The product analysis indicated that $C_2N_2^+$ was largely produced in a secondary reaction. In separate studies we have shown and characterized the occurrence of reactions [6] to [9] (8). All these reactions are seen to operate as secondary reactions in

[6] $CN^+ + C_2N_2 \rightarrow C_2N_2^+ + CN$
$\rightarrow C_3N^+ + N_2$
$\rightarrow C_2N^+ + CN_2$

[7] $C_2N^+ + C_2N_2 + He \rightarrow C_2N^+ \cdot C_2N_2 + He$

[8] $C_2^+ + C_2N_2 \rightarrow C_2N^+ + C_2N$
$\rightarrow C_3N^+ + CN$
$\rightarrow C_4^+ + N_2$

[9] $C^+ + C_2N_2 \rightarrow C_2N^+ + CN$

Fig. 3. Further C_2N_2 addition reactions establish $C_2N_2^+ \cdot C_2N_2$, $C_3N^+ \cdot C_2N_2$, $C_2N^+ \cdot C_2N_2$, and $C_4^+ \cdot C_2N_2$ already at relatively low flows of cyanogen.

The much larger variety of ion chemistry observed with He^+ in contrast to that observed with Xe^+ clearly is to be attributed to the much higher recombination energy of He^+. The high recombination energy results in charge transfer which is almost entirely dissociative so that fragment ions of $C_2N_2^+$ initiate the secondary ion chemistry. Dissociative charge transfer is endothermic with Xe^+ and the observed secondary ion chemistry appears to be initiated exclusively by $C_2N_2^+$.

Conclusions

(*1*) The two spin states of Xe^+ ($^2P_{3/2}$, $^2P_{1/2}$) react differently with C_2N_2. The $^2P_{1/2}$ state which has a recombination energy *higher* than IE(C_2N_2) reacts predominantly by charge transfer while the $^2P_{3/2}$ state which has a recombination energy *lower* than IE(C_2N_2) reacts to form the adduct $Xe^+ \cdot C_2N_2$.

(*2*) The $C_2N_2^+$ charge transfer product of the reaction with Xe^+ ($^2P_{1/2}$) reacts sequentially to add C_2N_2. The addition of two molecules of C_2N_2 was observed under the operating conditions adopted for the measurements reported here. The nature of the further reaction of $Xe^+ \cdot C_2N_2$ remains uncertain but we expect fast bimolecular reactions with C_2N_2 to be unlikely on thermodynamic grounds.

(*3*) If the two spin states of Xe^+ are produced in the ratio expected from statistical considerations, the ionization of Xe in a Xe/C_2N_2 mixture will result in rapid charge transfer with Xe^+ ($^2P_{1/2}$) to produce $C_2N_2^+$ which quickly establishes polymeric ions of the type $(C_2N_2)_x^+$ in sequential addition reactions. Consequently the charge transfer mechanism will make a substantial contribution to the enhanced rate of polymerization of C_2N_2 observed in the radiolysis of such mixtures. Formation of the cluster ion $Xe^+ \cdot C_2N_2$ will also proceed initially but the $Xe^+ \cdot C_2N_2$ is not expected to react rapidly with C_2N_2 in a bimolecular fashion. Consequently the 3/2 spin state of Xe^+ is expected to have a relatively minor effect on cyanogen polymerization.

The dependence of the rates of reduction of cobalt(III)-μ-peroxo complexes on isomeric structure

STEVE C. F. AU-YEUNG AND DONALD R. EATON[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received October 27, 1983

STEVE C. F. AU-YEUNG and DONALD R. EATON. Can. J. Chem. **62**, 2127 (1984).

The reaction of μ-peroxybis(ethylenediamine)bis(diethylenetriamine)cobalt(III) with ferrous ions has been studied by stopped flow spectrophotometry and by ^{59}Co nmr. Two separate initial reduction steps with second order rate constants of 1.07 and 3.04 M^{-1} s^{-1}, respectively, can be discerned in the stopped flow experiments. These two rate constants are assigned to inner sphere reduction of the aef,cd,b and edf,ac,b isomers of the peroxy cobalt complex, respectively. The different isomers can be distinguished by ^{59}Co nmr. If there is insufficient Fe^{2+} present to completely reduce the complex to Co(II) and water, the change in the relative intensities of the ^{59}Co resonances after partial reduction shows that one isomer has reacted faster than the other. The ^{59}Co resonances can be assigned to the different isomers on the basis of a point charge model for the chemical shifts and line widths. Based on this model it is concluded that the isomer with the central NH of the diethylenetriamine *trans* to the peroxy ligand reacts faster. This result is compared to literature reports on the relative rates of substitution of isomers of Co(III) complexes with ethylenediamine and diethylenetriamine ligands.

STEVE C. F. AU-YEUNG et DONALD R. EATON. Can. J. Chem. **62**, 2127 (1984).

Faisant appel à la spectrométrie par flux stoppé et à la rmn du ^{59}Co, on a étudié la réaction du μ-peroxy bis(éthylènediamine) bis(diétylènetriamine)cobalt(III) avec les ions ferreux. Dans les expériences à flux stoppé, on peut distinguer deux étapes initiales distinctes pour la réduction et leurs constantes de vitesses d'ordre deux sont respectivement 1,07 et 3,04 M^{-1} s^{-1}. On attribue ces deux constantes de vitesse aux réductions respectives, dans la sphère intérieure, des isomères aef,cd,b et edf,ac,b du complexe de peroxy cobalt. On peut distinguer les différents isomères grâce à la rmn du ^{59}Co. Si la quantité de Fe^{2+} présente n'est pas suffisante pour réduire complètement le complexe en Co(II) et en eau, le changement des intensités relatives de la résonance du ^{59}Co, après la réduction partielle, montre qu'un isomère réagit plus vite que l'autre. On peut attribuer les résonances du ^{59}Co aux différents isomères en se basant sur un modèle de charge ponctuelle pour les déplacements chimiques et les largeurs des pics. En se basant sur ce modèle, on conclut que l'isomère qui réagit le plus rapidement est celui qui porte le NH central de la diéthylènetriamine en position *trans* par rapport aux ligand époxy. On compare ce résultat à ceux répertoriés dans la littérature pour les vitesses relatives de substitution des isomères des complexes du Co(III) avec des ligands d'éthylènediamine et de diéthylènetriamine.

[Traduit par le journal]

Introduction

A series of compounds formed by the reaction of molecular oxygen with solutions containing Co(II) ions has been extensively studied (1−3). The complexes with the stoichiometry of two Co atoms to one oxygen molecule are correctly formulated as peroxy compounds containing Co in the 3+ oxidation state. One electron oxidation of these compounds leads to the corresponding superoxy complexes. Complete reduction of the peroxo compounds to Co(II) and water requires four equivalents of a one electron reducing agent. There have been a number of studies of the mechanisms of these reductions motivated by the analogies with reactions of biological importance (4−6). It seems well established (4) that the first step in the reduction of the superoxo complexes is an outer sphere electron transfer and that reduction of the peroxy compounds is initiated by an inner sphere electron transfer. Subsequent steps are less well understood.

McLendon and Martell (5) have examined the reduction of several of these compounds with ferrous ions. They found that the rate of the inner sphere electron transfer varied by two orders of magnitude for complexes with different amine ligands. In the present paper we show that this rate is also affected by different isomeric arrangements of the same amine ligands.

Experimental

Kinetic measurements were carried out on a Durrum D110 Stopped Flow spectrophotometer. Temperature was controlled with a thermostatted water bath. Data were collected on a Nicolet-1170 Signal Averager. The reaction was followed at 420 nm which is a wavelength corresponding to absorption of the product Fe^{3+}. Most measurements were carried out at pH 4.5 using potassium hydrogen phthalate buffer but some runs were made at pH's of 3.5 and 4.0. No significant difference in rates was found at the different pH values. The reactions were examined at 24°C and at a total ionic strength of 1.2 *M* ($NaClO_4$). The concentration of Co complex used was 0.78 m*M* and that of Fe^{2+} varied from 4 m*M* to 50 m*M*. It was apparent that two distinct reactions were occurring. The difference in rates (a factor of approximately 3) is sufficient to allow reasonably good separation of the two processes using the dual time base provided on the Nicolet-1170 signal averaging system. Good exponential formation curves were obtained indicating pseudo first order reactions. We estimate the errors in the rate constants to be ±10%.

^{59}Co nmr spectra were obtained using a Bruker WH90 FT spectrometer operating at 21 MHz. A few spectra were also run on WM250 and WM400 high field instruments to obtain optimum resolution of the isomers. Relative intensities of the different ^{59}Co resonances were obtained by computer fitting to the sum of the three Lorentzian lines centred at the chemical shifts of the three isomers. $Coen_3^{3+}$ was used as an internal intensity standard (concentration 8 m*M*). The peroxo complex was prepared as a perchlorate salt by the procedure of Duffy, House, and Weil (7). Its optical and nmr spectra agreed with those reported in the literature. Other chemicals were of reagent grade and used without further purification.

Results and discussion

Both of the reactions observed by stopped-flow spectrophotometry have rates which are first order with the Fe concentration. In agreement with the findings of McLendon and Martell (5), there is no significant change of rate with pH.

Measured pseudo first order rate constants are given in Table 1 and plots against Fe concentration are shown in Fig. 1. The second order rate constants obtained from these plots are 1.07 and 3.04 M^{-1} s^{-1} for the slower and the faster reaction, respectively. These may be compared with the value of 3.0 M^{-1} s^{-1} given by McLendon and Martell for the inner sphere reduction of the corresponding tetraethylene−pentamine complex with Fe^{2+}. Other complexes studied by these authors were dibridged and react significantly faster. It is clear that both the rate constants are best assigned to inner sphere reduction steps and it is suggested that they correspond to the reduction of different isomers. The change in optical absorption for the two reactions correspond reasonably well to the fractions of each isomer indicated by nmr.

This conclusion is supported by ^{59}Co nmr measurements. Figure 2 shows a ^{59}Co nmr spectrum of $[Co(dien)(en)]_2O_2^{4+}$ obtained at 94.5 MHz on a Bruker WH400 spectrometer (8). Separate resonances corresponding to the three possible isomeric arrangements of the dien and en ligands are clearly observed. The time dependence of the nmr spectrum of a reaction mixture equimolar in Co and Fe was examined. The amount of Fe present is insufficient to complete the reduction process. Reaction schemes have been suggested by Sykes (4) and McLendon and Martell (5). They differ in detail but agree that the first one electron reduction liberates one Co^{2+} ion and that the second electron reduces the other Co, leaving the oxygen moiety in the peroxide oxidation state. Two further electrons are required to reduce peroxide to water. In the case of strong reducing agents such as Cr^{2+} this may occur by direct reaction with the metal ion (6). In the case of Fe^{2+} a more likely sequence is decomposition of the peroxide to molecular oxygen and water (probably catalyzed by the metal ions present), followed by reaction of the oxygen with the Co^{2+} and amine to reform the Co/oxygen complex. It should be noted that at the end of this sequence half of the Co^{3+} has been reduced to Co^{2+} and half of the peroxide has been reduced to water. Reaction with more Fe^{2+} will eventually complete the reduction. The results of the nmr kinetic experiment shown in Fig. 3 are

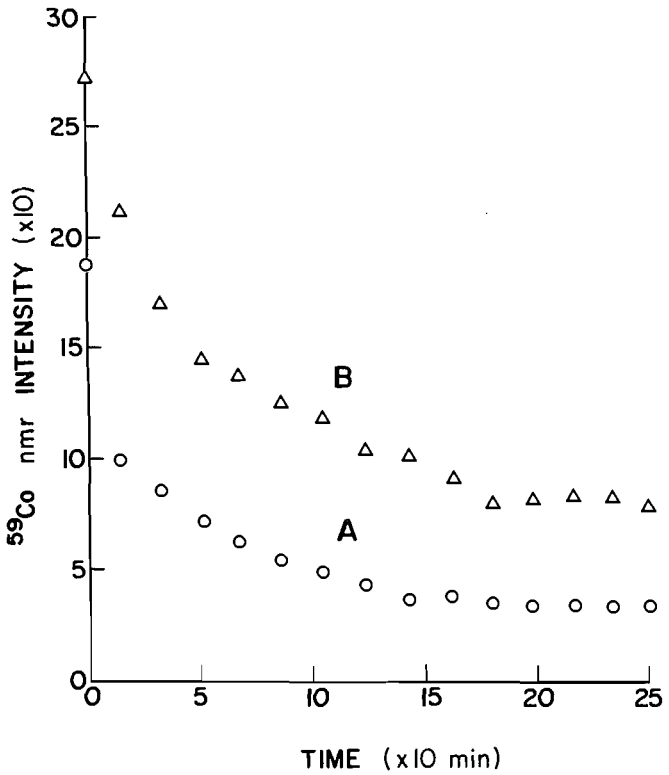

FIG. 3. ^{59}Co nmr intensity versus time plot of the reduction reaction of $[Co(en)(dien)]_2O_2^{4+}$ by $FeSO_4 \cdot 7H_2O$: (*A*) sym-edf,-ac,b-$[Co(en)(dien)]_2O_2^{4+}$; (*B*) sym-aef,cd,b-$[Co(en)(dien)]_2O_2^{4+}$. $[(Co(en)(dien))_2O_2^{4+}]_{tot}$, 20 m*M*. *T*, 6°C; pH, 4.5; $[FeSO_4 \cdot 7H_2O]$, 40 m*M*.

consistent with this scheme. The reactions studied by stopped-flow spectrophotometry are complete before the first nmr spectrum has been acquired. There is therefore a sharp initial decrease in ^{59}Co intensity followed by a much slower decay. The intensity does not fall to zero even after several hours, showing that some of the Fe has been used to reduce peroxide rather than Co. This experiment was performed at 6°C in the hope of identifying intermediates of the type postulated by Sykes and McLendon and Martell. There is no indication of other species other than the starting complexes and we infer that all the reactions in these schemes are fast compared to the time taken to obtain the nmr spectra. The important observation is that the relative intensities of the resonances arising from the different isomers is significantly different after the initial stage of the reaction is finished. Thus the ratio of the intensity of the high field line (*a* in Fig. 2) to that of the low field line (*c*) is 0.68 initially and 0.47 on the first nmr spectrum obtained on the reacting solution. Clearly one isomer is consumed faster than the other, confirming the interpretation of the stopped-flow data. Similar nmr experiments have been carried out using 1, 3, 4, and 5 mol of iron for each mole of dimeric cobalt complex. Rather more than 4 mol of reducing reagent are required to completely eliminate the ^{59}Co nmr signal. The ratio of the isomeric nmr signals after addition of Fe^{2+} differs in every case from the ratio before the addition of Fe^{2+} as described above for the 2:1 reaction mixture.

We have previously suggested the use of a point charge model for assigning ^{59}Co resonances (9). This model assumes the predominant influence of the paramagnetic term in determining the chemical shifts and uses simple crystal field theory

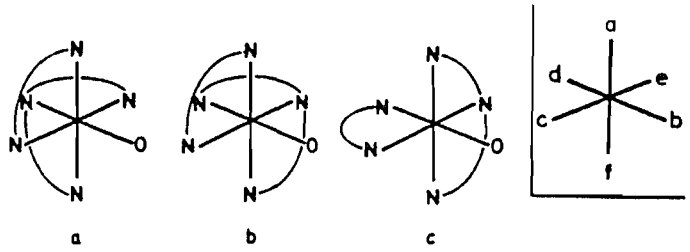

FIG. 4. Isomers of $[Co(dien)(en)]_2O_2^{4+}$: (*a*) edf,ac,b isomer, (*b*) def,ac,b isomer, (*c*) aef,cd,b isomer.

to obtain the energy differences required in the calculations. One parameter is required for each different kind of ligand and it was shown that the relative chemical shifts of isomeric compounds can be predicted to within a few ppm. The necessary parameters for the ligands of the present complexes have been reported previously (9). Figure 4 shows the isomeric structures. The calculated chemical shifts for the def,cd,b, the edf,ac,b and the def,ac,b isomers are 7795, 7681, and 7718 ppm compared with the experimental values of 7652, 7555, and 7572 ppm. There is an absolute discrepancy of about 140 ppm between the experimental and calculated values but the relative shifts allow assignment of the different isomers. This assignment can be confirmed by a further calculation of the expected line widths based on a point charge quadrupolar approximation. This leads to the prediction that the edf,ac,b isomer will have a linewidth approximately half of that of the other isomers as is apparent in Fig. 2. This result confirms the assignment given above. Thus the edf,ac,b isomer reacts faster than the aef,cd,b isomer. The third isomer is present in low abundance and is not well resolved at 21 MHz but appears to react slower than either of the others. It is interesting that the most reactive isomer has the central NH of the dien ligand, which is the ligand with the highest point charge (or crystal field splitting) parameter, *trans* to the peroxy group.

There have been a number of previous studies of the relative rates of reaction of isomeric Co(III) complexes. This area has been reviewed by House (10). The results most pertinent to the present findings are measurements of the rates of aquation, of base hydrolysis, and of Hg^{2+} assisted aquation of isomers of $Co(en)(dien)X^{2+}$ where X^- is a halide ion (10). For all three reactions a difference in rate of around three was found for the two isomers corresponding to the peroxy complexes discussed above. This ratio is very similar to that found in the present study. However, the direction of the effect is opposite since the aef,cd,b isomer reacts faster than the edf,ac,b isomer. This result is reasonable considering the nature of the reactions involved. In the peroxy reactions with Fe^{2+}, electrons must be donated from the peroxy ligand to the Co. Consistent with this π electron withdrawing ligands such as CN^- increase the rate of decomposition (11, 12). The initial step of a hydration reaction on the other hand is likely to be dissociation of the halide ion which removes electrons from the Co. The reverse dependence of the rate on structure is therefore to be anticipated.

The relative conformation of the aromatic rings and the amide bridge as well as important details of the two side chains of the title compound in a DMSO-d_6 solution have been established by use of non-selective and selective proton spin-lattice relaxation times coupled with nOe experiments. The complete analysis of ^{13}C spin-lattice relaxation times has shown the main features of the dynamic behavior of the title compound.

GIANNI VALENSIN, LIONELLO POGLIANI, MARIO GHELARDONI, VITTORIO PESTELLINI et ALESSANDRO SEGA. Can. J. Chem. **62**, 2131 (1984).

En se basant sur des déterminations sélectives et non-sélectives de temps de relaxation spin-réseau du proton couplées à des expériences d'effet Overhauser nucléaire, on a établi les configurations relatives des cycles aromatiques et du pont amide ainsi que des détails importants de deux chaînes latérales du composé mentionné dans le titre en solution dans le DMSO-d_6. L'analyse complète des temps de relaxation spin-réseau ^{13}C a permis de mettre en évidence les caractéristiques principales du comportement dynamique du composé mentionné dans le titre.

Introduction

When dealing with pharmacological and biological molecules one important step is the elucidation of conformational features in solution in order to find out the relationship with biological activity.

For this purpose nmr investigations are well suited, since several parameters can be pursued from which dynamic and conformational information can be obtained at the molecular level.

Here we present a study of the structure and dynamics of the title compound **1** (see Fig. 1), which is the first in a series of synthesized drugs which show smooth muscle relaxing activity (1). The combined discussion of (1) ^1H and ^{13}C chemical shifts, (2) ^1H and ^{13}C spin-lattice relaxation rates, (3) ^1H single-selective and double-selective spin-lattice relaxation rates, (4) nuclear Overhauser enhancement experiments, gave us the opportunity of measuring the $^{13}C—^1H$ and $^1H—^1H$ dipole–dipole interactions from which motional and structural features could be inferred. Namely, the dipolar interaction gives the function τ_c/r^6 and measuring τ_c from dipolar contributions to ^{13}C spin-lattice relaxation rates from directly bonded protons allows the evaluation of interproton distances, provided $^1H—^1H$ dipole–dipole mechanism dominates proton relaxation.

Results

The measured proton spin-lattice relaxation rates (R_1) of **1** are reported in Table 1 together with the chemical shift data. The R_1 values of the carbon nuclei of **1** are reported in Table 2 together with the chemical shift data. The assignments in the ^{13}C nmr spectrum were determined by observing selective decoupling of resonances on irradiation of single proton frequencies in the normal proton coupled spectrum. The non-selective and double-selective proton spin-lattice relaxation rates were measured for some protons relevant for conformational analysis (see below). The relaxation data, calculated in the initial slope approximation (2), were previously used to point out the main configurational features of the title compound (3). A typical nOe difference spectrum, showing positive nOe enhancements for H_5, H_3, H_{18}, and NH resonances with saturating irradiation of the H_6 resonance, is illustrated in Fig. 2. The full intensity perturbation pattern is summarized in Table 3, where the significant nOe enhancements are reported to be discussed for conformational purposes.

Discussion

^1H nuclear magnetic resonance chemical shift data

It is important for the following discussion to establish the stereochemistry of the amide group. The configuration around the nitrogen is planar or nearly planar as a consequence of the reduction of electronic density caused by electron withdrawing substituents (4). The configuration about the C—N amide bond must be *cis* with the carbonylic group and ring B on the same side, as *trans* configuration is forbidden by steric hindrance between the two aromatic rings (5).

The high value of the chemical shift of the $H_{10,10'}$ protons can be taken to indicate coplanarity between ring B and the carbonylic group, since it has been demonstrated (6) that whenever the carbonyl group is forced outside the plane of the benzene

ring the usual downfield shift of the protons *ortho* to this group is greatly reduced. On the other hand, the chemical shift of the H_3 proton and its small difference with respect to the chemical shift of the H_5 *para* proton could indicate a possible deviation from coplanarity between ring A and the amide carbonyl; however, in this case, a qualitative analysis of the chemical shifts is complicated by the presence of two *ortho* substituents.

The equivalence of the two ethyl groups at the quaternary nitrogen can be ascribed to rapid rotation around the C_{14}—N bond accompanied, but not necessarily, by fast free internal rotations (see discussion on relaxation times).

The unresolved lineshape of H_{13} and H_{14} may, on the contrary, be due to hindrance of fast internal motions with resulting incomplete averaging of electronic environments. In fact the quadrupolar interaction with the nitrogen atom is expected to give only a small contribution.

^{13}C nuclear magnetic resonance chemical shift data

The ^{13}C nmr spectrum, obtained at 50.309 MHz, ratifies the suggestion that the two ethyl groups at the quaternary nitrogen are equivalent due to fast rotation around the C_{14}—N bond. In a similar way the magnetic equivalence of the two C_9 and the two C_{10} carbons is pointing to fast rotation of the ring B around the C_8—C_{11} molecular axis. The chemical shifts found for ring B carbons are in perfect agreement with those reported for derivatives of benzanilide (7).

The most interesting result is the chemical shift for C_{13} and C_{14}. In **1**, C_{14} is found upfield with respect to C_{13} and their chemical shift difference is very small. On the contrary, in the ^{13}C nmr study of a series of benzocaine hydrochloride anesthetics (8) it has been found that C_{14} is downfield independently of the substituent in position 8. Similar results are also reported for acetylcholine (9). A downfield shift of the same order of magnitude is also observed for C_{16} with respect to benzocaine hydrochloride anesthetics, while, on the contrary, C_{15} is shifted 7 ppm upfield with respect to acetylcholine. The best explanation for these results is a change in the conformation of the N^+—C_{14}—C_{13}—O backbone and (to a lesser extent) an alteration of the electric field gradient at the nearby carbon atoms (10).

^1H and ^{13}C spin-lattice relaxation data

The relaxation of protons is mostly determined by mutual dipolar interaction of proton pairs. In dilute solutions intramolecular interactions are expected to yield the major contribution.

The measured proton spin-lattice relaxation rates (Table 1) do not allow any quantitative calculation of conformational and motional molecular features, but the following spectulations are nonetheless possible. The fast relaxation rates of H_{13}, H_{14}, H_{15}, and H_{16} suggest a restriction of free segmental motion and, as a consequence, a certain rigidity of this part of the chain; in fact the dipolar and/(or) scalar interaction with the nitrogen atom are not expected to be large enough to provide efficient relaxation pathways. The difference in relaxation rate between H_9 and H_{10} is due to an additional contribution to the relaxation of H_9 from the NH group and such difference may be taken as an aid in proton resonance assignments. The slowest relaxation rate of H_3 is consistent with the environment of that proton,

TABLE 4. Correlation times for internal motions of selected carbons of compound **1** (0.2 mol dm^{-3} in DMSO-d_6 at 298 K) with respect to a rotational molecular correlation time $\tau_R = 1.97 \times 10^{-10}$ s

Carbons	τ_G (s)
C_6, C_4, C_3	5.50×10^{-11}
C_9, C_{10}	5.50×10^{-11}
C_{13}	5.48×10^{-11}
C_{14}	2.95×10^{-11}
C_{16}	1.80×10^{-11}
C_{18}	1.00×10^{-11}

which has the dipolar interaction with H_4 as a unique relaxation pathway. On the contrary, H_6, which apparently experiences a molecular environment similar to that of H_3, displays a relatively fast R_1, suggesting the existence of additional proton–proton interactions leading to efficient relaxation.

Since the ^{13}C spin-lattice relaxation rates are almost exclusively determined by dipolar interaction with directly bonded protons (11, 12), the data reported in Table 2 can be suitably used to speculate about the molecular dynamics of compound **1**.

First of all, it is worth noting that all the protonated aromatic carbons display the same spin-lattice relaxation rates, with the exception of C_5 which relaxes with a faster kinetic constant. As already stated in other cases (11, 12), these findings can be accounted for in terms of a main molecular rotation axis which passes through C_5 and C_2 such that the C_5—H_5 vector undergoes slower tumbling motions as compared to the other C—H vectors. Since the relaxation rates of C_9 and C_{10} are very similar to those of C_3, C_4, and C_6, the same dynamic features can be inferred for ring B where the main molecular axis (C_8—C_{11}) can be suggested to be tumbling at the same reorientational rate as the C_5—C_2 axis. As a consequence, an anisotropic model made by rotational reorientation around the two molecular axes with some degree of internal motion (13) was used. Such a model can also be suitably applied to the other carbons in the molecule: the data shown in Table 4 were obtained where τ_R^{-1} represents the reorientational rate of the C_5—C_2 and C_8—C_{11} axes and τ_G^{-1} the rate of internal motions.

It can be seen that the degree of internal motion is increasing with the distance from the aromatic rings. It is worth noting that C_{13} does not show internal motions faster than those of the aromatic rings, but rather it looks as if it is reorientating jointly with the rings, in agreement with inferences from proton relaxation data.

The relaxation rates of C_{18}, C_{19}, and C_{20} show segmental motion through the aliphatic chain. Since C_{20} relaxes more slowly than C_{19}, as usually expected for segmental motion, any attractive interaction from the oxygen atom can be excluded, with consequent stabilization of a *gauche* conformation through the C_{18}—C_{19} bond. In fact such an attractive interaction has been shown to yield reduced T_1 values for terminal methyl groups in three carbon chains (14).

Selective proton relaxation data

Measuring non-selective (R_{ns}), single-selective (R_s), and double-selective proton spin-lattice relaxation rates has been suggested as a suitable aid to conformational studies in solution (15–17). In fact the ratio (R^i_{ns}/R^i_s) for any proton i allows evaluation of the extent to which pairwise dipole–dipole interactions provide the relaxation mechanism (the ratio is 1.5 for a purely dipolar mechanism).

The non-selective and single-selective relaxation rates of some protons of compound **1** were found (3) to yield R^i_{ns}/R^i_s ratios which are in fairly good agreement with the 1.5 value of the aromatic protons, while H_{20} and NH displayed ratios much lower than 1.5. Since it is not possible to avoid partial irradiation of proton resonances occurring in the neighborhood of the selectively irradiated proton, it could be suggested that mechanisms other than the dipolar interaction are not effective. Ratios lower than 1.5 can be ascribed to one or more of the following causes: (a) effectiveness of other relaxation mech-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

anisms, such as spin-rotation, scalar relaxation, or, seldom, chemical shift anisotropy; (b) scalar and (or) dipolar coupling with rapidly relaxing nuclear species, mostly nitrogen atoms; (c) reorientational correlation times much longer than the inverse of the nuclear Larmor frequency; (d) occurrence of more than one proton species at the same value of chemical shift: in this case, e.g., for a CH_3 or a CH_2 group, the selective relaxation rate contains also the cross-relaxation terms of the intermethyl or intermethylene proton dipolar interaction.

The ratio found for NH ($R_{ns}/R_s = 1.14$) could be suitably accounted for by cause (b), as has been shown by calculating the dipolar contribution from ^{14}N to protons at small internuclear distances (18), whereas the ratio found for methyl H_{20} ($R_{ns}/R_s = 0.98$) could be justified by cause (d) and, likely, by (a), i.e., an actual contribution from spin-rotation. In fact the slowest correlation time measured by ^{13}C nmr relaxation data excludes the possibility that the extreme narrowing limit does not hold.

The non-selective proton relaxation rate of H_9 ($R^9_{ns} = 1.538$) is faster than that of H_{10} ($R^{10}_{ns} = 1.250$), suggesting that, besides the dipolar H_9—H_{10} interaction, other protons, which means the NH proton, are yielding valuable contributions to the relaxation of H_9. In this case the double-selective irradiation of the two proton resonances allows the evaluation of structural parameters. The following equations can be, in fact, written:

$$[1] \quad R^9_{ns} = \rho_{9,10} + \rho_{9,NH} + \sigma_{9,10} + \sigma_{9,NH}$$

$$[2] \quad R^9_{9,10} = \rho_{9,10} + \rho_{9,NH} + \sigma_{9,10}$$

$$[3] \quad R^9_{ns} - R^9_{9,10} = \sigma_{9,NH}$$

where $R^9_{9,10}$ is the measured initial rate of recovery of the longitudinal magnetization of H_9 when H_9 and H_{10} are simultaneously inverted by a double-selective pulse. The ρ's are direct relaxation terms (20) and the σ's are cross-relaxation terms (20), which for a dipolarly coupled proton pair are given by (20):

$$[4] \quad \sigma_{ij} = \frac{1}{10}\frac{\hbar^2\gamma_H^2}{r_{ij}^6}\left\{\frac{6\tau_c}{1+4\omega_0^2\tau_c^2} - \tau_c\right\}$$

where r_{ij} is the interproton distance, ω_0 is the Larmor frequency, and τ_c is the motional correlation time.

By inspection of the single-selective relaxation rates of H_5 and H_4, which are found 2.45 Å apart as determined by neutron scattering data (19), theoretical values for R^4_s and R^5_s were calculated (3) which fit the experimental ones when using $\tau_c = (1.97 \pm 0.09) \times 10^{-10}$ s, which represents the molecular reorientational time. Using this value of τ_c, a distance of 2.52 ± 0.05 Å was calculated between the NH proton and H_9. This distance is in very good agreement with that calculated from a Dreiding molecular model of **1** on the basis of coplanarity between the amide unit and ring B (2.41 Å) (see Fig. 3). The difference between the two values can be accounted for in terms of an angle of ±10° between the two moieties.

Since the difference $R^{NH}_{ns} - R^{NH}_s$ should be expected to yield the same value as the difference $R^9_{ns} - R^9_{9,10}$, if the NH was interacting with H_9 only, and since this was not the case, the following equations can be given:

$$[5] \quad R^{NH}_{ns} - R^{NH}_s = \sigma_{9,NH} + \sigma_{3,NH}$$

$$[6] \quad \sigma_{3,NH} = (R^{NH}_{ns} - R^{NH}_s) - (R^9_{ns} - R^9_{9,10})$$

Using the value of $\sigma_{3,NH} = 0.12 \pm 0.03$ s^{-1} and $\tau_c = (1.97 \pm 0.09) \times 10^{-10}$ s it was possible to evaluate $r_{3,NH} = 2.81 \pm 0.06$ Å. This distance is consistent with an angle of ±55° between the plane of ring A and the plane defined by the amide unit and ring B (3).

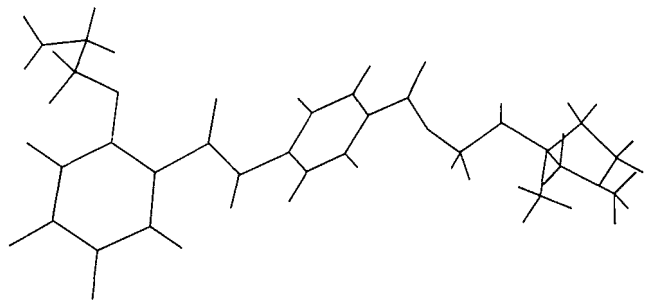

FIG. 3. Main conformation of **1** (0.2 mol dm^{-3}) in DMSO-d_6 solution.

The relatively fast non-selective and single-selective proton relaxation rates of H_6 ($R^6_{ns} = 2.33 \pm 0.11$ s^{-1}, $R^6_s = 1.61 \pm 0.07$ s^{-1}) (3) cannot be accounted for by considering only dipolar interactions with nearby aromatic protons, since the long distance between two protons in the *meta* position ($r = 4.30$ Å) is expected to give small contributions to the proton relaxation rate ($\rho = 0.02$ s^{-1}, $\sigma = 0.01$ s^{-1}). As a consequence, a dipolar interaction with protons within the propyloxy chain may be suggested. In this case, by applying the same equations as before, it was possible to calculate an average distance between H_6 and dipolarly coupled protons in the side chain of 2.42 ± 0.04 Å, which gives a strong contribution to proton relaxation.

The non-selective and double-selective proton relaxation rates of H_{10} are nearly equal, being the difference of the same order of magnitude of experimental error. In any case the small difference ($\sigma_{10,others} = 0.06 \pm 0.02$ s^{-1}) could be taken as a dipolar contribution from protons far away in the molecule. Since the NH is too far to exert any influence on dipolar relaxation of H_{10} ($r_{10,NH} = 4.74$ Å), a certain contribution from the H_{13} protons may be suggested. These findings might point to a configuration such that the C_{13} methylene is forced outside the plane defined by ring B and the carboxylic group.

The magnitude of dipolar contribution, however, excludes dramatic folding of the moiety around the quaternary nitrogen toward ring B: no protons at distances less than 3.15 Å can be found, according to calculations based on the previous analysis.

$^1H\{^1H\}$ nuclear Overhauser enhancement data

The origins of $^1H\{^1H\}$ nOe have been extensively investigated and a comprehensive review published (20). The fractional nOe enhancement of an observed spin d when spin s is saturated ($f_d(s)$) is given by:

$$[7] \quad f_d(s) = 0.5\ \rho_{ds}/R_d - 0.5 \sum_{n \neq d,s} \rho_{dn} f_n(s)/R_d$$

where:

$$[8] \quad R_i = \sum_{i \neq j} \rho_{ij} + \rho^*_i$$

$$[9] \quad \rho_{ij} = \gamma^2_i\gamma^2_j\hbar^2\ \tau_c(ij)/r^6_{ij}$$

$\tau_c(ij)$ is the correlation time of the vector r_{ij} between spin i and j, and ρ^*_i is the relaxation rate of spin i due to other relaxation mechanisms (see the discussion of ^{13}C and ^1H relaxation data). The R_i's correspond to the selective relaxation rate of proton i

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

($R_i = R_s^i$) provided other relaxation mechanisms are not relevant. The expression [7] is valid only at low concentration, where intermolecular dipole–dipole interactions can be neglected, and for loosely coupled spin $\frac{1}{2}$ systems.

A qualitative exploiting of nOe data (see Table 3), based on the relative nOe values, confirms the relative proximity of H_{18} protons to H_6. The absence of $f_{NH}(H_{19})$, $f_{NH}(H_{20})$, and $f_{H_{19}}(H_6)$ indicates that only the C_{18} methylene is somehow folded toward H_6, while the terminal part of the chain folds back and away from ring A and the amide unit.

It must be stressed that the relative distance is not the only parameter affecting the nOe enhancement. Cross-correlation and (or) cross-saturation terms, as stated in eq. [7], can make quantitative analysis a complicated matter, especially in cases where the loose coupling approximation breaks down.

In one case only was it worth running nOe analysis, namely, when presaturation of two different protons, *s* and *m*, produces nOe's at the same proton *d*. Then from eq. [7] the following relationship can be drawn, provided cross-saturation terms are irrelevant:

$$[10] \quad f_d(s)/f_d(m) = r^6_{dm}/r^6_{ds}$$

By applying this equation to the nOe's produced at H_3, upon presaturation of H_4 and NH, the distance $r_{3,NH}$ can be evaluated taking the fixed distance $r_{3,4} = 2.45$ Å. Such calculation gives $r_{3,NH} = 3.05$ Å, to be compared with the value $r_{3,NH} = 2.81$ Å calculated from single-selective measurements. Since, in theory, cross-saturation can affect the observed nOe's, the calculated distance can be thought to be in satisfactory agreement with the more accurate measurement from selective relaxation data.

Conclusions

The analysis of all the nmr parameters allows the delineation of the main conformational features of compound **1** (see Fig. 3). The amide unit, ring B, and the carboxylic group are nearly coplanar, while ring A forms an angle of ±55° with that plane. The angles of rings A and B with the amide unit can be measured by means of a clockwise or anti-clockwise rotation around the C_2—C_5 and C_8—C_{11} axes respectively; moreover, the librations of the two rings around the molecular axes can be paired or unpaired: namely ring B can be rotated +10°, with ring A rotated ±55°, or −10° with ring B rotated ±55°. The conformation sketched in Fig. 3 is only one of the possible preferred conformations.

The C_{18} methylene is brought near H_6 (mean distance 2.42 Å) while the terminal part of the chain folds back and away from ring A and the amide function. The C_{13} methylene could be forced outside the plane of ring B while the quaternary nitrogen moiety is stretched away from ring B.

The dynamic features of the two aromatic moieties keep a large part of the molecule in a fixed structure although some degrees of librational motion are allowed. Even the C_{13} methylene is somehow involved in the reorientational dynamics of the rings such that the motion of the C_{13}—H_{13} vectors is joined to the motion of ring B.

Experimental

The title compound was synthesized as already described (1). Solutions were made in 99.96% DMSO-d_6 and were carefully deoxygenated. The nmr spectra were taken on a Varian XL-200 spectrometer in the pulse-FT mode at probe temperatures of 25 ± 1°C; chemical shifts were referenced to the ^1H and ^{13}C resonances of internal TMS.

The ^1H and ^{13}C nmr spectra were measured with 5-mm and 10-mm od sample tubes respectively. Non-selective spin-lattice relaxation rates were measured with the inversion recovery pulse sequence $(t-\pi-\tau-\pi/2)_n$; 4 and 100 FIDs were collected for ^1H and ^{13}C T_1 experiments respectively; the $1/T_1 (= R_1)$ values were calculated from exponential regression analysis of the recovery curves of longitudinal magnetization components by using the computer of the spectrometer.

Single-selective and double-selective proton spin-lattice relaxation rates were measured with inversion recovery pulse sequences where the π pulse was given by the proton decoupler at the selected frequency for relatively long times at low power. The $\pi/2$ pulse was, on the contrary, the usual non-selective $\pi/2$ pulse given by the proton transmitter. The R_s values were measured in the initial slope approximation (2).

The nOes were determined by applying a 10-s low power saturating pulse at the appropriate peak position, followed immediately by a high power $\pi/2$ observing pulse. Since the maximum T_1 observed is of 1.09 s, the presaturating pulse is long enough to allow Overhauser equilibrium to establish. Off-resonance control spectra were measured with the presaturating pulse offset 1000 Hz to low field. Difference spectra were obtained by subtracting 40 on-resonance FIDs from 40 off-resonance FIDs followed by Fourier transformation.

S-Adenosylcoenzyme *M* and (±) *S*-methyl adenosylcoenzyme *M*. Preparation and role in methane biosynthesis

WILLIAM R. CULLEN,[1] DAVID DOLPHIN,[1] DALE HOFFMAN, AND EVERARD TRIP
Chemistry Department, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received December 22, 1983

WILLIAM R. CULLEN, DAVID DOLPHIN, DALE HOFFMAN, and EVERARD TRIP. Can. J. Chem. **62**, 2136 (1984).

5′-*S*-(2-Sulphoethyl)-5′-deoxy-5′-thioadenosine (*S*-adenosylcoenzyme M), **5**, was prepared from adenosine by reacting its 2′,3′-isopropylidine tosylate with the disodium salt of coenzyme M ($NaSCH_2CH_2SO_3Na$) followed by removal of the protecting group. Methylation of **5** to give methylsulphonium (±) *S*-adenosylcoenzyme M, **6**, was achieved with methyl iodide in acetic acid. Neither **5** nor **6** stimulated methane production from cell free preparations of *M. thermoautotrophicum*, negating the possibility of a biochemical analogy between **6** and *S*-adenosylmethionine (SAM).

WILLIAM R. CULLEN, DAVID DOLPHIN, DALE HOFFMAN et EVERARD TRIP. Can. J. Chem. **62**, 2136 (1984).

On a préparé la *S*-(sulfo-2 éthyl)-5′ déoxy-5′ thio-5′ adénosine (*S*-adénosylcoenzyme M), **5**, en faisant réagir l'isopropilidène-2′,3′ tosylate de l'adénosine avec le sel de disodium du coenzyme M ($NaSCH_2CH_2SO_3Na$), puis en éliminant le groupe protecteur. Grâce à sa réaction avec l'iodure de méthyle dans l'acide acétique, on a réussi à méthyler le composé **5**, pour obtenir le méthylsulfonium (±) *S*-adénosylcoenzyme M, **6**. Ni le composé **5** ni le composé **6** ne provoquent la production de méthane sous l'influence de préparations de *M. thermoautotrophicum* qui ne contiennent pas de cellules; d'après ce résultat, il ne peut y avoir d'analogie biochimique entre le composé **6** et le *S*-adénosylméthionine (SAM).

Introduction

It is estimated that more methane is produced biochemically than any other single organic compound. Despite this, details on the mechanisms by which methane is produced, or metabolised, are still far from complete.

Methane producing bacteria – the methanogens – represent an unusual and evolutionary primitive group of microorganisms which perform some unique biochemistry employing equally unique coenzymes and cofactors (1). A variety of carbon sources at all oxidation levels act as sources of methane (eqs. [1]–[4]).

[1] $4CH_3OH \rightarrow 3CH_4 + CO_2 + 2H_2O$

[2] $CH_3CO_2H \rightarrow CH_4 + CO_2$

[3] $4CO + 2H_2O \rightarrow CH_4 + CO_2$

[4] $CO_2 + 4H_2 \rightarrow CH_4 + 3CO_2$

The methyl groups of both methanol and acetic acid are incorporated "directly" into methane (eqs. [1], [2]) and methylcobalamin appears to be a cofactor in these reactions (2). However, although cobamide derivatives stimulate methane production from hydrogen and carbon dioxide (eq. [4]) this is thought to be an artifact and at the present time there is no definitive role for B_{12} derivatives in this reaction.[2] A 5′-deazaflavin (F_{420}) (3, 4) and a nickel tetrapyrrole (F_{430}) (5) are found only in the methanogens but, as with most biochemistry involving one-carbon fragments, a pterin, methanopterin (6), is probably involved as a carrier.

The transport and activation of methyl groups in most procaryotic and eucaryotic biochemistry is achieved via *S*-adenosyl methionine (SAM). Such is not the case with the methanogens, where the lowest molecular weight coenzyme so far reported, coenzyme M, 2-mercaptoethanesulfonic acid, serves in methyl transfer reactions, once again exemplifying the uniqueness of these microorganisms (7). Methyl coenzyme M, 2-(methylthio)ethanesulfonic acid (**2**), is the direct precursor of methane (8) and it has been variously reported (9, 10) that catalytic amounts of adenosine triphosphate (ATP) are required to activate the reduction of **2** to methane. We speculated that if the biochemistry of coenzyme M parallels that of SAM, then either *S*-adenosylcoenzyme M (**5**) or *S*-methyladenosylcoenzyme M (**6**) might be involved in methane production. We report here the synthesis of **5** and **6** and some results pertaining to their involvement in methane biosynthesis.

$HSCH_2CH_2SO_3H$ **1** $CH_3—S—CH_2CH_2SO_3H$ **2**

Experimental

All reactions were carried out under a nitrogen or argon atmosphere. The nmr spectra were run on a Varian XL-100 or Bruker WH-400 MHz spectrometer. Microanalyses were performed by Mr. Peter Borda (U.B.C).

2′,3′-O-Isopropylidene adenosine

The preparation parallels that reported previously (11) on a 1-mmol scale. The following procedure represents a direct scale-up (× 46) and includes some modifications, particularly in the isolation.

To a magnetically stirred suspension of adenosine (12.25 g, 46.2 mmol) in acetone (462 mL) was added 2,2-dimethoxypropane (38.7 g (46 mL), 0.37 mol). Di-*p*-nitrophenyl hydrogen phosphate 18.85 g (55.5 mmol, mp 173.5°C, was added and the solution stirred under N_2. After 2 h some solids remained and additional 2,2-dimethoxypropane (23 mL) was added. After stirring for a further 3 h the solution became homogeneous. The mixture was stirred overnight and then a solution of $NaHCO_3$ (9.33 g, 0.111 mol) in water (111 mL) was added. The mixture was taken to dryness by rotary evaporation (bath 50°C) and the yellow solid residue was pulverized and dried for 1 h at 70°C under high vacuum. The solid was then extracted five times with 200-mL portions of boiling $CHCl_3$. The chloroform extracts were combined, filtered, and taken down to dryness (bath 50°C) to give 14.78 g of crude product which was crystallized from boiling water (200 mL) to give, after air drying, 11.85 g (83%), mp 219–220°C, lit. (11) mp 216–217°C.

2′,3′-O-Isopropylidene-5′-O-toluene-p-sulfonyladenosine (3)

The procedure follows that previously reported (12), with these additional modifications. Reagent grade pyridine was distilled from

CaH_2 and the tosyl chloride purified by the method of Pelletier (13). Pyridine was removed by washing with 1 *N* H_2SO_4 until the last aqueous wash had a pH of 1. The chloroform was dried over sodium sulfate, filtered, and reduced in volume to 50 mL. This solution was then slowly added with stirring to petroleum ether (1.5 L). The amorphous solid was collected by filtration and dried over P_2O_5 under high vacuum to give 9.94 g (57%).

2′,3′-O-Isopropylidene-5′-S-(2-sulphoethyl)-5′-deoxy-5′-thioadenosine (4)

To a magnetically stirred solution of sodium coenzyme-M (2.07 g, 12.6 mmol, Pierce Chemical Co.) in liquid ammonia (125 mL), kept at −73°C under dry nitrogen, was added approximately 0.3 g (13 mmol) of sodium metal. The sodium was added in small chips until a light blue color persisted for a few minutes. To the resulting solution was added 2′,3′-*O*-isopropylidene-5′-*p*-toluenesulphonyladenosine, 4.61 g (10.0 mmol). The blue coloration was immediately discharged and, after 5 min, a clear, light-orange solution was produced. This solution was stirred for 3 h while the temperature was gradually increased to −40°C and then for a further 1 h in the temperature range −40 to −30°C. The cold bath was removed, the flask was wrapped in cotton, and the ammonia was allowed to evaporate over 4 h. After storage overnight at 4°C, the flask was put under high vacuum for 0.5 h to remove excess ammonia. The yellow residue was dissolved in 50 mL of H_2O and the aqueous phase was washed with one 50-mL and two 25-mL portions of $CHCl_3$ to remove small amounts of 2′,3′-*O*-isopropylideneadenosine and unreacted starting material. Thin-layer chromatography (in *n*-PrOH/concentrated NH_3/H_2O; 70:3:7 (v/v/v); Eastman silica gel) of the aqueous phase showed a single product spot at $R_f \sim 0.45$.

The aqueous phase was evaporated and the residual orange syrup dissolved in H_2O to a final volume of 60 mL. This solution was stirred and 1.0 *M* HCl was added dropwise to cause precipitation of **2** (final pH 1.5). The precipitate was filtered and dried under high vacuum, over frequent changes of P_2O_5 for 18 h, to give 3.69 g (85.5%) of colorless, amorphous product.

Attempted recrystallization of this material from boiling H_2O gave extensive hydrolysis to *S*-adenosylcoenzyme M.

5′-S-(2-Sulphoethyl)-5′-deoxy-5′-thioadenosine (S-adenosylcoenzyme M) (5)

To a magnetically stirred suspension of crude 2′,3′-*O*-isopropylidene-5′-*S*-(2-sulphoethyl)-5′-deoxy-5′-thioadenosine (1.73 g, 4.0 mmol) in 80 mL of H_2O heated at 55–60°C, was added 8.0 mL of a 20% (w/v) suspension of AG 50W-X2 (H^+) in H_2O (capacity of stock resin suspension ~1 mequiv./mL). Thin-layer chromatography (*n*-PrOH/concentrated NH_3/H_2O; 70:3:7; Eastman silica gel), after stirring 2 h, showed quantitative conversion of the starting material ($R_f \sim 0.45$) to product ($R_f \sim 0.25$). After 2.5 h the resin was filtered and washed well on the filter with H_2O. The filtrate was evaporated and the residual yellow syrup was dissolved in 4.0 mL of H_2O and then treated with 20 mL of warm MeOH. Crystallization was rapid and, after standing 1 h at room temperature and 3 h at 4°C, fine colorless needles were filtered and washed well with MeOH. Drying overnight under high vacuum over Drierite gave 1.45 g (88%) as the monohydrate; mp 152–156°C (dec.). *Anal.* calcd. for $C_{12}H_{17}N_5O_6S_2 \cdot H_2O$: C 35.20, H 4.68, N 17.10, S 15.66; found: C 35.16, H 4.60, N 16.87, S 15.44.

Methylsulphonium (±) S-Adenosyl Coenzyme M (6)

A suspension of *S*-adenosylcoenzyme M (328 mg, 0.8 mmol), in 30 mL of glacial acetic acid and 6.0 mL of H_2O, was warmed and swirled to dissolve the major part of the suspension. After cooling, 6.0 mL (96 mmol) of methyl iodide was added and the resulting mixture was magnetically stirred in the dark. After 4-1/2 days, tlc (*n*-PrOH/AcOH/H_2O; 85:5:10; Eastman silica gel) showed quantitative conversion of starting material ($R_f \sim 0.4$) to product ($R_f \sim 0.16$). The resulting deep red/orange solution was partitioned between 350 mL of H_2O and 150 mL of ether. The ether layer was discarded and the aqueous phase was washed with a further 3 × 50 mL of ether. The colorless aqueous phase was filtered and the filtrate was evaporated. The residual pale yellow syrup was dissolved in, and coevaporated three times with, 30-mL portions of H_2O to remove acetic acid. The residue was dried under high vacuum to give an almost colorless glass. Trituration of this glass with MeOH caused partial solidification. The MeOH was evaporated from the resulting suspension and the trituration was repeated. Evaporation then yielded 342 mg (77%) of very pale yellow amorphous product which was dried under high vacuum. Thin-layer chromatography (as above) of an aqueous solution of this product, when spotted heavily, showed only trace impurities at the origin and at $R_f \sim 0.35$. The microanalytical (found: C 33.25, H 4.66, N 14.27, I 8.90) data indicate an empirical formula of $C_{13}H_{20}N_5O_6S_2 \cdot 0.3HI$. Thus 2/3 of the product was the neutral zwitterion and 1/3 the hydriodic salt.

Results and discussion

Adenosylcoenzyme M was prepared by a route analogous to that developed for the synthesis of *S*-adenosyl methionine (14) as modified in the syntheses of other 5′-*S*-adenosine derivatives (12, 15). Condensation of 2,3′*O*-isopropylidene-5′-*O*-toluenesulfonyl adenosine (**3**) (16), Scheme 1, with the disodium salt of coenzyme M in liquid ammonia, gave an essentially quantitative conversion to 2′,3′-*O*-isopropylidene-5′-*S*-(2-sulphoethyl)-5′-deoxy-5′-thioadenosine (**4**) which was isolated as the zwitterion by precipitation at low pH. Quantitative removal of the isopropylidene protecting group was readily effected using a strongly acid ion exchanging resin (AG 50W-X2) at 50–60°C and **5** was isolated crystalline and in high yield.

The structure of **5** was confirmed by nmr spectroscopy (Table 1). The sugar proton resonances were assigned with the aid of spin decoupling experiments. The ribofuranoside ring protons have chemical shifts similar to those of **3** while the two diastereotopic 5′ hydrogens are shifted approximately 0.8 ppm upfield, consistent with the substitution at 5′ by the sulfur of coenzyme M. A singlet at 2.72 ppm contained the four ethanic protons of the coenzyme M moiety.

Previous workers (14, 17, 18) have successfully methylated 5′-alkylthio derivatives of adenosine, giving the 5′-alkylsulfonium derivatives, using methyl iodide in formic or acetic acids. Attempted methylation of **5** by similar reactions in formic or formic/acetic acid mixtures lead to extensive degradation. In glacial acetic acid little reaction was observed; however, in 83% acetic acid a quantitative conversion to **6** occurred over a period of 4 to 5 days. The product was isolated pure chromatographically, as a homogeneous amorphous solid. However, attempts at crystallization or other manipulations invariably led to the gradual breakdown of the product. SAM is similarly unstable, due in part to the nucleophilic attack of iodide at the activated methyl group. The structure of **6** was again confirmed by nmr spectroscopy. Methylation of the sulfur atom will produce a chiral sulphonium residue and give two diastereomeric products. The two methyl sulfonium groups exhibited slightly different chemical shifts at 3.09 and 3.10, shifted downfield by 0.8 ppm with respect to the methyl group of 2-(methylthio)ethane-sulfonic acid. The positively charged sulfur causes similar downfield shifts of the 5′ protons and a methylene group of the coenzyme M fragment.

Methyl transfers via SAM involve *inter alia* the transfer of a methyl group from N^5-methyltetrahydrofolic acid (a pterin) to homocystysteine to give methionine. Methionine is then adenylated using ATP to SAM. After transfer of a methyl group, the adenosylhomocysteine is cleaved to adenine and homocysteine such that methyl transfer under these conditions is not catalytic, but rather stoichiometric in ATP. Nevertheless, the

catalytic role of ATP in methane formation using coenzyme M could be envisaged as outlined in Scheme 2. This would require that adenosylcoenzyme M (**5**) should replace the need for the catalytic ATP and then **6** should give methane. Neither reaction is observed. Adenosylcoenzyme M (**5**) prepared as described here and separately by Romesser and Wolfe (19) did not replace the ATP requirement and no methane was generated (Table 2) upon the addition of **6**. Since these experiments were carried out on viable cell-free preparations, one can only conclude that neither **5** or **6** play a role in methane biosynthesis and that the catalytic role of ATP is not involved in sulfur alkylation but in some other, as yet to be elucidated, reaction.

Comparative analysis of hazardous compounds on fly-ash from municipal waste incineration by gas chromatography/mass spectrometry

A. C. VIAU, S. M. STUDAK, AND F. W. KARASEK[1]

The Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received November 17, 1983

A. C. VIAU, S. M. STUDAK, and F. W. KARASEK. Can. J. Chem. **62**, 2140 (1984).

Fly-ash samples from municipal incinerators in Canada and Norway were analyzed for polychlorinated dibenzo-*p*-dioxins using gas chromatography/mass spectrometry preceded by fractionation on column chromatography. Qualitative and quantitative differences in the organic compounds identified were found between the two samples. Many of the same dioxin congeners were present in both samples; however, tetrachlorodibenzo-*p*-dioxins were only detected in the Canadian sample.

A. C. VIAU, S. M. STUDAK et F. W. KARASEK. Can. J. Chem. **62**, 2140 (1984).

Faisant appel à une méthode impliquant un examen par chromatographie en phase gazeuse couplée à la spectrométrie de masse d'échantillons pré-fractionnés par chromatographie sur colonne, on a analysé des échantillons de suie provenant d'incinérateurs municipaux du Canada et de la Norvège afin de déterminer leur teneur en dibenzo *p*-dioxines polychlorées. On a trouvé des différences qualitative et quantitative dans les composés organiques identifiés dans les deux échantillons. Les deux échantillons contiennent sensiblement les mêmes congénères de la dioxine; toutefois, ce n'est que dans l'échantillon canadien que l'on a pu détecter les tétrachlorodibenzo *p*-dioxines.

[Traduit par le journal]

Introduction

Electrostatically precipitated fly-ash from municipal incinerators is known to contain hundreds of compounds, many being toxic in low concentrations (1). Classes of compounds found include hydrocarbons, polycyclic aromatic hydrocarbons (PAH), polychlorinated benzenes, polychlorinated biphenyls (PCB), polychlorinated dibenzo-*p*-dioxins (PCDD), and polychlorinated dibenzofurans (PCDF).

PCDD and PCDF have been found to be extremely toxic and have been the subject of numerous studies (1–4). Recent research has demonstrated that these compounds still occur after incineration above 1200°C (5). However, other chlorinated compounds have been identified in waterwall incinerators, while PAH and hydrocarbons are not found (6). The source of PCDD and PCDF has been suggested to be polyvinyl chloride (PVC) incineration, but no change in the level of these compounds was found in fly-ash samples obtained in a planned experiment in which additional PVC was added to the incinerator waste feed (6).

Organic compounds found on fly-ash samples from municipal incinerators in Norway and Canada are extracted and preseparated using pressurized liquid chromatography. The differences in the concentrations of hazardous compounds for these two samples are compared. Although these are single samples, it has been found that under normal operating conditions, the concentration of chlorinated species do not vary more than 70% relative, as compared to near 200% relative for alkanes (7). The analyses performed in this study can be considered representative of the differences in the emissions of harzardous compounds from municipal waste incineration, based on previous analyses of fly-ash from both countries.

It is found that fly-ash from Norway contained more PAH, thio-PAH, and chlorinated biphenyls than the Canada fly-ash. Canada fly-ash was found to have a greater concentration of PCDD, PCDF, chlorobenzenes, and chlorophenols. A comparison of individual compounds within a class shows that there is also a difference in the components. The levels of PCDD for both samples are also compared and observations are made.

[1]To whom all correspondence should be addressed.

Experimental

Sampling

Samples of fly-ash were received from two separate municipal incinerators. One was from Ontario, Canada, and the other from Oslo, Norway. These were collected from the hoppers of electrostatic precipitators.

Sample extraction and fractionation

The samples underwent a 16-h soxhlet extraction of 15–20 g of fly-ash with 200 mL of distilled-in-glass benzene and concentrated to 100 μL by rotary evaporation under aspirator vacuum (1). A column of 6 g 44% sulfuric acid/silica gel was washed with 50 mL of hexane. The concentrate was introduced and eluted with 75 mL of hexane and quantitatively concentrated to 100 μL. A 1 g alumina gel (Woelm Neutral) column 2 mm id was prepared by 10 mL sequential washings of methylene chloride, 10% carbon tetrachloride in hexane and hexane. It was then utilized for separation of the concentrate into three fractions; 20 mL each of hexane, 10% carbon tetrachloride in hexane and methylene chloride. The two adsorbents, alumina and silica gel, were kept in a 200°C oven previous to use. To enable a more rapid elution, 10 psig of air pressure was applied directly to the alumina column. Each of the three fractions were concentrated to 100 μL and analyzed for polychlorinated dibenzo-*p*-dioxins and other organic compounds by gc/ms. The clean-up and analysis was performed twice for PCDD on the Canada fly-ash to test the reproducibility of this method. An average relative standard deviation of 17% was observed; this is within variations previously published for this analytical system (8).

Gas chromatographic analysis

A Hewlett-Packard 5830A Gas Chromatograph was used with a 2 m × 2 mm id column with Aue packing and flame ionization detector for prescreening of extracts prior to gc/ms analysis (9). A temperature program of 90°C initial temperature to 250°C final temperature at 4°C per min was employed for all extracts. The He carrier gas flow rate was about 32 mL/min.

Gas chromatographic/mass spectrometry analysis

The extracts were analyzed with a Hewlett-Packard 5992A gc/ms/computer in the selected ion monitoring (SIM) mode for PCDD determination. This instrument was equipped with a cool-on-column injection port, 30 m × 0.32 mm id fused silica capillary columns with cross-linked DB-5 stationary phase (J&W Scientific, Rancho Cardova, CA), capillary glass restrictor inlet, $x-y$ plotter, and dual floppy disk system. The He carrier gas flow rate was 3 mL/min.

The ions monitored for tetrachlorodibenzo-*p*-dioxin (TCDD) were 319.9 and 321.9. Other ions selected for penta- through octachlorodibenzo-*p*-dioxin were 355.9 (P5CDD), 389.8 (H6CDD), 425.8 (H7CDD), and 459.7 (OCDD). A dwell time of 50 ms was used for each ion. SIM areas were used for quantification. PCDD congeners were quantified using a standard mixture of 1,2,3,4-TCDD, 1,2,3,4,7,8-H6CDD, 1,2,3,4,6,7,8-H7CDD, and OCDD. P5CDD was quantified using a response factor intermediate to TCDD and H6CDD standards (8).

Chromatographic conditions were as follows: initial oven temperature 180°C to 300°C final temperature at 4°C/min and the injection port temperature was 70°C.

Mass spectra were obtained by scanning from 500 to 50 amu at 330 amu/s. Spectra taken at the top of the eluting gc peaks were saved on floppy disk, in addition to those at the lowest valley between peaks for later background subtraction. A user-developed program called Dual Mode was employed which allowed storage of total ion abundances and mass chromatograms in addition to mass spectra.

Before operation, the mass spectrometer was tuned daily by the manufacturer-supplied program AUTOTUNE using a perfluorotributylamine calibration standard. Identification of compounds was based on their mass spectra by using Eight Peak Index of Mass Spectra and EPA/NIH Mass Spectral Data Base. The mass spectra search systems, Probability Based Matching (PBM) and Self-Training Interpretive Retreval system (STIRS) were accessed by telephone hook-up to Cornell University. This procedure provides an identification with varying degrees of certainty. The only way to provide a more certain identification is to directly obtain the mass spectrum and retention time of pure standards for each compound. The mass spectra of the compounds identified were well matched to their reference spectra. In cases where only the type of compound was indicated, mass spectra characteristic of that type were clearly obtained. If no identification resulted from this procedure, the compound was labelled unidentified. Not having the standards of the many isomers of the PCDD and PCDF compounds it was not possible to indicate these separately.

Further identification was done using the PAH retention index system (10). Retention data from other sources were also used (11, 12). It has been found that the retention index can vary for some compounds (12). Consequently, a window of two retention index units was used.

Compounds were quantified using response factors of standards and the peak height method. PAH compounds and thio-PAH compounds were quantitated using the response factor for fluorene, anthracene, fluoranthene, and pyrene. Chlorobenzenes and chlorophenols concentrations were calculated using the response factors of 1,2,3,4-tetrachlorobenzene, pentachlorobenzene, and hexachlorobenzene. The response factors of tetrachlorodibenzofuran (TCDF) and octachlorodibenzofuran (OCDF) were used in the estimation of the concentrations of PCDF and PCB. Since pure PCB isomers were not available at the time of the study, this method was used to closely approximate their concentrations.

Results and discussion

The extracted compounds for the two fly-ash samples were identified by gc/ms. These compounds are listed in Table 1 with their corresponding retention indices and labeled in Figs. 1 and 2. The majority of compounds were identified by both mass spectra and retention index. Compounds which were only identified by their mass spectra are marked. Saturated and unsaturated hydrocarbons were not identified or quantified because of their relative non-toxic nature. There were 36 individual compounds found in the sample from Canada and 46 compounds found in the sample from Norway.

Many organic compounds such as alkyl substituted benzenes and various polycyclic aromatic compounds (PAC) were found to occur. Also present were numerous chlorinated compounds such as chlorinated benzenes, chlorinated phenols, chlorinated

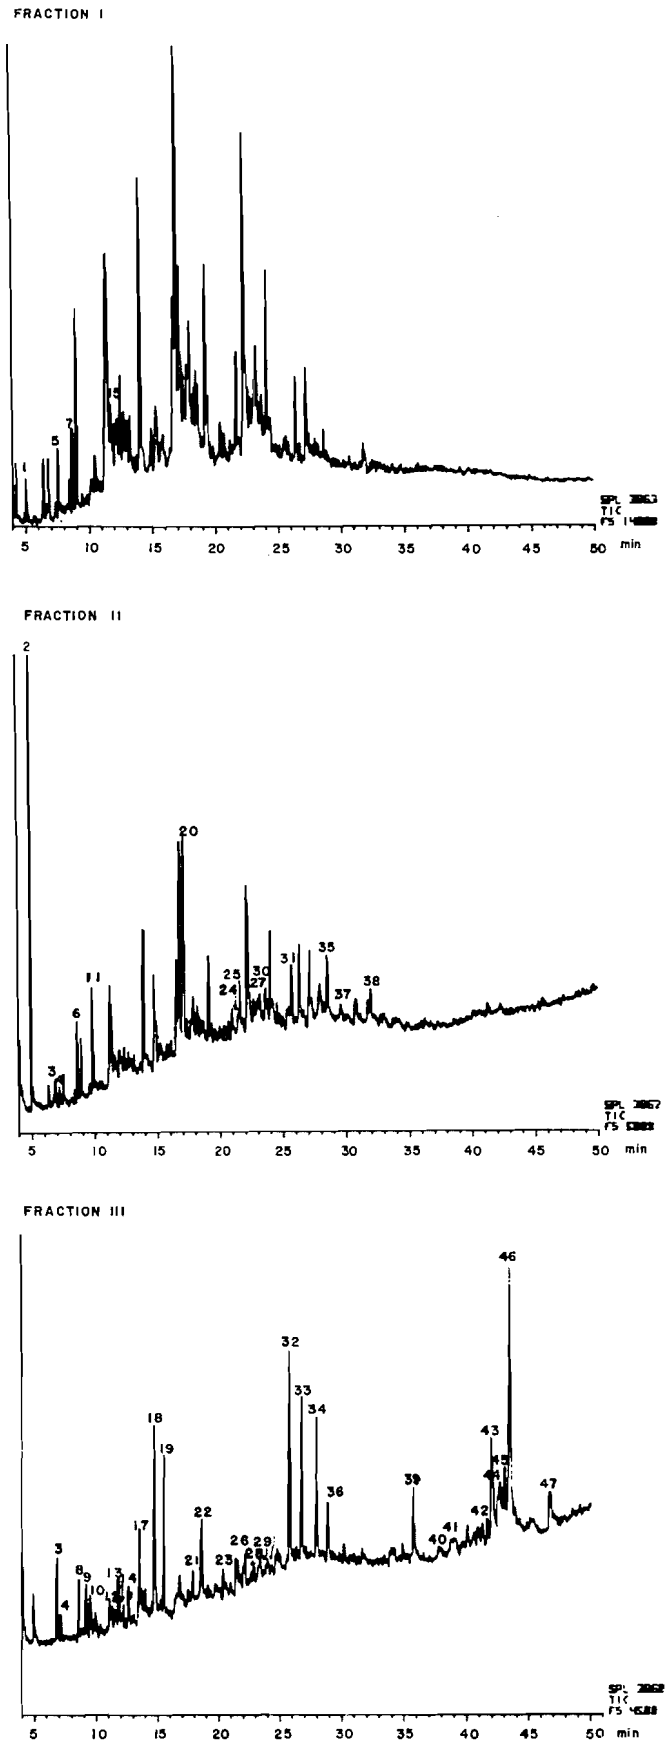

FIG. 2. Comparison of the total ion currents (TIC) from Norway fly-ash extract divided into three fractions. The numbered peaks correspond to the compounds identified in Table 2.

TABLE 2. Comparison of specific compounds from Canada and Norway fly-ash extracts in ng/g concentration

Compound		Concentration Norway	Canada
Polycyclic aromatic hydrocarbons	**Total**	**2125**	**735**
Naphthalene		760	130
Alkyl-substituted naphthalene		470	180
Biphenyl		70	190
Alkyl-substituted biphenyl		520	—
Phenanthrene		130	140
Fluoranthene		—	95
Fluorene		115	—
Methyldiphenylhexahydrocyclopentaindene		60	—
Polychlorinated biphenyls	**Total**	**360**	**—**
Trichloro-		110	—
Tetrachloro-		140	—
Pentachloro-		60	—
Hexachloro-		50	—
Polychlorinated benzenes	**Total**	**685**	**1130**
Trichloro-		235	—
Tetrachloro-		400	590
Pentachloro-		50	270
Hexachloro-		—	270
Polychlorinated phenols	**Total**	**11**	**94**
Trichloro-		11	35
Tetrachloro-		—	32
Pentachloro-		—	27
Polychlorinated dibenzofurans	**Total**	**20**	**830**
Tetrachloro-		—	20
Pentachloro-		—	350
Hexachloro-		20	260
Heptachloro-		—	200
Thio-PAH	**Total**	**75**	**50**
Alkyl-substituted dibenzothiophene		75	—
2,5-Bis(*p*-Chlorophenyl)1,4-diithin		—	50

biphenyls, chlorinated dioxins, and furans. More uncommon compounds such as alkyl-substituted dibenzothiophenes and chlorophenyl diithin were also identified.

Each fraction from the adsorption column contained groups of compounds. Fraction I had a high abundance of hydrocarbons, alkyl-substituted benzenes, and polychlorinated benzenes. Fraction II contained mainly PCB and chlorophenols. PAH, thiophenes, and indenes were present in both Fractions II and III. The PCDD and PCDF were present mainly in Fraction III.

Comparison of the two fractions was done by calculating the concentrations of selected hazardous compounds. Table 2 lists specific compounds classes and the corresponding concentrations (ng/g) for both Norway and Canada fly-ash extracts, seen in Figs. 1 and 2 calculated by the peak height method. The relative amounts of a component per weight of fly-ash for each sample can be compared.

From Table 2, the Norway extract is seen to contain more PAH and in greater concentration than in the Canada sample. Napthalene and alkyl-substituted naphthalene were present in both samples but were more abundant in the Norway fly-ash. The Canada extract did contain more biphenyl, phenanthrene, and fluoranthene than the Norway sample. Alkyl-substituted

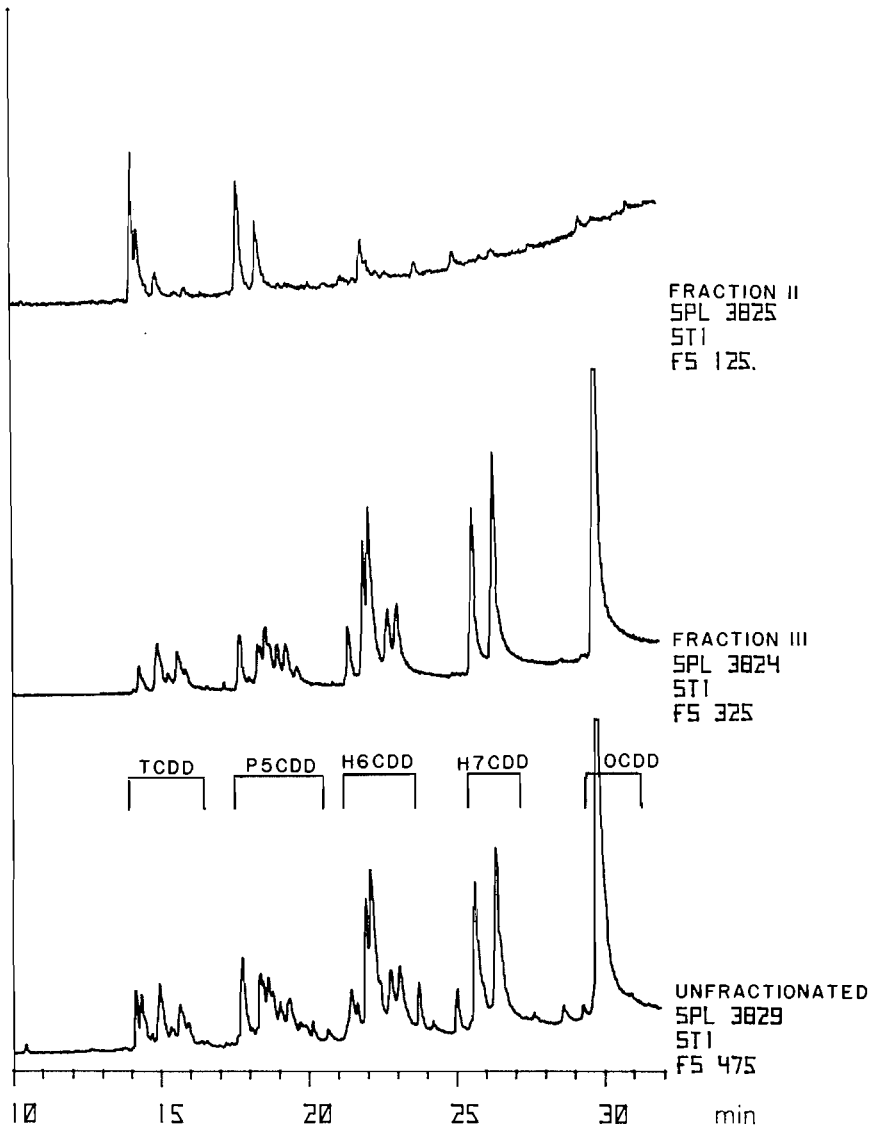

FIG. 3. Comparison of sim total ions (STI) for PCDD from Canada fly-ash unfractionated and Fractions II and III. Brackets indicate the elution retention times for the PCDD congeners.

biphenyl compounds were found only in the Norway sample and they were second in abundance to naphthalene, the most abundant of the PAH. Other substituted PAH were found to occur only in the Norway extract.

Chlorinated benzenes present in both extracts were more prominent in the Canada fly-ash, as seen in Table 2. The Canada extract contained tetrachlorobenzene as the most abundant compound with pentachlorobenzene and hexachlorobenzene occurring in equal amounts. In contrast, the Norway extract contained only trichloro-, tetrachloro- and pentachlorobenzene with tetrachlorobenzene being the most abundant compound of this class.

The Canada fly-ash also contained more chlorinated phenols than the Norway fly-ash. There was an equal amount of trichloro-, tetrachloro- and pentachloro-phenol in the Canada extract but only a small quantity of trichlorophenol was found in the Norway sample.

Polychlorinated biphenyls, trichloro- through to hexachloro-biphenyls were detected only in the Norway extract. Tetrachlorobiphenyl was the most abundant of the four isomeric classes.

In contrast, polychlorinated dibenzofurans (PCDF) were found mostly in the Canada sample. The Norway fly-ash contained only hexachlorodibenzofuran while the Canada fly-ash had the congeners from tetra- to octachlorodibenzofuran.

Thio-PAH were found in both samples. The compound 2,5-bis(*p*-chlorophenyl)1,4-diithin, identified by STIRS, was present only in the Canada fly-ash. Norway fly-ash contained a wide variety of alkyl-substituted dibenzothiophenes.

Compounds found specifically in the Norway extract but not in the Canada extract were 10*b*,10*c*-dihydro-10*b*,10*c*-dipropyltranspyrene, C2-akyl-9,10-anthracenedione, methyldiphenylhexahydrocyclopentaindene, and C2-alkyl(phenylmethyl)benzene isomers.

Table 3 lists concentrations (ng PCDD/g fly-ash) calculated using SIM areas of PCDD present in each extract, and Fig. 3 shows the SIM total ion (STI) which sums all SIM ions into one trace for the Canada fly-ash (13). It can be seen that PCDD are separated mostly in Fraction III. Some TCDD and P5CDD are present in Fraction II. The percentage recovery of PCDD from the Canada fly-ash was calculated by summing the calculated concentrations from Fractions II and III and comparing these

TABLE 3. Concentrations of PCDD on fly-ash from Canada and Norway

(*a*) Canada

Compound	Concentration (ng/g) Trial 1	Trial 2	Mean	Unfractionated	Recovery
TCDD	160	177	168	330	51%
P5CDD	226	183	204	390	52%
H6CDD	237	187	212	610	34%
H7CDD	190	148	169	460	37%
OCDD	380	275	328	470	35%

(*b*) Norway

Compound	Concentration (ng/g)	Corrected for recovery
TCDD	Not detected	—
P5CDD	15	29
H6CDD	38	112
H7CDD	62	167
OCDD	92	263

additions to the unfractionated sample. This percentage recovery was used for correction of the PCDD concentration in the Norway extracts. No PCDD were detected by SIM for the Norway unfractionated extract because of the high content of organic compounds.

The large amount of quantitative data now available on PCDD from municipal incinerators has revealed that the emission pattern of PCDD can be divided into two groups. Some incinerators emit PCDD on fly-ash so that H6CDD is among the highest congener found and TCDD is almost one-half the amount of OCDD present (14). The Canada fly-ash studied fits into this category.

The second group is characterized by having OCDD as the most concentrated PCDD congener and all other congeners in decreasing quantity, so that TCDD is approximately 3% of the OCDD concentration (15). This pattern has been found in France, Germany, and now Norway (5, 15, 16). The differences between these two groups have not been explained. Some suggest that burning efficiency and/or chlorine content of the fuel may have some effect (7, 16).

The uncorrected concentrations of organic compounds present on the Norway and Canada fly-ash from Table 3 can be summarized as follows:

Norway

PAH > chlorobenzenes > PCB > PCDD > thio-PAH > PCDF > chlorophenols

Canada

Chlorobenzenes > PCDD > PCDF > PAH > chlorophenols > Thio-PAH > PCB

It can be seen that there are more chlorobenzenes than any other chlorinated species present in either samples. This has been previously observed in a study of chlorinated compounds emitted from municipal incineration (16). It becomes evident that the Canada fly-ash is more concentrated in chlorinated organic compounds than the Norway fly-ash. Conversely, the Norway fly-ash is more concentrated in PAH and thio-PAH compounds than the Canada fly-ash. This indicates that the Canada municipal waste combustion must contain more chlorine than the Norway municipal waste combustion, strictly from mass balance. However, the primary source of chlorine need not be from PVC (6). It has been suggested that HCl in the furnace can be the reactant chlorine source (16). The greater concentration of thio-PAH compounds in the Norway fly-ash could be related to a substantial sulphur content in the furnace. Consequently, mass balance would dictate a higher content of thio-PAH. In both samples, the concentration of compounds are from reaction of an abundant reactant, chlorine or sulphur, to a PAH nucleus. This implies that dynamic radical molecular reactions could be occurring so that an incinerator furnace would be governed by mass balance. Consequently, reduction of PCDD emissions on fly-ash could be accomplished by alterations in the mass balance relationship.

Facile access to (*S*)-1,2,4-butanetriol and its derivatives

STEPHEN HANESSIAN, ANTONIO UGOLINI,[1] DANIEL DUBÉ AND ANI GLAMYAN
Department of Chemistry, Université de Montréal, Montreal, P.Q., Canada H3C 3V1

Received February 21, 1984

STEPHEN HANESSIAN, ANTONIO UGOLINI, DANIEL DUBÉ, and ANI GLAMYAN. Can. J. Chem. **62**, 2146 (1984).

The synthesis of (*S*)-1,2,4-butanetriol from the readily available (*S*)-malic acid in one step using borane – dimethyl sulfide is described.

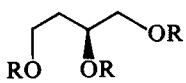
STEPHEN HANESSIAN, ANTONIO UGOLINI, DANIEL DUBÉ et ANI GLAMYAN. Can. J. Chem. **62**, 2146 (1984).

On décrit la synthèse en une seule étape du (*S*)-butanetriol-1,2,4 à partir de l'acide (*S*)-malique facilement obtenu en utilisant le complexe de borane – sulfur de diméthyl.

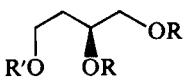
[Traduit par le journal]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

Optically active acetal derivatives of 1,2,4-butanetriol **1***a* and the corresponding aldehyde **3** are frequently used as starting materials for natural product synthesis (1,2). In the course of a program aimed at the total synthesis of avermectin Bla aglycon (3), we required substantial quantities of **3**, which can be readily obtained from a modified (4) pyridinium chlorochromate oxidation (5) of **2***a*. In a recent report,[2] Meyers and Lawson (6) have shown that all reported preparations of **2***a*



1*a* R = H
1*b* R = Ac
1*c* R = 3,5-dinitrobenzoyl

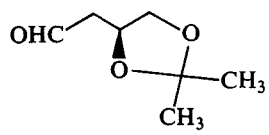


2*a* R,R = , R′ = H

2*b* R,R = , R′ = 3,5-dinitrobenzoyl

2*c* R,R = , R′ = H

2*d* R,R = , R′ = 3,5-dinitrobenzoyl



contain 10% of the isomeric 6-membered acetal and separation of the corresponding 3,5-dinitrobenzoate esters by fractional crystallization has been found necessary. The reported procedures for the preparation of **1***a* involve reduction of derivatives of malic acid (2). In some cases, prior O-protection of malic acid esters has been necessary (2*a*–*c*, *e*). However, these reductions using lithium aluminum hydride have proven to be somewhat tedious and low yielding at times in our hands. We wish to report on a facile and efficient preparation of (*S*)-1,2,4-butanetriol from (*S*)-malic acid using borane – dimethyl sulfide as reducing agent.

Borane reductions of carboxylic acids proceed rapidly, quantitatively, and under remarkably mild conditions (7). Thus, treatment of (*S*)-malic acid with borane – dimethyl sulfide in THF gave (*S*)-1,2,4-butanetriol **1***a* in quantitative yield. Acetylation with acetic anhydride afforded triacetate **1***b* in 93% yield. Esterification with 3,5-dinitrobenzoyl chloride afforded the solid derivative **1***c* in 97% yield. Alternatively, the crude triol **1***a* could be converted directly into **2***a* as a ~9:1 mixture of 5- and 6-membered acetals (92% overall yield from malic acid). The corresponding cyclohexylidene acetal **2***c* was prepared in 85% yield, in this case, containing only 5% of the isomeric 6-membered cyclohexylidene acetal. Unlike the case of the isopropylidene derivative, the 3,5-dinitrobenzoate **2***d* was prepared and purified by a single recrystallization. Pure **2***c* could thus be obtained from **2***d* by methanolysis. This simple access to (*S*)-1,2,4-butanetriol from the readily available (*S*)-malic acid should find many applications in natural products synthesis based on the chiral precursor (chiron) approach (8). A number of recent syntheses have relied on (*S*)-malic acid and its derivatives as chiral building blocks (1, 9) and in the confirmation of absolute configuration of natural products (10).

Experimental

Melting points are uncorrected. Optical rotations were measured on a Perkin–Elmer automatic spectropolarimeter, model 141. The ^{1}H nmr spectra were recorded on Bruker WH-90 (90 MHz) and WH-400 (400 MHz) spectrometers with tetramethylsilane as internal standard, in deuterochloroform as solvent, unless otherwise specified. Mass spectra were recorded on a VG-1212 mass spectrometer at low resolution. Column chromatography was done by the flash technique.

(S)-*1,2,4-Butanetriol*, *1*a

To a stirred solution of 2 *M* BMS·THF complex (11) (120 mL, 0.24 mol) and trimethylborate (12) (25 mL) at 0°C was added dropwise (*S*)-malic acid (10 g, 0.75 mol) in THF (50 mL). After stirring the homogeneous solution for an additional 5 min at 0°C, the cooling bath was removed. A white precipitate appeared and redissolved within 20 min. After stirring overnight, methanol (60 mL) was carefully added dropwise over 1 h and the resulting solution evaporated to dryness. A further three co-evaporations with methanol (50 mL) afforded 11.8 g of (*S*)-1,2,4-butanetriol containing residual boron by-products. Flash chromatography (CH_2Cl_2–MeOH; 9:1) of the crude triol yielded pure (*S*)-1,2,4-butanetriol **1***a* (quantitative), $[\alpha]_D$ −28° (*c* 1.07, MeOH), lit. (13) $[\alpha]_D$ −29° (*c* 1.03, MeOH)).

(S)-*1,2,4-triacetoxybutane*, *1*b

A solution of (*S*)-1,2,4-butanetriol (110 mg, 1.04 mmol) in dichloromethane (1 mL), containing acetic anhydride (340 mg, 3.3 mmol),

[1]NSERCC Postdoctorate Fellow, 1982–1983.

[2]Meyers and Lawson have found all reported preparations of **1***a* invariably lead to the formation of about 10% of the isomeric 6-membered acetonide.

pyridine (0.3 mL), and DMAP (12 mg), was stirred for 2 h at room temperature. The solution was diluted with EtOAc (20 mL) and washed successively with saturated $NaHCO_3$, water, and brine, then dried ($MgSO_4$) and evaporated to give (*S*)-1,2,4-triacetoxybutane, (225 mg, 93%),$[\alpha]_D$ −16.5° (*c* 1.43, acetone), as a colorless oil after flash chromatography (4.5:7 hexane−EtOAc); ir ν_{max}: 1740 cm^{-1} (OAc); ^1H nmr 400 MHz (benzene-d_6) δ: 5.2 (dddd, 1H, *J* = 3.4, 5.9, 5.9, 7.5 Hz, H-2), 4.17 (dd, 1H, *J* = 3.4, 12 Hz, H-1), 4.02 (ddd, 1H, *J* = 6.3, 7.4, 11.3 Hz, H-4), 3.93 (ddd, 1H, *J* = 5.7, 5.7, 11.4 Hz, H-4′), 3.85 (dd, 1H, *J* = 6.1, 12.4 Hz, H-1′), 1.69 (s, 6H, 2 OAc), 1.67 (s, 3H, OAc), 1.57−1.62 (m, 2H, H−3,3′); CI-ms *m/z* (%): 173 (100, MH^+ −HOAc), 113 (11.9, MH^+ −2HOAc).

(S)-*1,2,4-tris-(3,5-dinitrobenzoyloxy)butane,* **1**c

To a solution of (*S*)-1,2,4-butanetriol (125.6 mg, 1.18 mmol) in dichloromethane (2 mL) containing Et_3N (0.5 mL) and DMAP (11 mg) was added 3,5-dinitrobenzoyl chloride (873 mg, 3.79 mmol) in portions at 0°C. The suspension was allowed to warm to room temperature. After 3 h ether (25 mL) was added and the mixture washed successively with aqueous KH_2PO_4, saturated aqueous $NaHCO_3$, water, and brine. The organic phase was dried ($MgSO_4$) and evaporated and the residue eluted through a small SiO_2 plug to give (*S*)-1,2,4-tris-(3,5-dinitrobenzoyloxy)butane (791 mg, 97%), $[\alpha]_D$ −40.7° (*c* 1.0, pyridine), mp 172−174°C, after recrystallization from THF−hexane; ir ν_{max} (KBr pellet): 1730 (ester), 1550, 1350 cm^{-1} ($ArNO_2$); ^1H nmr (pyridine-d_5) δ: 9.2−9.0 (m, 9H, Ar), 6.1 (m, 1H, H-2), 5.1−4.7 (m, 4H, H-1, 1′, 4, 4′), 2.6−2.4 (m, 2H, H-3, 3′); CI-ms, *m/z* (%): 477 (11.5, $MH^+ - HO_2CC_6H_3(NO_2)_2$), 265 (15.8, $MH^+ - 2HO_2CC_6H_3(NO_2)_2$).

(S)*1,2*-O-*isopropylidenebutane-1,2,4-triol,* **2**a

The crude triol **1***a* (11.8 g) was dissolved in acetone (600 mL) containing *p*-TsOH (0.65 g) and stirred at room temperature overnight. Following the addition of Et_3N (0.5 mL), the solution was evaporated to near dryness, and filtered through a plug of SiO_2 with 30% acetone in hexane to give **2***a* (10 g, 92% from malic acid) containing about 10% of the corresponding 2,4-*O*-isopropylidene derivative (6). Transformation into the 3,5-dinitrobenzoate derivative and fractional recrystallization gave the crystalline ester **2***b*, mp 63−64°C (lit. (6) mp 62.5−63°C). Methanolysis as described by Meyers and Lawson (6) gave the pure title compound as a syrup.

(S)-*1,2,*-O-*cyclohexylidene-1,2,4-butanetriol,* **2**c

To (*S*)-1,2,4-butanetriol, obtained from the reduction of (*S*)-malic acid (10 g, 74.6 mmol), dissolved in cyclohexanone (400 mL) was added *p*-TsOH (1.4 g, 7.4 mmol) and the solution was stirred overnight. Triethylamine (5 mL) was added and the solution evaporated. The residue was flash chromatographed (3:7 EtOAc−hexanes) to give *O*-cyclohexylidene-1,2,4-butanetriol (11.8 g, 85%), consisting of a mixture of the 1,2- and 2,4-acetals (95:5 ratio). This mixture was dissolved in dichloromethane (100 mL) containing 10.6 mL (76 mmol) of triethylamine and 775 mg (6.3 mmol) of DMAP; then 17.5 g (75.9 mmol) of 3,5-dinitrobenzoyl chloride was added. After stirring at room temperature for 4 h, the solution was washed successively with aqueous KH_2PO_4, aqueous $NaHCO_3$, and brine, dried ($MgSO_4$) and evaporated to give the dinitrobenzoate **2***d*, (15.1 g, 65%); after recrystallization (Et_2O−hexane), mp 67−68°C; $[\alpha]_D$ −15.4° (*c* 1.2, acetone); ^1H nmr δ: 9.3−9.2 (m, 3H, Ar), 4.67 (t, 2H, *J* = 6.4 Hz, CH_2CH_2O), 4.3−4.1 (m, 2H, $CHCH_2O$), 3.77−3.57 (m, 1H, $CHCH_2O$), 2.14 (dt, 2H, *J* = 6.4, 6.7 Hz, CH_2CH_2O), 1.84−1.44 (bs, 10H, cyclohexylidene).

To dinitrobenzoate **2***d* (15.1 g, 38.3 mmol) in MeOH (400 mL) was added K_2CO_3 (8.2 g, 59.3 mmol) and the mixture stirred for 4 h at room temperature. The mixture was neutralized with Dowex 50W-X8, filtered, and evaporated. The pink residue was flash chromatographed (7:3 hexanes−EtOAc) to give pure alcohol **2***c*, (6.95 g, 94%), $[\alpha]_D$ −10.55 (*c* 1.1, MeOH); ir ν_{max}: 3400 cm^{-1}(OH); ^1H nmr (60 MHz) δ: 4.4−3.5 (m, 5H, OCH_2CH and CH_2OH), 3.0 (bs, 1H, OH), 1,85 (dt, 2H, CH_2CH_2OH).

Facile synthesis of the enantiomers of frontalin[1,2]

B. D. JOHNSTON AND A. C. OEHLSCHLAGER
Department of Chemistry, Simon Fraser University, Burnaby, B. C., Canada V5A 1S6

Received February 20, 1984

B. D. JOHNSTON AND A. C. OEHLSCHLAGER. Can. J. Chem. **62**, 2148 (1984).

S-(−)- and *R*-(+)-frontalin (1,5-dimethyl-6,8-dioxabicyclo[3.2.1]octane) were prepared from (*E*)-2-methyl-2,6-heptadiene-1-ol utilizing the Sharpless asymmetric epoxidation reaction to induce chirality. The six-step synthetic sequence proceeded in approximately 50% overall yield and was found to be suitable for the preparation of multi-gram quantities of either enantiomer with ≥ 90% ee.

B. D. JOHNSTON AND A. C. OEHLSCHLAGER. Can. J. Chem. **62**, 2148 (1984).

Faisant appel à la réaction d'époxydation asymétrique de Sharpless pour induire la chiralité, on a préparé les *S*-(−)- et *R*-(+)-frontalines (diméthyl-1,5 dioxo-6,8 bicyclo[3.2.1] octanes) à partir du (*E*)-méthyl-2 hetadiène-2,6 ol-1. La synthèse implique six étapes et procède avec un rendement global de 50%; on a trouvé qu'elle est appropriée pour la préparation de plusieurs grammes de chacun des énantiomères avec des ee ≥ 90%.

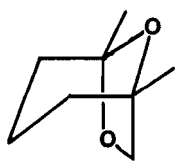
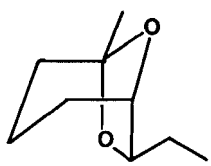
Our recent synthesis of both enantiomers of brevicomin (1) which utilized the Sharpless asymmetric epoxidation (2) in the key chiral induction step has led us to investigate the use of this reaction in the asymmetric synthesis of other natural products, particularly other chiral insect pheromones. Immediately obvious as synthetic targets were the chiral isomers of frontalin **1** which contain the 6,8-dioxabicyclooctane nucleus in common with brevicomin **2**.



1

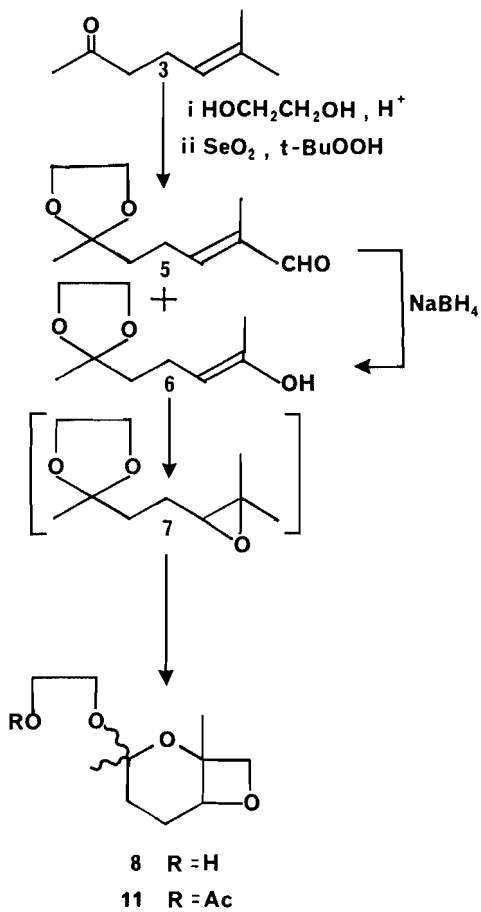


2

Frontalin has been shown to possess aggregation pheromone activity in several species of *Dendroctonus* bark beetles (3). As part of a collaborative multidisciplinary project involving the detection, monitoring, and control of bark beetle populations using pheromone baited traps, we required 3 − 5-g amounts of each chiral isomer of frontalin in order to determine if different *Dendroctonus* species would respond with chiral recognition to the enantiomers.

Frontalin has been a popular target for synthetic chemists and there have been a number of racemic (4) and chiral (5) syntheses of the molecule. An examination of the published chiral synthetic routes, however, reveals that several did not appear amenable to scale-up for the amounts we required and the others seemed only directly applicable to production of one of the two possible enantiomers.

Our initial synthetic plan was to utilize the Sharpless method in a short sequence, beginning with commercially available 6-methyl- 5-hepten-2-one, **3** (Scheme 1). The ketone was protected as the ethylene ketal. Subsequent allylic oxidation (6), followed by reduction of the mixture of aldehyde **5** and alcohol **6** with $NaBH_4$, gave an acceptable yield of the *E* allylic alcohol **6**. Unfortunately, Sharpless epoxidation (2) of **6** did not yield the expected epoxide **7** but rather the interesting dioxabicyclo



SCHEME 1

compound **8**. Evidently Sharpless epoxidation conditions promote opening of both the ketal and the epoxide. After completion of this work, Sharpless et al. (7) reported that the 4,4-dimethyl-2,6-dioxolane analog of **7** does not undergo this rearrangement and this epoxide can be efficiently (≈74% overall) converted to frontalin.

Structure **8** was assigned on the basis of spectroscopic analysis. The mass spectrum indicated a molecular ion of 202, which corresponded to the expected epoxide product, but the ^1H nmr spectrum in several solvents (DMSO-d_6, benzene-d_6, $CDCl_3$)

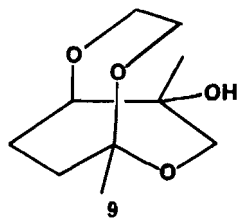
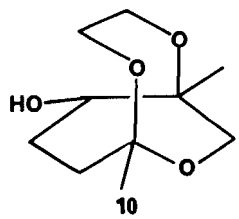
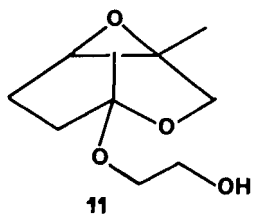
could not be reconciled with structure **7**. In particular, an AB pattern characteristic of an isolated methylene with diastereotopic hydrogens was apparent, but, under conditions where OH coupling was observed (DMSO-d_6, triplet, J = 6 Hz), no extra coupling was observed in the AB pattern. This indicated that, although a primary alcohol was present, the product could not be the expected epoxide, **7**.

Secondary and tertiary alcohol structures **9** and **10**, which were initially considered as possibilities, were also eliminated by this result. Comparison of the ^{1}H nmr of the acetate of **8** with that of the parent alcohol indicated that the AB pattern was still present but that a downfield shift of ≈0.5 ppm had occurred for a second highly coupled methylene group. A partial structure of $-OCH_2CH_2OH$ which must contain methylenes with diastereotopic hydrogens was therefore deduced. A choice between structures **8** and **11** was made on the basis of ^{13}C nmr. The chemical shifts of the carbons involved in the ether linkages of **8** were indicative of an oxetane rather than an epoxide (8). As further confirmation, attempted reduction of **8** with excess lithium tetrahydridoaluminate in ether at room



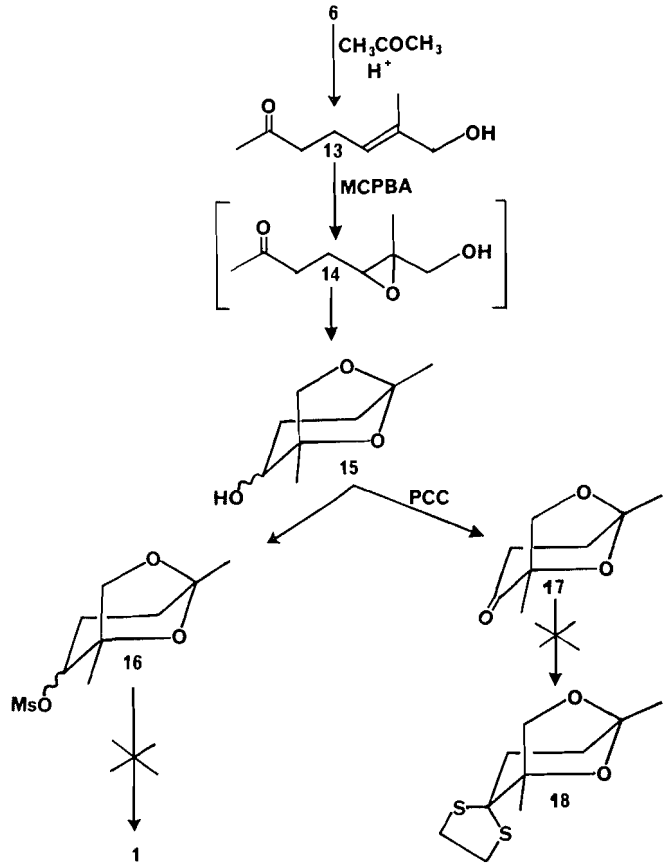




temperature resulted in recovery of starting material, a result which would not be expected if an epoxide had been present.

Reasoning that protection of the ketone as outlined in Scheme 1 might not be required, we undertook the alternate synthesis outlined in Scheme 2. The ethylene ketal protecting group was removed from allylic alcohol **6** to yield **13** which was subjected to Sharpless epoxidation. Again, the expected epoxide **14** could not be isolated due to epoxide hydrolysis and intramolecular ketal formation during the work-up. In order to determine if **14** was a stable, isolable compound, the epoxidation was performed racemically using *meta*-chloroperoxybenzoic acid. The epoxide (±)−**14** could be obtained in satisfactory yield with a nonaqueous work-up (9) but proved to be unstable and slowly cyclized to **15** (the same structure as obtained from Sharpless epoxidation) over a period of several days. The tendency of γ-keto epoxides to undergo thermal rearrangement to intramolecular ketals is well documented (10, 11).

The dioxabicyclo alcohol **15** corresponds to frontalin if the alcohol function was to be replaced with hydride. Towards this end, racemic **15** was converted to mesylate **16**. Unfortunately, reduction of this hindered, *neo*-pentyl-like mesylate was unsuccessful using either $LiAlH_4$ in Et_2O (no reaction) or $LiBHEt_3$ in refluxing THF (complex mixture of ring-opened products).



SCHEME 2

A further attempt to convert **15** to frontalin was also made. With the aim of deoxygenation through reduction of the dithiolane **18**, racemic **15** was oxidized with pyridinium chlorochromate to ketone **17**. Conversion of **17** to the dithiolane derivative **18** using 1,2-ethanedithiol and BF_3/Et_2O was, however, unsuccessful, leading to a complex mixture of sulfur-containing products.

The problems encountered in Schemes 1 and 2 appear to center around the presence of a ketone in either its free or protected form in the substrate during Sharpless epoxidation. We therefore decided to postpone introduction of the ketone to a later stage. Reasoning that a terminal alkene is synthetically equivalent to a methyl ketone, the diene alcohol **20** was prepared by the literature method (12). Sharpless epoxidation of **20** gave good yields of the expected chiral epoxides **21**. The enantiomeric excess of each chiral isomer was determined by integration of the diastereotopic hydrogens of the $-OCH_2-$ group in the (+)-α-methoxy-α-trifluoromethylphenyl acetate derivatives to be 95% ee for (−)-**21** and 96% ee for (+)-**21** (ee: enantiomeric excess).

Lithium tetrahydridoaluminate reduction of the chiral isomers of **21** using a nonacidic work-up and limited amounts of water gave excellent yields of the chiral diols **22**. Two different methods for completion of the synthesis were investigated. Initially, we employed a Wacker-type oxidation to obtain frontalin directly from diol **22**. This method has been employed by Grigg and co-workers (13), albeit in low yield, in a racemic synthesis of brevicomin. In an attempt to improve upon the original Wacker conditions ($CuCl$, O_2, Pd^{2+}) used by Grigg, we chose the modified conditons (H_2O_2, Pd^{2+}) developed by Roussel and Mimoun (14). Several attempts at this method

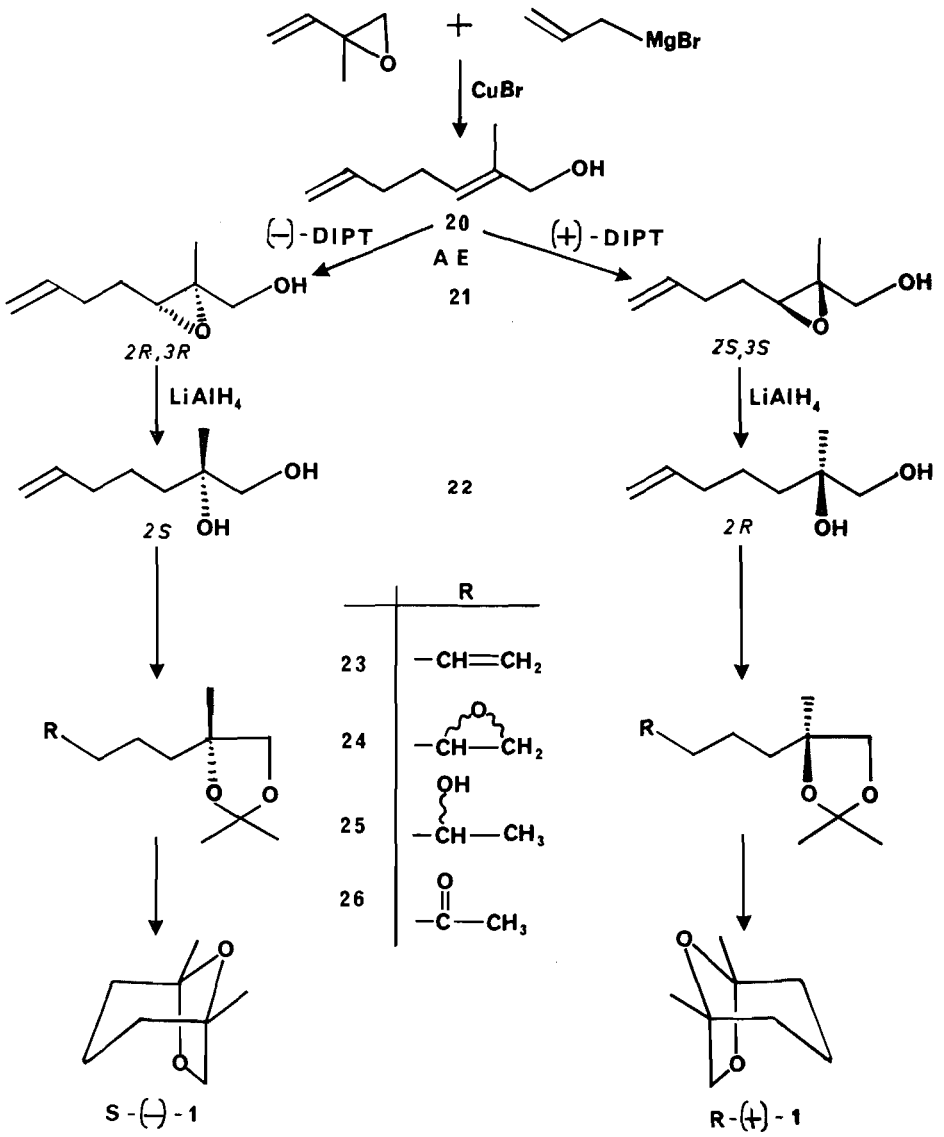

SCHEME 3

using various reaction conditions and work-up procedures gave dismally low yields of frontalin (10−12%) and the chemical purity of the final product could not be improved above 85% by simple fractional distillation.

The synthesis was completed in a satisfactory manner using the route from **22** outlined in Scheme 3. This relatively lengthy but nevertheless high yield sequence began by protection of the diol **22** containing the sensitive chiral tertiary alcohol function as the acetone ketal **23**. Peracid oxidation of the terminal double bond gave epoxide **24** as a mixture of diastereomers. Lithium tetrahydridoaluminate reduction of **24** afforded excellent yields of secondary alcohol **25**, again as a mixture of diastereomers. Sodium hypochlorite oxidation in acetic acid gave the methyl ketone **26** which, although it could be detected by gc analysis of the crude reaction mixture, was not isolated due to slow *in situ* hydrolysis of the ketal and spontaneous cyclization to cleanly give frontalin **1** in 75% yield.

The optical purity of the frontalin enantiomers as determined by a combination of optical rotation measurements and nmr integration in the presence of the chiral shift reagent tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]europium(III) indicated 89−93% ee for (+)-frontalin and 97% ee for (−)-frontalin. In the case of (+)-frontalin, we speculate that the decrease in optical purity from the initial Sharpless epoxidation product may be due to a small amount of acid-catalyzed racemization of one of the tertiary alcohol intermediates.

In summary, the application of the Sharpless asymmetric epoxidation reaction to an appropriate acyclic allylic alcohol precursor has been shown to afford both chiral (≥90% ee) frontalin enantiomers in overall chemical yields of ≈50% (from **20**). The synthetic sequence is suitable for the production of multi-gram quantities of the frontalin enantiomers and proceeds entirely without the necessity for chromatographic purification of intermediates.

Experimental

The ^{1}H nmr (400 MHz) and ^{13}C nmr (100 MHz) spectra were recorded using $CDCl_3$ solutions on a Bruker WM 400 spectrometer unless otherwise noted. Infrared spectra were recorded using neat films between NaCl plates on a Perkin Elmer 599B spectrophotometer unless otherwise noted. Mass spectra were obtained on a Hewlett−Packard 5985B gc−ms spectrometer. Optical rotations were measured with a Perkin Elmer P_{22} spectropolarimeter using a 0.5 dm × 5-mm id sample cell. Concentrations are reported in g/100 mL of solvent.

For personal use only.

Elemental analyses were performed by Mr. M. Yang of the Department of Biological Sciences, Simon Fraser University using a Perkin Elmer Model 240 elemental analyzer. Gas chromatographic analysis utilized a Hewlett–Packard 5880A operated with a J+W fused silica DB-1 capillary column (15 m × 0.25 mm), a flame ionization detector, and a suitable linear oven temperature program.

Solvents and reagents were used as supplied from commercial sources with the following exceptions. Anhydrous CH_2Cl_2 was obtained by distillation from P_2O_5. Anhydrous solutions of *tert*-butylhydroperoxide in CH_2Cl_2 were prepared from 90% *t*-BuOOH (Aldrich) using the azeotropic distillation method described by Sharpless et al. (7). Chromatography solvents were distilled before use and anhydrous ether was obtained only from freshly opened cans (Fisher Scientific).

*2-Methyl-2-(4-methyl-3-pentenyl)-1,3-dioxolane, **4***

This compound was prepared by the literature method using the acid catalyzed reaction of 6-methyl-5-heptene-2-one with ethylene glycol; yield 89%, bp 86–87°C/12 Torr (1 Torr = 133.3 Pa); lit. (15) bp 58°C/1.5 Torr.

*2-Methyl-2-(4-methyl-5-hydroxy-3-pentenyl)-1,3-dioxolane, **6***

To a solution of **4** (85 g, 0.50 mol) in CH_2Cl_2 (400 mL) was added *tert*-butylhydroperoxide (90%, 110 mL, 0.99 mol) and SeO_2 (5.5 g, 50 mmol). The mixture was refluxed with stirring for 9 h and then poured into a 2:1 mixture of saturated aqueous $NaHCO_3$ and 10% aqueous $Na_2S_2O_3$ solutions (300 mL). The organic phase was separated and the aqueous phase extracted with ether (3 × 200 mL). The combined organics were washed with saturated brine (100 mL), dried ($MgSO_4$), and concentrated to a syrup. Gas chromatographic analysis of this crude material indicated ≈3% starting alkene, ≈78% aldehyde **5**, and ≈14% alcohol **6**. The mixture was taken up in methanol (150 mL) and cooled with an ice bath while $NaBH_4$ (8g, 0.2 mol) was added in small portions over 0.5 h. After a further 0.5 h, the ice bath was removed and stirring continued for a further 0.5 h at ambient temperature. Water (600 mL) was then added and the reaction mixture extracted with ether (3 × 200 mL). The aqueous phase was saturated with NaCl and further extracted with ether (3 × 100 mL). The combined ether extracts were dried ($MgSO_4$) and concentrated *in vacuo*. Distillation (bp 102–110°C/0.5 Torr) yielded **6** (53.6 g, 58%). Spectral data were in accord with those reported in the literature (16).

This procedure, utilizing catalytic amounts of SeO_2, was found to be preferable to the reported procedure involving stoichiometric amounts of SeO_2 (16).

*Attempted Sharpless asymmetric epoxidation of **6***

*Preparation of 1,3-dimethyl-3-(2-hydroxyethoxy)-7-oxabicyclo [4.2.0]octane, **8***

To a solution of titanium tetraisopropoxide (28.4 g, 100 mmol) in dry methylene chloride (700 mL) was added (+)-diisopropyltartrate (DIPT) (25.7 g, 110 mmol) with the temperature maintained at −30°C with a CCl_4 slush. After 10 min, allyl alcohol **6** (18.6 g, 100 mmol) was added in one portion followed in 5 min by an anhydrous 5 *M* solution of *tert*-butylhydroperoxide in methylene chloride (50 mL, 0.25 mol). The reaction was kept in a freezer for 18 h (≈−30°C), quenched by the addition of water (10 mL, 0.56 mol), and stirred while warming to room temperature over 2.5 h. The CH_2Cl_2 was removed *in vacuo* and to the residue was added ether (700 mL) and saturated aqueous NaF solution (1 L). After stirring for 20 h at room temperature, the mixture was filtered through Celite and the filter cake washed with ether (4 × 150 mL). The DIPT was hydrolyzed by the addition of NaOH (8 g, 0.25 mol) followed by rapid stirring at room temperature for 2 h. The aqueous phase was separated, saturated with NaCl, and extracted with ether (4 × 150 mL). The combined ether extracts were dried ($MgSO_4$) and concentrated *in vacuo* to yield an almost colorless oil. Excess *tert*-butylhydroperoxide was removed over 4 h on high vacuum (0.1 Torr); yield 16.2 g (80%), >97% pure by gc. An analytical sample was purified by preparative tlc (hexane – ethyl acetate, 1:5); ir: 3460(s), 2940(s), 2885(s), 1645(w), 1450(m), 1390(s), 1380(s), 1358(m), 1270(m), 1245(s), 1210(s), 1130(s), 1105(s), 940(m), 843(s), 826(m) cm^{-1} ^1H nmr δ: 1.40 (3H, CH_3, s), 1.45 (3H, CH_3, s), 1.56 (1H, C(4)H, m), 1.80 (1H, C(4)H,m), 1.86 (2H, C(3)H, m), 2.29 (1H, OH, br s), 3.13 (1H, C(6)H, t, J = 2.5 Hz), 3.49 (1H, C(8)H, d, J = 7.5 Hz), 3.50 (1H, OCH, m), 3.72 (1H, OCH, m), 3.74 (2H, CH_2O, m), 3.76 (1H, C(8)H, d, J = 7.5 Hz); ^{13}C nmr δ: 18.9(q), 21.5 (t), 24.2(q), 31.1(t), 61.9(t), 71.0(t), 73.1(t), 76.4(d), 81.9(s), 108.2(s); ms: 202(5), 173(10), 145(56), 114(100), 99(72), 84(35), 71(48), 43(72). *Anal.* calcd. for $C_{10}H_{18}O_4$: C 59.35, H 8.99; found: C 59.19, H 9.09.

*1,3-Dimethyl-3-(2-acetoxyethoxy)-7-oxabicyclo[4.2.0]octane, **11***

Alcohol **8** (200 mg, 0.99 mmol) was dissolved in CH_2Cl_2 (5 mL). After addition of pyridine (350 mg, 4.4 mmol) and acetic anhydride (300 mg, 2.9 mmol), the mixture was stirred for 16 h at room temperature. The CH_2Cl_2 solution was washed with saturated $NaHCO_3$ solution (2 mL) and water (2 mL), dried ($MgSO_4$), and concentrated to a yellow syrup. Purification by preparative tlc (ethyl acetate – hexane, 3:1) yielded **11** (186 mg, 76%) as a colorless oil; ir 2990(m), 2945(m), 2890(m), 1744(s), 1450(m), 1392(m), 1382(m), 1256(s), 1213(m), 1113(m), 1050(m), 1033(m), 943(w), 890(w), 857(m), 830(w) cm^{-1} ^1H nmr δ: 1.38 (3H, CH_3, s), 1.45 (3H, CH_3, s), 1.55 (1H, C(4, 5)H, m), 2.06(3H, C(4,5)H, m), 3.48 (1H, C(8)H, d, J = 7.5 Hz), 3.61 (1H, −OCH−, m), 3.79 (1H, C(8)H,, d, J = 7.5 Hz), 3.83 (1H, −OCH−, m), 4.22 (2H, $-CH_2O-$, m). *Anal.* calcd. for $C_{12}H_{20}O_5$: C 59.00, H 8.25; found: C 59.16, H 8.41.

*2-Methyl-2-hepten-6-one-1-ol, **13***

Ethylene ketal **6** (53 g, 0.28 mol) was dissolved in acetone (150 mL) to which was added concentrated H_2SO_4 (5 drops) and the reaction stirred at room temperature for 2 h. Anhydrous K_2CO_3 (2 g) was then added and stirring continued for a further 0.5 h. Filtration, concentration, and distillation (bp 98–102°C/ 0.2 Torr) yielded **13** (30.5 g, 75%, >94% pure by gc); ir 3400 (m) 2910(m), 2860(m), 1715(s), 1410(m), 1360(m), 1165(m), 1070(m), 1015(m) cm^{-1}; ^1H nmr δ: 1.66 (3H, C(7)H_3, s), 2.13 (3H, C(2) methyl, br s), 2.29 (2H, C(4)H, q, J = 7 Hz), 2.48 (2H, C(5)H_2, t, J = 7Hz), 3.96 (2H, C(1)H_2, s), 4.32 (1H, C(3)H, triplet of quartets, J = 7, 1.25 Hz). *Anal.* calcd. for $C_8H_{14}O_2$: C 67.57, H 9.92; found: C 67.38, H10.04.

*(±)-2-Hydroxy-1,5-dimethyl-6,8-dioxabicyclo[3.2.1]octane, **15***

Alkene **13** (14.2 g, 100 mmol) was dissolved in anhydrous CH_2Cl_2 (200 mL) *meta*-Chloroperoxybenzoic acid (21.5 g of purity ≈85%, 106 mmol) was then added in small portions over a period of 15 min with ice-bath cooling. After stirring at ambient temperature for 0.5 h, anhydrous KF (24 g, 0.5 mol) was added and stirring continued for 1 h. Filtration and removal of the solvent yielded crude epoxide **14**; ^1H nmr (100 MHz, $CDCl_3$) δ: 1.17 (3H, C(2) methyl, s), 1.6–2.1 (2H, C(4)H_2, m) 2.26 (3H, C(7)H_3, s), 2.30 (1H, OH, br s), 2.68 (2H, C(5)H_2, t, J = 7 Hz), 3.05 (1H, C(3)H, dd, J = 8, 6 Hz), 3.59, 3.72 (2H, C(2)H_2, dd, J_{AB} = 15 Hz). This sample underwent slow, spontaneous rearrangement to bicyclo alcohol **15** over a period of several days.

The bulk of the crude material was dissolved in methanol (150 mL) and treated with $SOCl_2$ (5 drops). After 1 h, gc analysis showed the absence of epoxide **14** and the formation of two products in a ratio of ≈60:40. Equilibration of the acidic alcohol solution for 18 h at room temperature gave a 15:1 ratio of the two diastereomeric bicyclo alcohols **15** with the isomer of shorter retention time predominating. Removal of the solvent *in vacuo* and distillation of the residue yielded **15** (12.8 g, 81%), bp 80–95°C/0.05 Torr; ir: 3440(s), 2980(s), 2930(s), 2875(s), 1710(w), 1640(w), 1485(w), 1450(m), 1387(s), 1255(s), 1207(s), 1105(s), 1067(s), 1030(s), 972(m), 952(m), 938(m), 910(w), 887(w), 851(s), 811(m), 774(w), 707(m) cm^{-1}; nmr analysis of the initially formed mixture of diastereomers as well as the equilibrium mixture allowed the ^1H nmr of each isomer to be assigned as follows. Major isomer δ: 1.37 (3H, CH_3, s), 1.43 (3H, CH_3,s), 1.58 (1H, C(3,4)H, m), 1.75 (2H, C(3,4)H, m), 2.00 (1H, C(3,4)H,m), 2.28 (1H, OH, d, J = 9 Hz), 3.42 (1H, C(2)H, br d, J = 9 Hz), 3.52 (1H, C(7)H, d, J = 12 Hz), 3.84 (1H, C(7)H, d, J = 12 Hz). Minor isomer δ: 1.02 (3H, CH_3, s), 1.51 (3H, CH_3,s), 1.80 (2H, C(3,4)H, m), 2.08 (2H, C(3,4)H, m), 3.51 (1H, C(7)H, dd,

For personal use only.

J = 12, 2 Hz), 3.65 (1H, OH, br s), 3.67 (1H, C(7)H, J = 12 Hz), 4.07 (1H, C(2)H, dd, J = 7, 2 Hz); ms (major isomer): 158(M^+,2), 129(30), 114(66), 101(100), 99(52), 98(38), 84(94), 71(58), 70(76), 69(43), 61(45), 43(44); ms (minor isomer): 158(M^+,1.4), 127(10), 101(100), 98(13), 95(10), 85(43), 84(44), 83(61), 71(28), 58(41), 55(15), 43(46). *Anal.* calcd. for $C_8H_{14}O_3$: C 60.74, H 8.92; found: C 60.51, H 8.93.

Attempted Sharpless epoxidation of ***13***

Titanium tetraisopropoxide (3.0 mL, 2.9 g, 10 mmol) was dissolved in anhydrous CH_2Cl_2 (50 mL) and the solution cooled to < -30°C with a Dry Ice − acetone bath while successive additions of (+)-DIPT (2.6 g, 11 mmol), alkene **13** (1.0 g, 0.7 mmol), and *t*-BuOOH (20 mL of a 1 *M* anhydrous CH_2Cl_2 solution) were made at 10-min intervals. The reaction was kept at −30°C for 3.5 h and then poured into a rapidly stirred mixture of ether (300 mL) and 10% aqueous tartaric acid (50 mL). After stirring for 4.5 h at room temperature, the organic phase was washed with saturated aqueous $NaHCO_3$ (50 mL) and saturated NaCl (50mL). Drying ($MgSO_4$) and removal of the solvent yielded a mixture of crude **15**, excess *t*-BuOOH, and (+)-DIPT. Coevaporation with toluene (2 × 100 mL) removed most of the *t*-BuOOH and the residue was purified by column chromatography on silica gel (hexane − ethyl acetate, 1:2) to yield 0.82 g (74%) of **15** as a mixture (≈9:1) of alcohols with identical spectral and gc characteristics to those observed for the racemic material.

(±)-1,5-Dimethyl-2-methanesulfonyloxy-6,8-dioxabicyclo[3.2.1] octane, ***16***

Alcohol **15** (1.58 g, 10 mmol) was dissolved in pyridine (10 mL). Methanesulfonyl chloride (2.0 mL, 2.9 g, 26 mmol) was added and the reaction warmed to 50°C for 1.5 h. After cooling to room temperature, CH_2Cl_2 (100 mL) was added and the solution washed with saturated aqueous $NaHCO_3$ (2 × 50 mL) and water (2 × 50 mL). Drying ($MgSO_4$) and removal of the solvent *in vacuo* yielded an orange syrup which crystallized upon cooling. Recrystallization (hexane−$CHCl_3$, 50:1) gave **16** as light yellow crystals (1.32 g, 56%, mp 110−112°C); ir (KBr pellet): 3010(m), 2970(m), 2935(m), 2910(m), 1393(m), 1384(m), 1360(m), 1350(s), 1343(s), 1335(s), 1260(m), 1252(s), 1208(m), 1183(s), 1116(s), 1024(m), 1012(s), 991(m), 954(s), 938(s), 917(m), 900(m), 880(s), 854(s), 774(m), 750(m) cm^{-1}; ^1H nmr δ: 1.42 (3H, CH_3, s), 1.49(3H, CH_3,s), 1.66 (1H, C(4)H, ddd, J = 13.3, 6.0, 1.5 Hz), 1.90 (1H, C(4)H, td, J = 13.3, 5.7 Hz), 2.06 (1H, C(3)H, ddt, J = 15.5, 5.7, 1.5 Hz), 2.17 (1H, C(3)H, m), 3.10 (3H, $-SO_2CH_3$, s), 3.54 (1H, C(7)H, d, J = 7.9 Hz), 3.86 (1H, C(7)H, d, J = 7.9 Hz), 4.54 (1H, C(2)H, dd, J = 3.8, 1.9 Hz); ^{13}C nmr δ: 19.0(q), 24.0(q), 24.5(t), 30.7(t), 38.7(q), 72.6(t), 76.6(d), 80.8(s), 108.3(s); ms: 236(M^+,0.4), 140(11), 129(30), 114(13), 99(11), 98(15), 97(19), 87(18), 83(20), 71(12), 69(12), 57(13), 55(10), 43(100). *Anal.* calcd. for $C_9H_{18}O_5S$: C 45.75, H 6.82; found: C 45.75, H 7.00.

(±)-1,5-Dimethyl-6,8-dioxabicyclo[3.2.1]octan-2-one, ***17***

Alcohol **15** (110 mg, 0.69 mmol) was dissolved in CH_2Cl_2 (5 mL) and stirred while pyridinium chlorochromate (1.0 g, 4.6 mmol) was added in two portions at 2-h intervals. After 18 h at room temperature, the reaction mixture was passed through a short silica gel column using CH_2Cl_2 as the eluant. The solvent was removed and the residue subjected to bulb-to-bulb distillation to yield ketone **17** (72 mg, 67%); bp 80−100°C (bath temperature)/15 Torr. The purified material slowly crystallized (mp 50−52°C). An analytical sample was prepared by recrystallization from hexane; ir: 2991(w), 2940(s), 2881(s), 1729(s), 1480(w), 1449(s), 1417(m), 1388(s), 1379(s), 1261(m), 1214(s), 1184(s), 1168(m), 1135(s), 1106(s), 1079(s), 1036(s), 1011(m), 935(m), 907(m), 879(m), 855(s), 799(m) cm^{-1}; ^1H nmr (100 MHz, $CDCl_3$) δ: 1.40 (3H, CH_3,s), 1.58 (3H, CH_3, s), 2.34 (4H, C(3,4)H, m), 3.60 (1H, C(7)H, d, J = 8 Hz), 3.97 (1H, C(7)H, d, J = 8 Hz); ms: 156(M^+,2), 114(15), 99(100), 85(16), 71(22), 69(18), 58(17), 55(27), 43(58). *Anal.* calcd. for $C_8H_{12}O_3$: C 61.15, H 7.74; found: C 61.10, H 7.70.

2-Methyl-2-vinyloxirane, ***19***

The method of Reist *et al.* (17) for the preparation of this epoxide from isoprene was modified with a resulting increase in yield. Freshly distilled isoprene (125 g, 1.8 mol) was added to water (350 mL) and vigorously stirred with ice-bath cooling. *N*-bromosuccinimide (200 g, 1.1 mol) was then added in small portions over a period of 1 h with the temperature of the reaction maintained at 10−15°C. The cooling bath was removed and the reaction stirred at ambient temperature for 2 h, after which a test for an oxidizing agent with starch iodide paper proved negative. The lower organic phase was separated and the aqueous phase extracted with ether (3 × 125 mL). The combined organics were dried ($MgSO_4$), filtered, and concentrated on a rotary evaporator to ≈250 mL.

The resulting solution of isoprene bromohydrin was then added dropwise to a warm (50−55°C) aqueous 30% NaOH solution (300 mL) under aspirator vacuum (≈15 Torr). Volatile material which distilled was collected in a Dry Ice − acetone cooled trap placed in the line between the reaction flask and the water aspirator. The aqueous phase of this distillate was separated and discarded and the remainder dried over $MgSO_4$. Filtration and distillation (bp 75−82°C, 750 Torr) yielded 54.5 g (59%) of a 10:1 mixture of the desired product **19** and its isomer, isopropenyloxirane. Distillation of the mixture on a 30-cm spinning band column allowed separation of the isomers to yield pure **19**, bp 81−82°C/760 Torr, lit. (17) bp 78−82°C.

2-Methyl-2,6-heptadien-1-ol, ***20***

This compound was prepared by the coupling of allyl magnesium bromide with 2-methyl-2-vinyloxirane, essentially by the procedure briefly oulined in ref. 12. Thus, magnesium turnings (24.0 g, 1.0 mol) in dry ether (100 mL) were stirred rapidly under argon while a solution of freshly distilled allyl bromide (28.0 g, 232 mmol) in dry ether (150 mL) was added dropwise over 3 h. After cooling to room temperature over 0.5 h, the black solution was decanted from the excess magnesium into a dry, argon filled dropping funnel. The excess magnesium was rinsed with an additional portion of dry ether (50 mL) which was also decanted into the dropping funnel.

This solution, which was estimated to contain between 185 and 200 mmol of allyl magnesium bromide (18), was added dropwise over 1 h to a stirred solution of **19** (16.8 g, 200 mmol) in dry THF (250 mL) containing a catalytic amount of $CuBr/S(CH_3)_2$ (1 g, 5 mmol). The temperature during this addition was maintained at ≤ -30°C with a Dry Ice − acetone bath. The yellow color of allyl copper could be observed momentarily as each drop of Grignard solution entered this reaction mixture. After a further 0.5 h at −20° to −30°C, the reaction was quenched by the addition of saturated aqueous NH_4Cl solution (250 mL) and allowed to warm to ≈10°C. The aqueous phase was separated and further extracted with ether (3 × 200 mL). The combined ethereal extracts were washed with 14% NH_4OH solution (100 mL), water (100 mL), and dried over $MgSO_4$. Concentration of the extracts by distillation of the solvents at atmospheric pressure through a 30-cm Vigreux column followed by vacuum distillation of the residue yielded **20** (15.2 g, 73%; bp 88−92°C/12 Torr, lit. (12) bp 93°C/15 Torr). Analysis by gc indicated a purity of 93% with ≈4% of the 2-Z isomer and ≈3% of an unidentified more volatile impurity. The spectral data (^1H nmr, ir) were in accord with those reported (12).

*2,3-(−)-2,3-Epoxy-2-methyl-6-hepten-1-ol, (−)-****21***

A dry round-bottom flask (1 L) was charged with anhydrous CH_2Cl_2 (700 mL) and stirred in a Dry Ice − acetone bath until the temperature reached −30°C. Titanium tetraisopropoxide (30 mL, 28.6 g, 100 mmol) was then added, followed by (+)-diisopropyl tartrate (25 g, 107 mmol). After 10 min at −20 to −30°C, dienol **20** (12.6 g, 100 mmol) was added and, after a further 5 min, a 4 *M* anhydrous CH_2Cl_2 solution of *t*-BuOOH (50 mL, 200 mmol). After 2.5 h (−30°C freezer) gc analysis showed the absence of starting material. The cold reaction mixture was then poured in a thin stream into an ice-bath-cooled, rapidly stirred mixture of ether (750 mL) and 10% aqueous tartaric acid (250 mL). After stirring for 15 min in the ice bath, a clean separation into two clear layers could be achieved. The aqueous phase was further extracted with ether (2 × 100 mL) and the combined

organics washed with saturated $NaHCO_3$ solution (100 mL) and saturated NaCl solution (100 mL). After drying ($MgSO_4$), the solvents were removed on a rotary evaporator and the residue subjected to two successive vacuum distillations. In the first distillation, separation of most of the excess *t*-BuOOH and (+)-DIPT was achieved and the fraction containing the epoxide (bp 50−80°C/0.5 Torr) was redistilled to yield (−)-**21** (12.2 g, 86%; bp 52−54°C/0.2 Torr); $[\alpha]_D^{25}$ −4.4° (*c* 2.0, EtOH); ir (film): 3430(s), 3080(w), 3000(m), 2970(m), 2930(s), 2875(m), 1645(m), 1450(m), 1387(m), 1040(s), 917(m), 870(m) cm^{-1}; ^1H nmr δ: 1.29 (3H, C(2) methyl, s), 1.68(2H, C(4)H, m), 1.86 (1H, OH, br s), 2.25 (2H, C(5)H, m), 3.05 (1H, C(3)H, t, J = 6.25 Hz), 3.56 (1H, C(1)H, br dd, J = 12, 6 Hz), 3.69 (1H, C(1)H, d, J = 12 Hz), 5.00 (1H, C(7)H, d, J = 10.5 Hz), 5.06 (1H, C(7)H, d of q, J = 17, 2 Hz), 5.82 (1H, C(6)H, m, J_{trans} = 17 Hz, J_{cis} = 10.5 Hz, J_{vic} = 6 Hz); ms (EI): 67(35), 58(100), 57(85), 55(30), 43(71), 41(42); ms (isobutane CI): 143(47) (M^+ + 1). *Anal.* calcd. for $C_8H_{14}O_2$: C 67.57, H 9.92; found: C 67.39, H 10.05.

Preparation of the (+)-α-methoxytrifluoromethylphenyl acetate ((+)-MTPA ester) of (−)-**21** and of racemic **21** by the published method (19) and analysis of the differentially shifted diastereotopic C(1) methylene hydrogens by 400-MHz ^1H nmr gave 95 ± 1% ee for (−)-**21**.

2,3-(+)-2,3-Epoxy-2-methyl-6-hepten-1-ol, (+)-21

This material was described for (−)-**21** with the exception that (−)-DIPT was used in the asymmetric epoxidation to yield 84%, $[\alpha]_D^{25}$ +4.3 (*c* 2.2, EtOH) and 96 ± 1% ee by integration of the ^1H nmr of the (+)-MTPA ester as described above.

4-Methyl-4-(4-pentenyl)-2,2-dimethyl-1,3-dioxolane, 23

Lithium tetrahydridoaluminate (5.0 g, 130 mmol) was dissolved in anhydrous ether (300 mL) and the solution cooled with an ice bath while epoxide (−)-**21** (20.6 g, 145 mmol) dissolved in anhydrous ether (100 mL) was added dropwise over 1 h. The reaction was quenched by cautious sequential addition of water (5 mL), 15% aqueous NaOH (5 mL), and, finally, water (15 mL). Filtration and thorough extraction of the aluminum salts with additional ether (3 × 200 mL) followed by removal of the solvent provided diol *R*-**22** which was essentially pure by ^1H nmr δ: 1.17 (3H, C(2) methyl, s), 1.47 (4H, C(2)H, C(3)H, m), 2.05 (2H, C(5)H, q, J = 7 Hz), 2.13 (1H, C(2)OH, s), 2.37 (1H, C(1)OH, t, J = 6.5 Hz), 3.40 (1H, C(1)H, dd, J_{AB} = 11 Hz, J_{OH} = 6.5 Hz), 3.46 (1H, C(1)H, dd, J_{AB} = 11 Hz, J_{OH} = 6.5 Hz), 4.95 (1H, C(7)H, d of m, J_{cis} = 10 Hz), 5.01 (1H, C(7)H, d of q, J_{trans} = 17 Hz, $J_{gem,allylic}$ = 2 Hz), 5.78 (1H, C(6)H, 10 line multiplet, J_{trans} = 17 Hz, J_{cis} = 10 Hz, J_{vic} = 7 Hz).

The above diol was dissolved in 2,2-dimethoxypropane (50 mL) and stirred while *p*-toluenesulfonic acid (100 mg) was added. After 4 h at ambient temperature, the reaction mixture was diluted with ether (300 mL) and washed with saturated $NaHCO_3$ solution (50 mL). After drying with $MgSO_4$, filtration, and concentration *in vacuo*, the residue was distilled to yield *R*-**23** (23.9 g, 86% from **21**, bp 48−50°C/0.2 Torr); $[\alpha]_D^{25}$ ≈0 (*c* 5.4, EtOH); ir (film): 3070(w), 2980(s), 2930(s), 2860(s), 1640(m), 1455(m), 1375(s), 1370(s), 1245(s), 1210(s), 1115(m), 1060(s), 990(m), 910(s), 860(m), 805(m) cm^{-1}; ^1H nmr δ: 1.28 (3H, C(2) methyl, s), 1.39 (3H, CH_3, s), 1.41 (3H, CH_3, s), 1.53 (4H, C(3)C(4)H, m), 2.07 (2H, C(5)H, q, J = 6.5 Hz), 3.71 (1H, C(1)H, d, J_{AB} = 8.1 Hz), 3.79 (1H, C(1)H, d, J_{AB} = 8.1 Hz), 4.97 (1H, C(7)H, doublet of multiplets, J_{cis} = 10 Hz), 5.02 (1H, C(7)H, doublet of quartets, J_{trans} = 17 Hz, $J_{gem,allylic}$ = 2 Hz), 5.82 (1H,C(6)H, ten line multiplet, J_{cis} = 10 Hz, J_{trans} = 17 Hz, J_{vic} = 7 Hz); ms (EI): 169(100), 115(100), 109(97), 72(89), 67(54), 43(58); ms (isobutane CI): 185(100) (M^+ + 1). *Anal.* calcd. for $C_{11}H_{20}O_2$: C 71.69, H 10.94; found: C 71.98, H 11.25.

Preparation of S-23

Reduction of epoxide (+)-**21** and protection of the diol as the acetone ketal using the procedure described for the preparation of *R*-**23** yielded *S*-**23** in 85% yield; $[\alpha]_D^{25}$ −0.6 (*c* 5.7, EtOH). Spectral data for *S*-**23** were identical with those of *R*-**23**.

(2R)-4-Methyl-4-(3,4-epoxypentyl)-2,2-dimethyl-1,3-dioxolane, 24

Alkene *R*-**23** (23.0 g, 125 mmol) was dissolved in dry CH_2Cl_2 (300 mL) and stirred at ambient temperature while *meta*-chloroperoxybenzoic acid (28.0 g, 85% pure, 138 mmol) was added in small portions over 0.5 h. After 5 h, anhydrous KF (30 g, 0.52 mol) was added and stirring continued for a further 6 h (9). Insoluble material was removed by suction filtration and the filter cake washed with additional CH_2Cl_2 (3 × 100 mL). The combined CH_2Cl_2 solutions were concentrated to yield a 1:1 diastereomeric mixture of *R*-**24** as a colorless oil (24.8 g, 99%). An analytical sample was purified by bulb-to-bulb distillation (bath temperature 90−110°C/0.2 Torr); ir (film): 3043(w), 1458(m), 1380(s), 1370(s), 1250(s), 1213(5), 1120(m), 1060(s), 985(m), 915(m), 852(m), ms (EI) 185(72), 125(22), 115(93), 97(25), 81(41), 79(22), 72(100), 67(31), 57(38), 55(49), 43(90) cm^{-1}; ^1H nmr δ: 1.28 (3H, C(2) methyl, s), 1.38, 1.39 (6H, $2CH_3$, 2s), 1.56 (6H, C(3)C(4)C(5)H, m), 2.47 (1H, C(6)H, m), 2.75 (1H, C(7)H, t, J = 4.5 Hz), 2.92 (1H, C(7)H, br s), 3.70 (1H, C(1)H, d, J_{AB} = 8.3 Hz), 3.78, 3.79 (1H, C(1)H diastereomers, dd, J_{AB} = 8.3 Hz); ms (CI isobutane): 201 (M^+ + 1) (10). *Anal.* calcd. for $C_{11}H_{20}O_3$: C 69.97, H 10.07; found: 65.73, 9.85.

Preparation of 24

Epoxidation of *S*-**23**, as described above, yielded *S*-**24** quantitatively as a 1:1 diastereomeric mixture. Spectral data for *S*-**24** were identical with those of *R*-**24**.

(2R)-4-Methyl-4-(4-hydroxypentyl)-2,2-dimethyl-1,3-dioxolane, 25

Lithium tetrahydridoaluminate (4.5 g, 118 mmol) was added to dry ether (300 mL). With ice-bath cooling, a solution of *R*-**24** (23.8 g, 119 mmol) in dry Et_2O (100 mL) was added dropwise over 45 min. The cooling bath was removed and after 1 h at ambient temperature the reaction was quenched by the successive dropwise addition of water (4.5 mL), 15% NaOH (4.5 mL), and water (13.5 mL). Insoluble material was removed by suction filtration and the filter cake washed with additional ether (3 × 100 mL). Removal of the solvent *in vacuo* yielded a 50:50 diastereomeric mixture of *R*-**25** (24.0 g, 100%). An analytical sample was distilled (bulb-to-bulb, bath temperature 100−120°C/0.2 Torr); ir (film): 3420(m), 2980(s), 2870(m), 1457(m), 1375(s), 1245(m), 1215(s), 1125(m), 1060(s), 987(w); ^1H nmr δ: 1.18 (3H, C(2) methyl, d, J = 6.2 Hz), 1.26 (3H, CH_3, s), 1.36 (3H, CH_3, s), 1.44 (4H, C(3)C(4)H, m), 1.54 (2H, C(5)H, m), 1.70 (1H, OH, s), 3.69 (1H, C(1)H diastereomers, 2 doublets separated by 1.6 Hz, J = 8.3 Hz), 3.77 (1H, C(1)H diastereomers, 2 doublets separated by 1.6 Hz, J = 8.3 Hz), 3.81 (1H, C(6)H, m); ms (EI): 187(53), 127(32), 115(98), 109(100), 72(99), 47(35), 43(93); ms (CI isobutane): 203(8) (M^+ + 1). *Anal.* calcd. for $C_{11}H_{22}O_3$: C 65.31, H 10.96; found: C 65.20, H 11.20.

Preparation of 25

Lithium tetrahydridoaluminate reduction of *S*-**24** yielded *S*-**25** as a 1:1 diastereomeric mixture in 98% yield. Spectral data for *S*-**25** were identical with those of *R*-**25**.

(+)-Frontalin, 1

Alcohol *R*-**25** (23.0 g, 114 mmol) was dissolved in glacial acetic acid (100 mL). The solution was cooled in an ice bath and 5% aqueous NaOCl solution (160 mL, ≈130 mmol) was added dropwise over 0.5 h. After 18 h at ambient temperature and 5 h at 50°C, the reaction was diluted with water (400 mL) and extracted with ether (4 × 100 mL). The ether was washed with 5% aqueous NaOH solution until the washings were basic (4 × 80 mL), then with water (100 mL) and saturated NaCl solution (100 mL). After drying ($MgSO_4$), the extracts were concentrated to ≈50 mL by distillation of the solvent through a 30-cm Vigreux column at atmospheric pressure. The residue was fractionally distilled to yield *R*-**1** (12.4 g, 77%); bp 65−67°C/30 Torr; >98% pure by gc; $[\alpha]_D^{23}$ +50.7 (*c* 4.6, Et_2O). Infrared and ^1H nmr were in accord with the literature (5). The optical purity on the basis of the rotation, compared with the highest reported value (54.4°, reference (5)), was 93%. As confirmation, the nmr spectra of (±)-**1** and (+)-**1** were recorded in the presence of tris[3-trifluoromethylhydroxymethylene-*d*-camphorato]europium(III) shift re-

agent as described by Mori *et al.* (4). Inspection of the low field C(7) hydrogen showed a near baseline separation of the enantiomeric signals if the higher field C(7) hydrogen was simultaneously decoupled. Integration (cut and weigh) gave an estimated 89% ee.

Preparation of (−)-frontalin, 1

Alcohol *S*-**25** was oxidized and cyclized as described above to yield 74% of *S*-**1**; bp 66−67°C/30 Torr, $[\alpha]_D^{23}$ −52.9° (*c* 4.7, Et_2O). The optical purity of this material was estimated to be 97% ee by comparison of the observed rotation to that reported by Ohrui and Emoto (5).

Thermodynamics of protonation of weak bases in H_2SO_4-H_2O media, determined using the excess acidity method

ROBIN A. COX AND KEITH YATES

Department of Chemistry, University of Toronto, 80 St. George St., Toronto, Ont., Canada M5S 1A1

Received June 20, 1983[1]

ROBIN A. COX and KEITH YATES. Can. J. Chem. **62**, 2155 (1984).

The excess acidity method has been used to investigate the thermodynamics of the protonation process for those weak bases for which the ionization ratios (or optical densities) at several temperatures have been measured in aqueous sulfuric acid. Standard enthalpies and entropies, at 25°C in the aqueous reference state, are given for thirteen primary, one secondary, and two tertiary nitroanilines, three cyanocompounds, thirteen triphenylmethanols, three other carbocation precursors, two ketones, nine pyridines, and nine azine *N*-oxides. Guidelines for estimating pK_{BH^+} at any temperature for other weak bases are discussed.

ROBIN A. COX et KEITH YATES. Can. J. Chem. **62**, 2155 (1984).

On a utilisé la méthode des acidités en excès pour étudier la thermodynamique du processus de protonation des bases faibles pour lesquelles les rapports d'ionisation (ou les densités optiques) ont été mesurés dans l'acide sulfurique aqueux, à diverses températures. On rapporte les enthalpies et les entropies standards, à 25°C et dans l'état de référence aqueux, de nitroanilines primaires (13), secondaire (1) et tertiaires (2), de cétones (2), de pyridines (9), de *N*-oxydes d'azines (9), de composés cyanés (3), de triphénylméthanols (13) et de trois autres précurseurs de carbocations. On discute des normes qu'il faut appliquer pour évaluer, à n'importe quelle température, les pK_{BH^+} d'autres bases faibles.

Introduction

The excess acidity method for equilibria, reaction [1], involves the use of eq. [2] (1). Ionization ratios I of a weak base B are measured as a function of acid concentration, and these, with the proton concentration C_{H^+} and the excess acidity X (2, 3), give the intercept protonation acidity constant pK_{BH^+} defined for reaction [1].

$$[1]\quad B + H^+ \overset{K_{BH^+}}{\rightleftharpoons} BH^+$$

$$[2]\quad \log I - \log C_{H^+} = pK_{BH^+} + m^*X$$

$$[3]\quad ROH + H^+ \overset{K_{R^+}}{\rightleftharpoons} R^+ + H_2O$$

$$[4]\quad \log I - \log (C_{H^+}/C_{H_2O}) - 1.743 = pK_{R^+} + m^*X$$

The slope parameters m^* describe the protonation behaviour of B relative to the hypothetical standard base B* used in defining X (2), with values in sulfuric acid of 1.0 for primary aromatic amines, 1.4 for tertiary amines, 0.6 for amides, and so on (2). For the protonation–dehydration reaction [3] (H_R compounds (1)) the corresponding equation is eq. [4]. Here I is C_{R^+}/C_{ROH} and the 1.743 is included because definitions of K_{R^+} customarily do not include the water concentration (3); values of m^* of about 1.8 have been found for triarylcarbinols in aqueous HCl (3). The method has found widespread use for these equilibria, as has the corresponding method applied to reaction rates; many references are collected in ref. 1.

Often pK_{BH^+} values are needed at temperatures different from those at which they have been measured, for instance for kinetic studies. Common practice has been to use the same pK_{BH^+} regardless of temperature. Our more recent practice has been to assume that $\Delta S^0 = 0$ and to calculate $\Delta H^0/RT \ln 10 = \Delta G^0/RT \ln 10 = pK_{BH^+}$ at absolute temperature T (4–6), after finding experimentally that this worked well for methyl benzoate (4) (R is the gas constant). The purpose of this paper is to see if this practice is justified in general, and to calculate enthalpies and entropies of protonation in the aqueous standard state, by extrapolation, from existing ionization ratio data obtained as a function of temperature. Many of these data are provided by major studies of the variation of the H_0 (7, 8), H_R (9, 10), and H_A (11) acidity functions with temperature. The excess acidity X is easily corrected to different temperatures by taking advantage of its definition as a combination of transfer activity coefficients as discussed previously (4), by multiplying by the absolute temperature ratio: $X_T = 298.15X/T$. Thus X can be used at any temperature. This means that the hypothetical base B* used to define X (1) is now also defined as having $\Delta S^0 = 0$, and that the m^* slopes are temperature independent.

Experimental

In order to use eqs. [2] and [4], X was corrected to the measurement temperature as described above, and the existing log C_{H^+} values (1) were corrected using listed densities (12) and the method of Young *et al.* (13), which gives HSO_4^- concentrations in sulfuric acid at 0, 25, and 50°C. Unfortunately, this 1959 study is the only one available, but the correction is very small and could have been reasonably neglected (i.e., by using only the densities) without affecting the results. Water concentrations required for eq. [4] were also calculated from the solution densities (12).

$$[5]\quad pK_{BH^+} \text{ or } pK_{R^+} = \Delta G^0_{25°}/R\theta \ln 10 + \Delta H^0_{25°}/R\theta \ln 10 \times (\theta - T)/T$$

The method of Clarke and Glew (14) was used to express pK in terms of ΔG^0 and ΔH^0 as shown in eq. [5], as before (5). This has the advantage over the conventional expression in terms of ΔH^0 and ΔS^0 in that ΔG^0 and ΔH^0 are more easily and reliably separated (14); the values obtained are valid at the standard temperature θ of 298.15 K, or 25°C. ΔS^0 was calculated using $\Delta G^0 = \Delta H^0 - \theta\Delta S^0$. Equation [5] can be easily expanded to provide ΔC_p^0 and its derivatives (14), but this was found not to be justified by the data in the present work. Substitution of eq. [5] into eqs. [2] and [4] gives a double linear regression with variables X and $(\theta - T)/T$, which was solved by a suitably modified multiple linear regression program (15) on a Commodore PET microcomputer.

Log I data for the compounds studied came from the following sources. Major studies of many of the primary nitroanilines are by Johnson *et al.* at 25, 40, 60, 80, and 90°C (7), by Tickle, Briggs, and Wilson at 15, 25, 35, 45, and 55°C (8), and by Gel'bshtein and

co-workers at 20, 40, 60, and 80°C (16). Marcus' group report data at 25 and 60°C (17), and Boyd and Wang have studied 4-nitroaniline at 1, 10, 20, 25, 30, 40, and 50°C (18). Additional data at 25°C (19–24), 17°C (25), and "room temperature", taken as 22°C (26–28), are also available. The cyanocompounds have been studied by Boyd and Wang at −5, 1, 10, 20, 25, 40, and 50°C (18), and by Boyd at 25°C (29). Data for the pyridines and azine *N*-oxides at 25, 40, 60, 80, and 90°C have been reported by Dassanayake, of Johnson's group (11).

Optical density (D) measurements at 0, 15, 30, and 45°C are given by Arnett and Bushick (10) for nine triarylmethanols, two benzhydrols, hexamethylbenzene, xanthone, 4,4′-dimethoxybenzophenone, *N*-methyl-2-nitro-4-chloroaniline, and *N*,*N*-dimethyl-2,4,6-trinitroaniline. These data were curve fitted as described elsewhere (30) to give optimum values of D_B and D_{BH^+}, and ionization ratios calculated using $I = (D - D_B)/(D_{BH^+} - D)$. Interpolated log I values for thirteen triarylmethanols are given by Toone (9) at 25, 40, 60, 80, and 90°C; nine of these compounds were also studied by Arnett and Bushick (10). Bonner and Phillips (31) give log I values for 4,4′-dimethoxybenzophenone at 23°C, and Arnett and Mach (32) studied *N*,*N*-dimethyl-2,4,6-trinitroaniline at 26°C. Extensive optical density data provided by Vinnik's group (33) yielded log I values for *N*,*N*-dimethyl-2,4-dinitroaniline at 25, 40, 50, and 60°C; this compound was also studied at 25°C by Bascombe and Bell (19).

All of the log I data from the various sources, for each base, were amalgamated and treated together. The data were weighted using an error function given by Kresge and Chen (34), which ensured that log I values between ±1 received higher weighting, in accord with the sigmoid shapes of the original titration curves (34). Otherwise each data source was given equal priority. The computer program used rejected points which, to a 95% confidence level, did not belong in the data set (points in parentheses in Table 1 and Figs 1 and 2); this refers to any point falling more than about two standard deviations away from the best regression line, depending on the weighting. Less than 7.5% of the data points were rejected in this way. Full statistical information is given in Table 1.

Results

Table 1 lists all 55 compounds in the study, with their derived $\Delta G^0_{25°}$, $\Delta H^0_{25°}$, and $\Delta S^0_{25°}$ values. Also given are pK_{BH^+} at 25°C, and the m^* slopes. The experimental error of each of these is given as the standard deviation. Also listed are the number of data points per compound, together with the number rejected by the computer program (see Experimental), the multiple correlation coefficient and the root-mean-square error of the fit.

As an example chosen at random, the experimental data for 2,5-dichloro-4-nitroaniline (7, 8, 17, 26) are illustrated in Fig. 1. In this figure the lines for the different temperatures are separated for clarity; the intercepts range from −1.74 at 15°C to −1.70 at 90°C. As can be seen, the data (101 points in all) are fitted very well by the parameters in Table 1. No systematic departure from linearity is evident, and the same slope applies at all temperatures, as discussed above. Results obtained by the different groups agree quite well, on the whole (e.g. at 25°C), although the measurements by Marcus' group at 60°C (17) are somewhat divergent, as are the lowest points at the higher temperatures by Tickle *et al.* (8). In general divergent points tend to cancel out, as can be seen in Fig. 1 (six rejected points above the line, and six below).

Of the various possible linear correlations, perhaps the most useful is that of ΔG^0 against ΔH^0 (9, 11, 35), and one of these is given in Fig. 2, for the anilines. In addition to the Table 1 data, Fig. 2 includes results obtained in the pH region for 25 variously substituted anilines by Bolton and Hall (36–39), and by Liotta *et al.* (40). The data are represented by the line ΔH^0

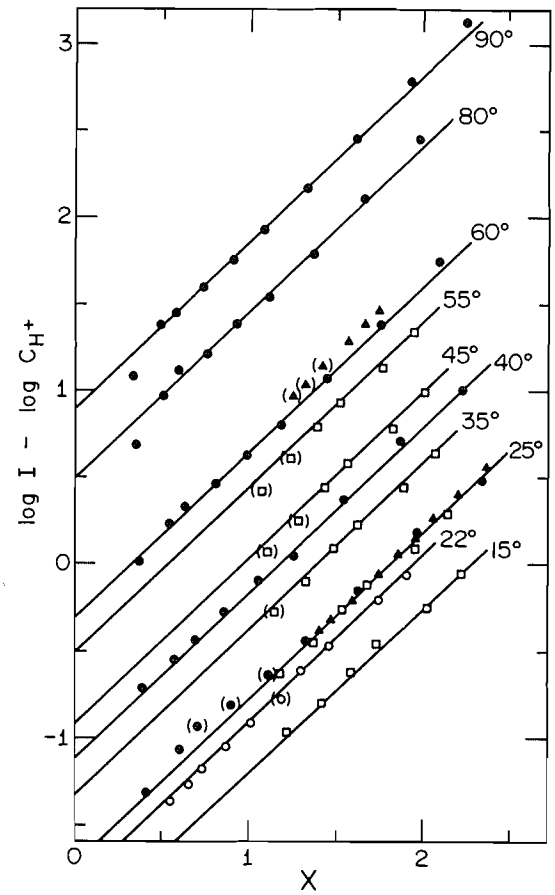

FIG. 1. Plots according to eq. [2] for 2,5-dichloro-4-nitroaniline. ●, ref. 7 (25, 40, 60, 80, and 90°C); □, ref. 8 (15, 25, 35, 45, and 55°C); ▲, ref. 17 (25 and 60°C); ○, ref. 26 (measurements at room temperature). The y-axis numbers refer to 25°C; all other lines are offset up or down, by amounts proportional to the measurement temperature, in order to avoid superimposition.

= (0.89 ± 0.01) ΔG^0 + (2.03 ± 0.06), with a root-mean-square error of 0.37 kcal/mol and a correlation coefficient of 0.997 over 38 points, one of which (that for 2,4,6-trinitroaniline) was rejected as being off the line. A similar plot for the triphenylmethanols, excluding those with the $^+NMe_3$ substituents, is ΔH^0 = (0.97 ± 0.07) ΔG^0 − (3.4 ± 0.6), σ_y = 1.05 kcal/mol, r = 0.979 (11 points). Plots for the other series of compounds were too scattered to be useful, particularly if literature data obtained for similar compounds in the pH region were included.

Discussion

The criterion for the rejection of anomalous data points used in this work is quite impartial. This is useful when measurements made by many different groups are combined, as is done here; each group naturally assumes that their results are accurate, and we should accept this and treat each measurement impartially. It was found, in fact, that very seldom were the results of one group systematically discarded because of disagreement with other workers, rejected points being scattered more or less at random. The example shown in Fig. 1 is typical. The primary data, i.e. the ionization ratios (or, better still, the original optical density data) as a function of acidity, are what can best be compared between the different groups. Agreement is, in general, excellent. However, because the pK_{BH^+} values

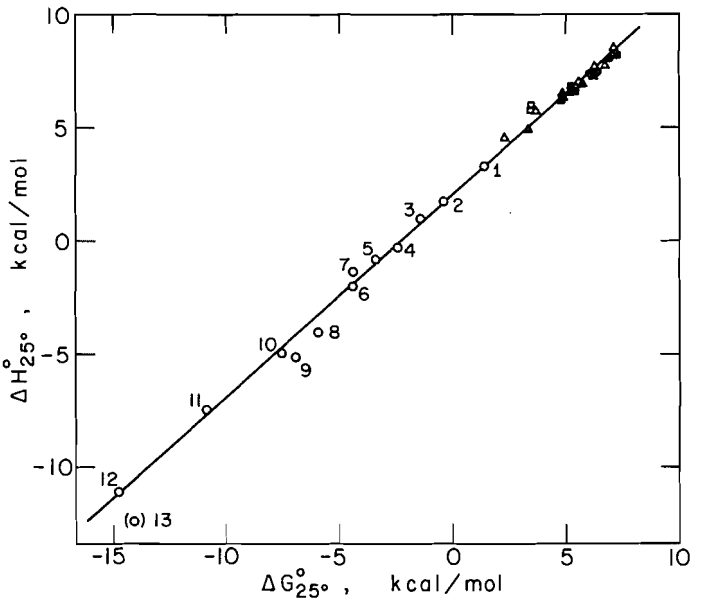

FIG. 2. Free energy/enthalpy plot for the protonation of substituted anilines. ○, this work (the numbers referring to Table 1); ●, aniline and *o*-, *m*-, and *p*-toluidine (36); ▲, *m*-OMe, Cl, Br, I, and NO_2 (37); ■, *p*-OMe, Cl, Br, and I (38); □, *o*-OMe, Cl, Br, and I (39); △, *m*- and *p*-Et, *m*- and *p*-OEt, *m*- and *p*-CN, and *m*- and *p*-F substituents (40).

obtained from this primary data are usually derived using different acidity functions, when ΔH^0 and ΔS^0 are in turn derived from pK_{BH^+} at different temperatures the numbers obtained by different groups are sometimes startlingly different. Arnett and Scorrano (41) have discussed this problem; a good example is the disagreement between refs. 9 and 10, discussed in ref. 9.

To illustrate that this is not a problem in this work, a "worst case" will be discussed. Combining the results obtained by Arnett and Bushick (10) and by Toone and co-workers (9) on the ionization of triarylmethanols could have presented problems; Bushick's data consist of optical density measurements with quite high random errors, and the log *I* values quoted by Toone and co-workers are interpolated to rounded sulfuric acid concentrations, meaning that much of the error information originally present is lost. As an example, after treatment as described here Toone's results for 4-methyltriphenylmethanol, taken alone, give $\Delta H^0 = -8.15 \pm 0.23$ kcal/mol and $\Delta S^0 = -4.1 \pm 0.8$ eu, $\sigma_y = \pm 0.052$, and $r = 0.992$ over 45 points, of which one was rejected. Bushick's data give $\Delta H^0 = -8.72 \pm 0.44$ and $\Delta S^0 = -6.8 \pm 1.6$; $\sigma_y = \pm 0.077$, and $r = 0.984$ over 32 points, five are rejected. The agreement is excellent and treatment of all of the data together gives the values in Table 1. In general, data for all nine compounds in both studies, when taken alone as described, gave results within two standard deviations of one another, and combination was possible in all but two cases. Thus the disagreement between the ΔG^0 and ΔH^0 values originally obtained by the two groups, discussed in ref. 9, is an artefact of the methods by which they were obtained. There is no disagreement.

Using the excess acidity method, and combining all of the data as described, means that the values in Table 1 should be much more reliable than those quoted by any one group of workers. They are in accord with reasonable expectations. For instance it is reasonable that the pK_{BH^+} of 2,4,6-trinitroaniline should be less than that of the 3-methyl derivative (electron donor) but more than that of the 3-bromo (electron acceptor). This is the order in which the excess acidity method gives them (ref. 2, Table 1), but not that given by the H_0 acidity function (7). It is also reasonable that ΔS^0 for the triphenylmethanols should be negative, since the reaction is bimolecular attack of water on a carbocation (reaction [3] in reverse), and that for the anilines should be positive, since the reaction is an acid dissociation (reaction [1] in reverse). Previous work gives positive ΔS^0 values in the latter case (35), but also mostly positive values for the former (9, 10). The data in Table 1 should refer only to the compounds themselves, since we have gone to some trouble to remove possible contributions caused by the changes of *X* and the H^+ and H_2O concentrations with temperature (see Experimental).

The numbers in Table 1 support the contention that the nitroanilines are a very "well-behaved" series of acidity indicators in sulfuric acid (2). The average m^* value is 1.01 ± 0.09 over 13 compounds. In contrast the other series of compounds have a much larger scatter, 1.86 ± 0.49 for twelve triarylmethanols (excluding the 4,4′,4″-trimethoxy compound, also found to be anomalous previously (3)), 0.96 ± 0.25 for seven pyridines, and 0.69 ± 0.14 for eight azine *N*-oxides (excluding pyridine 1-oxide).

By most criteria the free energy/enthalpy plot in Fig. 2 would be regarded as very good. The root-mean-square error of the fit, however, at 0.37 kcal/mol, is much larger than any of the errors in ΔH^0 found for these compounds (Table 1), and far larger still than the errors in the literature data (36–40). What this means is that these values should not be correlated by a line in the first place; the individual measurements are more accurate than the values predicted by the correlation. Thus, for the best results, thermodynamic parameters for compounds of interest should really be measured individually. Often this is not practical, however, and relationships such as Fig. 2 have been, are, and will be often used for estimates of thermodynamic parameters.

Figure 2 is a useful predictor for anilines, with the exception of 2,4,6-trinitroaniline. The reason for this exception is not clear, but it is interesting that the next weakest H_0 bases of the series used in really strong acids (27) are nitro-compounds, which presumably protonate on the nitro-group in media not that different from those in which trinitroaniline is assumed to protonate at NH_2. The slope of the line is significantly different from unity, which means that the agreement among the ΔS^0 values in Table 1, which average 8.3 ± 2.2 eu over the 13 anilines, is illusory rather than real.

The equation given for the triphenylmethanols, on the other hand, has a slope of unity within experimental error. Thus a reasonable estimate of ΔH^0 for these compounds could be obtained from ΔG^0 by assuming that a constant value of ΔS^0 applies to all of them. This value is -10.4 ± 3.3 eu, excluding the $^+NMe_3$-substituted compounds, clearly anomalous at -0.9 and $+6.4$ eu.

The pyridines and azine *N*-oxides show no clearly established trend. The slopes of free energy/enthalpy plots do not really differ from unity, and the ΔS^0 values do not really differ from zero ($+0.6 \pm 3.7$ and $+0.8 \pm 4.5$, respectively). It is clear from Table 1 that the term $T\Delta S^0$ becomes progressively less important the weaker the base, making the $\Delta S^0 = 0$ estimate more reasonable in stronger acids. For instance, for the nitroanilines $-T\Delta S^0$ is -2.47 ± 0.66 kcal/mol at 25°C, which makes only a small percentage contribution to ΔG^0 for the trinitroanilines, and for the triphenylmethanols it is +3.10

[a] Total number of experimental values; the number of these rejected as not being part of the data set, to 95% confidence, is in parentheses.
[b] Multiple correlation coefficient.
[c] Root-mean-square error of the fit.
[d] In kcal/mol.
[e] In entropy units.
[f] m = 1 because the acidity range covered is in the pH region.

± 0.98, also a small percentage contribution.

It must be concluded, however, that there is no substitute for the experimental determination of the thermodynamic behaviour of individual compounds. In cases where this is impossible or impractical, the results quoted in Table 1 and the free energy/enthalpy correlations may prove useful. It appears in general that the assumption that $\Delta G^0 = \Delta H^0$ is no better and no worse than other common assumptions, but that it does become a better one as the base becomes weaker.

Acknowledgements

We would like to thank Professors E. M. Arnett, C. D. Johnson, and A. J. Kresge for helpful discussions, and for providing unpublished ionization ratio data from theses. Financial support by the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged.

The interactions of the chloride and bromide ions in nematic lyotropic liquid crystalline solution

ALAN S. TRACEY

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received February 22, 1984

ALAN S. TRACEY. Can. J. Chem. **62**, 2161 (1984).

The binding interactions of chloride and bromide ions have been studied in nematic lyotropic liquid crystalline materials prepared using the mixed detergent system of potassium dodecanoate/dodecylpyridinium chloride. The results from this study show that a three-site model of binding is sufficient to describe the behaviour of the observed quadrupole splittings. The results clearly reveal that the selectivity of ion binding is a function not only of the counterion but also of the detergent ion to which it is bound. In the cationic mesophase prepared from decylpyridinium, Cl^- binds simultaneously to two and Br^- to three headgroups. This contrasts with the alkyltrimethylammonium bromide system, where Cl^- binds to three cationic amphiphiles while Br^- binds to two. Sodium ion appears indifferent to the type of cationic detergent present, a result in accordance with the expectation that its binding is determined only by the headgroup of the anionic detergent. Extension of the three-site theory to take into account the effect of surface charge on ion binding provides information concerning relative strengths of binding. In the dodecylpyridinium system Cl^- binds only weakly compared to Br^- whereas in the alkyltrimethylammonium system Cl^- binds more strongly than Br^-. K^+ binds most strongly to dodecanoate anion, Cs^+ least strongly, and the other alkali metal ions occupy intermediate positions.

ALAN S. TRACEY. Can. J. Chem. **62**, 2161 (1984).

On a étudié les interactions de liaison des ions chlorure et bromure dans des cristaux liquides lyotropes nématiques préparés en utilisant un système de détergent mixte à base de dodécanoate de potassium et de chlorure de dodécylpyridinium. Les résultats de cette étude montrent qu'un modèle de liaison par trois sites suffit pour décrire le comportement des couplages quadrupolaires observés. Les résultats révèlent clairement que la sélectivité de la liaison de l'ion dépend non seulement de l'ion opposé mais aussi de l'ion du détergent auquel il est lié. Dans la mésophase cationique préparée à partir du décylpyridinium, l'ion Cl^- se lie simultanément à deux groupes de tête alors que l'ion Br^- se lie à trois groupes de tête. Ce comportement est en opposition ave celui observé avec le système du bromure d'alkylméthylammonium dans lequel les ions Cl^- se lient à trois amphiphiles cationiques tandis que les ions Br^- se lient à deux amphiphiles cationiques. Les ions sodium semblent être indifférents au type de détergent cationique présent; c'est un résultat qui s'accorde avec l'hypothèse d'après l'aquelle sa liaison ne serait déterminée que par le groupe de tête du détergent anionique. L'extension de la théorie à trois sites, pour tenir compte de l'effet de la charge de surface sur la liaison de l'ion, fournit des informations concernant les forces relatives de liaison. Par opposition à l'ion Br^-, l'ion Cl^- ne se lie que faiblement dans le système dodécylpyridinium alors que c'est le contraire dans le système alkyltriméthylammonium. Vis-à-vis l'anion dodécanoate, le cation K^+ est celui qui se lie le plus fortement alors que l'ion Cs^+ est celui qui se lie le plus faiblement; les ions des autres métaux alcalins occupent des positions intermédiaires.

Introduction

The binding of ions to the polar groups of amphiphilic compounds is a subject of continuing interest and of great importance in various areas of chemistry and biochemistry (1–12). Unfortunately, as is often the case with biological systems, studies are hampered by the extreme complexity of the system being studied. For the particular case of ion binding a further impediment often encountered is that the details of the stereochemical requirements which are imposed on a substrate by the ion during binding interactions are not known. A study of simple systems can often provide the background information necessary for understanding the more complex systems.

A particularly suitable medium for studying ion interactions is that of lyotropic liquid crystals. Of these materials, those which have the property of spontaneously aligning in the magnetic field of a nuclear magnetic resonance spectrometer provide distinct advantages, the most important one being "sharp" nmr transitions, which result from the fact that the mesophase directors are aligned homogeneously by the magnetic field of the spectrometer (13).

Of particular utility in the study of ion binding is the mixed detergent system prepared from potassium dodecanoate (potassium laurate) and alkyltrimethylammonium bromide. This system has the advantage in that, under the appropriate conditions, the potassium dodecanoate can be replaced in a stepwise fashion by alkyltrimethylammonium bromide, thus progressing from the extreme of an anionic mesophase to that of a cationic mesophase (14, 15). Using this liquid crystalline system, in conjunction with the appropriate ions as additives, it was possible to show that there were distinct differences in the binding behaviour of the alkali ions to the dodecanoate ion throughout the series lithium to cesium. It was also possible to develop a picture of the binding sites specific to each ion. Similarly, a description of the binding of the halide ions, Cl^- and Br^-, to the trimethylammonium group was obtained (16).

It was found that the chloride ion binds differently from bromide, with the former ion simultaneously binding to three trimethylammonium headgroups while bromide binds simultaneously to only two. It was suggested that this occurred because of the interplay between electrostatic and steric forces. The trimethylammonium group is very bulky with the major charge-carrying species, the nitrogen, well shielded by the four alkyl groups. Since binding in such circumstances is probably significantly different from, say, nitrogen in an aromatic heterocyclic system it was decided to look at halide binding to the pyridinium group of the dodecylpyridinium detergent.

Unfortunately, because of the mesophase instability problems often encountered when anionic detergents are replaced with cationic detergents in a stepwise procedure, one is highly restricted to the systems which can be used. Undoubtedly, the list will be expanded from the two systems now known, potassium dodecanoate/*n*-alkyltrimethylammonium bromide (alkyl:

C_{10}, C_{12}, C_{14}, C_{16}) (14) and the present potassium dodecanoate/dodecylpyridinium chloride. The advantage of these mixed systems is that, by progressively changing the surface charge carried by the hydrocarbon superstructure, sites of one kind or another are being created or destroyed. From the binding model adopted, the behaviour of various physical parameters as a function of surface charge (mole fraction of either amphiphile in total amphiphile) can be predicted. With the adoption of a reasonable model of ion binding, the experimental results can be used both to support the model and to suggest refinements to it.

The physical parameter of interest in this study is the quadrupole splittings from the $^{35}Cl^-$ and $^{81}Br^-$ nuclei. This splitting is determined by the nuclear electric quadrupole moment of the nucleus and the alignment of electric field gradients, with which the quadrupole moment interacts, in the magnetic field of the nmr spectrometer.

The quadrupole splitting, $\Delta\nu$, is given by eq. [1],

$$[1] \qquad \Delta\nu = \frac{3QS}{2I(2I-1)}$$

where Q is the quadrupole coupling constant and S is the order parameter. I is the nuclear spin angular momentum, equal to 3/2 for both $^{35}Cl^-$ and $^{81}Br^-$. In the circumstance that the ion is undergoing rapid exchange between various binding sites, the observed splitting, $\Delta\nu$, is a weighted average of the splitting from the various sites; that is, the splitting is given by eq. [2],

$$[2] \qquad \Delta\nu = \sum_i \Delta\nu_i X_i$$

where X_i is the mole fraction of nuclei in site i and $\Delta\nu_i$ is the splitting characteristic for that site. In the previous study of ion binding it was found that consideration of averaging of the quadrupolar nucleus between three sites was sufficient to provide good agreement between calculated and observed quadrupole splittings and to account well for the bulk of experimental results. The present results show that some refinements to this model of ion binding are required.

In this three-site model of binding, the first site, site I, is taken to correspond to the counterion being bound, presumably through its hydration sphere, to n amphiphiles, where n ranges from 2 to 4. With partial replacement of this amphiphile by ones of opposite charge, sites of type I are destroyed and sites for binding of a second type, site II, in which the counterion binds to only one amphiphile, are created. The third site, site III, corresponds to counterions not bound to amphiphiles, although long range interactions with the micellar surface are occurring. This last site may correspond to free ions in the water located between the micellar elements which cause the formation of the liquid crystalline material. This interstitial water is expected to be essentially isotropic in nature.

Experimental

Potassium dodecanoate was prepared from dodecanoic acid by neutralization with KOH followed by recrystallization several times from ethanol (95%). Dodecylpyridinium chloride was prepared similarly to that previously described for hexadecylpyridinium chloride (17).

The lyotropic mesophases used in this study had the general molar composition: total detergent/salt/D_2O/decanol, 1.00/0.39/28.3–33.3/0.0–0.32. The percentage of potassium dodecanoate in total detergent was varied from 10 to 100% on a molar basis. With the above general composition, dodecylpyridinium chloride did not form the desired mesophase when it was used without at least 10 mol% of the potassium dodecanoate combined with it. The mesophase could be obtained with other compositions. A mesophase formation problem was also encountered at 60% dodecanoate. This problem, which is typical, derives from the strong positive interactions between the oppositely charged headgroups as found for the *n*-alkyltrimethylammonium system (14). No attempt to obtain the missing data point by using decyl- instead of dodecyl-pyridinium chloride was made.

The nematic materials were prepared by direct weighing of the components followed by alternate stirring and centrifuging until a homogeneous anisotropic fluid was obtained.

Nuclear magnetic resonance spectra were obtained from samples contained in 5 mm sample tubes using a 10 mm broadband probe of a 400 MHz spectrometer. All spectra were obtained at 25°C. The signs of quadrupole splittings given in the tables and displayed in the figures are relative signs only.

Results and discussion

From a three-site model of ion binding and under the condition that chemical exchange between all sites is fast on the nmr time-scale, the observed quadrupole splitting, $\Delta\nu$, is given by expression [3] which follows directly from eq. [2].

$$[3] \qquad \Delta\nu = \Delta\nu_I X_I + \Delta\nu_{II} X_{II} + \Delta\nu_{III} X_{III}$$

Under the condition that an insignificant number of the available binding sites are not occupied, a condition aided by the large proportion of added salt, eq. [4] can be obtained. A further assumption implicit in this equation is that sites of type I are occupied, if available, at the expense of occupancy in sites II or III and, correspondingly, site II is occupied at the expense of site III. In eq. [4],

$$[4A] \quad 1 \geq x \geq (1 - 1/n)$$
$$\Delta\nu = [\Delta\nu_I C_D(nx - (n-1)) + (n-1)\,\Delta\nu_{II} C_D(1-x) + \Delta\nu_{III} C_E]/[xC_D + C_E]$$

$$[4B] \quad (1 - 1/n) \geq x \geq 0$$
$$\Delta\nu = [\Delta\nu_{II} x C_D + \Delta\nu_{III} C_E]/[xC_D + C_E]$$

x is the mole fraction of potassium dodecanoate in total detergent, while n specifies the number of amphiphiles required by the counterion occupying a site I. This equation provides a description of alkali metal ions binding to the carboxylate headgroup of dodecanoate. C_D and C_E are the relative number of moles of detergent and electrolyte, respectively, in the liquid crystalline system. In practice, the parameter, n, varies from two to four for the alkali metal ions; 2 for Li^+, 3 for Na^+, and 4 for K^+, Rb^+, and Cs^+ (16).

For halide ion binding, x in the above expression, is replaced by $1 - x$. This replacement simply reflects the fact that halides are binding to the cationic amphiphiles, which mole fraction is given by $1 - x$ rather than x.

$$[5A] \quad 1 \geq x \geq 1/n$$
$$\Delta\nu = [\Delta\nu_{II}(1-x)C_D + \Delta\nu_{III} C_E]/[(1-x)C_D + C_E]$$

$$[5B] \quad 1/n \geq x \geq 0$$
$$\Delta\nu = [\Delta\nu_I(-nx+1)C_D + (n-1)\,\Delta\nu_{II} x C_D + \Delta\nu_{III} C_E]/[(1-x)C_D + C_E]$$

From this three-site model for ion binding to amphiphiles it is expected that the binding of an alkali metal ion, say Na^+, to carboxylate should be described by eq. [4], independent of which cationic amphiphile is used as the second component. Under these same circumstances, the halide ion which binds to the cationic amphiphile could show significantly different be-

haviour as this latter detergent is replaced by another.

Table 1 gives the mesophase compositions and the ^2H, $^{23}Na^+$, $^{35}Cl^-$, and $^{81}Br^-$ quadrupole splittings which were observed for the various mesophases studied. Unfortunately, under the limitation adopted here that the ratio of total amphiphile to electrolyte is a constant, a mesophase containing only dodecylpyridinium chloride could not be prepared. The corresponding lack of information is not a serious one since the observed curve is readily extrapolated to $x = 0$.

From these results one main point must be established. This is that the Na^+ quadrupole splittings behave according to eq. [4] with $n = 3$, as has been shown for the case when the cationic amphiphile is dodecyltrimethylammonium bromide (16) rather than the dodecylpyridinium chloride employed here. A curve calculated from the characteristic splittings $\Delta\nu_I$, $\Delta\nu_{II}$, and $\Delta\nu_{III}$, equal to 8.55, −4.1, and 1.0 kHz, respectively, fits the experimental results very well as shown in Fig. 1. The major region of discrepancy, which occurs also in the trimethylammonium case, is in the region for x equal to from 0.0 to 0.5.

Also of interest in this study is the behaviour of the deuterium quadrupole splitting of the deuterium in the deuterated water. As can be seen from Table 1, this splitting has a plateau-like region from $x = 1$ to $x \approx 0.75$, then a transition zone followed by a second fairly constant region from $x \approx 0.3$. Similar behaviour has previously been observed (15). This result may indicate that a fairly stable water structure is built around the carboxylate headgroups. This water structure appears to be stable until about 30% of the carboxylate is replaced by pyridinium or trimethylammonium, at which point it becomes unstable and, with continued replacement of carboxylate, eventually disappears. With about 70% replacement of dodecanoate apparently a second type of water structure appears, this one built around the pyridinium headgroups. Since the structures presumably are different, the quadrupole splittings also will be different. It should be noted that, because of rapid exchange, the observed splittings are on average of those from the near isotropic water in the interstitial regions and the water in the more organized areas of the mesophase. Since there is no apparent correlation between the behaviour of water quadrupole splitting and of the counterion quadrupole splittings, these two types of splittings probably arise by different mechanisms.

The bromide ion quadrupole splittings given in Table 1 are reproduced from eq. [5] with $n = 3$ when the characteristic values $\Delta\nu_I = -185.0$, $\Delta\nu_{II} = 51.5$, and $\Delta\nu_{III} = 5.9$ kHz, respectively, describe the calculated curve. As seen in Fig. 1 the agreement between calculated and observed curves is reasonable, with the major discrepancy occurring in the transition region as might be expected. This result is consistent with binding of Br^- to three pyridinium headgroups in the dodecylpyridinium mesophase. The results here are in contrast to those of the alkyltrimethylammonium case, where bromide binds to two headgroups (16). This result clearly establishes that the binding of counterions is a function not only of the properties of the counterion itself but also of the amphiphile to which it is bound.

Figure 1 also shows the observed chloride quadrupole splittings and dashed curves calculated according to $n = 2$ and $n = 3$. In this case, the agreement between the calculated and observed points is not particularly good for either calculated curve. It is necessary to provide an explanation of the deviation between the calculated and observed curves. This behaviour is typical but highly exaggerated here. The discrepancy is ion dependent and generally very much less than that exhibited by the Cl^- ion, as can been seen here for the Na^+ and Br^- ions.

In the cationic mesophase, Cl^- or Br^- is bound by the pyridinium headgroups. As the cationic amphiphile is replaced by the anionic amphiphile, sites of type I are destroyed and those of type II created but, simultaneously to this, the surface charge is being changed from positive to negative in a stepwise fashion. When binding is sufficiently strong the binding forces are able to compete successfully with the developing repulsive electrostatic forces and close agreement between observed and calculated curves is obtained. If binding is weak, then with the buildup of negative charge on the micellar surface the ion undergoing the binding interaction is progressively displaced into the interstitial water. This means that the various relevant quantities in eq. [4] and [5] may not properly represent the proportions of free and bound ions. In this regard, it should be noted that $\Delta\nu$ of eq. [5A] becomes nearly linear in x when C_E is much larger than $(1 - x)C_D$.

For the chloride ion through the range $x = 1$ to 0.5 an approximately linearity is observed for the quadrupole splitting which indicates that the concentration of ions in site III is effectively very large compared to $(1 - x)C_D$. This behaviour is probably related to the development of negative surface charge. It might then be expected that in conjunction with the

binding behaviour as described in eqs. [4] and [5] there is a systematic displacement of ions into the interstitial water as the surface charge is varied. In a first approximation this displacement may be assumed to be linear so that eq. [6] is obtained from eq. [4].

$$[6A] \quad 1 \geq x \geq (1 - 1/n)$$
$$\Delta\nu = [A(B + C] + \Delta\nu_{III}(xC_D(1 - A) + C_E)]/[xC_D + C_E]$$

$$[6B] \quad (1 - 1/n) \geq x \geq 0$$
$$\Delta\nu = [A\Delta\nu_{II}xC_D + \Delta\nu_{III}(xC_D(1 - A) + C_E)]/[xC_D + C_E]$$

In this expression, $A = k_0 - k_I(1 - xC_D)$, $B = \Delta\nu_I C_D(nx - (n - 1))$ and $C = (n - 1)\Delta\nu_{II}C_D(1 - x)$. A similar expression is readily written from eq. [5].

Within the limits of the approximation adopted here k_I is a measure of how tightly ions are being bound in the interface. A k_I equals to 1 means a minimum of sites are occupied while a k_I of 0 means all sites are occupied. When k_I takes values near 1 the basic assumption that $k_0 = 1$ is probably no longer valid. Beyond this, these results can provide little information concerning k_0. It is worth noting that within this approximation $k_I = 0.5$ means that with $x = 0.5$, 75% of all binding sites are occupied. Decreasing the value of k_0 from 1.0 to another value simply results in a scaling of the characteristic splittings $\Delta\nu_I$ and $\Delta\nu_{II}$ and has negligible effect on the calculated curve.

Figure 2 shows the best fit curves calculated using eq. [6] with $n = 2$ for Cl^- and $n = 3$ for Br^- and Na^+. The agreement is excellent in these three cases and similarly as good when the data of ref. 16 is utilized. Figure 1 tends to suggest that Cl^- in site I might be in an equilibrium situation, binding at one time to 2 headgroups and at another time to 3. Testing of such an assumption gives a much improved correlation between calculated and observed quadrupole splittings over that displayed in Fig. 1. The agreement, however, continually improves with decreasing admixture of the second component and clearly is maximized with 100% of the $n = 2$ component.

It is of interest to compare the various k_I values obtained from eq. [6]. Table 2 collects together the values obtained in this study and those calculated from the data in ref. 16. Particularly interesting are the values of k_I for the chloride ion. For the binding of chloride to the pyridinium headgroup this value is 0.96, indicating that binding is weak. This compares dramatically with the binding to the trimethylammonium headgroup where $k_I = 0.11$, indicative of very strong binding. Bromide ion has corresponding values of 0.55 and 0.40 again indicating a stronger binding to the trimethylammonium group. However, in this case the difference is much smaller.

The values of k_I for the binding of the alkali metal cations to the dodecanoate anion also show an interesting behaviour. The value of $k_I = 0.36$ for Li^+ rises to ≈0.44 for Na^+ then drops to ≈0.21 for K^+ then rises through 0.39 for Rb^+ to 0.69 for Cs^+. These values indicate that potassium is bound most tightly by the carboxylate anion and cesium least tightly while the others have intermediate strengths of binding. It is interesting to note that k_I for the first sodium entry in Table 2 is not very different from the other two entries, showing that the sodium cation is not very sensitive to the cationic detergent present. It should be mentioned that the dominating influence on the value obtained for k_I comes from experimental points in the region corresponding to ion binding to only one amphiphile, i.e. site II, so that k_I gives essentially no information concerning relative strengths of binding of ions in site I.

There does, however, appear to be a correlation between k_I and the strength of binding in site I. Turning to Fig. 2 it is seen that the remaining region of major discrepancy between calculated and observed curves lies in a more or less restricted transition zone between site I and site II. This discrepancy is small when binding is weak, as indicated by k_I (i.e. Cl^-), and increasingly large as binding is stronger as for Br^- and Na^+. Similar conclusions can be drawn from the information in ref. 16 and Table 2. This indicates that dispersive forces generated by changes in detergent ratios are, to an extent, overridden by the strength of binding in site I. The consequence of this is that in the transition region there will in general be more ions in site I than predicted by eq. [6]. In the future systems may be found where the opposite is true, this is to say that ions will move into site II faster than predicted by eq. [6], in fact Cl^- binding to pyridinium may be showing a slight tendency in this regard.

It is clear that considerably more study of these systems is

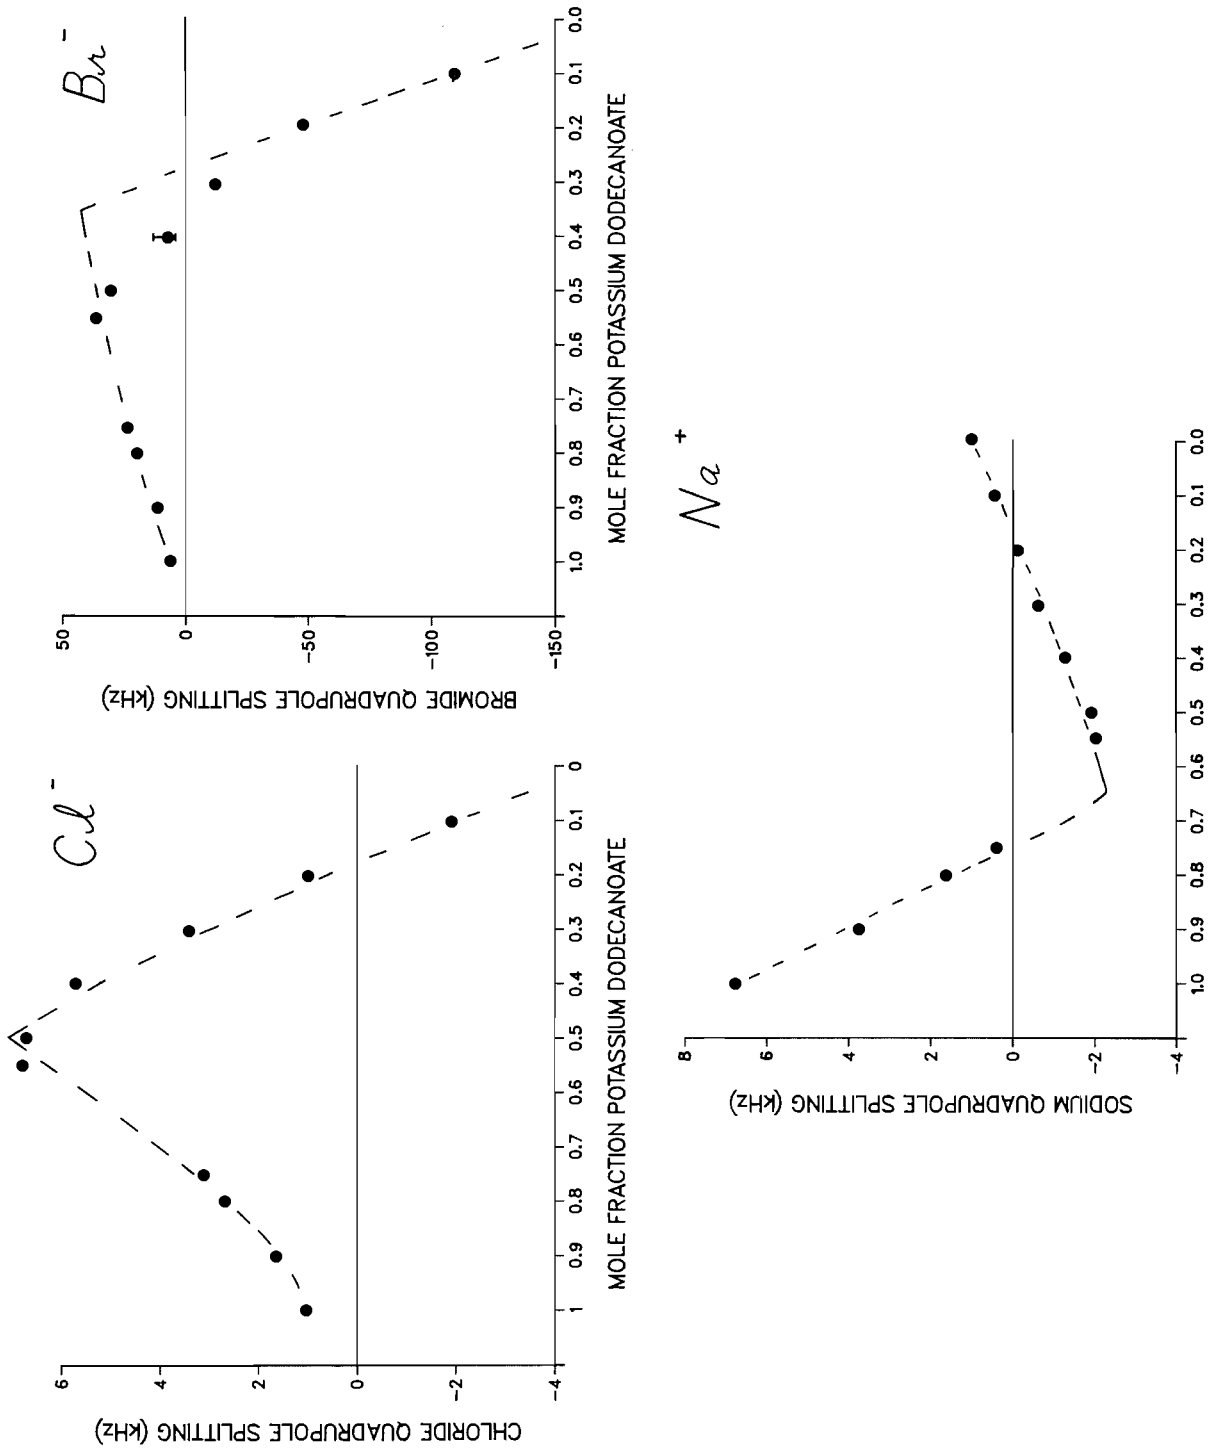

FIG. 2. The observed (●) and calculated (- - -) quadrupole splittings taking into account the development of charge on the bilayer interface.

required. In particular one must be concerned with effects of temperature and of changes in electrolyte concentration. The details of ion competition in these systems have not been properly addressed nor indeed the effects of changes in pH on binding. The problem of diffuse binding of ions in site III has not been examined in this study and this aspect of ion binding could be of importance. Extension of ion binding studies into these areas will enable development of this model of ion binding to proceed. Ultimately, of course, it may be superceded by an alternative description of the binding of ions in these amphiphilic systems.

A five-coordinate dicarbonyl rhodium(I) complex containing monohapto-2-diphenylphosphinothiophene: $[RhCl(CO)_2(DPT)_2]$

ALAN R. SANGER
Alberta Research Council, 11315-87 Avenue, Edmonton, Alta., Canada T6G 2C2

Received March 1, 1984

ALAN R. SANGER. Can. J. Chem. **62**, 2168 (1984).

Facile reversible addition of CO to *trans*-$[RhCl(CO)(Ph_2PC_4H_3S)_2]$ gives the five-coordinate complex $[RhCl(CO)_2(Ph_2PC_4H_3S)_2]$, which represents the first complex of the type $[RhCl(CO)_2(PR_3)_2]$ to be identified, and which is trigonal bipyramidal with axial carbonyls and equatorial phosphine ligands.

ALAN R. SANGER. Can. J. Chem. **62**, 2168 (1984).

Une addition réversible facile de CO au $[RhCl(CO)(Ph_2PC_4H_3S)_2]$-*trans* conduit au complexe penta-coordonné $[RhCl\text{-}(CO)_2(Ph_2PC_4H_3S)_2]$ qui correspond au premier complexe du type $[RhCl(CO)_2(PR_3)]$ à être identifié; sa géométrie est trigonale bipyramidale et il porte les ligands carbonyles en position axiale et les ligands phosphines en position équatoriale.

Introduction

The reactions of tertiary phosphines (PR_3; R = alkyl or aryl) with either $[Rh_2Cl_2(CO)_4]$, or with $[Rh_2Cl_2(cod)_2]$ (cod is 1,5-cyclooctadiene) under an atmosphere of CO, have been well studied (1). In all cases previously reported, when PR_3/Rh is two or more the ultimate product is *trans*-$[RhCl(CO)(PR_3)_2]$. Decarbonylation of aroyl chlorides using $[RhCl(PPh_3)_3]$ was reported to give both the *cis* and *trans* isomers of $[RhCl(CO)(PPh_3)_2]$ (2). Similarly, attempted synthesis of $[RhI(CO)(PPh_3)_2]$ by halogen exchange under various conditions gave different products which, on the basis of their ir spectra, were assigned *cis* and *trans* structures (3). No isolated complex of the form $[RhCl(CO)_2(PR_3)_2]$ has previously been reported. However, the pentacoordinate rhodium complexes $RHg[Rh(CO)_2(PPh_3)_2]$ and $Hg[Rh(CO)_2(PPh_3)_2]_2$ can be prepared by the reduction of *trans*-$[RhCl(CO)(PPh_3)_2]$ with sodium amalgam under an atmosphere of CO (4). The dicarbonyl complex $[RhH(CO)_2(PPh_3)_2]$ is formed from $[RhH(CO)(PPh_3)_3]$ and CO, and is of high hydroformylation catalytic activity due to facile ligand dissociation (5). Further, the complex $[IrCl(CO)_2(PPh_3)_2]$ is known, and is trigonal bipyramidal with axial triphenylphosphine ligands (6).

Experimental

Under an atmosphere of CO, $[Rh_2Cl_2(cod)_2]$ (0.597 g, 1.21 mmol) (or equivalent amount of $[Rh_2Cl_2(CO)_4]$) was added to a solution of 2-diphenylphosphinothiophene ("DPT") (1.59 g, 5.93 mmol) (7, 8) in dichloromethane (30 mL) to form an orange–yellow solution. Slowly, under a stream of CO, yellow crystals (1.11 g, 63%) of $[RhCl(CO)_2(DPT)_2]$, **1**, contaminated with a trace of *trans*-$[RhCl(CO)(DPT)_2]$, **2**, were formed. The remaining solution was diluted with ethanol, and then evaporation of dichloromethane gave pure **1** (0.73 g, 37%) as yellow needles.

Under an atmosphere of nitrogen a portion of **1** was dissolved in dichloromethane and then a layer of ethanol was added. The solvents mixed to form a yellow solution. Slow evaporation of dichloromethane gave light yellow crystals of *trans*-$[RhCl(CO)(DPT)_2]$, **2**.

Similarly, a sample of **2** was dissolved in dichloromethane, ethanol was added, and the solvents slowly evaporated under a stream of CO to give crystals of **1**.

Solutions of **1** or **2** in acetone under an atmosphere of CO, N_2, or air were each non-conducting. Spectra (Table 1) were obtained using the following instruments: ir, Perkin-Elmer 283; ^{13}C and ^{31}P nmr, Brüker WP80; gc-ms, Finnigan 4000/4500.

Results and discussion

The reaction of DPT (7, 8) with either $[Rh_2Cl_2(CO)_4]$ or $[Rh_2Cl_2(cod)_2]$ under an atmosphere of CO gave yellow crystals of a complex, **1**, which is assigned the formula $[RhCl(CO)_2(DPT)_2]$ and the structure shown in Fig. 1, based on elemental analyses and for the following reasons. Complex **1** is not an electrolyte. The phosphine ligands are equivalent (^{31}P nmr). The ^{13}CO (90% enriched) complex exhibits broader ^{31}P resonances, but $^2J(^{13}C—^{31}P)$ is not clearly resolved to −80°C. The increased breadth may be due to a reduction in the rate of exchange of ^{13}CO liquids at −80°C. The ^{13}C nmr spectrum (30°C) exhibited a single resonance (δ_C 187 ppm) in the carbonyl-^{13}C region. No coupling was evident at this temperature. The ir spectrum exhibits one very strong carbonyl band and one weak Rh—Cl band. When a solution of **1** is flushed with nitrogen the monocarbonyl complex **2** is formed, and **2** reacts with CO to reform **1**. Complex **1** therefore represents the first reported five-coordinate complex of the formula $[RhCl(CO)_2(PR_3)_2]$. The proposed structure differs from that of $[Rh(HgPh)(CO)_2(PPh_3)_2]$, which has inequivalent phosphine ligands (4), or $[IrCl(CO)_2(PPh_3)_2]$, which has axial phosphine ligands (6). For each of these complexes two carbonyl bands are observed in the ir spectrum, whereas for **1** there is only one.

Attempted recrystallization of **1** from dichloromethane/ethanol under an atmosphere of nitrogen gave exclusively the monocarbonyl complex **2**. This complex also contains equivalent phosphine ligands, is a non-electrolyte, and exhibits one carbonyl stretching band and one Rh—Cl band in the ir spectrum. The ^{31}P nmr spectrum of the ^{13}CO complex exhibits coupling to a single ^{13}C nucleus ($^2J(CP) = 16.5$ Hz). At −50°C coupling of ^{13}C to two ^{31}P was also observed (δ_C 187 ppm; $^1J(RhC)$ 74.5 Hz; $^2J(PC)$ 16.5 Hz). On the basis of the above data, and by comparison of the spectroscopic parameters with those known complexes of the form *trans*-$[RhCl(CO)(PR_3)_2]$ (1), complex **2** is assigned the structure *trans*-$[RhCl(CO)(DPT)_2]$. Reaction of **2** with CO regenerates **1**. The value of $^1J(Rh—P)$ for **1** is lower than for **2**, as is appropriate for a complex in which there are more competing σ-donor π-acceptor ligands about rhodium. It is noteworthy that for both **1** and **2** the phosphine ligands are equivalent to −50°C, therefore neither complex can have the structure *cis*-$[RhCl(CO)(PR_3)_2]$. As assignments of such a *cis* structure have been on the basis of ir spectra only, a reassessment of the nature of such materials is probably in order.

Addition of $NaBPh_4$ to a solution of **1** or **2** in ethanol caused no colour change, and no formation of an ionic complex of rhodium was detected. In contrast to complexes of

[g]Reference 6.

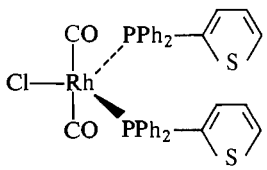

FIG. 1. Structure of complex **1**.

Ph_2PCH_2SPh (7), chelation of rhodium by coordination of the thioether function of DPT is not facile, probably due to the greater rigidity of DPT. Similar nonchelating behaviour of DPT was observed for complexes of cobalt(III) or nickel(II) (8).

Complexes of Rh^{I} similar to **2** are effective catalysts for hydrogenation, hydroformylation, carbonylation, or decarbonylation. Structures similar to **1** must now be considered as possible intermediates in such reactions; experiments to investigate the existence of complexes $[RhX(CO)_2(PPh_3)_2]$ (X = Cl, Br, I) will be described separately.

Acidité de Brønsted des phosphoranes à liaison P—H; identification de leurs bases conjuguées; détermination de leur pK_a

B. GARRIGUES, D. BOYER ET A. MUNOZ

E.R.A. C.N.R.S. N° 926, Université Paul Sabatier, 118 route de Narbonne, 31062 Toulouse Cedex, France

Reçu le 19 octobre 1983

B. GARRIGUES, D. BOYER et A. MUNOZ. Can. J. Chem. **62**, 2170 (1984).

Le proton P—H de phosphoranes contenant le ligand α hydroxyacide ou acide iminodiacétique, est suffisamment mobile pour être arraché à la température ambiante, par des bases moyennes comme la triéthylamine. Les entités phosphorées résultant de cette déprotonation, identifiées par rmn de ^{31}P, sont: (a) le phosphoranure pour le composé bicyclique préparé à partir de l'acide iminodiacétique, (b) le phosphite anionique isomère du phosphoranure, dans le cas d'un phosphorane contenant un ligand α hydroxyacide, (c) le phosphite et le phosphoranure en équilibre, pour les phosphoranes contenant deux ligands α hydroxyacide. Les pK_a, déterminés en solution dans le DMF par potentiométrie, en titrant les phosphoranes par la triéthylamine, correspondent à des acides moyens ou faibles. Cependant, les phosphoranes étudiés sont, dans le DMF, plus acides que les autres composés phosphorés à liaison P—H connus. Ils sont également plus dissociés, dans ce solvant, que les acides carboxyliques.

B. GARRIGUES, D. BOYER, and A. MUNOZ. Can. J. Chem. **62**, 2170 (1984).

The P—H proton of phosphoranes containing an α-hydroxy acid or iminodiacetic acid ligand is sufficiently mobile to be removed at room temperature by medium strength bases such as triethylamine. The deprotonation products identified by ^{31}P nmr are (a) the phosphoranide for the bicyclic compound prepared from iminodiacetic acid, (b) the anionic phosphite isomeric to the above, for phosphoranes containing the α-hydroxy acid ligand, (c) the phosphite and the phosphoramide in equilibrium, for phosphoranes containing two α-hydroxy ligands. The pK_a values potentiometrically determined in DMF solution by titration of the phosphoranes with triethylamine correspond to weak or mild acids. However, the phosphoranes studied are more acid in DMF than other known compounds containing the P—H bond. They are also more dissociated in this solvent than carboxylic acids.

[Journal translation]

I. Introduction

Si la liaison P—H, dans la coordinence V du phosphore a donné lieu à de nombreuses études physicochimiques, notamment par rmn et ir, les données quantitatives concernant sa dissociation sont beaucoup plus rares. On sait que dans les composés tri et tétracoordonnés, à l'exception des sels de phosphonium, cette dissociation est peu importante (1–4). Par exemple, le pK_a du diéthylphosphite est de 13, en solution dans l'eau (4).

Les résultats décrits en ce qui concerne les phosphoranes à liaison P—H, dans lesquels l'atome de phosphore est relié à plusieurs atomes de carbone, montrent que ces composés ne se singularisent pas des dérivés appartenant aux coordinences inférieures (5): le pK_a a été estimé pour l'un d'eux à 11,7, en solution dans l'eau (5*c*). Ce sont donc des acides faibles. La base conjuguée présente en rmn de ^{31}P, un singulet situé dans un champ de résonance proche de celui du phosphorane (5*b*, 5*c*). Il s'agit donc d'un composé du phosphore tétracoordonne dans lequel cet élément conserve dix électrons dans sa sphère de coordinence. Il a été désigné par le terme de "phosphoranure" (5*b*).

Les phosphoranes à liaison P—H, où l'atome de phosphore est relié à des atomes d'oxygène sont nettement plus réactifs vis-à-vis des bases que les composés homologues à liaison P—C. Ils sont susceptibles de réagir avec des bases moyennes comme la pyridine ou la triéthylamine (6). Suivant leur structure, ils peuvent donner lieu à deux types de phénomènes: formation d'un composé d'addition à phosphore hexacoordonné (6), et déplacement de l'équilibre phosphorane ⇌ phosphite vers la forme à phosphore tricoordonné (6). Dans le cas des phosphoranes contenant un reste α hydroxyacide, les amines aliphatiques, comme la diéthylamine conduisent au sel du phosphite isomère (6) (schéma 1).

[1] 
1 **1′**

SCHÉMA 1

Il est important de préciser que les composés **1** existent, pour les termes substitués, uniquement, en l'absence de base et au regard de la rmn, sous la forme phosphorane (6). Le résultat représenté par le schéma 1 peut s'interpréter par la déprotonation du phosphorane, conduisant au phosphoranure, lequel, peu stable, se transformerait finalement en phsophite **1′** (schéma 2).

SCHÉMA 2

Afin d'identifier le phosphoranure dans ce type de composés, les auteurs ont traité par les bases les tétraoxyspirophosphoranes les plus stables. C'est ainsi qu'en faisant réagir l'amidure de sodium sur le spirophosphorane contenant deux restes pinacol, Savignac *et al.* (7) ont observé des processus comparables à ceux du schéma 1. Là encore, le composé obtenu est le sel du phosphite isomère (7). Cependant, l'action, *in situ*, d'halogénures d'alcoyle sur le mélange phosphorane + base conduit au remplacement du proton P—H par le reste alcoyle, ce qui a été considéré par les auteurs comme une preuve de la formation préliminaire du phosphoranure (7).

Pour notre part, nous avons essayé de stabiliser le phosphoranure, en introduisant dans les composés **1** le maximum de facteurs favorables: c'est ainsi que nous avons envisagé les composés **2** contenant deux ligands α hydroxyacide. On sait que pour les termes substitués, l'équilibre phosphite ⇌ phosphorane n'a pas été mis en évidence par rmn, même à +120°C.

En revanche, cet équilibre a été décelé récemment, pour le terme non substitué (**2***a*) à des températures supérieures à +40°C (9).

Des résultats préliminaires observés en faisant réagir la pyridine et la triéthylamine sur le composé **2***e* ont permis de mettre en évidence un équilibre entre le phosphorane, le phosphite et le phosphoranure isomères, auxquels il convient d'ajouter des complexes d'addition à phosphore hexacoordonné (schéma 3) (10). Cependant ce dernier phénomène, seulement visible à basse température, est nettement minoritaire et peut être négligé.

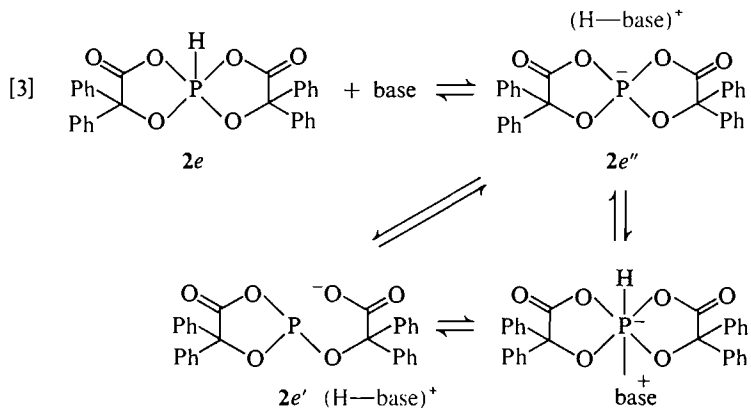

SCHÉMA 3

Des phénomènes analogues ont été observés avec le phosphorane dimère **2***f* (11).

Tout récemment, Schombourg *et al* (12) ont étudié l'action de la triéthylamine sur un phosphorane à liaison P—H homologue et ont déterminé la structure du phosphoranure correspondant par diffraction des rayons X. Le phosphoranure a été enfin stabilisé dans le cas du phosphorane bicylique **3**, (schéma 4) (13).

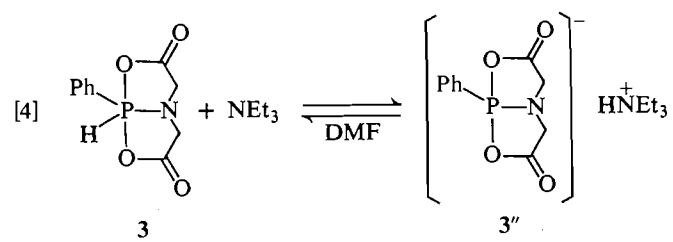

SCHÉMA 4

Nous avons montré que l'équilibre [4] était fortement déplacé vers le phosphoranure, dès la température ordinaire (13).

Remarquons que si les phosphoranures formés par déprotonation de phosphoranes à liaison P—H ont été identifiés seulement dans quelques cas, des phosphoranures halogénés ont été décrits, la structure cristalline de certains d'entre eux ayant même été déterminée (13). Cependant, à l'inverse des précédents, c'est l'acide conjugué, le phosphorane, qui n'est pas connu (14). Ces phosphoranures s'obtiennent, en effet, par addition d'un ion halogénure (ou cyanogène) sur l'atome de phosphore électrophile d'un trihalogénure (ou pseudo-halogénure) de phosphore (14). Signalons, en plus, l'existence de complexes métalliques où l'ion phosphoranure joue le rôle de ligand (15). Ces composés peuvent être considérés, également, comme des phosphoranes à liaison phosphore–métal.

La réactivité des composés **1**, **2** et **3** vis-à-vis de bases moyennes, comme la triéthylamine, ou même faibles, comme la pyridine, laisse présager, pour ces composés, d'une acidité de Brønsted relativement forte que nous avons entrepris de mesurer. Pour celà, nous avons titré les composés **1***d*, **2***b*–**2***f* et **3**, par la triéthylamine dans des solvants aprotiques polaires (DMF, DMSO), les phosphoranes réagissant avec les solvants protiques (eau, alcools). Le titrage a été suivi par potentiométrie. Afin de bien connaitre les entités qui participent aux

équilibres acido-basiques, nous avons étudié par rmn de ^{31}P, à différentes températures, les mélanges de ces phosphoranes avec la même base et, dans quelques cas particuliers avec le diazabicycloundécane (DBU) ou la pyridine.

Nous avons étudié également les composés **4** et **5**. Le premier, de structure comparable à celle de **3**, en diffère par le remplacement d'un groupement carbonyle par un reste méthylène, alors que le second est isologue du phosphorane **1*d***, le reste α hydroxyacide étant remplacé par le reste α aminoacide.

II. Action de la triéthylamine sur les phosphoranes *1*d–*5*

1. *Etude par résonance magnétique nucléaire de ^{31}P*

Nous avons étudié systématiquement, par rmn de ^{31}P à température variable, l'action de la triéthylamine sur les phosphoranes **1*d*–5**, généralement en solution dans le DMF. D'après ce qui précède, nous pouvons nous attendre à la déprotonation du phosphorane, avec formation de phosphoranure (schèma 4), de phosphite isomère salifié (schéma 1), d'un équilibre entre ces deux dérivés (schéma 3), ou efin à l'addition de la base sur le phosphorane pour donner un composé à phosphore hexacoordonné (schéma 3).

A la température ambiante, pour une quantité de triéthylamine inférieure ou égale à la quantité stoechiométrique, on observe la disparition de tout signal dans le spectre de rmn ^{31}P, des composés **1*d***, **2*b***, **2*c***, **2*e***, **2*f*** et **3**. Dans le cas du phosphorane **2*d***, le doublet P—H est remplacé par un singulet large dont le $\delta^{31}P$ varie avec la quantité de base: −14 (pour 1/2 équivalent), +51 (pour 1 équivalent). Quant aux phosphoranes **4** et **5** le doublet P—H reste inaltéré quelle que soit la quantité d'amine ajoutée.

Aux basses températures, des signaux apparaissent. D'une manière générale, pour des proportions de bases inférieures à la stoechiométrie, on observe la réapparition du doublet du phosphorane, accompagné de signaux à champ faible (tableau 1(a)). Ce doublet disparaît définitivement dès que la quantité d'amine atteint ou dépasse un équivalent (tableau 1(b)).

Ce phénomène montre que la base arrache le proton de l'atome de phosphore. L'absence de doublets P—H situés dans le domaine de résonance des composés à phosphore hexacoordonné permet d'exclure une réaction d'addition entre le phosphorane et la triéthylamine. Il s'agit bien d'un équilibre acido-basique: au fur et à mesure de son addition, la triéthylamine déprotone le phosphorane, l'évolution du spectre de rmn ^{31}P à basse température montrant la disparition progressive de l'acide à liaison P—H et l'apparition concomitante des signaux des formes déprotonées. Le fait qu'aucun signal ne soit observable à la température ambiante, indique que la vitesse d'échange du proton entre les espèces déprontonées, la triéthylamine et le phosphorane (pour des quantités de base inférieures à la stoechiométrie 1 : 1), est du même ordre de grandeur que l'échelle de temps de la rmn, qui, en conséquence ne distingue aucun signal. Remarquons que les signaux des formes déprotonées apparaissent nettement, à la température ambiante, avec une base plus forte comme le DBU (diazabicycloundecane). Par exemple, l'addition d'un équivalent de DBU à une solution de **2*d***, dans CH_2Cl_2, provoque la disparition du doublet P—H et l'apparition d'un singulet fin et intense à δ = +88,7. Le même résultat ne peut être atteint, avec la triéthylamine, qu'aux basses températures.

Les signaux des bases conjuguées sont situés, d'une manière générale, à champ faible. Ils se déplacent légèrement à champ fort quand on diminue encore la température. De ce fait, ils ne correspondent pas aux anions phosphoranure qui doivent résonner à champ fort: on sait, effectivement que ces composés présentent en rmn de ^{31}P un singulet dans le domaine des phosphoranes correspondants (**5*b***, **5*c***, 13).

D'autre part, si le singulet observé à la place du doublet P—H peut être attribué avec certitude au phosphite isomère dans le cas du composé **1*d*** (6), il n'en est pas de même pour les composés **2*b*–2*f***. En effet pour ces derniers, la forme phosphite **2′** a été mise en évidence, en ce qui concerne le terme non substitué **2*a***, à partir de 40°C (schéma 5).

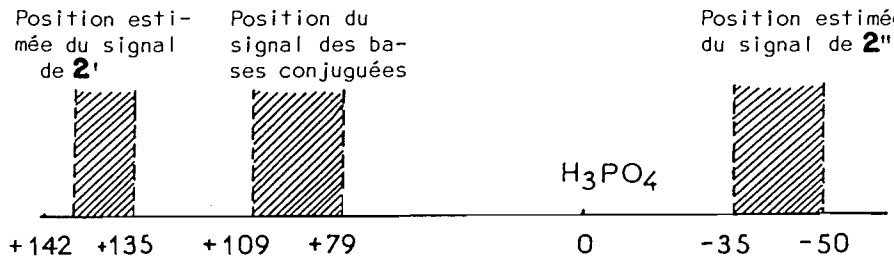

FIG. 1. Position des signaux des bases conjuguées des phosphoranes **2***b*–**2***f*.

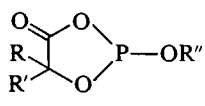
du signal, comme on peut le constater sur la série des phosphites isologues **6**.



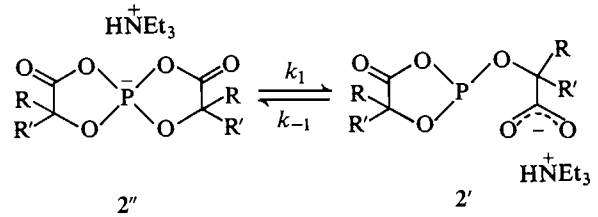
6

	$\delta^{31}P$
R = R′ = H, R″ = Pr	+135
R = Ph, R′ = H, R″ = iPr	+140, +137
R = R′ = CH_3, R″ = iPr	+137
R = R′ = CH_3, R″ = Ph	+127 (réf. 15)
R = R′ = Ph, R″ = Ph	+127 (réf. 15)

Cette valeur est très éloignée des $\delta^{31}P$ des produits de déprotonation des composés **2***b*–**2***f* (tableaux 1 et fig. 1). En fait, les pics observés sont situés entre le domaine des phosphoranures **2″** et celui des phosphites **2′** (fig. 1).

Nous retrouvons les phénomènes mis en évidence lors de l'action de la triéthylamine sur les phosphoranes **2***e* (10) (schéma 3) et **2***f* (11). Les résultats observés généralisent l'équilibre [3] aux phosphoranes **1***d*, **2***b*, **2***c*, **2***d*, **2***f* et **3**, les composés **1***d* et **3** constituant les cas extrêmes: pour le premier, au regard de la rmn, l'équilibre phosphite **1′***d* ⇌ phosphoranure **1″***d* est entièrement déplacé vers la forme à phosphore tricoordonné. A l'opposé, la déprotonation du phosphorane bicyclique **3** conduit exclusivement au phosphoranure **3″** (13) (schéma 4). Les composés **2***b*–**2***f* se situent entre ces deux limites (schéma 6).

[6]



2″ **2′**

SCHÉMA 6

Les constantes de vitesse k_1 et k_{-1}, même à basse température, sont grandes par rapport à l'échelle de temps de la rmn de ^{31}P, qui, de ce fait, distingue seulement un signal composite pour les deux espèces **2′** et **2″**. Pour appuyer l'existence de cet équilibre, les signaux se déplacent vers les champs forts aux basses températures à l'exception du composé **2***d* (voir ci-après) (tableaux 1). En outre, ils sont d'autant plus blindés (donc l'équilibre est d'autant plus favorable au phosphoranure **2″**) que les restes α hydroxyacide sont substitués (tableaux 1). On retrouve l'influence de la température et des substituants sur les équilibres chaîne ⇌ cycle (16).

Cas particuliers

Les phosphoranes **2***b*, et surtout **2***d*, posent un problème supplémentaire, par rapport à leurs homologues **2***c*–**2***e*, **2***f*. Les spectres de leurs mélanges avec la triéthylamine et notamment pour des quantités de base inférieures à un équivalent, présentent un singulet fin situé dans le domaine des composés du phosphore hexacoordonné (tableaux 1). Il ne correspond ni à un composé d'addition (**2***b*, Et_3N), (**2***d*, Et_3N), pour lequel on attend un doublet P—H à champ fort, ni à un dérivé du phosphore hexacoordonné formé à partir de 3 ligands bidentés α hydroxyacide, dont le signal est plus blindé (travail en cours). Son $\delta^{31}P$ varie légèrement avec la température: −88 à +30°C, −92 à −80°C, pour **2***b*, −93,4 à +30°C et −96,5 à −80°C pour **2***d*. Dans le cas de **2***d*, il est possible d'orienter la réaction de déprotonation vers la présence exclusive dans le spectre du pic à δ −95, en remplaçant la triéthylamine par un équivalent de HNa. Lorsque la quantité d'hydrure est supérieure, le spectre présente le singulet à δ +88 et non plus le pic à champ fort. Dans les deux cas, l'addition d'un excès d'iodure de méthyle conduit au phosphorane à liaison P—CH_3 correspondant, la réaction étant nettement plus lente dans le premier cas. Cependant, ces résultats montrent que le phosphoranure se forme avec les deux stoechiométries adoptées (10).

Nous étant assuré de la reproductibilité des résultats, des travaux sont en cours pour essayer d'attribuer le signal à champ fort.

Le spectre des mélanges (phosphorane **2***b* + Et_3N) et (phosphorane **2***c* + Et_3N) présente deux signaux attribuables à l'existence possible de 3 diastéréoisomères, aussi bien pour les phosphites que pour les phosphoranures. Ces derniers offrent, en effet, les mêmes possibilités d'isomérie que les phosphoranes correspondants (8). (*i*) Le composé **2***a*, non substitué sur le reste α hydroxyacide, réagit sur la triéthylamine pour conduire à des mélanges complexes de composés à phosphore tétracoordonné. Ses bases conjuguées **2′***a* et **2″***a*, instables, n'ont pu être identifiées. (*ii*) Les phosphoranes **4** et **5** ne réagissent pas sur la triéthylamine. Ce résultat négatif met bien en évidence la finesse des phénomènes étudiés: le simple remplacement d'un groupement carbonyle dans le squelette du phosphorane **3** ou d'un atome d'oxygène par un groupement NH, dans celui de **1***d*, abaisse l'acidité du proton P—H au point, de le rendre inerte vis-à-vis de bases moyennes. Les composés **4** et **5** sont, toutefois déprontonés par les bases fortes, comme les hydrures alcalins.

Proportions des formes phosphite et phosphoranure en équilibre

L'existence d'un seul pic composite pour les deux espèces **2′** et **2″** ne nous permet pas de connaître directement les taux respectifs de ces entités. Nous pouvons, cependant, les estimer à partir de leur $\delta^{31}P$. Pour la première, ce paramètre est compris entre +135 et +142, alors que pour la seconde, il convient de prendre en compte un $\delta^{31}P$ proche de celui du phosphorane correspondant (5*b*, 13) ($-50 < \delta^{31}P < -35$).

Dans le cas des composés **2***b*–**2***f*, on trouve, même à basse température, des pourcentages de phosphoranure **2″** nettement plus faibles que ceux du phosphite **2′** (tableau 2). Rappelons

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

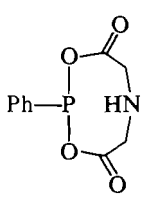
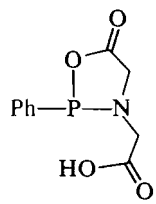
que pour le phosphorane **3** le spectre de rmn ^1H montre que l'équilibre est déplacé vers le phosphoranure (13).

En conclusion, l'action de la triéthylamine sur les phosphoranes **1***d*, **2***b*–**2***f* et **3** se traduit par la salification de la forme tricooordonnée en équilibre avec le phosphoranure, cet équilibre étant entièrement déplacé vers la première (composé **1***d*) ou vers la seconde (composé **3**) ou nettement favorable à la première (composés **2***b*–**2***f*). Ces résultats montrent que les phosphites **1′** et **2′** sont des acides de Brønsted plus forts que les phosphoranes **1** et **2**. Cependant, dans le cas des composés **2**, la présence dans les mélanges phosphorane + Et_3N, des deux bases conjuguées montre que la différence d'acidité entre le phosphorane et le phosphite isomères, n'est pas très importante.

Le phosphorane bicyclique **3** serait plus acide que la forme à phosphore tricoordonné tautomère. Nous pouvons envisager, pour ces dernières les composés **3′***a* et **3′***b*.



3′*a*



3′*b*

La première permet d'expliquer facilement pourquoi le phosphorane **3** serait plus acide, la fonction NH étant basique.

L'existence de la seconde signifierait que le composé **3** est plus acide que la fonction carboxylique de **3′***b*, ce qui est en contradiction avec les résultats observés pour le composé **1***d*.

Précisons que la seule forme à phosphore tricoordonné, tautomère de phosphoranes bicycliques analogues à **3**, mise en évidence par complexation avec des métaux de transition, a la structure **3′***a* et non **3′***b* (17).

2. *Etude potentiométrique: acidité de Brønsted des phosphoranes* **1**d, **2**b–**2**f *et* **3**

Les composés étudiés étant peu stables dans les solvants protiques, nous les avons titrés par la triéthylamine en solution dans le DMF. Le DMSO qui les oxyde en esters phosphoriques (composé **1***d*) ou en hydroxyphosphoranes (composés **2***b*–**2***f*) (18) n'a été utilisé que pour le phosphorane **3**, moins réactif dans ce solvant que les autres phosphoranes. La réaction de neutralisation a été suivie par potentiométrie. L'échelle électrique, en millivolts, a été étalonnée en unités de pH par titrage de deux acides étalons: les acides picrique et dichloroacétique (19).

D'après ce qui précède, la triéthylamine neutralise le phosphorane **3**. La valeur de pK_a tirée de la courbe de titrage correspondra effectivement à ce composé. En revanche, la même base sera protonée par la fonction acide carboxylique du phosphite **1′***d* plutôt que par le phosphorane **1***d*. Le pK_a sera attribué au premier et non au second. Enfin ce paramètre caractérisera l'acidité des phosphoranes **2** et de leur forme tricoordonnée tautomère **2′**, les bases conjuguées correspondantes étant en équilibre à la neutralisation. Nous aurons affaire à une valeur apparente.

Les courbes de neutralisation des phosphoranes **2** correspondent à des acides moyen-faibles, avec un point d'inflexion bien marqué, alors que les courbes des composés **1***d* et **3**, plus faibles, ne présentent pas de point d'inflexion. Pour les premiers, nous avons tiré les valeurs de pK_a par lecture de pH à demi-neutralisation, alors que pour les seconds nous avons adopté la valeur du pH à la demi-neutralisation théorique. L'indétermination est de 0,3 à 0,6 unités de pK_a (tableau 3).

Les pK_a ainsi déterminés, tout en étant élevés, correspondent à une acidité nettement plus forte que celle des autres composés organophosphorés à liaison P—H (tableau 4). Ils sont même inférieurs aux pK_a des acides carboxyliques, dans le même solvant (pK_a de l'acide benzoïque en solution dans le DMF: 12,3; dans le DMSO: 11) (20).

Il existe une différence remarquable entre les valeurs des composés **2**, d'une part, et de **1***d* et **3**, de l'autre. L'équilibre entre les deux acides, phosphorane **2** et phosphite **2′**, a pour résultat d'exalter considérablement l'acidité par rapport aux systèmes où l'acide neutralisé est univoque (phosphite **1′***d*, pour **1***d* et phosphorane **3**, pour **3**).

La labilité anormale du proton P—H, dans tous ces composés, s'explique par le caractère électrophile de l'atome de phosphore dont la densité électronique se trouve amoindrie par l'effet de conjugaison des groupements carbonyle intracycliques (19). Un seul groupement C=O n'est pas suffisant pour que ce phénomène soit sensible: ainsi, le composé **4** ne

réagit plus sur la triéthylamine. Par ailleurs, le remplacement du cycle oxo-4 dioxaphospholane-1,3,2 par un cycle oxo-4 oxazaphospholane (composé **5**) suffit également à anhiler la réactivité vis-à-vis de cette base.

III. Conclusion

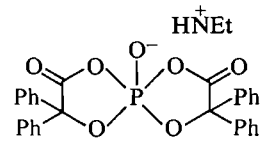
Notre travail se démarque, à notre sens, de l'ensemble important de résultats observés dans le domaine des phosphoranes préparés à partir de molécules α hydroxylées ou α hydroxyaminées (α diols, α hydroxyacides, éthanolamines, ortho-aminophénols, α aminoacides . . .). Pour la première fois leur base conjuguée phosphoranure a été identifiée et des sels correspondants isolés. Grâce à un effet de délocalisation dans les hétérocycles formés à partir de restes α hydroxyacide ou acide iminodiacétique, l'acidité du phosphorane a été suffisamment exaltée pour que le pK_a soit déterminé par titration directe.

Les valeurs de pK_a ainsi déterminées, correspondent à des acides beaucoup plus dissociés que les composés organophosphorés à liaison P—H connus. Ils sont même plus forts, dans le DMF que les acides carboxyliques, comme l'acide benzoïque. Ces résultats éclairent d'un jour nouveau la réactivité des phosphoranes et notamment leurs propriétés nucléophiles. L'existence fréquente de l'équilibre phosphorane, phosphite (ou amidophosphite) a masqué pendant longtemps celle de l'équilibre phosphorane, phosphoranure. Aussi les auteurs ont-ils inteprété de façon systématique, les réactions des phosphoranes sur les électrophiles, par l'intervention exclusive de la forme à phosphore tricoordiné comme entité réactive. Nos résultats observés sur des phosphoranes ne présentant pas, d'après la rmn, l'équilibre phosphorane, phosphite, montrent que, pour ces composés, il convient de prendre en compte le phosphoranure. Désormais, toute approche rigoureuse de la connaissance du mécanisme des réactions entre les phosphoranes et les électrophiles devra envisager, *à priori*, les formes phosphite et phosphoranure, en tant qu'entités réactives. L'élimination de l'une des deux ne pourra être décidée qu'à l'issue d'observations d'ordre cinétique.

Partie expérimentale

Les analyses élementaires ont été effectuées par le service Central d'Analyse du CNRS (BP 22 69390 Vernaison).

Dans les dosages du carbone, lorsque cet élément est particulièrement abondant (50–70%) nous avons quelquefois observé des erreurs absolues dépassant le 1% par défaut. Ce fait est fréquent dans les composés organophosphorés. Ainsi, nous avons observé des erreurs absolues comprises entre 1,7 et 2 (relevées pour plusieurs échantillons provenant de préparations différentes) pour le phosphorane ci-après, dont la structure cristalline a été déterminée par diffraction des rayons-X (18, 19).



Nous avons également remarqué des écarts de cet ordre pour des composés à phosphore hexacoordonné dont la pureté a été démontrée, soit par diffraction des rayons X (20) soit par une bonne rmn (21).

Les spectres de rmn ^{31}P ont été enregistrés sur un appareil Perkin–Elmer R32 à transformée de Fourier (36,433 MHz). Les déplacements chimiques ont été comptés négativement à champ fort par rapport au signal de l'acide phosphorique pris comme référence. Les spectres de rmn ^1H ont été enregistrés sur un appareil Varian T 60 (60 MHz).

I. *Action des bases sur les phosphoranes* ***1***, ***2***, ***3*** *et* ***5***

Les mélanges (phosphorane + base) étudiés par rmn de ^{31}P à température variable, ont été préparés par pesée sous atmosphère d'argon. Sans cette précaution, on observe la formation de composés parasites à phosphore tétracoordiné. Les spectres ont été enregistrés sur un spectrographe Perkin–Elmer R32 à transformée de Fourier (26,433 MHz).

Préparation des phosphites ***6***

Ces composés ont été synthétisés en faisant réagir les chlorures d'acide: PrO—PCl_2 (composé **6***a*), iPrO—PCl_2 (composés **6***b*, **6***c*) ou PhO—PCl_2 (composés **6***d* et **6***e*), mole à mole avec les α hydroxyacides correspondants, en présence de deux équivalents de triéthylamine, suivant le mode opératoire décrit dans un travail antérieur (22). Les phosphites **6***a*, **6***b* et **6***c*, moins stables que leurs homologues **6***d* et **6***e*, déjà décrits (15), ont été isolés sous forme de liquides, accompagnés de faibles quantités (environ 10%) du spirophosphorane correspondant **2**. Leur $\delta^{31}P$ (voir la partie théorique) est caractéristique des composés de cette famille.

Isolement des phosphoranures de triéthylammonium

Le phosphoranure de triéthylammonium correspondant au dimère

2*f*, préparé à partir de l'acide tartrique, a été déjà décrit (11).

*Sel du phosphoranure 2″*e

A 4,54 g de phosphorane **2***e* (0,01 mol) dissous dans 5 mL de DMF, on ajoute 4,04 g de triéthylamine (0,0025 mol). Il se produit un échauffement léger. On ajoute 20 mL d'éther: un précipité blanc se forme qui est décanté, lavé plusieurs fois à l'éther: un précipité blanc se forme qui est décanté, lavé plusieurs fois à l'éther, en atmosphère d'argon rigoureusement anhydre, puis séché; Rdt: supérieur à 90%; rmn ^1H ($CDCl_3$, TMS, 60 MHz): 10,48 (1H, s, *H*NEt_3), 7,33 (20H, m, C_6H_5), 2,76 (6H, q, $J_{H-C-C-H}$ = 7 Hz, N—CH_2), 1,06 (9H, t, $J_{H-C-C-H}$ = 7 Hz, N—CH_2—CH_3). *Anal.* calc. pour $C_{34}H_{36}NO_6P$: C 69,80, H 6,20, N 2,39, P 5,30; tr.: C 68,32, H 6,15, N 2,50, P 5,31%.

Sel du phosphoranure 3″: préparation du phosphorane 3

On disperse 2,6 g d'acide iminodiacétique (0,005 mol) dans 30 mL de DMF; 3,6 g de phényldichlorophosphine (0,005 mol) sont ajoutés en refroidissant dans un mélange alcool–Carboglace. Il se produit un échauffement. L'acide se dissout progressivement. On laisse pendant une demi-heure. Spectre rmn de $\delta^{31}P$ δ: −48, J_{P-H} = 780 Hz. On reprend par 20 à 30 mL d'eau froide: il se forme un précipité pâteux qui est lavé à l'eau (30 mL), filtré puis lavé à l'éther et séché. Une poudre blanche est finalement obtenue. Elle est dissoute dans CH_2Cl_2. Un peu d'insoluble est éliminé par filtration. Le filtrat, repris par l'éther laisse déposer une précipité blanc qui est filtré, lavé à l'éther et séché; Rdt: 80%. Soluble dans CH_2Cl_2, THF, CH_3CN et DMF; rmn de ^{31}P (CH_2Cl_2) δ: −51,4, J_{P-H} = 780 Hz; rmn ^1H ($CDCl_3$, TMS, 60 MHz): 7,5 (1H, d, J_{H-P} = 766 Hz, P—*H*), 7,1 (5H, m, C_6H_5), 3,22 (4H, m, CH_2). *Anal.* calc. pour $C_{10}H_{10}NO_4P$: C 50,20, H 4,18, N 5,85, P 12,97; tr.: C 49,59, H 4,21, N 5,83, P 12,97%.

Action de la triéthylamine: isolement du sel du phosphoranure 3″

On dissout 2,4 g de phosphorane **3** (0,01 mol) dans 20 mL de DMF; 2,02 g de triéthylamine (0,005 mol) sont ajoutés. La solution est reprise par 30 mL d'éther: un précipité se forme qui est décanté, lavé à l'éther et séché; Rdt: supérieur à 90%; rmn ^1H (DMSO-d_6, TMS, 60 MHz): 11,5 (1H, s, *H*NEt_3), 7,5 (5H, m, C_6H_5), 3,8 (4H, m, CH_2), 2,9 (6H, q, $J_{H-C-C-H}$ = 7 Hz, N—CH_2), 1,1 (9H, t, $J_{H-C-C-H}$ = 7 Hz, N—CH_2—CH_3).

Phosphorane 4

Ce composé a été préparé en faisant réagir la phényldichlorophosphine sur l'hydroxyaminoacide ci-après, en présence de triéthylamine, en solution dans le THF (travail en cours).

HO—CO—$C(CH_3)_2$—NH—CH_2—$C(CH_3)_2$—OH

II. *Mésures potentiométriques*

Les solvants, DMF et DMSO Aldrich, ont été distillés sous 12 Torr et conservés sur tamis moléculaires 4 Å pendant 2 jours avant d'être utilisés. Le point de fusion du DMSO ainsi obtenu est de 18°, 515°C: l'acide picrique a été recristallisé dans le benzène et utilisé dans le semaine suivant la recristallisation. La triéthylamine a été distillée sous la pession atmosphérique et conservée sur de la soude en paillettes.

Les titrages ont été effectués dans le laboratoire de Génie chimique associé au CNRS N° 192, sous la responsabilité du Professeur Comtat. Nous avons utilisé un titreur automatique Metrohm E536 muni d'électrodes de marque Tacussel. L'électrode de référence est au calomel dans le cas du DMF et au chlorure d'argent dans celui du DMSO. Les concentrations des solutions, préparées par pesée au 0,01 mg, sont voisines de 10^{-2} *M*. Les dosages ont été effectués sur 2 à 4 mL de solution. Les volumes de solution de triéthylamine utilisés pour les neutralisations diffèrent de 1 à 10% des volumes théoriques. L'erreur commise est liée au temps d'introduction du volume de titrant; elle est maximale pour les vitesses d'introduction rapides (5 et 10 min), ce qui indique une réponse lente de l'électrode de verre à la modification du pH de la solution. Pour des temps d'introduction de l'ordre de 2 h, on observe un décalage des courbes de neutralisation vers les pH faibles, vraisemblablement dû à l'absorption de la vapeur d'eau par le solvant. Ces observations nous ont conduit à choisir un temps d'introduction intermédiaire (30 min pour 3.5 cm^3 de triéthylamine) et à effectuer les prises d'essai et les titrages dans des récipients conservés en atmosphère d'argon. La forte densité de ce gaz par rapport à l'air protège le récipient de mesure de l'humidité ambiante pour des temps inférieurs à 40 min. Les valeurs en millivolts, lues sur l'appareil, varient avec la température et également dans le temps. Nous avons renoncé à thermostater les solutions, cette opération ayant pour résultat de prolonger la durée du titrage au-delà des conditions précédentes de sécurité vis-à-vis de l'humidité. Nous avons adopté deux stratégies: (*i*) etablissement d'une échelle moyenne basée sur plusieurs titrages des acides picrique et dichloroacétique, effectués dans une période ne dépassant pas 5 jours, pendant laquelle la température ambiante est restée située aux alentours de +23°C. (*ii*) Utilisation d'une échelle "du jour" établie sur des titrages des acides étalon effectués le même jour que ceux des phosphoranes. Nous avons considéré que les variations de pK_a dues à des différences de température étaient négligeables

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

devant la précision des titrages (0,3 unités de pK_a pour les phosphoranes **2** et 0,5 unités pour **3** et **1***d*).

Le tableau 5 rassemble l'ensemble des résultats observés.

Remerciement

Propriétés nucléophiles des phosphoranures[1]

B. GARRIGUES ET A. MUNOZ
E.R.A. N° 926, Université Paul Sabatier, 118 route de Narbonne, 31062 Toulouse Cédex, France

Reçu le 19 octobre 1983

B. GARRIGUES et A MUNOZ. Can. J. Chem. **62**, 2179 (1984).

Les phosphoranures formés par action des bases sur des phosphoranes à liaison P—H contenant les ligands α hydroxyacide, α aminoacide ou acide iminodiacétique, réagissent avec des électrophiles comme les halogénures d'alcoyle, l'azoture de phényle, le disulfure de carbone, les orthoquinones ou les cétoacides. Ces réactions ont permis de préparer des phosphoranes et des composés à phosphore hexacoordonné nouveaux.

B. GARRIGUES and A MUNOZ. Can. J. Chem. **62**, 2179 (1984).

The reaction of various bases with P—H bond-containing phosphoranes bearing α-hydroxy acid, α-aminoacid, or iminodiacetic acid ligands leads to the formation of phosphoronates which react with electrophiles such as alkyl halides, phenyl azide, carbon disulfide, orthoquinones, or keto-acids. New phosphoranes and hexacoordinated phosphorus compounds could thus be prepared.

I. Introduction

Dans un travail précédent (1), nous avons identifié par rmn, la base conjuguée des phosphoranes **1**, **2** et **3**, en traitant ces composés par la triéthylamine. Leur déprotonation conduit au phosphite **1′** seul dans le cas des premiers, à un équilibre entre le phosphoranure **2″** et le phosphite **2′** dans celui des seconds et au phosphoranure **3″** seul en ce qui concerne le troisième. Quant au phosphorane **4**, il ne réagit pas avec la triéthylamine.

Il est important de souligner que les composés **1**–**4** ne présentent pas, en solution, et au regard de la rmn, l'équilibre tautomère phosphite ⇌ phosphorane à l'exception des premiers termes non substitués **1***a* et **2***a* (R = R′ = H) (1, 2). Ces résultats nous inclinent à prendre en considération, pour les composés **2** et **3**, le phosphoranure **2″** et **3″** comme entité réactive vis-à-vis des électrophiles, plutôt que les formes phosphites tautomères. Ce choix parait d'autant plus justifié que les phosphites contenant le motif dioxaphospholane sont peu nucléophiles et manifestent même des propriétés d'électrophiles (3). Nous montrerons, d'ailleurs, sur quelques exemples de réactions entre des phosphoranes et des électrophiles que l'espèce réactive est bien le phosphoranure et non les phosphite.

Déjà en 1975, P. Savignac *et al.* (4) ont postulé l'intervention du phosphoranure et non du phosphite lors de la réaction d'iodures d'alcoyle sur un spirophosphorane, traité au préalable par des bases fortes.

Nous avons entrepris une étude systématique de la réactivité des phosphoranures, bases conjuguées des phosphoranes **2** et **3**, vis-à-vis d'électrophiles variés: halogénures d'alcoyle, azoture de phényle, disulfure de carbone, orthoquinones et cétoacides. Les phosphoranures ont été formés en traitant par la tri-

SCHÉMA 1

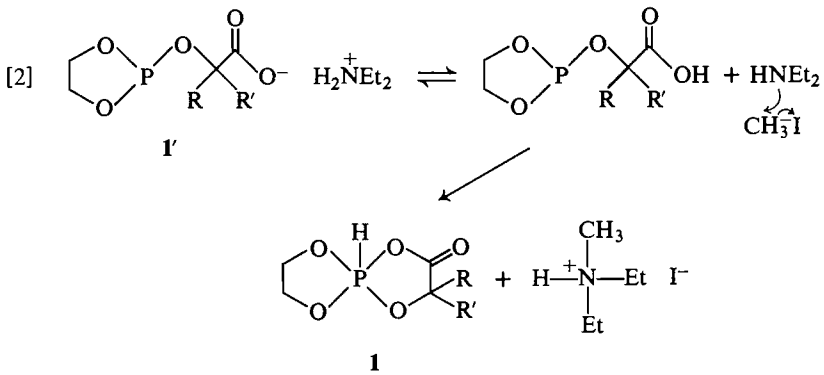

SCHÉMA 2

éthylamine les phosphoranes. Nous avons mené des essais parallèles en metant en contact ces derniers avec les électrophiles, en l'absence de base. Nous avons également étudié l'action de l'iodure de méthyle en présence de bases, sur les spirophosphoranes **1** et **4**, dont les phosphoranures n'on pas été identifiés (1).

II. Résultats et discussion

1. *Action des phosphoranures sur les halogénures d'alcoyle*

(a) *Réaction du phosphorane 4 avec l'iodure de méthyle en présence d'hydrure de sodium*

Nous avons opéré de trois façons différentes: (*i*) addition simultanée, à une solution de phosphorane **4** dans le DMF, de l'iodure de méthyle et de l'hydrure de sodium. Le spectre de rmn de ^{31}P montre la disparition du doublet P—H du composé **4** et l'apparition d'un quadruplet correspondant à un phosphorane à liaison P—CH_3. (*ii*) Addition de l'iodure de méthyle seul au spirophosphorane **4**: aucune réaction n'est observée au bout de 24 h. En ajoutant alors l'hydrure, on obtient quantitativement le même phosphorane à liaison P—CH_3. (*iii*) Si on inverse l'ordre d'introduction des réactifs, le résultat est différent: l'action de HNa sur le composé **4** conduit à l'amidosphosphite **4′** qui a été isolé (Schéma 1). Un résultat comparable a déjà été décrit pour un phosphorane contenant deux restes pinacol (4). Le composé **4′** réagit avec l'iodure de méthyle en donnant un mélange complexe de composés du phosphore tétracoordonné.

Le phosphorane à liaison P—CH_3 **5** a été isolé complexé à 0,4 molécules d'iodure de sodium. Ce dernier a été éliminé par passage sur de l'alumine activée (voir partie expérimentale).

Les résultats précédents excluent l'amidophosphite **4′** comme entité réactive dans la formation du phosphorane **5**. En fait, le produit cinétique de la réaction de HNa sur le phosphorane **4** doit être le phosphoranure **4″**, qui, en présence d'iodure de méthyle, conduit au composé **5**. En l'absence de ce réactif, il se transforme en amidophosphite **4′** qui est l'entité thermodynamiquement stable (Schéma 1).

(b) *Action des phosphoranes 1–3 sur les halogénures d'alcoyle en présence de triéthylamine*

La réaction de l'iodure de méthyle sur le sel de diéthylammonium des phosphites **1′** régénère les phosphoranes **1**. Le même résultat est observé quand on ajoute un excès d'iodure au mélange **1***d* (R = CH_3) + Et_3N ou **1***e* (R = C_6H_5) + Et_3N. Ces réactions confirment le faible caractère nucléophile de l'atome de phosphore des phosphites **1′**, possédant le motif dioxaphospholane, préalablement souligné par Hudson et Brown (3). En fait, c'est l'atome d'azote de la base, en équilibre avec son cation ammonium, qui attaque le groupement méthyle (schéma 2).

SCHÉMA 3

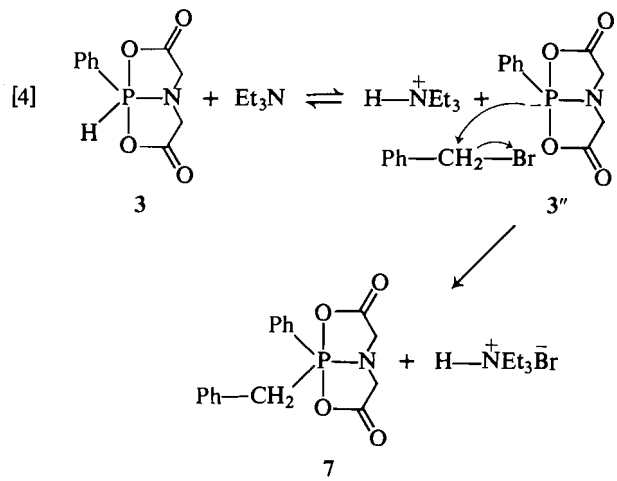

SCHÉMA 4

L'action d'un excès d'iodure de méthyle sur les mélanges phosphoranes **2** + base (Et_3N, DBU, HNa) ne régénère pas, comme précédemment, le phosphorane **2**. Dans tous les cas essayés, nous avons observé la formation du phosphorane à liaison P—CH_3 **6** que nous avons isolé en partant du phosphorane **2***e* (R = R′ = C_6H_5). Ce résultat montre encore que l'entité réactive est l'ion phosphoranure **2″** et non le phosphite **2′** (schéma 3).

Le phosphoranure **3″** est moins réactif que ses homologues **2″**: la formation du phosphorane à liaison P—CH_3 n'est pas observée, comme dans le cas des composés **2**, immédiatement après l'addition de CH_3—I. Cependant, en remplaçant ce dernier par le bromure de benzyle, nous avons préparé, avec un bond rendement, le phosphorane **7** (schéma 4).

2. *Action des phosphoranures sur l'azoture de phényle*

On sait que les phosphoranes réagissent sur les azotures organiques pour conduire, après élimination d'azote, à des aminophosphoranes. Cette réaction est facile quand le phosphorane est en équilibre avec sa forme à phosphore tricoordonné tautomère (5). Dans le cas où cette dernière n'est pas décelable à la température ambiante, la réaction n'a lieu qu'à température élevée (5).

Les phosphoranes **2***d* ou **3** ne réagissent pas sur l'azoture de phényle, à la température ambiante. En revanche, avec leurs phosphoranures de triéthylammonium, il se produit un dégagement immédiat d'azote. Le spectre de rmn de ^{31}P du mélange réactionnel montre que les phosphoranes **2***d* et **3** ont été transformés quantitativement en composés du phosphore pentacoordonné dépourvus de liaison P—H, **8** et **9**, que nous avons isolés (schéma 5).

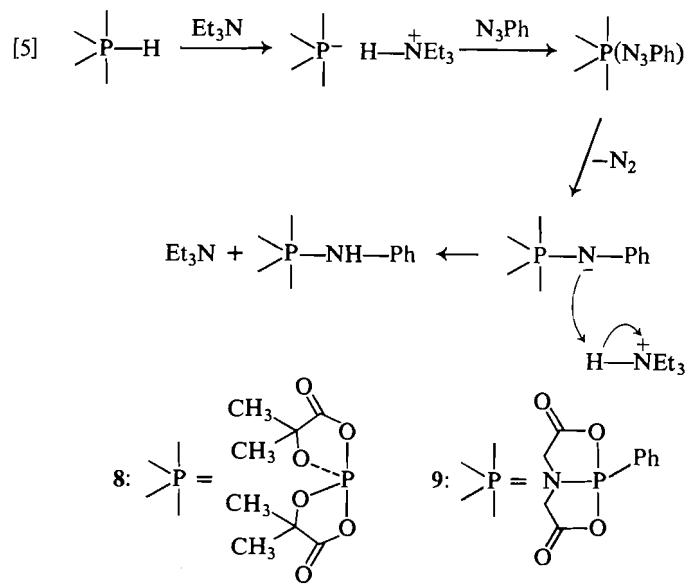

SCHÉMA 5

Nous pouvons proposer l'attaque du site déficient en électrons de l'azoture par le phosphoranure, suivie de la décomposition du produit intermédiaire, avec élimination d'azote, et de la formation d'un anion amidure, lequel, protoné donne finalement l'aminophosphorane **8** ou **9** (schéma 5).

3. *Action des phosphoranures sur le disulfure de carbone*

Le disulfure de carbone réagit avec de nombreux composés à phosphore tricoordonné pour donner, soit des composés d'addition (6), soit d'insertion, lorsque les substrats phosphorés contiennent des liaisons P—N (7). Des réactions d'insertion sont également connues, dans le cas de phosphoranes à liaison P—N. Dans ces derniers composés l'atome de phosphore atteint l'hexacoordination par retour d'un atome de soufre (8). Cependant, aucune réaction d'addition entre un phosphorane et le disulfure de carbone n'a encore été décrite, à notre connaissance.

Les phosphoranures de triéthylammonium **2″***d* (R = R′ = CH_3) et **3″** réagissent immédiatement et à la température ambiante, sur le disulfure de carbone. Nous avons isolé des substances cristallines fortement colorées. Dans le cas du phosphoranure **2″***d* (R = R′ = CH_3) nous en avons déterminé la structure par diffraction de rayons X. Nous avons affaire au sel de triéthylammonium d'un dithiophosphorane **10** (9). Cette structure est confirmée en solution, par les spectres de rmn (^{31}P et ^{1}H). A partir du phosphoranure **3″**, nous avons obtenu le phosphorane homologue **11** (schéma 6).

Comme dans le cas de l'azoture de phényle, aucune réaction n'est observée entre les phosphoranes **2***d*, **3** et le disulfure de carbone. Nous pouvons encore postuler une attaque du site électrophile, en l'occurrence l'atome de carbone du disulfure, par le doublet du phosphoranure (schéma 6).

4. *Action des phosphoranures 2″ sur les composés carbonylés: ditertiobutylorthoquinone et acide benzoylformique*

Les réactions des α dicétones ou orthoquinones et des cé-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

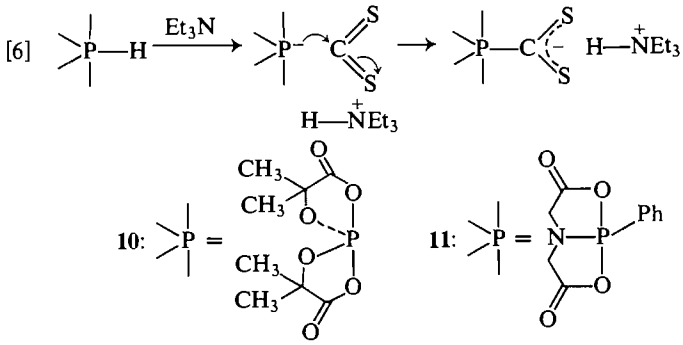

SCHÉMA 6

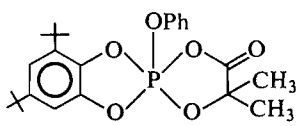
toacides avec les composés du phosphore tricoordonné, ont été abondamment étudiées (10, 11). La formation de phosphoranes qui en découle a été expliquée par des processus ayant comme point de départ l'attaque du doublet de l'atome de phosphore tricoordonné sur l'atome de carbone électrophile d'un groupement carbonylé (10, 11). La forme phosphite tautomère des phosphoranes à liaison P—H, peut également réagir avec les α dicétones pour donner un γ hydroxyphosphorane, capable de se transformer en présence de bases, en composé du phosphore hexacoordonné (12). Cependant, de telles réactions peuvent également se produire même quand l'équilibre phosphite ⇌ phosphorane n'est pas décelable à température relativement élevée. Ainsi le phosphorane **2***d* et la ditertiobutylorthoquinone réagissent, au bout de 12 h pour donner naissance au γ hydroxyphosphorane **12** (schéma 7). Sa structure est bien démontrée par son $\delta^{31}P$ (−44), très proche de celui de composé isologue **14** (13). En milieu basique (DMF, DMSO, solvant neutre + un équivalent de Et_3N), le composé 12 se transforme quantitativement d'après la rmn de ^{31}P, en composé du phosphore hexacoordonné **13**.



14 $\delta^{31}P = -46$ (réf. 13)

Ce dernier peut être obtenu directement et de façon instantanée, en mélangeant le phosphorane et la quinone en présence de triéthylamine.

Ces résultats peuvent s'interpréter par des schémas classiques à partir de la forme à phosphore tricoordonné **2′***d*, aussi bien par voie ionique (mécanisme proposé par Ogata et Yamashita (10)) que par voie radicalaire (Boekenstein *et al.* (14)). Cependant, nous pouvons également proposer un processus inspiré des schémas ioniques d'Ogata, faisant intervenir le phosphoranure (schéma 7), sans oublier toutefois que des entités radicalaires peuvent également jouer un rôle.

L'action des cétoacides sur les spirophosphoranes à liaison P—H, contrairement aux réactions avec les orthoquinones, n'a pas encore été décrite, à notre connaissance. Nous exposons, dans ce travail, des résultats préliminaires observés lors de la réaction entre le phosphorane **2***d* et l'acide benzoylformique.

On sait que les composés à phosphore tricoordonné (phosphites, phosphonites) contenant le motif dioxaphospholane réagissent avec les cétoacides. Le composé principal de la réaction est un spirophosphorane contenant le ligand α hydroxyacide résultant de la réduction de la fonction cétone en fonction alcool (11).

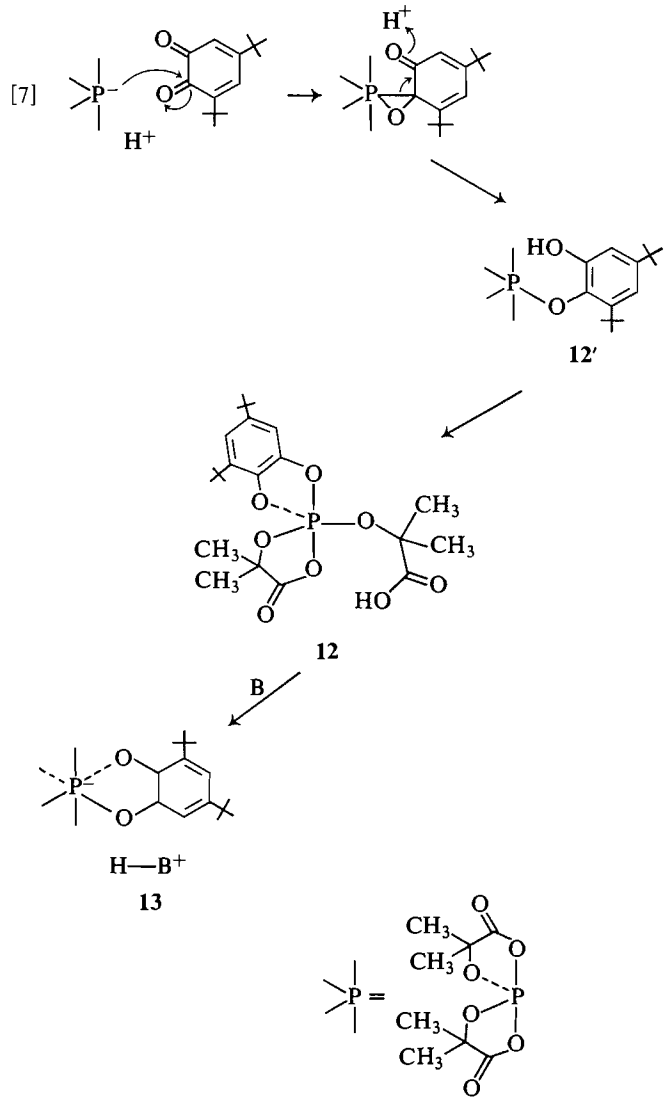


SCHÉMA 7

Les spirophosphoranes **2** ne réagissent pas à la température ambiante et sur une durée de plusieurs heures, sur l'acide benzoylformique. Cependant, en présence de triéthylamine qui entraîne la formation du phosphoranure **2″** on observe une réaction légèrement exothermique. Ainsi, avec le phosphoranure **2″***d*, R = R′ = CH_3, on observe la formation de composés dont le $\delta^{31}P$ correspond à des entités du phosphore hexacoordonné ($-108 < \delta^{31}P < -102$). Stables en solution (le spectre de rmn ^{31}P reste inchangé pendant plusieurs jours), ils se dégradent dès qu'ils sont isolés. Leur spectre de rmn de ^1H présente un multiplet à δ = 5,4 attribuable à des protons CH—C_6H_5.

La présence de ces signaux montre que la fonction cétonique a été réduite en fonction alcool et que le ligand cétoacide a été transformé en reste acide mandélique. Compte tenu de la valeur absolue élevée des $\delta^{31}P$, nous pouvons alors proposer la structure **15** (schéma 8), qui est confirmée par les intensités relatives des différents signaux de rmn ^1H. La multiplicité des signaux de rmn ^{31}P ainsi que celle des pics des protons CH—C_6H_5 et C—CH_3, s'explique par l'existence possible de nombreux diastéréoisomères.

La formation des composés **15** peut encore s'expliquer par l'attaque de l'atome de carbone électrophile de la fonction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

SCHÉMA 8

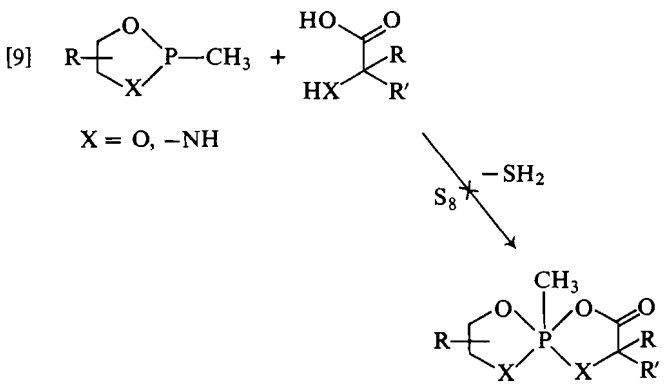

SCHÉMA 9

cétone de l'acide benzoylformique par le phosphoranure, suivie de réactions de réarrangement aboutissant finalement à la création de la fonction ester phosphorique P—O—CH—Ph (schéma 8). On peut remarquer que dans le benzène, la triéthylamine et l'ion benzoylformate ont une basicité comparable. Par conséquent le proton lié au phosphore peut être arraché par l'une ou l'autre des deux bases, d'où le schéma 8.

III. Conclusion

Jusqu'à ce jour, la réactivité des phosphoranes à liaison P—H a été envisagée, d'une façon générale, uniquement à travers l'intervention des formes à phosphore tricoordonné tautomères. Les résultats exposés dans ce travail montrent qu'il convient de prendre également en considération les phosphoranures.

Nous avons démontré que dans les réactions entre les phosphoranes **2**–**4** et les halogénures d'alcoyle, en présence de bases, les phosphoranures correspondants étaient les seules entités phosphorées réactives. Dans tous les autres cas étudiés nous pouvons affirmer que l'intervention exclusive de ces derniers est très probable.

Les réactions ainsi étudiées nous ont permis d'accéder à des phosphoranes originaux difficiles à préparer par des méthodes plus classiques. C'est le cas, notamment des phosphoranes **5** et **6** qui n'ont pas été obtenus à partir des réactions mises au point pour les pyrocatéchols, les diols et les éthanolamines (schéma 9) (15).

De même, les composés à phosphore hexacoordonné **15** n'ont pas été isolés par réaction directe d'α hydroxyacides sur le pentacholorure de phosphore alors que la condensation de pyrocatéchols (12*b*) ou d'acides benzhydroxamiques (16) sur le même substrat conduit assez facilement aux composés à phosphore hexacoordonné correspondants.

Quant aux phosphoranes isolés à partir du disulfure de carbone, ils représentent des exemples intéressants d'activation de ce dernier par les phosphoranures.

Ces résultats laissent entrevoir une utilisation systématique de ces composés comparable à celle des phosphines dont ils se rapprochent par leurs propriétés nucléophiles.

Partie expérimentale

Les analyses élémentaires ont été effectuées dans le service central d'analyse du CNRS (BP 22 69390 Vernaison).

Les spectres de rmn ^{31}P ont été enregistrés sur un appareil Perkin–Elmer R32 à transformée de Fourier (36, 433 MHz). Les déplacements chimiques ont été comptés négativement à champ fort par rapport au signal de l'acide phosphorique pris comme référence.

Les spectres de rmn ^{1}H ont été enregistrés sur un appareil Varian T60 (60 MHz) ou Perkin–Elmer R24 (60 MHz).

I. *Action des phosphoranes 1–4 sur CH_3I et $PhCH_2Br$ en présence de bases*

1. *Action de HNa sur le phosphorane 4: préparation du composé 4'*

La préparation du phosphorane **4** a été décrite (17); 1,93 g de phosphorane **4** (0,01 mol) sont dissous dans 5 mL de DMF; 1,2 g de HNa (0,05 mol) sont ajoutés en une seule fois: un fort dégagement gazeux est observé. Le volume de gaz recueilli, 220 mL, correspond environ à 0,01 mol d'hydrogène. On maintient sous agitation pendant 30 min. L'excès d'hydrure est filtré. Le filtrat présente en rmn de ^{31}P un seul pic à δ +135. Il est repris par 50 mL d'éther: un précipité blanc laiteux se forme que l'on centrifuge, lave à l'éther et sèche sous 10^{-2}

Torr (1 Torr = 133.3 Pa). On obtient une poudre blanche soluble seulement dans le DMSO. *Anal.* calc. pour $C_6H_{11}N\,NaO_4P$: C 33,52, H 5,16, N 6,52, Na 10,69, P 14,43; tr.: C 33,04, H 5,20, N 6,50, Na 10,70, P 14,07%.

2. *Action de CH_3I sur le phosphorane* **2**e *(R = R′ = Ph) en présence de triéthylamine*

A 0,01 mol (4,54 g) du phosphorane **2***e* (R = R′ = C_6H_5) on ajoute dans 10 cm^3 de DMF à la température ambiante, 0,04 mol (4,04 g) de triéthylamine. La réaction est instantanée. Un large excès d'éther entraîne la formation d'un précipité blanc qui est lavé plusieurs fois à l'éther. Le rendement est quantitatif.

A 5,85 g (0,01 mol) de sel de triéthylammonium du mélange **2′***e*, **2″***e* (R = R′ = C_6H_5) en équilibre, dispersés dans 20 mL de THF, on ajoute 4,26 g de CH_3I (0,03 mol). Un précipité d'iodure de triéthylammonium se forme qui est filtré. Le filtrat, repris par 20 mL d'hexane laisse déposer un precipité qui est filtré, redissous dans le THF, puis passé à travers une couche de silice. L'éluant, débarrassé du solvant sous 12 Torr abandonne une poudre blanche qui est le composé **6** pur; rmn de ^{31}P δ: −24 (sol. THF); rmn ^1H (DMSO-d_6, TMS, 60 MHz): 2,1 (3H, d, $^2J_{H-C-P}$ = 18 Hz, CH_3—P). *Anal.* calc. pour $C_{29}H_{23}O_6P$: C 69,94, H 4,66, P 6,23; tr.: C 70,8, H 5,28, P 6,19%.

3. *Action de Ph—CH_2—Br sur le phosphorane* **3** *en présence de Et_3N*

Préparation du composé **7**: 1,2 g de composé **3** (0,005 mol) sont dissous dans 5 mL de DMF; 1,01 g de Et_3N (0,01 mol) sont ajoutés, puis 1,4 g de bromure de benzyle (0,005 mol). Il se forme un précipité blanc de bromure de triéthylammonium. On filtre, lave à l'éther. Le filtrat est repris par 20 mL d'eau froide: un précipité se forme que l'on filtre, lave à l'eau puis à l'éther et sèche sous 10^{-2} Torr; Rdt: 80%; rmn ^{31}P δ: −31 (sol. DMF); rmn ^1H ($CDCl_3$, TMS, 60 MHz): 8 et 7,3 (10H, m, C_6H_5), 3,7 (d, $^2J_{H-C-P}$ = 11 Hz, CH_2—P), 3,3 (2q, parties AB d'un système ABX, X étant l'atome de phosphore, formé par les protons CH_2—N—P, J_{AB} = 15 Hz). L'ensemble de l'intensité des protons CH_2 représente 6 protons conformément à la structure **7**. *Anal.* calc. pour $C_{17}H_{16}NO_4P$: C 62,00, H 4,86, N 4,25, P 9,42; tr.: C 61,98, H 4,91, N 4,22, P 9,36%.

4. *Action de CH_3I sur le phosphorane* **4** *en présence de HNa*

Préparation du phosphorane **5**: 1,93 g de composé **4** (0,01 mol) sont dissous dans 10 mL de THF; 7,1 g d'iodure de méthyle (0,05 mol) sont introduits, suivis de 1,2 g d'hydrure de sodium (0,05 mol). Un fort dégagement gazeux se produit. Le volume de gaz, recueilli dans une éprouvette est de 220 mL. La solution est maintenue sous agitation pendant 1 h. L'iodure de sodium formé et l'excès d'hydrure sont éliminés par centrifugation. Le filtrat est concentré sous pression réduite; rmn de ^{31}P (sol. THF) δ: −24. On reprend par 50 mL d'hexane: une poudre précipite qui est filtrée, lavée à l'hexane et séchée; rmn ^1H (DMSO-d_6, TMS, 60 MHz): 5,33 (1H, d, $^2J_{H-N-P}$ = 19,5 Hz, P—N*H*—), 3,3 (4H, m, CH_2—O—), 1,63 (3H, d, $^2J_{H-C-P}$ = 18 Hz, CH_3—P), 1,27 (6H, s, C—CH_3). Ce spectre correspond bien au composé **6**. Cependant des quantités non négligeables d'iodure de sodium restent retenues (test de détection de l'ion iodure largement positif). L'analyse élémentaire correspond à **6** + 0,4 NaI.

La spectrographie de masse par désorption de champ permet de mettre en évidence les cations M^+, M + Na^+, 2M + Na^+. Ces résultats peuvent s'expliquer par la complexation du phosphorane et de l'iodure probablement au niveau du groupement carbonyle ou au niveau de l'atome de phosphore. Des phénomènes comparables ont été observés pour les adduits NaI, 3 DMF (18) et entre l'ion Al^{3+} et des composés organophosphorés (19). La poudre est soluble dans CH_2Cl_2. L'iodure a été éliminé par passage de la solution à travers une colonne d'alumine Merck 1077 activée par chauffage à +149°C, pendant 3 h. L'éluant, débarrassé du solvant sous pression réduite fournit directement le composé **5** pur sous la forme de cristaux blancs. *Anal.* calc. pour $C_7H_{14}NO_4P$: C 40,61, H 6,82, N 6,77, P 14,99; tr.: C 40,33, H 6,75, N 6,76, P 14,09%.

II. *Action de l'azoture de phényle sur les composés* **2**d *et* **3**

Les composés **2***d* ou **3** (0,0025 mol) sont dissous dans 10 mL de CH_2Cl_2; 0,25 g d'azoture de phényle (0,0025 mol) sont ajoutés. Aucun échauffement ni dégagement gazeux n'est observé. Le spectre de rmn de ^{31}P des solutions, 2 h plus tard présente seulement les signaux des phosphoranes **2***d* et **3**. On ajoute alors 0,25 g de Et_3N (0,0025 mol). Il se produit un dégagement gazeux abondant et un léger échauffement. On concentre sous pression réduite; rmn de ^{31}P (CH_2Cl_2) δ: −50,2 (peu intense), −58,3 (très intense), pour **2***d* et δ: +35,7, +17,6, +4,2 (très peu intenses) et −50,8 (très intense), pour **3**.

Isolement du composé **8**

On porte le volume de la solution à 10 mL de CH_2Cl_2, puis on ajoute 10 mL d'hexane: il se forme un trouble. On laisse à −20°C pendant 4 h. Des menus cristaux sont décantés, lavés à l'hexane et séchés; Rdt: 30%; rmn de ^{31}P ($CDCl_3$) δ: −57,6; rmn ^1H ($CDCl_3$, TMS, 60 MHz): 7,3 (5H, m, C_6H_5), 5,4 (1H, d, $^3J_{H-N-P}$ = 13 Hz, P—N*H*), 1,6 (12H, d, *J* = 4 Hz, C—CH_3). *Anal.* calc. pour $C_{14}H_{18}NO_6P$: C 51,37, H 5,50, N 4,28, P 9,44; tr.: C 50,77, H 5,46, N 4,28, P 9,51%.

Isolement du composé **9**

Le volume de la solution est porté à 20 mL. On ajoute 30 mL d'éther. Une huile dorée précipite. On laisse à −20°C pendant 16 h. On décante, lave à l'éther et sèche. Un solide jaune-clair est obtenu, qui, séché sous 10^{-2} Torr, se transforme en une poudre ocre clair. Celle-ci est dissoute dans 10 mL de CH_2Cl_2 et reprise par 1 mL d'éther: une huile orangée précipite qui est décantée immédiatement. On rajoute 2 mL d'éther au filtrat: un peu d'huile précipite encore que l'on décante. Le filtrat est laissé à −20°C pendant 4 h. Des microcristaux se forment que l'on décante, lave à l'éther et sèche; Rdt: 40%; rmn de ^{31}P ($CDCl_3$) δ: −50,8; rmn ^1H ($CDCl_3$, TMS, 60 MHz): 7,7, 7,4, 7,2 (10H, m, C_6H_5), 5,3 (1H, d, $^3J_{H-N-P}$ = 14 Hz, N*H*—P), 3,9 (4H, d, $J_{H-C-N-P}$ = 12 Hz, CH_2—CO—). *Anal.* calc. pour $C_{16}H_{15}NO_4P$: C 58,18, H 4,54, N 8,48, P 9,39; tr.: C 58,30, H 4,70, N 8,20, P 8,82%.

III. *Action du disulfure de carbone sur les phosphoranes* **2**d *et* **3**

Préparation des composés **10** *et* **11**

La préparation du composé d'addition **10** entre **2***d* et CS_2, en présence de Et_3N a été décrite (9).

Isolement du composé **11**

Phosphorane **3** (0,6 g; 0,0025 mol) est dissous dans 4 mL de CH_2Cl_2; 0,8 g de disulfure de carbone (0,01 mol) sont ajoutés. Le spectre de rmn de ^{31}P de la solution enregistré 3 h plus tard présente uniquement le doublet P—H du composé **3**; 0,25 g de Et_3N (0,0025 mol) sont alors ajoutés. Un léger échauffement se produit. La solution se colore rapidement en orangé intense; rmn de ^{31}P δ: −21, +11, +3,4 (très peu intense), −45,8 (très intense). On reprend par 30 mL d'éther: une huile orangée précipite qu'on laisse à −20°C pendant 2 h. On décante, lave à l'éther et sèche. On obtient une masse orangée visqueuse qui est redissoute dans 10 mL de CH_2Cl_2 puis reprise par 10 mL d'éther. Une huile orangée précipite. On laisse pendant quelques heures à la température ambiante. On décante, lave à l'éther et sèche. Une poudre orangée et hygroscopique est finalement obtenue; Rdt: 50%; rmn de ^{31}P δ: −46 (sol. CH_2Cl_2); rmn ^1H ($CDCl_3$, TMS, 60 MHz): 8 et 7,6 (5H, m, C_6H_5), 3,8 (4H, 5 raies, N—CH_2—CO—), 3,1 (6H, q, $J_{H-C-C-H}$ = 7 Hz, N—CH_2—), 1,2 (9H, t, $J_{H-C-C-H}$ = 7 Hz, N—CH_2—CH_3).

IV. *Action de la ditertiobutylorthoquinone sur le phosphorane* **2**d

Préparation du composé **12**

On dissout 2,4 g de phosphorane **2***d* dans 10 mL de THF; 2,2 g de ditertiobutylorthoquinone (0,01 mol), dissous dans 10 mL de THF sont ajoutés, à la température ambiante; rmn de ^{31}P après 12 h, δ: −45. La solution est reprise par 20 mL d'hexane: une huile brune précipite qu'on laisse déposer pendant 12 h à −20°C. Elle est ensuite décantée, lavée à l'hexane et séchée. Une poudre brune est ainsi finalement obtenue; PF: 128°C; ir (pastille KBr), $\nu_{C=O}$: 1725 et 1795 cm^{-1}; rmn de ^{31}P (CH_2Cl_2) δ: −45; rmn de ^1H ($CDCl_3$, TMS, 60

MHz): 9,7 (1H, s, O*H*), 7 (2H, s, C_6H_2), 1,4–1,7 (30H, m, *t*Bu et $C(CH_3)_2$).

Masse moléculaire: nous l'avons déterminée par cryoscopie dans le DMSO. Dans ce solvant, il faut prendre en compte les deux espèces chimiques anion hexacoordonné et H^+... DMSO qui constituent le composé à phosphore hexacoordonné **13**. La valeur trouvée est, dans ces conditions, apparente et il est nécessaire de la multiplier par deux pour avoir la masse réelle. PF, DMSO: 18,45°C; $K = 4{,}4$ K Kg mol^{-1}. Cette constante a été déterminée en étalonnant le solvant avec la triphénylphosphine et l'acide phénylphosphinique. Celle est conforme aux valeurs de la littérature (20, 21). Poids de **12**: 80,45 mg. Poids de DMSO: 4985 mg. $\Delta T = 0{,}36$°C. *M* apparente: 200; *M* réelle: 400; théorique pour **12**: 456. *Anal.* calc. pour $C_{22}H_{33}O_8P$: C 57,89, H 7,28, P 6,78; tr.: C 55,82, H 7,41, P 6,78%.

Isolement de 13 (HB = $HNEt_3^+$)

La réaction est conduite comme pour la préparation du phosphorane **12**. A la solution brute de ce composé dans le THF, on ajoute 1,01 g de Et_3N (0,01 mol). Il se produit un léger échauffement; rmn de ^{31}P δ: −98 (60%) et −100 (40%). Les deux pics correspondent à deux des huit diastéréoisomères possibles du composé **13**. On reprend par 20 mL d'hexane: un précipité brun se forme qu'on laisse déposer quelques heures à la température ambiante. On filtre, lave à l'hexane et sèche. Une poudre brune est finalement obtenue; Rdt: 80%; rmn de ^{31}P (THF) δ: −98 (60%), −100 (40%); rmn ^1H ($CDCl_3$, TMS, 60 MHz): 6,7 (2H, m, C_6H_2), 3,0 (6H, q, $J_{H-C-C-H} = 7$ Hz, N—CH_2—), 1,7 (39H, m, N—CH_2—CH_3 + C—CH_3 + $C(CH_3)_3$). *Anal.* calc. pour $C_{28}H_{49}NO_8P$: C 60,32, H 8,61, N 2,51, P 5,56; tr.: C 60,34, H 8,79, N 2,56, P 5,39%.

V. *Action de l'acide benzoylformique sur le spirophosphorane* **2**d *(R = R' = CH_3)*

Deux solutions sont préparées en dissolvant 1,18 g de phosphorane **2***d* (0,005 mol) et 0,75 g de Ph—CO—COOH (0,005 mol) dans 10 mL de benzène. A l'une des deux, on ajoute 0,5 g de Et_3N (0,005 mol). Un échauffement sensible se produit. On refroidit dans la glace. On laisse pendant 20 h à la température ambiante; rmn ^{31}P δ: −2, J_{P-H} = 630 Hz, −1 (10%), −104,3 (20%), −105,4 (45%), −107,2 (15%), −108 (10%). Le benzène est chassé sous 10^{-2} Torr. Il reste une substance résineuse légérement ambrée; rmn ^1H (60 MHz, C_6D_6, TMS): 8,7 (s, 1H, N*H*$^+$), 7 et 7,5 (m, 5H, C_6H_5), 5,4 (m, 1H, C*H*—C_6H_5), 2,6 (q, 6H, N—CH_2, *J* = 7 Hz), 1,6 (m, 12H, C—CH_3), 0,85 (t, 9H, N—CH_2CH_3, *J* = 7 Hz). Ce spectre correspond aux composés **15**.

Essai de purification: la substance précédente est dissoute dans 10 mL de CH_2Cl_2 puis reprécipitée par 20 mL d'éther. Une huile précipite que l'on décante. Le filtrat, débarrassé du solvant, abandonne une huile épaisse. Les spectres rmn ^{31}P des deux fractions ainsi obtenues sont à peu près les mêmes que celui du produit de départ. Cependant, la quantité de phosphonate à liaison P—H est plus importante (entre 10 et 30%). Les composés **15** se détériorent. Le spectre du produit brut en solution dans le benzène demeure inchangé pendant plusieurs jours. Spectre rmn ^{31}P de l'essai en l'absence de triéthylamine: δ −48, J_{P-H} = 934 Hz (phosphorane **2***d* de départ). Il reste inchangé après une semaine à la température ambiante.

Deux autres essais ont été effectués avec les mêmes quantités de réactifs, en remplacant le benzène par le chlorure de méthylène; rmn de ^{31}P (après 20 h de réaction) δ: +2, −0,5, −6, −8 (10%), −48, J_{P-H} = 934 Hz (15%), −101,7 (15%) −102,6 (45%), −103,5 (7%), −106,2 (8%).

Un fractionnement par redissolution dans CH_2Cl_2 et reprécipitation par l'éther ou l'hexane conduit à deux fractions dont les spectres de rmn ^{31}P sont comparables à celui du produit brut. Ce dernier reste stable en solution et s'altère assez rapidement une fois isolé (augmentation sensible du taux des phosphonates à liaison P—H).

Le spectre de rmn de ^{31}P des mélanges (**2***d* + PhCOCOOH) dans CH_2Cl_2 présente le doublet P—H du phosphorane de départ ($\delta^{31}P$: −48, J_{P-H} = 934 Hz). Vingt jours plus tard, ce doublet reste majoritaire. On note la présence de signaux larges à δ + 7, J_{P-H} = 727 Hz.

Remerciement

Nous remercions MM. Tran et Dall'ava pour leur collaboration technique.

Les liaisons phosphore–azote via l'étude cristalline et moléculaire d'un iminodiazaphospholane

MARIE-ROSE MARRE, MICHEL SANCHEZ[1] ET ROBERT WOLF

Synthèse, structure et réactivité de molécules phosphorées, ERA 926 associée à l'Université Paul Sabatier, 31062 Toulouse Cédex, France

ET

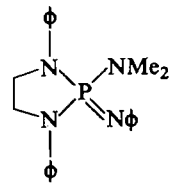
JOËL JAUD ET JEAN GALY

GITER, Laboratoire de chimie de coordination du C.N.R.S., 205 route de Narbonne, 31400 Toulouse, France

Reçue le 11 octobre 1983

MARIE-ROSE MARRE, MICHEL SANCHEZ, ROBERT WOLF, JOËL JAUD et JEAN GALY. Can. J. Chem. **62**, 2186 (1984).

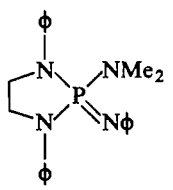
L'iminodiazaphospholane **1** cristallise dans le système monoclinique, groupe spatial $P2_1/c$ avec a = 10,243(9), b = 17,236(5), c = 11,992(9) Å et Z = 4. La structure a été déterminée par des méthodes de diffraction de rayons X sur monocristal et affinée jusqu'à R = 0,056 pour 1342 réflexions. La géométrie est celle d'un tétraèdre déformé. Les angles ∠NPN



varient de 91,8° (angle du cycle) à 121,7° $\angle N_1P_2N_6\phi$. Le cycle diazaphospholane a une conformation enveloppe, dont la pointe est représentée par l'un des 2 atomes de carbone. Les 3 atomes d'azote tricoordonné ont une structure planaire; les directions des doublets des deux atomes du cycle sont parallèles et toutes deux orthogonales au doublet de l'atome d'azote exocyclique (N_7). Les longueurs de liaison P—N sont relativement courtes, comprises entre 1,620 Å et 1,669 Å alors que la liaison $P_2{=}N_6$ de 1,539 Å est parmi les plus faibles valeurs de la littérature. A partir d'une méthode empirique la multiplicité des liaisons P—N a été évaluée: 0,10 pour les deux P—N cycliques, 0,25 pour P—N exocyclique et 0,60 pour P=Nϕ.

MARIE-ROSE MARRE, MICHEL SANCHEZ, ROBERT WOLF, JOËL JAUD et JEAN GALY. Can. J. Chem. **62**, 2186 (1984).

Iminodiazophospholane **1** was obtained as monoclinic crystals, space group $P2_1/c$ with a = 10.243(9), b = 17.236(5), c = 11.992(9) Å, and Z = 4. The structure was determined by single-crystal X-ray diffraction and was refined up to R = 0.056



for 1342 reflections. The geometry of the molecule is that of a distorted tetrahedron with ∠NPN angles varying from 91.8° (ring angle) to 121.7° for $\angle N_1P_2N_6\phi$. The diazophospholane ring has an envelope conformation where one of the 2 carbon atoms is at the tip. The three tricoordinated nitrogen atoms have a planar structure; the lone pairs on the two ring nitrogens have parallel orientation and both are orthogonal to the lone pair of the exocyclic nitrogen atom (N_7). The P—N bond lengths are relatively short, falling between 1.620 Å and 1.669 Å, while the $P_2{=}N_6$ bond of 1.539 Å is among the smallest values ever reported. The multiplicities of the P—N bonds were assigned on the basis of an empirical method: 0.10 for the two cyclic P—N, 0.25 for the exocyclic P—N, and 0.60 for P=Nϕ.

[Journal translation]

Introduction

L'étude cristallographique que nous présentons entre dans le cadre d'un travail concernant la liaison formellement double phosphore–azote d'iminophospholanes (>P=N—), et fait suite à un article paru dans cette même revue (1) sur quelques propriétés chimiques des iminophospholanes. La diversité du comportement réactionnel de la liaison phosphazène caractérisée par: (a) une réaction d'addition de la fonction X—H (X = —O, —N) sur >P=NR conduisant à des entités pentacoordonnées (>P(X)NHR) ou à des sels de phosphonium (>P⁺—NHR X^-) (1–3); (b) une aptitude à la dimérisation dépendante de la nature des substituants sur l'atome de phosphore et d'azote (4); (c) le caractère donneur de l'atome d'azote imino (1, 5), nous astreint à mieux connaître des structures

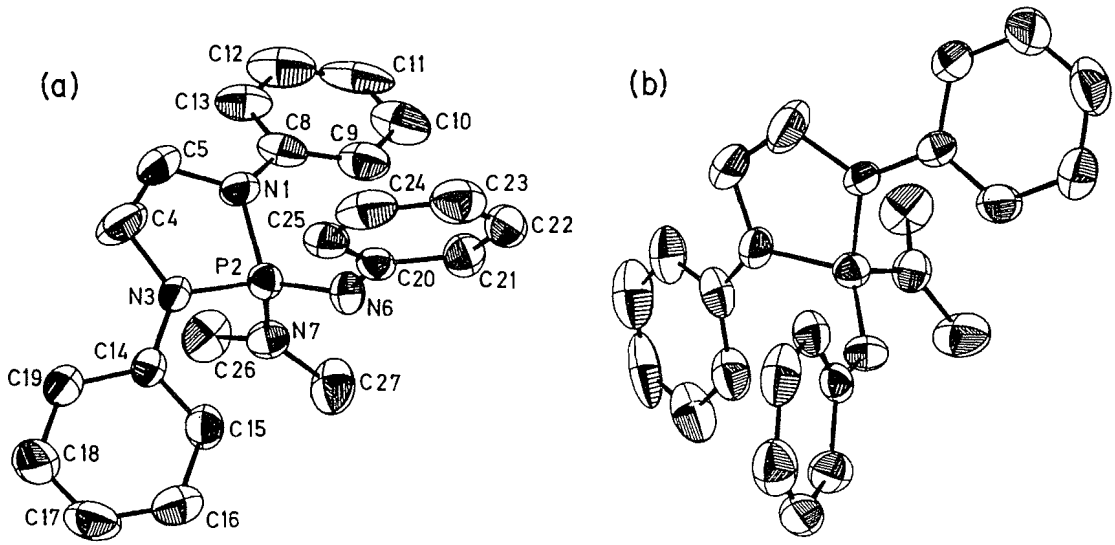

FIG. 1. (a) Vue perspective de la molécule et label des différents atomes. (b) Vue perspective (programme ORTEP).

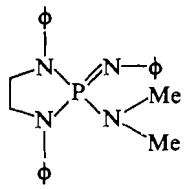
moléculaires contenant le motif $\rangle P{=}N$. S'il existe quelques déterminations de structures d'iminophosphanes acycliques (voir tableau VI), l'étude cristallographique de l'iminodiazaphospholane **1** est le premier exemple original de cette famille, comportant quatre liaisons phosphore–azote:



1

Au cours de ce travail nous nous proposons de préciser les points suivants: (*i*) configuration tétraédrique autour de l'atome de phosphore et conformation du cycle diazaphospholane; (*ii*) conformation planaire ou pyramidale des trois types d'atomes d'azote ce qui permet d'estimer les dispositions relatives des paires libres; (*iii*) longueurs comparées des liaisons phosphore–azote à caractère double (P=N—R) ou simple ($P{-}N\langle$) et utilisation de ce modèle moléculaire pour tester les formules empiriques concernant la multiplicité des liaisons P—N; (*iv*) relation entre la longueur de la liaison phosphazène et sa réactivité.

Résultats expérimentaux

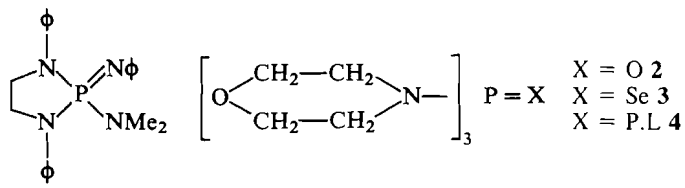
Le composé **1** ($C_{22}H_{25}N_4P$)[2] cristallise dans le système cristallin monoclinique, groupe spatial $P2_1/c$ avec les paramètres: a = 10,243(9) Å, b = 17,236(5) Å, c = 11,992(9) Å, V: 2028(2) Å^3, Z = 4, D_{exp} = 1,22 g cm^{-3}, D_X = 1,23, μ (MoK$_\alpha$) = 1,0 cm^{-1}.

Les conditions d'enregistrement sont celles définies dans une précédente publication (6). Précisons quelques points: température ambiante; radiation utilisant une lame de graphite orientée MoK$_\alpha$ (λ = 0,7106 Å). Un total de 1443 réflexions indépendantes ont été enregistrées avec un angle de Bragg maximum de 24°; 1342 réflexions ont été utilisées.

La structure cristalline résolue par les méthodes directes a été affinée par moindres carrées (programme MULTAN). Le facteur de fiabilité final est R = 0,056 pour 1342 réflexions et 245 variables. La détermination de la structure et son affinement ont été conduits de la manière suivante: affinement isotrope de l'ensemble des atomes (hydrogènes exclus) dont les positions ont été déterminées par utilisation du programme MULTAN (R = 0,12); affinement des mêmes atomes avec agitation thermique anisotrope (R = 0,08); localisation des atomes d'hydrogène par fonction différence et vérification des positions repérées par calcul théorique; lors du calcul final les atomes d'hydrogène sont introduits avec une agitation thermique isotrope (B_H = 1,2 B_A où B_A est l'agitation thermique équivalente de l'atome auquel l'hydrogène est lié) et une position fixe. L'extinction secondaire a été également affinée et sa valeur est de 0,555 × 10^{-6}.

Le label des différents atomes est précisé sur la vue perspective de la molécule (programme ORTEP) (Fig. 1).

Les distances interatomiques et les angles avec leur écart type sont regroupés dans les tableaux 1 et 2. Le tableau 3 présente par ailleurs une étude comparative des paramètres les plus significatifs entre quatre composés (**1** à **4**) de formule générale $(R_2N)_3P{=}X$



1

Les structures des dérivés **2**, **3** et **4** ont été résolues par Romming et Songstad (7, 8). Enfin le tableau 4 présente une

[2] La synthèse, les données spectroscopiques et les propriétés chimiques de **1** ont été décrites dans la réf. 1.

[3] Les tableaux rassemblant d'une part les coordonnées atomiques de tous les atomes et les facteurs d'agitation thermique et d'autre part les distances des principaux atomes aux plans moyens $P_2N_1C_3C_5$ et $P_2N_6N_7$ sont disponibles. On peut les obtenir en s'adressant au Dépôt de données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa (Ont.), Canada K1A 0S2.

* Les longueurs C—H ont été déterminées, elles sont comprises entre 0,97 et 1,00 Å.

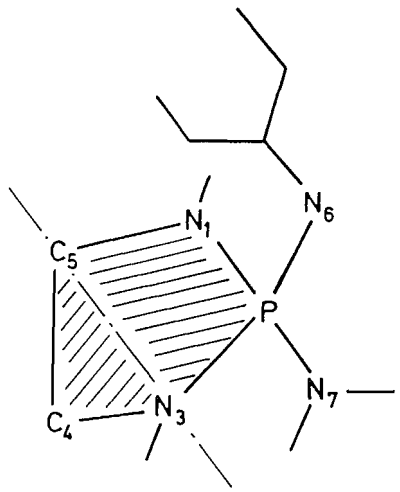

FIG. 2. Conformation enveloppe du cycle diazaphospholane.

compilation des longueurs de liaison P=N et des angles ∠P=N—R de treize iminophosphanes.

Description et discussion de la structure

L'examen des paramètres structuraux obtenus et des données comparatives (tableaux 1 a 4) nous permet d'apporter une réponse aux différentes questions que nous avons évoquées.

1. *Angles des liaisons autour de P*

La molécule est monomère à l'état cristallin; la rmn de ^{31}P du composé en solution dans le toluène ($\delta^{31}P$ = 1,5) constituait déjà une forte présomption pour trouver également une structure monomère à l'état solide.

L'atome de phosphore est au centre d'un tétraèdre déformé dont les longueurs des six arêtes N . . . N sont comprises entre 2,79 (6) pour N_1—N_6 et 2,39(2) Å pour N_3—N_1. Ces distances interatomiques s'harmonisent avec les valeurs des angles autour de P qui varient entre 121,7° (3) pour $\angle N_1P_2N_6$ et 91,8° (3) pour $\angle N_3P_2N_1$; cette dernière valeur est due à la contrainte du cycle pentagonal. La déformation angulaire la plus évidente concerne les angles $\angle N_1P_2N_6$ (121,7°) et $\angle N_3P_2N_6$ (118,1°). Celle-ci plus importante dans notre composé **1** que dans les dérivés **2** (moyenne des ∠NPO: 113°) et **3** (moyenne des ∠NPSe: 112°) (voir tableau 3).

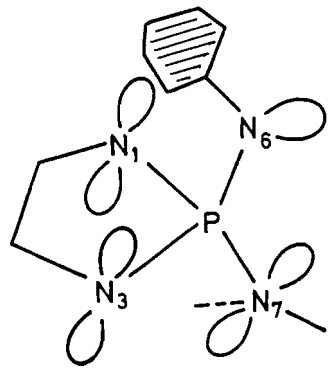

FIG. 3. Positions des doublets libres des atomes d'azote.

L'ouverture des angles ∠N—P=Nϕ montre en accord avec les règles de Gillespie (9) que la liaison P_2—N_6 se situe au plus loin des deux liaisons P_2—N_1 (N_1N_6 = 2,79 Å) et P_2N_3(N_3N_6 = 2,75 Å) afin de diminuer les interactions fortes entre les doublets libres des atomes d'azote N_1 et N_3 et les électrons de la liaison phosphazène P_2=N_6.

2. *Conformation du cycle*

Le cycle diazaphospholane défini par les cinq atomes N_1, P_2, N_3, C_4 et C_5 a une conformation enveloppe (Fig. 2). Le plan du rabat constitué par les atomes N_3, C_4, C_5 est dans la direction de l'espace opposé au groupe phényl imino (=Nϕ) et forme un angle de 10,7° avec le plan 1 moyen contenant les quatre atomes $N_1P_2N_3C_5$. Cette particularité mise à part le plan 2 ($P_2N_6N_7$) est pratiquement bissecteur du cycle à cinq chainons et des cycles benzéniques qui lui sont associés.

3. *Angles des liaisons autour de N et considérations conformationnelles*

La configuration des trois atomes d'azote tricoordonné (N_1, N_3, N_7) est pratiquement planaire puisque la somme des angles autour de N est respectivement de 360,0, 357,3 et 359,4° soit une valeur moyenne de 358,9°. Il est intéressant de comparer cette valeur à celle des dérivés **2** (352,9°) et **3** (348,2°) (tableau 3). Cette planéité presque parfaite des atomes d'azote dans **1** confirme les observations de Romming et Songstad (7) selon lesquelles l'accroissement de la polarité de la liaison P=Nϕ par rapport à >P=O ou >P=Se augmente le transfert électronique des atomes d'azote vers P et par suite accroît la structure plane de ces atomes d'azote. Corrélativement à la configuration des atomes d'azote nous avons cherché à préciser l'arrangement relatif des quatre doublets libres dans l'espace. La figure 3 en donne une représentation schématique; la direction de la paire libre d'un azote tricoordonné étant perpendiculaire au plan moyen des trois liaisons de cet atome, nous avons évalué les angles entre les directions des paires libres entre les atomes N_1, N_3 et N_7 (tableau 3). On constate que les doublets libres sur N_1 et N_3 sont presque parallèles (5, 7°) et tous deux orthogonaux aux doublets libres de N_7 (91,5°). Ce dernier doublet libre n'est pas en position *anti* par rapport à la liaison N=ϕ contrairement à **2** et **3** mais orthogonal au doublet libre de l'azote imino N_6 (Fig. 3).

4. *Longueur et multiplicité des liaisons P—N*

Il est couramment admis lorsqu'un atome d'azote est directement lié à un atome de phosphore qu'une structure planaire trigonale de l'azote favorise l'interaction $p\Pi$–$d\Pi$ entre la paire

N_3—N_7	91,2		115	109,1
P=X.N_7	84,8*	167,5	170	170,6

* N_7 désigne l'atome d'azote tricoordonné exocyclique dans **1** et celui de conformation *anti* par rapport à P=X dans **2** à **4**.

libre de N et les orbitales *d* vacantes du phosphore (10). En conséquence un raccourcissement de la liaison simple P—N doit être observé. Si l'on adopte comme longueur de liaison P—N simple 1,77 Å valeur déterminée par Cruikshank (11*a*) pour H_3N^+—PO_3^{2-} Na^+ ou 1,80 Å valeur déterminée par Cameron *et al.* (11*b*) pour H_3N^+—PO_3^{2-} K^+, les valeurs obtenues pour P_2—N_1 = 1,663 Å, P_2—N_3 = 1,669 Å, P_2—N_7 = 1,620 Å indiquent que ces liaisons présentent un caractère significatif de liaison multiple.

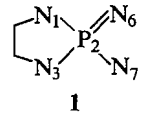
Les distances P_2—N_1 et P_2—N_3 sont équivalentes alors que P_2—N_7 est nettement plus courte, ce qui laisserait envisager une délocalisation des doublets Π, sur N_7, P_2 et N_6. Cette remarque serait confirmée par la longueur N_6—C_{20} = 1,368 Å plus petite que N_1—C_8 = 1,406 Å et N_3—C_{14} = 1,414 Å. Le résultat le plus important est la distance P_2—N_6 = 1,539 Å, la plus courte des quatre liaisons P—N, ce qui confirme son caractère de *double liaison*. Dans le tableau 4 nous avons classé par ordre croissant treize longueurs de liaison phosphazène P=N. On constate que la valeur trouvée pour **1** est une des plus courtes. De plus on peut observer un recouvrement entre la longueur de la liaison simple acyclique P_2—N_7 (1,620 Å) et celle formellement double à partir du composé ϕ_3P=N—C_3N_3ClNMe (20).

Il est intéressant d'avoir une idée plus quantitative de cette multiplicité. Pour cela, nous avons choisi d'appliquer la méthode des "valences de liaison" développée par Brown (12), basée sur les mesures des longueurs de liaison (R . X) qui permettent de calculer "les valences pondérées" autour d'un atome donné. Pour calculer la valence de liaison *s*, Brown propose l'équation générale:

$$s = \left(\frac{R}{R_0}\right)^{-n}$$

où *R*: longueur de liaison, R_0: longueur prise comme référence. Pour les composés phosphorés tétracoordonnés pentavalents, les paramètres sont les suivants: $N = 4{,}8$ et $R_0 = 1{,}70$ Å.

Nous avons appliqué cette équation au dérivé **1** et obtenu les valeurs suivantes:



1

s(P—N_1) = 1,09
s(P—N_3) = 1,11
s(P—N_7) = 1,26
s(P—N_6) = 1,61
Σs = 5,07

Ce résultat est tout à fait remarquable car d'une part la somme des valences de liaison est de 5,07, soit à 1,5% près la

TABLEAU 4. Longueurs de liaison P=N et angles P=N—R dans 13 iminophosphanes

Molécules	Longueur P=N	Angle P=N—R	Références
	1,47		*
	1,539*	131,3	Ce travail
	1,543	126,4	13
	1,567	124,2	14
	1,579	126,4	15
	1,595	123,0	16
	1,597	134,8	17
	1,608	131,0	18
	1,615	130,0	19

	1,630	130	21
$F\phi_2P{=}NMe$	1,641	119,1	22
$\phi_3P{=}NS_3N_3$	1,645	121,0	23

* H. G. Schäfer et E. Niecke, communication personnelle (1983).

valeur théorique 5, et d'autre part, il montre que le caractère de double liaison $P_2{=}N_6$ est de 61%, alors que les liaisons P—N simples dans le cycle (P_2N_1 et P_2N_3) et exocyclique P_2N_7 ont un caractère de multiplicité de 10% et de 25%. Cet accroissement de l'indice de valence pour les liaisons "simples" se fait donc au détriment de la liaison formellement double P=N.

5. *Relation entre réactivité et structure*

Le composé **1** est très peu réactif, en particulier lors de l'addition des alcools, nous n'avons pas observé de réaction d'addition sur la liaison phosphazène, mais une simple interaction de type pont hydrogène due à la basicité de l'atome d'azote imino (1). Il est généralement admis d'interpréter la réactivité de la liaison phosphazène en terme de polarisation $P^{\delta+}—N^{\delta+}$, celle-ci étant très liée à la nature des substituants sur l'atome de phosphore et d'azote. Dans le composé **1** la faible valeur de la longueur P_2N_6 = 1,539 Å confirme donc son caractère de double liaison et sa faible polarisation; par suite elle peut expliquer la grande stabilité chimique manifestée par ce composé.

En conclusion l'étude de la structure du diphényl-1,3 diméthylamino-2, phénylimino-2 diazaphospholane-1,3,2 nous a permis de déterminer sur un même modèle moléculaire trois types de liaison phosphore–azote. Ces liaisons de longueur comprise entre 1,539 (6) Å et 1,669 (7) Å présentent toutes un caractère de multiplicité que nous avons évalué grâce au modèle empirique de Brown (12). La liaison phosphazène $P_2{=}N_6$ est comme attendue la plus petite (1,539 Å); parmi les longueurs P=N relevées dans la littérature cette distance est une des plus courtes. Les trois atomes d'azote tricoordonné sont plans, les orientations relatives des doublets libres ont été précisées. La comparaison avec trois autres dérivés acycliques de type ($\diagdown$N)$_3$PX (X = O, Se, D.L) montrent une disposition originale des quatre doublets libres dans le dérivé que nous avons étudié.

Remerciements

MERCEDES MARCOS, ENRIQUE MELENDEZ, JOSE LUIS SERRANO, DIDIER MATHIEU, and ROGER PHAN TAN LUU. Can. J. Chem. **62**, 2192 (1984).

Binary, ternary, and quaternary mixtures of four nematogenic compounds, 2-hydroxy-4,4′-dihexoxy-α,α′-dimethylbenzalazine, 4′-butyl-2-hydroxy-4-octoxy-α,α′-dimethylbenzalazine, *S*-4′-butoxy-2-hydroxy-4-(2-methylbutoxy)-α,α′-dimethylbenzalazine, and 2-hydroxy-4′-nitro-4-octoxy-α,α′-dimethylbenzalazine, were studied. In the mixtures with a nitro group a S_A-induced phase appeared.

These systems of mixtures were studied using the Scheffé algorithm. A comparative study of the prediction methods of the eutectic points was made.

MERCEDES MARCOS, ENRIQUE MELENDEZ, JOSE LUIS SERRANO, DIDIER MATHIEU et ROGER PHAN TAN LUU. Can. J. Chem. **62**, 2192 (1984).

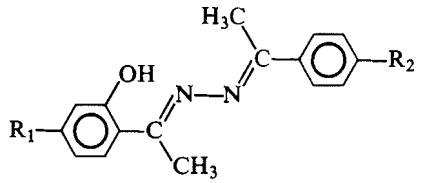
On a étudié des mélanges binaires, tertiaires et quaternaires de quatre composés nématogènes: hydroxy-2 dihexoxy-4,4′ α,α′-diméthylbenzalazine, butyl-4′ hydroxy-2 octoxy-4 α,α′-diméthylbenzalazine, *S*-butoxy-4′ hydroxy-2 (méthyl-2 butoxy)-4 α,α′-diméthylbenzalazine et hydroxy-2 nitro-4′ octoxy-4 α,α′-diméthylbenzalazine. Dans les cas des mélanges contenant le composé nitré, il apparait une phase induite S_A.

On a étudié ces systèmes de mélanges en utilisant un algorithme de Scheffé. On a fait une étude comparative des méthodes de prédiction des points eutectiques.

[Traduit par le journal]

Introduction

In this paper we report on our study of the binary, ternary, and quaternary mixtures of four synthesized nematogenic compounds.



A: $R_1 = R_2 =$ O-*n*-C_6H_{13} (ref. 1)
B: R_1 = O-*n*-C_8H_{17} R_2 = *n*-C_4H_9 (ref. 2)
C: R_1 = O-CH_2—*CH(CH$_3$)—C_2H_5 R_2 = O-*n*-C_4H_9 (ref. 3)
D: R_1 = O-*n*-C_8H_{17} $R_2 = NO_2$ (ref. 4)

It was observed that when the compound **D** (2-hydroxy-4-octoxy-4′-nitro-α,α′-dimethylbenzalazine) was one component of the mixture a S_A-induced mesophase appeared. This behaviour, which occurs in some mixtures containing compounds with a nitro or cyano group as a terminal chain, has already been described by other researchers. However, the —C≡N group has been more frequently studied (5–7) than the nitro group (8).

In this paper we report a detailed investigation of the induced mesophase in the binary, ternary, and quaternary mixtures. While binary mixtures are relatively easy to study, the more complex mixtures present some problems. We have recently published two papers on the study of mesogenic compounds by a mathematical method using Scheffé algorithm (9, 10).

We have compared the results of the thermal properties and the eutectic composition of the mixtures using the above-mentioned mathematical method and those using thermodynamic equations (11, 12).

Experimental

In the study of mixtures the Scheffé algorithm is applied sequentially, starting with the most simple models, which require the least number of experiments, and continuing with the more complicated models if satisfactory results are not obtained.

The evaluation of each model used is carried out by test points.

In our previous paper (10), it was observed that in the study of mixtures of four components the full cubic model gave satisfactory results. With this model only 20 experiments are required to obtain the coefficients of the equation and 6 additional experiments to give test points. It is therefore only necessary to make 26 mixtures, four of which correspond to the pure compounds (Fig. 1).

For each mixture the following properties were measured: Y_1 (melting point, in K), Y_2 (clearing point, in K), Y_3 (S_A-mesophase range), Y_4 (*N*-mesophase range), Y_5 (total mesophase range), and Y_6 (ΔH total transition-crystal mesophase, in cal/g).

In mixtures of nematic compounds, two transitions usually appear during the melting process (11). The first one corresponds to the eutectic mixture (crystal → crystal + mesophase) whereas the second corresponds to the transition of the entire mixture to the corresponding mesophase (crystal + mesophase → mesophase).

The data used for the Y_1 response (melting point) correspond to the transition crystal + mesophase → mesophase.

All the properties were studied using the full cubic model with the exception of the Y_3, induced S_A-mesophase range, which was studied by means of the quadratic model.

The composition of the prepared mixtures as well as their respective measured properties are shown in Table 1.

We have expanded on the experimental studies of the binary mixtures in order to study the induced S_A-phase and to compare the various predictions of the eutectic.

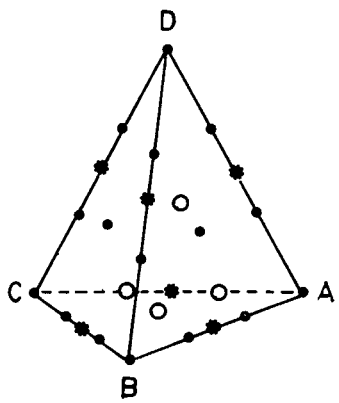

FIG. 1. Experimental domain: ●, experimental points; *, test points.

Table 2 shows the observed transitions and the thermal and thermodynamic data.

The mixtures were prepared by melting the compounds in a glass tube, stirring with a thin glass rod for 1 min, then cooling rapidly.

Transition temperatures and enthalpies were measured by differential scanning calorimetry (Perkin-Elmer DSC-2) operated at a scanning rate of 4 K/min on heating. The apparatus was calibrated by taking the known melting point and the known melting heat of indium (429.6 K, 6.8 cal/g).

Phase textures were identified using a polarizing microscope with a hot-stage (Reichert-Thermovar HT-1 B11).

Results and discussion

Studies were made with different orders of mathematical models. The best results for Y_1, Y_2, Y_4, Y_5, and Y_6 were obtained with the full cubic model. For Y_3, with an elevated number of zeros, the quadratic model gave a better approximation.

The equations for both models and the coefficients calculated using matrix algebra are shown in Table 3.

Data in an analytical form can be obtained for any mixture using the Scheffé algorithm as a starting point. Nevertheless, for the study of binary, ternary, and quaternary mixtures a graphic representation of the results, easily done using a computer, is much more effective.

Figures 3 to 8 show the isoresponse curves of the mixtures for the six parameters studied.

Quaternary mixtures corresponding to the inside of the tetrahedron can be studied easily by making regular sections parallel to one of the surfaces (Fig. 2). In this particular case the regular arrangement of the isoresponse curves on the surface of the tetrahedron provide fairly exact information about their distribution inside and thus we give only the interior sections for two properties, melting point (Y_1) (Fig. 9) and induced S_A-mesophase range (Y_3) (Fig. 10), as examples.

Figure 3 shows the calculated isoresponse surfaces of the melting points. The lowest melting points are to be found in an area very near component **B** and correspond to the binary mixtures of compounds **B** and **C**, where the first component is in greater quantity, and a small surface of the ternary and quaternary mixtures where the percentage of the other two components is very small.

Study of the quaternary mixture does not show any modification of the results found with the ternary mixtures (Fig. 9). The lowest melting points are found in very limited areas around the binary mixtures (see ruled zone in Fig. 3).

Figure 4 shows the calculated isoresponse curves for the clearing temperature. As expected, the variation of the curves is much smoother than that of the melting points. The highest

*Total ΔH of melting.

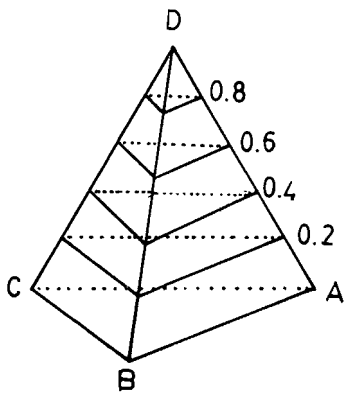

FIG. 2. Sections of a tetrahedron parallel to one surface.

clearing points are obtained in the area corresponding to the **A−D** binary mixture. This was expected because both compounds have the highest clearing temperatures.

Figure 5 corresponds to the calculated isoresponse curves for Y_3, the induced S_A-mesophase range.

The induced S_A-mesophase appears when compound **D** is present in the mixture. The highest value (approx. 60°) is obtained with a ternary mixture of compounds **A**, **B**, and **D** (**A**, ~30.2%; **B**, ~29.0%; **D**, ~40.8%).

The induced mesophase appears when a small concentration of compound **D** (approximately 10%) is present in the mixture but does not appear when its concentration is above 70%.

In quaternary mixtures the isoresponse surfaces are planes almost parallel to the plane defined by the **A−B−C** mixture, which does not show induced S_A-mesophase.

As can be seen in Fig. 10 the planes are slightly inclined towards the edge **CD**, which always shows the lowest values for this parameter. This can be explained by that compound **C**, with a chiral terminal chain, is the one that shows the greatest hindrance to the regular arrangement. Consequently, none of the quaternary mixtures has a greater induced S_A-mesophase range than that found in the **A−B−D** ternary mixture.

The calculated isoresponse curves for Y_4, the nematic mesophase range, are shown in Fig. 6.

As expected they show variation opposite to that shown by Y_3. The widest nematic mesophase ranges are found in areas next to the vertex of pures compounds **B** and **D** and correspond to binary and ternary mixtures where these compounds are

present in greater proportion. And the smallest ranges are in the regions where the induced S_A-mesophase exists.

Figure 7 shows the isoresponse curves for Y_5, the total mesophase range.

It is a combination of the two preceding parameters that a much smoother variation of the isoresponse curves can be seen. On the surface **A**−**B**−**C** the modifications with respect to Y_4 are practically void, although in this case they are more accurate.

It can be seen that wide mesophase ranges in the three types

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

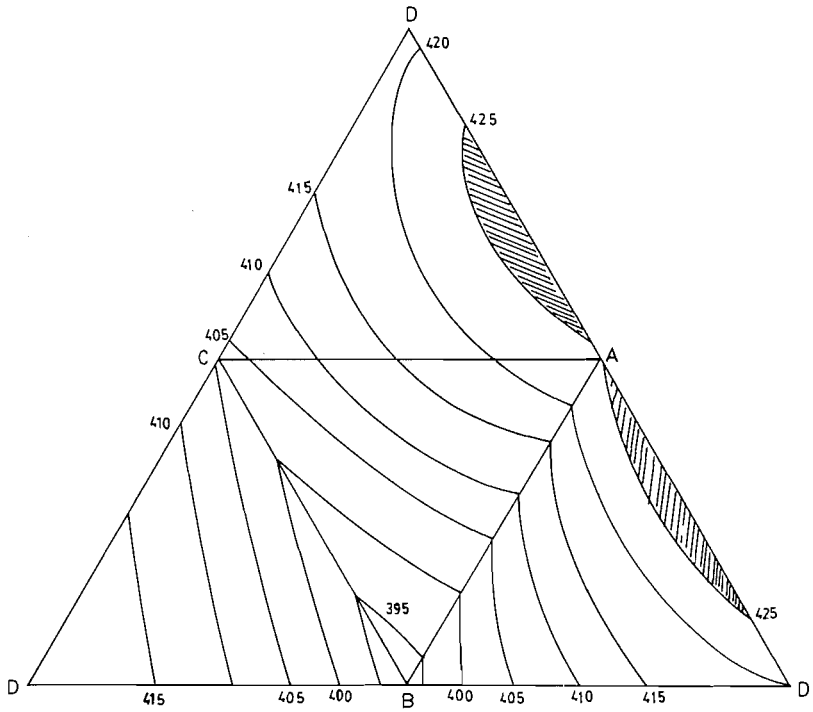

FIG. 4. Isoresponse curves for Y_2; cubic model.

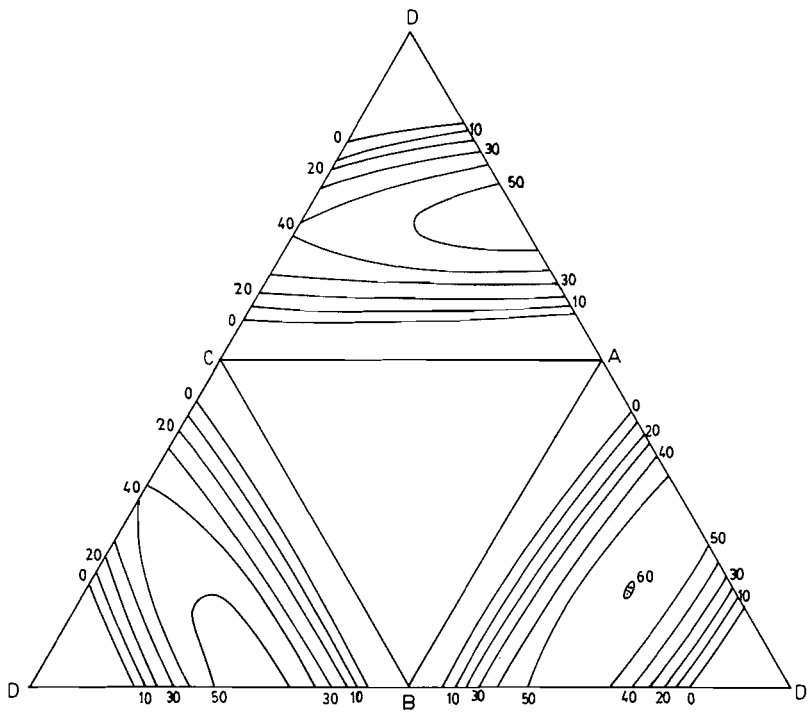

FIG. 5. Isoresponse curves for Y_3; quadratic model.

of mixture studied, binary, ternary, and quaternary, can generally be obtained. For ternary and quaternary mixtures of similarly-structured compounds, their mesophase ranges do not improve significantly over those of binary mixtures.

Y_6 represents the total ΔH of melting in cal/g. The calculated isoresponse curves are in Fig. 8. The highest values for Y_6 correspond to the pure compounds and they decrease gradually when the proportion of one or more of the other compounds in mixture increases. The lowest values of ΔH are obtained for a mixture zone near the vertex of component **B**, which shows a melting enthalpy much lower than that of the other three compounds.

It is notable that no change is observed in the data of the melting enthalpies in areas where the induced S_A-mesophase appears, and a regular variation of the isoresponse curves can be seen in the mixtures where compound **D** is present.

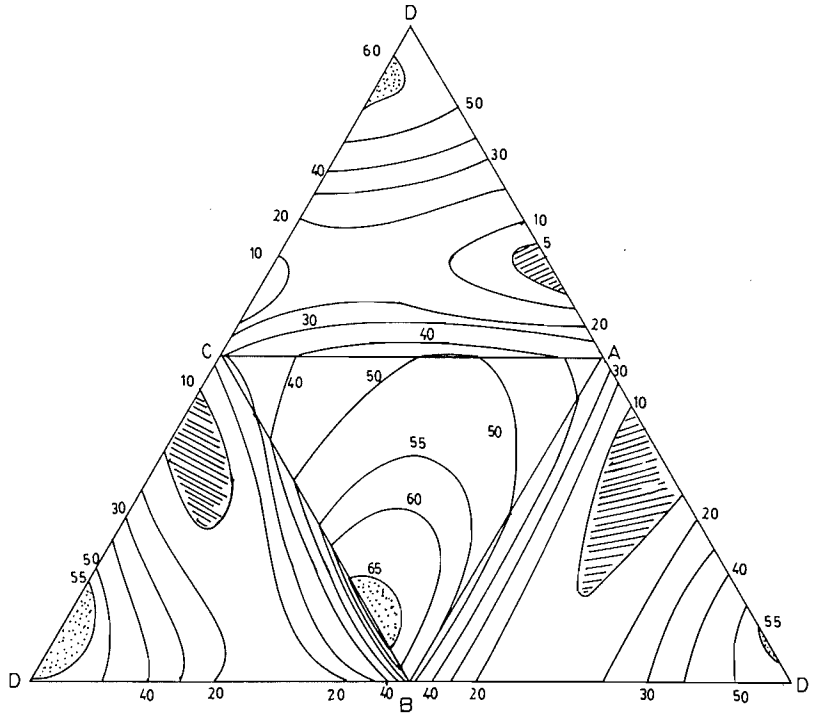

FIG. 6. Isoresponse curves for Y_4; cubic model.

Eutectic point study for binary, ternary, and quaternary mixtures

Binary mixtures

Experimental results obtained for binary mixtures are shown in Figs. 11 to 16.

The eutectic temperature was determined experimentally as the average temperatures of the crystal + mesophase → mesophase transition.

With the exception of **A**−**C** (2 points) and **C**−**D** (4 points) mixtures, this transition agrees with all the experiments carried out for each mixture.

With regard to the mixture **C**−**D** it could be thought that two eutectic points exist, and their form is similar to that described by Yu and Labes (7) in mixtures showing an induced S_A-mesophase for compounds with the cyano group. However, in this case the experimental data do not confirm that

phenomenon.

In mixtures where compounds **D** (**A**−**B**, **A**−**C**, **B**−**C**) is not present only one mesophase appears. In the three cases the eutectic point is well established and the N−I or Ch−I transition gives a practically linear variation.

In mixtures where compound **D** with the nitro group as a terminal chain participates, the appearance of an induced S_A-mesophase was observed (Figs. 13, 15, and 16).

The fact that in the mixtures **A**−**D** and **C**−**D**, the appearance of an induced S_A-mesophase does not have an effect on the temperature of the transition crystal + mesophase → mesophase and they are shown to be ideal mixtures is worth drawing

attention to. However, judging by its behaviour, mixture **B−D** (Fig. 15) is obviously not an ideal mixture, and a strong inflexion in the long line of the transition crystal + mesophase → mesophase in the binary diagram can be observed.

In the three mixtures a slight convex shape forms in the line of transition to isotropic liquid, caused by the induced S_A-mesophase, can be observed.

Table 4 shows the thermal data and the composition of the eutectic mixtures obtained experimentally for each of the binary mixtures, as well as the results obtained using the Scheffé algorithm and the Schröder − van Laar's equations (11) for melting points and $T_{cl} = \Sigma T_{cli} x_i$ (12) for clearing points.

In general none of the methods used is better in all cases. In melting temperatures of eutectic compositions either prediction method is quite good for five of the six mixtures studied. However, there are discrepancies observed in the **A−B** and

TABLE 4. Experimental and calculated eutectic composition and temperatures for binary mixtures

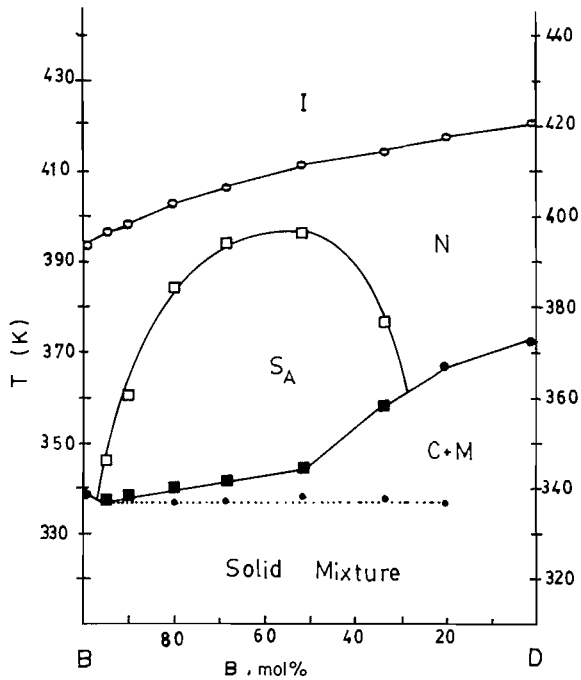

FIG. 15. Binary phase diagram of 4′-butyl-2-hydroxy-4-octoxy-α,α′-dimethylbenzalazine/2-hydroxy-4′-nitro-4-octoxy-α,α′-dimethylbenzalazine system.

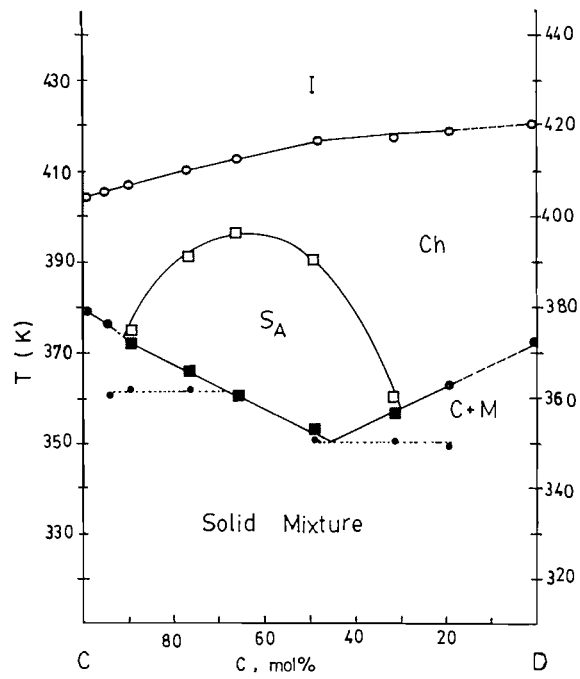

FIG. 16. Binary phase diagram of 4′-butoxy-2-hydroxy-4-(2-methylbutoxy)-α,α′-dimethylbenzalazine/2-hydroxy-4′-nitro-4-octoxy-α,α′-dimethylbenzalazine system.

B–D mixtures.

With regard to the former (Fig. 11), it is clear that the three experiments using the Scheffé algorithm are not sufficient. The curve obtained by the equation of the full-cubic model is not appropriate in that zone. The minimum predicted temperature in this case corresponds to the data of the pure component **B**.

On the other hand, with mixture **B–D** (Fig. 15) which is quite different from ideal, the data obtained by the mathematical model are much better.

As expected, something similar happens with the composition of the eutectic mixture, where, with the exception of the mixtures already referred to, the results obtained using the various methods are not too different and each method is successful in certain respects.

The same is true for the eutectic clearing temperature. In this case though, the experimental value is closer to the predicted values.

Ternary and quaternary mixtures

Here the eutectic point was studied in a manner different from that of the binary mixture.

The theoretical eutectic temperature and composition were calculated using the Schröder – van Laar's equation, and the eutectic temperature again calculated using Scheffé's algorithm.

Experiments were then performed to check the validity of the predictions. The results are gathered in Table 5.

It can be observed that in every case, a step closer to reality is obtained with the application of the mathematical method. This justifies its use in the study of complex mixtures whose behaviour is generally different from ideal.

Conclusions

The 2-hydroxy-4′-nitro-4-octoxy-α,α′-dimethylbenzalazine only shows a nematic mesophase, but as a component in mixtures with other nematogenic compounds induces the appearance of a S_A-mesophase.

In the binary, ternary, and quaternary mixtures studied, this mesophase already appears with a low concentration of this

compound (~10%) but not when its concentration is higher than 70%.

The principal modification caused by the induced S_A-mesophase can be seen in its change in the clearing temperatures. However, in general neither temperature nor enthalpy of transition from crystal to mesophase undergo marked changes.

The use of the Scheffé algorithm to study mixtures of mesogenic compounds gives excellent results, especially in the study of complex mixtures. It proves to be very valuable in the study of mixtures of liquid crystals, including the infrequent cases of the induced S_A-mesophase.

Reactions of α-aryl carbonyl compounds with lithium ester enolates

REINHOUT H. VAN DER VEEN, JAN A. J. GEENEVASEN, AND HANS CERFONTAIN[1]

Laboratory for Organic Chemistry, University of Amsterdam, Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands

Received December 9, 1983

REINOUT H. VAN DER VEEN, JAN A. J. GEENEVASEN, and HANS. CERFONTAIN. Can. J. Chem. **62**, 2202 (1984).

This report describes the synthesis of β-hydroxy esters in good yields by reaction of α-aryl substituted ketones and phenylethanal with lithium methyl acetate and derivatives as anionoid reagents. The incomplete substrate conversion is ascribed to the enolate formation of the α-aryl carbonyl compounds, which concurrent reaction is negligibly small with aliphatic carbonyl compounds. The conversion of β-tetralone with lithium methyl acetate has been examined in some detail.

REINOUT H. VAN DER VEEN, JAN A. J. GEENEVASEN, et HANS. CERFONTAIN. Can. J. Chem. **62**, 2202 (1984).

La réaction, en présence d'acétate de méthyl lithium ou de ses dérivés qui agissent comme réactifs anionoïdes, du phényléthanal avec des cétones portant des groupes aryles en position α correspond à une synthèse efficace des β-hydroxy esters qui sont obtenus avec de bons rendements. Le fait que la conversion du substrat n'est pas complète est probablement dû à la formation de l'énolate des composés carbonylés substitués en α par des groupes aryles; la réactivité de ces énolates vis-à-vis les composés carbonylés aliphatiques est faible. On a étudié plus en détail la conversion de la β-tétralone avec l'acétate de méthyl lithium.

Introduction

Lithiated enolates and dienolates are currently investigated by virtue of their applicability in organic synthesis, as appears from recent reports (1, 2). The broad accessibility of lithiated anions and dianions by proton abstraction from active methylene compounds such as nitriles (3, 4), esters (4), and acids (5) using lithium diisopropylamide (LiDIPA) as base is advantageous. Also the high yield in which α-haloalkyllithium reagents are formed on reaction of α,α-dihalogenoalkanes with butyllithium deserves attention (6). Recently, Freeman and Hutchinson and Bogdanović and Wermeckes developed a special route in which alkyl halogenides are converted into alkyllithium reagents in excellent yields (7).

The use of lithium methyl acetate (LiMA) as a synthon to convert aliphatic ketones into β-hydroxy esters was already described by Hauser and Dunnavant (8) and Rathke (9) as an improvement on the usual Reformatski procedure (10). With the latter method excellent yields of β-hydroxy esters are obtained within minutes on using ultrasonic irradiation (11). The use of the Reformatski reagent on a large synthetic scale is troublesome in view of the high exothermicity of the addition reaction.

Application of the addition of lithium enolates to aldehydes or ketones opens a route to α-vinylation.[2] Rathke and Sullivan (14) examined the addition of acetone to the lithium enolate of ethyl crotonate which afforded 78% of the β-hydroxy ester. However, several attempts to dehydrate the formed adduct in acidic or basic medium unexpectedly failed.[2] Also, various methods using *in situ* formed intermediates derived from methyl 2-(1′-hydroxy-1′-methyl)ethylbut-3-enoate with (*i*) methanesulfonyl chloride, (ii) thionyl chloride and pyridine, (iii) phenol, or (iv) trifluoromethanesulfonyl chloride and pyridine did not show the desired elimination, and frequently the starting β-hydroxy ester was recovered unchanged.[3]

A promising route leading to α-vinylation of β,γ-unsaturated carbonyl compounds would be the one-step joining reaction of activated olefins with thiolate anions and aldehydes or ketones (15), but the dehydration of the resulting β-hydroxy ester afforded the lactone rather than the desired diene ester. A successful route for α-vinylation proved to be the Michael addition of phenyl vinyl sulfoxide to β,γ-unsaturated esters and ketones (16).

Results and discussion

The conversion of a number of α-aryl ketones into the corresponding β-hydroxy esters has been carried out under the conditions described by Rathke (9) in satisfactory yields (Table 1). In the crude reaction mixtures there remained starting material. If the isolated yields are corrected for the amounts of (recovered) starting material then the converison is quantitative. This agrees with the observation that the ^{1}H nmr spectra of the crude reaction mixture residues only contained absorptions of the β-hydroxy ester and the starting ketone. Based on these observations and those of Kikkawa and Tadahiko (17), the incomplete substrate conversion is ascribed to the acidity of the α-hydrogen(s) of the α-aryl ketones and aldehyde (lithium methyl acetate enol is not only a reactive nucleophile but also a strong base), which leads to an unprofitable storage of these carbonyl compounds as their enol anions.[4] It should be realized that the acidity of the α-hydrogens is very much higher with the presently studied α-aryl ketones than aliphatic ketones which give higher yields of the β-hydroxy ester than the former (cf. entry XII with, for example, entry V).

The conversion of β-tetralone has been examined under different reaction conditions in order to obtain information as to

[1]Author to whom correspondence may be addressed.

[2]A useful synthetic application in this field developed by Clive et al. (12) and Kowalski and Dung (13) is the reaction of (phenylseleno)ethanal with lithium- and zinc-enolates prepared from ketones; PhSeOH elimination from the resulting addition product affords β,γ-enones. In a similar way Hudrlik and Kulkarni effected electrophilic α-vinylation by addition of α-(*tert*-butyldimethylsilyl)-aldehydes to lithium enolates of ketones or esters and subsequent elimination using $BF_3 \cdot Et_2O$ (13).

[3]P. M. N. Nossin and W. N. Speckamp, unpublished results.

[4]Profitable use of storage of a ketone as enolate is made in the well-known reaction of esters with Grignard reagents using an excess of triethylamine (17, 18). The intermediate ketone is then converted rapidly into its enolate, thus preventing subsequent addition of the Grignard reagent to the ketone which would yield the corresponding tertiary alcohol.

TABLE 1. Reaction of $CR^1R^2{=}C(OCH_3)OLi$ in the presence of an amine in THF at −78°C with α-aryl ketones and an aldehyde

[a]DIPA, N-IPCHA, and DTSA stand for diisopropylamine, *N*-isopropylcyclohexylamine, and di(trimethylsilyl)amine respectively.
[b]Number of equivalents relative to the amount of substrate.
[c]Yields without parentheses refer to isolated products, those within parentheses to yields estimated from ^1H nmr spectra of the reaction mixture residue.
[d]Some of the β,γ-unsaturated esters obtained by dehydration of the corresponding β-hydroxy ester contained up to 10% of the corresponding α,β-isomer.
[e]The reaction was performed as described before with reported yields of 50 and 83% for **5** and **5***a* respectively; see ref. 22.
[f]See ref. 9.

the origin of the incomplete substrate conversion. β-Tetralone on reaction with 1.0 equiv. LiMA, prepared using 1.0 equiv. LiDIPA, affords the addition product in 58% (entry V). Upon reaction with 2.0 equiv. LiMA (prepared using 2.0 equiv. of LiDIPA, entry VI), higher yields are obtained (75%), whereas an excess of diisopropyl amine (DIPA, 10 equiv., entry VII) reduces the yield of the β-hydroxy ester to 32%. The effect of the excess of amine implies a decrease in the ratio of the effective nucleophilicity to basicity of the LiMA, which may be the result of the change in the solvent composition or of coordination of the amine to the lithium of the LiMA. Attempts to suppress the substrate enolization by increasing the temperature up to −30°C, which was thought to accelerate the nucleophilic attack (19), had no effect (entry IX). Above −30°C the DIPA solution coloured due to self condensation as already described by Rathke (9). Also the use of a more sterically hindered amine such as di(trimethylsilyl)amine, chosen with the aim of decreasing the degree of enolate formation of the α-aryl ketones, was not successful (cf. entries III and X).

The nucleophilic attack of ester enolates on α-aryl carbonyl compounds is very susceptible to steric hindrance. This may be concluded from the lower yield of β-hydroxy ester on coupling of 2-phenylcyclopentanone with lithium methyl isobutyrate (39%, entry II) as compared with lithium methyl acetate (87%, entry III). In a similar way the low yield of β-hydroxy ester from β-tetralone and lithium methyl propionate (25%, entry VIII) as compared with lithium methyl acetate (58%, entry V) may be explained. The yield of coupling LiMA to 2-indanone is higher (80%, entry IV) as compared with its addition to β-tetralone (58%, entry V). This may be explained in terms of a lower degree of steric hindrance for the addition to 2-indanone, but also in terms of a reduction in the strain of the five-membered ring upon forming the addition intermediate.

Some of the prepared β-hydroxy esters have been dehydrated with thionyl chloride and pyridine in benzene (see Table 1) to yield the corresponding β,γ-unsaturated esters.

Experimental

The ^1H nmr spectra were recorded in $CDCl_3$ or CCl_4 as solvent on a Varian A 60-D or a Varian XL-100 FT spectrometer, using TMS as internal reference. The ir spectra were recorded on a Perkin Elmer 257 grating infrared spectrometer or a Perkin Elmer 298 instrument, using a neat film of purified oils or $CHCl_3$ solutions. Microanalyses were performed by the Institute for Organic Chemistry, TNO, Utrecht. The glc analyses were carried out on a Varian Model-3700 chromatograph and the semi-preparative glc separations were conducted using a Varian Model-2700 chromatograph.

THF was freshly distilled prior to use from sodium wire using benzophenone as indicator under nitrogen. $SOCl_2$ and pyridine were purified as described (20).

General procedure for the conversion of α-aryl ketones

To a solution of 30.4 g (300 mmol) diisopropylamine in 200 mL THF, 200 mL (300 mmol) n-BuLi in hexane (1.50 mmol/mL) were added dropwise over 45 min at −78°C, followed by slow addition of 300 mmol of the ester (30 min). The solution was stirred for 30 min and remained colourless. Then 1.0 equiv. (150 mmol) of the ketone was added rapidly at the desired temperature. The solution coloured immediately and the solution was stirred for another 30 min. Then the mixture was allowed to warm to −30°C and quenched with 100 mL aqueous THF (THF−H_2O, 1:1 v/v). Subsequently 100 mL 10% aqueous NH_4Cl was added and the solution acidified with 5% aqueous HCl to pH 4. The β-hydroxy ester was extracted with ether and the organic layer washed with 5% aqueous HCl (twice), water, brine, and then dried with anhydrous $MgSO_4$. The solvents were removed under reduced pressure, leaving a yellow oil which was distilled *in vacuo*.

Methyl 2-methyl-3-hydroxy-4-phenylbutanoate ***1***

Purified phenylethanal (2.45 g, 20.4 mmol) distilled from a mixture (1:1 v/v) with diethyl phthalate) was reacted with 40.8 mmol of lithium methyl propionate prepared from 4.14 g (40.9 mmol) diisopropylamine, 3.60 g (40.8 mmol) methyl propionate, and 28.5 mL (1.44 mmol/mL hexane) n-BuLi in 100 mL THF to afford a crude residual oil (4.60 g). Distillation at 105−107°C/1 Torr (1 Torr = 133.3 Pa) yielded 0.2 g of the aldehyde and 3.2 g of **1**, ir (liq. cap.; cm^{-1}): 3510, 3425 br (OH); 2980 (CH aliph.); 1735 (C=O); 1270, 1140 (O—CH_3); 700 (C_6H_5); ^1H nmr (CCl_4), 60 MHz (δ in ppm): 7.1 (s, 5H, arom.), 4.3−3.6 (m, C*H*—OH), 3.6 (s, 3H, OCH_3), 2.7 (br s, 1H, OH), 2.6 (d, J = 6 Hz, 2H, CH_2), 2.7−2.2 (m, 1H, CH—CO), 1.2 (d, J = 7 Hz, 3H, CH_3). *Anal.* calcd. for $C_{12}H_{16}O_3$: C 69.21, H 7.74; found C, 69.31, H 7.70.

Dehydration of **1** with thionyl chloride and pyridine failed and so did the reaction of **1** with concentrated hydrochloric acid in ethanol

and with a catalytic amount of diethylamine in ethanol. In all cases only the starting material was recovered.

Methyl 2-(1'-hydroxy-2'-phenylcyclopentyl)-2-methylpropanoate **2**

2-Phenylcyclopentanone (21) was treated with lithium methyl isobutyrate, and afforded 42 g of the crude mixture which contained 61% of the ketone and 39% of the β-hydroxy ester. In this case lithium *N*-isopropylcyclohexylamide was used for the preparation of lithium methyl isobutyrate. Distillation *in vacuo* at 73−75°C/0.05 Torr yielded 11.7 g (45%) of the ketone and 14.8 g (34%) of the β-hydroxy ester **2**; ir ($CHCl_3$, cm^{-1}): 3550, 2960 br (OH); 3000, 2960 (CH, aliph.); 1725 (C═O); 1280, 1150 (O—CH_3); 700 (C_6H_5); ^1H nmr (CCl_4), 60 MHz (δ in ppm): 7.2 (m, 5H, arom.), 3.5 (s, 1H, OH) 3.1 (s, 3H, OCH_3), 2.9 (t, J = 9 Hz, 1H, methine-H), 2.2−1.6 (m, 6H, $CH_2CH_2CH_2$), 1.2^2 + 1.1^9 (ds, 6H, $C(CH_3)_2$). *Anal.* calcd. for $C_{16}H_{22}O_3$: C 73.25, H 8.45; found: C 73.20, H 8.42.

Methyl 2-(2'-phenylcyclopent-1'-enyl)-2-methylpropanoate **2***a*

Dehydration of the β-hydroxy ester **2** (14.8 g) with thionyl chloride and pyridine afforded upon distillation (97−101°C/0.08 Torr), 12.3 g (89%) of a mixture containing the β,γ-unsaturated ester **2***a* and its β,γ-unsaturated isomer in a ratio of 4:1. Renewed distillation (bp 85−90°C/0.05 Torr) yielded 10.2 g of a colourless oil which was further purified by preparative glc (copper column, l = 3 m, ϕ = 1/4 in., 12% SE-30 on Chromosorb WAW 60−80 mesh, 180°C, helium flow rate 20 mL/min); ir ($CHCl_3$, cm^{-1}): 2960, 2850 (CH, aliph.); 1720 (C═O); 1280, 1165 (O—CH_3); 700 (C_6H_5); ^1H nmr ($CDCl_3$), 100 MHz (δ in ppm): 7.2−6.9 (m, 5H, arom.), 3.07 (s, 3H, OCH_3), 2.75−2.40 (m, 4H, CH_2—CH_2—CH_2), 2.05 (m, 2H, CH_2—CH_2—CH_2), 1.2 (s, 6H, $C(CH_3)_2$). *Anal.* calcd. for $C_{16}H_{20}O_2$: C 78.65, H 8.25; found: C 78.61, H 8.27.

Methyl 2-(1'-hydroxy-2'-phenylcyclopentyl)ethanoate **3**

2-Phenylcyclopentanone (21) (23.5 g, 147 mmol) was converted with 147 mmol lithium methyl acetate, prepared from 10.9 g (147 mmol) methyl acetate, 25.3 g di(trimethylsilyl)amine, and 100 mL n-BuLi in hexane (1.50 mmol/mL). The residue (31.4 g) was distilled *in vacuo* (125−127°C/1 Torr) and yielded 1.9 g (11.9 mmol), i.e. 8%, recovered ketone (bp 94−100°C/0.1 Torr) and 27.6 g (80%) of the 3-hydroxy ester **3** (bp 100−102°C/0.07 Torr); (ir liq. cap., cm^{-1}): 3550 (OH); 2970 (CH, aliph.); 1740, 1730 (C═O); 700 (C_6H_5); ^1H nmr (CCl_4), 60 MHz (δ in ppm): 7.2−7.1 (m, 5H, arom.), 3.5 (s, 3H, OCH_3), 2.7 (br s, 1 H, OH), 2.4 (s, 2H, CH_2CO), 2.4−1.8 (m, 7H, aliph.). *Anal.* calcd. for $C_{14}H_{18}O_3$: C 71.77, H 7.74; found: C 71.69, H 7.77.

Methyl 2-(2'-phenylcyclopent-1'-enyl)ethanoate **3**a

Dehydration of the β-hydroxy ester **3** (27.3 g) with thionyl chloride and pyridine afforded after distillation (88−90°C/0.1 Torr) 21.5 g of a mixture of the β,γ-unsaturated ester **3***a* and the α,β- and β,γ'-unsaturated ester isomers in a ratio of 6:3:1. Compound **3***a* was isolated and purified by preparative glc (copper column, l = 3 m, ϕ = 1/4 in., 12% SE-30 on Chromosorb WAW 60−80 mesh, 190°C, helium flow rate 20 mL/min.); ir ($CHCl_3$, cm^{-1}): 2970 (CH, aliph.); 1710 (C═O); 1600, 700 (C_6H_5); ^1H nmr (CCl_4), 60 MHz (δ in ppm): 7.3−7.0 (m, 5H, arom.), 3.6 (s, 3H, OCH_3), 3.1 (s, 2H, CH_2CO), 2.9−2.3 (m, 4H, aliph.), 2.1−1.6 (m, 2H, aliph.). *Anal.* calcd. for $C_{14}H_{16}O_2$: C 77.75, H 7.46; found: C 77.77, H 7.44.

Methyl 2-(2'-hydroxy-2'-indenyl)ethanoate **4**

2-Indanone (5 g, 37.8 mmol) was converted with 37.8 mmol lithium methyl acetate, prepared from 37.8 mmol lithium diisopropylamine in 100 mL THF, as described in the general procedure. The residue (7.5 g) contained 18% 2-indanone and 82% β-hydroxy ester. Distillation *in vacuo* (101°C/0.02 Torr) afforded 5 g (75%) of pure **4**; ir (liq. cap., cm^{-1}): 3545, 3440 br (OH); 2980 (CH, aliph.); 1740 (C═O); 1265, 1150 (O—CH_3); 705 (C_6H_4); ^1H nmr ($CDCl_3$), 60 MHz (δ in ppm): 7.1 (s, 4H, arom.), 3.6 (s, 4H, OCH_3 and OH), 3.0 (s, 4H, benzylic CH_2's), 2.6 (s, 2H, CH_2CO). *Anal.* calcd. for $C_{12}H_{14}O_3$: C 69.88, H 6.84; found: C 69.74, H 6.87.

Methyl 2-(2'-hydroxy-1',2',3'4'-tetrahydro-2'-naphthyl)ethanoate **5**

β-Tetralone (10.0 g, 68 mmol) was reacted with 136 mmol lithium methyl acetate prepared from 136 mmol lithium diisopropylamide in 300 mL THF to yield eventually a residue of 14.2 g. Based on the 1H nmr spectrum, it contained 25% unreacted ketone and 75% of the β-hydroxy ester. Distillation afforded 2.2 g β-tetralone (22%) and 10.4 g (69%) of the β-hydroxy ester **5** (bp 115°C/0.01 Torr); ir (liq. cap., cm^{-1}): 3540, 3440 br (OH); 2980 (CH, aliph.); 1735 (C═O), 1270, 1140 (O—CH_3); 700 (C_6H_4); ^1H nmr ($CDCl_3$), 60 MHz (δ in ppm): 6.90 (s, 4H, arom.), 3.60 (s, 3H, OCH_3), 3.40 (s, 1H, OH), 2.75 (br s, 2H, CH_2CO), 3.0−2.4 (m, 2H, C_{ar}—CH_2—CH_2), 2.45 (s, 2H, C_{ar}—CH_2—C_q), 2.01−1.5 (m, C_{ar}—CH_2—CH_2). *Anal.* calcd. for $C_{13}H_{16}O_3$: C 70.89, H 7.32; found: C 70.52, H 7.34.

Methyl 2'-(3',4'-dihydro-2'-naphthyl)ethanoate **5**a

The β-hydroxy ester **5** was dehydrated with thionyl chloride and pyridine in benzene to yield 75% of **5***a*. After distillation (115°C/0.015 Torr) the β,γ-unsaturated ester proved to be admixed with ca. 20% of the α,β-unsaturated isomer; an analytical sample was obtained by preparative glc (copper column, l = 5 m, ϕ = 1/4 in., 15% SE-30 on Chromosorb WAW 60−80 mesh, 240°C, helium flow rate 60 mL/min); ir (liq. cap., cm^{-1}): 2960, 2940 (CH, aliph.); 1740 (C═O); 1260, 1160 (O—CH_3); 770, 765 (C_6H_4); ^1H nmr (CCl_4), 60 MHz (δ in ppm): 7.2−7.0 (m, 4H, arom.), 6.30 (br s, 1H, olef.), 3.70 (s, 3H, OCH_3), 3.20 (br s, 2H, CH_2CO), 3.5−2.0 (m, 4H, CH_2−CH_2). *Anal.* calcd. for $C_{13}H_{14}O_2$: C 77.20, H 6.98; found: C 77.21, H 7.00.

Methyl 2-(2'-hydroxy-1',2',3',4'-tetrahydro-2'-naphtyl)propanoate **6**

This compound was prepared as described for **5** using lithium methyl propanoate instead of lithium methyl acetate. Based on the ^1H nmr spectrum, the residue contained 25% of the β-hydroxy ester and 75% unreacted ketone; ^1H nmr ($CDCl_3$), 60 MHz (δ in ppm): 6.90 (m, 4H, arom.), 4.1−3.8 (m, 1H, C_tH), 3.6 (s, 3H, OCH_3), 3.30 (br s, 1H, OH), 3.2−2.7 (m, 2H, C_{ar}—CH_2—CH_2), 2.7 (br s, 2H, C_{ar}—CH_2—C_q), 1.9−1.6 (m, 2H, C_{ar}—CH_2—CH_2), 1.3 + 1.1 (dd, J = 7 Hz, 3H, C_tCH_3).

Received November 3, 1983

FUMIO MORIYA, NAOHISA IGUCHI, KEISUKE MAKINO, SOUJI ROKUSHIKA, and HIROYUKI HATANO. Can. J. Chem. **62**, 2206 (1984).

The γ-irradiated aqueous solutions of four tripeptides were studied by the spin-trap hplc–esr method with 2-methyl-2-nitrosopropane. Four types of spin adducts were separated and identified as follows: (a) deamino adducts derived from short-lived radicals produced by reductive deaminations from the addition of hydrated electrons to the N-terminal peptide carbonyl groups, (b) C-terminal backbone adducts, (c) internal backbone adducts, and (d) side-chain adducts derived from short-lived radicals produced by hydrogen abstractions by hydroxyl radicals, mainly from so-called α-carbons in the C-terminal and internal main-chains and a carbon in an aliphatic side-chain, respectively. For polyglycine, internal backbone radicals produced by hydrogen abstraction were spin-trapped and detected.

FUMIO MORIYA, NAOHISA IGUCHI, KEISUKE MAKINO, SOUJI ROKUSHIKA et HIROYUKI HATANO. Can. J. Chem. **62**, 2206 (1984).

Faisant appel à la méthode rpe–clhp des pièges à spin et opérant dans des solutions aqueuses, on a étudié les réactions du méthyl-2 nitroso-2 propane avec quatre tripeptides irradiés aux rayons-γ. On a isolé quatre types d'adduits de spin et on les a identifiés comme suit: (a) les adduits désaminés provenant de radicaux à faibles temps de vie produits par la désamination réductrice causée par l'addition d'électrons hydratés sur les groupes carbonyles des peptides en position N-terminale, (b) les adduits sur le squelette carboné en position C-terminale, (c) les aduits en position interne du squelette carboné et (d) les adduits sur les chaines latérales qui proviennent de radicaux de faibles temps de vie qui ont été produits respectivement (pour les trois dernières catégories) par l'élimination d'hydrogènes, par des radicaux hydroxyles, des soit-disants carbones en α soit des chaînes principales en position C-terminale (cas b) ou interne (cas c) soit d'un carbone dans la chaîne latérale aliphatique (cas d). Dans le cas de la polyglycine, on a piégé les spin et détecté les radicaux formés par une abstraction d'hydrogène en position interne du squelette carboné.

Introduction

In order to understand the radiation chemistry of aqueous solutions of proteins, several workers have done numerous studies concerning such systems as amino acids and peptides (1–3, and refs. therein). Transient free radicals produced in proteins by active radiolytic species of water, hydrated electrons (e^-_{aq}), hydroxyl radicals (·OH), hydrogen atoms (·H), etc., are quite conceivably the primary species responsible for the radiation effects on proteins (2, 3).

For the elucidation of primary processes in the radiation chemistry of biomolecules, the analysis of unstable transient species has been introduced and has rapidly become important (2, 4). The spin-trapping method (5–7, and refs. therein) is one of several valuable techniques for detecting and identifying transient short-lived radicals in various reaction systems by means of which short-lived radicals are converted into relatively stable aminoxyl radicals[3] (spin adducts) through reactions with spin traps such as nitroso and nitrone compounds. When 2-methyl-2-nitrosopropane (MNP) is used as a spin trap, its reaction with a short-lived radical (R·) is represented by eq. [1].

The spin-trapping method with MNP has been applied to γ- and uv-irradiated aqueous solutions of amino acids and peptides (3, 9–13). Because of the complexity of the esr spectra arising from the overlapping of signals of several spin adducts present, however, few of the components could be identified. To better analyze such spectra, high-performance liquid chromatography (hplc) has been combined with spin trapping (the spin-trap hplc–esr method), and been applied to studies on γ-irradiated aqueous systems of several amino acids (14–20). The main general mechanisms found for aliphatic amino acids were reductive deamination reactions induced by e^-_{aq} addition to carboxyl carbons (eq. [2]) (2) and hydrogen abstraction

[1] $$t\text{-Bu}-N{=}O + R\cdot \longrightarrow t\text{-Bu}-\underset{\underset{O\cdot}{|}}{N}-R \leftrightarrow t\text{-Bu}-\overset{+}{\underset{\underset{O^-}{|}}{N}}\cdot-R$$

[2] $$NH_3^+-\underset{\underset{R}{|}}{CH}-\underset{\underset{O}{\|}}{C}-O^- + e^-_{aq} \longrightarrow NH_3^+-\underset{\underset{R}{|}}{CH}-\underset{\underset{O^-}{|}}{\dot{C}}-O^- \longrightarrow NH_3 + \cdot\underset{\underset{R}{|}}{CH}-\underset{\underset{O}{\|}}{C}-O^-$$

[3] $$\rangle C-H + \cdot OH \longrightarrow \rangle C\cdot + H_2O$$

reactions from most of the saturated alkyl carbons mainly by ·OH (eq. [3]). Especially in the case of L-isoleucine, spin adducts derived from the H abstractions from all of the C—H bonds were separated and detected (16).

When one wants to obtain basic information concerning the radiation damage of the main-chain structures in proteins, the use of peptides composed of glycine and L-alanine seems to simplify this subject. In previous papers (21, 22) we have

[3] The term "aminoxyl" was introduced during the International Symposium on Spin Trapping and Nitroxyl Radical Chemistry (at the University of Guelph, Guelph, Ont., Canada, July 12–18, 1981) and was deemed more appropriate than "nitroxyl"; see ref. 8.

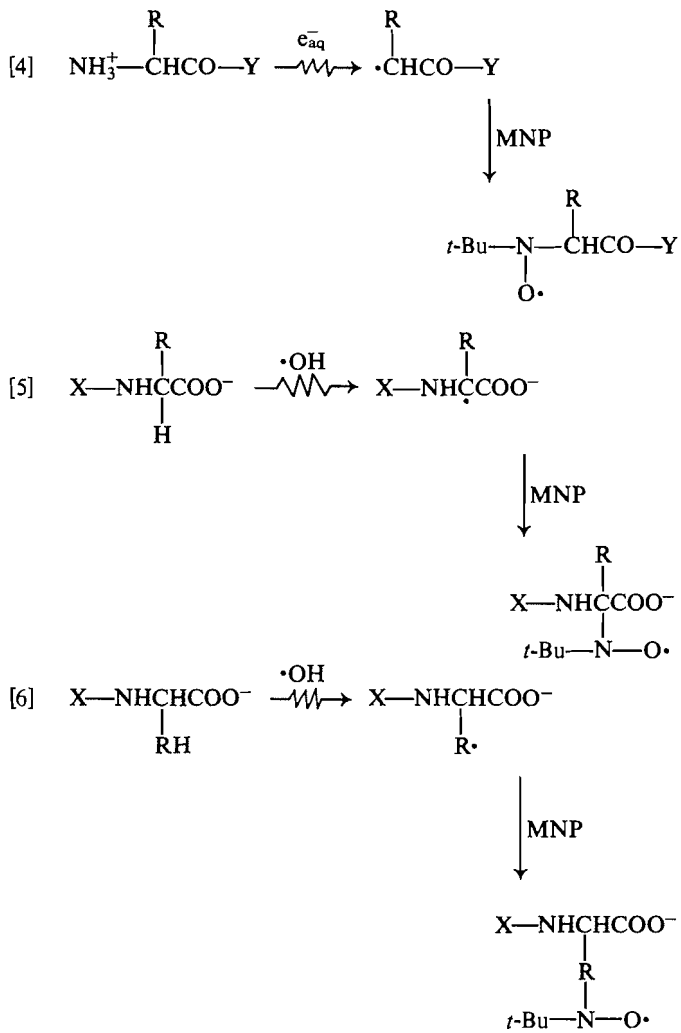
demonstrated that spin adducts produced in γ-irradiated aqueous solutions of dipeptides (Gly-Gly, Gly-L-Ala, L-Ala-Gly, and L-Ala-L-Ala) with MNP could be identified by this technique. These studies indicated that most of the short-lived radicals found in aqueous solutions of the dipeptides by other methods (23, 24) were spin-trapped. Consequently, γ-radiolytic and spin-trapping mechanisms shown in eqs. [4]–[6] for dipeptides have been proposed,



where X and Y represent amino acid residues, R is H or a side-chain, RH is an aliphatic side-chain, and the left, central, and right members of each equation are a dipeptide, a short-lived radical, and a spin adduct, respectively. The spin adduct in eq. [4] is derived from a deaminated radical resulting from the addition of e^-_{aq} to the peptide carbonyl group (2, 25). The spin adducts in eqs. [5] and [6] are produced from radicals generated by hydrogen abstractions from a so-called α-carbon in the C-terminal main-chain and a carbon in an aliphatic side-chain, respectively, mainly by ·OH. The spin adducts in eqs. [4]–[6] have been called a deamino adduct, a C-terminal backbone adduct, and a side-chain adduct, respectively.

This information about the amino acids and dipeptides (14–22) can be a good guide for understanding the radiation damage of N- and C-terminals and aliphatic side-chains in proteins. However, it gives no evidence of the radiation damage of inner parts of the main-chains in proteins. In the present work, in order to explore the primary radiation-chemical processes of inner parts of the main-chains, γ-irradiated aqueous solutions of tripeptides (Gly-Gly-Gly, Gly-Gly-L-Ala, Gly-L-Ala-Gly, and L-Ala-Gly-Gly) have been studied by the spin-trap hplc–esr method with MNP. Most of the spin adducts expected from eqs. [4]–[6] were found and characterized. Internal backbone adducts derived in analogy with C-terminal backbone adducts were newly found. We have also studied spin-trapping of γ-irradiated aqueous solutions of polyglycine and detected its internal backbone adduct.

Experimental

MNP was synthesized and purified according to the method of Stowell (26). Gly-Gly-Gly, Gly-Gly-L-Ala, L-Ala-Gly-Gly, and polyglycine (approximate molecular weight was 6000) were purchased from Sigma Chemical Co., Saint Louis, MO, USA. Gly-L-Ala-Gly was supplied from Prof. Haruaki Yajima, Kyoto University. Potassium nitrosodisulfonate (Fremy's salt, $\cdot ON(SO_3K)_2$) was synthesized and purified according to the method of Moser and Howie (27). All other chemicals were of reagent grade.

The tripeptides (0.1 *M*) were dissolved in 5 mg/mL of MNP aqueous solutions (28). Each of the sample solutions was cooled by ice and irradiated with ^{60}Co γ-rays at a dose rate of ca. 75 Gy/min to a total dose of 3 kGy (unless otherwise specified) without deaeration. The concentration of phosphoric ion in the irradiated solution was adjusted to that in the starting eluent by 2 *M* sodium phosphate, and 1.0 mL of the solution was added to a 0.75 × 60 cm cation-exchange column (IEX-210SC of Toyo Soda Manufacturing Co., Tokyo, Japan). The hplc was a Toyo Soda HLC-803. The eluate was passed through uv and esr detectors and collected into fraction tubes. The uv detector was a JASCO UVIDEC 100 (10-mm light path), which was tuned to 240 nm. The esr spectrometer was a JEOL PE-3X, which was operated at 100-kHz modulation frequency in the X-band. For detection of the radicals during chromatography, the magnetic field was fixed at the position where the esr signals were expected. The magnetic field modulation was used at a high amplitude of 1 mT to cover a wide range. A quartz flow cell (the practical part being 0.6 mm id and 5 cm long) was fixed in the esr cavity. Each of the parts in the chromatographic system was connected with 0.25-mm id PTFE tubing.

The esr spectra were recorded at ca. 25°C in the dark. The hyperfine splitting constants (hfsc's) were measured with Mn^{2+} in MgO as a reference. The concentration of the radicals was estimated by double integration of the first-derivative esr signal with a JEOL JEC-980A mini-computer, which was compared with Fremy's salt of known concentrations. Ninhydrin-positive fractions were analyzed by an amino acid analyzer (KLA-3B of Hitachi Corporation, Hitachi, Japan).

For other experimental details previous publications can be consulted (21).

Results and discussion

Glycylglycylglycine

Figure 1(a) shows the esr spectrum of a γ-irradiated aqueous Gly-Gly-Gly solution with MNP. The esr signals asterisked in Fig. 1(a) decayed relatively quickly and disappeared within 1 h. The chromatogram of the solution by uv and esr detections is shown in Fig. 1(b). The esr chromatogram exhibited three peaks (A–C) as shown by the solid line. Typical esr spectra for the fractions of peaks A–C are depicted in parts (a), (b) and (e) of Fig. 2, respectively. Most of the spin adducts produced by the self-trapping of MNP (29) were adsorbed on the column and eluted very slowly. In the uv chromatogram shown by the broken line in Fig. 1(b), peak D′ was due to intact Gly-Gly-Gly and peak E′ was mainly due to *tert*-butylnitrosohydroxylamine (*t*-BuN(OH)N=O) (28).

Figure 2(a) shows the esr spectrum (0.05 mT modulation amplitude) obtained for the peak A fraction, which can be

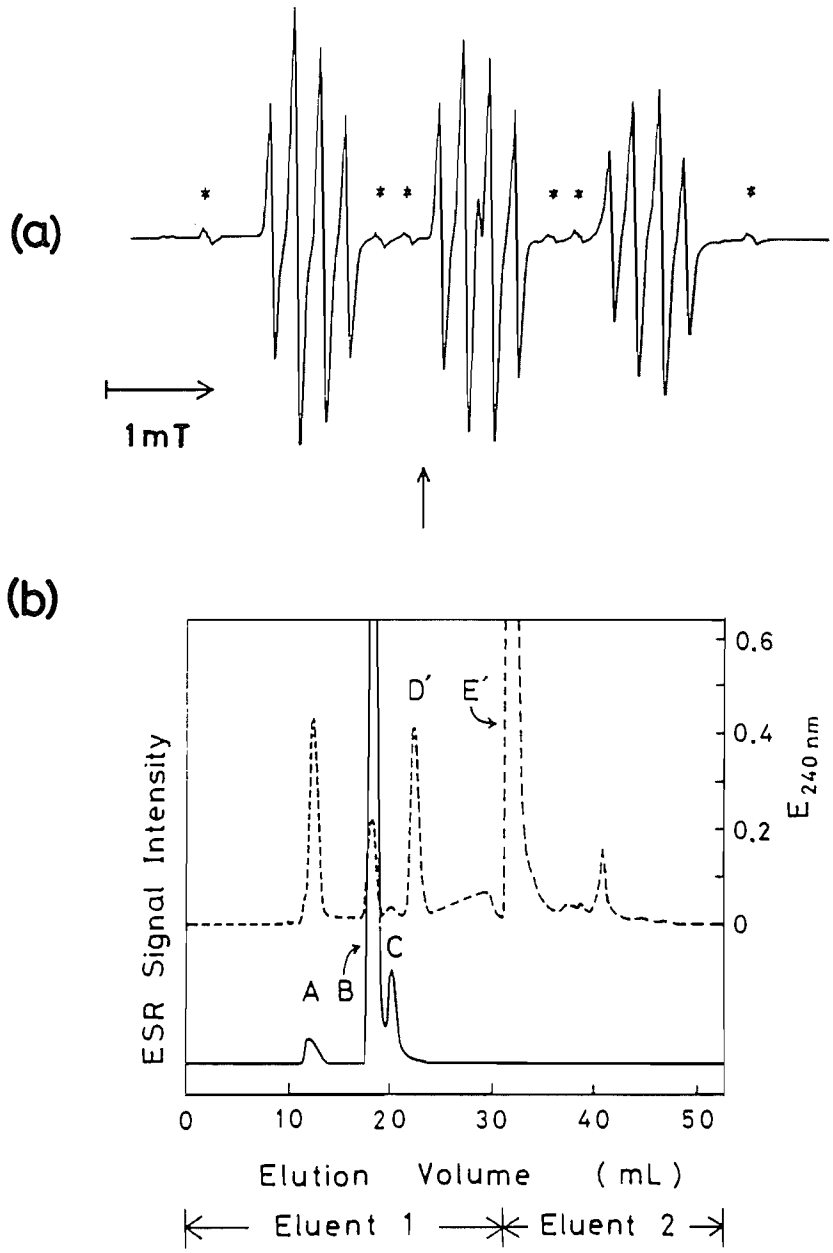

FIG. 1. (a) The esr spectrum of an aqueous solution of Gly-Gly-Gly with MNP observed just after γ-irradiation (at pH 5.7). During chromatography the magnetic field was fixed at the position indicated by the vertical arrow. (b) Chromatogram of the solution drawn by uv (broken line) and esr (solid line) detections: flow rate, ca. 0.3 mL/min; eluent 1, 0.25 *M* sodium phosphate buffer, pH 6.0; eluent 2, 0.2 *M* Na_2HPO_4–NaOH buffer, pH 11.5.

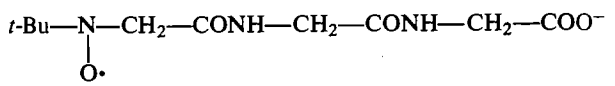
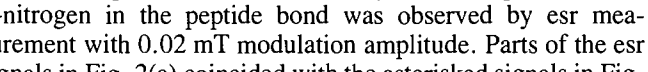
analyzed as a triplet-triplet. The primary triplet of 1.58 mT splitting is due to the nitrogen nucleus in the aminoxyl group. The secondary triplet of 0.92 mT splitting with an intensity ratio of 1:2:1 is assigned to two equivalent β-hydrogens. The spin adduct was assigned to structure **1**, the deamino adduct from Gly-Gly-Gly, on the basis of its hyperfine structure (hfs)



1

and elution position. In addition, a 0.03-mT triplet due to a γ-nitrogen in the peptide bond was observed by esr measurement with 0.02 mT modulation amplitude. Parts of the esr signals in Fig. 2(a) coincided with the asterisked signals in Fig. 1. The separated spin adduct **1** in the fraction of peak A was fairly stable in contrast to the unseparated one in the irradiated solution.

Parts (b) and (e) of Fig. 2 show the esr spectra for the fractions of peaks B and C, respectively, which are similar to each other. Each of them can be analyzed as a triplet of four lines with an apparent intensity ratio of 1:2:2:1. Around pH 6 the primary N-hfsc's (a_N) are 1.56 and 1.51 mT for peaks B and C, respectively. The difference between the N-hfsc's is significant. The secondary hfs is due to a β-hydrogen and a β-nitrogen ($a_{\beta H}$ = 0.20 mT and $a_{\beta N}$ = 0.24 mT for both peaks). This esr signal pattern suggests a spin adduct which has a



component part, *t*-BuN(O·)—CH—N<, that is, structure **2**, **3**, or **4**.

4

These spin adducts are derived from the hydrogen abstraction from one of three methylene groups in Gly-Gly-Gly.

In the neutral and alkaline solutions the esr spectral pattern of the peak B fractions was almost pH-independent (a_N = 1.59 mT, $a_{\beta H}$ = 0.20 mT, and $a_{\beta N}$ = 0.26 mT at pH 11.1), which suggests the absence of an amino group near the aminoxyl group. In contrast, in the acidic pH range (around pH 2) the spin adduct exhibited reversible pH-dependent shifts of the signals as shown in parts (c) and (d) of Fig. 2. At pH 0.6, the hfsc's a_N, $a_{\beta H}$, and $a_{\beta H}$ are 1.52, 0.16, and 0.255 mT, respectively. The remarkable spectral changes are mainly due to the increase in difference of the β-hfsc's and do not derive from new hyperfine splittings. Consequently, this acid dissociation property is ascribed to the protonation of a carboxyl group near the aminoxyl center, not to the protonation of the aminoxyl group itself which should give an additional H-hfsc of several gauss (30, 31). Therefore the spin adduct was assigned to the structure **2** (neither to **3** nor to **4**), the C-terminal backbone adduct from Gly-Gly-Gly. In the acid-dissociation equilibrium of the carboxyl group of adduct **2**, the observed hfsc's represented the weighted average of the acid form and the base form because of rapid interchange between the two forms (32).

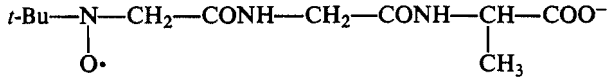
The esr spectral pattern for the peak C fraction changed little in the acidic, neutral, and alkaline pH ranges (a_N = 1.50 mT, $a_{\beta H}$ = 0.21 mT, and $a_{\beta N}$ = 0.235 mT at pH 0.7; a_N = 1.53 mT, $a_{\beta H}$ = 0.20 mT, and $a_{\beta N}$ = 0.23 mT at pH 11.2). This fact shows that neither a carboxyl group nor an amino group is close to the aminoxyl group. Therefore, the spin adduct was assigned to structure **3**, the internal backbone adduct from Gly-Gly-Gly.

The spectral pattern of spin adducts **2** and **3** near pH 6, a triplet of 1:2:2:1 quartet, is apparently a major component of the esr signals in Fig. 1(a). The signal component in the γ-irradiated solution exhibited reversible pH-dependent changes in the acidic pH range and changed little in the neutral and alkaline ranges. The pH effect on the spectral pattern was almost consistent with that of adduct **2**, not **3**. Therefore spin adduct **2**, which gives peak B, seems to be a major component of stable adducts from Gly-Gly-Gly. This inference is also supported by rough estimates of relative amounts of radicals in the fractions of the individual peaks.

Glycylglycyl-L-alanine

Figure 3 shows the esr spectrum and chromatogram of a γ-irradiated aqueous Gly-Gly-L-Ala solution with MNP, respectively. The esr signals asterisked in Fig. 3(a) decayed relatively quickly. The signal intensity at 33 min after the irradiation was one eighth that at 5.5 min. The time-dependent decay curve of the signal indicated that the kinetic order is larger than one. The esr chromatogram exhibited four peaks (A–D) as shown by the solid line in Fig. 3(b). Typical esr spectra for the fractions of peaks A–D are depicted in parts (a)–(d) of Fig. 4, respectively. In the uv chromatogram shown by the broken line in Fig. 3(b), peak E′ was due to intact Gly-Gly-L-Ala and peak F′ was mainly due to *t*-BuN(OH)NO (28).

Figure 4(a) shows the esr spectrum (0.05 mT modulation amplitude) obtained for the peak A fraction. The hfsc's are given in Table 1. The spin adduct was assigned to structure **5**,



5

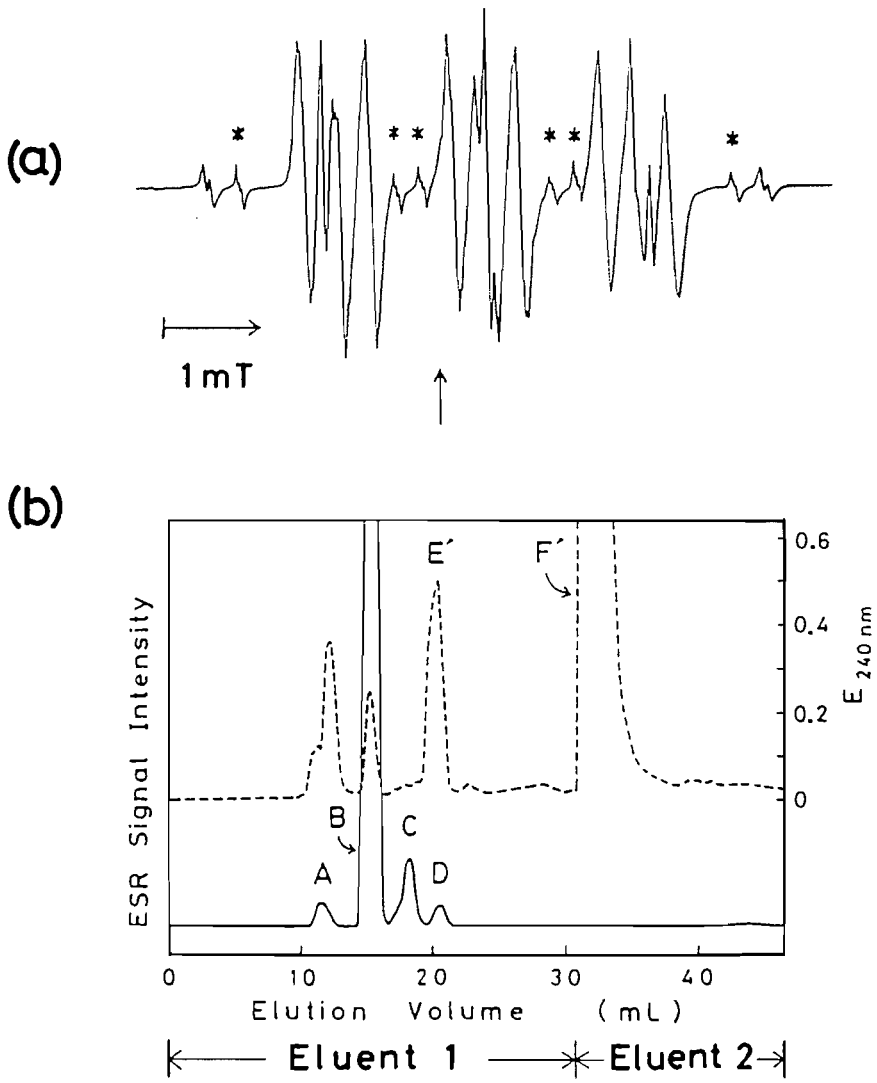


FIG. 3. (a) The esr spectrum of an aqueous solution of Gly-Gly-L-Ala with MNP observed just after γ-irradiation (at pH 5.7). During chromatography the magnetic field was fixed at the position indicated by the vertical arrow. (b) Chromatogram of the solution drawn by uv (broken line) and esr (solid line) detections: flow rate, ca. 0.2 mL/min; eluent 1, 0.25 *M* sodium phosphate buffer, pH 6.0; eluent 2, 0.2 *M* Na_2HPO_4–NaOH buffer, pH 11.5.

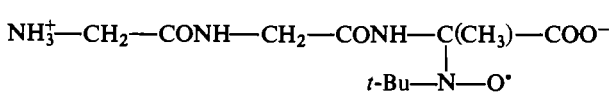
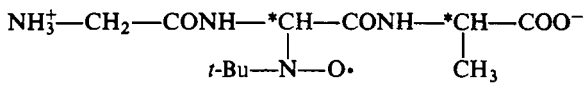
the deamino adduct from Gly-Gly-L-Ala. Parts of the esr signals in Fig. 4(a) coincided with the asterisked signals in Fig. 3(a). The separated spin adduct **5** in the peak A fraction was fairly stable.

Figure 4(b) shows the esr spectrum for the peak B fraction, which can be analyzed as a triplet-triplet, and which is apparently a major component of esr signals in Fig. 3(a). The primary hfsc of a nitrogen nucleus is 1.52 mT, and the secondary 0.33 mT triplet with equal intensities was assigned to a β-nitrogen. This esr signal pattern was assigned to structure **6**, the C-terminal backbone adduct from Gly-Gly-L-Ala.



6

Figure 4(c) shows the esr spectrum for the peak C. The secondary hfs consists of a β-hydrogen and a β-nitrogen. The spectral pattern was almost pH-independent. The hfsc's at pH 1.0, 6.0, and 12.0 are given in Table 1. The spin adduct was assigned to structure **7**, the internal backbone adduct from



7

Gly-Gly-L-Ala. Slight distortions observed in the esr spectra suggest the coexistence of a pair of diastereomeric adducts (15, 22, 33), *S-S* and *R-S* forms, by the primary asymmetric center of the L-alanyl residue and the new asymmetric center formed by the addition of MNP to the short-lived radical.

Figure 4(d) shows the esr spectrum for the peak D fraction, which apparently exhibits a mixture of six narrow and six broad lines. Each of the narrow lines further splits into a small doublet. Since the narrow set and the broad set gave the same *g* value and N-hfsc, the spectrum was inferred to be due to only one kind of spin adduct with line-width alternation (LWA). It can be analyzed as three groups of a 1:1:1:1 quartet whose internal pair is selectively broad. The hfsc's at pH 5.9 are as follows: a_N = 1.63 mT, $a_{\beta H}(2H)$ = 1.36 and 1.02 mT, and $a_{\gamma H}$ = 0.07 mT. Such a spectrum as shown in Fig. 4(d) is a typical pattern of an aminoxyl radical, *t*-BuN(O•)—CH_2—*CXYZ

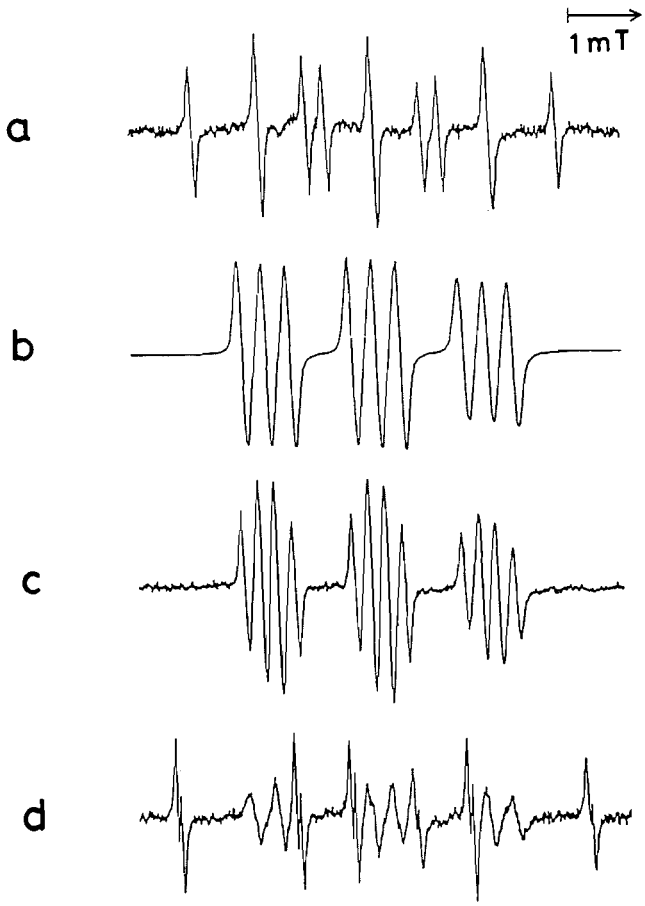

FIG. 4. The esr spectra of the separated spin adducts. (a)–(d) represent the spectra obtained from the fractions giving peaks A–D in Fig. 3(b), respectively. (a) and (d), pH 5.9; (b) and (c), pH 6.0.

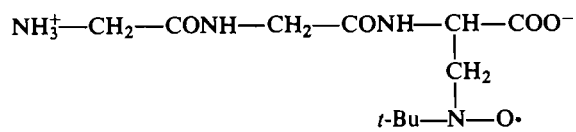
(34). The nonequivalence with LWA is interpreted by assuming, for instance, insufficiently rapid interconversion between two rotamers which have mutually different sets of β-H hfsc's. The mechanism of such hfs patterns has been discussed in detail by Gilbert and Trenwith (34). The spin adduct was assigned to structure **8**, the side-chain adduct from Gly-Gly-L-Ala.



8

The total concentration of stable spin adducts produced in the γ-irradiated aqueous solution of Gly-Gly-L-Ala (0.1 *M*) with MNP (5 mg/mL) was plotted against the total dose as shown in Fig. 5. Each of the concentrations was calculated from the esr spectrum obtained 3 h after the irradiation. The *G* value was estimated to be about 0.9 from the linearly increased range in Fig. 5. Although the *G* value of spin adducts does not always reflect that of short-lived radicals directly, the obtained spin adduct mixtures consist of adducts originating predominantly from Gly-Gly-L-Ala, particularly the backbone adducts. Therefore, the short-lived peptide radicals converted into the spin adducts seem never to be negligible during consideration of the primary processes of radiolysis of peptides.

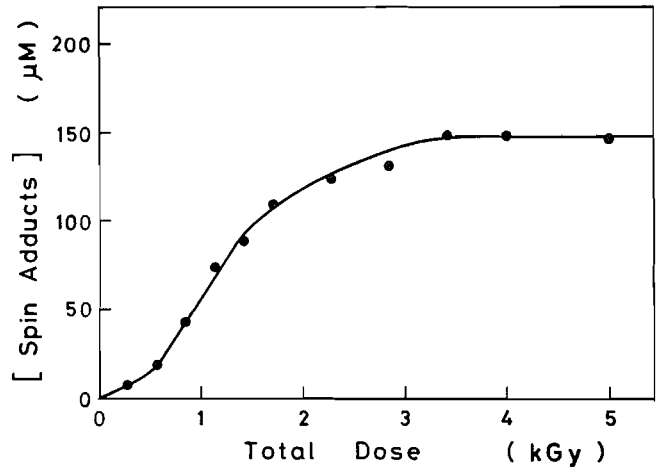


FIG. 5. Dose dependence of the concentration of stable spin adducts produced in γ-irradiated aqueous solutions of Gly-Gly-L-Ala with MNP. Each estimation of the concentration was carried out 3 h after the irradiation.

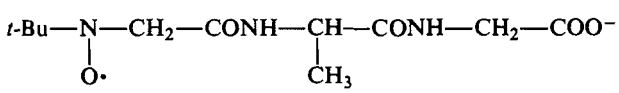
Figure 6 shows the dose dependence of the esr spectral patterns obtained from the γ-irradiated aqueous system of Gly-Gly-L-Ala with MNP. Most of the spin adducts which formed these spectra have already been separated individually by hplc and analyzed spectroscopically by esr. That is to say, spin adducts **5**–**8** from Gly-Gly-L-Ala were found in the present work, and the adducts by the self-trapping of MNP were reported in the previous paper (29). The observed spectral changes suggest transitions of concentration ratios of the individual spin adducts. For the complicated spectra shown in Fig. 6 it is very difficult to achieve computer simulations, even using the known esr parameters of these adducts, since there are too many parameters. Satisfactory simulated spectra have not been obtained so far.

Glycyl-L-alanylglycine

Figure 7 shows the chromatogram of a γ-irradiated aqueous Gly-L-Ala-Gly solution with MNP. The esr chromatogram exhibited four peaks (A–D) as shown by the solid line. Typical esr spectra for the fractions of peaks A–C are depicted in parts (a)–(c) of Fig. 8, respectively. In the uv chromatogram shown by the broken line in Fig. 7, peaks E′ and F′ were due to intact Gly-L-Ala-Gly and *t*-BuN(OH)NO (28).

Figure 8(a) shows the esr spectrum (0.05 mT modulation amplitude) obtained for the peak A fraction, and the hfsc's are given in Table 1. The spin adduct was assigned to structure **9**, the deamino adduct from Gly-L-Ala-Gly.



9

Parts (b) and (c) of Fig. 8 show the esr spectra for the fractions of peaks B and C, respectively, which are similar to each other. Both spin adducts exhibited little spectral change in the neutral and alkaline pH range, while in the acidic pH range they exhibited reversible pH-dependent shifts of their signals which resemble the behavior of adduct **2**. Their hfsc's at various pH's are given in Table 1. Both spin adducts were assigned to a pair of the diastereomeric C-terminal backbone adducts (*S*-*S* and *S*-*R* forms), that is

$$NH_3^+—CH_2—CONH—*CH(CH_3)—CONH—*CH(N(t\text{-Bu})—O\cdot)—COO^-$$

10

The adduct of peak B refers to structure **10***a* and that of peak C to **10***b*.

In the esr chromatogram, a slight shoulder of peak B was found at the position indicated by the vertical arrow in Fig. 7. The esr spectrum for the fraction at this position exhibited a fairly asymmetric triplet-quartet pattern with distortions, which suggested that the fraction contained new radicals other than spin adduct **10***a*. Since the C-terminal backbone adducts derived from peptides whose C-terminal residues are glycines are unstable and decay relatively quickly at strong acidic pH, spin adduct **10***a* was eliminated by lowering the pH of the fraction. Figure 8(d) shows the esr spectrum for the fraction measured more than 1 h after the adjustment of pH to 0.4. In the spectrum a triplet-triplet pattern was newly observed ($a_N = 1.46$ mT, $a_{\beta N}$

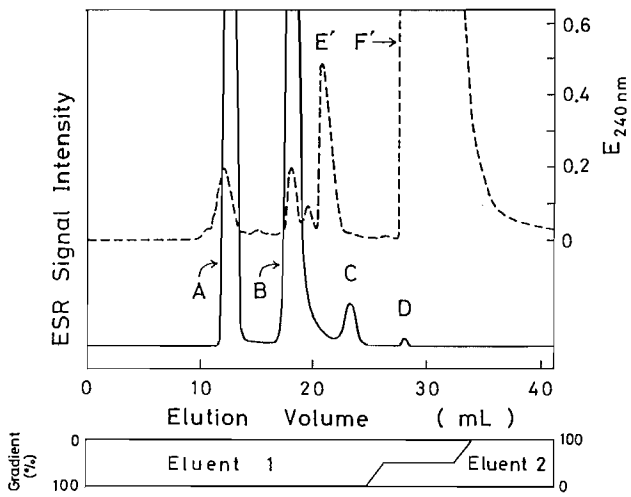

FIG. 9. Chromatogram of a γ-irradiated aqueous solution of L-Ala-Gly-Gly with MNP drawn by uv (broken line) and esr (solid line) detections: flow rate, ca. 0.2 mL/min; eluent 1, 0.35 *M* sodium phosphate buffer, pH 6.0; eluent 2, 0.2 *M* Na_2HPO_4–NaOH buffer, pH 11.5. The magnetic field fixed for the esr detection was 2.67 mT higher than the $g = 2.034$ signal of Mn^{2+} in MgO.

= 0.31 mT). The spin adduct was assigned to structure **11**, the internal backbone adduct from Gly-L-Ala-Gly.

$$NH_3^+—CH_2—CONH—C(CH_3)(t\text{-Bu}—N(O\cdot))—CONH—CH_2—COO^-$$

11

The esr spectrum for the peak D fraction contained two kinds of radicals. One was spin adduct **10***b* due to the tailing of peak C, and the other was a new spin adduct whose hfs was analyzed as follows: $a_{\gamma H} = 0.06$ mT and $2a_N + a_{\beta H1} + a_{\beta H2} = 5.78$ mT at pH 6.1. At pH ~ 6, the $2a_N + a_{\beta H1} + a_{\beta H2}$ values of the side-chain adducts, *t*-BuN(O·)—CH_2CH(NH—)CO—, give values between 5.64 and 6.04 mT (17, 21, 22). No other spin adducts can give these values. Accordingly, the new adduct was plausibly assigned to structure **12**, the side-chain adduct from Gly-L-Ala-Gly.

$$NH_3^+—CH_2—CONH—CH(CH_2(t\text{-Bu}—N(O\cdot)))—CONH—CH_2—COO^-$$

12

L-Alanylglycylglycine

Figure 9 shows the chromatogram of a γ-irradiated aqueous L-Ala-Gly-Gly solution with MNP. The esr chromatogram exhibited four peaks (A–D) as shown by the solid line. Typical esr spectra for the fractions of peaks A–C are depicted in parts (a)–(c) of Fig. 10, respectively. In the uv chromatogram shown by the broken line in Fig. 9, peaks E′ and F′ were due to intact L-Ala-Gly-Gly and *t*-BuN(OH)NO (28).

The spin adducts of peaks A–C were assigned to the deamino adduct (structure **13**), the C-terminal backbone adduct (**14**), and the internal backbone adduct (**15**) from L-Ala-Gly-Gly, respectively, and their hfsc's are given in Table 1.

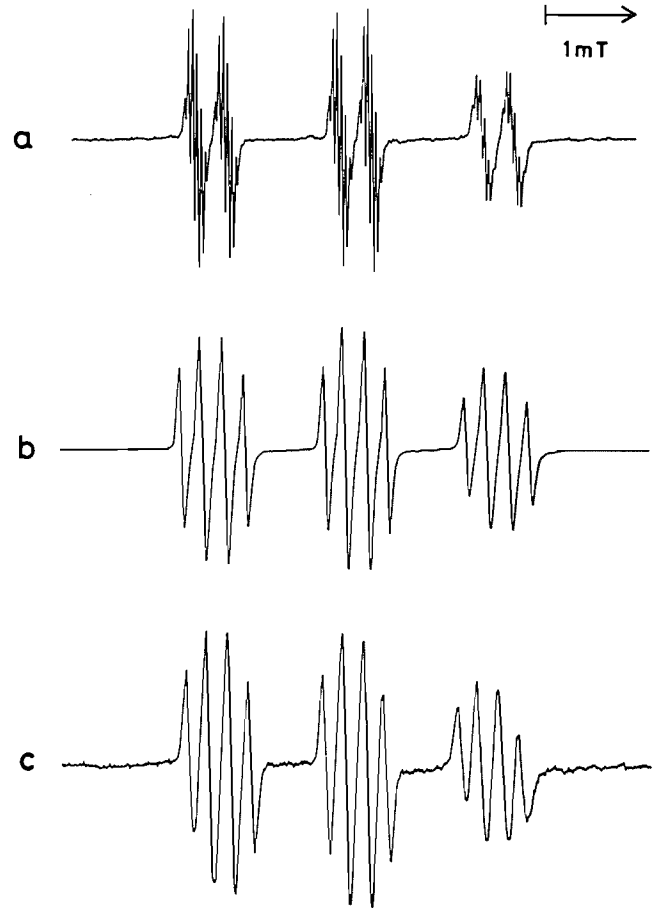

FIG. 10. The esr spectra of the separated spin adducts. (a)–(c) represent the spectra obtained from the fractions giving peaks A–C in Fig. 9, respectively. (a), pH 5.7; (b) and (c), pH 6.0.

$$t\text{-Bu}—N(O\cdot)—CH(CH_3)—CONH—CH_2—CONH—CH_2—COO^-$$

13

$$NH_3^+—CH(CH_3)—CONH—CH_2—CONH—CH(t\text{-Bu}—N(O\cdot))—COO^-$$

14

$$NH_3^+—CH(CH_3)—CONH—CH(t\text{-Bu}—N(O\cdot))—CONH—CH_2—COO^-$$

15

The esr spectrum for the peak D fraction was analyzed as a mixture of the side-chain adduct (structure **16**) from L-Ala-Gly-Gly and spin adduct **17** from *t*-BuN(OH)NO (29).

$$NH_3^+—CH(CH_2(t\text{-Bu}—N(O\cdot)))—CONH—CH_2—CONH—CH_2—COO^-$$

16

$$t\text{-Bu}—N(O\cdot)—CH_2—C(CH_3)_2—N(O^-)—N{=}O$$

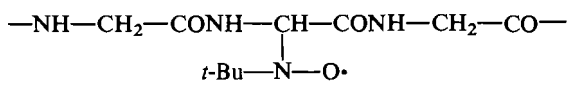
[e] Three equivalent hydrogens.
[f] Average value of two hydrogens.

Polyglycine

An aqueous solution of polyglycine (ca. 1 m*M*, approximate molecular weight 6000) with 5 mg/mL MNP was cooled by ice and γ-irradiated at a dose rate of ca. 75 Gy/min to a total dose of 0.2 kGy without deaeration. Figure 11 shows the esr spectra of the irradiated solution. The spectrum observed immediately after irradiation obviously contains more than two kinds of radicals, as shown in Fig. 11(a). The triplet signals asterisked in Fig. 11(a) (a_N = 1.72 mT) are due to di-*tert*-butyl nitroxide (29). These triplet signals decayed slowly at room temperature and became the extent of trace after ca. 11.5 h, as shown in Fig. 11(b). Almost pure esr signals in Fig. 11(b) are interpreted as a triplet of quartet with approximate intensity ratio of 1:2:2:1. The hfsc's at pH 4.7 are as follows: a_N = 1.50 mT, $a_{\beta H}$ = 0.25 mT, and $a_{\beta N}$ = 0.27 mT. The spectral pattern is ascribed to the basic structure of a backbone adduct from a glycyl residue, *t*-Bu—N(O·)—CH—N<. The results from γ-radiolytic aqueous systems of dipeptides (21, 22) and tripeptides suggest two possibilities for this polyglycine system: C-terminal and internal spin adducts. Considering that the backbone adduct from polyglycine seems to exist as a zwitterion form under the conditions of the esr measurements, the hfsc's obtained from the polyglycine adduct were compared with those of the backbone adducts (the *t*-BuN(O·)CH—N< type) from dipeptides (21, 22) and tripeptides at pH ~ 6. The hfsc of the aminoxyl nitrogen is 1.55 ± 0.01 mT for the C-terminal backbone adduct, while it is 1.51 mT for the internal backbone adduct. Therefore the observed polyglycine adduct (a_N = 1.50 mT) was assigned to structure **18**, the internal backbone adduct from polyglycine.

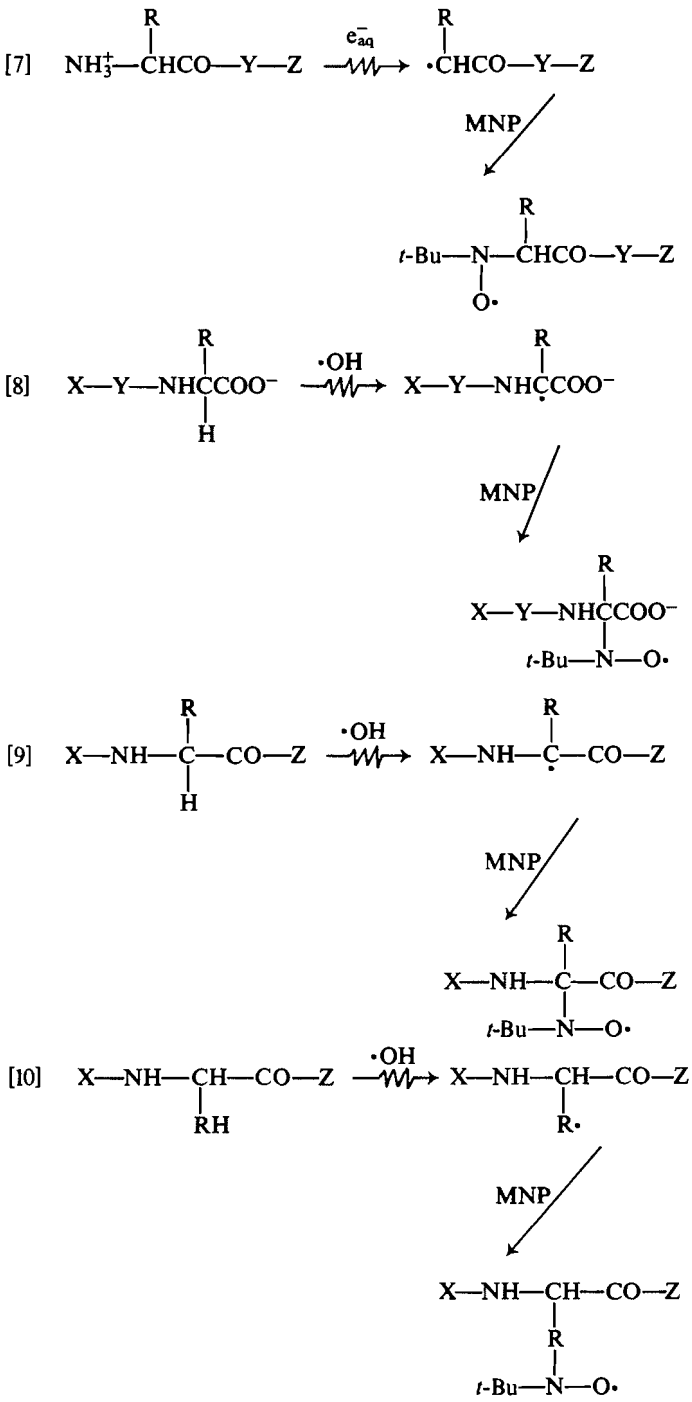


18

Conclusions

Many kinds of spin adducts in the γ-irradiated aqueous solutions of four tripeptides with MNP as a spin trap were separated and identified by the spin-trap hplc–esr method. Their hfsc's are summarized in Table 1. Spin adducts **1**, **5**, **9**, and **13** are deamino adducts derived from the reductive deaminations induced by the e_{aq}^- addition to the carbonyl group of the N-terminal peptide bond (2, 25). Spin adducts **2**, **6**, **10***a*, **10***b*, and **14** are C-terminal backbone adducts derived from the short-lived radicals produced by the hydrogen abstraction from a so-called α-carbon in the C-terminal main-chain, mainly by ·OH. Spin adducts **3**, **7**, **11**, and **15**, which are newly classified as a type characteristic of tripeptides, are internal backbone

adducts originating from the H abstraction from an α-carbon in the internal main-chain. Spin adducts **8**, **12**, and **16** are side-chain adducts originating from the H abstraction from the methyl group of the L-alanyl residue. From these results on tripeptide systems, proposed γ-radiolytic and spin-trapping mechanisms to produce spin adducts from the tripeptides are summarized as follows:



where X, Y, and Z represent amino acid residues, R is H or a side-chain, RH is a saturated aliphatic side-chain (16, 20), and the left, central, and right members of each equation are a tripeptide, a short-lived radical, and a spin adduct, respectively. The spin adducts in eqs. [7]–[10] are a deamino adduct, a C-terminal backbone adduct, an internal backbone adduct, and a side-chain adduct from a tripeptide, respectively.

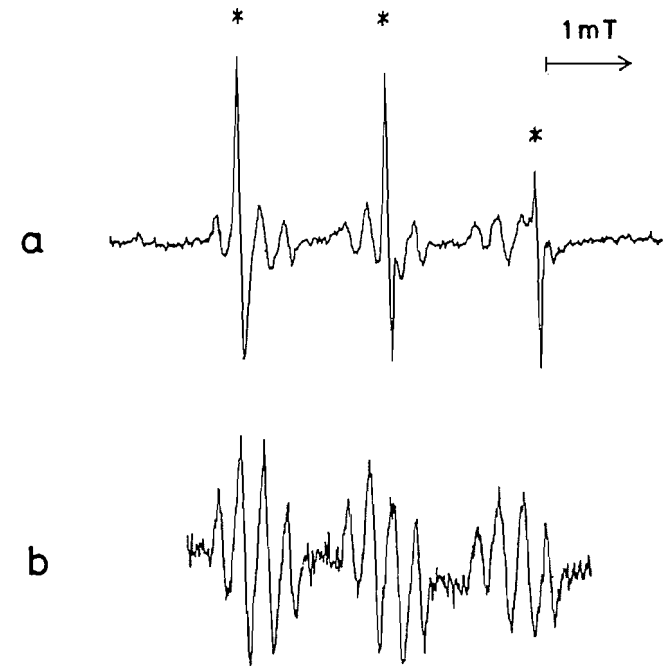


FIG. 11. (a) The esr spectrum of an aqueous solution of polyglycine with MNP observed just after γ-irradiation (at pH 4.7). (b) The esr spectrum of the solution ca. 11.5 h after irradiation.

It was reported that a hydroxyl radical attacks Gly-Gly at the α-position to the peptide nitrogen and not to the NH_3^+ group (1, 25). Hydrogen abstraction by ·OH at the α-position to the peptide nitrogen of dipeptides was observed by uv photolysis with H_2O_2 (24), and the $Ti^{3+}-H_2O_2$ method (35). It was confirmed that, for alphatic oligopeptides, the enhancement of reactivity of internal and C-terminal α-carbons toward ·OH is due to the disappearance of suppression by NH_3^+ groups (36). It is compatible with these previous conclusions that C-terminal and internal backbone adducts from tripeptides were detected and N-terminal backbone adducts such as *t*-BuN(O·)—$CH(NH_3^+)CONHCH_2CONHCH(CH_3)COO^-$ from Gly-Gly-L-Ala were not ascertained in the present work.

The second-order rate constants for reactions between e_{aq}^- and amino acids or peptides were determined by pulse radiolysis (2, 37). The results suggested that an e_{aq}^- attack on a peptide carbonyl group is much faster than on a carboxyl group. Therefore it is reasonable that "tertiary deamino adducts" originating from attacks of e_{aq}^- on carboxyl groups such as *t*-Bu—N(O·)—$CH(CH_3)COO^-$ from Gly-Gly-L-Ala were not found in our present work. "Secondary deamino adducts" such as *t*-BuN(O·)—$CH_2CONHCH(CH_3)COO^-$ from Gly-Gly-L-Ala were not ascertained in this study, which is consistent with previous results indicating that cleavage next to an internal peptide bond does not occur (2, 38, 39).

In the γ-irradiated aqueous polyglycine solution, spin adduct **18**, the internal backbone adduct from polyglycine, was found by the spin-trapping method with MNP. The backbone adduct for polyalanine was also reported previously (11). Consequently, these results on radiolysis of the tripeptides and polypeptides suggest that, in general, short-lived backbone radicals, —CONH—ĊR—CONH—, are produced in γ-irradiated aqueous solutions by hydrogen abstraction from an internal so-called α-carbon in main-chains of proteins, mainly by ·OH (eq. [11]).

Conclusions from the present and previous works (14–22) will be utilized for a general discussion on radiolysis of proteins in aqueous solutions, with conclusions on amino acids and peptides with functional or aromatic groups in side-chains, which will be presented in the future.

Electron behavior in mixed solvents: optical spectra and reactivities in water/alkane diols[1]

K. M. IDRISS-ALI AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 8, 1984

K. M. IDRISS-ALI and GORDON R. FREEMAN. Can. J. Chem. **62**, 2217 (1984).

Investigation of the effect of solvent structure on the optical absorption spectrum and reactivity of solvated electrons has been extended to diol/water mixed solvents, using 1,2-ethanediol (12ED) and 1,4-butanediol (14BD). The large effects that had been found in mono-ol/water mixed solvents did not occur in diol/water. Although addition of 3 mol% of a diol to water increased the optical absorption energies of e^-_s by 0.06 eV, similar to the shift caused by addition of 3 mol% of a mono-ol, the variation of the spectrum over the rest of the composition range was nearly ideal in diol/water, in contrast to the very non-ideal variation in mono-ol/water. Reaction rate constants k_S at 298 K in the diol/water mixed solvents vary approximately as the inverse viscosity, $\eta^{-1.0}$, in the diffusion-controlled limit. However, when reactions are two or three orders of magnitude slower than diffusion controlled, k_S at 298 K is independent of η. Toluene reacts with e^-_s at a 10^{-3}-fold smaller rate than does nitrobenzene; the difference is nearly completely due to a ~50 J/mol K lower entropy of activation of the former reaction.

Viscosities and their temperature coefficients are reported for the diol/water mixtures.

K. M. IDRISS-ALI et GORDON R. FREEMAN. Can. J. Chem. **62**, 2217 (1984).

On a étendu nos études sur la relation qui existe entre la structure du solvant et les spectres d'absorption optique ainsi que la réactivité des électrons solvatés dans le but d'inclure des solvants mixtes eau/diols comprenant l'éthanediol-1,2 et le butanediol-1,4. Dans ces cas, on ne retrouve pas les grands effets que l'on avait observé avec les solvants mixtes eau/mono-ols. Même si l'addition de 3 mol% de diol à l'eau augmente les énergies d'absorption optique des e^-_s par 0,06 eV et que ces résultats sont semblables à ceux causés par l'addition de 3 mol% de mono-ol, la variation du spectre sur le reste des compositions est pratiquement idéal par rapport aux diols/eau et ceci est en opposition avec la variation observée avec les mono-ols/eau alors que l'on observait une déviation importante par rapport à l'idéalité. A 298 K et dans la zone controlée par la diffusion, les constantes de vitesse des réactions, k_S, dans les solvants mixtes eau/diol, sont reliées d'une façon pratiquement inverse avec la viscosité, $\eta^{-1.0}$. Toutefois, lorsque les réactions ont des vitesses qui sont de cent à mille fois plus lentes que celles qui sont controlées par la diffusion, les valeurs de k_S à 298 K sont indépendantes de η. La vitesse de la réaction du toluène avec les e^-_s est mille fois plus lente que celle du nitrobenzène; cette différence est pratiquement complètement due à une entropie d'activation plus faible (environ 50 J/mol K) pour la première réaction.

On rapporte les viscosités ainsi que les coefficients de température des mélanges eau/diols.

[Traduit par le journal]

Introduction

The localization energy (1–9) and reactivity (10–16) of solvated electrons are strongly dependent upon the nature of the solvent. The internal structure of the liquid, reflected by the Kirkwood correlation parameter g_K, has a greater influence upon the energy levels of solvated electrons than does the magnitude of the dielectric constant or of the molecular dipole moment (6).

Optical absorption spectra of solvated electrons in mixed alcohol/water solvents have revealed unexpected effects that are attributed to changes in the internal structure of the liquid (7). The structure changes occur because of the interplay between nonpolar and hydrogen-bonding groups, and are reflected in physical properties such as heat of mixing (17, 18) and viscosity (19, 20). Allied reactivity studies have been reported for electrons in 2-propanol/water mixed solvents (16). The present article reports spectral and reactivity changes in water/diol solutions.

Reactivities in pure diol solvents are significantly different from those in mono-ol solvents when normalized for viscosity or electron trap depth (21). Two diols that have different distances between the hydroxy groups were chosen for study of aqueous mixtures: 1,2-ethanediol (12ED) and 1,4-butanediol (14BD). In the latter neat liquid the viscosity is larger but the solvated electron excitation (solvation) energy is smaller than

those in the former (22). The viscosities of the mixed solvents were measured, along with the optical and reactive properties of the solvated electrons.

Experimental

All chemicals were obtained from Aldrich Chemical Co. Purification of solvents and solutes and preparation of solutions were as described earlier (21). The methods of cell filling (23), temperature control, irradiation, dosimetry, and spectroscopy (24) were nearly the same as that reported in the references indicated. The main difference was in the optical system; the light beam was split into two parts, one passing below the optical cell and serving as a reference, the other passing through the sample solution. The two parts of the beam were adjusted to an appropriate ratio for subtraction, before they fell onto the monochromator (Bausch and Lomb 33-86-25, grating type 33-86-02) and dual detector (SGD-444-2). The oscilloscope traces were recorded with a series 1200 Zeta plotter (Zeta Research Inc.) interfaced with a Texas Instrument 980 minicomputer.

The temperature was controlled to within ±0.1 K. A 100 ns pulse of 1.9 MeV electrons delivered a dose of 2×10^{16} eV/g to the sample. Solvated electron decay rates were measured at the maximum of the optical absorption band at each temperature.

The compositions of the water/diol mixed solvents were 0, 10, 50, 97, and 100 mol% water. Concentrations of solute were in the range 0.028–0.21 m*M* (nitrobenzene), 0.37–2.2 m*M* (acetone), 19–113 m*M* (toluene), and 1.7–5.7 m*M* (allyl alcohol).

Viscosities and densities of the water/diol mixed solvents were measured in the manner described elsewhere (21). The results are listed in Table 1. Values for pure 12ED and water agreed with those in ref. 25 within 0.5% in density and 2% in viscosity.

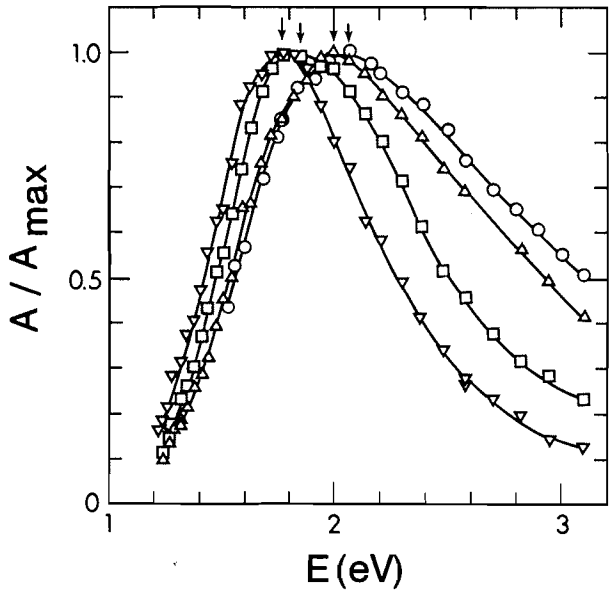

FIG. 5. Normalized absorption spectra of solvated electrons in 14BD/water mixed solvents at 296 K. Mol% water: ○, zero; △, 10; □, 50; ▽, 97.

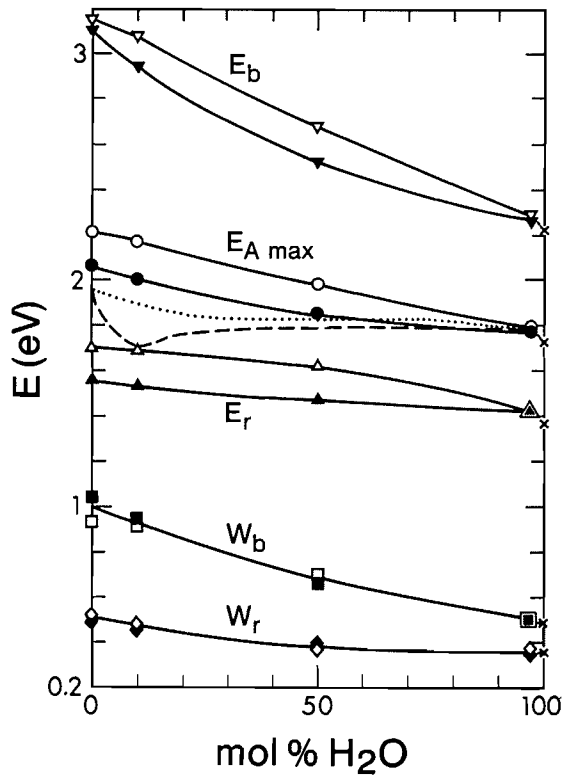

FIG. 6. Composition dependence of spectrum parameters in diol/water mixed solvents at ~296 K. 12ED, open points; 14BD, filled points; water, X. The E_{Amax} curves for aqueous methanol, ····, and 1-propanol, - - -, are shown for comparison (7). $W_r = E_{Amax} - E_r$; $W_b = E_b - E_{Amax}$; E_r and E_b are the energies at $A/A_{max} = 0.5$ on the red and blue sides of the band, respectively.

Results and discussion

Solvent viscosities

The viscosities of the mixed solvents display nonideal behavior. They are lower than if they were directly proportional to the mole fractions of the components (Fig. 1). The Arrhenius temperature coefficients decrease slightly with increasing temperature (Fig. 2). For example, in pure 14BD the coefficient is 35 kJ/mol at 308 K and 29 kJ/mol at 348 K. The coefficients are larger than if they varied linearly with mol% composition, except when up to 15 mol% water is added to 12ED (Fig. 3). These temperature coefficients indicate that the liquid structures in 12ED and 14BD change in different fashions when up to 50 mol% water is added.

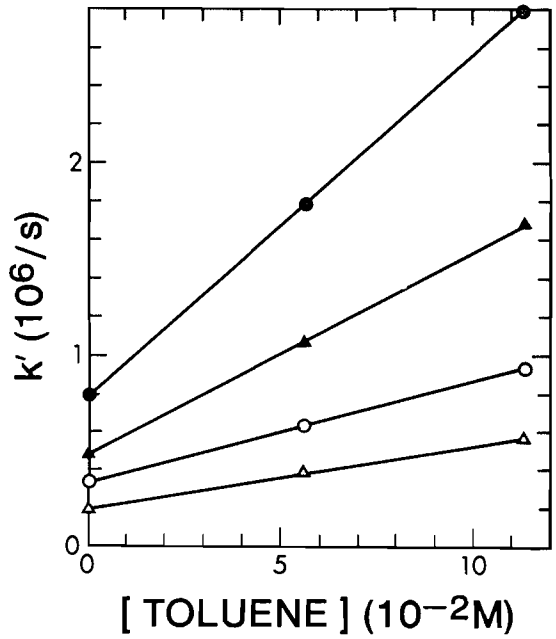

FIG. 7. First order decay constants of e^-_s in 10 mol% water in 14BD, as functions of toluene concentration and temperature. △, 283 K; ○, 296 K; ▲, 313 K; ●, 329 K.

Optical absorption spectra of e^-_s

The spectrum was measured in each solvent at ~296 K. The energy at the absorption maximum, E_{Amax}, decreases as the water content increases in each diol (Figs. 4 and 5). The values of E_{Amax} in aqueous solutions of the primary alcohols ethanol and 1-propanol have a minimum at 10 mol% water (7), but this does not occur in the aqueous diols (Fig. 6). The shapes of the curves of E_{Amax} against mol% water follow a sequence in which the minimum disappears and the curve becomes more nearly linear: primary alcohols RCH_2OH, methanol, 14BD, 12ED (Fig. 6). The liquid structures of the diols are less easily perturbed by water than is that of a primary alcohol. However, addition of 3 mol% of a diol to water causes the same blue shift in the absorption band as does 3 mol% of a mono-ol (Fig. 6). The water liquid structure is perturbed in a similar way by the addition of 3 mol% of either a mono- or di-ol.

The widths of the bands at half height on the red, W_r, and blue, W_b, sides of E_{Amax} are nearly independent of the diol molecular structure (Fig. 6). The band asymmetry factor W_b/W_r equals 1.9 ± 0.1 in both diols containing up to 50 mol% water, then decreases gradually and reaches 1.4 in pure water.

The temperature coefficients in 50 mol% water/12ED are similar to those in pure 12ED; $dE_{Amax}/dT \approx -3$ meV/K, and W_r is independent of temperature.

Reactivities of e^-_s with solutes

Rate constants were measured for four solutes that differ

[a] Stokes = 10^{-4} m^2/s.
[b] Measured near 306 K.
[c] Poise = Stokes × density = 0.1 Pa s. Values for 12ED and water agree with those in ref. 25 within 2%.

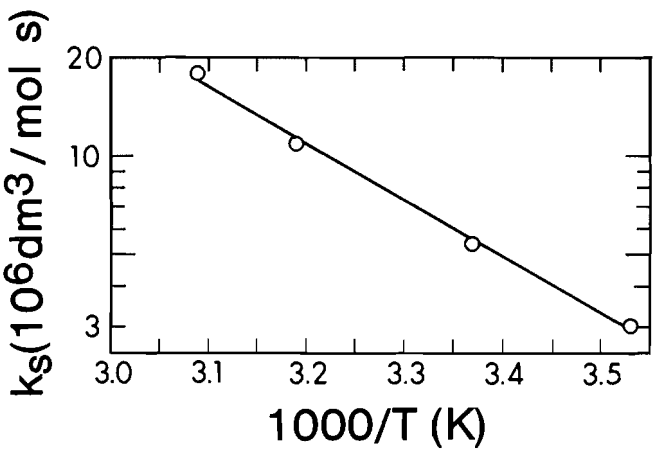

FIG. 8. Arrhenius plot of k_S (e^-_s + toluene) in 10 mol% water in 14BD. Data from Fig. 7.

widely in reactivity: nitrobenzene, acetone, allyl alcohol, and toluene. Figure 7 shows example plots of the first order decay rates of e^-_s as a function of toluene concentration in 10 mol% water/14BD. The values of the second order rate constants were obtained from the slopes and are displayed as an Arrhenius plot in Fig. 8. The reactivity parameters from eqs. [1] and [2] (15), corresponding to the data in Fig. 8, are $A_S = 2.1 \times 10^{12}$ dm^3/mol s, $E_S = 32$ kJ/mol and $\Delta S_S^{\ddagger} = -9$ J/mol K.

$$[1] \qquad k_S = A_S \exp(-E_S/RT)\ \text{dm}^3/\text{mol s}$$

$$[2] \qquad \Delta S_S^{\dagger} = 19\ (\log A_S - 12.8)\ \text{J/mol K at 298 K}$$

The values of log k_S at 298 K, log A_S, E_S, and $\Delta S_S^{\ddagger}$ for each of the solutes in each of the solvents are listed in Table 2.

The reaction of e^-_s with nitrobenzene is nearly diffusion controlled. The rate constants in water, 12ED, 14BD, and the water/diol mixtures at 298 K vary approximately as $\eta^{-0.9}$ (Fig.

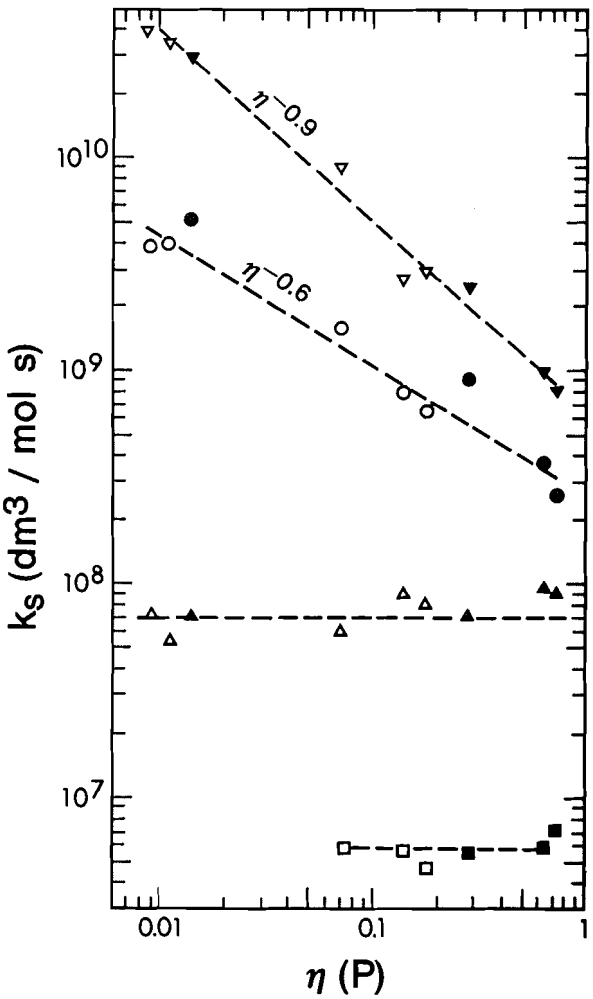

FIG. 9. Effect of solvent viscosity on k_S at 298 K. Open points, water and 12ED solutions; filled points, 14BD solutions. ▽, ▼, nitrobenzene; ○, ●, acetone; △, ▲, allyl alcohol; □, ■, toluene. The dashed lines are guides for the eye.

9). This reflects mainly the viscosity dependence of the diffusion coefficients of e^-_s and nitrobenzene. Reactions with other solutes that are progressively farther below the diffusion-controlled limit are progressively less dependent on the solvent viscosity. Thus, k_S at 298 K for acetone in the diol/water systems varies roughly as $\eta^{-0.6}$, while those for allyl alcohol and toluene are nearly independent of viscosity (Fig. 9).

The above result also means that at 298 K the values of k_S for allyl alcohol and toluene are nearly independent of the composition of the diol/water solvent. The temperature coefficient E_S for the least reactive solute, toluene, is nearly the same as that for the most reactive solute, nitrobenzene, in a given solvent (Table 2). The thousand-fold decrease of k_S on going from nitrobenzene to toluene is due mainly to a large decrease, 50 ± 10 J/mol K, in the entropy of activation (Table 2).

Electron capture by toluene, and probably by allyl alcohol, is stabilized by protonation (26, 27):

[3, -3] $e^-_s + S \rightleftarrows S^-_s$

[4] $S^-_s + ROH \rightarrow \dot{S}H + RO^-_s$

Reaction [4] involves the rotation of solvent dipoles adjacent to the reaction site as the charge center changes from S^- to RO^-; the reaction rate should correlate with the dielectric relaxation

time τ. The values of the Arrhenius temperature coefficients E_τ would probably be significantly different from those of E_η in the mixed solvents. A comparison of E_τ with E_S would be of great interest. Measurements of τ at different temperatures are needed.

There is no correlation of k_S with the optical absorption energy E_τ in diol/water solvents, as there is for inefficient scavengers in mono-ol solvents (14, 15).

Temperature and molecular structure dependences of optical spectra of electrons in liquid diols[1]

KIYOSHI OKAZAKI, K. M. IDRISS-ALI, AND GORDON R. FREEMAN
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received January 23, 1984

KIYOSHI OKAZAKI, K. M. IDRISS-ALI, and GORDON R. FREEMAN. Can. J. Chem. **62**, 2223 (1984).

In 1,2-propanediol (12PD) at 215 K the optical spectrum of e^-_s shifted unsymmetrically towards higher energy the first 500 ns. Approximating the decay of the low energy side and the growth of the high energy side of the band as first order, the mean decay time at $0.5E_{Amax}$ (e^-_s) was $\tau_d \approx 160$ ns and the mean growth time at $E > E_{Amax}$ (e^-_s) was $\tau_g \approx 40$ ns. The behavior in 1,3-butanediol (13BD) at 225 K was similar, with $\tau_d \approx 170$ ns at $0.5E_{Amax}$ and $\tau_g \approx 40$ ns at $E > E_{Amax}$. The solvation time constant τ_s is only slightly greater than τ_g. The larger value of τ_d is caused by replenishment of the state at $0.5E_{Amax}$ by relaxation from lower energy states. In all diols at $T \gtrsim 240$ K ($\geq$298 K for 14BD) the spectra reached their equilibrium shape within 150 ns after the start of the 100 ns radiation pulse. The value of E_{Amax} of e^-_s in the 1,2-diols is ~0.1 eV greater than those in the other diols and 0.2−0.3 eV greater than that in a primary alcohol at the same temperature. In the secondary−secondary diol 23BD at 296 K, E_{Amax} is 0.6 eV greater than that in 2-propanol. The vicinal diol part of the molecule dominates the intermolecular solvation site of the electron. The temperature coefficient ($-dE_{Amax}/dT$) increases from 2.6 meV/K in 12 ED to 3.6 meV/K in 23BD. The asymmetry factors W_b/W_r of the e^-_s bands in the diols are 1.6−2.1, somewhat lower than those in the analogous alcohols, 1.9−2.4. The values of W_r are similar, 0.54 ± 0.04 eV, in all the diols, independent of T, with $W_r/E_{Amax} = 0.24 \pm 0.02$; $dW_b/dT < 1.0$ meV/K. The value of $(G\epsilon)_{max}$ has an upper limit of ~2.5×10^4 e^-_s/100 eV M cm in the low temperature liquid diols. The value of $G_{fi}\epsilon_{max}$ is 1.2×10^4 in all diols except 23BD, in which it is 1.3×10^4, independent of T.

KIYOSHI OKAZAKI, K. M. IDRISS-ALI et GORDON R. FREEMAN. Can. J. Chem. **62**, 2223 (1984).

Dans le propanediol-1,2 (PD12), à 215 K, le spectre optique des e^-_s glisse d'une façon non symétrique vers les hautes énergies pendant les 500 premières nanosecondes. En faisant l'hypothèse que la décroissement du côté de faible énergie et que la croissance du côté de haute énergie de la bande sont d'ordre un, le temps moyen de décroissement à $0{,}5E_{Amax}$ (e^-_s) est $\tau_d = 160$ ns et le temps moyen de croissance à $E > E_{Amax}$ (e^-_s) est de $\tau_g = 40$ ns. A 225 K, le butanediol-1,3 (BD13) se comporte de la même façon et $\tau_d = 170$ ns à $0{,}5E_{Amax}$ et $\tau_g = 40$ ns à $E > E_{Amax}$. La constante de temps de solvatation τ_s n'est que légèrement supérieure à τ_g. La valeur plus élevée de τ_g est due au remplissage de l'état à $0{,}5E_{Amax}$ par une relaxation des états de plus faible énergie. Dans tous les diols, à des $T \geq 240$ K ($\geq$298 K pour le BD14), les spectres atteignent leur forme d'équilibre en moins de 150 ns après le début de la radiation pulsée de 100 ns. A des températures constantes, la valeur de E_{Amax} des e^-_s, dans les diols-1,2, est supérieure d'environ 0,1 eV à celles observées avec d'autres diols et de 0,2 à 0,3 eV supérieure à celle observée dans un alcool primaire. Dans le diol secondaire−secondaire (BD23), à 296 K, la valeur de E_{Amax} est de 0,6 eV supérieure à celle observée dans le propanol-2. La portion viccinale de la molécule de diol domine le site de solvatation intermoléculaire de l'électron. Le coefficient de température ($-dE_{Amax}/dT$) passe de 2,6 meV/K dans le ED12 jusqu'à 3,6 meV/K dans le BD23. Les facteurs d'asymétrie des bandes des e^-_s dans les diols, W_b/W_r, varient de 1,6 à 2,1; ces valeurs sont un peu plus faibles que celles observées avec les alcools analogues qui varient de 1,9 à 2,4. Les valeurs de W_r sont identiques (0,54 ± 0,04 eV) dans tous les diols, elles ne dépendent pas de T, et $W_r/E_{Amax} = 0{,}24 \pm 0{,}02$; $dW_b/dT < 1{,}0$ meV/K. Dans les diols liquides à basse température, la limite supérieure de la valeur de $(G\epsilon)_{max}$ est d'environ $2{,}5 \times 10^4$ e^-_s/100 eV M cm. Quelle que soit la température, la valeur de $G_{fi}\epsilon_{max}$ est de $1{,}2 \times 10^4$ dans tous les diols, à l'exception du BD23 pour lequel cette valeur est $1{,}3 \times 10^4$.

[Traduit par le journal]

Introduction

The influence of solvent structure on the optical absorption spectra of solvated electrons continues to grow in interest. Alcohols (1−5) and alcohol/water mixtures (6,7) have been particularly informative about the sensitivity of the spectrum to changes of internal structure of the liquid. In these liquids, structure changes occur because of the interplay between nonpolar and hydrogen-bonding groups. The electron spectral shifts are a source of information, although it has not yet been possible to quantify the structure changes.

A series of diols (dihydroxyalkanes), with different distances between the hydroxy groups and placed at different positions along the chain, offers another approach to the interplay between nonpolar and hydrogen bonding groups. Half the number of diol molecules could provide the multihydroxyl group configuration required to solvate the electron, compared to the number of monohydroxy alcohols. Solvated electron spectra have therefore been measured in a series of seven diols as functions of temperature.

Experimental

Materials

Diols obtained from Aldrich Chemical Co. were 1,2 ethanediol (12ED), 99+%; 1,2-propanediol (12PD), analyzed U.S.P. grade; 1,3-propanediol (13PD), 98%; 1,2-butanediol (12BD), analyzed 98%; 1,3-butanediol (13BD), 99+%; 1,4-butanediol (14BD), analyzed 99+%; 2,3 butanediol (23BD).

The diols were purified as described earlier (8).

Techniques

Five cm^3 of diol was transferred into a Spectrosil optical cell with a syringe, then bubbled with UHP argon (~5 cm^3/min for 40 min). The cell was then sealed with a flame by a technique that prevented diol vapor from contacting the hot glass (9).

The methods of irradiation, dosimetry, and temperature control (10, 15) were described earlier. Briefly, a 100 ns pulse of 1.9 MeV electrons delivered a dose of 2×10^{16} eV/g to the sample.

The optical system had a 0−97% rise time of 100 ± 10 ns (3).

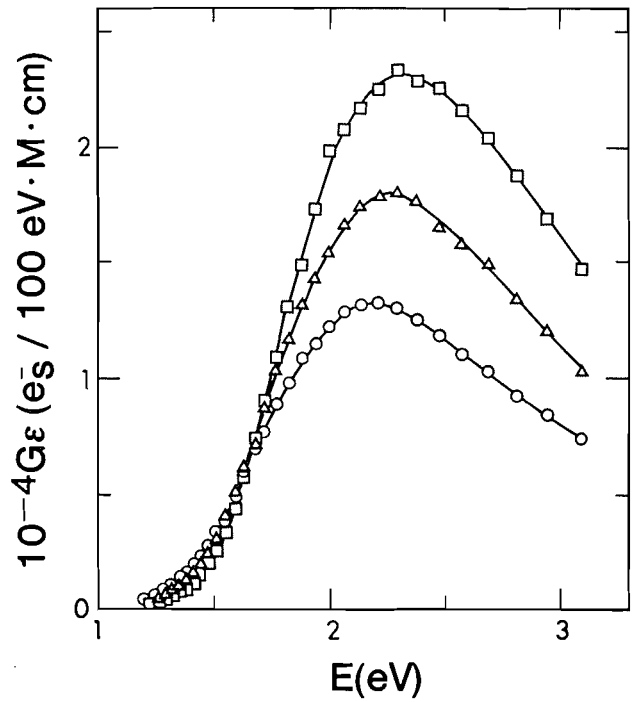

FIG. 2. Optical absorption spectra of e^-_s in 1,2-propanediol at 298 K, ○; 270 K, △; and 242 K, □. Time = 150 ns.

Results and discussion

The response characteristics of the measuring circuit were such that the optical absorption signal reached a maximum ~140 ns after the start of the 100 ns pulse, when decay after the pulse was fast (say 10% in 50 ns due to geminate reaction). The shortest time at which spectra were recorded was therefore 150 ns after the start of the pulse.

In most instances the shape of the optical spectrum in a given liquid at a given temperature was independent of time. The constant shape indicates that the electrons had relaxed into the equilibrium solvated state at $t \lesssim 100$ ns. However, the rate of decay of the signal had an initial fast portion corresponding to geminate reaction, followed by a slower part corresponding to the reaction of the free ions $(e^-_s)_{fi}$.

At the lowest temperatures in 12PD and 13BD spectral relaxation from lower to higher energies occurred over periods of ~500 ns. This corresponds to the final stages of relaxation of the localized electron and adjacent solvent molecules into the equilibrium solvated state.

In the figures the product $G\epsilon$ is plotted against photon energy, where G is the number of localized electrons formed/100 eV of energy absorbed and ϵ is the decadic molar absorbance M^{-1} cm^{-1}.

12ED

Spectra taken 150 ns after the start of a 100 ns pulse are shown in Fig. 1 for temperatures ranging from 235 to 314 K. At all temperatures the spectra decayed uniformly at all energies, indicating that the electrons had relaxed to the equilibrium solvated state e^-_s within the resolution time of the measurement. The energy at the absorption maximum, E_{Amax}, and the value of $(G\epsilon)_{max}$ increase with decreasing temperature.

12PD

Spectra taken at 242–298 K are shown in Fig. 2. The behavior is similar to that in 12ED. However, at 215 K for the first 500 ns the spectrum shape changed and shifted nonuniformly towards higher energies (Fig. 3). Approximating the decay of the absorbance in the low energy tail at 1.24 eV ($0.53E_{Amax}$ of e^-_s) as exponential, $\exp(-t/\tau_d)$, the mean decay time is $\tau_d \approx 160$ ns at 215 K. By comparison, the exponential growth

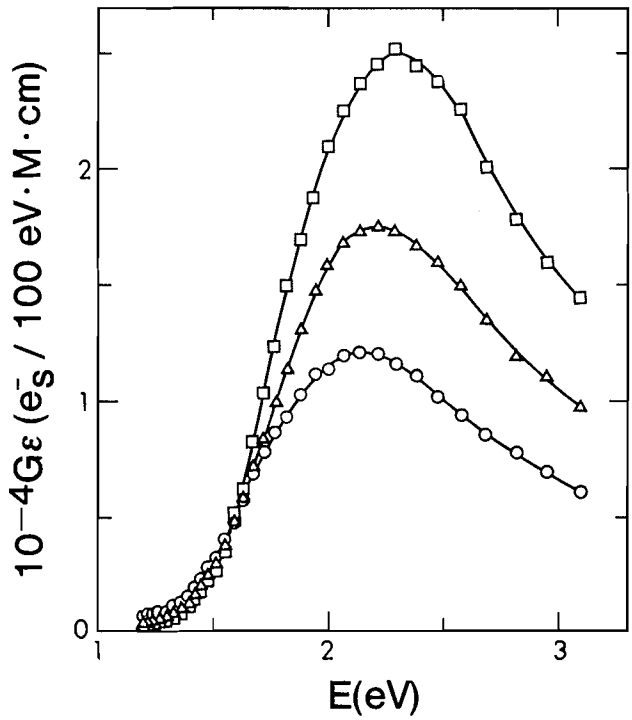

FIG. 4. Optical absorption spectra of e^-_s in 1,3-propanediol at 298 K, ○; 272 K, △; 248 K, □. Time = 150 ns.

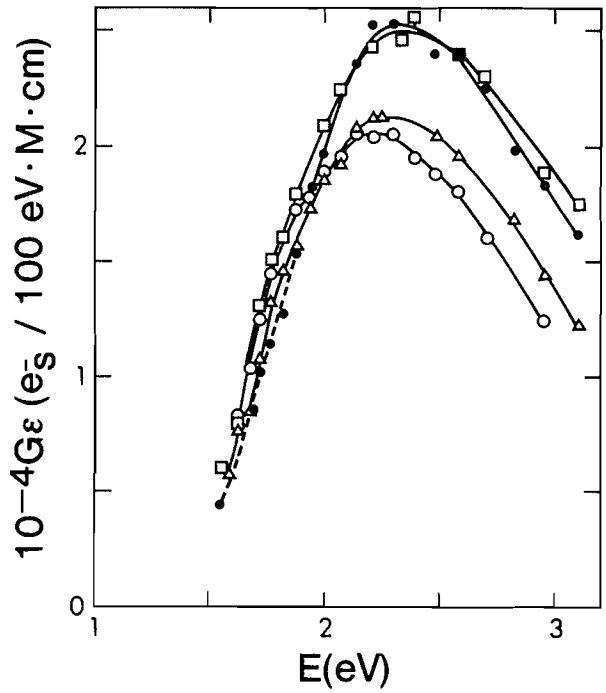

FIG. 5. Optical absorption spectra of e^-_s in 1,2-butanediol at 296 K, ○; 275 K, △; 257 K, □; 235 K, ●. Time = 150 ns.

time τ_g at $E > E_{Amax}$ of e^-_s is $\tau_g \approx 40$ ns at this temperature. Thus for the final stages of the spectrum shift, the value of τ_d at $E = 0.53E_{Amax}$ is about quadruple that of τ_g at $E > E_{Amax}$. Similar behavior was noted in 2-butanol at 171 K, where $\tau_d \approx 2\tau_g$ (3). In ref. 3 the symbol τ_s was used for τ_g, and the actual solvation time constant τ_s is probably similar to τ_g (see below).

13PD, 12BD, 13BD, 14BD, and 23BD

Similar observations were made with the other diols (Figs. 4–9).

In 12BD the spectrum at 150 ns shifted to higher absorbancies and higher energies as the temperature decreased from 295 to 257 K, as usual. However, at 235 K the spectrum became narrower and had approximately the same value of $(G\epsilon)_{max}$ as at 257 K (Fig. 5). The cause is probably that 12BD was a glass at 235 K. Solvated electron spectra tend to be narrower in a glass than in a liquid of the same material (11).

The behavior in 23BD (Fig. 9) was similar to that in 12BD.

The spectrum in 13BD at 225 K shifted slightly to higher energies during the period 150–500 ns (Fig. 7). The value of τ_d at 1.24 eV ($0.54E_{Amax}$) is ~170 ns, while $\tau_g \approx 40$ ns at $E > E_{Amax}$ of the equilibrium state. The times are similar to those in 12PD at 215 K.

Characteristic energies

The energy E_{Amax} at the absorption maximum, $(G\epsilon)_{max}$ in Figs. 1–9, varies little with the structure of the *n*-alkane-diols. The value of E_{Amax} in the 1,2-diols is 0.1 eV greater than those in the other diols (Fig. 10). The terminal —CH_2OH group is analogous to that in a primary alcohol. The —OH group on the adjacent carbon apparently provides a liquid phase structure that enhances electron solvation to the extent that E_{Amax} in a 1,2-diol at 298 K is 0.2–0.3 eV (10–15%) greater than that in a primary alcohol at the same temperature (Table 1 and refs. 12 and 13).

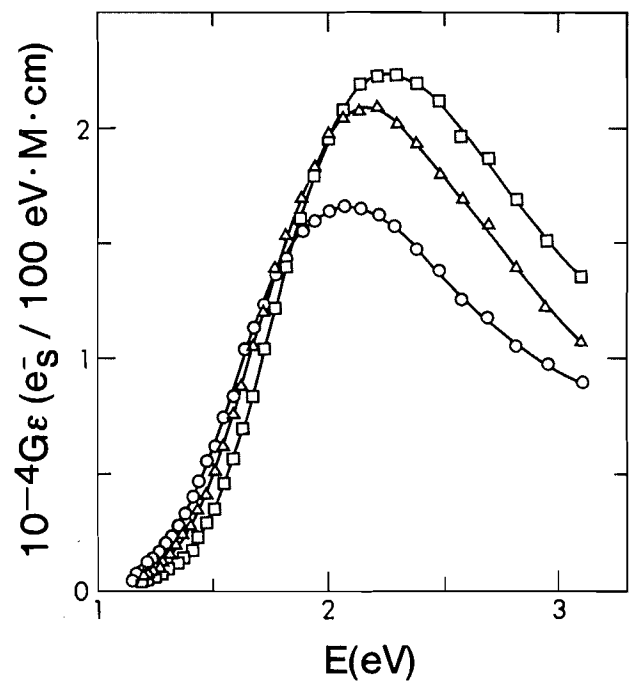

FIG. 6. Optical absorption spectra of e^-_s in 1,3-butanediol at 298 K, ○; 272 K, △; 248 K, □. Time = 150 ns.

The —OH groups in 23BD are both secondary, but the value of E_{Amax} in this diol at 296 K is 0.6 eV greater than that in 2-propanol at the same temperature (Table 1). Although E_{Amax} in a secondary alcohol is 0.4 eV lower than that in a similar primary alcohol (12), the value in 23BD is 0.1–0.2 eV higher than that in a primary alcohol at the same temperature. The vicinal diol part of the molecule dominates the intermolecular solvation site of the electron. Two vicinal diol molecules can readily provide the four —OH groups in close proximity that

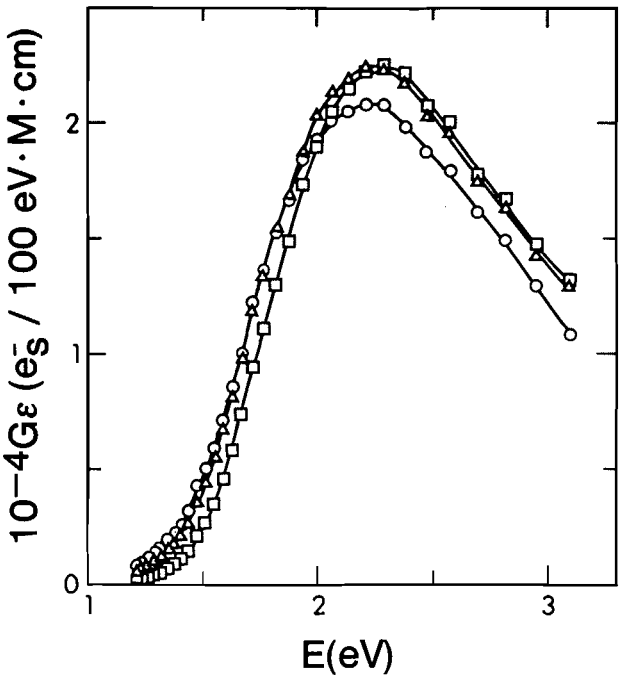

FIG. 7. Absorption spectra of localized electrons in 1,3-butanediol at 225 K at several times after the start of a 100 ns pulse. The times in ns are: 150, ○; 200, △; 500, □.

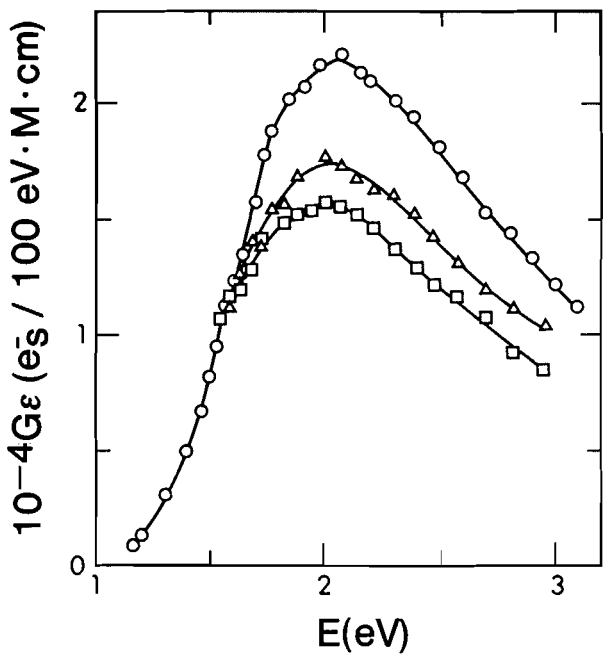

FIG. 8. Optical absorption spectra of e^-_s in 1,4-butanediol at 333 K, □; 314 K, △; 298 K, ○. Time = 150 ns.

constitute the solvated electron site in an alcohol (14).

The negative temperature coefficient ($-dE_{Amax}/dT$) in the liquid diols increases in magnitude from 2.5 meV/K in 12ED to 3.6 meV/K in 23BD (Table 1). The low value obtained for 14BD is uncertain due to the small temperature range accessible to measurement above the high freezing point. The relatively large coefficient in 23BD reflects its secondary alcohol structure. For comparison, the temperature coefficient in 2-propanol, −4.4 meV/K, is greater than that in 1-propanol, −3.3 meV/K (Table 1). The coefficient in 12ED is similar to

and 23BD (Table 1). Similar behavior has been observed in dipropyl ether glass (15).

The width of the band at half height is divided into the portions W_b on the high energy side of E_{Amax} and W_r on the low energy side. The ratio W_b/W_r is the asymmetry factor of the band. The asymmetry factor is always greater than unity and has values 1.3 ± 0.1 in liquids of the symmetrical compounds water (16) and ammonia (17), and 1.9−2.4 in methanol, ethanol, and 2-propanaol (12, 13). The values in the diols are in the range 1.6−2.1 (Table 1), somewhat lower than those in analogous alcohols. Lower values of the asymmetry ratio might indicate somewhat less disorder in the solvation sites.

The values of W_b in 12ED and 12BD are ~0.1 eV lower than those in the other diols (Fig. 10). The temperature coefficient is small, $dW_b/dT < 1.0$ meV/K.

The widths of the low energy side of the bands are similar, $W_r = 0.54 \pm 0.04$ eV, in all the diols, independent of temperature (Fig. 10). The values are similar to those in primary alcohols (compare 1-propanol in Table 1). The ratio W_r/E_{Amax} equals 0.23 ± 0.01 in all of the liquid diols except 12BD and 23BD, in which it equals 0.25 ± 0.01 (Table 1). The ratio in diols is slightly larger than in water, and slightly smaller than in analogous mono-alcohols (13, 18). It seems to be another indicator of the degree of disorder in the solvation sites.

Solvation time of e^-_{loc}

The change of optical absorbance A at $E \approx 0.5E_{Amax}$ (e^-_s) at short times is attributed to two processes: (*a*) dipolar reorientation of solvent molecules near e^-_{loc} due to the field of the electron, and (*b*) migration of e^-_{loc}. The first process tends to increase A by relaxation of sites at $E < 0.5E_{Amax}$ (e^-_s) to $E = 0.5E_{Amax}$ (e^-_s), but also to decrease A by relaxation of the latter sites to $E > 0.5E_{Amax}$ (e^-_s). Migration of e^-_{loc} to geminate ions decreases the absorbance, while migration to deeper traps

has the same double effect as (*a*). The observed mean decay time τ_d is governed by the balance between growth and decay at $0.5E_{Amax}$ (e^-_s), and is therefore longer than the actual mean time of the decay processes alone.

The growth of absorbance at $E > E_{Amax}$ (e^-_s) at short times is attributed to the above process (*a*) without loss by relaxation to still higher energy states, and to the portion of (*b*) that terminates in traps that have nearly the final equilibrium depths. Geminate neutralization of electrons that absorb at $E > E_{Amax}$ (e^-_s) reduces the net growth in absorbance at early times; at intermediate times it matches the growth so that the net is zero; at later times it causes the net absorbance to decay (see Fig. 7 in ref. 3). The observed net growth to the equilibrium spectrum may be crudely approximated as a sum of roughly first order processes (relaxation plus migration to deeper traps minus migration to geminate ions). By analogy with the approach of reversible first order reactions to equilibrium (19), one may write the mean net growth rate constant τ_g^{-1} for approach to maximum absorbance at $E > E_{Amax}$ (e^-_s) as:

$$[1]\quad \tau_g^{-1} \approx \tau_r^{-1} + \tau_m^{-1} + \tau_{gn}^{-1}$$

where τ_r is the mean relaxation time of the dielectric near e^-_{loc}, τ_m is the mean migration time of a localized electron into a deeper trap of nearly the equilibrium depth, and τ_{gn} is the geminate neutralization time crudely approximated as that of a first order process.[2]

The mean solvation time τ_s is related to the times in eq. [1] by:

$$[2]\quad \tau_s^{-1} \approx \tau_r^{-1} + \tau_m^{-1} \approx \tau_g^{-1} - \tau_{gn}^{-1}$$

The values of τ_{gn} for the geminate decay that occurs after the equilibrium spectrum has been attained, in low temperature alcohols, are an order of magnitude greater than τ_g (estimated from Figs. 7, 8, and 12 in ref. 3). Hence $\tau_{gn} >> \tau_g$, and from eq. [2] $\tau_s \approx \tau_g$.

The values of τ_d at 1.24 eV are larger than those of τ_g at 2.4 eV in glycols and alcohols (Table 2). The time τ_d is extended by replenishment of the 1.24 eV level by relaxation from lower energy states.

The τ_s = 5 ps reported for 12ED at 296 K (20) is a τ_g.

$(G\epsilon)_{max}$ and $G_{fi}\epsilon_{max}$ of e^-_s

The diffusion rates of the ions and solvated electrons decrease with decreasing temperature, so the time required for geminate reaction increases. When the time required to complete geminate reaction is greater than the response time of the system (100 ns), the value of $(G\epsilon)_{max}$ increases. In the present work $(G\epsilon)_{max}$ increased with decreasing temperature below 320 K in 12ED and the two PD's (Fig. 11). The increase occurred below 340 K in 14BD.

The value of $(G\epsilon)_{max}$ in the diols tends to have an upper limit of $\sim 2.5 \times 10^4$ e^-_s/100 eV *M* cm, where the low temperature liquid becomes glassy (Fig. 10). By analogy with behaviour in other polar systems (3, 15, 21–23), the value of $(G\epsilon)_{max}$ would probably decrease as the temperature of the glass was lowered farther. A greater fraction of electrons undergoes geminate reaction before relaxation to the solvated state is complete in the low temperature glasses.

The value of $G_{fi}\epsilon_{max}$ is 1.2×10^4 e^-_s/100 eV *M* cm in all of the diols except 23BD, in which it is 1.3×10^4, essentially independent of temperature (Fig. 11).

Decay of e^-_s free ions in purified solvents

The free ion e^-_s decayed by a first order reaction. The decay rate was measured after the geminate reaction was complete.

The decay rate at a given temperature was greatest in the vicinal diols and slowest in 14BD and 13BD (Fig. 12). The

The values of $(G\epsilon)_{max}$ were measured 150 ns after the beginning of a 100 ns pulse, or at the time when relaxation to e^-_s was just complete, whichever was the longer. ○, 12ED; △, 12PD; ▲, 13PD; □, 12BD; ■, 13BD; ◆, 14BD; ◇, 23BD. + = 1.16 ± 0.01 = ▲ and ■; × = 1.11 ± 0.01 = ○, △ and ▲.

[2]Geminate neutralization is a nonrandom process, so the concept of order does not apply to it. However, the concept of order is familiar and is sometimes used to make crude comparisons and quick estimates. The *rate* of geminate neutralization decreases relatively faster than does a first order reaction, which means that the effective order is greater than unity. The appropriate value of τ_{gn} in eq. [1] is therefore smaller than the value of τ for the total geminate neutralization process.

vicinal diols are the most easily oxidized, and therefore the most difficult to purify; they also appear to be the most reactive with solvated electrons. Repeated treatment of the diols with sodium borohydride under UHP argon and distillation under reduced argon pressure at temperatures below 100°C gave e^-_s decay that was at least partly due to reaction with the diol. Purification of a diol reduced not only the rate of e^-_s decay but also the activation energy of decay E_1, where

$$[3]\quad k_1(s^{-1}) = A_1 \exp(-E_1/RT)$$

For example, purification of 13PD reduced the apparent value of k_1 at 298 K from 3.1×10^6 s^{-1} to 0.6×10^6 s^{-1}, and E_1 from 32 to 22 kJ/mol. The most probable impurities are carbonyl compounds. The values of E_1 in the purified diols were much smaller than the activation energies E_{Ac} for reaction with acetone (Table 3). The values of E_1 listed in Table 3 are therefore upper limits.

The values of E_1 in the diols are about 2/3 the magnitude of E_η (refs. 8, 24, and Table 3). By contrast, the values of E_1 in the monohydric alcohols methanol and ethanol (25) were larger than E_η by about 1.5-fold, and were similar to E_τ for dielectric relaxation (refs. 26–28 and Table 3). Molecular rotational rearrangements are probably involved in the rate limiting step of the reaction of the electron with the solvent,

$$[4]\quad e^-_s \rightarrow RO^-_s + H$$

because the reaction is driven by the large difference between the solvation energies of RO^- and e^-, the former being larger (29). With the exception of 12ED, which has no unsubstituted alkyl group, the values of E_1 probably correlate with those of E_τ in the diols as well. For example, the viscous behaviour of 13BD is similar to that of 15PeD (30)[3] and E_1 in 13BD is similar to E_τ in 15PeD, where PeD is pentanediol (Table 3).

Acknowledgement

We are grateful to the personnel of the Radiation Research Center for aid with the electronics.

[3]The τ_2 determined by low frequency depolarized light scattering is similar to the τ_1 measured by microwave dispersion (molecular reorientation relatively unperturbed by fields).

Mécanisme des réactions du chlorite et du dioxyde de chlore. 2. Cinétique des réactions du chlorite en présence d'*ortho*-tolidine

GUY SCHMITZ ET HENRI ROOZE

Faculté des Sciences Appliquées, Université Libre de Bruxelles, 50 avenue F. Roosevelt, 1050 Bruxelles, Belgique

Reçu le 17 octobre 1983

GUY SCHMITZ et HENRI ROOZE. Can. J. Chem. **62**, 2231 (1984).

En présence d'*ortho*-tolidine (NH_2RNH_2), utilisée pour éliminer les complications dues aux réactions des produits intermédiaires de la dismutation du chlorite, la stoechiométrie est $HClO_2 + 2NH_2RNH_2 \rightarrow Cl^- + H^+ + 2NHRNH + 2H_2O$. On ne forme pas de chlorate. La loi cinétique, en l'absence de chlorure, est

$$-\,d[HClO_2]/dt = k\,[ClO_2^-]\,[Fe^{3+}]$$

$k = 269\ M^{-1}\ s^{-1}$ à 25°C et une force ionique de 1 *M*. Sans fer ajouté, la vitesse observée est due uniquement aux traces de fer toujours présentes comme impureté des réactifs. La réaction $2HClO_2 \rightarrow HClO + ClO_3^- + H^+$ n'est donc pas une réaction élémentaire.

GUY SCHMITZ and HENRI ROOZE. Can. J. Chem. **62**, 2231 (1984).

With added *ortho*-tolidine (NH_2RNH_2) in order to eliminate complicating side reactions of the intermediate products of the disproportionation of chlorite, the stoichiometry is $HClO_2 + 2NH_2RNH_2 \rightarrow Cl^- + H^+ + 2NHRNH + 2H_2O$. No chlorate is formed. The rate law, in the absence of chloride ions, is

$$-\,d[HClO_2]/dt = k\,[ClO_2^-]\,[Fe^{3+}]$$

$k = 269\ M^{-1}\ s^{-1}$ at 25°C and 1 *M* ionic strength. Without added iron, the observed rate is only due to the small amount of iron always present as an impurity in the reactants. Thus the reaction $2HClO_2 \rightarrow HClO + ClO_3^- + H^+$ is not an elementary reaction.

Introduction

Conservées à l'abri de la lumière, les solutions de chlorite sont stables en milieux alcalins. En milieux neutres elles se décomposent lentement suivant l'éq. [1]. La vitesse n'est notable que dans les solutions chaudes (1, 2).

[1] $3ClO_2^- = 2ClO_3^- + Cl^-$

En milieux acides elles se décomposent dès la température ordinaire, d'autant plus vite que l'acidité est grande. En absence de chlorure l'éq. [2] est la plus fréquemment citée mais des écarts importants ont été observés (réfs. 1 à 8).

[2] $4HClO_2 = 2ClO_2 + ClO_3^- + Cl^- + 2H^+ + H_2O$

Les ions chlorures augmentent la vitesse de décomposition et modifient la stoechiométrie. En milieux très acides et très riches en chlorures elle tend vers [3].

[3] $5HClO_2 = 4ClO_2 + Cl^- + H^+ + 2H_2O$

Dans notre article précédent (9), nous avons montré qu'une des causes de la variation des rapports stoechiométriques est l'existence d'une bifurcation dans le mécanisme, que l'on peut schématiser comme suit:

$$HClO_2 \rightarrow \rightarrow HClO \xrightarrow{HClO_2} Cl_2O_2 \begin{cases} \nearrow ClO_3^- \\ \searrow ClO_2 \end{cases}$$

En absence de chlorure la loi cinétique [4] proposée par Barnett (10) est généralement admise, avec éventuellement un effet de l'acidité sur la constante k_4 (réfs. 4 à 8, 11, 12).

[4] $-\,d[HClO_2]/dt = k_4\,[HClO_2]^2$

Kieffer et Gordon ont vérifié la loi [4] en milieux 2 et 1.2 molaires en $HClO_4$ mais ont constaté qu'elle n'est pas satisfaite en milieux 0.2 molaires. Ils n'on pas trouvé de loi satisfaisante dans ces conditions.

Nous avons étudié l'effet accélérateur des ions chlorures (9) et obtenu l'éq. [5] en bon accord avec les travaux précédents; $k_{II} = 9.1 \times 10^{-3}\ M^{-1}\ s^{-1}$ à 25°C et $I = 1\ M$; v_I représente la vitesse en l'absence de chlorure, objet de notre étude actuelle.

[5] $-\,d[HClO_2]/dt = v_I + k_{II}\,[HClO_2][Cl^-][H^+]$

Cherchant l'explication des écarts à la loi [4] observés par Kieffer et Gordon (8) nous avons fait une observation qui remet en cause les conclusions de plusieurs travaux antérieurs. La dismutation du chlorite est catalysée par des traces de fer, de l'ordre de celles que l'on trouve couramment comme impureté des réactifs. La figure 1 en donne un exemple. Pour étudier la cinétique de cette catalyse nous avons mis à profit les propriétés de l'*ortho*-tolidine, comme nous l'avions fait pour la catalyse par les ions chlorures.

Téchnique expérimentale

Nous avons vu (9) que l'*ortho*-tolidine ne réagit pas directement avec le chlorite mais est oxydée extrêmement rapidement par le dioxyde de chlore, le chlore et l'acide hypochloreux. Elle permet ainsi d'étudier la cinétique de la dismutation du chlorite en évitant les complications dues à la réaction entre le chlorite et le chlore ou l'acide hypochloreux. Toutes les vitesses indiquées dans cet article sont des vitesses initiales obtenues dans des conditions telles que l'effet des ions chlorures soit négligeable. Elles ont été mesurées en suivant l'absorbance des solutions due au dérivé oxydé de l'*ortho*-tolidine. Son absorbance molaire étant élevée ($\epsilon = 59\,750$) on obtient aisément des valeurs précises des vitesses initiales. Pour plus de détails, cf. la réf. 9. Les symboles suivants seront utilisés: NH_2RNH_2 et NHRNH, formules abrégées de l'*ortho*-tolidine et de son dérivé oxydé; $[NaClO_2]$, concentration totale du chlorite, c'est-à-dire $[HClO_2] + [ClO_2^-]$; [Fe] concentration totale du fer ajouté.

Résultats en présence de fer ajouté

Stoechiométrie

On ajoute le chlorite à un mélange d'acide perchlorique (0.1 *M*), d'*ortho*-tolidine en excès et de fer. Lorsque la réaction est terminée on mesure le pouvoir oxydant de la solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

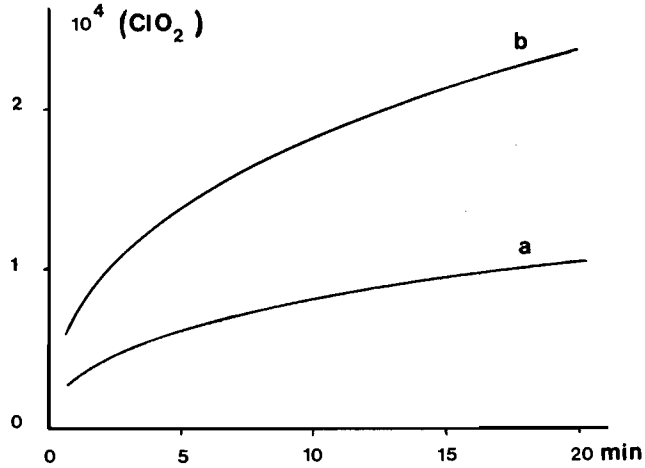

FIG. 1. Effet catalytique du fer sur la production de ClO_2. $[NaClO_2] = 2{,}5 \times 10^{-3}$ *M*, $[HClO_4] = 0{,}1$ *M*. (a) Sans addition de fer. (b) Addition de 5×10^{-6} *M* de fer.

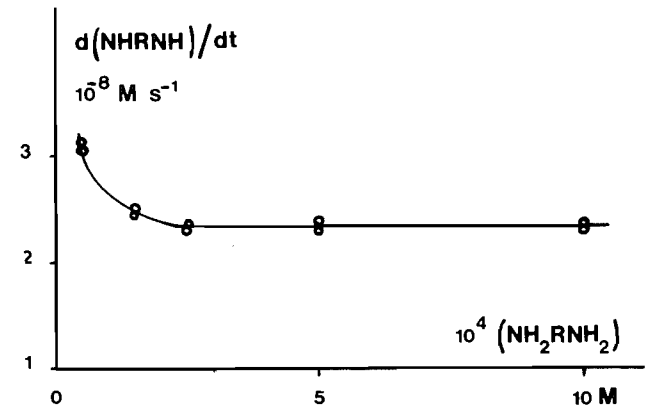

FIG. 2. Effet de l'*ortho*-tolidine sur la vitesse de [6]. $[HClO_4] = 0{,}105$ *M*, $[NaClO_2] = 1{,}97 \times 10^{-4}$ *M*, $[Fe] = 1{,}0 \times 10^{-6}$ *M*.

par iodométrie et l'*ortho*-tolidine oxydée par absorptiométrie. On constate que le pouvoir oxydant est conservé, normalité finale = 4.0 ± 0.2 $[NaClO_2]_0$, et que le rapport [NHRNH]/$[NaClO_2]_0$ vaut en moyenne 2.08 ± 0.15. L'*ortho*-tolidine supprime donc la formation de chlorate et le système évolue conformément à [6].

[6] $HClO_2 + 2NH_2RNH_2 = Cl^- + H^+ + 2H_2O + 2NHRNH$

Cinétique

L'effet de la force ionique *I* entre 0.2 et 1 *M* est faible. Elle a été fixée à 1 *M* avec du $NaClO_4$. La figure 2 montre que la vitesse de [6] est indépendante de la concentration de l'*ortho*-tolidine, à condition que celle-ci soit suffisamment grande. La valeur minimale de la concentration à utiliser augmente avec l'acidité et avec la concentration du chlorite. La raison de l'augmentation de la vitesse aux faibles concentrations apparaîtra lorsque nous discuterons la figure 5.

Les figures 3 et 4 montrent que la vitesse de [6] est proportionnelle à la concentration du fer. Nous ne considérons ici que les pentes des droites, les ordonnées à l'origine seront discutées dans le paragraphe suivant. Les résultats ne dépendent pas de la nature du sel de fer utilisé, nitrate de Fe(III), sulfate de Fe(III) ou sel de Mohr. Les pentes des droites de la figure 3 étant proportionnelles à $[NaClO_2]$ posons

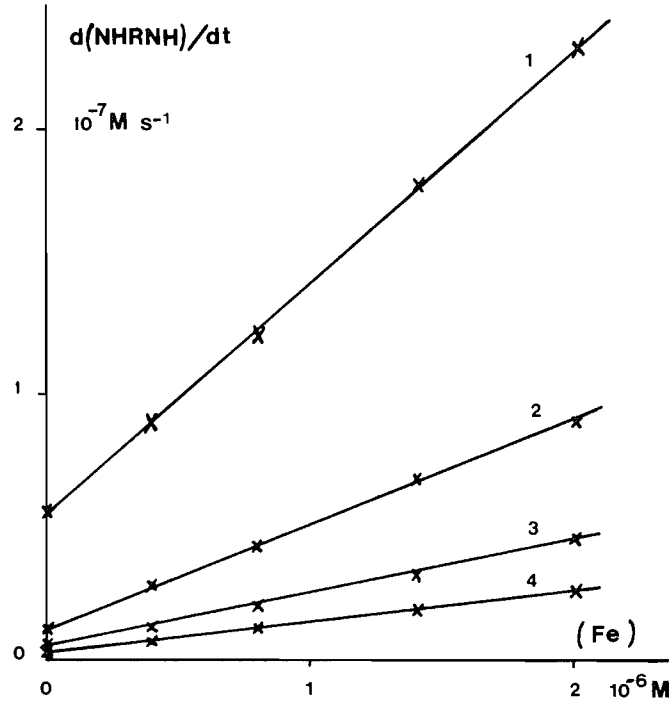

FIG. 3. Vitesses en présence d'*ortho*-tolidine. $[HClO_4] = 0{,}107$ *M*; $[NaClO_2] = 8{,}66 \times 10^{-4}$ *M* (1), $3{,}98 \times 10^{-4}$ *M* (2), $1{,}99 \times 10^{-4}$ *M* (3), $1{,}19 \times 10^{-4}$ *M* (4).

[7] $d[NHRNH]/dt = k' [NaClO_2][Fe]$

L'effet de l'acidité sur k' est donné dans le tableau 1. On constate que $1/k'$ est proportionnel à $1 + [H^+]/K_a$ avec $K_a = 2.4 \times 10^{-2}$, valeur obtenue par Hong et Rapson (7) pour la constante d'acidité de $HClO_2$ si $T = 25°C$ et $I = 1$ *M*. L'écart à la valeur thermodynamique $K_a = 1.1 \times 10^{-2}$ (9) correspond à une valeur vraisemblable du coefficient d'activité, $\gamma_\pm = 0.66$. On en déduit la loi cinétique [8].

[8] $d[NHRNH]/dt = k_8 [ClO_2^-][Fe^{3+}]$

$$k_8 = k' \left(1 + \frac{[H^+]}{K_a}\right)$$

Lors de la discussion du modèle cinétique nous montrerons qu'au cours de nos expériences la quasi-totalité du fer est maintenue sous forme de Fe(III). D'autre part la constante de première hydrolyse du Fe(III) vaut 9×10^{-4} (13, 14). Aux acidités considérées on a donc $[FeOH^{++}] \ll [Fe^{3+}]$ et $[Fe^{3+}] \simeq [Fe]$. Les valeurs du tableau 1 donnent $k_8 = 538 \pm 18$ M^{-1} s^{-1}.

Effet de la température

Nous avons vérifié la proportionnalité entre la vitesse de [6] et la concentration du fer à trois autres températures. Si $[HClO_4] = 0.41$ *M* on obtient $k' = 7.0$ (15.1°C), 110 (35.6°C), 267 (44.2°C) et une énergie d'activation apparente de 95 kJ/mol. Pour obtenir l'énergie d'activation relative à k_8 il faudrait connaître la variation de K_a en fonction de la température.

Résultats sans addition de fer

Dans la zone de pH étudiée le chlorite se dismute en absence de fer introduit intentionnellement, mais cela ne signifie pas qu'il existe un chemin réactionnel indépendant du fer. Les ordonnées à l'origine des figures 3 et 4 résultent des traces de fer inévitablement présentes dans les réactifs. Cette affirmation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

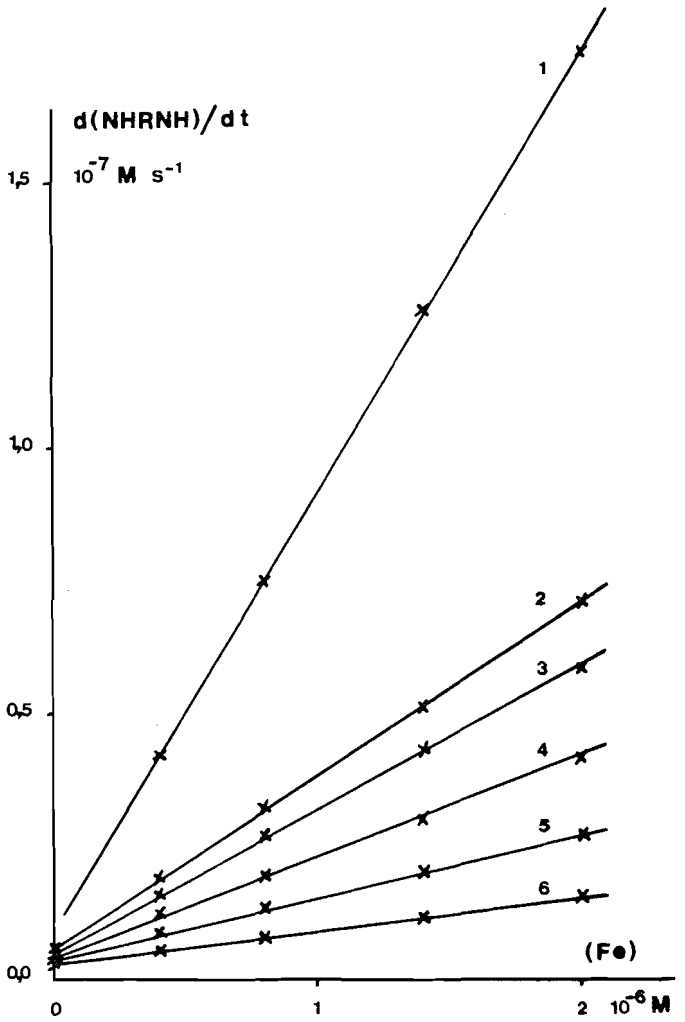

FIG. 4. Vitesses en présence d'*ortho*-tolidine. $[NaClO_2] = 2{,}13 \times 10^{-4}$ *M*; $[HClO_4]$ = 0,0087 *M* (1), 0,055 *M* (2), 0,075 *M* (3), 0,107 *M* (4), 0,208 *M* (5), 0,416 *M* (6).

remettant en cause un aspect important du mécanisme de la dismutation du chlorite nous détaillerons quelque peu nos observations.

Si l'on purifie davantage les réactifs les vitesses diminuent. On ne peut cependant les rendre négligeables à cause de la grande sensiblité de la réaction et de l'impossibilité d'éliminer suffisamment le fer des réactifs. L'acide perchlorique Merck "Suprapur" et le chlorite recristallisé plusieurs fois contiennent assez de fer pour catalyser la réaction. L'un de nous a montré (15) que les ordonnées à l'origine de droites telles que celles des figures 3 et 4 correspondent bien aux vitesses calculées par [7] en utilisant les valeurs des teneurs en fer des réactifs déterminées par spectroscopie d'émission de plasma.

En milieux perchloriques 1 *M* et en absence d'*ortho*-tolidine la dismutation du chlorite obéit à une loi d'ordre deux. La figure 5 montre nos résultats en présence d'*ortho*-tolidine. Si la concentration de celle-ci est faible on obtient une somme de deux termes, l'un d'ordre un, l'autre d'ordre deux. Si on l'augmente, on supprime le terme d'ordre deux. Les analyses par spectroscopie d'émission de plasma ont montré que lors des expériences de la figure 5 le fer provenait principalement de l'acide perchlorique, pour le reste de la solution d'*ortho*-tolidine et que la concentration totale du fer était quasi-indépendante du chlorite. Le terme d'ordre un est ainsi conforme à la loi [7].

TABLEAU 1. Constantes cinétiques; 25°C, I = 1 *M*

$[HClO_4]$ (*M*)	$[NaClO_2]$ (10^{-4} *M*)	k' (M^{-1} s^{-1})	k_8 (M^{-1} s^{-1})
0,107	1,19	98,9	539
0,107	1,99	103,6	564
0,107	3,98	101,3	552
0,107	8,66	102,2	557
0,0087	2,13	392	534
0,055	2,13	154,5	506
0,075	2,13	124,4	515
0,208	2,13	55,4	536
0,416	2,13	30,0	551
0,305	1,64	38,2	524
1,02	1,64	12,5	544

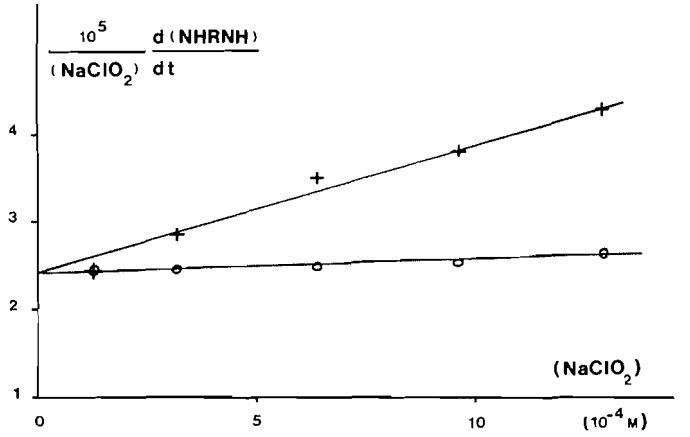

FIG. 5. Suppression par l'*ortho*-tolidine de la réaction d'ordre deux. $[HClO_4]$ = 1 *M*, $[NH_2RNH_2] = 2{,}5 \times 10^{-4}$ *M* (+), $2{,}5 \times 10^{-3}$ *M* (○).

La réaction d'ordre un étant catalysée par le fer on prévoit qu'un agent complexant tel que l'EDTA réduise sa vitesse, ce que nous avons vérifié. Par exemple si $[HClO_4] = 0.1$ *M*, $[NaClO_2] = 8.7 \times 10^{-4}$ *M* et $[NH_2RNH_2] = 2.5 \times 10^{-4}$ *M* nous avons obtenu $d[NHRNH]/dt = 5.48\ 10^{-8}$ *M* s^{-1} sans EDTA et 0.33×10^{-8} *M* s^{-1} avec 5×10^{-3} mol/L d'EDTA. Par contre, dans nos conditions expérimentales, il n'y a pas lieu de considérer de complexe avec l'*ortho*-tolidine, la vitesse de la réaction d'ordre un étant indépendante de sa concentration.

Discussion

La loi [8] peut être interprétée[1] en admettant l'étape déterminante [9].

[9] $ClO_2^- + Fe^{3+} \rightarrow ClO_2 + Fe^{2+}$

Nous savons (9) que le dioxyde de chlore oxyde très rapidement l'*ortho*-tolidine suivant [10].

[10] $2ClO_2 + NH_2RNH_2 \rightarrow 2HClO_2 + NHRNH$

Pour compléter le mécanisme nous nous basons sur les résultats d'Ondrus et Gordon (16). Ils ont étudié l'oxydation du Fe(II)

[1] Remarquons que nos résultats pourraient également être interprétés par $HClO_2 + FeOH^{2+} \rightarrow ClO_2 + Fe^{2+} + H_2O$, sans que cela change nos conclusions.

par le chlorite, en présence de phénol pour capter le HClO, et ont obtenu

$$-d[Fe^{2+}]/dt = k_{obs}\,[NaClO_2][Fe^{2+}]$$

k_{obs} est une fonction décroissante de l'acidité. Ils ont montré que l'étape déterminante correspond à l'échange d'un seul électron et ont admis le mécanisme suivant.

$$HClO_2 + Fe^{2+} \rightarrow Fe^{3+} + Cl(II)$$

$$ClO_2^- + Fe^{2+} \rightarrow Fe^{3+} + Cl(II)$$

$$Cl(II) + Fe^{2+} \rightarrow Fe^{3+} + HOCl$$

En considérant que l'intermédiaire qu'ils désignent par Cl(II) est le radical ClO leur mécanisme s'écrit:

[11] $HClO_2 + Fe^{2+} \rightarrow ClO + FeOH^{++}$

[12] $ClO_2^- + Fe^{2+} + H_2O \rightarrow ClO + Fe(OH)_2^+$

[13] $ClO + Fe^{2+} + H^+ \rightarrow HClO + Fe^{3+}$

$$Fe(OH)_2^+ + H^+ \rightleftharpoons FeOH^{++} + H_2O$$

$$FeOH^{++} + H^+ \rightleftharpoons Fe^{3+} + H_2O$$

Dans le domaine d'acidité étudié les concentrations des formes hydroxylées du Fe(III) sont négligeables. En présence d'*ortho*-tolidine, il est probable que le ClO est réduit directement, la réaction globale [14] remplaçant [13].

[14] $2ClO + 3NH_2RNH_2 \rightarrow 2Cl^- + 2H^+ + 3NHRNH + 2H_2O$

On obtient la stoechiométrie [6] en faisant la somme [9] + 1/2 [10] + [11] ou [12] + 1/2 [14].

En vitesse initiale, l'effet des ions Cl^- est négligeable et la vitesse est déterminée par [9]. On retrouve ainsi la loi expérimentale.

$$d[NHRNH]/dt = 2k_9\,[ClO_2^-][Fe^{3+}]$$

$$k_9 = 269 \pm 9\ M^{-1}\ s^{-1} \qquad K_a = 2.4 \times 10^{-2}$$

Pour obtenir les valeurs de k_{11} et k_{12} nous avons recalculé les valeurs de k_{obs} données par Ondrus et Gordon (16).

$$k_{11} + \frac{K_a}{[H^+]}\,k_{12} = \frac{1}{2}\left(1 + \frac{K_a}{[H^+]}\right)k_{obs}$$

Ayant $[HClO_4] = 0.05$ à 1 M le second nombre de cette relation dépend peu de K_a. Nous l'avons calculé en prenant $K_a = 2.4 \times 10^{-2}$. Un ajustement par la méthode des moindres carrés donne

$$k_{11} = 930; \qquad K_a k_{12} = 64 \quad (25°C,\ I = 2\ M)$$

Ces valeurs nous permettent de vérifier que nous pouvions interpréter [7] en admettant $[Fe^{3+}] \gg [Fe^{2+}]$. L'approximation de la stationnarité donne

$$\frac{[Fe^{3+}]}{[Fe^{2+}]} = \frac{2}{K_a k_9}\,(k_{11}\,[H^+] + K_a k_{12})$$

$$= 290\,[H^+] + 20 \gg 1$$

Conclusions

En présence d'assez d'*ortho*-tolidine on obtient uniquement la réaction [6], sans formation de chlorate, obéissant à la loi [7]. Il n'y a pas de réaction directe entre le chlorite et l'*ortho*-tolidine mais uniquement une décomposition du chlorite catalysée par le fer et l'oxydation de l'*ortho*-tolidine par les produits de cette décomposition.

Les vitesses observées en absence de fer ajouté sont dues aux traces de fer présentes dans les réactifs. La réaction $2HClO_2 \rightarrow HClO + ClO_3^- + H^+$ d'ordre deux obtenue en absence d'*ortho*-tolidine n'est pas une réaction simple, car si elle l'était, elle subsisterait en sa présence. Le mécanisme proposé pour la réaction [6] nous fournit les premiers éléments du mécanisme de la dismutation du chlorite en absence d'*ortho*-tolidine, objet de notre prochain article.

BETTY R. DEROSKI, JOHN S. RICCI, JR., J. A. HUGH MACBRIDE, and J. HODGE MARKGRAF. Can. J. Chem. **62**, 2235 (1984).

The structure of 1,8-diazabiphenylene (**5**) has been determined by X-ray methods. Crystals of **5** are monoclinic, space group $P2_1/n$, with a = 3.786(2), b = 8.532(1), c = 11.218 (2) Å, β = 92.24(2)°, and two molecules per unit cell. The planar molecule contains distorted aromatic rings with the smallest angle (112.9°) adjacent to the fused strained ring.

BETTY R. DEROSKI, JOHN S. RICCI, JR., J. A. HUGH MACBRIDE et J. HODGE MARKGRAF. Can. J. Chem. **62**, 2235 (1984).

Faisant appel à la diffraction des rayons-X, on a déterminé la structure du diaza-1,8 biphénylène (**5**). Les cristaux de **5** sont monocliniques, groupe d'espace $P2_1/n$, avec a = 3,786(2), b = 8,532(1), c = 11,218(2) Å, β = 92,24(2)° et contiennent deux molécules par maille. La molécule plane comporte des cycles aromatiques déformés dans lesquels l'angle le plus petit (112,9°) est adjacent au cycle condensé qui est tendu.

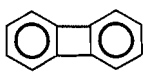
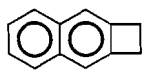
Introduction

The incorporation of strained rings into organic molecules is known to influence the physical properties and the chemical reactivity of such compounds. For the past two decades these effects have been studied extensively in aromatic systems containing fused, four-membered rings. The definitive work on the crystal structure of biphenylene **1** was reported by Trotter and co-workers, who noted that the internal angles of the six-membered rings differed significantly from 120° (1). The site of maximum distortion in the aromatic ring was the C(8b)—C(1)—C(2) angle, which averaged 115.2°; the same value was reported later by others (2). From structural studies on unsymmetrical systems (e.g. **2**) it is clear that the smallest angle of the benzene ring is always adjacent to the site of the fused four-membered ring (3–8).

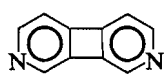


1

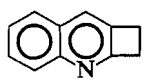


2

In contrast to the variety of carbocyclic systems, crystal structures have been determined for only two heterocyclic analogs: a quaternized derivative of 2,7-diazabiphenylene **3** (9) and 1,2-dihydrocyclobuta[*b*]quinoline **4** (10). In each case the position of the most acute angle of the six-membered rings was the



3



4

same as that in **1** and **2**. The C(3a)—N(3)—C(2a) angle of **4** (112.5°) was the smallest reported to date for such ring systems. In **3**, containing N(2) quaternized with an allyl substituent, the pyridinium ring exhibited a C(8b)—C(1)—N(2) angle of 114.4°, while the comparable angle in the pyridine ring was 119.2°. The availability of 1,8-diazabiphenylene **5** afforded a novel heterocyclic framework which combined features of both **1** (all carbons of the four-membered ring nominally sp^2) and **4** (nitrogen atom adjacent to the strained ring). Accordingly, we undertook an X-ray diffraction study of **5** to determine the extent of CNC bond angle distortion.

TABLE 1. Summary of data collection and processing parameters

Parameter	Value
Space group[a]	$P2_1/n$
Cell constants	a = 3.786(2) Å
	b = 8.532(1)
	c = 11.218(2)
	β = 92.24(2)°
	V = 362 Å^3
Molecular formula	$C_{10}H_6N_2$
Molecular weight	154.17
Molecules per cell	Z = 2
Density (calcd.)	ρ = 1.41 g cm^{-3}
Absorption coefficient (CuK_α)	μ = 7.02 g cm^{-1}
Total data collected	1685
Unique data	823
Data with $I \geq 3\sigma(I)$	614
Total variables	67
$R = \Sigma\|\|F_o\| - \|F_c\|\|/\Sigma\|F_o\|$	0.059
$R_w = (\Sigma_w(\|F_o\| - \|F_c\|)^2/\Sigma_w\|F_o\|^2)^{1/2}$	0.076

[a]Equivalent positions: $1/2 + x, y, z$; $1/2 - x, \bar{y}, \bar{z}$; $1/2 - x, 1/2 + y, 1/2 - z$; $1/2 + x, 1/2 - y, 1/2 + z$.

Experimental

Synthesis

1,8-Diazabiphenylene was prepared by flash vacuum pyrolysis of 4,5,9,10-tetra-azaphenanthrene (9, 11), mp 156.5–158.5°C.

[a]Anisotropic thermal parameters in the form $\exp[-(\beta_{11}h^2 + \beta_{22}k^2 + \beta_{33}l^2 + \beta_{12}hk + 2\beta_{13}hl + 2\beta_{23}hl)]$.
[b]Hydrogens were assigned the isotropic thermal parameter of 5.5 Å^2.

Data collection

Precession photographs and cell reduction calculations revealed the crystal to be monoclinic. The cell dimensions were determined by a least-squares fit of the observed 2θ angles for 24 reflections centered automatically. Reflections for $0k0$, $k \neq 2n$ and $h0l$, $(h + l) \neq 2n$ were absent.

Three dimensional intensity data were measured on a computer-controlled Enraf–Nonius CAD-4 diffractometer, using CuK_α (λ = 1.5418 Å) radiation monochromatized by reflection from a highly ordered graphite monochromator. The data crystal (ca. 0.1 × 0.1 × 0.2 mm), which was clear, yellow, and air stable, was coated with epoxy resin. Data were collected at 18°C by $\theta-2\theta$ scans to 2θ (CuK_α) = 154° ($\sin\theta/\lambda$ = 0.63). Peak backgrounds were measured as one-tenth of the total scan width on each side. Normal scans which did not result in sufficiently high precision on net intensity measurements were repeated at a slower scan speed. The take-off angle was 3.2° and the diffracted beam was automatically corrected for coincidence losses. Two complete independent sets of data were collected, yielding 1685 reflections. The intensities of three monitor reflections were measured periodically and showed no significant variation over the course of data collection. No correction for absorption was made. The data were averaged to yield 823 unique reflections.

Solutions and refinement of the structure

From space group consideration the molecule appeared to contain a center of inversion and thus to be disordered. The structure was solved by direct methods using MULTAN (12), which revealed all six nonhydrogen atoms of the asymmetric unit.

All six atoms located by direct methods were initially refined as carbon atoms by differential synthesis refinement,[3] and the hydrogen atoms were located as the first four peaks in a difference Fourier synthesis. The first two peaks corresponded to the ordered hydrogens and the next two peaks to the disordered hydrogens. The location of four independent hydrogen atoms confirmed a disordered structure with nitrogen and carbon atoms randomly occupying the same position. Atomic scattering factors were taken from a standard source (13), while that for hydrogen was the best spherically averaged value of Stewart *et al.* (14). The accommodate the disorder, N(1) and C(4) were refined using an atomic scattering factor based on an average of those for nitrogen and carbon. The hydrogens involved in the disorder, H(4) and H(5), were given an occupancy factor of 0.50. In the full-matrix least-squares calculations the function minimized was $\Sigma w\Delta^2$, where $\Delta = |F_o - F_c|$ with weights $w = 4F_o^2/\sigma^2(F_o^2)$ and $\sigma^2(F_o^2) = \sigma^2_{count}(I) + (0.02F^2)^2$. Using a three-sigma rejection, 614 reflections were included in the refinement of 67 parameters. In the final refinement all nonhydrogen atoms were allowed to vary anisotropically and hydrogen atoms were assigned an isotropic thermal parameter of 5.5 Å^2. The error in an observation of unit weight was 2.77. The maximum density in a final difference Fourier was 0.26 e Å^{-3}, which was 3.2% of the largest peak in a final observed Fourier. The data collection and processing parameters are summarized in Table 1. Positional and thermal parameters are listed in Table 2. Bond lengths and bond angles are given in Tables 3 and 4, respectively. The list of structure factors has been placed in the Depository of Unpublished Data.[4]

TABLE 3. Interatomic distances with estimated standard deviation in parentheses[a]

Bond	Length (Å)
N(1)—C(2)	1.404(3)
N(1)—C(8b)	1.311(2)
C(2)—C(3)	1.368(3)
C(3)—C(4)	1.386(3)
C(4)—C(4a)	1.331(2)
C(4a)—C(8b)	1.417(2)
C(4a)—C(4b)	1.518(3)
C(2)—H(2)	0.98 (3)
C(3)—H(3)	1.02 (3)
C(4)—H(4)	1.02 (5)
C(5)—H(5)	0.98 (5)

[a]Due to the disorder and the inversion center contained in the molecule the following atoms are related: N(1) = C(5), C(2) = C(6), C(3) = C(7), C(4) = N(8), C(4a) = C(8a), C(8b) = C(4b), and the corresponding hydrogens.

Results and discussion

The structure of 1,8-dizabiphenylene is shown in Fig. 1 together with atom labelling. The molecule is planar with a maximum deviation from planarity of 0.09(5) Å for a hydrogen atom and 0.006(2) Å for any other atom. A drawing of the packing in the unit cell is presented in Fig. 2. The distance between planes is 3.52 Å; the shortest intermolecular contacts are C(4)···H(5) of 2.593 Å and H(3)···H(5) of 2.425 Å.

A significant feature of **5** is the CNC bond angle of 112.9(2)°; the value is an average for (C8b)—N(1)—C(2) and C(3)—C(4)—C(4a), resulting from the inversion center and the disorder. This value compares favorably with that of the

C(4b)—C(5)—H(5)	132.6(31)
C(6)—C(5)—H(5)	114.5(31)

[a]Due to disorder and the inversion centers contained in the molecule the following atoms are related: N(1) = C(5), C(2) = C(6), C(3) = C(7), C(4) = N(8), C(4a) = C(8a), C(8b) = C(4b), and the corresponding hydrogens.

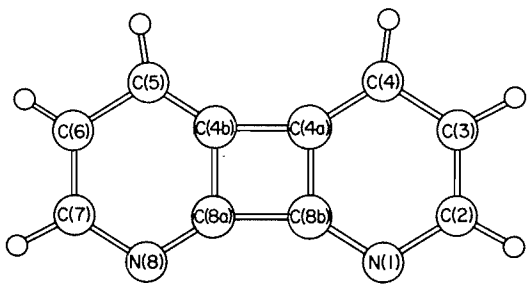

FIG. 1. Molecular structure of **5** with atom labelling.

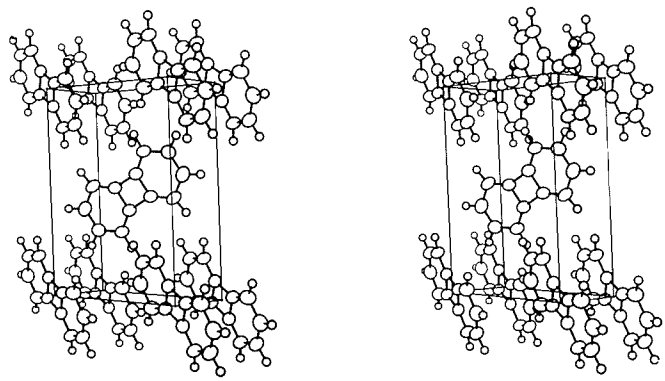

FIG. 2. The unit cell. Due to disorder, hydrogens occur with 50% occupancy at N(1) or C(5) and at N(8) or C(4) and are included to illustrate all possible modes of packing.

comparable angle in **4**, whose structure was determined recently (10) as a result of prior molecular orbital calculations which predicted a CNC angle of 112.1° (15). The observed angle was 112.5°, considerably smaller than the 117.3° reported for the corresponding angle in **2** (3*b*). Thus the present work on **5** represents only the second system in which an abnormally acute CNC angle adjacent to a fused strained ring has been confirmed.

Earlier papers in this series (16), as well as work by others (17), established that the fusion of a strained, four-membered ring across the [*b*] face of an aza-aromatic system causes a reduction in basicity. Compound **5**, with a pK_a of 1.92, affords a dramatic example of this effect (18); for comparison 2,2′-bipyridine has a pK_a of 4.33 (19).

Introduction

The vibrational spectra of toluene, aniline, and bromobenzene were extensively studied and analysed (1–3). Similar spectral investigations on isomers of toluidine, bromotoluene, and bromoaniline were reported by earlier workers (1, 4–7). The vibrational spectra of certain isomers of aminofluorotoluene (8, 9) and aminochlorotoluene (10) were already reported while those of aminobromotoluene were, so far, not reported and analysed. The present paper deals with the recording and analysis of the infrared absorption and laser Raman spectra of 4-amino-3-bromotoluene and 5-amino-2-bromotoluene.

Experimental

4-Amino-3-bromotoluene (2-bromo-4-methylbenzenamine) and 5-amino-2-bromotoluene (4-bromo-3-methylbenzenamine), hereafter referred to as molecules **A** and **B** respectively, were obtained from M/s. Fluka A. G., Switzerland. Both **A** and **B** are "purum" grade, the purity of **A** being greater than 98% and that of **B** greater than 99%. **A** is in liquid form and **B** is in solid form at room temperature. The infrared absorption spectra were recorded in the region 400–4000 cm^{-1} on a Zeiss UR-10 spectrophotometer using a 0.029 mm path length cell with KBr windows for **A**, and KBr pellet technique for **B**. The infrared spectrum of **B** was also obtained as a dilute solution in CCl_4 in the regions 800–1800 cm^{-1} and 2800–3600 cm^{-1}. The infrared spectrophotometer was calibrated using a thin film of polystyrene. The absorption spectrum of **B** in the far-infrared region was recorded on a Polytec FIR30 Fourier far-infrared spectrophotometer using polyethylene pellet technique. The laser Raman spectra of **A** (liquid form) and **B** (powder form) were obtained on Jobin Yvon Ramanor HG 2S and Cary 82 spectrophotometers, respectively. The polarization characteristics could be studied for some of the Raman lines of **A**. The infrared frequencies are accurate within ±2 cm^{-1} in the region 100–700 cm^{-1} and ±4 cm^{-1} in the region 700–4000 cm^{-1}. The Raman shifts are accurate within ±4 cm^{-1}. The traces of the spectra recorded are shown in Figs. 1–6.

Results and discussion

Assuming the substituents as single mass points, both **A** and **B** may be considered to belong to the C_s point group. Each of these molecules has 17 atoms and is expected to give rise to 45 vibrations — 30, characteristic of the phenyl ring and 15, characteristic of the substituent groups. These 45 vibrations, in C_s point group, are classified among the symmetry species as $31a' + 14a''$ and all are allowed both in the infrared and Raman spectra.

The vibrational spectra could be analysed in terms of the fundamental characteristic of the molecules, overtones, and combinations on the basis of Varsanyi's (1, 11) classification of the benzene derivatives, the frequency ranges suggested by him for each mode of vibration, and a comparison with the vibrational spectra of related molecules. **A** and **B** come under "1,4-dilight-2-heavy" and "1-heavy-2,4-dilight" classes, respectively (1). The frequencies obtained from the infrared and Raman spectra together with their visual intensities and probable assignments are shown in Table 1.

C—H and C—X (X = substituent) stretching vibrations

Benzene modes 2, 20*a*, 20*b* remain as C—H stretching modes while modes 7*a*, 7*b*, 13 transform into C—X stretching modes in both molecules studied.

The aromatic C—H stretching frequencies generally lie in the region 3000–3100 cm^{-1} and this is also the case in the present study.

The C—CH_3 stretching mode in a number of methylbenzenes was observed at around 1200 cm^{-1} (1, 4, 8–10, 12). The frequencies 1187 cm^{-1} (1185 cm^{-1})[3] in **A** and 1186 cm^{-1} in **B** are identified as due to C—CH_3 stretching vibrations and are attributed to mode 13. Primary aromatic amines absorb strongly in the region 1250–1340 cm^{-1}, due to stretching of the phenyl carbon–nitrogen bond (13). The medium intense absorption at 1270 cm^{-1} (1266 cm^{-1}) in **A** is taken to represent the C—NH_2 stretching mode in conformity with a similar vibration reported at 1278 cm^{-1} in aniline (1), 1265 cm^{-1}, 1265 cm^{-1}, 1273 cm^{-1} in bromoanilines (7), 1275 cm^{-1}, 1260 cm^{-1}, 1289 cm^{-1} in dibromoanilines (14), 1273 cm^{-1} in *p*-toluidine (4) and also in a number of other substituted anilines (1). In **B**, where the two "light" substituents NH_2 and CH_3 are vibrating out-of-phase in the *meta* position, the C—X stretching vibration, mode 7*b*, corresponding to one of the substituents will be observed below 1000 cm^{-1} (1, 11). The absorption at 950 cm^{-1} (940 cm^{-1}) in this molecule is assigned to C—NH_2 stretching vibration corresponding to mode 7*b*.

The C—X stretching vibration, mode 7*a*, of the "heavy" substituent lies in the low frequency region 200–480 cm^{-1}. The frequencies (345 cm^{-1}) in **A** and 320 cm^{-1} (328 cm^{-1}) in **B** are associated with the C—Br stretching mode by way of

comparison with the C—Br stretching frequencies reported in a number of bromobenzenes (1).

C—C stretching vibrations

The degeneracy of the C—C stretching modes 8*a*, 8*b*, and 19*a*, 19*b* of benzene is removed on reduction of symmetry. In the present class of molecules modes 8*a*, 8*b* are observable in the region 1555−1635 cm^{-1} while modes 19*a*, 19*b* lie in the region 1380−1515 cm^{-1}. Mode 8*b* appears at a higher frequency than mode 8*a* while mode 19*b* is found at a higher magnitude than mode 19*a*. The non-degenerate mode 14, the Kekule vibration, lies in the region 1220−1270 cm^{-1}. The asymmetric and symmetric deformation vibrations of the methyl group also give rise to absorptions in the vicinity of the C—C stretching modes 19*a*, 19*b*. The scissoring mode of the amino group appears in the neighbourhood of modes 8*a* and 8*b*. Assignments for all these vibrations are shown in Table 1.

The totally symmetric ring breathing vibration, mode 1, is very sensitive to substitution. In **A** this mode strongly couples with the C—X stretching vibration of a "light" substituent, resulting in a decrease in frequency when compared to benzene, the suggested frequency range being 600−700 cm^{-1} (1). However, in **B** mode 1 weakly couples with the C—X stretching mode of the "heavy" substituent; as a consequence of which the frequency is slightly increased when compared to benzene, the expected frequency interval being 1020−1060 cm^{-1} (1). The medium intense band at 674 cm^{-1} (680 cm^{-1}, polarized) in **A** and the strong band at 1026 cm^{-1} in **B** are attributed to the ring breathing mode and are in good agreement with those reported in similar class of molecules (1).

C—H and C—X (X = substituent) in-plane bending vibrations

The normal modes 3, 18*a*, 18*b* remain as C—H in-plane bending modes whereas modes 9*a*, 9*b*, 15 represent C—X in-plane bending vibrations in both molecules in the present study.

The non-degenerate C—H in-plane bending vibration, mode 3, appears generally as a weak band in the region 1270−1310 cm^{-1} in the present class of molecules (1). However, in *o*- and *m*-bromoanilines, this mode was identified with strong bands at 1316 cm^{-1}, 1320 cm^{-1} based on normal co-ordinate analysis (7). The absorption bands at 1304 cm^{-1} (1305 cm^{-1}) in **A** and 1315 cm^{-1} (1324 cm^{-1}) in **B** are assigned to the C—H in-plane bending mode 3. The degenerate C—H in-plane bending modes 18*a*, 18*b* are observable in the region 1045−1170 cm^{-1}, the former being at a higher frequency than the latter. The

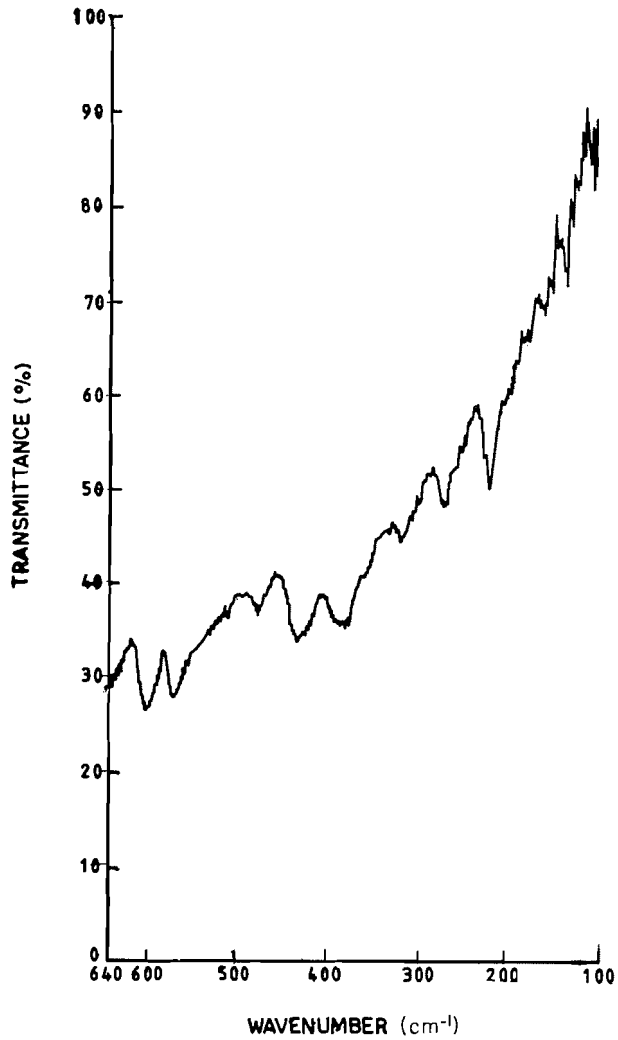

FIG. 4. Far-infrared spectrum of 5-amino-2-bromotoluene.

mode 18*a* could be identified in both molecules **A** and **B** whereas mode 18*b* is observed only in molecule **B**.

The C—X in-plane bending modes lie in the low frequency region below 440 cm^{-1}. The assignments made for these vibrations in the present study are shown in Table 1 and are in agreement with those reported in a number of related molecules (1, 4, 12, 15−19).

C—H and C—X (X = substituent) out-of-plane bending vibrations

The benzene modes 5, 11, 17*b* remain as C—H out-of-plane bending modes while the modes 10*a*, 10*b*, 17*a* correspond to C—X out-of-plane bending vibrations in **A** and **B**.

The above C—H out-of-plane bending modes lie in the region 800–990 cm^{-1}, the umbrella vibration, mode 11, appearing as a strong band with least frequency, and mode 17*b* occurring at a higher value than mode 5. The frequency due to the umbrella vibration can be well correlated with the number of unsubstituted vicinal hydrogen atoms on the aromatic ring. The present molecules have two unsubstituted vicinal hydrogen atoms on the ring, in which case there will be a strong band at 817 ± 13 cm^{-1} due to the C—H out-of-plane bending mode (13). The strong bands at 817 cm^{-1} in **A** and 824 cm^{-1} in **B** are accordingly identified with the umbrella vibration. The other C—H out-of-plane bending modes 5, 17*b* could be identified in **A** whereas only mode 5 is observed in **B**.

The C—X out-of-plane bending vibrations lie in the low frequency region below 350 cm^{-1}. The Raman frequencies 203 cm^{-1} (depolarized), 155 cm^{-1} in **A** and 216 cm^{-1} (225 cm^{-1} in the infrared), 138 cm^{-1} in **B** are taken to represent the C—NH_2 and C—Br out-of-plane bending modes, respectively, and are in good agreement with those reported in related molecules (1, 9, 10, 16).

C—C—C in-plane bending vibrations

Modes 6*a*, 6*b*, 12 are the C—C—C in-plane bending modes.

In the present class of molecules, vibration 6*a* appears at a higher frequency than that of benzene due to its coupling with the C—X stretching mode of the "heavy" substituent whereas mode 6*b* lies in the region 350–550 cm^{-1} (1). The frequencies (880 cm^{-1}), 467 cm^{-1} (475 cm^{-1}, polarized) in **A** and 874 cm^{-1}, 476 cm^{-1} in **B** are associated with the vibrational modes 6*a* and 6*b*, respectively. In both **A** and **B**, the normal mode 12 will be observed at a lower value than that of benzene as a result of its coupling with the C—X stretching vibration of a "light" substituent (1). The frequencies 772 cm^{-1} (773 cm^{-1}, polarized) in **A** and 743 cm^{-1} (732 cm^{-1}) in **B** are attributed to vibration 12.

C—C—C out-of-plane bending vibrations

The C—C—C out-of-plane bending vibrations are represented by modes 4, 16*a*, 16*b*.

Vibration 4, the C—C—C puckering mode, which was observed at 707 cm^{-1} in benzene, is rather insensitive to substitution. The absorptions at 713 cm^{-1} and 709 cm^{-1} in **A** and **B**, respectively, are assigned to this mode. The frequency of the vibrational components 16 rises on substitution as a result of coupling with out-of-plane C—X vibrations of lower frequencies, and mode 16*a* occurs at a higher frequency than mode 16*b* (1). Further, in 1,2,4-trisubstituted benzene derivatives, a medium intense or strong band appears in the region 428–476 cm^{-1} due to an out-of-plane ring deformation (15). The absorption bands at 550 cm^{-1}, 435 cm^{-1} in **A** and 567 cm^{-1}, 434 cm^{-1} in **B** are identified with the vibrations 16*a* and 16*b*, respectively.

Internal vibrations of the substituent groups

(*a*) CH_3 group: The methyl group gives rise to nine characteristic vibrations — two asymmetric stretchings, one symmetric stretching, two asymmetric deformations, one symmetric deformation, two rocking modes, and one torsion mode.

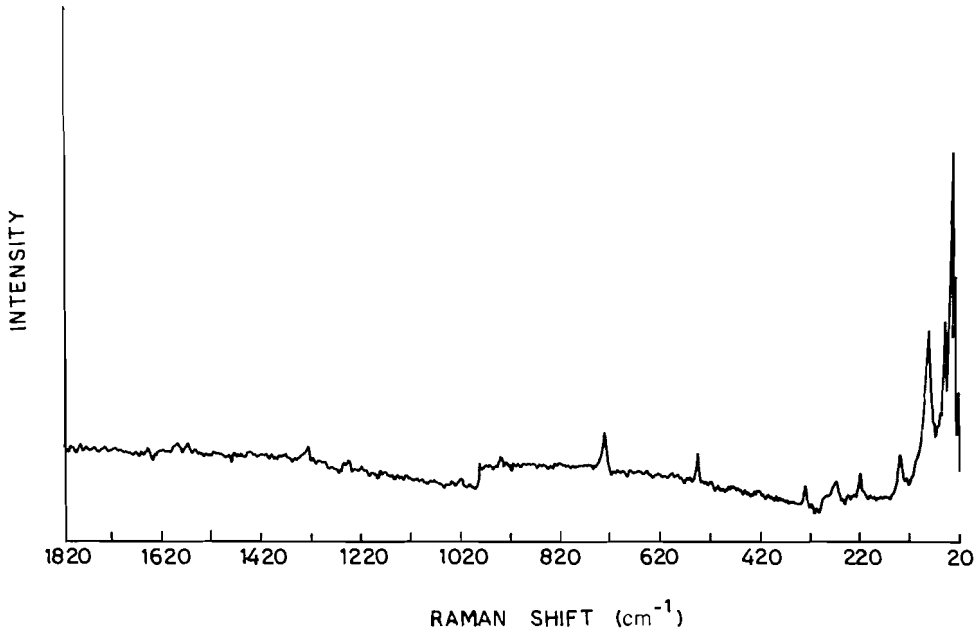

FIG. 6. Raman spectrum of 5-amino-2-bromotoluene (source of excitation — argon-ion laser).

The assignments made for these vibrations in these molecules are in very good agreement with those reported in a number of methylbenzenes (1, 6). The torsion mode could not be identified in either **A** or **B**.

(*b*) NH_2 group: The amino group gives rise to six characteristic vibrations — asymmetric and symmetric stretchings, scissoring, rocking, wagging, and twisting modes. Primary aromatic amines show absorptions in the region 3250–3550 cm^{-1} due to the asymmetric and symmetric stretching modes, the former mode being always at a higher frequency (20). The absorptions at 3474 cm^{-1}, 3378 cm^{-1} in **A** and 3420 cm^{-1}, 3335 cm^{-1} in **B** are associated with the asymmetric and symmetric stretching modes, respectively. The bands at 3217 cm^{-1} in **A** and 3235 cm^{-1} in **B** may involve a considerable contribution from an overtone of the scissoring mode intensified by Fermi resonance due to their proximity to the stretching fundamentals. A large frequency shift to a higher magnitude is observed in the NH_2 stretching frequencies of **B** in solution phase, indicating the likelihood of an association in the molecule through hydrogen bonds. The scissoring mode of the amino group in general lies in the region 1610–1640 cm^{-1} (1) where the C—C stretching modes 8*a* and 8*b* also give rise to absorptions. However, in almost all aniline derivatives, the scissoring mode is found at a higher frequency than the C—C stretching modes 8*a* or 8*b* (1). Further, Kumpawat *et al.* (7) calculated the HNH bending mode of the NH_2 group in isomers of chloroaniline, bromoaniline, and anisidine. They obtained a value of 1629 cm^{-1} for the *para* and *meta* isomers, and 1628 cm^{-1} for the *ortho* isomers. The frequencies 1630 cm^{-1} (1628 cm^{-1}) in molecule **A** and 1635 cm^{-1} (1646 cm^{-1}) in molecule **B** are attributed to the scissoring vibration of the amino group. This assignment is in excellent agreement with those reported in isomers of fluoromethylaniline (9) and chloromethylaniline (10). The assignments for the rocking and wagging modes in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

the present study are shown in Table 1 and are in good comparison with those reported in a number of anilines (1). The twisting mode could not be identified in either **A** or **B**.

Solvent effect on the dissociation of *p*-nitroanilinium ion in glycerol–water media at 25°C

AMRITA LAL DE[1] AND TAPAS KUMAR DE
Department of Chemistry, Presidency College, Calcutta-700073, India

Received January 16, 1984

AMRITA LAL DE and TAPAS KUMAR DE. Can. J. Chem. **62**, 2245 (1984).

Thermodynamic dissociation constants ($_sK$) of *p*-nitroanilinium ion (BH^+) have been determined at 25°C in aqueous mixtures of 10, 30, 50, 70, and 90 wt.% of glycerol (GL) by spectrophotometric measurements. Standard free energies, ΔG_t^0(B), of *p*-nitroaniline (B) from water to mixed solvents have been evaluated from the measurement of solubilities at 25°C. $p(_sK)$ values decrease with increase in mol% of GL and pass through a minimum and then increase very slowly. The solvent effect on the dissociation, $\delta(\Delta G^0) = 2.303RT[p(_sK)_N - p(_wK)_N]$ has been discussed in terms of the standard free energies of transfer ΔG_t^0 from water to aqueous mixtures of GL of the uncharged base (B), the hydrochloride of the base (BHCl), hydrochloric acid (HCl), and also in terms of the individual species involved in the dissociation process. The solvent effect in trihydric alcohol – water (GL + H_2O) system has been compared with those in dihydric alcohol – water (ethylene glycol + water) and monohydric alcohol – water (ethanol + water) systems available from literature. The much less solvent effect in GL + H_2O has been primarily attributed to the contrasting nature of interaction of H^+ and of partially charged H atoms of $—NH_3^+$ group in BH^+ compared to those in other two solvent systems.

AMRITA LAL DE et TAPAS KUMAR DE. Can. J. Chem. **62**, 2245 (1984).

Opérant à 25°C, dans des mélanges aqueux contenant 10, 30, 50, 70 et 90% en poids de glycérol (GL), et faisant appel à des mesures spectroscopiques, on a déterminé les constantes de dissociation thermodynamique ($_sK$) de l'ion *p*-nitroanilinium (BH^+). En se basant sur des mesures de solubilité à 25°C, on a évalué les énergies libres standard, ΔG_t^0(B), pour le passage de la *p*-nitroaniline (B) de l'eau à des solvants mixtes. La valeur du $p(_sK)$ diminue lorsqu'on augmente la teneur en GL; elle passe par un minimum puis augmente très lentement. On discute de l'effet du solvant sur la dissociation: $\delta(\Delta G^0) = 2{,}303RT[p(_sK)_N - p(_wK)_N]$, en fonction des énergies libres standard de transfer ΔG_t^0 pour le transfert de la base neutre (B), de son chlorhydrate (BHCl) et de l'acide chlorhydrique (HCl) de l'eau vers des mélanges aqueux de GL; on en discute également en fonction des espèces individuelles impliquées dans le processus de dissociation. On a comparé le rôle de l'effet du solvant dans le système glycérol–eau à ceux qui avaient été antérieurement observés avec les systèmes éthylèneglycol–eau et éthanol–eau et qui ont été rapportés dans la littérature. On attribue le fait que l'effet de solvant soit moins prononcé pour le système GL–eau à la nature contrastante de l'interaction de l'ion H^+ et des atomes d'hydrogène partiellement chargés du groupe NH_3^+ de l'ion BH^+ par comparaison à ceux des deux autres systèmes de solvants.

[Traduit par le journal]

Introduction

Dissociation constants of *p*-nitroanilinium ion (BH^+) were reported earlier in aqueous mixtures of monohydric (1) and dihydric (2) alcohols. This paper reports a study of the dissociation constants of *p*-nitroanilinium ion in aqueous mixtures of glycerol, a trihydric alcohol. Since the solvent effect involves $\Delta G_t^0(H^+)$ (2–5), the standard free energy of transfer of H^+ from water to other solvents concerned, a quantity giving a measure of the basicity of the solvent relative to that of reference solvent, water (5), and since $\Delta G_t^0(H^+)$ has been found to be of contrasting nature (positive magnitude) in glycerol–water (GL + H_2O) (6, 7) system compared to other solvent systems (2, 8–10), it would be interesting to study proton transfer process in this particular solvent system. In order to see the contribution of the uncharged base (2, 3, 11), *p*-nitroaniline (B), ΔG_t^0(B) values have been determined from the measurement of solubilities of B in water as well as in GL + H_2O mixtures.

Experimental

Glycerol (GR Merck) and water were purified as described (12). Preparation of solvents as well as HCl solutions and purification of *p*-nitroaniline were similar to those described earlier (2). The dissociation constant $(_sK)_m$ of *p*-nitroanilinium ion (BH^+) on the molal scale in aqueous mixtures of glycerol was determined spectrophotometrically using unbuffered solutions of HCl at different concentrations in a manner essentially similar to that described earlier (2, 3, 13, 14). The $p(_sK)_m$ values were obtained by linear extrapolation of the plots of $p(_sK)'_m$ of eq. [1] against μ to $\mu = 0$

$$[1] \quad p(_sK)'_m = -\log m_{SH_2^+} - \log \frac{\alpha}{1-\alpha} = p(_sK)_m + \log \frac{\gamma_{SH_2^+}\gamma_B}{\gamma_{BH^+}} = p(_sK)_m + f(\mu)$$

where α and $1 - \alpha$ are the fractions of the indicator species present in the neutral form B and the ionic form BH^+, respectively, and $m_{SH_2^+}$ is the effective molality of H^+ in the solution. A series of solutions were prepared by adding weighed amounts of HCl solutions and the solvent to weighed amounts of the *p*-nitroaniline solutions. The spectral absorbances were determined at 25 ± 0.2°C with a UNICAM SP 500 model spectrophotometer (England) with 1 cm quartz cells at 380 nm where the absorbance shows a maximum for the base form (13). The limiting absorbances of the acidic form at 380 nm, though small, were taken into account, and the absorbance readings were corrected, where necessary, for the identical total concentration of the indicator (*p*-nitroaniline). The limiting absorbances (2, 13) of the acidic and basic forms of *p*-nitroaniline were measured in very concentrated HCl solutions (6 *M*) and in very dilute sodium hydroxide solutions (0.001 *M*). The values of $\alpha/(1-\alpha) = (D - D_1)/(D_2 - D)$ were obtained from the optical densities D_1, D_2, and D of the completely acid form (BH^+), completely base form (B), and the mixture of the two forms measured at an identical concentration of the indicator in the same cell. The molality of the *p*-nitroanilinium ion at equilibrium was negligibly small with respect to the molality of HCl, so that $-\log m_{SH_2^+}$ was virtually the same as that of $-\log m_{HCl}$ in most cases. The values of μ were taken to be equal to $m_{HCl}d_s$, where d_s is the density of the solvent (12).

The standard free energies of transfer of the uncharged base, *p*-

nitroaniline (B) from water to mixed-solvents were computed by the method described earlier (2, 3, 11, 15) using the relation $\Delta G_t^0(B) = RT \ln ({}_wX_B/{}_sX_B)$ where ${}_wX_B$ and ${}_sX_B$ are the solubilities of the base in water and respective solvents (SH) on the mole fraction scale. As for uncharged solutes such as benzoic acid (16), tris(hydroxymethyl)aminomethane (2, 11), and nitroanilines (2, 3) in different aquo-organic solvents, the validity of this relation depends on the assumption that the ratio of activity coefficients of the uncharged base in the saturated solutions in the mixed solvent and in water is unity. Solubilities of B were determined at 25°C by the same method described earlier (2).

Results

The values of $p({}_sK)'_m$ corresponding to different molalities of HCl are shown in Table 1. The $p({}_sK)_m$ values obtained in the different solvent mixtures are also recorded in Table 1. The uncertainties in the $p({}_sK)_m$ values are of the order of ±0.005 unit. The solubilities of B and the $\Delta G_t^0(B)$ values at 25°C are recorded in Table 2. The maximum uncertainties in the $\Delta G_t^0(B)$ values are ±0.04 kJ mol^{-1}.

Discussion

For the sake of comparison (17) of the results in different solvent mixtures, the $p({}_sK)_m$ values have been converted into the mole fraction scale, $p({}_sK)_N$, by the usual relation (18) and are recorded in Table 1. In order to have a better understanding of the solvent effect, the changes of standard free energy accompanying the ionization of the acid BH^+ in any solvent, ${}_s\Delta G^0$, relative to that in pure water, ${}_w\Delta G^0$, have been computed at 25°C on the mole fraction scale using eq. [2].

$$[2] \quad \text{Solvent effect} = \delta(\Delta G^0) = {}_s\Delta G^0 - {}_w\Delta G^0 = 2.303RT\,[p({}_sK)_N - p({}_wK)_N]$$

Figure 1 illustrates the variations of $\delta(\Delta G^0)$ with mol% of glycerol (GL). For comparison, the corresponding profiles for the ethanol–water (EtOH + H_2O) (1) and ethylene glycol – water (EG + H_2O) (2) are also shown. For EtOH + H_2O system the dissociation constants were reported on the molal scale and the values were converted to the mole fraction scale for computation of $\delta(\Delta G^0)$ values. In GL + H_2O system $\delta(\Delta G^0)$ decreases with increase in mol% of GL and passes through a shallow minimum and then increases very slowly showing a small solvent effect on the dissociation of BH^+ ion. In contrast much larger solvent effect is observed in EtOH + H_2O and EG + H_2O systems showing a distinct minimum, the effect being greater in EtOH + H_2O. The characteristic minimum in the $\delta(\Delta G^0)$ curve for a BH^+-type acid has been observed in aqueous mixtures of many other organic solvents (1, 19, 20) but the solvent effect in the present case of study is less compared to those found in all other solvent systems.

The solvent effect on the dissociation of BH^+ is the resultant of free energy transfer values of the individual species involved in the ionization and is given by (2, 3, 15)

$$[3a] \quad \delta(\Delta G^0) = \Delta G_t^0(H^+) + \Delta G_t^0(B) - \Delta G_t^0(BH^+)$$

$$[3b] \quad = \Delta G_t^0(HCl) + \Delta G_t^0(B) - \Delta G_t^0(BHCl)$$

where $\Delta G_t^0(i)$ represents the free energy change accompanying the transfer of one mole of species i from the standard state in water to the standard state in the solvent concerned, both on the mole fraction scale. Variations of $\Delta G_t^0(B)$ in three alcohol–water systems are shown in Fig. 2. $\Delta G_t^0(B)$ values in EtOH + H_2O (21) and EG + H_2O (2) are taken from literature. The

increasing negative magnitudes of $\Delta G_t^0(B)$ with increase in mol% of EG has been primarily attributed (2) to the dispersion interaction of the benzene nucleus with the organic component of the solvent mixtures. Solvation through H-bond formation between —NH_2 and —NO_2 groups of the base and the solvent appears to contribute little to overall $\Delta G_t^0(B)$ values. GL (containing more —OH groups) has more associated structures than EG (bp of GL = 290°C; bp of EG = 197°C). It is also expected that GL + H_2O mixture is more associated than EG + H_2O. Consequently, it can be expected that less energy will be re-

quired to create a cavity for the accommodation of B in EG + H_2O compared to that in GL + H_2O, thus making the cavity formation contribution to the total $\Delta G_t^0(B)$ for B more negative in the EG + H_2O solvent system. This may explain the observed relative order of $\Delta G_t^0(B)$ in EG + H_2O and GL + H_2O. The number of —CH_2— groups relative to that of hydrophilic —OH groups being greater in EtOH, a greater dispersion effect is expected in EtOH + H_2O and this may be largely responsible for the greater stability of B (more negative $\Delta G_t^0(B)$) in EtOH + H_2O as observed.

$\Delta G_t^0(HCl)$ values (mole fraction scale) in GL + H_2O are available in literature (12) up to 70 wt.% GL (Table 3) and this permits the calculation of $\Delta G_t^0(BHCl)$ through eq. [3*b*]. It is noted from Table 3 that $\Delta G_t^0(HCl)$ increases progressively with increase in GL content of the solvent whereas $\Delta G_t^0(BHCl) - \Delta G_t^0(B)$ decreases simultaneously and the resultant of these two opposing factors is reflected in the variation of $\delta(\Delta G^0)$. Similar nature has been observed with other solvent systems (1–3, 20). But, in order to understand the solvent effect in various solvent systems, it is necessary to obtain the ΔG_t^0 values of all the individual species involved in the ionization equilibrium. $\Delta G_t^0(H^+)$ values for all the three alcohol–water solvent systems based on different extra-thermodynamic assumptions are available in literature (6–9) but, since the method using the reference electrolyte (RE = Ph_4AsBPh_4) (Ph = phenyl) assumption: $\Delta G_t^0(Ph_4As^+) = \Delta G_t^0(Ph_4B^-) = \frac{1}{2}\Delta G_t^0(Ph_4AsBPh_4)$ has been proved to be most sound, reasonable, and consistent (22, 23) and is widely used (8, 24), we have utilized $\Delta G_t^0(H^+)$ values based on RE assumption available from literature for EG + H_2O (9*a*) and GL + H_2O (6) to compute the $\Delta G_t^0(BH^+)$ values. For EtOH + H_2O, however, the reported values based on the average of Ph_4AsBPh_4 and Ph_4PBPh_4 assumptions (8*a*) have been used (results calculated via the two assumptions, however, differ by small amount which is within the range of experimental error (8*a*, *c*). Variations of $\Delta G_t^0(H^+)$ and $\Delta G_t^0(BH^+)$ on the mole fraction scale with mol% nonaqueous component are shown in Fig. 2. The relative positions of the $\Delta G_t^0(H^+)$ curve indicate a different nature of interaction of H^+ in GL + H_2O. The basicity of GL + H_2O mixture continuously decreases with increase in mol% of GL but, for the other two mixtures, it first decreases and then begins to rise and the more detailed interpretation of the behaviour in respective cases have been presented (6, 8).

It is observed from Fig. 2 that $\Delta G_t^0(BH^+)$ values are always less than those of $\Delta G_t^0(H^+)$ in each solvent system reflecting the dispersion interaction between the benzene ring of BH^+ and the organic component of the solvent mixture which is absent for H^+. Again, $\Delta G_t^0(BH^+)$ values are always greater as compared with $\Delta G_t^0(B)$ values and reflect the electrostatic interaction effect on charged BH^+ which is absent for uncharged base B. Figure 2 shows that $\Delta G_t^0(BH^+)$ values in EtOH + H_2O are almost constant at the initial composition and then a continuous decrease is observed but, in EG + H_2O, the values decrease continuously with increase in mol% EG. It is also noted from Fig. 2 that, though $\Delta G_t^0(B)$ values in EtOH + H_2O are somewhat more negative than those in EG + H_2O, the reverse is the case for $\Delta G_t^0(BH^+)$. The dielectric constant values for EtOH + H_2O mixtures being less (25) than those for EG + H_2O mixtures of similar compositions (mol%) a greater electrostatic interaction is expected in EtOH + H_2O and this

For personal use only.

may explain qualitatively the observed behaviour. $\Delta G_t^0(BH^+)$ values in GL + H_2O comparatively shows a somewhat different behaviour. Values first increase, pass through a maximum, and then decrease slowly to small negative values. Dielectric constant values of GL + H_2O mixture being only slightly less (25) than that of EG + H_2O mixture of similar mol% composition, the Born-type electrostatic interaction should be almost the same in both GL + H_2O and EG + H_2O systems. Since BH^+ is a positively charged ion, interaction will also take place predominantly through positively charged hydrogen centres of $—NH_3^+$ group (3) (interaction of BH^+ through $—NO_2$ group will be hindered (3)). Now, so far as interaction of H^+ is concerned, it has been mentioned earlier that the GL + H_2O system shows a difference in behaviour; $\Delta G_t^0(H^+)$ values unlike those in EG + H_2O and EtOH + H_2O, being increasingly positive with increase in mol% nonaqueous component. Similarly, the interaction of the three partially charged H atoms of NH_3^+ group in BH^+ is likely to make a positive contribution to the total free energy of transfer of BH^+ in GL + H_2O system and probably this can account for the observed behaviour of BH^+ in GL + H_2O relative to those found in other two solvent systems. The maximum in $\Delta G_t^0(BH^+)$ curve in GL + H_2O results from the combined effect of the opposing free energy transfer values, viz., the positive contribution due to electrostatic interaction and interaction with $—NH_3^+$ and the negative contribution due to other reasons as for the neutral base B. It appears that the large difference of solvent effect in GL + H_2O system is primarily ascribable to the different nature of interaction of H^+ and BH^+ with the GL + H_2O mixed solvents as compared with aqueous mixture of EtOH or EG.

Received February 16, 1984

FRANÇOIS ALLAIRE and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **62**, 2249 (1984).

Compounds of the types $[(CH_3Hg)_3X]$, $[(CH_3Hg)_4X]Z$, and $[(CH_3Hg)_3(HX)]Z$ (where $Z = NO_3^-$, ClO_4^-) were obtained by reacting the methylmercury cation with xanthine (H_3X) in aqueous media. The three acidic protons of H_3X at N(1), N(3), and N(7) are substituted by CH_3Hg^+ groups in $[(CH_3Hg)_3X].2H_2O$. Crystals of $[(CH_3Hg)_3(HX)]NO_3.H_2O$ belong to the triclinic $P\bar{1}$ space group, with $a = 7.319(3)$, $b = 9.466(8)$, $c = 12.004(3)$ Å, $\alpha = 96{,}06(5)$, $\beta = 95.00(3)$, $\gamma = 97.69(5)°$, and $Z = 2$. The structure was refined on 1610 nonzero reflections to an R factor of 0.038. The CH_3Hg^+ groups are linearly coordinated to N(3), N(7), and N(9) of a dianionic xanthine retaining its N(1)—H proton (mean Hg—N = 2.07(3) Å). The $[(CH_3Hg)_4X]NO_3$ compound is monoclinic, space group $C2/c$, $a = 24.55(2)$, $b = 17.016(4)$, $c = 19.108(9)$ Å, $\beta = 110.26(5)°$, $Z = 16$. The structure was refined on 1418 nonzero reflections to $R = 0.046$. The two independent $[(CH_3Hg)_4X]^+$ ions possess methylmercury groups linearly coordinated to the four nitrogen atoms of the X^{3-} anion (mean Hg—N = 2.07(5) Å). The compounds prepared were characterized by ir spectroscopy, and by ^1H and ^{13}C nmr. The $[(CH_3Hg)_3X].2H_2O$ and $[(CH_3Hg)_4X]Z$ compounds were found to remain undissociated in DMSO solution. The $[(CH_3Hg)_3(HX)]^+$ salts disproportionated to some extent into $[(CH_3Hg)_4X]^+$ and a lower complex which was identified as the N(7),N(9)-bonded $[(CH_3Hg)_2(H_2X)]^+$ ion.

FRANÇOIS ALLAIRE et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **62**, 2249 (1984).

Des composés de types $[(CH_3Hg)_3X]$, $[(CH_3Hg)_4X]Z$ et $[(CH_3Hg)_3(HX)]Z$ (où $Z = NO_3^-$, ClO_4^-) ont été préparés par réaction du cation méthylmercure avec la xanthine (H_3X) en milieu aqueux. Les trois protons acides de H_3X liés à N(1), N(3) et N(7) sont substitués par des groupes CH_3Hg^+ dans $[(CH_3Hg)_3X].2H_2O$. Les cristaux de $[(CH_3Hg)_3(HX)]NO_3.H_2O$ appartiennent au groupe triclinique $P\bar{1}$, $a = 7{,}319(3)$, $b = 9{,}466(8)$, $c = 12{,}004(3)$ Å, $\alpha = 96{,}06(5)$, $\beta = 95{,}00(3)$, $\gamma = 97{,}69(5)°$, $Z = 2$. La structure a été affinée au moyen 1610 réflexions significativement observées jusqu'à un facteur R de 0,038. Les groupes CH_3Hg^+ sont linéairement coordonnées aux azotes N(3), N(7) et N(9) de la xanthine dianionique qui a conservé son proton N(1)—H (Hg—N = 2.07(3) Å, moyenne). Le composé $[(CH_3Hg)_4X]NO_3$ est monoclinique, groupe spatial $C2/c$, $a = 24{,}55(2)$, $b = 17{,}016(4)$, $c = 19{,}108(9)$ Å, $\beta = 110{,}26(5)°$, $Z = 16$. La structure a été affinée au moyen de 1418 réflexions significativement observées jusqu'à $R = 0{,}046$. Les deux ions $[(CH_3Hg)_4X]^+$ indépendants possèdent des groupes CH_3Hg^+ linéairement liées aux quatre atomes d'azote de l'ion X^{3-} (Hg—N = 2.07(5) Å, moyenne). Les composés préparés ont été caractérisés par spectroscopie infrarouge et par rmn ^1H et ^{13}C. $[(CH_3Hg)_3X].2H_2O$ et $[(CH_3Hg)_4X]Z$ ne sont pas dissociés en solution dans le DMSO. Par contre, les sels de $[(CH_3Hg)_3(HX)]^+$ se dismutent partiellement dans le DMSO, pour donner $[(CH_3Hg)_4X]^+$ et un complexe de stoëchiométrie inférieure, qui s'est avéré être l'ion $[(CH_3Hg)_2(H_2X)]^+$, dans lequel les groupes CH_3Hg^+ sont liés à N(7) et N(9).

Introduction

As part of our continuing studies on the use of CH_3Hg^+ to probe the affinity of the basic sites of DNA constituents and related molecules for heavy metal ions (1), we are reporting on the reactivity of xanthine **1** in aqueous media. Complexes of the corresponding nucleoside xanthosine, in which the xanthine ring bears a ribose moiety at position N(9), have been recently prepared and characterized (2).

The present paper describes the preparation of various CH_3Hg/xanthine complexes and the crystal structures of two of these compounds. Their infrared spectra were studied in detail with the aim of identifying diagnostic bands which would be characteristic for each pattern of site occupancy. The behavior of these compounds in DMSO was examined by means of ^1H and ^{13}C nmr.

Experimental section

Xanthine (Aldrich) and CH_3HgOH (Alfa, 1 *M* aqueous solution) were used without further purification. Solutions of CH_3HgNO_3 and CH_3HgClO_4 were prepared as described elsewhere (3). Their concentrations were determined by mixing 1.00 mL of solution with 100 mL of 100% ethanol and titrating with standard 0.05 *M* aqueous KCl. The endpoint corresponding to complete formation of undissociated CH_3HgCl was detected with a Ag/AgCl electrode (4). Mercury in the complexes was determined by the same method. The sample (50−100 mg) was attacked with a few drops of concentrated HNO_3 before dilution in ethanol.

The infrared spectra were recorded on KBr pellets with a Digilab FTS-15 C/D Fourier transform spectrometer equipped with a Globar source and a wideband Hg/Cd/Te detector (Infrared Associates, New Brunswick, NJ). Typically, 100 interferograms of 4096 points recorded with an optical velocity of 1.2 cm s^{-1} and maximum optical retardation of 0.5 cm were co-added, apodized with a boxcar function and Fourier transformed with four levels of zero filling resulting in a spectral resolution of 2 cm^{-1}. The apparatus was purged with nitrogen during the experiment.

The ^1H nmr spectra were obtained with a Bruker WH-90 instrument and the ^{13}C spectra with a WH-80 instrument operating at 20.11 MHz. In all cases, the solvent used was DMSO-d_6 (Merck, Sharp and Dohme Canada) and the chemical shifts were referenced to TMS. Solutions of ~100 mg per mL were used whenever possible; otherwise, solutions saturated at room temperature were used.

Preparations

$[(CH_3Hg)_3X].2H_2O$ (2). Xanthine (0.15 g, 1.0 mmol) was suspended in a mixture of 75 mL of concentrated NH_4OH and 5.0 mL of 1 *M* CH_3HgOH (5.0 mmol). The suspension was refluxed for 4 days and allowed to cool to room temperature. Two days later, the white solid was filtered and dried *in vacuo* (0.69 g, 83%). *Anal.* calcd. for $C_8H_{14}Hg_3N_4O_4$: Hg 72.3; found, 72.0. The presence of three CH_3Hg^+ groups per xanthine was deduced from the integrated intensities of the

^{1}H resonances for H(8) and the methyl protons. The ν(OH) region of the infrared spectrum was consistent with the presence of water.

[(CH$_3$Hg)$_3$(HX)]NO$_3$.H$_2$O (3a). Xanthine (0.30 g, 2.0 mmol) was dissolved in a boiling mixture of 4.0 mL of 1 *M* CH_3HgOH (4.0 mmol), 4.6 mL of 0.44 *M* CH_3HgNO_3 (2.0 mmol), and 50 mL of water. The clear hot solution was stirred for 1 h and allowed to cool. After 3 days, the white crystalline solid was filtered, washed with ethanol, and dried *in vacuo* (1.51 g, 86%). The structure of this solid was determined by X-ray diffraction (*vide infra*). The ^{1}H spectrum showed the expected intensity ratio for the H(8) and methyl proton signals. *Anal.* calcd. for $C_8H_{13}Hg_3N_5O_6$: Hg 68.62, C 10.96, H 1.49, N 7.99; found: Hg 69.04, C 10.63, H 1.60, N 7.89.

[(CH$_3$Hg)$_3$(HX)]ClO$_4$.H$_2$O (3b). Same method as **3a**, after replacing CH_3HgNO_3 by CH_3HgClO_4. White powder, 1.51 g, 83%. *Anal.* calcd. for $C_8H_{13}Hg_3N_4O_7Cl$: Hg 65.8; found 66.1. The ^{1}H and ^{13}C nmr spectra were identical with those of **3a**.

[(CH$_3$Hg)$_4$X]NO$_3$ (4a). Xanthine (0.30 g, 2.0 mmol) was dissolved in a boiling mixture of 6.0 mL of 1 *M* CH_3HgOH (6.0 mmol), 4.6 mL of 0.44 *M* CH_3HgNO_3 (2.0 mmol), and 50 mL of H_2O, and stirred for 1 h. After 3 days, the white crystalline solid was filtered, washed with ethanol, and dried *in vacuo* (1.81 g, 83%). Its structure was determined
by X-ray diffraction (*vide infra*). *Anal.* calcd. for $C_9H_{13}Hg_4N_5O_5$: Hg 74.7; found 74.4. The 4:1 CH_3Hg:xanthine ratio was clearly indicated by ^{1}H nmr spectroscopy.

[(CH$_3$Hg)$_4$X]ClO$_4$.2H$_2$O (4b). Same method as **4a**, with CH_3HgClO_4 replacing the nitrate. Flaky white solid, 1.60 g, 70%. *Anal.* calcd. for $C_9H_{17}Hg_4N_4O_8Cl$: Hg 69.9; found 69.6. The ^{1}H and ^{13}C nmr spectra were identical with those of **4a**.

Structure of [(CH$_3$Hg)$_3$(HX)]NO$_3$.H$_2$O (3a)

Crystal data

$C_8H_{13}Hg_3N_5O_6$ fw = 876.99

Triclinic, $P\bar{1}$, a = 7.319(3), b = 9.466(8), c = 12.004(3) Å, α = 96.06(5), β = 95.00 (3), γ = 97.69(5)°, V = 815.2 Å^3, D_{calcd} = 3.572 g cm^{-3}, Z = 2, λ(MoK$\bar{\alpha}$) = 0.71067 Å (graphite monochromator), T = 293 K, μ(MoKα) = 280.8 cm^{-1}. Crystal dimensions: 0.72 mm (010−0$\bar{1}$0) × 0.22 mm (100−$\bar{1}$00) × 0.11 mm (001−00$\bar{1}$), transmission range: 0.014−0.120 (Gaussian integration, grid 8 × 8 × 8).

Crystallographic measurements and structure resolution. The crystals were grown by slow recrystallization from hot water. The precession and cone-axis photographs were consistent with space groups $P1$ and $P\bar{1}$. The $P\bar{1}$ space group was assumed and this choice was confirmed by successful refinement. The accurate cell parameters and the intensity data were obtained with an Enraf-Nonius CAD4 diffractometer, following a procedure described elsewhere (5). A set 2119 independent hkl, $h\bar{k}l$, $hk\bar{l}$, and $h\bar{k}\bar{l}$ MoKα reflections were collected within a sphere limited by $2\theta = 45°$. A total of 1610 reflections were retained ($I/\sigma(I) > 3.0$) for structure determination. These data were corrected for the effect of Lorentz, polarization and absorption.

The structure was solved by the heavy-atom method and refined on $|F|$ by full-matrix least-squares in the early stages. The three Hg atoms were located from a Patterson map and the remaining nonhydrogen atoms were found from a difference Fourier (ΔF) map. Isotropic refinement converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.098$ and $R_w = [\Sigma_w(|F_o| - |F_c|)^2/\Sigma_w|F_o|^2]^{1/2} = 0.113$. Refinement was terminated by block-diagonal least-squares. The hydrogen atoms H(1) and H(8) were fixed at ideal positions (B = 4.0 Å^2). Their parameters were not refined, but the coordinates were recalculated after each cycle. The hydrogens of the methyl groups were neglected. Anisotropic refinement of all nonhydrogen atoms converged to R = 0.038 and R_w = 0.052. The goodness-of-fit ratio was 2.02. The highest residuals on the final ΔF map (± (0.9−1.8) e Å^{-3}) were all around Hg atoms. The general background was below ±0.8 e Å^{-3}.

Structure of [(CH$_3$Hg)$_4$X]NO$_3$ (4a)

Crystal data

$C_9H_{13}Hg_4N_5O_5$ fw = 1073.59

Monoclinic, $C2/c$, a = 24.55(2), b = 17.016(4), c = 19.108(9) Å, β = 110.26(5)°, V = 7489 Å^3, D_{calcd} = 3.808 g cm^{-3}, Z = 16, λ(MoK$\bar{\alpha}$) = 0.71067 Å (graphite monochromator), T = 293 K, μ(MoKα) = 326.7 cm^{-1}, crystal dimensions: 0.44 × 0.06 × 0.06 mm^3, transmission range = 0.090−0.160 (Gaussian integration, grid 8 × 8 × 8).

Crystallographic measurements and structure resolution

Crystals suitable for X-ray work were grown by recrystallization from hot water. Cell dimensions and space group were determined from precession and cone-axis films. In space group $C2/c$, there are two molecules per asymmetric unit. The corresponding noncentric space group Cc would require four molecules per asymmetric unit. Structure resolution was attempted in $C2/c$ first and this choice was subsequently confirmed by successful refinement.

A total of 5187 independent hkl and $hk\bar{l}$ reflections ($h + k = 2n$) within a sphere limited by $2\theta = 46°$ was collected (MoK$\bar{\alpha}$ radiation). Only 1418 of these reflections were significantly above background ($I/\sigma(I) > 3.0$). They were corrected for the effect of Lorentz, polarization and absorption.

The structure was solved by direct methods, using the MULTAN80 package, which provided one solution with a combined FOM of 3.0. The eight strongest peaks corresponding to the nonequivalent Hg atoms were used to calculate a ΔF map and locate the remaining nonhydrogen atoms. The Hg atoms were refined anisotropically, the other nonhydrogen atoms isotropically. The H(8) hydrogens were fixed at the calculated positions and repositioned after each least-squares cycle. Those of the methyl groups were neglected. No attempts were made to refine the light atoms anisotropically because of the low proportion of observed reflections. The final residuals were R = 0.046 and R_w = 0.048. The goodness-of-fit ratio was 1.43. The residual background in the final ΔF map was below ± 0.45 e Å^{-3}, with several peaks (±(0.45−0.60) e Å^{-3}) near Hg.

The coordinates for both structures are listed in Table 1. The temperature factors and structure factor amplitudes are part of the supplementary material.[2] The scattering curves used were from standard sources (6). The real and imaginary contributions to anomalous dispersion of Hg was taken from Cromer (7). The programs used are listed elsewhere (8).

Results and discussion

Reactions and nmr spectroscopy

Xanthine **1** (H_3X) contains three acidic protons, two of which are attached to N(1) and N(3) in the pyrimidine ring (Scheme 1). From nmr studies in DMSO and DMSO/D_2O solutions, it was concluded that the third proton is bound to N(7) (9, 10). The N(7)—H tautomer was also observed in crystals of 3-hydroxyxanthine (11) and theophylline (1,3-dimethylxanthine) (12).

In strongly acidic media, the free imidazolic nitrogen of xanthine can accept a proton to form the H_4X^+ ion (pk_a = 1.2) (10). The dissociation equilibria H_3X/H_2X^- and H_2X^-/HX^{2-} are characterized by pk_a values of 7.7 and 11.9, respectively (13). Ionisation of HX^{2-} takes place only in very basic media, and the proton involved in this last dissociation step is definitely N(1)—H. On the other hand, it is not clear whether the proton lost by H_3X at pH 7.7 originates from N(7)—H, N(3)—H, or in part from both positions. Indeed, the most acidic proton of H_2X^- is probably involved in a tautomeric

[2]The supplementary material includes tables of temperature factors, structure factor amplitudes, and hydrogen coordinates, details on the least-squares planes, and lists of distances and angles related to intermolecular interactions for both structures. Figures of the Fourier-transform infrared spectra of the methylmercury complexes are also included. Copies can be obtained at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

equilibrium, whereby N(7), N(3), and even N(9), could act as acceptors. From nmr and uv studies (10), it was concluded that H_2X^- has N(1)—H and N(3)—H protons. However, the solid-state structure of $Na[H_2X]$ shows a xanthine moiety lacking a proton at N(3), whereas the imidazolic proton is attached to N(9) instead of N(7) (14). The only metal complex of xanthine for which crystallographic results are available, contains a H_2X^- anion as the above N(1)—H/N(3)—H tautomer, bonded to cobalt via N(9) (15). In the latter structure, H-bonding between H(3) and oxygen atoms in other ligands coordinated to cobalt might promote N(9)-coordination.

From the bulk of information available on complexes of guanosine, inosine, 9-methylhypoxanthine, xanthosine, and theophylline (11, 16), it can be anticipated that the carbonyl groups of xanthine will show only low affinity, if any, for mercury. Firstly, these hard sites are less suited than the softer nitrogen atoms to bind the soft CH_3Hg^+ cation. Secondly, coordination to the carbonyl group has been found to be favored by bulky ligands in the metal coordination sphere (17). These ligand render the endocyclic nitrogens inaccessible for the metal, while keeping the less hindered exocyclic carbonyl oxygens still accessible. As the CH_3Hg^+ ion has no other ligands in the plane perpendicular to the Hg—C bond, steric effects are minimized. Therefore, mercury binding to oxygen is unlikely. Even if only the nitrogen sites are considered, various types of CH_3Hg^+ complexes of xanthine can be anticipated. Neutral compounds could be obtained by displacement of one, two, or three acidic protons by CH_3Hg^+. These molecules could then accept an extra CH_3Hg^+ ion on the imidazolic nitrogen lone pair to produce cationic species. Among the possible species, those found in the present study are shown in Scheme 1. In some cases, different occupancy patterns for H^+ and CH_3Hg^+ ions are in principle possible, leading to different isomers possibly involved in tautomeric exchanges. Compounds in which H(8) is substituted by CH_3Hg^+ can probably be prepared (2), but no attempts have been made to obtain them in the present study.

Reacting xanthine **1** with excess CH_3HgOH yields the neutral 3:1 complex **2**, in which the three acidic protons are displaced. The low-field signals for these protons are absent from the ^1H nmr spectrum of the complex (Table 2) and the ir spectrum shows no ν(N—H) bands at ~3000 cm^{-1} (*vide in-*

fra). The upfield shift of 0.55 ppm on H(8) is similar to that observed for the theophylline (HTh) complex $[(CH_3Hg)Th].H_2O$ (0.42 ppm), in which the imidazolic N—H proton had been similarly substituted (18). X-ray work indicated (19) methylmercury binding to the theophylline N(7) position, which was the site formerly occupied by the displaced proton. This site was also favored over N(9) in theophylline, on the ground of steric hindrance from the N(3)—CH_3 group. Binding of the imidazolic CH_3Hg^+ group at N(7) in compound **2** is proposed by analogy, although coordination to N(9) or tautomeric exchange between N(7) and N(9) in solution cannot be ruled out, since position N(3) is occupied by a CH_3Hg^+ unit in this case, and simultaneous CH_3Hg^+ binding to N(3) and N(9) has been observed (ref. 20, and X-ray work below). ^{13}C nmr could provide more information, but the spectrum could not be obtained because of the low solubility of the complex in DMSO.

When xanthine is boiled in a solution containing 3 equiv. of CH_3HgOH and 1 equiv. of CH_3HgZ (Z = NO_3^- or ClO_4^-), compounds **4** are isolated (crystal structure described below). All acidic protons are absent from the ^{1}H nmr spectra and the H(8) signals, displaced upfield in the previous compound, return to the original position in xanthine after both imidazolic nitrogens have been occupied. A similar effect has been noted for the CH_3Hg/theophylline system (18). The ^{13}C nmr spectrum is given in Table 3. All xanthine signals are shifted downfield in **4**. Buncel, Norris, and co-workers (2) recently reported the spectrum of a 2:1 N(1)/N(3)-bonded xanthosine compound in which the six-membered ring is similar to ours. They observed for this compound the following displacement (Δδ) of the ^{13}C resonances with respect to xanthosine: C(2), 7.8; C(4), 7.2; C(5), 1.8; C(6), 4.0; C(8), −2.9 ppm. On the other hand, our five-membered ring is similar to that of $[(CH_3Hg)_2Th]NO_3$, for which the following Δδ values were found: C(2), −0.2; C(4), −1.2; C(5), 7.2; C(6), 2.3; C(8), 5.5 ppm (18). Our Δδ results for compound **4** are of the same sign and of roughly the same magnitude (except for C(4)) as the sum of the above effects: C(2), 8.8; C(4), 2.6; C(5), 9.5; C(6), 5.4; C(8), 4.5 ppm.

If xanthine is allowed to react with 1 equiv. of CH_3HgZ and only 2 equiv. of CH_3HgOH, the 3:1 cationic compounds **3** precipitate. The presence of H(1) is detected from the low-field signals at 11.1 ppm in the ^{1}H spectra. The H(8) resonances occur at a slightly lower field than those of **4**. The ^{13}C resonances of C(2) and C(5) are shifted by −2.8 and −2.3 ppm, respectively, with respect to **4**. The remaining signals are essentially unmoved.

When solutions of **3** (NO_3^- or ClO_4^-) are prepared by heat-

[b]Assignments from ref. 21.
[c]Minor components in warmed DMSO solutions of **3***a*. Similar signals in the corresponding perchlorate solutions **3***b*. The C(6) resonance was found in the spectra. The values in brackets were calculated assuming that the xanthine resonances would undergo the same shifts as in the analogous $[(CH_3Hg)_2Th].H_2O$ compound of theophylline (18).

ing the solid in DMSO, additional weak signals, not all resolved, appear in both the ^1H and ^{13}C spectra. Some of these signals correspond to the $[(CH_3Hg)_4X]Z$ salts. As a confirmation, ^1H spectra of solutions were recorded after adding increasing amounts of the pure 4:1 compound. The set of weaker signals initially assigned to the 4:1 compound were indeed found to gain intensity. At this point, it was suspected that the original samples of **3***a* and **3***b* could be impure. As a check, complete elemental analysis was carried out on **3***a* and it was found to be consistent with the proposed formula. The ir spectra and X-ray powder patterns of **3***a* and **3***b* were carefully examined and compared with those of **4***a* and **4***b*, respectively. In no case was it possible to gain evidence for significant amounts of 4:1 impurity in the 3:1 solid samples. Therefore, it was concluded that heating compounds **3** in DMSO induced some reaction. The presence of other peaks, in addition to those of **3** and **4**, suggested that the following disproportionation reaction was taking place:

$$2[(CH_3Hg)_3(HX)]^+ \rightleftharpoons [(CH_3Hg)_4X]^+ + [(CH_3Hg)_2(H_2X)]^+$$

According to the integration of the ^1H nmr peaks, 20% of the 3:1 compound had disproportionated. Evidence for the 2:1 species as the second product comes mainly from the presence of two low-field signals in the ^1H spectra at 12.0 and 11.2 ppm for H(3) and H(1), respectively. The H(8) signal cannot be distinguished from that of the 3:1 species. In the ^{13}C spectra, a resolved signal at 155 ppm, not found for the 3:1 and 4:1 ions, is assigned to C(6) of the 2:1 species. This resonance cannot be due to unreacted xanthine (which also exhibits a resonance at this position), since xanthine should also show well-defined peak for C(8) at 140 ppm. No such signal is present in the spectra. The positions of the other ^{13}C signals of $[(CH_3Hg)_2(H_2X)]^+$ were predicted by comparison with the Δδ values obtained for the analogous 2:1 theophylline complex (18). The contributions for C(2), C(5), and C(8) would be overlapping with those of the other two components. As to the C(4) signal predicted to occur at 148 ppm, it is normally weak in the spectrum of xanthine and its complexes, and no significant peak could be detected.

The nonequivalent CH_3Hg^+ groups produce only single resonances in the ^1H and ^{13}C spectra, indicating fast exchange of these groups on the nmr time scale. The chemical shifts in both types of spectra are not very informative of the complexation sites. The methyl protons signals show only one pair of satellites due to coupling between ^{199}Hg (17% abundance) and the methyl protons. The values of $^2J(^{199}Hg—^1H)$ are listed in Table 2. Other authors (22) have noticed that the ^2J constant is smoothly related in an inverse manner to the nucleophilic character of the site of attachement of mercury. Our results are in good qualitative agreement with these observations. As the order of increasing basic character is presumably N(9) < N(7) < N(3) < N(1), the ^2J value should be lowest for $[(CH_3Hg)_3X]$ and highest for $[(CH_3Hg)_3(HX)]Z$. This is indeed the observed order.

The present study in aqueous media led to compounds containing high CH_3Hg:xanthine ratios. We tried to prepare lower compounds, such as $[(CH_3Hg)_2(HX)]$ or $[(CH_3Hg)(H_2X)]$, by reacting xanthine with 2 or 1 equiv. of CH_3HgOH. The solid material so obtained invariably consisted of $[(CH_3Hg)_3X].2H_2O$ **2** and unreacted xanthine. However, the nmr spectra show that some reaction occurs when these solids are heated in DMSO to make solutions. So far we have been unable to determine the number of species formed and to identify them, because rapid equilibria between these complexes and even tautomeric exchanges between species of the same stoichiometries seem to be taking place. This problem is being further investigated.

*Crystal structure of $[(CH_3Hg)_3(HX)]NO_3.H_2O$ (**3**a)*

The $[(CH_3Hg)_3(HX)]^+$ cation is shown schematically in Fig. 1 with the bond lengths and some bond angles. The angles in the xanthine unit are listed in Table 4. Three CH_3Hg^+ ions having displaced altogether two acidic protons are found to occupy positions N(3), N(7), and N(9) of xanthine. An acidic proton still remains at N(1).

The Hg—C and Hg—N distances (ave. 2.07(3) Å in both cases) are normal (1, 20) and the linear two-coordination commonly found for Hg(II) is again found. In one case, significant departure from linearity is observed (N(9)—Hg(9)—C(9) = 174.2(8)°), but distortions of this magnitude are often noted, presumably in response to packing constraints. The presence of two CH_3Hg^+ groups on adjacent N(3) and N(9) sites has previously been found for several adenine complexes, namely the nitrate and perchlorate salts of $[(CH_3Hg)_3(Ade—H)]^{2+}$, a cation showing the CH_3Hg^+ similarly distributed on N(3), N(7), and N(9) of the purine (20). The C—N—Hg angles at both N(3) and N(9) are unequal (117(1)° vs. 131(1)° at N(3), 124(1)° vs. 131(1)° at N(9)) and the two CH_3Hg groups have slipped away from the xanthine plane in opposite directions. These indications suggest repulsive interactions between the neighboring Hg atoms, but the distance observed here (3.429(1) Å) is much greater than those found in the analogous adenine compounds (3.270(2) to 3.310(2) Å) (20), or in a methylcytosine compound (3.150(2) Å) (23). Therefore, un-

[a][Bis(dimethylglyoximato)(xanthinato)(tri-*n*-butylphosphine)cobalt(III)].

symmetrical coordination at N(3) and N(9) seems to result from molecular packing.

The distances in xanthine do not significantly differ from those reported for other compounds containing the same ring (14, 15, 23). The angles will be discussed later. The ring is planar within 2σ (0.04 Å). This plane also contains O(6), but O(2) is 0.09(1) Å from the plane. All three CH_3Hg^+ groups are significantly distant from this plane: Hg(3), 0.351(1); C(3), 0.79(3); Hg(7), 0.316(1); C(7), 0.61(3); Hg(9), −0.255(1); C(9), −0.66(3) Å. These distortions probably result from optimization of packing interactions.

A packing diagram is shown in Fig. 2. Planar complex cations oriented ~45° from the ***ac*** plane are stacked in columns along ***b***. The pyrimidine ring of one cation overlaps the imidazole ring of the adjacent cations, and *vice versa*. Water molecule O(20) contributes to cohesion in the column by forming a weak bond with Hg(9) of one ion and a H-bond with O(6) of the next ion (Table 5). Centrosymmetrically related cations in adjacent columns are linked by a pair of complementary N(1)—H(1)···O(2) hydrogen bonds. Space between the columns is filled with NO_3^- ions acting as multiple bridges between Hg atoms. The Hg···O distances are listed in Table 5 (more details are provided in Table 11, supplementary material). The NO_3^- ion is involved in a chelating interaction with Hg(3) through O(10) and O(11). At the same time, O(10) interacts with Hg(7) of a second cation and O(11) forms a very short contact (2.67(1) Å) with Hg(9) of a third cation. In all cases the Hg···O contacts lie close to the equatorial plane

(assuming that the H_3C—Hg—N direction is axial), the C—Hg—O and N—Hg—O angles being all within 90 ± 15°. The third nitrate oxygen, which shows much higher thermal motion than the other two, does not participate in H-bonding or Hg···O contacts.

*Crystal structure of $[(CH_3Hg)_4X]NO_3$ (**4**a)*

This crystal contains two symmetry-independent $[(CH_3Hg)_4X]^+$ cations (Fig. 3), which both contain CH_3Hg^+ ions bonded to the four N atoms available on xanthine, after displacement of the three acidic protons. None of the carbonyl oxygens is used to form strong coordination bonds to Hg. The distances and angles around Hg are given in Fig. 3. The bond angles in the xanthine ring are listed in Table 2. Distances in the ring have very high esd's and a complete list is provided only in the supplementary material.

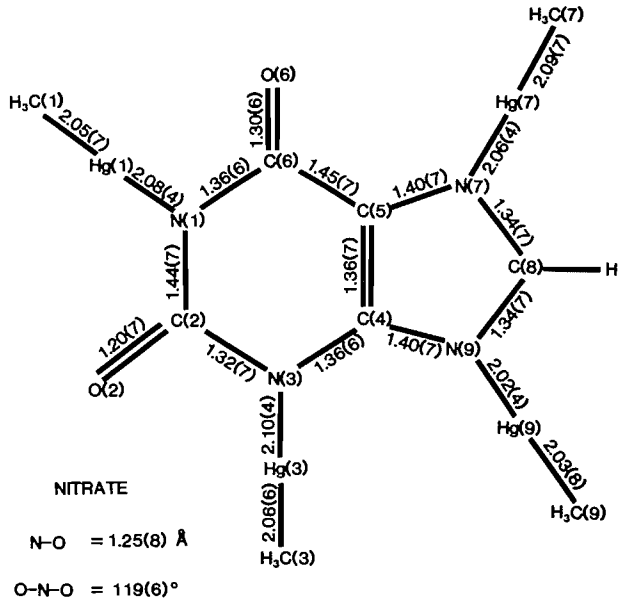

FIG. 3. Schematic representation of the $[(CH_3Hg)_4X]^+$ cation (**4***a*). The bond length values are averages for the two nonequivalent molecules in the unit cell. Individual values are given in the supplementary material.

The Hg—N and Hg—C distances (ave. 2.07, 2.06 Å, σ = 0.05 Å, respectively) as well as the N—Hg—C angles compare well with those of the previous structure (Tables 4 and 6). Again, two CH_3Hg^+ groups occupy nearby positions on N(3) and N(9), but the relatively large Hg···Hg separation (Hg(13)—Hg(19) = 3.639(4); Hg(23)—Hg(29) = 3.353(4) Å) is well above the low value of 3.15 Å mentioned earlier (3). Thus, there seems to be no significant repulsive interactions between these two groups. The xanthine rings are planar within 2σ (0.08 Å). The deviation of the CH_3Hg^+ groups from these planes is generally highly significant, and especially marked for Hg(13) and Hg(21). The atom-to-plane distances are Hg(11), 0.124(3); C(11), 0.18(6); Hg(13), −0.567(2); C(13), −1.35(6); Hg(17), 0.330(2); C(17), 0.56(7); Hg(19), 0.200(2); C(19), 0.49(5); Hg(21), 0.620(2); C(21), 1.31(7); Hg(23), −0.008(3); C(23), −0.13(7); Hg(27), −0.128(3); C(27), −0.05(7); Hg(29), −0.179(3); C(29), −0.24(8) Å.

The packing pattern shown in Fig. 4 is rather complex. It shows two columns of $[(CH_3Hg)_4X]^+$ cations. This time, the plane of the cation is roughly perpendicular to the direction of stacking. These columns are rigorously ordered and contain equal numbers of type #1 and of type #2 cations, according to a −1−2−2−1−1−2−2−1− pattern. The contacts between a

type #1 and a type #2 cations are particularly interesting. The six- and the five-membered ring of one cation are, respectively, overlapping the same rings in the other cation, but the latter is rotated with respect to the former by 180° about the direction through C(8) and the middle of the N(1)—C(2) bond. This brings Hg(11), O(12), Hg(13), and O(16) roughly below O(22), Hg(21), O(26), and Hg(23), respectively. These four Hg···O contacts vary between 2.81(4) and 3.08(4) Å. At the 1−1 or 2−2 interfaces, the xanthine units are in contact through opposite rings. The nitrate ions filling space between the columns are involved in an intricate network of Hg···O interactions (Table 6).

The high standard deviations on distances preclude any discussion concerning bond length changes in the xanthine moiety upon complexation. Angles generally respond to a more significant degree. Taylor and Kennard (24) have noticed that removing an N-H proton in purines increases the C—N—C angles by ~5°. In general, alkylated nitrogens behave like if they were protonated, whereas metal coordination does not drastically change the geometry of the nitrogen with free lone pair. The data in Table 4 follow these trends. For instance, $[(CH_3Hg)_4X]NO_3$ is the only compound lacking the N(1)-H proton and its C(2)—N(1)—C(6) angle is the smallest. Similarly, the highest values of C(4)—N(9)—C(8) are found for $Na[H_2X]$ and xanthosine, which have a proton and a ribosyl group, respectively, attached to N(9). Xanthosine and the Co-xanthine complex, which have retained their N(3)—H proton, show C(2)—N(3)—C(4) angles of 118.3(3)° and 120.7(4)°, respectively, whereas the same angles reduce to 114.7(7)° in $Na[H_2X]$ and 110(2)° in $[(CH_3Hg)_3(HX)]NO_3.H_2O$, which both have lost it. However, the $[(CH_3Hg)_4X]NO_3$ complex does not fit into this pattern. Simultaneous loss of N(1)-H seems to produce long range perturbations extending as far as N(3) and balancing the effect of N(3) deprotonation.

Infrared spectroscopy

The spectra of the complex salts contain the bands associated to the anion (25) Table 7. In addition to a strong absorption at ~1380 cm^{-1}, the NO_3^- ion produces weak features at ~820 cm^{-1}, a region where the ligand also absorbs. The ClO_4^- ion generates a very strong band ~1100 cm^{-1}, as well as a weaker, but well-defined, absorption at ~625 cm^{-1}.

The presence of the CH_3Hg^+ group in the complexes can be identified from characteristic infrared bands (26). A sharp absorption at ~2920 cm^{-1}, especially clear when the broad underlying ν(N—H) modes have been removed in $[(CH_3Hg)_3X].2H_2O$ and the $[(CH_3Hg)_4X]^+$ salts, originates in the $\nu_s(CH_3)$ mode. The corresponding antisymmetric mode is expected to show weakly at ~3000 cm^{-1} and the spectra indeed contain small features at 2994 cm^{-1}. The rocking motion produces a characteristic broad peak at ~800 cm^{-1}. Of the two expected deformation bands, only the symmetric mode leads to observable absorption at ~1200 cm^{-1} in infrared, although assignment is made difficult by the presence of ligand bands in the same region. The δ_a mode should appear very weakly at ~1400 cm^{-1}, but it is usually unobserved and the bands found in this region for our compounds probably have a different origin. All complexes show a broad, generally weak, absorption due to the ν(Hg—C) vibration at ~560 cm^{-1}.

The spectrum of xanthine is considerably modified by complexation. The most obvious changes take place between 1700 and 1550 cm^{-1}, where bands due to the C=O groups are

observed at 1702 and 1672 cm^{-1} (27). When the N—H proton is substituted by a CH_3Hg^+ ion, electron distribution in the —N—C=O region approximates that of the corresponding anion, leading to a reduction of the C=O bond orders and an increase of the C—N bond orders. When the two N—H protons of the six-membered ring are substituted (Scheme 2), both bands are shifted to lower wavenumbers (~1625 cm^{-1}). On the other hand, in the monosubstituted six-membered ring (Scheme 3), only one of the carbonyl groups is shifted. Since X-ray diffraction shows that the N(1)—H(1) bond is intact in these compounds, the higher wavenumber must correspond mainly to ν(C(6)=O(6)), whereas the other is due to ν(C(2)=O(2)).

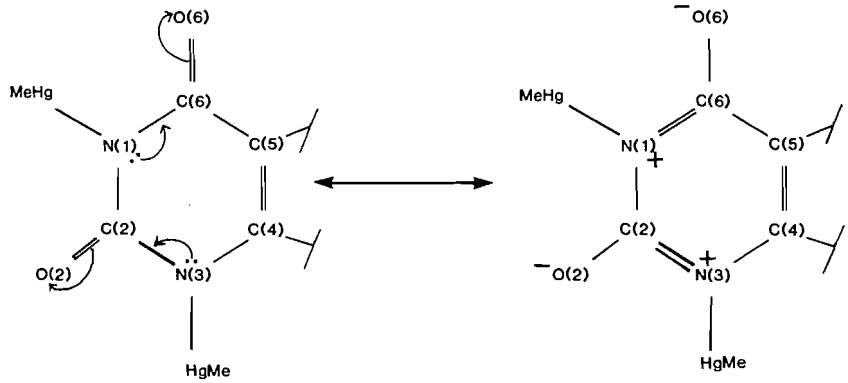
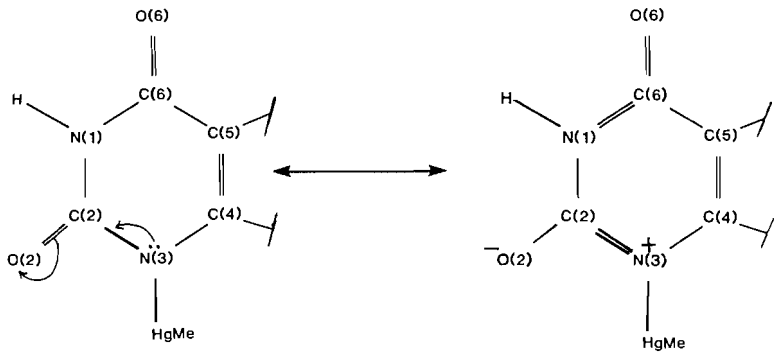


SCHEME 2



SCHEME 3

The C(4)=C(5) bond produces a band around 1570 cm^{-1} in all compounds, which is not very sensitive to the substitution pattern.

Other major changes are associated with the disappearance of the N—H vibrator. The stretching (2700–3200 cm^{-1}) and out-of-plane modes (850–900 cm^{-1}) are relatively pure (27). Their intensities are considerably reduced in the $[(CH_3Hg)_3(HX)]^+$ salts and washed out when all three N—H bonds are substituted in $[(CH_3Hg)_3X].2H_2O$ and the $[(CH_3Hg)_4X]^+$ compounds. In the high wavenumber region, the ν(C(8)—H(8)) mode at 3130 cm^{-1}, as well as a weak band at 2800 cm^{-1}, probably due to a combination mode, are clearly detected.

Extensive coupling with ring modes is anticipated for the three N—H bonds. Spectral changes resulting from complexation can arise both from the loss of this N—H coupling and from bond order changes in the ring. Detailed assignment is beyond the scope of this work. However, attempts have been made to empirically identify diagnostic bands which could be used to distinguish between the three complexation patterns observed here. Some modifications have been found to take place uniformly for all complex types. For instance, the bands at 1122 and 538 cm^{-1} lose most of their intensities in all cases, the former appearing as a small feature superimposed on the strong anion band for the ClO_4^- compounds. Other changes are more characteristic. The $[(CH_3Hg)_3(HX)]Z$ compounds possess a strong band at 1524 cm^{-1}, which is absent from the spectrum of xanthine and shifted to 1505 cm^{-1} in $[(CH_3Hg)_3X].2H_2O$ and $[(CH_3Hg)_4X]Z$. A very weak xanthine band at 1391 cm^{-1}, gaining intensity for $[(CH_3Hg)_3(HX)]Z$, is shifted to 1375 cm^{-1} for both other types of complexes. A similar distinction can be made from several other spectral regions. For instance, a weak ligand absorption at 1260 cm^{-1} disappears for $[(CH_3Hg)_3(HX)]Z$, but reappears at 1287 cm^{-1} for the remaining compounds. Similarly, weak ligand bands at 959, 895, 854, and 614 cm^{-1} are displaced to 912, 880, 866, and 602 cm^{-1}, respectively, in the spectra of the $[(CH_3Hg)_3(HX)]Z$ compounds, but absent in the other cases.

Distinction between the two types of N(1)-substituted compounds is more difficult. The best diagnostic feature is probably the 1336/1328 cm^{-1} doublet of xanthine. It is observed at 1320/1310 cm^{-1} for the $[(CH_3Hg)_3(HX)]Z$ salts, but gives rise to single bands at 1302 cm^{-1} for $[(CH_3Hg)_3X].2H_2O$ and at 1314 cm^{-1} for $[(CH_3Hg)_4X]Z$. A weak ligand doublet at 1161/1153 cm^{-1} is replaced by a single peak at 1153 cm^{-1} for $[(CH_3Hg)_3(HX)]Z$, at 1161 cm^{-1} for $[(CH_3Hg)_3X].2H_2O$ and 1168 cm^{-1} for the $[(CH_3Hg)_4X]Z$ compounds.

Concluding remarks

Reaction of methylmercury with xanthine in aqueous solution yields pure solid compounds only for high CH_3Hg:xanthine ratios. In the 4:1 cationic complex, saturation of all available nitrogens of xanthine is taking place, whereas in the 3:1 neutral compound, the N(9)-bound CH_3Hg^+ groups is removed. These materials are both stable when dissolved in DMSO. In contrast, the 3:1 cationic compounds, in which the N(1)—H(1) bond is retained, are found to disproportionate in warm DMSO into the 4:1 cationic compound and a lower species identified as $[(CH_3Hg)_2(H_2X)]^+$. Attempts to prepare compounds with a low CH_3Hg:xanthine ratio invariably led to mixtures of $[(CH_3Hg)_3X].2H_2O$ and unreacted xanthine. However, when these mixtures are warmed in DMSO, equilibration produces complex species of intermediate stoichiometries, which have not been unambiguously identified so far. Thus, reaction of xanthine in water appears to be limited by its very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

low solubility. The presence of three H-bond donors and three H-bond acceptors in relative orientations favorable to form complementary H-bond pairs, imparts to xanthine an insoluble character analogous to that of guanine. Pure compounds are isolated when H-bonding opportunity is reduced after substituting most of the N—H groups in the CH_3Hg-rich compounds. Compounds of lower stoichiometries are likely to exist in non-aqueous solvents having good H-bonding capabilities, which would improve xanthine solubility. This is being currently examined.

Experiments with a cyclic closed-loop gas chromatograph[1]

ROBERTA BACK[2] AND R. A. BACK
Division of Chemistry, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R6

Received March 24, 1984

R. BACK and R. A. BACK. Can. J. Chem. **62**, 2260 (1984).

A cyclic closed-loop gas chromatrograph, comprising a column, a thermal conductivity detector, and a peristaltic circulating pump, together with valves for sample pick-up and carrier gas admission, is described. Injected samples could be recycled many times, providing very long effective column lengths, and separations were markedly better than on a single-pass column of equivalent length. Separation of two components, and peak broadening with single components, were measured over many successive cycles for a variety of samples, carrier gases, and conditions. The use of the cyclic chromatograph for testing columns and for studying basic processes in gas chromatography is demonstrated and discussed.

R. BACK et R. A. BACK. Can. J. Chem. **62**, 2260 (1984).

On décrit un appareil à chromatographie en phase gazeuse munie d'une boucle fermée cyclique et comprenant une colonne, un détecteur à conductivité thermique, une pompe à circulation péristaltique ainsi que des valves pour l'injection des échantillons et l'entrée du gaz porteur. Les échantillons injectés peuvent être recyclés plusieurs fois, la longueur effective des colonnes devient très grande et les séparations sont bien meilleures que celles obtenues à l'aide de colonnes à passage unique de longueur équivalente. Opérant avec plusieurs cycles successifs et avec une variété d'échantillons, de gaz porteurs et de conditions expérimentales, on a mesuré la séparation des deux composants et l'élargissement des pics avec des composants uniques. On démontre l'utilité du chromatographe cyclique pour vérifier des colonnes et pour étudier les procédés de base de la chromatographie en phase gazeuse et on en discute.

Introduction

About 25 years ago, a brief note was published (1) describing a circular closed-loop gas chromatograph in which the exit gases were recirculated through the column and detector by a peristaltic pump. About ten years later a very similar system was developed independently in this laboratory (2). Samples of air were separated into N_2 and O_2 on a Porapak T column, and comparison with a single pass through a column of equivalent length showed that the cyclic closed-loop was much more efficient. There appear to be no other published accounts of similar cyclic chromatographs. These earlier experiments (1, 2) suggested some interesting possible uses for such a chromatograph, and the present paper describes a belated exploration of some of these.

Experimental

The chromatograph in its final form is shown schematically in Fig. 1, which is largely self-explanatory. The column used in all experiments was 3 ft. of 3/16th-in. od stainless-steel tubing packed with 80–100 mesh Porapak T, divided into two equal parts, as shown. This arrangement was found to give better performance than a single column of the same total length on one side or other of the pump; peaks were narrower, separations were better, and small pressure fluctuations caused by the circulating pump, which induced a ripple in the detector signal at low pump speeds, were damped out. All connecting tubing was 1/8th-in. od copper, and in all connections dead space was minimized. The detector was one side of a Carle model-100 thermistor microdetector, balanced against a Helipot variable resistor, operated at room temperature with only enough current to give a sensitivity which permitted easy measurement on a chart recorder with good signal-to-noise ratio. The sample loop, of 1/8th-in. copper tubing, had a volume of 0.2 cm^3. The circulatory pump was a Cole-Parmer Masterflex #1014 3-roller peristaltic pump, fitted with thick-walled, 5 mm od, 1.5 mm id silicone rubber tubing. It was run at settings of the speed control which gave volume flowrates of air from about 10 to 110 cm^3/min, measured with air at 1 atm. with zero pressure difference across the pump.

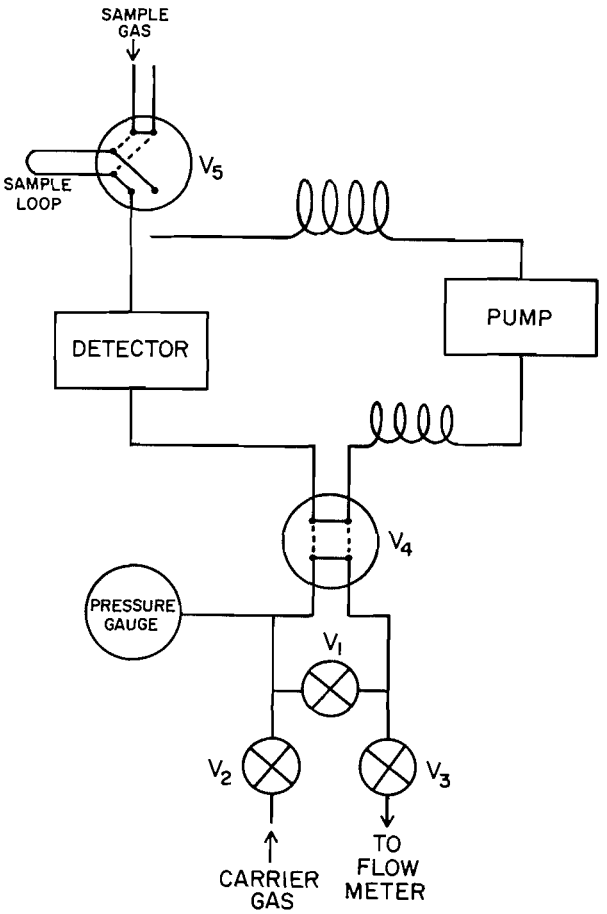

FIG. 1. Schematic diagram of cyclic chromatograph. V_1, V_2, and V_3 are simple on–off metal valves (Nupro #4J); V_4 and V_5 are 4- and 6-port, stainless-steel-and-Teflon switching valves (Valco).

In an experiment, the system was first pressurized and flushed with carrier gas through V_4, with V_1 closed and V_2 and V_3 open, with the pump and detector operating. When the baseline signal was steady and the pressure at the desired value, V_2 and V_3 were closed and V_1

[1]NRCC No. 23573.
[2]Summer assistant.

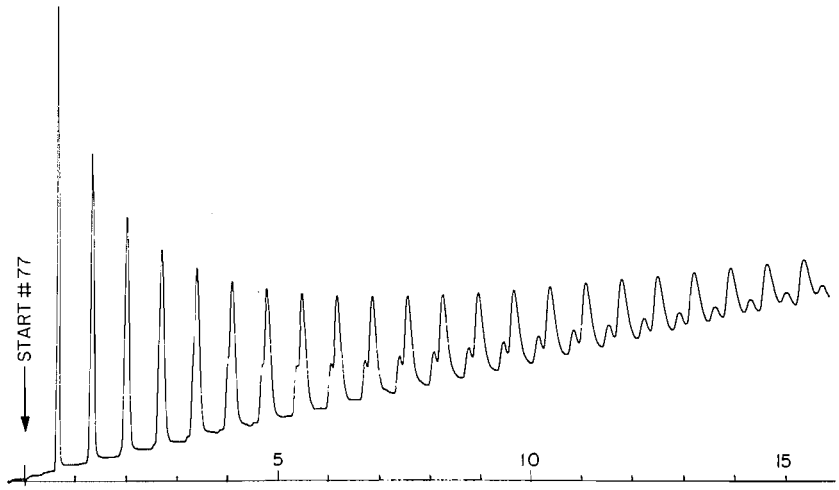

FIG. 2. Chromatogram of O_2–Ar sample in He carrier; O_2 has the shorter retention time. Peak height is plotted against retention time in minutes.

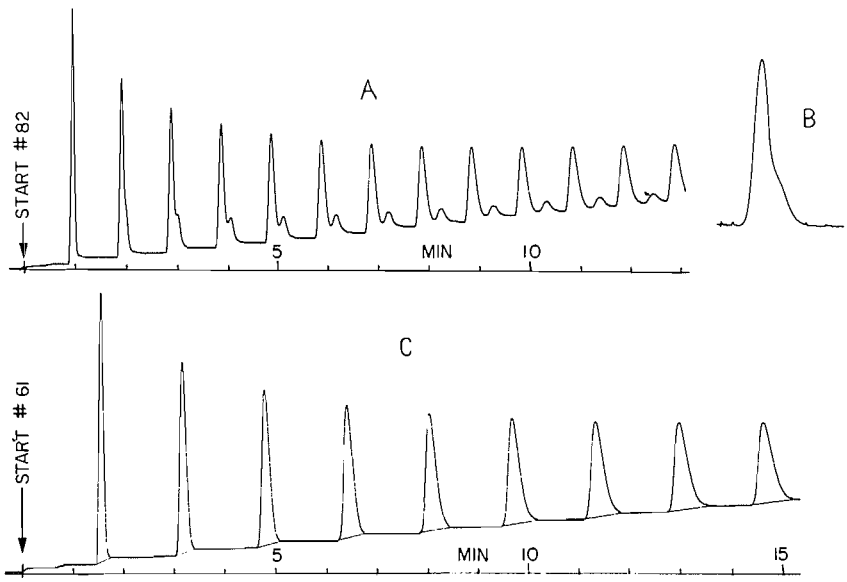

FIG. 3. *A*, chromatogram of air sample in He carrier, N_2 has the shorter retention time; *B*, chromatogram of air sample in He carrier from single pass through 50-ft. column; *C*, chromatogram of N_2 in He carrier, showing broadening of a single peak.

opened, so that the carrier gas continued to circulate through V_1. Pressure was recorded and could be monitored for a few minutes to test for leakage. V_4 was then switched to bypass the carrier gas supply, and finally V_5 was switched to pick up the sample gas which had been flushing through the sample loop.

Results and discussion

Figure 2 shows a typical chromatogram for a sample of O_2 and Ar in He carrier gas. The two components are first resolved on the ninth cycle and completely separated after 19 cycles, corresponding to 57 ft. of column. Faster separation is shown for a sample of air in He (Fig. 3*A*) where N_2 and O_2 are resolved after four cycles and separated after eight, corresponding to 24 ft. of column. For comparison an air peak is shown after a single pass through a 50-ft. column of Porapak T under comparable conditions (Fig. 3*B*) and it is seen that O_2 is only slightly resolved as a shoulder on the nitrogen peak. The improvement of the separation in the cyclic system is striking, probably reflecting the well-known loss of efficiency in the single-pass system due to the high pressure drop across the column and consequent non-uniform volume flowrate.

From the data in Figs. 2 and 3*A*, peak separations were measured and are plotted in Fig. 4 vs. the number of cycles. The separation of N_2 and O_2 increases linearly from zero, whereas that of O_2 and Ar shows some deviation. Lateral displacement of overlapping peaks,[3] and non-Gaussian peak shapes may have contributed to the different behaviour, and these measurements show how the cyclic system could be used to study factors affecting peak separation. The data in Figs. 2 and 3*A* also demonstrate a very practical use for the system for testing a particular column for a desired separation. Thus a short inexpensive column could be prepared and tested to determine whether a much longer column would be useful in a conventional single-pass chromatograph. We tested, for example, H_2–D_2 mixtures on the Porapak T column, and found no

[3]The position of the true maximum of a peak on a sloping baseline is not at the top of the peak, but rather is at the point at which the slope of the curve equals the slope of the baseline. For two overlapping peaks, this has the effect of pulling the apparent maxima closer together than the true maxima. For unequal peaks, the smaller is displaced more than the larger.

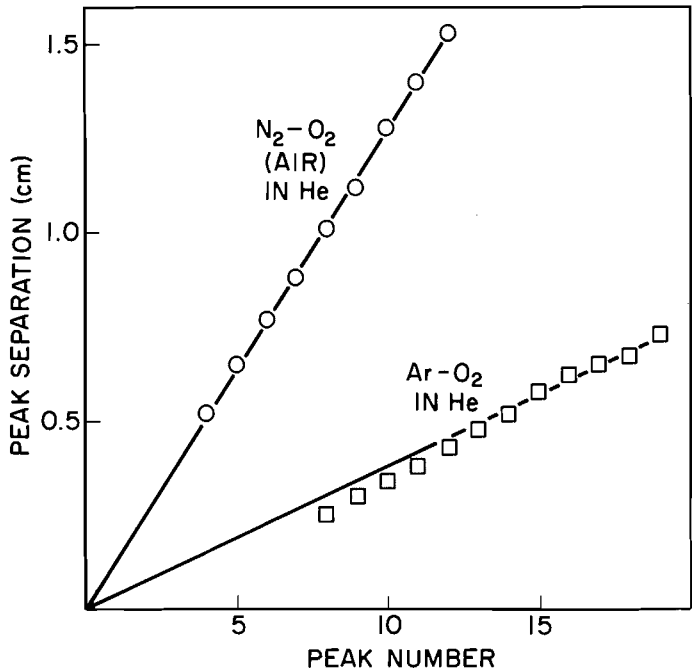

FIG. 4. Peak separation vs. peak number, from chromatograms in Figs. 2 and 3*A*.

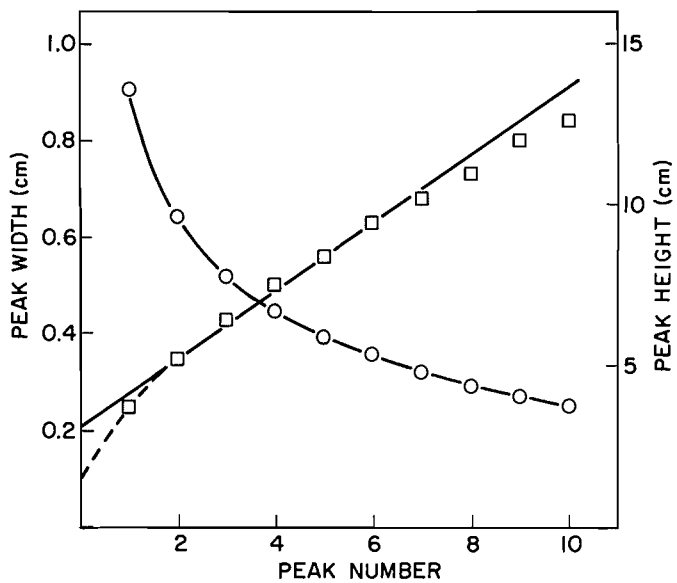

FIG. 5. Peak heights (○) and peak widths (□) from chromatogram in Fig. 3*C*.

separation after 51 cycles (153 ft. of column), although the sample peak was still well defined; there is clearly no point in trying a single column of this length for this separation.

The cyclic column could also be used itself for analysis of suitable two-component systems, but with more than two components overlap of peaks from successive cycles would probably cause problems. A second limitation is the need for a non-destructive detector such as a katharometer, which may lack the required sensitivity.

The cyclic chromatograph is also well suited to study the mechanism of peak broadening, which is of fundamental interest in gas chromatography. Figure 3*C* shows a fairly typical

TABLE 1. Peak broadening measurements

Carrier gas	Sample gas	Nominal* pump speed (cm^3/min)	Rate of broadening (min/cycle)	Time between peaks (min/cycle)

		73	0.018	1.094

*Nominal pump speeds were measured in air at 1 atm. and zero pressure drop across the pump. True carrier gas flows were less because of pressure drop on inlet side of pump, which in turn depends on the flow rate and the viscosity of carrier. Rate of broadening was measured from linear portions of plots of peak width as in Fig. 5.

chromatogram from a sample of N_2 in He carrier gas. In Fig. 5 are plotted peak heights and peak widths at half maximum against the number of cycles. For four or five cyles, beginning usually with the second peak, the increase in peak width was approximately linear, falling off with subsequent cycles. The first peak often fell below this straight line as in Fig. 5. The major cause of peak broadening in gas chromatography is the simple statistical effect of the adsorption and desorption of the sample as it moves along the column. As treated simply by Phillips (3), for example, first-order adsorption and desorption will lead to a Gaussian peak for which it can be shown that for a given sample species and column, the width at half maximum should increase linearly with increasing retention time. This corresponds in the present system to a linear increase with the number of cycles, as seen in Fig. 5. The intercept of the linear plot should ideally correspond to the initial width of the peak as it is injected on the column. In fact it is about twice the value which can be estimated from the pickup volume of 0.2 cm^3 plus a small contribution from the detector volume (0.058 cm^3). The true behaviour of the system probably follows approximately the dashed curve in Fig. 5, with an initial more-rapid peak broadening, perhaps due to saturation of the solid adsorbent at the high initial concentration injected, and perhaps also an effect involving the change from the initial square shape of the injected sample into a Gaussian form. These effects were not further investigated. Peak area, as esimated by the product of peak height and peak width at half maximum, was almost constant in these experiments (Fig. 5), indicating that peak tails were not overlapping appreciably; this could be a problem at larger numbers of cycles.

Measurements of the linear rate of peak broadening were made from plots like Fig. 5 for a variety of samples and carrier gases, for different pump speeds, and results are summarized in Table 1. Each combination of sample and carrier was mea-

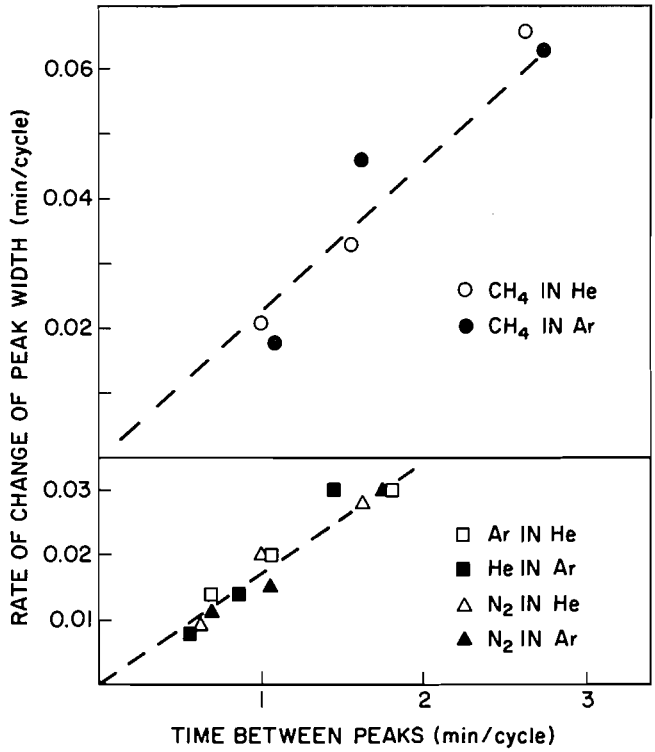

FIG. 6. Rate of peak broadening for a variety of sample and carrier gases.

sured at three different flowrates, and simple theory indicates that the peak broadening per cycle should increase linearly with the cycle period. Figure 6 shows that this is approximately true, and in fact the data from all the systems except those with methane samples fall around a single line. Two conclusions can be drawn from these data. First, there is little if any peak broadening due to circulation of the sample through the pump, valves, connections, detector, etc., i.e., the components in the loop other than the columns. If this occurred, peak broadening would be relatively faster at faster pump speeds, and the data in Fig. 6 would curve upwards. The absence of such broadening is not unexpected, as minimum-volume components were used throughout, but it is encouraging in as much as more fundamental causes of broadening can be examined without interference. Second, diffusion apparently contributes little to peak broadening in these experiments, as shown by the approximate similarity between systems such as He in Ar, N_2 in Ar, and Ar in He, in which the much faster diffusion of helium would have led to faster broadening if diffusion were an important factor. There are some minor but probably real trends evident in the data in Table 1 and Fig. 6 which will not be discussed further at the present time. The slopes of plots such as those in Figs. 5 and 6 are related to the number of theoretical plates for each system, and to the partition coefficient of the sample gas between the adsorbed phase and the gas phase, and such parameters could be obtained from these or similar measurements.

We have not attempted in this brief article to investigate and analyse rigorously factos affecting separation and broadening of peaks in gas chromatography. Liquid stationary phases would be better suited to this than the solid Porapak T employed, and results with the latter could doubtless be improved by more careful preparation and conditioning. We have instead tried to show how a simple cyclic closed-loop chromatograph can be operated, and to explore some of the ways it can be used to test columns and to study fundamental processes in gas chromatography.

Thermostable sites of palladium phthalocyanine in Shpol'skii matrices of mixed solvents

WEN-HSIUNG CHEN, KLAUS E. RIECKHOFF, AND EVA-MARIA VOIGT
Departments of Physics and Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received March 26, 1984

WEN-HSIUNG CHEN, KLAUS E. RIECKHOFF, and EVA-MARIA VOIGT. Can. J. Chem. **62**, 2264 (1984).

A study was made of the effects of three different mixed solvent Shpol'skii matrices at 4.2 K on site formation and on vibronic progressions of palladium phthalocyanine. It is found that only a limited number of thermostable sites are formed and these sites are common to all three matrices, but vary in their statistical weights. However, in all solvents the statistical weights of the first few most important sites are similar, with the predominant site at least eight or nine times stronger than the next. As well, the vibrational features of both the ground state and the first excited states of a few of the most populated sites examined are practically the same for the different mixed solvents. The absence of any significant differences in site splitting implies the absence of any dipolar interaction effects on these splittings.

The above findings provide a better insight into the interaction between phthalocyanine, intermediate solvent, and basic solvent (*n*-octane) in the three-component solutions and give a clear guideline for choosing convenient solvents and for using Shpol'skii matrices as a simple effective mechanism for producing quasi-line vibronic spectra of phthalocyanines and other related large molecules insoluble in the alkanes.

WEN-HSIUNG CHEN, KLAUS E. RIECKHOFF et EVA-MARIA VOIGT. Can. J. Chem. **62**, 2264 (1984).

Opérant à 4,2 K, on a étudié les effets de trois matrices, de type Shpol'skii et comportant trois solvants mixtes différents, sur le site de formation et sur les progressions vibroniques de la phtalocyanine de palladium. On a trouvé qu'il se forme un nombre restreint de sites thermostables, que ces sites sont communs à toutes les matrices, mais qu'ils varient dans leurs pondérations statistiques. Dans tous les solvants, les pondérations statistiques des quelques sites les plus importants sont toutefois toutes semblables et le poids statistique du site prédominant est au moins huit ou neuf fois plus important que celui du suivant. De la même manière, les caractéristiques vibrationnelles de l'état fondamental ainsi que du premier état excité, de quelques-uns des sites examinés les plus populeux, sont pratiquement les mêmes pour les différents solvants mixtes. L'absence de différences importantes dans le dédoublement des sites implique l'absence de tout effet d'interaction dipolaire sur ces dédoublements.

Ces observations fournissent une meilleure connaissance des interactions entre la phtalocyanine, le solvant intermédiaire et le solvant de base (*n*-octane) dans des solutions à trois composantes et elles fournissent des règles directrices claires dans le but de choisir des solvants convenables et pour utiliser des matrices de type Shpol'skii comme mécanisme efficace et simple de produire des spectres vibroniques quasi-lignes des phtalocyanines et d'autres molécules apparentées qui sont insolubles dans les alcanes.

[Traduit par le journal]

I. Introduction

The achievement of well-resolved vibronic spectra of phthalocyanine (Pc) complexes thus far has depended on the gas-phase supersonic jet-cooling (1) and low temperature matrix isolation of normal alkane (Shpol'skii) (2–4) and inert gas (5, 6) techniques. The technique of doping by substitution of suitable molecules in a condensed phase solution or crystal, although being successful in some smaller organic molecules (7, 8), is not applicable to the case of Pc due to the lack of substitutable molecules in the host. All the above techniques are capable of freezing the rotational degrees of freedom and producing resolved vibronic bands with width of several cm^{-1} or better, but the matrix isolation of Shpol'skii appears to be the simplest one for obtaining the desired effect. However, in this type of matrix one always encounters more than one possible site of symmetry for the Pc molecules and thus a number of different electronic potential curves result. This situation complicates the resulting overall vibronic structures. Therefore, it is useful to examine how many of these sites can actually be created by a specific host matrix under a fixed condition, what their statistical weights are, and how a slight change of host solvent can affect the site formation as well as the vibrational characteristics associated with each of the sites.

Since, in general, Pc complexes are not soluble in alkanes, intermediate solvents (inter-sols) can be used to incorporate them into the alkanes to achieve the Shpol'skii effect. The inter-sols used in this report included α-chloronaphthalene (α-ClN), tetrahydrofuran (THF), and benzene. These structurally different molecules are all mixed with the same alkane: *n*-octane $C_8H_{18}(C_8)$. When these mixed solvent Pc solutions are cooled quickly, one finds great inhomogeneity both in site formation (increasing the number of possible sites) and in the electronic potential curves of a site (broadening the band width of an individual site). Accordingly, these solutions must be frozen slowly to obtain a thermostable site distribution as well as to optimize the spectral band resolution.

Among the many metallophthalocyanines (M—Pcs) studied in our laboratory (3, 4, 9, 10), PdPc was found to be one of the best for experimental study of such complexes. The existing data (9, 10) show that it has fairly strong emissions in both fluorescence and phosphorescence, with a Q-band absorption that can be easily reached by a tunable laser using DCM dye. It exhibits several detectable sites of symmetry when incorporated into an alkane base mixed solvent. Aside from the well studied predominant site, represented by the set of origins {15286, 15355 cm^{-1}}, there is at least one more site whose vibrational features are strong enough to be adduced for comparison. The presence of two origins in the 0–0 fluorescence of a site comes from the lifting of the excited states E_u double degeneracy in a matrix environment as was reported in the cases of metalloporphyrins (M—Ps) (11, 12). We shall designate the upper origin, the zero-point high energy component of the first excited singlet state, S_y, and the lower origin, the vibrationless lower energy component, S_x. Counterparts of S_y

and S_x in the triplet state shall respectively be called T_y and T_x. At the experimental temperature, 4.2 K, in the fluorescence region, both the low and the high energy components (S_y and S_x) of the doublets of some strong sites are discernable. However, in the phosphorescence region this is not the case: one sees only the low energy component (T_x) of these sites. The doublet splitting detected either in the fluorescence region or from the emission−excitations varies from site to site between 60 to 90 cm^{-1}. The site−site separations normally are from a few to several tens of cm^{-1}. Therefore it is often possible to select an individual site for study by preferential excitation.

II. Experimental

The apparatus and techniques used in this report have been described previously (3, 4, 10). PdPc was obtained from K & K commercially and, without further purification, was dissolved in an inter-sol before being incorporated into C_8. The concentrations were about 10^{-5} *M* Pc or less in the mixed final solutions, which were cooled in a small glass cell inside a dewar. The emissions of the sample at liquid helium temperature were excited by a dye laser using DCM pumped by an Ar^+ laser and detected after dispersion by a Spex Industries 3/4 m (single grating) or a 1/2 m (double grating) spectrometer by a Philips 150 CVP (S1) or an ITT FW130 (S20) photomultiplier. The output signal was processed by either photon counters (PAR SSR 1105, SSR 1110) or lock-in-amplifiers (PAR model 124, HR 8). The total uncertainty in spectral band position is less than ±2.0 cm^{-1}.

III. Results and discussion

Although Pc complexes are difficult to separate, complexes have their own "finger-print" emissions and absorptions (or rather emission-excitations in our case) and hence can be identified. In the general 0−0 fluorescence region (15250−15450 cm^{-1}) of PdPc in the Shpol'skii matrices, there is no overlapping with other impurity Pc's 0−0 bands, especially the ubiquitous metal-free Pc. However, active vibrations of the first excited singlet states of most Pcs do fall into this region, but can be suppressed by the careful choice of monitoring positions during emission excitation study. Consequently, spurious excitation bands appearing in this region are distinguishable from the genuine ones, and all emission bands reported can be unambiguously assigned to the 0−0 fluorescence of the multiple sites of PdPc in the matrices. In the phosphorescence region (10070−9970 cm^{-1}) two impurity bands of non-Pc origin, 10037 and 9992 cm^{-1}, with intensities comparable to those of the minor site 0−0 phosphorescences, were found and not included in the discussion. In total, eight sites appeared consistently in both fluorescence and phosphorescence regions. The single band 0−0 phosphorescence positions represent, in order of decreasing energy (cm^{-1}), site A to site H. Detectable vibronic progressions normally cover a range of less than 1500 cm^{-1} above the origins. However, not all of the progressions belonging to the eight sites are detectable or suitable for recording.

(A) Symmetry-species in the α-ClN + C_8 Shpol'skii matrix

The general 0−0 fluorescences of the multiple sites of PdPc in Shpol'skii matrices spanned some 200 cm^{-1} in range, as was previously stated. This can be most easily seen in Fig. 8 (N) discussed later in III(*C*), where sharp band multiple site 0−0 fluorescences in α-ClN + C_8 are shown. Although the intensities of these emissions vary by orders of magnitude, we first of all enumerated in detail all of them; followed by pairwise grouping to determine the number of sites, since each pair

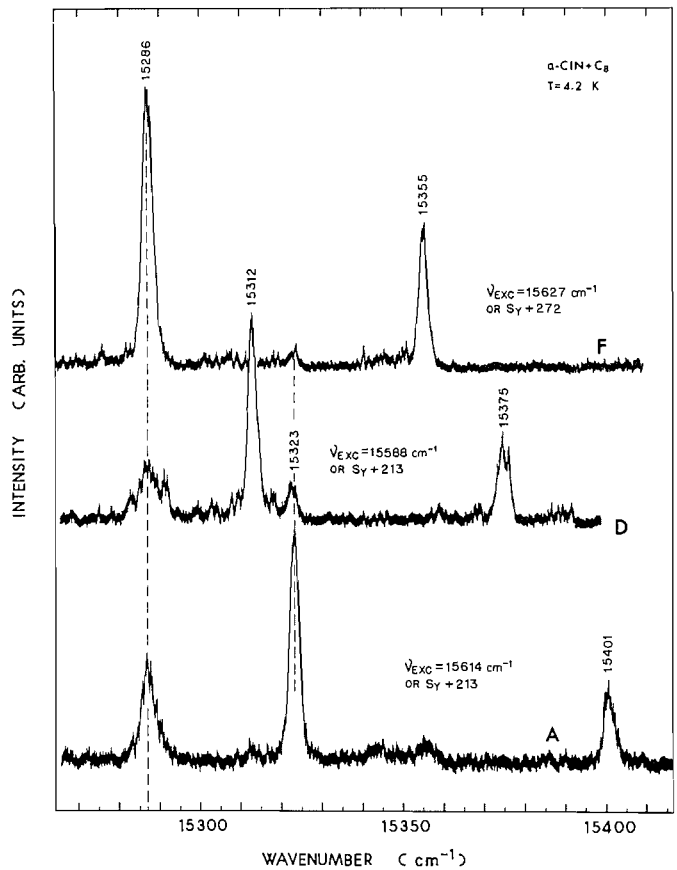

FIG. 1. 0−0 fluorescences of some of the most populated sites of PdPc in α-ClN + C_8 obtained by exciting the fundamentals of the S_y components of the sites, using ν_{exc} = 15627 (S_y(F) + 272), 15588 (S_y(D) + 213), and 15614 (S_y(A) + 213) cm^{-1}, respectively for (F), (D), and (A). The numbered bands represent the doublets of the sites. It is seen that the 15286 cm^{-1} band appeared also in the other two cases (D) and (A).

belongs to a single site of symmetry in the matrix and the number of pairs represents the number of sites. Figure 1 illustrates the doublet feature of some of the most populated sites of PdPc in α-ClN + C_8, obtained by exciting their S_y fundamentals. Since the high energy (S_y) components of the less populated sites are too weak to be excited in this manner, the doublet feature of these sites does not appear in this figure. However, the doublet can be easily seen in the excitation spectra that we shall discuss later.

The 0−0 phosphorescences of these thermostable sites were subsequently observed in the ir region of 10070−9970 cm^{-1} using the previously found 0−0 fluorescence frequencies as excitation. At 4.2 K only one band was observed for each site because of much faster relaxation from the T_y component into the lower energy T_x component than the radiative phosphorescent rate of the T_y component. Figure 2 shows the phosphorescences of these multiple sites in the matrix. These phosphorescence bands were shown to be genuine by their respective excitation spectra which have the doublet structures in the same positions as the 0−0 fluorescences of these sites. Figure 3 shows this correspondence in all of the eight sites. To conclude the present sub-section we list all the possible sites (from A to H) of PdPc in α-ClN + C_8 in Table 1 where the sites are represented by the doublet positions and the statistical weights by the intensity ratios with respect to the predominant

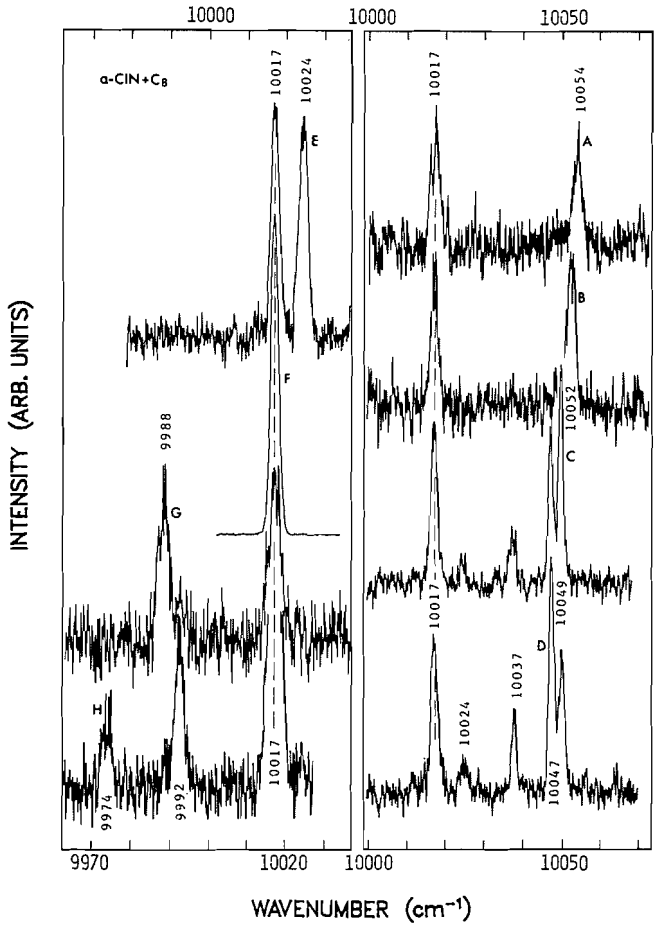

FIG. 2. 0−0 phosphorescences of the multiple site PdPc in α-ClN + C_8 at 4.2 K. From sites A to H, they are peaked at 10054, 10052, 10049, 10047, 10024, 10017, 9988, and 9974 cm^{-1}, respectively. Note that the 10017 cm^{-1} band of the prominent site F appears in all of the cases. The excitation frequencies used were the S_y components of the sites, except the one used for the F site, where S_x was used instead. Consecutively for site A to H, they are 15401, 15407, 15373, 15375, 15369, 15286, 15426, and 15344 cm^{-1}. Two impurity bands, 10037 and 9992 cm^{-1}, alongside of some PdPc phosphorescence bands are also shown.

site F (taken as 100).

PdPc aggregation species are not strong enough to compete with the symmetry species, and they do not emit or absorb in the same general region as the monomeric symmetry species. This is clear from the following. First, the concentrations of PdPc in the mixed solvents are low; second, the divalent Pd does not aggregate readily; and third, the size of the Davydov splitting of Pc complexes due to dimerization is known to be of the order of 1000 cm^{-1} or more (13), suggesting dimeric contributions be found at least 500 cm^{-1} away from the present region.

(B) Vibronic progressions of different site symmetries in different Shpol'skii matrices

The vibronic progressions for PdPc in matrices, just like most of the M—Pc complexes studied (3, 4, 14), show very strong 0−0, weak 0−1 (4% of the 0−0 or less), and even weaker 0−2 (usually undetectable) bands, characterizing a very small Stokes loss for the normal vibrations or very weak vibronic and electron−phonon interactions (15). Most of the fundamental vibrations that are found in the emissions can also be found in the excitations, which implies that the molecular symmetry is roughly preserved in the excited state. However, intensity mirror symmetry of these fundamentals between emission and excitation is not observed usually. Furthermore, these vibronic progressions are quite short and most of the important fundamentals are found in a range of less than 1000 cm^{-1} above their respective origins. Therefore it is sufficient to compare the fundamentals of the different sites in this spectral range.

1. Excitation spectra of sites in the α-ClN + C_8 matrix

Details of the fluorescence-excitation spectra on the predominant site F {15286, 15355 cm^{-1}} covering 1500 cm^{-1} above the doublet origins (S_x and S_y) have been reported elsewhere (10). The vibronic progressions of the next important site C {15311, 15374 cm^{-1}} show very much the same general features as those found in the predominant site reflecting an extremely weak effect of the local environment on the π-electron resonance of Pc. This can be clearly seen in Fig. 4 (NC and NF), illustrating the 0−0 fluorescence-excitations of the low energy S_x components of the C and F sites in α-ClN + C_8. The numbers marked on the progressive bands represent the vibrational energies with respect to the specific origins. Progressive bands that are not numbered belong to the S_y components. As there is a difference in crystal field splitting of the C and F sites ~(63 vs. 69 cm^{-1}), the relative spacings between the numbered and the unnumbered bands in these sites are not the same. Therefore, in order to show the correspondence of the numbered bands in the different sites of the matrices, we have employed a relative scale on the abscissa which puts all origins at zero. This scheme is used in Fig. 4 as well as in the next three figures. Figure 5 (NC and NF) displays the 0−0 fluorescence

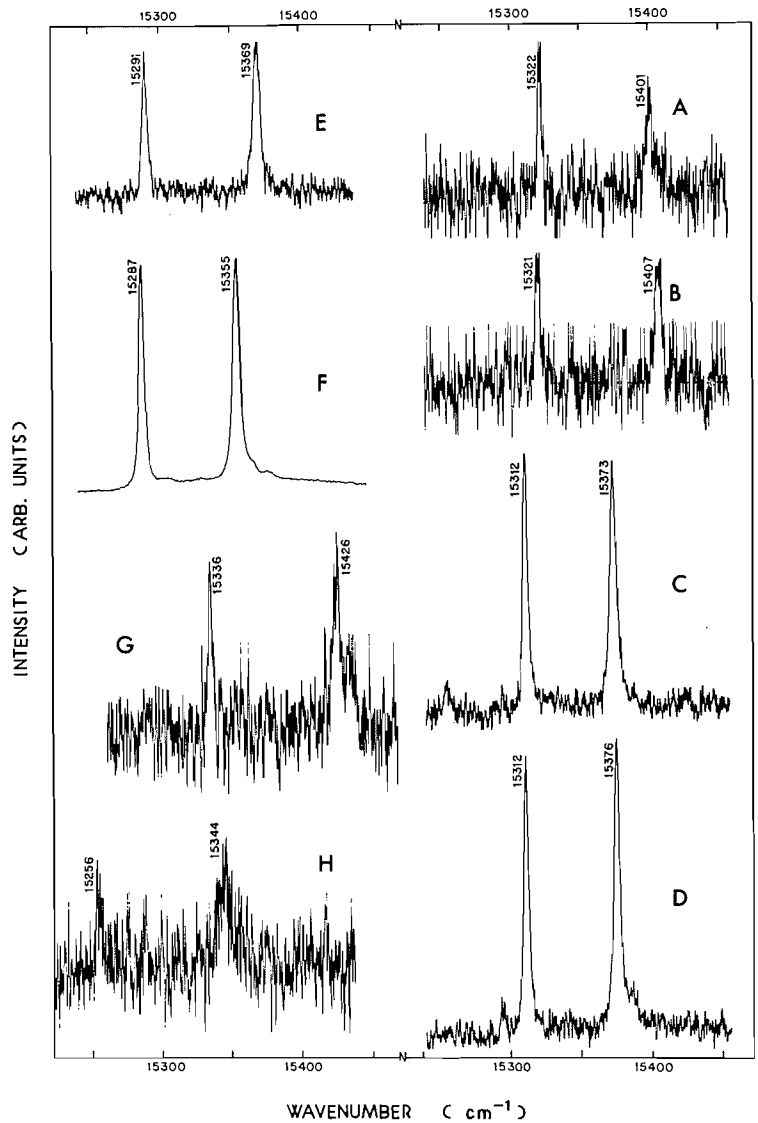

FIG. 3. Phosphorescence excitation spectra of the multiple site PdPc in α-ClN + C_8. Each shows a doublet feature corresponding to the two zero-point components of the first excited singlet state (S_x and S_y) of the sites. They are obtained by monitoring the intensities of the 0−0 phosphorescence (T_x) of the sites, from A to H, at 10054, 10052, 10049, 10047, 10024, 10017, 9988, and 9974 cm^{-1}, respectively.

excitations of the high energy S_y components of the sites in the matrix where, since the progressive bands are numbered with respect to these origins, the alignment of the vibrational bands in the C and F sites is seen to be restored. The effect of the crystal field is now on the weaker unnumbered bands of the S_x components and therefore not clearly perceptible.

2. Fluorescence/Raman spectra of sites in the α-ClN + C_8 matrix

While the fluorescence-excitation spectra of the vibronics of PdPc multiple sites are not interfered with by Pc impurity emissions from different centers, the fluorescence/Raman spectra, in contrast, are often masked or overlapped by contributions from impurities, especially the strong H_2Pc fluorescences. These Raman/fluorescence spectra on the whole cover a spectral region from 13400 to 15300 cm^{-1}, and those of the predominant site F in α-ClN + C_8 have been reported in detail and analyzed by us in another paper (10). These spectra can be obtained by exciting either the high energy S_y components or the low energy S_x components of the doublets. When excitation is made to S_x the progressions appear in Raman, whereas if excitation is made to S_y both progressions appear in Raman and fluorescence, causing overall weaker and messier spectra due to energy sharing and band overlapping. The concurrence of Raman and fluorescence bands with a single excitation frequency in PdPc (and in RuPc)[1] is an interesting case which is rare in the Pc complexes and deserves attention (10). The vibronic transitions from S_x of the B {15321, 15407 cm^{-1}}, C {15311, 15374 cm^{-1}}, and F {15286, 15355 cm^{-1}} sites in α-ClN + C_8 are presented in Fig. 6 (NB, NC, and NF). It is seen that the fundamentals of all three sites are the same when the origins are shifted to a common point. This is particularly clear for those vibrations with energies lower than the 0−0 fluorescences of H_2Pc (14410 and 14474 cm^{-1}). For those with energies higher than those 0−0's of H_2Pc, the same correspondence can be exemplified by the 1533±2 cm^{-1} fundamental. The combined Raman/fluorescence vibronic spectra obtained

[1]Unpublished results.

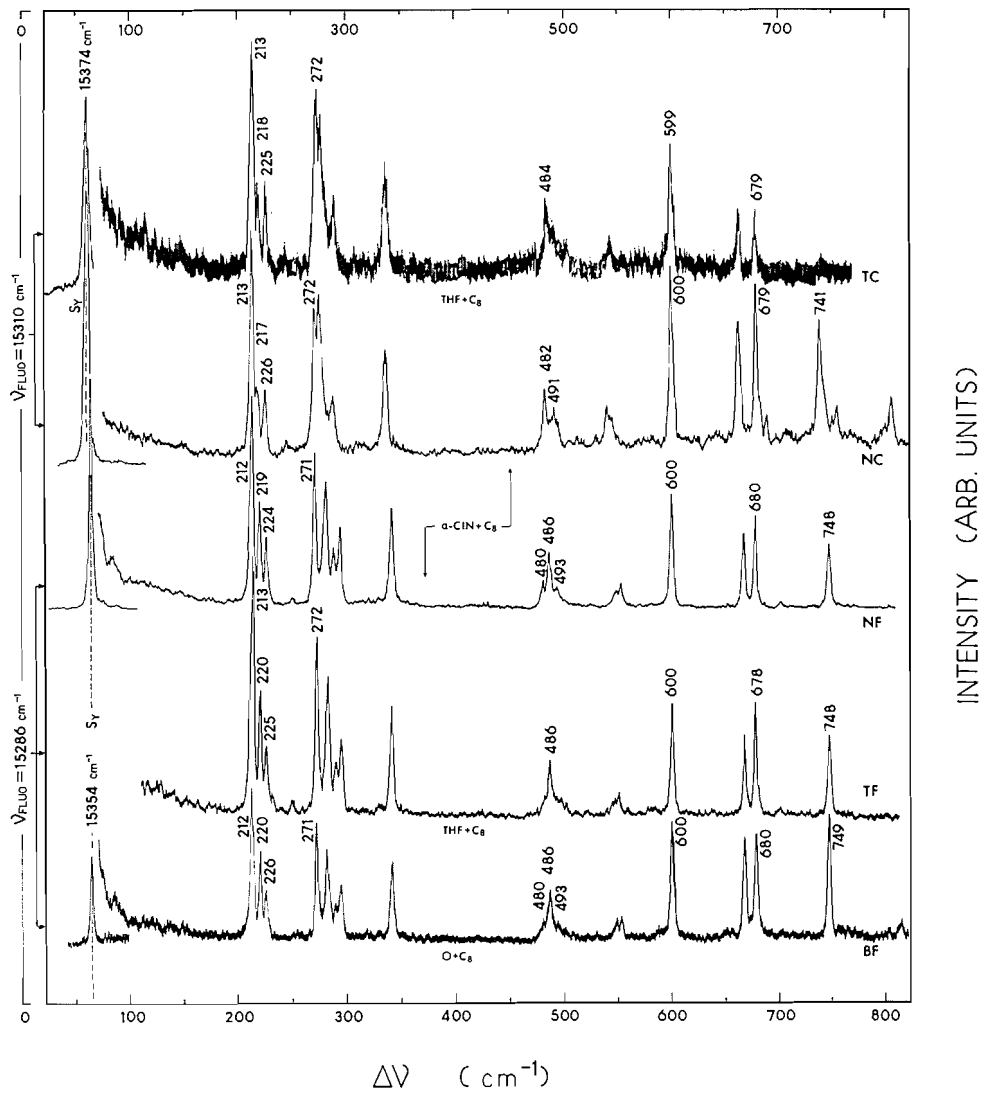

FIG. 4. 0−0 fluorescence excitation spectra of the C and F sites in both α-ClN + C_8 (NC and NF) and THF + C_8 (TC and TF), and the F site in benzene + C_8 (BF), using $\nu_{fluo} = S_x$. The abscissa measures the vibrational energies of S_x of the sites in the matrices. Absolute progressive band positions can be obtained by simply adding the vibrational numbers to their respective origins in cm^{-1}. Unnumbered bands are the vibronics of S_y components and are labeled in Fig. 5.

by exciting S_y of the C and F sites in α-ClN + C_8 are given in Fig. 7 (NC and NF). Although weaker and more complicated, the correspondence is recognizable in most of the low frequency vibrations. Here the correspondence was made in the fluorescence (F) bands, leaving the Raman (R) bands of the site C to shift a few cm^{-1} away from those of the site F due to unequal crystal field splittings mentioned previously in these two sites. From these results it is clear that the site effect on the molecular fundamental vibrations in the ground state is minimal or negligible, as well.

3. Vibronic progressions in the two other matrices

Fluorescence-excitation spectra of the C and F sites in THF + C_8 using $\nu_{fluo} = S_x$ and S_y are presented in Figs. 4 (TC and TF) and 5 (TC and TF), respectively. Those of the predominant F site in benzene + C_8 are given in Figs. 4 (BF) and 5 (BF), respectively. The emission spectra of the F site in THF + C_8 using $\nu_{exc} = S_x$ and S_y are shown in Figs. 6 (TF) and 7 (TF), respectively. The same spectrum of the F site in benzene + C_8 excited with S_x is presented in Fig. 6 (BF). The spectrum excited with S_y appeared too weak to provide any meaningful information and therefore is not included in Fig. 7. All of the spectra that belong to a particular site presented in Figs. 4−7 are found to be practically identical in all three matrices. The only difference among the same type of spectra in different matrices is the solvent-related overall intensity response and spectral quality. Therefore we conclude that the intermediate solvents (inter-sols) show no effect on the molecular symmetry in both the ground and the first excited states.

In general, we have found that for the best overall intensity response and spectral quality when using a good inter-sol, one can afford to increase the mixing ratio of C_8 to inter-sol and still get a good signal-to-noise ratio. Meanwhile, the high mixing ratio isolates the doublet components and prevents site/site communications more effectively, resulting in better intensity-balanced spectra originating from the doublet components of a site. The mixing ratio also appears to affect the weight distribution of the sites in different matrices.

(C) Comparison of symmetry-species in different matrices

PdPc in an α-ClN + C_8 matrix when excited with 15425

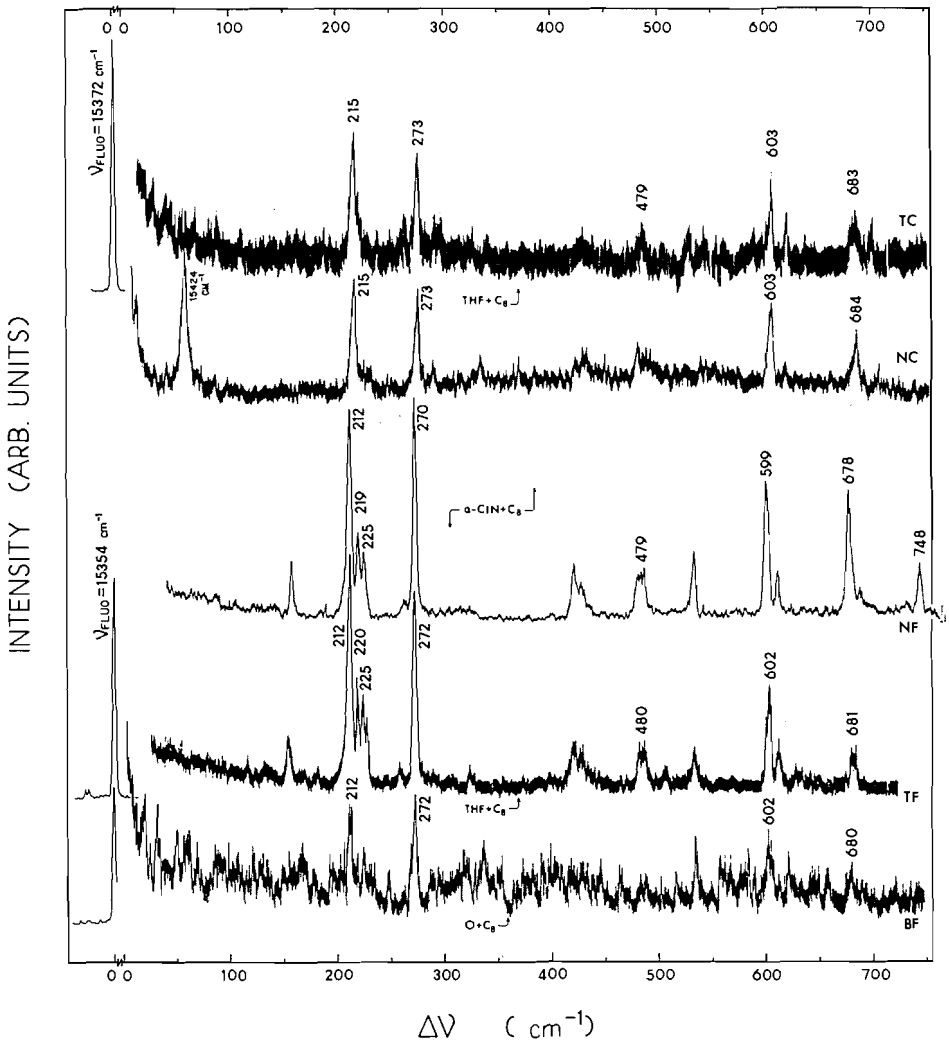

FIG. 5. 0−0 fluorescence excitation spectra of the C and F sites in both α-ClN + C_8 (NC and NF) and THF + C_8 (TC and TF), and the F site in benzene + C_8 (BF), using $\nu_{fluo} = S_y$. The horizontal axis scales the vibrational energies associated with their respective origins in cm^{-1}. A few unnumbered S_x fundamentals also showed up in the spectra which are labeled in Fig. 4 previously. The 15424 cm^{-1} band in (NC) may be assigned to the G site S_y.

cm^{-1} showed seven bands: Fig. 8 (N). These bands in fact depict all eight sites that are known to us: the 15256 and 15342 cm^{-1} (not resolved from the 15336 cm^{-1} band) stand for site H. The 15287 and 15356 cm^{-1} represent site F. The 15291 cm^{-1} band, residing on the high-energy shoulder of the prominant 15287 cm^{-1} band and masked by it, is the low energy (S_x) component of site E. The 15311 and 15373 cm^{-1} bands stand for the two unresolved sites of C and D, which are only 1−2 cm^{-1} apart; and the 15321 cm^{-1} band stands for the S_x components of two other unresolved sites A and B. Finally, the 15336 cm^{-1} band is the S_x component of site G. The unresolved sites in the figure resulted from the selection of excitation and slit width, which were chosen to display as many sites as possible with one single frequency. The same excitation frequency of 15425 cm^{-1} was subsequently used for the other two matrices: THF + C_8 and benzene + C_8. The results are illustrated in Fig. 8 (T) and (B). It is seen that some of the bands that showed up in Fig. 8 (N) are no longer discernable in (T) or (B). For example, the 15321 cm^{-1} band is not clearly seen in (T) and (B), and the 15256 cm^{-1} band is missing in (B). However, these missing bands can be made to reappear if their S_y counterparts are chosen as excitation reflecting the existence of these sites but with an overall variation of the statistical weight distribution of sites in the different matrices. The weight distribution of sites was found to vary with the concentration of PdPc, the sample freezing rate, and annealing process, the slight variation (uncertainty) in excitation frequencies (±1 cm^{-1}), the type of intermediate and basic solvents, and, possibly, the mixing ratio of the two solvents. Reproduction of the identical weight distribution of sites in one matrix can be obtained only when those variables are fully controlled. In our experimental situation, the Pc concentrations in the three different matrices were roughly the same and the freezing rate was also kept about the same (2 to 3 h to solidify the samples from room temperature). After solidification, the samples were subsequently chilled to 4.2 K and were not annealed at any higher temperatures. The mixing ratios of α-ClN, THF, and benzene to C_8 were approximately 1:5−6, 1:2, and 1:2, respectively. Under those conditions we have the weight distribution, represented by the intensity ratios, for each matrix as listed in Table 2. Even though there is a variation in the statistical weights of the minor sites, in these matrices there is a unique site that is dominant and constitutes at least 70% of the total site population.

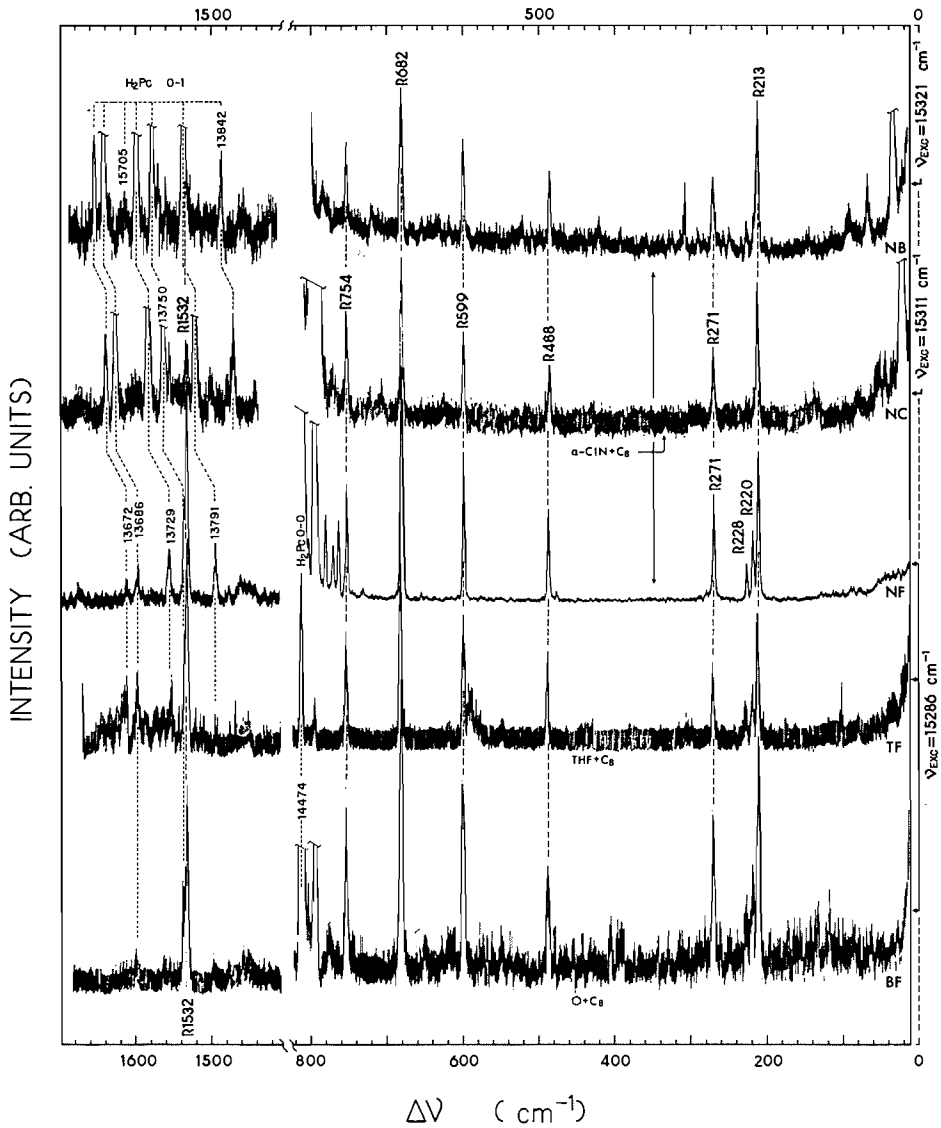

FIG. 6. Resonance Raman spectra of the B, C, and F sites in α-ClN + C_8 (NB, NC, and NF), and the F site in both THF + C_8 (TF) and benzene + C_8 (BF). The excitation frequencies used were the S_x components of the sites. The abscissa measures the vibrational energies of the ground state from zero and hence is relative. The letter R is used to emphasize the bands are Raman in nature. Their absolute positions can be calculated by subtracting the R numbers from their excitation frequencies. The five digit H_2Pc band positions in cm^{-1} are absolute.

Further examples which generalize the study of similar symmetry sites in different matrices are found in the site splittings of PtPc and ZnPc in α-ClN + C_8 and benzene + C_8 matrices, where, incidentally, the samples were frozen rapidly.[1] Since PtPc does not fluoresce, the investigation of the distinct sites was made in the phosphorescence region (10530−10580 cm^{-1}) with the 0−0 emission bands. We have found that all ten sites that the benzene + C_8 matrix can support are also to be found in the α-ClN + C_8 matrix. On the other hand, the site splittings of ZnPc were studied with the 0−0 fluorescence bands in the spectral range 14930−14800 cm^{-1}. Again, it is found that the site splittings in both matrices were the same. α-ClN is a molecule with a permanent electric dipole moment, whereas benzene is not. Therefore the above findings clearly indicate that the electric dipole moment associated with an inter-sol molecule has no effect on the site splitting. Such an absence of dipolar interaction effects on the spectral features sheds additional light on the relationship between Pc and the inter-sol molecules and that between the inter-sol and C_8 as is discussed below.

Porphyrin (P) and other structurally related molecules also exhibit multiple sites in the Shpol'skii matrices. A theoretical study of P in a C_8 matrix (16) has elucidated the nature of the particular defects corresponding to the observed sites in this system. It was shown that the C_8 lattice was capable of supporting two or three molecule vacancy cages which do not collapse and could accommodate a P molecule in such a way that its π-orbital system was less perturbed than is usual in typical solid environments. However, this work does not completely fit our study in two different aspects. First, in our case the host was not a pure C_8 crystalline matrix but rather a matrix obtained from the mixture of an inter-sol with C_8 whose crystalline condition is not yet explored. Second, the number of distinct sites found in our case is greater than those theoretically predicted for pure C_8. As was mentioned, to incorporate the PdPc into C_8 requires the aid of an inter-sol, thus two different views concerning the close association of the inter-sol molecule and the PdPc can be hypothesized: one is that the close association

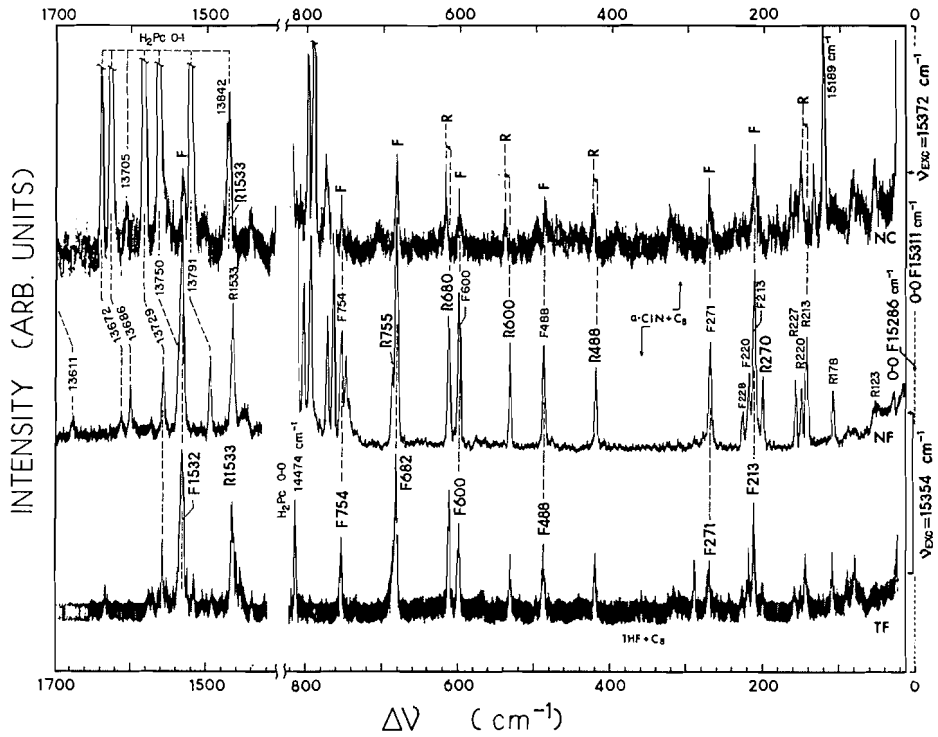

FIG. 7. Resonance Raman (R) and fluorescence (F) spectra of the C and F sites in α-ClN + C_8 (NC and NF) and the F site in THF + C_8 (TF). The excitation frequencies used were of the S_y components of the sites. The abscissa applies only to the F numbers which represent the fundamentals of the ground state of the system. The absolute positions of R and F bands can be obtained by subtracting the numbers from their excitation frequencies and 0−0 fluorescences, respectively. Bands labeled in five digit numbers are absolute and are contributions of impurities. In (NC) the 15189 cm^{-1} impurity band is related to the 10037 cm^{-1} band in Fig. 2, and R1533 is masked by the metal free 13842 cm^{-1} band and is not clearly seen.

of the inter-sol molecule and PdPc is maintained in the two component matrix, i.e., both inter-sol and Pc are found in the cage; the other is that this close association breaks down and only Pc is found in the cage. If the first view prevailed, we would anticipate no drastic reduction of the band-width when the spectra of Pc in inter-sol are compared with those in inter-sol + C_8. Furthermore, we would expect a more sensitive inter-sol dependency on the overall spectral response. Since we have found well defined spectral bands of only several cm^{-1} in width and we have demonstrated that site formation and vibronic features are hardly affected by a change of inter-sol, we are led to the second view that the "bare" PdPc is isolated in a matrix of mixed solvent. Such a mixed solvent matrix of unspecified crystalline state would provide more variety in vacancy defects into which a PdPc molecule could be accommodated than the theory described for P in a pure C matrix. Furthermore, the inter-sols in the mixed solvent matrices would have less direct influence on the π-orbital system of the PdPc than would the pure inter-sols in their own matrices. This interpretation is supported by a dynamic study in which it was found that the phosphorescence lifetime of PdPc remains the same when α-ClN in the mixed solvent matrix is replaced by α-IN (α-iodonaphthalene) (10).

IV. Conclusion

It was concluded that two component mixed solvents, such as α-ClN + C_8, THF + C_8, and benzene + C_8, form Shpol'skii matrices which have a limited number of vacancy defects in various weight distributions, comparable to the case described for pure C_8 (16, 17). As shown here in detail for PdPc and further confirmed by our analogous studies of ZnPc and PtPc,[1] any Pc molecule in a particular vacancy will interact weakly with its environmental "cage"; and depending on the cage size and relative orientation, it will have a different energy of doublet splitting. This interpretation explains why for matrices composed of C_8 plus different inter-sols of approximately the same size but of different electric dipolar nature:

we always find the same number of symmetry sites; the sizes of the doublet splitting vary; there is no discernable dipolar interaction effect on the details of the spectra; and there is no perceptible difference in the vibronic characteristics associ-

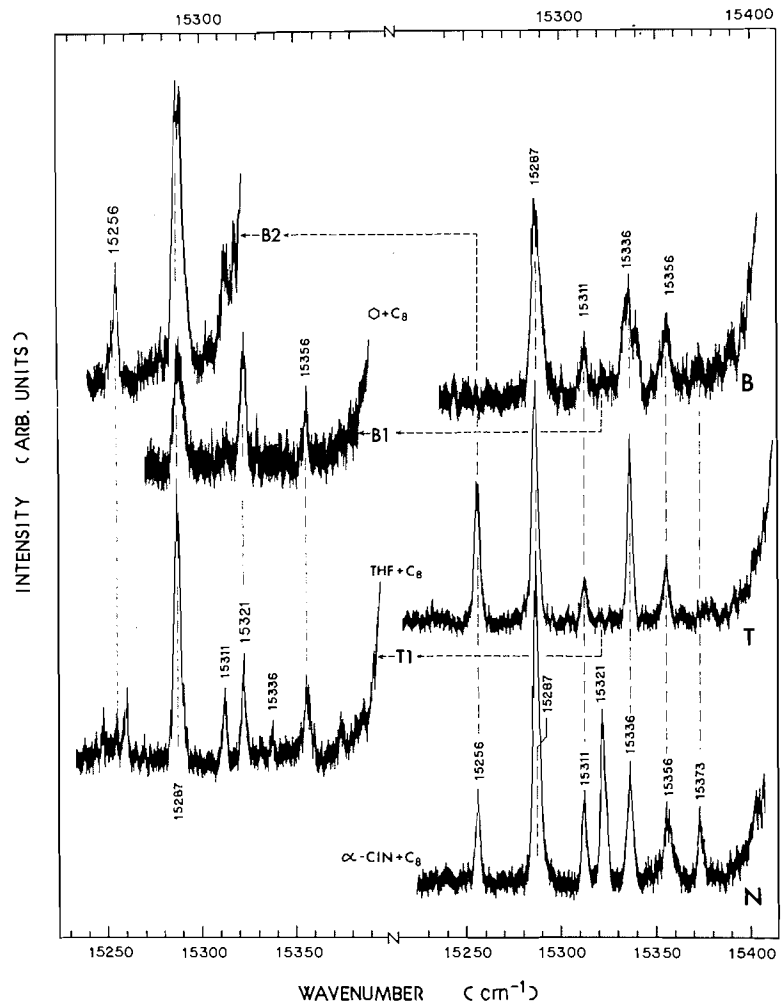

FIG. 8. 0−0 fluorescences of the multiple site PdPc in α-ClN + C_8 (N), THF + C_8 (T and T1), and benzene + C_8 (B, B1, and B2). The first three spectra on the right-hand side of the figure, (B), (N), and (T), were obtained by exciting with the same frequency of 15425 cm^{-1}. The 15321 cm^{-1} band not clearly seen in (T) and (B) is shown to reappear in (T1) and (B1) by utilizing ν_{exc} = 15408 cm^{-1}; and the 15256 cm^{-1} band, missing in (B), is shown to restore in (B2) by employing ν_{exc} = 15342 cm^{-1}.

ated with a given site among the different types of the two component matrices.

In all matrices examined there was always a unique thermodynamically most stable site which was weighted overwhelmingly in the distribution. This unique site is by its very nature an excellent representative for the study of the system and thus the analysis and interpretation of the complex vibronic features and other fundamental aspects of the multisite systems is greatly simplified.

Because the spectra detail is practically unaffected by the different inter-sol applied, one is free to select virtually any solvent that dissolves enough Pc and is also miscible with *n*-alkanes.

Gas phase chemistry of α-thio carbanions

STEEN INGEMANN AND NICO M. M. NIBBERING[1]

Laboratory of Organic Chemistry, University of Amsterdam, Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands

Received January 9, 1984

STEEN INGEMANN and NICO M. M. NIBBERING. Can. J. Chem. **62**, 2273 (1984.

Proton abstraction from CH_3SCH_3 and $C_6H_5SCH_3$ in the gas phase has been studied by the use of Fourier Transform Ion Cyclotron Resonance (FT-ICR) mass spectrometry. The gas phase acidity of CH_3SCH_3 is reported to be $\Delta G^0_{acid} = 1615 \pm 8$ kJ/mol. The methyl group in $C_6H_5SCH_3$ is observed to be the most acidic position. The gas phase acidity of this group is determined to be $\Delta G^0_{acid} = 1560 \pm 8$ kJ/mol. The structure and reactivity of the $[M - H]^-$ ions from CH_3SCH_3 and $C_6H_5SCH_3$ are probed by studying their reactions with various molecules. Rate constants are reported for the reactions of $CH_3SCH_2^-$ – and several other nucleophiles – with CH_3Cl, CH_3Br, and HCO_2CH_3.

STEEN INGEMANN et NICO M. M. NIBBERING. Can. J. Chem. **62**, 2273 (1984).

Opérant en phase gazeuse et faisant appel à la spectrométrie de masse par résonance cylotronique des ions combinée à la transformation de Fourier (RCI-TF), on a étudié l'abstraction de protons du CH_3SCH_3 et du $C_6H_5SCH_3$. L'acidité en phase gazeuse du CH_3SCH_3 est $\Delta G^0_{acide} = 1615 \pm 8$ kJ/mol. On observe que le groupe méthyle du $C_6H_5SCH_3$ est la position la plus acide. On a déterminé que l'acidité en phase gazeuse de ce groupe est $\Delta G^0_{acide} = 1560 \pm 8$ kJ/mol. On a évalué la structure et la réactivité des ions $[M - H]^-$ obtenus à partir du CH_3SCH_3 et du $C_6H_5SCH_3$ en étudiant leurs réactions avec diverses molécules. On rapporte les constantes de vitesse des réactions du $CH_3SCH_2^-$ – et de plusieurs autres nucléophiles – avec le CH_3Cl, le CH_3Br et le HCO_2CH_3.

[Traduit par le journal]

Introduction

The influence of a heteroatom on an adjacent carbanionic center has received considerable attention (1–9). The fact that the acidity of C—H bonds α to a heteroatom can be enhanced has led to the development of synthetically important organometallic compounds (1–3). The mechanism of the stabilization of the negative charge on a carbon atom adjacent to second row elements – especially sulfur – has been a matter of debate. Overlap between the carbanionic lone pair with a vacant 3*d* orbital on the sulfur atom has been used to explain the higher acidity of the α C—H bonds in sulfides compared to the α C—H bonds in ethers (1, 2). Earlier MO calculations indicated that the 3*d* orbitals on the sulfur atom had no effect on the proton affinity of α-thio carbanions (4, 5, 6*b*, 8). Recent calculations on geometry optimized ions predict, however, that the 3*d* orbitals are essential for a proper description of α-thio carbanions (10). On the basis of the PMO theory, interaction between the carbanionic lone pair and the anti bonding σ* orbital of the X—R (X = O, S) group was proposed to contribute to the stabilization of the carbanionic site (5, 7, 10). This interaction was argued to be stronger in the α-thio carbanions than in the α-oxy carbanions and to be more effective when the carbanionic lone pair is antiperiplanar to the X—R bond, thus providing a possible explanation for the preferential equatorial lithiation of 1,3-dithiane (11). Qualitatively, the lower proton affinity of α-thio carbanions compared to that of α-oxy carbanions has been ascribed to the larger polarizability of the sulfur atom compared to that of the oxygen atom (4, 6, 8).[2]

The experimentally obtained information on the properties of α-thio carbanions has been derived nearly exclusively from solution studies. Simple α-thio carbanions do not exist, however, as free ions in solution; only the corresponding organometallic compounds are known. In order to determine the stability and reactivity of simple α-thio carbanions free from solvent and counterion effects, it is necessary to generate them in the gas phase.[3] Proton removal from 1,3-dithiane and 1,3-dithiolane in the gas phase has been studied by Bartmess *et al.* (13), but no quantitative data on the gas phase acidity of these compounds could be obtained due to dominant elimination reactions and fragmentation of the formed carbanions. The present paper reports the gas phase acidity of CH_3SCH_3 and the methyl group in $C_6H_5SCH_3$. The reactivity of α-thio carbanions in the gas phase is probed by studying the reactions between $CH_3SCH_2^-$ and varius molecules. The results have been obtained by the use of Fourier Transform Ion Cyclotron Resonance (FT-ICR) mass spectrometry (14).

Experimental

All experiments were performed with a homemade Fourier Transform Ion Cyclotron Resonance (FT-ICR) mass spectrometer. The basic hardware (15), software (16), and the general operation procedure (17, 18) of the instrument have been described previously. The total pressure was normally $0{,}5-1{,}0 \times 10^{-4}$ Pa. The ratio of the partial pressures of $RSCH_3$, NH_3, and HA (conjugate acid of the anion of interest) was typically 1/0,5–1/0,5–1. The pressures were measured on an ionization gauge placed in a side arm of the main pumping line. The ionization gauge was calibrated against a MKS Baratron (type 170 M, head type 94 AH-1) placed in the same side arm using N_2 as calibrant.

General procedure

The primary reactant ions NH_2^-, OH^-, F^- and Cl^- were generated by dissociative resonance capture of electrons (electron energy in brackets) by NH_3 (5 eV), H_2O (6 eV; HO^- is formed via H^-), CF_4 (6 eV), and CCl_4 (0 eV) respectively. Dissociative resonance capture of electrons by NH_3 leads also to formation of H^- ions. The H^- ions were ejected from the cell by applying a radio frequency (rf) pulse with a frequency of 180 kHz to the trapping plates of the cell. This pulse was

[2]NOTE ADDED IN PROOF: Very recent *ab initio* calculations by P. v. R. Schleyer, T. Clark, A. J. Kos, G. W. Spitznagel, C. Rohde, D. Arad, K. N. Houk, and N. G. Rondan have shown that the stabilization of carbanions by second row substituents is due chiefly to polarization and to negative hyperconjugation, but not to *d*-orbital effects as suggested in ref. 10. We thank Professor Schleyer for communicating these results to us prior to publication.

[3]Mechanistic aspects of gas phase anion–molecule reactions are reviewed in ref. 12.

generated with the oscillator normally used for ejection of electrons (18). The pulse started simultaneously with the quench pulse (18) and ended shortly after the electron beam pulse. The other reactant ions used were generated by exothermic proton transfer to NH_2^-. The H^- ions formed from NH_3 were ejected in the cases of anions having a larger proton affinity than CH_3O^-. In the cases of anions having a lower proton affinity than no ejection of H^- was applied.

To observe the reactions of a given ion all other ions present in the cell were ejected by applying an rf pulse to the excitation plates. At the frequency corresponding to the m/z ratio of the ion of interest, the phase of this pulse was shifted 180 degrees. This causes a notch in the wave form of the ejection pulse at that frequency (16*b*). The relationship between a reactant ion and its product ion(s) was established in all cases by ejecting the reactant ion with an rf pulse starting just after the "notch ejection" pulse.

Rate and equilibrium constants

Rate and equilibrium constants were measured by monitoring the abundances of the ions present in the cell as a function of reaction time. In the kinetic experiments exponential decrease of the abundance of the reactant ion was observed in all cases. Correction for variation of the total ion current expressed as the sum of the ion abundances was achieved by normalizing this sum of ion abundances. The total ion current varied on an average less than 30% over the time interval studied. The pressures used to calculate the rate and equilibrium constants were measured with the ionization gauge. These pressures were used because oversaturation of the ionization gauge at pressures larger than 10^{-2} Pa led to a non-linear correlation with the Baratron readings in most of the cases.

Materials

The majority of the chemicals used were commercially available. The CH_3SCD_3 and $C_6H_5SCD_3$ (both about 99% d_3) compounds were prepared by reaction between RSK and CD_3I. The compounds were purified by preparative gc before use; CH_3SCD_3: OV 17, temperature 30–40°C; $C_6H_5SCD_3$: OV 17, temperature 100°C.

Results

CH_3SCH_3

Reaction of NH_2^-, $C_2H_5NH^-$, and $(CH_3)_2N^-$ with CH_3SCH_3 proceeds exclusively by proton transfer. The rate constants and reaction efficiencies are given in Table 1 (19).

The intramolecular kinetic deuterium isotope effects associated with the reaction between the amide ions and CH_3SCD_3 are given in Table 2. The values in Table 2 have been determined by monitoring the relative abundance of the $[M - H]^-$ and $[M - D]^-$ ions as a function of reaction time and then extrapolating to zero reaction time. This procedure proved necessary because hydrogen–deuterium exchange reactions between the ions and $C_2H_5NH_2$ or $(CH_3)_2NH$ caused a rather fast change in the relative abundance of the $[M - H]^-$ and $[M - D]^-$ ions with increasing reaction time (see ion structures).

In the OH^-/H_2O system equilibrium [1] is observed (see Fig. 1).

$$[1]\quad \underset{m/z\ 17}{HO^-} + CH_3SCH_3 \rightleftharpoons H_2O + \underset{m/z\ 61}{[M - H]^-}$$

The equilibrium constant for reaction [1] is determined to be $K = 0.058 \pm 0.012$. This value is the average of 7 experiments using different partial pressures of the acids. Moreover, the system has been allowed to reach equilibrium starting with either OH^- and CH_3SCH_3 or the $[M - H]^-$ ion and H_2O. Although propene has a gas phase acidity very close to that of H_2O (20), reaction [2] could not be observed.

$$[2]\quad \underset{m/z\ 41}{CH_2{=}CH{-}CH_2^-} + CH_3SCH_3 \not\rightleftharpoons CH_2{=}CH{-}CH_3 + \underset{m/z\ 61}{[M - H]^-}$$

TABLE 1. Rate constants for proton abstraction from CH_3SCH_3 by amide ions

A^-	k_{exp}[a]	k_{ADO}[b]	Efficiency[c]	ΔH_r^d (kJ/mol)
NH_2^-	2.7±0.4	2.60	1.04	−44
$C_2H_5NH^-$	0.8±0.1	1.82	0.44	−26
$(CH_3)_2N^-$	0.7±0.1	1.82	0.38	−14

[a]In units of 10^{-9} cm^3 molecule^{-1} s^{-1}. The error given is the standard deviation. Temperature assumed to be 298 K.
[b]In units of 10^{-9} cm^3 molecule^{-1} s^{-1}. Calculated using the Average Dipole Orientation Theory by Su and Bowers (19).
[c]The reaction efficiency is k_{exp}/k_{ADO}.
[d]Calculated using ΔH_f^0 data given in ref. 22 and Table 8.

TABLE 2. Intramolecular kinetic isotope effects associated with the reaction between CD_3SCH_3 and the amide ions

A^-	$PA(A^-)$ (kJ/mol)[a]	k_H/k_D[b]	No. of experiments
NH_2^-	1689	2.43±0.07	5
$C_2H_5NH^-$	1671	3.29±0.18	6
$(CH_3)_2N^-$	1658	2.92±0.03	4

[a]Values taken from ref. 20.
[b]Values obtained by extrapolation to zero reaction time and corrected for ^{13}C and ^{33}S contributions. The error given is the standard deviation. The actual error might be ~10%.

The weaker gas phase base CH_3O^- does not react with CH_3SCH_3 under the experimental conditions even though S_N2 substitution is exothermic.[4]

$$[3]\quad \underset{m/z\ 31}{CH_3O^-} + CH_3SCH_3 \not\rightarrow CH_3OCH_3 + \underset{m/z\ 47}{CH_3S^-}$$
$$\Delta H_r^0 = -53.6\ \text{kJ/mol}$$

In accord with this, no S_N2 substitution is observed in any of the other anion/CH_3SCH_3 systems studied.

The gas phase nucleophilicity of the $[M - H]^-$ ion from CH_3SCH_3 has been probed by studying its reactions with CH_3Cl, CH_3Br, and HCO_2CH_3. Rate constants for the displacement of Cl^- and Br^- from CH_3Cl and CH_3Br respectively have been measured for several nucleophiles in order to provide a basis for comparison. Furthermore these measurements have verified whether the rate constants for S_N2 substitutions previously measured with either the Ion Cyclotron Resonance (ICR) or the Flowing Afterglow (FA) method could be reproduced with our FT-ICR instrument (21, 23, 24). The data have been collected in Tables 3 and 4. The rate constants for the reaction of the $[M - H]^-$ ion from CH_3SCH_3 and the allyl anion with HCO_2CH_3 are given in Table 5.

The rate constants given in the tables have been obtained as outlined in the experimental section. The values are an average of 3–6 measurements using different partial pressures of the substrates. The error on the absolute values might be quite large (~50%), basically due to the uncertainty in the measurement of the exact pressure of the substrate. For a given substrate the relative values can be considered more accurate (~20%). The rate constants measured with our FT-ICR instrument agree

[4]Local energy barriers towards gas phase S_N2 substitutions have been discussed in ref. 21 and heat of formation data have been taken from refs. 20 and 22.

quite well with the values obtained by other experimental methods (see Tables 3 and 4).

$C_6H_5SCH_3$

$C_6H_5SCH_3$ contains several acidic sites. To determine whether the phenyl or the methyl hydrogen atoms are the more acidic, reactions of a series of anions with $C_6H_5SCD_3$ have been investigated. The competition between proton and deuteron abstraction in each system has been determined by monitoring the relative abundances of the $[M - H]^-$ and $[M - D]^-$ ions as a function of reaction time and extrapolating to zero reaction time (see Fig. 2 for an example). The results are given in Table 6. In the $CH_3O^-/C_6H_5SCH_3$ system equilibrium [4] is observed (Fig. 3).

[4] $CH_3O^- + C_6H_5SCH_3 \rightleftharpoons CH_3OH + [M - H]^-$
m/z 31 m/z 123

The equilibrium constant for reaction [4] is $K = 0.774 \pm 0.064$ as an average of 6 experiments. Different partial pressures of the acids have been used and the reaction has been studied from either side of eq. [4].

No reaction could be observed between the $[M - H]^-$ ion from $C_6H_5SCH_3$ and *p*-xylene or toluene although the latter compounds have gas phase acidities close to the value for CH_3OH (20). Similarly, no reaction between the $[M - H]^-$ ions from *p*-xylene or toluene and $C_6H_5SCH_3$ has been observed.

To gain more insight into the relative acidity of the different positions in $C_6H_5SCH_3$, hydrogen–deuterium exchange between the $[M - H]^-$ ion and D_2O has been studied (Fig. 4) (25). The corresponding results for the $C_6H_5SCD_3/OD^-/D_2O$ systems are shown in Fig. 5.

In the amide ion systems no S_N2 substitution is observed which would produce $C_6H_5S^-$ ions. In the OH^-/H_2O system a very minor amount of $C_6H_5S^-$ ions is formed after completion of proton transfer to OH^-. In the OD^-/D_2O system up to four

deuterium atoms are incorporated in the thiophenolate ions. These observations are analogous to those previously reported for reactions of anions with 2-, 3-, 4-fluoranisole, and anisole itself (26). The mechanistic interpretation is given in eq. [5].

[5] $C_6H_5SCH_3 + HO^- \underset{}{\overset{}{\rightleftharpoons}} [M - H]^- + H_2O$
m/z 17 *m/z* 123

$\rightarrow C_6H_5S^- + CH_3OH$
m/z 109

S_N2 substitution becomes significant in the CH_3O^-/CH_3OH system at longer reaction times (>1000 ms). This does not interfere, however, with the determination of the equilibrium constant for reaction [4] (see Fig. 3).

Discussion

Ion structures

In order to ascertain that the $[M - H]^-$ ion from CH_3SCH_3 has the structure of a primary carbanion, reactions of this ion with N_2O, CF_2O, and C_6F_6 have been studied. The product ions observed are listed in Table 7. All the observed reactions point to the primary carbanion structure **1**:

$CH_3SCH_2^-$ **1**

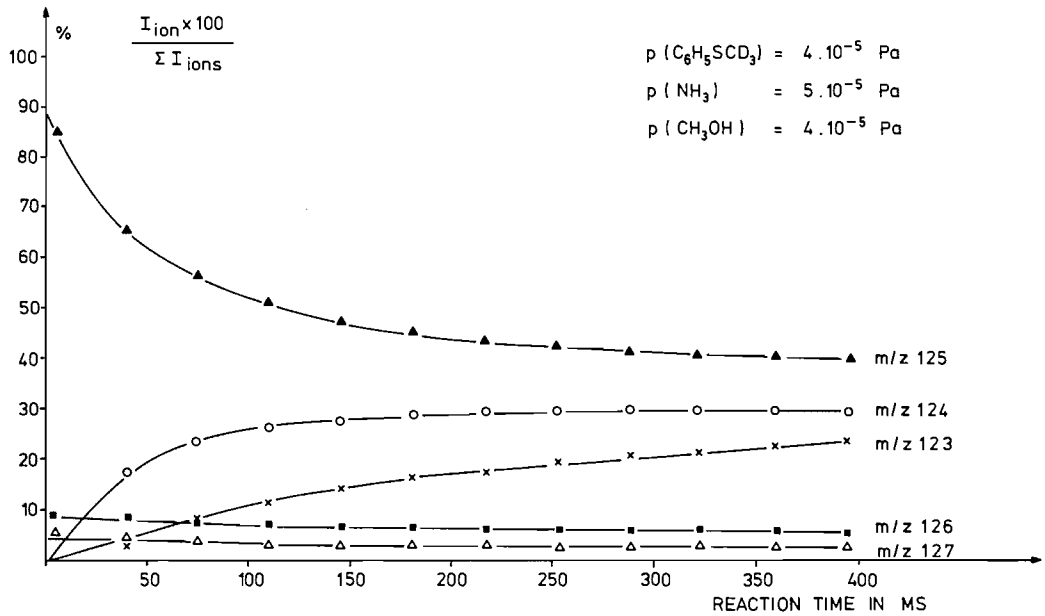

FIG. 2. Variation of the relative intensities of the m/z 123–127 ions formed in the $CH_3O^-/CH_3OH/C_6H_5SCD_3$ system with reaction time. The m/z 125 ion is the $[M - D]^-$ ion from $C_6H_5SCD_3$. The m/z 126 and 127 ions are the $^{13}C/^{33}S$ and ^{34}S isotopic species of the $[M - D]^-$ ions, respectively. The m/z 124 and 123 ions are formed by hydrogen–deuterium exchange reactions between the $[M - D]^-$ ions and CH_3OH.

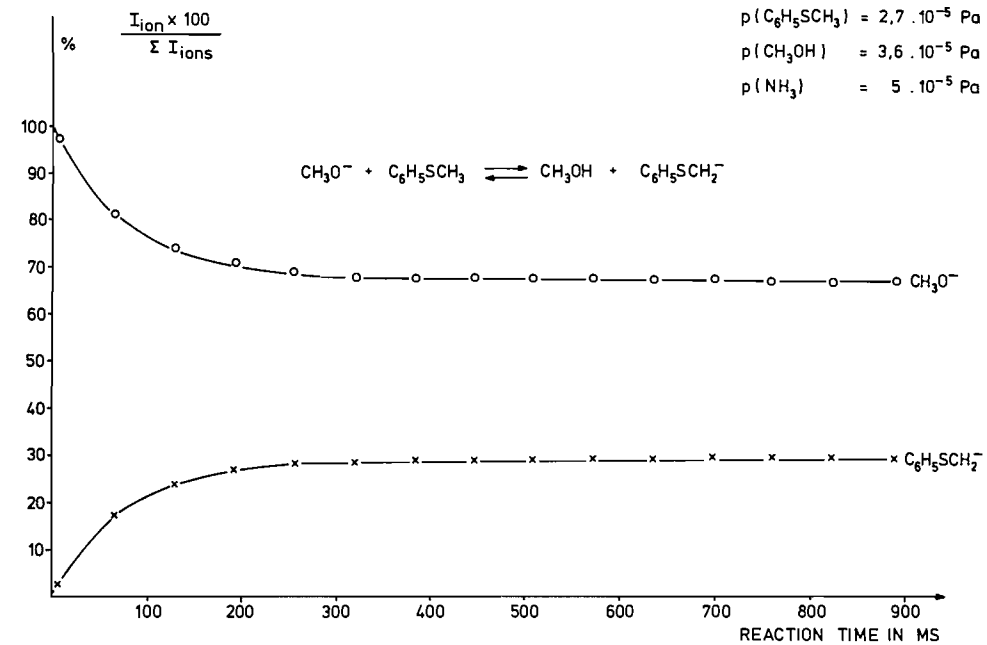

FIG. 3. Relative intensities of the CH_3O^- and $C_6H_5SCH_2^-$ ions in the $CH_3O^-/CH_3OH/C_6H_5SCH_3$ system followed as a function of reaction time.

The mechanisms of the reactions with N_2O and CF_2O have been reported previously in detail (27, 28). The reaction with C_6F_6 is rationalized in eq. [6].

$$[6]\quad \underset{m/z\ 61}{CH_3SCH_2^-} + C_6F_6 \xrightarrow{S_NAr} [C_6F_5CH_2SCH_3 \cdot F^-]^* \xrightarrow{-HF} [C_6F_5CHSCH_3]^* \rightarrow \underset{m/z\ 212}{C_6F_5CHS^{-\cdot}} + {}^{\cdot}CH_3$$

This reaction type has been discussed in previous articles (see refs. 18, 26, 29) and provides in general for a good probe as to the structure and reactivity of anions in the gas phase.

The $[M - H]^-$ and $[M - D]^-$ ions from CD_3SCH_3 react with CF_2O as shown in eqs. [7] and [8].[5]

$$[7]\quad \underset{m/z\ 64}{CD_3SCH_2^-} + CF_2O \rightarrow \underset{m/z\ 90}{CD_3S\bar{C}{=}C{=}O} + 2HF$$

$$[8]\quad \underset{m/z\ 63}{CH_3SCD_2^-} + CF_2O \rightarrow \underset{m/z\ 87}{CH_3S\bar{C}{=}C{=}O} + 2DF$$

[5]The ion formed by loss of 2 HF molecules from the collision complex reacts further with CF_2O. For example, the CD_3—S—$\bar{C}$=C=O ions react to give $C_3FO_2^-$ (m/z 87) and $C_3F_2SO_2^{-\cdot}$ (m/z 138) ions.

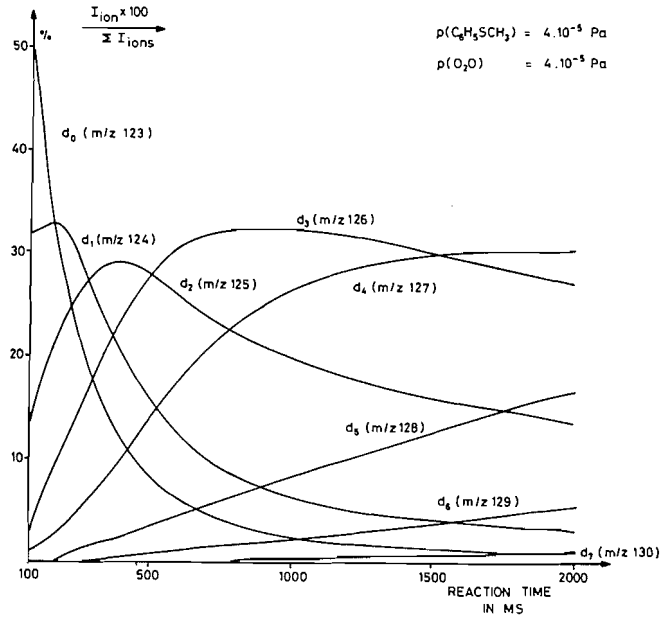

FIG. 4. The hydrogen–deuterium exchange reaction between the conjugate base of $C_6H_5SCH_3$ and D_2O followed as a function of reaction time. The time was increased linearly from 100 to 2000 ms in 24 steps. The relative intensities have not been corrected for isotopic contributions.

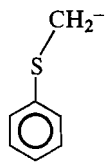
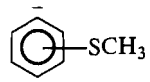
The clean occurrence of reactions [7] and [8] indicates that no 1,3-proton or deuteron shifts take place within the carbanion.

[9] $CH_3SCD_2^- \not\rightarrow {}^-CH_2SCD_2H$

The structure of the $[M - H]^-$ ion from CH_3SCH_3 has been probed further by studying hydrogen–deuterium exchange reactions between the ion and an exchange reagent (25). Under the experimental conditions no exchange could be observed if ND_3 was used as exchange reagent. In a system composed of $ND_3/(CH_3)_2NH/CH_3SCH_3$, however, exchange could be observed. In that case the exchange reagent is $(CH_3)_2ND$, which is prepared *in situ* from reaction between ND_3 and $(CH_3)_2NH$. Up to four hydrogen atoms in the $[M - H]^-$ ion could be exchanged with deuterium atoms in this system, supporting the conclusion that proton abstraction from CH_3SCH_3 leads to a primary carbanion. In the case of $C_6H_5SCH_3$, proton abstraction can lead in principle to a primary carbanion (ion **2**) and (or) a substituted phenide in (ion **3**) where the charge can be in the *ortho*, *meta*, or *para* position with respect to the CH_3S— group.



Ion **2**



Ion **3**

The results from reactions between the $[M - H]^-$ ion from $C_6H_5SCH_3$ (generated by hydroxide ions, see also Table 6) and N_2O, CF_2O, and HCO_2CH_3 are collected in Table 7. The reaction with CF_2O points to ion **2**[6] whereas the reactions with HCO_2CH_3 can be explained on the basis of both ions **2** and **3**. These results and the results from the hydrogen–deuterium exchange reactions (see Figs. 4 and 5) indicate that isomerization of the $[M - H]^-$ ion from $C_6H_5SCH_3$ to other structures than **2** or **3** is not occurring. The possibility exists, however, that ion **3** rearranges via an intramolecular proton shift to ion **2** when the negative charge is located in the *ortho* position. Such a rearrangement has been verified for carbanions derived from 2-, 3-, 4-fluoroanisole and anisole (26). For the $[M - H]^-$ ion from $C_6H_5SCH_3$ we have been unable to clarify whether such intramolecular proton shifts take place. An isomerization of ion **3** to the more stable ion **2** (see Acidities) can occur, of course, via reaction with molecules such as NH_3 or H_2O.

Acidities

Proton abstraction from CH_3SCH_3 by NH_2^- occurs with the collision rate (Table 1). The $C_2H_5NH^-$ and $(CH_3)_2N^-$ ions, which have lower proton affinities, abstract a proton from CH_3SCH_3 with lower efficiency. The intramolecular primary kinetic isotope effect associated with this process is observed to change when the proton affinity of the amide ions is changed (Table 2). The maximum in isotope effect observed for the $C_2H_5NH^-$ ion could mean that the transition state is more symmetric in this case than in the other two. The occurrence of these isotope effects indicates that there is a significant local energy barrier towards proton removal from CH_3SCH_3.[7] This is also reflected in the fact that reaction [10] is not observed to occur to any appreciable extent.

[10] $\underset{m/z\ 63}{CH_3SCD_2^-} + CH_3SCD_3 \not\rightarrow \underset{m/z\ 64}{CH_3SCD_2H} + CD_3SCH_2^-$

The thermochemical gas phase acidity ΔG^0_{acid} of CH_3SCH_3 can be obtained from eqs. [11] and [12] using the measured equilibrium constant for reaction [1].

[11] $\delta\Delta G^0_{acid} = -RT \ln K$

[12] $\delta\Delta G^0_{acid} = \Delta G^0_{acid}(CH_3SCH_3) - \Delta G^0_{acid}(H_2O)$

The temperature T in our system is not known, but is simply assumed to be 298 K. This gives $\delta\Delta G^0_{acid} = 7.1 \pm 0.5$ kJ/mol and $\Delta G^0_{acid}(CH_3SCH_3) = 1615 \pm 8$ kJ/mol with the use of $\Delta G^0_{acid}(H_2O) = 1608 \pm 4$ kJ/mol.[8] The error in the obtained gas phase acidity of CH_3SCH_3 might be somewhat larger due to the uncertainties in the measurement of the pressures and the temperature not being known accurately. The $\Delta H^0_{acid}(CH_3SCH_3) = PA(CH_3SCH_2^-)$ given in Table 8 has been obtained with the use of an estimated $\Delta S^0_{acid}(CH_3SCH_3)$ values.[9] No $[M - H]^-$ ion from CH_3OCH_3 has been observed, indicating that the ΔG^0_{acid} and the ΔH^0_{acid} of this compound is above those for NH_3 ($\Delta G^0_{acid} = 1657$ kJ/mol; $\Delta H^0_{acid} = 1689$ kJ/mol) (20). This indicates that substitution of the oxygen atom in CH_3OCH_3 by a sulfur atom increases the gas phase acidity of the methyl group by more than 42 kJ/mol. The decrease in proton affinity when going from $CH_3OCH_2^-$ to $CH_3SCH_2^-$ can be expected to be more than 44 kJ/mol with the use of the value for the $PA(CH_3SCH_2^-)$ given in Table 8. This can be compared with the result from *ab initio* calculations which indicate a

[6]The C_6H_5—S—$\bar{C}$=C=O ions added slowly to CF_2O leading to $C_9H_5F_2SO_2^-$ (m/z 215) ions.

decrease in proton affinity of ~33 kJ/mol (8). Relative to CH_3^- (PA = 1743 kJ/mol) (20), the CH_3S— group decreases the proton affinity by around 98 kJ/mol. This is comparable to the proton affinity decrease observed when going from CH_3^- to $CH_2{=}CH{-}CH_2^-$ (20).

The present experiments do not reveal anything directly about the mechanism(s) of the stabilization of the negative charge in the $CH_3SCH_2^-$ ion. The acidity order of CH_3OCH_3 and CH_3SCH_3 is observed, however, to follow the polarizability order of the heteroatoms. It can further be mentioned here that experiments carried out in our laboratory indicate that the acidity increases continuously down the series CH_3F, CH_3Cl, CH_3Br, CH_3I.[10]

Based upon the results in Table 6 it can be concluded that the most acidic position in $C_6H_5SCH_3$ is the methyl group and that only this position is involved in equilibrium [4]. The measured equilibrium gives $\delta\Delta G^0_{acid} = 0.6 \pm 0.2$ kJ/mol. With ΔG^0_{acid} (CH_3OH) = 1559 ± 8 kJ/mol,[11] the gas phase acidity of

[10]S. Ingemann and N. M. M. Nibbering, in preparation (see also ref. 23).

[11]This value is the one obtained using the ICR method (ref. 20). It should be noted that a value for ΔG^0_{acid} (CH_3OH) = 1667 ± 8 kJ/mol has been recommended in ref. 33.

TABLE 8. Estimated thermochemical data for CH_3SCH_3 and $C_6H_5SCH_3$

Compound	ΔG^0_{acid} [a] (kJ/mol)	ΔS^0_{acid} [b] (J/mol K)	ΔH^0_{acid} = PA($RSCH_2^-$) [c] (kJ/mol)	ΔH^0_f ($RSCH_2^-$) [c] (kJ/mol)
CH_3SCH_3	1615±8 [d]	101±8	1645±8	71±8
$C_6H_5SCH_3$	1560±8 [e]	103±8	1591±8	153±8

[a] Temperature assumed to be 298 K, see text.
[b] Estimated using the general approach in ref. 32.
[c] Appropriate ΔH^0_f data from ref. 22.
[d] Measured relative to H_2O (ΔG^0_{acid} = 1608 ± 4 kJ/mol) (see text and ref. 20).
[e] Measured relative to CH_3OH (ΔG^0_{acid} = 1559 ± 8 kJ/mol) (see text and ref. 20).

the methyl group becomes ΔG^0_{acid} ($C_6H_5SCH_3$) = 1560 ± 8 kJ/mol. The estimated PA($C_6H_5SCH_2^-$) and the ΔH^0_f ($C_6H_5SCH_2^-$) are given in Table 8.

The failure to observe proton abstraction from $C_6H_5CH_3$ (ΔG^0_{acid} = 1558 kJ/mol) (20) or *p*-$CH_3C_6H_4CH_3$ (ΔG^0_{acid} = 1562 kJ/mol) (20) by the $C_6H_5SCH_2^-$ ion indicates a kinetic barrier which apparently renders the reaction too slow to be observed. The fact that the $[M - H]^-$ ions from $C_6H_5CH_3$ or *p*-$CH_3C_6H_4CH_3$ do not react with $C_6H_5SCH_3$ even though proton transfer is thermochemically feasible can be accounted for similarly. Substitution of a methyl group in CH_3SCH_3 by a phenyl group can be seen to enhance the acidity by ~55 kJ/mol. This effect is somewhat larger than the one observed when going from CH_3OH to $C_6H_5CH_2OH$ where the acidity increases by ~40 kJ/mol (20). Relative to CH_3^- the $C_6H_5S^-$ group decreases the proton affinity with ~152 kJ/mol (see ref. 20 and Table 8). This effect is close to the decrease in proton affinity when going from CH_3^- to $C_6H_5CH_2^-$.

The relative order of the acidity of the different positions within $C_6H_5SCH_3$ is probed by the hydrogen–deuterium exchange reactions. In Fig. 4 it can be seen that the first four hydrogen atoms are exchanged somewhat faster than the rest. At the time (~750 ms) where the fifth exchange is rather unimportant there are only 2 deuterium atoms incorporated in the thiophenolate ions arising through the minor reaction [5]. In the $C_6H_5SCD_3/OH^-/H_2O$ system the hydrogen–deuterium exchange is relatively fast and in the $C_6H_5SCD_3/OD^-/D_2O$ system (see Figs. 4 and 5) 2 hydrogen atoms are relatively easily exchanged whereas the rest exchange more slowly. Combination of these results indicates that the methyl and the *ortho* hydrogen atoms are exchanged faster than the *meta* and *para* hydrogen atoms within the conjugate base of $C_6H_5SCH_3$ in the OD^-/D_2O system (see Ion structures). This can be interpreted as the relative gas phase acidity being methyl > *ortho* > *meta*, *para* (see also Table 6). It can here be mentioned that lithiation of $C_6H_5SCH_3$ initially yields a mixture of $C_6H_5SCH_2Li$ and 2- or 3-$LiC_6H_4SCH_3$ which after a prolonged reaction time converts nearly exclusively into $C_6H_5SCH_2Li$ (34).

Reactivity

The variation in reaction efficiencies for the S_N2 substitutions studied is observed to be somewhat larger for CH_3Cl than for CH_3Br (see Tables 3 and 4). The data for CH_3Cl provide, therefore, a better basis for comparison although the overall trend is the same for both substrates.

The reaction rates and efficiencies for displacement of Cl^- from CH_3Cl are observed to be similar for $CH_3SCH_2^-$ and $CH_2{=}CH{-}CH_2^-$. The exothermicity of these S_N2 substitutions is also similar. There is, however, in general no correlation between exothermicity and reaction efficiency for gas phase S_N2 substitutions (see also Tables 3 and 4) (21, 23). The similar reaction efficiency therefore points to a similar local energy barrier towards the displacement of Cl^- from CH_3Cl by $CH_3SCH_2^-$ and $CH_2{=}CH{-}CH_2^-$.

Compared to the other carbon nucleophile studied, i.e. $HC{\equiv}C^-$, the $CH_3SCH_2^-$ ion is 5 times as effective in displacing Cl^- from CH_3Cl. The oxygen nucleophile $C_2H_5O^-$ reacts with a higher efficiency, whereas the $C_2H_5S^-$ ion reacts with an efficiency 12 times lower than the isomeric $CH_3SCH_2^-$ ion. The data in Tabe 5 show that the $CH_3SCH_2^-$ ion reacts with HCO_2CH_3 with an efficiency similar to that of the $CH_2{=}CH{-}CH_2^-$ ion. The reaction proceeds, in both cases, most likely exclusively through the $B_{AC}2$ pathway:

$$[13]\quad RCH_2^- + HCO_2CH_3 \xrightarrow{B_{AC}2} [RCH_2CHO\cdot CH_3O^-]^* \begin{cases} \rightarrow CH_3O^- + RCH_2CHO \\ \rightarrow RCH{=}CHO^- + CH_3OH \end{cases}$$

R = $CH_2{=}CH$, CH_3S

The larger amount of CH_3O^- ions produced in the reaction of $CH_3SCH_2^-$ can be explained if it is assumed that the methylene hydrogen atoms in the RCH_2CHO molecule formed are somewhat less acidic for R = CH_3S— than for R = $CH_2{=}CH$—.

Conclusions

Proton abstraction from CH_3SCH_3 in the gas phase leads to a primary carbanion. The gas phase acidity of CH_3SCH_3 is determined to be ΔG^0_{acid} = 1615 ± 8 kJ/mol. The CH_3S— group stabilizes the carbanionic site by ~43 kJ/mol relative to a CH_3O— group.

The most acidic position within $C_6H_5SCH_3$ is the methyl group. The gas phase acidity of this position is found to be ΔG^0_{acid} = 1560 ± 8 kJ/mol. On the basis of this observation and the results from hydrogen–deuterium exchange reactions between the $[M - H]^-$ ion from $C_6H_5SCH_3$ and D_2O, the relative acidity of the different positions is established to be *methyl* > *ortho* > *meta*, *para*.

The reactivity of $CH_3SCH_2^-$ and $CH_2{=}CHCH_2^-$ ions in gas phase reactions with CH_3Cl, CH_3Br, and HCO_2CH_3 is observed to be similar.

Received October 21, 1983

JAMES L. DOUGLAS, ALAIN MARTEL, GILLES CARON, MARCEL MÉNARD, LINDA SILVEIRA, and JON CLARDY. Can. J. Chem. **62**, 2282 (1984).

Penems **5** were converted to exocyclic analogs **6** and **10**. These served as substrates for conversion to the sulfone **11** and oxopenam **12**. None of the products showed any activity as antibiotics or as β-lactamase inhibitors. A single cyrstal X-ray diffraction analysis of compound **6***a* verified the exocyclic penem structure.

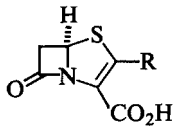
JAMES L. DOUGLAS, ALAIN MARTEL, GILLES CARON, MARCEL MÉNARD, LINDA SILVEIRA et JON CLARDY. Can. J. Chem. **62**, 2282 (1984).

On a transformé des pénèmes **5** en analogues exocycliques **6** et **10** qui servent de substrats pour leur conversion en sulfone **11** et oxopéname **12**. Aucun de ces produits ne présente d'activité comme antibiotique ou comme inhibiteur de β-lactamase. Faisant appel à une analyse par diffraction de rayons-X sur un cristal unique, on a vérifié la structure pénème exocyclique du composé **6***a*.

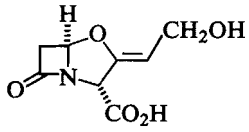
[Traduit par le journal]

Introduction

The synthesis of simple penem structures **1** (R = H, Me) by Woodward and co-workers (1) and the modification by various groups (2–4) of their synthetic methodology to give generalized 2-substituted[2] penems **1** have made such compounds readily available as substrates for conversion to other novel β-lactams. Furthermore, the observation of β-lactamase inhibitory properties for clavulanic acid (5) provides incentive for generating structures such as **2** in which the 5-membered ring has an exocyclic double bond. One can then envisage ozonolysis of the double bond to oxopenam **3** which could be used as a substrate for further transformation.

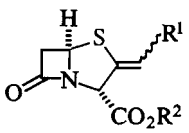


1

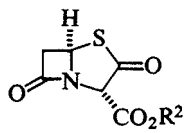


Clavulanic acid

As part of our ongoing program aimed at the discovery of β-lactam antibiotics (and (or) β-lactamase inhibitors) we set out to synthesize compounds of types **2** and **3** (and readily available) derivatives thereof).



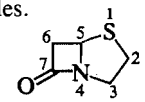
2



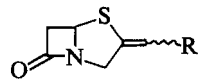
3

[1]For Part XIX, see ref. 16.

[2]The common penem numbers system as follows will be used, except in the Experimental titles.



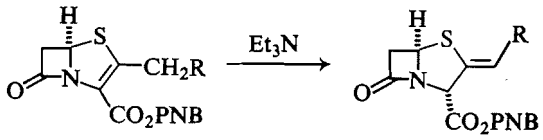
Since the inception of our work in this area, several research groups have published findings on the same or related compounds. A group at Sankyo has described the synthesis of oxopenam **3** (R^2 = H) and substituted derivatives from cephalosporins (6). Penicillin G has been converted to a 6-amido-oxopenam (7). The Glaxo research group has converted clavulanic acid into the exocyclic penem *Z*-**2** (R^1 = CH_2SAc, R^2 = H) but report it to have reduced antibacterial and β-lactamase inhibitory activity (3). Workers at Farmitalia have used a variation on the Woodward route (1) to prepare exocyclic penem **2** (R^1 = CO_2Et, R^2 = benzyl) (4). Beecham (8) and Pfizer (9) research groups have both prepared exocyclic penems **4** (lacking the important 3-carboxyl substituent) and report them to be devoid of antibacterial or β-lactamase inhibitory activity.



4

Results and discussion

The Beecham group have described the base catalyzed isomerization of the endocyclic double bond of oxapenems to the exocyclic (clavulanic acid type) position (10). Using their reaction conditions (organic base in an organic solvent) we have converted the 2-arylmethylpenems **5** (2) into the exocyclic penems **6**. In the case of R = phenyl, an equilibrium mixture of 80% **6** and 20% **5** was formed; for R = furyl or thienyl,



5 **6**

a R = phenyl *b* R = 2-furyl *c* R = 2-thienyl

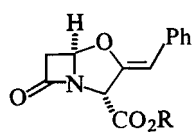
[a]Spectra were recorded at 60 MHz and are reported in ppm downfield from TMS. All esters were in $CDCl_3$; free acids in acetone-d_6 except **10***c* in DMSO-d_6 and salt **10***d* in D_2O. Coupling constants are in Hz. All PNB esters showed doublets at δ 8.15–8.27 and 7.47–7.58 (J = 8.5) and a singlet at 5.29–5.37.
[b]Reference 4.

virtually complete conversion to the exocyclic form occurred. Minor changes in the *exo*/*endo* ratio (when R = Ph) were made by varying the reaction solvent. That the reaction only occurs when R contains a function that can conjugate with the exocyclic double bond is shown by the example of **5** (R = CH_2CO_2PNB): no isomerization was observed after prolonged treatment with base. The relative stereochemistry[3] shown for **6** (3 and 5 positions) follows from analogy to that found for **2** (R^1 = CO_2Et, R^2 = benzyl) by the Farmitalia group (4) since nmr spectra of the vinyl, H-3, and H-5 protons show a very close match between **2** and **6** both in chemical shift and coupling constants (see Table 1). The Beecham group have evidence that their isomerization product **7** (R = Me) is the *Z* isomer shown; the vinyl proton has a chemical shift of 5.57 ppm (10). If one adds a shift value of 0.6 to 0.7 ppm for going from an oxygen ring to sulfur ring (11), then one would predict a vinyl proton shift of 6.2 to 6.3 ppm for the *Z* isomer **6***a*. In fact, a vinyl proton shift of 6.70 ppm was observed (see Table 1), thus supporting the *E* assignment. However, these minor differences in chemical shift values do not provide very compelling evidence without having both isomers on hand. Molecular models of structure **6** show marked steric crowding between the aromatic ring in the *E* isomer and the ester at the 3-position, whereas the *Z* isomer shows no steric congestion. Thus, while ^1H nmr arguments favor the *E* geometry for compounds **6**, steric arguments favor the *Z* geometry.

A single crystal X-ray diffraction analysis of **6***a* conclusively verified the nmr based stereochemical assignments for the 3,5-relationship, while the double bond was shown to have the *Z* geometry. The phenyl ring, at least in the solid state conformation, is twisted slightly out of the plane of the double bond (~11°) presumably to relieve steric congestion. The molecular parameters[4] were unsurprising for a penem and the bridgehead nitrogen was 0.43 Å out of the plane of its nearest



7

[3]All compounds described are racemates; for convenience, just one enantiomer is shown.

[4]Fractional coordinates and thermal parameters, bond distances, bond angles, and observed and calculated structure factors for structure **6***a* are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

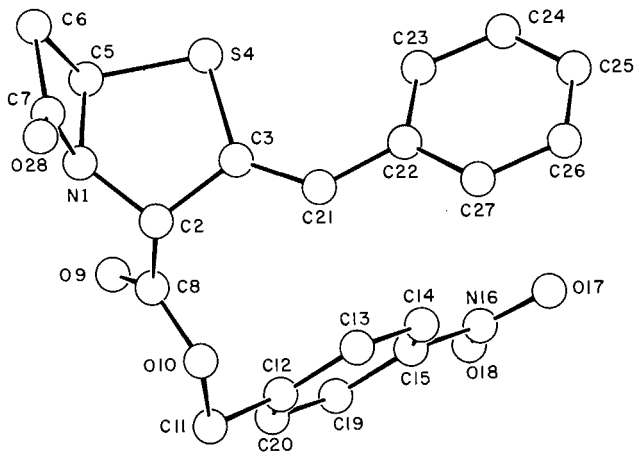

FIG. 1. A computer generated perspective drawing of the final X-ray model of **6***a*. Hydrogens are omitted.

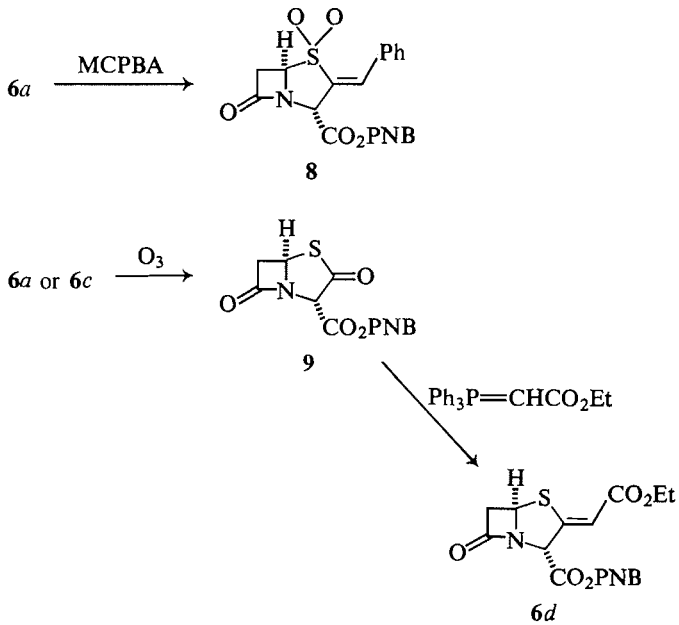
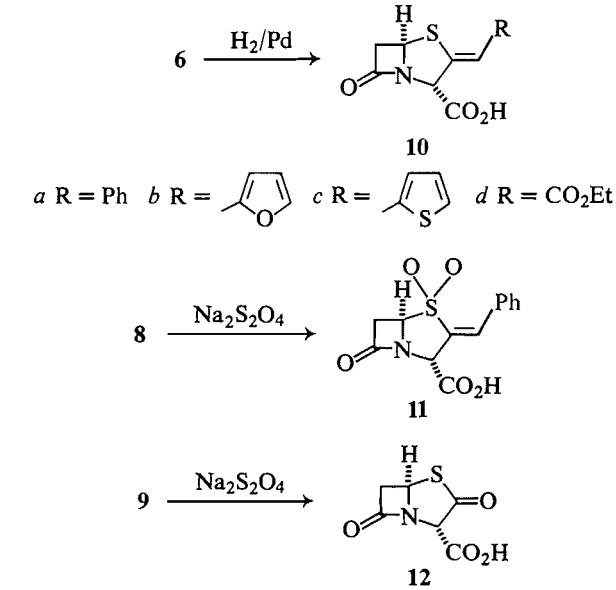


SCHEME 1

neighbors. A drawing of the final X-ray model is given in Fig. 1.

The sulfone **8** was prepared by the action of *m*-chloroperbenzoic acid on penem **6***a* (analogous to sulfone formation in the isocephems (12)) (see Scheme 1). The infrared spectrum of **8** shows strong peaks at 1320 and 1135 cm^{-1} (which do not appear in the spectrum of **6***a*), indicating the formation of the sulfone rather than the sulfoxide (ν(S=O) for sulfoxide: 1035–1070 cm^{-1}). Ozonolysis of the exocyclic double bond of **6***a* or **6***c* gave oxopenam **9**. Numerous attempts were made to carry out reactions between oxopenam **9** and Wittig reagents. All failed except for (carboxymethylene)triphenylphosphorane. This reagent gave penem **6***d* in low yield. Infrared and ^1H nmr spectra of **6***d* closely matched those reported for **2** (R^1 = CO_2Et, R^2 = benzyl) (4) (allowing for the difference between the *p*-nitrobenzyl and benzyl esters). The double bond geometry in **6***d* is uncertain but is probably *Z* in analogy with compound **6***a*.

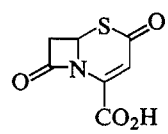
Deprotection of the esters **6** proceeded by the usual hydrogenolysis conditions (although in low yield for some) to give



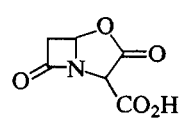
SCHEME 2

acids **10** (see Scheme 2). However, compounds **8** and **9** could not be hydrogenolyzed to their free acids due to the instability of the latter under these reaction conditions. Use of sodium dithionite (13) did give the acids **11** and **12** in good yield. The ^1H nmr spectrum of **12** was the same (allowing for the different solvents used) as the spectrum for **12** reported by the Sankyo group (6).

All of the free acids were insufficiently stable to be purified enough to give an acceptable elemental analysis (see, for example, compound **10***c* in the Experimental). However, it was felt that their level of purity (as determined by ^1H nmr) was such that microbiological evaluation would provide reliable qualitative data. In fact, none of the compounds showed any microbiological activity, either as antibacterials or as β-lactamase inhibitors. Because of concerns over stability affecting microbiological results, the chemical integrity of oxopenam **12** was determined under conditions of the β-lactamase inhibition tests: a solution of compound **12** in pH 7 buffer maintained at room temperature for 45 min showed continued presence of intact **12** (although some decomposition did occur). The lack of activity cannot be ascribed to chemical decomposition. Since oxopenem **7** (R = Na) is described as a potent β-lactamase inhibitor (10), the lack of activity in the sulfur analogs **10** must be ascribed to the replacement of oxygen by sulfur. It is interesting to note that the close analog of **12**, cephem **13**, is described as being "only marginally active against Staphylococcus aureus" (14) while the oxopenam **14** is claimed in a patent (15) as a β-lactamase inhibitor.



13



14

Experimental

Conversion of penems 5 to exocyclic penems 6

A solution of compound **5** (*a*, *b*, or *c*, 1.0 mmol), triethylamine (100 mg, 1.0 mmol), and tetrahydrofuran (4 mL) was stirred at 23°C for 15 min. The solution was concentrated *in vacuo* (40°C), the residue

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

was redissolved in dichloromethane (20 mL), and the solution was washed with 0.1 *M* hydrochloric acid, then water (10 mL each). The organic layer was dried and the solvent was evaporated *in vacuo* to give **6***a*, *b*, or *c*.

4-Nitrobenzyl 3-benzylidene-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate **6**a

With penem **5***a* (R = Ph) the reaction product consisted of an 80:20 mixture of **6***a* and **5***a* (as determined by ^{1}H nmr). Purification was achieved by column chromatography on silica gel: elution with ether/hexane, then with ether. The appropriate fractions were concentrated *in vacuo* to give compound **6***a* (ca. 95% pure), 65% yield; mp 110−113°C; ir (amorphous film) *ν*: 1785, 1745 cm^{-1}. A portion was recrystallized several times from benzene, the last time by very slow evaporation of solvent to give crystals suitable for X-ray diffraction analysis (see below).

4-Nitrobenzyl 3-(2-furylidene)-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate **6**b

With R = 2-furyl the reaction product consisted of almost pure **6***b* (97% yield); ir (amorphous film) *ν*: 1785, 1750 cm^{-1}.

4-Nitrobenzyl 3-(2-thienylidene)-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate **6**c

With R = 2-thienyl the reaction product consisted of pure **6***c* (99% yield); mp 103−104°C; ir ($CHCl_3$) *ν*: 1790, 1750 cm^{-1}; uv (EtOH) λ_{max}: 267 (ϵ = 15 700), 304 (ϵ = 18 300) nm. *Anal.* calcd. for $C_{18}H_{14}N_2O_5S_2$: C 53.72, H 3.51, N 6.96, S 15.93; found: C 53.77, N 3.50, N 6.90, S 16.15.

4-Nitrobenzyl 3-benzylidene-4,4,7-trioxo-4-thia-1-azabicyclo-[3.2.0]heptane-2-carboxylate **8**

A solution of compund **6***a* (198 mg, 0.50 mmol), *m*-chloroperbenzoic acid (220 mg, containing ca. 1.1 mmol), and dichloromethane (20 mL) was stirred at 23°C for 17 h. The solution was washed with 1% sodium bicarbonate (2 × 20 mL), dried, and concentrated *in vacuo*. The product was purified by chromatography on silica gel: elution with ether. Evaporation of solvent from the appropriate fractions gave the sulfone **8** as an oil; 95 mg (44% yield), in about 90% purity; ir (film) *ν*: 1800, 1750, 1320, 1135 cm^{-1}.

Ozonolysis of **6**a *and* **6**c

4-Nitrobenzyl 3,7-dioxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate **9**

A solution of compound **6***a* (396 mg, 1.0 mmol) or compound **6***c* (402 mg, 1.0 mmol) in ethyl acetate (20 mL) was ozonized at −78°C until a blue color persisted. The excess ozone was purged with oxygen and the solution was allowed to warm gradually to 23°C. The solution was washed with dilute aqueous sodium bicarbonate, then saturated sodium chloride, dried, and the solvent was evaporated *in vacuo* to give a yellow gum, 340 mg. The product was purified by column chromatography on silica gel: elution with hexane/ether 9:1 followed by ether. Evaporation of solvent from the appropriate fractions gave oxopenam **9**, 230 mg (70% yield), in greater than 90% purity. Recrystallization from benzene gave **9**; mp 114−117°C; ir (solid film) *ν*: 1790, 1750, 1710 cm^{-1}. *Anal.* calcd. for $C_{13}H_{10}N_2O_6S$: C 48.45, H 3.13, N 8.69, S 9.95; found: C 48.37, H 3.23, N 8.78, S 9.91.

4-Nitrobenzyl 3-carbethoxymethylene-7-oxo-4-thia-1-azabicyclo-[3.2.0]heptane-2-carboxylate **6**d

A solution of oxopenam **9** (97 mg, 0.30 mmol) and (carbethoxymethylene)triphenylphosphorane (111 mg, 0.32 mmol) in benzene (10 mL) was heated under reflux for 2 h. The solvent was evaporated *in vacuo* and the residue was purified by chromatography on silica gel (elution with ether) to give compound **6***d* as an oil, 30 mg (23% yield); ir ($CHCl_3$) *ν*: 1785, 1755, 1700 cm^{-1}.

Hydrogenolysis of p-*nitrobenzyl esters*

Compounds **6** were hydrogenated on a Parr apparatus (details for each compound below) at 30 to 50 psi (1 psi = 6.89 kPa) and 23°C. The catalyst was removed by filtration and the phases were separated. In the case of **6***a* and **6***b*, the aqueous phase was acidified with dilute hydrochloric acid and extracted with ethyl acetate. The organic extract was washed with saturated sodium chloride, dried, and the solvent was evaporated *in vacuo* to give the title compounds. In the case of **6***c* and **6***d*, work-up was as given below.

3-Benzylidene-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylic acid **10**a

Hydrogenolysis mixture: compound **6***a* (198 mg, 0.50 mmol), sodium bicarbonate (42 mg, 0.5 mmol), palladium on Celite (30%, 200 mg), tetrahydrofuran (30 mL), ether (30 mL), and water (30 mL) for 6 h. The product was obtained in 98% yield and recrystallized from ethyl acetate to give acid **10***a*; mp 153−154°C; ir (Nujol mull) *ν*: 1775, 1760, 1730 cm^{-1}; uv (EtOH) λ_{max}: 286 (ϵ = 18 100) nm.

3-(2-Furylidene)-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylic acid **10**b

Hydrogenolysis mixture as for preparation of **10***a* except: compound **6***b* (193 mg, 0.50 mmol). The product was obtained as a brown solid, 98% yield, in about 90% purity (by nmr); ir (Nujol mull) *ν*: 1755 (very broad) cm^{-1}; uv (EtOH) λ_{max}: 296 (ϵ = 20 400), 308 (ϵ = 17 600) nm.

3-(2-Thienylidene)-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylic acid **10**c

Hydrogenolysis mixture: compound **6***c* (344 mg, 0.855 mmol), palladium hydroxide (345 mg), tetrahydrofuran (60 mL), and water (30 mL) for 18 h. Dilute hydrochloric acid and ether were added, mixed, and the organic layer was separated and washed with water and saturated sodium chloride. The solvent was evaporated *in vacuo* and the residue was crystallized with benzene to give acid **10***c*, 100 mg (44% yield); mp 115°C (dec.); ir (Nujol) *ν*: 1775, 1765, 1730 cm^{-1}; uv (EtOH) λ_{max}: 304 (ϵ = 17 700), 315 (ϵ = 15 400) nm. *Anal.* calcd. for $C_{11}H_9NO_3S_2$: C 49.42, H 3.39, N 5.24, S 23.99; found: C 50.20, H 3.57, N 5.09, S 23.06.

Sodium 3-carbethoxymethylene-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate **10**d

Hydrogenolysis mixture: compound **6***d* (60 mg, 0.153 mmol), sodium bicarbonate (13 mg, 0.153 mmol), palladium on Celite (30%, 60 mg), tetrahydrofuran (8 mL), and water (8 mL) for 2 h. Ether was added, mixed, and the phases were separated. The aqueous phase was washed with ether, then lyophilized to give compound **10***d*, 6 mg (14% yield); ir (KBr) *ν*: 1772, 1698, 1660, 1630 cm^{-1}.

Ester cleavage by sodium dithionite

A solution of sodium dithionite (195 mg, 1.12 mmol for **8**; 260 mg, 1.5 mmol for **9**) in water (10 mL) was added to a solution of sulfone **8** (80 mg, 0.187 mmol) or oxopenam **9** (80 mg, 0.25 mmol) in tetrahydrofuran (10 mL) at 0°C. Dilute sodium bicarbonate was added until the solution was pH 7, it was stirred at 0°C for 30 min, and then it was washed with ether. The aqueous phase was acidified with dilute hydrochloric acid (0°C) to pH 2−2.5 and extracted with ethyl acetate (2 × 25 mL). The organic extracts were washed with saturated sodium chloride, dried, and the solvent was evaporated *in vacuo* to give the products as amorphous solids.

3-Benzylidene-4,4,7-trioxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylic acid **11**

Sulfone **11**: 45 mg (82% yield); 80−90% pure (by nmr); ir (solid film) *ν*: 1800, 1750 cm^{-1}.

3,7-Dioxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylic acid **12**

Oxopenam **12**: 39 mg (83% yield); ir (solid film) *ν*: 1790, 1730, 1718 cm^{-1}.

Stability of oxopenam **12**

The conditions of the chemical stability test were the same as those of the β-lactamase inhibition experiment with the exception of the following. Compound **12** was used in higher concentration (20 mg/mL vs. 0.1 mg/mL in the inhibition test), no bacteria were present (*Staphylococcus aureus* or *Klebsiella pneumoniae*), and no chromogenic cephalosporin indicator was present.

A solution of 5 mg of oxapenam **12** in 0.05 mL of acetonitrile plus 0.25 mL of phosphate buffer (pH 7) was maintained at 23°C for 45 min. Reversed phase thin-layer chromatography (Analtech RPSF

250-micron plates; developed with pH 7 buffer/acetonitrile 95:5; visualized with iodine; compound **12** at R_f 0.57) showed the presence of intact oxopenam **12** and some decomposition products.

Single crystal X-ray analysis of ***6***a

$C_{20}H_{16}N_2O_5S$ fw = 396.4

Triclinic, a = 5.529(2), b = 18.665(5), c = 13.481(4) Å, α = 129.04(3), β = 113.69(3), γ = 89.31(3)°, V = 931 Å^3, Z = 2, ρ_c = 1.41 g/cc, space group = $P\bar{1}$, (22°C, CuK$\bar{\alpha}$).

Preliminary X-ray photographs displayed only triclinic symmetry and accurate lattice constants, determined from a least-squares fit of fifteen diffractometer measured 2θ-values, were as above. A crystal of roughly cubic shape was used, 0.25 mm on a side. An estimated density indicated two molecules formed the unit cell and space group $P\bar{1}$ was assumed. All unique diffraction maxima with $2\theta \leq 114°$ were collected on a computer controlled four-circle diffractometer using a variable speed, 1° ω-scan and graphite monochromated CuK$\bar{\alpha}$ radiation. After correction for Lorentz, polarization, and background effects, 1715 (74%) of the 2357 reflections were judged observed. A phasing model was readily achieved using a multisolution sign determining procedure.[5] Block diagonal least-squares refinement with anisotropic nonhydrogen atoms and isotropic hydrogens have converged to a standard crystallographic agreement factor of 0.056 for the observed data. (Quantity minimized: $\Sigma w \| F_o | - | F_c \|^2$.) Fractional coordinates and thermal parameters, bond distances, bond angles, and observed and calculated structure factors are listed in Tables 2 to 5 respectively.[4]

[5]All crystallographic calculations were done on a Prime 850 computer, operated by the Cornell Chemistry Computing Facility. Principal programs employed were as follows. REDUCE and UNIQUE, data reduction programs: M. E. Lewonowicz. Cornell University, 1978. MULTAN 78, "A System of Computer Programs for the Automatic Solution of Crystal Structures from X-ray Diffraction Data", direct methods programs and fast Fourier transformation routine (locally modified to perform all Fourier calculations including Patterson syntheses): P. Main, S. E. Hull, L. Lessinger, G. Germain, J.-P. Declercq, and M. M. Woolfson. University of York, England, 1978. NQEST, CYBER 173 version negative quartets figure of merit calculation: C. M. Weeks. Medical Foundation of Buffalo, Inc., August 1976. BLS78A, anisotropic block-diagonal least-squares refinement: K. Hirotsu and E. Arnold. Cornell University, 1980. ORTEP, crystallographic illustration program: C. K. Johnson. Oak Ridge, TN. ORNL3794, June, 1965. Scattering factors were from ref. 17.

Acknowledgements

We would like to thank Dr. B. Belleau of McGill University for advice during the course of this work. We also thank Dr. M. Misiek of the microbiological department, Bristol Laboratories, Syracuse, N.Y., for the antibacterial and β-lactamase inhibitory tests.

A vectorial model of photon–molecule interactions and the development of an Octupole Rule of vibrational excitation

B. R. HOLLEBONE

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received January 4, 1984

B. R. HOLLEBONE. Can. J. Chem. **62**, 2287 (1984).

An alternative approach to the assignment of molecular vibrations is suggested in which both the molecule and the photon are taken as coincident quantum mechanical entities at the instant of impulse. This model permits the description of the excitation in a simple vectorial form. Using subduction techniques, complete and orthonormal basis vectors for both particles can be defined and the probabilities of excitation are directly related to the overlap of these basis vectors at the instant of space and time coincidence. The model obeys fully the requirements of the $3n - 6$ degrees of freedom rule and is found to express the motions of atoms in terms of their overlap with available multipole fields of the photon. To first order the photon–molecule interaction is taken as the Coulomb potential between the electric fields of the photon and those of the shielded atomic nuclei. The relatively low valence electron density is ignored but becomes important in second order. With this assumption, molecular translational motion correlates to, and exhausts, the dipolar photon field, rotation corresponds to three of the five components of the photon quadrupole and ungerade internal modes are first permitted by overlap with the photon octupole. Some of the consequences of this Octupole Rule are discussed with particular reference to octahedral molecules from which molecules of lower symmetry can be algebraically subduced.

B. R. HOLLEBONE. Can. J. Chem. **62**, 2287 (1984).

On suggère une approche de rechange pour attribuer les vibrations moléculaires; dans cette approche, la molécule et le photon sont considérés comme des entités de mécanique quantique qui sont coincidentes au moment de l'impulsion. Ce modèle permet de décrire l'excitation sous une forme vectorielle simple. En utilisant des techniques de subduction, chacune des particules peut être définie à l'aide de vecteurs complets et orthonormaux et les probabilités d'excitation sont directement reliées au recouvrement de ces vecteurs de base au moment de la coincidence de l'espace et du temps. Le modèle obéit pleinement aux exigences de la loi des $3n - 6$ degrés de liberté et on trouve qu'il exprime le mouvement des atomes en fonction de leur recouvrement avec les champs multipolaires disponibles du photon. En première approximation, on considère l'interaction photon–molécule comme le potentiel de Coulomb entre les champs électriques du photon et ceux des noyaux atomiques blindés. On ne tient pas compte de la faible densité des électrons de valence, mais celle-ci devient importante au deuxième ordre. Sur la base de cette hypothèse, (*a*) on peut établir une corrélation entre le mouvement moléculaire de translation et le champ dipolaire du photon et épuiser ce dernier; (*b*) la rotation correspond à trois des cinq composantes du quadrupole du photon et (*c*) les modes internes d'ungerade sont permis en premier par un recouvrement avec l'octupole du photon. On discute de quelques conséquences de cette règle de l'Octupole en se référant particulièrement aux molécules octaédriques à partir desquelles on peut subduire algébriquement des molécules de plus faible symétrie.

Introduction

Group theoretical analysis of selection rules of molecular vibrations has for many years provided useful insight into molecular structure. This utility is essentially due to the separation of radial and angular terms in the molecular basis functions imposed by the nature of the point groups. In molecules of more than three atoms, however, different internal modes may require identical representations in the finite group of the molecule. Since these assignments are not unique, the algebra of the point group cannot support the actual orthonormality of these different modes and hence is an incomplete description of the system.

This problem applies not only to the molecule itself but also to the exciting particle and to the description of the physical two body complex at the time of energy transfer. As a result, the excitation process is often described in a semiclassical model without identifying the covering symmetry and its accompanying selection rules. A description involving the covering symmetry is possible if some of the parameters of the process are restated. This restatement may provide an alternative approach to the description and calculation of energies and intensities of fundamental vibrations, particularly in molecules of moderate to high symmetry where the numbers of purely radial theoretical parameters is less than the number of available experimental observations.

Theory

Phenomenology of excitation of bound states

Most models of time dependent excitation processes involve a molecule of fixed mass in a fixed position with respect to a set of reference coordinates. Under these conservation conditions for both mass and position, $3n - 6$ degrees of internal freedom remain as fundamental bound excited states. The excitation process is then considered as a time-dependent disturbance of this fixed system by a second body, often in a semiclassical description (1).

In order to avoid the approximations of semiclassical theories which may obscure important features, the complete model of a mass body can be made fully quantum mechanical. Thus, all transitions involving all types of change are made to occur between bound states of the total potential. These transitions can include changes in mass and position. The potential appropriate to this situation is infinitely deep. The classical continuance representing translation or rotation of semiclassical models is avoided in this description.

The simplest infinitely deep potential is that representing simple harmonic motion. Any other more complex, infinitely deep potential, can be resolved into sums of SHM potentials so that the following considerations are readily extended if necessary to coupled systems of higher complexities. The SHM potential is characterized by rigid angular and radial symmetry.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

In particular there is no radial anharmonicity to introduce any dependence of energy difference between states on the total energy of the system.

However, the identification of states of individual molecules requires a series of specializations of this model. In the full potential, mass is a variable. A change in mass has full angular symmetry in the overall Hamiltonian and corresponds to the scalar operation within the infinite potential. Conservation of mass in a finite isolated mass system removes this degree of freedom and exhausts the scalar operation. Removal of the scalar operation coincides with removal of the scalar contribution to the infinitely deep potential. This removal of the scalar potential term reduces the radial symmetry of the body and must result in an anharmonic radial part of the potential (2). The descent in radial symmetry is from the U(3) group of SHM potentials to the C_0 (3) conservation group of the fixed mass. The resulting anharmonic potential must be finite in depth and resembles a Morse curve.

Conservation of position of a mass array which obeys Bose statistics corresponds to elimination of two further types of operation and hence two further terms from the Hamiltonian. The first is translation, which in three-dimensional mass systems is a triply degenerate dipolar operation. The dipolar movement of mass from one position to another leaves nothing behind. For a finite mass this is an unbound operation which completely exhausts the dipolar operations which may be performed on the body. The second operation is rotation about three independent axes and is again triply degenerate. In terms of the formal static potential it is an unbound operation and its removal from the potential exhausts three of the five components of the quadrupole operation.

Removal of the entire mass dipole and part of the mass quadrupole operations by considering systems in which translational and rotational motion are forbidden corresponds to removal of six additional vector components from the system potential. This further reduction in radial and angular symmetry beyond the loss of the scalar imposes increased anharmonicity on the remaining potential of the fully constrained system and results in the final shape of the three dimensional Morse potential for the chosen mass body.

The remaining degrees of freedom, identified by the $3n - 6$ rule, can only be excited by a symmetry change corresponding to the remaining two components of the quarupole or the components of any higher multipole tensorial operators. The exhaustion of the scalar, dipole, and part of the quadrupole operations by conserving the conditions which these operators could alter means that these operators, representing the possible influences of second bodies, cannot participate in altering the internal vibrational states of the mass body in any way.

Coupling of a mass body to a photon

No direct coupling of a pure mass body with a massless photon can occur. Indirect coupling can arise through an interaction of the electrical multipoles of the photon with the distributed electric field on the mass body. The details of this coupling will be determined by two overlap conditions. The first is the correspondence of the molecular electric field to the molecular mass array and the second is the overlap of the molecular mass-change field with the photon as a function of relative positions.

The coupling of the molecular mass and electric fields can be described using the descent in symmetry approximation just discussed. Considering only the mass field, internal fundamental excited states correspond to quadrupolar or higher perturbations of the initial body. Conversely, considering only the electric field in which the fundamental particles obey Fermi statistics, internal excited states may correspond to dipolar perturbations since this centre of charge is not displaced during a dipolar separation of charge. Hence the mass and electron arrays exist in *different effective potentials*, each with its characteristic depth, anharmonicity, separation energy between excited states, and selection rules. Indeed, since the restrictions on Bosons are more severe than on Fermions, the mass potential must be more anharmonic than the electron potential. This conclusion is borne out by experiment for in most molecules, bond breaking energies are 5 to 10 times lower than first ionization energies in the gas phase. These vectorial differences, reflected in the selection rules and the radial differences, are displayed in a mismatch of excitation energies mitigating strongly against any significant first order coupling of valence electrons with the mass field. Given this situation, the behaviour of valence electrons during excitation by external fields may be ignored to first order. A much more important electronic feature of the mass array is the coincident array of sharp cusps of positive charge representing the unshielded nuclear charge on each atom in the array. These cusps are well established by recent calculations (3) and are orders of magnitude more intense than the surrounding diffuse background of valence electron density. This array of positive cusps is strongly coupled to the mass array, remains coincident in first order during vibrational excitations, and is the relevant part of the molecular electric field for the excitation of the mass field.

The second stage of coupling involves the overlap of this array of positive cusps with the field of the photon. Under normal circumstances the wave length of the exciting photons is two orders of magnitude greater than the dimensions of the molecule (or the chromophore) being excited. Experimentally, it is almost always the normal modes localized at the centre of highest symmetry that are involved, for which the Brillouin displacement vector $\boldsymbol{K} = 0$ (5). This suggests that, to first order, the model needs only consider a photon with origin coincident with that of the molecule and no integration over time or space is necessary to identify the initial impulse. The most important consideration in describing the detailed overlap of the molecular positive cusp array and the photon at the point of coincidence of origins is the description of the structure of the photon itself. The conventional model of this particle defines the radiation field in terms of a vector potential $\boldsymbol{A}$ and a scalar potential, σ, the latter may be ignored by appropriate gauge selection. To first order, $\boldsymbol{A}$ may be considered a tensor of order 1 with three orthonormal vector components. In this form it is known as the electric dipole approximation (5, 6). It carries with it the implication that, because of the relative sizes of the photon and molecule, the field is constant across the molecule.

Superimposing this simplified photon on the molecule with mutually coincident origins, the effect of the photon tensor field gradient on the molecule is clear. All the positive cusps representing each atom will be accelerated in the same negative direction of the field for each of the three field components. This corresponds directly to the three translation degrees of freedom of the molecule. It does *not* correspond to an overlap of the photon and molecular fields which could initiate nuclear motion in opposite directions and hence preserve the centre of mass in an internal mode. This dipole field overlap is therefore *exhausted in inducing translation*.

For personal use only.

More detailed models of photon structure have been used, usually involving an electric multipolar expansion about the origin (7). The overlap of these higher pole field distributions with the molecular mass charge array shows that three quadrupole components lead directly to molecular rotation but that all other tensorial components of the higher poles may induce internal modes.

Transition probabilities

The quantitative description of this model again involves three stages, the quantum mechanical derivation of the coupled mass charge system, of the radiation field and of their mutual interaction.

(a) The molecular model

The quantum mechanical description of the mass charge array has been derived in earlier work. Essentially, the internal density harmonics of a spherical continuous mass are derived in momentum space. The imposition of conservation of monopole and dipole properties results in an anharmonic potential whose solutions arise from a non-linear second order differential equation of parametric form

$$-\frac{d^2\psi}{dr^2} - \frac{2(\lambda + 1)}{r}\frac{d\psi}{dr} + b\psi^2 - E\psi = 0$$

When $\lambda = 0$ the Lane–Ender equation for radial spherical systems results and this also corresponds to conservation of position in a one-dimensional space (4). The general form of this equation can be applied to the spherical mass body with conservation group symmetry C_1 (3), using an approximation based on the Poschl–Teller potential;

$$V_m = K(K - 1)k^2 \operatorname{cosech}^2(kx) - \lambda(\lambda - 1)k^2 \operatorname{sech}^2(kx)$$

The potential occurs in two parts, a positive term related to K representing a repulsive potential and a negative term related to λ representing the attractive potential. After conversion to spherical coordinates, the states related to the two potentials can be linearly combined to create two subspaces of states, those bound in an anharmonic well and those unbound above the well. The depth of the well is determined by the values of K and λ, which are related to the fixed amount of mass in the system.

The normal mode angular momenta of lower symmetry molecules are readily identified by subduction in a physically significant chain from the conservation group $C_1(3)$. By direct application of Racah's Lemma, the components of the angular parts of representations in $C_1(3)$, which are the spherical harmonics, may be linearly combined to mimic the states of any Hamiltonian in any array which may be derived by reduction in symmetry from the generative sphere (2). Thus, basic functions retain their generative group representations while being further specified by those of the subgroup used to label the recombined components (8).

(b) The photon model

The quantum mechanical description of the radiation field relies upon the demonstration that the classical radiation field may be regarded as a set of independent harmonic oscillators, each with its own Hamiltonian. From the vector potential

$$A = \sum_\alpha (q_\alpha A_\alpha + \bar{q}_\alpha \bar{A}_\alpha)$$

$$H_F = H_\alpha = 2D^2 \bar{q}_\alpha \cdot q_\alpha$$

where

$$q_\alpha = |q_\alpha| \exp(-iv_\alpha t)$$

Under this Hamiltonian a change of state occurs only when there is a gain or loss of one independent oscillator or photon by the field.

(c) The interaction model

The fully quantum mechanical description of interaction of the coupled mass – nuclear charge array with the field involves a Hamiltonian with three terms

$$H = H_M + H_F + H_I = H_0 + H_I$$

where H_I is the interaction term. The interaction operator is readily constructed for the P.T. potential in a Coulomb gauge which permits the scalar potential to be set to zero. Then, for the absorption of energy from the radiation field, the extinction coefficient becomes (6)

$$M_k = \sum_\alpha \frac{e}{mc} \left\langle a \left| \sum_{j=1}^{n} p_j A_{j\alpha} \right| a_0 \right\rangle \left\langle F |q_\alpha| F_0 \right\rangle$$

This element vanishes unless at least one of the photons is removed from the radiation field, when the matrix element is non-zero. The magnitude of M_k is determined by the sum of all interaction contributions for each harmonic oscillator of the field labelled and by the magnitude of the potential A_j at the position of each of the j charged particles in the coupled mass-charge array.

In the simplest approximation, a single photon event is considered. Then, the further approximation is made that all A_j are equal, that is, the field is constant. Then (6)

$$M_k = \frac{e}{mc} |\boldsymbol{A}| \sum_j \langle a | p_j | a_0 \rangle$$

The limitations due to these approximations have recently been examined (9). They are not determined for the excitation processes of electrons in atoms (9) but for the excitations of mass charge arrays they are clearly inappropriate. The extended array is large enough to encounter variations in direction and magnitude of $\boldsymbol{A}$ and vectorial properties must be retained in the dynamic Hamiltonian. Moreover, with all the $3n - 6$ degrees of freedom available it is inevitable that the lower poles of the harmonic oscillating photon will be exhausted and the higher poles needed for correct overlap to excite the remaining modes. This is not the case with excitation of electrons since only the dipole and occasionally the quadrupole is involved.

The expression of both p and $\boldsymbol{A}$ in conventional descriptions is clumsy in that it is evaluated at all points separately. Both are readily converted to spherical descriptions, the momenta as eigenvectors of the subduced molecular point group G descended from O(3) (8) and the field as the representations and components of the group R_3. This is particularly appropriate since under the $K = 0$ approximation both vectorial properties have the same origin.

Multiplication of the two tensor operators is equivalent to taking the direct product of the representations of allowed molecular momenta with available field tensors in the photon. Each of these two bodies is described in its own three dimensional space. The only phenomenon relevant to both is the coupling of electric fields in the molecule with those of the photon. Assuming strong coupling of the molecular charge array to the mass array, the direct product becomes equivalent to coupling the nuclear mass momenta with the photon. When strong coupling is lost this equivalence is lost. In each space the bodies are described by a dynamic point group. The photon is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

adequately described by R_3 and all molecular properties can be subduced from the $U(3)$ group representing the angular subgroup of $C_1(3)$ (10). The direct product must be restricted to three dimensions and this is achieved by collapsing the outer direct product down to the diagonal subgroup of the system. Within this diagonal subgroup, which is isomorphous with $SU(3)$, the representations can be equally applied to molecular momenta and photon fields because of the common electric field metric. However, the direct products are limited to the scalar result (6) and the complete formation for these coupled operators has the form

$$\sum_j |p_j A_j| \equiv \sum_{V=0}^{\infty} \sum_{L=0}^{\infty} |R_{LV}(r) \hat{V} \hat{L} \hat{C} c|$$

where $R_{LV}(r)$ is the radial overlap integral between the molecular and photon fields, V is the molecular momentum operator, L is the photon field operator, and C is the resultant coupled operator with its component c. For scalar coupling, $|\hat{C} c| = |00|$ and

$$\hat{V} = \hat{L}$$

by vector coupling rules (11) for all values. Thus, for all multipoles the matrix elements all have the form

$$R_{LV}(r) \langle V'L'C'c' | \hat{V}\hat{L}00 | VLCc \rangle$$

where V and V' characterize the molecular momenta in ground and excited states, L and L' characterize the initial and final photon states and C and C' the states of the coupled system. Since C is scalar, $C = C'$ and $c = c'$. As well, V is usually the ground molecular state with no momentum, so the matrix element is specialized to

$$R_{LV}(r) \langle V'0Cc | \hat{V}\hat{V}00 | 0V'Cc \rangle$$

The creation of a state V' is accompanied by the destruction of a photon field of the same symmetry without changing the net description C of the complete system. In physical terms, the photon is absorbed without exchange of energy with a third body.

Coupling of V and L by vector multiplication would represent an event in which the photon either completely (Rayleigh) or with partial absorption (Raman) leaving a polarized resultant photon. This will be discussed in further work.

Since the photon is fully absorbed by the change of state in the molecule with no exchange of energy to the medium, the excitation of any molecular momentum corresponds exactly with the photon field operator represented by L. Thus each of the $3n$ degrees of freedom of coupled mass charge array can be associated with one and only one component of one representation L. The scalar field $L = 0$ cannot change any angular momentum but can correspond to any change in $R_{00}(r)$ which describes the total mass charge of the system. (The radial operator could be derived from $E = mc^2$ and represents a change in mass.) The dipole field $\hat{L} = 1$ can initiate motion of all positively charged particles in the x, y or z orthonormal directions but is completely exhausted by this assignment since the photon is completely annihilated by this interaction. The quadrupole can initiate rotation xz, yz, or xy or internal gerade modes associated with z^2 or $x^2 - y^2$ displacements. The higher multipoles in $\hat{L}$ may all initiate changes in internal angular momenta.

As discussed qualitatively, the first three moments of $\hat{L}$ clearly represent excitation processes of change of mass content, centre of mass or rotation of mass respectively which are irrelevant to the excitation of internal normal modes. In molecules which are centro-symmetric derivatives from $U(3)$, all gerade normal modes are forbidden since in the operator $|\hat{V}\hat{L}\hat{C}c|$, $\hat{L}$ is ungerade for odd values. Thus, the first internal modes which permit absorption of photons are those subduced from the octupolar modes in $U(3)$ labelled $|3\Gamma_v\gamma_v\rangle$ for subgroup S of $U(3)$. This behaviour can be identified as an "*Octupole Rule*" for infrared spectroscopy (2, 10).

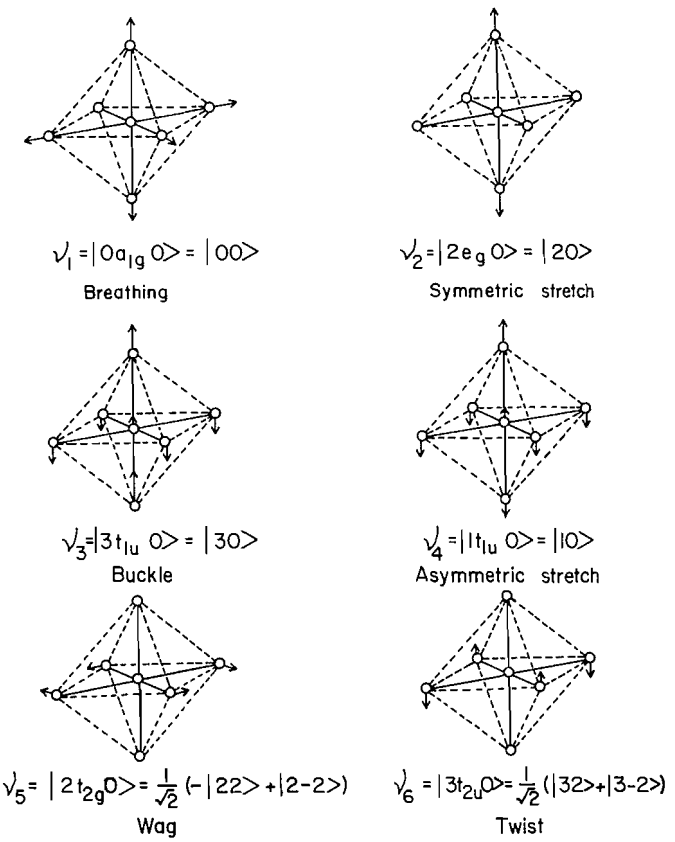

FIG. 1. Vibrational modes of an octahedral molecule.

Orders of transition moments

In all finite point groups the octupole is split into several different representations, for example in O_h it becomes A_2T_1 and T_2. In the T_1 representation it is coincident with the dipole and the orthonormality of these two basis vectors can only be specified by retention of the $U(3)$ labels in kets $|V_{vv}\rangle$.

In molecules with sufficient numbers of atoms to occupy the different available field regions of components of the octupole photon the overlap of these components with normal modes of vibration becomes obvious. In octahedra the acceleration acting on the positive points representing the seven atoms from both the $|3T_{1u}\gamma|$ and $|3T_{2u}\gamma|$ photon fields are readily identified (Fig. 1). Both are clearly "bending modes", the first being a buckling motion and the second a twist of the octahedral framework. The intensities of these modes may be identified with a "*first order octupole mechanism*".

There is a second type of T_1 mode corresponding to the antisymmetric stretch which is experimentally orthonormal to the $|3T_{1u}\rangle$ mode. It cannot be assigned as an octupole for this field is already exhausted. It has the appearance of a dipolar mode but is in fact subduced from $V' = 5$. However, under the fourfold symmetry of the octahedron $V' = 5$ is degenerate with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

$V' = 1$ and the mode has been labelled $|1T_{1u}\gamma\rangle$. Clearly, it is not a simple dipole which would not preserve the position of the centre of mass. Moreover, a first order dipole mode would be expected to have intensity 10^8 stronger than the first order octupole just identified, while in fact the two modes $|3T_{1u}\gamma\rangle$ and $|1T_{1u}\gamma\rangle$ show approximately equal intensities. This low intensity implies that the $|1T_{1u}\gamma\rangle$ is a *second order dipole* mode which obeys the Octupole Rule but gains intensity by weak coupling (10^{-8} of the first order) to other angular momenta in the molecule.

The most obvious coupling is to the valence electrons through a breakdown of the adiabatic assumption of the Born–Oppenheimer principle (1). Physically, the nature of the coupling seems straightforward. Antisymmetric stretching reduces valence electron density in the stretched area while it increases the density in the compressed area. For conventionally bonded systems, this is an oscillation of inter electron repulsion (IER) in the bond region which is directly coupled to the major nuclear motion. The IER phenomenon requires a two electron description and the strongest term arises from the quadrupolar product of two coupled dipolar intensity mechanisms. In other words, the dipolar nuclear motion is coupled to quadrupolar two-electron transitions of the molecule. The resulting intensity of the dipolar nuclear motion will be small for two reasons; quadrupolar intensities are 10^{-4} times less intense than dipolar transitions and the coupled, two-electron states are usually at 10^5 cm^{-1} while vibrational modes are at 10^3 cm^{-1}. In formal terms the second order intensity will be approximately $10^{-4}/10^5 \simeq 10^{-9}$ as strong as an allowed dipole and fall close to the expected intensities of allowed octupole transitions.

This distinction between first order octupole bending modes and second order dipolar antisymmetric stretching modes is carried down through physically significant chains to all molecules of lower symmetry. It means in practice that there are two distinct mechanisms in most molecules whose intensities cannot be solved with the one basis set and one absorption operator (usually a dipole) used in conventional normal mode analysis. This conclusion is corroborated by the well known instability of basis function solutions as functions of force constant choice (12).

Radial integrals and parameters

At a sufficiently high level of symmetry, all mechanical properties of matter can be described by quantum models. Considered in a four dimensional space, the structure of electron orbitals in atoms involves quantum behaviour of radial as well as angular properties and N, L, M_L, and M_s are all valid quantum numbers. The hydrogen atom retains this structure in the lower symmetry of three dimensions because there are no two-electron interactions. Proceeding to even higher symmetries in higher dimensional spaces the atomic charge Z may also be quantized. The work of Wulfman (13) suggests that the periodic table in the long form is isomorphous with the $SO(7)$ group in which each long period is one representation of this group. At this point, all mechanical properties are represented by quantized angular momenta.

This ascent in symmetry is neither trivial nor irrelevant to the problems of spectroscopic analysis in three dimensions. Rather, the choice of a generative group of high symmetry which can represent all mechanical features in quantized form provides a basis for deductive rather than conventional inductive methods for assignment of molecular states and the calculation of the fitting parameters. As the descent in symmetry from the generative group to the detectable point group takes place, angular nodes get converted into radial nodes (2). Through stepwise symmetry descent, the number of radial nodes in each molecular basis function remain well defined. As this process of conversion continues, progressively more of the mechanical information about the molecule is converted into scalar magnitudes of radial matrix elements which become mixed together in the magnitudes of spectroscopic fitting parameters. At the same time, the increasing complexity of the radial basis functions requires expression as linear combinations of discrete radial functions of different quantum numbers n (from 1 to ∞). Thus the effective value of n in each of the final molecular radial basis function is non-integer and is a variable function of bond lengths and charge distributions in ground and excited states (14).

The same formal concepts can be applied to the structure of the "one-vibration" (by analogy to the one-electron) mass-charge array. Indeed, the model has been extensively used to describe the very similar problem of fundamental vibrations of atomic nuclei (15).

This procedure can be applied to finding expansions of the experimental parameters under any operator. Under the Hamiltonian of the static molecule, radial parameters representing the energies of fundamental vibrations and overtones can be calculated. For small molecules possessing some symmetry this parametrization of the energies has some important advantages over conventional force field analysis. The first advantage is that the subduction process which identifies the radial parameter *guarantees* that the number of such parameters is the minimum required. Since the number of experimental measurements is often limited, it is a *practical advantage* to reduce the number of theoretical parameters to its minimum for this reduces the requirement for approximations of unknown quantities in the model. The second major advantage is that this procedure also guarantees that molecular data are completely *scalar* and can be compared directly with data in compounds of different symmetries. In conventional force field analysis the force constants at multiple centres are almost invariably vectorial entities unique to the molecule being analysed. Comparison of parameter magnitudes between molecules is then meaningless because these vectorial attributes vary, often in a complicated manner, from one compound to the next.

The advantages of a symmetry decent model are equally applicable to the dynamic Hamiltonian for the calculation of transient linear momenta, $R_{LV}(r)$, which evolve from the definition of transition probabilities. These radial integrals are a minimum set of truly scalar parameters and represent a sum of integrals characterized by a principal quantum number in the generative point group describing the overlapped particles, $U(3)$;

$$R_{LV}(r) = \sum_{N=1}^{\infty} C_{NM} R_{NM}(r)$$

where the C_{NM} are the mixing coefficients for each of the radial basis functions in the generative group (M represents the allowed coupling of L and V). The range of N is limited to the minimum value necessary for L and V to exist and to a maximum practical value beyond which the $R_{NM}(r)$ values become insignificant. Each of the $R_{NM}(r)$ is readily expanded, by means of coupling coefficients in the generative group, into overlap integrals of the fields in the two particles described in terms of angular momenta. Thus,

$$R_{NM} = \sum_{PQ} \int_0^\infty R_{N'M'}\, a_p \hat{R}_{Pa} R_{NM}\, \mathrm{d}r$$

$$= \sum_{PQ} a_P \langle R_{N'M'} | \hat{R}_{PQ} | R_{NM} \rangle$$

$$= \sum_{\substack{PQ \\ KU \\ LV}} a_P \sum_{\substack{KL \\ UV \\ K'L' \\ U'V'}} \begin{pmatrix} K'U'N' \\ L'V'M' \end{pmatrix} \begin{pmatrix} \hat{K}\hat{U}\hat{P} \\ LVQ \end{pmatrix} \begin{pmatrix} KUN \\ LVM \end{pmatrix}$$

$$\cdot (-1)^x [D] \langle R_{K'U'} \| \hat{R}_{\hat{K}\hat{U}} \| R_{KU} \rangle$$

in which the principal quantum numbers K and K' in the generative group of the molecule $U(3)$ and U and U' of the generative group R_3 of the photon are identified by the uncoupling calculation. The parameter x is the phase factor which is unity if chosen by analogy with earlier work, $[D]$ is a degeneracy term also set to unity (10) and $\langle R_{K'U'} \| \hat{R}_{\hat{K}\hat{U}} \| R_{KU} \rangle$ is the reduced matrix element describing the overlap of radial bases of the molecule and the photon. The remaining parameter a_p is a product of the effective charges generating the molecular and photon fields, Z_M and Z_p. The charge Z_M can be derived from single centre molecular orbital calculations (16). The "effective central charge" of the photon Z_p is the instantaneous charge when $\boldsymbol{K} = 0$ is valid; this would produce the electric field gradient of the $|00\rangle$ component of the photon. This is clearly an inverse function of wave length

$$Z_p \propto \frac{1}{\lambda} \propto \nu$$

since the larger Z_p the more sharply $|00\rangle$ falls off with r.

This expansion of the radial integral emphasizes several features of intensity calculation. One of them is that the radial wave functions of both the molecule and the photon involved in the overlap may have high principal quantum numbers. In the octupole transitions resulting in excitation of internal modes, both L' and V equal 3, thus K' and U must equal at least 4 and could be larger depending on the magnitudes of central charges. Thus, one or more radial nodes could appear within the molecular framework, causing a reversal of phase from the simple angular momentum assignment of normal mode motions. This is particularly important for the apparent dipolar asymmetric stretch where K' must be 6. Then up to 3 radial nodes could be involved in the vibrational excited mode.

Secondly, in order for resonance to occur between molecule and photon, there must be constructive overlap of the two sets of radial functions, that is, $R_{LV}(r)$ must reach a maximum value. Since molecules are usually one to two orders of magnitude smaller than the wave length of the photon it is not obvious that overlap could be maximized. However, the radial wave function of the molecule could constructively interfere with the photon in that region between the origin and the first radial node of the photon. If the principal quantum number of the photon is higher than the minimum value identified earlier, this distance could readily conform to the molecular dimensions in spite of the fact that the classical wavelength is long.

Finally, the expansion of both the angular and radial parts make it clear that a vibration, allowed by selection rules, may be inactive if no atoms in the molecule are sited on the available field gradients. Typical of this is the $|3T_{2u}\gamma\rangle$ mode of the octahedral molecule. While allowed by angular symmetry, there are no atoms at the sites of maximum field gradient which occurs in the middle of each edge of the octahedral array. The vibration is observed in crystal lattices, frozen solutions, and films (12) when ligands from a second coordination layer occupy these positions. In gas phase molecules such as MoF_6, TcF_6, and RuF_6, the transition is inactive because the F atoms remain on the angular nodes of the $|3T_{2u}\gamma\rangle$ distribution.

Phenomenology of coupled systems

This model of vibrational excitation can be incorporated into descriptions of other forms of vibronic coupling, Raman and resonance Raman, double photon Raman, circular and magnetic circular dichroism (10), and photochemistry (17). The essential feature is the retention of the overall octupole rule. In the current development, first and second order fundamentals were identified which both obeyed this rule. The vibrational octupole allowed transitions which attribute the entire change in angular momentum to the change in vibrational momentum. The vibrational dipole required, in contrast, an accompanying quadrupolar charge in the electronic structure. This can be generalized for coupling systems to the rule (10, 17).

$$|\Delta J| + |\Delta V| = |\Delta T| = 3$$

where ΔJ incorporates both orbital and spin moment changes.

Based on this rule, the selection rules for coupled systems can be derived and predictions are readily made of the specific vibrations to accompany specific electronic transitions allowed or forbidden. Some examples of vibronic coupling in absorption and MCD spectroscopy have already been analysed with this formalism (10) and a method of predicting the course of fast photochemical reactions of six coordinate transition metal complexes has been proposed (17). Various aspects of light scattering spectroscopy will be discussed in future work.

New complexes of the hydronium ion with crown ethers: synthesis and vibrational spectra

ROBERT CHÊNEVERT,[1] ANDRÉ RODRIGUE, PIERRE BEAUCHESNE, AND RODRIGUE SAVOIE[1]

Département de chimie et Centre de recherches sur les atomes et les molécules, Université Laval, Québec (Qué.), Canada G1K 7P4

Received February 14, 1984

ROBERT CHÊNEVERT, ANDRÉ RODRIGUE, PIERRE BEAUCHESNE, and RODRIGUE SAVOIE. Can. J. Chem. **62**, 2293 (1984).

The charged-component complexes H_3O^+.18-crown-6.$CF_3SO_3^-$, H_3O^+.18-crown-6.SbF_6^-, and $(H_3O^+.18\text{-crown-6})_2.PtCl_6^{2-}$ have been isolated and studied by infrared and Raman spectroscopy, along with the previously reported H_3O^+.18-crown-6.ClO_4^- and H_3O^+.18-crown-6.PF_6^- adducts. Also synthesized were the corresponding derivatives with BF_4^- and $PtCl_6^{2-}$ anions, using dicyclohexano-18-crown-6 as the host for the hydronium ion.

ROBERT CHÊNEVERT, ANDRÉ RODRIGUE, PIERRE BEAUCHESNE et RODRIGUE SAVOIE. Can. J. Chem. **62**, 2293 (1984).

Nous avons préparé les complexes H_3O^+.18-couronne-6.$CF_3SO_3^-$, H_3O^+.18-couronne-6.SbF_6^- et $(H_3O^+.18\text{-couronne-6})_2.PtCl_6^{2-}$, que nous avons étudié par spectroscopie infrarouge et Raman, de même que les dérivés H_3O^+.18-couronne-6.ClO_4^- et H_3O^+.18-couronne-6.PF_6^-, dont l'existence a déjà été rapportée. Nous avons également obtenu des dérivés analogues, dans lesquels l'éther dicyclohexano-18-couronne-6 sert d'hôte à l'ion hydronium.

Introduction

The first stoichiometric hydronium – crown ether complexes were obtained by Izatt *et al.* (1, 2); they consisted of H_3O^+.dicyclohexano-18-crown-6 adducts associated with the ClO_4^- and PF_6^- counterions. Cram *et al.* (3), in their exhaustive study on host–guest complexation using macrocyclic polyethers, later obtained similar complexes using hydronium *p*-toluenesulfonate and a 18-crown-6 ether in which a CH_2—CH_2 group was replaced by a 1,1′-dinaphthyl unit bound in the 2,2′ position. In recent years, it has been shown that 18-crown-6 (hereafter referred to as 18C6) is a good complexing agent for the hydronium ion, and H_3O^+.18C6 complexes of 1:1 stoichiometry have been obtained with associated BF_4^- (4, 5) and ClO_4^-, PF_6^-, I^-, Br_3^- (5) ions.

In these studies, it was generally assumed that the H_3O^+ ion in the adduct is located at, or near, the center of the macrocyclic ether cavity, as this would maximize the electrostatic interactions between the two units. This was also expected on the basis of the strong hydrogen bonds revealed from the infrared spectra, as these bonds presumably involve the H_3O^+ ion and the oxygen atoms lining the interior of the ether cavity. This hypothesis has recently been confirmed by an X-ray diffraction study on a similar complex, formed by a tetracarboxylic 18C6 ligand and H_3O^+ (6). Preliminary X-ray data on H_3O^+.18C6.BF_4^- also suggest a similar attachment of the hydronium to the crown ether (7).

In the present study, we report the synthesis of several new stoichiometric complexes of the hydronium ion with 18C6 and dicyclohexano-18C6. Raman and infrared spectroscopic measurements have been made on these systems, in order to determine the structure of the H_3O^+.crown adducts and to detect conformational changes which occur in some of these compounds at low temperature. Some other similar complexes with no definite composition are also discussed.

Experimental

The complexes were generally obtained by precipitation from a solution of 18C6 after addition of the acid. The precipitate was filtered, washed with diethyl ether, and dried under vacuum. All the complexes obtained were colorless, except for the orange colored $PtCl_6^{2-}$ derivative. The stoichiometry of the complexes was determined from the integrated intensity of the ^1H nmr peaks (Bruker HX-90 instrument) and, more accurately, by titration with 0.1 *N* NaOH after dissolution of the samples in water or methanol. The measured H_3O^+/crown ether ratio agreed with that calculated within ± 0.5% in all cases. Details pertaining to the individual complexes are given below:

H_3O^+.18C6.ClO_4^-

Concentrated (70%) $HClO_4$ (0.25 mL) is slowly added to a solution of 18C6 (2 mmol) in tetrahydrofuran (20 mL). The complex precipitates. Yield: 85%; mp: 163–164°C (dec.) (168–169°C reported by Heo and Bartsch (5)); ^1H nmr (CD_2Cl_2): δ 10.86 (H_3O^+) and 3.77 (18C6).

H_3O^+.18C6.$CF_3SO_3^-$

Trifluoromethanesulfonic acid (0.25 mL) is slowly added to a solution of 18C6 (2 mmol) in benzene (20 mL). After a few minutes, diethyl ether is added to the resulting solution until the complex precipitates. Yield: 76%; mp: 142–143°C; ^1H nmr ($CDCl_3$): δ 11.15 (H_3O^+) and 3.78 (18C6).

H_3O^+.18C6.PF_6^-

Concentrated hexafluorophosphoric acid (0.25 mL) is slowly added to a solution of 18C6 (2 mmol) in tetrahydrofuran (40 mL). After a few minutes the complex precipitates as colorless needles. Yield: 98%; mp: 141–142°C (Heo and Bartsch (5) have reported a mp of 131–132°C and a yield of 71% for this complex); ^1H nmr (CD_2Cl_2): δ 11.70 (H_3O^+) and 3.70 (18C6).

H_3O^+.18C6.SbF_6^-

A solution of hexahydrated hexafluoroantimonic acid (10 mL) dissolved in 10 mL tetrahydrofuran is added to a solution of 18C6 (2 mmol) in the same solvent (30 mL). The complex precipitates immediately. Yield: 78%; mp: 200°C (dec.); ^1H nmr (CD_2Cl_2): δ 11.20 (H_3O^+) and 3.77 (18C6).

$(H_3O^+.18C6)_2.PtCl_6^{2-}$

The method of preparation is identical to that for the SbF_6^- complex. Yield: 97%; mp: 161–162°C (decomp.); ^1H nmr (CD_3NO_2): δ 6.20 (H_3O^+) and 3.82 (18C6). *Anal.* cacld. for $(H_3O^+.18C6)_2.PtCl_6^{2-}$: C 29.58, H 5.64; found: C 29.19, H 5.58.

H_3O^+.DCy-18C6.BF_4^-

To a solution of 2 m*M* dicyclohexano-18-crown-6 (DCy-18C6) in 20 mL CH_2Cl_2 is added 2 mL of tetrafluoroboric acid (40%). After shaking the mixture for 15 to 30 min, the two phases are allowed to separate and the aqueous phase is washed with two portions of CH_2Cl_2 (10 mL). The organic phases are evaporated and the residue is recrystallized from a tetrahydrofuran/petroleum ether (110–165°C)

[1]To whom correspondence should be addressed.

solution (yield, 70%). Alternatively, the crown (1 m*M*) is dissolved in H_2O (20 mL) and the concentrated acid (2 mL) is added to the solution. After a few days the complex precipitates as large crystals (yield, 75%); mp: 110–120°C. *Anal.* calcd. for H_3O^+.DCy-18C6.BF_4^-: C 50.21, H 8.15, F 15.88; found: C 50.20, H 8.31, F 15.71. ^{1}H nmr ($CDCl_3$): δ 11.60 (H_3O^+), 3.78 (crown), and 1.2–2.3 (CH_2 from cyclohexano-).

$(H_3O^+.DCy\text{-}18C6)_2.PtCl_6^{2-}$

Prepared as by the first method given above for the BF_4^- complex, using solid hexahydrated hexachloroplatinic acid dissolved in 1 mL H_2O. The complex is orange colored. Yield: 68%; mp: 143–150°C; ^{1}H nmr (CD_3NO_2): δ 10.16 (H_3O^+), 3.83 (crown), and 1.0–2.3 (cyclohexano-).

Vibrational spectra

The infrared spectra were obtained from Nujol, hexachlorobutadiene, and Fluorolube mulls contained between Irtran-4 (ZnSe) or silver chloride windows. The low-temperature measurements were made on these same samples fixed in a conventional liquid nitrogen cryostat. The spectra were recorded on a Beckman IR 4250 spectrophotometer or on a Perkin Elmer Model 621 instrument linked to a North Star microcomputer.

For the Raman measurements, the solid samples were contained in sealed capillary cells. These were generally mounted on a motor shaft and rotated at high speed in order to prevent sample decomposition in the laser beam. For the low-temperature measurements, the cell was fixed inside a cavity in the copper tail section of a liquid nitrogen cryostat. The spectra were recorded on a microcomputer-controlled Spex Model 1400 spectrometer (8), using the 514.5 nm exciting line from a Spectra Physics Model 165 argon ion laser. Typical operating conditions were as follows: laser power at sample, 300 mW; spectral slit width, 2 cm^{-1}; integration time, 2 s per data point; frequency increment, 1 cm^{-1}. The orange colored $PtCl_6^{2-}$ complex could only be studied (at room temperature) in a rotating cell and with laser power at 40 mW or less.

Results and discussion

Although the structure of the H_3O^+.18C6 moiety need not be exactly the same in all the complexes discussed here, some general comments can be made about this adduct. First, the orientations of the lone pairs on the oxygen atoms of the crown, assuming sp^3 hybridization, are such that the H_3O^+ ion is expected to form hydrogen bonds with the three oxygen atoms located on the opposite side of the crown (see Fig. 1). This also helps to stabilize the adduct through electrostatic interactions by allowing the hydronium ion to penetrate farther into the ether cavity. Secondly, the H_3O^+ ion fits very loosely into this cavity, and both the spectroscopic (4) and X-ray data (6, 7) point to hydrogen bond lengths (O···O = 2.65–2.80 Å) which are appreciably shorter than expected for the crown ether in its highly symmetrical structure of D_{3d} symmetry (O···O = 2.95 Å (9)). The crown is therefore distorted to a lower symmetry in the H_3O^+.18C6 adduct, and this can be easily determined from the splitting of some of the infrared bands (e.g. 820/840, 950/970 cm^{-1} ...) which occur as singlets (835, 960 cm^{-1} ...) in the spectra of complexes such as K^+.18C6.Br^- (10) where the crown retains its full D_{3d} conformation. Particulars pertaining to specific complexes will now be discussed.

$H_3O^+.18C6.ClO_4^-$

The synthesis of this complex has already been reported by Heo and Bartsch (5). The infrared spectrum of the solid in the high-frequency region (Fig. 2*A*) is clearly indicative of the presence of the H_3O^+ ion (11). The stretching modes of this species are responsible for the very broad band at ~2950 cm^{-1}, which overlaps the sharper maximum arising from the C—H stretching motions of the crown ether in the 2900 cm^{-1} region. Also characteristic are the bands at 1680 and 2200 cm^{-1}, attributable to the ν_4 bending mode and to the first harmonic of ν_2 (symmetric bending mode) respectively. The ν_2 mode itself is of little use here, as it occurs in a region of strong absorption by the crown ether. The Raman bands of the H_3O^+ ion are normally extremely weak, and they were not detected in this study.

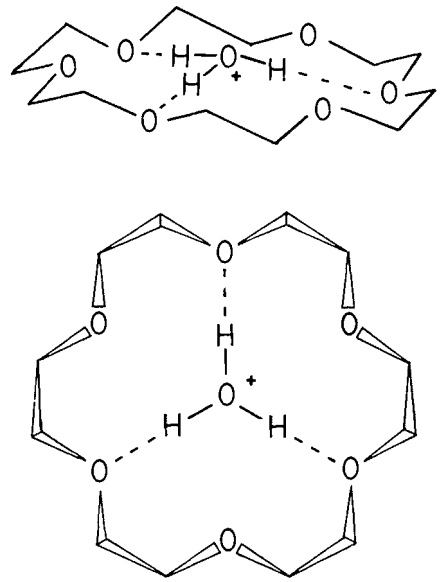

FIG. 1. Schematic representation of the H_3O^+.18-crown-6 adduct.

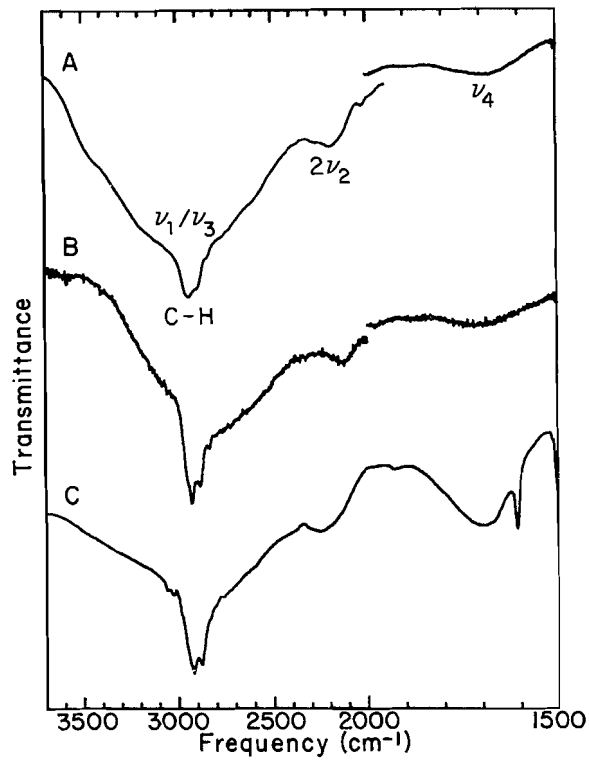

FIG. 2. High-frequency region of the infrared spectra of (*A*) H_3O^+.18C6.ClO_4^- (hexachlorobutadiene mull), (*B*) H_3O^+.18C6.-SbF_6^- (hexachlorobutadiene mull), and (*C*) oily liquid with approximate composition 18C6/*p*-toluenesulfonic acid/1.3 hydronium *p*-toluenesulfonate.

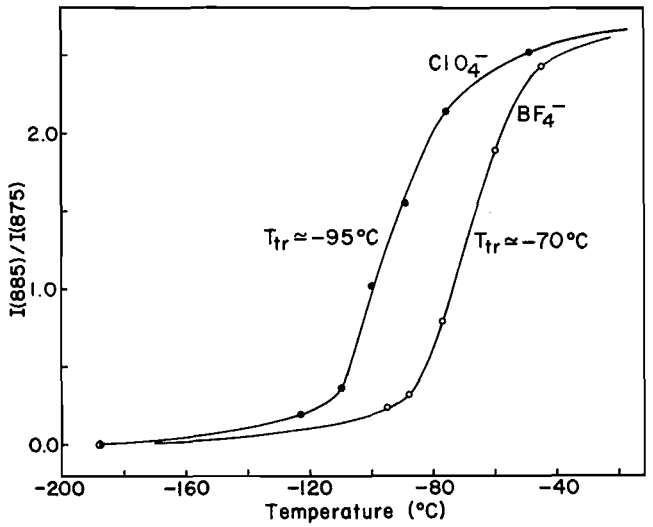

FIG. 3. Variation of the intensity ratio of the 885/875 cm^{-1} bands in the Raman spectra of $H_3O^+.18C6.ClO_4^-$ (full circles) and $H_3O^+.18C6.BF_4^-$ (open circles).

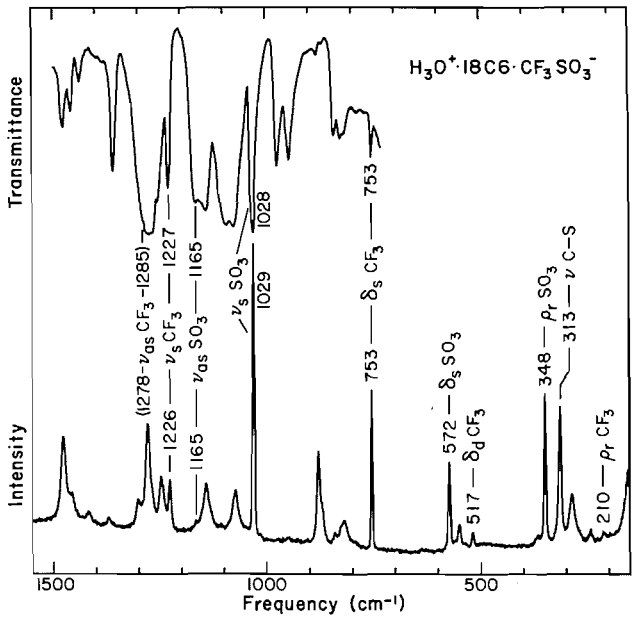

FIG. 4. Infrared (Nujol and hexachlorobutadiene mulls) and Raman spectra of the $H_3O^+.18C6.CF_3SO_3^-$ complex.

The complete ionization of $HClO_4$ in the complex is readily established from the absence in the Raman spectrum (not shown) of the characteristic bands of this acid (12–14), in particular at ~740 cm^{-1} (ν_{Cl-OH}). Instead, sharp peaks due to the ClO_4^- ions are observed at 932 cm^{-1} (ν_1), 458 cm^{-1} (ν_2), and 624 cm^{-1} (ν_4). These frequencies are comparable to those measured in the Raman spectrum of the high-temperature crystalline form of $H_3O^+.ClO_4^-$ (15, 16). In the infrared spectrum of the complex with 18C6 (not shown), the ν_4 mode gives a sharp peak at 626 cm^{-1}, whereas the ν_3 vibration gives a very strong absorption band near 1100 cm^{-1}.

The main difference between the ir spectrum of the $H_3O^+.18C6.ClO_4^-$ complex and that of the corresponding $H_3O^+.ClO_4^-$ salt at room temperature, besides the presence in the former of characteristic bands of the ether, comes from the vibrational bands of the H_3O^+ ion. The ν_3 band of this ion, centered at ~3250 cm^{-1} in $H_3O^+.ClO_4^-$ (15, 17), is shifted appreciably in the crown ether complex, where it merges with ν_1 to give the broad band at ~2950 cm^{-1} (Fig. 2*A*). This shift is indicative of widely different hydrogen bond lengths and energies in the two compounds. The $OH^+\cdots O$ ($O\cdots O$) distances in the hydronium salt are 2.9 Å on the average (18), whereas empirical relations between the ν_{OH} frequency and the $O\cdots O$ distance (11, 19) yield ~2.65 Å for the 18C6 complex. This is a good indication that the H_3O^+ ion in this complex is located within the macrocyclic cavity, and H-bonded to the oxygen atom of the ether. The situation is therefore similar to that encountered in the $18C6.H_3O^+.BF_4^-$ complex (4), for which preliminary X-ray diffraction data give $OH^+\cdots O$ distances of 2.66–2.81 Å (7), and in the complex formed by a tetracarboxylic 18C6 ligand with H_3O^+, and three $OH^+\cdots O$ hydrogen bonds of length 2.67–2.74 Å (6). One can also draw a parallel between the increase in H-bond energy in the $H_3O^+.18C6.ClO_4^-$ complex and the high melting point of this compound (dec. 163–164°C) relative to the $H_3O^+.ClO_4^-$ salt (50°C).

Except for the bands of the anions, the vibrational spectra of the $H_3O^+.18C6.ClO_4^-$ and $H_3O^+.18C6.BF_4^-$ (4) are identical, suggesting that they are structurally isomorphous. Furthermore, the conformational change which was found to take place in the tetrafluoroborate complex at ~−70°C (4) also occurs in the perchlorate complex, although at a somewhat lower temperature (−95°C). The progression of this conformational change, as followed by the intensity reversal of the 885/875 cm^{-1} Raman peaks, is illustrated in Fig. 3. This transition in the BF_4^- complex was explained by a gradual folding of the crown ether around the hydronium ion, which is too small to effectively fill the macrocyclic cavity. In the ClO_4^- complex, the pulling effect of the $OH^+\cdots O$ bonds appears to be slightly less than in the BF_4^- complex, as evidenced by the higher ν_{OH} frequency (2950 cm^{-1} in the ClO_4^- complex as compared to 2850 cm^{-1} in $H_3O^+.18C6.BF_4^-$), and the transition takes place at a lower temperature. The change appears to involve mainly the 18C6 molecules in the complex, and the ClO_4^- ions probably retain a high degree of symmetry at all temperatures, as no apparent site splitting of the degenerate vibrational modes of these ions is observed in the Raman spectrum of the complex.

$H_3O^+.18C6.CF_3SO_3^-$

The monohydrate of trifluorosulfonic acid has been shown by X-ray diffraction to exist as an ionic solid, $H_3O^+.CF_3SO_3^-$ (20). The corresponding complex with 18C6 also contains this basic unit, as evidenced by the presence in the infrared spectrum of the characteristic bands of this ion (2880, 2140, and 1725 cm^{-1}) and the absence of the undissociated acid bands (Fig. 4), particularly at 930 cm^{-1} (ν_{S-OH}) and 1400 cm^{-1} ($\nu_{as}SO_2$) (13). However, the high melting point of $H_3O^+.18C6.CF_3SO_3^-$ (141–142°C) with respect to that of the hydronium salt (35°C) strongly suggests that the H_3O^+ ion in this complex is H-bonded to the crown ether, as is the case in the BF_4^- complex. This conclusion is further substantiated by the splitting of some of the ether vibrational modes, namely, in the 840 and 960 cm^{-1} regions, which characterizes the $18C6.H_3O^+$ intra-cavity adduct.

The infrared and Raman spectra of the $H_3O^+.18C6.CF_3SO_3^-$ complex in the region below 1500 cm^{-1} (Fig. 4) are dominated by the strong bands of the anion, whose frequencies are slightly lower than in solid $NaCF_3SO_3$ and $Ba(CF_3SO_3)_2$, and in a concentrated aqueous solution of the $CF_3SO_3^-$ ion (21). In the

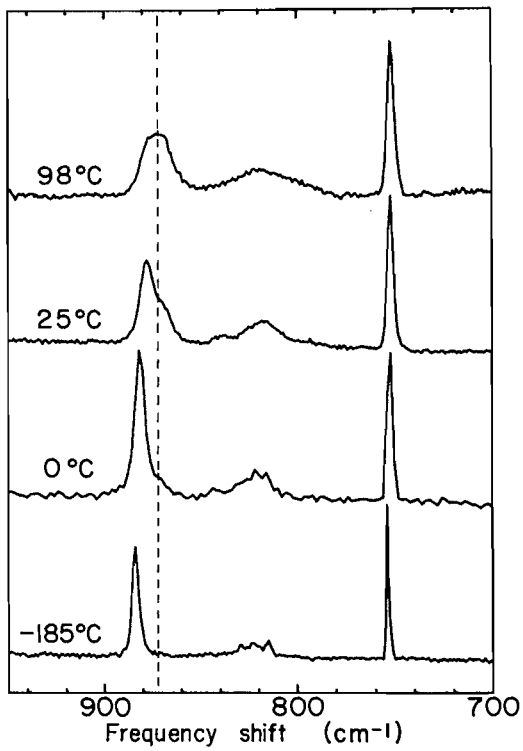

FIG. 5. Temperature-dependent spectral changes in the Raman spectrum of the $H_3O^+.18C6.CF_3SO_3^-$ complex.

regions of the spectra which are free of the bands of the anions, the vibrational bands of the crown ether are very similar to those in the BF_4^- and ClO_4^- complexes, which suggests that the $18C6.H_3O^+$ adduct has the same overall geometry in all three cases.

The vibrational spectra of $H_3O^+.18C6.CF_3SO_3^-$ do not indicate the occurrence of a conformational change in this complex at low temperature. However, spectral changes are observed upon raising the temperature to 100°C, and it appears that a conformational change, apparently different from that which occurs in the BF_4^- and ClO_4^- complexes at low temperature, does take place in the $CF_3SO_3^-$ complex in the temperature range 0–80°C. As shown in Fig. 5, the sharp peak at 883 cm^{-1} in the Raman spectrum progressively transfers its intensity to a broad band centered at 872 cm^{-1} over this temperature range. This band is due to the ring breathing mode of the ether, and the observed spectral changes suggest that conformational disorder sets in the crystal at high temperature. This disordering process, which seems to involve mainly the $H_3O^+.18C6$ adduct, probably takes place in most complexes of this type, as a similar trend was observed in the BF_4^- and ClO_4^- compounds, although in these cases the transition was not complete at 80°C. One can speculate that this disordering process involves a tunneling motion of the $H_3O^+.18C6$ pyramidal adducts between their two opposite mirror-image structures in the solid. Preliminary X-ray data on the $H_3O^+.18C6.BF_4^-$ complex (7) would be consistent with this interpretation, as they indicate that one half of the H_3O^+ ion is located on each side of the crown in this particular compound at room temperature.

$H_3O^+.18C6.SbF_6^-$

The $H_3O^+.SbF_6^-$ salt, first isolated and studied by vibrational spectroscopy by Criste *et al.* (22), along with the corresponding AsF_6^- derivative, is an extremely stable hydronium compound (dec. 357°C). Although this stability suggests strong anion–cation interactions, the relatively high values for the O—H stretching vibrations (3150/3300 cm^{-1}) indicate that the "H-bonds" are rather weak in this solid. These characteristics contrast sharply with those of the $H_3O^+.18C6.SbF_6^-$ complex (dec. 200°C), whose ir spectrum (Fig. 2*B*) reveals a low ν_{O-H} band (2850 cm^{-1}) characteristic of strong hydrogen bonds. These are certainly of the $^+O—H\cdots O$ type, and there seems to be no doubt that an intra-cavity $H_3O^+.18C6$ adduct is present in this complex. No attempt has been made in this study to prepare the $H_3O^+.18C6.AsF_6^-$ complex, but we have obtained the $H_3O^+.18C6.PF_6^-$ derivative already reported by Heo and Bartsch (5). Except for the bands of the anion, the spectrum of the latter is identical to that of the SbF_6^- complex.

The vibrational spectra of $H_3O^+.18C6.SbF_6^-$ (not shown) are easily interpreted, as they contain but few bands of the anion. In the Raman spectrum only the totally symmetric mode, $\nu_1(A_g)$, and the triply degenerate $\nu_5(F_g)$ mode give strong peaks, at 645 and 279 cm^{-1}, respectively, whereas in the infrared spectrum only the $\nu_3(F_{1u})$ mode falls in the region studied, giving an intense absorption band at 654 cm^{-1}. The corresponding bands in the $H_3O^+.18C6.PF_6^-$ complex are easily identified after comparison with salts such as KPF_6 (23) and $NaPF_6.H_2O$ (24); they are found at 739 cm^{-1} (ν_1) and 466 cm^{-1} (ν_5) in the Raman and at 837 cm^{-1} (ν_3) and 561 cm^{-1} (ν_4) in the infrared spectrum.

There are basic differences between the vibrational spectra of the $H_3O^+.SbF_6^-$ adduct in the free hydronium salt (22) and the corresponding unit in the 18C6 complex. Splitting of the SbF_6^- ion vibrational modes clearly occurs in the free hydronium salt. For example, the ν_1 vibration gives a well-resolved doublet at 640/674 cm^{-1} in the Raman spectrum at −120°C. This splitting, which is probably too large to be accounted for by an intermolecular vibrational effect, is likely caused by a distortion of the SbF_6^- ions from their basic octahedral conformation. No such effect is detected in the SbF_6^- and PF_6^- complexes with 18C6, for which the Raman spectra at both room and liquid-nitrogen temperatures show only one sharp peak for the ν_1 and ν_5 vibrations. This suggests that the AB_6^- ions in these complexes are isolated from one another and that they are little distorted from their ideal O_h symmetry. It should also be pointed out that the spectra of these two complexes give no evidence of a conformational change of the $18C6.H_3O^+$ adduct at low-temperature, as was observed in the BF_4^- and ClO_4^- complexes.

$(H_3O^+.18C6)_2.PtCl_6^{2-}$

The compound usually referred to as "chloroplatinic acid dihydrate" is in fact a hydronium salt: $(H_3O^+)_2.PtCl_6^{2-}$. This solid, which is stable up to 400°C, is extremely deliquescent. This probably explains why several different versions of its infrared spectrum have been published (25–27). The corresponding complex with 18C6 (dec. 161–162°C) retains much of the orange coloration of the starting hydronium salt, making it very difficult to study by Raman spectroscopy. It was nevertheless possible to obtain its spectrum in the low-frequency region (below 500 cm^{-1}) by using a rotating cell, at very low laser power excitation. The two main peaks detected at 335 and 310 cm^{-1} in this spectrum are readily assigned to the $\nu_1(A_g)$ and $\nu_2(E_g)$ modes of the $PtCl_6^{2-}$ ion (28), which proves the ionic nature of the complex. This is further substantiated by the high-frequency region of the ir spectrum, which shows the characteristic absorption pattern of the H_3O^+ ion.

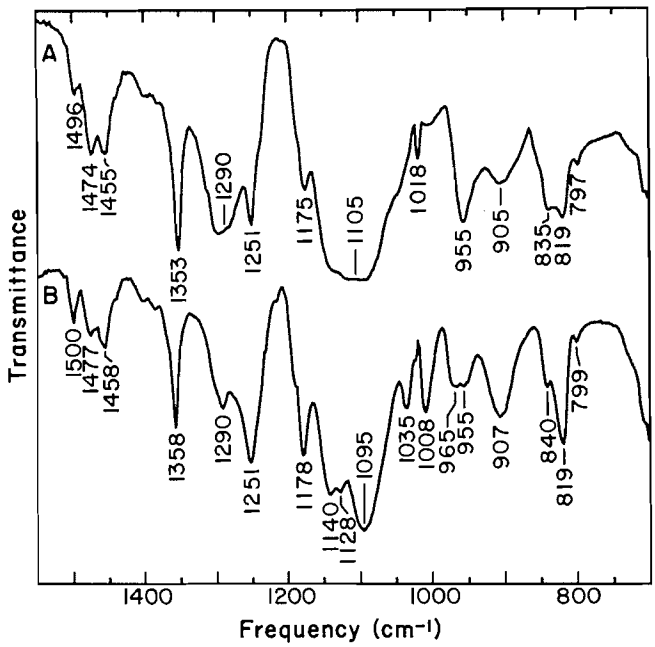

FIG. 6. Infrared spectra of mixtures of 18C6 and hydronium *p*-toluenesulfonate: (*A*) starting composition 18C6 + ($H_3O^+.CH_3-C_6H_4-SO_3^-$) and (*B*) composition as in Fig. 2*C*.

The 2:2:1 ratio of the H_3O^+:18C6:$PtCl_6^{2-}$ constituents in this complex is by itself indicative of the formation of a 18C6.H_3O^+ adduct; that is, the formula of the complex should be $(H_3O^+.18C6)_2.PtCl_6^{2-}$. The infrared spectrum of this complex, which is free of bands from the anion in the region studied, is quite similar to that of the SbF_6^- complex, and it is likely that the nature of the complexation is the same in both cases. However, the 2:1 anion/cation ratio in the $PtCl_6^{2-}$ complex probably makes it more difficult for these units to be packed into a highly symmetrical arrangement in the crystal, and this in turn could explain the relatively higher complexity of its ir spectrum, particularly at liquid-nitrogen temperature. As in the case of the PF_6^- and SbF_6^- complexes, no low-temperature conformational change of the 18C6 moiety in the $PtCl_6^{2-}$ derivative is indicated by its ir spectrum.

18C6 + ($H_3O^+.CH_3-C_6H_4-SO_3^-$)

Although a 1:1 complex between hydronium *p*-toluenesulfonate ($H_3O^+.PTS^-$) and 18C6 containing one 1,1′-dinaphtyl unit bound to adjacent oxygen atoms of the polyether host has been reported (3), attempts to form such a complex with unsubstituted 18C6 have failed (5). However, there is no doubt that some sort of association does take place between $H_3O^+.PTS^-$ and 18C6, as the latter makes soluble this hydronium salt in solvents such as CH_2Cl_2 and $CHCl_3$, in which it is normally quite insoluble.

We have used infrared and ^1H nmr spectroscopy to determine what happens when $H_3O^+.PTS^-$ is added to a solution of 18C6 in CH_2Cl_2 (1% w/w), in an attempt to form a 18C6.H_3O^+ complex through a solid-liquid phase transfer process. When an excess of the hydronium salt is used (4 acid:1 crown), typically 2.7 molecules of the "hydrated" acid dissolve for each 18C6 molecule in the solution. This process, however, occurs with a variable loss of "hydration" water. After evaporation of the solvent from the organic phase, one is left with an oily liquid containing non stoichiometric amounts of 18C6, PTSH, PTS^-, and H_3O^+. The H_3O^+/18C6 ratio in this mixture is larger than one (typically 1.4), most likely because of the presence of uncomplexed $H_3O^+.PTS^-$ in the CH_2Cl_2 medium used for the preparation. When one tries to impose a 1:1 H_3O^+/18C6 stoichiometry to the system in the preparation procedure, an oily liquid is obtained, which sometimes crystallizes (mp: 50–51°C, ^1H nmr ($CDCl_3$): δ 10.85 and 3.72). The solid thus obtained also contains nonstoichiometric amounts of PTSH and PTS^-.

Although the high-frequency region of the infrared spectra (Fig. 2*C*) indicates the presence of H_3O^+ in the mixtures obtained, it is probable that most of these ions are not linked to the ether molecules in the usual way: the lack of appreciable splitting of the crown vibrational mode at 958 cm^{-1} (Fig. 6) is characteristic of an undistorted, and most likely uncomplexed, molecule of D_{3d} symmetry (10). By comparison, the H_3O^+.-18C6 moiety in $H_3O^+.18C6.SbF_6^-$ gives a well-resolved infrared doublet with components at 947 and 972 cm^{-1}. Also present in the infrared spectrum is a band of variable intensity at 910 cm^{-1}, which is not present in the spectrum of the hydronium salt (19), but characterizes the free acid (29). Extra absorption at ~2400 cm^{-1} further suggests that the free acid molecules in the mixture are associated into dimeric units. The high stability of these H-bonded dimers (29) and their solubility in the solvent used could explain their presence in the 18C6 mixture obtained. This would also partly explain our failure to obtain a complex of definite $H_3O^+.18C6.PTS^-$ composition in this case.

Other complexes

Izatt *et al.* (1, 2) have shown that the *cis–syn–cis* isomer of dicyclohexano-18C6 (DCy-18C6) can form complexes with $H_3O^+.ClO_4^-$ and $H_3O^+.PF_6^-$. Due to the added rigidity of this crown, the complexes are not quite as stable as those with unsubstituted 18C6, whose melting points are higher by ~20°C. Nevertheless, the complexing ability of this ether towards the hydronium ion is quite high, and we were able to synthesize the complexes H_3O^+.DCy-18C6.BF_4^- and $(H_3O^+.DCy\text{-}18C6)_2.PtCl_6^{2-}$ (see Experimental section). No detailed spectroscopic investigation of these complexes was performed.

Attempts to form H_3O^+.15-crown-5 and H_3O^+.12-crown-4 complexes were not successful, inasmuch as no well defined stoichiometric compounds were obtained. Using a method of preparation similar to that for the H_3O^+.DCy-18C6 complexes, we have obtained an ill-defined solid complex $H_3O^+.BF_4^-.(15C5)_X$ (X = 1 to 2) (mp 118–119°C; ^1H nmr: 9.80 (H_3O^+) and 3.73 (15C5)). This result is very similar to that previously obtained with HPF_6 by Heo and Bartsch (5). These authors also obtained the $H_3O^+.(12C4)_2.PF_6^-$ complex. Our attempts to isolate the corresponding derivative with BF_4^- led to a colorless oily liquid of approximate stoichiometry $(H_3O^+.BF_4^-)_2.(12C4)_3$. The hypothesis put forward by Heo and Bartsch regarding the formation of sandwich type complexes of 12C4 and 15C5 with H_3O^+, each hydronium ion being H-bonded to two adjacent ether molecules, offers a good explanation for the present results.

We have found that carboxylic acids are readily complexed by 18C6, although in an unionized form. Among the complexes formed are the stoichiometric compounds $(CH_3COOH)_2.18C6$ and $(HCOOH)_3.(18C6)_2$. Halogenated derivatives of acetic acid are also complexed, yielding well-characterized solids of the type $(acid.H_2O)_x.18C6$ (with x = 1 or 2). Finally, some "inorganic" acids can form similar complexes: besides the $(HNO_3.H_2O)_2.18C6$ compound already reported

(5), we have found that hydrated H_2TiF_6 can also associate with 18C6. These neutral-component complexes will be the subject of a later publication.

Stability constants and spectral studies of complexes of 2-hydroxy-5-methylazobenzene-2′-carboxylic acid with some divalent metal ions

C. MAHALINGAM, J. K. STHAPAK,[1] D. D. SHARMA, R. L. TIWARI, AND SMITA STHAPAK
Department of Applied Chemistry, Government Engineering College, Jabalpur, India
Received March 29, 1983[2]

C. MAHALINGAM, J. K. STHAPAK, D. D. SHARMA, R. L. TIWARI, and SMITA STHAPAK. Can. J. Chem. **62**, 2299 (1984).

The stability constants of metal complexes of 2-hydroxy-5-methylazobenzene-2′-carboxylic acid have been determined spectrophotometrically. These follow the Irving–Williams sequence: log K_{OH}(H) = 10.67, log K_1(Co) = 9.02, log K_1(Ni) = 9.68, log K_1(Cu) =13.37, log K_1(Zn) = 7.58, and log $K_1(UO_2^{2+})$ = 11.63

The chelates of Mn(II), Fe(II), Co(II), Ni(II), Cu(II), Zn(II), and UO_2^{2+} with the dye have been prepared and characterized on the basis of their ir and reflectance spectra.

C. MAHALINGAM, J. K. STHAPAK, D. D. SHARMA, R. L. TIWARI et SMITA STHAPAK. Can. J. Chem. **62**, 2299 (1984).

On a déterminé spectrophotométriquement, les constantes de stabilité des complexes métalliques de l'acide hydroxy-2 méthyl-5 azobenzènecarboxylique-2′. Ces constantes obéissent à la séquence de Irwing–Williams: log K_{OH}(H) = 10,67, log K_1(Co) = 9,02, log K_1(Ni) = 9,68, log K_1(Cu) =13,37, log K_1(Zn) = 7,58, and log $K_1(UO_2^{2+})$ = 11,63.

Les spectres ir et les spectres de pouvoir réflecteur ont permis de caractérisér les chélates du Mn(II), du Fe(II), du Co(II), du Ni(II), du Cu(II), du Zn(II) et du UO_2^{2+} préparés à partir de ce colorant.

[Traduit par le journal]

Introduction

The formation of metal derivatives by those azo dyes which contain hydroxy, carboxyl, amino, etc., groups in one or more of the *ortho* positions has been studied in detail (2). Such compounds have found many applications in the dyeing of fabrics and in the preparation of organic pigments (3). The study of the stabilities of the complexes of such mordant azo dyes would be interesting because of their importance as a factor in the fastness of such dyes towards washing (4). This paper deals with the study of the stability constants of the complexes formed by metal ions Co(II), Ni(II), Cu(II), Zn(II), and UO_2^{2+} with 2-hydroxy-5-methylazobenzene-2′-carboxylic acid. The proton stability constants of the dye have been explained on the basis of hydrogen bonding as evidenced from the ir spectra of the dye obtained. The azo dye studied herein has the structure:

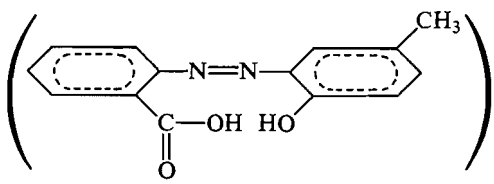

FIG. 1.

Experimental

The azo dye studied is not available commercially. It was, therefore, synthesized.

(A) *5-Methyl dye*

The dye was synthesized and stock solutions of metal ions and dye were prepared using AR grade salts, HCl, and NaOH. *Anal.* calc. for $C_{14}H_{12}N_2O_3$: C 65.63, H 4.68, N 10.94; found: C 65.53, H 4.71, N 10.70.

(B) *Synthesis of metal complexes of 2-hydroxy-5-methylazobenzene-2′-carboxylic acid*

The calculated quantities of the sodium salt of the dye solution and the metal salts were mixed in alcohol (100 mL) and were stirred at room temperature for one hour. The solid started precipitating, and was filtered and recrystallized to give the desired product.

(C) *Instruments*

A digital pH meter (Systronics) reading to 0.01 unit was used for pH reading after standardization at two points with suitable buffers in the region of the pH of the solution under study. Buffers used were potassium hydrogen phthalate (AR) and borax (AR). Absorbances were measured on a Beckman DU Grating Spectrophotometer with a tungsten lamp.

The absorption spectra of the ligand and metal complexes were measured in dimethylformamide solution. Silica cuvettes having 10-mm optical path-length, supplied with the instrument, were used. A Beckman DU spectrophotometer was used for diffuse reflectance spectra with spectroscopically pure magnesium carbonate as a reference. The structures of the ligand and their complexes were checked by ir spectra which were recorded on a Beckman IR-20 instrument in KBr. Conductivity measurements were made in dimethylformamide solution using a Metrohm conductivity bridge at 25°C ± 0.1°C.

Proton stability constant

In the case of the azo dye studied, only the log K_{OH}(H) value has been determined spectrophotometrically. The log K_{COOH}(H) value could not be determined for reasons offered in the discussion. The absorption spectra of the unionized species (OH group completely unionized at pH 6.50), and those of the ionized species (OH group completely ionized at pH ~ 14.00) were recorded and then the extinction coefficients at the chosen analytical wavelength were determined accurately; Beer's law was found to be obeyed.

Calculations

The proton stability constant log K_{OH}(H) was then determined by the relation (6):

$$\log K_{OH}(H) = pH + \log \frac{E_l - E}{E - E_u}$$

where the terms have their usual meanings (5). The values of E_u, E_l, and log K_{OH}(H) obtained at a wavelength of 470 nm, pH 10.00, temp. 25°C ± 0.1°, and ionic strength 8×10^{-5} *M* are 1740, 8450, and 10.67 ± 0.02, respectively.

Metal stability constants

Metal stability constants were determined by Janssen's spectrophotometric method (7) and the log K_1(M) values have been calculated from the equation

TABLE 1.

Metal ion	Ionic strength (M)	λ (nm)	pH	E_L	E_I	Log K_I(M)
Co^{2+}	2.8×10^{-4}	470	9.00	1740.0	5742	9.02 ± 0.08
Ni^{2+}	3.2×10^{-4}	490	10.00	978.8	8750	9.68 ± 0.02
Cu^{2+}	2.5×10^{-4}	500	13.00	694.0	9033	13.37 ± 0.10
Zn^{2+}	3.3×10^{-4}	480	7.00	1240.0	7415	7.58 ± 0.02
UO_2^{2+}	2.1×10^{-4}	450	11.00	3308.3	5191	11.63 ± 0.06

*Temperature: 25°C ± 0.1°.

$$K_I(M) = \frac{(A - E_L T_L)(E_I - E_L)F}{\{(E_I - E_L)T_M + E_L T_L - A\}(E_I T_L - A)}$$

where A, E_I, E_L, T_M, T_L, and F have their usual meanings described elsewhere (5).

Table 1 gives the wavelength chosen, E_L, E_I, and log K(M) values obtained for the various metal ions.

Discussion

(A) *Proton stability constant*

No change in the absorption spectra of the dye was observed in the whole recorded spectral region at pH 1 to 8 (below pH 1, the dye was too insoluble for any studies to be made and hence such values were unapproachable). Literature survey confirmed that Dieh and Ellingbde (8) had also found the same with their dyes (5-methyl dye and its naphthalene analogue). Presence of the COOH group was confirmed by elemental analysis and ir spectra of the ligand which show bands at 1680−1700 cm^{-1} due to —C=O asymmetric stretching of an aromatic carboxylic group. The band around 1590 cm^{-1} is due to —N=N— and those at 1250 cm^{-1} and between 1440−1395 cm^{-1} are due to C—O of phenol and COO^- symmetric stretching, respectively. The bands around 900−950 cm^{-1} could be assigned to —OH of the carboxylic group. Hence the presence of the —COOH group is confirmed. The spectrum also shows evidence for a strongly hydrogen-bonded hydroxyl group, as seen by a very broad absorption band extending from 3000 cm^{-1} to as low as 2300 cm^{-1}. The presence of a phenolic OH group in close proximity to a COOH group favours strong hydrogen bonding, which is known to stabilize the carboxyl ionized species as well as the phenolic unionized species quite considerably, the carboxylic group thus becoming more acidic and the phenolic less acidic than expected. The log K_{OH}(H) value of the dye (10.67) is comparable with that of *para*-cresol (10.26) (6), from which the dye is obtained by substituting the azo group in the *ortho* position. Normally, the effect of the azo group is electron withdrawing, being comparable to that of the nitro group. Therefore, the log K_{OH}(H) value of the dye may be expected to be about 2 units lower than that of *p*-cresol. The reason for the value actually being higher, instead of lower, is obviously the strong hydrogen-bonded character of the phenolic group.

(B) *Metal stability constants*

The data obtained in the present work are in full conformity with the Irving−Williams order (1) for the stability sequence of bivalent metal ions. UO_2^{2+} does not belong to the Irving−Williams series. The value for UO_2^{2+} obtained is lower than that of Cu(II) (see Table 1). This is in agreement with what has been reported in the literature for other ligands (9, 10).The lowest value of the metal stability constant has been obtained for Zn^{2+}, which is due to lack of bonding through the azo group of the dye. This has been confirmed from the ir spectrum of the solid complex. The spectrophotometric study, reported herein, shows no evidence at all for the formation of any 1:2 complexes in solution. Moreover, when a large excess of ligand is added to the solution of any of these metal ions, the absorbance throughout the recorded range is exactly the same as that calculated by the additivity rule, on the basis of the formation of 1:1 complex and the excess ligand remaining uncombined. Hence, only 1:1 complexes exist in solution. This has also been confirmed from conductance studies by Job's method of continuous variations (11). Infrared ir spectral studies provide evidence for the participation of the —N=N— group in complexation and hence the lack of formation of 1:2 species in solution due to steric factors.

Conductance and infrared spectral studies

The solid complexes of 2-hydroxy-5-methylazobenzene-2′-carboxylic acid with the metal ions reported herein are coloured, and are insoluble in organic solvents, viz., carbon tetrachloride, chloroform, benzene, and alcohol, but soluble in dimethylformamide and sodium hydroxide. Their molar conductances in dimethylformamide solution are low, indicating them to be nonelectrolytes.

The infrared spectra of Mn(II), Fe(II), Co(II), Ni(II), Cu(II), and UO_2^{2+} complexes show the disappearance of the band in the region 950 cm^{-1}, suggesting removal of proton from the ligand. The ν(C=N) shifts to the low-frequency region in all but the Zn(II) complexes, indicating coordination through the nitrogen atom of the azo group. Mn(II) and Co(II) complexes show a very broad band in the region 3000−3400 cm^{-1}, indicating the presence of water molecules in the complexes. In order to complete the octahedral stereochemistry of the complexes, one or two water molecules have to be coordinated to the metal ions. The UO_2^{2+} complex shows a strong but broad band at 900 cm^{-1}, which may be assigned to ν(asy. O—U—O) (12−16).

Absorbance and diffuse reflectance spectra

The absorption spectrum of the dye was recorded using dimethylformamide as the solvent. Two bands near 30 kK and 20 kK were observed which may be assigned to $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions, respectively, and are characteristic of the azo group (17).

The diffuse reflectance spectrum of the Co(II) − 5-methyl dye complex having bands in the region 10−10.65 kK (ν_1) may be assigned to the transition $4T_{1g}(F) \rightarrow 4T_{2g}(F)$. The band at 21−24 kK is due to $4T_{1g}(F) \rightarrow 4T_{1g}(P)$ (ν_3 transition). It is difficult to assign for the transition (ν_2) $4T_{1g}(F) \rightarrow 4A_{2g}(F)$ since this band and the ligand $n \rightarrow \pi^*$ transitions are expected in the same region.

Crystal field parameters Dq, B, and β have been calculated with the help of secular determinant (20) and are 1175 cm^{-1}, 909 cm^{-1}, and 0.812, respectively. The value of B in the free ion has been taken to be 1120 cm^{-1} from the literature (18). These values of crystal field parameters for the Co(II) complex with the 5-methyl dye can be compared with the values reported by Pappalarado and Seminora (19) for the high-spin octahedral Co(II) complexes.

The diffuse reflectance spectrum of the Ni(II) complex with the 5-methyl dye was studied in the range 265–1200 nm. Three bands in the region 9–30 kK were obtained. A lower energy band obtained near 10 kK can be assigned to the (ν_1) $3A_{2g}(F) \rightarrow 3T_{1g}(F)$ transition (ν_2). The ratio ν_2/ν_1 lies between 1.6 and 1.8. A third band near 19 kK may be assigned to the $3A_{2g}(F) \rightarrow 3T_{1g}(P)$ transition (ν_3) for an octahedral Ni(II) complex (21).

The complex of the 5-methyl dye with Fe(II) shows bands around 11.10 kK which may be assigned to $5T_{2g} \rightarrow 5E_g$ transitions. Other bands may be assigned to $n \rightarrow \pi^*$ or charge-transfer transitions of the ligand. A comparison of the spectrum of the 5-methyl dye and its complex with Fe(II) indicates that, after complexation, λ_{max} of the ligand shifts to the longer wavelength region.

The spectrum of the UO_2^{2+} complex generally shows well-defined vibronic structure between 21 280 and 30 300 cm^{-1} (19). In the present study, the complex shows two bands at 27 030 and 20 410 cm^{-1}. The latter band might be due to a ligand → metal charge-transfer transition. The Mn(II) complex exhibits bands around 29.41 and 19.23 kK. The Zn(II) complex is diamagnetic. The solution spectra of these complexes in dimethylformamide are similar to their diffuse reflectance spectra and so these complexes may have octahedral geometry.

Magnetic susceptibility measurements

The magnetic susceptibility measurements at room temperature were carried out by Gouy's method (see refs. 18 and 22). Magnetic data of the complexes of the azo dye with bivalent metal ions, viz. Mn(II), Fe(II), Co(II), and Ni(II) are 5.75 BM, 5.45 BM, 5.25 BM, and 3.20 BM, respectively. These magnetic moment values suggest octahedral geometry for the complexes of these bivalent metal ions.

Applications of the 5-methyl dye

This dye has been used as a metal-ion indicator in titrimetric determinations of various metal ions and also in the spectrophotometric determination of Th(IV).[3]

Laser-induced addition of hydrogen fluoride to unsaturated molecules: the HF + CH_2CF_2 system

WALTER H. BECK[1] AND GEORGE BURNS

Lash-Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received January 27, 1984

WALTER H. BECK AND GEORGE BURNS. Can. J. Chem. **62**, 2302 (1984).

Although certain classes of reactions are known to occur via 4-centre transition states, there has been no irrefutable proof that in the gas phase addition reactions also proceed via a 4-centre concerted process. Results of recent information theory calculations on the HF(v) + CH_2CF_2 system indicate that it should be possible to observe reaction products for HF(v = 5). Results are presented here on experiments attempting to achieve laser-induced 4-centre addition of HF to several unsaturated molecules (C_2H_2, C_2H_4, C_4H_6, CH_2CF_2, and CF_2CClF). A mixture of HF and co-reactant was irradiated by a dye-laser tuned photo-acoustically to the fifth vibrational level of HF, and the resulting mixture was analysed by gas chromatography and mass spectrometry. There was no evidence of any laser-induced products. An upper bound was deduced for the HF + CH_2CF_2 addition rate constant at 610 K: $k_r^{610} < 1 \times 10^8$ L mol^{-1} s^{-1}.

WALTER H. BECK et GEORGE BURNS. Can. J. Chem. **62**, 2302 (1984).

Même si on sait que certaines réactions se produisent par l'intermédiaire d'un état de transition à 4 centres, il n'existe aucune preuve irréfutable que les réactions d'addition en phase gazeuse se produisent également par l'intermédiaire d'un processus concerté à 4 centres. Des résultats récents, obtenus par des calculs basés sur la théorie de l'information et réalisés sur le système HF(v) + CH_2CF_2, indiquent qu'il devrait être possible d'observer des produits de réaction pour HF(v = 5). On rapporte les résultats d'expériences effectuées en vue de réaliser une addition à 4 centres, induite au laser, du HF sur diverses molécules insaturées (C_2H_2, C_2H_4, C_4H_6, CH_2CF_2 et CF_2CClF). On a irradié les mélanges de HF et de ses co-réactifs à l'aide d'un laser ajusté d'une façon photoaccoustique jusqu'au cinquième niveau vibrationnel du HF et on analysé les mélanges réactionnels obtenus en faisant appel à la chromatographie en phase gazeuse et à la spectrométrie de masse. On n'a pas pu mettre en évidence la présence de produits provenant d'une réaction induite au laser. On a déduit une limite supérieure pour la constante de vitesse d'addition de la réaction HF + CH_2CF_2, à 610 K: $k_r^{610} < 1 \times 10^8$ L mol^{-1} s^{-1}.

[Traduit par le journal]

Introduction

There is still much conjecture regarding the mechanism of the addition of hydrogen halides HX to unsaturated molecules in the gas phase (1). The reaction can be either a single-step, concerted process, proceeding through a 4-centre transition state, or can proceed via a chain mechanism made up of many separate steps, each of which is a bimolecular reaction involving atoms and radicals as intermediates (2, 3). The former process obviously leads to just one end-product, whereas the latter can produce several, depending on the complexity of the reactants. Determination of the addition reaction product/s would therefore be useful in determining the mechanism of reaction.

The existence of 4-centre reactions has been clearly demonstrated for certain classes of reactions: exchange reactions between alkali halides (4) and between isotopically labelled nitrogen oxides (5), ion/molecule reactions (6), and certain free radical reactions (7). On the other hand, what was once considered the classic example of a 4-centre concerted process, the H_2/I_2 reaction (2), has been shown by Sullivan (8) to be made up of a series of bimolecular atom/radical reactions.

Since the pioneering work of Farkas and Farkas (9) on the H_2 + H_2 exchange reaction, there has been a continual refinement in experimental (mainly shock tube) methods to attempt to elucidate the analogous D_2 + H_2 reaction. Measured activation energies (around 40 kcal mol^{-1} (10)) have typically been well below the expected value of 88 kcal mol^{-1} (11) for dissociation of H_2 by Ar, and even smaller than H—H bond energy (103.4 kcal mol^{-1}). This finding was taken to indicate that the reaction must proceed by some mechanism (such as 4-centre concerted) other than H_2 bond rupture as the first step. By monitoring H atom concentrations in shock-heated H_2/D_2 mixtures, Lifschitz and Frenklach (12) found that only a small proportion of their HD yield arose from H atom reactions, and that the remainder originated from a 4-centre bimolecular reaction with an activation energy of 38 ± 5 kcal mol^{-1}. However, since then, the experiments have been repeated in an ultra-clean shock tube (13) and the results have disproved the 4-centre mechanism. It was shown that the previous spurious results were due to minute impurities (probably hydrocarbons) leading to false interpretations of the role of H atoms in the mechanism.

Based on simple geometric considerations, it does not seem unreasonable for hydrogen halides to add to unsaturated molecules via a 4-centre transition state. Experimental addition reaction studies have so far been largely restricted to HI, since HF, HCl, and HBr in general require very high temperatures and pressures for reaction to occur. HI was found to add to several olefins (14, 15), butadiene (15), and other conjugated dienes (14, 16). Benson and Egger (14) found that the activation energy E_a for addition of HI to dienes was lower than that to olefins, and explained this result using the Benson and Bose model (17) of a 4-centre transition state. Kubota (15) obtained the same trend, but by invoking Woodward–Hoffmann symmetry rules (18), decided against a 4-centre transition state for addition of HI to butadiene. This conclusion is also backed by Gorton and Walsh (16), who favour a 6- over a 4-centre transition state.

Elimination of HX (the reverse reaction to addition) has been extensively studied using various techniques. Tschuikow-Roux co-workers (19) and Trotman-Dickenson and co-workers (20) have used the shock tube techniques to determine E_a for elimination of HF from various alkyl and ethylene fluorides. E_a values were found to be higher than those for elimination of HCl, HBr, HI from their corresponding alkyl halides, which is in agreement with the findings mentioned above on the HI

[1]Present address: Weapons Systems Research Laboratory, Defence Research Centre, Salisbury, South Australia.

addition reactions.

In a classic paper on HF elimination, Clough *et al.* (21) used the combination–elimination reaction

$$CH_3 + CF_3^{\ddagger} \rightarrow CH_3CF_3 \rightarrow CH_2CF_2 + HF\dagger$$

and the mercury-sensitized reaction

$$CH_2CF_2 + Hg^* \rightarrow CHCF + HF + Hg$$

to show that HF is produced rotationally and vibrationally (up to $v = 4$) excited. This effect was first observed by Berry and Pimentel (22), who monitored HF laser emission following uv photo-elimination of HF from CH_2CFH. Since then, Pimentel and co-workers (23) have succeeded in producing HF rotational chemical lasers via a similar flash-induced dissociation of CH_3CF_3 and CH_2CF_2.

The above uv photolytic methods are totally non-selective in that it is not even certain which alkyl halide transition is being excited to produce the reaction. The advent and development over the last 5–10 years of the ir multi-photon absorption (IRMPA) technique (24) has made it possible to gain higher selectivity in choosing which transition of the alkyl halide is excited. Moore and co-workers (25) used an optical parametric oscillator (3.3 μm) and a CO_2 laser (10 μm) to excite the CH stretching modes of ethyl chloride, bringing about the HCl photo-elimination reaction. Dissociation yields were measured as a function of laser fluence and wavelength. Jang and Setser (26) further studied the effect of added inert gas on dissociation yields from IRMPA of CH_3CH_2F and CH_3CF_3. They also observed only a single product (apart from HF) from the elimination reaction, indicating that it occurs via a concerted process. The same conclusion was reached by Steinfeld and co-workers (27) in their study of IRMPA of vinyl chloride using a CO_2 laser, followed by the elimination reaction.

In a molecular beam experiment, Lee and co-workers (28) studied the 4-centre unimolecular elimination of HCl from CH_3CCl_3, CH_3CF_2Cl, and $CHClCF_2$ using the IRMPA technique, and found that the combined energy of the two resulting species was only 20% of the barrier for the back (addition) reaction, suggesting that the energy deficit must be contained as internal (vibrational/rotational) energy of the species.

There is, of course, still a problem of non-selectivity using the IRMPA approach. Specifically, it is unclear what is the internal energy distribution of the reacting molecules when excited by the laser. Moore and co-workers (25) and Steinfeld and co-workers (27) were able to explain their results using a statistical approach, the molecular internal energy distribution being represented by a non-specific-mode model, and the reaction rates being calculated by RRKM approach which assumes a rapid attainment of microcanonical internal equilibrium of the molecule prior to reaction. More rigorous master equation calculations (29) for IRMPA confirm the above; Steinfeld and co-workers (27) based their statistical model on these approaches.

The production of vibrationally and rotationally excited HX from elimination reactions strongly suggests on the basis of the principle of microscopic reversibility that the excitation of HX (or the olefin?) may help accelerate the reverse addition reaction. Intuitively this seems logical, since it is the HX bond which will need to be broken, and more energy put selectively into this bond should accelerate the reaction.

The effect of vibrational excitation on reaction rate has been clearly shown. Very large enhancements have been determined for the atom/molecule reactions

$$D + H_2 \xrightarrow{k_v} HD + H, \text{ where } k(v = 1)/k(v = 0) > 10^4 \quad (30)$$

and for

$$H + HF(v) \xrightarrow{k_v} H_2 + F, \; k(v = 1)/k(v = 0) \simeq 5 \times 10^8 \quad (31)$$

Although no enhancement was found for the $HF(v)/D_2$ exchange reaction (1), presumably because the $HF(v)$ relaxation rate is too large relative to the reaction rate, a 4-centre concerted process could still not be ruled out.

Indirect evidence for vibrational enhancement for a molecule/molecule reaction came from the results of Horiguchi and Tsuchiya (32), who irradiated HI and HI/CO_2 mixtures with a CO_2 laser, and found an increased rate for the reaction

$$HI + HI \rightarrow H_2 + I_2$$

when CO_2 was present. This was said to be due to the near-resonant energy transfer from the excited CO_2 to the HI,

$$CO_2(001) + HI(v = 0) \rightarrow CO_2(000) + HI(v = 1)$$

followed by reaction between $HI(v = 1)$ and $HI(v = 0)$. An earlier molecular beam study on the HI + DI reaction made use of a seeded HI beam to raise the centre-of-mass (viz. translational) energy to as high as 110 kcal mol^{-1} (which lies well above the expected 4-centre concerted process activation energy of 44 kcal mol^{-1}), but still no reactive HD was detected (33). The relative importance of vibrational as against translational energy in the HI/DI system was thus clearly demonstrated.

The possibility of laser-induced, specific-mode reactions between HX and an olefin has been discussed by Marling *et al.* (34), and has been tested experimentally by several groups (35–38). Bauer (35) attempted to react vibrationally excited HF ($v = 1$, using a HF laser) with various substituted olefins and acetylene, while Herman and Marling (36) excited the $v = 5$ or 6 overtone of HCl and also the fourth overtone of the C_2H_2 asymmetric CH stretch in an attempt to obtain an addition reaction: both studies failed to show any laser-induced reaction. Berry (37) claimed to have found reaction between 2-methylpropene and HCl ($v = 5$, intra-cavity laser study), but there were no subsequent reports confirming this. Hager *et al.* (38) studied the deactivation by HBr of vibrationally excited C_2H_2 (01000), and concluded that the low collision number obtained for its relaxation could be interpreted as incipient chemical reaction.

The dominant process in all the above studies was the far greater rate of the inter- and intra-molecular relaxation of the laser-excited species compared to its reaction rate. If these relaxation processes could be slowed down, such as in a solid gas matrix where the rotational and translational modes are frozen out, then the reaction may be able to compete favourably with relaxation. In a very recent study, Frei and Pimentel (39) irradiated frozen mixtures of F_2, C_2H_4, and an inert gas over the range 1000–4000 cm^{-1}, and used FTIR spectroscopy to monitor the appearance of products. They described their results in terms of a 4-centre addition of F_2 to C_2H_4. Although the nature of their irradiation does not strictly correspond to single mode excitation, they claim that small peaks in their quantum yield versus wave number plots occurring at certain vibration combination modes indicate that excitation of these modes must lead to enhancement of reaction.

Assuming that the addition and elimination reactions do occur via a 4-centre transition state, it is possible to relate their

activation energies E_a via the reaction enthalpy change ΔH_T^0 as shown in Fig. 1. E_a^{el} for elimination of HX from several halogenated olefins has been measured by several workers (19, 40), enabling E_a^{ad} for the reverse addition reaction to be estimated (34). Direct measurements of E_a^{ad} for HI (14–16) and HCl (41–43) additions are also available. Several attempts have also been made to calculate theoretically E_a^{ad} for a 4-centre concerted process using a semi-empirical model based on bond order conservation (17, 44, 45). Some typical experimental and theoretical values of E_a^{ad} are presented in Table 1. Note that there is a general trend of E_a^{ad} decreasing down and across the table; this explains why most experimental studies on (non-mode-specific) addition reactions have been carried out with HI.

In the case of HF additions, even the reaction HF + CH_2CF_2 with the lowest value of E_a^{ad} (35.5 kcal mol^{-1}) still has a vanishingly small thermal rate. Figure 1 shows that if HF can be excited to a sufficiently high vibrational level, then its energy will be above the activation barrier E_a^{ad}. At this stage it is still not known how effective the HF vibrational excitation is in overcoming this barrier, although results on vibrational distribution in HF elimination reactions may provide a clue.

Berry (46) has concluded that of the total energy E_{tot} (= E_a^{el} = E_a^{ad} + ΔH_T^0; Fig. 1) available to the elimination reaction products, only about 15–40% ends up in HF vibration. This is confirmed in the detailed dynamical calculations of Kato and Morokuma (47), who examined the mechanism of energy disposal along the reaction pathway for the elimination reaction

$$CH_3CH_2F \rightarrow CH_2CH_2 + HF$$

~30% of E_{tot} ended up in HF vibration. One further important dynamical aspect arises from their calculations; at short distances (along their reaction coordinate) from the transition state, most E_{tot} is in the HF stretching mode, but as the distance increases, energy is lost very rapidly from this mode, being transferred largely to the HF – CH_2CH_2 relative translation "mode". These results suggest that for the reverse addition reaction, vibrational excitation alone is not sufficient to overcome the reaction barrier, but relative translational energy may also be important. This idea has been discussed before (36). On the other hand, the results of Clough *et al.* (21) on the CH_3CF_3 elimination reaction showed that most of E_{tot} ended up in HF *and* CH_2CF_2 internal energies, suggesting that excitation of *both* HF and CH_2CF_3 may be necessary to accelerate the reverse addition reaction. The question is still an open one.

Levine and co-workers (48) have used an information theoretic approach to predict the energy disposal for several elimination reactions, and using detailed balance have calculated vibrational enhancement factors for the reverse addition reactions. Their results for HF at 600 K are summarized in Table 2. When one considers that typical frequency factors for addition reactions are about 10^8 L mol^{-1} s^{-1} (34), then even with enhancement factors as large as $2 \times 10^{10} - 7 \times 10^{13}$, it is clear from the table that there is only one reaction system with an appreciable rate—CH_2CF_2 + HF. (Note from Table 1 that this reaction also has one of the lowest activation energies.)

*All data taken from ref. 48, Table 1, p. 2685.

The results of the above two theoretical approaches were published after Bauer's and Marling's first attempts to obtain a laser-enhanced reaction. Marling *et al.* (34, 36) studied HCl(v = 5, 6) + various olefins (but not CH_2CCl_2), and Bauer (35) attempted HF(v = 1) + CH_2CF_2, but neither has studied the system HX(v = 5) + CH_2CX_2 (X = F or Cl).

The aim of this report is to present results of experimental studies on this reaction, and also on the related HF(v = 5) + C_2H_2, C_2H_4, C_4H_6 (1,3-butadiene), and CF_2CClF systems. Assuming the reaction to be a 4-centred concerted process, the results also present a useful test of the predictive ability of information theory as applied to HX/olefin addition reactions.

Experimental method

The schematic of the experimental apparatus is shown in Fig. 2. The laser output was passed through the reaction cell containing the test gas mixture (HF + co-reactant) and then through a spectrophone cell used to tune the laser to the required HF transition.

The P(2) line of the HF(v = 5 ← v = 0) transition (563.6 nm) was excited using a Rhodamine-6G dye pumped by a Nd:YAG laser (Quanta Ray PDL-1 Dye Laser System). Laser pulses were typically 5 ns wide at an energy of 25–30 mJ, and by means of an intra-cavity high-finesse pressure-tuned etalon attained a linewidth of 0.15 cm^{-1}.

The reaction vessel was a 1.5 m length of 1.3 cm id SS316 tubing fitted at both ends with sapphire windows set at Brewster's angle. The whole gas handling system which came into contact with the test gases was also constructed of stainless steel. The cell could be heated by means of two heating coils wrapped around it — the temperature was estimated to be constant (up to 350°C) over at least 80% of its length by direct measurement at its centre using a thermocouple. The cell and remaining gas system were pumped down to 10^{-4} Torr for at least a day before each new experiment.

The spectrophone was constructed from a 25 cm length aluminium block with a 1.3 cm hole bored lengthways through it, and was again fitted with sapphire windows at Brewster's angle. A Bruel and Kjaar 4144 Microphone was mounted vertically so that it was just recessed from the bore. The output from the microphone was magnified by about a factor of 10 using a high-impedance low-capacitance amplifier, and then displayed on an oscilloscope. Typical signals were 10 mV at a HF pressure of 30 Torr, and with a laser pulse energy of 6 mJ.

The HF gas was frozen into vessel 8 at 77 K, and was pumped on for 15–20 min to remove any non-condensable gasses (e.g. H_2) present. After thawing, the gas was re-frozen in the same vessel with a dry ice/acetone mixture (195 K), and was further pumped for 1 min through another trap (vessel 7) at 77 K. Vessel 8 was then opened to a further vessel 9 at 77 K, and allowed to distil over a period of 30–40 min. After further pumping down of the distillation vessel 9 while still at 77 K, the gas was allowed to thaw slowly. This fractional distillation procedure gave good separation of HF and H_2O vapour (at 195 K, the equilibrium vapour pressures of HF and H_2O are 1–5 Torr and $4 - 10^{-4}$ Torr, respectively, so that a separation of at least 10^4:1 was possible). Other gasses (C_2H_2, purified, 99.6% min; C_2H_4, research purity, 99.99% min; C_4H_6, also research purity, 99.9% min; CH_2CF_2 and CF_2CClF, both research purity) were taken directly from their container (lecture bottle) without further purification. It was assumed that the purity of the gasses is sufficiently high and that any residual gasses are present in too low concentration to affect the course of the reaction. These impurities could not be detected in our gas chromatographic and mass spectrometric experiments.

A summary of the experimental procedure is as follows:

(*1*) HF gas distilled;

(*2*) HF added to spectrophone cell, laser tuned to HF transition (without any gas in the reaction vessel) by adjusting pressure in the pressure-tuned etalon;

(*3*) HF and co-reactant gas added to mixing vessel with HF added first, and left to mix for 15 min;

(*4*) laser warmed up (maximum energy and stability were obtained after a warm-up period of 5–10 min), tuning re-checked, gas mixture

added to pre-heated reaction cell and irradiated for appropriate time period;

(*5*) gas mixture frozen out directly from reaction vessel to Pyrex sample flasks cooled to 77 K;

(*6*) blank run carried out with freshly-prepared gas mixture, procedure as above repeated except laser de-tuned off HF transition by lowering pressure in the pressure-tuned etalon. (This procedure differs from that of Herman and Marling (36), who did not irradiate their blank);

(*7*) laser retuned, and experiment repeated;

(*8*) contents of flasks analysed by gas chromatography (Varian V1700 Gas Chromatograph with Porapak-Q column and flame ionization detector) and/or mass spectrometry. The sensitivity of both methods was tested with a series of dilutions of CH_2CF_2 in C_2H_2 — gas chromatography provided semi-quantitative separation down to 0.1%, while mass spectrometry could detect 0.01% dilutions.

Mixtures of HF + co-reactant in proportions ranging from 1:1 to 1:5, at pressures of 25−900 Torr and temperatures 295−630 K were irradiated for periods from 10−40 min.

Results

The experimental results are summarized in Table 3. Note that most runs involved the HF + CH_2CF_2 systems, and that most but not all runs were at 610 K.

Although reaction products were observed in several experiments, there was no evidence for any laser-induced reaction product. Run XII did produce a mass spectrometric signal at 69 m/e (the expected product of the HF + CH_2CF_2 addition reaction is CH_3CF_3, whose cracking pattern shows the largest peak at 69 m/e due to the CH_3 radical), but no blank run was available for comparison. Under other similar (or even more conducive) conditions (e.g. run XVIII), there was no product. Several runs (XV) at high temperature and pressure did yield significant product yields (up to 12%), but these were shown by gas chromatographic separation not to be the desired product, but rather longer chain species most likely due to wall or thermal chain reactions. They were not further identified, but experimental conditions after these runs were controlled to prevent these reactions from occurring. There were two cases (XVI and XVIII) where there did appear to be a laser-enhanced effect: gas chromatographic analysis of products showed a doubling of relative product yield for the laser-tuned case. These results could not be further reproduced (see run XIX, or even runs XX and XXI).

Discussion

In order to explain the apparent lack of any detectable laser-enhanced effect, it is necessary to examine in more detail the processes occurring in the irradiated gas mixture. Since most attention has been given to the HF + CH_2CF_2 system, it will be used as the example in the following model calculation. The procedure adopted will be as follows: calculate the proportion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

of HF(v = 5); set up a model describing the fate of these HF; develop an expression for the yield of product (i.e. CH_3CF_3); using available data on HF relaxation rates, estimate an upper bound for the HF + CH_2CF_2 reaction rate constant.

Proportion of HF (v = 5)

Although the calculation for the HF(v = 5) level has been given elsewhere (49), it will be repeated here since some experimental conditions may be different.

HF transition: $\nu_0 = 17743\ cm^{-1}$ (= 5.3192×10^{14} Hz)
Laser bandwidth: $\Delta\nu_0 = 0.15\ cm^{-1}$ (= 4.5×10^9 Hz)
Laser power: $P = 5.4$ MW
Laser pulselength: $\Delta t = 5 \times 10^{-9}$ s
Laser beam area: $A_c = 3.3 \times 10^{-5}\ m^2$
Reaction vessel length: $l_c = 1.5$ m
Reaction volume: $V_c = 2.00 \times 10^{-4}\ m^3$
HF pressure: $P_{HF} = 25$ Torr

From the above, one calculates:

Total HF concentration:
$$[HF]_{tot} = P_{HF}/RT = 3.96 \times 10^{20}\ m^{-3} \text{ (at 610 K)}$$
Total number of HF: $HF_{tot} = [HF]_{tot} V_C = 7.92 \times 10^{16}$
Concentration of $HF^{J=2}_{v=0}$: $[HF]_0^2 = 0.25[HF]_{tot} = 9.90 \times 10^{19}\ m^{-3}$

Laser flux per unit bandwidth is given by:

$$\frac{\phi}{\Delta\nu_o} = P/h\nu_0 \cdot 1/A_C \cdot 1/\nu_0 = 1.026 \times 10^{26} \text{ photons } m^{-2}$$

The absorbed flux is then:

$$-\Delta\phi = \frac{\phi}{\Delta\nu_0} \cdot l_C \cdot [HF]_0^2 \cdot A_{0\leftrightarrow 5} \cdot (2J' + 1)/(2J'' + 1) \times c^2/(8\nu^2_0)$$

where $A_{0\leftrightarrow 5} = 7.697 \times 10^{-3}\ s^{-1}$ is the Einstein coefficient for the transition (50).

Hence

$$-\Delta\phi = 2.078 \times 10^{24} \text{ photons } s^{-1}\ m^{-2}$$

The number of HF(v = 5) produced is

$$HF(v = 5) = -\Delta\phi \cdot \Delta t \cdot A_C = 3.447 \times 10^{11}$$

Lastly, the proportion of HF(v = 5) is

$$HF(v = 5)/HF_{tot} = 5.66 \times 10^{-6}$$

The model

Once formed, HF(v = 5) can either react with CH_2CF_2 to form products, or be relaxed by CH_2CF_2 or HF(v = 0) to lower vibrational levels:

Reaction

[I] $HF(v = 5) + CH_2CF_2 \xrightarrow{k_r^T} CH_3CF_3$

Relaxation ([II] + [III])

[II] $HF(v = 5) + CH_2CF_2 \xrightarrow{k_v^T} HF(v < 5) + CH_2CF_2$

[III] $HF(v = 5) + HF(v = 0) \xrightarrow{k_s^T} HF(v = 4) + HF(v = 1)$

Relaxation by radiative means has been neglected. Note that step [III] is not meant to imply a resonant energy transfer process (the energy deficit is about 662 cm^{-1} (51), but rather a generalized self-relaxation of HF. Further, although HF(v = 4) in step [III] could in principle also react with CH_2CF_2, its rate is predicted to be 100 times slower than with HF(v = 5) (48) — for this reason, only HF(v = 5) reactions are considered.

Product yield calculation

For the reaction steps above, it is possible to write two rate expressions, one for relaxation, one for reaction:

$$\text{Relaxation rate} = \{k_v^T \cdot [CH_2CF_2] + k_s^T \cdot [HF]_{tot}\} \times [HF(v = 5)]$$

$$\text{Reaction rate} = k_r^T \cdot [CH_2CF_2] \cdot [HF(v = 5)]$$

The relative rate is then:

[1] $$R = \frac{k_r^T}{k_v^T + k_s^T \cdot [HF_{tot}/[CH_2CF_2]}$$

Now let $\alpha = [HF(v = 5)]/[HF]_{tot}$, m = number of laser flashes, $\beta = [HF]_{tot}/[CH_2CF_2]$; then it is straightforward to derive an expression for the yield Y of product, expressed as a percentage of $[CH_2CF_2]$:

$$Y = 100mR\alpha\beta \qquad (\%)$$

Inserting typical values for an experimental run:

$m = 12000$
$\alpha = 5.66 \times 10^{-6}$ (see previous calculation)
$\beta = 0.5$

and taking $Y = 0.01\%$ as the experimental limitation on sensitivity (see experimental section), we get

[2] $$R \Leftarrow 0.00294$$

Hence, even if reaction rate [I] is a factor of 340 (i.e. 1/0.00294) slower than the combined relaxation rate ([II] + [III]), it should still be possible to detect the reaction product. Since no product was detected, the above expression can be used to set an upper bound to k_r^T, providing the relaxation rate constant k_v^T and k_s^T can be reasonably accurately estimated. This will now be considered.

HF relaxation studies

The self-relaxation of HF for v = 3, 4, 5, has recently been measured directly by a laser-excited vibrational-overtone fluorescence study in the temperature range 295–670 K (52). A value for HF(v = 5) relaxation, $k_s^{610} = 4.5 \times 10^{10}$ L mol^{-1} s^{-1} was obtained. This is about a factor of 10 faster than a value obtained by Kwok and Wilkins (53) of 5.2×10^9 L mol^{-1} s^{-1} at 298 K. Relaxation of HF(v = 5) by CH_2CF_2 has not been measured yet, although work on HF relaxation continues in this laboratory. Poole and Smith (40) measured the relaxation rate of HF(v = 5) by CH_4 to be 1.8×10^{10} L mol^{-1} s^{-1} (at 298 K), while relaxation of HF(v = 4) by isobutene was measured by Moore (54) to have an extremely fast rate, 9×10^{10} L mol^{-1} s^{-1}. In view of the above, values of $k_s^{610} = 1 \times 10^{10}$ L mol^{-1} s^{-1} and $k_v^{610} = 5 \times 10^{10}$ L mol^{-1} s^{-1} were adopted.

Reaction rate constant k_r^{610}

Using the above values, an upper limit for k_r^{610} can be calculated from [1] and [2]:

$$R = \frac{k_r^{610}}{k_v^{610} + k_s^{610} \cdot \beta} \Leftarrow 0.00294$$

Hence

$$k_r^{610} \Leftarrow 1 \times 10^8 \text{ L mol}^{-1} \text{ s}^{-1}$$

The gas kinetic collision rate for HF:HF is about 5×10^{11} L mol^{-1} s^{-1} (55), so that less than one in every 5000 collisions can lead to reaction — on the other hand, one in every 10 collisions leads to relaxation. Herman and Marling (36) also arrived at a similar conclusion for the addition reactions of HCl($v = 6$) + olefin, the rate constants being $10^{-1}-10^{-3}$ of the pre-exponential factor (i.e. collision number) for the corresponding thermal reaction.

Levine (48) arrived at a value of $k_r^{610} = 7.3 \times 10^6$ L mol^{-1} s^{-1} (see Table 2), so if a correction factor is applied to allow for the difference in temperature, $k_r^{610} = 1.5 \times 10^7$ L mol^{-1} s^{-1}. This value is in substantial agreement with the trend for k_r^{610} obtained here experimentally, there being approximately an order of magnitude difference between them. Although the results can neither confirm nor disprove the information theory predictions, they do indicate that if a factor of 10 increase in reaction rate, product yield, or product detection sensitivity could be attained, then according to the theory it should be possible to observe a laser-enhanced effect. By exciting HF($v = 6$ 480.4 nm), the addition reaction rate enhancement is 40 times larger, which more than offsets the factor of 10 lost in the term $A_{0\leftrightarrow 6}/\nu_0^2$ for the laser-excited transition (see Discussion). The further possibility of exciting both HF and CH_2CF_2 also remains, but this is not feasible in a bulk experiment if only such low proportions (1 in 10^5 for HF($v = 5$)) of the species are excited.

Conclusion

The present study on the addition reactions of HF to various unsaturated species was unable to detect any laser-induced 4-centre reaction. It was possible to deduce from these results an upper limit for the rate constant for the reaction HF($v = 5$) + CH_2CF_2, a value which supports (without confirming) information theory calculations of this system. The results also show that the failure to observe any reaction is almost certainly due to the very rapid relaxation rate of HF($v = 5$) compared to its reaction rate, and until these rates can be made more comparable, it is unlikely any reaction will be observed. This can be achieved either by increasing the reaction rate (such as by using HF($v = 6$), or by decreasing the relaxation rate (such as using cold gas matrices, or by "freezing" the HF in a combination laser/supersonic molecular beam experiment).

The solution phase photobromination of 2-bromobutane yields 2,2-dibromobutane, *meso*-2,3-dibromobutane, *dl*-2,3-dibromobutane, small amounts of 1,2-dibromobutane, and 2,2,3-tribromobutane. However, in the corresponding vapor phase bromination these products appear along with other polybrominated products. The yield of these polybromides increases with temperature. The increase in yield of the polyhalogenated materials is rationalized by considering the thermal instability of the β-bromoalkyl radical, which eliminates a bromine atom to form the corresponding alkene. It is demonstrated that in the vapor phase allylic bromination competes successfully with bromine addition. Reaction schemes are suggested to explain the formation of polybromides. An explanation is also offered for the discrepancy between these results and those of previously reported vapor phase work.

DENNIS D. TANNER, TOMOKO C. S. RUO, YOSHIO KOSUGI et ALAN POTTER. Can. J. Chem. **62**, 2310 (1984).

La photobromation en solution du bromo-2 butane conduit au dibromo-2,2 butane, au *méso*-dibromo-2,3 butane, au *dl*-dibromo-2,3 butane et à de petites quantités du dibromo-1,2 butane et du tribromo-2,2,3 butane. Cependant, lors de la bromation correspondante en phase gazeuse, ces produits sont accompagnés d'autres produits polybromés. Le rendement en produits polybromés augmente avec une augmentation de la température. On rationalise ce dernier résultat en faisant intervenir l'instabilité thermique du radical β-bromoalkyle qui élimine un atome de brome pour conduire à l'alcène correspondant. On démontre qu'en phase gazeuse la bromation allylique entre en compétition avec l'addition du brome. On suggère des mécanismes réactionnels pour expliquer la formation des dérivés polybromés. On avance aussi quelques suggestions pour expliquer les différences qui existent entre nos résultats et ceux rapportés antérieurement pour des bromations en phase gazeuse.

Introduction

The bromination of 2-bromobutane has been quite extensively studied.

The reaction was first investigated by Kharasch *et al.* (1) who used a "loop" reactor system which recycled the reactants; the products were separated by fractional distillation. The reaction was carried out at 100°C with a 2.5:1 ratio of 2-bromobutane/bromine. Although nominally a vapor phase reaction, the authors concede that this may have been a "wall reaction" and there may have been a fine mist of reactants in the reaction chamber. Five fractions were detected and attributed to: 2,2-dibromobutane (19%), *meso*-2,3-dibromobutane (22%), *dl*-2,3-dibromobutane (10%), a mixture of tribromides, mainly 1,2,3-tribromobutane (34%), and a mixture of tetrabromides (6%).

With the advent of gas–liquid partition chromatography (glpc) Tedder and co-workers (2–4) undertook a systematic study of the vapor phase halogenation of 1- and 2-halo-substituted butanes. A flow reactor system, developed primarily for highly exothermic fluorination reactions, was used to brominate 2-bromobutane at 146°C. One major product (almost 100% of the products detected) was reported, 2,2-dibromobutane. This result was in good agreement with the vapor phase brominations of 2-chloro- and 2-fluorobutanes (4). Here too, high yields of the α-bromo products were reported. These results were interpreted in terms of favorable resonance stabilization of the incipient α radical (3–5). Recently Tedder appears to have confirmed his earlier results in a static system (6).

The solution phase bromination of 2-bromobutane was first reported by Thaler (7). The products formed from a 5:1 molar ratio of 2-bromobutane/bromine at 60°C were reported as: 2,2-dibromobutane (16.3%), *meso*-2,3-dibromobutane (58.3%), and *dl*-2,3-dibromobutane (25.4%). The sharp contrast between Thaler's and Tedder's results has been noted (7, 8). In the same work (7), the solution phase bromination of 2-chlorobutane gave results which are in excellent agreement with Tedder's vapor phase work.

During the course of a study on the mechanism of the solution phase bromination of 2-bromobutane done in this laboratory (9), the vapor phase reaction was reinvestigated. A possible explanation of the current anomaly between vapor and solution phase results is offered.

Discussion and results

The results for a series of liquid phase photobrominations of 2-bromobutane carried out at different temperatures (−20 to 100°C) are shown in Table 1. In contrast to previous vapor phase work (4,6), five products were found: 2,2-dibromobutane, *meso*-2,3-dibromobutane, *dl*-2,3-dibromobutane, 1,2-dibromobutane, and 2,2,3-tribromobutane. The products were isolated by preparative glpc and were identified by a comparison of their ir, nmr, and mass spectra with those of authentic materials.

The product distributions at 0°, 30°, and 100°C in Table 1 are in good agreement with those reported previously for the liquid phase (60°C) bromination by Thaler (7) and by this group (−20 to 20°C) (9). The mechanistic study of the liquid phase photobromination (9) clearly contrasts with the vapor phase results reported by Tedder (6). The production of 2,2,3-tribromobutane can be attributed to the bromination of several of the product dibromides (see Scheme 1). Indeed, it has been shown with optical isomers and isotopically enriched bromine that the products found in the liquid phase are consistent with this scheme (9).

The liquid phase photobromination of 2-bromobutane

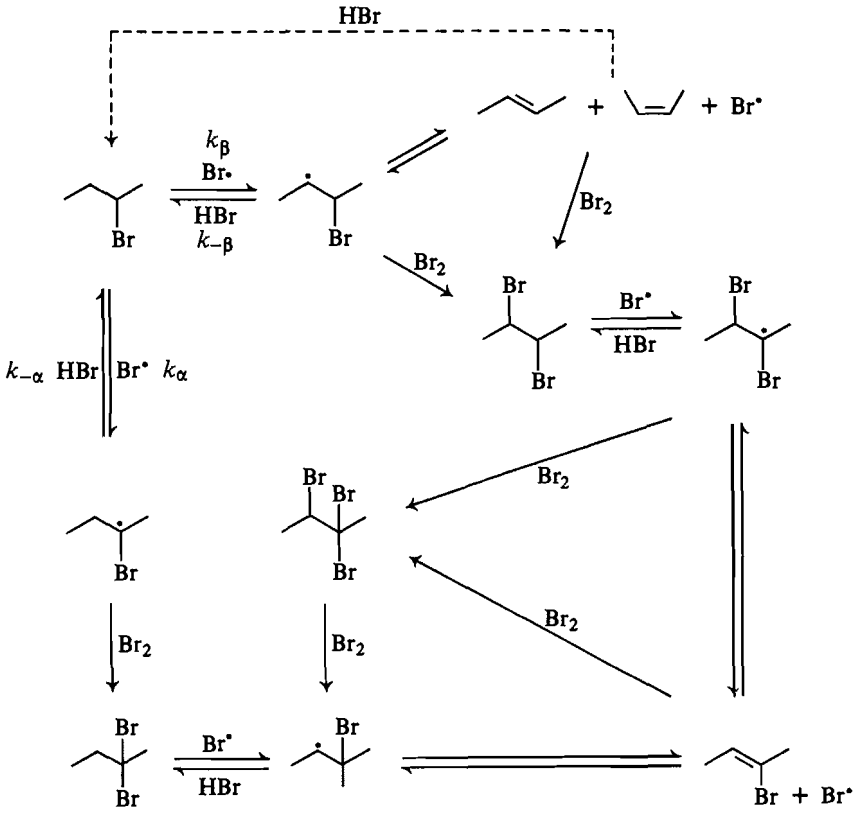

SCHEME 1

carried out at a series of increasing temperatures gives an apparently increasing yield of 2,2-dibromobutane, see Table 1. This can be accommodated by a reaction scheme in which there are two competing reactions that have diffeent activation energies, $E_\alpha > E_\beta$.

At low temperatures $k_\beta > k_\alpha$, but as the temperature rises k_α increases faster than k_β and the yield of 2,2-dibromobutane increases at the expense of the 2,3-dibromide.

Figure 1 shows a plot of the absolute yield of 2,2-dibromobutane vs. temperature. A straight line results; $Y = mT + C$, $m = 0.167$, $c = 5.42$, and the correlation coefficient = 0.981.

If it is assumed that the relative rates of formation of the

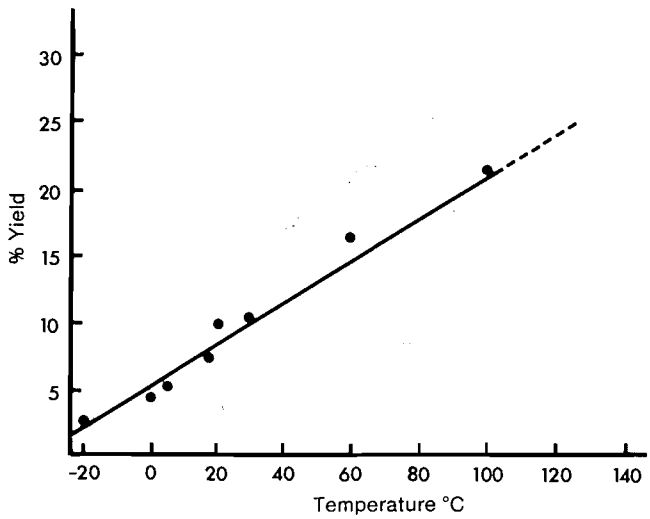

FIG. 1. Plot of % yield of 2,2-dibromobutane produced from the liquid phase photobromination of 2-bromobutane versus temperature.

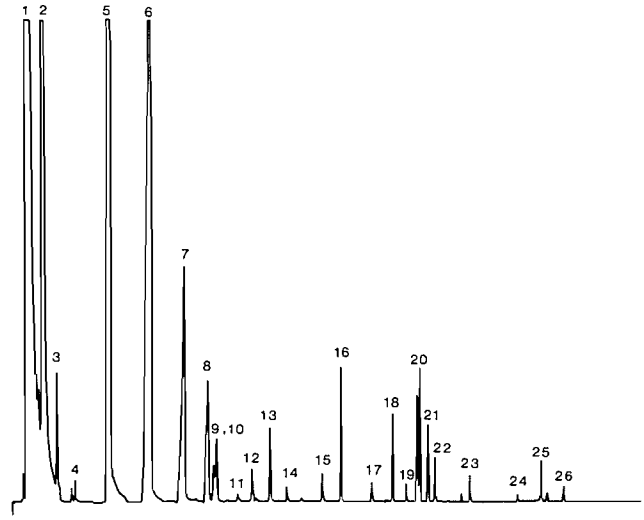

FIG. 2. Gas–liquid partition chromatogram of the reaction mixture obtained from the vapor phase photobromination of 2-bromobutane with molecular bromine, $T = 100°C$.

products in the liquid phase are the same as those in the vapor phase, then extrapolation of the plot predicts that a 30% yield of 2,2-dibromobutane would be expected at 146°C. This is contrary to the almost 100% formation of 2,2-dibromobutane reported by Tedder (4, 6).

In order to clarify these anomalous results the vapor phase bromination of 2-bromobutane was investigated at a series of temperatures in a static system (see Table 2). As well as 2,2-dibromobutane, *meso*- and *dl*-2,3-dibromobutane, many other brominated compounds were identified by gc/mass spectral analysis and, where possible, by comparison of their retention times with those of authentic materials. Capillary column glpc of the reaction mixtures indicated several distinct fractions of brominated materials (see Fig. 2).

The lowest boiling fraction contained three dibromides (2,2-dibromobutane, *meso*- and *dl*-2,3-dibromobutane) and a bromobutene (1-bromo-2-butene).

The intermediate fraction contained traces of two dibromides (1,2- and 1,3-dibromobutane) and six dibromobutenes (one of which was assigned the structure *trans*-1,4-dibromo-2-butene by a comparison of its glpc retention time with that of an authentic sample).

The highest boiling fraction revealed two tribromides, 2,2,3-tribromobutane and 1,2,3-tribromobutane, and five tribromobutenes. Traces of *meso*-1,2,3,4-tetrabromobutane and two other tetrabromobutanes were also indicated. A few other minor peaks were present but were not further characterized.

By using calibration factors determined for the di-, tri-, and tetrabromides on hand as representative values, a satisfactory material balance could be obtained for the brominations carried out at the elevated temperatures (see Table 2). These calculations were made assuming the addition of a bromine atom to the substrate consumed overall one bromine molecule and the formation of an allylic bromide also consumed overall one bromine molecule. Unknown peaks were determined using the calibration factor of the nearest known peak and assuming it was a similar type of compound.

At elevated temperatures the material balance of dibromides formed was very poor. Since the major product(s) at low temperature arises from the abstraction of a β-hydrogen it is conceivable that at elevated temperatures the polyhalogenated materials arise from the reactions of the β-radical (see Scheme 2).

There are numerous precedents for elimination of a bromine atom from β-bromoalkyl radicals (3, 8–15). This elimination is responsible for the rapid vapor phase isomerization of *trans*- and *cis*-alkenes during photoinitiated bromination (16–20). It is also well documented that allylic bromides are formed in high yields in the bromination of alkenes when the bromine concentration is kept low (17). Such an allylic bromination pathway could account for the 1,2,3-tribromobutane, the unsaturated bromides, and the saturated polyhalogenated materials. A similar mechanism was proposed for the vapor phase bromination of 1-bromobutane (20). The fate of the β-bromoalkyl radical can be affected by either the temperature of the system or the concentration of the transfer agents. As the temperature rises the yield of 2,3-dibromobutane decreases, i.e. the β-scission of the 2-bromomethylpropyl radical to alkene is facilitated. At constant temperature the yield of 2,3-dibromobutane decreases with decreasing bromine concentration since the intermediate radical has a longer lifetime in which to fragment. Similarly, the yields of polybromides increase with temperature rise as well as with decreasing bromine concentration (see Table 2).

Of the polybromides formed, the allylic bromides become prevalent at high temperature and low bromine concentration at the expense of 1,2,3-tribromobutane. This is consistent with Scheme 2. As bromine concentration falls, the reversible addition of a bromine atom to a double bond becomes less likely than the irreversible allylic bromination steps. Allylic bromides are unstable and frequently rearrange to the thermodynamic mixtures of all possible isomers (22–24). This would account for the number of polyhalogenated allylic bromides that were observed.

The proposal that allylic bromination preferentially occurs at low bromine concentration (ref. 17, p. 182) was substantiated by a study of the vapor phase bromination of 2-butene (see Table 3). At very low bromine concentration over 90% of the bromination products from either *trans*- or *cis*-2-butene are the allylic bromides. These results are in good accord with the proposed mechanism for the bromination of 2-bromobutane, i.e., 2-butene is formed from the unstable β-bromoalkyl radical and is brominated allylically. The unsaturated bromides produced are in turn brominated allylically to produce unsaturated

[a] % Yields based on bromine consumed.

di- and tribromides (see Scheme 2).

The product yields quoted in Table 2 are based on the amount of bromine consumed. The formation of polybromides causes the overall stoichiometry of the reaction to deviate from a 1:1 bromine-to-substrate ratio. However, assuming all the polybromides and 2,3-dibromobutanes are derived from the β radical, the real ratio of α- and β-radical products can be determined from the experimental data by calculating the overall stoichiometry (see $(\alpha/\beta)_{products}$, Table 2). It is realized that this assumption may not be completely true regarding the production of 2,2,3-tribromobutane since some of this product might arise from further bromination of both 2,2- or 2,3-dibromobutane; however, in the vapor phase reaction 2,2,3-tribromobutane is a very minor product.

Extrapolation of the plot derived from the liquid phase bromination over a temperature range (see Fig. 1) predicts the yields of 2,2-dibromobutane to be 16%, 22%, and 31% at 65°, 100°, and 152°C respectively. The calculated ratios of $(\alpha/\beta)_{products}$ would suggest that the absolute yields of the α-radical product in the vapor phase are slightly higher than the values predicted from the results of the solution phase reactions (see Table 2). Moreover, in the vapor phase the yield appears to be a function of bromine concentration as well as temperature.

As the reaction temperature increases, the amount of α-radical product increases at the expense of β-radical products, i.e. $(\alpha/\beta)_{products}$ increases. This is consistent with the liquid phase results and must be due to a decreasing difference between the activation energies E_α and E_β.

The formation of the α and β radicals in a kinetic distribution is determined by the ratio of the rate constants (k_α/k_β) and is therefore concentration independent. At low bromine concentration the α radical can form product or revert to starting material, whereas the β radical can also undergo elimination. In the vapor phase, the only straightforward way to affect the apparent ratio of products resulting from initial abstraction reactions at the α and β positions, by a change in bromine concentration is for the α or β radicals or a product derived from the β radical to be able to revert to starting material. Two cases are envisaged: (*i*) at low bromine concentration elimination from the β radical effectively competes with its transfer with HBr or Br_2. The resulting product distribution shows less 2,3-dibromobutane and more polyhalogenation (see Table 2). As the concentrations of 2-butene and HBr increase (as the reaction proceeds) the likelihood that 2-bromobutane can reform also increases. (*ii*) At high bromine concentration elimination is less likely and higher yields of dibrominated butanes are produced from the intermediacy of the α and β radicals which either transfer with hydrogen bromide or molecular bromine.

If starting material is reformed it will react again to form the α and β radicals in the ratio set by the absolute rate constants (k_α/k_β). This will lead to a net increase in the amount of 2,2-dibromobutane formed, at the expense of products from the β radical. Therefore, at low bromine concentration, the yield of 2,2-dibromobutane will be partially dependent upon the concentration of the chain transfer agents.

Reaction mixtures containing HBr and (or) bromine at the high concentrations were subjected to the reaction conditions in the absence of light (i.e. 45 min, 100°C). No bromination products were observed. Liquid phase reactions (2 days, 90°C) similarly showed no reaction in the absence of light. These observations would appear to rule out ionic reactions with 2-bromobutane which could conceivably lead to 2,3-dibrominated products. Vapor phase photobrominations with HBr added to the initial reaction mixture showed α/β product ratios slightly lower than those found in reactions run without added HBr under the same conditions (see Table 2). Hydrogen bromide can affect the ratio of 2,2- and 2,3-dibromobutane by two distinct processes. First, the α and β radicals can both competitively transfer with bromine and hydrogen bromide to yield dibromide and starting material, the ratio depending upon the relative ratio of their rate constants and the concentration of the two transfer reagents. By analogy with the bromination of 1-bromobutane (20), where transfer with hydrogen bromide affects the α radical more strongly than it does the β radical, it is predicted that the presence of added HBr in the reaction mixture would lower the ratio of α/β products. However, the

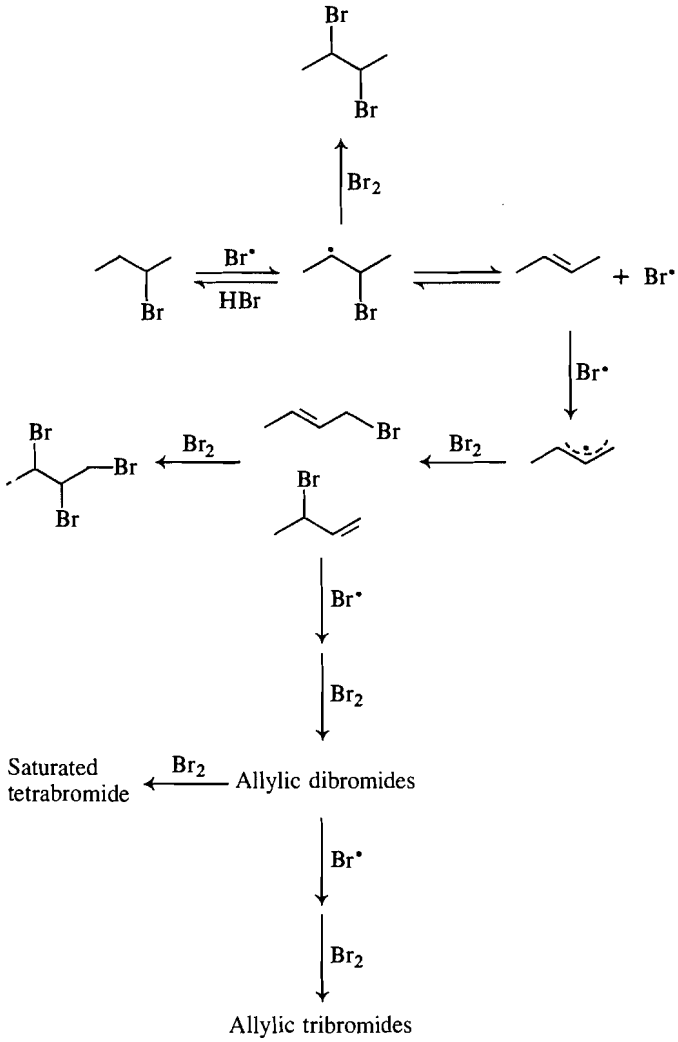

SCHEME 2

second process which regenerates starting material from 2-butene (a product from the β radical) with hydrogen bromide would cause an apparent increase in the ratio of α/β products. Under the conditions of high HBr concentrations apparently the first factor is the most influential (see Table 2). The possibility that 2,2-dibromobutane, itself, reacts further was also discounted. Two reactions which had 2,2-dibromobutane initially added also showed product distributions essentially the same as reactions run without its addition under the same conditions (see Table 2).

Moreover, the results show that the absolute yield of 2,2-dibromobutane formed in the gas phase reactions, as a function of temperature, agree remarkably well with those obtained in the solution phase bromination. The conclusions from these observations are identical with those reached for the bromination of 1-bromobutane under comparable conditions (20). It can be concluded that the α-bromoalkyl radical is stable under these conditions. In sharp contrast the yields of 2,3-dibromobutane are diminished at higher temperatures, due to the instability of the β-bromoalkyl radical.

Clearly, there is a discrepancy between these results and those reported by Fredericks and Tedder (4). This may very well be due to the differing conditions under which the reaction was studied.

In the present work the reaction was done under vacuum in sealed 100-mL glass ampoules. After completion of the reaction the product mixture was condensed, the reaction vessel opened, and the products were extracted with solvent. This ensured that *all* the products were present in the solution when it was analyzed by glpc.

Tedder studied the reaction in a flow system (3, 4); alkyl halide and halogen were fed, with nitrogen as a diluent, via two separate feeds into a heated reaction chamber. The mixture was irradiated with light as it passed through a glass tube. It was then passed through a column to remove hydrogen halide and excess halogen. The mixture was then frozen at −70°C, collected, and subjected to glpc analysis. Under these conditions no material balance could be obtained. It is possible that any polybrominated materials formed in the bromination of 2-bromobutane would not be carried through to the collection trap in this system. At 152°C much more 2,2-dibromobutane is formed relative to 2,3-dibromobutane. If this mixture was collected and analyzed, and the polyhalogenated material was not accounted for, it would give an apparent result similar to the one reported by Tedder.

Experimental

Materials

Bromine, *dl*-2-bromobutane, *meso* and *dl*-2,3-dibromobutane, and 2,2,3-tribromobutane were purified or synthesized as previously reported (9).

2,2-Dibromobutane was obtained by preparative glpc collection (80°C, 10 ft × 1/4 in. 10% Carbowax 20 M glass column) from the product mixture resulting from the liquid phase photobromination of 2-bromobutane.

1-Bromo-2-butene was obtained by preparative glpc collection (50°C, 6 ft × 1/4 in. 10% Carbowax 20 M TPA glass column) from commercially available crotyl bromide (Aldrich Chemical Co. Ltd.). A freshly collected sample had n_D^{25} = 1.4804 (lit. (21) n_D^{22} = 1.4822). The sample isomerized to a mixture of 1-bromo-2-butene and 3-bromo-1-butene on standing (22).

trans-1,4-Dibromo-2-butene was prepared by the method of Shantz (25). Equimolar amounts of 1,3-butadiene and bromine were allowed to react in chloroform at −30°C. The chloroform was removed by distillation and the product isolated by distillation under reduced pressure and recrystallized from methanol (mp 52–53°C (lit. (26) mp 53–54°C); mass spectra show parent peaks 212, 214, 216, 1:2:1 ratio).

1,2,3-Tribromobutane (City Chemical Corp.), and 1,2-dibromobutane (Eastman Kodak Co.) were used as supplied.

Gas–liquid chromatographic analysis

This was carried out as described previously (9).

Liquid phase photobromination of 2-bromobutane with molecular bromine

This was carried out as previously described (9). Brominations run at elevated temperatures proceeded more rapidly. At 100°C the reaction was complete within 10 min. A control reaction, i.e. the reactants were not photoinitiated, revealed no products after 24 h at both 17 and 90°C. Similarly, reaction mixtures containing RBr/Br_2/HBr (10:1:1), thermostated at both 17 and 90°C for 24 h and 0.5 h, also showed no reaction.

Vapor phase photobromination of 2-bromobutane with molecular bromine

Bromine and 2-bromobutane were accurately weighed into capillary tubes and placed in a reaction ampoule previously darkened with aluminium foil. The vessel was attached to a vacuum line and the reactants degassed three times. The ampoule was sealed under vacuum and thermostated, in the absence of light, at the required temperature for at least 10 min. The mixture was photolyzed with a 200-W incan-

descent lamp for 5 min. In all cases the bromine color was rapidly discharged. The total of the partial pressures of the products varied from 2 Torr to 20 Torr (1 Torr = 133.3 Pa) depending upon the initial bromine concentration. The total reactant pressure was approximately 80 Torr.[5] After irradiation the products were cooled with liquid nitrogen.

A reaction mixture was prepared and kept at 100°C in the dark for 45 min. Analysis of the mixture showed only 2% of the bromine had been consumed and only traces of products were observed by glpc analysis. Similarly, a reaction mixture containing HBr (0.3 mmol/L) and bromine (0.3 mmol/L) was kept at 100°C for 45 min in the absence of light. Analysis revealed that no reaction had occurred. The HBr had been manometrically measured and condensed into the reaction vessel. Two reaction mixtures with added HBr were photoinitiated and the products analyzed (see Table 2).

After any of the reactions run, aliquots of a chlorobenzene/Freon 113 solution (2 mL, 0.3 mmol/L), Freon 113 solvent (2 mL), and saturated aqueous sodium bicarbonate (2 mL) were each added to the frozen mixture. The resulting solutions were allowed to warm to room temperature and mixed by shaking. The organic layers were separated and dried over anhydrous sodium sulfate.

The reaction mixtures were analyzed by both capillary column glpc (10 meters, Methyl Silicone Fluid) and packed column glpc (10 ft × 1/4 in. 5% Carbowax 20 M on 80/100 Chromosorb PAW). The chromatograms revealed a complex mixture of products (see Fig. 2). The mixtures were subjected to capillary gc/mass spectral analysis and, where possible, this identification was confirmed by comparing their retention times and mass spectra with those of authentic samples.

A bromobutene (P^+ = 134, 136; Br doublet) was identified as 1-bromo-2-butene using an authentic sample. Five dibromobutanes (P^+ = 214, 216, 218; Br_2 triplet) were shown to be 2,2-dibromobutane, *meso*- and *dl*-2,3-dibromobutane, and 1,2- and 1,3-dibromobutane using authentic samples.

Mass spectral analysis revealed the presence of six dibromobutenes (P^+ = 212, 214, 216; Br_2 triplet) at slightly longer retention times. One of these was assigned to *trans*-1,4-dibromo-2-butene by comparison of its mass spectrum and retention time with that of an authentic sample.

A high boiling fraction showed a number of compounds. Two tribromobutanes (P^+ = 292, 294, 296, 298; Br_3 quartet, $[P - Br]^+$ = 213, 215, 217; Br_2 triplet) were seen, one was identified as 2,2,3-tribromobutane and the other as 1,2,3-tribromobutane using the authentic compounds. In the same fraction five tribromobutenes (P^+ = 290, 292, 294, 296; Br_3 quartet, $(P - Br)^+$ = 211, 213, 215, Br_2 triplet) were indicated. A small amount of *meso*-1,2,3,4-tetrabromobutane was detected by comparing its glpc retention time and ms cracking pattern with that of an authentic sample, as was the presence of two other tetrabromobutanes. A few other minor products were not further characterized.

Calibration factors determined for 2,3-dibromobutane, 1,2-dibromobutane, 1,3-dibromobutane, 2,2,3-tribromobutane, 1,2,3-tribromobutane, and *meso*-1,2,3,4-tetrabromobutane were used as representative values for all the products.

Vapor phase photobromination of 2-butene with molecular bromine

Bromine was accurately weighed in a capillary tube and sealed in a breakseal tube which was then attached to a vacuum line. A known amount of 2-butene (*cis or trans*) was manometrically measured. The reactants were allowed to enter a darkened reaction vessel of known volume and to equilibrate for 3 min. The total pressure of the reactants varied from 0.5 to 10 Torr. The reactants were then irradiated with a 200-W incandescent lamp for 5 min. The products were condensed into a collecting tube and treated as described above.

Products were identified by comparison of their glpc retention times with those of authentic materials. The products were: 3-bromo-1-butene, 1-bromo-2-butene, and *meso* and *dl*-2,3-dibromobutane (see Table 3).

[5] The saturation pressure for the reactant 2-bromobutane is 40 Torr at room temperature, while it is 200 Torr for bromine. The saturation pressures are even higher at higher temperature.

Acknowledgments

The authors wish to thank the Natural Sciences and Engineering Research Council of Canada and the University of Alberta for their generous support of this work. We would also like to thank Professor J. M. Tedder of the University of St. Andrews for his comments and for a preview of his unpublished results. Thanks are also expressed to Dr. A. Hogg of the University of Alberta for running the capillary gc/ms analyses.

Décomposition homolytique du peracide phényl-5 pentanoïque: réactivité du radical phényl-4 butyle et compétition entre deux mécanismes en chaïne

JEAN-YVES NEDELEC, JACQUES FOSSEY, DANIEL LEFORT ET JEANINE SORBA
C.N.R.S., G.R. 12, 2, rue H. Dunant, 94320 Thiais, France

Reçu le 28 décembre 1983

JEAN-YVES NEDELEC, JACQUES FOSSEY, DANIEL LEFORT et JEANINE SORBA. Can. J. Chem. **62**, 2317 (1984).

Le peracide phényl-5 pentanoïque, en solution à ébullition dans le cyclohexane, se décompose essentiellement en acide correspondant au lieu de se décarboxyler en phényl-4 butanol comme les termes inférieurs ou supérieurs; cette différence de comportement est expliquée par la cyclisation du radical phényl-4 butyle, lequel ne peut pas propager le mécanisme en chaîne conduisant au phényl-4 butanol et le peracide se transforme alors en acide par un autre mécanisme radicalaire en chaîne compétitif.

JEAN-YVES NEDELEC, JACQUES FOSSEY, DANIEL LEFORT, and JEANINE SORBA. Can. J. Chem. **62**, 2317 (1984).

5-Phenyl pentanoic peracid decomposes in boiling cyclohexane solution to the corresponding acid instead of decarboxylation as is observed for the related cases. This difference in behaviour is explained by the cyclization of the 4-phenyl butyl radical which can then no longer propagate any chain reaction leading to 4-phenyl butanol. The peracid, therefore, reacts by a competitive radical chain mechanism leading to the corresponding acid.

L'intérêt des peracides RCO_3H en chimie radicalaire résulte d'une double spécificité: ils sont à la fois source de radicaux libres $R^{\cdot}$ et substrat pour différents radicaux libres nucléophiles ($R^{\cdot}$) pour former des alcools. Ainsi, la décomposition thermique d'un peroxyacide aliphatique conduit à l'alcool ROH selon le mécanisme en chaîne suivant (I) (1).

[1] $RCO_3H \rightarrow RCO_2^{\cdot} + \dot{O}H$

[2] $RCO_2^{\cdot} \rightarrow R^{\cdot} + CO_2$

[3] $R^{\cdot} + RCO_3H \rightarrow ROH + RCO_2^{\cdot}$

Réactions de terminaison

MÉCANISME 1

Cependant dans certains cas liés au milieu réactionnel (2, 3) (nature du solvant, présence d'oxygène) ou lorsque le radical $R^{\cdot}$ est électrophile (3, 4), le produit principal est l'acide correspondant.

Ainsi nous avons déjà montré (3) que lorsque l'on n'opère pas à ébullition de la solution, l'oxygène dissous bloque le mécanisme I et que l'acide se forme par le mécanisme en chaîne II.

[4] $RCO_3H \rightarrow RCO_2^{\cdot} + \dot{O}H$

[5] $\dot{O}H + RCO_3H \rightarrow H_2O + RCO_3^{\cdot}$

[6] $RCO_3^{\cdot} \rightleftarrows R\dot{C}O + O_2$

[7] $R\dot{C}O + RCO_3H \rightleftarrows RCHO + RCO_3^{\cdot}$

[8] $RCHO + RCO_3H \rightarrow 2\ RCO_2H$

MÉCANISME II

Dans l'étude présentée ici nous allons montrer que ces deux mécanismes, qui diffèrent radicalement par la nature des entités radicalaires mises en jeu ($RCO_2^{\cdot}$ et $R^{\cdot}$ dans I, $RCO_3^{\cdot}$ et $R\dot{C}O$ dans II), évoluent de manière compétitive; nos travaux antérieurs (1−4) ont établi que la chaîne I est généralement plus rapide que la chaîne II quand le radical $R^{\cdot}$ est nucléophile.

Au cours de notre étude sur les transferts intramoléculaires d'hydrogène de cabone à carbone, nous avons produit une série de radicaux ω-phényl alkyle à partir des peracides correspondants.

$\phi\text{-}(CH_2)_n\ CH_2 - CO_3H$

Dans les conditions habituelles (décomposition dans un hydrocarbure à ébullition) la quantité d'acide est inférieure à 20% sauf quand $n = 3$: le peracide phényl-5 pentanoïque conduit en effet à 80% d'acide (5).

Pour expliquer les raisons de la particularité de ce peracide par rapport à ses homoloques et vérifier du même coup notre hyothèse de la compétition des mécanismes I et II, nous avons approfondi l'étude de la décomposition thermique de ce peracide, par comparaison avec la décomposition de l'homologue immédiatement inférieur.

Résultats

Les peracides sont décomposés en solution dans le cyclohexane *à ébullition* pour éliminer l'oxygène dissous.

Le tableau 1 montre la différence très nette de la distribution des produits, pour une même concentration initiale (0,1 *M*), entre les deux peracides phényl-4 butanoïque et phényl-5 pentanoïque. Pour ce dernier, quand on augmente la concentration initiale en peracide on constate, d'une part, que la quantité de phényl-4 butanol croit au détriment de l'acide phényl-5 pentanoïque et, d'autre part, que les quantités de phénylbutane, de tétraline et de cyclohexanol restent faibles et à peu près constantes. On notera qu'à 0,1 *M* le temps de demi-réaction est supérieur pour le peracide phényl-5 pentanoïque; ce ralentissement de la vitesse de décomposition, résultat de plusieurs mesures, est significatif.

Quand on décompose un mélange équimoléculaire des peracides dodécanoïque et phényl-5 pentanoïque (Tableau 2), on observe une augmentation très nette de la quantité de phényl-4 butanol par rapport à celle résultant de la décomposition du peracide phényl-5 pentanoïque seul (tableau 1); de plus, l'augmentation des concentrations initiales a pour conséquence d'accroître les quantités d'alcool RCH_2OH et $\phi\text{-}(CH_2)_3CH_2OH$ issus de chacun des peracides. On note également que la quantité de cyclohexanol est accrue mais que celles de phénylbutane et de tétraline restent du même ordre de grandeur.

Discussion

Il est raisonnable d'admettre que l'énergie de la liaison O—O n'est pas influencée par la position du phényle par rapport à la fonction peroxydique.

Le mécanisme I ne peut donc être ralenti qu'au niveau de la

réaction [2] ou de la réaction [3].

L'hypothèse d'une stabilisation du radical carboxyle par complexation intramoléculaire (6−8) expliquerait le ralentissement de la chaîne I par une diminution de k_2, constante de vitesse de décarboxylation.

[9] 
L'acide résulterait alors d'une réaction de ce radical sur le solvant

[10] 
Mais on devrait alors trouver des quantités équivalentes de cyclohexanol

[11] $^{\bullet}C_6H_{11} + RCO_3H \rightarrow C_6H_{11}OH + RCO_2^{\bullet}$

comme c'est le cas pour ϕCO_3H décomposé dans C_6H_{12} à ébullition (2).

De plus, un tel phénomène de complexation devrait jouer dans la décomposition du peroxyde de diacycle correspondant (9, 10), et devrait être accentué, pour des raisons entropiques, avec l'homologue inférieur, ce qui n'est pas le cas (5).

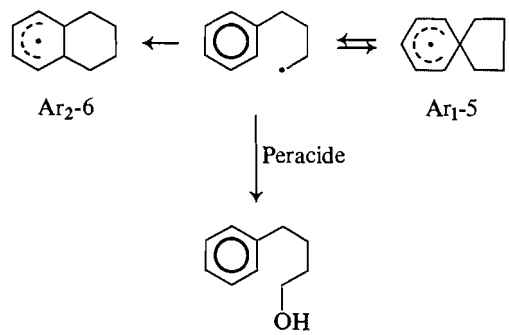
Il y a donc tout lieu de penser que les réactions de rupture homolytique [1] et de décarboxylation [2] sont aussi rapides que pour l'homologue inférieur. D'ailleurs la présence dans le mélange réactionnel de phényl-4 butanol qui se forme à partir du radical phényl-4 butyle montre bien que ces réactions ont lieu mais elles sont moins importantes que celles du mécanisme II pour les raisons que nous allons exposer.

La propagation de la chaîne peut être ralentie au niveau de la réaction [3]. Dans l'expression de la vitesse

$$\left[v_3 = k_3[R^{\bullet}][P]\right]$$

k_3 exprime la réactivité intrinsèque d'un radical carboné primaire $R'—CH_2^{\bullet}$. Or celle-ci ne peut être influencée notablement par un groupement phényle en position 4. C'est donc la concentration $[R^{\bullet}]$ qui doit déterminer la vitesse v_3.

On sait que le radical phényl-4 butyle se cyclise rapidement (9, 11) ($k_{cy} \simeq 5 \times 10^{-4}\ s^{-1}$) (12, 13) et de façon irréversible en Ar_2-6 et réversible en Ar_1-5 (14).



Il y a donc compétition entre la cyclisation et la réaction sur le peracide. La réaction unimoléculaire est la plus rapide quand [P] = 0,1 M puisque dans ce cas l'on trouve des quantités faibles de phényl-butane et de phényl-4 butanol.

On s'attend dès lors à trouver des quantités importantes de produits bicycliques, tétraline et dérivés. Mais le radical Ar_2-6 ne réagit pas sur le peracide ni non plus sur le solvant (il y a peu de cyclohexanol). Ainsi, puisqu'aucun radical ne peut propager

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

la chaîne I, celle-ci est tout simplement inhibée et le peracide se décompose essentiellement selon le mécanisme II. Comme les deux chaînes n'ont pas d'entité réactionnelle commune, il ne peut y avoir passage de l'une à l'autre.

Néanmoins ces deux chaînes sont bien compétitives comme le montrent l'étude de l'effet de la concentration et l'étude de la décomposition du mélange de peracides.

Quand on augmente la concentration en peracide, on accélère la réaction [3] qui est l'étape limitante de la chaîne I alors que le mécanisme II n'est pas sensible à la concentration initiale en peracide et l'alcool se forme bien aux dépens de l'acide. Quand la concentration en peracide est supérieure à 0,1 *M* on observe donc le déroulement simultané des deux mécanismes en chaîne.

Quand on décompose le peracide phényl-5 pentanoïque en présence d'une quantité équimolaire de peracide dodécanoïque, on lève l'inhibition du fait que le dernier se décompose normalement: le peracide dodécanoïque produit en effet des radicaux alkyles réactifs qui quand ils réagissent sur ϕ-$(CH_2)_4-CO_3H$ redonnent de l'importance à la décomposition selon le mécanisme I en générant les radicaux ϕ-$(CH_2)_4-CO_2^{\cdot}$

En conclusion: si pour l'essentiel, le détail de chacun des mécanismes en chaîne était établi, la présente étude montre clairement la délicate balance qui régit la compétition des deux mécanismes. Quand le radical alkyle produit par décarboxylation disparait rapidement, soit par réaction avec O_2 soit par réaction unimoléculaire comme la cyclisation, la chaîne I s'interrompt et la chaîne II devient prépondérante.

Partie expérimentale

Le cyclohexane utilisé est de qualité "spectroscopique". Les analyses cpg sont effectuées avec un appareil Girdel-75 et les spectres ir, en solution dans CCl_4, avec un appareil Hitachi-EPI G2. Les indices de peroxyde sont déterminés par iodométrie (15).

Preparation des peracides

On utilise la méthode décrite par Swern et coll. (16), à laquelle nous avons apporté quelques modifications (17) et qui consiste à faire agir H_2O_2 85% sur l'acide en solution dans CH_3SO_3H.

Le peracide est recristallisé dans l'hexane; sa pureté est contrôlée par les spectres ir et par détermination de l'indice de peroxyde. On obtient aisément des peracides à 96−98%.

Décomposition des peracides

Nous utilisons le même protocole que celui décrit précédemment (3). Les mélanges réactionnels sont analysés, après estérification par CH_2N_2, en cpg (Carbowax 20 M, 15%, 2 m, 150 à 160°C) en utilisant pour le dosage quantitatif, comme témoin interne, l'hexadécanoate de méthyle.

Etude vibrationnelle des associations ioniques dans les solvants aprotiques. 7. Solvatation de $(LiNCS)_p$ par les solvants peu polaires

MARTIAL CHABANEL ET ZHENGLIE WANG

Laboratoire de Spectrochimie des Ions, 2, rue de la Houssinière, 44072 Nantes Cedex, France

Reçu le 8 février 1984

MARTIAL CHABANEL et ZHENGLIE WANG. Can. J. Chem. **62**, 2320 (1984).

Les solutions de LiSCN dans des mélanges solvant donneur − benzène ont été étudiées par mesure de solubilité et par spectrométrie infrarouge. L'état d'association de LiSCN a été obtenu à partir des spectres ir dans la région ν(CN) 2100−2000 cm^{-1}. Les solvants étudiés (tétrahydrofuranne, pyridine, acétone, carbonate de diéthyle, acétate de butyle, éthylméthylcétone) sont plus ou moins associants vis à vis de LiSCN. L'addition de benzène renforce leur pouvoir associant. En faisant varier le solvant donneur et la quantité de benzène ajouté, il est possible de modifier les proportions de paire d'ions LiNCS, de dimère $(LiNCS)_2$ et d'agrégats supérieurs. Les vibrations du solvant permettent d'obtenir le nombre de solvatation du lithium. Chacun des processus d'association de LiSCN s'accompagne d'une désolvatation du lithium. Le nombre de coordination de cet ion dans les différentes espèces formées reste égal à 4 ou légèrement inférieur dans certains cas.

MARTIAL CHABANEL and ZHENGLIE WANG. Can. J. Chem. **62**, 2320 (1984).

Solutions of LiSCN in donor solvent − benzene mixtures have been investigated by solubility measurements and by infrared spectrometry. The state of aggregation of LiSCN has been obtained from the ir spectra in the ν(CN) region 2100−2000 cm^{-1}. The selected solvents (tetrahydrofuran, pyridine, acetone, diethylcarbonate, butylacetate, ethylmethylketone) are more or less associating towards LiSCN. The addition of benzene causes an increase of the associating ability of the solvents. By changing the donor solvent and the amount of benzene it has been possible to obtain the ion pair LiNCS, the dimer $(LiNCS)_2$, and higher aggregates in various proportions. The solvation number of lithium has been measured in solvent vibration regions. Each step of aggregation is accompanied by lithium desolvation. The coordination of lithium in all the species which are formed remains equal to 4, or slightly lower in some cases.

Introduction

En solution dans les solvants donneurs dits aprotiques les cations des sels interagissent fortement avec les molécules de solvant. Dans la première couche de solvatation ces molécules peuvent être suffisamment perturbées pour être spectroscopiquement discernables des autres molécules plus ou moins libres dans la solution. Ainsi la spectrométrie infrarouge est une technique capable en principe de donner les nombres de solvatation des cations, mais les difficultés pratiques apportent des limitations sérieuses. D'abord, les bandes libres et associées sont généralement mal séparées et, sauf en solution très concentrée, la bande associée est peu intense. Enfin son coefficient d'extinction molaire est mal connu. Ces difficultés sont en partie résolues si l'on remplace la plus grande partie du solvant donneur par un solvant suffisamment inerte pour ne pas entrer en compétition avec le solvant donneur dans la première couche de solvatation. Par ordre de pouvoir solvatant croissant on pourra prendre un alcane, le benzène ou le nitrométhane. Bien qu'il soit fortement polaire ce dernier composé a été utilisé (1, 2) car il n'est que faiblement donneur. Cette méthode est d'application facile lorsque le sel est soluble dans le solvant dit inerte, ce qui est souvent le cas pour le nitrométhane. La solvatation de Na^+ a ainsi été étudiée dans le système $NaAlBu_4$ − cyclohexane − solvant donneur (3, 4). Lorsque le solvant inerte ne dissout pas le sel il arrive que le solvant mixte le dissolve. Toutefois l'addition d'un solvant inerte peut aussi favoriser la formation de solvates solides ou la démixtion de la solution.

La connaissance de l'état d'ionisation ou d'association du sel est nécessaire pour déterminer complètement le mode de coordination du cation étudié dans les solvants non-aqueux peu ionisants ou associants. Dans nos travaux antérieurs sur la structure des solutions de LiSCN la plupart des agrégats formés ont été identifiés et leur structure établie. C'est pourquoi, dans le présent travail, ce seront les solutions de LiSCN qui seront étudiées dans des mélanges benzène − solvant donneur. Les espèces formées seront caractérisées par les fréquences ν(CN) du groupement SCN attribuées antérieurement. Les vibrations du solvant permettront d'obtenir par ailleurs le nombre de solvatation du lithium. On remarquera que le benzène joue un rôle non négligeable car nous n'avons pas réussi à préparer les solutions mixtes avec un solvant plus inerte encore, comme le cyclohexane par example.

La formule des thiocyanates à l'état de solide pur est généralement écrite MSCN, ce qui ne préjuge rien sur la liaison entre M^+ et SCN^-. Ainsi la formule de thiocyanate de lithium sera écrite LiSCN. Par contre les agrégats de ce sel ont une structure de type isothiocyanate et leur formule sera écrite $(LiNCS)_p$.

Résultats expérimentaux

Cosolubilité LiSCN − solvant donneur

Le thiocyanate de lithium, comme presque tous les sels inorganiques, est insoluble dans le benzène pur. Les essais préliminaires de solubilité en solvant mixte ont été effectués en utilisant des mélanges de concentration 1 *M* en solvant donneur. Lorsque celui-ci est très polaire (diméthylformamide, diméthylacétamide, carbonate de propylène) ou multidentate (dioxolanne, triglyme), on constate que le système ternaire se sépare en deux phases. La phase inférieure, qui contient la quasi totalité du sel, est donc stabilisée par les interactions à longue et à moyenne distance entre ions solvatés et entre dipôles.

Lorsque le solvant donneur est peu polaire comme le tétrahydrofuranne (THF), le carbonate de diéthyle (DEC), l'acétate de butyle et l'éthylméthylcétone (EMC) la solubilité du thiocyanate de lithium est à peu près proportionnelle à la concentration du solvant donneur dans le mélange. Cependant dans certains cas (pyridine, acétone) les phénomènes sont compliqués par la formation d'un solvate solide.

Si l'on désigne le solvant par *S* la réaction de dissolution s'écrit, pour un agrégat ionique d'ordre *p*,

$$\text{LiSCN (solide)} + nS = \frac{1}{p}\,(\text{LiNCS}, nS)_p$$

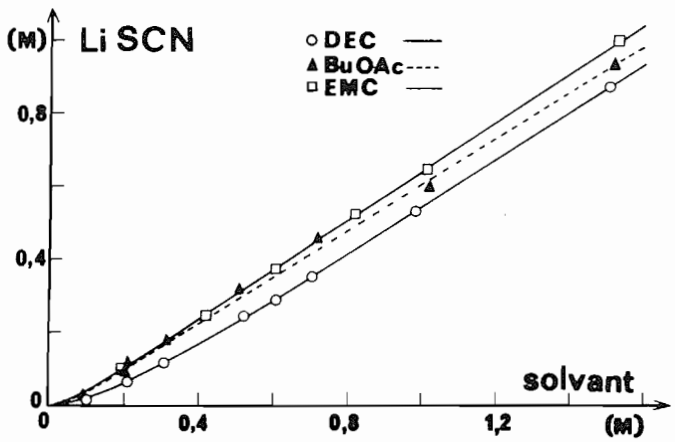

FIG. 1. Courbes de cosolubilité LiSCN – solvant donneur dans le benzène.

Si cette réaction est totale et si le mode d'association en change pas avec la concentration, la courbe de solubilité c de LiSCN en fonction de la concentration c_S en solvant doit être une droite de pente $1/n$ passant par l'origine. Les points expérimentaux (fig. 1) sont effectivement alignés sauf aux basses concentrations ($c < 0{,}1\ M$), ce qui montre que la réaction de dissolution est équilibrée. Les valeurs de n sont sensiblement les mêmes dans le DEC (n = 1,55), l'acétate de butyle (n = 1,6) et l'EMC (n = 1,45). La valeur obtenue dans le THF (n ~ 2,4) est peu précise car la saturation en LiSCN est difficile à obtenir. Puisqu'il reste toujours un peu de solvant libre, ces valeurs donnent une limite supérieure du nombre de solvatation moyen $\bar{n}$ du lithium.

Classification des solvants étudiés

La zone 2120–1980 cm^{-1} sert à caractériser les agrégats lithium–thiocyanate. Chaque agrégat possède une fréquence ν(CN) caractéristique qui varie dans une zone étroite (± 5 cm^{-1} environ) selon la constante diélectrique du solvant. Cette fréquence ν(CN) se situe en infrarouge à 2065 cm^{-1} (5) pour LiNCS, 2040 cm^{-1} pour $(LiNCS)_2$ (6), 2100 cm^{-1} pour LiNCSLi (7, 8), 1995 cm^{-1} pour $(LiNCS)_4$ de symétrie T_d (9).

Les solvants étudiés se classent schématiquement en deux catégories selon leur comportement plus ou moins associant (10) vis à vis de LiSCN. La première catégorie comprend les solvants peu associants (THF, pyridine, acétone) pour lesquels LiSCN en solution ($c \sim 0{,}1\ M$) est presque entièrement sous forme de paires d'ions; en solution concentrée ($c > 1M$) de petites quantités de dimère et d'ion triple apparaissent. La seconde catégorie comprend des solvants "associants" (EMC, acétate de butyle, DEC) pour lesquels on observe un équilibre paire–dimère.

L'addition de benzène rend tous ces solvants plus associants vis à vis de LiNCS. Ainsi, pour une concentration c_S en solvant de l'ordre de $1M$ dans le benzène, on observe, avec les solvants peu associants, que la dimérisation de LiNCS est pratiquement complète. Avec les solvants associants l'association dépasse le dimère, comme le montre l'apparition de trois nouvelles bandes entre 2000 et 2100 cm^{-1}.

Méthode d'analyse des spectres infrarouges

Les spectres infrarouges du solvant mixte et de la solution de LiSCN correspondante sont enregistrés séparément et on en retranche la contribution du spectre du benzène en tenant compte du volume occupé par le solvant donneur. Pour étudier la solvatation, les zones intéressantes du spectre sont celles qui comportent une vibration du solvant donneur à la fois intense et sensible à la fixation du lithium. Dans le spectre S_o du solvant mixte la bande du solvant libre apparaît seule. Pour obtenir la quantité de solvant libre dans la solution on retranche à son spectre S le spectre S_o multiplié par en coefficient ajusté pour que la bande libre disparaisse. On en déduit donc la quantité de solvant lié et le nombre de solvatation $\bar{n}$. La précision de cette méthode est maximale (~ ± 5%) lorsque le solvant libre est en proportion très inférieure à celle du solvant lié. Cette condition est réalisable dans les solvants associants et dans le THF. Par contre, dans la pyridine et l'acétone l'expérience montre qu'une proportion de solvant libre du même ordre que celle du solvant lié est nécessaire pour éviter la précipitation de solvates. Dans ce cas, la méthode ci-dessus est peu précise. C'est pourquoi les spectres ont été décomposés à l'ordinateur, chaque pic étant la somme de contributions de Gauss et de Lorentz.

Résultats

L'ensemble des résultats est rassemblé sur les tableaux 1 et 2. Les fréquences des vibrations utilisées pour le calcul des nombres de solvatation sont données en solution diluée dans le benzène. Les nombres de solvatation sont déterminés avec une incertitude estimée à ±0,1 sauf dans les solvants purs et dans les systèmes contenant de l'acétone ou de la pyridine (±0,2).

Discussion

Tétrahydrofuranne

Pour des concentrations en THF variant entre 0,5 et 2,5 M on a obtenu des nombres de solvatation moyens $\bar{n}$ de Li voisins de 2 (tableau 1). Comme la dimérisation de LiNCS est pratiquement totale à ces concentrations, on en a déduit que le nombre de solvatation de Li dans le dimère est égal à 2. Aux plus fortes concentrations en THF la valeur de $\bar{n}$ est légèrement supérieure à 2 ce qui correspond à l'apparition de paires d'ions plus solvatées que le dimère. La mesure du nombre de solvatation de la paire est possible dans les solutions concentrées LiSCN–THF sans benzène. Elle ne peut être effectuée qu'en film liquide. Dans les solutions en solvant mixte on a remarqué, avec des cellules d'épaisseur connue, que l'intensité intégrée est la même pour le THF à l'état libre ou à l'état associé. Dans le système LiSCN–THF, et pour des concentrations en LiSCN de l'ordre de 1 à $2M$, il apparaît que la paire LiNCS est largement prédominante (fig. 2). Par contre, en solution très concentrée (~ 3 à $4M$), la proportion de dimère et de groupement LiSCNLi, ion triple ou plus probablement agrégat en chaîne (7), augmente rapidement avec la concentration. Les nombres de solvatation ont été mesurés par décomposition des spectres dans la région ν(COC). Ils sont en bon accord avec un nombre de solvatation égal à 3 pour la paire et de l'ordre de 2 pour les autres espèces. L'équilibre de dimérisation s'écrit donc:

$$2\ LiSCN,\ 3THF = (LiNCS)_2,\ 4THF + 2THF$$

Le nombre de solvatation (n = 3) de la paire est égal à celui qui a été obtenu par TOTH *et al.* (11) pour la paire $LiNO_3$ en matrice moléculaire. Mais ces auteurs obtiennent des valeurs plus élevées (n = 4) lorsqu'ils utilisent le DMSO, plus polaire, ou l'acétonitrile, moins encombré.

La bande ν(COC) passe de 1069 cm^{-1} pour les molécules de THF libres à 1048 cm^{-1} pour les molécules de THF associées.

[b]Solution sans benzène, spectre en film liquide.

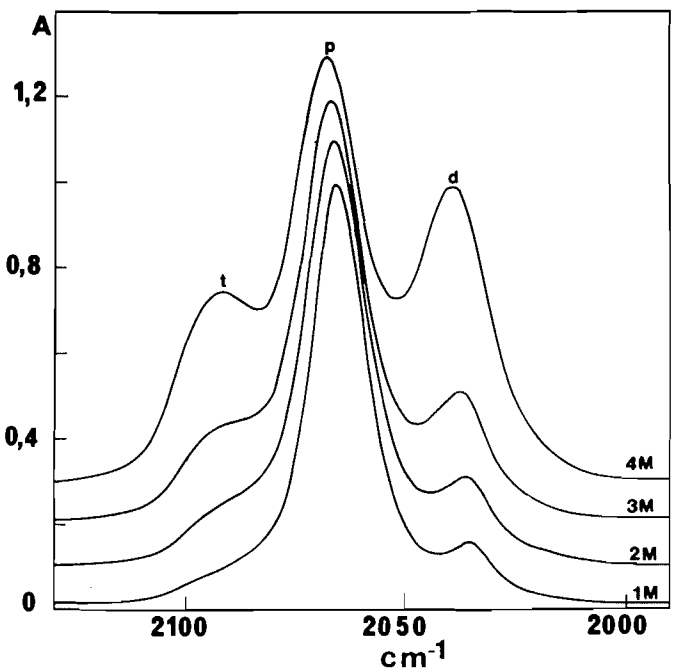

FIG. 2. Spectres infrarouges de LiSCN en solution concentrée dans le THF (film liquide) p = LiNCS, d = $(LiNCS)_2$, t = LiNCSLi.

Cet écart est pratiquement le même pour le dimère, dans le système THF−benzène, et pour la paire dans THF. Le déplacement de fréquence (-21 cm^{-1}) est à peine inférieur à celui observé pour la solvatation par le sodium (12) c'est à dire -19 cm^{-1}. Généralement les perturbations causées par le sodium sont nettement plus faibles que celles causées par le lithium. Ce nivellement pourrait provenir d'un encombrent stérique des molécules de THF autour du lithium.

Pyridine

En solution dans le benzène, la pyridine possède une bande ν(CNC) très fine ($\Delta\nu_{\frac{1}{2}}$ = 4 cm^{-1}) située à 1437,7 cm^{-1}. Cette bande se déplace vers les hautes fréquences d'environ 4 cm^{-1} lorsque la pyridine solvate le lithium, et sa largeur diminue encore ($\Delta\nu_{\frac{1}{2}}$ = 2,7 cm^{-1}). Dans les solutions pyridine−benzène ou a dû utiliser un excès de pyridine libre sinon il y a précipitation d'un solvate solide. Ceci diminue la précision des mesures de $\bar{n}$ qui est estimée à ± 0,2.

La figure 3(a) montre l'effet de la dilution dans le benzène sur une solution pyridine (3 *M*) − LiSCN (0,8 *M*). A chaque dilution d'un facteur 4 les hauteurs d'absorption ont également été mulitpliées par 4. L'examen de la zone ν(CN) (2100−2000 cm^{-1}) montre que la paire prédomine dans la solution concentrée, comme d'ailleurs dans la pyridine pure. La dilution provoque une dimérisation presque totale. Simultanément (fig. 3(b)) on constate le renforcement de la bande ν(CNC) libre, donc une désolvatation du lithium à la suite de la dimérisation. La bande ν(CNC) associée se déplace vers les hautes fréquences; le déplacement de fréquence passe de 4,0 cm^{-1} pour la paire à 4,7 cm^{-1} pour le dimère. L'interaction pyridine−lithium est donc plus forte dans le dimère que dans la paire. Ceci provient sans doute d'une gêne stérique entre les molécules de pyridine dans la paire. Cet effet est sensiblement plus marqué que dans le THF.

Les mesures des nombres de solvatation du lithium par la pyridine ont été faites par décomposition des spectres dans la région ν(CNC). L'intensité intégrée des spectres est indépen-

[a]Solutions saturées. Les unités sont données au tableau 1.

dante du caractère libre ou associé de la pyridine, ce qui montre que les intensités des bandes libre et associée ne sont pas significativement différentes. Les nombres de solvatation ont été obtenus à partir des rapports des intensités intégrées des deux bandes. Ils sont un peu inférieurs aux valeurs attendues (n = 2 pour le dimère et 3 pour la paire) pour un ion Li^+ tétracoordiné. Cet écart, de l'ordre de 20%, est supérieur aux erreurs de mesure (~10%). On le retrouve encore lorsqu'on applique le méthode de soustraction de la bande libre. Même avec ces valeurs le nombre de coordination de Li^+ reste proche de 4 (~3,6). Ces résultats sont en accord avec ceux obtenus dans le pyridine pure par Rouvière *et al.* (13). Par effet Raman ces auteurs ont obtenu un nombre de solvatation de l'ion Li^+ égal à 4, avec une marge d'incertitude assez large qui n'a pas été précisée.

Acétone

Les bandes ν(CO) libre et associée de l'acétone dans les solutions benzéniques de LiSCN se situent à 1715 et 1707 cm^{-1}. Ces valeurs sont les mêmes que celles obtenues en l'absence de benzène (14). Comme la séparation des bandes est insuffisante, il vaut mieux utiliser la vibration ν(CCC) pour étudier la solvatation (ν_l = 1219 cm^{-1} et ν_a = 1236 cm^{-1}). En l'absence de benzène, LiSCN dissous dans l'acétone est presque entièrement sous forme de paire. Les résultats obtenus sont tout à fait comparables à ceux obtenus dans la pyridine. Ainsi les nombres de solvatation de Li^+ semblent légèrement inférieurs à 2 pour le dimère et 3 pour la paire.

Solvants associants

Dans les mélanges solvant associant − benzène (c_S ~ 0,1 à 1 *M*) saturés et LiSCN on observe la formation non seulement du dimère mais aussi d'agrégat(s) supérieur(s). Avec l'acétate de butyle par exemple, de nouvelles bandes ν(CN) situées à 2076, 2018 et 2006 cm^{-1} apparaissent (fig. 4). Elles ne sont attribuables ni à LiNCS (~2065 cm^{-1}), ni à LiNCSLi (~2100 cm^{-1}), ni à $(LiNCS)_4$ de symétrie T_d (~1993 cm^{-1}) mais à un ou plusieurs autres agrégats qui sont les mêmes dans les trois solvants.

Les éléments disponibles ne permettent pas d'établir la structure de ces espèces qui viennent enrichir encore la chimie de coordination de LiSCN. On remarque cependant que les deux pics de basse fréquence ont toujours sensiblement la même intensité. Le pic à 2076 cm^{-1} a une intensité beaucoup plus faible. Dans les solutions saturées en LiSCN la proportion des agrégats est pratiquement indépendante de c_S. Si l'on se fonde sur les intensités intégrées on obtient environ 30 à 50% de LiSCN sous forme d'agrégat dans l'acétate de butyle et l'EMC et 20 à 30% dans le DEC. Dans les solutions saturées le rapport c_S/c est de l'ordre de 1,6. Si l'on augmente ce rapport la proportion d'agrégats supérieurs diminue rapidement. Ainsi pour c_S = 1 *M* et c_S/c = 2,5 ces agrégats ont pratiquement disparu au profit du dimère. Par dilution dans le benzène pur les agrégats supérieurs réapparaissent et la solution finit par précipiter au-delà d'une certaine dilution.

La position des fréquences ν(CN) des agrégats donne, sinon leur structure, du moins des informations sur la coordination des groupements SCN qui y sont engagés. Les fréquences 2018 et 2006 cm^{-1} sont à rapprocher de celles du doublet (2022, Raman et 1993, ir, Raman) caractéristique du tétramère (9). Cette zone de fréquence caractérise les groupements $SCNLi_3$ où l'azote est tridentate. Une bande faible vers 2100 cm^{-1} correspond aux groupements LiSCNLi. Une bande de moyenne intensité à 2076 cm^{-1}, peut-être dédoublée, devrait correspondre à des groupements $LiSCNLi_2$, dans la mesure où les déplacements de fréquence sont additifs. Elle pourrait provenir d'une interaction entre dimères par une liaison Li . . . S.

Dans les esters (BuOAc, DEC) les bandes ν(CO) libre et associée sont bien séparées ($\Delta\nu$ = −31 cm^{-1} dans BuOAc et

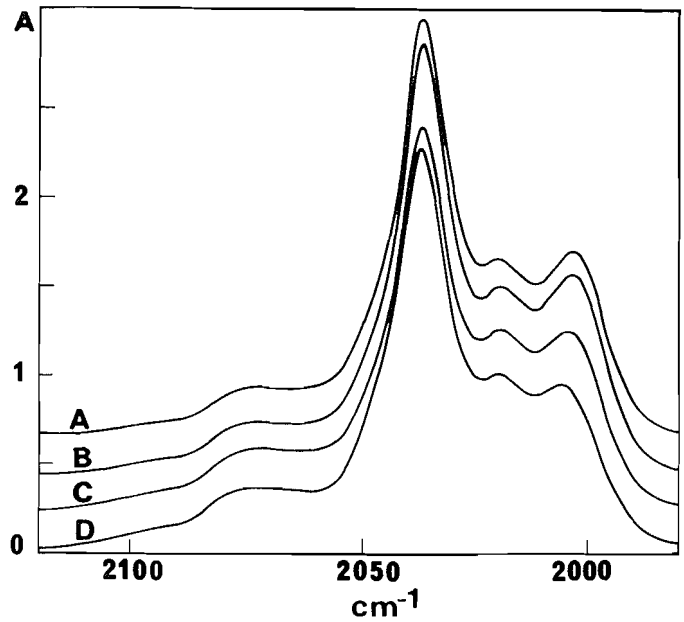

FIG. 4. Spectres infrarouges de solutions mixtes LiSCN – acétate de butyle dans le benzène (région ν(CN)). Concentrations (*M*): A 0,115 et 0,21; B 0,176 et 0,315; C 0,45 et 0,72; D 0,93 et 1,52. Les hauteurs des spectres ont été ramenées à 1 *M* en LiSCN.

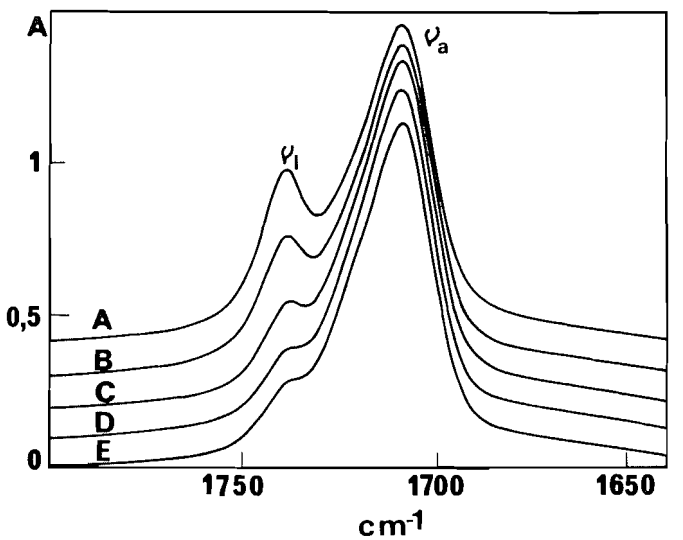

FIG. 5. Spectres infrarouges de solutions mixtes LiSCN – acétate de butyle dans le benzène (région ν(COC)). Concentrations (*M*): A 0,115 et 0,21; B 0,176 et 0,315; C 0,315 et 0,51; D 0,45 et 0,72; E 0,59 et 1,02. Les hauteurs des spectres ont été ramenées à 1 *M* en acétate de butyle.

DEC) de même que les bandes ν(CCO) ($\Delta\nu$ = 41 et 43 cm^{-1} dans BuOAc et DEC). Ces deux zones sont alors utilisables pour la détermination du nombre de solvatation et l'accord entre les résultats est excellent. Dans les solutions saturées l'intensité relative des bandes dues au solvant libre est faible (fig. 5) et elle décroît régulièrement lorsque la concentration augmente. La concentration en solvant libre que l'on en déduit, et qui est nécessaire pour assurer l'équilibre de dissolution, est pratiquement constante (~0,05 *M* dans l'acétate de butyle et ~0,14 *M* dans le DEC) dans tout le domaine de concentration étudié. Les résultats relatifs à l'EMC ont été obtenus, comme pour l'acétone, en utilisant la région ν(CCC) du spectre. Les solutions non saturées en LiSCN (tableau 2) donnent le nombre de solvatation du dimère pur avec $c_S/c \sim 2{,}5$ à 3. Pour les trois solvants ce nombre de solvatation est égal à 2. Dans les solutions saturées la valeur moyenne $\bar{n}$ du nombre de solvatation est comprise entre 1,4 et 1,6. Comme prévu les agrégats sont donc beaucoup moins solvatés que le dimère et leur nombre de solvatation moyen est probablement de l'ordre de 1.

Les résultats obtenus sur les différents systèmes étudiés montrent donc que le réaction de dimérisation de la paire LiNCS s'accompagne d'une désolvatation importante. Ce résultat avait été obtenu de façon indirecte dans un précédent travail (15) où nous avions montré que la dimérisation de LiNCS est un processus contrôlé par le terme entropique, ainsi d'ailleurs que la tétramérisation (16). Le nombre de coordina-

tion global du lithium reste égal à 4 ou voisin de 4 dans toutes les espèces formées. Les réactions d'association entre Li^+ et SCN^- sont donc des réactions où le solvant est remplacé par le ligand SCN dans la première couche de solvatation de Li^+.

Partie expérimentale

Le benzène utilisé est de qualité "pour spectroscopie" ainsi que l'acétone. Les autres solvants ont été distillés sur une colonne à 20 plateaux et séchés sur tamis moléculaire 4 Å. Toutes les manipulations ont été effectuées en boite à gants sèche.

Les spectres en solvant mixte ont été faits dans une cellule en CaF_2 d'épaisseur 26,8 μm. L'appareil utilisé est un spectromètre Bruker IFS 85 à transformée de Fourier. La résolution utilisée est 2 cm^{-1} sauf pour les spectres de la pyridine (0.5 cm^{-1}).

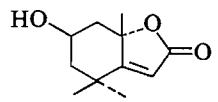
Reçu le 14 juin 1983[2]

HENRI ZAMARLIK, NOUKPO GNONLONFOUN et FRANCIS ROUESSAC. Can. J. Chem. **62**, 2326 (1984).

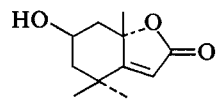
Au départ de l'acide homogéranique (isomère *trans*) **2**, nous décrivons une nouvelle synthèse totale et stéréosélective du (±)-loliolide **1**. La cyclisation de **2** avec le trifluoroacétate de mercure ou le chlorure de phénylsélénium conduit dans un premier temps à l'isodihydroactinidiolide **6** qui est transformé en (±)-loliolide après six étapes simples.



1

HENRI ZAMARLIK, NOUKPO GNONLONFOUN, and FRANCIS ROUESSAC. Can. J. Chem. **62**, 2326 (1984).

Starting from pure homogeranic acid **2**, in a stereoselective fashion, we describe a new synthesis of (±)-loliolide **1**. Cyclization of **2** with mercury trifluoroacetate or phenylselenenyl chloride provides the isodihydroactinidiolide **6** which was converted to the racemate of loliolide after six steps.



1

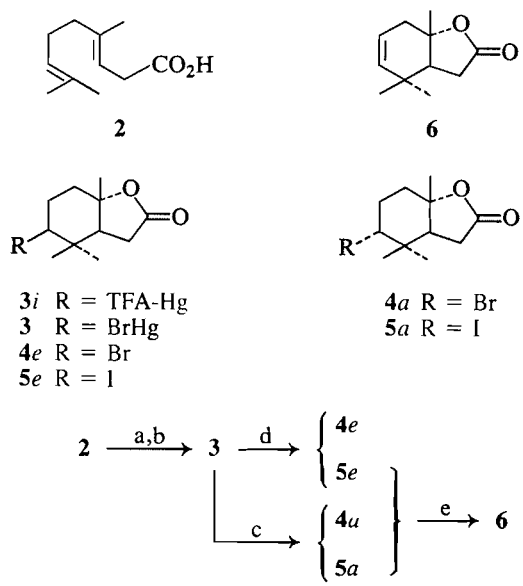
Le (±)-loliolide **1**[3] est un composé appartenant à un groupe particulier de lactones terpéniques à onze atomes de carbone qui comprend essentiellement les divers actinidiolides. Le composé **1** a été isolé à l'état de traces à partir de divers végétaux dont le *Lolium perenne* (1, 2), le *Fumaria officinalis* (3), le *Digitalis lanata* (4), le *Digitalis purpurea* (5) et le *Cystophora moniliformis* (algue brune) (6).

Sa structure a été établie par Hodges et Porte (1) ainsi que par Sato *et al.* (5). Sa configuration absolue a été déterminée par Isoe, Hyeon *et al.* (7, 8). Jusqu'à ce jour, quatre synthèses de **1** ont été effectuées à partir de la bromo-2 triméthyl-2,6,6 cyclohexanone (9), de l'isophorone (10), de l'acide homosafranique (11) et de l'hydroxy-4 triméthyl-2,2,6 cyclohexanone optiquement active (12).

Par ailleurs Hoye et Kurth (13) ont obtenu en 1978 et 1979 des composés biologiques, à jonction *trans*, apparentés aux tétrahydroactinidiolides, susceptibles de conduire à **1**.

La méthode retenue pour la synthèse totale du loliolide racémique repose sur la création du système bicyclique lactonique, par cyclisation électrophile de l'acide homogéranique **2** (isomère *trans* pur) (14), soit au moyen du trifluoroacétate de mercure, soit avec le chlorure de phénylsélénium. On obtient dans un premier temps la lactone éthylénique **6**, les intermédiaires réactionnels étant les lactones halogénées **4** ou **5** ou la sélénolactone **7** (15, 16) (schémas 1 et 2).

Traité par le trifluoroacétate mercurique, l'acide homogéranique en solution dans le nitrométhane se cyclise à température ambiante pour donner le tétrahydroactinidiolide substitué en 5 avec le groupement (TFA—Hg) en position équatoriale. Après remplacement de TFA par un atome d'halogène (Br ou I) au moyen d'une solution saturée d'halogénure de



(a) Hg $(CF_3CO_2)_2$; (b) KBr/H_2O/20°C/24 h; (c) X_2 (X = Br ou I)/pyr./*hν*/20°C/10 min; (d) Li I_3/dioxanne/eau/20°C/72 h ou Li Br + Br_2 (2:1)/pyridine/20°C/20 h; (e) LiCl anhydre/DMF/50°C/3 H (réf. 17).

SCHÉMA 2

potassium à l'abri de la lumière, on isole l'organomercuriel **3**, lui-même transformé en lactones bromées **4***e* ou **4***a* selon Hoye et Kurth (13).

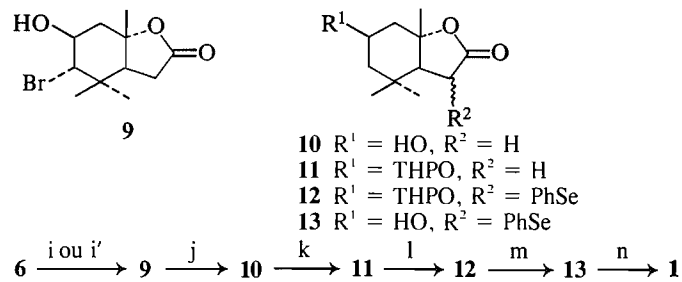
Nous avons déjà décrit une méthode de préparation de **4***e* en passant par la bromhydrine terminale de **2** (18), mais les meilleurs intermédiaires halogénés en vue d'accéder par déhydrohalogénation à **6**, sont constitués par les iodolactones **5***e* ou **5***a*. L'iodolactone équatoriale **5***e* est obtenue en agitant le dérivé mercuriel **3**, en solution dans du dioxanne, avec KI_3 à température ambiante (rendement global **2** → **6**:30%). Par contre en traitant **3**, par de l'iode en milieu pyridinique sous irradiation uv pour favoriser un mécanisme radicalaire, on prépare de manière stéréospécifique l'iodolactone axiale **5***a* (19) (rendement global **2** → **6**:25%). L'iodolactone **5***e*, traitée dans du DMF diméthylformamide fraîchement distillé, avec du chlorure de lithium anhydre, permet de préparer la lactone éthylénique **6** avec un rendement de 40%.

L'oxydation–élimination de la lactone séléniée **8** (16) est une autre voie d'accès à la même lactone éthylénique **6**. L'acide homogéranique **2**, en solution dans CH_2Cl_2 et à 0°C, traité par PhSeCl permet de préparer la lactone de monocyclisation **7** (15). En agitant **7** avec CF_3COOH à 10% dans CH_2Cl_2, on obtient la lactone bicyclique séléniée **8**. Le rendement global pour obtenir la lactone **6** par cette méthode est de 30% à partir de **2** ce qui est comparable à la voie précédemment décrite.

Le schéma 3 résume les dernières étapes de la synthèse du (±)-loliolide. La lactone éthylénique **6**, traitée par le *N*-bromoacétamide en milieu eau–acétone (1/3 d'eau), à 0°C ou par le *N*-bromosuccinimide en milieu eau–THF (1:1) à 0°C, conduit à la bromhydrine *trans* diaxiale **9** qui est alors réduite en dihydrololiolide **10** par le nickel de Raney en suspension dans CH_2Cl_2.

La création d'une double liaison en α du carbonyle de **10**, via l'énolate correspondant, conduit au (±)-loliolide. On commence par désactiver la fonction alcool de **10** pour éviter qu'elle soit le siège de réactions secondaires. Pour cela, **10** en solution dans l'éther sec est agité à 0°C avec du dihydropyranne en présence d'acide paratoluènesulfonique. Le dérivé tétrahydropyrannylique **11** obtenu, traité par le diisopropylamidure de lithium à −78°C dans du THF sec, conduit à l'énolate correspondant. On fixe le radical SePh (mélange des deux isomères) en agitant à −78°C l'énolate obtenu avec PhSe—SePh, en solution dans du THF, et en présence d'HMPT sec. L'α-phénylsélénolactone bloquée **12** en solution dans $(C_2H_5)_2O$, est enfin hydrolysée par une solution d'acide chlorhydrique 2 *N*.

Par oxydation–élimination de l'α-phénylsélénolactone **13** en solution dans l'acide acétique à 0°C, et de l'eau oxygénée à 30%, on obtient le (±)-loliolide qui est purifié par chro-



(i) NBS/eau–tétrahydrofuranne (1:1)/0°C puis température ambiante/3 jours; (i') NBA/eau–acétone (1:2)/0°C/ puis température ambiante/1 h; (j) Ni Raney/CH_2Cl_2/20°C/4 h; (k) dihydropyranne/éther/TsOH/20°C/6 h; (l) LiN($^{iPr}_{iPr}$)/tétrahydrofuranne/ −78°C/1 h puis $(PhSe)_2$/−78°C → 40°C/2 h; (m) HCl–H_2O (2 *N*)/Et_2O/20°C/6 h; (n) H_2O_2/AcOH–tétrahydrofuranne (1:10)/ 0°C/2 h

SCHÉMA 3

matographie sur gel de silice (benzène/éther 1:1). Le composé **1**, ainsi formé présente les mêmes caractéristiques que celles indiquées dans la littérature (1).

Cette synthèse s'insère dans les travaux que nous avons effectués pour obtenir des lactones dont le squelette à onze atomes de carbone est commun à celui de la famille des actinidiolides naturels. La préparation des dérivés glycosidés du (±)-loliolide **1** sera la prochaine étape de notre étude.

Partie expérimentale

Conditions générales

Les déterminations physico-chimiques ont été effectuées au moyen des appareils suivants: spectrophotomètre infrarouge Beckman Acculab 2; spectrophotomètre rmn ^1H Varian EM 360 60 MHz et EM 390 90 MHz; le TMS est utilisé comme référence interne; spectromètre de masse Kratos MS 25 couplé à un ordinateur Data Novo System 4 pour l'impact électronique (IE) 70 eV; spectromètre de masse quadrupôle Nermag R 10–10 pour l'ionisation chimique par NH_3 (IC).

Les microanalyses des nouveaux composés ont été effectuées au service central d'analyse du centre national de la recherche scientifique 69390 Vernaison (France). Silice pour chromatographie sur colonne: gel de silice 40 Merck (70–230 mesh ASTM).

1. *Hexahydro-3α,4,5,6,7,7aα (3H) trifluoroacétobromomercuro-5β triméthyl-4,4,7a benzofurannone-2* **3**i

A 1,70 g (9,34 mmol) d'acide homogéranique en solution dans 20 mL de nitrométhane sec, fraîchement distillé, on ajoute rapidement par petites fractions, sous azote, 4,38 g (10,27 mmol) de trifluoroacétate de mercure $(CF_3CO_2)_2Hg$. Le mélange est agité 1 h à température ambiante 20°C. On ajoute 20 mL d'H_2O; on filtre sur laine de verre après extraction au CH_2Cl_2, on sèche sur $MgSO_4$. Après évaporation des solvants on obtient 4,58 g d'une huile brune qui se solidifie lentement; ir (KBr) ν (CO_2): 1770 cm^{-1}; ccm, R_f = 0,14 (éluant: CH_2Cl_2/hexane/éther 1:1:1).

2. *Bromomercuro-5β hexahydro-3aα,4,5,6,7,7aα (3H) triméthyl-4,4,7a benzofurannone-2* **3**

La trifluoroacétomercurolactone brute est solubilisée dans CH_2Cl_2; on ajoute 150 mL d'une solution de KBr. Le mélange est agité à l'abri de la lumière pendant 3 jours. Après extraction, on sèche la phase organique sur $MgSO_4$. On évapore sous vide le solvant et on obtient 4,05 g de produit brut **3**; ccm R_f = 0,29 (éluant: CH_2Cl_2/hexane/éther 1:1:1); sm (IE) *m/e* (%): 462 (<1), 380 (<1), 181 (52,1) (−HgBr), 153 (11,7), 137 (15,5), 135 (12,3), 121 (28,5), 109 (12), 95 (34,9), 93 (12,7), 81 (24,1), 79 (12,5), 69 (100), 67 (23,7); sm (IC au NH_3) *m/e* (%): 463 (53) (M + 1), 479 (70), 480 (100) (M + NH_4^+), 200

(52). *Anal.* calc. pour $C_{11}H_{17}HgBrO_2$ (M = 461,77): C 28,61, H 3,72, O 6,93, Br 17,30, Hg 43,44%; tr.: C 28,82, H 3,32, O 7,03%.

3. *Hexahydro-3aα,4,5,6,7,7aα (3*H*) iodo-5β triméthyl-4,4,7a benzofurannone-2* **5**e

A 4 g (8,67 mmol) d'une solution de **3** dans 50 mL d'un mélange eau–dioxanne (10% H_2O) on ajoute goutte à goutte 25 mL d'une solution de KI_3, 1,2 équivalent (2,64 g de I_2 dans 25 mL d'une solution saturée de KI). Une fois l'addition terminée, on agite le mélange 3 jours à température ambiante (20°C). On rajoute 25 mL d'H_2O et on décolore la solution au disulfite de potassium. Après extraction à l'éther, séchage sur $MgSO_4$ et évaporation du solvant, on obtient 2,65 g de **5***e*; ccm R_f = 0,47 (éluant: CH_2Cl_2/hexane/éther 1:1:1); rmn ^1H ($CDCl_3$/TMS) δ en ppm: 1,05, 1,10, 1,40 (3s, CH_3), 4,20 (dd, J = 12 et 6 Hz, *H*—C—I); sm (IE) *m/e* (%): 309 (14) × 10, 293 (2,2) ($-CH_3$), 265 (2,2) ($-CO_2$), 182 (10,6), 181 (76) (−I), 153 (27,5), 137 (11,9), 135 (34,2), 121 (49,4), 111 (15,8), 101 (23,9), 95 (77,1), 69 (65,4), 67 (37,6), 55 (44,2), 43 (100); sm (IC au NH_3) *m/e* (%): 327 (18), 326 (100) (M + NH_4^+), 309 (22) (M + 1). *Anal.* calc. pour $C_{11}H_{17}IO_2$ (M = 308,19): C 42,87, H 5,57, O 10,38, I 41,18%; tr.: C 43,20, H 5,55, O 10,10%.

4. *Hexahydro-3aα,4,5,6,7,7aα (3*H*) iodo-5α triméthyl-4,4,7a benzofurannone-2* **5**a

Dans un mélange de 910 mg (2 mmol) de dérivé **3**, dissous dans 15 mL de pyridine sèche, on ajoute 0,77 g d'iode dissous dans 10 mL de pyridine. Après un barbotage d'azote (10 min), on irradie le mélange durant 10 min avec une lampe Hanovia 100 W, dans un tube Pyrex.

On récupère 580 mg (Rdt 94%) d'iodolactone axiale **5***a*, après traitement habituel. La lactone brute est recristallisée dans un mélange hexane–éther (4:1), F = 127°C (hexane/éther); spectre ir ν(C=O): 1741 cm^{-1}; rmn ^1H ($CDCl_3$/TMS) δ en ppm: 1,12, 1,16, 1,40 (3s, CH_3), 4,63 (dd J = 3 et 2,2 Hz, (*H*—C—I).

5. *Tetrahydro-3aα,4,7,7aα (3*H*) triméthyl-4,4,7a benzofurannone-2* **6**

Les 2,65 g (8,60 mmol) de **5** brut sont mis en solution dans du DMF sec fraîchement distillé et contenant 0,55 g de LiCl anhydre. On agite la solution 3 h à 50°C. Après refroidissement, on rajoute un peu d'eau, extrait à l'éther, et sèche ($MgSO_4$). On évapore le solvant puis on fait la chromatographie du produit brut sur gel de silice, éluant: éther/éther de pétrole (1:2). Rendement (**5***e* → **6**:40%); ccm R_f = 0,50 (même éluant); R_f = 0,67 (toluène/éther 1:1); ir (film) $\nu(CO_2)$: 1765 cm^{-1}; ν(C—H): 940 cm^{-1}; rmn ^1H ($CDCl_3$/TMS) δ en ppm: 1,05 (s, CH_3), 1,08 (s, CH_3), 1,35 (s, CH_3), 2,15 à 3,00 (m, 5H), 5,60 (m, 2H éthyl); sm (IE) *m/e* (%): 180 (6,1), 165 (42,2) ($-CH_3$), 137 (19,4), 136 (6,3) ($-CO_2$), 121 (17,8), 109 (28,1), 95 (21,7), 93 (25,2), 82 (69,7), 79 (19), 67 (35,7), 55 (29,1), 43 (100). $C_{11}H_{16}O_2$, M^+ calculé: 180,11502; trouvé: 180,1150. *Anal.* calc.: C 73,28, H 8,96, O 17,75%; tr.: C 73,31, H 8,96, O 17,81%.

6. *(2S,3R;3S,2R) méthyl-5 (méthyl-4 pentène-3 yl)-5 phénylséléno-4 butyrolactone* **7**

A une solution d'acide homogéranique (1,82 g, 10 mmol) **2** dans 10 mL de CH_2Cl_2, on ajoute 420 mg (7 mmol) d'acide acétique et 610 mg (6 mmol) de triéthylamine anhydre. On agite 5 min à température ambiante, puis on refroidit ce mélange à 5°C. On ajoute alors, goutte à goutte, sous azote, 1,2 g (3,1 mmol) de chlorure de phénylsélénium en solution dans 10 mL de CH_2Cl_2. On poursuit l'agitation durant 8 h à température ambiante avant de laver le mélange réactionnel avec une solution aqueuse de $NaHCO_3$ (40 mL). On extrait à l'éther, sèche ($MgSO_4$) et concentre. Le produit brut est chromatographié sur gel de silice. On recueille 2,4 g (Rdt 70%) de **7**, aux caractéristiques déjà décrites (15).

7. *Hexahydro-3aα,4,5,6,7,7aα (3*H *phénylséléno-5β triméthyl-4,4,7a benzofurannone-2* **8**

On ajoute sous azote à 2 g de **7** en solution dans 10 mL de CH_2Cl_2 anhydre, 0,2 mL d'acide trifluoroacétique. On agite 10 min, dilue avec 50 mL d'eau et 50 mL d'éther puis neutralise avec $NaHCO_3$. Après traitement habituel, le produit réactionnel brut est chromatographié sur silice (éluant C_6H_6), pour éliminer les traces de $(PhSe)_2$. On obtient ainsi 1,6 g de **8** (Rdt 80%), F = 141°C (éther/hexane), aux caractéristiques déjà décrites (16); sm (IE) *m/e* (%): 338 (20), 336 (11), 181 (39), 153 (24), 137 (11), 135 (35), 121 (57), 111 (15), 95 (64), 69 (84), 43 (100). *Anal.* calc. pour $C_{17}H_{22}SeO_2$ (M = 337,35): C 60,52, H 6,59, O 9,49, Se 23,41%; tr.: C 60,89, H 7,09%.

8. *Bromo-5α hexahydro-3aα,4,5,6,7,7aα (3*H*) hydroxy-6 triméthyl-4,4,7α benzofurannone-2* **9**

A 70 mg (0,39 mmol) de **6** solubilisé dans 5 mL d'acétone à 0°C, on ajoute 134,3 mg (0,973 mmol) de *N*-bromoacétamide dissous dans 3,5 mL d'eau. On laisse 2 h à 0°C. Une fois la solution revenue à température ambiante, on laisse 1 h à cette température. On évapore l'acétone, on ajoute de l'eau puis une solution de disulfite de potassium à 10% pour détruire HOBr en excès. On extrait à l'éther, sèche sur $MgSO_4$. Après évaporation du solvant on obtient 103 mg de la bromhydrine **9**; ccm R_f = 0,16 (éluant: CH_2Cl_2/hexane/éther 1:1:1); sm (IE) *m/e* (%): 279 (1), 278 (2,1), 276 (2,3), 263 (12,3) ($-CH_3$), 261 (12,8) ($-CH_3$), 197 (4) (−Br), 183 (2,4) (−Br $-H_2O$), 179 (7,6), 153 (36), 143 (15,1), 136 (31,9), 135 (29,8), 134 (30,1), 109 (14,4), 98 (65,5), 85 (73,5), 71 (76,7), 55 (62), 43 (100); sm (IC au NH_3) *m/e* (%): 296 (87), 294 (100) (M + NH_4^+), 279 (18), 277 (21) (M + 1). *Anal.* calc. pour $C_{11}H_{17}O_3Br$ (M = 277,18): C 47,66, H 6,19, O 17,32, Br 28,83%; tr.: C 47,42, H 6,00, O 17,10%.

9. *Hexahydro-3aα,4,5,6,7,7aα (3*H*) hydroxy-6 triméthyl-4,4,7a benzofurannone-2* ***10***

Les 103 mg de la bromhydrine **9** sont solubilisés dans 15 mL de CH_2Cl_2. On ajoute 1 g de Ni de Raney en suspension dans CH_2Cl_2 sous N_2 (ballon bouché). On agite 4 h à température ambiante. On filtre sur Büchner, puis on sèche le filtrat sur $MgSO_4$. Après évaporation des solvants, le dihydrololiolide obtenu est purifié par chromatographie sur gel de silice (toluène/CH_2Cl_2/éther 13:10:4). On obtient alors 52 mg de **10** pur. Il cristallise lentement; F = 126°C; ir (film) ν (OH): 3480, 920 cm^{-1}; ν (COO): 1785 cm^{-1}; rmn ^1H δ en ppm: 1,0, 1,15, 1,55 (3s, $3CH_3$), 2,10 (s, OH), 4,35 (m, *H*-COH); sm (IE) *m/e* (%): 199 (5) × 10, 198 (1) × 10, 183 (17,5) ($-CH_3$), 165 (14) ($-CH_3$ $-H_2O$), 155 (2,6), 137 (15,2), 136 (12,1), 121 (11,1), 109 (12), 99 (19,1), 98 (45,9), 95 (18,5), 85 (23,7), 83 (33,5), 71 (22,6), 70 (35,5), 69 (85,6), 43 (100); sm (IC au NH_3): 217 (17), 216 (100) (M + NH_4^+), 200 (5), 199 (55) (M + 1). *Anal.* calc. pour $C_{11}H_{18}O_3$ (M = 198,29): C 66,62, H 9,17, O 24,21%; tr.: C 66,54, H 9,38, O 24,10%.

10. *Hexahydro-3aα,4,5,6,7,7aα (3*H*) tétrahydropyrannoxy-6 triméthyl-4,4,7a benzofurannone-2* ***11***

On dissout 52 mg de l'alcool **10** dans l'éther à sec à 0°C; on ajoute quelques mg d'acide paratoluènesulfonique, puis goutte à goutte, le dihydropyranne (1,5 équivalent). On laisse 1 h à 0°C, puis 5 h à température ambiante 20°C. On neutralise par Na_2CO_3 jusqu'à pH basique. Après extraction à l'éther, les phases organiques sont lavées à l'eau saturée de NaCl, et séchées sur $MgSO_4$. On évapore l'éther et on obtient **11** avec un rendement quantitatif; ir ν (COO): 1785, 1200, 1130, 1080, 1030, 810 cm^{-1}.

11. *Hexahydro-3aα,4,5,6,7aα (3*H*) phénylséléno-3-tétrahydro-pyrannoxy-6 triméthyl-4,4,7a benzofurannone-2* ***12***

On ajoute 0,36 mL (2,71 mmol) de diisopropylamine à 1,6 mL de butyllithium (1,6 *M* dans l'hexane) soit 1,28 équivalent, sous azote à −78°C en agitant. Une fois l'addition terminée, le mélange est abandonné 1 h à température ambiante.

On ajoute 3 mL de THF anhydre au LDA formé et on refroidit à −78°C. On additionne goutte à goutte en 1 h 564 mg (2 mmol) de **11** dissous dans 3 mL de THF anhydre puis on agite le mélange 20 min à −78°C et 1 h à température ambiante.

L'énolate formé est ensuite refroidi à −78°C, on rajoute 754 mg (2,4 mmol) de diphényldiséléniде en solution dans 2 mL de THF anhydre et 430 mg (2,4 mmol) de HMPT. Une fois l'addition terminée on agite le mélange 40 min à −78°C, puis 2 h à −40°C. On acidifie le mélange par addition de HCl 1 *M*. On extrait à l'éther, les phases

organiques sont lavées à l'eau saturée de NaCl et séchées sur $MgSO_4$. Après concentration sous vide on fait la chromatographie du produit brut sur une colonne de silice (éluant: hexane/acétate d'éthyle 80:20). En tête de colonne on élue PhSe—SePh et PhSeH puis une huile très légèrement jaune constituée de 440 mg de **12**; Rdt: 50%; ir ν (=C—H) 3030, 1580, 740 cm^{-1}; ν (COO): 1760 cm^{-1}.

12. *Hexahydro-3aα,4,5,6,7,7aα (3H) hydroxy-6 phénylséléno-3 triméthyl-4,4,7a benzofurannone-2* ***13***

A 438 mg (1 mmol) du mélange des 2 épimères de **12** dissous dans 20 mL d'éther, on ajoute 10 mL de HCl 2 *M* et on agite 6 h à température ambiante 20°C. Après décantation, la phase aqueuse est lavée une fois avec 10 mL d'éther. Les phases éthérées sont ensuite lavées à l'eau saturée de NaCl, séchées sur $MgSO_4$, concentrées sous vide. On obtient 352 mg de **13** (rendement quantitatif); ir (film): 3030, 1580, 740 cm^{-1}; ν (OH): 3440 cm^{-1}; ν (COO): 1760 cm^{-1}.

13. *Hydroxy-6 tétrahydro-5,6,7,7a triméthyl-4,4,7a (4H) benzofurannone-2* ***1***

On agite 48 mg (0,135 mmol) de **13** en solution dans 5 mL de THF avec 0,15 mL d'H_2O_2 à 30% et 0,50 mL d'acide acétique à 0°C sous azote pendant 2 h (ballon bouché). Le mélange réactionnel est ensuite versé dans une solution saturée de $NaHCO_3$ et extrait à l'éther. Les phases organiques sont lavées avec H_2O saturées de NaCl, séchées sur $MgSO_4$ et concentrées sous vide. Après chromatographie sur une colonne de gel de silice, éluant benzène/éther (1:1), on obtient 20 mg de **1** pur. Le rendement de la dernière étape est de 75%. Le composé **1** est insoluble dans l'éther et le CCl_4 à froid. Il est recristallisé dans le CCl_4; F = 140°C en accord avec la littérature (1); rmn ^1H ($CDCl_3$/TMS) δ en ppm: 1,25, 1,45, 1,80 (3s, $3CH_3$), 4,35 (pq, 1H, $J \simeq 3,5$ Hz, C*H*OH), 5,70 (s, 1H éthyl).

Correlation pK_a – activité catalytique des thiols dans la réaction d'hydrolyse de l'acétate de *p*-nitrophényle

ALAIN BREMBILLA, DENIS ROIZARD, JACQUELINE SCHOENLEBER ET PIERRE LOCHON[1]

Laboratoire de Chimie-physique Macromoleculaire, C.N.R.S. – E.R.A. 23, Ecole Nationale Superieure des Industries Chimiques, 1, rue Grandville, 54042 Nancy Cedex, France

Reçu le 6 février 1984

ALAIN BREMBILLA, DENIS ROIZARD, JACQUELINE SCHOENLEBER et PIERRE LOCHON. Can. J. Chem. **62**, 2330 (1984).

L'étude cinétique de l'hydrolyse de l'acétate de *p*-nitrophényle en présence de thiols primaires montre une activité catalytique provenant de l'ion thiolate seul. La comparaison des constantes de second ordre k_{RS^-} met en évidence un comportement différent des thiols primaires purement aliphatiques et des thiols primaires substitués en position α par un groupement aromatique. Dans ce dernier cas apparaît une corrélation de Brönsted log $k_{RS^-} = \beta pK_{SH} + C$ avec $\beta = 0{,}40$ et $C = -0{,}85$.

ALAIN BREMBILLA, DENIS ROIZARD, JACQUELINE SCHOENLEBER, and PIERRE LOCHON. Can. J. Chem. **62**, 2330 (1984).

The kinetic study of the hydrolysis of *p*-nitrophenylacetate in the presence of primary thiols indicates the thiolate anion as the sole catalytic species. Comparison of the true second order rate constants (k_{RS^-}) reveals that purely aliphatic primary thiols behave differently from aromatic α-substituted primary thiols. In the latter group a correlation can be established between the true second order rate constants and the pK_{SH} values by means of the Brönsted equation log $k_{RS^-} = \beta pK_{SH} + C$, with β equal to 0.40 and C equal to −0.85.

Introduction

Les enzymes protéolytiques comme la papaïne, la ficine ou la bromelaïne possèdent en plus du noyau imidazole de l'histidine un groupe thiol contenu dans le motif cysteïne qui est essentiel pour leur activité d'esterases. Le mécanisme d'action de ce type d'enzymes apparaît comme le résultat probable d'une coopération entre un groupe nucléophile et un site basique dans une catalyse plurifonctionnelle. Cette hypothèse a incité certains chercheurs à réaliser l'association des fonctions précédentes sur des molécules simples (mercaptoalcoyl-4 imidazoles) (1, 2) ou sur des macromolécules formées d'enchaînements peptidiques allant du dipeptide à quelques polypeptides (3, 4). Une première étude a été réalisée au Laboratoire sur de nouvelles molécules formées d'une chaîne alcoylthiol en position 2 d'un cycle benzimidazole, (les mercaptoalcoyl-2 benzimidazoles) (5), dans la réaction d'hydrolyse de l'acétate de *p*-nitrophényle. Cependant, l'interprétation des effets catalytiques particuliers de ces thiols hétérocycliques exige la connaissance des propriétés générales de la fonction sulfhydryle seule dans ce domaine.

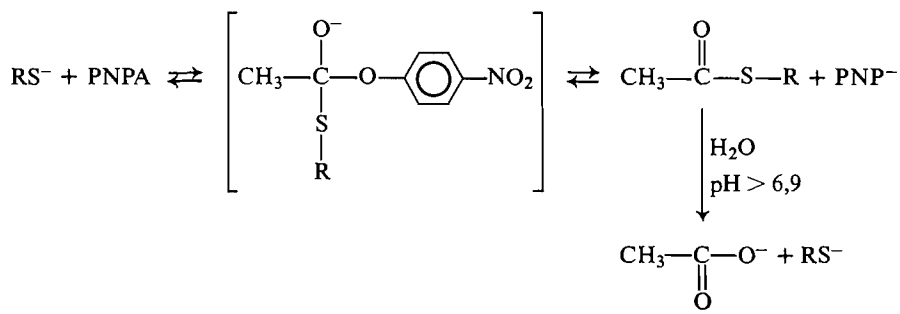
Les travaux mentionnés actuellement dans la littérature concernent soit des thiols aliphatiques comportant un substituant susceptible d'engendrer une activité catalytique supplémentaire (6–8), soit des thiols aromatiques (9, 10). Ces composés constituant des cas particuliers, il est apparu nécessaire d'étendre l'étude sur des exemples plus nombreux, en élargissant l'échelle des pK_a et tout en évitant d'introduire des fonctions parasites. Pour permettre une meilleure comparaison avec les molécules bifonctionnelles (en particulier les mercaptoalcoyl-2 benzimidazoles) la structure des mercaptans étudiés présente une certaine similitude (—CH_2—SH) au voisinage du groupe fonctionnel. Les composés répondant le mieux à cette condition sont les benzylmercaptans, facilement synthétisables et dont la nature et la position du substituant (*para* ou *méta*) sur le noyau benzénique permettent d'obtenir une gamme assez étendue de pK_{SH}. L'activité catalytique de ces thiols est comparée à celle de composés présentant une structure voisine comme le furyl-2 méthanethiol et d'autre part à celle d'éthanethiols β substitués tels que la cystéamine, le mercapto-2 éthanol ou le phényl-1 éthanethiol.

Propriétés catalytiques

Les propriétés catalytiques de ces thiols ont été étudiées en prenant comme réaction de base l'hydrolyse de l'acétate de *p*-nitrophényle (PNPA). Celle-ci est suivie à un pH donné en déterminant par spectrométrie uv la quantité d'ion *p*-nitrophénolate (PNP^-) libérée en fonction du temps.

Dans ce type de réaction catalysée par un thiol, il a été démontré (7) que la première étape est l'étape lente avec formation d'un thiolester via un intermédiaire tétraédrique d'addition, qui est ensuite très rapidement hydrolysé si le pH est supérieur à 6,9; il n'est alors plus possible de déceler une quantité appréciable de ce composé dans le milieu réactionnel.

Pour définir un ordre 1 par raport à l'ester, il n'est donc pas



[1] Personne à qui toute correspondance devrait être adressée.

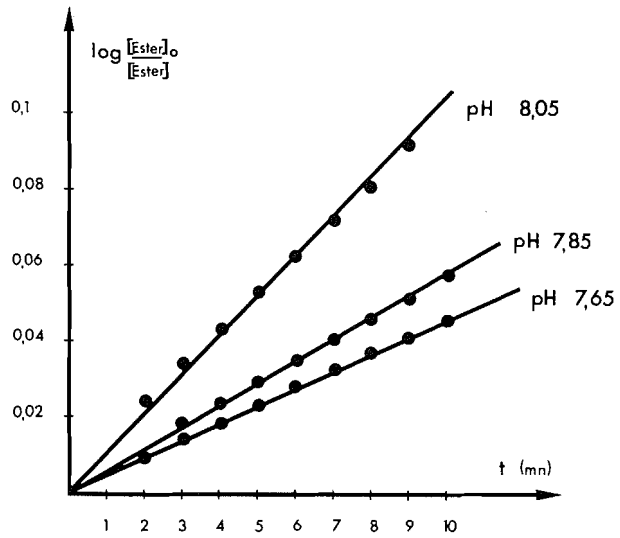


FIG. 1. Représentation de l'avancement de la réaction d'hydrolyse de l'acétate de *p*-nitrophényle (2×10^{-4} *M*) catalysée par le nitro-4 benzylmercaptan à différents pH et à différentes concentrations. Température: 30°C, solvant: eau–éthanol (28,5% d'éthanol vol.), tampon: phosphates (0,134 *M*) $I = 0{,}268$; pH = 7,65, $c = 2{,}23 \times 10^{-4}$ *M*; pH = 7,85, $c = 1{,}69 \times 10^{-4}$ *M*; pH = 8,05, $c = 1{,}96 \times 10^{-4}$ *M*.

nécessaire d'utiliser le thiol en large excès. Dans ces conditions, la cinétique du pseudo premier ordre s'exprime par la relation:

$$V(\text{vitesse globale}) = -\frac{d[PNPA]}{dt} = \frac{d[PNP^-]}{dt} = k_{obs}[PNPA]$$

k_{obs} = constante de vitesse globale de la réaction avec $k_{obs} = k_1 + k_{hydr}$

k_1 = constante de vitesse de pseudo-premier ordre de la réaction catalysée

k_{hydr} = constante de vitesse globale de la réaction non catalysée (hydrolyse propre de l'ester).

Les valeurs de k_{hydr} sont déterminées séparément pour chaque valeur du pH dans des conditions identiques à celles de la catalyse.

$k_{hydr} \times 10^4$ min^{-1}	pH
9,2	7,65
13,9	7,85
19,5	8,05

Comme pour les dérivés imidazoliques simples ne possédant qu'une seule fonction à caractère catalytique nucléophile (l'imidazole et le benzimidazole (11–13)) la réaction d'hydrolyse du PNPA catalysée par ces thiols simples est du pseudo premier ordre pour des concentrations en catalyseur égales et même inférieures à celles du substrat (fig. 1). En effet, pour un pH donné (fixé par la solution tampon), l'expression $x = f(t)$, représentant l'avancement de la réaction, varie linéairement avec le temps. Ce comportement a pu être vérifié pour certains composés jusqu'à un taux de conversion voisin de 50%, mais dans la pratique, les essais ont été limités à 25% d'avancement afin d'analyser principalement le début de la réaction et d'éviter par la suite le phénomène d'oxydation du catalyseur qui intervient de manière non négligeable.

L'examen du tableau 1 montre que la constante apparente du second ordre $k_2' = k_1/[\text{thiol}]_{total}$ qui caractérise l'efficacité du catalyseur à un pH donné, croît avec celui-ci mais reste invariante quelle que soit la valeur de rapport [catalyseur]/[substrat] (supérieur ou inférieur à 1), pour ce même pH.

Dans la série des benzylmercaptans, la constante k_2' dépend, à pH donné de la basicité de l'ion thiolate et par conséquent de la nature du substituant sur le noyau benzénique. Sa variation est identique en première approximation à celle du pouvoir donneur du substituant, ce dernier diminuant selon la séquence de substitution $p\text{-}OCH_3 > \rightarrow > p\text{-}NO_2$.

Séparation des effets catalytiques

L'interprétation de l'activité catalytique des thiols implique la prise en considération des différentes formes sous lesquelles peuvent exister ces composés dans le milieu réactionnel: RS^-, l'ion thiolate, caractérisé par la constante spécifique k_{RS^-}, et éventuellement la forme neutre RSH (constante spécifique k_{RSH}). Ces deux constantes sont reliées à k_1 et k_2' par les relations suivantes:

$$k_1 = k_2'([RS^-] + [RSH]) = k_{RS^-}[RS^-] + k_{RSH}[RSH]$$

En combinant avec la relation donnant la constante d'équilibre acide–base

$$RSH + H_2O \overset{K_{SH}}{\rightleftarrows} RS^- + H_3O^+$$

nous obtenons l'expression:

$$Y \equiv k_2'\left(1 + \frac{K_{SH}}{a_H}\right) = \frac{K_{SH}}{a_H} k_{RS^-} + k_{RSH} \text{ avec } a_H \simeq [H_3O^+]$$

La détermination des constantes spécifiques du deuxième ordre pour la réaction d'hydrolyse du PNPA catalysée par quelques thiols courants associés à une autre fonction conduisait Whitaker (7), puis Ogilvie *et al.* (8) à admettre que seul l'ion thiolate est responsable de l'activité catalytique. Les résultats que nous rapportons portent sur un plus grand nombre de composés ne comportant que la fonction thiol et pour une échelle de pK_a beaucoup plus large. Ils confirment et généralisent la conclusion précédente. En effet, même en tenant compte de l'imprécision expérimentale, le tracé du diagramme $Y = f(1/a_H)$ se compose d'un ensemble de droites passant par l'origine (fig. 2), l'ordonnée à l'origine calculée, qui représente la constante spécifique k_{RSH} de la molécule à l'état neutre, a une valeur négligeable ($-0{,}4 < k_{RSH} < +0{,}4$). L'espèce thiol neutre ne présente donc dans ce cas aucune réactivité sur la fonction carbonyle de l'ester et l'effet catalytique est uniquement attribué à l'ion thiolate. La constante spécifique k_{RS^-} (tableau 1) est déterminée à partir de la pente de la droite $Y = f(1/a_H)$ correspondante (méthode des moindres carrés). Nous observons en outre une bonne concordance entre les valeurs de k_{RS^-} ainsi obtenues et celles calculées (tableau 1) pour chaque valeur du pH et de la concentration en catalyseur, par la relation:

$$k_{RS^-} = k_2'(10^{pK_{SH} - pH} + 1)$$

(l'imprécision étant plus grande dans le cas du cyclohéxylméthanethiol, qui présente une très faible réactivité).

Pour l'ensemble des thiols étudiés, la constante spécifique k_{RS^-} est indépendante de la concentration en catalyseur et du pH. L'invariance de k_{RS^-} montre que même à des pH où la concentration en ions thiolate est faible, la forme non ionique du groupe thiol ou le reste de la molécule (cycle benzénique, furanne) n'ont pas d'action décelable. Ce résultat est également observé dans le cas des thiols comportant une fonction susceptible d'accroître l'activité catalytique à certains pH (supé-

[a] Solvant: eau–éthanol (28,5% d'éthanol vol.), T = 30°C, tampon phosphates (0,134 M) I = 0,268.
[b] k_{RS^-} calculé pour chaque valeur de la concentration en catalyseur et du pH.
[c] k_{RS^-} déterminé par la pente de la droite $Y = f(1/a_H)$; pK_{SH} déterminés dans un mélange eau–éthanol (28,5% d'éthanol vol.), T = 30°C, (solutions 10^{-3} M sans addition de KCl).

rieurs au pK_a) pour le mercapto-2 éthanol et la cystéamine. Dans ce dernier cas, l'espèce $R(NH_3^+)S^-$ est prépondérante aux pH étudiés (7,65 à 8,05) (14) et donc responsable de l'activité catalytique.

Influence de la basicité de l'anion sur sa nucléophilie

La basicité de l'ion thiolate définie par la mesure du pK_{SH} varie avec la nature du substituant dans une série de composés homologues. Dans le cas des benzylmercaptans il est possible d'établir une corrélation de Hammett (fig. 3) entre le pK_{SH} de la fonction thiol et les constantes classiques de substituants (15). Pour les dérivés *para* ou *méta* substitués nous obtenons une droite unique d'équation:

$$pK_{SH} = -1{,}30\sigma + 9{,}5 \text{ avec } R = 0{,}99$$

Le but de cette étude cinétique sur ces thiols simples est essentiellement d'examiner s'il existe une relation entre l'activité catalytique de l'ion thiolate et sa basicité. Pour cela nous utilisons une corrélation de Brönsted entre la constante spécifique de l'anion et le pK_a de la fonction thiol. Le diagramme log k_{RS^-} vs. pK_{SH} (fig. 4) présente un bon alignement des points repré-

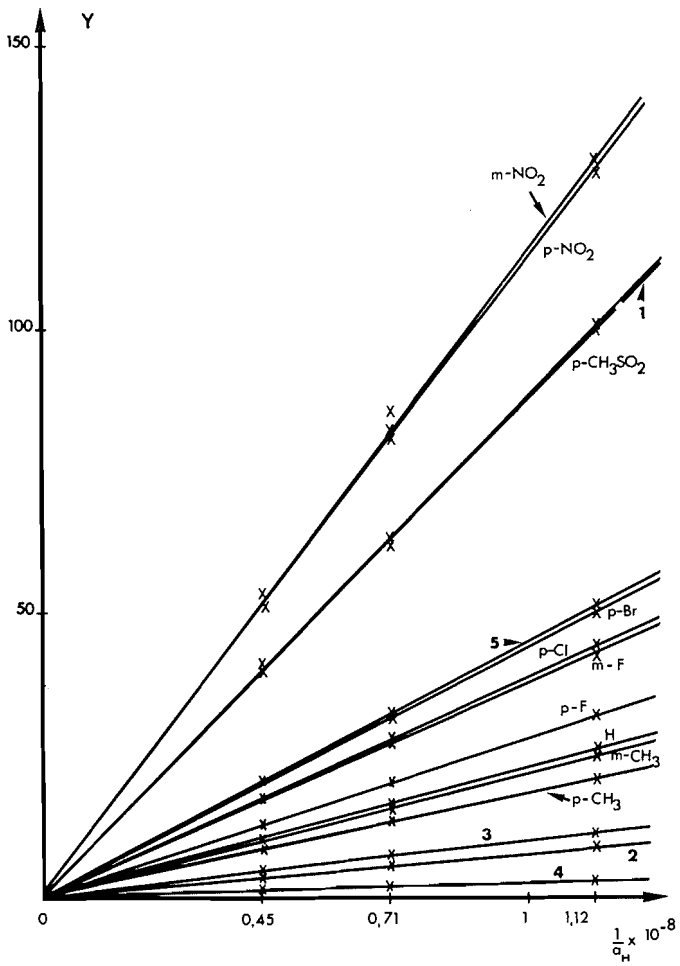

FIG. 2. Représentation de $Y = f(1/a_H)$ pour l'hydrolyse de l'acétate de *p*-nitrophényle catalysée par les différents thiols: benzylméthanethiols *méta* ou *para* substitués, **1** cystéamine, **2** mercapto-2 éthanol, **3** phényl-2 éthanethiol, **4** cyclohexylméthanethiol, **5** (furyl-2) méthanethiol; T = 30°C; mélange eau–éthanol (28,5% d'éthanol vol.); tampon phosphates (0,134 M) I = 0,268.

sentatifs des benzylmercaptans *méta* et *para* substitués ainsi que du composé de même structure, le furyl-2 méthanethiol.

La méthode des moindres carrés conduit à la relation:

$$\log k_{RS^-} = 0{,}4\ pK_{SH} - 0{,}85\ (R = 0{,}99)$$

Pour les ions thiolate avec un environnement stérique et électronique différant peu d'un composé à l'autre, il existe un parallèle entre la vitesse d'attaque du nucléophile sur le centre électrophile et l'affinité de ce même nucléophile pour le proton exprimé par sa basicité.

Dans le cas particulier des dérivés β substitués de l'éthanethiol (cystéamine, mercapto-2 éthanol et phényl-2 éthanethiol), la déviation négative de leurs points représentatifs par rapport à la droite précédente ne peut être attribuée à des erreurs expérimentales, mais plutôt à une diminution de l'activité catalytique de l'anion due à une augmentation de la longueur de la chaîne aliphatique entre le site catalytique et le noyau aromatique ou toute autre fonction. Nous constatons ainsi un accroissement de nucléophilie de l'anion lorsque le centre réactionnel n'est séparé d'un cycle à caractère aromatique que par un seul groupe méthylène. Une observation analogue est faite lors de l'étude de la réactivité d'un thiol comportant un groupe cyclohexyle séparé du site actif par un

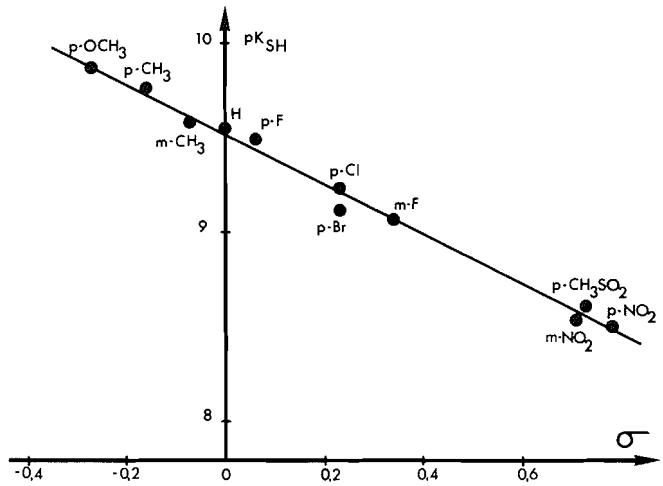

FIG. 3. Corrélation de Hammett pour les pK_{SH} des benzylméthanethiols.

seul méthylène (le cyclohexylmethanethiol). La diminution de nucléophilie de l'anion par rapport à celle d'un benzylmercaptan de même pK_{SH} semble provenir du caractère saturé du groupe fixé en position β.

L'équation de Brönsted trouvée pour la série des benzylmercaptans est très comparable à celle obtenue par Ogilvie *et al.* (8) (0,38 pK_{SH} − 0,75) pour la réaction d'alcanethiols sur le PNPA dans un mélange eau–dioxanne (1% de dioxanne en volume) à 25°C. La valeur β = 0,4 que nous obtenons confirme que la sensibilité à la basicité d'un nucléophile dans les réactions avec l'acétate de *p*-nitrophényle est plus faible dans le cas des bases contenant un atome de soufre que pour les bases oxygénées ou azotées (12). Ce résultat rejoint les conclusions d'Ogilvie *et al.* (8) selon lesquelles, d'un point de vue purement biologique, un thiol possédant un faible pK_{SH} sera un nucléophile très efficace dans le domaine des pH physiologiques. Toutefois, la comparaison des constantes β pour différents types de nucléophiles nécessite certaines réserves dans la mesure où la structure de l'état de transition varie avec la nature des composés (16).

Conclusion

L'étude des propriétés catalytiques sur l'hydrolyse de l'acétate de *p*-nitrophényle d'une série de méthanethiols α substitués par des groupements aromatiques confirme et généralise les premières conclusions avancés par Whitaker (7) en montrant que la fonction thiol est effectivement un catalyseur de type nucléophile uniquement sous la forme thiolate, même à très faible concentration, selon un mécanisme caractérisé par une première étape lente d'attaque sur le groupe carbonyle. La molécule à l'état neutre ne participe aucunement à la réaction.

Partie expérimentale

Méthode générale de préparation des benzylmercaptans

(Méthode à la thiourée – à l'exception des dérivés nitrés, qui nécessitent un procédé particulier).

A partir d'un alcool (17, 18)

On porte à reflux, sous courant d'azote pendant 24 h, un mélange de 0,1 mol d'alcool benzylique approprié, 0,3 mol d'acide bromhydrique à 48% et 0,1 mol de thiourée. Au mélange préalablement refroidi on ajoute 129 mL d'une solution de soude à 10%. On laisse poursuivre la réaction d'hydrolyse pendant 6 h à 100°C. toujours sous courant d'azote, mais sans agitation.

Il se forme une couche huileuse qui est séparée de la phase aqueuse.

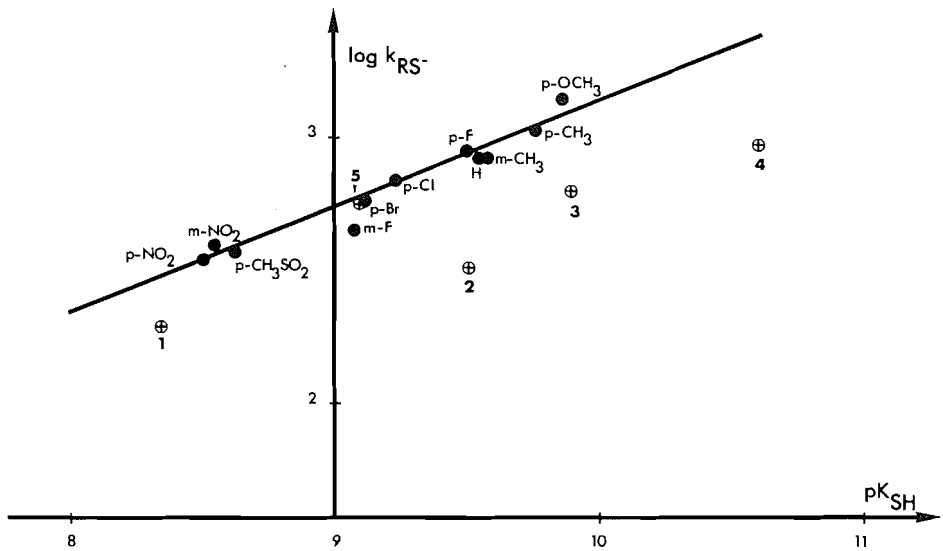

FIG. 4. Corrélation de Brönsted pour la réaction des ions thiolates avec l'acétate de *p*-nitrophényle dans un mélange eau–éthanol (28,5% d'éthanol vol.) à la température de 30°C; ● benzylméthanethiols; ⊕ **1** cystéamine, **2** mercapto-2 éthanol, **3** phényl-2 éthanethiol, **4** cyclohexylméthanethiol, **5** (furyl-2) méthanethiol.

Après refroidissement, la phase aqueuse est acidifiée et le thiol extrait à l'éther. L'extrait éthéré est mélangé à la phase organique, puis séché sur sulfate de calcium. Après évaporation du solvent, l'huile est distillée sous vide pour donner le benzylmercaptan recherché qui est conservé sous argon et à l'abri de la lumière.

Le rendement de la réaction varie entre 60 et 80% selon l'alcool utilisé.

A partir d'un dérivé halogéné

Un mélange de 1,12 mol de thiourée et 0,37 mol de dérivé halogéné dans 60 mL d'eau est porté à reflux sous courant d'azote pendant 6 h. A la solution refroidie on ajoute 2 mol de potasse dans 200 mL d'eau et on laisse poursuivre l'hydrolyse à 100°C pendant 6 h sous courant d'azote et sans agitation. La suite des opérations est identique à celle décrite dans la méthode précedente.

Benzylmercaptans (substituant nucléaire)	Produit de départ	Caractéristiques physiques (solvant de recristallisation, point d'ébullition, point de fusion)
p-CH_3	Alcool	Eb 53°C sous 1 Torr litt. (19) Eb_{14} = 99°C
m-CH_3	Alcool	Eb 49°C sous 1 Torr litt. (19) Eb_{12} = 90°C
p-F	Alcool	Eb 45°C sous 1 Torr
m-F	Alcool	Eb 23°C sous 0,6 Torr litt. (20) Eb_3 = 45°C
p-Br	Bromure	P.F. = 25°C litt. (21) F° = 25°C
p-CH_3SO_2	Bromure	Distillation sous vide F° = 46°C
Cyclohexylmethanethiol	Alcool	Eb_{11} = 54°C sous 11 Torr

La cystéamine, le mercapto-2 éthanol et le phényl-2 éthanethiol sont des produits commerciaux, ainsi que le furyl-2 méthanethiol et les benzylmercaptans (*p*-OCH_3, *p*-Cl, H).

Synthèse du bromure de méthylsulfonyl-4 benzyle

Ce composé n'est pas commercialisé, il a donc fallu envisager sa synthèse à partir de l'acide *p*-méthylsulfonylbenzoïque.

Préparation du chlorure de méthylsulfonyl-4 benzoyle

On porte à reflux pendant 4 h un mélange de 0,101 mol d'acide *p*-méthylsulfonylbenzoïque, 0,303 mol de chlorure de thionyle (23 mL) et 2,3 mL de diméthylformamide. Après élimination du chlorure de thionyle excédentaire par distillation, le chlorure d'acide est ensuite recristallisé dans le benzène; *F* = 129°C, rendement 85%.

Préparation du méthylsulfonyl-4 benzoate d'éthyle

On ajoute à froid, par petites quantités, 0,086 mol du chlorure d'acide dans un mélange alcool–pyridine. Celui-ci est chauffé au bain marie pendant 3 h, tout le chlorure passe alors en solution. Après refroidissement le produit précipite en masse. Il est essoré, puis abondamment lavé à l'eau pour éliminer la pyridine, puis à l'éther de pétrole. L'ester est recristallisé dans le benzène; *F* = 96–97°C. Rendement après recristallisation: 84%.

Réduction de l'ester

Borohydrure de lithium (0,025 mol) à 99% dans 25 mL de diglyme anhydre sont versés dans un ballon tricol équipé d'une agitation. On ajoute par petites portions 0,04 mol de méthylsulfonyl-4 benzoate d'éthyle (9, 12 g) et on chauffe le mélange au bain marie pendant 3 h. La solution obtenue est ensuite versée dans 50 g de glace pilée contenant 5 mL d'acide chlorhydrique concentré. Après extraction à l'éther et évaporation à sec, l'alcool obtenu a un aspect sirupeux et recristallise très difficilement. Il sera utilisé sans autre purification. Rendement en produit brut: 90%. Le diglyme utilisé est purifié selon une méthode décrite par Brown *et al.* (22).

Bromation de l'alcool méthylsulfonyl-4 benzylique

Nous avons adapté une méthode de bromation des alcools décrite par Kamm et Marvel (23). On ajoute goutte à goutte 2 g d'acide sulfurique concentré dans un mélange de 0,04 mol de l'alcool précédent, 0,49 mol d'acide bromhydrique à 48% et 2,5 g d'acide sulfurique concentré. La solution est portée à reflux pendant 6 h, puis versée dans de la glace pilée. Le bromure précipite sous forme de fines plaquettes. Le produit est recueilli sur verre fritté, et lavé à l'eau froide pour éliminer l'acide. Recristallation dans un mélange (méthylcyclohexane–benzène, 50:50 en volume); rendement quantitatif; *F* = 97°C.

Préparation des p- *et* m-*nitrobenzylmercaptans*

Les thiocyanates

A 0,1 mol de chlorure de *p*- ou *m*-nitrobenzyle dissoute dans 150 mL d'alcool absolu, on ajoute par petites quantités et sous bonne agitation 0,1 mol de thiocyanate de potassium sec et on porte le mélange à reflux pendant 6 h. La suspension est ensuite filtrée à chaud afin de séparer le chlorure de potassium qui a précipité au cours de la réaction. Le thiocyanate cristallise après refroidissement du filtrat.

Recristallisation dans l'alcool; rendement: 93%; dérivé *para*: F = 86°C; dérivée *méta*: F = 72°C. Caractérisation par spectroscopie infrarouge, ν(SC≡N): bande fine et intense à 2150 cm^{-1}.

Hydrolyse du thiocyanate par l'acide sulfurique

Le dérivé thiocyanaté (1 g) est ajouté dans 10 g d'acide sulfurique 36 *N* refroidi à 0°C. La solution est ensuite maintenue à 0°C sous agitation pendant une nuit, puis versée dans un mélange eau–glace. Le précipité formé (thiolamide) est essoré et lavé plusieurs fois à l'eau; rendement quantitatif.

Le composé *para* est recristallisé dans l'alcool absolu, F = 140–141°C; le dérivé *méta* dans le benzène, F = 122–123°C. Sur le spectre infrarouge on remarque la disparition de la bande ν(SCN) et l'apparition de la bande amide I ν(C=O) à 1660 cm^{-1}.

Hydrolyse de la thiolamide

Un mélange de 0,1 mol de thiolamide dans 150 mL d'acide chlorhydrique 6 *N* est porté à reflux sous azote pendant 12 h. Le mercaptan libéré au cours de la réaction est extrait à l'éther, séché sur sulfate de calcium puis distillé sous vide ou recristallisé; *m*-nitro, Eb 110°C sous 0,6 Torr (1 Torr = 133.3 Pa); *p*-nitro recristallisé dans l'éther de pétrole F = 55°C, litt. (24) F = 55°C.

Caractéristiques spectrales des différents thiols

Spectroscopie infrarouge

Les spectres ir ont été enregistrés sur un spectromètre Unicam SP 1200, cependant, l'absorption liée au mouvement d'élongation ν(SH) se manifeste vers 2550 cm^{-1} mais elle est trop peu intense pour la considérer comme déterminante.

Spectrométrie de résonance magnétique nucléaire (proton)

Les caractéristiques sont obtenues à partir d'un appareil Hitachi R 24-A 60 Mz. Les composés sont étudiés à l'état pur pour les liquides et en solution dans le chloroforme deutérié pour les solides (la référence interne étant le TMS). Le signal qui caractérise la fonction thiol apparaît dans les benzylmercaptans et le cyclohexylmethanethiol sous la forme d'un triplet résultant du couplage du proton SH et des protons méthylèniques. La position du pic central de ce signal se situant aux environs de 1,7 ppm.

Dosage chimique du groupe mercaptan

L'analyse élémentaire ne permet pas de s'assurer que la totalité du soufre contenu dans ces composés est présent uniquement sous la forme de fonctions thiols. Nous avons eu recours à une méthode de caractérisation chimique quantitative du groupe mercaptan décrite par Saville (25). L'évaluation du taux de fonction thiol est en outre rendu nécessaire pour les essais cinétiques.

Etude acidimétrique

Les fonctions thiols incluses dans les composés examinés peuvent être dosées par acidimétrie. Les pK_{SH} correspondants sont obtenus à partir des courbes de neutralisation et les pH mesurés au moyen d'un appareil Tacussel TS 70/N_1. On opère à 30°C ± 0,1, sous atmosphère d'azote dans le mélange eau–éthanol (28,5% d'éthanol en volume). La précision est estimée à ±0,02.

Mesures cinétiques

Les mesures ont lieu dans des milieux constitués, en raison de la solubilité de certains thiols, de 28,5% d'alcool et 71,5% d'eau. Le pH, ainsi que la force ionique du milieu, sont maintenus constants à l'aide de solution tampons, tandis que la température est fixée à 30°C ± 0,1. Les tampons normalement utilisés sont des solutions aqueuses de dihydrogénophosphate de potassium et d'hydrogénophosphate de sodium selon Clark et Lubs (26) à la concentration totale de 0,134 *M* et une face ionique I = 0,268.

La concentration en ester est fixée à 2×10^{-4} *M*. L'ester et le catalyseur sont intimement mélangés puis dissous dans la quantité nécessaire d'alcool. On complète alors au volume désiré (100 mL) par la solution aqueuse tampon à 30°C. Le temps $t = 0$ est pris au moment où l'on atteint le volume final. Une partie de la solution est alors transvasée dans la cellule de mesure. Les vitesses de réaction sont suivies par enregistrement à l'aide d'un spectrophotomètre uv–visible Hitachi 320. Les mesures sont faites à 405 nm maximum d'absorption du *p*-nitrophénolate. La formation d'ions est reliée à la disparition de l'ester par la relation $[\text{ester}] = [\text{ester}]_0 - D/\epsilon_{app} \times l$ avec l = 1 cm, D = densité optique à 405 nm, ϵ_{app} est le coefficient d'extinction molaire apparent à 405 nm et au pH considéré. Il est directement déterminé dans les mêmes conditions que les mesures cinétiques sur le *p*-nitrophénol et varie de 1,38 à 1,85 $\times 10^4$ L M^{-1} cm^{-1} dans le domaine des pH utilisés.

Electrostatic effects on disproportionation equilibria: dihalogeno and methyl derivatives of benzene

ZDENĚK FRIEDL[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received December 12, 1984

ZDENĚK FRIEDL. Can. J. Chem. **62**, 2337 (1984).

The disproportionation equilibria of benzene derivatives X—Ph—Y (X, Y = F, Cl, CH_3) in the gas phase, were calculated from their enthalpies and entropies of formation at 298 K. Calculations of the electrostatic energy based on the point charges approximation method predict reasonably well the reaction enthalpies of all *meta*-benzene derivatives and predict nearly as well the other fluoro- and methyl-derivatives. The theory fails if strong resonance and/or steric interactions are present. The generally better ability of the electrostatic theory to treat disproportionation or conformational equilibria than the proton transfer reactions is also discussed.

ZDENĚK FRIEDL. Can. J. Chem. **62**, 2337 (1984).

En utilisant leurs enthalpies et leurs entropies de formation, on a calculé l'équilibre de dismutation, à 298 K et en phase gazeuse, des dérivés benzéniques X—Ph—Y (X, Y = F, Cl, CH_3). Des calculs d'énergie électrostatique, basés sur la méthode d'approximation des charges ponctuelles, permettent de prédire convenablement les enthalpies de réaction de tous les dérivés du benzène substitués en position *méta* et permettent de faire des prédictions presqu'aussi bonnes pour les autres dérivés fluorés et méthylés. La théorie n'est pas adéquate si les molécules étudiées portent des groupes provoquant une forte résonance et/ou de fortes interactions stériques. On discute aussi du fait que la théorie électrostatique est généralement plus apte à traiter des équilibres de dismutation ou conformationnels que les réactions de transfert de proton.

Introduction

In previous papers in this series we have investigated the electrostatic effects on conformational (1–4) and ionization (5–7) equilibria to test the individual assumptions and approximations of the theory. In the cases of proton transfer reactions

[1] R—Z—H + Z^- = R—Z^- + Z—H

and conformational equilibria

[2] R—Z—X—Y (*anti*) = R—Z—X—Y (*syn*)

with a dipolar substituent R, the substituent effect on the equilibrium constant may be expressed within the framework of classical electrostatics. The Gibbs energy is then usually equated to the electrostatic energy

[3] $\Delta G^0 = -RT \ln K = N_A f(z_i, \mu_i, r_i, \theta_i, \epsilon_{ef})$

where r is the distance between charges z and/or dipoles μ, θ the angle between μ's or μ and r, and ϵ_{ef} effective relative permittivity.

The electrostatic theory has been applied to many ionization equilibria, mostly of carboxylic acids in mixed aqueous solvents (8–10). An application of the electrostatic theory in this case is heavily dependent on all of its approximations. One possible failing of the theory is the fact that the Z—H bond energies in the substituted (RZH) and unsubstituted (ZH) acid will probably not be exactly equal (1, 3–4, 6). Another difficulty can be a too strong non-electrostatic interaction, e.g., resonance, between the substituent R and the anion in RZ^-. Nevertheless, the most important complications originate in the experimental conditions. Except for some gas phase results available only recently (11, 12), the equilibrium constants of reaction [1] have been determined mostly in water or in aqueous polar solvents (8–10). Thus all the solute molecules and ions involved in the equilibria appear as solvated species and the solvation energies do not necessarily cancel (13). Finally, the effective relative permittivitiy ϵ_{ef} must be calculated from the solvent bulk permittivity ϵ_{ext} and the internal relative permittivity ϵ_{int} attributed to the solute molecule. In such a calculation the solute molecule is described as a spheroidal (14) or ellipsoidal (15–18) cavity and its geometrical parameters are adjusted in different ways (14–19).

The possibility of measuring proton transfer reactions in the gas phase is apparently the best way to test the electrostatic theory. There are no solvent molecules so that difficulty with the calculations of ϵ_{ef} are eliminated. In spite of these assumptions our recent study (7) of proton transfer reactions in the gas phase has disclosed fundamental shortcomings of the theory even for such condition.

In the case of conformational equilibria (1–4, 20–25), the electrostatic theory has been more successful due primarily to the possibility of working in non-polar solvents. This removes problems with calculating the effective relative permittivity by means of cavity models and ϵ_{ef} is simply set equal to the solvent bulk permittivity ϵ_{ext}, even if the ϵ_{ef} differs slightly from the ϵ_{ext} which occurs when the solute and solvent do not have the same permittivity. In addition, no bond is broken during the conformational change, so that cancellation of bond energies (5–7, 13) loses its importance.

On the other hand, the applicability of the theory is strongly restricted to model compounds in which the remaining non-electrostatic substituent effects are eliminated. This concerns particularly non-bonded interactions, torsional strain and resonance effects. In addition, despite the possibility of measuring the conformational equilibria in non-polar solvents, there still remains the necessity to consider different energies of solvation of both conformers.

For the above reasons we proposed (26) to test the electrostatic theory on the isodesmic equilibria of the disproportionation type (eq. [4]), which had not been discussed in the

[4] R—Z—X—Y + Z—X = R—Z—X + Z—X—Y

literature in this way so far. In general, the disproportionation

equilibria have the advantage versus the ionization and conformational equilibria that cavity models and differential solvation need not be taken into account, since the equilibria are investigated in the gas phase. In these reactions some bonds are broken but changes in the bond energies may be self-compensating and non-electrostatic interactions should not be stronger than in the preceding cases.

In this paper we investigate the disproportionation equilibria of fluoro-, chloro-, and methyl-disubstituted benzene derivatives.

[5] 
The thermodynamic data are compared with both electrostatic and quantum chemical calculations.

Results

Thermodynamic calculations

The experimental enthalpies ΔH_f^0 and entropies ΔS^0 of formation in the gas phase at 298 K were taken from ref. 27. The relative energies of the disproportionation equilibria ΔH^0 were obtained as a difference of the sums of ΔH_f^0 of reactants and products. To test the premise of a symmetry control of isodesmic reactions (28), the entropy change ΔS^0 was assumed to be due to changes of symmetry during reaction [5]:

$$[6] \quad \Delta S^0 \cong \Delta S_\sigma = R \ln K_\sigma$$

so that eq. [7]

$$[7] \quad \Delta G^0 = \Delta H^0 - T\Delta S^0$$

can be written consequently as

$$[8] \quad \Delta G^0 \cong \Delta E_{elst} - T\Delta S_\sigma$$

The experimental values ΔH^0 and $T\Delta S^0$ are listed in Table 1 together with the calculated terms $T\Delta S_\sigma$.

Electrostatic calculations

For disproportionation equilibrium [4] using the point charges approximation, the ΔE_{elst} term from eq. [8] acquires the form

$$[9] \quad \Delta E_{elst} = (N_A/4\pi\epsilon_o) \sum q_i q_j / r_{ij}$$

where r_{ij} is the distance between the charges q_i and q_j. The summation extends to all molecules involved with the reactants being taken with a negative sign. The charges q on individual atoms were obtained as previously (1) by dividing the bond moments by the bond lengths and summing up at each atom. Standard bond moments were used (29) (in 10^{-30} C m): C_{al}—H −1.0, C_{al}—F 4.67, C_{ar}—F 4.90, C_{ar}—Cl 5.34 plus resonance moment 0.33. The distances r_{ij} were calculated from the standard geometry parameters (30) (in pm): C_{ar}—C_{ar} 139, C_{ar}—H 108, C_{ar}—F 133, C_{ar}—C 170, C_{ar}—C 152, C—H 109, C—F 136. The benzene nucleus was assumed hexagonal and all remaining bond angles were assumed to be 109.5°. The results are listed in Table 1.

Quantum chemical calculations

The total energies and charge distributions of all benzene derivatives were calculated by the CNDO/2 method with the standard parametrizations (31) and standard geometries, which were the same as in the previous paragraph and were not optimized. The *ab initio* STO-3G calculations were taken from refs. 32 and 33 and had also been obtained without optimizing the standard geometry (30). The results are given in Table 1.

Discussion

In the past, several attempts have been made (34–37) to calculate absolute values of enthalpies of formation ΔH_f^0 in the gas phase by a simple electrostatic approach, treating the molecule as a system of discrete point charges in a vacuum. The results agreed generally well with experiments, considering the rough approximation of the theory.

When we had decided to test the electrostatic theory on disproportionation equilibria, we were restricted in the choice of suitable model systems to published ΔH_f^0 or ΔG_f^0 values in the gas phase (27). We chose the set of fluoro-, chloro-, and methyl-substituted benzene derivatives 1–11 (see Table 1), even though we were aware of possible shortcomings, notably possible resonance interactions.

The relative ΔH^0 and ΔE_{elst} energies of reaction [5] are given in Table 1 together with the experimental $T\Delta S^0$ and calculated entropy terms $T\Delta S_\sigma$. When comparing these values, there is an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

evident agreement with the assumption (eq. [6]), that the entropy change is practically all due to changes of symmetry during reaction [5]. When discussing the ΔE_{elst} data in Table 1, it is advisable to start with *meta*-substituted derivatives **2**, **5**, **8**, and **10**, because in these compounds the bonding, resonance, and steric interactions may be negligible. Provided this condition is fulfilled, only the polar (i.e. electrostatic) interactions will be significant. The agreement is reasonably good considering that the limiting value for the relative permittivity of gaseous molecules, as suggested recently (25), is 1.5. A worse but still reasonable agreement was obtained for the other fluoro and methyl *ortho*/*para*-derivatives **1**, **3**, **9**, and **11**. The reason for the failure of the theory for *ortho*-dichlorobenzene **4**, *para*-dichlorobenzene **6**, and *para*-fluorotoluene **7** is evidently the large polarizability and steric effects in **4**, and strong resonance interactions in **6** and **7** which interfere with the electrostatic interaction.

The results of the CNDO/2 and some STO-3G calculations are only able to qualitatively reproduce the experimental ΔH^0 values. Note the poorer agreement of the *ab initio* calculations (32, 33) in comparison with the simple semi-empirical CNDO/2 method. It is important to note that *ab initio* calculations, done using a minimum basis STO-3G set and without geometry optimization, are generally accepted as a standard method for description of isodesmic reactions (32, 38), but it can be shown that only optimized calculations at STO 4-31G level lead to any essential improvement (39). Electrostatic calculations based on CNDO/2 charge distribution do not agree with ΔH^0 either quantitatively or qualitatively and our preliminary attempts on the same level gave similarly poor results (2, 4). Probably it will be necessary to use a more sophisticated charge distribution (40) than that of the traditional Mulliken population analysis.

In summary, we can state that the electrostatic theory with its point charges approximation as expressed by eq. [10] is reasonably adequate for the description of the disproportionation equilibria investigated in this study. A more accurate proof should be possible in future, if further thermodynamic data of suitable model compounds become available.

The mass spectra of pyrimidines. II. 2(1*H*)-Pyrimidinethiones and some N(1)-substituted derivatives

ROBIN T. B. RYE,[1] OSWALD S. TEE, AND EVA M. KAZDAN
Department of Chemistry, Concordia University, 1455 de Maisonneuve Blvd., W., Montreal, P.Q., Canada H3G 1M8

Received July 11, 1983[2]

ROBIN T. B. RYE, OSWALD S. TEE, and EVA M. KAZDAN. Can. J. Chem. **62**, 2340 (1984).

The EI induced fragmentation of 2(1*H*)-pyrimidinethione (**1**), some N(1)-substituted derivatives, and 2(1*H*)-pyrimidineselenone (**4**) have been studied. Principal fragmentation pathways have been identified using ^{2}H-labelling, metastable defocussing, and exact mass measurements.

The fragmentations of **1** and **4** generally parallel those reported for 2(1*H*)-pyrimidinone. In contrast to the oxo-compound, however, direct expulsion of the exocyclic hetero atom is significant in the fragmentation of **1**, and dominates the spectrum of **4**.

Based on metastable peak abundances and kinetic energy release measurements, it is postulated that the $[M - H]^+$ entity generated from *N*-ethyl-2-pyrimidinethione has a thiazolinium structure.

ROBIN T. B. RYE, OSWALD S. TEE et EVA M. KAZDAN. Can. J. Chem. **62**, 2340 (1984).

On a étudié la fragmentation, induite par impact électronique, de la (1*H*)-pyrimidinethione-2 (**1**), de quelques-uns de ses dérivés substitués en position N(1) et de la (1*H*)-pyrimidinesélénone-2 (**4**). On a identifié les principales voies de fragmentation en faisant appel au marquage au ^{2}H, à la dispersion des ions métastables et à des mesures de masses exactes.

Les fragmentations des composés **1** et **4** sont généralement semblables à celles rapportées antérieurement pour la (1*H*)-pyrimidone-2. Cependant, contrairement à ce qui est observé avec le composé oxo, l'expulsion directe de l'hétéroatome exocyclique est importante lors de la fragmentation du composé **1** et elle est majoritaire dans le spectre du composé **4**.

En se basant sur les abondances relatives des pics métastables et sur les mesures d'énergie cinétique dégagée, on postule que l'entité $[M - H]^+$ générée par la *N*-éthyl pyrimidinethione-2 a une structure de thiazolinium.

[Traduit par le journal]

Introduction

It has been known for some time that the thio-analogues of the pyrimidine bases show significant biological activity. Lozzio and Wigler (1) interpreted the cytoxicity of 2-thiocytosine and 2-thiouracil in terms of interference with RNA synthesis, and the effect of 2-thiocytosine on mitosis in human lymphocytes has been reported (2). Holy and co-workers reported that 2-pyrimidinethione (**1**) showed marked *in vitro* bacteriostatic activity towards *E. coli* (3). We are interested in **1** and its derivatives as precursors for synthetic nucleosides. As part of this continuing study we have examined the mass spectra of **1**, its seleno-analogue, and the N(1)-substituted pyrimidinethiones listed in Table 1.

Experimental

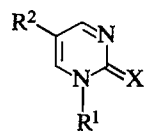
Synthesis[3]

Preparation of the pyrimidinethiones employed in this study followed the cyclization procedure described previously (4). The 2(1*H*)-pyrimidineselenone, **4**, was prepared in 38% yield from selenourea (Aldrich) via cyclization with 1,1,3,3-tetramethoxy propane; mp 174–176°C. *Anal.* calcd. for $C_4H_4N_2Se$: C 30.20, H 2.53, N 17.61, Se 49.64; found: C 29.99, H 2.58, N 17.57, Se 49.62.

Spectra

The mass spectra were taken on a Hitachi-Perkin-Elmer RMU-7 instrument using 70 V ionizing electrons and the lowest practicable source temperature. First field-free region metastable peaks were recorded by the accelerating voltage scan method, using an instrument modification previously described by McGillivray and co-workers (5). Exact mass measurements and additional metastable peaks data were obtained using a Kratos-AEI MS-902S instrument.

TABLE 1. Compounds studied



Compound	R^1 (R^2 = H, X = S)	Compound	R^2 (R^1 = H)

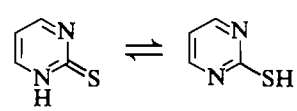
3	D	**4**	H, X = Se
5	CH_3		
6	C_2H_5		
7	Phenyl		
8	CD_3		
9	CH_2CD_3		
10	CD_2CH_3		
11	CD_2CD_3		
12	Phenyl-2,4,6-d_3		

Results and discussion

The 70 eV mass spectra of the compounds studied are reported in Table 2. Fragmentation pathways leading to the principal daughter ions have been deduced from exact mass measurements and from observed metastable decompositions.

The principal framentation pathways for **1**, shown in Scheme 1, are analogous to those reported for 2-pyrimidinone (4). Like its oxo-analogue, **1** can exist in two main tautomeric forms:



There is, however, little information as to which tautomer predominates in the gas phase. Beak and co-workers (6) studied the gas phase equilibrium of 2-thiopyridine and concluded that

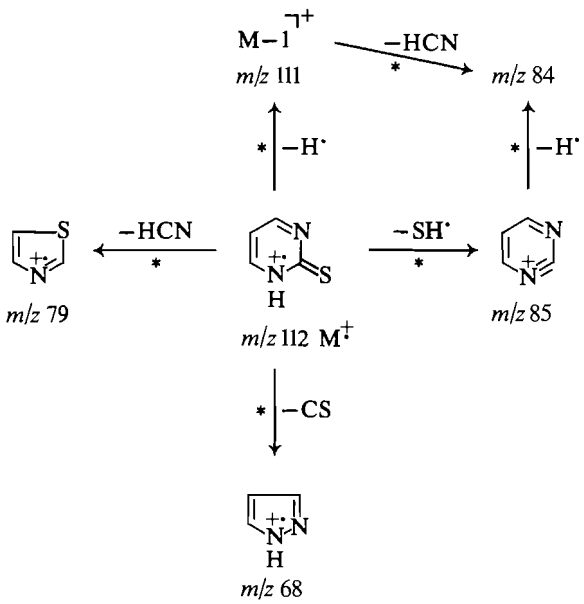

SCHEME 1. Principal fragmentation pathways for the molecular ion of **1**.

the 2-mercapto form predominates, in contrast to the solution results. Similar conclusions were reached by Gronneberg and Undheim (7) on the basis of ionization potential measurements. Few comparable studies have been reported for the thiopyrimidines. Berndt *et al.* (8) applied CNDO/2 methods to calculate that the —NH form of thiopyrimidine was stable with respect to the —SH form by 143 kJ mol^{-1}. Baddar *et al.* (9) investigated tautomerism in a series of 4,6-diarylpyrimidine-2(1*H*)-thiones and concluded that the thione form predominates in solution. Recent X-ray photoelectron spectroscopic measurements (10) on 6-(*m*-chlorophenyl)-4-phenyl pyrimidinethione lead to an estimate of 65% thione in the solid material.

Interpretation of the molecular ion region of the mass spectrum of the 1-d_1-pyrimidinethione, **3**, is complicated by the presence of unlabelled or back-exchanged material and by a kinetic isotope effect for H/D loss of unknown magnitude. An estimate of the relative importance of H· loss versus D· loss from the molecular ion of **3** was made, based on the assumption that H· loss from **3** would be less than or equal to H· loss from **1**. On this basis it was possible to assign limits to the relative intensities of peaks at *m/z* 112 and *m/z* 111 in the spectrum of **3** due to loss of H· and D·, respectively. These calculations put the contribution of D· loss from $M^{+\cdot}$ as 25–30% of the peak intensity at *m/z* 111, with the remainder being due to the H· loss from unlabelled material. Loss of the tautomeric hydrogen would thus appear to be considerably more important in the fragmentation of **1** than was found to be the case for the 2-pyrimidinone, but it should be noted that this does not confirm that there is a significant concentration of the —NH tautomer in the gas phase. If the S—H bond strength in the molecular ion is significantly lower than the N—H bond strength, loss of the tautomeric hydrogen from the thiol form may compete with SH· loss. This latter process is characteristic of the mass spectra of aliphatic, cyclic, and α-cyclic thioketones (11) and thiopyridines, and occurs to a significant extent (R.I. = 8%) in the mass spectrum of **1**.

Calculations similar to those described above were done for the molecular ion region of the spectrum of 5-d_1-pyrimidinethione, **2**, in order to correct for unlabelled material. Within the limits of the method there is no evidence for significant D· loss from the molecular ion of **2**, and we conclude that for **1**, as was found for 2-pyrimidinone, the principal sites of H· loss are C(4) and/or C(6).

2(1H)-Pyrimidineselenone (4)

The general characteristics of the mass spectra of selenoheterocycles have been the subject of several reports, and have been summarized by McCloskey *et al.* (12). Whereas direct loss of the exocyclic heteroatom is absent or occurs only to a minor extent in the fragmentation of the oxo- and thioanalogues, loss of Se or SeH by direct expulsion from $M^{+\cdot}$ is a prominent feature of the mass spectra of selenium containing compounds. Likewise, in the present case *m/z* 79 ($M^{+\cdot}$ − SeH) and *m/z* 80 ($M^{+\cdot}$ − Se) are major peaks in the spectrum of **4**. While the characteristic selenium isotope pattern makes identification of Se containing fragment ions a straightforward matter, comparison with the spectra of **1** and of 2-pyrimidinone is facilitated by presentation of the data as the monoisotopic (^{80}Se) spectra (Fig. 1). The corresponding fragmentation scheme (Scheme 2) shows few other differences from that of **1**.

N(*1*)-R-*Pyrimidinethiones*

The principal fragmentation pathways observed for **5**, **6**, and **7** generally parallel those reported for the oxo-compounds, and

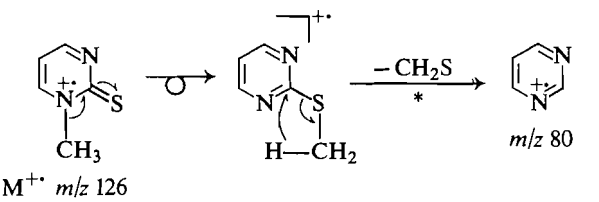
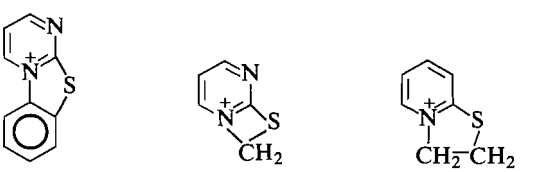


SCHEME 3. Formation of *m/z* 80 from **5**.

only significant differences will be discussed here. The expected loss of SH· from M^{+}· is a significant process (R.I. = 35%) in the fragmentation of **6**; in both **5** and **6** intense metastable peaks were observed for this elimination. The analogous OH· loss from M^{+}· of the pyrimidinones was not observed. Ion peaks at *m/z* 80 in the spectra of **5** and **6** can be explained in terms of migration of the N-alkyl group to sulfur, followed by H atom transfer to the ring and elimination of (R^1—H)S (Scheme 3). When $R^1 = CD_3$ the ion peak shifts to *m/z* 81 as predicted by this mechanism. The driving force for this reaction is presumably the formation of the stable pyrimidinium ion; however, the analogous process was not observed in the oxo-compounds. The spectrum of **7** has *m/z* 187 (M^{+}· − H·) as the base peak, and this ion fragment carries 25% of the total ion current. As was the case for the *N*-phenyl-2-pyrimidinone an intense metastable peak was associated with H· loss. However, in contrast to the fragmentation of the ^{2}H-labelled pyrimidinone, loss of D· from **12** was also associated with an intense metastable peak. Thus while we have previously concluded that the oxazolium structure is, at best, only a minor component of the $(M - H)^{+}$ ion generated from *N*-phenyl-2-pyrimidinone, we propose that rearrangement to give an ion with the thiazolium structure **13** is a significant feature in the fragmentation of **7**, with the stability of **13** accounting for the predominance of the *m/z* 187 peak in the spectrum. It should be noted that stable salts (perchlorates) of **13** are easily prepared (7), although adequate mass spectra were not obtainable in this laboratory. Ions of structures **14** and **15** might reasonably be expected to have stabilities comparable to that of **13**. Loss of H· from the molecular ions of *N*-methyl and *N*-ethyl-2-pyrimidinones has been shown to occur predominantly by simple bond cleavage without prior rearrangement from both ring and alkyl substituent sites. In the case of the thio-compounds **5** and **6**, the observation that moderately intense metastable peaks were associated with H· loss suggested that rearrangement leading to **14** (from **5**) and **15** (from **6**) could be significant reaction pathways.



The kinetic energy release, *T*, associated with a metastable decomposition has been widely used (13) to characterize the reacting configurations of gas phase ions. Values of *T* corresponding to the widths of the metastable peaks at half height, $T_{0.5}$, give a convenient basis for the comparison of closely related metastable decompositions.

The metastable peaks for H· loss from **8** ($R^1 = CD_3$) and **11** ($R^1 = CD_2CD_3$) were of low intensity and we assume, therefore, that the relatively intense metastable peaks observed for H· loss from **5** ($R^1 = CH_3$), **9** ($R^1 = CH_2CD_3$) and **10** ($R^1 = CD_2CH_3$) can be assigned to H· loss from the alkyl substituent only, without introducing a significant error in the measured $T_{0.5}$ values (Table 3). There is a significant isotope effect on the abundance of the metastable peak for H· loss from the methylene carbon of the *N*-ethyl substituent. In contrast to the mod-

[c] Metastable peak too weak for $T_{0.5}$ measurement.

erately intense metastable peak for H· loss from **9**, the metastable peak for D· loss from **10** was too weak to permit an accurate measurement of $T_{0.5}$. Such an isotope effect on metastable peak abundance can be associated with a steep curve for k vs. E_{int}, with deuterium substitution lowering k to a value which puts it outside the range accessible to the metastable window (13). It has been pointed out that a steep k vs. E_{int} curve is associated with a fragmentation having a high entropy of activation (14), i.e. simple cleavage rather than rearrangement. Comparison shows that $T_{0.5}$ for H· loss from **9** is significantly lower than that observed for H· loss from **10**, and is comparable to that for H· loss from **5**. We infer from these observations that loss of H· from the methylene group of **9**, and from **5**, involves predominantly simple cleavage with little prior rearrangement. On these grounds **14** would appear to be ruled out as a major contributor to the ($M^{+\cdot}$ − H) ion generated from **5** and **9**.

A more positive case can be made for the production of **15** in the fragmentation of **9**. Loss of H· from the methyl group of **10** shows only a small isotope effect on the metastable peak abundance, and the significantly larger $T_{0.5}$ is consistent with a rearrangement process. Indirect evidence for the formation of **15** also is found by examination of the source generated ($M^{+\cdot}$ − H) ions from *N*-ethyl-2-pyrimidinone fragmenting further by loss of ethylene. Similar fragmentations were observed for **9**, **10**, and **11**; however, ($M^{+\cdot}$ − D) ions generated from these precursors did not eliminate ethylene in the metastable time frame. This observation is consistent with structure **15**, for which ethylene loss would require the rupture of the stable thiazolinium ring.

The simultaneous analysis of chlorine-36, sulphur-35, and phosphorus-32 in urine[1]

GARY H. KRAMER AND SIDNEY JOSEPH[2]

Biomedical Research Branch, Health Sciences Division, Atomic Energy of Canada Limited Research Company, Chalk River Nuclear Laboratories, Chalk River, Ont., Canada K0J 1J0

Received January 16, 1984

GARY H. KRAMER and SIDNEY JOSEPH. Can. J. Chem. **62**, 2344 (1984).

A method has been developed for the simultaneous analysis of phosphorus-32, sulphur-35, and chlorine-36 in urine. The sample must be divided for the analysis; therefore, at least 500 mL of urine is required. Chlorine-36 is estimated by counting AgCl after interferences have been removed by $Fe(OH)_3$, $Ca_3(PO_4)_2$, and $BaSO_4$ precipitations. Sulphur-35 is estimated as $BaSO_4$ and phosphorus-32 is estimated as $BiPO_4$ after interferences have been removed by cation exchange and coprecipitation. Cross-contamination of the radionuclides is negligible and the chemical recoveries and limits of detection are as follows: Cl-36, 90% (269 mBq); S-35, 95% (144 mBq); P-32, 70% (38 mBq).

GARY H. KRAMER et SIDNEY JOSEPH. Can. J. Chem. **62**, 2344 (1984).

On a mis au point une méthode qui permet d'analyser simultanément du phosphore-32, du soufre-35 et du chlore-36 dans l'urine. Pour les fins de cette analyse, l'échantillon doit être divisé; pour ce faire, il faut donc au moins 500 mL d'urine. Pour évaluer le chlore-36, on effectue un comptage sur le chlorure d'argent après avoir éliminé les produits qui interfèrent grâce à des précipitations par le $Fe(OH)_3$, le $Ca_3(PO_4)_2$ et le $BaSO_4$. On évalue le soufre-35 sous forme de $BaSO_4$ et le phosphore-32 sous forme de $BiPO_4$ après avoir éliminé les produits qui interfèrent grâce à des coprécipitations et des échanges de cations. La contamination entre radionuclides est négligeable; les récupérations chimiques et les limites de détection sont les suivantes: Cl-36, 90% (269 mBq); S-35, 95% (144 mBq); P-32 70% (38 mBq).

[Traduit par le journal]

Introduction

The radionuclides in this report, P-32, S-35, and Cl-36, are principally pure β emitters (Cl-36 has two other minor decay pathways, 1.9% electron capture and 0.0012% positron emission) with a variety of half-lives and maximum β energies. These values are P-32, 14.3 d, 1.71 MeV; S-35, 88 d, 0.167 MeV; Cl-36, 3×10^5 a, 0.714 MeV.

It is generally assumed that the chemical form of the radionuclide that is ingested or inhaled in a possible occupational contamination incident is inorganic. It is believed that there is no area in the human body that contains non-exchangeable chloride (1) and that greater than 90% of a radioactive sulphate intake is still excreted in that chemical form after seven days (2). Phosphorus, on the other hand, has a higher metabolic conversion to organically bound phosphorus compounds than either the chloride or the sulphate (3–5); therefore, this method has been developed using an organic form of phosphorus and inorganic forms of chlorine and sulphur to test the procedures.

A search of the literature for a satisfactory method for determining P-32, S-35, or Cl-36 in urine showed that very little work has been carried out on low level measurements of these radionuclides. Phosphorus-32 has previously been determined by extraction of molybdophosphoric acid into an organic solvent (6) but the removal of some of the possible interferences can be lengthy (7). Sulphur-35 has been previously estimated as a barium sulphate precipitate (8), but no account was taken of the whole host of cations and anions that will also be coprecipitated. In particular, K-40 is a problem in urine samples when trying to estimate low levels of S-35 (9). Chlorine-36 appears to have received no attention in the past.

This paper describes the simultaneous analysis of Cl-36, P-32, and S-35 in urine. A 100 mL portion of urine is reserved for the Cl-36 analysis and the remainder used for the S-35 and P-32 determination. The possible cross-contaminations by S-35 and P-32 in the Cl-36 analysis are eliminated by removal of the sulphates and phosphates by precipitation. Chlorine-36 is estimated as a dry silver chloride precipitate using a gas proportional counter. Liquid scintillation cannot be used due to the extreme photosensitivity of wet silver chloride. The portion of urine reserved for S-35 and P-32 analysis is ashed to remove the possible cross-contamination by Cl-36 and to convert some, if not all, of the organic sulphur and phosphorus compounds to the inorganic form. Except for an intake of an organic form of a radionuclide, the amount of activity that would be found in the organic constituents of urine is expected to be very small. The ashed urine residue is redissolved and all the cations, except H^+, are removed by cation exchange. The interfering anion, sulphate or phosphate, is removed by precipitation. Sulphur-35 is estimated as a gel-suspended barium sulphate precipitate in a liquid scintillation counter. Phosphorus-32 can be estimated either as a gel-suspended bismuth phosphate precipitate in a liquid scintillation counter, or as a dry precipitate in a gas proportional counter.

Experimental

Procedure

The urine sample should be at least 500 mL because it will be divided to perform the simultaneous analysis. The sample is initially divided into two portions, 100 mL for the Cl-36 analysis and the remainder for S-35 and P-32.

Chlorine-36

Ferric chloride (50 mg) and calcium nitrate (1.5 g) are added to the raw urine and dissolved. Aqueous ammonia is added, with stirring, until the pH is approximately 10. The precipitates are removed by filtration and washed with 20 mL of a dilute ammonia solution. The precipitates are discarded and the pH of the combined filtrates is adjusted to 1.2. The solution is then heated to approximately 70°C. A barium nitrate solution (1 g/10 mL) is added and the mixture is stirred. The solution is allowed to cool to room temperature before removing the precipitate by filtration. The precipitate is washed with a dilute nitric acid solution (5 mL) and then discarded. The filtrates are combined and 25 mL silver nitrate solution (0.15 g/mL) are added. The solution is stirred and the precipitate allowed to settle overnight.

The bulk of the supernatant is decanted and the precipitate separated from the remaining liquid by centrifugation. The precipitate is washed twice with dilute nitric acid (10 mL); the supernatants being discarded

at each step. The precipitate is dried in an oven at 100°C for approximately 2 h. The dried precipitate is transferred to a weighed 5 cm stainless steel counting dish and the precipitate is ground to an even layer. The precipitate is placed back in the oven until it is completely dried. The cooled dish is counted for β activity.

Sulphur-35 and phosphorus-32

The urine is wet ashed as follows. The sample is made approximately 2 mol/L in nitric acid and boiled to almost dryness. At this point the ashing is continued using fuming nitric acid (CAREFULLY). The orange–brown residue will often catch fire leaving a yellow salt residue with some carbon. Further additions of the fuming nitric acid to the heated salts will remove the carbon and turn the residue white. The residue is dissolved in a minimum of 8 mol/L nitric acid (10–30 mL) and then diluted to 250 mL using distilled water. If necessary, the pH is adjusted to between 2–3 using aqueous ammonia. The solution is passed through a cation exchange column at a flow rate of 1–2 mL/min. After the sample has passed through the column the resin is washed with distilled water (300–400 mL) until the pH of the eluate has reached 4.5. At this point the solution is divided into two equal portions.

Sulphur-35

The pH is adjusted to 1.0 and heated to 90°C. Excess bismuth nitrate is added (15.6 mL of a 10% w/v solution per 0.1 g phosphorus present) and the solution allowed to cool. The precipitate is centrifuged and then discarded after washing with dilute nitric acid (20 mL). The pH of the combined supernatants is adjusted to between 2–3 and heated. Excess barium chloride is added (9 mL of a 10% w/v solution per 0.1 g sulphur present) and the solution allowed to cool. The supernatant is discarded and the precipitate is transferred to a liquid scintillation vial. The volume of the precipitate and liquid is made up to 5 mL with distilled water and 10 mL of scintillation cocktail added. The resulting gel is counted for β activity.

Phosphorus-32

The procedure given for sulphur-35 is reversed. The barium sulphate is removed first and the bismuth phosphate is retained for counting either by liquid scintillation as given above or by transferring the precipitate to a 5 cm diameter stainless steel dish drying and then counting in a gas proportional counter.

Apparatus and tracers

Radioactive counting was performed with either a liquid scintillation (LS) counter or a gas proportional (GP) counter. The approximate counting efficiencies of the radionuclides were S-35, 60% (LS); P-32, 90% (LS), 35% (GP); Cl-36, 10% (GP). The counting efficiency of the GP counter for P-32 and Cl-36 was determined in a similar manner. A known amount of activity was precipitated from aqueous solution by the appropriate reagent (Bi or Ag) and the precipitate plated, dried, and weighed. A second precipitate on the same aqueous solution was used to estimate residual activity (usually less than 0.1%).

The LS counter was calibrated by adding known amounts of precipitate to a known amount of activity. The aqueous layer was well slurried before the LS-cocktail was added to form a gel.

The radionuclides were obtained in the following chemical forms: Cl-36, NaCl from the Radiochemical Company, Ottawa; S-35, Na_2SO_4 from New England Nuclear Ltd.; P-32, Adenosine 5′ [γ-^{32}P] triphosphate from the Radiochemical Centre, Amersham, England. Typically, the amount of activity used to test the analyses was 44 Bq. The amount of activity used for the cross-contamination studies was 0.7 MBq.

The ion exchange column was charged with enough Dowex 50W X12 cation exchange resin to accommodate 650 mEq ($\cong$ 15 g Na^+ or $\cong$ 25 g K^+ or $\cong$ 13 g Ca^{2+}). This amount of resin is capable of absorbing the cationic components of two standard urine samples (10). The resin was used in the H^+ form. The liquid scintillation cocktail was "Scintiverse" supplied by the Fisher Chemical Company, Canada.

Results and discussion

Unlike most radiochemical separations on urine, where a major problem is the presence of large amounts of other interfering elements, the analysis of chlorine-36, sulphur-35, or phosphorus-32 is made difficult by the large amounts of inorganic chloride, sulphate, and phosphate (4.4 g Cl/days urine, 0.8 g S/days urine, and 0.9 g P/days urine — ref. 10). The large quantities of inorganic anions limit the volume of urine that can be analysed. For chlorine-36 the optimum volume was found to be 100 mL (11). The average amount of silver chloride obtained from this volume was found to be 2.3 g which gave a counting efficiency of approximately 10%. The chemical recovery of Cl-36 was found to be 90 ± 5% with 8 ± 3% being lost to the phosphates and 3 ± 1% being lost to the sulphates. Cross-contaminations by S-35 and P-32 were negligible. It was also found necessary to manipulate wet silver chloride under red-light conditions; however, dry silver chloride is able to withstand short exposures to room light with no noticeable effect.

The portion of urine reserved for S-35 and P-32 analysis is ashed thoroughly. All the Cl-36 will be driven off either as Cl_2 or HCl. It was found necessary to remove all the cationic species, except for H^+, due to the coprecipitation problems encountered in estimating S-35 as barium sulphate. Specifically, significant amounts of K-40 were found in the precipitates. It is also well known that barium sulphate will coprecipitate group II elements, actinides, Cu, Cd, Zn, Ni, Mn, Fe(II), Al, Cl^-, I^-, and others, any of which could give rise to estimation problems. The chemical recovery of S-35 was found to be 95 ± 5% with 3 ± 1% lost to the phosphates. The chemical recovery of P-32 was found to be 70 ± 8% with 3 ± 1% lost to the sulphates. The remaining P-32 is unaccounted for because only 4 ± 3% was found in the remaining supernatant. It is postulated that the loss is due to the ashing procedure but the mechanism is unknown. Cross-contaminations of S-35 in the P-32 estimation, or vice versa, were found to be negligible.

The detection limits (12) for S-35, P-32, and Cl-36 at the 95% confidence level are estimated to be: 144 mBq, 38 mBq, and 269 mBq, respectively. These estimates include the effects of ambient background (20 cpm, LS; 1.5 cpm, GP), chemical recoveries counter efficiency, and a 20 min counting time. The detection limits may be halved if the counting time is increased to 60 min.

J. C. SCAIANO and DAVID E. NICODEM. Can. J. Chem. **62**, 2346 (1984).

2-Phenylbenzophenone is proposed to have two nearby triplets, a low lying π,π^* state similar to that of biphenyl and a benzophenone-like triplet lying ~4 kcal/mol higher. The triplet lifetimes of this photostable ketone are extremely short, e.g. 0.56 and 2.5 ns at 300 K in toluene and isooctane, respectively, and are believed to be controlled by population of the benzophenone-like triplet and decay from this state via interaction of the carbonyl chromophore with the phenyl ring in the *ortho* position. The two triplets interconvert via ring rotation. The Arrhenius parameters for triplet decay in five solvents show some dependency with the temperature dependence of the solvent viscosity.

J. C. SCAIANO et DAVID E. NICODEM. Can. J. Chem. **62**, 2346 (1984).

On suggère que la phényl-2 benzophénone possède deux états triplets voisins, soit un état de basse énergie π,π^* semblable à celui du biphényle et un état triplet semblable à celui de la benzophénone dont le niveau énergétique est environ 4 kcal/mol plus élevé. Les temps de vie du triplet de cette cétone photostable sont extrêmement courts, soit 0,56 et 2,5 ns respectivement dans le toluène et l'osooctane à 300 K et on pense qu'ils sont contrôlés par la population du triplet similaire à celui de la benzophénone et sa dégénérescence à partir de cet état se produit par le biais d'une interaction entre le chromophore du carbonyle et le groupe phényle en position *ortho*. Les deux triplets se convertissent l'un dans l'autre par une rotation de cycle. Les paramètres d'Arrhénius pour la dégénérescence du triplet dans cinq solvants montrent qu'il existe une certaine relation avec l'influence de la température sur le viscosité du solvant.

Introduction

The photoreactions of benzophenone and its derivatives are among the best studied photochemical processes (1, 2). It is thus surprising that some rather simple substituted benzophenones behave in a seemingly unpredictable way. For example, 2-phenylbenzophenone does not photoreduce significantly (3, 4) under conditions where 4-phenylbenzophenone does (1). The latter is in turn substantially less reactive than benzophenone itself (5). In the case of 2-phenylbenzophenone, it should be noted that the aromatic ring in the *ortho* position is not expected to be able to lead to an "all planar" configuration; this in turn, would be expected to enhance the carbonyl triplet reactivity, since the reactivity towards photoreduction is expected to decrease with increasing π,π^* character of the triplet state (6).

Several observations in related systems provide, in fact, a basis for the understanding of the unreactivity of 2-phenylbenzophenone: (*a*) 2-methylbenzophenone undergoes photoenolization — involving hydrogen transfer — very efficiently (7), (*b*) 2-hydroxybenzophenone undergoes rapid intramolecular deactivation (8), a process that is widely used in polymer photostabilization (9), (*c*) β-phenylpropiophenone triplets decay via interaction of the excited carbonyl group with the β-phenyl ring, a process that occurs with rate constants in the neighbourhood of $10^9\ s^{-1}$ (10–12), and (*d*) 2-methoxy- and 2-benzyloxybenzophenone decay via intramolecular hydrogen abstraction (13), demonstrating that processes that involve interactions more remote than the conventional 6-center process (e.g. Norrish Type II) can occur quite efficiently (14).

2-Phenylbenzophenone can be regarded as a rather special case of a bichromophoric molecule. This molecule presents a biphenyl, as well as a benzophenone moiety which share one aromatic ring. Examples of energy transfer in bichromophoric systems in the literature frequently involve systems where the rate and efficiency of the process is controlled by the transfer step itself or by the ability of the two chromophores to approach sufficiently for energy transfer to occur (15). In contrast, in the case of 2-phenylbenzophenone we can anticipate intramolecular motion to play an important role.

This paper reports the results of quantum yield and laser flash photolysis studies of the photochemistry of 2-phenylbenzophenone in homogeneous solutions, including the effect of solvents and temperature on the kinetics of triplet deactivation.

Experimental

2-Phenylbenzophenone was prepared by addition of phenyl lithium to 2-phenylbenzoic acid (16). It was purified by column chromatography on silica gel and repeated recrystallization from 2-propanol, followed by sublimation. Melting point and spectral data were in full agreement with literature values (4, 16, 17).

All other reagents and solvents were commercially available and were purified by standard procedures.

Quantum yield and product studies

Quantum yields of photoreduction were measured in deaerated samples using a merry-go-round type of reactor. Typical ketone concentrations were around $1.5 \times 10^{-3}\ M$ which is enough to absorb >99% of the light at 313 nm. This mercury line (from a 450 W Hanovia lamp) was isolated using a K_2CrO_4 filter solution. Benzophenone — 1,3-cyclohexadiene was used as an actinometer system (18). Analysis was performed by opening the ampoules, diluting the sample, and measuring the absorbance at 290 nm for quadruplicate samples that had been irradiated and the same number of nonirradiated samples. It was found that upon extensive irradiation the absorbance at 290 nm was reduced to less than 5% of its original value in 2-propanol and that there was no change in absorbance when *t*-butanol was substituted. The quantum yield for photoreduction in neat 2-propanol was found

[1]NRCC No. 23388.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

to be $(6.2 \pm 1.8) \times 10^{-4}$. When 3.33 *M* 2-propanol in *t*-butanol was used the quantum yield was 45% of the original value.

Laser flash photolysis

All experiments were carried out on deaerated samples using for excitation the pulses (337.1 nm, ~8 ns, up to 10 mJ) from a Molectron UV-24 nitrogen laser. The detection system has a rise time of ~1 ns, but the shortest lifetime that can be accurately determined without deconvolution is about 12 ns. The signals, initially captured by an R-7912 Tektronix transient digitizer, are then transferred to a PDP11/23 computer that also controls the experiment and provides suitable processing, storage, and hardcopy facilities. Further details can be found elsewhere (19).

Some of our experiments involved the addition of 1-methylnaphthalene as a triplet quencher. This approach usually allows the determination of $k_q\tau_T$ from a Stern–Volmer type of analysis on the yield of triplet 1-methylnaphthalene, and has been described in some detail earlier (e.g. ref. 20). In the case of 2-phenylbenzophenone the concentrations of quencher needed were sufficiently high that partial light absorption by 1-methylnaphthalene had to be taken into consideration. The corrections introduced take into account the decreased light absorption by the substrate, as well as the formation of triplet 1-methylnaphthalene via direct excitation (21).

The lifetimes obtained for the 1-methylnaphthalene triplet formed by energy transfer from 2-phenylbenzophenone were the same as those obtained when the triplet was obtained by direct excitation at 308 nm, thus indicating that the energy transfer process is irreversible under our experimental conditions.

Results

By comparison with benzophenone, 2-phenylbenzophenone should be regarded as a photostable ketone. Even in the highly reactive solvent 2-propanol, the quantum yield for photoreduction is only 6.2×10^{-4}. This extremely low yield is the result of the composite effect of a low reactivity towards hydrogen abstraction, and a very short triplet lifetime, controlled by other deactivation pathways (*vide infra*). The quantum yield of photoreduction changes from 6.2×10^{-4} in neat (13.1 *M*) 2-propanol, to $\sim 2.8 \times 10^{-4}$ for 3.3 *M*, with *tert*-butanol as cosolvent. In *tert*-butanol 2-phenylbenzophenone is, for all practical purposes, photostable.

An important implication of the results presented above is that permanent chemical change is, in all cases, sufficiently small ($\Phi < 10^{-3}$) that these processes cannot be expected to play any important role in the transient phenomena studied using laser flash photolysis techniques. These experiments are presented below.

The transient signals observed at room temperature decayed too rapidly for accurate kinetic study; the signals simply followed the shape of the laser pulse.

Figure 1 shows the transient spectrum obtained in isooctane at 190 K, where the triplet lifetime is 115 ns. The decay kinetics were monitored in several solvents at low temperatures and fitted with an Arrhenius expression; the results are given in Table 1, and a summary of the Arrhenius parameters in Table 2; representative plots are shown in Fig. 2. The shape of the decay traces was the same at all wavelengths in the region monitored (345 to 800 nm) and could be fitted by a single exponential. This is consistent with the involvement of a single transient, which decays to yield the parent molecule or permanent products; in this case our quantum yield studies (*vide supra*) indicate that the decay regenerates the parent ketone. Even in the case of 2-propanol, where some photoreduction takes place, the yields are low enough that this process does not need to be taken into account in the interpretation of transient phenomena.

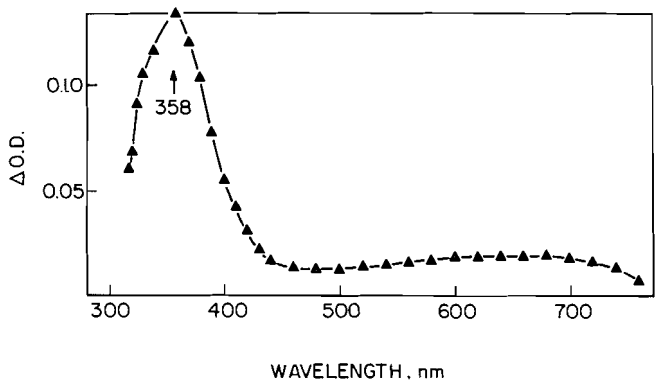

FIG. 1. T–T spectrum of 2-phenylbenzophenone recorded at 190 K in isooctane, between 20 and 70 ns following laser excitation.

[a]In units of s^{-1}.

The triplet lifetimes at ambient temperatures could also be determined from the integration of the area under the corresponding trace, using the technique described earlier (22). The values obtained were consistent with those calculated from an extrapolation of the Arrhenius plot, but did not represent a substantial improvement.

The assignment of the transient signals observed to the triplet state was also confirmed by addition of 1-methylnaphthalene, which leads to the formation of its triplet state via energy transfer. The yields of triplet 1-methylnaphthalene can be treat-

ed in a Stern–Volmer type of approach (20), and used to obtain $k_q\tau$, even at temperatures where triplet decay is too fast for direct monitoring: i.e.

$$[1] \quad \frac{1}{\Phi_N} = \frac{1}{\Phi_{ISC}} + \frac{1}{k_q\tau[N]}$$

where Φ_N and Φ_{ISC} are the quantum yields of triplet 1-methylnaphthalene and intersystem crossing, respectively, and [N] is the concentration of 1-methylnaphthalene. In terms of the transient absorbances due to triplet 1-methylnaphthalene (A_N), which were monitored at 420 nm,

$$[2] \quad \frac{1}{A_N} = a + a/k_q\tau[N]$$

where a is a constant that depends on instrumental response, and in a matched series of experiments is also proportional to Φ_{ISC}^{-1}. The values of $k_q\tau$ obtained in this way are given in Table 3. A few representative plots are shown in Fig. 3.

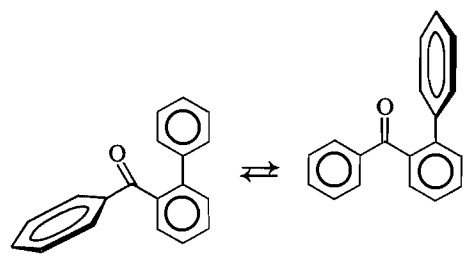
In the cases of benzene and 2-propanol, we also determined Φ_{ISC}. These were based on the intercepts of the Stern–Volmer plots (i.e., a) for 2-phenylbenzophenone and benzophenone, under identical experimental conditions and in samples of the same optical density at the excitation wavelength (337 nm). The values of Φ_{ISC} obtained were 0.67 ± 0.11 and 0.85 ± 0.14 at 300 K in benzene and 2-propanol, respectively. It should be noted that all the data obtained using 1-methylnaphthalene include the corrections due to partial absorption of the light by the quencher, as already mentioned in the Experimental section (21).

TABLE 3. Stern–Volmer slopes obtained using 1-methylnaphthalene in various solvents at 300 K

Solvent	$k_q\tau/M^{-1}$
Diethylether	5.6
Toluene	2.5
Benzene	3.8
Isooctane	9.1
Methanol	12.5
2-Propanol	7.2

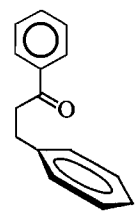
Discussion

As a bichromophoric molecule 2-phenylbenzophenone is rather peculiar since the biphenyl and benzophenone chromophores share an aromatic ring. This is naturally the same situation as in 4-phenylbenzophenone; however, in the case of the *ortho*-isomer one can expect steric hindrance to prevent the three rings to approach planarity at any given time. We propose that on a first approximation conformations **I** and **II** are important in understanding the photochemistry of this ketone.



I **II**

We believe that the decay of the triplet state occurs predominantly from conformation **II**, which closely approaches the geometry (**III**) from which β-phenylpropiophenone and related ketones have been shown to undergo triplet deactivation (12).



III

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

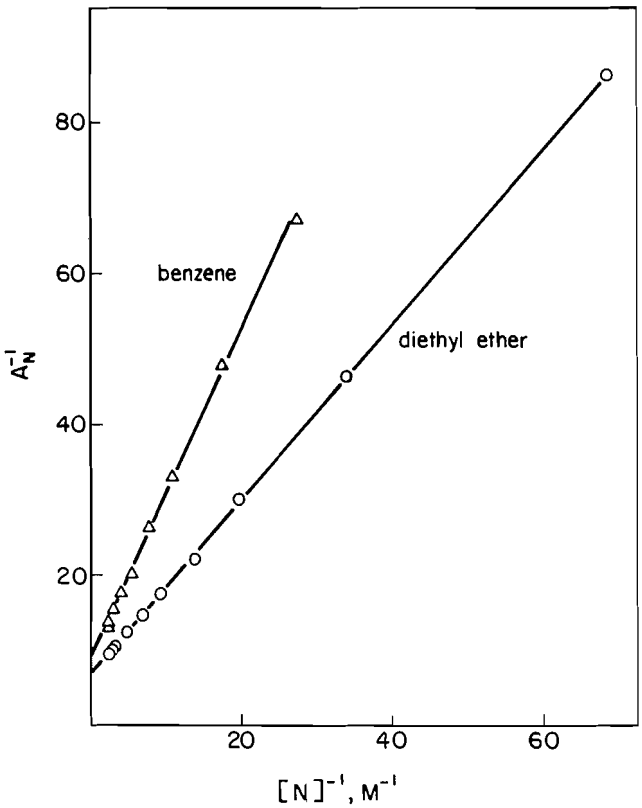

FIG. 3. Stern–Volmer plots according to eq. [2], for benzene and diethylether.

The conclusion that **III** represents the optimum conformation for deactivation was based on the analysis of decay parameters for a series of ketones having β-phenyl rings and cyclopropyl or cyclobutyl rings which introduce conformational restrictions in these molecules (12).

In the case of 2-phenylbenzophenone, the lowest triplet energy conformation is expected to correspond to **I**, since biphenyls have triplet energies somewhat lower than that for benzophenone. Consistently with this, the T–T spectrum (Fig. 1) resembles that of biphenyl (λ_{max} ~365 nm) (23) rather than that of benzophenone (λ_{max} ~525 nm) (e.g. ref. 24). In the case of the ground state, **II** is expected to approach the most favourable conformation, since in this case both chromophores are in their preferred ground state geometry (25, 28); further, the ground state absorption spectrum of 2-phenylbenzophenone at $\lambda >$ 300 nm strongly resembles that of benzophenone, with a well defined n,π* band.

The fact that the values of Φ_{ISC} are below one indicates that triplet **I** is reached inefficiently; our results do not show if this inefficiency occurs at the singlet level, or as a result of partitioning of initially formed triplet **II** between ground state **II** or triplet **I**. This latter possibility, which we favour (*vide infra*), effectively means that triplet **II** is too short-lived to be quencheable by 1-methylnaphthalene.

The essentials of the mechanism proposed are shown in Fig. 4. Several facts make us believe that intersystem crossing occurs from ^{1}**II***, rather than ^{1}**I*** (not included in Fig. 4). First initial excitation takes place predominantly in the n,π* ketone band (337 nm, where biphenyl is transparent), and any ground state equilibrium conformation **I** would not be expected to be excited. Second, ^{1}**I*** is likely to be somewhat higher in energy than ^{1}**II***, and finally, the relaxation ^{1}**II*** → ^{1}**I***, even if the

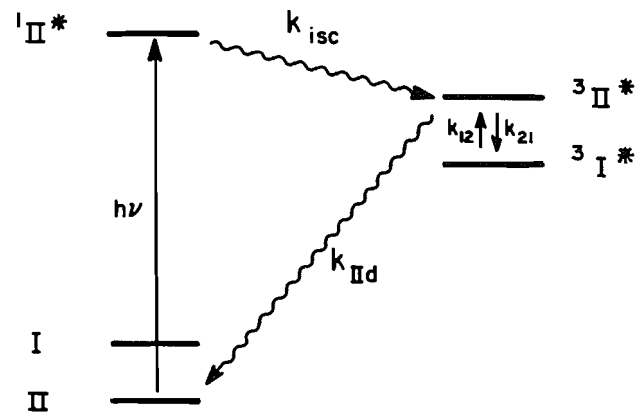

FIG. 4. Proposed mechanism for the photochemistry of 2-phenylbenzophenone in solution.

latter was lower in energy, would be unlikely to compete with ultrafast intersystem crossing processes in the benzophenone moiety (29), while even moderately viscous solvents can affect this process in biphenyl itself (e.g., ref. 30).

Kinetic analysis according to the mechanism of Fig. 4, after the steady state, has been established leads to:

$$[3] \quad \frac{-\partial[^3\mathbf{I}^*]}{\partial t} = k_{12}\frac{k_{IId}}{k_{21} + k_{IId}}[^3\mathbf{I}^*]$$

$$[4] \quad k_{decay} = \frac{k_{12}k_{IId}}{k_{21} + k_{IId}}$$

$$[5] \quad \Phi_{ISC} = \Phi^0_{ISC}\frac{k_{21}}{k_{21} + k_{IId}}$$

where t is the time, k_{decay} is the experimentally determined rate constant for triplet decay (i.e. $\tau_T^{-1} = k_{decay}$) and Φ^0_{ISC} refers to the yield of triplets initially reaching ^{3}**II***, rather than the experimentally determined Φ_{ISC}. Equations [3] and [4] apply only after the initial relaxation of ^{3}**II***, since the steady state assumption has been applied the concentration of ^{3}**II***. Rearranging eq. [5] leads to

$$[6] \quad 1 - \frac{\Phi_{ISC}}{\Phi^0_{ISC}} = \frac{k_{IId}}{k_{21} + k_{IId}}$$

dividing eqs. [4] and [6] gives,

$$[7] \quad k_{12} = \frac{k_{decay}}{1 - \Phi_{ISC}/\Phi^0_{ISC}}$$

If Φ^0_{ISC} is taken as 1.0, as is usually the case for benzophenones, it is possible to estimate the rate constants for the up-conversion, k_{12}. The corresponding values are 5.4×10^9 and 7.6×10^9 s^{-1} at 300 K in benzene and 2-propanol, respectively. The former has been used combining benzene data with the k_{decay} value obtained by extrapolation of the low temperature toluene data.

The decay from the upper triplet, k_{IId} can be expected to have only a small activation energy, since otherwise this process would be unlikely to compete with the internal conversion, k_{21}. The overall activation energy (see Table 1) will be the sum of the energy gap between the two triplets, plus the activation energy corresponding to k_{IId}; thus, the gap between ^{3}**II*** and ^{3}**I*** will be around 4 kcal mol^{-1}. This puts k_{21} in the neighbourhood of 10^{12} s^{-1} or slightly less, assuming, as a first approximation, that entropy changes between the two states can be neglected. Since Φ_{ISC} values indicate $k_{21} > k_{IId}$, then,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

k_{IId} must be around 10^{11} s^{-1}, or about 100 times faster than in the case of β-phenylpropiophenone (12). This probably reflects lower entropic requirements to achieve the transition state (less interval rotations need to be frozen) in the case of 2-phenylbenzophenone.

The quantum yield data for the photoreduction of 2-phenylbenzophenone in 2-propanol can be combined with the laser data to estimate the rate constant for hydrogen abstraction from the solvent, i.e.

$$[8] \quad \Phi_{photored} = \Phi_{ISC} \frac{k_a[Me_2CHOH]}{k_{decay}}$$

where it has been assumed that for these low quantum yields $k_a[Me_2CHOH] \ll k_{decay}$, and k_a is the rate constant for hydrogen abstraction from 2-propanol. From the data presented before, we estimate $k_a \sim 7 \times 10^4\ M^{-1}\ s^{-1}$, which should be compared with values of $\sim 4 \times 10^6\ M^{-1}\ s^{-1}$ for benzophenone (2) and $\sim 1 \times 10^3\ M^{-1}\ s^{-1}$ for 4-phenylbenzophenone (5). The results are entirely consistent with the idea that the three aromatic rings cannot simultaneously approach planarity. Thus, while abstraction 2-phenylbenzophenone may require up-conversion to an upper state, the reactivity for this state is not unlike that of benzophenone itself.

Other carbonyl compounds, in particular those containing *p*-methoxybenzoyl moieties present similar characteristics; i.e. a two-state system in which reaction seems to occur from the upper state, while the spectroscopic properties of the triplet are largely determined by the more heavily populated low lying π,π* state (6, 31, 32). However, these systems do not seem to require the relatively large conformational changes proposed in the case of 2-phenylbenzophenone.

The data in Table 1 suggest a moderate trend of E_a with the temperature dependence of the solvent viscosity, but clearly other factors (such as solvation) must also be playing a role.

Comparison of the quenching of excited states by 5-DOXYL and 12-DOXYL-stearates in micellar solution[1]

J. C. SCAIANO AND C. I. PARASKEVOPOULOS[2]
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received February 8, 1984

J. C. SCAIANO and C. I. PARASKEVOPOULOS. Can. J. Chem. **62**, 2351 (1984).

The relative reactivity of the nitroxides tetramethylpiperidin-*N*-oxide, 5-DOXYL-stearic acid and 12-DOXYL-stearic acid in the quenching of excited states in sodium dodecyl sulfate micelles has been examined. 12-DOXYL-stearic acid is a better quencher in the case of very hydrophobic sensitizers, such as pyrene singlets or phenanthrene (singlet or triplet states). The converse is true for the hydrophilic xanthone triplet or excited $Ru(bipy)_3^{2+}$. The results support the idea of preferential solubilization in different regions of the micelle and provide a method for probing this preference.

J. C. SCAIANO et C. I. PARASKEVOPOULOS. Can. J. Chem. **62**, 2351 (1984).

On a étudié les réactivités relatives des nitroxydes suivants, soit le *N*-oxyde de la tétraméthylpipéridine, l'acide DOXYL-5 stéarique et l'acide DOXYL-12 stéarique, comme pièges d'états excités dans des micelles de dodécylsulfate de sodium. L'acide DOXYL-12 stéarique est un meilleur piège dans le cas de sensibilisateurs très hydrophobes comme les états singulets du pyrène ou les états singulet ou triplet de l'anthrène. L'inverse est également vrai pour les sensibilisateurs hydrophiles comme l'état triplet de la xanthone ou l'état excité du $Ru(bipy)_3^{2+}$. Les résultats sont en accord avec l'hypothèse selon laquelle il se produit des solubilisations préférentielles dans différentes portions de la micelle et ils fournissent une méthode de déterminer cette préférence.

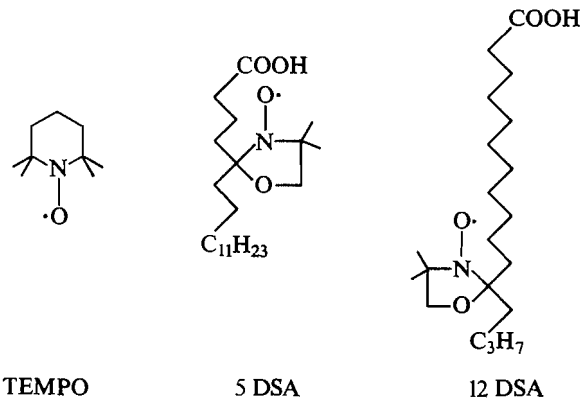
Introduction

Singlet and triplet sensitizers are frequently used as probes in organized systems, particularly micellar solution (1–5). Of particular relevance is the question of the effect of probe and/or quencher location on the rates and efficiency of quenching. The most drastic effect is achieved when full separation of the reaction partners between the aqueous and organic pseudo-phases is achieved. Relatively more subtle differences can be expected when quencher and sensitizer are present in the same micellar aggregates, but have preference for different locations within the micelle. Effects of this type have been examined by others; for example, Thulborn and co-workers (5, 6) have used *n*-(9-anthroyloxy)-fatty acids as fluorescent probes. Singer *et al.* (7) have examined the quenching of pyrene-containing cationic fluorescers of different lengths by a surfactant nitroxide. Bales and Kevan (8) have used stearic acid DOXYL probes of the same type employed here to examine spatial effects on electron scavenging in micelles. Smith *et al.* (9) have studied membrane permeability using epr techniques to monitor the behaviour of nitroxide probes.

In this work we examine the quenching of various sensitizers by tetramethylpiperidin-*N*-oxide (TEMPO), 5-DOXYL-stearic acid (5DSA), and 12-DOXYL-stearic acid (12DSA) in micellar and homogeneous solution.

The reactions were examined using fluorescence spectroscopy and laser flash photolysis techniques.



TEMPO 5 DSA 12 DSA

Experimental section

Materials

All spin labels were obtained from Aldrich and were used as received, although concentrations were based on epr measurements, not on the weight of material used (*vide infra*). Sodium dodecyl sulfate (SDS) from BDH (specially purified grade), was used as received. All sensitizers were commercially available and were recrystallized or distilled before use.

Sample preparation

The samples of spin labels were dissolved in absolute ethanol. The concentrations of the stock solutions (typically in the 0.3–0.9 *M* range) were determined by comparing the double integrated epr spectrum of appropriately diluted samples with samples of DPPH standards.

The samples of the sensitizer (usually 0.1 *M* in SDS) were contained in sample tubes made of square 7 × 7 mm^2 (laser photolysis) or 10 × 10 mm^2 (fluorescence) Suprasil tubing. They were deaerated of bubbling oxygen-free nitrogen. The quenchers were added by injecting known volumes of the concentrated stock solutions.

Luminescence

These measurements were carried out in an LS-5 Perkin-Elmer spectrofluorimeter controlled by a Model-3600 data station.

Laser flash photolysis

The samples were excited with the pulses (337.1 nm, ~8 ns, up to 10 mJ/pulse) from a Molectron UV-24 nitrogen laser. The transient absorption signals, initially captured by a Tektronix R-7912 transient digitizer, were transferred to a PDP 11/23 computer that controlled the experiment and provided suitable processing, storage, and hard-copy facilities. Further details have been reported elsewhere (10).

Results

Luminescence quenching

The experiments were carried out in order to establish reactivity differences between the two DOXYL derivatives, and between these and the model compound, TEMPO. The ap-

proach used involved conventional Stern–Volmer analysis of the quenching data, eq. [1]

$$[1] \quad \frac{I^0}{I} = 1 + k_q\tau[Q]$$

where I^0 and I are the luminescence intensities on the absence and presence of quencher Q, respectively and $k_q\tau$ is the Stern–Volmer constant. These plots were found to be reasonably linear under our experimental conditions. Representative plots are included in Fig. 1, which illustrates the quenching of pyrene singlets; all other systems showed less curvature than this one (*vide infra*). In this particular system the excitation wavelength was 350 nm and the emission was monitored at 400 nm. The results for pyrene and the other luminescent sensitizers have been summarized in Table 1. Experiments with TEMPO were generally used in order to establish the experimental conditions under which studies with the costly DOXYL derivatives were more likely to succeed.

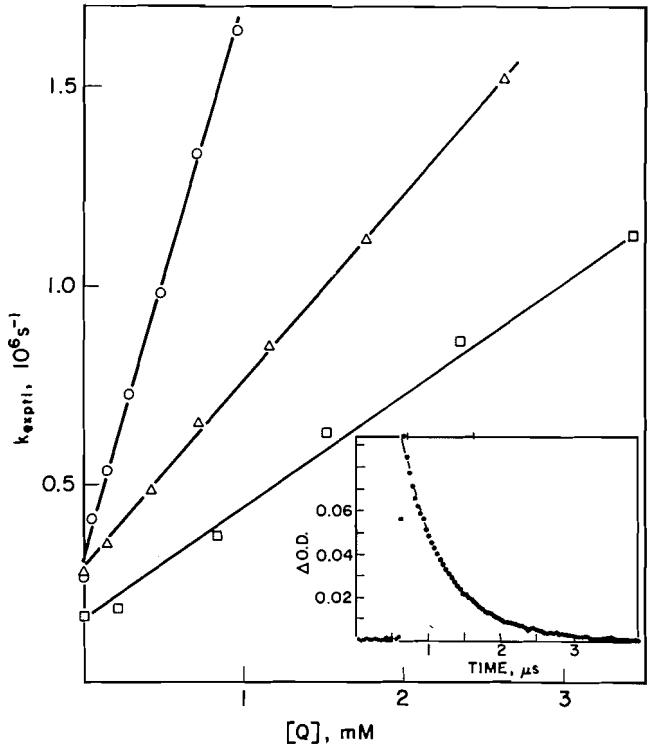

FIG. 2. Quenching of xanthone triplets by TEMPO (○), 5DSA (△), and 12DSA (□) in 0.1 *M* SDS at 300 K. (*Insert*) Decay of xanthone triplets (monitored at 600 nm) in the presence of 0.95 m*M* TEMPO.

Triplet quenching studies using laser-photolysis

In this case the decay of the sensitizers was monitored directly from the time evolution of the triplet–triplet absorption signals at the appropriate wavelengths. For example, in the case of xanthone triplets, the decay can be conveniently monitored at 600 nm (10) (see insert in Fig. 2). We find that the decay profiles can be reasonably fitted with a first order kinetic expression and a quenching rate constant, k_q, can be derived according to eq. [2]

$$[2] \quad k_{exptl} = k_0 + k_q[Q]$$

where k_{exptl} is the pseudo first order rate constant for triplet decay, k_0 is the rate constant in the absence of quencher (i.e., $k_0 = \tau_T^{-1}$), and [Q] the quencher concentration. Figure 2 shows the corresponding plots for xanthone quenching by the three nitroxides in micellar solution, and Table 2 summarizes the data for the various sensitizers used. Experiments with phenanthrene were rather difficult because singlet quenching leads to a substantial decrease in the triplet input at the higher nitroxide concentrations. The relatively large error limits reflect these problems. In the case of anthracene triplets the rate constants for TEMPO were quite slow (11), thus requiring relatively high quencher concentrations; as a result, no experiments were attempted with the costly DOXYL derivatives.

Discussion

It is important to establish under which type of conditions a given type of experiment can be useful in establishing reactivity differences between the two DOXYL derivatives, or between these and the model compound, TEMPO. For example, in the case of static quenching experiments, if we encountered a situation where quenching occurred with 100% efficiency every

[b]Errors as $\pm 2\sigma$.

time a sensitizer and one quencher molecule were in the same micelle at the time of excitation, no difference would be expected among the various substrates; i.e. quenching experiments would only reflect the statistical distribution of reaction partners. Thus, when sensitizer and quencher are resident in the same micelle at the time of excitation, we need a competition between quenching and some other process, such as luminescent emission and/or exit from the parent micelle.

We find TEMPO to be generally more reactive than the DOXYL derivatives, and the difference is quite large in the case of $Ru(bipy)_3^{2+}$. It seems reasonable to assume that the ruthenium complex will be resident at the micelle–water interphase (whether it is held there by electrostatic interactions or by chemical bonding (12)). Thus, the more efficient quenching by TEMPO must be a reflection of its higher mobility and of the absence of a long hydrophobic chain. Similarly, the higher Stern–Volmer constant for 5DSA compared with 12DSA indicates that the former can access the micellar surface more easily. The converse seems true of at least some of the aromatic hydrocarbons. Thus, in the cases of pyrene and phenanthrene, 12DSA is a better quencher than 5DSA, reflecting that these hydrocarbons spend more time near the non-polar core of the micelle which must be more readily accessible in the case of 12DSA. Such preference is not unexpected, given the hydrophobic nature of these substrates.

The absence of any significant differences in the Stern–Volmer slopes for the DOXYL derivatives in the cases of perylene and anthracene are rather surprising. In these cases we tentatively suggest that there is no preference between the regions around 5 and 12 carbon atoms away from the polar head of the probe. It should also be noted that quenching in these cases must be quite fast, since the singlet lifetimes for anthracene and perylene are only a few nanoseconds.

In the case of time-resolved experiments, one can expect to be able to detect differences in the reactivity of the various quenchers provided that static quenching is not so rapid as to be complete within the response time of our instrumentation. In fact our determinations seem to be quite sensitive in these systems. In all cases we observe that in homogeneous solution 5DSA and 12DSA are equally reactive. In the case of xanthone, the data in micellar solution indicates that 5DSA is almost twice as reactive as 12DSA. The difference is in line with the expected hydrophilicity of the polar xanthone triplet. In fact, in other organized media (13) (e.g. polyelectrolyte–surfactant aggregates) xanthone has been shown to relocate to a more polar environment following excitation into the triplet state.

p-Methoxyacetophenone shows virtually no preference for 5DSA or 12DSA, probably a reflection of a relatively homogeneous distribution within the micelle.

Phenanthrene triplets show a preference for the less polar micellar core, as indicated by the higher rate constant for 12DSA compared with 5DSA. Such preference is consistent with the observations in the case of the singlet state (see Table 1). It should be noted that the ratio of values for 5DSA and 12DSA quenching of phenanthrene are different in Tables 1 and 2. In fact, there is no reason why they should be equal, since they refer to different electronic states; further while the Stern–Volmer approach deals with static and dynamic phenomena, the time-resolved approach relates only to the dynamic component.

Conclusion

Nitroxide probes attached to amphiphilic molecules, such as stearic acid, are useful in the study of the location of excited probes in micellar solutions. Similar applications have been suggested earlier in the case of photoionization processes (8), as well as in studies of lipid membrane permeability (9). An alternative approach, using *n*-(9-anthroyloxy) fatty acids as fluorescent probes has been recently reviewed by Thulborn (5).

The two techniques used show good sensitivity and can easily distinguish between the location of different probes. While all the plots obtained here in the time-resolved and luminescence studies were approximately linear, it should be noted that this need not be the case for all similar probes or in different ranges in concentration. Indeed the reasons leading to curved Stern–Volmer plots in micellar solution are well established (14). Our claim is simply that since the plots show only a very slight curvature, the ratio of slopes can be used as a measure of the preference for the reactive 5 or 12 position in the stearic acid chain.

Received February 20, 1984

J. C. SCAIANO, W. J. LEIGH, and G. FERRAUDI. Can. J. Chem. **62**, 2355 (1984).

The photodecomposition of $[Co(NH_3)_5OC(O)CH_2C_6H_5](ClO_4)_2$ is a convenient source of benzyl radicals in aqueous systems. The radicals react with cupric ions with a rate constant of $(2.1 \pm 0.2) \times 10^7\ M^{-1}\ s^{-1}$ to yield a complex that is formed reversibly. This complex can decay to Cu(I), but at high radical concentrations the recombination of benzyl radicals in equilibrium with it can become the predominant decay path. The reaction of benzyl radicals (from 1,3-diphenylacetone) in anionic micelles in the presence of Cu^{2+} leads to strong signals from the same intermediate, $CuCH_2C_6H_5^{2+}$.

J. C. SCAIANO, W. J. LEIGH et G. FERRAUDI. Can. J. Chem. **62**, 2355 (1984).

La décomposition photochimique du $[Co(NH_3)_5OC(O)CH_2C_6H_5](ClO_4)_2$ est une source commode de radicaux benzyles dans des systèmes aqueux. Les radicaux réagissent avec les ions cuivriques avec une constante de vitesse de $(2{,}1 \pm 0{,}2) \times 10^7\ M^{-1}\ s^{-1}$ pour donner un complexe qui est formé d'une façon réversible. Ce complexe peut se dégrader en Cu(I); toutefois, si les concentrations en radical sont élevées, la recombinaison des radicaux benzyles en équilibre avec le complexe peut devenir le processus prédominant de la dégradation. La réaction des radicaux benzyles (provenant de la diphényl-1,3 acétone), dans des micelles anioniques et en présence de Cu^{2+}, permet de déceler de forts signaux attribuables au même intermédiaire, soit le $CuCH_2C_6H_5^{2+}$.

[Traduit par le journal]

Introduction

The widespread use of photochemical free radical sources has largely concentrated on systems in organic solvents, where many convenient precursors are well known (e.g., ref. 1). The situation is quite different in aqueous solutions, where few well documented photochemical sources of organic free radicals are known. In particular, laser photolysis techniques are seldom applied to organic radicals in water. The increase of the interest in free radical processes in organized assemblies and in biological systems (2, 3) has made evident the need of reliable water soluble precursors (2, 3). Thus, it becomes important to understand the mechanism and kinetics of the reactions of relatively hydrophobic radicals in water.

The photodecomposition of cobalt(III) complexes of the type $[Co(NH_3)_5OC(O)R](ClO_4)_2$ has been recognized for over a decade, but their potential use as a free radical source in aqueous systems has received very little attention (5–7).[2] These compounds are stable, easy to prepare and purify, and R can be virtually any group (8). The photochemistry of the phenylacetato complex shows wavelength dependence, but the generation of $C_6H_5CH_2\cdot$ was found to be sufficiently efficient at 308 nm to make it a convenient precursor.

In this paper we report the details of a study of the flash photodecomposition of $[Co(NH_3)_5OC(O)CH_2C_6H_5]^{2+}$ to generate $C_6H_5CH_2\cdot$ and the subsequent reaction of these radicals with cupric ions. This latter reaction is recognized as a very efficient process and has been used as a diagnostic test of radical exit processes in micelles (9). We find the reaction to be considerably slower than we had anticipated, and to involve an intermediate that is formed reversibly.

The question of benzyl radical trapping in micellar systems has also been examined using 1,3-diphenylacetone as the radical precursor.

Experimental

The phenylacetato complex $[Co(NH_3)_5OC(O)CH_2C_6H_5](ClO_4)_2$, was synthesized and purified according to reported procedures (8). Sodium dodecyl sulfate, SDS, was from BDH, specially purified, while cetyltrimethylammonium chloride (CTAC) from K&K was purified by multiple recrystallizations from acetone/methanol. 1,3-Diphenylacetone (Aldrich) was recrystallized from ethanol. All other materials were of the highest purity commercially available and were used as received.

Laser flash photolysis experiments were carried out using for excitation a Lumonics TE-860-2 excimer laser operated with Xe/HCl mixtures (308 nm, ~5 ns, up to 80 mJ/pulse). Similar, but much weaker transient signals were obtained using a Molectron UV-24 nitrogen laser (337.1 nm, ~8 ns, up to 10 mJ/pulse). All experiments were carried out at 300 K using a flow system in which the cell compartment has been built of 7×7 mm^2 Suprasil tubing. The stock solution under study was deaerated with oxygen-free nitrogen in a nearby container; typical flow rates were ca. 0.2 mL/pulse. The transient signals, initially captured by a R-7912 Tektronix transient digitizer, were transferred to a PDP 11/23 computer which controls the experiments and provides suitable processing, storage, and hard-copy facilities. Further details have been reported elsewhere (10).

Conventional flash experiments were carried out using a system which has been described elsewhere (11). Briefly, pulses of white light, with a typical duration of 30 μs were obtained for stored energies of ≤250 J/pulse. In order to ensure light absorption by the cobalt complex in the presence of cupric ions, a solution of $CuSO_4$ (usually ≤0.1 M) was used as a filter; this leads to $\lambda_{excitation} \leq 275$ nm.

The products of reaction were identified by gc–ms, using a Hewlett–Packard Model 5995 instrument.

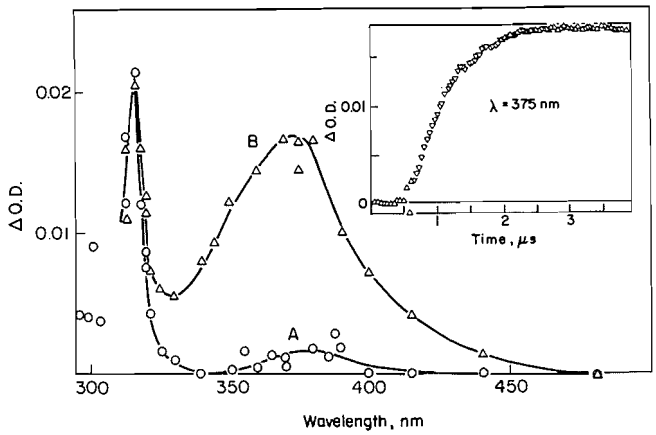

FIG. 1. Spectra recorded immediately (*A*) and 2.5 μs (*B*) after excitation of a solution of 0.0014 *M* $[Co(NH_3)_5OC(O)CH_2C_6H_5]$-$(ClO_4)_2$ and 0.03 *M* $CuSO_4$ at pH 2.8 (flow system, 300 K). (*Insert*) Build-up trace monitored at 375 nm.

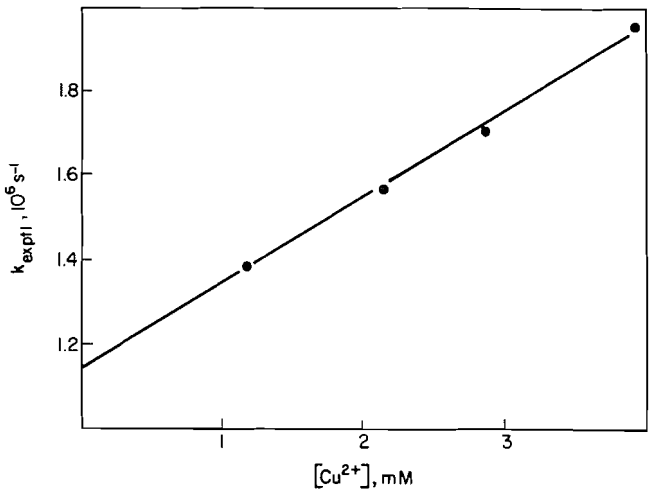

FIG. 2. Dependence of the rate of formation of $CuCH_2C_6H_5^{2+}$ on the concentration of Cu(II), according to eq. [3].

Results

Laser photolysis of deaerated aqueous solutions of $[Co(NH_3)_5OC(O)CH_2C_6H_5]^{2+}$, usually ~0.002 *M*, led to $C_6H_5CH_2\cdot$ (λ_{max} 317 nm) as the only transient species detected (12), reaction [1].

$$[1]\quad [Co(NH_3)_5OC(O)CH_2C_6H_5]^{2+} \xrightarrow{h\nu} Co^{2+} + 5NH_3 + CO_2 + C_6H_5\dot{C}H_2$$

While reaction [1] may involve the intermediacy of $C_6H_5CH_2C(O)O\cdot$ as a discrete transient, our experiments, usually in the 50 ns to 500 ms time domain, show no evidence for this species. Acyloxy radicals, particularly those leading to stabilized radicals, are believed to be very short-lived (13).

In the absence of scavengers benzyl radicals decayed predominantly with second order kinetics in both laser and conventional flash experiments, the radical concentration being substantially lower in the latter.

Cupric ions were added as $CuSO_4$. Optical spectroscopy did not indicate any thermal reaction between the cobalt complex and cupric ions. The pH of the samples was adjusted to 2.8 by addition of $HClO_4$ to prevent the precipitation of cobalt(II) hydroxide on photolysis. Addition of cupric ions led to a small increase of the decay rate of $C_6H_5CH_2\cdot$ and the formation of a new transient with λ_{max} ~ 375 nm; its formation followed pseudo-first order kinetics. Figure 1 shows the spectra obtained at two different times after laser excitation. The formation of a species with absorptions in this region is in line with similar observations for other carbon centered radicals (6, 14) and is attributed to reaction [2].

$$[2]\quad C_6H_5CH_2 + Cu^{2+}_{(aq)} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} CuCH_2C_6H_5^{2+}$$

Such intermediates have been proposed before on the basis of kinetic (15) and product analysis data (16).

A study of the rate of formation of $CuCH_2C_6H_5^{2+}$ for different concentration of $Cu^{2+}_{(aq)}$, under conditions where the decay of $Ph\dot{C}H_2$ is at least one order of magnitude slower, leads to k_2 from a plot of the pseudo-first order rate constant, k_{exptl}, against $[Cu^{II}]$, eq. [3].

$$[3]\quad \ln\frac{A_{eq}}{A_{eq} - A} = k_{exptl}\cdot t = (k_2[Cu^{II}] + k_{-2})t$$

where A_{eq} and A are the transient absorbances at equilibrium and at time t, respectively, and the equation neglects the slow decay in the absence of Cu^{II}. The corresponding plot (Fig. 2) leads to $k_2 = (2.1 \pm 0.2) \times 10^7\ M^{-1}\ s^{-1}$ and $k_{-2} = (1.14 \pm 0.06) \times 10^6\ s^{-1}$ at 27°C (errors as $\pm 2\sigma$). The equilibrium yield of 375 nm transient was proportional to $[Cu^{II}]$, as expected.

The signal intensity at 317 nm (mostly due to the benzyl radical) was reduced, but not eliminated, by addition of cupric ions. Even after the formation of the 375 nm absorption is complete, the 317 nm band remains in exactly the same position, and just as sharp as it is in the absence of Cu^{II} (see Fig. 1).

The decay of the 375 nm species occurs concurrently with that of the benzyl radical (monitored at 317 nm), over a wide range of transient concentrations. In the laser photolysis experiments, which involve higher radical concentrations, the decay incorporated a considerable degree of second order kinetics, particularly at the higher laser doses. In the conventional flash experiments the decay kinetics followed first order, single exponential behavior at both wavelengths 317 and 375 nm; in these the yield of 375 nm transient was linearly proportional to the flash energy at energies below 200 J/pulse, and was also higher for the higher Cu^{2+} concentrations.

The mixed first and second order kinetics observed in the laser experiments at either 317 or 375 nm are expected if the equilibrium conditions (reaction [2]) lead to a competition of radical decay processes via reactions [4] and [5].

$$[4]\quad 2C_6H_5\dot{C}H_2 \xrightarrow{2k_t} C_6H_5CH_2CH_2C_6H_5$$

$$[5]\quad CuCH_2C_6H_5^{2+} \xrightarrow[(H_2O)]{k_5} Cu^{+}_{(aq)} + C_6H_5CH_2OH$$

High $Cu^{2+}_{(aq)}$ and low radical concentrations (as in conventional flash experiments) lead to predominant first order decay via reaction [5], while reaction [4] can predominate in laser experiments. Typical experimental lifetimes for $CuCH_2C_6H_5^{2+}$ are in the 25–70 μs range, but usually involve some second order decay. The correct lifetime for reaction [5], obtained by extrapolation at low transient concentrations, is close to 100 μs (k_5^{-1}). An "apparent" rate constant for the trapping of benzyl by cupric ions can be obtained by monitoring the small changes in the decay at 317 nm and lead to $k_{app} = k_5k_2/k_{-2} = (2.1 \pm 1.0) \times 10^5\ M^{-1}\ s^{-1}$. The large error

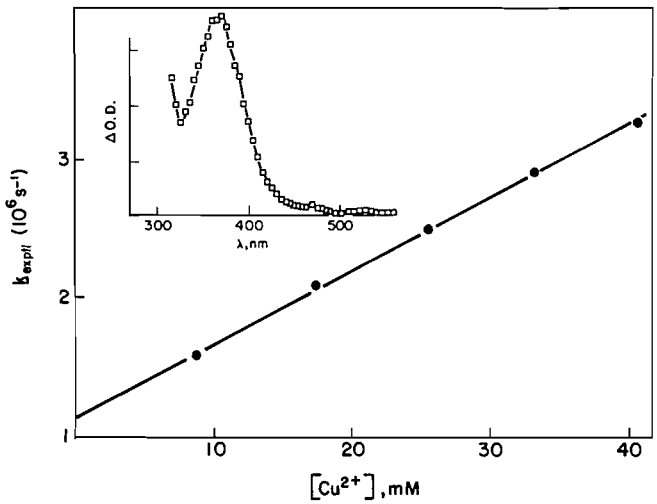

FIG. 3. Dependence of the rate of formation of $CuCH_2C_6H_5^{2+}$ on the concentration of cupric sulfate in 0.2 *M* SDS solution, using 1,3-diphenylacetone as a radical precursor. (*Insert*) Spectrum recorded between 1 and 10 μs following excitation.

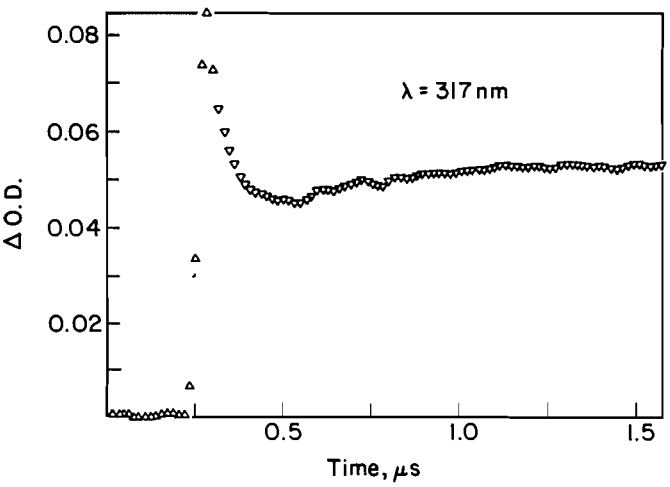

FIG. 4. Trace recorded at 317 nm, for a solution of 0.006 *M* 1,3-diphenylacetone in 0.2 *M* SDS, at 300 K.

results mainly from interference by reaction [4]. An estimate of k_5 that can also be obtained by combining the value of k_{app} with k_2 and k_{-2}; this leads to $k_5 \sim 1.2 \times 10^4$ s^{-1}, in good agreement with the value given above.

Product studies (gc−ms) in steady state irradiations with excitation light centered around 300 nm lead to $C_6H_5CH_2OH$, $C_6H_5CH_2C(O)OCH_2C_6H_5$, and $C_6H_5CH_2CH_2C_6H_5$ as the main products, in approximate ratios 1.0:0.6:0.2. The ester is believed to result from reaction of benzyl radicals with the cobalt complex. A trace of $C_6H_5CH_2Cl$ was also observed, although its origin is unclear. The expected formation of Cu(I) was confirmed by reaction with 2,9-dimethylphenanthroline.

A few laser photolysis experiments were also carried out in micellar solutions using 1,3-diphenylacetone as the radical precursor. In the case of CTAC micelles (typically 0.05 *M* surfactant) the signal at 375 nm is detectable with some difficulty, but definitely much weaker than those in just water. This may reflect a separation of quencher and radical, promoted by the positive micelles.

In SDS micelles, by contrast, the 375 nm transient is easily detectable and virtually identical to the species detected in water. The insert in Fig. 3 illustrates the spectrum obtained under these conditions. The build-up of the complex $CuCH_2C_6H_5^{2+}$ followed pseudo-first order kinetics, and for example had a growth lifetime of ~300 ns for $[Cu^{2+}] = 0.045$ *M* and [SDS] = 0.2 *M*. This rate of formation was linearly dependent on the concentration of cupric ions. The plot shown in Fig. 3 (compare with Fig. 2) leads to an overall rate constant for trapping $k_{trapping} = (5.3 \pm 0.3) \times 10^7$ M^{-1} s^{-1}, to be compared with $k_2 = 2.1 \times 10^7$ M^{-1} s^{-1} in water. Clearly SDS promotes quenching.

In the absence of Cu^{2+}, the signal from $C_6H_5\dot{C}H_2$ can be easily monitored at 317 nm. Under these conditions ([SDS] = 0.2 *M*) we observe a partial decay with a lifetime of ca. 60 ns, followed by a modest growth, with a lifetime in the 200−350 ns range (for this process it is difficult to determine a more accurate value). A representative trace is illlustrated in Fig. 4.

TABLE 1. Representative kinetic parameters for the reaction of carbon centered radicals with cupric ions

Radical	k_2[a,b]	k_{-2}[a,c]	k_5[a,c]	Reference
$\dot{C}H_2CO_2^-$	6.4×10^8	1×10^2	2.8	14
$CH_3\dot{C}HCO_2^-$	5×10^8	8.6×10^3	0.2	14
$\dot{C}H_2OH$	1.6×10^8			14
$\dot{C}H_2CH_2OH$	3.1×10^7		3.3×10^2	14
$CH_3\cdot$	7.4×10^5		7×10^2	6
$C_6H_5\dot{C}H_2$	2.1×10^7	1.1×10^6	1.2×10^4	This work

[a]The reactions refer to $C_6H_5\dot{C}H_2$ or to the equivalent reaction for the radical listed in each case.
[b]In units of M^{-1} s^{-1}.
[c]In units of s^{-1}.

Discussion

The formation of complex intermediates by reaction of carbon centered radicals with cupric ions seem to be a rather general phenomenon; some representative examples studied by pulse radiolysis (14), flash photolysis (16), and laser photolysis have been summarized in Table 1. Judging from the similarity of spectral shape and λ_{max}, the bonding interactions in all these species must be essentially the same. For example, λ_{max} is ~350, 370, and 375 nm for $\dot{C}H_2(CH_3)_2COH$ (14), $\dot{C}H_3$ (6), and $C_6H_5\dot{C}H_2$, respectively.

The apparent rate of benzyl radical scavenging by Cu^{2+} (i.e. k_5k_2/k_{-2}) is only 2.1×10^5 M^{-1} s^{-1}, in fact not a very efficient process. The vast majority of the initial trapping events (~99%) lead to the dissociation of the intermediate, with only ~1% leading to products (compare k_{-2} and k_5 in Table 1).

It is important to examine more quantitatively the implications of these results in terms of the relative contributions of reactions [4] and [5] to the decay of benzyl radicals. Thus, for a 0.1 *M* concentration of Cu^{2+} the ratio of radicals removed by each process is:

$$\frac{\text{termination}}{\text{trapping}} \sim 2k_t \times (1.11 \times 10^{-4})[C_6H_5\dot{C}H_2]_{total}$$

where $[Ph\dot{C}H_2]_{total} = [C_6H_5\dot{C}H_2] + [CuCH_2C_6H_5^{2+}]$ and the value of 1.11×10^{-4} includes all other relevant rates determined herein. Thus, if $2k_t \sim 4 \times 10^9$ M^{-1} s^{-1},[3]

$$\frac{\text{termination}}{\text{trapping}} \cong 4.4 \times 10^5[C_6H_5\dot{C}H_2]_{total}$$

[3]Reported values in water range for ca. 2 to 9×10^9 M^{-1} s^{-1} (17).

As a result of this analysis, we conclude that in homogeneous systems, cupric ions will be good traps of benzyl radicals, when the radical concentration is low as in steady irradiation experiments. However, trapping will be inefficient for high radical concentrations, such as those frequently achieved using pulsed techniques. For example, in laser flash photolysis experiments, radical concentrations around or over 10^{-5} M are not uncommon.

The situation may be even more complex in micellar systems (9) where exit–entry processes and electrostatic interactions may play a role in determining the efficiency of trapping. Given the overall trapping rate of $2.1 \times 10^5 M^{-1} s^{-1}$ determined here in water, it would appear that for a benzyl radical in water, its probability of entering a micelle would be, under most experimental conditions, much higher than the probability of irreversible quenching.

Our exploratory experiments in micellar systems using 1,3-diphenylacetone as a benzyl radical precursor illustrate some of the problems mentioned above. The photochemistry of 1,3-diphenylacetone in compartmentalized systems (9, 18) can be expected to follow the mechanism of reactions [6]–[11].

[6] $C_6H_5CH_2COCH_2C_6H_5 \xrightarrow{h\nu} \longrightarrow {}^3[C_6H_5\dot{C}H_2 + C_6H_5CH_2\dot{C}O]$

[7] ${}^3[C_6H_5\dot{C}H_2 + C_6H_5CH_2\dot{C}O] \xrightarrow[\text{ISC}]{k_7} \longrightarrow C_6H_5CH_2COCH_2C_6H_5$

[8] ${}^3[C_6H_5\dot{C}H_2 + C_6H_5CH_2\dot{C}O] \xrightarrow{k_8} {}^3[2C_6H_5\dot{C}H_2] + CO$

[9] ${}^3[C_6H_5\dot{C}H_2 + C_6H_5CH_2\dot{C}O] \xrightarrow{k_9} [C_6H_5CH_2\dot{C}O] + C_6H_5\dot{C}H_2$

[10] $[C_8H_5CH_2\dot{C}O] \xrightarrow{k_{10}} [C_6H_5\dot{C}H_2] + CO$

[11] ${}^3[2C_6H_5\dot{C}H_2] \xrightarrow[\text{ISC}]{k_{11}} \longrightarrow C_6H_5CH_2CH_2C_6H_5$

[12] ${}^3[2C_6H_5\dot{C}H_2] \xrightarrow{k_{12}} [C_6H_5\dot{C}H_2] + C_6H_5\dot{C}H_2$

where square brackets identify species in the same compartment (geminate pairs). Reaction [9] actually corresponds to exit by either radical, since these processes are indistinguishable (i.e. k_9 is the sum of both exit rate constants).

The decay constant of 60 ns observed, corresponds to the composite of reactions [7], [8], and [9]; i.e. $(k_7 + k_8 + k_9) \sim 1.7 \times 10^7$ s^{-1}, the predominant process being reaction [7], since the others would contribute to the kinetics but not to the readily detectable (Fig. 4) depletion of signal. The modest growth observed presumably reflects reaction [10], and is consistent with recent rate measurements for this process in homogeneous solution (19). These processes are not unlike those reported by Turro *et al.* (9, 18), frequently in CTAC, except that our data include a substantial amount of information in the ~50 ns range, which was not examined in detail in earlier reports.

The very weak 375 nm signals detected in CTAC micelles emphasize the efficient separation of free radicals and scavenger caused by the repulsive interaction between Cu^{2+} and the micellar surface, as well as the efficient micellization of $C_6H_5\dot{C}H_2$.

The scavenging of benzyl radicals by cupric ions in SDS micellar solution has already been examined (20). Surprisingly, the intense band at 375 nm escaped comment, apparently undetected. The formation of this band is in fact the dominant feature when the system is examined using laser flash photolysis techniques. Quite clearly micellization leads to a significant enhancement in the formation of $CuCH_2C_6H_5^{2+}$, consistent with the strong binding of Cu^{2+} to the micelle (21).

Adsorption of sodium cyclododecylmethanoate and cycloundecylmethanoate at the air/water interface

JAN J. SPITZER[1]

Department of Chemistry, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4

Received October 25, 1983[2]

JAN J. SPITZER. Can. J. Chem. **62**, 2359 (1984).

Surface tension measurements on aqueous solutions of sodium cyclododecylmethanoate and sodium cycloundecylmethanoate in sodium carbonate/bicarbonate buffers and at constant sodium ion concentration at 25°C were used to obtain the standard free energies of adsorption, the saturation areas per surfactant ion, and the critical "micelle" concentrations of these compounds. Similar measurements were done for solutions of sodium dodecanoate for comparisons.

The standard free energies of adsorption of CH_2 group that is located in a macrocyclic cycloalkyl ring appears to follow the "rule of two" ($-RT$ ln 2) that is also valid for straight chain ionic surfactants. The saturation areas of both cyclododecylmethanoate and cycloundecylmethanoate are about 52 Å^2/ion as compared to about 32 Å^2/ion for normal dodecanoate.

For large ring cycloalkylmethanoates the critical "micelle" concentrations appear to decrease by a factor of about 4/5 for each CH_2 group added to the ring as compared to the factor of about 1/2 for each CH_2 group added to the chain of normal alkanoates. The data suggest that large cycloalkyl rings have "collapsed ring", or "double chain", conformation in aqueous solutions and in the adsorbed state.

JAN J. SPITZER. Can. J. Chem. **62**, 2359 (1984).

Opérant à 25°C, dans des tampons de carbonate et de bicarbonate de sodium et à une concentration constante en ion sodium, on a mesuré les tensions de superficielles de solutions aqueuses de cyclododécylméthanoate de sodium et de cycloundécylméthanoate de sodium et l'on a utilisé les valeurs ainsi déterminées pour obtenir les énergies libres standard d'adsorption, les surfaces de saturation par ion tensioactif et les concentrations critiques de "micelles" de ces composés. Pour fins de comparaison, on a aussi effectué des mesures semblables sur des solutions de dodécanoate de sodium.

Les énergies libres standard d'adsorption du groupe CH_2 situé dans le cycloalkyle macrocyclique semblent suivre la "règle de deux" ($-RT$ ln 2) qui est également valable pour les agents tensioactifs ioniques à chaîne droite. La surface de saturation du cyclododécylméthanoate ainsi que celle du cycloundécylméthanoate sont d'environ 52 Å^2/ion par comparaison avec environ 32 Å^2/ion pour un dodécanoate normal.

Pour les cycloalkylméthanoates à grands cycles, les concentrations critiques de "micelle" semblent diminuer par un facteur d'environ 4/5 pour chaque CH_2 qui est ajouté au cycle; ceci se compare à un facteur 1/2 pour chaque CH_2 ajouté à une chaîne normale d'alkanoates. Les données suggèrent que, en solutions aqueuses et à l'état adsorbé, les cycloalkyles à grands cycles adoptent des conformations de "cycle effondré" ou de "double chaîne".

[Traduit par le journal]

Introduction

As part of our program of measurements leading to interfacial and micellization (or aggregation) data for surfactants that do not have long paraffinic chains in their molecular structure (1, 2), we now report surface tension measurements of aqueous solutions of sodium cyclododecylmethanoate and sodium cycloundecylmethanoate. For comparisons, similar measurements were also done for sodium dodecanoate.

The micellization of straight chain carboxylates has been extensively studied, and there is now a wealth of experimental and theoretical data (3–9). On the other hand the surface activity of normal alkanoates appears to be known only semi-quantitatively. Early workers recognized the large pH effects on the surface tension of solutions of carboxylates (10–12), particularly the effect of atmospheric carbon dioxide (13), but few data seem to have been published since. The most reliable data are probably those of Roe and Brass (14) on potassium dodecanoate and potassium palmitate. Graphical data for sodium decanoate, dodecanoate, and tetradecanoate have large minima in their surface tension vs. logarithms of concentration curves (15). These minima probably indicate the hydrolysis of carboxylate ions, or the presence of impurities (16).

The aggregation behaviour of surfactants with non-paraffinic hydrophobic structures depends on the geometrical structure of the hydrophobic moiety. A useful classification of various types of aggregation has been given by Mukerjee together with a discussion of possible data treatments (17). Most of the relevant aggregation data are for surfactants with structures based on bile acids, and these types of compounds continue to receive attention (18, 19). There are also some thermodynamic data on cycloalkylamine hydrobromides and non-paraffinic potassium carboxylates (20, 21). The surface activity of non-paraffinic hydrophobic solutes has not been much investigated (1) in spite of early elegant experiments by Hartley on double chain ethers of resorcinol (22, 23), even though these kinds of compounds occur naturally in biological systems (24), in crude oil as non-hydrocarbon bases and acids (25), and some are synthesised for technological applications (26). Again there are some data on cholate adsorption at various oil interfaces (27), while the effects of molecular structure on surface activity have been reviewed by Rosen recently (28).

Experimental

Surface tension measurements

Surface tensions were measured by the drop volume method as described earlier (1, 2). This time the Agla (Wellcome) precision microsyringe was used in preference to Gilmont syringe; the all-glass Agla syringe is easy to clean and assemble for measurements. The temperature was 25°C controlled to ±0.1°C. The surface tensions were calculated from volumes of 10–25 drops.

Conductivity measurements

These were done with the LKB 5300B precision conductoanalyzer

(which was checked against standard resistances) using Yellow Springs Instrument Co. conductivity cell No. 3403 at 25.0°C. The cell was calibrated with a KCl solution in the usual manner.

Preparation of salts

(*a*) Sodium dodecanoate was prepared by neutralization of BDH specially pure lauric acid dissolved in ethanol with 0.5 *M* ACS Certified NaOH in pure water (Gelman Water I System). The reaction mixture was refluxed for 12 h; solvents were then evaporated on a steambath. The sodium dodecanoate was then extracted with ether for two weeks. The solid in the thimble was stirred once a day because the ether drained too fast from the thimble. This resulted in extraction of solids from only along the walls of the thimble. The surface tensions of solutions of this salt in appropriate buffers did not show aging effects over a period of 5–10 min.

(*b*) Sodium cyclododecylmethanoate was prepared from cyclododecylmethanoic acid (Fluka Purum) by the same procedure as sodium dodecanoate. The elemental analysis (Galbraith Laboratories) showed purity of 99.8–100.1% for C, H, and Na. There were no observable aging effects during the surface tension measurements.

(*c*) Sodium cycloundecylmethanoate was prepared from cycloundecylmethanoic acid (Fluka Pract.) as above. The elemental purity was 99.9–100.1% for C, H, and Na. However, the surface tensions of the aqueous solutions of this salt showed surface tension aging. These aging effects could not be reduced by repeated crystallizations from a variety of solvents. The surface tensions in this case are those determined from drops aged 15 min (after which the decrease of surface tension was quite slow). The data for this salt are therefore less accurate than the data from the other salts, which are good to $\pm$ 0.1$_5$ mN m^{-1}.

The surface tension measurements were done in sodium carbonate (Fisher Certified, dried at 270°C for 2 h)/sodium bicarbonate (used as such) buffers to eliminate the hydrolysis of the carboxylate ions. Two buffer solutions were made. The first one, which will be referred to as 0.01 *M* buffer (and the subscript 0.01 used for free energies and cmc's obtained in these buffer solutions), was made up from equimolar mixtures of 0.01 *M* $NaHCO_3$ and 0.01 *M* Na_2CO_3. The second one, which will be referred to as 0.1 buffer, was made up from equimolar mixtures of 0.1 *M* $NaHCO_3$ and 0.1 *M* Na_2CO_3. All the solutions had pH of 10.3 ($\pm$ 0.1), and this gives the concentration of free carboxylic acids at less than 1×10^{-6} *M* even in the most dilute carboxylate solutions. The constant Na^+ concentration experiments were all done in 0.01 buffers. The solutions were made up by mixing appropriate volumes of solutions of the carboxylates in 0.01 buffer with solutions of NaCl (Fisher Certified dried at 550°C for 1 h) in 0.01 buffer. Water from the Gelman System I had surface tension of 71.8 mN m^{-1}.

The conductivity was determined for solutions made up in 0.01 buffer.

Results and discussion

In view of uncertainties in deriving free energies of adsorption from raw data (1, 2), the original data are given in Tables 1, 2, and 3.

The free energies of adsorption were derived by fitting 3rd degree polynomials

$$\gamma = a_0 + a_1C + a_2C^2 + a_3C^3$$

and the Szyszkowski equation

$$\Pi = a \ln (1 + bC)$$

where γ and Π are surface tension and spreading pressure respectively, C is molarity, and a_0, a_1, a_2, a_3, a, b are least-squares coefficients, to the experimental data. Experimental data in the region of saturation adsorption were not used in these least-squares fits. The least-squares coefficients determine the Traube constants (limiting slopes of the function of surface tension or spreading pressure vs. molarity at zero molarity), as $\alpha_3 = -a_1$ and $\alpha_s = ab$, where a_3 and a_s are Traube's constants determined from the 3rd degree polynomial and Szyszkowski least-squares analyses. For calculations of free energies of adsorption from bulk buffer solutions the average values of Traube's constants were used in the expression (29, 30).

$$[1] \quad \Delta G_{ad} = -RT \ln \alpha$$

Other definitions of free energies of adsorption are also possible (31, 32). The free energies of adsorption derived from the 3rd polynomial fit and from the Szyszkowski equation fit agreed to within 2%. The reference states in eq. [1] are surface pressure of 1 mN m^{-1} for the surface phase, and the hypothetical ideal 1 *M* solution of the surfactant in the appropriate buffer solution for the bulk phase. The standard free energies at zero buffer concentration were obtained by extrapolation from the two values of the free energies of adsorption at 0.1 *M* and 0.01 *M* buffer concentration. The values of the free energy of adsorption in 0.01 buffer were only about 0.5 kJ mol^{-1} more negative than the extrapolated infinite dilution values. These values are given in Table 4.

The saturation adsorption areas per ion were obtained from constant Na^+ ion concentration data graphically (1). For cyclo-

dodecylmethanoate the constant Na^+ concentration was kept both below and above the critical micelle concentration (cmc) in order to check (1) that the saturation area per ion does not depend on the counter ion concentration, Table 1, which the data confirm.

The critical "micelle" concentrations were determined graphically as the intersection of two straight lines in the plot of surface tension against log of molarity and also from the plots of conductivities vs. molarities as shown in Fig. 1. The data are given in Table 4.

The free energies of adsorption appear to follow the rule of "two" ($-RT$ ln 2). This rule gives about 1.7 kJ mol^{-1} for each CH_2 group added to the ring. It is likely that this rule remains valid for larger rings but may not be valid for smaller rings because of their increased rigidity. In conjunction with previous data (28) it appears that this rule is valid for a variety of ionic surfactants, and that the way in which the CH_2 groups in the hydrophobic structures are arranged is not very important. From Table 4, the value of the free energy of adsorption of cyclododecylmethanoate is lower (by an equivalent of about 3 CH_2 groups) than the free energy of adsorption of straight chain dodecanoate. This is a large structural difference because the number of atoms in these two hydrophobic moieties is nearly the same ($CH_{12}H_{23}$ for cyclododecylmethanoate and $C_{11}H_{23}$ for dodecanoate). This suggests that the cyclododecylmethanoate ion exists in aqueous solution in "collapsed ring" conformation, as short as about octanoate, but with thicker "double" chain.

The saturation adsorption areas for both cyclododecylmethanoate and cycloundecylmethanoate are about the same of around 52 ± 1 Å^2/ion, as compared to about 33 Å^2/ion for straight chain dodecanoate. Because straight chain carboxylates have saturation adsorption areas independent of the length of the chain, the value of 33 Å^2/ion is thought to be determined by the size of the solvated charged carboxyl group (32). In our case the saturation adsorption areas are determined by the size of the cycloalkylmethanoate hydrophobic moiety. If we consider that cyclododecylmethanoate ions are standing up at the interface with their rings as two short double chains, then we get a value of 26 Å^2 per chain. These values can be compared with the value of about 21 Å^2 per chain derived from insoluble monolayer studies for paraffinic compounds. The difference of 5 Å^2 is probably a measure of water penetration into the adsorbed monolayer of cyclododecylmethanoate.

A saturation area of 93.2 Å^2 ion has been determined for sodium cyclododecyl sulfate (33). The large difference between our value of 52 Å^2/ion and the cited value is due to different experiments from which the saturation areas were derived. The value of 93.2 Å^2/ion was obtained from experiments with no added salt, whereas our value is derived from experiments at constant counter-ion (sodium) concentration. This is another example of persisting ambiguity about the meaning and determination of saturated areas as has been recently discussed by Ikeda (34). The least unambiguous procedure for the determination of saturated areas of surfactants is to perform constant counter-ion experiments (1, 35). Such experimentally derived saturation areas are independent of the actual but constant counter-ion concentration (e.g., our results for sodium dodecanoate), and yield the surface excess concentration per surfactant ion only (35).

The critical micelle concentrations determined from both the surface tension and conductance measurements are given in Table 4. The cmc determined from the surface tension data are consistently higher. Similar trends were also found in the case of paraffinic carboxylates (15). The reported cmc for cyclododecyl sulfate is 0.070 mol dm^{-3} which can be compared to our mean value of 0.083 mol dm^3 for cyclododecyl carboxylate. The lower value for the sulfate is due to the sulfate ester oxygen which can be counted as part of the hydrophobic moiety (36). This conclusion appears to be collaborated by the cmc value of 0.083 mol dm^{-3} (unfortunately at unknown ionic strength) for the double-chain surfactant undecyl-6-sulfate (37). The conductivity data can be also used to estimate the degree of dissociation of micelles as the ratio of the specific conductance vs. molarity slopes above and below the cmc (38). In the present case the unusually high degrees of over 80% indicate a small aggregation number for the cyclododecyl (80%) and cycloundecyl (86%) carboxylate micelles (38).

[a]From surface tension measurements.
[b]From conductivity measurements.

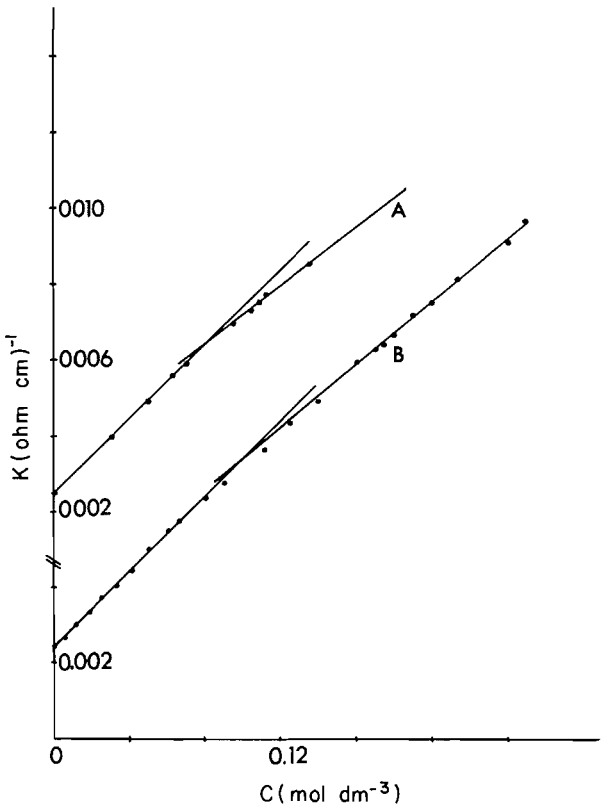

FIG. 1. The plot of specific conductance vs. molarity for determination of cmc: (*A*) cyclododecylmethanoate, (*B*) cycloundecylmethanoate.

Though the data pertain to only two members of the cycloalkylmethanoate homologous series, the critical micelle concentrations seem to follow a "rule" of 4/5 (0.8). That is the cmc decreases by a factor of 0.8 for each CH_2 group added to the ring. For straight chain carboxylates the factor is close to 0.5 for each CH_2 group added to the chain. If it were considered that the cycloalkylmethanoate ring behaves as a double chain that is made longer by one half of the CH_2 group for each CH_2 group that is added to the ring, then the cmc factor would be 0.71 (square root of 0.5). It thus appears that the ring is not quite collapsed into a double chain, and that two CH_2 groups added to the ring make the double chain conformation longer by a little less than one CH_2 group.

Ion/molecule reactions in allene. II. Collisional stabilization of the dimer ion $(C_3H_4)_2^{+\cdot}$ by non-polar molecules

KENZO NAGASE[1] AND JAN A. HERMAN

Centre de Recherches sur les atomes et les molécules et le département de Chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received January 31, 1984

KENZO NAGASE and JAN A. HERMAN. Can. J. Chem. **62**, 2364 (1984).

The relative deactivation efficiencies, k_s, for collisional stabilization of $(C_3H_4)_2^{+*}$ ion species, produced by photoionization at 10.03 eV of allene, were obtained in various bath gases, such as rare gases, N_2, CO, CO_2, and CF_4. A linear relationship between ln $(k_s\sqrt{\mu})$ and ϵ_{M-M} was obtained, where ϵ_{M-M} stands for the intermolecular well-depth potential between pairs of neutral M and μ is the reduced mass of colliding partners. Similar relations were examined for other collisionally stabilized ion species.

KENZO NAGASE et JAN A. HERMAN. Can. J. Chem. **62**, 2364 (1984).

Opérant dans divers bains de gaz, tels les gaz rares, le N_2, le CO, le CO_2 et le CF_4, on a déterminé les efficacités de désactivaction relatives, k_s, pour la stabilisation collisionnelle de l'espèce ionique $(C_3H_4)_2^{+*}$ produite par photoionisation, à 10,03 eV, de l'allène. On a obtenu une relation linéaire entre ln $(k_s\sqrt{\mu})$ et ϵ_{M-M}, où ϵ_{M-M} correspond au puit de potentiel intermoléculaire entre les paires neutres M et où μ est la masse réduite des partenaires entrant en collision. On a étudié des relations similaires pour d'autres espèces ioniques stabilisées par collision.

[Traduit par le journal]

Introduction

Ion/molecule reactions of allene have been studied by mass-spectrometry using various types of instruments (1–5). At low pressure ($P < 0.02$ Torr) the major reaction is $C_3H_4^{\cdot+}(C_3H_4,H^{\cdot})C_6H_7^+$ and it is assumed that this reaction proceeds via a long-lived collision complex, $(C_3H_4^{\cdot+}.C_3H_4)$ (5, 6). The cross-section of this reaction is dependent upon the internal energy and diminishes with increasing energy (5). It was also suspected that the collision complex might isomerize into more stable $C_6H_8^{\cdot+}$ species of lower heat of formation, since some of its isomers are considered to have heats of formation lower than the calculated threshold energy for the main reaction leading to $C_6H_7^{\cdot+}$ and $H^{\cdot}$ (5, 7).

However, the $C_6H_8^{\cdot+}$ species (m/z 80) was not observed at low pressure in the mass spectrum of pure allene, probably because of high reactivity of the collision complex or excited dimer ion, $(C_3H_4)_2^{\cdot+*}$. Our recent study of ion/molecule reactions in allene indicates that $C_6H_8^+$ species and even of its solvates are present at high pressure (up to 3.5 Torr), but their fractional abundances are low (<2%) (8). One may expect the mass peak $m/z = 80$ to be more intense if a successful energy transfer from the excited $(C_3H_4^{\cdot+}.C_3H_4)^*$ species to a suitable third body could occur. As shown in Fig. 1 the heats of formation of some $C_6H_8^{\cdot+}$ isomers are below the sum of the heats of formation of $C_6H_7^+ + H^{\cdot}$ species. If the energy barrier towards isomerization is not too high, one can expect to observe a $C_6H_8^{\cdot+}$ peak in the mass spectrum. The mass peak of the $C_6H_8^{\cdot+}$ ion was observed in the present experiments and its fractional intensity increased with increasing pressure of the third body (M) and, moreover, depended on the nature of M. The relative deactivation efficiencies, k_s, for the stabilization of the excited dimer ion, $(C_3H_4)_2^{+*}$, by M could be followed through the variation of the fractional intensity ratio of $C_6H_8^{\cdot+}$ against other ionic species.

Experimental

The apparatus and the experimental procedure have been already described (9, 10). The ion/molecule reactions were studied under field-free conditions inside the collision chamber and with an electric field at low intensity (~5 V/cm) in the ion optics. The distance in the collision chamber between the plane of formation of the parent-ions by photon impact of 10.03 eV krypton resonance line and the exit slit was fixed at 4.2 mm. The temperature of the cell was kept at 25 ± 2°C as measured by a thermocouple connected to the wall of the collision chamber. The mass spectra of allene were measured in the pressure range of 0.1–10 Torr under the above conditions.

The allene from Matheson of 99.5% purity was used without further purification. All other gases, also from Matheson, were of instrumental grade purity. The mixtures of known concentrations were prepared in a conventional high vacuum manifold. The usual concentration of allene in the mixtures was kept around 10%.

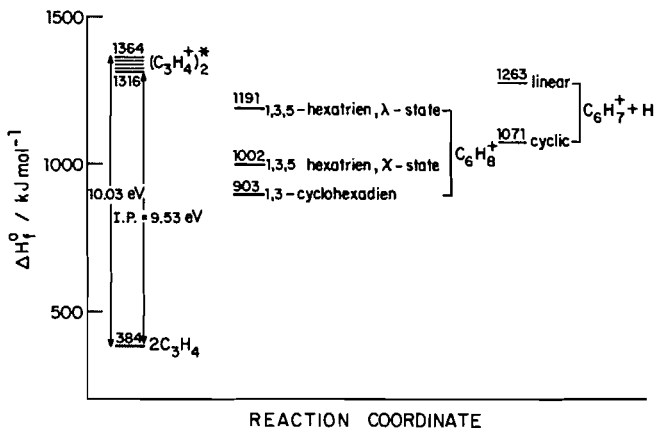

FIG. 1. Energy state of allene, its activated dimer ion, and some isomers of $C_6H_8^{\cdot+}$ and $C_6H_7^+$.

Kinetic considerations

The m/z values and the corresponding fractional intensities of ions produced by photoionization in pure allene in the present experiments agree well with those already published (8). The major products were $C_6H_7^+$, $C_6H_9^+$, $C_7H_7^+$, and their clusters. At this relatively high pressure $C_6H_8^{\cdot+}$ species is also observed, confirming our previous results (8). In the case of mixtures of allene with added gases (rare gases, N_2, CO, CO_2,

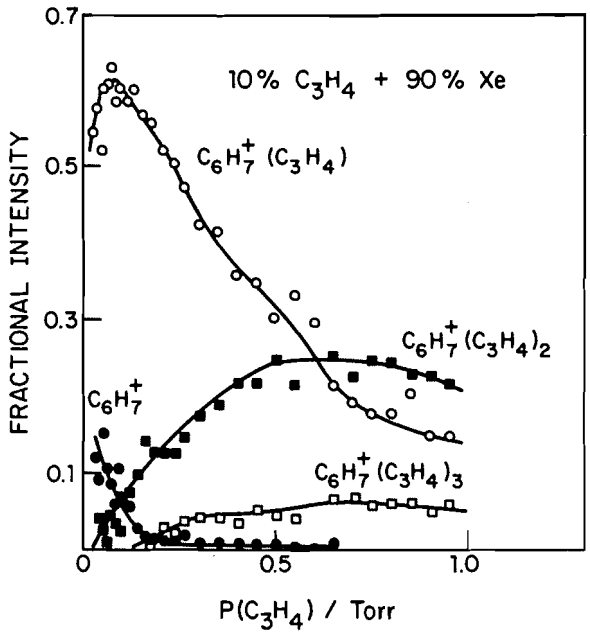

FIG. 2. Fractional intensities for the members of the $C_6H_7^+$ family in the xenon mixture, as a function of the partial pressure of allene.

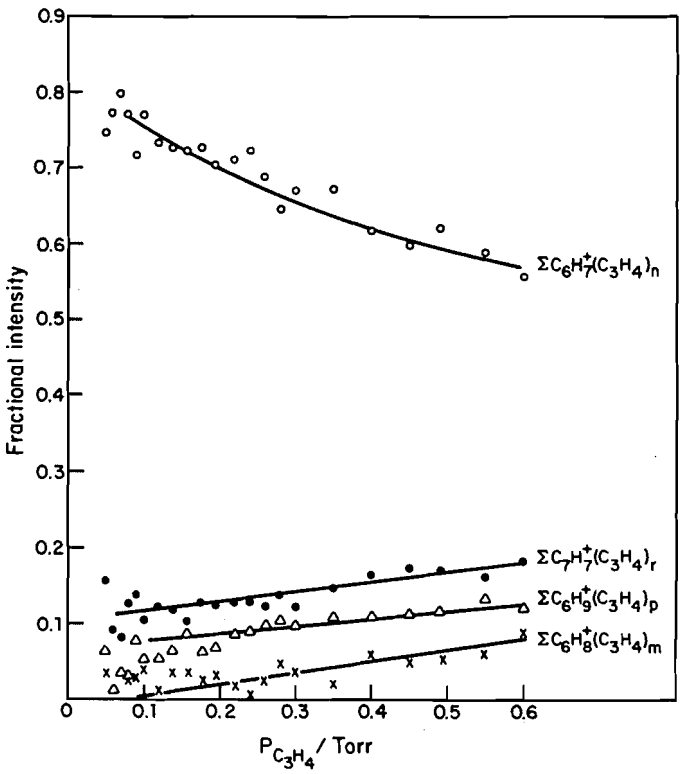

FIG. 3. Pressure dependence of the fractional intensities for the four major ion families of allene (10%) in the Kr (90%) mixture.

and CF_4) a similar mass spectra are obtained, but the fractional intensities of some peaks are different from those in the mass spectrum of pure allene. As an example we show in Fig. 2 the mass spectrum of $C_6H_7^+$ and its clusters $C_6H_7^+(C_3H_4)_n$ in the mixture of 10% allene in Xe. With increasing pressure the highly clustered species tend to increase in abundance, indicating that the condensation processes may occur very rapidly prior to the fragmentation and rearrangement reactions. Therefore, the total abundance of $C_6H_7^+$ may be represented by the sum of $C_6H_7^+(C_3H_4)_n$ species, the same applying to other species. The relative abundances of $C_6H_7^+$, $C_6H_8^{\cdot+}$, $C_6H_9^+$, and $C_7H_7^+$, which are given by the sum of the fractional intensities of the corresponding solvated ion species, change with the partial pressure of allene either pure or in the mixture as shown in Figs. 3–5. Starting from a pressure around 0.2 Torr the abundance of $C_6H_7^+$ ion species decreases, whereas the fractional intensities of other ionic species increase with increasing partial pressure of allene. It was noticed that the rate of abundance decrease of $C_6H_7^+$ and that increasing of $C_6H_8^+$ depended on the nature of bath gas M, whereas the abundances of both $C_6H_9^+$ and $C_7H_7^+$ were only weakly influenced by M. These observations suggest the following reaction scheme (8), (henceforward, we shall abbreviate the ion-dimer $(C_3H_4)_2^+$ by A^+):

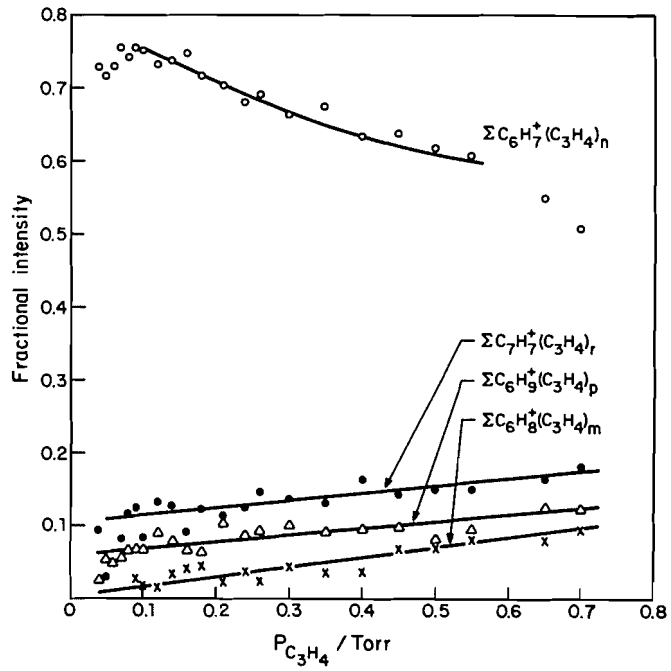

FIG. 4. Pressure dependence of the fractional intensities for the four major ion families of allene (10%) in the Xe (90%) mixture.

[1] $C_3H_4^{\cdot+*} + C_3H_4 \rightarrow (C_3H_4)_2^{\cdot+*} \longrightarrow C_6H_7^+ + H^{\cdot}$

[2] $A^{+*} \xrightarrow{C_3H_4} C_6H_9^+ + C_3H_3^{\cdot}$

[3] $\xrightarrow{C_3H_4} C_7H_7^+ + C_2H_5^{\cdot}$

[4] $\xrightarrow[(k_s \text{ or } k_s)]{C_3H_4 \text{ or M}} C_6H_8^{\cdot+}$

Reaction [1] is a unimolecular decomposition of the activated dimer A^{+*} and reactions [2] and [3] are bimolecular processes of A^{+*} with neutral allene. Reaction [4] is a collisional stabilization (or deactivation) of A^{+*} by M or by allene itself.

On the basis of the above scheme, the following kinetic expressions [5] to [8] can be derived:

[5] $d[(C_6H_7^+)_f] = k_1[A^{+*}]$

[6] $d[(C_6H_9^+)_f] = k_2[A^{+*}][C_3H_4]$

[7] $d[(C_7H_7^+)_f] = k_3[A^{+*}][C_3H_4]$

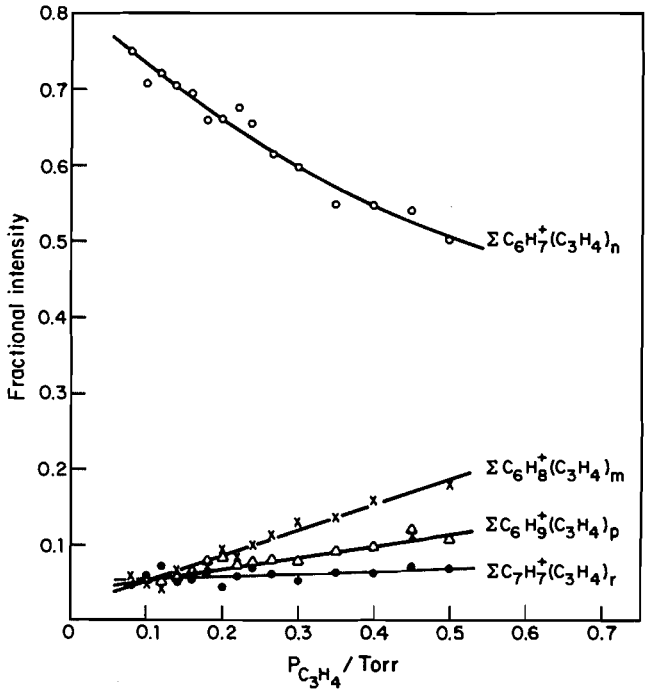

FIG. 5. Pressure dependence of the fractional intensities for the four major ion families of allene (10%) in the CF_4 (90%) mixture.

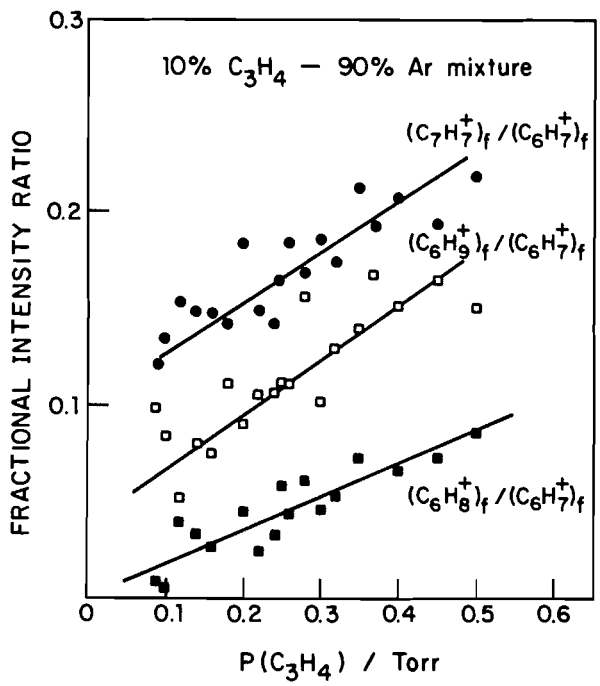

FIG. 6. Fractional intensity ratios of the three ion families against $(C_6H_7^+)_f$ family, as a function of the partial pressure of allene in the argon mixture.

[8] $$d[(C_6H_8^+)_f] = k_s[A^{+*}][M] + k_{s'}[A^{+*}][C_3H_4]$$

The subscript f indicates that the corresponding family of ions is involved. Neglecting the mass discrimination effects the ratios of the rates can be replaced by the ratios of the fractional intensities, and one can derive the following expressions:

[9] $$I(C_6H_9^+)_f/I(C_6H_7^+)_f = (k_2/k_1)P_{C_3H_4}$$

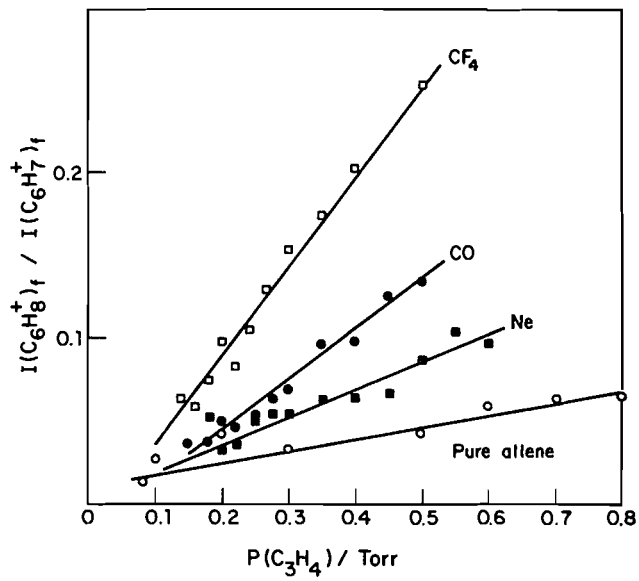

FIG. 7. Fractional intensity ratios for pure allene and the mixtures as a function of the pressure of allene.

[10] $$I(C_7H_7^+)_f/I(C_6H_7^+)_f = (k_3/k_1)P_{C_3H_4}$$

[11] $$I(C_6H_8^+)_f/I(C_6H_7^+)_f = [k_s/(Rk_1) + k_{s'}/k_1]P_{C_3H_4}$$

where $P_{C_3H_4}$ stands for the partial pressure of allene and R stands for the mixing ratio of allene in the mixture, $R = P_{C_3H_4}/P_M$. As an example the plot of the above intensity ratios versus $P_{C_3H_4}$ for the mixture of argon ($R = 0.11$) is shown in Fig. 6. Almost linear lines were obtained for $(C_6H_9^+)_f$, $(C_7H_7^+)_f$, and $(C_6H_8^{\cdot+})_f$ ion species for all mixtures measured in the present experiments. It should be noticed that the line of the $(C_6H_8^{\cdot+})_f$ species passes almost through the origin of the axes, suggesting that the source of this species is the activated ion-dimer only. The lines of the other two species, however, take positive values of the intercept, suggesting that at low pressure they originate not only from the activated ion-dimer but also from other sources. Another source of $C_6H_9^+$ ion might be the condensation reaction of $C_3H_5^+$, since its presence with a fractional intensity, $I = 0.14$ at 0.02 Torr has been reported (4). The reaction $C_4H_4^+(C_3H_4,H)C_7H_7^+$, which has been suggested (2, 4), might be another source of $C_7H_7^+$.

Results and discussion

All "inert" gases showed a linear relation when the ratios $I(C_6H_8^+)_f/I(C_6H_7^+)_f$ were plotted as a function of the partial pressure of allene, Figs. 7–9. From the slopes of these graphs the values of the coefficient $[k_s/(Rk_1) + k_{s'}/k_1]$ can be measured. This value is a measure of the relative efficiency of the total stabilization of the activated ion-dimer, A^{+*}, by "inert" molecules M and allene itself. The value of $k_{s'}/k_1$, which corresponds to the stabilization by allene, was obtained from the slope of the pure allene system and is equal to 0.07 + 0.02 $Torr^{-1}$. A least-square treatment analysis (95% confidence) given the values k_s/k_1 tabulated in Table 1.

The values k_2/k_1 and k_3/k_1, which correspond to the relative rates of reaction of A^{+*} with allene, were obtained for all mixtures from relations [9] and [10] respectively, and are also presented in Table 1. The mean values of k_2/k_1 and k_3/k_1 for the mixtures are 0.24 and 0.20 $Torr^{-1}$, respectively, and are almost equal to the corresponding values in pure allene.

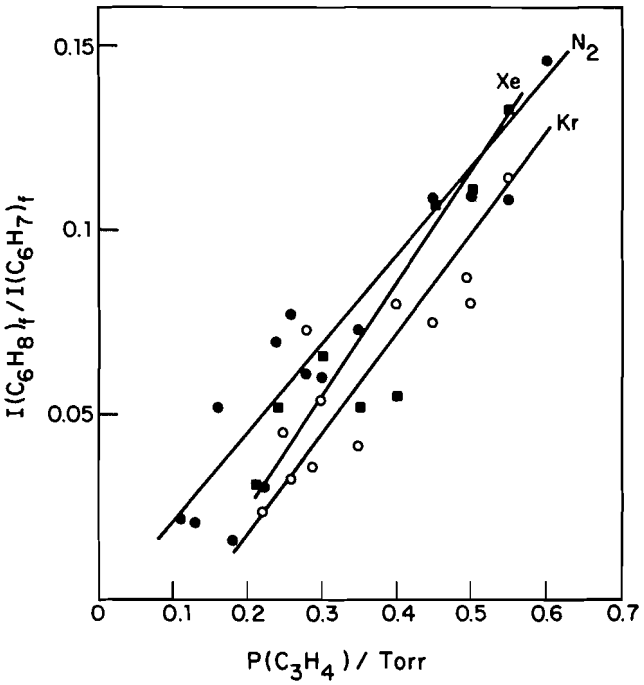

FIG. 8. Fractional intensity ratios for the mixtures as a function of the pressure of allene.

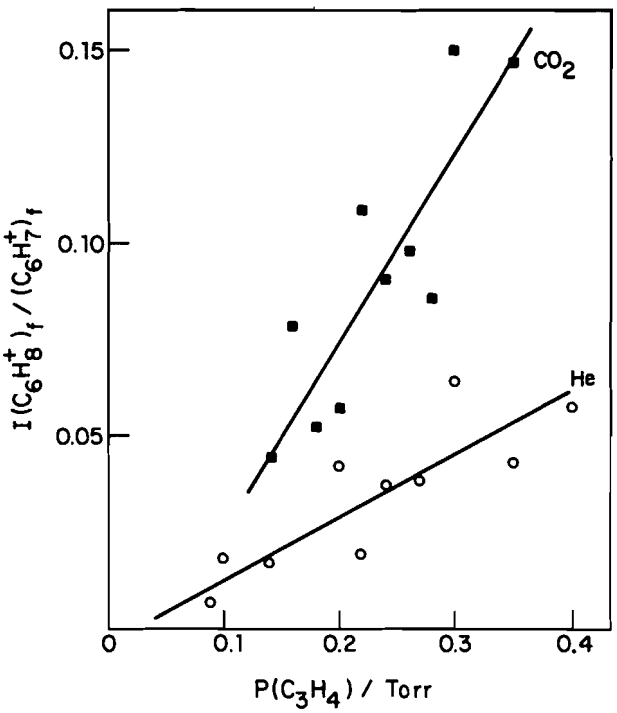

FIG. 9. Fractional intensity ratios for the mixtures as a function of the pressure of allene.

For reasons of comparison, the ratios k_s/k_1, k_2/k_1, and k_3/k_1 were recalculated as relative values and are tabulated in the last three columns of Table 1. For k_s/k_1 the value for the mixture He + allene was chosen as unity, whereas for k_2/k_1 and k_3/k_1, the values corresponding to pure allene were chosen as unity. The values of $k_{s,rel}$ depend on the nature of M, whereas those of $k_{2,rel}$ and $k_{3,rel}$ are almost constant within the experimental error for the mixtures: M + allene. This seems to be a strong addi-

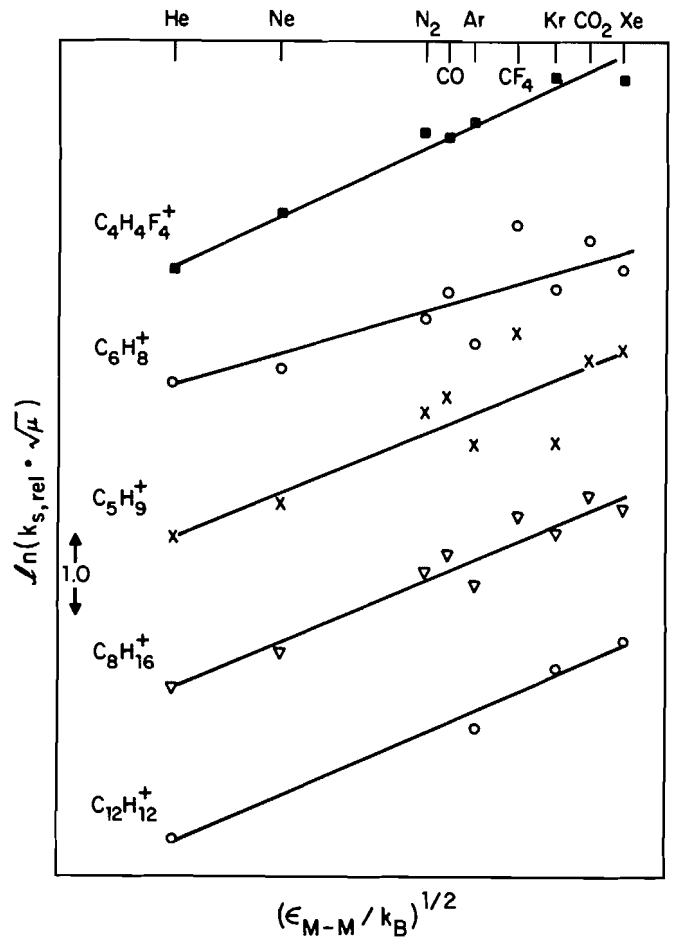

FIG. 10. Correlation between the logarithms of the relative deactivation efficiencies and the square-roots of the potential well-depths, ϵ_{M-M}, between the pairs of the non-polar bath gases, for the five excited ions.

tional support to the reaction scheme [1] to [4].

In the preceding paper on the stabilization by non-polar molecules of the excited dimer $(C_4H_8)_2^{+*}$ formed in photoionized isobutene, we showed that there is a linear relationship between the logarithm of the deactivation (or stabilization) efficiencies (where the differences in collisional rates for various M are taken into account), represented by $(k_s\sqrt{\mu})$, and the square-root of the interaction potential of pairs of M, ϵ_{M-M}, (10). Here, μ is the reduced mass of the system. We tried to apply this correlation for k_s values obtained in the present study and to extend it for k_s values of $C_5H_9^{+*}$, $C_4H_4F_4^{+*}$, and $C_{12}H_{12}^{+*}$ ion species reported elsewhere (11, 12). As shown in Fig. 10, a similar linear relationship is found in all cases. Therefore, we suggest that this relationship (of stabilization processes of excited ions by atomic or by small non-polar polyatomic molecules) may be general.

The slopes of the straight lines in Fig. 10 are different for various A^{+*}. In increasing order the slopes are $C_6H_8^{+*}$ (0.16) < $C_5H_9^{+*}$ (0.20) < $C_8H_{16}^{+*}$ (0.22) ~ $C_{12}H_{12}^{+*}$ (0.22) < $C_4H_4F_4^{+*}$ (0.24). The slopes appear to increase with the increasing size of A^{+*}.

The results shown in Fig. 10 suggest that the collisional stabilization efficiency can be described from a phenomenological point of view by the interaction potential between the excited ion species, A^{+*}, and the neutral M, since the potential can be approximated by the combined rule:

TABLE 1. Kinetic parameters of ion/molecule reactions of pure allene and the 10% C_3H_4 + 90% mixtures

CF_4	0.051 ± 0.006	0.25 ± 0.05	0.14 ± 0.05	5.9 ± 0.7	1.1 ± 0.2	0.6 ± 0.2

[a] Relative to k_s(He) = 1.
[b] Relative to k_2(pure allene) = 1.
[c] Relative to k_3(pure allene) = 1. The mean values of k_2/k_1 and k_3/k_1 in the mixtures are 0.24 and 0.20 Torr^{-1}, respectively, and they are near the corresponding values in pure allene.

$$\epsilon_{A^{+*}-M} = (\epsilon_{A^{+*}-A^{+*}}\epsilon_{M-M})^{1/2}$$

According to the approach of Parmenter and co-workers (13) the final expression for the stabilization process of A^{+*} by M is

$$[12] \quad \ln k_s = \text{const} + (\epsilon_{A^{+*}-A^{+*}}/k_B T^2)^{1/2}(\epsilon_{M-M}/k_B)^{1/2}$$

where k_B is the Boltzmann constant. At constant temperature and for an A^{+*} species common to all collisional pairs, relation [12] can be replaced by

$$[13] \quad \ln k_s = C + C'\epsilon_{M-M}^{1/2}$$

The linear relation in Fig. 10 agrees with this expression. In this figure ϵ_{M-M} values are taken from ref. 13.

The slopes of the straight lines in Fig. 10 correspond to the respective C' values and as noticed previously, they vary from 0.16 to 0.24 along with the increasing size of A^{+*}. Since polarizability is a measure of the molecular size and the bath gas molecules studied have different polarizabilities, these results indicate that the effect of molecular size on the collisional deactivation efficiency is accounted for by the molecular polarizabilities. This is in agreement with an earlier conclusion of Su and Bowers (14).

Excess volumes of binary mixtures of *n*-octane with each of the hexane isomers at 298.15 K[1]

M. K. KUMARAN[2] AND GEORGE C. BENSON

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received April 12, 1984

M. K. KUMARAN and GEORGE C. BENSON. Can. J. Chem. **62**, 2369 (1984).

Excess molar volumes, measured at 298.15 K in a tilting dilution dilatometer, are reported for the five binary systems formed by mixing *n*-octane with *n*-hexane, 2-methylpentane, 3-methylpentane, 2,2-dimethylbutane, and 2,3-dimethylbutane. The Flory theory of mixtures provides a reasonable correlation of the results in combination with excess molar enthalpies measured previously.

M. K. KUMARAN et GEORGE C. BENSON. Can. J. Chem. **62**, 2369 (1984).

Faisant appel à un dilatomètre à dilution inclinable et opérant à 298,15 K, on a mesuré les volumes molaires d'excès de cinq systèmes binaires formés par le mélange du *n*-octane avec le *n*-hexane, le méthyl-2 pentane, le méthyl-3 pentane, le diméthyl-2,2 butane et le diméthyl-2,3 butane. La théorie des mélanges de Flory, combinée aux enthalpies molaires d'excès que l'on a mesurées antérieurement, fournit une corrélation raisonable des résultats.

[Traduit par le journal]

Isomer effects in binary mixtures of hydrocarbons or substituted hydrocarbons have been the subject of a number of previous investigations (1, 2). In particular, considerable effort has been devoted to studying the thermodynamic properties of mixtures of various hydrocarbons with the isomers of hexane (3, 4): *n*-hexane (*n*-C_6), 2-methylpentane (2-MP), 3-methylpentane (3-MP), 2,2-dimethylbutane (2,2-DMB), and 2,3-dimethylbutane (2,3-DMB). Our previous work in this field includes determinations of excess enthalpies (5), excess volumes (6), ultrasonic speeds and isentropic compressibilities (7), and excess isobaric heat capacities (8) for (*n*-heptane + a hexane isomer), and of excess enthalpies and excess volumes (9) for (*n*-dodecane + a hexane isomer). Most recently we reported excess enthalpies (10) for binary mixtures of *n*-octane with each of the hexane isomers. As a continuation of that investigation, we have measured excess volumes at 298.15 K for the same five mixtures.

Experimental

Component liquids

The *n*-octane was Aldrich Chemical Co. Gold Label reagent with a specified purity of 99+ mol%. The isomeric hexanes were Phillips Research Grade reagents with purities 99.88 mol% or greater. At 298.15 K, the densities (in kg m^{-3}) of the samples used for the dilatometric studies were as follows: *n*-octane, 698.63; *n*-C_6, 654.92; 2-MP, 648.50; 3-MP, 659.82; 2,2-DMB, 644.47; 2,3-DMB, 657.06.

Dilatometric measurements

Excess molar volumes V_m^E were determined in a tilting dilution dilatometer. This apparatus and its operation have been described by Kumaran and McGlashan (11). For the present mixtures, the error of the measurements is estimated to be less than 0.0010 cm^3 mol^{-1}.

Results and discussion

The measurements of V_m^E at 298.15 K for $\{xn\text{-}C_8H_{18} + (1 - x)C_6H_{14}\}$ are summarized in Table 1. The results for each mixture were fitted with a polynomial of the form:

$$[1]\quad V_m^E/(cm^3\ mol^{-1}) = x(1 - x)\sum_{j=0}^{n-1} v_j(1 - 2x)^j$$

where x is the mole fraction of *n*-octane. Values of the coefficients v_j determined by the method of least-squares with all points weighted equally are listed in Table 2 along with the standard deviations s of the representations.

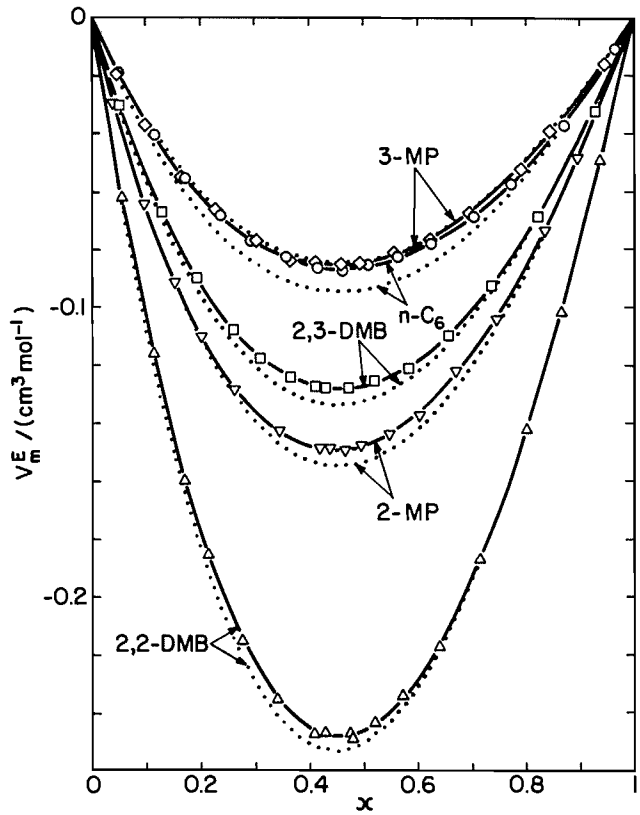

FIG. 1. Excess molar volumes V_m^E for $\{xn\text{-}C_8H_{18} + (1 - x)C_6H_{14}\}$ at 298.15 K. Experimental results: ○, *n*-C_6; ▽, 2-MP; ◇, 3-MP; △, 2,2-DMB; □, 2.3-DMB. Curves: —, calculated from eq. [1] with coefficients from Table 2; ···, calculated from Flory theory.

The experimental results and their representations by eq. [1] are shown in Fig. 1. The curves for *n*-C_6 and 3-MP are very similar, particularly for $x < 0.5$ where their difference is less than their estimated uncertainties. In all cases the curves are only approximately quadratic and exhibit a definite, albeit small, skew toward low mole fractions of the *n*-alkane (*n*-octane). Similar behavior has been observed for mixtures of the

hexane isomers with *n*-heptane (6), *n*-dodecane (9), and *n*-hexadecane (4). A comparison of the results for different *n*-alkanes shows that the skew of the curves increases with the chain length of the *n*-alkane.

The only V_m^E data found in the literature for the present mixtures at 298.15 K are those of Goates *et al.* (12) for (*n*-octane + *n*-C$_6$), and of Handa *et al.* (13) for (*n*-octane + 2,3-DMB). Comparisons of these with our results are given in Fig. 2, where deviations from our smoothing equations are plotted. Both sets of results show more scatter than ours, but in general their smoothed values agree with ours over most of the mole fraction range within the combined uncertainties of the respective investigations.

In our studies of mixtures of *n*-heptane (5, 6) and of *n*-dodecane (9) with the hexane isomers, we found that the excess volumes could be interpreted in terms of the Flory theory (14, 15) when the interchange energy parameter was adjusted to give a fit between the experimental and theoretical excess enthalpy curves. This same treatment was investigated for the present *n*-octane mixtures. The calculation used the molar volumes V_m, isobaric thermal expansivities α_p, and isothermal compressibilities κ_T given in Table 3 for the component liquids at 298.15 K. The properties of the hexane isomers are the same as in our earlier work where their sources are indicated (6). For *n*-octane, α_p was derived from density data (16), and κ_T was estimated from values of the speed of sound and isobaric heat capacity measured in our laboratory. The characteristic pressures p^*, molar volumes V_m^*, and temperatures T^*, obtained from the Flory formalism, are also listed in Table 3 along with the ratio s_{12} of molecular surface areas of contact and the interchange energy parameter X_{12} for each mixture. The values of s_{12} are based on the simple assumption that the molecules are spherical; the values of X_{12} were obtained by fitting the Flory formula for the excess molar enthalpy H_m^E to our smoothed experimental results (10). The dotted curves in Fig. 1 were calculated from the Flory formula for V_m^E using the parameters in Table 3. It can be seen that the theory again predicts the order and asymmetry of the curves correctly. That for 3-MP is nearly identical to the experimental curve. For the other isomers, the theory tends to overestimate the magnitude of V_m^E, as was found for the mixtures with *n*-dodecane (10).

TABLE 3. Component properties and parameters used in calculations for (*n*-octane + hexane isomer) mixtures at 298.15 K by the Flory theory[a]

Component	V_m / cm^3 mol^{-1}	α_p / kK^{-1}	κ_T / TPa^{-1}	p^* / J cm^{-3}	V_m^* / cm^3 mol^{-1}	T^* / K	s_{12}	X_{12} / J cm^{-3}
n-C_8H_{18}	163.51	1.164[b]	1302.4[c]	436.9	127.70	4827.0

Reçu le 27 janvier 1984

JACKY KISTER, HENRI PAUL POMMIER, JACQUES METZGER et ROBERT GUGLIELMETTI. Can. J. Chem. **62**, 2372 (1984).

L'étude de la substitution dans les positions 3, 5, 6, 7 et 8 des spiropyrannes benzothiazoliniques a permis de mettre en évidence l'aspect tout-à-fait complémentaire des positions 3 et 5, sur la stabilité du système délocalisé de type mérocyanine. Les interactions de non liaison ont une influence directe sur la fermeture de la molécule de spiropyranne. Les paramètres stéréoélectroniques judicieusement choisis permettent de modifier l'équilibre forme fermée/forme ouverte dès le développement synthétique.

JACKY KISTER, HENRI PAUL POMMIER, JACQUES METZGER, and ROBERT GUGLIELMETTI. Can. J. Chem. **62**, 2372 (1984).

Benzothiazolinic spiropyrans substituted in the 3, 5, 6, 7, and 8 positions have been studied. The results obtained show the equivalent role of the 3 and 5 substituted positions during the synthesis of merocyanin type compounds. Non-bonded interactions play a direct role in ring closing to spiropyran compounds. The relative stabilities of open and closed ring compounds depend on stereoelectronic parameters.

L'utilisation des spiropyrannes photochromiques comme substrats photosensibles dans des procédés photographiques implique la recherche de composés dont la structure est adaptée au procédé que celui-ci comporte ou non une étape d'amplification du signal photonique primaire (1, 2). Les divers résultats obtenus dans ce domaine (2, 3) nous ont amené à étudier plus particulièrement la série benzothiazolinique substituée principalement dans les positions 3, 6, 8 sur la partie chroménique et 3′, 4′, 6′ sur la partie benzothiazolinique (schéma 1):

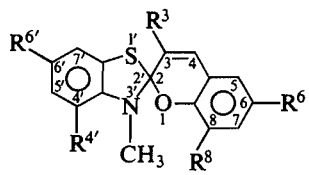

SCHÉMA 1. Nomenclature officielle de la molécule de spiropyranne benzothiazolinique.

La numérotation des atomes est conforme aux règles énoncées dans le "Ring-Index" et la nomenclature officielle est la suivante: spiro [R_3, R_6, R_8 benzo 2*H* [1] pyranne-2,2′ méthyl-3′, R'_4, R'_6 benzothiazoline].

I. Définition des effets de substitution

Si de tels composés sont interessants, en vue de leur utilisation photochimique possible, par contre leur synthèse devient particulièrement complexe et délicate (3, 4) en fonction des substituants choisis correlativement à l'optimisation des paramètres spectro-cinétiques de la réaction de fermeture après irradiation uv (schéma 2).

Il est traditionnellement admis et démontré que le caractère photochromique des spiropyrannes azahétérocycliques est lié à la substituion dans les positions 6 et 8 de la partie benzopyrannique par des couples NO_2/R (3*a*, 5) où R est souvent un groupement OCH_3 intéressant par les propriétés conférées et également par la commodité d'accès synthétique. R peut également être du type CH_2X ou OR′ pour lesquels X = Cl, OR′, $N(R')_2$ avec R′ = H, CH_3, C_2H_5, ...$(CH_2)_nCH_3$, cycle ... (6).

En première approximation, on peut dire que les substituants de chacune des deux parties benzopyrannique et benzothiazolinique affectent les cinétiques de façon indépendante (3, 7−9). En règle générale les substituants électron-attracteurs placés sur la partie benzopyrannique ralentissent la fermeture des photomérocyanines alors que les substituants électron-donneurs l'accélèrent. L'effet est inverse mais très atténué pour la partie benzothiazolinique. Les substituants placés au voisinage du carbone central et dont l'effet est essentiellement stérique accélèrent la décoloration thermique (2, 3, 8, 9). La présence simultanée de plusieurs substituants conduit à des résultats difficilement interprétables (2, 4).

Dans ce présent mémoire, nous nous intéressons aux facteurs sensibilisant la refermeture de la forme ouverte (FO) en forme fermée (FF) sans tenir compte des considérations spectro-cinétiques de l'équilibre photochromique. Par souci d'homogénéité et pour présenter les résultats des études physico-chimiques et l'analyse des effets de substitution en 3, 5 et 7, nous avons réalisé la synthèse des composés dont le couple de substituants en position 6/8 peut être H/H, NO_2/H et H/OCH_3.

En position 3′, nous choisissons un groupement méthyle, lequel est rendu électrophile par ouverture de la liaison C_2—O_1. Il convient de rappeler que la labilité de ce méthyle peut être mesurée en utilisant la réaction de déméthylation par la triphénylphosphine (10).

En position 6′, le substituant placé en position *para* de l'atome d'azote hétérocyclique exerce une influence importante sur la délocalisation électronique du système. C'est ainsi que nous avons placé un groupement méthoxy correspondant à une optimisation des photochromes adaptés aux procédés photographiques avec amplification (3*c*, 4).

En position 3, position adjacente au carbone spiropyrannique, les groupes fonctionnels oxygénés comme le méthoxy et le phénoxy exercent un important ralentissement sur les cinéti-

[1]Auteur à adresser toute correspondance.

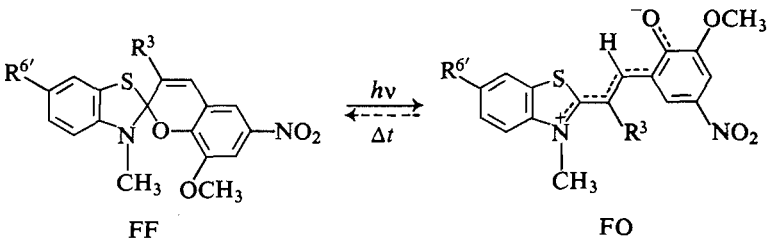

SCHÉMA 2. Equilibre photochromique forme fermée/forme ouverte (FF/FO).

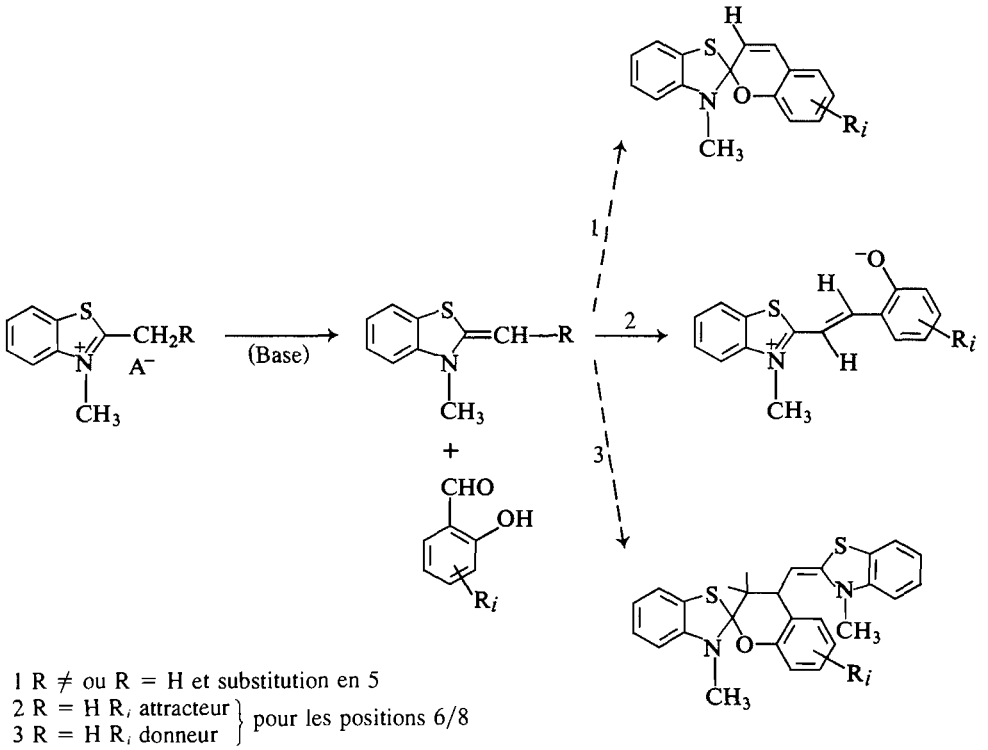

SCHÉMA 3. Reactions de condensation spiropyrannique.

ques de décoloration thermique (3*a*, 7). Cette stabilisation de la FO est d'autant plus forte que le substituant est moins encombrant. La simultanéité de substitution par le groupement méthoxy en position 3 et 6′ a conduit à l'obtention d'une mérocyanine permanente (2, 3*b*, 7), l'équilibre photochromique étant totalement déplacé vers la "photomérocyanine."

En position 5 et 7: ces positions n'ont pas fait l'objet de recherches approfondies en série benzothiazolinique. Nous avons étudié l'influence d'un groupement méthyle en position 5, sur l'obtention de formes fermées alors que la position 3 reste non substituée. Smets et coll. (11) avaient déjà étudié cette position 5 en série benzothiazolinique et ceci simultanément avec la substitution en position 3. La séparation des effets de substitution en 3/5 n'avait pas été réalisée.

La condensation du sel quaternaire de diméthyl-2,3 benzothiazolium (donnant un hydrogène en position 3) sur des aldéhydes salicyliques porteurs de groupements électron-attracteurs, conduit à des mérocyanines (FO permanentes) (12) tandis que la condensation sur des aldéhydes salicyliques porteurs de groupements électron-donneurs conduit à l'obtention de composés tricycliques de type spirodihydropyrannique (12), schéma 3.

Enfin l'étude de composés porteurs de longues chaînes aliphatiques avait été développée dès 1972 (13) et l'influence de ces chaînes grasses sur la solubilisation des FO a été utilisée pour l'étude physicochimique des mérocyanines (14, 15). Les mérocyanines classiques sont en effet particulièrement insolubles dans la plupart des solvants polaires ou apolaires à fortiori. Par ailleurs, il n'était pas venu à l'idée de placer un hydrogène en position 3 puisque l'on cherchait également à accroitre le système π susceptible de former des complexes stables par adsorption sur semi-conducteurs. Les groupements phénoxy et β naphtoxy étaient alors particulièrement intéressants en position 3 (2, 3, 7).

L'ensemble de ces considérations expérimentales nous a conduit à étudier les spiropyrannes et mérocyanines présentés dans les tableaux 1 et 2. Les spiropyrannes **4**−**7** et **11**−**15** sont présentés pour comparaison. Le mode de synthèse est maintenant connu (2 à 7); il nécessite la synthèse intermédiaire de sels quaternaires de benzothiazolium par quaternisation de bases benzothiazoliques. Celles utilisées dans ce mémoire ont fait l'objet d'études et de publications (2−5, 7). L'aldéhyde salicylique utilisé pour la condensation finale avec le sel quaternaire peut-être le classique nitro-5 méthoxy-3 salicylaldéhyde (3, 5). Dans le cas des aldéhydes conduisant aux composés substitués en 5/7, ils résultent de synthèses délicates (13, 16). L'alkylation des aldéhydes se fait par le tosylate d'hexadécyle dans l'éthanol à reflux pendant 12 h; les composés obtenus sont

recristallisés dans l'acétone. Les rendements sont de l'ordre de 70%. La préparation des spiropyrannes s'effectue par reflux de quantités équimoléculaires de sels de benzothiazolium, d'aldéhyde et de pipéridine dans l'éthanol; les rendements varient de 50 à 70%.

II. Analyses spectroscopiques

Les diverses études spectroscopiques (ir, uv−vis, rmn^{1}H) ont été réalisées. Les composés obtenus peuvent être sous forme de FF pure, de FO pure ou de mélange FF/FO. Les techniques d'identification s'avèrent fiables par le grand nombre de caractérisations FF/FO effectuées sur des séries homogènes de spiropyrannes diversement substitués.

A. spectroscopie infrarouge

La spectroscopie infrarouge apparait comme la méthode la plus adaptée pour différencier rapidement les formes fermées et formes ouvertes et estimer la pureté des produits obtenus (17−19). Les spectres infrarouges ont été enregistrés sur spectrographes Perkin Elmer 125 et 225. Les échantillons ont été examinés sous forme de pastilles KBr (environ 1,50 mg de produit pour 150 mg de KBr).

Les spiropyrannes FF sont caractérisés par (17−19) (fig. 1): (*i*) quatre bandes entre 1700 et 1550 cm^{-1} dont trois sont imputables aux vibrations du noyau benzopyrannique et une au noyau benzothiazolinique. Le sommet ir correspondant au ν(C=C) est faible et ne peut pas être observé; (*ii*) une bande forte vers 1515 cm^{-1} correspondant au $\nu_a(NO_2)$; (*iii*) un sommet intense vers 1490−1470 cm^{-1} dû au noyau benzothiazolinique (17, 19); (*iv*) un maximum vers 1340 cm^{-1} ($\nu_s(NO_2)$; (*v*) des bandes attribuables aux mouvements ν(CO) intracycliques et ν(=C—OR) et aux vibrations du noyau benzothiazolinique entre 1300 et 1200 cm^{-1}.

Les mérocyanines FO sont caractérisées par (17−19): (*i*) la présence d'un massif intense au dessous de 1600 cm^{-1} (quatre absorptions théoriques) résultant du glissement des absorptions du noyau benzopyrannique; (*ii*) un $\nu_a(NO_2)$ inchangée par rapport à la FF; (*iii*) une bande forte vers 1500 cm^{-1} correspondant au glissement de la bande FF (1490−1470); (*iv*) l'apparition d'un sommet intense vers 1400 cm^{-1} qui peut être attribuée à une vibration ν(C=N); (*v*) une bande vers 1200 cm^{-1}, intense non attribuée; (*vi*) un massif complexe entre 1300 et 1200 cm^{-1} comportant les absorptions ν(=C—OR), les vibrations du noyau benzothiazolinique, les ν(C—O) intracycliques intenses et très larges et la bande correspondant aux $\nu_s(NO_2)$ très abaissée par rapport à la FF.

De ces considérations générales on en déduit pour nos composés (tableau 3):

Les composés **1**, **3**, **8** sont obtenus sous forme de mélange FF/FO.

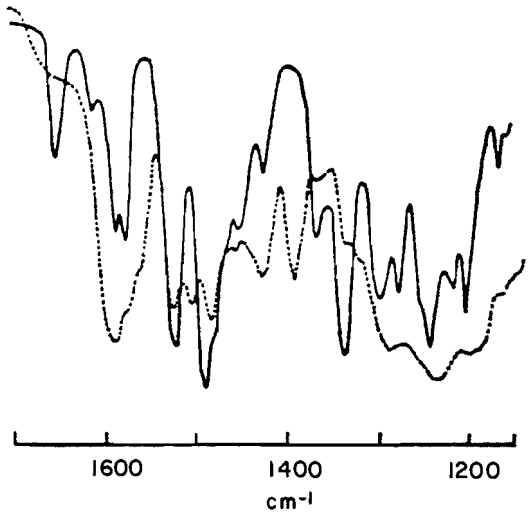

FIG. 1. Différenciation spectroscopique entre la FF (——) et FO (– – –) d'une molécule benzothiazolinique de type **5** dans la région 1100–1700 cm^{-1}.

Les composés **2**, **4**, **9**, **10**, **11** donnent les spectres caractéristiques des FO.

Les composés **5**, **6**, **7**, **12**, **14**, **15** sont obtenus soit en mélange soit en FF ou FO pure selon que le composé issu de la réaction de condensation est analysé sous forme brute en fin de synthèse après refermeture complète dans le toluène chaud (FF pure) ou après ouverture et photoprécipitation (FO pure).

Le composé **13** donne directement la FF, il n'est pas photochrome.

B. Spectroscopies ultraviolette et visible

Les spectres des spiropyrannes benzothiazoliniques ont été réalisés dans le dioxanne et l'éthanol sur un spectrophotomètre Cary 14 à double faisceau et sur un spectrophotomètre Perkin Elmer 137. La faible solubilité des mérocyanines ne permet pas une grande précision pour l'estimation du coefficient d'extinction moléculaire ϵ. L'identification de certaines bandes caractéristiques a été réalisée en décomposant la molécule en deux parties (3*a*, *b*).

P. Appriou *et al.* (20) ont étudié les interactions des deux parties et la redistribution des niveaux d'énergie (20, 21). La durée de vie des FO en solution est généralement courte et leur solubilité faible et la décoloration de la solution montre l'évolution vers la FF. L'on obtient ainsi souvent le spectre d'un mélange FF/FO.

Les résultats sont regroupés dans le tableau 4 et la fig. 2 montre la différenciation entre la FF et la FO. Lors des mesures des constantes cinétiques de refermeture des FO dans l'éthanol et le toluène (2, 3, 7, 9) effectuées par photolyse éclair, les caractéristiques spectroscopiques uv–visible des FF et FO pures ont été mesurées. Ces résultats sont regroupés dans le tableau 4. Ces mesures ne sont fournies que pour les composés photochromes conduisant à des mérocyanines pouvant se refermer en solution (composés **5**, **6**, **7**, **12** et **14**).

Ainsi on peut vérifier que les composés **1**, **3**, **8** sont obtenus sous forme de mélange FF/FO; que les composés **2**, **4**, **9**, **10** et **11** sont des mérocyanines insolubles. Le composé **2** peut être analysé et légèrement solubilisé du fait de la présence d'une chaine grasse en position 7.

C. Analyse de résonance magnétique nucléaire du proton

Les déplacements chimiques sont toujours exprimés en ppm

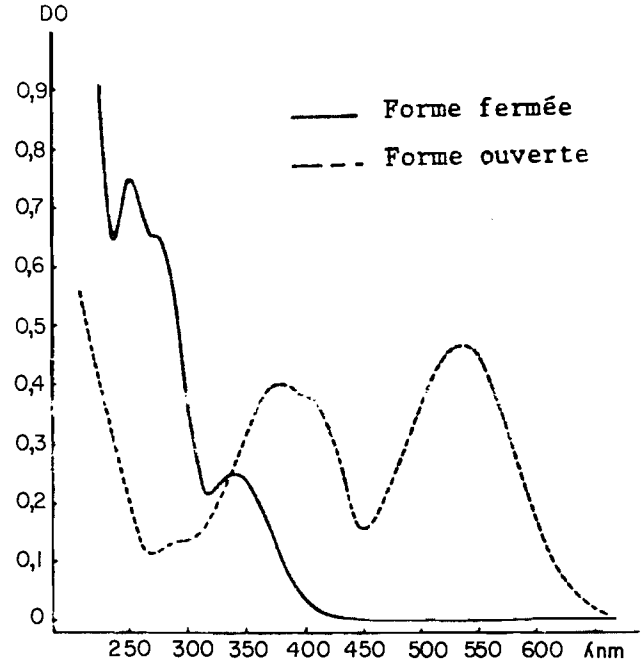

FIG. 2. Spectre d'absorption électronique du spiropyranne **6** et de la photomérocyanine correspondante (EtOH).

par rapport au TMS. Les spectres ont été réalisés sur des appareils de type Varian XL 100 et Cameca 250 MHz. L'enregistrement des spectres de FF pures ne pose aucun problème, leur solubilité étant acceptable (2, 3). Il existe beaucoup moins de résultats relatifs aux FO (22, 23). Cependant la rmn protonique apporte des résultats importants sur la polarité et la structure des FO. Trois problèmes limitent l'étude des FO: la solubilité, la stabilité en solution et l'obtention de FO isolées. La présence de chaînes grasses et l'utilisation d'appareil à transformée de Fourier permet l'étude de solutions peu concentrées évitant la photoprécipitation et la refermeture de la FO dans un solvant polaire tel que DMSO-d_6.

Dans cette étude nous nous intéressons plus spécialement au déplacement chimique du groupe méthyle fixé sur l'azote benzothiazolinique. Ainsi on peut constater une variation de son déplacement chimique de 0,9 à 1,5 ppm lorsque l'on passe d'une Forme Fermée à une Forme Ouverte (2, 23).

Ce résultat confirme la déficience électronique sur la partie azahétérocyclique et les déplacements chimiques observés, comparés à ceux obtenus dans le cas des sels quaternaires de benzothiazolium ($4{,}30 < \delta\overset{+}{N}CH_3 < 4{,}70$ dans le TFA), indiquent une localisation importante de la charge positive sur cette partie de la molécule (ceci est confirmé par le déplacement paramagnétique du proton H_4 (3*b*, 23) et par l'étude radiocristallographique aux rayons X effectuée sur une mérocyanine benzothiazolinique (24).

La rmn des FF et FO montre bien l'existence d'interactions stéréoélectroniques entre le doublet libre de l'oxygène en position 3 et le proton H_5 quand il existe (3*b*, 23). Ainsi le tableau 5 montre les déplacements observés pour les composés **1** à **15**. Les déplacements chimiques δNCH_3 des composés **1**, **2**, **8** sont bien caractéristiques d'un mélange FF/FO avec $1{,}10 < \Delta\delta NCH_3 < 1{,}20$ ppm. Les composés **2**, **4**, **9**, **10** et **11** donnent un déplacement chimique caractéristique d'une FO. Les composés **5**, **6**, **8** et **12** peuvent être analysés à l'état de FO pures ou FF pures. Les composés **7**, **13**, **14** et **15** sont par leur

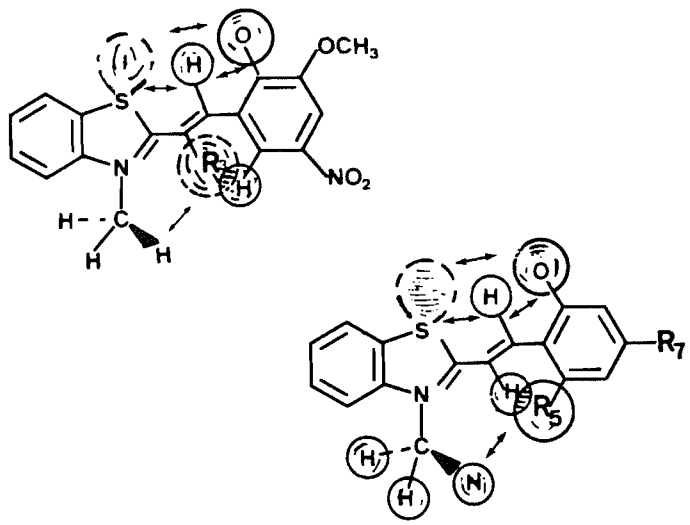

SCHÉMA 4. Visualisation des intéractions de non-liaison d'origine stérique et électronique (H_3/R_5-R_3/H_5).

TABLEAU 5. Analyse résonance magnétique nucléaire de ^1H dans $CDCl_3$ (ref. TMS) des FF/FO (déplacements chimiques en ppm)

N°	δNCH_3 FF	$\delta\overset{+}{N}CH_3$ FO
1	3,0	4,10
2	—	3,80 *DMSO-d_6
3	2,95	4,14
4	—	3,80 *DMSO-d_6 mérocyanine stable
5	3,0	4,14
6	3,02	4,33
7	3,02	—
8	3,04 $CDCl_3$	4,14 *DMSO-d_6
9	—	3,85 *DMSO-d_6
10	—	3,80 *DMSO-d_6
11	—	4,38
12	3,22	4,38
13	3,20	—
14	3,20	—
15	3,24	—

*Solubilité partielle.

déplacement chimique des FF pures. Ainsi pour l'ensemble de ces composés

$$2{,}95 < \delta NCH_{3\ FF} < 3{,}24 \text{ ppm}$$

$$3{,}80 < \delta\overset{(+)}{N}CH_{3\ FO} < 4{,}38 \text{ ppm}$$

Dans un précédent travail, nous avons montré que cette étude comparative permet d'évaluer la capacité d'une mérocyanine à céder son méthyle (2). Cette capacité est mesurée par ailleurs en mettant en oeuvre une réaction de déméthylation (2, 10).

III. Conclusion

Ainsi les trois techniques spectroscopiques confirment bien l'obtention partielle de FF dans le cas de non substitution en position 3 mais avec encombrement stérique en position 5. L'on peut ainsi nettement mettre en évidence les interactions équivalentes H_3/R_5 et R_3/H_5 (schéma 4). Dans le cas des composés **3** et **6**, une stabilisation complémentaire des FO est

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

obtenue par les interactions entre les hydrogènes en position 3 ou 5 et l'oxygène du méthoxy en 3 ou de l'hexadecyloxy en 5.

A Samat *et al.* ont effectué des calculs d'interactions de non-liaison dans le cas de mérocyanines et photomérocyanines benzothiazoliniques (25); les résultats obtenus montrent:

1. Une différence très importante de l'ordre de 190 kcal d'énergie pour la forme la plus stable entre la mérocyanine stable (composé n° **4**, H en 3) et la photomérocyanine issue du composé n° **5** (CH_3 en 3). Ceci est en accord avec le fait qu'en série benzothiazolinique la FO est peu contrainte stériquement et la refermeture sous forme spiropyrannique n'a pas lieu.

2. Avec une atome d'hydrogène en position 3, les énergies d'interactions stériques sont faibles, par contre la présence d'un groupement volumineux permet de négliger l'effet électrostatique au profit de l'effet stérique. La série benzoxazolinique (26) conduit en général à des photomérocyanines thermiquement plus stables que leurs homologues benzothiazoliniques. L'atome d'oxygène allie les effets électroniques et stériques favorisant cette stabilisation, par contre on observe en série benzosélénazolique les effets contraires (27).

Il serait intéressant d'examiner dans la même perspective les problèmes liés à la substitution ou non dans les positions 5 et 7 lorsque la position 3 est occupée par un atome d'hydrogène. Il apparaît néanmoins que la position 7 doit jouer un rôle beaucoup plus négligeable que la position 5 dans l'obtention des FF lorsque la position 3 n'est pas substituée. Les interactions stéréoélectroniques entre les groupements situées en position 3 et 5 sur les mérocyanines montrent un effet complémentaire dans l'obtention des FF ou des FO.

Remerciements

Ce travail a été réalisé dans le cadre du contrat DRET 80/084. Nous remercions la DRET pour l'aide financière apportée.

Reçu le 23 novembre 1983

MARCEL ASSO, DAVID BENLIAN, LILIANE ASSO et CLAUDE GRANIER. Can. J. Chem. **62**, 2379 (1984).

Les constantes de stabilité des complexes formés entre l'acétylaspartylvalylaspartylalanine (Ac-DVDA-OH) et divers cations métalliques ont été déterminées par mesures potentiométriques. Les spectres rmn des protons ont permis d'apporter des informations sur la conformation des espèces prépondérantes en solution. Les déplacements induits par le cation praseodyme sont fortement dépendant du pH. Au pH physiologique, en présence de Ca(II), les résonances relatives aux deux résidus aspartyl subissent d'importantes modifications. Ces résultats montrent une interaction spécifique entre le tétrapeptide synthétique et les cations Ca^{2+} ou Pr^{3+} au niveau des deux groupements carboxylates des résidus aspartyl en milieu neutre, avec le groupement carboxylate C-terminal en milieu acide.

MARCEL ASSO, DAVID BENLIAN, LILIANE ASSO, and CLAUDE GRANIER. Can. J. Chem. **62**, 2379 (1984).

Formation constants for complexes between acetylaspartylvalylaspartylalanine (Ac-DVDA-OH) and a number of transition metal cations have been determined by potentiometric titrations. The ^1H nmr spectra have been recorded in order to support the potentiometric results and to obtain information concerning the conformation of the detected species. The praseodymium induced shifts of most resonances are observed to be strongly dependent on pH. The Ca^{2+} complexes generate a different ^1H nmr spectrum for the aspartyl resonances at neutral pH. These observations are shown to be consistent with stepwise binding of the Ca^{2+} or Pr^{3+} cations to the carboxylate of Ala C-terminus in acidic medium, and to the carboxylates of aspartyl residues in neutral pH.

Introduction

Les études de la sélection exercée par les systèmes biologiques lors de la fixation d'éléments métalliques mettent en jeu des facteurs liés à la stéréochimie du ligand et à la géométrie de coordination préférentielle du cation métallique (1−5).

Une approche possible est la simulation de la partie active de la protéine par un peptide de synthèse qui constitue un modèle de l'environnement du métal (6−9).

Dans plusieurs protéines telles que la concanavaline (10) et la thermolysine (11), l'élément métallique notamment Ca(II) est lié préférentiellement au groupement carboxylate de résidus aspartyl ou glutamyl. L'examen des séquences actives vis à vis du calcium révèle, pour la thermolysine l'alternance (-Asp^{57}-Ala-Asp^{59}).

Comme les fragments complexants dans ces protéines contiennent séquentiellement soit deux résidus aspartyl soit un résidu aspartyl et un résidu glutamyl séparés par un résidu d'acide aminé non fonctionnel, nous avons réalisé la synthèse d'un peptide représentant un modèle simplifié ayant la séquence suivante: Ac-Asp-Val-Asp-Ala-OH (fig. 1).

Dans ce travail, nous présentons une détermination des groupes fonctionnels coordinants du tétrapeptide synthétique Ac-DVDA-OH (cf abréviations), en présence de divers éléments métalliques afin d'établir un ordre d'affinité sélectif. Les complexes ont été caractérisés en solution acide et neutre par titrages potentiométriques et pour certains d'entre eux, par les mesures des déplacements chimiques des noyaux ^1H.

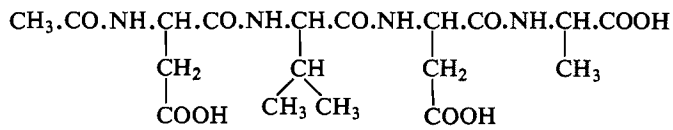

FIG. 1. Acetylaspartylvalylaspartylalanine.

Notations

Tous les acide aminés sont en configuration L. La nomenclature IUPAC des acides aminés a été employée. D: acide aspartique; A: alanine; V: valine; Ac: acetyl; Boc: tertiobutoxycarbonyl.

C_A, C_M: concentration analytique du ligand Ac-DVDA-OH, de l'ion métallique M: M = Ca^{2+}, Cu^{2+} etc...

$H_qA = L_q$: tétrapeptide sous la forme monomère contenant q protons dissociables: q = 0, 1, 2 et 3 (ex: A = L_o: forme trianionique)

$\bar{q}$: nombre moyen de protons échangeables par molécule de ligand

$\bar{r}$: nombre moyen de ligands complexés par atome métallique

k_q: constante de dissociation partielle: $[H_{q-1}A][H]/[H_qA]$

β_{pqr}: constante de stabilité globale issue de l'équilibre $pM + qH + rA \rightleftarrows M_pH_qA_r$

: β_q si $p = 1$ et $r = 1$, cas de complexes mononucléaires à un seul ligand

f_{L_q}, f_{ML_q}: fractions molaires des espèces libres L_q, complexées ML_q

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

δ_{L_q}, δ_{ML_q}: déplacements chimiques d'un noyau dans le cas d'espèces libres L_q, complexées ML_q

Δ_{ML_q}: déplacement induit limite: $(\delta_{ML_q} - \delta_{L_q})$

: Δ_q pour les complexes monométalliques à un seul ligand

Principe

Méthode potentiométrique

Le réseau des courbes normalisées pH = $f(\bar{q})$ permet en principe, d'effectuer une estimation des paramètres p, q, r caractérisant l'espèce $M_pH_qA_r$ relative à l'équilibre de complexation:[2]

$$[1] \quad pM + qH + rA \rightleftharpoons M_pH_qA_r$$

La détermination des constantes de formation β_{pqr} est alors effectuée selon un procédé classique (14–16), à partir des relations exprimant la conservation des espèces:

$$[2] \quad C_M = m + \sum p(\beta_{pqr} m^p \cdot h^q \cdot a^r)$$

$$[3] \quad C_H = h - oh + \sum q(\beta_{pqr} m^p \cdot h^q \cdot a^r)$$

$$[4] \quad C_A = a + \sum r(\beta_{pqr} m^p \cdot h^q \cdot a^r)$$

en formulant les différentes combinaisons pour p, q et r. Signalons cependant que les hypothèses peuvent être réduites si l'on procède à une estimation de $\bar{r}$, nombre moyen de coordinats fixés par atome métallique (17):

$$[5] \quad \bar{r} = (C_A - a)/(C_M)$$

Les valeurs des constantes ainsi prétablies sont ensuite optimalisées par un calcul en retour $\bar{q} = f(\text{pH})$.

A l'aide des valeurs de k_p, β_{pqr}, C_A et C_M, on calcule successivement a, m puis $\bar{q}$ ($\bar{q}$ cal) que l'on compare à $\bar{q}$ expérimental (15).

Titrages de la résonance magnétique nucléaire

La constante de complexation β_{pqr} donne le bilan de l'état stationnaire obtenue entre les différents constituants d'une solution. Si les échanges sont rapides par rapport au temps d'observation de la rmn, on n'observe qu'un pic moyen intégrant pour un noyau donné.

Dans ces conditions, en présence d'un cation paramagnétique fort réactif de déplacement chimique (18), et à pH fixe, le déplacement chimique observé est la moyenne pondérée des déplacements des espèces libres et complexées (19, 20).

$$[6] \quad \delta_{obs} = f_{L_q} \cdot \delta_{L_q} + f_{ML_q} \cdot \delta_{ML_q}$$

avec $f_{L_q} + f_{ML_q} = 1$. Cette expression peut être transformée en (20, 21):

$$[7] \quad \delta = f_{ML_q} \cdot \Delta_{ML_q}$$

où $\delta = \delta_{obs} - \delta_{L_q}$ est une fonction linéaire de la quantité de complexe formé en solution.

En donnant à β_{pqr} des valeurs fixées arbitrairement et au moyen des relations [1] à [4], on calcule la quantité $f_{ML_q} = [ML_q]/C_A$ pour chaque rapport C_M/C_A donné, les valeurs de k_q et [H] étant connues.

Les valeurs de β_{pqr} retenues sont celles qui conduisent à des valeurs de f_{ML_q} qui portées dans la relation [7] donnent par régression linéaire le meilleur coefficient de corrélation (20).

Dans le cas d'un complexe unique, mononucléaire, la relation permettant de déterminer f_{ML_q} se réduit à:

$$[8] \quad [ML_q]^2 - [ML_q](1 + \beta_q(C_A + C_M)) + \beta_q \cdot C_A \cdot C_M = 0$$

Dans le cas d'un complexe dit "fort" (β_{pqr} élevé), on peut atteindre sans problème le déplacement induit limite Δ_{ML_q} même si l'échange est rapide par extrapolation à $C_M \gg C_A$ où l'espèce totalement complexée est seule présente (22). La constante de stabilité a alors pour expression:

$$[9] \quad \beta_{pqr} = (Y \cdot C_A)/(C_A - C_M - Y \cdot C_A^2 - Y \cdot C_A \cdot C_M + Y^2 \cdot C_A^2)$$

avec $Y = (\delta_{obs} - \delta_{L_q})/(\delta_{ML_q} - \delta_{L_q})$.

Partie expérimentale

Matériaux

Les sels métalliques $CaCl_2 \cdot 2H_2O$, $MnCl_2 \cdot 6H_2O$, $NiCl_2 \cdot 6H_2O$, $CuCl_2 \cdot 2H_2O$, $CoCl_2 \cdot 6H_2O$, $ZnSO_4 \cdot 7H_2O$, $CdCl_2 \cdot 2{,}5\ H_2O$, KCl et K_2CO_3 sont des produits Fluka.

$PrCl_3$ est obtenu par attaque de l'oxyde Pr_6O_{11} (Fluka) à chaud dans HCl concentré. Les acides aminés N protégés: Nα Boc alanine, Nα Boc valine, Nα Boc, γ Benzyl acide aspartique sont également des produits Fluka.

Le tétrapeptide Ac-DVDA-OH a été synthétisé selon le procédé en phase solide (12), la préparation ayant été effectuée sur 5 g de résine chlorosubstituée UCB. Notons seulement que la fixation du résidu C terminal a été obtenue en préparant au préalable le sel de césium Boc-Ala-Cs suivant la méthode développée par Gisin (13). Le rendement après réaction dans HF est de 61%. La purification a été effectuée par chromatographie liquide à haute pression avec un instrument Waters Associates modèle 204 sur colonnes Merck Lickrosorb RP 18.

L'analyse des acides aminés a été effectuée sur un Analyseur Biotronik CC 7000 et a donnée la composition suivante: Asp: 2,02; Ala: 1,00; Val: 0,99.

Appareillage

Les titrages potentiométriques ont été réalisés à 25 ± 1°C dans une enceinte thermostatée sous azote, à l'aide d'un pHmètre Metrohm E 603 couplé à une micro-électrode Metrohm EA 120. Toutes les mesures ont été effectuées sur des solutions contenant 4×10^{-3} *M* de Ac-DVDA-OH et des concentrations croissantes en sels métalliques (0 à 8×10^{-3} *M*) et en milieu de force ionique KCl = 0,5 *M* et K_2SO_4 = 0,5 *M*.

Les spectres rmn ont été enregistrés sur un spectromètre Bruker 200 MHz équipé d'un microprocesseur Aspect 2000 dans D_2O (pD = pH + 0,39) dans les mêmes conditions de température. La concentration en substrat après deutération de tous les protons échangeables est de $1{,}08 \times 10^{-2}$ *M*, celle en cations varie de 0 à $5{,}40 \times 10^{-2}$ *M*.

Résultats

Titrages potentiométriques

Les réseaux des courbes de neutralisation pH = $f(\bar{q})$ de Ac-DVDA-OH en présence de divers cations métalliques, montre une acidification dans la zone de pH étudié 3 < pH < 7 (fig. 2).

A titre d'exemple nous avons porté sur la figure 3, les courbes obtenues en présence de Ni(II) à différentes concentrations. Un équilibre de complexation existe donc, en milieu acide, lorsque les fonctions carboxyliques des deux résidus aspartyl commencent à être dissociées (pk_2 = 3,70; pk_1 = 4,84).

L'examen des courbes $\bar{r} = f(\log L_q)$ pour les différents rapports C_M/C_A montre que les valeurs de $\bar{r}$ sont faibles (0,1 <

[2]Pour une commodité d'écriture, les charges positives, neutres ou négatives n'ont pas été mentionnées.

For personal use only.

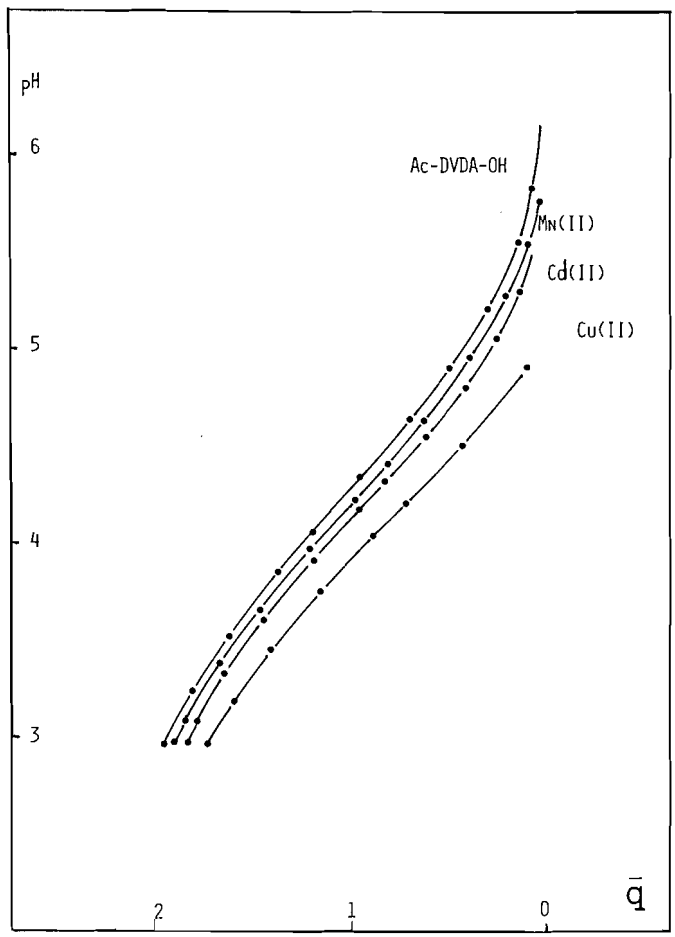

FIG. 2. Courbes de neutralisation pH = $f(\bar{q})$ de Ac-DVDA-OH ($4 \times 10^{-3} M$) en présence de divers cations métalliques ($4 \times 10^{-3} M$).

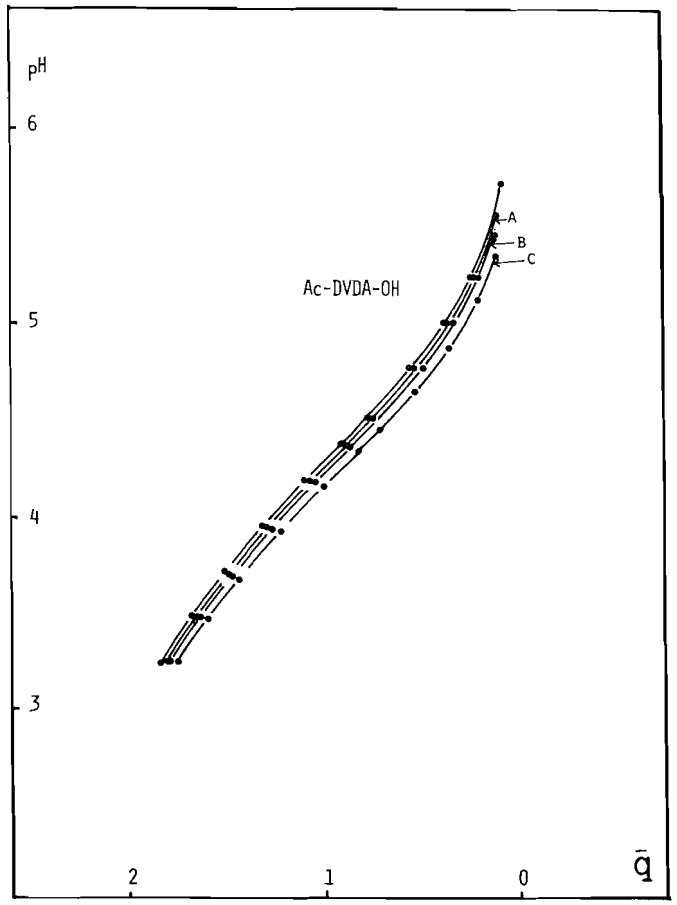

FIG. 3. Courbes de neutralisation pH = $f(\bar{q})$ de Ac-DVDA-OH ($4 \times 10^{-3} M$) en présence de $NiCl_2$: A, $Ni^{2+} = 2 \times 10^{-3} M$; B, $Ni^{2+} = 4 \times 10^{-3} M$; C, $Ni^{2+} = 8 \times 10^{-3} M$.

$\bar{r} < 0{,}4$) pour tout l'intervalle de pH considéré.

Compte tenu de ce résultat, nous nous sommes limités dans un premier temps, à la formation de complexes à un seul ligand. D'autre part, la concentration en sel métallique étant peu élevée (C_M max = $8 \times 10^{-3} M$), nous avons envisagé, en première approximation, la formation des complexes mononucléaires à un seul ligand, issus des équilibres.

$$[10] \quad \begin{aligned} &H_2A \rightleftharpoons Ha + H \ (k_2) \\ &M + HA \rightleftharpoons MHA \ (\beta_{111}) \end{aligned}$$

$$[11] \quad \begin{aligned} &HA \rightleftharpoons A + H \ (k_1) \\ &M + A \rightleftharpoons MA \ (\beta_{101}) \end{aligned}$$

où H_2A, HA et A représentent respectivement le tétrapeptide à 1, 2 et 3 charges négatives. Les constantes de stabilité β_{111} et β_{101} sont déterminées successivement pour $2 < \bar{q} < 1$ puis $1 < \bar{q} < 0$.

La calcul donne alors une valeur approchée de ces constantes. Ces valeurs sont ensuite optimalisées par un calcul complet des courbes de titrage à l'aide d'un microprocesseur Commodore 8032.

Afin de mieux cerner le phénomène de complexation, nous avons tenu compte des équilibres pouvant apparaître dans les zones de pH (ou $\bar{q}$) extrémales du réseau. En milieu acide, pour $q \simeq 2$, la présence du complexe MH_2A formé à partir du tétrapeptide chargé négativement sur le groupement carboxylate du résidu alanine C terminal doit être considérée, même si l'écartement des courbes du réseau pH = $f(\bar{q})$ est peu important. La détermination de la constante β_{121} est de ce fait peu précise. Elle a été estimée à 4 ± 1. Une meilleure approche du milieu acide a pu être effectuée par rmn, grace à l'utilisation du cation paramagnétique Pr^{3+}.

La dernière partie du réseau ($\bar{q} < 0{,}15$) est caractérisée par une évolution très lente des potentiels des solutions, contenant les éléments Zn(II), Cu(II) et Cd(II), peu avant la zone de précipitation. Outre la présence d'hydroxocomplexes du type $M(OH)^+$ établie par certains auteurs (23), il est nécessaire d'envisager la formation possible de complexes polynucléaires. Cependant, les calculs basés sur l'abaissement du pH des solutions dans cette zone instable ne sont pas assez rigoureux pour formuler une estimation convenable du phénomène.

L'ensemble des résultats sont regroupés dans le tableau 1. Des valeurs des constantes β_{pqr}, on tire les concentrations des espèces présentes en solution. Les courbes de répartition en fonction de pH ou de $\bar{q}$ permettent de préciser les proportions relatives des espèces ainsi que leur domaine de formation, comme on peut le constater sur la figure 4.

Cette étude a été nécessaire pour suivre par rmn les variations des déplacements chimiques des protons en présence des cations Ca^{2+} et Pr^{3+}.

de concentration 1,08 × 10^{-2} *M* ajustées à pH = 2,50 et 7,00.

Le fait le plus marquant est le déplacement vers les champs forts des groupements —CH_2 et Hα des deux résidus aspartyl ainsi que celui de H_α du résidu alanyl, lors de la neutralisation. Les expériences ont été ensuite reproduites dans des conditions identiques en présence de quantités croissantes de $PrCl_3$ (0 à 5,4 × 10^{-2} *M*). Les résultats des déplacements des pics sont groupés sur les figures 5 et 6. L'introduction du cation Pr^{3+} provoque: en milieu acide, une variation importante des résonances des protons H_α et —CH_3 de l'alanine, alors que les

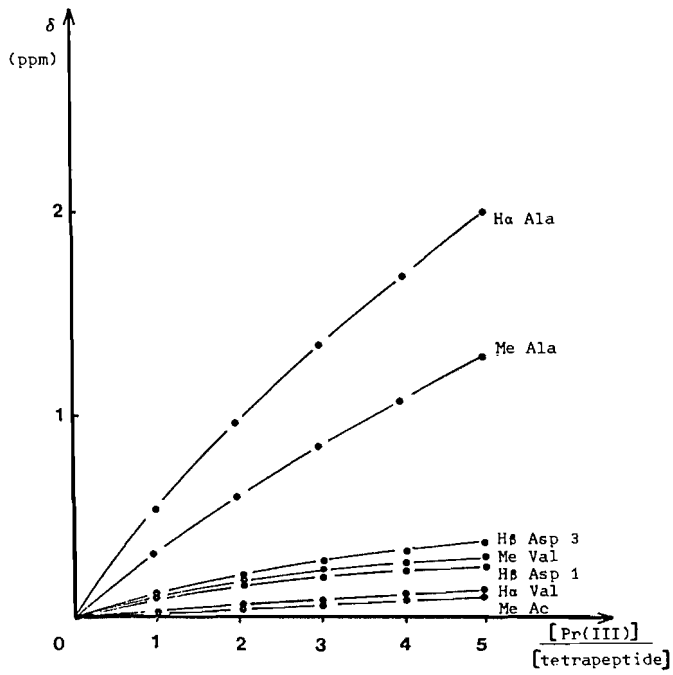

FIG. 5. Variation du déplacement chimique (ppm) des noyaux ^1H de Ac-DVDA-OH en fonction de la concentration en $PrCl_3$ à pH = 2,50.

autres protons sont peu perturbés; en milieu neutre, les groupements —CH_2 des résidus aspartyl subissent le plus fort glissement chimique (fig. 6).

A partir de ces variations nous avons procédé à une estimation des constantes de stabilité au moyen des relations [1] à [4] et [7].

TABLEAU 2. Constantes de stabilité β_2 et déplacements induits limites Δ_2 (Hz) des complexes Ac-DVDA-OH − Pr(III) = ML_2 à pH = 2,50, KCl = 0,5 *M*

Paramètre	H_β (Asp^1)	H_α (Val)	Me (Val)	H_α (Asp^3)	H_β (Asp^3)	H_α (Ala)	Me(Ala)	Me (Ac)

3	4,40	9,20	0,16	0,60	0,24	9,53	4,21	0,63	0,15	0,22
4	4,13	9,57	0,14	0,63	0,23	10,2	3,60	0,69	0,09	0,23

*Par convention les protons H_B résonnent à champ fort, les rotamères I, II, III correspondent aux angles de torsion $\chi_1 = -60$ (I), 180 (II), 60 (III).

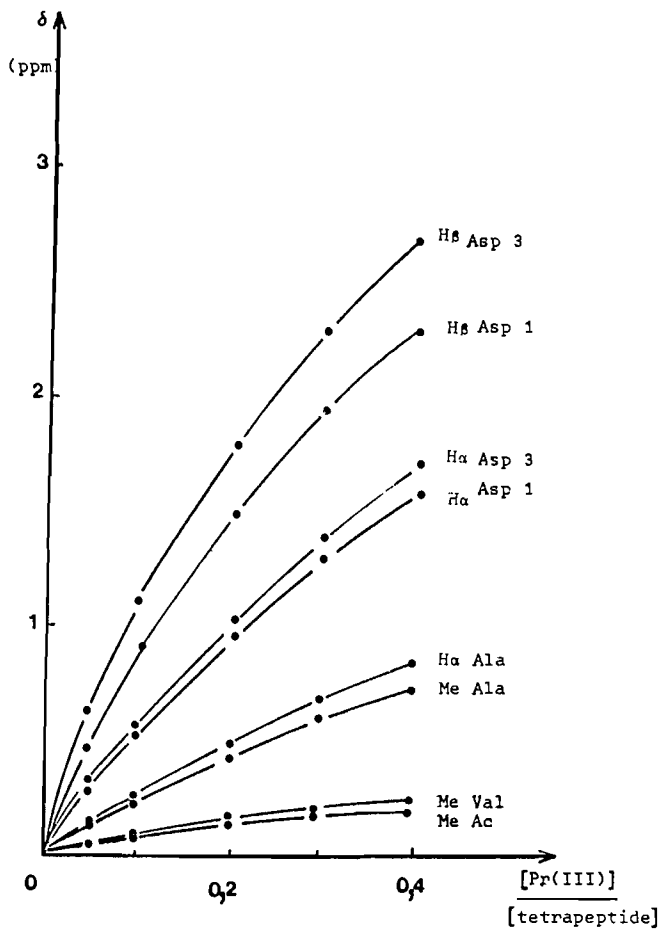

FIG. 6. Variation du déplacement chimique (ppm) des noyaux ^1H de Ac-DVDA-OH en fonction de la concentration en $PrCl_3$ à pH = 7,00.

A pH 2,50 les espèces H_3A, H_2A et MH_2A sont essentiellement présentes. La relation [6] devient:

[12] $\delta_{obs} = f_{L_3} \cdot \delta_{L_3} + f_{L_2} \cdot \delta_{L_2} + f_{ML_2} \cdot \delta_{ML_2}$

qui après transformation s'écrit:

[13] $\delta = f_{ML_2} \cdot \Delta_{ML_2} = f_{ML_2} \cdot \Delta_2$ (cf. notations)

Le meilleur accord est obtenu pour $\beta_{121} = \beta_2 = 6 \pm 1$. Rappelons que la détermination de β_{121} effectuée par potentiométrie a permis d'avoir seulement un ordre de grandeur de la constante de complexation du fait de la faible modification des valeurs de pH.

Les résultats concernant la détermination des constantes β_2 et les déplacements induits limites Δ_2 sont regroupés dans le tableau 2.

Couplages en présence de $CaCl_2$

Alors qu'en milieu acide, l'addition de $CaCl_2$ n'apporte pas de modifications de la partie spectrale correspondant aux résonances des résidus Asp, au pH physiologique les couplages J_{AX} et J_{BX} subissent une variation en fonction du rapport [Ca^{2+}]/[Ac-DVDA-OH]. Nous observons en particulier, une augmentation de J_{AX} (5,98 à 10,2 Hz) pour le résidu aspartyl en position 3 (tableau 3).

L'analyse des constantes de couplage vicinales, effectuée au moyen de la relation de Karplus−Bystrov (24):

[14] $^3J_{HC^\alpha C^\beta H} = 11 \cos^2 \theta - 1{,}4 \cos \theta + 1{,}6 \sin^2 \theta$

donnent un angle dièdre $\theta = 148°$ ($H^\alpha C^\alpha C^\beta H^{\beta 1}$) et $\theta = 70°$ ($H^\alpha C^\alpha C^\beta H^{\beta 2}$) pour le résidu Asp 3.

Le rotamère caractérisé par l'angle χ_1 ($NC^\alpha C^\beta C^\gamma$) = −60° est le principal conformère présent en solution (~69%). Ces résultats sont à rapprocher de ceux obtenus pour un autre peptide transporteur de calcium (25).

Discussion

Les constantes d'équilibre des systèmes Ac-DVDA-OH − cations métalliques établies dans ce travail ont permis de dégager les points suivants.

En milieu acide, l'examen de la constante β_2 obtenue par titrage rmn en présence de $PrCl_3$ montre qu'un complexe labile, certainement monodentate, est formé par interaction entre le cation Pr^{3+} et le groupement —COO^- C terminal du résidu alanine. Les déplacements chimiques ayant pour origine une interaction dipolaire sont exploitables dans un calcul en raison

de la relation géométrique simple existant entre la position du cation paramagnétique et celle du noyau perturbé (26). Cette relation, dans le cas où le complexe présente un axe de symétrie principal, s'écrit:

$$[15] \quad \Delta = D(3\cos^2\theta_i - 1)/r_i^3$$

où D est un terme constant pour un complexe donné, r_i est la distance entre le noyau i et le centre paramagnétique, θ_i est l'angle entre l'axe de symétrie principal du complexe et le vecteur $\vec{r_i}$. On remarque, effectivement, que les noyaux les plus proches du site d'interaction subissent la plus forte variation: H_α et le groupement Me de l'alanine. L'interaction s'atténue très rapidement avec la distance $(1/r_i^3)$; de ce fait les autres noyaux subissent peu de variation (fig. 5).

En milieu neutre, l'étude basée sur la variation du pH des solutions et celle des fréquences de résonances des ^1H montre: une forte augmentation de la constante de stabilité (environ 10^3 fois) pour les différents systèmes étudiés; une perturbation importante des noyaux $-CH_2$ des deux groupements aspartyl même en présence de faibles quantités de $PrCl_3$; une augmentation de la constante de couplage J_{AX} relative aux groupements aspartyl notamment pour le résidu Asp^3, lorsque la concentration de $CaCl_2$ est supérieure à celle du ligand. L'affinité relative des cations étudiés vis à vis des groupements carboxylates du tétrapeptide diminue du cuivre au manganèse selon: Cu(II) $\gg$ Ni(II) > Ca(II) > Zn(II) > Pr(III), Cd(II) > Co(II), Mn(II). Par comparaison avec les données établies par Williams (27), il ressort de cette étude que le tétrapeptide Ac-DVDA-OH a une nette affinité vis à vis de Ca^{2+}. Le cuivre montre également une forte interaction avec le modèle synthétisé. Une stabilisation importante due au cuivre est d'ailleurs vérifiée pour la plupart des systèmes peptidiques analogues (28, 29).

Pour rendre compte de ces résultats, il s'impose d'avoir recours à la formation possible d'un chélate où le cation métallique, ici Ca^{2+} ou Pr^{3+}, interagit fortemment, à la fois avec deux groupements carboxylates des deux résidus aspartyl. Cette hypothèse est à comparer aux modèles proposés pour l'interaction Angiotensine$-Yb^{3+}$ (30). Nous ne disposons encore que de données trop peu nombreuses pour formuler des propositions sur une conformation préférentielle. Il est vraisemblable que la portion de la chaîne comprise entre Asp^1 et Asp^3 garde une souplesse importante. Cette étude a permis de souligner l'importance de l'interaction du calcium vis à vis d'un modèle peptidique présentant deux groupements carboxylates rapprochés sur les chaînes latérales. Cette affinité montre donc une coordination sélective de l'élément alcalino terreux dans un environnement favorable. Les mesures de constantes de couplage mettent en évidence une réorientation préférentielle du système en présence de Ca(II), en particulier la formation privilégiée d'un conformère de rotation autour de $C^\alpha—C^\beta$.

Conclusion

Le tétrapeptide Ac-DVDA-OH homologue d'un fragment actif de protéines contenant du calcium, montre une affinité pour Ca^{2+} nettement plus importante que pour d'autres peptides courts étudiés jusqu'ici.

La substitution isomorphe des cations Ca^{2+} par les cations de lanthanides utilisés comme réactifs de déplacement chimique, Pr^{3+} dans l'étude, permet de mettre en évidence en solution aqueuse l'existence de deux modes de complexation dont l'un concerne la fonction carboxylique située en bout de chaine en milieu acide, et l'autre les deux résidus aspartyl des chaines latérales pour le pH physiologique.

Remerciements

Déplacements homolytiques intramoléculaires. 2. Décomposition du perpentène-4 oate de *tert*-butyle dans les éthers

A. KHARRAT, C. GARDRAT[1] ET B. MAILLARD[2]

Laboratoire de Chimie Appliquée, Université de Bordeaux I, 351, cours de la Libération, 33405 Talence-Cedex, France

Reçu le 10 janvier 1984

A. KHARRAT, C. GARDRAT et B. MAILLARD. Can. J. Chem. **62**, 2385 (1984).

La thermolyse du perpentène-4 oate de *tert*-butyle **1** dans le THF conduit à de nombreux produits; le composé majoritaire, le (tétrahydrofuryl-2)-5 pentanolide-4, obtenu avec un rendement de 42%, provient d'une décomposition induite du perester par suite de l'addition du radical tétrahydrofuryle-2 sur la double liaison. Cette réaction a pu être effectuée à basse température en utilisant un amorceur annexe, le perdicarbonate de butyle, mais il n'a pas été possible de préciser le type de mécanisme (concerté ou en deux étapes). L'intérêt synthétique de la thermolyse de **1** dans d'autres éthers (THP, oxépanne, dioxanne-1,4, éther de dipropyle) a pu être mis en évidence puisqu'un certain nombre de nouvelles γ-lactones ont ainsi été préparées.

A. KHARRAT, C. GARDRAT, and B. MAILLARD. Can. J. Chem. **62**, 2385 (1984).

The thermolysis of *tert*-butyl perpent-4-enoate **1** in THF led to several compounds; the main product, 5-(2-tetrahydrofuryl)-4-pentanolide (yield 42%) comes from an induced decomposition of the perester occurring with the addition of 2-tetrahydrofuryl radical to the double bond. A similar reaction was performed at a lower temperature, using butyl perdicarbonate as initiator, but did not define the mechanism (concerted or two-step). The thermolysis of **1** in ethers (THP, oxepane, 1,4-dioxane, dipropyl ether) appears to be a useful synthetic tool: several new γ-lactones have been obtained in this way.

Introduction

Dans un travail précédent (1) nous avons montré que la thermolyse du perpentène-4 oate de *tert*-butyle **1** dans les cyclanes conduisait à la formation de cycloalkyl-5 pentanolides-4 en quantités relativement importantes. L'obtention de ces lactones est due à une décomposition induite du perester; elle résulte de l'addition d'un radical cycloalkyle sur la double liaison et d'un déplacement homolytique intramoléculaire d'un radical *tert*-butoxyle. La phase de propagation de la réaction, ayant lieu en chaîne, est la suivante:

[1] $S^{\bullet} + H_2C{=}CH{-}(CH_2)_2{-}CO_3tBu \longrightarrow S{-}CH_2{-}\underset{\displaystyle O}{\overset{\displaystyle O}{\langle}}{=}O + tBuO^{\bullet}$

[2] $tBuO^{\bullet} + SH \longrightarrow tBuOH + S^{\bullet}$

Les éthers subissent très facilement un arrachement d'hydrogène par les radicaux *tert*-butoxyle (2−4) conduisant à des radicaux qui s'additionnent aux doubles liaisons de composés éthyléniques fonctionnels ou non (2, 5−9). Nous avons donc décidé d'aborder dans un premier temps l'étude de la thermolyse du perpentène-4 oate de *tert*-butyle dans le tétrahydrofuranne afin d'essayer de préciser le mécanisme réactionnel de la thermolyse de **1**. Dans un deuxième temps, nous avons étendu cette réaction à d'autres éthers afin d'en tester les possibilités synthétiques.

Résultats

Décomposition du perpentène-4 oate de tert*-butyle dans le tétrahydrofuranne*

Ayant décidé de rechercher l'intérêt synthétique de la décomposition induite de **1** par les radicaux dérivant d'éthers, nous avons essayé, avant toute étude, de définir les conditions optimales d'obtention de la lactone à partir d'un composé modèle, le tétrahydrofuranne. Pour cela, nous avons recherché l'influence de la température (donc du temps de chauffage) et des rapports molaires **1**/THF sur les quantités de lactone formée. Le tableau 1 montre les principaux résultats.

TABLEAU 1. Variation du rendement en (tétrahydrofuryl-2)-5 pentanolide-4 en fonction des conditions de la réaction

Rapport molaire **1**/THF	Rendement en **10**%*		
	2 h à 130°C	4 h à 120°C	8 h à 110°C
1:5	20	18	25
1:10	28	24	39
1:20	27	24	42
1:50	26	26	39
1:100	20	20	38

*Calculé par rapport au perester mis en jeu et déterminé par cpg.

Les produits formés par thermolyse de **1** dans le THF sont de deux types comme cela avait été observé lors de la réaction effectuée dans le cyclohexane (1): (*i*) composés provenant uniquement du perester (*tert*-butanol **2**, acétone **3**, butène-1 **4**, gaz carbonique **5**, acide pentène-4 oïque **6**) ou du solvant ((tétrahydrofuryl-2)-2 tétrahydrofuranne **7**); (*ii*) composés comportant dans leur molécule à la fois des motifs provenant du perester et du solvant (butyl-2 tétrahydrofuranne **8**, acide (tétrahydrofuryl-2)-5 pentanoïque **9**, (tétrahydrofuryl-2)-5 pentanolide-4 **10**, *tert*-butoxy-2 tétrahydrofuranne **11**).

Dans le tableau 2 sont rassemblés les nombres de moles de chacun de ces produits formés par la décomposition d'une mole de perester **1**.[3]

Isomères $\alpha/\beta + \gamma$	100/0	84/16	68/32	—	100/0

*Conditions: rapport **1**/éther = 1:20; température: 110°C; durée: 8 h.
†Calculé sur la fraction de distillation par rapport au perester mis en jeu.

Décomposition du perpentène-4 oate de tert-*butyle* **1** *dans divers éthers*

La thermolyse du perpentène-4 oate de *tert*-butyle effectuée dans le tétrahydropyranne, l'oxépanne, le dioxanne-1,4 et l'éther de dipropyle conduit dans les deux premiers cas à plusieurs lactones isomères alors que dans les deux derniers un seul produit de substitution de l'éther semble être obtenu. Les compositions des fractions isolées et leurs rendements sont rapportés dans le tableau 3.

Discussion

Origine des divers produits formés dans la réaction de thermolyse de **1** *dans le THF*

Les composés **2** et **3** sont les produits d'évolution classique des radicaux *tert*-butoxyle alors que **7** est formé par couplage des radicaux tétrahydrofuryle-2.

La présence simultanée de **4**, **5** et **6** pourait être expliquée par l'évolution du radical pentène-4 oyloxyle décrite fig. 1 (R = $(CH_2)_2CH{=}CH_2$, SH:THF). En fait, comme nous le verrons par la suite **6** est obtenu par une autre voie.

Les composés **8** et **9** ont *a priori* deux origines possibles (fig. 2): (*i*) addition radicalaire au butène-1 **4** ou à l'acide pentène-4 oïque **6** formés dans la décomposition de **1**; ou (*ii*) décomposition du (tétrahydrofuryl-2)-5 perpentanoate de *tert*-butyle **1***a* formé à partir du radical A par arrachement d'hydrogène dans l'hypothèse d'une décomposition induite en deux étapes.

Les additions radicalaires du THF au butène-1 **4** et à l'acide pentène-4 oïque **6** amorcées par le peroxyde de di-*tert*-butyle à 140°C conduisent bien à **8** et **9** confirmant la validité de la première hypothèse.

Le (tétrahydrofuryl-2)-5 perpentanoate de *tert*-butyle **1***a* a été préparé à partir de **9** et thermolysé en solution dans le THF (110°C, 8 h, rapport molaire 1:20) afin de montrer la possibilité d'existence du deuxième mécanisme avancé. Après réaction le butyl-2 tétrahydrofuranne **8** et l'acide **9** sont obtenus avec des rendements respectifs de 5% et 80% par rapport au perester mis en jeu. D'autres produits correspondant aux 15% manquants sont observés; ils résultent vraisemblablement des réactions des radicaux dans la cage de solvant, comme cela est généralement observé lors de décomposition de peresters (10, 11).

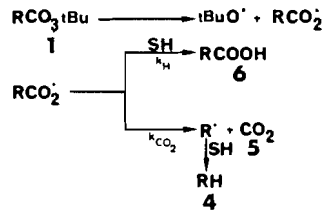

FIG. 1.

La mise en évidence de la formation de **1***a* lors de la décomposition thermique de **1** dans le THF permettrait de montrer que la deuxième hypothèse de formation de **8** et **9** a une réalité. La stabilité thermique de ce perester étant similaire à celle de **1** nous avons décidé d'effectuer la décomposition induite de **1** en initiant la réaction en chaîne par un amorceur annexe se décomposant avec une vitesse très supérieure à **1** et **1***a* à des températures plus basses; le perdicarbonate de n-butyle a été utilisé. Le chauffage à 65°C pendant 13 h d'une solution de ce peroxyde et de **1** dans le THF (rapport 0,2:1:20) a conduit à **10** (rendement 20% par rapport au perester mis en jeu) alors que 50% de **1** sont récupérés inchangés. Le perester **1***a* a été vainement recherché à l'aide de la hplc analytique en comparant le temps de rétention d'un échantillon de référence à celui des produits contenus dans les fractions renfermant le composé peroxydique séparé des produits lourds par chromatographie liquide–solide sur une colonne de silice (éluant: pentane). Dans ces conditions, nous voyons qu'au moins à 65°C si la réaction de décomposition induite se fait en deux étapes, le déplacement homolytique s'effectue avec une vitesse beaucoup plus importante que le transfert d'hydrogène pouvant conduire à **1***a*.

Au niveau de la formation de **9** les deux mécanismes paraissent également plausibles. Par contre, **8** est essentiellement formé par addition radicalaire du THF au butène-1 **4** puisque le rapport **8**/**9** obtenu pour la thermolyse de **1** dans le THF (6:17) est très supérieur à celui (5:80) qui est observé lors de celle du (tétrahydrofurfuryl-2)-5 perpentanoate de *tert*-butyle **1***a* dans les mêmes conditions.

La comparaison des produits de décomposition du perester **1** dans le THF et le cyclohexane, de **1***a* dans le THF et du cyclohexyl-5 perpentanoate de *tert*-butyle **1***b* dans le cyclohexane laisse apparaître la formation d'acide uniquement pour les thermolyses effectuées dans l'éther cyclique.

Dans l'hypothèse d'un mécanisme de décomposition représenté fig. 1, le rapport des quantités d'acide et de carbure formés à partir de **1***a* indique que les valeurs numériques des constantes k_H et k_{CO_2} doivent être voisines. Kaptein (12) ayant estimé que k_{CO_2} est de l'ordre de 10^{10} s^{-1} à 100°C, la valeur calculée pour la constante de vitesse d'arrachement d'hydrogène du THF par les radicaux acyloxyle k_H paraît excessive surtout si on la compare avec celle de la même réaction effectuée par les radicaux *tert*-butoxyle ($k \sim 10^7$ s^{-1} mol^{-1} à 100°C) (4).

De même la comparaison des quantité d'acides et de carbures obtenus lors des décompositions de **1***a* et **1***b*[4] respectivement dans le THF et le cyclohexane permet de trouver, avec la même hypothèse de mécanisme de décomposition (fig. 1), une limite inférieure du rapport des constantes de vitesse d'arrachement

[4]On suppose pour cela que la décomposition de la fonction perester n'est pas affectée par la nature du substituant en 5 (tétrahydrofuryl-2 ou cyclohexyl). Le rapport acide/carbure formés dans la thermolyse de **1***b* dans le cyclohexane est pris égal à 1:99 (valeur maximale de la proportion d'acide compte-tenu de la limite de détection).

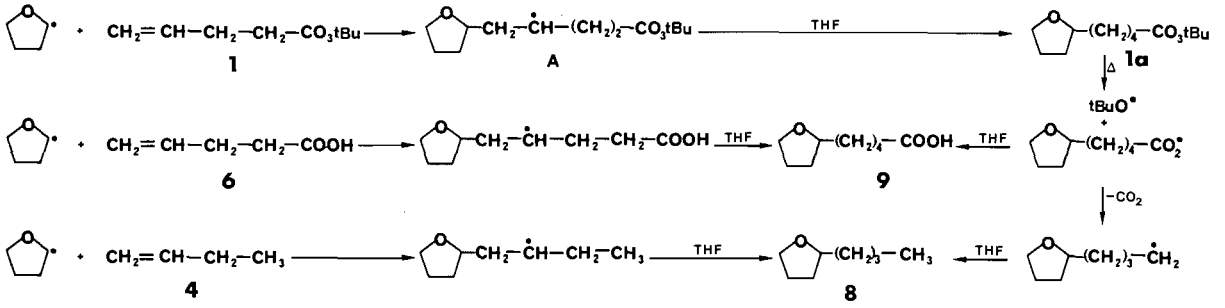

FIG. 2.

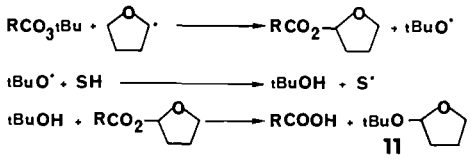

FIG. 3.

d'hydrogène du THF et du cyclohexane par les radicaux acyloxyle: $k_{H_{THF}}/k_{H_{C_6H_{12}}} \sim 10^3$. A partir des résultats de la littérature (3, 4), nous avons pu calculer la valeur du rapport $k_{H_{THF}}/k_{H_{C_5H_{10}}} \sim 10$ pour les radicaux *tert*-butoxyle. Des réactivités voisines des hydrogènes du cyclohexane et du cyclopentane vis-à-vis des mêmes radicaux (13) montrent que l'on peut considérer que $k_{H_{THF}}/k_{H_{C_6H_{12}}}$ est de l'ordre de 10. La comparaison de ces rapports laisse apparaître une grande différence de sélectivité entre les radicaux acyloxyle et *tert*-butoxyle, ce qui peut paraître surprenant.

Dans ces conditions si, dans la thermolyse de peresters dans le THF, les carbures semblent bien se former par décarboxylation des radicaux acyloxyle, il semble qu'il faille rechercher une autre origine pour la formation des acides. Huyser (14) propose une explication sur la formation d'acide et de *tert*-butoxy tétrahydrofuranne **11** dans la thermolyse du peracétate de *tert*-butyle dans le THF par la décomposition induite de ce dernier par les radicaux dérivant du solvant (fig. 3). Bien que dans la décomposition de **1** et **1***a* nous observions une quantité plus faible de **11** que d'acide (0,04:0,06 et 0,57:0,80), il est difficile d'exclure le mécanisme proposé par Huyser.

La γ-lactone **10** est formée dans la décomposition induite du perester **1** par les radicaux tétrahydrofuryle-2; comme dans le cas des cyclanes (1) nous venons de voir qu'il est difficile de savoir si cette réaction a lieu en deux étapes (addition, déplacement homolytique) ou fait appel à un mécanisme concerté du même type que celui qui est avancé par Hart et Chloupeck (15).

Les résultats précédents nous montrent en outre qu'il semble vain de poursuivre dans cette voie pour la mise en évidence d'un mécanisme en deux étapes. La compétition de la réaction de déplacement homolytique avec des réarrangements intramoléculaires sera notre prochain objectif dans la recherche d'une preuve de ce schéma réactionnel. De plus, l'existence d'une telle compétition pourrait permettre une détermination de la constante de vitesse du déplacement (16).

Le composé **11** a déjà été observé au laboratoire dans les réactions de thermolyse du percarbonate de vinyle dans le THF (9). Les auteurs ont attribué la formation au couplage des radicaux *tert*-butoxyle et tétrahydrofuryle-2 comme Sosnovsky lors de sa communication préliminaire (17). Compte-tenu de la valeur de la constante de vitesse ($k_H \sim 10^7$ s^{-1} mol^{-1}) de réaction des radicaux *tert*-butoxyle avec le THF (concentration $\sim$ 10 mol/L), dans l'hypothèse d'une limite du couplage des radicaux par la diffusion moléculaire ($k_t \sim 10^{10}$ s^{-1} mol^{-1}) comme nous avons:

[3] $v_{\text{transfert}} = k_H\,[t\text{BuO}^\cdot]\,[\text{SH}]$

[4] $v_{\text{couplage}} = k_t\,[t\text{BuO}^\cdot]\,[\text{S}^\cdot]$

la concentration stationnaire des radicaux tétrahydrofuryle-2 devra être supérieure à 10^{-2} mol/L pour que la réaction de couplage soit plus rapide que celle de transfert. Si l'on considère la concentration initiale du peroxyde, au moins dans la décomposition du percarbonate de vinyle (~1 mol/L) et la constante de vitesse de décomposition de ce dernier (~10^{-3} s^{-1}) (18), il paraît impossible que les concentrations en radicaux tétrahydrofuryle-2 soient aussi élevées.

La proposition faite par Huyser (14) et reprise par Walling et Azar (19) paraît donc actuellement mieux rendre compte de la formation de **11** que le couplage des radicaux (9, 17).

Thermolyse de 1 dans divers éthers

Les rendements de fonctionnalisation des éthers cycliques sont tout à fait comparables à ceux enregistrés lors de leur acétonylation (8) et de leur formylméthylation (9) ce qui n'était pas le cas avec les cyclanes (13). En outre, alors que dans le cas du THP, les répartitions des attaques en α d'une part, β et γ d'autre part sont les mêmes, pour l'oxépanne, nous pouvons noter une moins grande sélectivité dans cette étude. Nous signalerons que, comme pour l'acétonylation le rapport THP ou oxépanne/perester est sans effet sur la composition du mélange d'isomères. Dans ces conditions, il semble que l'on puisse admettre que les proportions relatives des produits finaux reflètent convenablement les pourcentages initiaux de l'attaque des radicaux *tert*-butoxyle sur les éthers cycliques. Il est probable que la diminution de la sélectivité avec l'augmentation de la taille du cycle est due à des effets stéréoélectroniques (3, 4) comme cela a déjà été envisagé (8).

On outre, il faut noter que le produit d'attaque en β n'est pas observé dans le cas de l'éther de dipropyle. Nous mentionnerons qu'un essai de décomposition de **1** dans l'éther de diisopropyle a été effectué. La γ-lactone recherchée est obtenue en mélange avec de nombreux autres produits.

Conclusion

En conclusion de cette étude sur la thermolyse de **1** dans les éthers nous retiendrons comme point important une certaine généralisation de l'utilisation de cette réaction pour préparer des lactones fonctionnelles. Nous signalerons aussi l'existence d'une décomposition induite de **1** par réaction des radicaux tétrahydrofuryle sur la fonction perester. Comme cela avait été le cas pour les cyclanes, l'analyse des produits secondaires n'a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

pas permis de savoir si la réaction procède par un mécanisme en deux étapes ou concerté malgré la tentative de mise en évidence d'un perester d'addition. Une décomposition induite du perpentène-4 oate de *tert*-butyle par les radicaux tétrahydrofuryle-2 a pu être effectuée à plus basse température ouvrant la voie à la recherche d'une amélioration du procédé; les radicaux ont été engendrés par la thermolyse d'un amorceur annexe dans la solution tétrahydrofurannique de **1**.

Partie expérimentale

L'analyse des produits liquides par chromatographie en phase gazeuse (cpg) a été effectuée sur un appareil Intersmat IGC 112 F (ionisation de flamme; gaz vecteur: azote (débit ~ 30 mL/min)) équipé de colonnes en acier Inox (longueur: 2 m; diamètre intérieur: 2 mm). Deux phases ont été principalement utilisées: OV-275 (10% sur Chromosorb WHP, 80/100 mesh) et FFAP (10% sur Chromosorb WAW, 80/100 mesh). Les identifications ont été réalisées par comparaison des temps de rétention avec ceux d'échantillons préparés en référence ou par couplage avec un spectromètre de masse. Les dosages ont été effectués par la méthode de l'étalon interne.

Les produits gazeux de réaction avec le THF ont été récupérés sur une cuve à eau et analysés par cpg à l'aide d'un appareil Varian 920 (Catharomètre; gaz vecteur: hélium (débit ~ 12 mL/min)) équipé d'une colonne en acier Inox (longueur: 9 m; diamètre intérieur: 2 mm), la phase étant DC-200 (28%) sur Chromosorb PAW (60/80 mesh). Un mélange gazeux a servi de référence. Les échantillons ont été prélevés à l'aide d'une seringue à gaz.

L'étude par hplc a été effectuée sur un appareil Waters (colonne μPorasil (3,9 mm × 30 cm); détecteur: réfractomètre différentiel; solvant: hexane/éther 70:30; débit: 3 mL/min).

Les spectres rmn du proton ont été enregistrés sur un appareil Perkin–Elmer R12 B opérant à 60 MHz à partir de solutions à 10% dans le tétrachlorure de carbone (déplacements chimiques en δ ppm par rapport au TMS).

Les spectres rmn du ^{13}C ont été enregistrés sur un appareil Bruker WP 60 fonctionnant à 15,08 MHz équipé d'un calculateur Nicolet BNC 12 (déplacements chimiques en δ ppm par rapport au TMS) à partir de solutions dans le chloroforme deutéré.

Les spectres de masse ont été obtenus, en général par couplage masse–cpg sur des appareils Micromass 16F et 70-70 sous impact électronique (70 eV). Nous n'indiquons que les pics dont l'abondance dépasse 10%.

Etude des décompositions

Les études analytiques ont été réalisées en introduisant 2 cm^3 de solution dans des ampoules en Pyrex scellées placées pendant le temps adéquat dans un bain thermostaté à la température choisie (110, 120 ou 130°C).

Les études préparatives ont été effectuées sur des volumes de l'ordre de 100 cm^3 dans un autoclave de 125 cm^3 placé dans une étuve thermorégulée préalablement portée à la température souhaitée. Après élimination du solvant en excès, le produit recherché est distillé sous pression réduite puis purifié par chromatographie liquide–solide sur une colonne de gel de silice (Kiesel 60, 35–70 mesh).

Matières premières

Les éthers, le *tert*-butanol, l'acétone et le butène-1 sont des produits commerciaux. Le (tétrahydrofuryl-2)-2 tétrahydrofuranne a été obtenu par décomposition du peroxyde de di-*tert*-butyle dans le THF. Les synthèses de l'acide pentène-4 oïque et du perpentène-4 oate de *tert*-butyle ont été décrites dans réf. (1).

Le butyl-2 THF a été synthétisé par addition radicalaire du THF sur le butène-1 en présence de peroxyde de *tert*-butyle (rapports molaires THF/butène-1/PDTB = 20:1:0,1; température: 140°C; durée: 10 h); pé 68°C/22 Torr; n_D^{20} = 1,4462 (litt. (20) pé 158–159°C/750 Torr; n_D^{20} = 1,4287); rmn δ: 0,7 à 2,1 (1 massif, 13H), 3,3 à 3,9 (1 massif, 3H).

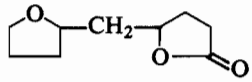
L'acide (tétrahydrofuryl-2)-5 pentanoïque a été préparé par addition radicalaire du THF (2 mol) à l'acide pentènoïque (0,1 mol) en présence de peroxyde de di-*tert*-butyle (0,02 mol) à 140°C pendant 10 h; pé 112°C/0,1 Torr; n_D^{20} = 1,4625; rmn δ: 1,1 à 2,7 (1 massif, 12H), 3,5 à 4,1 (1 massif, 3H), 9,85 (1 signal large, 1H).

Le (tétrahydrofuryl-2)-5 perpentanoate de *tert*-butyle a été obtenu par action du *N*,*N'*-carbonyldiimidazole sur l'acide correspondant dans le THF anhydre suivi d'une addition d'hydroperoxyde de *tert*-butyle. Il a été purifié par passage sur gel de silice; taux de perester déterminé selon (21): 98%; rmn δ: 1,1 à 2,5 (1 massif, 12H), 1,3 (1 s, 9H), 3,4 à 4,0 (1 massif, 3H).

Le *tert*-butoxy-2 tétrahydrofuranne a été préparé par décomposition du perbenzoate de *tert*-butyle dans le THF en présence de bromure de cuivre (17); pé 53°C/22 Torr; n_D^{20} = 1,4221 (litt. (17) pé 40°C/11 Torr; n_D^{25} = 1,4186); rmn δ: 1,2 (1 s, 9H), 1,6 à 2,2 (1 massif, 4H), 3,5 à 4,0 (1 massif, 2H), 5,2 à 5,4 (1 massif, 1H).

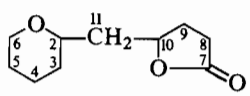
Caractéristiques physiques des différentes lactones substituées[5,6]

(Tétrahydrofuryl-2)-5 pentanolide-4 **10**: pé 116–117°C/0,3 Torr; n_D^{20} = 1,4697; rmn ^1H δ: 0,8 à 2,7 (1 massif, 10H), 3,4 à 4,2 (1 massif, 3H), 4,3 à 4,9 (q, 1H); principaux pics du spectre de masse *m*/*z* (abondance): 71 (100), 43 (20), 85 (20).

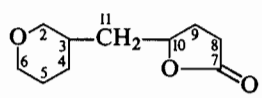


10

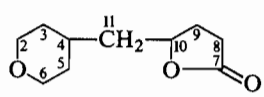
(Tétrahydropyrannyl)-5 pentanolide-4 **12**: point d'ébullition du mélange des trois isomères 126–128/0,3 Torr.



12*a*



12*b*



12*c*

[5]Les déterminations par rmn ^{13}C des structures isomères des composés **12** et **13** ont été effectuées par comparaison des valeurs des déplacements chimiques observées et calculés selon réf. 22 à partir de modèles décrits dans la littérature (1, 22, 23). Pour **12***b* et **12***c* nous sommes basés essentiellement sur les déplacements chimiques des carbones C_2 et C_6, pour **13***b* et **13***c* sur ceux des carbones C_2 et C_7.

[6]Toutes les lactones décrites donnent des microanalyses C, H en accord avec les formules proposées. Toutefois pour le produit **15** il faut signaler un écart plus important avec les valeurs théoriques.

Reaction of diphenylcarbene with oxygen: a laser flash photolysis study[1]

N. H. WERSTIUK,[2] H. L. CASAL, AND J. C. SCAIANO
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received April 18, 1984

N. H. WERSTIUK, H. L. CASAL, and J. C. SCAIANO. Can. J. Chem. **62**, 2391 (1984).

Diphenylcarbene reacts with oxygen with a rate constant of $5 \times 10^9\ M^{-1}\ s^{-1}$ in acetonitrile at 300 K. The reaction leads to an intermediate which absorbs strongly at ~410 nm, believed to be the carbonyl oxide, Ph_2COO.

N. H. WERSTIUK, H. L. CASAL et J. C. SCAIANO. Can. J. Chem. **62**, 2391 (1984).

Le diphénylecarbene réagit avec l'oxygène dans la solution d'acetonitrile avec une constante de vitesse $5 \times 10^9\ M^{-1}\ s^{-1}$ à 300 K. Cette réaction forme un produit intermédiaire possédant une absorption forte à ~410 nm que nous croyons être l'oxyde de carbonyle Ph_2COO.

Triplet carbenes are known to react readily with oxygen (1–7); but little is known about the kinetics of these reactions (4, 8). In the case of diphenylcarbene (DPC) the reaction ultimately leads to benzophenone and its diperoxide (3). There is some evidence that at least some of the benzophenone is produced in its triplet state in glasses at low temperature (7). Several authors have speculated as to the type of mechanism and reactive intermediates involved in the process; there is some consensus that benzophenone-oxide, Ph_2COO (i.e. the Criegee intermediate (9)) is probably involved; this species has recently been detected in other systems involving cyclopentadienylidene at low temperatures using vibrational spectroscopy (10). While this communication was being considered for publication we learned about the recent detection of 10,10-dimethyl-10-silaanthracen-9[10*H*]-one oxide by laser flash photolysis (11).[3]

Pulsed laser photodecomposition (308 nm, ~4 ns, up to 80 mJ/pulse) of diphenyldiazomethane (typically $10^{-4}\ M$) in acetonitrile at 300 K yields, after carbene intersystem crossing, triplet diphenylcarbene (^{3}DPC), easily detectable by its strong optical absorption around 315 nm (12).[4] The triplet carbene can be readily scavenged by oxygen, as evidenced by the decrease in lifetime in the presence of increasing concentrations of oxygen. The decay of ^{3}DPC follows clean pseudo-first order kinetics in the presence of oxygen. A plot of the corresponding rate constants for carbene decay vs. the oxygen concentrations yields $k_{O_2} = 5 \times 10^9\ M^{-1}\ s^{-1}$, based on the reported solubility of oxygen in acetonitrile (14).

$$[1]\quad Ph_2C^{\uparrow\uparrow} + O_2 \xrightarrow{k_{O_2}} Ph_2COO$$

Oxygen usually does not scavenge singlet carbenes (8) since this process would only be allowed if it yielded a triplet product. This is confirmed by our experiments, where only the lifetime of the triplet, but not its yield, were affected by oxygen.

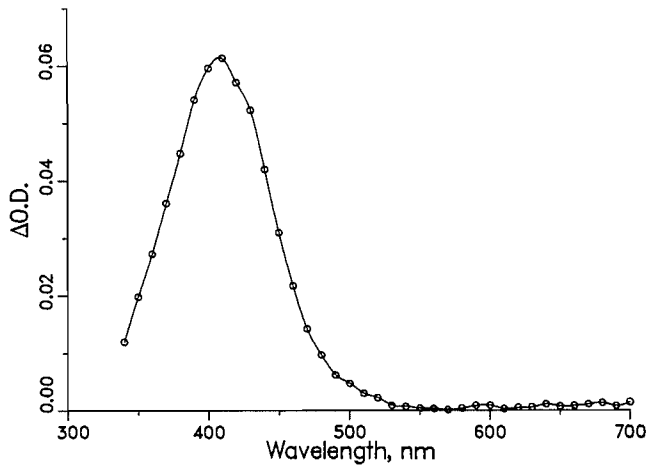

FIG. 1. Transient absorption spectrum obtained 10 μs after laser excitation of a 10^{-4} *M* solution of diphenyldiazomethane in acetonitrile (300 K) containing 7.7×10^{-3} *M* oxygen.

We have observed that quenching by oxygen is accompanied by the formation of a long-lived intermediate ($\tau > 100$ μs) which shows relative intense absorptions with $\lambda_{max} \sim 410$ nm (see Fig. 1). There is only one other recent example where intermediates of this type have been detected by uv–vis spectroscopy (11). We tentatively assign these signals to the carbonyl-oxide Ph_2COO, which is ultimately responsible for the formation of benzophenone. The absorption spectrum is not sufficiently informative to decide on the structure of Ph_2COO; while an ylide structure is quite possible, other possibilities, such as a biradical or 3-member ring cannot be ruled out.

A few experiments have been carried out in order to characterize this transient better. Electron deficient olefins scavenge the 410 nm transient, a common reaction for carbene-derived ylides (15); for example, $k = 1.5 \times 10^6\ M^{-1}\ s^{-1}$ for diethylfumarate. Slow ($k \sim 4 \times 10^5\ M^{-1}\ s^{-1}$), but detectable quenching is also observed in the case of the carbene precursor, diphenyldiazomethane. Oxygen, at pressures of up to 1 atm, does not quench this intermediate. The same intermediate has also been detected in benzene and in methylene chloride solution, thus confirming that the 410 mm band does not result from reactions involving the solvent.

Carbonyl oxides are known to be good oxygen-transfer reagents, reacting readily with a wide range of organic substrates,

[3] We are grateful to Dr. M. T. H. Liu for bringing this work to our attention.

[4] Details of our laser facility have been reported elsewhere (13). All experiments were carried out using a flow system and employing solutions saturated with O_2/N_2 mixtures of known composition. An excimer laser (Lumonics TE860-2) was used for excitation.

including aromatic hydrocarbons and olefins (e.g. refs. 16, 17). The 410 nm transient was scavenged by 2,5-dimethyl-2,4-hexadiene with a rate constant of $\sim 1 \times 10^6\ M^{-1}\ s^{-1}$ in acetonitrile at 300 K.

Further laser and product studies, including substituent and solvent effects are currently in progress, in an attempt to elucidate further the mechanisms and kinetics of these reactions.[5]

Thermolysis of unsymmetrically substituted vinylcyclopropanes. The effect of substituents on the site-selectivity of homo-[1,5]-sigmatropic hydrogen migrations

EDWARD PIERS AND ANDERSON RICHARD MAXWELL

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received June 1, 1984

EDWARD PIERS and ANDERSON RICHARD MAXWELL. Can. J. Chem. **62**, 2392 (1984).

Thermolysis of the unsymmetrical vinylcyclopropanes **18**–**24** reveals a notable substituent effect on the site-selectivity of homo-[1,5]-sigmatropic hydrogen shifts. Rearrangement of **18**–**20** (OMe substituent) produces only products **25**–**27**, respectively (H_A migration). In sharp contrast, thermolysis of **24** (Me_3Si substituent) provides exclusively substance **34** (H_X migration). Thermolysis of substrates bearing methyl (**21**, **22**) or phenyl (**23**) groups provide, in each case, mixtures of the two possible products.

EDWARD PIERS et ANDERSON RICHARD MAXWELL. Can. J. Chem. **62**, 2392 (1984).

La thermolyse des vinylcyclopropanes **18**–**24** révèle l'existence d'un effet important des substituants sur la sélectivité du site des transpositions homo-[1,5]-sigmatropiques d'hydrogènes. Les transpositions des produits **18**–**20** (substituant OMe) ne conduisent respectivement qu'aux produits **25**–**27** (migration de H_A). Par opposition, la thermolyse de **24** (substituant Me_3Si) ne conduit qu'à la substance **34** (migration de H_X). Lors de la thermolyse de substrats portant des groupes méthyles (**21**, **22**) ou phényle (**23**), on obtient dans chaque cas des mélanges des deux produits possibles.

[Traduit par le journal]

Reactions involving thermal homo-[1,5]-sigmatropic hydrogen migrations, exemplified by the "parent" transformation **1** → **2** (eq. [1]) (1, 2), are quite well known (3, 4) and have found some use in organic synthesis (5–7). However, studies which have provided information regarding site-selectivity in the thermolysis of unsymmetrical vinylcyclopropanes (**3** → **4** and (or) **5**, eq. [2])[1] have been rare. High site-selectivity in such processes, apart from being of theoretical interest, could have important consequences for synthetic organic chemistry.

Nearly two decades ago, Ohloff (8) reported that thermolysis of compound **6** produces exclusively products which could have arisen only from initial migration of H_A. More recently (9), work in our laboratory showed, *inter alia*, that thermolysis of substrates **7** and **8** provided, as the sole products, compounds **9** and **10** (eq. [3]). Thus, in all three cases (**6**–**8**), only the hydrogen (H_A) not associated with the oxygen substituent underwent migration.

A number of questions come to mind in connection with the conversions outlined in eq. [3]. For example, (a) does the

[1] For the sake of clarity and brevity, the hydrogens migrating from carbons bearing no substituent are designated H_A, while those migrating from carbons containing a substituent are designated H_X (see eq. [2]). This convention is employed throughout this communication.

including aromatic hydrocarbons and olefins (e.g. refs. 16, 17). The 410 nm transient was scavenged by 2,5-dimethyl-2,4-hexadiene with a rate constant of $\sim 1 \times 10^6\ M^{-1}\ s^{-1}$ in acetonitrile at 300 K.

Further laser and product studies, including substituent and solvent effects are currently in progress, in an attempt to elucidate further the mechanisms and kinetics of these reactions.[5]

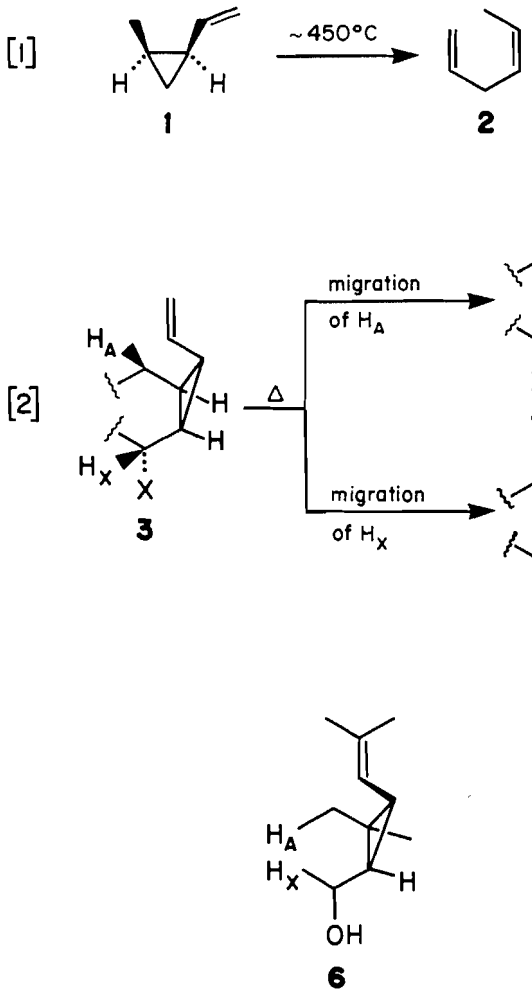
[Traduit par le journal]

Reactions involving thermal homo-[1,5]-sigmatropic hydrogen migrations, exemplified by the "parent" transformation **1** → **2** (eq. [1]) (1, 2), are quite well known (3, 4) and have found some use in organic synthesis (5–7). However, studies which have provided information regarding site-selectivity in the thermolysis of unsymmetrical vinylcyclopropanes (**3** → **4** and (or) **5**, eq. [2])[1] have been rare. High site-selectivity in such processes, apart from being of theoretical interest, could have important consequences for synthetic organic chemistry.

Nearly two decades ago, Ohloff (8) reported that thermolysis of compound **6** produces exclusively products which could have arisen only from initial migration of H_A. More recently (9), work in our laboratory showed, *inter alia*, that thermolysis of substrates **7** and **8** provided, as the sole products, compounds **9** and **10** (eq. [3]). Thus, in all three cases (**6**–**8**), only the hydrogen (H_A) not associated with the oxygen substituent underwent migration.

A number of questions come to mind in connection with the conversions outlined in eq. [3]. For example, (a) does the

[1] For the sake of clarity and brevity, the hydrogens migrating from carbons bearing no substituent are designated H_A, while those migrating from carbons containing a substituent are designated H_X (see eq. [2]). This convention is employed throughout this communication.



conjugated carbonyl function attached to the vinyl moiety of substrates **7** and **8** influence the site-selectivity of the reaction? (b) What is the effect of substituents other than OR? (c) Is the placement of the oxygen atom (e.g. external vs. internal with respect to the ring) a significant factor in determining the site-selectivity of the rearrangement? We report herein some results which relate to questions (a) and (b), while, hopefully, a future report will provide information regarding question (c).

Conversion (9, 10) of the tetrahydropyranyl ether of 2-cyclohexen-1-ol (**11**) into the dibromocyclopropane **16**,[2] followed by reduction (*n*-Bu_3SnH) of the latter substance, gave a mixture of **17** and the corresponding *exo* bromide (ratio 2.3:1, respectively). Chromatographic separation provided (20% from **11**) the required *endo* bromide **17** which, upon subjection to an appropriate sequence of reactions (2 equiv. *t*-BuLi, Et_2O, −78°C; $HCONMe_2$, Et_2O, −78°C → room temperature; $Ph_3P{=}CH_2$, tetrahydrofuran; pyridinium *p*-toluenesulfonate, EtOH, 50°C; NaH, MeI, tetrahydrofuran, reflux) afforded *trans*-2-methoxy-*endo*-7-vinylbicyclo[4.1.0]heptane (**18**). By use of similar, quite straightforward chemical reactions, the alkenes **12**−**15** were converted into the vinylcyclopropanes **19**−**24**.[3]

TABLE 1. Thermal rearrangement of vinylcyclopropanes **18**−**24**[a]

Experiment	Substrate	Product(s) (ratio)	Yield (%)[b]
1	**18**	**25**	80
2	**19**	**26**	90[c]
3	**20**	**27**	90
4	**21**	**28** + **29** (60:40)	—[d]
5	**22**	**30** + **31** (57:43)	96[e]
6	**23**	**32** + **33** (18:82)	87
7	**24**	**34**	90

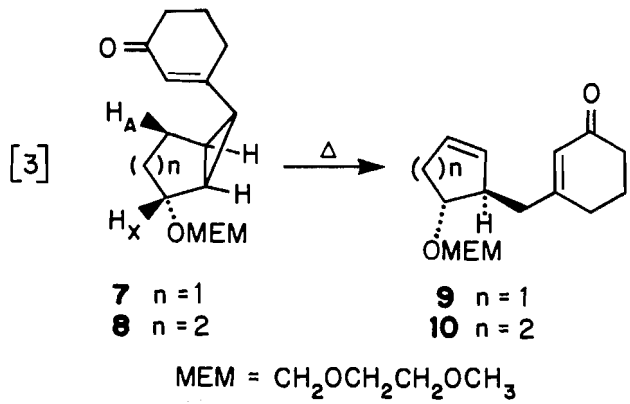
[a]Unless otherwise noted, thermolysis of each of the substrates was performed in benzene solution (230−240°C, 6−8 h) in sealed, base-washed, silylated glass tubes. In each case, the cooled reaction mixture was analyzed directly by gas−liquid chromatography (glc). The benzene was removed, the product(s) was (were) distilled and subjected again to analysis (glc, ^1H nmr spectroscopy).

[b]Unless otherwise noted, yield of isolated, distilled product(s).

[c]Rearrangement was carried out both neat and in benzene solution. The yield is given for the neat experiment.

[d]Rearrangement was performed in C_6D_6. The yield was not determined, but the ^1H nmr spectrum of the cooled thermolysis solution indicated clean rearrangement into two products.

[e]Rearrangement of **22** was accomplished by heating this substance (neat) at 215°C for 15 min.



The results obtained from thermal rearrangement of compounds **18**−**24** are summarized in Table 1. The reactions were, in general, very clean and, for experiments 1−3, we were not able to detect any of the products which would have resulted from migration of H_X in substrates **18**−**20**. In contrast, thermolysis of **24** provided exclusively the H_X migration product **34**. The product pairs obtained from each of experiments 5 and 6 were separated and all four compounds (**30**−**33**) were fully characterized.

Although a detailed discussion of the results given in Table 1 is not appropriate here, a few comments should be made. The results obtained from experiments 1−5, along with those summarized by eq. [3], make it clear that the presence or absence

[2]All compounds reported herein exhibited spectra consistent with assigned structures. New compounds were fully characterized and gave satisfactory molecular mass determinations (high-resolution mass spectrometry). The stereochemical assignments for compounds **16**−**24** are based on a number of considerations, including steric approach control arguments, ^1H nmr spectral data, and chemical correlations with known compounds. Details concerning the stereochemical conclusions (see also ref. 9), as well as complete descriptions of the preparation of substrates **18**−**24**, will be given in a full paper.

[3]For methods involved in the conversion of **12** and **13** into substrates **20** and **22**, respectively, see ref. 9. Alkenes **13** and **14** were prepared by $CuBr{\cdot}Me_2S$ catalyzed coupling (Et_2O, 0°C) of CH_3MgI and C_6H_5MgBr with 3-bromocyclohexene (**A**), while **15** was obtained by the coupling (tetrahydrofuran, 5°C → room temperature) of Me_3SiCl and **A** in the presence of magnesium turnings (ref. 11).

of a conjugated carbonyl group on the vinyl function is not crucial in determining the site-selectivity of the sigmatropic rearrangements. Thus, question (a), above, may be answered negatively. With respect to the effect of substituents, experiments 1–3 show, in agreement with previous results (9) (eq. [3]), that an oxygen-containing group impressively retards the rate of hydrogen migration. On the other hand, a methyl group has very little effect on the site-selectivity of the process (experiments 4 and 5), while a phenyl substituent moderately facilitates the migration of an adjacent hydrogen (experiment 6). In sharp contrast to the OMe group, the Me_3Si moiety markedly enhances the ease of hydrogen migration (experiment 7). Thus, remarkably, thermolysis of the structurally comparable substrates **18** and **24** provides, exclusively, products resulting from migration of H_A and H_X, respectively. Clearly, quite apart from speculation regarding the underlying cause(s) of this site-selectivity, these observations could well be of considerable value in organic synthesis.

Although a definitive rationalization of the results obtained from this preliminary study is difficult, it is tempting to tentatively postulate that in the transition states of these sigmatropic rearrangements, there is an accumulation of electron density ("partial negative charge") at the carbon from which the hydrogen migrates. On this basis, the slight rate-retarding effect of a methyl group and the moderate rate-enhancing effect of a phenyl group (stabilization of negative charge by resonance and (or) inductive effects) can be understood. Furthermore, the ability of the Me_3Si group to stabilize adjacent negative charge is well documented (12). On the other hand, it is more difficult, on the basis of this postulate, to account for the effect of OR groups.[4] However, it seems possible that the transition states which would be involved in the migration of H_X in substrates **7**, **8**, and **18–20** could be destabilized by interaction of the "partial negative charge" on carbon with the lone pairs of electrons on oxygen.

[4]Does an oxygen atom stabilize or destabilize an adjacent negative charge? It appears that the answer to this question is not clear-cut, although evidence suggests that the effect is destabilizing when the carbanion is planar or nearly planar (negative charge associated with a *p* orbital) (13). For other reports related to this general question, see ref. 14.

effect) and the second is the sum of steric and stereoelectronic interactions due to ring closure (enthalpy effect). The synthesis of medium rings is disfavored by the entropy effect (the chain is too long and the number of degrees of freedom is too large) and by severe transannular steric interactions.

In principle, a very simple approach for the synthesis of medium rings is to find a device to restrict the rotational possibilities of the chain (9) and to eliminate transannular steric interactions. A very simple device is to replace two methylene groups of a chain by a double (and (or) triple) bond. This has the effect of diminishing the number of degrees of freedom of the chain and, if more than one double (and (or) triple) bond is used and appropriately located in the chain, it could eliminate at the same time most of the transannular steric interaction. Examination of molecular models indicates that this might well be the case for the 10-membered ring system **2** (Scheme 1) having either double bonds (*cis* or *trans*) and (or) triple bonds. Interestingly, in the cyclization **1** → **2**, there are only six degrees of freedom and space filling models do not indicate severe transannular steric interactions, except for **2** having two triple bonds. The appropriate acyclic ten-carbon precursors **1** were synthesized[4] (Schemes 2 and 3) and the cyclization was

[4]For all new substances, the spectra (ir, 250 MHz and 60 MHz ^1H nmr, ^{13}C nmr, and high resolution mass spectra) were in complete agreement with the assigned structures.

†See ref. 7 for a similar cyclization.

studied at 10^{-2} and 10^{-3} molar solutions, and not high dilution. The results are described in Table 1. Each acyclic precursor **1** gave the corresponding cyclic monomer **2** and dimer **3**, except for the *cis-cis* acyclic case (6) which gave only the cyclic monomer **2**. Even the cyclic monomer **2** (7) having two triple bonds was formed in a reasonable yield. All cyclic compounds are crystalline and it is interesting to notice that the dimerization process yielding the 20-membered ring always competes favorably with polymerization.

In the above cyclization, two of the four carbomethoxy groups of the chain take a pseudo-axial position in the 10-membered ring and this must create additional steric interactions which should disfavor monomer formation. Accordingly, the cyclization of diacetylene **4** (Scheme 1), having only one carbomethoxy group in the middle of the chain, was studied and it was found to give a respectable 70% yield of monomer **5** along with 13% of the corresponding cyclic dimer.

Takahashi *et al.* (4) have recently shown that the intramolecular alkylation of cyanohydrin ethers is an excellent general method for the direct production of 2,6-cyclodecadienones. Previously, Ito and co-workers (3) had demonstrated that the anion-induced cyclization of epoxy-phenyl sulfides was also a convenient and efficient route to macrocyclic germacradienes.

The 10-membered ring is one of the most difficult medium rings to synthesize. The above studies constitute examples (18) that the synthesis of medium and large rings by a simple direct method of cyclization is indeed possible.

The development of new direct methods using various organic reactions for the construction of a large variety of medium and large rings via the above general strategy is now in progress in our laboratory.

syn–anti Stereoselection in the Diels–Alder reactions of spiro[bicyclo[2.2.2]octane-2,1′-[2,4]cyclopentadiene]

D. JEAN BURNELL, H. BRUCE GOODBRAND, STEPHANIE M. KAISER, AND ZDENEK VALENTA
Department of Chemistry, University of New Brunswick, Bag Service #45222, Fredericton, N.B., Canada E3B 6E2

Received May 28, 1984

D. JEAN BURNELL, H. BRUCE GOODBRAND, STEPHANIE M. KAISER, and ZDENEK VALENTA. Can. J. Chem. **62**, 2398 (1984).

No significant differences were found between the *syn* to *anti* adduct ratios established for the Diels–Alder cycloadditions, both thermal and catalysed, of spiro[bicyclo[2.2.2]octane-2,1′-[2,4]cyclopentadiene] (**1**) to a variety of dienophiles. This suggests that, in the *exo* region, the distance between the addends at the transition state is approximately the same in all the cases studied.

D. JEAN BURNELL, H. BRUCE GOODBRAND, STEPHANIE M. KAISER et ZDENEK VALENTA. Can. J. Chem. **62**, 2398 (1984).

On n'a pas trouvé de différences significatives entre les rapports *syn/anti* d'adduits formés lors des cycloadditions de Diels–Alder, thermiques ou catalysées, du spiro[bicyclo[2.2.2]octane[2.4]cyclopentadiène-2,1] (**1**) avec divers diénophiles. Ceci suggère que dans l'état de transition de la région *exo*, la distance entre les produits qui s'additionnent est approximativement la même dans tous les cas étudiés.

[Traduit par le journal]

Frontier molecular orbital calculations by Houk and Strozier (1) showed that secondary attractive interactions are much stronger in Lewis acid-catalysed Diels–Alder reactions than in thermally-induced reactions. Therefore, they reasoned, the transition state of a catalysed reaction could be expected to be "tighter" than that of a thermal reaction; this accounts well for the enhanced *endo* stereoselectivity and chiral induction observed in catalysed reactions. The tight-transition-state hypothesis has been extended to explain the greater *endo* stereoselectivity in the thermal reactions of more reactive dienophiles, such as maleic anhydride and *N*-phenylmaleimide, compared to less reactive dienophiles, such as acrolein and butenone (2). Consistent with this hypothesis, reactions involving more reactive dienophiles and, especially, catalysed reactions have smaller volumes of activation as determined by high-pressure techniques (3).

If the distance between the addends at the transition state decreases as the reaction rate increases, then, with a given plane-nonsymmetrical diene, the more reactive dienophiles should be closer to the source of plane-nonsymmetry at the transition state; consequently, greater *syn–anti* stereoselectivity should be observed with these dienophiles.

Because of its symmetry and the subtle steric difference between its two faces, compound **1**[1] seemed particularly attrac-

[1]The synthesis of **1** will be described in the full paper.

syn–anti Stereoselection in the Diels–Alder reactions of spiro[bicyclo[2.2.2]octane-2,1′-[2,4]cyclopentadiene]

D. JEAN BURNELL, H. BRUCE GOODBRAND, STEPHANIE M. KAISER, AND ZDENEK VALENTA
Department of Chemistry, University of New Brunswick, Bag Service #45222, Fredericton, N.B., Canada E3B 6E2

Received May 28, 1984

D. JEAN BURNELL, H. BRUCE GOODBRAND, STEPHANIE M. KAISER, and ZDENEK VALENTA. Can. J. Chem. **62**, 2398 (1984).

No significant differences were found between the *syn* to *anti* adduct ratios established for the Diels–Alder cycloadditions, both thermal and catalysed, of spiro[bicyclo[2.2.2]octane-2,1′-[2,4]cyclopentadiene] (**1**) to a variety of dienophiles. This suggests that, in the *exo* region, the distance between the addends at the transition state is approximately the same in all the cases studied.

D. JEAN BURNELL, H. BRUCE GOODBRAND, STEPHANIE M. KAISER et ZDENEK VALENTA. Can. J. Chem. **62**, 2398 (1984).

On n'a pas trouvé de différences significatives entre les rapports *syn/anti* d'adduits formés lors des cycloadditions de Diels–Alder, thermiques ou catalysées, du spiro[bicyclo[2.2.2]octane[2.4]cyclopentadiène-2,1] (**1**) avec divers diénophiles. Ceci suggère que dans l'état de transition de la région *exo*, la distance entre les produits qui s'additionnent est approximativement la même dans tous les cas étudiés.

[Traduit par le journal]

Frontier molecular orbital calculations by Houk and Strozier (1) showed that secondary attractive interactions are much stronger in Lewis acid-catalysed Diels–Alder reactions than in thermally-induced reactions. Therefore, they reasoned, the transition state of a catalysed reaction could be expected to be "tighter" than that of a thermal reaction; this accounts well for the enhanced *endo* stereoselectivity and chiral induction observed in catalysed reactions. The tight-transition-state hypothesis has been extended to explain the greater *endo* stereoselectivity in the thermal reactions of more reactive dienophiles, such as maleic anhydride and *N*-phenylmaleimide, compared to less reactive dienophiles, such as acrolein and butenone (2). Consistent with this hypothesis, reactions involving more reactive dienophiles and, especially, catalysed reactions have smaller volumes of activation as determined by high-pressure techniques (3).

If the distance between the addends at the transition state decreases as the reaction rate increases, then, with a given plane-nonsymmetrical diene, the more reactive dienophiles should be closer to the source of plane-nonsymmetry at the transition state; consequently, greater *syn–anti* stereoselectivity should be observed with these dienophiles.

Because of its symmetry and the subtle steric difference between its two faces, compound **1**[1] seemed particularly attrac-

[1]The synthesis of **1** will be described in the full paper.

TABLE 1. Diels–Alder adducts obtained by reaction with **1**

Dienophile	X	Y	Thermal Yield (%)	Thermal Type I/Type II[a]	Catalysed Yield (%)	Catalysed Type I/Type II[a]
Maleic anhydride	—C(=O)—O—C(=O)—		95	86:14	71	90:10
N-phenylmaleimide	—C(=O)—N(Ph)—C(=O)—		100	86:14	98	93:7
1,4-Benzoquinone	—C(=O)—CH=CH—C(=O)—		100	86:14	95	89:11
Dimethyl maleate	CO_2CH_3	CO_2CH_3	80	89:11	—	—
Acrolein	CHO	H	85	86:14	—	—
Methyl acrylate	CO_2CH_3	H	83	88:12	—	—
Butenone	$COCH_3$	H	61	89:11	—	—

[a]Ratios were determined by signal integration in the 360-MHz ^{1}H nmr spectra of adduct mixtures.

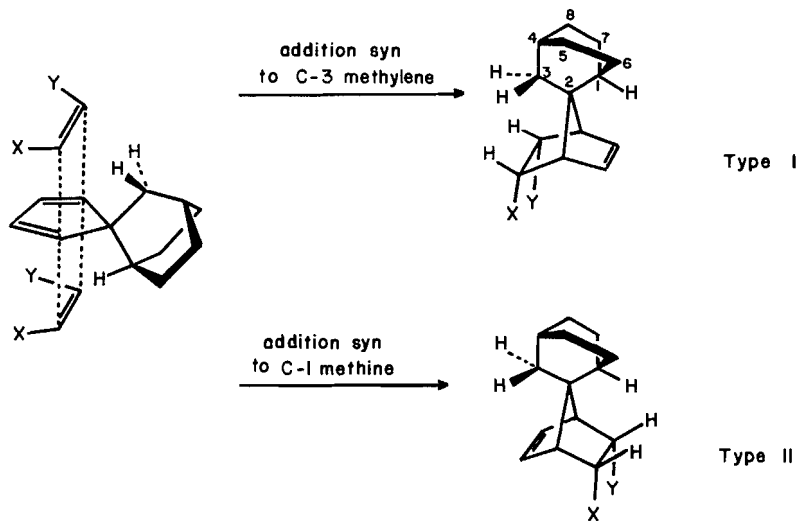

FIG. 1

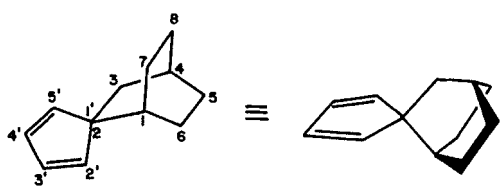

1

tive as a diene substrate with which to test this hypothesis (Fig. 1). Dichloromethane solutions of each of the dienophiles[2] listed in Table 1 were heated under reflux with **1**. Times required for complete reaction varied from a few hours with equimolar amounts of maleic anhydride, *N*-phenylmaleimide, and 1,4-benzoquinone, to a week with more than a forty-fold excess of butenone. Additions of **1** to dichloromethane solutions of three dienophiles, each in the presence of an equivalent of boron trifluoride etherate at −78°C, provided catalysed-reaction products.[3]

Every reaction gave a major and a minor adduct. The major one from the addition of maleic anhydride to **1** was isolated by repeated crystallization. Its Type I structure[4] was proven by irradiating the protons on the carbons α to its carbonyl groups, which resulted in a nuclear Overhauser enhancement of 11% for the signals arising from the protons on C-3 of its bicyclo[2.2.2]octane moiety.[5] Then, a comparison of the relative chemical shifts and the coupling constants of the signals in the 360-MHz ^{1}H nmr spectra of all the reaction products estab-

[2]The dienophiles were chosen to represent a range of reactivity while keeping the potential for steric interaction roughly constant; thus, during cycloaddition, each dienophile projects two hydrogens towards the bicyclo[2.2.2]octane moiety of **1**.

[3]Thermally-induced reaction of **1** with 1,4-benzoquinone proceeds relatively sluggishly at 0°C. However, by quenching the catalysed reaction mixture with an excess of cyclopentadiene, we have shown that, in the presence of the Lewis acid, adduct formation is essentially complete within 30 min at −78°C.

[4]This structure has been confirmed crystallographically by Dr. P. S. White of this Department. Details of this determination will be published in the full paper.

[5]We thank Dr. Thomas T. Nakashima of the University of Alberta for kindly running this experiment.

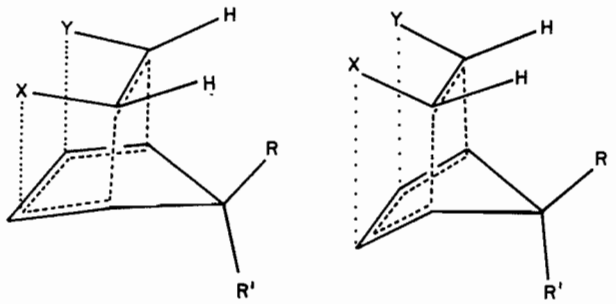

FIG. 2

lished that every major adduct was of Type I and that every minor adduct was of Type II (not an *exo*-addition product).

The Type I/Type II ratios given in Table 1 are very similar,[6] even though the relative rates of reaction must span several orders of magnitude. Steric interactions with the bicyclo-[2.2.2]octane moiety can be assumed to be important at both transition states, because both faces of **1** are much less reactive than cyclopentadiene itself.[7,8] This implies that the difference in steric hindrance between the two faces of **1** is nearly constant, regardless of the reaction rate, which in turn suggests that the relative positions of the sterically interacting groups must be similar in all the reactions summarized in Table 1.

This does not necessarily mean that the tight-transition-state hypothesis is incorrect. This hypothesis was formulated to explain phenomena associated with the *endo* region of a reacting diene. Our results must reflect the geometry of the *exo* region. Refining the hypothesis of Houk and Strozier (1) with the conclusions which we have drawn from our results with **1**, we can postulate a difference in transition-state geometry between a relatively reactive dienophile and a relatively unreactive one as shown in Fig. 2. Thus, in the *exo* region, the two transition states are geometrically very similar. In contrast, in the case of a relatively reactive dienophile, the secondary, ultimately non-bonding, atoms in the *endo* region are significantly closer together at the transition state. As can be appreciated from Fig. 2, the σ-bond-forming carbons of the less reactive system must have more sp^3 character at the transition state because its addends are less planar.[9] Therefore, this system may be regarded as being further along the reaction coordinate (as described by hybridization and not by the distance between the addends). This is in accord with Hammond's postulate (9), and it is still consistent with the volumes of activation data.

[6]The adducts were not formed under equilibrating conditions, as the following results testify. Heating a dichloromethane solution of the above-mentioned pure Type I adduct under reflux for many hours failed to produce a mixture of Type I and Type II adducts. Furthermore, the *N*-phenylmaleimide adducts of **1** did not equilibrate with cyclopentadiene; neither did the 1,4-benzoquinone adduct of cyclopentadiene equilibrate with **1**.

[7]This was established by competitive experiments. 5,5-Dimethylcyclopentadiene is also much less reactive than cyclopentadiene (4).

[8]Recent studies (5, 6) have demonstrated that hyperconjugation can be important in controlling *syn*−*anti* stereoselection. Certain resonances in the ^{13}C nmr spectrum of **1** are significantly upfield of their expected positions (in $CDCl_3$, C-1 at δ 31.4 and, more significantly, C-3 at δ 28.9), which may be symptomatic of appreciable hyperconjugation of various σ-orbitals of the bicyclo[2.2.2]octane moiety with the diene π-orbital(s). At present, it is uncertain whether hyperconjugative effects in **1** are strong enough to modify the *syn*−*anti* stereoselectivity. We are investigating this possibility.

[9]*Ab initio* calculations of the butadiene plus ethylene system have shown that there is considerable sp^3 character for the reacting carbons at the transition state (7, 8).

Mechanistic variation in the reactions of substituted acetamides in aqueous sulfuric acid

LINDA M. DRUET AND KEITH YATES[1]

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received February 8, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

LINDA M. DRUET and KEITH YATES. Can. J. Chem. **62**, 2401 (1984).

The acid-catalyzed reactions of acetamide **1**, *N-tert*-butylacetamide **2**, and several *p*-substituted *N*-benzylacetamides (**3** = H, **4** = CH_3, **5** = OCH_3, **6** = Cl, **7** = NO_2) have been studied as a function of acidity and temperature over a wide range of aqueous sulfuric acid solutions (0–91%). Analysis of the reaction products and rate–acidity profiles revealed that four different mechanisms are operative over different acidity regions depending on the structure of the substrate. These are: two A-2 hydrolysis mechanisms with *N*-acyl fission of the substrate (with participation of one or several water molecules in the rate-determining step); A-1 hydrolysis with *N*-alkyl fission; and sulfonation, followed by hydrolysis. These conclusions are supported by three complementary and detailed kinetic treatments based on the hydration parameter, transition state activity coefficient, and excess acidity approaches. The acidity domains of each mechanism have been established for each substrate. The mechanistic conclusions are fully supported by the different values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ obtained in different regions of acidity.

LINDA M. DRUET et KEITH YATES. Can. J. Chem. **62**, 2401 (1984).

Opérant avec des solutions aqueuses d'acide sulfurique à des concentrations variant de 0 à 91%, on a étudié les réactions acido-catalysées de l'acétamide (**1**), du *N-tert*-butylacétamide (**2**) et de plusieurs *N*-benzylacétamides substitués en *para* (**3** = H, **4** = CH_3, **5** = OCH_3, **6** = Cl, **7** = NO_2) en fonction de l'acidité et de la température. Une analyse des produits de réaction ainsi que des courbes reliant les vitesses de réaction et l'acidité révèle que, suivant la nature du substrat, quatre mécanismes différents peuvent intervenir dans diverses régions d'acidité. Il s'agit de: deux mécanismes d'hydrolyse de type A-2 impliquant une rupture *N*-acyle du substrat (avec la participation d'une ou de plusieurs molécules d'eau dans l'étape déterminante); une hydrolyse de type A-1 impliquant une rupture *N*-alkyle; et une sulfonation suivie d'une hydrolyse. Ces conclusions sont en accord avec trois études cinétiques complémentaires et détaillées et qui sont basées sur des approches reliées au paramètre d'hydratation, au coefficient d'activité de l'étape déterminante et aux acidités en excès. Pour chacun des substrats, on a établi les domaines d'acidité associés à chacun des mécanismes. Les différentes valeurs de $\Delta H^{\ddagger}$ et de $\Delta S^{\ddagger}$ obtenues dans diverses régions d'acidité supportent bien les conclusions relatives aux mécanismes.

[Traduit par le journal]

Introduction

Most studies of amides in aqueous acid solution involve the normal acid-catalyzed hydrolysis process (1). In recent years, supporting evidence has appeared for the component processes of this mechanism, including pre-equilibrium oxygen protonation of the amide (2), and subsequent formation of a tetrahedral intermediate via nucleophilic attack by water molecules (3). The ^1H nmr results indicate that the accompanying proton exchange process, postulated to occur via a very small concentration of the *N*-protonated species (4), is consistent with the currently accepted hydrolysis mechanism, shown in eq. [1]. (In eq. [1] the number of water molecules involved in the rate-determining step is designated by *r*. Hydration of the various species by water molecules is not shown.)

The possibility of other types of amide hydrolysis in aqueous acid media has been considered by a few workers. The results of limited temperature, rate, and product studies on *N-tert*-alkylamides have suggested unimolecular *N*-alkyl cleavage of the *N*-protonated amide, shown in eq. [2] (5) although a similar A-1 scission of the predominant *O*-protonated form, to give initially the imido form of the product, cannot be ruled out. Temperature, rate, and substituent studies of nitro-substituted acetanilides led to the proposal (6) of unimolecular *N*-acyl cleavage of the protonated amide at high acid concentrations, as in eq. [3]. Acetanilide derivatives, and benzamides containing electron-donating ring substituents, have been shown to form sulfonated products, which subsequently undergo unimolecular hydrolysis (eq. [4]).

[1] $R'-C(=O)-NHR \underset{(fast)}{\overset{1/K_{AH^+}}{\rightleftharpoons}} R'-C(=OH^+)-NHR$

$R'-C(=OH^+)-NHR \xrightarrow[(slow)]{rH_2O} R'-C(OH)(OH_2^+)-NHR \xrightarrow{fast} R'-C(=O)-OH + RNH_3^+$

More recently, acid-catalysed hydrolyses of acylpyrroles have been shown to involve S_E2 mechanisms rather than typical A2 processes (7). It is thus evident that amide chemistry in aqueous acids does not always consist solely of a relatively straightforward hydrolytic process.

To investigate these possibilities further, the kinetic study reported here was undertaken. This involved acetamide **1**, *N-tert*-butylacetamide **2**, and a series of *N-para*-substituted benzylacetamides **3**–**7**. For these compounds, the occurrence of unimolecular *N*-alkyl fission would result in carbonium ions with varying degrees of inductive and resonance stabilization.

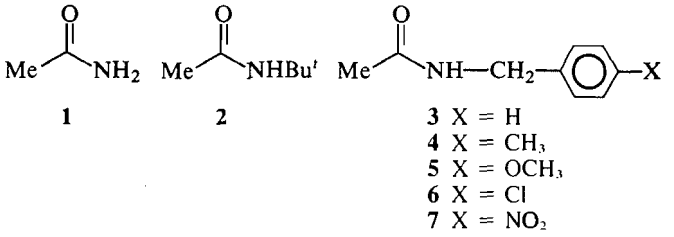
Since the *N*-benzyl substituents used range from strongly electron withdrawing to electron donating, their ability to form sulfonated products should also vary significantly. Acetamides were chosen to obviate possible complications from concurrent acylium ion formation.

Kinetic models currently used for analysis of amide hydrolysis data include the r (8) or ϕ (9) hydration parameter treatments, the transition state activity coefficient approach (10), and the excess acidity treatment (11). The theoretically linear hydration parameter plots are not obtained experimentally for amides. Actual plots for normal bimolecular hydrolysis are gently curved (3*b*, 3*c*, 9, 12). One proposed interpretation is medium variation of the activity coefficient ratio, log $(f_{SH^+}/f_{S^\ddagger_{p+r}})$ where, by conventional notation, f_{i_h} is a hydration activity coefficient and the subscript h is the species' average hydration number. Another explanation considered is a decrease in hydration number of the transition state with increasing acidity and therefore the occurrence of more than one individual rate process (3*c*, 12*c*). An explanation invoking more than one distinct reaction has also been used for substituted acetamides whose hydration plots show sharply changing curvature. This is consistent with a mechanistic change from a bimolecular to a unimolecular process at high acidities (6*e*, 6*f*).



The shape of transition state activity coefficient (TSAC) plots (13) for amides closely parallels the shape for normal bimolecular ester hydrolysis (14), as is expected from the normal amide hydrolysis mechanism. The plot for β-lactam hydrolysis (13*c*) is similar to that for acylium ion formation in ester hydrolysis (15) and different from that for the proposed S_N2-like displacement process for acid-catalyzed oxygen exchange in methanol (16). It is therefore clear that the TSAC plots can provide evidence of diverse amide reaction mechanisms.

Application of the excess acidity treatment of rate data (11*b*, 17) to normal bimolecular amide hydrolysis has shown (18) that a gradual change of mechanism can occur. The observed rate constant can be dissected into two components, involving three water molecules in the rate-determining step in dilute acid, and one water molecule in more strongly acidic solutions. This treatment has yet to be applied to analysis of rate data which indicate abnormal amide behaviour in aqueous acids.

Experimental

Reagents

Sulfuric acid solutions were prepared by diluting CIL reagent grade sulfuric acid (≥95.5% w/w)[2] and were standardized either by titration against standard sodium hydroxide solution or by densitometry (Anton Paar Model DMA-02C). Perchloric acid solutions were prepared by diluting Fisher Reagent A.C.S. perchloric acid (≥70% w/w)[2] and acids were standardized by titration against standard sodium hydroxide solution.

Commercially available **1** was recrystallized from acetone. Compound **2** was prepared by adding acetyl chloride (136 mL) to a cooled solution of *tert*-butylamine (200 mL) in chloroform (400 mL). After filtration of *tert*-butylamine hydrochloride and subsequent solvent evaporation, the crude product was isolated and recrystallized from hexane to yield white crystals, mp 98.0–99.5°C (lit. (19) mp 97–98°C).

[2] All percentage acid values referred to subsequently are in w/w.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

The Schotten–Baumann procedure (20) was used for the preparation of **4**, **6**, and **7**. In each case, recrystallization from toluene and hexane gave white crystals having melting points in good agreement with literature values (21).

Due to their low water solubility, **3** and **5** were prepared by a nonaqueous route. A solution of acetyl chloride (9.8 mL, 0.092 mol) in chloroform (15 mL) was slowly added to an ice-cooled solution of the appropriate benzylamine (20 mL, 0.18 mol) in chloroform (50 mL). After filtration, isolation of the crude product by solvent evaporation, and recrystallization from toluene and hexane, white crystals were obtained whose melting point agreed well with literature values (21*b*, 22). Chromatographic and elemental analyses were used to check the purity of all the amides.

Reaction products

A detailed ^{1}H nmr product study in 5.00–91.50% H_2SO_4 was carried out. For **2**, **3**, **4**, and **5** this involved a comparison of the ^{1}H nmr spectra of aqueous acid solutions containing reacted or unreacted amide both before and after addition of acetamide, acetic acid, ammonium sulfate, and the appropriate amine. For the *p*-methyl-, *p*-methoxy-, and unsubstituted benzylamines and benzyl alcohols, as well as for *tert*-butylamine and *tert*-butyl alcohol, the study involved ^{1}H nmr monitoring of aqueous acid solutions heated under the reaction conditions.

Nuclear magnetic resonance kinetic methods

The ^{1}H nmr chemical shifts of the amide (—*NH*C(O)—), phenyl, and methylene (—CH_2C(O)—) peaks of substituted *N*-benzylacetamides are acidity dependent. At lower acidities the amide, phenyl, and (or) methylene signals are obscured by the water peak, and kinetic measurements involved monitoring of the acetyl methyl signals of the substrate and product acetic acid. Above 82% H_2SO_4 the rate of change from the phenyl singlet of the substrate to that of the corresponding *N*-benzylammonium ion was measurable. The acetyl methyl signal of acetic acid was nearly coincident with that of the substrate at high acidities, necessitating either monitoring the phenyl region or utilization of expanded sweep widths for kinetic measurements. This chemical shift information is summarized in Table 1, which indicates which ^{1}H nmr signals were used for all kinetic measurements.

Three kinetic methods were employed, depending on the stability of the amide and its reactivity in a given aqueous acid. The standard quenching technique involved heating (thermostated oil bath) for recorded times an aqueous acid solution of the amide using sealed, thick-walled ^{1}H nmr tubes as reaction vessels, discontinuing timing when the tubes were removed from the bath and cooled for ^{1}H nmr analysis, and resuming timing upon return to the bath. A Varian T-60 or EM360 spectrometer was used for the analysis. The standard technique was generally employed except for special cases requiring one of the two *in situ* techniques.

In the *in situ* technique for faster reactions, one sealed glass insert containing D_2O and DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) was placed in the bottom of each cooled aqueous acid solution of the amide in regular ^{1}H nmr tubes, which were subsequently sealed. The probe of a Varian XL-100 nmr spectrometer was tuned at reaction temperature using one sample tube which was then quickly replaced by another, with concurrent starting of a timer and recording of peak integrals. In most cases the time required to reach probe temperature (1–3 min) was negligible in terms of the rate of reaction being studied. For the faster reactions, only the integrals obtained from solutions which had reached probe temperature were used to calculate k_ψ values. This procedure was used for following hydrolysis of **1** at 60.0 and 76.9°C in acidities near the maximum of the rate profile, and for hydrolysis of **4** at 60°C in ≥82.5% H_2SO_4 and at 76.9, 87.0, and 92.0°C in 77.7% H_2SO_4.

In the technique used for sparingly soluble amides, ca. 10^{-4} mol of amide and 0.5 mL of aqueous acid were stirred with a glass plunger in a regular ^{1}H nmr tube. A sealed glass insert (D_2O/DSS) was added to each tube, which was then sealed and cooled. One sample tube was inserted into the Varian XL-100 probe for instrument tuning and timing was begun. Peak integrations were obtained at recorded times. Dissolution of the amide was considered to be complete when the ratio of the peak heights of the total acetyl methyl signals (starting material plus product) to the peak height of the methyl signal of DSS from the insert was constant. This method was used to follow the hydrolysis of **6** and **7** in acidites up to 25% H_2SO_4.

With all three methods, 0.125–0.500 *M* amide solutions were employed. Reactions were followed for at least one, and usually two, half-lives. For the amides analyzed by the first two methods, duplicate or triplicate runs were carried out. Kinetics determined by the *in situ* technique for sparingly soluble amides were not generally performed in duplicate, therefore many nmr integrations were obtained to compensate for this. Good pseudo-first-order rate constants (correlation coefficients ≥0.990) were obtained from plots of ln([Pd] + [SM]/[SM]) vs. time, where [SM] and [Pd] are the nmr integral heights of a starting material peak and the corresponding product peak at time *t*. The standard deviations were generally better than ±10%, indicating good results within the limitations of the ^{1}H nmr method. Reduced precision in a few cases was due to either the low substrate concentrations used for sparingly soluble amides, or the short times involved in the case of the fastest reactions of **2**. In some cases, proximity of the monitored peaks of starting material and product also reduced the precision.

Hydration parameter plots[3]

The *r* treatment (8) involves plotting log k_ψ, the logarithm of the protonation-corrected rate constant, versus log a_{H_2O}. As shown in eq.

[5], log k_p may be defined in terms of the ionization ratio, $I = [SH^+]/[S]$.

$$[5] \quad \log k_p = \log k - \log \frac{[SH^+]}{[SH^+] + [S]} = \log k - \log \frac{I}{I + 1}$$

Temperature-corrected I values were obtained using the excess acidity equation: $I = \text{antilog}\,(m^*X + pK_{AH^+} + \log [H^+])$ (17). Temperature-corrected X values, X_T, were obtained using eq. [6] (17). Temperature-corrected values of log $[H^+]$ were kindly supplied by Dr. R. A. Cox

$$[6] \quad X_T = X\left(\frac{298.15}{(273.15 + T)}\right)$$

(17*a*). Water activities in mole fraction units were available at any temperature by the method of Giauque *et al.* (23). These were later converted via the densities (24) to the molarity units typically used in the excess acidity plots.

Substrate activity coefficients

For the dilute solutions employed, values of D_0 and D_s, the distribution coefficients with water and the aqueous acid solution, respectively, were used to obtain medium effect activity coefficients, f_i, by eq. [7].The distribution coefficients for acetamides at 25°C in

$$[7] \quad f_i = \frac{D_0}{D_s}$$

chloroform/aqueous sulfuric acid mixtures were obtained by the nmr method outlined by McClelland (10*c*). These experimental activity coefficients were not corrected for the extent of protonation of substrate and the symbol f_i was therefore replaced by the more appropriate symbol $f_{([SH^+]+[S])exp}$. These values of $f_{([SH^+]+[S])exp}$ for **2**, **3**, **5**, and **6** were fitted to a polynomial expression of n terms ($y = a_0 + a_1 + a_2x^2 + \ldots + a_nx^n$). Activity values at any acidity were then available by interpolation. However, the validity of the polynomial expression was limited to acidities at most 5% higher than the highest acidity in which experimental values were obtained. For the four amides listed above, the highest acidity used for f_i measurements was 60.3%, 46.0%, 52.4%, and 46.0% H_2SO_4, respectively.

Transition state activity coefficients

As previously reported (10*c*), protonation corrections for the transition state activity coefficient, $f_{S^\ddagger}$, and the experimental activity coefficients f_i were unnecessary in the $f_{S^\ddagger}$ calculation through use of eq. [8]. Hydronium ion activities $a^*_{H^+}$ relative to tetraethylammonium ion are

$$[8] \quad \log f_{S^\ddagger} - \log k_0 = \log a^*_{H^+} + \log f_{([SH^+]+[S])exp} + pK_{AH^+} - \log k$$

available (10*a*). The rate constants for the four substrates (**2**, **3**, **5**, and **6**) were expressed at 25°C using plots of k_ψ vs. log a_{H_2O} (a_{H_2O} in molarity units) at several temperatures. For each water activity used in eq. [8] activation parameters were calculated and used to give k_ψ values at 25°C. The log k_0 values are intercepts of plots of % H_2SO_4 vs. the right-hand side of eq. [8]. Estimates of log $f_{S^\ddagger}$ were obtained by substitution of the other quantities into eq. [8].

Excess acidity treatment

Application of this treatment to rate data (11*b*, 18, 25) for each amide involved curve fitting, to give the optimum combination of two kinetic equations for the component processes. The analysis for **7** used equations for a single reaction temperature (76.9°C) (11*b*). Data for the other substrates were available at three or four temperatures (60, 76.9, 87.0, and 92.0°C) and the component kinetic expressions for these reactions required simple modifications which have been previously reported (11*b*, 18, 25). This modified treatment was used in the analysis of the rate data for **1**, **5**, and **6**.

The kinetic data for **4** and **5** at one temperature (76.9°C) and that for **3** at four temperatures (60.0, 76.9, 87.0, and 92.0°C) were fitted to a combination of equations for three component processes. For each substrate the optimum combination of kinetic expressions was identified by the fact that it gave the smallest root-mean-square error and standard deviation of all tested combinations.

Activation parameters

Two methods were used. The first (26) was a simple least-squares analysis of eq. [9], where h and k are the Planck and Boltzmann constants. It involved plotting ln (k/T) vs. $(1/T)$ at either constant acidity or water activity.

$$[9] \quad \ln k/T = \ln k/h + \Delta S^\ddagger/R - \Delta H^\ddagger/RT$$

Activation parameters at constant water activity (11*c*) were required for calculations of $f_{S^\ddagger}$. In this case temperature corrected values of log a_{H_2O} were used to obtain interpolated rate constants at 25°C for every value of log a_{H_2O} in which activity coefficients had been measured. The second method involved the excess acidity treatment for the five substrates for which kinetic data at several temperatures had been obtained. Solutions for the optimum kinetic expressions resulted in standard state activation parameters for the component processes along with standard state rate constants.

Results and discussion

Analysis of the complex behaviour of these seven acetamides in aqueous sulfuric acid required thorough product studies, which were performed under typical reaction conditions. In 5–80% H_2SO_4 **1**, **6**, and **7** were observed to form only the normal hydrolysis products, acetic acid and either ammonium ion in the case of acetamide hydrolysis or the corresponding *N*-benzylammonium ion in the case of the two latter amides. For the *p*-chloro compound another reaction product was observed and became the exclusive reaction product above 90% H_2SO_4. The peak signalling this new product was the distinctive ^1H nmr signal of ammonium ion (27). Under the reaction conditions, it must arise from normal acid-catalyzed hydrolysis of acetamide. The acetamide, in turn, must have come from *N*-alkyl cleavage of **6**. A unimolecular *N*-alkyl cleavage of the protonated amide is therefore postulated.

For the three other *N*-benzylacetamides (**3**–**5**) the normal hydrolysis products were found to be gradually replaced by *N*-alkyl cleavage products in moderately concentrated sulfuric acid solutions. The acidity at which normal hydrolysis products ceased to form varied from 82.5% to 63.75% to 52.4%, in these three cases, and *N*-alkyl cleavage products were formed in 63.75–87.35%, 60.3–87.7%, and 34.7–73.5% H_2SO_4, for **3**, **4**, and **5** respectively. It is clear that the amide producing the most stable *para*-substituted benzyl carbonium ion shows the onset of *N*-alkyl cleavage in the lowest acidity.

Precipitates were often found to accompany the *N*-alkyl cleavage process. For the reaction of **5** in 73.5% H_2SO_4, the crude material was isolated and the ^1H nmr spectrum in $CDCl_3$/TMS exhibited multiplets at δ 3.63–3.76 and δ 6.61–7.06 with integrals in the ratio 5:3. *p*-Methoxybenzyl alcohol subjected to the same conditions gave identical results, suggesting that dimerization of two molecules to form the ether has occurred in both cases. The precipitate formed by reaction of the amide or alcohol in lower acidities exhibited multiplets with similar chemical shifts and integrals in the ratio 5:4, a value which is in accord with a product resulting from polymerization of more than two molecules. Formation of this polymeric product is analogous to the result from N—C bond fission of *N*-benzylarylsulfonamides with concentrated sulfuric acid (28).

A third reaction pathway was indicated by the formation of other reaction products; the lowest acidity in which these were observed was 83.5%, 79.0%, and 79.0% H_2SO_4 for **3**, **4**, and **5** respectively. Formation of this product was detected by com-

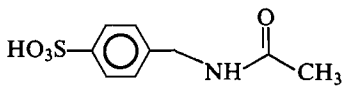
For personal use only.

parison of the ^1H nmr spectra of unreacted and completely reacted **3** in concentrated sulfuric acid. The product exhibits an amide NH signal, phenyl multiplet, methylene doublet, and acetyl methyl singlets. This and the integration support a ring-monosulfonated benzylacetamide as in **8**. Additional support for an amide product was obtained by dilution of the solution with water and subsequent heating. The resultant spectrum indicated acetic acid and a substituted *N*-benzylammonium ion, the expected products from normal amide hydrolysis of **8**. The nmr peaks due to the substituted *N*-benzylammonium ion were similar to those obtained from heating a solution of benzylamine in concentrated sulfuric acid.



8

Sulfonation reactions of benzene and toluene under similar reaction conditions are well known (29). Several phenyl-substituted amides have been found to sulfonate (6*d*) in more concentrated sulfuric acid solutions, but acetanilide reacts similarly in acidities as low as 70% w/w H_2SO_4 (30). In addition, sulfonation in all acidities greater than 40% H_2SO_4 occurs with 4-chloro-*N*-phenylbenzamide and *N*-benzyl-4-chlorobenzamide (31).

A summary of the more complex results is shown in Fig. 1, which includes results for **1**. Identification of *tert*-butylamine, which results exclusively from normal hydrolysis of this amide, was possible only at 5.1% H_2SO_4, partly due to the coincidence of amine and amide methyl signals, as indicated in Table 1. Products due to *N*-alkyl cleavage were more easily identified: *tert*-butyl alcohol in acidities up to 72.8% H_2SO_4 and acetamide in 54.8–91.5% H_2SO_4. Appearance of the latter in lower acidities is obscured due to coincidence of its acetyl methyl peak with that of the substrate. Structures shown in brackets in Fig. 1(d) are those whose presence can only be inferred from the nmr spectra, due to coincidence of ^1H nmr signals in the case of acetamide and *tert*-butylamine or subsequent reaction in the case of *tert*-butyl alcohol.

Kinetics

For all seven substrates reaction rates were measured via ^1H nmr spectroscopy in dilute to concentrated sulfuric acid solutions. With the exception of **7** (76.9°C) and **1** (60.0, 76.94, 87.0°C), rates were generally measured at four reaction temperatures (60.0, 76.94, 87.0, and 92.0°C). Since the acid concentration is effectively constant in these solutions, good pseudo-first-order rate constants *k* were obtained from the standard analysis (ref. 26, pp. 230–232) of the data. The rate–acidity data obtained at 76.9°C are plotted in Fig. 2.[4]

The rate profiles exhibit four types of acidity dependence. For **1**, as well as for **6** and **7**, there is a rate maximum at intermediate acidities followed by a very slow reaction in more concentrated acids. For **3** and **4**, there is a rate maximum at intermediate acidities, followed by a sharp increase in rate in more concentrated acids. For **5**, there is the normally observed rate maximum at intermediate acidities followed first by a local

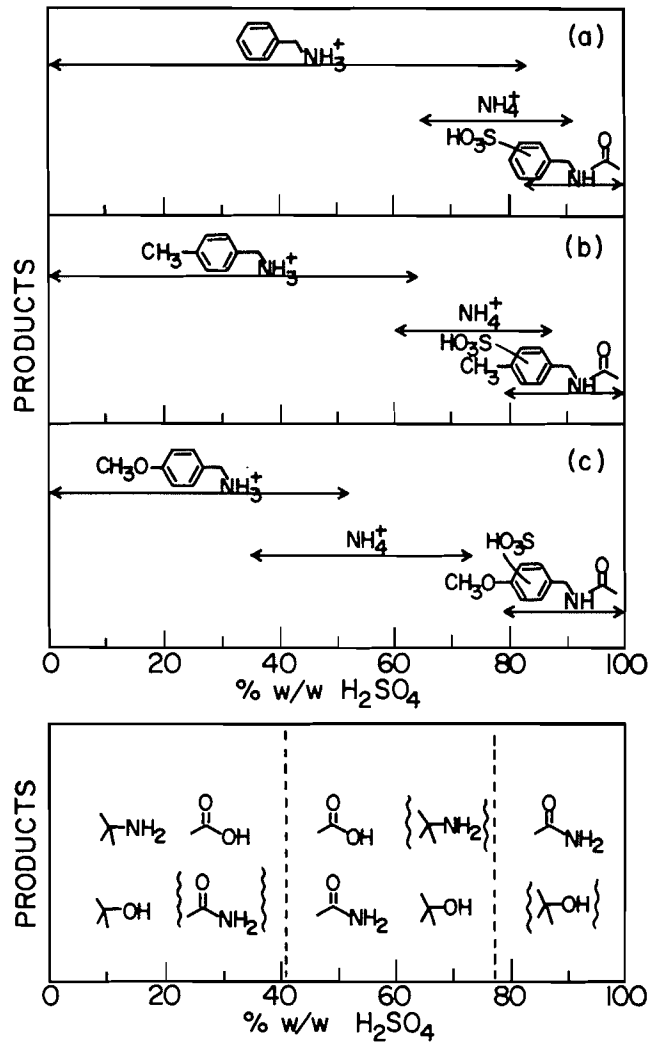


FIG. 1. Product ranges in aqueous acid for the reactions of **3** (a), **4** (b), **5** (c), and **2** (d). In (d) the presence of products shown in brackets is inferred from other products initially formed (see text).

minimum, second by a second local rate maximum at higher acidities, and finally by a sharp increase in rate in the most concentrated acids. Only for **2** is there a monotonic increase in reaction rate with increasing acid concentration.

Several interesting features are shown in Fig. 2. Firstly, the position of the rate maximum for **1** (ca. 22% H_2SO_4) agrees with other reports (12*e*). Secondly, the decreased reactivity of the secondary amides at low acidities relative to that of acetamide is striking but not completely unexpected (12*c*, 12*e*). Thirdly, the double rate maximum in the profile for **5** is a phenomenon unique to this amide. A study of the reactivity of this substrate in aqueous perchloric acid also resulted in a profile which exhibited two local rate maxima. Fourthly, the rate profile for **2** agrees well with earlier work (5*a*, 5*b*). This is the only substrate exhibiting a continuous increase in k_ψ with increasing acidity, with no indication of the typical bell-shaped profile normally found for acid-catalyzed amide hydrolysis.

On the basis of the product studies, it appears that the diversity in these rate profiles is due to at least three types of acid-catalyzed reaction. These include normal bimolecular amide hydrolysis, unimolecular *N*-alkyl cleavage to give a substituted carbonium ion and acetamide (which subsequently hydrolyses), and electrophilic aromatic substitution to give a

[4] Values of the measured pseudo-first-order rate constants for all seven substrates are in tables of supplementary material which are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

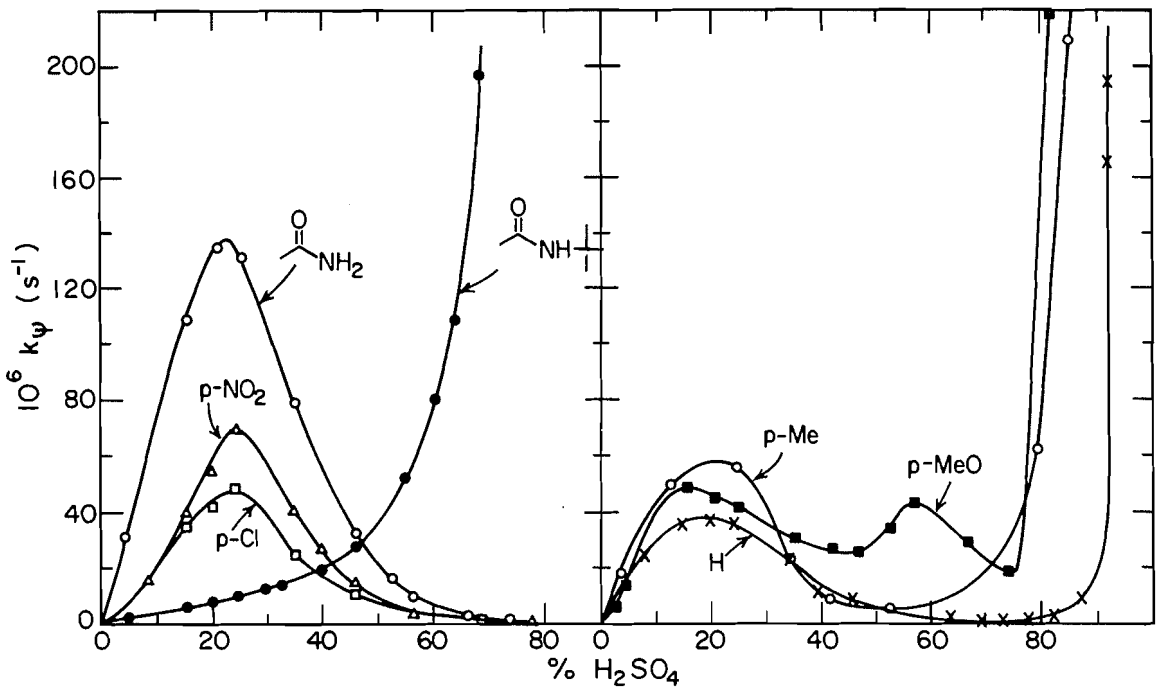

FIG. 2. Rate–acidity profiles for the reactions of acetamide (**1**), *N-tert*-butylacetamide (**2**), and substituted benzylacetamides (**3**–**7**). (all k_ψ measured at 76.9°C, except for **1** at 50.0°C.)

monosulfonated *N*-benzylacetamide. The question arises as to whether these quite different rate–acidity dependences can be treated quantitatively by a uniform approach. The results of three standard kinetic treatments will be presented in an attempt to answer this question, but first the acid dissociation constants of these amides must be considered, since they are needed for all three quantitative analyses.

Acid dissociation constants pK_{AH^+}

Accurate pK_{AH^+} values were obtained by application of the excess acidity method to ^1H chemical shifts of the substrates (16*b*). Differences in δ between pairs of well-spaced protons were employed. There was usually only one suitable set of values for each acetamide due to interference by solvent peaks. A curve-fitting computer analysis gave pK_{AH^+} values at absolute temperatures T_1 and T_2, respectively. Equation [10] assumes that the standard state enthalpy for the acid-dissociation

$$[10] \quad (pK_{AH^+})_2 = (pK_{AH^+})_1 \cdot \frac{T_1}{T_2}$$

reaction is essentially temperature independent. Any error introduced by this assumption should not significantly affect the present kinetic analysis.

The results are shown in Table 2. The trends in four of the pK_{AH^+} values are reasonable, in terms of substituent effects. The anomalously low value for the *p*-methyl compound may be attributable to difficulties encountered in the nmr measurements used for its pK_{AH^+} determination. *N-tert*-butylacetamide with $pK_{AH^+} = -0.41$ is the strongest base of all six amides, as intuitively expected. This was in good agreement with previously reported values for this amide (32).

r *Hydration parameter plots*

Equation [11] for the modified *r* hydration parameter treatment (7, 11*b*) states that if acidity is defined in terms of a function H_s which is strictly appropriate to the type of substrate

$$[11] \quad \log k_p = \log k + H_s = r \log a_{H_2O} + \text{constant}$$

being investigated, the slope of a plot of log k_p vs. log a_{H_2O} should correspond to the average number of water molecules required to convert a protonated substrate molecule to transition state. This is supported by the *r* plots obtained for **1** and **7**, which react solely via normal bimolecular (A-2) hydrolysis. As Fig. 3 shows, an initially steep dependence on water activity gradually changes above 50% H_2SO_4 to a much shallower dependence. This type of behaviour has been observed with other amides (12*c*).

A generally similar result was obtained with **6** up to the high acidity region where a negative curvature is evident. (This is more pronounced in the *r* plots constructed from the data for this substrate at higher temperatures.) Such curvature is in sharp contrast with that for normal A-2 amide hydrolysis (e.g. the published *r* plot of benzamide extends to 80% H_2SO_4 and has a positive curvature throughout (33).) Similar negative curvature in *r* plots for ester hydrolysis (34) has been associated with unimolecular (A-1) cleavage. For the *p*-chloro compound

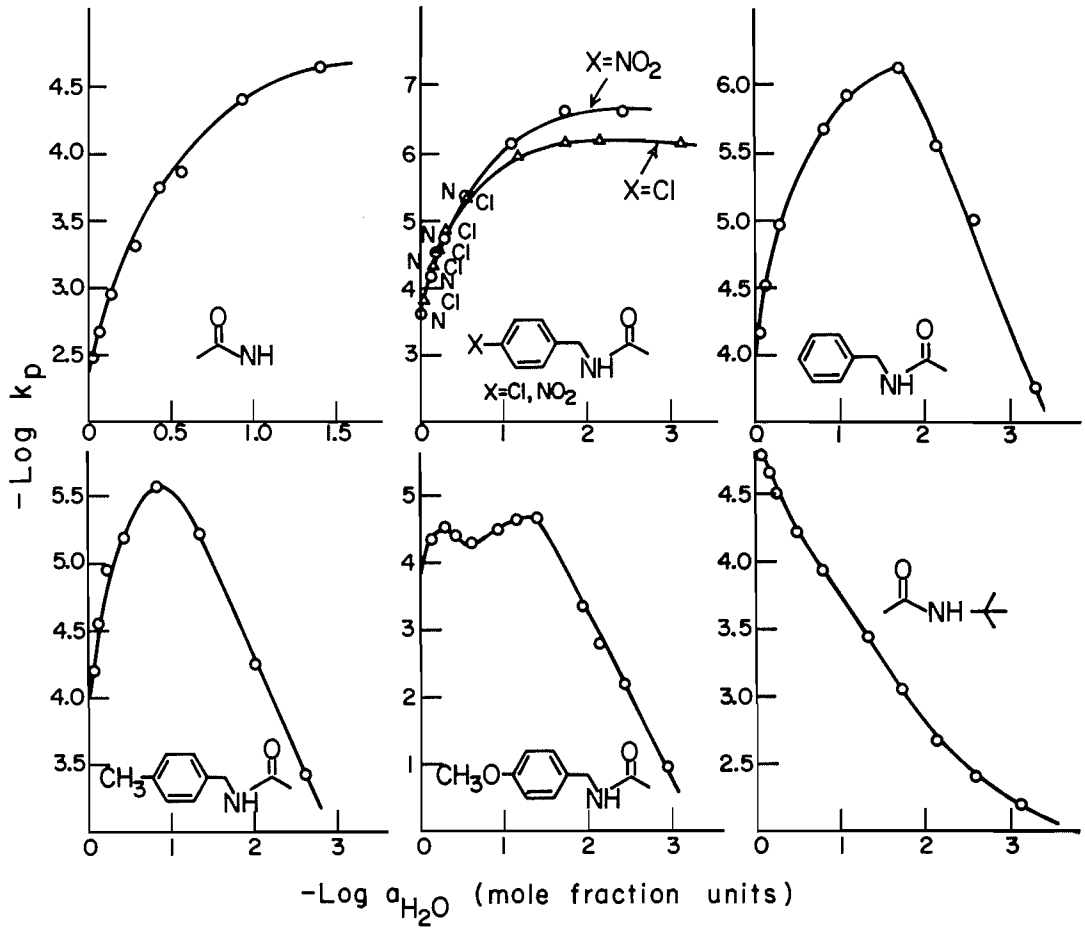

FIG. 3. r Hydration parameter plots of log k_ψ vs. log a_{H_2O} (see text) for substrates **1**–**7** at 76.9°C.

a unimolecular process is consistent with the *N*-alkyl cleavage indicated by the product study in higher acidities.

For **3** a water activity dependence typical of normal amide hydrolysis is observed up to 80% H_2SO_4 although typical hydrolysis products form exclusively only up to 60% H_2SO_4, where *N*-alkyl cleavage products begin to appear. The r plot in 60–80% H_2SO_4 apparently describes a combination of the normal hydrolyses of **3** and **1**, the latter having resulted from fast, prior *N*-alkyl cleavage of **3**. The strongly negative curvature above 80% H_2SO_4 markedly resembles the negative dependence found for *tert*-butyl acetate and *p*-methoxybenzyl acetate hydrolyses (34), for which A-1 reactions are the dominant processes at all acidities. (The sulfonation of **3** is probably a pseudo-first-order process also occurring in this acidity region.)

For **4**, the r-plot curvature expected for normal hydrolysis extends to 63.75% H_2SO_4. Above this acidity the onset of negative curvature indicates unimolecular *N*-alkyl cleavage, which is overtaken above 79% H_2SO_4 by sulfonation.

The sixth r plot in Fig. 3 exhibits a series of unique, sharp changes in slope. The gradually decreasing, positive curvature of the r plot for **5** indicates normal A-2 hydrolysis up to 40% H_2SO_4. The next two changes of slope, the negative curvature of a unimolecular process followed by the positive curvature of normal hydrolysis, may be explained by noting that the k_ψ values obtained by monitoring the acetyl methyl region were influenced by normal hydrolysis and *N*-alkyl cleavage, with each process influencing k_ψ to differing extents, depending on the acidity. In low acidities normal amide hydrolysis dominates k_ψ and the r plot curvature is positive. In 40–60% H_2SO_4 the A-1 cleavage reaction is of comparable importance in the overall k_ψ value and its effect is to make the r plot more negative. Thus the first negative region of the plot results. In 60–70% H_2SO_4 the A-1 cleavage reaction dominates the normal A-2 hydrolysis; therefore, conversion of substrate to acetamide is much faster than the measured formation of acetic acid. The r plot will reflect this slower process and again shows positive curvature for bimolecular hydrolysis of acetamide. The final negative curvature in the highest acidities is representative of the independence of the sulfonation reaction on water, for stabilization of its transition state.

This explanation for the r plot of **5** is consistent with the implications obtained from a comparison of the rate profile for this substrate with those of **1** and **2** in 20–80% H_2SO_4. This is illustrated in Fig. 4. It suggests that the overall reaction rate obtained by monitoring the acetyl methyl signals in 20–40% H_2SO_4 is dominated by amide hydrolysis. The overall rate in 40–60% H_2SO_4 is affected significantly by both hydrolysis and *N*-alkyl cleavage processes. The *N*-alkyl cleavage rate for **5** in 60–80% H_2SO_4 is so fast that only the subsequent acetamide hydrolysis is measured by the ^1H nmr method. The strongly negative water activity dependence exhibited by **2** in Figure 3 is analogous to that for the A-1 cleavage processes of *tert*-butyl acetate and *p*-methoxybenzyl acetate (15). There is no indication of positive r values at low acidities. This fact along with the detection of *tert*-butylamine only in 5.08% H_2SO_4 may

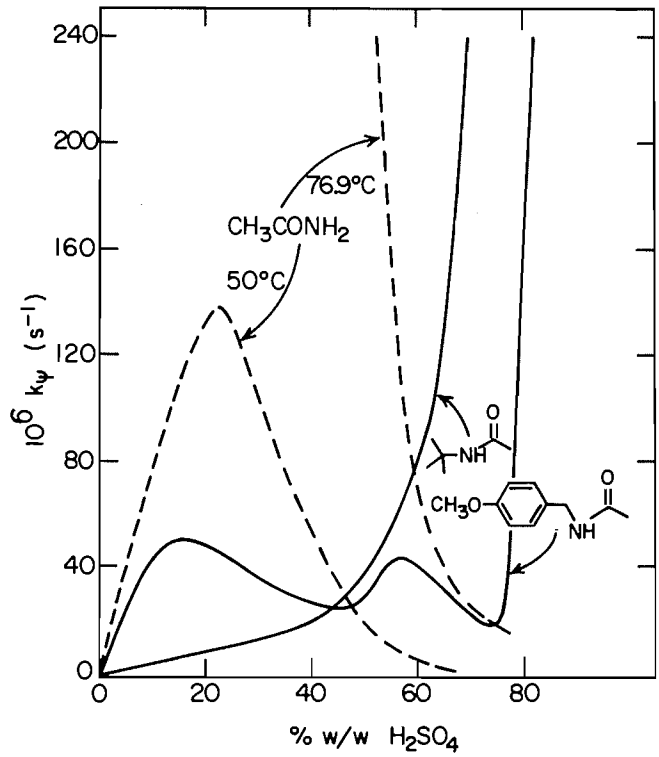

FIG. 4. Schematic comparison of the rate behaviour of **2** and **5** at 76.9°C with that of **1** at 50.0°C and 76.9°C.

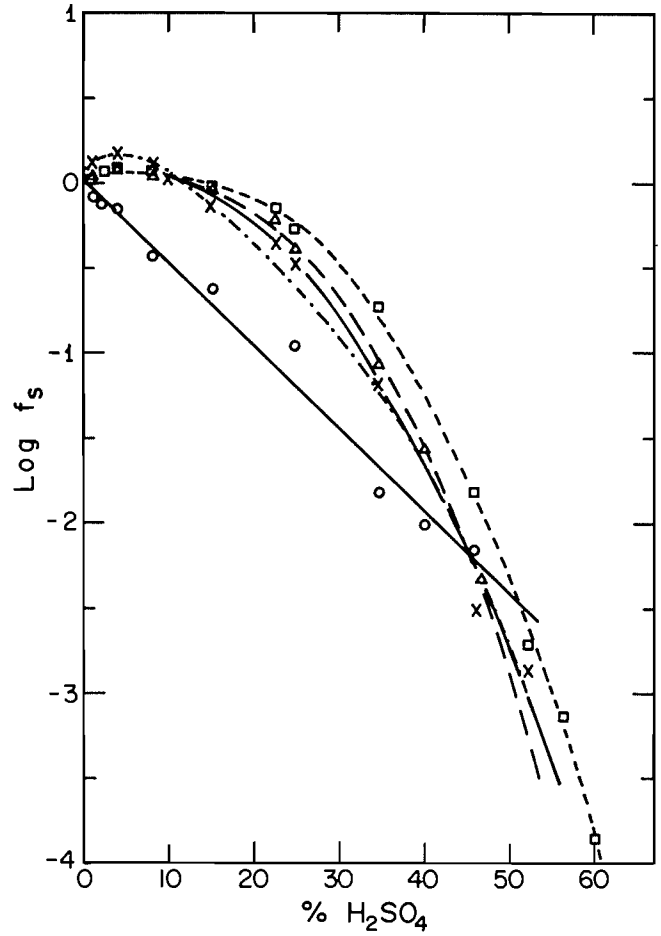

FIG. 5. Activity coefficient (lot f_s) behaviour of substituted acetamides as a function of acidity (% H_2SO_4). Open circles, **2**; triangles, **3**; crosses, **5**; squares, **6**.

mean that normal amide hydrolysis is only important in acidities less concentrated than this. Previous workers have not detected this process at any acidity (*5a*, *5b*, *5c*).

Transition state acidity coefficient treatment

Figure 5 includes values of $\log f_{([SH^+]+[S])exp}$, as well as the curve constructed from the polynomial expression for the logarithm of the activity coefficients $\log f_{([SH^+]+[S])exp}$ for **2**, **3**, **5**, and **6**. The three substituted *N*-benzylacetamides initially demonstrate a weak salting-out (35) at low acidities; that is, the $\log f$ values become increasingly positive with increasing acid concentration. At higher acidities the three display a strong salting-in; that is, with increasing acid concentration the values become increasingly negative. This behaviour is similar to that found for any benzamides and other weak organic bases. On the other hand, **2** is salted-in over the entire acidity range.

Values of $\log f_{S^\ddagger}$ are plotted versus % H_2SO_4 for these four substituted acetamides in Fig. 6. Figure 6 also includes $\log f_{S^\ddagger}$ curves for pertinent literature examples, i.e., benzamide (36), *p*-methoxybenzylacetate (*14a*), and *tert*-butyl acetate (*14a*). TSAC curves for the three substituted benzylacetamides (**3**, **5**, and **6**) exhibit a general conformity with that for normal acid-catalyzed hydrolysis of benzamide (36) and other amides (*13c*). This result is not entirely unexpected since throughout the entire acidity range over which it was possible to make activity coefficient measurements, the normal hydrolysis mechanism is important for all but **2**. Thus in spite of their striking differences in rate profiles, products, and *r*-plot behaviour, the three substituted *N*-benzylacetamides are virtually indistinguishable in terms of their transition state solvation requirements up to 45% H_2SO_4.

The *N-tert*-butyl compound is the only one of the four substituted acetamides with a distinct $\log f_{S^\ddagger}$ curve, but even this difference is not pronounced. In contrast, plots of *p*-methoxybenzyl acetate and particularly *tert*-butyl acetate hydrolyses are very different (8) from those for the three substituted *N*-benzylacetamides. The difference between $\log f_{S^\ddagger}$ of the latter ester and **2** suggests that the transition state solvation requirements for A-1 reactions of amides are quite different from those for A-1 ester reactions. This result does not contradict the previous conclusion that an A-1 process instead of a normal A-2 hydrolysis is operative for **2** over most of the acidity range. It is generally supposed that the hydration requirements of esters and amides differ appreciably (*12c*). Hydration changes upon transition state formation may well reflect this difference. Another possibility is that A-1 reactions of amides can take place via the predominant *O*-protonated form, rather than exclusively from the *N*-protonated form, as has been generally been assumed to be the case (5). This would tend to reduce the difference in $\log f_{S^\ddagger}$ behaviour between A-1 and A-2 reactions, since both would start from a common cationic form of the substrate.

Excess acidity treatment

In the application of the excess acidity treatment (11, 18, 25), the kinetic data were fitted to an optimum combination of the general A-1 and A-2 kinetic expressions, shown in eqs. [12] and [13], respectively, for the reactions of predominantly protonated substrates, at one temperature. Here *r* is the number of

$$[12] \quad \log k_p = (m^\ddagger - 1)\, m^*X + \log k_0$$

For personal use only.

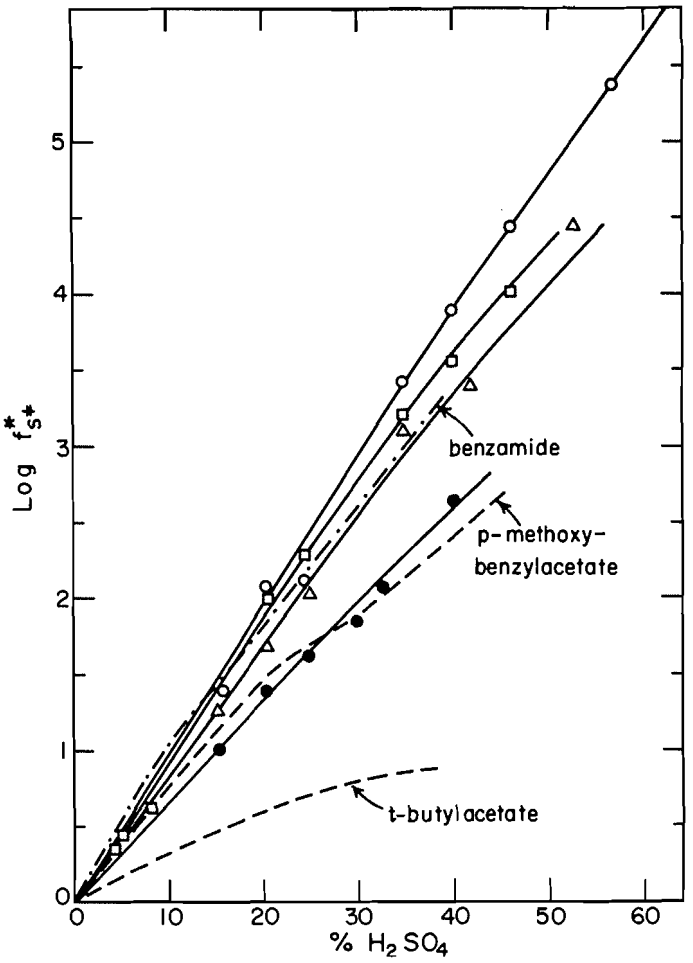

FIG. 6. Variation of the transition state activity coefficient ($\log f_{S^+}$) as a function of acidity for the hydrolyses of **2** (closed circles), **3** (squares), **5** (triangles), and **6** (open circles). Corresponding data for benzamide, *p*-methoxybenzamide, and *tert*-butyl acetate hydrolyses taken from refs. 14*a* and 36.

$$[13]\quad \log k_p = (m^\ddagger - 1)\, m^* X + \log k_0 + r \log a_{H_2O}$$

water molecules involved, $m^\ddagger$ is a slope parameter, and k_0 is the standard state rate constant. For reactions at more than one temperature, substitution into eqs. [12] and [13] of the k_0 definition, given in eq. [14], is necessary:

$$[14]\quad \log k_0 = \left(\frac{k}{h} \ln 10\right) + \log T - \frac{\Delta G^\ddagger_{25°}}{R\theta \ln 10} + \frac{\Delta H^\ddagger_{25°}}{R\theta \ln 10}\left(\frac{(T-\theta)}{T}\right)$$

The resulting expressions allow construction of plots of calculated rate constants for the overall and component processes. The data obtained from the analysis are available for all seven amides in the tables of supplementary material.[4] Excellent agreement between calculated overall rate constants and experimental values was observed in all cases.

For **1** as well as **6** and **7**, the analysis gave similar results, which are illustrated for the former (**6**) at 76.9°C in Fig. 7. The plot of the overall calculated rate constant vs. excess acidity curves downward with increasing acidity. This might be expected (18) from a bimolecular process involving water, whose concentration must decrease as the acid concentration increases. In ≤35% H_2SO_4 the calculated overall rates are indistinguishable from those of one of the component processes, A-2 hydrolysis involving three water molecules designated A-2, $3H_2O$. In ≥65% H_2SO_4 the calculated overall rates are indistinguishable from those calculated for the other component process, A-2 hydrolysis involving one water molecule (designated as A-2, $1H_2O$.) In intermediate acidities the calculated total rates contain significant contributions from both of these processes.

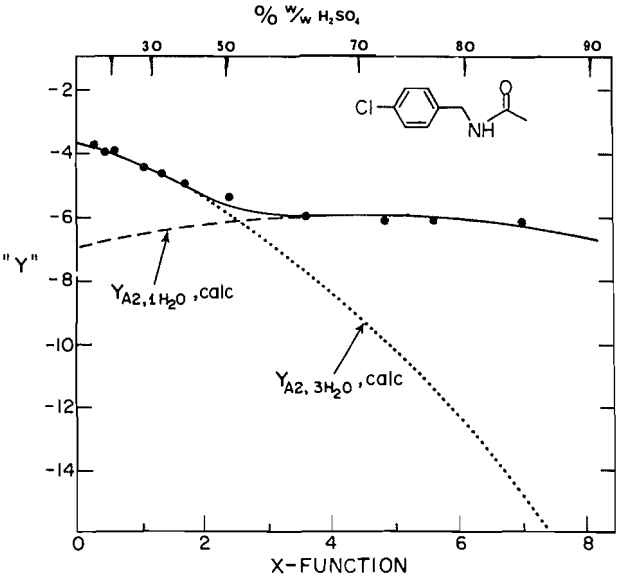

FIG. 7. Plots of calculated rate constant, Y_{nH_2O},calc = ($\log k_\psi$ − log $[SH^+]/([SH^+] + [S])$ − $n \log a_{H_2O}$) versus excess acidity, X = [log $(f_S f_{H^+}/f_{SH^+})]/m^*$, for component reactions of **6** at 76.9°C (see top of figure for corresponding acidity in terms of % H_2SO_4). Circles and upper curve show experimental values for overall reaction.

This result is surprising for **6** above 85% H_2SO_4 where no normal hydrolysis products are formed and *N*-alkyl cleavage must first occur, to give the observed products. However, if the rate of this unimolecular process is large relative to the rate of subsequent acetamide hydrolysis, then the measured rate constants will reflect the slower process, i.e., acetamide hydrolysis. This is apparently not entirely the case, since the r plot shows a significant contribution of the unimolecular process to the k_ψ values. Therefore, it seems that the magnitude of the observed rate constants for *N*-alkyl cleavage and those which might be predicted for normal amide hydrolysis are not vastly different in these acidities.

As Fig. 8 illustrates for **8** at 76.9°C, in ≤73.5% H_2SO_4 the bimolecular three and one water molecule processes dominate in a manner analogous to the foregoing results for the first three amides, and the excess acidity plot exhibits characteristic downward curvature. In 73.5–82.5% H_2SO_4 there is a change to positive curvature as expected (25*b*) of a process described by the A-1 kinetic expression. In >82.5% H_2SO_4 the observed rates are indistinguishable from those calculated for an A-1 reaction. These results confirm the mechanistic proposals for these acidities, with the A-1 rate expression corresponding to the pseudo-first-order sulfonation of **3**. The overall experimental rate profile is therefore best explained as a composite of three processes, i.e., normal bimolecular hydrolyses involving three and one water molecules respectively, and sulfonation in the most concentrated sulfuric acids.

Identical results were obtained from excess acidity analysis

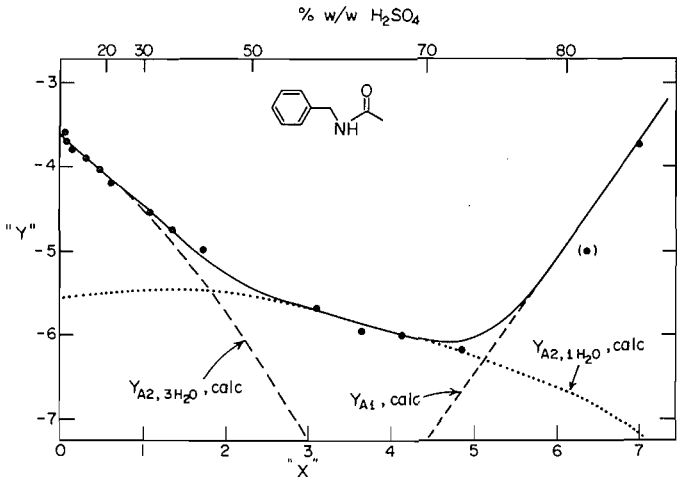

FIG. 8. Plots of Y_{nH_2O},calc versus excess acidity (X) (see caption for Fig. 7) for component reactions of **3** at 76.9°C (see top of figure for corresponding acidity in terms of % H_2SO_4). Circles and upper curve show experimental values for overall reaction.

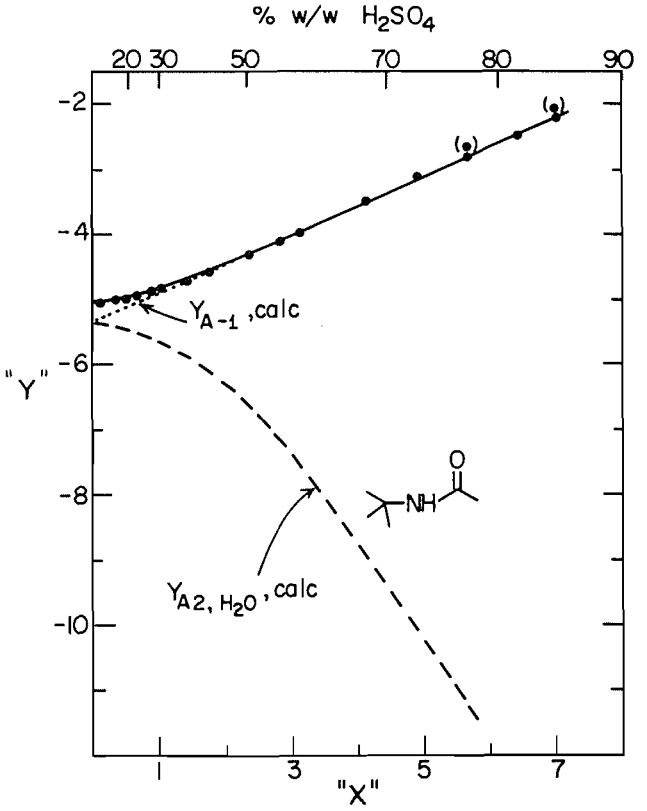

FIG. 9. Plots of Y_{nH_2O},calc (see caption for Fig. 7) versus excess acidity (X) for component reactions of **2** at 76.9°C. Circles and upper curve show experimental values for overall reaction.

of the data for **5** in acidities as high as 85.9% H_2SO_4. Data in acidities up to 85.9% H_2SO_4 were available for this substrate at a single temperature, 76.8°C. It is surprising that an expression for the contribution of the *N*-alkyl cleavage process does not appear in the analysis for this substrate. When the data at four temperatures, available up to 73.5% H_2SO_4, were treated separately, the optimum combination was found to be that of the "bimolecular" three and one water molecule processes; again no contribution from an equation representative of the *N*-alkyl cleavage was required to fit the data. An obvious explanation of the anomalous excess acidity results is that the effect of the *N*-alkyl cleavage process on the k_ψ values does not occur over a range of acidities that is large enough to be recognized by the analysis as a distinct process, due to the early onset of sulfonation. Analysis of the r plot indicates that at most three of the experimental k_ψ values contain a dominant contribution from *N*-alkyl cleavage.

Results from excess acidity analysis of the 76.9°C data for **4** implicated bimolecular three and one water molecule processes followed by an A-1 process, which becomes dominant at a much lower acidity than in the case of **3**. This result is easily explained. As Table 1 and the r plot for this substrate indicate, the *N*-alkyl cleavage process makes a significant and measureable contribution to the k_ψ values. Thus for **3** the positive curvature in the excess acidity plot is due to the occurrence of two A-1 or pseudo-first-order processes. It is initially due to *N*-alkyl cleavage and, at higher acidities, sulfonation. Thus, of the three substituted *N*-benzylacetamides reacting via a unimolecular cleavage pathway, this is the one for which the excess acidity analysis offers the strongest support for the process.

The excess acidity results for **2** consist of a combination of normal bimolecular hydrolysis at low acidities and an A-1 process at higher acidities, with the latter process completely dominating above 40% H_2SO_4. Except for a small region in the lowest acidity region the overall profile exhibits strongly positive slope, as expected for an A-1 process. Figure 9 illustrates the minor extent of the bimolecular process at low acidities, where either of the three or one water molecule kinetic expressions give equally good fits of the data. This obvious limitation of the analysis may reflect the tendency of the excess acidity treatment to compress the data along the x-axis in the very dilute acid region.

The analysis does, however, suggest that for **2**, normal hydrolysis may contribute in acidities as high as 40% H_2SO_4. In contrast, the product study identified normal hydrolysis products only at a single, much lower acidity and the r treatment gave no indication of normal bimolecular hydrolysis. The above treatment has clearly supplied a plausible acidity range for operation of the normal mechanism for this substrate.

Activation parameters

Activation parameters were calculated at constant water activity for **1**, **2**, **3**, **5**, and **6**. Although these are naturally composite values for the various reactions competing in each acidity range, they should reflect the dominant kinetic process at any given acidity. Kinetic data at three or four temperatures were used. The resultant correlation coefficients ($\geq$0.990) and standard deviations in $\Delta H^\ddagger$ and $\Delta S^\ddagger$ ($<\pm$10%) were quite satisfactory for the nmr kinetic method. Table 3 summarizes the results for **1**, **3**, and **6** and includes individual values for **2** and **5**.

For **1** as well as **3** and **6**, in 4–75% H_2SO_4, the activation enthalpies lie within the range 13.4 to 22.4 kcal mol^{-1} and the activation entropies lie in the range -17.2 to -42.5 eu. Although these are fairly typical values for normal amide hydrolysis (1*b*, 1*c*, 1*d*, 12*c*, 18), there is a clear distinction between a dominant bimolecular three water molecule process at low acidities and an analogous one water molecule process at higher acidities, particularly in the $\Delta S^\ddagger$ terms, as will be shown later.

The activation parameters for **3** in 91.5% H_2SO_4 should be representative of the sulfonation process which occurs exclu-

sively here. The rate of sulfonation of benzene in 93.4% H_2SO_4 has been reported at three temperatures (29*a*), allowing the following activation parameters to be calculated: $\Delta H^{\ddagger}$ = 17.01 kcal mol^{-1}, $\Delta S^{\ddagger}$ = −11.00 eu (corr. coeff = 0.9998). Comparison with the values for **3** in 91.5% H_2SO_4 shows that the latter are consistent with a dominant sulfonation reaction at this acidity.

While the activation enthalpies for **5** simply support bimolecular amide hydrolysis, the activation entropies provide much more insight into the foregoing complex results for this substrate. In the three lowest acidities $\Delta S^{\ddagger}$ is in the range (−21.7 to −23.3 eu) expected for normal amide hydrolysis. In the next four acidities the $\Delta S^{\ddagger}$ values become increasingly positive, changing progressively from −13.1 eu in 34.7% H_2SO_4 to +1.4 eu in 52.4% H_2SO_4. This result is expected, since the onset of unimolecular *N*-alkyl cleavage should change $\Delta S^{\ddagger}$ from a strongly negative value for bimolecular hydrolysis to a more positive value. In the last three acidities $\Delta S^{\ddagger}$ again becomes more negative. Ranging from −4.2 eu to −20.8 eu, the values reflect the bimolecular hydrolysis of acetamide which occurs after very fast *N*-alkyl cleavage of **4**. Thus, although $\Delta S^{\ddagger}$ values were not available in the highest acidities, where sulfonation occurs, the values in all other acidities provide strong evidence for the mechanistic proposals for this substrate.

Activation parameters for **2** also support the mechanistic interpretations. The $\Delta H^{\ddagger}$ values are generally more positive than for normal bimolecular hydrolysis, as expected for a substrate exhibiting predominant, if not exclusve, unimolecular cleavage (11*b*). In 15.5% H_2SO_4 the small, negative activation entropy (−5.0 eu) may be the result of contributions from both an A-2 process, which alone would produce a large negative value, and an A-1 process, which alone would produce a small positive value. In higher acidities the observed positive $\Delta S^{\ddagger}$ values emphasize the importance of the unimolecular process which dominates above 35% H_2SO_4.

Table 4 shows an attempt to dissect the observed composite $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ behaviour into individual values for the com-

[b] Unimolecular fission of protonated amide to give carbonium ion (A-1).

peting processes. Standard state activation enthalpies and entropies were calculated from the excess acidity analysis of the variable temperature data for five of the substrates. These values complement those of Table 3. For example, although similar $\Delta H^{\ddagger}$ values are calculated for the A-2, $3H_2O$ and A-2, $1H_2O$ processes, the former has consistently lower $\Delta H^{\ddagger}$ values, as might be expected. Also, the $3H_2O$ process has much more negative $\Delta S^{\ddagger}$ values than the $1H_2O$ mechanism, which is in full accord with the higher degree of solvent restriction expected for this type of transition state. The A-1 process for **2** is the only hydrolysis mechanism for which a positive value of $\Delta S^{\ddagger}$ is calculated, as would be expected.

Along with standard state activation parameters, estimates of the standard state rate constants for the individual rate processes were also obtained from the application of the excess acidity treatment. The log k_0 values were calculated by adding the value r log a_{H_2O} (where r is the appropriate number of water molecules) to eq [14]. The resultant values then refer to a standard state of pure water (55.35 M) at 25°C and have been termed log k_0' in Table 4. The data indicate that the intrinsic relative reactivities of the amides toward the bimolecular three and one water molecule hydrolyses are acetamide > *N*-(*p*-methoxybenzyl)acetamide > *N*-benzylacetamide > *N*-(*p*-chlorobenzyl)acetamide > *N*-*tert*-butylacetamide. This order of reactivities is easily rationalized in terms of steric and inductive effects. Thus the least sterically crowded primary amide, acetamide, is most reactive, whereas the most bulky secondary amide, *N*-*tert*-butylacetamide, is least reactive. In addition, the order of reactivity of the three substituted *N*-benzylacetamides, i.e., *p*-methoxy > hydrogen > *p*-chloro, is

that of the electron-donating ability of the three substituents, implying a reaction favoured by increased electron supply from the aromatic ring. The ease of amide protonation in the pre-equilibrium step of the hydrolysis pathway would also be expected to be influenced in a similar fashion.

In summary, it may be concluded that rate and product studies, combined with activation parameters and three quantitative analytical treatments have produced an extensive description of the reaction modes available to this series of substituted acetamides. Table 5 is a summary of the overall results, which shows that the chemistry of the protonated amides in aqueous acid solutions encompasses normal bimolecular hydrolytic processes in addition to unimolecular *N*-alkyl cleavage and aromatic sulfonation reactions. There is no evidence for unimolecular acylium ion formation. It is also evident that the three kinetic treatments applied to the rate data provide complementary information, which taken together offers strong support for proposed mechanistic explanations based on rate-profile and product studies alone.

Stereocontrolled total synthesis of the triquinane marine sesquiterpene $\Delta^{9(12)}$-capnellene

LEO A. PAQUETTE AND KENNETH E. STEVENS
Evans Chemical Laboratories, The Ohio State University, Columbus, OH 43210, U.S.A.

Received January 10, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

LEO A. PAQUETTE and KENNETH E. STEVENS. Can. J. Chem. **62**, 2415 (1984).

A total synthesis of $\Delta^{9(12)}$-capnellene, a *cis-anti-cis*-tricyclo[6.3.0.0^{2,6}]undecane sesquiterpene of marine origin, is described. Starting with bicyclic enone **5**, which was prepared by a Nazarov cyclization, the remaining portion of the molecule is elaborated by means of a new and relatively efficient cyclopentenone annulation scheme. The relative stereochemistries of the chiral centers are properly incorporated by taking advantage of prevailing steric factors.

LEO A. PAQUETTE et KENNETH E. STEVENS. Can. J. Chem. **62**, 2415 (1984).

On décrit une synthèse totale de la $\Delta^{3(12)}$-capnellène, un sesquiterpène du type tricyclo[6.3.0.0^{2,6}]undécane-*cis-anti-cis* d'origine marine. Partant de l'énone bicyclique **5** que l'on prépare par une cyclisation de Nazarov, on élabore le reste de la molécule en faisant appel à une méthode, nouvelle et relativement efficace, d'annellation en cyclopentènone. On incorpore correctement les stéréochimies relatives appropriées des centres chiraux en tirant profit de facteurs stériques existants.

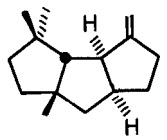
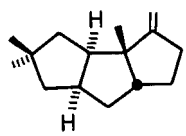
The soft coral *Capnella imbricata*[1] has proven to be a rich source of an interesting family of non-isoprenoid sesquiterpenes which share in common the *cis-anti-cis* tricyclo[6.3.0.0^{2,6}]undecane ring system. These marine natural products known as capnellanes occur in various stages of oxidation ranging from purely hydrocarbon[1,2] to polyhydric derivatives[3–7]. $\Delta^{9(12)}$-Capnellene (**1**), the presumed biosynthetic precursor of the capnellenols, reveals the typical arrangement of methyl groups about the linear triquinane nucleus[8]. These features differentiate the capnellanes from their terrestrial counterparts, the hirsutanes (e.g., hirsutene (**2**)), which possess



1



2

a geminal dimethyl unit at C-2 and an angular methyl group at C-10 (ref. 9, hirsutene; ref. 10, hirsutic acid; ref. 11, coriolin).

Although the capnellane group seemingly serves as agents of chemical defense within the coral reef biomass to ward off algal and microbial growth[12] and to prevent larval settlement[13], their detailed biological function is not known. The compelling biosynthetic position held by **1**[4,12] has caused it to become a focal point of substantive synthetic activity[15–20][2]. In this paper, we describe in detail a short, stereocontrolled total synthesis of **1**, which features two different methods for regiospecific cyclopentenone annulation[15].

From the retrosynthetic perspective, bicyclic ketone **6** appeared to be an ideal advanced intermediate for elaboration of the third five-membered ring. Attention was therefore directed to its acquisition. Conjugate addition of lithium dimethylcuprate to **5** was envisioned to be a suitably viable approach to **6** (Scheme 1). With these goals in mind, cyclopentenyl carboxaldehyde **3** was prepared by the method of Magnusson and Thorén[21]. Their protocol provides **3** admixed with approximately 20% of the 3,3-dimethyl isomer. Although the unwanted component could be removed by reaction with an appropriate quantity of Girard's reagent T, it proved more convenient to effect condensation of the mixture with vinylmagnesium bromide and to separate the dienols by high pressure liquid chromatography. Manganese dioxide oxidation of the appropriate vinyl carbinol proceeded smoothly to deliver the sensitive dienone **4** which was subjected directly to Nazarov cyclization[22]. The combination of 8% phosphorus pentoxide in methanesulfonic acid[23] at 20°C for only 2 min sufficed to provide a 68% yield of **5** with the double bond crucially positioned in the central, more highly substituted region of the molecule. In accord with previous experience[24], immediate treatment of **5** with the cuprate reagent led efficiently to **6**. Detailed chromatographic and spectral analysis at this juncture failed to give evidence of isomeric material.

With **6** in hand, [3+2] cyclopentannulation with regiospecific bonding of a new carbonyl group to the site of the old as in **17** was given attention. Several procedures have been developed which effect such a transformation[25]. However, most lack the intrinsic regiochemical control required to deliver exclusively the proper linearly fused tricyclopentanoid framework. The one known exception, that based upon vinylsilane acylation–cyclization[26], proceeds in the desired sense because production of the vinylsilane is usually achieved by proton abstraction from the less substituted α carbon[27].

For this reason, **6** was converted via its triisopropylbenzenesulfonyl hydrazone[28] to **7** (Scheme 2). Attempts to acylate **7** with 3-chloropropionyl chloride according to previously developed procedures[26] proved not to be successful. When application of more forcing conditions than normal led to destruction of the vinylsilane, an alternate route to dienone **9** was sought. Recourse to a smaller electrophilic species, viz. that resulting from the action of aluminum chloride on dichloromethyl methyl ether[29], led successfully to aldehyde **8** from which **9** could be prepared conventionally. However, this dienone failed to undergo Nazarov cyclization as induced by a wide range of Bronsted and Lewis acids. Our inability to arrive at **11**

[1]Collections were made off the coast of Serwaru, Leti Island, Indonesia and Liang Island off the north coast of New Guinea.

[2]For syntheses of $\Delta^{8(9)}$-capnellene, see ref. 20(*a*); for $\Delta^{9(12)}$-capnellene-8α,10α-diol, see ref. 20(*b*).

SCHEME 2

in this fashion may be the result of steric impedance by the geminal methyl groups to attainment of planarity within the pentadienyl cation intermediate (**10**) which must experience the requisite conrotatory electrocyclization (cf. Newman's Rule of Six[30]).

Although not previously encountered, this limitation to the Nazarov procedure mandated that an alternative regiospecific cyclopentenone annulation method be developed. From the outset, early introduction of the new carbonyl group was viewed as especially desirable. This issue was addressed by condensing **6** with lithium acetylide[31] and treating propargyl alcohol **12** with formic acid containing sulfuric acid at 90°C to effect Rupe rearrangement[32]. This sequence proved to be highly efficient and to exhibit a high predilection for formation of the lesser substituted enone **13** (Scheme 3). This substance in turn was exposed to vinylmagnesium bromide and cuprous iodide in tetrahydrofuran at −78°C[33]. The isomerically pure substance which was produced proved to be **14**. Although the precise stereochemical relationship of the acetyl and vinyl groups was not known with rigor at the time, *exo* delivery of the vinyl cuprate was anticipated for the usual steric reasons. Since protonation of the resulting enolate from the less hindered β face must compress the acetyl group tightly against the *endo* methyl group of the geminal pair, we deemed it likely that this energy demanding state of affairs might be avoided.

In any event, the ozonolysis of **14** proceeded readily. Resulting keto aldehyde **15** was cyclized with 5% potassium hydroxide in a 2:1 mixture of tetrahydrofuran and ether[34] which also contained a catalytic amount of tetra-*n*-butylammonium hydroxide. Tricyclic enone **16** was isolated in 79% yield. During the $\Delta^{9(12)}$-capnellene synthesis later developed by the Geneva group[18], two isomers of keto aldehyde **15** were obtained. The major isomer (identical to **15**) was again found to cyclize cleanly under the mild two-phase conditions just described. The minor isomer, which was recovered intact from this treatment, was converted to **16** only when more stringent conditions (KOH, C_2H_5OH) were applied. These results agree fully with our original stereochemical assumptions.

To secure the target molecule, **16** was subjected to sequential catalytic hydrogenation and Wittig olefination. The ^1H nmr spectrum of the resulting racemic hydrocarbon was identical with that of the authentic natural product as recorded by Professor Djerassi. Thus, $\Delta^{9(12)}$-capnellene has been stereoselectively assembled in 8 laboratory steps from bicyclic enone **5** in 8.3% overall yield.

Experimental

8,8-Dimethylbicyclo[3.3.0]oct-1(5)-en-2-one (**5**)

2,3-Epoxy-4,4-dimethylcyclohexanol[21] (30.0 g, 0.21 mol) in toluene (240 mL) was added over 2 h to a solution of lithium bromide (41 g, 0.47 mol) and hexamethylphosphoramide (82 g, 0.46 mol) in the same solvent (240 mL) while being heated at reflux under nitro-

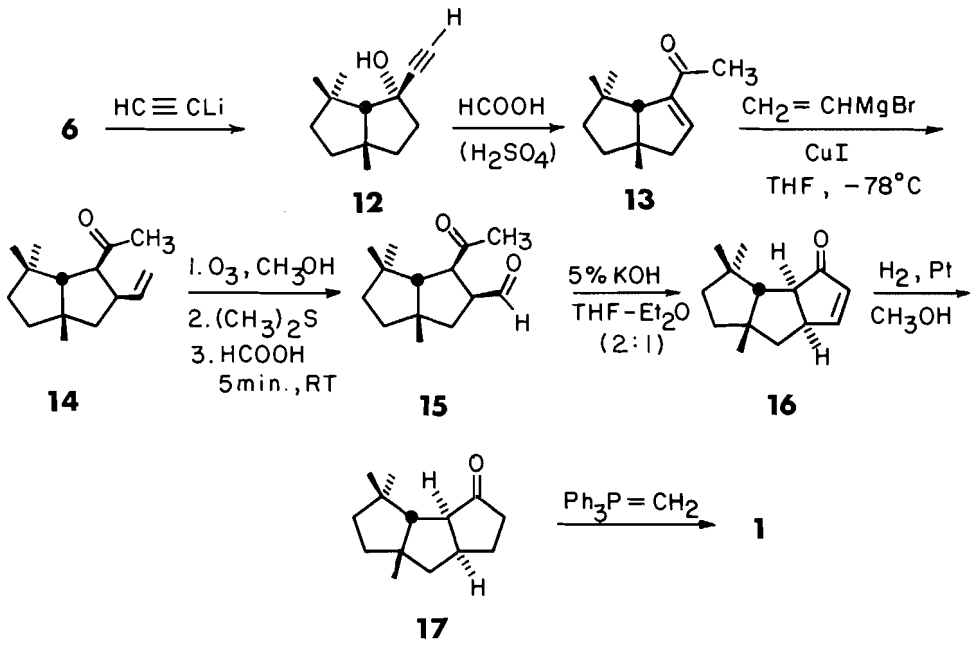

SCHEME 3

gen. Upon completion of the addition, heating was immediately discontinued and the reaction mixture was allowed to cool to room temperature during 1.5 h, diluted with ether (200 mL), washed with water (4 × 100 mL), and dried. The solvents were removed at reduced pressure, leaving the mixture of **3** and its 3,3-dimethyl isomer as a pale yellow oil. This material was dissolved in anhydrous tetrahydrofuran (200 mL) and added during 1.5 h to a cold (10°C) slurry of vinylmagnesium bromide (prepared from magnesium (10 g, 0.42 g-atom) and vinyl bromide (33 mL, 0.44 mol)) in tetrahydrofuran (500 mL). The mixture was allowed to warm to room temperature during 3 h, poured into saturated ammonium chloride solution, and stirred for 1 h. The organic phase was removed and the aqueous layer was extracted with ether (3 × 100 mL). The combined organic solutions were dried and concentrated to leave a colorless oil from which the desired vinyl alcohol was separated by preparative hplc (Waters Prep 500, elution with 9% ethyl acetate in petroleum ether). Distillation afforded 9.55 g (30% overall) of product as a colorless, mobile oil, bp 114°C (43 Torr (1 Torr = 133.3 Pa)). As distillation caused partial polymerization with loss of water, this manipulation was not carried out generally. Under these conditions, the overall yield averaged 14.65 g (46%); *m/z* calcd. (M^+): 152.1201; found: 152.1205.

A mixture of the vinyl alcohol (2.29 g, 15.0 mmol) and manganese dioxide on carbon[35] (22.9 g) in petroleum ether (150 mL) was stirred at room temperature for 24 h. Filtration and solvent evaporation left pure **4** (2.14 g, 95%) which was used without further purification; ir (CCl_4): 1715, 1660, 1605 cm^{-1}; ^1H nmr (CCl_4) δ: 1.24 (s, 6H), 1.58–1.92 (m, 2H), 2.28–2.7 (m, 2H), 5.40–5.68 (m, 1H), 5.94–6.26 (m, 1H), 6.48–6.95 (m, 2H); *m/z*. calcd. (M^+): 150.1045; found: 150.1048.

The analytical sample was obtained by molecular distillation at 100°C and 30 Torr. *Anal.* calcd. for $C_{10}H_{14}O$: C 79.96, H 9.39; found: C 79.96, H 9.50.

The preceding material was placed in a round-bottomed flask equipped with a magnetic stirrer, thoroughly cooled in ice, and treated in one portion with a solution of phosphorus pentoxide in methanesulfonic acid (3.5 mL of 1:10 by weight). A vigorously exothermic reaction resulted. After 2 min, the resulting brown tarry mixture was carefully added to a mixture of ether (50 mL) and saturated sodium bicarbonate solution (75 mL). After neutralization, the aqueous phase was extracted with ether (2 × 20 mL) and the combined organic layers were washed with saturated sodium bicarbonate solution, dried, and concentrated to leave 1.58 g of pale yellow oil. Further purification by mplc on silica gel (elution with 15% ethyl acetate in petroleum ether) gave **5** as a colorless oil (1.45 g, 65% from the alcohol) which darkened considerably on standing and therefore was utilized without undue delay; ir ($CHCl_3$): 1685, 1630 cm^{-1}; ^1H nmr (CCl_4) δ: 1.18 (s, 6H), 2.00–2.28 (m, 2H), 2.28–2.70 (m, 6H); *m/z* calcd. (M^+): 150.1045; found: 150.1039. *Anal.* calcd. for $C_{10}H_{14}O$: C 79.96, H 9.39; found: C 79.84, H 9.39.

5,8,8-Trimethyl-bicyclo[3.3.0]octan-2-one (6)

A solution of lithium dimethylcuprate was prepared by the addition of $CH_3Li \cdot LiBr$ in ether (1.8 mL of 1.4 *M* solution, 2.52 mmol) to a cold (0°C), magnetically stirred slurry of cuprous iodide (241 mg, 1.26 mmol) in ether (5 mL) under nitrogen. A solution of **5** (97 mg, 0.65 mmol) in ether (2 mL) was introduced via cannula. After 30 min, the reaction mixture was siphoned into half-saturated ammonium chloride solution (20 mL) made basic by the addition of concentrated ammonium hydroxide. After the copper salts had been solubilized, the aqueous phase was extracted with ether (2 × 10 mL) and the combined organic layers were washed with saturated ammonium chloride solution (10 mL), dried, and concentrated to leave **6** as a pale yellow oil (87 mg, 80%); ir ($CHCl_3$): 1730 cm^{-1}; ^1H nmr (CCl_4) δ: 0.94 (s, 3H), 1.14 (s, 3H), 1.30 (s, 3H), 1.39–1.91 (series of m, 7H), 2.18 (pseudo t, *J* = 7.5 Hz, 2H); *m/z* calcd. (M^+): 166.1358; found: 166.1361. *Anal.* calcd. for $C_{11}H_{18}O$: C 79.47, H 10.91; found: C 79.47, H 10.89.

The 2,4,6-triisopropylbenzenesulfonylhydrazone derivative was prepared by adding the sulfonylhydrazine (3.20 g, 9.7 mmol) to a magnetically stirred solution of **6** (1.60 g, 9.6 mmol) in acetonitrile (10 mL) at room temperature. Concentrated hydrochloric acid (1 mL) was introduced and the mixture was stirred overnight, allowed to stand in a freezer for 12 h, and suction filtered to recover the precipitated solid. This material was washed with cold methanol and air dried to give 3.40 g (79%) of colorless crystals, mp 148–151°C (from methanol–dichloromethane): *m/z* calcd. (M^+): 446.2967; found: 446.2980. *Anal.* calcd. for $C_{26}H_{42}N_2O_2S$: C 69.91, H 9.48; found: C 69.81, H 9.50.

5,8,8-Trimethyl-2-(trimethylsilyl)-bicyclo[3.3.0]oct-2-ene (7)

A solution of *n*-butyllithium in ether (6.0 mL of 2.26 *M*, 13.5 mmol) was added over 15 min to a cold (−65°C), magnetically stirred slurry of the triisopropylsulfonylhydrazone of **6** (2.00 g, 4.5 mmol) in a solution of tetramethylethylenediamine (2.0 mL) and hexane (20 mL). After 30 min. at −70°C. the reaction mixture was allowed to warm to 0°C over 20 min, giving a clear, pale yellow solution. After 15 min at this temperature, chlorotrimethylsilane (1.8 mL, 14.1 mmol) was added over 10 min. Following this, the

For personal use only.

solution was poured into a mixture of ice and water (total volume ca. 60 mL). After shaking, the layers were separated and the aqueous phase was extracted with ether (2 × 10 mL). The combined organic layers were washed with water (2 × 20 mL), saturated cupric sulfate solution (20 mL), and water (2 × 10 mL) prior to drying and solvent evaporation. The resulting pale yellow oil (1.81 g) was filtered through a plug of silica gel (elution with petroleum ether) and purified by mplc on silica gel (same eluent). There was isolated 580 mg (58%) of **7** as a colorless oil. The analytical sample was prepared by vpc (3 ft × 0.25 in. 5% SE-30 on Chromosorb P, 120°C); ^{1}H nmr (CCl_4) δ: 0.12 (s, 9H), 0.75 (s, 3H), 1.07 (s, 3H), 1.10 (s, 3H), 1.55 (m, 4H), 2.23 (br s, 3H), 5.83 (m, 1H). *Anal.* calcd. for $C_{14}H_{26}Si$: C 75.59, H 11.78; found: C 75.63, H 11.73.

Formylation of 7

Anhydrous powdered aluminum chloride (0.2 g, 1.5 mmol) was added in one portion under a stream of nitrogen to a cold (−70°C), magnetically stirred solution of dichloromethyl methyl ether (190 mg, 1.65 mmol) and vinylsilane **7** (238 mg, 1.07 mmol) in dichloromethane (10 mL). After 15 min at −70°C, the reaction mixture was allowed to warm to 0°C over 30 min, poured onto ice (25 g), and stirred for 30 min. The layers were separated, the aqueous phase was extracted with dichloromethane (2 × 10 mL), and the combined organic layers were washed with water (10 mL) prior to drying and concentration. Preparative tlc purification of the residue on silica gel (elution with 5% ethyl acetate in petroleum ether) returned 60 mg of unreacted **7** and furnished 72 mg (50% based on consumed silane) of **8** as a colorless oil; ir (CCl_4): 1685 cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.97 (s, 3H), 1.13 (s, 3H), 1.23 (s, 3H), 1.30−2.10 (series of m, 4H), 2.38 (br s, 3H), 6.32−6.58 (m, 1H), 9.77 (s, 1H).

Vinylation−oxidation of 8

A solution of vinylmagnesium bromide under nitrogen was prepared from magnesium turnings (130 mg, 5.34 mg-atoms) and vinyl bromide (0.61 g, 5.66 mmol) in anhydrous tetrahydrofuran (10 mL). The solution was cooled to 0°C and **8** (117 mg, 0.66 mmol) in the same solvent (5 mL) was added. After 1 h at 0°C, the reaction mixture was poured into saturated ammonium chloride solution (20 mL), the layers were separated, and the aqueous phase was extracted with ether (3 × 10 mL). The combined organic layers were dried and evaporated to give the dienol (137 mg), which was dissolved in dry petroleum ether (20 mL), treated with manganese dioxide on carbon (1.4 g), and stirred vigorously for 17 h. The solids were separated by filtration and the filtrate was concentrated to leave pure **9** (134 mg, 100%); ir (CCl_4): 1662, 1605 cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.97 (s, 3H), 1.10 (s, 3H), 1.77 (s, 3H), 1.33−1.75 (m, 4H), 2.28−2.60 (m, 3H), 5.61 (dd, J = 10 and 3 Hz, 1H), 6.17 (dd, J = 17 and 3 Hz, 1H), 6.45 (m, 1H), 6.82 (dd, J = 17 and 10 Hz, 1H).

*2-Ethynyl-5,8,8-trimethyl-bicyclo[3.3.0]octan-2-ol (**12**)*

A solution of lithium acetylide was prepared by bubbling acetylene (dried by passage through a −78°C cold trap) into cold (−78°C), magnetically stirred dry tetrahydrofuran (100 mL) containing *n*-butyllithium (35 mL, 1.37 *M* in hexane, 48.0 mmol). A nitrogen atmosphere was restored and a solution of **6** (832 mg, 5.01 mmol) in anhydrous tetrahydrofuran (15 mL) was added during 15 min. The reaction mixture was allowed to warm to −20°C and was poured into saturated ammonium chloride solution (100 mL). The layers were separated, the aqueous phase was extracted with ether (3 × 10 mL), and the combined organic layers were dried and concentrated. The resulting yellow oil (1.24 g) was purified by mplc on silica gel (elution with 4.5% ethyl acetate in petroleum ether). In addition to recovery of 86 mg of unreacted **6**, there was isolated 677 mg (70.5%) of **12** as a colorless oil; ir (CCl_4): 3605, 3310 cm^{-1}; ^{1}H nmr (CCl_4): δ: 1.02 (s, 3H), 1.11 (s, 3H), 1.32 (s, 3H), 1.4−2.1 (series of m, 10H), 2.31 (s, 1H); m/z calcd. ($M^+ - CH_3$): 177.1279; found: 177.1275. *Anal.* calcd. for $C_{13}H_{20}O$: C 81.20, H 10.48; found: C 81.19, H 10.54.

*2-Acetyl-5,8,8-trimethyl-bicyclo[3.3.0]oct-2-ene (**13**)*

A magnetically stirred solution of **12** (255 mg, 1.33 mmol) in 98% formic acid (6 mL) containing concentrated sulfuric acid (3 drops) was heated at 92°C for 15 min. After cooling, the reaction mixture was diluted with ether (100 mL), washed with water (6 × 10 mL) and saturated sodium bicarbonate solution (3 × 10 mL), dried, and concentrated. There was obtained 227 mg (88.7%) of **13** as a colorless oil; ir (CCl_4): 1670, 1610 cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.68 (s, 3H), 1.16 (s, 6H), 1.36−1.68 (m, 4H), 2.20 (s, 3H), 2.27−2.46 (m, 2H), 2.53 (s, 1H), 6.39 (t, J = 3 Hz, 1H); m/z calcd. (M^+): 192.1514; found 192.1519. *Anal.* calcd. for $C_{13}H_{20}O$: C 81.20, H 10.48; found: C 80.95, H 10.49.

*2-Acetyl-5,8,8-trimethyl-3-vinyl-bicyclo[3.3.0]octane (**14**)*

A solution of vinylmagnesium bromide in anhydrous tetrahydrofuran (3 mL) under nitrogen (prepared from magnesium (61 mg, 2.52 mg-atoms) and vinyl bromide (379 mg, 3.54 (mmol)) was diluted with tetrahydrofuran (5 mL), cooled to −10°C, and treated with cuprous iodide (248 mg, 1.30 mmol). The internal temperature rose to −5°C and after exactly 3 min at −5 to −10°C, the dark mixture was rapidly (< 3 min) cooled to −78°C and a solution of **13** (81 mg, 0.42 mmol) in the same solvent was added dropwise. The reaction mixture was stirred at −78°C for 30 min, allowed to warm to room temperature, poured into weakly basic saturated ammonium chloride solution, and stirred for 30 min. The layers were separated, the aqueous phase was extracted with ether (2 × 10 mL), and the combined organic layers were washed with saturated ammonium chloride solution (10 mL), dried, and concentrated. Purification of the residual yellow oil (108 mg) by mplc on silica gel (elution with 2% ethyl acetate in petroleum ether) gave **14** (51 mg, 54.8%) as a colorless oil; ir (CCl_4): 1713, 1636, 1352, 980, 905 cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.92 (s, 3H), 1.01 (s, 3H), 1.18 (s, 3H), 1.23−1.90 (m, 6H), 1.98 (d, J = 4 Hz, 1H), 2.12 (s, 3H), 2.44−2.84 (m, 1H), 2.84−3.31 (m, 1H), 4.64−5.11 (m, 2H), 5.31−5.99 (m, 1H); m/z calcd. (M^+): 220.1827; found: 220.1832.

Ozonolysis−cyclization of 14

A solution of **14** (70 mg, 0.32 mmol) in methanol (10 mL) was cooled to −78°C and treated with a stream of ozone for 5 min whereupon the solution turned faintly blue, The cold solution was deoxygenated with a stream of nitrogen, dimethyl sulfide (0.5 mL) was added, and the reaction mixture was maintained at −78°C for 30 min prior to warming to 20°C. Removal of the solvent left the dimethyl acetal which was dissolved in formic acid (98%, 2 mL) and swirled at room temperature for 5 min. Ether (50 mL) was added, the solution was washed with water (4 × 10 mL) and saturated sodium bicarbonate solution (10 mL), and the organic phase was dried and evaporated. The resulting aldehyde, which exhibited a single spot on tlc analysis, was dissolved in tetrahydrofuran (10 mL) and ether (5 mL). Aqueous potassium hydroxide (5%, 5 mL) and tetra-*n*-butylammonium hydroxide (40%, 2 drops) were added and the two-phase mixture was vigorously stirred and heated at gentle reflux under nitrogen for 4 h. After cooling, the layers were separated, the aqueous phase was extracted with ether (4 × 10 mL), and the combined organic layers were dried and concentrated. The residue was purified by mplc on silica gel (elution with 9% ethyl acetate in petroleum ether) and gave 55 mg (84,3%) of **16** as a colorless oil; ir (CCl_4): 1712 cm^{-1}; ^{1}H nmr (CCl_4): δ: 0.97 (s, 3H), 0.99 (s, 3H), 1.56 (s, 4H), 1.20−2.19 (series of m, 3H), 2.53 (dd, J = 6 and 3 Hz, 1H), 3.19−3.57 (m, 1H), 5.91 (dd, J = 6 and 2 Hz, 1H), 7.47 (dd, J = 6 and 3 Hz, 1H); m/z calcd. (M^+): 204.1514; found: 204.1518.

*$\Delta^{9(12)}$-Capnellene (**1**)*

Enone **16** (45 mg, 0.22 mmol) was hydrogenated at atmospheric pressure in methanol (10 mL) over platinum oxide (16 mg). The catalyst was separated by filtration and the filtrate was concentrated to give crude **17**.

A solution of potassium *tert*-butoxide was prepared by heating potassium metal (17 mg, 0.43 mg-atom) in *tert*-butyl alcohol (0.5 mL) and benzene (2 mL) under nitrogen. After cooling to room temperature, methyltriphenylphosphonium bromide (120 mg, 0.34 mmol) was added and the deep yellow mixture was stirred at room temperature for 20 min. A solution of **17** in benzene (1 mL) was intro-

duced via cannula and the reaction mixture was heated at reflux for 21 h, cooled, and treated with saturated oxalic acid solution (10 mL). The product was extracted into petroleum ether (2 × 10 mL) and the combined organic layers were washed with saturated brine (10 mL), dried, and evaporated. The residual material (49 mg) was eluted through a plug (10 g) of silica gel with petroleum ether (100 mL) and the eluate was carefully concentrated to furnish 16 mg (36%) of **1** as a colorless oil. The ^{1}H nmr spectrum of this substance was identical in all respects to that of the authentic natural product provided by Professor Djerassi.

Total assignment of ^1H and ^{13}C spectra of kauradien-9(11),16-oic acid with the aid of heteronuclear correlated 2D spectra optimized for geminal and vicinal $^{13}C-^1H$ coupling constants: or what to do when "INADEQUATE" is impossible

Received March 27, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

WILLIAM F. REYNOLDS, RAUL G. ENRÍQUEZ, LAURA I. ESCOBAR, and XAVIER LOZOYA. Can. J. Chem. **62**, 2421 (1984).

It is shown that heteronuclear correlated spectra in which delay times are optimized for geminal and vicinal $^{13}C-^1H$ couplings rather than direct $^{13}C-^1H$ couplings can be used to assign quaternary carbons in the ^{13}C spectrum of kauradien-9(11),16-oic acid. These spectra in combination with normal heteronuclear correlated spectra plus homonuclear correlated spectra can be used to completely and unambiguously assign the ^{13}C and ^1H spectral peaks for the title compound. The main advantage of this approach over the use of $^{13}C-^{13}C$ connectivity ("INADEQUATE") experiments is sensitivity.

WILLIAM F. REYNOLDS, RAUL G. ENRÍQUEZ, LAURA I. ESCOBAR, et XAVIER LOZOYA. Can. J. Chem. **62**, 2421 (1984).

On démontre que l'on peut utiliser les spectres hétéronucléaires corrélés, dans lesquels on a optimisé les couplages géminal et vicinal $^{13}C-^1H$ plutôt que les couplages $^{13}C-^1H$ directs, pour attribuer les carbones quaternaires du spectre ^{13}C de l'acide kauradiène-9(11),16 oïque. On peut combiner ces spectres avec les spectres hétéronucléaires corrélés normaux et les spectres homonucléaires corrélés normaux pour faire une attribution complète et sans ambiguité des pics présents dans les spectres ^{13}C et ^1H. C'est la sensibilité qui est l'avantage principal de cette approche par rapport aux expériences de connectivité $^{13}C-^{13}C$ ("INADEQUATE").

[Traduit par le journal]

Introduction

As part of a systematic investigation of medicinal properties of natural products isolated from Mexican plants (1), we were interested in using some of the recently developed two dimensional nmr pulse sequences (2, 3) as an aid in characterizing these products and assigning their ^1H and ^{13}C spectra.

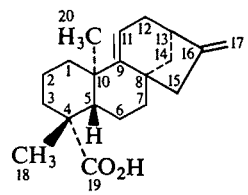
The techniques for simultaneously assigning hydrogens and protonated carbons by 2D nmr are now well established (3). For example, one can use heteronuclear ($^1H-^{13}C$) correlated spectroscopy (4) in conjunction with either homonuclear correlated spectroscopy (5, 6) or the more recently developed relayed coherence spectroscopy (7) for this purpose. Either of the latter allow establishment of hydrogen connectivity maps via vicinal $^1H-^1H$ coupling while the former identifies pairs of directly bonded carbons and hydrogens.

However, these experiments provide no assignments for either quaternary carbons or isolated protonated carbons (e.g. methyl groups attached to quaternary carbons) and may also fail in other special cases (see Discussion).

The ultimate approach is either the one-dimensional (8) or two-dimensional (9) $^{13}C-^{13}C$ connectivity experiment which allows assignment of the entire carbon skeleton. Unfortunately, due to the extremely low sensitivity of these experiments, this approach is often impractical. However, recently Richarz *et al.* (10) and Hull (11) have independently suggested the possibility of modifying the heteronuclear correlated experiment by choosing delay times appropriate for transferring magnetization via geminal ($^1\underline{H}—C-^{13}\underline{C}$) or vicinal ($^1\underline{H}—C—C-^{13}C$) couplings rather than the usual direct $^1H-^{13}C$ coupling.[1] In this manuscript, we show that this technique can be used in conjunction with other correlation experiments to provide a total and unambiguous assignment of all ^1H and ^{13}C signals of a typical natural product.

Results and discussion

The compound chosen for initial investigation was kauradien-9(11),16-oic acid, **1**, which was isolated from the plant *Montanoa tomentosa* ("zoapatle" in Mexican folk medicine) (1). This was chosen not only for its interesting and important medicinal properties (1) but also because only limited ^1H spectral data (13) and no ^{13}C spectral data were available for this compound.



1

A ^1H spectrum (200 MHz in $CDCl_3$, see Fig. 1) indicated the presence of several partially overlapping multiplets in the aliphatic region. However, all peaks were resolved in the ^1H-decoupled ^{13}C spectrum. Consequently, a heteronuclear correlated experiment was carried out (see Fig. 2). This allowed straightforward determination of which ^1H signals were associated (by direct bonding) with which ^{13}C signals. A homonuclear correlated experiment (6) was then carried out in an attempt to determine $^1H-^1H$ connectivity patterns. However, some of the connectivities could not be clearly established, because of multiplet overlap. Consequently, the heteronuclear and homonuclear experiments were repeated in C_6D_6. While the ^{13}C chemical shifts were almost unchanged (see Table 1),

[1]After initial submission of this manuscript, a report appeared demonstrating the utility of this approach for sequencing polypeptides (12).

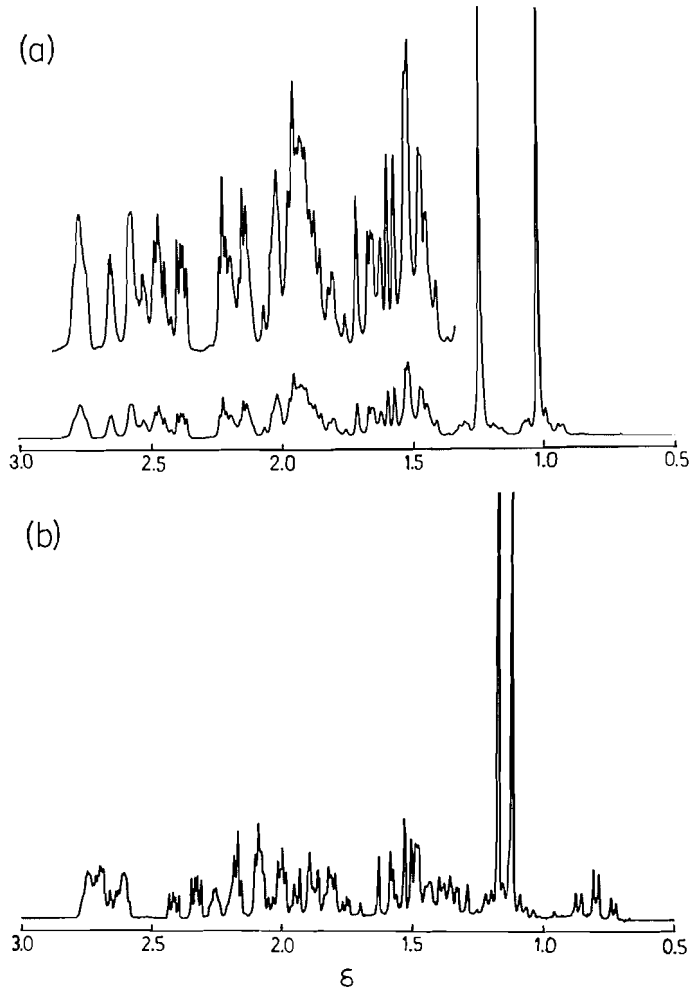

FIG. 1. Aliphatic ^1H spectral region (δ 0.5−3.0) for **1** in (a) $CDCl_3$ (b) C_6D_6.

aromatic solvent-induced shifts altered the ^1H spectrum sufficiently that previously overlapping multiplets could be resolved, allowing completion of the assignment of $^1H-^1H$ connectivities. This was aided by the fact that many of the carbons had two attached hydrogens which provided independent pathways for establishing connectivities.

The two types of 2D experiments in the two solvents allowed unambiguous assignment of most hydrogen and protonated carbon signals. Specifically the fragments —C(5)H—C(6)H_2—C(7)H_2— and —C(11)H—C(12)H_2—C(13)H—C(14)H_2 could be assigned, starting in each case with the underlined hydrogen. The protons of one C(sp^3)H_2 group showed allylic coupling to the C(17) olefinic protons in the homonuclear correlated experiments, allowing identification of this group as C(15)H_2, while C(17)H_2 could be assigned from the heteronuclear correlated experiments as the only C(sp^2)H_2 group. Finally the CO_2H group could be assigned on the basis of its unique ^{13}C chemical shift. However, while we could also identify the fragment —C(1)H_2—C(2)H_2—C(3)H_2 and assign C(2)H_2, it was impossible to determine which of the two remaining groups was C(1)H_2 and which was C(3)H_2, since each end of the sequence was terminated by a quaternary carbon. Similarly, the two CH_3 groups could not be definitively assigned since each is also attached to a quaternary carbon. Finally, the experiments described above provided no basis

[a]The first listed value is the chemical shift of each proton in $CDCl_3$ while the second value (in brackets) is the chemical shift in C_6D_6.
[b]Equatorial proton or methyl group.
[c]Axial proton or methyl group.
[d]Pairs of hydrogens could be interchanged.
[e]Assigned on the basis of an observed cross peak between C(16) and $H(14)_\alpha$ in Fig. 3 (see text).
[f]It cannot be determined which of these olefinic hydrogens is *cis* to C(13) and to C(15). Note that the labels α and β do not apply.
[g]Very broad CO_2H peak.

for assigning the three quaternary sp^3 carbons, C(4), C(8), and C(10), as well as the two quaternary sp^2 carbons, C(9) and (16).

Several of these signals (particularly the two CH_3 groups) could have been tentatively assigned on the basis of previous assignments of closely related compounds (14). However, we were interested in making the assignments with a minimum of *a priori* assumptions since one can never be absolutely confident of the validity of the earlier assignments. Consequently, we decided to try the idea of Richarz *et al.* (10) and Hull (11) of altering the delay times in the heteronuclear correlated experiment to values appropriate for promoting magnetization transfer via geminal ^1H—C—^{13}C and (or) vicinal ^1H—C—C—^{13}C couplings rather than direct $^1H-^{13}C$ couplings, as normally used. The use of magnetization transfer from CH_3 signals seemed particularly promising, both because these sharp singlets should give the most intense peaks in the 2D (heteronuclear correlated) spectrum and because the similar magnitudes of geminal and vicinal $^1H-^{13}C$ couplings involving methyl hydrogens should allow simultaneous establishment of connectivities via both types of couplings in a single experiment.

Inspection of the structure of **1** shows that the C(18)H_3 signal should transfer magnetization to C(3), C(4), C(5), and C(19) while the C(20)H_3 signal should transfer magnetization to C(1), C(5), C(9), and C(10). As shown below, this is sufficient to allow unambiguous assignment of all previously unassigned signals.

The heteronuclear correlated pulse sequence (4*b*) is illustrated in **2**. With the Varian software, one enters a value of J_{CH}

(in Hz) with Δ_1 set at $1/2J$ and Δ_2 at $1/3J$. Repeated preliminary experiments with different input J_{CH} values indicated that best results were obtained for $J_{CH} = 10$ Hz (i.e. $\Delta_1 = 0.05$ s, $\Delta_2 = 0.033$ s) even though $^2J_{CH}$ and $^3J_{CH}$ couplings involving methyl hydrogens are typically ca. 5 Hz (15). Two factors are likely responsible for this. First, the value $\Delta_2 = 1/3J$ is actually a compromise value for different CH_n groups with $\Delta_2 \simeq 1/5J$ being optimum for CH_3 groups (2), i.e., optimum $\Delta_2 \simeq 0.2/5 = 0.04$ s. By contrast, the theoretical optimum Δ_1 is independent of the type of CH_n group, i.e. optimum $\Delta_1 = 0.10$ s. However, ^1H magnetization is decaying towards zero during this delay period. Due to short ^1H relaxation times in large molecules, the use of a shorter than theoretically optimum Δ_1 may actually maximize the residual magnetization available for transfer to ^{13}C in the final stage of the pulse sequence.[2]

Results are shown in Figs. 3 and 4. Figure 3 shows the low field ^{13}C region. It is seen that the low field $C\underline{H}_3$ group transfers magnetization to $\underline{C}(19)O_2H$. Thus, this signal corresponds to $C(18)\underline{H}_3$. Similarly the high field $C\underline{H}_3$ group transfers magnetization to the low field quaternary $C(sp^2)$ signal, simultaneously confirming that the former is $C(20)\underline{H}_3$ and that the latter is C(9). The methyl ^{13}C signals can then be assigned from the normal heteronuclear correlated experiment (Fig. 2) while C(16) is assigned on the basis that it is the only remaining quaternary $C(sp^2)$ signal.

Figure 4 illustrates the aliphatic ^{13}C region. The low field $C\underline{H}_3$ peak ($C(18)\underline{H}_3$) transfers magnetization to three peaks on the left hand side of the spectrum, corresponding to C(3), C(4), and C(5). The final assignment of these three peaks is straightforward due to their different numbers of attached protons (respectively 2, 0, and 1). Similarly, one can identify (C1), C(5), and C(9) on the basis of magnetization transfer from $C(20)\underline{H}_3$ and their different numbers of attached protons (respectively 2, 1, and 0). Note that this experiment provides a check of the self-consistency of the approach since it provides two independent assignments of C(5) which can be compared with the earlier assignment of this carbon based on proton–proton connectivities. All three assignments agree. Finally, C(8) can be assigned as the only quaternary sp^3 carbon which receives no magnetization from either $C(18)\underline{H}_3$ or $C(20)\underline{H}_3$, thus completing the assignment. Strong peaks are also observed corresponding to $\underline{C}(18)\underline{H}_3$ and $\underline{C}(20)\underline{H}_3$, even though the chosen delay time is far removed from the optimum value for magnetization transfer via direct $^{13}C-^{1}H$ coupling. However, this is redundant information since these connectivities have already been established (see Fig. 2).

Some additional peaks are observed in Figs. 3 and 4 corresponding to connectivities between methine or methylene hydrogens and adjacent carbons. Most of these correspond to *anti* vicinal $^{13}C-^{1}H$ coupling, as expected, since the chosen delay times are close to optimal (2) for this type of coupling (*anti* $^3J_{CH} \simeq 9$ Hz (15)) but not for the much smaller *gauche* coupling. In all cases, the observed cross peaks support the earlier ^{13}C and ^{1}H assignments. For example, in Fig. 3, there are two cross peaks corresponding to $^{13}\underline{C}O_2H$ plus protons assigned as H(3)β and H(5), both of which are in an *anti* vicinal arrangement with

[2]No attempt was made to independently optimize Δ_1 and Δ_2 since this would be extremely time consuming.

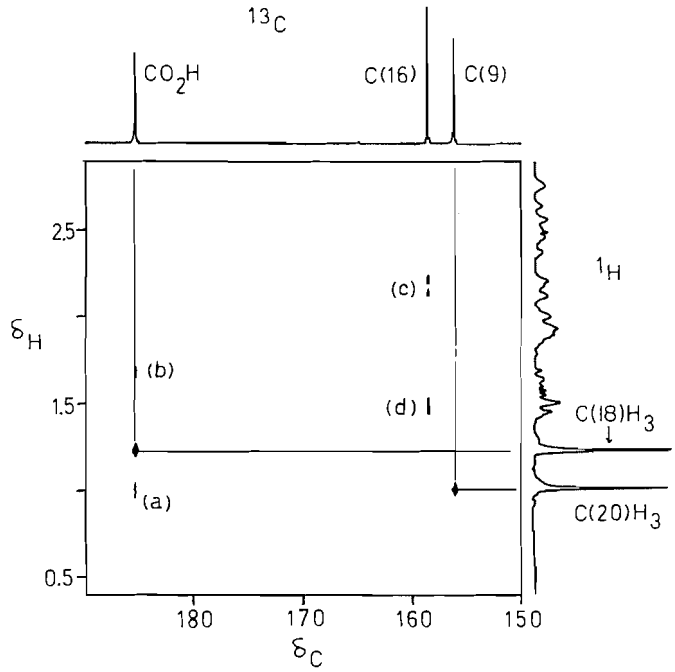

FIG. 3. Long range heteronuclear correlated spectrum (emphasizing $^2J_{CH}$ and $^3J_{CH}$ couplings) for **1** in $CDCl_3$ with the low field ^{13}C spectral region along the horizontal and the aliphatic ^1H spectral region along the vertical. Crossed lines point out the main peaks used for assignment purposes. Redundant peaks discussed in the text include (a) $\underline{C}O_2H—\underline{H}(5)$ (b) $\underline{C}O_2H—\underline{H}(3)\beta$ (c) $\underline{C}(16)—H(15)$ (d) $C(16)—\underline{H}(14)\alpha$.

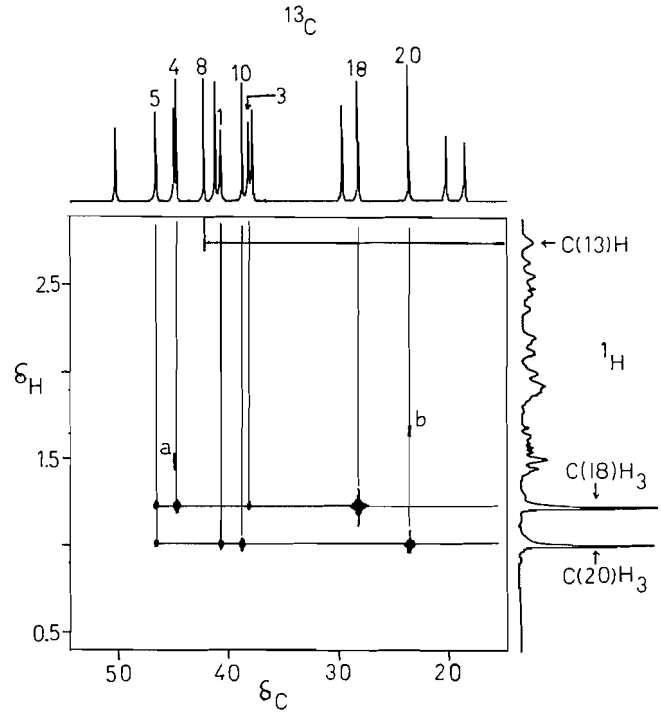

FIG. 4. Long range heteronuclear correlated spectrum for **1** in $CDCl_3$ with the aliphatic ^{13}C spectral region along the horizontal. Crossed lines point out the main peaks used for assignment purposes with the assigned carbons labelled. Redundant peaks discussed in the text include (a) C(14)—H(7)β and (b) C(20)—H(5). Note the absence of a peak for C(18)—H(5).

respect to CO_2H. There are cross peaks between C(16) and one of the C(15) protons plus one of C(14) protons, presumably the one *anti* to C(16), both supporting the assignment of C(16) given above. Similarly in Fig. 4, there is a cross peak between C(8) and the *anti*-vicinal H(13), supporting the assignment of this quaternary carbon. A peak is also observed establishing a connectivity between C(14) and one of the C(7) protons. Interestingly, there is also a cross peak between C(20) and H(5) but not between C(18) and H(5), consistent with the *anti* orientation of the former coupling and the *gauche* orientation of the latter coupling. Thus, the modified heteronuclear correlated experiment can not only be used to establish geminal and vicinal $^{13}C-^1H$ connectivities but can also provide conformational information in the case of vicinal coupling. It should be noted that spectra recorded at higher vertical gain show many additional geminal or vicinal $^{13}C-^1H$ peaks which are consistent with our assignments. The vertical gains for Figs. 3 and 4 were chosen to give relatively clean spectra, emphasizing the key cross peaks involving the methyl hydrogens, since the other peaks provide redundant information.

Final assignments are provided in Table 1. The assignment of methylene hydrogens as α or β is based on the known stereochemistry of **1** plus the presence or absence of a large vicinal coupling constant (indicative of an axial orientation) in individual proton multiplets (cross-sections through each ^{13}C peak in Fig. 1 were used to better determine ^1H multiplet patterns). In three cases, it was impossible to unambiguously assign pairs of methylene hydrogens on a single carbon. Otherwise, the assignment is complete and unambiguous. Furthermore, this assignment has required no prior assumptions, other than the trivial one that can distinguish CO_2H from quaternary sp^2 carbons separated by over 25 ppm.
