These studies were undertaken to gain more structural information on the nature of the [crown ether·Ca^{2+}] complex, particularly with the mono- and *syn*-dipiperidine acids **1***c* and **2***c*.

From previous ^1H nmr studies on analogous compounds (5, 21), the following general observations on the conformation of the crown ether have been made. Firstly, the observable vicinal coupling constant (^3J = 2–3 Hz) of the chiral center is consistent with a diaxial orientation of the amide and carboxyl groups. Such conformation was also noted in X-ray crystal structures of related compounds (6, 21). Secondly, this chiral barrier fragment (—O—$\overset{*}{C}$HX—$\overset{*}{C}$HY—O—) is relatively rigid, suggesting that any conformational change in the molecule should implicate the ethylenedioxy segments of the crown ether ring. Thirdly, the amide N*H* proton is involved in a strong intramolecular hydrogen bond to the adjacent ether oxygen of the crown. Although ^1H nmr spectroscopy can provide a powerful tool for the investigation of the conformation of crown ether carriers and their ion complexes, it gives no direct information on the environment of the carboxylate group itself. Furthermore, the estimation of T_1 relaxation times of the $-CH_2O-$ group of the crown is rather tedious since the spectral bands highly overlap in the region of interest and provide relatively little information.

As noted in the previous section, the main forces involved in the complexation process are electrostatic interactions between the carboxylate groups of the crown and its bound cation. Therefore, there is a particular interest in exploring this region to gain more structural information on the nature of the complex formed, particularly with the Ca^{2+} ion.

Figure 1 demonstrates that ^{13}C nmr spectroscopy is a reliable technique for the investigation of the carboxylate environment of our crown ether molecules **1***c* and **2***c*, since the spectra exhibit two well-separated resonances in the carbonyl region. The free salts (pH 11.6) show two narrow resonances: the amide

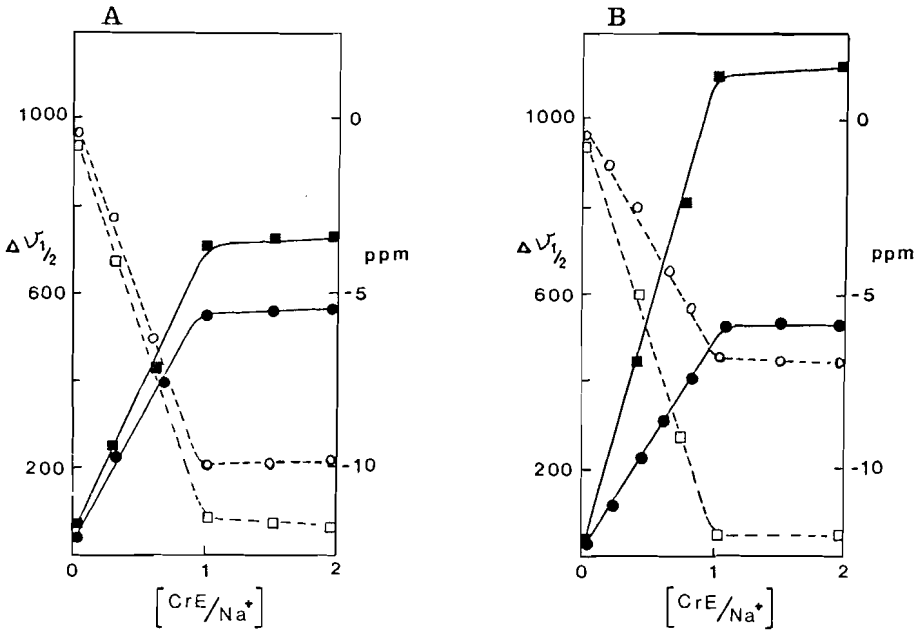

FIG. 2. ^{23}Na chemical shift (dashed lines) and line width ($\Delta\nu_{1/2}$) (solid lines) as a function of added monopiperidine **1***c* (A) and *syn*-dipiperidine **2***c* (B); $[Na^+] = 0.1$ *M* in CD_3OD/D_2O (90:10 v/v); circles, pH = 2.0 (HCl); squares, pH = 10.0 (Me_4NOH). CrE means the corresponding crown ether.

band between 171 and 173 ppm and the carboxylate band near 175–177 ppm (spectra A and D). Addition of $Ca(SCN)_2$ to give a 2:1 ratio (CrE/Ca^{2+}) changes appreciably the appearance of the spectra. Figure 1B clearly shows a downfield shift coupled with the appearance of two new resonances at 181.8 and 181.5 ppm. The same trend is observed for **2***c* (Fig. 1E), which also suggests the presence of three discrete carboxylate forms in solution: a tight (T), a loose (L), and a free carboxylate (F). These carboxylate – metal ion interactions have been described previously by Fyles and Whitfield (21), where an asymmetric or tight carboxylate–cation pair might be viewed as a purely electrostatic interaction involving the carboxylate charge fully localized on one oxygen atom and interaction with a proximal cation. In the more symmetrical or loose ion pair interaction, however, the charge could be seen as more delocalized on the carboxylate and with the metal ion more distant. Under the conditions of concentration used, we expect to be looking at the 2:1 crown ether – calcium complex. Indeed, both **1***c* and **2***c* exist mainly as a dimer with the metal being coordinated with both the crown and the carboxylate groups of one molecule but assisted by only the carboxylate group of the other macrocycle. In fact, this behavior is quite similar to naturally occurring linear carboxylic acid ionophores such as A-23187 and X-14547A, which form 2:1 complexes with calcium ion (23).

In the 1:1 complexes (Figs. 1C and 1F), where a stoichiometric amount of metal ion leads to a preferential coordination with the crown carboxylate groups, only a tight carboxylate–cation interaction seems to dominate. In such a situation, the metal ion nuclear quadrupole typically broadens the lines.

Information on the structure and molecular motion can also be obtained by nmr relaxation time (T_1) measurements. Studies using this approach (24) have been carried out on neutral [18]-crown-6 compounds, and typical values in 9:1 $MeOH/D_2O$ were in the order of 1.3 s for the free ligand and of 1.1 s for the corresponding Na^+ complexes. In our case, we found that the $-CH_2O-$ crown carbons of **2***c* had a value of 0.05 s and a value of 0.16 s for **1***c*. Consequently, these surprisingly low values seem to indicate that these species in solution are in an aggregated form. A recent study on aliphatic monoacid [18]-crown-6 analogs showed no evidence of such aggregated species (21).

In a complementary approach, we became interested in looking directly at the magnetic resonance of the ion bound to the crown ether. For this, ^{23}Na nmr ($I = 3/2$, 100% abundance) is known to be a very direct probe for evaluating the degree of symmetry of the crown ether – ion complex (25). Indeed, ^{23}Na chemical shifts are directly related to the perturbation of the electrons of the sodium atom and consequently are expected to be very sensitive to the immediate environment of the ion (26). Furthermore, in the solvated form, the nmr relaxation rate of ^{23}Na is relatively long if the ion is symmetrically solvated, while when bound to a crown ether, the symmetry around the cation could be considerably reduced, resulting in a faster nuclear relaxation (27).

Figure 2 illustrates the ^{23}Na chemical shift and line-width ($\Delta\nu_{1/2}$) variations of the sodium nucleus upon addition of **1***c* (Fig. 2A) or **2***c* (Fig. 2B) to a 0.1 *M* NaSCN solution at two different pH values. These data clearly show that the complexes are completely formed after the addition of one equivalent of the crown ether to the solution, in both acidic or basic media. For compound **1***c*, the expected upfield variation in the chemical shifts observed for a complex of 1:1 stoichiometry is comparable in either acidic or basic solution, indicating a similar coordination and shielding electron density at the metal nucleus. However, the chemical shifts in compound **2***c* are significantly different for the two different pH's. This larger variation is probably related to the concerted effect of the two *syn* dicarboxylic acid functions.

It is noteworthy that the line-width variations of **1***c* and **2***c* in acidic condition are also comparable, indicating a preferential coordination by the crown ether ring without participation of the oxygens of the carboxylic groups. However, a much larger variation is observed under basic conditions, indicating clearly that the carboxylate forms increase the asymmetry about the sodium nucleus. This asymmetry change is especially seen in

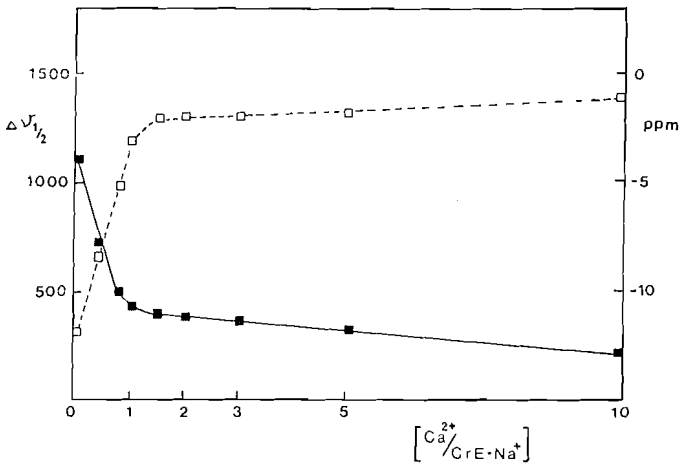

FIG. 3. Variation in the ^{23}Na chemical shift (dashed lines) and line width ($\Delta\nu_{1/2}$) (solid lines) as a function of Ca^{2+} ion added to *syn*-dipiperidine **2***c* complexed to Na^+ ion at a 1:1 [CrE·Na^+] ratio, pH = 10.0.

syn **2***c* where a difference of almost 600 Hz is observed between acidic and basic conditions.

Since the stability constant (Table 2) for **2***c* and Ca^{2+} ion in basic solution is 10^4-fold more important than for Na^+ ion, one would expect that addition of a Ca^{2+} solution to a stoichiometric [**2***c*·Na^+] complex should induce a narrowing of the observed ^{23}Na resonance as well as a downfield shift. Figure 3 illustrates this behavior for *syn* **2***c* and clearly indicates that the calcium ion is strongly complexed into the crown dicarboxylate system, even in the presence of sodium in the medium.

In general, the addition of any competitive cation to a 1:1 complex should induce a downfield shift and a narrowing of the observed ^{23}Na resonances in going from a fully complexed state to a lower (less than 1:1) complex state. However, the magnitude of the change in $\Delta\nu_{1/2}$ and chemical shift is very dependent upon the stability constants of the ions implicated in the competition experiment. For instance, if no preferential complexation for Ca^{2+} ion is taking place, the chemical shift of ^{23}Na should take a value around −6.5 ppm after the addition of one equivalent of Ca^{2+}; i.e., the value observed in a situation where 50% of the crown ether is complexed with sodium ion. In the case of *syn* **2***c*, the observed chemical shift after addition of Ca^{2+} was around −4 ppm. Clearly, the crown discriminates in favor of Ca^{2+} ion over Na^+ ion. For [**1***c*·Na^+] in competition with Ca^{2+}, a similar situation occurred, but to a smaller extent. The ^{23}Na resonance after addition of one equivalent of Ca^{2+} was at −5 ppm as compared to a value of −6.2 ppm for a 50% sodium–crown solution. This indicates again that the stability constant of **1***c* for Ca^{2+} is higher than for Na^+ ion.

In summary, our ^{23}Na nmr results indicate that both mono- and dicarboxylic derivatives (**1***c* and **2***c*) complex sodium in a similar fashion in acidic medium, and the results can be rationalized in terms of protonation of the carboxylic groups with Na^+ ion near the center of the macrocycle, with only a small participation of the adjacent acidic function. However, in basic medium, a shift in the position of the Na^+ ion within the macrocycle towards the carboxylate is a plausible explanation for the differences noted in ^{23}Na nmr experiments.

Experimental

Reagents

Sodium thiocyanate (Anachemia Inc.) was twice recrystallized from MeOH and dried under vacuum at 50°C for 2 days. Calcium thiocyanate was purchased as a 62% aqueous solution (Pfaltz and Bauer Inc.) and was dried *in vacuo* at 50°C for 4 days.

Methanol-d_4 and D_2O (Cambridge Isotope Lab.) were used directly from the manufacturer's sealed vials without further purification.

Macrocyclic polyethers **1***c* and **2***c* were passed over DOWEX 50-X8 (H^+ form) resin and stored into a carefully washed vessel.

Tetramethylammonium hydroxide pentahydrate (Aldrich) was dried at 40°C under vacuum for 1 day. All glassware used in this study was washed with concentrated HCl to remove any remaining cations.

*(2R,3R)-(+)-N-4′-(2′,2′,6′,6′-Tetramethylpiperidine)-2-carboxamido-1,4,7,10,13,16-hexaoxacyclooctadecane-3-carboxylic acid (**1**c)*

2,2,6,6-Tetramethyl-4-aminopiperidine (187.2 mg, 1.2 mmol) was dissolved in 15 mL of anhydrous dichloromethane. To this solution was added a solution of the monoanhydride [18]-crown-6 (200 mg, 0.6 mmol) (7) in 15 mL of dichloromethane, under a N_2 atmosphere. After 2 h of stirring at ambient temperature, the monopiperidine monoacid **1***c* precipitated as a white solid (yield: 90%, mp 161–163°C). The product was then eluted from a Dowex 50W-X8 column (H^+ form) with water and recrystallized from acetone–methanol mixture; $[\alpha]_D^{25}$ +29.0° (*c* 1.0, MeOH); ir (KBr), cm^{-1}: 1625, 1400, 1100; ^1H nmr (D_2O, 90 MHz) δ: 8.41 (s, 1H, acid), 7.43 (s, 1H, N*H* amide), 4.23 and 4.02 (dd, 2H, J_{ab} = 3.5 Hz), 3.73 (m, 20H, crown), 1.65 and 1.52 (s, 12H, methyl); ms (EI) *m/e*: 490 (M^+). *Anal.* calcd. for $C_{23}H_{42}N_2O_9$: C 56.31, H 8.63, N 5.71; found: C 55.89, H 8.47, N 5.60.

The corresponding methyl ester **1***d* was obtained by dissolving the compound (348 mg, 0.71 mmol) in 1 mL of MeOH, cooling to 0°C, and adding 2 mL of an ethereal CH_2N_2 solution. The progress of the reaction was followed by tlc (MeOH). The solvent was evaporated after completion of the reaction and the product purified on a silica gel column. A white solid (271 mg, 0.54 mmol) was obtained in 76% yield (mp 79–81°C); $[\alpha]_D^{25}$ +25.1° (*c* 1.0, $CHCl_3$); ir ($CHCl_3$), cm^{-1}: 1750 (ester), 1670 (amide), 1350 (*gem*-CH_3), 1110; ^1H nmr ($CDCl_3$, 90 MHz) δ: 4.41 and 4.25 (dd, 2H, J_{ab} = 2.9 Hz), 3.82 (s, 3H, OCH_3), 3.61 (m, 21H, crown, C*H*—N), 1.30 (m, 4H, CH_2—N—CH_2), 1.35 and 1.43 (2s, 12H, CH_2); ms (EI) *m/e*: 505 ($M + H^+$).

*(2R,3R)-(+)-2-Carbomethoxy-3-carboxanilide-1,4,7,10,13,16-hexaoxacyclooctadecane (**1**e) and its precursor, the corresponding acid*

The monoanhydride [18]-crown-6 (565 mg, 1.7 mmol) (7) was dissolved in 15 mL of dichloromethane and, to this solution, aniline (0.7 mL in 15 mL CH_2Cl_2) was added dropwise. After 2 h of stirring at ambiant temperature under a N_2 atmosphere, the reaction mixture was washed twice with 5 mL of 5% HCl solution and three times with 5 mL of 5% NMe_4OH solution. The aqueous phase was acidified with 5% HCl and the desired product extracted with chloroform. The volume of the chloroformic extract was reduced and 60 mL of heptane was added to precipitate the product. This acid was recrystallized from a dichloromethane–toluene mixture to give 622.6 mg (1.5 mmol) of a white solid (yield, 88%; mp 143–145°C); $[\alpha]_D^{25}$ +85.7° (*c* 1.0, $CHCl_3$); ir ($CHCl_3$), cm^{-1}: 1750 (amide), 1100; ^1H nmr ($CDCl_3$, 90 MHz) δ: 8.91 (s, 1H, N*H* amide), 7.33 (m, 5H, phenyl), 4.52 and 4.40 (dd, 2H, J_{ab} = 2.7 Hz), 3.63 (m, 20H); ms (CI) *m/e* 428 ($M + H^+$).

This monoanilide monoacid [18]-crown-6 (316 mg, 0.7 mmol) was dissolved in 1 mL THF, cooled to 0°C, and to this solution was added 2 mL of an ethereal CH_2N_2 solution. The reaction was followed by tlc ($MeOH/CHCl_3$, 1:2) and, after completion, the solvent was evaporated and the resulting methyl ester **1***e* purified by column chromatography on silica gel. A pale yellow oil (314 mg, 0.7 mmol) was obtained in 96% yield; ir ($CHCl_3$), cm^{-1}: 3000, 2900, 1750, 1680, 1140; ^1H nmr ($CDCl_3$, 90 MHz) δ: 9.42 (s, 1H, N*H* amide), 7.31 (m, 5H, phenyl), 4.52 and 4.40 (dd, 2H, J_{ab} = 2.35 Hz), 3.83 (s, 3H, OCH_3), 3.90 (m, 20H, crown); ms (CI) *m/e*: 442 ($M + H^+$).

*(2R,3R)-(+)-2-(4′,4′-Dimethyl-2-oxazoline-2-yl)-3-carboxanilide-1,4,7,10,13,16-hexaoxacyclooctadecane (**1**f)*

A mixture of the monoanilide monoethyl ester [18]-crown-6 **1***e*

(57.8 mg, 0.12 mmol), 2-amino-2-methyl-propanol (0.3 mL, 0.52 mmol), and P_2O_5 (150 mg) in 10 mL of xylene was refluxed for 30 h under a N_2 atmosphere. After filtration, the solvent was evaporated and the residue chromatographed on a silica gel column. A yellow oil (42.8 mg, 0.09 mmol) was recovered in 69% yield; ir ($CHCl_3$), cm^{-1}: 1680 (amide), 1600 (C=N—C), 1100; ^1H nmr ($CDCl_3$, 90 MHz) δ: 7.39 (m, 5H, phenyl), 4.35 (m, 2H), 3.68 (m, 22H, crown and CH_2 of oxazoline), 1.40 (m, 6H, CH_3); ms (CI) *m/e*: 481 ($M + H^+$). *Exact Mass* calcd. for $C_{24}H_{36}N_2O_8$: 480.2471; found: 480.2456.

(2R,3R)-(+)-2-(4',4'-Dimethyl-2-oxazolidine)-3-carboxanilide-1,4,7,10,13,16-hexaoxocyclooctadecane (1g)

The monooxazoline **1***f* (33.9 mg, 0.07 mmol) was dissolved in 5 mL of a 1:1 THF/MeOH mixture. The temperature of the solution was brought to −30°C and the pH was ajusted to 7 with 9 *N* HCl. $NaBH_4$ (3 mg, 0.07 mmol), dissolved in cool water, was added dropwise and the conditions maintained for 2 h. If the reaction was not complete, 0.25 equiv. of $NaBH_4$ was added again and the reaction continued for another hour. The reaction was stopped by addition of few millilitres of EtOH and the solution made alkaline by addition of a small amount of 10% NaOH. The aqueous phase was then separated and the organic layer washed with water. After a silica gel column purification, 17.7 mg (0.04 mmol) of a yellow semisolid material (57%) was recovered; ir ($CHCl_3$), cm^{-1}: 1740, 1260, 1120; ^1H nmr ($CDCl_3$, 400 MHz) δ: 9.50 (s, 1H, N*H* amide), 7.33 (m, 5H, phenyl), 3.63 (m, 22H, crown, CH_2 of oxazolidine), 1.25 (m, 7H, CH_3, N*H* oxazolidine); ms (CI) *m/e*: 483 ($M + H^+$). *Exact Mass* calcd. for $C_{24}H_{38}N_2O_8$: 482.2628; found: 482.2622.

Procedure for the preparation of only the syn *isomer (2c): (2R,3R,11R,12R)-(+)-N,N'-di-4'-(2',2',6',6'-tetramethyl-piperidine)-2,11-dicarboxamido-1,4,7,10,13,16-hexaoxacyclo-octadecane-3,12-dicarboxylic acid*

A solution of the dianhydride [18]-crown-6 (418 mg, 1.2 mmol (6) in 15 mL of dichloromethane was slowly added to 2,2,6,6-tetramethyl-4-aminopiperidine (374.4 mg, 2.4 mmol) dissolved also in 15 mL of dichloromethane, and containing 1 mL of triethylamine. After a few hours, the product precipitated out of the solution. It was filtered and recrystallized from acetone–water to obtain 616 mg (1.1 mmol) of *syn* **2***c* in 95% yield (mp 190°C (dec.)); $[\alpha]_D^{25}$ +31.4° (*c* 1.0, $CHCl_3$); ir (KBr), cm^{-1}: 3400, 1650, 1390, 1145; ^1H nmr (D_2O, 400 MHz) δ: 4.10 and 3.93 (dd, 2H, J_{ab} = 5.58 Hz), 3.71 (m, 18H, crown, -C*H*), 2.22 (m, 10H, CH_2 piper., N*H*), 1.53 and 1.52 (s, 12H, CH_3), 1.45 and 1.43 (s, 12H, CH_3); ms (CI) *m/e*: 717 ($M + H^+$). *Anal.* calcd. for $C_{34}H_{60}N_4O_{12}$: C 56.97, H 8.44, N 7.82; found: C 56.57, H 8.09, N 7.70.

The corresponding *syn*-dimethyl ester **2***d* was obtained in 80% yield by treating **2***c* with an ethereal CH_2N_2 solution (mp 200°C (dec.)); $[\alpha]_D^{25}$ +45.6° (*c* 1.0, $CHCl_3$); ir ($CHCl_3$), cm^{-1}: 1650, 1400, 1130; ^1H nmr ($CDCl_3$, 400 MHz) δ: 4.31 and 4.11 (s, 4H), 3.73 (m, 18H), 3.25 (s, 24H, CH_3); ms (CI) *m/e*: 745 ($M + H^+$).

Procedure for the preparation of the anti *isomer (3c)*

The dianhydride [18]-crown-6 (242.4 mg, 0.6 mmol) (6) in 10 mL of dichloromethane was added to a solution of 2,2,6,6-tetramethyl-4-aminopiperidine (416.4 mg, 2.7 mmol), also in 10 mL of dichloromethane. During the reaction, 385.7 mg (0.5 mmol) of a mixture of *syn* and *anti* isomers precipitated (yield, 83%). Even after repeated chromatography, the *anti* isomer **3***c* was always contaminated by 20% of **2***c*. The corresponding *anti* dimethyl ester **3***d* was obtained as an oil.

syn-*(2R,3R,11R,12R)-(+)-2,11-Dicarboxanilide-1,4,7,10,13,16-hexaoxacyclooctadecane (2e)*

The precursor dianilide diacid has already been reported (6). It was dissolved in THF, mixed with ethereal CH_2N_2, and left at 0°C overnight. It was then purified by chromatography to yield a yellowish oil (81%); $[\alpha]_D^{25}$ +67.6° (*c* 1.0, $CHCl_3$); ir ($CHCl_3$), cm^{-1}: 1750, 1680, 1120; ^1H nmr ($CDCl_3$, 90 MHz) δ: 9.22 (s, 2H, N*H* amide), 7.40 (m, 10H, phenyl), 4.41 (s, 4H), 3.85 (s, 6H, OCH_3), 3.73 (m, 16H, crown); ms (CI) *m/e*: 619 ($M + H^+$).

syn-*(2R,3R,11R,12R)-(+)-2,11-Bis(4',4'-dimethyl-2-oxazoline-2-yl)-3,12-dicarboxanilide-1,4,7,10,13,16-hexaoxocycloocta-decane (2f)*

Under reflux for 24 h, a mixture of the dianilide dimethyl ester **2***e* (42.3 mg, 0.07 mmol) and 2-amino-2-methyl-propanol (0.12 mL, 0.3 mmol) was treated in 10 mL of xylene in the presence of P_2O_5. After reflux, the solution was filtered, most of the solvent evaporated, and the residue chromatographed on silica gel to obtain 41.3 mg (0.06 mmol) of a yellow oil (yield, 86%); $[\alpha]_D^{25}$ +47.8° (*c* 1.0, $CHCl_3$); ir ($CHCl_3$), cm^{-1}: 1670, 1600, 1100; ^1H nmr ($CDCl_3$, 90 MHz) δ: 7.42 (m, 10H, phenyl), 4.51 (m, 4H), 3.63 (m, 20H, crown, CH_2 oxazoline), 1.42 (m, 12H, CH_3); ms (CI) *m/e*: 349 ($M + 2H^+/2$). *Exact Mass* calcd. for $C_{36}H_{48}N_4O_{10}$: 696.3370; found: 696.3312.

syn-*(2R,3R,11R,12R)-(+)-2,11-Bis(4',4'-Dimethyl-2-oxazolidine)-3,12-dicarboxanilide-1,4,7,10,13,16-hexaoxacyclooctadecane (2g)*

The same procedure as for the synthesis of **1***g* was followed to obtain **2***g* as a semi-solid yellow material (yield, 50%); ^1H nmr ($CDCl_3$, 90 MHz) δ: 9.02 (s, 2H, N*H* amide), 7.41 (m, 10H, phenyl), 4.48 and 4.41 (dd, 4H, J_{ab} = 1.99 Hz), 3.72 (m, 20H, crown, C*H* and CH_2 oxazolid.), 1.32 (m, 14H, CH_3, N*H* oxazolid.). *Exact Mass* calcd. for $C_{36}H_{52}N_4O_{10}$: 700.3683; found: 700.3598.

Transport studies

Transport experiments were performed in a thermostated room (20 ∓ 1°C), using a U-shaped cell constructed of 17-mm id tubing. The tube had a total capacity of 55 mL and consisted of a 10-mL membrane phase interfaced to both a 15-mL source phase of 0.01 *M* picrate salts solution at pH 9.7 (diethanolamine HCl 0.05 *M*) and a 15-mL blank buffer receiving phase. The membrane phase was made of alcohol-free spectroscopic grade chloroform containing 10^{-3} *M* carrier. The aqueous phases were stirred at a constant rate of 80 rpm and the organic phase at 400 rpm for all the experiments. Blank experiments (no carrier present) were performed to determine the membrane leakage. No detectable movement of cation across the chloroform membrane was found in the blank unit within 8 h. The rates of ion transport were determined by monitoring the picrate concentration in the receiving phase by visible spectroscopy at 354 nm. Samples were withdrawn from the receiving phase at 30-min intervals for 8 h and the absorption of picrate recorded. For low concentration of metal picrate in the receiving phase the solution samples could be removed, analysed, and replaced. For high concentration, it was necessary to dilute the samples from the receiving phase to calculate the concentration. Therefore, for high concentrations, a 100-μL sample of the receiving phase was removed, diluted as necessary, and subsequent experimental readings were corrected for the resulting change in volume. It should be noted that in the case of calcium transport experiments, the apparent rate of picrate transport was divided by two, to take into acount the divalent nature of the cation. A plot of moles of cation transported into the receiving phase vs. time was made for each system. The data were fitted to a straight line, the slope of which gave values of transport rate. Linear fits of the data (zero-order regime) and agreement between different runs of the same system was within ± 10%.

Determination of pK_a and pK_s

The methods used have been previously described in detail (7).

^{13}C, ^{23}Na nuclear magnetic resonance studies

Noise decoupled, natural abundance ^{13}C nmr spectra were obtained at 20.17 MHz using a Bruker WP-80 spectrometer in the pulsed transform mode.

The sample solution was placed in a 9-mm id nmr tube and chemical shifts were referred to Me_4Si. Solutions were 0.17 *M* (**1***c*) and 0.25 *M* (**2***c*) in CD_3OD:D_2O 9:1 v/v, and acid (HCl) or base (tetramethylammonium hydroxyde pentahydrate) was added to give a target value of pH (2 and 11.6). All solutions were prepared by weighing the desired amount of the ligand and salt.

^{13}C relaxation times (T_1's) were measured by the fast inversion–recovery technique $(180°\tau-90°-t)_n$ where 15 different pulse intervals,

τ, were used for each individual measurement and were chosen so that at least 10 points were included for each T_1 calculation (28). Usually 1000–3000 scans were necessary for each τ value to obtain a reasonable signal-to-noise ratio. On the average, each run required 48 h.

Sodium-23 nmr measurements were obtained on the same instrument at 21.21 MHz. Samples solutions were 0.1 *M* NaSCN in $CD_3OD:D_2O$ 9:1 v/v and were pH adjusted to give target values of 2 (HCl) and 10 ($Me_4NOH \cdot 5H_2O$). Sodium complexes of **1***c* and **2***c* were made by adding weighed amounts of the crown ethers into the 9-mm nmr tube. A 3 *M* deuterated aqueous sodium chloride solution was used as reference and the reported sodium-23 chemical shifts were referred to this solution. Relaxation times for ^{23}Na were determined from the line widths of the absorption spectra.

Dry calcium thiocyanate was used in the competition experiment.

Resonance Raman spectroscopic evidence for the formation of covalent complexes between *N*-acylamino acid dithioesters and mercury papain[1]

HO-HI LEE, RONALD H. ANGUS, PAUL R. CAREY, AND ANDREW C. STORER
Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received December 31, 1986

HO-HI LEE, RONALD H. ANGUS, PAUL R. CAREY, and ANDREW C. STORER. Can. J. Chem. **65**, 1521 (1987).

Ethyl dithioesters of *N*-acylglycine and *N*-acylalanine are shown to bind tightly to the active site of papain in which the side chain of cysteine-25 is in the mercurated form. Although both classes of dithioester bind to the active site mercury via their thiono (C=S) sulfur atoms, the resulting adducts are quite different. Absorption and resonance Raman data, supported by comparison with model compounds and by ^{15}N and $^{13}C{=}S$ isotopic substitutions, show that the glycine and alanine dithioesters are converted to enethiolates and 4-methyloxazolin-5-thiones, respectively. The difference in product formation is explained by a mechanism in which stereospecific proton removal is brought about by the $-COO^-$ side chain of Asp-158, which is situated in the vicinity of the active site. For glycine dithioesters the Asp-158 catalyses the removal of a C_α proton whereas for alanine dithioesters the alanine's NH proton is removed.

HO-HI LEE, RONALD H. ANGUS, PAUL R. CAREY et ANDREW C. STORER. Can. J. Chem. **65**, 1521 (1987).

On a démontré que les dithioesters éthyliques de la *N*-acylglycine et de la *N*-acylalanine se lient intimement au site actif de la papaïne dans laquelle la chaîne latérale de la cystéine-25 est mercurée. Même si le deux classes de dithioesters se lient au mercure du site actif par le biais de leurs atomes de soufre thiono (C=S), les adduits qui en résultent sont très différents. Les données d'absorption et de résonance Raman, appuyées par une comparaison avec des composés modèles et par des substitutions isotopiques avec du ^{15}N et du $^{13}C{=}S$, démontrent que les dithioesters de la glycine et de l'alanine se transforment respectivement en thioénolates et en méthyl-4 oxazolinethiones-5. On explique cette différence de comportement par un mécanisme impliquant un enlèvement stéréospécifique d'un proton par le COO^- de la chaîne latérale de l'Asp-158, qui est située près du site actif. Dans le cas des dithioesters de la glycine, l'Asp-158 catalyse l'enlèvement d'un proton du C_α alors que, pour les dithioesters de l'alanine, c'est le proton du NH de l'alanine qui est enlevé.

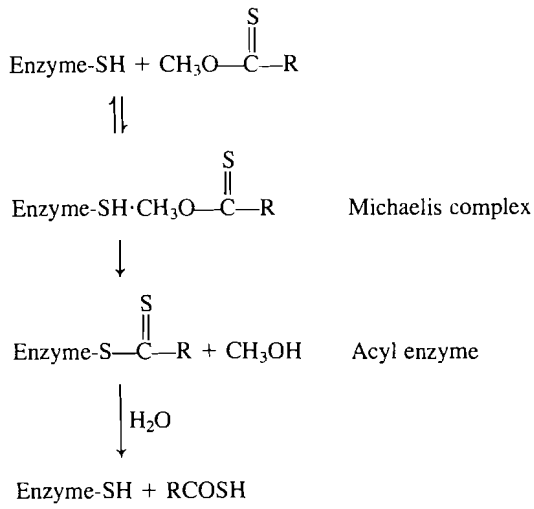
Introduction

Active papain can be reversibly converted to an inactive form by treatment with mercuric chloride. It has been shown that inactivation is the result of the binding of a single mercury atom to the essential cysteine (Cys-25) in the active site (1). The enzymatic activity can be regenerated readily by the addition of a thiol reducing agent, e.g. β-mercaptoethanol.

As well as possessing proteinase activity, papain also acts as an esterase and recent work from this laboratory has centered on resonance Raman (RR) studies of transient covalent enzyme–substrate complexes formed during the hydrolysis of thionoesters (2, 3). The transient complexes studied are dithioesters formed between the enzyme's active site cysteine residue and the acyl portion of the thionoester:



Initially the enzyme binds the substrate to give a Michaelis complex, which reacts to form an acyl enzyme (in this case a chromophoric dithioester, λ_{max} 315 nm), which then deacylates to enzyme and thiolacid. We have acquired considerable information on the acyl enzyme, but none as yet on the Michaelis complex. Therefore, it was decided to test dithioesters in place of thionoesters as substrates to produce chromophoric Michaelis complexes to study by RR spectroscopy. Although we have shown (unpublished data) that dithioesters are bound to papain without significant hydrolysis, we decided initially to use inactive Hg-papain. This proved to be a poor choice as a model for a Michaelis complex since the thiocarbonyl groups of the dithioesters were found to interact quite strongly with the enzyme-bound mercury. Interestingly, however, *N*-acylglycine and *N*-acylalanine dithioesters showed differential binding behaviour; this report describes the different products resulting from binding the two dithioesters and focuses on the ability of Asp-158 to perform stereospecific proton removal from the bound dithioesters.

Experimental

Papain was purchased from the Sigma Chemical Co. as a suspension in 50 m*M* sodium acetate pH 4.5. Mercury papain was prepared from this source by affinity chromatography on a mercurial-agarose column according to the method of Sluyterman and Wijdenes (4). Papain concentrations were estimated using an A^{280} 1% of 25 and a MW of 23 000.

The unlabelled and ^{15}N and $^{13}C{=}S$ labelled *N*-acyl glycine ethyl dithioesters were prepared and characterized as described in Lee *et al.* (5). The *N*-benzoyl-DL-alanine ethyl dithioester (and its $^{13}C{=}S$ labelled analogue) were synthesized as described in Angus *et al.* (6). 4-Ethyl-2-phenyloxazolin-5-one was supplied by Dr. C. Chuaqui. The RR spectra were obtained using 324 or 337-nm Kr^+ laser excitation and a diode array based detection system described previously (7).

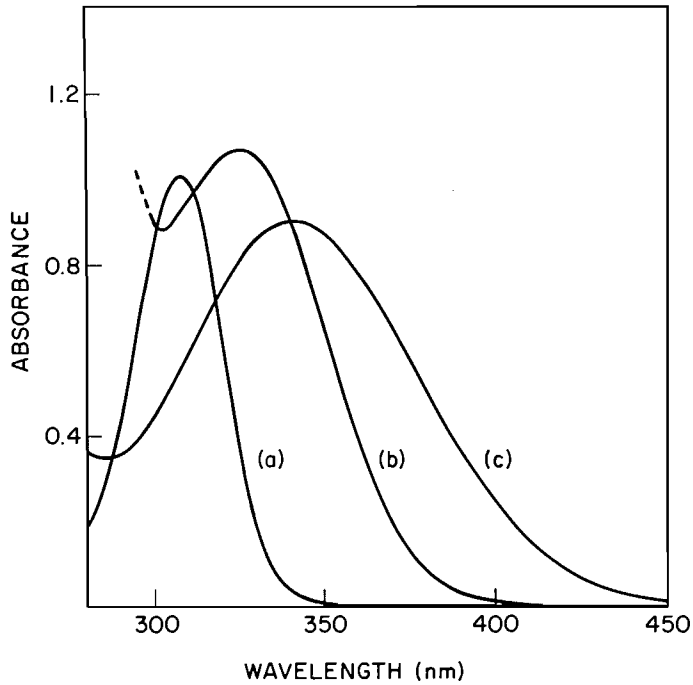

FIG. 1. Absorption spectra of *N*-benzoylglycine ethyl dithioester (1.0×10^{-4} *M*) (*a*) in acetate buffer (pH 4.5); (*b*) in the presence of 1.57×10^{-4} *M* Hg-papain, pH 4.5; (*c*) in 0.1 *N* NaOH (as the enethiolate form).

Results and discussion

(i) N-Benzoylglycine or N-(β-phenylpropionyl)glycine ethyl dithioester bound to Hg-papain

When either *N*-benzoylglycine or *N*-(β-phenylpropionyl)glycine ethyl dithioester is mixed with Hg-papain, in the pH range 4–7, marked changes occur in the absorption and RR spectral properties of the dithioester chromophore. These changes indicate that a complex is formed between the dithioester and Hg-papain, and the spectral data allow us to discuss the molecular details of each complex. The absorption spectrum of *N*-benzoylglycine ethyl dithioester, λ_{max} 308 nm in acetate buffer pH 4.5, is compared in Fig. 1 with the absorption spectrum of its complex formed with Hg-papain, which has a λ_{max} at 326 nm. Included in Fig. 1 is the spectrum of the enethiolate, λ_{max} 340 nm, formed from the dithioester at pH 13 in the absence of Hg-papain (8). Formation of both the complex and the enethiolate results in a red shift in λ_{max} and a broadening of the absorption band, both effects being more pronounced for the enethiolate. A red shift in λ_{max}, from 308 nm to 312 nm, and band broadening are also observed for *N*-(β-phenylpropionyl)glycine ethyl dithioester upon complexing with Hg-papain (data not shown). However, it should be noted that the absorption spectral data for this complex is less precise due to the fact that the shifted band near 312 nm is broad and appears as an unresolved shoulder on the main protein peak near 280 nm. The enethiolate produced at pH 13 from this dithioester has a blue shifted (λ_{max} 298 nm) and broadened absorption peak (8). It has been established that the electronic transition giving rise to the absorption band near 305 nm in dialkyl dithioesters and *N*-acylglycine dithioesters is localized on the -C(=S)S- group. The red shift and broadening of the absorption peaks for *N*-benzoylglycine and *N*-(β-phenylpropionyl)glycine ethyl dithioesters upon binding to Hg-papain suggest that, upon complexation, the electronic transition giving rise to the chromophore becomes delocalized over a larger region of the molecule. The RR data for the complexes provide some information as to the nature of this delocalization.

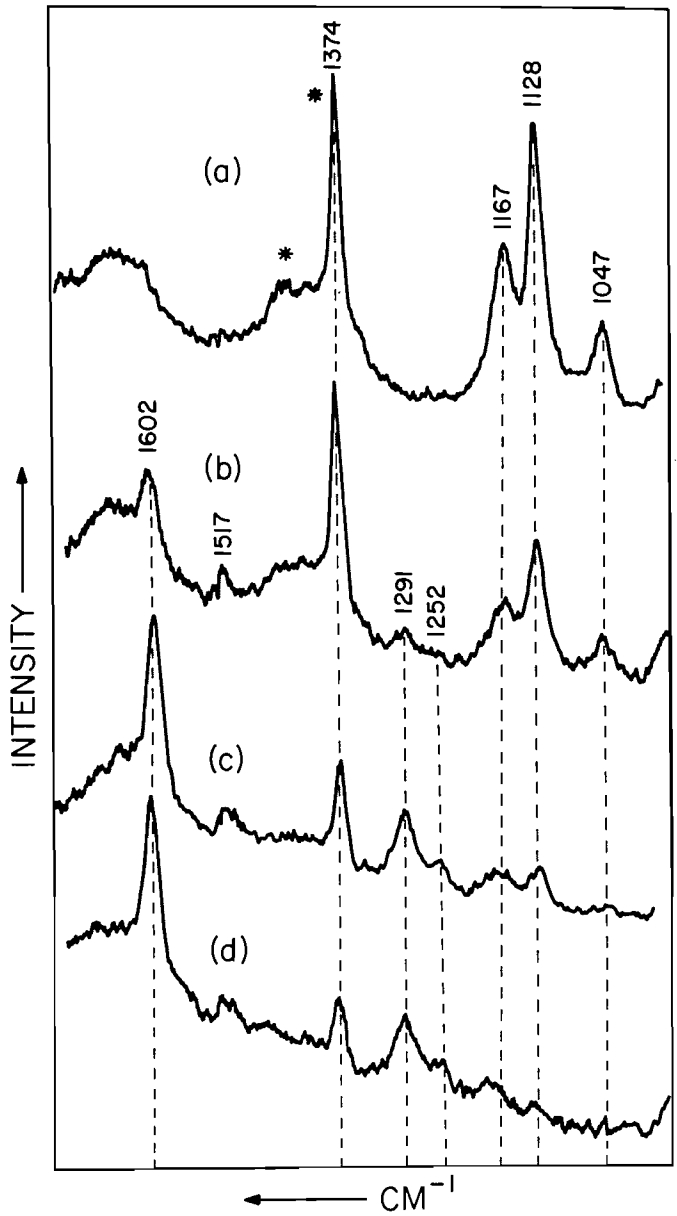

FIG. 2. Resonance Raman spectra of *N*-benzoylglycine ethyl dithioester (1.2×10^{-4} *M*) (*a*) in 10% CH_3CN and in the presence of (*b*) 3.0×10^{-5} *M* Hg-papain, (*c*) 9.0×10^{-5} *M* Hg-papain, (*d*) 2.6×10^{-4} *M* Hg-papain. All solutions contain acetate buffer, pH 4.5. Asterisks denote CH_3CN features. The broad feature near 1650 cm^{-1} is due to water.

Figure 2 shows the 324-nm excited RR spectra of solutions containing different ratios of *N*-benzoylglycine ethyl dithioester and Hg-papain. In each spectrum the peak near 1375 and the shoulder near 1425 cm^{-1} are due to the presence of 10% CH_3CN, used to keep the dithioester in solution. In traces (*a*) and (*b*) the peaks at 1167, 1128, and 1047 cm^{+1} are due to free, unbound dithioester. As the relative amount of Hg-papain increases, the features due to the free dithioester become relatively less intense (trace (*c*)) and in the presence of a twofold excess of Hg-papain it is difficult to detect any peaks due to free dithioester (trace (*d*)). Concomitant with the

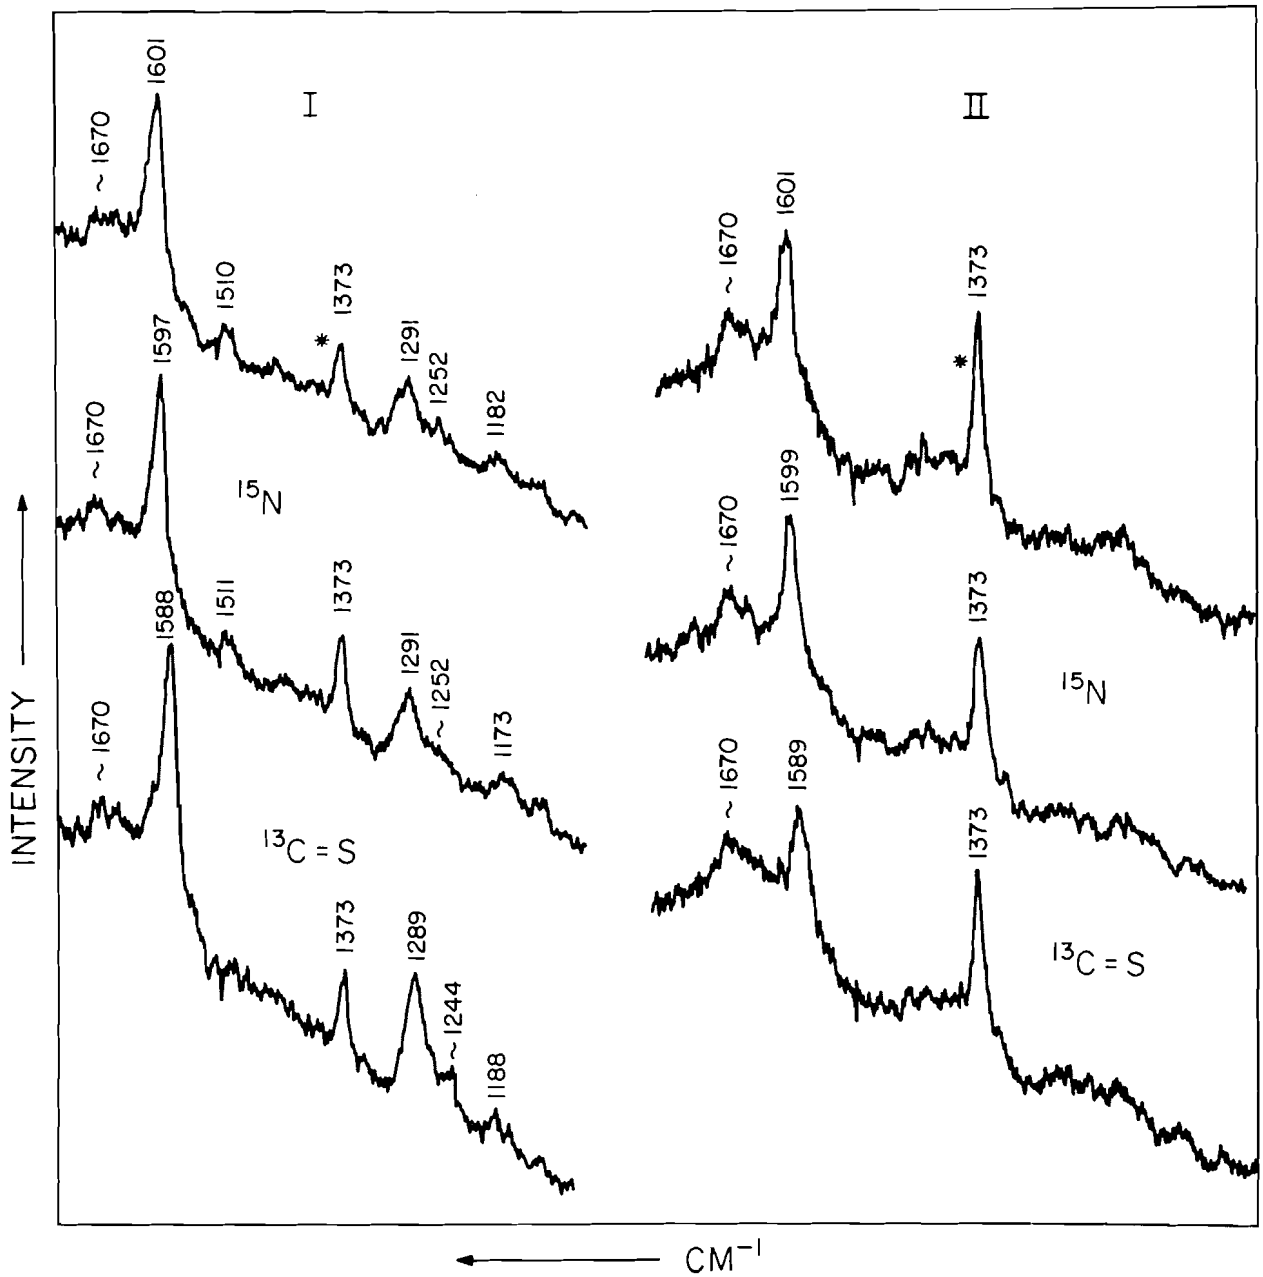

FIG. 3. Resonance Raman spectra of dithioesters *N*-benzoyl (I), and *N*-(β-phenylpropionyl) (II) glycine dithioesters and their ^{13}C, ^{15}N analogs in the presence of Hg-papain. Dithioesters, 1.0×10^{-4} *M*; Hg-papain, 2.73×10^{-4} *M*; in 10% CH_3CN, pH 4.5 acetate buffer.

decrease in free dithioester features, peaks due to the Hg-papain–dithioester complex appear at 1602, 1291, and 1252 cm^{-1} with increasing intensity. The data in Fig. 2 allow us to estimate, semiquantitatively, the dissociation constant, K_d, for the Hg-papain – *N*-benzoylglycine ethyl dithioester complex. Assuming a 1:1 stoichiometry in the complex, K_d is in the range 10^{-4}–10^{-5} *M*, indicating fairly tight binding between the ligand and the protein.

Further information on the origin of the RR features due to the enzyme–dithioester complex comes from the results of isotopic substitution experiments. Figure 3 shows the RR spectra of isotopically labelled, ^{15}N or $^{13}C{=}S$, *N*-benzoylglycine (I) and *N*-(β-phenylpropionyl)glycine (II) ethyl dithioesters bound to Hg-papain. ^{15}N substitution brings about a shift of 2–4 cm^{-1} for the intense feature near 1600 cm^{-1} in both complexes (Fig. 3) while $^{13}C{=}S$ substitution results in a 12–13 cm^{-1} decrease for this band in both cases. These results are compared in Table 1 to those for the enethiolates formed from the dithioesters at pH 13.0 in aqueous solution in the absence of enzyme (8). There is a marked similarity, both in the general appearance of the enethiolate (8) and dithioester–Hg-papain complex RR spectra (Figs. 2 and 3) and in their response to ^{15}N and $^{13}C{=}S$ substitution. However, the correspondence is not complete; the intense feature near 1590 cm^{-1} occurs at slightly higher wavenumbers for the dithioester–Hg-papain complexes. For the enethiolates the 1590 cm^{-1} band was assigned to a double bond-like mode partially delocalized through the glycinic linkages (8). Thus, it is likely that the 1601 cm^{-1} peaks seen in Figs. 2 and 3 for the dithioesters bound to Hg-papain arise from an analogous delocalized "double bond" mode, but that the degree of delocalization is slightly less for these species in the enzyme–substrate complexes. This conclusion is consistent

TABLE 1. Comparison of the isotope shifts of the major spectral features for the enethiolate and Hg-papain bound form of the dithioesters

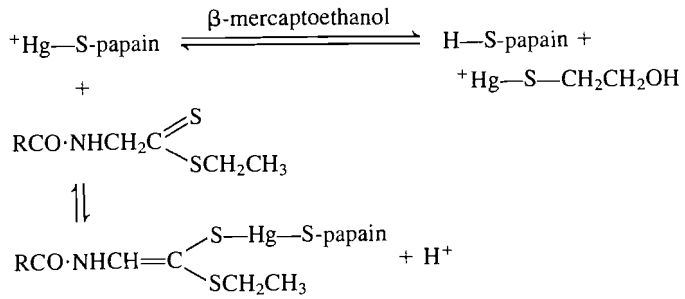
[a]From ref. 8.

with the absorption data shown in Fig. 1 since the red shift for *N*-benzoylglycine ethyl dithioester bound to Hg-papain is less than that for the enethiolate formed from this dithioester (8). Further evidence for the differing degrees of delocalization comes from the observation that phenyl ring modes could be observed near 1500 and 1000 cm^{-1} for the enethiolate but not for the Hg-papain complex formed from *N*-benzoylglycine ethyl dithioester, indicating that delocalization into the phenyl ring is important only for the enethiolate.

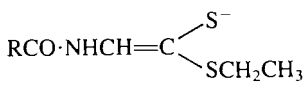
The spectroscopic data indicate, therefore, that both *N*-benzoylglycine and *N*-(β-phenylpropionyl)glycine ethyl dithioesters bind to Hg-papain in a form resembling, but not identical to, the corresponding enethiolate species. Additional experiments were undertaken to investigate the mode of binding. The dithioester and enzyme could not be separated by passage of the complex down a 1 × 20 cm Sephadex G-15 chromatography column, which is consistent with the tight binding indicated by $K_d = 10^{-4}$–10^{-5} *M* (see above). Significantly, papain can be denatured by reducing the pH to 2.0 or less and this was performed on a solution containing Hg-papain – *N*-benzoylglycine ethyl dithioester complex that had been formed near neutral pH. The denatured Hg-papain dithioester complex showed a shift in λ_{max} from 326 to 320 nm. When the solution containing the denatured complex at pH 2.0 was passed down the G-15 column, preequilibrated at this pH, again no separation of protein and dithioester occurred. This demonstrates that tight binding still exists between the dithioester and the denatured enzyme and that the binding includes a covalent linkage.

The spectroscopic properties of the Hg-papain complexes could not be mimicked by mixing aqueous $HgCl_2$ with either *N*-benzoylglycine or *N*-(β-phenylpropionyl)glycine ethyl dithioester; thus, the enzyme appears to be required for the formation of the observed complexes. Moreover, no complex was formed by adding either dithioester to denatured Hg-papain. In an additional experiment, β-mercaptoethanol was shown to displace the dithioesters from Hg-papain. The β-mercaptoethanol (50 m*M*) was added to a 1.1×10^{-4} *M* solution of Hg-papain – *N*-benzoylglycine ethyl dithioester complex. The λ_{max} of the Hg-papain–dithioester complex changed from 326 nm to 308 nm and the RR spectrum (not shown) became equivalent to that for the dithioester in the absence of Hg-papain (Fig. 2*a*). Thus, the interaction between the dithioester and Hg-papain is broken by β-mercaptoethanol and the spectral properties revert to those of the free dithioester.

The following proposed mechanism incorporates all of the above observations:



The analogy of the dithioester adduct formed in the Hg-papain–dithioester complex to an enethiolate



is immediately clear.

(ii) N-*Benzoylalanine ethyl dithioester bound to Hg-papain*

Changes also occur in the absorption and RR spectra of *N*-benzoyl-DL-alanine ethyl dithioester upon mixing with Hg-papain. The absorption spectrum of *N*-benzoylalanine ethyl dithioester in solution has a λ_{max} at 311 nm, which broadens and shifts to 320 nm on addition of Hg-papain and to 349 nm upon subsequent addition of β-mercaptoethanol. This contrasts with the behaviour of *N*-benzoylglycine ethyl dithioester, which on addition of Hg-papain exhibits a red shift from 308 to 326 nm that is reversed by the addition of β-mercaptoethanol. The RR spectrum of the *N*-benzoylalanine ethyl dithioester – Hg-papain adduct is shown in Fig. 4*b* along with the spectrum of the free dithioester, Fig. 4*a*. From a comparison of Figs. 4*b* and *c* it can be seen that the substitution of a ^{13}C label into the thiocarbonyl group results in a decrease in relative intensity of a feature at 1579 cm^{-1} and very small shifts in other peaks in the spectrum of the adduct.

RR spectra of the unlabelled and ^{13}C labelled enethiolates formed from *N*-benzoylalanine ethyl dithioester at high pH are shown in Fig. 5. From a comparison of the adduct (Figs. 4*b* and *c*) and enethiolate spectra (Fig. 5) and their differential responses to ^{13}C substitution it is clear that, unlike the glycine case, *N*-benzoylalanine ethyl dithioester does not form an enethiolate type adduct with Hg-papain. However, there are marked similarities between the RR spectrum of the Hg-enzyme

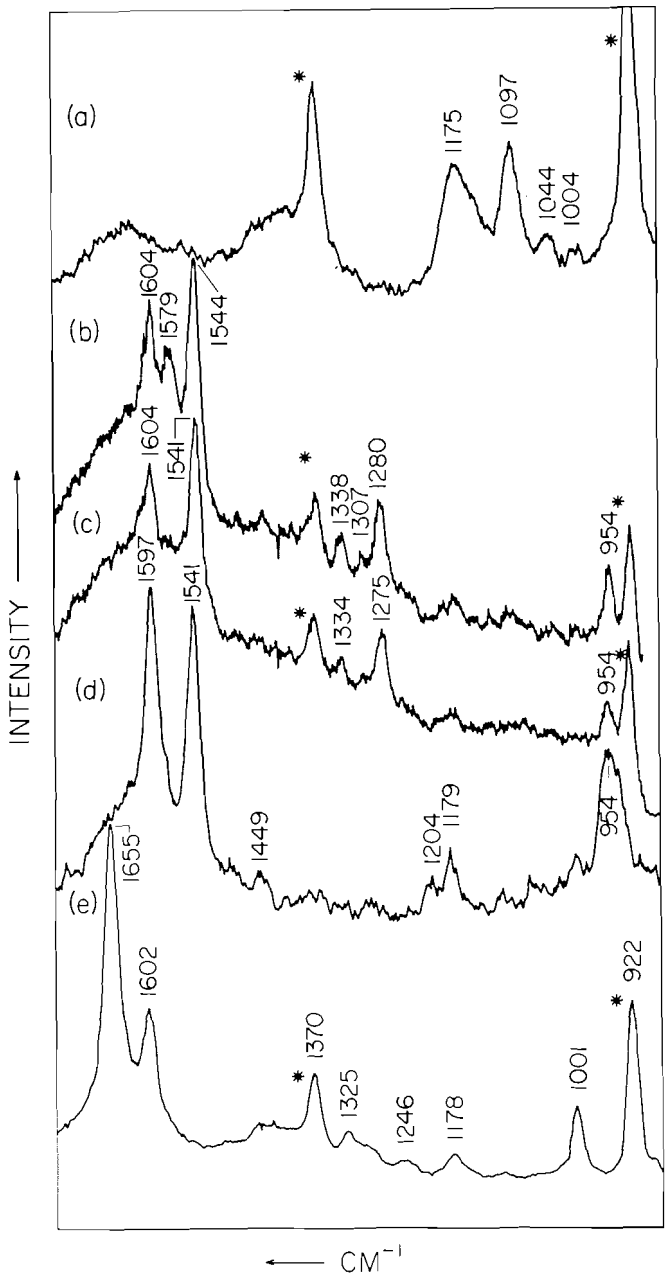

FIG. 4. Resonance Raman spectra of (*a*) *N*-benzoylalanine ethyl dithioester (1.6×10^{-4} *M*) in acetate buffer pH 4.5; (*b*) unlabelled and (*c*) $^{13}C{=}S$ labelled *N*-benzoylalanine ethyl dithioester (0.8×10^{-4} *M*) and Hg-papain (2.3×10^{-4} *M*) in acetate buffer pH 4.5; and 4-ethyl-2-phenyl oxazolin-5-one (*d*) 0.6 m*M* in 0.01 *N* NaOH and (*e*) 60 m*M* in 40% CH_3CN. Asterisks denote CH_3CN features.

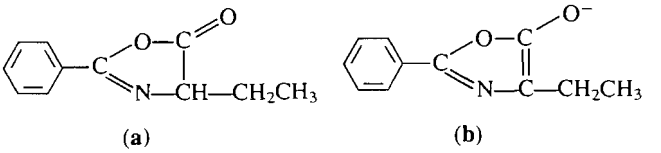
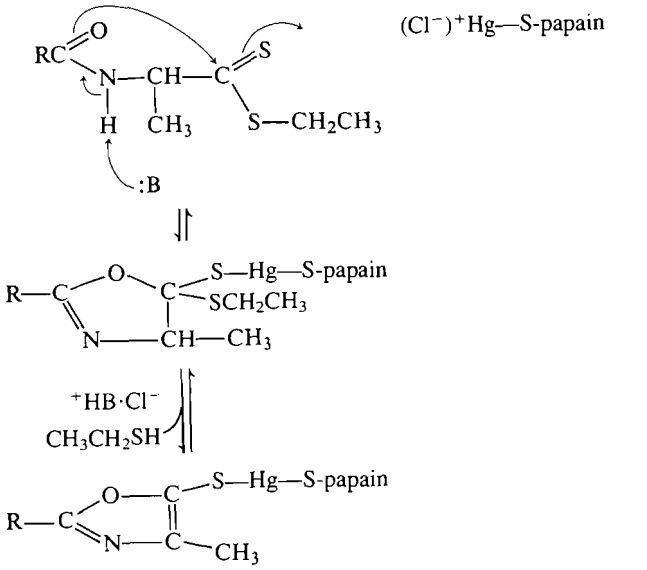
complex and the spectra of oxazolin-5-one type compounds. The RR spectra of oxazolin-5-ones that have their conjugated π-electron chain extended by the presence of a benzylidene group at the 4-position are dominated by two or three intense features in the 1550–1610 cm^{-1} region (9, 10). The analogy to Figs. 4*b* and 4*c* is further strengthened by the fact that these benzylidene substituted oxazolin-5-ones show only small frequency shifts but large changes in peak intensities when ^{13}C is substituted into the oxazolinone ring (9, 10). The correspondence of Fig. 4*b* to the RR spectrum of a highly conjugated oxazolinone-type species is reinforced by comparison with the RR spectrum of the ionized form of 4-ethyl-2-phenyl oxazolin-5-one (structure **b**) recorded in 0.01 *N* NaOH.



(a) (b)

The RR spectra of 4-ethyl-2-phenyl oxazolin-5-one at pH 12 and neutral solution are shown in Figs. 4*d* and *e* respectively. Several similarities exist between the spectra of the enzyme adduct (Fig. 4*b*) and the ionized oxazolinone (Fig. 4*d*); intense peaks occur near 954, 1540, and 1600 cm^{+1} in both spectra. Although there is not a one-to-one correspondence between the spectra in Figures 4*b* and 4*d*, the similarities in the major features are sufficient to indicate that the *N*-benzoylalanine ethyl dithioester in the Hg-papain complex is in a form resembling that of an oxazolin-5-one at high pH. A suggested mechanism giving rise to such a species on the enzyme is:



Treatment of this complex with β-mercaptoethanol would result in the release of the corresponding oxazolin-5-thione rather than in regenerating the dithioester. Thus this mechanism explains the lack of reversibility of adduct formation involving the alanine dithioester. Attempts at obtaining the RR spectrum of the product formed by the addition of β-mercaptoethanol were thwarted by very high fluorescence from the sample. Also, since papain is capable of catalysing the hydrolysis of both esters and thionoesters (11), i.e., the activity of the enzyme is not adversely affected by the S for O substitution, and since oxazolin-5-ones are substrates for papain (12), it is probable that the active enzyme, generated in the presence of β-mercaptoethanol, would rapidly hydrolyse the oxazolin-5-thione formed.

Papain must be participating actively in the formation of the dithioester–Hg-papain complexes since in the absence of native enzyme similar complexes are not formed between Hg and the dithioesters. There are two ways in which the enzyme can assist in complex formation. Firstly, it can utilize its specificity for *N*-acylamino acid esters to orient the dithioesters in order to favour their reaction with the enzyme-bound mercury. That this effect does indeed occur is supported by the observation that denatured Hg-papain does not form complexes with dithioesters. The second way in which papain can assist in complex formation is to provide a base to specifically abstract a proton, from the α-CH group in the case of glycine or from the NH group in the case of the alanine dithioesters. In all

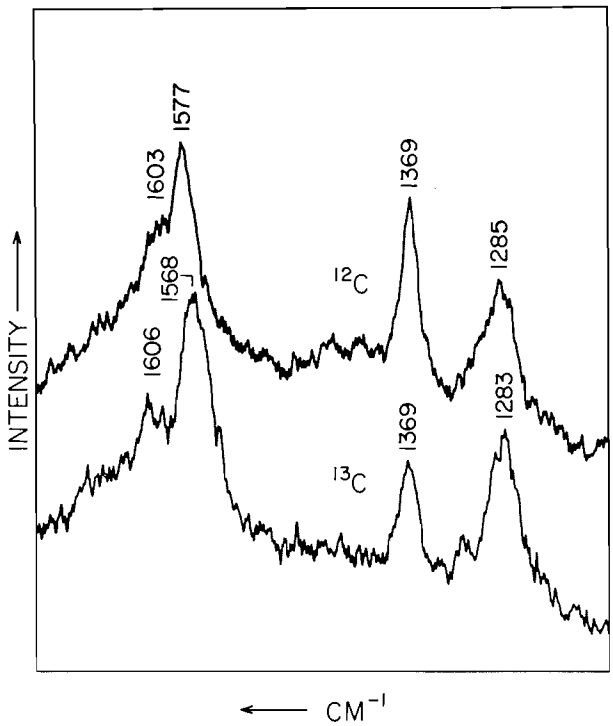

FIG. 5. Resonance Raman spectra of labelled and unlabelled *N*-benzoylalanine ethyl dithioester (5×10^{-4} *M*) in 1 *N* NaOH. These spectra were obtained using 337-nm laser excitation.

likelihood both steric complementarity and proton abstraction operate to stabilize the observed complexes; the mechanism of base-catalysed proton removal is discussed further below. Finally it should be remembered that both the D and L forms of the alanine dithioester are available for binding to papain. However, papain's strong preference for the L form of the amino acid binding at the S_1–P_1 site is well established (13) and it has been further demonstrated that papain shows no detectable binding capacity for D-amino acid esters or thionoesters (unpublished results, this laboratory). Thus it is assumed that only the L form of *N*-benzoylalanine ethyl dithioesters is bound in the active site. It is expected therefore that on mixing *N*-benzoyl-DL-alanine dithioester with excess Hg-papain only 50% of the dithioester should be converted to oxazolin-5-thione. This is consistent with the broad feature obtained in the absorption spectrum of the mixture. However, it is apparently inconsistent with the data in Figs. 4*b* and *c*. In these figures it appears that greater than 50% of the dithioester is converted to the cyclic oxazolin-5-thione. However, due to differences in concentration and resonance intensity enhancement it can be calculated that the dithioester features in Figs. 4*b* and *c* in the 1100–1200 cm^{-1} range are $\gg 10$ times weaker than the corresponding features in Fig. 4*a*.

The different Hg-papain complexes formed by the glycine and alanine dithioesters tested can be explained readily by a mechanism in which an enzyme side chain acts as a base to catalyse formation of the adducts. Examination of a 3-dimensional model of papain identifies the carboxylate side chain of Asp-158 as a prime candidate for this base. If it is assumed that the benzoylamido portion of the dithioesters bind to the enzyme in the manner proposed for substrates (14), i.e., the carbonyl group is hydrogen bonded to the NH of Gly-66, and also that the thiocarbonyl sulphur is directed towards the sulphur of Cys-25, then both the amide proton and the α-CH proton in the L-configuration lie in close proximity to the side chain of Asp-158. For the glycine-based dithioesters it is apparent that the $-COO^-$ group of Asp-158 preferentially removes the α-CH proton to form an enethiolate. However, for the alanine-based dithioester the position taken up by the labile glycine α-CH proton is occupied by alanine's CH_3 side chain. Thus in the alanine case the amide proton is removed, catalysing the formation of a 4-methyl-2-phenyloxazolin-5-thione complex in the active site.

The crystal chemistry of complex In(III) halides is discussed and compared with that of other Group III elements and Fe(III), with critical comments and analysis of the available information. The cation/anion packing types occurring among $A^+[M^{3+}X_4]$ halides are classified according to volume per formula unit and the relative ionic sizes of M, X, and A, and the structural trends in this class of compounds are identified. The effect of systematic factors responsible for variation in M(III)—Cl bond lengths is examined in detail. It is shown that the *mean* M(III)—Cl bond lengths in $[MCl_nL_m]^\epsilon$ (M = Al, Ga, Fe, In, Tl; L = Cl or a neutral ligand) complexes can be approximated, to within about 0.02 Å, by a linear function of the coordination number CN = $n + m$ and the charge ϵ over the range $3 \leq CN \leq 6$ and $-3 \leq \epsilon \leq 2$. This analytical expression provides a norm for comparing M(III)—Cl bond lengths and demonstrates that the CN is always a more important factor than ϵ in determining the variation in the mean bond length and that it becomes dominant when M is small. The crystal structure of $(Me_2NH_2)_4[InCl_6]Cl$ ($P2_12_12$, a = 10.156(4) Å, b = 13.007(4) Å, c = 8.751(3) Å, Z = 2) has been determined and those of $(NH_4)_2[InCl_5(H_2O)]$ (*Pnma*, a = 13.953(4) Å, b = 10.086(5) Å, c = 7.152(3) Å, Z = 4), $K_3InCl_6 \cdot nH_2O$ (*I*4*mm*, a = 15.659(8) Å, c = 18.106(5) Å, Z = 14) and $(MeNH_3)_4[InCl_6]Cl$ ($P2/n$, a = 16.113(3) Å, b = 7.446(2) Å, c = 16.163(4) Å, β = 103.75(2)°, Z = 4) redetermined. The water in $K_3InCl_6 \cdot nH_2O$ appears to be in part zeolitic; the hydrate examined contained more water than the monohydrate reported previously. Hydrogen bonding in these and related structures is described and discussed in detail; descriptions of the hydrogen-bonding schemes in $(NH_4)_2[InCl_5(H_2O)]$ and $(MeNH_3)_4[InCl_6]Cl$ constitute the main improvement over earlier structure determinations.

OSVALD KNOP, T. STANLEY CAMERON, D. ADHIKESAVALU, BEVERLY R. VINCENT et JAMES A. JENKINS. Can. J. Chem. **65**, 1527 (1987).

On discute de la chimie des cristaux des complexes des halogénures de l'In(III) et on la compare à celle des complexes du Fe(III) et des autres éléments du groupe III; on fait des commentaires critiques ainsi qu'une analyse des informations disponibles. On a classifié les divers types d'empillements cation/anion que l'on retrouve dans les halogénures $A^+[M^{3+}X_4]$ d'après les volumes par unité de formule ainsi que d'après les grosseurs relatives des ions M, X et A et l'on a identifié les tendances structurales dans cette classe de composés. On a étudié en détail l'effet des facteurs systématiques qui sont responsables de la variation des longueurs des liaisons M(III)—Cl. On démontre qu'on peut faire une approximation valable (à ±0,02 Å) des longueurs moyennes des liaisons M(III)—Cl dans les complexes $[MCl_nL_m]^\epsilon$ (M = Al, Ga, Fe, In, Tl; L = Cl ou un ligand neutre) en utilisant une fonction linéaire du nombre de coordination (NC = $n + m$) et de la charge (ϵ) pour des écarts de $3 \leq NC \leq 6$ et $-3 \leq \epsilon \leq 2$. Cette expression analytique fournit une norme pour comparer les longueurs des liaisons M(III)—Cl et démontre que le NC est toujours un facteur plus important que ϵ dans la détermination de la variation de la longueurs moyenne de la liaison et que ce facteur devient dominant lorsque M est petit. On a déterminé la structure cristalline de $(Me_2NH_2)_4[InCl_6]Cl$ ($P2_12_12$, a = 10,156(4), b = 13,007(4) et c = 8,751(3) Å, Z = 2) et on a redéterminé celles de $(NH_4)_2[InCl_5(H_2O)]$ (*Pnma*, a = 13,953(4), b = 10,086 et c = 7,152(3) Å, Z = 4), $K_3InCl_6 \cdot nH_2O$ (*I*4*mm*, a = 15,659(8) et c = 18,106(5) Å, Z = 14) et $(MeNH_3)_4[InCl_6]Cl$ ($P2/n$, a = 16,113(3), b = 7,446(2) et c = 16,163(4) Å, β = 103,75(2)°, Z = 4). La molécule d'eau du $K_3InCl_6 \cdot nH_2O$ semble être partiellement zéolithique; l'hydrate examiné contenait plus d'eau que le monohydrate qui avait été examiné antérieurement. On décrit et on discute en détail des liaisons hydrogènes qui existent dans ces structures et dans des composés apparentés; les descriptions des schémas des liaisons hydrogènes des complexes $(NH_4)_2[InCl_5(H_2O)]$ et $(MeNH_3)_4[InCl_6]Cl$ constituent la principale amélioration par rapport aux déterminations de structures faites antérieurement.
[Traduit par la revue]

In this contribution to the structural chemistry of In–halogen compounds we offer (**A**) a *catalogue raisonné* of the crystal chemistry of halogeno complexes of In(III) and related compounds; (**B**) a detailed analysis of the systematic factors responsible for variation in M—Cl bond lengths in Group III and Fe(III) complex chlorides, and a resulting scheme which permits these bond lengths to be rationalized and predicted; (**C**) crystal-structure determinations or re-determinations of the four title compounds; and (**D**) a discussion of hydrogen bonding in these and other In(III) halides. Our discussion of the crystal chemistry attempts not merely to unify results published to date, but also to offer critical comment and identify gaps in our present knowledge. It therefore includes complex In(III) fluorides, which are usually treated as belonging to the solid-state rather than to the coordination chemistry of indium, even though their structures often contain recognizable InF_n^ϵ units (some of which may exist in fluoride melts). A few pseudo-halogeno complexes are also mentioned. On the other hand, halogeno complexes containing In—C bonds have been deliberately excluded; the presence of the covalent In—C bond introduces factors, additional to the coordination number (CN) and the charge ϵ on the complex, which affect the In—Hal bond lengths but which we are not prepared to discuss at present.

The four topics are presented in the above order. Most of the In(III) halides discussed in the following and for which

crystallographic information exists, are listed in Table 1. The literature references for these are not repeated in the text. The structural results for the four title compounds are described in **C**, but they will be drawn upon in **A** and **B**; details of the crystal structure analysis have been relegated to the end of this paper (Experimental).

A. Crystal chemistry of complex In(III) and related halides

The crystal chemistry of complex In(III) halides exhibits a considerable variety. Apart from the well-represented six-coordinate species, examples of which occur in the four title compounds, structures containing In in four-, five-, and seven-coordination are known (Table 1). Indium analogs of almost all the types of complex halides of other Group III elements are known. Among the species not yet reported for In are those containing isolated single M—X—M bridges, such as occur in the bent $[X_3MXMX_3]^-$ (M = Al, Ga; X = Cl, Br, I) ions, but their absence from the chemical literature may simply be due to accident rather than to their reluctance to form.

By and large the crystal chemistry of In^{vi} and In^{iv}, relative to that of other M(III) elements in halides of corresponding compositions, is determined by the position of In^{3+} in the sequence of the effective ionic radii; the extent of structural similarity in relation to ionic size will emerge more clearly from the discussion below. From the limited data available at present it would appear that the upper size limit for isostructural behaviour is between Tl and Y, although a cubic elpasolite Cs_2KYF_6 isostructural with Cs_2KInF_6 has been reported (56). Some of the fluoride structures are quite insensitive to the size of M and tolerate substitutions ranging over most of the M^{3+} sequence, e.g. Cs_2KMF_6 (M = Al, Ga, Co, Fe, Sc, In, Tl, Y) (56) or the chiolites $K_5M_3F_{14}$ (M = Al, In, Tl). In many respects the crystal chemistry of In(III) resembles closely that of Fe^{3+} and Tl^{3+}, but there are exceptions. Thus the $A_2[MCl_5(H_2O)]$ chlorides have *Pnma* structures for M = Fe, Sc, In and A = K, Rb, NH_4. However, the Cs salt is *Pnma* for In and Tl, but *Cmcm* for Fe. Occasional differences are found for In/Tl pairs of compounds, not only in regard to structure but also to properties. For example, Cs_2KTlF_6 is stated to be very hygroscopic, while Cs_2KInF_6 can be handled in atmospheric air (56).

Isolated octahedra

The structures of A_3InF_6 cryolites derive from the idealized cubic ($Fm3m$, $Z = 4$) $A^{xii}{}_2A^{vi}[MF_6]$ aristotype, which may be viewed as an ordered $AA_{0.5}M_{0.5}F_3$ perovskite arrangement.

[a] See **A** for structural representation and a more detailed treatment. Compounds containing In—C and other covalent bonds are not included. Z is number of formula units per unit cell.

[b] Space group in ref. 13 wrongly stated as $P2_1/c$.

[c] The Tl and Rb analogs are isostructural on powder diffraction evidence (23). The compound analyzing to $(Me_4N)_2InCl_5 \cdot H_2O$ (25) is presumably of this type, but no structural or spectroscopic evidence for this has so far been presented.

[d] The Rb and Cs analogs are isostructural on powder diffraction evidence (55).

[e] *cis* relative to the halogen atom.

[f] BEDT—TTF = 3,4;3′,4′-bis(ethylenedithio)-2,2′,5,5′-tetrathiafulvalene.

The symmetries of the actual structures are lower owing to rotational displacements of the InF_6 octahedra, and the crystal chemistry is complicated by the occurrence of polymorphic transitions (57). The monoclinic, antiferrorotatory ($P2_1/n$, Z = 2) α-Na_3InF_6 is isostructural with the mineral cryolite, Na_3AlF_6, and the corresponding Tl and Sc analogs (16, 58, 59). The K, Rb, Cs, Tl, and NH_4 compounds have been examined (60–62), but the structural relationships in this family cannot be regarded as firmly established even for the room-temperature phases. The Rb compound has been reported as $Fm3m$ (60) as well as $I4/mmm$ (62); the K compound as $Fd3$ (60), $Fd3m$ (63), and isostructural with K_3TlF_6 (59); the Cs compound as tetragonal, probably $P4/mnc$ (60, 62), c/a = 1.011 (63); and the NH_4 compound as $P4/mnc$ (60) or $P2_1/n$ (64) below $T_{tr} \sim$ 355 K, and $Pa3$ or $Fm3m$ above T_{tr} (64).

No A_3InCl_6 cryolites with cubic or near cubic unit cells and Z = 4 seem to be known, although a cubic phase with a P or I lattice was obtained (47) by quenching molten Ag_3InCl_6; for a = 16.650 Å a Z of 16 would seem appropriate. The same authors indexed an X-ray powder pattern of Na_3InCl_6 as orthorhombic, Z = 6. The literature statements concerning A_3InCl_6 (A = K, Rb, Cs, NH_4) require a more detailed comment and are discussed separately below. The orthorhombic, pseudotrigonal In_2Cl_3 ($Pnma$, Z = 32) is essentially $In_3[InCl_6]$ (14), isostructural with α-$Tl_3[TlCl_6]$ (65).

The cubic elpasolites, $A^{xii}{}_2B^{vi}[MX_6]$, are a variant of the cryolite structure and may be regarded as ordered perovskites, $AB_{0.5}M_{0.5}X_3$. This populous family is well represented by In halides. The fluorides A_2BInF_6 (A = K, Rb, Cs, NH_4, Tl; B = Na, K, Ag, Tl; not in all A, B combinations) (56, 62, 66–68), the chlorides $Rb_2LiInCl_6$, $In_2LiInCl_6$, $Rb_2NaInCl_6$, Cs_2BInCl_6 (B = Li, Na, K) (7, 8, 14, 69, 70) and $Cs_2NaInBr_6$ (71) all have this structure under ordinary conditions. The slight tetragonal distortion of Rb_2TlInF_6 (68), c/a = 1.008, points to the existence of a transition to the cubic form above room temperature. $Cs_2In[InCl_6]$ exhibits three phases: *III* ($Fm3m$, Z = 4), *II* ($P4/nbm$, Z = 4), and *I* ($Pban$?, Z = 4); $Cs_2TlInCl_6$ (*III*) and $Cs_2TlInCl_6$ (*II*) are analogous (70).

The hexagonal (12L) elpasolite structure typified by $Cs_2Na[CrF_6]$ (72) is adopted by Cs_2LiMCl_6, M = In or Sc (73). Other structure types encountered among In fluorides are represented by the weberite $Na_2Mg[InF_6]F$ (11); $LiMg[InF_6]$, presumed to be related to the hexagonal ($P\bar{3}1m$) $Li_2[ZrF_6]$ (74); and the garnet ($Ia3$) $Na_3Li_3In_2F_{12}$, which can be formulated as $Na_3Li_3[InF_6]_2$ and is isostructural with its Al (cryolithionite), Sc, and Rh analogs (15).

In $(Ph_4As)[In(NCS)_6]$ the ions are both too large and unwieldy to give a classical cryolite packing. It would be interesting to see whether $(Me_4N)_3[In(NCS)_6]$, hitherto unreported, is isostructural with its Fe(III) analog, the structure of which ($C2/c$, Z = 8) has been determined (75).

The structures of the four alkylammonium salts containing InX_6^{3-} ions (Table 1) are interesting mainly for their hydrogen bonding and are discussed in **D**.

Infrared and Raman spectra of $[Co(NH_3)_6]InCl_6$ indicate (76) that this salt contains isolated $InCl_6$ groups and is isostructural with the cubic ($Pa3$) $[Co(NH_3)_6][TlX_6]$ (X = Cl, Br) (77) and probably also (apart from possible orientational ordering) with $[Co(NH_3)_4(H_2O)_2][TlCl_6]$ (78). The cation/anion packing in these crystals is of the NaCl type.

A number of compounds containing In^{vi} complexes with mixed ligands have also been studied. The octahedral complexes in $[InI_2(dmso)_4][InI_4]$ and $(S_4N_3)[InCl_4(H_2O)_2]$ have *cis* configurations. Similar situations are encountered in

other M(III) compounds: the *cis* configuration is found in $[FeCl_2(H_2O)_4][FeCl_4] \cdot H_2O$ (79), $[AlCl_2(bipy)_2]Cl$ (80), and $[GaCl_2(bipy)_2][GaCl_4]$ (81), while in $[FeCl_2(dmso)_4][FeCl_4]$ (82), $[FeCl_2(H_2O)_4]Cl \cdot 2H_2O$ (83), $[FeCl_2(H_2O)_4][SbCl_6] \cdot 4H_2O$ (84), and $[MCl_2(py)_4][MCl_4]$ (M = Al, Ga) (85, 86) the configuration is *trans*.

In $[InCl_3(H_2O)_3] \cdot (dioxan)_3$ the configuration is *fac*, as it is in $[AlCl_3(py)_3]$ (85), and similar to that in $[Cl_3(H_2O)Sn—OH—]_2 \cdot (dioxan)_3$, but without the formation of a di-μ-O dimer (cf. ref. 87). In $[InX_3(py)_3] \cdot (py)$ (X = Cl, Br), $[TlBr_3(py)_3]$ (88), and $[TlCl_3(py)_3] \cdot (py)$ (33), however, the configuration is *mer*; predictably, it is *mer* also in the isomorphous $[MCl_3(terpy)]$ (M = Al, Ga, In, Tl, and probably Fe) group of complexes (31, 32, 80, 89).

A_3InX_6 and $A_3InX_6 \cdot nH_2O$ (X = Cl, Br)

The ready formation of hydrates and the difficulty in retaining the high-temperature phases by quenching are responsible for a number of inconsistencies in the literature statements concerning anhydrous A_3InX_6.

X-ray powder patterns of A_3InCl_6 (A = Na, K, Rb, Cs, NH_4, Ag; α, annealed low-temperature phase; β, quenched high-temperature phase) have been reported by Atkinson and Field (47), who indexed them all as tetragonal except for the Na and β-Ag salts (see above). The β-K, Rb, and α-Cs unit cells are obviously of the same type, and the α-K cell is dimensionally similar when transformed by taking $a\sqrt{2}$ instead of a. These authors also state (23) to have obtained, by evaporation of aqueous solutions of the chlorides at 0°C under vacuum, α-K_3InCl_6 from a K/In = 1:2 solution and β-K_3InCl_6 from a K/In = 1:1 solution. The product obtained by evaporation at −20°C under vacuum gave a powder pattern "similar to that of the α-K_3InCl_6 but with a slightly larger and distorted unit cell. This product, which probably contained lattice water, could be converted to β-K_3InCl_6 by heating to above 150°C." Furthermore, Atkinson *et al.* (90) observed that their β-K_3InCl_6 changed, on prolonged X-irradiation, to a material with a powder pattern of their α-K_3InCl_6. However, Wignacourt (18) has shown that neither form of Atkinson's K_3InCl_6 was in fact the anhydrous high-temperature form. Wignacourt's quenched β-K_3InCl_6, also tetragonal, had a = 8.031 Å, c = 9.572 Å, while his low-temperature α-K_3InCl_6 had unit-cell dimensions very similar to those of the β-K_3InCl_6 of ref. 47.

Indeed, when the unit-cell volumes of Atkinson's β-K, Rb, and α-Cs and Wignacourt's α-K phases are plotted against c, the four points fall on a smooth curve (Fig. 1, top), while the point for Atkinson's α-K (transformed cell) is completely off. Furthermore, three of the four $\bar{a} = (V/Z)^{1/3}$ (Z taken as 8, see below) values plotted against Shannon's (91) ionic radii $r^{xii}(A^+)$ fall on a straight line, with the point for β-K lying somewhat above and that for Atkinson's α-K appreciably below that line (Fig. 1, bottom). This can be taken as evidence that Atkinson's β-K, Rb, and α-Cs and Wignacourt's α-K have unit cells of the same type and are in all likelihood the authentic anhydrous low-temperature A_3InCl_6 phases. Although $(NH_4)_3InCl_6$ in ref. 47 is considered to be isostructural with β-K, Rb, and α-Cs, barring a mispring in Table 1 of that paper the unit-cell dimensions do not support this claim.[4]

Comparison of the unit-cell dimensions of Atkinson's α-

[4]The NH_4 and β-Cs phases were somewhat unstable and showed evidence of decomposition on cooling from the melt (47).

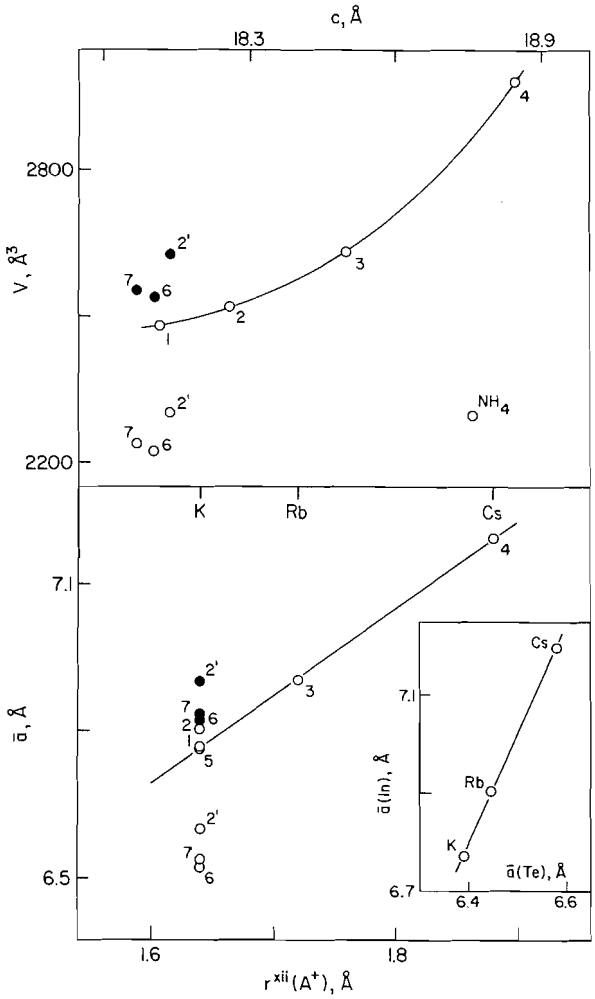

FIG. 1. Tetragonal A_3InCl_6 chlorides. (*Top*) Variation of the unit-cell volume with c. (*Bottom*) Variation of the mean unit-cell dimension $\bar{a} = (V/Z)^{1/3}$ with Shannon's effective ionic radius $r^{xii}(A^+)$. Open circles: *1*, α-K_3InCl_6 (18); *2*, β-K_3InCl_6 (47, 90); *3*, Rb_3InCl_6 (47); *4*, Cs_3InCl_6 (47); *5*, high-temperature (β) K_3InCl_6 (18); *6*, $K_3InCl_6 \cdot nH_2O$ (this work); *7*, $K_3InCl_6 \cdot H_2O$ (18, 27); *2′*, α-K_3InCl_6 (47, 90); NH_4, $(NH_4)_3InCl_6$ (47). Full circles: (16/14)V of *2′*, *6*, and *7* (see text). *Inset*: $\bar{a}(A_3InCl_6)$ plotted against $\bar{a}(A_2TeCl_6)$.

K_3InCl_6 with those of $K_3InCl_6 \cdot nH_2O$ (Table 2) shows that, allowing for a reasonable variation and taking into account the preparative circumstances, the presumed anhydrous α phase must have been a K_3InCl_6 hydrate. From the structure determinations we know (see **C**) that for $K_3InCl_6 \cdot nH_2O$ Z is 14. At the same time, the volume V_1 per formula unit of the hydrate should not be smaller than the V_1 of anhydrous K_3InCl_6. We also know, from comparison with In_3InCl_6 and Tl_3TlCl_6 (14, 65), that $V_1(K_3InCl_6)$ must be of the order of 290 Å^3. This indicates that for the anhydrous low-temperature phases $Z = 8$, i.e. to compare the unit-cell volumes in Fig. 1 the value for Atkinson's α-K_3InCl_6 must be multiplied by 16/14. The adjusted value is about 6% larger than Wignacourt's V(α-K_3InCl_6), a reasonable increment. The similarly treated V values for the hydrate (Table 2) fall in the same region of the plot as Atkinson's V(α-K_3InCl_6).

Unlike in $K_3InCl_6 \cdot nH_2O$ (see **C**), in the anhydrous A_3InCl_6 the In coordination polyhedra can only be $InCl_6$. The above volume and other relationships therefore suggest that, in spite of the initial appearance to the contrary, the structures of the α-A_3InCl_6 (A = K, Rb, Cs) chlorides do derive from the cubic cryolite aristotype (In in 000 etc., A^{vi} in $\frac{1}{2}00$ etc., A^{xii} in $\frac{1}{4}\frac{1}{4}\frac{1}{4}$ etc.), by distortions such that the $InCl_6$ octahedra are tilted away from the a as well as from the c axis so as to double but simultaneously shorten the c period. The tilt must be appreciable, as the observed tetragonal c/a ratios for the K, Rb, and Cs compounds are 1.548, 1.550, and 1.498, respectively. Since no cryolite chlorides of a similar type are known, we compare in Fig. 1 (inset) the $\bar{a}$(α-A_3InCl_6) values with those for the closest available cognates of the cubic cryolite structure, the $Fm3m$ A_2TeCl_6; these hexachlorides may be viewed as defect cryolites, $A^{xii}{}_2\square^{vi}[TeCl_6]$. The resulting linear relationship supports the suggested derivation.

The hydrated A_3MX_6 (M = In, Tl) cryolites might be expected to be analogous to the stoichiometric hydrate $K_3RhCl_6 \cdot H_2O$, the structure of which consists of a distorted fcc array of $[RhCl_6]^{3-}$ octahedra interspersed with K^+ and H_2O (92, 93). However, the three salts reported to date, $K_3InCl_6 \cdot nH_2O$, $K_3InBr_6 \cdot nH_2O$, and $K_3TlCl_6 \cdot nH_2O$ (Table 1 and **C**), are zeolitic and, as discussed in detail in **C**, their $I4mm$ structures ($Z = 14$) are characterized by the simultaneous presence of $[MX_6]^{3-}$ and $[MX_5(H_2O)]^{2-}$ ions. These structures can be derived from the cryolite structure presumed for the anhydrous A_3MX_6 as follows. The idealized cubic A_3MX_6 cryolite structure may be formally regarded as a combination of the NaCl and the *anti*-CaF_2 structure types, $A'A''_2[MX_6]$: the $[MX_6]^{3-}$ anions form a fcc array with A′ in positions corresponding to Na in NaCl and A″ in positions corresponding to F in CaF_2 (cryolite if A′ = A″, elpasolite if A′ ≠ A″). When the cubic cryolite cell ($Z = 4$) is quadrupled to form a tetragonal bc cell with $a_{tet} = a_{cub}\sqrt{2}$, $c_{tet} \sim 2c_{cub}$, omission of two of the sixteen $K_3[MX_6]$ units from this cell and conversion of two of the remaining fourteen $[MX_6]^{3-}$ ions to $[MX_5(H_2O)]^{2-}$ ions generate the framework of the hydrated cryolite:

$$K_3MX_6 = \quad K_{48} \quad [MX_6]_{12} \quad [MX_6]_4$$

$$K_3MX_6 \cdot \tfrac{1}{7}H_2O = K_{42}\square_6 \quad [MX_6]_{12} \quad [MX_5(H_2O)]_2X_2$$

The X^- ions take the place of the removed $[MX_6]^{3-}$ ions. The resulting readjustment of one of the K positions (K(6), see **C**) produces additional space in the structure which, together with one third of the □ vacancies (those at 2(*a*) in $I4mm$, see **C**), permit the zeolitic water molecules to be incorporated. It is remarkable that the conversion of $[MX_6]^{3-}$ to $[MX_5(H_2O)]^{2-} + X^-$ on hydration should stop, in all three cases, at the $[MX_5(H_2O)]/[MX_6] = \frac{1}{6}$ ratio and that any extra water entering the structure should remain uncoordinated to M.

Connected octahedra

The layer perovskites $AInF_4$ (A = K, Rb, Cs) (16, 61, 62) can be represented as $A[InF_2F_{4/2}]$ structures (cf. ref. 94 for possible derivation from the $P4/mmm$ $TlAlF_4$ aristotype). The ambiguity of the space-group assignment of the K and Rb compounds from X-ray diffraction (*Pbam* or *Pba*2 ⊂ *Pbam*, ref. 61) was resolved, on ir and Raman evidence, in favour of *Pbam* (62). The Cs compound ($Pca2_1$, $Z = 4$) is stated (61) to be isostructural with α-$RbFeF_4$ and α-$CsFeF_4$.

$NaInF_4$ has been indexed as hexagonal ($P3_112$ or $P3_121$, $Z = 8$), isostructural with $NaScF_4$ (16, 58), but in ref. 62 it is stated to be orthorombic, $Pca2_1$, $Z = 4$. Attempts to quench the high-temperature form were unsuccessful (16).

Shared octahedra of *two* types occur in the tetragonal $A_5In_3F_{14}$ (A = K, NH_4), which have the chiolite-type structure, $A_5[InF_2F_{4/2}][InF_4F_{2/2}]_2$, as does $K_5Tl_3F_{14}$ (59).

The $A_3In_2X_9$ halides (95, 96) contain isolated $In_2X_9^{3-}$ groups consisting of two InX_6 octahedra sharing a face, i.e. tri-μ-$[X_3InX_3InX_3]^{3-}$. The two classes reported to date represent different stacking variants. The rhombohedral ($R\bar{3}c$, Z = 6) $A_3[In_2Cl_9]$ (A = Rb, Cs, In, Tl), $Cs_3[In_2Cl_8Br]$ and $Cs_3[In_2Cl_7Br_2]$(*I*) are not isostructural with $Cs_3Fe_2Cl_9$ but related to $Cs_3Fe_2F_9$; $Cs_3M_2X_9$ (MX = ScCl, TlCl, YCl, YBr) are of the same type (96, 97). The hexagonal ($P6_3/mmc$, $Z = 2$) $Cs_3[In_2Cl_7Br_2]$(*II*) and $Cs_3[InCl_{9-n}Br_n]$ (n = 3, 6, 9) are isostructural with $Cs_3Cr_2Cl_9$.

Five-coordinated In

The $[InCl_5]^{2-}$ complex in $(Et_4N)_2InCl_5$ is an almost regular square pyramid of C_2 symmetry (39, 40), as is the $[TlCl_5]^{2-}$ complex in the isostructural Tl compound (40).[5] $(Et_2NH_2)_2TlCl_5$ has been prepared and analyzed (98) and may be of this type. Square-pyramidal geometry is also present in $(n\text{-}Bu_4N)_2$-{InX[SC(CN)=C(CN)S]$_2$} (X = Cl, Br) and their isostructural Tl analogs (43). As would be expected, in $[InCl_3(PPh_3)_2]$ the coordination figure is a *trans* trigonal bipyramid, as it also is in $InCl_3\cdot 4H_2O = [InCl_3(H_2O)_2]\cdot 2H_2O$ and in $\{InCl_3$-$[OP(NMe_2)_3]_2\}$; the Tl complexes $[TlBr_3(py)_2]$ (99), $[TlBr_3$-$(OPPh_3)_2]$ (100), and $[TlBr_3(Opy)_2]$ (101) are of the same coordination type.

Indium analogs of compounds containing $[X_3M—MX_3]^{2-}$ ions (e.g. $(Me_4N)_2[Ga_2Cl_6]$ (102), $(n\text{-}Pr_4N)_2[Ga_2Br_6]$ (103), and $Ga_2[Ga_2I_6]$ (104)) have been prepared and authenticated by vibrational spectroscopy ($(n\text{-}Bu_4N)_2[In_2X_6]$, X = Cl, Br, I (105)), but their crystal structures have not been determined.

An $[InCl_5]^{2-}$ complex is presumed to exist also in the primitive cubic $BaInCl_5$ (47) (Z = 16?), crystallographically different from $BaInF_5$, $BaFeF_5$, $SrFeF_5$ (106), $BaGaF_5$, or any of the three known forms of $BaAlF_5$ (107). While the existence of $BaInCl_5$ was confirmed in the dry $BaCl_2$–$InCl_3$ system (108), no double salt was found in the $BaCl_2$–$InCl_3$–H_2O system at 24°C (109).

Seven-coordinated In

It is mainly the emergence of this coordination that signals a division between the structural chemistry of In(III) and Fe(III) halides. Only fluoride structures have been reported to date.

Isolated irregular InF_7 polyhedra are found in Sr_2InF_7, which is isostructural with K_2NbF_7 (ref. 1; cf. also ref. 106).

Edge- and vertex-sharing pentagonal InF_7 bipyramids connected to form three-dimensional frameworks occur alone (KIn_2F_7) or in combination with InF_6 octahedra ($RbIn_3F_{10}$, $Rb_2In_3F_{11}$). Thus $K_2InF_7 = K[InF^{eq}{}_{4/2}F^{eq}{}_{1/2}F^{ax}{}_{2/2}]_2$ can also be represented as $K[\mu\text{-}F^{eq}{}_{4/2}F^{ax}{}_{2/2}InF^{eq}InF^{ax}{}_{2/2}F^{eq}{}_{4/2}]$ (3). $RbIn_3F_{10}$ can be formulated as $Rb[InF_{4/2}F_{2/2}][InF_{2/2}F_{2/2}F_{1/2}F_{2/2}]_2$ (5); the NH_4 compound (17) is probably isostructural. The related $Rb_2In_3F_{11}$ contains two nonequivalent InF_7 units: $Rb_2[InF_{2/2}F_2F_{2/2}][InF^{eq}{}_{4/2}F^{eq}{}_{1/2}F^{ax}{}_{2/2}]_2$ (6). Each InF_7 bipyramid in these structures shares four equatorial corners to form characteristic infinite chains reminiscent of those found in $PaCl_5$; the chains are cross-linked in different ways to form sheets and stacking sequences perpendicular to the sheets. A simpler variant of this type of arrangement occurs in $N_2H_5InF_4\cdot H_2O = N_2H_5[InF^{eq}{}_{4/2}F^{eq}{}_{1/1}F^{ax}{}_{1/1}(H_2O)^{ax}]$, where the coordination polyhedron is a *trans*-$InF_6(H_2O)$ bipyramid.

Yet another arrangement is found in α-$Ba_3[In_2F_{12}]$ (ref. 4; cf. also ref. 106). In this structure two trigonal In coordination prisms sharing a vertical edge, each augmented on the far vertical face, form isolated [di-μ-$F_5InF_2InF_5]^{6-}$ groupings. The structure differs from that of low $Ba_3Al_2F_{12} = Ba_6F_4[Al_4F_{20}]$ (*Pnnm*, Z = 4), which contains "isolated" $[F_{4/1}AlF_{2/2}]_4$ rings similar to $[MF_5]_4$ (M = Nb, Ru (110).

Isolated tetrahedra

With the exception of the fluorides (see above), all the $AInX_4$ halides with known structures contain isolated InX_4^- tetrahedra. No example of linked InX_4 tetrahedra seems to have been reported to date.

The K, β-Rb, and NH_4 chlorides (47), which crystallize with tetragonal structures of the scheelite type, are isostructural with the corresponding Tl(III) (111, 112) but not Ga(III) or Fe(III) (52, 113) chlorides.[6] The hydrogen-bonding scheme in NH_4InCl_4 is thus almost certain to correspond to that in NH_4TlCl_4 (111): each of the four equivalent H atoms participates in a bifurcated, almost symmetric N—H···2Cl bond, d(H···Cl) ~ 2.5 Å.

Only powder patterns were available for the Na, β-Cs (water-quenched high-temperature form), and the annealed, low-temperature α-Rb and α-Cs chlorides (47). Assuming that the indexing in ref. 47 corresponds to the actual structure, the following can be noted. The $(b + c)/4 = a'$ mean for the orthorhombic $NaInCl_4$ defines a tetragonal cell dimensionally similar ($a/a' = 2.395$) to the scheelite cells and a volume V_I per formula unit which is compatible with $V_I(KInCl_4)$ and V_I(β-$RbInCl_4$). The $NaInCl_4$ structure may thus turn out to be a variant of the scheelite structure.[7] The large tetragonal cells reported in ref. 47 for α-$RbInCl_4$ and α-$CsInCl_4$ are consistent with Z = 28.

The orthorhombic $KInBr_4$ (48) and In[InI_4] (45), which have cation/anion packings of a distorted CsCl type, are isostructural with Ga[$GaCl_4$] (114),[8] $KTlBr_4$ (116), NH_4TlBr_4 (116), and Tl[$TlBr_4$] (117), while Tl[$TlCl_4$] has the scheelite structure (111) and Ga[GaI_4] (104) has an unusual, complex rhombohedral ($R3c$, Z = 6) structure. The existence of In[$InCl_4$] is in dispute. Low- (α) and high-temperature (β) forms of $InInCl_4$ are claimed (44, 118) to have been obtained; the powder pattern of the β phase was indexed as orthorhombic, on a unit cell dimensionally similar to that of Ga[$GaCl_4$] (and of β-$TlInCl_4$, ref. 118). However, no phase of the composition $InCl_2$ was found in a recent re-investigation (97) of the system In–Cl. The unit-cell volume of $InGaCl_4$ ($BaSO_4$ type, ref. 113) would suggest that the In and Ga atoms in this crystal are disordered.

No other $AInBr_4$ or $AInI_4$ structures with simple cations have so far been reported, though one would expect them to be similar to those of the corresponding Tl compounds, which have been studied in some detail. The existence of peritectic transformations makes investigation of the bromides difficult. $CsTlBr_4$ at room temperature has $P2_12_12_1$ symmetry (116).[9]

[5]The crystal symmetry of $(Et_4N)_2InBr_5$ from optical investigation is reported (38) as cubic. Spectroscopic evidence (25) seems to suggest that this bromide is in fact $(Et_4N)_2[InBr_4]Br$.

[6]The observation (47) that the powder patterns of the K, NH_4, and β-Rb salts could also be indexed on cubic cells with $a_{cub} = a_{tet}\sqrt{5} = c_{tet}$ has its root in the fortuitous circumstance that the c/a ratios of these salts are very close to $\sqrt{5}$. This is not so for scheelites in general.

[7]Attempts to prepare $NaTlCl_4$ and $CsTlCl_4$ by the method which yielded the K, Rb, and NH_4 chlorides failed (111).

[8]^{35}Cl nqr spectra indicate that Ga[$GaCl_4$] undergoes a transition, at ca. 320 K, in which the $GaCl_4$ tetrahedron, of low symmetry in the high-temperature phase, *increases* its symmetry in the low-temperature phase (115). An analogous transition, at ca. 250 K, is observed in $KGaCl_4$ (115); the phase above 250 K has been reported as monoclinic, $P2_1$ (113).

[9]It is interesting to note that $V_I(CsTlBr_4)$ is 4.2% *smaller* than $V_I(NH_4TlBr_4)$. A monoclinic form of $CsTlBr_4$ is mentioned in ref. 119; cubic symmetry ($Fm3c$) is reported in ref. 120 (also for $CsTlI_4$).

The pseudohexagonal mixed halide $Tl[TlCl_2Br_2]$ crystallizes in the same space group ($Z = 4$), but its unit-cell dimensions are not related to those of $CsTlBr_4$; the packing in this crystal is of the *anti*-NiAs type (121). The cubic ($Z = 24$) $ATlI_4$ iodides can be prepared by direct synthesis under anhydrous conditions or by dehydrating the respective cubic $ATlI_4 \cdot nH_2O$ hydrates. The latter can lose water already at temperatures well below ambient, with retention of the cubic structure and almost without change in the unit-cell dimensions (119, 122). While a structure of an anhydrous $ATlI_4$ has not yet been reported, it would seem that the nonaqueous part of the hydrate structure (see *Hydrated species*) is preserved. This receives some support from ^{127}I nqr spectra (122), which at room temperature contain a *single* ν_1 resonance line for $KTlI_4 \cdot 2H_2O$ (and also for the Rb, Cs, and NH_4 salts) as well as for $KTlI_4$; the resonance in the room-temperature spectrum of NH_4TlI_4, however, was a doublet. For $CsGaI_4$ at room temperature the ν_1 resonance is a quartet (123), which excludes a cubic structure.

The tetrahalides $Et_4N[InX_4]$ have the *anti*-NiAs ($P6_3mc$) ion packing for $X_4 = Cl_4$ (49), $ClBr_3$ (ordered) (50), and probably Br_4 (38), with the ethyl groups orientationally disordered. Et_4NTlBr_4, Et_4NTlBr_3I (124),[10] Et_4NFeCl_4,[11] and $Me_4SbGaCl_4$ (125) are also of this type.[12] The structure of $Et_4NInClI_3$, however, is of the NaCl type,[13] with Cl and I disordered, and so are the structures of $Et_4NTlBr_2I_2$, $Et_4NTlBrI_3$, Et_4NTlI_4 (124), and $Et_4NFeI_4(I)$ (127).[14] Interestingly, $Et_4NGaClI_3$ (Cl and I disordered) (128) and the isostructural $Et_4NFeI_4(II)$ (127) are of yet another type: the orthorhombic (*Pnnm*) unit cell is pseudohexagonal, $a \sim c\sqrt{3}$, and the structure is based on a distorted NiAs packing arrangement.

The n-$Bu_4N[InCl_{4-n}Br_n]$ ($n = 0, 1, 3, 4$) salts are orthorhombic (*Pnna*), as are the isostructural Tl compounds ($n = 0, 4$) (126), but n-Bu_4NTlI_4 is monoclinic ($P2_1/n \subset Pnna$) (129).[15] The cation/anion packing in the *Pnna* structures is of the NaCl type.

$Ph_4As[InCl_4]$ is isostructural with the corresponding Ga, Fe, and Tl chlorides (52, 53, 126). The ion packing in these crystals (and in Ph_4AsI) is of the tetragonally distorted zincblende type; the structure reflects the symmetries of the two ions.

With the possible exception of Et_4NTlI_4, in none of the $A[MX_4]$ compounds mentioned here (and included in Fig. 2) has the MX_4^- ion the T_d symmetry, though in some of them it is very nearly a regular tetrahedron. Unless significantly pertured by the orientational disorder of the ethyl group, a regular tetrahedron can, however, be expected for InI_4^- in Et_4NInI_4, as yet not investigated.

The cation/anion packing type for $A[InX_4]$ halides can be related, in a general way, to ionic size, but for this to be instructive the In compounds are best considered in the overall context of the $A[M(III)X_4]$ structures. A plot of the volume V_1 per formula unit against Shannon's (91) $r^{iv}(M^{3+})$ (Fig. 2) involves a minimum of assumptions, as V_1 derives directly from experiment and reflects the effective size of both A and X, and the sequence (though not necessarily the values) of $r^{iv}(M^{3+})$ is reasonably well established.[16] The relevance of relative ionic size is evident. The boundary, at low V_1, between the 6:6 ($BaSO_4$) and the 8:8 ($CaWO_4$ and $GaGaCl_4$) packing types is quite sharp, although $GaGaCl_4$ itself falls in the 6:6 region of the plot; the $GaGaCl_4$ type appears to be favoured as V_1 increases.[17] Above $V_1 \sim 300$ Å^3 (ignoring $ATlI_4$, with structures not yet known) only 6:6 packing types occur. The exception is $Ph_4As[MCl_4]$, which are of the 4:4 zincblende type, but this is probably because of the particular, more or less rigid geometry of the Ph_4As group which requires the tetrahedral anion to fit with economy of space between the phenyl rings of adjacent cations. Moreover, the increasing cation size tends to give rise to packing of the NaCl type, and the importance of the relative size of the anion disappears. The reason for the occurrence of *both* the NiAs and the *anti*-NiAs packing types as alternatives to the NaCl-type packing is not obvious, although it may have its origin in the tendency to minimize X–X repulsions between neighbouring anions. In the hexagonal *anti*-NiAs structure the MX_4 tetrahedra are aligned, at $c/2$ intervals, in polar columns on threefold axes, the successive orientations alternating so as to produce staggered sequences $\|c$; the perpendicular spacing between the columns is a, hence X–X contacts are possible only between adjacent tetrahedra in a column. In the orthorhombic NiAs-type structure, however, the interval between the eclipsed anions on a threefold axis is the full $b \sim 14$ Å translation, hence X–X contacts are possible only *between* columns, which have perpendicular separations of ca. $c/\sqrt{3} \sim a/3$.

A more detailed, though more presumptive, distribution of the packing types is obtained when the effective cation radius $r^{vi}(A^+)$ is plotted against the sum of Shannon's $r^{iv}(M^{3+})$

[10]The unindexed powder patterns given in ref. 124 can be indexed as hexagonal and consistent with $P6_3mc$ for Et_4NTlBr_4 ($a = 8.43$ Å, $c = 13.73$ Å) and Et_4NTlBr_3I ($a = 8.55$ Å, $c = 13.99$ Å), and fcc for $Et_4NTlBr_2I_2$ ($a = 12.17(2)$ Å), $Et_4NTlBrI_3$ ($a = 12.29(3)$ Å), and Et_4NTlI_4 ($a = 12.44(1)$ Å).

[11]B. R. Vincent, T. S. Cameron, and O. Knop. To be published.

[12]Salts analyzing to Me_4NTlX_4 and Et_4NTlX_4 (X = Cl, Br) have been prepared but apparently not examined by X-ray diffraction (126).

[13]Figure 1 of ref. 50 does not agree with x(N) of Table I of that paper; it shows a zincblende arrangement of the ions. The $V(Et_4NInClBr_3)$ in Table I and the In—Cl distance in that compound in Table III are in error. One would also expect U_{iso}(Cl) to be larger than U_{iso}(Br) and U_{iso}(I) in Table II.

[14]In ref. 127 the structure of $Et_4NFeI_4(I)$ is described as tetragonal ($a = 8.652(2)$ Å, $c = 12.236(2)$ Å, $Z = 2$) and refined in $I\bar{4}m2$. However, $a\sqrt{2} = 12.236(3)$ Å $= c$, $x(I)\sqrt{2} = z(I)$, and the positions of the Fe, N, and I atoms are equally well described in the cubic group $F\bar{4}3m$. These relationships hold too well to be fortuitous, and in the absence of any reference to them in that paper, and in view of ref. 50, it must be assumed that the true space group is in fact $F\bar{4}3m$, expressed in ref. 127 as the $I\bar{4}m2$ setting of $F\bar{4}2m \subset F\bar{4}3m$.

[15]The ^{35}Cl, ^{81}Br, and ^{127}I nqr spectra of the n-Bu_4NGaX_4 halides (130, 131) indicate trigonal symmetry for the $GaCl_4^-$ and $GaBr_4^-$ ions and the existence of disordered $GaCl_nBr_{4-n}^-$ ions in the $X_4 = Cl_nBr_{4-n}$ compounds. The tetraiodide is not isostructural with the tetrachloride and tetrabromide.

[16]The differences between the V_1 values for corresponding In,Tl pairs of $A[MX_4]$ halides (AX = KCl, NH_4Cl, RbCl, KBr, Et_4NBr, n-Bu_4NCl, n-Bu_4NBr; cf. Fig. 2) would suggest that $r^{iv}(Tl^{3+})$ relative to $r^{iv}(In^{3+})$ is not constant but is larger than the latter when $V_1 < 250$ Å^3 and smaller when $V_1 > 250$ Å^3: $V_1(Tl) = 8.23 + 0.968V_1(In)$, $r^2 = 1.00$, $\sigma = 3$ Å^3. For the difference $V_1(In) - V_1(Tl)$ at either end of the V_1 range to arise from poor experimental accuracy the lattice parameters would have to be in error by an appreciable amount, ~0.5% on the average. The differences are therefore likely to be real and possibly connected with the greater polarizability, by external charges, of the Tl—X bond, which in the isolated ion may be shorter than the corresponding In—X bond. Unfortunately, a direct comparison of In—X and Tl—X bond lengths in MX_4^- is precluded by the lack of structure determinations of matched $A[MX_4]$ pairs; theoretical estimates of these bond lengths do not seem to exist.

[17]A formal relationship between the $BaSO_4$ (*Pnma*) and $GaGaCl_4$ (*Pnna*) structure types is derived, via the common supergroup *Imma*, in ref. 132. However, an argument based on symmetry alone does not account for the difference in the cation/anion coordination in the two structures.

For personal use only.

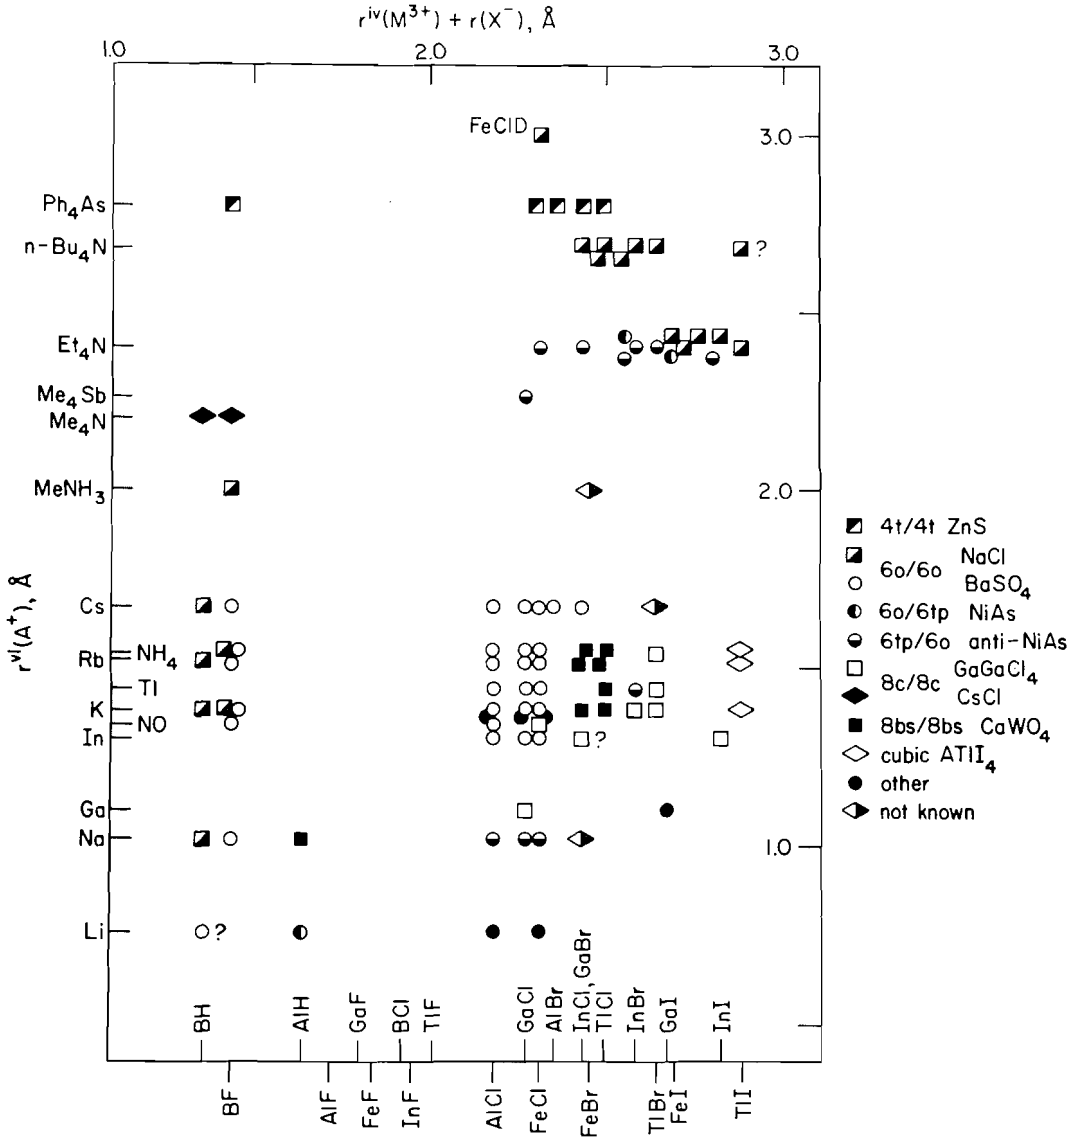

FIG. 3. Distribution of the gross-structure (cation/anion packing) types among $A[M(III)X_4]$ halides according to Shannon's $r^{iv}(M^{3+}) + r(X^-)$ and $r^{iv}(A^+)$ (the value used for $r^{iv}(Tl^{3+})$ is 0.68 Å). The cation/anion coordination ratios and polyhedra are represented by *6tp/6o* etc., where *bs* = combination of square and tetragonal bisphenoid of overall symmetry D_{2d}, *c* = cube, *o* = octahedron, *t* = tetrahedron, *tp* = trigonal prism. Although distinguished in the plot, the $BaSO_4$ and NaCl packing types differ only in the degree of distortion of the coordination octahedra, and similarly for the coordination cubes of the CsCl and $GaGaCl_4$ packing types. The structures of the Me_4N, $MeNH_3$, Ph_4As, and Ph_4Bi tetrafluoroborates (not yet determined) are assumed to be of the same type as those of the corresponding perchlorates. FeClD = $[trans\text{-}FeCl_2(dmso)_4]^+$.

and $r(X^-)$ (Fig. 3).[18] This plot involves, in addition to the deficiencies of Fig. 2, uncertainty about the size of A^+, both because of differences in the CN of A^+ between compounds and because the size estimates assigned to the composite cations are of necessity somewhat arbitrary. Furthermore, the radius sum is not an entirely satisfactory substitute for a representative M—X bond length, which would be preferable to use if it could be obtained with confidence for all the M,X combinations in the plot. Including ABF_4, ABH_4 and $AAlH_4$ serves to strengthen the conclusion from Fig. 2, viz. 6:6 packing types prevail over a surprisingly wide range of cation and anion sizes, with 8:8 types occurring only with combinations of large simple (and NH_4^+) cations and large anions, and with combinations of composite cations and very small anions. The last-named set requires further investigation, for apart from Me_4NBH_4 it contains only one other compound, Me_4NBF_4, the structure of which has not yet been determined but has been inferred from similarity with Me_4NClO_4. Low packing coordination ratios have so far been found only with $LiAlCl_4$ and $LiFeCl_4$ (ratios not clearly defined), and with the Ph_4AsMCl_4 chlorides mentioned above.

Hydrated species

The binary halide hydrates, $InCl_3 \cdot 4H_2O$ and $InBr_3 \cdot 2H_2O$, are reported (18, 20) as orthorhombic, the chloride as *Pnma* ($Z = 4$), the bromide as *Pmcm* or $Pmc2_1$ or $P2cm$. The chloride is almost certainly isostructural with $TlCl_3 \cdot 4H_2O$ and $TlBr_3 \cdot 4H_2O$ (133), hence by implication the In complex is a slightly distorted $[trans\text{-}InCl_3(H_2O)_2]$ trigonal bipyramid (see above).

[18]Here and in what follows $r^{iv}(Tl^{3+})$ is taken as 0.68 Å (see footnote 16). The other $r^{iv}(M^{3+})$ values are Shannon's: 0.39, 0.47, 0.49, and 0.62 Å for Al, Ga, Fe, and In, respectively.

TABLE 3. The $X_{ax}MX_{eq}$ angle (deg) of the $[MX_5(H_2O)]^{2-}$ anion in $A_2[MX_5(H_2O)]$ and $K_3MX_6 \cdot nH_2O$

	$A_2[MX_5(H_2O)]$			$K_3MX_6 \cdot nH_2O$

CsFeCl	94.4(2)	94.4(2)	135, 138		

[a]The site symmetry at the M atoms in $A_2[MX_5(H_2O)]$ is *m* except in $Cs_2[FeCl_5(H_2O)]$, where it is *mm*; in $K_3MX_6 \cdot nH_2O$ the site symmetry at M(3) is *4mm*.

[b]Maximum $X_{ax}MX_{eq}$ angle. The average uncertainty of this angle is of the order of 0.1°. This angle always involves the X atoms related by the plane of reflection through M.

The orthorhombic (*Pnma*) $A_2[InX_5(H_2O)]$ (X = Cl, Br; for A, see Table 1) salts belong to a large family of $A_2MX_5 \cdot H_2O$ compounds, many of which are isostructural and which have been studied in detail for a variety of reasons (the main features of the *Pnma* structure are described in **C**; new spectroscopic results on some of these salts will be reported elsewhere). The nonplanarity of the In or Tl atom in the $[MX^{ax}X^{eq}_4(H_2O)]^{2-}$ octahedron with the four X^{eq} atoms is not due to any special tendency of In and Tl to formation of MX_5 complexes. As Table 3 shows, the nonplanarity is present not only in the In and Tl compounds but in their Fe(III) analogs as well, and although the *mean* $X^{ax}MX^{eq}$ angle in the octahedron is ~92.4°, the *largest* of the four $X^{ax}MX^{eq}$ angles is ~94° and thus not much inferior to that in $K_3MX_6 \cdot nH_2O$, ~96°C. The deviation of the $X^{ax}MX^{eq}$ angle from 90° is attributable to the electrostatic repulsion of the X atoms and the compression of the $X^{eq}MO$ angle as a consequence of the smaller effective size of the oxygen atom: in the truly five-coordinate, square-pyramidal $InCl_5^{2-} = [InCl^{ax}Cl^{eq}_4\square]^{2-}$ ion in $(Et_4N)_2InCl_5$ (39) the $Cl^{ax}InCl^{eq}$ angle is 103.9(4)°.

Although we were not successful in duplicating the preparation (23) of $K_2InCl_5 \cdot 2H_2O$ (see **C**), our failure does not mean that this hydrate does not exist, even though a phase of this composition was not found in the $KCl–InCl_3–H_2O$ system at room temperature (18, 20, 139). Rather it reflects the delicate nature of the phase relationships in that system, for in the corresponding Tl system the dihydrate $K_2TlCl_5 \cdot 2H_2O$ forms under conditions of crystallization which in the other $ACl–TlCl_3–H_2O$ systems (A = Rb, Cs, NH_4) lead without difficulty to the monohydrates (134). The crystal structure of $K_2TlCl_5 \cdot 2H_2O$ ($P2_1/c$, $Z = 4$) contains isolated centrosymmetric pairs of $TlCl_6$ octahedra sharing an edge, with the water molecules interspersed between them, i.e. the compound is $K_4[di\text{-}\mu\text{-}Tl_2Cl_{10}] \cdot 4H_2O$. In flowing N_2 the crystal loses water completely already at 72°C; the freshly dehydrated material retains the X-ray powder diffraction pattern of the dihydrate. However, on heating the dihydrate under static conditions (in a Guinier–Simon camera) a powder pattern "identical" with that of the tetragonal $K_3TlCl_6 \cdot 2H_2O$ was observed above 110°C (134). Since the presence of lines of a second phase ($KTlCl_4$) is not mentioned, it seems quite likely that this pattern was in fact that of $(K_{8/3}Tl^+_{1/3})TlCl_6$ formed by solid-state conversion with the loss of two Cl atoms.[19] In contrast, the $K_2InCl_5 \cdot 2H_2O$ of ref. 23 is stated to have dehydrated, by heating to 150°C, to $K_2InCl_5 \cdot H_2O$, which was stable up to >400°C.[20] The difference between the Tl and the In compound on heating thus appears to reflect the much greater reluctance of In(III) to reduce to In(I). Evidently a much more extensive and systematic effort will be required to establish beyond doubt the full range of species in the $KCl–InCl_3–H_2O$ system. The monoclinic $(Me_3S)_4In_2Cl_{10} \cdot 3H_2O$ of ref. 38 may very well turn out to be an analog of the above Tl compound, $(Me_3S)_4[In_2Cl_{10}] \cdot 3H_2O$.

The monoclinic $KInBr_4 \cdot 2H_2O$ is $K[trans\text{-}InBr_4(H_2O)_2]$ (19). In contrast, the cubic ($F\bar{4}3c$) Tl bromides and iodides of the corresponding empirical formula are in fact $A[TlX_4] \cdot nH_2O$, with structures consisting of threedimensional frameworks of TlX_4 tetrahedra and AX_{12} cuboctahedra, and with the extra A atoms and the zeolitic water molecules distributed at random over the available interstices, though not necessarily in the same manner for the different A elements (119). In the $A[TlI_4] \cdot nH_2O$ (A = K, Rb, Cs, NH_4) iodides, $0 \leq n \leq 2$; existence of transitions between room temperature and −90°C in the Rb, Cs, and NH_4 salts has been detected by ^{127}I nqr spectroscopy (119, 122). Other isostructural compounds described in ref. 119 are $KTlBr_4 \cdot 2H_2O$ (cf. also ref. 140, where the structure is refined in $Fm3c$), $RbTlBr_4 \cdot H_2O$, $CsTlBr_4 \cdot H_2O$, and $NH_4TlBr_4 \cdot 2H_2O$ as well as the Li and Na bromide dihydrates.[21] While the iodides can be dehydrated to $ATlI_4$ with retention of the cubic structure, complete dehydration of the bromides results in structural change (119, 122). Analogous compounds of In(III), if they exist, do not appear to have been studied.

The reported In—O distances in aquo complexes range from ~2.13 to ~2.36 Å (Table 4). The values are too few, and in part not sufficiently accurate, to detect with confidence any trends

[19]Thermal degradation of $(NH_4)_2TlCl_5 \cdot H_2O$ in a stream of N_2 led to a loss of water in one step at 270°C. Further heating produced, at 320–325°C, a residue of TlCl (134).

[20]According to ref. 18, $K_2InCl_5 \cdot H_2O$, under dynamic heating conditions, loses its water between 190 and 230°C to yield K_2InCl_5.

[21]According to ref. 141, $KTlBr_4 \cdot 2H_2O$ is obtained from solutions with K/Tl > 1, while solutions with K/Tl = 1 yield $KTlBr_4 \cdot H_2O$.

that may exist with respect to charge on the complex and the nature, size and configuration of the co-ligands.

B. M—Cl bond lengths in complex M(III) chlorides

If comparisons of available In—Cl bond lengths (as determined by X-ray diffraction) are to have any meaning in relation to the chemistry of the complexes, it must be shown that the differences that may exist between complexes are significant and attributable to systematic rather than accidental causes.

The limits to meaningful comparisons are set by the following considerations. The *accuracy* of an individual In—Cl bond length in a routine structure determination is probably not much better than ±0.01 Å. This represents about 2% of the total spread, ~0.5 Å, of observed uncorrected In—Cl distances (see below). Variation in the In—Cl bond length in the same complex in a particular crystal amounts to perhaps another 0.01 Å, except where the bond lengths are constrained to a single value by symmetry. Differences of less than 0.02 Å between uncorrected bond lengths in different compounds can therefore rarely be regarded as chemically significant; strong asymmetry of the crystal environment of the complex and hydrogen bonding may double this limit even without contribution from special factors (e.g. the "*trans*" effect). Corrections for thermal motion are model dependent and in general not likely to increase the reliability of bond-length comparisons. For such comparisons to reveal rather than obscure the trends that may exist, they must be systematic but not too detailed, and they must encompass the widest possible variety of crystal structures.

Effect of coordination number and ionic charge

The primary systematic factors determining the In—Cl bond lengths in $[InCl_nX_m]^\epsilon$ complexes are the CN = $n + m$ and the charge ϵ on the complex. When the size disparity of the ligands is appreciable, the effect of the CN may be difficult to ascertain; ligand configuration may also be a significant factor. In an attempt to improve on previous comparisons of In—Cl bond lengths, the present examination draws upon all the available information we could locate as well as on our extensive SCF calculations at the 6-31G* level (split-valence basis set with polarization functions included for all atoms) for free $[AlCl_n]^\epsilon$ and $[AlF_n]^\epsilon$ species,[22] but even so, consideration of X other than Cl remains restricted largely to H_2O in five- and six-coordinated aquochloro complexes. The paucity of information on mixed-ligand complexes is regrettable, as their inclusion is essential if the effect of ϵ is to be investigated separately from the effect of CN.

To investigate the trends in the variation of the In—Cl bond lengths we have compiled (Table 5) the *mean* uncorrected In—Cl distances $D(CN,\epsilon)$ for all the chloro complexes listed in Table 1 and elsewhere in this paper. Examination of the $\sigma(D)$ values and sample sizes for the individual CN,ϵ combinations shows that the $[InCl_6]^{3-}$ and $[InCl_5(H_2O)]^{2-}$ samples are of reasonable size and that the mean bond length in $[InCl_6]^{3-}$ in particular varies surprisingly little from structure to structure (cf. similar constancy in other halogeno complexes, e.g. $[AlF_6]^{3-}$ (146) and $[SnCl_6]^{2-}$ (147, 148)). For the other CN,ϵ combinations the spread is somewhat larger but still not appreciable, considering that the mean for CN,ϵ = 5,2−, for example, is obtained from complexes as different as the trigonal-bipyramidal $[InCl_5]^{2-}$ and the square-pyramidal $\{InCl[SC(CN)=C(CN)S]_2\}^{2-}$. However, owing to the very small sample sizes the D values of Table 5 for such CN,ϵ combinations must be regarded as less representative.

In the CN,ϵ = 6,ϵ series the D/ϵ increment is approximately constant and ~0.025 Å. This suggested that D might, in the first approximation, be representable as a linear function of ϵ and possibly also of CN. Regressing D on CN and ϵ showed that this supposition indeed is plausible. When D was mapped on CN and ϵ along the gradient of $D_{calcd} = c_0 + c_\epsilon\epsilon + c_{CN}CN$ (i.e. perpendicular to the constant-D contours), the points for $D(CN,\epsilon)$ fell very close to the appropriate points of the CN,ϵ lattice. This could, of course, be fortuitous owing to the restrictive distribution of the available CN,ϵ combinations (CN ≥ 4, $\epsilon \leq 0$). Similar, separate regressions were therefore obtained for Al, Ga, Fe(III), and Tl(III) chloro complexes (Table 5).[23] With the exception of Ga, for which only three D values were available, the D were in each case reasonably approximated by D_{calcd}. Furthermore, it was found that c_0, c_ϵ, and c_{CN} could all be adequately represented, in the M size range under consideration, by $c_i = k_{i0} + k_{i2}r_M^2$, where r_M is short for $r^{iv}(M^{3+})$.[18] These findings strongly suggested that D(M—Cl) could be approximated by a linear function of r_M^2,

[22] S. C. Choi, R. J. Boyd, and O. Knop. To be published.

[23] The compounds included in the regressions and the pertinent references are listed in Table 6, see footnote 24.

[a]The mean bond length $\bar{d}_k$ in complex k is $\Sigma w_i d_i/\Sigma w_i$, with a standard deviation $\sigma(d_k)$, where d_i is an individual uncorrected M—Cl bond length in that complex and $w_i = \sigma^{-2}(d_i)$ is calculated from the esd's quoted. The aggregate mean bond length $D(CN,\epsilon)$ in a sample of p CN,ϵ-complexes is $(\Sigma\bar{d}_k)/p$, with a standard deviation $\sigma[D(CN,\epsilon)]$; in the table, p is the number after the oblique stroke. When $p = 1$, $D = \bar{d}_k$ and $\sigma(D) = \sigma(\bar{d}_k)$.

[b]See text for values actually used in the regression of D on r_M^2, CN, and ϵ.

CN, and ϵ. Before proceeding with the triple regression, the aggregate of D values (Table 5) was examined in detail, taking into account observations made on the separate regressions for each M.

The CN,ϵ combinations in each D(M—Cl) set are distributed nonuniformly, favouring high CNs. The regression function can therefore be expected to approximate D less well at low CNs and positive ϵ charges. Inclusion of $D(3,0)$ values, from MCl_3 monomers, in the regression is thus particularly important. However, M—Cl bond lengths in MCl_3 (determined by electron diffraction in the gas phase) appear to be available only for Al and Fe; for Fe the quoted uncertainty is ±0.03 Å (Table 6).[24] To obtain an estimate for $GaCl_3$ and an improved value for $FeCl_3$, the d values for the AlF_3, $AlCl_3$, AlI_3, $GaBr_3$, and GaI_3 monomers (cf. ref. 149) were regressed on r_M and $r^{vi}(X^-)$.[25] The regression equation gave d_{calcd}(Al—F) = 1.627(8) Å and d_{calcd}(Al—Cl) = 2.077(8) Å, both in excellent agreement with the corresponding d_{SCF} values, 1.621 and 2.077 Å, respectively. For $GaCl_3$ and $FeCl_3$ the d_{calcd} values are 2.098(8) and 2.103(8) Å, respectively. These values for the free MCl_3 monomers would correspond, in the crystal, to the M—Cl bond lengths *corrected for thermal motion*. For inclusion in the aggregate D set they were therefore adjusted by subtracting 0.05 Å from D_{calcd}(Al—Cl), 0.04 Å from D_{calcd}(Ga—Cl), and 0.03 Å from D_{calcd}(Fe—Cl) (see below).

The function resulting from the triple regression was

$$[1]\quad D_{calcd} = 1.5273 + 1.4092r_M^2 + 0.10531(1 - 1.1556r_M^2)CN - 0.01693(1 + 2.2918r_M^2)\epsilon$$

($r^2 = 0.990$, $\sigma = 0.016$ Å). The overall agreement of D_{calcd} and D is shown in Fig. 4. The rates of change of D_{calcd} with CN and ϵ are $\partial D_{calcd}/\partial CN = 5.4\sigma$ for Al but 3.1σ for Tl, and $\partial D_{calcd}/\partial\epsilon = -1.4\sigma$ for Al and -2.2σ for Tl (Table 7). This

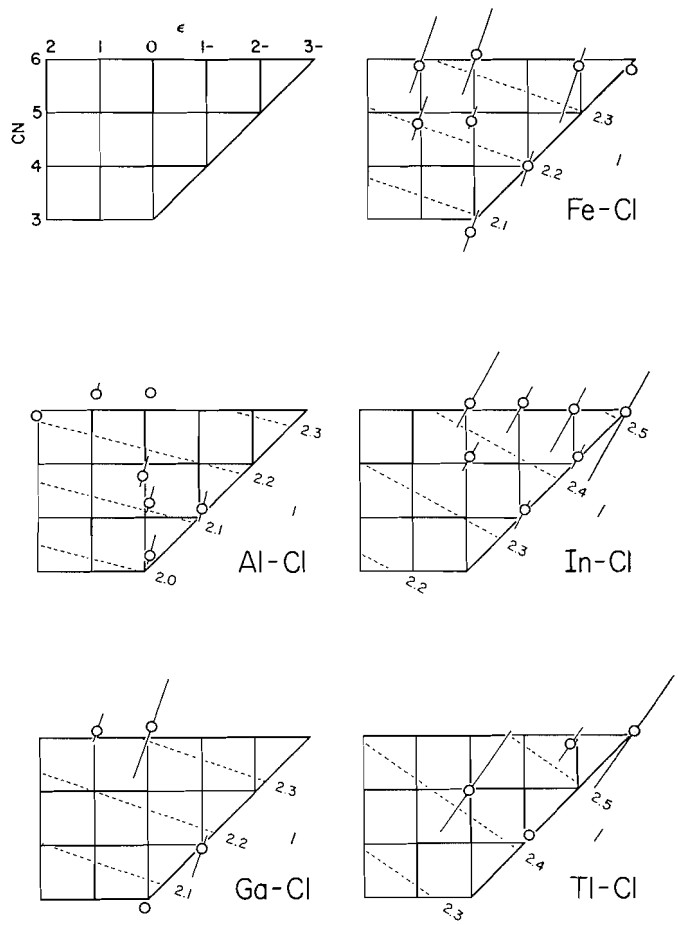

FIG. 4. The mean observed M—Cl bond length D in $[MCl_nX_m]^\epsilon$ complexes mapped on the CN = $n + m$ and the charge ϵ. Lengths of the bars represent the longest and the shortest d(M—Cl) reported for that CN,ϵ combination. The lengths of the small bars on the right-hand side of each plot represent 1σ of the D regression. The constant-D_{calcd} contours (in Å) are defined by the regression of D on CN and ϵ (Table 7; eq. [1]). Distances from the appropriate CN,ϵ lattice points measure the difference $D_{calcd} - D$.

[24]Copies of these tables can be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[25]$d_{calcd} = 0.2816 + 0.2544r_M + 0.9372r^{iv}(X^-)$, $r^2 = 1.00$, $\sigma = 0.008$ Å.

implies that individual $\bar{d}$ for neighbouring CN,ϵ combinations may be statistically indistinguishable.

As far as the goodness of fit is concerned, the price to pay for approximating D(M—Cl) by a single equation, and the coefficients c_i by a two-term quadratic in r_M, is the relatively high σ, which amounts to ~3% of the D spread. Separate regressions of D on CN and ϵ for each M resulted in lower σ's (0.013, 0.014, 0.003, and 0.008 Å for Al, Fe, In, and Tl, respectively), and it is possible (although we have not investigated this) that the c_i could be approximated more closely by another function of r_M.[26] For In in particular the individual regression gave a noticeably better fit, though this improvement may be without physical significance (see below).

The simplicity of eq. [1] has the advantage of bringing to light the effects of CN and ϵ in a straightforward manner (Table 7). The effect of CN decreases and that of ϵ increases from Al to Tl; the effect of CN relative to that of ϵ, i.e. the ratio $\lvert c_{CN}/c_\epsilon \rvert$, decreases from ~3.8 for Al to ~1.4 for Tl. The CN is thus always a more important factor than ϵ in determining the variation in D; it becomes dominant when the M atom is small.

The five c_{CN} values obtained in the separate regressions, i.e. without involving r_M, could be represented as $c_{CN} = k_{CN,0} + k_{CN,2}r_M^2$ to a high degree of correlation ($r^2 = 0.98$, σ = 0.0025), hence the two-term quadratic must be a good local approximation function and its inclusion in the triple regression is justified. The variation of c_{CN} with r_M^2 can be interpreted as a dependence of c_{CN} on the "effective surface area" of the atom M: the larger M, the less D varies with CN. If the expression for c_{CN} in Table 7 held past Tl, it would imply that in $[YCl_n]^{3-n}$ ($n \leq 6$) complexes D would be independent of n.

Is a linear *approximation of* D *appropriate over the entire CN, ϵ range?*

The functional dependence of D on CN and ϵ, and hence the suitability of the linear approximation, could be investigated properly only if a D value were available for every point of the CN,ϵ lattice of Fig. 4. The covering of the lattice is, however, quite incomplete, only about 40% for Fe and less for the other M, for many of the CN,ϵ combinations are not accessible under ordinary chemical conditions and of those that are accessible some have not been investigated structurally. For example, very little information exists on species such as $[MCl_{4-n}X_n]^\epsilon$ (n = 1–3) or $[MCl_{3-n}X_n]^\epsilon$ (n = 1, 2), where X is not a halogen; $AlCl_6^{3-}$ does not appear to form; seven-coordinate indium in halogeno complexes occurs only in combination with fluorine; MCl_2^+ and MCl^{2+} have not been reported.[27] However, some assistance comes from SCF calculations for the chemically inaccessible species of interest here. At present, calculations at the 6-31G* level (lowest-level basis set deemed adequate for realistic comparisons with experiment) have been found practicable only for free $[AlF_n]^\epsilon$ ($n \leq 6$) and $[AlCl_n]^\epsilon$ ($n \leq 4$) species. Within this limitation, optimized d values are now available for $\epsilon = 3 - n$ and for a number of other ϵ values as well.[22]

The $\bar{d}_{SCF}$ values[28] for $[AlF_n]^{3-n}$ and $[AlCl_n]^{3-n}$ are compared in Fig. 5 with the D and D_{calcd} values. Two experimental values are available to check the validity of the Al–F set, d = 1.63(1) Å for free AlF_3 (cf. ref. 149) (smoothed to 1.627(8) Å, see above) and D = 1.807(1) Å for $[AlF_6]^{3-}$ (146), and two for the Al–Cl set, d = 2.068(4) Å for free $AlCl_3$ (cf. ref. 149) (smoothed to 2.077(8) Å, see above) and D = 2.125(9) Å for $[AlCl_4]^-$ (Table 5). As pointed out above, the d for AlF_3

[26] The quadratic approximations obviously are valid only locally, in the limited range of r_M, for r_M does not increase indefinitely.

[27] Formation of $FeCl_2^+$ and $FeCl^+$ in gas-phase reactions has been detected by mass spectrometry (150), but no other information on these species is available.

[28] Except for n = 5, all the d values in an $[AlX_n]^{3-n}$ complex are identical, i.e. $d = \bar{d}$; for n = 5, $\bar{d} = \frac{3}{5}d_{eq} + \frac{2}{5}d_{ax}$.

and $AlCl_3$ are in excellent agreement with the $\bar{d}_{SCF}$ values, 1.621 and 2.077 Å, respectively. However, the $\bar{d}_{SCF}$ values for $[AlF_6]^{3-}$ and $[AlCl_4]^-$, 1.857 and 2.169 Å, respectively, are about 0.05 Å above the corresponding D. Although the uncertainty in $\bar{d}_{SCF}$ is difficult to estimate, it is highly probable that the discrepancy has its cause in the experimental bond-length values and can be attributed, at least in part, to the effect of thermal motion. The $\bar{d}_{SCF}$ values are to be compared with the fully corrected $\bar{d}$ values in the crystal, whereas the D are the means of *uncorrected* $\bar{d}$ values.[29] For $[AlCl_4]^-$ the magnitude of the correction has been considered in detail by Mairesse *et al.* (151), who found that the uncorrected Al—Cl bond lengths in $A[AlCl_4]$ (A = Li, Na, K, Cs, NH_4, NO)[30] were increased by as much as 0.05 Å, depending on the model (rigid-body or riding motion), the particularities of the crystal structure, and the inclusion of absorption correction. The corrected Al—Cl bond lengths averaged 2.156(6) Å for the rigid-body model and 2.146(3) Å for the riding-motion model. When a correction of this order is applied to $D(AlCl_4^-)$, the difference between D and $\bar{d}_{SCF}$ disappears, hence the $\bar{d}_{SCF}$ curve of Fig. 5 for Al—Cl may be regarded as consistent with observation. The $[AlF_6]^{3-}$ ion presents more difficulty. Here the correction for thermal motion has been found to amount to only about 0.005 Å (146); the reasons for the residual difference of ~0.04 Å between D and $\bar{d}_{SCF}$ are not fully understood at present.[31]

The important feature in Fig. 5 is the *shape* of the $\bar{d}_{SCF}$ curves. The Al—F curve becomes quasi-linear past CN 4, and the shape of the Al—Cl curve suggests that this curve, too, becomes quasi-linear in the CN 4–6 range. The two lines are roughly parallel, and their quasi-linear portions are roughly parallel to the D_{calcd} lines. This provides circumstantial support for our initial assumption that $D(CN,\epsilon)$ can be approximated by a linear function of CN and ϵ for CN $\geq$ 4. At CN 3 the faithfulness of the linear approximation begins to deteriorate, and at CN < 3 a nonlinear regression function would be required.

While the mean bond length D agrees quite well with D_{calcd} (Fig. 4), the individual $\bar{d}$, and even more the individual d, bond lengths may deviate from D_{calcd} appreciably. The largest and the smallest d implicit in D are indicated in Fig. 4 by the lengths of the bars associated with the D points. The high–low spread of d for a particular CN,ϵ combination may amount to as much as 0.17 Å, i.e. ~10σ of the D regression. It is most pronounced in *mer*-MCl_3X_3 complexes, where in an extreme case, that of [*mer*-$GaCl_3$(terpy)] (89), the difference between the d involving a *trans*-Cl and the d involving the middle Cl amounts to 0.168(4) Å, i.e. the difference in that complex alone accounts for the maximum spread in d shown in Fig. 4. The $\bar{d}$ spread in *cis*/*trans* pairs is smaller, less than ~0.06 Å or ~4σ of the D regression: 0.056(23) Å for $[FeCl_2(H_2O)_4]^+$ (79, 83), and 0.024(4) Å for Al and 0.048(8) Å for Ga in the [*cis*-$MCl_2(bipy)_2$]/[*trans*-$MCl_2(py)_4$] pairs (80, 81, 85, 86). High–low d spread of ~3σ or more is also noted in $[MCl_5(H_2O)]^{2-}$, [*cis*-$FeCl_2$(PIH)(H_2O)]$^+$ (153), and α-Tl_3TlCl_6 (65).

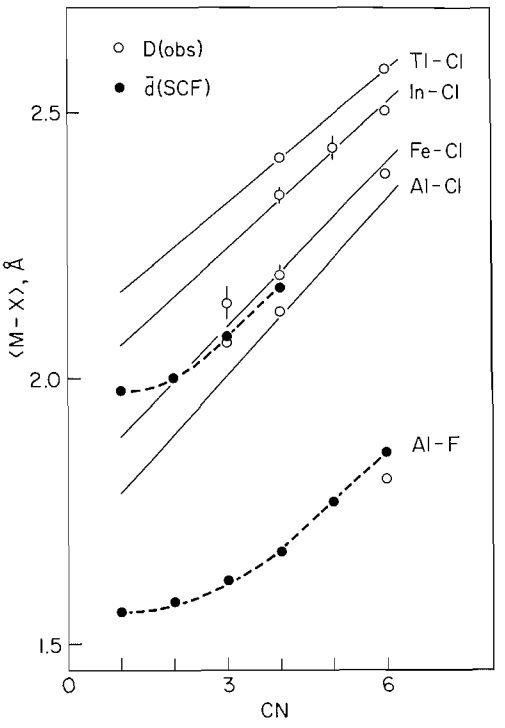

FIG. 5. Comparison of D, D_{calcd}, and $\bar{d}_{SCF}$ values for $[AlF_n]^{3-n}$ and $[MCl_n]^{3-n}$ (M = Al, Fe, In, Tl) complexes. The straight lines represent D_{calcd}; the broken lines indicate the trends in the $\bar{d}_{SCF}$ series for Al—Cl and Al—F. The d and $\bar{d}_{SCF}$ points for $[AlF_3]^0$ are not distinguishable on the scale of this drawing.

Binuclear complexes

The complexes so far considered have been almost all mononuclear in M(III). In *isolated* binuclear chloro complexes the terminal M—Cl bonds are shorter than the bridging M—Cl bonds, typically by about 0.2 Å,[32] but the number of reliable determinations is too small to permit a detailed treatment. Complexes for which bond lengths are available are the MCl_3 dimers [di-μ-$Cl_2MCl_2MCl_2$]^0 (also electron diffraction data for the gas phase); the [tri-μ-$Cl_3MCl_3MCl_3$]$^{3-}$ ions; and the [di-μ-Tl_2Cl_{10}]$^{4-}$ ion in $K_2TlCl_5 \cdot 2H_2O$ (134). While the CN of the M atom is clearly defined, it is not self-evident what *charge* is appropriate when using eq. [1] to evaluate D_{calcd}. Since changing ϵ by one unit produces a change in $\bar{d}$ of only about 0.025 Å, the bond lengths must be known with good accuracy if one is to determine the formal charge to be used. Examination of the $\bar{d}$ values for the above binuclear complexes shows that the best agreement between $\bar{d}$ and D_{calcd} is obtained when the complex $[Cl_xMCl_yMCl_x]^{6-2x-y}$ is partitioned in such a way that the mononuclear entity is $[Cl_xMCl_y]^{3-x-y}$, CN = x + y; i.e. $[M_2Cl_6]^0 \rightarrow MCl_4^-$, $[M_2Cl_9]^{3-} \rightarrow MCl_6^{3-}$, and $[M_2Cl_{10}]^{4-} \rightarrow MCl_6^{3-}$. The agreement between $\bar{d}$ and D_{calcd} is good for Ga_2Cl_6, Fe_2Cl_6, $[In_2Cl_9]^{3-}$, and $[Tl_2Cl_{10}]^{4-}$, and also for $[Y_2Cl_9]^{3-}$ (97) if $r^{iv}(Y^{3+})$ is taken as 0.72 Å. It is less good for Al_2Cl_6.

Conclusions

In sum, eq. [1] is capable of reproducing the mean uncor-

[29]The Tl—Cl bond lengths determined for $TlCl_4^-$ and $TlCl_6^{3-}$ *in solution* (152) agree with the corresponding bond lengths in crystals corrected for thermal motion.

[30]All of these are included in the D of $AlCl_4^-$ in Table 5.

[31]The $\bar{d}_{SCF}$ value for $[AlF_6]^{3-}$ may in fact be an overestimate. In general, larger basis sets are required to calculate the equilibrium geometries of anions to the same accuracy as obtained for neutral molecules with smaller basis sets. Within a series of anions, a given basis set is expected to become less adequate as the charge increases, with the resulting progressive overestimation of bond lengths.

[32]As pointed out in ref. 149, $d_{terminal}$ in free M_2X_6 dimers is the same as d in free MX_3, for which CN,ϵ = 3,0.

TABLE 9. $(NH_4)_2[InCl_5(H_2O)]$: bond distances (Å) and angles (deg)

[a]Number after oblique stroke: correction to be added ($\times 10^3$, rigid-body motion model).
[b]Weighted by σ^{-2}.

rected M—Cl bond lengths D in the $[M(III)Cl_nX_m]^\epsilon$ complexes studied to date to about 0.02 Å, regardless of the nature of X, except when X forms an M—C bond. In that case the M—Cl distance increases with m, adding roughly 0.05 Å per X. Thus in $\{InCl[-2-(Me_2NCH_2)C_6H_4-]_2\}$ (32), d is 2.465(1) Å compared to $D(5,0)$ = 2.371(12) Å (Table 5) and $D_{calcd}(5,0)$ = 2.362(16) Å. Similarly, in $Me_4As[MeInCl_3]$ and $Me_4Sb[MeInCl_3]$, $\bar{d}$ = 2.401(7) Å (154), compared to $D(4,1-)$ = 2.346(13) Å and $D_{calcd}(4,1-)$ = 2.335(16) Å; and for Ga—Cl in $Me_4Sb[GaCl_{4-n}Me_n]$ (125), $\bar{d}$ = 2.172(30) Å for n = 0, 2.223 Å for n = 1, 2.277 Å for n = 2, and 2.381 Å for n = 3, compared to $D(4,1-)$ = 2.170(12) Å and $D_{calcd}(4,1-)$ = 2.178(16) Å. The reason for the lengthening of the M—Cl bond is to be looked for in the covalency of the M—C bond: the increase in $\bar{d}$ with n in the Ga complexes correlates with an increase in the Ga—C bond length, a decrease in the ESCA Ga(3d) ionization potential, and an increase in the relative negative charge on the Ga atom (125).

Perhaps the most useful feature of the regression exemplified by eq. [1] is that in D_{calcd} it provides a hitherto lacking but much needed reference standard for judging the "normalcy" of experimental M—Cl bond lengths in $[M(III)Cl_nX_m]^\epsilon$ complexes. The validity of this standard will improve as the sample on which the D values of Table 5 are based becomes chemically and structurally more representative: the present sample reflects both the vagaries of, and changes in emphasis in, the natural accumulation of structural information. The composition of the existing sample (Tables 1 and 6[24]) may serve to show where further work is needed.

Before recalculating the D regression at some future date consideration might be given to the possibility of finding an $r^{iv}(M^{3+})$ set that would suit the purpose better than Shannon's set. One should keep in mind that $r^{iv}(M^{3+})$ as used in eq. [1] is merely an artificial parameter introduced to order the M^{3+} according to their relative contribution to the M—Cl bond length in a particular $[MCl_n]^{3-n}$ series, irrespective of the actual CN, even though for CN 4 it has direct relevance for tetrahedral species. In this context it will be desirable to investigate the effect of the spin state of Fe^{3+} on this parameter and on D calculated from the regression equation.

C. Crystal structures of the title compounds

Crystal data of the four compounds will be found in Table 2. Details of the structure determinations are described in Experimental at the end of this paper.

$(NH_4)_2[InCl_5(H_2O)]$

The only ternary compound in the system NH_4Cl–$InCl_3$–H_2O at 25°C is stated (139) to be $(NH_4)_2InCl_5 \cdot H_2O$, therefore not surprisingly it was a product of this composition that was obtained by crystallization from an aqueous solution of NH_4/In = 2 at room temperature. A determination of the crystal structure by photographic methods was reported in 1948 (24), but as it yielded In—Cl distances longer than 2.5 Å, a redetermination was indicated.

The hydrogen atoms were located from a difference Fourier map. The only constraint applied in the refinement was to the N—H and O—H bond lengths, 1.02 and 0.98 Å, respectively, and to the HNH and HOH angles.

As would be expected, the atomic positions in this structure (Table 8) are very similar to those in the K salt (22). The σ^{-2}-weighted mean of the In—Cl distances, 2.480(9) Å, is indistinguishable within 1σ from that for the K salt, 2.482(7) Å, and the In—O distances are the same within 3σ (Table 9). The hydrogen-bonding system (Table 10) is illustrated in Figs. 6 and 7. Each two neighbouring $InCl_5(H_2O)$ octahedra not on the same mirror plane are linked together by two strong and almost straight O—H_w···Cl(4) bonds (related by a centre of symmetry) to form infinite zigzag chains $\| b$ (Fig. 6*A*). These chains are cross-linked by N—H···Cl bonds (Fig. 6*B*), with H···Cl distances ranging from 2.52(11) Å to ~3.2 Å (corresponding to NHCl > 90°) (Fig. 7). Each Cl atom is an acceptor of at least four hydrogen bonds (Table 10). All the N—H···Cl bonds are asymmetrically bifurcated, although additional, more distant Cl atoms probably participate as weak partners in these bonds.

$(NH_4)_2[InCl_5(H_2O)]$ is isostructural with its Fe analog (136), but the orientation of the ammonium ion is slightly different, the result being that the hydrogen-bonding features in the two compounds are not identical. Direct comparison of H···Cl distances and NHCl angles is not possible, as the N—H distances in the refinement of the Fe compound were not constrained and the reported apparent bond lengths are as short as 0.78(5) Å. When the N—H distances in the structure of ref. 136 are adjusted to 1.02 Å by extending the N—H vectors,

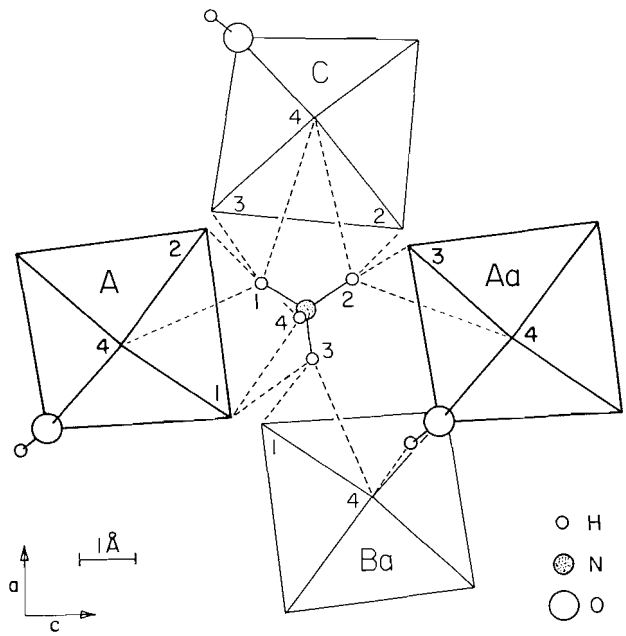

FIG. 7. $(NH_4)_2[InCl_5(H_2O)]$: environment of the ammonium ion (projection on (010)). For symmetry code and H···Cl distances and NHCl angles see Table 10. The H(4)···Cl(2A) bond is partially omitted for clarity.

the corrected H···Cl distances and NHCl angles are seen to be distributed somewhat differently from those in the In salt (Fig. 8). They follow the same trend but the overall H_N-bonding scheme seems to be somewhat stronger in the Fe compound. In both crystals the shortest H_N···Cl distance is H(3A)···Cl(1Ba); the O—H···Cl(4) bond has practically the same geometry.

Detailed comparison of the (uncorrected) bond lengths and angles in the MCl_5O octahedron in the NH_4In, NH_4Fe (136),

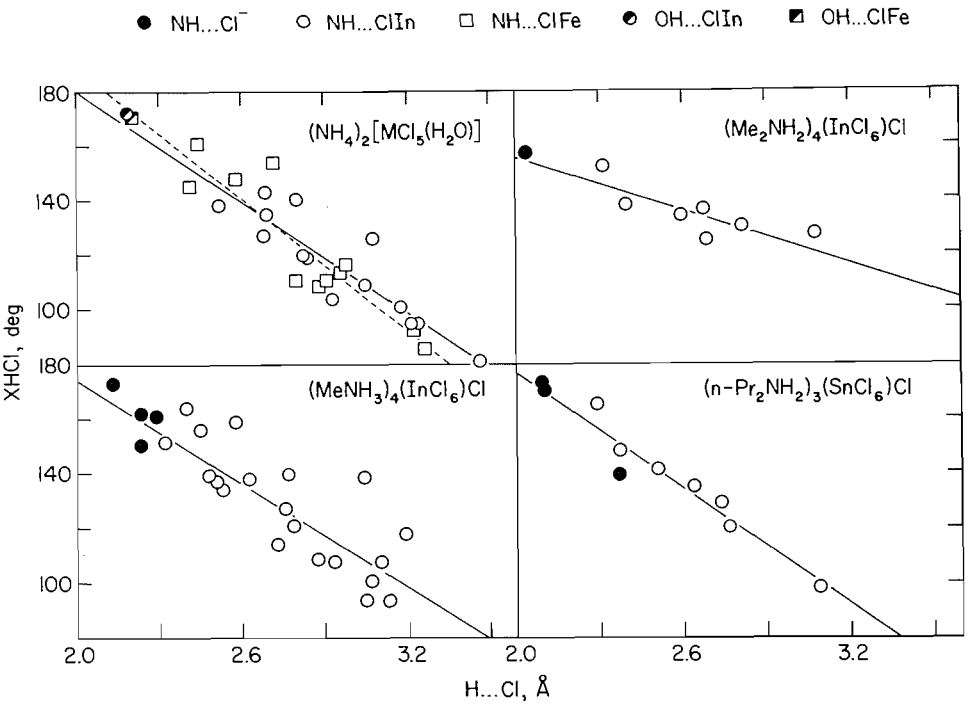

FIG. 8. Variation of the XHCl angle with the H···Cl distance in $(NH_4)_2[MCl_5(H_2O)]$ (solid regression line, M = In; broken regression line, M = Fe, from data of ref. 136, see text), $(MeNH_3)_4[InCl_6]Cl$, $(Me_2NH_2)_4[InCl_6]Cl$, and $(n\text{-}Pr_2NH_2)_3[SnCl_6]Cl$ (from ref. 148).

and KIn (22) salts reveals that, apart from an overall shortening of the bond lengths by about 0.12 Å in the NH_4Fe salt, the octahedra in the two ammonium salts are dimensionally closely similar, while significant differences in some of the angles exist between NH_4In and KIn. This indicates that the geometry of the octahedron is affected more by the N—H···Cl bonding than by any possible differences resident in the central atom.

The ir spectra of the H-containing entities in $(NH_4)_2[InCl_5(H_2O)]$ will be reported elsewhere (cf. ref. 155).

$K_3InCl_6 \cdot nH_2O$

The hydrates reported to exist in the system $KCl–InCl_3–H_2O$ correspond to K/In ratios of 2 and 3. The existence of $K_2InCl_5 \cdot H_2O$ is well established (18, 20, 21, 23, 55, 139, 156), but the K/In = 3 phase has been formulated variously as $K_3InCl_6 \cdot H_2O$ (18, 27, 28), $K_3InCl_6 \cdot \frac{3}{2}H_2O$ (157, 158), and $K_3InCl_6 \cdot 2H_2O$ (139, 159). In addition, a material analyzing to $K_2InCl_5 \cdot 2H_2O$ and dehydrating to $K_2InCl_5 \cdot H_2O$ when heated to 150°C, is stated (23) to have been obtained by evaporation of an aqueous solution of the chlorides (K/In = 2) at room temperature. Being curious about the mode of incorporation of the extra molecule of water in the structure of this dihydrate, we repeated the preparation as closely as the description in ref. 23 permitted, even though a phase of this composition had not been found in the ternary system at room temperature (20, 139).

The first crop of crystals was dried carefully by repeated pressing between layers of filter paper and then in air until the crystals were completely free-flowing. Structure analysis on a crystal selected from this visually uniform crop was carried, without prejudice as to composition, to $R = 11\%$. At this stage 14 octahedrally coordinated In atoms were identified in the tetragonal unit cell, plus a number of atoms taken to be potassium. The In atoms in 8(*c*)–*xxz* etc. and 4(*b*)–$0\frac{1}{2}z$ etc. formed isolated $InCl_6$ anions, while those in 2(*a*)–00*z* etc. appeared to be inside $InCl_5O$ octahedra. These features, the unit-cell dimensions and the unusual *Z* value showed that the compound had to be either identical with or closely similar to the $K_3InCl_6 \cdot H_2O$ of Wignacourt *et al.* (18, 27) (Table 2). This salt was formulated as $K_{21}[InCl_6]_4[InCl_6]_2[InCl_5(H_2O)]Cl \cdot 6H_2O$ and related to the dimensionally similar $K_3TlCl_6 \cdot 2H_2O$, for which a structure had been proposed many years ago by Hoard and Goldstein (160). The K/In ratio of our product being consistent with the expectation from the phase diagram and not 2:1, it was clear that the conditions leading to $K_2InCl_5 \cdot 2H_2O$ would have to be stated much more explicitly than in ref. 23 for the duplication to succeed, and we did not pursue the preparative efforts further. However, the structure proposed in refs. 18 and 27 was of such an unexpected complexity that we thought it worthwhile to verify the structure of our compound in detail, especially in view of the conflicting reports as to the degree of hydration of the K/In = 3 chloride.

The positions of the $InCl_6$ and $InCl_5O$ octahedra and of the K(1) to K(5) atoms being virtually the same in both cases (Table 11,[24] Fig. 9), we placed the remaining nonhydrogen atoms as in refs. 18 and 27 (cf. Fig. 10). The isotropic refinement converged at $R = 9.2\%$, but a number of discrepancies became evident. The K(6) atom in 2(*a*) and the O(2) atom in 8(*d*),[33] both at half occupancy, did not refine properly, giving unsatisfactory temperature factors and leaving residual electron density in a difference map. Furthermore, repeated density measurements on our material gave values consistently higher than quoted in ref. 27 but close to 2.483 reported for $K_3InCl_6 \cdot 2H_2O$ by Wallace (159).

Wignacourt (18), in addition to $K_3InCl_6 \cdot H_2O$, also determined the structure of $K_3InBr_6 \cdot \frac{3}{2}H_2O$ ($R = 7.5\%$) and redetermined the structure of $K_3TlCl_6 \cdot 2H_2O$ ($R = 4.0\%$), taking the water content of the Tl compound to be $\frac{3}{2}H_2O$

[33] Numbering as in refs. 18 and 27.

[a]Analyzed for water.
[b]But mixed crystals $K_3(Tl, In)Cl_6$, Tl/In ~ 4, contained $\frac{3}{2}H_2O$.
[c]From solutions with K/Tl ≥ 3.
[d]From solutions with NH_4/Tl > 1.
[e]In the air the crystals lost water so rapidly that crystal measurements were not possible; water could not be determined.

and assuming that both compounds were isostructural with $K_3InCl_6 \cdot H_2O$.[34] The differences in the degree of hydration of these hexahalides suggested to us that some of the discrepancies we observed could be due to a difference in the water content.

Examination of the literature evidence bearing on the water content (Table 12), the axial ratio (Table 13) and the density (Table 14) of tetragonal A_3MX_6 (M = In, Tl; X = Cl, Br) hydrates indeed supports the view that some of the water in these crystals is zeolitic and can be lost by spontaneous dehydration at room temperature (cf. in particular KInBr, Table 12). It also suggests that these hydrates can be formulated as $A_3MX_6 \cdot nH_2O$, $1 \leq n \leq 2$. The loss of water appears to be reflected in the c/a ratio (cf. KInCl, Table 13) and significantly affects the density (Table 14). We therefore concluded that our crystal had essentially the structure proposed in ref. 27 but a higher water content.

The highest peak in a difference map which was computed with Wignacourt's O(2), O(3), Cl(4), K(6), and K(7) omitted, was at the 2(*a*) position corresponding to K(6). The strength of the peak in the 2(*a*) position corresponding to K(7) was less than 2/3 of the highest peak. Similarly, the strength of the peak corresponding to O(2) in 8(*d*) was about twice that of the peak corresponding to O(4) in 8(*d*). This, combined with consideration of stoichiometry and interatomic distances, led us to the following modification of Wignacourt's model (Table 15, Fig. 10):

The O(4) atom is in 8(*d*) at half occupancy as O(43) (renamed). K(6) is in 2(*a*) with full occupancy; this satisfies the potassium stoichiometry for K_3InCl_6. Wignacourt's K(7), in

[34]The composition of the bromide was established from a phase equilibrium study of the system KBr–$InBr_3$–H_2O at 21°C (18); it is not clear how the water content of the Tl compound was arrived at. In ref. 27 the compositions of these two hydrates are stated as $K_3InBr_6 \cdot H_2O$ and $K_3TlCl_6 \cdot 2H_2O$. The presence of a $[TlCl_5(H_2O)]^{2-}$ ion in the K_3TlCl_6 hydrate crystal was suggested on Raman evidence already in ref. 76, although possibly on grounds that may not be valid (cf. ref. 18).

[d]This work.

the second 2(*a*) position at half occupancy, is now replaced by O(44) at full occupancy, and O(2) = O(41) is in 8(*d*) at full occupancy. The remaining two Cl atoms, Cl(4), are placed in 8(*d*) in statistical disorder with O(3) = O(42), but while only four oxygens are accommodated in this equipoint in ref. 27, to agree with the composition $K_3InCl_6 \cdot H_2O$, up to six oxygens are located there now. The present model therefore contains six more water molecules, as O(41) and O(44), per unit cell plus an additional zero to two as O(42), compared with ref. 27. This corresponds to $1.43 \leq n \leq 1.57$.

The occupancy factors of O(41), O(43), O(44), and Cl(4) refined to values close to those assumed (Table 15). Placing 2Cl(4) + 4O(42) in the mixed 8(*d*) site left, on refinement, significant electron density in a difference map. The calculated crystal density for this occupancy is 2.464 g/cm^3, that for six O(42) is 2.477 g/cm^3, a difference of 0.013(4) g/cm^3. Since the measured density was 2.49(1) g/cm^3, we assumed full occupancy for the mixed site, i.e. $n = 1.57$.

All the atoms (hydrogens always excluded) were refined anisotropically. The final difference map showed a residual peak (of approximate strength 1 e/Å^3) very close to Cl(4), but attempts to resolve the O(42) from the Cl(4) position were unsuccessful. These two atoms were therefore refined together, yielding a final R of 5.7%.

The dimensions of the $In(1)Cl_6$ and $In(2)Cl_6$ octahedra agree well with those of ref. 27 (Table 16). The In(1)—Cl(12) bond in $In(1)Cl_6$ is significantly longer, by 0.076(14) Å, than the mean of the other five bonds, 2.501(11) Å, i.e. the distortion along the In(1)—Cl(12) axis is of approximately C_{4v} symmetry (Fig. 9). The lengthening of the In(1)—Cl(12) bond may be attributable to the hydrogen bond presumed to exist between Cl(12) and O(31). The orthorhombically distorted $In(2)Cl_6$ octahedron is

TABLE 17 (*concluded*)

Atoms					Distance
Symmetry code[c]					
A	x	y	z	a	X + (1, 0, 0)
B	x	$-y$	z	b	X + (0, 1, 0)
C	$-x$	$-y$	z	c	X + (½, ½, ½)
D	y	x	z	d	X + (−½, ½, ½)
E	$-y$	x	z	e	X + (½, ½, −½)
F	$-y$	$-x$	z	f	X + (−½, −½, −½)

[a] $\Delta = [d(\text{ref. 27}) - d(\text{this work})] \times 10^3$; values in parentheses, esd of ref. 27.
[b] $\times 10^2$.
[c] Where there is no letter designation, *xyz* are as per Tables 11 and 15.

compressed along the Cl(21)—Cl(22) axis, i.e. $\|c$; the difference between the equatorial and the axial bond lengths is 0.12(1) Å ~ 5%. These distortions contrast with the almost regular $InCl_6$ octahedral geometry in $(MeNH_3)_4[InCl_6]Cl$ and $(Me_2NH_2)_4[InCl_6]Cl$.

The K···Cl distances in the well-defined $K(1)Cl_8$, $K(2)Cl_8$, and $K(3)Cl_8O$ coordination polyhedra range from 3.11(1) to 3.47(1) Å (Table 17). Their mean, 3.27(10) Å, can be compared with the K^{viii}···Cl distances calculated from Shannon's ionic radii, 3.32 Å. The shortest of the K···Cl distances, K(1)···Cl(23Ea) = 3.11(1) Å, is shorter than the K^{vi}···Cl separation in KCl, 3.147 Å (Shannon's radii give 3.19 Å), but as the ionic charges in $K_3InCl_6 \cdot nH_2O$ are not symmetrically balanced, the distance is marginally still in the range expected. The mean difference between our K···Cl distances and those of refs. 18 and 27 is |0.013| Å, i.e. on the average within slightly more than one esd.

The shortest K···O distances to clearly defined oxygens, 2.68(3), 2.96(7), 3.01(3), and 3.21(3) Å, agree to within |0.03| Å with refs. 18 and 27 except for K(5)···O(43) = 2.96(7) Å. This distance in refs. 18 and 27, 2.51(2) Å, is far too short: K^{vi}···O_w in the alums $KM(SO_4)_2 \cdot 12H_2O$ (M = Al, Cr) is 2.94–2.97 Å, but the CN of K(5) is 8–9. The K(4)···O(41) distance, which is 2.68(3) Å in this work and 2.70(1) Å in refs. 18 and 27, is too short in both cases.

In the analysis of the single-crystal Raman spectrum of $K_3InCl_6 \cdot H_2O$ (28) it is pointed out that the chlorine closest to O(31) is Cl(12), at 3.51 Å (3.52(2) Å in Table 17) and that the $H_2O(31)$ molecule is therefore not involved in hydrogen bonding. However, if this molecule is oriented so that its hydrogens point symmetrically at the Cl(12) atoms (two equivalent positions are possible, Figs. 9 and 10), then $d(H \cdots Cl) \sim 2.60$ Å and O(31)H(31)Cl(12) ~ 156°. This implies that weak hydrogen bonding is possible and indeed likely (cf. Fig. 8), even though the H atoms have not been located by X-rays and spectroscopic evidence of the hydrogen bond is lacking. Given the low relative abundance of $H_2O(31)$ in the crystal (⅐ of the total water) and the incomplete resolution of the $\nu(H_2O)$ and $\delta(H_2O)$ features in the ir and Raman spectra, it is doubtful that features specific to $H_2O(31)$ could be distinguished in the spectra of ref. 28 and pertinent frequency comparisons made. The other water molecules in the crystal almost certainly participate in hydrogen bonding, but the

particulars of their involvement cannot be determined from the evidence at hand.

Although the main features of the $K_3InCl_6 \cdot nH_2O$ structure proposed by Wignacourt and confirmed here may be regarded as established, the exact distribution and location of the K^+, Cl^-, and H_2O constituents occurring in the columns with In(3)—O(31) as axes (Fig. 10) are still somewhat uncertain and, indeed, may vary with the overall water content of the crystal. The distribution we propose for our crystal is consistent with the X-ray evidence and has the polar character appropriate to the *I*4*mm* space group, but the distribution of charges is better balanced in Wignacourt's model for the monohydrate. It is unfortunate that the Rb and Cs analogs of $K_3InCl_6 \cdot nH_2O$ do not appear to exist. If they did, the location of K(6) (and Wignacourt's K(7)) could be established with considerably more confidence. Hoping that $Tl_3InCl_6 \cdot nH_2O$ *might* exist and be isostructural with the K compound, we attempted to obtain crystals of this chloride from aqueous TlCl + $InCl_3$ solutions with Tl/In ≥ 3 at room temperature. However, the crystals that formed were those of $Tl_2[InCl_5(H_2O)]$.

$(MeNH_3)_4[InCl_6]Cl$

This salt was originally described as tetragonal (38). Its structure was determined from visually estimated photographic intensities by Schlimper and Ziegler (12) (Table 2). Our redetermination, in the less oblique $P2/n$ setting, confirms their result in all but detail (Tables 18 and 19,[24] Fig. 11) and supplements it by establishing the hydrogen-bonding scheme. The hydrogen atoms were located from a difference Fourier map; the C—H and N—H bond lengths were constrained in the refinement to 1.08 and 1.02 Å, respectively, and the HCH and HNH angles to tetrahedral.

[a]The coordinates from ref. 12 have been converted from $P2/c$ to $P2/n$ (cf. Table 2) and the atoms renumbered as follows (ref. 12 → this work): In(1) → In(2), In(2) → In(1), Cl(1) → Cl(22), Cl(2) → Cl(23), Cl(3) → Cl(13), Cl(4) → Cl(2), Cl(5) → Cl(21), Cl(6) → Cl(11), Cl(7) → Cl(12), Cl(8) → Cl(1), N(3) → N(4), N(4) → N(3), C(1) → C(2), C(2) → C(1), C(3) → C(4), C(4) → C(3). Equivalent positions have been substituted where required.

The structure consists of $MeNH_3^+$, $InCl_6^{3-}$, and Cl^- ions. It may be viewed as a highly distorted CsCl-type packing of $[(MeNH_3)_4Cl]^{3+}$ and $[InCl_6]^{3-}$ units. The $[Cl(\cdots HNMeH_2)_4]^{3+}$ "cation" is hydrogen-bonded to the eight $InCl_6^{3-}$ anions which surround it at the corners of a monoclinic coordination prism. All the In atoms are in the *ac* plane. The two sets of Cl^- atoms occupy the 2(*e*) and 2(*f*) positions of $P2/n$, but their refined $|y|$ coordinates are indistinguishable, so that the $[InCl_6^{3-} + Cl^-]$ anion sublattice may be regarded as a monoclinic (subgroup) distortion of a higher-symmetry arrangement, viz. $Pmna \supset P2/n$ with In in 2(*a*) and 2(*b*) and Cl^- in 4(*g*), and with the $InCl_6$ octahedra of approximately $2/m$ symmetry.

The In(1)Cl_6 and In(2)Cl_6 octahedra are more regular than reported in ref. 12 (Table 20). The mean uncorrected In—Cl distance is 2.509(6) Å, with a high–low spread of only 0.015(8) Å, and the In(1)—Cl(11) and In(2)—Cl(22) distances,

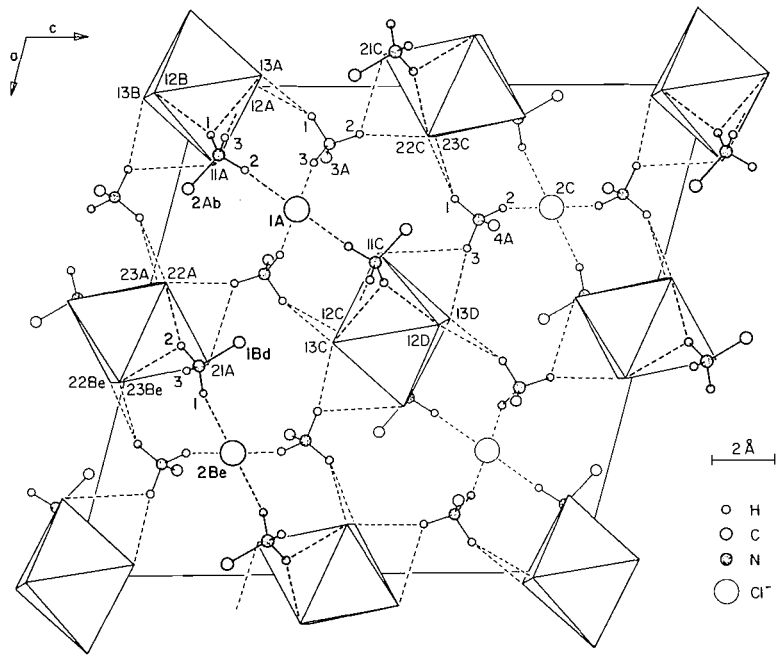

FIG. 11. $(MeNH_3)_4[InCl_6]Cl$: projection of the structure on (010). Hydrogen bonds are indicated by broken lines. For symmetry code, H···Cl distances and NHCl angles see Table 21. The bonds from H(13Bd) to Cl(22Bb), Cl(21Ab), Cl(23Ab), and the H(21Ab)···Cl(11A) bond are not shown. The Me hydrogens are omitted for clarity.

[c]Weighted by σ^{-2}.
[d]In—Cl mean quoted in ref. 12: 2.523(14) Å.

both unusually long in ref. 12, are close to the mean.[35] The differences in the In—Cl bond lengths and ClInCl angles arise mainly from the significant differences in the unit-cell dimensions between the two determinations.

[35]In this the $InCl_6$ geometry closely resembles the dimensional homogeneity of the $InBr_6$ octahedra in the isostructural $(MeNH_3)_4[InBr_6]Br$, where the In—Br mean is 2.670(11) Å, with a high–low spread of 0.023(4) Å (13).

The H···Cl distances and NHCl angles are distributed quite uniformly (Fig. 8). All H_N atoms are engaged in N—H···Cl bonds (Fig. 11, Table 21). One hydrogen in each of the four nonequivalent $—NH_3$ groups has a Cl^- ion as acceptor. The other two hydrogens are bonded to Cl atoms of the $InCl_6^{3-}$ anions by highly bent, bifurcated, or trifurcated bonds. The bifurcated and trifurcated bonds are always to Cl atoms of the same complex anion. Each Cl^- is hydrogen-bonded to four cations, and each Cl in an $InCl_6^{3-}$ anion acts as acceptor to at

least two N-hydrogens. The hydrogen bonds to the Cl^- ions are strong, as indicated both by the short H···Cl^- distances and the large NHCl angles, and by the low NH stretching frequency in the ir spectrum (Fig. 12; see next paragraph).

$(Me_2NH_2)_4[InCl_6]Cl$

Attempts to obtain an aquopentachloroindate(III) of Me_2NH from aqueous solutions of Me_2NH/In ratio of 2:1 resulted in products the ir spectra of which contained no indication of the presence of H_2O. However, the spectra of undeuterated and deuterated samples (Fig. 12) showed clearly that the complex NH stretching absorption fell in two groups centering at approximately 3140 and 2730 cm^{-1}. Such separation is characteristic of mixed-anion halides (e.g. alkylammonium hexachlorostannate(IV) chlorides, cf. refs. 147 and 148 and work in progress) and indicative of the simultaneous presence of long and short N—H···Cl bonds, the latter involving the Cl^- ion. This made us suspect that the product was in fact the $(Me_2NH_2)_4InCl_7$ salt first described by Ekeley and Potratz (38) and believed (13, 25) to be an analog of $(MeNH_3)_4[InCl_6]Cl$. Our suspicion was vindicated by the crystal-structure analysis (Tables 2 and 22).

The salt crystallizes in the relatively uncommon chiral group $P2_12_12$. The hydrogen atoms were placed from geometric considerations and refined isotropically (Tables 22 and 23).[24] The structure consists of $Me_2NH_2^+$ cations of two types, Cl^- and almost regular $InCl_6^{3-}$ anions (Table 20). The In atoms and the Cl^- ions are situated on twofold axes. If the $[InCl_6^{3-} + Cl^-]$ complex is regarded as the anion sublattice (distorted fcc), then the cation/anion arrangement may be described as a distorted *anti*-CaF_2 packing. The symmetry of the heterogeneous anion sublattice approaches $Pbam \supset P2_12_12$.

The structure is built up from alternating layers $\parallel(001)$ of two kinds (Fig. 13). One (at $z \sim \frac{1}{2}$) contains the $InCl_6$ octahedra and cations 2 joined by bifurcated N(2)—H(21)···2Cl and N(2)—H(22)···2Cl bonds, the bifurcation involving Cl atoms of the same octahedron (Table 24). In layers of the second kind (at $z \sim 0$) Cl^- ions and the C(1)—N(1)—H(11) portions of cations 1 form an almost planar system held together by very short H(11)···Cl^- bonds. Adjacent layers are cross-linked by trifurcated N(1)—H(12)···3Cl bonds to three *fac*-Cl atoms.

The involvement of the Cl^- ion in the two short hydrogen bonds related by the twofold axis through Cl^- is reflected in the strong anisotropy of the thermal motion of the ion, $U_{11} \sim U_{33}$, $2U_{22}/(U_{11} + U_{33}) \sim 2.2$, as well as in the magnitude of the mean amplitude perpendicular to the H(11)···Cl^-···H(11′) bond, ~0.4 Å. This is in marked contrast to the motion of the Cl^- ions in $(MeNH_3)_4[InCl_6]Cl$, where the presence of a *second*

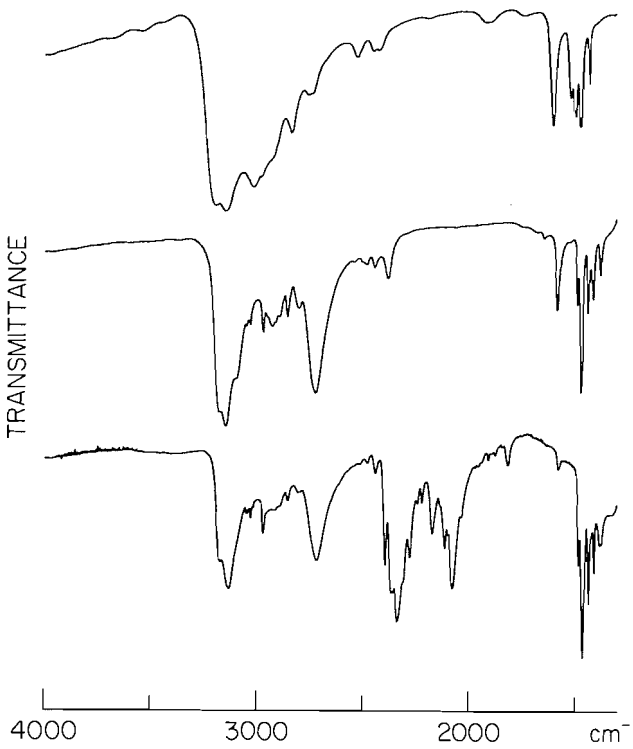

FIG. 12. Infrared spectra of $(MeNH_3)_4InCl_7$ (*top*), $(Me_2NH_2)_4InCl_7$ (*middle*), and $(Me_2NH_2)_4InCl_7$ (~60% D) (*bottom*).

pair of C_2-related N—H···Cl^- bonds resulted in a more nearly isotropic motion (Table 18, Fig. 11).

D. Hydrogen bonding

$(Me_3NH)_3[InCl_6]$

The Me_3NH^+ cation is too large to be readily accommodated in the octahedral (minority) sites of the cubic cryolite structure, and the molecular symmetry of the cation does not coincide with the site symmetry of either cation site in that structure. Moreover, the N-hydrogens can be expected to form N—H···Cl bonds and cause the cation to assume preferential orientation. As a result, the structure of $(Me_3NH)_3InCl_6$ (9) resembles only remotely the cryolite structure. It is dominated by the effect of the hydrogen bonding and by the requirement that each anion be engaged in hydrogen bonds to three cations. The structure may be regarded as consisting of columns of centrosymmetric $InCl_6$ groups $\|c$. The positions of the N-hydrogens have not been determined, but it is clear from the positions of the Me groups that each anion is associated with two N(1) cations related by the centre in the In atom and with their N-hydrogens pointing into opposite faces of the octahedron, i.e. forming trifurcated N—H···3Cl bonds. Because of the disorder in the structure the third cation (N(2) of ref. 9) can occupy one of the two available positions to form a third trifurcated N—H···3Cl bond, the three bonds being in a *mer* configuration. The columns, which are "insulated" from one another by the outwardly oriented Me groups, are vertically related by the 4_1 axes inside the channels formed by the columns. The $\{(Me_3NH)_3[InCl_6]\}$ units do not appear to be linked by hydrogen bonds to their neighbours within a column or between columns. The crystal may thus be regarded as consisting of neutral $\{(Me_3NH)_3[InCl_6]\}$ "molecules".

In forming exclusively trifurcated N—H···3Cl bonds $(Me_3NH)_3InCl_6$ resembles $(Me_3NH)_2SnCl_6$ (147). In the latter, completely ordered structure the centrosymmetric neutral $\{(Me_3NH)[SnCl_6](HNMe_3)\}$ units form a fcc array; in the former, a similar array of In atoms is severely compressed along the *c* axis.

[a] U_{iso}.

$(MeNH_3)_4[InCl_6]Cl$ and $(Me_2NH_2)_4[InCl_6]Cl$

The most interesting aspect of hydrogen bonding in these mixed-anion salts is the competition for hydrogen-bond forma-

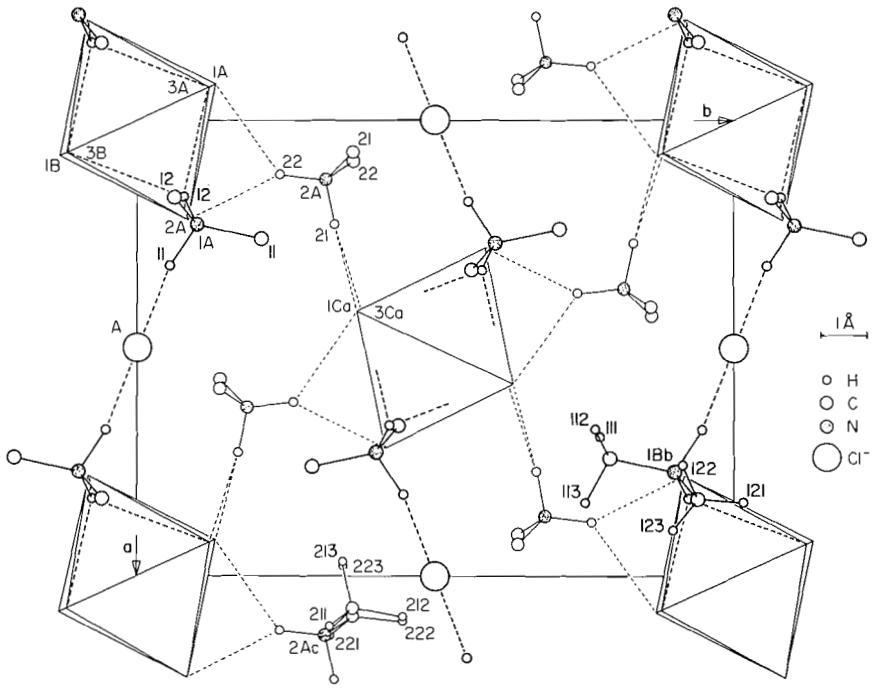

FIG. 13. $(Me_2NH_2)_4[InCl_6]Cl$: projection of the structure on (001). Hydrogen bonds are indicated by broken lines. For symmetry code, H···Cl distances and NHCl angles see Table 24. Only one set of Me hydrogens each is shown for clarity. The H(12A)···Cl(2A) bond is barely visible in this projection.

tion between the triply-charged $InCl_6^{3-}$ anion, with a formal charge of $\frac{1}{2}-$ on each Cl atom, and the compact Cl^- ion. The number of N-hydrogens bonded to Cl^- is $\frac{1}{4}$ of the total number of N-hydrogens in both compounds, but the Cl atoms of $InCl_6^{3-}$ (Cl_M for short) in $(Me_2NH_2)_4[InCl_6]Cl$ are less strongly involved in hydrogen bonding than the Cl_M atoms in $(MeNH_3)_4[InCl_6]Cl$. To show that the hydrogen bonding to Cl^- occurs, preferentially, at the expense of the bonding to Cl_M, the two salts are compared, in Table 25 and Fig. 14, to each other and to other suitable salts for which the hydrogen-bonding schemes are known. It is seen that non-hydrogen-bonded Cl_M occur already at an H_N/Cl_{total} ratio of $\frac{6}{7}$ for the mixed-anion salts (**3**), whereas in the pure hexachloro salts non-bonded Cl_M does not appear until $H_N/Cl_{total} = \frac{1}{3}$ (**10**). Even then it occurs only in the Et compound (**10**) but not in the corresponding Me compound (**9**), which has a structure of a different type. It would be interesting to know whether a similar situation exists between $(Me_3NH)_3[InCl_6]$ (**11**) and $(Et_3NH)_3[InCl_6]$ (structure as yet not determined). In **4**, which contains *two* Cl^- ions per formula unit, the $SnCl_6$ octahedron is involved only in two normal $H\cdots Cl_M$ bonds, with the other four Cl_M non-bonded.

The connection that may exist between the extent of hydrogen bonding and the tendency of alkylammonium hexachloro compounds to form mixed-anion salts has not yet been explored. For a salt $(R_nNH_{4-n})_{6-p+m}[M^pCl_6]Cl_m$, $H_N/Cl_{total} = (4 - n)[1 - p/(6 + m)]$; if each Cl^- engages $2r$ N-hydrogens to form $H\cdots Cl^-$ bonds, $H_N/[MCl_6] = (4 - n)(6 - p) + (4 - n - 2r)m$. Hence $H_N^{max}/[MCl_6] = 12 + (4 - 2r)m$ ($n_{min} = 0$, $p_{min} = 3$), $H_N^{max}/Cl_M = 2 + m(4 - 2r)/6$, e.g. for $(NH_4)_{3+m}[InCl_6]Cl_m$; $H_N^{min}/[MCl_6] = 1 + (1 - 2r)m$, $H_N^{min}/Cl_M = [1 + m(1 - 2r)]/6$, e.g. for $(R_3NH)_{1+m}[SbCl_6]Cl_m$. For H_N/Cl_M to be zero, $m = (4 - n)(p - 6)/(4 - n - 2r)$, in which case the octahedra are non-bonded, and it is possible that in such circumstances the mixed-anion salt will not form. To determine how far this formalism is relevant to the existence of mixed-anion salts will require additional experimental effort.

[a] $\frac{1}{2}$ represents contribution from a bifurcated, $\frac{1}{3}$ from a trifurcated N—H···Cl bond; $\frac{2}{2} = 2 \times \frac{1}{2}$, $\frac{2}{3} = 2 \times \frac{1}{3}$.
[b] B. R. Vincent, T. S. Cameron, and O. Knop. To be published.

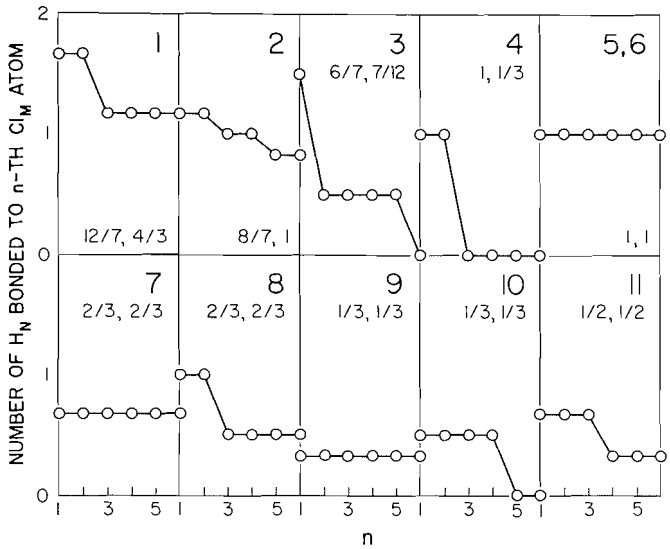

FIG. 14. The extent to which an MCl_6 octahedron in compounds **1–11** of Table 25 is involved in hydrogen bonding. The first number refers to the number of H_N atoms per total Cl; the second number refers to the mean number of H_N atoms bonded to a Cl atom (Cl_M) in the MCl_6 octahedron.

or paired with another X^- through a symmetry operation to form an identifiable substructure entity. In this $(MeNH_3)_4[InCl_6]Cl$ and $(Me_2NH_2)_4[InCl_6]Cl$ are no exception: the Cl^- ion in both is located on a twofold axis. In compounds **3** and **4** it forms almost planar $(\cdots Cl\cdots H—N—H\cdots)_2$ rings, centrosymmetric and $\|(001)$ in **3**, and of C_2 symmetry and $\|(010)$ in **4**; the stacks of these rings define channels $\|c$ in **3** and $\|b$ in **4**.

The distributions of H···Cl,NHCl pairs (including H···Cl,OHCl pairs for $(NH_4)_2[MCl_5(H_2O)]$) are shown in Fig. 8. As would be expected, the H···Cl^- bonds are stronger than the H···Cl_M bonds, but this does not make the H···Cl^-,$NHCl^-$ points stand out in the distributions, and the appearance of each distribution is such that a linear regression can be attempted. Although the legitimacy of a linear relationship between the NHCl bond angle and the H···Cl distance may not be unassailable, the coefficients of determination r^2 for the linear regressions are sufficiently high to suggest that significant correlation exists: 0.75 for $(MeNH_3)_4[InCl_6]Cl$, 0.81 for $(Me_2NH_2)_4[InCl_6]Cl$, 0.91 for the cognate $(n\text{-}Pr_2NH_2)_3[SnCl_6]Cl$ (148), and 0.84 and 0.87, respectively, for $(NH_4)_2[InCl_5(H_2O)]$ and $(NH_4)_2[FeCl_5(H_2O)]$. The increased opportunity for hydrogen bonding is reflected in the number of dissimilar H···Cl distances, which is larger for the low-symmetry $(MeNH_3)_4[InCl_6]Cl$ ($H_N/Cl_{total} = \frac{12}{7}$) than in the somewhat higher-symmetry $(Me_2NH_2)_4[InCl_6]Cl$ ($H_N/Cl_{total} = \frac{8}{7}$).

The H···Cl,NHCl distributions show that whatever may be the principle which governs the distribution and the most probable value of the XHY angle in *molecular* crystals (cf. for ex. refs. 165 and 166), in ionic crystals containing X^+—H···Y^- bonds, such as those under consideration here, the H···Y^-,XHY^- distribution appears to be the result of optimization of the overall hydrogen-bonding energy within the geometric framework determined primarily by Coulombic forces, with the XHY^- angle and the type of hydrogen bond (normal, bifurcated, trifurcated) incidental to the particulars of the cation/anion packing. Secondly, the linear regressions of Fig. 8 hold over the approximate 90–180° interval, hence there is no natural cut-off d(H···Cl) value for effective hydrogen-bonding interaction that could be determined from the properties of the distribution alone. In some cases the longest H···Cl distance that, *geometrically*, may qualify as corresponding to a hydrogen bond, occurs at an NHCl angle appreciably larger than 90° and may therefore be taken as the cut-off value: in $(Me_2NH_2)_4[InCl_6]Cl$ this is observed at ~3.1 Å and ~125°, but the H···Cl distance is too long on conventional criteria for effective hydrogen bonding. In most cases, however, there are H···Cl,NHCl points in the distribution down to NHCl = 90–100° and d(H···Cl) > 3.2 Å. It is possible that our traditional notions about hydrogen bonding between charged entities may require revision, but for the problem of the cut-off angle to be treated meaningfully, experimental as well as theoretical assessments of charge-density distribution in the H···Cl region of such presumed hydrogen bonds must first be obtained. In the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

meantime, comparison of H···Cl and NHCl means in the distributions for different compounds and of the slopes of the regression lines can be used to estimate the *relative* strength of the overall hydrogen bonding in a crystal. These matters will be elaborated elsewhere.

Experimental

$(MeNH_3)_4InCl_7$ and $(Me_2NH_2)_4InCl_7$ resulted from room-temperature crystallization of solutions containing the alkylammonium chloride and $InCl_3$ in a molar ratio of 2:1. The solutions were prepared by dissolving $In(OH)_3$ in conc. HCl, evaporating, redissolving in a minimum amount of water and adding a methanolic solution of $MeNH_3Cl$ or Me_2NH_2Cl. The products were recrystallized from MeOH. For the preparation of $(NH_4)_2[InCl_5(H_2O)]$ and $K_3InCl_6 \cdot nH_2O$ see **C**.

Densities were determined by flotation in suitable liquid mixtures. Infrared spectra were obtained on a Bomem DA3.02 Fourier transform spectrometer, using fluorolube mulls supported between CaF_2 plates.

Structure determination

A CAD-4 four-circle diffractometer was used in the determination (at ~19°C) of the unit-cell dimensions and in the intensity collection. As nearly equiaxial crystals as could be found, typically 0.01–0.02 mm^3 in volume, were used. The intensities were reduced by routine procedures (167). Lorentz and polarization corrections were applied but no absorption or extinction corrections. The scattering factors for neutral atoms were taken from ref. 168. The structures were solved using the SHELX (169) and CRYSTALS (170) systems.

After the nonhydrogen atoms had been located, full-matrix least-squares ($w\Delta F^2$ = min) refinement was carried out with isotropic temperature factors until R was reduced to a reasonably low value. The hydrogen atoms were then located from a difference map or from structural considerations, and the refinement was continued with anisotropic temperature factors on the nonhydrogen atoms and isotropic factors on the hydrogens. The anisotropic temperature factor is defined as $T = \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$. The least-squares weights were of the type $w^{-1} = a\sigma^2|F_o| + b|F_o|^2$ (SHELX) or $w^{-1} = \sigma^2|F_o|$ (CRYSTALS, $(Me_2NH_2)_4InCl_7$). The crystal data on the title compounds are given in Table 2 and the structure factors in Tables 26–29.[24]

Acknowledgments

We thank Dr. M. Falk for obtaining the ir spectra and Dr. S. P. Deraniyagala for assistance with some of the preparative work. We are also indebted to Dr. J.-P. Wignacourt for providing us with a copy of ref. 18. This investigation was supported by grants from the Natural Sciences and Engineering Research Council of Canada to O.K. and T.S.C.

^{13}C magnetic resonance studies. 131.[1,2] An examination of β-enolization in an unsaturated [3.2.1] system: 3,3-dimethylbicyclo[3.2.1]oct-6-en-2-one

GREG A. ANTONIADIS, MICHAEL T. M. CLEMENTS,[3] SRIYAWATHIE PEIRIS, AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 8, 1987

GREG A. ANTONIADIS, MICHAEL T. M. CLEMENTS, SRIYAWATHIE PEIRIS, and J. B. STOTHERS. Can. J. Chem. **65**, 1557 (1987).

Under homoenolization conditions (*t*-BuO$^-$/*t*-BuOH/185°C), 3,3-dimethylbicyclo[3.2.1]oct-6-en-2-one (**5**) is converted into six products through three reaction pathways. The major product, 3,3-dimethylbicyclo[3.3.0]octan-2-one, arises by unidirectional β-enolate rearrangement of **5** to the isomeric unsaturated [3.3.0] ketones, which (*a*) undergo efficient reduction to **2**, by single electron transfer, and (*b*) suffer Haller–Bauer cleavage to two isomeric 2,2-dimethyl-3-cyclopentenylpropanoic acids. In competition with these processes is the reversible conjugate addition of *t*-BuO$^-$ to **5** to furnish the 6-*tert*-butoxy derivative, which undergoes β-enolate rearrangement to two isomeric ketones. The structures of these products were established primarily from their ^1H and ^{13}C magnetic resonance spectra.

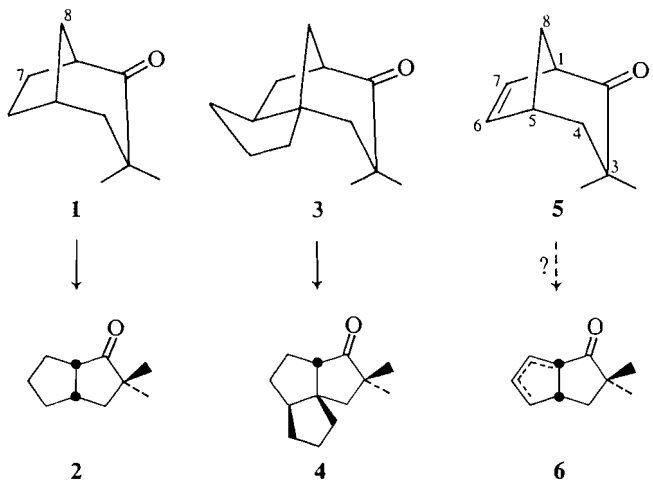
GREG A. ANTONIADIS, MICHAEL T. M. CLEMENTS, SRIYAWATHIE PEIRIS et J. B. STOTHERS. Can. J. Chem. **65**, 1557 (1987).

Dans des conditions d'homoénolisation (*t*-BuO$^-$/*t*-BuOH/185°C), la diméthyl-3,3 bicyclo[3.2.1]octène-6 one-2 (**5**) se transforme en six produits, par le biais de trois voies réactionnelles. Le produit principal, la diméthyl-3,3 bicyclo[3.3.0]octanone-2, provient d'une transposition unidirectionnelle du β-énolate du composé **5** en cétones [3.3.0] insaturées isomères (*a*) qui subissent une réduction efficace en **2** par un transfert unique d'électron et (*b*) qui subissent un clivage de Haller–Bauer pour conduire à deux acides diméthyl-2,2 cyclopentène-3 yl propanoïques isomères. Ces processus sont en compétition avec l'addition conjuguée réversible de l'anion *t*-BuO$^-$ au composé **5** qui conduit au derivé *tert*-butylate-6 qui subit une transposition β-énolique conduisant à deux cétones isomères. Pour déterminer les structures, on a principalement fait appel aux spectres de résonance magnétique nucléaire du ^1H et du ^{13}C.

[Traduit par la revue]

Introduction

Over the past several years, the rearrangements of several polycyclic ketones have been found to occur by homoenolization through proton abstraction from carbons remote from the carbonyl group (1), generally from β-carbons via β-enolates, although there are a few examples of γ-enolization leading to rearrangement (2). In a few cases we have utilized β-enolate rearrangements for the generation of the ring systems of some interesting natural products (3). In each of these cases, the key step was patterned after the known conversion of 3,3-dimethylbicyclo[3.2.1]octan-2-one (**1**) to its [3.3.0] isomer **2** (4), as exemplified by the conversion of **3** → **4** (3*a*). Thus, it was of interest to examine the possible isomerization of an unsaturated system analogous to **1** as a potential synthetic route to substituted 3,3-dimethylbicyclo[3.3.0]octane derivatives, several of which have been employed in the syntheses of a variety of natural products (5). Consequently, the behavior of 3,3-dimethylbicyclo[3.2.1]oct-6-en-2-one (**5**) has been studied under typical homoenolization conditions (*t*-BuO$^-$/*t*-BuOH at elevated temperatures) to determine whether its transformation to **6** proceeds in a manner similar to that exhibited by **1**. The results of these experiments are presented in this paper.



Results

Ketone **5** was prepared from norbornenone (**7**) as outlined in Scheme 1. This route is less efficient than a directed ring expansion by homoketonization of the cyclopropoxide derived from **7**, a route that we had found to be effective for several other bicyclic ketones (6) but this sequence follows a different course with **7** (7). Reaction of **7** with trimethylsilyl cyanide (8) gave **8** in 96% yield and reduction with LAH furnished **9** in 86% yield. Tiffeneau–Demjanov rearrangement (9) of **9** yielded a 1:1 mixture of **10** and **11** (70%), which were readily identified by ^{13}Cmr (10). Although this mixture is separable by glc, it was methylated to furnish the corresponding mixture of **5** and **12**, which was more readily separated by flash chromatography (11); these ketones were identified by their ^1H, ^{13}Cmr, and mass spectra. The ^{13}C data are collected in Table 1.

Following our usual procedures (4), ketone **5** was dissolved in anhydrous *t*-BuO$^-$/*t*-BuOH (1.25 *M*) to furnish a solution 0.30 *M* in **5**. Aliquots of this solution were transferred to glass tubes under nitrogen, sealed under vacuum, and heated to 185°C for varying periods of time (24, 48, and 96 h). The neutral product from each tube was isolated by pentane extraction in yields that steadily decreased with increased reaction time. Each product was analyzed by glc after passing each, in pentane, through a short silica column to remove apparently polymeric material. Over the course of 96 h, glc revealed the

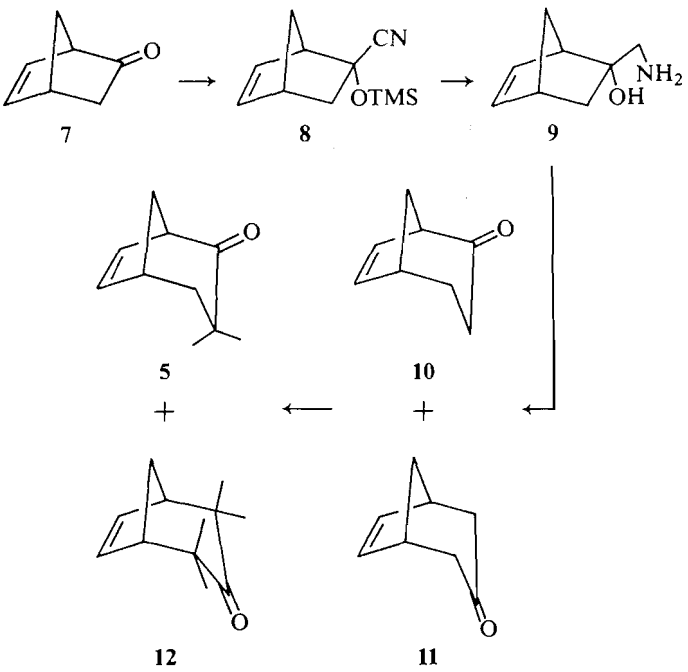

SCHEME 1

smooth conversion of **5** to four new components, of which the major one constituted 50% of the neutral product. Samples of each were obtained by preparative glc and each gave rise to strong carbonyl absorption in the infrared showing all to be ketones. From its carbonyl absorption at 1740 cm^{-1} and its ^{13}Cmr spectrum the major component was readily shown to be **2** (4). The distribution of the components in the neutral fractions as a function of time is given in Table 2. An acidic fraction was isolated in ca. 20% yield from the 96 h runs by ether extraction of the aqueous phase; glc analysis of this material indicated the presence of a single band.

The second new ketone (1695 cm^{-1}, $CHCl_3$), constituting 15% of the neutral fraction after 24 h but only 8% after 96 h, was found to have the molecular formula $C_{14}H_{24}O_2$ and lacked olefinic absorption in its ^1H and ^{13}Cmr spectra. The presence of a *tert*-butoxyl group was evident from the 9-proton singlet at δ 1.190 and ^{13}C absorption at δ_C 28.3 (Me_3) and 73.5 (quat C). The proton spectrum also contained two methyl singlets (1.097, 1.148) and two one-proton doublets of doublets at δ 3.99 and 2.80, each of which was coupled to a pattern at δ 1.80 with couplings of 3.3 and 7.5 Hz, respectively. The δ 1.80 multiplet also contained couplings of 15.0 and 1.8 Hz of which the larger interaction was readily ascribed to geminal coupling with a proton at δ 2.20. The latter pattern also exhibited splittings of 7.0 Hz (common to the δ 3.99 pattern) and 1.8 Hz. The requisite decoupling experiments confirmed these interactions and led to structure **13** for this ketone, for which the *endo*-6 proton absorbs at δ 3.99, H-1 at 2.80, and the *exo*- and *endo*-7 protons at 1.80 and 2.20, respectively. In addition, the *syn*- and *anti*-8 proton absorptions appeared at δ 1.66 and 2.10 (J_{gem} = 12 Hz) with the latter containing a 4.5-Hz coupling to H-1. A partially obscured multiplet near δ 2.24 (H-5) and a two-proton pattern centred at 1.75 (H-4) were also apparent. The ^{13}C shieldings are listed in Table 1.

The third ketone (1690 cm^{-1}, $CHCl_3$) also had the molecular formula $C_{14}H_{24}O_2$ by precise mass measurement and could be assigned structure **14** on the basis of its spectral data. Both the ^1H and ^{13}Cmr spectra lacked olefinic absorption. In addition to methyl singlets at δ 1.049 (3H), 1.156 (3H), and 1.165 (9H), the proton spectrum contained a singlet at δ 3.73 (*syn* H-8), a doublet, δ 2.68, J = 7.5 Hz (H-1), a broad multiplet, δ 2.30, $\nu_{1/2}$ = 14 Hz (H-5), and complex multiplets centred at 2.15 (2H) and 1.70 (4H). The ^{13}C shieldings are collected in Table 1. The assignment of the *anti* orientation for the *tert*-butoxyl group followed from the lack of coupling of the carbinyl proton, since a *syn* proton in this system has a dihedral angle with respect to each bridgehead proton of ca. 90°.

The minor, fourth ketone (1730 cm^{-1}, $CHCl_3$; δ_C 224.8) was found to be isomeric with **13** and **14** by precise mass measurement. The proton spectrum exhibited three methyl singlets (1.012 (3H), 1.139 (3H), 1.164 (9H)), carbinyl proton absorption (3.75, m, $\nu_{1/2} \sim$ 14 Hz), bridgehead proton patterns at δ 3.00 ("dt", J = 4, 10 Hz) and 2.60 ("dq", J = 2.5, 10 Hz) with complex multiplets centred at 2.08 (2H) and 1.65 (4H). Decoupling at δ 3.75 collapsed the 2.60 pattern to an apparent 1:3:3:1 quartet without affecting the 3.00 absorption, while simultaneous irradiation of the latter pattern changed the 2.60 multiplet to a doublet of triplets without altering the carbinyl absorption at 3.75. On the basis of these data, we conclude that this ketone is *exo*-6-*tert*-butoxy-3,3-dimethylbicyclo[3.3.0]octan-2-one (**15**) and the ^{13}C shieldings fit nicely upon comparison with those for **2** with due allowance for the effects of the 6-alkoxy substituent (Table 1).

The acidic fraction, isolated from the 96-h product, was esterified with diazomethane and, although glc analysis indicated a single component, the ^1H and ^{13}C spectra revealed the presence of a 1:2 mixture of isomeric methyl esters. The molecular formula was found to be $C_{11}H_{18}O_2$ by precise mass measurement. The olefinic proton absorption consisted of a broadened singlet, δ 5.65, and a pair of doublets of "quartets", δ 5.60 (J = 5.6 and 2.1 Hz) and 5.70 (J = 5.6 and 2.4 Hz), each with comparable intensities. The ^{13}C spectrum contained three equally intense signals for monoprotonated olefinic carbons, which were comparable to a methine and four methylene signals in the higher field region. The latter were accompanied by one methine and one methylene signals, each of which was half as intense as the others. At highest field, three methyl signals in a 1:1:1 ratio were found, each somewhat less intense than the single methoxyl signal. These data led to the assignment of structures **16***a* and *b* to the minor and major esters, respectively; the ^{13}C data are listed in Table 1.

Hydrogen–deuterium exchange in **5** under these strongly basic conditions was briefly examined. The total ^2H content in samples of **5**-d_x recovered after 2, 4, and 16 h was determined by mass spectrometry and the labelling level at the various sites undergoing exchange was obtained by integration of the ^2Hmr signals. The earlier samples exhibited strong signals at δ 2.9, 5.8, and 6.1, readily assigned to deuterium at C-1, -7, and -6, respectively, upon comparison with the proton data (see Experimental) and, after 16 h, weak signals in a 3:1 ratio appeared at 1.00 and 1.05, indicative of much slower *exo*- and *endo*-methyl exchange. The incorporation results are summarized in Table 3 from which it is apparent that rapid exchange occurs at the α-bridgehead and both olefinic positions with significantly slower exchange at both methyl sites, the more rapid of which is presumably the *exo*-methyl by analogy with several other related systems (1). It may be noted that an additional sample of **5**-d_x recovered after 50 h showed no evidence of ^2H exchange at C-8.

The ^{13}C spectrum of a 1:1 mixture of **5** with **5**-d_x isolated after 2 h in deuterated base revealed the characteristic ^2H-induced

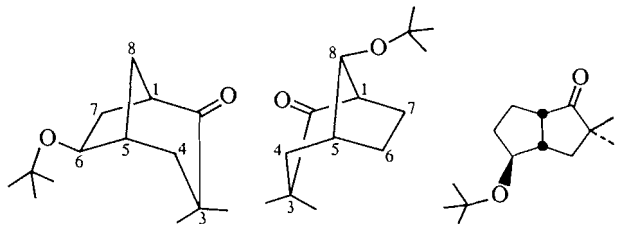
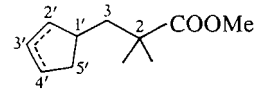
effects (12) that served to confirm the assignments listed in Table 1. The methylene absorptions at δ_C 40.4 and 39.5 arising from C-4 and -8, respectively, differed in that the latter contained a component shifted by 75 ppb (1 ppb = 0.001 ppm), owing to deuterium at C-1. The C-5 pattern at δ_C 39.3 included components ascribable to species having ^2H at C-6 (110 ppb) and C-7 (30 ppb, $J \sim 1.4$ Hz), while the C-1 absorption, δ_C 55.3, exhibited components shifted by 76 ppb (^2H-7) and 16 ppb, $J \sim 1.2$ Hz (^2H-6). Deuterium incorporation at C-6 and C-7 was evident from the appearance of the characteristic triplets, $J_{CD} = 26$ Hz, shifted upfield by 290 and 270 ppb, respectively. The C-6 pattern also contained components shifted by 25 ppb (^2H-1) and 150 ppb (^2H-7); these were indistinguishable from the noise for C-7 because of the high level of incorporation (86%) at this centre. Other isotope shifts observed were 24 ppb (C-3, ^2H-1) and 16 ppb (*endo*-Me, ^2H-1).

An examination of **12** under homoenolization conditions showed that it is stable; even after 240 h at 185°C, **12** was recovered in >85% yield with no evidence (glc and ^{13}Cmr) of the presence of any isomeric material.

Discussion

The reactivity of **5** under homoenolization conditions contrasts sharply with that of the isomeric bicyclooctenones **17** and **18**, which are cleanly equilibrated under the same conditions with negligible side reactions (13). In fact, the most striking feature of the **17** ⇌ **18** equilibration is the enhanced rate relative





16*a* $\Delta^{3'}$
b $\Delta^{2'}$

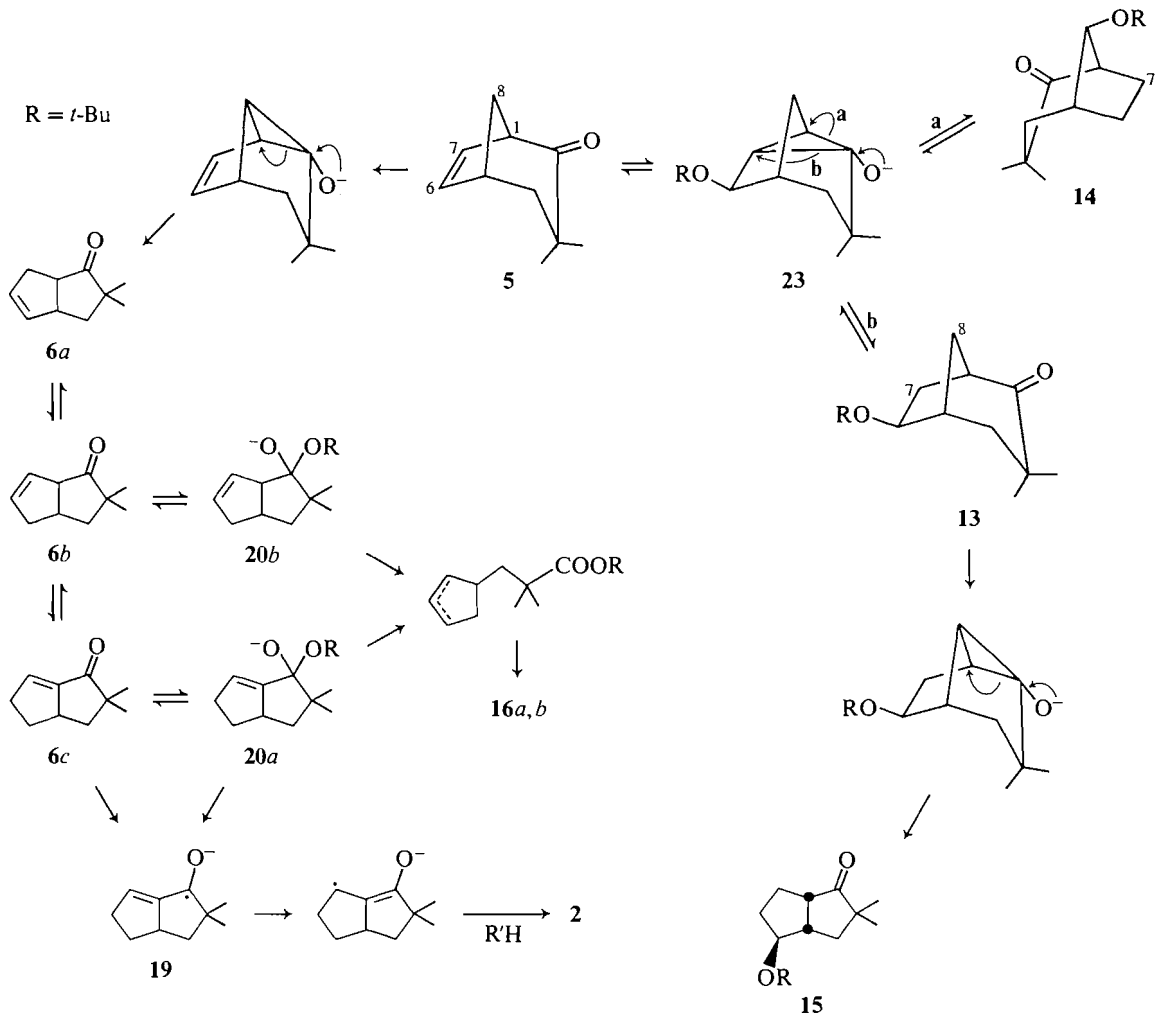

SCHEME 2

to the behavior of several other bicyclic ketones, since equilibrium is established in ca. 20 h. It may be noted that the rate of rearrangement of **17** is more than 100 times faster than that found for its saturated analog (14). At the outset of this study of **5** it was anticipated that a significant rate enhancement over that exhibited by **1** → **2** might be realized, with the formation of one or more of the **6** isomers. However, while the rate of disappearance of **5** is faster than that found for **1** (4), a multicomponent product results. The generation of the products obtained from **5** upon treatment with *t*-BuO$^-$/*t*-BuOH at 185°C can be explained as outlined in Scheme 2.

Since **2** is the predominant product from **5** it is clear that proton abstraction at C-8 is the major process, but the isomeric unsaturated ketones **6** do not survive the reaction conditions. It is apparent that reduction occurs but we were unable to detect an oxidized product. We suggest that the α,β-unsaturated isomer **6***c* undergoes reduction by electron transfer from the *tert*-butoxide anion, either directly from ketyl **19** or by homolysis of the addition product **20***a*. A similar reduction process was observed earlier for the related ketone **21**, which is smoothly converted to a mixture of **2** and its 6-*tert*-butoxy derivative **22** under the same conditions (15). The absence of 8-*tert*-butoxy-**2** among the products from **5** indicates that **22** may arise from Michael addition of *t*-BuO$^-$ to **21** rather than by reaction with a *tert*-butoxide radical as suggested earlier (15). Haller–Bauer cleavage of **20***a* to form an ester could also occur (Scheme 2) but the addition product **20***b* from **6***b* may be more susceptible to cleavage since the process leads to an allylic carbanion. Upon formation of the monocyclic ester(s), equilibration of the $\Delta^{2'}$ and $\Delta^{3'}$ isomers can occur readily in the strongly basic medium via allylic anions. It has been shown previously that *tert*-butyl esters from such ketonic cleavages do not survive the reaction conditions and are isolated as the corresponding carboxylic acids (16). Since the samples of **5**-d_x recovered from the experiments in deuterated base lacked detectable deuterium at C-8, proton abstraction from this site must be irreversible such that opening of the resulting β-enolate leads only to **6***a*. This is exactly analogous to the result for its saturated analog **1** (4).

Approximately one-fourth of the neutral fractions consisted of material containing a *tert*-butoxyl substituent. Thus, addition of *t*-BuO$^-$ to the double bond of **5** is a competitive process. The addition of *t*-BuO$^-$ can lead directly to β-enolate **23** (Scheme 2), which can open in two other ways: path **a** leading to **14** and path **b** to **13**. Proton abstraction from C-8 in **13** provides a route to **15** and may be expected to be unidirectional by analogy with the findings for **1** and **5** upon proton abstraction from the methano bridge. Proton abstraction from C-7 in **13** and **14** to form **23** is also analogous to the findings for **1** (4). Elimination of *tert*-butyl alcohol from **13**-*d*, formed in deuterated base, would account for the relatively rapid deuterium incorporation at C-7 in **5** (Table 3). In contrast to **1** for which bridgehead

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

exchange of H-1 is nearly complete in 1 h at 185°C, the corresponding process in **5** is much slower, perhaps owing to increased strain imposed by the 6,7 double bond in the α-enolate. It may also be noted that exchange at the methyl sites in **5** is 3–5 times slower than the rates of methyl exchange in **1**. Exchange at C-6 may involve homoconjugative deuteronation at C-6 with subsequent loss of the original 6-hydrogen or direct vinyl exchange; the process occurs at a rate comparable to that of bridgehead exchange (Table 3).

In summary, ketone **5** undergoes β-enolization at C-8 leading irreversibly to the isomeric unsaturated [3.3.0] system **6**, which, unfortunately in terms of the original premise for this study, does not survive under the reaction conditions but suffers reduction and Haller–Bauer ring cleavage. Reversible conjugate addition of *tert*-butoxide also occurs at C-6 in **5** to generate **13**, which exhibits β-enolization to both C-7 and C-8 leading to **14** and **15**, respectively. Furthermore, the material balance is much lower than is usually found upon similar treatment of several closely-related ketones, indicating that other unidentified processes consume starting material in significant amounts, perhaps by polymerization.

Experimental

Gas–liquid chromatography was carried out on a Varian 920 instrument using columns of 6% FFAP or 20% DEGS on Chromosorb W, as indicated. Ether was dried over sodium and freshly distilled before use; methyl iodide was dried over 4A sieves. Norbornenone (**7**) was employed as starting material and its preparation had been described earlier (7).

Infrared spectra were recorded with a Beckman 4250 instrument and mass spectra were obtained on a Varian MAT-311A system at 70 eV (direct inlet). Routine ^{1}Hmr spectra were recorded with a Varian EM-360 instrument while data for pure samples were collected with a Varian XL-200 instrument. The ^{2}H and ^{13}Cmr spectra were obtained at 46.1 and 75.4 MHz, respectively, with a Varian XL-300 system, and comparison of the fully decoupled ^{13}C spectra with those recorded with either the APT (17) or DEPT (18) sequences identified the number of hydrogen atoms on each carbon.

*Bicyclo[3.2.1]oct-6-en-2- and -3-ones (**10**, **11**)*

Trimethylsilyl cyanide (7.14 g, 0.072 mol) was added slowly to a stirred mixture of norbornenone (8.2 g, 0.066 mol) and ZnI_2 (20 mg) under N_2 at ice temperature. The ice bath was removed after the addition and stirring was continued for 20 h at room temperature. Removal of the excess reagents afforded the cyanohydrin ether **8** (15.1 g, 96%); ir ($CHCl_3$): 2400 cm^{-1}; ^{13}Cmr ($CDCl_3$) δ_C: 1.2 ($SiMe_3$), 44.9, 47.8 (2 × CH_2), 43.7, 54.7, 131.4, 139.0 (4 × CH), 73.5 (quat C), 123.2 (CN).

Cyanohydrin ether **8** (8.3 g, 0.040 mol) in Et_2O (50 mL) was added to a stirred suspension of LAH (1.9 g, 0.050 mol) in anhydrous Et_2O (50 mL) under N_2 at a rate that maintained gentle reflux and the mixture was heated under reflux for 16 h before the destruction of excess LAH by the addition of water. The precipitate was removed by filtration, washed with Et_2O, and the washings added to the filtrate before drying over $MgSO_4$. Evaporation of the solvent furnished the aminoalcohol **9** (4.8 g, 86%); ir ($CHCl_3$): 3450, 1610 cm^{-1}; ^{13}Cmr ($CDCl_3$) δ_C: 41.4, 48.7, 50.9 (3 × CH_2), 42.3, 49.4, 133.4, 139.2 (4 × CH), 80.9 (quat C).

A solution of aminoalcohol **9** (10.1 g, 0.073 mol) in glacial HOAc (5.2 mL) and water (80 mL) was cooled to 0°C with stirring before a solution of $NaNO_2$ (6.2 g, 0.090 mol) in water (80 mL) was slowly added dropwise over a period of 45 min. Stirring was continued for 1 h before the reaction mixture was heated under reflux for 1 h. Upon cooling to room temperature, the acidic solution was neutralized with aqueous $NaHCO_3$ solution before isolation of the product by ether extraction (8 × 100 mL). The combined extracts were dried over $MgSO_4$. Evaporation of the solvent gave a yellow oil (6.3 g, 70%) that was a 1:1 mixture of two major components, by glc analysis (DEGS), which were identified as **10** and **11** by ^{13}Cmr (10). The crude product was subjected to flash chromatography (Et_2O – petroleum ether, 20:80) to remove traces of minor impurities before the methylation step.

*3,3-Dimethylbicyclo[3.2.1]oct-6-en-2-one (**5**)*

To a vigorously stirred suspension of $NaNH_2$ (8.25 g, 0.2 mol) in Et_2O (200 mL) under N_2 was slowly added a solution of the mixture of **10** and **11** (2.5 g) in Et_2O (25 mL) at room temperature before the mixture was refluxed for 3 h. After cooling, methyl iodide (9.4 mL, 0.15 mol) was added slowly before the mixture was heated under reflux overnight. After cooling to room temperature, a second portion of MeI (3.2 mL, 0.05 mol) was added and refluxing continued for 3.3 h before the addition of a third portion of MeI (3.2 mL, 0.05 mol). After a reflux period of 3.3 h, the reaction mixture was cooled to room temperature before the slow addition of water (50 mL). The ether layer was separated and the aqueous layer extracted with ether (5 × 100 mL). The combined extracts were dried over $MgSO_4$, and the product, recovered by evaporation of the solvent as a yellowish oil (2.6 g, 77%), was found to be a 1:1 mixture of two major components, by glc analysis (FFAP), that was readily separable by flash chromatography (Et_2O – petroleum ether, 10:90). The first major component was obtained as a crystalline solid, mp 77–78°C, by preparative glc (FFAP) and found to be **5**; ir ($CHCl_3$): 1690, 1380 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.012 (s, 3H, Me), 1.045 (s, 3H, Me), 1.48 (ddd, 1H, *endo*-H-4, J_{gem} = 13.5, $J_{4,5}$ = 2.3, $J_{4,8}$ = 2.3 Hz), 1.70 (dd, J = 13.5, 4.3 Hz, 1H, *exo*-H-4), 1.91 (bd, J = 11.3 Hz, 1H, *syn*-H-8), 2.17 (dddd, J = 11.3, $J_{8,1}$ = 4,5, $J_{8,5}$ = 5.4 Hz, $J_{8,4}$ = 2.3 Hz, *anti*-H-8), 2.68 (m, 1H, H-5), 2.90 (dd, $J_{1,8}$ = 4.5, $J_{1,7}$ = 3.0 Hz, 1H, H-1), 5.77 (dd, $J_{7,6}$ = 5.5, $J_{7,1}$ = 3.0 Hz, 1H, H-7), 6.12 (dd, $J_{6,7}$ = 5.5, $J_{6,5}$ = 2.5 Hz, 1H, H-6); ^{13}Cmr: see Table 1. *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1045; found: 150.1040.

*2,2,4,4-Tetramethylbicyclo[3.2.1]oct-6-en-3-one (**12**)*

The second component isolated from the methylation product mixture by flash chromatography was shown to be **12**; mp 25–26°C; ir ($CHCl_3$): 1695, 1380 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.887 (s, 6H, Me), 1.099 (s, 6H, Me), 1.760 (dt, J = 5.2, 11.6 Hz, 1H, *anti*-H-8), 2.263 (bd, J = 11.6 Hz, 1H, *syn*-H-8), 2.270 (bm, 2H, H-1,5), 6.08 (bs, 2H, H-6,7); ^{13}Cmr: see Table 1. *Exact Mass* calcd. for $C_{12}H_{18}O$: 178.1358; found: 178.1355.

Homoenolization experiments

The general procedures described previously (19) were followed, whereby a solution of **5** in *t*-BuO$^-$/*t*-BuOH, prepared from potassium metal and *t*-BuOH (water content < 200 μg/mL), was prepared under N_2 (mole ratio: ketone/*t*-BuO$^-$/*t*-BuOH; 1:4:40) and aliquots were quickly transferred to predried, thick-walled glass tubes. The solutions were degassed before the tubes were sealed under vacuum and then heated at 185°C for varying periods of time. After cooling, the reaction mixture was washed from the tube with water and the neutral products were isolated by pentane extraction. Evaporation of the solvent gave a black oil, which was passed through a short column of silica gel before glc analysis (DEGS) that revealed the presence of four significant bands in addition to that for remaining starting material. Samples of these five bands were obtained by preparative glc (DEGS) and each exhibited strong carbonyl absorption in the ir and was identified, primarily from the nmr data. These ketones were eluted, in this order: **2**, **5**, **14**, **15**, and **13**. The basic aqueous phase was acidified with 5% HCl solution before ether extraction. The extracts were dried over $MgSO_4$ before evaporation of the solvent. The resulting product was treated with diazomethane, generated from Diazald in the usual fashion, and allowed to stand overnight before evaporation of the solvent. Gas–liquid chromotographic analysis (FFAP) indicated the presence of a single major band, which consisted of a 2:1 mixture of isomeric methyl esters by ^{13}Cmr, after isolation by preparative glc.

An analogous series of experiments was carried out with **12** as the starting material. In all cases, the neutral product, >85% recovery, contained only the initial ketone; there was no evidence (glc, ^{13}Cmr) of the presence of a new component.

A series of samples of **5** with *tert*-butylalcohol-O-d_1 (99% deuterated; H_2O content < 200 μg/mL) was also run to examine the exchange processes of **5** under the same reaction conditions; the results are described in the text.

exo-*6*-tert-*Butoxy-3,3-dimethylbicyclo[3.2.1]octan-2-one (13)*

The second ketonic product from **5** was assigned structure **13** on the basis of the following data: ir ($CHCl_3$): 1695, 1035 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.097 (s, 3H, CH_3), 1.148 (s, 3H, CH_3), 1.190 (s, 9H, $3CH_3$), 3.99 (dd, J = 3.3, 7.0 Hz, *endo*-H-6), 2.80 (dd, J = 4.5, 7.5 Hz, H-1), 2.20 (ddd, J = 1.8, 7.0, 15.0 Hz, *endo*-H-7), 2.24 (m, H-5), 2.10 (bdt, $J \sim 4.5$, 12 Hz, *anti*-H-8), 1.80 (dddd, J = 1.8, 3.3, 7.5, 15.0 Hz, *exo*-H-7), 1.66 (bd, $J \sim 12$ Hz, *syn*-H-8), 1.75 (m, 2H, H-4), ^{13}Cmr: Table 1. *Exact Mass* calcd. for $C_{14}H_{24}O_2$: 224.1776; found: 224.1771.

anti-*8*-tert-*Butoxy-3,3-dimethylbicyclo[3.2.1]octan-2-one (14)*

The third ketone isolated from the neutral product from **5** was assigned structure **14** from the following data: ir ($CHCl_3$): 1690, 1067 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.049 (s, 3H, CH_3), 1.156 (s, 3H, CH_3), 1.165 (s, 9H, $3CH_3$), 3.73 (bs, *syn*-H-8), 2.68 (bd, $J \sim 7.5$ Hz, H-1), 2.30 (m, $\nu_{1/2} \sim 14$ Hz, H-5), 2.15 (m, 2H), 1.70 (m, 4H); ^{13}Cmr: Table 1. *Exact Mass* calcd. for $C_{14}H_{24}O_2$: 224.1776; found: 224.1769.

exo-*6*-tert-*Butoxy-3,3-dimethylbicyclo[3.3.0]octan-2-one (15)*

The minor ketone from the homoenolization of **5** was found to be **15** from the following data: ir ($CHCl_3$): 1730, 1195 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.012 (s, 3H, CH_3), 1.139 (s, 3H, CH_3), 1.164 (s, 9H, $3CH_3$); 3.75 (m, $\nu_{1/2} \sim 14$ Hz, *endo*-H-6), 3.00 (ddd, $J \sim 4$, 10, 10 Hz, H-1), 2.60 (dddd, J = 2.5, 10, 10, 10 Hz, H-5), 2.08 (m, 2H), 1.65 (m, 4H); ^{13}Cmr: Table 1. *Exact Mass* calcd. for $C_{14}H_{24}O_2$: 224.1776; found: 224.1772.

*Methyl $\Delta^{2'}$ and $\Delta^{3'}$-3-cyclopentenyl-3,3-dimethylpropanoates (16*a, b*)*

The acidic fraction isolated from the 96-h runs with **5** was esterified with diazomethane in the usual fashion. The single major band indicated by glc (FFAP) to represent >95% of the product was purified by preparative glc; the ^{1}H and ^{13}Cmr spectra showed the presence of two components in an approximately 1:2 ratio. The following spectral data for these compounds led to the assignments of structures **16***a* and *b*, respectively; ir ($CHCl_3$): 3050, 1720 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.204 (s, 3H, CH_3), 1.214 (s, 3H, CH_3), 3.668 (s, 3H, OCH_3), 2.70 (m, ~1H), 1.25–2.5 (complex patterns, ~6H), 5.65 (bs, H-3′,4′ minor isomer) 5.60 (ddt, $J \sim 5.6$, 2.1, 2.1 Hz), and 5.70 (ddd, $J \sim 5.6$, 2.4, 2.4 Hz, H-2′ and 3′) in the major isomer; ^{13}Cmr: Table 1. *Exact Mass* calcd. for $C_{11}H_{18}O_2$: 182.1307; found: 182.1300.

Selected-ion flow tube studies of reactions of the carbene cation $:C_4N^+$ and their implications for interstellar gas cloud chemistry

DIETHARD K. BOHME, STANISŁAW WŁODEK, AND ASIT B. RAKSIT

Department of Chemistry and Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received December 1, 1986

DIETHARD K. BOHME, STANISŁAW WŁODEK, and ASIT B. RAKSIT. Can. J. Chem. **65**, 1563 (1987).

The carbene cation $:C_4N^+$ was generated in a Selected-Ion Flow Tube (SIFT) apparatus from allyl cyanide by electron impact and reacted at room temperature in helium buffer gas at ca. 0.33 mm Hg with the molecules H_2, CO, HCN, CH_4, CD_4, H_2O, HC_3N, C_2H_2, CH_3CN, CD_3CN, H_2S, NH_3, ND_3, and C_4H_2. The reactions were observed to exhibit a range in reactivity and a variety of reaction products. The observed products are consistent with expectations based on the carbene character of $:C_4N^+$. The results have implications for the role of $:C_4N^+$ as a reaction intermediate in the chemistry of interstellar gas clouds. Possible synthetic routes initiated by $:C_4N^+$ are proposed for the formation of dicyanoacetylene, cyanodiacetylene, and several acyclic as well as cyclic neutral carbenes.

DIETHARD K. BOHME, STANISŁAW WŁODEK et ASIT B. RAKSIT. Can. J. Chem. **65**, 1563 (1987).

Opérant à la température ambiante, dans de l'hélium à environ 0,33 Torr comme gaz tampon et utilisant du cyanure d'allyle soumis à un impact électronique que l'on fait réagir avec des molécules de H_2, CO, HCN, CH_4, CD_4, H_2O, HC_3N, C_2H_2, CH_3CN, CD_3CN, H_2S, NH_3, ND_3 et C_4H_2, on a produit le cation carbènique $:C_4N^+$ dans un tube à écoulement à sélectif pour les ions (SIFT). On a observé que les réactivités varient beaucoup et que les réactions conduisent à un grand nombre de produits. Les produits obtenus correspondent à ceux que l'on peut espérer en se basant sur le caractère carbènique du $:C_4N^+$. Les résultats ont des implications concernant le rôle du $:C_4N^+$ comme intermédiare dans la chimie des nuages gazeux interstellaires. On propose diverses voies de synthèse, initiées par le $:C_4N^+$, pour la formation du dicyanoacétylène, du cyanodiacétylène et de plusieurs carbènes neutres tant acycliques que cycliques.

[Traduit par la revue]

Introduction

A recent experimental study in our laboratory of ion/molecule reactions with cyanoacetylene has suggested a pivotal role for this molecule in the chemical evolution of interstellar gas clouds (1, 2). The presence of cyanoacetylene in a number of these clouds has been firmly established by radioastronomers (3). Gas phase cyanoacetylene is destroyed in these clouds predominantly by reaction with carbon ions (4, 5). This destruction reaction has been shown in our laboratory to proceed with an extremely high specific rate, $k = 6.1 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} at 296 ± 2 K, and to establish both C_3H^+ and C_4N^+ as product ions in the relative amounts indicated by reaction [1].

$$[1] \quad C^+ + HC_3N \xrightarrow{0.8} C_3H^+ + CN$$

$$\xrightarrow{0.2} C_4N^+ + H$$

This result in turn points towards a pivotal role for C_3H^+ and C_4N^+ as intermediate reactant ions in the further chemical evolution of these environments by ion/molecule reactions. We have explored the interesting chemistry of C_3H^+ in a separate study (6–8). Here we report the results of measurement directed towards the characterization of the chemistry of C_4N^+.

The C_4N^+ was produced from allyl cyanide by electron impact and is likely to have the resonance structure indicated in [2]. The ion has carbene character and a charge which is

$$[2] \quad :C^+—C{\equiv}C—C{\equiv}N: \leftrightarrow :C{=}C{=}C^+—C{\equiv}N:$$

$$\leftrightarrow :C{=}C{=}C{=}C{=}N^+:$$

delocalized. There is one report of an ionization energy for C_4N (9) and it indicates a moderate recombination energy for C_4N^+ of 11.9 ± 0.5 eV. The high value reported for the heat of formation of C_4N^+, 449 kcal mol^{-1} (9), is suggestive of a high chemical reactivity. We are not aware of any previous laboratory measurements of this reactivity.

The reactivity of C_4N^+ is of interest in interstellar cloud chemistry because of its possible role in the synthesis of cyanopolyacetylenes, cyanoacetylene itself, cumulated and disubstituted carbenes (10), and other molecules not yet identified in the interstellar medium.

Experimental

The measurements were performed with the Selected-Ion Flow Tube (SIFT) apparatus in the Ion Chemistry Laboratory (8, 11). The C_4N^+ was generated in an axial electron impact ionizer (Extranuclear Model 0413) from allyl cyanide, CH_2CHCH_2CN, either pure or diluted with helium, at electron energies in the range from 50 to 55 eV. The ion spectrum recorded downstream when C_4N^+ is selected upstream is shown in Fig. 1. The major impurity ion was C_3^+ which is thought to arise from the collisional dissociation of C_4N^+. The CHO^+ and $C_3H_2N^+$ ions may arise from reactions of C_4N^+ with water impurities in the helium buffer gas, while H_3O^+ will be formed by the further reaction of CHO^+ with water. The ions were injected into helium buffer gas at ca. 12 to 50 V. The total pressure was in the range from 0.32 to 0.35 mm Hg and the ambient temperature was 296 ± 2 K. The reagent gases and vapours as well as the helium buffer gas were generally of high purity with a minimum purity of 99.5 mol%. Hydrogen cyanide was prepared according to the procedure described by Glemser (12).

Results

Table 1 summarizes the rate constants and product distributions obtained in this study. It includes all the primary product ions which were observed to contribute 5% or more to the total products. The reactions are listed in order of decreasing ionization energy of the neutral substrate. Rate constants and product distributions were derived in the usual manner (6, 13). In the derivation of minor product distributions complications were introduced by reactions of the C_3^+ initially present in the flow tube which in some instances gave products in common with the products of the C_4N^+ reactions. These reactions of C_3^+

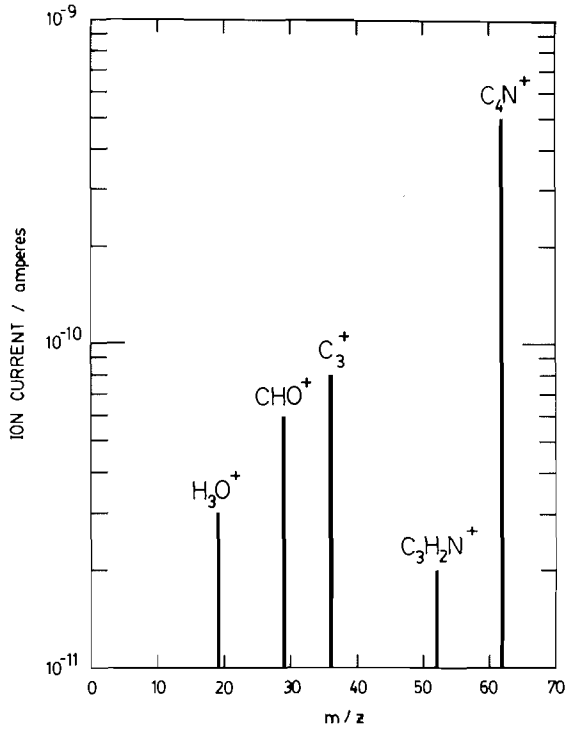

FIG. 1. SIFT spectrum for C_4N^+ derived from pure allyl cyanide by electron ionization at 50 eV. The buffer gas is helium at 0.35 mm Hg and the ion injection energy is ca. 50 V. The background "chemical noise" arises from the collisional dissociation of C_4N^+ and from reactions with water impurity in the buffer gas.

were measured separately and their contributions to the C_4N^+ product spectrum were subtracted where required.

H_2

Molecular hydrogen was observed to react with C_4N^+ only slowly with a specific rate of 2.2×10^{-11} cm^3 molecule^{-1} s^{-1}. The only product which was apparent is indicated in reaction [3]. There was no evidence for hydrogen atom transfer or the

[3] $C_4N^+ + H_2 \rightarrow C_3H^+ + HCN$

addition of molecular hydrogen to C_4N^+. The C_3H^+ product ion reacted further to add molecular hydrogen in a manner reported elsewhere (8).

CO

Only addition was observed with carbon monoxide as shown in reaction [4]. The effective bimolecular rate constant obtained

[4] $C_4N^+ + CO \rightarrow C_5NO^+$

from the decay of C_4N^+ at a total pressure of 0.323 mm Hg and a helium density of 1.05×10^{16} atoms cm^{-3} was 9.3×10^{-11} cm^3 molecule^{-1} s^{-1}. The reaction can be presumed to proceed in a termolecular fashion under these operating conditions but no measurements were made as a function of pressure. The C_5NO^+ ion did not appear to add a second molecule of CO.

HCN, HC_3N

Hydrogen cyanide and cyanoacetylene were observed to react with C_4N^+ in a similar fashion. Adduct formation was the predominant channel observed with both molecules at the moderate helium pressures employed. For the addition reaction [5] with HCN an effective bimolecular rate constant of

[5] $C_4N^+ + HCN \rightarrow C_5HN_2^+$

TABLE 1. Summary of rate constants (in units of 10^{-9} cm^3 molecule^{-1} s^{-1}) and product distributions measured for reactions of :C_4N^+ with the SIFT technique at 296 ± 2 K

Neutral reactant	Products	Branching[a] ratio	k_{exp}[b]	k_c[c]
H_2	$C_3H^+ + CHN$	1.0	0.022	1.5
CO	C_5NO^+	1.0	0.093[d]	0.78
HCN	$C_5HN_2^+$	1.0	0.84[d]	3.2
CH_4	$C_3H_2N^+ + C_2H_2$	0.35	0.57	1.05
	$C_4H_3^+ + CHN$	0.30		
	$C_2H_3^+ + C_3HN$	0.25		
	$CH_2N^+ + C_4H_2$	0.05		
	$C_5H_2N^+ + H_2$	0.05		
H_2O	$C_3H_2N^+ + CO$	0.5	1.5[d]	2.4
	$CHO^+ + C_3HN$	0.4		
	$C_4H_2NO^+$	0.1		
HC_3N	$C_7HN_2^+$	1.0	1[d]	3.3
C_2H_2	$C_5H^+ + CHN$	≥0.7	0.80[d]	1.0
	$C_6H_2N^+$	≤0.3		
CH_3CN	$C_2H_3^+ + C_4N_2$	0.6	3.1	3.7
	$C_4HN_2^+ + C_2H_2$	0.4		
H_2S	$CHS^+ + C_3HN$	0.60	0.89[d]	1.4
	$C_2NS^+ + C_2H_2$	0.25		
	$C_3HS^+ + CHN$	0.10		
	$C_4H_2NS^+$	0.15

	$C_8H_2N^+$	0.6		

[a]Primary product ions which contribute more than 5%. The branching ratio has been rounded off to the nearest 5% and is estimated to be accurate to ±30%.

[b]The accuracy of the rate constants is estimated to be better than ±30%.

[c]Collision rate constants derived from the combined variational transition state theory — classical trajectory study of Su and Chesnavich (14).

[d]In helium buffer gas at a total pressure of ca. 0.3 mm Hg and concentration of ca. 1×10^{16} atoms cm^{-3}.

8.4×10^{-10} cm^3 molecule^{-1} s^{-1} was measured at a total pressure of 0.33 mm Hg and a helium density of 1.1×10^{16} atoms cm^{-3}. A second molecule of HCN was observed to add, but more than 10 times slower. A third molecule was also observed to add slowly at higher additions of HCN. Previous experiments reported from our laboratory have shown that one molecule of cyanoacetylene also adds rapidly to C_4N^+ according to reaction [6] when the C_4N^+ is generated from the

[6] $C_4N^+ + HC_3N \rightarrow C_7HN_2^+$

reaction of C^+ with HC_3N at a total pressure of 0.31 mm Hg and a helium density of 1.0×10^{16} atoms cm^{-3} (2).

CH_4, CD_4

The product ions observed for the reaction of C_4N^+ with methane are indicated in reaction [7] along with their relative

[7] $C_4N^+ + CH_4 \xrightarrow{0.35} C_3H_2N^+ + C_2H_2$

$\xrightarrow{0.30} C_4H_3^+ + CHN$

$\xrightarrow{0.25} C_2H_3^+ + C_3HN$

$\xrightarrow{0.05} CH_2N^+ + C_4H_2$

$\xrightarrow{0.05} C_5H_2N^+ + H_2$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12

yields. The overall rate constant determined from the decay of C_4N^+ was 5.7×10^{-10} cm^3 molecule^{-1} s^{-1}. Measurements with CD_4 excluded $C_4H_4^+$, CHN^+, and $C_2H_4^+$ as possible product ions. C_3HN^+, which has the same mass as $C_4H_3^+$, could not be completely excluded. Some $m/z = 52$ ions were observed with CD_4. The source for this ion was uncertain. For example, it may be produced from the C_3^+ impurity ions. In any case, the observed ion signals for this ion correspond to a maximum contribution to the products of 5%. The reaction with CD_4 has a measured rate constant of 5.0×10^{-10} cm^3 molecule^{-1} s^{-1}.

The reaction with CH_4 was also investigated using the reaction of C^+ with cyanoacetylene as a source for C_4N^+. Sufficient cyanoacetylene was added into the flow tube to quench most of the C^+ and methane was then added further downstream. The major ion in the flow tube under these conditions was C_3H^+ but the addition of methane did allow an assessment of the products of the C_4N^+ reaction since the products of the reaction of C_3H^+ with methane were known from previous measurements in our laboratory (8). The experiment was carried out at low resolution and products were observed at $m/z = 51 + 52$, $27 + 28$, and 76, in approximately the same proportions as those observed when C_4N^+ was derived directly from allyl cyanide. Also the rate constant determined under these conditions for the decay of C_4N^+, $k = 5.5 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}, is consistent with the rate constant determined when C_4N^+ was derived by electron impact on allyl cyanide. Finally, both the adduct ions $C_3H^+.HC_3N$ and $C_4N^+.HC_3N$ present under these operating conditions were observed not to react with CH_4, $k \leq 10^{-11}$ cm^3 molecule^{-1} s^{-1}.

H_2O

Two major bimolecular channels were observed for the reaction with H_2O. Adduct formation was observed as a minor channel. The reaction was rapid overall, $k = 1.5 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}. The product distribution is indicated in reaction [8]. There was no evidence for the occurrence of

$$[8]\quad C_4N^+ + H_2O \xrightarrow{0.5} C_3H_2N^+ + CO$$
$$\xrightarrow{0.4} CHO^+ + C_3HN$$
$$\xrightarrow{0.1} C_4H_2NO^+$$

hydrogen atom or oxygen atom abstraction. The CHO^+ reacted further with H_2O to establish H_3O^+.

C_2H_2

C_4N^+ appeared to react with acetylene to produce predominantly C_5H^+ as shown in reaction [9]. The reaction was rapid,

$$[9]\quad C_4N^+ + C_2H_2 \rightarrow C_5H^+ + CHN$$

$k = 8.0 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}. The C_5H^+ rapidly reacted further by adding acetylene to produce $C_7H_3^+$. Because of insufficient resolution at the signal intensities of these experiments it was not possible to exclude the possibility of some (less than about 30%) formation of the $C_6H_2N^+$ adduct from the reaction of C_4N^+. There was no evidence for the occurrence of charge transfer or the formation of C_3H^+.

CH_3CN, CD_3CN

A rapid reaction was observed between C_4N^+ and acetonitrile, $k = 3.1 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}. Two products were formed in about equal amounts according to reaction [10].

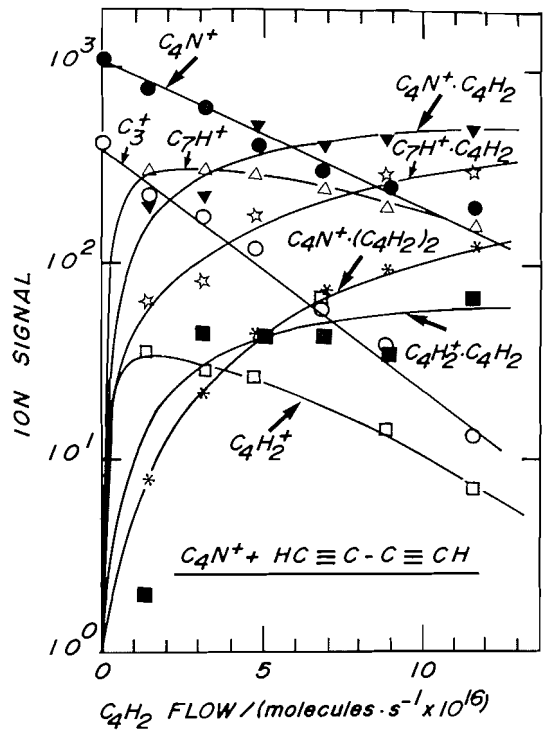

FIG. 2. The variations in ion signals observed for the addition of diacetylene into the reaction region of the SIFT apparatus in which the C_4N^+ cation is initially established in helium buffer gas. $P = 0.348$ mm Hg, $\bar{v} = 6.5 \times 10^3$ cm s^{-1}, $L = 46$ cm, and $T = 295$ K. The C_4N^+ is derived from allyl cyanide at an electron energy of 55 eV.

$$[10]\quad C_4N^+ + CH_3CN \xrightarrow{0.6} C_2H_3^+ + C_4N_2$$
$$\xrightarrow{0.4} C_4HN_2^+ + C_2H_2$$

Experiments with CD_3CN excluded CHN^+ and $C_5H_3N^+$ as possible reaction products. Trace amounts (about 1%) of an ion corresponding to the adduct $C_4N^+.CH_3CN$ were also observed to be formed as a primary product. The predominant primary products $C_2H_3^+$ and $C_4HN_2^+$ both were observed to react further by proton transfer to form CH_3CNH^+ which in turn rapidly added a molecule of acetonitrile to form the protonated dimer $(CH_3CN)_2H^+$.

H_2S

The reaction with hydrogen sulphide was observed to be rapid, $k = 8.9 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}, and to lead to a variety of products in the yields indicated in reaction [11].

$$[11]\quad C_4N^+ + H_2S \xrightarrow{0.60} CHS^+ + C_3HN$$
$$\xrightarrow{0.25} C_2NS^+ + C_2H_2$$
$$\xrightarrow{0.10} C_3HS^+ + HCN$$
$$\xrightarrow{0.05} C_4H_2NS^+$$

The occurrence of some charge transfer ($\lesssim 5\%$) could not be ruled out.

NH_3, ND_3

Charge transfer was the predominant reaction channel observed with ammonia. Other products observed were $C_3H_2N^+$ and CH_2N^+ and trace amounts ($\lesssim 1\%$) of the adduct $C_4H_3N_2^+$. The specific rate for the total reaction with ammonia was

1.5×10^{-9} cm^3 molecule^{-1} s^{-1}. Experiments with deuterated ammonia excluded $C_2N_2^+$, N_2^+, and $C_2H_4^+$ as possible reaction products. The branching ratios were determined with ND_3 to be as indicated in reaction [12]. The total rate constant with ND_3

$$[12]\quad C_4N^+ + ND_3 \xrightarrow{0.65} ND_3^+ + C_4N$$
$$\xrightarrow{0.20} C_3D_2N^+ + CDN$$
$$\xrightarrow{0.15} CD_2N^+ + C_3DN$$

was measured to be 1.2×10^{-9} cm^3 molecule^{-1} s^{-1}.

C_4H_2

The reaction of C_4N^+ with diacetylene was observed to be rapid, $k = 1.6 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}. The predominant channels were as indicated in reaction [13]. Figure 2 shows

$$[13]\quad C_4N^+ + C_4H_2 \xrightarrow{0.4} C_7H^+ + CHN$$
$$\xrightarrow{0.6} C_8H_2N^+$$

representative data. In determining the branching ratio for C_7H^+ account had to be taken of the production of some of the C_7H^+ ion from the C_3^+ ion which is initially present. The $C_4H_2^+$ observed in Fig. 2 could be attributed entirely to charge transfer with C_3^+. The adduct ion $C_4N^+.C_4H_2$ ($C_8H_2N^+$) was seen to add a second molecule of diacetylene.

Discussion and conclusions

The observed reactions of $:C_4N^+$ exhibit an interesting variety of products. Many of these products are consistent with the carbene character of this ion and may be rationalized in terms of σ bond insertion or in terms of coordination with an unbonded electron pair. The structure of the $:C_4N^+$ generated from allyl cyanide by electron impact is taken to be that in which the atom sequence is CCCCN as given in [2]. The heavy atom backbone of allyl cyanide is assumed to be maintained in the dissociative ionization and not to rearrange to a different atom sequence such as CCCNC, for example.

Possible coordination with an unbonded electron pair is evident from the high specific rate of the association reaction with carbon monoxide for which the product ion may be O=C=C=C=C=C=N:$^+$. The C_4N^+ also has nitrene character so that formation of :C=C=C=C=N$^+$=C=O is also plausible.

The reactions between $:C_4N^+$ and molecules of type HX are likely to proceed by carbene insertion into the H—X bond to give the substituted propargyl-like ion NC—C≡C—C$^+$(H)X which may then rearrange, dissociate or be collisionally stabilized. The collisionally stabilized adduct was observed as a partial product in the reactions with HX = H_2O, H_2S, C_2H_2, and C_4H_2, and as the exclusive product in the reactions with HX = HCN and HC_3N. Rearrangement to a substituted cyclopropenyl-like ion with subsequent decomposition or collisional stabilization has been advanced earlier as a possible reaction mechanism for the analogous reactions with the carbene cation $:C_3H^+$ (7, 8, 15). For reactions with $:C_4N^+$ the rearrangement with subsequent decomposition may be expressed in the following manner:

[14] NC—C≡C—C:$^+$ + HX → [NC—C≡C—C$^+$(H)X] → [cyclopropenyl-like ion] → NC—C≡C—H + :CX$^+$

A more direct mechanism involving 1,2 hydrogen migration in which the cyclopropenyl-like ion does not participate as an intermediate is also feasible and indeed may be preferred. The reaction products observed with CH_3CN are more consistent with a mechanism involving C—C bond insertion.

An inspection of the observed products suggests that the intermediate reaction complex is sufficiently long-lived in these reactions to allow proton transfer to occur before the products separate. This appears to be the case in the formation of $C_3H_2N^+$ and CHO^+ from H_2O and in the formation of $C_3D_2N^+$ and CD_2N^+ from ND_3. Also, two sets of ionic products in the reaction with methane may be connected in this manner, viz. $C_3H_2N^+/C_2H_3^+$ and $C_4H_3^+/CH_2N^+$. A long life-time for the intermediate complex may also have the consequence of allowing secondary carbene insertion steps before the products separate. Such steps would provide ready explanations for the observation of the bimolecular product ions other than $:CX^+$ (and ions derived from $:CX^+$ by proton transfer). For example, the products observed with H_2 may be accounted for by the following reaction sequence:

[15] $:C_4N^+ + H_2 \rightarrow$ [NC—C≡C$^+$H$_2$] → [cyclopropenyl-like ion] → [H—C≡C—H + :C_2N^+] → [H—C≡C—CH$^+$—CN] → :C_3H^+ + HCN

The reaction of C_2N^+ with acetylene has been measured separately in our laboratory and has been observed to produce C_3H^+ and HCN with high efficiency. A similar mechanism may apply to the formation of C_5H^+ from C_2H_2, C_7H^+ from C_4H_2, C_3HS^+ from H_2S, and $C_4H_3^+$ from CH_4.

Several of the reactions which have been identified in this study have implications for the chemistry of interstellar gas clouds where C_4N^+ is expected to be a likely reaction intermediate due to reaction [1]. First, the observed low reactivity of C_4N^+ towards molecular hydrogen suggests that this ion may be available for reaction with other, less abundant, constituents in interstellar gas clouds which are rich in molecular hydrogen. The degree to which this is the case will depend on the magnitude of the rate constant of reaction [3] at cloud temperatures which may be much less than the small rate constant of 2.2×10^{-11} cm^3 molecule^{-1} s^{-1} measured at 296 K if the reaction has a small activation energy. The availability of C_4N^+ in interstellar gas clouds may be much more sensitive to the presence of atomic hydrogen. Known heats of formation (16) indicate that the channels in reaction [16] are about

[16] $C_4N^+ + H \rightarrow C_4H^+ + N$
$\rightarrow C_3H^+ + CN$

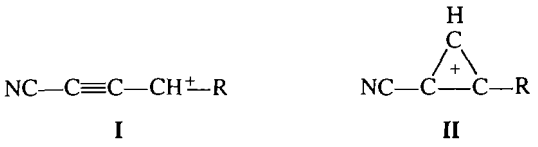
70 kcal mol^{-1} and 4 ± 8 kcal mol^{-1} exothermic, respectively, and so may be important loss processes in cloud regions richer in atomic hydrogen.

The measurements reported here indicate that the reaction with the second most abundant molecular gas CO can lead to loss of C_4N^+ in dense interstellar gas clouds only by radiative association as indicated in reaction [17]. The efficiency of this

[17] $C_4N^+ + CO \rightarrow C_5NO^+ + h\nu$

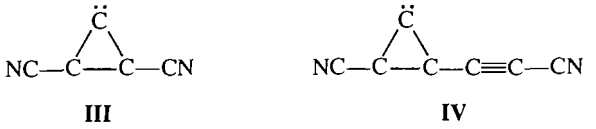
radiative association is uncertain but it may be noted that the specific rate of association observed at the higher pressures of our SIFT experiments is moderately large, viz. within a factor of ten of the collision rate. This result implies the formation of a moderately strong bond (17–19) and consequently a moderately high efficiency for radiative association (20).

The specific rates of association of C_4N^+ with HCN and HC_3N are within a factor of four of the collision rate. We have argued elsewhere that such high rates may be indicative of covalent bond formation in the adduct ion by C—H bond insertion (21). The much lower specific rates observed for the addition of a second molecule of HCN or HC_3N (which is more likely to lead to weaker electrostatic bonding) are consistent with such an interpretation. Covalent bonding with one molecule of HCN or HC_3N may result in acyclic or cyclic structures as indicated by ions **I** and **II** where R = CN or C_3N.



I **II**

Neutralization of these structures may lead to the acyclic disubstituted carbenes :C(CN)C_3N and :C$(C_3N)_2$ or the cyclic carbenes **III** and **IV** (10).



III **IV**

Interestingly, the reaction observed in the SIFT experiments with CH_3CN has quite different implications for molecular synthesis. The reaction between C_4N^+ and CH_3CN appears to be a suitable source for dicyanoacetylene. Sixty percent of this reaction leads directly to the neutral molecule C_4N_2 which is likely to be dicyanoacetylene. The remainder of the reaction leads to the protonated form of C_4N_2 which may subsequently neutralize to yield C_4N_2. One such neutralization event was observed in the proton transfer reaction between $C_4HN_2^+$ and CH_3CN. The proton affinity of dicyanoacetylene is not known but the latter observation establishes that PA (C_4N_2) < PA (CH_3CN) = 188.4 kcal mol^{+1} (22).

The rapid charge transfer reaction observed between C_4N^+ and ammonia provides a direct neutralization route for this ion in interstellar clouds which contain ammonia and is therefore a source for neutral C_4N.

The reaction with methane also has implications for molecular growth. In particular it appears to provide a source for diacetylene and cyanodiacetylene: 35% of the reaction either leads to C_4H_2 directly or to its protonated form, 5% of the reaction leads to $C_5H_2N^+$ which is likely to be protonated cyanodiacetylene, the remaining 60% appears to generate neutral or protonated cyanoacetylene. In the interstellar chemistry these latter products lead to chemical feedback in the sense that the cyanoacetylene will become available for reaction with C^+ which regenerates the C_4N^+.

The reactions of C_4N^+ with acetylene and diacetylene have the potential to lead to unsaturated or slightly saturated carbon chains and so represent contributing pathways to interstellar carbon and hydrocarbon molecules. Neutralization of the product ions C_5H^+ and C_7H^+ by proton transfer or electron/ion recombination may lead to C_5 and C_7, respectively, while neutralization by charge transfer will lead to the C_5H and C_7H radicals. Neutralization reactions of this type with interstellar molecules have been observed with C_3H^+, for example (8). The observation of the pentynylidyne radical C_5H has recently been reported for the circumstellar envelope of IRC + 10216 (23).

The reaction of chloro(triphenylphosphine)gold(I) with 1-methylthymine

R. FAGGIANI, H. E. HOWARD-LOCK, C. J. L. LOCK,[1] AND M. A. TURNER
The Laboratories for Inorganic Medicine, Institute for Materials Research, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 8, 1986

R. FAGGIANI, H. E. HOWARD-LOCK, C. J. L. LOCK, and M. A. TURNER. Can. J. Chem. **65**, 1568 (1987).

1-Methylthyminato-N^3-triphenylphosphinegold(I) was prepared by reacting chloro(triphenylphosphine)gold(I) with 1-methylthymine in aqueous methanol at pH 11. The product was examined by X-ray crystallography and was found to have the orthorhombic space group $C222_1$ (no. 20) with cell dimensions a = 12.760(7) Å, b = 11.530(2) Å, c = 31.893(5) Å, and eight formula units in the unit cell. Data were collected with use of MoKα radiation and a Syntex $P2_1$ diffractometer. The crystal structure was determined by standard methods and refined to R = 0.112 and R_w = 0.076 on the basis of 4760 unique reflections. Bond lengths and bond angles are normal. Packing in the crystal lattice is dominated by the triphenylphosphine rings which arrange roughly as blades of a propellor and are the source of the crystal's chirality. The title and related compounds were also examined by ^{1}H nmr, ^{13}C nmr, and vibrational spectroscopy.

R. FAGGIANI, H. E. HOWARD-LOCK, C. J. L. LOCK et M. A. TURNER. Can. J. Chem. **65**, 1568 (1987).

On a préparé le méthyl-1 thyminato N^3-triphénylphosphineor(I) en faisant réagir le chloro(triphénylphosphine)or(I) avec la méthyl-1 thymine, en solution méthanolique aqueuse et à un pH de 11. On a étudié le produit par diffraction des rayons-X et on a trouvé que les cristaux sont orthorhombiques, groupe d'espace $C222_1$ (no. 20), avec a = 12,670(7), b = 11,530(2) et c = 31,893(5) Å et Z = 8. On a recueilli les données en utilisant la radiation MoKα et un diffractomètre Syntex $P2_1$. On a déterminé la structure par les méthodes standards et on l'a affinée jusqu'à des valeurs de R = 0,112 et R_w = 0,076 pour 4760 réflexions indépendantes. Les longueurs et les angles de liaisons sont normaux. L'empillement dans le réseau cristallin est dominé par les cycles triphénylphosphines qui s'arrangent approximativement comme des hélices d'avion et qui sont la source de la chiralité des cristaux. On a aussi étudié le composé mentionné dans le titre ainsi que d'autres composés apparentés à l'aide de la spectroscopie rmn du ^{1}H et du ^{13}C ainsi que par spectroscopie vibrationnelle.

Introduction

The phosphine coordinated gold(I) complex, auranofin, is used in the treatment of rheumatoid arthritis (1). Unlike the other anti-arthritis gold drugs, auranofin has also shown evidence for anti-cancer activity in *in vivo* studies of P388 lymphocytic leukemia and sarcoma 180 tumors in mice (2–4). These results have prompted further investigation of the interaction of auranofin and analogous gold compounds with DNA both *in vivo* and *in vitro* (5–7).

Gel electrophoresis studies of compounds analogous to auranofin ([1,2-bis(diphenylphosphino)ethane]bis[chlorogold(I)] and chloro(triethylphosphine)gold(I), the synthetic precursor to auranofin), show an alteration in the mobility of pBR322 circular DNA, indicating *in vitro* binding of the gold complex to reactive sites on the DNA strand (8, 9). Auranofin itself showed no activity. These results complement those of Blank and Dabrowiak (10) who investigated changes in the absorption and CD spectra of nucleosides and calf thymus DNA in the presence of gold compounds. Again, activity was observed only when an easily displaced ligand was bound to gold (i.e. Cl^- or Br^- but not SR^-). Actual products of reaction were not isolated in these studies although interaction with DNA was observable *in situ*.

The characterization of gold compounds with nucleobases was begun on the basis of the electronic and structural similarity of Au(III) to Pt(II) (11). However, evidence obtained in XANES experiments (12) suggests that Au(III) is reduced to Au(I) *in vivo* (probably by free thiol groups on transport proteins such as albumin) before it enters the cell and becomes available for interaction with DNA. Gold(I) complexes with nucleobases have also been prepared and characterized by Mössbauer, nmr, and infrared spectroscopies (13–15). Beck *et al.* (16) have determined the structure of the complex of (triphenylphosphine)gold(I) with adenine, where the metal binds to the deprotonated N(9) position, a site occupied by the sugar group in biological systems. We have investigated the interaction of chloro(triphenylphosphine)gold(I) with 1-methylthymine and have characterized the resulting complex both by spectroscopic methods and X-ray diffraction.

Experimental section

1-Methylthymine (Fluka) was used without further purification. Analyses were performed by Atlantic Microlab, Atlanta, GA.

Potassium 1-methylthyminate

1-Methylthymine (0.2 g) was dissolved in 15 mL of distilled water. The pH of this solution was raised to 12 by addition of 5 *N* KOH. After heating for several minutes, the solvent was evaporated under reduced pressure and the residue was dried *in vacuo* at 80°C for 3 h. The resulting solid was used without further purification in infrared spectroscopy.

Chloro(triphenylphosphine)gold(I)

$HAuCl_4.3H_2O$ (1.00 g, 2.5 mmol) was dissolved in 20 mL distilled water and cooled in an ice bath. To this was added, dropwise, a solution of 500 μL (5.0 mmol) of thiodiglycol in 1 mL ethanol. An ethanol solution (20 mL) of 0.70 g (2.5 mmol) triphenylphosphine was added and the mixture was stirred for 30 min. The product was filtered and dried *in vacuo* for 12 h then recrystallized twice from dichloromethane/hexane. Yield 86%.

*1-Methylthyminato-N^3-triphenylphosphinegold(I) (**A**)*

1-Methylthymine (0.70 g, 5.0 mmol) was dissolved in 20 mL of distilled water and the pH was raised to 11.1 by addition of 0.5 *N* NaOH. A methanol solution (20 mL) of chloro(triphenylphosphine)gold(I) (2.47 g, 5.0 mmol) was added and the covered solution was stirred. After 6 h, all but 10 mL of the solvent was removed under reduced pressure and the resulting suspension was filtered, the precipitate washed with cold water, and dried *in vacuo*. Crystals suitable for diffraction were obtained by slow recrystallization from methanol/water (50/50 v/v) at 4°C. Yield 74%: (*Anal.* calcd. for $C_{24}H_{22}AuN_2O_2P$: C 48.2, H 3.7, N 4.7; found: C 48.3, H 3.9, N 4.6.

[a] $R_{int} = (\Sigma(N\Sigma(w(\langle F\rangle - F)^2))/\Sigma(N-1)\Sigma wF^2)^{1/2}$.
[b] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.
[c] $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)^{1/2}$.

magnetic resonance spectra were recorded on a Bruker WM-500 spectrometer. Samples for infrared spectroscopy (4000–250 cm^{-1} range) were prepared as KBr pellets (5–10% w/w) and spectra were recorded on a Perkin Elmer 283 spectrometer with use of polystyrene for calibration. Spectra in the 500–100 cm^{-1} range were obtained on an indene calibrated Nicolet 7199 FT-IR spectrometer from Nujol mulls between polyethylene plates. Raman spectra of powder samples excited by the λ 514.5 nm line from a Coherent Radiation Argon Laser Model 52 were recorded on a SPEX 14018. The spectra were calibrated against $HgCl_2$.

Collection of diffraction data and solution of the structure

The crystal of **A** used for diffraction was a colourless prism. Precession photographs showed the crystal to be orthorhombic. Cell parameters were obtained by least-squares refinement of the setting angles of 15 automatically centered reflections (19° < 2θ < 26°) on a Syntex $P2_1$ diffractometer with use of graphite monochromatized MoKα radiation (λ 0.71069 Å). Crystal data and other information related to data collection are given in Table 1. The crystal density was measured by flotation in an aqueous zinc chloride solution. Intensity data were measured at 22°C on the $P2_1$ diffractometer. The methods of selection of scan rates and initial data treatment have been described (17, 18). Corrections were made for Lorentz and polarization effects but not for absorption. Absorption corrections were attempted, but the crystal was of such a shape that an analytical correction was not possible. In addition, it was not possible to get adequately spaced strong high angle reflections for a proper χ-scan correction. Such a correction was attempted, but gave results no better than those presented here. Attempts to grow better crystals were unsuccessful. Ignoring the absorption correction will introduce a maximum error in F_o of 8%.

A three dimensional Patterson map was used to locate the Au atom. The positions of all the other non-hydrogen atoms were obtained from subsequent electron density difference maps. Further refinement of all parameters, including anisotropic temperature factors for all atoms, was done by full-matrix least-squares methods, and minimized the function $\Sigma w(|F_o| - |F_c|)^2$. Refinement was terminated when the maximum (shift/error) was less than 0.2. Peaks of residual electron density were very close to the Au atom. No attempts were made to locate the hydrogen atoms. Corrections were made for secondary extinction by the method used in SHELX.[2]

Since the space group was chiral, an alternative refinement was tested where $-x$, $-y$, $-z$ replaced x, y, z for all atoms. The structure converged to the larger R and R_w factors of 0.1213 and 0.0899; evidence that the correct enantiomorph had been chosen. Parameters were also refined to convergence with use of a truncated set of data where $I > 3\sigma$ (2685 reflections). The resulting R factors of 0.0594 and R_w of 0.0627 were significantly improved because of the deletion of a large number of weak reflections; however, esd's and consequent errors in bond lengths and angles increased. The parameters of the more accurate solution are reported as suggested by Seiler *et al.* (22). The atom parameters are listed in Table 2.[3]

*$U_{eq} = (1/3)(U_{11} + U_{22} + U_{33})$.

Results and discussion

Gold(I) is considered a soft or class b metal ion (24) and likely to interact with the relatively soft sites on DNA

[2]All calculations were carried out on CYBER 170/730 and 815 computers. The programs DATCO5 and DATRDN from the XRAY76 package (18) were used for preliminary treatment of data. The structure solution and refinement were done with use of the SHELX package (19), geometry calculations were done with NRC 22 (20), and diagrams were prepared with use of ORTEP (21).

[3]Tables of anisotropic temperature factors, dihedral and torsional angles, and moduli of F_o and F_c are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S7.

bases. In studies involving *cis*-dichlorodiammine platinum(II), (*cis*-DDP), Pt(II) binds preferentially at the N(7) position of guanine residues (25). However, in other experiments, when attempts are made to strip platinum off the DNA strand with cyanide ion, the small fraction of the metal which remains is bound to thymine residues (26). Reaction of Pt(II) with deprotonated thymine is apparently not reversible as with other bases. The pH at which this reaction occurs *in vitro* is higher than physiological pH and whether the reaction with thymine can occur *in vivo* is not known. Nevertheless, the possibility of metal assisted pK shifts or enzyme assistance can not be ruled out. We have shown that interactions of DNA bases with metals at one site can markedly affect the pK of another site. Thus the interaction of Pt(II) with N(7) of guanine causes an acid shift of the N1 proton of 1.6 pK units and Pt(II) can bind at pH 7 to the exocyclic O(4) or N(4) groups of 1-methylthymine, 1-methylcytosine, and 1-methyluracil by a process of deprotonation, even though the pK of the NH_2 group in 1-methylcytosine is formally >12. (The pK's of the OH groups in the enol forms of 1-methyluracil and 1-methylthymine are unknown.) This reaction apparently involves initial binding of another Pt(II) atom at N3 of cytosine (27). Because of evidence for the stability of a platinum–thyminate interaction, it was expected that gold would also form a stable compound, and it does.

The structure of 1-methylthyminato-N^3-triphenylphosphinegold(I) is shown in Fig. 1 and selected bond distances and angles are given in Table 3. The molecule itself is chiral because of the propellor-like arrangement of the phenyl rings on phosphorus. Bond lengths and angles involving gold, phosphorus, and the phenyl rings (C—C ave 1.42(3) range 1.35(4)–1.52(4), C—C—C ave 119(3)°, range 112(3)–125(2)°) are consistent with results for chloro(triphenylphosphine)gold(I) (28). Coordination to (triphenylphosphine)gold(I) which involves deprotonation at N3 has the effect on 1-methylthymine of lengthening the C(4)—O(4) bond distance to 1.31(2) Å in A vs. 1.237(4) Å in 1-methylthymine (29). In neutral 1-methylthymine, C(4)=O(4) is involved in hydrogen bonding and is therefore already a relatively long bond (cf. C(2)=O(2) 1.20(2) Å. The Au....O(4) distance is slightly shorter (3.04(2) Å) than the Au....O(2) distance (3.12(2) Å) which may indicate a slightly stronger Van der Waals interaction of the Au with the negative, more polarizable O(4). The C(5)—C(6) distance in the gold complex is shortened (1.30(2) Å) compared to that for 1-methylthymine

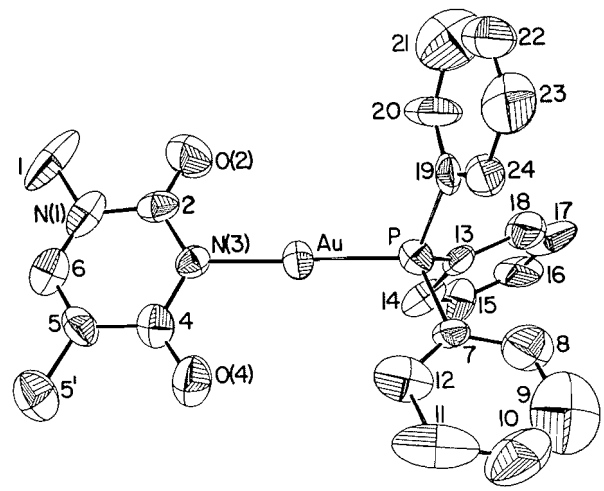

FIG. 1. 1-Methylthyminato-N^3-triphenylphosphinegold(I) showing the atom numbering. Carbon atoms are indicated by numbers only.

(1.346 Å (29)). A possible explanation may be that, since the hydrogen bonding holding the dimers together in 1-methylthymine is disrupted in the process of deprotonation in order to form the (triphenylphosphine)gold(I) complex, there is no longer electron delocalization from the C(5)=C(6) bond into the carbonyl group (see Fig. 3). No firm conclusions should be made, however, until the structure of 1-methylthyminate ion has been determined.

Other effects of gold binding on interatomic distances are the lengthening of the N(3)—C(4) (1.42(2) Å vs. 1.375(4) Å (29)) and N(1)—C(2) (1.44(2) Å vs. 1.379(4) Å (29)) distances. The C(4)—N(3)—C(2) angle (126.2(4)° in 1-methylthymine (28)) narrows to 122(2)° in **A**. Other angles (C(6)—N(1)—C(2), N(1)—C(2)—N(3), N(3)—C(4)—C(5), C(4)—C(5)—C(6)) in the ring open accordingly to compensate. (Triphenylphosphine)gold(I) is apparently more able to stabilize N(3) in an sp^2 form than the proton as it is a poorer electron acceptor. It has been observed for Pt(II) binding to cytosine that angle opening is not as great as that caused by protonation (30).

The packing is shown in Fig. 2. The molecules are arranged in sets of bilayers parallel to the ***ab*** plane. Within a given bilayer, molecules are oriented such that the thyminate–gold–

[a]Abbreviations: s = strong, m = medium, w = weak, v = very, sh = shoulder, br = broad.
[b]Raman peak intensity relative to strongest peak taken as 100.
[c](ph) refers to phenyl rings of triphenylphosphine.
[d](thy) refers to the thymine ring.
[e]For definition of q, r, t, u, y and *x*-vib (36) see Fig. 4.

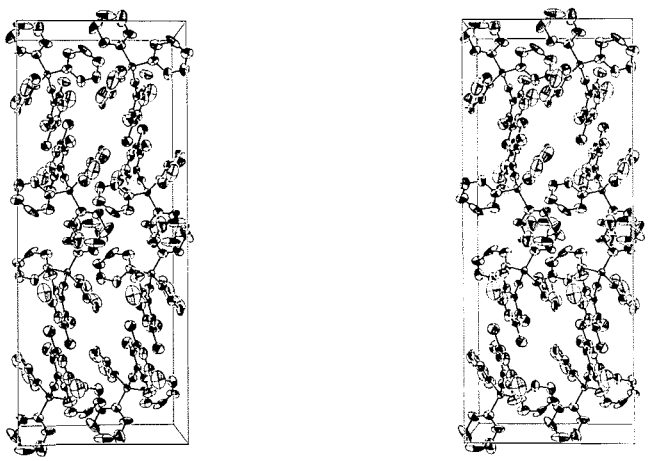

FIG. 2. The packing of 1-methylthyminato-N^3-triphenylphosphinegold(I) within the unit cell. ***a*** and ***c*** are parallel to the bottom and sides of the page and the view is down ***b***.

phosphine dipole is roughly in the ***b*** direction which will maximize any dipole–dipole interaction. In the adjacent bilayer in the ***c*** direction, dipoles are in the opposite direction along the ***b*** axis. The molecules are inclined from the ***b*** direction, however, such that there are hydrophobic layers formed by the phenyl groups at $z = 0, 1/2$ and hydrophilic layers formed by the thyminate groups at $z = 1/4, 3/4$.

The question arises as to why this crystal is chiral (as is the crystal of the starting compound, chloro(triphenylphosphine)gold(I)) (2), since the preparative reaction should give a racemic product. Surprisingly, in a compound with so many aromatic rings, there is very little evidence of any $\pi-\pi$ interaction of the rings, except for the small interaction of the thyminate group in one molecule with the C(7–12) ring of the adjacent molecule in the ***a*** direction related by the C centering operation. This interaction may be responsible for the rather small Au—P—C(7)—ring(C(7)) dihedral angle of 14°, but it is then unlikely to be the main cause of the chirality, since when the dihedral angle is 0° the phenyl ring exerts no selective force on the other rings in determining their configuration. Indeed, apart from the above interaction, there is no evidence of any interactions, other than van der Waals, which could cause the crystal to be chiral and we can see no good reason why the chiral space group is preferred.

The proton and carbon-13 nmr data for 1-methylthymine, potassium 1-methylthyminate, and 1-methylthyminato-N^3-triphenylphosphinegold(I) are given in Table 4. The positions of the peaks arising from methyl protons are similar in the three compounds. Small upfield shifts in the methyl resonances of the 1-methylthyminate ion (1.77 to 1.68 ppm and 3.24 to 3.15 ppm) compared to 1-methylthymine may be because the larger amount of electron density delocalized around the thymine ring has a shielding effect. On the other hand, (triphenylphosphine)gold(I) appears to be a better electron-withdrawing group than the proton, as the methyl peaks of the complex are shifted slightly downfield compared to those of the neutral ligand (1.77 to 1.86 ppm and 3.24 to 3.27 ppm). The effects of removal of the H(3) proton and its substitution by gold are more pronounced for H(6), the proton bound to C(6) than for the methyl groups. An upfield shift is observed (7.36 to 7.17 ppm) on deprotonation, again explained by the larger electron density in the ring. In the gold-substituted case, however, a further upfield shift (to 6.88 ppm) is observed, opposite to that noticed for the methyl groups external to the ring. We speculate that the downfield shift of the methyl resonances upon gold binding is an inductive effect caused by the electronegativity of the (triphenylphosphine)gold cation, whereas the upfield shift of H(6) is a result of increased electron density at the *para* position. Complexation to gold has also affected the electronic structure of thymine enough to eliminate the small coupling

(^4J 1 Hz) between H(6) and the C(5′) methyl protons observed in both neutral and anionic 1-methylthymine spectra.

Assignment of peaks in the carbon-13 nmr spectrum of 1-methylthymine in D_2O is in agreement with literature assignments for DMSO-d_6 solutions of thymine (31, 32).[4] The positions of peaks caused by the C(5′), C(1), and C(5) atoms change very little in the three compounds. The C(6) signal shows a significant upfield shift in the gold complex compared to the neutral and anionic species which is further evidence of the shielding power of electron density from the gold atom at the *para* position. Deprotonation has a marked effect on the resonance of C(2) and C(4). The electronegativity of the oxygen atoms appears to increase and deshield these carbon atoms. Complexation with gold partially compensates for the absence of the N(3) proton. C(4) is the carbon which shows the greatest sensitivity to changes in the electronic structure.

The vibrational spectra of 1-methylthyminato-N^3-triphenylphosphine gold(I) and related species are summarized in Table 5. Assignments were facilitated by previous vibrational analyses by Susi and Ard (34) on 1-methylthymine, Guay *et al.* (35) on 1-methylthyminate, and Whiffen (36) on monosubstituted benzenes, Shobatake and Nakamoto (37) on metal triphenylphosphines, and Shobatake *et al.* (38) on triphenyl compounds of group Va elements. Deprotonation at N(3) of 1-methylthymine, or substitution of this proton by a heavy metal ion, is expected to result in the disappearance of the N(3)—H modes (νN(3)—H at 3155 cm^{-1} and γN(3)—H at 897 cm^{-1}) of 1-methylthymine. Potassium thyminate bands occurring in the 2800 cm^{-1} to 3100 cm^{-1} region, caused by various C—H stretches, are unaffected by deprotonation or binding to gold.

The three peaks for 1-methylthymine in the 1600–1700 cm^{-1} region assigned to νC(2)=O(2) (1698 cm^{-1}), νC(4)=O(4), νC(5)=C(6) in-phase (1654 cm^{-1}), νC(4)=O(4), νC(5)=(6) out-of-phase (1638 cm^{-1}) (34) are all shifted to lower frequency (1663, 1610, and 1570 cm^{-1}, respectively) upon N(3) deprotonation. This can be explained by a decrease in double bond character because of electron delocalization throughout the O—C—N—C—O system, resulting from N(3) deprotonation.

The peak at 1525 cm^{-1} assigned to the "alternate bond stretch" (38) shows a very large increase in intensity in the infrared and Raman spectra of the anion compared to 1-methylthymine and agrees with results obtained for the anion (39). A similar assignment was made for the 1462 cm^{-1} peak in uracil (40). The increase in absorption is probably a result of a large dipole moment being created upon loss of the proton. Further changes in the frequencies of these bands are observed when gold is bound to 1-methylthyminate. It is expected that binding a heavy metal to N(3) would result in the release of electron density into the thymine ring, increasing the basicity of the carbonyl groups in agreement with nmr results. For the purpose of comparison, spectra of potassium 1-methylthyminate are more suitable than those of the neutral ligand, since 1-methylthymine exists in the solid as a dimer whose hydrogen bonding affects the nature of its conjugated bonds (see Fig. 3). At 1580 cm^{-1}, the peak arising from the νC(4)=O(4), νC(5)=C(6) out-of-phase mode is found 10 cm^{-1} higher in the complex than in the anion, and the in-phase mode at 1590 is 20 cm^{-1} lower (1610 cm^{-1} in the anion). The extent of lowering of the νC(2)=O(2) frequency (1663 cm^{-1} in 1-methylthyminate to 1655 cm^{-1} in **A** from 1698 cm^{-1} in neutral 1-methylthymine) is somewhat surprising in light of the C(2)=O(2) bond length. Such shifts indicate more single bond character in both the 1-methylthyminate ion and the ion bound to gold. It must be remembered, however, that the structure reported here is not particularly accurate, and the errors are such that the C(2)—O(2) bond in **A** may well be sufficiently longer than in the neutral molecule to explain the shift. There is no close interaction between Au and O(2) and O(4), as there is in the Ag complex (41).

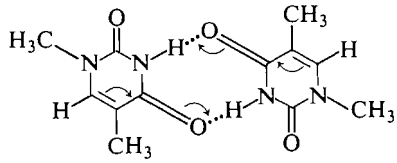

FIG. 3. Hydrogen bonding in the 1-methylthymine dimer (29).

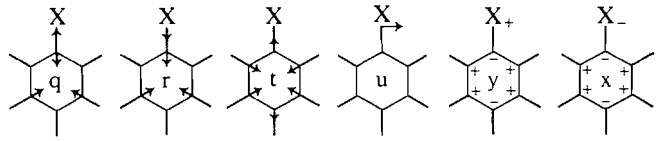

FIG. 4. Whiffen's *q*, *r*, *t*, *u*, *y* and *x* modes (36).

As an approximation, certain bands in the vibrational spectra of triphenylphosphine and triphenylphosphine gold chloride and the thyminato complex can be interpreted in terms of the spectra of monosubstituted benzene. Whiffen (36) has categorized the bands of monosubstituted benzenes into those vibrations which are and are not affected by changes in the substituent group. Six of the fundamental modes (Whiffen's *q*, *r*, *t*, *u*, *y*, and *x* bands, depicted in Fig. 4) are sensitive to substituent change. In the *q*, *r*, and *t* modes, there is vibration along the Ph—X bond (X = substituent), whereas *u*, *y*, and *x* are Ph—X bending vibrations. When triphenylphosphine is coordinated to either chlorogold(I) or 1-methylthyminato-N^3-gold(I), the *q*, *r*, and *t* bands are shifted to higher frequency, while the *u*, *y*, and *x* bands are not significantly shifted. The *q*-band at 1089 cm^{-1} in triphenylphosphine shifts to 1100 cm^{-1} in chloro(triphenylphosphine)gold(I), the *r*-bands shift from 688, 680 cm^{-1} to 705, 688 cm^{-1} and the *t*-bands shift from 425, 413 cm^{-1} to ≈450, 440 cm^{-1}. Of these, the *t*-bands show the larger shift.

In general, it is difficult to assign metal–phosphorus stretching bands because triphenylphosphine itself exhibits a number of bands in the low frequency region. In the past, the metal isotope substitution technique has been used for some complexes; for example, *trans*-Pd[P(C_6H_5)$_3$]$_2$$Cl_2$, and the bands having the larger isotopic shifts have been assigned to Pd—Cl and Pd—P stretching vibrations (37). The latter at 191 and 155 cm^{-1} seem to us to be very low and are more typical of metal–chlorine bending motions. Indeed, our experience with force constant analyses shows that bending vibrations can have a larger isotopic shift than stretching vibrations, depending on the interactions of force constants and the potential energy distribution. In the present work no bands can be assigned to purely Au—P or Au—N stretching modes. We expect the

[4]There is confusion in the literature about the assignment of the C4 and C6 ^{13}C nmr peaks. The Sadtler index (33) interprets the results of Krugh (31) such that the C4 and C6 peaks are interchanged compared to the assignment of Goldstein and Tarpley (32). Part of the problem arises because there is no explicit statement about the pyrimidine ring numbering in the work by Krugh; if it is assumed, however, that I.U.P.A.C. numbering is used the two sets of results are consistent.

Au—P modes to be strongly coupled to the vibrations of the triphenylphosphine ligand, and because the phenyl rings are "tilted" there will be a component of motion along the Au—P bond even for the ligand-bending vibrations. The ligand *t*-band is essentially P—phenyl stretch, and it will be coupled to the Au—P and Au—N stretching vibrations. In the ligand *x*-vibration, two of the phenyl rings contribute a component of motion along the P—Au—N axis and hence one can assume Au—N as well as Au—P coupling. It is reasonable for this "out-of-plane" phenyl ring bend to be at higher wavenumber than the "in-plane" *u*-vibration because it contains more phenyl–phenyl ring interaction.

The band at 181 cm^{-1}, absent in the thyminate complex, is typical of metal–chlorine bending vibrations, and is so assigned. Other low frequency bands are likely δNAuP, in-plane and out-of-plane motions (with respect to the plane of thyminate ring).

It is apparent that Au(I) can bind to DNA bases at similar positions to Pt(II) although, because of geometric requirements, any interactions with more than one base on a DNA strand will be different to those for *cis*-DDP. Thus, while any anti-cancer activity of gold(I) complexes may be the result of DNA base interaction, it is unlikely to be of the same type as *cis*-DDP. It will be worthwhile examining these differences in more complex polynucleotide systems.

A ^{13}C and ^{15}N nuclear magnetic resonance study of the protonation of a retinal Schiff base by acids of different pK_as and in solvents of different polarities

DANIEL COSSETTE AND DANIEL VOCELLE[1]

Département de chimie, Université du Québec à Montréal, C.P. 8888, Succ. A, Montréal (Qué.), Canada H3C 3P8

Received September 5, 1986

DANIEL COSSETTE and DANIEL VOCELLE. Can. J. Chem. **65**, 1576 (1987).

^{13}C and ^{15}N nuclear magnetic resonance spectra of mixtures of all-*trans*-retinylidene *tert*-butylamine (RtBA) and substituted acetic acids in equimolar concentrations in both $CDCl_3$ and CD_3OD were studied in relation to two questions: the nature of the state of protonation of a retinal Schiff base in the presence of carboxylic and mineral acids in solvents of different polarities, and secondly, to determine the nature of the interactions (if any) between the polar groups located on the acids and the polyenic chain of the retinal derivative. Using carboxylic acids of different pK_as and three mineral acids, we present results that indicate that, in solvents of low polarity, weak acids can only partially protonate RtBA while, in a more polar milieu, the protonation percentages are higher. With polar groups such as NO_2, Cl, Br, I, and CN, no specific interaction could be found between the polyenic chain of the imine and these groups. Variations in the intensity of certain peaks of RtBA were noted and these could possibly be related to the presence of the polar groups on the acids. Comparisons of our results with those obtained on rhodopsin and bacteriorhodopsin indicate that the milieu surrounding the chromophore must be polar if protonation is complete, while in a less polar environment partial protonation can be expected.

DANIEL COSSETTE et DANIEL VOCELLE. Can. J. Chem. **65**, 1576 (1987).

Les spectres de résonance magnétique nucléaire de ^{13}C et de ^{15}N de mélanges de tout-*trans*-rétinylidène *tert*-butylamine (RtBA) et d'acides acétiques substitués, en concentrations équimolaires dans des solvants comme $CDCl_3$ et CD_3OD, ont été étudiés relativement à deux questions : la nature de l'état de protonation d'une base de Schiff du rétinal en présence d'acides carboxyliques dans des solvants de polarités différentes, et deuxièmement, de déterminer la nature des interactions (si elles existent) entre les groupes polaires localisés sur les acides et la chaîne polyénique. Par l'utilisation d'acides carboxyliques ayant des pK_as variés et également de trois acides minéraux, nous montrons des résultats qui indiquent que dans des solvants de faibles polarités, les acides faibles ne peuvent protoner RtBA que partiellement tandis qu'en des milieux plus polaires, la protonation peut être complète. Avec des groupes comme NO_2, Cl, Br, I et CN, aucune interaction spécifique n'a pu être trouvée entre la chaîne polyénique de l'imine et ces groupes. Des variations dans l'intensité de certains pics de RtBA ont été aperçues qui peuvent possiblement être reliées à la présence des groupes polaires des acides. Des comparaisons de nos résultats avec ceux obtenus à partir de rhodopsine et de bactériorhodopsine indiquent que le milieu entourant le chromophore doit être polaire pour une protonation complète tandis qu'en milieu moins polaire une protonation partielle est probable.

Introduction

Several ^{13}C and ^{15}N nmr studies of visual and bacterial (1, 2) pigments and of related model systems (3–11) have been made recently and these techniques have been successful in revealing some important facts about the structure of these protein membranes. Still, the exact interactions between the chromophore (a Schiff base of retinal) and its surrounding protein moiety are not known. These interactions come, first, from protonation and the subsequent formation of a salt bridge between the protonated Schiff base and its counterion and, second, from interactions between the chromophore and some charged groups of the protein. In this last respect, negatively charged groups (probably carboxylate anions) located near C11–C13 for rhodopsin (12) and near C5 for bacteriorhodopsin have been proposed (13), as well as some positively charged groups around C7 for bacteriorhodopsin (2*d*). These works have relied heavily on studies made of model systems, especially those by Blatz *et al.* (14), and used all-*trans*-retinylidene *n*-butylamine (RnBA) and many strong acids as protonating agents. Blatz *et al.* were able to show that the λ_{max} of RnBA was strongly influenced by the strength of the binding between the counterion and the positively charged nitrogen atom of the azomethine function. As for the secondary interactions with charged groups, often called "the opsin shift" by the group headed by Nakanishi (13), several model systems have been built to show how these charges could operate and under what conditions (15).

For, interesting as they are, these models have inherent weaknesses: the shifts obtained are very small or the acids used are too strong or in too large excesses. It appears then especially important to devise a model system where the protonating acid would have an acidity strength similar to glutamic (pK_a 4.25) or aspartic acids (pK_a 3.89) since these two acids are likely candidates for both the protonation of the Schiff base and for secondary interactions (16). The question of the solvent to be used in these models is also highly important. It is not known as yet what is the polarity of the milieu surrounding the chromophore in both rhodopsin and bacteriorhodopsin. Some are proposing a nonpolar environment (17) while others (18) advocate a more polar one. At this stage, it appears interesting to conduct studies in both mediums.

Finally, ^{13}C and ^{15}N nmr spectroscopies are eminently suited for this type of work since both nuclei respond readily to the influences of charges. For all these reasons then, we have devised a model system of rhodopsin and bacteriorhodopsin that consists of all-*trans*-retinylidene *tert*-butylamine (RtBA) and several carboxylic acids having a large spectrum of pK_as (Fig. 1). The solvents used were chloroform, since it is a good nonpolar solvent, and methanol, because of its solvating capacity and its greater polarity. Since, in the pigments, it is probable that both the protonating agent and the charged group are in a 1:1 molar ratio with the chromophore, the same ratio was also used in our study. Finally, our model was investigated by high resolution ^{13}C nmr (at 100 MHz) and ^{15}N nmr (40.4 MHz) to detect as precisely as possible any effect by polar groups. This study follows a similar one made on a much simpler imine, *trans*,*trans*-2,4-heptadienylidene *tert*-butylamine (HBA), and many references will be made to it (19).

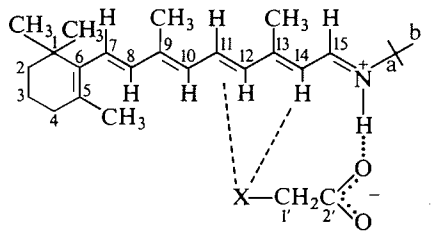

FIG. 1. All-*trans*-retinylidene *tert*-butylamine in the presence of a substituted acetic acid with numerotation used in the text.

Experimental

All-*trans*-retinylidene *tert*-butylamine (RtBA) was prepared according to a method already described (20). The use of the *tert*-butyl derivative instead of the more customary *n*-butylamine (RnBA) in the model of the visual pigment is based on the rationale that it is far more stable. Many hours are needed to take the ^{15}N nmr spectra, and this added stability becomes quite an important asset. It must be remembered that aldimines can enter into many reactions: among them, hydrolysis and polymerization can become a real nuisance, especially in acidic solutions (21). In this study, great care has been taken to prevent these secondary reactions and ^{13}C nmr spectra were obviously free of them (absence of unrelated peaks), while for ^{15}N nmr spectra this question is less clear. The facts that the chemical shifts found were linearly correlated with the pK_as of the acids (see Results and discussion), that often only a few hundred scans were necessary, and that visual inspection of the sample after the nmr analysis showed only slight increase in coloration, are good indications that RtBA was fairly stable during the time required to take the spectra. Nevertheless, completely anhydrous conditions (dry box, N_2 atmosphere), freshly distilled imine, absence of direct light, and relatively rapid time of analysis are important parameters in taking good nmr spectra of this Schiff base.

Solution concentrations for ^{13}C nmr spectra were of the order of 0.07 *M* and of 0.6–1 *M* for ^{15}N spectra; the ratio of Schiff base to acid was always 1:1. In the case of RtBA – propionic acid, the conditions used differed slightly since good spectra are surprisingly difficult to achieve with this acid; 0.05 *M* chromium acetate was added to the solution to assure better contacts. Deuterated chloroform and deuterated methanol were used as solvents and to ensure a good lock. The spectra were taken on a high resolution Bruker WH 400 instrument at a frequency of 100 MHz for ^{13}C and 40.4 MHz for ^{15}N. The ^{13}C proton noise-decoupled spectra resulted from 400–600 scans taken with rf pulses of 5 μs, a pulse angle of 45°, at intervals of 3.2 s. The unprotonated NtBA ^{15}N proton noise-decoupled spectra resulted from 2000–5000 scans with rf pulses of 12 μs, an angle of 90°, a pulse delay of 1.6 s, and an acquisition time of 0.4 s; the protonated Schiff base permited the use of the INEPT sequence (22) and only 200–400 scans were then necessary.

All ethylenic ^{13}C atoms were obtained as separate peaks for the protonated Schiff base. Identification of all peaks was done as follows. First of all, the ^{13}C nmr spectrum of RnBA in $CDCl_3$ has already been analyzed by Mateescu and co-workers (3*c*) and all the peaks have been identified. Since RtBA is an imine quite similar to RnBA, the same assignations could have been made. Nevertheless, a complete analysis was done using 2D nmr. Figure 1 shows our model with the numerotation of carbon atoms retained in this paper. Carbon atoms a, b, 15, 13, 9, 6, 1′, and 2′ are easily identified by their specific chemical shifts or by their intensities. Carbon atoms at 14, 12, 11, 10, 8, and 7 are somewhat more difficult to assign. First, it must be remembered that all odd-numbered atoms are deshielded while all even-numbered ^{13}C are shielded (zigzag pattern, see Results and disscusion). To ascertain the exact position of the protons, a normal proton–proton COSY 2D (23) was done followed by a long-range cross-section proton–proton COSY 2D. These two operations allowed the right assignations of all protons located at 14, 12, 11, 10, 8, and 7. Following these proton assignations, a 2D proton–carbon correlation allowed the proper identification of all carbon atoms. The assignations were identical with those published.

Results and discussion

^{13}C nuclear magnetic resonance results

Chemical shifts of C5–C15 are presented in Table 1 for spectra of RtBA and acids in equimolar concentrations in $CDCl_3$ and in Table 2 when the solvent was CD_3OD. In parentheses are given the differences in chemical shifts ($\Delta\delta$) obtained by subtracting, for a given carbon atom, the chemical shift of that carbon from the corresponding system with acid (e.g. C15[RtBA–acid] − C15[RtBA]). As typical examples, ^{13}C nmr spectra of RtBA – 3-nitropropanoic acid in CD_3OD and RtBA–TCA appear in Figs. 2*a* and 2*b* respectively.

In deuterated chloroform, Table 1 indicates deshielding (positive sign) for all odd-carbon atoms and shielding (negative sign) for even-numbered ones. Deshielding is greatest for C13 and it decreases as the distance of the carbon atom from the azomethine group increases. Figure 3 shows the zigzag pattern obtained when, for a given acid (in this case trichloroacetic acid (TCA) in $CDCl_3$), the $\Delta\delta$ are plotted against the position of the carbon atoms. This pattern originates from the fact that all odd-numbered carbon atoms are in a resonance position. If a curve is drawn by joining the tips in the zigzag pattern (dash line in Fig. 3) or, even better, if curves between ln $\Delta\delta$ and the carbon atoms are drawn (Fig. 4), the expected deshielding for C15 should be far more important than the one actually measured. It is worth mentioning that curves such as the one shown in Fig. 4 have correlation coefficients of 0.98 and more. For TCA, HCl, HBr, and HI, these calculated deshieldings are shown in Table 3. The difference between the expected C15 deshieldings and the actual values can be evaluated by subtracting values of Table 1 from those of Table 3. The actual very weak deshieldings experienced by C15 have been explained by Sharma and Roels (24) on the basis of a shielding effect due to a marked decrease in the anisotropy of the C=N bond on protonation, a shielding that is counterbalanced by the strong deshielding effect of having a C^+—N bond (resonance position). This difference between the expected value and what is actually obtained is then a measure of the loss of anisotropy of the C=N bond and consequently is a measure of the degree of protonation. From a previous study of these same systems by FTIR (25) and from works done on HBA (19), we can safely postulate that mineral acids are able to completely protonate NtBA. Consequently, a difference of 26 ppm between the expected and the actual deshieldings signifies full protonation. For the medium strong acids (like chloroacetic acid), the difference is about 16 ppm, which implies a percentage of protonation of 60–70%, while for the weak acids the value is about 5–10%.

Another way of calculating these degrees of protonation is by comparing the $\Delta\delta$ of C13 (or C11) for all the systems studied. Again, from Table 1, it is possible to postulate that a deshielding value of approximately 17.5 ppm corresponds to complete protonation. From the same table, it is quite easy to measure the degree of protonation caused by propionic acid (9% protonation) and by chloro, fluoro, and cyanoacetic acids (60–70% protonation). Both methods give the same value.

Now, if we compare the degrees of protonation of RtBA with the simpler imine HBA (19), we find that propionic acid gives different values for both imines (10 and 20% respectively) while monohalogenated acids give the same percentages (60–70%) and cyanoacetic acid also gives similar values (70–80%). The

[a]In parentheses, the difference in chemical shifts between RtBA and RtBA–acids.

similarity of both systems makes HBA, even though much simpler, a reasonable model of the chromophore of rhodopsin. The reason for this similarity can be found by comparing Tables 1 and 2; it appears clear that in NtBA the perturbation caused by the presence of the acid is felt by all ethylenic carbon atoms but the effect is stronger for C11–C15, a region that corresponds to HBA. These two methods of calculating the percentages of protonation appear theoretically valid since all $\Delta\delta$ for all carbon atoms are linearly correlated with the pK_as of the carboxylic acids (measured in water). Correlation coefficients of 0.996 for C15, 0.998 for C14, 0.994 for C13, 0.990 for C11, and 0.995 for C9 are good examples of this behavior. These good correlation coefficients between $\Delta\delta$ and the pK_as imply also that the polar groups located on the acids (like Cl, F, etc.) do not significantly alter the chemical shifts of the ethylenic carbons of the retinal Schiff base.

The interaction of the polar groups with the polyenic chain might possibly be revealed by the peak intensities of C11 and C14. Depending on the acids and solvents used, the intensities of the peaks of RtBA in the ethylenic region vary considerably. Table 4 shows the ratio obtained by relating the integration of the peak relative to that of C8. That carbon atom was chosen because it is located rather far away from the azomethine function and its intensity remained constant for all cases studied. In deuterated chloroform, the intensity of the C15 peak is slightly affected (as based on its surface integration) by the presence of acids. The C14 and C11 peaks behave similarly: their intensities decrease more than half in the presence of acids substituted by polar groups. In deuterated methanol the C14, C11, and C15 peaks are affected when in the presence of weak to medium strong acids. It is difficult to ascribe these losses of intensity to one particular cause. However, since mineral acids affect very slightly the intensities of these peaks in both $CDCl_3$ and CD_3OD while substituted acetic acids are able to do so more strongly, this could possibly indicate an interaction of the polar groups with the ethylenic carbon atoms of RtBA. With HBA these losses of peak intensities were not present since the molecule is much smaller than RtBA. Pattaroni and Lauterwein (11), in their remarkable ^1H and ^{13}C nmr studies of protonated and unprotonated RnBA, present spectra that show the same variation in peak intensities. In conclusion then, polar groups attached to the protonating agents do not alter significantly the

spectra of the retinal Schiff base except by possibly reducing the peak intensity of some carbon atoms of the polyenic chain. We have indicated in a previous paper (26) that ^1H nmr data obtained from these same systems could be interpreted by assuming point-charge interactions between the polar groups of the acids and the polyenic chain of the Schiff base. There is no inconsistency between both statements since proton nmr may well be more sensitive to such effects than ^{13}C nmr. This can be shown by looking at the nmr data for position 14. Table 1 shows that C14 is not as shielded as C13 is deshielded while ^1H nmr indicated that it was H14 that was the most strongly deshielded proton.

The mineral acids induce chemical shifts on RtBA that do not correlate well with those of the carboxylic acids, and Table 1 shows that TCA, HCl, and HBr affect RtBA roughly the same way even though their pK_as are quite different. It seems that when the Schiff base is fully protonated, as undoubtedly it is with these acids, the chemical shifts of the carbon atoms respond weakly to other effects. HI behaves somewhat differently since its action on RtBA is much stronger than the others (but still in the right direction). We do not know why this is so but it must be remembered that, compared to the others, iodide is a very big counterion, which binds weakly with the protonated Schiff base in chloroform (*2a*).

In deuterated methanol, the ^{13}C nmr data show the same zigzag pattern as previously described and Table 2 indicates that this solvent, compared to $CDCl_3$, induces a more pronounced deshielding by some 3 ppm for C15. Furthermore, protonation is much more important. Using the same methods as described earlier, we find that all three strong acids (TCA, HCl, and HBr) have roughly the same chemical shifts (levelling effects) and that protonation is complete. Considering that a $\Delta\delta$ of 10 ppm for C11 indicates 100% protonation (see Table 2), we then find the following protonation percentages: propionic acid, 43%; 3-nitropropanoic acid, 73%; and iodoacetic acid, 86%. For HBA, the protonation percentages for these same systems were 20–30%, 60–70%, and 80–90% respectively. RtBA is then slightly more protonated than HBA under the same conditions, quite probably because of increased stabilization of the protonated Schiff base due to more extended conjugation. Nevertheless, HBA again appears a good model for the more complexed RtBA and the same conclusions can be applied for both systems.

^{15}N nuclear magnetic resonance data

Values obtained by this method appear in Table 5. Since more than 100 ppm separates the values of protonated and unprotonated Schiff base (27, 28), ^{15}N nmr is particularly good in calculating precise protonation percentages. In deuterated chloroform, if we accept that a chemical shielding of approximately 150 ppm (between NtBA and NtBa–HCl) corresponds to 100% protonation, then the protonation percentages are the following: propionic acid, 25%; chloroacetic acid 75%; TCA 95%. Again we note that HI exerts a very strong shielding effect and the same reasoning that we advanced before can also be applied here. It is also comforting to observe the close similarity of these results with those obtained by ^{13}C nmr. The percentage is greater than expected for propionic acid but still it is the one that protonates RtBA the least. Shielding, as

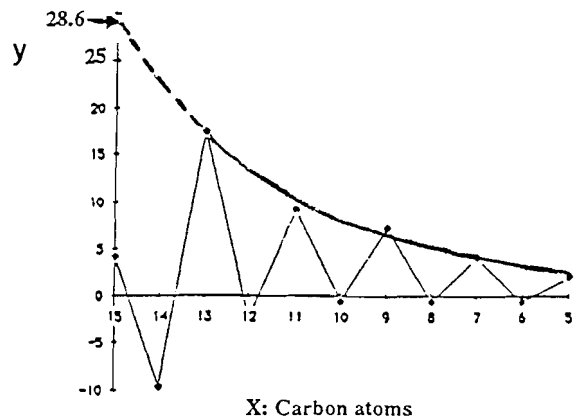

FIG. 3. Zigzag pattern representing the actual deshielding values (y) of specific carbon atoms (x) of RtBA when in the presence of an equimolar concentration of trichloroacetic acid in $CDCl_3$. The dashed line represents the expected deshielding for C15.

expected, is more important in deuterated methanol. There is some 14 ppm difference between the nonpolar $CDCl_3$ and the polar CD_3OD for RtBA. Protonation is also more pronounced in methanol. By using the same method as described before, the percentages of protonation are 39% for propionic acid, 90% for iodoacetic acid, and all three strong acids are evidently 100% protonated. These degrees of protonation compare remarkably well with those found by ^{13}C nmr or when compared with the related HBA system.

Comparisons with other systems

The usual model system of rhodopsin and bacteriorhodopsin is all-*trans*-retinylidene *n*-butylamine (RnBA) and its salts, usually the hydrochloride. The fact that we used a *tert*-butyl group implies that a correction must be made to account for the difference in structure. This correction factor can be determined by comparing our ^{13}C nmr results with those obtained on RnBA. The unprotonated Schiff base has been studied using ^{13}C nmr by

Mateescu and co-workers (3*c*), by Pattaroni and Lauterwein (11), by Rabiller and Danho (10) (in this case, the all-*trans*-retinylidene Schiff base made with $H_2N(CH_2)_3CO_2t$-Bu was used as a reference), and finally by Inoue *et al.* (5). All these groups measured the chemical shifts of RnBA (or analogs) for C5–C15 and the solvents used were $CDCl_3$, CD_2Cl_2, and CCl_4. Comparisons with their results indicate that the chemical shifts of C5–C14 are all very similar except for the data found by Inoue in CCl_4. Harbison *et al.* (2*b*) also published data on the solid-state ^{13}C nmr of RnBA; again the values differed considerably from those obtained in CD_2Cl_2 or $CDCl_3$. Because of these differences we used as a base of comparison only those data obtained in these two solvents. For RnBA, C15 values were also very similar: the average value was 159.5 ppm. When this chemical shift is compared to that for RtBA (153.8), a difference of 5.7 ppm is found. It represents the shielding brought by the *tert*-butyl group on C15. In deuterated methanol, the correction for the *tert*-butyl can be determined by comparing our results with those of Inoue *et al.* (5) on RnBA. Again values for C5–C14 are very similar except for C11, where there is a difference of 1.8 ppm. For C15, a correction factor of 4.6 ppm is needed. Spectra of RnBA–HCl were also recorded by Mateescu in both $CDCl_3$ (1*d*) and CD_2Cl_2 (3*c*), by Harbison for solid-state samples (4), and by Inoue in CD_3OD (5). In deuterated methanol the C5–C14 region has chemical shifts that are similar to the data of Table 2. For RnBA–HCl in $CDCl_3$ and in CD_2Cl_2, all odd-numbered carbon atoms had chemical shifts that were different in these two nonpolar solvents, the difference being smaller as the distance from the azomethine function increased. When these two spectra were compared to those of RtBA, the same situation arose. Since both RtBA–HCl and RnBA–HCl spectra were taken in $CDCl_3$ we can evaluate the impact of the *tert*-butyl group on the polyenic chain. The values are 6.27 ppm for C15, 1.55 for C13, 0.59 for C9, 0.45 for C7 and 0.37 ppm for C5. Finally, a comparison can be established between our RtBA–TCA system in $CDCl_3$ and Pattaroni and Lauterwein's system of RnBA–TFA in CD_2Cl_2. Since the chemical shifts are very similar in these two solvents, TCA and trifluoroacetic acid should induce similar effects on the Schiff base since their pK_as are very close. This being the case, the differences between both systems are for C15 = 5.6, C13 = 1.62, C11 = 1.08,

TABLE 5. ^{15}N chemical shifts of RtBA in presence of acids in deuterated chloroform and deuterated methanol at 25°C

C9 = 0.78, C7 = 0.36, and C5 = 0.51 ppm. These differences are similar to those found previously for HCl.

Let us compare now our results with those obtained with the natural pigments. Mateescu *et al.* (1*f*) found, for rhodopsin solubilized in octyl β-glucoside, 165.9 ppm for C15, 130.0 ppm for C14, 168.1 ppm for C13, 148.8 ppm for C9, and 137.0 ppm for C6. For bacteriorhodopsin, the values were 166.0, 130.0, 168.9, 148.5, and 135.6 ppm respectively. By CP-MAS, these same authors found 150 for C15 and 143.7 ppm for C13. Yamaguchi *et al.* (6) found, for bacteriorhodopsin in octyl β-glucoside, 118.9 ppm for C14 and 169 ppm for C15. Harbison *et al.* (2*b*), using the CP-MAS technique, found 122.0 ppm for C14, 134.3 for C12, 139.1 for C11, and 133.0 ppm for C10 for the all-*trans* isomer of bacteriorhodopsin. From these works we note immediately that thin films give chemical shifts that differ considerably from those in solutions. With models, the same differences were also noted. Another discrepancy can be seen for C14: Mateescu finds a value of 130 ppm for this atom, while for Yamaguchi the value is 118 ppm. Since there is little doubt that the chromophore of bacteriorhodopsin is protonated (29), a value of 130.0 ppm simply cannot fit. By comparison with models (including our own presented in this paper), a protonated chromophore must have a chemical shift in the 120-ppm region. For these reasons, we prefer retaining a value near 120 ppm for C14. For solubilized rhodopsin the following comparisons can be made. In deuterated chloroform, C15 has values ranging from 160.72 to 164.33 ppm after applying a correction factor of 6.27 ppm uniformly from propionic acid to HI in Table 1. In deuterated methanol, C15 has values ranging from 164.0 to 167.4 ppm (correction factor of 4.9 ppm) for the protonated species. Since Mateescu finds 166 ppm for this carbon atom in rhodopsin, it follows that our model in deuterated methanol resembles rhodopsin much more than it resembles the one in $CDCl_3$. It could possibly signify that the environment surrounding the chromophore in rhodopsin has a polarity similar to methanol. This statement can be extended to bacteriorhodopsin, which must have an environment even more polar than rhodopsin since a value of 169 ppm is found for C15. This is in concordance with the works of Rafferty and Shichi (30) and Hildebrandt and Stockburger (31), which indicated water molecules around the chromophore. If we compared the value of 118 ppm obtained by Yamaguchi for C14 of bacteriorhodopsin with our own C14 values in CD_3OD (no correction needed here), we find that C14 has values ranging from 125.57 to 120.27 ppm. These data mean that for medium strong acids, the Schiff base in CD_3OD is more shielded than in $CDCl_3$. This implies that if the environment surrounding the chromophore is more polar than methanol, shielding could well reach 118 ppm.

What can we say about the protonating agent? For rhodopsin, Glu and Asp have pK_as similar to 3-nitro propanoic acid. In CD_3OD, this acid induces a corrected chemical shift for C15 of 165.7 ppm (that is, 160.82 + 4.9). This compares very well with the 165.9 ppm found by Mateescu. This similarity in the results indicates that Glu and Asp can partially protonate the Schiff base (around 75%). For bacteriorhodopsin, Glu and Asp can well be the protonating agents, since in a very polar milieu these two acids are able to fully protonate a Schiff base. It is interesting to note that if we extrapolate the chemical shift of C14 for the system RtBA – propionic acid to a solvent like water, a value of 119.8 ppm is found. For a stronger acid this value could well reach 118 ppm and even less.

Studies of our ^{15}N nmr with those obtained on models or on natural pigments are limited by two facts: many different sample states have been used so that comparisons with other works are difficult and there has been, to our knowledge, no study done on the solubilized pigments. The ^{15}N nmr spectra of bacteriorhodopsin were obtained by CP-MAS techniques using lyophilized samples. Mateescu *et al.* (1*d*) and Harbison *et al.* (2*a*) used this technique and obtained different results, probably because of differences in the way of preparing the samples. Mateescu *et al.* (1*f*) mentions a fact that we consider highly important: the degree of protonation of the chromophore seems to be regulated by the degree of hydration of the sample. This statement is in line with what we think of the environment surrounding the chromophore in both rhodopsin and bacteriorhodopsin. If water molecules do exist near the Schiff base, lyophilization under high vacuum should extract much of it and, consequently, will affect the degree of protonation of the Schiff base since the milieu will become less polar. Correspondingly, if water molecules are used in a proton transfer relay (32, 33), its absence will also cause the Schiff base to become unprotonated. Our data in deuterated chloroform confirm this fact, that rather weak acids like Glu and Asp can fully protonate a retinal Schiff base only in a very polar milieu. This does not prove that there are water molecules in the vicinity of the chromophore but indirectly suggests that water could create conditions favorable to full protonation. If we compare our results with those of Mateescu and co-workers (3*c*) in dichloromethane, we find that a correction of some 20 ppm is needed for the *tert*-butyl group of unprotonated RtBA and of 14 ppm for the hydrochloride salt.

Acknowledgements

The authors wish to express their sincere thanks to Professor Camille Sandorfy for helpful discussions and to the Laboratoire régional de RMN à haut champ (Dr Phan Viet Minh Tan) of the Université de Montréal for all ^{13}C and ^{15}N nmr spectra. It is a pleasure to acknowledge the financial help of the National Research Council of Canada (grant A0943) and of the Université du Québec à Montréal.

The characterisation and X-ray crystal structure of pentabromodiselenium hexafluoroarsenate, $Se_2Br_5AsF_6$; some thermodynamic considerations and the nonexistence of $Se_2I_5AsF_6$

MICHAEL P. MURCHIE, JACK PASSMORE, AND PETER S. WHITE

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received September 26, 1986[1]

MICHAEL P. MURCHIE, JACK PASSMORE, and PETER S. WHITE. Can. J. Chem. **65**, 1584 (1987).

The crystal structure of $Se_2Br_5AsF_6$ was determined by low-temperature X-ray diffraction methods. Single crystals of $Se_2Br_5AsF_6$ are rhombohedral, space group $R3$ with $a = 13.367(4)$ Å, $c = 19.000(6)$ Å, $V = 2940$ Å^3, and $Z = 9$. The structure was refined to final agreement indices of $R = 0.087$, $R_w = 0.093$ for 604 observed ($I > 3\sigma(I)$) reflections and 71 parameters. The structure consists of essentially discrete $Se_2Br_5^+$ cations and AsF_6^- anions with some cation–anion interaction. The $Se_2Br_5^+$ cation, of essentially C_{2h} symmetry contains two *trans* $SeBr_2$ units, linked by a bridging bromine atom. The two terminal selenium–bromine bond distances are 2.291(7) and 2.268(6) Å, of bond order 1, and the angle between them is 100.0(3)°. The bridging bromine atom lies at the inversion centre of the $Se_2Br_5^+$ cation, with an Se—Br distance of 2.582(3) Å, corresponding to a bond order of about 0.5. The two angles between the bridging Se—Br and terminal Se—Br bonds are 97.4(1)° and 98.9(2)°. $Se_2Br_5AsF_6$ decomposes slowly at room temperature and rapidly at 100°C leading to the formation of $SeBr_3AsF_6$, $SeBr_4$, and elemental selenium. It reacts with Br_2 to give $SeBr_3AsF_6$ and $SeBr_4$. $Se_2Br_5AsF_6$ is prepared by the reaction of $Se_4(AsF_6)_2$ and the appropriate quantity of Br_2. The analogous reaction with I_2 leads to $I_2SeSeSeSeI_2(AsF_6)_2$ and not $Se_2I_5AsF_6$. These differences have been accounted for on the basis of estimates of the appropriate bond and crystal lattice energies. The ^{77}Se nmr of $SeBr_3^+$ and $Se_2Br_5^+$ in SO_2 solution, and the Raman spectrum of $SeBr_4$ are reported.

MICHAEL P. MURCHIE, JACK PASSMORE et PETER S. WHITE. Can. J. Chem. **65**, 1584 (1987).

Faisant appel à des méthodes de diffraction des rayons-X à basse température, on a déterminé la structure cristalline du composé $Se_2Br_5AsF_6$. Les monocristaux de $Se_2Br_5AsF_6$ sont rhomboédriques, groupe d'espace $R3$, avec $a = 13{,}367(4)$ et $c = 19{,}000(6)$ Å, $V = 2940$ Å^3 et $Z = 9$. On a affiné la structure jusqu'à des valeurs finales de $R = 0{,}087$ et $R_w = 0{,}093$ pour 604 réflexions indépendantes avec ($I > 3\sigma(I)$) et 71 paramètres. La structure comporte essentiellement des cations $Se_2Br_5^+$ et des anions AsF_6^- individuels qui interagissent faiblement l'un avec l'autre. Le cation $Se_2Br_5^+$, dont la symétrie est essentiellement C_{2h}, contient deux unités $SeBr_2$ *trans* qui sont liées par un atome de brome. Les distances des deux liaisons sélénium/brome terminales sont égales à 2,291(7) et 2,268(6) Å, d'ordre de liaison 1, et l'angle entre ces liaisons est égal à 100,0(3)°. L'atome de brome qui agit comme pont se trouve au centre d'inversion du cation $Se_2Br_5^+$ et la distance Se—Br de 2,582(3) Å correspond à un ordre de liaison d'environ 0,5. Les deux angles entre les liaisons Se—Br (servant de pont) et Se—Br (terminale) égalent 97,41(1)° et 98,9(2)°. Le $Se_2Br_5AsF_6$ se décompose lentement à la température ambiante et rapidement à 100°C pour conduire à la formation de $SeBr_3AsF_6$, de $SeBr_4$ et de sélénium élémentaire. Il réagit avec le Br_2 pour conduire au $SeBr_3AsF_6$ et au $SeBr_4$. Le $Se_2Br_5AsF_6$ se prépare par réaction du $Se_4(AsF_6)_2$ avec une quantité appropriée de Br_2. La réaction analogue avec du I_2 conduit au $I_2SeSeSeSeI_2(AsF_6)_2$, non pas au $Se_2I_5AsF_6$. On peut expliquer ces différences en se basant sur une évaluation des énergies de liaison et de réseau cristallin appropriées. On rapporte aussi les spectres rmn du ^{77}Se du $SeBr_3^+$ et du $Se_2Br_5^+$, en solution dans le SO_2, ainsi que le spectre Raman du $SeBr_4$.

[Traduit par la revue]

Introduction

Various neutral selenium bromides are known (ref. 1, p. 219) reminiscent of the chlorides (ref. 1, p. 134), and in contrast to the iodides (ref. 1, p. 272) which are nonexistent. The structures of the neutral selenium bromides α- and β-$SeBr_4$ (4) and α- and β-SeBr (5, 6) have been determined by X-ray crystallography, while $SeBr_2$ has been identified by Raman and uv–visible spectroscopy (7). The selenium–bromine anion, $SeBr_6^{2-}$, has been shown to have an octahedral structure by infrared and Raman spectroscopy (8), and X-ray crystal structures of the novel anions $SeBr_4^{2-}$ and $Se_2Br_6^{2-}$ (with $[P(C_6H_5)_4^+]_2$ counterions) have been determined (9). The only binary selenium–bromine cation to be characterised fully is $SeBr_3^+$, prepared as the salt of the weakly basic AsF_6^-, SbF_6^- (10), $AlCl_4^-$ and $AlBr_4^-$ (11) anions. The Raman spectra of $SeBr_3MF_6$ (M = As, Sb) (10) showed the $SeBr_3^+$ cation to have essentially C_{3v} symmetry, with stretching frequencies and force constants somewhat higher in energy than those of the isoelectronic $AsBr_3$ (12). More recently, the structure of crystalline $SeBr_3SbF_6$ has been determined by X-ray diffraction (13).

In addition, we have previously reported the preparation of $Se_2Br_5AsF_6$ (10) according to reactions [1] and [2].

$$[1]\quad 4Se + 5Br_2 + 3AsF_5 \xrightarrow{\text{liquid } SO_2} 2Se_2Br_5AsF_6 + AsF_3$$

$$[2]\quad Se_4(AsF_6)_2 + 5Br_2 \xrightarrow{\text{liquid } SO_2} 2Se_2Br_5AsF_6$$

In this paper, the identity and structure of $Se_2Br_5AsF_6$ is established by a low-temperature X-ray crystal structure determination. The $Se_2Br_5^+$ cation is the first reported example of a $M_2Hal_5^+$ species (M = main group (VI) element; Hal = halogen).

Experimental

Except where otherwise stated, apparatus, reagents, and techniques are as previously described (14, 15). Elemental selenium (B.D.H.) was used without further purification. Literature methods were used to prepare $Se_4(AsF_6)_2$ (16) and $SeBr_4$ (17). Infrared spectra were obtained with a Perkin–Elmer 687 spectrometer using AgCl plates. Nuclear magnetic resonance spectra were recorded at room tempera-

[a]All spectra were recorded at room temperature. Vibrational frequencies are in cm^{-1}.
[b]Product **I** is a mixture of the more soluble product **II** and the least soluble product **III**.
[c]$SeBr_4$ was prepared according to ref. 17. Raman vibrational frequencies and intensities are those obtained in this work.
[d]Raman spectral data for crystalline $SeBr_3AsF_6$ were obtained from ref. 10.
[e]Raman spectral data for powdered $SeBr_3AsF_6$ are as recorded in this work. The intensities of $\nu_1(AsF_6)$ and $\nu_5(AsF_6)$ for samples of powdered $SeBr_3AsF_6$ were observed to be lower than those for crystalline $SeBr_3AsF_6$.
[f]Assignments for $SeBr_3AsF_6$ are those quoted in ref. 10. Assignments for $SeBr_4$ and made by comparison with those cited for the infrared of $SeBr_4$ and the infrared and Raman of solid $SeCl_4$, $TeCl_4$, and $TeBr_4$ (20).
[g]The region below 136 cm^{-1} was obscured by the exciting line.

ture on a Varian XL-200 spectrometer using a 10-mm probe (broad-band over the frequency range 20–125 MHz) tuned to 38.164 MHz to observe ^{77}Se. Fluorine-19 spectra were obtained on the same probe by using the ^1H decoupler coil retuned to 188.220 MHz as the observe coil. Typically, for ^{77}Se and ^{19}F nmr spectra, the free induction decays were accumulated in 32 kwords of memory over a spectral width of 100 kHz (6.1 Hz/data point, line broadening of 5 Hz, pulse repetition time 0.16 s) with pulse widths of 20 and 6 μs, in 2000–7000 and 1000–3000 scans, respectively. Samples were run unlocked (field drift, <1 Hz/h) and were referenced externally to $(CH_3)_2Se$ and CCl_3F. The samples were prepared in 10-mm od thick-walled nmr tubes fitted with J. Young (o-ringette PTFE stopcock; model BST/2) valves.

Preparation of single crystals of $Se_2Br_5AsF_6$

The preparation of $Se_2Br_5AsF_6$, briefly referred to in an earlier publication (10), was repeated in order to obtain single crystals and a sample for ^{77}Se and ^{19}F nmr spectroscopy. Typically, AsF_5 (1.21 g, 7.14 mmol) and Br_2 (1.94 g, 12.14 mmol) were condensed onto a mixture of Se (0.76 g, 9.66 mmol) and liquid SO_2 (4.67 g). An intense red–brown solution over a dark solid was formed on warming to room temperature. This red–brown solution was filtered after 1 day, leaving a dark purple precipitate which was washed through the sintered-glass frit by 10 extractions with about 2 mL of the solvent. The volatile products were very slowly removed over a 5-h period by pumping under dynamic vacuum with the valve opened very slightly, leaving 3.59 g of a highly-crystalline dark purple solid (calculated yield for $Se_2Br_5AsF_6$, based on Se is 3.61 g). Single crystals were quickly mounted in well-dried capillaries in the dry box, which were then rapidly flame-sealed when taken out of the dry box, as described in ref. 15, and stored at −20°C prior to the X-ray crystal structure determination.

Characterisation of $Se_2Br_5AsF_6$

The $Se_2Br_5AsF_6$ product was identified in solution by ^{77}Se and ^{19}F nmr spectroscopy at room temperature only, since the solubility of $Se_2Br_5AsF_6$ decreases rapidly with decrease in temperature. The ^{77}Se nmr spectrum for a solution of $Se_2Br_5AsF_6$ (0.83 g) in SO_2 (3.85 g) contained a broad singlet at $\delta(Me_2Se)$ = 1331.1 ppm. The ^{19}F nmr spectrum contained a 1:1:1:1 quartet (J_{As-F} = 892 ± 6 Hz) at $\delta(CCl_3F)$ = −57.2 ppm which confirmed the presence of the AsF_6^- anion (18). The ^{77}Se and ^{19}F nmr spectra, obtained *in situ*, for a fresh sample of $Se_2Br_5AsF_6$ prepared by the reaction of $Se_4(AsF_6)_2$ and Br_2 according to reaction [2] were identical to those described above. The infrared spectrum of solid $Se_2Br_5AsF_6$ also showed the presence of the AsF_6^- anion (19). Attempts to obtain Raman spectra (exciting line 5145 Å) of solid $Se_2Br_5AsF_6$ at room temperature and at −196°C (with and without spinning) were unsuccessful. Good elemental analyses have already been obtained (10) for $Se_2Br_5AsF_6$.

Thermal stability of $Se_2Br_5AsF_6$

Samples of $Se_2Br_5AsF_6$ were sealed in glass sample tubes and stored at ca. −20°C without noticeable decomposition for >1.5 years. However, at room temperature, samples of $Se_2Br_5AsF_6$ slowly decomposed after periods ranging from 2 h to 2 days. The thermal instability was indicated by the formation of a red–brown liquid film on the crystals and loss of crystallinity of the sample. The thermal instability of $Se_2Br_5AsF_6$ made it necessary to carry out all room-temperature manipulations of the solid as quickly as possible and to determine its X-ray crystal structure at low temperature. A sample of $Se_2Br_5AsF_6$ (1.11 g, 1.49 mmol) was held at 100°C and subjected to a dynamic vacuum for 3 h. The volatile product was collected in a U-tube at −196°C and identified as $SeBr_4$ (0.30 g) by comparison of its Raman spectrum with that of a sample prepared by published (17) methods. The weight and colour of the remaining solid (0.82 g), a mixture of pale yellow and gray–black material, were consistent with the presence of $SeBr_3AsF_6$ and elemental selenium in a 2:1 mole ratio. The Raman spectrum of the yellow solid was identical to that reported (10) for $SeBr_3AsF_6$.

Attempted synthesis of $Se_2Br_7AsF_6$

(a) Reaction of $Se_4(AsF_6)_2$ with bromine. $Se_4(AsF_6)_2$ (0.87 g, 1.25 mmol) and Br_2 (1.42 g, 8.89 mmol) were reacted at a 1:7.1 mole ratio in liquid SO_2 (9.72 g) in a two-bulbed reaction vessel. A yellow–orange precipitate beneath an intense red–brown solution was formed immediately. The Raman spectrum of the combined precipitate (**I**) (i.e. before separating the more soluble product (**II**) from the least soluble product (**III**)), obtained *in situ*, indicated the presence of a mixture of $SeBr_3AsF_6$ and $SeBr_4$ (Table 1). The solution was filtered, and the more soluble product (**II**) was extracted by washing the combined precipitate (**I**) approximately ten times with 1–2 mL of the solvent. The

[a]The mean of the principal axes of the thermal ellipsoid.

solvent was slowly condensed back onto the least soluble product (**III**), thus isolating the more soluble product. The Raman spectrum of the more soluble product (**II**) (Table 1) indicated that it was predominantly $SeBr_3AsF_6$ with a small amount of $SeBr_4$. The solvent was slowly removed from the vessel by pumping under dynamic vacuum. The Raman spectrum of the least soluble product (**III**) indicated the presence of only $SeBr_4$.

(b) Reaction of $Se_2Br_5AsF_6$ with bromine. In one reaction, Br_2 (0.25 g, 1.59 mmol) was condensed onto a frozen solution of $Se_2Br_5AsF_6$ (1.03 g, 1.38 mmol) and SO_2 (3.79 g) in a 10 mm od nmr tube. An intense red–brown solution over a yellow–orange precipitate was noted on warming to room temperature. No change in the solution or precipitate was noted after standing at room temperature for 4 days. The ^{77}Se nmr spectrum, obtained at room temperature, contained a singlet at $\delta(Me_2Se)$ = 1323.1 ppm which indicated the presence of $SeBr_3^+$ (cf. $\delta(Me_2Se)$ = 1326.1 ppm for a solution of $SeBr_3AsF_6$ (0.55 g, 1.07 mmol) in SO_2 (3.11 g)). The Raman spectrum, obtained *in situ*, of the yellow–orange precipitate contained several peaks which indicated the presence of a mixture of $SeBr_3AsF_6$ and $SeBr_4$. The volatile material was removed by pumping under vacuum. The infrared spectrum of the yellow–orange solid indicated the presence of the AsF_6^- anion (19). An elemental analysis of the yellow–orange precipitate was consistent with a 1:1 mixture of $SeBr_3AsF_6$ and $SeBr_4$. *Anal. calcd.*: Se 17.43, Br 61.73, As 8.27, F 12.58; found: Se 15.91, Br 63.25, As 7.36, F 12.9. Empirical formula $Se_{2.0}Br_{7.9}As_{1.0}F_{6.7}$.

The X-ray crystal structure of $Se_2Br_5AsF_6$ [2]

Initial attempts to examine single crystals of $Se_2Br_5AsF_6$ at room temperature failed because of decomposition of the compound, which seemed to be accelerated by exposure to the X-ray beam. Even at 100 K, crystals exposed to MoKα radiation fluoresced heavily and only diffracted for about 1 h. It was therefore decided to undertake the structure determination at low temperature using CuKα radiation, even though the absorption coefficient for this wavelength radiation is extremely high. A number of crystals were used to determine possible space groups (Rc or $R3$) and approximate cell parameters. The procedure used the search program of the Enraf-Nonius CAD-4 diffractometer as well as a number of axial photographs and the cell reduction program of LePage (21). The intensity data collection and final cell parameter determination was made on one crystal from a fresh sample of the compound. Because the crystals do not possess well-defined faces, an effort was made to select one with equal dimensions in three directions. The data were collected using an Enraf-Nonius low-temperature device, which cools the crystal in a stream of cold N_2. Two unique sets of data were collected. A summary of the crystallographic data is given in Table 2.

The structure was solved using the MULTAN-80 (22) suite of direct methods programs. A spherical absorption correction was applied to the data and after refining with isotropic thermal parameters the empirical absorption routine DIFABS (23) was used. One of the AsF_6^- units was found to be disordered and was modelled as three rigid octahedra with a common F—As—F axis. The final least-squares refinement included all atoms except for the disordered fluorines with anisotropic thermal parameters. The final atomic coordinates are given in Table 3. The least-squares refinement was performed using SHELX-76 (24); all other calculations used a local implementation of the NRCVAX system of programs (25), on a Wicat S-160 computer.

Results and discussion

Preparation and properties of $Se_2Br_5AsF_6$

Highly crystalline purple $Se_2Br_5AsF_6$ was prepared quantitatively as previously described (10) either by reaction of the appropriate amounts of Se, Br_2, and AsF_5, according to reaction [1], or $Se_4(AsF_6)_2$ and $5Br_2$, according to reaction [2]. It is possible that the $Se_2Br_5^+$ cation exists as such in sulphur dioxide solution and is characterised by a broad singlet in the ^{77}Se nmr spectrum at $\delta(Me_2Se)$ = 1331.1 ppm at room temperature. It is also possible that it is in equilibrium with $SeBr_2$ and $SeBr_3^+$ in solution.

$Se_2Br_5AsF_6$ decomposes slowly at room temperature and rapidly at 100°C into $SeBr_3AsF_6$, $SeBr_4$, and elemental selenium. This is consistent with the initial evolution of $SeBr_2$, according to reaction [3], followed by its disproportionation into $SeBr_4$ and elemental selenium (1), reaction [4].

[3] $Se_2Br_5AsF_6(s) \rightarrow SeBr_3AsF_6(s) + SeBr_2(g)$

[4] $2SeBr_2(g) \rightarrow SeBr_4(s) + Se(s)$

On addition of bromine to a solution of $Se_2Br_5AsF_6$ in sulphur dioxide solution, a mixture of $SeBr_3AsF_6$ and $SeBr_4$ are obtained, according to reaction [5]. We could find no evidence for the formation of $Se_2Br_7AsF_6$.

[5] $Se_2Br_5AsF_6(s) + Br_2(l) \rightarrow SeBr_3AsF_6(s) + SeBr_4(s)$

A comparison of the products of reactions of Se_4^{2+} with iodine and bromine in SO_2 solution and an explanation for the nonexistence of $Se_2I_5AsF_6$

Reactions of $Se_4(AsF_6)_2$ and varying amounts of iodine in SO_2 solution, followed by ^{77}Se nmr spectroscopy, produced $Se_4I_4^{2+}$ (34, 35) according to reaction [6].

$$[6]\quad Se_4^{2+} + 2I_2 \xrightarrow{SO_2} Se_4I_4^{2+}$$

The $Se_4I_4^{2+}$ cation itself was in equilibrium with small amounts of $Se_6I_2^{2+}$ and SeI_3^+ according to reaction [7].

$$[7]\quad 2Se_4I_4^{2+} \rightleftharpoons Se_6I_2^{2+} + 2SeI_3^+$$

The same peaks appeared in the ^{77}Se nmr spectrum at all mole ratios of $Se_4(AsF_6)_2$:I_2, i.e. $Se_4I_4^{2+}$ did not react further with iodine and did not form $Se_2I_5^+$.

In contrast, the ^{77}Se nmr spectra for the products obtained in the reactions of $Se_4(AsF_6)_2$ with bromine showed a large number of peaks at ratios of $Se_4(AsF_6)_2$:Br_2 less than 1:5. The number of peaks varied with the particular value of the mole ratio. Most of the peaks were broad and unidentified and are presently under investigation. At a $Se_4(AsF_6)_2$:Br_2 mole ratio of 1:5, corresponding to the formation of $2Se_2Br_5^+$, only one peak in the ^{77}Se nmr spectrum was observed. Thus, whereas the reaction of Se_4^{2+} with iodine is completed with the formation of $Se_4I_4^{2+}$, the $Se_4Br_4^{2+}$ cation, if it is formed at all, reacts with more bromine to give $Se_2Br_5^+$. The reason for this is that the reaction of $Se_4I_4^{2+}$ and more iodine, according to reaction [8], is not thermodynamically favourable (ΔH[8] $\simeq$ +15 kcal mol^{-1}) whereas the reaction of the hypothetical $Se_4Br_4^{2+}$ and bromine, according to reaction [9], is favourable (ΔH[9] $\simeq$ −9 kcal mol^{-1}).

$$[8]\quad I_2Se^+SeSeSe^+I_2 + I_2(s) \rightarrow 2I_2Se^+SeI$$

$$\Delta H[8] = -2\Delta H[\text{Se—I}] + \Delta H[\text{atomisation energy of } I_2(s)] + \Delta H[\text{Se—Se}]$$
$$\simeq -82 + 51 + 46 \text{ (ref. 36)}$$
$$\simeq +15 \text{ kcal mol}^{-1}$$

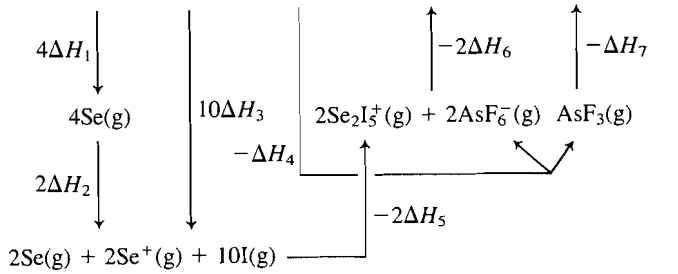
$$[9]\quad Br_2Se^+SeSeSe^+Br_2 + Br_2(l) \rightarrow 2Br_2Se^+SeBr$$

$$\Delta H[9] = -2\Delta H[\text{Se—Br}] + \Delta H[\text{atomisation energy of } Br_2(l)] + \Delta H[\text{Se—Se}]$$
$$\simeq -108 + 53 + 46 \text{ (ref. 36)}$$
$$\simeq -9 \text{ kcal mol}^{-1}$$

Br_2Se^+SeBr and/or its disproportionation products may then react with one more molecule of bromine to give the observed $Se_2Br_5^+$.

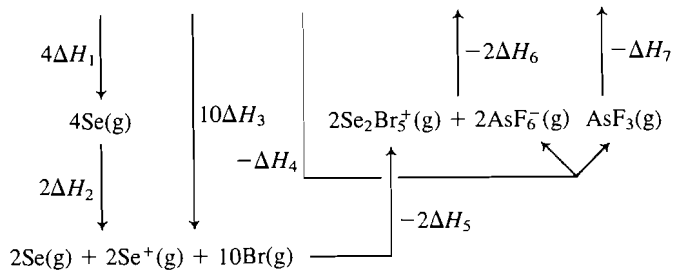
Consistently, the energy cycles below show that the formation of $Se_2Br_5AsF_6$ from selenium, bromine, and AsF_5 according to reaction [11] is much more favourable (ΔH[11] $\simeq$ −161 kcal mol^{-1}) than the corresponding formation of $Se_2I_5AsF_6$ (ΔH[10] $\simeq$ −19 kcal mol^{-1}). The estimates of some of the thermodynamic quantities involved in Table 4 are in the nature of guesstimates. Nevertheless the difference in ΔH values for reactions [10] and [11] is clearly substantial, and is almost entirely due to the Se—Br bond energy being greater than the Se—I bond energy (ΔH_5 below). The free energy change in these reactions will be less favourable than the estimated enthalpy values given here, as entropy favours the reactants, not the products. Thus the ΔG value for reaction [10] could be approximately zero, in contrast to ΔG for reaction [11] which will undoubtedly be substantially negative.

$$[10]\quad 4Se(s) + 5I_2(s) + 3AsF_5(g) \rightarrow 2Se_2I_5AsF_6(s) + AsF_3(l)$$



$$\Delta H[10] = 4\Delta H_1 + 2\Delta H_2 + 10\Delta H_3 - \Delta H_4 - 2\Delta H_5 - 2\Delta H_6 - \Delta H_7$$
$$\simeq 216 + 450 + 255 - 233 - 2\Delta H_5 - 228 - 9$$
$$\simeq 451 - 2\Delta H_5 \simeq 451 - 470 \simeq -19 \text{ kcal mol}^{-1}$$

$$[11]\quad 4Se(s) + 5Br_2(l) + 3AsF_5(g) \rightarrow 2Se_2Br_5AsF_6(s) + AsF_3(l)$$



$$\Delta H[11] = 4\Delta H_1 + 2\Delta H_1 + 2\Delta H_2 + 10\Delta H_3 - \Delta H_4 - 2\Delta H_5 - 2\Delta H_6 - \Delta H_7$$
$$\simeq 216 + 450 + 265 - 233 - 2\Delta H_5 - 234 - 9$$
$$\simeq 455 - 2\Delta H_5 \simeq 455 - 616 \simeq -161 \text{ kcal mol}^{-1}$$

Crystal structure

The structure of the $Se_2Br_5^+$ cation, including bond distances and angles, is illustrated in Fig. 1, and a packing diagram is given in Fig. 2. Relevant bond distances and angles are presented in Table 5. The shortest cation–anion contact is 2.75(8) Å (Table 5) which suggests that $Se_2Br_5AsF_6$ essentially consists of $Se_2Br_5^+$ and AsF_6^- ions, with cation–anion interactions. The $Se_2Br_5^+$ cation is the first example of an $M_2Hal_5^+$ species (M = main group (VI) element; Hal = halogen) but is related to the $O_2H_5^+$ cation shown to be present in H_5O_2Br (38) and *o*-$C_6H_4(COOH)SO_3H\cdot 3H_2O$ (39) by neutron diffraction.

The $Se_2Br_5^+$ cation contains two $SeBr_2$ units linked by Br(1) which is on an inversion centre and has approximately C_{2h} symmetry. The two terminal selenium–bromine bond distances in $Se_2Br_5^+$ (2.291(7) and 2.268(6) Å) are comparable to those distances (Table 6) in other species where the selenium–bromine bond order is ca. 1.0. In $Se_2Br_5^+$, the bridging selenium–bromine bond distance of 2.582(3) Å is roughly the same order of magnitude as other related bridging selenium–bromine distances (Table 6), and corresponds to a bond order of approximately 0.5. In valence bond terms, the structure may be represented by a combination of resonance structures **I** and **II** of equal weight, and lesser amounts of resonance structure **III**. The resultant charge on selenium may be somewhat higher than 0.5, depending upon the importance of structure **III**. The Se—Br—Se bond angle of 180° is consistent with the structure being represented by **I** and **II** or **III** where the bridging bromine atom has, in VSEPR terms, an AX_2E_3 configuration (42), or the bonding in the bridging region being represented by a three-centre four-electron bond.

Comparison of Figs. 1 and 3 shows that the overall geometry

$SeBr_3AsF_6(s) \rightarrow SeBr_3^+(g) + AsF_6^-(g)$	127 ± 5	*c*

[a]The heat of reaction for the formation of $2AsF_6^-(g)$ and $AsF_3(g)$ may be estimated as follows:

	ΔH (kcal mol^{-1})
$As(s) + (3/2)F_2(g) \rightarrow AsF_3(g)$	−187.8 (ref. 27)
$AsF_5(g) \rightarrow As(s) + (5/2)F_2(g)$	295.6 (ref. 29)
$F_2(g) + 2e^- \rightarrow 2F^-(g)$	−119 (ref. 29)
$2AsF_5(g) + 2F^-(g) \rightarrow 2AsF_6^-(g)$	−222 (ref. 30)
$3AsF_5(g) + 2e^- \rightarrow 2AsF_6^-(g) + AsF_3(g)$	−233 kcal mol^{-1}

[b]The atomization energies of $Se_2Br_5^+(g)$ and $Se_2I_5^+(g)$ were estimated from the sums of the respective bond dissociation energies. It is assumed that the selenium–bromine single bond energy in cations containing a positively charged terminal Se(IV)—Br bond is the same as that in neutral $SeBr_2$ (54.0 kcal mol^{-1}, ref. 26). Since neutral selenium–iodine compounds are nonexistent (ref. 3) the selenium–iodine bond energy for SeI_2, calculated by Sanderson (41.2 kcal mol^{-1}, ref. 31), was used and assumed to be about the same as that for the terminal $Se(IV)^+$—I in $Se_2I_5^+$. It is likely that the $Se(IV)^+$—Br bond strength is slightly stronger than that for Se(II)—Br, since Se—Br bond lengths in $Se(IV)^+$—Br species are slightly shorter than in Se(II)—Br species. The Se—Br bond lengths in $[SeBr_3^+][SbF_6^-]$ and $SeBr_2$ are 2.269(8) and 2.32(2), respectively (Table 5) and are likely significantly different. However, the $Se(IV)^+$—I bond length in SeI_3AsF_6 (2.510(3) Å; ref. 33) is essentially the same as that estimated for the Se(II)—I bond length in SeI_2 (2.50 Å, ref. 33), indicating that the $Se(IV)^+$—I and Se(II)—I bond strengths are the same. The linear Se—Br—Se and Se—I—Se bridging bonds in $Se_2Br_5^+$ and $Se_2I_5^+$ are similar to the linear I—I—I bridging bonds in I_3^-, Topol (ref. 32) has shown that there is a gain in energy of 24 kcal mol^{-1} in the formation of $I_3^-(g)$ according to the following equation: $I^-(g) + I_2(g) \rightarrow I_3^-(g)$. Therefore, the sum of the bridging I—I bond energies in I_3^- equals 24 plus 36.1 (I—I bond energy in $I_2(g)$) kcal mol^{-1}, and the ratio of bridging bond energies in $I_3^-(g)$ to the bond energy in $I_2(g)$ is (24 + 36.1)/36.1 = 1.7.

Assuming that the bridging bond energies in $Se_2Br_5^+$ and $Se_2I_5^+$ may be estimated in a similar fashion, then their atomization energies may be estimated as follows:

$Se_2Br_5^+$	$Se_2I_5^+$
4(Se—Br) = 4(54.0)	4(Se—I) = 4(41.2)
+ bridging bonds = 1.7(54.0)	+ bridging bonds = 1.7(41.2)
$\therefore \Delta H_5$ = 308 kcal mol^{-1}	$\therefore \Delta H_5$ = 235 kcal mol^{-1}

The values of ΔH_5 may in fact be somewhat higher than estimated here, especially in the $Se_2Br_5^+$ case.

[c]Bartlett *et al.* (ref. 30) have shown that there is an essentially linear relationship, for simple A^+B^- salts (e.g. NaCl, KBr, KI) between the lattice energies and (molecular volume)$^{-1/3}$, where the equation of the line may be represented by: $\Delta H_L = 556.3(\text{molecular volume})^{-1/3} + 26.31$ kcal mol^{-1}. Therefore, the crystal lattice energy of $Se_2Br_5AsF_6$ (molecular volume is 326.7 Å^3) is estimated as 107 ± 5 kcal mol^{-1}. However, Bartlett *et al.* noted that for species such as ClO_2BF_4 and SF_3BF_4 there was a positive deviation (6–8 kcal mol^{-1}) from the line, which was attributed to the dispersion energies of these salts being greater than those of the simple salts (e.g. NaCl, KBr). A conservative estimate of 10 kcal mol^{-1} has been used for the positive deviation of $Se_2Br_5AsF_6$, and therefore, ΔH_L (corrected) for $Se_2Br_5AsF_6$ is estimated as 117 ± 5 kcal mol^{-1}. Similarly, the crystal lattice energy of $SeBr_3AsF_6$ (molecular volume 232.0 Å (ref. 13)) is estimated as 127 ± 5 kcal mol^{-1}.

The ratio of the molecular volume of the hypothetical $Se_2I_5AsF_6$ to SeI_3AsF_6 is assumed to be similar to that of $Se_2Br_5AsF_6$ to $SeBr_3AsF_6$. Therefore

$$V_{Se_2I_5AsF_6} = \frac{V_{SeI_3AsF_6} \times V_{Se_2Br_5AsF_6}}{V_{SeBr_3AsF_6}} = \frac{265.0 \text{ Å}^3 \text{ (ref. 33)} \times 326.7 \text{ Å}^3}{232.0 \text{ Å}^3 \text{ (ref. 13)}} = 373.2 \text{ Å}^3$$

The lattice energy of $Se_2I_5AsF_6$ is therefore estimated to be 114 ± 5 kcal mol^{-1}.

TABLE 6. Comparison of selenium–bromine bond distances (Å)

Molecule	Se—Br (terminal)	Average	Se—Br (bridging)	Average	Reference
$Se_2Br_5AsF_6$	2.291(7) 2.268(6)	2.28	2.582(3)		This work
$SeBr_3SbF_6$	2.280(8) 2.254(7) 2.272(8)	2.27			1,13
α-$SeBr_4$[a]	2.44 2.35 2.31	2.37	3.05 3.02 2.87	2.98	1,4
α-SeBr	2.357(2)				1,6
β-SeBr	2.366(1) 2.369(1)	2.37			1,5,6
$SeBr_2$[b]	2.32(2)				1,40
$[P(C_6H_5)_4]_2SeBr_4$	2.595(1) 2.596(1)	2.60			9
$[P(C_6H_5)_4]_2Se_2Br_6$	2.485(1) 2.399(1)	2.44	2.887(1) 2.710(1)	2.80	9
$SeBr_2$(tmtu)[c]	2.569(3) 2.620(3)	2.70	3.34		41

[a] β-$SeBr_4$ is isostructural, but not isomorphous, with α-$SeBr_4$ (1, 4).
[b] The Se—Br bond length in $SeBr_2$ was determined by electron diffraction studies of the decomposition products at 200°C of $SeBr_4$(g) which are presumably $SeBr_2$(g) and Br_2(g) according to ref. 40.
[c] tmtu = tetramethyl thiourea ($C_5H_{12}N_2S$).

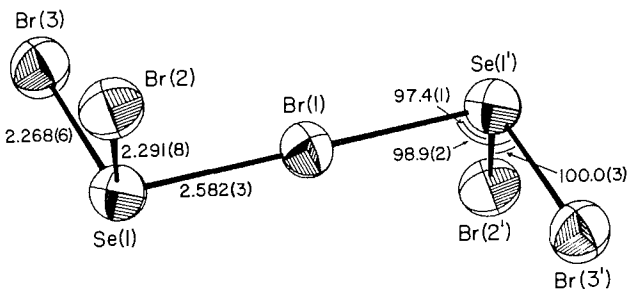

FIG. 1. The structure of the $Se_2Br_5^+$ cation in $Se_2Br_5AsF_6$.

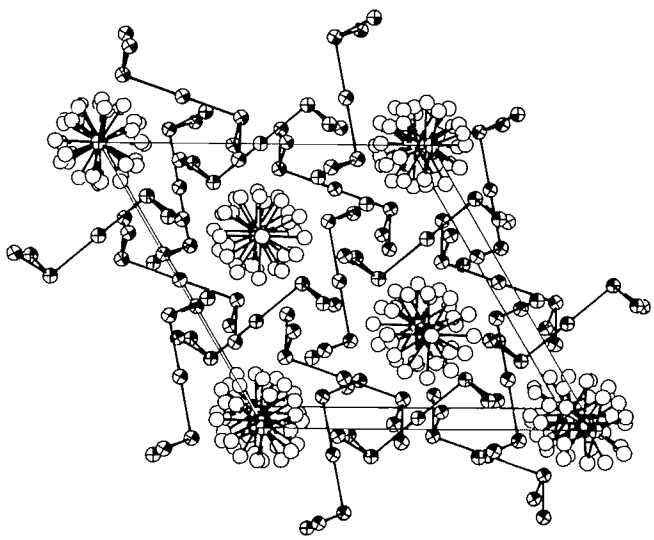

FIG. 2. Crystal packing in $Se_2Br_5AsF_6$.

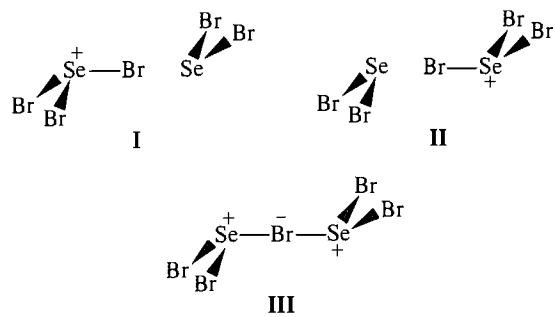

of the $Se_2Br_5^+$ cation is similar to that in the *trans* cation in (α)$6SbF_3 \cdot 5SbF_5$ (43) and $5SbF_3 \cdot 3SbF_5$ (44) and about the bridging iodine atom in the $[(S_7I)_2I]^{3+}$ cation (45). Interestingly, $Se_2Br_5^+$ may be viewed as isolating the bridging halogen unit in $[(S_7I)_2I]^{3+}$ by replacing the chalcogen–chalcogen bonds of the rings with terminal chalcogen–halogen bonds. This geometry minimises both the repulsion between the lone pairs on the two selenium atoms and the electro-static repulsions between the terminal bromine atoms that certainly carry some partial positive charge. Calculations performed on Cl_5^+, as a model for I_5^+, have shown that electrostatic repulsion between the terminal atoms are responsible for the transplanar geometry of Cl_5^+ and hence that of I_5^+ (15). The $O_2H_5^+$ cations in H_5O_2Br (38) and *o*-$C_6H_4(COOH)SO_3H \cdot 3H_2O$ (39) contain OH_2 units joined by a bridging hydrogen atom with a bridging angle of almost 180°. The bridging bond distances are almost equal. However, the overall structure is staggered.

The average terminal selenium–bromine bond distance of 2.280(7) Å found in $Se_2Br_5^+$ is somewhat shorter than that found in the neutral and anionic selenium–bromine species, but it is slightly longer, though not significantly different, than the average 2.269(8) Å selenium–bromine distance in $SeBr_3^+$ (see Table 6). The longer bond in $Se_2Br_5^+$ may be accounted for by

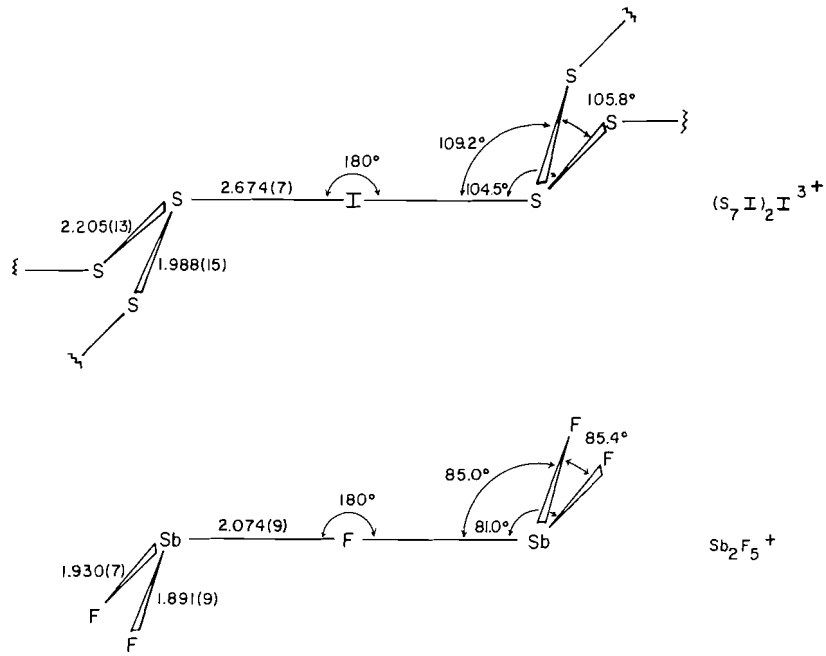

FIG. 3. Geometries about the bridging halogen atoms in $[(S_7I)_2I]^{3+}$ and $Sb_2F_5^+$ (in $5SbF_3 \cdot 3SbF_5$); analogous to geometry about Br(1) in $Se_2Br_5^+$.

TABLE 7. Comparison of the terminal and bridging linear M—X bond lengths (M = S, Se, Sb, Br, I; X = F, Br, I)

Compound	M—X(terminal) (Å)	M—X(bridging) (Å)	M—X(terminal) / M—X(bridging)	References
$Se_2Br_5AsF_6$	2.28	2.582(3)	0.88	This work
$((S_7I)_2I)(SbF_6)_3$	2.34	2.674(7)	0.87	45
$(Se_6I_2)(AsF_6)_2/(Se_6I)_n \cdot n(AsF_6)$	2.45	2.736(3)	0.90	46
$Sb_2F_5^+$ in $5SbF_3 \cdot 3SbF_5$	1.91	2.074(9)	0.92	44
$Br_2/(C_6H_5N_2)(Br_3)$	2.28	2.54	0.90	2
$I_2/((C_2H_5)_4N)(I_3)$	2.67	2.928(3)	0.91	2
I_5AsF_6	2.65	2.895(1)	0.91	15

the contribution of $SeBr_2$ (valence bond structures **I** and **II**), which has a longer (2.32(2) Å) bond length, and the lower charge of 0.5 on the Se atom. The bridging selenium–bromine bond length of 2.582(3) Å is also shorter than other bridging selenium–bromine distances found in the neutral or anionic species (Table 6). This is expected as distances are shorter in species containing positively charged selenium atoms than in those that are formally neutral. Nevertheless, the ratio of M—X (terminal) to M—X (bridging) (M = S, Se, Sb, Br, I; X = F, Br, I) distances in a variety of species are all very similar (see Table 7).

The relative sizes of the Br—Se—Br bond angles in $Se_2Br_5^+$ are consistent with a VSEPR model, i.e. the smaller angle is associated with the longer adjacent bonds (42). Consistently, the Br—Se—Br bond angles in $SeBr_3^+$ are larger than those in $Se_2Br_5^+$ (Figs. 1 and 4).

There are two unique AsF_6^- anions in the crystal structure of $Se_2Br_5AsF_6$. The anion containing As(2) is a regular octahedron with an average As—F bond distance of 1.72 Å and F—As—F bond angle of 90.0° (Table 5). The anion containing As(1), which is disordered in the equatorial plane such that each equatorial fluorine atom has only ca. 33% occupancy, has an average As—F bond distance of 1.74 Å, the bond angles were fixed by the disorder model.

There are weak interactions between the selenium atoms in the cation in $Se_2Br_5AsF_6$ and the fluorine atoms in the anion (Table 5, Figs. 4 and 5) that are significantly less than the sum of the van der Waals radii (3.37 Å) (37). The very weak contact Se(1)—F(21k) is only 1% shorter than the sum of the van der Waals radii and will not be discussed further. Three of the contacts are to disordered fluorine atoms of ca. 33% occupancy (i.e. F(14), F(15), F(16)). Since their environments with respect to the cation are very similar, they may be qualitatively considered as one contact. Therefore, the bond distances and angles of Se(1)—F(14), Se(1)—F(15), and Se(1)—F(16) have been averaged such that the Se(1)—F(ave) bond distance is 3.00 Å and the bond angles are Br(3)—Se(1)—F(ave), 167.0°; Br(2)—Se(1)—F(ave), 77.4°; Br(1)—Se(1)—F(ave), 77.3°; and F(21f)—Se(1)—F(ave), 101.2°. The strongest contacts Se(1)—F(21f) and Se(1)—F(ave) are opposite to the Se(1)—Br(2) and Se(1)—Br(3) bonds in the cation, i.e. F—Se—Br bond angles are both about 180° (Figs. 4 and 5). The Se—F contact distances in $Se_2Br_5AsF_6$ (i.e. F(21f), 2.98; F(ave), 3.00; F(11k), 3.12 Å) are considerably longer than those in

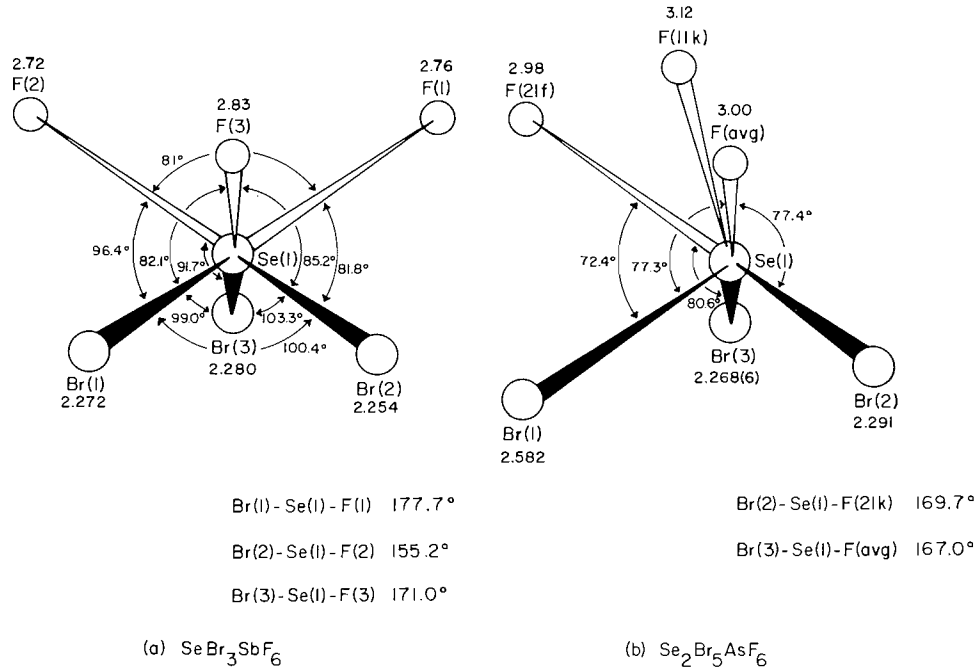

FIG. 4. Comparison of the environment around the selenium atoms in (*a*) $SeBr_3SbF_6$ and (*b*) $Se_2Br_5AsF_6$.

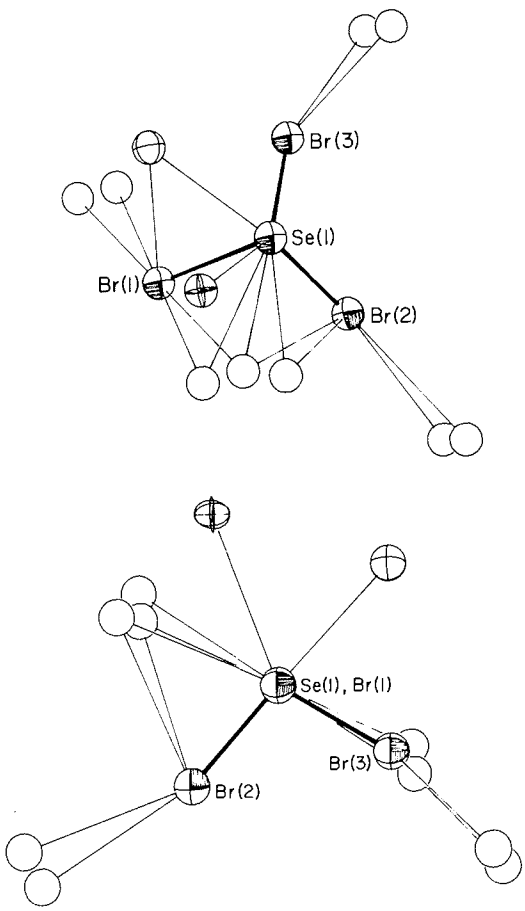

FIG. 5. Fluorine atom contacts to the selenium and bromine atoms in $Se_2Br_5AsF_6$ (all Se---F ≦ 3.330 Å; Br---F ≦ 3.290 Å). Partially filled, unlabelled circles represent fluorine atoms of 100% occupancy and empty circles represent fluorine atoms of ca. 33% occupancy.

$SeBr_3SbF_6$ (2.72, 2.83, and 2.76 Å (13)) which is consistent with each selenium atom in $Se_2Br_5AsF_6$ having a positive charge of less than 1.

It is not altogether easy to describe the stereochemistry about the selenium atoms in VSEPR terms (42). The positively charged selenium atoms of valence bond structures **I**, **II**, and **III** are clearly AX_3E whereas the neutral selenium atoms in **I** and **II** are AX_2E_2. Presumably each selenium atom is a combination of AX_3E and AX_2E_2. However, assuming a primary coordination of AX_3E, the complete geometry around Se(1) in $Se_2Br_5AsF_6$ can be expressed as $AX_3Y_2Y'E$ where the secondary contacts F(21f) and F(ave) designated Y_2, cap two of the faces of the tetrahedron around the lone pair (see Figs. 4 and 5), and the weakest of the contacts (Se(1)—F(11k)), designated Y', lies between edge bridging and face capping positions. Alternatively the geometry around Se(1) in $Se_2Br_5^+$ may also be regarded as AXY_4E (see Figs. 4 and 5), but in compounds having a similar AXY_4E environment around the central atom, the shortest bond in the molecule or ion is *trans* to the lone pair.

The bonding in the $Se_2Br_5^+$ cation may be regarded as involving only *p*-orbitals, with the selenium 4*s* orbital inert. The two strongest contacts to Se(1) at 180° to the strong Se—Br bonds therefore may involve donation of charge from the fluorine atoms to the σ* Se—Br orbitals. The three-centre four-electron bond in the bridging region, places non-bonding electron density in 4*p* lobes along the Se(1)—Br(1)—Se(1a) axis, consistent with the absence of atoms in this region (see Figs. 4 and 5). There is a similar empty region *trans* to the bridging bonds in I_5^+ and I_{15}^{3+} in I_5AsF_6 (15) and $I_{15}(SbF_6)_3$ (3) which may also be considered as containing three-centre four-electron bonds. It is also possible that the bonds in the bridging region may involve *sp* hybrid orbitals on the Se(1) atom, increasing the steric activity of the two lone pairs *trans* to the colinear Se(1)—Br(1)—Se(1*a*) bond.

The Br—F contact distances in $Se_2Br_5AsF_6$ (Table 4) are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12

longer than those in $SeBr_3SbF_6$ (i.e. 3.01, 2.85, and 3.02 Å) (13); consistent with the higher charge per selenium atom in $SeBr_3^+$ than $Se_2Br_5^+$.

Specific patterns of short range solvation — aliphatic amines in benzene–dimethylsulfoxide mixed solvents

EDWARD D. BERMAN, ROSEMARIE THOMAS, PHILIP STAHL, AND RONALD M. SCOTT[1]
Department of Chemistry, Eastern Michigan University, Ypsilanti, MI 48197, U.S.A.

Received October 30, 1986

EDWARD D. BERMAN, ROSEMARIE THOMAS, PHILIP STAHL, and RONALD M. SCOTT. Can. J. Chem. **65**, 1594 (1987).

The trends in the values of equilibrium constants for the formation of proton transfer complexes between 2,4-dinitrophenol and various aliphatic amines are used to infer the nature of the short range solvation of the amines in benzene–DMSO solvent mixtures. Hydrogen bonds between the DMSO oxygen and the amine proton increase the basicity of the primary and secondary amines. Equilibrium constants for this bond formation are estimated for secondary amines.

EDWARD D. BERMAN, ROSEMARIE THOMAS, PHILIP STAHL et RONALD M. SCOTT. Can. J. Chem. **65**, 1594 (1987).

On utilise les tendances dans les valeurs des constantes d'équilibre pour la formation de complexes de transfert de protons entre le dinitro-2,4 phénol et diverses amines aliphatiques pour tirer des conclusions relatives à la nature de la solvatation à courte distance d'amines dans des mélanges de solvants formés de benzène et de DMSO. Les liaisons hydrogènes entre l'oxygène du DMSO et le proton de l'amine augmente avec la basicité des amines primaires et secondaires. On a évalué les constantes d'équilibre pour la formation de cette liaison dans des amines secondaires.

Introduction

Solvation influences on dissolved reactants fall into two categories: long range and short range effects. Long range solvation effects depend on solvent polarity and the resultant ability of the solvent to disperse charge, facilitating the separation of unlike charges. Various terms have been generated to describe or quantify this solvent property. Terms such as dielectric constant are based on a physical measurement made on either pure solvent or a solvent mixture and depend for their usefulness on the existence of a close correlation between the property measured and the ability of the solvent to disperse charge. Other terms such as Taft's π value are based on the relative degree to which model reactions occur in the solvent (1). Short range solvation effects depend on specific interaction as by hydrogen bonding between the reactant and the solvent. Tendencies for specific solvents to interact by hydrogen bond formation with solutes have been described by such constants as the α and β values of Taft (2).

We are here studying the formation of a proton-transfer complex in which a phenolate ion is hydrogen bonded to an aliphatic ammonium ion. Such a structure occurs by the formation first of a phenol-amine hydrogen bonded adduct followed by the transfer of the proton of the phenol to the amine along the hydrogen bond axis. Clearly charge separation is involved and the effect of long range solvation on this reaction has been reported in several papers (3).

Solvent systems used to study solvation effects on this reaction often have not allowed a differentiation of long range from short range effects. Mixtures of dioxane and water are frequently used because these two miscible liquids allow a vast range (approximately 2.2 to 80) of dielectric constant to be studied. However, both dioxane and water have electrons to donate, water has protons to donate, and the two compounds can and do interact with one another in a potentially complex fashion (4).

We wish as much as possible to isolate for study specific short range interactions. For this purpose the benzene–dimethylsulfoxide (DMSO) solvent system has been selected. The two liquids are miscible. Benzene is very non-polar ($\epsilon = 2.3$) and is capable of only very weak electron donation, yet it will dissolve the reactants under study. DMSO is an electron donor but is not a proton donor ($\epsilon = 45$, $\beta = 0.764$). The solvents therefore do not interact appreciably with one another, and self interaction does not extend to hydrogen bonding. Attention is focused on the effect of the electron-donating properties of DMSO on the proton-transfer complex reaction. Amounts of DMSO added are kept small so as to minimize the change in the long range solvation environment of the solution.

The reaction used as a model, the formation of a proton-transfer complex between 2,4-dinitrophenol (DNP) and a variety of aliphatic amines, is selected for the following reasons. DNP has sufficient strength as an acid to form a proton-transfer complex with aliphatic amines in pure benzene. Unfortunately in DNP there is an internal hydrogen bond between the phenolic-OH and the *ortho* nitro group. Although this hydrogen bond would break in favor of an external bond to DMSO, the DMSO will be displaced as the more basic amines are added to solution. However, DNP presents no other opportunities for hydrogen bonding to DMSO and is therefore considered free of short range solvation effects in this solvent system. Tertiary aliphatic amines present only one site for short range interaction with the solvent, that being the unshared amine electrons. Since these are involved in the interaction with DNP, tertiary amines are also free of short range interactions with the solvent. Interactions between tertiary amines and DNP are used as control studies illustrating the long range solvation effects on the formation of the proton-transfer complex as the composition of solvent is altered.

Primary and secondary amines are capable through their amine proton of forming a hydrogen bond with DMSO. It is the effect of this specific short range solvation interaction on the formation of the proton-transfer complex that we report.

Experimental

The benzene was Aldrich spectra grade and was used without further purification. DMSO was Eastman spectra grade and was stored over calcium hydride after opening. DNP (Aldrich) was dissolved in benzene, dried with $MgSO_4$, and recrystallized. The amines studied were triethylamine (TEA), diethylamine (DEA), *n*-butylamine (*n*BA), Diisopropylamine (DIpA), morpholine (Mo), and *N*-methylmorpho-

line (NMM). All amines were purified by distillation, then stored under nitrogen.

All samples for spectral analysis were assembled by weight. The five solutions used in each study included a constant amount of DNP, one had no amine and the four others contained differing amounts of amine. Quantities of solvent mixture were prepared on a percent by weight of DMSO basis and were then used to prepare all solutions used in sample preparation. All spectra except those involving morpholines were measured using a Perkin–Elmer Lamba 7 uv–visible spectrophotometer. Temperature was regulated by a Perkin–Elmer electronic temperature control accessory. For runs where thermodynamic parameters were to be calculated the spectra were run at five temperatures ranging from 15 to 55°C. Morpholine data were measured using a Beckman DK-2A spectrophotometer, temperature being regulated by use of a jacketed cell and circulating water bath.

In each solvent mixture and for each amine studied, the spectrum for the pure proton-transfer complex was taken. Absorbances were read from all samples at 365, 370, 430, and 440 nm. Equilibrium constants were calculated from the absorbances at each wavelength by two methods. In one the composition of the mixture was calculated directly from the known concentrations of reactants and the minimum, maximum, and sample absorbances. In the other, the iterative method, only the minimum and sample readings were used. A deliberately low value for maximum absorbance at that wavelength was estimated and the equilibrium constants for all samples were determined using that value. Then the estimated maximum absorbance was slightly incremented and the constants again were determined. This was repeated until the calculated equilibrium constant values showed no tendency to increase or decrease with increasing amine concentration. The measured maximum absorbances and those predicted by the iterative technique were in good agreement. The set of equilibrium constants for each reaction was averaged and the standard deviation was calculated.

The equilibrium constants for the formation of the hydrogen bond between DMSO and DEA or DIpA were estimated by assuming that the plateau in the increase in K_{eq} with increasing DMSO concentration that occurs at around (0.8–1.0) wt.% DMSO represents complete hydrogen bonding. From concentrations of reactants added and the fraction of the plateau absorbance obtained at each DMSO concentrations the K_{eq} was calculated (see Fig. 1).

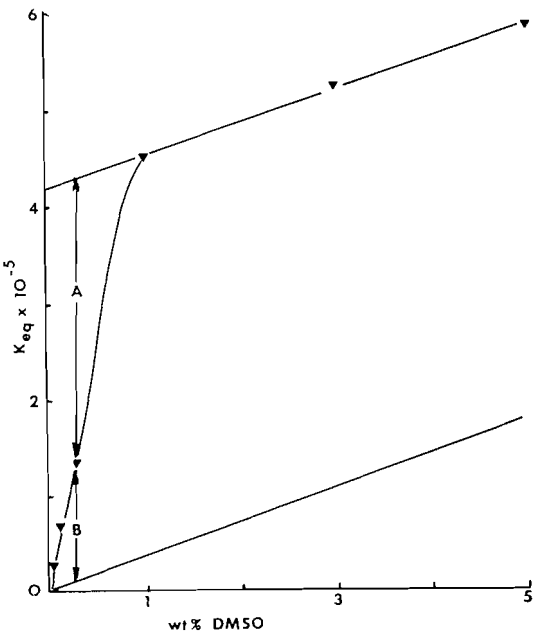

FIG. 1. Equilibrium constant values are plotted versus wt.% DMSO from DEA showing the assumptions made in calculating the equilibrium constant for DMSO–amine hydrogen bond formation. The ratio of A to B is assumed to be the ratio of non-hydrogen bonded amine to hydrogen bonded amine.

Results

The values obtained for equilibrium constants for the formation of proton-transfer complexes between DNP and the amines studied in benzene solution to which varying amounts of DMSO have been added are presented in Table 1. Corresponding values for morpholine are shown in Table 2. The data are plotted for the aliphatic amines in Fig. 2 and for the morpholines in Fig. 3. The equilibrium constants for the formation of a hydrogen bond between DMSO and the amine protons of DEA and DIpA are 9.87 M^{-1} and 15.52 M^{-1}, respectively. Thermodynamic parameters obtained are shown in Table 3.

Discussion

A few of the constants determined in this study had been reported previously. Our equilibrium constant values for the proton-transfer reaction in benzene for DEA and TEA are very

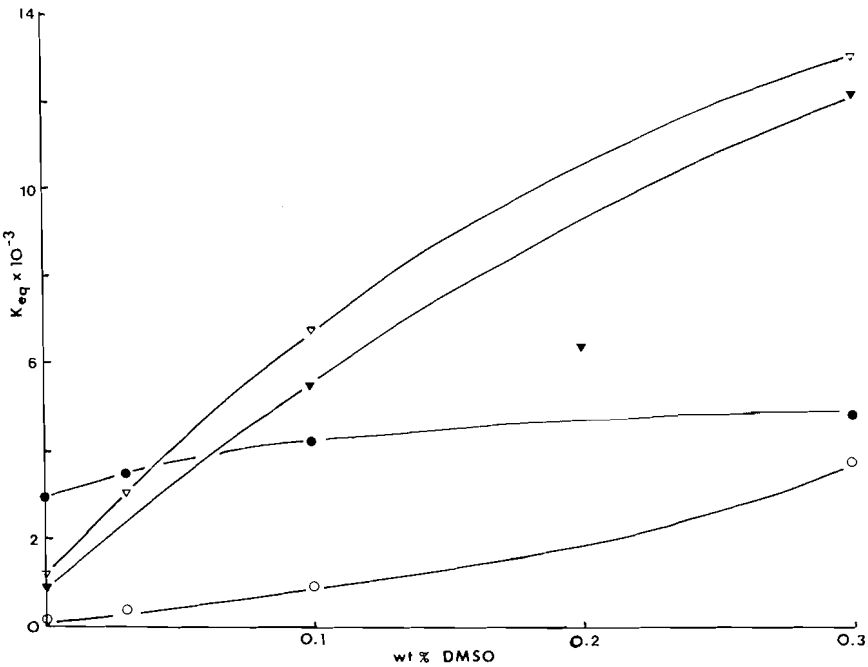

FIG. 4. Trends in the values of equilibrium constants are displayed for the addition of the first 0.3 wt.% DMSO. Legend is as in Fig. 2.

benzene–DMSO solvent system (5). In that study the acid used was *p*-nitrophenol (*p*NP) but in other respects the system was the same. Because *p*NP is a much weaker acid than DNP (pK_a = 7.21 vs. 4.09), it was not possible to perform a proton-transfer reaction to a measurable degree in pure benzene, or in fact in any mixture with less than 30 wt.% DMSO. The DMSO concentration ranged from 30 wt.% to 100 wt.% in that study. Under these conditions there was a large change in solvent dielectric constant, making the observation of the separate contribution of short range solvation forces impossible. However, it was then established by proton nmr that hydrogen bonding does occur between amine protons and DMSO, and there was a clear indication using the *p*NP–TEA interaction as a reference that DMSO does increase the reactivity of both DEA and *n*BA in the proton-transfer reaction.

The data presented in this report show that TEA and NMM, the tertiary amines, show a relatively small increase in the value of the equilibrium constant for the formation of the proton-transfer complex as the solvent is varied from pure benzene to benzene with 5 wt.% DMSO (Figs. 2, 3). Since there are no groups available for hydrogen bond formation between TEA and DMSO, we attribute this small change to the increase in dielectric constant of the solvent with increasing DMSO content. Assuming that a change in dielectric constant would affect all of the amines in the same fashion, this curve allows us to estimate the portion of the increase in equilibrium constant observed with the other amines that is due to long range solvation forces.

A comparison of the TEA and DEA data reveals that the equilibrium constant for DEA rises very sharply at concentrations of DMSO up to 1.0 wt.%. Beyond this the value increases less rapidly, in fact with a slope comparable to that seen for TEA or NMM. Data for *n*BA display a similar increase in equilibrium constant as DMSO is added to that observed with DEA, but the increase continues beyond 1 wt.% DMSO.

The effect of DMSO on the reactivity of primary and secondary amines in both the earlier and the present study is due to the formation of a hydrogen bond between the DMSO oxygen and the amine proton. To the degree that such bonding withdraws the proton from the nitrogen of the unreacted amine the electron density around the nitrogen becomes higher, and the basicity of the amine is enhanced. Once the proton transfer complex is formed and the amine is positively charged, the hydrogen bond to DMSO is even more favored. The hydrogen bond with DMSO would then correct the charge somewhat, stabilizing and so encouraging the formation of the complex. Notice that exactly the same effect is obtained with DIpA and Mo, the other two secondary amines in this study. In the case of primary amines there is an opportunity for two hydrogen bonds to form between the amine and DMSO. The first such DMSO–amine hydrogen does not form as readily as is the case with the secondary amines. In support of this statement we offer a plot of the addition of the first 0.3 wt.% DMSO to the system (Fig. 4). Here we see the shift in the order of basicity of the amines from that determined by the inductive effect of the alkyl groups, such that the tertiary amine is the stronger as has previously been reported for non-polar solvent systems (6), toward one determined by the short range solvation of the amines, such that the primary amine is the stronger as also has been observed previously (3, 7). Notice here that the slope of the change in K_{eq} as DMSO is added is considerably smaller for *n*BA than for DEA. Once the first DMSO has hydrogen bonded to the primary amine, its effect is similar to the inductive effect of the alkyl group, i.e. electron density on the nitrogen is increased, and the slope of increased K_{eq} with increased DMSO concentration approaches that displayed by the secondary amine (Fig. 2). Due to the ability of the primary amine to hydrogen bond two molecules of DMSO the K_{eq} for the primary amine continues to rise, surpassing that of the secondary amines. In an attempt to observe a plateau in the primary amine data higher concentrations of DMSO were added (Table 1) but no plateau was observed. At these higher levels of DMSO long-range solvation may well have become a significant factor. Under these circumstances no effort was made to estimate an equilibrium constant for hydrogen bond formation between DMSO and *n*BA amine protons.

Summary

Equilibrium constants for the formation of proton-transfer complexes between 2,4-dinitrophenol and various aliphatic amines have been measured in benzene and benzene with small additions of DMSO as solvent. These have been used to infer the nature and relative importance of short range solvation in this reaction. Using interactions with tertiary amines as a non-reacting reference system, a sharp rise in the equilibrium constant is observed on the addition of up to 1 wt.% DMSO, after which the increase is less pronounced. It is proposed that the formation of a hydrogen bond between the secondary amine hydrogen and the DMSO oxygen increases the basicity of the amine and thus the value of the equilibrium constant. By 1 wt.% DMSO this bond formation is complete. Based on this assumption equilibrium constants for the hydrogen bond formation have been estimated. Primary amines show similar behavior but continue to display an increase in equilibrium constant beyond 1 wt.% DMSO due to their ability to bond to two DMSO molecules. The response to increasing DMSO concentration indicates that the hydrogen bond formation with primary amines goes less readily than with secondary amines.

Received October 10, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

B. Foster, B. Gaillard, N. Mathur, A. L. Pincock, J. A. Pincock, and C. Sehmbey. Can. J. Chem. **65**, 1599 (1987).

Singlet excited state rate constants have been measured for both the heterolytic and homolytic photocleavage of 3- and 4-methoxy and 3- and 4-cyano (1-naphthylmethyl)trimethylammonium chlorides, **6**–**10**. The results are interpreted in terms of the *meta* effect or changes in charge distribution upon excitation and the competition between bond cleavage, electron transfer, and hydrogen atom transfer in the contact pairs resulting from the two types of cleavage.

B. Foster, B. Gaillard, N. Mathur, A. L. Pincock, J. A. Pincock et C. Sehmbey. Can. J. Chem. **65**, 1599 (1987).

On a mesuré les constantes de vitesse de l'état excité singulet pour la photoclivage tant hétérolytique qu'homolytique des chlorures des méthoxy-3 (et -4) et des cyano-3 (et -4) (naphtyl-1 méthyl)triméthylammonium (**6**–**10**). On interprète les résultats en fonction de l'effet *méta* ou de changements dans la distribution de charge lors de l'excitation ainsi que par la compétition qui se développe entre le clivage des liaisons, les transferts électroniques et les transferts d'atomes d'hydrogène dans les paires de contact qui proviennent de deux types différents de clivage.

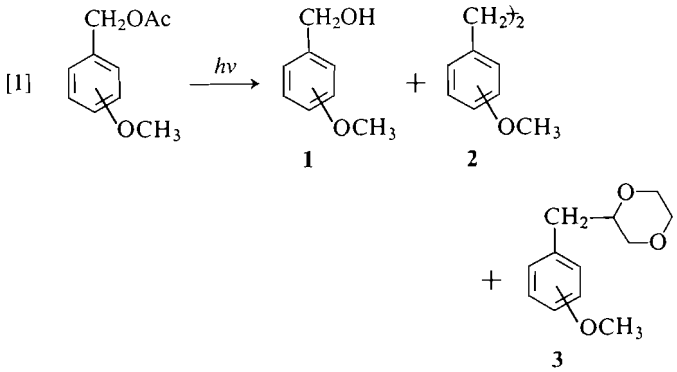
Introduction

The subject of excited state cleavage of a σ bond between a leaving group and a benzylic carbon has recently been reviewed (1). The results compiled clearly indicate that the processes leading to products derived from homolytic and heterolytic cleavage are in competition and that this competition is controlled by factors such as multiplicity, solvent, leaving group, and substituent. In a recent paper (2), we have reported a detailed, excited singlet state rate study of leaving group effects for 1-naphthylmethyl compounds. We now present a similar study on the effect of ring substituents on these reactions.

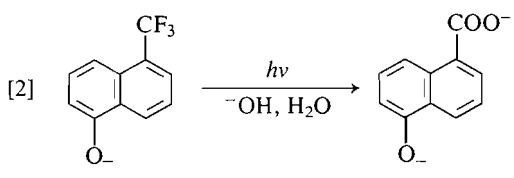
In their pioneering work on photo-benzylic cleavages, Zimmerman *et al.* (3, 4) observed the "*meta*" effect. As shown in eq. [1], photolysis of benzyl acetates in aqueous dioxane gave



benzyl alcohols, **1**, derived from trapping of the corresponding benzyl cation, and two products, **2** and **3**, which are formed from the related benzyl radical. In contrast to ground state predictions, the *meta* methoxy substrate gave an increased yield ($\phi = 0.13$) of the alcohol **1** relative to the *para* isomer ($\phi = 0.016$). Several other examples of this effect were reported at the same time. Moreover, the observation could be rationalized by HMO calculations of the change in charge distribution that results from excitation of a benzylic substrate.

Since that time, several reports supporting this observation have appeared. For instance, the quantum yield for photosolvolysis of benzyltrimethylammonium salts is much reduced, relative to other substituents, for an electron-withdrawing cyano group at the *meta* position (5). Moreover, irradiation of several substituted benzyloxycarbonyl glycines gives a maximum in the quantum yield for the *meta* methoxy substituent (6). Of course, these changes in quantum yield do not necessarily reflect true changes in the reactivity of the substrate since they are determined by ratios of reactive to nonreactive pathways. Since all rates may be affected by substitution, some care must be exercised in interpreting results of this type.

More detailed studies involving rate constant evaluation have been attempted as well. Cristol and Bindel (7, 8) have reported an extensive study of benzylic chlorides. Unfortunately, these substrates react from both the singlet and triplet state, and sorting out the relative reactivity of the two is not easy. Moreover, the reactivity of excited triplet states is inherently more complex because heterolytic cleavage must involve a triplet to singlet conversion. Because of these difficulties, rate data could only be obtained for the triplet state; the lifetimes of these excited states are at, or beyond, the limit for reliable measurement using normal quenching techniques. Wan and Turro (9, 10) have reported enhanced rates of proton quenching of fluorescence for 3-CH_3O, 3-CH_3, and 3-F substituted benzyl alcohols but a complete study was impossible due to the low reactivity of the unsubstituted and 4-substituted cases. Perhaps the best quantitative confirmation of the *meta* effect or, more precisely, changes in charge distribution upon excitation controlling the rate of heterolytic bond cleavage is the work of Seiler and Wirz (11, 12) for the photohydrolysis of trifluoromethyl substituted 1- and 2-naphthols, eq. [2] being an example. In a reaction assumed to proceed by an initial ionic



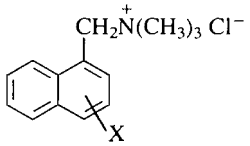
[1]Department of Chemistry, University of Texas at Austin, Austin, TX 78712, U.S.A.

[2]Author to whom correspondence may be addressed.

cleavage of the carbon–fluorine bond, rates as a function of the relative position of the naphthoxide oxygen and the trifluoromethyl group were well correlated with calculated charge density changes upon excitation.

In contrast to these observations supporting the original *meta* effect argument, there are a few opposing reports. Givens and Matuszewski (13) have observed a normal ground state order for the photosolvolysis of a series of benzylic phosphates and McKenna and co-workers (14) report decreased yields of ionic cleavage for 3,5-dimethoxybenzylammonium salts.

In this paper, we report a complete, excited state rate study for both heterolytic and homolytic cleavage for the 1-naphthylmethylammonium chlorides, **6–10**, a series that contains both



6 (X = H), **7** (X = 4-CH_3O), **8** (X = 3-CH_3O), **9** (X = 4-CN), **10** (X = 3-CN)

electron-donating and electron-withdrawing substituents. As outlined in detail previously (2), these compounds were chosen because the parent compound, **6**, gave mixtures of products resulting from ionic and radical intermediates, the triplet state was unreactive, the singlet state had a lifetime that was within the range of nanosecond single-photon counting measurement, and the quantum yield of reaction was high enough to measure conveniently.

Results and discussion

Synthesis of 1-naphthylmethyltrimethylammonium chlorides

The salts were prepared from the corresponding chlorides using anhydrous gaseous trimethylamine. The initial plan was to prepare the chlorides from methylnaphthalene derivatives by *N*-chlorosuccinimide free radical substitution but this only worked satisfactorily for the cyano cases. The methoxy compounds gave complex product mixtures that included ring chlorination, presumably because these naphthalene derivatives are overly activated toward electrophilic chlorination. For these cases the chlorides were prepared from the corresponding alcohols using HCl. The synthetic routes are outlined: Scheme 1 for **7**, Scheme 2 for **8**, Scheme 3 for **9**, and Scheme 4 for **10**. The unsubstituted compound, **6**, has been reported previously (2). Details and appropriate references are in the experimental section.

The ultraviolet spectra in methanol are plotted in Fig. 1 and are sufficiently different to confirm clearly the substitution pattern, since they agree well with absorption maxima and extinction coefficients in methanol for sample analogues: 4-methoxy-1-methylnaphthalene, λ_{max} 295 nm (ε 4530); 3-methoxy-1-methylnaphthalene, λ_{max} 327 (ε 1110), 315 (ε 620), 286 (ε 3160), 272 (ε 3840), 262 (ε 3450); 4-cyano-1-methylnaphthalene, λ_{max} 299 (ε 6110); and 3-cyano-1-methylnaphthalene, λ_{max} 334 (ε 2540), 320 (ε 1550), 294 (ε 5420), 282 (ε 7140). There are two transitions above 250 nm for naphthalene derivatives (15), a longitudinal polarized ^1L_b band and a transverse polarized ^1L_a band. Substitution in the 4 position by the conjugating methoxy or cyano groups causes bathochromic and hyperchromic effects on the ^1L_a band so that the weaker ^1L_b band is obscured. In contrast, substitution in the 3 position has a similar effect on the ^1L_b band so that it is now readily observable; this is particularly true for the methoxy group.

Preparative scale photolysis of the salts, 7–10

Irradiation of the salts in methanol with nitrogen purging using a Pyrex filtered 200-W Hanovia medium pressure mercury lamp gave clean conversion to the methyl ether, **11**, and the methylnaphthalene, **12** (2), eq. [3]. Calibrated hplc analysis of the reaction mixtures, Table 1, showed excellent mass balance and no evidence for other products. These reactions were irradiated until no further increase in product peaks was obvious and therefore the yields represent mass balance with essentially complete conversion of starting material. Continuous monitoring by hplc during photolysis indicated that the product ratios were independent of extent of conversion and controls showed that there was no conversion of **11** to **12**.

Reaction multiplicity; quantum yields and singlet reaction rates

Before attempting quantum yield and rate studies for these salts, information on reaction multiplicity was necessary to insure that only the singlet was reacting. As reported previously (2), this is straightforward for **6** (X = H) since xanthone sensitization gives no reaction; direct irradiations must be singlet reactions. For the other substrates this experiment is more difficult since their ultraviolet spectra, Fig. 1, extend to longer wavelengths and compete for absorption with xanthone, λ_{max} 338 nm (ε 6800). Using a $BiCl_3$ filter solution with a cut-off at 342 nm, xanthone concentration of 8.5×10^{-4} *M* (*A* = 2 at 350 nm), and the 4-methoxy compound **7** at 2.5×10^{-3} *M* (*A* = 0 at 350 nm), clean conversion to the methyl ether **11** was observed. That xanthone does transfer triplet energy to the salt in methanol was confirmed by flash photolysis studies. The transient triplet–triplet absorption spectrum of xanthone with λ_{max} 610 nm (16) is quenched by the salts **6–10**, leading to the appearance of the triplet–triplet absorption of the salt with a broad structureless band centered at approximately 440 nm. Decay of this band was first order and allowed calculation of the triplet lifetimes in methanol, which are reported in Table 1. Since we wished to examine the singlet reactivity of these salts, we did not pursue these sensitization studies but rather chose to quench any possible triplet state reaction.

Triplet quenching of these substrates (E_T = 56–62 kcal/mol, Table 1) should be close to the diffusion controlled rate (1.8×10^{10} M^{-1} s^{-1} in methanol (17*a*)) by 2,5-dimethylhexadiene (E_T = 58.7 kcal/mol (17*b*)). However, singlet state quenching of naphthalene derivatives by this diene is also very rapid (18) and a value of 9.3×10^{9} M^{-1} s^{-1} has been reported previously for **6** (2). Stern–Volmer fluorescence intensity quenching plots for **6–10** are shown in Fig. 2 and the $k_q\tau_S$ values from the slopes are listed in Table 2 along with the k_q values calculated using τ_S values from Table 1. The k_q values for the singlet are close to the diffusional value for the cyano cases but there is obviously a small substituent effect. This effect is as expected, based on the observation (18) that this singlet quenching represents exciplex formation involving electron transfer from the diene to the naphthalene derivative.

Fortunately, the more than three orders of magnitude difference between the singlet, τ_S, and triplet lifetimes, τ_T, of the naphthylammonium salts makes selective quenching possible. The quantum yields for formation of **11** and **12** for all five substrates **6–10** are given in Table 3. These values were obtained at the specific concentration of the diene given.

The percent of triplet excited states quenched, Table 3, at this concentration of diene is calculated from the known triplet lifetimes (Table 1) by the relationship, eq. [4], assuming $k_q = k_{diff} = 1.8 \times 10^{10} M^{-1} s^{-1}$.

$$[4] \quad \%T = 100\, k_q[D] \Big/ \left(\frac{1}{\tau_T} + k_q[D]\right)$$

Because the triplet energy gap between the naphthalenes and the

diene is not exothermic for all cases, the k_q values are likely to be less than diffusional (19). The diene concentration used for the quantum yields was deliberately chosen to be high enough so there was no ambiguity about the quenching of essentially all the excited triplets.

The percent of singlet excited states quenched at this concentration of diene can be calculated from an expression identical to eq. [4] except that the k_q values are known. These values are also in Table 3. They range from 3 to 20%. The measured quantum yields of singlet reaction to form **11** and **12** are therefore lower than the real quantum yields by this amount. Corrected values are given in Table 3.

The mechanism of photocleavage

The mechanistic steps required to discuss the bond cleavage reactions are shown in Scheme 5. These steps will now be discussed in detail.

The light absorption step 1 is the ^1L_b transition under conditions used for the quantum yields since the wavelengths chosen were 280 nm for **6**, **8**, and **10** and 300 nm for **7** and **9** (see Fig. 1). For the 4-methoxy and 4-cyano salts this transition is very close in energy to the ^1L_a one and, although difficult to tell, this may be S_1. For the other three compounds rapid internal conversion from S_2 to S_1 is expected to give the ^1L_a state. Although there has been some suggestion from flash photolysis experiments that S_1 for chloromethylnaphthalene does not dissociate efficiently and that bond cleavage occurs more efficiently upon excitation to S_2 (19), more recently results (20) have shown that the 1-naphthylmethyl radical can be

1. $S_0 + h\nu \rightarrow S_1$
2. k_F $S_1 \rightarrow S_0 + h\nu_F$
3. k_{ISC} $S_1 \rightarrow T_1$
4. k_R^T $T_1 \rightarrow ArCH_2^{\bullet} + {}^{\bullet}\overset{+}{N}(CH_3)_3$
5. k_Q^T $T_1 + Q \rightarrow S_0$
6. k_Q^S $S_1 + Q \rightarrow S_0$
7. k_I $S_1 \rightarrow [ArCH_2^+ :N(CH_3)_3]$
8. k_R $S_1 \rightarrow [ArCH_2^{\bullet} {}^{\bullet}\overset{+}{N}(CH_3)_3]$
9. k_D $S_1 \rightarrow S_0$
10. k_{HT} $[ArCH_2^{\bullet}\ H{-}CH_2{-}\overset{+}{N}(CH_3)_2 \rightarrow ArCH_3 + CH_2{=}\overset{+}{N}(CH_2)$
11. k_{ET} $[ArCH_2^{\bullet} {}^{\bullet}\overset{+}{N}(CH_3)_3] \rightarrow ArCH_2^+ + :N(CH_3)_3$
12. k_{RD} $[ArCH_2^{\bullet} {}^{\bullet}\overset{+}{N}(CH_3)_3] \rightarrow ArCH_2^{\bullet} + {}^{\bullet}N(CH_3)_3$
13. k_{ID} $[ArCH_2^+ :N(CH_3)_3] \rightarrow ArCH_2 + :N(CH_3)_3$
14. $ArCH_2^+ + CH_3OH \rightarrow ArCH_2OCH_3 + H^+$

SCHEME 5. Mechanistic scheme for the photolysis of the naphthylmethyl ammonium salts, **6**–**10**.

generated from S_1. We have not examined wavelength effects for the efficiency of photocleavage, but the fluorescent quantum yield for **6** was independent of excitation wavelength from 280 to 320 nm.

The S_1 fluorescence step 2 is efficient for all of these naphthyl derivatives and the quantum yields are listed in Table 2. The associated rate constants for fluorescence, $k_F = \phi_F/\tau_S$, are also listed in Table 2 and we note that the order is at least qualitatively as expected from the absorption spectra in Fig. 1 (2). The 4-methoxy and 4-cyano compounds with the highest extinction coefficient have the fastest fluorescence rate and the unsubstituted compound has the slowest. From the absorption and fluorescence spectra the position of the (0,0) band can be estimated to give the singlet energies listed in Table 1.

The intersystem crossing efficiency, step 3, is unknown for these naphthyl derivatives. It is worth noting, however, that the sum of the quantum yields of fluorescence and singlet reaction for these substrates (ϕ_T) is similar to, but usually somewhat larger than, that for the ϕ_F of the corresponding unreactive cases: **6**, $\phi_T = 0.31$, naphthalene, $\phi_F = 0.24$ (2); **7**, $\phi_T = 0.45$, 1-methoxynaphthalene, $\phi_F = 0.43$ (21); **8**, $\phi_T = 0.49$, 2-methoxynaphthalene, $\phi_F = 0.33$ (21); **9**, $\phi_T = 0.53$, 1-cyanonaphthalene, $\phi_F = 0.37$ (21); **10**, $\phi_T = 0.64$, 2-cyanonaphthalene, $\phi_F = 0.53$ (21). Moreover, for unreactive naphthalene derivatives the sum of $\phi_F + \phi_{ISC}$ is close to unity; for instance, naphthalene (0.20 + 0.80), 1-methylnaphthalene (0.21 + 0.77), and 1-methoxynaphthalene (0.43 + 0.50) (17*c*). Therefore, it is probable that the photoprocess unaccounted for in the case of **6**–**10** is intersystem crossing rather than internal conversion of S_1 to the ground state.

That intersystem crossing does occur from these substrates is well established since they all show phosphorescence in a rigid matrix at 77 K. This phosphorescence can be used to calculate the triplet energies in Table 1. Furthermore, the triplet state of these substrates can be observed by flash photolysis in methanol at room temperature as a broad transient absorption centered at about 440 nm. Decay of this transient was difficult to monitor as it always overlapped with another transient with a maximum at 360 nm, which we have assigned to the naphthylmethyl radical. Similar observations have been made for 1-chloromethylnaphthalene (19, 20). In that case, decay of the triplet was much faster than decay of the radical and the method was used to study the chemistry of the radical. For these ammonium salts the two transients decayed with similar lifetimes. Cleaner spectra of the triplets could be generated by xanthone sensitization as described above.

[e]Quantum yields corrected for % of quenched.
[f](Errors) are standard deviations.

Bond cleavage from the excited triplet as in step 4 can only give a radical pair since heterolytic cleavage leading to a pair of singlet products must be a singlet process. For the unsubstituted naphthylmethylammonium salt, **6**, no reaction occurs upon sensitization with xanthone (2). Since the rate of triplet decay is $1.1 \times 10^5\ s^{-1}$, the rate of reaction must be considerably slower to be undetected. A reasonable explanation for this slow rate is the high bond strength expected for these salts. An estimate of the carbon–nitrogen bond strength in (1-naphthylmethyl)amine is 61 kcal/mol, based on a value of 64 kcal/mol for benzylamine (22) minus about 3 kcal/mol for the stabilization of the naphthylmethyl radical relative to benzyl (23). Substitution of the methyl groups at the nitrogen will weaken the bond further but quaternization of an amine to an ammonium salt is known, by MO calculations, to lead to large increases in bond strength.[3] For instance, using third-order Møller–Plesset perturbation theory at the 6-31G** level and the 6-31G* optimized geometry yields a calculated bond dissociation energy for CH_3—NH_2 of 87 kcal/mol, which increases to 117 kcal/mol for CH_3—$^+NH_3$. The bond strength of **6** is therefore likely higher than the available triplet energy of 62 kcal/mol. Despite the expected endothermicity of this process, xanthone sensitized irradiation of **7** did in fact result in the methyl ether expected from ionic cleavage of the carbon–nitrogen bond (see above). It seems unlikely therefore that this represents reactivity of the triplet state of this substrate and adds support to Schuster's suggestion that sensitization of these naphthylmethyl compounds results in exciplex formation (24). Further work on this topic of sensitization is obviously required before definite conclusions can be reached.

The steps 5 and 6 represent quenching of the excited triplet and singlet state, respectively, of the naphthyl derivatives. Both of these rates are rapid but, as discussed above, the irradiations were done with concentration of the quencher chosen so that triplets were quenched effectively but singlets were not (see Table 3). Consequently, the results reflect only the reactivity of the excited singlet state.

Steps 7 and 8 are therefore the rates of interest, the first is for heterolytic cleavage of the carbon–nitrogen bond to give the 1-naphthylmethyl cation and trimethylamine, the second for homolytic cleavage to the 1-naphthylmethyl radical and the trimethylamine radical cation. (In both cases, the dissociated species are shown as contact pairs; the diffusion to solvent separated pairs is shown in steps 12 and 13.) Both of these processes could be rapid since the singlet energies (Table 1) are above the expected bond strengths. It is these two rate constants, k_I and k_R, that are required to assess substituent effects properly and to confirm whether charge distribution changes upon excitation control the two rates of photocleavage. However, there are complications that make unambiguous determination of these values difficult.

The quantum yields of formation of the ethers **11** in eq. [3] and the singlet lifetimes, τ_S, of the substrates allow evaluation of an operational rate constant for product formation, k_{11}, according to eq. [5]. A similar expression is used for k_{12}. The

$$[5] \quad \phi_{11} = \frac{k_{11}}{k_F + k_D + k_{ISC} + k_{11}} = k_{11}\tau_S$$

values are in Table 3 for the substrates **6**–**10**. The complications in relating these operational rate constants to k_I and k_R are outlined in steps 9–13 of Scheme 5.

The first of these, step 9, is the internal conversion of S_1 to S_0. For unreactive naphthalene derivatives, as discussed above, the quantum yields of fluorescence plus intersystem crossing are usually close to unity, therefore internal conversion is not an important component of singlet decay. This is presumably a result of the large energy gap in a rigid molecule, making vibrational overlap poor. For these reactive naphthalene cases, this step could, in contrast, be quite important. For instance, reversal of either k_I or k_R, that is, internal return from the intimate pair resulting from either heterolytic or homolytic cleavage, would be a method of excited state decay that would only be detectable as k_D. If this were true, measured k_{11} and k_{12} would be smaller than k_I and k_R. There are two pieces of evidence that suggest that internal return is not important. The first is that, as discussed above, the sum of the quantum yields of reaction plus fluorescence for these substrates is larger than that for unreactive models where the only other mode of excited singlet decay is intersystem crossing. The second is the observation that no racemization of starting material is observed

for the photolysis of an analogous chiral benzylammonium salt (25).

Steps 10 and 11 are two processes that may well be competitive with each other. Step 10 is hydrogen atom transfer from the radical ion of trimethylamine to the naphthylmethyl radical. Since the C—H bond strength in this radical ion is much lower (34 kcal/mol) (26) than that expected for 1-methylnaphthalene (82 kcal/mol) (22), this process should be exothermic by approximately 48 kcal/mol and therefore rapid. In fact, this process must be faster than step 12, which is the diffusional separation of the contact pair to give the free 1-naphthylmethyl radical. Photolysis of 1-naphthylmethyl derivatives in methanol normally gives the dimer of the 1-naphthylmethyl radical as a major product derived from homolytic cleavage (2, 24). Only with trimethylamine as the leaving group is 1-methylnaphthalene the exclusive product. This observation suggests that, for this leaving group, the radical never gets free of the contact pair. In the case of the corresponding benzylic substrates, a related observation is that formation of the dimer occurs only from the triplet excited state (27) in which hydrogen atom transfer should be slower because of the spin restriction in a process leading from triplet contact pairs to singlet products. Diffusional separation now occurs.

Step 11 is electron transfer in the contact pair. If this process is important, then there is a pathway for formation of the 1-naphthylmethyl cation by a route that initially involved homolytic cleavage of the carbon–nitrogen bond. The operational rate constant k_{11} would then be greater than the real rate constant for heterolytic cleavage. In fact, solution oxidation potentials for the benzyl radical (+0.40 V vs. $Ag/AgNO_3$ in CH_3CN) (28) and trimethylamine (+0.82 V vs. $Ag/AgNO_3$ in CH_3CN) (29) indicate that electron transfer like that for Step 11 would be exothermic by 10 kcal/mol. The oxidation potential for the 1-naphthylmethyl radical itself is not known and therefore an exact determination of the exothermicity for the particular electron transfer involved with these substrates cannot be made. Moreover, the substituted naphthalene derivatives would have differing oxidation potentials depending on the substituent. At any rate, it appears that electron transfer in the contact pair derived from homolytic cleavage should be favorable. Possibly this effect is being most strongly observed for the 4-methoxy substrate, **7**, where the only observable product is the ether **11**, derived from the 1-naphthylmethyl cation.

This point concerning electron transfer should, in fact, be important for all photochemical benzylic cleavages. Many of the usual leaving groups have oxidation potentials higher than that for trimethylamine: bromide (0.7 V vs. SCE in CH_3CN) (30), chloride (1.1 V vs. SCE in CH_3CN) (30), dimethylsulfide (1.4 V vs. $Ag/AgNO_3$ in CH_3CN) (31), and alcohols (no oxidation in CH_3CN up to solvent limit) (32). This implies that electron transfer in the pair generated from homolytic cleavage should, in general, be favorable. It is perhaps surprising that products derived from the benzylic radical are ever observed, since the process in competition with electron transfer is diffusion from the solvent cage. In the case of trimethylamine studied by us, the process in competition with electron transfer is hydrogen atom transfer. Both should be exothermic and it is very difficult to predict their relative rates. Cases of slow exothermic electron transfer are now well established (32) and seem to be attributed to the solvent reorganization required according to Marcus theory as the charge moves from one site to the other. Since complete electron transfer is not observed, it is possibly correct to assume that electron transfer does not compete with hydrogen atom transfer. If this is true, then the product ratios and quantum yields observed are a direct reflection of the initial homolytic and heterolytic cleavage steps, and the calculated rates k_{11} and k_{12} do correspond to k_I and k_R.

Before discussing these rate variations, it is worth mentioning that the original *meta* effect was attributed to charge distribution changes on excitation using SHMO calculations (3, 4). The prediction was not only that an electron-donating substituent *meta* to the reactive site would be activating for heterolytic cleavage but also that a *para* substituent would be deactivating relative to the unsubstituted case. The converse would be true for an electron-withdrawing substituent: activation for the *para* substitution and deactivation for the *meta*. The idea was that these effects would be most important for generation of the cationic intermediate and that the radical intermediate would perhaps form at a more or less constant rate independent of substituent. Calculations at the SHMO level for excited states are, of course, very naive and, for instance, do not even take into account that the degeneracies of both the HOMO and LUMO, which predict only one transition, are lost by differing electron correlation in the various possible configurations. The result is three transitions: ^1L_b, ^1L_a, and ^1B (15*b*). In methoxynaphthalenes, the 2-isomer has the lowest lying state as ^1L_b, but for the 1-isomer, S_1 is more likely to be ^1L_a (see Fig. 1). Excited state electron densities have been calculated for 1- and 2-methoxynaphthalene (33). The results suggest that for a 1-methoxy substituent the electron density *para* should decrease for both the ^1L_b and the ^1L_a states; for a 2-methoxy substituent, the electron density increases *meta* in the ^1L_b state. In other words, the *meta* effect is still predicted.

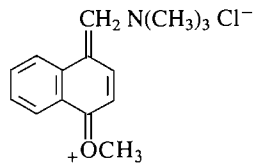
The first fact that should be pointed out concerning the rate constants k_{11} and k_{12} in Table 3 is the relatively small total range of the values, a factor of about 20 for the heterolytic process, k_{11}, and about 40 for the homolytic one, k_{12}. This point is particularly interesting when compared to analogous ground state processes. For instance, the solvolysis of substituted cumyl chlorides by an S_N1 mechanism to generate a carbocation has a predicted rate spread of 10^8 going from the activating 4-methoxy group to the deactivating 4-cyano group, giving a ρ^+ value of -4.5 (34). The much lower rate spread for the photochemical process is probably a reflection of the exothermic nature of the rate-determining step so the substituent selectivity is lost. For ground state processes leading to benzylic radicals the range of substituent effects is quite variable because of the changing polarity of the transition state. For instance, hydrogen abstraction from substituted toluenes by bromine atoms gives a rate spread of 10^2 and a ρ^+ value of -1.4 (35), but the substituent effect drops to almost zero for the pyrolysis of benzylic azo compounds (35). In processes that truly reflect radical stability, both 4-methoxy and 4-cyano are rate accelerating and 3-methoxy and 3-cyano are rate retarding, as predicted by the $\sigma^\cdot$ scale (36). Again substituent effects are very small, for instance, a range of only three for the methylenearylcyclopropane rearrangement (37). Not surprisingly, rationalizing these small rate changes has been considerably more difficult since more than just transition state stability will be important. The rate range for the exothermic photochemical homolytic cleavages of **6**–**10** is then actually quite large by comparison. The second point to mention is this: the spread in rate constants is greater for the homolytic process than it is for the heterolytic one. As mentioned above, the original concept of the *meta* effect was directed at electron density changes upon excitation

having major effects on heterolytic bond cleavage, with no mention made of the homolytic one. It is in fact difficult to predict the way in which substituent effects should influence the homolytic cleavage of the quite polar carbon–nitrogen bond in these ammonium salts. Quite possibly a neutral leaving group might lead to considerably different results.

Examination of the values reveals that, if the 4-methoxy substrate is omitted for the moment, the *meta* effect may be controlling the rate constants. For the heterolytic process, the rates are close to the expected order: 3-methoxy > hydrogen > 4-cyano > 3-cyano with only 4-cyano too slow to fit the scheme. Surprisingly, the homolytic process follows exactly the order predicted by the *meta* effect for a heterolytic cleavage. Possibly, the electron density changes on excitation are influencing the rate of bond cleavage, and the final product distribution is actually a function of electron transfer distribution in the two developing fragments.

Finally, the 4-methoxy compound, **7**, reacts with both a rate constant (higher) and a product partitioning (exclusively heterolytic) that seem out of line with the other substituents. Similar high yields of ionic cleavage have been observed for a related 4-methoxybenzylammonium salt (25). Their results are, of course, not predicted by the *meta* effect. Perhaps, in fact, the mechanism changes because of direct interaction between the electron-donating methoxy group and the inductively electron-withdrawing trimethylammonium group. The ground state probably has considerable charge delocalization, as in **12**. This is seen in the absorption spectrum where the extinction coefficient for **7** increases to 10500 from 4500 for the corresponding 4-methoxy-1-methylnaphthalene. This effect should be most pronounced for a very electronegative group like a positively charged nitrogen, although, contrary to this prediction, positively charged oxygens as leaving groups still seem to retain the *meta* effect (9, 10). At any rate, internal charge transfer of this type may modify the nature of the charge changes on excitation and favour heterolytic cleavage. Cristol and Bindel (1) have made this suggestion for some substituted benzyl compounds and have even applied the Weller equation to rationalize observed bond cleavages.

Since the *meta* effect arguments do not rationalize these rate constants very well, it was obviously of interest to look at Hammett type substituent approaches. Four scales of σ value should be considered: normal σ and σ^+, $\sigma^\cdot$ (36) for radical stability, and σ^{ex} (38) derived from the excited singlet state pK_a of phenols. Differentiating between σ and σ^+ is probably impossible with the substituents available since only 4-methoxy will have a different value on the two scales. However, the plot of log k_{11} (the heterolytic process) versus σ gives $\rho = -1.4 \pm 0.2$ ($r = 0.96$) and versus σ^+ gives $\rho^+ = -0.9 \pm 0.2$ ($r = 0.94$). In both cases it is perhaps significant that the 3-methoxy value is above the line and the 3-cyano below the line (the *meta* effect?). The negative ρ values indicate that, in general, electron-donating groups favour this process as expected for a ground state cation-forming reaction. For k_{11} (the homolytic process) there is no obvious σ or σ^+ correlation. The $\sigma^\cdot$ scale for radical stability is also of little help since it predicts that both 4-methoxy and 4-cyano should be rate accelerating and 3-methoxy about equal in reactivity to the unsubstituted case. Finally, consideration of the σ^{ex} scale reveals that there is no value for 3-cyano but that the remaining four points give a correlation for k_{11}, $\rho = 0.52 \pm 0.1$ ($r = 0.94$), that is dominated by the large σ^{ex} value of 1.6 for 4-cyano but again shows the trend of negative ρ value.



13

Independent of the reason for the enhanced heterolytic cleavage observed for **7**, one of the objectives of this study was to learn enough about substituent effects in photochemical benzylic cleavages to be able to design synthetically useful reagents for controlling the partitioning between the two possible pathways. This objective has been reached and uses of the 4-methoxynaphthyl methyl group are currently being studied.

Experimental

Preparation of (1-naphthylmethyl)trimethylammonium chlorides

6, (X = H): Prepared as described previously (2): mp 251–252°C. The melting point reported previously (231–232°C) was a typographical error.

7, (X = 4-CH_3O): 4-Methoxy-1-naphthaldehyde was prepared from 1-methoxynaphthalene by the previously reported method (39); bp 178–179°C at 3 Torr (1 Torr = 133.3 Pa) (lit. (39) bp 205–206°C at 16 Torr); nmr ($CDCl_3$) δ: 9.90 (s, 1H), 8.0–8.2 (m, 1H), 7.2–7.7 (m, 5H), 6.53 (d, J = 8 Hz, 1H), 3.83 (s, 3H).

4-Methoxy-1-naphthaldehyde was reduced to 4-methoxy-1-naphthylmethanol as follows. To a solution of 4.6 g (0.12 mol) of sodium borohydride in 50 mL of ethanol was slowly added a solution of 44.5 g (0.24 mol) of the aldehyde in 30 mL of ethanol with the temperature kept below 50°C. After 1 h, 1000 mL of water was added and the mixture extracted with 2 × 200 mL of ether. The ether layer was washed with 2 × 200 mL of water, dried with $MgSO_4$, and evaporated to give 43.3 g (0.23 mol, 96%) of crude alcohol. Recrystallizing from benzene gave the pure alcohol, mp 76–77°C; nmr ($CDCl_3$) δ: 8.0–8.2 (m, 1H), 7.6–7.8 (m, 1H), 7.2–7.45 (m, 2H), 7.00 (d, J = 7 Hz, 1H), 6.35 (d, J = 7 Hz, 1H), 3.70 (s, 3H), 2.95 (br s, exchangeable, 1H).

The alcohol (2 g, 0.011 mol) was dissolved in 80 mL of ether and hydrogen chloride gas was bubbled for 1 h. The ether solution was then washed with 50 mL of water and 50 mL of 5% sodium bicarbonate, dried over $MgSO_4$, and concentrated to give 2.01 g (8.7 mmol, 88%) of crude chloro-(4-methoxy-1-naphthyl)methane; nmr ($CDCl_3$) δ: 7.75–8.2 (m, 2H), 7.2–7.5 (m, 2H), 7.13 (d, J = 8 Hz, 1H), 6.43 (d, J = 8 Hz, 1H), 4.80 (s, 2H), 3.75 (s, 3H).

The crude chloride was dissolved in 100 mL of ether and trimethylamine was bubbled through the solution slowly for 3 h. The reaction was left overnight and the white solid filtered to give 2.34 g (8.5 mmol, 77% based on the alcohol) of crude (4-methoxy-1-naphthyl)methyltrimethylammonium chloride, **7**. This salt was purified by recrystallization from acetonitrile; mp 219–220°C; ultraviolet (Fig. 1); nmr (220 MHz, D_2O) δ: 8.24 (d, J = 8.5 Hz, 1H), 8.08 (d, J = 8.5 Hz, 1H), 7.75 (t, 1H), 7.62 (t, 1H), 7.60 (d, J = 8.1 Hz, 1H), 7.00 (d, J = 8.1 Hz, 1H), 4.81 (s, 2H), 4.11 (s, 3H), 3.13 (s, 9H); mass spectrum: 216 (41), 215 (67), 214 (51), 209 (30), 208 (60), 207 (48), 206 (84), 200 (40), 184 (38), 173 (45), 172 (71), 171 (100), 157 (17), 142 (37), 141 (55), 129 (36), 128 (49), 127 (27), 115 (34), 59 (37), 58 (46), 57 (19), 52 (11), 50 (24). *Anal.* calcd. for $C_{15}H_{20}NOCl$: H 7.59, N 5.27, Cl 13.34; found: H 7.90, N 5.38, Cl 13.33.

8, (X = 3-CH_3O): 1-Bromo-3-methoxynaphthalene was prepared as described previously (40); nmr ($CDCl_3$) δ: 7.1–8.0 (m, 5H), 6.77 (d, J = 2 Hz, 1H), 3.63 (s, 3H).

A Grignard reagent was prepared from 5.3 g (23 mmol) of the bromo derivative, 0.60 g (25 mmol) of magnesium, and 15 mL of ether, and then 12 mL of benzene was added. To this solution was added formaldehyde, generated from the pyrolysis of 0.80 g (26 mmol) of dried paraformaldehyde. The solution was refluxed for 1 h after the addition and then poured into a solution of 5 mL of HCl in 500 mL of water. This mixture was extracted with 3 × 50 mL of ether. The ether

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

was washed with 2 × 50 mL of saturated $NaHCO_3$, dried over $MgSO_4$, and concentrated to give 3.4 g of a crude mixture of starting bromide and product alcohol. Chromatography using silica gel and benzene eluent gave 1.9 g (10 mmol, 46%) of the alcohol, which was recrystallized from low boiling petroleum ether to give pure (3-methoxy-1-naphthyl)methanol; mp 88–89°C, nmr ($CDCl_3$) δ: 7.99 (d, J = 8.3 Hz, 1H), 7.77 (d, J = 8.2 Hz, 1H), 7.44–7.50 (t, 1H), 7.36–7.42 (t, 1H), 7.23 (d, J = 2.3 Hz, 1H), 7.09 (d, J = 2.4 Hz, 1H), 5.12 (s, 2H), 3.92 (s, 3H), 2.67 (br s, exchangeable, 1H).

The alcohol, 2.2 g (12 mmol), was placed in a round-bottomed flask and melted in an oil bath. To it was added 20 mL of concentrated HCl and the mixture was stirred for 2 h. After cooling, 120 mL of $CHCl_3$ was added and the mixture was washed with 60 mL of water and 60 mL of saturated $NaHCO_3$. The $CHCl_3$ layer was dried with $MgSO_4$ and concentrated to give 2.2 g (11 mmol, 92%) of crude chloro-(3-methoxy-1-naphthyl)methane as a yellow solid. The chloride was dissolved in 100 mL of anhydrous ether and trimethylamine was bubbled slowly through the solution for 3 h and then the reaction was left overnight. Filtration of the white solid gave 1.75 g (6.6 mmol, 55% based on starting alcohol) of crude (3-methoxy-1-naphthyl)methyltrimethylammonium chloride, **8**. Recrystallization from acetonitrile gave the pure salt; mp 174–176°C; ultraviolet (Fig. 1); nmr (220 MHz, D_2O) δ: 8.03 (m, 1H), 7.87 (m, 1H), 7.5–7.7 (m, 2H), 7.38 (d, J = 2.4 Hz, 1H), 7.21 (d, J = 2.4 Hz, 1H), 4.73 (s, 2H), 3.99 (s, 3H), 3.12 (s, 9H); mass spectrum: 215 (37), 209 (20), 208 (57), 207 (44), 206 (70), 173 (40), 172 (70), 171 (100), 158 (21), 157 (49), 156 (42), 141 (22), 129 (45), 128 (59), 127 (39), 115 (15), 59 (46), 58 (50), 57 (23), 50 (17). *Anal.* calcd. for $C_{15}H_{20}NOCl$: H 7.59, N 5.27, Cl 13.34; found: H 7.82, N 5.65, Cl 13.44.

9, (X = 4-CN): 4-Cyano-1-methylnaphthalene, mp 50–51°C (lit. (41) mp 53–54°C), was prepared as described previously (41) from 4-bromo-1-methylnaphthalene (42).

A solution of 5.0 g (30 mmol) of 4-cyano-1-methylnaphthalene and 5.3 g (40 mmol) of *N*-chlorosuccinimide in 10 mL of chlorobenzene was irradiated for 8 h using a 300-W tungsten lamp (43). The reaction refluxed during the irradiation from the heat of the lamp. Monitoring by nmr indicated no further conversion was occurring. The mixture was allowed to cool and then filtered. The solid was washed with CCl_4 and the filtrate evaporated to give 5.4 g of material, which, by nmr analysis, consisted of 50% chloro-(4-cyano-1-naphthyl)methane and 50% 4-cyano-1-methylnaphthalene.

The mixture was dissolved in 50 mL of ether and trimethylamine was bubbled through the solution for 3 h. The reaction mixture was filtered after standing overnight to give 3.5 g of the ammonium salt. Recrystallization from acetonitrile gave the pure salt, **9**; mp 243–245°C; ultraviolet (Fig. 1); nmr (220 MHz, D_2O) δ: 8.29 (d, J = 8.2 Hz, 1H), 8.04 (m, 1H), 8.01 (d, J = 7.6 Hz, 1H), 7.7–7.9 (m, 3H), 5.06 (s, 2H), 3.20 (s, 9H); mass spectrum: 210 (45), 202 (29), 201 (17), 200 (58), 181 (49), 180 (30), 167 (53), 166 (99), 165 (18), 164 (36), 140 (47), 139 (45), 65 (33), 59 (35), 58 (48), 57 (18), 50 (15). *Anal.* calcd. for $C_{15}H_{17}N_2Cl$: H 6.57, N 10.74, Cl 13.61; found: H 6.48, N 10.32, Cl 13.40.

10, (X = 3-CN): 1-Acetamido-4-methylnaphthalene; mp 166–168°C (lit. (43) 168–169°C) was prepared by Beckmann rearrangement of the oxime derived from 1-acetyl-4-methylnaphthalene (44). All attempts to brominate this compound gave mixtures that could not be separated. However, 1-amino-4-methylnaphthalene was cleanly brominated by the procedure of Kosolapoff (45).

The amide, 10 g (51 mmol), was dissolved in 12 mL of 95% ethanol, 12 mL of concentrated HCl was added, and the mixture refluxed for 3 h. To the cooled solution was added 200 mL of water and NaOH pellets until the pH was 10. The aqueous layer was extracted with 2 × 100 mL of chloroform and the extract washed with water, dried over $MgSO_4$, and concentrated to give 8.0 g (100%) of the amine; nmr ($CDCl_3$) δ: 7.7–8.1 (m, 2H), 7.3–7.6 (m, 2H), 7.1 (d, J = 8 Hz, 1H), 6.67 (d, J = 8 Hz, 1H). To the amine dissolved in 16 mL of dioxane, 21 mL of water, and 6 g of potassium hydroxide was added over 2 h a solution of 2.6 mL (50 mmol) of bromine in 85 mL of dioxane. Then 100 mL of H_2O was added and the mixture extracted with 2 × 100 mL of $CHCl_3$. The extracts were washed with 50 mL of 40% KOH and 50 mL of H_2O, dried over $MgSO_4$, and concentrated to give 8.8 g (74%) of 1-amino-2-bromo-4-methylnaphthalene; nmr ($CDCl_3$) δ: 7.3–8.0 (m, 5H), 4.4 (br s, 2H), 2.50 (s, 3H).

The amine was deaminated as follows (46). To 21 g (89 mmol) of the amine in 55 mL of 95% ethanol, 90 mL of H_2O, and 37 mL of concentrated H_2SO_4 cooled to 10°C was added dropwise a solution of 10.4 g of sodium nitrite in 18 mL of H_2O. The mixture was stirred for 2 h and then 2.5 g of copper powder was added, followed by heating at 60°C for 1 h and then in a boiling water bath for 10 min. The reaction mixture was left overnight at room temperature. The reaction was diluted with 100 mL of H_2O and extracted with 2 × 100 mL of benzene. The benzene extract was washed with 50 mL of H_2O, 50 mL of 5% NaOH, 50 mL of 10% HCl, 50 mL of H_2O, and dried over $MgSO_4$. Concentration gave 18 g of a dark oil, which was distilled, 100–104°C at 0.5 Torr, to give 10.5 g (54%) of 3-bromo-1-methylnaphthalene; nmr ($CDCl_3$) δ: 7.3–8.1 (m, 6H), 2.67 (s, 3H); mass spectrum: 222 (95), 221 (16), 220 (100), 141 (71), 139 (25), 115 (19), 71 (15).

The cyanation procedure was that of Friedman and Schechter (47). A solution of 6.4 g (29 mmol) of the bromide and 3.0 g of cuprous cyanide in 6 mL of dimethyl formamide was refluxed for 4 h. The reaction mixture was poured into a solution of 25 mL of H_2O, 4 mL of concentrated HCl, and 20 g of ferric chloride, and heated at 65°C for 20 min. The mixture was extracted with 2 × 20 mL of benzene and the extract washed with 40 mL of 10% HCl and 40 mL of 5% NaOH, dried over $MgSO_4$, and concentrated to give 2.7 g of crude product. Recrystallization from hexane gave 2.0 g (41%) of 3-cyano-1-methylnaphthalene; mp 67–68°C; nmr ($CDCl_3$) δ: 7.3–7.9 (m, 4H), 7.18 (s, 1H), 2.47 (s, 3H); mass spectrum: 167 (100), 166 (61), 140 (32), 139 (16).

The 3-cyano-1-methyl derivative was chlorinated as follows (43). To 0.87 g (5.2 mmol) of the cyano derivative in 15 mL of chlorobenzene was added 0.91 g (7.8 mmol) of *N*-chlorosuccinimide. The mixture was irradiated with a 300-W tungsten lamp for 14 h. The reaction mixture was diluted with 20 mL of CH_2Cl_2 and extracted with 2 × 10 mL of H_2O, dried over $MgSO_4$, and concentrated by pumping in a warm water bath to give 0.84 g of material, which by nmr analysis consisted of 83% chloro-(3-cyano-1-naphthyl)methane and 17% 3-cyano-1-methylnaphthalene.

This mixture was dissolved in 40 mL of ether and trimethylamine was bubbled through the solution for 4 h. After standing overnight, the reaction mixture was filtered to give 425 mg of the ammonium salt. Recrystallization from acetonitrile gave the pure salt, **10**; mp 254–255°C; ultraviolet (Fig. 1); ir (KBr): 2210 cm^{-1}; nmr (220 MHz, D_2O) δ: 8.56 (s, 1H), 8.33 (d, J = 8.2 Hz, 1H), 8.10 (d, J = 8.1 Hz, 1H), 7.97 (d, J = 1.4 Hz, 1H), 7.91 (t, 1H), 7.78 (t, 1H), 5.04 (s, 2H), 3.18 (s, 9H); mass spectrum: 210 (51), 209 (20), 203 (33), 202 (16), 201 (73), 167 (74), 166 (100), 164 (43), 152 (15), 140 (69), 139 (61), 115 (20), 113 (23), 87 (21), 75 (17), 74 (21), 69 (21), 63 (31), 59 (55), 58 (66), 57 (37), 51 (19), 50 (37).

Preparative scale photolyses of 1-naphthylmethyltrimethylammonium chlorides, 7–10

Preparative scale irradiations were done using a Pyrex filtered 200-W medium pressure Hanovia mercury lamp in a 300-mL immersion well with nitrogen purging. The reactions were monitored by hplc with a Brownlee 10-μm RP-8 reverse phase column using 80% methanol/water as eluant and detection at 280 nm. Yields are shown in Table 1. The photoproduct mixtures were obtained from the photolysis solution by adding 300 mL of H_2O and extracting with hexane (3 × 300 mL). The hexane was dried with $MgSO_4$ and concentrated. The residue was then chromatographed on silica gel to isolate the photoproducts.

The products and their isolated yields are as follows:

7, X = 4-CH_3O; 300 mg (1.13 mmol); methoxy-(4-methoxy-1-naphthyl)methane; bp 70–72°C, 0.2 Torr; nmr ($CDCl_3$) δ: 7.85–8.1 (m, 1H), 7.6–7.85 (m, 1H), 6.4 (d, J = 7 Hz, 1H), 4.60 (s, 2H), 3.77 (s, 3H), 3.58 (s, 3H); 184 mg (82%).

8, X = 3-CH_3O; 190 mg (0.71 mmol); 3-methoxy-1-methylnaph-

thalene; mp 45–46°C; nmr ($CDCl_3$) δ: 6.73–7.90 (m, 6H), 3.78 (s, 3H), 2.58 (s, 3H); 71 mg (50%); methoxy-(3-methoxy-1-naphthyl)methane; nmr ($CDCl_3$) δ: 6.85–7.98 (m, 6H), 4.75 (s, 2H), 3.80 (s, 3H), 3.57 (s, 3H).

9, X = 4-CN; 151 mg (0.60 mmol): 4-cyano-1-methylnaphthalene; *vide supra*; 49 mg (38%); methoxy-(4-cyano-1-naphthyl)methane; mp 70.5–71°C; nmr ($CDCl_3$) δ: 7.1–8.15 (m, 6H), 4.86 (s, 2H), 3.48 (s, 3H); 41 mg (35%).

10, X = 3-CN; 114 mg (0.45 mmol): 3-cyano-1-methylnaphthalene; nmr ($CDCl_3$) δ: 7.3–8.1 (m, 6H), 2.72 (s, 3H); 20 mg (31%); methoxy-(3-cyano-1-naphthyl)methane; nmr ($CDCl_3$) δ: 7.6–8.3 (m, 6H), 4.90 (s, 2H), 3.50 (s, 3H); 14 mg (16%).

Quantum yields and fluorescence measurements were determined as described previously (2).

Benzodiazepine stereochemistry: crystal structures of the diazepam antagonist Ro 15-1788 and the anomalous benzodiazepine Ro 5-4864

ANDREW HEMPEL AND NORMAN CAMERMAN
Biochemistry Department, University of Toronto, Toronto, Ont., Canada M5S 1A8

AND

ARTHUR CAMERMAN
Departments of Medicine (Neurology) and Pharmacology, University of Washington, Seattle, WA 98195

Received August 28, 1986[1]

ANDREW HEMPEL, NORMAN CAMERMAN, and ARTHUR CAMERMAN. Can. J. Chem. **65**, 1608 (1987).

The crystal and molecular structures of the benzodiazepine antagonist Ro 15-1788, and of Ro 5-4864, a diazepam derivative with low affinity for central benzodiazepine receptors, have been determined. Stereochemical comparisons with diazepam have resulted in the conclusion that the steric bulk of the 4′-chlorine atom alone is responsible for the lowered activity of Ro 5-4864, and have suggested possible structural reasons for the antagonist/weak agonist activities of Ro 15-1788.

ANDREW HEMPEL, NORMAN CAMERMAN et ARTHUR CAMERMAN. Can. J. Chem. **65**, 1608 (1987).

On a déterminé les structures cristalline et moléculaire de l'antagoniste de la benzodiazépine, le composé Ro 15-1788, et du composé Ro 5-4864, un dérivé du diazépam possédant une faible affinité pour les récepteurs centraux de la benzodiazépine. En se basant sur des comparaisons stéréochimiques avec le diazépam, on peut conclure que l'encombrement stérique de l'atome de chlore en position 4′ est le seul responsable de l'activité plus faible du composé Ro 5-4864 et on peut suggérer des raisons structurales possibles pour les activités antagoniste/faible agoniste du composé Ro 15-1788.

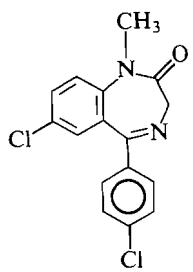
Introduction

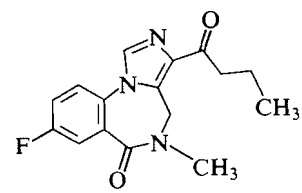
A large number of benzodiazepine (BZ) derivatives have been synthesized in attempts to achieve compounds specific for a particular pharmacological effect in the benzodiazepine spectrum of activities, such as anxiolytic or anticonvulsant action. Two analogues of considerable interest are Ro 15-1788 (ethyl-8-fluoro-5,6-dihydro-5-methyl-6-oxo-4*H*-imidazo[1,5-*a*][1,4]benzodiazepine-3-carboxylate), an antagonist of BZ binding, and Ro 5-4864 (7-chloro-1,3-dihydro-1-methy-5-(*p*-chlorophenyl)-2*H*-1,4-benzodiazepine-2-one), a compound that demonstrates a number of effects upon BZ-receptors. Ro 15-1788 is a representative of a novel class of BZ derivatives which have the unique pharmacological activity of selectively antagonizing the behavioral and neurological effects of diazepam through specific inhibition of BZ receptor-binding (1–3),



Ro 5-4864

a property which could make them useful as antidotes to BZ-induced intoxications. Although initial studies indicated that Ro 15-1788 was a pure antagonist, more recent results suggest that at high doses it possesses partial agonist activity (4). These properties make Ro 15-1788 a useful model to compare with the more standard BZ's in order to define the stereochemical characteristics of agonist/antagonist activities. Ro 5-4864 is a compound that has aroused interest for many years, partly because of conflicting reports of its actions.

[1]Revision received February 18, 1987.



Ro 15-1788

Differing from diazepam structurally only in the possession of a 4′-Cl atom, Ro 5-4864 binds only very weakly to high affinity CNS (central nervous system) BZ-binding sites (5) but demonstrates strong specific binding to peripheral-type BZ receptors (6). In addition, other Ro 5-4864 binding sites in brain and spinal cord which differ pharmacologically from classical BZ receptors have been reported recently (7).

We have determined the crystal and molecular structures of Ro 15-1788 and Ro 5-4864 and compared their three-dimensional structures with diazepam in an attempt to correlate pharmacological properties with stereochemical characteristics in BZ derivatives; we now report the results of these studies.

Experimental section

A. Ro 15-1788

Crystals were obtained from aqueous solution. Crystal data are given in Table 1; the space group was established from the systematically absent reflections on Weissenberg and precession photographs. A prism 0.3 × 0.2 × 0.3 mm was selected and intensities of reflections with $2\theta < 130°$ (corresponding to a minimum interplanar spacing of 0.85 Å) were measured on an automated four-circle diffractometer with Ni-filtered CuKα radiation using the $2\theta/\theta$ scan technique. One octant of reciprocal space was measured and equivalent reflections merged ($R = 0.047$). No absorption corrections were applied. A total of 1194 unique reflections were considered to be observed ($I > 3\sigma(I)$) out of 2264 measured and were used in the refinement. The structure was solved using the direct phasing program MULTAN80 (16). Atomic positional and anisotropic thermal parameters were refined by full-matrix least squares. All hydrogen atoms were located on difference electron-density plots and their coordinates were refined with fixed isotropic temperature factors. The final discrepancy index converged

Absorption coefficient (cm^{-1})	9.4	39.2

to $R = 0.047$ with $S = 1.41$. (R for all measured reflections = 0.12.) The highest features in the final difference electron density map were −0.33 and +0.30 e Å^{-3}.

B. Ro 5-4864

Crystals were obtained from acetone; crystal data are given in Table 1. A plate, 0.3 × 0.08 × 0.2 mm was used for X-ray data collection in a procedure similar to that described above. A total of 2200 unique reflections were recorded ($2\theta_{max} = 120°$) in the positive hkl octant of which 876 were considered to be observed ($I > 3\sigma(I)$). In addition to the usual data reduction procedure, an empirical correction for absorption based on ϕ angle was applied (transmission factors ranged from 0.61–0.99). The space group was established by the systematic absences on Weissenberg and precession photographs. The structure was solved and refined as described for Ro 15-1788. The final discrepancy index R was 0.068 (observed reflections) and 0.14 (all reflections). $S = 1.84$. The highest features in the final difference map were ±0.50 e Å^{-3}. In both structures, unit weights were used in the least-squares calculations and the function minimized was $\Sigma(|F_o| - |F_c|)^2$. The atomic scattering factors used were as cited for nonhydrogen (8) and hydrogen (9) atoms. Computer programs used were XFLS (17) and some local programs.

Table 2 lists the atomic fractional coordinates and equivalent isotropic thermal parameters; the anisotropic thermal parameters, hydrogen positional parameters, and a list of the observed and calculated structure factors are available.[2]

Results and discussion

Description of the structures

Figure 1 shows the molecular structures of Ro 15-1788[3] and Ro 5-4864 and the atomic numbering schemes. Bond lengths and angles are given in Table 3. The halogenated-phenyl rings in both compounds are planar, as is the five-membered heterocycle in Ro 15-1788; the bond lengths confirm that

C12—N13 (1.30 Å) and C8—C14 (1.36 Å) in that ring are formal double bonds. The bond lengths and angles in Ro 5-4864 do not differ significantly from the corresponding values in diazepam (10). The N10—C11 bond in Ro 15-1788 is 1.34 Å vs. 1.29 Å in Ro 5-4864 and diazepam reflecting loss of formal double bond character concomitant with N10 methylation and the carbonyl function at C11; the angles at N10 are still trigonal, however, and nitrogen lone-pair electrons undoubtedly contribute to the amide nature of the bond. The seven-membered diazepine rings in both compounds adopt boat-shaped conformations, as is the case in diazepam, with the C11 carbonyl

[2]Complete set of data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[3]After this work was completed an independent structure determination of Ro 15-1788 was reported (ref. 13). That determination is of extremely low precision: fewer than 600 data with $I > 2\sigma(I)$ were obtained, vs. 1194 data with $I > 3\sigma(I)$ here; atomic equivalent isotropic thermal parameters ranged from 8.5–25.8 Å^2 with a mean of 14.0 Å^2, vs. 2.8–7.8 Å^2 with a mean of 4.0 Å^2 in the present determination; and the final R was 0.071 vs. 0.047 here. In addition, no hydrogen atoms were located in that structure determination and nonhydrogen atom bond parameters are not given. The structural basis for agonist activity proposed therein is different from our postulations. See Discussion.

group causing the boat to be somewhat shallower in Ro 15-1788 than in the other two molecules. There are no hydrogen bond donors in either molecule and the intermolecular interactions in both crystals consist only of van der Waals contacts.

Stereochemical comparisons with diazepam

A superposition of the Ro 5-4864 structure with that of diazepam (not shown) demonstrates that in addition to the close similarity in molecular parameters, the two molecules share virtually identical conformations. There appear to be no transmitted effects of the 4′-chloro substitution in Ro 5-4864 and differences in receptor binding must be attributable to the steric effects of the 4′-chlorine atom. The high affinity CNS BZ-binding sites must accommodate the extra bulk of the chlorine only with difficulty, while the peripheral and the uncharacterized brain and spinal cord Ro-4864 sites are sufficiently different structurally to allow entry of the *p*-chloro substituent.

This hypothesis is supported by animal data available for two other 4′-substituted diazepam derivatives. Although receptor-binding studies have not been performed for 4′-fluoro and 4′-methoxy nordiazepam, these drugs have been tested for efficacy against metrazol-, minimal electroshock-, and maximal electroshock-induced convulsions in mice (11). Both compounds were ineffective at the highest dose measured against metrazol and minimal electroshock tests (the usual experimental

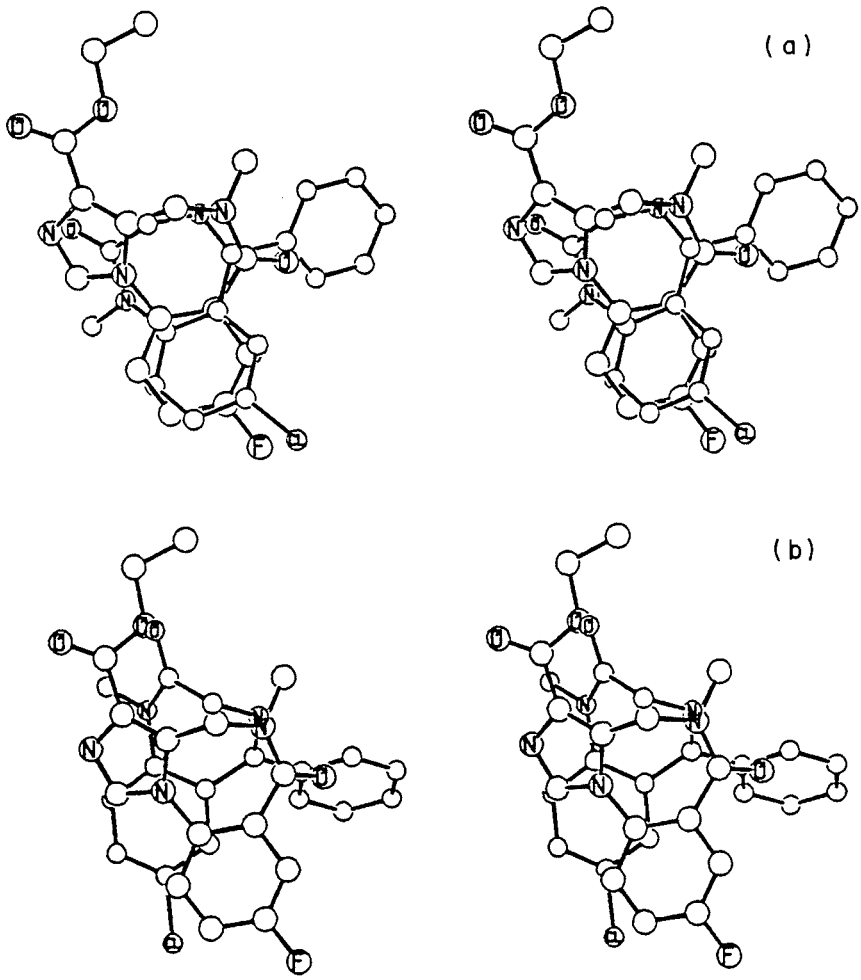

FIG. 2. Stereoscopic superpositions of Ro 15-1788 (large circles, light bonds) and diazepam so that (*a*) atoms N10 and N13 of Ro 15-1788 are maximally fitted to N10 and O19 of diazepam; (*b*) atoms N10 and O16 of Ro 15-1788 are maximally fitted to N10 and O19 of diazepam. The atomic numbering scheme for diazepam is identical to that used for Ro 5-4864 (Fig. 1).

model for petit mal seizures) but showed some activity against the maximal electroshock procedure (the usual experimental model for grand mal or generalized seizures). Median effective doses (ED_{50}) for the fluoro and methoxy substituted BZ's were 50 and 400 mg/kg, respectively. Since protection against electrically induced convulsions is mediated through binding to CNS receptors and since the steric effects of methoxy are considerably greater than for fluorine, these data are consistent with the conclusion we draw about the steric effects of the Ro 5-4864 4′-chlorine from the crystal structure analysis.

A superposition of the benzodiazepine portions of Ro 15-1788 and diazepam has been deposited. Our previous structure-activity studies on BZ's and other antiepileptic drugs (12) have suggested that when corresponding hydrophobic regions are superposed, two hydrogen bond acceptor atoms occupy similar positions in each molecule and are very likely necessary for the central nervous system receptor-mediated anticonvulsant properties of these compounds. Assuming that N10 and the C8 carbonyl oxygen are required for receptor interactions which trigger the pharmacological response, one can rationalize the BZ antagonist properties of Ro 15-1788 in terms of substitution of a carbon atom (C14) in the position of the carbonyl oxygen. Receptor binding could still occur through hydrophobic interactions and hydrogen bonding to N10, probably with extra interactions involving the ester grouping, but the lack of a correctly-positioned carbonyl oxygen or other hydrogen bond acceptor could prevent the interaction necessary to effect pharmacological action.

There are a number of ways the structural results could be interpreted to rationalize the partial agonist activity observed at high concentrations of Ro 15-1788. There are some electronegative atoms in Ro 15-1788 whose vectoral separations approximate that of N10-019 of diazepam and whose superpositions onto these latter atoms results in an overall Ro 15-1788 conformation which loosely approximates diazepam, including gross similarities in distribution of hydrophobic moieties. Two examples are shown in Fig. 2: the N10...N13 distance is 4.50 Å and the N10...O16 separation is 3.86 Å while the corresponding N...O distance in diazepam is 3.35 Å. Although receptor binding in either of these modes may not be favored for Ro 15-1788, in high concentrations this may occur sufficiently to explain the weak agonist properties of the compound. Additionally, if some hydrolysis of the ester takes place (speculation) this could facilitate the occurrence of a binding mode such as shown in Fig. 2; higher concentrations of Ro 15-1788 would result in higher amounts of the hydrolyzed species and increased "agonist" mode binding.

We explain the partial agonist properties of Ro 15-1788 at high concentrations by postulating that it can bind weakly to the BZ receptor in a second orientation in which the gross conformation (distribution of hydrophobic and hydrophillic groups) resembles diazepam and in which two electronegative

For personal use only.

atoms superpose with the two electronegative sites in diazepam putatively involved in the pharmacological response. A model for BZ receptor binding has been suggested by Codding and Muir (13) in which all agonists, antagonists, and inverse agonists occupy the same BZ receptor site in one common orientation and exert their diverse effects through combinations of seven different interactions with unspecified receptor groups. This model does not explain how Ro 15-1788 can show both antagonist and weak agonist behaviour. In addition, as pointed out by Dodd *et al.* (14), the model does not distinguish between antagonists and inverse agonists, and moreover, fails for agonists in the case of the agonist β-carboline-3-carboxylates ZK91296 and ZK93423 (15).

Acknowledgments

Samples of Ro 15-1788 and Ro 5-4864 were gifts from Hoffmann La Roche, Inc. Support was from NIH grant NSO9839 from the NINCDS. A.C. is a Klingenstein Senior Fellow in the Neurosciences.

Reçu le 14 novembre 1986

LUC MAURY, JEAN-LOUIS DELARBRE, JOËLLE RAMBAUD et BERNARD PAUVERT. Can. J. Chem. **65**, 1613 (1987).

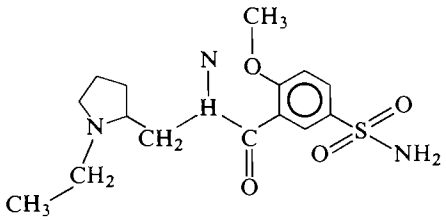
Les auteurs ont caractérisé deux formes du sulpiride par absorption infrarouge et diffusion Raman (vibrations du réseau). L'analyse des spectres a permis de proposer une attribution des vibrations caractéristiques des groupements amide et sulfonamide en relation avec les longueurs des liaisons hydrogène inter ou intra-moléculaires. La comparaison des spectres du chlorhydrate de sulpiride et du sulpiride indique que le chlorhydrate lui-même se présenterait sous forme chélatée.

LUC MAURY, JEAN-LOUIS DELARBRE, JOËLLE RAMBAUD, and BERNARD PAUVERT. Can. J. Chem. **65**, 1613 (1987).

The authors have characterized two forms for sulpiride by infrared spectroscopy and Raman scattering (lattice vibrations). An assignment of the fundamental vibrations of the amide and sulfonamide groups involved in the inter or intramolecular hydrogen bonds has been proposed. Comparison of the sulpiride chlorhydrate spectra with those of sulpiride indicates that the chlorhydrate itself will be in the chelated form.

Introduction

Lors de travaux antérieurs (1, 2), nous avons mis en évidence la nécessité de mettre en oeuvre des techniques variées et complémentaires afin de pouvoir distinguer polymorphisme et isomérie, notions très souvent confondues ou ignorées. Nous poursuivons actuellement ce même type d'études en série orthométhoxybenzamide et plus particulièrement sur le *N*-[(éthyl-1 pyrrolidinyl-2 méthyl]méthoxy-2 sulfamoyl-5 benzamide ou sulpiride.



Le sulpiride, utilisé en thérapeutique comme régulateur de la vasomotricité de la muqueuse gastrique et comme antipsychotique majeur non sédatif, a fait l'objet d'études en relation avec le polymorphisme (3); cependant, la détermination des structures des deux formes a révélé qu'il s'agissait non de polymorphisme mais d'isomérie. Par ailleurs, il a été démontré que l'efficacité neuroleptique du sulpiride est en relation avec la stéréochimie de l'énantiomère (4–6) et qu'il existe une analogie de structure chimique (7) entre les orthométhoxybenzamides et d'autres familles de neuroleptiques. Le centre actif serait le noyau aromatique avec présence obligatoire d'un substituant, dont la position et la nature sont importantes, et un groupement azoté situé à une certaine distance du nuage électronique. Ces analogies structure–activité seraient liées à la formation d'une liaison hydrogène intramoléculaire, entre les groupements méthoxy et amide, constituant ainsi un pseudo-cycle à 6 chaînons, partiellement plan, branché sur le cycle aromatique (7–9). Il nous a donc paru intéressant d'entreprendre une étude spectrale des deux formes du sulpiride, racémique (R) et énantiomère dextrogyre (E) (les spectres du lévogyre et du dextrogyre ne pouvant être distingués), qui correspondent aux deux types de cristaux obtenus par recristallisation. Après les avoir caractérisés, nous discuterons l'attribution de certains modes fondamentaux, en relation avec les liaisons hydrogène inter- ou intramoléculaires. Par ailleurs, dans le domaine 4000–2000 cm^{-1}, nous envisagerons le cas des deux chlorhydrates correspondants.

1. Auteur à qui adresser toute correspondance.

Matériel et méthode

Produits

Le sulpiride base, racémique et énantiomère, est un produit Delagrange; à partir de ces produits nous avons préparé les deux chlorhydrates.

Des recristallisations à partir du sulpiride base ont été effectuées dans différents solvants : eau; alcools méthylique, éthylique, propylique, isopropylique, butylique, amylique; dioxanne; tétrahydrofuranne; acétone; chloroforme; dichloroéthane et dans deux mélanges de solvants : eau–éthanol et eau–acétone.

Spectrométrie d'absorption infrarouge

Les spectres infrarouges ont été enregistrés à température ambiante sur un spectromètre Perkin–Elmer 983 G; les échantillons étaient placés sous forme de pastille KBr.

Spectrométrie de diffusion Raman

Les spectres Raman des poudres cristallines ont été enregistrés sur un spectromètre Jobin Yvon «Ramanor HG2 S». La technique utilisée était celle de la diffusion à 90° en incidence normale. La radiation excitatrice est la raie 514.5 nm d'un laser Spectra Physics, modèle 164, à argon ionisé; la puissance sur l'échantillon était maintenue à 200 mW et aucune modification des échantillons n'a été observée.

Résultats et discussion

Recristallisations

Les recristallisations à froid des différentes solutions n'ont généralement donné que des résultats médiocres. En revanche, à partir de solutions saturées à chaud, trois types de cristallisations ont été obtenues : (*i*) cristallisation homogène : formée de cristaux d'aspect cubique (cristaux I) isolés à partir de solutions dans l'eau, l'acétone et les mélanges eau–éthanol ou eau–

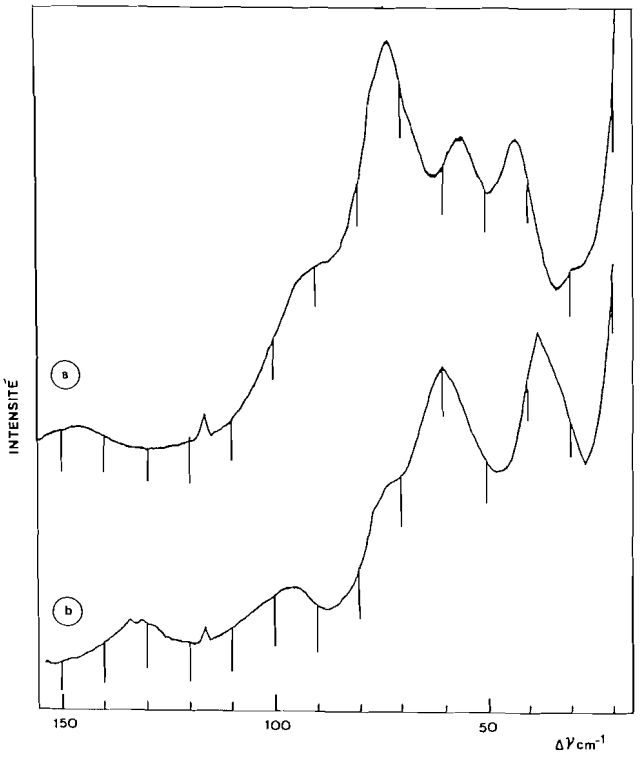

FIG. 1. Spectres Raman des vibrations du réseau du sulpiride; (*a*) racémique; (*b*) énantiomère.

acétone; ces cristaux correspondent au sulpiride racémique; (*ii*) cristallisation homogène : constituée de cristaux en forme de lamelles (cristaux II) obtenus à partir de solutions dans le méthanol ou le chloroforme; ils correspondent au sulpiride énantiomère; (*iii*) cristallisation hétérogène : apparaît comme un mélange des deux formes cristallines précédentes.

L'identification des cristaux I et II respectivement au racémique et à l'énantiomère a pu être réalisée grâce aux produits dont nous disposions : le sulpiride racémique et le sulpiride dextrogyre.

Diffusion Raman : vibrations du reseau cristallin

Les spectres Raman des vibrations du réseau (phonons) représentés sur la figure 1 permettent immédiatement de distinguer les formes (R) et (E); la première est caractérisée par quatre raies principales à 42, 55, 73 et 93 cm^{-1} alors que la seconde présente deux raies très intenses, à 38 et 60 cm^{-1}, accompagnées de massifs moins intenses à 72, 96 et 132 cm^{-1}.

Analyse vibrationnelle

Les spectres Raman (fig. 2) et infrarouge (fig. 3) du racémique et de l'énantiomère, dans le domaine des vibrations internes, présentent de très nombreuses différences à l'inverse de ce que l'on observe dans le cas de polymorphisme. Toutefois, les différences essentielles se manifestent au même niveau, c'est-à-dire au niveau des groupements impliqués dans des liaisons hydrogène. C'est pourquoi nous discuterons principalement les attributions de ces groupements, l'ensemble de nos propositions d'attribution étant reporté dans le tableau 1.

Structure cristalline

L'analyse des structures cristallines (8, 9) révèle que dans le racémique comme dans l'énantiomère, il existe une liaison hydrogène intramoléculaire de type N—H...O entre le proton amide et un doublet électronique de l'oxygène du groupement méthoxy, comme d'ailleurs dans un autre composé de cette série, le métoclopramide (7). Ces liaisons sont «bifurquées», les distances NH...O étant respectivement de 1,88 (R) et 2,10 Å (valeur moyenne pour les énantiomères). En outre, dans le racémique, deux liaisons hydrogène intermoléculaires sont présentes par l'intermédiaire des deux protons du groupement $-SO_2—NH_2$: ces deux liaisons, la première de type N---O, la seconde de type N---N, ont des longueurs de 2,88 et 2,94 Å. En revanche, dans l'énantiomère, une seule liaison de type N---O de longueur 2,86–3,00 Å se manifeste; dans les deux cas l'atome accepteur est l'oxygène du groupement carbonyle.

Analyse spectrale

Domaine 4000–2000 cm^{-1} : Les spectres Raman et infrarouge des deux composés (R) et (E) révèlent d'importantes modifications dans ce domaine spectral. Les vibrations de valence ν CH des groupements alkyle, méthoxy et aromatique (observées en deçà de 3100 cm^{-1}) ne seront pas discutées. Par contre, les vibrations de valence des groupements NH et NH_2 qui se traduisent par de fortes bandes infrarouges nécessitent une discussion.

En effet, si des corrélations entre les fréquences des vibrations de valence ν NH_2 d'un groupement amine et les longueurs des liaisons N---X (X = O, N) ont été établies (13), il n'en est pas de même pour ce qui concerne les vibrations de valence d'un groupement sulfonamide. Les résultats obtenus sur le sulpiride

[a]FF = très fort; F = fort; M = moyen; f = faible; ep = épaulement.
[b]Pour les bandes attribuées au noyau aromatique (ϕ) on a adopté la notation de Wilson.

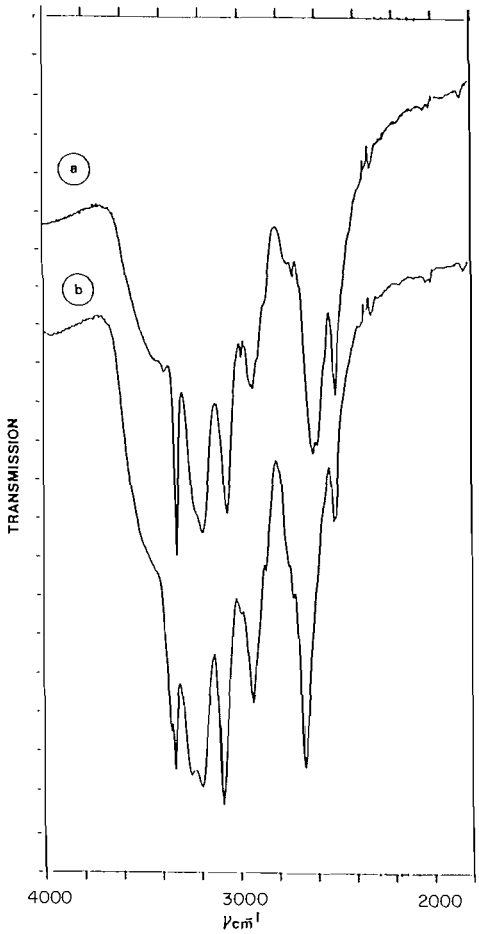

FIG. 4. Spectres infrarouge du sulpiride chlorhydrate (4000–2000 cm^{-1}); (*a*) racémique; (*b*) énantiomère.

peuvent toutefois être rapprochés de ceux obtenus sur des composés renfermant le même groupement $-SO_2 \cdot NH_2$ (10).

Contrairement à ce qui est observé dans les sulfamides (1, 2, 10) les spectres du sulpiride, qui renferme également un groupement sulfonamide, ne révèlent pas deux bandes fines et intenses caractéristiques des vibrations ν_{as} NH_2 et ν_s NH_2. La raie fine et intense située entre 3320 et 3380 cm^{-1} selon le composé (base ou chlorhydrate (fig. 4), racémique ou énantiomère), est attribuée au mode antisymétrique ν_{as} NH_2. La bande large et intense vers 3200 cm^{-1} rend compte du mode symétrique ν_s NH_2; cette bande présente un épaulement qui est attribué à l'harmonique 2ν C=O qui vient perturber le mode ν_s NH_2. Les attributions de ces modes du groupement sulfonamide sont en accord avec celles proposées par Novak *et al.* (10) dans le cas du benzènesulfonamide et du sulfanilamide dans lesquels les liaisons N.....O ont des longueurs comparables à celles de type $NH_2 \ldots X$ (X = O, N) présentes dans le sulpiride.

Dans le cas du chlorhydrate (E), les modes sont dédoublés ce qui pourrait traduire l'existence de dimères cycliques comme cela a déjà été observé sur le sulfaméthoxypyridazine (11) ou le pentobarbital (12). Le mode ν NH amide, engagé dans la liaison hydrogène intramoléculaire, se manifeste par la bande située vers 3120 cm^{-1} (E), valeur proche de celle trouvée dans le sulfaméthoxozole (2), cette fréquence étant absente du spectre du sulpiride (R). Ceci peut être relié au fait que la distance NH....O est beaucoup plus courte dans le racémique (1,88 Å) que dans les énantiomères (moyenne des distances 2,10 Å).

La présence de cette bande dans les deux chlorhydrates est donc en faveur de l'existence de ces deux composés sous forme chélatée, ce que la détermination des structures devrait nous permettre de confirmer. Signalons que les bandes observées sur les spectres des chlorhydrates à 2627, 2600 et 2506 cm^{-1} (R) et à 2656 et 2512 cm^{-1} (E) sont caractéristiques des absorptions $NH^+ \ldots Cl^-$ (13, 14).

Domaine 2000–200 cm^{-1} : De très nombreuses vibrations apparaissent communes aux deux espèces et traduisent les vibrations du noyau aromatique (10) ou pyrrolidine (15). On observe toutefois que les fréquences traduisant les modes amide et sulfonamide sont perturbées.

Quelle que soit la forme (R ou E) du sulpiride, la bande amide I se traduit par des raies d'intensité forte ou moyenne en infrarouge ou en Raman. Cette bande apparaît à 1643 cm^{-1} (R) et à 1620 cm^{-1} (E) par suite de l'existence de liaisons N—H...O différentes.

En accord avec Toppart *et al.* (16) nous attribuons la bande 1548 cm^{-1} (R) et 1555 cm^{-1} (E) à la bande amide II.

Dans le domaine 1305–1250 cm^{-1} se situe la bande amide III mettant en jeu les modes δ NH et ν CN (17). L'attribution de cette bande est ici rendue difficile par suite de la présence, dans

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

ce domaine, du mode ν_{as} SO_2; cependant, il nous semble possible d'attribuer les bandes 1310 cm^{-1} (R) et 1320 cm^{-1} (E) à l'amide III, la raie très intense 1340 cm^{-1} traduisant le mode ν_{as} SO_2. Le mode ν_s SO_2 apparaît, comme cela est généralement observé, sous forme d'un doublet (10) très net à 1190–1176 cm^{-1} (E) et sous forme d'une raie intense 1177 cm^{-1} munie d'un épaulement à 1190 cm^{-1} (R). Le dernier mode du groupement sulfone concerne la déformation δ SO_2 très intense en absorption vers 580 cm^{-1} quel que soit le composé, alors que dans tous les sulfamides étudiés, ce mode se traduisait par un doublet très intense vers 540–576 cm^{-1}.

Les attributions proposées pour le groupement SO_2 montrent que ses vibrations apparaissent dans les deux composés aux mêmes fréquences, ce qui confirme l'absence de liaison hydrogène intéressant les atomes d'oxygène de ce groupement.

Les dernières vibrations discutées concernent le groupement méthoxy dont l'oxygène participe à la liaison hydrogène intramoléculaire. Pour le chaînon ϕ—O—CH_3, mis à part les modes des protons, on attend deux vibrations de valence, deux déformations dans le plan et deux hors du plan. Comme les masses des atomes C et O sont sensiblement voisines, ces vibrations provoquent des déplacements des atomes de carbone du cycle aromatique : en conséquence, des couplages sont observés (18) entre les vibrations du groupe méthoxy et celles du noyau aromatique, couplages qui donnent les vibrations d'ensemble notées de I à IV dont les attributions (tableau 1) sont en accord avec celles proposées sur des composés analogues (19–21).

Received October 22, 1986

JOSEPH ARMAND, LINE BOULARES, CHRISTIAN BELLEC, and JEAN PINSON. Can. J. Chem. **65**, 1619 (1987).

The structure of fluorindine is established by nmr as the 5,14-dihydroquinoxalino[2,3-*b*]phenazine. The catalytic hydrogenation of 2,3-di(*p*-methoxyphenyl)pyrazino[2,3-*b*]phenazine **2***a* leads to the 6,11-dihydro derivative **4***a*. The electrochemical reduction in an hydroorganic medium furnishes **4***a* and then the 1,4,6,11-tetrahydro derivative **8***a*. In dry DMSO the voltammogram shows four monoelectronic reversible systems corresponding to the successive formation of a radical anion, dianion, radical trianion, and tetraanion. Thus **2***a* appears as a new example of the very restricted class of compounds leading to tetraanions upon electrochemical reduction. The catalytic hydrogenation of 2,7-diphenylpyrazino[2,3-*g*]quinoxaline **1***a* or the reaction of $LiAlH_4$ with 1,2,7,8-tetramethylpyrazino[2,3-*g*]quinoxaline **1***b* leads to 1,2,3,4-tetrahydro compounds. The electrochemical reduction of **1***a* and **1***b* in hydroorganic medium leads successively to 1,4-dihydro and then to 1,4,6,9-tetrahydro compounds which undergo a further rearrangement. In dry DMSO **1***a* and **1***b* behave differently from **2***a*: one only observes two reversible monoelectronic systems.

JOSEPH ARMAND, LINE BOULARES, CHRISTIAN BELLEC et JEAN PINSON. Can. J. Chem. **65**, 1619 (1987).

Par rmn on montre que la fluorindine est la dihydro-5,14 quinoxalino [2,3-*b*] phénazine. Par hydrogénation catalytique la di(*p*-methoxyphenyl)-2,3 pyrazino [2,3-*b*] phenazine **2***a* fournit le dérivé dihydro-6,11 **4***a*. La réduction électrochimique en milieu hydroorganique fournit **4***a* puis le dérivé tétrahydro-1,4,6,11 **8***a*. Dans le DMSO très sec le voltamogramme montre la présence de quatre pics monoélectroniques réversibles correspondant à la réduction successive en radical anion, dianion, radical trianion et enfin tétraanion : **2***a* est un nouvel exemple de composés – très peu nombreux – susceptibles d'engendrer un tétraanion par réduction électrochimique. L'hydrogénation catalytique de la diphényl-2,7 pyrazino [2,3-*g*] quinoxaline **1***a* ou l'action de $AlLiH_4$ dans le cas de la tétraméthyl-1,2,7,8 pyrazino [2,3-*g*] quinoxaline **1***b* conduit au dérivé tétrahydro-1,2,3,4. La réduction électrochimique en milieu hydroorganique de **1***a* et **1***b* conduisent successivement aux dérivés dihydro-1,4 puis tétrahydro-1,4,6,9, ce dernier se réarrangeant. Dans le DMSO très sec **1***a* et **1***b* ont un comportement différent de celui de **2***a* puisqu'on observe seulement la présence de 2 pics monoélectroniques réversibles.

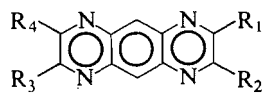
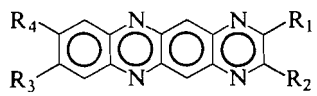
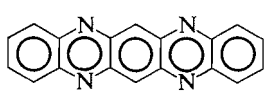
We have been interested for sometime in the chemical and electrochemical reduction of *N*-heterocyclic compounds (1, 2). We now report the behaviour of pyrazino[2,3-*g*]quinoxalines **1**, pyrazino[2,3-*b*]phenazines **2**, and quinoxalino[2,3-*b*]phenazines **3**. Through the examination of such a series of compounds, we intend to observe the modification of chemical and physicochemical properties with the increased number of cycles.



1

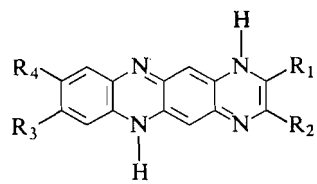


2

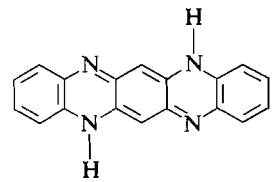


3

To our knowledge the reduction of **1** has not been studied previously, whereas that of **2** has been investigated for analytical purposes (3–5). In order to titrate traces of α-dicarbonyl derivatives, these compounds were reacted with 2,3-diaminophenazine to give **2** which was reduced by hypophosphorus acid into a dihydro derivative **4**. This last compound presents a strong visible absorption ($\lambda_{max} \simeq 600$ nm). The structure **4′** of **4**, i.e., a quinonoïd 1,6-dihydro derivative, was assigned on the basis of this visible absorption (3–5).



4′



5′

In the same way a quinonoïd structure was assigned to fluorindine **5** and its derivatives which have been used as a drug (8) and as an acid–base indicator (9). Fluorindine **5** has been given a 5,12-dihydroquinoxalino[2,3-*b*]phenazine structure **5′** by all previous authors (6–9).

Structure of fluorindine **5**

This compound is a dihydro derivative of quinoxalino-[2,3-*b*]phenazine **3** which has not yet been prepared; the oxidation of **5** leads only to a quinone (6, 7), and **5** is very slightly soluble in all solvents. It was, however, possible to

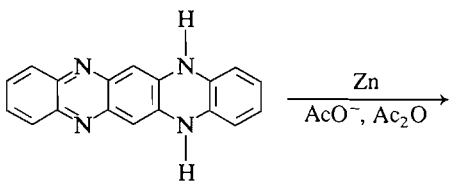
[a]Solvent DMSO-d_6; δ values in ppm relative to internal TMS.
[b]Broad signal exchanged with D_2O.

obtain a well-resolved 250-MHz spectrum in DMSO-d_6 after 1000 accumulations. The nmr data are given in Table 1.

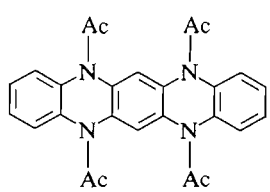
This spectrum unambiguously shows that fluorindine has structure **5**, i.e., it is a 5,14-dihydro derivative and not a 5,12-dihydro compound as previously stated.

Protons 1, 2, 3, and 4 form an AA′BB′ pattern analogous to that of 5,10-dihydrophenazine (6.06–6.70 ppm); the chemical shifts of these protons are significantly lower than that of benzene (7.23 ppm). It is known that in a benzene ring the electronic effects of the amino groups on the *ortho* and *meta* protons amount to a shielding of several tenths of a ppm (e.g., in *o*-phenylene diamine the benzene protons give a singlet at 6.70 ppm). This also explains the chemical shift of H_6 and H_{13} at 6.34 ppm. The 8, 9, 10, and 11 protons also give rise to an AA′BB′ pattern but at lower field and in the same region as the benzene protons of quinoxaline (δ = 7.7–8.2 ppm).

Neutral solutions of **5** are pink–violet whereas acidic solutions are blue. The pK_a of the protonated form measured by spectrophotometry is 2.30. Fluorindine can be reduced by Zn + Ac_2O to give 5,7,12,14-tetraacetyl 5,7,12,14-tetrahydroquinoxalino[2,3-*b*]phenazine (6).

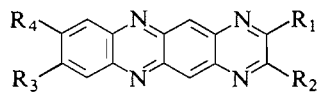


5

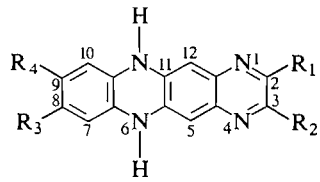


*Reduction of pyrazino[2,3-*b*]phenazine*

Catalytic hydrogenation in the presence of Pd/C of 2,3-di(*p*-methoxyphenyl)pyrazino[2,3-*b*]phenazine **2***a* gives a dihydro compound **4***a*. The nmr spectrum shows that **4***a* is the 6,11-dihydro-2,3-di(*p*-methoxyphenyl)pyrazino[2,3-*b*]phenazine.



2*a*
$R_1 = R_2 = p\text{-}OCH_3C_6H_4$
$R_3 = R_4 = H$



4*a*
$R_1 = R_2 = p\text{-}OCH_3C_6H_4$
$R_3 = R_4 = H$

The equivalence of 5-H and 12-H protons and the observation of an AA′BB′ pattern for 7-H, 8-H, 9-H, 10-H permit one to exclude structure **4′** which corresponds to a 1,6-dihydro derivative. Besides, the chemical shifts of 7-H, 8-H, 9-H, and 10-H are located between 6.10 and 6.60 ppm; this demonstrates that the two NH protons are on the 6 and 11 positions. If they had been on the 1,4 positions, protons 7-H, 8-H, 9-H, and 10-H would have shown an AA′BB′ pattern between 7.4 and 7.7 ppm (as in the case of **5** discussed above).

Reduction of **2***a* in dilute solution by zinc in acetic acid, by electrochemistry, or by H_3PO_2 — following the experimental procedure used during the titration of α-dicarbonyl compounds (3–5) — also leads to **4***a* (as shown by polarography) and not to a 1,6-dihydro derivative as had been postulated before. Reductions with $LiAlH_4$ furnished complex mixtures which could not be separated.

Electrochemical reduction of **2***a* has also been investigated.

In a water–DMF medium (40–60), **2***a* shows a two-electron wave which is pH dependent between pH 4 and 10 ($E_{1/2}$(V) = +0.30–0.06 pH). In more acidic or more basic media, **2***a* becomes unstable. The first wave is followed by a second pH-dependent two-electron wave: $E_{1/2}$(V) = +0.06–0.06 pH. Electrolysis of a dilute solution of **2***a* at pH 8 at a potential corresponding to the first plateau gives the dihydro derivative **4***a* as shown by comparison of the polarogram of the solution with that of the hydrogenation product under the same conditions. Electrolysis on the second plateau of **2***a*, i.e., at a potential corresponding to the reduction of **4***a*, furnishes an easily oxidizable compound which gives an anodic wave whose $E_{1/2}$ value is near that of the second cathodic wave of **2***a*.

The voltammogram of **2***a* at pH 7 ($v = 0.2\ V\ s^{-1}$) shows two reversible two-electron peaks at $E^0 = -0.075$ V and $E^0 =$

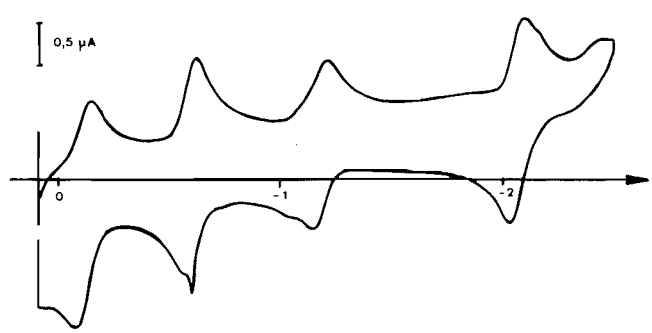


FIG. 1. Voltammogram of **2***a*, $c = 5 \times 10^{-4}$ *M*, in DMSO dried over Al_2O_3, 10^{-1} *M* NEt_4ClO_4, $v = 250\ mV\ s^{-1}$; reference: sce.

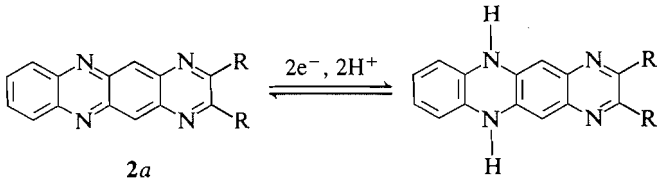
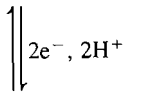
-0.825 V, the first one showing a spiky shape indicative of a reactant adsorbed on the electrode.

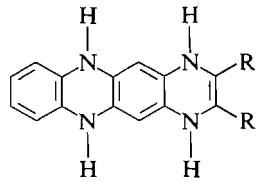
In view of our preceding results concerning the electrochemical reduction of compounds containing a pyrazine ring (1, 10, 11), we propose the following reduction scheme for **2***a*:



2*a*
R = *p*-$OCH_3C_6H_4$

4*a*





8*a*

The first reversible system observed on the voltammogram corresponds to the reduction **2***a* $\rightleftharpoons$ **4***a* whereas the second reversible system corresponds to **4***a* $\rightleftharpoons$ **8***a*. We have indeed shown previously (1, 10, 11) that compounds with a pyrazine ring are reversibly reduced to 1,4-dihydro pyrazines. Thus, at the difference of most 1,4-dihydro-compounds, no rearrangement of the primary reduction product is observed in pyrazino[2,3-*b*]phenazines. In aprotic medium (very dry DMSO) the cyclic voltammogram of **2***a* shows four perfectly reversible one-electron peaks ($E_{p_c} - E_{p_i} = 60$ mV) located at $E_1^0 = -0.03$ V, $E_2^0 = -0.51$ V, $E_3^0 = -1.09$ V, $E_4^0 = -2.00$ V corresponding to the successive formation of a radical anion, a dianion, a radical trianion, and a tetraanion (Fig. 1). We are presently trying to obtain these species in order to investigate their charge distribution through the examination of their nmr and esr spectra.

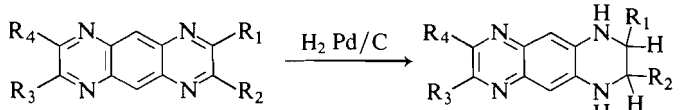
Reduction of pyrazino[2,3-g]quinoxalines: 1

Catalytic hydrogenation (Pd/C) of 2,7-diphenylpyrazino-[2,3-*g*]quinoxaline **1***a* furnishes a 1,2,3,4-tetrahydro derivative **6***a*.

In the case of 1,2,7,8-tetramethylpyrazino[2,3-*g*]quinoxaline **1***b*, one obtains only decomposition products, one of which is biacetyl.

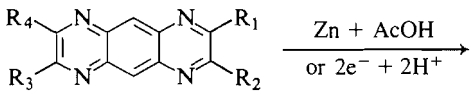
Reduction by $LiAlH_4$ leads to the *cis*-1,2,3,4-tetrahydro **6***b* in the case of **1***b* and to a complex mixture in the case of **1***a*.

Reduction by zinc and acetic acid leads to a compound which can also be obtained by electrochemical reduction (see below); the polarograms of both solutions are identical. This compound, which is very oxidizable and could not be isolated without reoxidation, is most likely the 1,4-dihydro derivative **7**.

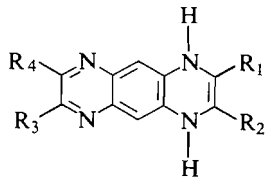


1*a* $R_1 = R_3 = C_6H_5$, $R_2 = R_4 = H$
1*b* $R_1 = R_2 = R_3 = R_4 = CH_3$

6*a* $R_1 = R_3 = C_6H_5$, $R_2 = R_4 = H$
6*b* $R_1 = R_2 = R_3 = R_4 = CH_3$



1*a*
1*b*

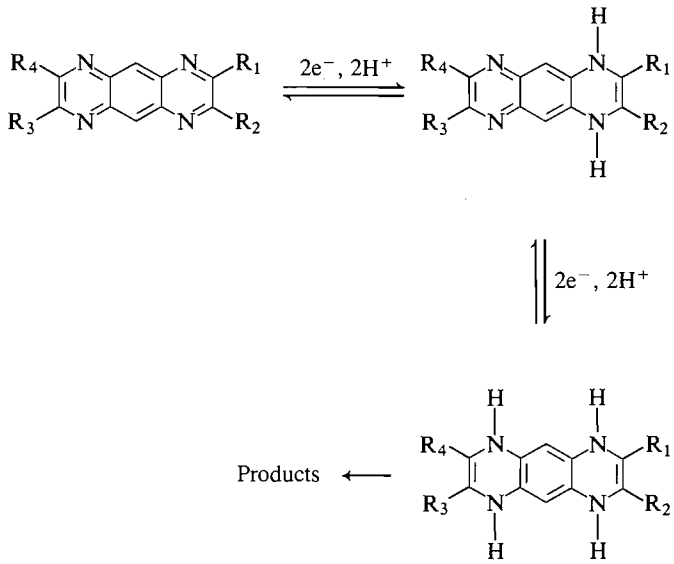


7*a*
7*b*

Electrochemical reduction of **1***a* and **1***b* has also been investigated.

In a water–DMF medium (50–50) **1***a* presents a two-electron wave which is pH dependent between pH 2 and 12: $E_{1/2}$ (V) = $+0.1 - 0.090$ pH from pH 2 to pH 3.7, corresponding to reduction to a protonated form of **7**, and $E_{1/2}$ (V) = 0.00–0.063 pH from pH 3.7 to pH 12, where **7** is obtained. This wave is followed by a second two-electron wave distorted by adsorption phenomena; this wave is pH-dependent between pH 2 and 12: $E_{1/2}$ (V) = $-0.37 - 0.073$ pH. Electrolysis of a dilute solution of **1***a* at pH 7.25 at a potential corresponding to the first plateau gives a readily oxidizable compound which presents an anodic wave whose $E_{1/2}$ is near that of the first cathodic wave of **1***a*. Electrolysis at a potential corresponding to the second plateau of **1***a* furnishes a compound which does not give any anodic wave. A voltammogram of **1***a* at pH 7.25 (0.06 V s^{-1}) shows two reversible 2e peaks located at $E^0 = -0.44$ V and $E^0 = -0.91$ V. Compound **1***b* shows similar behaviour: the first two-electron wave is pH-dependent between pH 2 and 12: $E_{1/2}$ (V) = 0.08–0.095 pH from pH 2 to pH 5.75 and $E_{1/2}$ (V) = $-0.11 - 0.062$ pH from pH 5.75 to pH 12. This first wave is followed by a second two-electron wave which is pH-dependent between pH 2 and 12: $E_{1/2}$ (V) = $-0.55 - 0.060$ pH, and this wave is distorted by adsorption phenomena. Electrolysis of **1***b* in dilute solution gives the same results as **1***a*. A voltammogram of **1***b* at pH 7.25 ($v = 0.06$ V s^{-1}) shows a first set of cathodic–anodic waves where the cathodic peak is located at $E_{p_c} = -0.60$ V and the anodic peak at $E_{p_a} = -0.49$ V; the lack of reversibility of this system is probably due both to a slow electron transfer and to adsorption phenomena, the cathodic peak is broad and symmetrical. The second set of cathodic–anodic waves is reversible: $E^0 = -0.95$ V.

In view of the similarity of these results with those already obtained for **2***a*, it appears that **1***a* and **1***b* are first reduced to a 1,4-dihydro derivative and then to a 1,4,6,9-tetrahydro compound. The 1,4-dihydro compound is responsible for the first anodic wave observed during electrolysis in dilute solutions and for the first anodic wave on the voltammogram. The 1,4,6,9-tetrahydro derivative corresponds to the second anodic peak on the voltammogram but rearranges to nonoxidizable compound as shown by the electrolysis of the dilute solution. Indeed, we have shown before (1, 10, 11) that pyrazine rings are reduced in a protic medium to 1,4-dihydropyrazine rings, giving rise to a more or less reversible system. The very low solubility of **1***a* and **1***b* prevented us from carrying out a preparative electrolysis in order to isolate the rearranged products.



In aprotic medium (DMSO or DMF) **1***a* presents (at 0.2 V s^{-1}) two reversible waves located at $E_1^0 = -0.90$ V (DMSO and DMF) and at $E_2^0 = -1.51$ V (DMF) or $E_2^0 = -1.46$ V (DMSO) corresponding to the formation of a radical anion and a dianion. An electrolysis in dry DMSO on the second wave of this system leads to a dark solution which can be reoxidized by air. **1***a* is recovered as shown by cyclic voltammetry and thin-layer chromatography. In acetonitrile two reversible waves are observed at $E_1^0 = -0.89$ V and $E_2^0 = -1.37$ V followed by a two-electron irreversible wave at $E_{p_c} = -2.12$ V. In DMSO **1***b* gives rise to two reversible electron-transfer processes at $E_1^0 = -1.30$ V and $E_2^0 = -1.85$ V.

Discussion

Although the study of such highly conjugated nitrogen heterocycles is rendered difficult by their low solubility and the oxidability of the reduced compounds, some interesting features can be seen. In a hydroorganic medium, the pyrazine rings are reduced one by one, always leading to compounds where the two nitrogens of the same ring are hydrogenated. In an aprotic medium, they lead when the conjugation is extended enough (i.e., with four cycles) through the stepwise addition of electrons to a tetraanion. Very few such species are known: bianthryl (12) leads to a tetraanion through a pair of two-electron transfers, the two anthracene rings behaving independently. Other examples include acepleiadylene (13), cyclophanes (14), and annulenes (15) which have been obtained by addition of alkali metals. Electrochemical methods should permit us to prepare more selectively the different reduced species. This is currently in progress in our laboratories.

Experimental

Melting points are uncorrected. ^{1}H-nmr spectra were recorded on a Bruker WH 80, a Varian A 60, and a Bruker 250-MHz spectrometer using tetramethylsilane (TMS) as internal standard. The apparatus and techniques used for the electrochemical studies and pH measurements have been described previously (11). All potentials referred to saturated calomel electrode (sce); the temperature of the solution was 20°C. Dimethylsulfoxide used in the cyclic voltammetric experiments was distilled under vacuum, deoxygenated with nitrogen, and dried over phosphorus pentoxide. The calomel electrode was separated from the solution by a bridge filled with dry DMSO. The microanalyses were performed by the "Service de microanalyse, Université Pierre et Marie Curie". The following abbreviations are used in reporting nmr results: s = singlet, d = doublet, t = triplet, q = quadruplet, m = multiplet. All the described compounds gave correct elemental analysis.

Preparation of **1**a, **1**b, **2**a, *and* **5**

2,7-Diphenylpyrazino[2,3-g]quinoxaline **1**a. A mixture of phenylglyoxal hydrate (1.07 g), 1,2,4,5-tetraaminobenzene tetrahydrochloride (1 g), and sodium acetate trihydrate (1.92 g) in 50 mL of ethanol was stirred at room temperature for 2 h. The solid material was filtered, washed with water and ethanol, and dried to give 930 mg (79%) of **1***a*. Melting point 215°C dec. ^{1}H-nmr ($CDCl_3$): 2-Ph + 7-Ph, m, 7.55 ppm (6H) and 8.26 ppm (4H); 5-H, 10-H, s, 8.88 ppm (2H); 3-H, 8-H, s, 9.40 ppm (2H).

1,2,7,8-Tetramethylpyrazino[2,3-g]quinoxaline, **1**b was obtained (16) by condensation of diacetyl and 1,2,4,5-tetraamino benzene.

2,3-Di(p-Methoxyphenyl)pyrazino[2,3-b]phenazine, **2**a was prepared according to ref. 17, using 4,4′-dimethoxybenzil instead of benzil. Yield 11%, mp 220°C dec. ^{1}H-nmr ($CDCl_3$): O-CH_3, s, 3.91 ppm (6H); 3′-H, 5′-H, 3″-H, 5″-H, d, 6.91 ppm (4H); 2′-H, 2″-H, 6′-H, 6″-H, d, 7.65 ppm (4H); 7-H, 8-H, 9-H, 10-H, AA′BB′ pattern at 7.82 and 8.27 ppm (2 × 2H); 5-H, 12-H, s, 9.17 ppm (2H).

Fluoridine **5** was prepared according to ref. 6.

Hydrogenation of **2**a*: preparation of* **4**a. A catalytic hydrogenation was carried out at room temperature with 150 mg of **2***a* in 25 mL of dimethylformamide in the presence of 100 mg of 10% Pd/C. After 3 h of stirring and consumption of one mole of H_2 per mole of **2***a*, the solution was filtered, poured into 150 mL of water, and then extracted with $CHCl_3$. The extracts were dried over Na_2SO_4 and evaporated to give 60 mg of **4***a*. Melting point 230°C dec.

Hydrogenation of **1**a*: preparation of* **6**a. A catalytic hydrogenation was carried out at room temperature with 250 mg of **1***a* in 70 mL of dimethylformamide in the presence of 100 mg of Pd/C. After 5 h of stirring and consumption of two moles of H_2 per mole of **1***a*, the solution was filtered, washed with water, and dried to give 195 mg of **6***a* (77%). Melting point 263–265°C dec. ^{1}H-nmr (DMSO-d_6 + D_2O): 3-CH_2, m, 4.52 ppm (2H); 5-H + 10-H, 2d, 6.81 ppm and 6.94 ppm (2H); 2-H + 2-Ph + 7-Ph, m, 7.0–8.2 ppm (11H); 8-H, s, 8.76 ppm (1H).

Reduction with $LiAlH_4$ *of* **1**b*: preparation of* **6**b. $LiAlH_4$ (400 mg) was added slowly to a solution of **1***b* (300 mg) in freshly distilled tetrahydrofuran (50 mL). After 7 h of stirring at room temperature, the mixture was quenched with 5 mL of water and filtered. Tetrahydrofuran was evaporated and the solid which precipitated was filtered, washed with water, and dried. Compound **6***b*: 200 mg (65%). Melting point 268–270°C dec. ^{1}H-nmr ($CDCl_3$): N_1—H + N_2—H, br.s. exchanged with D_2O, 2.20 ppm (2H); 7-CH_3 + 8-CH_3, s, 2.65 ppm (6H); 2-H, 3-H, m, 3.70 ppm (2H); 5-H, 7-H, s, 7.00 ppm (2H).

Received July 24, 1986[2]

MOHAMMED MUNEER, RAVINDRA K. TIKARE, PRASHANT V. KAMAT, and MANAPURATHU V. GEORGE. Can. J. Chem. **65**, 1624 (1987).

The reaction of several Δ^2-oxazolin-5-ones (**1***a–c*, **12**) and bioxazolinones (**17**, **26**) with potassium in THF has been investigated. Treatment of **1***a* with potassium in THF gave a mixture of dibenzamide (**11***a*), *N*-benzoyl-*C*-phenylglycine (**6***a*), and *C*-phenylglycine (**10***a*). A higher yield of **11***a* was obtained, together with benzoic acid (**9**), when the reaction of **1***a* was carried out in THF saturated with oxygen. The reaction of **1***b* gave a mixture of β-phenylalanine (**10***b*) and **9**, whereas **1***c* gave a mixture of *N*-benzoyl-*C*,*C*-diphenylglycine (**6***c*) and *N*-benzoyl-*C*,*C*-diphenylmethylamine (**5***c*). Similarly, the reaction of **12** gave a mixture of α-benzamidocinnamic acid (**15**) and **9**. The reaction of the bioxazolinone **17** with potassium gave a mixture of **11***a*, **6***a*, and **10***a*, along with an appreciable yield of 2,3,5,6-tetraphenylpyrazine (**25**), whereas **26** under analogous conditions gave a mixture of **15**, **6***b*, and benzamide (**29**). Reasonable mechanisms, involving the initial formation of radical anion intermediates and their subsequent transformation to give the observed products, have been suggested. Potassium superoxide oxidation of some of these substrates gives similar product mixtures. Cyclic voltammetric studies have been carried out to measure the reduction potentials of **1***a–c*, **12**, **17**, and **26** in the generation of their radical anions. The radical anions of these substrates were also generated pulse radiolytically in methanol and their spectra showed absorption maxima in the region 295–350 nm.

MOHAMMED MUNEER, RAVINDRA K. TIKARE, PRASHANT V. KAMAT et MANAPURATHU V. GEORGE. Can. J. Chem. **65**, 1624 (1987).

On a étudié la réaction de plusieurs Δ^2-oxazolinones-5 (**1***a–c*, **12**) et bioxazolinones (**17**, **26**) avec le potassium dans le THF. La réaction de **1***a* avec le potassium dans le THF conduit à un mélange de dibenzamide (**11***a*), de *N*-benzoyl *C*-phénylglycine (**6***a*) et de *C*-phénylglycine (**10***a*). Lorsqu'on a effectué la réaction de **1***a* dans du TFH saturé en oxygène, on a obtenu de l'acide benzoïque (**9**) et un meilleur rendement de **11***a*. La réaction du produit **1***b* conduit à un mélange de β-phénylalanine (**10***b*) et de composé **9**; par ailleurs, le composé **1***c* conduit à un mélange de *N*-benzoyl *C*,*C*-diphénylglycine (**6***c*) et de *N*-benzoyl *C*,*C*-diphénylméthylamine (**5***c*). De la même manière, la réaction du composé **12** conduit à un mélange d'acide α-benzamidocinnamique (**15**) et de composé **9**. La réaction de la bioxazolinone **17** avec le potassium conduit à un mélange de composés **11***a*, **6***a* et **10***a* aux côtés d'une quantité appréciable de tétraphényl-2,3,5,6 pyrazine (**25**); par ailleurs, le composé **26** soumis aux mêmes conditions conduit à un mélange des composés **15**, **6***b* et de benzamide **29**. On suggère des mécanismes raisonnables impliquant la formation initiale d'intermédiaires anions radicaux et leurs transformations subséquentes pour donner les produits observés. L'oxydation de quelques-uns de ces substrats par le superoxyde de potassium conduit à des mélanges réactionnels semblables. On a effectué des études de voltamétrie cyclique pour mésurer les potentiels de réduction des composés **1***a–c*, **12**, **17** et **26** lors de la génération de leurs radicaux anions. On a aussi généré les radicaux anions de ces substrats par radiolyse pulsée dans le méthanol; leurs spectres présentent des maxima d'absorption dans la région de 295–350 nm.

[Traduit par la revue]

Introduction

In a recent investigation (1), we examined the reactions of several 2(3*H*)-furanones and bifurandiones with potassium in THF and showed that several products, arising through the initial formation of radical anions and their subsequent reaction with oxygen, are formed in these cases. Thus the reaction of 3,3,5-triphenyl-2(3*H*)-furanone with potassium in THF, for example, gave a mixture of 4-oxo-2,2,4-triphenylbutanoic acid, 1,3,3-triphenyl-2-propen-1-one, and benzoic acid. The reaction of a bifurandione such as 2,2′,3,3′,4,4′-hexaphenyl-2,2′-bifuran-5,5′(2*H*,2′*H*)-dione with potassium, on the other hand, gave a mixture of a 2(5*H*)-furanone, 2,3-diphenylpropenoic acid, and benzoic acid. In this context, it was felt worthwhile to investigate the reaction of some representative Δ^2-oxazolin-5-ones and bioxazolinones with potassium in THF, to study the type of products formed in these cases and also their reaction pathways.

Results and discussion

We have examined, in the present studies, the reactions of 2,4-diphenyl-Δ^2-oxazolin-5-one (**1***a*), 4-benzyl-2-phenyl-Δ^2-oxazolin-5-one (**1***b*), 2,4,4-triphenyl-Δ^2-oxazolin-5-one (**1***c*), and 4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one (**12**). In addition, the reactions of two bioxazolinones such as bi-4,4′-(2,4-diphenyl-Δ^2-oxazolin-5-one) (**17**) and bi-4,4′-(4-benzyl-2-phenyl-Δ^2-oxazolin-5-one) (**26**) have been investigated.

The reaction of **1***a* with potassium in THF, for example, gave

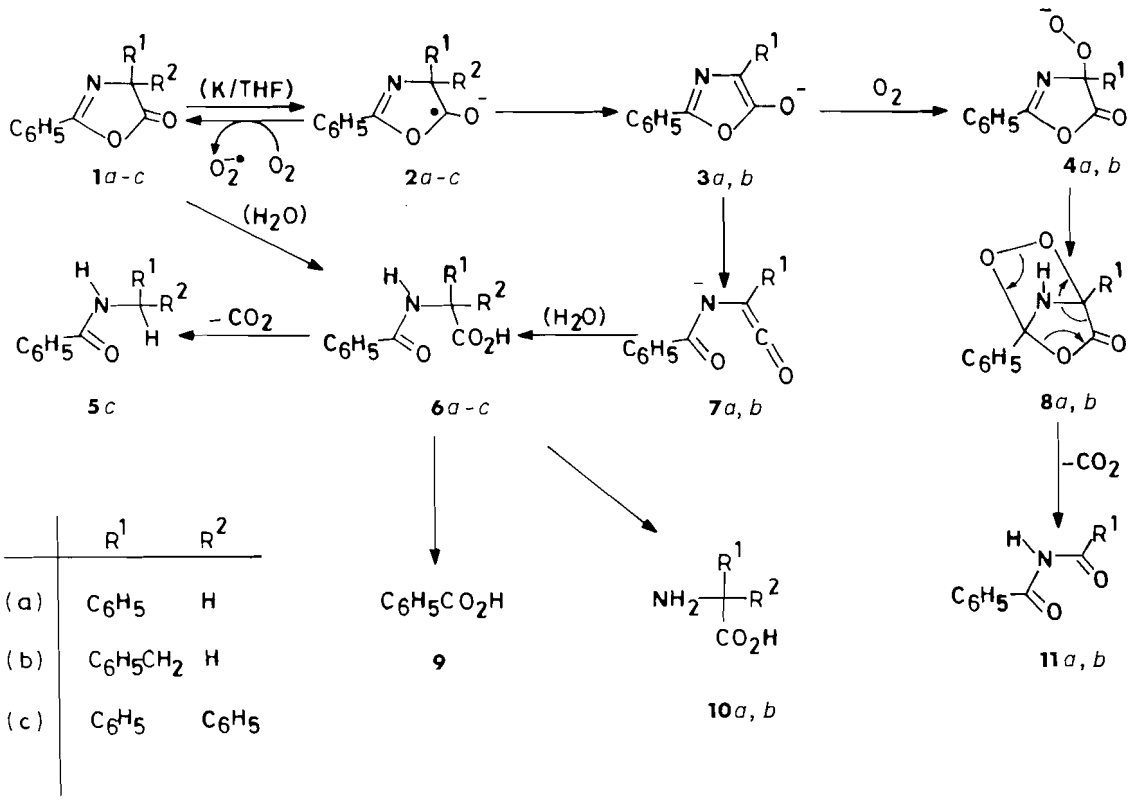

SCHEME 1.

a mixture of dibenzimide (**11***a*), *N*-benzoyl-*C*-phenylglycine (**6***a*), and *C*-phenylglycine (**10***a*). When the reaction of **1***a* with potassium, however, was carried out in THF saturated with oxygen, a much higher yield of **11***a* was obtained, along with appreciable amounts of benzoic acid (**9**). The reaction of **1***b* with potassium in THF gave a mixture of β-phenylalanine (**10***b*) and benzoic acid. Under analogous conditions, the reaction of **1***c* with potassium in THF gave a mixture of *N*-benzoyl-*C*,*C*-diphenylglycine (**6***c*) and *N*-benzoyl-*C*,*C*-diphenylmethylamine (**5***c*). On the other hand, when the reaction of **1***c* with potassium was carried out in THF saturated with oxygen, a mixture of **6***c*, **5***c*, and benzoic acid was formed.

The formation of the different products in the reaction of **1***a–c* with potassium in THF could be understood in terms of the pathway shown in Scheme 1. It has been assumed that the initial step in the reaction involves an electron transfer process leading to the formation of the radical anions **2***a–c*, which can, through the loss of a hydrogen atom, give the anionic intermediates **3***a*,*b*. These intermediates **3***a*,*b*, in turn, can lead to the carboxylic acids **6***a*,*b*, through the corresponding ketene intermediates **7***a*,*b*. The carboxylic acids **6***a–c* can also be directly formed from **1***a–c*, under hydrolytic conditions of work-up. Products such as **5***c*, **9**, and **10***a*,*b* in these reactions, however, could arise through the further transformations of **6***a–c*. The formation of **11***a*,*b*, on the other hand, could be understood in terms of the reaction of **3***a*,*b* with oxygen, under work-up conditions, to give the hydroperoxy intermediates **4***a*,*b*, which will then lead to the observed products through the endoperoxides **8***a*,*b*. The fact that enhanced yields of **11***a* were obtained in the reaction of **1***a* with potassium in THF saturated with oxygen, and also when treated with potassium superoxide in benzene containing 18-crown-6, would support the involvement of oxygen and superoxide in the transformations of **1***a–c*, as implicated in Scheme 1. It may be pointed out here that recent studies by Bates *et al.* (2) have shown that 4-isopropyl-2-phenyl-Δ^2-oxazolin-5-one and 4-benzyl-2-phenyl-Δ^2-oxazolin-5-one are readily converted to the corresponding acyclic imides, *N*-isobutyrylbenzimide and *N*-(phenylacetyl)benzamide, respectively, on bubbling oxygen gas through their solutions in dimethyl sulfoxide. The formation of the cyclic imides corresponding to **11***a*,*b* in these reactions has been explained in terms of hydroperoxy intermediates, analogous to **4***a*,*b* (Scheme 1). Similarly, Warnhoff and co-workers (3) have shown that oxygen reacts with 4-alkylidene-2-phenyl-Δ^2-oxazolin-5-ones in the presence of triethylamine to give the corresponding imides, again arising through hydroperoxy intermediates, analogous to **4***a*,*b*, shown in Scheme 1. The reaction of **1***b* with potassium superoxide and 18-crown-6 in benzene likewise gave a mixture of the oxygenated products *N*-benzoylphenylacetamide (**11***b*), *N*-benzoyl-β-phenylalanine (**6***b*), and benzoic acid (**9**), whereas the reaction of **1***c* with potassium superoxide and 18-crown-6, under analogous conditions, gave an excellent yield of *N*-benzoyl-*C*,*C*-diphenylglycine (**6***c*). It may be mentioned in this connection that recent studies by Chuaqui *et al.* (4) have shown that the reaction of potassium superoxide with Δ^2-oxazolin-5-ones gives different products depending on the substituents present in the oxazolinone ring system. Thus, the reaction of 4,4-dimethyl-2-phenyl-Δ^2-oxazolin-5-one with potassium superoxide gave the ring-opened product, *N*-benzoyl-α-aminoisobutyric acid, whereas the reaction of 4-ethyl-2-phenyl-Δ^2-oxazolin-5-one gave a mixture of *N*-benzoyl-α-aminobutyric acid and *N*-benzoylpropionamide. The formation of the ring-opened α-aminoacid derivatives in these reactions has been explained in terms of the initial nucleophilic attack of the superoxide on the starting Δ^2-oxazolin-5-ones, followed by further transformation. The formation of *N*-benzoylpropionamide in the reaction of 4-ethyl-2-phenyl-Δ^2-oxazolin-5-one, however, has been explained in

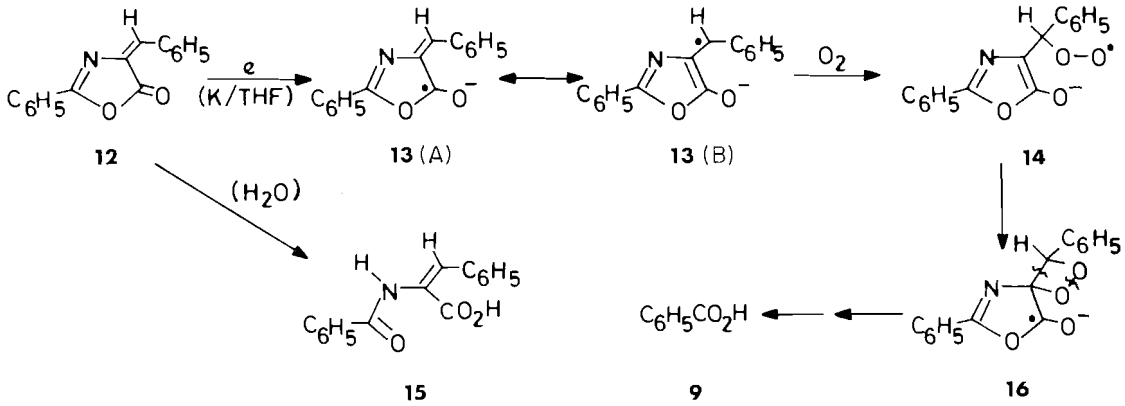
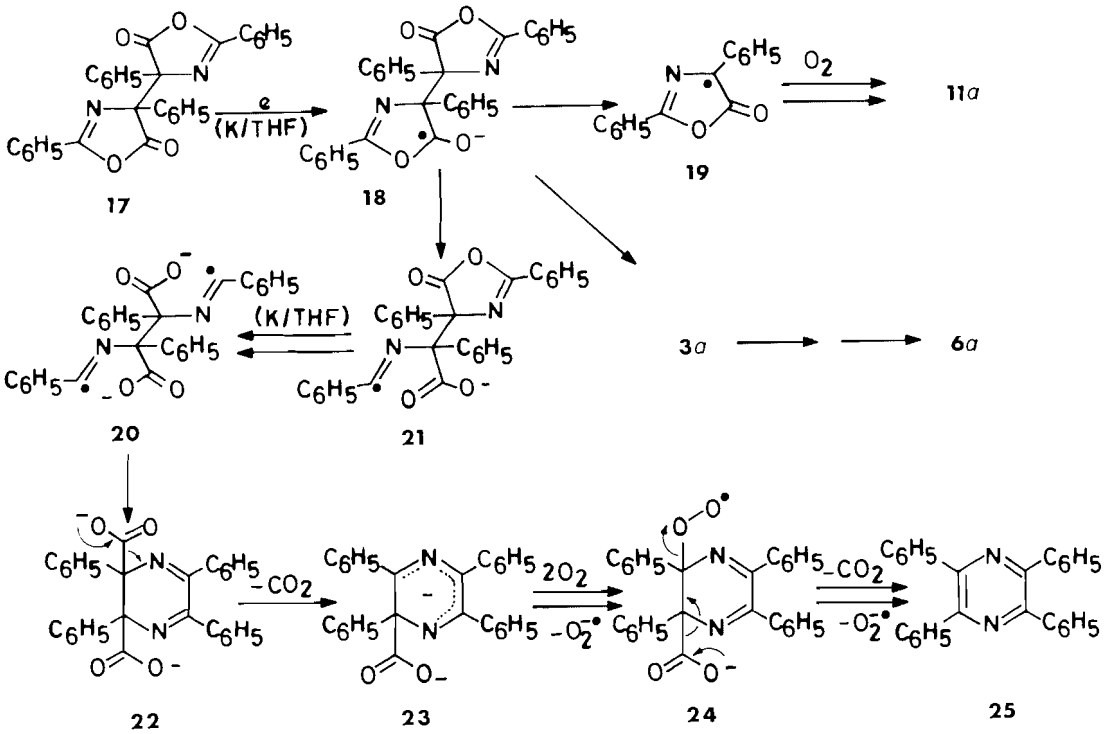


SCHEME 2.



SCHEME 3.

terms of a 1,3-dipolar cycloaddition of singlet oxygen to the N-protonated zwitterionic form of the oxazolinone, followed by the loss of CO_2 and further transformations. We feel that under our reaction conditions the pathway shown in Scheme 1, involving the radical anion intermediates **2***a–c*, may be operative (see later reports on cyclic voltammetric and pulse radiolysis studies).

The reaction of 4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one (**12**) with potassium in THF gave a mixture of α-benzamidocinnamic acid (**15**) and benzoic acid (**9**). The formation of these products, on the basis of analogy to the reactions of other Δ^2-oxazolinones, can be rationalized in terms of the pathway shown in Scheme 2.

The reaction of a bioxazolinone such as **17** with potassium in THF gave a mixture of dibenzimide (**11***a*), *N*-benzoyl-*C*-phenylglycine (**6***a*), *C*-phenylglycine (**10***a*), and 2,3,5,6-tetraphenylpyrazine (**25**) (Scheme 3), whereas the reaction of **26** with potassium in THF gave a mixture of α-benzamidocinnamic acid (**15**), *N*-benzoyl-β-phenylalanine (**6***b*), and benzamide (**29**) (Scheme 4). The reaction of **26** with potassium superoxide and 18-crown-6, however, gave a mixture of **15** and benzoic acid (**9**). The formation of the different products in the reaction of **17** and **26** with potassium in THF could be rationalized in terms of the pathways shown in Schemes 3 and 4. The initially formed radical anion **18** in the case of **17**, for example, could undergo fragmentation to give both the radical **19** and the anionic species **3***a*, which in turn could lead to **11***a* and **6***a*, respectively, as shown in Scheme 3. The radical anion intermediate **18** could also undergo transformation to give **21**, which could ultimately lead to 2,3,5,6-tetraphenylpyrazine (**25**), through the intermediates **20**, **22**, **23**, and **24**, as shown in Scheme 3. It may be pointed out here that **25** has also been reported to be formed from **17** in small amounts under thermal conditions (5). Similarly the radical anion **27**, formed from **26**, could lead to the different products as shown in Scheme 4.

Cyclic voltammeric studies

As highlighted in our earlier studies (20), electrochemical investigations would prove valuable in the characterization of radical anions, the primary intermediates involved in the

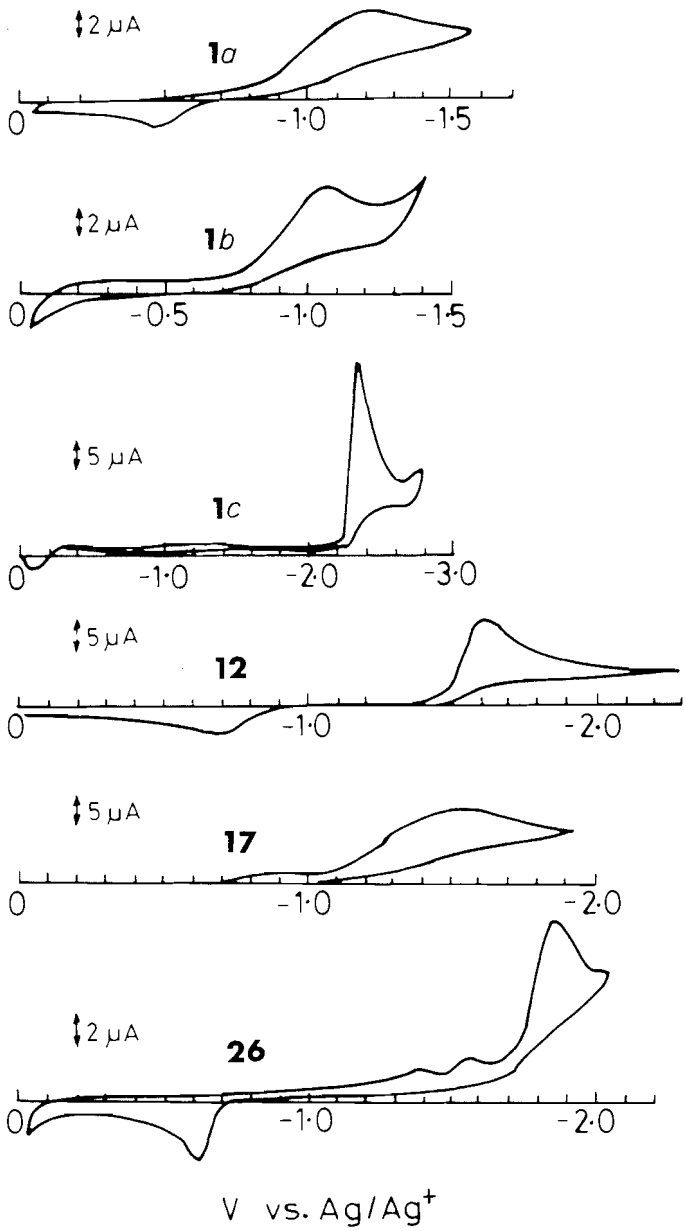

FIG. 1. Cyclic voltammograms of **1***a–c*, **12**, **17**, and **26** in deaerated acetonitrile containing 0.1 *M* tetrabutylammonium perchlorate (TBAP). Sweep rate was 200 mV/s.

reaction of different unsaturated organic substrates with potassium in THF. In the present study, we have generated electrochemically the radical anions of the Δ^2-oxazolin-5-ones **1***a–c*, **12**, and the bioxazolinones **17** and **26**, the substrates under investigation. The cyclic voltammograms of **1***a–c*, **12**, **17**, and **26** are shown in Fig. 1 and the reduction peak potentials are summarized in Table 1. All the substrates exhibited irreversible reduction peaks with the reduction potentials in the range of -0.9 to -2.35 V versus Ag/Ag^+ reference.

Pulse radiolysis studies

It has been reported earlier that the radical anions of unsaturated organic compounds can be generated through their reaction with solvated electrons (e_s^-) under pulse radiolytic conditions (6–8). In the present study, the radical anions of the Δ^2-oxazolin-5-ones **1***a–c* and **12** and the bioxazolinones **17** and **26** were generated pulse radiolytically in methanol, and their absorption spectra are presented in Fig. 2. These radical anions exhibited strong absorption maxima in the region of 295–350 nm and were shortlived in methanol ($\tau_{1/2}$ = 2.3–214 μs). As is evident from Table 1, these radical anions are formed from their appropriate precursors through reaction with solvated electrons under diffusion controlled rates.

Experimental

All melting points are uncorrected and were determined on a Mel-Temp apparatus. Petroleum ether was the fraction with bp 60–80°C. THF was dried over sodium and distilled immediately before use. Gold label (Aldrich) acetonitrile was used for cyclic voltammetric studies and spectral grade methanol (Fisher Scientific) was used for pulse radiolysis.

Starting materials

2,4-Diphenyl-Δ^2-oxazolin-5-one (**1***a*) (5*b*), mp 104–105°C; 4-benzyl-2-phenyl-Δ^2-oxazolin-5-one (**1***b*) (9), mp 69–70°C; 2,4,4-triphenyl-Δ^2-oxazolin-5-one (**1***c*) (10), mp 136–137°C; 4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one (**12**) (11), mp 165–166°C; bi-4,4′-(2,4-diphenyl-Δ^2-oxazolin-5-one) (**17**) (12, 13), mp 193–194°C; and bi-4,4′-(4-benzyl-2-phenyl-Δ^2-oxazolin-5-one) (**26**) (12, 13), mp 209–210°C, were prepared by reported procedures.

Reaction of Δ^2-oxazolin-5-ones **1**a–c *with potassium in THF*

A general procedure was to shake 5.0 mmol of the appropriate Δ^2-oxazolin-5-one with potassium (10 mmol) in dry THF (125 mL) for several hours in a stoppered flask. A few clean, broken glass pieces were added to the mixture to ensure a fresh surface of the metal throughout the reaction. The reaction mixture underwent pronounced color changes, indicative of the formation of radical anion inter-

mediates. On completion of the reaction, the mixture was poured into moist THF (100 mL) to destroy any unchanged potassium and the solvent was removed under vacuum. The residual solid was treated with water (10 mL) and extracted with ethyl acetate. Work-up of the organic layer by removal of the solvent under vacuum and fractional crystallization from suitable solvents gave some of the reaction products. Acidification of the aqueous layer with dilute hydrochloric acid, followed by work-up in the usual manner, gave some of the acidic products, which were purified by recrystallization from suitable solvents.

Reaction of **1**a

Treatment of **1***a* (1.2 g, 5.0 mmol) with potassium (0.39 g, 10 mmol) in THF for 4 h and work-up in the usual manner gave 140 mg (12%) of dibenzamide (**11***a*) (solid from ethyl acetate extract was fractionally crystallized from benzene), mp 144–145°C (mixture mp) (14); 250 mg (33%) of *C*-phenylglycine (**10***a*) (mother liquor after removal of **11***a* was evaporated under vacuum and the residual solid was recrystallized from ethanol), mp 270–280°C (mixture mp) (15); and 350 mg (27%) of *N*-benzoyl-*C*-phenylglycine (**6***a*) (acidification of the aqueous layer with dilute hydrochloric acid and recrystallization from ethanol), mp 117–178°C (mixture mp) (5*b*).

Treatment of **1***a* (500 mg, 2.1 mmol) with potassium (160 mg, 4.1 mmol) in THF saturated with oxygen (100 mL) for 10 h and work-up in the usual manner gave 190 mg (40%) of **11***a* (extraction of the reaction mixture with methylene chloride, chromatographing the residual solid over alumina, elution with ethyl acetete – benzene (4:6), and recrystallization from benzene), mp 144–145°C (mixture mp), and 80 mg (32%) benzoic acid (**9**) (acidification of the aqueous layer with dilute hydrochloric acid and recrystallization from hot water), mp 120–121°C (mixture mp).

Reaction of **1**b

Treatment of **1***b* (1.25 g, 5.0 mmol) with potassium (0.39 g, 10 mmol) in THF for 4 h and work-up in the usual manner gave 200 mg (33%) of benzoic acid (**9**) (acidification of the aqueous layer with dilute hydrochloric acid and recrystallization from hot water), mp 120–121°C (mixture mp); 300 mg (37%) of β-phenylalanine (**10***b*) (removal of the solvent under vacuum from the ethyl acetate extract and fractional crystallization from ethanol), mp 284–288°C (mixture mp); and 70 mg (6%) of recovered starting material **1***b* (mother liquor after removal of **10***b* was evaporated under vacuum and recrystallized from petroleum ether).

Reaction of **1**c

Treatment of **1***c* (1.56 g, 5.0 mmol) with potassium (0.39 g, 10 mmol) in THF for 45 h and work-up in the usual manner gave 0.5 g (30%) of *N*-benzoyl-*C*,*C*-diphenylglycine (**6***c*) (extraction of the reaction mixture with methylene chloride, removal of the solvent under vacuum, and recrystallization from benzene), mp 166–167°C (mixture mp) (10), and 0.81 g (57%) of *N*-benzoyl-*C*,*C*-diphenylmethylamine (**5***c*) (acidification of the aqueous layer with dilute hydrochloric acid and recrystallization from ethanol), mp 191–192°C (mixture mp) (10).

Treatment of **1***c* (0.4 g, 1.28 mmol) with potassium (80 mg, 2 mmol) in THF saturated with oxygen (100 mL) for 6 h and work-up in the usual manner gave 80 mg (19%) of **6***c*, mp 166–167°C (mixture mp); 250 mg (68%) of **5***c*, mp 191–192°C (mixture mp); and 50 mg (32%) of benzoic acid (**9**), mp 120–121°C (mixture mp).

*Reaction of 4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one (**12**) with potassium in THF*

A mixture of **12** (1.15 g, 4.6 mmol) and potassium (0.39 g, 10 mmol) was shaken in THF (125 mL) for 3 h and poured into moist THF (100 mL). Removal of the solvent under vacuum gave a solid, which was treated with water (10 mL) and extracted with methylene chloride. Acidification of the aqueous layer gave 0.48 g (39%) of α-benzamidocinnamic acid (**15**), mp 222–224°C (mixture mp) (16), after recrystallization from ethanol. The mother liquor on concentration gave 0.22 g (39%) of benzoic acid (**9**), mp 120–121°C, after recrystallization from hot water. Removal of the solvent from the methylene chloride extract gave 0.1 g (9%) of the unchanged starting material (**12**), mp 165–166°C (mixture mp).

*Reaction of bi-4,4'-(2,4-diphenyl-Δ^2-oxazolin-5-one) (**17**) with potassium in THF*

A mixture of **17** (0.94 g, 2.0 mmol) and potassium (0.25 g, 6.4 mmol) was shaken in THF for 5 h. Work-up as in the earlier cases by treatment with moist THF and removal of the solvent under vacuum gave a solid, which was treated with water (10 mL) and extracted first with benzene and later with ethyl acetate. Removal of the solvent from the benzene extract gave 0.15 g (17%) of dibenzimide **11***a*, mp 144–145°C (mixture mp). Removal of the solvent from the ethyl acetate extract gave 80 mg (14%)[3] of *C*-phenylglycine (**10***a*), mp 270–280°C (mixture mp), after recrystallization from ethanol. The mother liquor on evaporation gave 0.31 g (41%) of 2,3,5,6-tetraphenylpyrazine (**25**), mp 248–249°C (mixture mp) (17), after recrystallization from ethanol. Acidification of the aqueous layer with dilute hydrochloric acid gave 80 mg (8%)[3] of *N*-benzoyl-*C*-phenylglycine (**6***a*), mp 177–178°C (mixture mp).

*Reaction of bi-4,4'-(4-benzyl-2-phenyl-Δ^2-oxazolin-5-one) (**26**) with potassium in THF*

A mixture of **26** (0.95 g, 1.9 mmol) and potassium (0.25 g, 6.4 mmol) in THF (125 mL) was shaken for 5 h. Work-up in the usual manner by treatment of the reaction mixture with moist THF and removal of the solvent under vacuum gave a solid, which was treated with water (10 mL) and extracted with benzene and later with ethyl acetate. Removal of the solvent from the benzene extract gave 0.2 g (20%)[3] of **15**, mp 222–224°C (mixture mp), after recrystallization from ethanol. Removal of the solvent from the ethyl acetate extract gave 0.15 g (15%) of **6***b*, mp 186–187°C (mixture mp), after recrystallization from methanol. The mother liquor was concentrated to give a solid, which was recrystallized from methanol to give 50 mg (11%)[3] of benzamide (**29**), mp 128–129°C (mixture mp).

Reaction of Δ^2-oxazolin-5-ones **1**a–c *with potassium superoxide*

A general procedure was to stir a mixture of 2 mmol of the appropriate Δ^2-oxazolin-5-one, 4 mmol of potassium superoxide, and 2 mmol of 18-crown-6 in benzene (100 mL) for 24 h at room temperature. On completion of the reaction, the excess of superoxide was destroyed by adding water (20 mL) and extracted with an aqueous solution of sodium chloride. The aqueous layer was acidified with dilute hydrochloric acid and extracted with suitable solvents to give some of the products. Work-up of the organic layer gave the remaining products.

Reaction of **1**a

A mixture of **1***a* (0.5 g, 2 mmol), potassium superoxide (0.29 g, 4.1 mmol), and 18-crown-6 (0.53 g, 2.1 mmol) was stirred for 24 h and worked up in the usual manner. The aqueous layer was acidified with dilute hydrochloric acid and extracted with ethyl acetate. Removal of the solvent under vacuum gave 40 mg (7%) of **6***a*, mp 177–178°C (mixture mp), after recrystallization from ethanol. Removal of the solvent from the organic layer gave 260 mg (55%) of **11***a*, mp 144–145°C (mixture mp), after recrystallization from benzene.

Reaction of **1**b

Treatment of **1***b* (0.4 g, 1.6 mmol) with potassium superoxide (0.22 g, 3.1 mmol) and 18-crown-6 (0.4 g, 1.6 mmol) in benzene (60 mL) for 24 h and work-up as in the earlier case gave 100 mg (23%) of **6***b* (acidification of the aqueous layer with dilute hydrochloric acid, extraction with ethyl acetate, and recrystallization from methanol), mp 186–187°C (mixture mp); 90 mg (46%) of **9** (concentration of the mother liquor and fractional crystallization from hot water), mp 120–121°C (mixture mp); and 80 mg (21%) of **11***b* (from organic layer), mp 129–130°C, after recrystallization from benzene (lit. (18) mp 129–130°C).

[3]Yield based on the assumption that one mole of the starting material gives two moles of the product.

Reaction of **1***c*

Treatment of a mixture of **1***c* (0.67 g, 2.1 mmol), potassium superoxide (0.56 g, 7.9 mmol), and 18-crown-6 (1.0 g, 3.9 mmol) in benzene for 24 h and work-up in the usual manner gave 0.6 g (85%) of **6***c* (acidification of the aqueous layer with dilute hydrochloric acid and recrystallization from ethanol), mp 166–167°C (mixture mp), and 70 mg (10%) of recovered starting material **1***c* (removal of the solvent from the organic layer under vacuum and recrystallization from ethanol).

*Reaction of bi-4,4'-(4-benzyl-2-phenyl-Δ^2-oxazolin-5-one) (**26**) with potassium superoxide*

A mixture of **26** (0.5 g, 1.0 mmol), potassium superoxide (0.14 g, 2.0 mmol), and 18-crown-6 (0.26 g, 1.0 mmol) in benzene (80 mL) was stirred at room temperature for 24 h. Work-up of the mixture as in the earlier cases gave 0.15 g (28%)[3] of **15** (acidification of the aqueous layer with dilute hydrochloric acid and recrystallization from ethanol), mp 222–224°C (mixture mp); 50 mg (21%)[3] of **9** (from mother liquor), mp 120–121°C (mixture mp); and 200 mg (40%) of recovered starting material **26** (removal of the solvent from the organic layer and recrystallization from benzene – petroleum ether (1:9)), mp 209–210°C (mixture mp).

Cyclic voltammetry

Measurements were made with a Princeton Applied Research (PAR) Model 173 potentiostat/galvanostat, a PAR Model 175 universal programmer, and a Kipp and Zonen X–Y recorder. Experiments were performed in a standard three-compartment cell equipped with a Pt-disc working electrode, a Pt-wire counter electrode, and a Ag/Ag^+ reference electrode. The cyclic voltammograms were recorded in a deaerated acetonitrile containing 0.1 *M* tetrabutylammonium perchlorate (TBAP). The direction of the initial scan was cathodic and the scan rate was 200 mV/s.

Pulse radiolysis

The description of the pulse radiolysis apparatus, which allows the determination of the transient spectra at various time intervals after the pulse and the kinetic measurements of the spectral changes, has been reported earlier (19). The irradiation was carried out with 5-ns electron pulses from the Notre Dame 8-MeV ARCO LP-7 linear accelerator, using dose rates of $\sim 2 \times 10^{16}$ eV/g per pulse. The solutions of the appropriate substrates in methanol were deaerated before pulse radiolysis by bubbling nitrogen for at least 30 min and the deaeration was continued in the reservoir from which the solution was allowed to flow slowly and continuously through the cell. The rate constants for the reactions with solvated electrons (e_s^-) were determined from the kinetic analysis of the enhanced rate of decay of e_s^- in the presence of the appropriate substrate or from the growth rate of the radical anion.

Received October 6, 1986

HÉLÈNE DESLAURIERS, WLODZIMIERCZ MAKULSKI, and GUY J. COLLIN. Can. J. Chem. **65**, 1631 (1987).

A complete study of the 184.9 nm photolysis of *cis*- and *trans*-2-butene has been done in the gas phase. The main primary processes (>90%) are the α(C—C) and β(C—H) bond ruptures. Both processes have similar quantum yield values in *cis*-2-butene: ϕ(C—C)/β(C—H) ≅ $0.95_7 \pm 0.13$. Conversely, the α(C—C) bond rupture is more important in *trans*-2-butene: ϕ(C—C)/β(C—H) ≅ $1.34_6 \pm 0.20$. These values are compared with those measured in propene (0.57) and isobutene (0.95). No simple molecular property seems sufficient to explain such an effect.

HÉLÈNE DESLAURIERS, WLODZIMIERCZ MAKULSKI et GUY J. COLLIN. Can. J. Chem. **65**, 1631 (1987).

Une étude complète de la photolyse à 184,9 nm des *cis*- et *trans*-butènes-2 a été réalisée en phase gazeuse. Les principaux processus primaires (>90%) sont les ruptures des liaisons α(C—C) et β(C—H). Les deux processus ont des importances similaires dans le cas du *cis*-butène-2 : ϕ(C—C)/β(C—H) ≅ $0{,}95_7 \pm 0{,}13$. Dans le cas du *trans*-butène-2, le même rapport est de $1{,}34_6 \pm 0{,}20$, donc plus important. Ces valeurs sont rapprochées de celles mesurées dans le propène (0,57) et l'isobutène (0,95). Aucune propriété moléculaire simple ne semble appropriée pour expliquer un tel effet.

Introduction

The vacuum and the very far uv photolysis of 2-butene is relatively well known. Chesick used a zinc lamp (202.6–206.2 nm) (1), and Borrell *et al.* a mercury one (184.9 nm) (2). Both laboratories investigated the effects of pressure on the total product yields and the product distributions. We also reported the yields of primary products as well as the yields of products formed from the decomposition of primary fragments at 123.6 nm, 147.0 nm (3), and ca. 174 nm (9, 20). The aim of the present authors is to measure the primary photochemical processes occurring in the 184.9 nm photolysis of *cis*-2-butene and *trans*-2-butene, particularly in view of the effect of the geometry of the starting molecule. For example, some differences were noticed in our previous studies at 174 nm (9, 20). More recently, we have studied the 184.9 nm photolysis of propene and isobutene. In this class of alkenes which do not have a C—C bond located in the β position relative to the double bond, the primary fragmentation processes involve the rupture of either an α(C—C) bond or a β(C—H) bond. The α(C—C)/β(C—H) ratios are 0.57 (σ = 0.054) and 0.95 (σ = 0.10) in propene and isobutene, respectively (4). We had no firm explanation for the observed values of the above-mentioned ratios. Obviously, it is interesting to try to measure the same ratio in the two 2-butene molecules.

Experimental

All the experimental techniques are well known and are described in the literature (3, 4, 9, 20).

Materials

2-Butenes are Phillips 66 products. *cis*-2-Butene (stated purity: 99.94 mol%) contains 1,3-butadiene, 24–26 ppm; *n*-butane, 1.4–2.0 ppm; isobutene, 17–19 ppm; 1-butene, 21–22 ppm; and *trans*-2-butene, 406–432 ppm. *trans*-2-Butene (stated purity: 99.48 mol%) contains *cis*-2-butene, 0.45%; *n*-butane, 150 ppm; and 1,3-butadiene + 1-butene, 2.5 ppm.

Oxygen (99.98%), Research purity, and nitric oxide, C.P. (99.0%) are from Matheson and are used as received. Deuterium sulfide and deuterium iodide (rather than H_2S or HI) are used as radical scavengers. They are from Merck, Sharp, and Dohme of Canada. They are also used as received after being degassed under high vacuum and at liquid nitrogen temperature.

Photolysis

All the photolyses are performed in a 90.3 cm^3 Pyrex cell (equipped with two 1 mm-thick suprasil quartz windows) placed in front of a low pressure mercury lamp (Philips) (5). The emission of the lamp as well as the absorption through the cell were checked with a 0.5-m McPherson monochromator (5). Chemical actinometry was used as comparing the formation of *n*-butane in the 184.9 nm photolysis of ethylene: $\Phi(n\text{-}C_4H_{10}) = 0.153$ (6, 7). In some experiments we used an 185 nm Acton Research filter in order to eliminate emission from the 253.7 nm line.

Typical rates of photon input in the cell are in the ranges (2–6) × 10^{13} or (6–10) × 10^{13} photons s^{-1}. The absorption coefficients of the mercury line (184.9 nm) by olefins are very high (8). For example, at a pressure of 0.3 Torr, ca. 99% of the incident beam is absorbed by *cis*-2-butene. Thus, it may be assumed that no correction for absorption is needed, provided the pressure is higher than 0.5 Torr in the 25 cm-long cell. In order to make the appropriate corrections for partial absorption at low pressures ($P < 0.5$ Torr), the photon beam was collimated and resulted in a lower intensity. Photolytic times were adjusted so that the number of photons injected in the cell never exceeded 0.5% of the total number of butene molecules in order to avoid back reactions.

Analysis

Photolysis materials were analyzed on two different gas chromatographs equipped with a dual flame ionization detector and either a squalane (6 m × ϕ6 mm; 25%) or UCON LB 550X (7 m × ϕ6 mm; 20%) column (4).

Results

Fifteen product quantum yields are reported in Table 1 for various selected butene pressures. Except for methane which is only slightly affected, the quantum yield values for the C_2 and C_3 hydrocarbons decrease with an increase in the pressure. For the C_4, C_5, and C_6 products, the quantum yield values are roughly independent of the pressure. The situation is similar in the photolysis of *trans*-2-butene:Nitric oxide mixtures, except that there is no formation of C_5 and C_6 products and the propyne quantum yield is constant over the 0.5–100 Torr pressure scale. In the presence of DI, there is a large increase in the methane quantum yields (Table 3). Conversely, there is no difference in the quantum yields of acetylene, propyne, and allene measured

[1]Present address: Department of Chemistry, Warsaw University, Zwirki i Wigury 101, 02-089 Warsaw, Poland.

[2]To whom all correspondence should be addressed.

either in the presence of nitric oxide oxide or DI. There is more 1,3-butadiene formed in the presence of DI than in that of nitric oxide.

Similar results are obtained in the photolysis of *cis*-2-butene either in the absence or the presence of the same additives (Tables 4–6).

Discussion

The behavior of the photoexcited molecules is relatively well known as far as gaseous alkenes are concerned. As was stated above, fragmentation involves mainly the rupture of either an α(C—C) or a β(C—H) bond (1–5).

[1] $2\text{-}C_4H_8 + h\nu \rightarrow {}^1(2\text{-}C_4H_8)^* \rightarrow 2\text{-}C_4H_8^{**}$

[2][3] $CH_3CH{=}CHCH_3^{**} \rightarrow CH_3CH{=}\dot{C}H^* + CH_3$

$\Delta H = 389$ kJ mol^{-1}

[3] $CH_3CH{=}CHCH_3^{**} \rightarrow CH_3\overline{CHCHCH_2}^* + H$

$\Delta H = 355$ kJ mol^{-1} (10)

$^1(M)^*$ is a singlet electronic excited state and $2\text{-}C_4H_8^{**}$ represents the photoexcited molecule in its fundamental electronic state, where all the energy of the incident photon is transferred in its vibrational framework. These primary processes are followed by secondary processes, in which the excited fragments, the 1-propenyl and α-methallyl radicals may suffer either further fragmentation, isomerization, and/or stabilization through collisions. The energy of the incident photon is 644 kJ einstein^{-1} (154 kcal einstein^{-1}). Thus, there is an excess energy of at least 260 kJ mol^{-1} available to energize the fragments. This excess energy must be partitioned in both sets of radicals formed in processes [2] and [3].

It may be assumed that the partitioning is roughly proportional to the number of internal degrees of freedom of each partner (ref. 11, pp. 240–242; ref. 12). Thus, on the ground of energetic considerations, both unsaturated radicals formed in processes [2] and [3] have many open channels.

[4*a*] $CH_3CH{=}\dot{C}H^* \rightarrow CH_3 + CH{\equiv}CH$

$\log A = 13.95$ and $E_A = 171$ kJ mol^{-1} (13)

[4*b*] $CH_3CH{=}\dot{C}H^* \rightarrow H + CH_3C{\equiv}CH$

$\log A = 13.7$ and $E_A = 184$ kJ mol^{-1} (13)

[4*c*] $CH_3CH{=}\dot{C}H^* \rightarrow \overline{CH_2CHCH_2}^*$

$E_A = 147$ kJ mol^{-1} (13, 14)

[5] $\overline{CH_2CHCH_2}^* \rightarrow H + CH_2{=}C{=}CH_2$

[6] $C_3H_5^* + M \rightarrow M + C_3H_5$

[7] $CH_3\dot{C}HCHCH_2^* \xrightarrow{k_d} H + CH_2{=}CHCH{=}CH_2$

$E_A \cong 210$ kJ mol^{-1} (15)

[8] $CH_3\dot{C}HCHCH_2^* + M \xrightarrow{k_s} M + CH_3CHCHCH_2$

These secondary processes are followed by the usual radical–radical disproportionation/combination reactions and the addition of hydrogen atoms to the starting material (16).

[9*a*] $H + 2\text{-}C_4H_8 \rightarrow CH_3\dot{C}HCH_2CH_3^{\ddagger}$

[9*b*] $H + 2\text{-}C_4H_8 \rightarrow H_2 + C_4H_7$

[10*a*] $CH_3\dot{C}HCH_2CH_3^{\ddagger} \rightarrow CH_3 + CH_3CH{=}CH_2$

[10*b*] $CH_3\dot{C}HCH_2CH_3^{\ddagger} \rightarrow CH_3CH_2CH_2\dot{C}H_2^{\ddagger}$

[11] $CH_3CH_2CH_2\dot{C}H_2^{\ddagger} \rightarrow CH_3\dot{C}H_2 + CH_2{=}CH_2$

[12] $C_4H_9^{\ddagger} + M \rightarrow M + C_4H_9$

[13] $CH_3 + CH_3 \rightarrow C_2H_6$

[14*a*] $CH_3 + CH_3\dot{C}HCH_2CH_3 \rightarrow CH_4 + C_4H_8$

[14*b*] $\rightarrow CH_3CH(CH_3)CH_2CH_3$

[15*a*] $CH_3 + CH_3\overline{CHCHCH_2} \rightarrow CH_3CH(CH_3)CH{=}CH_2$

[15*b*] $\rightarrow CH_3CH{=}CHCH_2CH_3$ (*cis* + *trans*)

[15*c*] $\rightarrow CH_4 + CH_2{=}CHCH{=}CH_2$

[16*a*] $CH_3 + CH_3CH{=}\dot{C}H \rightarrow CH_4 + C_3H_4$

[16*b*] $\rightarrow CH_3CH{=}CHCH_3$ (*cis* + *trans*)

[17*a*] $CH_3 + \overline{CH_2CHCH_2} \rightarrow CH_4 + C_3H_4$

[17*b*] $\rightarrow CH_3CH_2CH{=}CH_2$

[18*a*] $2C_4H_9 \rightarrow n\text{-}C_4H_{10} + n\text{-}C_4H_8$

[18*b*] $\rightarrow C_8H_{18}$

[19] $2\overline{CH_2CHCH_2} \rightarrow CH_2{=}CHCH_2CH_2CH{=}CH_2$

[20] $2CH_3\overline{CHCHCH_2} \rightarrow C_8H_{14}$

...etc.

All these reactions are almost sufficient to explain the formation of the products reported in Tables 1, 2, 4, and 5. This mechanism finds very good support from the experiments performed in the presence of a few percent of a radical scavenger, such as D_2S or DI (Tables 3 and 6). In these experiments, a stable, thermalized radical abstracts an hydrogen (deuterium) atom from the additive (17, 18).

[21] $R + XH(D) \rightarrow RH(D) + X$; $X \equiv I$, H(D)S

This process is efficient in all cases except in the case of allylic radicals where only hydrogen iodide is efficient (17). This particular behaviour (Table 3) explains the lower propene yields, measured in the presence of hydrogen sulfide, in comparison with what is observed in the presence of hydrogen iodide, and gives very strong support to the isomerization process of 1-propenyl radicals: process [4*c*].

At this time we would not like to explain systematically all the above-mentioned reactions, preferring to ask the interested reader to go back to the original papers (1–3, 18, 19). We would prefer to focus our attention on the main differences occurring between *cis*- and *trans*-2-butene. Obviously this goal will force us to emphasize the main features and even in some cases, to stress some minor characteristics.

From Tables 2 and 5, the main products observed in the presence of either oxygen or nitric oxide are propene and 1,3-butadiene. Both products are clearly related to the presence of hydrogen atoms: processes [7]–[10]. From this mechanism, the inverse of the 1,3-butadiene (B) quantum yield is a linear function of pressure (ref. 11, pp. 235–245)

[I] $[\Phi(B)]^{-1} = [\Phi_0(B)]^{-1}(1 + k_s[M]/k_d)$

The agreement with the Stern–Volmer line observed in Fig. 1 is good except for a strong negative curvature observed at pressures higher than 10 Torr. Eventually, a plateau region is established at pressures around or higher than ≅70 Torr. From the extrapolation of the quantum yields to zero pressure (Fig. 2*A*), one can extract the quantum yields of process [7], i.e. in the absence of a stabilizing process [8]: the $\Phi_0(1,3\text{-}C_4H_6)$ values are 0.29 and 0.21 in *cis*- and *trans*-2-butene, respec-

[3] $\Delta H_f^0(CH_3CH{=}\dot{C}H) = 56.8$ kcal mol^{-1}, see ref. 14.

[a]There is no formation of ethane, C_5, and C_6 products: $\Phi < 0.001$.

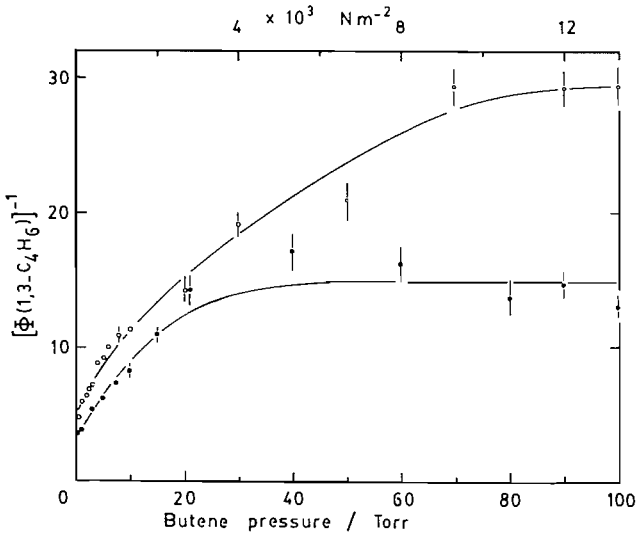

FIG. 1. The inverse of the 1,3-butadiene quantum yields vs. the 2-butene pressure in the presence of a radical scanvenger such as NO or O_2: $\Phi_0 \cong 0.29$ and 0.12 in *cis*- (●) and *trans*-2-butene (○), respectively.

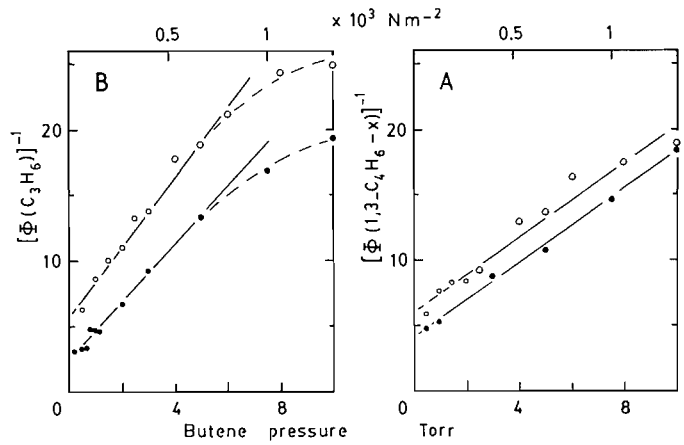

FIG. 2. The inverse of quantum yields vs. the *cis*- (●) or *trans*-2-butene (○) pressure in the presence of O_2 or NO, respectively. *A*: $[\Phi(1,3\text{-}C_4H_6) - 0.067]^{-1}$, (●), $y = 4.06 + 1.43x$, $r^2 = 0.99$ and $[\Phi(1,3\text{-}C_4H_6) - 0.035]^{-1}$, (○), $y = 6.08 + 1.43x$, $r^2 = 0.96$; *B*: $[\Phi(\text{propene})]^{-1}$, (●), $y = 2.61 + 2.15x$, $r^2 = 0.99$ and (○), $y = 5.95 + 2.67x$, $r^2 = 0.98$.

tively. Thus, at first sight, it seems that the β(C—H) bond rupture (process [3]) is more important in *cis*-2-butene. A similar behavior can be expected from the propene quantum yields (Fig. 2*B*). The evaluation of zero pressure quantum yields of propene leads to the Φ_0(propene) values: they are 0.40 and 0.17 in *cis*- and *trans*-2-butene, respectively. Again, there are more hydrogen atoms formed from *cis*- than from *trans*-2-butene. However, several processes add to the hydrogen atom formation: see for example, processes [4*b*], [5], [7]. Moreover, the above mechanism assumes that for each 1,3-butadiene molecule, two hydrogen atoms are formed. If this were the case, one would expect a hydrogen quantum yield larger than, or at least equal to 0.58 at zero pressure in *cis*-2-butene. Since the zero pressure quantum yield of propene is only 0.40, there is a deficit in the hydrogen atom budget. At least two corrections must be applied to this mechanism. The first one involves the

[a]There is no formation of ethane, *n*-butane, 1-butene, C_5 and C_6 hydrocarbons: $\Phi < 0.002$.

[b]High intensity experiment: $I \cong 8\ 10^{13}$ photons s^{-1}; elsewhere: $I \cong 2\text{–}6\ 10^{11}$ photons s^{-1}.

hydrogen atom abstraction process (reaction [9*b*]) with a k_{9a}/k_{9b} ratio much higher than the one measured for thermalized systems: $0.23 \leqq k_{9b}/k_{9a} \leqq 0.117$ (21). The second adds a new fragmentation process for the photoexcited molecule:

[22] $\quad 2\text{-}C_4H_8{}^{**} \rightarrow H_2 + 1,3\text{-}C_4H_6$

One may assume that such a concerted process is not pressure dependent: in other words that the photoexcited molecule has a lifetime shorter than the time available between two collisions, at least at sub-atmospheric pressures (22). From the plateau regions observed in Fig. 1, the quantum yields for process [22] may be evaluated at 0.067 and 0.035 in *cis*- and *trans*-2-butene, respectively. This correction lowers the ϕ(process [7]) values to 0.246 and 0.165 in *cis*- and *trans*-2-butene, respectively.

The formation of acetylene is linked to the primary α(C—C) bond rupture: processes [2] and [4*a*]. In agreement with a chemical activation study (13), the hot 1-propenyl radicals may either decompose, giving rise to the formation of acetylene and

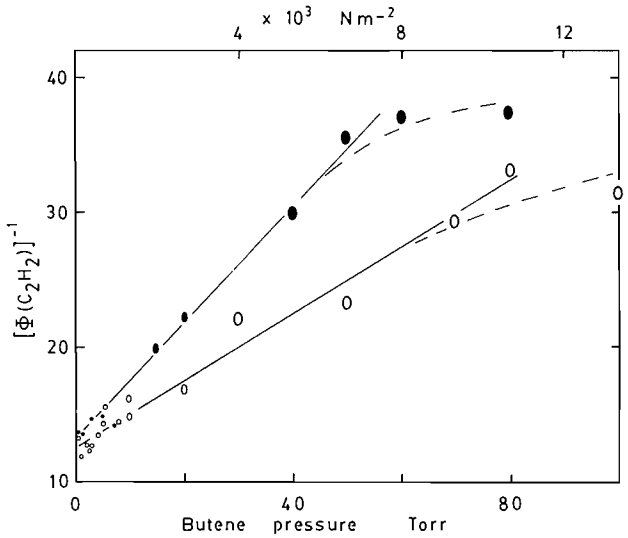

FIG. 3. The inverse of acetylene quantum yields vs. the 2-butene pressure in the presence of a radical scavenger such as NO or O_2 in *cis*-2-butene (●), $y = 13.16 + 0.42x$, $r^2 = 0.98$ and *trans*-2-butene (○), $y = 12.58 + 0.248x$, $r^2 = 0.98$.

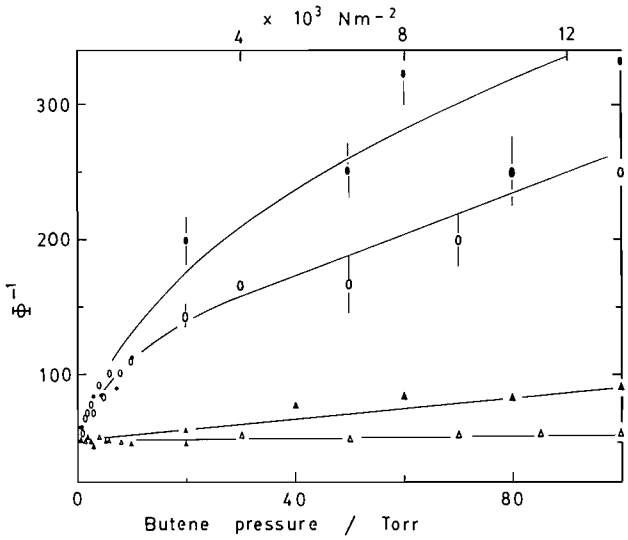

FIG. 4. The inverse of quantum yields of propyne (lower curves: △,▲) and allene (upper curves: ○,●) vs. the 2-butene pressure in the presence of a radical scavenger such as NO or O_2 in *cis*- (●,▲) and *trans*-2-butene (○,△).

propyne or isomerize to the allyl structure. With an internal energy of 266 kJ mol^{-1}, the relative rate constants, $k_{4a}/k_{4b}/k_{4c}$ are 1.0/0.2/0.2 (13) and are likely to be dependent on the internal energy content of the precursor. In the present study, the maximum available energy is 644 − 385 = 259 kJ mol^{-1}. This excess energy is divided in both methyl and 1-propenyl radicals, more precisely in the vibrational degrees of freedom of each fragment (11). On statistical ground, the mean energy content of the 1-propenyl radicals is only 18/27 of this maximum energy, E^*(1-propenyl) ≅ 173 kJ mol^{-1} (11). Thus, in comparison with the activation study mentioned above, and from the known energy barriers for processes [4*a*]–[4*c*], the isomerization process must be favored, and the ratio k_{4a}/k_{4b} must be increased. Acetylene is the major compound (Tables 2 and 5) and Figs. 3 and 4 show the Stern–Volmer plots of the acetylene and C_3H_4 quantum yields. It is obvious from these figures that the acetylene quantum yield is much more dependent on pressure than that of propyne. This observation indicates that both products are not entirely formed from the same precursor. It must be added that the main fate of hot allyl radicals is isomerization towards the 2-propenyl and 1-propenyl radicals (13). Thus, the hot C_3H_5* radicals is a complex mixture of the three isomers. Finally, the molecular elimination of methane concurrently with propyne from the photoexcited molecules must be questioned. The low pressure dependence of the propyne quantum yield is consistent with this process and a large fraction of the propyne formation may be ascribed to the following process.

[23] $\quad 2\text{-}C_4H_8^{**} \rightarrow CH_4 + CH_3C{\equiv}CH$

This process explains part of the formation of methane observed in the presence of either NO or O_2.

The formation of ethylene may derive from at least two different processes (Fig. 5). At low pressures, the very strong inverse dependence of its quantum yield on the pressure supports the involvement of vibrationally excited 1-butyl radicals (processes [9]–[12]), and does not demand more explanations (23). At high pressures ($P > 50$ Torr), a fragmentation process involving a photoexcited C_4H_8** molecule cannot be precluded. One of the two following processes may be proposed:

[24] $\quad 2\text{-}C_4H_8^{**} \rightarrow 2C_2H_4$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12

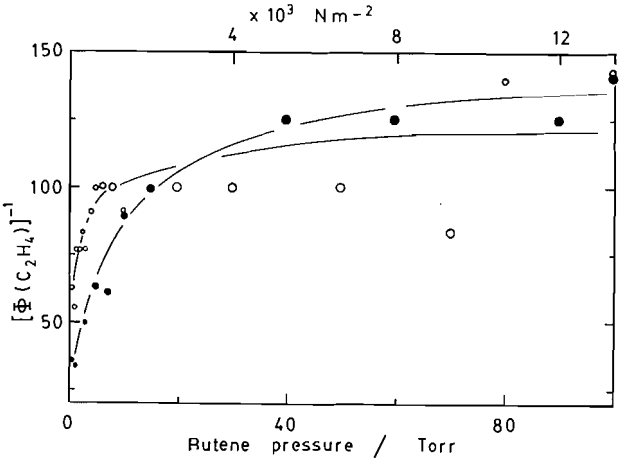

FIG. 5. The inverse of the ethylene quantum yields vs. the *cis*- (●) or *trans*-2-butene (○) pressure in the presence of O_2 or NO, respectively.

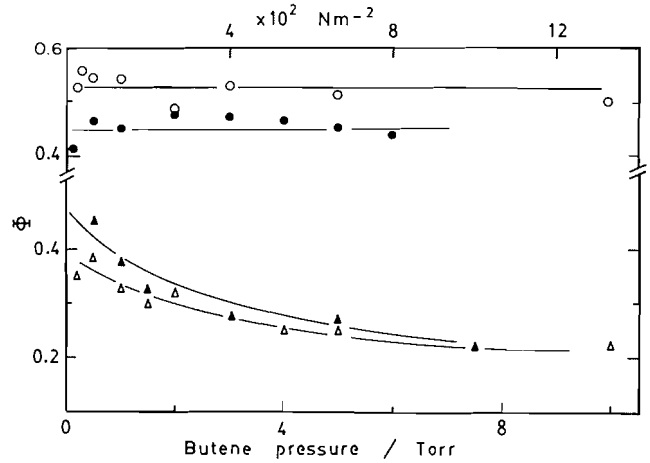

FIG. 6. The pressure dependence of the $\Phi[\beta(C—H)]$ values (relationships [II‴], lower part) and $\Phi[\alpha(C—C)]$ values ([IV′], upper part) in the 184.9 nm photolysis of *cis*- (●,▲) and *trans*-2-butene (○,△); see text. For clarity, the *y*-axis has been displaced.

$$[25a]^4 \quad 2\text{-}C_4H_8{}^{**} \rightarrow (C_4H_8)^{**} \rightarrow C_2H_5{}^* + C_2H_3 \qquad \Delta H = 428 \text{ kJ mol}^{-1}$$

$$[26] \quad C_2H_5{}^* \rightarrow C_2H_4 + H \qquad \Delta H = 151.5 \text{ kJ mol}^{-1}$$

The molecular process (reaction [24]) involves an internal rearrangement of the photoexcited molecules. Processes [25] and [26] are supported by the small increase in the ethylene yield in the presence of DI (Tables 3 and 6). The difference between the $\Phi_{DI}(C_2H_4)$ and $\Phi_{O_2,NO}(C_2H_4)$ values may be linked through process [21] to the formation of vinyl radicals: $\Phi(C_2H_3) \cong 0.01$. A similar process may lead to the formation of acetylene and ethyl radicals.

$$[25b] \quad 2\text{-}C_4H_8{}^{**} \rightarrow (C_4H_8)^{**} \rightarrow C_2H_5 + C_2H_3{}^*$$

$$[27] \quad C_2H_3{}^* \rightarrow C_2H_2 + H \qquad \Delta H = 143.4 \text{ kJ mol}^{-1} \text{ (25)}$$

This mechanism is supported by the formation of a small amount of ethane in the presence of DI: $\Phi(C_2H_5) \cong 0.012$ and adds to the formation of acetylene. One must add that on energetic consideration acetylene, ethylene, and two hydrogen atoms cannot be formed from the same photoexcited molecule. Finally, isomerization of *cis*-2-butene to *trans*-2-butene is observed at low pressures (Table 5) as well as at high pressures (2) with low quantum yields.

From Tables 2 and 5, it is obvious that the total of the product quantum yields observed in the presence of either NO or O_2 is less than 0.5 (Φ(propene) is not included in this sum). Thus, the majority of the primary products are probably radicals. This observation is corroborated in Tables 1 and 4, where many products are formed in pure butene through radical–radical processes. For example, processes [15*a*], [15*b*], and [17*b*] are simple reactions to explain the 3-methyl-1-butene, 2-pentene, and 1-butene formations, respectively. By looking at these products, one may have access to the quantum yield of the primary β(C—H) bond rupture: $\phi[\beta(C–H)]$. This quantum yield is given by the following relationship:

$$[II] \quad \phi[\beta(C—H)] = \phi(\text{process [7]}) + \phi(\text{process [8]})$$

ϕ(process [7]) is equal to the difference between the quantum yield of 1,3-butadiene measured in the presence of either NO or O_2, Φ_{NO,O_2}(1,3-butadiene), and the quantum yield of process [22]. As far as ϕ(process [8]) is concerned, it may be obtained from the sum of radical–radical reactions involving α-methallyl radicals:

$$[II'] \quad \phi[\beta(C—H)] = \Phi_{NO,O_2}(1,3\text{-}C_4H_6) - \phi(\text{process [22]}) + \phi(R + \alpha\text{-}C_4H_7) + 2\phi(\alpha\text{-}C_4H_7 + \alpha\text{-}C_4H_7)$$

Unfortunately, only the $\phi(CH_3 + \alpha\text{-}C_4H_7)$ values have been measured (Tables 1 and 4). Thus, the best estimate of $\phi(R + \alpha\text{-}C_4H_7)$ that can be made will happen when the methyl radical quantum yield is maximum, i.e. at zero pressure where the fragmentation of the vibrationally excited *s*-butyl radical is maximum. As far as the last term of II′ is concerned it may be calculated from the following ratio (26):

$$[III] \quad \frac{[\Phi(CH_3 + CH_3)]^2}{\Phi(CH_3 + \alpha\text{-}C_4H_7)\Phi(\alpha\text{-}C_4H_7 + \alpha\text{-}C_4H_7)} = 4.0$$

Thus, at 0.4–5.0 Torr, Φ(process [20]) are 0.073 and 0.067 in *cis*- and *trans*-2-butene, respectively.

$$[II'''] \quad \phi[\beta(C—H)] \cong \Phi_{NO,O_2}(1,3\text{-}C_4H_6) - \Phi(\text{process [22]}) + \phi(CH_3 + \alpha\text{-}C_4H_7) + 2\phi(\alpha\text{-}C_4H_7 + \alpha\text{-}C_4H_7) \quad \text{at } P \rightarrow 0$$

The results are displayed in Fig. 6. At zero pressure, the $\phi[\beta(C—H)]$ values may be estimated at 0.47 ± 0.04 and 0.39 ± 0.04 in *cis*- and *trans*-2-butene, respectively.

The combination reaction between 1-propenyl and methyl radicals yields the starting material or its isomer. Thus, it is difficult to evaluate the $\phi[\alpha(C—C)]$ values from the reaction processes of the 1-propenyl radicals. An easier way for this evaluation resides in the measurement of the quantum yields of the primary methyl radicals.

$$[IV] \quad \phi[\alpha(C—C)] = \Phi_{pr}(CH_3) = \Phi(CH_3) - \Phi_{O_2}(C_3H_6) - \Phi(C_2H_2)$$

The quantum yield of the methyl radical may be equated to the difference between the methane quantum yield measured in the presence of DI and the one measured in the presence of either O_2 or NO. Equation [IV] must be corrected for the formation of propene and acetylene, since both products are formed concurrently with secondary methyl radicals.

[4] $\Delta H_f^0(C_2H_5) = 118.5 \pm 1.7$ kJ mol^{-1} (24*a*) and $\Delta H^0(C_2H_3) = 301 \pm 8$ kJ mol^{-1} (24*b*).

TABLE 7. The 184.9 nm photofragmentation of *cis*- and *trans*-2-butene

Process $2\text{-}C_4H_8^{**} \rightarrow$	Φ^a *cis*	Φ^a *trans*
$CH_3 + CH_3\dot{C}H{=}\dot{C}H^*$	0.45 ± 0.03	$0.52_5 \pm 0.03$
$H + CH_3\dot{C}HCHCH_2^*$	0.47 ± 0.04	0.39 ± 0.04
$H_2 + CH_2{=}CHCH{=}CH_2$	0.067	0.035
$CH_3C{\equiv}CH + CH_4$	0.013	0.02
$C_2H_4 + C_2H_3 + H$	0.007	0.01
$C_2H_5 + C_2H_2 + H$	0.012	0.012
Total	1.019	0.992

[a]Quantum values are extrapolated to zero pressure.

$$[IV'] \quad \phi[\alpha(C{-}C)] = \Phi_{DI}(CH_4) - \Phi_{O_2,NO}(CH_4) - \Phi_{O_2}(C_3H_6) - \Phi_{O_2}(C_2H_2)$$

The so-calculated $\phi[\alpha(C{-}C)]$ values are $0.52_5 \pm 0.03$ and 0.45 ± 0.03 in *trans*- and *cis*-2-butene, respectively, on the 1–10 Torr pressure scale (Fig. 6). The 184.9 nm processes are summarized in Table 7. Owing to the relatively larger uncertainties arising from the methods used above, the quantum yields for fragmentation are unity. Both systems are similar except for a larger difference in the $\alpha(C{-}C)/\beta(C{-}H)$ ratio.

Taking into account the error limits indicated in Table 7, the $\alpha(C{-}C)/\beta(C{-}H)$ ratios measured in *cis*- and *trans*-2-butene are $0.95_7 \pm 0.13$ and $1.34_6 \pm 0.20$, respectively. These values must be compared with 0.57 and 0.95 obtained in propene and isobutene, respectively. A very interesting and intriguing effect appears to be attached to the number and location of the methyl substituents. This effect may be due to the electrophilic property of the methyl group. Unfortunately, it is difficult to link the increase in this ratio from propene to *trans*-2-butene to any simple molecular property of these molecules. In fact, it is likely that the $\alpha(C{-}C)/\beta(C{-}H)$ ratio is not dependent on one parameter only.

The above mechanism is consistent with the view that the internal conversion of electronic excitation energy to vibrational energy is preceding the bond cleavage processes. However, it cannot be precluded that bond cleavage is part of the conversion process itself. In that case, the geometry (symmetry, ...) of the molecule may play a role in the redistribution of energy.

The difference for this ratio may be discussed in terms of the spectroscopy of these compounds. Both Rydberg and valence states are populated at 184.9 nm. Do the two fragmentation pathways result from the same excited state or different ones? If each exit channel is linked to one electronic excited state, the $\alpha(C{-}C)/\beta(C{-}H)$ ratio can be explained in terms of differences in the absorption processes. It is apparent from Fig. 6 that the primary $\alpha(C{-}C)$ process is pressure independent on the 0–10 Torr pressure scale. On the other hand, the primary $\beta(C{-}H)$ quantum yield decreases on the same pressure scale. Given that the extinction coefficient of a Rydberg transition decreases with increasing pressure, while that of a valence transition is pressure independent (27), the above data suggest that the $\alpha(C{-}C)$ process is π,π^*-derived and the $\beta(C{-}H)$ process, $\pi,3s(R)$-derived. Since the $\alpha(C{-}C)/\beta(C{-}H)$ ratio is pressure dependent, then it indicates that both processes do not occur from a common excited state. This proposal is somewhat different from that given by Borrel *et al.* (2). The Rydberg state was proposed to break down to a variety of products unless they are collisionally deactivated. Conversely, isomerization is the only reaction path for the V state (2).

However, it must be recalled that the quantum yield of the primary $\beta(C{-}H)$ process is measured through eq. [II‴], that is strictly valid at zero pressure. In fact, products arising from $s\text{-}C_4H_9 + \alpha\text{-}C_4H_7$ interactions were not measured: the larger the pressure, the more important are these reactions. Thus, the decrease of the primary $\beta(C{-}H)$ bond rupture reported on Fig. 6 may be the result of the way this quantum yield is measured. It must be said that the pressure dependence of the $\beta(C{-}H)$ quantum yield is rather strong in comparison with the decrease in extinction coefficient of a Rydberg transition (28). Conversely, the ethylene (a product mainly originating from the decomposition of hot *s*-butyl radicals) is strongly pressure dependent on the 0–20 Torr pressure scale (Fig. 5). Thus, stabilization of hot *s*-butyl radical–radical is very efficient at moderate pressure and part of $\alpha\text{-}C_4H_7$ radicals disappear in radical–radical reactions and, as such, are not included in [II‴].

Acknowledgments

The authors would like to thank the Natural Sciences and Engineering Research Council of Canada (programme de Développement de la recherche) for the support given to this project and the salary to one of us (W.M.). We would also like to thank Dr. R. Back (NRCC, Ottawa) for the gift of one *trans*-2-butene sample. We are also indebted to an unknown referee who made very valuable comments.

If the internal energy of target molecules highly dispersed in a heat bath is monitored as a function of time, their one-photon laser excitation and subsequent bulk collisional relaxation yields information only about energy transfer in the bulk system (a macroscopic time-dependent property). This paper discusses three special cases when $\langle \Delta E \rangle$, the average energy transferred in a collision (a microscopic property) can be deduced from bulk relaxation data without knowledge of the collisional transition probability: (*i*) initial excitation is a δ function; (*ii*) relaxation of bulk average energy follows simple exponential law; or (*iii*) it is linear in time. The implications of exponential relaxation is that $\langle \Delta E \rangle$, which is the first moment of the collisional transition probability, is a linear function of internal energy. These conclusions are illustrated using available laser relaxation data on azulene, benzene, and hexafluorobenzene, and are compared with similar data on toluene and two cycloheptatrienes. Some inconsistencies are noted, the probable origin of which is discussed.

WENDELL FORST, GUO-YING XU et GRIGORIOS GIDIOTIS. Can. J. Chem. **65**, 1639 (1987).

Si l'on suit, en fonction du temps, l'énergie interne des molécules-cible excitées par l'absorption d'un photon laser et hautement dispersées dans un bain à température constante, leur relaxation subséquente par collisions ne fournit l'information que sur le transfert d'énergie-en-masse (une propriété macroscopique, fonction du temps). Dans ce travail l'on discute de trois cas spéciaux qui permettent d'obtenir $\langle \Delta E \rangle$, l'énergie moyenne transférée par collision (une propriété microscopique) sans connaître la forme de la probabilité de transition par collision : (*i*) la distribution initiale d'énergie est une fonction δ; (*ii*) la relaxation-en-masse suit une loi exponentielle simple, ou (*iii*) est linéaire dans le temps. L'implication de la relaxation exponentielle est que $\langle \Delta E \rangle$, soit le premier moment de la probabilité de transition par collision, est une fonction linéaire de l'énergie. Ces conclusions sont illustrées à l'aide des données disponibles dans la littérature au sujet de la relaxation de l'azulène, du benzène et de l'hexafluorobenzène excités au laser, et qu'on compare ensuite à des données semblables sur le toluène et deux cycloheptatriènes. On note un certain manque de consistence entre les données, dont on discute la source probable.

Introduction

In a gaseous system, intermolecular collisional energy transfer takes place in principle whenever the pressure is finite, which is the case of every process of practical interest; therefore the quantitative characterization of such energy transfer is an important element in the understanding and modelling of gas phase reaction processes. We shall focus here on the particular case of energy transfer in a bulk system: it is a thermal system, i.e. one in contact with a heat bath, in which some average system property is monitored; an obvious example is a thermal reaction. Historically, thermal reactions were the first to be used for extracting energy transfer information (1).

It is clear that bulk systems cannot provide any insight into state-to-state dynamics, but this is not too serious a handicap in the present context since the principal information necessary for modelling purposes is $\langle \Delta E \rangle$, the average energy transferred in a collision (defined below in eq. [3]), and for this purpose bulk systems can yield the necessary data. However, energy transfer in bulk systems is often accompanied by some other process (e.g. chemical reaction), and as a result extracting energy transfer data from bulk experiments is not as straightforward and unambiguous as one might wish (1), except in special circumstances. One such special circumstance (a somewhat idealized experimental version of which is described below) is the object of much current interest since it is experimentally realizable and allows a more direct access to $\langle \Delta E \rangle$.

In this version of a bulk experiment, the molecule of interest (henceforth referred to as the "target" molecule) is highly dispersed in an inert gas heat bath, large enough so that bath properties (temperature in particular) remain constant throughout. A laser pulse of short duration excites the target molecule, by one-photon absorption, to a high energy state (or states), preferably not high enough to open a reactive channel. The system is then left undisturbed and its time history is monitored by recording the average internal (i.e. vibrational) energy $\langle\langle y \rangle\rangle$ of the target molecules as a function of time.

Under these conditions the excitation energy deposited initially in the molecule is dissipated exclusively by binary collisions between target and heat bath molecules, so that such a system represents the case of "pure" bulk relaxation, uncomplicated by the simultaneous occurrence of any other process, e.g. chemical reaction. If the heat bath consists of a large excess of rare gas, then the process taking place in such a bulk system is pure V–T (vibration-to-translation) energy transfer.

Theory

It is important at the outset to make clear the distinction between a microscopic and macroscopic property. The internal energy y of a molecule, for instance, is an intrinsic molecular property at the microscopic level; similarly $\langle \Delta E \rangle$ (the information sought in the present context) represents the average outcome of single-collision events and thus is likewise a microscopic property. In a bulk system, however, what is accessible to measurement in the type of experiment described

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

above are not the *microscopic* molecular properties, but instead only average properties of the whole (bulk) system, i.e. bulk observables, which represent the *macroscopic* properties of the system. Such macroscopic properties are bulk averages (2) (defined below in eqs. [1] and [2]), and will be denoted here by double brackets $\langle\langle \ldots \rangle\rangle$ in order to distinguish them from per-collision averages denoted by single brackets $\langle \ldots \rangle$; this notation and nomenclature follows that of ref. 2. A lucid exposition of the general concepts developed here for the specific case of collisional energy transfer may be found in van Kampen (3).

Let $c(y,t)$ represent the time-dependent population density, i.e. the probability, per unit energy, that a molecule shall have internal energy y at time t. The assumption is that the molecule is sufficiently large and the energy sufficiently high so that there is a quasi-continuum of molecular energy levels. The macroscopic bulk observable which corresponds to a given (energy-dependent) microscopic property is defined as the average of the latter over $c(y,t)$. Thus, in particular, the observable or bulk-average energy is given by

$$[1] \quad \langle\langle y \rangle\rangle = \int y\, c(y,t)\, \mathrm{d}y$$

and the macroscopic or bulk-average energy transfer by

$$[2] \quad \langle\langle \Delta E \rangle\rangle = \int \langle \Delta E \rangle\, c(y,t)\, \mathrm{d}y$$

which represents the average energy transferred per collision in the bulk system.

The intrinsic or microscopic energy transfer $\langle \Delta E \rangle$ is defined by

$$[3] \quad \langle \Delta E \rangle = \int (x - y)\, q(x,y)\, \mathrm{d}x$$

where $q(x,y)$ is the collisional transition probability, i.e. the probability, per collision and per unit energy, that if a molecule had energy y before the collision, it shall have energy x after the collision. Equation [3] shows that $\langle \Delta E \rangle$ is in fact the first moment of the transition probability $q(x,y)$. Note that $\langle \Delta E \rangle$, which represents the total energy transferred in a collision, may be positive ("up-collision") or negative ("down-collision") depending on the pre-collision energy y.

It can be shown that if the collision frequency in the relaxing system is ω, then (3, 4)

$$[4] \quad \mathrm{d}\langle\langle y \rangle\rangle/\mathrm{d}t = \omega \langle\langle \Delta E \rangle\rangle$$

so that $\langle\langle \Delta E \rangle\rangle$ is obtainable directly from the time decay of $\langle\langle y \rangle\rangle$. In the case of the experimental laser system described in the Introduction, $\langle\langle \Delta E \rangle\rangle$ will be always negative because, overall, the target molecules are losing energy to the heat bath. Clearly $\langle\langle \Delta E \rangle\rangle$ depends not only on $q(x,y)$, i.e. on the intrinsic (microscopic) properties of the collision partners, but also on the particular experimental conditions: excitation level, pressure, etc. In addition, $\langle\langle \Delta E \rangle\rangle$ is a function of time (cf. eq. [2]).

The obvious difficulty here is that the quantity accessible to measurement (via the decay of $\langle\langle y \rangle\rangle$) is $\langle\langle \Delta E \rangle\rangle$, whereas the information desired is $\langle \Delta E \rangle$. This amounts to the classic problem of recovering a function from its average.

The standard way to deal with a relaxation problem of the kind described above is first to write down the master equation for a polyatomic molecule having a quasi-continuum of energy levels in the form (5)

$$[5] \quad \mathrm{d}\, c(x,t)/\mathrm{d}t = \omega \int q(x,y)\, c(y,t)\, \mathrm{d}y - \omega\, c(x,t)$$

Equation [5] is solved for $c(x,t)$, either analytically (4–6) or numerically (7), using several assumed models of the transition probability $q(x,y)$ (gaussian, stepladder, exponential, etc.). Whichever model leads to the best fit between the calculated (via eq. [1]) and experimental decay of $\langle\langle y \rangle\rangle$ is then used to obtain $\langle \Delta E \rangle$ from eq. [3]. Models of $q(x,y)$ usually contain adjustable parameters, so that several models can be made to fit a given relaxing system, with the result that $\langle \Delta E \rangle$ so obtained is model-dependent, and consequently ambiguous.

There are in principle three special cases which do not require the master equation be actually solved in order to determine $\langle \Delta E \rangle$. Thus no model for $q(x,y)$, parametrized or not, need be postulated, with the result that the $\langle \Delta E \rangle$ so obtained is model-independent. The three special cases are set out below and are the main subject of this work.

(*i*) One special case arises when the initial distribution is a δ function at, say, y_0: $c(y,0) = \delta(y - y_0)$. From the record of the time dependence of $\langle\langle y \rangle\rangle$ one can easily obtain $\mathrm{d}\langle\langle y \rangle\rangle/\mathrm{d}t$, which, when extrapolated back to $t = 0$, yields $\langle\langle \Delta E \rangle\rangle_0$, the initial value of $\langle\langle \Delta E \rangle\rangle$, since (cf. eq. [4]) $\lim_{t\to 0} \mathrm{d}\langle\langle y \rangle\rangle/\omega\, \mathrm{d}t = \langle\langle \Delta E \rangle\rangle_0$. From eq. [2], we then have directly $\langle\langle \Delta E \rangle\rangle_0 \equiv \langle \Delta E \rangle$; in other words, for an initial δ function distribution, $\langle\langle \Delta E \rangle\rangle_0$ becomes identical with the microscopic $\langle \Delta E \rangle$. Thus $\langle \Delta E \rangle$ can be obtained at y_0, but its energy dependence is unknown; to do that it would be necessary to run a number of experiments with different initial δ function excitation energies y_0.

(*ii*) The second way to deal with the relaxation problem is represented by the special case, much discussed in the literature (3, 8, 9), when $\langle\langle y \rangle\rangle$ decays via a simple exponential (Bethe–Teller law):

$$[6] \quad \langle\langle y \rangle\rangle_\infty - \langle\langle y \rangle\rangle = (\langle\langle y \rangle\rangle_\infty - \langle\langle y \rangle\rangle_0) \exp(-t/\tau)$$

where $\langle\langle y \rangle\rangle_0$ and $\langle\langle y \rangle\rangle_\infty$ are, respectively, the initial and final (= equilibrium) values of $\langle\langle y \rangle\rangle$ (at $t = 0$ and $t \to \infty$), and τ is the relaxation time. A well-known theorem due to Shuler, Weiss, and Andersen (9) states that when the system relaxes via a simple exponential, the first moment of the transition probability (i.e. $\langle \Delta E \rangle$) must be a linear function of energy (this is the so-called "linear sum rule"), a relation that is valid for all y:

$$[7] \quad \langle \Delta E \rangle = a + by$$

where a and b are constants. Taking the bulk average of both sides of eq. [7], we get

$$[8] \quad \langle\langle \Delta E \rangle\rangle = a + b\langle\langle y \rangle\rangle$$

which holds at all times, in particular at $t \to \infty$, which in a non-reactive system represents equilibrium with the heat bath. Under these conditions, $\langle\langle y \rangle\rangle \to \langle\langle y \rangle\rangle_\infty$ and $\langle\langle \Delta E \rangle\rangle \to 0$ since at equilibrium there is no net energy transfer in the bulk system. Thus $a = -b\langle\langle y \rangle\rangle_\infty$, and so

$$[9] \quad \langle\langle \Delta E \rangle\rangle = -b(\langle\langle y \rangle\rangle_\infty - \langle\langle y \rangle\rangle)$$

These considerations show clearly that this analysis is inapplicable in a reactive system. The (observable) relaxation time is commonly defined by

$$[10] \quad \tau = \frac{\langle\langle y \rangle\rangle_\infty - \langle\langle y \rangle\rangle}{\mathrm{d}\langle\langle y \rangle\rangle/\mathrm{d}t}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

which, in view of eq. [4], can be written equivalently as

$$[11] \quad \tau = \frac{\langle\langle y\rangle\rangle_\infty - \langle\langle y\rangle\rangle}{\omega\langle\langle \Delta E\rangle\rangle}$$

Combining eqs. [6] and [11] we get

$$[12] \quad \langle\langle \Delta E\rangle\rangle = \langle\langle \Delta E\rangle\rangle_0 \exp(-t/\tau)$$

where $\langle\langle \Delta E\rangle\rangle_0 = \langle\langle y\rangle\rangle_\infty - \langle\langle y\rangle\rangle_0$. From the comparison of [9] and [11] it follows that $-b = 1/\omega\tau$, so that eq. [7] becomes

$$[13] \quad \langle \Delta E\rangle = \frac{1}{\omega\tau}(\langle\langle y\rangle\rangle_\infty - y)$$

Thus the microscopic property $\langle \Delta E\rangle$ is given entirely in terms of the macroscopic observable $\langle\langle y\rangle\rangle$ and its time derivative which defines the relaxation time τ (via eq. [10]). Unlike in the preceding special case, the functional dependence of $\langle \Delta E\rangle$ on energy is now known for all energies. To achieve this, it was not necessary to solve the master equation, and therefore no assumption had to be made as to the nature of the model for the transition probability $q(x,y)$. Hence the result shown in eq. [13] is model-independent, but applies only if the decay of $\langle\langle y\rangle\rangle$ in a non-reactive system follows the simple exponential (eq. [6]).

It is of some interest to note that when $y = 0$, eq. [13] indicates a positive intercept, i.e. under these conditions $\langle \Delta E\rangle$ is not zero but is positive. This means that at low energies the energy dependence of $\langle \Delta E\rangle$ does not become much smaller than implied by eq. [13], as is sometimes suggested, but merely shows that in the vicinity of $y = 0$ only up-collisions occur. This is understandable since a molecule whose pre-collision energy is zero can only gain energy in a collision.

Inasmuch as $\langle\langle y\rangle\rangle_\infty$ can be easily calculated (e.g. from the Einstein function for a collection of harmonic oscillators), the only other parameter necessary to completely characterize $\langle \Delta E\rangle$ of eq. [13] (in addition to pressure which determines ω) is τ, which is readily obtainable from the experimentally observed time decay of $\langle\langle y\rangle\rangle$. Taking the logarithm of both sides of eq. [6] we see that a plot of $\ln(\langle\langle y\rangle\rangle - \langle\langle y\rangle\rangle_\infty)$ vs. time will yield a straight line of slope $-1/\tau$.

(*iii*) The third way to deal with the relaxation problem on hand concerns the special case when the decay of $\langle\langle y\rangle\rangle$ is *linear* over a time span that covers the dissipation of an *appreciable* fraction of initial excitation energy (clearly any decay will look linear if the time span corresponds to the dissipation of a small enough fraction of excitation energy). It can be shown (10) that this is an unmistakeable sign that the transition probability $q(x,y)$ is exponential. The consequence of this is that $\langle \Delta E\rangle$ is an energy-independent constant over the time span that corresponds to the linear portion of the $\langle\langle y\rangle\rangle$ decay. It follows from eq. [2] that consequently $\langle \Delta E\rangle \equiv \langle\langle \Delta E\rangle\rangle$ since $c(y,t)$ is normalized to unity.

Under these conditions there is therefore no distinction between the microscopic and macroscopic average energy transfers, and thus (cf. eq. [4]) the slope of the linear portion of the $\langle\langle y\rangle\rangle$ decay, divided by ω, gives $\langle \Delta E\rangle$ directly. However, as the system gets closer to equilibrium, $\langle \Delta E\rangle$ and $\langle\langle \Delta E\rangle\rangle$ do become distinct from one another, and $\langle\langle \Delta E\rangle\rangle$ eventually decays to zero, as of course it must when the system reaches equilibrium (cf. Fig. 3*b* in ref. 10).

Experimental results

The common feature of laser experiments that lend themselves to the analysis presented above is that the excitation of the target molecule (carefully selected for its "clean" photophysics) is achieved by one-photon absorption, first to an excited electronic state, which is then followed by fast internal conversion to produce the vibrationally excited target molecule in the ground electronic state. It is the relaxation of this vibrationally excited ground electronic state, immersed in a heat bath, that provides the signal which is a measure the internal energy as a function of time.

Two different methods were used to monitor the time-dependence of the internal energy of the excited molecule: infrared fluorescence from C—H stretch modes in the case of azulene, and uv absorbance measurements in all other cases. Details of the experiments can be found in the cited literature, and therefore only the most salient features will be mentioned here. The results shown below in the figures were recalculated from published data when necessary.

Probably the best-documented case of collisional relaxation is that of azulene studied by Barker and co-workers (1). Several thousand experiments were performed repetitively using signal-averaging in order to improve the signal/noise ratio, and the "calibration", i.e. the method for converting the measured signal (ir fluorescence in this particular case) into $\langle\langle y\rangle\rangle$ was carefully analysed (12). Arguments were presented to show that the ensemble of excited ground electronic state azulene molecules had a distribution of vibrational energies no wider than room temperature Boltzmann distribution, i.e. essentially a microcanonical (δ-function) distribution.

Two results of experiments performed with a nitrogen laser (excitation energy 337 nm = 29674 cm^{-1}) are shown in Fig. 1. In this and following figures a semi-logarithmic plot is used to provide a rapid visual check on exponential decay. The signal in Fig. 1 is seen to be quite free of noise over more than half the energy range, showing the relaxation to be clearly exponential, until increasing noise in the system makes interpretation uncertain. Similar experiments (not shown) were also performed at the lower excitation energy of 600 nm = 16667 cm^{-1}.

Time-resolved uv absorption measurements on excited benzene (B) were reported by Nakashima and Yoshihara (13), and on excited hexafluorobenzene (HFB) by Nakashima and Yoshihara (14), both using an ArF laser (excitation energy 193 nm = 51813 cm^{-1}). In this case the "calibration" was based on the modified Sulzer–Wieland model (15) of high-temperature spectra, with the assumption that the microcanonical distribution of excitation energy deposited in ground-state B or HFB produces absorption spectra that can be represented by a high-temperature Boltzmann (canonical) distribution involving all the vibrational modes, the average energy of which is equal to excitation energy. The time decay of the system is thus described by a series of Boltzmann distributions of progressively lower temperatures.

Figure 2 shows the relaxation of benzene in the presence of a number of bath gases, and generally shows exponential decay, except perhaps in the benzene–argon case (panel *a*) where there appears to be some drift. It is noteworthy that benzene self-relaxation shows good exponential decay all the way down to ~2000 cm^{-1}.

Similarly, Fig. 3 shows the relaxation of HFB, where there is some deviation from exponential behavior after about one-half of the excitation energy has decayed (using only the initial clearly linear parts of the plots would decrease the slopes by about 10%). Panel *a* of Fig. 3 also shows that in the case of HFB self-relaxation there is some small dependence on the observing frequency. All the data published in refs. 13 and 14 were based on the evaluation of oscilloscope traces of single experiments.

A summary of the experimental data on azulene, benzene, and HFB evaluated according to eq. [13] (linear energy dependence of $\langle \Delta E\rangle$) is shown in Table 1 where listed separately are the parameters $a = \langle\langle y\rangle\rangle_\infty/\omega\tau$, $b = -1/\omega\tau$ and $\omega\tau$. The dimensionless relaxation time $\omega\tau$ can be considered to represent roughly the number of collisions necessary to dissipate the excitation energy. For the purpose of comparing the various results at the same energy, the last column of Table 1 gives the absolute value of $\langle \Delta E\rangle$ calculated from eq. [7] for the arbitrarily chosen reference energy of $y = 30\,000$ cm^{-1}.

These results can be compared with those obtained by the Göttingen group (16–18) on the same or similar molecules at comparable excitation energies (KrF laser excitation at 248 nm = 40323 cm^{-1}).

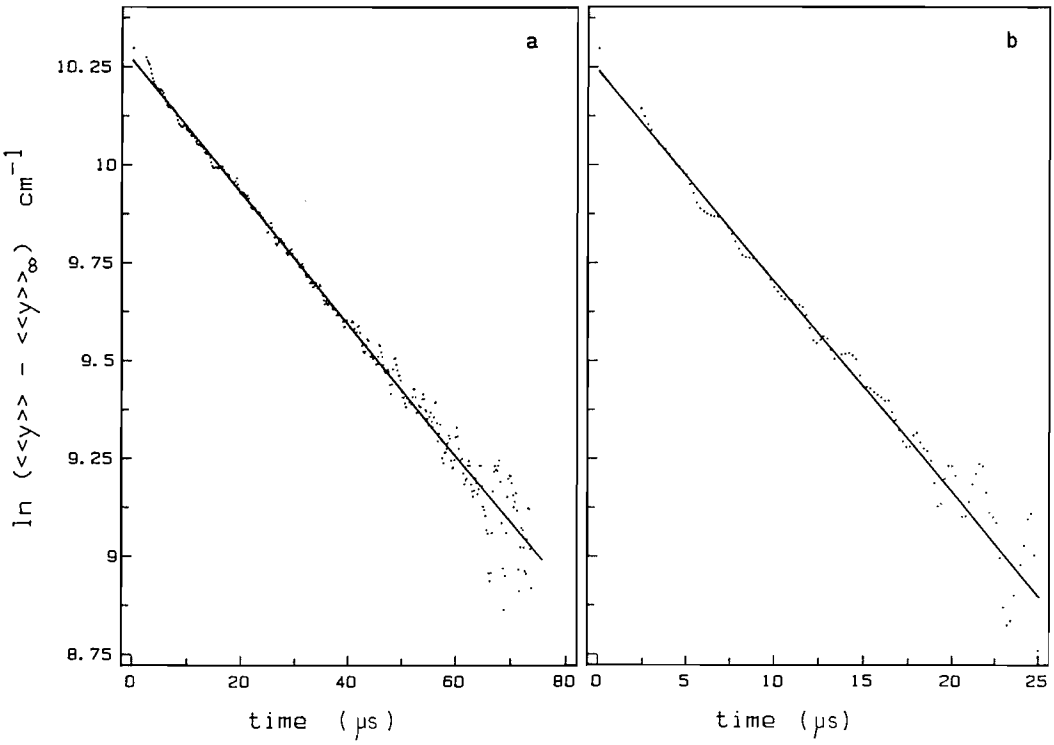

FIG. 1. Relaxation of azulene: (*a*) azulene self-relaxation, 8.9 mTorr (7306 laser shots); (*b*) azulene–argon mixture, 298 mTorr total pressure (9832 laser shots). Vertical scale is the same for both (*a*) and (*b*). Dots represent output from multichannel analyzer, converted into $\langle\langle y\rangle\rangle$; continuous line is the least-squares line calculated from smoothed experimental $\langle\langle y\rangle\rangle$ (data of refs. 11 and 12).

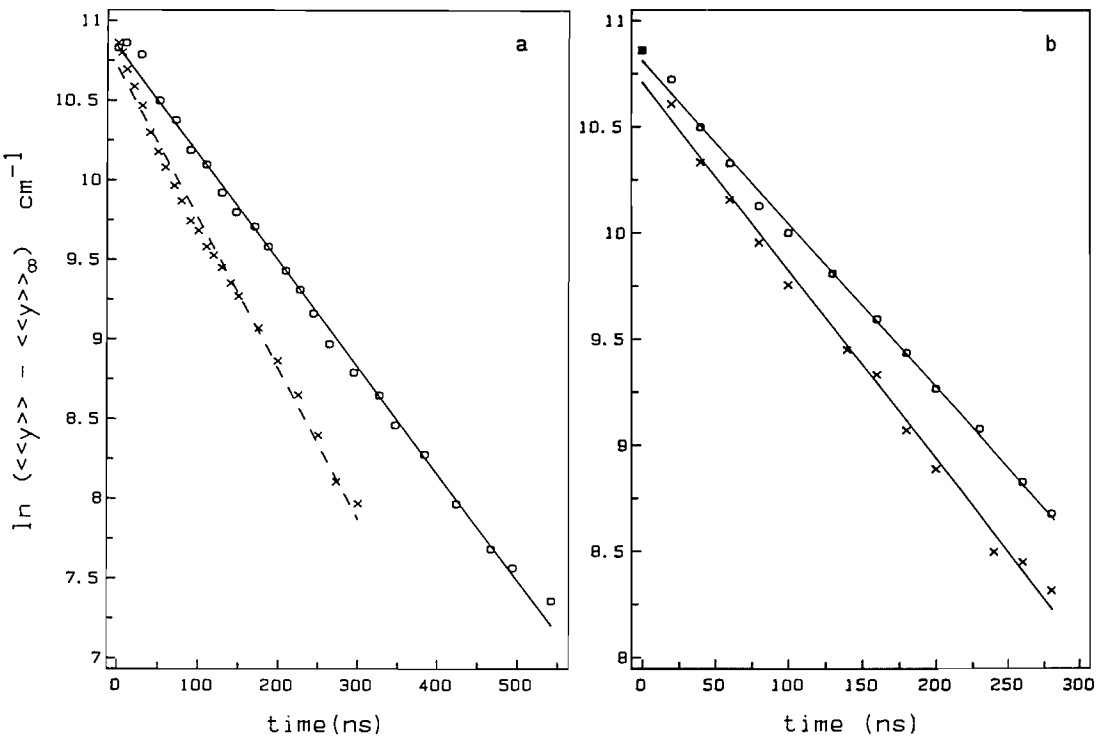

FIG. 2. Relaxation of benzene, observing frequency 220 nm: (*a*) ○: benzene self-relaxation, 8 Torr, ×: benzene–argon mixture, 802 Torr total pressure; (*b*) ○: benzene–N_2 mixture, 418 Torr total pressure; ×: benzene–isopentane mixture, 14 Torr total pressure. Straight lines calculated by least squares from experimental points (data of ref. 13).

They also used the calibration procedure based on the Sulzer–Wieland model and found, from the evaluation of single oscilloscope traces, that the decay of $\langle\langle y\rangle\rangle$ was linear in time, and therefore $\langle\Delta E\rangle$ was energy-independent (except, presumably, at very low energies; however, *vide supra*). This suggests an exponential transition probability. The molecules studied were azulene (16), toluene (17), ethylcycloheptatriene (18), and isopropyl cycloheptatriene (18).

A selection of these results is shown in Table 2, and it may be seen immediately that in spite of the disagreement about the energy dependence of $\langle\Delta E\rangle$, these results are roughly comparable (and for

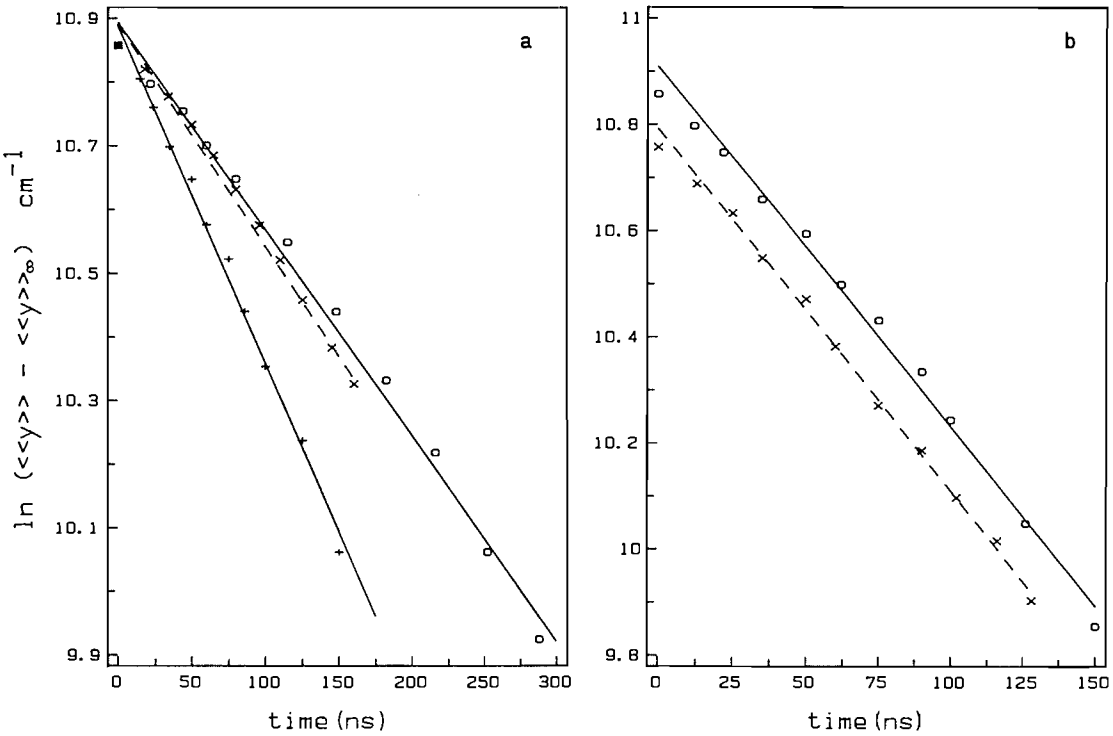

FIG. 3. Relaxation of hexafluorobenzene (HFB) observing frequency 300 nm except where noted: (*a*) ○: HFB self-relaxation, 6 Torr, ×: HFB self-relaxation, 6 Torr (350 nm observing frequency), +: HFB–argon mixture, 26 Torr total pressure; (*b*) ○: HFB–O_2 mixture, 27 Torr total pressure, ×: HFB–N_2 mixture, 28 Torr total pressure (displaced downward 0.1 $\log_e$ units for clarity). Straight lines calculated by least squares from experimental points (data of ref. 14).

TABLE 1. Parameters in equation $\langle \Delta E \rangle = a + by$ (eq. [7]) (all energies in cm^{-1})[a]

System	a	$-b$	$\omega\tau$	$\lvert\langle \Delta E \rangle\rvert$ at $y = 3 \times 10^4$
Az–Az	46.24	4.72×10^{-2}	21.2	1270
Az–Ar	8.22	8.40×10^{-3}	119	244
B–B	14.29	3.91×10^{-2}	25.6	1159
B–Ar	0.324	8.87×10^{-4}	1127	26
B–N_2	0.429	1.17×10^{-3}	855	35
B–ip*	10.13	2.77×10^{-2}	36.1	820
HFB–HFB	49.0	3.23×10^{-2}	30.9	920
HFB–Ar	5.57	3.68×10^{-3}	272	105
HFB–N_2	7.08	4.67×10^{-3}	214	133
HFB–O_2	6.70	4.43×10^{-3}	226	126

[a] $\omega\tau = -1/b$; Az = azulene, B = benzene, HFB = hexafluorobenzene, ip* = isopentane.

azulene–argon almost identical) to those shown in Table 1: larger colliders (this includes self-relaxation) yield for $\langle \Delta E \rangle$ values of the order of 1000 cm^{-1}, and diatomic or monoatomic colliders yield $\langle \Delta E \rangle$ roughly in the 200–300 cm^{-1} range. This comparison also reinforces the impression that the results in Table 1 for benzene–Ar and benzene–N_2 show anomalously low values of $\langle \Delta E \rangle$.

Discussion

In a very general way, and with the exceptions noted below, the results shown in Table 1 are roughly mutually consistent, in that the $\langle \Delta E \rangle$ values for self-relaxation are all in the 1000 cm^{-1} range, whereas relaxations involving argon and the diatomics lead to $\langle \Delta E \rangle$ in the range 100 to 200 cm^{-1}. This is also reflected in the dimensionless relaxation time $\omega\tau$ (third column in Table 1), inasmuch as $\omega\tau\langle \Delta E \rangle \sim y$. It is interesting to note in this connection that ultrasonic measurements yield (19) $\omega\tau \sim 50$ for benzene self-relaxation, which is within a factor of 2 of the value given in Table 1.

TABLE 2. Selection of Göttingen (16–18) results[a]

System	$\lvert\langle \Delta E \rangle\rvert$, cm^{-1}	System	$\lvert\langle \Delta E \rangle\rvert$, cm^{-1}
Az–Ar	210	CHT–Ar	180
		CHT–N_2	250
T–T	770	CHT–O_2	230
T–Ar	130	CHT–np	800
T–N_2	130		
T–np	740	iCHT–Ar	240
		iCHT–np	940

[a] Az = azulene, T = toluene, CHT = ethylcycloheptatriene, iCHT = isopropyl cycloheptatriene, np = *n*-pentane.

The exceptions seem to be the results involving benzene–Ar and benzene–N_2 where $\langle \Delta E \rangle$ appears to be too small by an order of magnitude. There is no obvious explanation for this discrepancy: although there seems to be some drift from exponential decay in these cases (Fig. 2), it is no worse (argon perhaps excepted) than in the case of HFB.

Given that — with the exceptions noted above — the numerical results in Table 1 and 2 are approximately comparable, the main disagreement between the results in Tables 1 and 2 is really only about the *form* of the energy dependence of $\langle \Delta E \rangle$. The question whether the decay of $\langle\langle y \rangle\rangle$ is linear, or exponential, or of some other form — which, as we have seen, determines ultimately the energy dependence of $\langle \Delta E \rangle$ — hinges crucially on the *shape* of the decay curve, which must therefore be well characterized. One of the difficulties is that we are dealing here with what are inherently noisy systems, especially if the data are obtained from a single oscilloscope trace at a single excitation

energy (as is the case of the work reported in refs. 13, 14, 16–18), so that judging the shape of the decay curve of $\langle\langle y\rangle\rangle$ is difficult at best. (Note, however, that it is shown in ref. 13 that assumption of constant $\langle\Delta E\rangle$ leads to decay curves that despite the noise are in clear disagreement with experiment.)[1]

In addition, toluene and the cycloheptatrienes are reactive systems where collisional relaxation occurs in competition with unimolecular reaction (e.g. toluene fragments into benzyl + H) which was assumed to be unimportant at the excitation energies used, but which nevertheless introduces an element of uncertainty into the interpretation of the experiments.[2] In this respect the azulene work is clearly superior, both on account of the signal averaging used and the absence of a reactive channel, and also because the energy dependence of $\langle\Delta E\rangle$ as shown in Table 1 could be approximately confirmed directly in the separate series of experiments using 600 nm excitation energy (11) (an example of special case (*i*)).

A more fundamental difficulty resides in the "calibration", i.e. in the fact that the signal actually measured is not $\langle\langle y\rangle\rangle$ but uv absorbance (or ir fluorescence intensity in the azulene work) which must then be converted into $\langle\langle y\rangle\rangle$. The shape of the calibration curve, i.e. the $\langle\langle y\rangle\rangle$ dependence of the signal, clearly has a major influence on the shape of the time decay of $\langle\langle y\rangle\rangle$, and thus on the energy dependence of $\langle\Delta E\rangle$. None of the calibration methods used so far are entirely free of objections. In principle, the question of the energy dependence of $\langle\Delta E\rangle$ could be settled more or less without calibration problems by experiments at a number of different excitation energies.[2]

Finally, a word about exponential decay which, as we have seen, is the macroscopic consequence of the linear dependence of $\langle\Delta E\rangle$ on y. It implies such severe restrictions (21) on the nature of the microscopic transition probability $q(x,y)$ as to make *strictly* exponential decay the exception rather than the rule, and therefore rather suspect. However, it can be shown (22) that *approximately* exponential decay (and this is all that can be ascertained in noisy systems) is very much less restrictive (23), and results in a $\langle\Delta E\rangle$ *approximately* linear in y. The corresponding dimensionless relaxation time $\omega\tau$ is then related to an *average* eigenvalue that characterizes the initial decay of the nonequilibrium ensemble.

[1]These experiments will be repeated using signal-averaging. (N. Nakashima, private communication).

[2]In a very recent series of experiments, Chung and Carr (20) have re-examined the collisional deactivation of ethylcycloheptatriene, this time excited to four different excitation energies. Master equation calculations using the stepladder model for collisional deactivation and RRKM theory for the fragmentation rate constant show that, within experimental error, $\langle\Delta E\rangle$ is an increasing *linear* function of energy in the range 35 000 to 43 000 cm^{-1}. Since this is a reactive system, the interpretation of $\langle\Delta E\rangle$ in terms of the constants that appear in eq. [13] does not apply here. It is also not clear what distortion (if any) has been introduced into the energy dependence of $\langle\Delta E\rangle$ by use of the stepladder model. This study is nevertheless significant in that it avoids the calibration difficulties associated with the other cited work.

VANDANA, OLE HINDSGAUL, and JACQUES U. BAENZIGER. Can. J. Chem. **65**, 1645 (1987).

The trisaccharide βDGalNac(1→4)βDGlcNAc(1→2)αDMan (**2**) and its 4″-*O*-sulfate ester (**3**) have been chemically synthesized as their 8-methoxycarbonyloctyl glycosides. Structures **2** and **3** contain oligosaccharide sequences unique to the asparagine-linked carbohydrate chains of pituitary glycoprotein hormones. The characteristic chemical shift for H-4 of the βDGalNAc residue in the sulfate ester **3** (4.692 ppm) is identical to that in the ^{1}H nuclear magnetic resonance spectrum of glycopeptides isolated from bovine lutropin (luteinizing hormone), thus establishing the position of sulfation in the natural structures.

VANDANA, OLE HINDSGAUL et JACQUES U. BAENZIGER. Can. J. Chem. **65**, 1645 (1987).

On a synthétisé chimiquement le trisaccharide βDGalNAc(1→4)βdGlcNAc(1→2)αDMan (**2**) et son ester *O*-sulfate-4″ (**3**), sous la forme de glycosides de méthoxycarbonyl-8 octyle. Les structures **2** et **3** contiennent la séquence oligosaccharide qui est unique aux chaînes d'hydrates de carbones des hormones glycoprotéines pituitaires qui sont liées à l'asparagine. Le déplacement chimique caractéristique pour le H-4 du résidu βDGalNAc, du sulfate de l'ester **3** (4,692 ppm), est identique à celui observé dans le spectre de résonance magnétique nucléaire du ^{1}H des glycopeptides isolés de la lutropine bovine (hormone de lutéinisation); ces résultats établissent donc la position de la sulfatation dans les structures naturelles.

[Traduit par la revue]

Introduction

Green *et al.* (1, 2) have recently reported the structural elucidation of the asparagine (Asn)-linked carbohydrate chains of the pituitary glycoprotein hormone lutropin (luteinizing hormone). The carbohydrates were found to contain varying amounts of DGalNAc and sulfate, which occurred in both complex and hybrid oligosaccharide structures. The major ionic oligosaccharide isolated was the disulfated biantennary structure **1**, which accounted for 31% of the total carbohydrate. This structure contains the unusual sequence $SO_3 \rightarrow$ βDGalNAc(1→4)βDGlcNAc(1→2)αDMan---, which appears unique to pituitary glycoprotein hormones. The position of the sulfate ester could not be established but was restricted to either the 3 or 4 position of the βDGalNAc residues in both **1** and related hybrid structures. These unusual oligosaccharides are found on lutropin and in small amounts of follitropin but not on other glycoproteins synthesized by the pituitary gonadotroph (3).

To aid in assessing the functional significance of this unique hormonal glycosylation we have chemically synthesized the lutropin trisaccharide terminus βDGalNAc(1→4)βDGlcNAc-(1→2)αDManOR (**2**) and its 4″-*O*-sulfate ester (**3**), as their 8-methoxycarbonyloctyl glycosides (R = $(CH_2)_8COOCH_3$) (4). Compound **2** should be useful as an acceptor in assaying the pituitary sulfotransferase activity, which we expect will catalyze its conversion to **3** in the presence of adenosine 3′-phosphate 5′-phosphosulfate (3). Compound **3**, as its synthetic glycoconjugates, will be used in the production and isolation (5) of antibodies directed to the "completed" hormonal structures.

Results and discussion

The target trisaccharides **2** and **3** were prepared from the key intermediate **16**, which was protected in a manner that allowed the selective liberation of the 4″-OH group for sulfation prior to deblocking. Two different routes were examined for the preparation of **16**. In the first approach, **16** was prepared by addition (using **11**) of the terminal DGalNAc residue to the preformed disaccharide derivative **15**. Since at the time this work began the position of the sulfate ester on the terminal DGalNAc was not known, this route offered the advantage of allowing the terminal addition of a DGalNAc derivative different from **11**, which could then later be sulfated at the 3- instead of the 4-position. The second route examined involved the addition of the preformed βDGalNAc(1→4)DGlcNAc disaccharide derivative **22** to the mannose residue **13**. While this route would be less efficient, it could be easily extended to the construction of larger oligosaccharides terminating in the required βDGalNAc(1→4)βDGlcNAc--- sequence should the need for such structures arise.

Reductive opening of the benzylidene ring in the readily accessible DGlcNAc derivative **4** (6), using $NaCNBH_3$/HCl (7), gave the 3,6-di-*O*-benzyl derivative **5** (8) (89%). Glycoside **5** was acetylated to provide **6** whose allyl group was removed by sequential isomerization using tris(triphenylphosphine)rho-

dium(I) chloride (9) and mercuric ion catalyzed hydrolysis to provide an anomeric mixture of reducing sugars **7** (86%). Reaction of **7** with oxalyl chloride (10), in the presence of dimethylformamide, then gave the glycosyl chlorides **8** (8).

Condensation of **8** and **13**, prepared by de-*O*-acetylation of previously reported **12** (11), in the presence of silver trifluoromethanesulfate and *sym*-collidine, gave the expected (12) β-linked disaccharide **14** in 69% yield. The β configuration of the new glycosidic linkage in **14** was evident from the observation of the signal for the H-1′ (5.286 ppm, $J_{1',2'}$ = 8.0 Hz) in its ^{1}H nmr spectrum. De-*O*-acetylation of **14**, with sodium methoxide in methanol, then gave the alcohol **15**.

The glycosyl chloride **11**, required for the homologation of **15** to **16**, was conveniently prepared from the DGlcNAc derivative **5**. Reaction of **5** with trifluoromethanesulfonic anhydride (13), in dichloromethane–pyridine, gave the 4-*O*-trifluoromethanesulfonate, which was not characterized but converted directly to the DGalNAc derivative **9** (83%) by reaction of tetraethylammonium acetate in dimethylformamide. Removal of the allyl group in **9** gave the reducing sugars **10**, which were converted, as before, to the glycosyl chlorides **11**.

Condensation of **11** and **15** gave the β-linked key intermediate **16** (64%) whose structure was supported by its ^{1}H nmr spectrum, which showed the presence of two signals for anomeric protons at 5.337 and 5.104 ppm with coupling constants of 8.5 and 8.0 Hz, respectively. Reaction of **16** with hydrazine acetate in refluxing methanol (14) gave the di-*N*-acetyl derivative **17** in acceptable (69%) yield. Attempted

conversion of **16** to **17** using hydrazine hydrate in refluxing methanol (15) gave only low (15–40%) yields that were not reproducible. The major side products in these latter reactions appeared to be derived from attack of hydrazine on the methyl ester, based on the absence of the methoxy signal in the ^{1}H nmr spectra of the crude products. De-*O*-acetylation of **17** gave the 4″-OH compound **18**.

Sulfation of **18** proceeded smoothly using sulfur trioxide – pyridine (16) complex in dimethylformamide at room temperature to yield **19** (93%) as its sodium salt after ion exchange. Removal of the remaining benzyl ether protecting groups in **18** and **19** using hydrogenolysis over palladium on charcoal gave the target trisaccharides **2** (82%) and **3** (84%).

The alternate route to **16** required the preparation of the disaccharidic glycosyl chloride **22** and its condensation with **13**. Glycosylation of **5** with **11** gave the β(1→4)-linked disaccharide **20** (66%) (H-1′, 5.329 ppm, $J_{1',2'}$ = 8.2 Hz), which was easily elaborated into **22** by allyl group removal followed by conversion of the reducing sugar **21** (85%) to the glycosyl chloride **22** in conventional fashion. Condensation of **13** with **22** (1.4 equiv.) then gave the β-linked trisaccharide **16** in 47% yield. It is expected that this yield could be substantially improved by use of a larger excess of **22** in the glycosylation since hydrolysis and elimination of HCl to form the glycal are known (12) to be major side reactions of phthalimido-halo sugars such as **22**. Such conditions were, however, not explored in this work since sufficient **16** had already been generated by the previous stepwise route.

Comparison of the ^{1}H nmr spectra of **2** and **3** showed that sulfation of OH-4″ of **2** produced a large downfield shift in the signal for H-4″ in **3**. This signal is a characteristic doublet of doublets ($J_{3,4} \approx 3.2$ Hz, $J_{4,5} < 1$ Hz) in simple βDGalNAc glycosides (17) and is found near 3.9 ppm in such structures, as well as in **2**, where it is obscured by other ring protons. In the sulfated structure **3**, however, a doublet for H-4″ (4.692 ppm, $J_{3'',4''} = 2.3 \pm 0.2$ Hz) was clearly visible in the "anomeric region" of the spectrum, which coupled to H-3″ at 3.91 ppm. The observed decrease in $J_{3'',4''}$ is expected (18) as a result of the antiperiplanar orientation of the electronegative sulfate group to

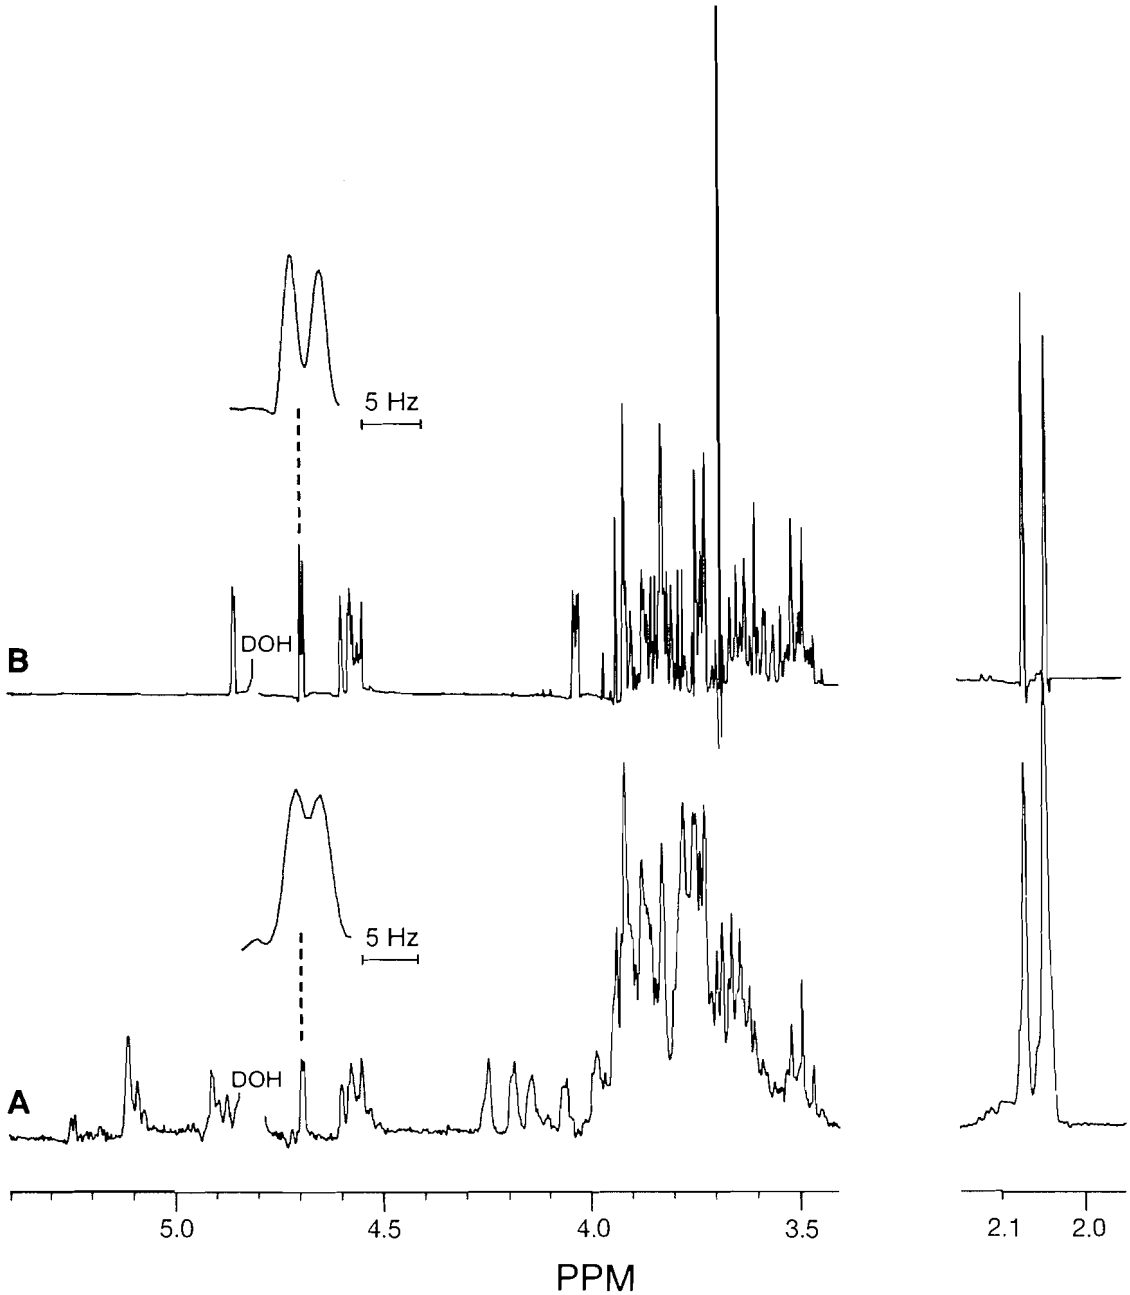

FIG. 1. Comparison of the resolution-enhanced 360-MHz ^{1}H nmr spectra of a glycopeptide mixture isolated from bovine lutropin (2) (A) and the synthetic 4″-O-sulfated trisaccharide **3** (B). The inset expansions show the signals assigned to H-4 of the terminal sulfated βDGalNAc residues. Spectra were recorded in D_2O at 296 K, acetone internal standard (δ 2.225 ppm).

H-3″. $J_{4'',5''}$ could not be resolved and was therefore significantly less than 1 Hz.

The characteristic shift of H-4″ in synthetic **3** could be used to unequivocally establish the position of sulfation of the βDGalNAc residues in the naturally occurring structures. In Fig. 1 the ^{1}H nmr spectrum of a mixture of monosulfated hybrid and complex lutropin glycopeptides (2, 3) is compared with a spectrum of **3** recorded under identical conditions. The glycopeptides show the expected anomeric signals for additional αDMan and βDGlcNAc residues not present in **3** but the key feature is the appearance of the characteristic βDGalNAc H-4 doublet at δ 4.692 ppm ($J_{3,4} \approx 2.2$ Hz) in both spectra. This signal collapsed to a singlet on irradiation at 3.91 ppm in both samples. Signals corresponding to the *N*-acetyl methyl groups of **3**, at 2.071 and 2.044 ppm, are also present in the glycopeptide spectrum.

Comparison of the spectra shown in Fig. 1 leaves no doubt that the βDGalNAc residues in the major lutropin glycopeptides are sulfated at the 4-position. The possibility that a minor fraction of these structures bear 3-*O*-sulfated βDGalNAc residues cannot be excluded on the basis of this evidence. We have, however, recently synthesized the 3″-sulfate ester of **2**,[2] namely 8-methoxycarbonyloctyl 2-*O*-[2-acetamido-4-*O*-(2-acetamido-2-deoxy-3-*O*-sulfo-β-D-galactopyranosyl)-2-deoxy-β-D-glucopyranosyl]-α-D-mannopyranoside sodium salt (**23**). The ^{1}H nmr spectrum of **23** displays characteristic signals for

H-3″ (dd, 4.437 ppm, $J_{2'',3''}$ = 11.0 and $J_{2'',4''}$ = 3.0 Hz), H-4″ (d, 4.254 ppm, $J_{4'',5''} < 1$ Hz), and H-1″ (d, 4.675 ppm, $J_{1'',2''}$ = 8.8 Hz). The absence of a signal for H-3 of an αDGalNAc residue near 4.4 ppm in Fig. 1, A, strongly suggests that Asn-linked oligosaccharides are exclusively 4-*O*-sulfated on the terminal βDGalNAc residues.

Experimental

All solvents and reagents used were reagent grade. All solid reactants for glycosylation were dried overnight over phosphorus pentoxide in a high vacuum prior to use. Solution transfers where anhydrous conditions were required were done under nitrogen using standard syringe techniques. Unless otherwise stated, all reactions were performed at ambient temperatures. Molecular sieves were purchased from BDH Chemicals.

Thin-layer chromatograms (tlc) were performed on precoated silica gel 60-F254 plates (E. Merck, Darmstadt) and visualized by quenching of fluorescence and (or) by charring after spraying with 5% sulfuric acid in ethanol. Unless otherwise stated, chromatography was performed on silica gel 60 (40-63 μm, E. Merck No. 9385). Organic solutions were dried over sodium sulfate prior to solvent removal on a rotary evaporator under the vacuum of a water aspirator with bath temperatures of 40°C or lower. For gel filtration, Bio-Gel P-2 (200–400 mesh) (Bio-Rad Laboratories, Richmond, CA) was used.

Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded at either 300 MHz (Bruker AM-300) or 360 MHz (Bruker WM-360) with either tetramethylsilane (δ = 0 in $CDCl_3$ and CD_3OD) or acetone (δ = 2.225 in D_2O) as internal standard at ambient temperature. Carbon-13 nuclear magnetic resonance (^{13}C nmr) spectra were recorded at either 75.5 MHz (Bruker AM-300) or 90.56 MHz (Bruker WM-360) with either internal tetramethylsilane (δ = 0 in $CDCl_3$ or CD_3OD) or external 1% 1,4-dioxane (δ = 67.4 in D_2O) as reference standard. Only partial nmr data are reported. Other spectra features were in accord with the proposed structures. The ^{1}H nmr coupling constants are reported as though they were first order. Assignments of ^{13}C resonances are tentative. Optical rotations were determined on a Perkin–Elmer 241 polarimeter in a 1-dm cell at ambient temperatures (23 ± 1°C).

*Allyl 3,6-di-*O*-benzyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (**5**)*

A mixture of allyl 3-*O*-benzyl-4,6-*O*-benzylidene-2-deoxy-2-phthalimido-β-D-glucopyranoside (**4**) (6.50 g, 12.3 mmol), sodium cyanoborohydride (4.42 g, 70.3 mmol), and a crystal of methyl orange in tetrahydrofuran (80 mL) was stirred at 0°C under nitrogen atmosphere. To this clear solution was added dropwise over 0.5 h a solution of diethyl ether saturated with hydrogen chloride (10 mL) until the red color of the indicator persisted. The reaction mixture was diluted with dichloromethane (100 mL), solids were removed by filtration, and the filtrate was washed with saturated $NaHCO_3$ followed by water. Solvent removal left a residue, which was dissolved in a mixture of methanol–dichloromethane (1:1) and passed through a deionized mixed bed ion-exchange resin (Amberlite MB-1, 20 mL). The resin was washed with methanol–CH_2Cl_2 (1:1) and the solvent was evaporated to provide a syrup, which was purified by chromatography using ethyl acetate – toluene (1:6) as eluent. The title compound, **5**, was obtained as a clear syrup (5.80 g, 89%); $[\alpha]_D$ +31.4° (*c* 1.0, chloroform); R_f 0.36 in ethyl acetate – toluene, 1:3; ^{1}H nmr ($CDCl_3$) δ: 5.666 (m, 1H, CH_2=C*H*CH_2), 5.190 (d, 1H, $J_{1,2}$ = 8.0 Hz, H-1), 3.123 (d, 1H, $J_{4,OH}$ = 3.0 Hz, D_2O exchangeable, OH); ^{13}C nmr ($CDCl_3$) δ: 117.26 (*C*H_2=CHCH_2), 97.31 (C-1), 69.69 (C-6), 55.30 (C-2). *Anal.* calcd. for $C_{31}H_{31}NO_7$: C 70.30, H 5.90, N 2.64; found: C 70.51, H 5.84, N 2.56.

*Allyl 4-*O*-acetyl-3,6-di-*O*-benzyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (**6**)*

Acetic anhydride (5 mL) was added to a solution of **5** (1.25 g, 2.36 mmol) in dry pyridine (10 mL) and the solution was kept for 2 h. Excess acetic anhydride was decomposed by dropwise addition of ethanol (2 mL) to the ice-cold reaction mixture and the solvent was evaporated. The residue was dissolved in dichloromethane (20 mL), washed with water, and the aqueous layer was extracted with dichloromethane. The combined dichloromethane extracts were washed with 5% HCl, and with saturated $NaHCO_3$ followed by water. Solvent removal left a white solid (1.30 g, 96%); $[\alpha]_D$ +65.4° (*c* 0.37, chloroform); R_f 0.39 (ethyl acetate – hexane, 2:3); ^{1}H nmr ($CDCl_3$) δ: 5.678 (m, 1H, CH_2=C*H*CH_2), 5.192 (d, $J_{1,2}$ = 8.5 Hz, H-1), 5.135 (dd, $J_{3,4}$ = 9.0 Hz, $J_{4,5}$ = 10.0 Hz, H-4), 1.940 (s, 3H, $COCH_3$); ^{13}C nmr ($CDCl_3$) δ: 169.64 (*C*OCH_3), 117.46 (*C*H_2=CHCH_2), 97.27 (C-1), 55.45 (C-2), 20.90 (CO*C*H_3). *Anal.* calcd. for $C_{33}H_{33}NO_8$: C 69.34, H 5.82, N 2.45; found: C 69.04, H 5.82, N 2.55.

*4-*O*-Acetyl-3,6-di-*O*-benzyl-2-deoxy-2-phthalimido-α,β-D-glucopyranose (**7**)*

A solution of **6** (1.30 g, 2.27 mmol), tris(triphenylphosphine)rhodium(I) chloride (295 mg, 0.32 mmol), and 1,8-diazabicyclo[2.2.2]-octane (107.3 mg, 0.96 mmol) in ethanol–benzene–water (7:3:1; 80 mL) was heated at reflux for 24 h. Solvent was removed and the residue dissolved in acetone (50 mL) containing mercuric oxide (10 mg). To this solution was added a solution of mercuric chloride (3.09 g) in acetone–water (9:1, 50 mL) and the mixture was stirred for 2 h. Following solvent evaporation the residue was dissolved in dichloromethane (100 mL) and washed with 30% KBr followed by water. Evaporation left a syrup, which was purified by chromatography using ethyl acetate – hexane (2:3) as eluent. The title compound was obtained as a white solid (1.04 mg, 86%); R_f 0.36–0.40 (ethyl acetate – hexane, 1:1); ^{1}H nmr ($CDCl_3$) δ: 5.36 (1H, H-1β ($J_{1,2}$ = 8.5 Hz) and H-1α), 3.489 (d, ≈0.15H, D_2O exchangeable, $J_{1,OH}$ = 5.5 Hz, OHα), 3.179 (d, ≈0.85H, D_2O exchangeable, J = 8.0 Hz, OHβ), 1.939 (s, ≈2.5H, $COCH_3$β), 1.915 (s, ≈0.5H, $COCH_3$α). *Anal.* calcd. for $C_{30}H_{29}NO_8$: C 67.78, H 5.50, N 2.64; found: C 67.78, H 5.76, N 2.47.

*4-*O*-Acetyl-3,6-di-*O*-benzyl-2-deoxy-2-phthalimido-α,β-D-glucopyranosyl chloride (**8**)*

A solution of oxalyl chloride (394 μL, 4.52 mmol) in dichloromethane (1 mL) was added dropwise to a stirring solution of **7** (800 mg, 1.51 mmol) and *N*,*N*-dimethylformamide; (35 μL, 0.45 mmol) in dichloromethane (2 mL). After stirring for 2 h the mixture was diluted with dichloromethane (10 mL) and poured into ice water. The organic layer was washed with cold water (3 × 25 mL), dried (Na_2SO_4), and concentrated to a pale yellow foam that showed the presence of two compounds by tlc. The major anomer (**8**β) had R_f 0.45 and the minor anomer (**8**α) had R_f 0.55 in ethyl acetate – hexane (7:10); ^{1}H nmr ($CDCl_3$) δ: 6.224 (d, ≈0.3H, $J_{1,2}$ = 3.5 Hz, H-1α), 5.981 (m, ≈0.7H, $J_{1,2}$ = 9.0 Hz, H-1β), 1.942 (s, ≈2H, $COCH_3$β), 1.898 (s, ≈1H, $COCH_3$α).

*Allyl 4-*O*-acetyl-3,6-di-*O*-benzyl-2-deoxy-2-phthalimido-β-D-galactopyranoside (**9**)*

Compound **5** (1.27 g; 2.40 mmol) was dissolved in dry dichloromethane (20 mL), dry pyridine (1 mL) was added, and the mixture was cooled to −5°C. To this stirring mixture was added dropwise a solution of trifluoromethanesulfonic anhydride (0.97 mL; 5.76 mmol) in dry dichloromethane (2 mL) and the reaction mixture was stirred for 0.5 h. After dilution with dichloromethane (20 mL) and washing with ice-cold 5% HCl and ice water, solvent was evaporated at 0°C to leave a foam that showed a single spot on tlc examination (R_f 0.31 in ethyl acetate – hexane, 2:5), presumably the trifluoromethanesulfonyl ester of **5**. To this residue was added a solution of tetraethylammonium acetate (2.27 g, 11.98 mmol) in dry dimethylformamide (22 mL) and the resulting mixture was stirred for 4 h. Solvent was evaporated and the residue was dissolved in chloroform and washed with cold water (3 × 20 mL). Solvent removal left a syrup, which was purified by chromatography using ethyl acetate – hexane (2:5) as eluent. The title compound was obtained as a foam (1.14 g, 83%); $[\alpha]_D$ +54.9° (*c* 0.89, chloroform); R_f 0.34 in ethyl acetate – hexane 1:2; ^{1}H nmr ($CDCl_3$) δ: 5.668 (m, 2H, CH_2=C*H*CH_2) and H-4 (dd, $J_{3,4}$ = 3.2 Hz, $J_{4,5}$ = 1.0 Hz)), 5.182 (d, 1H, $J_{1,2}$ = 8.5 Hz, H-1), 2.138 (s, 3H, $COCH_3$);

^{13}C nmr ($CDCl_3$) δ: 170.44 ($COCH_3$), 117.45 (CH_2=$CHCH_2$), 97.56 (C-1), 52.92 (C-2), 20.92 ($COCH_3$). *Anal.* calcd. for $C_{33}H_{33}NO_8$: C 69.34, H 5.82, N 2.45; found: C 69.16, H 5.81, N 2.46.

*4-O-Acetyl-3,6-di-O-benzyl-2-deoxy-2-phthalimido-α,β-D-galactopyranose (**10**)*

The allyl group in **9** (870 mg, 1.52 mmol) was removed exactly as described for the preparation of **7**. Purification by chromatography using ethyl acetate – hexane (7:10) as eluent gave **10** as a white solid (690 mg, 85%) that showed the presence of both anomers on tlc; R_f 0.30 (**10β**) and R_f 0.37 (**10α**) in ethyl acetate – hexane (1:1); ^{1}H nmr ($CDCl_3$) δ: 5.660 (dd, >0.9H, $J_{3,4}$ = 3.2 Hz, $J_{4,5}$ = 1.0 Hz, H-4β), 5.326 (dd, >0.9H, $J_{1,2}$ = 8.5 Hz, $J_{1,OH}$ = 8.0 Hz, H-1β), 3.092 (d, >0.9H, D_2O exchangeable, OHβ), 2.142 (s, >2.7H, $COCH_3$β), 2.108 (s, <0.3H, $COCH_3$α). *Anal.* calcd. for $C_{30}H_{29}NO_8$: C 67.78, H 5.50, N 2.64; found: C 67.46, H 5.50, N 2.73.

*4-O-Acetyl-3,6-di-O-benzyl-2-deoxy-2-phthalimido-α,β-D-galactopyranosyl chloride (**11**)*

Compound **10** (800 mg, 1.51 mmol) was reacted with oxalyl chloride as described for the conversion of **7** to **8**. The product was obtained as a yellowish foam (800 mg, 97%) that showed the presence of both anomers by tlc: R_f 0.41 (**11β**) and R_f 0.48 (**11α**) in ethyl acetate – hexane (7:10); ^{1}H nmr ($CDCl_3$) δ: 6.329 (≈0.2H, $J_{1,2}$ = 3.5 Hz, H-1α), 5.986 (d, ≈0.8H, $J_{1,2}$ = 9.0 Hz, H-1β), 2.160 (s, ≈2.4H, $COCH_3$β), 2.080 (s, ≈0.6H, $COCH_3$α).

*8-Methoxycarbonyloctyl 3,4,6-tri-O-benzyl-α-D-mannopyranoside (**13**)*

8-Methoxycarbonyloctyl 2-*O*-acetyl-3,4,6-tri-*O*-benzyl-α-D-mannopyranoside (**12**, 1.10 g, 1.66 mmol) was dissolved in dry methanol (20 mL) containing sodium methoxide (10 mg). After 4 h, the solution was neutralized by addition of Amberlite IR-120 (H) resin, resin was removed by filtration, and solvent was evaporated to provide **13** as a clear syrup (1.0 g, 97%); $[\alpha]_D$ +38.6° (*c* 0.36, chloroform); R_f 0.38 in ethyl acetate – hexane 7:10; ^{1}H nmr ($CDCl_3$) δ: 4.881 (d, 1H, $J_{1,2}$ = 1.5 Hz, H-1), 4.025 (ddd, 1H, $J_{2,3}$ = 3.2, $J_{2,OH}$ = 2.5 Hz, H-2), 3.685 (s, OCH_3), 2.469 (d, 1H, D_2O exchangeable, OH), 2.291 (t, 2H, *J* = 7.5 Hz, CH_2COO); ^{13}C nmr ($CDCl_3$) δ: 174.26 ($COOCH_3$), 99.16 (C-1, $^1J_{C,H}$ = 167.5 Hz), 51.43 (OCH_3), 34.07 (CH_2COO). *Anal.* calcd. for $C_{37}H_{48}O_8$: C 71.58, H 7.79; found: C 71.50, H 7.95.

*8-Methoxycarbonyloctyl 2-O-(4-O-acetyl-3,6-di-O-benzyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl)-3,4,6-tri-O-benzyl-α-D-mannopyranoside (**14**)*

A mixture of **13** (1.10 g, 1.77 mmol) and silver trifluoromethanesulfonate (1.71 g, 6.65 mmol) was dried *in vacuo* over P_2O_5, dry dichloromethane (2 mL) was added followed by *sym*-collidine (0.87 mL, 6.61 mmol) and 4Å molecular sieves (0.5 g), and the mixture was stirred at −20°C for 0.5 h. The α,β-mixture **8** (2.92 g, 5.32 mmol) in dichloromethane (2 mL) was then added and after 2 h at −20°C the reaction mixture was warmed to room temperature and stirring was continued for an additional 14 h. The mixture was then diluted with dichloromethane (100 mL), solids were removed by filtration, and the organic solution was washed with water, 5% HCl, saturated $NaHCO_3$, and water. Solvent evaporation left a syrup that was purified by chromatography using ethyl acetate – toluene (1:10) as eluent to provide **14** (1.39 g, 69%) as a clear syrup; $[\alpha]_D$ +12.1° (*c* 0.66, chloroform); R_f 0.33 in ethyl acetate – toluene 1:6; ^{1}H nmr ($CDCl_3$) δ: 5.286 (m, 1H, $J_{1',2'}$ = 8.0 Hz, virtual coupling to H-3', H-1'), 5.153 (m, 1H, $J_{3',4'} \approx J_{4',5'} \approx$ 9.5 Hz, virtual coupling to H-2', H-4'), 3.647 (s, OCH_3), 2.278 (t, 2H, *J* = 7.5 Hz, CH_2COO), 1.953 (s, 3H, $COCH_3$); ^{13}C nmr ($CDCl_3$) δ: 174.25 ($COOCH_3$), 96.97 and 96.90 (C-1 and C-1'), 55.36 (C-2'), 51.41 (OCH_3), 34.07 (CH_2COO), 20.91 ($COCH_3$). *Anal.* calcd. for $C_{67}H_{75}NO_{15}$: C 70.94, H 6.67, N 1.23; found: C 70.65, H 6.61, N 1.13.

*8-Methoxycarbonyloctyl 2-O-(3,6-di-O-benzyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl)-3,4,6-tri-O-benzyl-α-D-mannopyranoside (**15**)*

De-*O*-acetylation of **14** (200 mg, 0.18 mmol), as described for the preparation of **13**, gave the title compound as a clear syrup (190 mg, 99%); $[\alpha]_D$ −3.2° (*c* 0.79, chloroform); R_f 0.31 in ethyl acetate – hexane, 2:3); ^{1}H nmr ($CDCl_3$) δ: 5.266 (d, 1H, $J_{1',2'}$ = 8.0 Hz, H-1'), 4.454 (d, 1H, $J_{1,2}$ = 1.8 Hz, H-1), 3.652 (s, 3H, OCH_3), 3.017 (d, D_2O exchangeable, $J_{4',OH}$ = 2.0 Hz, OH), 2.282 (t, 2H, *J* = 7.5 Hz, CH_2COO); ^{13}C nmr ($CDCl_3$) δ: 174.29 ($COOCH_3$), 97.02 (2 × C, C-1 and C-1'), 55.20 (C-2'), 51.43 (OCH_3), 34.09 (CH_2COO). *Anal.* calcd. for $C_{65}H_{73}NO_{14}$: C 71.47, H 6.74, N 1.28; found: C 71.01, H 6.61, N 1.24.

*8-Methoxycarbonyloctyl 2-O-[4-O-(4-O-acetyl-3,6-di-O-benzyl-2-deoxy-2-phthalimido-β-D-galactopyranosyl)-3,6-di-O-benzyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl)-3,4,6-tri-O-benzyl-α-D-mannopyranoside (**16**)*

A. From **11** and **15**: A mixture of **15** (300 mg, 0.27 mmol), silver trifluoromethanesulfonate (155 mg, 0.60 mmol), *sym*-collidine (80 μL, 0.60 mmol), and 4Å molecular sieves (0.2 g) in dichloromethane (1.0 mL) was stirred for 0.5 h and a solution of α,β-mixture **11** (302 mg, 0.55 mmol) in dichloromethane (1.0 mL) was then added dropwise. After 12 h, the reaction was diluted with dichloromethane (50 mL), solids were removed by filtration, and the filtrate was washed sequentially with water, 5% HCl, saturated $NaHCO_3$, and water. After solvent evaporation the residue was purified by chromatography using ethyl acetate – toluene (1:8) as eluent to provide **16** as a white foam (283 mg, 64%); $[\alpha]_D$ 0° (*c* 0.95, chloroform); R_f 0.37 in ethyl acetate – toluene, 1:6; ^{1}H nmr ($CDCl_3$) δ: 5.622 (dd, 1H, $J_{3'',4''}$ = 3.0 Hz, $J_{1'',2''} \approx$ 1.0 Hz, H-4''), 5.337 (d, 1H, $J_{1'',2''}$ = 8.5 Hz, H-1''), 5.104 (d, 1H, $J_{1',2'}$ = 8.0 Hz, H-1'), 4.379 (H-1 and H-2''), 4.252 (H-2'), 3.942 (dd, 1H, $J_{1,2}$ = 1.5 Hz, $J_{2,3}$ = 3.0 Hz, H-2), 3.649 (s, OCH_3), 2.261 (t, 2H, CH_2COO), and 2.028 (s, 3H, $COCH_3$); ^{13}C nmr ($CDCl_3$) δ: 174.25 ($COOCH_3$), 170.24 ($COCH_3$), 97.51 (C-1''), 96.88 and 96.79 (C-1 and C-1'), 55.55 (C-2'), 53.74 (C-2''), 51.40 (OCH_3), 34.05 (CH_2COO), and 20.82 ($COCH_3$). *Anal.* calcd. for $C_{95}H_{100}N_2O_{21}$: C 71.05, H 6.28, N 1.74; found: C 70.96, H 6.29, N 1.77.

B. From **13** and **22**: Alcohol **13** (82 mg, 0.132 mmol), silver trifluoromethane sulfonate (53 mg, 0.21 mmol), *sym*-collidine (30 μL, 0.228 mmol), 4Å molecular sieves (85 mg), and the α,β-mixture **22** (187 mg, 0.18 mmol) were mixed and stirred in dichloromethane for 24 h as described in procedure A above. Trisaccharide **16** (100 mg, 47%) was isolated in the same manner and had identical ^{1}H nmr and optical rotation as the material characterized in procedure A.

*8-Methoxycarbonyloctyl 2-O-[2-acetamido-4-O-(2-acetamido-4-O-acetyl-3,6-di-O-benzyl-2-deoxy-β-D-galactopyranosyl)-3,6-di-O-benzyl-2-deoxy-β-D-glucopyranosyl]-3,4,6-tri-O-benzyl-α-D-mannopyranoside (**17**)*

A mixture of **16** (150 mg, 0.093 mmol) and hydrazine acetate (258 mg, 2.80 mmol) was refluxed in dry methanol (15 mL) for 3 h, more hydrazine acetate (258 mg, 2.80 mmol) was then added, and the refluxing was continued for a further 20 h. The reaction was then taken to dryness, the residue was dissolved in pyridine (3 mL), and acetic anhydride (2 mL) was added. After stirring for 16 h, excess of acetic anhydride was decomposed by dropwise addition of ethanol to the reaction mixture at 0°C. Solvent was evaporated and toluene (2 × 5 mL) was added to and evaporated from the residue, which was then dissolved in dichloromethane and washed with 5% HCl, saturated $NaHCO_3$, and cold water. Evaporation left a white solid, which was purified by chromatography using acetone–hexane (2:3) as eluent. The title compound was obtained as a clear syrup (92 mg, 69%); $[\alpha]_D$ +6.9° (*c* 0.72, chloroform); R_f 0.33 in acetone–hexane, 2:3; ^{1}H nmr ($CDCl_3$) δ: 5.791 (d, 1H, D_2O exchangeable, $J_{NH',2'}$ = 8.0 Hz, NH'), 5.562 (d, 1H, $J_{3'',4''}$ = 3.0 Hz, $J_{4'',5''}$ < 1 Hz, H-4''), 5.032 (d, 1H, $J_{1',2'}$ = 7.4 Hz, H-1'), 4.985 (d, 1H, D_2O exchangeable, $J_{NH'',H-2''}$ = 7.5 Hz, NH''), 4.771 (d, $J_{1'',2''}$ = 8.0 Hz, H-1''), 4.095 (H-2), 3.655 (s, OCH_3), 3.492 (m, H-2''), 3.235 (m, H-2'), 2.291 (t, 2H, CH_2COO), 2.004 (s, 3H, $OCOCH_3$), 1.786 and 1.740 (each s, 3H, $NHCOCH_3$); ^{13}C nmr ($CDCl_3$) δ: 174.32 ($COOCH_3$), 171.17, 170.42, and 170.24 (3 × C, $COCH_3$), 99.47 (C-1''), 97.69 (2 × C, C-1 and C-1'), 56.50 (C-2'), 54.41 (C-2''), 51.45 (OCH_3), 23.55 and 23.37 (2 × C, $NHCOCH_3$), 20.84 ($OCOCH_3$). *Anal.* calcd. for $C_{83}H_{100}O_{19}N_2$: C 69.73, H 7.05, N 1.96; found: C 69.47, H 6.91, N 2.07.

8-Methoxycarbonyloctyl 2-O-[2-acetamido-4-O-(2-acetamido-3,6-di-O-benzyl-2-deoxy-β-D-galactopyranosyl)-3,6-di-O-benzyl-2-deoxy-β-D-glucopyranosyl]-3,4,6-tri-O-benzyl-α-D-mannopyranoside (18)

Compound **17** (60 mg, 0.042 mmol) was de-*O*-acetylated as described for the preparation of **13** to provide a clear syrup (55 mg, 95%); R_f 0.35 in ethyl acetate – hexane, 3:1; ^{1}H nmr ($CDCl_3$) δ: 5.844 (br d, 1H, D_2O exchangeable, $J_{NH',2'}$ = 8 Hz, NH′), 5.074 (br d, 1H, D_2O exchangeable, $J_{NH'',2''}$ = 8 Hz, NH″), 5.008 (d, 1H, $J_{1',2'}$ = 7.5 Hz, H-1′), 4.754 (H-1), 4.714 (d, $J_{1'',2''}$ = 8.0 Hz, H-1″), 3.654 (s, OCH_3), 2.475 (br s, 1H, D_2O exchangeable, OH), 2.295 (t, 2H, J = 7.5 Hz, CH_2COO), 1.788 and 1.733 (each s, 3H, $NHCOCH_3$). This material was not further characterized but was used directly in the preparation of **19**.

8-Methoxycarbonyloctyl 2-O-[2-acetamido-4-O-(2-acetamido-3,6-di-O-benzyl-2-deoxy-4-O-sulfo-β-D-galactopyranosyl)-3,6-di-O-benzyl-2-deoxy-β-D-glucopyranosyl]-3,4,6-tri-O-benzyl-α-D-mannopyranoside sodium salt (19)

Compound **18** (50 mg, 0.036 mmol) was dissolved in dry dimethylformamide (1.0 mL) and sulfur trioxide – pyridine complex (29 mg, 0.182 mmol) in dry dimethylformamide (2 mL) was added dropwise. The resulting solution was stirred for 4 h and excess of reagent was destroyed by the addition of methanol (1 mL). Solvent was evaporated and the residue was dissolved in chloroform and washed with cold water. Chloroform evaporation left a white solid, which was dissolved in methanol and passed through Dowex 50-X8 (Na^+) (10 mL) in methanol. Solvent removal provided the title compound as a hygroscopic white solid (50 mg, 93%); $[\alpha]_D$ +15.1° (*c* 0.86, methanol); R_f 0.41 in dichloromethane–methanol, 9:1; ^{1}H nmr (CD_3OD) δ: 4.994 (d, 1H, $J_{3'',4''}$ = 3.0 Hz, $J_{4'',5''}$ < 1 Hz, H-4″), 4.744 (d, 1H, $J_{1,2}$ = 1.8 Hz, H-1), 4.139 (dd, 1H, $J_{2,3}$ = 3.2 Hz, H-2), 3.668 (s, OCH_3), 3.304 (dd, 1H, $J_{2'',3''}$ = 11.0 Hz, H-3″), 2.307 (t, 1H, J = 7.5 Hz, CH_2COO), 1.860 and 1.810 (each s, 3H, $NHCOCH_3$); ^{13}C nmr (CD_3OD) δ: 175.94 ($COOCH_3$), 173.48 (2 × C, $NHCOCH_3$), 101.77, 101.01, and 98.69 (C-1, C-1′, and C-1″), 81.55 (C-4″), 56.46 (C-2′), 54.24 (C-2″), 51.96 (OCH_3), 34.77 (CH_2COO), and 23.30 (2 × C, $NHCOCH_3$). *Anal.* calcd. for $C_{81}H_{97}N_2O_{21}SNa\cdot 2.5\,H_2O$: C 63.39, H 6.37, N 1.82; found: C 63.21, H 6.39, N 1.66.

8-Methoxycarbonyloctyl 2-O-[2-acetamido-4-O-(2-acetamido-2-deoxy-β-D-galactopyranosyl)-2-deoxy-β-D-glucopyranosyl]-α-D-mannopyranoside (2)

Compound **18** (16 mg, 0.012 mmol) was dissolved in 95% ethanol (3 mL) containing 5% palladium on carbon (20 mg) and was stirred under hydrogen (1 atm (101.3 kPa)) for 20 h. Catalyst was removed by filtration, washed with 95% ethanol, and the solvent was evaporated to dryness. The residue was then passed through a column of Bio-Gel P2 (200–400 mesh) (2.5 × 50 cm) using 10% aqueous ethanol as eluent. The carbohydrate containing fractions were pooled, concentrated, and lyophilized to provide a white powder (7.2 mg, 82%); $[\alpha]_D$ +9.6° (*c* 0.99, water); R_f 0.32 in chloroform–methanol–water, 60:35:6; ^{1}H nmr (D_2O) δ: 4.854 (d, 1H, $J_{1,2}$ = 1.6 Hz, H-1), 4.559 (m, 1H, $J_{1',2'}$ = 8.2 Hz, virtual coupling to H-3′, H-1′), 4.514 (d, 1H, $J_{1'',2''}$ = 8.4 Hz, H-1″), 4.032 (dd, 1H, $J_{2,3}$ = 3.4 Hz, H-2), 3.94 (H-2″), 3.73 (H-2′), 3.687 (s, OCH_3), 2.387 (t, 2H, J = 7.5 Hz, CH_2COO), 2.068 and 2.045 (each s, 3H, $COCH_3$); ^{13}C nmr (D_2O) δ: 178.67 ($COOCH_3$), 175.55 (2 × C, $COCH_3$), 102.60, 100.24, and 97.55 (C-1, C-1′, and C-1″), 68.88 (OCH_2CH_2), 62.32, 61.75, and 60.69 (C-6, C-6′, and C-6″), 55.50 (C-2′), 53.35 (C-2″), 52.88 (OCH_3), 34.53 (CH_2COO), 23.15 and 23.01 ($NHCOCH_3$). *Anal.* calcd. for $C_{32}H_{56}N_2O_{18}\cdot 2H_2O$: C 48.48, H 7.12, N 3.53; found: C 48.06, H 6.94, N 3.82.

8-Methoxycarbonyloctyl 2-O-[2-acetamido-4-O-(2-acetamido-2-deoxy-4-O-sulfo-β-D-galactopyranosyl)-2-deoxy-β-D-glucopyranosyl]-α-D-mannopyranoside sodium salt (3)

Compound **19** (46 mg, 0.031 mmol) was hydrogenated as described for the preparation of **2**. After passage through a column of Bio-Gel P-2 and lyophilization, the residue was dissolved in water and passed through Dowex 50-X8 (Na^+) (10 mL). Lyophilization of the eluate gave a hygroscopic white powder (22.2 mg, 84%); $[\alpha]_D$ +2.5° (*c* 0.81, water); R_f 0.23 in chloroform–methanol–water, 60:35:6; ^{1}H nmr (D_2O) δ: 4.856 (d, 1H, $J_{1,2}$ = 1.5 Hz, H-1), 4.692 (d, 1H, $J_{3'',4''}$ = 2.3 Hz, H-4″), 4.587 (m, 1H, $J_{1'',2''}$ = 8.2 Hz, virtual coupling to H-3″, H-1″), 4.558 (m, 1H, $J_{1',2'}$ = 8.3 Hz, virtual coupling to H-3′, H-1′), 4.032 (dd, 1H, $J_{2,3}$ = 3.4 Hz, H-2), 3.91 (m, H-2″ and H-3″), 3.76 (H-2′ and H-3′), 3.687 (s, OCH_3), 2.386 (t, 2H, J = 7.5 Hz, CH_2COO), 2.071 and 2.044 (each s, 3H, $COCH_3$); ^{13}C nmr (D_2O) δ: 178.66 ($COOCH_3$), 175.61 (2 × C, $COCH_3$), 102.61, 100.31, and 97.61 (C-1, C-1′, and C-1″), 80.48 (C-4″), 68.94 (OCH_2CH_2), 62.38, 61.83, and 60.97 (C-6, C-6′, and C-6″), 55.52 (C-2′), 53.78 (C-2″), 52.94 (OCH_3), 34.58 (CH_2COO), 23.21 and 23.08 (2 × C, $COCH_3$). *Anal.* calcd. for $C_{32}H_{55}N_2O_{21}SNa\cdot 2H_2O$: C 42.95, H 6.20, N 3.13; found: C 42.75, H 6.00, N 2.94.

Allyl 4-O-(4-O-acetyl-3,6-di-O-benzyl-2-deoxy-2-phthalimido-β-D-galactopyranosyl)-3,6-di-O-benzyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (20)

Condensation of **5** (307 mg, 0.58 mmol) with **11** (450 mg, 0.82 mmol) in the presence of silver trifluoromethanesulfonate (235 mg, 0.92 mmol) and *sym*-collidine (130 μL, 0.98 mmol), as described for the preparation of **16**, provided a crude syrupy product, which was purified by chromatography using ethyl acetate – toluene (1:8) as eluent. Compound **20** was obtained as a white foam (397 mg, 66%); $[\alpha]_D$ +27.1° (*c* 0.30, chloroform); R_f 0.30 in ethyl acetate – toluene, 1:6; ^{1}H nmr ($CDCl_3$) δ: 5.616 (dd, $J_{3',4'}$ = 3.0 Hz, $J_{4',5'} \approx$ 1.0 Hz, H-4′), 5.605 (m, $CH_2{=}CHCH_2$), 5.329 (d, 1H, $J_{1',2'}$ = 8.2 Hz, H-1′), 4.999 (d, $J_{1,2}$ = 8.2 Hz, H-1), 2.030 (s, 3H, $COCH_3$); ^{13}C nmr ($CDCl_3$) δ: 170.23 ($COCH_3$), 117.15 ($CH_2{=}CHCH_2$), 97.47 and 97.18 (C-1 and C-1′, 55.67 (C-2), 53.72 (C-2′), 20.82 ($COCH_3$). *Anal.* calcd. for $C_{61}H_{58}N_2O_{14}$: C 70.23, H 5.60, N 2.69; found: C 70.23, H 5.58, N 2.78.

4-O-(4-O-Acetyl-3,6-di-O-benzyl-2-deoxy-2-phthalimido-β-D-galactopyranosyl)-3,6-di-O-benzyl-2-deoxy-2-phthalimido-α,β-D-glucopyranose (21)

Reaction of **20** (235 mg, 0.23 mmol) under the conditions described for the conversion of **6** to **7** gave, after chromatographic purification using ethyl acetate – toluene (1:4) as eluent, the title compound as a white solid (193 mg, 85%); R_f 0.20 (**21**α) and R_f 0.14 (**21**β) in ethyl acetate – toluene, 1:3; ^{1}H nmr ($CDCl_3$) δ: 5.622 (dd, 1H, $J_{3',4'}$ = 3.0, $J_{4',5'} \approx$ 1.0 Hz, H-4′), 5.323 (d, ≈0.8H, $J_{1',2'}$ = 8.0 Hz, H-1′β), 5.300 (d, ≈0.2H, $J_{1',2'}$ = 8.0 Hz, H-1′α), 5.232 (dd, ≈0.2H, $J_{1,OH}$ = 4.0, $J_{1,2}$ = 4.0 Hz, H-1α), 5.157 (dd, ≈0.8H, $J_{1,OH}$ = 8.5, $J_{1,2}$ = 8.5 Hz, H-1β), 4.752 (d, ≈0.2H, D_2O exchangeable, OHα), 2.824 (d, ≈0.8H, D_2O exchangeable, OHβ), 2.021 (s, ≈2.4H, $COCH_3$β), 2.001 (s, ≈0.6H, $COCH_3$α).

4-O-(4-O-Acetyl-3,6-di-O-benzyl-2-deoxy-2-phthalimido-β-D-galactopyranosyl)-3,6-di-O-benzyl-2-deoxy-2-phthalimido-α,β-D-glucopyranosyl chloride (22)

Reaction of **21** (193 mg, 0.192 mmol) with oxalyl chloride/dimethylformamide, as described for the preparation of **8**, gave **22** as a pale yellow foam (190 mg, 97%); R_f 0.36 in ethyl acetate – toluene, 1:6; ^{1}H nmr ($CDCl_3$) δ: 6.131 (d, ≈0.2H, $J_{1,2}$ = 3.5 Hz, H-1α), 5.809 (d, ≈0.8H, $J_{1,2}$ = 8.0 Hz, H-1β), 5.654 (dd, ≈0.2H, $J_{3',4'}$ = 3.0 Hz, $J_{4',5'} \approx$ 1.0 Hz, H-4′α), 5.616 (dd, ≈0.8H, $J_{3',4'}$ = 3.0 Hz, $J_{4',5'} \approx$ 1.0 Hz, H-4′β), 5.334 (d, $J_{1',2'}$ = 8.2 Hz, H-1′α), 5.328 (d, $J_{1',2'}$ = 8.2 Hz, H-1′β), 2.01 (3H, $COCH_3$ α and β).

Rotating frame nuclear magnetic resonance experiments on metal complexes

RICHARD J. BUIST AND DONALD R. EATON[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 3, 1986

RICHARD J. BUIST and DONALD R. EATON. Can. J. Chem. **65**, 1653 (1987).

Measurements of the rate of nuclear magnetic relaxation in the rotating frame ($T_{1\rho}$) have the potential to provide significant information not readily available by other nmr methods. Some applications to metal complex chemistry are described. The method has been applied to ^{59}Co nmr and used to obtain ^{59}Co–^{14}N spin–spin coupling constants for the tris(ethylenediamine)cobalt(III) and hexanitrocobaltate(III) ions. The larger coupling constant in the latter compound is related to the different hybridization of the nitrogen atom. Proton $T_{1\rho}$ measurements on thiourea and its zinc complex have demonstrated that at room temperature broadening of the ^{1}H resonance is very largely ascribable to scalar relaxation rather than to chemical exchange processes.

RICHARD J. BUIST et DONALD R. EATON. Can. J. Chem. **65**, 1653 (1987).

Les mesures de taux de relaxation magnétique nucléaire dans le référentiel tournant ($T_{1\rho}$) peuvent éventuellement fournir des informations importantes qui ne sont pas facilement accessibles par d'autres méthodes rmn. On décrit quelques applications à la chimie des complexes métalliques. On a appliqué la méthode à la rmn du ^{59}Co et on l'a utilisée pour déterminer les constantes de couplage spin–spin ^{59}Co–^{14}N des ions tris(éthylènediamine)cobalt(III) et hexanitrocobaltate(III). On relie la constante de couplage qui est plus grande dans le dernier composé avec une hybridation différente de l'atome d'azote. Des mesures de $T_{1\rho}$ sur la thiourée et son complexe de zinc ont démontré que, à la température ambiante, l'élargissement de la résonance du ^{1}H est principalement dû à une relaxation scalaire plutôt qu'à des processus d'échanges chimiques.

[Traduit par la revue]

Introduction

Most nmr relaxation studies have involved measurement of either the spin-lattice relaxation time, T_1, or the spin–spin relaxation time T_2. There is, however, a third relaxation time which can be rather easily obtained using a pulsed nmr instrument. This is the relaxation time in the rotating frame, commonly designated $T_{1\rho}$. Measurements of this parameter can yield chemically significant information not easily obtained by other methods. The present paper describes some applications of $T_{1\rho}$ measurements to metal complex chemistry.

$T_{1\rho}$ is the relaxation time of transverse magnetization measured in the presence of a strong radiofrequency field which is known as the spin-locking field (B_1). The basic experiment used to measure $T_{1\rho}$ is quite straightforward (1). A 90° pulse along the x axis in the rotating frame rotates the magnetization to the y axis. As soon as this pulse is completed, the phase of the radio frequency is changed by 90° so that B_1 also lies along the y axis also. Since the magnetization is now in the same direction as the rf field, no torque is exerted and it remains in that direction. The spins are said to be "locked" along the y axis. This magnetization will, however, still decay and the rate at which this occurs is a measure of $T_{1\rho}$. Since it is difficult to measure the magnetization in the presence of the spin locking field, the normal procedure is to carry out a series of experiments with B_1 applied for increasing periods of time and measure the initial height of the FID after the spin-locking field is turned off. It is also usual to measure $T_{1\rho}$ as a function of B_1. It is obvious that if B_1 becomes small $T_{1\rho}$ approaches T_2. However, at large values of B_1, $T_{1\rho}$ does not equal T_2 but rather approaches the value of T_1. In the intermediate region $T_{1\rho}$ lies between T_1 and T_2 and the measurements provide information on any processes which cause these two relaxation times to differ. In solution scalar relaxation and chemical exchange are the usual causes of such differences (2).

The first use of $T_{1\rho}$ measurements was reported by Solomon (3). This was a proton study of formamide and provided information on scalar relaxation of the second kind resulting from coupling to the quadrupolar ^{14}N nucleus. Both the N–H coupling constant and the ^{14}N T_1 were obtained. A paper by Meiboom (4) and several subsequent papers (5–7) report $T_{1\rho}$ measurements on water. The situation is quite complicated and both proton exchange and scalar relaxation by ^{17}O contribute to the observed results. Chemical exchange studies include work by Deverell *et al.* (8) on chair to chair isomerization of cyclohexane, Ohuchi *et al.* (9) on isomerization of decalin, Hennig and Limbach (10) (tautomers of *meso*-tetraphenylporphine), Stilbs and Moseley (11) (ureas), and Dodrell *et al.* (12) (benzaldehydes). There has also been a number of studies of scalar relaxation caused by quadrupolar nuclei including those by Mlynarik (13) (nitrobenzene and pyridine), Ohuchi *et al.* (9) (chlorocarbons), and Morgan and Strange (14) (liquid HCl and HBr). Chopra, McClung, and Jordan (15) have used $T_{1\rho}$ measurements to analyze the relaxation of solvent molecules by paramagnetic ions. These authors showed that, under the appropriate conditions, the number of molecules in the solvation shell can be determined as well as the paramagnetic chemical shift and the exchange lifetime. To our knowledge this was the first application of $T_{1\rho}$ measurements in the area of transition metal chemistry.

Experimental

The nmr experiments were performed on Bruker CXP-200 and WM-250 instruments. The CXP-200 instrument is best equipped for this type of experiment since the broad-band transmitter power is directly attenuable from the console. This means that $T_{1\rho}$'s can be determined for any nucleus observable on this instrument. For ^{1}H experiments the high power decoupler was used to provide the variable strength spin-locking field. Since the attenuation available directly on the decoupling unit was limited to about 10 dB, additional attenuation was obtained by inserting a variable attenuator with settings ranging from 3 to 100 dB into the decoupler line. Excessive sample heating was not found to be a problem if spin-locking times were kept below 2 s and if a 30-s cooling time was inserted between experiments. In the case of the Bruker WM-250 instrument, cooling air was passed over the

sample. On this instrument the spin-locking field was applied through the decoupler channel. The decoupler and receiver leads on the computer were connected together to ensure a constant phase relationship between the two. Since the decoupler is used the power available for spin locking is much more limited on the WM-250 than on the CXP-200. All ^{59}Co measurements were made on the CXP-200. Proton measurements were made on both instruments and good agreement between the two sets of data was obtained in the region at low B_1 levels where comparison was possible. Except for a few ^{59}Co runs, all measurements on both instruments were taken with one scan. The decoupler power was measured by finding the 180° null or averaging the results obtained from a 180° null with that from a 360° null. This gives B_1 by using the relationship $(\pi/t180) = \gamma B_1$. $T_{1\rho}$'s were either calculated from a log I vs. time plot or obtained directly from the instrument using the Bruker T_2 calculation routine. Since the T_1's and $T_{1\rho}$'s measured were quite short, no attempt was made to remove O_2 from the solutions. It was estimated that in these circumstances relaxation by the paramagnetic O_2 should not result in significantly large errors. The probe temperature was 293 K for the CXP-200 and 294 K for the WM-250. Estimated errors are around 15% for the ^{59}Co data and 10% for ^{1}H data. Random errors are considerably less than this. T_1's were measured using the standard inversion–recovery pulse sequence.

The cobalt complexes studied were obtained commercially and used without further purification. Unbuffered aqueous solutions of approximately 0.2 M concentration were used. The pH's of these solutions were approximately 5 for the cobaltinitrite and 6 for the ethylenediamine complex. The zinc thiourea complex was prepared in a manner described previously (16). Nuclear magnetic resonance spectra were obtained using approximately 0.1 M solutions in acetone-d_6.

^{59}Co measurements

For cobalt complexes of low symmetry, quadrupolar or chemical shift anisotropy relaxation mechanisms are very effective, leading to short relaxation times and very broad lines. For complexes of higher symmetry these relaxation mechanisms become less important and if the metal is bonded to a nucleus with $I > 0$ scalar relaxation of the second kind must be considered. This mechanism is only effective if the relaxation time of the coupled nucleus is short. This is usually the case for quadrupolar nuclei. The most common such ligand nucleus is ^{14}N with $I = 1$. Spin–spin coupling constants between two such directly bonded nuclei potentially provide information on the bonding but multiplets cannot be directly observed because of the short relaxation times. $T_{1\rho}$ measurements provide an indirect approach to these coupling constants.

Two other methods are available for obtaining the ^{59}Co–^{14}N coupling constant indirectly. The first involves isotopic substitution with ^{15}N. The latter nucleus has $I = 1/2$ and the nitrogen resonance is therefore reasonably narrow allowing the cobalt coupling to be observed. Yamasaki *et al.* (17) have performed such an experiment on the tris(ethylenediamine) complex and report $^1J(^{59}\text{Co}–^{15}\text{N}) = 63.8$ Hz which corresponds to an ^{14}N coupling constant of 45.5 Hz. The ^{15}N spectra were significantly broadened by scalar relaxation with the ^{59}Co and computer simulation of the experimental curves was necessary. From this curve fitting these authors obtained a T_1 for the cobalt of 13 ms. The second possible method is to measure both T_1 and T_2 for the ^{59}Co and T_1 for the coupled nucleus (in this case ^{14}N) and then calculate J from

$$1/T_{1I} - 1/T_{2I} = (1/3)\{(2\pi J)^2 T_{1S} n_s S(S + 1)\}$$

In this equation n_s is the number of ^{14}N nuclei coupled to the Co, the subscript I refers to Co, and the subscript S to N. The formula is only valid when $(\omega_1^2 - \omega_S^2)(T_{1S})^2 \gg 1$. This condition is satisfied in the case of ^{59}Co and ^{14}N. Since the T_2's are more difficult to measure by pulse methods it is usual to obtain them from linewidths and to assume that for ^{14}N, $T_1 = T_2$. This neglects instrumental line broadening and also the possibility that scalar relaxation of the ^{14}N by the ^{59}Co will contribute to the ^{14}N linewidth. It is also possible that coupling with other nuclei, e.g. the protons in the tris(ethylenediamine) complex, will contribute to the Co linewidth. Dodrell *et al.* (18) have demonstrated that this occurs by showing that the linewidth of the hexamminne complex was reduced by both ^{14}N and ^{1}H decoupling. Rose and Bryant (19, 20) have used this second method to obtain ^{59}Co–^{14}N coupling constants for several Co complexes.

[a]Aqueous solution pH 6.
[b]Aqueous solution pH 5.

As is apparent from the above discussion both of these methods for obtaining coupling constants have limitations and $T_{1\rho}$ measurements may have advantages. We have therefore carried out such measurements for the two complex ions $Co(en)_3^{3+}$ and $Co(NO_2)_6^{3-}$. The results for the former complex may be compared with the literature values obtained indirectly. They therefore constitute a check on the reliability of the method. The measured $T_{1\rho}$'s for different values of B_1 are given in Table 1. Values of T_1 are also required and these were found to be 9.5 and 34.1 ms for the ethylenediamine and nitrite complexes, respectively. Following the treatment of Morgan and Strange (14) we obtain

$$[1] \quad \frac{1}{T_{1\rho}} - \frac{1}{T_1} = \frac{8(\pi J)^2 T_1^N}{3(1 + \omega_1^2 T_1^{N2})}$$

This equation contains two unknowns, J and T_1^N (the nitrogen relaxation time) and the linear plots shown in Figs. 1 and 2 enable both to be obtained. As a check the ^{14}N T_1's have also been measured directly by inversion recovery. They are quite short (less than a millisecond) but can be obtained reasonably accurately using the CXP-200 high power instrument. All of these data are presented in Table 2. The scatter of the experimental data is quite small, as is apparent from Figs. 1 and 2, and the major source of error may well lie in the use of eq. [1] which is strictly only valid over a restricted range of B_1 values.

The internal consistency of these results is good as shown by a comparison of the calculated and directly measured nitrogen T_1's. In the case of the ethylenediamine complex they are 0.431 and 0.445 ms, respectively, and in the case of the nitrite complex 0.140 and 0.150 ms, respectively. The agreement in both cases is well within the possible errors. The intercepts of Figs. 1 or 2 can be used to calculate T_2 for the Co and hence

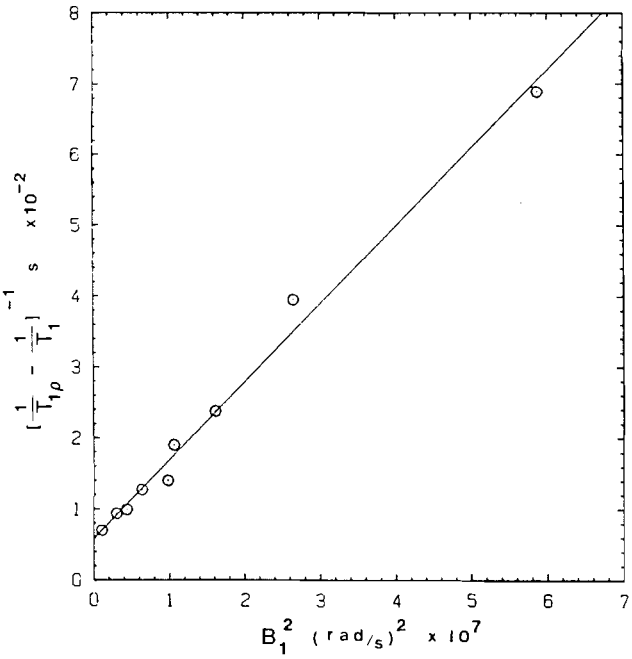

FIG. 1. Plot of $\left(\frac{1}{T_{1\rho}} - \frac{1}{T_1}\right)^{-1}$ vs. B_1^2 for $Co(en)_3^{3+}$. ^{59}Co data. Axes marked in units of s $\times$ 10^{-2} and $(rad/s)^2 \times 10^7$.

the linewidth. For the ethylenediamine complex the calculated linewidth is 87.1 Hz and the experimental value 90 Hz, which is acceptable agreement. Additional broadening due to unresolved coupling with the protons can be no more than a few hertz in agreement with the findings of Doddrell *et al.* (18). For the cobaltinitrite a value of 23.9 Hz is calculated compared to the experimental 55 Hz. It is not clear whether this discrepancy arises from magnetic field inhomogeneity, or from other factors but in this case use of the linewidth to obtain T_2 and hence J leads to a large error (a value of J = 80 Hz was reported previously (21) based on this assumption). If it is assumed that

[a]Solvent acetone-d_6.

$T_1 = T_2$ for the ^{14}N resonance of cobaltinitrite the calculated linewidth of 2195 Hz agrees well with the observed value of 2200 Hz.

The coupling constant obtained for the tris(ethylenediamine) complex, 49.8 Hz, agrees satifactorily with the literature values of 45.5 Hz (17) and 50 Hz (19) obtained by other methods. The cobaltinitrite value of 58.9 Hz does not agree with that reported in the literature (20) (46 Hz) but the latter value was based on an incorrect ^{14}N assignment (21). The correctness of the revised assignment is further supported by the good agreement between the ^{14}N linewidth calculated from the relaxation time and that observed experimentally. The significantly larger coupling constant for the nitro complex than for ammine complexes can be correlated with the change in the hybridization of the nitrogen (22). For the ammines, the N is sp^3 hybridized but for the nitro group it is closer to sp^2. The increase in s character would be expected to lead to an increase in coupling constant.

Proton measurements on thiourea and its zinc complex

The above ^{59}Co measurements can only be interpreted in terms of scalar relaxation. In other systems, there are possibilities for either scalar relaxation or chemical exchange effects. An example of such a case is provided by the proton spectra of thiourea and its metal complexes. The linewidths of these compounds have been examined at low temperatures (16, 23–26) and the variations have been ascribed to chemical exchange

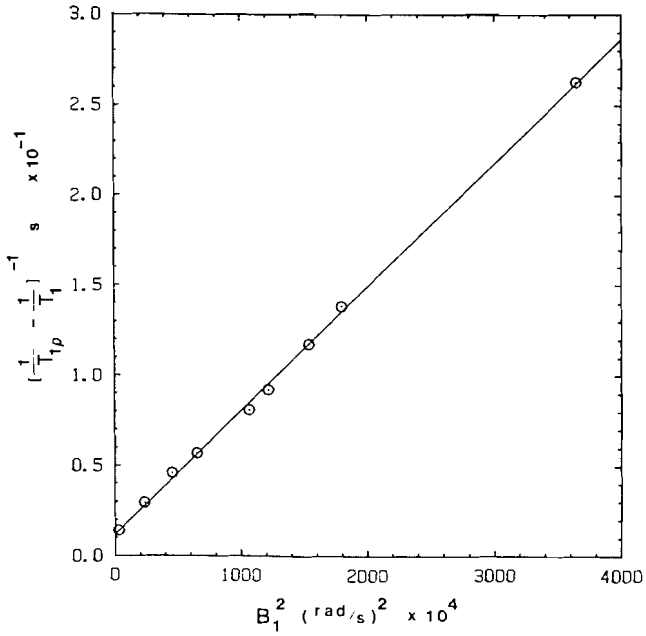

FIG. 3. Plot of $\left(\frac{1}{T_{1\rho}} - \frac{1}{T_1}\right)^{-1}$ vs. B_1^2 for thiourea. ^{1}H data.

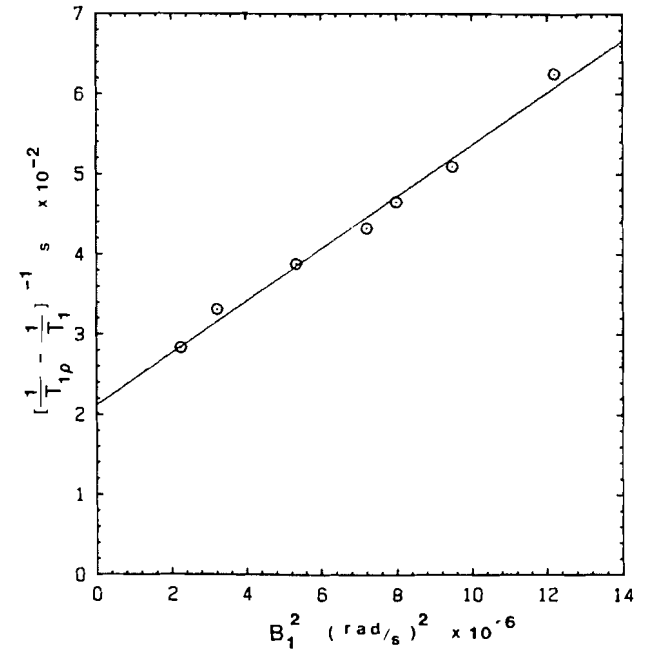

FIG. 4. Plot of $\left(\frac{1}{T_{1\rho}} - \frac{1}{T_1}\right)^{-1}$ vs. B_1^2 for Zn thiourea perchlorate. ^{1}H data.

processes attributable to restricted rotation about the C—N bond or to ligand exchange. The possible contribution of scalar relaxation due to coupling with the ^{14}N has not been explicitly considered. Generally the effects of rapid chemical exchange will be more pronounced at low temperatures, since the inverse of the chemical shift difference is then small enough to be comparable with the rate of the reaction. Scalar relaxation effects, on the other hand, usually become more pronounced at high temperatures, since relaxation times increase with increasing temperature and this leads to more effective scalar relaxation (1). $T_{1\rho}$ measurements on these compounds have therefore been carried out at room temperature, which is considerably higher than the temperatures employed in the chemical exchange studies.

TABLE 4. Analysis of proton $T_{1\rho}$ data

Parameter	Value	
	Thiourea	$Zn(tu)_4(ClO_4)_2$
$T_1(^1H)$ (s)	2.2	0.815
$T_2(^1H)$ (s)	0.011	0.023
$J(^1H-^{14}N)$ (Hz)	64.9	67.7
$T_1(^{14}N)$ (ms)	0.761	0.396

Data, obtained at 21°C, illustrating the variation of $T_{1\rho}$ with B_1 for both thiourea and its zinc perchlorate complex are given in Table 3. Appropriate plots of these data are shown in Figs. 3 and 4. These plots are expected to be linear no matter whether the variation of $T_{1\rho}$ is caused by chemical exchange or by scalar relaxation. There is a rather simple experiment to settle the origin of the effect. If chemical exchange is responsible for line broadening and hence the variation of $T_{1\rho}$, the widths of the ^{15}N satellite lines of the NH_2 resonance should be equal to that of the main line corresponding to ^{14}N. If scalar relaxation is the cause, the widths should be markedly different since the T_1 of ^{15}N ($I = 1/2$) will be much longer than that of ^{14}N with $I = 1$. The rate of relaxation of the ^{15}N is too slow to effectively relax the coupled proton. The width of the main resonance in acetone-d_6 at 21°C is 30 Hz. Since ^{15}N has only 0.365% natural abundance the satellites are difficult to observe in the normal spectrum. However, a SEFT experiment (28) which magnifies small sharp peaks with long T_2's at the expense of large broad peaks with short T_2's (run with τ = 0.05 s) gave a very well-resolved low noise spectrum of the two satellites separated by 90.8 Hz with widths of 1.9 Hz. Clearly, the broadening of the central line is primarily due to scalar relaxation. The data of Fig. 3 can therefore be analysed in the same manner as that used for the ^{59}Co data. The results of this analysis and a similar one for the zinc complex are shown in Table 4. The ^{14}N–^{1}H coupling constantof 64.9 Hz obtained from the $T_{1\rho}$ measurements may be compared with the value of 64.7 Hz calculated from the ^{15}N satellite spectrum. This agreement confirms that the variation of $T_{1\rho}$ has been correctly attributed to scalar relaxation. The T_2 value obtained from the intercept of Fig. 3 also agrees well with the value calculated from the linewidth which confirms this conclusion.

Having demonstrated that chemical exchange does not contribute to the nmr spectrum at room temperature for the thiourea ligand one might ask whether the same is true for metal complexes. The data for the Zn perchlorate complex is particularly pertinent since the rate of ligand exchange may be very rapid and contribute to line broadening at higher temperatures than does restricted rotation. This complex is an effective catalyst for anil formation transimination reactions (27) and the rate of ligand exchange is of significance to the understanding of the mechanisms of catalysis. The $T_{1\rho}$ data (Fig. 4) are quite similar to those obtained for the free ligand and show no anomalies attributable to chemical exchange effects. The N–H coupling constant obtained from the analysis (67.7 Hz) is slightly larger than that for free thiourea and the relaxation times are shorter as expected for a larger molecule.

Conclusion

The application of $T_{1\rho}$ measurements to the study of scalar relaxation in metal complexes has been demonstrated. This

experiment is useful in the determination of spin–spin coupling constants when one or both of the nuclei are quadrupolar. The major advantage is that linewidth measurements are not required and errors arising from B_0 inhomogeneity are avoided. Both of the significant variables are determined in one set of experiments on the same sample at the same temperature. It is not necessary to measure the T_1 of the coupled nucleus which, in the case of nuclei with small magnetogyric ratios, such as ^{14}N, can be difficult. The same general method can also be applied to chemical exchange problems. Low temperature measurements in the slow exchange region are not necessary and no assumptions about the temperature dependence of the chemical shift differences are required. In principle, if both chemical exchange and scalar relaxation are present, the two can be separated by measuring $T_{1\rho}$ as a function of temperature since the effect of the former on $T_{1\rho}$ decreases with temperature while the latter increases. Calculations of rotation barriers in the thioureas and similar molecules based on line broadening data may be in error since no allowance is usually made for the effect of scalar relaxation. For the determination of chemical exchange rates the technique complements the various forms of spin saturation transfer and two dimensional nmr now available for rate determinations. The former method applies in the region of fast exchange following line coalescence and the latter methods are useful in the slow exchange region.

Received March 11, 1986[2]

B. Mario Pinto, H. Bernhard Schlegel, and Saul Wolfe. Can. J. Chem. **65**, 1658 (1987).

The crystal structures of 2-substituted heterocyclohexanes containing exocyclic X and endocyclic Y exhibit systematic variations in their XCY bond angles. When X is in the more stable axial orientation, corresponding to the anomeric effect, the XCY angle is larger than tetrahedral; when X is in the equatorial orientation the XCY angle is smaller than tetrahedral. These geometrical effects are predicted by the perturbational molecular orbital analysis employed previously to account for the existence of the anomeric effect and its variation with changes in X and Y. *Ab initio* molecular orbital calculations, with full geometry opimization, of selected conformations of XCH_2YH molecules also reproduce this geometrical effect.

B. Mario Pinto, H. Bernhard Schlegel et Saul Wolfe. Can. J. Chem. **65**, 1658 (1987).

Les structures cristallines d'hétérocyclohexanes substitués en position 2 et contenant un groupement X exocyclique et un groupement Y endocyclique présentent des variations systématiques de leurs angles de liaisons XCY. Lorsque X se trouve dans l'orientation axiale la plus stable, correspondant à l'effet anomère, l'angle XCY est plus grand que celui d'un tétraèdre; par ailleurs, lorsque X est dans l'orientation équatoriale, l'angle XCY est plus petit que celui d'un tétraèdre. On peut prédire ces effets géométriques en faisant appel à l'analyse des orbitales moléculaires perturbationnelle qui a été utilisée antérieurement pour expliquer l'existence de l'effet anomère ainsi que sa variation avec des changements dans X et Y. On peut aussi reproduire cet effet géométrique en faisant appel à des calculs d'orbitales moléculaires *ab initio*, impliquant une optimisation complète de la géométrie, de conformations choisies de molécules XCH_2YH.

[Traduit par la revue]

Introduction

Molecules of the type XYCAB, in which X and Y are heteroatoms, exhibit interesting geometries. When AB is a double bond ($XYC{=}CH_2$), the XCY angle is substantially smaller than the 120° angle associated with sp^2-hybridized carbon: X = Y = F, ∠XCY = 109.4°; X = F, Y = Cl, ∠XCY = 112.0°; X = Y = Cl, ∠XCY = 114.4° (1).[3] For A = B = H, a shortening (strengthening) of the C—X and C—Y bonds, compared to CH_3X and CH_3Y, is normally observed (2, 3). The magnitude of this shortening is attenuated by torsion about the C—X and (or) C—Y bonds when X and (or) Y are rotors (XR, YR) and is a manifestation of the Edward–Lemieux (anomeric) effect (4).

The bond strengthening observed in $XYCH_2$ is an electrostatic (coulombic) effect in which one substituent causes a change in the charge density at the central carbon and this, in turn, causes a change in the length of the bond to the second substituent (5–7). The XCY bond angles in $XYC{=}CH_2$ and the torsional behaviour and bond length variations in $RXCH_2YR'$ have been rationalized, both qualitatively (1, 6, 8) and quantitatively (1, 6, 9), by a perturbational molecular orbital (PMO) treatment that focuses on the two-orbital two-electron stabilizing orbital interactions that contribute to the HOMO of XYCAB. In this treatment the relevant interaction involves a doubly occupied nonbonding orbital on X and an unoccupied acceptor orbital on YCAB or, alternatively, a doubly occupied nonbonding orbital on Y and an unoccupied acceptor orbital on XCAB (1, 9). The magnitude of this interaction is proportional to the square of the overlap between the interacting orbitals, and is inversely proportional to their energy difference.

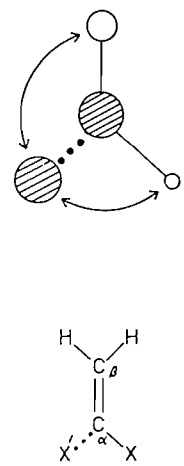

FIG. 1. The stabilizing orbital interaction that contributes to the HOMO of a 1,1-disubstituted ethylene.

Figure 1 illustrates the application of this procedure to $X'XC{=}CH_2$, with the interaction taken as $X'\cdots CX{=}CH_2$. The acceptor orbital of $CX{=}CH_2$ has nodal planes between X and C_α, and between C_α and C_β, and the coefficient of C_β is larger than the coefficient at X (1). For $X'CX{=}CH_2$ to be formed from the interaction of X′ with $CX{=}CH_2$, the primary overlap, of X′ with C_α ($\cdots$), must be in-phase (positive). With this requirement, it can be seen that the secondary overlap (depicted by double-headed arrows), between X′ and C_β, and between X′ and X, is out-of-phase (negative). Maximum

[a]Compounds have been numbered according to the convention for carbohydrate derivatives.

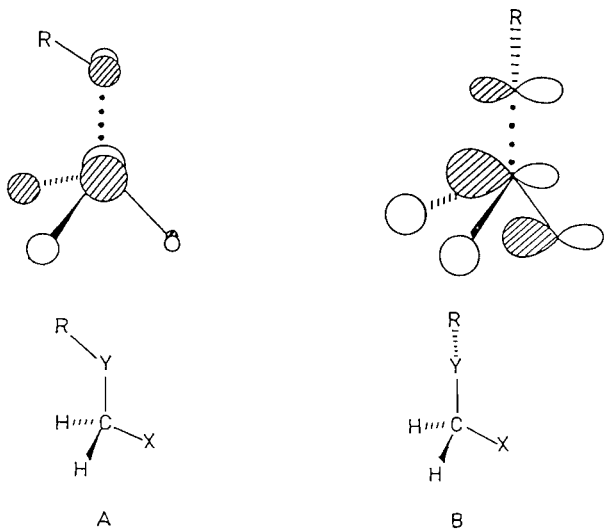

FIG. 2. The stabilizing orbital interaction that contributes to the HOMO of XCH_2YR. A, antiperiplanar conformation; B, perpendicular conformation.

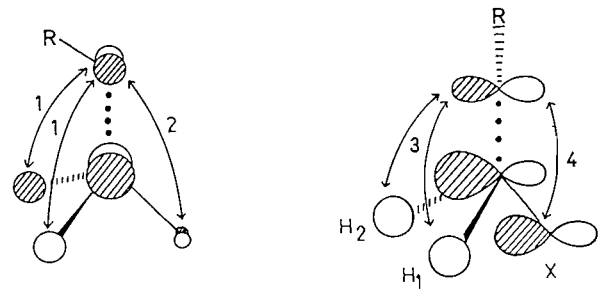

FIG. 3. The primary (···) and secondary (↷) overlap in the stabilizing orbital interactions of Fig. 2.

overlap between X′ and $CX{=}CH_2$ will therefore be achieved by an increase in the $C_\beta C_\alpha X'$ angle, and a concomitant decrease in the $X'C_\alpha X$ angle.

Figure 2 illustrates the application of the PMO procedure to C—Y torsion in XCH_2YR, with the interaction taken as $RY\cdots CH_2X$. In each conformation shown, the doubly occupied orbital is n_p, the *p*-type nonbonding orbital on Y, and the acceptor orbital is the unoccupied orbital of CH_2X that has the proper symmetry for non-zero primary overlap with n_p. In the antiperiplanar conformation, this is $\pi^*_{CH_2X}$, and in the perpendicular conformation, the acceptor orbital is $\sigma^*_{CH_2X}$. Since the σ* orbital lies lower than the π* orbital (6, 10), there is greater stabilization in the n–σ* interaction than in the n–π* interaction. This analysis accounts for the greater stability of the *gauche* conformations of XCH_2YR molecules in comparison to the *syn* or antiperiplanar conformations (4, 6); it also predicts a longer C—X bond in the more stable *gauche* conformation, because there is greater charge transfer to the antibonding C—X region in this case. Furthermore, if the CYR moiety of XCH_2YR is incorporated into a heterocyclohexane, the analysis can account for the existence of the anomeric and related (11) effects, and for the trends in these effects as both X and Y are varied (8).

Results and discussion

The purpose of this manuscript is to point out that the analysis of Fig. 1 can be incorporated into Fig. 2 to predict that the XCY bond angles of XCH_2YR molecules will differ systematically in the *gauche* and antiperiplanar conformations. Figure 3 is similar to Fig. 2, but now emphasizes the primary (····) and secondary

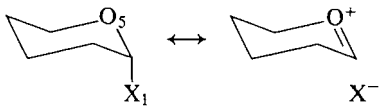

FIG. 4. The hyperconjugative interaction proposed for a 1-axially substituted pyranoside.

(↷) overlap in the $n-\pi^*$ interaction of the antiperiplanar conformation and the $n-\sigma^*$ interaction of the perpendicular conformation. In the antiperiplanar conformation, although the interaction is stabilizing and attractive with respect to the CH_2X group as a whole, the secondary overlap interactions 1 and 2 are both out-of-phase, and result in a repulsive force. If the CH_2X group is assumed to be rigid, the YCH and YCX angles cannot both increase.[4] Because the hydrogen atoms of $\pi^*_{CH_2X}$ have larger coefficients than X (6, 10), 1 is more repulsive than 2: the YCH angles increase, and the YCX angle decreases. Maximum overlap between RY and CH_2X is achieved by a *decrease* in the XCY angle from the idealized tetrahedral angle depicted in Fig. 3. This decrease reduces the secondary overlap 1 at the expense of a small increase in the secondary overlap 2.

In the perpendicular conformation, the secondary overlaps 3 and 4 are both negative, but 4 is more repulsive than 3. Maximum overlap between RY and CH_2X in this conformation can be achieved by minimizing overlap 4 at the expense of an increase in 3.[5] This leads to an *increase* in the XCY angle from the idealized tetrahedral angle depicted in Fig. 3.

Variations of the foregoing argument have been employed to account for methyl tilt angles in CH_3X molecules (12), and for bond angle trends in lactones and lactams (13).

To check the validity of the argument in the present case, quantitative PMO analyses (6) were performed on FCH_2OH in its antiperiplanar and perpendicular conformations, with particular reference to the interactions depicted in Fig. 3 and the charge distributions in the acceptor orbitals. At the 4-31G level, the optimized perpendicular structure is 5.27 kcal/mol more stable, and the optimized geometrical parameters are, perpendicular: C—F 1.404 Å, C—O 1.383 Å, ∠FCO 110.8°, $\angle OCH_1$ 107.7°, $\angle OCH_2$ 112.9°; antiperiplanar: C—F 1.386 Å, C—O 1.398 Å, ∠FCO 106.6°, ∠OCH 111.9°.

In the antiperiplanar conformation, the $2p$ atomic orbital coefficients on carbon and on fluorine in $\pi^*_{CH_2F}$ are C, 1.49; F, −0.18, and the $1s$ atomic orbital coefficients on the hydrogens are ±1.61 (out-of-phase with C_{2p}). In the perpendicular structure, the hybrid orbital depicted for carbon in Figs. 2 and 3 comprises C_{2s}, 0.45, and C_{2px}, −1.29; the hybrid orbital depicted for, e.g., fluorine in Figs. 2 and 3 comprises F_{2s}, 0.74, and F_{2px}, −0.42; the $1s$ coefficients are H_1, −0.73; H_2, −0.76. The secondary overlap associated with the $2s$ component of fluorine approximately cancels the secondary overlap associated with H_1 and H_2, because the fluorine is in the plane of the oxygen donor orbital and the hydrogens are not. Interaction 4 therefore dominates because of the $2px$ component of fluorine.

To carry this latter point further, additional quantitative PMO analyses were performed on the perpendicular structure, with the FCO angle decreased to 106.6°, the value in the antiperiplanar structure. At the smaller angle, the hydrogen atomic orbital coefficients increase, to H_1, −0.81; H_2, −0.88; the $2s$ component of the fluorine decreases, to 0.72, and the total overlap between O_{2px} and $\sigma^*_{CH_2F}$ decreases from 0.298 to 0.282. The changes in the atomic orbital coefficients on H_1, H_2, and on F reflect the adjustment of the charge distribution and secondary overlap to the smaller FCO angle.

Table 1 summarizes experimental data, taken from X-ray and neutron diffraction crystal structures, of α- and β-pyranoses and pyranosides (14–17), 1-axially and 1-equatorially oriented β-D-xylopyranosyl fluorides (18), and axial and equatorial tetrahydropyranyl acetals (16). In all of these structures the $O_5—C_1—X_1$ valence bond angle is systematically larger than the tetrahedral value when X is axial, and systematically smaller than the tetrahedral value when X is equatorial.

The larger than tetrahedral X—C—Y bond angle in 1-axially substituted pyranoses has been commented upon previously by Lemieux *et al.* (15), and rationalized in terms of the greater trigonal character of the central carbon atom (C_1) associated with the hyperconjugative interaction depicted in Fig. 4. However, such an argument would not account for the decrease in the X—C—Y bond angle that is observed in 1-equatorially substituted pyranoses. The PMO argument, on the other hand, anticipates both effects.

To probe these trends further, the bond angle variations in X—C—Y fragments were examined computationally on the model compounds XCH_2YH, in which X = NH_2, OH, SH, Cl, F, and Y = O, S, NH. The calculations were performed using GAUSSIAN 80 (19) with the 4-31G basis set, and full geometry optimization of all structures. To facilitate the discussion, Fig. 5 shows the conformations of XCH_2YH that correspond to local minima on the potential energy surface, and their relationship to the conformations of heterocyclohexanes.

Table 2 summarizes the relative energies of the XCH_2YH conformations, the optimized C—X and C—Y bond lengths, and the optimized X—C—Y bond angles. Although the individual values of these geometrical parameters are basis set

[4]An alternate argument supposes that the interaction of X with $RYCH_2$ tends to open the XCH angles. This interaction is the same in both conformations, and it will cause the XHC angles to be the same in both conformations, i.e., a rigid CH_2X group.

[5]For small changes in the XCY angle, the change in the primary overlap will be negligible.

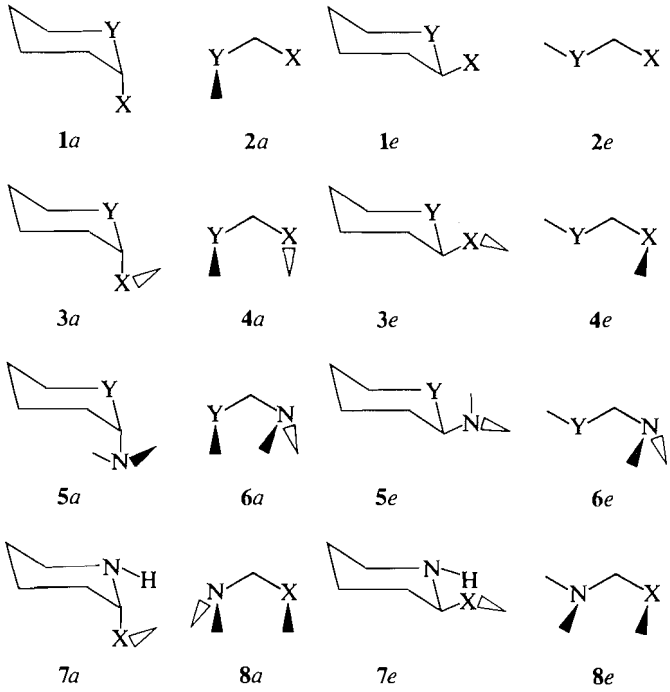

FIG. 5. Conformations of XCH_2YH molecules and their relationship to the conformations of 2-substituted heterocyclohexanes.

dependent, the trends are not (20–22). In each case, the minimum energy conformation of XCH_2YH corresponds to that conformation of the heterocyclohexane in which the substituent is axially oriented, in accord with the anomeric effect, and the bond length variations are consistent with the analysis of Fig. 2. The trends in the X—C—Y bond angles are also clear: the angle is larger than tetrahedral in conformations of the "*a*" series, and close to or smaller than tetrahedral in conformations of the "*e*" series in most cases.

Acid-catalyzed rearrangement of cyclobutanols. A novel rearrangement

E. LEE-RUFF AND FRED J. ABLENAS
Department of Chemistry, York University, Toronto, Ont., Canada M3J 1P3

Received July 29, 1986[1]

E. LEE-RUFF and FRED J. ABLENAS. Can. J. Chem. **65**, 1663 (1987).

The acid-catalysed dehydration–rearrangement reaction of α-thienyl cyclobutanols **3** and **4** resulted in the formation of tetrahydronaphtho[2,3-*b*]thiophenes **5***a* and **6***a*. The rearrangement to the linearly fused PAH system instead of the expected angularly fused system reflects α-scission of the cyclobutyl ring. A mechanism based on deuterium labelling studies is proposed to account for the product formation.

E. LEE-RUFF et FRED J. ABLENAS. Can. J. Chem. **65**, 1663 (1987).

La réaction acid-catalysée de transposition–deshydratation des α-thiénylcyclobutanols **3** et **4** conduit à la formation des tétrahydronaphto[2,3-*b*]thiophènes **5***a* et **6***a*. La transposition conduisant à un système PAH comportant une fusion linéaire plutôt qu'au système attendu comportant une fusion angulaire est le reflet d'une scission en α du noyau cyclobutyle. Afin d'expliquer la formation des produits observés, on propose un mécanisme qui est basé sur des études impliquant des atomes de deutérium comme marqueurs.

Bicyclic cyclobutanones with an α-aryl substituent undergo selective β-scission under acid catalysis to give tricyclic ketones by way of intramolecular orthoannelation of an intermediate carbocation (1–3). This observation has been used as a general approach towards the synthesis of polynuclear aromatic hydrocarbons (PAH) in which non-benzenoid and heterocyclic rings are incorporated in the PAH ring system as terminal units. These studies were also extended to bicyclic cyclobutanols bearing at least one α-aryl substituent. Acid reaction of typical bicyclic cyclobutanols effects dehydration and rearrangement to give angularly fused hydroarenes that are readily dehydrogenated to PAH's (4) (Scheme 1). The intermediate carbocations are the result of selective β-scission of the cyclobutanol ring and are stabilized by positive charge delocalizing groups such as a vinyl or heteroatom group. The cyclobutanols are readily obtained from the corresponding cyclobutanones, which in turn are prepared from aryl ketene cycloadditions to cycloolefins. As an extension to these studies we were interested in the possibility of cyclobutanols with α-heteroaromatic substituents undergoing similar transformations to give heteroaromatic PAH's. Both α- and β-thienylketene precursors are commercially available and such transformations would constitute a general synthetic route to PAH's incorporating a terminal thiophene nucleus. A number of these compounds are of interest in environmental chemistry and toxicology due to their presence in fossil fuel and coal sources and their mutagenic activity (5). In this study we report a different and heretofore unreported acid-catalyzed dehydration–rearrangement of two α-thienyl bicyclic cyclobutanols in which regiospecific α-ring opening is involved.

Results and discussion

The preparation of cyclobutanones **1** and **2** was accomplished by generating 2- or 3-thienylketene *in situ* by dehydrochlorination of the acid chloride with triethylamine in the presence of 1,3-cyclohexadiene. In each case a stereoisomeric mixture was obtained in which the *endo*-substituted product predominates and column chromatography on silica gel causes the equilibration to the thermodynamic *exo*-substituted product (6). The *endo*-substituted derivative is predicted to be the kinetic product based on orbital symmetry considerations of the $2\pi a + 2\pi s$ transition state (7).

Reduction of ketones **1** and **2** with excess lithium aluminum hydride gave alcohols **3** and **4** (X = H, Y = H) respectively as a mixture of diastereomers in 78–80% yields. The relative distribution of the diastereomers **3** and **4** is reflected by the diastereomeric distribution of the starting ketones **1** and **2**, indicating that hydride addition takes place stereospecifically. It would be anticipated from steric considerations that hydride addition proceeds from the *exo* face of the carbonyl group, giving the *endo* bicyclic alcohols **3** and **4**, although the stereochemistry of the alcohols could not be unequivocally assigned on the basis of the nmr data.

Reaction of a diastereomeric mixture of alcohol **3** in a 50:50 mixture of 10% aqueous H_2SO_4 and 95% ethanol proceeded to give a single product identified as the tetrahydronaphthothiophene **5***a*. The regiochemistry of the ring opening and annelation reaction was established by conversion of **5***a* to the known naphtho[2,3-*b*]thiophene (8) (7) upon dehydrogenation with DDQ. The assignment of **5***a* was based on the proton nmr spectrum, which exhibited a singlet at δ 6.3 ppm assigned to the *meso* vinylic proton. Labelling experiments and synthesis confirmed the assigned regiochemistry of **5***a*. Reduction of ketone **1** with lithium aluminum deuteride gave the reduced alcohol **3** in 81% yield with 100% retention of deuterium at the α-position, as was evident by mass spectrometry and nmr. Acid dehydration of 2-d_1-**3** with a 50:50 mixture of aqueous 10%

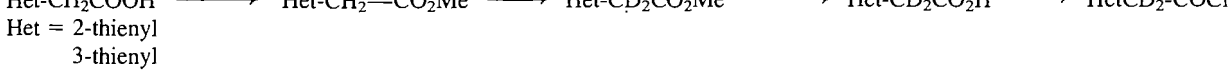
7

H_2SO_4 and 95% ethanol gave **5***b* in 49% yield, identical in all respects to **5***a* except that the singlet peak associated with the *meso* vinyl proton in **5***a* was absent. Mass spectrometric analysis of **5***b* indicated a 100% deuterium retention. Dehydrogenation of **5***b* provided **7** (X = D, Y = H) with 99% deuterium retention. The singlet signal at δ 8.32 ppm associated with the C-9 proton in **7** was absent in the monodeuterated derivative. Alternatively, the monodeuterated alcohol **3** (Y = D, X = H, 76% d_1 retention), in which the β-position was labelled, was prepared. This alcohol was available by lithium aluminum hydride reduction of the corresponding ketone **1** (d_1), which was obtained from the cycloaddition of 2-thienylketene (α-d_1) with 1,3-cyclohexadiene. The deuterated ketene precursor, the α,α-dideutero-2-thienylacetyl chloride, could be prepared by the sequence shown in Scheme 2.

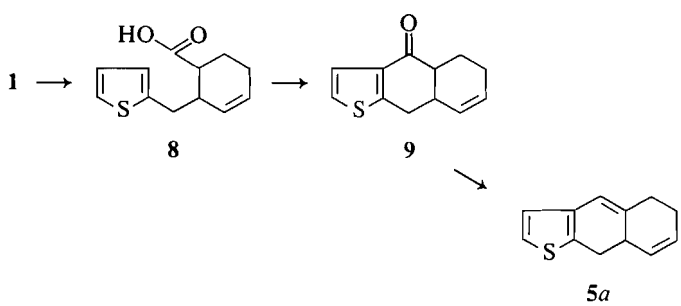


a, $SOCl_2$; b, CH_3OH; c, NaOMe, MeOD; d, NaOD, D_2O; e, H_3O^+; f, $SOCl_2$.

SCHEME 2

It is interesting to note that the deuteration exchange step c in the above scheme resulted not only in the exchange of the benzylic hydrogens but also the aromatic hydrogen at C-5 in the thiophene ring. Not surprisingly, this ring deuteration was reversed during the acid-catalyzed rearrangement of the resultant cyclobutanol **3** to the tetrahydroarene **5***b*. The 3-thienyl derivative did not undergo ring deuteration under these conditions.

Reaction of **3** (d_1, Y = D) with acid gave exclusively **5***c* (76% d_1 retention), which was converted to **7** (Y = D, X = H) with 47% d_1 retention. The position of the label was assigned on the basis of reduction in the intensity of the singlet at δ 8.37 ppm in the nmr spectrum when compared with the perhydroderivative **7** (X = Y = H). Further confirmation of structure **5***a* was obtained by independent synthesis. Ketone **1** was subjected to α-ring opening with sodium hydroxide in 1,2-dimethoxyethane to give carboxylic acid **8**. Ring closure to the ketone **9** was effected by converting **8** to the acid chloride with thionyl chloride and reaction of the acid chloride with $TiCl_4$ in dichloromethane. Standard reduction of ketone **9** with $LiAlH_4$ and acid-catalyzed dehydration provided **5***a*, identical in all respects with the sample obtained from the acid-catalyzed dehydration and rearrangement of alcohol **3**.



8 **9** **5***a*

Similarly the acid-catalyzed dehydration and rearrangement of cyclobutanol **4** provided the tetrahydronaphthothiophene **6***a* in 80% yield. The regiochemistry of the ring-opening reaction and olefinic sites was established by similar specific deuterium labelling experiments using the sequence:

4 (X = D, Y = H) → **6***b* → **7** (Y = D, X = H)

and

4 (X = H, Y = D) → **6***c* → **7** (Y = H, X = D)

The regiospecific formation of the tetrahydronaphthothiophenes can be rationalized according to the following scheme (Scheme 3). The bicyclic cyclobutyl cation **10** formed upon acid dehydration could undergo β-alkylation giving ion **11**. Deprotonation of **11** would give the cross-conjugated system **12**, which would be expected to equilibrate to the heteroaromatic compound **5***a*. The alternate mechanism that could account for α-ring opening of cyclobutyl cation **10** would involve a hydride shift to the bridgehead bicyclic cation **13** (Scheme 4). Its valence tautomeric form **14** could undergo β-alkylation giving **15**. However, analysis of the product obtained from the acid rearrangement of alcohols **3** and **4** indicated the exclusive formation of regioisomers **5** and **6** respectively, with no indication of the thermodynamic product **15** being present. The labelling experiments point to the absence of any equilibration of ion **10** by way of non-classical species (9) or hydride transfer

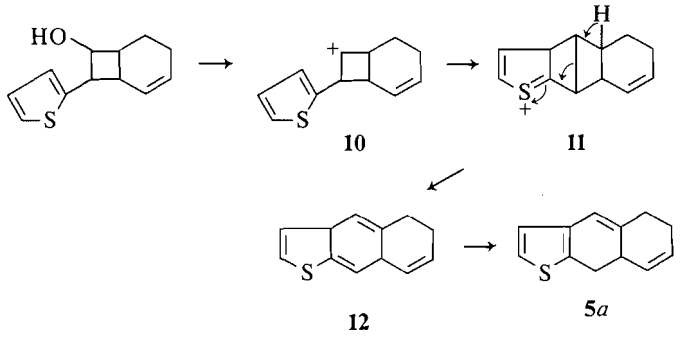
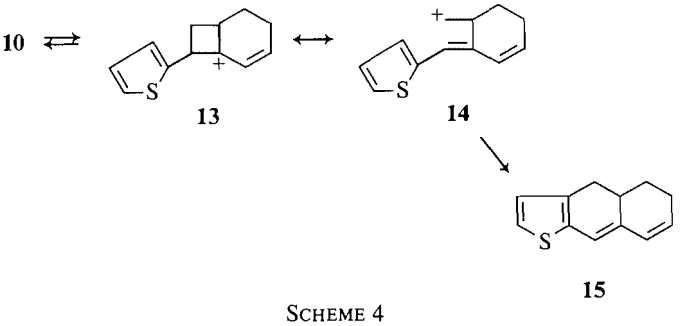


SCHEME 3



SCHEME 4

processes. The regiochemistry of the ring-opening reactions of these α-thienylbicyclic alcohols is in sharp contrast to the observed β-ring-opening reactions associated with the corresponding α-naphthyl and α-phenylbicyclic alcohols. The difference may be due in part to the greater nucleophilic character of the thiophene ring relative to a phenyl group. This greater nucleophilicity of thiophene would impart substantial stabilization to ions such as **11** leading to the observed α-ring-opening processes. Further studies are in progress to establish the generality of these unique rearrangements and to develop this methodology as a route to linear annelated thiopheno and related heterocyclic PAH's.

Experimental

The ^{1}H nmr spectra were recorded in $CDCl_3$ solution with TMS as an internal reference on a CFT-20 or AM-300 nmr spectrometer. Infrared spectra were recorded neat on NaCl discs on a Unicam SP1000 instrument, low resolution mass spectra were obtained on a VG Micromass 16F instrument, and high resolution mass spectra were obtained on a VG ZAB-E instrument. Deuterium incorporations based on mass spectra were corrected for natural isotopic abundances.

Anhydrous methanol was obtained by distilling A.C.S. grade methanol from magnesium methoxide. Methanol-*d* (99.5% *d*: CH_3OD) and LAD (98 at.% *d*) were obtained from the Aldrich Chemical Company. Toluene, triethylamine, and diethyl ether were dried with sodium.

Elemental analyses were performed by Guelph Chemical Laboratories.

2-Thienylacetyl chloride

This compound was prepared by the procedure of Miller *et al.* (10). Distillation at 39°C (0.05 Torr; 1 Torr = 133.3 Pa) afforded the acid chloride (95% yield); ir ν: 1805 cm^{-1}.

3-Thienylacetyl chloride

3-Thienylacetic acid (4.50 g, 32 mmol) was combined with thionyl chloride (3.5 mL, 1.5 equiv.) and heated at 60°C for 2 h. The oil was cooled and excess thionyl chloride evaporated off. Distillation afforded the acid chloride, bp 36°C (0.005 Torr) (lit. (11) bp 112°C), (4.90 g, 95%).

Methyl thienylacetates

2-Thienylacetyl chloride (1.25 g, 7.8 mmol) was added to dry methanol (3 mL) with stirring. After 30 min, saturated sodium bicarbonate solution (5 mL) was added and the solution extracted with dichloromethane (10 mL). The organic layer was dried ($MgSO_4$), filtered, and solvent removed to yield the crude ester, which was distilled, bp 50°C (0.06 Torr), to yield methyl 2-thienylacetate (0.99 g, 82%); ir ν: 1730 cm^{-1}; ^{1}H nmr δ: 7.2 (d, J = 5.4 Hz, H5), 6.9–7.2 (m, 2H), 3.83 (s, CH_2), 3.71 (s, CH_3) ppm.

Methyl 3-thienylacetate was obtained by a similar procedure. The crude ester was used for further reactions without purification; ir ν: 1730 cm^{-1}; ^{1}H nmr δ: 7.28 (dd, J = 5.4, 0.9 Hz, H5), 7.14 (m, H2), 7.04 (d, J = 5.4 Hz, H4), 3.70 (s, CH_3), 3.66 (s, CH_2) ppm.

α,α-d$_2$-Thienylacetyl chlorides

Methyl 2-thienylacetate (0.99 g, 6.4 mmol) was dissolved in methanol-*d* (1.0 mL) and added to a solution of sodium methoxide (0.3 *M*) in methanol-*d* (3.0 mL). After refluxing for 1 h, the methanol-*d* was evaporated off and the red oil redissolved in methanol-*d* (3.0 mL). After a further 1 h reflux, the solution was diluted with dichloromethane (10 mL) and washed with water (3 × 5 mL), dried ($MgSO_4$), filtered, and the solvent removed to yield the crude α,α-d_2 ester (0.784 g, 78%), ^{1}H nmr showing disappearance of the peak at δ 3.83 ppm due to the methylene group.

The ester was refluxed in sodium deuteroxide/deuterium oxide (4 *M*, 5 mL) for 1.5 h, cooled, and poured into ice/1 *M* hydrochloric acid. The resulting aqueous solution was extracted with dichloromethane (3 × 10 mL), and the organic layers combined, washed with water (10 mL), dried ($MgSO_4$), filtered, and solvent removed to yield the d_3-acid (0.61 g, 85%), mp 59–61°C (lit. (12) mp 62°C); ^{1}H nmr δ: 6.96 (s, H3, H4), 11.21 (s, O*H*) ppm; ms *m/z*: 145 (47), 144 (4), 100 (100).

The d_3-acid was converted to 5,α,α-trideuterio-(2-thienyl)-acetyl chloride by reaction with thionyl chloride (*vide supra*).

α,α-d_2-3-Thienylacetyl chloride was prepared by a similar sequence, although in this isomer the ^{1}H nmr shifts of the corresponding methyl ester occurred at δ 3.66 and 3.70 ppm (CH_2 and CH_3 respectively).

*8-(2-Thienyl)-bicyclo[4.2.0]oct-2-ene-7-one (**1**)*

2-Thienylacetyl chloride (1.00 g, 6.2 mmol) and 1,3-cyclohexadiene (3.0 mL, 5 equiv.) were dissolved in dry toluene (30 mL) and the solution warmed to 50°C. Triethylamine (0.98 mL, 7.0 mmol) was added dropwise and the solution stirred for 1 h.

The solution was poured onto ice and the organic layer removed. The aqueous layer was extracted with dichloromethane (30 mL) and the organic layers combined and washed successively with water (20 mL), 2 *M* hydrochloric acid (20 mL), saturated sodium bicarbonate solution (10 mL), and water (10 mL), dried ($MgSO_4$), filtered, and solvent removed to afford an oil (1.1 g).

The oil was chromatographed on silica gel (41 g) (dichloromethane:carbon tetrachloride (50:50) eluant) to yield **1** as an oil (0.40 g, 32%); ir ν: 1780 cm^{-1}; ^{1}H nmr δ, (*endo* isomer): 7.20 (d, J = 5.6 Hz, H5), 6.97 (m, 1H), 6.90 (m, 1H), 5.95 (m, 1H), 5.55 (m, 1H), 4.88 (d, J = 7.0 Hz, H8), 3.70 (m, 1H), 3.30 (m, 1H), 1.5–2.2 (m, 4H); (*exo* isomer): 7.20 (d, J = 5.6 Hz, H5), 6.97 (m, 1H), 6.90 (m, 1H), 6.10 (m, 1H), 5.97 (m, 1H), 4.27 (m, H8), 3.67 (m, 1H), 3.05 (m, 1H), 1.7–2.2 (m, 4H) ppm; *m/z*: 204 (100), 176 (38), 148 (55), 124 (96), 97 (91). This compound was air and light sensitive. *Exact Mass* calcd. for $C_{12}H_{12}OS$: 204.0609; found: 204.0618.

*8,5′-Dideuterio-8-(2-thienyl)-bicyclo[4.2.0]oct-2-ene-7-one (8,5′-d$_2$-**1**)*

Addition of triethylamine (0.41 mL, 1.0 equiv.) to a solution of 5′,α,α-trideuterio-(2-thienyl)-acetyl chloride (2.99 mmol) and 1,3-cyclohexadiene (1.50 mL, 5.2 equiv.) in dry toluene (20 mL) ultimately afforded the 8,5′-dideuterio cyclobutanone (186.5 mg, 30%). Integration of the ^{1}H nmr peak at δ 4.88 ppm indicated 88% deuterium retention at C8, as well as at C5 of the thiophene ring; ms *m/z*: 206 (100), 205 (91), 204 (24).

*8-(3-Thienyl)-bicyclo[4.2.0]oct-2-ene-7-one (**2**)*

The 3-thienyl isomer **2** of **1** was obtained by a similar procedure; **2** was obtained as an oil (33%); ir ν: 1790 cm^{-1}; ^{1}H nmr δ (endo isomer):

7.24 (d, J = 5.6 Hz, H5), 7.18 (s, H2), 6.88 (d, J = 5.6 Hz, H4), 5.99 (m, 1H), 5.50 (m, 1H), 4.70 (d, J = 7.0 Hz, H8), 3.70 (m, 1H), 3.25 (m, 1H), 1.5–2.2 (m, 4H); (*exo* isomer): 7.30 (d, J = 5.6 Hz, H5), 7.15 (m, H2), 7.00 (d, J = 5.6 Hz, H4), 6.13 (m, 1H), 5.99 (m, 1H), 4.17 (m, H8), 3.62 (m, 1H), 3.00 (m, 1H), 1.5–2.2 (m, 4H) ppm; ms m/z: 204 (100), 176 (35), 148 (58), 124 (98), 97 (95). This compound was air and light sensitive. *Exact Mass* calcd. for $C_{12}H_{12}OS$: 204.0609; found: 204.0615.

8-d_1-***2***

The 8-d_1 analogue of **2** was obtained by the cycloaddition reaction of the ketene derived from α,α-dideuterio-(3-thienyl)acetic acid. 8-d_1-**2** was obtained as an oil (10%), estimated by ^{1}H nmr to be 69% d_1, based on the integration of the H8 signal.

*8-(2-Thienyl)-bicyclo[4.2.0]oct-2-ene-7-ol (**3**)*

The diastereomeric mixture of cyclobutanones **1** (205.5 mg, 1.01 mmol) was dissolved in dry diethyl ether (3 mL), lithium aluminum hydride (43.0 mg, 4.5 equiv.) was added, and the solution stirred 1 h.

Ethyl acetate (1.0 mL) was added and the solution diluted with dichloromethane (5 mL) and washed with 2 *M* hydrochloric acid (5 mL), followed by saturated sodium bicarbonate solution (5 mL). The organic layer was dried ($MgSO_4$), filtered, and solvent removed to yield a diastereomeric mixture of cyclobutanols (192.9 mg).

Flash chromatography (silica gel, 21 g, dichloromethane eluant) afforded the *exo* isomer, followed by the *endo* isomer (161.3 mg total, 78%), white needles, mp 70–70.5°C (EtOH); ir ν: 3450 (br), 2950, 1430, 1130 cm^{-1}; ^{1}H nmr δ (*exo* isomer): 7.16 (dd, J = 5.1, 1.2 Hz, H5), 6.96 (dd, J = 5.1, 2.4 Hz, H4), 6.87 (m, H3), 5.85 (m, 2H), 4.30 (q, H7), 3.42 (t, H8), 2.67 (m, 1H), 2.35 (m, 1H), 1.65–2.2 (m, 5H); (*endo* isomer): 7.19 (dd, J = 5.1, 1.2 Hz, H5), 7.04 (m, H3), 6.98 (dd, J = 5.1, 3.6 Hz, H4), 6.02 (m, 1H), 5.70 (m, 1H), 4.70 (q, H7), 4.23 (t, H8), 3.12 (m, 1H), 2.84 (m, 1H), 2.33 (m, 1H), 1.6–2.1 (m, 4H) ppm; ms m/z: 206 (2), 188 (2), 148 (96), 126 (100). *Anal.* calcd. for $C_{12}H_{14}OS$: C 69.86, H 6.85, S 15.54; found: C 69.08, H 6.80, S 15.44. *Exact Mass* calcd. for $C_{12}H_{14}OS$: 206.0765; found: 206.0763.

7-d_1-***3***

Reduction of the diastereomeric cyclobutanones (198.8 mg, 0.975 mmol) by lithium aluminum deuteride (28.7 mg, 3.1 equiv.) afforded the 7-d_1 alcohols (163.4 mg, 81%); no ^{1}H nmr peak observed at δ 4.70 or 4.30 ppm; ms m/z: 207 (2), 189 (1), 149 (100), 127 (100), indicating 100% d_1.

8-d_1-***3***

Reduction of d_2-**1** (97.8 mg, 0.475 mmol) by LAH (21.1 mg, 4.7 equiv.) in diethyl ether (3 mL) afforded the d_2-alcohols (74.9 mg, 76%) determined by ^{1}H nmr to be 30% 8-d_1 and 57% 5′-d_1; ms m/z: 208 (11), 207 (20), 206 (20), 57 (100).

*8-(3-Thienyl)-bicyclo[4.2.0]oct-2-ene-7-ol (**4**)*

Reduction of the diastereomeric ketones **2** (270.8 mg, 1.33 mmol) by LAH (49.2 mg, 3.9 equiv.) in diethyl ether (4 mL) ultimately afforded the *endo* and *exo* isomers of **4** (85.1 and 101.8 mg, respectively, 68% total yield), mp 64.5–65.0°C (EtOH); ir ν: 3450 (br) (OH), 2950, 1430, 1130 cm^{-1}; ^{1}H nmr δ (*endo* isomer): 7.36 (m, H2), 7.30 (d, J = 5.4 Hz, H5), 7.05 (d, J = 5.4 Hz, H4), 6.00 (m, 1H), 5.75 (m, 1H), 4.70 (q, H7), 4.05 (t, H8), 3.10 (m, 1H), 2.82 (m, 1H), 2.35 (m, 1H), 1.6–2.1 (m, 4H); (*exo* isomer): 7.31 (d, J = 5.4 Hz, H5), 7.28 (s, H2), 7.03 (d, J = 5.4 Hz, H4), 5.83 (m, 2H), 4.30 (q, H7), 3.27 (t, H8), 2.68 (m, 1H), 2.30 (m, 1H), 1.7–2.2 (m, 5H) ppm; ms m/z: 206 (11), 188 (21), 148 (96), 126 (100). *Anal.* calcd. for $C_{14}H_{14}OS$: C 69.86, H 6.84, S 15.54; found: C 69.62, H 7.05, S 15.28.

7-d_1-***4***

Reduction of the diastereomeric mixture of ketones **2** (92.4 mg, 0.453 mmol) with lithium aluminum deuteride (20.0 mg, 4.2 equiv.) in diethyl ether (3.0 mL) ultimately afforded the 7-d_1 alcohol (84.4 mg, 90%); ^{1}H nmr indicated 100% d_1-labelling at the 7-position; ms m/z: 207 (5), 206 (2), 149 (30), 97 (100), 148 (2).

8-d_1-***4***

Reduction of the diastereomeric mixture of 69% d_1-**2** (53.0 mg, 0.259 mmol) with LAH (10.5 mg, 4.3 equiv.) in diethyl ether (2.0 mL) afforded 8-d_1-**4** (50.3 mg, 94%), determined to be 60% d_1 at position 8; ms m/z: 207 (1.2), 206 (0.5), 188 (1.2), 127 (100).

*4,4a,7,8-Tetrahydronaphtho[2,3-b]thiophene (**5**a)*

The alcohol **3** (62.9 mg, 0.305 mmol) was dissolved in 95% ethanol (4 mL) and added to refluxing 10% sulfuric acid (4 mL). After 1 h the solution was cooled and extracted with dichloromethane (3 × 5 mL), the organic layers combined and washed with water (5 mL), dried ($MgSO_4$), filtered, and solvent removed to provide an oil (59.5 mg), which was flash chromatographed (silica gel, petroleum ether) to afford ***5a*** (55.0 mg, 96%), mp 41–45°C; ^{1}H nmr δ: 7.04 (d, J = 5.0 Hz, H2), 6.83 (d, J = 5.0 Hz, H1), 6.27 (s, H9), 5.88 (m, 1H), 5.68 (m, 1H), 2.1–3.2 (m, 7H) ppm; ms m/z: 188 (100), 171 (66), 159 (23), 147 (57). *Anal.* calcd. for $C_{12}H_{12}S$: C 76.54, H 6.44, S 17.03; found: C 76.46, H 6.86, S 16.88.

5a *from **9***

The ketone **9** (53.1 mg, 0.260 mmol) in dry diethyl ether (3 mL) was reduced with LAH (12.1 mg, 0.318 mmol) to afford the crude 4,4,7,8,8a,9-hexahydro-9-hydroxynaphtho[2,3-*b*]thiophene (49.1 mg, 92%); ^{1}H nmr δ: 6.90 (s, 2H), 5.75 (m, 1H), 5.50 (m, 1H), 4.1–4.5 (m, 2H), 1.6–3.0 (m, 6H) ppm.

The crude alcohol was dissolved in dry toluene (10 mL) and refluxed in the presence of *p*-toluenesulfonic acid (4.2 mg, 0.020 mmol) for 1 h, cooled, basic alumina (3 g) added, and the solvent removed. The residue was placed on a column of basic alumina (10 g), and petroleum ether eluted ***5a*** (23.4 mg, 48% from **9**).

*4-Deuterio-4,4a,7,8-tetrahydronaphtho[2,3-b]thiophene (**5**c)*

The 8,5′-d_2-alcohol **3** was rearranged to yield ***5c*** (87%), determined to be 50% d_1 at position 4 only, due to a doublet of decreased intensity at δ 3.03 ppm in the ^{1}H nmr.

*9-Deuterio-4,4a,7,8-tetrahydronaphtho[2,3-b]thiophene (**5**b)*

The 7-d_1-alcohol **3** was rearranged to afford 100% d_1-***5c*** (49%), lacking the vinylic ^{1}H nmr signal of ***5a*** at δ 6.27 ppm.

*5,6,8a,9-Tetrahydronaphtho[2,3-b]thiophene (**6**a)*

The alcohol **4** (82.4 mg, 0.400 mmol) in 95% ethanol (3 mL) was rearranged in refluxing 10% sulfuric acid (3 mL) to afford ***6a*** (61.7 mg, 82%), mp 37–39°C; ^{1}H nmr δ: 7.01 (d, J = 5.0 Hz, H2), 6.84 (d, J = 5.0 Hz, H3), 6.27 (s, H4), 5.85 (m, 1H), 5.65 (m, 1H), 2.1–3.2 (m, 7H) ppm; ms m/z: 188 (100), 171 (56), 147 (51). This compound was not stable to air or light. *Exact Mass* calcd. for $C_{12}H_{12}S$: 188.0648; found: 188.0654.

*4-Deuterio-5,6,8a,9-tetrahydronaphtho[2,3b]thiophene (**6**b)*

The 7-d_1 alcohol **3** was rearranged to afford 100% d_1-***6b*** (53.3 mg, 98%), lacking a vinylic singlet at δ 6.27 ppm; ms m/z: 189 (100), 188 (1).

*9-Deuterio-5,6,8a,9-tetrahydronaphtho[2,3-b]thiophene (**6**c)*

The 8-d_1 alcohol **3** was rearranged to afford ***6c*** (16.1 mg, 36%), with a decreased ^{1}H nmr doublet at δ 2.92 ppm; ms m/z: 189 (82), 188 (100), indicating 45% d_1-labelling.

*Naphtho[2,3-b]thiophene (**7**)*

From ***5a***: The tetrahydroarene ***5a*** (35.6 mg, 0.189 mmol) was dissolved in dry toluene (40 mL) together with DDQ (103.9 mg, 2.4 equiv.) and refluxed 2 h. The slurry was cooled, concentrated on the rotovap, and passed through a column of basic alumina (10 g, petroleum ether:toluene (75:25)) to yield the arene **7** (86%), mp 187–188.5°C (pet. ether) (lit. (8) mp 189–190°C); ^{1}H nmr δ: 8.37 (s, H4), 8.33 (s, H9), 7.90–8.00 (m, H5,8), 7.51 (d, J = 5.6 Hz, H2), 7.45–7.50 (m, H6,7), 7.43 (d, J = 5.6 Hz, H1) ppm; ms m/z: 184 (100), 139 (16), 92 (11).

7 from **6**a

6*a* was dehydrogenated to yield the arene **7** (82%), identical to the arene derived from **5***a*.

4-d_1-*7 from* **6**b

6*b* was dehydrogenated to yield 100% 4-d_1-**7** (19%), lacking a signal for H4 at δ 8.37 ppm in the ^{1}H nmr; ms *m/z*: 185 (100), 184 (0).

4-d_1-*7 from* **5**b

5*b* was dehydrogenated to yield 41% 4-d_1-**7** (76%), with a signal at δ 8.37 ppm corresponding to 0.50 proton in the ^{1}H nmr; ms *m/z*: 185 (100), 184 (97).

9-d_1-*7 from* **5**c

5*c* was dehydrogenated to yield 100% 9-d_1-**7** (95%), lacking a signal at δ 8.33 ppm in the ^{1}H nmr; ms *m/z*: 185 (100), 184 (0).

9-d_1-*7 from* **6**c

6*c* was dehydrogenated to yield 9-d_1-**7** (19%), with a signal at δ 8.33 ppm corresponding to 0.59 proton in the ^{1}H nmr; ms *m/z*: 185 (89), 184 (100).

2-(2-Thenyl)-cyclohex-3-ene-1-carboxylic acid (8)

The cyclobutanone **1** (410.0 mg, 2.01 mmol) in 1,2-DME (3 mL) was refluxed with sodium hydroxide solution (1 *M*, 4.20 mL) for 2 h, cooled, diluted with water (50 mL), and acidified to pH 2. The resultant solution was extracted with dichloromethane (3 × 15 mL), the organic layers combined, washed with water, and then extracted with saturated sodium bicarbonate solution (5 × 15 mL).

The aqueous layers were combined and acidified to pH 5, causing a flocculant tan precipitate that was collected by vacuum filtration to afford **8** (231.4 mg, 50%), mp 94.0–94.5°C (EtOH:H_2O (50:50)); ir ν: 1660 cm^{-1}; ^{1}H nmr δ: 9.80 (br s, 1H), 7.20 (d, *J* = 5.1 Hz, H5), 7.00 (m, H4), 6.90 (m, H3), 5.60 (br s, 2H), 2.5–3.1 (m, 3H), 1.7–2.2 (m, 5H) ppm; ms *m/z*: 222 (1), 204 (11), 124 (11), 96 (61). *Anal.* calcd. for $C_{12}H_{14}O_2S$: C 64.83, H 6.34, S 14.42; found: C 64.41, H 6.40, S 14.65.

8a-H-*4,4a-7,8-Tetrahydro-9-oxonaphtho[2,3-*b*]thiophene (9)*

The carboxylic acid **8** (131.9 mg, 0.594 mmol) was dissolved in thionyl chloride (0.08 mL, 1.9 equiv.) and warmed to ca. 70°C for 2 h, cooled, and excess thionyl chloride removed on the rotovap by repeatedly dissolving the viscous oil in dichloromethane (1.0 mL) and removing volatiles on the rotovap (three times).

The crude acid chloride was dissolved in dry dichloromethane (3.0 mL) and titanium tetrachloride (0.07 mL, 1.1 equiv.) added at room temperature with stirring.

After 1 h, the solution was diluted with dichloromethane (10 mL) and washed with 2 *M* hydrochloric acid (10 mL), water (10 mL), then dried ($MgSO_4$), filtered, and solvent removed to afford an oil (147.8 mg), which was flash chromatographed (silica gel, dichloromethane:carbon tetrachloride (50:50)) to afford the ketone **9** (60.6 mg, 50%), mp 104–104.5°C (EtOH); ir ν: 1655, 1261 cm^{-1}; ^{1}H nmr δ: 7.02 (d, *J* = 5.0 Hz, H2), 6.81 (d, *J* = 5.0 Hz, H3), 5.80 (m, 1H), 5.52 (d, *J* = 6.3 Hz, 1H), 3.12 (m, 1H), 2.68 (m, 2H), 2.48 (m, 1H), 2.0–2.3 (m, 3H), 1.40 (m, 1H) ppm.

Preparation and thermal rearrangement of 2-(*tert*-butyldimethylsiloxy)-5-methyl-6-*exo*-[(*Z*)-3-methyl-1-butenyl]-4-*exo*-vinylbicyclo[3.1.0]hex-2-ene. A total synthesis of (±)-sinularene

EDWARD PIERS AND GRACE L. JUNG

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received December 24, 1986

EDWARD PIERS and GRACE L. JUNG. Can. J. Chem. **65**, 1668 (1987).

A total synthesis of the marine sesquiterpenoid (±)-sinularene (**1**) is described. The alcohol **19** was converted via an 8-step sequence into the bicyclic enone **28**. Conjugate addition of lithium divinylcuprate to the latter substance afforded mainly the ketone **30**, which was transformed into the enol silyl ether **6**. Thermolysis (220°C, 4.5 h) of **6** provided cleanly the bicyclic triene **7**, which, in two steps, was converted into the tricyclic olefinic ketone **34**. Hydrogenation of **34** and subsequent Wittig olefination of the resultant ketone **4** with methylenetriphenylphosphorane provided (±)-sinularene (**1**).

EDWARD PIERS et GRACE L. JUNG. Can. J. Chem. **65**, 1668 (1987).

On décrit une synthèse totale du sesquiterpénoïde marin (±)-sinularène (**1**). Utilisant une séquence de réactions impliquant 8 étapes, on a transformé l'alcool **19** en l'énone bicyclique **28**. L'addition conjuguée de divinylcuprate de lithium à cette dernière substance conduit principalement à la cétone **30** qui a été transformé en l'éther énolique silylé **6**. La thermolyse (220°C, 4,5 h) du composé **6** conduit proprement au triène bicyclique **7** qui, en deux étapes, est transformé en la cétone tricyclique oléfinique **34**. L'hydrogénation du composé **34** fournit la cétone **4** qui, par oléfination subséquente à l'aide du méthylènetriphénylphosphore et selon la méthode de Wittig, conduit au (±)-sinularène (**1**).

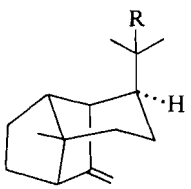
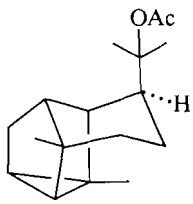
Introduction

The hydrocarbon (−)-sinularene was isolated some ten years ago from the soft coral *Sinularia mayi*, obtained from Telukdalam, Nias Island, Indonesia. This structurally unusual natural product was shown to possess the constitution and absolute stereochemistry depicted by structural formula **1** (1). Subsequently, two oxygenated sinularane-type sesquiterpenoids, (−)-12-acetoxysinularene (**2**) and (+)-12-acetoxycyclosinularene (**3**), were obtained from a dichloromethane extract of



1 R = H
2 R = OAc



3

Clavularia inflata, collected near Laing Island, Papua – New Guinea (2). To our knowledge, three total syntheses of (±)-sinularene (**1**) have been reported (3–5) in addition to that described herein. A preparation of (±)-12-acetoxysinularene (**2**) has also been accomplished (6). We report herein the details of our total synthesis of racemic sinularene (**1**).[1]

Results and discussion

(a) General considerations

If, in a retrosynthetic sense, one "converts" the olefinic double bond of **1** into a carbonyl group (to provide the ketone **4**) and then disconnects the C-8—C-9 single bond with concomitant functionalization at C-9, one would arrive at the substituted bicyclo[3.2.1]octanone **5** (X = leaving group). The conversion, in a synthetic sense, of **5** into the tricyclic ketone **4** would involve a straightforward intramolecular alkylation. Compound **4** had already served as an intermediate in the Collins–Wege total synthesis of (±)-sinularene (**1**) (3).

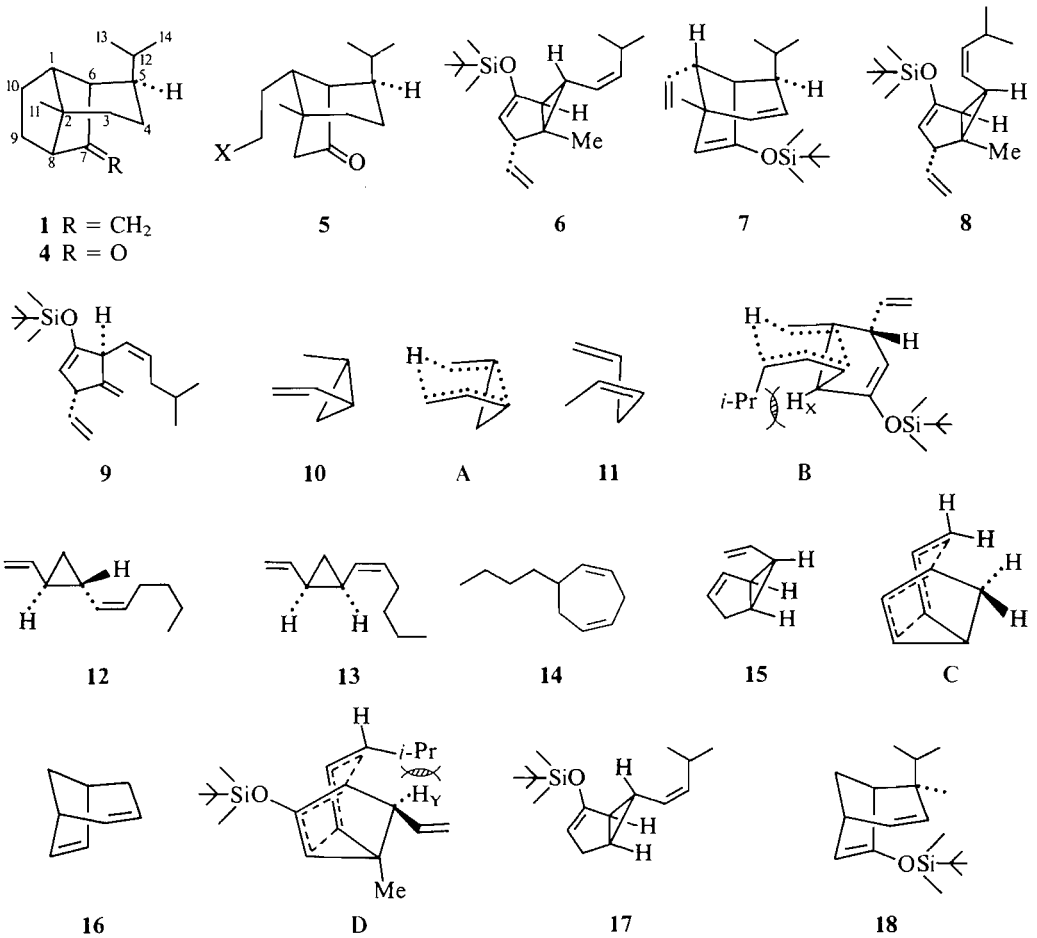
[1]For a preliminary account of this work, see ref. 7.

In view of the results obtained from our earlier studies (8, 9) on the thermal rearrangement of 6-*exo*-(1-alkenyl)bicyclo[3.1.0]hex-2-ene systems as a method for preparing substituted bicyclo[3.2.1]octa-2,6-dienes, we envisaged that an interesting total synthesis of (±)-sinularene (**1**) might be effected via a route in which the key step would involve thermal (Cope) rearrangement of a highly functionalized bicyclo[3.1.0]hex-2-ene such as **6**. If this reaction were to proceed in the desired manner, the product would be the substituted bicyclo[3.2.1]octa-2,6-diene **7**. It seems evident that suitable functional group manipulations would readily transform **7** into the required ketone **5**.

Presumably, the desired Cope rearrangement of **6** would involve isomerization of **6**, via a diradical intermediate (10*a*), into the epimer **8**, which would then undergo a concerted bond reorganization (10*b*, 11–13) to produce **7**. However, it should be noted that, in theory, thermolysis of **6** could lead to rearrangement processes other than the desired Cope reaction. For example, it is possible that a homo-[1,5]-sigmatropic hydrogen migration (13, 14) from the angular methyl group to C-2 of the (*Z*)-3-methyl-1-butenyl side chain could occur. This process would form, at least initially, the highly substituted (and probably unstable) cyclopentene **9**.

A clear-cut prediction as to which rearrangement pathway would be preferred is not straightforward. For the thermal conversion of (*Z*)-1-methyl-2-vinylcyclopropane (**10**) into (*Z*)-1,4-pentadiene (**11**), the energy of activation E_a is 31.2 kcal/mol ($\log A = 11.03\ s^{-1}$) (15). Presumably, this "simplest" homo-[1,5]-sigmatropic hydrogen shift is a concerted process that proceeds by way of a transition state that can be represented by **A** (13, 14). The presumed transition state (see **B**) for the analogous transformation of **6** into **9** would be destabilized by a notable steric interaction between the isopropyl group and H_X and, therefore, the energy of activation for this reaction would be expected to be significantly larger than that of **10** → **11**.

Turning now to Cope rearrangements, it is well known (10–13) that the rate-determining step of rearrangement of most *trans*-divinylcyclopropane systems is the epimerization of the *trans* compound to the corresponding *cis*-divinylcyclopropane.



1 R = CH_2
4 R = O

5 **6** **7** **8**

9 **10** **A** **11** **B**

12 **13** **14** **15** **C**

16 **D** **17** **18**

For example, the E_a values associated with the thermal conversions of **12** and **13** into the cycloheptadiene **14** are 32.8 (log A = 14.54 s^{-1}) and 20.5 kcal/mol (log A = 10.70 s^{-1}), respectively (16).

For the thermal rearrangement of 6-*endo*-vinylbicyclo-[3.1.0]hex-2-ene (**15**) into bicyclo[3.2.1]octa-2,6-diene (**16**), presumably via transition state **C** (10*b*, 11–13), the energy of activation (E_a) is 22.9 kcal/mol (log A = 11.7 s^{-1}) (17). Even though the Cope transition state for the conversion of **8** into **7** would suffer from a significant nonbonded interaction between the isopropyl group and H_Y (see **D**), it is unlikely that this repulsion would raise the value of E_a for this process to the region of 32–35 kcal/mol. Therefore, it seems reasonable to propose that the slow step of the overall conversion of **6** into **7** would be the isomerization of **6** into **8**. Furthermore, if one assumes (*a*) that the E_a value associated with the latter conversion would be similar to that for **12** → **13** (32.8 kcal/mol) and (*b*) that E_a for **6** → **9** (via transition state **B**) would be significantly *higher* than that of **10** → [**A**] → **11** (31.2 kcal/mol), then it does not appear unreasonable to conclude that thermolysis of **6** would proceed in the desired (Cope) sense to provide **7**. In this connection, it is pertinent to point out that earlier work (9, 18) had shown that thermolysis of **17** proceeded smoothly to give the diene **18**. Of course, the substrate **17** lacked an angular (C-5) methyl group and, therefore, a homo-[1,5]-sigmatropic hydrogen migration (cf. **6** → **9**) was precluded. Nevertheless, the successful conversion of **17** into **18** showed that a Cope rearrangement via a transition state resembling **D** was, indeed, a viable process.

(b) Synthesis and thermolysis of compound **6**

Treatment of a tetrahydrofuran (THF) solution of 1-lithio-3-methyl-1-butyne with 2-methylpropenal provided, in excellent yield, the alcohol **19** (see Scheme 1). Subjection of the latter substance to a triethyl orthoacetate-based Claisen rearrangement process (19) gave, stereoselectively, the expected ester **20** (58%), which was hydrolyzed with base to give the acid **21**. Conversion (oxalyl chloride, hexane) of **21** into the corresponding acid chloride **22**, followed by reaction of the latter compound with diazomethane in diethyl ether, gave the diazo ketone **23**. Copper(II) acetylacetonate-catalyzed cyclization of **23** produced, in 52% overall yield from the ester **20**, the substituted bicyclo[3.1.0]hexan-2-one **24**. In the ^1H nmr spectrum of **24**, the protons H_X and H_Y give rise to a doublet (δ 1.69, J_{XY} = 3 Hz) and a doublet of doublets (δ 1.87, J_{XY} = 3 Hz, J_{YZ} = 1.7 Hz), respectively. The magnitude of the H_X–H_Y coupling constant shows that, as expected, these two cyclopropyl protons have a *trans* relationship (20). The long-range coupling between H_Y and H_Z was confirmed by an appropriate decoupling experiment (see Experimental).

Hydrogenation of **24** in the presence of Lindlar's catalyst (21) provided the keto alkene **25**. The expected stereochemistry of the alkene double bond in **25** was confirmed by the ^1H nmr spectrum, which shows that J_{XY} = 11.5 Hz, a coupling constant typical of mutual coupling between *cis* vicinal alkene protons.

To allow for the introduction of an *exo* vinyl group to the C-4 position of the bicyclic ketone **25**, it was necessary to transform **25** into the corresponding enone **28**. To this end, **25** was subjected to Reich's (22) "one-pot" selenenylation – selenoxide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12

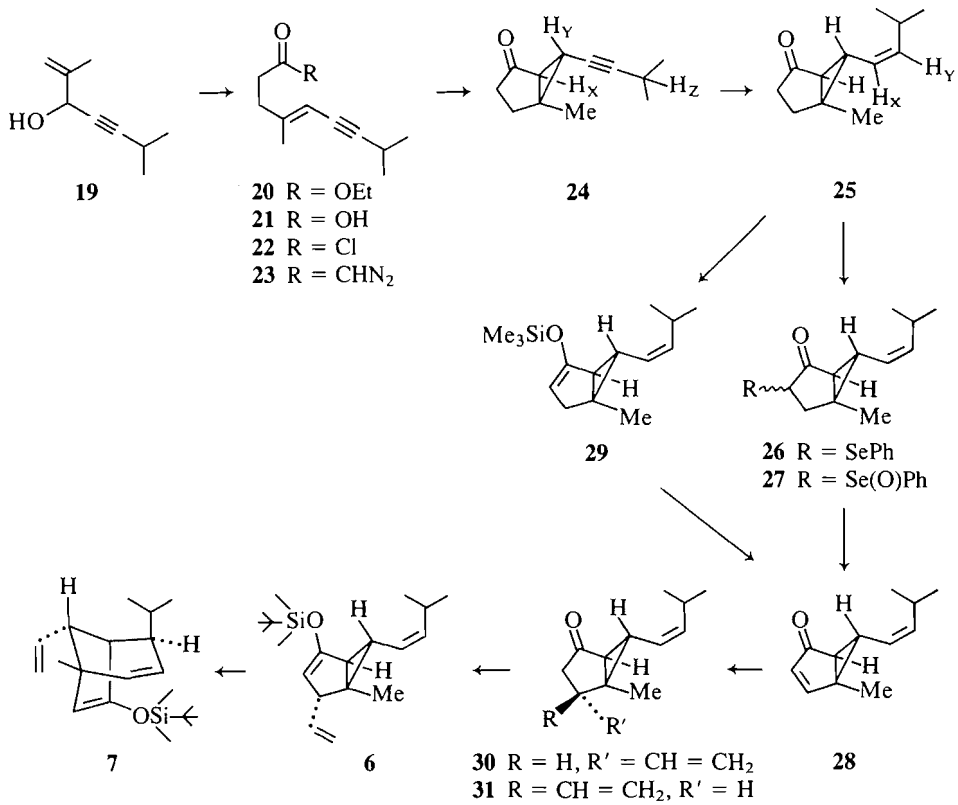

SCHEME 1

elimination sequence involving the intermediates **26** and **27**. However, this procedure provided the enone **28** in mediocre yield (50% at best). Other procedures, in which the α-phenylseleno ketone **26** was isolated prior to oxidation, were even less efficient.

Better results were obtained by application of the method reported by Saegusa and co-workers (23). Thus, conversion (Me_3SiI, Et_3N, CH_2Cl_2, −78°C) of the ketone **25** into the rather unstable enol silyl ether **29**, followed by immediate treatment of the latter substance with palladium(II) acetate in dry acetonitrile, gave, in 78% yield, a colorless oil. Analysis of this material by gas–liquid chromatography (glc) showed that it consisted of a mixture of the desired enone **28** (~85%) and the ketone **25** (~15%). Since efforts to effect efficient chromatographic separation of **25** and **28** proved fruitless, the mixture was employed for the next synthetic step.

Reaction of an 85:15 mixture of **28** and **25** with lithium divinylcuprate in diethyl ether (−30°C to room temperature) provided an oil that, on the basis of an analysis by glc, consisted of an 83:9:8 mixture of the desired product **30**, the epimer **31**, and the ketone **25**, respectively.[2] Separation of this mixture by column chromatography on silica gel provided the pure products **30** (46% from **25** via **29** and **28**) and **31** (6% from **25**).

Conjugate addition of divinylcuprate to the enone **28** would be expected to take place primarily from the less hindered convex face of the molecule to provide **30** as the predominant product. This expectation was confirmed by ^1H nmr spectroscopy. Thus, analysis of the ^1H nmr spectrum of the major product **30**, along with suitable decoupling experiments, showed that the resonances due to H_J, H_K, H_L, H_M, and H_N appear at δ 2.25, 1.89, 2.91, 2.15, and 2.67, respectively. In a nuclear Overhauser enhancement (nOe) difference experiment, irradiation at δ 2.15 (H_M) caused enhancement of the signals at δ 2.25, 2.91, and 2.67 (H_J, H_L, H_N, respectively). This result showed that, in the major conjugate addition product, H_L is *endo* to the bicyclic ring system and, therefore, the vinyl group must have an *exo* orientation.

Further evidence for the stereochemistry of **30** and **31** was provided by the magnitude of the mutual coupling constants associated with the protons H_J, H_K, and H_L in the two compounds. A molecular model indicates that, in compound **30**, the dihedral angle between H_K and H_L is close to 90° and, therefore, these protons would be expected to be only weakly coupled. Indeed, in a decoupling experiment, irradiation at δ 2.91 (H_L) caused the signal due to H_J (δ 2.55) to collapse from a pair of doublets (J_{JK} = 18.5 Hz, J_{JL} = 8 Hz) to a doublet (J_{JK} = 18.5 Hz), but did not affect the resonance (δ 1.89) derived from H_K, which remained a doublet with J_{JK} = 18.5 Hz. On the other hand, analysis of the ^1H nmr spectrum of the minor conjugate addition product **31**, along with appropriate decoupling experiments, showed that proton H_L (δ 2.91) is coupled to both H_J (δ 2.08, J_{JL} = 9.5 Hz) and H_K (δ 2.20–2.29, overlapped with the signal due to H_M, J_{KL} = 9.0 Hz). Considering the size of the H_J—H_L and H_K—H_L dihedral angles in compound **31** (molecular model), the magnitudes of these coupling constants are reasonable.

Routine conversion of the ketone **30** into the enol silyl ether **6** (96%) set the stage for investigating the "crucial" thermolysis of the latter substance. In the event, when a benzene solution of **6** was heated (sealed tube) at 220°C for 4.5 h, a single product was formed in 86% yield. It was gratifying to find that this material

[2]Interestingly, reaction of **28** with vinylmagnesium bromide in the presence of a catalytic amount of copper(I) bromide – dimethyl sulfide complex was somewhat less stereoselective, producing (63% yield) epimers **30** and **31** in a ratio of about 70:30, respectively.

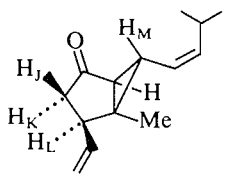
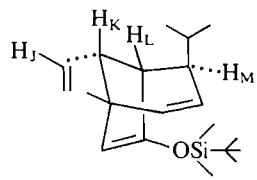
30



31

was the desired bicyclo[3.2.1]octa-2,6-diene **7**. No evidence could be found for the formation of compound **9**, which would have been derived from a homo-[1,5]-sigmatropic hydrogen migration (*vide supra*). Therefore, our expectation (hope?) that the Cope rearrangement process would be energetically more favorable than the sigmatropic hydrogen shift proved to be valid.

The constitution and relative stereochemistry of **7** was fully corroborated by the spectral data derived from this substance. For confirmation of the stereochemical assignment, the ^{1}H nmr spectrum was particularly useful. For example, suitable decoupling experiments showed that H_K, H_L, and H_M give rise to a doublet (δ 2.46, J_{JK} = 9.0 Hz), a broad singlet (δ 2.26), and a multiplet (δ 1.92–1.97), respectively, and that the H_K–H_L and H_L–H_M couplings are very weak. The latter obervations are in accord with the stereochemistry shown in **7**, since, in the conformationally rigid structure of this molecule, the H_K–H_L and H_L–H_M dihedral angles are both close to 90° (molecular model).



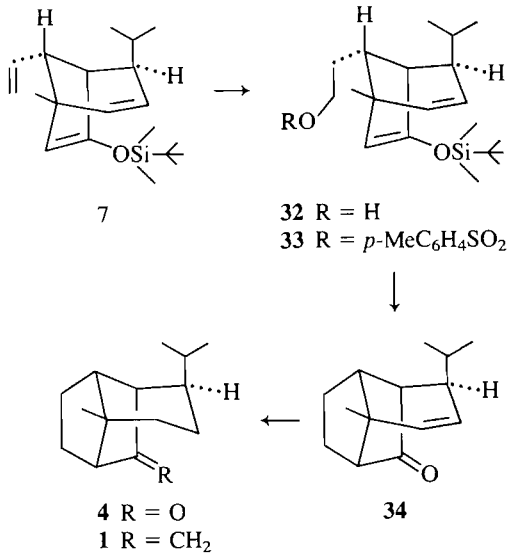
7

(c) Conversion of compound 7 into (±)-sinularene (1)

Treatment of the triene **7** with disiamylborane (24) in THF (0°C to room temperature), followed by oxidation of the resultant trialkylborane with alkaline hydrogen peroxide, effected clean, chemoselective functionalization of the vinylic double bond. When the resultant primary alcohol **32** (see Scheme 2) was treated with *p*-toluenesulfonyl chloride and 4-dimethylaminopyridine in dichloromethane at room temperature, the product was not the initially expected *p*-toluenesulfonate **33**, but proved to be the tricyclic ketone **34** (68% from the triene **7**). Evidently, under the conditions of the *p*-toluenesulfonylation reaction or during the subsequent work-up procedure, the initially formed product **33** underwent a solvolytic ring closure with accompanying cleavage of the silyl ether linkage. In any case, the direct, efficient conversion of **32** into **34** was a pleasing result.

Hydrogenation of **34** in methanol in the presence of palladium-on-carbon gave, in 91% yield, the ketone **4**. The ^{1}H nmr and infrared (ir) spectra of this material were found to be identical with those derived from the same compound previously prepared by Collins and Wege (3).[3]

The ketone **4** had previously been converted into (±)-sinularene (**1**) via a three-step sequence of reactions (3). However, we have found that this transformation could be performed conveniently in a single operation by treatment of **4** with an



7

SCHEME 2

excess of methylenetriphenylphosphorane in refluxing THF. Although the Wittig reaction was slow, (±)-sinularene (**1**) was formed cleanly and efficiently (78%). The material thus obtained was spectrally identical with (±)-sinularene previously prepared by Oppolzer *et al.* (4).[4]

Experimental

General

Distillation temperatures are uncorrected. Infrared (ir) spectra were recorded on a Perkin–Elmer model 710B spectrophotometer and were calibrated using the 1601 cm^{-1} band of polystyrene film. Proton (^{1}H) and carbon (^{13}C) nuclear magnetic resonance (nmr) spectra were recorded on deuteriochloroform solutions using tetramethylsilane as an internal standard. In cases of compounds containing a *tert*-butyldimethylsilyl group, the resonance positions were determined relative to the chloroform signal (δ 7.25). Analytical gas–liquid chromatography (glc) was performed with Hewlett–Packard models 5832A (columns: 6 ft × 0.125 in., 5% OV-17 on 80–100 mesh Chromosorb W (HP); 6 ft × 0.125 in., 5% OV-210 on 80–100 mesh Chromosorb W (HP); 10 ft × 0.125 in., 10% SE-30 on 80–100 mesh Chromosorb W (HP)) and 5880A (column: 25 m × 0.21 m fused silica column coated with cross-linked SE-54) gas chromatographs. Thin-layer chromatography (tlc) was accomplished using commercial aluminum-backed silica gel plates (E. Merck, Type 5539). Unless otherwise noted, conventional column chromatography was performed using 70–230 mesh silica gel (E. Merck), while flash column chromatography was carried out with 230–400 mesh silica gel (E. Merck). High resolution mass spectrometric measurements were recorded on a Kratos/AEI MS-50 mass spectrometer.

2,6-Dimethyl-1-hepten-4-yn-3-ol (19)

To a cold (−78°C), stirred solution of 3-methyl-1-butyne (0.375 mL, 3.67 mmol) in dry THF (5 mL) (argon atmosphere) was added a solution of *n*-butyllithium (4.04 mmol) in hexane, and the mixture was stirred at −30°C for 1 h. 2-Methylpropenal (0.34 mL, 4.04 mmol) was added dropwise, the mixture was stirred for 1 h at −30°C, and then was poured into saturated aqueous ammonium chloride. The resultant mixture was extracted thoroughly with ether. The combined extract was washed successively with saturated aqueous ammonium chloride, saturated aqueous sodium bicarbonate, and brine, and then was dried ($MgSO_4$). Removal of the solvent (water aspirator), followed by distillation (air-bath temperature 67–72°C/0.1 Torr; 1 Torr = 133.3 Pa) of the residual yellow oil, provided 480 mg (95%) of the alcohol **19** as a

[3]We thank Professor Wege for copies of the ^{1}H nmr and ir spectra of (±)-**4**.

[4]We thank Professor Oppolzer for copies of the ^{1}H nmr, ir, and mass spectra of (±)-sinularene (**1**).

clear, colorless oil that exhibited ir (film): 3350, 2220, 1650 cm^{-1}; ^1H nmr (80 MHz) δ: 1.17 (d, 6H, J = 7 Hz), 1.77 (br s, 1H, exchanges with D_2O), 1.85 (br s, 3H), 2.61 (d septet, 1H, J = 2, 6.5 Hz), 4.77 (br s, 1H), 4.90 (br s, 1H), 5.15 (br s, 1H). *Exact Mass* calcd. for $C_9H_{14}O$: 138.1045; found: 138.1044.

*Ethyl (*E*)-4,8-dimethyl-4-nonen-6-ynoate (**20**)*

A stirred mixture of the alcohol **19** (460 mg, 3.33 mmol), triethyl orthoacetate (3.05 mL, 16.6 mmol), and propanoic acid (0.015 mL, 0.2 mmol) was heated at 130°C for 20 h. Most of the triethyl orthoacetate was removed by fractional distillation at atmospheric pressure. The residual oil was subjected to flash column chromatography (125 g of silica gel, elution with 1:25 ether – petroleum ether). Distillation (air-bath temperature 81–86°C/0.1 Torr) of the oil obtained from the appropriate fractions gave 402 mg (58%) of the ester **20** as an odoriferous, colorless oil that exhibited ir (film): 1730 cm^{-1}; ^1H nmr (400 MHz) δ: 1.19 (d, 6H, J = 7 Hz), 1.25 (t, 3H, J = 7 Hz), 1.87 (s, 3H), 2.36–2.45 (m, 4H), 2.70 (septet, 1H, J = 7 Hz), 4.13 (q, 2H, J = 7 Hz), 5.29 (br s, 1H). *Exact Mass* calcd. for $C_{13}H_{20}O_2$: 208.1463; found: 208.1453.

*(*E*)-4,8-Dimethyl-4-nonen-6-ynoic acid (**21**)*

A stirred mixture of the ester **20** (500 mg, 2.4 mmol), potassium hydroxide (276 mg, 2.88 mmol), water (1 mL), and methanol (10 mL) was refluxed for 4 h. The solution was cooled to room temperature, washed twice with petroleum ether, filtered through a layer of Celite, cooled to 0°C, and acidified with 10% hydrochloric acid. The resultant mixture was extracted thoroughly with ether. The combined extract was dried ($MgSO_4$) and the solvent was removed under reduced pressure. The residual oil was crystallized from hexane at −78°C to furnish 294 mg (68%) of the acid **21** as a colorless oil that exhibited ir (film): 3300–2500 (br), 1705 cm^{-1}; ^1H nmr (80 MHz) δ: 1.22 (d, 6H, J = 7 Hz), 1.90 (s, 3H), 2.30–3.00 (m, 5H), 5.30 (br s, 1H), 10.85 (br s, 1H). *Exact Mass* calcd. for $C_{11}H_{16}O_2$: 180.1150; found: 180.1151.

*(*E*)-4,8-Dimethyl-4-nonen-6-ynoyl chloride (**22**)*

A stirred solution of the acid **21** (9.75 g, 54.1 mmol) and oxalyl chloride (14.2 mL, 162.4 mmol) in dry hexane (235 mL) was refluxed under an atmosphere of argon for 1 h. The solvent and excess oxalyl chloride were removed under reduced pressure (water aspirator) and the brown residue was distilled (air-bath temperature 94–99°C/0.1 Torr) to afford 10.3 g (95%) of the acid chloride **22** as a pale yellow oil. This material exhibited ir (film): 2200, 1790, 1623 cm^{-1}; ^1H nmr (80 MHz) δ: 1.20 (d, 6H, J = 7 Hz), 1.88 (s, 3H), 2.32–3.13 (m, 5H), 5.31 (br s, 1H). *Exact Mass* calcd. for $C_{11}H_{15}{}^{37}ClO$: 200.0782; found: 200.0783.

*5-Methyl-6-*exo*-(3-methyl-1-butynyl)bicyclo[3.1.0]hexan-2-one (**24**)*

To a cold (0°C), stirred solution of diazomethane (240 mg, 5.67 mmol) in ether (15 mL) was added dropwise, via a flame-polished pipette, a solution of the acid chloride **22** (250 mg, 1.26 mmol) in ether (3 mL). The resulting solution was stirred at 0°C for 30 min and at room temperature for 1 h. The residual diazomethane was dispelled by bubbling argon through the yellow solution, via a flame-polished pipette, for 30 min. Removal of the solvent gave 250 mg of the crude diazo ketone **23** as a viscous yellow oil. This material, which was not purified further, exhibited ir (film): 2200, 2085, 1633 cm^{-1}.

To a stirred suspension of $Cu(acac)_2 \cdot H_2O$ (24 mg, 0.092 mmol) in refluxing dry benzene (7 mL), under an atmosphere of argon, was added dropwise a solution of the crude diazo ketone **23** (250 mg, 1.23 mmol) in dry benzene (3 mL). The resulting dark brown mixture was refluxed for 1 h and then was cooled to room temperature. Most of the benzene was removed carefully under reduced pressure (water aspirator) and the residual material was subjected to flash column chromatography (70 g of silica gel, elution with 1:3 ether – petroleum ether). Disillation (air-bath temperature 85–88°C/0.1 Torr) of the oil thus obtained provided 178 mg (81% from the acid chloride **22**) of the bicyclic ketone **24** as a colorless oil that exhibited ir (film): 1725, 1172 cm^{-1}; ^1H nmr (400 MHz) δ: 1.14 (d, 6H, J = 7 Hz), 1.44 (s, 3H), 1.69 (d, 1H, J = 3 Hz), 1.87 (overlapped dd, 1H, J = 3, 1.7 Hz), 1.94–2.14 (m, 4H), 2.53 (d septet, 1H, J = 1.7, 7 Hz). Decoupling experiment: irradiation at δ 1.87 caused the signals at δ 1.69 and 2.53 to collapse to a singlet and a septet (J = 7 Hz), respectively. *Anal.* calcd. for $C_{12}H_{16}O$: C 81.76, H 9.16; found: C 81.69, H 9.20. *Exact Mass* calcd.: 176.1201; found: 176.1196.

*5-Methyl-6-*exo*-[(*Z*)-3-methyl-1-butenyl]bicyclo[3.1.0]hexan-2-one (**25**)*

A suspension of 5% palladium on calcium carbonate (49 mg, prepared with lead acetate as described by Lindlar and Dubois (21)) in dry pentane (7 mL) was prehydrogenated at room temperature and atmospheric pressure. To the mixture was added dropwise a solution of the alkyne **24** (973 mg, 5.53 mmol) in dry pentane (3 mL) and the reaction mixture was stirred efficiently under an atmosphere of hydrogen. The progress of the reaction was monitored by glc, which showed that the starting material had been consumed after a period of 3 h. Filtration of the mixture through a layer of Celite and concentration of the filtrate gave a colorless oil that was subjected to flash column chromatography (125 g of silica gel, elution with 1:5 ether – petroleum ether). Distillation (air-bath temperature 78–80°C/0.1 Torr) of the oil thus obtained afforded 900 mg (91%) of the keto alkene **25** as a colorless oil, which exhibited ir (film): 1719, 1650 cm^{-1}; ^1H nmr (400 MHz) δ: 0.98, 1.00 (d, d, 3H each, J = 7 Hz), 1.32 (s, 3H), 1.57 (poorly resolved d, 1H, J = 2 Hz), 1.90–2.25 (m, 5H), 2.60–2.73 (m, 1H), 4.91 (overlapped dd, 1H, J = 11.5, 10 Hz), 5.36 (overlapped dd, 1H, J = 11.5, 10 Hz). *Exact Mass* calcd. for $C_{12}H_{18}O$: 178.1358; found: 178.1357.

*5-Methyl-6-*exo*-[(*Z*)-3-methyl-1-butenyl]bicyclo[3.1.0]hex-3-en-2-one (**28**)*

(a) Via selenoxide elimination

To a cold (−78°C), stirred solution of lithium diisopropylamide (2.3 mmol) in dry THF (15 mL), under an atmosphere of argon, was added dropwise a solution of the ketone **25** (273 mg, 1.53 mmol) in dry THF (3 mL), and the mixture was stirred at −78°C for 30 min. A solution of phenylselenenyl chloride (440 mg, 2.30 mmol) in dry THF (4 mL) was added dropwise and the solution was stirred at 0°C for 30 min. After acetic acid (0.175 mL, 3.06 mmol) had been introduced, a solution of 30% aqueous hydrogen peroxide (0.868 g) in 2 mL of water was added dropwise. The reaction mixture was stirred at 0°C for 30 min, diluted with 1:1 ether – petroleum ether, and then was poured into saturated aqueous sodium bicarbonate. The layers were separated and the aqueous phase was extracted thoroughly with ether. The combined extract was washed twice with brine, dried ($MgSO_4$), and concentrated. Subjection of the residual material to flash column chromatography (70 g silica gel, elution with 1:7 ether – petroleum ether), concentration of the appropriate fractions, and distillation (air-bath temperature 76–80°C/0.1 Torr) of the oil thus obtained furnished 136 mg (50%) of the enone **28** as a colorless oil. This material exhibited ir (film): 1690 cm^{-1}; ^1H nmr (400 MHz) δ: 0.97, 0.98 (d, d, 3H each, J = 7 Hz), 1.45 (s, 3H), 1.99 (poorly resolved d, 1H, J = 3 Hz), 2.36 (dd, 1H, J = 9.5, 3 Hz), 2.60–2.73 (m, 1H), 4.91 (overlapped ddd, 1H, J = 12, 9.5, 1 Hz), 5.40 (overlapped ddd, 1H, J = 12, 9, <1 Hz), 5.66 (dd, 1H, J = 5.5, 1 Hz), 7.52 (dd, 1H, J = 5.5, 1 Hz). Decoupling experiments: irradiation at δ 4.91 caused the signal at δ 2.60–2.73 to sharpen and the resonances at δ 2.36 and 5.40 to collapse to doublets (J = 3, 9 Hz, respectively); irradiation at δ 7.52 caused the signals at δ 1.99 and 5.66 to collapse to a dd (J = 3, 1 Hz) and a d (J = 1 Hz), respectively. *Exact Mass* calcd. for $C_{12}H_{16}O$: 176.1201; found: 176.1203.

*(b) Via $Pd(OAc)_2$ oxidation of the enol silyl ether **29***

To a cold (−78°C), stirred solution of the ketone **25** (713 mg, 4.0 mmol) and triethylamine (4.46 mL, 32.0 mmol) in dry dichloromethane (40 mL), under an atmosphere of argon, was added, dropwise, freshly prepared (25) trimethylsilyl iodide (14 mmol). The resulting dark orange suspension was stirred at −78°C for 30 min. The reaction mixture was diluted with ether and then was poured into a 1:1 mixture of 5% aqueous sodium thiosulfate and saturated aqueous sodium bicarbonate. The layers were separated and the organic layer was dried ($MgSO_4$) and concentrated. The residual material, which was shown by glc analysis to be a 12:1 mixture of the enol silyl ether **29** and the

For personal use only.

starting material **25**, was dissolved in dry acetonitrile (3 mL) and the resultant solution was added, dropwise, to a stirred suspension of palladium(II) acetate (1.80 g, 8.0 mmol) in dry acetonitrile (3 mL). The mixture was stirred at room temperature for 1 h and then was filtered. The filtrate was washed twice with saturated aqueous sodium bicarbonate, dried ($MgSO_4$), and concentrated to give a dark brown oil. Subjection of this material to flash column chromatography (70 g of silica gel, elution with 1:7 ether – petroleum ether) and concentration of the appropriate fractions afforded 554 mg (78%) of a colorless oil. On the basis of glc analyses and the ^{1}H nmr spectrum, this material consisted of an 85:15 mixture of the desired enone **28** and the ketone **25**, respectively. Since attempts to separate these two compounds by chromatography were not successful, the mixture was used for the next reaction.

*5-Methyl-6-*exo*-[(Z)-3-methyl-1-butenyl]-4-*exo*-vinylbicyclo[3.1.0]-hexan-2-one (**30**) and the C-4 epimer **31***

To a stirred solution of tetravinyltin (258 mg, 1.14 mmol) in dry ether (5 mL), under an atmosphere of argon, was added dropwise a solution of phenyllithium (4.54 mmol) in a mixture of ether and cyclohexane. A white precipitate formed almost immediately and the resulting reaction mixture was stirred for 30 min. The stirring was stopped and the white precipitate was allowed to settle to the bottom of the flask. The pale yellow solution was transferred (syringe) to another dry flask (argon atmosphere) and then was cooled with stirring to −63°C. Copper(I) bromide – dimethyl sulfide complex (467 mg, 2.27 mmol) was added and the mixture was stirred at −63°C for 20 min to furnish a dark grey suspension. A solution of an 85:15 mixture of the enone **28** and the ketone **25**, respectively, (200 mg) in dry ether (3 mL) was added dropwise and the resultant dark purple mixture was stirred at −30°C for 15 min and at room temperature for 1 h. Saturated aqueous ammonium chloride (pH 8) (6 mL) and ether (5 mL) were added and the mixture was stirred vigorously until the aqueous layer became deep blue. The layers were separated and the aqueous phase was extracted twice with ether. The combined organic extract was washed successively with saturated aqueous ammonium chloride (pH 8) and brine, and then was dried ($MgSO_4$). Removal of the solvent, column chromatography (50 g silica gel, elution with 1:5 ether – petroleum ether) of the resultant oil, and distillation (air-bath temperature 91–97°C/0.1 Torr) of the two oils thus obtained afforded 136 mg (46% from **25**) of the ketone **30** and 19 mg (6% from **25**) of the epimeric substance **31**.

Compound **30** exhibited ir (film): 1722, 1635, 920 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.00, 1.01 (d, d, 3H each, J = 6.5 Hz), 1.20 (s, 3H), 1.63 (br s, 1H, $w_{1/2}$ = 5.5 Hz), 1.89 (d, 1H, J = 18.5 Hz), 2.15 (ddd, 1H, J = 8.5, 3, 1 Hz), 2.55 (dd, 1H, J = 18.5, 8 Hz), 2.67 (dd septet, 1H, J = 9.5 Hz, <1, 6.5 Hz), 2.91 (overlapped dd, 1H, J = 10, 8 Hz), 4.91 (overlapped ddd, 1H, J = 10.5, 8.5, <1 Hz), 5.04–5.12 (m, 2H), 5.39 (overlapped ddd, 1H, J = 10.5, 9.5, 1 Hz), 5.72 (overlapped ddd, 1H, J = 17, 10, 10 Hz). Difference nuclear Overhauser enhancement (nOe) experiment: irradiation at δ 2.15 caused enhancement of the signals at δ 2.55, 2.67, and 2.91. Decoupling experiments: irradiation at δ 5.39 caused the signals at δ 2.15, 2.67, and 4.91 to collapse to a dd (J = 8.5, 3 Hz), a poorly resolved septet (J = 6.5 Hz), and a poorly resolved d (J = 8.5 Hz), respectively; irradiation at δ 4.91 caused the resonances at δ 2.15, 2.67, and 5.39 to change to an overlapped dd (J = 3, 1 Hz), a d septet (J = 9.5, 6.5 Hz), and a poorly resolved d (J = 9.5 Hz), respectively; irradiation at δ 2.15 sharpened the signal at δ 1.63 and collapsed the signals at δ 4.91 and 5.39 to a d (J = 10.5 Hz) and a dd (J = 10.5, 9.5 Hz), respectively; irradiation at δ 2.91 simplified the multiplet at δ 5.04–5.12 and changed the resonances at δ 2.55 and 5.72 to a d (J = 18.5 Hz) and a dd (J = 17, 10 Hz), respectively. *Exact Mass* calcd. for $C_{14}H_{20}O$: 204.1514; found: 204.1517.

Compound **31** exhibited ^{1}H nmr (400 MHz) δ: 1.00 (d, 6H, J = 6.5 Hz), 1.31 (s, 3H), 1.63 (br s, 1H, $w_{1/2}$ = 5.5 Hz), 2.08 (dd, 1H, J = 18, 9.5 Hz), 2.20–2.29 (m, 2H), 2.68 (dd, septet, 1H, J = 9.5, <1, 6.5 Hz), 2.91 (overlapped ddd, 1H, J = 9.5, 9, 7 Hz), 4.89 (overlapped ddd, 1H, J = 10.5, 9, <1 Hz), 5.10–5.17 (m, 2H), 5.38 (overlapped ddd, 1H, J = 10.5, 9.5, 1 Hz), 5.83 (ddd, 1H, J = 17.5, 10, 7 Hz). Decoupling experiments: irradiation at δ 4.89 simplified the signal at δ 2.20–2.29 and caused the signals at δ 2.68 and 5.38 to change to a dd (J = 9.5, 6.5 Hz) and a br d (J = 9.5 Hz), respectively; irradiation at δ 2.91 simplified the multiplets at δ 2.20–2.29 and 5.10–5.17, and collapsed the signals at δ 2.08 and 5.83 to a d (J = 18 Hz) and a dd (J = 17.5, 10 Hz), respectively; irradiation at δ 5.10–5.17 caused the signal at δ 2.91 to sharpen and the resonance at δ 5.83 to collapse to a d (J = 7 Hz). *Exact Mass* calcd. for $C_{14}H_{20}O$: 204.1514; found: 204.1510.

*2-(*tert*-Butyldimethylsiloxy)-5-methyl-6-*exo*-[(Z)-3-methyl-1-butenyl]-4-*exo*-vinylbicyclo[3.1.0]hex-2-ene (**6**)*

To a cold (−78°C), stirred solution of lithium diisopropylamide (3.35 mmol) in dry THF (16 mL), under an atmosphere of argon, was added a solution of the ketone **30** (623 mg, 3.05 mmol) in dry THF (4 mL) and the solution was stirred at −78°C for 30 min. A solution of freshly sublimed *tert*-butyldimethylsilyl chloride (690 mg, 4.57 mmol) and hexamethylphosphoramide (6.1 mmol) in dry THF (6 mL) was added and the solution was stirred at −78°C for 30 min and at room temperature for 2 h. The reaction mixture was poured into saturated aqueous sodium bicarbonate and the layers were separated. The aqueous layer was extracted with ether, the combined organic extract was washed thrice with brine, and dried ($MgSO_4$). Removal of the solvent, followed by column chromatography of the residual oil on a short column of neutral alumina (80–200 mesh, elution with petroleum ether) and distillation (air-bath temperature 118–123°C/0.1 Torr) of the oil thus obtained, gave 933 mg (96%) of the enol silyl ether **6** as a colorless oil. This material exhibited ir (film): 1635, 1620, 960, 920, 790 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.17 (s, 6H), 0.94 (s, 9H), 0.99 (d, 6H, J = 7 Hz), 1.13 (s, 3H), 1.34 (overlapped dd, 1H, J = 2.5, 1 Hz), 1.40 (br dd, 1H, J = 9, 2.5 Hz), 2.71 (dd septet, 1H, J = 9, 1, 7 Hz), 3.10 (br d, 1H, J = 9 Hz), 4.20 (dd, 1H, J = 2.5, 1 Hz), 4.92 (overlapped ddd, 1H, J = 11, 9, 1 Hz), 4.98 (dd, 1H, J = 10, 2 Hz), 5.04 (ddd, 1H, J = 17, 2, 1 Hz), 5.29 (overlapped ddd, 1H, J = 11, 9, 1 Hz), 5.74 (ddd, 1H, J = 17, 10, 9 Hz). *Exact Mass* calcd. for $C_{20}H_{34}OSi$: 318.2379; found: 318.2370.

*6-(*tert*-Butyldimethylsiloxy)-4-*exo*-isopropyl-1-methyl-8-*exo*-vinylbicyclo[3.2.1]octa-2,6-diene (**7**)*

A solution of the enol silyl ether **6** (170 mg, 0.534 mmol) in 3 mL of dry benzene was placed in a glass pyrolysis tube (2-mm wall thickness) and the solution was degassed. The tube was cooled with liquid nitrogen and was sealed under vacuum (0.1 Torr). After the tube had been heated at 220°C for 4.5 h in a steel container packed with sand, it was cooled to room temperature and then was unsealed. Removal of the solvent, column chromatography of the residual oil on neutral alumina that had been pretreated with a solution of triethylamine (elution with petroleum ether), and distillation (air-bath temperature 88–99°C/0.1 Torr) of the oil thus obtained afforded 146 mg (86%) of the bicyclic triene **7**, which exhibited ir (film): 1630, 1620, 940, 915, 784 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.13, 0.15, 0.92, 0.95 (s, s, s, s, 3, 3, 9, 3H, respectively), 0.97, 1.00 (d, d, 3H each, J = 7 Hz), 1.67–1.79 (m, 1H), 1.92–1.97 (m, 1H), 2.26 (br s, 1H), 2.46 (d, 1H, J = 9 Hz), 4.74 (s, 1H), 5.01 (dd, 1H, J = 10, 2.5 Hz), 5.08 (ddd, 1H, J = 17, 2.5, <1 Hz), 5.35 (ddd, 1H, J = 9.5, 3, 2 Hz), 5.96 (ddd, 1H, J = 17, 10, 9 Hz), 6.00 (dd, 1H, J = 9.5, 2 Hz). Decoupling experiments: irradiation at δ 5.35 caused the signals at δ 1.92–1.97 and 6.00 to collapse to a br d (J = 7 Hz) and a d (J = 2 Hz), respectively, and the signal at δ 2.26 to sharpen; irradiation at δ 1.95 caused the signals at δ 1.67–1.79, 5.35, and 6.00 to collapse to a septet (J = 7 Hz), a dd (J = 9.5, 2 Hz), and a d (J = 9.5 Hz), respectively, and the signal at δ 2.26 to sharpen; irradiation at δ 2.26 changed the signals at δ 1.92–1.97 and 5.35 to an overlapped ddd (J = 7, 3, 2 Hz) and a dd (J = 9.5, 3 Hz). *Exact Mass* calcd. for $C_{20}H_{34}OSi$: 318.2379; found: 318.2365.

*6-(*tert*-Butyldimethylsiloxy)-8-*exo*-(2-hydroxyethyl)-4-*exo*-isopropyl-1-methylbicyclo[3.2.1]octa-2,6-diene (**32**)*

To a cold (0°C), stirred solution of disiamylborane (0.346 mmol) in dry THF (2 mL), under an atmosphere of argon, was added a solution of the triene **7** (50 mg, 0.157 mmol) in dry THF (2 mL) and the resulting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

mixture was allowed to warm to room temperature over a period of 1.5 h. The reaction mixture was recooled to 0°C and a solution of sodium hydroxide (13.8 mg, 0.346 mmol) in water (1 mL) and a 30% aqueous solution of hydrogen peroxide (0.106 mL, 1.04 mmol) were added. The stirred mixture was allowed to warm to room temperature over a period of 1 h. The reaction mixture was diluted with a 1:1 mixture of ether – petroleum ether and then was poured into saturated aqueous ammonium chloride. The layers were separated, the aqueous layer was extracted thoroughly with ether, and the combined organic extract was washed with brine and dried ($MgSO_4$). Removal of the solvent gave a light yellow oil, which was subjected to column chromatography on 18 g of 80–200 mesh neutral alumina. Elution of the column with petroleum ether (30 mL), and ether (30 mL), followed by concentration of the appropriate fractions, provided 45 mg (86%) of the alcohol **32** as a colorless, odoriferous oil that exhibited ir (film): 3300, 1622 cm^{-1}; ^1H nmr (400 MHz) δ: 0.11, 0.13, 0.90, 0.99 (s, s, s, s, 3, 3, 9, 3H, respectively), 0.95, 0.97 (d, d, 3H each, J = 6.5 Hz), 1.49–1.70 (m, 3H), 1.73–1.82 (m, 1H), 1.85–1.91 (m, 1H), 1.94 (dd, 1H, J = 10, 3.5 Hz), 2.28 (br s, 1H), 3.63–3.79 (m, 2H), 4.69 (s, 1H), 5.30 (ddd, 1H, J = 9.5, 3, 2 Hz), 5.98 (dd, 1H, J = 9.5, 2 Hz). *Exact Mass* calcd. for $C_{20}H_{36}O_2Si$: 336.2485; found: 336.2486.

10-exo-*Isopropyl-7-methyltricyclo[4.4.0.0^{3,7}]dec-8-en-2-one (**34**)*

To a cold (0°C), stirred solution of 4-dimethylaminopyridine (236 mg, 1.93 mmol) in dry dichloromethane (5 mL) was added a solution of *p*-toluenesulfonyl chloride (184 mg, 0.964 mmol) in dry dichloromethane (2 mL) and the mixture was stirred at room temperature, under an atmosphere of argon, for 30 min. A solution of the alcohol **32** (216 mg, 0.643 mmol) in dry dichloromethane (3 mL) was added, the reaction mixture was stirred at room temperature for 1.3 h, and then was diluted with ether and poured into saturated aqueous sodium bicarbonate. The layers were separated and the aqueous layer was extracted thoroughly with ether. The combined organic extract was washed successively with brine, 5% hydrochloric acid, saturated aqueous sodium bicarbonate and brine, and then was dried ($MgSO_4$). Removal of the solvent, followed by distillation (air-bath temperature 83–87°C/0.1 Torr) of the residual yellow oil, furnished 103 mg (79%) of the olefinic ketone **34**, a colorless oil that exhibited ir (film): 1743, 1630 cm^{-1}; ^1H nmr (400 MHz) δ: 0.95, 0.98 (d, d, 3H each, J = 7 Hz), 1.09 (s, 3H), 1.35–1.43 (m, 1H), 1.52–1.66 (m, 2H), 1.90–1.96 (m, 1H), 1.98–2.07 (m, 3H), 2.28 (br s, 1H, $w_{1/2}$ = 5.5 Hz), 2.35 (br d, 1H, J = 3 Hz), 5.59 (d, 1H, J = 10 Hz), 5.63 (ddd, 1H, J = 10, 3.5, 1.5 Hz). Decoupling experiment: irradiation at δ 5.61 caused the signals at δ 1.90–1.96 and 2.28 to collapse to a dd (J = 9.5, 2.5 Hz) and a d (J = 2.5 Hz), respectively. *Exact Mass* calcd. for $C_{14}H_{20}O$: 204.1514; found: 204.1526.

10-exo-*Isopropyl-7-methyltricyclo[4.4.0.0^{3,7}]decan-2-one (**4**)*

To a vigorously stirred, prehydrogenated suspension of 10% palladium-on-carbon (4 mg) in methanol (2 mL), under an atmosphere of hydrogen, was added a solution of the olefinic ketone **34** (43 mg, 0.21 mmol) in methanol (2 mL). The mixture was stirred at room temperature and reaction progress was monitored by glc. After 24 h, the hydrogenation had become quite sluggish and another 3 mg of the palladium catalyst was introduced. The reaction mixture was stirred for another 3 h and then was filtered through a layer of Celite. Concentration of the filtrate and distillation (air-bath temperature 93–98°C/0.1 Torr) of the residual oil gave 40 mg (91%) of the ketone **4** as a colorless oil that exhibited ir (film): 1740 cm^{-1}; ^1H nmr (400 MHz) δ: 0.89, 0.92 (d, d, 3H each, J = 6.5 Hz), 1.00 (s, 3H), 1.38–1.64 (m, 6H), 1.66–1.77 (m, 2H), 1.91–2.00 (m, 2H), 2.02–2.11 (m, 2H), 2.14 (br d, 1H, J = 4.5 Hz). The ir and ^1H nmr spectra of **4** were identical with those of a sample of this ketone prepared previously by Collins and Wege (3).[3] *Exact Mass* calcd. for $C_{14}H_{22}O$: 206.1671; found: 206.1671.

*(±)-Sinularene (**1**)*

To a stirred, yellow solution of methylenetriphenylphosphorane (1.05 mmol) (prepared by treatment of a suspension of methyltriphenylphosphonium bromide (376 mg, 1.05 mmol) in 10 mL of dry THF with a hexane solution of 1.05 mmol of *n*-butyllithium) was added a solution of the ketone **4** (21.7 mg, 0.105 mmol) in dry THF and the resulting mixture was heated under reflux. Reaction progress was monitored by glc, which indicated that, after 46.5 h, starting material was still present and the reaction had become quite sluggish. Consequently, a solution of 1.05 mmol of methylenetriphenylphosphorane in 10 mL of dry THF was added (syringe) and the reaction mixture was refluxed for an additional 22.5 h. A few drops of water were added and most of the solvent was removed under reduced pressure (water aspirator). The residue (white solid plus an oil) was treated with petroleum ether and the resultant mixture was dried ($MgSO_4$) and then was filtered through a column of silica gel (2.5 g, 6 × 160 mm column, elution with petroleum ether). Removal of the solvent from the eluate gave 17 mg (78%) of (±)-sinularene (**1**), which exhibited one peak on glc and one spot on tlc analyses; ir (film): 3060, 1661, 1462, 1385, 1382, 1370, 878 cm^{-1}; ^1H nmr (400 MHz) δ: 0.90, 0.92 (d, d, 3H each, J = 6.5 Hz), 0.91 (3H, s), 1.05–1.32 (m, 5H), 1.46–1.51 (m, 2H), 1.56–1.81 (m, 3H), 1.85–1.95 (m, 1H), 2.14 (br d, 1H, J = 3.5 Hz), 2.20 (br s, 1H, $w_{1/2}$ = 7 Hz), 4.58 (br s, 1H, $w_{1/2}$ = 3 Hz), 4.78 (br s, 1H, $w_{1/2}$ = 4 Hz); ^{13}C nmr (100.6 MHz): three methyl carbons (δ 20.7, 20.8, 21.4), four methylene carbons (δ 22.4, 26.0, 30.2, 31.7), five methine carbons (δ 29.1, 42.9, 49.2, 50.2, 53.5), one quaternary carbon (δ 46.9), two alkene carbons (δ 101.2, 163.3). The ir and ^1H nmr spectra of (±)-**1** were identical with those of racemic sinularene prepared previously by Oppolzer, Strauss, and Simmons (4).[4] *Exact Mass* calcd. for $C_{15}H_{24}$: 204.1878; found: 204.1880.

Received August 25, 1986[1]

ALAN SHAVER, JAMES M. MCCALL, VICTOR W. DAY, and SARAH VOLLMER. Can. J. Chem. **65**, 1676 (1987).

The crystal and molecular structures of $(\eta^5\text{-}C_5H_5)_2ZrS_5$, **2**, and $(\eta^5\text{-}C_5H_5)HfS_5$, **3**, have been determined by single crystal diffractometry methods. Both compounds crystallized with four molecules in a monoclinic unit cell of dimensions: a = 8.984(3) Å, b = 13.336(4) Å, c = 11.421(2) Å, β = 93.10(2)° for **2**, and a = 9.012(2) Å, b = 13.291(2) Å, c = 11.381(2) Å, β = 93.25(1)° for **3**; the space group is $P2_1/n$ for both. These crystals of **2** and **3** are thus isomorphous with those of $(C_5H_5)_2TiS_5$, **1**, studied by Epstein *et al.* (3*a*). The structures of all three complexes are very similar consisting of a cyclohexane-like six-membered MS_5 ring with two C_5H_5 rings attached to the metals in an axial and equatorial position. The coordination spheres of **2** and **3** are less crowded than that of **1**. The consequences of this are discussed with respect to the barriers to ring inversion in these complexes.

ALAN SHAVER, JAMES M. MCCALL, VICTOR W. DAY et SARAH VOLLMER. Can. J. Chem. **65**, 1676 (1987).

Utilisant des méthodes de diffractométrie sur des cristaux uniques, on a déterminé les structures cristallines et moléculaires des composés $(\eta^5\text{-}C_5H_5)_2ZrS_5$ (**2**) et $(\eta^5\text{-}C_5H_5)_2HfS_5$ (**3**). Chacun des composés cristallise avec quatre molécules dans une cellule unitaire monoclinique avec a = 8,984(3), b = 13,336(4) et c = 11,421(2) Å et β = 93,10(2)° pour le composé **2** et a = 9,012(2), b = 13,291(2) et c = 11,381(2) Å et β = 93,25(1)° pour le composé **3**; dans chacun des cas, le groupe d'espace est $P2_1/n$. Les cristaux des composés **2** et **3** sont donc isomorphes avec ceux du composé $(C_5H_5)_2TiS_5$ (**1**) étudié par Epstein et ses collaborateurs (3*a*). Les structures de ces trois complexes sont très semblables; elles comportent chacune un cycle à six chaînons de MS_5 qui adopte une forme semblable à celle d'un cyclohexane ainsi que deux cycles de C_5H_5 qui sont attachés aux métaux dans les positions axiale et équatoriale. Les sphères de coordination des composés **2** et **3** sont moins encombrées que celles du composé **1**. On discute de ces résultats en fonction des barrières à l'inversion de cycle dans ces complexes.

[Traduit par la revue]

Introduction

Recently a general method for the preparation of metallacyclosulfanes (i.e. species of the type MS_x) was reported (1). Treatment of the appropriate dichloro precursors with non-aqueous solutions of Li_2S_x, prepared in situ, gave the series Cp_2MS_5 and $Cp^*_2MS_3$, where M = Ti, Zr, and Hf, Cp = C_5H_5, and Cp* = C_5Me_5. The complex Cp_2TiS_5, **1**, had been reported previously (2) and had been shown (3) to have a cyclohexane-like six-membered ring with axial and equatorial Cp rings. At room temperature ring inversion is slow on the nmr time scale for the titanium complex (4); however, only upon cooling the zirconium, **2**, and hafnium, **3**, analogues it was possible to resolve two signals for their Cp rings (1). The X-ray structures of the latter two complexes have been determined in order to compare their structures to that of **1** seeking an explanation for their relative ease of ring inversion. The availability of these three complexes also provided an opportunity to compare the structures for the complete series.

Experimental

Crystal data

$C_{10}H_{10}S_5Zr$ fw = 381.7

Monoclinic, $P2_1/n$, a = 8.984(3), b = 13.336(4), c = 11.421(2), β = 93.10(2), V = 1366.3 Å^3, Z = 4, ρ_c = 1.86 g cm^{-3}, (MoK_α λ = 0.71073 Å, μ = 1.50 mm^{-1} (6*a*)).

$C_{10}H_{10}S_5Hf$ fw = 468.9

Monoclinic, $P2_1/n$, a = 9.012(2), b = 13.291(2), c = 11.382(2), β = 93.25(1), V = 1360.9 Å^3, Z = 4, ρ_c = 2.29 g cm^{-3}, (MoK_α = 0.71073 Å, μ = 8.77 mm^{-1} (6*a*)).

Large-well shaped single crystals of **2** and **3** suitable for X-ray diffraction studies were obtained as previously described (1). Both compounds crystallize in the centrosymmetric monoclinic space group $P2_1/n$ (an alternate setting of $P2_1/c$-C_{2h}, No. 14) (5). Intensity measurements were made on a computer-controlled Nicolet PĪ autodiffractometer for a spherical specimen of **2** which had a diameter of 0.69 mm (μr = 0.52) and an irregularly shaped crystal of **3**. Intensity measurements for both compounds utilized graphite-monochromated MoKα radiation and full (1.0°) wide ω scans and gave a total of 5096 independent reflections having $2\theta_{MoK\alpha} < 71.0°$ for **2** and 4663 reflections having $2\theta_{MoK\alpha} < 63.7°$ for **3**. For all reflections of **2** a scanning rate of 3° min^{-1} was employed for the scan between ω settings 0.50° above and below the calculated Kα doublet value (λ = 0.71073 Å). Similar scans for those reflections of **3** having $2\theta_{MoK\alpha} <$ 43° utilized a scanning rate of 4° min^{-1} while a scanning rate of 3° min^{-1} was used for all the other reflections. Each 1.0° scan of both compounds was divided into 19 equal time intervals, and those 13 contiguous intervals which had the highest single accumulated count at their midpoint were used to calculate the net intensity from scanning. Background counts, each lasting for one-half (**2**) or one-fourth (**3**) of the total time used for the net scan (13/19ths of the total scan time), were measured at omega settings 1.0° above and below the calculated Kα doublet value for each reflection. Since the absorption of X-rays by a spherical crystal having μr = 0.90 is virtually independent of scattering angle (7), the data for **2** were not corrected for absorption. The intensity data of **3** were corrected empirically for variable absorption using χ scans for five reflections having 2θ values between 11° and 31°.

The non-hydrogen atoms of **2** were located using Patterson and difference Fourier techniques, and those of the isomorphous hafnium compound, **3**, were derived from the parameters of **2**. Atomic positions were calculated for all hydrogens of both compounds assuming sp^2 hybridized geometry for the cyclopentadienyl carbons and a C—H bond length of 0.95 Å. The non-hydrogen parameters initially used for these calculations were those resulting from the full-matrix least-squares refined model (R_1 (8) (unweighted, based on F) = 0.029 and 0.035 for **2** and **3** respectively) which incorporated

[a]Numbers in parentheses are the estimated standard deviations in the last significant digit.
[b]For each atom type, the coordinates are reported in two lines corresponding to complexes **2** and **3**, respectively. Atoms are labeled in agreement with Figs. 1 and 2.
[c]This is one-third of the trace of the orthogonalized B_{ij} tensor.

unit-weighting and anisotropic thermal parameters for all non-hydrogen atoms and reflections having $2\theta_{MoK\alpha} < 43°$ and $I > 3\sigma(I)$. They were periodically updated. The R values are defined as $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_2 = \{\Sigma\omega(|F_o| - |F_c|)^2/\Sigma\omega|F_o|^2\}^{1/2}$, where ω is the weight given each reflection. The function minimized is $\Sigma\omega(|F_o| - K|F_c|)^2$, where K is the scale factor. All structure factor calculations for both compounds employed recent tabulations of atomic form factors (6*b*) and an anomalous dispersion correction (6*c*) to the scattering factors of the Hf, Zr, and sulfur atoms. A least-squares refinable extinction correction (8) of the form $1/(1 + gIc)^{1/2}$ was employed for structure factors of **2**. A careful examination of the final F_o and F_c values for **3** indicated the absence of extinction effects. The final cycles of empirically-weighted[2] full-matrix least-squares refinement which employed isotropic thermal parameters for fixed hydrogen atoms and anisotropic thermal parameters for all other atoms converged to values of 0.029 and 0.036 for R_1 and R_2 (weighted, based on F), respectively, for 4465 independent reflections of **2** having $2\theta_{MoK\alpha} < 71.0°$ and $I > 3\sigma(I)$. Similar refinement cycles for **3** gave $R_1 = 0.037$ and $R_2 = 0.045$ for 3635 independent reflections having $2\theta_{MoK\alpha} < 63.7°$ and $I > 3\sigma(I)$. Hydrogen atom parameters were not varied for either **2** or **3**.

Results and discussion

The final atomic coordinates for the non-hydrogen atoms of **2** and **3** are presented with estimated standard deviations in Table 1.[3] A perspective ORTEP drawing illustrating the numbering scheme is given in Fig. 1. The crystals of **2** and **3** used in this study are isomorphous with the crystal of **1** studied by Epstein *et al.* (3*a*). The volume of the unit cells follow the expected order Ti < Hf < Zr. The volumes for the isostructural and isomorphous indenyl series $(\eta^5\text{-}C_9H_7)_2M(CH_3)_2$, M = Ti, Zr, and Hf followed the same order; this has been attributed to the lanthanide contraction effect (9).

[2]Empirical weights were calculated from the equation $\rho = \sum_0^2 a_n|F_o|^n = 0.548 - (2.23 \times 10^{-3})|F_o| + (1.00 \times 10^{-4})|F_o|^2$ for **2** and $\sigma = \sum_0^3 a_n|F_o|^n = 1.91 - (1.66 \times 10^{-2})|F_o| + (2.36 \times 10^{-4})|F_o|^2 - (4.94 \times 10^{-8})|F_o|^3$, the a_n being coefficients derived from the least-square fitting of the curve $||F_o| - |F_c|| = \sum_0^2 a_n|F_o|^n$, where F_c values were calculated from the fully refined model using unit weighting and an $I > 3\sigma(I)$ rejection criterion.

[3]Crystal structure analysis reports for **2** and **3**, Fig. 2 (ORTEP drawing of **3**), Table 2 (anisotropic thermal parameters for the non-hydrogen atoms of **2** and **3**), Table 3 (hydrogen atom coordinates for **2** and **3**), Table 5 (bond lengths and angles about the non-hydrogen atoms of the cyclopentadienyl rings in **2** and **3**), Table 7 (structure factors for **2**), Table 8 (structure factors for **3**), (56 pages) may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]Numbers in parentheses following individual entries are the estimated standard deviations in the last significant digit.

[b]Atoms are labeled in agreement with Figs. 1 and 2.

[c]The data given for **1** were taken or calculated from ref. 3*a*.

[d]See footnote 4.

[e]The least-squares mean planes for the following groups of atoms in **2** and **3** are defined by the equation: $aX + bY + cZ = d$ where X, Y, and Z are orthogonal coordinates measured along $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}^*$, respectively, of the crystal system: (*a*) C_{a1}, C_{a2}, C_{a3}, C_{a4}, and C_{a5} for **2**, $a = 0.287$; $b = -0.707$, $c = 0.646$, $d = 1.947$; (*b*) C_{b1}, C_{b2}, C_{b3}, C_{b4}, and C_{b5} for **2**, $a = 0.505$, $b = 0.809$, $c = -0.302$, $d = 3.563$; (*c*) C_{ga}, Zr, and C_{gb}, $a = -0.402$, $b = 0.526$, $c = 0.749$, $d = 3.341$; (*d*) S_1, Zr, and S_5, $a = 0.257$, $b = 0.856$, $c = -0.449$, $d = 1.128$; (*e*) S_1, S_2, S_4, and S_5 for **2**, $a = 0.624$, $b = -0.419$, $c = 0.660$, $d = -0.934$; (*f*) S_2, S_3, and S_4 for **2**, $a = 0.454$, $b = 0.830$, $c = -0.324$, $d = -0.987$; (*g*) C_{a1}, C_{a2}, C_{a3}, C_{a4}, and C_{a5} for **3**, $a = 0.282$, $b = -0.709$, $c = 0.646$, $d = 1.943$; (*h*) C_{b1}, C_{b2}, C_{b3}, C_{b4}, and C_{b5} for **3**, $a = 0.504$, $b = 0.811$, $c = -0.298$, $d = 3.548$; (*i*) C_{ga}, Hf, and C_{gb}, $a = -0.383$, $b = 0.538$, $c = 0.751$, $d = 3.355$; (*j*) S_1, Hf, and S_5, $a = 0.257$, $b = 0.855$, $c = -0.450$, $d = 1.105$; (*k*) S_1, S_2, S_4, and S_5 for **3**, $a = 0.622$, $b = -0.422$, $c = 0.660$, $d = -0.917$; (*l*) S_2, S_3, and S_4 for **3**, $a = 0.451$, $b = 0.830$, $c = -0.327$, $d = -1.008$; where C_{ga} and C_{gb} refer to the center of gravity of the five membered rings of the cyclopentadienyl rings of *a* and *b*, respectively.

[f]This is the dihedral angle between the least-square mean planes through the two groups of atoms listed.

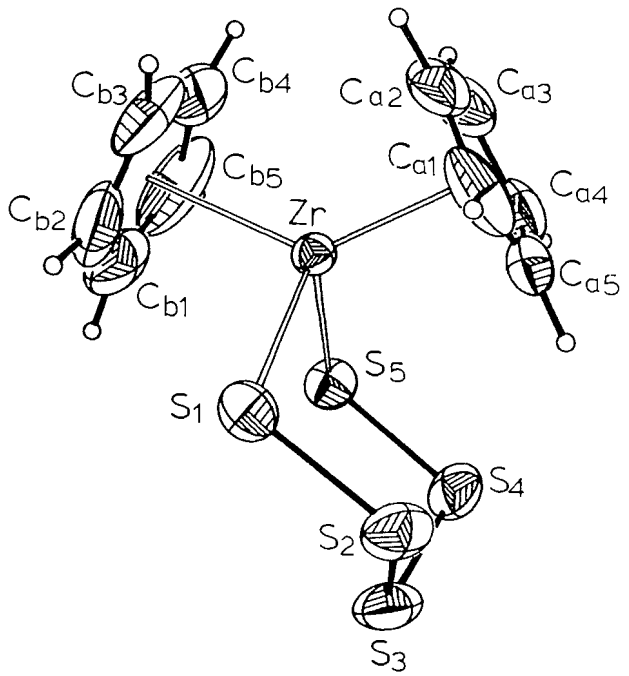

FIG. 1. A perspective ORTEP drawing of $(\eta^5\text{-}C_5H_5)_2ZrS_5$, **2**, showing the atom labelling scheme used for **2** and **3**. A similar drawing of **3** is shown in Fig. 2. (see footnote 3). All nonhydrogen atoms are represented by thermal vibration ellipsoids drawn to encompass 50% of the electron density; hydrogen atoms are represented by arbitrarily-sized spheres for purposes of clarity.

All three compounds **1**, **2**, and **3** are isostructural being discrete, mononuclear Cp_2MX_2 species in which the metal ions adopt the familiar pseudotetrahedral "bent sandwich" configuration. The X groups in these cases are the terminal atoms of the bidentate pentasulfide chain thus forming a six-membered ring which adopts a chair conformation. The molecules approximate C_s-*m* point symmetry with the idealized mirror plane passing through the two Cp ring centroids (C_{ga} and C_{gb}), the metal atom and the central sulfur atom (S_3). Selected bond lengths and angles about the metal and sulfur atoms in **1**, **2**, and **3** are given in Table 4. The bond lengths and angles for the non-hydrogen atoms of the cyclopentadienyl rings in **2** and **3** are given in Table 5.[3]

Parameters describing the Cp_2M portion of the coordination spheres of **2** and **3** differ little from those of **1** and correspond well with other group IVB Cp_2MX_2 moieties. The average metal-to-carbon bond distances for **2** and **3** (2.499(3,16,32,10)[4] Å for **2** and 2.477(10,17,32,10) Å for **3**) are about 0.12 Å larger than the average (2.376(1) Å) for **1**; this is consistent with the approximately 0.12 Å smaller covalent radius of titanium. These distances correspond closely with other group IVB Cp_2MX_2 species for a variety of X ligands and cyclopentadienyl ligands (9) wherein the metal-to-carbon distances are remarkably constant for each metal. In **2** and **3**, the five carbon atoms of the cyclopentadienyl ligands are coplanar to within 0.005 Å and those carbon atoms nearest the sulfur atoms are slightly but significantly further from the metal atom. This was also observed for **1** (3*a*) and probably reflects the steric bulk of the pentasulfido-ligand.

[4]The first number in parentheses following an averaged value of a bond length or angle is the root-mean-square estimated standard deviation of an individual datum. The second and third numbers, when given, are the average and maximum deviations from the averaged value, respectively. The fourth number represents the number of individual measurements which are included in the average value.

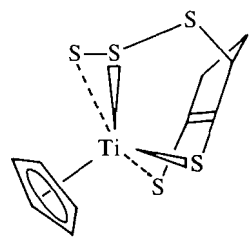
S_5...C_{a4}	3.36	C_{a3}...C_{b4}	3.19
S_5...H_{a4}	3.18		

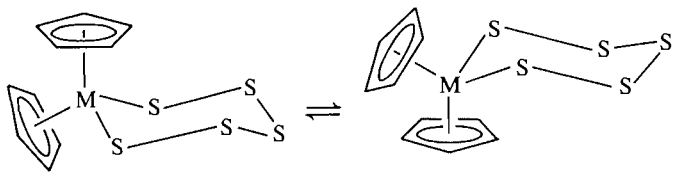
[a]Atoms are labeled in agreement with Figs. 1 and 2 and Tables 1–3.

The plane determined by the metal atom and the two cyclopentadienyl ring centers intersects the plane of the metal, S_1 and S_5 atoms in dihedral angles of 90.5°, 90.6°, and 90.8° for **1**, **2**, and **3**, respectively. However, the bidentate sulfur ligand is displaced from the "equatorial girdle" (the plane passing through the metal and bisecting the C_{ga}—M—C_{gb} angle) towards the ring *b* such that the intramolecular contacts between ring *b* and S_1 and S_5 atoms are considerably shorter than those for ring *a* (Table 6). This distortion has been previously noted (3*a*) for **1** and was attributed to a combination of steric repulsions between the axial cyclopentadienyl ring (*a*) and the sulfur atoms S_2 and S_4 and attractive interactions between ring *b* and sulfur atoms S_1 and S_5. These contacts provide a structural rationale for the novel migration of one of the cyclopentadienyl rings in **1** to the sulfur ligand as observed by Giolando and Rauchfuss (10).



In **2** and **3** the sulfur atoms S_1, S_2, S_4, and S_5 are coplanar to within 0.01 Å. The dihedral angles for the pairs of planes $S_1MS_5/S_1S_2S_4S_5$ and $S_1S_2S_4S_5/S_2S_3S_4$ are similar (Table 4) and indicate similar MS_5 ring shapes. The shortest S—S bond length is the S_2—S_3 bond in all three compounds. Although the S_1—S_2 and S_4—S_5 bond lengths are equal within experimental error in **1**, **2**, and **3**, the two M—S bonds and the central S_2—S_3 and S_3—S_4 bonds are unequal in length. In each case the longer M—S_1 bond is opposite the longer S_3—S_4 bond, and the shorter M—S_5 bond lies opposite the shorter S_2—S_3 bond. Unequal Ti—S distances were also found for $Cp_2Ti(SPh)_2$ (11) which are on average shorter (2.410 Å) than the average Ti—S

distance in **1**. The inequality of S—S bond lengths found in **1**, **2**, and **3** was also observed in Cp_2VS_5 (3*b*) and in Cp_2WS_4 (12). The salts $M_2'S_5$ ($M' = NH_4$ (13), K (14), Rb (15), Tl (16) which contain discrete S_5^{2-} chains, also displayed a variation in bond lengths. For the rubidium salt the two inner bond lengths were 2.054(8) Å and 2.109(7) Å, and the two outer bond lengths were 2.019(7) Å and 2.036(8) Å with the longest S—S bond adjacent to the shortest S—S bond. The S—S bonds in the Cp_2MS_5 molecules, with the exception of the short S_2—S_3 bonds, are all longer than those found in Rb_2S_5. Cyclohexasulfur, S_6, crystallizes in the chair conformation with all S—S bond lengths equal at 2.068(2) Å (17). This distance is marginally greater than the average S—S distances of 2.060 Å for **1**, 2.055 Å (1, 4, 7, 4) for **2**, and 2.059 Å (3, 8, 17, 4) for **3**, respectively. The S—S—S angles are larger in the Cp_2MS_5 molecules than those in S_6 (102.61(6)°) (17). The non-bonded *trans*-annular sulfur–sulfur distances $S_1 \cdots S_5$ follow the order Ti < Hf < Zr, consistent with the trend in the S_1—M—S_5



M = Ti, Zr, Hf

angles, and the M—S bond distances; however the $S_2 \cdots S_4$ distances are nearly the same. The "end-to-end" $M \cdots S_3$ distances in the **2** and **3** are only slightly shorter than for **1**.

Clearly the structures of **1**, **2**, and **3** are quite similar with any significant differences being attributed to differences in the size of the metal atoms. Given this close similarity, the differences observed for their barriers to ring inversion (kJ mol^{-1}: 76.3, **1** (4*b*); 48.6, **2** (1); 58.0, **3** (1)) might initially seem surprising. However, while the coordination spheres of all three compounds are sterically quite conjested, that of **1** is more conjested than those for **2** and **3** due to the smaller covalent radius of titanium. If the non-bonded contacts between the cyclopentadienyl rings and the sulfur atoms were due, at least in part, to attractive forces, then the MS_5 ring in **1** might be expected to have a higher barrier to ring inversion than those in **2** and **3**. Consistent with this, it was found (1) that reducing the cyclopentadienyl ring – sulfur interaction by "tying-back" the C_5 rings with a bridging methylene group in $CH_2(C_5H_4)_2TiS_5$ lowered the barrier to 66.5 kJ mol^{-1} (the C_gTiC_g angle is 121° in $CH_2(C_5H_4)_2TiCl_2$(18) and 131° in Cp_2TiCl_2 (19)). Finally it is noted that the structures of **1**, **2**, and **3** are clearly different from that of $(C_5Me_5)_2ThS_5$ which contains a twist-boat conformation of the ThS_5 ring with a 1,2,4,5-tetrahapto S_5 ligand (20).

Synthesis and Diels–Alder reactions of 1-((*E*)-2-*tert*-butyldimethylsiloxy)ethylidene-4a-carbomethoxy-1,2,3,4,4a,5,6,7-octahydronaphthalene and related substances. Preparation of functionalized decahydro-1*H*-phenalenes

EDWARD PIERS AND RICHARD W. FRIESEN

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received February 10, 1987

EDWARD PIERS and RICHARD W. FRIESEN. Can. J. Chem. **65**, 1681 (1987).

The preparation of the structurally novel dienes **7** and **8** is described. The results of a study of the Diels–Alder reactivity of these substances and the "parent" diene **9** are summarized and the potential use of the resultant Diels–Alder adducts in organic synthesis is demonstrated.

EDWARD PIERS et RICHARD W. FRIESEN. Can. J. Chem. **65**, 1681 (1987).

On décrit la préparation des dièmes **7** et **8** qui sont nouveaux par leur structure. On présente un résumé des résultats obtenus au cours d'une étude sur la réactivité, vis-à-vis de la réaction de Diels–Alder, de ces composés ainsi que de leur hydrocarbure de base (**9**); on démontre aussi l'utilité potentielle des adduits de Diels–Alder qui en résultent dans le domaine de la synthèse organique.

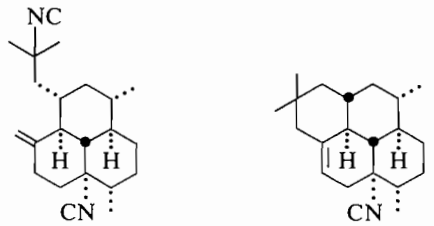
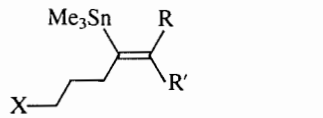
The amphilectane-type diterpenoids (e.g. 8,15-diisocyano-11(20)-amphilectene, **A**; 8-isocyano-10-cycloamphilectene, **B**)

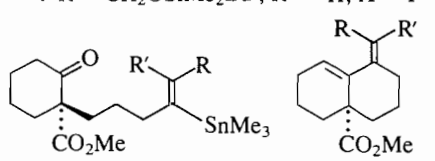


A **B**

are structurally unusual natural products that have been isolated from sponges (1, 2). In connection with an investigation into the preparation and chemical reactivity of novel bicyclic dienes, with the goal of effecting a total synthesis of substances such as **A** and **B**, we outline herein (*a*) the efficient synthesis of the structurally unique dienes **7** and **8**, (*b*) the Diels–Alder reactivity of these substances along with that of the "parent" diene **9** (3), and (*c*) the synthetic utility of (some of) the resultant Diels–Alder adducts.



1 R = H, R′ = CO_2Me, X = Cl
2 R = CO_2Me, R′ = H, X = Cl
3 R = H, R′ = $CH_2OSiMe_2Bu^t$, X = I
4 R = $CH_2OSiMe_2Bu^t$, R′ = H, X = I



5,6 **7,8,9**

5,7 R = H, R′ = $CH_2OSiMe_2Bu^t$
6,8 R = $CH_2OSiMe_2Bu^t$, R′ = H
9 R = R′ = H

Conversion of methyl 6-chloro-2-hexynoate[1,2] into the geometrically isomeric α,β-unsaturated esters **1** and **2** via known methods (4), followed, in each case, by suitable functional group modifications (*i*-Bu_2AlH, Et_2O; *t*-$BuMe_2SiCl$, imidazole, dimethylformamide; NaI, acetone), provided the alkylating agents **3** and **4** (45–50% overall). Alkylation (KH, THF) of 2-carbomethoxycyclohexanone with **3** and **4** gave compounds **5** (88%) and **6** (69%). Conversion of the latter substances into the corresponding bicyclic dienes **7** (61%) and **8** (65%) was accomplished via a "one-pot" sequence of reactions involving deprotonation (lithium diisopropylamide, THF, −40°C), enol triflate formation ($PhN(SO_2CF_3)_2$, THF, −40°C → room temperature) (5) and palladium(0)-catalyzed ring closure (addition of 3 mol% $(Ph_3P)_4Pd$, THF, reflux) (6, and refs. cited therein). Thus, importantly, the cyclization step is stereospecific and even the formation of the *cisoid cis* diene **8** is clean and efficient. Furthermore, use of alkylating agents related to **2** (X = I in place of Cl) and **4** (R = CH_2OCH_2OMe in place of $CH_2OSiMe_2Bu^t$) affords dienes **8** (R = CO_2Me or CH_2OCH_2OMe in place of $CH_2OSiMe_2Bu^t$) as single products. The stereochemistry of the various diene systems that we have prepared was confirmed by suitable ^1H nmr nuclear Overhauser enhancement (nOe) difference experiments.[3]

In connection with exploring the chemical reactivity of the structurally unique dienes **7** and **8** and related substances, we have thus far investigated the Diels–Alder reactivity of **7**, **8**, and the "parent" diene **9** (3). Some of the results obtained to date are summarized in Table 1 (see Chart 1 for structural formulas).

[1]This material was prepared from 5-chloro-1-pentyne: MeLi, tetrahydrofuran(THF), −20°C; $ClCO_2Me$, THF, −20°C → room temperature (69%).

[2]All compounds reported herein gave spectral data in full accord with structural assignments. New compounds gave satisfactory molecular mass determinations (high resolution mass spectrometry) and (or) microanalytical data.

[3]For example, in the ^1H nmr spectrum of **8** (R = CH_2OCH_2OMe instead of $CH_2OSiMe_2Bu^t$), irradiation at δ 5.59 (signal due to cyclohexene olefinic proton) caused enhancement of the signal (δ 4.20) due to the CH_2OCH_2OMe protons.

TABLE 1. Diels–Alder reactions of dienes **7–9**

Entry	Diene	Dienophile[a]	Reaction conditions	Product(s) (ratio;[b] combined yield,[c] %)
1	**9**	**C**	THF, room temperature, 30 min	**10**,[d] **13** (96:4;83)
2	**7**	**C**	THF, room temperature, 30 min	**11**, **14** (88:12;74)[e]
3	**8**	**C**	Et_2O, reflux, 15 h	**12**[d] (72)
4	**7**	**D**	PhH, reflux, 18 h	**15** (63)
5	**8**	**D**	PhH, reflux, 3 days	**16** (18)
6	**9**	**E**	Et_2O, room temperature, 3 h	**17**, **18**, **25** (3:1:2;83)

CHART 1

A number of points should be made regarding the data given in Table 1. (*a*) The structures of a number of "key" products (**10**, **12**, **19**, **21**, **26**, **27**) were determined by X-ray crystallography.[4] Other structural assignments were made on the basis of analogy, chemical correlation, and (or) spectral (mainly ^1H nmr) comparisons. (*b*) Reactions of **7–9** with unsymmetrical dienophiles are completely regioselective (Entries 6–10). These results are in accord with predictions based on biradical arguments (7) or frontier orbital postulates (8). (*c*) Sterically demanding dienophiles (e.g. tetracyanoethylene (**C**)) or dienophiles having a high predilection for an *endo* transition state (e.g. maleic anhydride (**D**)) approach the diene systems of **7–9** largely or completely from the side opposite to the angular CO_2Me function (β-attack) (Entries 1–5). However, with other dienophiles (e.g. nitroethylene (**E**), methyl acrylate (**F**), dimethyl acetylenedicarboxylate[5]) β-attack is favored over α-attack to a lesser degree (1.8–3:1, respectively) (Entries

[4]We are very grateful to Dr. S. J. Rettig for these structure determinations, the details of which will be reported elsewhere.

[5]Reaction (PhH, reflux, 6 h) of **9** with this dienophile provided (78%) the β- and α-attack products in a ratio of 3:1, respectively. The structure of the major product was confirmed by X-ray crystallography.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

6–10). (*d*) Approach of the dienophiles **D–F** from the β face of the dienes **7–9** occurs exclusively (Entries 4, 5) or primarily (Entries 6, 7, 9, 10) via *endo* transition states. In contrast, α-attack of the dienophiles proceeds exclusively via *exo* transition states presumably because α-face *endo* transition states are significantly destabilized by steric interaction of the dienophile substituent with the angular CO_2Me group of the dienes. (*e*) Base-catalyzed equilibration of compounds **17**, **19**, **21**, and **23** (*t*-BuOK, *t*-BuOH, 80°C for **17**, **19**; MeONa, MeOH, reflux for **21**, **23**) affords, in each case, predominately or exclusively the corresponding epimers **18**, **20**, **22**, and **24**, respectively. (*f*) Not unexpectedly, the Diels–Alder reactivity of the *cisoid cis* diene **8** is much lower than that of the geometric isomer **7**. Indeed, only reaction of **8** with very reactive dienophiles (e.g. **C**, **D**) gave normal Diels–Alder products (Entries 3, 5) and, even then, the yield was low in one case (Entry 5). An anomalous reaction occurred when **8** was treated with nitroethylene (**E**) in refluxing ether (Entry 8), since the product mixture obtained was essentially identical with that derived from reaction of **7** with **E**. It appears that, in the former process, a rate-determining, nitroethylene-promoted isomerization of **8** into **7** (electron-transfer mechanism?) precedes a normal Diels–Alder transformation. When a solution of **8** in ether was refluxed in the absence of **E**, the diene could be recovered unchanged in high yield.

The (potential) synthetic utility of the Diels–Alder adducts was demonstrated as follows. Treatment of the *mixture* of **17**, **18**, and **25** (Table 1, Entry 6) with MeONa in MeOH, followed by addition of aqueous $TiCl_3$–NH_4OAc (9), afforded a *single* product **30** (90%). Apparently, under the reaction conditions, compound **29**, which would have been present in the initial product mixture, epimerized to the more stable epimer **30**.[6]

[6]The stereochemistry of **30** was confirmed by a ^1H nmr nOe difference experiment, in which irradiation at δ 3.69 (CO_2Me) caused enhancement of the signal (δ 2.82) due to the angular proton adjacent to the ketone carbonyl group. Calculations (MM2) (see ref. 10) indicate that isomer **30** should be ~2.6 kcal/mol more stable than **29**. We are very grateful to Professor L. Weiler for carring out these calculations.

Treatment of **30** with *t*-BuOK–*t*-BuOH provided the α,β-unsaturated ketone **31** (uv λ_{max}(MeOH) = 242 nm).

Further extensions to this work, including the possible application of the methods to the total synthesis of amphilectane-type diterpenoids (e.g. **A**, **B**), are being actively pursued.

^{39}K and ^{13}C nuclear magnetic resonance studies of the potassium cation – dibenzo-30-crown-10[1] complex in solution

CHRISTIAN DETELLIER[2] AND MARC ROBILLARD

Ottawa–Carleton Chemistry Institute, University of Ottawa Campus, Ottawa, Ont., Canada K1N 9B4

Received March 10, 1987

CHRISTIAN DETELLIER and MARC ROBILLARD. Can. J. Chem. **65**, 1684 (1987).

The structure and microdynamics in solution of the dibenzo-30-crown-10 – potassium thiocyanate complex have been studied by ^{39}K and ^{13}C nuclear magnetic resonance. In the four solvents studied (nitromethane, acetonitrile, acetone, and pyridine), the large crown ether wraps around the potassium cation and expels the conjugate anion and the solvent molecules from the cation coordination sphere. Measurements of ^{39}K quadrupolar and ^{13}C dipole–dipole relaxation times in acetone-d_6 gave the effective correlation time of the complex and the ^{39}K quadrupolar coupling constant (1.4 ± 0.3 MHz). The comparison between ^{23}Na and ^{39}K quadrupolar coupling constants for the complexes Na^+–dibenzo-24-crown-8 and K^+–dibenzo-30-crown-10 showed that the electric field gradients at the metal nucleus sites are quasi identical ($q(^{39}K)/q(^{23}Na) \simeq 0.9$) in the two complexes.

CHRISTIAN DETELLIER et MARC ROBILLARD. Can. J. Chem. **65**, 1684 (1987).

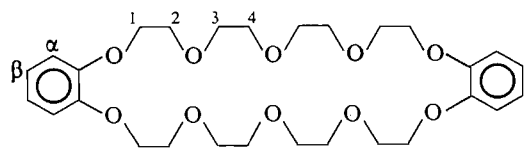
Nous avons étudié la structure et la microdynamique en solution du complexe dibenzo-30-couronne-10 – thiocyanate de potassium par la résonance magnétique nucléaire du ^{39}K et du ^{13}C. Dans les quatre solvants étudiés (nitrométhane, acétonitrile, acétone et pyridine), le grand éther en couronne s'enroule autour du cation potassium, expulsant de la couche de coordination l'anion conjugué et les molécules de solvant. La mesure des temps de relaxation quadripolaire en ^{39}K et dipole–dipole en ^{13}C dans l'acétone deutérée a permis de calculer le temps de corrélation effectif du complexe et la constante de couplage quadripolaire du ^{39}K (1.4 ± 0.3 MHz). La comparaison entre les constantes de couplage quadripolaires du ^{23}Na et du ^{39}K des complexes Na^+–dibenzo-24-couronne-8 et K^+–dibenzo-30-couronne-10 a montré que les gradients de champ électrique au site du noyau métallique sont quasi identiques ($q(^{39}K)/q(^{23}Na) \simeq 0{,}9$) dans les deux complexes.

Introduction

Large crown ethers, such as dibenzo-30-crown-10 (DB30C10, **1**) (1) show some analogies with cryptands (2) in their complexation behaviour. They selectively complex alkali metal cations, creating a three-dimensional cavity during the complexation process. The equilibrium constants for the formation of the complexes M^+–DB30C10, in acetone, are 3.5×10^2 for Na^+, 2×10^4 for K^+, and 1.7×10^4 for Cs^+ (3). DB30C10, like dibenzo-18-crown-6 (DB18C6) (4), cryptand [2,2,2] (5, 6), and the antibiotic ionophore valinomycin (7), selectively complexes K^+. The recognition of K^+ by DB30C10 is conformationally controlled, whereas in the case of cryptands the control is mainly constitutional because their cavity was built during the synthesis. This makes DB30C10 a good model for valinomycin and others for which the cation recognition also relies mainly on conformational controls (7).

X-ray results on the KSCN–DB30C10 complex have shown that the large crown ether wraps around K^+. The ligand has a stable conformation with a majority of "*trans*" C—O and "*gauche*" C—C bonds (8). Live and Chan have shown by ^1H and ^{13}C nmr that the complex in acetone-d_6 solutions has a structure analogous to the crystalline one (3). A ^{13}C nmr study by Shamsipur and Popov supported this conclusion (9). We have shown previously that a 2:1 K^+–DB30C10 complex (10) and 2:1 and 3:2 Na^+–DB30C10 complexes (11) are formed in nitromethane.

In this paper, we show that a 1:1 K^+–DB30C10 complex is quantitatively formed in several nonaqueous solvents with the complete expulsion of solvent molecules from the first coordination shell of the cation. This is very similar to what was observed previously for the Na^+–DB24C8 complex (12). The electric field gradients of ^{23}Na–DB24C8 and ^{39}K–DB30C10 are identical within the limits of the experimental errors. This shows the quasi identity of the coordination shells of Na^+ and K^+ in the two complexes.



1

SCHEME 1

Experimental

Dibenzo-30-crown-10 (Parish Chemical Co.) was recrystallized in a minimum of acetone; after cooling and washing by a few millilitres of acetone, it was dried under vacuum for several hours (mp 105–106°C). Potassium thiocyanate (Aldrich, 99+%) and potassium hexafluorophosphate (Aldrich, 98%) were vacuum dried (60°C) over P_2O_5 for at least 4 h prior to use.

Nitromethane (Aldrich, gold label) and acetonitrile (BDH, assured) were dried under reflux over calcium hydride, fractionally distilled, and stored over 4 Å molecular sieves under argon. Pyridine (Aldrich, gold label) and acetone (Fisher, spectranalyzed) were stored over 4 Å molecular sieves under argon at least two days prior to use. The nmr tubes were tightly capped under argon. All the spectra were recorded within 24 h of preparation of the samples.

The ^{39}K nmr spectra were obtained at 13.997 MHz (Varian XL-300). The chemical shifts were measured with respect to a 0.1 *M* KCl solution in D_2O–H_2O 10:90. The lineshapes were Lorentzian in all cases, and linewidths at half-height were measured graphically. The 90° pulse width was 90 μs.

^{13}C T_1 measurements were done at 75.43 MHz in acetone-d_6 on degassed samples (argon bubbling) containing an excess of salt over the crown. The inversion–recovery 180°–τ–90° pulse sequence was

[1]Dibenzo-30-crown-10: 6,7,9,10,12,13,15,16,23,24,26,27,29,-30,32,33-hexadecahydrodibenzo[*b*,*q*][1,4,7,10,13,16,19,22,25,28]-decaoxacyclotriacontin.

used. The 90° pulse width was 22 μs. The T_1 was obtained from a three-parameter nonlinear regression analysis on nine experimental data points. Nuclear Overhauser enhancement measurements were done using a gated decoupling technique, with a recycling time more than ten times larger than T_1.

Results

Figure 1 shows the ^{39}K chemical shifts of a 0.050 *M* KSCN solution in four solvents (nitromethane (NM), acetonitrile (AN), acetone (AC), pyridine (PY)) as a function of ρ, the ratio [DB30C10]/[KSCN]. In the cases of acetone, acetonitrile, and pyridine, a quasi-linear variation of the chemical shift was observed, until a plateau value was reached for $\rho \geq 1.0$. This is characteristic of the formation of a 1:1 complex with an equilibrium constant of formation larger than 10^4 (3). In acetone, $\log K_f = 4.3$ (3). For $0.0 < \rho < 1.0$, the chemical shift observed was the average mean between the two limiting values for solvated and complexed potassium. In nitromethane, the chemical shift variation was not linear. This has been shown to be indicative of the 2:1 K^+–DB30C10 complex formation (10). In all four solvents, the complex exhibited the same characteristic chemical shift value (−13.3 ± 0.2 ppm). A slight deviation was observed in pyridine at high crown concentrations. The value of the chemical shift of the complex (−13.3 ppm) is in the range expected for a potassium in an oxygen environment: we measured the chemical shift of a 0.1 *M* KSCN solution in methanol as being −8.9 ppm. This value is similar to the one previously published by Shih and Popov (13). The linewidths of the complex span a range of values between 49 Hz (AN) and 95 Hz (PY) (Table 1). These values are close to those measured in ^{23}Na nmr for sodium complexed by DB24C8 (12), and both are linearly related to the viscosity of the solvent. Figure 2 shows the relationship between the solvent viscosity and the measured linewidth of ^{39}K or ^{23}Na in the complexes K^+–DB30C10 and Na^+–DB24C8 respectively. The slopes of the linear relationships are in the same order of magnitude (11.4 Hz/mP for ^{23}Na and 7.2 Hz/mP for ^{39}K).

In the absence of chemical exchange contributions, and because of the effectiveness of the quadrupolar relaxation, the observed linewidth of a quadrupolar nucleus depends only upon the inhomogeneity and the quadrupolar contributions to the relaxation rate (eq. [1]) (16).

$$[1] \quad \frac{1}{T_{2,\text{obs}}} = \pi\nu_{1/2} = \frac{1}{T_{2,\text{inh}}} + \frac{1}{T_{2,\text{q}}}$$

$(T_{2,\text{inh}})^{-1}$ is given by eq. [2] (17, 18).

$$[2] \quad (T_{2,\text{inh}})^{-1} = (T_{2,\text{obs}})^{-1} - (T_{1,\text{obs}})^{-1}$$

The comparison between T_2 and T_1 (eq. [2]) gave $(T_{2,\text{inh}})^{-1} = 21 \pm 4$ Hz. This is comparable to the values of $(T_{2,\text{obs}})^{-1} - (T_{1,\text{obs}})^{-1}$ previously determined in nitromethane under similar experimental conditions (10). Under extreme narrowing conditions, and neglecting the asymmetry parameter, the quadrupolar contribution to the transverse relaxation rate $(T_{2,\text{q}})^{-1}$ is given by eq. [3] (16), where τ_c is the correlation time characteristic of

$$[3] \quad \frac{1}{T_{2,\text{q}}} = \frac{3\pi^2}{10}\frac{2I+3}{I^2(2I-1)}\chi^2\tau_c$$

the quadrupolar relaxation and χ is the quadrupolar coupling constant (QCC), which is given by eq. [4]:

$$[4] \quad \chi = \frac{e^2qQ(1+\gamma_\infty)}{h}$$

Q is the quadrupole moment, q the electric field gradient at

the quadrupolar nucleus site, and $(1 + \gamma_\infty)$ the Sternheimer antishielding factor.

For a spin 3/2 nucleus, such as ^{23}Na or ^{39}K, eq. [3] is reduced to eq. [5]:

$$[5] \quad \frac{1}{T_{2,q}} = \frac{2\pi^2}{5}\chi^2\tau_c$$

If the correlation time, τ_c, characteristic of the electric field gradient fluctuation, has an origin purely reorientational, it should obey the Debye–Stokes–Einstein relationship (eq. [6])

$$[6] \quad \tau_c = \frac{4}{3}\pi a^3 \frac{\eta}{kT} f_r$$

(16). This condition is fulfilled if the lifetime of a spatially well-defined coordination shell of the complex is long with respect to the time characteristic of the molecular reorientation.

In eq. [6], a is the molecular radius, η the medium macroscopic viscosity, and f_r the microviscosity coefficient (19). The experimentally observed linear relationship between the ^{39}K linewidth and the viscosity of the solvent can be easily interpreted from eqs. [1], [5], and [6]. If χ, the quadrupolar coupling constant, were independent of the solvent nature, one would expect a direct relationship between $(T_{2,q})^{-1}$ and τ_c, which is proportional to the viscosity of the solvent. One can assume that, at first approximation, a, the molecular radius of the complex, is independent of the solvent. Moreover, f_r, the microviscosity coefficient, which depends mainly upon the relative size of the complex and of the solvent molecule (19), should also be, at first approximation, independent of the solvent. In the case of Na^+–DB24C8, we have estimated f_r to be ~0.24 in a series of nonaqueous solvents (12).

At this point, two independent observations indicate that the solvent molecules do not participate in the K^+ coordination shell of the complex: the ^{39}K chemical shifts are independent of the solvent, and the linewidths are linearly related to the solvent macroscopic viscosity. The latter behaviour is expected only if the ^{39}K quadrupolar coupling constant does not depend upon the solvent and, consequently, if the symmetry of the electric charges around K^+ is identical in all the solvents. This would be the case if the crown oxygen donor atoms were the only coordinating atoms of K^+.

To evaluate the quadrupolar coupling constant, χ, we need to know τ_c (eq. [5]). We have to make the approximation that τ_c is identical to a reorientational correlation time measured on other nuclei of the supramolecule, the ligand ^{13}C for example. This approach has been used previously and has permitted the calculation of the ^{23}Na quadrupolar coupling constants of Na^+ complexed by some cryptands (20), by the large crown ether DB24C8 (12), and by 15C5 and 18C6 (21). Under extreme narrowing conditions, the ^{13}C dipole–dipole relaxation rate $(1/T_{1,DD})$ is given by eq. [7], where N_H is the number of directly attached hydrogens, r_{CH} the C—H bond length, and τ_{eff} the effective correlation time (22).

$$[7] \quad \frac{1}{T_{1,DD}} = \left(\frac{\mu_0}{2\pi}\right)^2 N_H \gamma_H^2 \gamma_c^2 \hbar^2 r_{CH}^{-6} \tau_{eff}$$

Taking $r_{C—H}$ = 0.1085 nm, eq. [7] is reduced to eq. [8] (the constant term has s^{-2} units).

$$[8] \quad \frac{1}{T_{1,DD}} = 2.2086 \times 10^{10} N_H \tau_{eff}$$

The dipole–dipole contribution to the observed longitudinal relaxation time, $T_{1,obs}$, can be obtained from the measurement of the nuclear Overhauser enhancement (nOe), as shown by eq. [9].

$$[9] \quad T_{1,DD} = T_{1,obs} \times \frac{1.98}{(nOe)_{obs}}$$

Table 2 shows the results of the ^{13}C measurements in the cases of DB30C10–KSCN and DB30C10–KPF_6 in deuterated acetone. Within the limits of the experimental errors, the ^{13}C correlation times, τ_{eff}, are identical for the two complexes (23 ± 4 ps and 16 ± 3 ps respectively). Making the approximation that $\tau_{eff} = \tau_c$, the knowledge of τ_c permits the calculation of χ from eq. [5]. The values of χ for $^{39}K^+$–DB30C10 in $(CD_3)_2CO$ are 1.4 ± 0.3 MHz (SCN^-) and 1.6 ± 0.3 MHz (PF_6^-).

Discussion

The complex K^+–DB30C10 is characterized by the same ^{39}K chemical shift (−13.3 ppm) in each of the four solvents of this study: nitromethane, pyridine, acetone, and acetonitrile. When an excess of crown is present with respect to K^+ the chemical

For personal use only.

shift is constant, showing the absence of complexes other than the 1:1. The slight deviation observed in the case of pyridine for high [crown]:[K^+] ratios could be due to a slight concentration of the sandwich complex. Chemical shift values of K^+ complexed by other ionophores have been reported by Neurohr *et al.* (23). They are given relative to KSCN in a methanol–D_2O 95:5 mixture. The valinomycin–KSCN complex resonates 14.3 ppm highfield from K^+ in methanol, which corresponds to −24 ppm from K^+ in water (K^+ in methanol resonates at −10 ppm from K^+ in water (13)). In the cryptand [2,2,2] – K^+ complex, the ^{39}K chemical shift is +1 ppm relative to K^+ in water (23). In the same study, the ^{39}K quadrupolar coupling constants of the valinomycin–K^+ and of the [2,2,2]–K^+ complexes were measured to be respectively 1.2 MHz and 2.6 MHz (23). A proportionality between the ^{23}Na chemical shifts and the quadrupolar coupling constants has been found for Na^+ encaged in cryptands (20) and was corroborated by the chemical shift and the quadrupolar coupling constant values of $^{23}Na^+$–DB24C8 (12). On the basis of that correlation, assuming that it can be applied to ^{39}K parameters, we can roughly estimate the ^{39}K QCC of the KSCN–DB30C10 complex: the interpolation between the two data from ref. 23 gives 1.7 MHz. The agreement with the value that we have experimentally measured is excellent: 1.7 MHz, to be compared with 1.4 ± 0.3 MHz or 1.6 ± 0.3 MHz! ^{39}K QCC's of 15C5–$KClO_4$ and 15C5–KI in CD_3CN have been determined by Eliasson *et al.* to be 1.4 MHz (21). In the same study, much higher values (3.4 and 3.5 MHz) were attributed to the systems 18C6–$KClO_4$ and 18C6–KI (21).

It is particularly interesting to compare ^{23}Na and ^{39}K QCC's in the two complexes Na^+–DB24C8 and K^+–DB30C10. In the two cases, we have strong indications of the similarity of the cationic environment. The coordination sphere is made of ether oxygens only, since all the solvent molecules and the counter-anion have been expelled from the sodium or the potassium coordination sphere during the complexation process. This similarity should be reflected in the electric field gradient at the site of the metal cation. From eq. [4], and from known values (16) of the quadrupole moment (Q = 0.055 barn (^{39}K) and 0.12 barn (^{23}Na)) and of the Sternheimer antishielding factor (24) ($|(1 + \gamma_\infty)|$ = 5.26 for ^{23}Na and 19.96 for ^{39}K), one can estimate the ratio of the two electric field gradients: $q(^{39}K)/q(^{23}Na) \simeq 0.9$ (KSCN complex) and $\simeq 1.1$ (KPF_6 complex). The similarity of the two electric field gradients is thus remarkable and confirms that the environment of Na^+ and K^+ in DB24C8 and DB30C10 complexes, respectively, consists only of oxygen atoms from the ligand. The structure of the complex in solution is similar to the structure in the crystal where DB30C10 has been shown to wrap around K^+ (8). ^{13}C and ^1H nmr studies of the ligand have suggested the same conclusion (3, 9). Moreover, the crown ether coordination shell is rigid on the time scale of the molecular reorientation of the complex. This means that the chemical exchange of K^+ between different ligands is not responsible for the quadrupolar relaxation. This is expected on the basis of the known time scale for such processes, 10^4–$10^6\ s^{-1}$ (18), much slower than molecular tumbling. But it means also that no internal fluctuations in the potassium coordination shell can be detected from the quadrupolar relaxation rate, $(T_{2,q})^{-1}$. In the complex, the crown ether segmental motions and the cation mobility into the cavity are frozen in the time scale of the overall molecular reorientation. When complexing K^+, DB30C10 appears as a rigid matrix, with its oxygen ether atoms pointing to the inside and surrounding K^+, tightly maintained in the cavity.

Kinetic and equilibrium study of the ring opening of 2-aryl-1-methyl-1-pyrrolinium ions in aqueous solution

ROBERT A. MCCLELLAND AND N. ESTHER SEAMAN
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received August 11, 1986

This paper is dedicated to Professor John T. Edward

ROBERT A. MCCLELLAND and N. ESTHER SEAMAN. Can. J. Chem. **65**, 1689 (1987).

Ultraviolet spectral and kinetic measurements are reported for the transformations in aqueous solution undergone by the cyclic iminium ion, the 2-aryl-1-methyl-1-pyrrolinium ion $\mathbf{I}^+$. In solutions with pH < 9.5 this ion equilibrates with a ring-opened hydrated form, the protonated 4-methylaminobutyrophenone $\mathbf{SH}^+$. The concentration of the latter at equilibrium is small, but it can be observed using nuclear magnetic resonance spectroscopy. A kinetic analysis provides a measure of the $\mathbf{I}^+ \rightleftarrows \mathbf{SH}^+$ equilibrium constant. Values range from 0.06 for 4-methoxyphenyl to 0.17 for 3-chlorophenyl. In acid solutions (pH < 5) the equilibration is slow (half-life ≈ 20 min for phenyl) and pH independent. Above pH 5 this process becomes first order in hydroxide ion. In strongly basic solutions a neutral species is formed in equilibrium with these two cations, with pK(app) for the transformation cations ⇄ neutral + H^+ ranging from 11.8 to 11.3. Spectral arguments imply that the base species is the ring-opened 4-methylaminobutyrophenone **S**, with less than ten percent of the pseudobase of I^+ present.

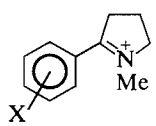
ROBERT A. MCCLELLAND et N. ESTHER SEAMAN. Can. J. Chem. **65**, 1689 (1987).

On a mesuré les spectres ultraviolets et la cinétique des transformations que subit l'ion cyclique iminium, l'ion aryl-2 méthyl-1 pyrrolinium I^+, dans des solutions aqueuses. Dans des solutions de pH < 9,5, cet ion s'équilibre avec la forme hydratée qui est ouverte, soit la méthylamino-4 butyrophénone protonée SH^+. À l'équilibre, la concentration de ce composé est faible; toutefois, on peut l'observer par rmn. Une analyse cinétique fournit une mesure de la constante d'équilibre $I^+ \rightleftarrows SH^+$. Les valeurs de cette constante varient de 0,06 pour le méthoxy-4 phényle à 0,17 pour le chloro-3 phényle. Dans des solutions acides (pH < 5), l'équilibre est lent (demi-vie ≈ 20 min pour le phényle) et ne dépend pas du pH. Au-dessus d'un pH de 5, ce processus devient du premier ordre en ions hydroxydes. Dans des solutions fortement basiques, il se forme une espèce neutre qui est en équilibre avec ceux deux cations; le pK(app) pour la transformation des cations ⇄ forme neutre + H^+ varie de 11,8 à 11,3. Les arguments basés sur les spectres indiquent que l'espèce basique est la méthylamino-4 butyrophénone à chaîne ouverte S; il y aurait moins de dix pourcent de la pseudobase de I^+ qui serait présente.

[Traduit par la revue]

The reversible addition of hydroxide ion to heterocyclic cations is well documented (1). The pseudobase product of this reaction is usually also the tetrahedral adduct of an intramolecular nucleophilic addition to a carbonyl (or acyl) group. As

[1] 
such, the pseudobase frequently exists in equilibrium with a ring-opened form, a phenomenon which has been termed "ring-chain tautomerism" (1). As part of a program of study of tetrahedral intermediates (2, 3) we have investigated a series of cyclic iminium ions I^+. This study was prompted by suggestions that

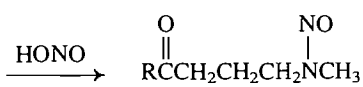


I^+; X = 4-MeO, 4-Me, H, 4-Cl, 3-Cl

nitrosamines derived from nicotine are forming by way of iminium salts, one of which has a structure analogous to I^+ (4, 5).

As our analysis will demonstrate, the I^+ system has the interesting property of having the cation in equilibrium with a ring-opened amino ketone. This may explain the ease of formation of the ring-opened N-nitroso derivative of nicotine.

[2] 
R = 3-pyridyl



Experimental

2-Aryl-1-methyl-1-pyrrolinium trifluoromethanesulfonates

2-Aryl-1-pyrrolines (6, 7) were dissolved in methylene chloride freshly distilled from concentrated H_2SO_4; an equivalent amount of methyl trifluoromethanesulfonate was slowly added, with the solution being cooled in an ice bath. Anhydrous ether was then added and the resultant white solid collected by filtration. This was purified by redissolving in methylene chloride and reprecipitation with ether. Proof of structure was accomplished through ^1H nmr spectroscopy. The spectrum of the unsubstituted compound was identical to that reported for the perchlorate salt (8).

Kinetic and ultraviolet spectral measurements were made on a Cary 2390 spectrophotometer and a Durrum–Gibson stopped-flow spectrophotometer. In general, stock solutions of the I^+ salt of concentrations $1–2 \times 10^{-4}$ M in water were used to initiate studies. For reactions in base this stock solution was mixed with an equivalent volume of sodium hydroxide solution; kinetics were studied on the stopped-flow apparatus, with final spectra being recorded on the Cary. The kinetic measurements reported in weakly basic, neutral, and acidic solutions were performed by adding the stock solution to an equivalent volume of 0.20 M NaOH. This solution was then mixed with an equal volume of solution of the appropriate pH, also containing 0.10 M HCl. First-order rate constants were obtained as the average of 3–8 runs, by least-squares analysis of plots of $\ln(A - A_\infty)$ or $\ln(A_\infty - A)$ versus time. Wavelengths employed for kinetic studies were 305 nm (4-$MeOC_6H_4$), 276 nm (4-MeC_6H_4), 265 nm (C_6H_5), 280 nm (4-ClC_6H_4), and 275 nm (3-ClC_6H_4).

Results

The analysis principally involved uv spectral and kinetic measurements; observations are presented in detail here for the unsubstituted ion, which was examined most thoroughly. The

TABLE 1. Observed constants for the transformations of 2-aryl-1-methyl-1-pyrrolinium ions (25°C, ionic strength = 0.1)

Aryl group	pK(app)	A	B	C
4-MeOC$_6$H$_4$	11.89	1.94	161	6.76×10^{-4}
4-MeC$_6$H$_4$	11.86	3.01	294	6.46×10^{-4}
C$_6$H$_5$	11.67	4.52	496	7.41×10^{-4}
4-ClC$_6$H$_4$	11.53	5.04	799	7.59×10^{-4}
3-ClC$_6$H$_4$	11.39	5.95	1395	6.03×10^{-4}

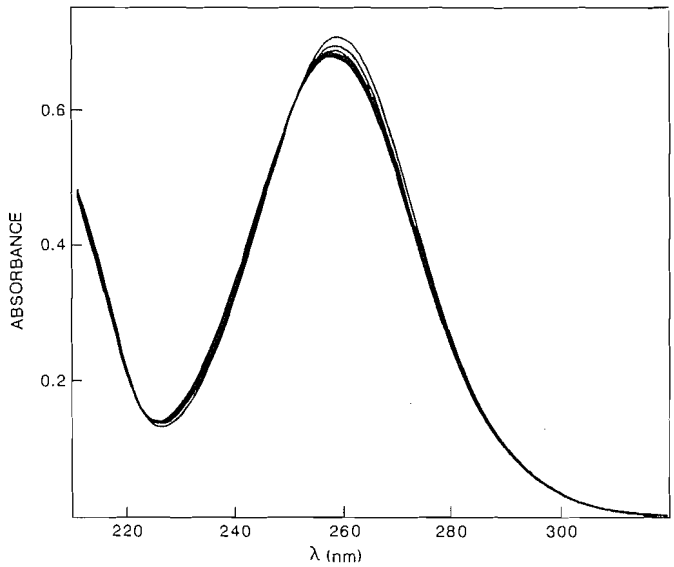

FIG. 1. 1-Methyl-2-phenyl-1-pyrrolinium trifluoromethanesulfonate ($7.5 \times 10^{-5} M$) in $10^{-3} M$ HCl, with spectra recorded every 20 min. The absorbance decreases with time at 260 nm, and increases at 240 nm.

other derivatives behave qualitatively the same. The empirical constants presented in this section are symbolized as K(app) (app = apparent) or $A, B \ldots$, while the rate and equilibrium constants derived on the basis of a mechanistic scheme in the discussion section are symbolized as $k_1, K_1 \ldots$ A summary of the empirical constants obtained for all the ions is given in Table 1.

Figure 1 shows uv spectra observed on dissolving iminium salt in weakly acidic solution. There is a small but reproducible spectral change with the intensity at the 257-nm λ_{max} decreasing slightly and an accompanying absorbance increase at lower wavelengths. More dramatic spectral changes are observed in strongly basic solutions, and they occur very quickly, requiring stopped-flow spectroscopy for the change actually to be observed (see kinetics, later). A typical spectrum in base is that shown as the initial spectrum in Fig. 2, with λ_{max} at 245 nm. (Although the actual solution here is acidic, the transformation that is occurring is quite slow, and the starting spectrum is that of a base solution.)

As might be expected, the absorption spectra in base are pH dependent, ranging from the 245-nm λ_{max} at high hydroxide ion concentrations to the 257-nm λ_{max} at very low hydroxide concentrations. Figure 3 shows absorbance dependencies at 240 nm and 265 nm, wavelengths slightly off the λ_{max} being chosen in order to have larger overall absorbance changes. These describe acid–base titration curves, and acidity constants were calculated as

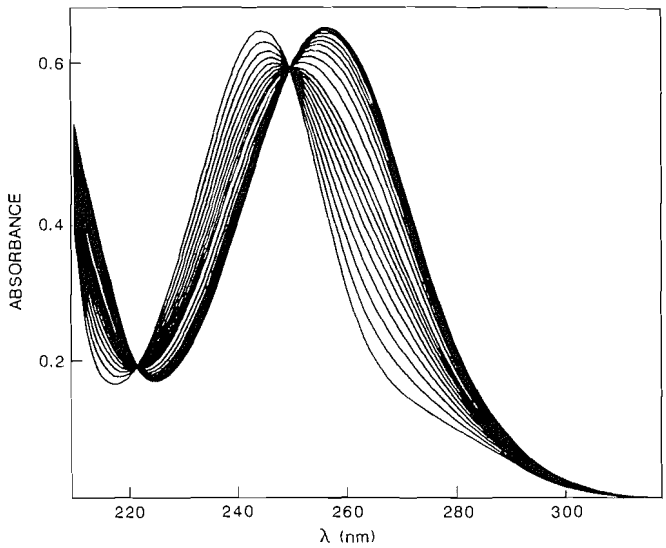

FIG. 2. 1-Methyl-2-phenyl-1-pyrrolinium trifluoromethanesulfonate added to $0.10 M$ NaOH, followed by acidification to pH 2 by addition of HCl. Final concentration of substrate is $7.5 \times 10^{-5} M$. The first ten spectra were recorded with 8-min intervals, thereafter 20 min.

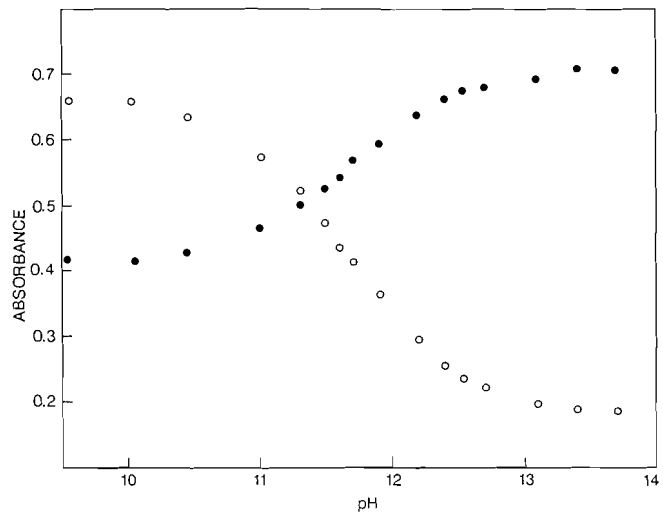

FIG. 3. 1-Methyl-2-phenyl-1-pyrrolinium ion absorbances in base solution; ●, 265 nm; ○, 240 nm. All solutions were $7.5 \times 10^{-5} M$ substrate, and up to $0.1 M$ NaOH had ionic strength (μ) of 0.1 maintained with NaCl. Solutions below pH 11 were carbonate buffers, and above pH 11 they contained sodium hydroxide. The pH in solutions containing more than $0.01 M$ NaOH was calculated with pK_w of 13.7 at $\mu = 0.1$ (9).

$$[3] \quad K(\text{app}) = \frac{A_{base} - A}{A - A_{acid}} [H^+]$$

where A, A_{base}, and A_{acid} are absorbances in the solution in question, base ($1 M$ NaOH), and acid (pH < 10) respectively.

That a reversible acid–base type of equilibrium exists throughout the pH range is demonstrated by the experiment described in Fig. 2. This shows the spectral changes that occur when a basic solution with the 245-nm absorbance is reacidified, with the result that the 257-nm absorbance is regenerated. The change is quite slow, at least in strong acids. The rate, within experimental error, is identical with that of the much smaller

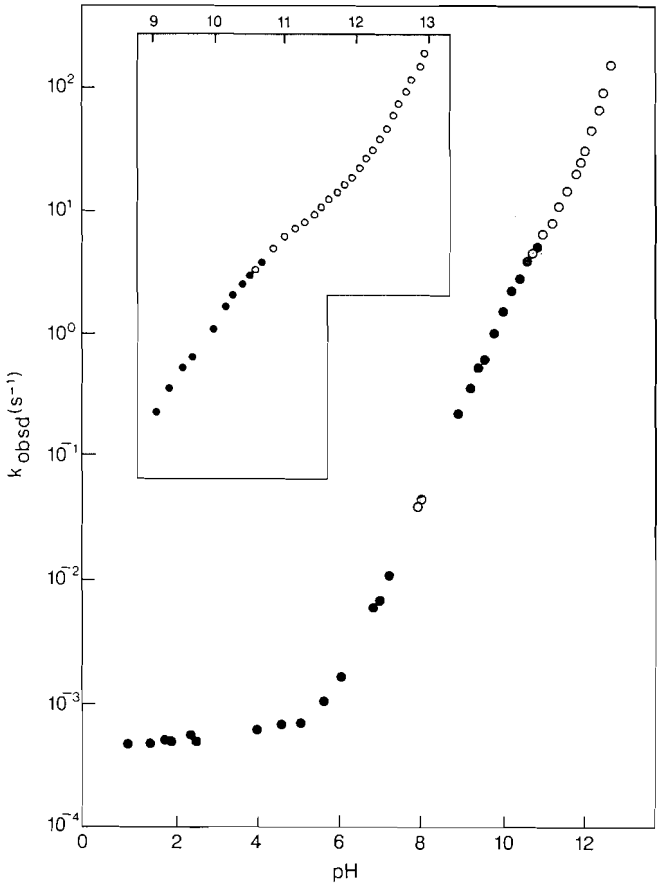

FIG. 4. Observed rate constants (s^{-1}, 25°C, 0.1 ionic strength) for transformations of the 1-methyl-2-phenyl-1-pyrrolinium ion; ○, starting with neutral solution of ion; ●, starting with 0.1 *M* NaOH solution. Rate constants in buffer solutions (pH 4–11) were based upon extrapolation to zero buffer concentration or were determined in dilute (0.002 *M*) buffers. The insert is an expansion of the high pH region.

spectral change found on adding iminium ion directly to a solution of the same pH.

The various transformations all obey excellent first-order kinetics, with no evidence for intermediates. First-order rate constants are shown in Fig. 4. Those in strongly basic solutions were obtained by mixing, on a stopped-flow spectrophotometer, a neutral solution of iminium ion with aqueous sodium hydroxide. Other rate constants were obtained using the procedure described in Fig. 2, by preparing an 0.1 *M* NaOH solution and mixing this with an appropriate neutralizing buffer, either on the stopped-flow apparatus or in a conventional uv cuvette.

The rate constants in base (pH > 7) accurately follow the empirical relationship

$$[4] \quad k_{obsd} = \frac{A[OH^-] + B[OH^-]^2}{C + [OH^-]}$$

and values of the three coefficients were determined by a non-linear least-squares fit of the experimental data to this equation. The quantity A/C is the slope of the approximately linear plot of k_{obsd} vs. $[OH^-]$ in the pH 7–10 region, while the quantity B is the limiting slope of a similar plot at high hydroxide ion concentration. In acid solution (pH < 5) the rate constants level, with $k_{obsd} = D = 5.0 \times 10^{-4}\ s^{-1}$ for the unsubstituted compound. (The other derivatives were not studied in detail in acids.) Catalysis by the buffer is also observed in acids, but this was not investigated in detail.

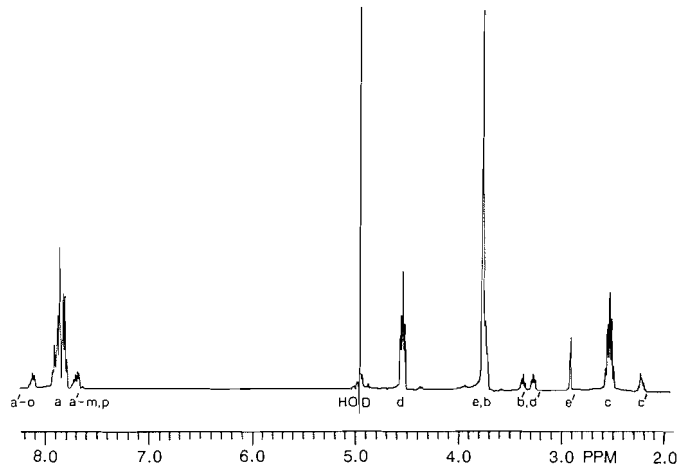

FIG. 5. The 400-MHz ^1H nmr spectrum in D_2O solution, pD ~ 2, of the 1-methyl-2-phenyl-1-pyrrolinium ion, recorded 24 h after solution preparation.

Figure 5 shows a 400-MHz nmr spectrum in weakly acidic D_2O, a day after solution preparation. A spectrum recorded immediately consisted only of the larger signals, with the smaller signals indicated by primes appearing with time. No further change occurred beyond that shown in the figure. It can be noted that the kinetics show that the equilibration, whatever it represents, is complete within a day.

Discussion

Nature of the acid species

Both uv (Fig. 1) and nmr (Fig. 5) show that the iminium ion is not completely stable in acids, but that another minor species is formed in equilibrium. We propose that this is the ring-opened protonated amino ketone SH^+.

$$[5] \quad C_6H_5\overset{a}{C}{=}\overset{+}{N}(\overset{e}{CH_3})\overset{b}{CH_2}\overset{c}{CH_2}\overset{d}{CH_2} \rightleftharpoons C_6H_5\overset{a'}{C}(=O)\overset{b'}{CH_2}\overset{c'}{CH_2}\overset{d'}{CH_2}\overset{+}{N}H_2\overset{e'}{CH_3}$$

SH^+

Peak assignments for the nmr spectrum in Fig. 5 are shown in eq. [5]. The spectrum assigned to I^+ is very similar to that recorded in a nonhydroxylic solvent (8). The ketone spectrum is characterized by the two triplets for the b′ and d′ methylene groups, as well as the separation of the aromatic *ortho* hydrogen signals from the *meta*:*para* signals, which is typical of the C_6H_5CO grouping. As will become apparent in the next section, the small uv change of Fig. 1 is also consistent with the formation of a small amount of the butyrophenone derivative. The nmr integration shows that at equilibrium the ketone is formed to the extent of about ten percent. A more accurate figure will be derived through the kinetic analysis.

Nature of the base species

There are two candidates for the product that is formed in base, the pseudobase IOH of the iminium ion or the neutral

$$[6] \quad Ar\text{-}\underset{HO\ CH_3}{N} \rightleftharpoons ArC(=O)CH_2CH_2CH_2NHCH_3$$

IOH S

amino ketone S. The uv spectrum of the latter should resemble that of acetophenone or butyrophenone, while the spectrum for the former should be like that of benzene or toluene, being much weaker in intensity (10). In fact, the spectrum is virtually identical to that of a benzoyl ketone. It is, of course, impossible to exclude the presence of a small amount of IOH, but there is likely less than 10% of this.

With the structural assignments, predominantly I^+ in acid and predominantly S in base, the K(app) approximately represents the equilibrium $I^+ \rightleftarrows S + H^+$. With p$K$(app) around 12 and [IOH]/[S] less than 0.1, pK_R for the equilibrium $I^+ \rightleftarrows IOH + H^+$ must be 13 or greater. Perhaps the closest analog of I^+ that has been studied in this regard is the 2-methyl-3,4-dihydroisoquinolinium cation, which has a pK_R value of 11.0

[7] 
(11). This cyclic cation has a phenyl ring at the position of OH attachment. Its major difference is the presence of a hydrogen at that carbon, while I^+ has the methylene unit that is part of the ring. The effect of substituting hydrogen for alkyl cannot be determined with certainty, but it is likely to be such that a 2-log unit increase in pK_R is not improbable. The hydration of ketones and aldehydes, for example, shows large effects of substituting hydrogen for methyl (12). An example in a heterocyclic context is that shown in eq. [8] where the addition equilibrium is 350 times less favourable for R = CH_3 than for R = H (13).

[8] 
Interestingly, with the cation in eq. [7], the base equilibrium apparently favours the pseudobase form. This is likely a reflection of the generally more favourable additions to aldehydes, although ring size may also be important.

Kinetic analysis

[9] 
A scheme that satisfies the observed kinetics, as well as the previous discussion, is presented in eq. [9]. Three species are involved, I^+, S, and SH^+, with the simple protonation equilibrium involving the last two being very fast. The pseudobase IOH must also be involved but, since it is not present in significant amounts, it can be taken as a steady-state intermediate. There is a question as to whether the $I^+ \rightleftarrows$ IOH stage or the IOH $\rightleftarrows$ S stage is rate limiting, but for the analysis this does not need to be known, the kinetics being satisfied by eq. [9]. The following definitions are made:

$$[10] \quad K_{I^+} = \frac{[S][H^+]}{[I^+]} = \frac{k_1 K_w}{k_{-1}} = \frac{k_2}{k_{-2}}$$

$$[11] \quad K_{SH^+} = \frac{[S][H^+]}{[SH^+]}$$

$$[12] \quad K_+ = \frac{[SH^+]}{[I^+]} = \frac{K_{I^+}}{K_{SH^+}}$$

$$[13] \quad K(\text{app}) = \frac{[S][H^+]}{([I^+] + [SH^+])} = \frac{K_{I^+} K_{SH^+}}{K_{I^+} + K_{SH^+}}$$

The last quantity defines the spectroscopic acidity constant based upon this scheme.

Ignoring the k_2, k_3 terms and their reverse, and recognizing that the kinetics refer to an approach to equilibrium, the following expression is obtained:

$$[14] \quad k_{obsd} = \frac{k_1 \dfrac{K_w}{K(\text{app})}[OH^-] + k_1[OH^-]^2}{\dfrac{K_w}{K_{SH^+}} + [OH^-]}$$

(The derivation makes use of the relationship between k_1 and k_{-1} noted in eq. [10].) Equation [14] has the same form as the empirical eq. [4], and we can set $A = k_1 K_w/K(\text{app})$, $B = k_1$, and $C = K_w/K_{SH^+}$. The observed values of A, B, C then provide the three constants k_1, K(app), and K_{SH^+}, and these in turn provide other constants, all of which are listed in Table 2. The identity, within experimental error, of the K(app) values derived kinetically and spectroscopically points to the consistency in the analysis. The ammonium pK_{SH^+} values lie within the range expected, and show little effect associated with the remote aromatic substituent. As expected, pK_{I^+} values indicate stabilization of the iminium ion form by electron-donating substituents. This is also true for the K_+ values. These are all small, consistent with the nmr analysis, but they do show increasing amounts of the protonated ketone form with electron-withdrawing substituents in the aromatic ring.

In terms of the rate–pH profile of Fig. 4, the region at very high pH has k_{obsd} approaching $k_1[OH^-]$. This represents conversion of the iminium ion to the amino ketone S. The other region of linearity in hydroxide ion (pH 7–10) has

$$[15] \quad k_{obsd}(\text{pH } 7\text{–}10) = \frac{k_1 K_{SH^+}}{K(\text{app})}[OH^-] = \left(k_1 + k_{-1}\frac{K_{SH^+}}{K_w}\right)[OH^-]$$

Here k_{obsd} refers to the kinetics of approach to equilibrium of the two ions I^+ and SH^+. The last part of eq. [15] is written in terms of forward and reverse rate constants. Since $[I^+] > [SH^+]$ at equilibrium, it is the rate constant for the reverse process $SH^+ \rightarrow I^+$, $k_{-1}K_{SH^+}[OH^-]/K_w$, which makes the greater contribution to k_{obsd}. The hydroxide ion dependency arises because of the requirement for SH^+ deprotonation.

TABLE 2. Rate and equilibrium constants for the transformations of 2-aryl-1-methyl-1-pyrrolinium ions (25°C, ionic strength = 0.1)

	4-$MeOC_6H_4$	4-MeC_6H_4	C_6H_5	4-ClC_6H_4	3-ClC_6H_4
k_1, M^{-1} s^{-1} [a]	1.6×10^2	2.9×10^2	5.0×10^2	8.0×10^2	1.4×10^3
k_{-1}, s^{-1} [b]	1.8	2.8	4.2	4.4	5.1
pK_{SH^+} [c]	10.53	10.51	10.57	10.58	10.48
pK(app), kinet [d]	11.78	11.71	11.66	11.50	11.32
pK(app), spect [e]	11.89	11.86	11.67	11.53	11.39
pK_{I^+} [f]	11.76	11.68	11.62	11.44	11.26
K_+ [g]	0.059	0.067	0.089	0.137	0.165

[a] B from Table 1.
[b] k_1K_w/K_{I^+}.
[c] K_w/C.
[d] BK_wA.
[e] Taken directly from Table 1.
[f] $K_{SH^+}K(app)/(K_{SH^+} - K(app))$.
[g] K_{I^+}/K_{SH^+}.

The plateau region in acid also represents I^+–SH^+ equilibration, occurring by the k_2/k_{-2} process in eq. [9], so that

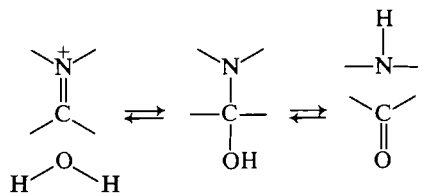
$$[16] \quad k_{obsd}(pH < 5) = \frac{k_2K_{SH^+}}{K(app)} = k_2 + k_{-2}K_{SH^+}$$

Now the need for SH^+ deprotonation in the reverse direction is exactly balanced by the H^+ catalysis of the S → I^+ reaction.

Mechanism

Mechanisms of the reversible formation of imines and iminium ions from amines and carbonyl compounds are well established (14). A carbinolamine (the pseudobase of this study) is an intermediate and, for the reaction written in the hydrolysis

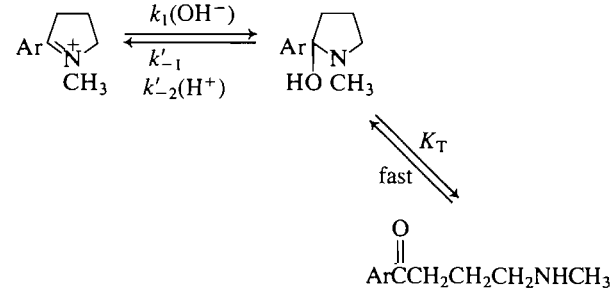
[17]



direction, breakdown of the intermediate to products is usually found to be rate limiting in acid solution, with formation of the intermediate rate limiting in neutral and basic solutions. The change in rate-limiting step is explained in terms of H^+ catalysis of the reverse of the formation, while the breakdown to products requires no catalysis.

The change in rate-limiting step is characterized experimentally by the appearance of a downward break in the rate–pH profile at some pH (14). For the I^+ system the absence of such a break, other than that associated with amine protonation, implies that there is no change in rate-limiting step. This makes the actual mechanistic assignment somewhat uncertain. Equation [18] is written with the iminium ion – pseudobase interconversion rate limiting throughout.

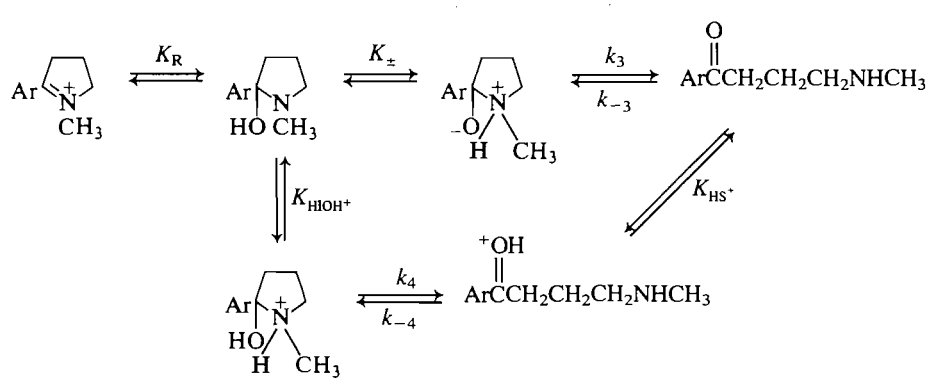
[18]



This reaction occurs in the forward direction with addition of hydroxide ion and addition of water coupled with H^+ loss. The microscopic reverse of the latter process has H^+ assisting OH departure from the pseudobase. This mechanism corresponds to the more general eq. [9], with k_1 and k_2 having the same meaning, and $k_{-1} = k'_{-1}/K_T$ and $k_{-2} = k'_{-2}/K_T$.

The alternative mechanism where pseudobase–aminoketone equilibration is rate limiting is written as

[19]



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

Here the reaction in neutral and base solution is that proceeding by way of the zwitterion with k_1 of eq. [9] = $k_3K_{\pm}K_R/K_w$ and $k_{-1} = k_3$. The acid reaction involves the N-protonated pseudobase and O-protonated amino ketone, with $k_2 = k_4K_R/K_{HIOH^+}$ and $k_{-2} = k_{-4}/K_{HS^+}$.

The mechanisms of eqs. [18] and [19] are kinetically equivalent, and both satisfy the observed kinetics. Precedence would suggest eq. [17] to better represent the correct mechanism, since the addition stage is normally rate limiting in base. However, hydrolysis of the 1,3-diphenyl-2-imidazolinium ion, a cyclic ion not unlike I^+, has the breakdown stage rate limiting (15), so that it may be dangerous to generalize with a cyclic system.

[20] 
The experimental k_{obsd} in acid requires for the mechanism of eq. [18] a k_2' value greater than $10^8 M^{-1} s^{-1}$, since $K_T < 0.1$. For the mechanism of eq. [19], k_{-4} is required to be of the order of $10^{11} s^{-1}$, since pK_{HS^+} for protonated acetophenones is of the order of -4 (16).

Summary

Despite the mechanistic ambiguity, the basic features of the aqueous chemistry of I^+ are clear. In solutions with pH < 10, equilibration occurs to produce a small amount (6–14% depending upon substituent) of the ring-opened protonated amino ketone. The equilibration is quite slow in acids (pH < 5), where it occurs by a pH independent reaction, but it rapidly accelerates above pH 6 due to a process with a hydroxide ion dependency. In strongly basic solutions, a neutral species is produced very rapidly in a pH dependent equilibrium with apparent pK values ranging from 11.3 to 11.9. Spectral comparisons suggest that the neutral form is amino ketone, with the pseudobase of I^+ being present to, at best, only a very small amount.

Keto ethers. IV.[1] Products formed on reaction of dihydro-2,2,5,5-tetramethyl-3(2*H*)-furanone with strong acids

PETER YATES AND PATRICK MICHAEL BURKE[2]

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received August 20, 1986

This paper is dedicated to Professor John T. Edward

PETER YATES and PATRICK MICHAEL BURKE. Can. J. Chem. **65**, 1695 (1987).

Reaction of tetrahydro-2,2,5,5-tetramethyl-3(2*H*)-furanone (**1**) with 96 or ca. 100% sulfuric acid or hot polyphosphoric acid followed by aqueous quenching gave the following products: 2-hydroxy-2,5-dimethyl-4-hexen-3-one (**3**), 2,4,4-trimethyl-2-cyclopenten-1-one (**7**), 3,5,5-trimethyl-2-cyclopenten-1-one (**8**), tetrahydro-3,4,5,5-tetramethylfuran-2,3-diol (**11**), 2,5-dihydro-3,5,5-trimethyl-2-methylenefuran (**17**) and its dimer **20**, 2,5-dihydro-2,3,5,5-tetramethyl-2-furanol (**18**), 4-hydroxy-2,4-dimethyl-2-pentenoic acid γ-lactone (**22**), 2,3,5-trimethyl-2-cyclopenten-1-one (**23**), and tetramethylfuran (**25**). In 96% sulfuric acid the products arise by ring opening, ring opening followed by reclosure to carbocyclic products, methyl migration from C-2 to C-3 to give rearranged furan derivatives, and oxidation. In ca. 100% sulfuric acid or hot polyphosphoric acid further methyl migrations can occur to give **23** and **25**.

PETER YATES et PATRICK MICHAEL BURKE. Can. J. Chem. **65**, 1695 (1987).

La réaction de la tétrahydro tétraméthyl-2,2,5,5 2*H*-furannone-3 (**1**) avec de l'acide sufurique à 96 ou à environ 100% ou avec de l'acide polyphosphorique à chaud, suivie par un piégeage avec de l'eau, conduit aux produits suivants : l'hydroxy-2 diméthyl-2,5 hexène-4 one-3 (**3**), la triméthyl-2,4,4 cyclopentène-2 one-1 (**7**), la triméthyl-3,5,5 cyclopentène-2 one-1 (**8**), le tétrahydro tétraméthyl-3,4,5,5 furannediol-2,3 (**11**), le dihydro-2,5 triméthyl-3,5,5 méthylène-2 furanne (**17**) et son dimère **20**, le dihydro-2,5 tétraméthyl-2,3,5,5 furannol-2 (**18**), la γ-lactone de l'acide hydroxy-4 diméthyl-2,4 pentène-2 oïque (**22**), la triméthyl-2,3,5 cyclopentène-2 one-1 (**23**) et le tétraméthylfuranne (**25**). Dans l'acide sulfurique à 96%, les produits proviennent d'ouvertures de cycle, d'ouvertures de cycle suivies d'une recyclisation conduisant à des produits carbocycliques, de transpositions de groupements méthyles de la position C-2 à la position C-3 conduisant à des dérivés furanniques transposés et d'oxydations. Dans l'acide sulfurique à environ 100% ou dans l'acide polyphosphorique à chaud, il se produit d'autres migrations de groupements méthyles qui conduisent aux composés **23** et **25**.

[Traduit par la revue]

There have been many investigations of the reactions of organic compounds with strong acids (3, 4). Several of these have concerned substrates with saturated or unsaturated carbonyl functions. Less attention has been paid to carbonyl compounds containing other functional groups. We report on an investigation of the variety of reactions undergone by the keto ether **1** in strongly acidic media.[3] We describe here the isolation and determination of the structures of the products formed in such reactions and plan, in a subsequent publication, to discuss the formation of these products in terms of the site(s) of protonation of **1** and the nature of the cationic intermediates.

Compound **1** is readily available from the ynediol **2** (6). Reactions in strongly acidic media followed by aqueous quenching gave mixtures of products whose composition was dependent on both the nature of the medium and the time of reaction. These products were isolated by standard procedures and identified by their spectra (Tables 1 and 2) and by comparison in most cases with independently synthesized samples.

Vapor phase chromatographic (vpc) analyses of product mixtures from 96% sulfuric acid showed that one compound was formed rapidly and that the amount of this product reached a maximum after 2 h and then fell to zero after several days. This compound was shown to be **3** by comparison with an authentic sample prepared as in Scheme 1 (2, 7). It has been reported that **3** fails to form a 2,4-dinitrophenylhydrazone (7); our attempts to form such a derivative in ethanol gave the 2,4-dinitrophenylhydrazone of the *O*-ethyl analogue of **3**.

A second product that was detected by vpc analysis increased in amount gradually to a maximum of about 5% after 6 h and then remained essentially constant in amount. This compound was shown to be **7** by comparison with an authentic sample (Scheme 1). Treatment of **2** with hot 50% sulfuric acid gave the dienyne **4** (8) in 45–50% yield, accompanied by a complex mixture of other products, three of which were identified as **1**, **3**, and **5**; the structural assignment **5** is based on spectroscopic data (see Experimental). Cuprous ion-catalyzed addition of hydrogen chloride to **4** gave a product whose ^{1}H nmr spectrum

showed it to be 3,4-dichloro-2,5-dimethyl-2,4-hexadiene (**6**) and not the corresponding 1,3-dichloro compound as earlier considered (8).[4] Treatment of **6** with hot 85% sulfuric acid gave **7**.

A second cyclopentenone was detected among the reaction products from treatment of **1** with 96% sulfuric acid; it was present in only trace amounts, but was formed in greater, albeit still small, amounts from **1** on treatment with ca. 100% sulfuric acid (*vide infra*). This product was shown to be 3,5,5-trimethyl-2-cyclopenten-1-one (**8**) by comparison with an authentic sample (10), obtained as a 2:3 mixture with 3,4,4-trimethyl-2-cyclopenten-1-one (**9**). The individual structural assignments

8 **9**

are based on an alternative, unambiguous synthesis of **9** (11) and are confirmed by comparison of the ^{1}H nmr spectra of these compounds and **7** (Table 2).

Work-up of the reaction mixture of **1** and 96% sulfuric acid after short reaction times gave, in addition to compounds **3**, **7**, and **8**, a crystalline, highly water-soluble compound, $C_8H_{16}O_3$, which could only be isolated by continuous extraction. The yield of this product increased in the first two hours and decreased to zero after 12 days. It is assigned the gross structure **11** on the following basis. Its ir spectrum shows the presence of one or more hydroxyl groups and the absence of a carbonyl group. Oxidation with lead tetraacetate followed by basic hydrolysis gave diacetone alcohol (**14**) (Scheme 2). It was independently synthesized by treatment of the hydroxy lactone **10** (12) with methylmagnesium iodide. This reaction also gave **12**, identified by comparison with an authentic sample prepared by treatment of **1** with methylmagnesium iodide (13), and a high-melting crystalline product **13**. The structure of the latter was not established, but it may be related to 2,3,5-trimethyl-2,3,5-hexanetriol since it gave **12** on treatment with 50% sulfuric acid. While **11** was obtained as a crystalline solid with a 2° melting range, its ^{1}H and ^{13}C nmr spectra exhibit a complex series of peaks in the methyl proton region, indicating that in solution it exists as a mixture of diastereomers (the ^{1}H nmr data given in Table 2 are the signals assigned to the major tautomer). These diastereomers should be readily interconvertible via ring–chain tautomerization, although none of the ketonic tautomer could be observed spectroscopically.

Two interesting reactions of the diol **11** were observed. When injected onto a vpc column (see Experimental) at 140°C it underwent pinacol rearrangement to give **1**; this reaction appears to be catalyzed by acid sites on the column, since no reaction was observed on heating **11** alone at 150°C. When a solution of **11** in benzene was boiled in the presence of a catalytic amount of *p*-toluenesulfonic acid, bimolecular dehydration occurred to give a high-melting crystalline product lacking hydroxyl or carbonyl groups. This is assigned the gross structure **15**, the head-to-tail isomer being preferred on mechanistic grounds and because both **15** and **11** dissolve in 96% sulfuric acid to give rapidly and quantitatively the same cationic species, as shown by ^{1}H nmr spectroscopy.

After long reaction times (5–12 days) the ^{1}H nmr spectrum of the reaction mixture of **1** and 96% sulfuric acid indicated that only one major cationic species was present. However, the usual work-up conditions (quenching in water) gave rise to a complex mixture of "infinity" products. It soon became evident that this was because the product initially formed on quenching was extremely sensitive both to acids and to atmospheric oxygen. When the reaction mixture was quenched in aqueous base and precautions were taken during work-up to avoid contact of the product with adventitious acid and to minimize contact with air, a volatile product was obtained. This was shown to be **17** by comparison with an authentic sample prepared by treatment of the enynol **16** (14, 15) with aqueous mercuric acetate (Scheme 3).[5]

When the base-quenched reaction mixture of **1** and 96% sulfuric acid was worked up without precautions to avoid contact with adventitious acid the major product isolated was not **17**, but a compound that decomposed to give **17**. This compound is assigned structure **18** on the basis of its conversion on standing to **17** and the fact that the latter in the presence of water is converted to the former. On longer standing both **17** and **18** formed the same bimolecular product, **17** via dimerization and **18** via dehydration and dimerization. This product was also isolated from the mixture of infinity products from **1** and 96% sulfuric acid on quenching with water (*vide supra*). It is assigned structure **20** on spectroscopic grounds and because of its conversion on hydrogenation to a dihydro derivative considered to be **21** (Scheme 3). The ir spectrum of **20** shows ethylenic stretching bands analogous to those of **17** and its uv spectrum shows a maximum at 261 nm (ε 7100) with a small bathochromic shift as expected in relation to the maximum of **17** at 254 nm. Its ^{1}H nmr spectrum shows the presence of five CH_3—C(sp^3) and two CH_3—C(sp^2) groups, the latter each being allylically coupled to a vinyl proton; in addition, a one-proton singlet at δ 4.15 ppm is attributable to the HC=C—O proton of **20**, analogous to the H_2C=C—O proton signals of **17** at δ 3.67 and 3.99 ppm. The relationship of the ^{13}C spectra of **20** and **17** (Table 2) confirms the structural assignment.

The hydrogenation of **20** is considered to occur in 1,4 fashion giving **21**, whose ^{1}H nmr spectrum shows the presence of five CH_3—C(sp^3) groups, two CH_3—C(sp^2) groups, and a single vinyl proton, coupled to one of the latter CH_3 groups. It is considered that the conversion of **17** and **18** to **20** is effected by traces of adventitious acids, involving reversible protonation of **17** to give the cation **19** and attack of this on **17** followed by loss of a proton. The ease of conversion of **17** to **20** is shown by the fact that treatment of **16** with mercuric acetate in 2% sulfuric acid gives **20** rather than **17** (Scheme 3).

It was noted above that the nature of the product mixture from **1** and 96% sulfuric acid is affected by the presence of atmospheric oxygen. This led to the formation of an additional product, whose relative amount was increased when the reaction mixture was exposed to air *after* quenching and work-up. This product was identified as the lactone **22** by comparison with an authentic sample obtained by dehydration of **10** (Scheme 2) (12). It is clear that this product arises by autoxidation of either **17** or its cationic precursor.

When **1** was treated with 99.5–100.3% sulfuric acid, the

[4]Loewenthal (9) has reached the same conclusion regarding the structure of this intermediate.

[5]This synthesis is based on that of 2,5-dialkylfurans (16). Arens and Brandesma and co-workers have prepared **17** by base-catalyzed cyclization of **16** (17) and rearrangement of 4,5-epoxy-3,5-dimethyl-1-hexyne (18).

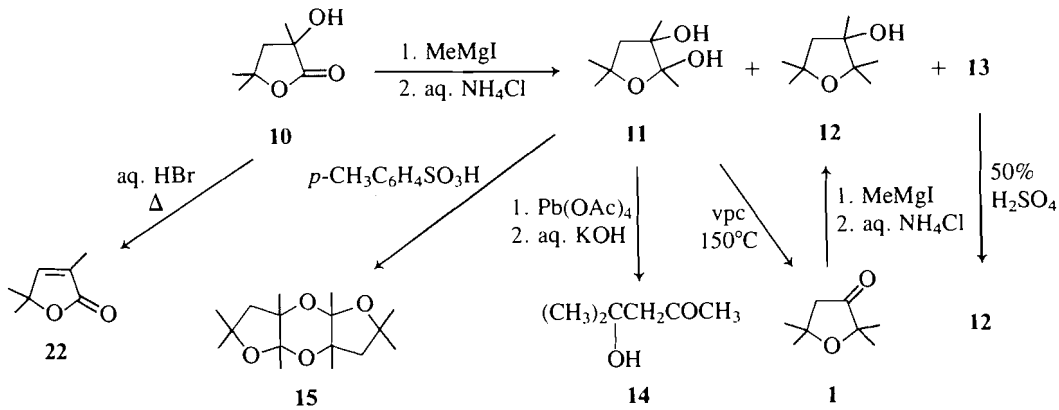
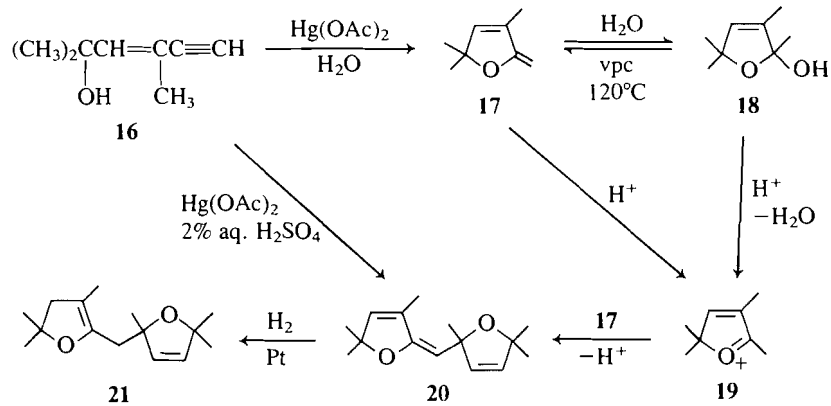


SCHEME 2

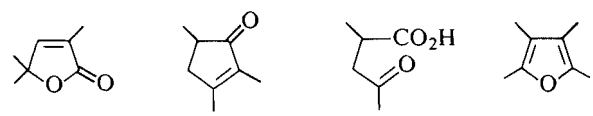


SCHEME 3

product distribution after quenching was markedly different from that observed on treatment with 96% sulfuric acid. The amount of the diene **17** was greatly reduced and the product mixture consisted largely of the cyclopentenones **7** and **8**, together with a new product, which in the case of 100.3% sulfuric acid was the preponderant product. This was isomeric with **7** and **8** and was identified as the cyclopentenone **23** on the following basis. Its spectra indicated that it is either 2,3,5-trimethyl-2-cyclopenten-1-one (**23**) or 2,3,4-trimethyl-2-cyclopenten-1-one. The latter compound has been prepared previously (19) and the melting point of its semicarbazone does not correspond with that of the semicarbazone prepared from the product obtained in the present work. Furthermore, ozonolysis of this product followed by oxidative work-up gave a mixture of α-methyllevulinic acid (**24**) (20) and its tautomeric lactol. Thus the product from **1** and 99.5–100.3% sulfuric acid has structure **23**.[6]

When **1** was heated with polyphosphoric acid for 2 h at 100°C the diene **17** and the cyclopentenone **7** were observed after quenching, together with a major additional product. When the reaction mixture was heated for 6 h at 120°C, this new product was formed almost exclusively. It was identified as tetramethylfuran (**25**) by comparison of it and its *exo* adduct with maleic anhydride with authentic samples (22, 23).

In summary, **1** on treatment with 96% sulfuric acid followed by quenching gives the products shown in Scheme 4. The hydroxy enone **3** and the diol **11** are isolated only after relatively short reaction times, while the diene **17** is the major product after long reaction times. The cyclopentenones **7** and **8** are formed in relatively small amounts but persist after long reaction times. Autoxidation gives the lactone **22**. Reaction of **1** with 99.5–100.3% sulfuric acid followed by quenching gives increased amounts of the cyclopentenones **7** and **8** together with the diene **17** and the cyclopentenone **23**. In hot polyphosphoric acid **1** gives, after quenching, tetramethylfuran (**25**) together



22 **23** **24** **25**

with cyclopentenone products. Thus in 96% sulfuric acid the products arise by (*i*) ring opening,[7] (*ii*) ring opening followed by reclosure to carbocyclic products, (*iii*) methyl migration to give rearranged furan derivatives, and (*iv*) autoxidation. In 99.5–100.35% sulfuric acid or hot polyphosphoric acid solutions further methyl migrations can occur to give **23** and **25**.

Experimental

Melting points were determined on a Fisher–Jones micro hot stage and are uncorrected. Infrared spectra were recorded in CCl_4, unless otherwise indicated; ultraviolet spectra were recorded in 95% EtOH.

[6]The fact that the ir carbonyl stretching band of **9** has a shoulder while those of **7**, **8**, and **23** do not is in accord with expectation, based on our studies of Fermi resonance in the spectra of 2-cyclopenten-1-ones (21).

[7]We have shown that cleavage of **1** to **3** is reversible (2).

SCHEME 4

The ^1H and ^{13}C nmr spectra were recorded in CCl_4 and $CDCl_3$, respectively.

Vapor phase chromatographic (vpc) analyses were carried out on an F and M Model 500 gas chromatograph. Helium was used as carrier gas and the flow rate was adjusted to 35–45 mL/min. The columns used were commercially available (F and M Scientific Corporation) and consisted of coiled stainless steel tubes with 0.25-in. od containing one of the following packings (10% substrate in each case): diisodecyl phthalate (DIDP) on 60–80 mesh Chromsorb P (6 ft); neopentylglycol sebacate (NPGS) on 60–80 mesh Chromsorb P (8 ft); fluorosilicone on 60–80 mesh Diatoport S (6 ft); Carbowax 1500 on 60–80 mesh Chromsorb P (6 ft). Preparative vapor phase chromatographic separations were performed on an F and M Model 770 automatic preparative gas chromatograph with helium at a rate of 1.5–2.0 L/min as carrier gas. The column consisted of two 4-ft, 0.75-in. od stainless steel tubes connected at the bottom with a 0.25-in. jumper tube. The column packing consisted of NPGS supported on 60–80 mesh Chromsorb W (10% substrate). Dry Ice – acetone was used in the cooling bath.

The 96% H_2SO_4 used in this work was C.P. reagent grade concentrated H_2SO_4, specified to contain a minimum of 95.5% by weight H_2SO_4. The 100.3% H_2SO_4 was made by addition of 30% oleum (Fisher reagent grade fuming H_2SO_4 specified to contain 30–33% free SO_3; 80 g) to 96% H_2SO_4 (120 g). Its strength was determined by titration. The 99.5% H_2SO_4 was made in similar fashion.

Dihydro-2,2-5,5-tetramethyl-3(2H)-furanone (1)

Compound **1** was prepared from 2,5-dimethyl-3-hexyne-2,5-diol by the method of Leonard *et al.* (6). The product was distilled to give a colorless liquid, bp 54–55°C (22 Torr; 1 Torr = 133.3 Pa); n_D^{23} 1.4192 (lit. (6) bp 150–151°C; n_D^{20} 1.4211); ir, λ_{max}: 5.68, 8.67 μm; uv, λ_{max}: 295 (ε 32), 245 nm (sh, ε 88). *The 2,4-dinitrophenylhydrazone of 1* was prepared by the method of Shriner, Fuson, and Curtin (24); recrystallization from 95% EtOH gave yellow plates, mp 179.5–180.5°C (lit. (6) mp 178–179°C).

Reactions of compound 1 in 92–96% sulfuric acid

(i) Isolation of products formed after 10 min – 25 h

Solutions of **1** in 96% H_2SO_4 were allowed to stand for the following periods: 10 min, 2 h, 6 h, 12 h, 18 h, 25 h, and 12 days. The following procedure was used in carrying out the reactions and working up the reaction mixtures.

Compound **1** (2.00 g) was added dropwise with gentle swirling to 96% H_2SO_4 (20 g), which was cooled in ice-water. The reaction mixture was allowed to stand at room temperature in a stoppered flask. The initially light yellow solution slowly darkened on standing for some hours and finally became black after ca. 2 days. After being allowed to stand for a specified time, the solution was poured in a thin stream into a rapidly stirred ice–water mixture (200 g). The aqueous solution was extracted with ether (2 × 100 mL) and the extract was dried over a mixture of anhydrous $MgSO_4$ (10 g) and K_2CO_3 (2 g). Removal of the solvent gave an oil (Extract I). The remaining aqueous solution was contiguously extracted with ether for 2 days. The extract was dried over $MgSO_4$–K_2CO_3 and the solvent was evaporated. The residue (Extract II) generally crystallized on standing in petroleum ether or cyclohexane.

Extract I was analyzed by vpc on a DIDP column at 150°C. The products were isolated by allowing the effluent carrier gas stream from the exit port to pass through U-tubes cooled in Dry Ice – acetone as each peak appeared on the chromatogram.

The following results for a reaction time of 6 h exemplify those obtained with the procedure described above. Extract I consisted of a pale yellow oil (0.72 g) that slowly turned dark red on being exposed to air. Its ir spectrum showed bands at 2.75, 2.8–2.9, 5.68, 5.84, 5.95, and 6.0–6.17 μm. Vapor phase chromatography on a DIDP column at 150°C showed the presence of three components.[8] These were (with retention times given in parentheses) residual compound **1** (3.7 min), *2,4,4-trimethyl-2-cyclopenten-1-one* (**5**)[9] (6.8 min), and *2-hydroxy-2,5-dimethyl-4-hexen-3-one* (**3**)[9] (11.1 min). Quantitative comparison of the vpc peak area produced by a known volume of compound **1** with that produced by the same volume of Extract I indicated that ca. 54% of the latter was retained on the column.

Extract II consisted of a viscous yellow oil (0.66 g). Its ir spectrum showed prominent bands at 2.75, 2.8–2.9, 9.15, and 10.5–1.07 μm. On standing alone or in petroleum ether, the oil deposited long, needle-like crystals of *tetrahydro-2,3,5,5-tetramethylfuran-2,3-diol* (**11**).[9]

Analysis by vpc of Extract I from the 12-, 18-, and 25-h reactions revealed the presence of an additional product with longer retention time (13.8 min), which was found to be *4-hydroxy-2,4-dimethyl-2-pentenoic acid γ-lactone* (**22**).[9] These analyses were carried out on samples that had stood in air for several days. It was subsequently found that the relative amount of this component in the mixtures increased with time of standing. Moreover, reexamination of a sample

[8]Thin-layer chromatography on silica gel with chloroform – 10% methanol as eluent and iodine vapor as developer indicated the presence of at least four components in the mixture; it was subsequently found that trace amounts of compound **8** (*vide infra*) were present.

[9]Identified by comparison with an authentic sample (*vide infra*).

of Extract I from the 6-h reaction that had stood for 2 weeks now indicated the presence of ca. 5% of **22**.

The composition of Extract I, as indicated by the vpc and spectroscopic analyses, varied with the reaction time as follows: the amount of compound **3** increased to a maximum at 2 h and then decreased gradually to zero after 12 days; that of compound **7** increased in the first 6 h and then remained constant. The amount of product retained on the vpc column increased with time, becoming ca. 94% of Extract I after 12 days. The composition of Extract II, as indicated by spectroscopic analysis, remained essentially constant for the different reaction times. The yield of **11** increased during the first 2 h, then remained approximately constant up to a reaction time of 25 h and decreased to zero after 12 days.

Each of compounds **3**, **7**, and **11** was isolated in pure form by vpc of a sample of Extract I in which it appeared in optimum concentration. With the use of temperatures 10–20°C lower than those used for the analytical runs, it was found that sample sizes up to 100 μL could be separated on the analytical columns without serious loss of resolution.

(ii) Isolation of infinity products

(a) Work-up under acidic conditions. A solution of **1** (10.0 g) in 92% H_2SO_4[10] (100 g) was allowed to stand at room temperature for 5 days in a loosely stoppered flask. The solution was then poured in a thin stream into rapidly stirred ice-water (1 kg). A black scum that formed on the surface of the aqueous solution was filtered and the brown filtrate was extracted with ether (500 mL; 2 × 250 mL). The extract was washed with saturated aqueous $NaHCO_3$, 250 mL) and water (250 mL) and dried over $MgSO_4$. Evaporation of the solvent gave a pale yellow liquid (6.2 g); ir, λ_{max}: 5.84, 6.02–6.10, 10.5 μm. Vapor phase chromatographic analysis on an NPGS column at 120°C indicated the presence of three components with low retention times (3.2, 4.2, and 7.6 min) and one component that gave rise to a broad peak with a very long retention time (54.2 min; ca. 65% of total). Distillation of the product mixture gave a colorless liquid (1.25 g), bp 85–87°C (0.65 Torr). This slowly turned red on exposure to air. Two further distillations gave pure *compound 20*,[9] bp 73–74°C (0.35 Torr).

(b) Work-up under basic conditions. A solution of **1** (50 g) in 94% H_2SO_4[10] (1 kg) was allowed to stand at room temperature for 3 weeks. Part of this solution (200 g) was added through a capillary to the periphery of a rapidly stirred solution of NaOH (200 g) in water (1 L) cooled to ca. 5°C and surrounded by an ice bath. When the addition was complete the alkaline solution was steam distilled. The distillate (250 mL) was saturated with NaCl and extracted with ether (200 mL; 2 × 150 mL). The extract was dried over K_2CO_3 and the solvent was evaporated to give *2,5-dihydro-2,3,5,5-tetramethyl-2-furanol* (**18**) as a pale yellow, mobile liquid (6.82 g). Distillation, which was accompanied by much decomposition, gave **18** as a colorless liquid (1.6 g), bp 80–81°C (27 Torr).

When compound **18** was allowed to stand in a tightly stoppered flask for 2 weeks globules of water were formed. The ^1H nmr spectrum of the resulting organic product was identical with that of compound **20**.

In a second experiment all glassware with which the extract from the basified reaction mixture was to come into contact was soaked in aqueous 10% NaOH before use. Under these conditions the product (15.7 g) from 400 g of a similar acid reaction solution to that above showed much reduced absorption in the 2.75–2.9 μm region of its ir spectrum. Distillation gave two well-separated fractions: (*i*) bp 46–48°C (30 Torr) (5.3 g) and (*ii*) bp 103°C (2 Torr) (3.7 g). The latter was shown to be compound **20**. Fraction (*i*) was a clear, colorless liquid with a strong mint-like odor; ir, λ_{max}: 5.85, 6.05–6.10, 10.45 μm; uv (EtOH), λ_{max}: 254 nm. Analysis by vpc (NPGS, 85°C) and collection of fractions showed the presence of compound **7** and *2,5-dihydro-3,5,5-trimethyl-2-methylenefuran* (**17**),[9] the latter being the major product.

Reactions of compound 1 in 99.5–100.3% sulfuric acid

(i) 100.3% sulfuric acid

(a) Work-up under acidic conditions. Compound **1** (10.0 g) was added slowly with stirring to 100.3% H_2SO_4 (200 g) cooled to 10°C at such a rate that the temperature did not rise above 20°C. The solution rapidly developed a deep red color, which darkened slowly on standing. The reaction mixture was allowed to stand for 4 h and was then added through a capillary to rapidly stirred ice-water (2 kg). The aqueous acid solution was extracted with ether (3 × 300 mL) and the extract was washed with saturated aqueous $NaHCO_3$ (100 mL) and dried over $MgSO_4$. Removal of the solvent gave a light yellow, sweet-smelling liquid (4.1 g); ir, λ_{max}: 5.84, 6.10 μm. Analysis by vpc (NPGS, 130°C) showed the presence of three compounds (retention times and relative yields are in parentheses): compound **1** (6.0 min; 44%), *3,5,5-trimethyl-2-cyclopenten-1-one* (**8**)[9] (12.0 min; 1.7%), and *2,3,5-trimethyl-2-cyclopenten-1-one* (**23**)[9] (12.0 min; 54%). These were separated by preparative vpc (NPGS, 120°C).

(b) Work-up under basic conditions. The reaction of **1** (10.0 g) with 100.3% H_2SO_4 (200 g) was allowed to proceed as above for 5 h. The reaction mixture was then added through a capillary to aqueous 10% NaOH (2 L) and cooled to 5°C in an ice bath. Steam distillation and extraction with ether gave a yellow liquid (6.0 g); ir, λ_{max}: 5.84, 6.10 μm. Analysis by vpc (NPGS, 130°C) indicated the presence of the same three components, in the same relative yields, as above. These were separated by preparative vpc.

(ii) 99.5% H_2SO_4

The following results exemplify those obtained. Compound **1** (20.0 g) was added dropwise with swirling to 99.5% H_2SO_4 (200 g), which was cooled to 5°C in an ice bath. The deep red mixture was allowed to stand at 5°C for 24 h and then at room temperature for a further week. Work-up under basic conditions as described above gave a yellowish liquid (14.9 g); ir, λ_{max}: 2.75, 2.90, 5.84, 6.05–6.10 μm. Analysis by vpc (NPGS, 110°C) indicated the presence of four compounds: **7** (65%), **8** (1.4%), **17** (25%), and **23** (8.4%).

Reactions of compound 1 in polyphosphoric acid

A mixture of **1** (2.00 g) and polyphosphoric acid (PPA; Victor Chemical Co.; 25 g) was heated at 100°C for 7 h in a 3-necked flask fitted with a condenser, thermometer, and $CaCl_2$ drying tube. The reddish-brown reaction mixture was allowed to cool to room temperature and poured into water (100 mL), and the flask was washed out with further water (100 mL). The combined aqueous solutions were extracted with ether (2 × 200 mL) and the extract was washed with saturated aqueous $NaHCO_3$ (100 mL) and water (2 × 200 mL) and dried over Na_2SO_4. Evaporation of the ether gave a pale yellow liquid (1.45 g); ir, λ_{max}: 2.85–2.95, 5.84, 6.09 μm. Its ^1H nmr spectrum showed strong signals at δ 1.75 and 2.08. Vapor phase chromatographic analysis (NPGS, 110°C) indicated the following composition (retention times and relative yields in parentheses): compound **17** (4.5 min; 8%),[11] compound **1** (7.0 min; 5%), *tetramethylfuran* (**25**)[9] (87.7 min; 81%), compound **7** (14.3 min; 6%).

Compounds **1**, **7**, and **17** were collected from the analytical column. Compound **25** was isolated by preparative vpc (NPGS, 100°C) as a colorless liquid (0.54 g).

The yields of the three products when **1** was heated with PPA under different conditions are given in Table 3.

2-Hydroxy-2,5-dimethyl-4-hexen-3-one (3)

2-Acetoxy-2,5-dimethyl-4-hexen-3-one was prepared from 2,5-dimethyl-3-hexyne-2,5-diol (**2**) and hydrolyzed to give **3**, as previously described (2, 7).

2-Ethoxy-2,5-dimethyl-4-hexen-3-one-2,4-dinitrophenylhydrazone

To a solution of **3** (200 mg) in 95% EtOH (2 mL) was added 2,4-dinitrophenylhydrazine reagent (24) (8 mL). The mixture was allowed to stand for 24 h and filtered to give orange-yellow crystals (340 mg), mp 93–98°C. Four recrystallizations from aqueous 70% EtOH gave orange needles, mp 108–110°C; ir, λ_{max}: 3.02, 6.18 μm; uv, λ_{max}: 360 nm (ε 22 600); ^1H nmr, δ: 1.18 (t, J = 7 Hz, 3H), 1.48 (s, 6H), 1.67 (s, 3H), 2.08 (s, 3H), 3.40 (q, J = 7 Hz, 2H), 5.81 (s, 1H), 7.9–8.4 (m, 2H), 9.08 (d, J = 3 Hz, 1H), 11.20 (s, 1H). *Anal.* calcd. for $C_{16}H_{22}N_4O_5$: C 54.84, H 6.33, N 15.99; found: C 54.99, H 6.28, N 16.04.

[10]Similar results were obtained in 96% H_2SO_4.

[11]Variable amounts of **17** were retained on the vpc column.

TABLE 3. Yields of products from the reactions of compound **1** with PPA

Reaction time (h):	4	7	8.5	6
Temperature (°C):	100	100	110	120
Combined yield (%):	77	80	82	81
Relative yield (%): **7**	13	6.6	6.0	1.0
17[a]	14.5	8.4	0	0
25	72.5	85	94	99

[a]See footnote 10.

2,4,4-Trimethyl-2-cyclopenten-1-one (7)

A mixture of 2,5-dimethyl-3-hexyne-2,5-diol (**2**) (71 g; 0.50 mol) and 50% H_2SO_4 (90 g) was stirred rapidly and heated at 50°C for 2 h under nitrogen. The organic layer (53.0 g) was removed, dried, and distilled. The major fraction was *2,5-dimethyl-1,5-hexadien-3-yne* (**4**), obtained as a pale yellow liquid (27.0 g), bp 40°C (28 Torr); ir, λ_{max}: 6.20 (w), 11.20 μm; ^{1}H nmr, δ: 1.90 (t, J = 2 Hz, 6H), 5.25 (m, 4H). On standing for 2 days this product polymerized to a viscous yellow oil. Subsequent distillation fractions were shown by vpc analysis (Carbowax, 120°C) to contain five components. The major component was isolated by vpc and is considered to be *tetrahydro-2,2,5-trimethyl-4-pyrone* (**5**); ir, λ_{max}: 5.81 μm; ^{1}H nmr, δ: 0.92 (d, J = 7 Hz, 3H), 1.14 (s, 3H), 2.28 (br s, 2H), 2.50 (m, 1H), 3.2–4.2 (m, 2H). The *2,4-dinitrophenylhydrazone of 5* was prepared in the usual manner (24); after five recrystallizations from 95% EtOH it was obtained as yellow needles, mp 151.5–153°C. *Anal.* calcd. for $C_{14}H_{18}N_4O_5$: C 52.17, H 5.61, N 17.38; found: C 51.85, H 5.67, N 17.47.

Two of the other products from the higher-boiling fractions from the original reaction mixture were identified by vpc and ^{1}H nmr analysis as compounds **1** and **3**.

A mixture of **4** (19.2 g), concentrated hydrochloric acid (150 mL), cuprous oxide (0.5 g), ammonium chloride (1.0 g), and copper bronze (0.50 g) was heated at 60–65°C for 4.5 h under nitrogen. The reaction mixture was cooled to room temperature, diluted with water (100 mL), and extracted with ether (3 × 60 mL). The combined extracts were washed with saturated aqueous $NaHCO_3$ (2 × 30 mL) and water (50 mL), and dried. Distillation of the residue after removal of solvent gave *3,4-dichloro-2,5-dimethyl-2,4-hexadiene* (**6**) (12.8 g), bp 29–31°C (0.65 Torr); n_D^{20} 1.4940); ^{1}H nmr, δ: 1.73 (s, 6H), 1.88 (s, 6H).

Compound **6** (12.0 g) was stirred rapidly with 85% H_2SO_4 (100 g) at 60°C for 2 h. The mixture was cooled, diluted with water (50 mL), and extracted with ether (2 × 100 mL). The extract was washed with saturated aqueous $NaHCO_3$ (50 mL) and dried. Distillation of the residue after removal of the solvent gave a colorless liquid (5.5 g), bp 42–52°C (3 Torr), which was shown by ^{1}H nmr spectroscopic analysis to be a mixture of **6** and *2,4,4-trimethyl-2-cyclopenten-1-one* (**7**). The latter was separated by the use of Girard's Reagent T (25) and obtained as a colorless liquid, bp 52°C (10 Torr); n_D^{25} 1.4606 (lit. (19*a*) bp 66°C (20 Torr); n_D^{25} 1.4573). The *2,4-dinitrophenylhydrazone of 7* was prepared in the usual manner (24); after recrystallization from EtOAc–EtOH it was obtained as orange crystals, mp 211.5–223°C. *Anal.* calcd. for $C_{14}H_{16}N_4O_4$: C 55.25, H 5.30, N 18.41; found: C 55.33, H 5.43, H 18.14.

3,5,5-Trimethyl-2-cyclopenten-1-one (8) and 3,4,4-trimethyl-2-cyclopenten-1-one (9)

A solution of redistilled 2-methyl-2-butene (47 g) in $CHCl_3$ (140 mL) was cooled in an ice bath and rapidly stirred. Nitrosyl chloride was slowly bubbled through this solution until a permanent green color was produced (ca. 2 h). Removal of the solvent gave crude *3-chloro-3-methyl-2-butanone oxime* as a bright blue viscous liquid (85 g; 95%); ir ($CHCl_3$), λ_{max}: 2.80, 2.90–3.10 μm; ^{1}H nmr, δ: 1.75 (s, 6H), 2.01 (s, 3H), 9.6 (s, 1H).

Sodium (15.0 g, 0.65 mol) was dissolved in dry EtOH (250 mL) and freshly distilled ethyl acetoacetate (81 g, 0.7 mol) was added to the solution. The mixture was cooled in ice-water and the crude oxime (85 g, 0.63 mol) in dry EtOH (50 mL) was added slowly over 25 min. The mixture was allowed to stand overnight and the precipitated NaCl was filtered. Removal of the EtOH from the filtrate gave a pale brown crystalline mess. This was heated with boiling 50% aqueous KOH (1200 g) under reflux for 4 h. The resulting solution was steam distilled and the steam distillate was extracted with ether (2 × 200 mL). Evaporation of the ether gave a pale brown liquid (20.5 g), which on distillation gave a colorless liquid (9.5 g), bp 62–85°C (10 Torr), consisting of the cyclopentenones **8** and **9** (2:3 by vpc analysis); these were readily separated by preparative vpc (NPGS, 120°C).

3,5,5-Trimethyl-2-cyclopenten-1-one (**8**) (2.04 g), n_D^{20} 1.4670, the component with the lower retention time, was obtained as a colorless liquid. The *2,4-dinitrophenylhydrazone of 8* was prepared in the usual manner (24). Two recrystallizations from EtOAc–EtOH gave orange needles, mp 227.5–228.5°C. *Anal.* calcd. for $C_{14}H_{16}N_4O_2$: C 55.25, H 5.30, N 18.41; found: C 55.27, H 5.32, N 18.51.

3,4,4-Trimethyl-2-cyclopenten-1-one (**9**) was obtained as a colorless liquid, n_D^{20} 1.4737. The *semicarbazone of 9* was prepared in the usual manner (24); on recrystallization from EtOH it was obtained as white platelets, mp 201–202°C (dec.) (lit. (10) mp 199–200°C).

Tetrahydro-2,3,5,5-tetramethyl-2,3-furandiol (11)

To a solution of 2,4-dihydroxy-2,4-dimethylpentanoic acid γ-lactone (**10**; 7.2 g, 0.050 mol) (26) in dry ether (100 mL) was added 1.24 *M* ethereal methylmagnesium iodide (110 mL, 0.15 mol). The mixture was allowed to stand overnight and worked up with aqueous NH_4Cl. The clear supernatant layer was separated, and the inorganic cake was washed with ether (2 × 50 mL). The ethereal solutions were combined, dried, and freed of solvent to give **11** as an oil (2.9 g, 36%). This slowly crystallized on standing in petroleum ether – cyclohexane. Two recrystallizations from this solvent mixture gave **11** as colorless crystals, mp 72–74°C. *Anal.* calcd. for $C_8H_{16}O_3$: C 59.98, H 10.07; found: C 60.11, H 10.17.

Extraction of the inorganic cake with hot $CHCl_3$ (3 × 30 mL) and evaporation of the combined extracts gave *compound 13* as a white solid (3.9 g), which was insoluble in ether, CH_2Cl_2, and $CHCl_3$. It was recrystallized from acetone–EtOAc to give white prisms, mp 227–229°C (dec.); ir (Nujol), λ_{max}: 3.02 (m) μm. Compound **13** was converted to **12** (*vide infra*) on treatment with 50% H_2SO_4.

The inorganic cake remaining after the above extraction was dissolved in 50% H_2SO_4, and the solution was extracted with $CHCl_3$ (3 × 100 mL). A pale brown crystalline product (1.03 g) was obtained on removal of the solvent. Purification by vpc (fluorosilicone, 100°C) gave *tetrahydro-2,2,3,5,5-pentamethyl-3-furanol* (**12**) as a white crystalline solid, mp 75–76°C (lit. (13) mp 76–77°C); ir, λ_{max}: 2.75 (w), 2.90 (m) μm. This was shown to be identical with an authentic sample of **12** prepared by treatment of **1** with methylmagnesium iodide (13).

Lead tetraacetate cleavage of 14. Formation of diacetone alcohol (14)

To a solution of **11** (100 mg) in water (3 mL) was added a suspension of lead tetraacetate (346 mg) in glacial acetic acid (3 mL). After 2 h the mixture was filtered, and the filtrate was made strongly alkaline with aqueous KOH and allowed to stand for a further 90 min. The solution acquired a strong odor of diacetone alcohol (**14**). 2,4-Dinitrophenylhydrazine reagent (24) was added and the solution was allowed to stand for 2 days, giving orange-yellow crystals, mp 198–202°C. Recrystallization from 80% EtOH gave *diacetone alcohol, 2,4-dinitrophenylhydrazone* as yellow needles, mp 202–204°C (lit. (24) mp 203°C).

Rearrangement of 11 to 1 on vapor phase chromatography

When a 10% solution of **11** in $CHCl_3$ was injected on a vpc column (DIDP or NPGS) at 140°C a peak with retention time equal to that of **1** was produced. Collection from the column gave a colorless liquid, the ir spectrum of which was identical with that of authentic **1**. Peak area measurements indicated a yield of ca. 30%. No change was observed when **1** was heated alone at 150°C.

Acid-catalyzed self-condensation of 11. Formation of 15

A solution of **11** (0.60 g) in benzene (50 mL) containing a crystal of

p-toluenesulfonic acid was boiled under reflux for 30 min. The solution was washed with water (30 mL) and dried. Evaporation of the solvent gave a crystalline product that showed no hydroxyl or carbonyl absorption in its ir spectrum. Three recrystallizations from hexane gave *compound* ***15*** as colorless crystals, mp 190.5–191.5°C (sealed cap); ir, λ_{max}: 8.5–8.6, 8.85, 10.55 μm; ^{1}H nmr, δ: 1.25 (s, 6H), 1.32 (s, 6H), 1.39 (s, 6H), 1.47 (s, 6H), 1.90 (J = 13 Hz, H), 2.00 (d, J = 13 Hz, 2H). *Anal.* calcd. for $C_{16}H_{28}O_4$: C 67.57, H 9.93, *Mol. Wt.* 284; found: C 67.66, H 9.93. *Mol. Wt.* (Rast) 284.

*2,5-Dihydro-3,5,5-trimethyl-2-methylenefuran (**17**)*

A solution of lithium acetylide was prepared from acetylene and lithium wire (1.73 g, 0.25 mol) in liquid ammonia (250 mL) in the presence of hydrated ferric nitrate (50 mg). Mesityl oxide (24.5 g, 0.25 mol) in dry ether (25 mL) was added with stirring and cooling. A slow stream of acetylene was passed continuously through the solution, which was stirred and cooled for a further 2.5 h. Ammonium chloride (20 g) was cautiously added and the ammonia was allowed to evaporate overnight. Extraction with ether and evaporation of the solvent gave a mixture (1.76 g) consisting only of *3,5-dimethyl-4-hexen-1-yn-3-ol* and unconsumed mesityl oxide (28.5% conversion from vpc analysis). A pure sample of the product was collected from a vpc column (NPGS, 85°C); ir, λ_{max}: 2.78, 3.02, 4.75, 6.0–6.1, 10.9 μm; ^{1}H nmr, δ: 1.51 (s, 3H), 1.71 (s, 3H), 1.87 (s, 3H), 2.33 (s, 1H), 2.38 (s, 1H), 5.32 (s, 1H).

The mixture (15 g) of the above ynol and mesityl oxide from a larger scale run was dissolved in ether (150 mL) and the solution was shaken for 30 min with 50% H_2SO_4 (150 mL). The ethereal layer was separated and the aqueous solution was extracted with ether (150 mL). The combined ethereal solutions were washed with water (2 × 50 mL), dried over $CaCl_2$, and concentrated. Fractional distillation with a spinning band column gave *2,4-dimethyl-3-hexen-5-yn-3-ol* (**16**) (1.2 g), bp 59–61°C (15 Torr) (lit. (14) bp 65–66°C (20 Torr)); ir, λ_{max}: 2.78, 3.02, 4.78, 6.17, 10.5 μm; ^{1}H nmr, δ: 1.34 (s, 6H), 1.86 (s, 3H), 2.71 (s, 1H), 3.25 (s, 1H), 5.89 (s, 1H).

A solution of **16** (180 mg) in ether (5 mL) was shaken for 3 min with a solution of mercuric acetate (30 mg) in water (5 mL). The organic layer was separated and the aqueous layer was washed with ether (10 mL). The combined ethereal solutions were dried over K_2CO_3 and the solvent was removed. The residue (120 mg) exhibited a single peak on vpc analysis (NPGS, 75°C). Collection of the product from the vpc column gave *2,5-dihydro-3,5,5-trimethyl-2-methylenefuran* (**17**). *Anal.* calcd. for $C_8H_{12}O$: C 77.37, H 9.74; found: C 76.51, H 9.94.

Shaking an ethereal solution of **16** with mercuric sulfate in 2% w/v sulfuric acid gave **20**, the dimer of **17** (*vide infra*).

*Dimerization of **17**. Formation of **20***

On standing, compound **17** neat or in solution in CCl_4 underwent dimerization to give **20**, which was also formed via spontaneous dehydration of **18** on standing. Repeated distillation, with precautions to minimize contact with air, gave **20** as a colorless liquid, bp 73–74°C (0.35 Torr). An analytical sample was prepared by vpc on an NPGS column at 150°C. *Exact Mass* calcd. for $C_{15}H_{21}O_2$ (M − CH_3): 233.1542; found: 233.1542. *Anal.* calcd. for $C_{16}H_{24}O_2$: C 77.37, H 9.74; found: C 76.90, H 9.58.

*Hydrogenation of **20**. Formation of **21***

A solution of **20** (3.07 g) in EtOH (50 mL) containing reduced platinum oxide (120 mg) was stirred under hydrogen at a slight positive pressure. One molar equivalent of hydrogen was adsorbed in 100 min. Further uptake of hydrogen was extremely slow (0.28 molar equiv. after 12 h). The solution was filtered and the solvent was removed. Distillation of the residue gave **21** as a colorless liquid, bp 66–70°C (0.7 Torr). *Exact Mass* calcd. for $C_{16}H_{26}O_2$ (M), $C_{15}H_{23}O_2$ (M − H): 250.1983, 249.1854; found: 250.1900, 249.1862.

*4-Hydroxy-2,4-dimethyl-2-pentenoic acid γ-lactone (**22**)*

2,4-Dihydroxy-2,4-dimethylpentanoic acid γ-lactone (**10**) (26) was heated for 14 h with boiling 47% hydrobromic acid under reflux (12) to give **22** in almost quantitative yield. Recrystallization from heptane gave white needles, mp 54.5–55°C (lit. (12) mp 55–56°C).

*Ozonolysis of **23**. Formation of α-methyllevulinic acid (**24**)*

A stream of ozonized oxygen (ca. 20% O_3; 15 L/h) was passed into a solution of **23** (0.47 g) in CH_2Cl_2 (100 mL) cooled in a Dry Ice – acetone bath, until the solution had turned deep blue (45 min). The excess ozone was removed by passing a stream of nitrogen through the solution for 5 min. The solution was added dropwise to water (30 mL) and the mixture was shaken vigorously and allowed to stand overnight. Aqueous 40% NaOH (10 mL) and aqueous 6% H_2O_2 (15 mL) were added. The mixture was shaken for 5 min and allowed to stand at room temperature for 20 h. The organic layer was separated and the aqueous solution was acidified with 10% H_2SO_4. Extraction of the acid solution with ether (4 × 50 mL) and removal of the solvent gave a mixture of **24** and its tautomeric lactol as an oil (0.59 g); ir, λ_{max}: 2.75–2.80, 3–4.1, 5.62–5.70, 5.80 μm. The remainder of the acidic product from the ozonolysis (ca. 0.5 g) was mixed with a solution of semicarbazide hydrochloride (400 mg) and sodium acetate (300 mg) in water (0.3 mL) and the solution was allowed to stand overnight. The resulting solid (147 mg) was filtered and twice recrystallized from 70% aqueous EtOH to give the *semicarbazone of **24*** as colorless prisms, mp 178–178.5°C, undepressed when mixed with an authentic sample prepared from ethyl 2-bromoproprionate and ethyl acetoacetate (20).

*Maleic anhydride adducts of tetramethylfuran (**25**)*

The mixture of adducts (22, 23) was repeatedly crystallized from heptane to give the *exo* adduct as long needles, mp 96.5–97.5°C (lit. (22) mp 95–96°C); ir, λ_{max}: 5.37, 5.62, 9.24 μm; ^{1}H nmr, δ: 1.60 (s, 6H), 1.64 (s, 7.3H), 1.69 (s, 1.3H), 3.01 (s, 2H), 3.48 (s, 0.42H). *Anal.* calcd. for $C_{12}H_{14}O_4$: C 64.85, H 6.35; found: C 64.76, H 6.39.

Equimolar solutions of maleic anhydride and tetramethylfuran in $CHCl_3$ were mixed and the ^{1}H nmr spectrum of the resulting solution was recorded after approximately 1, 3, and 6 min. The ratios of the peak heights at δ 3.01 and 3.48 were 2.05, 2.95, and 4.6, respectively. This ratio remained constant after 6 min and was the same as that observed when the pure *exo* isomer was dissolved in $CHCl_3$.

Hydrolysis of 5-neopentoxy-1,3-diiminoisoindoline gave 5-neopentoxy-1*H*-isoindole-1,3(2*H*)-dione (4-neopentoxyphthalimide), which, on treatment with Lawesson's reagent, yielded the thiophthalimides, 5-neopentoxy-1*H*-isoindole-1,3(2*H*)-dithione, 2,3-dihydro-6-neopentoxy-3-thioxo-1*H*-isoindol-1-one, and 2,3-dihydro-5-neopentoxy-3-thioxo-1*H*-isoindol-1-one. Attempted S-alkylations of the thiophthalimides resulted in the formation of β-isoindigos and N-alkylation products. In a new phthalocyanine synthesis crossed condensations of 1,3-diiminoisoindoline with 5-neopentoxy-1*H*-isoindole-1,3(2*H*)-dithione yielded mixtures of phthalocyanines from which 2-neopentoxyphthalocyanine and 2,16-dineopentoxyphthalocyanine could be purified in part from other phthalocyanines.

CLIFFORD C. LEZNOFF, SHAFRIRA GREENBERG, BEN KHOUW et A. B. P. LEVER. Can. J. Chem. **65**, 1705 (1987).

L'hydrolyse de la néopentoxy-5 diimino-1,3 indoline conduit à la néopentoxy-5 1*H*-isoindole (2*H*)-dione-1,3 (néopentoxy-4 phtalimide) qui, par traitement avec le réactif de Lawesson, fournit les thiophtalimides, néopentoxy-5 1*H*-isoindole (2*H*)-dithione-1,3, dihydro-2,3 néopentoxy-6 thioxo-3 1*H*-isoindolone-1 et dihydro-2,3 néopentoxy-5 thioxo-3 1*H*-isoindolone-1. Des essais de S-alkyler les thiophtalimides ont conduit à la formation de β-isoindigos et de produits de N-alkylation. Dans une nouvelle synthèse de la phtalocyanine, des condensations de la diimino-1,3 isoindoline avec la néopentoxy-5 1*H*-isoindole (2*H*-dithione-1,3 ont conduit à des mélanges de phtalocyanines à partir desquels on a pu purifier en partie la néopentoxy-2 phtalocyanine et la dinéopentoxy-2,16 phtalocyanine.

[Traduit par la revue]

Although symmetrical tetra (1–3) and octasubstituted (4–6) phthalocyanines are well known, the synthesis of simple mono- (7), disubstituted (8), and other unsymmetrical phthalocyanines (9, 10) remains a difficult problem. A typical symmetrical phthalocyanine synthesis involves the self-condensation of 5-substituted or 4,5-disubstituted-1,3-diiminoisoindolines (4, 11). A simple strategy available to form unsymmetrical phthalocyanines is the mixed condensation of two different 1,3-diiminoisoindolines to obtain the desired mono-, di-, or trisubstituted phthalocyanines. In fact, condensation of 1,3-diiminoisoindoline (**1**) and 5-neopentoxy-1,3-diiminoisoindoline (**2**) does give mixtures of unsubstituted, mono-, di-, tri-, and tetraneopentoxyphthalocyanines (**3**–**8**) as expected when analyzed by mass spectroscopy.[2]

We envisioned that a completely new approach to phthalocyanine synthesis was required. If we could perform a crossed condensation of substrates in which one of the substrates is unable to self-condense and if we could lower the temperature of phthalocyanine formation so that crossed condensation is favoured over self-condensation of the other substrate, then specifically substituted phthalocyanines could be formed as shown in Scheme 1.

Although phthalic anhydrides self-condense, probably via phthalimides to form phthalocyanines in the presence of urea (12) at very high temperatures, phthalimides are inert to self-condensation under 150°C. On the other hand, 1,3-diiminoisoindoline (**1**) and its derivatives readily form phthalocyanines at 150°C but only slowly below 100°C unless special catalytic bases are used (13). We believed that if we used thiophthalimides in crossed condensation reactions, then the nucleophilic addition of the 1,3-diiminoisoindoline (**1**) to a dithiophthalimide such as 1*H*-isoindole-1,3(2*H*)-dithione (**9**) or 5-neopentoxy-1*H*-isoindole-1,3(2*H*)-dithione (**10**) would in fact be much faster than self-condensation of **1**, as the high reactivity of the thiocarbonyl group is well known (14). It is thus possible that a crossed condensation of **1** and **10** could occur even at ambient temperature to form exclusively the desired 2,16-dineopentoxyphthalocyanine (**5**) (along with 2,17-dineopentoxyphthalocyanine), but no other compounds. In addition, any self-condensation of **1** would yield the highly insoluble unsubstituted phthalocyanine (**3**), which may then be separable from the organic solvent-soluble **5**. Another attractive feature of this strategy is the fact that only **5** (the "*para*" disubstituted isomer) would be formed and not 2,9-dineopentoxyphthalocyanine (**6**) (the "*ortho*" disubstituted isomer).

The first step in the realization of the strategy outlined in Scheme 1 is the preparation of the required thiophthalimide. Thus treatment of 4-nitrophthalimide (**11**) with neopentoxides led only to the recovery of **11**, and no 4-neopentoxyphthalimide (**12**) was formed (Scheme 2). Indeed, the preparations of 4-alkoxyphthalimides are known in the literature (15) but only through a lengthy 5-step synthesis from diethyl 4-nitrophthalate. Since it is known that 1,3-diiminoisoindolines can be hydrolyzed to phthalimides (16) and since we readily had available 5-neopentoxy-1,3-diiminoisoindoline (**2**) from previous studies on binuclear phthalocyanines (17), **2** was converted to 4-neopentoxyphthalimide (**12**) by refluxing **2** in aqueous dioxane (Scheme 2). Treatment of **12** with excess 2,4-bis(4-methoxyphenyl)-1,3-dithia-2,4-diphosphetane-2,4-disulfide (**13**) (Lawesson's reagent) (18) gave 5-neopentoxy-1*H*-isoindole-1,3(2*H*)-dithione (**10**) in 82% yield while the reaction of **12** with only 0.5 equivalents of **13** gave **10**, admixed with the two possible monothionated products, 2,3-dihydro-6-neopentoxy-3-thioxo-1*H*-isoindol-1-one (**14**) and 2,3-dihydro-5-neopentoxy-3-thioxo-1*H*-isoindol-1-one (**15**) in 37, 16, and 24% yields respectively. The new thiophthalimides **10**, **14**, and **15** were fully characterized by elemental analysis and spectroscopic data and compared with the known **9** and monothiophthalimide by uv–vis (Table 1) (19) and ^{13}C nmr (Table 2) (20) spectroscopy.

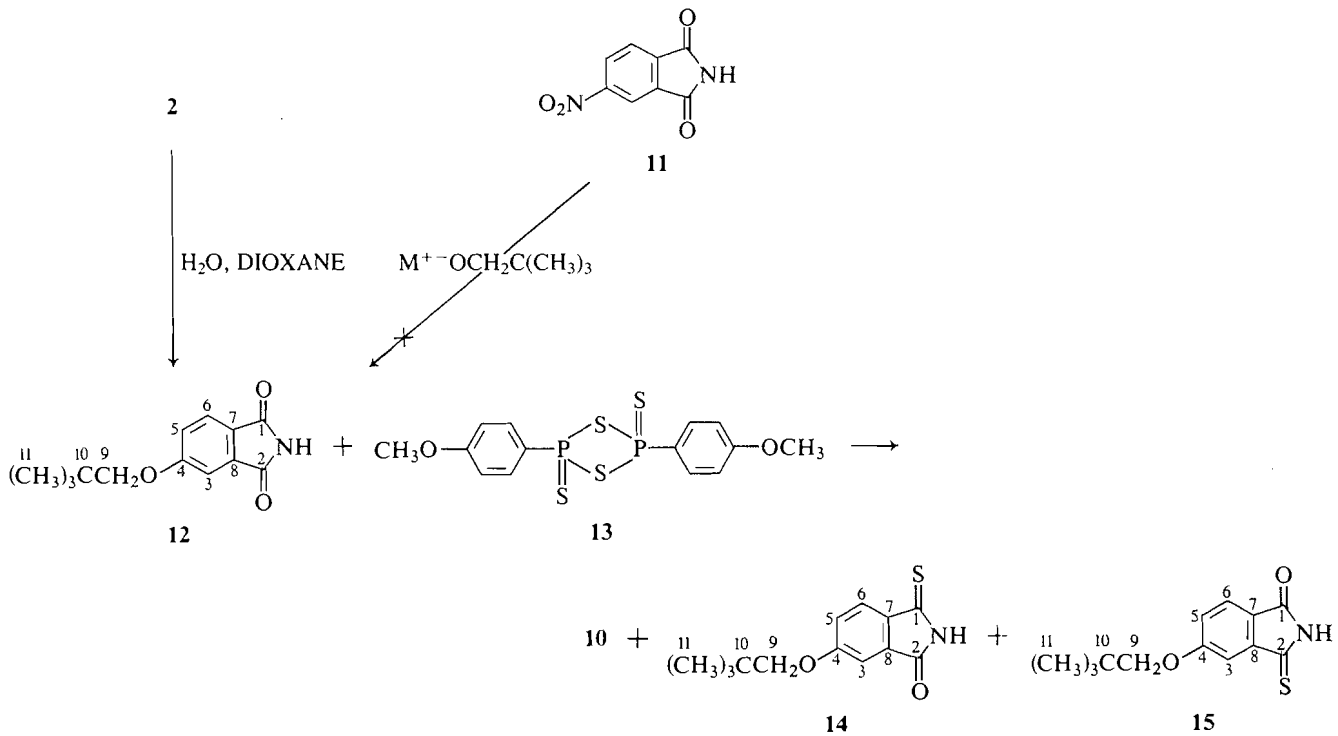

SCHEME 2

In previous studies (17) we had shown that **2** readily self-condenses to 2,9,16,23-tetraneopentoxyphthalocyanine (**8**) at 150°C in 2-*N*,*N*-dimethylaminoethanol. Control studies conducted to determine the maximum temperature at which **1** will not exhibit phthalocyanine formation showed that **1** was stable in 2-*N*,*N*-dimethylaminoethanol at 70°C or below and only reacted slowly below 95°C. Thus, **1** was dissolved in 2-*N*,*N*-dimethylaminoethanol at 50°C and **10** was added to this mixture and stirred at 80–90°C for 24 h to give, after precipitation with water, a dark-coloured residue containing phthalocyanines (Experiment 1) (Scheme 1). Extraction of the residue with methanol removed most non-phthalocyanine impurities. Thus the formation of phthalocyanines by the crossed condensation of a dithiophthalimide with a 1,3-diiminoisoindoline has been demonstrated for the first time. Further extraction of the residue with tetrahydrofuran (THF) (first phthalocyanine extract) yielded a solution of phthalocyanines that contained a mixture of **3**–**8** as revealed by mass spectroscopy (Table 3). The mixture contained 2,16-dineopentoxyphthalocyanine (**5**) (and possibly the 2,9-dineopentoxyphthalocyanine isomer (**6**)) as desired but significant quantities of phthalocyanine (**3**), 2-neopentoxyphthalocyanine (**4**), and 2,9,16-trineopentoxyphthalocyanine (**7**) were also produced, while 2,9,16,23-tetraneopentoxyphthalocyanine (**8**) was formed in traces only. Of course, the relative ratio of the parent ions of **3**–**8** is not necessarily an accurate representation of the relative abundances of **3**–**8**, but it does give us a strong indication that the exclusive formation of **5** did not occur. As phthalocyanines give strong parent ions in their mass spectra (21) and pure **8** does not give fragment ions corresponding to **3**–**7** (17), we can be confident that the

[a]The numbering of the carbon atoms in the listed compounds follows that given for these structures in the schemes and does not follow from the names of the compounds.
[b]The ^{13}C nmr spectra of these and related known compounds (20) were recorded and used to help assign the chemical shifts of the other unknown compounds.
[c]These values may be interchanged.
[d]The chemical shift of the N-methyl group is 31.04 ppm. In comparison, the chemical shift of the S-methyl group of **17** is 13.49 ppm.

ions observed are parent ions due to **3**–**8** and not fragment ions corresponding to **3**–**7**. Further extraction of the crude residue with toluene and, finally, with more tetrahydrofuran gave, again by mass spectroscopic analysis (Table 3), smaller quantities of phthalocyanines but fractions richer in the mono- and unsubstituted phthalocyanines **4** and **3** respectively. From previous work in our laboratory (9) we knew that mixtures of substituted mononuclear phthalocyanines are almost impossible to separate by flash chromatography (22) or even preparative thin-layer chromatography (tlc), probably because of aggregation phenomena. Since we had some phthalocyanine extracts that were already partially rich in **5** and **4**, we felt that vacuum liquid chromatography (vlc) (23), a very powerful separation technique, may give us pure samples of **5** and **4**. Thus further efforts to purify the first extract by vlc were attempted. Although it appeared that several blue-green bands readily separated on the column, again mass spectroscopic examination of each band (Table 3) showed that substantial contamination of each fraction remained. Some fractions obtained by vlc were rich in 2,16-dineopentoxyphthalocyanine (**5**) and one fraction contained almost pure 2-neopentoxyphthalocyanine (**4**) (with a trace of **5**) (Table 3), again by mass spectroscopic analysis of each chromatographic fraction. It should be noted that our previously reported (9) synthesis of an unsymmetrical phthalocyanine was based on a polymer support method yielding only the desired product, and no exhaustive chromatography was necessary to isolate the desired product. In addition mass spectroscopy revealed the presence of the desired product only. As a word of caution, other workers have recently reported the preparation of a mononitrophthalocyanine (7), a dicarboxyphthalocyanine (8), and an unsymmetrical octasubstituted phthalocyanine (10). Although the products were purified by flash chromatography in some cases (10) and the compounds gave sometimes acceptable elemental analysis (7, 10), no mass spectral data were recorded in detail (7, 8, 10) and in these instances mixtures of phthalocyanines may have been obtained. For example, an elemental analysis of a disubstituted phthalocyanine could be identical to that of a mixture of unsubstituted, mono-, di-, tri-, and tetrasubstituted phthalocyanines, especially since a mixture of this type usually shows up as one spot on tlc examination.[2]

In another experiment (Table 3, Experiment 2), we tried to optimize the formation of 2-neopentoxyphthalocyanine (**4**) by partially self-condensing an excess of **1** at 120°C and then adding a minimal quantity of **10** in a crossed phthalocyanine condensation (Scheme 1). The dark residue, obtained after the

[a]Extractions of phthalocyanines were performed as follows; extract 1 with THF for 5 h, extract 2 with THF for 19 h (In Expt. 1 a prior extraction with toluene for 10 h was performed), extract 3 with THF for 48 h.

[b]The peaks at 514, 600, 686, 772, and 858 are assigned as the parent peaks of **3**, **4**, **5** + **6**, **7**, and **8** respectively.

[c]Before further purification.

[d]Further flash chromatography of vlc fraction 1 gave fractions 1a, 1b, and 1c, which were analyzed by mass spectroscopy.

[e]This fraction is the same as the above entry (vlc fraction 3) but has been recrystallized.

[f]This sample is the evaporated filtrate.

[g]This sample is a precipitate formed before evaporation of the filtrate.

[h]Unextracted residue.

reaction, was purified as before to give a blue phthalocyanine solid. Extraction with THF for 5, 19, and 48 h gave extracts 1–3 respectively. From extract 3 a blue product precipitated. Mass spectroscopic analysis (Table 3) of extracts 1, 2, 3 (precipitate) and 3 (filtrate) and the remaining residue again showed that extracts 1 and 2 contained varying amounts of **3–7**, extracts 3 (precipitate) contained mostly **3** and **4**, while extract 3 (filtrate) contained mostly **4** and **5**. The solid blue residue contained mostly **3**. Further purifications by vlc on these extracts were not attempted.

Although we had succeeded in developing a new phthalocyanine synthesis at moderate temperatures based on thioimides, the yields of phthalocyanines in the key crossed condensation steps were low and the desired selectivity leading to mono- or disubstituted phthalocyanines was at best only partially achieved. Since 1-alkoxy-3-iminoisoindolines have been implicated as intermediates in phthalocyanine formation (24), we believed that 1-thioalkoxy-3-thioisoindolines could be used as a reactive partner instead of dithiophthalimides in phthalocyanine synthesis. Alkylation of thioamide-type compounds has been accomplished in many studies (25–29) giving exclusive S-alkylation as opposed to N-alkylation. In a model study of alkylations on dithiophthalimide (**9**) by a wide variety of methods encompassing basic (25–27), Lewis acid (27, 28), or neutral (29) conditions (Table 4), only N-alkylation or the formation of dialkyldithio-β-isoindigos took place (Scheme 3, Tables 1, 2, and 4). Thus methylation (25) of **9** with dimethyl sulfate and base gave *N*-methyldithiophthalimide (**16**) in 25–63% yield but the use of iodomethane and base (26, 27) gave mostly *S,S'*-dimethyldithio-β-isoindigo (**17**) (30) in 12–60% yield (Table 4). Another method using **9** and triethylorthoformate (29) at 180°C gave *N*-ethyldithiophthalimide (**18**) and *S,S'*-diethyldithio-β-isoindigo (**19**) (30), but again no simple S-alkylation occurred (Table 4). Still other alkylation methods (27, 28) exhibited no reaction or gave intractable products (Table 4).

Since the desired S-alkylated dithiophthalimide could not be prepared and since 3-ethoxyisoindol-1-one (**20**) was known (31), then simple treatment of **20** with Lawesson's reagent (**13**) (18) should yield 3-ethoxyisoindol-1-thione (**21**), which could be used in a cross-condensation reaction with **1**. Treatment of **20** with **13** did not give the desired **21**, but an unstable red compound **22**, which we tentatively assign by spectroscopic data (Tables 1 and 2) to 3-(3-ethoxy-1*H*-isoindol-1-ylidene)-2,3-dihydro-1*H*-isoindol-1-thione (**22**) as shown in Scheme 4. This last experiment indicates to us that the use of thiocarbonyl compounds in phthalocyanine synthesis is invariably complicated by the concomitant formation of isoindigos.

There have only been a few studies on the mechanism of phthalocyanine formation from phthalonitriles (32) or via amine–imidine condensations (24, 33). The formation of phthalocyanines **4–8** from condensation of **1** and the dithione **10** must obviously result from the displacement and hence removal of

SCHEME 4

the thione functional groups by ammonia, amines, or imines. The original hypothesis assumed that condensation of **1** and **10** would give in the first step an intermediate trimeric species (**23**) (Scheme 5), which on reaction with a 2nd equivalent of **10** would lead to **5**. Indeed, the lower temperature at which phthalocyanine formation is initiated (as low as 20°C) indicates that this first step is a likely possibility. It could happen, however, that although we have lowered the *initiation* step of phthalocyanine formation, the *propagation* step can still proceed rapidly at these modest temperatures. Thus intermediate **23** may react with more **10** giving 2,16-dineopentoxyphthalocyanine (**5**), but it could also react with more **1** giving the monosubstituted 2-neopentoxyphthalocyanine (**4**). In addition, **23** may undergo a N–H tautomeric shift giving the trimeric intermediate **24**. Trimeric intermediate **24** could react with **1** in two ways, giving two dimeric intermediates **25** and **26**, the former possessing a neopentoxy substituent. A N–H tautomeric shift of **25** could give a different dimeric intermediate **27**. The unsubstituted dimeric intermediate **26** could self-condense or react with **1** or **27** to give the phthalocyanine (**3**) or more **4**. The substituted dimeric intermediate **27** could react with **1** or **26** to give **2** or more **4** and with itself to give **5** and 2,9-dineopentoxyphthalocyanine (**6**). The generation of the monomeric 5-neopentoxy-1,3-diiminoisoindoline (**2**) in this reaction opens the door to other pathways of phthalocyanine formation. Thus **2** could react with **25** to generate 2,9,16-trineopentoxyphthalocyanine (**7**), or to form a new dimeric intermediate **28** containing two neopentoxy substituents. Intermediate **28** can further self-condense or react with **2** to give 2,9,16,23-tetraneopentoxyphthalocyanine (**8**). Alternatively **28** can condense with **26** to give **6** directly. Further condensation of **28** with **1** or **26** could give a new trimeric intermediate **29**, containing two neopentoxy substituents. Condensation of **29** with **2**, **10**, or even **25** could give more **7**, while condensation with **1**, **26**, or **27** could give **6**. Although Sato *et al.* (34) have shown that elemental sulfur (perhaps as thiolate anions) can act as a catalyst in the formation of 1,3-diiminoisoindolines from phthalonitriles, there was no report that phthalocyanine formation occurred under their conditions. We did notice in our reactions of **1** with **10** that a small amount of elemental sulfur was produced and this sulfur could account for the catalytic self-condensation of **1** to **3**. Indeed, control experiments conducted on **1** and elemental sulfur showed phthalocyanine formation starting at 50°C.[2] Elemental sulfur could not account directly for the formation of **4**–**8** but could further catalyze the reactions outlined in Scheme 5. Another complication not outlined in Scheme 5 is the possible production of ammonia gas, which could form **2** directly from **10**. The fact that the condensations of **1** and **10** are conducted under a steady stream of argon somewhat vitiates against this possibility. A full description of phthalocyanine formation is still clouded by the multiplicity of

possible intermediates and catalysis by intermediates and by-products.

In this paper we have demonstrated that phthalocyanine formation readily occurs at modest temperatures from a 1,3-diiminoisoindoline and a dithiophthalimide, but that selective formation of mono- or disubstituted phthalocyanines was only partially achieved.

Experimental

Matheson high-purity argon was used to maintain inert atmosphere conditions. Infrared (ir) spectra were recorded on a Pye Unicam SP1000 infrared spectrophotometer using KBr discs for solids or as neat films between NaCl discs. Nuclear magnetic resonance (nmr) spectra for carbons and protons were recorded on a Bruker AM300 nmr spectrometer using deuterochloroform as solvent and tetramethylsilane as the internal standard unless otherwise stated. The positions of the signals are reported in δ units. (The splittings of the signals are described as singlets (s), doublets (d), triplets (t), quartets (q), or multiplets (m).)

The visible–ultraviolet spectra (uv) were recorded on a Hewlett Packard HP8451A Diode Array spectrophotometer. Mass spectra (ms) were recorded at 70 eV on a VG Micromass 16F mass spectrometer in the EI mode.

Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are uncorrected. Thin-layer chromatography (tlc) was performed using silica gel G as the adsorbent. Flash chromatography was performed using silica gel of particle size 20–45 μm. All reactions were stirred with a magnetic stirrer. All solvents were freshly distilled before use. Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ont.

4-Neopentoxyphthalimide (12)

A suspension of 5-neopentoxydiiminoisoindoline (**2**) derived from 134 mg (0.63 mmol) of 4-neopentoxyphthalonitrile in 3 mL of a 1:1 mixture of water–dioxane was refluxed for 22 h. Since the crude diiminoisoindoline contained sodium methoxide (from the method of preparation), 28 mg of ammonium chloride (0.52 mmol) was added to the mixture. During the first 2–3 h ammonia was evolved and the suspension turned clear, and later a precipitate was formed. After cooling to room temperature the crude product was diluted with ethyl acetate and the organic layer was washed thoroughly with water, dried over anhydrous magnesium sulfate, filtered, and concentrated to a small volume. The crude product was purified using silica gel column chromatography and elution with ethyl acetate – petroleum ether (1:4). The product was recrystallized from a mixture of ethyl acetate – hexanes to give, in 75% yield, 110 mg of 5-neopentoxyphthalimide (**12**) as white crystals, mp 170–171°C (with previous darkening at 151–153°C); ir (cm^{-1}): 3240 (NH), 1780 (CO), 1740 (CO), 1630, 1370, 1240, 1020, 760; ^1H nmr δ: 7.75 (d, J = 8.3, 1H), 7.73 (br, 1H, NH), 7.32 (d, J = 2.2, 1H), 7.20 (dd, J = 8.3, 2.2, 1H), 3.75 (s, 2H, CH_2O), 1.07 (s, 9H, $(CH_3)_3C$); ms m/z: 233 (M^+, 10), 218 ($M^+ - 15$, 2.5), 175 (11), 164 (12), 71 (65), 43 (100). *Anal.* calcd. for $C_{13}H_{15}NO_3$: C 66.94, H 6.48, N 6.00; found: C 66.84, H 6.64, N 5.96.

5-Neopentoxy-1H-isoindole-1,3(2H)-dithione (10), 2,3-dihydro-6-neopentoxy-3-thioxo-1H-isoindol-1-one (14), and 2,3-dihydro-5-neopentoxy-3-thioxo-1H-isoindol-1-one (15)

A suspension of 192 mg (0.83 mmol) of **12** and 177 mg (0.44 mmol) of Lawesson's reagent (**13**) (18) in 2 mL of dry toluene was stirred at 90°C for 2.5 h. The reaction was followed by tlc (eluant toluene) and was stopped after 2.5 h, due to the formation of blue material at the base line when examined by tlc, even though not all of the starting material had reacted. After cooling to room temperature the crude product was purified by flash chromatography (22) using toluene as eluant. The first dark moving band gave, in 37% yield, 80 mg of 5-neopentoxy-1*H*-isoindole-1,3(2*H*)-dithione (**10**) as dark red-brown needles, mp 194–196°C (with previous softening); ir (cm^{-1}): 3260 (NH), 1625, 1480, 1450, 1350, 1230, 1120, 930, 840; ^1H nmr δ: 9.95 (br, 1H, NH), 7.78 (d, J = 8.4, 1H), 7.26 (d, J = 2.1, 1H), 7.20 (dd, J = 8.4, 2.1, 1H), 3.75 (s, 2H, CH_2O), 1.07 (s, 9H, $(CH_3)_3C$); ms m/z: 265 (M^+, 90), 250 ($M^+ - 15$, 10), 195 (93), 162 (60), 71 (45), 43 (100). *Anal.* calcd. for $C_{13}H_{15}NOS_2$: C 58.83, H 5.70, N 5.28; found: C 58.89, H 5.89, N 5.30.

Continued elution with toluene gave a yellow moving band. After evaporation of the solvent 2,3-dihydro-6-neopentoxy-3-thioxo-1*H*-isoindol-1-one (**14**) was isolated in 16% yield (33.5 mg) as orange crystals, mp 159–160°C; ir (cm^{-1}): 3240 (NH), 1745 (C=O), 1610, 1310, 1250, 1110, 830; ^1H nmr δ: 9.08 (br, 1H, NH), 7.86 (d, J = 8.4, 1H), 7.23 (d, J = 2.1, 1H), 7.18 (dd, J = 8.4, 2.1, 1H), 3.72 (s, 2H, CH_2O), 1.07 (s, 9H, $(CH_3)_3C$); ms m/z: 249 (M^+, 44), 179 (71), 71 (44), 43 (100). *Anal.* calcd. for $C_{13}H_{15}NO_2S$: C 62.62, H 6.07, N 5.62; found: C 62.77, H 6.00, N 5.79.

Continued elution with toluene gave a pink moving band. After evaporation of the solvent, 2,3-dihydro-5-neopentoxy-3-thioxo-1*H*-isoindol-1-one (**15**) was isolated in 23% yield (48.4 mg) as pink crystals, mp 139–142°C; ir (cm^{-1}): 3260 (NH), 1745 (C=O), 1605, 1490, 1310, 1085, 860, 775, 700; ^1H nmr δ: 9.45 (br, 1H, NH), 7.69 (d, J = 8.3, 1H), 7.40 (d, J = 2.1, 1H), 7.18 (dd, J = 8.3, 2.1, 1H), 3.74 (s, 2H, CH_2O), 1.07 (s, 9H, $(CH_3)_3C$); ms m/z: 249 (45), 179 (57), 71 (53), 43 (100). *Anal.* calcd. for $C_{13}H_{15}NO_2S$: C 62.62, H 6.07, N 5.62; found: C 62.40, H 5.99, N 5.84.

Some unreacted **12** was not recovered.

N-Methyldithiophthalimide (16)

A solution of 110 mg of dithiophthalimide (**9**) (0.61 mmol) in 1 mL of 95% ethanol and 0.3 mL of 2 *M* sodium hydroxide (0.6 mmol) was diluted with 1 mL water and cooled to 0°C according to the procedure of Baguley and Elvidge (25). The red solution was stirred while 0.15 mL of dimethylsulfate was added dropwise during 2–5 min. After a further 5 min the solution was diluted with 2 mL water. The crude product was extracted with ether and the organic layer was washed with water, dried over anhydrous magnesium sulfate, and evaporated to give 157 mg of crude product. The crude product was chromatographed using normal grade silica gel. Elution with toluene gave, in 25% yield, 30 mg of pure dark needles, mp 103–104°C (lit. (35) mp 98–100°C, 91–92°C); ir (cm^{-1}): 1460, 1410, 1355, 1330–1310, 1050, 960, 760, 750, 650; ^1H nmr δ: 7.78 (dd, J = 8.6, 2.5, 2H), 7.60 (dd, J = 8.6, 2.5, 2H), 3.77 (s, 3H, N-CH_3); ms m/z: 193 (M^+, 100), 117 ($M^+ - CS_2$, 28).

S,S-Dimethyldithio-β-isoindigo (17)

To a solution of 207 mg of **9** (1.16 mmol) in 3 mL of 0.8 *M* sodium hydroxide and 1 mL methanol, 0.06 mL of methyl iodide was added (0.96 mmol). The red solution became less intense in color and after a while a precipitate was formed. The suspension was stirred at room temperature for 18 h during which a red precipitate of *S,S*-dimethyldithio-β-isoindigo (**17**) appeared and the solution became clear. The methanol was evaporated under reduced pressure, water was added, and the insoluble material was filtered and washed with water. The crude product was dissolved in hot ethyl acetate and the hot suspension was filtered to remove 20 mg of insoluble material, which by mass spectra and ^1H nmr was shown to have a structure corresponding to an isoindigo trimer. This fraction was not further characterized. The crude **17** was recrystallized from ethyl acetate to give, in 60% yield, 92.8 mg of pure **17** as red or golden needles according to the concentration of the crystallizing solution, mp 260–263°C (lit. (30) mp 258°C); ir (cm^{-1}): 1470, 1455, 1340, 1265, 1030, 755, 660; ^1H nmr δ: 8.79 (d, J = 7.5, 2H), 7.60–7.40 (m, 6H), 2.95 (s, 6H, SCH_3); ^{13}C nmr δ: 172.70, 145.56, 139.80, 137.82, 129.22, 128.16, 126.56, 119.81, 13.49; ms m/z: 322 (M^+, 100), 307 ($M^+ - 15$, 80), 274 ($M^+ - SCH_3$, 73), 161 (M^{+2}, 10), 146 ($M - 15$, 25).

The fine structure of **17** regarding geometrical isomerism is not clear. Elvidge and Golden (36) suggested the *trans* form for dialkylimino-β-isoindigos since these compounds did not form complexes with metals. Dithio-β-isoindigo, on the other hand, did form metal complexes and was suggested by Drew and Kelly (30) to be in the *cis* form.

N-Ethyldithiophthalimide (18) and S,S-diethyldithio-β-isoindigo (19)

A solution of 125 mg of dithiophthalimide (**9**) (0.70 mmol) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

10 mL of triethylorthoformate was heated to 160°C for 3 h and then to 180°C according to the procedure of Rutavichyus and Iokubaitite (29). The volatile material (5–7 mL) had been removed by distillation through a fractionating column at 180°C. The solution was cooled and the excess triethylorthoformate was removed under pressure at 60°C/0.1 Torr (1 Torr = 133.3 Pa). Preliminary purification of the crude reaction mixture was done by column chromatography using normal grade silica gel. Elution with ether – petroleum ether (1:9) gave some elemental sulfur and 18.3 mg of *N*-ethyldithiophthalimide **18** (13% yield) as red needles, mp 51–53°C (lit. (35) mp 47–48°C, 81–83°C); ir (cm^{-1}): 1465, 1355, 1065, 765, 720, 700; ^1H nmr δ: 7.85 (dd, J = 8.7, 2.5, 2H), 7.66 (dd, J = 8.7, 2.5, 2H), 4.50 (q, J = 7, 2H, N-CH_2), 1.29 (t, J = 7, 3H, CH_2CH_3), ms m/z: 207 (M^+, 100), 191 (29), 179 (31).

Further elution of the silica gel gave 88 mg of a mixture consisting of *N*-ethyldithiophthalimide **18**, *S,S*-diethyldithio-β-isoindigo, **19**, and unreacted starting material, **9**. This mixture was further purified by preparative tlc using ether – petroleum ether (1:9) as eluting solvent. The yellow moving band consisting of **19** was extracted with ether in a Soxhlet apparatus to give, after solvent evaporation, 10 mg of pure **19** as golden needles in 8% yield, mp 126–128°C (with previous softening) (lit. (30) mp 162°C); ir (cm^{-1})): 1470, 1450, 1330, 1270, 1245, 1020, 745, 650; ^1H nmr δ: 8.78 (d, J = 7.3, 2H), 7.67–7.40 (m, 6H), 3.57 (q, J = 7.4, 4H, S-CH_2), 1.62 (t, J = 7.4, 6H, CH_2CH_3); ms m/z: 350 (M^+, 80), 321 ($M^+ - 29$, 100).

The unreacted dithiophthalimide was not recovered.

*3-(3-Ethoxy-1*H*-isoindol-1-ylidene)-2,3-dihydro-1*H*-isoindol-1-thione (**22**)*

A suspension of 1.08 g (6.09 mmol) of 3-ethoxy-isoindol-1-one (**20**) (31) and 1.36 g (3.36 mmol) of Lawesson's reagent (**13**) (18) in 10 mL of dry toluene was refluxed under argon for 2 h. After cooling to room temperature the crude product was purified by flash chromatography using toluene as eluant to give, in 12% yield, 111 mg of **22** as red crystals, mp >300°C; ir (cm^{-1}): 1635, 1530, 1340, 1140, 1080, 750; ^1H nmr (acetone-d_6) δ: 8.97 (d, J = 7.7, 1H), 8.63 (d, J = 7.8, 1H), 8.02 (d, J = 7.7, 1H), 7.78–7.54 (m, 5H), 4.79 (q, J = 7.0, 2H, CH_2O), 1.57 (t, J = 7.0, CH_3CH_2); ^{13}C nmr (DMSO-d_6) δ: 190.88, 170.66, 137.04, 136.03, 135.28, 132.73, 132.13, 131.64, 130.34, 129.75, 129.66, 128.41, 126.80, 124.44, 123.73, 120.56, 65.30, 14.38; ms m/z: 306 (M^+, 100), 277 ($M^+ - 29$, 87).

*A synthesis of 2-neopentoxyphthalocyanine (**4**) and 2,16-dineopentoxyphthalocyanine (**5**) (Experiment 1)*

The crude 1,3-diiminoisoindoline derived from 200 mg of phthalonitrile (1.56 mmol) in 2 mL of *N,N*-dimethylaminoethanol was heated to 50°C until completely dissolved. After 1 h, 274 mg of **10** (1.03 mmol) was added. The very light green solution turned red and then dark. The solution was stirred at 80–90°C under an argon atmosphere for 24 h. The mixture was cooled to room temperature, diluted with water, filtered, and washed thoroughly with water and then with methanol until the filtrate was almost clear. The crude product (112 mg) was extracted with methanol in a Soxhlet extractor for 10 h until the extract was almost clear. This process removed brown impurities. The desired product was then extracted for 5 h (extract 1) with freshly distilled THF to give 42 mg of a mixture of phthalocyanines. Mass spectra (Table 3) of the mixture showed that it consisted of mainly the 2,16-dineopentoxyphthalocyanine (**5**) (with perhaps 2,9-dineopentoxyphthalocyanine (**6**)) with a trace of the 2,9,16,23-tetraneopentoxyphthalocyanine (**8**) and some 2,9,16-trineopentoxyphthalocyanine (**7**), 2-neopentoxyphthalocyanine (**4**), and phthalocyanine (**3**). This fraction was purified by vacuum liquid chromatography (vlc) (23) using hexane (200 mL) as the eluting solvent, followed by hexane–toluene (1:1 × 700 mL) hexane–toluene (1:4 × 200 mL), toluene (500 mL), and finally 2-methoxyethanol–toluene (1:9 × 700 mL). The different fractions were examined by mass spectra (Table 3). Only partial separation was achieved.

The original mixture of phthalocyanines was subsequently extracted with toluene for 10 h and with THF for 19 h (extract 2) to give 27 mg of a mixture of phthalocyanines consisting mainly of monosubstituted phthalocyanine (**4**) and some unsubstituted, disubstituted, and a trace of trisubstituted phthalocyanines (Table 3). Further purification by vlc as above removed all trineopentoxyphthalocyanine but did not completely separate the dineopentoxyphthalocyanine from the mononeopentoxyphthalocyanine (Table 3). However, most of the unsubstituted phthalocyanine (**3**) was left on the column. The monosubstituted phthalocyanine (**4**) was recrystallized from toluene from a fraction (vlc fraction 3, Table 3) containing a trace amount of disubstituted phthalocyanine (**5**) but the crystallized product (**4**) still contained a trace of the disubstituted phthalocyanine (vlc fraction 3[e], Table 3).

Subsequent extraction of the original mixture with THF for 48 h (extract 3) removed 12.6 mg of a fraction consisting mainly of unsubstituted phthalocyanine (**3**) along with some **4** and a trace of **5** (Table 3). The phthalocyanines remaining in the thimble after the three extractions were the unsubstituted one and some monosubstituted (Table 3).

*A synthesis of 2-neopentoxyphthalocyanine (**4**) (Experiment 2)*

The crude 1,3-diiminoisoindoline derived from 2.0 g of phthalonitrile (15.6 mmol) in 15 mL of *N,N*-dimethylaminoethanol was heated to 120°C under an argon atmosphere for 2 h. Compound **10**, 135 mg (0.51 mmol), was then added and the mixture was kept at 120°C for an additional 3 h. The mixture was cooled to room temperature, diluted with water, filtered, and washed thoroughly with water followed by methanol until the filtrate was almost clear. The crude product was extracted with methanol in a Soxhlet apparatus until the extract was almost clear to remove brown and yellow impurities. The 1.56 g of the desired product was fractionally extracted with freshly distilled THF for 5 days. At intermittent times the solvent was evaporated, the phthalocyanines mixture was examined by mass spectra (Table 3), more solvent was added, and the extraction continued. The total amount of phthalocyanines removed by extraction after 5 days was 63.4 mg; 1.50 g was left in the thimble. The first extract contained a trace of **7**, some **5** (plus **6**), mainly **4** and **3** (Table 3). Subsequent extractions contained increasing amounts of the **5** and **4** without **7** (Table 3). During the last extraction a precipitate was formed which was filtered off to give 19.1 mg of mainly **3**, some **4**, and a trace of **5** (Table 3). The filtrate, 12.2 mg, contained **5** and **4** (Table 3).

Enolization of the benzocyclohexadienone formed during the bromination of 1-naphthol in aqueous solution

OSWALD S. TEE[1] AND N. RANI IYENGAR

Department of Chemistry, Sir George Williams Campus, Concordia University, Montréal, P.Q., Canada H3G 1M8

Received November 17, 1986

This paper is dedicated to Professor John T. Edward

OSWALD S. TEE and N. RANI IYENGAR. Can. J. Chem. **65**, 1714 (1987).

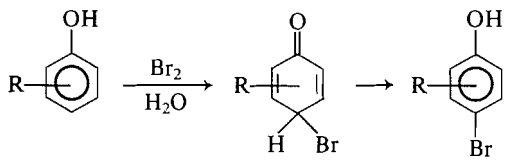
Benzo-4-bromo-2,5-cyclohexadienone (**5**) has been observed in the aqueous bromination of 1-naphthol and the kinetics of its enolization to 4-bromo-1-naphthol have been studied in the pH range 0–7. This process is catalyzed by the proton, hydroxide ion, water, buffer acids, and by buffer bases. For catalysis by general bases the Brønsted $\beta = 0.59$ whereas catalysis by general acids has a value of $\alpha \sim 0$. These findings are very similar to those obtained previously for the 4-bromo-2,5-cyclohexadienone **2***b*, formed during the aqueous bromination of 2,6-dimethylphenol. The mechanistic implications of the results are discussed. The enolization of the related dienone **8**, formed from bromine and 1-naphthol-2-carboxylic acid, was also studied. At acidic pHs the dienone **8** is much more reactive than **5**, with the 2-COOH behaving as an internal catalyst having an "effective molarity" of about 110 *M*. The enolization of **8** is also catalyzed by buffer bases.

OSWALD S. TEE et N. RANI IYENGAR. Can. J. Chem. **65**, 1714 (1987).

On a observé la formation de benzo bromo-4 cyclohexadiène-2,5 one (**5**) au cours de la bromation du naphtol-1 en milieu aqueux; opérant à des pH allant de 0 à 7, on a étudié la cinétique de son énolisation en bromo-4 naphthol-1. La réaction est catalysée par les protons, les ions hydroxydes, l'eau, les tampons acides ainsi que basiques. Dans le cas de la catalyse générale par les bases, la valeur β de Brønsted = 0,59 alors que pour la catalyse générale par les acides, la valeur $\alpha \sim 0$. Ces résultats sont semblables à ceux obtenus antérieurement pour la bromo-4 cyclohexadiène-2,5 one (**2***b*) qui se forme au cours de la bromation du diméthyl-2,6 phénol, en milieu aqueux. On discute des implications mécanistiques de ces résultats. On a aussi étudié l'énolisation de la dièнone **8** apparentée qui se forme à partir du brome et de l'acide naphtol-1 carboxylique-2. À des pH acides, la dièнone **8** est beaucoup plus réactive que **5** à cause du COOH en position 2 qui agit comme catalyseur interne et qui aurait un « molarité efficace » d'environ 110 *M*. L'énolisation de **8** est aussi catalysée par les tampons basiques.

[Traduit par la revue]

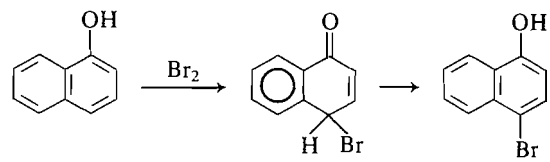
In acidic aqueous solution the bromination of phenol (1) leads largely to *para* substitution (**1***a* → **2***a* → **3***a*) (2). The cyclohexadienone (**2***a*) that is involved in this reaction can be observed (3) but detailed study of its behaviour is difficult because of its short half-life (<44 ms) and because the difference between its rates of formation and decay is not large (3, 4). Several methylated dienones have been generated and studied, particularly the 2,6-dimethyl derivative **2***b*, which is formed much more quickly and decays more slowly than does **2***a* (3, 4). Cyclohexadienones cannot be observed during the aqueous bromination of phenols bearing electron-withdrawing substituents (4). Such phenols react slowly with bromine (1, 2, 5, 6) whereas the intermediate dienones must enolize more rapidly than **2***a* (4).



1 **2** **3**

a: R = H; *b*: R = 2,6-dimethyl

Enolization of the cyclohexadienone **2***b* shows catalysis by general acids and general bases (4). Catalysis by the latter is quite straightforward with a Brønsted $\beta = 0.54$. This value, together with primary and solvent isotope effects, can be explained by simple rate-limiting deprotonation of **2** leading to the anion of the product **3**. In contrast, the general acid catalysis has a Brønsted $\alpha \sim 0$, which cannot be explained by simple mechanisms. It was attributed to a termolecular transition state (water, dienone, general acid HA) in which proton transfer from the dienone to the base (water) is far in advance of that from HA to the dienone oxygen (4).



4 **5** **6**

Since this type of mechanism is not usual for ketone enolization (7), we have sought another phenol from which a dienone of reasonable lifetime could be formed and which could, therefore, be studied in detail. A good candidate appeared to be 1-naphthol (**4**) for two reasons. Firstly, since it is a naphthalene, in which each benzenoid ring is less "aromatic" than benzene (8), 1-naphthol should be much more reactive towards bromine[2] than is phenol. Secondly, the benzo ring in the dienone **5** should be a stabilizing feature and so give rise to an intermediate having a longer lifetime than **2***a*. These expectations have been realized and the present paper describes studies of the enolization of **5**. In addition we have also studied the dienone **8** formed from 1-naphthol-2-carboxylic acid (**7**) and bromine. The intention here was to see if the 2-COOH functions as an internal catalyst in the enolization of **8**.

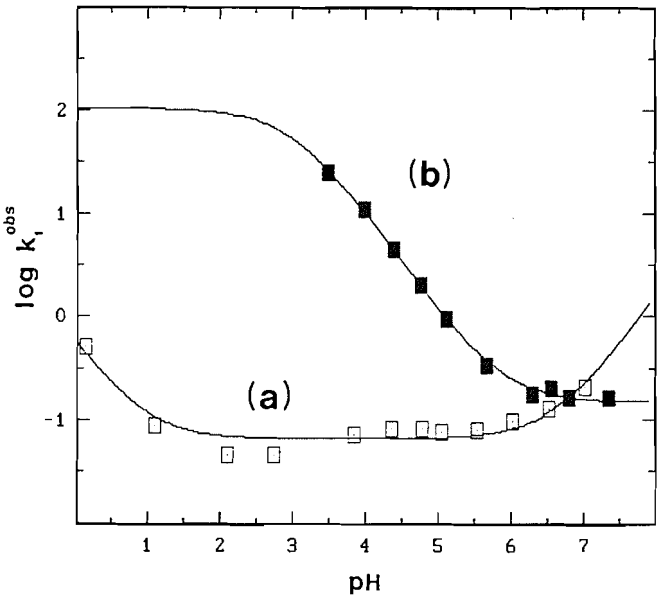

FIG. 1. pH–rate profiles for the enolization of (*a*) dienone **5** (open symbols); (*b*) dienone **8** (closed symbols).

Results

As anticipated, 1-naphthol reacts rapidly with aqueous bromine. Indeed, even at spectrophotometric concentrations the uv absorption bands of bromine and tribromide ion[3] disappear within the dead time of the stopped-flow apparatus. At longer times, however, one can observe a decrease in absorbance around 270 nm that is ascribed[4] to the enolization of the dienone **5** to **6**. The product of the overall reaction is 4-bromo-1-naphthol (**6**), as one expects from synthetic brominations (12).

First-order rate constants (k_{obs}) for the conversion of **5** to **6** vary with pH as shown in Fig. 1*a*. In the pH range 2–6 these values are essentially constant but they rise at higher and lower pHs. The results may be represented by eq. [1] in which k_H is the catalytic coefficient for hydronium ion catalysis, k_0 is the rate constant for a "spontaneous" or "water-catalyzed" reaction, and k_{OH} is for hydroxide ion catalysis.

$$[1] \quad k_{obs} = k_H[H^+] + k_0 + k_{OH}K_w/[H^+]$$

For the data shown in Fig. 1*a* appropriate constants are $k_H = 0.52 M^{-1} s^{-1}$, $k_0 = 0.065 s^{-1}$, and $k_{OH}K_w = 1.6 \times 10^{-8} M s^{-1}$. From this last value and $pK_w = 13.80$ (13) a value of $k_{OH} = 1.0 \times 10^6 M^{-1} s^{-1}$ is estimated. The data in the central region do not conform well to a constant value of k_0, due to buffer catalysis (see below). Consequently, a better estimate of k_0 (for the purposes of analysis) was obtained from the intercepts of buffer plots.

Catalysis by carboxylic acid buffers was found at pHs spanning the range 1.90–4.92. Individual buffer plots are linear over the concentration range used, with no upward curvature indicative of second-order terms in the buffer. Analysis of the slopes of the buffer plots in terms of the fractions of the acidic and basic components of the buffers yielded the catalytic coefficients (k_{HA} and k_A) given in Table 1. Also given there are values for the hydronium ion, hydroxide ion, and water.[5] The value of k_A for water[6] is taken as $k_0/(55.5 M)$, where $k_0 = 0.0463 s^{-1}$ was obtained from the average of the intercepts of all the buffer plots. The catalytic constant for hydronium ion in Table 1 was estimated from the data point at highest acidity and the value of k_0, just given.

Clearly, the conversion of **5** to **6** is catalyzed by general acids and general bases, as was found earlier for the enolization of the dienone **2***b* (4). Figure 2 shows the Brønsted plots generated from the values of k_A and k_{HA} in Table 1. They are both very

TABLE 1. Catalytic constants for enolization of the dienone **5**

Acid (HA)	pK_a	k_A	k_{HA}
Hydronium ion	−1.74	8.34×10^{-4}	0.626
Cyanoacetic	2.23	0.198	0.459
Chloroacetic	2.74	0.472	0.439
Methoxyacetic	3.52	0.855	0.966
3-Chloropropionic	3.93	2.29	2.05
Acetic	4.65	4.02	3.04
Water	15.54[b]	(1.0×10^6)[c]	—

[b]Equals log 55.5 + pK_w, where $pK_w = 13.80$ (13).
[c]Not included in Fig. 2.

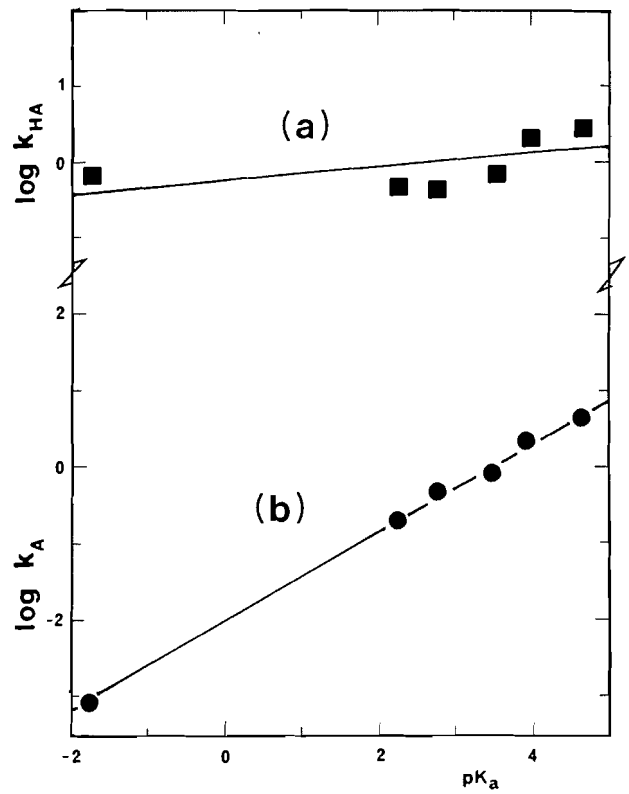

FIG. 2. Brønsted plots for catalysis of the enolization of the dienone **5** by (*a*) general acids, HA; (*b*) general bases, A^-.

[3]For various reasons (10) kinetic studies of bromination reactions are usually carried in the presence of a large excess of added bromide ion (1, 2, 6, 10). Consequently, a considerable fraction of the initial bromine is present as Br_3^- (1, 10).

[4]Naphthalenones similar to **5** have 3 or 4 absorption maxima in the region 230–300 nm (11).

[5]The values for hydronium ion and hydroxide ion are not particularly accurate as they are based on limited data (Fig. 1*a*). However, they are probably within a factor of two of the correct values.

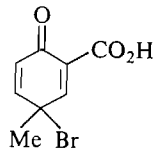
[6]The k_0 term in eq. [1] is ascribed to water acting as a general base. As previously (3, 4), it cannot be due to OH^- attacking the protonated form of the dienone. Such would require an unrealistically large second-order rate constant.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

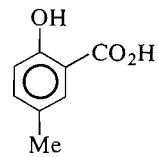
similar to the analogous plots obtained for **2***b* (4). The values of k_A (excluding the value for OH^-) give $\beta = 0.59$ (sd = 0.02, r = 0.9979) for general base catalysis.[7]

The values of k_{HA} for the buffer acids show little variation and are not very different from the value for H_3O^+. Taken as a whole these data give $\alpha = -0.09$ (sd = 0.06). Without the point for H_3O^+ the data for the carboxylic acids give a negative value: $\alpha = -0.38$ (sd = 0.06)!

The benzocyclohexadienone **8** was generated from 1-naphthol-2-carboxylic acid (**7**) and bromine. The pH–rate profile for its decomposition is shown in Fig. 1*b*. At pH > 6 the profile is essentially flat and **8** shows a reactivity very similar to that shown by the unsubstituted dienone **5** in its pH-independent region. However, below pH 6 the profile for **8** rises steeply, indicating an enhanced reactivity relative to that of **5**. Unfortunately, the solubility of undissociated **7** in water is very low and it was not possible to extend the profile below pH 3.5.



9



10

For the structurally similar dienone **9**, generated from 5-methylsalicylic acid (**10**), the pK_a of the carboxyl group is 3.06 (14, 15). Therefore, the pK_a of the carboxyl group of **8** should be about 3 and, as shown in Fig. 1*b*, the rate profile should have an inflection in the region that is not accessible due to low solubility (see above). The profile for **8** can be represented by eq. [2], where k_1 describes the flat portion of the profile and the second term assumes that the reactive species at low pH is the undissociated form of **8** reacting with rate constant k_2.

$$[2] \quad k_{obs} = (k_1 K_a + k_2[H^+])/(K_a + [H^+])$$

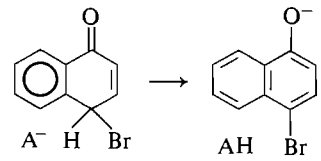
The data conform well to this equation with $k_1 = 0.14\ s^{-1}$ and $k_2 = 110\ s^{-1}$, assuming that the pK_a is 3.[8]

The enolization of the dienone **8** was also studied in two buffers. Around pH 5, where the second term of eq. [2] is dominant, there is strong catalysis by acetate buffers that corresponds to attack of acetic acid on the anion of **8**, with $k_{HA} = 78\ M^{-1}\ s^{-1}$ and no detectable catalysis by acetate ion. Above pH 6, in the region where k_1 becomes dominant in eq. [2], catalysis was found in phosphate buffers. Analysis of the buffer plots indicates catalysis by both buffer components with catalytic constants of $46\ M^{-1}\ s^{-1}$ for $H_2PO_4^-$ and $22\ M^{-1}\ s^{-1}$ for HPO_4^{2-}.

Discussion

The present results for the enolization of the benzocyclohexadienone **5** are very similar to those obtained earlier for the 2,6-dimethyl derivative **2***b*, with **5** being slightly less reactive. Thus, the various catalytic constants for **5** (Table 1) are about 5 times smaller than those for **2***b* (4) and so the Brønsted exponents (α and β) for the two dienones are virtually the same.

For general base catalysis of the enolization of **5** by carboxylate ions and water the value of β equals 0.59. It is possible that hydroxide ion also follows the same correlation.[7] As found previously for **2***b* (4), the results are quite consistent with simple rate-limiting deprotonation of the dienone by the general base to give the anion of the product (Scheme 1).



5

SCHEME 1. General base-catalyzed enolization of dienone **5**.

The value of α for general acid catalysis is essentially zero,[9] much lower than is normally found for ketone enolization (7). As argued earlier, this difference in behaviour is probably due to the fact that the enolization of cyclohexadienones is highly *exo*thermic (4, 16)[10] whereas that of simple ketones is significantly *endo*thermic (7, 17, 18). In explanation, we suggested that the transition state contains water, dienone, and the general acid (HA) (Scheme 2) and that transfer of the C4 proton of the dienone to water is far in advance of the proton transfer from HA to the dienone oxygen. This mechanism effectively avoids the protonated form of the dienone, which should be a relatively high energy species (4).

A mechanism that is kinetically indistinguishable from that just described involves A^- as the base and hydronium ion as the acid. For this mechanism the data for **2***b* and **5** require β to be about 1, which is not reasonable. Simple proton abstraction from **5** by general bases (Scheme 1) has $\beta = 0.59$ and so a *lower* value than this should be obtained for proton abstraction assisted by hydrogen bonding or by proton transfer from the hydronium ion.

A disturbing feature of the present data for general acid catalysis (Fig. 2*a*), as with the previous data (4), is that without the point for hydronium ion the value of α is decidedly *negative*. While it is conceivable that catalysis by H_3O^+ and by carboxylic acids is due to different mechanisms, we have no detailed explanation of why catalysis by carboxylic acids should have a negative α value. In view of the accumulated errors involved (see Experimental), the value of α should probably be taken as zero. For the mechanism outlined in the previous paragraph, a value of $\beta > 1$ would be required, equally anomalous.

Anomalous Brønsted exponents have been discussed by various authors (19). They cite several studies of the ionization of nitroalkanes in which it was found that structural change *in the nitroalkane* corresponds to an α value outside the normal range. However, for a given nitroalkane and a series of bases,

[7]If hydroxide ion is included in the plot, $\beta = 0.42$ (sd = 0.06, r = 0.9472). Thus, it may well be that OH^- also belongs on the correlation for general bases but that the Brønsted plot shows some curvature over 17 pK_a units.

[8]Nonlinear fitting of eq. [2] to the data gives $k_1 = 0.147\ s^{-1}$, $k_2 = 104\ s^{-1}$, and $K_a = 9.74 \times 10^{-4}\ M$ (pK_a = 3.01).

[9]As pointed out by a referee, water must fall off the line with $\alpha = 0$ since it does not swamp the effect of other general acids. This is reasonable, we believe, for the proposed mechanism in Scheme 2. We visualize that proton transfer from HA occurs after some negative charge has built up the dienone oxygen (4). This transfer can be thermodynamically favourable for carboxylic acids ($\alpha \sim 0$) but *must* be unfavourable ($\alpha \sim 1$) for water since the product pK_a is less than 10. Consequently, over the range of pK_a −2 to 16 the Brønsted plot for general acids must be curved.

[10]In our earlier paper (4) we employed pKs to estimate that phenol is favoured over 2,5-cyclohexadienone by a factor of 10^{11} (equivalent to 15 kcal/mol) in aqueous solution. More recently, using gas phase measurements, Shiner *et al.* have deduced that the dienone is less stable than phenol by 10 ± 3 kcal/mol (16).

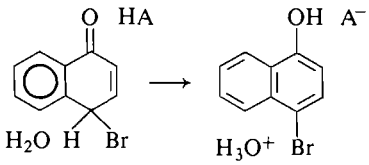
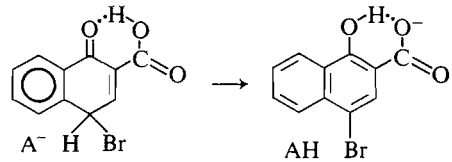


SCHEME 2. General acid-catalyzed enolization of dienone **5**.



8

SCHEME 3. Enolization of dienone **8** catalyzed by the *internal* acid group and an *external* base.

normal β values were found (19). In contrast, our work on the dienones **2***b* and **5** yields unusual α values for a series of general acid catalysts. It is probably the case that the proton transfers, electronic reorganization, and solvation changes are appreciably asynchronous[11] so that the transition state for dienone enolization in Scheme 2 does not strongly resemble either reactants *or* products. In such a case, normal Brønsted exponents may not be appropriate (19).

In an attempt to provide additional information about the mechanism of enolization of cyclohexadienones we have studied the behaviour of the dienone **8**. This molecule contains a carboxyl group adjacent to the dienone oxygen that might function in place of the external general acid HA required by the mechanism depicted in Scheme 2. Earlier attempts in this laboratory to observe enolizable cyclohexadienone intermediates in the bromination of salicylic acids were unsuccessful (14), and so it was concluded that they were too transient to be detected by stopped-flow technique. The present results for the dienone **8** support this conclusion, since over most of the pH range studied it is much more reactive than **5**. This implies that the analogous dienone derived from salicylic acid would be significantly more reactive than the dienone **2***a* and so it would not have been observable at the pHs used.

The rate profile for the enolization of the carboxyl-bearing dienone **8** has two distinct regions (Fig. 1*b*), which can be described by the two terms in eq. [2]. The first term is attributed to water abstracting the C4 proton from the anion of **8**, since its value ($0.14\,s^{-1}$) is similar to k_0 ($0.046\,s^{-1}$) for the water-catalyzed deprotonation of **5**.[6] There may also be proton abstraction by general bases, since buffer catalysis was observed in phosphate buffers, as discussed later.

The second term in eq. [2] is attributed to reaction of the undissociated form of the carboxylic acid, **8**. However, the increase in rate at pH < 6 could be due to a proton-catalyzed reaction of the anion of **8**. If such were the case, the rate constant for H^+ catalysis would be $1.1 \times 10^5\,M^{-1}\,s^{-1}$, meaning that the anion of **8** is 200 000 times more reactive than the dienone **5** in acid-catalyzed enolization. This factor is not reasonable for a simple substituent effect of a *meta* carboxylate group, since the appropriate substituent constant is virtually zero (20). Likewise, the rate enhancement is much too large for an electrostatic effect of the carboxylate ion on the rate of proton transfer; such effects are relatively small (less than a factor of 100) for monoanions It is also unreasonable to ascribe the rate increase to hydrogen-bond stabilization of the incipient protonated dienone oxygen, since in energy terms this would have to be 7.2 kcal/mol.

We conclude, therefore, that **8** reacts as its undissociated form at pH < 6 and that the 2-carboxyl group functions as an intramolecular general acid catalyst. It is envisaged that water (or another general base) abstracts the C4 proton of **8** and there is proton transfer from the 2-carboxyl group to the dienone oxygen (Scheme 3), the two processes not necessarily being synchronous. This mechanism is an intramolecular analogue of that proposed for the general acid-catalyzed enolization of **5** (Scheme 2), with the 2-carboxyl replacing HA. Moreover, the mechanism in Scheme 3 is similar to that for the debromination of the "*ipso* dienone" **9**, which also exhibits intramolecular catalysis (14, 15).

From the value of $\alpha = -0.09$ for the enolization of **5** it is estimated that an acid of $pK_a = 3$ (appropriate for **8**) should have a value of k_{HA} of $1.0\,M^{-1}\,s^{-1}$. Therefore, since the dienone **8** reacts with $k_2 \sim 110\,s^{-1}$, the *effective molarity* (EM) (22) of the internal carboxyl group is about $110\,M$.[12] This EM is within the normal range of values found for intramolecular general acid catalysis (22) and is similar to the value of $58\,M$ that we found for the debromination of **9** (14, 15).

If, as depicted in Scheme 3, general bases other than water can be involved in the enolization of **8**, then catalysis by buffers is to be expected. Indeed, strong catalysis was found in acetate and phosphate buffers. Operationally, the catalysis in acetate buffers appears as acetic acid catalysis on the anion of **8** ($k_{HA} = 78\,M^{-1}\,s^{-1}$). However, this is ascribed to the kinetic equivalent: acetate ion acting as the base on undissociated **8** with $k_A = 3500\,M^{-1}\,s^{-1}$ (Scheme 3).

In phosphate buffers (pH near 6) there is catalysis by both the acidic and basic components. The apparent catalysis by the dihydrogen phosphate ion ($k_{HA} = 46\,M^{-1}\,s^{-1}$) is assigned to the attack of the hydrogen phosphate dianion on undissociated **8** (Scheme 3) with $k_A = 1.6 \times 10^5\,M^{-1}\,s^{-1}$. The catalysis by HPO_4^{2-} is most probably due to direct attack by that ion on the anion of **8** ($k_A = 22\,M^{-1}\,s^{-1}$); the alternative of the triphosphate trianion attacking undissociated **8** would need to have an unrealistic rate constant of $5 \times 10^{10}\,M^{-1}\,s^{-1}$.

Conclusions

The kinetics of enolization of the benzocyclohexadienone **5** are very similar to those found earlier (4) for the monocyclic derivative **2***b*. Consequently, similar mechanistic conclusions are drawn. The enolization of the derivative of **5** bearing a carboxyl group at C_2, viz. **8**, exhibits intramolecular general acid catalysis (EM ~ $110\,M$) and catalysis by buffer bases.

Experimental

The substrates 1-naphthol and 1-naphthol-2-carboxylic acid (both from Aldrich) were recrystallized before use.

Procedures for carrying out kinetics experiments were as described in previous publications (3, 4, 6, 10, 14, 15). The transient cyclohexadienones (**5** and **8**) were generated *in situ* in the stopped-flow apparatus by mixing equal volumes of substrate solution (0.20 or 0.50 mM) and bromine solution (0.05 or 0.10 mM). For acetate and chloroacetate buffers both of these solutions contained the buffer. For the other

[11]Very recently, Bernasconi has proposed a "Principle of Imperfect Synchronization" and discussed it in relation to proton transfer reactions (23).

[12]Using the value of $\alpha = -0.38$ (for carboxylic acids), as a referee suggested, gives a higher EM of $150\,M$.

For personal use only.

buffers, which react slowly with bromine, only the initial substrate solution contained buffer (of twice the desired strength); the bromine solution was simply prepared in aqueous NaCl. For the pH–rate profiles (Fig. 1) $I = 0.11\,M$ ($0.1\,M$ KBr + $0.01\,M$ buffer salt) except in dilute acid where pH < 2. The studies of buffer catalysis were all carried out with $I = 1.0\,M$ (NaCl + buffer salt).

The decays of the dienones **5** and **8** were monitored at 270 nm relative to little or no change at 360 nm.

The individual "observed" rate constants, reported in the Supplementary Material,[13] are the averages of 3–5 determinations; they are reproducible within 5%. The standard deviations of the slopes of the buffer plots varied from 1 to 8% of the slope value. The derived values of k_{HA} have standard deviations of 3–15%. Accordingly, the probable error in α is such that its value should be taken as zero.

Hydration reactivity of ketenes generated by flash photolysis

ANNETTE D. ALLEN, A. JERRY KRESGE, NORMAN P. SCHEPP, AND THOMAS T. TIDWELL
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received December 15, 1986

This paper is dedicated to Professor John T. Edward

ANNETTE D. ALLEN, A. JERRY KRESGE, NORMAN P. SCHEPP, and THOMAS T. TIDWELL. Can. J. Chem. **65**, 1719 (1987).

The ketenes *n*-BuCH=C=O, PhCH=C=O, and Ph_2C=C=O have been generated by flash photolysis and their reactivities toward water, including acid and base catalysis, have been measured in wholly aqueous media by ultraviolet spectrophotometry. The phenyl group electronically enhances the reactivity of ketenes relative to *n*-butyl toward water and hydroxide, but retards reaction with protic acids. The presence of bulky groups, including phenyls, on each side in the ketene plane sterically retards nucleophilic attack. The reactions are interpreted as involving in-plane attack by nucleophilic water or hydroxide in the neutral and base-induced reactions, and electrophilic protonation perpendicular to the ketene plane for the acid-catalyzed reaction.

ANNETTE D. ALLEN, A. JERRY KRESGE, NORMAN P. SCHEPP et THOMAS T. TIDWELL. Can. J. Chem. **65**, 1719 (1987).

Faisant appel à la photolyse éclair, on a préparé les cétènes *n*-BuCH=C=O, PhCH=C=O et Ph_2C=C=O; utilisant la spectrophotométrie ultraviolette et opérant dans des milieux aqueux, on a mesuré leurs réactivités vis-à-vis de l'eau, tant sous l'influence de catalyseurs acides que basiques. Par comparaison avec le groupement *n*-butyle, le groupement phényle augmente la réactivité des cétènes vis-à-vis de l'eau et de l'ion hydroxyde; toutefois, il retarde la réaction avec les acides protiques. La présence de groupements encombrants, y compris les groupements phényles, de chaque côté du plan du cétène retarde l'attaque nucléophile. Pour expliquer les réactions qui se produisent en milieux neutre ou basique, on fait appel à un mécanisme impliquant une attaque, par l'eau du l'hydroxyde nucléophiles, qui se produirait dans le plan; par ailleurs, les réactions catalysées par les acides se produiraient par le biais d'une protonation électrophile qui se ferait d'une façon perpendiculaire au plan du cétène.

[Traduit par la revue]

The kinetic study of the hydration of ketenes in wholly aqueous media is complicated not only by the strong tendency of the ketenes to dimerize but also by their high reactivity with water. Previously, only by using *in situ* generation of ketenes by flash photolysis of diazoketones to give arylketenes (1) or of cyclobutanone to give ketene (2), together with fast measurement techniques, have such studies been accomplished (eqs. [1], [2]) for these ketenes.

[1] $ArCOCHN_2 \xrightarrow{h\nu} ArCH{=}C{=}O \xrightarrow{H_2O} ArCH_2CO_2H$

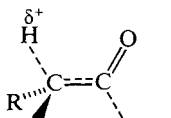
[2] 
In these previous flash photolytic studies (1, 2), the reactions were monitored by measuring changes in conductivity of the reacting solutions brought about by ionization of the carboxylic acid products. This technique could be used only over a limited pH range: high background conductivity made it inapplicable below pH 4 and above pH 11. Consequently, only the uncatalyzed hydration reaction could be studied; acid and base catalysis remained undetected.

Other studies of ketene hydration have utilized mixed solvents to circumvent the high reactivity of ketenes in pure water; these include diphenylketene and dimethylketene in H_2O/dioxane or ether (3, 4), and a variety of alkylketenes in H_2O/acetonitrile (5, 6). The very crowded di-*tert*-butylketene has also recently been found to be sufficiently unreactive towards water that its hydration may be studied in pure water at 25°C by conventional spectrophotometric methods (6). In these systems acid (3–6) and base (6) catalysis have been observed. The hydration of ketenes has also been studied in the gas phase (7) and by theoretical methods (8).

At least partly because of the diversity of methods and conditions that have been used for these studies of ketene hydration there are also widely divergent views of the mechanisms of these processes, and these have been recently reviewed (10). We have advocated (5, 6) the processes shown in eqs. [3]–[5]

[3] 
1

[4] 
2*a*



2*b*

[5] 
3

with transition states **1**–**3** for the neutral, acid, and base induced processes, respectively, whereas cyclic transition state **4** has been proposed for the neutral hydration in mixed solvents (3, 4), and transition states **5** (8) and **6** (9) have been advanced in the theoretical studies.

In eq. [3] attack by water in the plane of the ketene is envisaged (6), and for the acid catalyzed reaction proton attack

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12

4 5 6

occurs perpendicular to the ketene plane, either to give an acylium-ion-like transition state **2***a*, or possibly with concerted "enforced" attack of water via **2***b* (5, 6). The hydroxide induced reaction (eq. [3]) resembles that for the neutral hydration (eq. [1]) (6). The nucleophilic attack of H_2O and OH^- occur on the LUMO **7** of ketenes, whereas electrophilic protonation occurs on the HOMO **8** (11).

7 8

In contrast to the transition states **1**–**3**, in the concerted additions to the C=C bond via **4** and **5**, attack would have to occur in the plane perpendicular to the ketene, while **6** resembles the well-studied hydration transition state of aldehydes and ketones (12).

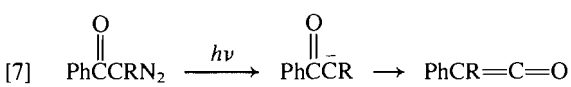
To help resolve these highly discordant interpretations, we have begun a study of ketene hydration using flash photolysis with spectrophotometric detection. This technique allows us to measure reaction rates over the entire pH range from strongly acidic to strongly basic solutions and to examine the acid and base catalyzed processes as well as the uncatalyzed reactions. In this paper we report results for *n*-butylketene (**9**), phenylketene (**10**), and diphenylketene (**11**); the first of those was

n-BuCH=C=O PhCH=C=O Ph_2C=C=O

9 **10** **11**

generated by photolyzing cyclohexanone (eq. [6]) (13), while the latter two were made by photo-Wolff rearrangement (eq. [7], R = H, Ph) (1, 14).

[6]



[7]

Results

n-*Butylketene*

Rates of hydration of this ketene were measured in aqueous perchloric acid solutions over the concentration range $[HClO_4]$ = 0.01–0.10 *M* and in aqueous sodium hydroxide solutions over the concentration range [NaOH] = 0.002–0.06 *M*; the ionic strength was maintained constant at 0.10 *M* by adding sodium chloride as required. These data are summarized in Tables S1 and S2.[1]

The hydration reaction showed both acid and base catalysis, with observed first-order rate constants accurately proportional to acid or base concentrations. Linear least-squares analysis gave the catalytic coefficients $k_{H^+} = (3.98 \pm 0.09) \times 10^3 M^{-1} s^{-1}$ and $k_{HO^-} = (3.29 \pm 0.04) \times 10^4 M^{-1} s^{-1}$. Both sets of data also showed significant zero-catalyst-concentration intercepts or "uncatalyzed" reactions, and gave uncatalyzed rate constants in good agreement with each other: $k_0 = (8.85 \pm 0.49) \times 10^1 s^{-1}$ from the acidic solutions and $k_0 = (9.61 \pm 0.93) \times 10^1 s^{-1}$ from the basic solutions.

Rates of hydration of *n*-butylketene were also measured in aqueous $H_2PO_4^-/HPO_4^{2-}$ buffer solutions. These measurements were made in a series of solutions of constant buffer ratio ($[H_2PO_4^-]/[HPO_4^{2-}] = 0.60$) and constant ionic strength (0.10 *M*), with buffer concentration changing over the range [buffer] = 0.009–0.05 *M*. These data are summarized in Table S3.[1]

Hydration rates in these buffer solutions showed little variation with buffer concentration. Linear least-squares analysis of the relationship between observed first-order rate constants and buffer concentration gave a catalytic coefficient just barely greater than its standard deviation: $k_{cat} = \Delta k_{obs}/\Delta[buffer] = (8.7 \pm 5.8) \times 10^1 M^{-1} s^{-1}$. The zero-buffer-concentration intercept, on the other hand, was well defined, $k_0 = (1.01 \pm 0.02) \times 10^2 s^{-1}$, and consistent with the less precise determinations of this quantity in perchloric acid and sodium hydroxide solutions. The weighted average of all three values is $k_0 = 99.4 \pm 1.6 M^{-1} s^{-1}$.

Phenylketene

Rates of hydration of phenylketene were measured in aqueous perchloric acid solutions over the concentration range $[HClO_4]$ = 0.01–0.10 *M* and in aqueous sodium hydroxide solutions over the concentration range [NaOH] = 0.001–0.10 *M*; the ionic strength was maintained at 0.10 *M* by adding sodium chloride as required. These data are summarized in Tables S4 and S5.[1]

This hydration reaction showed no acid catalysis. Linear least-squares analysis of the relationship between observed first-order rate constants measured in perchloric acid solutions and the acid concentration gave a negative hydronium catalytic coefficient with absolute magnitude comparable to its standard deviation: $k_{H^+} = \Delta k_{obs}/\Delta[HClO_4] = -(4.6 \pm 2.1) \times 10^3 M^{-1} s^{-1}$. The rate constant of the uncatalyzed reaction, however, was well defined by these experiments: $k_0 = (4.65 \pm 0.14) \times 10^3 s^{-1}$.

Observed rate constants determined in sodium hydroxide solutions, on the other hand, increased strongly with base concentration. The relationship between these two variables was linear, and least-squares analysis gave $k_{HO^-} = (1.22 \pm 0.05) \times 10^6 M^{-1} s^{-1}$, and an uncatalyzed rate constant, $k_0 = (5.50 \pm 0.03) \times 10^3 s^{-1}$, consistent with the result from perchloric acid solutions.

Some measurements of the rate of hydration of phenylketene were also made in H_2O and D_2O solutions with no added acid or base. The ionic strength of these solutions was fixed at 0.10 *M* by adding sodium chloride. These data are summarized in Table S6.[1] They provide the solvent isotope effect $k_{H_2O}/k_{D_2O} = 1.44 \pm 0.14$ for the uncatalyzed reaction.

The measurements in H_2O give another estimate of the rate constant for the uncatalyzed hydration of phenylketene: $k_0 = (4.54 \pm 0.30) \times 10^3 s^{-1}$. This result is in agreement with the determinations made in perchloric acid and sodium hydroxide

[1]Tables S1–S8 of rate data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council, Ottawa, Ont., Canada K1A 0S2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

solutions, and the weighted average of all three values is $k_0 = (4.77 \pm 0.12) \times 10^3\ s^{-1}$.

Diphenylketene

Rates of hydration of this ketene were measured in aqueous perchloric acid solutions over the concentration range $[HClO_4] = 0.002–0.10\ M$ and in aqueous sodium hydroxide solutions over the concentration range $[NaOH] = 0.001–0.10\ M$. Ionic strength was maintained at $0.10\ M$ by adding sodium chloride as required. These data are summarized in Tables S7 and S8.[1]

This hydration reaction also showed no acid catalysis. Linear least-squares analysis gave $k_{H^+} = \Delta k_{obs}/\Delta[HClO_4] = -(1.18 \pm 0.98) \times 10^2\ M^{-1}\ s^{-1}$ and $k_0 = (2.74 \pm 0.04) \times 10^2\ s^{-1}$. Catalysis by hydroxide ion, on the other hand, was strong, with observed rate constants accurately proportional to base concentration. Linear least-squares analysis gave the hydroxide ion catalytic constant $k_{HO^-} = (6.11 \pm 0.11) \times 10^4\ M^{-1}\ s^{-1}$ and a rate constant for the uncatalyzed process, $k_0 = (1.97 \pm 0.48) \times 10^2\ s^{-1}$, consistent with the more precise determination of this quantity in perchloric acid solutions.

Some additional measurements of the rate of hydration of diphenylketene were also made in H_2O and D_2O containing sodium chloride ($0.10\ M$). These data are summarized in Table S6.[1] They give a solvent isotope effect of $k_{H_2O}/k_{D_2O} = 1.74 \pm 0.13$ on the uncatalyzed reaction. The measurements in H_2O provide another estimate of the rate constant for the uncatalyzed reaction, $k_0 = (2.85 \pm 0.12) \times 10^2\ s^{-1}$, which is consistent with the results obtained in perchloric acid and sodium hydroxide solutions. The weighted average of all three values is $k_0 = 275 \pm 3\ s^{-1}$.

Our value of $4770\ s^{-1}$ for k_{H_2O} for PhCH=C=O measured by uv spectrophotometry at 25°C is in good agreement with that of $4900\ s^{-1}$ at 26°C obtained previously (1) by conductivity (Table 1). Similarly, our measurement of the solvent isotope effect $k_{H_2O}/k_{D_2O} = 1.44 \pm 0.14$ for PhCH=C=O is probably within the experimental uncertainty of the previously reported (1) value of 2.

Our measured value of k_{H_2O}/k_{D_2O} of 1.74 for $Ph_2C{=}C{=}O$ in pure water is in good agreement with the reported (4*b*) values of 1.7–2.0 in dioxane/water mixtures.

Discussion

The observed value of k_{H_2O} for *n*-BuCH=C=O may be usefully compared to those of other aliphatic ketenes (2, 6) as given by Table 2.

The comparative data in Table 2 show that *n*-BuCH=C=O is more reactive than $CH_2{=}C{=}O$ by a factor of 2.2, and this small difference appears reasonable for the differential effect of the *n*-butyl substituent, compared to hydrogen, on the ground states and transition states for the mechanism of eq. [3]. Similarly *n*-BuCH=C=O is more reactive than the isomeric *t*-BuCH=C=O by a small factor of 2.6, and this result shows that the presence of a single bulky group has no major effect on the reactivity. This result is expected for the transition state **1** in eq. [3] in which the nucleophilic water can attack in the ketene plane opposite the bulky group. The small retardation for *t*-BuCH=C=O may arise from steric hindrance to solvation of the polar transition state.

The reactivity of *n*-BuCH=C=O is greater than that of $Et_2C{=}C{=}O$ and *t*-$Bu_2C{=}C{=}O$ by factors of 12 and 6×10^5, respectively. In the case of $Et_2C{=}C{=}O$ each side of the ketone possesses a moderate sized substituent, and so a rate decrease is expected due to the hindrance to the nucleophile in the transition state **1**, regardless of the side of approach in the plane. When two very bulky *tert*-butyl groups are present the rate is enormously decreased; this distinctively nonadditive effect of the second *tert*-butyl group is exactly what is expected if hydration occurs by in-plane attack of the nucleophile, but is *not* the behaviour expected for attack perpendicular to the ketene plane as shown in the cyclic transition state **4**, where the effect of the *tert*-butyl groups would be close to additive.

TABLE 1. Summary of rate constants for ketene hydration in aqueous solution at 25°C, ionic strength = $0.10\ M$

	Ketene		
Rate constant	*n*-Butyl	Phenyl	Diphenyl
$k_{H^+}/M^{-1}\ s^{-1}$	3 980	—	—
$k_{HO^-}/M^{-1}\ s^{-1}$	32 900	1 220 000	61 100
$(k_0)_{H_2O}/s^{-1}$	99.4[a]	4 770[a]	275[a]
$(k_0)_{D_2O}/s^{-1}$	—	3 150	164

Thus the comparative rate data for the aliphatic ketenes shown in Table 2 give evidence that substituent effects of aliphatic groups on ketene hydration by neutral water are rather small, insofar as these arise from electronic influences on the stabilities of the ground states and transition states, and from effects on solvation. However, steric effects are large when nucleophilic attack by water in the ketene plane is impeded, and this provides strong support for the mechanism of eq. [3], as we have proposed previously (6, 10).

The observed solvent isotope effects for the hydration of *n*-BuCH=C=O, PhCH=C=O, and $Ph_2C{=}C{=}O$ (Table 1) are similar to the values of 1.45–2.58 found for alkylketenes in mixed solvents (6). Solvent isotope effects for rate-limiting attack of water on the carbonyl carbon of a variety of ketones, esters, and carboxylic anhydrides have been observed in the range of 2.2–4.0 (15), and these have been generally interpreted in terms of general base assistance by a second water molecule to attack on the carbonyl carbon. If this interpretation is correct, then the observed solvent isotope effects for *n*-BuCH=C=O, PhCH=C=O, and $Ph_2C{=}C{=}O$ may indicate that such general base catalysis by a second water molecule is also involved in the ketene hydration transition state **1** (eq. [3]).

The reaction of ketenes with hydroxide has been proposed (6) to occur through attack of the nucleophile in the plane of the ketene as shown in eq. [5], and there is little doubt that the reaction of *n*-BuCH=C=O proceeds by this path as well. However for *t*-$Bu_2C{=}C{=}O$ the reaction with HO^- was so slow that it could not be reliably detected, whereas less crowded aliphatic ketenes were so reactive that it was necessary to use mixed solvents to measure their reaction rates using conventional uv spectrophotometry (6). Thus the current measurements are the first reported reaction rates of ketenes with hydroxide in wholly aqueous media.

The reactivity of PhCH=C=O towards H_2O is significantly greater than that of the alkylketenes, and exceeds the values in Table 2 by factors of 48 (*n*-BuCH=C=O), 130 (*t*-BuCH=C=O), 580 ($Et_2C{=}C{=}O$), and 110 ($CH_2{=}C{=}O$). The rate of PhCH=C=O towards hydroxide exceeds that of *n*-BuCH=

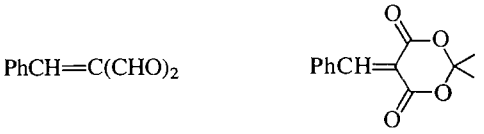
C=O in reactivity by a factor of 37, and the resemblance of the rate factors towards H_2O and HO^- argues for a similarity in mechanism. The high reactivity of PhCH=C=O is consistent with a polar, enolate-like transition state, such as **1**, in which there is significant negative charge buildup adjacent to the phenyl ring. A relatively nonpolar cyclic transition state such as **4** is difficult to reconcile with the high reactivity of PhCH=C=O; not only would the phenyl stabilization of charge development at C_β be absent in such a transition state, but also the ground state of PhCH=C=O is stabilized by conjugation of phenyl with the C=C double bond, and this conjugation is diminished in the cyclic transition state, and reduced reactivity would be expected. Invocation of a highly polar cyclic transition state appears unjustified, as such a transition state does not explain the steric effects. Little steric or electronic effect of substituents is expected in the carbonyl hydration transition state **6**, so this path is also evidently unimportant in solution.

The 20-fold greater reactivity of PhCH=C=O compared to Ph_2C=C=O in both the neutral and OH^- induced reactions provides a further significant indication as to the mechanism of these reactions. There is evidently no conflict of opinion that the OH^- induced reaction proceeds by nucleophilic attack in the plane of the ketenes as depicted in eq. [5], and the similarity in the rate differences for the two reactions is suggestive that the H_2O reaction follows a similar path, namely that of eq. [3]. The second phenyl is expected to stabilize both the ground state and an enolate-like transition state, but the most important effect is a large steric barrier in the plane of the ketene that cannot be avoided when two bulky phenyl groups are present. Such steric barriers are well documented both in preparative (10) and kinetic (5, 6) studies. While there might be a small steric barrier to a cyclic transition state such as **4**, there is little evidence for such effects for attack perpendicular to alkenes (16) and these effects would also be cumulative, whereas for attack in the plane there is an abrupt change to a high steric barrier when two bulky groups are present, as is observed. Thus the observed reactivity of PhCH=C=O and Ph_2C=C=O towards H_2O and OH^- favours reaction occurring in the plane through transition states such as **1** and **3**, respectively, and argues against the intervention in solution of cyclic transition states such as **4**–**6**.

The pK_a values of the enols Ph_2CH=CHOH and PhCH=CHOH have recently been determined as 9.4 and 9.5, respectively.[2] As shown in eq. [8], the proton dissociation of enols

[8] 
involves conversion of a neutral to an anionic species *without* a change in hybridization from sp^2 of the carbon bearing the substituents, and this is closely analogous to the additions of water and hydroxide to ketenes shown in eqs. [3] and [5]. The slightly greater acidity of Ph_2C=CHOH is supportive that in the absence of a steric barrier to in-plane nucleophilic attack Ph_2C=C=O would be more reactive than PhCH=C=O.

The observed ratios of k_{HO^-}/k_{H_2O} of 330, 260, and 220 for *n*-BuCH=C=O, PhCH=C=O, and Ph_2C=C=O, respectively, are noticeably less than those reported for many carbonyl group hydrations, including 1.6×10^6 for $PhCOCF_3$ (12*a*), 1.2×10^7 for 3-ClC_6H_4CHO (12*b*) and 5.0×10^5 for CH_2O (12*c*) (k_{OH^-} in units of $M^{-1}\,s^{-1}$, k_{H_2O} in s^{-1}). Similar small values of this ratio have been observed for other ketenes (6), and for the α,β-unsaturated carbonyl compounds shown below (12 h), but the origin of the variation in this ratio has not been elucidated. However, the relative constancy of the ratio for ketenes is supportive of the similarity of mechanisms for the neutral and hydroxide induced reactions shown in eqs. [1] and [3], respectively.



k_{HO^-}/k_{H_2O} 3.3×10^3 1.3×10^3

The value of k_{H^+}/k_{H_2O} of 40 (Table 1) obtained for *n*-BuCH=C=O is comparable to values of 140 and 280 for Et_2C=C=O and *t*-BuCH=C=O, respectively, which we obtained previously in mixed solvents at lower temperatures (6). No acid catalyzed reaction at all could be detected for PhCH=C=O and Ph_2C=C=O, and this is consistent with the large rate retarding effect expected for protonation next to phenyl, as illustrated by the average deceleration of 690 relative to hydrogen observed for the *cis*- and *trans*-2-phenylvinyl methyl ethers (eq. [9]) (17). There must be a sizeable rate retardation for k_{H^+} of PhCH=C=O as well, or this reaction would have been detected in the current experiments.

[9] $PhCH{=}CHOCH_3 \xrightarrow{H^+} PhCH_2\overset{+}{C}HOCH_3$

In summary, the generation of ketenes by flash photolysis combined with uv spectrophotometric measurement of reaction rates has been shown to be a valuable technique for examining these intermediates. These initial studies on *n*-BuCH=C=O, PhCH=C=O, and Ph_2C=C=O demonstrate the polar and steric influences of substituents on ketene hydration reactivity, and provide strong evidence for the mechanisms of eqs. [3]–[5] involving in-plane attack of nucleophilic water or hydroxide, and perpendicular attack at C_β in acid.

Experimental

Materials

The ketene precursor $PhCOCHN_2$ was prepared by reaction of PhCOCl with CH_2N_2 in ether with added triethylamine (14), while $PhCOCN_2Ph$ was obtained by the reaction of $PhCOC(NNH_2)Ph$ (Aldrich) with HgO (18).

Flash photolysis

A kinetic flash photolysis system of conventional design (19) was employed. The excitation flash of 50-μs width at half-length was produced by electrical discharge of 2000-J energy from a Xenon Corporation Model A Micro Pulser power supply through two Xenon Corporation FPA-5-100C xenon flash lamps. The monitoring light was supplied by an Osram Model XBO 150-W xenon lamp, operating from an Oriel Model 68700 universal arc lamp power supply. This light was passed first through a 10-cm water-jacketed (25.0 ± 0.05°C) sample cell and then through an Oriel Model 77250 grating monochrometer, and the output from that was detected by an Oriel Model 77341 photomultiplier. The signal from the photomultiplier was sent to a Biomation Model 805 transient recorder and A-D converter, and the digitized output was fed into a Commodore PC 10 microcomputer.

First-order rate constants were calculated by fitting time and absorbance data to an exponential function by nonlinear least-squares analysis.

Effect of mercerization on the crystallite size and crystallinity index in cellulose from different sources

J. F. REVOL, A. DIETRICH, AND D. A. I. GORING

Department of Chemistry, Pulp and Paper Building, McGill University, Montreal, P.Q., Canada H3A 2A7

Received November 4, 1986

This paper is dedicated to Professor John T. Edward

J. F. REVOL, A. DIETRICH, and D. A. I. GORING. Can. J. Chem. **65**, 1724 (1987).

Native cellulose samples having a wide range of crystallinity and crystallite size were mercerized by treatment with sodium hydroxide. The resultant cellulose II samples showed only a narrow range of crystallinity and an essentially constant crystallite size. For the low-crystallinity samples, crystallinity and crystallite size actually increased on mercerization. These results are in line with the proposal that mercerization involves the mingling of chains from adjacent and antiparallel cellulose I *microfibrils* to form cellulose II crystals of antiparallel chains.

J. F. REVOL, A. DIETRICH et D. A. I. GORING. Can. J. Chem. **65**, 1724 (1987).

Utilisant de l'hydroxyde de sodium, on a mercerisé divers échantillons de cellulose naturelle possédant un large éventail de cristallinités et de grosseurs de cristaux. Les échantillons de cellulose II qui en résultent ne présentent qu'un éventail restreint de cristallinités et la grosseur des cristaux est pratiquement constante. Pour des échantillons de faible cristallinité, la cristallinité et la grosseur des cristaux augmente avec la mercerisation. Ces résultats sont en accord avec l'hypothèse selon laquelle la mercerisation implique un mélange des *microfibres* de cellulose I adjacentes et antiparallèles pour former des cristaux de cellulose II de chaînes antiparallèles.

[Traduit par la revue]

Introduction

Although the conversion of cellulose I to cellulose II in mercerization has been studied by a variety of methods (1–4), its mechanism is not yet fully understood. It has been shown that the alkali-induced conversion of cotton from cellulose I to cellulose II is governed by the swelling of the fibre (5). More recently it was found that, in wood and in bamboo, the degree of mercerization of cellulose depends on the degree of swelling (6, 7). There is, therefore, no doubt that swelling is necessary to convert cellulose I to cellulose II on mercerization.

There seems to be a growing body of opinion that, in native cellulose, each elementary microfibril contains chains of the same polarity (parallel chains) (8–11), while regenerated and mercerized cellulose contains chains of alternating polarity (antiparallel chains) (12). The mechanism by means of which such chain reversal occurs in mercerization has been discussed by Blackwell *et al.* (1), by Revol and Goring (6), and more recently by Okano and Sarko (13, 14). Their explanation is as follows. Single microfibrils in native cellulose contain chains of the same polarity, but they can point alternately up and down. This hypothesis was confirmed recently by Revol and Goring (15) who showed that in the Valonia cell wall, cellulose microfibrils in close proximity have their fibre *c* axis alternately up and down (in opposite directions). Two neighbouring microfibrils of opposite polarity may coalesce during swelling in alkali, and allow the chains to adopt the antiparallel arrangement needed to form cellulose II. Recent X-ray diffraction studies seem to indicate that an antiparallel arrangement is already present in the alkali cellulose (14) found as an intermediate state during the conversion.

If the above concepts are correct, the cellulose I crystal structure will be entirely destroyed by swelling during mercerization and the subsequent cellulose II crystal structure created when the alkali is removed. Thus we would not expect to find a correlation between the crystallinity and crystallite size in the native cellulose and those parameters in the corresponding mercerized product. The purpose of the present work was to test this hypothesis. Native celluloses, having a wide range of crystallite size and crystallinity index, were selected from different sources. These were then mercerized conventionally. The crystallite size and crystallinity index were determined on the resulting cellulose II and compared with the corresponding parameters of the original native cellulose.

Experimental

The different native celluloses chosen are listed in Table 1. Each sample was refluxed in an aqueous solution of 4% sodium hydroxide for 12 h, rinsed with water, and refluxed in an aqueous solution of 1% HCl for 4 h. It was then rinsed with water until neutral in pH. For Valonia cellulose, an additional treatment of reflux in an aqueous solution of 4% HCl for 5 h was given. Such a treatment allows better mercerization of the sample, which is otherwise very resistant to alkali. This Valonia sample was then stretched as much as possible to orient the microfibrils in one direction, and twisted to eliminate any preferential orientation that is known to exist in the original cell wall. For mercerization, the samples were treated for 1 h in an aqueous solution of 18% sodium hydroxide at room temperature. They were then thoroughly washed until the wash water was neutral in pH. In the case of Valonia, this treatment was repeated 3 times.

X-ray diffraction patterns were recorded on flat film in a Warhus camera: Ni-filtered Cu-Kα radiation was used. The X-ray patterns were then analyzed with a microdensitometer (MK III CS. Joyce Loebl).

The degree of crystallinity or crystallinity index (C.I.) for cellulose I was determined (16) by

$$[1] \quad \text{C.I.} = \frac{I_{020} - I_{18.5°}}{I_{020}}$$

and for cellulose II (17) by

$$[2] \quad \text{C.I.} = \frac{I_{110} - I_{15.0°}}{I_{110}}$$

The crystal size was determined (18) from

$$[3] \quad t = \frac{0.9\lambda}{\beta \cos \theta}$$

where t is the thickness of the crystallite, λ the wavelength, β the corrected angular width at half maximum intensity, and θ the Bragg angle. The value of β was obtained (18) from

$$[4] \quad \beta = B^2 - b^2$$

TABLE 1. Crystallinity parameters for the various cellulose samples before and after mercerization

Cellulose sources	*d* spacing of the (020) planes (nm)	C.I. (crystallinity index)	Crystal size perpendicular to the (020) planes (nm)
Valonia ventricosa	0.387	0.95	15.4
Mercerized *Valonia ventricosa*		0.66	3.6
Ramie	0.387	0.83	5.8
Mercerized ramie		0.65	4.0
Kraft pulp (black spruce)	0.393	0.67	4.0
Mercerized kraft pulp (black spruce)		0.66	3.7
Celery	0.407	0.41	3.0
Mercerized celery		0.50	3.4
Swiss chard	0.403	0.43	2.9
Mercerized Swiss chard		0.60	4.4

where *B* is the observed angular width at half maximum intensity, and *b* the angular width at half maximum intensity of the reflection given by crystals of hexamethylenetetramine. The crystal size, *t*, was determined perpendicular to the (020) plane for both cellulose I and cellulose II. The amorphous contribution of cellulose has been evaluated and subtracted by hand according to a procedure used previously (19). For cellulose II, the overlapping of the 110 and 020 reflections was resolved by a technique similar to that of Patil *et al.* (20).

Results and discussion

The *d* spacing of the (020) planes is listed in Table 1 for the different celluloses. Values of *d* for *Valonia* and ramie were equal. However, the spacing becomes larger for the kraft pulp and still larger for celery and Swiss chard. Changes in the crystallinity index and in the size of the crystals perpendicular to the (020) plane follow a reversed tendency. Spacings of more than 0.4 nm for the (020) planes as shown in Table 1 for celery and Swiss chard have been reported previously for the primary wall of cotton fibres and in the wall of rose cells cultured in vitro (21, 22). These correspond generally to cellulose microfibrils of low crystallinity and small lateral size, as seen in Table 1, which contrasts with the high crystallinity and large size of the cellulose microfibrils contained in the *Valonia* cell wall. The least crystalline specimens are obviously more distorted, which results in a looser packing of the chains and hence larger unit cell dimensions.

After conversion to cellulose II by mercerization, crystallinity index and crystal size tend toward similar values for all the celluloses as shown in Table 1. The crystallinity index for the mercerized celluloses remains in a narrow range of 0.50–0.66 while it varies from 0.41 to 0.95 for the native celluloses. The crystal size is approximately constant for the mercerized celluloses, from 3.4 nm to 4.4 nm, while it varies from 2.9 nm to 15.4 nm in native celluloses. There is thus an evident convergence of the crystallinity and of the crystal size during the conversion from cellulose I to cellulose II by mercerization of native cellulose from different sources.

The present results indicate clearly that in native cellulose of high crystallinity, mercerization reduces crystallinity and crystal size, while for low crystallinity celluloses the reverse occurs. These trends would not be expected if the conversion of cellulose I to cellulose II was simply a change in conformation of the chain or arrangement of atoms in the unit cell. The present results are more in line with the idea that mercerization involves a complete destruction of the cellulose I structure by separation of the molecular chains followed by a reforming of the crystal structure as cellulose II. And this concept is compatible with the proposal that mingling of chains from the adjacent and antiparallel *microfibrils* of cellulose I to give the antiparallel *chains* of cellulose II occurs during mercerization.

Of course, we have no definitive proof that the picture presented above is correct. However, as far as the authors are aware, the present paper is the first report that larger crystals and higher crystallinity may be obtained by mercerizing cellulose. This finding will help to elucidate the ultrastructure of cellulose in its natural state as well as the way in which it is mercerized.

Thermodynamics of ionization of aqueous alkanolamines

JIN-HO KIM,[1] CELINA DOBROGOWSKA, AND LOREN G. HEPLER
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received December 22, 1986

This paper is dedicated to Professor John T. Edward

JIN-HO KIM, CELINA DOBROGOWSKA, and LOREN G. HEPLER. Can. J. Chem. **65**, 1726 (1987).

We have made electrochemical measurements with a glass electrode that have yielded pK values at T = 298.15 K for monothanolamine (MEA), triethanolamine (TEA), diisopropanolamine (DIPA), and methyldiethanolamine (MDEA) relative to the already well-known pK for diethanolamine (DEA), with all pK values referring to equilibria of the type $AmH^+(aq)$ = $Am(aq) + H^+(aq)$ in which Am(aq) represents an alkanolamine in aqueous solution and $AmH^+(aq)$ represents the corresponding protonated alkanolamine. We have also made calorimetric measurements leading to ΔH^0 values for dissociation of the protonated species of all five of these alkanolamines in aqueous solution at T = 298.15 K. These pK and ΔH^0 values have led to ΔG^0 and ΔS^0 values for the corresponding dissociation reactions of all five $AmH^+(aq)$ species.

JIN-HO KIM, CELINA DOBROGOWSKA et LOREN G. HEPLER. Can. J. Chem. **65**, 1726 (1987).

On a effectué des mesures électrochimiques à l'aide d'une électrode de verre qui ont permis d'obtenir, à 298,15 K, des valeurs de pK de la monoéthanolamine (MEA), de la triéthanolamine (TEA), de la diisopropanolamine (DIPA) et de la méthyldiéthanolamine (MDEA) relatives à la valeur bien connue du pK de la diéthanolamine (DEA); toutes les valeurs de pK se réfèrent à des équilibres du type $AmH^+(aq)$ = $Am(aq) + H^+(aq)$ dans lesquels Am(aq) représente une alkanolamine en solution aqueuse et $AmH^+(aq)$ représente l'alkanolamine protonée correspondante. On a aussi effectué des mesures calorimétriques qui ont conduit à des valeurs de ΔH^0 pour la dissociation des espèces protonées de chacune de ces cinq alkanolamines, en solutions aqueuses, à 298,15 K. Ces valeurs de pK et de ΔH^0 ont permis de déterminer les valeurs de ΔG^0 et de ΔS^0 pour les réactions de dissociation correspondantes de chacune des cinq espèces $AmH^+(aq)$.

[Traduit par la revue]

Introduction

Investigations of the acid–base properties of many organic substances have contributed in important ways to our understanding of relationships between molecular structures, properties of individual atoms or groups of atoms within molecules, and "chemical reactivity" as measured by equilibrium constants or by rate constants. In this connection the need for and uses of thermodynamic data (equilibrium constants or free energies, enthalpies, and entropies) for acid–base reactions in solution (where solvation effects occur along with "intrinsic" acid–base effects) and in the gas phase (no solvent) has been discussed recently in a perceptive paper (1) by Professor Edward.

Our general interest in the thermodynamic properties of organic acids and bases comes from considerations discussed in the paper (1) by Edward and as also reviewed elsewhere (2). Our specific interest in alkanolamines is derived partly from our general interest in thermodynamics of aqueous acids and bases and also comes partly from the present and potential uses of aqueous solutions of alkanolamines in removing acidic gases from industrial gas streams (3, 4).

As a result of the interests summarized above, we have made potentiometric and calorimetric measurements leading to pK, ΔG^0, ΔH^0, and ΔS^0 values for reactions of the general type represented by

[1] $AmH^+(aq) = Am(aq) + H^+(aq)$

in which Am(aq) represents an alkanolamine and $AmH^+(aq)$ represents the protonated alkanolamine, all in aqueous solution.

Experimental

Monoethanolamine (MEA, from Aldrich), diethanolamine (DEA, from Aldrich), triethanolamine (TEA, from Fisher), methyldiethanolamine (MDEA, from Aldrich), and diisopropanolamine (DIPA, from Eastman) were distilled twice at reduced pressure in an atmosphere of nitrogen and then stored over silica gel in desiccators filled with nitrogen.

Perchloric acid solutions were prepared from concentrated stock solution (≈70%, from Fisher) and double distilled water. These solutions, which were used in potentiometric titrations to check purities of the alkanolamines, in preparation of solutions used in determining equilibrium constants for reactions of type [1], and in calorimetric measurements, were standardized by potentiometric titrations in which tris(hydroxymethyl)aminoethane (from Fisher) was used as an alkalimetric standard.

Potentiometric titrations and measurements leading to pK values for reactions of type [1] were carried out with a Fisher Model 825 MP Accumet pH meter and Fisher electrodes (glass and calomel).

The method (5) used for determination of pK values for reactions of type [1] was based on calibration of the glass electrode – pH meter system with reference buffer solutions of Am/AmH^+ type. As shown previously (5), this convenient method minimizes common problems associated with junction potentials and activity coefficients. A fundamental requirement for application of this method is that we must have a reliable value (based on proper considerations of activity coefficients) for the pK of some reference compound that is similar to the compounds of interest. We have chosen diethanolamine (DEA) as our reference, because this substance is similar to the other alkanolamines of interest and because Bower, Robinson, and Bates (6) have provided an accurate and reliable pK = 8.883 for

[2] $DEAH^+(aq) = DEA(aq) + H^+(aq)$

at T = 298.15 K.

All calorimetric measurements have been made with a "home made" isoperibol calorimeter, which consisted of a glass Dewar vessel (370 cm^3 capacity) suspended in a brass can that was immersed in a constant temperature bath maintained at 25.00 ± 0.01°C and held constant during each calorimetric measurement to ±0.001°C, using a Tronac temperature controller (Model TPC-41) with an auxiliary cooling system maintained at 24.80 ± 0.05°C. Temperature changes in the calorimeter were measured with a thermistor (YSI 44045) combined with a Current Comparator Resistance Bridge (Guildline 9975). Our method of calorimetric measurement involved placing a weighed sample of alkanolamine in a small glass ampoule that was fastened to

TABLE 1. Equilibrium constants ($pK = -\log K$) for ionizations of type [1], enthalpies of solution as in eq. [3], enthalpies of reaction as in eq. [4], and standard enthalpies of proton ionization (ΔH^0, as in eq. [1]) of alkanolamines at $T = 298.15$ K

Amine[a]	pK	ΔH_3 (kJ mol^{-1})	ΔH_4 (kJ mol^{-1})	ΔH^0 (kJ mol^{-1})
MEA	9.508±0.01	−11.43±0.09	−61.98±0.11	50.55±0.14
DEA	[b]	−14.50±0.06	−56.43±0.10	41.93±0.12
TEA	7.80 ±0.03	−14.38±0.08	−48.29±0.13	33.91±0.15
DIPA	8.88 ±0.03	−4.5 ±0.14	−47.2 ±0.16	42.7 ±0.2
MDEA	8.52 ±0.03	−20.5 ±0.2	−55.7 ±0.2	35.2 ±0.3

[a]Abbreviations are as follows: MEA = monoethanolamine, DEA = diethanolamine, TEA = triethanolamine, DIPA = diisopropanolamine, and MDEA = methyldiethanolamine.

[b]We have used $pK = 8.883$ from ref. 6 as reference or standard for calibration (5) of our glass electrode – pH meter system.

the end of the stirrer in the calorimeter. Gentle pressure on the top of the stirrer caused the bulb to break on the bottom of the Dewar vessel, thus introducing the alkanolamine to the solution in the calorimeter. The calorimeter was calibrated electrically for each experiment.

We have checked the accuracy of the calorimetric system described above by way of measurements of the enthalpy of solution of KCl(c) in distilled water, the enthalpy of solution of 4-aminopyridine in excess aqueous acid (7, 8) and the enthalpy of neutralization of tris(hydroxymethyl)aminomethane by excess aqueous acid. Results of these measurements, as fully reported elsewhere (9) along with a more detailed description of the calorimeter, agreed to within 0.5%, 0.04%, and 0.02%, respectively, with the "best" values from the literature.

Results and calculations

Results of our pH measurements leading to pK values (based on molal standard states for solutes) for equilibria of type [1] at $T = 298.15$ K are summarized in Table 1.

We have measured enthalpies of solution of pure alkanolamines (DIPA is solid at 298.15 K, others are liquid) into dilute aqueous sodium hydroxide. Results of these measurements (after small "corrections" for the enthalpy effect due to hydrolysis) are the enthalpies of solution represented by

[3] $\mathrm{Am(pure)} = \mathrm{Am(aq)} \qquad \Delta H_3$

We have also measured enthalpies of solution and reaction of pure alkanolamines in excess dilute perchloric acid as represented by

[4] $\mathrm{Am(pure)} + \mathrm{H^+(aq)} = \mathrm{AmH^+(aq)} \qquad \Delta H_4$

Results of all these calorimetric measurements are summarized in Table 1, where ΔH_3 and ΔH_4 values refer to $T = 298.15$ K.

Combinations of our ΔH_3 and ΔH_4 values in Table 1 for reactions of types [3] and [4] as in

[5] $\Delta H_1 = \Delta H_3 - \Delta H_4$

lead to ΔH_1 values for reactions of type [1]. Because the enthalpies of solution of alkanolamines as in reaction [3] were independent of concentration in dilute solutions and because of the electrical symmetry of reactions represented by eqs. [1] and [4], we take these calculated ΔH_1 values to be equal to the desired standard state enthalpies (ΔH^0) of reactions of type [1], as listed in the fifth column in Table 1.

Results of our measurements, as summarized in Table 1, can be related to results of earlier investigators as follows.

Two excellent electrochemical investigations (10, 11) have led to $pK = 9.498$ and 9.500 for dissociation of $MEAH^+$(aq) at 298.15 K. Other investigators (12–14) have reported $pK = 9.51$, 9.52 (interpolation between 20 and 30°C), and 9.50. All of these results are in good agreement with our $pK = 9.508$. Two investigations (10, 11) that led to pK values at several temperatures also led by way of $d \ln K/dT = \Delta H^0/RT^2$ to $\Delta H^0 = 50.54$ and 50.88 kJ mol^{-1} for the dissociation of $MEAH^+$(aq) as in reaction [1], in excellent agreement with our calorimetric $\Delta H^0 = 50.55$ kJ mol^{-1}. Some earlier calorimetric measurements (15–18) have led to $\Delta H^0 = 50.50$, 50.50, 50.38, and 50.63 kJ mol^{-1}, also in good agreement with our calorimetric result. Two other calorimetric investigations (19, 20) and one $d \ln K/dT$ investigation (13) have led to ΔH^0 values in poor agreement with the "best" results above (10, 11, 15–18).

We have already selected $pK = 8.883$ for the dissociation of $DEAH^+$(aq), based on the measurements of Bower, Robinson, and Bates (6), as our reference or standard for calibrating our glass electrode – pH meter system; other values having larger uncertainties have been reported (14, 21). The $\Delta H^0 = 42.40$ kJ mol^{-1} calculated from application of $d \ln K/dT$ to the results of Bower, Robinson, and Bates (6) is in reasonable agreement with our calorimetric $\Delta H^0 = 41.93$ kJ mol^{-1} and with $\Delta H^0 = 41.88$ kJ mol^{-1} from earlier calorimetric measurements (17), but is in poor agreement with ΔH^0 values from one other $d \ln K/dT$ investigation (21) and one other calorimetric (20) investigation.

Careful electrochemical measurements by Bates and Allen (22) have led to $pK = 7.762$ and (from $d \ln K/dT$) $\Delta H^0 = 33.45$ kJ mol^{-1} for dissociation of $TEAH^+$(aq). We also have $\Delta H^0 = 34.14$ kJ mol^{-1} from calorimetric measurements by Christensen and colleagues (17). All of these results are in satisfactory agreement with our $pK = 7.80$ and $\Delta H^0 = 33.91$ kJ mol^{-1}. Other pK (14, 23, 24) and ΔH^0 (20, 24) values have been reported, but we consider all of these to be less accurate than those listed above in this paragraph.

For dissociation of $DIPAH^+$(aq) the only earlier results we can cite are from equilibrium measurements (in 1.00 M KCl) by Blauwhoff and Bos (25), who have reported that pK values for $DIPAH^+$(aq) and $DEAH^+$(aq) are "essentially equal" over the temperature range 293–323 K. The resulting implications that $pK \approx 8.88$ and that $\Delta H^0 \approx 42$ kJ mol^{-1} for dissociation of $DIPAH^+$(aq) are consistent with our $pK = 8.88$ and $\Delta H^0 = 42.7$ kJ mol^{-1}.

Our $pK = 8.52$ for dissociation of $MDEAH^+$(aq) is in good agreement with $pK = 8.52$ at 298 K from Schwabe, Graichen, and Spiethoff (26); the ΔH^0 value that can be obtained by

TABLE 2. Selected "best" thermodynamic properties at $T = 298.15$ K for reactions of alkanolamines represented by $AmH^+(aq) = Am(aq) + H^+(aq)$

Amine[a]	pK	ΔG^0 (kJ mol^{-1})	ΔH^0 (kJ mol^{-1})	ΔS^0 (J K^{-1} mol^{-1})
MEA	9.500	54.225	50.52	−12.43
DEA	8.883	50.703	41.90	−29.53
TEA	7.762	44.305	34.01	−34.53
DIPA	8.88	50.69	42.7	−26.8
MDEA	8.52	48.63	35.2	−45.0

[a]Abbreviations are identified below Table 1.

application of $d \ln K/dT$ to their results has a very large uncertainty. Douheret and Pariaud (14) have reported pK values that are larger than values mentioned above.

In addition to the pK and ΔH^0 values that have been cited, we also have some information about ΔC_p^0 for reactions of type [1]. The only "direct" evaluation by way of heat capacity measurements that we know about is $\Delta C_p^0 = -13\,J\,K^{-1}\,mol^{-1}$ for dissociation of $MEAH^+(aq)$ from the work of Cabani, Matteoli, and Selli (27). Levi, McEwan, and Wolfenden (15) have made calorimetric measurements leading to ΔH^0 values at 10, 20, and 30°C and thence to $\Delta C_p^0 = +17\,J\,K^{-1}\,mol^{-1}$ for dissociation of $MEAH^+(aq)$ at 298.15 K. Only a few of the investigations leading to pK values at different temperatures permit meaningful evaluation of ΔH^0 at several temperatures by way of $d \ln K/dT$ and then evaluation of ΔC_p^0 by way of $d\Delta H^0/dT$. In this connection we cite (10, 11) $\Delta C_p^0 = -5$ and $+45\,J\,K^{-1}\,mol^{-1}$ for dissociation of $MEAH^+(aq)$. We also have $\Delta C_p^0 = +49\,J\,K^{-1}\,mol^{-1}$ (6) for dissociation of $DEAH^+(aq)$ and $\Delta C_p^0 = +52\,J\,K^{-1}\,mol^{-1}$ (22) for dissociation of $TEAH^+(aq)$. Because of the uncertainties in these values and the observation that ΔC_p^0 values for isocoulombic reactions such as [1] are commonly small (as is the case for all the values listed here), the best that we can do now is say that $\Delta C_p^0 \approx 0$ for the reactions under present consideration.

On the basis of our results in Table 1 and the other results (pK values, ΔH^0 values from $d \ln K/dT$, and ΔH^0 values from calorimetric measurements) already cited, we have selected what we consider to be the best available thermodynamic quantities for dissociation of the five $AmH^+(aq)$ species that we have investigated. These selected thermodynamic values are listed in Table 2.

Detailed analysis of the thermodynamic results reported here for alkanolamines in terms of such useful equations as those proposed and developed by Hammett and Taft or analysis of the relationships between thermodynamic data that apply to aqueous solutions and similar data that apply to the gas phase as discussed by Edward (1) are subjects for continuing research.

Arylphosphonic acids. I. Substituent effects on their first and second dissociations

K. NAGARAJAN, KEVIN P. SHELLY, R. R. PERKINS, AND ROSS STEWART
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received November 24, 1986

This paper is dedicated to Professor John T. Edward

K. NAGARAJAN, KEVIN P. SHELLY, R. R. PERKINS, and ROSS STEWART. Can. J. Chem. **65**, 1729 (1987).

Thermodynamic pK_1 and pK_2 values of 36 arylphosphonic acids have been determined. The pK values of the *meta* and *para* compounds are correlated well by the σ^n parameter, suggesting that there is little conjugation between the phosphonic group and the aromatic ring; the ρ values of the first and second dissociations are 0.923 and 1.140, respectively. The $-PO_3H^-$ group itself appears to be electron donating, contrary to earlier literature reports. The effect of *ortho* groups has been examined using multivariate analysis; the steric component of the proximity effect is acid weakening and has a larger effect on the second dissociation than on the first, presumably because a greater change in degree of solvation accompanies the second dissociation than the first.

K. NAGARAJAN, KEVIN P. SHELLY, R. R. PERKINS et ROSS STEWART. Can. J. Chem. **65**, 1729 (1987).

On a déterminé les valeurs des pK_1 et pK_2 thermodynamiques de 36 acides arylphosphoniques. On a pu établir une bonne corrélation entre les valeurs des pK des composés *méta* et *para* et le paramètre σ^n; ce résultat suggère qu'il existe peu de conjugation entre le groupement phosphonique et le cycle aromatique; les valeurs de ρ pour les première et deuxième dissociations sont respectivement 0,923 et 1,140. Contrairement à ce qui a pu être publié antérieurement, le groupement $-PO_3H^-$ semble être électrodonneur. Faisant appel à une analyse multi-variable, on a aussi examiné l'effet des groupements en *ortho*; la composante stérique de l'effet de proximité a pour effet de diminuer l'acidité et cet effet est plus important sur la deuxième dissociation que sur la première; ce résultat est probablement causé par le fait que le changement dans le degré de solvatation qui accompagne la deuxième dissociation est plus important que celui qui accompagne la première.

Introduction

As part of a study of general acid and general base catalysis of protolytic reactions we have prepared a series of arylphosphonic acids, $ArPO_3H_2$, and examined the effectiveness of the three catalytic species, $ArPO_3H_2$, $ArPO_3H^-$, and $ArPO_3^{2-}$, on the enolization of acetone (1); the present paper deals with the acid dissociation constants of the first two of these species.

There are a number of reports in the literature of the effect of substituents on the pK_1 and pK_2 values of arylphosphonic acids, most notably those of Jaffé *et al.* (2, 3) and of Nualláin (4). We are particularly concerned with proximity effects in prototropic reactions and we needed pK data for *ortho*, *meta*, and *para* derivatives. The data of Jaffé *et al.* include such compounds but the pK values are not thermodynamic values; the data of Nualláin, which are much less extensive, have been corrected for ionic strength effects but include only two *ortho* compounds. Since we needed a set of self-consistent pK values for our catalytic work we have measured the first and second dissociation constants of a considerable number of arylphosphonic acids and corrected them to the standard state. The effects of substituents on the dissociation constants are interesting in their own right, first with respect to the degree of conjugation between the ring and the phosphonic acid unit, and secondly with respect to pK_1/pK_2 variations and associated solvent and related effects.

Results and discussion

The pK_1 and pK_2 values of 36 arylphosphonic acids are reported in Table 1. For those compounds whose pK values have been previously determined by Jaffé *et al.* (2, 3) the agreement is, in general, satisfactory, when account is taken of concentration effects. Seven of the compounds have had their pK values determined by Nualláin and corrected to zero ionic strength. The agreement here is good, except that we find the strongest acids, which contain nitro groups, to be slightly less acidic than did he.

Meta *and* para *compounds, substituent effects*

The π-bonding abilities of phosphorus and carbon are known to be quite different (5–7). With regard to arylphosphonic acids, the degree of conjugation between aryl ring and the acidic functional group appears to be considerably less than is the case with aryl carboxylic acids, judging from the *ortho* effects to be discussed later. Accordingly, one might expect that ordinary Hammett σ values would overestimate the electron-releasing capacity of groups such as alkoxy in the *para* position and that the modified substituent constant σ^n, which is intended for use with systems that have no through conjugation, would be better for correlating arylphosphonic acid pK values (8–10). In deriving values of σ^n, Hoefnagel and Wepster had examined the then existing data for pK_2 and noted that the substituent constant for the 4-amino substituent was high in comparison with other systems in which through conjugation was not possible at all (10). They concluded, therefore, that σ^n did not correlate with log K_2 of arylphosphonic acids. (Zwitterion formation in neutral 4-aminophenylphosphonic acid prevents a similar test being made on log K_1.) Along similar lines, reported correlations of pK with σ for ring-substituted phosphonic acids led Hudson to conclude that π bonding with the phosphorus atom is significant (5*a*), although others have reached different conclusions (5*b*, *c*).

We find that our data for log K_2 are correlated very well by σ^n (Fig. 1 and eq. [1]) and rather poorly by σ (eq. [2]), indicating the degree of π bonding between ring and phosphorus to be small.

$$[1] \quad \log K_2 = 1.140\sigma^n + 7.55 \text{ (corr. coeff. 0.9970)}$$

$$[2] \quad \log K_2 = 0.980\sigma + 7.48 \text{ (corr. coeff. 0.9778)}$$

The situation with respect to K_1 is less clear, partly because the bellwether amino substituent is, perforce, absent and partly because the precision of the K_1 values is less (see Experimental). Indeed the correlation between log K_1 and σ^n (Fig. 1 and

[a]Corrected to zero ionic strength; in water, 25°C.
[b]Erratic values obtained, likely because of low solubility.
[c]pK_3.
[d]pK_2 = 4.37.
[e]pK_2 = 4.27.

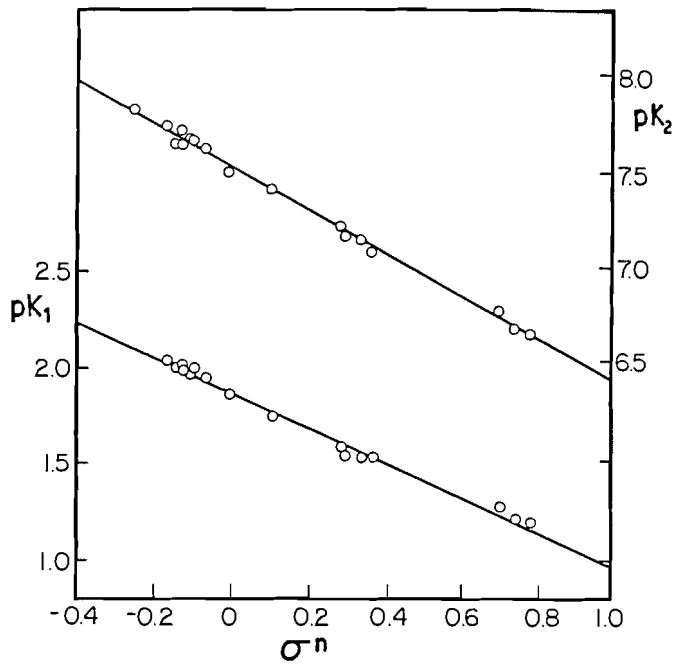

FIG. 1. Plot of pK_1 (lower curve and left-hand axis) and pK_2 (upper curve and right-hand axis) for arylphosphonic acids against the substituent constant σ^n.

eq. [3]) is not dramatically better than that for σ (eq. [4]) when all points are included. However, when lines are drawn with respect to the *meta* compounds and the *para* nitro and cyano compounds (those for which $\sigma \approx \sigma^n$), the values of slope and intercept are 1.143 and 7.55, respectively, for K_2 and 0.926 and 1.89 for K_1. These values are almost identical to those given in eqs. [1] and [3] and are considerably different from those given in eqs. [2] and [4], showing conclusively that σ^n, not σ, is the parameter of choice for both pK_1 and pK_2.

[3] $\log K_1 = 0.924\sigma^n + 1.88$ (corr. coeff. 0.9954)

[4] $\log K_1 = 0.856\sigma + 1.84$ (corr. coeff. 0.9872)

The pK_2 values of the 3- and 4-carboxyphenylphosphonic acids refer to the dissociation of the carboxyl group and this allows a check to be made of the previously reported substituent effect of the $-PO_3H^-$ group. Jaffé *et al.* measured pK values for these compounds some time ago (2) but the values of the derived substituent constants (σ_m and σ_p) appear to have been transposed in their paper, an error that has been retained in several recent compilations of Hammett substituent constants. (See, for example, ref. 11*a*.) Furthermore, their pK values were not corrected for ionic strength effects, which can be quite large for the second and higher dissociations of polyprotic acids. Their uncorrected pK results indicated that the $-PO_3H^-$ group is electron withdrawing, with the effect being greater from the *para* than from the *meta* position. After being corrected to zero ionic strength our results suggest that the $-PO_3H^-$ group is electron donating relative to hydrogen rather than electron withdrawing, with the relative ordering for *meta* and *para* being the same as that indicated by the pK values of Jaffé *et al.* Since charged groups are notorious for the inconstancy of their Hammett substituent values (11*b*, *c*), the significance of the values we can derive for the $-PO_3H^-$ group ($\sigma_m = -0.17$ and $\sigma_p = -0.07$) is uncertain.

Reaction constants for K_1 *and* K_2

The reaction constant for the first dissociation is smaller than that for the second, $\rho_1^n = 0.924$, $\rho_2^n = 1.140$ (Fig. 1). (Nualláin found ρ_1 to be 0.902 and ρ_2 to be 1.023 (4).) We find it difficult to rationalize the somewhat greater effect of substituents on K_2 than on K_1 and, because of our concern that the first ionization constants for the most acidic phosphonic acids might be greater than the measured values (*vide infra*), thus lowering the observed value of ρ, we cast about for analogous systems to which the present system could be compared. There is, in fact, little known about the electronic effect of aryl substituents on successive dissociations of oxygen acids. The ρ_1 and ρ_2 values for 5-substituted isophthalic acids are virtually identical (12). The limited precise data available for *meta* and *para* arylarsonic acids indicate that ρ_1 is larger than ρ_2 (2, 13, 14). The successive dissociation constants of $C_6H_5CO_2H_2\cdot$ have been determined (15, 16) but, unfortunately, their *meta* and *para* derivatives do not appear to have been studied. Successive additions of electrons to a neutral molecule to give the mono and dianion are in

For personal use only.

many ways analogous to successive deprotonations; evidence here is also sparse but there are indeed cases where the ρ of the second step is considerably larger than that of the first, e.g., the stepwise reduction of maleimide (17).

Our concern regarding the pK_1 values of the most acidic compounds, in particular the nitro substituted phenylphosphonic acids, stems from observations of differences in the degrees of ionization and dissociation of strong and moderately strong acids (18, 19). The pertinent equilibria are shown in eq. [5]

[5] $ArPO_3H_2 + H_2O \rightleftharpoons ArPO_3H^- \cdot H_3O^+ \rightleftharpoons ArPO_3H^- + H_3O^+$

For weaker acids ionization and dissociation are synonymous and so pK values measured potentiometrically will correspond to the ionization process; for stronger acids this may not be so. It would be expected that the reaction constant of a Hammett type correlation would correspond to the ionization process, which would mean that the ρ we have measured for the first dissociation might be slightly low. Since our main concern is the determination of catalytic effects in prototropic reactions of the A-2 type, which depend on dissociative phenomena, the potentiometrically determined pK_1 values are all we require. It should be noted, however, that in acid catalyzed reactions of the A-S_E2 type (ref. 19, p. 260; refs. 20 and 21), in which a proton is transferred in the rate-controlling step, the pertinent catalytic species for strong and moderately strong acids may be the ion pair or the non-ionized acid and it is not known if the use of potentiometric pK values is appropriate.

Ortho *effects*

Unlike benzoic acids, where virtually any *ortho* group has a marked acid-strengthening effect, most arylphosphonic acids with *ortho* substituents have acidities that are very roughly comparable to those of their *para* analogues, at least when direct interactions such as hydrogen bonding are absent, and this has been remarked upon previously (3). Since the generally accepted explanation for the acid-strengthening effect of *ortho* groups in benzoic acids involves steric hindrance to conjugation in the neutral molecule, it is to be expected that arylphosphonic acids, in which conjugation between the acid unit and the ring is slight (*vide supra*), would not exhibit the marked acid-strengthening effect of *ortho* groups that is characteristic of benzoic acids. The proximity effects that do appear in arylphosphonic acid ionizations were analyzed by the multivariate analysis method of Bijloo and Rekker (23), which is based on the work of Fujita and Nishioka (24; see also ref. 25).

Their method assigns a value to the electronic effect of an *ortho* group by taking the effect of the corresponding *para* substituent and augmenting it by a special *ortho* inductive effect σ_I^o; the well-known steric parameter E_S is assumed to make the other contribution to the *ortho* effect. Equation [5] should correlate the pK values of all ring substituted arylphosphonic acids, σ^n being used for the electronic effect since it gives a superior correlation for *para* substituents.

[6] $pK_0 - pK = \Delta pK = \rho\sigma^n + \rho_I\sigma_I^o + \delta E_S^o$

where pK_0 is the value for the unsubstituted compound (experimental values 1.86 and 7.51 for the successive dissociations); σ^n for *ortho* and *para* groups are taken as identical; ρ_I is the reaction constant for the special *ortho* inductive effect; and δ is the corresponding quantity for the steric effect.

When all the data of Table 1 were subjected to multivariate analysis using eq. [6], satisfactory correlations could be obtained provided the *ortho* alkoxy groups were omitted; these compounds show anomalously high pK_1 and pK_2 values, presumably because of hydrogen bonding between the oxygen of the alkoxy unit and the proton(s) of the phosphonic groups (4). The results are shown in eqs. [7] and [8].

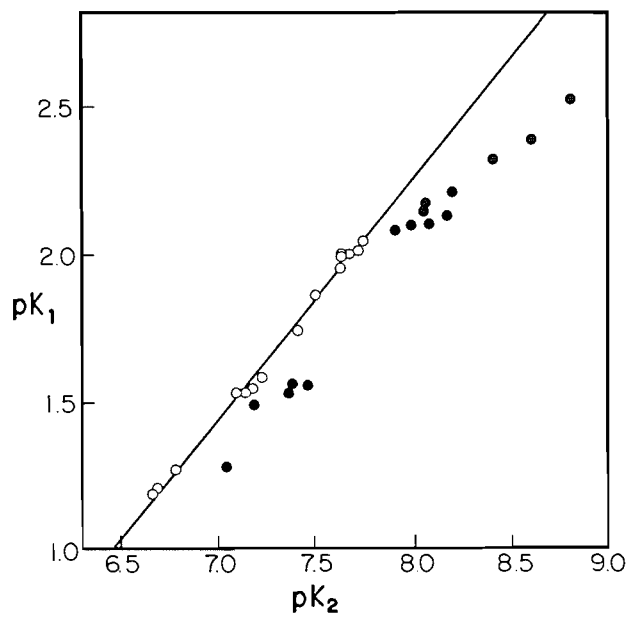

FIG. 2. Plot of pK_1 against pK_2 for arylphosphonic acids; *meta* and *para* compounds (open circles) and *ortho* compounds (filled circles).

[7] $1.86 - pK_1 = 0.87\sigma^n + 0.32\sigma_I^o + 0.13E_S^o$

(corr. coeff. 0.986, 29 acids)

[8] $7.52 - pK_2 = 1.07\sigma^n + 0.29\sigma_I^o + 0.33E_S^o$

(corr. coeff. 0.988, 30 acids)

The high correlation coefficients, the closeness of the ρ values to those found when *meta* and *para* compounds only are used (eqs. [3] and [1]), and the close agreement between the experimental and calculated pK values of the unsubstituted compound suggest that *ortho* effects can be successfully treated using eq. [6]. (The agreement is not nearly as good when ρ values for the *meta*/*para* and *ortho* series are directly compared (23), although satisfactory correlation coefficients are obtained in all cases.)

What is the significance of the other coefficients? The values of ρ_I are fairly modest, much smaller than those found for benzoic acids (eq. [9]) (23). The values of δ are positive, meaning that steric effects are acid weakening, the reverse of the situation found with benzoic acids. The values of −0.13 and −0.33 for the first and second dissociation can be compared with the value of +0.40 for benzoic acids.

[9] $4.21 - pK = 0.96\sigma + 1.32\sigma_I^o - 0.40E_S^o$

The steric effect of *ortho* groups is probably associated principally with hindrance to solvation and, if this be so, the larger δ for K_2 than for K_1 is reasonable, indicating a greater change in solvation going from anion to dianion than from neutral acid to monoanion (5*b*). Indeed, the neutral molecule, being highly acidic, may be quite highly solvated, particularly if the ion-pair form is present in significant amounts (eq. [5]). The differential steric effect of *ortho* groups can be seen in Fig. 2, where pK_1 is plotted against pK_2. The horizontal displacement

of the *ortho* compounds from the line for the *meta* and *para* compounds can be considered to be a measure of the enhanced steric effect on the second dissociation.

Experimental

Materials

Most of the arylphosphonic acids were prepared in good yields by a published method that involves the treatment of the aryl iodide or bromide with triethyl phosphite at 180°C in the presence of anhydrous nickel bromide (26, 27). The diethyl arylphosphonates so produced were hydrolyzed to the corresponding acids by refluxing them with concentrated hydrochloric acid for 6–8 h. The 3- and 4-carboxyphenylphosphonic acids were prepared in quantitative yields by starting with the corresponding methyl iodobenzoates. Dimethyl 2,6-dimethylphenylphosphonate was obtained by photolysis of a mixture of 2,6-dimethyliodobenzene and trimethyl phosphite (28).

The acid hydrolysis route to the phosphonic acids is not suitable for those esters having an acid-sensitive group, e.g., cyano, or for those phosphonic acids that undergo dephosphonation under the drastic conditions employed during hydrolysis, e.g., the 2,6-dimethyl, 2,4,6-trimethyl, 2-methoxy, and 2-ethoxy compounds. In such cases the acid hydrolysis route produced a very poor yield of the desired products and so an alternative route, based on the method of Blackburn and Ingleson (29), was developed. This involves dealkylating the esters by treatment with iodotrimethylsilane to give the trimethylsilyl esters, which undergo hydrolysis in water at room temperature to give the phosphonic acids in excellent yields. The detailed procedure follows.

The dialkyl arylphosphonate (20 mmol) in 25 mL of anhydrous carbon tetrachloride cooled to 0°C was treated with 6 mL iodotrimethylsilane (42 mmol) in small portions. The mixture was allowed to warm to room temperature and was stirred for 30 min. The volatiles were removed by evaporation, 50 mL water was added, and the mixture stirred overnight. A pinch of sodium bisulfite was used to remove the dark colour caused by the presence of iodine, the water evaporated off, and the resulting white crystalline mass recrystallized from a 1-propanol/ethyl acetate/petroleum ether mixture.

The halo and 4-nitro phenylphosphonic acids were prepared from the corresponding diazonium fluoroborates (30). In the case of 2-bromophenylphosphonic acid, phosphorus tribromide was employed, since the use of phosphorus trichloride, as suggested by Freedman *et al.* (31), produced a mixture containing a significant amount of 2-chlorophenylphosphonic acid impurity. When phosphorus tribromide is used in the synthesis of 2-iodophenylphosphonic acid, as recommended by Doak and Freedman (32), the product was contaminated with 2-bromophenylphosphonic acid. Here the use of phosphorus trichloride produced the desired product, 2-iodophenylphosphonic acid, cleanly. 4-Aminophenylphosphonic acid was prepared from the 4-bromo compound by the method of Grummit *et al.* (33).

3-Nitrophenylphosphonic acid was prepared by nitrating phenylphosphonic acid with fuming nitric acid followed by crystallization of the magnesium salts of the isomeric nitration mixture (34).

2-Nitrophenylphosphonic acid was prepared by the method of Cadogan *et al.* (35).

Table 2 lists the melting points and analytical data for the arylphosphonic acids that are not well documented in the literature, some having been previously unreported, and some reported without analytical data.

pK Measurements

The dissociation constants were obtained from potentiometric titrations of the arylphosphonic acid with standardized sodium hydroxide solutions using a Radiometer Model 26 pH meter and a Radiometer GK 2421C combined glass electrode. The pH meter was standardized with aqueous buffer solutions over the range 2–7. Titrations were done in a jacketed container fitted with a cover having holes to accommodate a nitrogen bleed, the electrode, and the tip of the microburette. A temperature of 25.0 ± 0.1°C was maintained by circulating water from a thermostated water bath through the jacket. A nitrogen atmosphere was maintained over the solution during the titrations; an Ascarite guard tube kept over the microburette eliminated absorption of carbon dioxide by the alkali.

TABLE 2. Melting point and analytical data for substituted phenylphosphonic acids[a]

Substituent	Melting point, °C[b]	Analysis: Calculated C	Calculated H	Found C	Found H

3-Fluoro	102–103[g]	40.93	3.44	40.93	3.41

[a]Compounds that are not well documented in the literature.
[b]Uncorrected.
[c]Reference 38 gives 174–179°C.
[d]Reference 39 gives 177°C.
[e]Reference 27 gives 179–182°C; ref. 31 gives 202–203°C.
[f]Reference 22 gives 146–149°C.
[g]Reference 27 gives 95–98°C.

The dissociation constants were calculated using the method of Speakman (36) as adapted by Albert and Serjeant; the calculations were done on a computer using their Fortran IV programme (35). The above method was preferred over the conventional equations, to overcome problems in the estimation of very low pK values. For the same reason the titrations were performed in different concentration regions wherever solubility permitted, as suggested by Albert and Serjeant (37). The pK_2 values could be reproduced within ± 0.03 unit whereas pK_1 values below 2.0 could be reproduced only within ± 0.08 unit. Accordingly, a large number of determinations were made in the latter cases and averages taken.

Acknowledgements

One of the authors (K.N.) thanks Ramakrishna Mission Vivekananda College Madras, India, for granting sabbatical leave during this period. We acknowledge the work of three summer students, Alex Lee, Lisa Wong, and Lakhbir Rai, who helped with the pK determinations. We also thank Dr. U. Maciejewska for preparing one of the arylphosphonic acids used in the work. Finally, we acknowledge the financial support of the Natural Sciences and Engineering Research Council of Canada.

Arylphosphonic acids. II. General acid and general base catalysis of acetone enolization

KEVIN P. SHELLY, K. NAGARAJAN, AND ROSS STEWART
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received November 24, 1986

This paper is dedicated to Professor John T. Edward

KEVIN P. SHELLY, K. NAGARAJAN, and ROSS STEWART. Can. J. Chem. **65**, 1734 (1987).

We have measured the rate constants for the enolization of acetone catalyzed by 29 arylphosphonate dianions ($ArPO_3^{2-}$) and by 20 arylphosphonic acids ($ArPO_3H_2$). An excellent Brönsted correlation is found for the former reaction, with most *ortho* substituted compounds falling on the line drawn for the *meta* and *para* compounds ($\beta = 0.72$). The largest deviation is found for *o*-iodo, whose small positive deviation is ascribed to a polarizability effect in the transition state. The arylphosphonic acids give a fairly good Brönsted plot ($\alpha = 0.37$) but here the *ortho* substituents tend to react slightly faster than would be expected on the basis of their equilibrium acid strengths. Catalysis by the monoanion $ArPO_3H^-$ is difficult to detect; such ions appear to be acting as general acids, not general bases, and do not appear to act as bifunctional catalysts; it is shown that protonating acetone is 3.4×10^4 times as effective as deprotonating $ArPO_3H^-$. The Brönsted coefficients (β) for the rate-controlling steps for the enolization of acetone by the principal routes are shown to be inversely related to the magnitude of the rate constants.

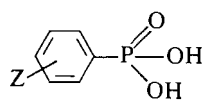
KEVIN P. SHELLY, K. NAGARAJAN et ROSS STEWART. Can. J. Chem. **65**, 1734 (1987).

On a mesuré les constantes de vitesse pour l'énolisation de l'acétone, catalysée par 29 dianions arylphosphonates ($ArPO_3^{2-}$) et par 20 acides arylphosphoniques ($ArPO_3H_2$). On a obtenu une excellent corrélation de Brönsted pour la première réaction; la plupart des composés substitués en *ortho* se retrouvent sur la courbe obtenue à l'aide des composés *méta* et *para* ($\beta = 0{,}72$). On a trouvé que le dérivé *o*-iodo conduit à la plus grande déviation et on attribue sa petite déviation positive à un effet de polarisabilité dans l'état de transition. Les acides arylphosphoniques ont conduit à une courbe de Brönsted assez bonne ($\alpha = 0{,}37$); toutefois, dans ce cas, les vitesses de réaction des composés portant des substituants en position *ortho* sont généralement plus grandes que celles que l'on pourrait attendre en se basant sur les forces de leur équilibre acide. Il est difficile de détecter la présence de catalyse par le monoanion $ArPO_3H^-$; ces ions semblent agir par catalyse acide générale, non par catalyse basique générale, et ils ne semblent pas agir comme catalyseurs bifonctionnels; on démontre que la protonation de l'acétone est $3{,}4 \times 10^4$ fois plus efficace que la déprotonation de $ArPO_3H^-$. On démontre qu'il existe une corrélation inverse entre l'amplitude des constantes de vitesse et les coefficients de Brönsted (β) des étapes contrôlant la vitesse d'énolisation de l'acétone par le principales voies.

[Traduit par la revue]

Introduction

Enolization of carbonyl compounds is one of the most important catalytic processes in organic chemistry, being the first step in a number of condensation, racemization, halogenation, and oxidation processes. As part of our study of prototropic reactions we have examined the catalytic effect of a series of arylphosphonic acids **1** on the enolization of acetone, a substance that has come to be regarded as the prototypical carbonyl compound.



1

There are good reasons for choosing arylphosphonic acids as the catalytic species. We have shown previously that proton removal from activated methyl groups in a number of cyclic conjugated systems is catalyzed by general acids and bases and exhibits steric activation. Activation by adjacent alkyl groups in the substrate has been demonstrated in many cases (1–5) and in two instances (involving general base catalysis) by adjacent groups in the base (6, 7). The latter reactions are the deprotonations of 1,2,3-trimethylpyrazinium ion and methylcreatininium ion by carboxylate ions (eqs. [1] and [2]), in which the more hindered bases, e.g. *ortho*-substituted benzoate ions, exhibit marked positive deviations from the Brönsted line drawn for the least hindered carboxylate ions (see also ref. 8).

The substrates in eqs. [1] and [2], being cationic, are for all practical purposes subject only to general base catalysis, not to general acid catalysis. We have encountered difficulties in trying to assess the effects of hindered carboxylic acids and carboxylate bases on substrates such as acetone, mainly because of acute solubility problems. For a number of reasons these problems are less severe with phosphonic acids; they have the further advantage of providing three catalytic entities for study, the neutral acid, the monoanion, and the dianion, enabling us to pursue another matter of particular interest to us: the effect on the reaction rate of changing the charge on catalyst or substrate (9, 10).

[2] $RCO_2^- +$  $\longrightarrow RCO_2H +$ 
Results and discussion

The mechanism of the enolization of acetone catalyzed by general acids (HA) and their conjugated bases (A^-) is given in eqs. [3] and [4] (11, 12).

In the case of catalysis by neutral phosphonic acids eq. [3] (general acid catalysis) is operative; in the case of catalysis by phosphonate dianions eq. [4] (general base catalysis) is operative. In the case of phosphonate monoanions either route might

[3a] $CH_3—\overset{\overset{O}{\|}}{C}—CH_3 + HA \rightleftharpoons CH_3—\overset{\overset{+OH}{\|}}{C}—CH_3 + A^-$

[3b] $CH_3—\overset{\overset{+OH}{\|}}{C}—CH_3 + A^- \rightarrow CH_3—\overset{\overset{OH}{|}}{C}=CH_2 + HA$

[4] $CH_3—\overset{\overset{O}{\|}}{C}—CH_3 + A^- \rightarrow CH_3—\overset{\overset{O-}{|}}{C}=CH_2 + HA$

be followed. Indeed, since such species could act simultaneously as both acid and base, the possibility of bifunctional catalysis exists (eq. [5]).

[5] $CH_3—C(=O)—CH_3 + HO—P(—Ar)(—O^-)=O \rightarrow CH_3—C(—OH)=CH_2 + {}^-O—P(—Ar)(—HO)=O$

In this connection Spaulding *et al.* (13) showed that the dianion of phosphoric acid, HPO_4^{2-}, does not appear to function as a bifunctional catalyst for the enolization of acetone, despite earlier indications to the contrary.

Brönsted relation

The catalytic constants for enolization of acetone by arylphosphonic acids $ArPO_3H_2$ and their dianions $ArPO_3^{2-}$ are given in Table 1. The Brönsted plot for catalysis by arylphosphonic acids (the composite reaction [8]) is shown in Fig. 1, the Brönsted coefficient α being equal to 0.390 for *meta* and *para* compounds (correlation coefficient 0.9901). The Brönsted plot for catalysis by arylphosphonate dianions (eq. [9]) is shown in Fig. 2, the Brönsted coefficient β being equal to 0.718 (correlation coefficient 0.9954), again for the *meta* and *para* compounds. (We use α when the variable species is the proton donor and β when it is the proton acceptor; we have also applied standard statistical corrections to rate and equilibrium constants (14, 15).)

[6] $ArPO_3H_2 + CH_3—\overset{\overset{O}{\|}}{C}—CH_3 \rightleftharpoons ArPO_3H^- + CH_3—\overset{\overset{+OH}{\|}}{C}—CH_3$

[7] $ArPO_3H^- + CH_3—\overset{\overset{+OH}{\|}}{C}—CH_3 \rightarrow ArPO_3H_2 + CH_3—\overset{\overset{OH}{|}}{C}=CH_2$

Adding eqs. [6] and [7] gives eq. [8].

[8] $ArPO_3H_2 + CH_3—\overset{\overset{O}{\|}}{C}—CH_3 \rightarrow CH_3—\overset{\overset{OH}{|}}{C}=CH_2 + ArPO_3H_2$

[9] $ArPO_3^{2-} + CH_3—\overset{\overset{O}{\|}}{C}—CH_3 \rightarrow CH_3—\overset{\overset{O^-}{|}}{C}=CH_2 + ArPO_3H^-$

For catalysis by the neutral phosphonic acids the Brönsted plot shows some divergence between the *meta* and *para* compounds on the one hand and the *ortho* compounds on the other. The latter deviate to a small extent in the positive direction. That is, they tend to be slightly more effective catalysts than would be suggested by their equilibrium acid strengths. The deviations, which are not large, are more pronounced for the

more acidic compounds, suggesting that a slightly larger Brönsted coefficient may govern the reactivity of the *ortho* rather than that of the *meta* and *para* compounds. (For reasons that are unclear to us, the precision of the rate constant derived for the *o*-bromo compound was less than those of the other halogen compounds.) Even when the *ortho* compounds are omitted, there is more scatter in the Brönsted plot for catalysis by $ArPO_3H_2$ (Fig. 1) than in that for catalysis by $ArPO_3^{2-}$ (Fig. 2), an effect that is probably due to the precision of the measurements of both pK_1 and k_{H_2A} being somewhat lower than the measurements of pK_2 and $k_{A^{2-}}$. The Brönsted equations for catalysis by neutral arylphosphonic acids are summarized in eqs. [10]–[12], where n = number of compounds and r = correlation coefficient.

$$[10] \quad (m, p) \qquad \log k_{H_2A}/p = 0.390 \log (p/qK) - 4.32 \qquad n = 10,\ r = 0.9901$$

$$[11] \quad (o) \qquad \log k_{H_2A}/p = 0.444 \log (p/qK) - 4.20 \qquad n = 10,\ r = 0.9861$$

$$[12] \quad (m, p, o) \qquad \log k_{H_2A}/p = 0.405 \log (p/qK) - 4.28 \qquad n = 20,\ r = 0.9795$$

For the phosphonate dianions a very good Brönsted relationship is obtained when the points for the charged substituent $-CO_2^-$ are omitted (Fig. 2). This group shows marked negative deviations from the Brönsted plot for both the *meta* and *para* positions. Similar deviations for dicarboxylate ions compared to monocarboxylate ions have been observed previously (6, 13).

Ortho substituents in the dianion conform well to the Brönsted line drawn with respect to the *meta* and *para* compounds. The largest deviations occur with the *o*-iodo and *o*-bromo groups, which appear to confer small but real degrees of activation, particularly when they are compared to the other halogens. (A similar effect is present in the case of acid catalysis, Fig. 1.) The greater polarizabilities of iodo and bromo, compared to chloro and fluoro, are probably responsible for these effects.

With the exception of iodo and bromo, there appears to be no special proximity effect on the rate of reaction. That is, *ortho* groups exert essentially the same effect on the dissociation equilibrium of the monoanions as on the rate of proton abstraction by the arylphosphonate dianions (eqs. [13]–[15]). This is in sharp contrast to the effect that neighbouring groups produce in reactions [1] and [2], where significant positive deviations from Brönsted plots are observed. We conclude that proton transfer from acetone to the ion $ArPO_3^{2-}$ is normal in the sense that the effect of nearby substituents on the transition state and on the product is similar. In the case of proton transfer from the conjugate acid of acetone to the ion $ArPO_3H^-$, *ortho* groups show a small degree of activation.

We have shown elsewhere (16) that the effect of *ortho* groups on pK_1 and pK_2 of arylphosphonic acids is largely electronic with the steric component being relatively small, particularly for pK_1. Thus, proton transfer to and from arylphosphonic acids and their anions is not subject to major steric effects, either with respect to rate or equilibrium.

$$[13] \quad (m, p) \qquad \log k_{A^{2-}}/q = 0.718 \log (p/qK) - 10.09 \qquad n = 14,\ r = 0.9954$$

$$[14] \quad (o) \qquad \log k_{A^{2-}}/q = 0.712 \log (p/qK) - 10.06 \qquad n = 13,\ r = 0.9907$$

$$[15] \quad (m, p, o) \qquad \log k_{A^{2-}}/q = 0.703 \log (p/qK) - 9.99 \qquad n = 27,\ r = 0.9944$$

Catalysis by the monoanion is difficult to observe, although it has been detected in the pH range 3.1–5.5 in the case of the *meta*-nitro, the 3,4-dimethyl, and the unsubstituted compounds. Using nearly saturated solutions of these phosphonic acids and making use of the known catalytic constants for H^+, HO^-, water, the neutral acids, and the dianions, a residual contribution, presumably made by the monoanions, could be observed.

The catalytic rate constants for these monoanions are approximately $10^{-7} M^{-1} s^{-1}$, values that suggest that they are acting as general acids, not as general bases, since they correspond much more closely to an extension of the Brönsted plot for $ArPO_3H_2$ than to that for $ArPO_3^{2-}$. (The calculated values for these monoanions acting as bases is in the range of 10^{-9}–10^{-8} $M^{-1} s^{-1}$; acting as acids they should be in the range of 10^{-6}–$10^{-7} M^{-1} s^{-1}$). Furthermore, if bifunctional catalysis of the sort shown in eq. [5] (tautomeric catalysis (17, 18)) were important, the catalytic constants would be expected to be considerably increased over the values calculated on the basis of the Brönsted plots for both $ArPO_3H_2$ and $ArPO_3^{2-}$.

As one proceeds along the series to weaker acids there should come a point where the monoanion $ArPO_3H^-$ is found to act predominantly as a base rather than as an acid. Assuming the Brönsted lines for $ArPO_3H_2$ and $ArPO_3^{2-}$ also govern the catalytic activity of the species $ArPO_3H^-$, one can show that such a role reversal will not take place with even the weakest of the arylphosphonic acids we have examined.

What is the significance of the Brönsted coefficients found in this work? It is generally agreed that for systems of like structure the coefficient should increase in size as reactivity decreases. This would lead to a curved Brönsted plot if a sufficiently wide span of reactivities were produced by changing substituents. In practice, curvature is usually undetectable

TABLE 2. Brönsted coefficients and rate constants of reactions [7] and [9]

[c] Calculated value; see text.

for a single series although Bell, by combining several kinds of substrate and catalyst, produced a distinctly curved plot, albeit one with considerable scatter (19). More frequently, the inverse relationship between Brönsted coefficient and reactivity is sought by comparing Brönsted coefficients for related series whose reactivities are considerably different. In the case of acetone enolization catalyzed by arylphosphonic acids, the Brönsted coefficients of the two important rate-controlling steps (reactions [7] and [9]) can be compared. They are shown in Table 2 together with the rate constants for the unsubstituted compounds.

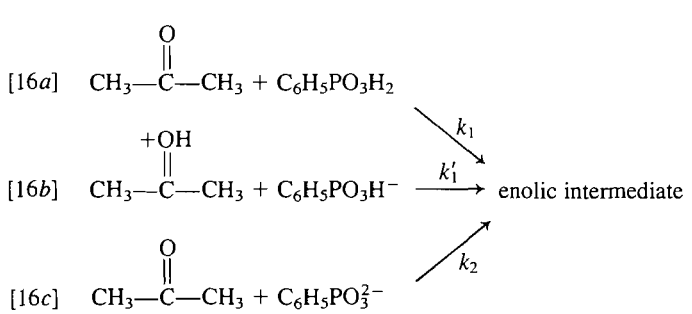
The Brönsted coefficient for the first reaction in Table 2 (eq. [7]) has been taken as $1.00 - \alpha$, where α is the measured value for eq. [8]. This follows from eq. [6] being a protolytic equilibrium with an effective constant of unity. That is, the effect of substituents on the equilibrium acid strengths of $ArPO_3H_2$ is identical to that on the equilibrium shown in eq. [6]. The rate constant has been calculated as shown in the following section.

It can be seen from the results in Table 2 that there is, indeed, an inverse relationship between reactivity and Brönsted coefficient. Unfortunately, the Brönsted coefficient for the reaction between $ArPO_3H^-$ and $(CH_3)_2C{=}O$ cannot be determined because, as we have seen, the reaction of most members of the series is too slow to be detected.

Activation by protonation or deprotonation

In prototropic reactions activation can be achieved either by protonating the substrate or by deprotonating the catalytic species that removes a proton from the substrate. In the cases of enolization of acetone by water, the activation conferred by protonating the substrate (proton activating factor, *paf*) is about 10^7, whereas that conferred by deprotonating the base (deprotonating factor, *dpf*) is about 10^{10} (9).

As we have seen, reaction between phenylphosphonate monoanion, $C_6H_5PO_3H^-$, and acetone is slow. As in the case referred to above, activation can be achieved by either protonating the substrate (to give $(CH_3)_2C{=}\overset{+}{O}H$) or by deprotonating the catalyst (to give $C_6H_5PO_3^{2-}$). It can be shown that the former is much more effective than the latter. Consider eqs. [16*a*]–[16*c*].



If we assume that the actual pathway for catalysis by phenylphosphonic acid (eq. [16*a*]) is given by eq. [16*b*], and letting Z and ZH^+ represent acetone and its conjugate acid, then $k_1[Z][C_6H_5PO_3H_2] = k_1'[ZH^+][C_6H_5PO_3H^-]$. Substituting the following values for the pertinent protolytic equilibria (eqs. [17] and [18]) gives eq. [19].

[17] $K_{ZH^+} = [Z][H^+]/[ZH^+] = 8 \times 10^2$ (see ref. 12, p. 121)

[18] $K_1 = [H^+][C_6H_5PO_3H^-]/[C_6H_5PO_3H_2] = 1.4 \times 10^{-2}$

[19] $k_1'/k_1 = [Z][C_6H_5PO_3H_2]/[ZH^+][C_6H_5PO_3H^-] = 5.7 \times 10^4$

Since $k_1 = 0.60k_2$ (Table 1), then

$$k_1' = 3.4 \times 10^4 k_2 \text{ (or } 1.0\,M^{-1}s^{-1})$$

Thus, using the reaction between acetone and the phenylphosphonate monoanion as a reference point, protonating the substrate (to form $(CH_3)_2C{=}\overset{+}{O}H$) is 3.4×10^4 times as effective as deprotonating the catalyst (to form $C_6H_5PO_3^{2-}$). On the other hand, when the base is water protonating the substrate is only 10^{-3} times as effective as deprotonating the base (to form HO^-).

Experimental

Materials

The preparation of the arylphosphonic acids has been described elsewhere (16). Acetone was refluxed with potassium permanganate, fractionally distilled, and stored overnight over calcium carbonate. The liquid was filtered and fractionally distilled a second time.

Rate measurements

The rates of enolization of acetone were determined iodometrically by following the decrease in the absorbance of the triiodide ion at 353 nm, 400 nm, or 440 nm. In general, aliquots from stock solutions of phosphonate buffer were mixed in 5- or 10-mL volumetric flasks with sodium chloride and acetone. The ionic strength was adjusted to 0.1 *M* for the measurement of the diacid catalytic constants (k_{H_2A}) and to 0.05 *M* for the measurement of the dianion catalytic constants ($k_{A^{2-}}$) by adding the appropriate quantities of sodium chloride. A 3-mL sample of this solution was temperature equilibrated at 25°C for 15 min in a closed cuvette. The iodination was initiated by the addition of 50 μL of triiodide ion solution. The decrease in absorbance was followed with a Cary 16 spectrophotometer equipped with a cell holder thermostated at 25 ± 0.1°C. The concentrations of acetone that were used varied from 0.1 to 0.5 *M* and those of iodide plus triiodide ion varied from 4×10^{-5} to 5×10^{-4} *M*. Each observed first-order rate constant (k_{obs}) was calculated from the linear slope of the plot of absorbance against time by use of the equation k_{obs} = slope/($\varepsilon_{I_3^-}$[acetone]) where $\varepsilon_{I_3^-}$ is the extinction coefficient of triiodide ion at the chosen wavelength. The values of $\varepsilon_{I_3^-}$ used were $2.45 \times 10^4 M^{-1}cm^{-1}$ at 353 nm (20), $5.9 \times 10^3 M^{-1}cm^{-1}$ at 400 nm (value determined in this work), and $1818\,M^{-1}cm^{-1}$ at 440 nm (5). The fact that all plots were linear from the time of the first reading (about 30 s after the addition of the triiodide aliquot) until at least 70% of the iodine had reacted showed that the kinetics of iodine consumption were zero order. The pH values of buffer solutions before and after rate measurements were unchanged. The catalytic constants calculated from rate measurements at 353 nm, 400 nm, and 440 nm were identical. The catalytic constants calculated from a number of rate measurements where acetone concentration was varied were identical. For phosphonate dianion catalysis a number of buffers reacted with triiodide. We were unable to study the enolization in these cases except for 2-iodophenylphosphonate dianion, where in the absence of acetone the disappearance of iodine was a slow first-order reaction that could be satisfactorily corrected for. The enolization process is zero order in iodine and it could be shown that the reaction of iodine with the buffer anion has a

negligible effect on the measured rate of enolization. For phosphonic acid catalysis a relatively concentrated solution of buffer is needed for the neutral acid to make a significant contribution to the observed rate; in the case of several of these compounds low solubility prevented values of k_{H_2A} being obtained.

(a) Phosphonate dianion catalysis: all the phosphonate buffers were prepared by the addition of between 4/3 and 5/3 equivalents of sodium hydroxide to the free acid. The proportion of dianion in the buffer was taken to be the fraction in excess of one equivalent, that of monoanion to be unity minus this fraction, and that of the diacid to be zero. Since $K_1/K_2 > 10^5$, the concentrations obtained in this way are quite accurate. The dependence of k_{obs} upon the composition of the buffers (at moderately low buffer concentrations) is given by eq. [20] where k_{sum} is the contribution from hydronium ion, water, and hydroxide ion. Equation [20] can be rewritten as eqs. [21] or [22], where r is the buffer ratio of monoanion to dianion ($[HA^-]/[A^{2-}]$).

$$[20] \quad k_{obs} = k_{sum} + k_{HA^-}[HA^-] + k_{A^{2-}}[A^{2-}]$$

$$[21] \quad k_{obs} = k_{sum} + [HA^-]\left\{k_{HA^-} + \frac{1}{r}\cdot k_{A^{2-}}\right\}$$

$$[22] \quad k_{obs} = k_{sum} + [A^{2-}]\{k_{A^{2-}} + r\cdot k_{HA^-}\}$$

Plots of k_{obs} against $[HA^-]$ at a given buffer ratio were found to be linear, the slopes s being equal to $k_{HA^-} + k_{A^{2-}}/r$ and the intercepts to k_{sum}. For phenylphosphonate and 3,4-dimethylphenylphosphonate, s was determined at 3 buffer ratios. Plots of s against $1/r$, which were found to be linear, give a slope of $k_{A^{2-}}$ and an intercept k_{HA^-}. However, the intercept values were too small to be detected, indicating the absence of any significant catalysis by the monoanions. Accordingly, for the other buffer systems, $k_{A^{2-}}$ was simply determined from the slopes of the lines obtained from plots of k_{obs} against $[A^{2-}]$ using eq. [22]. At least two buffer ratios were studied (r = 2, 1, or 0.5); the values of $k_{A^{2-}}$ from these determinations generally agreed within ±3% of the average value. The $k_{A^{2-}}$ values obtained in this manner for phenylphosphonate and 3-4-dimethyl phenylphosphonate agreed with those obtained by plotting s against $1/r$. Generally, four different concentrations at each buffer ratio were examined, and the pH of each solution was found to be the same. Rates of iodination were measured at 353 nm except in the case of nitrosubstituted phosphonates, which were measured at 400 nm because of significant absorption of same at 353 nm.

(b) Phosphonic diacid catalysis: upon the addition of between 1/2 and 2/3 equivalent of sodium hydroxide to the free acid, in an analogous treatment to that described above, the dependence of k_{obs} on the species present was expected to be given by eq. [23]. This can be rewritten as eq. [24], where n is the buffer ratio of diacid to monoanion $\{[H_2A]/[HA^-]\}$.

$$[23] \quad k_{obs} = k_{sum} + k_{H_2A}[H_2A] + k_{HA^-}[HA^-]$$

$$[24] \quad k_{obs} = k_{sum} + [H_2A]\{k_{H_2A} + 1/nk_{HA^-}\}$$

Unlike the case of $[HA^-]/[A^{2-}]$ buffers, we found that with $[H_2A]/[HA^-]$ buffers the pH varied with concentration. Thus the treatment used to determine the dianion catalytic constants was of no avail in these cases. For each particular solution at a particular pH, the concentration of the diacid was determined from eq. [25], where $[H_2A]_0$ is the initial concentration of free acid and B is the number of equivalents of sodium hydroxide added. Equation [24] reduced to eq. [26].

$$[25] \quad [H_2A] = [H_2A]_0 - [B] - [H^+]$$

$$[26] \quad k_{obs} = k_{H^+}[H^+] + k_{H_2A}[H_2A]$$

Knowing $k_{H^+} = 2.84 \times 10^{-5} M^{-1} s^{-1}$ (21), values of k_{H_2A} are determined at different pH values and varying quantities of base. The good agreement between catalytic constants so determined shows there is no significant catalysis by the monoanion. Generally four values of k_{H_2A} were obtained, each being within ±5% of the average value. Because of the speed of these reactions, a wavelength of 440 nm was generally used for the kinetic determinations.

(c) Catalysis by phosphonic–carboxylic trianions: the buffers were prepared by the addition of between 7/3 and 8/3 equivalents of sodium hydroxide to the free acid. The proportion of trianion in the buffers was taken to be the fraction in excess of two equivalents, that of dianion to be one minus this fraction, and that of the monoanion and triacid to be zero. In these cases $K_2/K_3 > 10^3$. The dependence of k_{obs} upon the buffer composition is given by eq. [27] where y is the buffer ratio of dianion to trianion ($[HA^{2-}]/[A^{3-}]$).

$$[27] \quad k_{obs} = k_{sum} + [A^{3-}]\{k_{A^{3-}} + yk_{HA^{2-}}\}$$

The trianion catalytic constants were determined from the slopes of the lines obtained from plots of k_{obs} against $[A^{3-}]$. The consistency of results obtained in this way at different buffer ratios, y, indicates the absence of any significant catalysis by the dianion, HA^{2-}.

(d) Catalysis by phosphonic–carboxylic triacids: a similar treatment to that used for the diacid catalysis using eqs. [28] and [29] afforded the triacid catalytic constant.

$$[28] \quad [H_3A] = [H_3A]_0 - [B] - [H^+]$$

$$[29] \quad k_{obs} = k_{H^+}[H^+] + k_{H_3A}[H_3A]$$

Interactions between beef lung heparin and Mg^{2+} and La^{3+} counterions, in the presence of sodium ions, have been investigated by ^{13}C-nmr spectroscopy. The chemical shift displacements observed for the carbons of the main disaccharide unit of heparin, when analysed on the basis of counterion condensation theory, indicate that the association between the heparin polyanion and Mg^{2+} is a delocalized process. This is analogous to the Ca^{2+}/Na^{+}/heparin system, despite the fact that the binding affinity of heparin for Ca^{2+} is stronger than that for Mg^{2+}. By contrast, the interaction with La^{3+} is in excess of the theoretical predicted, which suggests that there is at least a partial site-binding of this counterion. In Ca^{2+}/M^{+}/heparin systems in which $M^{+} = Na^{+}$ or K^{+}, the selective binding preference of heparin for the univalent cations may be related to the order of their crystallographic ionic radii. A critical assessment is offered of the validity of this nmr spectroscopic approach to the study of counterion binding to heparin.

PHOTIS DAIS, QIN-JI PENG et ARTHUR S. PERLIN. Can. J. Chem. **65**, 1739 (1987).

Faisant appel à la rmn du ^{13}C, on a étudié les interactions entre l'héparine de poumon de bœuf et des ions Mg^{2+} et La^{3+}, en présence d'ions sodium. Une analyse des déplacements chimiques observés pour les carbones de l'unité dissacharidique principale de l'héparine en faisant appel à la théorie de condensation des contre-ions indique que l'association entre le polyanion de l'héparine et le Mg^{2+} est un processus délocalisé. Ceci est analogue au système Ca^{2+}/Na^{+}/héparine, même si l'affinité de l'héparine pour le Ca^{2+} est plus forte que pour le Mg^{2+}. Par ailleurs, l'interaction avec le La^{3+} est plus importante que celle prévue sur une base théorique; ceci suggère qu'il existe au moins un site de liaison partiel pour ce contre-ion. Dans les systèmes Ca^{2+}/M^{+}/héparine, dans lesquels $M^{+} = Na^{+}$ ou K^{+}, on peut établir une corrélation entre la liaison sélective préférentielle pour les cations univalents et l'ordre de leurs rayons ioniques cristallographiques. On offre une évaluation critique de la validité de cette approche par spectroscopie rmn pour étudier la liaison de contre-ions avec l'héparine.

[Traduit par la revue]

Introduction

In a previous study (1), the binding of calcium ions (Ca^{2+}) by heparin in the presence of sodium ions was examined by monitoring ^{13}C chemical shift displacements as a function of the calcium ion concentration and total ionic strength. The results (1) are consistent with the counterion condensation model (2–4), thereby indicating that the association between the heparin polyanion and calcium ions is a delocalized process, rather than one involving specific binding.

We now report the results obtained for the interaction of beef lung heparin with magnesium (Mg^{2+}) or lanthanum (La^{3+}) ion, in the presence of sodium (and chloride) ions. Studies (5–8) on the binding of Mg^{2+} to heparin have shown that this cation interacts less strongly than Ca^{2+} and, in accord with the counterion condensation model, binds in a delocalized or territorial fashion. Although it has been suggested (9) that $Co(NH_3)_6^{3+}$, a trivalent cation, forms localized ion pairs with heparin and other acidic polysaccharides, the binding observed was treated as a mass-action type of process, and the possibility that it is territorial was not evaluated. The main objectives of this study were: (*a*) to examine whether the order of binding to heparin, $Ca^{2+} > Mg^{2+}$ established by other methods (5–8), is also reflected in ^{13}C chemical shifts; (*b*) whether Mg^{2+} and La^{3+} binding conform to the Manning two-variable approach (2–4); and (*c*) to probe the binding preference between divalent and trivalent metal ions by performing competitive experiments with the La^{3+}/Ca^{2+}/heparin system. In addition, the selectivity between univalent cations, Na^{+} and K^{+}, first addressed theoretically by Manning (4) and observed experimentally for heparin, by Mattai and Kwak (5), is examined with systems containing heparin in the presence of Ca^{2+} and either Na^{+} or K^{+} (Ca^{2+}/Na^{+}/HEP or Ca^{2+}/K^{+}/HEP).

Experimental

Samples of sodium heparin, extracted from beef lung, were furnished by Upjohn Co. of Canada. The samples were purified by dialysis against distilled water and freeze-dried. Equivalent weights were determined by passage through a column of Amberlite IR-120 (H^{+}) resin, and subsequent conductimetric titration of the acidic eluate with NaOH (0.1 *M*). The equivalent weight of the beef lung heparin was found to be 178, whereas the sulfate to carboxylate ratio was 2.4. Potassium and calcium heparin were prepared from the heparinic acid solution by neutralization with 0.1 *M* solutions of KOH and $Ca(OH)_2$, respectively, and further purification by dialysis against distilled water, followed by freeze-drying. Polymer concentrations were 0.025, 0.05, and 0.1 *M*, depending on the experiment. Magnesium and lanthanum ions were introduced in the form of solid $MgCl_2$ and $LaCl_3$, respectively, in appropriate amounts.

The ^{13}C nmr experiments were conducted with a Varian XL-300 spectrometer operating at 75.4 MHz for carbon. Spectra were recorded in D_2O at 70°C and ^{13}C chemical shifts (reproducibility ±2 Hz) were referred to TSP as an external reference.

Results and discussion

Table 1 lists the ^{13}C chemical shift displacements for all carbons of the main disaccharide unit of heparin (**1**), for the systems Mg^{2+}/Na^{+}/HEP, La^{3+}/Na^{+}/HEP, La^{3+}/Ca^{+2}/HEP,

and Ca^{2+}/K^+/HEP at two total ionic strengths of ~0.2 and 0.4 M, and a constant ratio ($X = C_2/C_p = 1.0$) of metal ion (C_2) to heparin (C_p) concentration. In addition, Table 1 contains comparative data (1) for the system Ca^{2+}/Na^+/HEP. In general, the chemical shift displacements for all carbons of the system Mg^{2+}/Na^+/HEP at a given ionic strength, reflecting the extent of binding, are smaller than those for the Ca^{2+}/Na^+/HEP system. This indication of stronger binding to heparin by calcium than magnesium, in accord with earlier findings (5–8), may be explained on the basis that the hydrated Ca^{2+} is better able to displace Na^+ from the polyanion surface than is the comparatively larger hydrated Mg^{2+}.

For the system La^{3+}/Na^+/HEP (Table 1), the opposite effect is observed. The chemical shift displacements are larger than those for the system Ca^{2+}/Na^+/HEP, the greatest differential being observed for carbon I-6, i.e., the carboxyl carbon of the α-L-idopyranosyluronic acid 2-sulfate residue. A stronger binding of La^{3+} relative to Ca^{2+} also is seen in the chemical shift changes for the system La^{3+}/Ca^{2+}/HEP (Table 1). Displacement by La^{3+} of the Ca^{2+} condensed onto the polyanion surface is a direct consequence of the charge-density rule (2–4), because the introduction of the trivalent cation shifts the minimum of the charge-density parameter to $\xi = 1/3$, which is well below the minimum of $\xi = 1/2$ for calcium binding.

The effect of the total ionic strength on the binding of La^{3+} to heparin is recorded in Table 2, which summarizes chemical shift displacements as a function of La^{3+} concentration (X-ratio) at two ionic strengths.

A noteworthy feature of these data is the gradual decrease in the differential between chemical shift displacements with increasing concentration of La^{3+}, that reflects a decrease in binding as the X-ratio increases. This anti-cooperative behavior, also observed in the Ca^{2+}/Na^+/HEP (1) and Mg^{2+}/Na^+/HEP systems (not shown) is attributable, according to Manning's two-variable theory (2–4), to an entropy effect. At low concentrations of divalent (θ_2) and/or trivalent (θ_3) counterion, the concentration gradient of univalent ions between the "condensed" region surrounding the polyanion and the bulk solution is high. With the addition of more La^{3+} (or Ca^{2+}), i.e., increasing θ_3 (or θ_2), this concentration gradient decreases, and hence the entropy gain accompanying the release of Na^+ ions decreases with increasing θ_3 (or θ_2). Consequently, the extent of metal ion binding decreases with increasing θ_3 (or θ_2). The anti-cooperativity is more noticeable at lower ionic strengths and at low θ_3 (or θ_2), where the inequality $I \gg C_2$ holds (2). This is in agreement with the experimental data in Table 2. At high concentrations of La^{3+} (or Ca^{2+}), i.e. for θ_3 (or θ_2) near saturation, the inequality $I \gg C_2$ becomes invalid and then reversed (2), indicating that the polyanion is in an aqueous environment of La^{3+} (or Ca^{2+}) with negligible amounts of Na^+. In this region, where counterion binding is minimal, the magnitude of the chemical shift displacements is expected to remain unchanged, or even to decrease when the aforementioned inequality is reversed. Although such effects are not apparent in the chemical shift displacements of the systems Ca^{2+}/Na^+/HEP and Mg^{2+}/Na^+/HEP, it is noticeable for some carbons in the system La^{3+}/Na^+/HEP (Table 2). For instance, the magnitude of the chemical shift displacements for carbons I-1, A-3, and A-5 decreases from $X = 0.5$ onwards, whereas it remains practically constant for the I-5 and A-6 carbons in the same region of concentration. By contrast, other carbons (e.g. I-3) show a definite trend of increasing chemical shift displacements. No satisfactory explanation for these diverse observations is apparent at present.

As already noted, the thermodynamic driving force for metal ion binding is regarded (2) to be almost entirely entropic. The free energy gradient for the release of univalent counterions by trivalent ions is from the "condensed" volume around the

[e]Positive values (downfield shifts).

polyanion to the bulk solution. At low ionic strength, this concentration gradient is large; hence, La^{3+} binding and a release of univalent counterions is a favorable entropic process. At high ionic strength, the smaller gradient should lead to a reduced binding of La^{3+}. Overall, a change in this direction is observed (Table 2) for most of the carbons affected by an increase in the ionic strength from 0.175 to 0.350, although carbons A-3 and I-5 are atypical in that they exhibit an increase in chemical shift displacement. Perhaps this inconsistency is related to such questions (see later) as the applicability of counterion condensation theory at high concentration levels, and the influence on chemical shift of conformational changes induced in the polyanion by the binding of metal ions.

Binding selectivity of univalent counterions to heparin

In their study of the binding of Ca^{2+} and Mg^{2+} to heparin by a dye spectrophotometric method, Mattai and Kwak (5) showed that either cation binds to a greater extent in the presence of Na^+, than of K^+. This tendency was rationalized on the basis of size selectivity (10) in the hydrated form, with Na^+ being larger than K^+. Therefore, the smaller hydrated K^+ is more difficult to replace than Na^+, and hence the number of bound divalent counterions (θ_2) for the system $M^{2+}/Na^+/HEP$ must be greater than that in the system $M^{2+}/K^+/HEP$. However, it should be emphasized that the difference found between $\theta_2(M^{2+}/Na^+/HEP)$ and $\theta_2(M^{+2}/K^+/HEP)$ was quite small. For instance, at I = 0.001 M, C_p = 0.001 M, and C_2/C_p = 0.5, the values of θ_2 for the systems $Ca^{2+}/Na^+/HEP$ and $Ca^{2+}/K^+/HEP$ were 0.282 and 0.267, respectively (5). This small difference was attributed (5) to the presence of two types of charged groups in heparin that have different binding affinities for univalent counterions: delocalized binding to the sulfate groups, for which the order of preference depends on hydrated size (K^+ over Na^+), and partial site binding to the carboxylate groups, for which the order of preference depends on the crystallographic radius (Na^+ over K^+). Because the heparin has a high sulfate content (the sulfate/carboxylate ratio was ca. 2.7 (5)), the overall preference was in favor of a decreasing size of the hydrated ion.

Recent experimental findings by the same authors (10), on divalent metal ion binding to polyelectrolytes having different structures and functional groups, show that the greater interaction of divalent counterions with carboxyl than with sulfate groups is not related to specificity in the replacement of the univalent counterion. Nevertheless, polymers having sulfonate groups, which exhibit delocalized binding, do discriminate slightly between the univalent counterions.

By contrast, Manning's theoretical (11) and experimental (12) studies on species selectivity suggest that site-binding mechanisms play no role in the association between univalent counterions and polyelectrolytes, and that ion-selectivity may be attributed to the local dielectric constant of the medium surrounding the polyelectrolyte. This dielectric constant is, perhaps, equivalent to a 1 M aqueous ionic solution (the local concentration of territorially-bound univalent counterions is estimated (2, 11) to be of the order of 1 M for polyanions of typical charge-densities). Manning, using the Born approximation, was able to calculate the contribution of the molar free energy of transfer of a counterion from the bulk dilute solution of dielectric constant D_{H_2O} = 78.3 to the local polyanion environment with dielectric constants (13) D_{Cs^+} = 70.6 and D_{Na} = 66.7 corresponding to their respective 1 M ionic solution. The results indicated (11) that the polyelectrolyte selects the larger Cs^+ counterion (in terms of crystallographic radius) than the smaller Na^+, because the positive free energy of transfer to an environment of lower dielectric constant was found to be less for the larger ion. However, it is possible to interpret (14) these results in terms of the direct size selectivity proposed by Mattai and Kwak (5, 10), because Na^+ is the larger of the two counterions in their hydrated form.

Data in Table 1 indicate a trend in selectivity opposite to that reported by Mattain and Kwak for heparin (5), because the chemical shift displacements for the system $Ca^{2+}/Na^+/HEP$ are smaller than those observed for the system $Ca^{2+}/K^+/HEP$. Although this differential in the chemical shifts is slightly above the experimental error (±2–3 Hz), it is reproducible, indicating that the binding preference of heparin follows the order of the ions' crystallographic radii. This discrepancy may

be due to the following: firstly, our measurements required more concentrated solutions in order to obtain nmr spectra of acceptable quality (see below), whereas species selectivity generated by tiny differential free energies (0.2 to 0.5 kcal at 25°C (11)) is better manifested in dilute solution. Secondly, as the sulfate/carboxylate ratio of our sample of heparin (ca. 2.4) is smaller than those of Mattai and Kwak, the lower proportion of sulfate groups might lead to the overall binding preference for the ion of lesser crystallographic radius. Also, the small difference between the θ_2 values for these two systems, which is comparable to the experimental uncertainty of the measurements, may not exhaust the range of differences possible among heparin samples from various sources. Consequently, a more systematic study with various alkali metal counterions and heparin samples is required before definite conclusions on species selectivity of heparin are justified.

Quantitative interpretation of the chemical shift data

Further information about the nature of Mg^{2+} and La^{3+} binding to heparin was obtained by comparing the experimental data with quantitative predictions of the two-variable theory (2–4). According to this theory, a counterion–polyanion interaction is a function of the charge-density parameter ($\xi = 2.43$ for heparin (15)), and is independent of the nature of the charged group. The counterions are bound in a delocalized or territorial manner, retaining the fully hydrated state, although moving in an unrestricted and random way along the length of the polyanion chain. To describe the effect of Na^+ on the extent of binding of N-valent ion, M^{N+}, the following parameter has been defined (1, 16, 17)

$$[1] \quad n = \frac{\theta_1^0 - \theta_1}{\theta_N}$$

θ_1^0 and θ_1 are the fractions of the bound Na^+ ions before and after the addition of the M^{N+} ions, respectively, and θ_N is the fraction of the bound N-valent ions. According to the counterion condensation theory, θ_1^0 is invariant, or moderately different, for high ionic strengths up to 1.0 M. For the present system, θ_1^0 equals 0.59 (1). Although n may not remain constant as the cation is added incrementally, it can be interpreted as a stoichiometric coefficient in the stoichiometric ion-exchange equilibrium,

$$[2] \quad n\mathrm{Na}_b^+ + \mathrm{M}_f^{N+} \rightarrow n\mathrm{Na}_f^+ + \mathrm{M}_b^{N+}$$

in which the subscripts b and f refer to bound and free states of heparin, respectively, with respect to Na^+ and M^{N+}. Calculations based on either the Poisson–Boltzmann equation or the counterion condensation theory have shown (16) that $n < N$ (N equals 2 and 3 for Mg^{2+} and La^{3+}, respectively). Therefore, if the binding of M^{N+} to heparin can be described satisfactorily by the counterion condensation model, then the stoichiometry of the bound M^{N+} should not be a constant quantity, but should vary with the M^{N+} concentration, to a maximum value of N. Following our earlier (1) mathematical treatment relating the observed chemical shift, ν^{obs}, with the chemical shifts of the bound and free states of heparin, ν^b and ν^f, respectively, we obtain the following expression for the observed chemical shift displacements.

$$[3] \quad \nu^{obs} - \nu^{Na^+/HEP} = (\nu_M^b - \nu_{Na}^b) n\theta_N$$

where $\nu^{Na^+/HEP}$ is the chemical shift of Na^+/HEP salt before the addition of M^{N+}. It appears from eq. [3] that the observed chemical shift displacements depend not only on θ_N, but also on the stoichiometry of the M^{N+} binding.

Provided that the quantity $(\nu_M^b - \nu_{Na}^b)$ is constant, the chemical shift displacement $(\nu^{obs} - \nu^{Na^+/HEP})$ will be a linear function of the product $n\theta_N$. This, indeed, is observed in Fig. 1 for the system Mg^{2+}/Na^+/HEP, at $I = 0.2\,M$ and $C_p = 0.05\,M$, which also illustrates the nonlinear behavior of the chemical shift displacements vs. θ_2 alone, also predicted by eq. [3]. Values of θ_2 and n for the system M^{2+}/Na^+/HEP were calculated using the two-variable theory of Manning (2–4), as expressed by eqs. [6]–[9] in ref. 1. By numerical iteration of those equations and using $\xi = 2.43$, $N = 3$, theoretical values of θ_3, θ_1, and n were obtained for the system La^{3+}/Na^+/HEP at $C_p = 0.025$, $0.05\,M$ and ionic strengths 0.175 and $0.35\,M$, respectively. These values, and the values for the product $n\theta_3$ and the association constant $K_3 = \theta_3/C_{3f}$ (C_{3f} is the concentration of the free La^{3+} in the bulk), are summarized in Table 3. The smaller degree of binding to heparin by Mg^{2+} than by Ca^{2+} is reflected in the slopes of the linear plots $(\nu^{obs} - \nu^{Na^+/HEP})$ vs. $n\theta_2$ for their respective carbons. For example, the slopes for carbons I-1 and A-1 in the system Mg^{2+}/Na^+/HEP are 13.0 and 26.4, respectively, whereas the corresponding values for Ca^{2+}/Na^+/HEP are 59.5 and 107.1, respectively. The characteristics of the chemical shift displacements for carbons I-2, I-3, I-6, and A-1 in the system La^{3+}/Na^+/HEP vs. $n\theta_3$ (or θ_3) are depicted in Fig. 2. The observed nonlinear behavior of the quantity $(\nu^{obs} - \nu^{Na^+/HEP})$, particularly vs. $n\theta_3$, is in excess of theoretical predictions, suggesting that at least part of the bound La^{3+} is site bound. Apparently, La^{3+} binds to a much larger extent than would be predicted on the basis of long-range electrostatic forces, although the charge-density requirement of the binding appears valid.

We conclude that such divalent metal ions as Ca^{2+} and Mg^{2+}, interact with heparin, in a delocalized manner, whereas the trivalent La^{3+} counterion is characterized by some specific binding to heparin. This view is reinforced by consideration of the following questions in terms of the nmr data in Table 1. (*a*) Does the divalent or trivalent counterion bind to a unique site? For divalent counterions the answer is in the negative, because Ca^{2+} and Mg^{2+} induce chemical shift displacements for most of the carbons of the disaccharide unit. By contrast, binding to a unique site is expected to influence the chemical shifts of only a limited number of carbons near the site of binding (18). Although the same is true for La^{3+}, the fact that it induces a much larger chemical shift displacement of I-6, relative to the other carbons, than is brought about by Mg^{2+} and Ca^{2+}, is indicative of preferential binding to the carboxyl group of the iduronic acid residue. On the basis of this discussion a positive response can be given to the second question: (*b*) are there other binding sites? The first type of binding site is the carboxylate or sulfate group. Binding to either of these sites is expected to induce chemical shift changes for carbons that bear the charged groups, and/or are influenced by electrostatic effects due to the bound counterion (18). Hence, chemical shift changes are expected to be larger for La^{3+} than Ca^{2+} (or Mg^{2+}), because the local electrostatic potential should be higher for trivalent than divalent counterions. From these considerations and the data in Table 1, one could attempt to classify the sulfate groups on the basis of their relative affinity for binding, as may be reflected in the respective chemical shift displacements for carbons I-2, A-2, and A-6. However, the binding process is too complex a phenomenon for such a simplistic interpretation since it, itself, may induce conformational changes in heparin that independently affect the magnitude of its chemical shifts (1). A second type of binding site is offered by the hydroxyl groups. Nevertheless, as there is only one hydroxyl

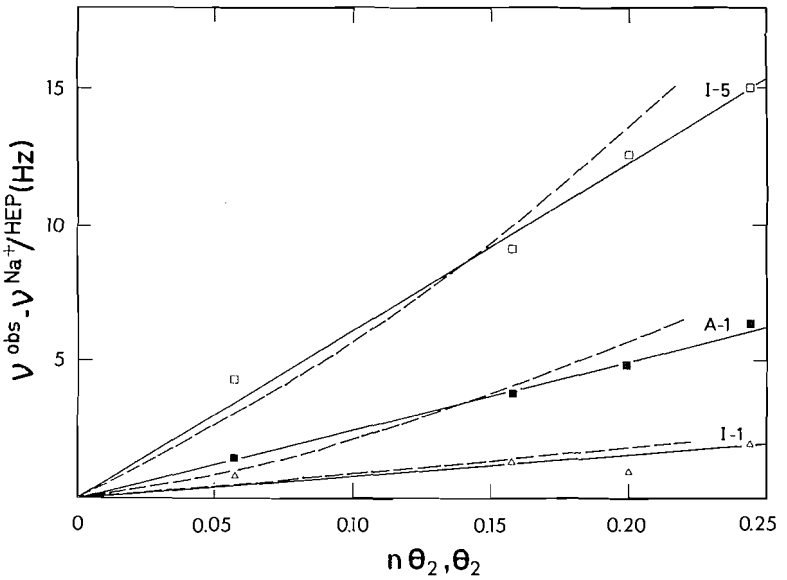

FIG. 1. $n\theta_2$ vs. ^{13}C chemical shift displacements ($\nu^{obs} - \nu^{Na^+/HEP}$) for I-1, I-5, and A-1 carbon resonances of beef lung heparin (C_p = 0.05 M, I = 0.2 M) induced by Mg^{2+} counterion binding. The non-linear behavior of the chemical shift displacements vs. θ_2 alone is illustrated by the dotted lines.

[c]C_p = 0.025 M.

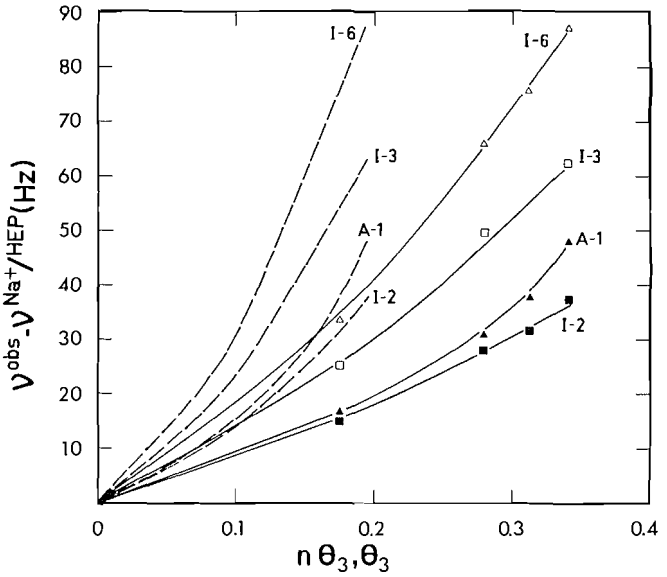

FIG. 2. $n\theta_3$ vs. ^{13}C chemical shift displacements ($\nu^{obs} - \nu^{Na^+/HEP}$) for I-2, I-3, I-6, and A-1 carbon resonances of beef lung heparin (C_p = 0.025 M, I = 0.175 M) induced by La^{3+} counterion binding. The behavior of the chemical shift displacements vs. θ_3 alone is illustrated by the dotted lines.

group per monosaccharide unit, these sites are fewer than the charged groups and likely play no more than a minor role in the concept of electrostatic interactions addressed here. (*c*) Do the counterions spend a large part of their time in privileged sites? This question cannot be answered on the basis of the ^{13}C nmr data cited in Table 1. ^{13}C, and possibly ^{33}S, spin–lattice relaxation times of the I-6 carbon and the sulfate groups as a function of counterion concentration and ionic strength, may be an appropriate probe. That is, if the counterions are trapped preferentially by the carboxylate groups most of the time, they will not relax the sulfate groups efficiently. Only a high concentration of counterions will relax the sulfate groups more, because the stronger sites will then be saturated. Uniform relaxation, on the other hand, would reflect equal mobility of the counterions over the charged groups of heparin.

An assessment of nmr measurements of binding interactions

It is worthwhile to comment here on the validity of the nmr approach and the various approximations used in this study and earlier (1) to interpret the binding behavior of heparin in mixed counterion systems. Evidently, the nmr method is very useful for this type of application at the molecular level, because it provides a large number of parameters, i.e., chemical shifts, coupling constants, spin–lattice relaxation times, and line widths. In particular, the sensitivity of the observed ^{13}C chemical shifts to electrostatic effects caused by the bound counterions, is a direct measure of the local counterion subpopulations surrounding the polyanion surface, and an indirect probe of conformational changes induced in the polyanion. However, owing to the low natural isotopic abundance of the ^{13}C nucleus (~1.1%), the ^{13}C nmr spectra were recorded at relatively high concentrations, so as to give acceptable S/N ratios. The laws governing counterion condensation in polyelectrolyte solutions are "limiting laws", referring to the "limit of infinite dilution" (2–4, 10). This mathematical limit, attained when $C \rightarrow 0$, is a

necessary condition under which exponential terms in the electrostatic free energy can be linearized. For practical cases, linearization can be achieved as well, if the condition (2–4, 11)

$$[4] \quad kb \ll 1$$

is fulfilled. For many polyelectrolytes, b, the average axial separation between charged groups (in Å) is so small as compared to the Debye screening length, k^{-1}, that eq. [4] holds even at ionic strengths that are not especially low. The Debye screening parameter depends on the ionic strength, and for aqueous solutions of 1:1 electrolytes at 70°C is given by (19).

$$[5] \quad k^{-1} = (3.07 \times 10^{-8}) I^{-1/2} \text{ cm}$$

An equivalent, and appealing, criterion for the applicability of the counterion condensation model over a range of ionic strengths is (2–4)

$$[6] \quad \frac{I}{C_s^{loc}} = 2.7k^2b^2 \ll 1$$

in which the invariant local concentration, C_s^{loc}, of territorially bound counterions is much greater than the bulk ionic strength. For heparin in aqueous solution of 1:1 electrolytes, and $I = 0.4M$, k^{-1} equals 4.85 Å according to eq. [5], and b equals 2.9 Å (15), so that $kb = 0.60$ and $I/C_s^{loc} = 0.98$. The range of allowable ionic strengths is seen to approach $0.4M$ in a 1:1 salt solution. Consequently, our nmr measurements were conducted at close to the limit imposed by the counterion condensation theory.

The validity of our conclusion from Figs. 1 and 2 (and Fig. 5 of ref. 1) implies that the quantity $(\nu_M^b - \nu_{Na}^b)$ in eq. [3] is constant. Moreover, ν_M^b and ν_{Na}^b must be individually constant, unless their variations are exactly compensated for at least over the range of concentration studied here. Coincidental compensation cannot be disproved without an independent means of determining ν_M^b and ν_{Na}^b. A theoretical basis for examining this assumption is offered by eq. [18] of ref. 1, which can be generalized to

$$[7] \quad \nu^{M^{N+}}/\text{HEP} = \nu^f + (\nu_M^b - \nu^f)\theta_N^0$$

for the system $M^{N+}/M^{N+}/HEP$. This equation was derived on the basis of a general conclusion about the counterion condensation model, which is that the addition of a simple electrolyte to a salt–polyanion solution containing the same counterion does not change the fraction of bound counterions, θ_N^0. This conclusion in relation to eq. [7] implies that ν_M^b must be a constant quantity. Indeed, addition of NaCl or $CaCl_2$ salts to Na^+/HEP and Ca^{2+}/HEP, respectively, showed insignificant chemical shift changes for all the carbons of the heparin. These findings, in agreement with earlier (7) c.d. measurements for the same systems, constitute clear evidence that ν_M^b and ν_{Na}^b must individually be constant, regardless of the composition of the solution.

An important quantity in the counterion condensation theory is the charge-density parameter given by (2–4)

$$[8] \quad \xi = \frac{e^2}{b\epsilon kT}$$

which controls the onset of condensation and the fraction of condensed counterions. This non-adjustable parameter is determined by the structure of the polyelectrolyte, namely, the axial separation, b, between charged groups. For heparin, the latter quantity was determined from molecular models of the disaccharide repeat sequence in its most extended form, from which a value of 2.9 Å was obtained (15). This compares with a value of 3.0 Å from X-ray scattering measurements (20). The determination of the quantity, b, and hence, ξ, assumes an idealized repeating structure of heparin, which may not be true, since heparin is a highly heterogeneous polymer (21), and its composition may vary substantially with the source. This means that the SO_3^-/CO_2^- ratio may vary from sample to sample, and so b (or ξ) also can vary (15). Moreover, the linear charge-density parameter chosen is for a polyelectrolyte in its most extended form. This assumption, inherent in Manning's theory, is in contrast to experimental evidence (8, 22, 23) that heparin in solution exists in a less fully extended conformation.

The counterion condensation theory of Manning is intuitively attractive, and yields a soundly analytical description of various properties of polyelectrolyte–salt solutions. Applications, including the present study, have been made to a large number of polyelectrolyte systems (1–3, 5, 10, 12, 14, 15). However, as an approximate theory in its mathematical treatment, it has received several criticisms (24–34) based on discrepancies with experimental observations. These have resulted in the development of extended treatments of the polyelectrolyte theory, by application of the Poisson–Boltzmann (24–30) or Gouy–Chapman (31) equations. An extension of Manning's theory without an explicit reference to the condensed phase has been considered as well (32).

In relation to the particular system, La^{3+}/Na^+/HEP, Manning's theory does not take into account specific interactions nor the case in which a polyanion, such as heparin, bears charged groups of different types. The latter property is fundamental in the sense that one group may show site-binding affinity to counterions, whereas the affinity of another group on the same polyanion is consistent with the requirements characterizing delocalized or territorial binding. As noted by Mattai and Kwak (10), one possible approach for including specific interactions in the condensation theory is modification of the entropy of mixing terms of the bound counterions (in eq. [28] of ref. 2) and/or the use of the condensation volume, V_p, as an adjustable parameter in the two-variable theory to account for the restricted nature of the counterion in the condensed phase. The need for a variable, V_p, parameter has already been stressed by other authors (24, 34). However, these suggestions do not go beyond a qualitative prediction of localized counterion binding. A quantitative description of site binding can be approached on the basis of Mass-Action Law (24, 25, 31) for mixed counterions. Accordingly, the extent of site-binding for the La^{3+}/Na^+/HEP system can be evaluated by methods presented in the appendices of refs. 24 and 25, with the appropriate equations adjusted for a solution of univalent and trivalent counterions. An isolated model for measuring the binding constant would be a disaccharide corresponding to the main unit of heparin, and the binding constant determined would actually be a weighted average of those for the carboxylate and sulfate groups.

In summary, this nmr study presents evidence that the binding affinity of heparin is stronger for Ca^{2+} than Mg^{2+} ions, in agreement with earlier observations, and that Mg^{2+} ions bind in a territorial manner consistent with the counterion condensation model. For La^{3+}, counterion binding exceeds predictions of the two-variable theory, indicating at least partial site-binding. ^{13}C chemical shift displacements in the systems Ca^{2+}/Na^+/HEP and Ca^{2+}/K^+/HEP show that the binding preference of hepa-

rin for univalent Na^+ and K^+ cations follows the order of their crystallographic radii, although other experiments in progress may help to clarify this aspect of species selectivity. Finally, the validity of our nmr approach for studying the binding of counterions to heparin has been critically assessed.

General solution to axially symmetric quadrupole interaction in nuclear magnetic resonance of solids

B. C. SANCTUARY AND G. CAMPOLIETI
Department of Chemistry, 801 Sherbrooke St. W., Montreal, P.Q., Canada H3A 2K6

Received November 24, 1986

This paper is dedicated to Professor John T. Edward

B. C. SANCTUARY and G. CAMPOLIETI. Can. J. Chem. **65**, 1746 (1987).

Spins with magnitude I greater than $\frac{1}{2}$ have nuclear electric quadrupole interactions that perturb the Zeeman splitting. To calculate the spin dynamics of multipulse sequences, it is necessary to know how the system evolves between pulses under the quadrupole. Prior work gave specific solution for $\frac{1}{2} < I \leq \frac{9}{2}$ in tabulated form. In this paper, a single expression is obtained, which is valid for all I.

B. C. SANCTUARY et G. CAMPOLIETI. Can. J. Chem. **65**, 1746 (1987).

Les spins dont l'amplitude I est plus grande que $\frac{1}{2}$ possèdent des interactions quadrupolaires électriques nucléaires qui perturbent le couplage Zeeman. Dans le but de calculer la dynamique des spins dans des séquences multispins, il est nécessaire de connaître comment le système évolue entre les pulsations, sous l'effet du quadrupole. Un travail antérieur a fourni une solution spécifique, sous la forme de tableau, du cas où $\frac{1}{2} < I \leq \frac{9}{2}$. Dans le présent travail, on a obtenu une expression unique qui est valide pour toutes les valeurs de I.

[Traduit par la revue]

I. Introduction

Spin dynamic calculations of multipulse sequences require knowledge of the evolution of the spin system under the interaction Hamiltonian. For solids containing spin $I > \frac{1}{2}$, the nuclear quadrupole interaction often dominates (1). Typically, a principle axis frame is chosen so that two parameters e^2qQ *and* η are required. Solution of this problem in the presence of a magnetic field is difficult as a consequence of the two different symmetries of the Zeeman and quadrupole Hamiltonians. When the asymmetry term η is zero and the principal axis lies along the magnetic field direction, an exact solution is possible. In a previous paper (2) the solutions were given for specific I values from $I = 1$ to $\frac{9}{2}$. Hence the evolution of the full density matrix was obtained from arbitrary initial conditions.

The difficulty with the solutions of ref. 2, although exact, is that they are specific for each I magnitude. No general transformation was found that solved the complete problem for any I. In contrast, knowledge of the transformation that diagonalizes the quadrupole Hamiltonian would allow the symmetry properties to be studied and these, in turn, would aid in finding perturbation solutions when $\eta \neq 0$, that is, when the field and principal axis do not coincide.

In this paper we report the general solution, using the multipole formulations, to the axially symmetric quadrupole problem in which the principal axis and magnetic field direction coincide. The solutions are valid for all I magnitudes. Table 1 of ref. 2 is obviated and a simple expression for all the transformations is given. The results of Table 3 of ref. 2 reduce to one simple equation.

II. Background

The Hamiltonian in question is given by

$$[1] \quad H_Q = -\gamma\hbar I_Z H_Z + \hbar Q_I\{3I_Z^2 - I(I+1)\}$$

where

$$[2] \quad Q_I = \tilde{Q}/[2I(2I-1)]$$

The object is to calculate the full spin density matrix, $\sigma_I(t)$, which evolves according to

$$[3] \quad i\hbar \frac{\partial\sigma_I(t)}{\partial t} = [H_Q, \sigma_I]$$

To proceed, the spin density operator is expanded in terms of spherical tensor operators (3, 4),

$$[4] \quad \sigma_I = \frac{1}{2I+1}\left[E_I + \sum_{k=1}^{2I}\sum_{q=-k}^{k} \phi_q^k(t)\mathcal{Y}^{kq}(I)\right]$$

The problem is then to obtain the coefficients $\phi_q{}^k(t)$. These are loosely referred to as polarizations with multipole magnitude k and multiquantum coherence q. More exactly, the k even quantities are alignments while the k odd are polarizations. Moreover, $q = 0$ are not coherences but incoherent superpositions of populations for the single spin case. The $q \neq 0$ terms are correctly coherences. These distinctions are not made in this work and all $\phi_q{}^k(t)$ are considered polarizations with coherence q.

In the rotating frame, defined by

$$[5] \quad \hat{\phi}_q{}^k(t) = \exp(-iq\omega_0 t)\phi_q{}^k(t)$$

where $\omega_0 = \gamma H_Z$, the Hamiltonian [1] gives

$$[6] \quad \frac{\partial\hat{\phi}_q^k}{\partial t} = \frac{3}{2}q\tilde{Q}\left[\frac{(2I+k+2)(2I-k)[(k+1)^2-q^2]}{I^2(2I-1)^2(2k+1)(2k+3)}\right]^{1/2}\hat{\phi}_q^{k+1} - \frac{3}{2}q\tilde{Q}\left[\frac{(2I+k+1)(2I-k+1)[k^2-q^2]}{I^2(2I-1)^2(2k-1)(2k+1)}\right]^{1/2}\hat{\phi}_q^{k-1}$$

It is these sets of coupled equations which have been solved from initial conditions $\phi_q{}^k(0)$ for special cases of I and q and which are reported in ref. 2, Tables 1 and 3. As I increases, the dimensionality of the resulting matrices increases. The unitary transformations required to diagonalize these become increasingly difficult to obtain. From Tables 1 and 3 of ref. 2 some inherent symmetries appear to be present, but these are not obvious.

III. Alternate solutions

From eq. [3], the solution to $\sigma(t)$ is

$$[7] \quad \sigma(t) = \exp\left(\frac{-i}{\hbar} H_Q t\right) \sigma(0) \exp\left(\frac{i}{\hbar} H_Q t\right)$$

where

$$\sigma(0) = |\psi(0)\rangle\langle\psi(0)|$$

Using eq. [3] and the orthogonality of the spherical tensor operators

$$[8] \quad \mathrm{Tr}\{\mathcal{T}^{k'q'\dagger}\mathcal{T}^{kq}\} = (2I + 1)\delta_{kk'}\delta_{qq'}$$

where † is the operator adjoint, the density operator becomes

$$[9] \quad \phi_q^k(t) = \frac{1}{2I+1} \sum_{k'q'} \langle\langle \mathcal{T}^{kq}| \, e^{-iH_Q t/\hbar} \mathcal{T}^{k'q'} \, e^{iH_Q t/\hbar} \rangle\rangle \phi_{q'}^{k'}(0)$$

The inner product is defined

$$[10] \quad \langle\langle A|B\rangle\rangle = \mathrm{Tr}\{A^+ B\}$$

The Wigner–Eckart theorem (5, 6) gives

$$[11] \quad \langle IM|\mathcal{T}^{kq}|I'M'\rangle = \delta_{II'}(-1)^{I-M} \begin{pmatrix} I & k & I \\ -M & q & M' \end{pmatrix} \times \langle I\|\mathcal{T}^k\|I\rangle$$

where the reduced matrix element is

$$[12] \quad \langle I\|\mathcal{T}^k\|I\rangle = i^k \cdot \sqrt{(2I+1)(2k+1)}$$

Using this, eq. [9] becomes

$$[13] \quad \hat{\phi}_q^k(t) = \sum_{k'=0}^{2I} \sum_{M=-I}^{I} (i)^{k'-k} \sqrt{(2k+1)(2k'+1)} \times \begin{pmatrix} I & I & k \\ M & -M-q & q \end{pmatrix} \begin{pmatrix} I & I & k' \\ M & -q-M & q \end{pmatrix} \times e^{i3\omega^I_Q q(q+2M)t} \phi_q^{k'}(0)$$

with

$$\omega^I_Q = -Q_I$$

which is the exact solution for the time evolution of the full density matrix under Hamiltonian [1] from arbitrary initial conditions $\phi^k{}_q(0)$.

IV. Discussion

The multipole operators (7) $\mathcal{T}^{kq}(I) \equiv |kq\rangle\rangle$ are useful for describing pulsed nmr primarily because they are rotated under the Zeeman interaction. In contrast, the quadrupole Hamiltonian is diagonal in the $|IM\rangle\langle IM'|$ basis. The relation between the $|kq\rangle\rangle$ and $|IM\rangle\langle IM'|$ basis is

$$[14] \quad |kq\rangle\rangle = i^k[(2I+1)(2k+1)]^{1/2} \sum_M (-1)^{I-M} \times \begin{pmatrix} I & k & I \\ -M & q & M-q \end{pmatrix} |IM\rangle\langle IM-q| \equiv (2I+1)^{1/2} \sum_M \mathcal{T}_q{}^{kM}(I)|IM\rangle\langle IM-q|$$

It then follows that the solution [13] can be written as

$$[15] \quad \hat{\phi}^k{}_q = \sum_{k'} \sum_{M=-I}^{I} (\mathcal{T}(I)^{-1})_q{}^{q+M,k} \times \exp[i3\omega^I_Q q(q+2M)t] \mathcal{T}^{k',q+M}(I)\phi_q^{k'}(0)$$

where

$$[16] \quad (\mathcal{T}(I)^{-1})_q{}^{Mk} \equiv \mathcal{T}_q{}^{kM}(I)^*$$

which is to be compared to [23] of ref. 2. Equation [15] generates all the results of Table 3 of ref. 2 while the expression for $\mathcal{T}_q{}^{kM}(I)$, eq. [14], generates Table 1 of ref. 2.

The symmetries of $\mathcal{T}$ are simply those of 3–j coefficients. Using these and the explicit expressions in eq. [9] will be useful in obtaining perturbative solutions to problems where the principal axis differs from the symmetry axis or when $\eta \neq 0$.

Rate constant for hydroxylation of a primary alkyl radical by induced decomposition of an alpha hydroperoxyalkyl diazene

CHANDRA LAKHANI, LUKOSE MATHEW, AND JOHN WARKENTIN
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 11, 1986

This paper is dedicated to Professor John T. Edward

CHANDRA LAKHANI, LUKOSE MATHEW, and JOHN WARKENTIN. Can. J. Chem. **65**, 1748 (1987).

Rate constants for induced decomposition of 5-hexenyl(1-hydroperoxy-1-methylethyl) diazene ($(CH_3)_2C(OOH)N{=}N(CH_2)_4CH{=}CH_2$, **2**) have been estimated. Thermolysis of **2** at 50°C affords 5-hexenyl radicals which abstract the hydroxyl group from **2** in competition with cyclization of 5-hexenyl to cyclopentylmethyl radicals. The known rate constant (k_c) for that cyclization was used to clock the bimolecular hydroxyl abstraction process. For reaction in hexafluorobenzene at 50°C, the rate constant for abstraction of hydroxyl from **2** (k_{OH}) was found to be dependent on the concentration of **2**. For example, at [**2**] = 0.4 *M*, $k_{OH} = 3.2 \times 10^6 M^{-1} s^{-1}$ whereas, at [**2**] = 0.10 *M*, $k_{OH} = 1.8 \times 10^7 M^{-1} s^{-1}$. The concentration dependence of k_{OH} is attributed to the effects of intermolecular hydrogen bonding and the large absolute values of k_{OH} are ascribed to concerted induced decomposition, the O—O bond being broken in concert with scission of the nearest C—N bond of the azo function. The relevance of the results, to synthetic application of α-hydroperoxyalkyl diazenes in hydroxyalkylation reactions, is discussed.

CHANDRA LAKHANI, LUKOSE MATHEW et JOHN WARKENTIN. Can. J. Chem. **65**, 1748 (1987).

On a évalué les constantes de vitesse pour la décomposition induite de l'hexène-5 yl (hydroperoxy-1 méthyl-1 éthyl) diazène ($(CH_3)_2C(OOH)N{=}N(CH_2)_4CH{=}CH_2$, (**2**). La thermolyse du composé **2**, à 50°C, conduit à des radicaux hexène-5 yles qui enlèvent le groupement hydroxyle du composé **2**; cette réaction est en compétition avec la cyclisation de l'hexène-5 yle en radical cyclopentylméthyle. On a utilisé la constante de vitesse (k_c) de cyclisation qui est connue comme chronomètre pour mesurer la vitesse du processus d'enlèvement bimoléculaire de l'hydroxyle. Dans le cas de la réaction dans l'hexafluorobenzène, à 50°C, on a trouvé que la constante de vitesse pour l'enlèvement de l'hydroxyle du composé **2** (k_{OH}) dépend de la concentration du composé **2**. Par exemple, pour [**2**] = 0,4 *M*, $k_{OH} = 3{,}2 \times 10^6 M^{-1} s^{-1}$: par ailleurs, si [**2**] = 0,1 *M*, $k_{OH} = 1{,}8 \times 10^7 M^{-1} s^{-1}$. On attribue la relation entre k_{OH} et la concentration aux effets des liaisons hydrogènes intermoléculaires et on attribue les valeurs absolues élevées de k_{OH} à une décomposition induite concertée dans laquelle le bris de la liaison O—O se fait simultanément avec la scission de la liaison C—N la plus près de la fonction azo. On discute de l'influence que ces résultats pourraient avoir sur les possibilités d'utiliser les α-hydroxyalkyl diazènes dans les réactions d'hydroxyalkylation.
[Traduit par la revue]

Introduction

α-Hydroperoxyalkyl diazenes (**1**) are readily prepared in solution by autoxidation of hydrazones of aldehydes or ketones, reaction [1] (1–5). They undergo thermal homolysis reactions at moderate temperatures and have been used to initiate radical

[1] $R_2C{=}NNHR' \xrightarrow{O_2} \underset{\mathbf{1}}{R_2C(OOH)N{=}NR'}$

polymerization (6) and as sources of hydroxyl radicals for aromatic substitution (7) or monomer-addition studies (8).[1] Recently, it was shown that **1** are useful reagents for hydroxyalkylation of enol ethers and of some alkenes, reaction [2] (10), and that the overall reaction is a consequence of the radical chain chemistry shown in reactions [3]–[6].

[2] $R_2C(OOH)N{=}NR' + CH_2{=}CHY \rightarrow R'CH_2CH(Y)OH + R_2CO + N_2$

Initiation

[3] $\underset{\mathbf{1}}{R_2C(OOH)N{=}NR'} \rightarrow R_2CO + HO\cdot + N_2 + R'\cdot$

Propagation

[4] $R'\cdot + H_2C{=}CHY \rightarrow R'CH_2\dot{C}HY$

[5] $R'CH_2\dot{C}HY + \mathbf{1} \rightarrow R'CH_2CH(Y)OH + R_2CO + N_2 + R'\cdot$

Termination

[6] 2 Radicals → Non-radical products

The chain propagation step, in which the adduct radical, $R'CH_2\dot{C}HY$, induces decomposition of **1** by abstraction of hydroxyl, reaction [5], was particularly intriguing, not only because overall hydroxyalkylation is a new reaction but also because hydroxyl abstraction from **1** appeared to be much more facile than the analogous induced decomposition of simple hydroperoxides. It became of interest to us to estimate the rate constant for reaction [5] because that constant, and the rate constants for competing reactions (e.g., telomer formation) that consume $R'CH_2\dot{C}HY$, define the synthetic scope of **1** as hydroxyalkylating agents.

Methods, results, and discussion

A convenient technique for determining the rate constant of a bimolecular free radical – molecule reaction involves the use of an internal clock (11), which is usually a competing unimolecular reaction of that radical for which the rate constant is known. Cyclization of the 5-hexen-1-yl radical was chosen as the radical clock for this study not only because the rate constant for the reaction is a reliable number (11, 12) but also because it seemed to be of the right order of magnitude. Accordingly, 5-hexenyl(1-hydroperoxy-1-methylethyl)diazene (**2**) was synthesized and thermolyzed in hexafluorobenzene. Scheme 1 describes the major reactions and products.

The relationship between rate constants and concentrations (or

[1]Non-radical chemistry of α-hydroperoxyalkyl diazenes has been reviewed recently by Baumstark (9).

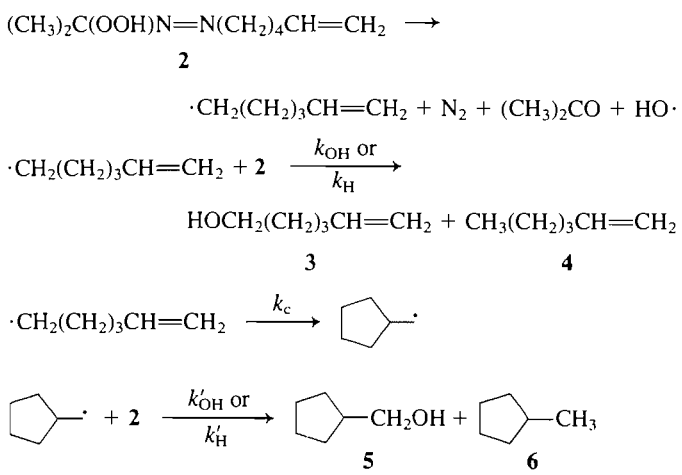
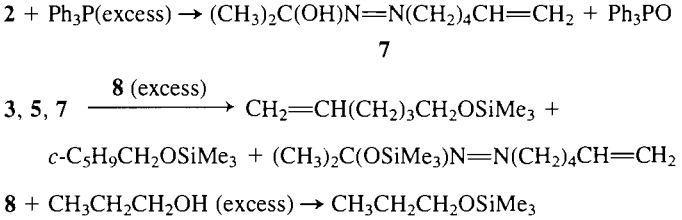


SCHEME 1



SCHEME 2

yields) of products is given by eq. [7], provided that there are no other products derived from cyclopentylmethyl radicals and that there are no appreciable differential losses resulting from reactions of the first-formed products in subsequent processes.

$$[7]\quad \frac{[\mathbf{3}]}{[\mathbf{5}]+[\mathbf{6}]} = \frac{k_{OH}[\mathbf{2}]_{ave}}{k_c}$$

Decomposition of **2** was stopped after about 10% conversion, by cooling the samples, in order to provide for pseudo-first-order conditions and to minimize attack by free radicals on the products. The remaining hydroperoxide was reduced by addition of triphenylphosphine in excess, and the resulting hydroxyalkyl diazene (**7**) as well as **3** and **5** were silylated with *N,O*-bis(trimethylsilyl)trifluoroacetamide (**8**), and excess **8** was destroyed by addition of propanol (Scheme 2). The reduction and silylation reactions were carried out under conditions that did not permit loss of 1-hexene and methylcyclopentane, the most volatile products in eq. [7], and the final solution was analyzed for the trimethylsilyl ethers (of **3**, **5**, **7**) and for **6** by glpc.[2]

An alternative, much simpler procedure was adopted initially. That procedure involved low temperature, high-vacuum, closed-system distillation of the products from 10% reaction of α-hydroperoxyalkyl diazene; essentially a bulb-to-bulb separation of solvent and products from unreacted hydroperoxide. The distillate was then analyzed for **3** and **5** (unsilylated) and for **6** by glpc. Although a large number of runs were completed in this way, the method was abandoned because of unacceptably large scatter in the values of k_{OH} so obtained.[3]

5-Hexen-1-ol (**3**) was the major product (60–70%) followed by methylcyclopentane (12–18%) and cyclopentylmethanol (9–11%). Those three products accounted for about 90% of the 5-hexenyl moieties from the **2** that had reacted. The remaining 10% included 1-hexene and some unidentified minor products. The yields of 1-hexene ranged from 2% to about 8%; those yields showed the greatest scatter but they never exceeded half the yields of methylcyclopentane from corresponding runs. In view of the poor reproducibility of the 1-hexene yields, discussion of their significance has to be tentative. Fortunately, those yields do not enter into the calculation of k_{OH} (eq. [7]), and the experimental scatter in those yields therefore does not affect k_{OH} values.

The low yields of 1-hexene are not surprising. Cyclization of 5-hexenyl radical (**12**) occurs with rate constant 5.4×10^5 s^{-1} at 50°C while abstraction of hydroperoxyl hydrogen from **2** by 5-hexenyl has a rate constant estimated to be near 2×10^4 $M^{-1}\,s^{-1}$ at 50°C.[4] It follows that the yield of 1-hexene should be less than 1% of the yield of cyclopentyl products from runs in which [**2**] = 0.2 *M*, and correspondingly smaller yet for lower concentrations of **2**.[5] The actual yields of 1-hexene, 2–8%, probably reflect errors in that estimate or significant H-abstraction from other sites in **2**.[5]

Before discussing the yields in Table 1, we turn briefly to potential problems besetting a system as complex as this one, where a series of reactions had to be used to turn excess starting material into a derivative that would not produce one or more of the products of interest during analysis for those products. Care was taken to assure that the product ratios were characteristic of the chemistry of Scheme 1 and not artifacts arising out of the subsequent chemistry of the assay procedure (Scheme 2). A distortion of the ratio could arise from thermolysis of **7** (formed from destruction of excess **2** with Ph_3P, Scheme 2) during analysis, if silylation of **7** were incomplete. The hydroxydiazene (**7**) but not its trimethylsilyl ether, decomposed partially under the gc analysis conditions forming, *inter alia*, **6**. To ensure that this potential source of error was

[2]This seemingly complex procedure was necessary because both the α-hydroperoxyalkyl diazene and the α-hydroxyalkyl diazene decompose on both hlpc and glpc columns to yield one or more of the products in eq. [7]. The trimethylsilyl ether derived from the α-hydroxyalkyl diazene was stable under the conditions of analysis.

[3]Careful examination of the distillates and of the residue showed that a trace of α-hydroperoxyalkyl diazene was actually being transferred to the receiving flask during long-time distillation and that some alcohols remained in the residue from short-time distillation. Whatever the reason for the scatter in values of k_{OH} for a given set of conditions, the simple approach also gave absolute values of k_{OH} ca. five-fold smaller than those obtained by the more elaborate method.

[4]The rate constant for abstraction of hydroperoxyl hydrogen from *t*-butyl hydroperoxide by a primary alkyl radical, ca. $2 \times 10^4\,M^{-1}\,s^{-1}$ at 50°C (13) was taken as the best model available.

[5]We assume that the hydroperoxyl group of **2** is the primary source of abstractable hydrogen. The allyl-type methylene groups of **2** (N=NCH$_2$ and CH$_2$CH=CH$_2$) are the next best H-donors but the rate constants, at least that for abstraction from the allylic methylene group by primary alkyls, are probably smaller (ca. $10^3\,M^{-1}\,s^{-1}$) (see footnote 6) than that for abstraction from the hydroperoxyl group (13).

[6]This estimate is based on the following data. 1-Pentene is 8.1-fold better as a H-donor than 2,2,4-trimethylpentane at 338 K, toward methyl radicals (14). The room temperature rate constant for abstraction by methyl from 2,2,4-trimethylpentane (15) is $20\,M^{-1}\,s^{-1}$. If the correction for the ca. 40°C difference in temperatures is taken to be about 2^4, then the rate constant for abstraction of allylic hydrogen by methyl at 338 K comes to about $2590\,M^{-1}\,s^{-1}$ and the value at 323 K to less than $1000\,M^{-1}\,s^{-1}$.

[a]Initial concentration of **2** in C_6F_6.

[b]Estimated by gc analysis of remaining **2**, as the trimethylsilyl ether, and of the products derived from the 5-hexenyl portion of **2**, not counting 1-hexene which was a minor product.

[c]Calculated from the average percent reaction for two experiments at each initial concentration.

[d]Duplicate experiments at each concentration of **2** and duplicate product analyses for each experiment. Compounds **3**, **4**, **5**, and **6** are 5-hexen-1-ol, 1-hexene, cyclopentylmethanol, and methylcyclopentane, respectively. The alcohols were analyzed as the corresponding trimethylsilyl ethers. Relative yields were determined from enlarged (3×) recorder traces by the "cut and weigh" method. Those of methylcyclopentane contain a correction factor (1.3) for its lower molar detector response compared to that of 5-hexenyl trimethylsilyl ether. Isomeric trimethylsilyl ethers were assumed to have the same detector response, within experimental error. The sum of the yields of **3**, **5**, and **6** was estimated to be 90% or greater. The symbol nd means "not determined."

[e]Calculated with the use of eq. [7], where $k_C^{50°C} = 5.4\times10^5\ s^{-1}$ (12). The single rate constant for each concentration was calculated from $[2]_{ave}$ for two runs and from the average product ratio **3**/(**5** + **6**) for that concentration. The error is the standard deviation of rate constants calculated from individuals product ratios and $[2]_{ave}$ for a particular $[2]_{initial}$.

eliminated, the silylation reactions themselves were monitored by gc and reaction solutions were subjected to the treatment with propanol (Scheme 2) and to subsequent analysis only after silylation of **3**, **5**, and **7** was complete.

The fact that methylcyclopentane was an important product is cause for additional concern about the validity of the yields of alcohols. If methylcyclopentane arose primarily from abstraction of hydroperoxyl hydrogen,[5] then the peroxyl radicals that resulted would have formed, in sequence, tetraoxide and oxygen. Oxygen so formed would have led to 5-hexenyl hydroperoxide and cyclopentylmethyl hydroperoxide which, in turn, would have led to **3** and **5** during the treatment with Ph_3P. Although this problem can not be dismissed, there are several reasons for believing that the distortion of the data, from formation of O_2, should be minor. First, the maximum possible yield of transient O_2 by the above mentioned mechanism is only about half that of methylcyclopentane. Second, the peroxyl radicals can follow pathways other than coupling, such as H-abstraction from the side chain of **2** and addition to the double bond. Those processes would produce radicals that would compete for the limited supply of oxygen, and that lead to products different from **3** and **5**. Third, since both alkyl radical precursors of **3** and **5** would react fast with oxygen, the distortion of the true yield ratio (eq. [7]) would be small because both the numerator and the denominator would be larger than they ought to be in view of the second source of the alcohols. The above factors, taken together, make it unlikely that our k_{OH} values for the 5-hexenyl radical should be too large by a factor as large as 1.1, from the incursion of tetraoxide-derived oxygen. Assuming that all potential sources of serious error have been dealt with, we turn to the discussion of the data in Table 1.

A striking feature of the analytical results (Table 1) is that the yields of **6** exceed those of **5** under all conditions that were studied. The reverse is true for the acyclic analogs, where the yields of **4** (although least accurately determined), were much below those of **3**. Thus, the ratio of rate constants, k_{OH}/k_H, must be substantially larger for the 5-hexenyl radical than for the cyclopentylmethyl radical. A rough estimate leads to $(k_{OH}/k_H)^{5\text{-hexenyl}} \geq 4.9(k_{OH}/k_H)^{\text{cyclopentylmethyl}}$, which was obtained as follows. The upper limit of the yield of **4** from any run is one half the yield of **6** for that run (see above). That upper limit leads to $(k_{OH}/k_H)^{5\text{-hexenyl}} > 7.8$, using the averaged data in Table 1, from all three concentrations. Averaged relative yields of **5** and **6** lead to $(k_{OH}/k_H)^{\text{cyclopentylmethyl}} = 1.6$ and $7.8/1.6 = 4.9$.

Although the reduced selectivity of cyclopentylmethyl could be the result of either a diminished k_{OH} or an enhanced k_H (or both) relative to corresponding rate constants for 5-hexenyl, there is a reasonable argument for a diminished k_{OH}. The hydroxy oxygen of **2** is undoubtedly more protected by steric hindrance than the hydroperoxy hydrogen and the cyclopentylmethyl radical, because it is β-branched and has two γ-hydrogens eclipsing the CH_2 group, could well be more sensitive toward steric hindrance than the isomeric 5-hexenyl radical.

A second striking feature of the yield data is the small decrease of the ratio, **3**/(**5** + **6**), attending a four-fold increase in the concentration of **2**. The expected result, based on Scheme 1,[7] is a four-fold increase in that ratio with a four-fold increase in [**2**]. The data can be accommodated within the framework of

[7]Loss of **3** at higher concentrations of **2**, by epoxidation (9) of **3**, is not likely to be serious because the conversions were kept to about 10%.

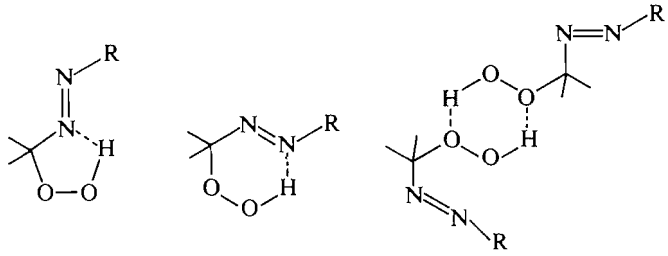
Scheme **1** only if k_{OH} is dependent on the concentration of **2**, as indicated in Table 1. We now turn to the examination of that dependence in mechanistic terms.

Induced decomposition of **2** and of analogous azohydroperoxides is presumably a concerted process involving the scission of the O—O bond and, at least, the nearest C—N bond (16). Such a concerted induced decomposition has a geometric requirement; the breaking σ bonds must be either *anti*- or *syn*-periplanar. The latter geometry is provided for, more or less, by virtue of intramolecular H-bonding in monomeric **2**, as in **9** and **10**. Intermolecularly, H-bonded species (e.g., **11**)



9 **10** **11**

which become prevalent at high [**2**], do not retain the alignment of orbitals required for facile induced decomposition and the observed rate constant, a composite of rate constants for monomeric and associated **2**, falls with increasing concentration of [**2**]. Steric hindrance to attack at hydroxy oxygen of associated **2**, already mentioned earlier, would operate in the same sense, to reduce k_{OH} below that applicable to the monomeric species.

Attempts to work with **2** at 0.02 *M* initial concentration were not rewarding, because the constraint of low conversion necessary to use eq. [7] (pseudo first order kinetics) led to very noisy data. Presumably, k_{OH} for attack on monomeric **2** by 5-hexenyl exceeds $1.8 \times 10^7 M^{-1} s^{-1}$ at 50°C. Whatever the limiting rate constant may be, it is clear that induced decomposition of azohydroperoxides by relatively unhindered carbon-centered radicals is very fast at commonly used concentrations of such peroxides.

Induced decomposition of simple hydroperoxides, as opposed to azo hydroperoxides, by free radicals is probably much less facile. Although absolute rate constants for the reaction, R·(alkyl) + R′OOH → ROH + R′O·, have not been reported, it is possible to estimate an upper limit for a model hydroperoxide. Thus, 5-hexenyl radical reacts with *t*-butyl hydroperoxide (**12**) to form 1-hexene rather than 5-hexen-1-ol (13). If it is assumed that some 5-hexen-1-ol was actually formed but in ≤5% yield, then it follows from $k_H = 2 \times 10^4 M^{-1} s^{-1}$ that $k_{OH} \leq 1 \times 10^3 M^{-1} s^{-1}$, for **12**.[8] *t*-Butyl hydroperoxide is a reasonable model for the steric effects to be expected in **2** and the fact that k^2_{OH} is larger by a factor ≥10^3 than k^{12}_{OH} therefore implies that there is a substantial electronic effect of the azo substituent or else that different mechanisms apply in the two cases. The latter explanation is more likely to be correct than the former. Induced decomposition of **12**, by radical attack at hydroxyl oxygen, affords alcohol and *t*-butoxyl. Analogous induced decomposition of **2** can lead to alcohol and either alkoxy radical or ketone plus diazenyl radical; the latter products are formed if O—O bond cleavage occurs in concert with scission of the nearest C—N bond. The thermochemistry for the concerted induced decomposition is considerably more favourable than that for induced scission of the O—O bond alone[9] and the extra driving force provided by partial formation of the strong carbonyl double bond at the transition state is presumably responsible for the facile induced decomposition of α-hydroperoxyalkyl diazenes as compared to their alkyl hydroperoxide counterparts.[8] Evidence for a concerted mechanism of unimolecular thermolysis of an α-benzoylperoxyalkyl diazene was presented earlier (17) and that result, reinforced with the present findings, suggests that concertedness may be a common mechanism for both induced and uninduced decomposition of α-hydroperoxyalkyl diazenes and some of their derivatives.

The implications of the present results to synthesis with α-hydroperoxyalkyl diazenes deserve brief discussion. At first sight, the large values of k_{OH} and the low yields of 1-hexene from 5-hexenyl radicals are encouraging. However, if α-hydroperoxyalkyl diazenes are to serve as reagents for hydroxyalkylating multiple bonds, then the rate constants of interest are those for attack of secondary and tertiary radicals[10] at the OH group. The results are less encouraging in the latter regard, for even a branched primary radical (cyclopentylmethyl) abstracts H faster than OH under some conditions. The sensitivity of OH abstraction to steric hindrance that this result implies was already suspected when it was found that norbornene is hydroxyalkylated in very low yield by α-hydroperoxyalkyl diazenes (18). For synthetic application there is nothing to be gained from the concentration dependence of k_{OH} because the increase in k_{OH} with dilution is cancelled, more or less, by the decrease in the value of the concentration term in the equation for the second order rate of hydroxyl abstraction. It is clear then that structural modification of the reagent is required, to reduce steric hindrance to approach at the hydroxyl oxygen and/or to hold the hydroperoxy function in a conformation better suited to concerted induced decomposition. We plan to test new reagents, having one or both of those modifications, in the future.

Experimental

5-Hexenyl[1-hydroperoxy-1-methylethyl]diazene (**2**) was prepared by the procedure described earlier (19), involving autoxidation of the 5-hexenyl hydrazone of acetone in light petroleum. It was stored as that solution in a freezer. Samples of **2** in hexafluorobenzene were prepared by removing the solvent from an aliquot of the solution of **2** in petroleum using a steam of dry N_2, weighing the residual **2**, and adding the appropriate volume of C_6F_6. Samples sizes were 0.6–1.0 mL of **2** in C_6F_6.

Thermolyses were carried out with degassed solutions of **2** in C_6F_6, in sealed Pyrex tubes. A solution of **2** was heated at 49.8 ± 0.2°C in an oil bath for 25–30 min. That time had been determined, by experiment with solutions of **2** in nmr tubes, to cause ca. 10% decomposition. The sample was chilled, the tube was cut and the cold contents were transferred to a small glass-stoppered flask containing triphenylphosphine in 50% excess over the hydroperoxide. The flask was left overnight in the refrigerator before *N*,*O*-bistrimethylsilyl trifluoro-

[8]5-Hexen-1-ol was not reported as a coproduct of the reaction of 5-hexenyl radicals with *t*-butyl hydroperoxide in chlorobenzene (13). In a personal communication one of the authors (J.A.H.) emphasized that, although 5-hexen-1-ol was not an important reaction product, small amounts could have been missed because they were not looking for it.

[9]For the concerted induced decomposition, R· + $(CH_3)_2C(OOH)$-N=N—R → ROH + $(CH_3)_2CO$ + ·N=NR, we estimate ΔH = −97 kcal mol^{-1} whereas, for the hypothetical induced decomposition, R· + $(CH_3)_2C(OOH)N{=}NR$ → ROH + $(CH_3)_2C(O\cdot)N{=}NR$, ΔH is about −50 kcal mol^{-1}.

[10]Except for the case of addition to ethylene or to an alkyne, the adduct of R· and acceptor will be either a 2°- or a 3°-radical, if the addition is to a C—C multiple bond.

acetamide (BSTFA), in 15- to 20-fold excess over initially present hydroperoxide, was added. The flask was again stoppered securely and the contents were kept at ca. 20°C until silylation of **3**, **5**, and **7** was complete, as judged by periodic gc analysis. Silylation of **7** was slowest, taking about 4 days, but solutions were left for a full week before excess propanol was added to destroy the remaining BSTFA. The solution was then analyzed by gc, with two columns. Column 1 (10′ × ⅛″, steel) packed with Carbowax 20M (5%) on Chromosorb P (100/120 mesh) separated 1-hexene and methylcyclopentane from the solvent and from other products. It was used with N_2 flowing at 10 mL min^{-1} at a temperature of 35°C until **4**, **6**, and the solvent had been eluted. The temperature was then raised to 200°C to purge the column. Column 2 (6′ × ⅛″, glass) packed with OV-17 (3%) on Chromosorb P (100/120 mesh) did not resolve **4** from **6** but it separated the silyl ethers of **3**, **5**, and **7** cleanly from other components. It was operated with N_2 flowing at 10 mL min^{-1} and with the following temperature program: 40°C (2 min) increased to 150°C at 5° min^{-1} and finally to 300°C at 25° min^{-1} to purge the column of Ph_3P and Ph_3PO. Calibration of the two column procedure with solutions of **6** and the trimethylsilyl ether of **5** showed that reproducibility of the volume injected was reliable and that only a multiplicative factor of 1.3, for the signal from **6**, was required. Detector response factors for isomers **4** and **6**, on the one hand, and for the trimethylsilyl ethers of **3** and **4**, on the other hand, were assumed to be the same.

Spectra of products

The following nmr spectra of authentic materials, synthesized form the alcohols by treatment with BSTFA, matched those of products formed from **2** by thermolysis and subsequent treatment. Nuclear magnetic resonance spectra were run at 90 MHz with C_6F_6 as solvent and with internal TMS. Mass spectra are the low resolution, ei, type. Peaks with intensities below 5% are not included unless they correspond to molecular ions.

Vinyl ether hydrolysis. XVIII. The two-stage reaction of 2,3-dimethoxy-1,3-butadiene[1]

A. Jerry Kresge and Ya Yin

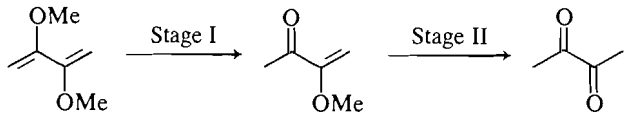
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received December 15, 1986

This paper is dedicated to Professor John T. Edward

A. Jerry Kresge and Ya Yin. Can. J. Chem. **65**, 1753 (1987).

The kinetics of acid-catalyzed hydrolysis of 2,3-dimethoxy-1,3-butadiene (**1**) to 3-methoxy-3-buten-2-one (**2**) and the subsequent 10^4 times slower conversion of the latter to biacetyl (**3**):

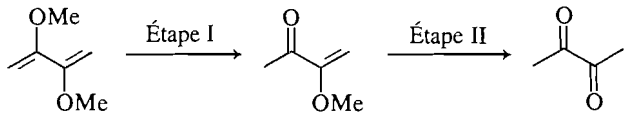


1 **2** **3**

were studied in aqueous solution at 25°C. Both stages of this process give substantial hydrogen ion isotope effects, k_{H^+}/k_{D^+} = 2.95 for Stage I and k_{H^+}/k_{D^+} = 1.83 for Stage II, and Stage I shows general acid catalysis in formic and acetic acid buffers; both stages are therefore assigned the conventional mechanism for vinyl ether hydrolysis involving rate-determining proton transfer from catalyzing acid to substrate. The second vinyl ether group of the initial substrate (**1**) is found to have only a slight (3-fold) accelerative effect on the reactivity of the first group, but the acetyl substituent present in the intermediate **2** decreases its reactivity by a factor of 10^4; the latter appears to be due largely to the electron-withdrawing inductive effect of acetyl, with little or no influence from a countervailing electron-supplying resonance effect.

A. Jerry Kresge et Ya Yin. Can. J. Chem. **65**, 1753 (1987).

Opérant à 25°C et dans des solutions aqueuses, on a déterminé la cinétique de l'hydrolyse acido-catalysée du diméthoxy-2,3 butadiène-1,3 (**1**) en méthoxy-3 butène-3 one-2 (**2**) et de la transformation subséquente de ce dernier, qui est 10^4 fois plus lente que la réaction précédente, en biacétyle (**3**). Pour chacune des étapes, on observe des effets isotopiques cinétiques de l'ion



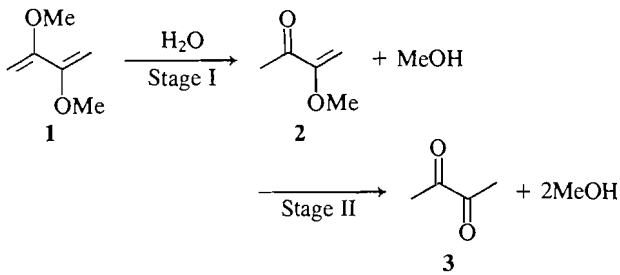
1 **2** **3**

hydrogène qui sont importants, k_{H^+}/k_{D^+} = 2,95 pour l'étape I et k_{H^+}/k_{D^+} = 1,83 pour l'étape II: de plus, l'étape I est soumise à une catalyse acide générale dans des tampons d'acide formique ou d'acide acétique. Pour chacune des étapes, on attribue donc le mécanisme conventionnel d'hydrolyse des éthers vinyliques impliquant une étape déterminante comportant un transfert de proton de l'acide agissant comme catalyseur vers le substrat. On a observé que le deuxième groupement éther vinylique du substrat original (**1**) n'a qu'une faible influence (facteur d'environ 3) sur le réactivité du premier groupement; toutefois, le groupement acétyle présent dans l'intermédiaire **2** diminue la réactivité par un facteur de 10^4. Il semble que ce dernier effet est principalement dû à l'effet inductif électro-affinitaire du groupement acétyle et que l'effet électro-donneur inverse provenant de la résonance n'a que peu ou pas d'influence.

[Traduit par la revue]

2,3-Dimethoxy-1,3-butadiene, **1**, contains two vinyl ether functional groups whose consecutive hydrolysis, eq. [1], might

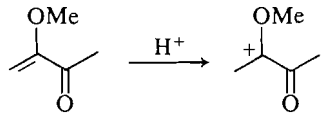
[1]



1 **2** **3**

be expected to occur in separate stages proceeding at rather different rates. This follows from the fact that the conventional mechanism for vinyl ether hydrolysis involves rate-determining proton transfer from a catalyzing acid to the substrate in a step that generates a carbocation intermediate (1), and α-acyl substituents such as that present in the product of the first hydrolysis stage, **2**, are likely to be carbocation destabilizing, eq. [2] (2).

[2]



2

We wish to report that we have examined the kinetics of hydrolysis of 2,3-dimethoxy-1,3-butadiene and have found this to be the case. Our results provide a quantitative estimate of this α-acetyl effect on carbocation stability, a subject of some current interest (2), and also give information on the effect of one vinyl ether group in 2,3-dimethoxy-1,3-butadiene on the reactivity of the other.

Results

Reaction identification

2,3-Dimethoxy-1,3-butadiene has a strong uv absorption band

[1]Part XVII: ref. 21.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

with λ_{max} = 230 nm. In acidic solutions this band gradually diminishes in intensity and is replaced, through a change showing a tight isosbestic point at λ = 255 nm, by a somewhat weaker but still strong absorbance at λ_{max} = 250 nm. This new absorption band then also diminishes, but much more slowly, to give a final spectrum with no apparent uv or visible absorbance; the final solution, however, has a faint yellow color.

These two spectral changes occur on time scales that differ by four orders of magnitude. We were therefore able to isolate the intermediate substance with λ_{max} = 250 nm and show, through comparison of its proton nmr spectrum with a published description (3), that it is indeed 3-methoxy-3-buten-2-one, **2**; in addition, the value λ_{max} = 250 nm agrees well with that expected for an α,β-unsaturated ketone with an α-methoxy substituent (4). We also isolated a yellow material as the final reaction product, and its nmr spectrum showed it to be biacetyl, **3**; a previous study (3) also found biacetyl to be the sole reaction product of the acid-catalyzed hydrolysis of 3-methoxy-3-butene-2-one.

These considerations thus demonstrate that 2,3-dimethoxy-1,3-butadiene does indeed hydrolyze by the two-stage process shown in eq. [1], and that the velocities of the two stages are sufficiently different to allow detailed kinetic examination of each.

Kinetics

We measured rates of the first stage of this hydrolysis reaction in perchloric acid solutions by stopped-flow techniques and in formic and acetic acid buffer solutions by conventional spectrophotometry. The determinations in perchloric acid solutions were done in H_2O and in D_2O, in H_2O over the acid concentration range 0.02–0.10 *M* and in D_2O over the acid concentration range 0.01–0.06 *M*. The ionic strength was maintained at 0.10 *M* by adding sodium chloride as required. These data are summarized in Table S1.[2]

The rate data obtained in both solvents adhered well to the first-order rate law, and observed first-order rate constants were accurately proportional to acid concentration. Linear least-squares analysis gave the catalytic coefficients k_{H^+} = 4.37 ± 0.03 M^{-1} s^{-1} and k_{D^+} = 1.48 ± 0.02 M^{-1} s^{-1}, which provide the isotope effect k_{H^+}/k_{D^+} = 2.95 ± 0.04. For both solvents, the zero-acid-concentration rate intercepts were less than their experimental uncertainty.

Rate measurements of the first stage of the hydrolysis reaction in formic and acetic acid buffers were performed in series of solutions of constant buffer ratio and constant ionic strength (0.10 *M*) but changing buffer concentration (fivefold variation). These data are summarized in Table S2.[2]

These rate data also adhered well to the first-order rate expression, and observed first-order rate constants were accurately proportional to buffer concentration. This is the expected behavior for a general acid-catalyzed reaction, such as vinyl ether hydrolysis (1), and the data were therefore fitted to the rate law that governs such a process, eq. [3]. Linear least-squares

$$[3] \quad k_{obs} = k_{H^+}[H^+] + k_{HA}[HA]$$

analysis gave formic acid catalytic coefficients determined at two different buffer ratios in good agreement with each other, k_{HA} = (2.24 ± 0.04) × 10^{-2} M^{-1} s^{-1} ([HA]/[A^-] = 0.91) and k_{HA} = (2.28 ± 0.05) × 10^{-2} M^{-1} s^{-1} ([HA]/[A^-] = 1.9), and hydrogen ion catalytic coefficients, k_{H^+} = 4.13 ± 0.08 and 4.17 ± 0.06 M^{-1} s^{-1}, consistent with the value determined in perchloric acid solutions, k_{H^+} = 4.37 ± 0.03 M^{-1} s^{-1}. Measurements in acetic acid buffers were made at only one buffer ratio ([HA]/[A^-] = 1.1); these data gave the acetic acid catalytic coefficient k_{HA} = (4.08 ± 0.05) × 10^{-3} M^{-1} s^{-1} and the hydrogen ion catalytic coefficient k_{H^+} = 4.34 ± 0.10 M^{-1} s^{-1}. Hydrogen ion concentrations of the buffer solutions needed for this analysis were obtained by calculation, using thermodynamic dissociation constants for formic (5) and acetic (6) acids and activity coefficients recommended by Bates (7).

TABLE 1. Summary of rate constants for the first and second stages in the hydrolysis of 2,3-dimethoxy-1,3-butadiene to biacetyl at 25°C

Rate constants/M^{-1} s^{-1}	Stage I	Stage II
k_{H^+}	4.37	0.000241
k_{D^+}	1.48	0.000132
k_{HCO_2H}	0.0226	—
$k_{CH_3CO_2H}$	0.00408	—

The second stage of this hydrolysis reaction, the conversion of 3-methoxy-3-buten-2-one (**2**) to biacetyl (**3**), was much slower than the first, and rate measurements were therefore made only in perchloric acid solutions. Concentrated as well as dilute acid solutions were used; the concentration range covered was 0.2–47 wt.% acid (0.02–6.3 *M*), and ionic strength was equal to the concentration of the acid. These data are summarized in Table S3.[2]

These data showed good first-order behavior, and observed first-order rate constants increased with increasing acidity, with the increase being somewhat stronger than in direct proportion to acid concentration. Such behavior is typical of reactions in which proton transfer to carbon is rate determining. The data are usually analyzed using acidity functions, and the X_0 scale (8) appears to be the best quantity currently available for this purpose (9). In the present case, a plot of log (k_{obs}/[H^+]) versus X_0 was accurately linear, and least-squares analysis gave slope = 0.71 ± 0.01 and intercept = −3.618 ± 0.007; the latter leads to the hydrogen ion catalytic coefficient k_{H^+} = (2.41 ± 0.04) × 10^{-4} M^{-1} s^{-1}.

A few measurements of the rate of the second hydrolysis stage were also made in D_2O solutions of perchloric acid over the concentration range 0.02–0.10 *M*, ionic strength = 0.10 *M*. These data are summarized in Table S4;[2] they give the hydrogen ion catalytic coefficient k_{D^+} = (1.31 ± 0.03) × 10^{-4} M^{-1} s^{-1}, which leads to the isotope effect k_{H^+}/k_{D^+} = 1.83 ± 0.05.

All of the catalytic coefficients determined here for both stages of this vinyl ether hydrolysis reaction are listed in Table 1.

Discussion

Reaction mechanism

The results obtained here show that the hydrolysis of 2,3-dimethoxy-1,3-butadiene to 3-methoxy-3-buten-2-one (eq. [1], Stage I) is a general acid-catalyzed process, which indicates that proton transfer occurs in the rate-determining step of this reaction. This conclusion is reinforced by the strong hydrogen-ion isotope effect, k_{H^+}/k_{D^+} = 2.95, and the two pieces of evidence together suggest that the conventional, rate-determining proton transfer mechanism for vinyl ether hydrolysis is operating. This hydrogen ion isotope effect in fact agrees remarkably well with the value, k_{H^+}/k_{D^+} = 3.12, predicted from a correla-

[2]Tables S1–S4 of rate data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

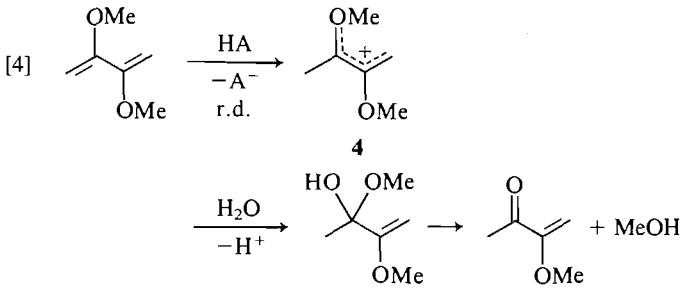
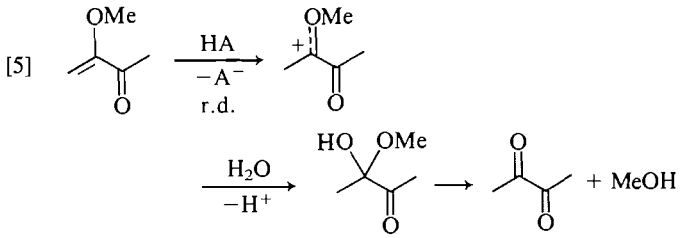
tion of isotope effects with free energy of activation for the hydrolysis of a large group of vinyl ethers known to react by the conventional mechanism (1*b*). It would appear safe to conclude, therefore, that this first stage in the hydrolysis of 2,3-dimethoxy-1,3-butadiene occurs as shown in eq. [4].



The hydrogen ion isotope effect on the second stage of the hydrolysis of 2,3-dimethoxy-1,3-butadiene, conversion of 3-methoxy-3-buten-2-one (**2**) to biacetyl (**3**), also agrees well with the value expected on the basis of this correlation: $(k_{H^+}/k_{D^+})_{obs} = 1.83$, $(k_{H^+}/k_{D^+}) = 1.57$. This suggests that this stage also occurs by the conventional mechanism, as shown in eq. [5].

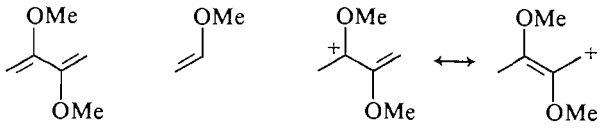


These mechanistic assignments are reinforced by the fact that examination of the proton nmr spectrum of the reaction mixture midway through the second stage of hydrolysis of 2,3-dimethoxy-1,3-butadiene conducted in D_2O solution showed only one deuterium atom in the methyl group of 3-methoxy-3-buten-2-one and no deuterium incorporation in its vinyl group. This indicates that neither of the carbon protonation steps of eqs. [4] and [5] is reversible. This is significant in view of the fact that the only variant on the conventional mechanism for vinyl ether hydrolysis ever proposed is a scheme in which the carbon protonation step is reversible (10).

The mechanisms of eqs. [4] and [5] show the carbocation products of carbon protonation as discrete intermediates; this implies that they are stable species with lifetimes at least as long as the period of a molecular vibration, $\tau \sim 10^{-13}$ s (11). There is no direct information on the lifetimes of carbocations such as these in aqueous solution, but an estimate may be made by extrapolating a σ^+ correlation of rates of reaction with water for a series of more stable carbocations (12). This method gives a lifetime of 1×10^{-8} s for the vinyl-substituted methoxymethyl cation (**4**), formed in the first stage of the hydrolysis reaction, eq. [4],[3] which is easily long enough to allow this species to be a viable intermediate in aqueous solution. The lifetime estimated in this way for the acetyl-substituted methoxymethyl cation (**5**) formed in the second hydrolysis step (eq. [5]), 5×10^{-12} s,[4] is much shorter but still safely over the 10^{-13} s limit. The latter lifetime, however, is just below the rotational correlation time of water, 1×10^{-11} s (15), which might be a measure of the time required for a water molecule solvating the vinyl ether substrate to rotate into correct position for bonding to the carbocationic center. If the lifetime of this carbocation is indeed too short to allow such repositioning of a water molecule to take place, then the repositioning would have to occur before proton transfer to carbon, and a preassociation mechanism would result.

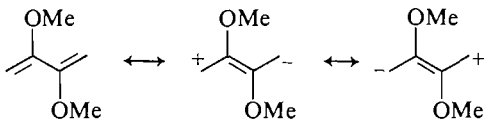
Reactivity

The hydrogen ion rate constant determined here for the hydrolysis of 2,3-dimethoxy-1,3-butadiene, **1**, divided by two to allow for the fact that this molecule has two identical vinyl ether groups, is only 2.9 times the corresponding rate constant for the hydrolysis of methyl vinyl ether, **6** (1*b*). This weak effect of introducing a vinyl substituent indicates that allylic resonance of the type **7** → **8**, offset somewhat by the opposing inductive



1 **6** **7** **8**

effect of the α-methoxyvinyl group, contributes very little more to the stability of the transition state of this reaction than does 1,3-butadienyl resonance (**9** → **10** → **11**) to the stability of its

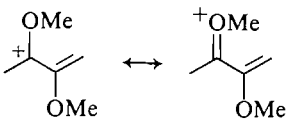


9 **10** **11**

initial state. This contrasts sharply with the effect of vinyl substituents on the rate of hydration of simple alkenes, a reaction that also occurs through rate-determining protonation of a carbon–carbon double bond to form a carbocationic intermediate (16). For example, the hydrogen ion catalytic coefficient for the hydration of 2-methyl-1,3-butadiene, **12** (13), is 10^4 times that for the hydration of propene, **13** (17), and a similar comparison of 1,3-butadiene itself, **14** (13), with ethene, **15** (17), gives the even greater rate factor 10^7. This

12 **13** **14** **15**

difference in behavior between vinyl ethers and simple alkenes may be attributed to the great effectiveness of methoxyl group resonance, **16** → **17**, at stabilizing the transition state of the



16 **17**

vinyl ether hydrolysis reaction: this type of conjugation is so effective that there is little demand for additional stabilization by the vinyl group. A similar, though attenuated, example of this phenomenon may be seen in the comparison of **12** and **13** on one hand with **14** and **15** on the other, where introduction of a cation-stabilizing methyl group reduces the vinyl substituent effect from 10^7 down to 10^4.

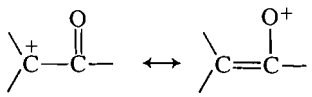
The second stage of the hydrolysis of 2,3-dimethoxy-1,3-butadiene is much slower than the first: the rate retardation calculated, making allowance for the presence of two vinyl ether groups in the diene, amounts to a factor of 9.1×10^3. This

[3]This estimate is based upon use of the σ^+ constant for $CH_2{=}CH{-}$ (ref. 13) in place of the (unknown) σ^+ constant of $CH_2{=}C(OMe){-}$.

[4]Estimated using $\sigma^+ = 0.47$ for $CH_3CO{-}$ (ref. 14).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

may be attributed to a cation-destabilizing effect of the α-acetyl substituent in the cationic intermediate formed in the rate-determining step of this second reaction stage, eq. [2]. The electronic influence of acyl substituents on adjacent electron-deficient centers has traditionally been attributed to an electron-withdrawing inductive effect, but evidence has recently been supplied for a countervailing electron-supplying resonance effect, **18** → **19** (19). It is of interest to inquire whether or not such an



18 **19**

effect operates in the present system. This may be done by using a σ^+ correlation (16*b*, 18) to predict the rate constant of the present reaction. Although this correlation was originally based upon hydrogen-ion rate constants for the hydration of alkenes, it also works well for the hydrolysis of vinyl ethers; for example, it predicts $k_{H^+} = 0.29\,M^{-1}\,s^{-1}$ for the hydrolysis of methyl vinyl ether whereas the observed value is $k_{H^+} = 0.76\,M^{-1}\,s^{-1}$. The inductive effect of the acetyl group in the present reaction may be estimated using this correlation with only an inductive σ constant. Use of $\sigma_I = 0.30$ (20) gives $k_{H^+} = 6.0 \times 10^{-5}\,M^{-1}\,s^{-1}$, which is only 4 times less than the observed value, $k_{H^+} = 2.4 \times 10^{-4}\,M^{-1}\,s^{-1}$. This suggests that the countervailing electron-supplying resonance effect of acetyl is quite weak in the present system, and that is consistent with the strong electron-supplying resonance effect of methoxyl, which again leaves the system with little demand for additional resonance stabilization by other substituents.

Experimental

Materials

2,3-Dimethoxy-1,3-butadiene (Aldrich) was purified by distillation; its proton nmr spectrum was consistent with its structure. 3-Methoxy-3-buten-2-one was prepared by partial hydrolysis of 2,3-dimethoxy-1,3-butadiene: 1 g of the latter substance was dissolved in 25 mL 0.4 *M* $HClO_4$ and the solution was allowed to stand at room temperature for 2 min; the acid was then neutralized with sodium hydroxide, the product was extracted with ether, the ether was evaporated, and the residue was purified by gas chromatography. Its proton nmr spectrum was consistent with its structure and agreed with a literature description (3).

All other materials were best available commercial grades. Solutions were prepared with deionized water purified further by distillation; D_2O (Merck Sharp & Dohme, 99.8%) D) was used as received.

Kinetics

Rate determinations were made spectrophotometrically by monitoring the decrease in absorbance at λ = 230 nm for the first hydrolysis stage and at λ = 250 nm for the second hydrolysis stage. Measurements were made using a Cary 118 spectrometer with cell compartment thermostatted at 25.0 ± 0.02°C or a Durrum–Gibson stopped-flow spectrometer operating at 25.0 ± 0.1°C. Observed first-order rate constants were evaluated by least-squares fitting of the data to an exponential (Cary measurements) or a linear (Durrum–Gibson measurements) function.

Phase transitions and molecular motions in adamantane derivatives: 1-adamantanol

PIERRE D. HARVEY, DENIS F. R. GILSON,[1] AND IAN S. BUTLER[1]

Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, P.Q., Canada H3A 2K6

Received December 11, 1986

This paper is dedicated to Professor John T. Edward

PIERRE D. HARVEY, DENIS F. R. GILSON, and IAN S. BUTLER. Can. J. Chem. **65**, 1757 (1987).

An order–disorder transition occurs in 1-adamantanol at 359 K on heating and at 342 K on cooling, with transition entropies of 36 and 34 $J\,K^{-1}\,mol^{-1}$, respectively. FT-ir spectra show that free hydroxyl groups exist in the high temperature phase, but the majority of the O—H groups remain hydrogen bonded. The barrier to adamantyl group rotation in the low-temperature phase, determined from proton spin–lattice relaxation time measurements, is 20.9 $kJ\,mol^{-1}$, and the barrier to rotation in the high-temperature phase is 35.0 $kJ\,mol^{-1}$.

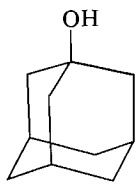
PIERRE D. HARVEY, DENIS F. R. GILSON et IAN S. BUTLER. Can. J. Chem. **65**, 1757 (1987).

Avec l'adamantanol-1, il se produit une transition ordre/désordre à 359 K lorsqu'on chauffe et à 342 K lorsqu'on refroidit: les entropies de transition sont respectivement 36 et 34 $J\,K^{-1}\,mol^{-1}$. Les spectres ir/TF démontrent que des groupements hydroxyles libres existent dans la phase à haute température; toutefois, des liaisons hydrogènes relient encore la majorité des groupements O—H. Dans la phase à basse température, la barrière à la rotation du groupement adamantyle, telle que déterminée à partir des temps de relaxation spin/réseau des protons, est égale à 20,9 $kJ\,mol^{-1}$; dans la phase à haute température, la barrière à la rotation est égale à 35,0 $kJ\,mol^{-1}$.

[Traduit par la revue]

Introduction

The cage hydrocarbon adamantane, $C_{10}H_{16}$, affords the best known example of an organic molecular crystal which undergoes an order–disorder phase transition. Simple substitution on the adamantyl skeleton does not prevent the transition from occurring, but can lead to a wide variation in the temperature and entropy of the transition. In many cases, the phase transitions occur below room temperature, and, therefore, the crystal structures of the ordered phases are seldom known. One particular exception is 1-adamantanol, in which the transition is reported to occur at 353 K with an entropy change of 40.6 $J\,K^{-1}\,mol^{-1}$ (1, 2). These values are very much higher than those of adamantane itself (3), 208 K and 16.2 $J\,K^{-1}\,mol^{-1}$, presumably due to the presence of the hydrogen-bonded substituent. The crystal structure of the room-temperature phase is tetragonal, space group $P4_2/n$, with eight molecules per unit



cell. Four adamantane molecules form a tetramer with the hydroxyl protons hydrogen bonded along the sides of a square, but the hydrogen atoms occupy one of two possible orientations, and the structure is, to this extent, disordered. The large entropy change is strong evidence of an order–disorder transition probably to a face-centered cubic structure in which the molecules undergo extensive molecular motion. The latter is confirmed by the observation of relatively narrow lines in the ^{13}C nmr spectrum of the high-temperature phase, narrow enough to observe the chemical shifts of different carbon atoms (4).

Phase transitions have also been observed in two other hydrogen-bonded adamantane derivatives. In the adamantyl carboxylic acid, the transition occurs at 251 K, with an entropy change of 8.97 $J\,K^{-1}\,mol^{-1}$ (5). In adamantanamine hydrochloride, the transition is at the remarkably low temperature of 124 K, with an entropy change of only 2.52 $J\,K^{-1}\,mol^{-1}$ (6). Studies of the Raman and ir spectra of these compounds showed that the vibrational peaks remain quite sharp and exhibit factor group splittings in the high-temperature phases and, therefore, do not involve a disordered high-temperature phase. This has been confirmed by a study of the crystal structure of adamantanamine hydrochloride (7). In both these compounds, the hydrogen bonding is sufficiently strong that the substituent group is held rigidly in the lattice, but the hydrocarbon portion of the molecule is capable of reorientation. The barriers to rotation have been determined from the proton spin–lattice relaxation times (5, 6). The aim of the present study was to examine the barrier to rotation and the temperature dependence of the vibrational spectrum of 1-adamantanol for comparison with the previously reported behaviour of the carboxylic acid and amine hydrochloride compounds.

Experimental

1-Adamantanol (Aldrich Chemical Co.) was purified by slow sublimation (60°C, 10^{-3} mm Hg). Differential scanning calorimetry studies were performed on a Perkin-Elmer DSC 2. For the ir spectroscopic studies, the sample was sealed between NaCl plates and the temperature controlled by a flow of heated nitrogen gas and measured with a digital thermometer. The spectra were recorded on a Nicolet model 6000 Ft-ir spectrometer. Proton spin–lattice relaxation times were measured (at 33 MHz) as described previously (5, 6).

Results and discussion

The differential scanning calorimetry results showed a transition, on heating, at 359 K with enthalpy and entropy of transition of 13 $kJ\,mol^{-1}$ and 36 $J\,K^{-1}\,mol^{-1}$, respectively. On cooling, the transition showed hysteresis, shifting to 342 K, with enthalpy and entropy changes of 12 $kJ\,mol^{-1}$ and 34 $J\,K^{-1}\,mol^{-1}$. No changes were observed upon cycling through the transition several times or by varying the scanning rate below 5° min^{-1}. The transition temperatures are in reasonable agreement with those reported by Amoureux *et al.* (1), except that the hysteresis was not, apparently, observed in that study, and the enthalpy and entropy changes are somewhat smaller. The transition properties of various substituted adamantyl derivatives are

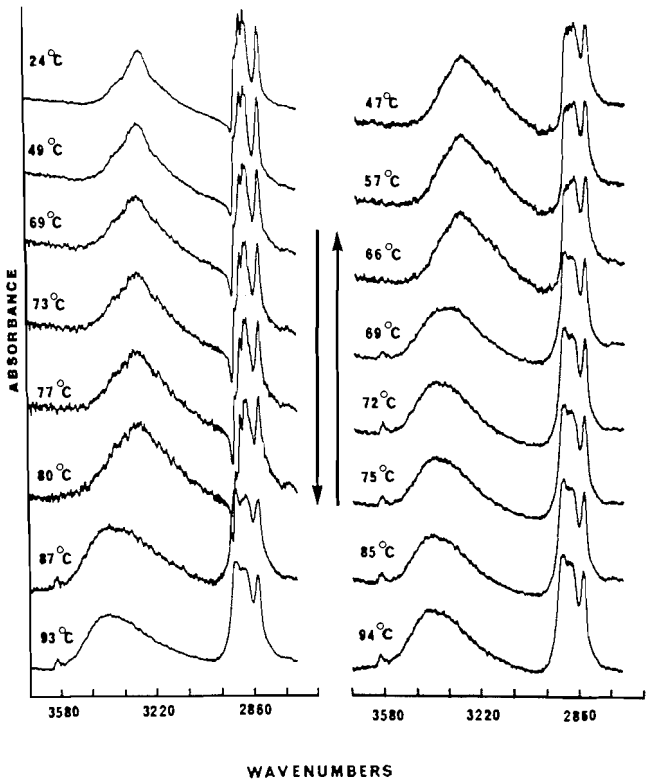

FIG. 1. The temperature dependence of the FT-ir spectra of 1-adamantanol in the 3700–2620 cm^{-1} region: 25 scans, 2 cm^{-1} resolution.

compared in Table 1. The transition temperature in 1-adamantanol is much higher than other adamantane derivatives. This is, at first sight, not surprising, since it can be attributed to the influence of the hydrogen bonding, but the entropy of transition in 1-adamantanol is also much larger than that of adamantane (3), or any other 1-substituted derivative, and resembles that of 2-adamantanone, which has a complicated phase behaviour (8) and also exhibits a large hysteresis. The crystal structure data indicate that the positions of the hydroxyl protons are already disordered and therefore the transition entropy is lowered by at least $R \ln 2$. Even allowing for an excess entropy of the type proposed by Clark *et al.* (9), an entropy change of (35 − approx. 10.5) J K^{-1} mol^{-1} is equivalent to a ratio of about 18:1 for the ratio of distinguishable positions in the ordered and disordered phases.

At room temperature, the vibrational spectra show sharp peaks with clear splittings due to the factor group effects. The frequencies and assignments are listed in Table 1. As the temperature is increased, the O—H stretching frequency shifts to higher energy, and, at the transition temperature, there is broadening and loss of splittings in the C—H vibrations and a

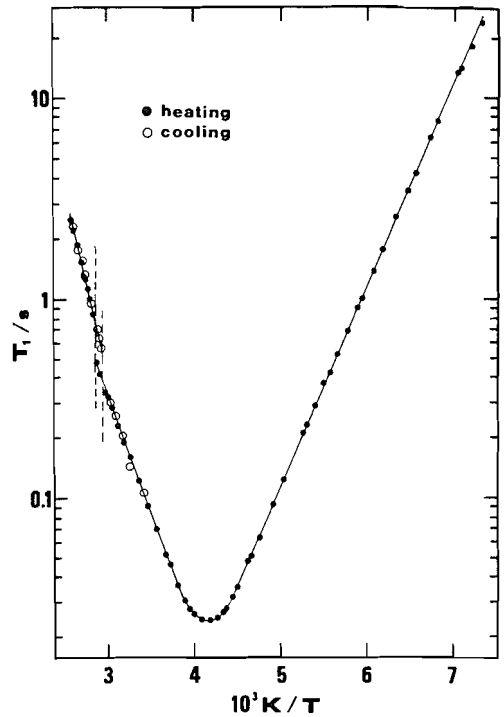

FIG. 2. Proton spin–lattice relaxation time versus reciprocal temperature. Heating (●), cooling (○).

weak absorption appears at 3593 cm^{-1} (Fig. 1). On cooling, this behaviour is reversed except that the temperature of the spectral changes exhibit a hysteresis similar to that observed in the dsc studies.

The sharp peaks observed in the vibrational spectra are consistent with the presence of an ordered phase at room temperature. Although it was not possible to confirm the eight molecules per unit cell given in the crystal structure report (1), the spectral splittings do indicate that there are several molecules per unit cell. Since one of the interests in the present study centered on the influence of hydrogen bonding on the properties of the solid phase, the FT-ir spectrum of the O—H stretching region was studied as a function of temperature. At room temperature, a broad absorption is observed at 3280 cm^{-1}, with shoulders located at 3360 and 3200 cm^{-1}. These correspond to the combination and hot band of the O—H and O···H vibrations. The latter can be evaluated to be about 80 cm^{-1} and may be observed in the Raman spectrum as a weak band at 77 cm^{-1}. The O—H frequency shifts to higher energy with increasing temperature, perhaps as a result of an increase in intensity of the hot band. Broad absorptions of medium intensity appear in the ir spectrum at 1453 and 1418 cm^{-1} and are assigned to O—H···O bending modes. In the vapour phase, the free molecule O—H stretching vibration occurs at 3637 cm^{-1} (10), shifting to 3606 cm^{-1} in dilute solution in carbon tetrachloride and 3595 cm^{-1} in carbon disulphide (11). From the appearance of the absorption at 3593 cm^{-1}, it is evident that free O—H groups are present in the disordered phase, but it is equally apparent that extensive hydrogen bonding persists.

The behaviour of the proton spin–lattice relaxation time with change of temperature is shown in Fig. 2. The T_1 measurements clearly show the phase transition and the hysteresis.

The spin–lattice relaxation time, assuming that dipolar relaxation is the dominant mechanism, is given by eq. [1]:

$$[1] \quad 1/T_1 = (2/3)C\tau\{1/(1 + \omega^2\tau^2) + 4/(1 + 4\omega^2\tau^2)\}$$

where T is the resonance frequency, C is a constant dependent on the change in the second moment produced by the motion, and $\tau = \tau_0 \exp(E/RT)$ is a correlation time for the molecular motion. The low-temperature phase showed a V-shaped curve, typical of relaxation by dipolar mechanism, with a minimum in the spin–lattice relaxation time at value of $\omega\tau \simeq 0.62$. Rotation of the adamantyl group about the molecular 3-fold axis is assumed to be responsible for relaxation in the low-temperature phase of 1-adamantanol because the contribution to the total relaxation rate arising from rotation of the single hydroxyl proton is small compared with the fifteen protons of the cage and the value of the minimum in T_1 is similar (28 ms, $C = 7.9 \times 10^9$ rad^2 s^{-2}) to those observed for other compounds in which rotation about the 3-fold axis is believed to occur (6, 12–14). The internal barrier to rotation of the hydroxyl group has been determined by Craven (15) from far-ir studies to be 4.8 kJ mol^{-1}, and the energy required to break the hydrogen bond can be estimated from the O—H stretching frequency to be about 26 kJ mol^{-1}. Thus, the barrier to hydroxyl group rotation probably exceeds 30 kJ mol^{-1}.

In fitting eq. [1] to the experimental data, it was apparent that the slopes of the reciprocal temperature plots on either side of the minimum were not the same and thus gave slightly different values for the activation energy, 19.7 and 21.5 kJ mol^{-1}. However, as the crystal structure does not indicate any asymmetric units in the unit cell, the difference in activation energies does not arise from non-equivalent molecules. Therefore, we do not attribute any great significance to the difference except that it might arise from a distribution in correlation times as the hydrogen bonding arrangements dictate slight changes in local molecular positions.

In the high-temperature phase, the correlation times are too short to give a minimum in T_1, $\omega\tau \ll 1$, and the relaxation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

time is inversely proportional to the correlation time. The activation energy for this phase was 35.0 kJ mol^{-1}. A comparison of barrier heights for various adamantane derivatives is given in Table 3. Note that the barrier in 1-adamantanol is quite low in the ordered phase, but highest in the disordered phase. Since no structural information exists for the disordered phase, we can only assume that the high entropy of transition indicates extensive disorder, but the evidence from the ir spectroscopic studies indicates that hydrogen bonding persists in the high-temperature phase. The residence times of certain molecular orientations are long compared with the vibrational time scale, while they may be short for the nmr scale. We assume that the measured barrier is that for isotropic rotation and, possibly, translational diffusion of 1-adamantanol molecules.

The conformational preference of methoxyl and acetoxyl groups in 3-oxycyclohexenes, 2-oxymethylenecyclohexanes, and 1-oxytetralins and the generalized anomeric effect[1]

ADAMA OUÉDRAOGO, MINH TAN PHAN VIET,[2] JOHN K. SAUNDERS,[3] AND JEAN LESSARD[4]

Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received December 22, 1986

This paper is dedicated to Professor John T. Edward

ADAMA OUÉDRAOGO, MINH TAN PHAN VIET, JOHN K. SAUNDERS, and JEAN LESSARD. Can. J. Chem. **65**, 1761 (1987).

The ^{13}C and ^{1}H nuclear magnetic resonance data of 3-oxycyclohexenes, 2-oxymethylenecyclohexanes, and 1-oxytetralins show (*i*) that the pseudoaxial preference is larger for the acetoxyl group than for the methoxyl group in 3-oxycyclohexenes, (*ii*) that the methoxyl and the acetoxyl groups have the same pseudoaxial preference in 1-oxytetralins, and (*iii*) that in 2-oxymethylenecyclohexanes, the acetoxyl group prefers the equatorial orientation whereas the methoxyl group prefers to be axial. These results are interpreted in terms of the orbital picture ($\pi-\sigma^*$ stabilization of the axial conformer) of the generalized anomeric effect to which is opposed a conformational effect termed the "unsaturation effect" in 2-acetoxymethylenecyclohexane and probably also, but to a much smaller extent, in 1-acetoxytetralin. The results also show that *cis* and *trans tert*-butyl analogues of 3-oxycyclohexenes do not represent the true limit conformers whereas *cis* and *trans* 4-*tert*-butyl derivatives of 2-oxymethylenecyclohexanes do not differ drastically from the limit conformers.

ADAMA OUÉDRAOGO, MINH TAN PHAN VIET, JOHN K. SAUNDERS et JEAN LESSARD. Can. J. Chem. **65**, 1761 (1987).

Les données de la résonance magnétique nucléaire du ^{13}C et du ^{1}H montrent (*i*) que la préférence pseudo-axiale d'un groupe acétoxyle est supérieure à celle d'un groupe méthoxyle dans les oxy-3 cyclohexenes, (*ii*) que les groupements méthoxyle et acétoxyle des oxy-1 tétralines ont la même préférence pseudo-axiale et (*iii*) que, dans les oxy-2 méthylènecyclohexanes, le groupement acétoxyle préfère l'orientation équatoriale tandis que le groupement méthoxyle préfère l'orientation axiale. Ces résultats sont interprétés en termes des interactions orbitalaires (stabilisation $\pi-\sigma^*$ du conformère axial) de l'effet anomère généralisé auquel s'oppose un autre effet appelé « effet d'insaturation » dans l'acétoxy-2 méthylènecyclohexane; cet effet serait présent aussi dans l'acétoxy-1 tétraline mais serait beaucoup moins fort. Les résultats montrent encore que les dérivés *tert*-butyles *cis* et *trans* ne représentent pas les vrais conformères des oxy-3 cyclohexènes alors que les dérivés *tert*-butyles en position 4 des oxy-2 méthylènecyclohexanes ne diffèrent pas trop des vrais conformères.

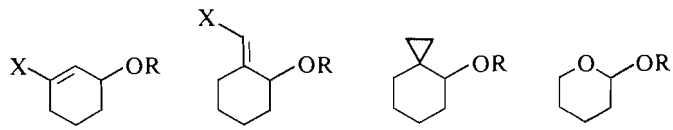
Introduction

We reported earlier (1) that the methoxyl group of 3-methoxycyclohexene (**1***a*, X = H) and 2-methoxymethylenecyclohexane (**2***a*, X = H) exists preferentially in the pseudoaxial or axial orientation. This preference is increased upon introducing an electron-donating group (X = phenyl, methoxyl) on the double bond and decreased upon introducing an electron-withdrawing group (X = cyano) (1–3). Glycenoses and alkenes having the general formula $RCH(OCH_3)CH{=}CHX$ (**3**) show an analogous conformational behaviour (4). These observations have been explained by a stereoelectronic effect, namely the $\pi-\sigma^*_{C-O}$ stabilization of the axial (or its equivalent) orientation of the methoxyl group (1–5). In 4-methoxyspiro[5.2]octane (**4***a*), a similar electronic interaction involving orbitals of the cyclopropane ring and the σ^*_{C-O} orbital has been suggested to account for the axial preference of the methoxyl group (6). The axial preference (or its equivalent) of the alkoxyl group in compounds **1***a*–**4***a* is analogous to the preference for the axial conformation in 2-methoxytetrahydropyran (**5***a*) (7–9)—the anomeric effect (10)—and to the general preference for the *gauche* conformation about a carbon–heteroatom bond in R—X—C—Y systems—the generalized anomeric effect (11, 12)—and constitutes a *further generalization* of the anomeric effect (1, 13). The anomeric effect has been explained both in terms of an $n-\sigma^*_{C-O}$ interaction stabilizing the axial (*gauche*) orientation (14–18) and in terms of electrostatic interactions destabilizing the equatorial (*anti*) orientation (19–21). The two types of interactions are most probably involved in the anomeric effect (22, 23). In compounds **1***a*–**4***a*, however, electrostatic interactions (e.g. dipole–quadrupole interactions) are probably less important than in 2-methoxytetrahydropyran (**5***a*) and in systems R—X—C—Y in general (1), and probably also less important than the orbital ($\pi-\sigma^*_{C-O}$) interaction (1).



1 **2** **4** **5**

a, R = CH_3; *b*, R = $COCH_3$

The preference for the pseudoaxial or axial orientation is larger for the acetoxyl group (R = $COCH_3$) than for the methoxyl group (R = CH_3) in 4-oxyspirooctanes (**4**) (6) and in 2-oxytetrahydropyrans (**5**) (9, 24), as expected from the orbital interaction picture of the generalized anomeric effect: larger $\pi-\sigma^*_{C-O}$ or $n-\sigma^*_{C-O}$ stabilization (overlap) of the axial conformer in the case of the acetoxyl group, which is more electron withdrawing and thus a better electron acceptor (σ^*_{C-O} lower in energy) than the methoxyl group (1, 6, ref. 13, p. 71).

To evaluate further how general is the generalized anomeric effect and to obtain more quantitative data on the conformational preference of 3-oxycyclohexenes **1**, we studied the 3-oxycyclohexenes **1** (X = H), **6**, and **7**, the 2-oxymethylenecyclohexanes **2** (X = H), and the 1-oxytetralins **8** by ^{1}H and ^{13}C nmr spectroscopy. The results (*i*) confirm the pseudoaxial preference of the oxygenated substituent in 3-oxycyclohexenes (**1**, X = H) and establish the larger pseudoaxial preference of

6 (*cis*) **7** (*trans*) **8**

a, R = CH_3; *b*, R = $COCH_3$

the acetoxyl group as compared to the methoxyl group. (*ii*) They emphasize further the fact that "model conformers" of cyclic compounds locked by a large *tert*-butyl group do not always represent the true limit conformers (26). (*iii*) They show that the *generalized anomeric effect is overrun by some other effect in 2-acetoxymethylenecyclohexane* (**2***b*, X = H), which prefers the equatorial conformation, but not in 2-acetoxytetralin (**8***b*), which exists preferentially as the axial conformer. (*iv*) In 1-oxytetralins **8**, however, the pseudoaxial preference of the acetoxyl group is similar to that of the methoxyl group.

Results and discussion

3-Oxycyclohexenes ***1*** *(X = H)*

The evidence for the pseudoaxial preference of the oxygenated substituent in 3-oxycyclohexenes **1***a* and **1***b* (X = H) comes from the chemical shift of C-5 (Table 1) and from the linewidth at half-height ($\Delta\nu_{1/2}$) of H-3 (Table 2) and has already been discussed (1). We want to emphasize here the larger pseudoaxial preference of the acetoxyl group (**1***b*, X = H) as compared to the methoxyl group (**1***a*, X = H). Indeed, C-5 is more shielded (Table 1) and $\Delta\nu_{1/2}$ is smaller (Table 2) for **1***b* than for **1***a*. Furthermore, the coupling constant $J_{H\text{-}2,H\text{-}3}$ is larger for **1***b* than for **1***a* (Table 2), showing that the dihedral angle between H-2 and H-3, $\Phi_{H\text{-}2,H\text{-}3}$, is smaller for **1***b*. From the Dreiding model of a 3-substituted cyclohexene, $\Phi_{H\text{-}2,H\text{-}3}$ is smaller in the pseudoaxial conformer (H-3 pseudoequatorial: $\Phi_{H\text{-}2,H\text{-}3} \simeq 40\text{–}45°$) than in the pseudoequatorial conformer (H-3 pseudoaxial: $\Phi_{H\text{-}2,H\text{-}3} \simeq 75\text{–}80°$).

Additional evidence for the greater pseudoaxial preference of the acetoxyl group is provided by the low-temperature dynamic ^1H nmr measurements on solutions of **1***a* and **1***b* (X = H) in a one-to-one (v/v) mixture of $CHFCl_2$ and CHF_2Cl down to 110 K.[5] The ^1H nmr spectrum of 3-methoxycyclohexene (**1***a*, X = H) at 100 MHz does show a coalescence of the H-3 proton between 125 and 120 K. At 110 K there are two broad and not fully resolved signals with the higher field one, corresponding to the pseudoequatorial conformer, being much smaller. The signals were too broad and the resolution too poor to allow a complete analysis of the spectrum. The approximate difference in chemical shifts ($\Delta\delta \simeq 3$ ppm) shows that the barrier to inversion should be lower than 27 kJ/mol and thus similar to the published values for other cyclohexene derivatives (27, 28). In the case of 3-acetoxycyclohexene (**2***b*, X = H), no coalescence could be detected down to 100 K presumably because there was essentially one conformer present, the pseudoaxial conformer. Again the signals were very broad at the lowest temperatures. Thus the pseudoaxial preference in 3-oxycyclohexenes **1** (X = H) is larger for the acetoxyl group than for the methoxyl group as in 4-oxyspirooctanes (**4**) (6) and in 2-oxytetrahydropyrans (**5**) (9, 24), and as predicted by the orbital picture of the generalized anomeric effect: a better $\pi\text{–}\sigma^*_{C\text{–}O}$ stabilization of the pseudoaxial orientation in the case of the more electron-withdrawing ($\sigma^*_{C\text{–}O}$ lower in energy) acetoxyl group.

[5]We are grateful to Professor C. H. Bushweller of the University of Vermont for carrying out the low-temperature ^1H nmr measurements.

As shown in Tables 1 and 2, we have studied the ^{13}C and ^1H nmr spectra of *cis* and *trans* 6-*tert*-butyl-3-oxycyclohexenes **6** and **7**. These compounds are expected to be conformationally rigid with the oxygen substituent pseudoaxial in the *cis* isomer **6** and pseudoequatorial in the *trans* isomer **7**. And indeed, C-5 is more shielded (Table 1), $\Delta\nu_{1/2}$ of H-3 is smaller, and $J_{H\text{-}2,H\text{-}3}$ is larger (Table 2) for *cis* **6** than for *trans* **7**. In Table 3 are listed pseudoaxial populations for the unsubstituted 3-oxycyclohexenes **1***a* and **1***b* (X = H) calculated from the nmr parameters of Tables 1 and 2. The ^{13}C chemical shifts of **6** and

	(ref. 1)[c]		CCl_4				77

[a]Calculated from $K_e = (\delta_{trans}-\delta)/(\delta-\delta_{cis})$ or $(J-J_{trans})/(J_{cis}-J)$, etc.

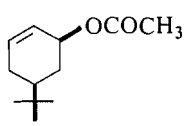
[b]The C-3 and C-5 chemical shifts of **6***a–c* and **7***a–c* were corrected for the effect of the *tert*-butyl group using the chemical shift differences between 3-*tert*-butylcyclohexene and cyclohexene: +0.7 ppm for C-3; −2.0 ppm for C-5.

[c]In ref. 1, $\Delta\nu_{1/2}$ for the pseudoequatorial conformer was estimated to be 17.0 Hz (close to the observed value for 5,5-dimethyl-3-oxycyclohexenes: 16.0 to 16.5 Hz) and 6.5 Hz for the pseudoaxial conformer. The $\Delta\nu_{1/2}$ values reported for **2***a* and **2***b* are 9.6 and 8.9 Hz respectively in CCl_4 (1).

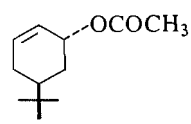
[d]The C-3 chemical shifts of **9** and **10** were taken from ref. 29. The authors used the chemical shift difference between *tert*-butylcyclohexane and cyclohexane (+0.1 ppm on C-3) as a correction for the effect of the *tert*-butyl group.

[e]Senda and Imaizumi (29) reported 68% based on a chemical shift of 69.08 ppm for C-3 of **1***b*. We found 68.2 ppm (see Table 2).

7 were corrected for the effect of the *tert*-butyl group by using the chemical shift differences between 3-*tert*-butylcyclohexene and cyclohexene (see Table 3, footnote *b*). The calculated pseudoaxial populations based on the C-3 chemical shifts of *cis* and *trans* 5-*tert*-butyl-3-acetoxycyclohexenes **9** and **10**



9 (*cis*)



10 (*trans*)

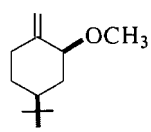
reported by Senda and Imaizumi (29)[6] and those based on the $\Delta\nu_{1/2}$ values reported in ref. 1 are also included in Table 3. It is clear from the scattered values of Table 3 that the influence of the *tert*-butyl group varies according to its position on the ring and depending on the nmr parameter used. The large *tert*-butyl substituent must have an effect on the ring geometry. This effect cannot be evaluated accurately and the use of a *tert*-butyl group to lock the conformation of a cyclohexene ring is inaccurate, if not invalid, as already stressed (26).

According to δ_{C-5} (Table 1) and $J_{H-2,H-3}$ (Table 2) for **1***a* and **1***b* (X = H), the polarity of the solvents seems to have little effect on the pseudoaxial preference of the methoxyl and the acetoxyl groups of 3-oxycyclohexenes. The methoxyl group appears to be more pseudoaxial in $CDCl_3$ (C-5 more shielded, $J_{H-2,H-3}$ larger) than in CCl_4. This could be accounted for by a stronger solvation of the methoxyl group in $CDCl_3$ since solvation should lower the energy of the σ^*_{C-O} orbital and lead to an increase of the stabilizing $\pi-\sigma^*_{C-O}$ interaction.

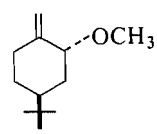
[6]Senda and Imaizumi (29) reported 69.08 ppm for the C-3 chemical shift of **1***b* (X = H) and calculated a pseudoaxial population of 68% from this chemical shift value and those of C-3 of **9** and **10**. We found 68.2 ppm for the C-3 chemical shift of **1***b* (Table 1) and the calculated pseudoaxial population becomes 88%.

2-Oxymethylenecyclohexanes **2** *(X = H)*[7]

The nmr data of Table 4 and the conformational equilibria obtained from them show clearly the axial preference of the methoxyl group in 2-methoxymethylenecyclohexane (**2***a*, X = H). The value of ΔG_{e-a} in CF_2Br_2, 1.4 kJ/mol, is close to the value reported previously, 1.7 kJ/mol, from which the generalized anomeric effect has been estimated at 3 kJ/mol (1). Using the ΣJ_{H-2} value of 7.6 Hz for **2***a* (X = H) in CCl_4 at 310 K (Table 5) and the ΣJ_{H-2} values for *cis* (**11**) and *trans* (**12**) 4-*tert*-butyl-3-methoxymethylenecyclohexanes of 15 and 5.5 Hz respectively, the axial preference of the methoxyl group in **2***a* (X = H) was estimated to be 78% (ΔG^0_{e-a} = 3.2 kJ/mol). Zefirov and Baranenkov (3) found exactly the same axial preference at ca. 300 K using a $\Delta\nu_{1/2}$ value of 8.4 Hz in CCl_4 and $\Delta\nu_{1/2}$ values of 17.6 Hz (axial conformer) and 5.8 Hz (equatorial conformer) obtained from the low temperature ^1H nmr spectrum of **2***a* (X = H) in CS_2. Thus it would appear that the *tert*-butyl derivatives **11** and **12** do represent adequately the



11 (*cis*)



12 (*trans*)

true limit conformers of **2***a* (X = H), contrary to the 3-oxycyclohexene case discussed in the previous section. However, a ΔG^0_{e-a} of 3.2 kJ/mol in CCl_4 appears to be large compared to the value of 1.4 kJ/mol in CF_2Br_2. The latter is also a nonpolar solvent although it is probably more polar than CCl_4, and the axial preference of **2***a* does decrease as the polarity of the solvent increases (see Tables 4 and 5, and the discussion

[7]This section is abstracted from the Ph.D. thesis of M. T. Phan Viet, Université de Sherbrooke, Sherbrooke (Québec), 1979. Some of the results appeared in a preliminary communication (24).

[a]CF_2Br_2 and $CHFCl_2$ designate a mixture of CF_2Br_2–CD_2Cl_2 80:20 or $CHFCl_2$–CD_2Cl_2 80:20 containing 2% TMS and 4% (w/v) of **2***a* and **2***b*.

[b]From 22.63-MHz spectra, relative to TMS, ±0.05 ppm.

[c]Calculated from $K_e = (\delta_{eq} - \delta)/(\delta - \delta_{ax})$.

[d]ΔG^0 was more or less constant over the temperature range studied (from 160 to 270 K) and $\overline{\Delta G^0_{e-a}}$ represents the mean value (±15%) from the various determinations of K_e.

[e]Due to the insolubility of **2***b* in CF_2Br_2, it was not possible to record its nmr spectrum in this solvent at low temperatures.

[f]No signal corresponding to the axial conformer could be detected. For the determination of K_e, we assumed that the γ-effect was the same as in 3-methoxycyclohexene (**1***a*, X = H): $\delta_{eq} - \delta_{ax}$ = 4.7 ppm for C-4; $\delta_{eq} - \delta_{ax}$ = 4.4 ppm for C-6.

below). We believe that the conformational equilibria determined from ^{13}C chemical shifts (Table 4) are more reliable than those obtained from the ^1H nmr data ($\Delta\nu_{1/2}$ or ΣJ_{H-3}).

The similarity of the conformational behaviour of 2-methoxymethylenecyclohexane (**2***a*, X = H) and of 3-methoxycyclohexene (**1***a*, X = H) (they both show a generalized anomeric effect, which is enhanced upon the introduction of a methoxyl group on the double bond (1)) cannot be extended to the acetoxyl derivatives **2***b* and **1***b* (X = H). Indeed, we have seen in the preceding section that 3-acetoxycyclohexene (**1***b*, X = H) shows a larger axial preference than 3-methoxycyclohexene (**1***a*, X = H) as expected from the orbital picture of the generalized anomeric effect. On the contrary, 2-acetoxymethylenecyclohexane (**2***b*, X = H) exists preferentially as the equatorial conformer: $\Delta G^0_{e-a} = -4.0$ kJ/mol in $CHFCl_2$.[8] This does not mean that the $\pi-\sigma^*_{C-O}$ interaction is absent in **2***b* (X = H). In fact, Zefirov and Baranenkov (30) reported that the proportion of axial conformer in CS_2 at ca. 300 K increases from 40% for **2***b* (X = H) to 53% for 2-trifluoroacetoxymethylenecyclohexane (**2**, X = H, R = $COCF_3$). We consider this as evidence in favor of the presence of a $\pi-\sigma^*_{C-O}$ interaction in the axial conformer of 2-acyloxymethylenecyclohexanes (**2**, X = H, R = COR'), the interaction being stronger with the more electronegative trifluoroacetoyl group (σ^*_{C-O} lower in energy) than with the acetoxyl group. *We conclude therefore that, in* **2**b *(X = H), the generalized anomeric effect is overcome by another effect, which has yet to be identified.* Since other oxygenated substituents in which the oxygen is directly attached to an unsaturated system (e.g. vinyloxyl, phenoxyl) also show a smaller axial preference in 2-oxymethylenecyclohexanes **2** (X = H) than do alkoxyl substituents, the effect was termed the "unsaturated effect" (24).

As seen from Tables 4 and 5, the axial preference of the methoxyl group in **2***a* (X = H) decreases with the polarity of the solvent: ΔG_{e-a} = 1.4 kJ/mol in CF_2Br_2 and 0.8 kJ/mol in $CHFCl_2$ (Table 4); ΣJ and $\Delta\nu_{1/2}$ for H-2 are larger (Δ = 0.5–0.6 Hz), C-4 and C-6 are less shielded (Δ = 0.5–0.6 ppm), in $CHCl_3$ than in CCl_4 (Table 5). This is contrary to what has been observed with 3-methoxycyclohexene (**1***a*, X = H) where the axial preference of the methoxyl group increases with the polarity of the solvent. The solvent effect is much larger for **2***a* than for **1***a* and, if the small effect in the case of **1***a* is real, it would even be in the opposite direction. This could be explained if electrostatic interactions are more important in **2***a* than in **1***a* and destabilize the equatorial orientation (1). Then, these electrostatic interactions would be less important in a more polar solvent. The solvent effect is less pronounced in the case of 2-acetoxymethylenecyclohexane (**2***b*, X = H) ($\Delta\Delta\nu_{1/2}$ = 0.2 Hz; Δδ (C-4 and C-6) = 0.2 ppm) because the electrostatic interactions could be less important and (or) the solvation

[8]We were unable to record the ^{13}C nmr spectrum of **2***b* (X = H) in CF_2Br_2 at low temperature because of insolubility problems (see Table 4, footnote *e*).

weaker with the less basic acetoxyl group than with the methoxyl group.

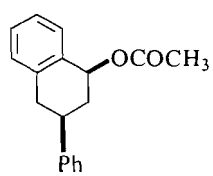
1-Oxytetralins 8

The 1-oxytetralins **8** have an oxygenated substituent adjacent to an sp^2 alicyclic ring carbon, as do the 3-oxycyclohexenes **1** and the 2-oxymethylenecyclohexanes **2**. They resemble 3-oxycyclohexenes **1** in having two adjacent sp^2 carbons in the alicyclic ring[9] but at the same time they also bear some resemblance to 2-oxymethylenecyclohexanes **2** in having an exocyclic double bond. So we studied the 1-oxytetralins **8***a* and **8***b* to see if the generalized anomeric effect and the "unsaturation effect" (smaller axial preference of the acetoxyl group when compared to the methoxyl group) were operating on their conformational behaviour.

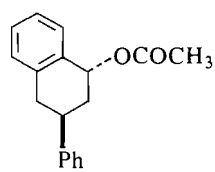
The ^{13}C nmr spectra of **8***a* and **8***b* at 100.62 MHz in CF_2Br_2 and $CHFCl_2$ showed no change with temperature down to 151 K. Thus either the barrier to inversion is lower than 30 kJ/mol and therefore similar to that of 3-methoxycyclohexene (**1***a*, X = H) ($\Delta G^{\ddagger} \leq 27$ kJ/mol) rather than similar to that of 3-methoxymethylenecyclohexane (**2***a*, X = H) ($\Delta G^{\ddagger} = 37$ kJ/mol) (1), or there is essentially one conformer present.

The nmr data of Table 6 show clearly the axial preference of the oxygenated substituent in **8***a* and **8***b*. Indeed, the signal of H-1 is a relatively narrow triplet ($J \approx 2.4$–4.6 Hz) implying that H-1 is essentially pseudoequatorial.[10] Thus the generalized anomeric effect is operating also in 1-oxytetralins **8**.

As seen from the $\Sigma J_{H\text{-}1}$ values of Table 6, the acetoxyl group of *cis* 1-acetoxy-3-phenyltetralin (**13**) is clearly pseudoequatorial (H-1 pseudoaxial: doublet of a doublet, J = 6.5 and 11 Hz) and that of the *trans* isomer **14**, pseudoaxial (H-1



13 (*cis*)



14 (*trans*)

pseudoequatorial: triplet J = 3.5 Hz) (34). Assuming that the phenyl group is nearly 100% pseudoequatorial and does not introduce any distortion in the ring, the pseudoaxial preference of the acetoxyl group of **8***b* in $CDCl_3$ would be ≤87%.

[9]The conformation of the alicyclic ring of tetralin is a half-chair as in cyclohexene (31, 32).

[10]Yamaguchi *et al.* (33) report 4.0 Hz for $J_{H\text{-}1}$ of **8***b* in $CDCl_3$. We obtained 4.2 Hz (see Experimental).

TABLE 6. C-3 chemical shift of 1-oxytetralins **8** and $\Sigma J_{H\text{-}1}$ of **8**, **13**, and **14**

No.	OR	Solvent	$\Sigma J_{H\text{-}1}$[a] (Hz)	$\delta_{C\text{-}3}$[b] (ppm)	$\delta_{C\text{-}5}$ of **1** (X = H)[b] (ppm)

[c]CCl_4 = CCl_4–CD_3COCD_3 90:10.
[d]Mixtures of CF_3Br_2 ($CHFCl_2$)–CD_2Cl_2 80:20.
[e]Taken from ref. 34.

The C-3 chemical shift of **8***a* is about the same as that of **8***b* in a given solvent at a given temperature (Table 6). Thus, in 1-oxytetralins, **8**, the methoxyl group and the acetoxyl group have nearly the same axial preference. The narrower $\Sigma J_{H\text{-}1}$ for **8***b* is probably due, at least in part, to an electronegativity effect on the vicinal coupling constants (35).

The C-5 chemical shifts for 3-methoxycyclohexene (**1***a*, X = H) and 3-acetoxycyclohexene (**1***b*, X = H) are also included in Table 6 for comparison purposes and they are quite similar to the C-3 chemical shifts of **8***a* and **8***b*. This similitude reflects the similarity in structure of tetralins and cyclohexenes[9] and the pseudoaxial preference of the oxygenated substituent in both structures. However, there is a slight difference in the conformational behaviour of 1-oxytetralins **8** and 3-oxycyclohexenes **1** (X = H). In the latter, the axial preference of the acetoxyl group is greater than that of the methoxyl group but the two substituents have the same axial preference in the former. The "unsaturation effect" could be responsible for this small difference in the conformational behaviour of **8** and **1**. But, obviously, this effect would be much smaller in the 1-oxytetralins **8** than it is in the 2-oxymethylenecyclohexanes **2** (X = H). Judging from the C-3 chemical shifts of Table 6, the solvent effect ($CDCl_3$ vs. CCl_4, $CHFCl_2$ vs. CF_2Br_2) on the axial preference in 1-oxytetralins **8** is small, as in 3-oxycyclohexenes **1** (X = H).

Conclusion

The results of this paper confirm that the generalized anomeric effect is operating in allylic ethers like 3-methoxycyclohexene (**1***a*, X = H) and 2-methoxymethylenecyclohexane (**2***a*, X = H) and show that it is operating in benzylic ethers such as 1-methoxytetralin (**8***a*). The methoxyl group prefers the axial or pseudoaxial orientation as a result of π–σ^*_{C-O}

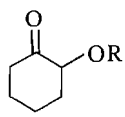
stabilization although a contribution from electrostatic interactions (e.g. dipole–quadrupole destabilizing the equatorial orientation) cannot be excluded (1). The pseudoaxial preference of the acetoxyl group is larger than that of the methoxyl group in the 3-oxycyclohexene series, as expected from a stronger $\pi-\sigma^*_{C-O}$ interaction in the case of the acetoxyl group (σ^*_{C-O} lower in energy). However, in 2-acetoxymethylenecyclohexane (**2***b*, X = H) where the equatorial conformer largely predominates (~80% at ca. 0°C), the generalized anomeric effect is overrun by another effect termed the "unsaturation effect." This effect might be operating to a small extent in 1-acetoxytetralin (**8***b*) where the axial preference is the same as in 1-methoxytetralin (**8***a*). In the seven-membered ring analogues of 1-oxytetralins **8**, 3-oxybenzocycloheptenes, the acetoxyl group has a smaller preference for the axial orientation than does the methoxyl group, probably as a result of the "unsaturation effect" playing against the generalized anomeric effect.[11]

tert-Butyl analogues of 3-oxycyclohexenes **1** cannot be used as models for the limit conformers because of distortions introduced in the cyclohexene ring, whereas in 4-*tert*-butyl analogues of 2-oxymethylenecyclohexanes **2** the ring does not appear to be seriously distorted.

It is interesting to compare the 2-oxymethylenecyclohexanes **2** (X = H) with the analogous 2-oxycyclohexanones **15**. The latter resemble 2-oxymethylenecyclohexanes **2** (X = H) in having an exocyclic double bond although they are quite different from **2** because a carbonyl group is strongly polarized and its π and π^* orbitals are much lower in energy than those of an exomethylene group. Nevertheless, the conformational behaviour of **2** (X = H) and **15** shows some similarity. In both structures, the methoxyl group prefers the axial orientation (~76% for **2***a* (X = H) and 63% for **15***a* (36) at ca. 300 K in CCl_4) and the acetoxyl group prefers the equatorial orientation (~65% for **2***b* (X = H) and ≤100% for **15***b* (37) at ca. 300 K),



15 *a*, R = CH_3; *b*, R = $COCH_3$

although not to the same extent. The axial preference of the methoxyl group in **15***a* cannot be explained by a $\pi_{C=O}-\sigma^*_{C-O}$ interaction because of the low energy of the $\pi_{C=O}$ orbital.[12] But it can be explained in terms of a $\sigma_{C-O}-\sigma^*_{C=O}$ (38, 39) or an $n-\pi^*_{C=O}$ (40) interaction as proposed for 2-halogenocyclohexanones.[13] Such interactions would be less important in 2-acetoxycyclohexanone (**15***b*) because the energy of the σ_{C-O} and *n* orbitals should be lower in an acetoxyl group than in a methoxyl group. However, other effects (the "unsaturation effect" (?)) are probably operating in the strong equatorial preference of the acetoxyl group of **15***b*.

Experimental

Melting points were determined on a Buchi apparatus and are uncorrected. Infrared spectra were taken on a Perkin–Elmer 257 spectrometer. Mass spectra were recorded on a Hitachi RMU-6E or a VG-ZAB-1F spectrometer. Vapor phase chromatographic analyses were performed on a Hewlett Packard chromatograph, model 5710, equipped with a flame ionization detector using an OV-101 (dimethylsilicone on Carbowax 20 M) quartz column 12 m long. Preparative vapor phase chromatography was carried out on a Varian Aerograph chromatograph, model 2800, equipped with a thermal conductivity detector: OS-138 (10% polyphenylether on Chromosorb W) column with o.d. 0.125 in. and length 6 ft. Flash column chromatography was done on Merck silica gel 60 (230–400 mesh). Merck silica gel $60F_{254}$ was used for thin (0.25 mm) and preparative (1–2 mm) layer chromatography.

Nuclear magnetic resonance spectra

Routine proton spectra were obtained on a Varian A-60 spectrometer or a Bruker WP-60 Fourier transform spectrometer in deuterochloroform (solutions approximately 0.4 *M*) using TMS as internal standard. The linewidths and (or) coupling constants were determined on a Bruker HX-90 or WM-250 Fourier transform spectrometer. The temperature, solvent, and concentration are given in Tables 2, 5, and 6.

For carbon-13 spectra, TMS was used as internal standard. They were recorded on a Bruker HX-90 or WM-250 Fourier transform spectrometer. Variable temperature and low temperature data were obtained with a Bruker HX-90 (±3 K, see ref. 1) or Bruker WM-400 (±1 K, control unit BVT 1000 calibrated with methanol) Fourier transform spectrometer. The temperature, solvent, and concentration are indicated in Tables 1, 4, 5, and 6.

Materials

Compounds not commercially available were prepared either as described in the literature or by standard procedures. All compounds were pure (>98%) according to vpc analyses unless otherwise stated.

The preparation of 3-methoxycyclohexene (**1***a*, X = H), 3-acetoxycyclohexene (**1***b*, X = H), and 2-methoxymethylenecyclohexane (**2***a*, X = H) has already been described (1).

*2-Acetoxymethylenecyclohexane (***2**b, *X = H)*

2-Hydroxymethylenecyclohexane (see ref. 1) (1.12 g, 7.27×10^{-3} mol) was stirred overnight in acetic acid (5 mL) containing sodium acetate (0.4 g). The usual work-up followed by microdistillation (85°C/25 Torr; 1 Torr = 133.3 Pa) gave **2***b* (X = H) (1.45 g, 90%); ir (CCl_4) ν_{max}: 1750, 1657, 1360, and 1228 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.4–2.4 (8H), 2.09 (s, CH_3CO), 4.80 (m, 2H-7), 5.20 (m, H-2) ppm; ^{13}Cmr ($CDCl_3$) δ: 21.2 (CH_3CO), 23.4 (C-4), 27.6 (C-5), 33.4 and 33.5 (C-6 and C-3), 74.3 (C-2), 107.2 (C-7), 146.6 (C-1), 170.0 (C=O) ppm; *m/e*: 154 (M^+).

cis *and* trans *4-*tert*-Butylcyclohexene-1-ols*

These were prepared from 4-*tert*-butylcyclohexanone according to a published procedure (25). The 29:71 mixture of *cis* and *trans* isomers (85% yield, mp 40.5–43°C) was separated by flash column chromatography (hexane and ethyl acetate – hexane mixtures as eluent) to yield the pure isomers, which were recrystallized from pentane. *Cis* isomer: mp 54.5–55°C (lit. (5) mp 51–54°C). *Trans* isomer: mp 37–38°C (lit. (5) mp 32–34°C).

cis *6-*tert*-Butyl-3-methoxycyclohexene (***6**a)*

cis 4-*tert*-Butylcyclohexen-1-ol (0.144 g, 0.94×10^{-3} mol) was methylated (5) to give **6***a* (0.105 g, 57%) after purification by preparative layer chromatography on silica gel; ir ($CHCl_3$) ν_{max}: 1070 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.90 (s, 9H), 1.50 (m, H-5), 1.75 (m, H-4), 1.9–2.1 (m, H-6), 3.40 (s, CH_3O), 3.55 (m, H-3), 5.85 (br d, *J* = 10.2 Hz, H-2), 5.95 (d of t, *J* = 10.2 and 1.5 Hz, H-1) ppm; ^{13}Cmr ($CDCl_3$) δ: 19.0 (C-5), 27.2 (C-4), 27.4 and 32.7 (*tert*-butyl), 46.5 (C-6), 56.1 (OCH_3), 72.2 (C-3), 126.9 (C-1), 134.3 (C-2) ppm; *m/e*: 168 (M^+).

trans *6-*tert*-Butyl-3-methoxycyclohexene (***7**a)*

trans 4-*tert*-Butylcyclohexen-1-ol (1.04 g, 6.76×10^{-3} mol) was methylated (5) to give **6***b* (0.496 g, 44%) after microdistillation (90–

[11]M. St-Jacques, unpublished results. We thank professor Maurice St-Jacques for communicating these results to us.

[12]The energy of the π orbital of formaldehyde is lower than that of ethylene by 3.58 eV according to photoelectron spectroscopy (37).

[13]We have shown (2) that such interactions are not involved in 2-methoxymethylenecyclohexanes (**2***a*, X = OCH_3, H, CN) as expected from the fact that a $\pi^*_{C=C}$ orbital is higher in energy than a $\pi^*_{C=O}$ orbital.

For personal use only.

105°C/15 Torr); ir ($CHCl_3$) ν_{max}: 1090 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.90 (s, 9H), 1.2–1.5 (m, H-2), 1.90 (m, H-4), 2.15 (m, H-6), 3.40 (s, OCH_3), 3.75 (m, H-3), 5.7–5.8 (m, H-1 and H-2) ppm; ^{13}Cmr ($CDCl_3$) δ: 22.7 (C-5), 29.2 (C-4), 27.2 and 32.9 (*tert*-butyl), 46.3 (C-6), 53.4 (OCH_3), 76.2 (C-3), 129.6 (C-1), 131.6 (C-2) ppm; *m/e*: 168 (M^+).

cis 6-tert-*Butyl-3-acetoxycyclohexene (6b)*

cis 4-*tert*-Butylcyclohexen-1-ol (0.306 g, 1.99 × 10^{-1} mol) was acetylated at ca. 0°C (ice bath) with acetyl chloride (0.22 mL, 3.1 × 10^{-3} mol) in dry ether (4 mL) containing pyridine (0.28 mL, 3.48 × 10^{-3} mol) for 90 min. The reaction mixture was stirred at room temperature for 5 h. The usual work-up followed by preparative layer chromatography (ethyl acetate – hexane) gave **6***b* (0.37 g, 95%); ir ($CHCl_3$) ν_{max}: 1720 and 1250 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.90 (s, 9H), 1.40 (m, H-5), 1.90 (m, H-4), 2.00 (s, CH_3CO), 2.15 (m, H-6), 5.10 (br s, H-3), 5.85 (br d, J = 10.2 Hz, H-2), 6.05 (d, J = 10.1 Hz, H-1) ppm; ^{13}Cmr ($CDCl_3$) δ: 19.2 (C-5), 21.4 (CH_3CO), 28.4 (C-4), 27.4 and 32.7 (*tert*-butyl), 46.2 (C-6), 66.5 (C-3), 125.9 (C-1), 135.9 (C-2), 170.8 (C=O) ppm; *m/e*: 196 (M^+).

trans 6-tert-*Butyl-3-acetoxycyclohexene (7*b)

trans 4-*tert*-Butylcyclohexen-1-ol (0.905 g, 5.88 × 10^{-3} mol) was acetylated as above to give **7***b* (1.15 g, 88%) after flash chromatography (ethyl acetate – hexane); bp 88–91°C/6 Torr; ir ($CHCl_3$) ν_{max}: 1720 and 1250 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.90 (s, 9H), 1.40 (m, H-5), 1.7–2.0 (m, H-4), 2.10 (s, CH_3CO), 2.15 (m, H-6), 5.25 (m, H-3), 5.60 (br d, J = 10.6 Hz), 5.80 (d of q, J = 10.4 and 1.8 Hz) ppm; ^{13}Cmr ($CDCl_3$) δ: 21.4 (CH_3CO), 22.6 (C-5), 28.9 (C-4), 27.2 and 32.9 (*tert*-butyl), 45.9 (C-6), 70.5 (C-3), 128.1 (C-1), 133.0 (C-2), 170.9 (C=O) ppm; *m/e*: 196 (M^+). *Exact Mass* calcd. for $C_{12}H_{20}O_2$: 196.1463; found (ms): 196.1466.

*1-Methoxytetralin (8*a)

α-Tetralol (3.15 g, 0.02 mol) was treated with NaH, then with CH_3I in THF at 0°C (25), to give, after extraction with CH_2Cl_2, the methoxyl derivative **8***a* as a liquid (3.32 g, 96%). Flash chromatography and preparative layer chromatography on silica gel, and distillation (bp 94°C/4 Torr) did not improve the purity (96% by vpc); ir ($CHCl_3$) ν_{max}: 1600, 1495, 1080 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.7–2.1 (H-2 and H-3), 2.7–2.9 (m, H-4), 3.40 (s, OCH_3), 4.30 (t, J = 4.5 Hz, H-1), 7.1–7.2 (H-5, H-6, and H-7), 7.35 (m, H-8) ppm; ^{13}Cmr ($CDCl_3$) δ: 18.8 (C-3), 27.5 (C-4), 29.1 (C-2), 56.1 (OCH_3), 76.9 (C-1), 125.7, 127.6, 129.0, 129.3 (C-5, C-6, C-7, C-8), 136.7 (C-10), 137.6 (C-9) ppm; *m/e*: 162 (M^+). *Exact Mass* calcd. for $C_{11}H_{14}O$: 162.1044; found: 162.1032.

*1-Acetoxytetralin (8*b)

α-Tetralol (2.08 g, 0.014 mol) was acetylated as described for **6***b* above to give **8***b* as a liquid (2.56 g, 96% yield). It was purified by preparative layer chromatography (ether–benzene); ir ($CHCl_3$) ν_{max}: 1720, 1600, 1495, 1370, 1240 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.8–2.0 (H-2 and H-3), 2.10 (s, CH_3CO), 2.7–2.9 (m, H-4), 6.00 (t, J = 4.2 Hz, H-1), 7.1–7.3 (4 aromatic H) ppm; ^{13}Cmr ($CDCl_3$) δ: 18.9 (C-3), 21.4 (CH_3CO), 29.0 (C-4), 29.2 (C-2), 70.2 (C-1), 126.2, 128.1, 129.1, 129.5 (C-5, C-6, C-7, C-8), 134.7 (C-10), 138.0 (C-9), 170.8 (C=O) ppm; *m/e*: 190 (M^+). *Exact Mass* calcd. for $C_{12}H_{14}O_2$: 190.0993; found: 190.0996.

cis *and* trans *4-*tert*-Butyl-2-acetoxymethylene cyclohexanes (11 and 12)*

A mixture of *cis* and *trans* 4-*tert*-butyl-2-acetoxycyclohexanones was prepared as described in ref. 36. In a 250-mL three-necked flask, dry methyltriphenylphosphonium bromide (15.0 g, 0.042 mol) was suspended in dry THF (55 mL). The suspension was cooled to 0°C (ice bath), *n*-butyllithium 1.6 *M* in hexane (0.045 mol) was added, and the mixture was stirred at room temperature for 30 min. It was cooled to 0°C and the mixture of 4-*tert*-butyl-2-acetoxycyclohexanones (3.80 g, 0.02 mol) in dry THF (20 mL) was added dropwise. The reaction mixture was stirred at room temperature overnight, refluxed for 1 h, then concentrated in a rotatory evaporator. Pentane (150 mL) was added and the precipitate was filtered and washed with ether, then with a pentane–THF mixture. The resulting solution was passed through basic alumina (activity 1) and concentrated. Upon addition of pentane, a precipitate was formed again and was removed by filtration. Evaporation of the solvent gave a liquid mixture of **11** and **12** (3.09 g, 85%), which was separated by vpc.

11: ir (CCl_4) ν_{max}: 1650, 1360, 1130, 1110, 1077, 890 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.87 (s, 9H), 1.4–2.4 (8H), 3.46 (s, OCH_3), 3.60 (m, H-2), 4.70–4.90 (m, 2H-7) ppm; ^{13}Cmr ($CDCl_3$) δ: 27.6 and 32.0 (*tert*-butyl), 29.0 (C-5), 34.2 (C-6), 35.7 (C-3), 47.1 (C-4), 57.4 (OCH_3), 82.1 (C-2), 103.8 (C-7), 148.9 (C-1) ppm; *m/e*: 182 (M^+).

12: ir (CCl_4) ν_{max}: 1648, 1360, 1100, 1080, 1070, 895 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.85 (s, 9H), 1.2–2.4 (8H), 3.19 (s, CH_3O), 3.71 (br t, J = 2.7 Hz, H-2), 4.75–4.90 (m, 2H-7) ppm; ^{13}Cmr ($CDCl_3$) δ: 27.5 and 32.0 (*tert*-butyl), 28.6 (C-5), 30.5 (C-6), 34.3 (C-3), 41.0 (C-4), 55.2 (OCH_3), 81.6 (C-2), 110.6 (C-7), 147.7 (C-1); *m/e*: 182 (M^+).

A carbon-13 nuclear magnetic resonance study of the basicities of aliphatic alcohols

DONALD G. LEE AND KENNETH J. DEMCHUK
Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received October 4, 1986

This paper is dedicated to Professor John T. Edward

DONALD G. LEE and KENNETH J. DEMCHUK. Can. J. Chem. **65**, 1769 (1987).

Carbon-13 nmr chemical shifts have been used to determine the basicity constants for nine alcohols. The method involves comparing the chemical shifts for carbon atoms adjacent to the site of protonation with those for carbon atoms in a more remote position. The differences in the chemical shifts (Δ values) at different acidities are then used to calculate basicity constants for the alcohols. The pK_{BH^+} values, determined by use of the "X function" are as follows: ethanol −2.12, 1-propanol −2.12, 3-chloro-1-propanol −2.24, 2-chloroethanol −2.45, 2-bromoethanol −2.41, 2-nitroethanol −2.09, 2-methoxyethanol −1.93, 2-phenoxyethanol −1.87, and 2-propanol −2.06. The typical slope parameter, m^*, is 0.17. Two linear free energy correlations are obtained: when the alcohols are considered to be a series of monosubstituted ethanols, the Hammett plot has a slope of 0.65; when they are considered to be a series of mono- and disubstituted methanols, the slope is 1.7. Alcohols bearing oxygen-containing substituents are more basic than predicted by about 0.5 pK units, presumably because their conjugate acids can be stabilized by intramolecular hydrogen bonding.

DONALD G. LEE et KENNETH J. DEMCHUK. Can. J. Chem. **65**, 1769 (1987).

On a utilisé les déplacements chimiques de la rmn du ^{13}C pour déterminer les constantes de basicité de neuf alcools. La méthode implique une comparaison des déplacements chimiques des atomes de carbones adjacents au site de protonation avec ceux des atomes de carbones dans des positions plus éloignées. On utilise alors les différences dans les déplacements chimiques (valeurs Δ) à différentes acidités pour calculer les constantes de basicité des alcools. Les valeurs de pK_{BH^+}, déterminées en utilisant la « fonction X », sont: éthanol, −2,12; propanol-1, −2,12; chloro-3 propanol-1, −2,24; chloro-2 éthanol, −2,45; bromo-2 éthanol, −2,41; nitro-2 éthanol, −2,09; méthoxy-2 éthanol, −1,93; phénoxy-2 éthanol, −1,87 et propanol-2 −2,06. Le paramètre typique de la pente, m^*, est 0,17. On obtient deux corrélations linéaires d'énergie libre; lorsque les alcools sont considérés comme une série d'éthanols monosubstitués, la pente de la courbe de Hammett est égale à 0,65; lorsqu'on les considère comme une série de méthanols mono- ou disubstitués, la pente est égale à 1,7. Les alcools portant des oxygènes contenant des substituants sont plus basiques que les valeurs prédites, par environ 0,5 unités de pK; ce résultat est probablement dû au fait que leurs acides conjugués peuvent être stabilisés par des liaisons hydrogènes intramoléculaires.

Introduction

A quantitative knowledge of the basicity of organic compounds is essential to an understanding of a myriad of acid-catalyzed reactions (1). As a consequence, numerous attempts have been made to develop methods to accurately determine equilibrium constants for the dissociation of the conjugate acids of various organic bases, B, as in reaction [1]. The pK_{BH^+} values, defined by eq. [3], may then be obtained if the terms on the right can be defined. The first of these can be obtained if it is possible to determine the ionization ratio, $I = [BH^+]/[B]$, experimentally — a measurement that is usually

[1] $$BH^+ \overset{K_{BH^+}}{\rightleftharpoons} B + H^+$$

[2] $$K_{BH^+} = a_B a_{H^+}/a_{BH^+}$$

[3] $$pK_{BH^+} = \log [BH^+]/[B] - \log [H^+] - \log \gamma_B\gamma_{H^+}/\gamma_{BH^+}$$

accomplished by employing some form of spectroscopy. For example, absorbances have been used to obtain ionization ratios for a variety of compounds that contain uv/vis-active chromophores (2–4).

Nuclear magnetic resonance is more appropriate for use with aliphatic compounds which lack chromophores (5–15). Furthermore, Edward has noted that medium effects on the absolute chemical shifts may be cancelled by using the difference between the shifts for two nuclei in the same molecule (16). In the present work, carbon-13 nuclear magnetic shifts were used to estimate the extent of protonation of a number of aliphatic alcohols. Since the chemical shift differences for a partly protonated compound, Δ, is a weighted average of the chemical shift for the neutral molecule, Δ_B, and its conjugate acid, Δ_{BH^+}, the ionization ratio is given by eq. [4], and the first term in eq. [3] is thereby obtained.

[4] $$I = (\Delta - \Delta_B)/(\Delta_{BH^+} - \Delta)$$

The third term on the right of eq. [3] has been called the "excess acidity," because it is the difference between the observed acidity of a solution and that which it would have if it were ideal (17, 18). Various approaches have been made to an evaluation of this term, with the most successful being that of Cox and Yates who defined an average acidity function, X, and included a slope parameter, m^*, to account for the observation that the activity coefficient ratios for most compounds are linearly related (19). Equation [3] can then be restated as in eq. [5], the form in which it is most commonly used.

[5] $$\log I - \log [H^+] = m^*X + pK_{BH^+}$$

Plots of ($\log I - \log [H^+]$) against the X function are consequently expected to be linear with a slope of m^* and an intercept of pK_{BH^+}.

Experimental

Materials

Certified reagent grade sulfuric acid (Fisher) was used to prepare the acidic solutions. Stock sulfuric acid, which had been titrated with a standard sodium hydroxide solution, was determined to be 95.90 wt.% H_2SO_4. The concentration of sulfuric acid in each of the solutions was calculated using this value and confirmed by titration.

All alcohols were reagent grade and were used as received without further purification.

Collection of nmr spectra

Carbon-13 nuclear magnetic resonance spectra were obtained using

a Bruker HX-90 spectrometer operating in the Fourier transform, proton noise decoupled mode at 22.63 MHz. In all cases, 8K of data were collected using a Nicolet 1080 series computer. The fluorine field lock signal was obtained from hexafluorobenzene in a coaxial insert of a 10 mm nmr tube. Tetramethylsilane was added to the locking compound for a spectrum reference. All spectra were recorded using a 3000 Hz sweep width, giving 2.7 data points per hertz resolution.

In a typical procedure, a 1.0 mL glass syringe was used to transfer a 0.20 mL aliquot of an alcohol to a clean dry 5.0 mL volumetric flask. The flask was then made up to volume at room temperature with an acid solution of known concentration. The nmr spectrum of the solution was obtained at a probe temperature of 22°C immediately after preparation. To obtain a reasonable spectrum in the shortest time, approximately 200 to 1000 scans were collected. The maximum time between sample preparation and the completion of data acquisition was approximately 30 min.

The procedure was then repeated using acid solutions with different concentrations.

Results

During the collection of the spectra for each alcohol, a phenomenon similar to that reported by McClelland and Reynolds (12) was observed; in stronger acid solutions, less time was required to obtain a good spectrum. It has been suggested that this is due to the shortened spin–lattice relaxation times in the more viscous sulfuric acid solutions.

Similar changes in the carbon-13 chemical shifts were observed for all alcohols as the concentrations of the sulfuric acid solutions increased. These changes were relatively small and regular. The carbon attached to the hydroxylic oxygen always shifted to lower and lower fields as the sulfuric acid concentrations increased. This indicated that the electron density at the carbon atom decreases as the extent of oxygen protonation increases.

The carbon β to the oxygen usually moved to slightly higher fields as the concentration of the acid solution was increased. This could possibly be the result of a solvent effect or an alternating resonance effect associated with the protonated oxygen (12). Since only chemical shift differences were used in subsequent calculations, the absolute magnitude of the shifts

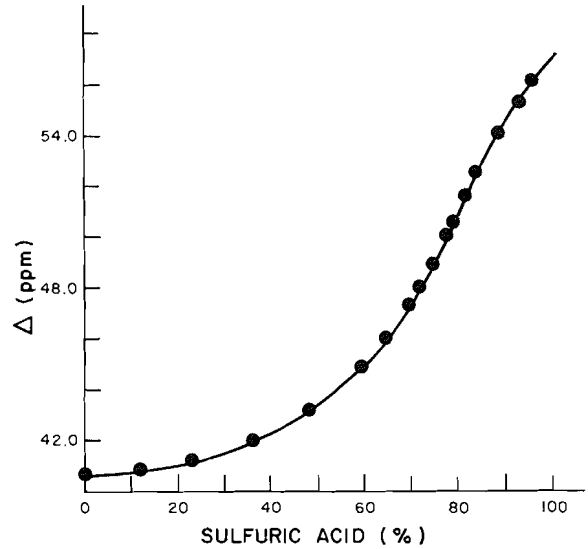

FIG. 1. Titration curve for the protonation of ethanol.

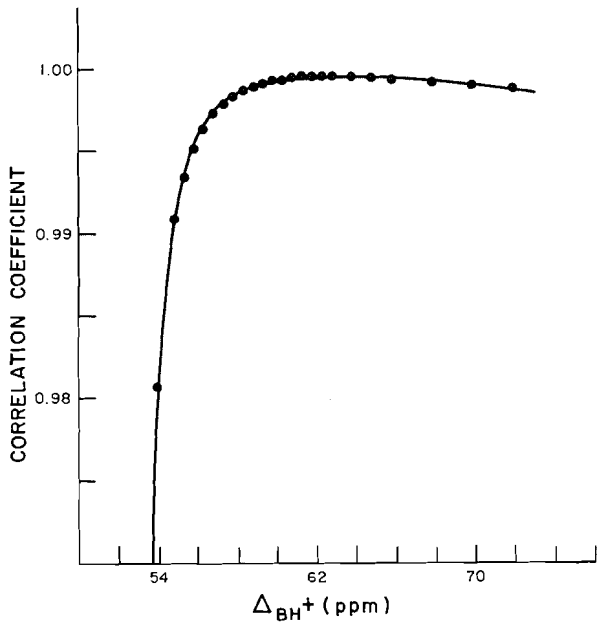

FIG. 2. Correlation coefficients of the X-function plot (eq. [4]) as a function of Δ_{BH^+} for the protonation of ethanol.

(relative to TMS) is not important. For all of the alcohols studied, the absolute value of the change in the shift of the α-carbon was always larger than the accompanying change in the β-carbon shift. Therefore, the chemical shift difference between these two, Δ, was found to become more positive with increasing sulfuric acid concentration.

Another phenomenon observed with all of the alcohols was esterification in concentrated sulfuric acid solutions. The tendency of alcohols to produce sulfate esters in highly concentrated sulfuric acid was first reported by Edward and co-workers (16) and later by Lee and Cameron (5). Although the appearance of sulfate ester proton nmr peaks interferes with the measurement of hydrogen-1 chemical shifts, such spectral interference is not a problem when carbon-13 nmr is used to monitor the extent of protonation. Carbon-13 signals for the sulfate esters were observed to be significantly different from those of the protonated alcohols. In very concentrated sulfuric acid solutions, only peaks for the sulfate esters could be found.

The extent of protonation in each solution was monitored by calculating the difference in the chemical shifts of the α and β carbons. This difference increases as the acidity of the solutions increases, and a plot of Δ vs. % H_2SO_4 produces, in theory, a titration curve from which the pK_{BH^+} can subsequently be obtained. A typical example of the complete carbon-13 data for one alcohol, ethanol, is presented in Table 1 and the data for the other alcohols are summarized in Table 2.

When the data for ethanol is plotted, as in Fig. 1, it is apparent that the upper plateau of the titration curve is not defined; i.e., Δ values for the fully protonated alcohol (Δ_{BH^+} values), which are required for the calculation of the ionization ratios (I), are not available experimentally. Consequently, a procedure for calculating Δ_{BH^+} values, previously described in the literature (5, 20), was modified for use in the present study. In this procedure the best values are obtained by comparing the correlation coefficients of the X-function plots for a range of Δ_{BH^+} values. Since theory predicts that these plots should be linear, it can be assumed that the highest correlation coefficient would be obtained when the correct Δ_{BH^+} value is used in the calculation. Experimentally, it was found that the correlation coefficients increased sharply up to a certain point and then remained constant over a fairly broad range before declining slightly as in Fig. 2. The Δ_{BH^+} values corresponding to the point at which the maximum was first achieved were used in all subsequent calculations. The calculated values have been included in Tables 1 and 2.

Having calculated reliable values for Δ_{BH^+} it was then possible to prepare plots of (log I − log [H^+]) vs. the X function from which the pK_{BH^+} values can be obtained. Three typical plots have been reproduced in Fig. 3 and the data obtained for all of the alcohols has been summarized in Table 3.

For the most part, only ionization ratios which were within the range of log I = ±1.0 were used in the least-squares

[a]Correlation coefficient of a linear regression analysis.

analyses. This was done to decrease the potential for errors in log I measurements, since it is known that errors in I increase with increasing distance from 50% ionization. Khaldna (21) has suggested that when the absolute value of log I is greater than 1.0 it is too inaccurate to use in sensitive calculations. Many other authors have followed this same convention (3, 5, 8, 12, 17, 18, 22).

Calculations were made only on data obtained in solutions of less than 85% sulfuric acid because it has been reported that acidity function equations fail in concentrated acid solutions. Cox and Yates have suggested that this is due to the presence of large amounts of undissociated sulfuric acid, and that an alternative formulation of the X function might be necessary for very concentrated sulfuric acid mixtures (10). Therefore, Δ values obtained in acid solutions greater than 85% were not incorporated into these calculations.

Other authors, particularly Cox and Yates, have reported that medium effects are of substantial importance when carbon-13 nmr data are used to measure the basicity of amides (11). The results for alcohols, reported in this paper, did not in themselves appear to require the application of any special corrections for medium effects. However, a referee has reported that the use of the program developed by Cox and Yates with our data gives pK_a values of similar magnitudes but substantially larger uncertainties. Consequently, because the final chapter on the analysis of protonation data does not appear to have been written, we have chosen to publish all of our Δ values, thus making them conveniently available to other workers who may in future develop better ways to handle the problem of medium effects.

Discussion

Much of the alcohol basicity data in the older literature is not reliable because the pK_{BH^+} values were often reported as the H_0 at which the alcohol was one-half protonated (21). As a consequence widely divergent values for the basicity constants of simple alcohols may be found in the literature (23). The difficulty arises, in part, because the acidity function plots were originally assumed to have a slope of 1.00 for all compounds. However, plots of log I versus $-H_0$ for alcohols resulted in slopes far from unity (5, 24). Thus the H_0 values at half ionization do not correspond to thermodynamic pK_{BH^+} values and should only be used as indicators of relative basicities, a fact early recognized by Edward and co-workers (16).

The basicities of two simple alcohols, ethanol and methanol, have been determined by use of the Bunnett–Olsen equation, which does not presume a similar slope for all compounds. The pK_{BH^+} value obtained from the carbon-13 nmr data of ethanol

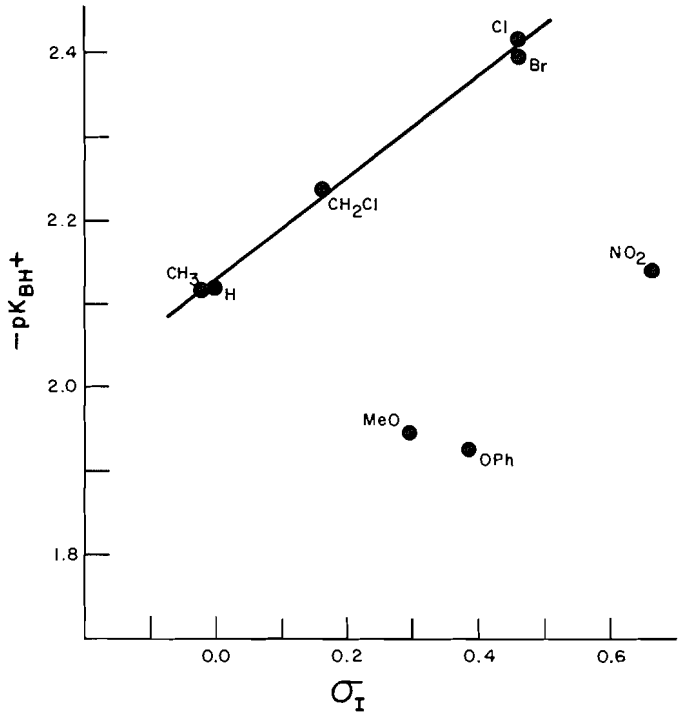

FIG. 4. Linear free energy plot for the basicity of a series of 2-substituted ethanols.

(−2.12) does not agree well with the value of −1.98 obtained by Lee and Cameron using H-nmr data (7). However, the comparison becomes much better when the original data is recalculated using the latest H_0 and log $[H^+]$ values (18, 25, 26). Application of the X-function method to the H-nmr data then gives a pK_{BH^+} of −2.12 with m^* equal to 0.23.

When Bonvicini and co-workers (20) applied the Bunnett–Olsen equation (27, 28) to the proton nmr data for methanol, a pK_{BH^+} of −1.98 was obtained. They used a method similar to the procedure described above to determine chemical shifts for the fully protonated alcohol.

The low values of m^* reported in Table 3 are very likely as a consequence of the high solvation requirements for the protonated alcohols relative to their neutral forms. Because each increase in acidity is necessarily accompanied by a decrease in the amount of water available in the solution, oxonium ions which require extensive solvation (through hydrogen bonding), are less readily formed than other cations. The consequence of this reality is low m^* values.

The alcohols in this study, with the exception of 2-propanol, can be considered to be a series of monosubstituted ethanols. The inductive effects of the substituents can then be observed from a plot of basicity constants against the substituent constants, σ_I, as in Fig. 4 (29, 30). From this plot it can be seen that the points for ethanol, 1-propanol, 3-chloropropanol, 2-chloroethanol, and 2-bromoethanol all fall on a single straight line. A linear regression analysis of the data gives a slope of +0.65 ± 0.06 and an intercept of 2.12. The correlation coefficient of this plot (0.996) can be considered as "excellent" (31). The positive slope indicates that the reaction is facilitated by electron-withdrawing substituent groups, as would be predicted since these reactions are defined in terms of the dissociation of the conjugate acids.

The plot in Fig. 4 also indicates that the basicities for the nitro-, methoxy-, and phenoxy-substituted ethanols do not

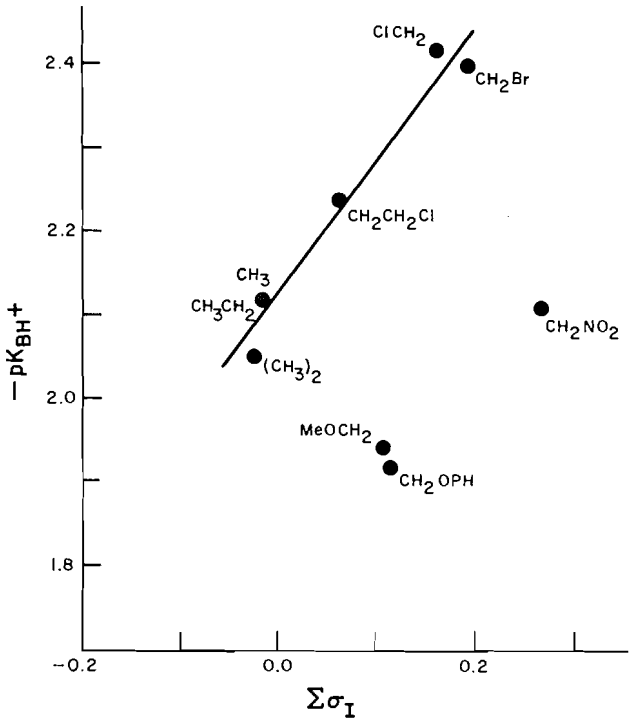

FIG. 5. Linear free energy plot for the basicity of a series of mono- and disubstituted methanols.

correlate with the other alcohols. Since the points for these three alcohols fall below the others it appears that alcohols which bear oxygen-containing substituents are more basic than would be predicted by about 0.5 pK units; i.e., for these alcohols equilibrium [1] appears to be shifted slightly to the left. The reason for this seems likely to be stabilization of the conjugate acids by internal hydrogen bonding, an effect that has previously been noted in the literature (32).

A similar inductive effect correlation can be made by treating the alcohols as a series of substituted methanols (Fig. 5). Since substituent constants have been shown to be additive (31, 33), the data for 2-propanol can also be included in this correlation. The plot has a slope of $+1.7 \pm 0.1$ and intercept of 2.11. Although the correlation coefficient (0.970) is not as good as that obtained for the plot in Fig. 4, it is typical of linear free-energy plots and still very acceptable (31). The more positive slope is obtained because the substituents are now considered to be one methylene group closed to the protonated center. This ρ value (+1.7) is similar to that found for the protonation of dialkyl ethers (+2.0), acetophenones (+1.69), and thiobenzoic acids (+1.4) (20, 34, 35).

The ratio of the ρ values from the plots in Figs. 3 and 4 is 0.4. This ratio, which has been called the methylene transmission coefficient (36), is an attenuation of the inductive effect by one methylene group. It has previously been calculated to be approximately 0.4 ± 0.1 (37), but often varies with the nature of the substituent (36).

The transmission coefficient can be used to estimate a σ_I value for the nitromethylene group from the value for NO_2. The σ_I value for the nitro group (0.67) times the transmission coefficient (0.4) gives an approximate σ_I value for O_2NCH_2 of +0.27. When this value is included in the plot for the substituted methanols (Fig. 4), it can be seen that the three alcohols bearing oxygen-containing substituents fall below the others, again by about 0.5 pK units.

Because extensive compilations of σ_I values are available in the literature (25, 26), the use of these correlations now permit the calculation of basicity constants for a large number of alcohols.

Conclusions

(1) The pK_{BH^+} values for aliphatic alcohols can be estimated from the equation, $pK_{BH^+} = 0.65\sigma_I + 2.12$, if the alcohols are considered to be a series of 2-substituted ethanols. If the alcohols are considered to be mono- or disubstituted methanols the correlation equation becomes $pK_{BH^+} = 1.7\sigma_I + 2.11$.

(2) Alcohols bearing oxygen-containing substituents on the β-carbon are more basic by about 0.5 pK units than predicted by the above correlations.

Received November 30, 1986

This paper is dedicated to Professor John T. Edward

PETER WAN, S. MURALIDHARAN, IAIN MCAULEY, and CHRISTOPHER A. BABBAGE. Can. J. Chem. **65**, 1775 (1987).

The photooxygenation of nitrobenzyl derivatives **1–10** has been studied in aqueous solution as a function of pH. For *m*-nitrobenzyl ethers **2–4** and **9**, stable α-hydroperoxy ethers (**11–13**) are the primary photochemical products. Acid hydrolysis of **11–13** gives *m*-nitrobenzaldehyde and hydrogen peroxide. Quantum yields for photooxygenation are reported for a number of derivatives as a function of pH. Acid and base catalyses of photooxygenation are observed for several compounds. A mechanism involving photogenerated nitrobenzyl carbanion intermediates is proposed.

PETER WAN, S. MURALIDHARAN, IAIN MCAULEY et CHRISTOPHER A. BABBAGE. Can. J. Chem. **65**, 1775 (1987).

Opérant en solutions aqueuses, on a étudié la photo-oxydation des dérivés nitrobenzyliques (**1–10**) en fonction du pH. Dans les cas des éthers *m*-nitrobenzyliques (**2–4** et **9**), les produits photochimiques primaires sont les éthers α-hydroperoxylés stables (**11–13**). L'hydrolyse acide des composés **11–13** conduit au *m*-nitrobenzaldéhyde et au peroxyde d'hydrogène. Dans les cas d'un certain nombre de dérivés, on rapporte les rendements quantiques pour la photo-oxygénation en fonction du pH. Dans les cas de plusieurs composés, on a observé que la photo-oxygénation est soumise à une catalyse acide/base. On propose un mécanisme impliquant, comme intermédiaires, des carbanions nitrobenzyliques générés photochimiquement.

The photochemistry of aliphatic and aromatic nitro compounds has received considerable attention and several reviews (1–4) have been published. Recently, we (5–7) and others (8, 9) have noted that some *m*- and *p*-nitro-substituted benzenes display unexpected reactivity when irradiated in aqueous solution, especially in the presence of hydronium and hydroxide ions as catalysts for the transformations (5–8). Whereas it is well known (1–4) that *o*-nitrobenzyl systems are photolabile due to the proximity to the substituent of the reacting nitro chromophore, resulting in initial intramolecular hydrogen abstraction via the n,π^* triplet excited state, it had been assumed for many years that the corresponding *meta* and *para* derivatives should not be photolabile, except for simple photoreduction. However, in aqueous solution, a number of *m*- and *p*-nitro-substituted derivatives have been found to react via new photochemical processes (5–9). In a preliminary report (10) we had demonstrated that molecular oxygen can react with photoexcited nitrobenzyl derivatives, which represent an additional example of the rich and sometimes unpredictable photochemistry of *m*- and *p*-substituted nitroaromatic compounds. In this work, we report the generality and proposed mechanisms for the photooxygenation reaction of a variety of *m*- and *p*-nitro-substituted derivatives. In addition, the thermal aqueous chemistry of several photogenerated α-hydroperoxy *m*-nitrobenzyl ethers isolated in these studies will be presented.

Results

Product studies

The compounds chosen for the study, **1–10**, are shown below. Both *m*- and *p*-nitrobenzyl alcohols **1** and **7**, respectively, are commercially available. In addition, their aqueous photochemistry under *deaerated* conditions has been reported by us (6, 7). Nitrobenzyl ethers **2–5** and **8** are available from their corresponding nitrobenzyl chlorides, via the appropriate Williamson ether synthesis. Acetate **6** was made by treating **1** with acetyl chloride in the presence of pyridine. 2-Methoxy-(*m*- and *p*-nitrophenyl)ethanols **9** and **10** were made via acid-catalyzed methanolysis of the corresponding nitrophenyl epoxides. The details of these syntheses are presented in the experimental section.

10

Rafizadeh and Yates (8) have reported that *m*-nitrobenzyl ethers **2**, **3**, **5**, and **9** (and related compounds not shown above) all reacted in *deaerated* aqueous solution to give *m*-nitrobenzaldehyde as the only isolable product in low quantum yield (0.011 for **2** in pH 7). In this study, we have found that when ethers **2–4** are irradiated in *aerated* aqueous solution (typical scale 200–500 mg; 20% CH_3CN/H_2O; oxygen purged; Hanovia 450-W medium pressure lamp; 30-min photolysis), the major products are the corresponding α-hydroperoxides, obtained in about 40% yield (eq. [1]). The minor product consists of about 5% of the corresponding alkyl *m*-nitrobenzoate and a trace (<5%) of *m*-nitrobenzaldehyde. The remainder of the photolysate is recovered starting material. When the same photolysis is carried out under an argon atmosphere, the only

product is *m*-nitrobenzaldehyde, obtained in low yield, as was reported by Rafizadeh and Yates (8). The photooxygenation (eq. [1]) is not observed in oxygenated aqueous solution when kept in the dark, even for extended periods (>1 day). Thus, in the presence of oxygen, there is a new photochemical pathway that involves overall insertion of molecular oxygen into the benzylic C—H bond of **2–4**. Extended photolysis of **2–4** (>1 h) results in an increased proportion of esters **14–16** in the photolysate. Furthermore, independent photolysis of α-hydroperoxides **11–13** in aqueous solution or in pure CH_3CN (both under argon) results in the formation of **14–16**, respectively, as the only product. This is taken as evidence that esters **14–16** are secondary photoproducts of **11–13**, presumably via a mechanism involving initial O—O bond cleavage on excitation (eq. [2]). The small amount of *m*-nitrobenzaldehyde always ob-

[2] 
11–13 **14–16**

served in these photolyses is presumably due to the residual photoredox pathway (as observed in argon purged solutions) reported previously (8). Alternatively, it may be due to residual thermal hydrolysis of **11–13** (*vide infra*).

α-Hydroperoxides **11–13** are, as far as we are aware, new compounds. They are yellow oils and are relatively stable in hydrocarbon and nonhydroxylic solvents. For example, refluxing in benzene for several hours results in only about 20% conversion of **11–13** to the corresponding ester, via an overall dehydration of the compound. We have fully characterized **11–13** via standard spectroscopic techniques (see Experimental). For example, the methine proton is shifted downfield to δ 5.8 compared to δ 5.5 for the methine signal of *m*-nitrobenzaldehyde dimethyl acetal. The OOH proton resonates at δ 8.8 (exchangeable), considerably downfield shifted from alcoholic OH's, which resonate in the region δ 2–5. These α-hydroperoxides are reducible with either aqueous KI or Na_2SO_3, to give *m*-nitrobenzaldehyde cleanly as the only product (in addition to the alcohol fragment, which was not characterized), via eq. [3]. In aqueous KI, the course of the reduction may be judged by the increase in coloration (to a final deep yellow) due to the formation of I_2.

[3] 
11–13

α-Hydroperoxides **11–13** are unstable in aqueous solution, especially in low pH. Below pH 3 they suffer acid-catalyzed hydrolysis, to give *m*-nitrobenzaldehyde, the corresponding alcohol fragment, and hydrogen peroxide (eq. [4]). Hydrogen peroxide was detected after complete hydrolysis, by its characteristic reaction with KI (to give I_2). To gain insight into the mechanism of hydrolysis, hydroperoxide **11** was solvolyzed in pure MeOH, with several drops of concentrated H_2SO_4 added as catalyst. The products were *m*-nitrobenzaldehyde dimethyl acetal and methyl *m*-nitrobenzoate in a 25:75 ratio (eq. [5]).

[4] 
11–13

[5] 
These products were characterized by comparison of the nmr signals with the authentic samples. Although methyl *m*-nitrobenzoate is probably formed via dehydration of **11** (as the simplest explanation), clearly the dimethyl acetal is formed via initial heterolytic cleavage of the C—OOH bond of **11**, i.e., the hydroperoxy group being the leaving group in the solvolysis. Additional discussion regarding the mechanism of hydrolysis of **11–13** will be given in the Discussion. Above pH 3, the hydrolysis pathway is very slow and only dehydration of **11–13** is observed, to give the corresponding alkyl *m*-nitrobenzoates.

Several observations provide insight into the mechanism of photooxygenation of **2–4**. The reaction does not take place in the commonly available organic solvents (CH_3CN, MeOH, EtOH, benzene, diethyl ether, etc., all oxygenated during photolysis). Rose Bengal sensitization for singlet oxygen (λ_{excit} > 400 nm) gives only low yields (<5%) of *m*-nitrobenzaldehyde and methyl *m*-nitrobenzoate for **2**; no α-hydroperoxide is observed, even under low conversion experiments. That singlet oxygen is responsible for these photooxygenations is therefore unlikely, especially considering the fact that singlet oxygen is not known to react with benzylic hydrogens to give hydroperoxides and additionally is not known to exhibit the drastic solvent dependence of reactivity as observed above.

The reaction requires an α-oxygen substituent in the structure since *m*-nitrotoluene does not undergo the reaction. However, the presence of an α-oxygen is not a sufficient requirement since both **5** and **6** are totally nonreactive. It is not clear at this time why **5** and **6** are not reactive. The reaction appears to be very sensitive to the presence of electron-withdrawing groups in R of **1–6**. As there are no accessible low energy states in the acetoxy or phenoxy chromophores, photophysical quenching of reaction of **5** and **6** appears unlikely.

The discovery that, in the presence of oxygen, certain *m*-nitrobenzyl ethers react via a new pathway led us to reinvestigate the photochemistry of *m*-nitrobenzyl alcohol **1**. We have

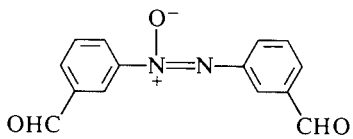
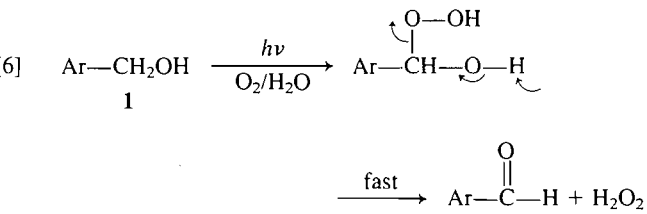
reported the aqueous redox photochemistry of both *m*- and *p*-nitrobenzyl alcohols **1** and **7** in deoxygenated aqueous solution (6, 7). For **1**, the products are *m*-nitrobenzaldehyde (70%) and *m*-azoxybenzaldehyde **17** (30%). Compound **17** is the



17

"reduction" product in the overall photoredox pathway, the mechanism of which has been discussed in some detail (6, 7). However, when **1** is irradiated in oxygenated aqueous solution, the only product is *m*-nitrobenzaldehyde, with a concurrent 20% increase in quantum efficiency (from 0.087 to 0.10). Additionally, hydrogen peroxide was detected in the aqueous portion (after CH_2Cl_2 extraction) by its characteristic reaction with KI. These observations are consistent with a photooxygenation pathway for **1** when irradiated in oxygenated aqueous solution (eq. [6]), analogous to that observed for ethers **2–4**.

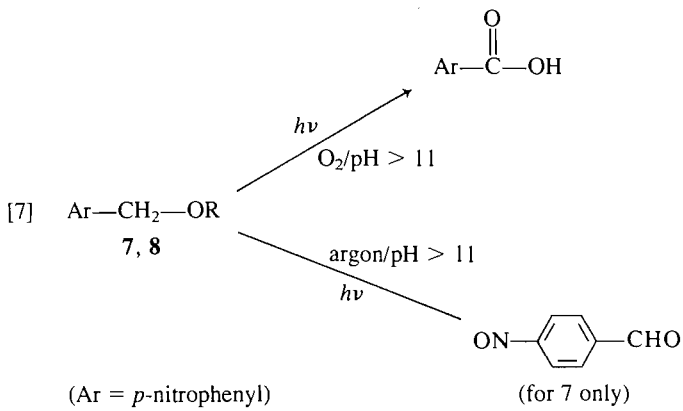


[6] $Ar{-}CH_2OH \xrightarrow[O_2/H_2O]{h\nu} Ar{-}CH(OOH){-}OH \xrightarrow{fast} Ar{-}C(=O){-}H + H_2O_2$

1

However, the initially formed α-hydroperoxy alcohol is unstable and decomposes to *m*-nitrobenzaldehyde and hydrogen peroxide. This reaction and the ones already described above for **2–4** offer a means for the photochemical activation of molecular oxygen, to give hydrogen peroxide. It is made more attractive by the fact that **1–4** absorb well beyond 300 nm (to about 370 nm), thus enabling solar radiation to effect the conversion.

p-Nitrobenzyl derivatives **7** and **8** showed no reaction in oxygenated solution in the pH region 0–11. In these cases, complete recovery of starting material was possible after photolysis. Above pH 11, photolysis of **7** and **8** gives *p*-nitrobenzoic acid as the only product (eq. [7]), the yield increasing

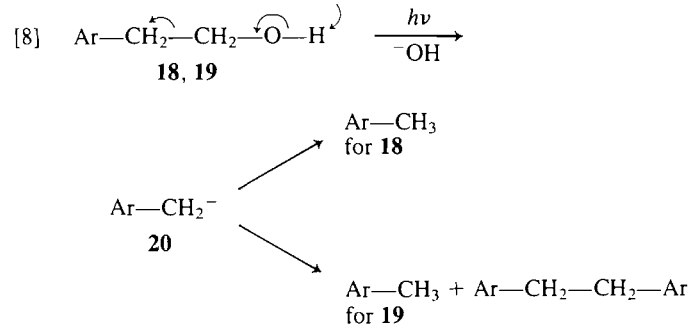


[7] $Ar{-}CH_2{-}OR$ (**7, 8**) → ($h\nu$, O_2/pH > 11) → $Ar{-}C(=O){-}OH$; ($h\nu$, argon/pH > 11) → $ON{-}C_6H_4{-}CHO$

(Ar = *p*-nitrophenyl) (for 7 only)

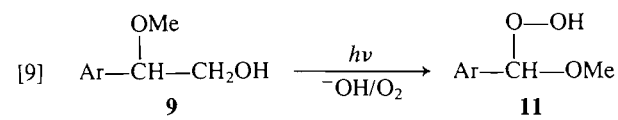
with pH (*vide infra*). We have reported (6, 7) that **7** gives *p*-nitrosobenzaldehyde when photolyzed above pH 11 in deoxygenated solutions (eq. [7]). Compound **8** is photoinert under the same conditions. It is apparent, however, that in the presence of oxygen, a different photochemical pathway is followed by **7**, whereas photoreaction is observed for **8** only in *oxygenated* aqueous base.

To gain additional insight into the mechanism of photooxygenation of **1–4** and **7**, **8**, nitrophenyl derivatives **9** and **10** were studied. We have recently reported (5) that both *m*- and *p*-nitrophenethyl alcohols (**18** and **19**, respectively) react via a retro-aldol type pathway in deoxygenated aqueous solution, to give *m*-nitrotoluene in the case of **18** and both *p*-nitrotoluene and *p,p'*-dinitrobibenzyl in the case of **19** (eq. [8]). The



[8] $Ar{-}CH_2{-}CH_2{-}O{-}H$ (**18, 19**) $\xrightarrow[{}^-OH]{h\nu}$ $Ar{-}CH_2^-$ (**20**) → $Ar{-}CH_3$ for **18**; $Ar{-}CH_3 + Ar{-}CH_2{-}CH_2{-}Ar$ for **19**

reactions are base catalyzed. Arguments were presented (5) that support the intermediacy of photogenerated nitrobenzyl carbanions **20**. Based on this and previous studies (6, 7), we suspected that the present photooxygenation reactions of **1–4** and **7**, **8** also proceed via photogenerated nitrobenzyl carbanions. We find that when **9** is photolyzed in oxygenated aqueous solution, the only product is the α-hydroperoxy ether **11** obtained in good yields (>50%). The reaction is base catalyzed (*vide infra*). On extended photolysis, methyl *m*-nitrobenzoate is observed, which was shown to be a secondary photoproduct of **11**. However, photolysis of **10** in neutral or acidic media (pH 0–11; oxygenated) gave only methyl *p*-nitrobenzoate in low yields (<15%); the α-hydroperoxide corresponding to **11** is not observed. At high pH (pH > 11), *p*-nitrobenzoic acid is the only product, with increasing yields with increasing pH. Thus the dichotomy of reactivity observed for **9** and **10** some-



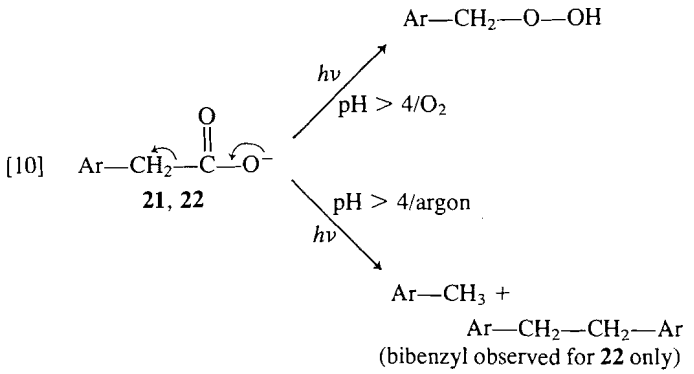
[9] $Ar{-}CH(OMe){-}CH_2OH$ (**9**) $\xrightarrow[{}^-OH/O_2]{h\nu}$ $Ar{-}CH(O{-}OH){-}OMe$ (**11**)

what parallels the results already observed for **1–4** and **7**, **8**. Corroborative evidence, which suggests that photogenerated nitrobenzyl carbanions can react with molecular oxygen to give reasonably stable hydroperoxides, is the recent finding[2] that both *m*- and *p*-nitrophenyl acetate ions (**21** and **22**, respectively) give the corresponding hydroperoxides in high quantum efficiency ($\Phi > 0.5$) on photolysis in oxygenated aqueous solution (eq. [10]). The photodecarboxylation of **21** and **22** has already been shown by Margerum and Petrusis (12) to proceed via nitrobenzyl carbanion intermediates, which in deoxygenated solutions give the corresponding toluenes and, in the case of the *para* isomer, significant yields of *p,p'*-dinitrobibenzyl.

Quantum yields and pH effects

The photooxygenation of **2–4** and **9** may be conveniently followed by uv spectrophotometry. For example, as shown in Fig. 1, photolysis of **2** in oxygenated pH 7 solution results initially in very little change in the uv absorption spectrum. However, on addition of several drops of 30% H_2SO_4 to the

[2]P. Wan and S. Muralidharan. Manuscript in preparation.



[10]

cuvette solution, a "grow-in" of a band at about 235 nm (assignable to *m*-nitrobenzaldehyde) takes place. This observation is consistent with the product studies reported above, in which the initially photogenerated α-hydroperoxides are relatively stable in neutral pH but suffer acid-catalyzed hydrolysis in acidic medium. That very little absorbance change occurs on initial generation of the α-hydroperoxide (trace 1 of Fig. 1) is consistent with the fact that **2** and **11** have nearly identical λ_{max} and ε_{max} (for **2**, λ_{max} = 266 nm, ε_{max} = 7 300; for **11**, λ_{max} = 264 nm, ε_{max} = 7 000). *m*-Nitrobenzaldehyde, of course, has a very different uv absorption spectrum, with λ_{max} = 235 nm (ε_{max} = 23 000).

Quantum yields for α-hydroperoxide formation were measured for **2**–**4** and **9** at pH 7 (λ_{excit} = 254 nm), using the known quantum yield for photoredox reaction of **1** in deoxygenated solution (Φ = 0.087), as measured by Rafizadeh and Yates (8), as an actinomer (Table 1). The procedure used involves measuring the amount of *m*-nitrobenzaldehyde produced via uv spectrophotometry after acidification of the initially photolyzed solution with aqueous H_2SO_4, as shown in Fig. 1. Sufficient time was allowed for complete hydrolysis of the initially generated α-hydroperoxide prior to final measurement. A dilution factor was incorporated in the calculations due to the dilution effect on addition of the acid. Using the same procedure, quantum yields were measured for **2** and **9** as a function of pH (from 0 to 14), to gain insight into the pH effect of reaction. The results of the pH study are shown in Fig. 2. Compound **9** shows strong base catalysis above pH 11, with a maximum quantum yield of 0.21 at pH 14. Compound **2**, on the other hand, does not show base catalysis, but both **2** and **9** exhibit weak acid catalysis below pH 2. Studies were not carried out in the H_0 acidity region since the generated α-hydroperoxides are quickly hydrolyzed to *m*-nitrobenzaldehyde, and also because a competitive redox pathway may be operative with significant quantums yields in the higher acidity region (6–8). It may not be possible to separate the oxygenation pathway from the internal redox pathway at these acidities, but studies are under way to explore the extent of the photooxygenation pathway at higher acidities.

The quantum yields for photooxygenation of the *p*-nitro-substituted compounds **7**, **8**, and **10** were much lower than the corresponding *meta* isomers. Thus for **10** at pH 7, Φ for methyl ester formation is about 0.02 and increases to about 0.08 at pH 14. There is no acid catalysis of reaction. For **7** and **8**, measurable quantum yields are observed only above pH 12 (the product is *p*-nitrobenzoic acid), reaching a quantum yield of about 0.05 at pH 14 for both **7** and **8**. The base catalysis of reaction is shown in Fig. 3. Again there is no measurable acid catalysis of reaction, both **7** and **8** being photoinert in the pH 0–11 region.

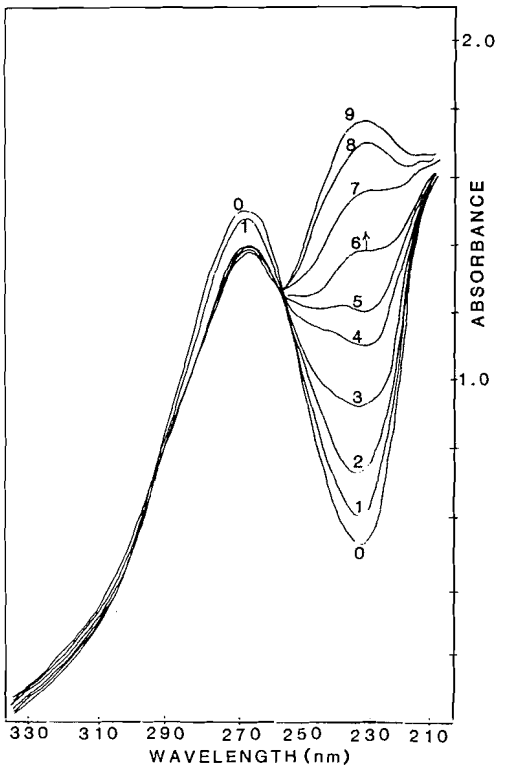


FIG. 1. Ultraviolet traces of the photooxygenation of **2** and subsequent acid-catalyzed hydrolysis of the α-hydroperoxy ether **11**. Trace 1 was taken immediately after photolysis at 254 nm (Rayonet reactor). Traces 2–9 were recorded initially about every 10 min after the addition of several drops of 30% H_2SO_4 to the cuvette solution, later increasing to every 20 min.

α,α-Dideutero-*m*- and *p*-nitrobenzyl alcohols (α,α-*d*-**1** and α,α-*d*-**7**, respectively) were readily available from a previous study (6, 7). We find that these compounds are less reactive than **1** and **7**, respectively, towards photooxygenation at pH 7. The values are Φ_H/Φ_D = 1.9 for the *para* isomer and 1.4 for the *meta* isomer, where Φ_H and Φ_D are the quantum yields for photooxygenation of the parent alcohol and the α,α-dideuterated compound, respectively.

Solvent isotope effects of photooxygenation were measured for ethers **1**–**4** and **9** and **10**. The results are shown in Table 2. All these compounds are less reactive in H_2O than in D_2O, which supports a mechanism involving solvent participation (see Discussion).

Reactivity of photogenerated α-hydroperoxy ethers

As was discussed above, α-hydroperoxy ethers **11**–**13** suffer acid-catalyzed hydrolysis, to give *m*-nitrobenzaldehyde (eq. [4]). Above pH 3, however, the hydrolysis pathway is very

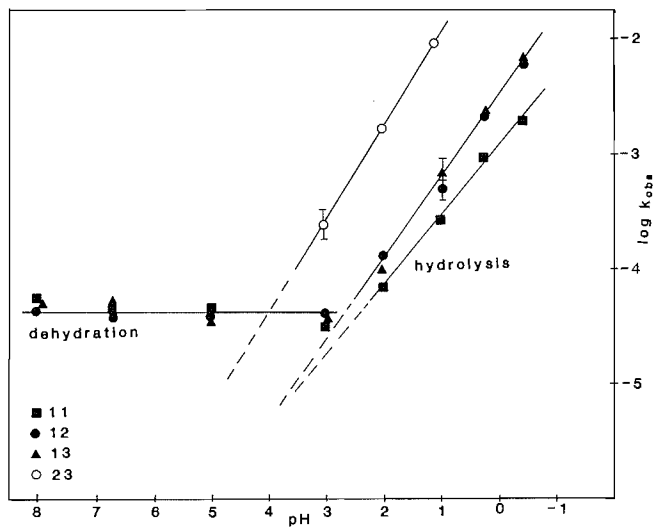

FIG. 4. Logarithmic plot of first-order rate constants for hydrolysis of **11–13** and **23**, and the dehydration of **11–13** as a function of pH.

Observed first-order rate constants for dehydration of **11–13** in the pH 3–8 region were also measured and are given in Table 4. Compound **23** does not react via a dehydration pathway. All of the above rate constants are plotted together in logarithmic form in Fig. 4. The hydrolysis rates of **11–13** are significantly slower (by more than one log unit) than for **23** at the same pH. However, they all exhibit the same dependence on acidity below pH 3 (slope ≃ 1). In the series **11–13**, the ethyl and propyl ethers (**12** and **13**) are measurably more reactive than the methyl ether **11** towards hydrolysis, but all have similar rates for dehydration in the pH 3–8 region.

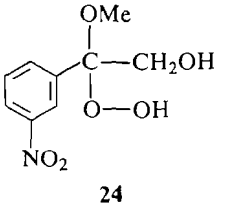
Discussion

The photoretro-aldol type reaction of **18** and **19** and related compounds, as well as the photodecarboxylation of **21** and **22** (which may be formally regarded as a photoretro-aldol type reaction) are believed to proceed via nitrobenzyl carbanion intermediates (5, 12). Margerum and Petrusis (12) have observed a transient at 350 nm in the decarboxylation of *p*-nitrophenylacetate ion **22**, which has been assigned to the *p*-nitrobenzyl carbanion. The lifetime of this intermediate in neutral water is at least several seconds (12). The corresponding *m*-nitrobenzyl carbanion has not been observed and available data (12) indicate that it is much shorter lived, which is consistent with the expected relative stability of these two species (the *p*-nitrobenzyl carbanion can be stabilized via a resonance form in which the negative charge resides at the nitro group). It is well known that carbanions generated in the ground state react efficiently with oxygen (13–15), to give initially hydroperoxides, which readily dehydrate in many cases to give carbonyl compounds, which themselves may undergo further oxygenation to give carboxylic acids as the final oxidation product. Russell *et al.* (15) have shown that the base-catalyzed oxygenation of *p*-nitrotoluene in potassium *tert*-butoxide in *tert*-butanol gives *p*-nitrobenzoic acid, via reaction of *p*-nitrobenzyl carbanion with molecular oxygen. Since strong base is required to generate the *p*-nitrobenzyl carbanion in the ground state, the initially formed hydroperoxides are not isolable (15). However, when **21** and **22** are irradiated in oxygenated aqueous solution, the major products are the corresponding hydroperoxides (eq. [10]). The observation that these hydroperoxides are not formed when **21** and **22** are irradiated in oxygenated organic solvents or in oxygenated aqueous solution when pH $< pK_a$ of the substrate argues against a simple free radical autoxidation mechanism (16) for photooxygenation. These results indicate that when *m*- and *p*-nitrobenzyl carbanions are photogenerated in oxygenated aqueous solution, they react preferentially with oxygen, and not with protons from solvent water.

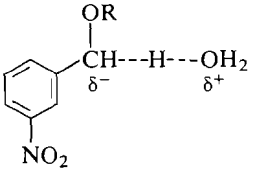
The base-catalyzed photooxygenation reaction of **9** (eq. [9]; Fig. 2) is also consistent with a mechanism involving an initial photoretro-aldol step to generate the α-methoxy-*m*-nitrobenzyl carbanion, followed by rapid reaction with oxygen to give **11**, and not with a free radical mechanism for oxygenation. Moreover, a simple free radical autoxidation pathway would give hydroperoxide **24** as the oxidation product (via reaction of the benzyl radical from hydrogen abstraction of **9** with oxygen), which is not observed. If **24** is formed, it should survive in the



24

reaction mixture since very similar compounds (viz. hydroperoxides **11**–**13**) are isolable under the same reaction conditions.

We now turn our attention to a discussion of the photooxygenation mechanism for the parent nitrobenzyl systems **1**–**4** and **7**, **8**. The reactions of **1**–**4** and **7**, **8** are closely related to those of **9** and **21**, **22**. In addition, several observations rule out a free radical pathway. The photooxygenations are not observed at all in oxygenated organic solvents. A free radical mechanism would not exhibit such a drastic solvent dependence. Compounds **7** and **8** exhibited base catalysis of photooxygenation, and **1**–**4** exhibited acid catalysis, observations that are clearly incompatible with a radical pathway. The substantial solvent isotope effect for reaction (Table 2) for a number of these derivatives clearly implicates the involvement of solvent water in mediating the reaction, acting as a base (D_2O in a weaker base than H_2O) and also perhaps acting as a proton source (D_2O is a weaker acid than H_2O). Therefore, it is proposed that the mechanism of photooxygenation of **1**–**4** and **7**, **8** involves photogenerated nitrobenzyl carbanions, formed via deprotonation of the benzylic C—H bond by solvent water for **1**–**4**, where no base catalysis is observed, and by hydroxide ion for **7** and **8**, where base catalysis is observed. We propose also that the generated carbanions are "hydrogen bonded" species (to the departing proton) and not free carbanions, as shown by structure **25** for the *meta* derivatives. It reacts with



25

oxygen to give the corresponding hydroperoxides, but in the absence of oxygen returns to starting material without incorporation of deuterium from D_2O. It is not clear at this time whether **25** is an electronically excited or ground state species. However, deactivation to the ground state is expected to be very fast and subsequent reaction with oxygen could take place from there.

We are not aware of any precedents in the literature of photochemical mechanisms in which the primary photochemical event involves deprotonation of a C—H bond, except in a related reaction reported by us (6, 7), which also involves nitroaromatic compounds. We showed (6, 7) that deprotonation of a benzylic C—H bond of nitroaromatic compounds in aqueous solution is a viable mechanism, and leads to some interesting chemistry. Again, we were unable to observe deuterium incorporation from D_2O into recovered substrate (6, 7). Free nitrobenzyl carbanions are known to react with D_2O (if oxygen is not present in solution) to give the α-deuterated species. For example, when **21** and **22** are photodecarboxylated in D_2O, the nitrotoluene photoproducts are incorporated with deuterium at the benzylic position.[2] That free carbanions are probably not generated via simple photodeprotonation of C—H bonds is perhaps not surprising because it is well known that there is an inherent activation barrier for heterolytic C—H bond cleavage, which is believed to be due to the inability of the deprotonating base to initially form a hydrogen bonded complex with the departing proton prior to the actual deprotonation (17). This has the consequence of making rates of proton transfers to and from carbon slower than expected in most cases. Since excited states are short lived, simple deprotonation of a C—H bond would generally not be a competitive deactivational process, which is consistent with the lack of reported photochemical reactions via this mechanism. However, the results of this work along with those of a related reaction (6, 7) indicate that, in exceptionally reactive substrates such as nitrobenzyl systems, partial deprotonation of the benzylic C—H bond by solvent water or hydroxide ion in the excited state can lead to photochemical reaction.

The dichotomy of catalytic effects observed in this study and

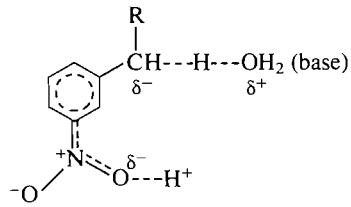
For personal use only.

in a previous study (6, 7), in which the simple *meta* nitro-substituted isomers exhibit acid catalysis and the simple *para* isomers exhibit base catalysis of reaction, is apparently a general phenomenon in the photochemistry of these nitroaromatic compounds in aqueous solution (6, 7). It is well known that there is better electronic transmission of charge at the *meta* than at the *para* position in the excited state of substituted benzenes (17–19). The acid catalysis observed for the *meta* derivatives may be due to assistance of the deprotonation step from the polarized excited state, via protonation of the electron-rich nitro group, as shown by structure **26**. Such a transition



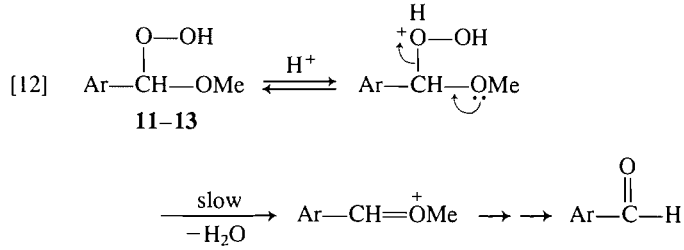
26

state structure would also account for the observed solvent isotope effect of greater than unity in these reactions (Table 2). It would also explain why these reactions are observed only in aqueous solution, since the reaction requires the solvent to act as a base and as a proton source, in addition to the requirement of high dielectric constant. Water is by far the most polar of all the known protic solvents. It is not clear at this time why acid catalysis of reaction for the *para* isomers is not observed.

We have not made any attempts to determine directly the multiplicity of the reactive state of these photooxygenations due to the fact that the solutions were saturated with oxygen during reaction. However, the close analogy of these reactions with the photoredox processes (6–8) and photoretro-aldol reactions (5) would suggest that the same reactive state is involved, viz. the triplet excited state.

The propensity for nitrobenzyl carbanion formation in these systems can be rationalized by considering the enhanced electron-withdrawing ability of photoexcited aromatic nitro groups (5–8, 18, 20). The *m*-nitro group, having better electron-withdrawing ability, accounts for the ease of reaction of the *meta* isomers in these reactions and in others requiring the same type of stabilization (5–8, 18, 20). The *p*-nitro group, on the other hand, does not have the same electron-withdrawing power (but enhanced compared to the ground state, nevertheless) and requires base catalysis for reaction in all cases.

Finally, the thermal hydrolysis of the photogenerated α-hydroperoxides **11–13** requires comment. As shown in Fig. 4, the α-hydroperoxy ethers hydrolyze more slowly than **23**, but with the same catalytic effect (slope of log k vs. pH = 1). Since we were able to demonstrate that methanol will substitute for the hydroperoxy group when the solvolysis is carried out in pure methanol (eq. [5]), the hydrolysis mechanism of **11–13** must involve initial loss of hydrogen peroxide in a specific acid-catalyzed mechanism (eq. [12]). This mechanism also accounts



for the fact that the ethyl and propyl ethers **12** and **13**, respectively, are slightly more reactive than the methyl ether **11**, since they would be expected to have a better inductive electron-donating effect, thus speeding up the second step of eq. [12].

In summary, this study has shown that nitrobenzyl derivatives react via an oxygenation pathway when photolyzed in aqueous solution. In several cases, the initially formed α-hydroperoxides are isolable and therefore provide a convenient route to such species. Additionally, the study has provided insight into the general mechanistic behaviour of the photochemistry of nitrobenzyl derivatives in aqueous solution, opening up new avenues for further investigation.

Experimental

General

Ultraviolet spectra were recorded on Unicam SP8 and LKB Ultrospec II instruments. The ^{1}H nmr spectra were recorded on a Perkin–Elmer R32S instrument and the ^{13}C nmr spectra on a Bruker WM250 instrument. All nmr spectra were taken in $CDCl_3$ with TMS as internal standard. The ir spectra were recorded on a Perkin–Elmer 1320 instrument and mass spectra on a Finnigan 3300 spectrometer. Photolyses were carried out using a Hanovia 450-W medium pressure mercury arc housed in a water-cooled quartz jacket and placed inside a Pyrex immersion reaction vessel. The emission of the lamp was filtered through a Corex filter sleeve. Small scale photolyses and quantum yield measurements were carried out using a Rayonet RPR 100 photochemical reactor equipped with 254-nm lamps.

Materials

Nitrobenzyl ethers **2–5** were prepared by the reaction of the corresponding sodium alkoxides with *m*-nitrobenzyl chloride (Aldrich) in the appropriate alcohol solvent, or in THF for **5**.

m-*Nitrobenzyl methyl ether* **2**

To a 150-mL solution of dry MeOH was added 1.34 g (0.058 mol) of metallic sodium spheres. The solution was stirred until complete dissolution of the sodium metal. To this was added 5.0 g (0.029 mol) of *m*-nitrobenzyl chloride and the solution refluxed for 20 min, after which a fine precipitate of NaCl was observed. After a further 20 min, the reaction was quenched by pouring the solution into 200 mL ice-water. After acidification, the solution was extracted with CH_2Cl_2, which gave a yellow oil. Distillation gave the methyl ether in 70% yield, bp 81°C (2 Torr; 1 Torr = 133.3 Pa); ir (film): 2800–3100 (w), 1600 (m), 1520 (s), 1340 (s), 1200 (m), 1100 (s) cm^{-1}; ^{1}H nmr δ: 3.4 (s, 3H, OMe), 4.5 (s, 2H, $ArCH_2O$—), 7.3–8.3 (m, 4H, arom.); mass spectrum (CI): 168 ($M^+ + 1$). In a similar fashion, ethers **3** and **4** were prepared.

m-*Nitrobenzyl ethyl ether* **3**, bp 92–95°C (2 Torr); ir (film): 2810–3100 (w), 1603 (m), 1522 (s), 1340 (s), 1210 (m), 1105 (s) cm^{-1}; ^{1}H nmr δ: 1.25 (t, J = 8 Hz, 3H, OCH_2CH_3), 3.5 (q, J = 8 Hz, 2H, OCH_2CH_3), 4.5 (s, 2H, $ArCH_2O$—), 7.3–8.4 (m, 4H, arom.); mass spectrum (CI): 182 ($M^+ + 1$).

m-*Nitrobenzyl* n-*propyl ether* **4**, bp 85°C (1 Torr); ir (film): 2830–3090 (w), 1604 (m), 1530 (s), 1335 (s), 1200 (m), 1100 (s) cm^{-1}; ^{1}H nmr δ: 0.96 %t, J = 8 Hz, 3H, —CH_2CH_3), 1.65 (m, 2H, —CH_2-CH_2CH_3), 3.45 (t, J = 8 Hz, 2H, —$CH_2CH_2CH_3$), 4.6 (s, 2H, $ArCH_2O$—), 7.3–8.3 (m, 4H, arom.); mass spectrum (CI): 196 ($M^+ + 1$).

m-*Nitrobenzyl phenyl ether* **5**

This ether was made in a similar manner except that 2 equiv. of phenol was first dissolved in 150 mL dry THF prior to the addition of sodium metal. The solution was refluxed for 2 h immediately after the addition of sodium. The isolated material was a yellow viscous oil and was distilled at 120°C on a Kugelrohr apparatus (2 Torr); ir (film): 2800–3100 (w), 1600 (m), 1530 (s), 1330 (s), 1203 (m), 1100 (s) cm^{-1}; ^{1}H nmr δ: 5.05 (s, 2H, $ArCH_2O$—), 6.8–7.3 (m, 5H, —OPh), 7.3–8.3 (m, 4H, $ArCH_2$—); mass spectrum (CI): 230 ($M^+ + 1$).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

p-*Nitrobenzyl methyl ether* **7**

This ether was made via the same procedure used for **2** (it should be noted that this procedure fails for the ethyl and *n*-propyl *p*-nitrobenzyl ethers; the only product from these reactions is *p,p'*-dinitrostilbene); ir (film): 2800–3100 (w), 1605 (s), 1525 (s), 1335 (s) cm^{-1}; ^1H nmr δ: 3.4 (s, 3H, OMe), 4.5 (s, 2H, $ArCH_2O$—), 7.45 (d, J = 9 Hz, 2H, arom.), 8.15 (d, J = 9 Hz, 2H, arom.); mass spectrum (CI): 168 (M^+ + 1).

(m-*Nitrobenzyl)acetate* **6**

This was readily prepared by reaction of **1** with acetic anhydride in pyridine, bp 70°C (2 Torr); ir (film): 2800–3100 (w), 1735 (s), 1600 (w), 1530 (s), 1335 (s) cm^{-1}; ^1H nmr δ: 2.2 (s, 3H, OCOMe), 5.3 (s, 2H, $ArCH_2O$—), 7.3–8.3 (m, 4H, arom.).

2-Methoxy(*m*- and *p*-nitrophenyl)ethanols **9** and **10** were prepared based on the procedure of Jacober and Hanzlik (21), via acid-catalyzed methanolysis of the corresponding nitrophenyl epoxides, which are known compounds (22–24).

2-Methoxy-(m-*nitrophenyl)ethanol* **9**

To a 50-mL solution of dry MeOH was added 2 g of *m*-nitrophenyl epoxide and 1 mL concentrated H_2SO_4 and refluxed for 1.5 h. The solution was quenched with solid sodium bicarbonate, cooled, and water was added. Extraction with CH_2Cl_2 gave an oil that could be recrystallized from ligroin in the cold to give a low melting solid, mp 10°C; ir (film): 3140–3700 (br, m), 2800–3100 (m), 1525 (s), 1350 (s), 1110 (s) cm^{-1}; ^1H nmr δ: 2.4 (br, 1H, OH), 3.35 (s, 3H, OMe), 3.65 (d, J = 8 Hz, 2H, —CH_2OH), 4.4 (t, J = 8 Hz, 1H, ArCH), 7.4–8.3 (m, 4H, arom.); mass spectrum (CI): 198 (M^+ + 1).

2-Methoxy-(p-*nitrophenyl)ethanol* **10**

Using the same procedure as for **9**, **10** was obtained as a solid from ligroin, mp 56°C; ir (Nujol): 3140–3700 (br, m), 1600 (m), 1520 (s), 1350 (s), 1100 (s) cm^{-1}; ^1H nmr δ: 2.7 (br, 1H, OH), 3.3 (s, 3H, OMe), 3.65 (d, J = 8 Hz, 2H, —CH_2OH), 4.4 (t, J = 8 Hz, 1H, ArCH), 7.5 (d, J = 9 Hz, 2H, arom.), 8.2 (d, J = 9 Hz, 2H, arom.); mass spectrum (CI): 198 (M^+ + 1).

m-Nitrobenzaldehyde dimethyl acetal **23** was readily prepared by refluxing *m*-nitrobenzaldehyde in excess methanol in the presence of trimethyl orthoformate as the dehydrating agent. Esters **14–16** were prepared by refluxing *m*-nitrobenzoic acid with the corresponding alcohols, with acid catalysis.

Preparative photolyses

Large scale photolyses of **1–10** were generally carried out on 0.5–1.0 g scales using a Hanovia 450-W immersion reactor, and smaller scale photolyses with 100–200 mg samples using a Rayonet RPR 100 reactor with 254-nm lamps.

α-*Hydroperoxy-*m-*nitrobenzyl methyl ether* **11**

In a typical photolysis, 500 mg of **2** was dissolved in 200 mL CH_3CN/800 mL distilled water. A pinch of sodium bicarbonate was added. The solution was transferred to the immersion well and purged with a stream of oxygen for 10 min, with stirring, prior to photolysis. The solution was also purged with oxygen during the photolysis. After 45 min, the lamp was switched off and the solution worked up by extraction with CH_2Cl_2, after addition of NaCl (to saturate the aqueous solution with salt). The ratios of the products were calculated by ^1H nmr integration, using the methoxy singlets of **2** (δ 3.4), **11** (δ 3.65), and **14** (δ 4.0), and the formyl proton of *m*-nitrobenzaldehyde (δ 10.1). It showed 54% substrate, 40% **11**, 5% **14**, and a trace of *m*-nitrobenzaldehyde. The crude mixture was separated by chromatography on silica gel (CH_2Cl_2) to give pure **11** (120 mg, 24% overall yield) as an oil; ir (film): 3150–3600 (br, m), 2800–3100 (w), 1610 (w), 1525 (s), 1350 (s), 1200 (s), 1100 (s) cm^{-1}; ^1H nmr δ: 3.65 (s, 3H, OMe), 5.8 (s, 1H, ArCH), 7.4–8.6 (m, 4H, arom.), 8.8 (br, 1H, OOH); ^{13}C nmr (^1H decoupled) δ: 56.59 (OMe), 105.88 (ArCH), 122.23, 123.93, 129.31, 133.08, 137.96, 148.18 (arom. C); mass spectrum (EI): 199 (M^+, very weak). Chemical analysis was not attempted due to the presence of small amounts of thermal decomposition products, which eluded separation.

α-*Hydroperoxy-*m-*nitrobenzyl ethyl ether* **12**

In a similar manner as above, **12** was isolated and characterized; ir (film): 3150–3600 (br, m), 2800–3100 (w), 1610 (w), 1530 (s), 1350 (s), 1205 (s), 1100 (s) cm^{-1}; ^1H nmr δ: 1.3 (t, J = 8 Hz, 3H, OCH_2CH_3), 3.7–4.3 (m, diastereomeric H, 2H, OCH_2CH_3), 5.9 (s, 1H, ArCH), 7.4–8.3 (m, 4H, arom.), 8.9 (br, 1H, OOH); mass spectrum (EI): 213 (M^+, very weak).

α-*Hydroperoxy-*m-*nitrobenzyl* n-*propyl ether* **13**

^1H nmr δ: 1.0 (t, J = 8 Hz, 3H, —$CH_2CH_2CH_3$), 1.75 (m, J = 8 Hz, 2H, —$CH_2CH_2CH_3$), 3.5–4.1 (m, diastereomeric H, 2H, —CH_2-CH_2CH_3), 5.9 (s, 1H, ArCH), 7.4–8.4 (m, 4H, arom.), 8.9 (br, 1H, OOH); ir (film): 3150–3600 (br, m), 2800–3100 (w), 1610 (w), 1530 (s), 1350 (s), 1200 (s), 1100 (s) cm^{-1}; mass spectrum (EI): 227 (M^+, very weak).

Rose Bengal sensitization of **2**

The light source used for this experiment consists of the above Hanovia 450-W lamp but filtered through a uranium glass filter and a filter solution consisting of 0.6 g $K_2Cr_2O_7$ in 1 L of water, which has a cutoff at 400 nm. A typical experiment using this setup consists of dissolving 100 mg of Rose Bengal (Aldrich) and 200 mg of **2** in 50 mL CH_3CN/350 mL water, and transferring this solution to a Pyrex vessel, which is placed adjacent to the light source. The solution is photolyzed with a stream of oxygen purging through the solution. That singlet oxygen is generated efficiently is shown by the fact that when 1 g of 2-methylfuran is used as the substrate, a 10-min photolysis using the above procedure results in complete conversion of the furan (to a hydroperoxide derivative), which is a known singlet oxygen trap (25). When **2** is irradiated under this setup for 30 min, no reaction is observed (similar time scale as for direct photolysis runs without Rose Bengal). On extended photolysis (4 h), the reaction gives 8% *m*-nitrobenzaldehyde and 2% methyl *m*-nitrobenzoate **14**. The rest of the photolysate is recovered starting material **2**. No trace of hydroperoxide **11** is detected. It is clear from this experiment that singlet oxygen can react with **2** but relatively inefficiently, and, more importantly, does not give hydroperoxides.

Reactivity of **11**

Hydrolysis of **11**

Two solutions each of 100 mg of **11** in 20 mL CH_3CN/80 mL pH 1 and 20 mL CH_3CN/80 mL pH 7 were prepared and left at room temperature with stirring in the dark for 2 days. After work-up, the pH 1 hydrolysis yielded 100% *m*-nitrobenzaldehyde whereas the pH 7 hydrolysis showed a mixture of 40% methyl *m*-nitrobenzoate **14** and 60% starting material **11**; no trace of *m*-nitrobenzaldehyde was observed. The aqueous layer of the pH 1 run was tested for H_2O_2 with KI, which gave a positive test. On the other hand, the test was negative for the pH 7 hydrolysis. As there is no convenient *in situ* method for detecting H_2O_2 (11), we have shown that our method works when authentic H_2O_2 is added to solutions of similar composition. The rate of reaction of authentic H_2O_2 with KI (monitored at 358 nm) is also similar to the rate obtained with the aqueous layer of the hydrolyzed **11**, as a further indication that hydrogen peroxide is produced. In a typical run with 10^{-4} *M* H_2O_2 and 10^{-2} *M* KI, the observed rate is 9.3×10^{-4} s^{-1} (25°C). The KI test is negative when **23** is used as the substrate.

Reduction of **11**

A solution of 100 mg of **11** in 20 mL CH_3CN and 500 mg of Na_2SO_3 (or KI) in 80 mL water was prepared and stirred for several hours. In the case of KI, the solution turned to a deep yellow with time. After work-up, the product was *m*-nitrobenzaldehyde.

Photolysis of **11**

A solution of 100 mg of **11** in 20 mL CH_3CN/80 mL water was photolyzed in a quartz reaction vessel in a Rayonet reactor (254-nm lamps) with argon purging for 2 h. After work-up, the nmr of the photolysate showed 30% methyl ester **14** and 70% starting material. Photolysis of **11** in pure CH_3CN gave the same product mixture. No reaction was observed without irradiation. Refluxing a solution of **11**

in benzene for 2 h in the dark gave 20% conversion to **14**. No reaction was observed without reflux.

Quantum yield measurements

Quantum yields for α-hydroperoxide formation for **2–4** and **9** were measured spectrophotometrically with 254-nm irradiation, using the known quantum yield (0.087) of photoredox reaction of **1** (in argon) as the actinometer (8). The major product of this reaction is *m*-nitrobenzaldehyde with *m*-azoxybenzaldehyde as the minor product. Both have λ_{max} at 235 nm with essentially the same ε (23 000 and 25 000). The reported quantum yield (7, 8) is for the total quantum yield of the two products. Solutions of **1–4** and **9** were prepared in quartz cuvettes, ensuring that they have the same OD at 254 nm. The solution containing **1** was saturated with argon while the solutions containing **2–4** and **9** were saturated with oxygen. The cuvettes were then irradiated at 254 nm in a merry-go-round apparatus for 3 min. After photolysis, the increase in OD at 235 nm for **1** was measured. For **2–4** and **9**, 1.0 mL was removed from each via a pipette and 1.0 mL of 30% H_2SO_4 added to effect hydrolysis of the photogenerated α-hydroperoxides. After complete hydrolysis (typically requiring 1 h), the OD's at 235 nm were measured and normalized back to the initial concentration, accounting for the dilution factor. Quantum yields for α-hydroperoxide formation were then calculated by equating it to the quantum yield for *m*-nitrobenzaldehyde formation measured in each solution, using **1** as the reference. This procedure is valid because essentially all the *m*-nitrobenzaldehyde formed is due to hydrolysis of the initially produced α-hydroperoxide (except for **1**, which was the reference). The same procedure was employed in the study of pH effect on reaction for **2** and **9**, as well as the solvent isotope effects given in Table 2.

Rate measurements

The hydrolysis and dehydration rates for **11–13** and **23** were measured by following the increase in OD at 235 nm. Kinetic runs were carried out by injecting a stock solution of the compound (dissolved in CH_3CN) into a solution of known pH and monitoring the OD at 235 nm at 30 ± 2°C in a spectrophotometer. Alternatively, the hydroperoxide may be photogenerated *in situ* by photolysis of the corresponding starting material and the rate of reaction obtained by following the increase in OD at 235 nm in the dark. In all cases, good pseudo first-order kinetics were observed.

A number of fluorescent steroids with unsaturated sidechains have been analyzed by high resolution ^{1}H and ^{13}C nmr spectroscopy. The geometry of the olefinic systems was assigned on the basis of ^{1}H–^{1}H shift-correlated spectra (COSY) and selected nOe difference experiments. For one of these compounds, a ^{13}C–^{1}H shift-correlated spectrum, a COSY spectrum, a ^{1}H *J*-resolved spectrum as well as nOe experiments on the angular methyl groups permitted complete ring proton assignment and coupling constant analysis. The high degree of similarity of the ring carbon ^{13}C chemical shifts of these steroids and cholesterol would indicate that the former have the potential for use as fluorescent probes of cholesterol domains in membranes.

JACINTA DREW, JEAN-ROBERT BRISSON, PETER MORAND et ARTHUR G. SZABO. Can. J. Chem. **65**, 1784 (1987).

Faisant appel à la rmn du ^{1}H et du ^{13}C, on a analysé un certain nombre de stéroïdes fluorescents qui portent des chaînes latérales qui ne sont pas saturées. On a attribué la géométrie des systèmes oléfiniques en se basant sur des spectres de corrélation homonucléaire ^{1}H–^{1}H (COSY) et sur des expériences sélectives d'eOn différentiel. Pour l'un de ces composés, un spectre de corrélation ^{13}C–^{1}H, un spectre COSY, un spectre de ^{1}H résolu pour *J* ainsi que des expériences d'eOn sur les groupements méthyles angulaires ont permis de faire une attribution complète pour les protons du cycle ainsi qu'une analyse complète des constantes de couplage. La grande similitude qui existe entre les déplacements chimiques ^{13}C des carbones du cycle de ces stéroïdes et ceux du cholestérol indiquerait que les premiers pourraient être utilisés comme sondes fluorescentes des domaines du cholestérol dans les membranes.

Introduction

Cholesterol is an important lipid component of many membranes but its role in influencing the structure and function of membranes is not fully understood (1). This is partly due to the difficulty of monitoring any property of cholesterol when it is in such an inhomogeneous environment as a membrane. Hence, an external material with an easily measurable property is usually added to the system under question in order to probe the effect of cholesterol on the system.

Fluorescence is one of the most sensitive probe techniques available. Consequently, very little external fluorescent probe material needs to be added, thereby minimizing any possible perturbations of the system by the probe. Many fluorescent probes bearing no resemblance to natural membrane constituents have been used in cholesterol/membrane studies, particularly diphenylhexatriene (2). For our projected studies, we wished to have a fluorescent probe which resembled cholesterol closely, especially with regard to its amphipathic nature and molecular geometry.

We have synthesized the fluorescent cholesterol analogues **1** → **6** with conjugated unsaturation in the sidechain (3).[3] We believe that these analogues resemble cholesterol most closely of all the currently available fluorescent cholesterol-like probes (4). In the synthesis of compounds **1** → **6**, one of the double bonds in the sidechain was formed in a Wittig reaction, hence there was the possibility of the product being a mixture of two isomers. In order to be able to use these probes in fluorescence lifetime and anisotropy studies, it was important that they be a single isomer. So, 500 MHz ^{1}H nmr spectroscopy was used to determine which isomers were present, and the ratio of the isomers if applicable. This meant an analysis of the downfield region (~6 → 8 ppm) of the ^{1}H nmr spectrum. It was decided to analyze the upfield (ring proton) region of the spectrum as well, since few steroids have had their ^{1}H nmr spectrum fully assigned and analyzed for coupling constants. Comparison of the ring ^{13}C chemical shifts with those reported in the literature for cholesterol (5) could also give us an idea of how similar these cholesterol-type probes are to cholesterol.

Results and discussion

(a) Olefinic and aromatic proton assignments of ***1*** → ***6***

The downfield portion of a one-dimensional (1D) ^{1}H nmr spectrum of a mixture of **1** and **2** is shown in Fig. 1. Due to the presence of the two geometrical isomers, straightforward analysis of the 1D spectrum was not possible. A ^{1}H–^{1}H shift-correlated spectrum (COSY) (6) of the same region is shown in Fig. 2. The 22-H resonances were recognized due to their coupling with the corresponding 21-methyl resonances at

~1.9 ppm (not shown). The connectivities of the olefinic proton resonances in the two isomers was then easily established (for chemical shifts see Table 1). The COSY spectrum also confirmed the presence of an olefinic proton resonance under the aromatic envelope, a fact suspected from integration of the 1D spectrum.

By coupling constant analysis (Table 2) of the olefinic proton multiplets (J_{trans} ~ 15 Hz, J_{cis} ~ 11 Hz from numerous studies of carotene systems (7) for example), and from integration of the 22-H resonance of **1** versus the identical 6-H resonance of both isomers, it was determined that the isomers **1** and **2** were present in the ratio 40:60. Simulation of the olefinic proton resonances using a 50:50 ratio and the measured chemical shifts and coupling constants, produced a spectrum virtually identical to the experimental 1D spectrum except for the intensity ratios (Fig. 1). Although **1** and **2** had been obtained by a Wittig

reaction on the 20(22) *E*-aldehyde **7** (3*a*), the geometry of the C-20, C-22 double bond of the two isomers was not confirmed as being *E* by the 1D or COSY experiments. This is because the similarity of transoid and cisoid allylic coupling constants does not allow unambiguous assignment (8).

Nuclear Overhauser effect (nOe) experiments (9) allowed us to determine the C-20, C-22 double bond geometry since the magnitude of this effect is dependent on internuclear distance to the inverse sixth power. In a 20(22)*E*-isomer of the compounds under study, one would expect to see an n0e enhancement of the 21-methyl resonance upon saturation of the 23-H resonance due to the proximity of these protons. Saturation of the 22-H resonance should not lead to an enhancement of the 21-methyl resonance since these protons are on opposite sides of a double bond and hence too far apart for a nOe to occur. On the other hand, in a 20(22)Z-isomer, an nOe enhancement of the 21-methyl resonance should occur upon saturation of the 22-H resonance but not the 23-H resonance. Nuclear Overhauser

effect experiments were performed on a purified sample of **1** (Table 3) and since an enhancement of the 21-methyl resonance at 1.85 ppm was observed upon saturation of the 23-H resonance, the C-20, C-22 double bond geometry was confirmed as being *E*, as expected from the synthetic route to this compound (3*a*).

Analysis of the signals in the olefinic proton region of the 1D ^{1}H nmr spectra of the conjugated dienes **3** → **6** was straightforward after the geometry of the conjugated trienes **1** and **2** had been determined unequivocally. (For a diagram of the nOe experiments performed on **3**, see Fig. 3.) All that remained was to assign the aromatic proton resonances. The assignment of the *ortho*-, *meta*-, and *para*-proton resonances of **1**, **3**, and **4** followed from inspection of the multiplicity and integration of the three multiplets in the aromatic region (for **3**, see Fig. 3). The identical *ortho*-protons (2′-H,6′-H) should give a doublet resonance which integrates to two protons, the identical *meta*-protons (3′-H,5′-H) should give a triplet resonance which also integrates to two protons while the *para*-proton (4′-H) should give a triplet resonance which only integrates to one proton. Likewise the assignment of the naphthyl proton resonances in **5** came from multiplicity and integration arguments although the individual chemical shifts of the 4′-, 5′-, and 8′-naphthyl protons could not be extracted from the multiplet centred at 7.76 ppm. The relative order of the naphthyl proton chemical shifts agreed with that reported for 2-methylnaphthalene (10). All the downfield ^{1}H chemical shifts determined for compounds **1** → **6** are given in Table 1, while ^{1}H–^{1}H coupling constants are given in Table 2.

(b) Ring proton chemical shifts of 1

The cholesterol ring system with its Δ^5 double bond, 3β-OH and 17β substitution, as found in compounds **1** → **6**, presents quite a challenge to the nmr spectroscopist for proton assignment as there are 23 proton signals within 1.7 ppm. The only known attempts at ring proton resonance assignment of cholesterol are given in Table 4. These assignments were made by comparing spectra of deuterated cholesterol derivatives (11*a*) or by the use of lanthanide shift reagents (11*b*). Since compounds **1** → **6** do not possess the C_8H_{17} saturated sidechain of cholesterol, their ^{1}H nmr assignment was easier, especially with the aid of the recently acquired battery of two-dimensional (2D) nmr techniques (6, 12). These 2D nmr techniques have been successfully used to assign ring proton resonances of other steroids, usually those with a larger number of functional groups and (or) double bonds resulting in some simplification of the spectrum (ref. 13*a*–*f*, for a recent application of 2D NMR techniques to closely related triterpenes see ref. 13*g*).

The first step in the assignment was to distinguish the methine from the methylene proton resonances. This was achieved by performing a DEPT experiment (6*b*) to identify the methine and methylene carbons (Fig. 4). Then a ^{13}C–^{1}H shift correlated spectrum (6) with proton decoupling in both dimensions (Fig. 5) allowed determination of corresponding methine proton chemi-

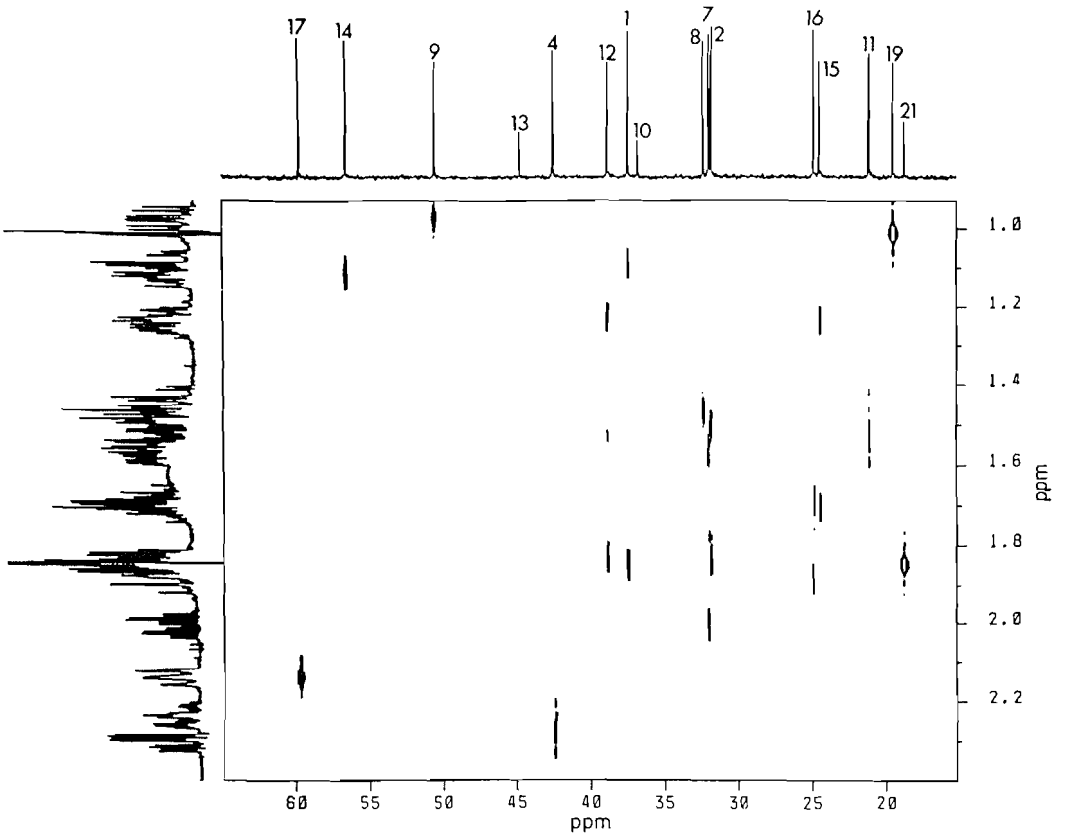

FIG. 5. Upfield region of the $^{13}C-^{1}H$ shift-correlated spectrum of **1**.

cal shifts. Of the four methine proton resonances, the most downfield one (2.135 ppm) was assigned to 17α-H because of its proximity to the 20(22) double bond. The three remaining methine proton resonances due to 8β-H, 9α-H, and 14α-H could only be assigned after analysis of nOe difference experiments and a COSY spectrum.

The second step in the assignment was to distinguish the axial methylene proton resonances from the equatorial proton resonances, since the chemical shifts of axial and equatorial protons in cyclohexyl ring systems differ due to the shielding effect of 1,3-diaxial interactions (13*e*). This was possible from the proton-decoupled $^{13}C-^{1}H$ shift correlated spectrum mentioned above since two non-equivalent methylene protons give two peaks in the ^{1}H dimension for each methylene carbon (Fig. 5). Because of the 1,3-diaxial interaction, the axial proton can be assigned to the more upfield of the two resonances.

The third step was to assign proton numbers to the observed chemical shifts (Table 4). This was achieved in large part by analysis of a COSY spectrum (Fig. 6), with the help of the few known resonances (3α-H, 6-H, and 17α-H). For example, the methine proton 14α-H was distinguished from the 8β and 9α methine protons through its coupling with the 15α and β protons (coupled weakly to 17α-H at 2.135 ppm). Then since 8β-H but not 9α-H couples with 14α-H, the two remaining methine proton resonances were assigned. However, the spin system 1α, 1β, 2α, 2β could not be easily distinguished from the 12α, 12β, 11α, 11β spin system. Furthermore, the methylene protons of the cyclopentyl D ring could not be simply assigned as α or β on the basis of the axial/equatorial proton chemical shift difference found for cyclohexyl systems.

Both of these problems were solved by selective nOe difference experiments. The rigid cholesterol ring system, with its two angular methyl groups at C-18 and C-19 makes it an ideal molecule for nOe experiments. Through saturation of the 18-methyl and 19-methyl resonances, the axial protons on the β face of the molecule can be observed (Table 3). Both the 11β and the 2β protons are axial, but while saturation of the 19-methyl resonance will lead to an enhancement of both these resonances, saturation of the 18-methyl resonance will only affect the 11β proton. On this basis, the spin systems 1α, 1β, 2α, 2β and 12α, 12β, 11α, 11β were assigned. These nOe difference experiments also allowed assignment of the 15β-H and confirmation of the assignment of the 4β and 8β axial protons. All that remained was to assign the 16-H resonances since the 16β-H had not been observed by the nOe experiment on the 18-methyl group.

It had been noted from the nOe experiment performed on the 22-H resonance to determine the 20(22) double bond geometry (see section A) that enhancements were seen to two ring proton resonances centred at 2.15 ppm and 1.90 ppm as well as to the 18-methyl group at 0.59 ppm (Table 3). From a Dreiding model it was determined that, upon rotation of the C-17, C-20 bond, the 22-H approaches the 17α and the 16β ring protons most closely. Since the nOe is dependent on internuclear distance to the inverse sixth power (9), the two resonance enhancements must be due to these two protons. The 2.15 ppm resonance had already been independently assigned to 17α-H, and the 1.90 ppm resonance did correspond to one of the 16-H chemical shifts previously determined so the 16β-H and hence 16α-H were assigned.

(c) Ring proton–proton coupling constants of ***1***

Our interest in obtaining proton–proton coupling constants from the multiplets in this crowded region of the spectrum was

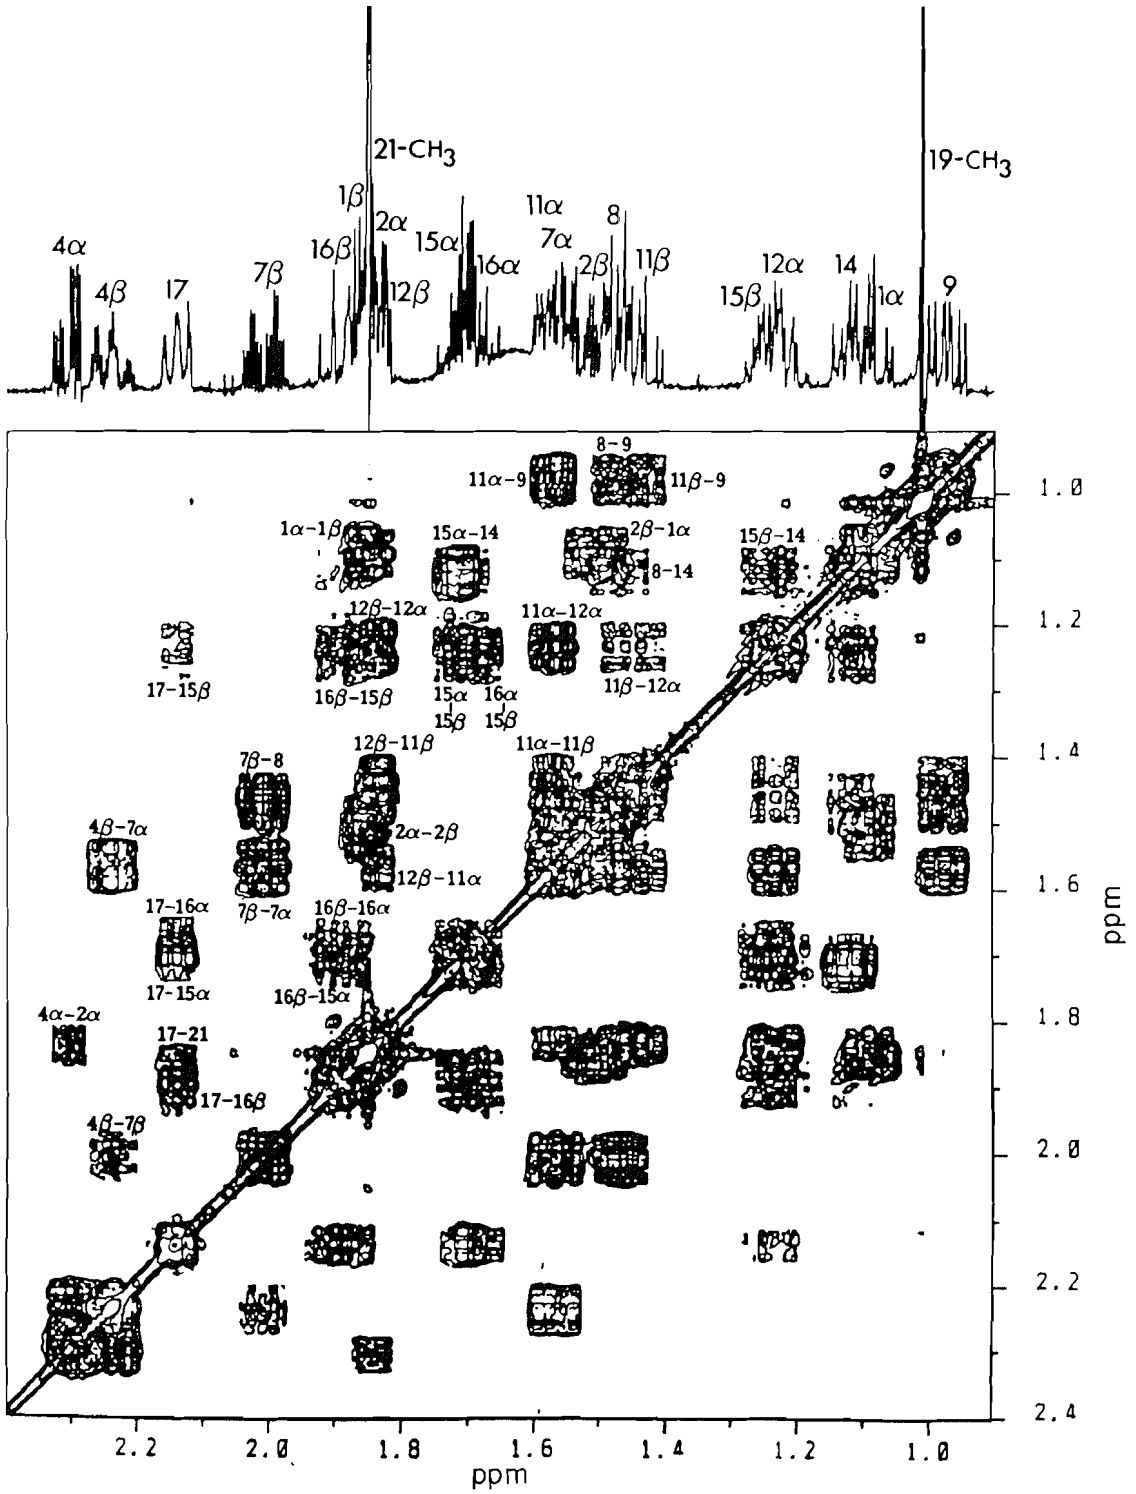

FIG. 6. Upfield region of the COSY spectrum of **1**.

threefold. Firstly, their determination would provide a further means of confirming the assigned proton chemical shifts, particularly for those geminal proton pairs whose axial proton was on the α-face of the molecule and hence had not been confirmed by nOe experiments. Secondly, given the precedence for allylic and homoallylic coupling (8) and the previously observed ^4J coupling to steroid angular methyl groups (8, 13*e*), it was of interest to determine the extent of long-range coupling in a cholesterol-type ring system. Lastly, due to the dependence of vicinal coupling constants on dihedral angle (14) a coupling constant analysis of the D ring protons could give us an idea of the D ring conformation of **1** in solution.

A ^{1}H homonuclear *J*-resolved spectrum (6) of **1** was measured. In such a spectrum, the various proton multiplets are seen as single lines in the second dimension f_2 (in this case allowing confirmation of the chemical shifts), and as separated multiplets in the first dimension f_1 allowing measurement of the various coupling constants. For those resonances that were

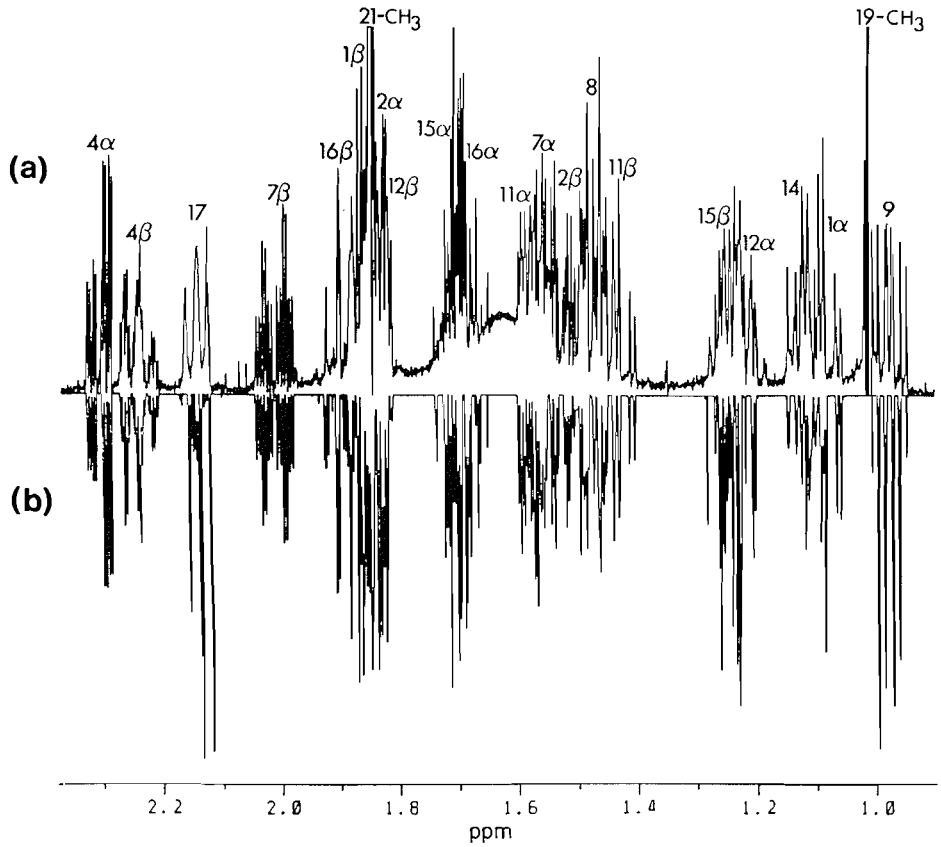

FIG. 7. Upfield region of the 500 MHz ^{1}H nmr spectrum of **1**. (*a*) Experimental spectrum. (*b*) Simulated spectrum.

overlapping in the ^{1}H 1D spectrum, the f_1 cross-sections of the *J*-resolved spectrum were plotted and the coupling constants determined. The chemical shifts and coupling constants were used as initial values to generate a simulated ^{1}H 1D spectrum in the region 0.9 → 2.4 ppm, excluding the methyl resonances at 1.01 pm and at 1.85 ppm (Fig. 7). The coupling constants obtained after spin simulation are given in Tables 5 and 6.

The simulated spectrum matched the experimental spectrum well except for the D ring proton resonances which were line broadened in the latter case. This line broadening is probably due to an intermediate exchange of the chemical shifts of these resonances (15), because of a somewhat hindered rotation about the C-17, C-20 bond of the sidechain modulating the environment of the ring D protons, in particular the 17 proton ($\delta_{17\alpha\text{-H}}$ = 2.135 ppm). The line broadening could also be a result of modulation of the coupling constants due to conformational flexibility of the D ring itself. Because of this line broadening and the strong overlap of the resonances due to the 15α and 16α protons, the error associated with the coupling constants of the D-ring protons is larger than for the other ring protons. However, these D-ring coupling constants are quite similar to those determined for other steroids (11*a*, *b*, *d*, *e*), for example there is a large difference in the coupling constants of the geminal protons 15α and 15β with the 16β proton (0.5 and 10.0 Hz, respectively).

As far as long-range coupling is concerned, there was evidence from the COSY spectrum of ^4J coupling between the 18-methyl group and both the 12α and 17α proton resonances (not shown in Fig. 6), and also between the 19-methyl group and the 1α and 9α protons (see Fig. 6) as found in some other steroids (8, 13*e*). However, there was no evidence of coupling between the 18-methyl group and the 14α proton, not even from a long-range COSY experiment (6). Long-range coupling between the 2α and 4α protons was also seen in the COSY spectrum (Fig. 6), and measured from the well-separated 4α proton resonance to be 1.2 Hz. These two protons and the four σ-bonds between them are in the familiar "W" arrangement, a condition found to be necessary for long-range coupling not involving a double bond. This is the first known example of a non-allylic/non-carbonyl long-range coupling in the steroid nucleus not involving one of the angular methyl groups.

Allylic couplings were seen between protons on either side of the C-5, C-6 double bond, as to be expected from similar studies of Δ^4-steroids (8). The magnitude of the allylic coupling was greater between the 6 and 4β protons than between the 6 and 4α protons (2.7, 2.3 Hz, respectively). This is in keeping with theoretical agruments (8) where the closer the angle between the plane of the double bond and the vinyl C—H bond is to 90°, the larger the coupling. Homoallylic coupling was also seen between the 4β proton and both the 7α and 7β protons (see Fig. 6). However, there was no coupling between the 4α (equatorial) proton and the 7α and 7β protons.

(d) ^{13}C chemical shifts of 1

Since the proton chemical shifts of **1** were known, assignment of the ^{13}C chemical shifts of **1** was straightforward from the ^{13}C–^{1}H shift-correlated spectrum (Fig. 5). However, of the five quaternary carbon resonances, only the C-10 and C-13 resonances could be assigned based on literature values for other steroids (5). The three remaining quaternary carbon resonances were separated by only 3 ppm (δ 140.85, δ 140.20, and δ 137.74). After measurement of the ^{13}C nmr spectrum for

[a]Refined values after spin simulation (±0.5 Hz).

compounds **3**, **4**, and **5**, the 140.84 ppm resonance was assigned to C-5 due to its insensitivity to the structure of the sidechain (Table 7). The remaining two quaternary carbon resonances of **1** were due to C-20 and C-1′ and were assigned after performing a selective INEPT experiment (16). In this experiment, a specific proton resonance is saturated and the parameters for ^{13}C spectrum acquisition are such that only the carbon atom which is long-range coupled ($J_{CH} \sim 10$ Hz) to the irradiated proton is observed. In our case, upon saturation of the 21-methyl proton resonance, only the quaternary signal at 140.20 was observed and assigned to C-20 (Fig. 4). Hence the remaining quaternary carbon resonance at 137.74 ppm was assigned to C-1′.

*(e) Nuclear magnetic resonance assignments of **3**, **4**, and **5***

Ring ^{13}C resonances of **3**, **4**, and **5** were assigned by analogy to those determined for **1** due to the similarity of the chemical shifts of the carbon signals in the four compounds (Table 7). The only small differences (0.17 ppm at most, for C-17) occurred for the chemical shifts of the D ring carbons, as to be expected from the different sidechain structures.

Olefinic ^{13}C resonances of **3** were determined from a CHORTLE experiment (17) (not from a $^{13}C-^1H$ shift-correlated spectrum due to low sample concentration) by their correlation with the known olefinic proton resonances (Table 7). The CHORTLE experiment also allowed the ring proton resonances of **3** to be assigned. The resulting proton chemical shifts were very similar to those obtained for **1** by spin simulation (Table 4).

Finally, the ring ^{13}C chemical shifts of cholesterol (5) have been included in Table 7. Comparison of these values with those measured in this work for **1**, **3**, **4**, and **5** indicate that the effect of the unsaturated sidechains of these latter compounds on the cholesterol ring system is small. Hence these fluorescent steroids bear a close resemblance to cholesterol with their free 3β-OH, their cholesterol ring system and their hydrophobic sidechain, and should prove useful in fluorescence studies of cholesterol domains in membranes.

Experimental section

All nmr measurements were performed with a Bruker AM-500 instrument at 300 K. Chemical shifts are relative to internal TMS. Sample concentrations were typically 3–5 mg/0.5 mL $CDCl_3$ for 1D experiments. The 2D experiments are outlined below.

The $^1H-^1H$ shift-correlated spectrum (COSY) of a mixture of **1** and **2** was acquired and processed using the standard software provided by Bruker. The f_2 spectral width was 4000 Hz or 8 ppm. The initial (t_1,t_2) matrix of 512 × 2K real data points was zero-filled to 2K × 2K data points to give a final resolution of 1.95 Hz/point. Processing was done using sine bell squared functions and a magnitude calculation. For each FID, 32 transients were accumulated requiring a total acquisition time of 16 h. Sample concentration was 25 mg/0.5 mL $CDCl_3$.

The COSY spectrum of **1** was acquired with an f_2 spectral width of 1400 Hz or 2.8 ppm. The initial (t_1,t_2) matrix of 256 × 1K real data points was zero-filled to 1K × 1K points to give a digital resolution of 1.37 Hz/point. Data manipulation was done using sine bell functions and a magnitude calculation. For each FID, 64 transients were accumulated. Sample concentration was 40 mg/0.5 mL $CDCl_3$.

The $^{13}C-^1H$ shift-correlated spectrum of **1** with proton decoupling in the F_1 domain was obtained with the usual pulse sequence (18). The spectral widths were 4000 Hz (8 ppm) in f_1 and 18500 Hz (~145 ppm) in f_2. The initial (t_1,t_2) matrix of 256 × 1K real data points was zero-filled to 1K × 2K data points to give a digital resolution of 4 Hz/point and 9 Hz/point in the f_1 and f_2 domains, respectively. Processing was done using gaussian functions and a power spectrum calculation. For each FID, 800 transients were accumulated for a total acquisition time of 60 h.

Nuclear Overhauser effect difference spectra of **1**, **3**, **4**, and **5** were obtained using spectral widths of 5000 Hz (10 ppm) and 8K real data points, to give a digital resolution of 0.6 Hz/point. Each line in a multiplet was irradiated sequentially (19) for a total irradiation time of 2 s per multiplet.

The ^1H *J*-resolved spectrum of **1** was acquired with spectral widths of 1000 Hz (2 ppm) and 31.25 Hz in the f_2 and f_1 domains, respectively. The initial (t_1,t_2) matrix of 32K × 2K real data points was zero-filled to 64 × 2K data points to give a digital resolution of 0.49 Hz/point in both dimensions. Processing was done with sine bell functions and a magnitude calculation.

The CHORTLE analysis of **3** (5 mg/0.5 mL $CDCl_3$) was performed using the pulse sequence of Pearson (17), with four proton evolution times of 0.24, 1.00, 2.40, and 3.20 ms and 14000 transients per point.

All ^{13}C spectra, including the DEPT spectrum of **1** (for the pulse sequence used see ref. 20), were acquired with spectral widths of 31250 Hz (250 ppm), 16K real data points and 12000 transients. The selective INEPT spectrum of **1** was acquired using the pulse sequence of Bax (16) except that there was no ^1H broadband decoupling and no refocussing of the ^{13}C resonances due to hardware restrictions in switching from high to low power. A total of 1680 transients was accumulated.

Spectral simulations were made using the PANIC program provided by Bruker.

Pulse cyclic voltammetry. II. Flowing solutions

GORDON N. ECCLES AND WILLIAM C. PURDY[1]

Department of Chemistry, McGill University, 801 Sherbrooke St. West, Montreal, P.Q., Canada H3A 2K6

Received December 16, 1986

This paper is dedicated to Professor John T. Edward

GORDON N. ECCLES and WILLIAM C. PURDY. Can. J. Chem. **65**, 1795 (1987).

By the use of pulse cyclic chronovoltammetry, better analytical data are sometimes obtained during the reverse scans. This is demonstrated by a chronovoltammetric FIA study of the quinone–hydroquinone couple. A quantitative FIA pulse cyclic chronovoltammetric investigation of the ferri–ferrocyanide reversible couple showed linearity for time-integrated fourier-smoothed data for reduction scan currents as well as the total of the forward and reverse scan peak currents. The detection limit was found to be $2 \times 10^{-6} M$.

GORDON N. ECCLES et WILLIAM C. PURDY. Can. J. Chem. **65**, 1795 (1987).

Lorsqu'on utilise la chronovoltamétrie cyclique pulsée, on obtient quelquefois de meilleurs données analytiques durant les balayages inverses. On a mis cette propriété en évidence au cours d'une étude chronovoltamétrique FIA du couple quinone/hydroquinone. Une étude chronovoltamétrique cyclique pulsée FIA quantitative du couple réversible ferri/ferrocyanure présente une bonne linéarité pour les données, intégrées en fonction du temps et lissées par transformation de fourier, relatives aux courants de balayage pour la réduction ainsi que pour les courants totaux de balayage dans les deux sens. On a trouvé que la limite de détection est de $2 \times 10^{-6} M$.

Introduction

Research on electrochemical detection methods for electroactive species in flowing streams is focussing on improving selectivity without compromising sensitivity or detection limits. This is one area of major concentration in our laboratory and this paper will describe a rapid scan detector that utilizes a modified cyclic voltammetry (CV) waveform as the applied signal. This development adds another dimension to the detector, the possibility of both qualitative and quantitative analysis.

Amperometric electrochemical detectors are the most common (1, 2) and offer high sensitivity, relatively simple instrumentation and reasonable selectivity through judicious selection of the applied potential. Pulse and square-wave linear sweep applied waveforms add the additional dimension of qualitative information to highly selective electrochemical detectors (3–8). Flow injection analysis and CV have been shown to be compatible and easily combined as a potentially new way to perform electrochemical experiments (9, 10).

To date the majority of electrochemical studies on organic compounds have involved oxidations; organic reductions await the development of a reliable mercury electrode (11, 12). The advantages of a mercury electrode are its relatively high hydrogen overpotential, its renewable surface that can discard adsorbed reaction products and its low capacitative background current. Disadvantages are its toxicity and the difficulties involved in controlling the drop in flowing streams. The use of carbon electrodes eliminates these two problems. Hepler, Weber, and Purdy evaluated Low-temperature Isotropic Carbon (LTIC) as an electrode material and found it to have higher hydrogen overpotentials when compared to electrodes made of carbon paste or glassy carbon impregnated with ceresin wax (13). This compares adequately as a substitute for a Hg electrode. Electrochemical cleaning of solid electrodes in situ can be accomplished by pulse methods (7, 14) but interference from electrode charging current remains a limitation with carbon.

In spite of this disadvantage, a wealth of voltammetric information can be obtained by applying a pulse cyclic voltammetric waveform as the excitation signal (15, 16). This work will show some of the merits achieved when applying this waveform to an LTIC electrode in flow-injection analysis (FIA) using the hydroquinone–quinone couple. In addition, a FIA quantative study of the ferri–ferrocyanide couple with integration and fourier-smoothing techniques will be illustrated.

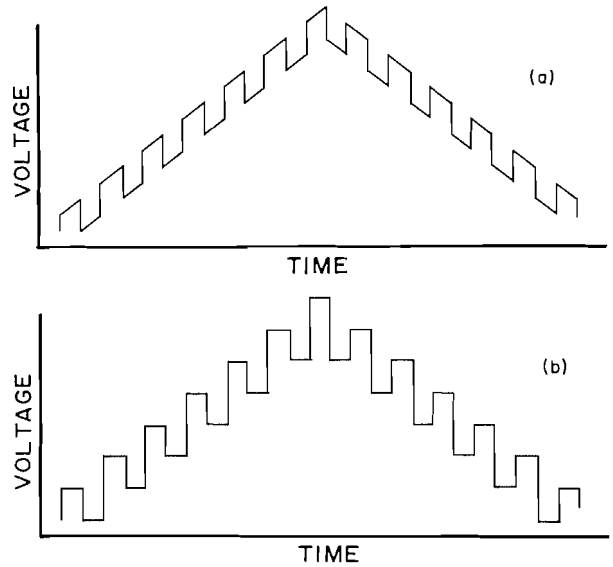

FIG. 1. Working electrode waveforms. (*a*) Pulse cyclic voltammetry. (*b*) Square-wave cyclic voltammetry.

Experimental

Flow injection apparatus

The flow injection system consisted of a constant flow reciprocating pump (Model 590 Waters Associates, Milford, MA) and a 20 μL loop injector (Model 7010, Rheodyne, Berkeley, CA). Coiled Teflon tubing measuring 195 cm in length and 0.292 in. in diameter with Teflon and stainless steel couplings was used. The mobile phase was 1 *M* sulfuric acid and the flow rate was 0.150 mL/min in all experiments.

Electrochemical apparatus

The microprocessor-controlled potentiostat used to carry out CV and pulse cyclic voltammetry (PCV) has been described previously (15). The work described in that paper was based on the waveform shown in Fig. 1*a*. This type of waveform offers electrochemical information in two time domains. In addition to the conventional CV time scale,

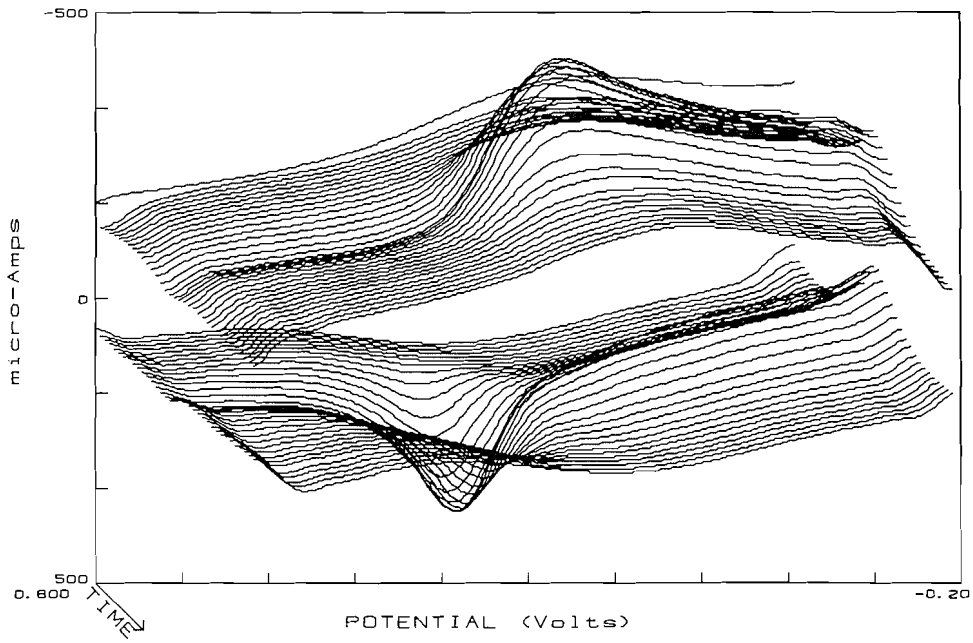

FIG. 2. Fourier-smoothed cyclic chronovoltammogram of 1 m*M* quinone in 1 *M* sulfuric acid. Initial time delay = 35 s. Number of cycles = 35. Data acquisition frequency = 120 Hz. Voltage ramp = 1 V/s.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

another short time scale is obtained from the negative and positive going pulses. During the lifetime of a pulse in this waveform the potential continues to ramp, introducing a charging current component. Recently a modification to our instrument was undertaken to generate the waveform in Fig. 1*b* which is similar to the new waveform that was developed by Drake, Van Duyne, and Bond (17). The difference is that a square wave is applied as opposed to a pulse train and will be termed square-wave cyclic voltammetry. Preliminary results using this waveform indicate the expected decrease in the background current and consequently a relative increase in the faradaic component. The extent of the improvement at the LTIC electrode is currently under investigation.

Additional equipment that is required includes an IBM PC with 640 Kbytes of memory, an IBM colour monitor, a HP 7470 2-pen plotter, and a parallel opposed channel electrode flow cell (1 μL volume) consisting of a 2 mil Teflon spacer sandwiched between two LTIC (available from Carbomedics Inc., Austin, TX) plates with a downstream silver/silver chloride reference electrode. One plate was used as the working electrode and the other operated as the auxiliary. The data were obtained and stored in computer memory until each run was completed. Then the results were transferred to a hard disk.

The software language used to operate the instrument and manipulate the data was written in TURBO Pascal-87. The program is menu-driven and communicates interactively with the operator for smooth operation. The fourier-smoothing program was modified to handle our data format and translated to TURBO Pascal-87 from a routine written in BASIC (18).

Chemicals

Reagent grade chemicals were used in preparation of all solutions. A 2.00 m*M* stock solution of potassium ferricyanide was prepared by dissolving the salt in 1 *M* sulfuric acid. Solutions of 1.00, 0.400, 0.200, and 0.080 m*M* were subsequently prepared by diluting the appropriate volume of the stock solution in 1 *M* sulfuric acid. A solution of 1 m*M* quinone was prepared by dissolving the required weight in 1 *M* sulfuric acid.

Procedure

Cyclic and pulse cyclic chronovoltammograms were obtained for a 1 m*M* solution of quinone in 1 *M* sulfuric acid. The sequence was to inject 20 μL of the solution, hold the working electrode at 0.800 V vs. an Ag/AgCl reference for 35 s and then apply the waveform. The time delay was predetermined by an initial run at a faster sweep rate and was used to reduce the amount of blank cycles. One run containing several consecutive cycles was obtained for each mode of operation.

Pulse cyclic chronovoltammograms were obtained for various concentrations of ferricyanide in 1 *M* sulfuric acid. The sequence was identical to the one described above. A total of 3 runs containing 35 consecutive cycles was obtained for each concentration.

The data were stored on the hard disk in the computer. Later, the response current vs. potential curves were processed and smoothed prior to plotting.

Results and discussion

FIA of quinone using a rapid scan CV and PCV detector

In static solutions it was found that the residual current becomes reproducible after completion of the first cycle during a multiple scan CV (16). This behaviour is also observed in flowing streams and is illustrated by the results of a multiple scan CV of a 20 μL injection of 1 m*M* quinone in 1 *M* sulfuric acid shown in Fig. 2. The forward and reverse current traces are arbitrarily spaced apart to reduce overlapping lines. The upper curves represent the forward scans (peaks are reduction currents of quinone to hydroquinone) and the lower curves are results of the reverse scans (peaks are oxidation currents of hydroquinone to quinone). The oxidation peak is well defined in contrast to the broad reduction peak indicating that this couple is not electrochemically reversible.

The data in Fig. 3 were obtained from a multiple scan pulse cyclic chronovoltammogram of a 20 μL injection of 1 m*M* quinone in 1 *M* sulfuric acid. Again the upper and lower traces are arbitrarily spaced apart for clarity. The upper traces correspond to data acquired at the end of positive-going pulses, while the lower traces represent data from negative-going pulses. The current axis is of greater magnitude than in Fig. 2, indicating a sensitivity increase using PCV in contrast to CV. On the left of the switching potential (−0.200 V), the major peak in negative microampere range corresponds to reduction

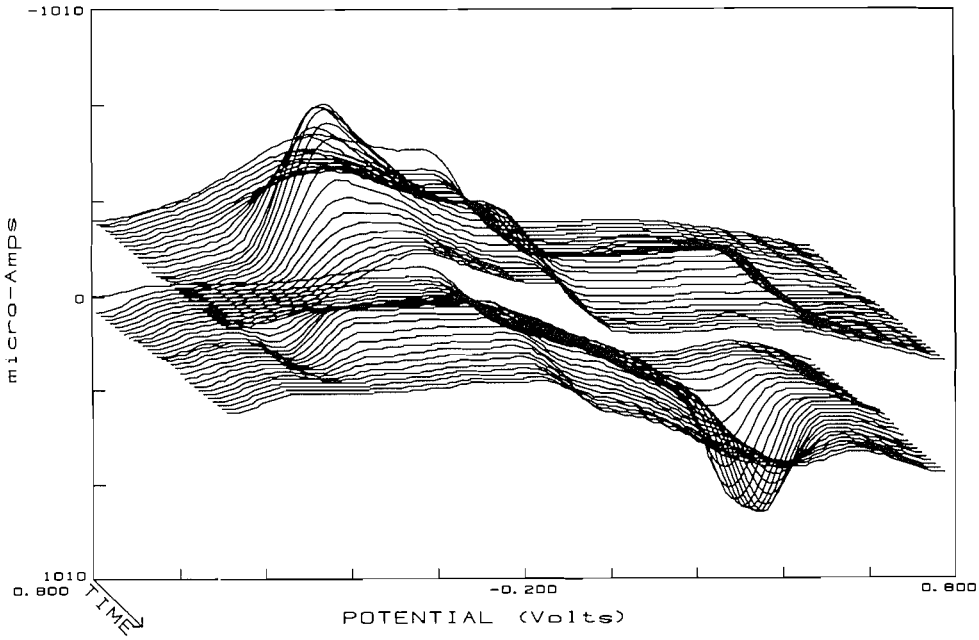

FIG. 3. Fourier-smoothed pulse cyclic chronovoltammogram of 1 m*M* quinone in 1 *M* sulfuric acid. Initial time delay = 35 s. Number of cycles = 30. Data acquisition frequency = 120 Hz. Square wave frequency = 60 Hz. Square wave amplitude = 100 mV. Voltage ramp = 1 V/s.

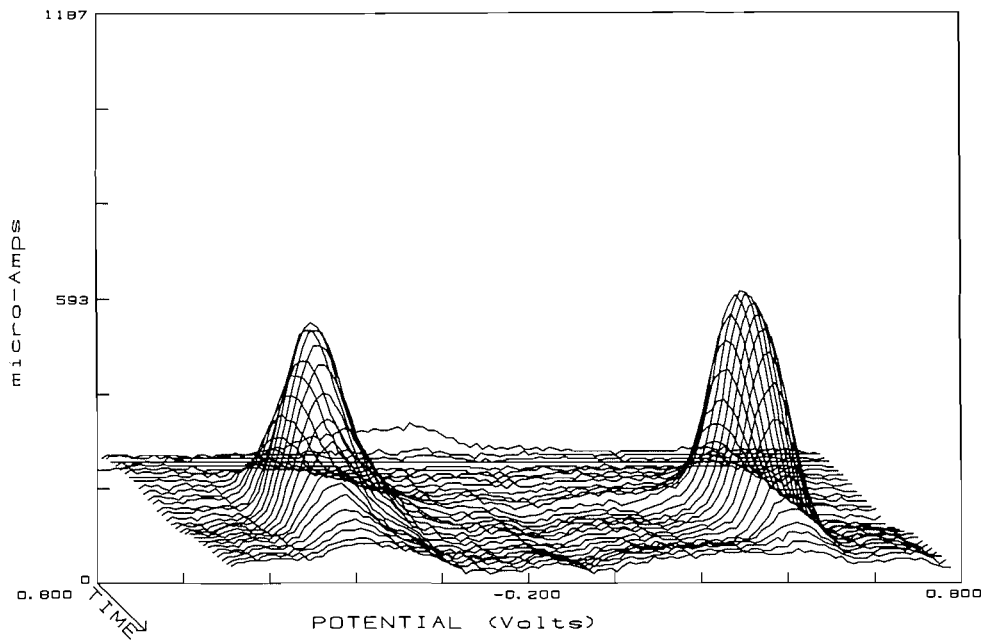

FIG. 4. Fourier-smoothed background corrected absolute difference plot obtained from the data in Fig. 3.

currents obtained from the conversion reaction of quinone to hydroquinone and the minor peak was constructed from oxidation currents obtained from the conversion of the generated hydroquinone to quinone (during the pulse time scale). On the right hand side of the switching potential the reverse scan voltammetric information displays a major peak in the positive microampere region for the oxidation of the generated hydroquinone during the long time scale of the process. Less electrochemical activity is observed here during the pulse time scale (upper traces) than during the forward scans.

It is shown in Fig. 3 that the oxidation currents during the short and long time scales predominate. Another way to display these data is by plotting the absolute current difference between a point acquired during a forward pulse and another during the respective reverse pulse; shown in Fig. 4. The peak on the right of this background corrected plot shows the major oxidation current obtained and the smaller peak on the left represents the major reduction current. Thus, it is clear that for an injected volume of quinone the oxidation current during the long time scale provides better analytical sensitivity. This demonstrates the analytical ability of a PCV detector in that better analytical data can sometimes be found in the reverse scan.

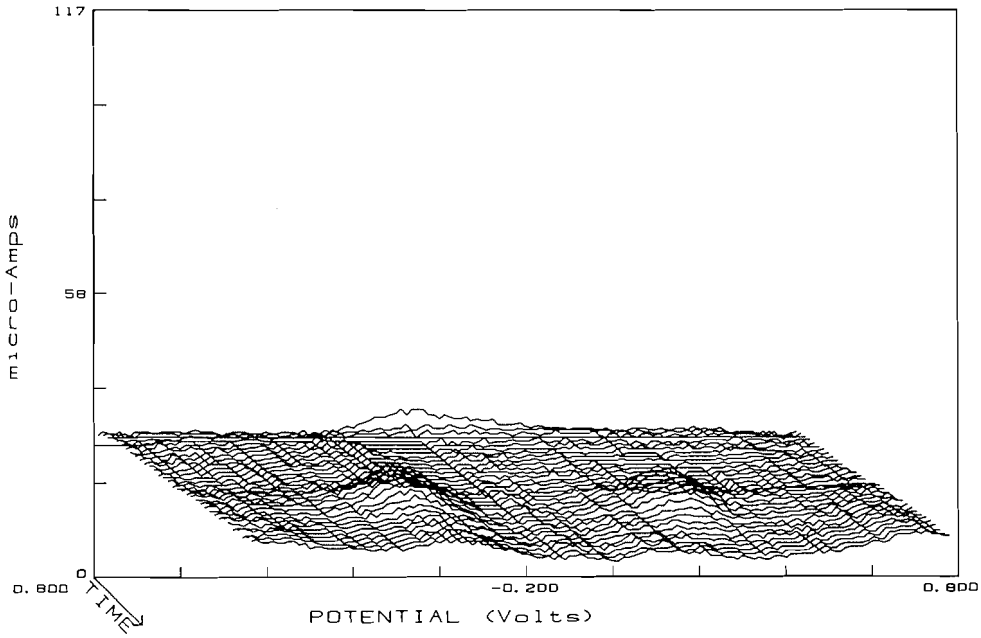

FIG. 5. Background corrected absolute PCV difference plot of 0.08 m*M* ferricyanide in 1 *M* sulfuric acid. Initial time delay = 35 s. Number of cycles = 35. Data acquisition frequency = 130 Hz. Square wave frequency = 65 Hz. Square wave amplitude = 100 mV. Voltage ramp = 1 V/s.

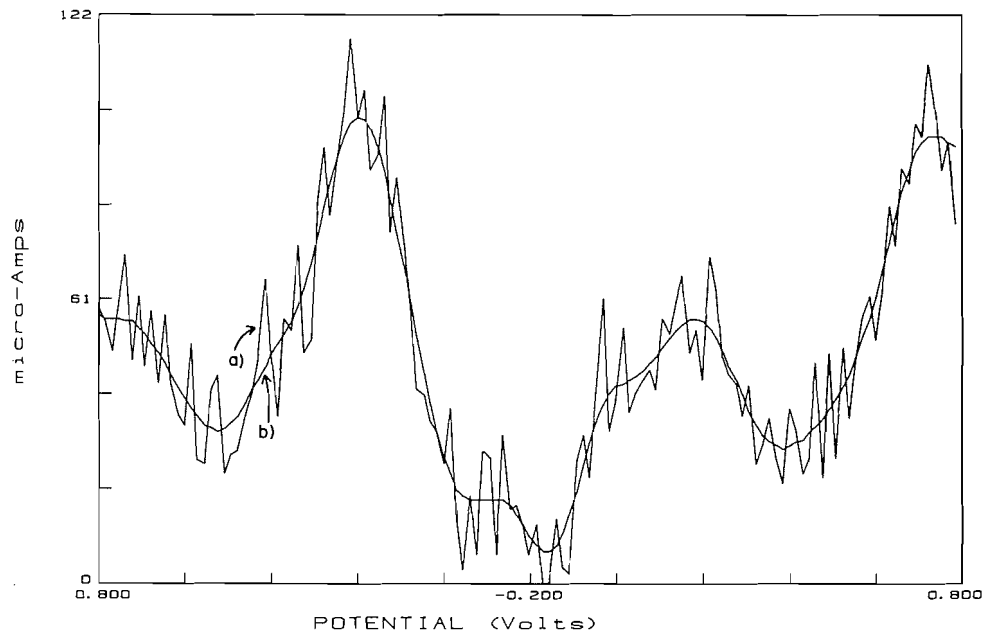

FIG. 6. Time-integrated plot of Fig. 4. (*a*) Before fourier smoothing. (*b*) After fourier smoothing.

Quantitative study of ferricyanide using FIA with a rapid scan PCV detector

A multiple scan PCV background corrected absolute difference plot is shown in Fig. 5 for 0.08 m*M* potassium ferricyanide in 1 *M* sulfuric acid. The major reduction currents obtained during the negative scans are shown on the left side of the switching potential and the major oxidation currents on the right. The signal is enhanced up to a factor of ten by integrating the pulse cyclic chronovoltammogram with respect to the time axis for those cycles containing a response; a plot of these results is shown in Fig. 6*a*. The outcome is a single total current response curve containing significant high frequency noise. After fourier smoothing, the noise is reduced considerably and peak currents are easily measured (see Fig. 6*b*). Plots of reduction scan currents, oxidation scan currents and the totals of these two against concentration of ferricyanide are shown in Fig. 7. Signal drop at the high concentration may be due to departure from the dynamic range of the technique. The equation of the line (high concentration omitted) for the reduction scans is $y = 11.25 + 499.9x$ with a correlation coefficient of 0.9903. The detection limit was found to be 2×10^{-6} *M*. The total current line equation (high concentration omitted) is $y = 44.69 + 773.0x$ with a correlation coefficient of 0.993. The separation that is observed between the reduction

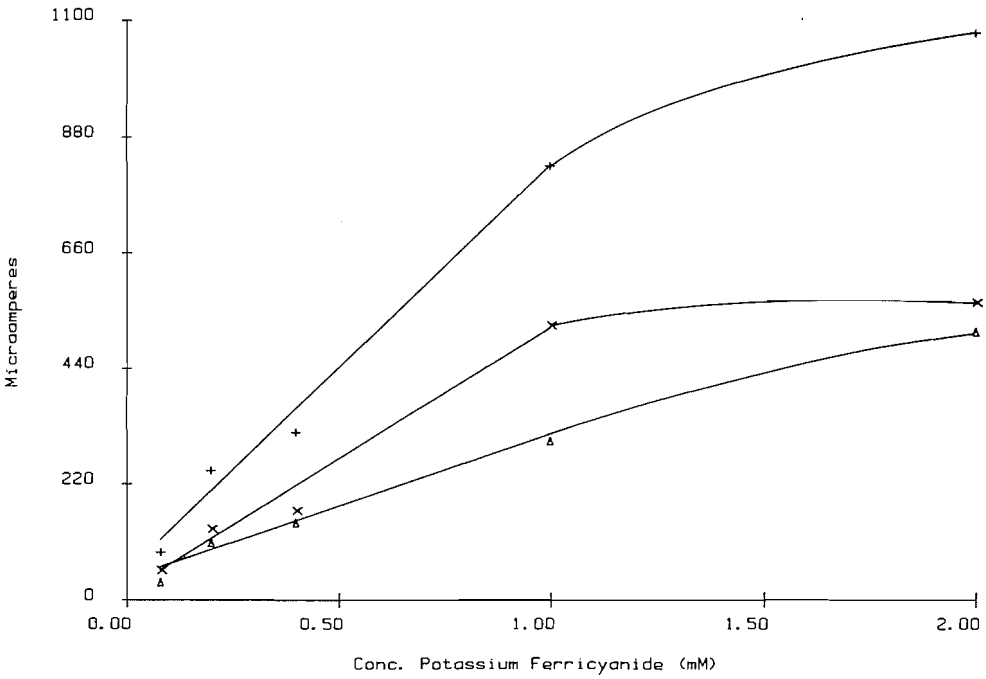

FIG. 7. Peak height vs. concentration of ferricyanide of various time-integrated fourier-smoothed difference plots. (×) Forward scan currents, (△) reverse scan currents, (+) total currents.

scan peak current and the oxidation scan peak current may be due to the timing involved with the flowing sample front, the electrode and the applied waveform. This is currently being investigated.

Conclusions

A rapid scan CV and PCV detector in FIA offers the advantage of generating an electroactive compound initially absent in the injected sample and studying its electroactive properties during the reverse scan. This was illustrated using the quinone hydroquinone redox couple. The relative sensitivity was shown to be greater for the PCV detector.

Linear calibration curves were obtained by plotting the time-integrated reduction scan peaks and the total forward and reverse scan peak currents against the concentration of ferricyanide. The detection limit was found to be $2 \times 10^{-6} M$.

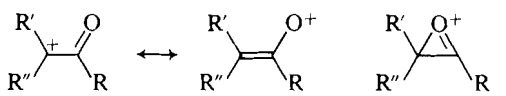
Introduction

The destabilization of carbocations with electron-withdrawing groups imparts certain properties that are unique to such systems, and has prompted a number of recent investigations of their structures and reactivities (1). An α-formyl group, when coplanar with a cationic carbon, functions as a π-donor and σ-acceptor with the overall effect being destabilizing (2). Higher level calculations show H_2C^+CHO to collapse without a barrier to the oxygen-bridged cyclic ion **2** (3) and this structure is very weakly stabilized relative to the open structure (4). However, it is expected that alkyl and (or) aryl substitution will stabilize the open form. Solvolytic studies of their α-keto-sulphonate precursors indicate that only minor rate-retarding effects are observed with a carbonyl group present (5). In certain cases (5) an α-keto substituent actually enhanced rates of solvolysis relative to hydrogen.

The stabilizing effect of a carbonyl group may be associated with two charge delocalization mechanisms. Delocalization of the positive charge via π-delocalization (mesomeric effect) would produce a vinyl oxenium ion **1**. Alternatively, neighboring group interaction (σ-bridging) would give a 3H-oxirenium cation **2**. Ionization of α-chloroepoxides has been shown to



1 **2**

provide an alternate route to α-carbonyl cations (6). Although *ab initio* calculations for the parent ion (R, R′, R″ = H) indicate that the bridged species **2** is slightly more stable (3) for the formylmethyl cation, no experimental evidence is found either from solvolytic data (7) or from nmr observations of these species under stable ion conditions (8) of the substituted derivatives to indicate that these ions are bridged (4). Replacing the carbonyl group with a thiocarbonyl group would be expected to enhance charge delocalization by both mesomeric and σ-bridging mechanisms and perhaps stabilize adjacent cations.[1] MO calculations of the thioformyl methyl cation show that the bridged species is significantly more stable (4) and this is corroborated by product studies on chiral α-thiocarbomethoxymethyl mesylates (9). Furthermore, the stabilization by an α-thiocarbonyl group of an adjacent carbocation is indicated by rate enhancements in the solvolyses of these derivatives (9) relative to carbonyl substituents. Having previously observed diaryl α-carbonylcarbocations under stable ion conditions and studied their reactivity (10), we were interested in comparing aryl and diaryl α-thiocarboxamidyl carbocations with their oxygen analogues. In this study we report the low temperature nmr data and reactivity of six such derivatives.

Results and discussion

The precursors to the carbocations are the alcohols **3**, which were prepared by reaction of lithium *N*,*N*-dimethylthioformamide anion, generated *in situ* from LDA and *N*,*N*-dimethylthioformamide in THF, with the corresponding aryl aldehyde or ketone at −78°C.

The carbocations **4** were prepared by mixing either SO_2 or CD_2Cl_2 solutions of the alcohols and chlorosulphonic acid in a 10-mm nmr tube at −95°C. In all cases except **3***a*, red coloured solutions were observed. The ^{13}C nmr spectra of these ions were obtained and the chemical shifts for the thiocarbonyl and

[1] A. C. Hopkinson and M. H. Lien, unpublished results; calculations at the 6-31G* level using the equation

$$CH_3—\overset{+}{C}HX + CH_4 \rightarrow CH_3^+ + CH_3CH_2X$$

give ΔE = 0.7 kcal/mol for X = O and ΔE = 25.6 kcal/mol for X = S.

TABLE 1. ^{13}C chemical shifts of **4**[a] (δ ppm)

Ion	C^+	C=S (C=S for alcohol **3**)	
4*b*	151.0 or 148.7[b]	190.8	(203.8)
4*c*	131.1[c]	181.7	(205.7)
4*d*	169.4[d]	185.6 or 182.3[e]	(206.5)
4*e*	183.6[d]	181.8	(203)
4*f*	186.9[d]	185.3	(206.5)

[a]Full nmr data for ions **4***b–f* are reported in the experimental section.

[b]Assignment is based on H-coupled ^{13}C spectra. However, specific assignment between C^+ and C—H (arene) could not be made.

[c]Assignment is based on JMOD ^{13}C spectra.

[d]Assignment is based on specific ^{13}C labelling using alcohols **3***d–f* labelled at carbinol carbon.

[e]The thiocarbonyl carbon and the *p*-methoxy aryl carbon could not be differentiated.

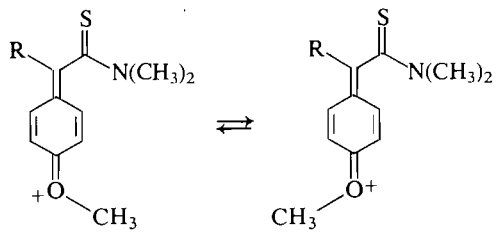
cation carbons tabulated in Table 1. That a single species was present was evident from the high field signals associated with *N,N*-dimethyl carbons. The specific assignments of the chemical shifts for the thiocarbonyl and cationic carbons were based on H-coupled and JMOD ^{13}C nmr spectra[2] for ions **4***b* and *c* respectively. For ions **4***d–f* the specific assignments for these two carbons were based on specifically ^{13}C labelled alcohols **3***d–f* labelled at the carbinol carbon with tenfold enrichment. It is noteworthy that ion **4***c* exhibits an unusually high shifted cationic carbon signal relative to the other ions. This could be attributed to sulphur σ-bridging effects in this ion, in which the presence of two electron-withdrawing aryl groups would be expected to promote this type of interaction. However, caution must be exercised in extrapolating charge densities on the basis of nmr chemical shifts (11). Alcohol **3***a* did not readily undergo dehydrative ionization under these conditions (*vide infra*) as was evident from its inertness to unimolecular reaction. It would appear that one phenyl substituent in **4***a* is not sufficiently stabilizing for its observation.

Quenching of ions **4***c,e*, and *f* in SO_2 solution by addition to ice resulted in the formation of benzothiophenes **5** and the reduced products **6** in approximately equal amounts. In contrast, when the solutions of **4***b,c,e*, and *f* in CH_2Cl_2 and **4***b* in SO_2 were quenched in ice under identical conditions, no reduced product **6** could be detected and only products **5** were isolated. The formation of **6** in the presence of SO_2 may be associated with the reducing properties of H_2SO_3 formed upon the addition of water. That rearrangement of cation **4** to the corresponding protonated benzothiophene **5** had not occurred at −78°C was ascertained by obtaining ^{13}C nmr spectra of solutions of **5** in triflic acid/CD_2Cl_2 at room temperature.[3] The spectra of protonated **5** were completely different from those obtained from alcohols **3** in acid solution and it was evident that the protonation occurs exclusively at the expected β-position of the thiophene ring in **5** by the appearance of a CH_2 signal at high field for the aldehyde adducts.

The aromatic region in the ^{13}C nmr spectra of ions **4***b* and *d* was more complex than expected for a single isomer. The additional aromatic carbon signals for these ions can be attributed to geometric isomerism associated with the restricted

[2]"J" modulated spin-echo pulse sequence, which distinguishes CH/CH_3 carbon nuclei from quaternary/CH_2 nuclei.

[3]The ^{13}C chemical shifts of cations **4** were essentially independent of the choice of CD_2Cl_2 or SO_2 as cosolvents.

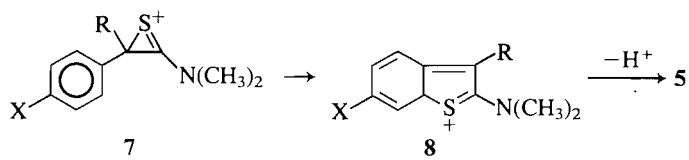


SCHEME 1

barrier to rotation of the methoxyl group (Scheme 1). Observation of a single methoxy and *N,N*-dimethyl carbon signals implies coincidental equivalence of these carbon centers in the two isomers. Such phenomena have been previously reported for protonated anisaldehyde in which the rotational barrier is sufficiently large that at room temperature two distinct species are observed (12).

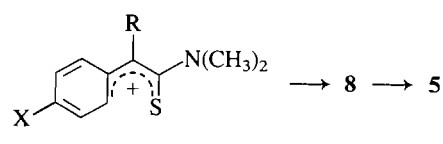
The studies of the acid rearrangement product formation from alcohols **3** were performed using methanesulphonic acid in methylene chloride. The solutions of **3** in chlorosulphonic acid led to water soluble products, presumably due to sulphonation. Alcohols **3***b–f* underwent dehydrative cyclization to benzothiophenes **5** in quantitative yield within 5 min at ambient temperature. The reaction of alcohol **3***a* was sluggish under these conditions and **3***a* had to be heated to reflux in chlorobenzene solution with 5 equiv. of methanesulphonic acid to give the benzothiophene **5***a* in 31% yield. The spectral data for benzothiophene **5***a* were compared with those of a previously reported sample and were found to be identical (13). The molecular structural assignments for **5***b–f* were based on spectral and analytical data.

It is noteworthy that alcohol **3***a*, which did not undergo ionization in $ClSO_3H$ at −70°C, does undergo the cyclization reaction but at a significantly slower rate. This observation can be rationalized in terms of the low stabilization of the cation **4***a* by the substituents. Once the ion is formed, albeit under more vigorous conditions, the reactivity of **4***a* should be greater than those of ions **4***b–f*. Two mechanisms for the cyclization of ions **4** can be envisaged. Rearrangement of a bridged species **7** (Scheme 2) to **8** could proceed in similar fashion to a vinyl



SCHEME 2

cyclopropane rearrangement (14) with sulphur attack on the ring. Alternatively (Scheme 3) the ions **4** can be regarded as 4π-thiapentadienyl cations **9** and cyclizations of these to thiacyclopentenyl cations in carbocyclic analogues are common (15). It is interesting to note that in the unsymmetrical ions **4***d* and *e* (where X = OCH_3, F) cyclization occurs to the



SCHEME 3

For personal use only.

substituted aryl group. The regioselectivity of the cyclization ring suggests that a significant amount of positive charge is delocalized into the substituted aryl ring and that sulphur cyclization proceeds by a nucleophilic attack of S to this ring in both **4***d* and *e*. The corresponding diphenylacetamidyl methyl cation undergoes fluorene cyclization (10) in contrast to ion **4***f*. The lack of fluorene cyclization in ions **4***c–f* suggests that the nucleophilic reactivity of sulphur is greater than that for oxygen, thus leading exclusively to heteroatomic cyclization in these diaryl derivatives.

Experimental

The ^{1}H nmr spectra were recorded in $CDCl_3$ solution with TMS as an internal reference on a CFT-20 or AM-300 nmr spectrometer, and ^{13}C nmr spectra were recorded in $CDCl_3$ solution (unless otherwise noted). Infrared spectra were recorded on a Unicam SP1000 instrument, and mass spectra were obtained on a VG Micromass 16F instrument. Elemental analyses were performed by Guelph Chemical Laboratories.

Tetrahydrofuran was dried with sodium; *N*,*N*-dimethylthioformamide (Aldrich) was dried over 3A molecular sieves.

Carboxyl-^{13}C-labelled benzoic acid and d_2-dichloromethane were obtained from MSD Isotopes.

Preparation of α-hydroxy thioacetamides (general procedure)

A solution of the carbonyl compound (3.79 mmol) and *N*,*N*-dimethylthioformamide (0.32 mL, 3.78 mmol) in dry THF (2.0 mL) was added to a solution of LDA at −78°C, which was prepared by adding *n*-butyllithium (3.80 mmol) to diisopropylamine (0.53 mL, 3.79 mmol) in THF (40 mL). The resultant solution was allowed to slowly warm to room temperature over 3 h.

The reaction was quenched by adding saturated ammonium chloride solution (40 mL), and transferring the resultant two-phase mixture to a separatory funnel. The organic layer was removed, dried ($MgSO_4$), filtered, and solvent evaporated to yield the crude α-hydroxy thioacetamide. The desired product was purified either by recrystallization from 95% ethanol or flash chromatography (silica gel; petroleum ether:dichloromethane, 50:50).

N,N-*Dimethyl-2-hydroxy-2-phenylthioacetamide* **3**a

The benzaldehyde adduct was obtained as colourless crystals, mp 102–102.5°C (80%); ir (KBr) *ν*: 3420 (OH), 1540 (s), 1310 (s) (thioamide I and II), 1215 (C—O) cm^{-1}; ^{1}H nmr δ: 7.30–7.50 (m, 5H), 7.20 (s, O*H*), 5.30 (s, 1H), 3.55 (s, 3H), 3.10 (s, 3H) ppm; ^{13}C nmr δ: 203.6 (C=S); 139.8 (ArC1); 128.9, 127.3 (ArC2, C3); 128.4 (ArC4); 73.9 (C-OH); 45.5, 41.1 (NMe_2) ppm; ms *m/z*: 195 (31), 89 (77), 88 (100). *Anal.* calcd. for $C_{10}H_{13}NOS$: C 61.51, H 6.71, N 7.17, S 16.42; found: C 61.47, H 6.85, N 6.89, S 16.08.

N,N-*Dimethyl-2-anisyl-2-hydroxythioacetamide* **3**b

The adduct was obtained as pale yellow crystals, mp 103–103.5°C (83%); ir (KBr) *ν*: 3300 (OH), 1480 (s) and 1350 (s) (thioamide I and II) cm^{-1}; ^{1}H nmr δ: 7.35 (d, 2H, J = 8.6 Hz), 6.79 (d, 2H, J = 8.7 Hz), 5.18 (s, 2H), 3.72 (s, 3H), 3.45 (s, 3H), 3.04 (s, 3H) ppm; ^{13}C nmr δ: 203.8 (C=S); 159.5 (ArC4); 132.0 (ArC1); 128.6 (ArC2); 114.2 (ArC3); 73.3 (OMe); 55.2 (C-OH); 45.6 and 41.0 (NMe_2) ppm; ms *m/z*: 225 (8), 137 (70), 109 (40), 90 (87), 88 (30), 57 (85). *Anal.* calcd. for $C_{11}H_{15}NSO_2$: C 58.65, H 6.72, N 6.22, S 14.23; found: C 59.00, H 6.78, N 5.99, S 14.23.

N,N-*Dimethyl-2,2-di-(4-fluorophenyl)-2-hydroxythioacetamide* **3**c

This compound was obtained as white crystals, mp 95.0–95.5°C (64%); ir ($CHCl_3$) *ν*: 3240 (br) (OH); 1508, 1225 (s) (thioamide I and II), 1210 (C—F), 1160 (m) (C—O) cm^{-1}; ^{1}H nmr δ: 7.27 (dd, $J_{H,H}$ = 8.8 Hz, $J_{H,F}$ = 5.3 Hz, 4H), 6.98 (t, J = 8.7 Hz, 4H), 6.53 (s, OH), 3.53 (s, 3H), 2.73 (s, 3H) ppm; ^{13}C nmr δ: 205.7 (C=S); 162.2 (d, $^1J_{C,F}$ (16) = −256 Hz, C—F); 138.1 (d, $^4J_{C,F}$ = +3.2 Hz); 130.1 (d, $^3J_{C,F}$ = +8.1 Hz); 115.2 (d, $^2J_{C,F}$ = +21 Hz); 81.5 (C-OH); 47.9, 45.2 (NMe_2) ppm; ms *m/z*: 307 (7), 219 (24), 122 (100), 95 (40). *Exact Mass* calcd. for $C_{16}H_{15}F_2NOS$: 307.0842; found: 307.0847.

N,N-*Dimethyl-2-anisyl-2-hydroxy-2-phenylthioacetamide* **3**d

This compound was obtained as an oil that could not be crystallized (83%); ir ($CHCl_3$) *ν*: 3180 (OH), 1510, 1250 (s) (thioamide I and II), 1040 (C—O) cm^{-1}; ^{1}H nmr δ: 7.20–7.35 (m, 7H), 6.82 (d, J = 7.2 Hz, 2H), 6.53 (s, OH), 3.77 (s, OCH_3), 3.53 (s, 3H), 2.73 (s, 3H) ppm; ^{13}C nmr δ: 206.5 (C=S); 159.0 (anisyl C4); 142.5 (phenyl C1); 134.2 (anisyl C1); 129.7, 128.3, 128.2 (ArC); 127.7 (phenyl C4); 113.5 (anisyl C3); 82.1 (C-OH); 55.2 (OCH_3); 47.9, 45.2 (NMe_2) ppm; ms *m/z*: 301 (6), 213 (73), 135 (85), 105 (54), 90 (100). *Exact Mass* calcd. for $C_{17}H_{19}NO_2S$: 301.1137; found: 301.1136.

N,N-*Dimethyl-2-*p*-fluorophenyl-2-phenyl-2-hydroxythioacetamide* **3**e

This compound was obtained as pale yellow crystals, mp 98–98.5°C (85%); ir (KBr) *ν*: 3200 (OH), 1520 (s) and 1280 (s) (thioacetamide I and II) cm^{-1}; ^{1}H nmr δ: 7.37 (m, 7H), 7.06 (t, J = 8.6 Hz, 2H), 6.60 (s, OH), 3.6 (s, 3H), 2.8 (s, 3H) ppm; ^{13}C nmr δ: 203.1 (C=S); 161.5 (d, $^1J_{C,F}$ = 284 Hz, C—F); 142.1 (phenyl C1); 138.2 (d, $^4J_{C,F}$ = 3 Hz); 130.3 (d, $^3J_{C,F}$ = 8 Hz); 128.3, 128.2, and 127.9 (phenyl C2, C3, and C4); 105.1 (d, $^2J_{C,F}$ = 22 Hz); 81.9 (C-OH); 47.9 and 45.2 (NMe_2) ppm; ms *m/z*: 289 (10), 201 (30), 123 (60), 105 (34), 89 (30). *Anal.* calcd. for $C_{16}H_{16}FNOS$: C 66.41, H 5.57, F 6.56, N 4.84, S 11.08; found: C 66.59, H 5.55, F 6.72, N 5.09, S 11.39.

N,N-*Dimethyl-2-hydroxy-2,2-diphenylthioacetamide* **3**f

The benzophenone adduct was obtained as white crystals, mp 147–148°C (benzene) (80%); ir (KBr) *ν*: 3450 (OH), 1520, 1246 (s) (thioamide I and II), 1210 (C—O) cm^{-1}; ^{1}H nmr δ: 7.30–7.40 (m, 10H), 6.62 (s, O*H*), 3.58 (s, 3H), 2.76 (s, 3H) ppm; ^{13}C nmr δ: 206.5 (C=S); 142.3 (ArC1); 128.4, 128.2 (ArC2, C3); 127.8 (ArC4); 82.5 (C-OH); 47-9, 45.3 (NMe_2); ms *m/z*: 271 (13), 183 (38), 105 (100). *Exact Mass* calcd. for $C_{16}H_{17}NOS$: 271.1031; found: 271.1040.

Preparation of 10 at.% 2-^{13}C-2-hydroxythioacetamides

The ^{13}C-labelled compounds **3***d*, **3***e*, and **3***f* were prepared from the corresponding labelled benzophenones, which were in turn prepared from the Friedel–Crafts acylation of anisole (17*a*), fluorobenzene (17*c*), and benzene (17*b*), respectively, with 10 at.% carboxyl-^{13}C-benzoyl chloride. The ^{13}C content of **3***d*, *e*, and *f* was ascertained by mass spectrometry and nmr.

*Preparation of 2-dimethylaminobenzo[*b*]thiophenes (general procedure)*

The α-hydroxy thioacetamide (0.316 mmol) was dissolved in dichloromethane (10 mL) and cooled to 0°C. Methanesulfonic acid (0.10 mL, 1.54 mmol) was added, resulting in a green-brown solution that decolourized within 10 min, when tlc indicated the absence of starting material.

The solution was washed with saturated sodium bicarbonate solution (10 mL), water (10 mL), dried ($MgSO_4$), filtered, and solvent removed to yield the arene, which was recrystallized from 95% ethanol or petroleum ether.

*2-Dimethylaminobenzo[*b*]thiophene* **5**a

This compound was prepared by the rearrangement of **3***a* in refluxing chlorobenzene (2 h), affording the product as a brown solid that was sublimed to afford **5***a* as colourless crystals, mp 34–37°C (lit. (13) mp 35–36°C) (31%), identical to the authentic compound.

*2-Dimethylamino-6-methoxybenzo[*b*]thiophene* **5**b

Rearrangement of **3***b* afforded **5***b* as a pale yellow crystal, mp 69–70°C (pet. ether, 80%); ^{1}H nmr δ: 7.3 (d, J = 8.6 Hz, H4), 7.1 (d, J = 2.3 Hz, H7), 6.85 (dd, J = 8.6 and 2.3 Hz, H5), 5.95 (s, 1H), 3.8 (s, 3H), 2.95 (s, 6H) ppm; ms *m/z*: 207 (66), 192 (100), 164 (7), 150 (7). *Anal.* calcd. for $C_{11}H_{13}NOS$: C 63.43, H 6.29, N 6.72, S 15.39; found: C 63.65, H 6.33, N 6.42, S 15.13.

*6-Fluoro-3-(4-fluorophenyl)-2-dimethylaminobenzo[*b*]thiophene* **5**c

Rearrangement of **3***c* afforded **5***c* as white crystals, mp 56.0–57.5°C (pet. ether); ir (KBr) *ν*: 1590, 1500 (aryl C=C), 1212 (s) (C—F) cm^{-1}; ^{1}H nmr δ: 7.36–7.46 (m, 3H), 7.27–7.33 (m, H7), 7.15 (t, J = 8.8 Hz, H9,11), 6.83 (dt, J = 8.8, 2.3 Hz, 1H), 3.76 (s, 6H) ppm; ms *m/z*: 289 (100), 278 (21), 263 (33), 237 (24). *Anal.* calcd. for $C_{16}H_{13}F_2NS$: C 66.41, H 4.54, F 13.13, N 4.84, S 11.08; found: C 66.50, H 4.50, F 13.10, N 4.41, S 11.16.

*2-Dimethylamino-6-methoxy-3-phenylbenzo[*b*]thiophene* **5**d

Rearrangement of **3***d* afforded **5***d* as an oil that could not be crystallized (96%); ir ($CHCl_3$) ν: 1585, 1040 (s) (C—O) cm^{-1}; ^1H nmr δ: 7.20–7.45 (m, 6H), 7.15 (d, J = 2.1 Hz, H7), 6.79 (dd, J = 7.8, 2.1 Hz, H5), 3.78 (s, 6H) ppm; ms m/z: 283 (94), 268 (100). *Anal.* calcd. for $C_{17}H_{17}NOS$: C 72.04, H 6.06, N 4.94, S 11.31; found: C 72.24, H 5.89, N 4.78, S 11.00.

*2-Dimethylamino-3-phenyl-6-fluorobenzo[*b*]thiophene* **5**e

This was obtained from the rearrangement of **3***e* as a colorless crystal, mp 69–70°C (pet. ether, 80%); ^1H nmr δ: 7.40 (m, 5H), 7.30 (m, 1H), 7.1 (m, 1H), 6.9 (m, 1H), 2.70 (s, 6H) ppm; ms m/z: 271 (38), 149 (15), 97 (35), 85 (37), 68 (100). *Anal.* calcd. for $C_{16}H_{14}FNS$: C 70.82, H 5.20, F 7.00, N 5.16, S 11.81; found: C 70.91, H 5.13, F 7.20, N 4.88, S 11.68.

*2-Dimethylamino-3-phenylbenzo[*b*]thiophene* **5**f

This compound was prepared by the rearrangement of **3***f* at room temperature. **5***f* was obtained as white crystals, mp 86.5–88.5°C (95% EtOH, 80%); ^1H nmr δ: 7.67 (d, J = 7.0 Hz, 1H), 7.10–7.50 (m, 8H), 2.74 (s, 6H) ppm; ms m/z: 253 (100), 238 (13), 237 (16), 223 (26). *Exact Mass* calcd. for $C_{16}H_{15}NS$: 253.0925; found: 253.0925.

*The ^{13}C nmr spectra of carbocations (***4***) (general procedure)*

The alcohol (0.249 mmol) was dissolved in sulfur dioxide (0.50 mL) at −78°C in a 10-mm nmr tube, then frozen solid at −95°C. A solution of chlorosulfonic acid in sulfur dioxide (50%, 1.0 mL) at −95°C was added and the alcohol mixture dissolved at this temperature. The precooled deuterium lock (CD_2Cl_2) was then added to the pale red solution and the spectrum recorded at −75 to −65°C. Phasing of the signals in the JMOD spectrum is indicated by (+) for C-quaternary and CH_2, and (−) for CH and CH_3.

N,N-*Dimethyl-2-anisylthioacetamide-2-yl cation* **4**b: ^{13}C nmr δ: 190.8 (C=S); 178.1 (aryl C-OMe); 156.0 ($J_{C,H}$ = 181 Hz), 152.7 ($J_{C,H}$ = 177 Hz) (aryl C); 151.0 (J = 168 Hz), 148.7 (J = 188 Hz) (aryl C and C^+), 193.5 ($J_{C,H}$ = 173 Hz) (aryl C); 135.4 (aryl C1); 129.2 ($J_{C,H}$ = 176 Hz), 128.5 ($J_{C,H}$ = 179 Hz), 122.3 ($J_{C,H}$ = 179 Hz) (aryl C); 64.4 (OCH_3); 48.1 and 46.0 (NMe_2) ppm.

N,N-*Dimethyl-2,2-di-(4-fluorophenyl)thioacetamide-2-yl cation* **4**c: ^{13}C nmr δ: 181.7 (+) (C=S); 179.2 (+) (C4-F, $^1J_{C,F}$ (16) = −295 Hz); 153.5 (−), 146.1 (aryl C); 131.1 (+) (C^+); 124.2 (−) ($^3J_{C,F}$ = 18 Hz); 49.7 and 48.2 (NMe_2) ppm.

N,N-*Dimethyl-2-anisyl-2-phenylthioacetamide-2-yl cation* **4**d: ^{13}C nmr δ: 185.6 (+), 182.3 (+) (C=S and C4-OMe); 169.4 (+) (C^+); 153.1, 143.5, 140.4, 136.2, 131.8, and 130.1 (−) (aryl C—H); 129.9 (+) 127.2 (+) (phenyl and anisyl C1); 120.9 (−) (aryl C—H); 62.3 (−) (OCH_3); 48.2 and 47.0 (−) (NMe_2) ppm.

N,N-*Dimethyl-2-*p*-fluorophenyl-2-phenylthioacetamide-2-yl cation* **4**e: ^{13}C nmr δ: 184.8 (+) (C^+); 181.8 (+) (C=S); 180.6 (+) (C4-F, $^1J_{C,F}$ = −300 Hz); 155.4 (−) and 147.2 (−) (C2, $^3J_{C,F}$ = 15 and 18 Hz); 152.8 (−) (aryl C1); 134.9 (−) (aryl C1); 134.0 (+) and 131.8 (+) (aryl C1 and C1); 124.6 (−) (aryl C3, $^2J_{C,F}$ = 23 Hz); 49.7 and 48.1 (−) (NMe_2) ppm.

N,N-*Dimethyl-2,2-diphenylthioacetamide-2-yl cation* **4**f: ^{13}C nmr δ: 186.9 (+) (C^+); 181.2 (+) (C=S); 154.0 (−) (phenyl C—H); 149.9 (−) and 141.2 (−) (phenyl C2); 134.4 (−) (phenyl C—H); 133.6 (+) (phenyl C1); 48.9 and 47.3 (−) (NMe_2) ppm.

N,N-*Dimethyl-2,2-di-(4-fluorophenyl)thioacetamide* **6**c

The hydroxy thioacetamide **3***c* (93.4 mg, 0.304 mmol) was dissolved in SO_2 (0.50 mL) and, at −95°C, $SO_2/ClSO_3H$ (0.50 mL, ca. 5 equiv.) was added and the thioacetamide dissolved to afford a red solution.

The solution was poured onto ice, saturated sodium bicarbonate solution was added, and the ice allowed to melt. The aqueous layer was extracted with dichloromethane (10 mL), and the organic layer dried ($MgSO_4$), filtered, and solvent removed to afford an oil (76.5 mg), which was flash chromatographed to afford **5***c* (36.7 mg, 42%) followed by **6***c* (31.9 mg, 36%), obtained as white crystals, mp 109–110°C (EtOH); ir (KBr) ν: 1505, 1230 (thioamide I and II) cm^{-1}; ^1H nmr δ: 7.20 (dd, J = 8.8, 5.3 Hz, 4H), 7.0 (t, J = 8.8 Hz, 4H), 5.55 (s, 1H), 3.55 (s, 3H), 3.30 (s, 3H) ppm; ms m/z: 291 (9), 258 (8), 201 (27), 163 (100). *Exact Mass* calcd. for $C_{16}H_{15}F_2NS$: 291.0893; found: 291.0899.

N,N-*Dimethyl-2-*p*-fluorophenyl-2-phenylthioacetamide* **6**e

Quenching and work-up of the solution of the cation **4***e*, derived from **3***e* (87.3 mg), gave a mixture of the **5***e* and **6***e* (81.1 mg; yield of **6***e* estimated by ^1H nmr is 41%, **5***e* is 59%, based on the signals due to $CHC(S)NMe_2$ at δ 5.53 (s, 1H), 3.52 (s, 3H), and 3.15 (s, 3H) ppm for **6***e*, and the signal due to NMe_2 of **5***e* at δ 2.70 (s, 6H) ppm).

N,N-*Dimethyl-2,2-diphenylthioacetamide* **6**f

Quenching and work-up of the solution of cation **4***f*, derived from **3***f* (118.8 mg), afforded a mixture of **5***f* and **7***f* (94.1 mg; yield of **7***f* estimated by ^1H nmr is 21%); ^1H nmr δ: 7.30–7.10 (m, 10H), 5.60 (s, 1H), 3.52 (s, 3H), 3.32 (s, 3H) ppm.

Structural studies of oligosilanes produced by catalytic dehydrogenative coupling of primary organosilanes

C. AITKEN, J. F. HARROD, AND U. S. GILL
Chemistry Department, McGill University, Montreal, P.Q., Canada H3A 2K6

Received October 26, 1986

This paper is dedicated to Professor John T. Edward

C. AITKEN, J. F. HARROD, and U. S. GILL. Can. J. Chem. **65**, 1804 (1987).

The structures of some poly(organosilylenes), -(SiRH)$_n$- (R = Ph, *p*-tolyl, *n*-hexyl, and benzyl), produced by catalytic dehydrogenative coupling of primary silanes have been studied by infrared, nuclear magnetic resonance, and mass spectroscopies. These results, combined with data on molecular weights and molecular weight distributions from vapour pressure osmometry and gel permeation chromatography, lead to the conclusion that the polymers are linear and have SiH_2R end groups. The polymers all have degrees of polymerization of ca. 10 and very narrow molecular weight dipersions. Some possible features of the mechanism that gives rise to this behaviour are discussed.

C. AITKEN, J. F. HARROD et U. S. GILL. Can. J. Chem. **65**, 1804 (1987).

Faisant appel aux spectroscopies d'infrarouge, de résonance magnétique nucléaire et de masse, on a étudié les structures de quelques poly(organosilylènes), -(SiRH)$_n$- (R = Ph, *p*-tolyl, *n*-hexyl et benzyl), qui sont produits par un couplage déshydrogénant de silanes primaires.Ces résultats, combinés aux données de poids moléculaires et de distributions des poids moléculaires obtenues par osmométrie de tension de vapeur et par chromatographie par perméation de gel, conduit à la conclusion que les polymères sont linéaires et qu'ils contiennent des groupements terminaux SiH_2R. Les degrés de polymérisation des polymères sont tous d'environ 10 et les dispersions de leurs poids moléculaires sont très étroites. On discute de quelques-unes des caractéristiques du mécanisme qui donne lieu à ce comportement.

Introduction

We have recently described the dehydrogenative coupling of organosilanes catalyzed by titanocene and zirconocene derivatives (1, 2). A preliminary communication gave a brief description of the characterization of the oligosilanes produced (3). In the present paper we give a detailed description of the results of a number of physicochemical measurements that have been applied to determining the structure of these materials.

Synthetic methods for the catenation of silicon are few. The Wurtz-type coupling of halosilanes with highly electropositive metals is the most commonly used strategy and a fairly large number of papers describing this type of chemistry have appeared (for a review of the synthesis and properties of organopolysilanes see ref. 4). Despite the difficulty of controlling the heterogeneous Wurtz-type coupling, and the problems of by-products and of handling liquid alkali metals, these reactions are still the only source of high molecular weight polysilylenes. All of the information regarding the interesting properties of polysilanes as silicon carbide fibre precursors (5) and as photoactive materials (6) has been obtained with such materials. Recently, a report has appeared of the catalytic redistribution of di- and other oligosilanes to give higher molecular weight polysilanes (7).

Given the potential applications of polysilanes, new methods for their synthesis assume some importance. Therein lies the relevance of the catalytic dehydrogenative coupling reaction shown in eq. [1]. With titanocene and zirconocene based

$$[1]\quad n\mathrm{RSiH_3} \longrightarrow \mathrm{H}\text{-}\left(\mathrm{Si}(\mathrm{R})(\mathrm{H})\right)_n\text{-}\mathrm{H} + (n-1)\mathrm{H_2}$$

catalysts, the selectivity for removal of only two hydrogens from the silicon is very high and the yields of product are essentially quantitative. The structural characterization of the polymers produced in eq. [1] is not simple because each silicon is a stereo centre and the polymer, like all atactic polymers, is a mixture of a large number of stereoisomers.

Results and discussion

^{1}H and ^{29}Si nuclear magnetic resonance spectra

The ^{1}H nmr spectra of all of the polymers prepared so far show broad unresolved massifs in the regions characteristic of the functional group protons. In particular, there is a broad set of resonances in the region of 4–5 ppm due to Si—H, and others for the aryl and (or) alkyl protons of the R group. The spectrum of poly(phenylsilylene) is shown in Fig. 1. Although such spectra give little information on the fine structure of the polymer, they do consistently integrate in the manner expected for the stoichiometry of eq. [1]. The broadness of the resonances is most likely due to the presence of an envelope of Si—H species with different chemical shifts, which are in turn split by H–H coupling to vicinal Si—H groups. Stepwise replacement of the SiH_3 protons with silicon causes a progressive downfield shift of the residual proton resonances. For example, the shifts for $PhSiH_3$ and $PhSiH_2SiH_2Ph$ are 4.22 and 4.39 ppm respectively (C_6D_6). It is therefore tempting to conclude that the massif between 4.3 and 5.0 ppm in Fig. 1 is due to $Ph(Si)SiH_2$ and that the one above 5.0 ppm is due to $Ph(Si_2)SiH$. On the other hand, the fact that the integral for the downfield massif is always smaller than that for the high field argues against such a simple assignment.

^{29}Si nuclear magnetic resonance spectroscopy is similarly uninformative about the details of polymer structure. The normal mode spectrum is a complex massif of poorly resolved peaks in the range of −50 to −70 ppm. The application of a polarization transfer sequence (DEPT [8]) gives more useful information, since it can distinguish silicon atoms bearing two protons from those bearing one or three protons. Figure 2 shows the DEPT spectra of a poly(*n*-hexylsilylene) for different pulse angles. These spectra clearly show that the dominant species present is Si—H, but the presence of SiH_2 groups in the

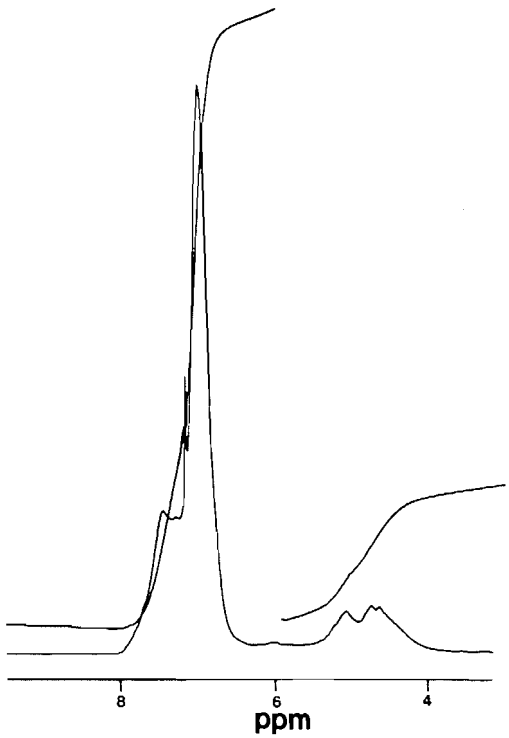

FIG. 1. 200-MHz ^{1}H nmr spectrum of poly(phenylsilylene) in C_6D_6.

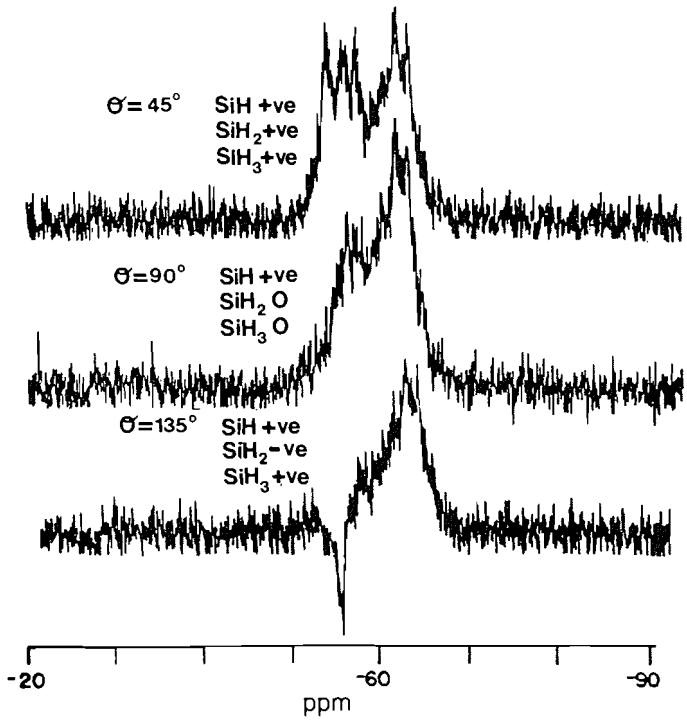

FIG. 2. Natural abundance ^{29}Si nmr DEPT spectra of poly(*n*-hexylsilylene) in C_6D_6.

polymer is also evident. Similar spectra were obtained for poly(phenylsilylene). It is interesting to note that the relative positions of the silicon resonances of SiH and SiH_2 are reversed relative to the positions of the proton resonances. Similar behaviour has been observed previously with SiH compounds.[1]

Infrared spectra

The ir spectra of all of the polysilylenes produced so far exhibit, in addition to the bands due to the alkyl or aryl substituents, an intense ν_{Si-H} band at ca. 2100 cm^{-1} and a strong band at ca. 910 cm^{-1}. The band at ca. 2100 cm^{-1} is at about 60 cm^{-1} lower frequency than that of the primary silane monomers. This shift to lower frequency typically occurs when the hydrogens of silane are progressively replaced by an alkyl or a silyl group (10). The frequencies observed for the polymers are in the right range for tertiary Si—H. The band at 910 cm^{-1} can be assigned to the bending mode of a SiH_2 group (11). This band is present in all primary and secondary alkyl and arylsilanes, but notably absent from tertiary silanes. Its presence in the polymers is further clear evidence for terminal $PhSiH_2$ groups. It is also relevant to note that these SiH_2 groups can be selectively hydrosilated by reaction of the polymer with a 1-alkene, or norbornadiene, in the presence of dimethyltitanocene as catalyst (14). Such hydrosilation results in the diminution, or disappearance, of the 910 cm^{-1} peak and little change in the 2100 cm^{-1} peak.

The position of the 2100 cm^{-1} band and the relative intensities of the 2100 and 910 cm^{-1} bands are both sensitive to molecular size in the range of molecular weight exhibited by these polymers. In Table 1 we show these values for a number of simple alkyl- and aryl-substituted silanes and for two oligomers,

which were shown by mass spectroscopy (*vide infra*) to have degrees of polymerization of 5 and 8 respectively.

Molecular weight studies

In a preliminary report, the average degrees of polymerization ($\bar{D}_n$) of the poly(silylenes) were found by vapour pressure osmometry (vpo) to be about 10 (3). Some vpo results are shown in Table 2.

The molecular weight properties of the polymers have now been studied by gel permeation chromatography (gpc). The column used was able to clearly resolve a mixture of phenylmethylcyclotri- (D_3^{Ph}) and phenylmethylcyclotetrasiloxane (D_4^{Ph}). Calibration samples of nearly monodisperse polystyrene of $\bar{M}_n$ = 530, 950, and 2800 Da were also easily resolved. Unfortunately, the lack of correlation between retention times and molecular weights of these and other calibrants

highlighted the extreme difficulty of obtaining accurate estimates of molecular weight in this range by gpc. At best it can be concluded that the gpc results are not in disagreement with those of vpo.

Despite the failure to obtain accurate molecular weight, gpc does give other important information concerning molecular weight distribution and relative molecular size. Some relevant chromatograms are shown in Fig. 3. The distributions of the poly(phenylsilylenes) are bimodal. The distribution of the lighter fraction is narrow enough to indicate that it is a monodisperse species. The heavier fraction is due to at least two species. The relative amount of the higher molecular weight component increases with increasing monomer concentration for a constant reaction time. The character of the chromatogram is remarkably insensitive to variation in reaction conditions and does not vary significantly for catalysts as different from

each other as Cp_2TiMe_2, $Cp_2Ti(CO)_2$, and $CpCp^*TiMe_2$. This behaviour is unusual and points to an unusual mechanism for the polymerization reaction.

Mass spectroscopy

The mass spectra of the polysilylenes produced in this study were all successfully measured by direct inlet methods. In Table 3 we show a listing of ms data for a poly(phenylsilylene) produced by dehydrogenative coupling and for a previously reported hexaphenylcyclohexasilane, synthesized by Hengge and Lunzer by classical methods (12). The gross differences between the spectra are those expected for a linear and a cyclic molecule. In the cyclic case, the primary event is probably cleavage of a Si—Si bond, followed by an unzipping of the chain. The initial cleavage does not result in a mass loss and the parent ion is observed in high abundance. In the linear case, the primary event is also a Si—Si cleavage, but in this case cleavage leads to fragmentation and the parent ion is only observed at very low abundance. In both linear and cyclic cases the loss, and migration to adjacent silicon, of phenyl groups and loss of hydrogen are both important secondary processes, a behaviour typical of aryl silanes (13).

The linear pentasilylene whose spectrum is listed in Table 3 was obtained from a very slow reaction run at 0°C and was chosen for comparison with the cyclic compound because of the relative simplicity of its spectrum and because it is the only poly(phenylsilylene) for which the parent ion has been observed. Under all other experimental conditions investigated, polysilylenes of slightly higher degrees of polymerization were obtained. The mass spectra of a number of differently substituted polysilylenes are listed in Table 4. Most of the peaks listed are the most intense in a cluster that originates from a combination of isotope distribution and sequential hydrogen stripping. The peaks are due to a multiplicity of species and the listed ion assignments are those considered most likely to be a major component at a particular mass.

Apart from the increased complexity due to increased degree of polymerization, the fragmentation patterns for the phenyl and *p*-tolyl polymers are very similar to that of the pentamer listed in Table 3. The *n*-hexyl polymer behaves somewhat differently in that the (parent − 1) ion is highly abundant and fragmentation involves extensive cleavage of the alkyl side chain. The listing for the *n*-hexyl polymer is only partial below m/e = 400 since

the spectrum becomes very complicated below this mass due to the increased presence of alkyl chain fragmentation products. The other listings are more or less complete down to the lowest cited mass.

The structure and molecular weights of the polymers

No single physical measurement cited in the preceding sections gives an unequivocal answer as to the structure and size of the polysilylenes. Although accurate quantitative determination of the relative proportions of SiH, SiH_2, and SiH_3 is not possible in a DEPT experiment, the spectrum shown in Fig. 2 allows the conclusions that most of the silicon hydride protons are present as Si—H, that there is an amount of SiH_2 present, which is not out of line with that expected for a linear polymer of the chain length indicated by the other measurements, and, by a process of elimination, there cannot be much Si of any other kind. The relatively high intensity of the 910 cm^{-1} band in the polymers also argues for the presence of SiH_2 end groups. That the polymers are not cyclics is strongly indicated by the mass spectra, but none of the evidence excludes the possibility that there may be a small amount of branching. The weight of the evidence is nevertheless against a significant amount of branching.

Given that we are dealing with essentially linear polymers with predominantly SiH_2 end groups, the next important question is, what are their molecular weight properties? The gpc results show that the polymers have molecular sizes comparable to that of polystyrene with a molecular weight of ca. 1000 Da ($\bar{D}_n$ ca. 10). This corresponds to a chain of ca. 20 C atoms. If we make the simplistic assumption that the size of a polysilicon chain relative to a polycarbon chain varies in relation to the covalent radius ratio for the two elements (C/Si = 0.6), it leads to the conclusion that most of the polysilylenes prepared with titanocene based catalysts are about 10–12 silicons long. Given the relative weakness of the underlying assumption, this is in good agreement with both the vpo (uncertainty ca. ±5%) and the ms results. A more careful analysis of the poly(phenylsilylene) chromatograms, using the same assumption, leads to the conclusion that the lighter fraction has a chain of 9 Si and the heavier fraction a chain of 14–16 Si. The vpo value for the molecular weight of the poly(phenylsilylene) produced at room temperature with 2 mol% catalyst agrees well with the gpc result, since the polymer consists mostly of the lighter fraction at the monomer concentration used in its preparation.

In the case of the ms results, the highest observed mass may only represent a lower limit if higher mass fragments are below the limit of detection, or if heavier fragments are too unstable to be observed. We consider these eventualities to be unlikely and believe that the highest observed masses represent in fact the *upper limit* on molecular weight.

The chromatograms shown in Fig. 3 show that the polysilylene molecular weight distributions are usually, if not always, polymodal; in the case of the poly(phenylsilylenes) the distributions are bimodal. The dispersity of the lighter component is so narrow as to indicate it is due to an essentially monodisperse molecular species. The heavier fraction is probably due to at least two species of differing molecular size. Perfect monodispersity in terms of molecular size is not expected since the average dimensions of the different stereoisomers at a particular degree of polymerization are not expected to be the same. The same is of course true of the polystyrene and the D_n^{Ph} standards, and their behaviour does not lend any support to the idea that

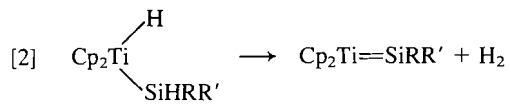
the two components of the poly(phenylsilylenes) are different stereoisomers. The mass spectra exclude the possibility that one of the components is cyclic and the other linear. This leaves only the possibility that we are dealing with two linear molecules differing in length by a few silicon atoms. From Fig. 3, it is evident that the higher molecular weight species is produced more abundantly as the monomer concentration is increased. This leads us to favour a hypothesis that the two fractions are the products of two different chain termination mechanisms operating on a common metal polysilylene species.

The mechanism of the polymerization reaction

The essential features of the catalytic dehydrogenative coupling reaction are the following: the polymerization is selective for primary silanes; it does not proceed by the production of measurable amounts of species of intermediate molecular weight; polydispersities are extremely narrow; high catalyst concentration leads to higher molecular weight; the limiting molecular weight is very insensitive to reaction variables; polymerization rates are very sensitive to steric factors (14). In general terms these facts point towards a mechanism in which propagation occurs very rapidly relative to termination until the growing chain reaches a certain size, at which point the propagation rate drops by a sufficient amount that virtually all growing chains are terminated before another monomer addition can occur.

Results reported elsewhere show that most of the catalyst remains in an inactive form during the polymerization, but the inactive species are probably in equilibrium with the active form (1, 14). This, coupled with the effect of catalyst concentration on molecular weight and lack of dependence of molecular weight on conversion, excludes a standard "living polymerization" mechanism (15).

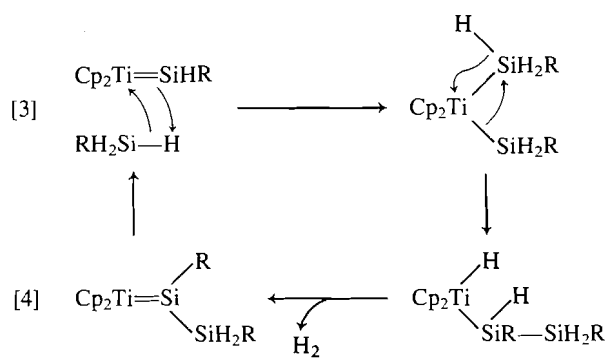
Kinetic studies indicate that the active species is a mononuclear titanium complex, and we have previously suggested that propagation occurs through α-hydride elimination at a Ti(IV)silyl centre (14), thus:



[2] $Cp_2Ti(H)(SiHRR') \longrightarrow Cp_2Ti{=}SiRR' + H_2$

where R′ = H or polysilyl.

A mechanism involving α-hydride elimination is attractive from the point of view of its analogy to similar eliminations observed with the alkyls of lighter transition element metallocenes (16) and from the fact that eq. [2] is not possible for a secondary silane beyond the first homologation step. A number of equally plausible mechanisms for the production of polymer from a silylene complex can be envisaged on the basis of present data. The simplest is the following:



[3] $Cp_2Ti{=}SiHR$ / $RH_2Si{-}H$ → $Cp_2Ti(H)(SiH_2R)(SiH_2R)$

[4] $Cp_2Ti{=}Si(R)(SiH_2R)$ → H_2 + $Cp_2Ti(H)(H)(SiR{-}SiH_2R)$

It is unlikely that the silylene complex exists for any significant time as a terminal complex, if at all. We consider it more likely that it participates as a bridging silylene. The α-hydride elimination steps of a mechanism such as illustrated in eqs. [3] and [4] provide ample opportunity for the intervention of steric effects. The cyclopentadienyl ligands are sterically encumbering and could well impede the achievement of the eclipsed conformation that would favour the migration of the hydride from the silicon to the titanium. Further experiments to test this hypothesis are currently in progress.

Of several possible termination steps, only hydrogenolysis of the Ti—Si bond can be definitively excluded. Studies published elsewhere (14) showed that polymer molecular weights are unaffected by wide variations in the free hydrogen concentration in solution during the polymerization. The gpc results for poly(phenylsilylene) described above reveal the presence of at least two termination processes, one dependent on monomer concentration and the other independent. The monomer-independent termination could be either a spontaneous reductive elimination of silane from the bis(silyl) intermediate in eq. [3], or the hydridosilyl intermediate in eq. [4], or a simple homolysis of a Ti—Si bond followed by hydrogen atom abstraction by the silyl radical. At our present level of understanding of the mechanism it is not clear what kind of process could lead to a monomer dependent termination.

Experimental

Materials and reagents

All solvents were carefully dried and deoxygenated by standard procedures before use. Silanes were prepared by $LiAlH_4$ reduction of the appropriate chlorosilane using modifications of literature methods (17). Dimethyltitanocene was prepared by a literature procedure (9) and freshly recrystallized before use.

Spectroscopic methods

The nmr spectra were recorded on a Varian model XL-300 FT spectrometer. The DEPT pulse sequence for the acquisition of the spectra in Fig. 2 was as follows: 90°(H,Y)–τ–180°(H,X), 90°(Si,X)–τ–σ (H,X), 180°(Si,X)–τ–decouple, acquire. A τ value of 0.0025 s, based on a J_{Si-H} of 200 Hz, was used in conjunction with a θ array of 45°, 90°, and 135°.

Mass spectra were acquired with a ZAB-HS model 2F spectrometer using the direct inlet mode, an electron impact energy of 70 eV, and a probe temperature ranging from ca. 60 to 100°C.

Molecular weight determinations

Molecular weights by vpo were determined using a Corona/Wescan model 232 apparatus. All measurements were made in toluene at 50°C and care was taken to protect the samples from oxygen. Calibrations were performed with sucrose octaacetate and with Waters Associates calibration standard no. 41994. Measurements were estimated to be accurate to within ±40 Da. The gpc measurements were carried out on a Varian 5000 liquid chromatograph interfaced to a Varian Vista 402 data station and equipped with a Waters Associates 10^3 Å Ultrastyragel column. All gpc measurements were carried out using air-free, chromatographic grade THF as solvent. The calibrants used were made by Toyo Soda Manufacturing Co. Ltd. and supplied by Varian Associates. The molecular weight characteristics of the calibrants were [M_n, dalton (M_w/M_n)]: 5.26×10^2 (1.15); 9.5×10^2 (1.13); 2.8×10^3 (1.05).

Polymerization reactions

Polymerizations may be carried out under a wide range of conditions. The following is a representative example. Dimethyltitanocene (10.0 mg) was dissolved in toluene (1.0 mL) under argon. Phenylsilane (1.0 mL) was added to the solution. In a few minutes the color of the solution changed from pale yellow to dark blue and a rapid evolution of

hydrogen commenced. The effervescence continued at a progressively decreasing rate for several days. After 7 d at room temperature the effervescence had essentially ceased and the solution had become quite viscous. All volatile material was pumped off under vacuum to give a dark blue glassy solid. This solid was redissolved in ca. 1.5 mL of toluene and added to a 20 × 2 cm column of Florisil in toluene. The polymer was recovered by slow elution with toluene (80 mL) followed by vacuum evaporation of the eluent. After pumping the resulting solid for 1 h, the product was obtained as a colourless, brittle glass (750 mg).

Similar results were obtained with tetrahydrofuran as solvent, or with no solvent at all. A reaction identical to that described above, except that it was maintained at 0°C, yielded a gum (550 mg). This material was used to obtain the mass spectrum given in Table 3. Poly(*p*-tolylsilylene) was obtained as a glassy solid, but the benzyl and *n*-hexyl polymers were oils.

Photochemistry of substituted cyclic enones. Part 6. Photochemical reactions of 5-arylmethyl-3-phenylcyclopent-2-enones. A photostationary state[1,2]

MICHAEL T. M. CLEMENTS AND T. BRIAN H. MCMURRY[3]
University Chemical Laboratory, Trinity College, Dublin 2, Ireland

Received November 27, 1986

This paper is dedicated to Professor John T. Edward

MICHAEL T. M. CLEMENTS and T. BRIAN H. MCMURRY. Can. J. Chem. **65**, 1810 (1987).

Photolysis of 5-(1- and 2-naphthylmethyl)-3-phenylcyclopent-2-enones affords [2 + 2] cycloaddition products, the 7,8- and 5,6-benzo-fused 10-phenyltetracyclo[7.2.1.$0^{3,10}$.$0^{4,9}$]dodeca-5,7-dien-2-ones respectively, in equilibrium with the starting enones. A similar dibenzo-fused photoproduct is formed from the corresponding 9-phenanthrylmethyl substituted cyclopentenone. The photoproducts revert to the respective enones on acid treatment, or pyrolysis, and on photolysis.

MICHAEL T. M. CLEMENTS et T. BRIAN H. MCMURRY. Can. J. Chem. **65**, 1810 (1987).

La photolyse des (naphtyl-1 ou -2 méthyl)-5 phényl-3 cyclopentène-2 ones conduit à des produits de cycloadditions [2 + 2], soit respectivement les benzo-7,8 ou -5,6 phényl-10 tétracyclo[7.2.1.$0^{3,10}$.$0^{4,9}$] dodécadiène-5,7 ones-2, qui sont en équilibre avec les énones de départ. Si l'on part de la cyclopentènone correspondante substituée par une phénanthryl-9 méthyle, il se forme un photoproduit similaire qui est fusionné à un dibenzo. Par traitement avec des acides, par pyrolyse ou par photolyse, les photoproduits se retransforment dans leurs énones respectives.

[Traduit par la revue]

In recent publications (1, 3, 4) we have described the photochemical intramolecular cyclisation of 5-allyl and substituted 5-allylcyclopentenones. In all these cases the reactions were regiospecific, as far as the direction of addition, but in the case of the compounds with cinnamyl side chains there was loss of stereoselectivity of the phenyl substituent. We wished to discover whether aromatic "double bonds" could be incorporated into cycloaddition products and, if so, whether the regiospecificity would be affected. Furthermore, to our knowledge, no example is known where enone adds onto a naphthalene ring although, where two naphthalene rings are linked by a suitable chain, then photoaddition of the two rings is found (5).

Synthesis

The 5-arylmethyl-3-phenylcyclopentenones were synthesised by standard routes (Scheme 1). The ring closure of the diketo esters involves the hydrolysis of the ester and decarboxylation of the keto acid, followed by cyclisation of the resultant 1,5-diketone. In this way, 5-benzyl-, 5-(1-naphthylmethyl)-, 5-(2-naphthylmethyl)-, and 5-(9-phenanthrylmethyl)-3-phenylcyclopentenones (**1***a–d*) were prepared.

Photochemical rearrangements

We photolysed the ketones using a medium pressure Hg lamp and a Pyrex filter. Under these conditions, we could detect no photoproduct from the benzyl ketone **1***a* other than a mixture of dimers whose structures we have not investigated further. In the case of the 1-naphthylmethyl compound **1***b*, a photoproduct builds up in the reaction mixture to a concentration of about 22%, but the reaction does not appear to proceed further. The isolation of this product **2***b* proved difficult, as it was labile to acid and, indeed, partially decomposed on silica. However, it could be isolated in a pure state by chromatography on a basic alumina column, and we confirmed that it reverted to **1***b* on pyrolysis or acid treatment. Photolysis of pure **2***b* reverts mainly to **1***b*.

(2) (a) NaH, $CH_3OCH_2CH_2OCH_3$
(b) $PhCOCH_2Br$

(3) KOH, 1%, then 10%

SCHEME 1

The structure of **2***b* follows from its infrared spectrum, which showed a peak at 1740 cm^{-1} characteristic of this ring system (1, 3, 4), and by its ^1H and ^{13}C nmr spectra. In the ^1H spectrum the 5- and 6-hydrogen signals both appear as double doublets, coupled to each other, and separately to the 4-proton, as found in other related photoproducts containing the dihydronaphthalene skeleton (6–8). Of the hydrogens in the 11- and 12-methylene groups, one proton signal lies at a lower field than any of the others, and is assigned to the 12-*exo* hydrogen as it is in the deshielding zone of the fused benzene ring.

The 2-naphthylmethyl derivative **1***c* behaves similarly on photolysis. In this case, the mixture contained 15% of the photoproduct **2***c*, which reverted to **1***c* on heating or acid treatment, and mainly to **1***c* on photolysis. The 7- and 8-proton signals in this case appeared as doublets coupled to each other. The 12-*exo* signal in this case lies at higher field than that of **2***b*,

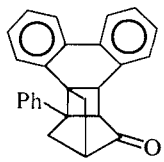
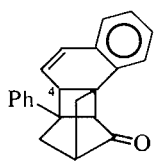
2*c*



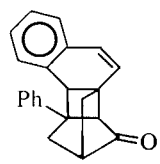
2*d*

as the fused benzene ring is not close enough to deshield it. The 4-H signal in **2***c* lies at lower field than the corresponding signal in **2***b*. This is to be expected, as it is benzylic in **2***c* but only allylic in **2***b*.

We have confirmed the structures **2***b* and **2***c* by using the lanthanide shift reagent, Eu(fod)$_3$. The 3-, 1-, and 4-hydrogens in this order show the greatest shift, followed by the 11-*exo* and 12-*endo* hydrogens. Had the alternative structures **3***b* and **3***c*



3*b*



3*c*

been correct, the corresponding 4-hydrogen shift would have been much smaller than the shift of either of the 12-hydrogens and would be comparable to the shifts of the olefinic protons. It is significant that the europium reagent appears to complex more strongly with **2***b* than with **2***c*. In the latter case the fused aromatic ring would inhibit approach of the bulky reagent to the carbonyl group.

When the phenanthryl ketone **1***d* was irradiated, it afforded one product **2***d* in 14% yield. The ir spectrum showed a peak at 1745 cm^{-1} characteristic of the ring system and, in its ^{1}H nmr spectrum, the 12-*exo* proton appears downfield as in **2***b* but not **2***c*. As with the other compounds, **2***d* reverts to **1***d* on pyrolysis, on acid treatment, and on photolysis.

Discussion

It is interesting that the photocyclisation of 5-allylcyclopentenones is completely regiospecific (1, 3, 4, 9), with but a few exceptions (10), where there is an electron-donating group at the 3-position and further substituents at the 2-position. The photolysis reactions using a naphthalene or phenanthrene skeleton to provide the ene-component afford products with the same regiospecificity. This is to be compared with the case of the cycloaddition reaction of acrylonitrile with α- and β-naphthols and their trimethylsilyl ethers. In these cases, the regioselectivity is governed by the position of the oxygen substituent (8). In our cases, the position of the naphthalene substituent does not affect the regioselectivity.

Srinivasan and Carlough and Liu and Hammond (11) have offered an explanation of regioselectivity in ring closure reactions in terms of "the rule of five." Preferably, reactions proceed in such a way that the diradical intermediates lie in, or are external to, five-membered ring(s). Very recently a rationalisation of this rule has been given by Gleiter and Sander (12) in terms of molecular orbital theory. Of course the rule of five could explain either regioisomer of type **2** or **3**. The position of the carbonyl group must be crucial in determining the obtained regioselectivity.

We believe that the reverse reaction must proceed by excitation of the dihydronaphthalene chromophore, either directly, as happens with some of the photoadducts of acrylonitrile with naphthalenes (8), or by transfer of energy intramolecularly from the carbonyl triplet to the dihydronaphthalene or the corresponding dihydrophenanthryl chromophore.

Experimental

For general conditions, see Part 1 (ref. 13). Photolyses were carried out using a Hanovia 460-W medium pressure mercury lamp, and a Pyrex filter. In flash chromatographic separations, we employed silica Merck grade 9385 and a solvent mixture hexane:ethyl acetate (85:15) unless otherwise stated. Alumina chromatography employed Merck Grade 1076 (Basic). 1,2-Dimethoxyethane was dried over sodium hydroxide, followed by calcium hydride, and distilled before use. The ir spectra of liquids were measured as films, of solids in Nujol mulls. The nmr spectra were measured in deuteriochloroform solution.

Synthetic experiments

Ethyl 2-acetyl-2-benzyl-4-oxo-4-phenylbutanoate

Ethyl 2-benzyl-3-oxobutanoate (14) (1.4 g) in dry 1,2-dimethoxyethane (5 mL) was added dropwise to a suspension of sodium hydride (0.26 g) in dry 1,2-dimethoxyethane (5 mL) and the mixture heated at 25°C for 30 min. The mixture was cooled to room temperature, phenacyl bromide (1.27 g) in dry 1,2-dimethoxyethane (5 mL) added, and the mixture stirred for 18 h. Water was added, and the resulting solution extracted with ether (3 × 10 mL). The combined ether layers were washed and dried ($MgSO_4$). Removal of the solvent and flash chromatography of the residue gave ethyl 2-acetyl-2-benzyl-4-oxo-4-phenylbutanoate as an oil (1.53 g; 33%); ν_{max}: 1740, 1720, 1690 cm^{-1}; δ_H: 1.14 (t, *J* 7.7 Hz, ester CH_3), 2.38 (s, CH_3CO), 3.22 and 3.47 (ABq, *J* 13.5 Hz, PhCH_2), 3.45 (s, 3-H), 4.03 (q, *J* 7.9 Hz, ester CH_2), and 6.65–7.65 (m, aromatic H) ppm.

5-Benzyl-3-phenylcyclopent-2-en-1-one

Potassium hydroxide solution (1%, 630 mL, deoxygenated) and the above diketoester (7.9 g) were refluxed for 2 h under nitrogen. This mixture was cooled to room temperature, the strength of the potassium hydroxide increased to 10%, and the resulting mixture refluxed under nitrogen for a further 2.5 h. The cooled mixture was extracted with chloroform (3 × 75 mL). The combined organic layers were washed and dried ($MgSO_4$). Removal of solvent and flash chromatography of the residue afforded *5-benzyl-3-phenylcyclopent-2-en-1-one* **1***a* as needles (2.6 g; 42%), mp 70–71°C; λ_{max}: 285 and 224 nm (log ε 4.18 and 3.92 respectively); ν_{max}: 1690 and 1500 cm^{-1}; δ_H: 2.62–2.95 (m, 4- and 5-H), 3.15 (m, PhCH_2), 6.35 (t, *J* 2 Hz, 2-H), and 7.05–7.53 (m, aromatic H) ppm. *Anal.* calcd. for $C_{18}H_{16}O$: C 87.1, H 6.5; found: C 87.0, H 6.4%.

Ethyl 2-acetyl-2-(1-naphthylmethyl)-4-oxo-4-phenylbutanoate

Ethyl 2-(1-naphthylmethyl)-3-oxobutanoate (15) (23.1 g) in dry 1,2-dimethoxyethane (70 mL) was added dropwise to a suspension of sodium hydride (3.4 g) in dry 1,2-dimethoxyethane (50 mL) under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

nitrogen. The mixture was stirred for 10 min, phenacyl bromide (16.9 g) in dry 1,2-dimethoxyethane (30 mL) added, and the resulting mixture stirred at 20°C for 12 h. Water was added and the solution extracted with chloroform (3 × 50 mL). The combined organic layers were washed and dried ($MgSO_4$). Removal of solvent afforded an oil, which on flash chromatography gave the *diketoester* (4.0 g) as needles, mp 116–117°C; δ_H: 1.10 (t, *J* 7.7 Hz, ester CH_3), 2.49 (s, CH_3CO), 3.53 (s, 1-H), 3.79 and 4.04 (ABq, *J* 14.0 Hz, $ArCH_2$), 4.08 (q, *J* 7.7 Hz, ester CH_2), and 7.08–7.96 (m, aromatic H) ppm. *Anal.* calcd. for $C_{25}H_{24}O_4$: C 77.3, H 6.0; found: C 77.3, H 6.2%.

5-(1-Naphthylmethyl)-3-phenylcyclopent-2-en-1-one **1**b

Potassium hydroxide solution (1%, 600 mL, deoxygenated) and the naphthylmethyl diketoester (10.5 g) were refluxed for 4 h under nitrogen. The mixture was cooled to room temperature, the potassium hydroxide concentration increased to 10%, and the refluxing continued for 4 h. The solution was extracted with chloroform (3 × 250 mL) and the combined organic layers were washed and dried ($MgSO_4$). Removal of solvent and flash chromatography of the residue afforded *5-(1-naphthylmethyl)-3-phenylcyclopent-2-en-1-one* **1***b* (3.2 g, 40%), as needles, mp 127–128°C; λ_{max}: 283 and 223 nm (log ε 4.46 and 4.59 respectively); ν_{max}: 1690, 1510, and 1500 cm^{-1}; δ_H: 2.88–3.19 (m, 4- and 5-H), 4.0 (s, $ArCH_2$), 6.62 (t, *J* 1.5 Hz, 2-H), and 7.32–8.34 (m, aromatic H) ppm. *Anal.* calcd. for $C_{22}H_{18}O$: C 88.55, H 6.1; found: C 88.9, H 5.8%.

Ethyl 2-acetyl-2-(2-naphthylmethyl)-4-oxo-4-phenylbutanoate

Ethyl 2-(2-naphthylmethyl)-3-oxobutanoate (15) (2.01 g) in dry 1,2-dimethoxyethane (30 mL) was added to a suspension of sodium hydride (330 mg) in dry 1,2-dimethoxyethane (20 mL) and the mixture stirred for 15 min. Phenacyl bromide (1.47 g) in dry 1,2-dimethoxyethane (20 mL) was added dropwise to the solution at 0°C and the resulting mixture stirred at 0°C for 1.5 h. Water was added and the aqueous solution extracted with ether (3 × 25 mL). The combined ether layers were washed and dried ($MgSO_4$). Removal of solvent and flash chromatography of the residue afforded ethyl 2-acetyl-2-(2-naphthylmethyl)-4-oxo-4-phenylbutanoate as an oil (1.3 g, 45%); δ_H: 1.15 (t, *J* 7.7 Hz, ester CH_3), 2.44 (s, CH_3CO), 3.31 (s, 3-H), 3.40 and 3.59 (ABq, *J* 7.6 Hz, $ArCH_2$), 4.17 (q, *J* 7.7 Hz, ester CH_2), and 6.99–7.82 (m, aromatic H) ppm.

5-(2-Naphthylmethyl)-3-phenylcyclopent-2-en-1-one **1**c

Aqueous potassium hydroxide (5%, 500 mL, deoxygenated) and ethyl 2-acetyl-2-(2-naphthylmethyl)-4-oxo-4-phenylbutanoate (10 g) were refluxed for 60 h under nitrogen. The solution was extracted with chloroform (3 × 100 mL). The combined organic layers were washed and dried, and the solvent removed. The residue was chromatographed to give the *2-naphthylmethyl cyclopentenone* **1***c* (1.9 g, 26%) as needles, mp 74–75°C; λ_{max}: 281 and 222 nm (log ε 4.51 and 4.64); ν_{max}: 1690, 1515, and 1500 cm^{-1}; δ_H: 2.59 and 3.03 (m, 4- and 5-H), 3.5 (m, $ArCH_2$), 6.56 (t, *J* 2 Hz, 2-H), and 7.23–7.87 (m, aromatic H) ppm. *Anal.* found: C 88.8, H 6.1%.

Ethyl 3-oxo-2-(9-phenanthrylmethyl)butanoate

Ethyl acetoacetate (4.85 g) in dry 1,2-dimethoxyethane (30 mL) was added slowly to a suspension of sodium hydride (1.48 g) in dry 1,2-dimethoxyethane (25 mL) under nitrogen, and the mixture stirred for 20 min. 9-Bromomethylphenanthrene (16) (10.3 g) in dry 1,2-dimethoxyethane (120 mL) was added dropwise, and the resulting mixture stirred at 60°C for 15 h. Water was added, and the solution extracted with ether (3 × 75 mL). The combined ether layers were washed and dried ($MgSO_4$). Removal of the solvent gave the ketoester, which was used without further purification; ν_{max}: 1740, 1715, 1650, and 1620 cm^{-1}.

Ethyl 2-acetyl-4-oxo-2-(9-phenanthrylmethyl)-4-phenylbutanoate

Ethyl 3-oxo-2-(9-phenanthrylmethyl)butanoate (11 g) in dry 1,2-dimethoxyethane (150 mL) was added dropwise to a suspension of sodium hydride (1.36 g) in dry 1,2-dimethoxyethane (30 mL) under nitrogen, and the mixture was stirred for 30 min. It was then cooled to 0°C, and phenacyl bromide (6.8 g) in dry 1,2-dimethoxyethane (35 mL) was added dropwise. The resulting solution was stirred at 0°C for 3 h and at 20°C for a further 1 h. Water was added, and the mixture extracted with ether (3 × 50 mL). The combined ether layers were washed and dried and the solvent removed to leave the residue, which was used unpurified in the next stage; ν_{max}: 1745, 1715, 1690, 1650, and 1620 cm^{-1}.

5-(9-Phenanthrylmethyl)-3-phenylcyclopent-2-en-1-one **1**d

The above diketoester (14.3 g) and 1% aqueous potassium hydroxide (600 mL, deoxygenated) were refluxed for 3 h with stirring under nitrogen. The concentration of potassium hydroxide was increased to 10%, and the refluxing continued for a further 3.5 h. The aqueous mixture was extracted with chloroform (3 × 250 mL). The combined organic layers were washed and dried ($MgSO_4$). The solvent was removed and the residue chromatographed to give *5-(9-phenanthrylmethyl)-3-phenylcyclopent-2-en-1-one*, **1***d* (680 mg; 6%) as needles, mp 134°C; λ_{max}: 290 (log ε 4.55), 278 (log ε 4.55), and 253 nm (log ε 4.82); ν_{max}: 1690, 1650, and 1500 cm^{-1}; δ_H: 2.71–3.28 (m, 4-H, 5-H), 4.10 (m, $ArCH_2$), 6.60 (t, *J* 1.5 Hz, 2-H), and 7.45–8.80 (m, aromatic H) ppm. *Anal.* calcd. for $C_{26}H_{20}O$: C 89.6, H 5.8; found: C 89.0, H 5.8%.

Photolysis experiments

Photolysis of 5-benzyl-3-phenylcyclopentenone **1**a

The cyclopentenone **1***a* (600 mg) in degassed benzene (550 mL) was irradiated for 5 h. Removal of solvent and flash chromatography (hexane 90: ethyl acetate 10) of the residue afforded a dimer mixture (210 mg; 35%), mp 174°C; λ_{max}: 228 nm (log ε 3.75); ν_{max}: 1750 cm^{-1}. The major dimer component had δ_H: 2.12 (m, 4-H), 3.0 (m, 3-H, $PhCH_2$), 3.35 (s, 1-H), 6.55–6.69, and 6.96–7.44 (m, aromatic H) ppm; δ_C: 34.7 (t, $PhCH_2$), 41.8 (t, 4-C), 47.2 (d, 1-C), 47.8 (d, 3-C), 52.8 (s, 5-C), 126.1, 129.3, 139.1, 143.8 (aromatic C), and 215.5 (s, 2-C) ppm. *Anal.* calcd. for $C_{36}H_{32}O_2$: C 87.1, H 6.5; found: C 86.9, H 6.4%.

Pyrolysis of dimer

The dimer mixture (100 mg) was heated to 120°C for 5 h. Flash chromatography of the residue afforded the starting enone (64 mg), mp 170°C, identified by its ^1H nmr spectrum.

Photolysis of 5-(1-naphthylmethyl)-3-phenylcyclopent-2-en-1-one **1**b

The cyclopentenone **1***b* (200 mg) in degassed benzene (600 mL) was irradiated for 2 h. The solvent was removed and the residue chromatographed on alumina to afford *7,8-benzo-10-phenyltetracyclo[7.2.1.0^{3,10}.0^{4,9}]dodeca-5,7-dien-2-one* **2***b* (44 mg; 22%), mp 131–132°C; ν_{max}: 3050, 3020, 2920, 2845, 1740, 1490, and 1480 cm^{-1}; δ_H: 1.75 (br d, *J* 11.7 Hz, 11 *endo*-H), 2.06 (d, *J* 11.7 Hz, 11 *exo*-H), 2.21 (br d, *J* 12.3 Hz, 12 *endo*-H), 2.98 (m, 1-H, 4-H, 12 *exo*-H), 3.25 (s, 3-H), 5.67 (dd, *J* 9.7 and 2.5 Hz, 5-H), 5.92 (dd, *J* 9.7 and 1.0 Hz, 6-H), and 6.67–7.33 (m, aromatic H) ppm; δ_C: 38.6 (t, 12-C), 44.3 (t, 11-C), 48.4 (d, 3- and 4-C), 48.8 (s, 9-C), 51.5 (d, 1-C), 61.8 (s, 10-C), 123.7–138.1 (aromatic and olefinic C), and 214.1 (2-C) ppm. *Exact Mass* calcd. for $C_{22}H_{18}O$: *m/z* 298.1358; found: M^+, *m/z* 298.1346.

Photolysis of the photoproduct **2**b

The photoproduct (30 mg) in [$^2H_6$]-benzene was irradiated for 20 min. The nmr spectrum of the resulting solution showed the presence of the cyclopentenone **1***b*.

Pyrolysis of the photoproduct **2**b

The photoproduct (20 mg) was heated at 120°C for 4 h. The product was identified by tlc and ^1H nmr as the enone **1***b*.

Acid catalysed rearrangement of **2**b

The photoproduct **2***b* (50 mg) was absorbed onto silica, and eluted with hexane – ethyl acetate (85:15). Analysis by tlc and ^1H nmr showed the presence of the enone **1***b*.

Photolysis of 5-(2-naphthylmethyl)-3-phenylcyclopent-2-en-1-one **1**c

The cyclopentenone **1***c* (200 mg) was irradiated in degassed benzene (600 mL) for 3 h. Removal of solvent and chromatography of the residue on alumina afforded *5,6-benzo-10-phenyltetracyclo[7.2.1.0^{3,10}.0^{4,9}]dodeca-5,7-dien-2-one* **2***c* (30 mg; 15%) as needles, mp 88–89°C; ν_{max}: 3060, 3020, 2920, 2845, 1740, 1490, and

1480 cm^{-1}; δ_H: 1.81 (ddd, *J* 11.5, 3.0, and 1.5 Hz, 11 *endo*-H), 2.11 (d, *J* 11.5 Hz, 11 *exo*-H), 2.20 (dd, *J* 12.3 and 3.0 Hz, 12 *endo*-H), 2.31 (dd, *J* 12.3 and 1.5 Hz, 12 *exo*-H), 2.96 (br t, *J* 1.5 Hz, 1-H), 3.34 (s, 4-H), 3.39 (s, 3-H), 5.52 (d, *J* 9.5 Hz, 8-H), 6.10 (d, *J* 9.5 Hz, 7-H), and 6.55–7.83 (m, aromatic H) ppm; δ_C: 43.5 (t, 11-C), 44.5 (t, 12-C), 48.7 (s, 9-C), 48.8 (d, 4-C), 49.7 (d, 3-C), 54.1 (d, 1-C), 63.6 (s, 10-C), 125.5–138.1 (aromatic and olefinic C), and 215.0 (2-C) ppm. *Exact Mass* found: M^+, *m/z* 298.1351.

Photolysis of the photoproduct **2**c

The photoproduct (20 mg) **2***c* in purified [$^2H_6$]-benzene was irradiated for 20 min. The resulting mixture contained **2***c* and **1***c*.

Pyrolysis of the photoproduct **2**c

The photoproduct (15 mg) was heated at 120°C for 4 h. The product was identified by tlc and ^1H nmr as the enone **1***c*.

Acid catalysed rearrangement of **2**c

The photoproduct **2***c* was absorbed onto silica. Elution with ethyl acetate – hexane (15:85) afforded a mixture; ^1H nmr showed the presence of **1***c*.

Photolysis of 5-(9-phenanthrylmethyl)-3-phenylcyclopent-2-en-1-one **1**d

The cyclopentenone **1***d* (200 mg) in degassed benzene (600 mL) was irradiated for 2.5 h. The solvent was removed and the residue chromatographed on alumina to give *5,6;7,8-dibenzo-10-phenyltetracyclo[7.2.1.0^{3,10}.0^{4,9}]dodeca-5,7-dien-2-one* **2***d* (28 mg; 14%), mp 112°C; ν_{max}: 3050, 2985, 2970, 1745, 1485, and 1445 cm^{-1}; δ_H: 1.85 (ddd, *J* 11.9, 2.0, and 1.0 Hz, 11 *endo*-H), 2.2 (d, *J* 11.9 Hz, 11 *exo*-H), 2.29 (dd, *J* 13.2 and 2.0 Hz, 12 *endo*-H), 3.09 (m, 1-H and 12 *exo*-H), 3.34 (s, 3-H), 3.54 (s, 4-H), and 6.46–7.56 (m, aromatic H) ppm; δ_C: 40.3 (t, 12-C), 44.6 (t, 11-C), 49.46 (s, 9-C), 49.49 (d, 4-C), 49.6 (d, 3-C), 54.1 (d, 1-C), 62.3 (s, 10-C), 122.8–137.9 (aromatic C), and 214.8 (s, 2-C) ppm. *Exact Mass* calcd. for $C_{26}H_{20}O$: *m/z* 348.1514; found: M^+, *m/z* 348.1504.

Photolysis of the photoproduct **2**d

The photoproduct **2***d* (10 mg) was irradiated in [$^2H_6$]-benzene (0.6 mL) for 2 h. The resulting solution was shown (tlc, ^1H nmr) to contain the enone **1***d*, and **2***d*.

Europium shift experiments

Aliquots of Eu(fod)$_3$ were added to a 0.1 *M* solution of **2***b* and **2***c* and the nmr spectra recorded.

$$\Delta M = \frac{\Delta\delta}{[\text{Eu(fod)}_3]/[\text{Ketone}]}$$

For **2***b*, ΔM values: 6.2 (3-H), 5.38 (1-H), 4.15 (4-H), 3.28 (11 *exo*-H), 3.15 (12 *endo*-H), 2.17 (12 *exo*-H), 2.12 (11 *endo*-H), 1.23 (5-H), and 0.75 (6-H).

For **2***c*, ΔM values: 5.1 (3-H), 4.43 (1-H), 3.31 (4-H), 2.5 (11 *exo*-H and 12 *endo*-H), 1.78 (11 *endo*-H), 1.73 (12 *exo*-H), 0.95 (8-H), and 0.69 (7-H).

Received December 30, 1986

This paper is dedicated to Professor John T. Edward

SVANTE WOLD, LENNART ERIKSSON, SVEN HELLBERG, JÖRGEN JONSSON, MICHAEL SJÖSTRÖM, BERT SKAGERBERG, and CONNY WIKSTRÖM. Can. J. Chem. **65**, 1814 (1987).

Previously derived principal property scales for the 20 coded amino acids have been extended to six noncoded amino acids, namely ornithine, norvaline, norleucine, O-methylated threonine, α-amino butyric acid, and citrulline. This has been done first, for the 20 coded amino acids, by developing PLS models for the relations between the previously derived scales (z_1, z_2, and z_3) and newly measured thin-layer chromatography data, proton nuclear magnetic resonance data, plus literature data describing amino acid "bulk" (van der Waals volume and molecular mass). Thereafter, z values for the noncoded amino acids were calculated by inserting the same measured data for these compounds into the PLS models. As a validation, the calculated z values were then used to describe the structural variation of a set of 60 oxytocin peptide analogues for which literature data on biological measurements existed. The models explain 71–81% of the variance of the biological data and are highly significant according to cross-validation. Prediction errors of about twice the estimated biological measurement error are obtained for the 11 peptide analogues containing noncoded amino acids.

SVANTE WOLD, LENNART ERIKSSON, SVEN HELLBERG, JÖRGEN JONSSON, MICHAEL SJÖSTRÖM, BERT SKAGERBERG et CONNY WIKSTRÖM. Can. J. Chem. **65**, 1814 (1987).

Des échelles de propriétés principales qui avaient été développées antérieurement pour les 20 acides aminés codés ont été étendues à six acides aminés non-codés, soit l'ornithine, la norvaline, la norleucine, la thréonine *O*-méthylée, l'acide α-aminobutyrique et la citrulline. Dans un premier temps, on a développé des modèles PLS pour les 20 acides aminés codés en se basant sur les relations entre les échelles développées antérieurement (z_1, z_2 et z_3) et les nouvelles données mesurées par chromatographie en couche mince et par résonance magnétique nucléaire ainsi que des données de la littérature décrivant le «volume» des acides aminés (volume de van der Waals et masse moléculaire). Ensuite, on a calculé les valeurs z des acides aminés non-codés en insérant les mêmes données pour ces composés dans les modèles PLS. Afin de valider nos conclusions, on a ensuite utilisé les valeurs z pour décrire la variation de structure d'un ensemble de 60 analogues du peptide oxytocine pour lesquels des données relatives aux mesures biologiques existent dans la littérature. Les modèles expliquent de 71 à 81% de la variance des données biologiques et, d'après des contre-validations, elles sont très significatives. Pour 11 des analogues peptidiques contenant des acides aminés qui ne sont pas codés, on peut prédire des erreurs qui sont le double de l'erreur évaluée pour les mesures biologiques.

[Traduit par la revue]

Introduction

We have earlier developed three scales summarizing a number of properties of the 20 coded amino acids, i.e., those coded by RNA in the protein synthesis (1–3). We called these three scales, z_1, z_2, and z_3, *principal properties* (PPs) of the amino acids. The PPs were used for a quantitative description of the variation in sequence in families of peptide analogues, thereby allowing the construction of models of the relation between structure and biological activity for these peptide families (3–5). Since amino acids other than the 20 coded ones are often included in synthetic peptide sequences, it is of interest to extend the z-scales to such noncoded acids.

The purpose of the present article is to outline a working procedure for this extension of z-scales, based on data measured on the amino acids (see Tables 1 and 2) and multivariate PLS models (partial least-squares projections to latent structures). Finally, the results are validated on a set of oxytocin peptide analogues varying in five of the nine amino acid positions. Five biological measurements were available for these compounds. Three of these were oxytocin-like (OT), and two vasopressin-like (VP), activity measurements. This set included 11 peptides containing one of the six noncoded amino acids. Two PLS models were developed, one for OT, and one for VP, relating the variation in peptide sequence in the training sets to the biological activity data. The training sets comprised peptides with coded amino acids only and with complete biological data.

Method

Data measured on a set of similar objects, here a set of amino acids, can be well approximated by a bilinear model, i.e., a principal components (PC) or a PLS model (6–8). PLS (partial least-squares projection to latent structures) was originally developed by H. Wold for the modeling of complex social science systems (8), and was later modified for solving a number of data analytic problems in chemistry and neighboring sciences (10–13). PLS allows the modeling of the relationship between any data measured on a set of similar objects and any other data or data aggregates relating to the same set.

We have previously shown that physicochemical data measured on the 20 coded amino acids are adequately summarized by a model with three PCs. The score vectors in this PC model were denoted z_1–z_3 and called *principal properties* (PPs) of the amino acids. Tentatively, we interpreted these three scales as related to lipophilicity, side chain bulk, and electronic properties of the amino acids.

The PPs have been found relevant for quantifying the variation in sequence within sets of similar peptides and the relation between this sequence variation and the variation in biological potency in such sets (2–4).

TABLE 1. Conditions for the tlc and nmr experiments corresponding to variables 1–10, and the two "bulk" describing variables

Variable no.	Type	Eluent (tlc) or pD (nmr)
Thin-layer chromatography		
1	Silica gel	Ethanol–water (7:3)[a]
2	Silica gel	1-Butanol – acetic acid–water (4:1:1)
3	Silica gel	Phenol–water (3:1 weight/weight)
4	Silica gel	Butanone–pyridine – acetic acid – water (70:15:2:15)
5	Cellulose	Ethanol–water (7:3)
6	Cellulose	Pyridine–isoamylalcohol–water (7:6:6)
7	Kieselguhr	Butanone–water–phenol–acetone–ethanol (1:1:1:1:1)
Proton nmr		
8		pD = 2.0[b] α-Proton shift in ppm
9		pD = 7.0 α-Proton shift in ppm
10		pD = 12.5 α-Proton shift in ppm
11	van der Waals volume (cm^3/mol)	
12	Molecular weight (g/mol)	

[a]The composition of the eluents refers to parts by volume.
[b]The pD refers to measurements by a pH electrode in heavy water corrected by 0.45 units (see ref. 9).

PCA

The PC model for a matrix X with the n rows corresponding to objects, here amino acids or peptides, and the p columns containing different measurements made on these objects, is given by

$$[1] \quad X = 1\bar{x} + TP' + E$$

Here 1 denotes a column vector with elements of unity, and $\bar{x}$ denotes the vector of column averages of X. The $(n \times A)$ score matrix T contains information about the n objects expressed as A vectors, components, and the $(A \times p)$ loading matrix P' contains coefficients expressing how the original x-variables are combined to form T. The rows in P' are normalized to length one. The residual matrix E contains the deviation between data and model, i.e., the part unexplained by the model.

The number of statistically significant model dimensions, A, may be determined by cross-validation (12). This procedure is based on a repeated analysis of the data matrix, each time with part of its elements treated as missing observations. The model is developed on the remaining data and the pseudo-missing observations are then predicted from the model. The differences between the predicted and the actual values are used to evaluate whether the current model dimension improves the predictive power of the model.

From a model developed on a "training set" of objects, scores (t values) for new objects are simply calculated from their x-data, a row vector x, as

$$[1b] \quad t = xP$$

This also gives a measure of dissimilarity between a new object and the training set, calculated as the standard deviation of the residuals (rsd):

$$[1c] \quad e = x - tP'$$

The primary use of PCA is to get an overview of a data matrix in terms of a picture (the plot of columns in T against each other) and for estimating the number of "factors" in the matrix.

PLS

The predictive two-block PLS model relates a matrix X to a matrix Y with the purpose of predicting Y from X. For the X part the model is the same as for PCA (eq. [1]), but in addition a matrix W of PLS-weight vectors results from the computations. The Y block is modeled in the same way as the X block:

$$[2] \quad Y = 1\bar{y} + UC' + F$$

In addition, the Y-block score matrix U (dimension $n \times A$) is modeled by the "inner relation", where B is a diagonal coefficient matrix, and H is a $(n \times A)$ residual matrix:

$$[3] \quad U = TB + H$$

The number of model dimensions, A, is typically small (1, 2, or 3) as long as the modeled objects are similar to each other with respect to the measured data.

Inserting eq. [3] into eq. [2] gives the predictive model for Y (the asterisks indicate that C^* differs from C, etc.):

$$[4] \quad Y = 1\bar{y} + TC^{*\prime} + F^*$$

Similarly to PCA, the significance of the model dimensions is evaluated by cross-validation.

Predictions of the y values for new objects are obtained from the x-data for these objects inserted into the PLS model (W is the PLS-weight matrix):

$$[4a] \quad y = xW'(PW')^{-1}c$$

The main use of predictive two-block PLS models is for the same data analytical problems as multiple regression (MR), i.e., to get a predictive model of Y in terms of X. A difference between MR and PLS is that PLS can handle collinearities in X, even to the extent that the number of variables in X (p) can exceed the number of objects (n). Also, PLS does not assume that the x-variables are 100% relevant, but tolerates that X contains systematic and unsystematic parts that are unrelated to the problem of interest in the analysis, i.e., the modeling of Y.

A PLS model relating PPs to newly measured physicochemical data

The previous PPs (2, 3) were derived by a PCA of values for the physicochemical data that were obtained mainly from the literature. This makes it difficult to extend the *z*-scales to amino acids for which the corresponding literature data are unavailable. To get around this problem, we have measured multivariate data on the individual amino acids with the hope that these data contain sufficient information to constitute a basis for the *z*-scales. These data comprise retention data in seven thin-layer chromatography (tlc) systems, and proton nmr data for the amino acid α-proton at three different conditions (see Table 1).

In addition, we have used the van der Waals volume and molecular weight to describe the variation in bulk between the amino acids.

With these 12 variables (Table 2) comprising the matrix *X*, a two-block single *y* PLS model (8, 10, 11) was developed for each *z*-scale as the dependent (*y*) variable.

For each *z*-scale, a measure of the explained variance and the predicted variance is obtained. If these measures are sufficiently small, the *z*-scales may be predicted from (i.e., calculated from) the physicochemical measurements used as *x*-variables in the present study.

Predicting PPs (z-scales) for new amino acids

Once a PLS model is developed for the relation between a *z*-scale and the 12 physicochemical variables, the *z* values for new amino acids may be predicted (calculated) from their 12 physicochemical measurements inserted in the earlier developed PLS model.

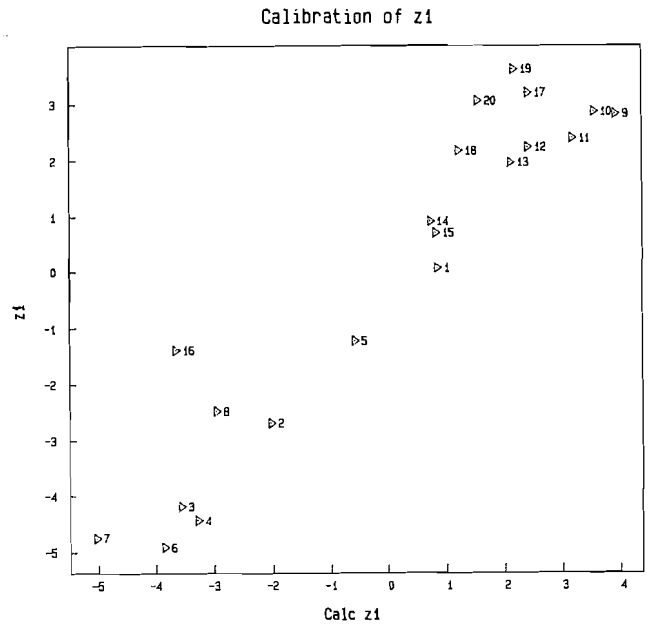

FIG. 1. A PLS model of the first PP, z_1, modeled as a linear combination of the 12 physicochemical variables, mainly nos. 1–7 (see Table 3). The model explains 89% of the variance in z_1. The amino acids are numbered according to Table 2.

Peptide QSAR

To develop a quantitative structure–activity relationship (QSAR) for a family of peptides, one essential problem to be solved first is the translation of the variation in sequence to the variation in one or several quantitative variables. Having the three PPs, i.e. *z*-scales, for the amino acids, we translate the

For personal use only.

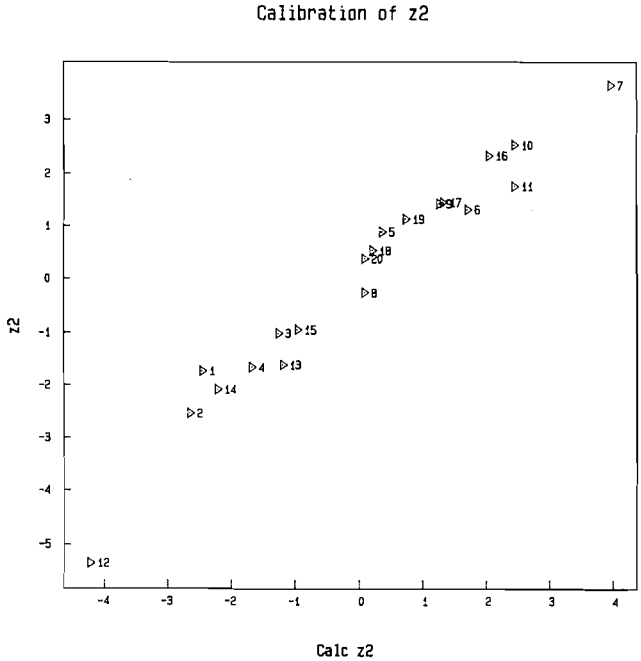

FIG. 2. A PLS model of the second PP, z_2, modeled as a linear combination of the 12 physicochemical variables, mainly nos. 8–12 (see Table 3). The model explains 95% of the variance in z_2. The amino acids are numbered according to Table 2.

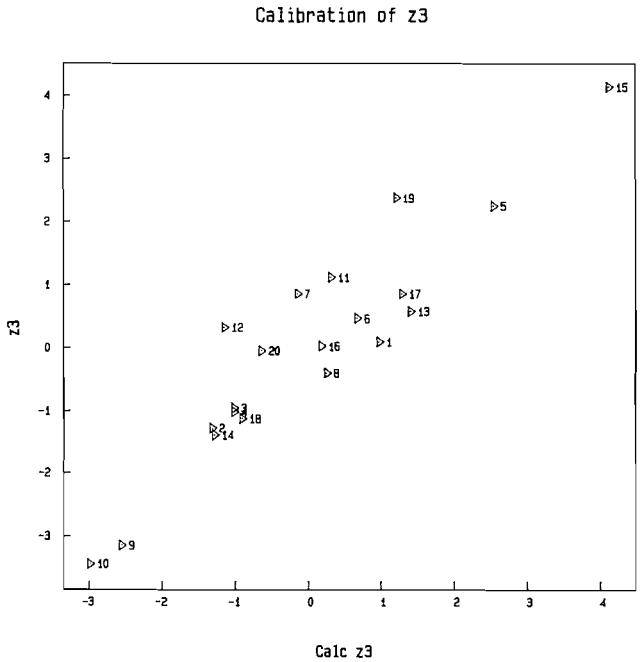

FIG. 3. A PLS model of the third PP, z_3, modeled as a linear combination of the 12 physicochemical variables (see Table 3). The model explains 85% of the variance in z_3. The amino acids are numbered according to Table 2.

variation in amino acid sequence into the variation in z values. Thus, each varying peptide position is translated to the values of the three z-scales.

This gives as the result a matrix (X) describing the sequence variation in the peptide family. This matrix has as many rows as there are peptides and as many columns as there are varying positions times three (three z-scales).

In a PLS model of a QSAR, the Y-matrix contains the measured activity values of a training set of peptides. The activity values for a set of oxytocin analogues were obtained from the literature (14). This Y-matrix is related to the X-matrix describing the structure by a PLS model. The appropriate number of model dimensions (PLS components) is determined by cross-validation (12, 13).

Predictions of the activities (Y) of new peptides may thereafter be obtained by first translating their peptide sequence to an x-vector using the z-scales, and then inserting the x-vector in the PLS model developed earlier.

Results

Using PLS modeling and the measured data described above, we arrived at the following results:

PLS models relating previously developed z-scales to measured physicochemical data

Significant PLS models were obtained for each of z_1, z_2, and z_3, with 1, 3, and 4 model dimensions, respectively. The agreement between the previous z values and those predicted by the PLS model of the physicochemical data is shown in Figs. 1–3.

The explained variances of z_1–z_3 are 89, 95, and 85%, respectively, which we feel are adequate for the present purposes.

PPs (z-scales) for six new amino acids

By means of these PLS models (see above), z values were calculated for the six noncoded amino acids giving the values in Table 2 (nos. 21–26).

Oxytocin analogues QSAR

This quantitative structure relationship (QSAR) is an extension of the one previously reported (3) where only two biological activity variables were modeled for oxytocin related nonapeptides of the general structure: Cys-x-x-x-x-Cys-Pro-x-Gly-NH_2 (see Table 4). Here three additional biological effect variables were compiled and analysed (see Figs. 4–8).

1. PCA of five biological activities

First a PCA was made of the biological activity data for all peptides. Two highly significant PCs (cross-validation) were obtained. The loading plot of p_2 against p_1 shows that the biological variables are clustered in two groups containing nos. 1–3 and 4 and 5, respectively.

These two groups of activity variables were analyzed separately, as described below.

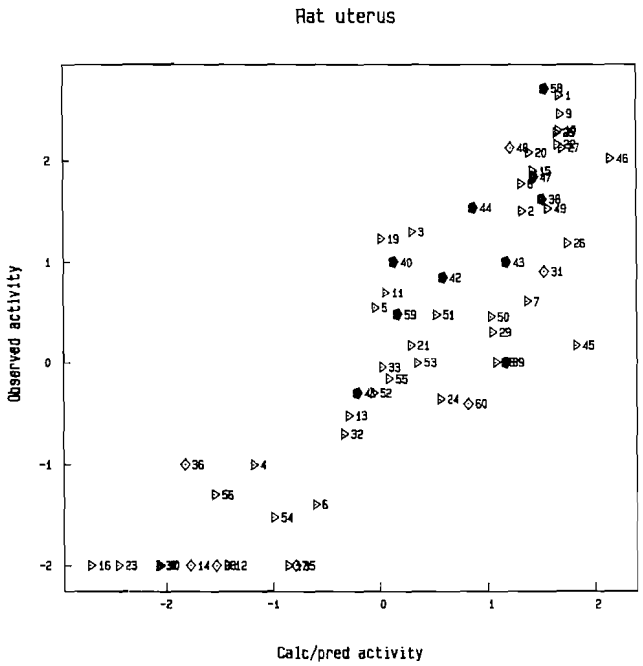

FIG. 4. PLS predictions of the first biological activity variable, rat uterus contractile activity, plotted against the observed values. The triangles denote the training set points for the 20 coded amino acids, rhombes denote predictions for the test set peptides with coded amino acids, and pentagons (filled) the predictions for test set peptides containing noncoded amino acids. The peptides are numbered according to Table 4.

2. PLS model for the three oxytocin-like activities (OT)

The variation in peptide sequence for the oxytocin analogues was translated to 15 *x*-variables by describing each varying position (nos. 2, 3, 4, 5, and 8) by the three *z*-scales derived as described above.

A training set of peptides was formed by those having only coded amino acids and all three biological activities defined.

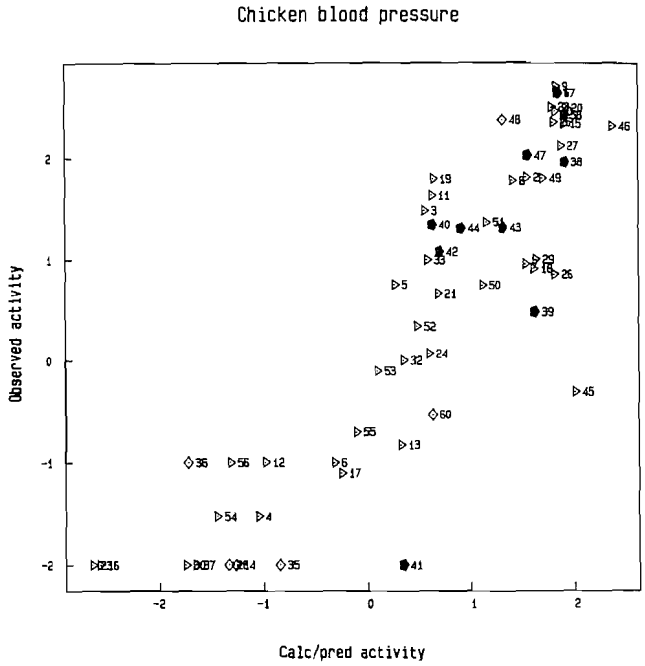

FIG. 5. PLS predictions of the second biological activity variable, chicken blood pressure, plotted against the observed values. Notation and numbering same as in Fig. 4.

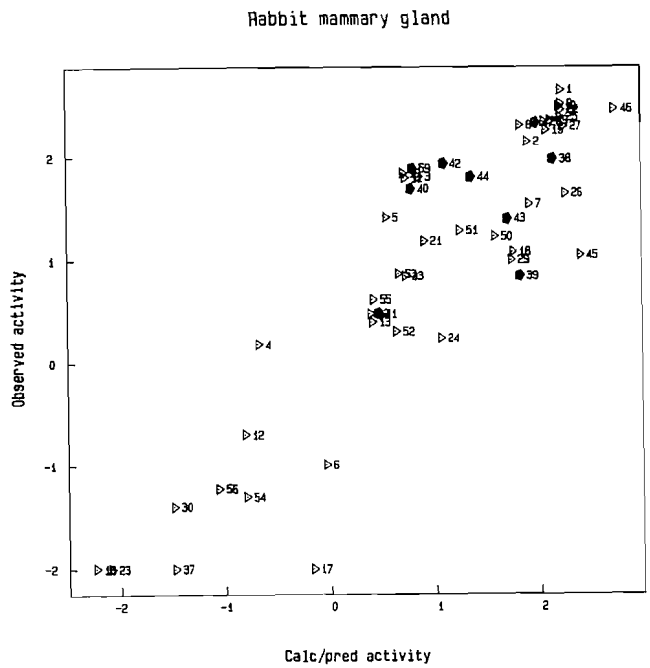

FIG. 6. PLS predictions of the third biological activity variable, rabbit mammary gland activity, plotted against the observed values. Notation and numbering same as in Fig. 4.

The test set thus contained peptides with coded amino acids and incomplete biological data, plus peptides with a noncoded amino acid in some position.

A highly significant three-dimensional PLS model resulted for the training set. The relations between observed activities and those predicted by the model are illustrated in Figs. 4–6.

The resulting PLS parameters (given as supplementary material) may be used to construct peptides that are likely to be more active than the present 60 analogues. However, since in the present case the experimental design, i.e., the selection of

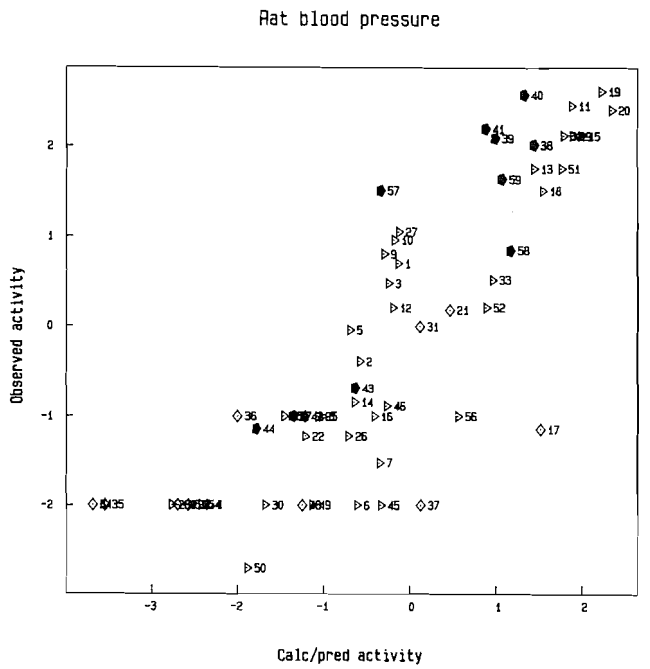

FIG. 7. PLS predictions of the fourth biological activity variable, rat blood pressure, plotted against the observed values. Notation and numbering same as in Fig. 4.

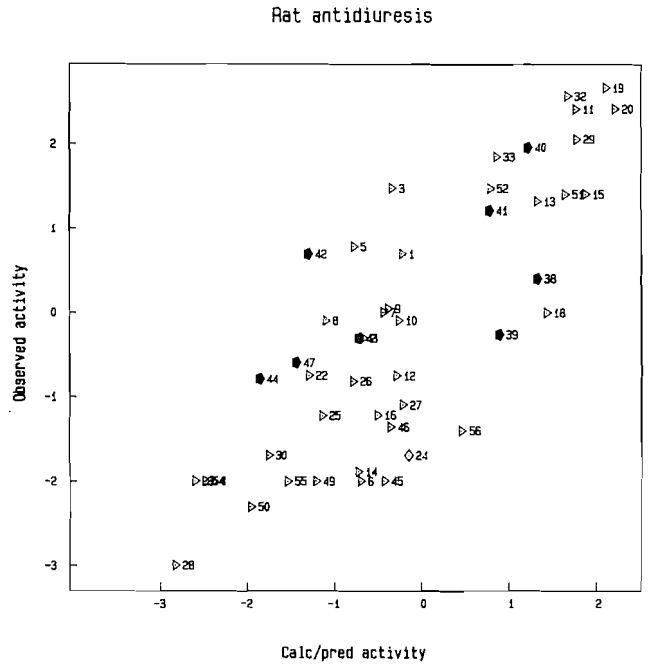

FIG. 8. PLS predictions of the fifth biological activity variable, rat antidiuresis, plotted against the observed values. Notation and numbering same as in Fig. 4.

training compounds, is highly unbalanced from the statistical point of view, such extrapolations are uncertain and should be regarded with caution. There are ways of constructing balanced training sets of compounds, which efficiently probe the chemical properties of several amino acid positions simultaneously (3, 5).

3. PLS model for the two vasopressin-like activities (VP)

In the same way, a PLS model was developed for the two VP-like biological activity variables. A PLS model with two significant dimensions was obtained, giving predictions plotted in Figs. 7 and 8.

Discussion

The multivariate modeling of chemical data may be used to find the number of "inherent factors" in a chemical system, and to obtain values for the factors (latent variables) for pertinent cases (objects). This approach has previously been used, for instance, by Edward *et al.* to investigate the complexity of the ionization of weak acids (15) and other interesting systems (16). Here it is used to get a quantitative description of amino acids, which then is utilized in models relating the variation in peptide sequence to the variation in biological activity.

We see in Figs. 4–8 that the models are not "perfect", but still the predictive power of the model is remarkably good considering the crudeness of the approach. These results are of some interest with respect to the traditional "lock-and-key" interpretation of the biological activity of organic molecules. The present results indicate either that shape is less important or that shape and conformation are in some way inherent in the z values. Regardless of the interpretation this has practical consequences in that, at least for small peptides, we may not need to go via the cumbersome three-dimensional structural approach with crystallography, molecular graphics, and similar methods.

The z values developed here are not final, and final values will perhaps never be obtained. The approach of soft modeling does not aim at final answers, if such exist, but rather to develop a working approach to the study of complexity. With the change in time and problem formulation, the perspective on a given system changes, and thereby its latent variables and their values. Hence, the z values should be taken as scales useful in a certain context, which may change tomorrow when a better understanding of peptide QSARs is reached.

Supplementary material

Tables of resulting PLS parameters for the peptide QSAR models are given as supplementary material to allow interested readers to check results and make their own predictions.[2]

A novel reaction of α-haloepoxides with trialkylstannates

L. D. COREY, S. M. SINGH, AND A. C. OEHLSCHLAGER
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received November 25, 1986

This paper is dedicated to Professor John T. Edward

L. D. COREY, S. M. SINGH, and A. C. OEHLSCHLAGER. Can. J. Chem. **65**, 1821 (1987).

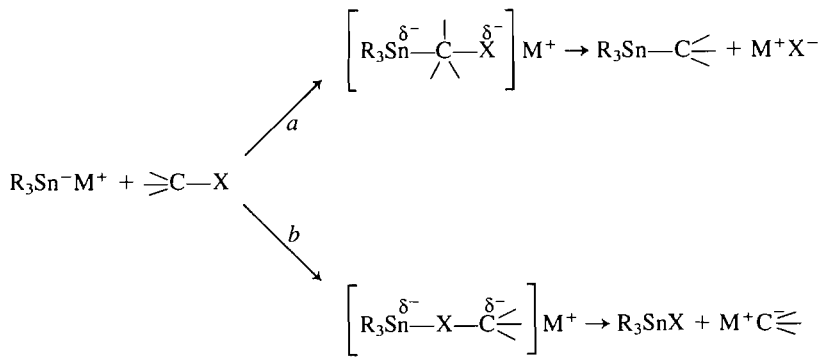
The reaction of α-haloepoxides with zinc powder or reagents containing the trialkylstannate anion yields allylic alcohols by *anti* elimination of the carbon halogen and adjacent carbon epoxy oxygen bonds. Appreciable $Z \rightarrow E$ isomerization occurs in both types of reactions but the experimental results indicate that the conversion of *erythro* α-bromoepoxides to *E* allylic alcohols by zinc or trialkylstannates shows sufficient stereospecificity to be synthetically useful.

L. D. COREY, S. M. SINGH et A. C. OEHLSCHLAGER. Can. J. Chem. **65**, 1821 (1987).

La réaction des α-haloépoxydes avec de la poudre de zinc ou avec des réactifs contenant l'anion trialkylstannate conduit à des alcools allyliques par une élimination *anti* des liaisons carbone/halogène et carbone adjacent/oxygène de l'époxyde. Dans chacun des types de réactions, il se produit une quantité appréciable d'isomérisation $Z \rightarrow E$; ce résultat indique que la conversion des α-bromo époxydes *érythro* en alcools allyliques *E*, sous l'influence du zinc ou des trialkylstannates, présente suffisamment de stéréospécificité pour être utile d'un point de vue de synthèse.

[Traduit par la revue]

The nucleophilic replacement of halogen by trialkylstannates (reaction *a*) is a well-documented process (1).



Less well known are the reactions of trialkylstannates with organohalides to give trialkylstannyl halides and organometallics (reaction *b*). Indeed, the latter process would not be expected to proceed in the direction shown unless the carbanionic center in the organic residue were stabilized by an appropriate electron withdrawing group.

Nozaki and co-workers (2) have recently discovered interesting examples of the latter reaction (*b*). His group has shown that α-haloketones (**1***a*) and α-haloesters (**1***b*) rapidly undergo reaction with tributylstannyl-diethylaluminum (**2**) to provide

$$n\text{-}Bu_3Sn\text{—}AlEt_2$$
2

tributyltin bromide (**3**) and the diethylaluminum enolates (**4**) of the dehalogenated α-halocarbonyl compounds. The synthetic utility of this reaction lies in the fact that conversion of **1** to **4** may be conducted in the presence of aldehydes that undergo *in situ* aldol reactions with **4**. The conversion of **1** to **4** was illustrated as a cyclic process (Scheme 1) involving the *syn* conformer of **1**.

The initial goal of the present investigation was to determine if **2** and related trialkylstannates would convert α-haloepoxides (**5**) to allylic alcohols (**6**). The envisioned process involved conversion of α-hydroxyepoxides (**7**) to α-haloepoxides (**5**) (via α-tosylepoxides, **8**) and thence to allylic alcohols (**6**). Such a process when used in conjunction with the Sharpless asymmetric epoxidation (3) of primary alcohols (**5**, $R^1 = R^2 = H$) would potentially allow preparation of chiral secondary alcohols (**6**, $R^1 = R^2 = H$) in yields higher than those achievable through the application of Sharpless kinetic resolution.

The second goal of this study was to compare the stereochemistry of the conversion of **5** ($R^1 \neq R^2$) to **6** ($R^1 \neq R^2$) by powdered zinc (4) with that effected by trialkylstannates. We considered it likely that the former reaction would proceed by an *anti* elimination whereas a trialkylstannate mediated elimination would proceed by a *syn* elimination.

Results

We chose the conversion of *E*-2-octen-1-ol (**9***a*) to 1-octen-3-ol (**6***a*) as an initial test of the proposed strategy since the enantiomers of the desired product (**6***a*) were required for biological testing as pheromone synergist for *Oryzaephilus mercator* and *O. surinamensus* (5). Conversion of **9***a* to **5***a* proceeded cleanly for both the racemic series and the chiral series. Epoxidation of **9***a* (6, 7) with *m*-chloroperoxybenzoic acid gave (±)-**7***a* in 87% yield. The chiral enantiomers (2*S*,3*S*)-**7***a* and (2*R*,3*R*)-**7***a* were prepared from **9***a* by reaction under Sharpless asymmetric epoxidation conditions (8) using either (+) or (−)-diisopropyl tartrate as the chiral auxiliary ligand in 91 and 51% yield respectively. Preparation of the Mosher ester ((+)-α-methoxy-α-trifluoromethyl-phenylacetyl derivative) (9) of (2*S*,3*S*)-**7***a* and (2*R*,3*R*)-**7***a* followed by analysis of the resulting diastereoisomeric mixture by capillary gc revealed an enantiomeric excess of 90% for (2*S*,3*S*)-**7***a* and 80% for (2*R*,3*R*)-**7***a*. Racemic **7***a* and each enantiomer were converted to the corresponding tosylates, (±)-**8***a*, (2*S*,3*S*)-**8***a*, and (2*R*,3*R*)-**8***a* by treatment with *p*-toluenesulfonyl chloride and powdered potassium hydroxide in ether to yield 91, 61, and 98% respectively (10). The tosylates were each converted to the corresponding iodides, (±)-**5***a*, (2*R*,3*S*)-**5***a*, and (2*S*,3*R*)-**5***a*, by the reaction with sodium iodide in reagent grade acetone in yields of 91, 90, and 96% respectively (11).

Initially we examined the reaction of (±)-**8***a* with zinc powder and $Bu_3SnAlEt_2$ (**2**) to determine if these reagents would effect the conversion of **8***a* to 1-octen-3-ol (**6***a*). This reaction was of interest because, if successful with either reagent, it would allow the conversion shown in Scheme 2 without generation of the corresponding halogen substrate. Unfortunately, reaction of (±)-**8***a* with zinc powder failed to produce (±)-**6***a*. However, reaction of (±)-**5***a*, (2*R*,3*S*)-**5***a*, and (2*S*,3*R*)-**5***a* with zinc powder gave (±)-**6***a*, (*S*)-**6***a*, and (*R*)-**6***a* respectively in good yields. In the case of the reaction of (2*R*,3*S*)-**5***a*, the chemical yield of the zinc mediated reaction was 85%, and no diminution of chiral purity at C3 was detected during the reaction. In the case of (2*R*,3*S*)-**5***a*, the chemical yield was 75%.

We next examined the reaction of various α-substituted epoxides with $Bu_3SnAlEt_2$ (**2**). Of the several methods available to generate **2**,[1] we chose a route via reaction of tributyltin hydride and lithium diisopropylamide followed by addition of diethylaluminum chloride. We have found this to be the most efficient route to **2** of those reported.[1] Reaction of (±)-**8***a* with **2** in THF failed to give detectable amounts of **6***a*, and we

[1] Bu_3SnLi was prepared by BuLi + $SnCl_2$, Li + Bu_3SnCl, Li + Bu_6Sn_2 (ref. 1*b*), BuLi + Bu_6Sn_2, Li/NH_3 + Bu_3SnCl, Li/NH_3 + Bu_6Sn_2 (ref. 32*a*), and lithium diisopropylamide + Bu_3SnH (refs. 32*b*, 33).

recovered good yields of starting material. However, reaction of (±)-**5***a* with **2** gave **6***a* in 74% yield.

To determine the stereochemistry of the zinc powder and trialkylstannate mediated conversion of α-haloepoxides to allylic alcohols observed above, *erythro*-2-bromo-3,4-epoxyoctane, **5***b*, and *threo*-2-bromo-3,4-epoxyoctane, **5***c*, were prepared and subjected to reaction with zinc powder and selected trialkylstannate reagents. The choice of *Z* geometry in the epoxide group of these substrates was dictated by the reported *threo* selectivity of *m*-CPBA in the epoxidation of *Z* secondary allylic alcohols (12); this reaction would easily allow access to *threo*-3,4-epoxy-2-octanol, **7***b*. The reported *erythro* selectivity of the reduction of α-ketoepoxides would allow access to the corresponding *erythro*-3,4-epoxy-2-octanol, **7***c* (13).

The synthesis of **5***b* and **5***c* commenced with reaction of 1-hexynyllithium with ethanol (14) to give 3-octyn-2-ol in 49% yield. This alcohol was reduced to the *Z* allylic alcohol **9***b* by P-2 nickel and hydrogen in nearly quantitative yield (15). Epoxidation of **9***b* with *m*-CPBA gave **7***b*, which exhibited an ^{1}H nmr spectrum consistent with it being *threo*-3,4-epoxy-2-octanol, **7***b*, ($J_{2,3}$ coupling of 8.0 Hz). An epoxide hydrogen coupling ($J_{3,4}$) of 4.3 Hz indicated a *Z* epoxide.[2] The tosylate, **8***b*, was prepared by reaction of **7***b* with *p*-toluenesulfonyl chloride and potassium hydroxide in ether (10). When **8***b* was reacted with lithium bromide in acetone (11), the expected product was not obtained; instead the product of an S_N2' reaction, *threo*-4-bromo-2,3-epoxyoctane **10**, was obtained in 41% yield.

The structure **10** was verified by comparison of the calculated ^{1}H nmr chemical shifts of the hydrogens on the epoxide bearing carbons (δ 3.55 and 3.80 ppm) and for the hydrogen on the carbon bearing the bromine (4.23 ppm) (16) with the observed chemical shifts (3.14, 3.28, 3.77 ppm respectively). Associated coupling indicated these hydrogens to be on C3, C2, and C4 respectively. The observed coupling of 4.1 Hz for $J_{2,3}$ indicates that **10** has the *Z*-2,3 geometry.[2] *Threo* stereochemistry of the product is assigned since substitution of bromide at C4 would be expected to proceed with inversion as should tosylate displacement by oxygen at C2.

Reaction of **10** with zinc powder in methanol gave *E*-3-octen-2-ol, **6***b*, in 81% yield, which was independently generated by reduction of 3-octyn-2-ol with lithium tetrahydridoaluminate. The conversion of **10** to **6***b* by zinc powder requires the transformation to proceed via a formal *syn* elimination of the leaving groups. We suspect the elimination was actually *anti*, and **6***b* was formed by subsequent isomerization of the initially formed *Z* isomer of **6***b*.

The conversion of **7***b* to *erythro*-2-bromo-3,4-epoxyoctane, **5***b*, was achieved using Mitsunobu conditions in 49% yield (17). The observed ^{1}H nmr coupling constant between the C2 and C3 hydrogens for **5***b* is 8.9 Hz. Reaction of **5***b* with zinc powder produced a **6***c*:**6***d* ratio of 95:5. The ratio of **6***c* to **6***d* was determined by ^{1}H nmr analysis of the isolated mixture and by gc analysis. There was approximately 5% of **5***c* that could be found in **5***b*.

Authentic samples of **6***c* and **6***d* were prepared independently by reduction of 2-octyn-4-ol (14) with lithium tetrahydridoaluminate to give **6***c* or by P-2 nickel to give **6***d* (10).

[2]For (*Z*)-*threo*-3,4-epoxy-2-pentanol, the $J_{3,4}$ coupling is 4.3 Hz, and for (*E*)-*threo*-3,4-epoxy-2-pentanol, the $J_{3,4}$ coupling is 2.2 Hz (ref. 34).

To prepare *threo*-2-bromo-3,4-epoxyoctane (**5***c*), **7***b* was oxidized (71%) to *Z*-3,4-epoxy-2-octanone with oxalyl chloride in dimethylsulfoxide (18). *Erythro* selective reduction of this ketoepoxide with zinc borohydride (13) gave **7***c* in 88% yield. This product was assigned *erythro* stereochemistry on the basis of its ^{1}H nmr spectrum, which exhibited a $J_{2,3}$ coupling of 7.7 Hz. Comparison of the ^{1}H nmr spectra of **7***b* and **7***c* revealed that the chemical shifts of the hydrogens on C2, C3, and C4 are different and integration could be used to determine the *threo*:*erythro* ratio. The *threo*:*erythro* ratio for **7***b* is 94:6 and that for **7***c* is 4:96.

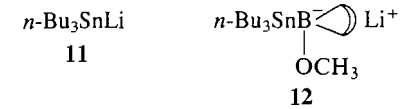
Conversion of **7***c* to the desired bromoepoxide, **5***c*, was achieved using hexamethylphosphorous triamide (HMPT) and carbon tetrabromide (CBr_4) at −78°C (19). The observed C2H–C3H coupling in the ^{1}H nmr of **5***c* is 9.4 Hz. Reaction of **5***c* with zinc powder produced a **6***c*:**6***d* ratio of 89:11. We also converted **7***c* to the corresponding chloride (**5***d*) by reaction with triphenylphosphine in carbon tetrachloride (CCl_4) in 62% yield (20). Subsequent reactions of **5***d* with zinc powder and $Bu_3SnAlEt_2$ resulted in recovered starting material without a trace of the expected product.

Most likely the zinc powder conversion of α-haloepoxides, **5***b* and **5***c*, to allylic alcohols, **6***c* and **6***d*, proceeds by *anti* elimination of the departing groups and, in the case of conversion of **5***c*, isomerization of the expected initial product (**6***d*) occurs.

The results of our study of the reaction of α-haloepoxides **5***b* and **5***c* with various trialkylstannates are shown in Table 1. Reaction of **5***b* or **5***c* with *n*-$Bu_3SnAlEt_2$ (**2**) gave predominantly **6***c* (Entries 1 and 2). *Anti* elimination of the departing groups in **5***b* would be expected to give **6***c*, which was in fact obtained in high (1:99) stereochemical purity from this reaction. Conversion of **5***c* by **2** to a mixture rich (11:89) in **6***c* suggested initial conversion to **6***d* followed by isomerization to **6***c*. Indeed, in an independent experiment **6***d* was shown to isomerize to a 1:1 mixture of **6***c* and **6***d* when treated with **2** at 0°C for 1 h. Entry 3 shows the failure of attempts to avoid the isomerization of **6***d* to **6***c* by conducting the reaction of **5***c* with **2** with BF_3–Et_2O as a Lewis acid catalyst. When the reaction shown in this entry was conducted below room temperature, no reaction occurred over 12 h.

The conversion of α-haloepoxides **5***b* and **5***c* to allylic alcohols **6***c* and **6***d* is also efficient with Bu_3SnLi, **11** (Entries 4–8). Conversion to products is most efficient when two molar equivalents of stannate reagent are used (compare Entries 4–7). As with **2**, conversion of **5***c* to **6***d* by **11** was accompanied by isomerization to **6***c*.

Reaction of Bu_2SnLi (**11**) with *B*-methoxy-9-borabicyclo-[3.3.1]nonane yields the stannylborate reagent, **12** (21). Reac-



tion of **12** with **5***b* was carried out at 65°C for 4 h to provide **6***c* (Entries 9, 10). Conversion of **5***c* to **6***d* by **12** also required heating and gave isomerization to **6***c* (Entry 11).

The most efficient stannate induced conversion of α-haloepoxides to allylic alcohols investigated utilized Bu_3SnLi **11**. Reactions with this reagent were the most rapid and gave the cleanest products upon work-up.

The observation that α-tosylepoxide, **8***a*, and α-chloroepoxide, **5***d*, failed to react with $Bu_3SnAlEt_2$ (**2**) whereas

TABLE 1. Reaction of Bu_3SnM with α-haloepoxides **5***b* and **5***c*

[a]$BF_3 \cdot OEt_2$ (2 equiv.) was added.
[b]Conversion and the product ratio (*Z*-**6***d*:*E*-**6***c*) were determined on capillary gc.
[c]Product was not isolated.
[d]Bu_3SnB reagent was prepared by the treatment of Bu_3SnLi with *B*-methoxy-9-borabicyclo[3.3.1]nonane.

α-iodoepoxide, **5***a*, and α-bromoepoxides **5***b* and **5***c* underwent smooth reaction with this reagent suggests to us that stannate mediated conversion of α-haloepoxides to allylic alcohols (Scheme 2) proceeds via attack of stannate anion on halogen (Scheme 1, reaction *b*). The alternative possibility that stannate anion attack occurs at the epoxide carbon adjacent to the α-halogen followed by rapid elimination of stannyl halide cannot be ruled out.

Experimental

General procedures

Routine gc analyses were run on a Hewlett–Packard 5880A gas chromatograph using a DB-1 capillary column (0.2 mm id × 15 m) and suitable temperature control programs. Infrared spectra were determined on a Perkin–Elmer 599B spectrophotometer. Samples were run as neat films between NaCl plates or as KBr pellets. The CH stretching and CH bending absorptions are not reported for ir spectra. The ^1H nmr spectra were recorded on a Bruker 400 WM nmr spectrometer in $CDCl_3$ using the residual $CHCl_3$ for internal standard. Low resolution mass spectra were obtained either via direct insertion or via gc inlet on a Hewlett–Packard 5985B coupled gas chromatograph/mass spectrometer. All samples were run using an electron impact ionization voltage of 70 eV. All reactions requiring anhydrous and (or) oxygen-free conditions were conducted with a positive pressure of argon or nitrogen in flame-dried glassware. Tetrahydrofuran was freshly distilled from sodium or potassium metal with benzophenone as an indicator. Methylene chloride was dried by distillation over P_2O_5 or CaH_2. Acetonitrile was dried by distillation from CaH_2 and stored over 4A molecular sieves. Pyridine was dried by distillation and storing over KOH. Dimethylformamide was dried by distillation and stored over 4A molecular sieves. All boiling points and melting points are uncorrected. The enantiomeric excess of the chiral alcohols was determined by gc analysis of the derivatives of (+)-α-methoxy-α-trifluoromethylphenylacetic acid (MPTA).

Preparation of E-*2,3-epoxy-1-octanol ((±)-7*a)

This was obtained in 87% yield from *E*-2-octen-1-ol (6, 7) and 85% *m*-chloroperoxybenzoic acid, mp 28–29°C (lit. (22) mp 33–34°C).

*Preparation of (2*S*,3*S*)-2,3-epoxy-1-octanol ((2*S*,3*S*)-7*a)

To 18.2 mL (19.1 g, 67.2 mmol) of $Ti[OCH(CH_3)_2]_4$ in 200 mL of dry CH_2Cl_2 at −23°C (Dry Ice/CCl_4 bath) under argon was added 18.3 mL (16.4 g, 70 mmol) of diisopropyl L(+)-tartrate in 20 mL of dry CH_2Cl_2. After 10 min, 8.5 g (66.3 mmol) of **9***a* dissolved in 10 mL of dry CH_2Cl_2, followed by 135 mmol of dry *tert*-butylhydroperoxide (23) in CH_2Cl_2, was added to the solution and stirred for 10 min. The reaction was placed in the freezer at −23°C until complete, and quenched by dilution with 200 mL of ether and 18.2 mL of saturated aqueous Na_2SO_4 solution. The quenched reaction mixture was filtered through a bed of Celite and the filtrate was mixed with 100 mL of saturated aqueous NaCl in 2 *M* NaOH. The organic layer was separated and the aqueous layer was extracted with ether (4 × 50 mL), dried ($MgSO_4$), filtered, and concentrated *in vacuo* to give a liquid that crystallized upon refrigeration to yield 91% (8.66 g) of (2*S*,3*S*)-**7***a*, mp 33–34.5°C. The spectroscopic data were in agreement with those given for (±)-**7***a*. To 100 mg (0.69 mmol) of (2*S*,3*S*)-**7***a* in 1 mL of CH_2Cl_2 were added 5 drops of dry C_6H_5N and 200 mg (0.79 mmol) of MTPA-Cl. The solution was stirred to react overnight, then washed with 1 mL of H_2O. Gas chromatographic analysis of the organic layer showed two diastereoisomers of the ester in the ratio of 5:95 (R_t 10.5 and 10.24, 160°C isothermal). The molecular ions of the diastereoisomers were confirmed by CI/gc/ms.

*Preparation of (2*R*,3*R*)-7*a

The procedure was identical to that described above for the preparation of (2*S*,3*S*)-**7***a* except that diisopropyl D(−)-tartrate was used. The crude product was purified by chromatography on a silica gel column using hexane:ethyl acetate (1:1) as eluent to yield 51% (4.4 g) of (2*R*,3*R*)-**7***a* from **9***a*, mp 34–35°C. The spectroscopic data were in agreement with those given for (±)-**7***a*. Gas chromatographic analysis of the MTPA-ester of (2*R*,3*R*)-**7***a* showed two diastereoisomers of the ester in the ratio of 90:10 (R_t 10.05 and 10.24, 160°C isothermal). The molecular ions of the diastereoisomers were confirmed by CI/gc/ms.

Preparation of E-*2,3-epoxy-1-octanyl tosylate ((±)-8*a)

To 9.7 g (67.3 mmol) of (±)-**7***a* in 150 mL of anhydrous ether at −10°C was added 14.18 g (74.4 mmol, 1.1 equiv.) of *p*-toluenesulfonyl chloride and 47.5 g (338 mmol, 5 equiv.) of powdered KOH, which was divided in 5 portions and added over 20 min, keeping the temperature below 0°C. The solution was stirred at 0°C for 30 min and then poured into 400 mL of ice water. The organic layer was separated and the aqueous layer was extracted with ether (3 × 75 mL). The combined organic extract was backwashed with brine (2 × 50 mL),

For personal use only.

dried ($MgSO_4$), filtered, and concentrated *in vacuo* to give a crystalline solid (18.3 g, 91%), mp 23–25°C; ir (KBr pellet): 1360, 1180, 960, 815, 770, 670, and 560 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.87 (3H, C(8), t, J = 6.7 Hz), 1.28 (4H, C(7), C(6), m), 1.37 (2H, C(5), m), 1.50 (2H, C(4), m), 2.43 (3H, $ArCH_3$, s), 2.76 (1H, C(3), dt, J = 2.1, 11.1 Hz), 2.93 (1H, C(2), ddd, J = 2.1, 3.7, 6.0 Hz), 3.96 (1H, C(1)H(a), dd, J = 6.6, 12.0 Hz), 4.17 (1H, C(1)H(b), dd, J = 3.5, 12.0 Hz), 7.34 (2H, Ar, d, J = 8.0 Hz), 7.78 (2H, Ar, d, J = 8.0 Hz); ms, *m/e* (%, relative intensity): 155 (100%), 91 (57%), 55 (12%). *Anal.* calcd. for $C_{15}H_{22}O_3S$: C 60.38, H 7.43; found: C 60.43, H 7.67.

Preparation of (2S,3S)-8a

The procedure was identical to that described above for the preparation of (±)-**8***a*, except that (2*S*,3*S*)-**7***a* was used. The yield of (2*S*,3*S*)-**8***a* was 61% (10 g). The spectroscopic data were in agreement with those given above for (±)-**8***a*.

Preparation of (2R,3R)-8a

The procedure was identical to that described above for the preparation of (±)-**8***a*, except that (2*R*,3*R*)-**7***a* was used. The yield of (2*R*,3*R*)-**8***a* was 98% (8.7 g), mp 23–25°C. The spectroscopic data were in agreement with those given above for (±)-**8***a*.

Preparation of E-2,3-epoxy-1-iodooctane ((±)-7a)

To 10.0 g (33.5 mmol) of (±)-**8***a* in 200 mL of dry acetone was added 10.1 g (67 mmol, 2 equiv.) of dry NaI and the solution was stirred for 3 h. The solution was filtered and the filtrate concentrated to yield yellow crystals. The crystals were dissolved in a pentane:water (50 mL:50 mL) mixture. The organic layer was separated and the aqueous layer was extracted with pentane (4 × 50 mL). The combined organic extract was dried ($MgSO_4$), filtered, and concentrated *in vacuo* to give a liquid that crystallized upon refrigeration, mp 22.5–25°C. The yield of (±)-**5***a* was 97% (8.2 g); ir (KBr pellet): 1723, 1250, 1180, 892, 815, 750, 670, 610, and 560 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.93 (3H, C(8), t, J = 6.7 Hz), 1.36 (4H, C(7), C(6), m), 1.47 (2H, C(5), m), 1.57 (2H, C(4), m), 2.81 (1H, C(3), dt, J = 1.8, 5.5 Hz), 3.03 (2H, C(2), C(1)H(a), m), 3.27 (1H, C(1)H(b), dd, J = 4.8, 8.9 Hz); ms, *m/e* (%, rel. int.): 127 (87%), 83 (100%), 57 (32%), 55 (86%), 41 (19%). *Anal.* calcd. for $C_8H_{15}IO$: C 37.81, H 5.95; found: C 38.07, H 6.00.

Preparation of (2R,3S)-5a

The procedure was identical to that described above for the preparation of (±)-**5***a* except that (2*S*,3*S*)-**8***a* was used. The yield of (2*R*,3*S*)-**5***a* was 90% (6.9 g), mp 23–25°C. The spectroscopic data were in agreement with those given above for (±)-**5***a*.

Preparation of (2S,3R)-5a

The procedure was identical to that described above for the preparation of (±)-**5***a* except that (2*R*,3*R*)-**8***a* was used. The yield of (2*S*,3*R*)-**5***a* was 96% (6.9 g), mp 23.5–26°C. The spectroscopic data were in agreement with those given above for (±)-**5***a*.

Preparation of (S)-1-octen-3-ol ((S)-6a) by reaction of (2R,3S)-5a with zinc powder

To 6.5 g (25.6 mmol) of (2*R*,3*S*)-**5***a* in 125 mL of absolute methanol was added 5.02 g (76.8 mmol, 3 equiv.) of powdered zinc and the solution was refluxed for 3 h. After cooling, 125 mL of pentane was added and the solution was filtered, backwashed with saturated aqueous NaCl solution (2 × 50 mL), dried ($MgSO_4$), filtered, and concentrated *in vacuo* to give 85% (2.8 g) of (*S*)-**6***a* as a liquid. The spectroscopic data were in agreement with those reported for (±)-**6***a* (24–26), bp 62.5–63.5°C (1.25 Torr; 1 Torr = 133.3 Pa). Gas chromatographic analysis of the MTPA-ester of (*S*)-**6***a* showed two diastereoisomers of the ester in the ratio of 96:4. The molecular ions of the diastereoisomers were confirmed by CI/gc/ms.

Preparation of (R)-1-octen-3-ol, (R)-6a

The procedure was identical to that described above for the preparation of (*S*)-**6***a*, except that (2*S*,3*R*)-**5***a* was used (2.6 g, 75%). The spectroscopic data were in agreement with those reported for (±)-**6***a*, bp 65–66°C (1.25 Torr); gc analysis of the MTPA-ester of (*R*)-**6***a* showed two diastereoisomers of the ester in the ratio of 90:10. The molecular ions of the diastereoisomers were confirmed by CI/gc/ms.

Preparation of 1-octen-3-ol ((±)-6a)

The procedure described above was applied using (±)-**5***a* and zinc powder, bp 50°C (0.25 Torr) (lit. (24) bp 62–65°C (1 Torr)) to yield 80% (61 mg) of (±)-**6***a*. The ^1H nmr (25) and ir (26) spectra were in agreement with those previously reported.

Preparation of 1-octen-3-ol ((±)-6a), by reaction of (±)-5a with $Bu_3SnAlEt_2$ (2)

To the LDA (10 mmol) (freshly prepared) in THF, was added 2.64 mL (10 mmol) of nBu_3SnH in 2.5 mL of THF at −70°C. The reaction was maintained at −78°C for 2 h and 10 mL of Et_2AlCl (1 *M*, 10 mmol) was slowly added. The temperature was increased to 0°C and maintained at this temperature for 1 h.[1] At this point, 2.55 g (10 mmol) of (±)-**5***a* in 5 mL of dry THF was added and the reaction was stirred for 1 h. The reaction was quenched with 10 mL of 1 *M* HCl, the organic layer was separated out, and the aqueous layer was extracted with ether (4 × 10 mL). The combined organic extract was dried ($MgSO_4$), filtered, and concentrated *in vacuo* to give a crude concentrate. The concentrate was purified by chromatography on a silica gel column using hexane:ethyl acetate (4:1) as eluent. The yield of (±)-**6***a* was 74% (0.94 g).

Preparation of Z-3-octen-2-ol (9b)

To 2.64 g (10.6 mmol) of $Ni(OAc)_2 \cdot 4H_2O$ in 50 mL of 95% ethanol with H_2 purge was added 10 mL (14.2 mmol) of a solution containing 0.5 g of $NaBH_4$ in 12 mL of absolute ethanol and 0.65 mL of 2 *M* NaOH. After 5 min, 1.6 mL (23.9 mmol) of ethylenediamine was added, followed by 11.5 g (91.1 mmol) of 3-octyn-2-ol (27). The reaction was stirred for 4 h under H_2 purge and monitored by gc analysis of aliquots. Just prior to total conversion, the reaction was quenched with 100 mL of brine and acidified with 1 *M* HCl (≈50 mL). The solution was extracted with ether (4 × 50 mL). The combined organic extract was backwashed with brine, with 2 mL of 1 *M* HCl, dried ($MgSO_4$), filtered, and concentrated *in vacuo* to provide 98% (11.5 g) of **9***b* as a liquid, bp 80–81°C (20 Torr) (lit. (27) bp 82°C (21 Torr)); ir (27) (film): 3360, 1712, 1280, 1110, 1055, 922, and 740 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.91 (3H, C(8), t, J = 6.7 Hz), 1.25 (3H, C(1), d, J = 5.3 Hz), 1.35 (4H, C(7), C(6), m), 1.81 (1H, OH, br), 2.08 (2H, C(5), m), 4.65 (1H, C(2), quint, J = 6.7 Hz), 5.42 (2H, C(4), C(3), m); ms, *m/e* (%, rel. int.): 113 (31%), 110 (20%), 71 (100%), 68 (15%), 58 (32%), 57 (52%), 45 (29%), 43 (77%), 41 (33%).

Preparation of threo-3,4-epoxy-2-octanol (7b)

To 18.2 g (85.8 mmol) of 85% *m*-chloroperoxybenzoic acid (12) in 200 mL of CH_2Cl_2 at 0°C was added 11 g (85.8 mmol) of **9***b* in 10 mL of CH_2Cl_2. The solution was warmed to room temperature and stirred for 2 h. The reaction was quenched with 200 mL of saturated Na_2CO_3 and stirred for 1 h. The organic layer was separated and the aqueous layer extracted with pentane (4 × 50 mL). The combined organic extract was dried ($MgSO_4$), filtered, and concentrated *in vacuo* to give 95% (12.5 g) of **7***b* as a liquid, bp 60°C (0.2 Torr); ir (film): 3440, 1725, 1575, 1285, 1262, 1110, 1072, 900, 887, 828, 812, 758, and 735 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.93 (3H, C(8), t, J = 7.3 Hz), 1.28 (3H, C(1), d, J = 7.0 Hz), 1.40 (4H, C(7), C(6), m), 1.57 (2H, C(5), m), 2.00 (1H, OH, br), 2.89 (1H, C(3), dd, J = 4.3, 8.0 Hz), 3.05 (1H, C(4), m), 3.67 (1H, C(2), d quint, J = 1.5, 7.0 Hz). From decoupling experiments, $J_{2,3}$ = 8.0 Hz; ms, *m/e* (%, rel. int.): 69 (49%), 58 (100%), 57 (58%), 55 (18%), 45 (37%), 43 (49%), 41 (46%).

Preparation of threo-3,4-epoxy-2-octanyl tosylate (8b)

To 11 g (76.3 mmol) of **7***b* in 150 mL of anahydrous ether at −10°C was added 15.8 g (82.7 mmol, 1.1 equiv.) *p*-toluenesulfonyl chloride and 21.4 g (381 mmol, 5 equiv.) of powdered KOH divided in five portions that were added over 20 min. The solution was stirred for 1 h and quenched with ice water. The organic layer was separated, and the

aqueous layer was extracted with ether (3 × 50 mL). The combined organic extract was backwashed with brine, dried ($MgSO_4$), filtered, and concentrated *in vacuo* without heating to give a liquid that crystallized upon refrigeration (mp 21–22°C). The yield of **8***b* was 83% (18.9 g); ir (KBr pellet): 1725, 1600, 1365, 1195, 1180, 910, 820, 790, 670, 580, and 562 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.90 (3H, C(8), t, J = 6.7 Hz), 1.38 (4H, C(7), C(6), m), 1.44 (3H, C(1), d, J = 6.7 Hz, 2H, C(5), m), 2.44 (3H, $ArCH_3$, s), 2.92 (2H, C(4), C(5), m), 4.42 (1H, C(2), quint, J = 6.7 Hz), 7.33 (2H, Ar, d, J = 7.3 Hz), 7.83 (2H, Ar, d, J = 7.3 Hz); ms, *m/e* (%, rel. int.): 241 (4.5%), 212 (4.8%), 155 (83%), 127 (19%), 91 (100%), 69 (43%), 65 (50%), 57 (24%), 55 (19%), 43 (45%), 41 (85%). *Anal.* calcd. for $C_{15}H_{22}O_3S$: C 60.38, H 7.43; found: C 60.34, H 7.65.

Preparation of threo-*4-bromo-2,3-epoxyoctane (**10**)*

To 3.11 g (10.4 mmol) of **8***b* in 50 mL of dry acetone was added 7.22 g (83.3 mmol, 8 equiv.) of LiBr and the solution was stirred overnight in a darkened flask. Then 20 mL of water and 10 mL of pentane were added and the solution was stirred for 10 min. The organic layer was separated and the aqueous layer was extracted with pentane (4 × 10 mL). The combined organic extract was washed twice with water, dried ($MgSO_4$), and concentrated *in vacuo* to give a liquid that was purified by chromatography on a silica gel column using hexane:ethyl acetate (6:1) as eluent. The yield of **10** was 55% (1.19 g); bp 45–46°C (0.01 Torr); ir (film): 1725, 1260, 1185, 1120, 1060, 980, 930, 825, 755, 740, 705, and 645 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.92 (3H, C(8), t, J = 7.3 Hz), 1.30 (3H, C(1), d, J = 5.6 Hz), 1.42 (4H, C(6), C(7), m), 1.83 (1H, C(5)H(a), m), 1.91 (1H, C(5)H(b), m), 3.14 (1H, C(3), dd, J = 4.0, 9.6 Hz), 3.28 (1H, C(2), qd, J = 4.1, 5.6 Hz), 3.77 (1H, C(4), ddd, J = 5.5, 8.0, 9.6 Hz); ms, *m/e* (%, rel. int.): 127 (75%), 109 (13%), 85 (22%), 83 (30%), 71 (13%), 69 (28%), 67 (15%), 57 (38%), 55 (100%), 45 (17%), 43 (30%), 41 (55%). *Anal.* calcd. for $C_{15}H_{22}BrO$: C 46.39, H 7.30; found: C 46.82, H 7.60.

Preparation of E-*3-octen-2-ol (**6**b) by reaction of **10** with zinc powder*

To 0.50 g (2.41 mmol) of **10** in 10 mL of absolute methanol was added 0.47 g (7.23 mmol, 3 equiv.) of powdered zinc and the solution was refluxed for 5 h. The flask was cooled to room temperature, then 5 mL of ether and 4 mL of 2 *M* HCl were added sequentially. The organic layer was separated and the aqueous layer was extracted with ether (3 × 10 mL). The combined organic extract was backwashed with brine, dried ($MgSO_4$), filtered, and concentrated *in vacuo* to give 81% (0.25 g) of **6***b* as a liquid, bp 79–81°C (12 Torr) (lit. (27) bp 82.3–83°C (15 Torr)); ir (27) (film): 3370, 1740, 1675, 1300, 1265, 1155, 1130, 1070, 975, 955, 927, 758, and 745 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.84 (3H, C(8), t, J = 8.1 Hz), 1.20 (3H, C(1), d, J = 7.5 Hz), 1.29 (4H, C(6), C(7), m), 1.96 (2H, C(5), q, J = 7.8 Hz), 4.19 (1H, C(2), quint, J = 7.5 Hz), 5.45 (1H, C(3), tdd, J = 1.5, 7.5, 15.3 Hz), 5.57 (1H, C(4), dtd, J = 0.8, 7.5, 15.3 Hz); ms, *m/e* (%, rel. int.): 128 (0.4%), 113 (1.8%), 110 (0.6%), 85 (13%), 71 (100%), 59 (20%), 57 (38%), 55 (15%), 45 (15%), 43 (64%), 41 (37%).

Preparation of erythro-*2-bromo-3,4-epoxyoctane (**5**b)*

To 2.88 g (20 mmol) of **7***b* and 10.66 g (40 mmol, 2 equiv.) of triphenylphosphine in 100 mL of dry THF were added 2.25 g (10 mmol, 0.5 equiv.) of $ZnBr_2$ and 5.70 mL (40 mmol, 2 equiv.) of diisopropylazodicarboxylate in 50 mL of dry THF. The reaction was stirred for 3 h and then passed through a silica gel column using hexane as eluent to remove the inorganic by-products. The yield of **5***b* was 49% (2.01 g), bp 41–43°C (0.1 Torr); ir (film): 1780, 1270, 1250, 1175, 1005, 945, 920, 820, 810, and 640 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.94 (3H, C(8), t, J = 7.3 Hz), 1.85 (3H, C(1), d, J = 6.8 Hz), 2.47 (6H, C(5), C(6), C(7), m), 3.06 (1H, C(4), td, J = 4.5, 7.5 Hz), 3.13 (1H, C(3), dd, J = 4.0, 9.5 Hz), 3.71 (1H, C(2), qd, J = 6.5, 9.5 Hz); ms, *m/e* (%, rel. int.): 127 (62%), 71 (38%), 69 (100%), 57 (18%), 41 (18%). *Anal.* calcd. for $C_{15}H_{22}BrO$: C 46.39, H 7.30; found: C 46.61, H 7.66.

*Reaction of **5**b with zinc powder*

To 0.50 g (2.41 mmol) of **5***b* in 15 mL of absolute methanol was added 0.47 g (7.23 mmol, 3 equiv.) of powdered zinc and the solution was refluxed for 3 h. The flask was cooled to room temperature and 5 mL of ether and 4 mL of 2 *M* HCl were added. The organic layer was separated and the aqueous layer was extracted with ether (3 × 10 mL). The combined organic extract was backwashed with saturated aqueous $NaHCO_3$ (2 × 10 mL). The ether extract was dried ($MgSO_4$), filtered, and concentrated *in vacuo* to give 68% (0.21 g) of **6***c* as a liquid, bp 120°C (15 Torr) (lit. (28) bp 91°C (11 Torr)); ir (28) (film): 3370, 1680, 1320, 1150, 1080, 1050, 1030, 1010, 972, 905, and 738 cm^{-1}; ^1H nmr (28) ($CDCl_3$) δ: 0.91 (3H, C(8), t, J = 7.4 Hz), 1.34 (4H, C(7), C(6), m), 1.50 (3H, C(5), OH, m), 1.72 (3H, C(1); dd, J = 1.7, 7.4 Hz), 4.02 (1H, C(4), q, J = 7.4 Hz), 5.48 (1H, C(3), qdd, J = 1.7, 7.2, 15.4 Hz), 5.66 (1H, C(2), dqd, J = 1.0, 7.4, 15.2 Hz); ms, *m/e* (%, rel. int.): 128 (0.4%), 113 (2.0%), 99 (1.0%), 95 (1.5%), 86 (18%), 71 (100%), 43 (10%).

Preparation of Z-*2-octen-4-ol (**6**d) from 2-octyn-4-ol*

To 2.49 g (10 mmol) of $Ni(OAc)_2 \cdot 4H_2O$ in 50 mL of 95% ethanol with H_2 bubbling through the solution was added 10 mL of a solution comprised of 0.5 g $NaBH_4$, 12 mL of 100% ethanol, and 0.65 mL 2 *M* NaOH. After 5 min, 1.6 mL (23.9 mmol) of ethylenediamine was added. This was followed by the addition of 1.0 g (7.92 mmol) of 2-octyn-4-ol (28). The reaction was followed by gc analysis of aliquots. After completion, the solution was diluted with 20 mL of saturated aqueous NaCl, acidified with 2 *M* HCl, and the layers were separated. The aqueous layer was extracted with ether (2 × 10 mL) and the combined extract was backwashed with brine, dried ($MgSO_4$), filtered, and concentrated *in vacuo* to yield 80% (0.83 g) of **6***d*, bp 64.5–67°C (18 Torr) (lit. (28) bp 63–65°C (20 Torr)). The ^1H nmr and ir spectra corresponded to those previously reported (28).

Preparation of Z-*3,4-epoxy-2-octanone*

To 6.35 mL (69 mmol) of oxalyl chloride in 50 mL of CH_2Cl_2 at −60°C was added 10.7 mL (138 mmol) of dry DMSO in 10 mL of CH_2Cl_2. After 2 min, 9 g (63 mmol) of **7***b* in 10 mL of CH_2Cl_2 was slowly added. After 15 min, 50 mL (357 mmol) of Et_3N was added and the reaction stirred for 5 min. It was warmed to room temperature and diluted with 100 mL of H_2O. The layers were separated, and the aqueous layer was extracted with hexane (2 × 30 mL). The combined extract was washed with saturated aqueous NaCl, 1 *M* HCl until acidic, H_2O, 5% aqueous Na_3CO_3 until basic, and finally H_2O. The organic layer was dried ($MgSO_4$), filtered, and concentrated *in vacuo* to give a liquid that distilled at 35°C (0.10 Torr) (lit. (29) bp 55–56°C (2 Torr)) to yield 71% (6.4 g) of Z-3,4-epoxy-2-octanone. The mass spectrum corresponded to that previously reported (30).

Preparation of erythro-*3,4-epoxy-2-octanol (**7**c)*

To 6 g (42.2 mmol) of Z-3,4-epoxy-2-octanone in 40 mL ether at 0°C under argon was added 88.6 mL (≈21.1 mmol) of $Zn(BH_4)_2$ (31). After 1 h the reaction was quenched with 20 mL of 1 *M* HCl and the organic layer was separated, dried ($MgSO_4$), filtered, and concentrated *in vacuo* to give 88% yield (5.35 g) of **7***c*, bp 66°C (0.45 Torr); ir (film): 3430, 1270, 1105, 1065, 955, and 810 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.96 (3H, C(8), t, J = 7.3 Hz), 1.37 (3H, C(1), d, J = 7.0 Hz), 1.49 (7H, C(5), C(6), C(7), OH, m), 2.82 (1H, C(3), dd, J = 4.1, 7.7 Hz), 3.01 (1H, C(4), ddd, J = 4.0, 5.2, 7.0 Hz), 3.73 (1H, C(2), br, d quint, J = 1.9, 6.5 Hz). From decoupling experiments, $J_{2,3}$ = 7.7 Hz; ms, *m/e* (%, rel. int.): 69 (69%), 58 (100%), 57 (50%), 55 (18%), 45 (25%), 43 (32%), 41 (34%).

Preparation of threo-*2-bromo-3,4-epoxyoctane (**5**c)*

To 0.4 g (2.77 mmol) of **7***c* and 0.92 g (2.77 mmol) of CBr_4 in 12 mL of THF at −78°C was added dropwise 4.5 mL (24.9 mmol) of HMPT. The reaction was allowed to warm up to room temperature over a period of 12 h. Ice water (10 mL) was added to quench the reaction. The layers were separated and the aqueous layer was extracted with pentane (5 × 20 mL). The combined organic layer was backwashed with saturated aqueous NaCl, dried (Na_2SO_4), filtered, and concentrated *in vacuo*. The liquid was purified by silica gel chromatography using hexane:ethyl acetate (9:1) as eluent to yield 74% (0.42 g) of **5***c*, bp 42–44°C (0.01 Torr); ir (film): 1752, 1265, 1210, 1060, 1045, 1030, 990, 980, 918, 830, 815, 740, and 655 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.91 (3H, C(8), t, J = 7.0 Hz), 1.46 (6H, C(5), C(6), C(7), m), 1.74 (3H, C(1), d, J = 7.2 Hz), 3.14 (2H, C(3), C(4), m), 3.86 (1H,

C(2), qd, J = 7.0, 9.3 Hz). The ^{1}H nmr did not show any signals corresponding to **5***b*; ms, *m/e* (%, rel. int.): 127 (67%), 109 (10%), 71 (38%), 69 (100%), 57 (19%), 43 (12%), 41 (27%); CI 209 (55%), 207 (53%), 191 (9%), 189 (10%), 127 (95%), 109 (100%), 85 (59%).

Reaction of **5**c *with zinc powder*

To 47 mg (0.72 mmol) of zinc powder in 5 mL of absolute methanol was added 50 mg (0.24 mmol) of **5***c*. The solution was refluxed for 5 h and then cooled to room temperature. The solution was diluted with 10 mL of ether and extracted with saturated aqueous NaCl (3 × 10 mL). The organic layer was dried ($MgSO_4$), filtered, and concentrated *in vacuo* to yield 75% (23 mg) of **6***c*. Gas chromatographic and ^{1}H nmr analysis indicated a 11:89 ratio of **6***d*:**6***c*.

Reaction of **5**b *and* **5**c *with stannates*

$Bu_3SnAlEt_2$ (Table 1, Entries 1 and 2)

To LDA (0.145 mmol) in 10 mL of THF was added 145 μL (0.145 mmol) of Bu_3SnH at −20°C. After 30 min, 145 μL of 1.0 *M* (0.145 mmol) Et_2AlCl was added. After 15 min, 0.5 or 1.0 equiv. of **5***b* or **5***c* was added and the reaction stirred for 1 h at the temperature indicated. The reaction was quenched with 20 mL of water. The organic layer was separated, and the aqueous layer was extracted with ether (5 × 20 mL). The extracts were combined, dried ($MgSO_4$), filtered, and concentrated *in vacuo* to give a liquid that was chromatographed on silica gel using hexane:ethyl acetate as eluent. The fractions shown to contain **6***c* and **6***d* by gc analysis were concentrated *in vacuo* and distilled at 120°C (15 Torr) to give **6***c* and **6***d* in the yields and isomeric ratios (gc) reported in Table 1.

$Bu_3SnAlEt_2/BF_3\cdot Et_2O$ (Table 1, Entry 3)

The reaction of **5***c* with $Bu_3SnAlEt_2$ was conducted as described above except that 2 equiv. of $BF_3\cdot Et_2O$ with respect to **5***c* were added and the reaction was stirred at room temperature for 12 h prior to work-up. The gc analysis of the **6***c*:**6***d* ratio is given in Table 1.

n-*Bu_3SnLi (Table 1, Entries 4–8)*

To 70 μL (0.50 mmol) of diisopropylamine in 2.0 mL of THF at −20°C was added 0.2 mL of 2.4 *M* (0.50 mmol) BuLi in *n*-hexane and the reaction was stirred for 15 min. Then 135 μL (0.50 mmol) of Bu_3SnH was added slowly. The reaction was stirred for 30 min at −20°C, then 0.33, 0.5, or 1 equiv. of **5***b* or **5***c* in 2.0 mL of THF was added and the reaction stirred for 1 h at the temperature indicated. The reaction mixture was quenched with 20 mL of ice water and the reaction mixture worked up as described above for entries 1 and 2. The isolated yields of **6***c* and **6***d* as well as the isomeric ratios (gc) obtained were recorded in Table 1.

Lithium B-*tributyltin*-B-*methoxy*-9B-*bicyclo[3.3.1]nonanylborate (12) (Table 1, Entries 9–11)*

To a solution of *n*Bu_3SnLi (0.50 mmol) in 2.0 mL of THF prepared as above, was added *B*-methoxy-9-borabicyclo[3.3.1]nonane (76 μL, 0.50 mmol) at −20°C. The reaction was stirred at this temperature for 45 min, then warmed to 0°C over 15 min. At this point 0.5 or 0.8 equiv. of **5***b* or **5***c* was added and the reaction was conducted for the time and at the temperature specified in Table 1. Each reaction was quenched by addition of 20 mL of ice water and worked up as described above for Entries 1 and 2. The isolated yields of **6***c* and **6***d* as well as the isomer ratios (gc) obtained are recorded in Table 1.

Isomerization of **6**d *with $Bu_3SnAlEt_2$*

To LDA (1 mmol) in 5 mL of THF was added 265 μL (1 mmol) of Bu_3SnH at −78°C. After 1 h, 1 mL of 1 *M* (1 mmol) Et_2AlCl was slowly added and the temperature was allowed to rise to 0°C for 30 min. Then 128 mg (1 mmol) of **6***d* was added and stirred for 1 h. The reaction was quenched with 1 mL of 1 *M* HCl and the layers separated. The aqueous layer was extracted with ether (3 × 5 mL) and the combined layers were dried ($MgSO_4$), filtered, and concentrated *in vacuo*. The gc analysis of the concentrate revealed a **6***c*:**6***d* ratio of 1:1.

Intramolecular rearrangements: Epimerization of bicyclic vinyl tertiary alcohols via a [2,3] sulfoxide sigmatropic rearrangement

WILLIAM L. BROWN AND ALEX G. FALLIS

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received November 21, 1986

This paper is dedicated to Professor John T. Edward

WILLIAM L. BROWN and ALEX G. FALLIS. Can. J. Chem. **65**, 1828 (1987).

A general method for inverting the stereochemistry of bicyclic vinyl *endo* alcohols such as **6** and **12** to give the corresponding *exo* isomers **10** and **18** is described. The procedures employ a [2,3] sulfoxide rearrangement as a key step. In the case of the norbornene alcohol **12** the intermediate sulfenate ester **13** gives the oxetane **14** rather than the expected sulfoxide **17**. It was therefore prepared by thionyl chloride induced rearrangement of **12** to the allylic chloride **15** followed by displacement (PhSNa) and oxidation (*m*-chloroperbenzoic acid). The *exo* alcohol thus obtained underwent smooth anionic oxy-Cope rearrangement (KH, THF) to the *cis*-hydrindenone **19**.

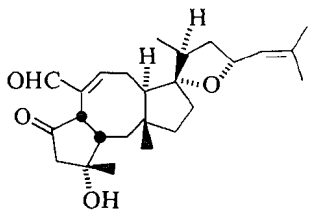
WILLIAM L. BROWN et ALEX G. FALLIS. Can. J. Chem. **65**, 1828 (1987).

On décrit une méthode générale pour procéder à l'inversion de la stéréochimie des alcools vinyliques bicycliques *endo*, comme les produits **6** et **12**, pour obtenir les isomères *exo* correspondants (**10** et **13**). L'étape clé de ces méthodes implique une transposition [2,3] du sulfoxyde. Dans le cas particulier de l'alcool norbornénique **12**, l'ester sulfénique intermédiaire **13** conduit à l'oxétane **14** plutôt qu'au sulfoxyde **17** attendu. On l'a donc préparé par une transposition du composé **12**, induite par le chlorure de thionyle, en chlorure allylique **16** qui est suivie d'une substitution (PhSNa) et d'une oxydation (acide *m*-chloroperbenzoïque). L'alcool *exo* qui est ainsi obtenu donne lieu à une transposition oxy-Cope anionique (KH, THF) qui conduit à l'hydrindénone-*cis* (**19**).

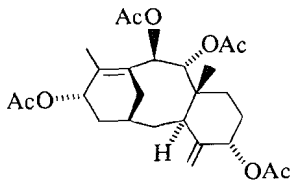
[Traduit par la revue]

Introduction

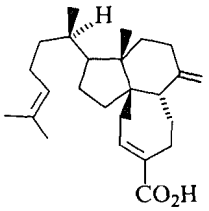
The total synthesis of complex, multicyclic, natural products remains an area of fundamental importance and intense international activity. A particularly powerful transformation for the intramolecular construction of cyclohexanones in these systems is the anionic oxy-Cope rearrangement. This [3,3] sigmatropic rearrangement proceeds under mild conditions (1) and occupies a central role in the approach to ophiobolin A being developed by Paquette *et al.* (2), the route to taxusin under examination by



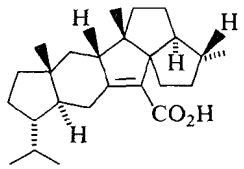
Ophiobolin A



Taxusin

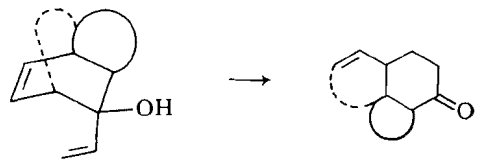


Gascardic acid

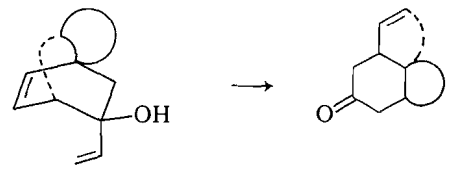


Retigeranic acid

Martin *et al.* (3), and our own studies directed toward the total syntheses of gascardic acid (4) and retigeranic acid (5). The general transformations **1** to **2** and **3** to **4** are representative of the type of multicyclic spiro-fused skeletons whose preparation may be envisaged using this chemistry. The versatility of this approach is further exemplified by the ease with which different functionality may be introduced on the periphery of the ring system.



1 **2**



3 **4**

Successful [3,3] sigmatropic rearrangement clearly requires that the reactive components in the 1,5 diene unit bear a *cis* relationship. In cyclic systems this has frequently required the insertion of additional groups to control the stereochemistry. It is well established that nucleophilic addition to 2-norbornanone type ketones occurs preferentially from the *exo* face although products from *endo* attack predominate when an appropriate *syn* C-7 substituent is present. This procedure has been used by Jung *et al.* in their approach to steroids (6, 7) and to reserpine (8) via an anionic oxy-Cope pathway. A more general, alternative solution would involve the epimerization of the undesired isomer to afford the required *cis* diene stereochemistry.

It is known that configurational inversion of tertiary alcohols by the Mitsunobu method (diethyl azodicarboxylate–triphenylphosphine) is not feasible (9). However, previous inversions in prostaglandin intermediates (10) as well as earlier work by Evans *et al.* (11–13) with *tert*-butyl substituted cyclohexanes indicated that in these sterically biased systems the allylic sulfoxide rearrangement proceeded across the equatorial face of the cyclohexylidene ring to give predominantly the equatorial alcohol. These studies revealed that the transition state for these

(a) CH_2 = CHMgBr, THF, 0°C, 1 h, 99%
(b) *n*-BuLi, THF, 0°C then −78°C, PhSCl, 1.5 h, 21°C, 12 h, 46%
(c) $(MeO)_3P$, MeOH, 65°C, 24 h, 56%

migrations was strongly influenced by steric effects as revealed by product geometry. Thus in ring systems in which there is a choice between the *exo* and *endo* surface it seemed likely that the normal preference for *exo* attack by vinyl nucleophiles could be reversed via a sulfenate–sulfoxide–sulfenate interconversion, since allylic sulfoxides such as **8** and **17** should rearrange preferentially across the less congested *exo* surface. The steroid nucleus possesses a related stereochemical bias and while our work was in progress Morera and Ortar reported an epimerization procedure based on this rearrangement pathway for the preparation of 17β-vinyl-17α-hydroxy steroids from the more accessible 17-epimers (14). We wish to report the details of a general procedure to epimerize allylic tertiary alcohols via a [2,3] sulfoxide sigmatropic rearrangement as illustrated for the two bicyclic alcohols **6** and **12**, described previously in preliminary form (15).

Results and discussion

The feasibility of this approach was established as follows. Addition of vinylmagnesium bromide to 2-bicyclo[2.2.1]heptanone (**5**) in tetrahydrofuran at 0°C gave, as expected, the *endo* alcohol **6** exclusively in quantitative yield. Treatment of **6** with *n*-butyllithium followed by freshly distilled benzenesulfenyl chloride at −78°C afforded, via the sulfenate ester **7** which was not isolated, the sulfoxide **8** in 45% yield after flash chromatography. Temperatures above −40°C resulted in rapid addition of benzenesulfenyl chloride to the double bond. Thermal rearrangement of **8** occurred smoothly in refluxing methanol containing trimethyl phosphite as a thiophile, to the desired *exo* alcohol **10** (ratio of *exo* alcohol **10** to *endo* alcohol **6** was 8:1). This result confirmed that the rearrangement had occurred in the desired manner with a high level of selectivity and should also suffice for norbornenones.

Similar Grignard addition of vinylmagnesium bromide to norbornenone **11** at −78°C gave only the *endo* alcohol **12** in 62% yield. In contrast to the results above, none of the sulfoxide **17** was formed when either the lithium or potassium alkoxide derived from **12** was exposed to PhSCl at −78°C. Instead, the tricyclic oxetane **14** was formed in 60% yield. The structure of this material was established by analogy with related examples of this ring system reported previously (16), and ruled out the alternative twistane isomer (17). The ^1H nmr coupling constant (J = 5 Hz) of the two methine hydrogens attached to the carbons bearing heteroatoms established that the thiophenyl and oxygen substituents bore a *cis* relationship and suggested that **14** arose via *syn* addition of the polarized sulfenate ester **13** (see following paper, ref. 19). Other sulfur transfer reagents (dimethyl disulfide, *N*-thiophenyl phthalimide, and succinimide) were also not effective for preparing the sulfoxide.

To circumvent these difficulties the following general solution was developed. Allylic (SNi′ type) rearrangement of the vinyl alcohol **12** with thionyl chloride in hexane afforded the unstable primary chloride **15** in 40% yield after chromatography. The chlorine was displaced with sodium thiophenolate to give **16** and this thioether oxidized at −78°C with *m*-chloroperbenzoic acid to the desired sulfoxide **17** (86%). Under these conditions no epoxides were detected although the sulfoxide was accompanied by some (7%) of the corresponding sulfone. This allylic sulfoxide was heated in refluxing methanol containing sodium thiophenolate to give the vinyl alcohols **18** and **12** in 46 and 5% yield respectively. Trimethyl phosphite was less effective as a thiophile and resulted in lower yields and significant decomposition. The *cis* hydrindenone **19** was obtained in 70% yield when the potassium anion of alcohol **18** was heated in refluxing THF for 20 min. As expected, treatment of the *endo* alcohol **12** under the same conditions caused no reaction.

These procedures are of general synthetic utility for adjusting the stereochemistry of vinyl alcohols and will facilitate the extended use of the oxy-Cope rearrangement to a variety of related ring systems. Direct rearrangement via a sulfenate ester intermediate may still be feasible with less reactive double bonds than norbornene. These concepts are under further investigation and their application to natural product synthesis is being developed.

Experimental

Melting points were determined in capillary tubes with a Thomas–Hoover Unit-Melt apparatus or on a Fisher–Johns melting point

apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 237B or 451 grating spectrophotometer and were calibrated with the 2850 and 1601 cm^{-1} bands of polystyrene film. Proton magnetic resonance spectra were measured at 80 MHz with a Bruker WP80 spectrometer employing a chloroform lock or at 60 MHz with a Varian EM 360 spectrometer. Signal positions are reported in ppm downfield from tetramethylsilane (δ scale) as an internal standard; multiplicity, the number of protons, coupling constants, and proton assignments are indicated in parentheses. Mass spectra were determined on a V.G. Micromass 7070 HS instrument using an ionization energy of 70 eV.

Thin-layer chromatographic analyses were carried out on commercial precoated silica gel plates with fluorescent indicator (Eastman Kodak silica gel 13181). Preparative thin-layer chromatography was conducted on 20 × 20 cm glass plates coated with silica gel $PF^{254+366}$ type 60 (E. Merck). Flash chromatography using BDH silica gel Kieselgel 60, 230–400 mesh, was employed for all column chromatography.

Petroleum ether refers to a fraction with boiling range 30–60°C. Anhydrous diethyl ether (ether), tetrahydrofuran (THF), dimethoxyethane (DME), and dioxane were obtained by distillation from lithium aluminium hydride or potassium/benzophenone. Absolute ethanol and methanol were dried by distillation from magnesium. Dry hexamethylphosphoramide (HMPA), dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and diisopropylamine were prepared by distillation from calcium hydride. Solutions in organic solvents were dried over anhydrous magnesium sulfate and stripped of solvent with a Buchi rotary evaporator connected to a water aspirator. Unless otherwise indicated, all reactions were conducted under an atmosphere of dry nitrogen.

endo-*2-Vinyl-2-bicyclo[2.2.1]heptanol (6)*

Norcamphor (5.00 g, 45.40 mmol, Aldrich) in THF (100 mL) was added dropwise to a solution of vinylmagnesium bromide (45.40 mL, 45.40 mmol, 1.0 *M*, Aldrich) at 0°C. After stirring for 1 h the reaction mixture was quenched with 3 *M* HCl, extracted with ether, the combined ether extracts washed with water, brine, dried, concentrated, and the product purified by chromatography (50% ether/petroleum ether), to yield the *endo* alcohol **6**, 6.22 g (99%); ir (film): 3348 (O-H), 1645 (RCH=CH_2) cm^{-1}; ^1H nmr (CCl_4) δ: 0.90–2.65 (m, 10H), 3.40 (br s, 1H, OH), 4.80–4.98 (dd, 1H, *J* = 2 Hz, C=CH), 5.00–5.30 (dd, 1H, *J* = 2 Hz, 18.4, C=CH), 5.88–6.30 (dd, 1H, *J* = 11 Hz, 18.4 Hz, RCH=C).

Reaction of the lithium anion of alcohol 6 with benzenesulfenyl chloride

(a) From −40 to 21°C, endo-*2-(1-thiophenyl-2-chloroethanyl)-2-bicyclo[2.2.1]heptanol*

n-Butyllithium (0.49 mL, 4.96 mmol, 10.2 *M*, Aldrich) was added dropwise to a solution of alcohol **6** (0.57 g, 4.13 mmol) in THF (40 mL) at 0°C. After stirring for 10 min the reaction temperature was lowered to −40°C and an ether solution (20 mL) of benzenesulfenyl chloride (prepared from thiophenol (0.55 g, 5.00 mmol, Aldrich) and sulfuryl chloride (0.67 g, 5.00 mmol, Aldrich)) added dropwise. After the addition was complete the reaction mixture was warmed to 21°C, quenched with water, extracted with ether, the combined ether extracts washed with water, brine, dried, concentrated, and the product purified by chromatography (50% ether/petroleum ether) to give *endo*-2-(1-thiophenyl-2-chloroethanyl)-2-bicyclo[2.2.1]heptanol, 0.95 g (82%); ir (film): 3490 (O-H), 3050 (Ar-H), 2930 (C-H) cm^{-1}; ^1H nmr (CCl_4) δ: 1.00–2.50 (br m, 10H), 3.70 (m, 3H), 4.55 (t, 1H, CH(SPh)CH_2Cl), 7.28 (m, 5H, Ar-H). *Exact Mass* calcd. for $C_{15}H_{19}SOCl$: 282.0845; found: 282.0854.

(b) From −78 to 21°C, 2-(1-phenylsulfinylethenyl)bicyclo[2.2.1]-heptane (8)

n-Butyllithium (2.78 mL, 6.96 mmol, 2.5 *M*, Aldrich) was added dropwise to a solution of alcohol **6** (0.80 g, 5.80 mmol) in THF (25 mL) at 0°C. After stirring for 10 min the reaction was cooled to −78°C and a freshly distilled solution of benzenesulfenyl chloride (0.83 g, 5.80 mmol) in ether (25 mL) was added dropwise over 45 min. The reaction was stirred at −78°C for an additional 1.5 h and then allowed to warm to 21°C and stirred for a further 12 h. The reaction mixture was quenched with water and worked up as above. The product was purified by chromatography (50% ether/petroleum ether) to yield sulfoxide **8**, 0.66 g (46%); ir (film): 3045 (=C-H), 2930 (C-H), 1675 (C=C), 1040 (S=O) cm^{-1}; ^1H nmr (CCl_4) δ: 1.30 (br m, 7H), 2.10 (m, 2H), 2.58 (br s, 1H), 3.32 (d, 2H, *J* = 8 Hz, =CH-CH_2), 5.18 (t, 1H, *J* = 8 Hz, =CH-CH_2), 7.42 (m, 5H, Ar-H). *Exact Mass* calcd. for $C_{15}H_{16}SO$: 244.0922; found: 244.0934.

exo-2-*Vinyl-2-bicyclo[2.2.1]heptanol* (**10**)

The vinyl sulfoxide **8** (1.00 g, 4.07 mmol) and trimethylphosphite (4.78 mL, 40.65 mmol, Aldrich) in dry methanol (60 mL) were refluxed for 24 h. The solution was concentrated, the residue dissolved in ether, washed with water, brine, dried, and concentrated to yield a yellow oil. The oil was purified by chromatography (10% ethanol/hexanes) to give *exo* alcohol **10**, 0.32 g (56%) and some *endo* isomer **6**, 0.04 g (7%); ^{1}H nmr (CCl_4) δ: 0.90 (m, 10H), 3.40 (br s, 1H, O-H), 4.75–4.96 (dd, 1H, J = 1.5 Hz, J = 10 Hz, C=CH), 4.95–5.25 (dd, 1H, J = 1.5 Hz, J = 18 Hz, C=CH), 5.80–6.25 (dd, 1H, J = 10 Hz, J = 18 Hz, RCH=C).

Bicyclo[2.2.1]hept-5-en-one (**11**)

Bicyclo[2.2.1]hept-5-en-2-ol (mixture of *exo* and *endo* isomers) (10.00 g, 90.90 mmol, Aldrich) in dichloromethane (150 mL) was added in one aliquot to a slurry of pyridinium chlorochromate (29.30 g, 136.40 mmol) in dichloromethane (150 mL). It darkened immediately and, after stirring for 2 h, anhydrous ether (300 mL) was added and the supernatant solution decanted from the black gum. This residue was washed with ether, and the combined organic phases were filtered through Florisil and concentrated to give a yellow oil. The oil was purified by distillation, bp 60–62°C/12 Torr (lit. (18) bp 80–90°C/80 Torr) (1 Torr = 133.3 Pa) to yield **11**, 7.10 g (72%); ir (film): 3055 (=C-H), 2960 (C-H), 1740 (C=O), 1640 (C=C) cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.75 (m, 2H, CH_2 bridge), 2.05 (m, 2H, CH_2C=O), 2.90 (m, 1H, CH bridgehead), 3.18 (m, 1H, CH-C=O), 6.05 (dd, 1H, J = 6 Hz, J = 3.6 Hz, CH=C), 6.52 (dd, 1H, J = 6 Hz, J = 3 Hz, CH=C). *Exact Mass* calcd. for C_7H_8O: 108.0575; found: 108.0559.

endo-2-*Vinylbicyclo[2.2.1]hept-5-en-2-ol* (**12**)

Ketone **11** (2.00 g, 18.52 mmol) in THF (50 mL) was added dropwise to a stirred solution of vinylmagnesium bromide (18.52 mL, 18.52 mmol, 1.0 *M*, Aldrich) in THF (80 mL) at −78°C. After stirring at −78°C for 1 h and warming to 21°C the reaction mixture was quenched with 3 *M* HCl and extracted with ether. The combined ether extracts were washed with water, brine, dried, concentrated, and the product purified by chromatography (50% ether/petroleum ether) to yield the *endo* alcohol **12**, 1.57 g (62%); ir (film): 3355 (O-H), 3050 (=C-H), 2910 (C-H), 1630 (C=C) cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.10 (dt, 1H), 1.48 (d, 2H), 1.75–2.10 (dd, 1H), 2.49 (br s, 1H), 2.70 (m, 1H), 2.85 (br s, 1H, O-H), 4.88–5.05 (dd, 1H, J = 2 Hz, J = 11 Hz, RC=CH), 5.10–5.45 (dd, 1H, J = 2 Hz, J = 18 Hz, RC=CH), 5.87–6.50 (m, 3H, CH=CH, RCH=C).

2-Phenylthio-5-vinyl-4-oxatricyclo[3.2.1.0^{3,6}]octane (**14**)

n-Butyllithium (3.52 mL, 8.82 mmol, 2.5 *M*, Aldrich) was added slowly to a solution of alcohol **12** (1.00 g, 7.35 mmol) in THF (50 mL) at 0°C. After stirring for 10 min the reaction temperature was lowered to −78°C and a solution of benzenesulfenyl chloride (1.05 g, 7.35 mmol) in ether (40 mL) was added dropwise over 1 h. The reaction was warmed to 21°C, stirred for an additional 16 h, and the reaction mixture quenched with water. After ether extraction, the combined ether extracts were washed with water, brine, dried, concentrated, and product purified by chromatography (50% ether/petroleum ether) to yield the oxetane **14**, 1.08 g (60%); ir (film): 3050 (=C-H, Ar-H), 2940 (C-H), 1645 (C=C), 1090 (C-O-C), 960 (oxetane); ^{1}H nmr (CCl_4) δ: 1.20–2.10 (m, 4H), 2.85 (m, 1H, bridgehead H), 3.32 (dd, 1H, J = 5 Hz, J = 2 Hz, 1H, CHSPh), 3.60 (d, 1H, J = 2 Hz, bridgehead H), 4.25 (dd, 1H, J = 2, 5 Hz, HC-O), 5.00 (dd, 1H, J = 10 Hz, J = 2.5 Hz, RHC=C*H*H, *cis*), 5.15 (dd, 1H, J = 16 Hz, J = 16 Hz, J = 2.5 Hz, RHC=CH*H*, *trans*, 1H), 5.80 (dd, 1H, J = 10 Hz, J = 16 Hz, RC*H*R=CH_2), 7.20 (m, 5H, Ar-H). *Exact Mass* calcd. for $C_{15}H_{16}SO$: 244.0922; found: 244.0934.

2-(1-Chloroethenyl)bicyclo[2.2.1]hept-5-ene (**15**)

Alcohol **12** (0.44 g, 3.24 mmol) and thionyl chloride (0.46 g, 3.88 mmol, Aldrich) in hexane (25 mL) were stirred at 0°C. After 16 h the reaction mixture was quenched with cold water, extracted with hexane, and the combined organic extracts washed with water, brine, dried, and concentrated. The product was purified by chromatography (30% ether/petroleum ether) (compound decomposes slightly on the column), to give chloride **15**, 0.20 g (40%); ir (film): 3020 (=C-H) cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.45 (br m, 2H), 2.00 (br m, 2H), 3.05 (m, 1H), 3.52 (br s, 1H), 3.92 and 4.08 (both d, together 2H, both *cis* and *trans* isomers, =CHC*H*$_2$Cl), 5.50 (m, 1H, RR′C=CHR), 6.00 (m, 2H, RCH=CHR).

2-(1-Phenylthioethenyl)bicyclo[2.2.1]hept-5-ene (**16**)

Thiophenyl (4.10 g, 37.22 mmol, Aldrich) in DME (25 mL) was added dropwise to a stirred suspension of sodium hydride (1.63 g, 40.93 mmol, 60% suspension in oil, Aldrich, previously washed with hexane) in DME (50 mL) at 0°C. The chloride **16** (5.21 g, 33.83 mmol) in DME (50 mL) was added dropwise to the sodium thiophenolate and after the addition was complete the temperature of the reaction was increased to 21°C and stirring was continued for 18 h. The reaction mixture was quenched by the addition of water, extracted with ether, the combined ether extracts washed with water, brine, dried, concentrated, and the product purified by distillation, bp 105–110°C/0.05 Torr, to yield thioether **16**, 3.13 g (41%); ir (film): 3048 (=C-H), 2910 (C-H), 1675 (R$_2$C=CRH) cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.50 (br s, 4H), 2.75 (br s, 1H), 3.00 (br s, 1H), 3.30 and 3.48 (d, 2H, both *cis* and *trans* isomers, CH_2SPh), 5.20 (br m, 1H, RR′C=CHR), 5.90 (m, 2H, RCH=CHR), 7.10 (m, 5H, Ar-H). *Exact Mass* calcd. for $C_{15}H_{16}S$: 228.0973; found: 228.0985.

2-(1-Phenylsulfinylethenyl)bicyclo[2.2.1]hept-5-ene (**17**)

The bicyclic sulfide **16** (3.13 g, 13.87 mmol) and *m*-chloroperbenzoic acid (3.00 g, 13.87 mmol, 80%, Aldrich) in dichloromethane (50 mL) were stirred at −78°C for 5 h. The reaction mixture was filtered to remove *m*-chlorobenzoic acid. The filtrate was washed with water, 10% sodium sulfite, saturated sodium bicarbonate, brine, dried, concentrated, and the products purified by chromatography (60% ether/pentane) to yield sulfoxide **17**, 2.88 g (86%); ir (film): 3045 (=C-H, Ar-H), 2950 (C-H), 1675 (R$_2$C=CHR), 1040 (S=O) cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.30 (br m, 4H), 2.75 (br m, 1H), 3.30 (br m, 3H, CH_2SOPh, CH bridgehead), 5.10 (br m, 1H, C=C*H*), 5.90 (m, 2H, CH=CH), 7.45 (br s, 5H, Ar-H).

2(1-Phenylsulfonylethenyl)bicyclo[2.2.1]hept-5-ene, 0.25 g (7%); ir (film): 3040 (=C-H, Ar-H), 2950 (C-H), 1676 (C=C), 1320, 1140 (SO_2) cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.40 (br m, 4H), 2.85 (m, 1H), 3.10 (br s, 1H), 3.65 (two doublets, both isomers, 2H, CH_2SO_2Ph), 5.20 (br m, 1H, C=CH), 5.85 (br s, 2H, CH=CH), 7.55 (br m, 5H, Ar-H). *Exact Mass* calcd. for $C_{15}H_{16}SO_2$: 260.0871; found: 260.0830.

exo-2-*Vinylbicyclo[2.2.1]hept-5-en-2-ol* (**18**)

Thiophenol (6.06 g, 54.94 mmol, Aldrich) in methanol (30 mL) was added slowly to a stirred suspension of sodium hydride (2.20 g, 54.94 mmol, 60% suspension in oil, Aldrich, previously washed with hexane) in DME (30 mL) maintained at 0°C. This was followed by the addition of sulfoxide **17** (1.34 g, 5.49 mmol) in methanol (30 mL). The reaction mixture was refluxed for 24 h, quenched with water, and extracted with ether. The combined ether extracts were washed with water, brine, dried, concentrated, and the product purified by chromatography (30% ether/petroleum ether) to give the *exo* alcohol **18**, 0.34 g (46%), and the *endo* isomer **12**, 0.04 g (5%); ir (film): 3360 (O-H), 1630 (C=C) cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.80–2.20 (m, 2H), 2.60 (m, 1H), 2.85 (br s, 1H, O-H), 4.65–4.70 (dd, 1H, J = 2 Hz, J = 11 Hz, RC=CH), 4.95–5.35 (dd, 1H, J = 2 Hz, J = 18 Hz, RC=CH), 5.50–6.20 (m, 3H, CH=CH, RHC=C).

cis-*Bicyclo[4.3.0]non-7-en-3-one* (**19**)

Alcohol **18** (0.10 g, 0.74 mmol) in THF (5 mL) was added to a mixture of potassium hydride (0.09 g, 0.81 mmol, 35% suspension in oil, Aldrich, previously washed with hexane) in THF (10 mL) at 0°C. The reaction mixture was refluxed for 20 min, quenched with water, and extracted with ether. The combined ether extracts were washed with water, brine, dried, concentrated, and the product purified by chromatography (20% ether/petroleum ether) to yield *cis*-bicyclo[4.3.0]non-7-en-3-one (**19**), 0.07 g (70%); ir (film): 3025 (=C-H), 2875 (C-H), 1715 (C=O) cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.50–2.30 (m, 6H), 2.40–3.20 (m, 4H, CH_2COCH_2), 5.30–5.80 (m, 2H, CH=CH). *Exact Mass* calcd. for $C_9H_{12}O$: 136.0888; found: 136.0889.

Similar treatment of alcohol **12** afforded only recovered starting material.

Cyclic ether synthesis: sulfenyletherification with benzenesulfenyl chloride/*N,N*-diisopropylethylamine and sulfenate ester cycloadditions

SUDERSAN M. TULADHAR AND ALEX G. FALLIS

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received November 23, 1987

This paper is dedicated to Professor John T. Edward

SUDERSAN M. TULADHAR and ALEX G. FALLIS. Can. J. Chem. **65**, 1833 (1987).

A general method for the formation of the cyclic ethers **9**, **10**, **13**, **14**, **16**, and **28** and the lactone **30** is described. The procedure employs benzenesulfenyl chloride prepared *in situ* in acetonitrile and *N,N*-diisopropylethylamine to generate a thiiranium (episulfonium) ion intermediate from which the cyclic products arise by internal nucleophilic displacement. In the special case of the norbornene alcohols **1** and **2** the oxetanes **5** and **6** are formed by intramolecular sulfenate ester cycloaddition.

SUDERSAN M. TULADHAR et ALEX G. FALLIS. Can. J. Chem. **65**, 1833 (1987).

On décrit une méthode générale de formation des éthers cycliques **9**, **10**, **13**, **14**, **16** et **28** ainsi que de la lactone **30**. La méthode est basée sur l'utilisation du chlorure de benzénesulfényle préparé *in situ* dans l'acétonitrile et de la *N,N*-diisopropyléthylamine pour préparer l'ion thiiranium (épisulfonium) intermédiaire à partir duquel les produits cycliques se forment par une réaction de substitution nucléophile interne. Dans le cas particulier des alcools norborniéniques **1** et **2**, les oxétanes **5** et **6** se forment par une cycloaddition intramoléculaire de l'ester sulfénique.

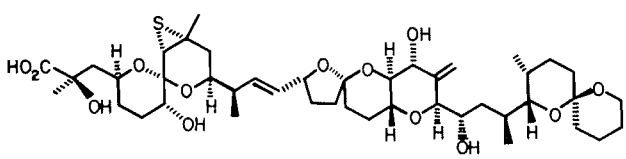
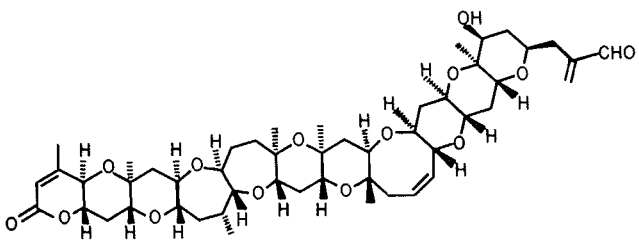
Introduction

Marine species are a rich source of secondary metabolites containing cyclic ethers. Compounds such as acanthifolin (1) and brevetoxin (2, 3) are particularly challenging synthetic targets which require procedures for the facile construction of tetrahydrofuran and pyran rings with suitable functionality for further elaboration. Consequently there is considerable interest in devising viable synthetic methods for the preparation of cyclic ethers (3–6).

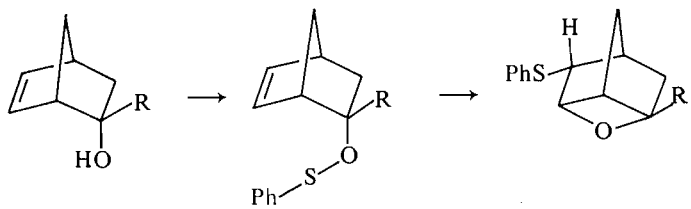


Acanthifolin



Brevetoxin

In the preceding paper we reported that the lithium alkoxide of the norbornene-alcohol **1** afforded the functionalized oxetane **5** via the likely intermediacy of the sulfenate ester **3** upon treatment with benzenesulfenyl chloride at −78°C (7). This observation, although unexpected, was of considerable synthetic interest since straightforward differential functionalization of norbornenes is difficult. In addition, it appeared that oxetanes of this type could be opened selectively, the oxidation level of the sulfur substituent altered as desired to facilitate alkylations, and thus they could be useful synthetic intermediates. We also wondered if *syn* addition of a polarized



1 R = CH = CH_2 **3** R = CH = CH_2 **5** R = CH = CH_2
2 R = CH_3 **4** R = CH_3 **6** R = CH_3

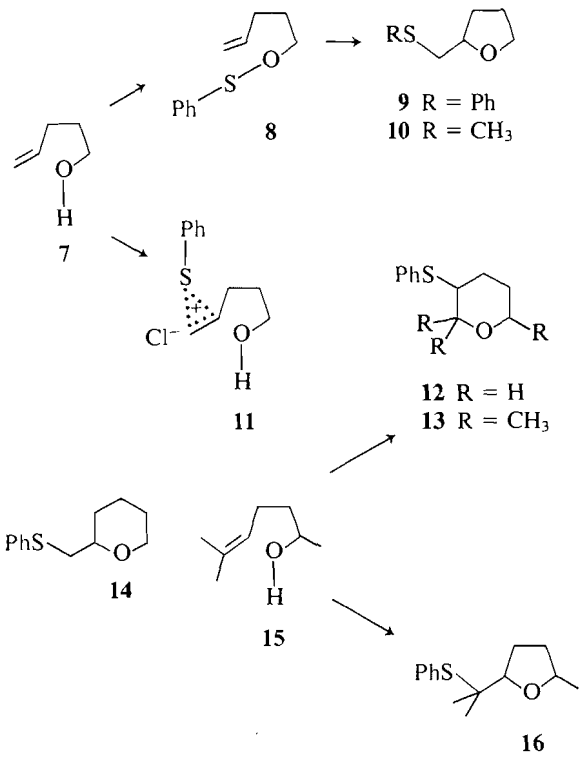
sulfenate ester to a double bond was a general reaction. However, as described below it appears not to be, but we have developed a mild, general intramolecular route to cyclic ethers from unsaturated alcohols with benzene or methanesulfenyl chloride generated *in situ* in acetonitrile at room temperature (21°C) followed by the addition of *N,N*-diisopropylethylamine. These studies are related to the recent report of O'Malley and Cava (6) which employed dimethyl(methylthio)sulfonium fluoroborate for this type of transformation and provide access to the sulfur analogue of selenium based methods for cyclic etherification and lactonization (8–11).

Results and discussion

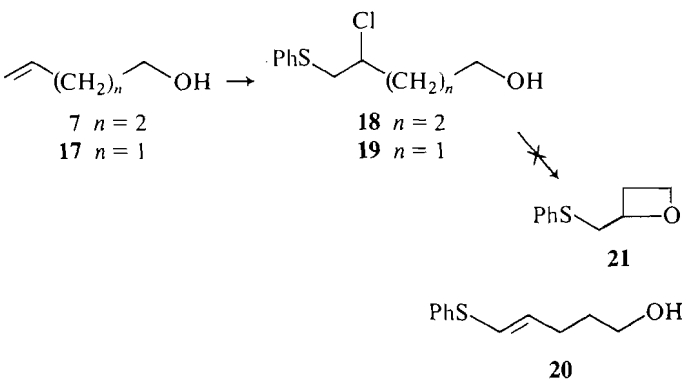
Initially, to examine the reactivity of simple sulfenate esters, methyl benzenesulfenate was prepared and mixed with norbornene but after several hours in refluxing THF the components were recovered unchanged. In order to ascertain if oxetane formation was limited to intramolecular examples the behaviour of sulfenate ester **8** derived from **7** was examined but it also did not form **9** at temperatures up to 85°C. Recently Edstrom and Livinghouse have described the addition of benzenesulfenates to alkenes in the presence of Lewis acids followed by arene annulation of the resulting thiiranium (episulfonium) ion intermediate (12). Treatment of the sulfenate ester **8** with either boron trifluoride etherate or silica gel afforded the tetrahydrofuran **9** in modest yield (~50%) accompanied by the alcohol **7**. Unfortunately this procedure may have limited synthetic potential as a preparative method, since it failed in the more complex case of the sulfenate ester derived from the bicyclic alcohol **26**.

In contrast to this behaviour, the substituted tetrahydrofuran **9**

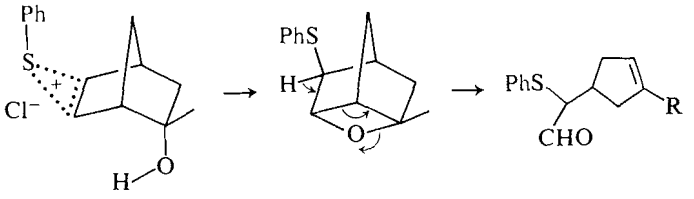
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.



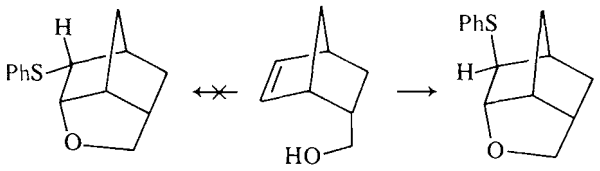
was formed from **7** in 84% yield when the alcohol was treated with a solution of benzenesulfenyl chloride generated *in situ* in acetonitrile at 21°C followed by *N*,*N*-diisopropylethylamine. (The yield was not improved when distilled benzenesulfenyl chloride was employed.) A parallel procedure employing methanesulfenyl chloride afforded the corresponding ether **10** (6). These results are consistent with the initial formation of a thiiranium (episulfonium) ion intermediate of type **11** which is displaced by the internal oxygen nucleophile. The products arise via a preferred 5-*exo-tet* cyclization of **11** (13, 14). The alternative 6-*endo-tet* mode of ring closure to the pyran **12** was not observed. However, six-membered rings were formed exclusively when the alternative choice was a 7-*endo-tet* ring closure, so that pyran **14** was formed from 5-hexen-1-ol in 85% yield. In the more highly substituted olefin **15** a 1:1 mixture of the two cyclic ethers **13** and **16** was obtained. One might expect, based on results from the addition of substituted benzenesulfenyl chlorides to alkenes (15), that the major kinetically controlled product should arise from attack at the least hindered carbon of the thiiranium ion. However, this product (**12**) was not observed from **7** and in the case of **15** where both modes of attack were encountered the product composition apparently reflects the sterically crowded environment in the intermediate and the relative ease of ring formation. Another route could involve the formation of addition product followed by cyclization in the presence of the amine base. However, cyclization did not occur to form the simple oxetane **21** from 3-buten-1-ol (**17**) but intermolecular attack by the chlorine nucleophile took precedence to give the Markovnikov addition product **19**. Furthermore, cyclization of **19** to **21** by treatment with additional bases was also not possible. In a similar fashion **18** was prepared from **7** (PhSCl, Et_2O, 21°C, 2 h). Although on standing it slowly formed a small amount of the tetrahydrofuran, treatment of **18** with sodium hydride at 21°C did not enhance cyclization and only starting material was recovered. In contrast, when *n*-butyllithium was employed (0–21°C) elimination to form **20** was observed, although, some of this enol ether may have arisen from the tetrahydrofuran **9**, since it opened cleanly to **20** at 0°C with *n*-butyllithium. As a route to protected aldehydes this may be of further synthetic utility.



It was anticipated that examination of the behaviour of the two norbornene-type alcohols **2** and **26** would permit a distinction to be made between the sulfenate ester cycloaddition and the thiiranium ion pathways due to the different stereochemistry of the products which should result in each case. Thus alcohol **2** was treated at 0°C with *n*-butyllithium followed by PhSCl at −78°C. The products, other than alkene addition (46%), consisted of two unstable materials, the oxetane **6** (20%) and the thio-aldehyde **24** (14%) from the ring opening of **6**. The magnitude of the coupling constant (J = 5.0 Hz) between the two adjacent *exo* hydrogens of **6** was consistent with a *syn* addition as observed in the case of **1** above. Unfortunately the benzenesulfenyl chloride/diisopropylethylamine procedure did not afford the oxetane **23** that was expected from intermediate **22** but only a low yield (17%) of the ring-opened aldehyde **24**. In spite of the fact that the oxetane **23** was not detected it is the most probable intermediate. In the presence of the amine base the *endo* proton on the sulfur-bearing carbon may be readily abstracted leading to facile ether cleavage to form the enol followed by tautomerization. The geometry for this elimination-opening process is clearly more favourable for **23** than for either **5** or **6**. Previously the ring-opened aldehyde **25** from **1** was not encountered; however, examination (^{1}H nmr) of a sample of **1** which had been stored for more than a year at 0–5°C revealed that it contained a significant amount of aldehyde and indicated that even in storage these oxetanes undergo ring cleavage.

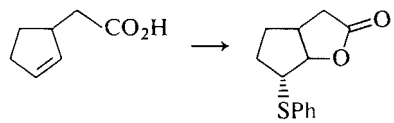


In principle the tetrahydrofuran ring that would be formed from **26** should exhibit greater stability and it was examined next. However, the sulfenate ester cycloaddition failed to give **27** even with added Lewis acids. It therefore appears that this intramolecular reaction is limited to reactive norbornene double bonds in which the sulfenate ester is aligned in the correct geometry. In contrast, the benzenesulfenyl chloride/diisopropylethylamine procedure gave the tricyclic tetrahydrofuran **28** in 83% yield. The stereochemistry was established on the basis of the *trans* coupling constant (J = 2.5 Hz) between the *endo*



27 26 28

and *exo* hydrogens attached to the carbons bearing heteroatoms and by analogy with related selenium examples (11). As expected from related studies (16, 17) the procedure may also be employed for sulfenyllacetonization (**29**–**30**). The results of these studies and the examples discussed above are summarized in Table 1.



29 30

In conclusion this *in situ* benzenesulfenyl chloride/*N*,*N*-diisopropylethylamine procedure provides a general, mild route to sulfur-substituted cyclic ethers in which the sulfur functionality may be modified for further synthetic manipulations. Thus after oxidation of the sulfur moiety it may be reductively removed, alkylated at the adjacent carbon, or eliminated to give a substituted alkene, depending upon the ultimate synthetic objective. These features and the simplicity of this cyclization method should facilitate its extended use in synthesis.

Experimental

Infrared spectra were recorded on a Perkin–Elmer 237B or 451 grating spectrophotometer, and were calibrated with the 2850 and 1601 cm^{-1} bands of polystyrene film. Proton magnetic resonance spectra were measured at 80 MHz with a Bruker WP80 spectrometer employing a chloroform lock or at 60 MHz with a Varian EM 360 spectrometer. Signal positions are reported in ppm downfield from tetramethylsilane (δ scale) as an internal standard, multiplicity, the number of protons, coupling constants, and proton assignments are indicated in parentheses. Mass spectra were determined on a V.G. Micromass 7070 HS instrument using an ionization energy of 70 eV.

Thin layer chromatographic analyses were carried out on commercial precoated silica gel plates with fluorescent indicator (Eastman Kodak silica gel 13181). Preparative thin layer chromatography was conducted on 20 × 20 cm glass plates coated with silica gel $PF^{254+366}$ type 60 (E. Merck). Flash chromatography using BDH silica gel Kieselgel 60, 230–400 mesh was employed for all column chromatography. Additional chromatographic purification was achieved using a Harrison Research Chromatotron Model 7924T.

Petroleum ether refers to a fraction with boiling range 30–60°C. Anhydrous diethyl ether (ether), tetrahydrofuran (THF), dimethoxyethane (DME), and dioxane were obtained by distillation from lithium aluminium hydride or potassium/benzophenone. Absolute ethanol and methanol were dried by distillation from magnesium. Dry hexamethylphosphoramide (HMPA), dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and diisopropylamine were prepared by distillation from calcium hydride. Solutions in organic solvents were dried over anhydrous magnesium sulphate and stripped of solvent with a Buchi rotary evaporator connected to a water aspirator. Unless otherwise indicated all reactions were conducted under an atmosphere of dry nitrogen.

General sulfenyletherification procedure

A solution of benzenesulfenyl chloride was prepared *in situ* in dry acetonitrile (10 mL) containing dry pyridine (2 drops) and diphenyldisulfide (0.634 g, 2.90 mmol) to which sulfuryl chloride (0.24 mL, 2.96 mmol) in acetonitrile (3 mL) was added dropwise. This solution was stirred at 21°C for 1 h and then added dropwise to a magnetically stirred solution of 4-penten-1-ol (0.50 g, 5.81 mmol, Aldrich) in dry acetonitrile (10 mL) at room temperature (21°C). Stirring was continued for 0.5 h after addition was complete, a solution of *N*,*N*-diisopropylethylamine (1.20 mL, 6.89 mmol) in acetonitrile (5 mL) was added, and the reaction mixture stirred for a further 0.5 h. The reaction mixture was concentrated under reduced pressure, extracted with ether (50 mL), the combined ether extracts washed with water (3 × 50 mL), saturated aqueous ammonium chloride (2 × 25 mL), dried, filtered, concentrated, and the product purified by chromatography (5% ethyl acetate/*n*-hexane), to give 2-phenylthiomethyltetrahydrofuran (**9**). Yield 0.94 g (84%); ir (film): 2900, 2880, 1580 (C=C), 1060 (C—O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.60–2.19 (m, 4H, CH_2CH_2), 3.06 (m, 2H, CH_2—S), 3.69–4.14 (m, 3H, HC—O, CH_2—O), 7.14–7.44 (m, 5H, ArH); ^{13}C nmr ($CDCl_3$) δ: 25.80, 31.01, 39.04, 68.26, 77.84, 126.11, 129.02, 129.44, 130.30. *Exact mass* calcd. for $C_{11}H_{14}OS$: 194.0764; found: 194.0753.

*2-Methylthiomethyltetrahydrofuran (**10**)*

A parallel procedure was used with methanesulfenyl chloride. A solution of methanesulfenyl chloride was prepared *in situ* in dry acetonitrile (10 mL) containing dry pyridine (2 drops) and dimethylsulfide (0.272 g, 2.90 mmol) to which sulfuryl chloride (0.24 mL, 2.96 mmol) in acetonitrile (3 mL) was added dropwise. This solution was stirred at 21°C for 1 h and then added dropwise to a magnetically stirred solution of 4-penten-1-ol (0.50 g, 5.81 mmol, Aldrich) in dry acetonitrile (10 mL) at room temperature (21°C) as described above to afford **10** in 86% yield (6); ir (film) 2880, 1580 (C=C), 1060 (C—O); ^1H nmr ($CDCl_3$) δ: 1.59–2.25 (m, 4H, CH_2CH_2), 2.17 (s, 3H, CH_3S), 2.64 (dd, 2H, CH_2—S), 3.70–4.13 (m, 3H, CH_2O, HC—O); ^{13}C nmr ($CDCl_3$) δ: 16.41, 25.81, 31.11, 39.40, 68.29, 78.63. *Exact mass* calcd. for $C_6H_{12}OS$: 132.0608; found: 132.0604.

*2-Phenylthiomethyltetrahydropyran (**4**)*

The above procedure with 5-hexen-1-ol (0.60 mL, 5.0 mmol, Aldrich) afforded the pyran **14**, 0.92 g (88%); ^1H nmr ($CDCl_3$) δ: 1.32–1.87 (m, 6H, —$(CH_2)_3$), 3.01 (m, 2H, CH_2S), 3.24–3.53 (m, 2H, CH_2O), 4.00 (m, 1H, HC—O), 7.13–7.43 (m, 5H, ArH); ^{13}C nmr ($CDCl_3$) δ: 23.41, 25.97, 31.35, 39.90, 68.78, 76.73, 126.03, 129.10, 129.36, 137.39. *Exact mass* calcd. for $C_{12}H_{16}OS$: 208.0921; found: 208.0947.

*5-Methyl-2-phenylthiomethyl(1,1-dimethyl)tetrahydrofuran (**16**) and 2,2,6-trimethyl-3-phenylthiotetrahydropyran (**13**)*

The above procedure with 6-methyl-5-hepten-2-ol (0.60 mL, 3.95 mmol, Aldrich) gave an inseparable 1:1 mixture of **16** and **13**, 0.78 g (84%); ir (film) 1585 (C=C), 1090 (C—O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.11 (d, 3H, J = 6.5 Hz, CH_3C—O), 1.25 (d, 3H, J = 6.5 Hz, CH_3C—O), 1.41 (s, 6H, 6H, $(CH_3)_2C$), 3.15 (t, 1H, J = 3 Hz, HC—SPh), 3.68 (m, 1H, HC—O); The ratio of **16**:**13** was 48:52 based on the ^{13}C nmr signals at 55.20 (CHS) and 53.49 (CH—O). *Exact mass* calcd. for $C_{14}H_{20}OS$: 236.1234; found: 236.1229.

*5-exo-Phenylthio-3-oxatricyclo[4.2.0.0^{4,8}]nonane (**28**)*

The above procedure with 5-norbornene-2-methanol (**26**) (0.60 mL, 4.96 mmol, 17% *endo*, Aldrich) provided the tricyclic ether **28**, 0.65 g (83% based on *exo* isomer); ir (film) 1595 (C=C), 1100 (C—O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.16–2.73 (m, 7H), 3.01 (d, 1H, J = 2.5 Hz, HC—S), 3.67–3.83 (m, 2H, CH_2—O), 4.18 (d, 1H, J = 5 Hz, HC—O), 7.23–7.41 (m, 5H, ArH); ^{13}C nmr ($CDCl_3$) δ: 36.06, 38.02, 38.28, 39.64, 46.48, 56.73, 74.76, 86.13, 125.77, 129.10, 130.04, 130.89. *Exact mass* calcd. for $C_{14}H_{16}OS$: 232.0921; found: 232.0935.

*3-Chloro-4-phenylthiobutanol (**19**)*

The above procedure with 3-buten-1-ol (0.50 mL, 5.81 mmol) gave the addition product **19**, 1.21 g (97%); ir (film) 3350 (br, OH), 1583 (C=C) cm^{-1}.

*8-Phenylthio-2-oxabicyclo[3.3.0]octan-3-one (**30**)*

The above procedure with 2-cyclopentene-1-acetic acid (0.60 mL, 4.98 mmol, Aldrich) afforded the lactone **30**, 0.98 g (87%) (16); ir

(film) 1780 (C=O), 1590 (C=C), 1175 (C—O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 3.80 (m, 1H, HC—S), 4.81 (d, 1H, J = 6 Hz, HC—O), 7.35 (m, 5H); ^{13}C nmr ($CDCl_3$) δ: 30.07, 32.04, 35.63, 37.42, 51.44, 89.88, 128.14, 129.36, 130.64, 131.58, 176.69. *Exact mass* calcd. for $C_{13}H_{14}O_2S$: 218.0765; found: 218.0778.

4-Chloro-5-phenylthiopentanol (18)

A solution of benzenesulfenyl chloride was prepared *in situ* in dry diethyl ether (15 mL) containing dry pyridine (0.05 mL) and diphenyldisulfide (0.418 g, 1.91 mmol) to which sulfuryl chloride (0.255 g, 1.91 mmol) in ether (3 mL) was added dropwise. This solution was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

stirred at 21°C for 2 h and then added dropwise to a magnetically stirred solution of 4-penten-1-ol (0.50 g, 5.81 mmol, Aldrich) in dry ether (15 mL) at 21°C. The reaction was stirred for a further 2 h, diluted with ether, quenched with saturated aqueous ammonium chloride solution, and extracted with ether (3 × 20 mL). The combined ether extracts were washed with water, brine, dried, filtered, concentrated, and the addition product **18** obtained as a pale yellow viscous oil, 0.804 g (62%); ir (film) 3400 (br, OH), 1585 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.40–2.20 (m, 4H, CH_2CH_2), 2.95–4.05 (m, 5H), 3.85 (br s, 1H, OH), 7.10–7.50 (m, 5H, ArH).

5-Phenylthio-4-penten-1-ol (20)

Treatment of **18** (0.80 g, 3.47 mmol) or **9** (0.357 g, 1.84 mmol) in dry ether (20–30 mL) at 0°C with *n*-butyllithium in hexane (2.20 mL, 3.52 mmol and 1.20 mL, 1.92 mmol respectively) for 1 h was followed by quenching with saturated aqueous ammonium chloride. The reaction was extracted with ether, the combined ether extracts washed with brine, dried, filtered, and concentrated and purified by chromatography (10% ether acetate/*n*-hexane) to give **20**, 0.412 g (66%) and 0.35 g (83%) respectively, ir (film) 3320 (OH), 1580 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.20–2.40 (m, 4H, CH_2CH_2), 3.55 (t, 2H, J = 7.0 Hz, CH_2—O), 3.90 (s, 1H, OH), 5.5–6.30 (m, 2H, HC=CH), 7.00–7.40 (m, 5H, ArH).

endo-*2-Phenylthio-5-methyl-4-oxatricyclo[3.2.1.0^{3,6}]octane (6) and 2-phenylthio-(3-methyl-3-cyclopentenyl)ethanal (24)*

n-Butyllithium in hexane (0.60 mL, 1.62 mmol, Aldrich) was added dropwise at 0°C to a stirred solution of *endo*-2-methyl-5-norbornen-2-ol (**2**, from norbornenone and methyllithium) (18) (0.20 g, 1.61 mmol) in dry ether (20 mL). After 4 h the reaction mixture was cooled to −78°C and a solution of benzenesulfenyl chloride (prepared as described above from sulfuryl chloride (0.11 g, 0.80 mmol) and diphenyldisulfide (0.18 g, 0.82 mmol) in dry ether (10 mL) containing dry pyridine (1 drop)) was added dropwise over 1 h. The reaction was stirred for a further 1 h at −78°C after addition was complete and allowed to rise to room temperature (21°C) and stirred for a further 15 h. Water was added, the reaction mixture extracted with ether, the combined ether extracts washed with water, saturated aqueous ammonium chloride, dried, filtered, concentrated, and the products purified by chromatography (5% ethyl acetate/*n*-hexane) to give the thioaldehyde **24** 0.052 g (14%); ir (film) 2720 (HC=O), 1715 (C=O), 1580 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.71 (br s, 3H, CH_3C=), 2.15–2.75 (m, 5H), 3.50 (m, 1H, HC—S), 5.30 (m, 1H, HC=C), 7.21–7.48 (m, 5H, ArH), 9.36 (d, 1H, J = 4.7 Hz, HC=O); ^{13}C nmr ($CDCl_3$) δ: 16.40, 36.99, 37.25, 41.35, 123.12, 123.29, 128.42, 129.36, 132.78, 139.44.

Oxetane **6**, 0.074 g (20%); ^1H nmr ($CDCl_3$) δ: 1.30 (s, 3H, CH_3C), 2.75 (m, 1H, bridehead H), 3.21 (m, 3H), 3.68 (br s, 1H, bridgehead H), 4.40 (dd, 1H, J = 2, 5 Hz, HC—O), 7.4 (m, 5H, ArH). The major products 0.20 g (46%) arose from addition to the norbornene double bond.

Phenylthio-4-pentenol (8)

A solution of *n*-butyllithium in hexane (2.90 mL, 4.65 mmol, 1.6 *M*, Aldrich) was added dropwise to a stirred solution of 4-penten-1-ol (0.5 g, 5.8 mmol, Aldrich) in dry ether (20 mL) at 21°C. An ether solution (10 mL) of benzenesulfenyl chloride (1.91 mmol) prepared as outlined above was added dropwise over 10 min, stirring was continued for a further 2 h at 21°C and the reaction quenched with aqueous saturated ammonium chloride solution. The solution was extracted with ether, the combined ether extracts were washed with water, brine, dried, filtered, and concentrated, to give the sulfenate ester **8**, 0.392 g 35% as a pale yellow liquid; ir (film) 3070 (=C—H), 1645 (C=C), 740, 695 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.0–2.1 (m, 4H), 3.76 (t, 2H, J = 7 Hz, H_2C—O), 4.80 (m, 1H, C=CH), 5.00 (m, 1H, C=CH), 5.35–6.0 (m, 1H, RCH=C), 7.73 (m, 5H, ArH). This material was recovered unchanged after 3 h in refluxing dimethoxyethane (85°C). However, stirring at 21°C in ether with a 2:1 weight ratio of 60–120 mesh silica gel afforded a 50% yield of tetrahydrofuran **9** and the starting alcohol.

In the case of the sulfenate ester derived from **26** neither refluxing an ether – silica gel slurry (10 h) nor treatment at 21°C for 3 h in the presence of boron trifluoride etherate afforded any cyclic ether products.

Received December 22, 1986

This paper is dedicated to Professor John T. Edward

RONALD KLUGER, GREGORY R. J. THATCHER, and WILLIAM C. STALLINGS. Can. J. Chem. **65**, 1838 (1987).

Compounds **1–5** were prepared to compare reactivity patterns of cyclic and acyclic phosphonylurea esters. The rates and products of reactions of phosphonylurea esters (**1–3**) with hydroxide in aqueous acetonitrile were analyzed. In these compounds the phosphonate moiety is in a strained five-membered ring, which also contains the ureido group. Structural determination of **1** by X-ray crystallography indicates that the five-membered ring is planar and the internal ring angle at phosphorus is 93.1°. The endocyclic N—C—N angle of the ureido group is 111°. The compounds undergo hydrolysis in alkaline aqueous acetonitrile at 35°C with a rate about 10^6 times that of analogues (**4**, **5**) in which the phosphonate group is exocyclic to the ureido ring. Compound **1** undergoes alkaline hydrolysis ($k = 9.0 \times 10^3\ M^{-1}\ s^{-1}$) to release the phenoxy group to give **6**. The hydrolysis of alkyl esters **2** ($k = 2.4 \times 10^4\ M^{-1}\ s^{-1}$) and **3** ($k = 1.3 \times 10^3\ M^{-1}\ s^{-1}$) leads to cleavage of the endocyclic P—N bond, producing **7** and **8** respectively. The exocyclic alkyl esters (**4** and **5**) also cleave at the P—N bond with respective rate constants of $6.5 \times 10^{-3}\ M^{-1}\ s^{-1}$ and $4.4 \times 10^{-2}\ M^{-1}\ s^{-1}$. The data are consistent with a mechanism in which hydroxide adds to **1** to form a pentacoordinate phosphorus intermediate with the phenoxy group in an equatorial position and the ureido ring in apical and equatorial positions (with nitrogen apical). The departure of the urea group is slower than pseudorotation of the intermediate and expulsion of phenoxide. In the isomerized intermediate, phenoxy is apical but the methylene group of the ring, which has low apicophilicity, must also be apical. Reactions of **2** and **3**, which have more basic oxygen leaving groups, occur with P—N cleavage because expulsion from the isomerized intermediate in those cases is not sufficiently fast. These results fit reaction patterns at phosphorus that are determined by ring strain and electronegativity of ligands. Contributions from effects due to antiperiplanar interactions between bonding and nonbonding electrons are not detected.

RONALD KLUGER, GREGORY R. J. THATCHER et WILLIAM C. STALLINGS. Can. J. Chem. **65**, 1838 (1987).

Dans le but d'évaluer les comportements réactionnels des esters phosphonylurées cycliques ainsi qu'acycliques, on a préparé les composés **1–5**. On a analysé les vitesses ainsi que les produits des réactions des esters phosphonylurées (**1–3**) avec l'hydroxyde dans l'acétonitrile aqueux. Dans ces composés, la portion phosphonate se trouve dans un cycle à cinq chaînons qui est tendu et qui contient aussi le groupement uréido. En se basant sur une détermination de structure du composé **1** par diffraction des rayons-X, on peut en déduire que le cycle à cinq chaînons est plan et que l'angle interne du cycle au niveau du phosphore est de 93°. L'angle endocyclique N—C—N du groupement uréido est de 111°. À 35°C et en solution acétonitrile alcaline, les composés subissent une hydrolyse dont la vitesse est environ 10^6 fois celle de ses analogues **4** et **5** dans lesquels le groupement phosphonate est exocyclique par rapport au cycle uréido. Le composé **1** subit une hydrolyse alcaline ($k = 9{,}0 \times 10^3\ M^{-1}\ s^{-1}$) qui conduit à une élimination du groupement phénoxy et à la formation du composé **6**. L'hydrolyse des esters alkylés **2** ($k = 2{,}4 \times 10^4\ M^{-1}\ s^{-1}$) et **3** ($k = 1{,}3 \times 10^3\ M^{-1}\ s^{-1}$) conduit à une rupture de la liaison P—N et à la formation respectivement des composés **7** et **8**. Les esters alkylés exocycliques (**4** et **5**) se coupent aussi au niveau de la liaison P—N avec des vitesses respectives de réaction de $6{,}5 \times 10^{-3}\ M^{-1}\ s^{-1}$ et $4{,}4 \times 10^{-2}\ M^{-1}\ s^{-1}$. Ces données sont en accord avec un mécanisme dans lequel l'ion hydroxyde s'additionne au composé **1** pour former un intermédiaire phosphoré pentacoordonné comportant le groupement phénoxy dans une position équatoriale et le cycle uréido dans les positions apicale et équatoriale (avec l'azote apical). Le départ du groupement urée est plus lent que la pseudorotation de l'intermédiaire et l'expulsion du phénolate. Dans l'intermédiare isomérisé, le phénoxy est apical mais le groupement méthylène du cycle, qui a peu de tendance à prendre la position apicale, doit aussi être apical. Les réactions des composés **2** et **3**, qui portent des groupements nucléofuges oxygénés plus basiques, se produisent avec une rupture de la liaison P—N parce que, dans ces cas, l'expulsion de groupements à partir de l'intermédiaire isomérisé n'est pas suffisamment rapide. Ces résultats sont en accord avec les comportements réactionnels au niveau du phosphore qui sont déterminés par des tensions de cycles et par l'électronégativité des ligands. On n'a pas pu détecter de contributions des effets dus aux interactions antipériplanaires entre les électrons liants et non-liants.

[Traduit par la revue]

Introduction

The reactivity patterns of cyclic tetracoordinated phosphorus esters are dominated by effects due to ring strain and the electronegativity of groups attached to phosphorus (1, 2). The kinetic effects of competition between these and other factors in structurally defined systems provide a quantitative basis for evaluation of the factors controlling reactivity. In this paper we report the rate of hydrolytic reactions of esters of cyclic phosphonylureas (**1–3**) in alkaline aqueous acetonitrile and the reactions of analogues in which the phosphorus atom is not contained in a ring (**4**, **5**). An X-ray crystal study of the cyclic phosphonylurea ester (**1**) provides a basis for the necessary structural analysis. The identity of the reaction products (**6–8**) and the rates of the reactions provide information that can be used to understand general reactivity patterns for phosphorus esters.

purchased from the Aldrich Chemical Company and BDH Canada Limited. Inorganic chemicals were Fisher reagents.

Methods

Nuclear magnetic resonance spectra

Proton nmr spectra were recorded at 200 MHz using a Varian XL-200 spectrometer for samples in deuterated solvents. Carbon nmr spectra (20 MHz) were recorded on a Varian CFT-20 and phosphorus nmr spectra were recorded at 32 MHz using a Bruker WP-80.

Elemental analyses were determined by Galbraith Laboratories (Knoxville, Tennessee, U.S.A.).

Syntheses

1,4-Dimethyl-2-phenoxy-1,4,2-diazaphospholidine-2,5-dione (1)

The procedure is a modification of that reported by Birum (3). A mixture of 1,3-dimethylurea (4.4 g), paraformaldehyde (1.5 g), acetic anhydride (6 mL), and acetic acid (5 mL) was heated at 70°C for 4 h. Triphenyl phosphite (13.1 mL) was added and the mixture was kept at 90°C for 2 h. The mixture was concentrated *in vacuo* (1 Torr (133.3 Pa)). The residue was dissolved in 100 mL chloroform and washed with two 100-mL portions water. The chloroform layer was dried over magnesium sulfate and concentrated. Addition of anhydrous ether caused the product to precipitate. The material was recrystallized from chloroform–ether. Yield: 4.8 g (50%), mp 118–120°C; ir (KBr): 1713, 1591, 1490, 1288; ^{1}H nmr (chloroform-*d*, ppm downfield from Me_4Si) δ: 7.20, 7.15 (5H, 2s/m, ArH), 3.48 (2H, d, J = 15 Hz, N—CH_2P), 2.92 (3H, d, J = 2 Hz, C—N—CH_3), 2.82 (3H, d, J = 8 Hz, P—N—CH_3); ^{31}P nmr (chloroform-*d*, ppm downfield from phosphoric acid) δ: 23.46. *Anal.* calcd. for $C_{10}H_{13}N_2O_3P$: C 50.00, H 5.45, N 11.66, P 12.90; found: C 49.77, H 5.36, N 11.36, P. 12.68.

1,4-Dimethyl-2-methoxy-1,4,2-diazaphospholidine-2,5-dione (2)

This was prepared by the reaction of *N,N'*-dimethyl-*N*-methoxymethylurea and trimethyl phosphite using the method reported by Kluger *et al.* (4).

1,4-Dimethyl-2-ethoxy-1,4,2-diazaphospholidine-2,5-dione (3)

This was prepared by the reaction of *N,N'*-dimethyl-*N*-methoxymethylurea and triethyl phosphite (4).

Sodium 1,4-dimethyl-2-oxy-1,4,2-diazaphospholidine-2,5-dione (**6**) was prepared by reaction of sodium iodide (0.47 g) in 25 mL dry butanone with **2** with stirring and refluxing for 3 h (5). The white precipitate was collected by filtration, washed with butanone, dissolved in methanol, and precipitated by the addition of ether. The resulting powder was dried in a vacuum desiccator. Proton nmr (acetonitrile-d_3, relative to internal Me_4Si) δ: 3.21 (2H, d, J = 14 Hz, P—CH_2N), 2.80 (3H, s, N—CH_3), 2.66 (3H, d, J = 7 Hz, P—N—CH_3).

Phenyl phenylphosphonochloridate

Phenol (10.5 g) and pyridine (8.5 g) in 35 mL dry benzene were added to a stirred solution of phenylphosphonochloridate during 30 min. The solution was filtered and the filtrate distilled at 145°C, 2 Torr (6) in 60% yield.

Phenyl (1-imidazolidinone)methylphosphonate (4)

Imidazolidinone (1.67 g) and triethylamine (3.73 mL) were dissolved in 80 mL dry ether and added to a stirred solution of phenyl methylphosphonochloridate (3.7 g) in 20 mL dry ether at −5°C. The mixture was stirred for 5 h, then warmed to room temperature and allowed to stand for 24 h. The resulting precipitate was washed with ether. The filtrate and washings were concentrated *in vacuo*. The residue was dissolved in 50 mL chloroform and washed with two 50-mL portions of water. The chloroform layer was dried over magnesium sulfate and concentrated. The concentrate was placed on a column of silica gel (5 × 50 cm) and eluted with 10% methanol in chloroform. Fractions containing the product were detected by thin-layer chromatography. Evaporation yielded a white crystalline solid; uv (λ_{max}, acetonitrile): 262 nm; ^{1}H nmr (chloroform-*d*, relative to internal Me_4Si) δ: 7.17, 7.12 (5H, 2s, ArH), 5.98 (1H, s, NH), 3.05–3.8 (4H, m, NCH_2CH_2), 1.88 (3H, d, J = 18 Hz, P—CH_3). *Anal.* calcd. for $C_{10}H_{13}N_2O_3P$: C 50.00, H 5.45, N 11.66, P 12.90; found: C 49.76, H 5.40, N 11.52, P 12.89.

Phenyl (1-imidazolidinone)phenylphosphonate (5)

Imidazolidinone (0.34 g) and triethylamine (0.57 mL) in 20 mL methylene chloride were added to a stirred solution of phenyl phenylphosphonochloridate (0.97 g) in 5 mL methylene chloride during 20 min. This was stirred for an additional 20 min at room temperature followed by addition of benzene and methylene chloride, then concentrated. The precipitate was collected by filtration and washed with benzene. The filtrates were combined and concentrated *in vacuo* to yield a white powder, which was recrystallized from benzene (0.75 g), mp 145°C; ir spectrum (KBr): 1729, 1251 cm^{-1}; uv (λ_{max}, acetonitrile): 266 nm; ^{1}H nmr (chloroform-*d*, relative to internal Me_4Si) δ: 7.38 (5H, s, O—ArH), 7.1–8.3 (5H, m, P—ArH), 5.8 (1H, s, NH), 3.1–4.0 (4H, m, NCH_2CH_2N); ^{31}P nmr (chloroform-*d*) δ: 13.57.

Kinetics

Reactions were conducted in solutions of 60% acetonitrile–water (mixtures by volume) due to the low solubility of most of the substrates in water. Deuterated solvents were also used in the same proportion. Lower percentages of acetonitrile were used in some runs to determine solvent effects.

pH measurement

For solutions of low basicity, the apparent pH of the solution was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

determined with a Canlab combination pH electrode and Radiometer pH meter 26. Jordan has shown that pH-meter readings give accurate measurements in acetonitrile–water mixtures (7). For solutions of moderate to high basicity, hydroxide concentration was determined by titration of the aqueous component, and the concentration reported is of that component. To arrive at values for second-order rate constants for the reactions of the acyclic compounds, the observed first-order rate constants were fit to a linear least-squares best fit as a function of aqueous hydroxide concentrations. However, for the cyclic compounds, the reactions were measured in solutions containing aqueous acetonitrile whose acidity was measured with a pH electrode. Therefore, an estimate of hydroxide concentration is necessary. We used the ion product for pure water at 35°C (13.68). The data were fit to the expression $k_{obs} = k_w + k_{OH^-}[OH^-]$.

Proton nuclear magnetic resonance spectroscopy

Products of the hydrolysis reaction of **1–5** were determined periodically by proton nmr analysis of deuterated reaction solutions and comparison of the product spectra with independently synthesized samples.

Ultraviolet kinetics

The production of phenoxide from the hydrolysis of **1**, **4**, and **5** was observed by its absorption at 259 nm using a Varian Cary 210 spectrophotometer with the sample in a cell contained in a jacketed cell holder maintained at 35°C with a Neslab Exacal circulator. Acetonitrile (1.8 mL) and the basic aqueous solution in water were equilibrated at 35.0°C. The substrate was added to the cell and the cell was stoppered, inverted, and shaken. Data were collected at intervals of 0.5 s using a microprocessor-controlled interface to the PET computer and collected in a memory array of the computer. These data were transferred to diskettes and analyzed using the kinetic overrelaxation algorithm (8), giving first-order rate constants with correlation coefficients of at least 0.99998 and confidence intervals of 1% (confidence intervals are two standard deviations). The effect of ionic strength was found to be very small since repetition of experiments using added potassium chloride (0.05 *M*) did not affect the observed rate in a test with each compound.

pH-stat method

Since the hydrolysis reactions of **1**, **2**, and **3** produce phosphonic acids rapidly, the rate of product formation can be followed using a pH-stat (Radiometer pH meter 28, titrator adapter TT11, and autoburette 12, volume 0.125 mL). A Heath potentiometric variable-voltage strip-chart recorder was connected to the apparatus via a 50-turn potentiometer against a 1-V reference cell (alkaline battery), which was connected to the rotating shaft of the autoburette. This converts volume of added titrant to voltage, which is recorded as a function of time. The reactions were conducted in a jacketed beaker maintained at 35°C by a circulating water bath. A mixture of 3 mL acetonitrile and 2 mL 0.1 *M* potassium chloride was stirred and equilibrated in the reaction vessel with the apparatus set to maintain the pH reading of the meter through the addition of 0.01 *M* or 0.05 *M* potassium hydroxide in water from the autoburette. The substrate was added and the pH of the solution maintained by the pH-stat. The substrate concentration ranged from 0.2 m*M* to 2.5 m*M*. The data from the chart were entered into the same program as was used for nmr and uv kinetics. Correlation coefficients of at least 0.9999 were obtained with an uncertainty of 1% (two standard deviations).

X-ray crystallography

1,4-Dimethyl-2-phenoxy-1,4,2-diazaphospholidine-2,5-dione (**1**) crystallized as long parallelepipeds in space group $P2_1/n$ with a = 12.461(3), b = 5.497(2), c = 16.889(4) Å, β = 97.24(2)°, and four molecules per unit cell. Three-dimensional diffraction data were measured at room temperature with a Nicolet diffractometer using graphite monochromated CuKα radiation; the $\theta/2\theta$ scan mode was employed, and the maximum value of θ was 64°. A 0.1 × 0.1 × 0.4-mm sample was sealed in an X-ray glass capillary. Of the 1919 unique reflections collected, 1594 had intensities, I, greater than an observation threshold of $2.0\sigma(I)$, where $\sigma(I)$ was derived from counting statistics. As indicated by the systematic decrease in intensity of three periodically monitored reflections (15% in 61 exposure-hours), the data were corrected for irradiation-induced decay. In addition, an empirically determined curve was used to correct the intensities for X-ray absorption. The data were converted to structure factor amplitudes by the application of Lorentz and polarization factors, and placed on an absolute scale using a Wilson plot. Values of $\sigma(F)$ were calculated from $\sigma(F) = (F/2)\{[\sigma^2(I)/I^2] + \delta^2\}^{1/2}$ where δ is an instrumental uncertainty determined from the variation of three periodically monitored reflections (δ = 0.0327).

The molecular skeleton was correctly positioned in an E-map calculated using phases derived from direct methods (9) and the structure, including hydrogen atoms located in intermediate Fourier syntheses, was refined (10, 11) by full-matrix least squares using published X-ray scattering factors (12, 13). The function minimized in the least-squares process was $\Sigma w(|F_o| - |F_o|)^2$ where the weights, w, were $\sigma^{-2}(F)$. The unweighted crystallographic residual for the observed data is 0.055 with a weighted residual of 0.049. Coordinates are listed in Table 1; refined temperature factors (anisotropic parameters for the non-hydrogen atoms and isotropic parameters for the hydrogen atoms) as well as observed and calculated structure factors have been deposited as supplementary material.[1] The crystals are a racemic mixture; the reported coordinates are for an arbitrarily selected isomer. Programs utilized in this study include ICRRMLS (10, 11), VIEW (14), and other programs from the crystallographic library at the Fox Chase Institute for Cancer Research, Philadelphia, PA.

Results

The observed rate constants for hydrolysis of the cyclic compounds (**1–3**) in 60% acetonitrile–water solutions are given in Table 2. The limited solubilities of the reactants and products in water necessitated the use of acetonitrile as a cosolvent. Deuterated solvents were used to permit us to follow the reactions by proton nmr spectroscopy. The rate constants for hydrolysis of the exocyclic phosphonates (**4** and **5**) in acetonitrile–water solutions are listed in Table 3. This table also contains data showing the effect of decreasing the proportion of acetonitrile on the reaction rate, and rates observed in deuterated media. Increasing the aqueous content of the solution increases the rate of reaction as expected, but only to a small degree. For example, the rate of hydrolysis of **5** in 60% acetonitrile containing 0.25 *M* hydroxide is about 1/5 the rate for the same compound in 0.5 *M* hydroxide in 23% acetonitrile. This shows that the solvent effect is not significant in terms of the comparisons of cyclic and acyclic compounds. The structural changes affect reactivity by many orders of magnitude in rate while the solvent effects cause rate changes within a single order of magnitude.

The data in Table 4 summarize second-order rate constants for the reactions of the five substrates with hydroxide in 60% aqueous acetonitrile. Since the activity of hydroxide and deuteroxide in the acetonitrile solutions is not known, the absolute values of the rate constants are subject to future correction but comparison of relative magnitudes should be valid. As expected, the cyclic phosphonates (**1–3**) are much more reactive toward hydrolysis than are the exocyclic phosphonates (**4**, **5**). However, the products and rates of the reactions depend on the solution conditions.

Base catalysis

The three cyclic phosphonates undergo hydrolysis that increases in rate with hydroxide concentration in solutions with pH > 6. The phenyl ester, **1**, undergoes hydrolysis with

methyl ester (**2**) is faster than the phenoxy cleavage reaction of **1** while the cleavage of the ethyl ester (**3**) is slower than the phenoxy cleavage of **1**.

Solvent isotope effects

Since the measurement of pH and pD in aqueous acetonitrile and the activity of deuteroxide versus hydroxide under the conditions are not known, the data are not compared in this study.

Crystallographic analysis

The structure of **1** was determined by X-ray crystallography (Fig. 1). The bond lengths and angles that characterize the substituted phospholidine ring are summarized in Fig. 1. The molecule is fully extended with the five- and six-membered rings almost parallel. Analysis of the packing in the crystal structure reveals no apparently unusual interactions. All of the intermolecular associations are best characterized as van der Waals contacts.

The atoms of the phospholidine ring, including the *N*-methyl substituents and carbonyl oxygen, are essentially coplanar; deviations from the least-squares plane calculated through the urea-like atoms are described in Fig. 1. The planarity of this ring arises from resonance structures that require sp^2 hybridization and consequent overlap of the p_z orbitals on the C, N, and O atoms of the ureido moiety; evidence that the carbon and

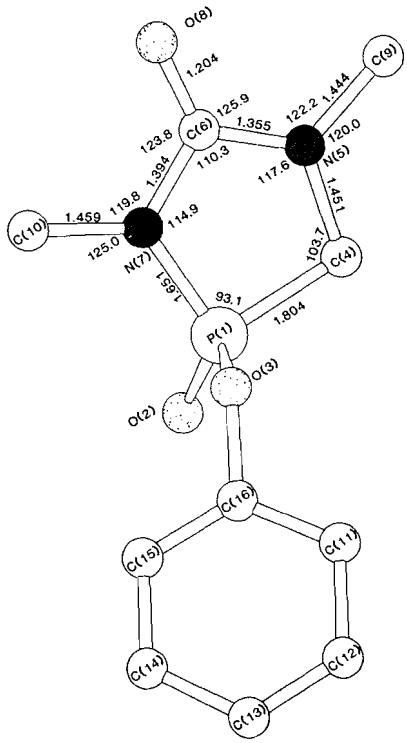

FIG. 1. The structure of **1** as determined by X-ray crystallography. Coordinates can be found in Table 1.

nitrogen atoms of the urea are trigonal is given by noting that, within experimental error, the sum of the valence angles about these atoms is in each case 360°C. The phosphorus and methylene carbon atoms that close the ring, like the carbonyl oxygen and *N*-methyl groups, are therefore coplanar substituents of sp^2 hybridized atoms and all 8 atoms thus adopt a planar arrangement. The P—N(7) bond length of 1.651 Å indicates a bond order greater than unity, and suggests the possibility of π character in this bond. The difference in the C(6)—N bond lengths is in line with this reasoning: if N(7) shares its p_z lone-pair electrons in bonds with phosphorus and the ureido carbonyl carbon, then one would anticipate the observed lengthening of the C(6)—N(7) bond relative to the C(6)—N(5) bond since the N(5) lone pair forms a bond solely with the carbonyl carbon. The present structure is perhaps most directly comparable to that of 1,3-dimethyl-2-methylamino-1,3,2-diazaphospholidine-2,4,5-trione (15) and related compounds (16) where, similarly, the planarity of the five-membered ring is attributed to resonance effects between linked carboxamide moieties.

The coplanarity of the atoms of the phospholidine ring must introduce considerable strain into the molecule. This is manifested most noticeably in the N(7)—P—C(4) (93.4°) and N(7)—C(6)—N(5) (110.3°) angles, but each of the valence angles around the ring is considerably contracted from standard trigonal or tetrahedral values.

Strain calculations

The reactivity of cyclic phosphate derivatives is affected by the strain of the ring system and the nature of the substituents attached to phosphorus (1, 2). The pentacoordinate intermediate generated by addition of a nucleophile to phosphorus is trigonal bipyramidal, and has been shown to be expected to be much less strained (or unstrained) (17). Thus, the effect of ring strain on reactivity can be approximated by comparing the rate of reaction of a strained cyclic compound and an acyclic analogue.

The ring strain in **1** can be approximated using molecular mechanics methodology, following the general procedure described by Westheimer and co-workers (18, 19), which is based on the equations of Shimanouchi *et al.* (20). Holmes has provided a sophisticated force field model that greatly extends the methodology using computer calculations (21). For the purposes of our approximate analysis, the earlier method provides sufficient accuracy. The Westheimer method uses the formula below to calculate the strain energy, E:

$$E = 1/2b^*[\delta\theta]^2$$

The quantity b is the bending force constant for a bond with units of cal mol^{-1} deg^{-2} and the quantity in brackets is the deviation from the equilibrium angle in degrees. The values of the force constant and exponent are uncertain but a value of the force constant of 45 cal mol^{-1} deg^{-2} has given reasonable agreement with experimental determinations, as has the value of the exponent. For the basis of comparison of different compounds, the absolute value is not necessary. While this method cannot generate an optimized structure from first principles, since the structure is known, we can estimate relative strain energies.

Using optimal angles for sp^3 centers as 109.5° and optimal angles for sp^2 centers as 120°, and the bending force constant given above, the strain energy of **1** is calculated to be 8.6 kcal mol^{-1}. Since **1** hydrolyzes at a rate about 10^5 to 10^6 times that of its acyclic analogue, the free energy of activation for **1** is between 7 and 9 kcal/mol^{-1} less than its acyclic analogue. However, unlike the acyclic analogue, **1** must react via a pentacoordinate phosphorus intermediate in which the methylene group of the ring is in an apical position. The electronic barrier to formation of this isomer works against the relief of strain that accompanies its formation. Therefore the acceleration due to ring strain is even larger than is implicit in the differences in free energy of activation from rate constant ratios of cyclic and acyclic compounds.

For comparison, methyl ethylene phosphate is less strained than **1**. We have performed calculations using the same bending force constant, which give a strain energy of 4.6 kcal mol^{-1}, which is about half that of **1**. Yet the acceleration of the rate of hydrolysis relative to an acyclic analogue is the same as it is for **1**. In the case of methyl ethylene phosphate, no electronically unfavourable intermediate is involved in the reaction and the full effect of ring strain can be manifested in the rate constant.

Discussion

The reaction patterns we observe are consistent with the reactions reflecting the stability of the pentacoordinated phosphorus intermediates that are produced. Holmes has summarized preference rules (based on the original rules proposed by Westheimer (2)) for the structure of intermediates in pentacoordinated trigonal bipyramidal phosphorus compounds and ranked these in order of importance (1). Those which apply to our system are as follows:

1. Five-membered cyclic systems preferentially span one apical and one equatorial position.
2. The most electronegative ligands prefer apical sites.
3. π-Bonding ligands prefer equatorial sites.
4. Steric effects are minimized with bulky groups in equatorial positions.

We apply these rules in our analysis.

Enhanced reactivity of cyclic ureaphosphonates

The rate constant for the alkaline hydrolysis of the cyclic phenyl ester (**1**) is about 5×10^5 times as large as that for the

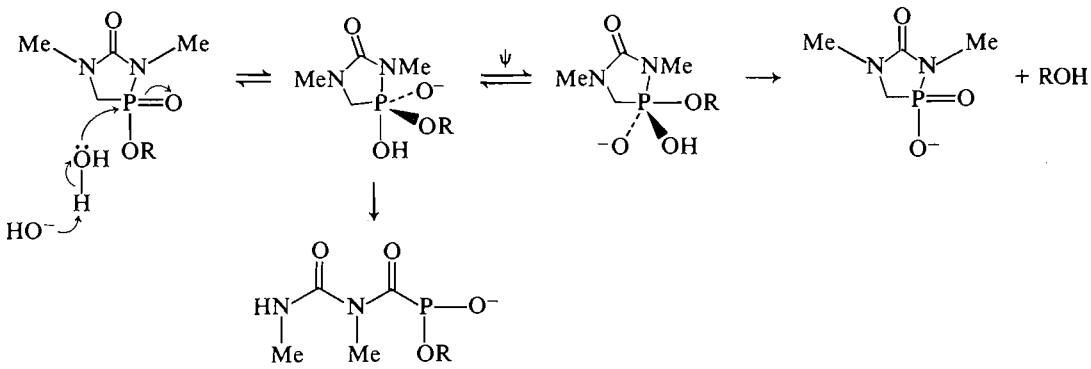
For personal use only.



SCHEME 1

base-catalyzed hydrolysis of its acyclic analogue, **4**. The methyl and ethyl esters, **4** and **5**, undergo P—N bond cleavage while acyclic analogues tend to undergo P—O cleavage. Still, the rate of P—N cleavage in the cyclic alkyl esters exceeds the rate of P—O cleavage in the acyclic esters by a large factor. These results agree with those observed by Hudson and co-workers for cyclic phosphoramides (22).

The mechanism of exocyclic cleavage

The tendency for strained cyclic phosphate ester derivatives to undergo rapid hydrolysis reactions has been well documented and has been established as due to reduced strain in the transition state of the rate-determining step. In the case of methyl ethylene phosphate (23–25), the leaving group for exocyclic cleavage is methoxide (pK 15.7) while ring cleavage involves the less basic 2-oxyethyl species (pK ~ 14.7). The transition state probably resembles the high energy intermediate and little development of charge would occur on the leaving group in the transition state. The cyclic phosphonylurea esters with alkoxy leaving groups (**2**, **3**) cleave the phosphorus–urea bond while the phenyl ester (**1**) cleaves at the exocyclic bond. Since phenoxide is a better leaving group than alkoxides, this result is in the expected direction. Based on the low reactivity in alkaline solution of materials analogous to ring-opened material **7** (4), as well as the low reactivity of the ethyl ester of a ureaphosphonate **8** (4), it is reasonable that exocyclic cleavage of the ester is a primary reaction and does not result from recyclization of the endocyclic cleavage product (**7**). Mechanisms based on this analysis are presented in Scheme 1. For the phenyl ester, **1** (R = phenyl), the initially formed intermediate undergoes pseudorotation followed by P—O cleavage to produce the cyclic phosphonylurea, while the alkyl esters (**2** and **3**, R = methyl or ethyl) cleave the ring to produce the methylphosphonylated dimethyl urea derivative. The reaction is shown as involving proton abstraction from water since it is known that reactions of cyclic phosphate triesters may be subject to general base catalysis (26).

The reaction of **1** with hydroxide will produce a trigonal bipyramidal intermediate in which the methylene group of the phosphonylurea ring occupies an equatorial position, while the urea nitrogen adjacent to phosphorus occupies an apical position. Since hydroxide is expected to enter via the apical position, the leaving phenoxy group occupies an equatorial position and pseudorotation of the intermediate is necessary to allow the phenoxy group to occupy an apical position from which it will leave most readily. The pseudorotation places the methylene group of the ring in the apical position. Since the methylene group has low apicophilicity there is a considerable energy barrier to arriving at this intermediate. However, our results suggest that the energy available from relief of strain in forming the five-coordinated intermediate is sufficient to overcome this barrier. Alternatively, phenoxide could leave from the equatorial position of the original trigonal bipyramid. While avoiding the pseudorotation to the higher energy intermediate, the expulsion from the equatorial position must itself be higher in energy than expulsion from an apical position.

Holmes has presented an empirical scale for estimating the apicophilicity of substituents (1). This method gives the difference in free energies between otherwise identical trigonal bipyramidal phosphorus derivatives, in which a pair of apical and equatorial ligands are interchanged, as well as the energy of a square pyramidal transition state. The arbitrary starting free energy is 0.0 for carbon in an equatorial position. Exchange of carbon to an apical position is 7 kcal mol^{-1} endergonic. In general, nitrogen also is at a lower energy in an equatorial position but the difference is much smaller (0.8 kcal) so that the net cost is around 6 kcal mol^{-1}. However, since in the present case the nitrogen atom is also attached to a carbonyl group, its electronegativity is increased. If it is equal in electronegativity to oxygen, then the apical position is preferred by 1.3 kcal mol^{-1} and the interchange of ligands costs about 8 kcal mol^{-1}. Other factors considered by Holmes include changes in steric interactions, but in this case the differences are probably not significant. Thus, the pseudorotation introduces a high cost in terms of electronegativity preferences, which diminishes the apparent acceleration of the cyclic compared to acyclic compounds.

Hall and Inch have reported elegant stereochemical studies of hydrolysis reactions of cyclic phosphoramidic thiones (27). Their results show that retention of stereochemical configuration at phosphorus occurs even when rings are cleaved. These workers explain that thermodynamic apicophilicities, such as those derived by Holmes, cannot account for the reactivity patterns. They propose the concept of apicopotentiality, in which groups that have a thermodynamic preference for the apical position in stable trigonal bipyramids may prefer equatorial positions in transition states. Since these compounds are somewhat similar to those we have studied, the kinetic effects may require further consideration.

To identify the rate-determining step of the reaction, the pseudorotation must be taken into account. Addition of hydroxide to **1** produces the initial intermediate. The barrier to expulsion of hydroxide should normally be higher than that for phenoxide, given the lower basicity of the phenoxide ion. However, since an energetically unfavourable pseudorotation precedes expulsion of phenoxide, the barrier to expulsion of phenoxide must include the energy difference between the pseudorotamers. Thus the rate-determining step is associated with the high energy pseudorotamer. The possibilities for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

reaction of this intermediate are expulsion of phenoxide or pseudorotation back to the lower energy isomer. The heights of the barriers are not known but, since the pseudorotation involves no bond breakage and is in the thermodynamically favoured direction, we are inclined to identify the phenoxide expulsion step as being rate determining.

Effects of antiperiplanar electrons

The addition of hydroxide to **1** does not involve any of the possible postulated special antiperiplanar-oriented interactions between lone pairs of electrons of endocyclic ligands and the entering nucleophile (28, 29) (but see also ref. 24). The importance of such effects in the hydrolysis of acetamidines has recently been shown to be much less significant than originally was proposed (30). The lone pair of electrons on the nitrogen adjacent to phosphorus of **1** is in an orbital synperiplanar to the σ bond that is formed between the adding hydroxide ion and the phosphorus atom. After pseudorotation the lone pair of electrons on nitrogen is still clinal with respect to the σ bond between phosphorus and the leaving group. Since either formation of the intermediate or pseudorotation of the intermediate is rate determining, there is no possibility for stereoelectronic acceleration due to antiperiplanar lone-pair interactions, yet the rate is enhanced to the same degree as in systems in which such assistance has been postulated. However, we have seen that relief of ring strain in arriving at the transition state is the source of considerable acceleration of the rate of reaction of the cyclic ester, as is the case in methyl ethylene phosphate (23). Thus our results indicate that stereoelectronic effects due to antiperiplanar interactions between σ bonds and nonbonding electrons must contribute no more than a very small portion of any acceleration in other systems that show no greater rate enhancement than shown in the cyclic phosphonylurea esters.

The apparent twofold barriers to rotation about the exocyclic C—C bonds in $ArCH_2X$ (X = SH, SMe, S(O)Me, SO_2Me) compounds have been determined in CS_2 and in benzene-d_6, from the magnitudes of long-range proton–proton coupling constants. The work extends earlier studies of the systems X = F, Cl. Except for X = F, all of the title compounds have a low energy conformation in which the C—X bond is perpendicular to the plane of the benzene ring. The introduction of two *meta*-chlorine substituents leads to a 2 kJ/mol relative destabilization of this structure for X = F, Cl, SH. The trend in the rotational barriers associated with the sulfur substituents is SH, SMe ≪ S(O)Me, SO_2Me. *Ab initio* calculations, with geometry optimization at the STO-3G level for X = F, Cl, SH, reproduce the experimental results, and also the magnitudes of the rotational barriers. Quantitative PMO analyses of these *ab initio* wavefunctions have been employed to distinguish between "steric" and "other" interpretations, and reveal that the preferred conformation of X = F is determined by a first order perturbational effect, manifested in an electrostatic attraction between the heteroatom and a *syn*-periplanar *ortho*-hydrogen. For X = Cl, the PMO analysis suggests that a π_{Ar}–σ^*_{CX} interaction, analogous to the n–σ^*_{CX} interaction postulated as the origin of the anomeric effect in heterocyclohexanes, plays a dominant role. For X = SH, both π_{Ar}–σ^*_{CX} and σ_{CX}–π^*_{Ar} interactions are found; the latter is not possible in the anomeric effect itself. It is concluded that a benzylic anomeric effect exists, and that its magnitude, as a function of X, is S(O)Me, SO_2Me > Cl > SH, SMe > F.

GLENN H. PENNER, TED SCHAEFER, RUDY SEBASTIAN et SAUL WOLFE. Can. J. Chem. **65**, 1845 (1987).

Utilisant les amplitudes des constantes de couplage proton–proton à longue distance, on a déterminé les barrières binaires apparentes à la rotation autour des liaisons exocycliques C—C des composés $ArCH_2X$ (X = SH, SMe, S(O)Me et SO_2Me) dans le CS_2 et dans le benzène-d_6. Ces études sont une extension d'etudes antérieures sur des systèmes dans lesquels X = F et Cl. Excepté pour le cas où X = F, tous les composés mentionnés dans le titre présentent une conformation de basse énergie dans laquelle la liaison C—X est perpendiculaire au plan du noyau benzénique. L'introduction de deux chlores en positions *méta* conduit à une déstabilisation relative de 2 kJ/mol de cette structure pour X = F, Cl et SH. Cette tendance dans les barrières rotationnelles associées avec les substituants contenant du soufre est la suivante : SH, SMe ≪ S(O)Me, SO_2Me. Des calculs *ab initio* impliquant des optimisations de la géométrie au niveau STO-3G ont été réalisés sur les composés contenant X = F, Cl et SH et ils permettent de reproduire les résultats expérimentaux ainsi que les amplitudes des barrières à la rotation. On a utilisé des analyses quantitatives PMO de ces fonctions d'onde *ab initio* pour distinguer entre les interprétations *stériques* et *autres*; ces analyses révèlent que la conformation privilégiée pour X = F est déterminée par un effet de perturbation du premier ordre qui se manifeste par une attraction électrostatique entre l'hétéroatome et un hydrogène *ortho syn* et périplanaire. Pour X = Cl, l'analyse PMO suggère que l'existence d'une interaction π_{Ar}–σ^*_{CX}, semblable à l'interaction n–σ^*_{CX} qui a été suggérée comme étant à l'origine de l'effet anomère dans les hétérocyclohexes, joue un rôle dominant. Pour X = SH, on a trouvé des interactions π_{Ar}–σ^*_{CX} ainsi que σ_{CX}–π^*_{Ar}; ce dernier n'est toutefois possible dans l'effet anomère lui-même. On en conclut qu'un effet anomérique benzylique existe et que son amplitude, en fonction de X, est la suivante : S(O)Me, SO_2Me > Cl > SH, SMe > F.

[Traduit par la revue]

Introduction

The sixfold barrier to internal rotation in toluene is only 0.06 kJ/mol (1) and the preferred conformation is unknown. Semi-empirical INDO-MO computations give results consistent with this low barrier, and suggest that, in the conformation of lowest energy (**1**), the α C—H bond lies in the plane of the benzene ring (2). The same structure is obtained in geometry-optimized STO-3G calculations, but the internal barrier is found to be only 0.015 kJ/mol (3*a*). This is probably below the level of computational significance, as is the barrier computed at the 4-21G level (3*b*). In propylene, the internal barrier to rotation becomes relatively large and threefold. The most stable conformation (**2***a*) has a methyl hydrogen in the plane of the carbon–carbon double bond (4), while in 3-X-substituted propenes either X or H lies in this plane (5). For X = CH_3, the H-in-plane conformation (**3***a*) of ethylbenzene is 3.6 kJ/mol lower[2] in energy than the X-in-plane conformation (**3***b*), and the H-in-plane conformation (**4***a*) of 1-butene is more stable than the X-in-plane conformation (**4***b*) by 0.6–2.2 kJ/mol (6).

It seems reasonable to rationalize these conformational preferences in terms of the concept of "steric effects". In the language of perturbational molecular orbital theory (PMO theory) (7), **2***a* is more stable than **2***b* because the two-orbital four-electron destabilizing interaction between π_{CC} and π_{CH_3} (see **2***a*′ and **2***b*′), which makes the dominant contribution to the HOMO, is minimized in **2***a* (**2***a*′), mainly because of the effect of the secondary overlap depicted by the double-headed arrows. This destabilizing interaction, also known as "overlap

repulsion" (8) or "conjugative destabilization" (9), can be regarded as the MO counterpart of a "steric effect".

The question posed in the present work is whether any additional "conformational effects" (10) have to be invoked to account for the conformational preferences of benzyl-X compounds when X ≠ CH_3. For example, a perpendicular structure such as **5** contains a potential *two*-orbital *two*-electron *stabilizing* interaction between π_{Ar} and σ^*_{C-X}. To the extent that such an anomeric type "effect" (11) exists, it will enhance the conformational preference for this structure.

The magnitude of the anomeric effect, i.e., the conformational preference for **6***a* over **6***b*, is known to be solvent dependent (12), and to decrease for a given electronegative ligand X as the solvent becomes more polar. The conformational behaviour of benzyl fluoride and benzyl chloride is also solvent dependent (3*a*, 3*b*), but the trend is opposite to that observed in the anomeric effect. In CS_2, benzyl fluoride appears to prefer the conformation in which the C—F bond lies in the plane of the benzene ring; as the solvent is changed from CS_2 to DMSO or acetone, the perpendicular structure **5** undergoes relative stabilization by 2 kJ/mol. In benzyl chloride, the low energy conformation is **5**, and the rotational barrier increases from 8.8 kJ/mol in CS_2 to 11.2 kJ/mol in acetone.

Molecular orbital calculations with full geometry optimization at the STO-3G level (3*c*), and the constraint that the benzene ring remain a regular hexagon, reproduce these experimental observations (3*a*, 3*b*). In benzyl fluoride, the calculated low energy conformation has the C—F bond in the plane of the benzene ring, and is 1.6 kJ/mol more stable than **5**. In benzyl chloride, the calculated low energy conformation is **5**, and the rotational barrier is 8.6 kJ/mol. Since benzyl fluoride and benzyl chloride thus exhibit opposite conformational preferences which do not vary with solvent in the same manner as the anomeric effect, this might imply that stabilizing anomeric-type orbital interactions are not important in these compounds. That there is no anomeric effect in benzyl fluoride is evident from its planar conformational preference.

To probe these points further, the *ab initio* wave functions of benzyl fluoride and benzyl chloride were subjected to a quantitative PMO analysis (7). Since the calculated STO-3G dipole moment of planar benzyl fluoride is 1.06 D, and the 3-21G//STO-3G dipole moment is 1.96 D, compared to an experimental value of 1.77 D in benzene at 298 K (13), the analyses of benzyl fluoride were performed on the 3-21G//STO-3G wavefunctions. Extensive experience with quantitative PMO analysis has demonstrated that trends in total energies from conformation to conformation are reproduced by the trends in the orbital interactions that contribute to the HOMO's of these conformations (14), provided that the trend in the HOMO's parallels the trend in the total energies (15). This is the case whenever the properties of the fragment orbitals are dominated by second order perturbational effects (i.e., the familiar in-phase and out-of-phase combinations of interacting orbitals). However, strongly electronegative substituents can cause a lowering (pull-down effect) of the fragment orbital energies and, therefore, a lowering of the energies of the molecular orbitals. This is a first order perturbational effect (16), and it causes the HOMO energy and the total energy to vary in opposite directions for different conformations (17). When this first order effect becomes important the usual PMO analysis will fail, unless the contribution of electronegativity can be taken into account.

Interestingly, benzyl fluoride, which prefers the conformation that apparently maximizes "steric effects", belongs to this latter class of compounds. At the 3-21G//STO-3G level, the planar conformation is 18.5 kJ/mol lower in energy than the perpendicular conformation **5**, but its HOMO lies 24.3 kJ/mol *higher*. In contrast, for benzyl chloride at the STO-3G//STO-3G level, the perpendicular conformation **5** is 8.6 kJ/mol lower in energy than the planar conformation, and its HOMO energy is also lower, by 3.6 kJ/mol. The quantitative PMO analysis was, therefore, expected to reproduce the total energy trend of benzyl chloride, but not that of benzyl fluoride.

The orbital interactions that contribute to the HOMO's of the planar and perpendicular structures of the benzyl halides are depicted in Figs. 1 and 2, respectively. In each case, interactions **1** and **2** are destabilizing, and interactions **3**–**5** are stabilizing. In Fig. 1, π_1 is the in-phase combination of π_{CH_2} with p_X, π_2 is the out-of phase combination of π_{CH_2} with p_X, and π_3 is the out-of-phase combination of $\pi^*_{CH_2}$ with p_X. In Fig. 2, σ_1 is the in-phase combination of the $2a_1$ CH_2 orbital with p_X, σ_2 is the in-phase combination of the $1b_1$ CH_2 orbital with p_X, and σ^* is the out-of-phase combination of $1b_1$ with p_X. The results of the quantitative PMO analyses are summarized in Tables 1 and 2.

For benzyl fluoride, the PMO analysis predicts relative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12

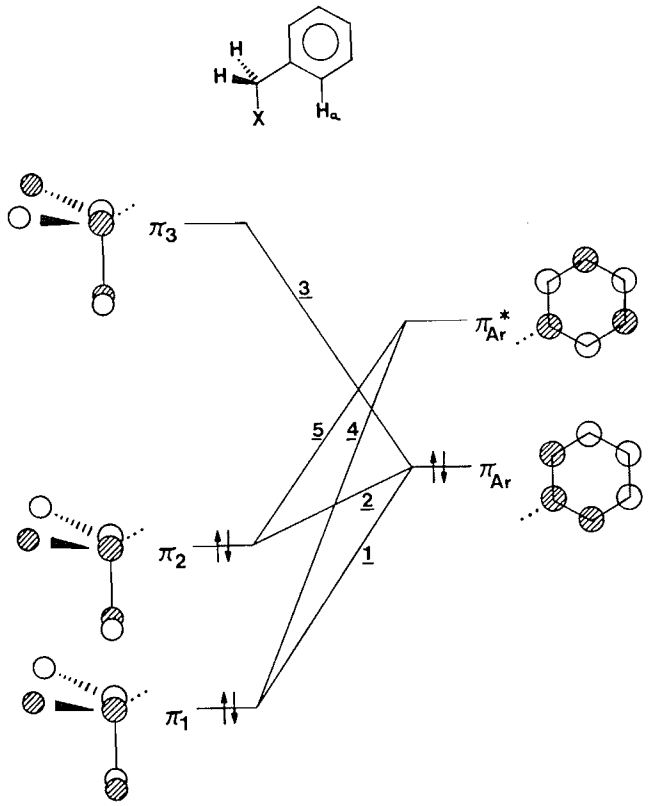

FIG. 1. Frontier orbital interactions between Ph··· and ···CH_2X in planar benzyl halides.

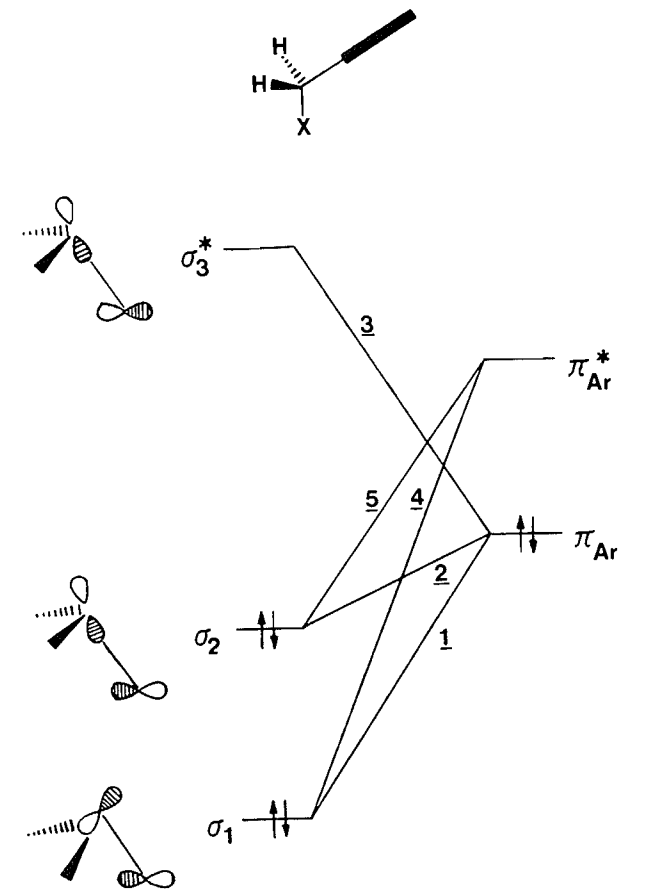

FIG. 2. Frontier orbital interactions between Ph··· and ···CH_2X in perpendicular benzyl halides.

destabilization of the planar conformation by 30.0 kJ/mol, in agreement with the trend in the relative energies of the HOMO's but in disagreement with the trend in the relative total energies. This result was expected, on the basis of the foregoing discussion. In addition, the relative destabilization of the planar conformation is caused almost entirely by the difference in the destabilizing interactions; there is no significant contribution from an anomeric-type interaction in the perpendicular conformation. The PMO analysis thus predicts, ignoring electronegativity, that the conformation of benzyl fluoride is determined by "steric effects", but, as we have seen, this leads to the wrong result.

The electronegativity effect is manifested, in the planar conformation, through an electrostatic interaction between the fluorine atom and H_a, the *ortho*-hydrogen *syn*-periplanar to this fluorine (see Fig. 1). From the net atomic charges on the fluorine (−0.401 electron) and on this hydrogen (+0.267 electron), and their internuclear distance (2.363 Å), the magnitude of the coulombic interaction is calculated to be 62.9 kJ/mol. When this interaction is taken into account in the analysis, the planar conformation now becomes more stable than the perpendicular conformation by 25.7 kJ/mol. This coulombic interaction, and not an anomeric-type effect is, therefore, the origin of the planar conformational preference of benzyl fluoride.

Benzyl chloride differs from benzyl fluoride in several respects. The PMO analysis predicts net stabilization of the perpendicular structure by 22.8 kJ/mol, in agreement with the trend in the relative energies of the HOMO's and also in agreement with the trend in the total energies. The coulombic interaction in the planar conformation is 8.2 kJ/mol; taking this interaction into account reduces the energy difference to 14.6 kJ/mol. Most importantly, the π_{Ar}–σ^* anomeric-type interaction makes a dominant contribution to the relative stabilization of the perpendicular conformation. The conformational preference of benzyl chloride may, therefore, be attributed to the anomeric effect associated with the presence of the Second Row substituent, chlorine.

These considerations lead to an interesting experimental situation for the series of X's SR, S(O)R, SO_2R. Assuming that the R group adopts the staggered orientation shown in **7***a* and **7***b*, the sulfide is expected to prefer the perpendicular conformation **7***b* if there is a benzylic anomeric effect associated with the Second Row substituent, sulfur. However, the sulfoxide and the sulfone may be either planar (**8***a*, **9***a*) or perpendicular (**8***b*, **9***b*), depending on the relative contributions of the electronegativity and benzylic anomeric effects.

The electronegativity effect in **8***a* and **9***a* originates in the O···H_a coulombic interaction. If this dominates, the relative stabilities of the perpendicular conformations will be sulfide > sulfoxide > sulfone.

The magnitude of the benzylic anomeric effect will increase progressively in the series **7***b* > **8***b* ≈ **9***b* because the energies of the σ^*_{C-X} orbitals decrease in this direction. For example, the quantitative PMO analyses of the full optimized 3-21G* structures of $^-CH_2SCH_3$, $^-CH_2S(O)CH_3$, and $^-CH_2SO_2CH_3$ (18) include a stabilizing n_C–σ^*_{C-X} interaction, and the energy of σ^*_{C-X} decreases from 0.350 au in the sulfide to 0.310 au (105.0 kJ/mol) in the sulfoxide and sulfone. Thus, if the benzylic anomeric effect dominates, the relative stabilities of the perpendicular conformations will be sulfide < sulfoxide ≈ sulfone.

The experimental objectives of the present work are, therefore, as follows: (*1*) to synthesize a series of compounds

TABLE 1. Orbital interactions in benzyl fluoride

Experimental

3,5-Dichlorobenzyl methyl sulfide

A solution of 3,5-dichlorobenzyl alcohol (1.71 g, 9.6 mmol) in dry pyridine (2.0 mL) was cooled to −40°C and treated dropwise, with stirring under nitrogen, with a solution of *p*-toluenesulfonyl chloride (2.86 g, 15 mmol, freshly recrystallized from petroleum ether (40–60°C)) in dry pyridine (8.0 mL). Stirring was continued at −40°C for 1 h after addition was complete, and the mixture was then poured onto ice–water (200 g), allowed to warm to room temperature, and extracted with ether (4 × 20 mL). The combined ether extracts were washed successively with 10% HCl (2 × 25 mL), 10% sodium carbonate (2 × 25 mL), and water, and dried ($MgSO_4$). Removal of the ether yielded an oil, which crystallized rapidly. This material was dissolved in dry benzene (10 mL) and treated, dropwise at 0°C, with a solution of sodium methylmercaptide, prepared by addition of sodium metal (0.21 g, 9.3 mg-atoms) to absolute methanol (5.0 mL), followed by addition of excess methanethiol and removal of the the excess mercaptan in a stream of nitrogen. When the addition of sodium methyl mercaptide was complete, the milky reaction mixture was stirred for 10 min, poured onto ice-cold 10% NaOH (50 mL), and extracted with ether (4 × 20 mL). The organic extracts were washed with 10% NaOH (1 × 20 mL) and water (3 × 20 mL), dried, and evaporated to yield 1.51 g of crude product. This was purified by chromatography on silica gel. Elution with petroleum ether – ethyl acetate (9:1) afforded 710 mg of colourless oil, R_f 0.57 (petroleum ether – ethyl acetate 9:1).

3,5-Dichlorobenzyl methyl sulfoxide

3,5-Dichlorobenzyl methyl sulfide (100 mg, 0.48 mmol) was dissolved in methylene chloride (3 mL), cooled to 0°C, and an ice-cold solution of *m*-chloroperbenzoic acid (98.1 mg, 0.48 mmol) in methylene chloride (4 mL) was added dropwise during 35 min. The mixture was washed successively with 5% sodium thiosulfate (10 mL), saturated sodium bicarbonate (10 mL) and water, and dried. Removal of the solvent afforded the sulfoxide, 87 mg, mp 83–84°C, R_f 0.11 (20% ethyl acetate – chloroform).

3,5-Dichlorobenzyl methyl sulfone

3,5-Dichlorobenzyl methyl sulfide (100 mg, 0.48 mmol) was dissolved in methylene chloride (3 mL) and a solution of *m*-chloroperbenzoic acid (206 mg, 1.01 mmol) in methylene chloride (4 mL) was added in three portions. The resulting suspension was stirred overnight and then extracted with 5% sodium thiosulfate (2 × 10 mL), saturated sodium bicarbonate (10 mL), brine (10 mL), dried, and

[b]Numbers in parentheses are standard deviations in the last significant figure.
[c]Although all observed peaks were assigned and the rms error is small, there are large correlations for some parameters, e.g. −0.506 for $^4J(H,CH_2)/^5J(H,CH_2)$; −0.808 for ν_2/ν_3; 0.831 for $\nu_2/^5J_{25}$; −0.817 for $\nu_2/^3J_{34}$; −0.827 for $\nu_3/^5J_{25}$; 0.856 for $\nu_3/^3J_{34}$; −0.952 for $^4J_{24}/^3J_{34}$. They arise because of the small chemical shift between the *ortho* and *meta* protons.

evaporated to give the sulfone, 110 mg, mp 124.5–125.5°C, R_f 0.41 (20% ethyl acetate – chloroform).

The preparation of samples for ^{1}H nmr analysis followed the procedure described previously in detail (19). Concentrations and solvents are given in the following sections. The cw methods were used for all but benzylthiol, again as described previously (20).

A typical procedure for the accumulation of ^{1}H nmr spectra at 300 MHz proceeded as follows. A wide sweepwidth survey spectrum was obtained in order to reference the spectrum with respect to TMS, and to obtain the locations of the aromatic and sidechain regions. Each spectral region was examined in detail, with sweepwidth and data region adjusted to given acquisition times of about 40 s. For example, the ring proton region of benzyl thiol was examined with 32 scans with a sweepwidth of 200 Hz and an acquisition time of 41 s, using 16K of memory. Zero-filling to 32K was followed by resolution enhancement using a Lorentz–Gauss transformation (LB = −0.11, GB = 0.6) to yield a frequency spectrum with linewidths at half-height near 0.05 Hz.

The STO-3G MO computations on benzylthiol employed the program MONSTERGAUSS (21) and were performed on an Amdahl 470 V8 system. Quantitative PMO analyses (7) were performed on the above structures using GAUSSIAN 80 (22).

Results and discussion

Spectral analyses

The ^{1}H nmr spectrum of benzylthiol was analyzed with the computer program NUMARIT (23), yielding the spectral parameters given in Table 3. The program LAME (24, 25) was used for the analysis of the ^{1}H nmr spectra of the compounds whose spectral parameters are listed in Table 4.

The analysis of the ^{1}H nmr spectrum of benzyl thiol (Table 3) gave low standard deviations of the spectral parameters. The peak widths were about 0.05 Hz. However, because the chemical shift between the *ortho* and *meta* protons was only 4.4 Hz and, because of the particular parameter combinations, $^4J(H,CH_2)$ and $^5J(H,CH_2)$ had a correlation coefficient of −0.51. Fortunately, the other important coupling constant, $^6J(H,CH_2)$, did not correlate significantly with other coupling or shift values.

The internal barrier in benzyl thiol

The long-range nuclear spin/spin coupling constants between methyl and ring protons in toluene over four, five, and six formal bonds have been written (19, 26–29) as

[e]For ring and methylene protons only.

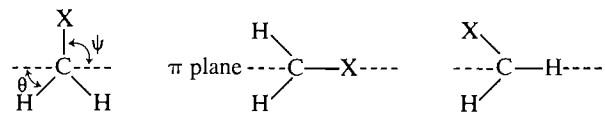
$$[1]\quad {}^4J(\text{Hz}) = -1.08\langle\sin^2\theta\rangle - 0.32\langle\cos^2\theta\rangle$$

$$[2]\quad {}^5J(\text{Hz}) = 0.336\langle\sin^2\theta\rangle + 0.322\langle\sin^2(\theta/2)\rangle$$

$$[3]\quad {}^6J(\text{Hz}) = -1.20\langle\sin^2\theta\rangle$$

In eqs. [1] to [3], $\langle\sin^2\theta\rangle$ is the expectation value of $\sin^2\theta$ and θ is the angle by which the α C—H bond twists out of the benzene plane. The coefficients of $\langle\sin^2\theta\rangle$ represent the hyperconjugative or σ–π electron contribution to the couplings, and will here be denoted by ^nJ (n = 4, 5, or 6). The coefficient of $\langle\sin^2(\theta/2)\rangle$ is the σ electron contribution to ^5J and is written as ^5J. For an n-fold internal barrier ($n \geq 2$), $\langle\sin^2(\theta/2)\rangle$ is 0.5. The term in $\langle\cos^2\theta\rangle$ can be regarded as a σ electron component of $^4J(1)$.

In toluene, the internal barrier to rotation is low and sixfold in nature. Consequently, the expectation values in eqs. [1] to [3] are all 0.5. Substitution to yield a benzyl compound leads to a predominantly twofold barrier, possibly with a significant fourfold contribution. The conformation of lowest energy may, in principle, be any of **10**–**12**.



10 θ = 30°, ψ = 90° **11** θ = 60°, ψ = 0° **12** ψ = 60°

The expectation values of $\sin^2\theta$ and $\cos^2\theta$ in eqs. [1] to [3] need no longer be 0.5, unless the internal barrier vanishes. It follows that, if the intrinsic perturbation of J^π and J^σ caused by the substituent, X, can be established, measurements of ^nJ allow determination of the expectation values. These can, in turn, be related to the parameters of a hindered rotor model, viz., the reduced moment of inertia, the temperature, and the internal barrier. Hence ^nJ yields internal barriers to rotation. For example, ^6J has been used in such studies (29) to yield twofold barriers for a variety of benzyl derivatives.

An early study of 3,5-dichlorobenzyl thiol in benzene-d_6 solution led to a barrier of 7.5 ± 0.8 kJ/mol, assumed to be

			Total	20.24

[a]The calculated total energy difference (STO-3G//STO-3G) is 7.75 kJ/mol in favour of the perpendicular structure.
[b]The electrostatic interaction is destabilizing.

twofold, for rotation about the exocyclic C_{sp^2}—C_{sp^3} bond (30). The chlorine substituents were necessary because the available 100 MHz ^{1}H nmr spectrum of benzyl thiol itself was too complex for a reliable spectral analysis.

If ^6J at $\theta = 90°$, $^6J_{90}$, can be determined, then $\langle\sin^2\theta\rangle$ follows immediately from eq. [3] and the observed value of ^6J in benzyl thiol, −0.402(1) Hz (Table 3). From tables of $\langle\sin^2\theta\rangle$ as a function of the internal barrier, the temperature and the reduced moment of inertia, the magnitude of the barrier and the low energy conformation follow directly (29, 31). Recent and detailed studies of benzyl chloride (13*b*), benzyl fluoride (13*a*), and derivatives of benzyl methyl ether (32) yield $^6J_{90}$ as −1.06, −0.95, and −1.02 Hz, respectively, for these compounds. On a scale on which the electronegativities of H, Cl, O—R, and F are 1.78, 3.0, 3.31, and 3.92, respectively, the electronegativity of SH is 2.5 (33–35) and yields $^6J_{90}$ as −1.12 Hz at $\theta = 90°$.

It follows that $\langle\sin^2\theta\rangle$ for benzyl thiol in CS_2 solution at 300 K is 0.359, that the preferred conformer has $\theta = 30°$, as in **10**, and that V_2 is 7.0 kJ/mol. The largest uncertainty in this barrier estimate arises from the uncertainty in $^6J_{90}$. Thus, if $^6J_{90}$ is −1.20 Hz, as in toluene (19), V_2 becomes 9.1 kJ/mol. Accordingly, one may conclude that the barrier to rotation about the C_{sp^2}—C_{sp^3} bond in benzyl thiol in CS_2 solution, *if twofold*, is 8.0 ± 1.0 kJ/mol.

Presumably the ^4J term in eq. [1] will suffer a reduction in magnitude similar to that of $^6J_{90}$, also a π electron transmitted coupling. On this assumption, together with a $\langle\sin^2\theta\rangle$ of 0.359, eq. [1] yields ^4J as −0.567 Hz, compared to the observed value of −0.559 Hz. If the $^4J^\sigma$ term is also reduced by a factor of 1.12/1.20, then ^4J becomes −0.554 Hz. On the other hand, if no reductions occur in $^4J^\pi$ and $^4J^\sigma$ relative to toluene, that is, $^6J^\pi$ is taken to be −1.20 Hz, then ^4J is calculated to be −0.575 Hz. These comparisons could be taken as affirmation of a $^6J_{90}$ near −1.12 Hz, were it not for the substantial correlation between ^4J and ^5J (Table 3). The correlation of −0.51 implies that the sum or difference of these two coupling constants is more reliable than are their individual values.

In fact, agreement between the experimental ^5J of 0.293 Hz and that computed from eq. [2] demands that $^5J^\sigma$ be increased by a factor of 1.12 over its value in toluene. A similar increase has been noted for benzyl chloride (13*b*), and it is known (27) that an electronegative substituent attached to the atoms in the coupling path increases $^5J^\sigma$. However, the correlation between the experimental ^4J and ^5J values casts some doubt upon these considerations.

Computed barrier in benzyl thiol

At the STO-3G level, seven energies, computed at 15° intervals of ψ, can be fit to a potential given by eq. [4]. The

$$[4]\quad V(\psi)/\text{kJ mol}^{-1} = 7.71 \pm 0.04 \sin^2(\psi + 90°) - 0.79 \pm 0.03 \sin^2 2(\psi + 90°)$$

errors are standard deviations at the 95% confidence level. During the computations, all bond lengths and bond angles were optimized, under the constraint that the carbon framework of the phenyl group remain a regular hexagon. The energy at $\psi = 90°$ was −659.644 913 au. The computed twofold component of 7.7 kJ/mol agrees with the apparent twofold barrier deduced from ^6J above.[3]

The theoretical barrier contains a fourfold component of 0.8 kJ/mol. Such a magnitude, ca. 10% of the twofold component, causes a change in $\langle\sin^2\theta\rangle$ of 0.006 at 300 K and, in principle, an error of nearly 0.5 kJ/mol in a twofold barrier of 8 kJ/mol. Evidently the ^6J value is rather insensitive to the presence of a fourfold component of this magnitude.

The computed potential yields a classical $\langle\sin^2\theta\rangle$ of 0.343 at 300 K, as compared to the 0.359 deduced on the basis that $^6J_{90}$ is −1.12 Hz and of 0.335 for $^6J_{90}$ = −1.20 Hz. Of course, the computation refers to an isolated molecule, whereas the coupling data refer to a molecule surrounded by small, nonpolar CS_2 molecules.

The internal barriers in 3,5-dichlorobenzyl-X (X = SH, SCH_3, $S(O)CH_3$, SO_2CH_3)

For X = SH, ^6J is −0.417(4) Hz (30), and for X = SCH_3, ^6J is −0.414(2) Hz, both in benzene-d_6 solution. The internal barrier is thus the same in the two compounds and, if $^6J_{90}$ is −1.12 Hz, the apparent V_2 is 6.1 kJ/mol (the value quoted for the thiol previously assumed the $^6J_{90}$ value for toluene). It has

[3]Similar close agreement between STO-3G barriers and those deduced from coupling constants in CS_2 solutions was found for benzyl chloride (13*b*) and benzyl fluoride (13*a*).

previously been found that 3,5-dichloro substitution stabilizes conformation **11** by ca. 2 kJ/mol in both benzyl fluoride (13*a*) and benzyl chloride (13*b*). Apparently, a similar effect is present in benzyl thiol.

In the sulfoxide and the sulfone, ^6J is $-0.33(1)$ Hz. The electronegativities of the $S(O)CH_3$ and SO_2CH_3 groups are rather larger than that of an SCH_3 group. Hence $^6J_{90}$ for these groups should be less than $|1.12|$ Hz (see above). An *upper* limit to an assumed twofold barrier for the sulfoxide and the sulfone follows as 20 kJ/mol because the *lower* limit of $\langle \sin^2 \theta \rangle$ is $-0.32/-1.12 = 0.286$. The electronegativity of SO_2CH_3 is given as 3.1 (36), implying a $^6J_{90}$ of -1.05 Hz. This means that $\langle \sin^2 \theta \rangle$ becomes 0.31(1), corresponding to an apparent V_2 of 12.6 ± 2.5 kJ/mol. An electronegativity of 2.8 for the $S(O)CH_3$ moiety implies a $^6J_{90}$ of -1.09 Hz and hence an apparent V_2 of 13.8 ± 2.5 kJ/mol. In view of the uncertainties in the nature of the barrier, it is best to conclude that the internal barriers in the sulfoxide an sulfone are substantially larger than in the sulfide or thiol.

Quantitative PMO analyses of benzyl mercaptan and the benzylic anomeric effects of benzyl methyl sulfoxide and benzyl methyl sulfone

The PMO analyses were performed on the STO-3G wavefunctions of benzyl mercaptan, and are summarized in Table 5. The planar conformation is seen to be more destabilized, as in the total energy calculations, and as is observed experimentally. Superficially, the perpendicular conformational preference appears to be the result of "steric effects", because the classical $\sigma^*-\pi_{Ar}$ anomeric-type interaction is relatively small. However, closer examination of Table 5 reveals that the $\sigma_1-\pi^*_{Ar}$ and the $\sigma_2-\pi^*_{Ar}$ stabilizing orbital interactions are not negligible in this molecule. This kind of interaction is not possible in the traditional anomeric effect, because the nonbonding heteroatom orbital associated with the $n-\sigma^*$ interaction in the anomeric effect has no antibonding counterpart. Consequently, whether the perpendicular conformational preference of a heteroatom X in benzyl-X can be considered to be the result of a benzylic anomeric effect is less certain in the case of benzyl mercaptan than in the case of benzyl chloride.

Interestingly, in the heterocyclohexanes, the anomeric effect of chlorine is significantly larger than that of SR. For compounds of type **6**, in CCl_4 solvent, the anomeric effect is ≥ 7.5 kJ/mol for X = Cl (37), and 1.46 kJ/mol for X = SCH_3 (38). When the ring heteroatom is sulfur, the anomeric effect is 7.32 kJ/mol for X = Cl, and 1.76 kJ/mol for X = SEt (39).

In view of the borderline benzylic anomeric effect calculated to exist in benzyl mercaptan, and the present experimental findings that $ArCH_2SH$ and $ArCH_2SCH_3$ exhibit similar rotational behaviour, the much greater perpendicular conformational preferences of the sulfoxide and sulfone must be attributed to an enhancement of a benzylic anomeric effect in these latter cases. Unfortunately, such systems are just beyond the current capabilities of reliable *ab initio* computations.

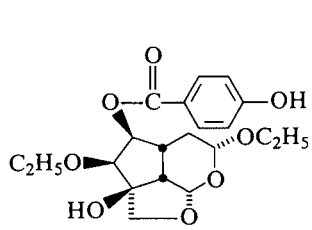
Introduction

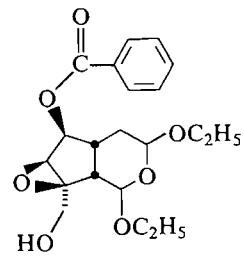
The spruce budworm, *Choristoneura fumiferana*, is a pest that infests North American fir and spruce forests. In Eastern Canada the larvae of the budworm begin to feed on the buds or the newly opened shoots of the host tree in mid-May, while they consume the greatest amount of foliage during their sixth instar in late June. During a budworm outbreak, this inflicts huge damage to the forest resource, and has devastating consequences for the pulp and paper industry. Efforts to control the spruce budworm up to now have relied on the spraying of insecticides. A strategy that has been suggested for pest control is to employ antifeedants to interfere with the feeding behaviour of insects. The term antifeedant is defined as a chemical that inhibits feeding but does not kill the insect directly, i.e., the insect remains near the treated leaves and dies through starvation (1). The approach is attractive since, in principle, it protects current year foliage while leading indirectly to budworm mortality through use of an agent that may not be generally toxic in the conventional sense. The feeding preferences of spruce budworm larvae have been studied (2). In eastern Canada, balsam fir (*Abies balsamea*) is the most favorable host species, followed by white spruce (*Picea glauca*), red spruce (*Picea rubens*), and black spruce (*Picea mariana*).

In screening programs, a number of natural products have been found to have antifeedant activity against spruce budworm (3, 4). Recently, Chang and Nakanishi reported their studies on extracts of the leaves of 40 different trees that are not attacked by the budworm (4). The extracts were assayed for antifeedant activity using budworm fed on artificial diets with or without the extract. This led to the isolation of the active component from the leaves of *Catalpa speciosa* Warder (Bignoniaceae). They named the compound specionin and proposed its structure to be **1** on the basis of its spectroscopic data (4). However, a chemical synthesis of **1** was recently reported (5) and comparison of spectral data revealed that it was not identical with the natural compound. An alternative structure, **2**, was proposed for specionin and recently synthesized (5).

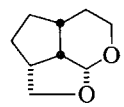
A common structural feature of many antifeedants known to date, including azadirachtin (6) and clerodin (7), is that they are polyoxygenated compounds. However, there has been little study of structure–activity relationships with respect to antifeedant activity.



1



2



3

The present study led to development of a facile method to obtain the tricyclic structure **3** and several polyoxygenated compounds thereof. At least one of these compounds was found to have definite antifeedant activity against spruce budworm larvae.

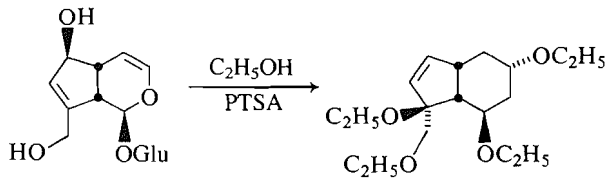
While the structures of **1** and **2** are relatively simple so that they are amenable to total synthesis (5), we feel that a totally synthetic approach is not likely to yield compounds in quantities sufficient for large-scale bioassay either in the laboratory or eventually in the field. Our strategy is to effect the syntheses of these compounds starting from iridoid natural products, which are abundant. Furthermore, since the natural antifeedant is likely to be optically active, optical resolution or asymmetric synthesis would be required in a totally synthetic approach. On the other hand, it may be possible to correlate configurationally one of the iridoid natural products with specionin.

As a starting material, we have chosen aucubin (**4**), an iridoid glycoside. It is present to the extent of ~1% of fresh plant weight in *Aucuba japonica* (8, 9) and can be extracted and purified in large quantities (9).[1] In fact, aucubin has been used as starting material for the synthesis of optically active prostaglandinoids (9, 10).

Derivatives from aucubin

The reaction of aucubin with CH_3OH–HCl has been reported

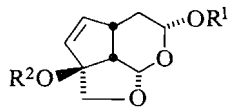
[1]We thank Professor Berkowitz for providing us with the procedure for the extraction of aucubin.



4 5

in the literature (11, 13). Normally, aucubin is degraded extensively under acidic conditions. After trying a number of reaction conditions (BF_3·etherate, HCl, H_2SO_4, etc.), we found that ethanolysis of aucubin with catalytic amounts of *p*-toluenesulfonic acid (PTSA) at room temperature for 11 days gave compound **5** in relatively good yield (~60%). The structure of **5** was based on spectroscopic evidence, in particular, 2D nmr. The absence of the glucose moiety was evident from its tlc mobility and the absence of OH absorption in its ir spectrum. The presence of four ethoxy groups was deduced by its chemical ionization mass spectrum (MH^+ = 315 and base peak at m/z = 269, M − OC_2H_5) and confirmed by the four ethoxy methylene carbons in the ^{13}C nmr spectrum (Table 1). The migration of the double bond is the result of an acid-catalysed allylic rearrangement. In normal allylic rearrangement under acidic conditions, the thermodynamically more stable allylic isomer, which usually is the more substituted double bond isomer, predominates (12). In the present as well as previous cases (11, 13), it is surprising that the less substituted double bond isomer is the only isolable product. The only (speculative) explanation that we can offer at this time is that the ethoxy group, being at C-8 instead of at C-6, can cooperate with the other ethoxy groups in the molecule to form hydrogen bonds more effectively with the solvent or with the acid.

If the ethanolysis of aucubin was carried out with boron trifluoride-etherate as the catalyst, compound **6** was also obtained in addition to **5**. Compound **6** has no hydroxy group according to its ir and ^1H nmr spectra (Table 2). It has only two ethoxy groups, evidenced by its ^{13}C nmr spectrum. The ^1H nmr spectrum of **6** is in agreement with those published for **7***a* and **7***b* (5). Compound **6** could also be prepared from the cyclization of **5**. Thus, when **5** was subjected to *p*-toluenesulfonic acid treatment in methylene chloride instead of ethanol, compound **6** was obtained in moderate yield.

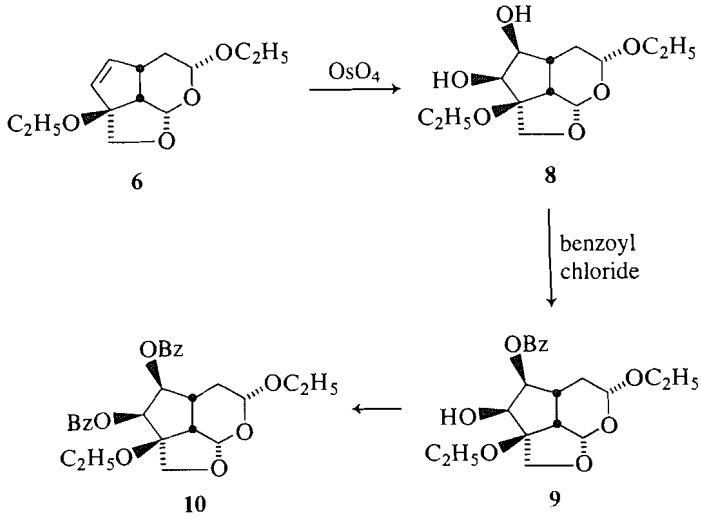


6: $R^1 = R^2 = C_2H_5$
7a: $R^1 = R^2 = H$
7b: $R^1 = C_2H_5$, $R^2 = H$

The double bond of **6** can be further functionalized by hydroxylation or epoxidation to give polyoxygenated derivatives. Oxidation of **6** with osmium tetroxide/pyridine at the less hindered *exo* face gave the diol **8**. Benzoylation of **8** gave the monobenzoate **9** first, then the dibenzoate **10**. Epoxidation of the double bond with *m*-chloroperbenzoic acid gave the epoxide **11**, again from the *exo* face. Treatment of **11** with *p*-toluenesulfonic acid monohydrate gave the tetracyclic alcohol **12**. The structure of **12** was assigned on the basis of spectroscopic data. The alternative structure **12′** was ruled out on the basis of ^1H 2D-HOMO correlation nmr spectrum which showed that H-7 coupled with the hydroxy proton (Fig. 1).

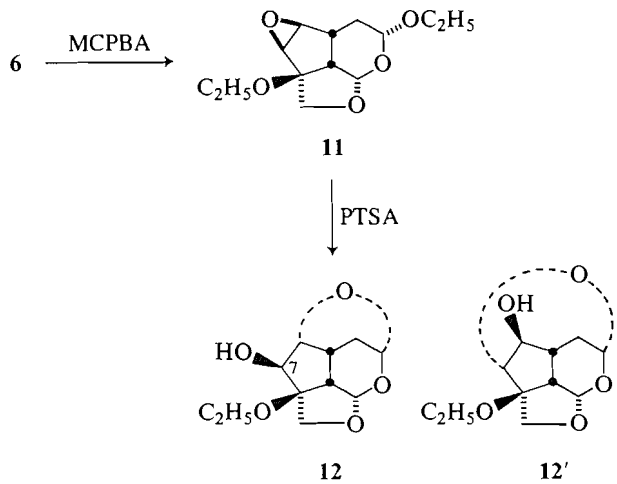
Ethanolysis of catalposide

Both **1** and **2** are structurally similar to catalposide (**13**), the major iridoid compound from the *Catalpa* species. Indeed, Chang and Nakanishi (4) have suggested that specionin could be an artifact derived from catalposide during ethanol extraction.



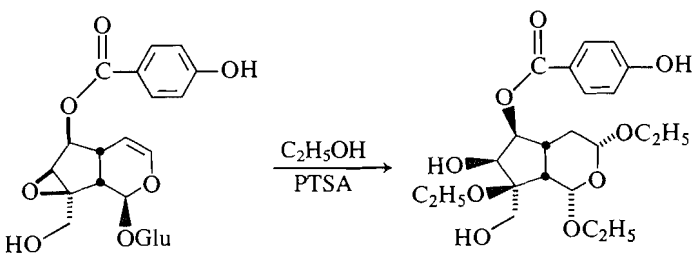
6 8 10 9

In view of the ease of ethanolysis of aucubin, we also attempted the ethanolysis of catalposide. However, in spite of repeated attempts under different conditions, catalposide either resisted ethanolysis or suffered extensive degradation. Using the mildest conditions (catalytic amount of PTSA in ethanol at room



11 12 12′

temperature for 60 days), we were able to isolate compound **14** in very poor yield. Every effort to isolate an intermediate with the epoxide moiety still intact was unsuccessful. It is interesting to note that in the opening of epoxide to give **14**, the ethanol attacked at the more hindered carbon (C-8) with resultant *cis* stereochemistry. The positions of the hydroxyl groups at C-7 and C-10 were assigned by ^1H nmr of **14** in DMSO-d_6, which



13 14

showed the appropriate coupling between the hydroxyl protons and the adjacent methine (H-7) and methylene (H-10) protons. The relative stereochemistry was determined by nuclear Overhauser effects in that irradiation of H-7 resulted in enhancement of H-6, H-10, and the OH at C-7. Presumably, under the acidic conditions used, epoxide opening proceeded via an S_N1-like

TABLE 3. Mean development stage (instar) of spruce budworm larvae after 15 days at 26°C

Diet	Mean instar[a]
Treated control	5.28
Untreated control	5.12
Compound **13**	5.32
Compound **15**	5.12
Compound **9**	4.40*
Compound **10**	5.32
Compound **11**	4.36*
Compound **12**	4.96
Compound **14**	4.60

[a]Maximum = 6.00 (i.e., all larvae 6th instars).
*Means significantly different from treated control ($P \leq 0.05$, Mann–Whitney U-test).

mechanism with the ethanol molecule attacking the carbonium ion from the *exo* face.

Biological assay

Compounds **9**, **10**, **11**, **12**, and **14** were tested for antifeedant activity against spruce budworm larvae. As control, catalposide **13** was also included. To exclude the possibility that specionin could be an artifact derived from catalposide during ethanol extraction, a sample of catalposide was treated with ethanol for 30 days, and then the solvent was removed. The residue, referred to as ethanol-treated catalposide (sample **15**), was also bioassayed.

Two different bioassays were conducted (see Experimental), both of which involved feeding laboratory-colony spruce budworm larvae on artificial diet (14) containing 0.2% (wet weight) of the test compounds. The first assay showed that the development of larvae reared from second instar on test diets was significantly retarded by compounds **9** and **11**, but not by the other compounds (Table 3). Recognizing that reduction in development rate could be caused by factors other than reduced feeding, a second assay was devised to provide a true reflection of the amount of food ingested by 6th (final) instar larvae. In this test it was found that only compound **11** caused significant reduction in frass produced and moth weight for both male and female insects (although **10** showed significant reductions for males alone) (Table 4).

It is interesting to note that none of the catalposide-derived samples (**13**, **14**, and **15**) showed significant antifeedant activity at the concentration tested. This suggests that specionin is not likely to be an artifact resulting from the ethanolysis of catalopside, since Nakanishi reported that specionin is active at the ca. 50–100 ppm level.

The definite biological activity observed for compound **11** (and possibly compound **10**) provides a lead for further study in the structure–activity relationship of spruce budworm antifeedants.

Experimental

Infrared spectra were obtained on thin films on NaCl plates for liquids and in solution in 0.1-mm cells for solids, using a Perkin–Elmer 297 spectrophotometer. The nmr spectra were recorded on a Varian XL-300 or XL-200 nmr spectrometer. Mass spectra were taken on a Dupont 492B or HP-5980A mass spectrometer. Column chromatography was performed on silica gel 60 (Merck). Elemental analyses were performed by the Institute of Elemento-organic Chemistry, Nankai University, Tianjin, China.

Aucubin and catalposide were isolated according to literature procedure (9).

Ethanolysis of aucubin

A solution of 200 mg of aucubin, 10 mg of *p*-toluenesulfonic acid (PTSA) monohydrate, and 20 mL of C_2H_5OH was stirred at room temperature. Thin-layer chromatography was used to follow the reaction. The colour of the reaction mixture changed from blue to green, brown, and finally yellow. After 11 days, the solution was neutralized with aqueous $NaHCO_3$, filtered, and evaporated under vacuum. Elution on SiO_2 flash chromatography with a mixture of ethyl acetate and hexane (1:2) afforded 0.1 g of compound **5**. (yield 58%); $[\alpha]_D^{22}$ 115.5° (*c* 2.1, $CHCl_3$); ms (CI) (*i*-Bu): 315 (0.3), 314 (0.2), 269 (100), 223 (13). *Anal.* calcd. for $C_{17}H_{30}O_5$: C 64.94, H 9.62; found: C 64.60, H 9.31.

*Cyclization of compound **5** to the tricyclic compound **6***

To 200 mL of CH_2Cl_2 was added 1.2 g of **5** and 0.1 g of PTSA monohydrate. The solution was stirred for 10 h at room temperature. After neutralization with $NaHCO_3$ the mixture was filtered and evaporated under vacuum. Elution of the residue on SiO_2 column flash chromatography with a mixture of ethyl acetate and hexane (1:2) gave 0.60 g of compound **6** as a colorless liquid; $[\alpha]_D^{22}$ 158.4° (*c* 1.9, $CHCl_3$); ms (CI, *i*-Bu): 241 (3), 240 (2), 239 (14), 211 (100), 195 (30). *Anal.* calcd. for $C_{13}H_{20}O_4$: C 64.98, H 8.39; found: C 64.52, H 8.11.

*Epoxidation of compound **6***

To a solution of 0.5 g of **6** in 20 mL of benzene was added 0.2 g of *m*-chloroperbenzoic acid (MCPBA). After stirring for 10 h at room temperature, another 0.2 g of MCPBA was added. Stirring was continued for 5 h at 50–60°C. Additional MCPBA (2 × 0.2 g) was added after each 5 h stirring at 50–60°C. The mixture was washed with aqueous $NaHCO_3$ and dried with $MgSO_4$. It was filtered and evaporated under vacuum. The residue was eluted on SiO_2 column flash chromatography with a mixture of ethyl acetate and hexane to give 0.23 g of **11** as a waxy low-melting white solid; $[\alpha]_D^{22}$ 126.7° (*c* 2.0, $CHCl_3$); ms (CI, *i*-Bu): 257 (14), 256 (2), 255 (14), 211 (100). *Anal.* calcd. for $C_{13}H_{20}O_5$: C 60.92, H 7.87; found: C 60.51, H 7.38.

*Hydroxylation and benzoylation of compound **6***

To 0.11 g of **6** in 10 mL of pyridine was added 0.13 g of OsO_4 in 10 mL pyridine at 5°C. The mixture was kept for 2 h, then at room temperature for 40 h. The mixture was evaporated under vacuum. The residue was eluted on SiO_2 flash chromatography with a mixture of ethyl acetate and hexane (1:1) to give 0.065 g of the diol **8**. The diol was benzoylated without further purification.

To 0.05 g of **8** and 1.0 g of pyridine in 5 mL of $CHCl_3$ was added a solution of 0.03 g benzoyl chloride in 5 mL of $CHCl_3$, dropwise at room temperature. The mixture was stirred at room temperature for 48 h. It was evaporated under vacuum and the residue was purified by silica gel flash chromatography with a mixture of ethyl acetate and hexane (1:1).

Compound **9** (0.03 g) was obtained as the monobenzoate; $[\alpha]_D^{22}$ −18.7° (*c* 1.8 $CHCl_3$); ms (CI, *i*-Bu): 378 (1), 377 (4), 333 (23), 315 (29), 211 (100). *Anal.* calcd. for $C_{20}H_{26}O_7$: C 63.48, H 6.93; found: C 63.71, H 7.23.

If benzoylation was carried out under identical conditions but with excess benzoyl chloride (0.50 g), the dibenzoate **10** was obtained. It had $[\alpha]_D^{22°C}$ −65.05° (*c* 1.5, $CHCl_3$); ms (CI, *i*-Bu): 483 (2), 481 (2), 437 (74), 315 (100). *Anal.* calcd. for $C_{27}H_{30}O_8$: C 67.20, H 6.27; found: C 67.06, H 6.05.

*Acid catalysed reaction of epoxide **11***

To 0.05 g of **11** in 15 mL of ether, 0.01 g of PTSA monohydrate was added. The solution was refluxed for 3 h, then neutralized with aqueous $NaHCO_3$. The ether solution was dried and evaporated under vacuum. The residue was purified on SiO_2 flash chromatography with a mixture of ethyl acetate and hexane to 0.035 g of compound **12**. It had $[\alpha]_D^{22}$ 39.4° (*c* 3.5, $CHCl_3$); ms (EI): 228 (8), 211 (5), 198 (33), 181 (29), 169 (48), 28 (100). *Anal.* calcd. for $C_{11}H_{16}O_5$: C 57.89, H 7.07; found: C 57.99, H 7.37.

Ethanolysis of catalposide

To a solution of 0.5 g of catalposide in 30 mL of C_2H_5OH, 0.05 g of PTSA monohydrate was added. The mixture was stirred at room

[c]Means significantly different from treated control ($P \leq 0.05$, t-test).

temperature for 60 days. Thin-layer chromatography was used to follow the reaction. The mixture was neutralized with $NaHCO_3$, filtered, and evaporated under vacuum. The residue on elution from Al_2O_3 column by flash chromatography with a mixture of ethyl acetate and hexane (1:2) gave 0.03 g of compound **14**. It had $[\alpha]_D^{22°C}$ −61.6° (c 2.75, $CHCl_3$); ms (CI, i-Bu): 439 (1), 423 (2), 395 (21), 349 (100).

Bioassays

Diet containing 0.2% (wet weight) of the test compounds was prepared by treating lyophilized diet (14) with a solution of the compound, usually in methylene chloride, and then removing the solvent completely at 30°C on a rotary vacuum evaporator. The residual powder was rehydrated to 80% water content with 0.4% aqueous potassium sorbate solution (fungicide). Control diets were treated as above with solvent alone, or were untreated. In the first assay, newly-emerged 2nd-instar larvae were reared individually at 26°C, 17-h photoperiod, 25 replicates per test compound. After 15 days, the larvae were sacrificed and their mean development stage determined (Table 3). In the second assay, newly-moulted 6th-instar larvae were reared under the same conditions. At pupation, the frass were dried (60°C) and weighed. Moths were allowed to emerge and were sacrificed after 24 h, dried, and weighed (Table 4).

Acknowledgement

We thank Professor J. T. Edward for samples of aucubin and catalposide. Financial support from NSERC and FCAC are gratefully acknowledged.

Synthesis of carbocycles from ω-substituted α,β-unsaturated esters via radical-induced cyclizations

STEPHEN HANESSIAN,[1] DALJIT S. DHANOA, AND PIERRE L. BEAULIEU
Department of Chemistry, Université de Montréal, Montréal (Qué.), Canada H3C 3J7

Received December 16, 1986

This paper is dedicated to Professor John T. Edward

STEPHEN HANESSIAN, DALJIT S. DHANOA, and PIERRE L. BEAULIEU. Can. J. Chem. **65**, 1859 (1987).

The intramolecular radical cyclization of ω-bromo α,β-unsaturated esters for the synthesis of carbocyclic compounds is described. The effect of carbon chain substituents, the bulk of the ester group, and the olefin geometry were examined. The highest level of stereoselectivity (*trans*/*cis*: 9/1) was achieved with the *Z* ester via an *exo* cyclization. The sequential radical cyclization of a dihalodienoate to give a *cis*-fused bicyclic structure is also described.

STEPHEN HANESSIAN, DALJIT S. DHANOA et PIERRE L. BEAULIEU. Can. J. Chem. **65**, 1859 (1987).

Nous décrivons l'utilisation d'une réaction de cyclisation radicalaire intramoléculaire des esters ω-bromo α,β-insaturés pour la synthèse de composés carbocycliques. Nous avons étudié les paramètres suivants : la substitution de la chaîne, l'encombrement stérique dû à l'ester ainsi que la géométrie de la double liaison des précurseurs radicalaires. Le plus haut degré de stéreosélection (*trans*/*cis*: 9/1) fut obtenu avec l'ester α,β-insaturé *Z*. *exo*. De plus, la cyclisation radicalaire en série d'un dihalogéno dièneoate donne un produit bicyclique.

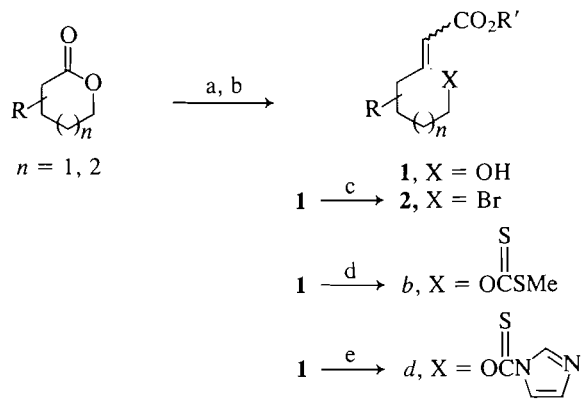
The utilization of radical reactions for carbon–carbon bond formation in synthetic organic chemistry has recently attracted considerable interest (1–10). The increasing popularity of radical-based synthetic methods in organic synthesis is attributable to the mild reaction conditions and their compatibility with a number of unprotected functional groups. Despite these recent applications in synthesis (1–10), the formation of carbocycles from α,β-unsaturated esters via intramolecular radical cyclization of esters has received relatively little attention. As part of a program dealing with radical-mediated processes in this laboratory (2, 3), we recently described an efficient use of the intramolecular Michael-type cyclization of a vinyl radical to an α,β-unsaturated ester for the synthesis of the hexahydrobenzofuran subunit of the avermectins (2). We now report our studies on the stereochemical and synthetic aspects of the radical-induced intramolecular cyclization of ω-substituted α,β-unsaturated esters for the production of carbocyclic systems.

Preparation of intermediates

The radical precursors **2** for the intramolecular cyclization were prepared from the corresponding lactones[2] using a three-step reaction sequence outlined in Scheme 1. The lactones were reduced with diisobutylaluminum hydride (DIBALH) to give the corresponding lactols, which were further treated with carboalkoxymethylenetriphenylphosphorane (see, for example, ref. 11) to afford the ω-hydroxy α,β-unsaturated esters **1**. The hydroxyesters **1** were converted to the desired precursors **2** by the action of carbon tetrabromide and triphenylphosphine in dichloromethane (12). Treatment of the hydroxyester **1***a* with sodium hydride, carbon disulfide, and methyl iodide in diethyl ether gave the desired xanthate ester (**2***b*, Table 1) (13). Thiocarbonylimidazolide (**2***d*, Table 1) was obtained by refluxing the corresponding hydroxyester **1***d* with *N*,*N*′-thiocarbonyldiimidazole in dichloromethane (14). The (*R*)-*O*-methylmandelic ester (**2***h*, Table 1) was prepared from the corresponding methyl ester **2***g* by hydrolysis to the corresponding acid derivative, conversion to the acid chloride, and condensation with (*R*)-*O*-methylmandelic alcohol in the presence of pyridine and trace amount of 4-*N*,*N*-dimethylaminopyridine (DMAP).



(a) DIBALH, toluene, −78°C; (b) $Ph_3P{=}CHCO_2R'$, cat. $PhCO_2H$, CH_3CN, reflux; (c) Ph_3P, CBr_4, CH_2Cl_2; (d) NaH, CS_2, CH_3I; (e) *N*,*N*′-thiocarbonyldiimidazole, CH_2Cl_2, reflux

SCHEME 1

Haloesters **2***l* and **2***m* were prepared in a straightforward manner. Baeyer–Villiger oxidation of the known 2-(2′-chloroethyl)cyclopentanone (15) with *m*-chloroperbenzoic acid (MCPBA) led to the expected δ-lactone, which was reduced with DIBALH to a mixture of chlorolactols. These halolactols were then heated with carbomethoxymethylenetriphenylphosphorane in acetonitrile to produce the desired α,β-unsaturated ester **2***l*, which in turn was transformed to the bromochloroester **2***m* by treatment with Ph_3P–CBr_4 in dichloromethane (12). Dihalodienoate **2***n* was prepared from ethylacetoacetate according to standard literature methods (see experimental section).

The conjugate radical cyclization of α,β-unsaturated esters to carbocyclics was performed by the slow addition of a benzene or toluene solution of *n*-Bu_3SnH or Ph_3SnH and azobisisobutyronitrile (AIBN) to refluxing solutions of the radical precursors **2** in the same solvent. The corresponding carbocyclic compounds were formed in good to excellent yields (Table 1). The *cis*/*trans* ratios of the cyclized products were determined by high field ^1H and ^{13}C nmr spectroscopic analysis.

Discussion

Several notable features of the intramolecular radical-induced cyclization of ω-halo α,β-unsaturated esters are revealed by

[1]Author to whom correspondence may be addressed.

[2]Lactones were obtained by Baeyer–Villiger oxidation of known ketones.

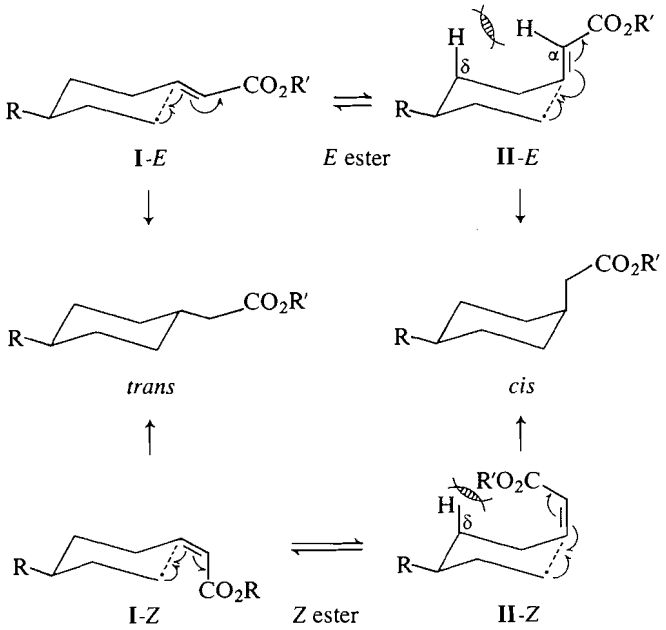

SCHEME 2

the data presented in Table 1. The radical ring closures to carbocycles occurred in 5- or 6-*exo* modes (16) without contamination with the possible *endo* ring closure products to any detectable extent as evidenced by ^{1}H nmr analysis (5, 17). The unsaturated haloester **2***l* failed to cyclize in the 7-*exo*- or 8-*endo* mode, indicating the much slower rate of cyclization compared to the reduction of the C—Cl bond (entry 12). The influence of the position of C-alkyl substituents on the carbon chain of the radical precursors **2** seems to be modest and favours the *trans*-cyclized products (entries 5–7). The stereochemical outcome of the intramolecular radical cyclization appears to be unaffected by the increase in the steric bulk of the carbon chain substituents, as indicated by the unchanged *cis*/*trans* product ratio in going from the C-methyl to the C-*tert*-butyl series (entries 7 and 9). The stereoselectivity can be somewhat improved by increasing the bulk of the ester group of the radical precursors (entries 9 and 10).

Finally, examination of the effect of the C=C geometry of the unsaturated haloesters proved useful in enhancing the stereoselectivity of radical cyclization (7). While the *E*-bromo ester **2***j* gave a 1:3 mixture of *cis*/*trans* products, the *Z*-bromo-ester **2***k* afforded a 1:9 mixture of *cis*/*trans* cyclized *tert*-butylesters (entries 10 and 11). The *trans* stereoselectivity in those cases that produce 1,4-disubstituted cyclohexanes may be rationalized according to the relative stabilities of the respective transition states as shown in Scheme 2.

Of the two chair-like conformations corresponding to the transition states of the *E* and *Z* esters, those derived from **I**-*E* and **I**-*Z* are expected to be of lower energy than their relatively less stable conformers **II**-*E* and **II**-*Z* (Scheme 2). The unfavourable destabilizing nonbonded interactions between the α-vinylic H and the pseudo-axial H at the δ-carbon that are present in **II**-*E* (absent in **I**-*E*) may account for the stereoselectivity observed in favour of the *trans* product. The nonbonding interactions between the bulky ester group and the pseudo-axial H at the δ-carbon of the *Z* ester are more severe in **II**-*Z* (cf. **II**-*E* and **II**-*Z* in Scheme 2), thus giving rise to higher *trans* selectivity in the 6-*exo* cyclization of *Z* esters (entry 11, Table 1). Another noteworthy feature in the cyclizations to form six-membered rings was the apparent absence of intramolecular hydrogen abstraction.[3]

We reasoned that extension of the above radical cyclization method to sequential radical cyclization would constitute an efficient methodology for the construction of bicyclic or tricyclic systems commonly encountered in natural product synthesis (for serial radical cyclizations, see ref. 10). The successful realization of this strategy required chemoselective generation of the radical in substrates such as dihalodienoate (**2***n*, Table 1). The chemoselective radical generation was tested on a simpler system (**2***m*, Table 1). Treatment of **2***m* with Ph_3SnH/AIBN in benzene afforded the expected 5-*exo* cyclized chloroester **3***m* as a 7:3 stereoisomeric mixture (presumably the *cis* isomer as the major product) in 66% yield. Having developed the conditions effective for chemoselective radical generation in the dihaloester **2***m*, the method was applied to the substrate dihalodienoate **2***n* designed for the sequential radical cyclization. When solutions of Ph_3SnH and AIBN in benzene were added to a refluxing benzene solution of **2***n* over 10 h, using a syringe pump, intramolecular radical cyclization (5-*exo*) occurred to give the expected monocyclic chloroester **3***n* as a 19:1 mixture of olefinic esters in 60% yield. Notably, the 5-*exo* ring cyclization led to the deconjugated ester. In the case of sequential cyclization, tratment of **2***n* with Ph_3SnH/AIBN in benzene for 10 h at 90°C, followed by its treatment with Ph_3SnH/AIBN in toluene for 10 h at 120°C, led to the *cis*-fused bicyclic ester **4** in good yield (entry 15).

In summary, the radical-induced intramolecular Michael type cyclization of unsaturated esters, in which the ester group acts as an activating group, constitutes a preparatively useful method for the synthesis of five- and six-membered mono- and bicyclic carbocyclic systems, which are ubiquitous in synthetic organic and natural products chemistry.

Experimental

The ^{1}H nmr spectra were recorded on Varian EM360A and WH-400 nmr spectrometers with TMS as internal standard. The ^{13}C nmr spectra were recorded on WP80 and WH-400 spectrometers. Infrared spectra were recorded on a Perkin–Elmer 781 infrared spectrophotometer. Low resolution mass spectra were recorded on a VG-1212 mass spectrometer and high resolution mass spectra were recorded on a Kratos MS50TCTA instrument. Flash column chromatography was done on silica gel using ethyl acetate – hexane as eluents.

*General procedure for the preparation of ω-hydroxy α,β-unsaturated esters, **1***

A solution of lactol (5 mmol), carboalkoxymethylenetriphenylphosphorane (6 mmol), and a catalytic amount of benzoic acid in acetonitrile (10 mL) (or dimethoxyethane or toluene or methanol) was refluxed (11). Upon completion of the reaction (tlc monitoring) the solvent was removed under reduced pressure and the residue was flash chromatographed (30% EtOAc in hexane) to afford the products **1** in over 60% yield.

*Ethyl 7-hydroxy-2-(*E*)-heptenoate, **1**a*

(Reaction solvent, 1,2-dimethoxyethane); ir: 3420 (OH), 1720, and 1655 cm^{-1}; ^{1}H nmr (60 MHz) δ: 6.875 (dt, 1H, J = 16 Hz, 7 Hz), 5.7 (dt, 1H, J = 16 Hz, 1.5 Hz), 4.1 (q, 2H, J = 7 Hz), 3.7–2.8 (m), 2.50–1.85 (m), 1.75–1.40 (m), 1.25 (t, 3H, J = 7 Hz).

*Methyl 8-hydroxy-2-(*E*)-octenoate, **1**c*

(Reaction solvent, acetonitrile); ^{1}H nmr (60 MHz) δ: 7.07 (dt, 1H, J = 16 Hz, 7 Hz), 5.88 (dt, 1H, J = 16 Hz, 1.5 Hz), 3.77 (s, 3H), 3.64 (t, 2H, J = 6.5 Hz), 3.0 (bs, 1H), 2.50–2.0 (m, 2H), 2.00–1.20 (m, 6H).

*Methyl 8-hydroxy-2-(*E*)-noneonate,* **1**d

(Reaction solvent, acetonitrile); ^{1}H nmr (400 MHz) δ: 7.15–6.92 (m, 1H), 5.82 (dq, 1H, J = 16 Hz, 1.5 Hz), 4.04–3.95 (m, 1H), 3.73 (s, 3H, CO_2CH_3), 2.26–2.16 (m, 2H), 2.10–1.97 (m, 1H), 1.87–1.79 (m), 1.76–1.58 (m), 1.57–1.28 (m), 1.15 (d, 3H, J = 7 Hz).

*Methyl 8-hydroxy-7-methyl-2-(*E*)-octenoate,* **1**e

(Reaction solvent, acetonitrile); ^{1}H nmr (60 MHz) δ: 6.95 (dt, 1H, J = 16 Hz, 7 Hz), 5.75 (dt, 1H, J = 16 Hz, 1.5 Hz), 3.7 (s, 3H), 3.36 (d, 2H, J = 5.5 Hz), 2.7–1.9 (m, 2H), 1.8–1.15 (m, 5H), 0.9 (d, 3H, J = 6.5 Hz).

*Methyl 8-hydroxy-5-methyl-2-(*E*)-octenoate,* **1**f

(Reaction solvent, acetonitrile); ^{1}H (60 MHz) δ: 6.98 (dt, 1H, J = 16 Hz, 7 Hz), 5.83 (dt, 1H, J = 16 Hz, 1.5 Hz), 3.75 (s, 3H), 3.6–3.25 (m, 2H), 2.35 (s, 1H), 2.6–1.95 (m, 2H), 1.9–1.15 (m, 5H), 0.97 (d, 3H, J = 6.5 Hz).

*Methyl 8-hydroxy-6-methyl-2-(*E*)-octenoate,* **1**g

(Reaction solvent, acetonitrile); ^{1}H nmr (60 MHz) δ: 7.10 (dt, 1H, J = 16 Hz, 7 Hz), 5.90 (dt, 1H, J = 16 Hz, 1.7 Hz), 3.80 (s, 3H), 3.73 (t, 2H, J = 7 Hz), 2.5–2.0 (m, 3H), 1.8–1.1 (m, 5H), 0.95 (d, 3H, J = 6.5 Hz).

*Methyl 8-hydroxy-6-*tert*-butyl-2-(*E*)-octenoate,* **1**i

(Reaction solvent, toluene); ir: 3600–3100 (OH), 1725, and 1658 cm^{-1}; ^{1}H nmr (60 MHz) δ: 7.03 (dt, 1H, J = 16 Hz, 7 Hz), 5.85 (dt, 1H, J = 16 Hz, 1.5 Hz), 3.7 (s, 3H), 3.63 (t, 2H, J = 7 Hz), 2.60–1.00 (m, 8H), 0.93 (s, 9H).

tert-*Butyl 8-hydroxy-6-*tert*-butyl-2-(*E*)-octenoate,* **1**j

(Reaction solvent, acetonitrile); ir: 3600–3100 (OH), 1720, and 1650 cm^{-1}; ^{1}H nmr (60 MHz) δ: 6.86 (dt, 1H, J = 16 Hz, 7 Hz), 5.7 (dt, 1H, J = 16 Hz, 1.5 Hz), 4.65 (bs, 1H), 3.6 (t, 2H, J = 7 Hz), 2.75–1.00 (m, 7H), 1.5 (s, 9H), 0.9 (s, 9H).

tert-*Butyl 8-hydroxy-6-*tert*-butyl-2-(*Z*)-octenoate,* **1**k

(Reaction solvent, methanol); ^{1}H nmr (400 MHz) δ: 6.09 (dt, 1H, J = 12 Hz, 8 Hz), 5.69 (dt, 1H, J = 12 Hz, 1.5 Hz), 3.65 (m, 2H), 2.62–2.00 (m, 2H), 1.87 (bs, 1H), 1.85–1.75 (m, 1H), 1.67–1.58 (m, 1H), 1.49 (s, 9H), 1.42–1.295 (m, 1H), 1.24–1.15 (m, 1H), 1.07–1.00 (m, 1H), 0.89 (s, 9H).

General procedure for the preparation of ω-bromo α,β-unsaturated esters, **2**

To a dichloromethane solution of carbon tetrabromide (1.2 equiv.) and triphenylphosphine (1.2 equiv.) (12), was added a dichloromethane solution of the hydroxyester **1**. The resulting solution was stirred for 15 min and then treated with methanol. The volatiles were removed *in vacuo* and the remaining residue was purified by flash chromatography (10% EtOAc in hexane) to afford the corresponding ω-bromo α,β-unsaturated esters.

*Ethyl 7-bromo-2-(*E*)-heptenoate,* **2**a

Yield 61%; ir: 1715 and 1658 cm^{-1}; ^{1}H nmr (60 MHz) δ: 7.025 (dt, 1H, J = 16 Hz, 7 Hz), 5.866 (dt, 1H, J = 16 Hz, 1.5 Hz), 4.22 (q, 2H, J = 7 Hz), 3.425 (t, 2H, J = 7 Hz), 2.60–1.45 (m, 6H), 1.32 (t, 3H, J = 7 Hz); ^{13}C nmr δ: 166.3311, 147.8093, 121.9955, 60.1592, 32.9599, 32.0849, 31.2099, 26.6159, 14.2924; ms m/e: 237 (M^+ + 1, ^{81}Br), 235 (M^+ + 1, ^{79}Br).

*Methyl 8-bromo-2-(*E*)-octenoate,* **2**c

Yield 94%; ^{1}H nmr (60 MHz) δ: 7.03 (dt, 1H, J = 16 Hz, 7 Hz), 5.84 (dt, 1H, J = 7 Hz, 1.5 Hz), 3.75 (s, 3H), 3.43 (t, 2H, J = 7 Hz), 2.50–1.30 (m, 7H), 0.92 (d, 3H, J = 7 Hz); ms m/e: 249 (M^+ + 1, ^{81}Br), 247 (M^+ + 1, ^{79}Br).

*Methyl 8-bromo-7-methyl-2-(*E*)-octenoate,* **2**e

Yield 62%; ir: 1720 and 1658 cm^{-1}; ^{1}H nmr (60 MHz) δ: 6.85 (dt, 1H, J = 16 Hz, 7 Hz), 5.7 (dt, 1H, J = 16 Hz, 1.5 Hz), 3.66 (s, 3H), 3.3 (d, 2H, J = 5.5 Hz), 2.50–2.00 (m, 2H), 2.00–1.20 (m, 5H), 1.03 (d, J = 6.5 Hz); ms m/e: 263 (M^+ + 1, ^{81}Br), 261 (M^+ + 1, ^{79}Br).

*Methyl 8-bromo-5-methyl-2-(*E*)-octenoate,* **2**f

Yield 61%; ir: 1720 and 1655 cm^{-1}; ^{1}H nmr (60 MHz) δ: 6.93 (dt, 1H, J = 16 Hz, 7 Hz), 5.8 (dt, 1H, J = 16 Hz, 1.5 Hz), 3.75 (s, 3H), 3.4 (t, 2H, J = 6 Hz), 2.50–1.10 (m, 7H), 0.96 (d, 3H, J = 6.5 Hz).

*Methyl 8-bromo-6-methyl-2-(*E*)-octenoate,* **2**g

Yield 94%; ^{1}H nmr (60 MHz) δ: 7.03 (dt, 1H, J = 16 Hz, 7 Hz), 5.84 (dt, 1H, J = 7 Hz, 1.5 Hz), 3.75 (s, 3H), 3.43 (t, 2H, J = 7 Hz), 2.50–1.30 (m, 7H), 0.92 (d, 3H, J = 7 Hz); ms m/e: 263 (M^+ + 1, ^{81}Br), 261 (M^+ + 1, ^{79}Br).

*Methyl 8-bromo-6-*tert*-butyl-2-(*E*)-octenoate,* **2**i

Yield 70%; ir: 1725 and 1655 cm^{-1}; ^{1}H nmr (60 MHz) δ: 6.95 (dt, 1H, J = 16 Hz, 7 Hz), 5.8 (dt, 1H, J = 16 Hz, 1.5 Hz), 3.75 (s, 3H), 3.4 (t, 2H, J = 7 Hz), 2.55–1.00 (m, 7H), 0.93 (s, 9H).

tert-*Butyl 8-bromo-6-*tert*-butyl-2-(*E*)-octenoate,* **2**j

Yield 81%; ir: 1725, and 1655 cm^{-1}; ^{1}H nmr (400 MHz) δ: 6.84 (dt, 1H, J = 16 Hz, 7 Hz), 5.757 (dt, 1H, J = 16 Hz, 1.5 Hz), 3.45 (ddd, 1H), 3.405 (m, 1H), 2.33–2.20 (m, 1H), 2.20–2.12 (m, 1H), 2.11–2.00 (m, 1H), 1.71–1.60 (m, 2H), 1.5 (s, 9H), 1.23–1.04 (m, 2H), 0.9 (s, 9H).

tert-*Butyl 8-bromo-6-*tert*-butyl-2-(*Z*)-octenoate,* **2**k

Yield 76%; ^{1}H nmr (400 MHz) δ: 6.08 (dt, 1H, J = 12 Hz, 8 Hz), 5.695 (dt, 1H, J = 12 Hz, 1.5 Hz), 3.52–3.44 (m, 1H), 3.42–3.34 (m, 1H), 2.70–2.61 (m, 2H), 2.11–2.05 (m, 1H), 1.74–1.57 (m, 2H), 1.495 (s, 9H), 1.23–1.13 (m, 1H), 1.12–1.04 (m, 1H), 0.89 (s, 9H).

*Ethyl 7-*S*-methyl dithiocarbonoloxy-2-(*E*)-heptenoate,* **2**b

An ethereal solution of the hydroxyester **1***a* (0.288 g, 1.67 mmol) was refluxed with sodium hydride (1.1 equiv.) and carbon disulfide (1.5 equiv.) for 3 h. To the resulting mixture was added methyl iodide (3 equiv.) and this mixture was refluxed for 3 h (13). Upon completion of the reaction, the mixture was diluted with ether and quenched carefully with water. The aqueous layer was extracted with ether. The ethereal extracts were dried, concentrated, and purified by flash chromatography (10% ethyl acetate in hexane) to give the xanthate ester (**2***b*), (30% yield); ir: 1720, 1660, 1225, and 1065 cm^{-1}; ^{1}H nmr (400 MHz) δ: 6.945 (dt, 1H, J = 15.6 Hz, 6.9 Hz), 5.84 (dt, 1H, J = 15.65 Hz, 1.58 Hz), 4.604 (t, 2H, J = 6.46 Hz), 4.186 (q, 2H, J = 7.1 Hz), 2.57 (s, 3H), 2.230–2.24 (m, 2H), 1.87–1.80 (m, 2H), 1.66–1.57 (m, 2H), 1.29 (t, 3H, J = 7.13 Hz); ms m/e: 263 (M^+ + 1).

*Methyl-8-thiocarbonylimidazolyl-2-(*E*)-nonenoate,* **2**d

A solution of the hydroxyester **1***d* (0.483 g, 2.59 mmol) and *N,N'*-thiocarbonyldiimidazole (0.89 g, 5 mmol) in dichloromethane (20 mL) was refluxed overnight (14). After work-up, the residue was purified by flash chromatography (36% EtOAc in hexane) to give the imidazolide **2***d* (0.59 g, 77%); ^{1}H nmr (60 MHz) δ: 8.4 (bs, 1H), 7.7 (bs, 1H), 7.1 (bs, 1H), 7.20–6.78 (m), 6.05–5.47 (m), 3.73 (s, 3H), 3.15–2.94 (m, 1H), 2.48–1.25 (m), 1.45 (d, 3H, J = 7 Hz).

*(*R*)-O-Methylmandelyl-8-bromo-6-methyl-2-octenoate,* **2**h

To a benzene solution of the 8-bromo-6-methyl-2-octenoic acid (0.112 g, 0.476 mmol in 3 mL of benzene) was added oxalyl chloride (0.07 mL), and the resulting solution was stirred at room temperature for 2 h. The solvent was removed under reduced pressure and to the resulting oil were added (*R*)-*O*-methylmandelic alcohol (0.076 g, 0.5 mmol), pyridine (1 mL), and a catalytic amount of 4-dimethylaminopyridine. The mixture was stirred overnight at room temperature. Removal of the solvent and flash chromatography (10% EtOAc in hexane) of the resulting oil gave **2***h* in 16% yield; ^{1}H nmr δ: 7.4–7.3 (m, 5H), 6.98 (dt, 1H, J = 16 Hz, 7 Hz, *trans* isomer), 6.225 (dt, 1H, J = 11 Hz, 7 Hz, *cis* isomer), 5.875 (dt, 1H, J = 16 Hz, 2 Hz, *trans* isomer), 5.825 (dt, 1H, J = 11 Hz, 2 Hz, *cis* isomer), 4.46 (dd, 1H, CHOMe, *trans* isomer), 4.43 (dd, 1H, CHOMe, *cis* isomer), 4.3–4.185 (m, 2H), 3.63–3.38 (m, 2H), 3.3 (s, 3H, OCH_3), 3.295 (s, 3H, OCH_3, *cis* isomer), 2.32 (m, 2H), 1.94–1.76 (m, 1H), 1.75–1.50 (m, 2H), 1.55–1.45 (m, 1H), 1.36–1.25 (m, 1H), 0.93 (d, 3H, J = 6 Hz, *trans* isomer), 0.927 (d, 3H, J = 6 Hz, *cis* isomer).

*Methyl 9-chloro-7-hydroxy-2-(*E*)-nonenoate,* **2**l

Baeyer–Villiger oxidation of the known 2-(2'-chloroethyl)cyclopentanone (15) with MCPBA in dichloromethane gave the corresponding 5-(2'-chloroethyl)-δ-lactone. DIBALH reduction of the halo-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

lactone in toluene at −78°C afforded the corresponding halolactol, which was then converted to the desired chlorohydroxy ester **2***l* by refluxing with carbomethoxymethylenetriphenylphosphorane in CH_3CN (see general procedure). The product was purified by flash chromatography (20% EtOAc in hexane) to give **2***l* as an oil; ^{1}H nmr (60 MHz) δ: 7.02 (dt, 1H, J = 16 Hz, 6.5 Hz), 5.87 (dq, 1H, J = 16 Hz, 1.5 Hz), 3.90–3.60 (m, 1H), 3.80 (s, 3H), 3.74 (t, 2H, J = 7 Hz), 2.50–1.30 (m, 9H).

*Ethyl 7-bromo-9-chloro-2-(*E*)-nonenoate,* **2***m*

Dihaloenoate **2***m* was prepared from 2-(2′-chloroethyl)cyclopentanone (15) in a straightforward manner as described above for **2***l*. The corresponding chlorohydroxy ester **2***l* was transformed to the bromochloro ester **2***m* by treating with Ph_3P–CBr_4 in CH_2Cl_2 (12) to give an oil; ^{1}H nmr (60 MHz) δ: 7.0 (dt, 1H, J = 16 Hz, 7 Hz), 5.83 (dq, 1H, J = 16 Hz, 1.5 Hz), 4.19 (q, 2H, J = 6.5 Hz), 3.73 (t, 2H, J = 7 Hz), 3.6 (m, 1H), 2.60–1.50 (m, 8H), 1.30 (t, 3H, J = 7.3 Hz).

Ethyl 3-oxo-7-octenoate

Ethyl acetoacetate (7 mL, 55 mmol) was added dropwise to a suspension of sodium hydride (60 mmol) in tetrahydrofuran (130 mL) at 0°C under a nitrogen atmosphere. After 0.25 h, a solution of *n*-BuLi (1.65 *M* in hexane, 60 mmol) was added and the mixture stirred for additional 0.25 h at 0°C to generate the dianion of ethyl acetoacetate (18). To the solution of dianion was added 4-bromo-1-butene (8.17 g, 60.5 mmol) and the stirred mixture was allowed to reach room temperature. After discharge of the orange colouration, the reaction mixture was quenched with 30% aqueous HCl and then concentrated under reduced pressure to give the product as an oil; ^{1}H nmr (60 MHz) δ: 5.80–5.30 (m, 1H), 4.10 (q, 2H, J = 7.0 Hz), 3.23 (s, 2H), 2.50 (t, 2H, J = 7.0 Hz), 2.30–1.20 (m, 4H), 1.20 (t, 3H, J = 7.0 Hz).

Ethyl 3-hydroxy-7-octenoate

An ethanol solution of the above ketoester was added dropwise to a stirring solution of sodium borohydride (0.946 g, 25 mmol) in ethanol containing a drop of aqueous 1 *M* sodium hyroxide. The mixture was stirred for 1 h, then quenched with 10% aqueous HCl solution. After this usual work-up, flash chromatography (10% EtOAc in hexane) of the crude material gave the desired product as an oil (5.06 g, 49% from ethyl acetoacetate); ir: 3700–3200, 1730, and 1645 cm^{-1}; ^{1}H nmr (60 MHz) δ: 6.10–5.40 (m, 1H), 5.15–4.60 (m, 2H), 4.10 (q, 2H, J = 7.0 Hz), 3.80 (m, 1H), 3.15 (bs, 1H), 2.30 (d, 2H, J = 6.0 Hz), 2.0 (m, 2H), 1.7–1.3 (m, 4H), 1.25 (t, 3H, J = 7.0 Hz).

Ethyl 3-bromo-7-octenoate

To a solution of ethyl 3-hydroxy-7-octenoate (1.518 g, 8.15 mmol) and carbon tetrabromide (3.317 g, 10 mmol) in dichloromethane (50 mL) at 0°C was added triphenylphosphine (2.623 g, 10 mmol) in small portions, and the mixture stirred for 6 h at room temperature. After removal of the solvent under reduced pressure, flash chromatography (hexane) of the residue afforded the desired product as a colourless oil (1.305 g, 64%); ir: 1740 and 1642 cm^{-1}; ^{1}H nmr (60 MHz) δ: 6.20–5.40 (m, 1H), 5.30–4.70 (m, 2H), 4.35 (m, 1H), 4.15 (q, 2H, J = 7.0 Hz), 2.80 (d, 2H, J = 7.0 Hz), 2.40–1.50 (m, 6H), 1.30 (t, 3H, J = 7.0 Hz).

3-Bromo-7-octen-1-ol

An ethereal solution of ethyl 3-bromo-7-octenoate (0.854 g, 4.13 mmol) was added to a suspension of lithium aluminum hydride (excess) in ether and the mixture stirred at room temperature. After completion of reduction (tlc monitoring), water was added slowly to the reaction mixture and the crude product extracted with ether. Purification of the crude material by flash chromatography (10% EtOAc in hexane) gave the product as a colourless oil (0.351 g, 49%); ir: 3700–3100 and 1645 cm^{-1}; ^{1}H nmr (60 MHz) δ: 6.10–5.40 (m, 1H), 5.20–4.80 (m, 2H), 4.0 (m, 1H), 3.60 (q, 2H, J = 6.5 Hz), 2.40–1.00 (m, 8H).

6-Bromo-8-chloro-1-octene

3-Bromo-7-octen-1-ol (0.383 g, 1.85 mmol) and carbon tetrachloride (0.57 g, 3.7 mmol) were dissolved in dichloromethane (25 mL). To the ice-cold solution, triphenylphosphine (0.97 g, 3.7 mmol) was added in small portions and the mixture stirred at room temperature until the bromohydrin was consumed. Removal of the solvent under reduced pressure followed by flash chromatography (hexane) of the residue gave the desired bromochloro-octene as an oil; ir: 1650 cm^{-1}; ^{1}H nmr (60 MHz) δ: 6.20–5.50 (m, 1H), 5.30–4.80 (m, 2H), 4.10 (quintet, 1H, J = 6 Hz), 3.70 (t, 2H, J = 6.5 Hz), 2.4–1.0 (m, 8H).

5-Bromo-7-chloro-heptanal

Ozone was bubbled through a dichloromethane (20 mL) solution of the dihalo-olefin (0.417 g, 1.85 mmol) at −78°C until its complete consumption. The reaction mixture was then flushed with argon, quenched with dimethyl sulfide at −78°C, and then allowed to warm to room temperature. After removal of the solvent, flash chromatography (20% EtOAc in hexane) of the residue afforded the bromochloro aldehyde (0.167 g, 40%); ir: 1735 cm^{-1}; ^{1}H nmr (60 MHz) δ: 9.80 (t, 1H, J = 1 Hz), 4.20 (quintet, 1H, J = 6.5 Hz), 3.70 (t, 2H, J = 6.5 Hz), 2.70–1.40 (m, 8H).

*Methyl 9-bromo-11-chloro-2-(*E*)-4-(*E*)-undecenoate,* **2***n*

Sodium hydride (0.024 g, 1 mmol) was added to a stirred suspension of methyl crotonyltriphenylphosphonium bromide (0.441 g, 1 mmol) in THF. To the resulting phosphorane was added a THF solution of 5-bromo-7-chloro-heptanol (0.167 g, 0.73 mmol) and the mixture refluxed for 3 h. The solvent was then removed and the residue was purified by flash chromatography (20% EtOAc in hexane) to give the desired dihalodienoate **2***n* (0.022 g) as an oil; ^{1}H nmr (400 MHz) δ: 6.25–6.06 (m, 3H), 5.81 (d, 1H, J = 15 Hz), 4.22 (m, 1H), 3.77–3.72 (m, 2H), 3.75 (s, 3H, OMe), 2.27–2.16 (m, 2H), 1.85 (m, 2H), 1.81–1.70 (m, 1H), 1.67–1.57 (m, 1H); ms *m/e*: 311 (M^+ + 1).

General procedure for radical cyclization

Benzene or toluene solutions of n-Bu_3SnH or Ph_3SnH (0.07–0.1 *M*, 1.2–1.5 equiv.) and AIBN (0.003 *M*, 0.05 equiv.) were injected, using a syringe pump over 10 h, into a refluxing solution (0.015 *M*) of the unsaturated bromides **2**, or xanthate ester **2***b*, or thiocarbonylimidazolide **2***d*, in the same solvent. Upon completion of the reaction, the solvent was removed *in vacuo* and the residue was purified by flash chromatography (hexane to 5% EtOAc in hexane gradient) to give the cyclized product as homogeneous oils (see Table 1).

Ethyl cyclopentylacetate, **3**a: ir: 1738 cm^{-1}; ^{1}H nmr (400 MHz) δ: 4.12 (q, 2H, J = 7 Hz), 2.33–2.26 (m, 2H), 2.26–2.17 (m, 1H), 1.88–1.78 (m, 2H), 1.69–1.50 (m, 4H), 1.26 (t, 3H, J = 7 Hz), 1.22–1.10 (m, 2H); ^{13}C nmr δ; 173.2585, 60.0133, 40.4707, 36.5330, 32.4495, 25.0116, 14.2924; ms *m/e*: 156 (M^+ + 1).

*Methyl 2-(*E*)-octenoate,* **3**b: ^{1}H nmr (400 MHz) δ: 6.98 (dt, 1H, J = 16 Hz, 8 Hz), 5.82 (dt, 1H, J = 16 Hz, 1.5 Hz), 3.73 (s, 3H, CO_2CH_3); ^{13}C nmr (100.62 MHz) δ: 149.7, 120.7, 32.1, 31.2, 27.6, 23.4; ms *m/e*: 157 (M^+ + 1).

Methyl cyclohexylacetate, **3**c: ^{1}H nmr (400 MHz) δ: 3.66 (s, 3H, CO_2CH_3), 2.19 (d, 2H, J = 8 Hz), 1.85–0.90 (m, 11H); ^{13}C nmr (100.62 MHz) δ: 173.5, 51.2, 41.9, 34.8, 32.9, 26.0, 25.9; ms *m/e*: 157 (M^+ + 1).

Received October 28, 1986

This paper is dedicated to Professor John T. Edward

RANDY M. DUHAIME and ALAN C. WEEDON. Can. J. Chem. **65**, 1867 (1987).

The production of stable solutions of *Z*-dienols by ultraviolet light irradiation of α,β-unsaturated ketones at low temperatures (ca. −76°C) in d_4-methanol is reported. The rates of reketonisation of the dienols via a 1,5-sigmatropic hydrogen shift were determined at various temperatures between −43°C and +2°C by monitoring the proton nmr spectra of the dienols. From the data the activation parameters for the reaction were calculated. For the dienol *Z*-2-hydroxy-4-methyl-2,4-pentadiene, **2**, derived from photoenolisation of 4-methyl-3-penten-2-one, **1**, the activation energy from the Arrhenius plot is 62 ± 4 kJ/mol, and the activation entropy and enthalpy from the Eyring plot are −87 ± 15 J/mol K and 60 ± 4 kJ/mol, respectively. For the dienol *Z*-4-*tert*-butyl-2-hydroxy-2,4-pentadiene, **4**, obtained from photoenolisation of 4,5,5-trimethyl-3-hexen-2-one, **3**, the activation energy, entropy, and enthalpy were found to be 47 ± 5 kJ/mol, −135 ± 19 J/mol K, and 45 ± 5 kJ/mol, respectively.

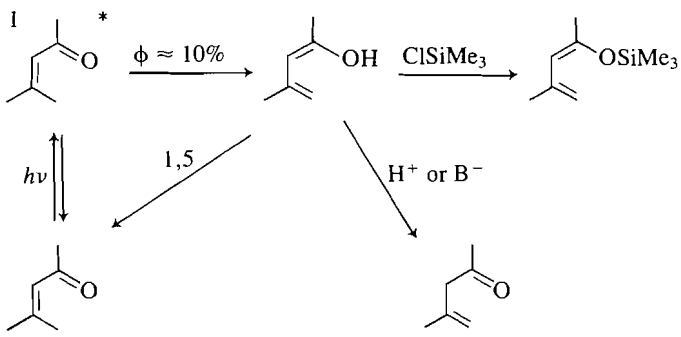
RANDY M. DUHAIME et ALAN C. WEEDON. Can. J. Chem. **65**, 1867 (1987).

On rapporte la production de solutions stables de diènols-*Z* par irradiation ultraviolette de cétones α,β-nonsaturées, à basse température (environ −76°C), dans le méthanol-d_4. Opérant à des températures allant de −43°C à +2°C et utilisant les variations observées dans les spectres rmn du proton des diènols, on a déterminé les vitesses de recétonisation des diènols qui se produisent par le biais d'une transposition sigmatropique-1,5 d'hydrogène. Pour le diènol hydroxy-2 méthyl-4 pentadiène-2,4-(*Z*) (**2**), qui provient de la photoénolisation de la méthyl-4 pentène-3 one-2 (**1**), l'énergie d'activation que l'on peut déduire de la courbe d'Arrhénius est égale à 62 ± 4 kJ/mol et l'enthalpie et l'entropie d'activation que l'on peut déduire de la courbe de Eyring sont respectivement égales à 60 ± 4 kJ/mol et −87 ± 15 J/mol K. Pour le diènol *tert*-butyl-4 hydroxy-2 pentadiène-2,4 (**4**), qui est obtenu par photoénolisation de la triméthyl-4,5,5 hexène-3 one-2 (**3**), on a trouvé que les énergie, entropie et enthalpie d'activation sont respectivement égales à 47 ± 5 kJ/mol, −135 ± 19 J/mol K et 45 ± 5 kJ/mol.

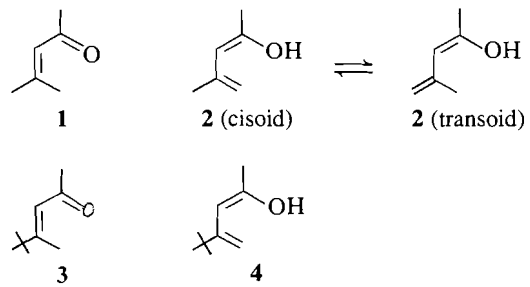
[Traduit par la revue]

Introduction

Ultraviolet light irradiation of β-alkyl-α,β-unsaturated ketones results in efficient *E*–*Z* isomerisation, and less efficient photoenolisation (1) to produce transient dienols, which can be trapped as their silyl ethers (2–4) as is shown in Scheme 1. The dienols are formed from the singlet excited state of the ketones (2, 3) and with a quantum efficiency of approximately 10% (1). They are produced with *Z*-geometry (2) and can reketonise by acidic or basic catalysis to give a β,γ-unsaturated ketone (3, 5), or they can reketonise via a non-catalysed pathway for which a 1,5-sigmatropic hydrogen shift mechanism has been proposed (1–5). Similar results have been obtained with α,β-unsaturated esters (6). The dienols have also been generated by flash photolysis of unsaturated ketones in aqueous base, and the rates of reketonisation of the corresponding dienolates by protonation by water have been measured; in the same experiments the rate of the non-catalysed (1,5-hydrogen shift) reaction was also determined, but rather inaccurately due to limitations in the technique (7). Reported here are the results of experiments in which stable solutions of the dienols **2** and **4** were produced by low temperature irradiation of unsaturated ketones **1** and **3**, respectively, and in which the rate of the non-catalysed reketonisation process was determined for each dienol at a variety of temperatures.



SCHEME 1



Results

Ketones **1** and **3** were dissolved in d_4-methanol in nmr tubes which were suspended in an acetone/dry ice slurry and irradiated with ultraviolet light. The ^{1}H nmr spectra of the irradiated solutions were recorded at −76°C and indicated that a new set of signals had been formed at the expense of the starting ketones. Disappearance of the ketones was not complete and the rate of their disappearance became slower at higher conversion. This is attributed to overlap of the absorption spectra of the products and those of the starting ketones: as will be discussed below, the photoproducts are assigned structures **2** and **4**, and

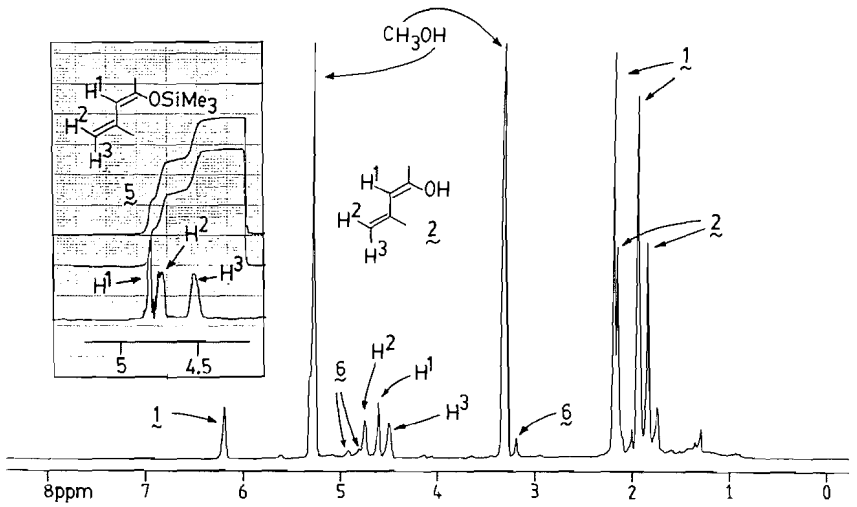

FIG. 1. The ^{1}H nmr spectrum (200 MHz) of dienol **2** in d_4-MeOH at −23°C in the presence of CH_3OH (added for temperature calibration), and ketones **1**, and **6**. Insert: partial ^{1}H nmr spectrum (100 MHz) of siloxydiene **5** recorded at ambient temperature in $CDCl_3$. Assignments for H^2 and H^3 for **2** may be reversed.

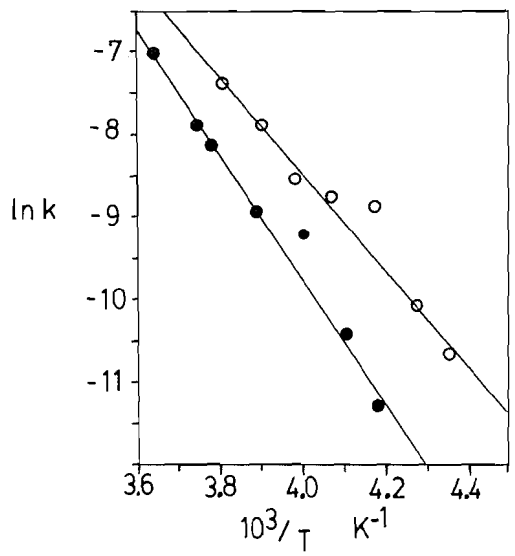

FIG. 2. Arrhenius plot for conversion of dienols **2** and **4** to ketones **1** and **3**, respectively, in d_4-methanol. Upper line, **4**; lower line, **2**.

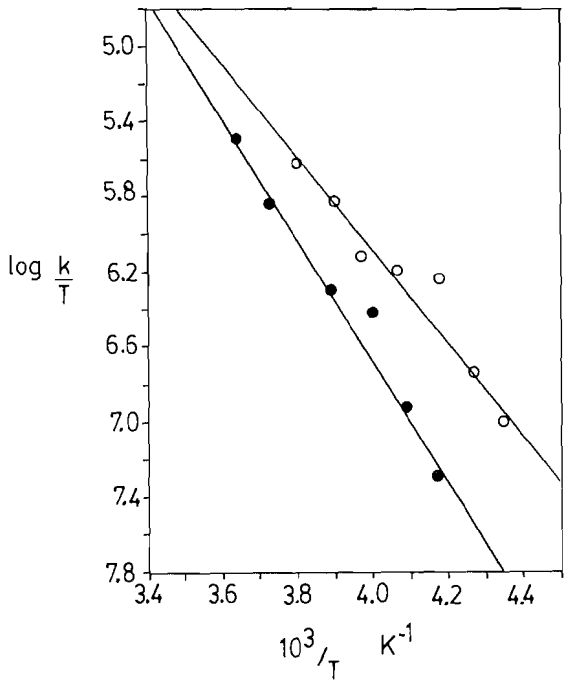

FIG. 3. Eyring plot for conversion of dienols **2** and **4** to ketones **1** and **3**, respectively, in d_4-methanol. Upper line, **4**; lower line, **2**.

the uv absorption spectra of siloxydienes such as **5** (4) indicate that the dienols **2** and **4** should absorb in the same region as the $\pi \rightarrow \pi^*$ absorption band of the ketone. It was found that mixtures of ketone and dienol in which approximately 50% conversion had occurred could be generated before the rate of conversion slowed appreciably, and further conversion was not attempted in order to avoid photochemical *E–Z* isomerisation of the dienol. Such isomerisation has been observed during the preparation of *Z*-siloxydienes such as **5** by trapping of the photochemically produced *Z*-dienols by chlorotrimethylsilane (4). The ^{1}H nmr spectrum recorded at −23°C of the mixture derived from irradiation of ketone **1** is shown in Fig. 1. The solutions appeared to be stable at −76°C, but if they were allowed to warm up to room temperature the new signals disappeared and those of the starting ketones were regenerated. Following their regeneration partial deuteration of the methyl groups of **1** and **3** was apparent. At temperatures intermediate between −76°C and ambient the rate of the reversion process was slow enough to be measured by integration of the peak areas of the signals assigned to the ketones and photoproducts. The rate of the reversion process was measured for the transients from both ketones **1** and **3** at a variety of temperatures. The reversion reaction proceeded with first order kinetics, and the rate constants derived were used to obtain the Arrhenius and Eyring plots shown in Figs. 2 and 3.

Discussion

The photoproducts formed by low temperature irradiation of ketones **1** and **3** are identified as the dienols **2** and **4**, respectively, and the assignment is based upon the similarity of their ^{1}H nmr spectra to that of the siloxydiene **5**, and upon the fact that upon warming they are smoothly converted back into the ketone precursors. The chemical shifts of the protons assigned to **2** recorded in d_4-methanol at −23°C are shown in

TABLE 1. Proton nmr data for dienols **2** and **4** and siloxydiene **5**[a]

Compound	Solvent	T (°C)	H^1	H^2	H^3	CH_3	R^1
2	d_4-MeOH	−23	4.58	4.74*	4.48*	1.80	1.88
4	d_4-MeOH	−43	4.62	5.28*	4.96*	1.86	1.06
5	$CDCl_3$	35	4.88	4.81	4.59	1.73	1.81

[a]Spectra of **2** and **4** were recorded at 200 MHz, and that of **5** at 100 MHz. Solutions of **2** and **4** contained 5% methanol for temperature calibration (see ref. 17 and Experimental). Chemical shifts for **2** and **4** are given relative to the methanol peak at 3.30 ppm. Data for compound **5** is taken from ref. 4. Assignments for signals marked by an asterisk may be reversed (see Discussion). R′ is the 4-Me or 4-Bu′ substituent in **2** and **4**, respectively.

Table 1 along with those of the corresponding siloxydiene **5** in $CDCl_3$ at ambient temperature. Allowing for solvent and temperature effects upon the chemical shifts, the spectra are sufficiently similar to support strongly the assignment of the dienol structure to the photochemical product, and are in accord with the shifts predicted from calculation using standard chemical shift correlations (8). The signals in the spectrum of **5** have been fully assigned using coupling constant data (4); protons H^2 and H^3 (see Table 1) are geminally coupled (J = 2.7 Hz) as well as coupled allylically (J = 0.8, 0.5 Hz) and therefore their signals are substantially broader in appearance than the signal due to H^3 which is allylically coupled only (J = 0.8 Hz). The signals corresponding to these protons in **5** are shown in the insert in Fig. 1. The olefinic protons in **2** also give broadened signals due to a mixture of allylic and geminal coupling (see Fig. 1). Sufficient resolution could not be obtained at the low temperatures to allow measurement of the coupling constants in the spectrum of **2**. However, the signals at 4.74 ppm and 4.48 ppm were broader than that at 4.58 ppm, and on this basis the latter is assigned to H^1 and the former pair are assigned to protons H^2 and H^3, and their broadness is ascribed to geminal coupling to each other. In the spectrum of the dienol **2**, shown in Fig. 1, small amounts of the deconjugated isomer **6** can also be seen; these were present in the starting ketone and the amount present was unchanged during the experiments, indicating that none was formed photochemically during the irradiation, or during the warming period in which the dienol intermediate was beginning to revert to the starting ketone.

Similar results were obtained when the ketone **3** was irradiated under the same conditions as **1**. In this case, however, the ketone, which was initially present almost exclusively as the *E*-isomer, underwent rapid *E*–*Z* isomerisation during the initial stages of the irradiation, and this was followed by slower conversion to the dienol **4**. In addition, very small amounts of the cyclopropane **7** were formed from irradiation of the *Z*-isomer, as has been reported previously (3, 9). The chemical shifts of the signals seen for **4** in d_4-methanol at −43°C are shown in Table 1. As was the case for **2**, two of the three olefinic protons show evidence of greater broadening due to allylic coupling; thus the signals at 5.28 ppm and 4.96 ppm in the spectrum of **4** are assigned to H^2 and H^3, and that at 4.62 ppm to H^1. Comparison of the chemical shifts of the olefinic protons in **4** with those of **2** and **5** (see Table 1) indicate that protons H^2 and H^3 are to lower field in **4** than in **2** and **5**. This can be rationalised in terms of the preferred conformation of the diene. The dienols would be expected to exist in either a cisoid or transoid planar conformation in order to maximise delocalisation of the π system, and studies have indicated (10) that the transoid conformation is generally preferred in dienes. However, the bulky *tert*-butyl group in **4** might be expected to freeze the diene in a cisoid conformation so as to minimise steric interactions with the enol hydroxyl, whereas dienol **2** is free to adopt the electronically more stable transoid conformation. If this is so, then the protons H^2 and H^3 of **4** will be more deshielded by the OH group of the enol and so appear to lower field than the corresponding hydrogens in **2** and **5**.

When the temperatures of the solutions of the dienols were raised from −76°C to ambient, the new spectra disappeared and the spectra of the conjugated ketones cleanly reappeared. No deconjugated ketones were formed; this supports the proposition that the dienols reketonise via the proposed 1,5-sigmatropic hydrogen shift mechanism and not by an acid or base catalysed sequence, since it has been shown that the main product formed under the latter conditions is the β,γ-unsaturated ketone (1). Since the dienols cleanly reverted to the ketones it was possible to use the relative peak areas of the olefinic protons of each in the ^1H nmr spectra to determine the rate of the reversion reaction at a variety of temperatures. The reversion process followed clean first order kinetics as would be expected for a unimolecular non-catalysed process such as the 1,5-sigmatropic hydrogen shift mechanism. The first order rate constants are shown in Table 2; they indicate that the dienol **2** has a lifetime at 240 K of 23 h while dienol **4** has a lifetime at the same temperature of only 2 h. The greater stability of **2** meant that solutions at temperatures as high as +2°C had a half life of ca. 20 min.

The faster rate of reketonisation of **4** compared with **2** is consistent with the arguments proposed above concerning the preferred conformations of **2** and **4** based upon their ^1H-nmr data. It is also in accord with earlier work reported from this laboratory: using the evidence of steady state kinetic and quantum yield studies of the photochemical deconjugation reaction of α,β-unsaturated esters and ketones it has been suggested (3, 6) that substituents on the dienol can control the conformation of the molecule and freeze it in either the cisoid or transoid conformation, and hence greatly affect the rate of the 1,5-hydrogen shift mechanism for reketonisation. For example, it has been shown that irradiation of the ester **8** results in very efficient photochemical deconjugation towards the isopropyl group to give **9**, unless base is added to the system in which case **10** is also formed. This can be explained if dienols **11** and **12** are formed as transient intermediates in the reaction. In **11** the substituted diene suffers steric interactions between the hydroxyl group of the enol and the methyl substituents which forces the molecule into the transoid conformation. This slows the 1,5-hydrogen shift reaction to the point that acid or base catalysis by the solvent can convert **11** to **9**. In contrast, dienol **12** is held in a cisoid conformation, also for steric reasons, and the 1,5-hydrogen shift is rapid unless a base is added to catalyse its conversion to the deconjugated isomer **10**. Similar arguments can be applied to **2** and **4** to rationalise their relative rates of reketonisation.

The lifetimes of dienols **2** and **4** appear to be shorter than the

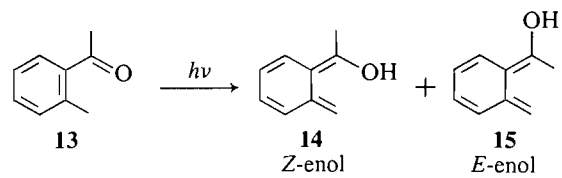
lifetimes of simple enols, which are relatively stable in the absence of acidic and basic catalysts, and which have been characterised by a variety of spectroscopic techniques in solution (11). The greater stability of simple enols can be attributed to the fact that in the absence of acidic or basic catalysts the only reasonable mechanism for unimolecular reketonisation of an enol in which orbital symmetry conservation requirements are met is a 1,3-sigmatropic antarafacial hydrogen shift; however, the 4-centre antarafacial transition state, while allowed thermally, is generally unattainable by first row elements. In contrast, for the dienols **2** and **4** the reketonisation via a 1,5-hydrogen shift involves a 6-centre transition state with a suprafacial orbital overlap requirement which can readily be attained.

It is informative to compare the rate of the 1,5-hydrogen shift process in **2** and **4** with that in the enols obtained by irradiation of *ortho*-alkyl aromatic carbonyl compounds such as **13** as shown in Scheme 2. It has been shown (12, 13), that irradiation of ketones such as **13** leads to a mixture of *E*- and *Z*-enols, and that the *E*-enols have lifetimes of seconds and require acid or



13 **14** *Z*-enol **15** *E*-enol

SCHEME 2

base to catalyse their reketonisation. The *Z*-enols, however, revert to the ketones by a rapid unimolecular process which is assumed to be a 1,5-hydrogen shift. The rate is solvent dependent: in non-polar solvents the lifetime of the enol is ca. 30 ns at ambient temperature whereas in polar solvents the lifetime is ca. 1 μs, and is presumably lengthened because of hydrogen bonding of the solvent to the enol. The much faster rates of reversion in the aromatic systems as compared with those observed for dienols **2** and **4** may reflect the fact that the aromatic system is being reformed, and also that the enol is constrained in the cisoid orientation necessary for the 1,5-shift to occur.

The rates of reversion of the dienols **2** and **4** were also measured at a variety of temperatures and the activation parameters obtained from the Arrhenius and Eyring plots shown in Figs. 2 and 3 are given in Table 2, along with the data reported for the *Z*-enol **14** derived from the aromatic system **13**. The activation energies for **2**, **4**, and **14** are comparable, but a much larger pre-exponential factor is reported for **14** (14, 15); this may reflect the cisoid orientation forced upon the aromatic system as compared with the conformational flexibility of the dienols **2** and **4**.

The errors in the activation parameters shown in Table 2 are considerable. However, if the differences between the values for the dienols **2** and **4** are taken to be real, then they indicate the reverse to what might be expected. Based upon chemical shift data and the arguments put forward to explain the photochemical reactivity of the ester **8** and related systems it was proposed above that the enol **4** is held in a cisoid conformation because of steric interactions between the Bu^t group and the enol hydroxyl, whereas **2** is more able to adopt the electronically more stable transoid conformation. If this is so, it might be

expected that the activation entropy for the 1,5 hydrogen shift in **2** would be greater than in **4** since **2** must undergo a conformational change in order to reach the transition state. However, the reverse is indicated by the data, with **2** having a smaller entropy of activation than **4**. In addition, independent of the conformation, the activation enthalpy for both **2** and **4** would be expected to be similar, and yet the activation enthalpy for **4** is less than that for **2**.

To rationalise this anomaly the effects of solvation can be considered. It might be expected that the less efficient delocalisation in **4** (arising from poorer overlap of the π-system because of the adoption of a cisoid conformation) might make the hydroxyl function more basic and so more strongly hydrogen bonded than would be the case for **2**. This will weaken the OH bond and lower the activation enthalpy for a 1,5-hydrogen shift as observed; it would also serve to increase the activation entropy due to the need for greater solvent reorganisation as the transition state is approached.

Alternatively, if the dienol **2** is indeed more stable in the transoid conformation, then the observed rate constant for decay will in fact be the product of the rate constant for reversion to the ketone via the 1,5-hydrogen shift and the equilibrium constant for the conformational equilibrium between the cisoid and transoid forms of **2** (assuming that the rate of conformational interconversion is rapid relative to the rate of the 1,5-shift). Thus the activation parameters determined for **2** are a composite of the temperature dependencies of 1,5-shift rate constant and the equilibrium constant for the cisoid–transoid conformational interconversion, and are therefore not directly comparable with those for **4**, where the observed rate constant is equal to that for the 1,5-shift if this dienol exists preferentially in the cisoid conformation.[3]

In previous work reported from this laboratory approximate values of the rate of the 1,5-hydrogen shift reaction for dienols **2** and **4** were estimated in water at ambient temperatures using the technique of flash photolysis. The value found for **4** was ca. 50 s^{-1} and for **2** the rate was slower and indistinguishable from zero. Extrapolation to room temperature of the values found for **4** and **2** in d_4-methanol at low temperature yields very inaccurate values of the rate which are at least 50 times slower than those observed in water. It has been shown (12) for aromatic enols such as **14** that the lifetimes are little affected by changing solvent from water to methanol (at most a factor of two) but it has been shown that large isotope effects can exist, and that these increase at lower temperatures. Thus for example, the deuterium isotope effect upon the reketonisation rate of **14** is 3 at 298 K and 180 at 140 K (14). Consequently in the case of **2** and **4** the difference between the rates measured at room temperature in water by flash photolysis and those obtained by extrapolation from the results obtained at low temperature in d_4-methanol may be attributed at least in part to a large deuterium isotope effect.

Experimental

A commercially available sample of ketone **1** was used. Ketone **3** was prepared from ethyl 3,4,4-trimethyl-2-pentenoate (6); the ester was hydrolysed to the acid with ethanolic KOH, and the acid was converted to the ketone with methyl lithium using the procedure of Theus *et al.* (16). Both ketones were purified by preparative gas chromatography prior to use.

Procedures for irradiation and kinetic measurements

Solutions of each of the ketones in CD_3OD (0.01–0.05 *M*, ca. 0.5 mL) containing a small quantity (ca. 5%) of non-deuterated methanol were placed in 0.4 mm internal diameter Pyrex nmr tubes which were suspended in a Dewar containing a slurry of dry ice in acetone. The tubes were held in a sleeve similar to that used to hold tubes in nmr probes, and the tube was spun using a jet of compressed air to rotate the sleeve. A quartz rod was placed in the nmr tube so that one end entered the solution of the ketone. The diameter of the quartz rod was optimised so as to minimise the air gap between it and the walls of the nmr tube as much as possible as was consistent with obtaining free rotation of the tube. Pyrex and water filtered light from a 100-W high pressure mercury lamp was focussed into the exterior end of the quartz rod which thereby acted as a light pipe to channel the lamp's output into the ketone solution. The dienols' uv spectra are comparable to those of the ketones (see Discussion). Thus, in order to obtain appreciable conversion of the ketones to the corresponding dienols it was found essential to mix the ketone solutions by rotating the tubes, and also to use solutions with optical densities less than unity so as to ensure that the whole length of the solution was irradiated. Up to 50% conversion to the dienol could be attained after 3–4 hours' irradiation. The irradiated solutions were kept at −76°C until required, and then rapidly transferred to the precooled probe of a Varian XL 200 NMR spectrometer. The probe was then warmed to the desired temperature and the decays of the dienols back to the corresponding ketones were monitored periodically by integration of the olefinic proton signals of both the ketone and the dienol relative to the methyl group of the methanol present. The plots of the areas of the peaks against time at each temperature yielded from their gradients the values of the rate constants shown in Table 2; these were calculated using a least-squares program to fit the data and the error limits indicated in the table are standard deviations calculated from the least-squares fit. The temperatures of the solutions were determined by measuring the separation of the added methanol peaks according to the method of Van Geet (17). The temperature dependent separation of the peaks was not altered by the presence of d_4-methanol, as determined by comparison of the peak separation in pure methanol under identical instrumental conditions.

This paper is dedicated to Professor John T. Edward

ALMERIA NATANSOHN and ADI EISENBERG. Can. J. Chem. **65**, 1873 (1987).

Proton and carbon nuclear magnetic resonance spectra in solution of poly(methyl methacrylate-*co*-4-vinyl pyridine), poly(methyl methacrylate-*co*-2-methyl-5-vinyl pyridine), and of their derivatives obtained by quaternization with methyl iodide are presented. The vinyl pyridine structural units content of the samples is ca. 10%. In different solvents, the spectra provide information about the sequence distribution and configuration of the copolymers. A "coisotactic" alternating addition, defined as the probability of finding a methoxy group and a pyridine ring neighboring each other on the same side of the main chain, can be estimated as about 0.5 in both cases. This information arises from the splitting of the aromatic and of the methoxy signals (both in proton and carbon spectra). As expected, quaternization does not affect the copolymer configuration. Heteronuclear-correlated two-dimensional spectra can help in assigning the spectra.

ALMERIA NATANSOHN et ADI EISENBERG. Can. J. Chem. **65**, 1873 (1987).

On rapporte les spectres rmn du ^{1}H et du ^{13}C, mesurés en solution, du poly(méthacrylate de méthyle-*co*-vinyl-4 pyridine), du poly(méthacrylate de méthyle-*co*-méthyl-2 vinyl-5 pyridine) et de leurs dérivés obtenus par quaternisation avec l'iodure de méthyle. Les unités structurales vinylpyridines forment environ 10% des échantillons. Dans les différents solvants, les spectres fournissent de l'information sur la distribution des séquences ainsi que sur la configuration des copolymères. Dans chacun des cas, on peut évaluer à 0,5 la proportion d'addition « coisotactique » alternante, définie comme la probabilité de trouver un groupement méthoxy et un cycle pyridine côte à côte sur le même coté de la chaîne principale. On peut déduire cette information à partir du dédoublement des signaux dus aux groupements aromatiques et méthoxy (tant en rmn du ^{1}H que du ^{13}C). Comme on pouvait s'y attendre, la quaternisation n'affecte pas la configuration du copolymère. Les spectres bidimensionnels hétéronucléaires peuvent être utiles dans l'attribution des spectres.

[Traduit par la revue]

Introduction

The mechanical properties of a range of ionomers based on various vinyl pyridine units have been studied extensively in this laboratory and compared with those of the non-ionic polymers. Both random and block copolymers were studied. Random copolymers of methyl methacrylate (MMA), ethyl acrylate, butyl acrylate, or styrene with 4-vinyl pyridine (4VP) or 2-methyl-5-vinyl pyridine (2M5VP), respectively, were investigated (1, 2). Studies of ABA block copolymers of styrene (B) with 4VP (A) were performed and the results compared with those of the random copolymers (2). The influence of the chain length of the quaternization agent on the glass transitions was determined (3), and the swelling behavior of the block ionomers was investigated.[2] The random copolymers were also used as components of ionomer blends. When mixed with a proton-donating copolymer, such as poly(styrene-*co*-styrene sulfonic acid), the proton is transferred to the pyridine unit, creating ionic pairs that act as a driving force for compatibilization. This procedure was used to improve the miscibility of poly(ethyl acrylate) with poly(styrene) (4) and with sulfonated poly(phenylene) (5). Recently, blends of poly(MMA-*co*-4VP) with poly(S-*co*-SSA) were proven useful in the study of the process of coil overlap using nmr spectroscopy (6). The kinetics of coil overlap in solution are being thoroughly studied in our laboratory as a function of molecular weight, total solution concentration, ionic group concentration, and temperature.[3] However, since the main utilization for blends is as materials in the solid state, the next step in investigating interactions in this type of material will be CP-MAS ^{13}C nmr spectroscopy, which will give information about coil overlap and its kinetics directly in the solid state.

Before studies in the solid state can be carried out, it is useful to obtain information on the detailed peak assignments and the microstructure of the copolymers. These have to be obtained in solution. This paper therefore presents the ^{13}C nmr spectra of the poly(MMA-*co*-4VP), poly(MMA-*co*-2M5VP), and their quaternized derivatives in solution. To our knowledge, these spectra have not been reported in the literature, and only the proton spectra of poly(MMA-*co*-4VP) were reported earlier by one of us (7). This paper does not intend to elucidate the microstructural mechanism that governs the copolymerization of MMA with 4VP or with 2M5VP.

A survey of the literature showed that ^{13}C nmr spectra of poly(MMA) have been analysed and that signals for the quaternary, carbonyl, and α-methyl carbons are sensitive to configuration, whereas the methoxy signal is not split (8, 9). The methylene signal position also depends on the homopolymer configuration (10). Poly(vinyl pyridines) have also been investigated. The carbon spectrum of poly(4VP), especially the sensitivity of C4 to the polymer configuration, was reported by several authors (11–13). Quaternization of the polymer, using different quaternizing agents, and the influence on the carbon spectra were also reported (14–16). Again, only C4 remained sensitive to configuration. The carbon spectrum of poly(2M5VP) was briefly mentioned in a table in ref. 11. The spectrum was not completely assigned and the configuration sensitivity could not be explained.

Experimental

The copolymers analysed here were prepared by bulk radical copolymerization. Quaternization of the copolymers was performed using methyl iodide. Both copolymerization and quaternization were part of

another project (1). Proton and carbon nmr spectra were obtained on a Varian XL-300 spectrometer in different solvents. Low flip angles (40°) were used to avoid delays between pulses. Two-dimensional heteronuclear-correlated (HETCOR) spectra were recorded on the same spectrometer, using the pulse sequence offered by Varian (17).

Sequence distribution estimation was made using Markov statistics with two parameters, the reactivity ratios of the two comonomers (18). The reactivity ratios were calculated from the copolymerization data and the feed ratio of the two comonomers was used in the calculation (1). There was a systematic error introduced by the fact that copolymerization conversions were higher than 5%, but this error could be neglected at the low fractions obtained. Sequence fractions for samples with the highest content of vinyl pyridine units are presented in Table 1.

Results and discussion

Choosing the right solvent to obtain a good nmr spectrum is very important in this case. The spectra of the normal and quaternized copolymers have to be compared, yet due to their different polarity, the samples have different solubility behavior. At a composition of 10 mol% vinyl pyridine units, the non-ionic copolymers are very soluble in chloroform but only marginally so in the quaternized form. Thus, the spectra of the quaternized copolymers in $CDCl_3$ are of rather poor quality. However, the quaternized samples dissolve very well in DMSO, and their spectra show little difference in peak position when compared with the spectra taken in chloroform. Therefore analysis of microstructural splittings in the quaternized copolymers was performed mainly in DMSO. On the other hand, the solubility of non-quaternized copolymers in DMSO was rather poor, but some spectra were taken and utilized for assignments. Another solvent used was benzene, which was proven very useful by inducing more splittings, due to its aromatic shielding effect (6). This solvent can be used for non-quaternized samples only, for solubility reasons, but it is reasonable to believe that the copolymer configuration is not affected by quaternization. There will be only conformational changes, but these cannot be observed when using different solvents. In the following discussion and presentation of the spectra, only the best spectra obtained will be presented for each sample.

With the exception of the aromatic region, the 4VP and

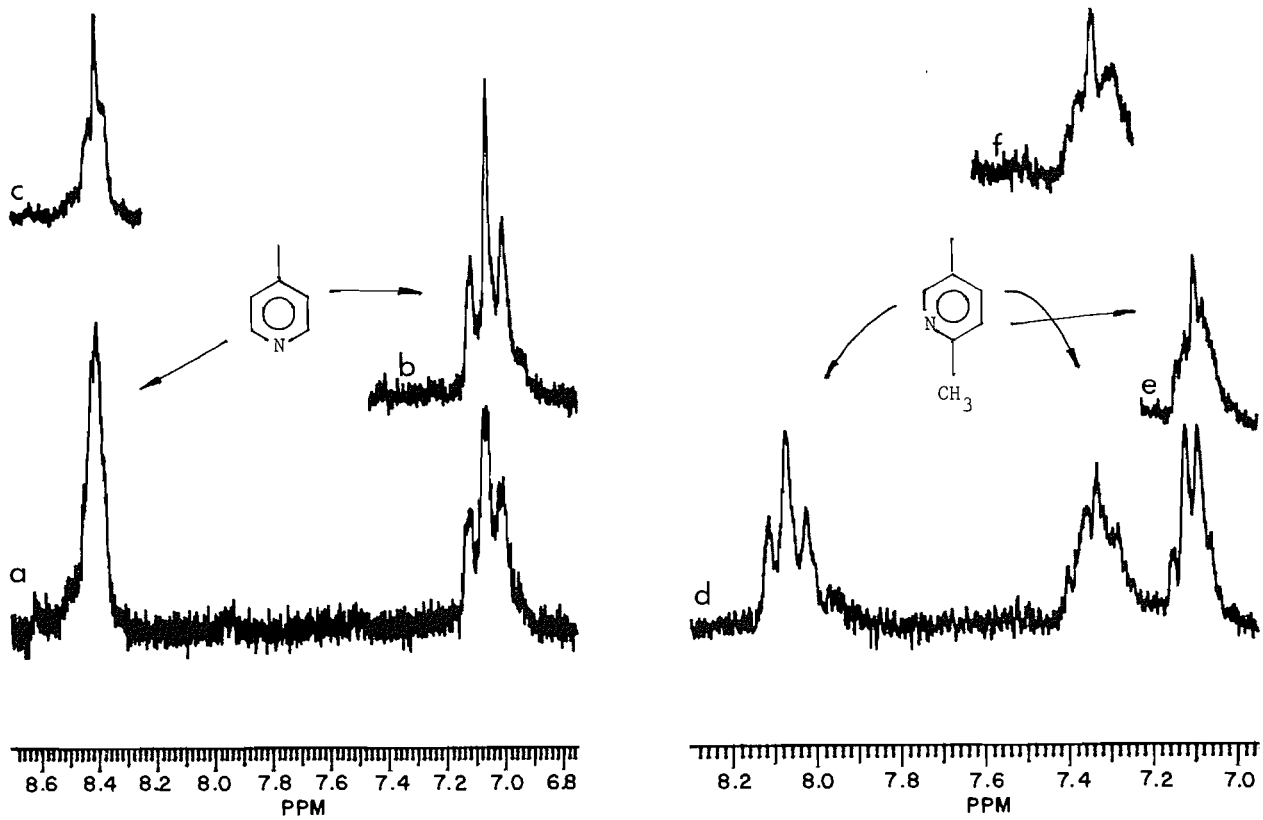

FIG. 2. Aromatic proton spectra of poly(MMA-*co*-4VP) (a), irradiated at 8.40 ppm (b), irradiated at 7.06 ppm (c), and of poly(MMA-*co*-2M5VP) (d), irradiated at 7.33 ppm (e), and irradiated at 7.10 ppm (f) registered in DMSO-d_6 at 70°C.

2M5VP copolymer spectra are rather similar when analysing the main signals and the microstructural splitting. Therefore the spectra will be presented together.

The carbonyl region

The C=O signal of poly(MMA) is split according to pentads and the assignment has been made in the literature (8, 9). It consists mainly in three parts assignable to rr, mr, and mm triads with increasing fields. The rr triad signal, the most intense in radically polymerized MMA, is split in three: mrrm, rrrm, and rrrr pentads, also with increasing field. Figure 1 shows the carbonyl region of the ^{13}C nmr spectra of poly(MMA-*co*-4VP) in C_6D_6 and of quaternized poly(MMA-*co*-4VP) in DMSO-d_6. One can note that, basically, the signal is influenced by MMA configuration only. In the non-ionic copolymer there are at least three signals that appear, probably from the vicinity of a pyridine unit, but they are rather small and their assignment is uncertain. In the quaternized sample, the chemical shifts of these signals probably coincide with the more intense configurational signals. There are some differences here, especially in the iso to hetero region, but again they are difficult to assign properly. Spectra in benzene do not present more splitting than those in chloroform or DMSO in the carbonyl region.

The aromatic region

Figure 2 presents the aromatic spectra of poly(MMA-*co*-4VP) and poly(MMA-*co*-2M5VP) registered in DMSO at 70°C. The solubility of the copolymers in DMSO is not very good, and no carbon spectra were registered in DMSO. For the proton spectra, DMSO is preferable to $CDCl_3$ or C_6D_6, because it lacks interfering signals. The signals belonging to each aromatic proton are split, and the splitting can be either a sequence distribution or a configurational effect. No such splitting is reported for the vinyl pyridine homopolymers. *ortho*-Proton coupling introduces more splitting and can hinder microstructural assignments of the signals. For this reason, Fig. 2 also

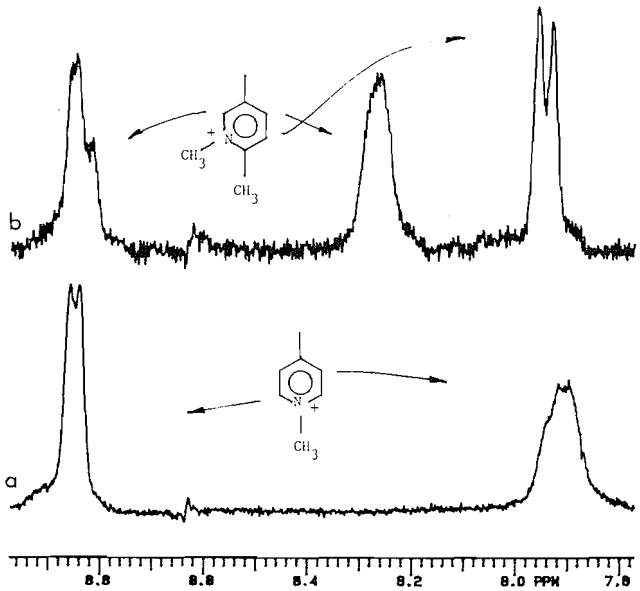

FIG. 3. Aromatic proton spectra of quaternized poly(MMA-*co*-4VP) (a) and quaternized poly(MMA-*co*-2M5VP) (b) registered in DMSO-d_6 at 70°C.

presents the results of decoupling experiments. The only non-coupled signal in these spectra belongs to the aromatic proton 6 in the 2M5VP nucleus (spectrum (d), at 8.07 ppm). This signal is split into three main parts (at 8.11, 8.07, and 8.02 ppm) in a ratio of approximately 1:2:1 and also has a rather small additional signal at 7.95 ppm. The triplet cannot be assigned to sequence splitting, because from Table 2 one can see that 2-centered triads have normalized fractions of 0% (222), 10% (221), and 90% (121). In other words, 90% of the 2M5VP units are isolated between two MMA units, whereas about 10% form blocks of two 2M5VP units. The fraction of a block of three 2M5VP units is practically nil. Consequently, one can tentatively assign the small signal at 7.95 ppm as appearing from a 221 triad, whereas the three main signals of the proton 6 belong to 121 triads and their splitting is due to the configuration of the adjacent MMA unit. At this point, a "coisotactic" addition probability has to be defined as the probability that a MMA unit and a 2M5VP unit neighboring each other will have the methoxy group and the pyridine ring on the same side of the main chain (σ).

The splitting of the main signal belonging to proton 6 can be assigned to 1m2m1, 1m2r1, and 1r2r1 triads (m being previously defined as a methoxy and pyridine ring on the same side of the main chain) or to 1r2r1, 1m2r1, and 1m2m1 triads with the increasing field. The second assignment seems more probable when one considers the shielding induced by the carbonyl groups of the MMA units. In poly(MMA), the α-methyl proton signal is split into three due to this shielding, and the syndiotactic triads resonate at higher fields (19). The shielding introduced by one carbonyl group is ca. 0.17 ppm in DMSO (6). For poly(MMA-*co*-2M5VP) the shielding experienced by the aromatic proton 6 is only 0.05 ppm. The triplet appearance of the signal suggests that σ is approximately 0.5, i.e., there is a random configurational distribution of the alternate sequences. A similar value was obtained for poly(MMA-*co*-4VP) by analysing the methoxy signal in the proton spectra (7). The results of the decoupling experiments show that indeed the triplet pattern is common for all the proton signals but the magnitude of the splittings induced by the carbonyl group is not the same for every signal. This is expected, because the geometry of the molecule allows for the carbonyl group to be closer to some protons than to others. The results of the decoupling experiments are much clearer in poly(MMA-*co*-4VP), where the distance on the chemical shift scale between the coupled protons is much greater.

Quaternization of the copolymers generates an overall shift of the aromatic signals toward lower fields. Figure 3 presents the aromatic region of the proton spectra of quaternized poly(MMA-*co*-4VP) (a) and quaternized poly(MMA-*co*-2M5VP) (b). Similar decoupling experiments were performed on these samples and the results were identical to those obtained in the case of the neutral copolymers. The signals are sensitive to the configuration of the neighboring MMA units and the ratio within a triplet does not change. This indicates an unchanged configuration after quaternization, as expected. The shifts of all signals in the quaternized samples as compared with the neutral ones are summarized in Table 2.

The aromatic carbon spectra obtained in chloroform for the two neutral copolymers are presented in Fig. 4. In this case, there are no scalar couplings to interfere with the configurational and sequence distribution splitting. Carbon 4 of 4VP (155 ppm) does not seem to be split. Carbons 2 and 6 (149 ppm) and 3 and 5 (124 ppm) present the same splittings as the decoupled proton signals. The signals at 149 ppm clearly show the 221 sequence signal (150.3 ppm) and the triplet due to the configuration of the neighbouring MMA units (the chemical shift difference between peaks is ca. 0.4 ppm). The assignment of the signals for poly(MMA-*co*-2M5VP) is somewhat complicated by the lack of literature data. The broad signal at about 136 ppm belongs to carbons 4 and 5 and the triplet at 123 ppm is the resonance of carbon 3 (11). To assign the signals at 156 ppm and 149 ppm to carbons 2 or 6, a two-dimensional HETCOR spectrum is presented in Fig. 5. It clearly shows correlation between signals at 123 ppm (C3) and 6.9 ppm (H3), 136 ppm (C4) and 7.2 ppm (H4), and 149 ppm (C6) and 8.1 ppm (H6). Hence, the signal at 156 ppm is assigned to carbon 2.

Signals belonging to carbons 2, 6, and 3 in Fig. 4 present the characteristic triplet splitting.

Quaternization produces the same shift downfield of most carbon resonances. The chemical shift differences are presented in Table 2 for spectra registered in chloroform. No spectra of the neutral samples were taken in DMSO. Figure 6 shows the spectrum of quaternized poly(MMA-co-4VP) in DMSO. Carbon 4 is shifted downfield to ca. 165 ppm and is probably highly split due to sequence distribution and configuration. Being such a small signal, it appears over a rather broad area and its assignment is very difficult. The other two signals present the triplet configurational splitting.

The aliphatic region

A. Proton spectra

Figure 7 presents the aliphatic region of the proton spectra of poly(MMA-*co*-4VP) and poly(MMA-*co*-2M5VP) registered in benzene at 60°C. Benzene was chosen as a solvent because it maximizes microstructural splitting (6). The main assignments are given in the figure. The methoxy signal consists in a main part, at ca. 3.4 ppm, and a smaller part (ca. 3 ppm) assignable to the methoxy groups that are directly subjected to the screening effect of a neighboring VP ring (i.e., belonging to sequences 2m11 and 2m1r2). This assignment of the splitting of a methoxy

signal was recently confirmed by two-dimensional nuclear Overhauser enhancement (nOe) correlated spectroscopy (20). From the area of the two main peaks one can calculate the probability of a "coisotactic" addition (σ), using the formula proposed by Ito and Yamashita (21). It has to be emphasized that the value obtained from one single sample is not very reliable. To obtain a more precise value, one has to analyse samples covering most of the possible compositional range. It is not within the scope of our paper to study the microstructural mechanism of synthesis of these copolymers, therefore the value obtained for σ will be used as an approximate one. Values obtained for σ for both copolymers are around 0.5, as previously determined from the splitting of the aromatic signals. They are 0.48 for poly(MMA-*co*-4VP) and 0.49 for poly(MMA-*co*-2M5VP).

There are more signals that appear from different sequences in the copolymers. They can be tentatively assigned using Klesper's hypothesis (22), which postulates that the substitution of a structural unit does not change the configurational splitting. Thus, the two peaks of the "screened" methoxy signal can be assigned to 1r1m2 triads (2.93 ppm in poly(MMA-*co*-4VP) and 2.99 ppm in poly(MMA-*co*-2M5VP)) and 1m1m2 triads (3.00 ppm in poly(MMA-*co*-4VP) and 3.06 ppm in poly(MMA-*co*-2M5VP)). The signals at 3.33 ppm (poly(MMA-*co*-4VP)) and 3.31 ppm (poly(MMA-*co*-2M5VP)) would then be assigned to 1r1r2 triads, with the corresponding 1m1r2 signal being overlapped by the intense signal at 3.39 ppm belonging to the 1r1r1 triads. In a similar manner, the α-methyl signals at 0.96 and 1.00 ppm belong to 1r1r2 and 1m1r2, respectively. In

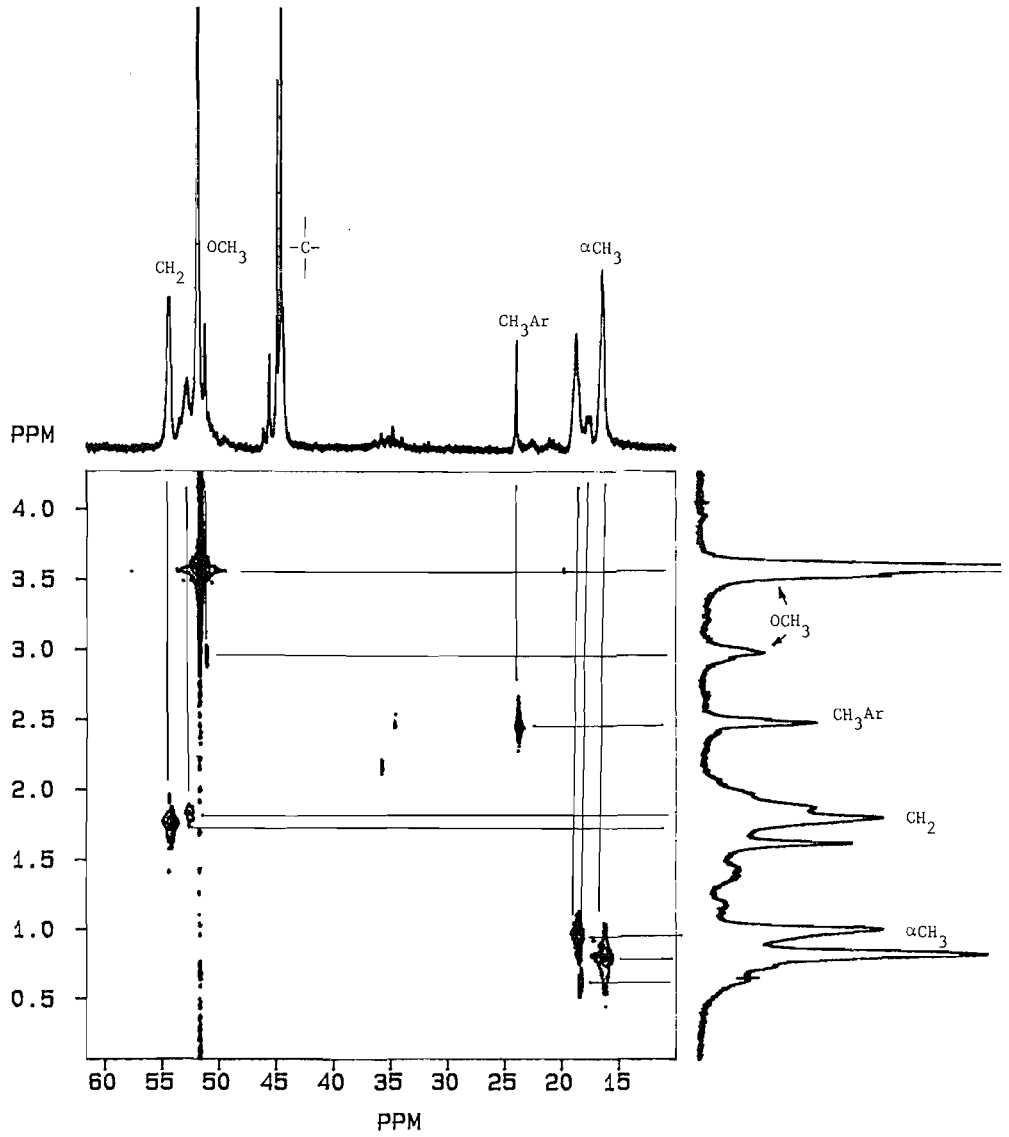

FIG. 9. HETCOR spectrum of poly(MMA-*co*-2M5VP) registered in $CDCl_3$ at room temperature.

this case, a "cosyndiotactic" cross-addition has to be considered, because the "coisotactic" one was defined as the methoxy group and the pyridine ring on the same side of the main chain. The signals at 1.16 ppm are assigned to the 1r1m2 triads. The signal at 2.45 ppm belongs to the methyl group bonded to the pyridine ring. As in the case of the aromatic protons, this signal is split in three by the different configurations of the adjacent MMA units, and the appearance is that of a triplet, confirming the random configuration of the cross-addition (σ = 0.5).

The effect of quaternization on the proton spectra of the copolymers is presented in Fig. 8. To enhance their quality, the spectra presented are taken in DMSO. There are new signals appearing from the methyl groups bonded to the pyridinium nitrogen, appearing at 4.32 ppm for poly(MMA-*co*-4VP) and at 4.26 ppm for poly(MMA-*co*-2M5VP). The fact that these chemical shifts differ slightly can be explained by the differences in the pyridinium rings in the two copolymers. In DMSO, the main methoxy signal is not split according to the configuration of the MMA units, as it is in benzene. The chemical shift of the methyl group directly bonded to the aromatic ring is now 2.8 ppm, due to major changes in the electronic density of the aromatic ring from pyridine to the pyridinium ion. This change can be better observed in spectra registered in chloroform, where it shifts from 2.4 to 3.2 ppm. However, there is another concurrent effect in chloroform solutions, and this can be observed on the shielded methoxy signal. It shifts from 3.00 to ca. 3.4 ppm and it becomes much broader when the ring is quaternized. The only explanation for such a shift is that it is due to a conformational effect of the pyridinium ions in chloroform solutions. Such effects are known for copolymers of styrene with MMA and methyl acrylate, respectively (23). Therefore, the shift of the ring-bonded methyl group in chloroform has to be explained by a combination of electronic density and conformational changes induced by quaternization. In DMSO, the position of the shielded methoxy peak does not change significantly when the copolymer is quaternized, indicating that the copolymer conformation remains basically the same. In Fig. 8 there is some overlapping from the residual water signal, but the chemical shifts of the shielded methoxy peaks can be determined to be 3.15 ppm (poly(MMA-*co*-4VP)) and 3.05 ppm (poly(MMA-*co*-2M5VP)). They were

TABLE 3. Chemical shift differences between the two methoxy carbon signals (ppm)

	Poly(MMA-*co*-4VP)		Poly(MMA-*co*-2M5VP)

DMSO	—	0.50	—	0.63
C_6D_6	0.65	—	—	—

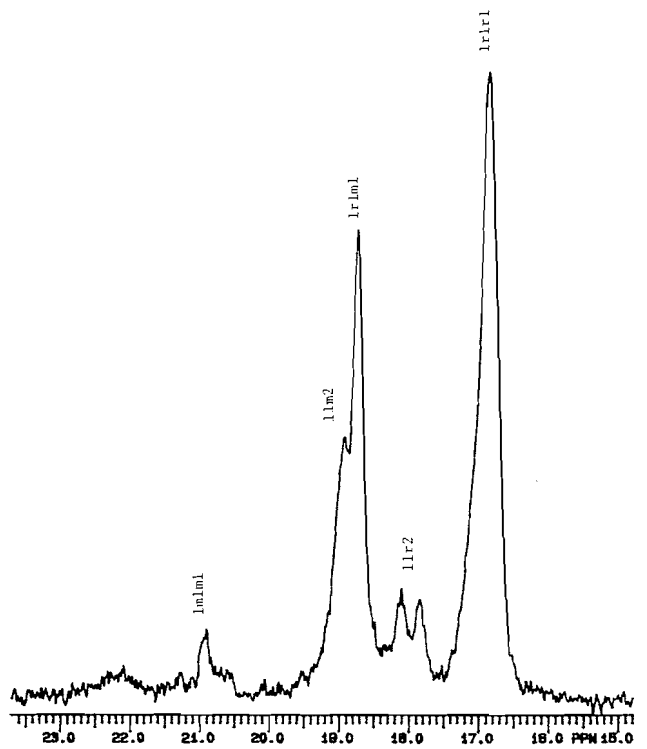

FIG. 10. α-Methyl carbon spectrum of quaternized poly(MMA-*co*-4VP) registered in DMSO-d_6 at 70°C.

different for the neutral samples also (Fig. 7), reflecting small conformational differences induced by the slightly different aromatic rings.

B. Carbon spectra

To facilitate the assignments of the carbon spectra, HETCOR two-dimensional charts were recorded for all the samples in different solvents. Figure 9 presents the HETCOR spectrum of poly(MMA-*co*-2M5VP) as an example of the assignment procedure. The main methoxy signal resonantes at 51.8 ppm (3.6 ppm for protons). The shielded methoxy also gives a separate signal in the carbon spectrum. The difference in chemical shift when compared to the main methoxy signal is 0.45 ppm (as compared with ca. 0.5 ppm for protons, both toward higher fields). This difference varies with the solvent used for spectrum registration. A quaternized sample will present no splitting for the methoxy signal in chloroform, indicating the same conformational change that was observed in the proton spectra. Table 3 summarizes the chemical shift differences observed for different samples in different solvents. The α-methyl group presents mainly three signals arising from the iso (1m1m1), hetero (1m1r1), and syndiotactic (1r1r1) triads with the increasing magnetic field, both in carbon and proton spectra. Cross-peaks can be observed for the syndiotactic signal (16.42 and 0.8 ppm) and for the heterotactic signal (18.66 and 1.0 ppm). The isotactic peak is too small. The 112 sequences, which resonate at higher fields than 1r1r1 in the proton spectra (Fig. 7), present a cross-peak with a signal at 17.66 ppm, situated between the syndiotactic and heterotactic peaks. Finally, the main chain resonances, which present an unresolved multiplet structure in the proton spectrum, are resolved into two, at 52.78 and 54.26 ppm, assignable to the VP main chain resonances and to the MMA methylene main chain, respectively. The only signal in the carbon spectrum without any correlation in the proton spectrum belongs to the quaternary carbons of the MMA units. It is split basically in three parts, 44.53 ppm (syndio), 44.86 ppm (hetero), and 45.53 ppm (isotactic MMA sequences) (10). HETCOR spectra for the other samples show that in chloroform the methyl carbons bonded to the quaternized ring shift to 21.47 ppm (2.47 ppm upfield), and that the methyl bonded to the pyridinium nitrogen resonates at 48.90 ppm (poly(MMA-*co*-4VP)) and 37.26 ppm (poly(MMA-*co*-2M5VP)).

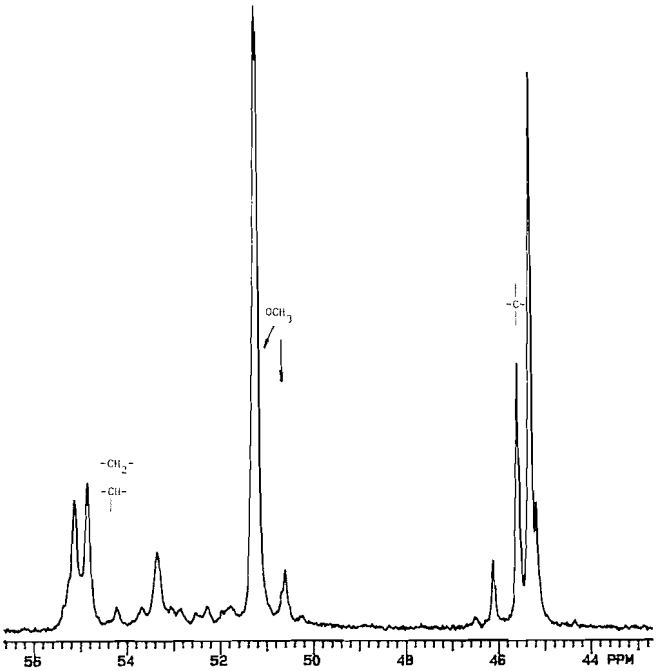

FIG. 11. Main chain carbon spectrum of poly(MMA-*co*-4VP) registered in C_6D_6 at 60°C.

Figure 10 represents the α-methyl signal in the carbon spectrum of the quaternized poly(MMA-*co*-4VP). The spectrum registered in DMSO is better resolved than the spectrum taken in chloroform. The two signals at 17.83 and 18.10 ppm were assigned with the help of the HETCOR spectrum to the 11r2 sequences. The shoulder at 18.93 ppm most likely belongs to the corresponding 11m2 triads. This assignment could not be confirmed by a HETCOR experiment, due to poor resolution. The three main signals belong to the 111 sequences, syndio (16.84 ppm), hetero (18.71 ppm), and isotactic (20.92 ppm).

Figure 11 shows the main chain (including methoxy) carbon spectrum of poly(MMA-*co*-4VP) registered in benzene at 60°C. In the quaternary carbon resonance there is only one signal, the shoulder at 45.21 ppm that can appear from a cross-addition, which can be tentatively assigned to the 112 triads. The main chain resonance is more complicated, with the methylene resonance of the MMA units split into two signals at 55.13 and 54.85 ppm. They can be assigned to the *meso* and racemic diads with increasing field, according to data found in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

literature (10). The signal at 53.35 ppm belongs to the methylene groups of the 4VP units. Complete assignment of this area could not be accomplished from the few available samples.

Conclusions

Both proton and carbon spectra of poly(MMA-*co*-4VP), of poly(MMA-*co*-2M5VP), and of their quaternized derivatives offer a wealth of information on the copolymer microstructure. There are signals, especially in the aliphatic region, that can be directly assigned to one of the structural units neighboring the other. There are also signals that offer information on the configuration of the cross-addition, especially in the aromatic region of the spectra. It can be estimated that the probability of a "coisotactic" cross-addition is ca. 0.5, indicating a perfectly random nature in such sequences. The MMA sequences have the same configuration as in poly(MMA) obtained by radical polymerization, whereas no information could be obtained about the VP sequences. At copolymer compositions low in VP, the probability of longer VP sequences is nil. This information about the analysed copolymers is needed for the assignments of the solid-state high-resolution nmr spectra.

Catalytic hydrolysis of cAMP

JIK CHIN[1] AND XIANG ZOU
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received January 8, 1987

This paper is dedicated to Professor John T. Edward

JIK CHIN and XIANG ZOU. Can. J. Chem. **65**, 1882 (1987).

[Co(trien)(OH_2)(OH)]Cl_2 is highly efficient in catalyzing the hydrolysis of cAMP to adenosine in neutral water (6×10^{-6} $M^{-1}\,s^{-1}$ at 50°C). The cobalt complex promoted hydrolysis of cAMP is estimated to be about a hundred million times faster than the uncatalyzed hydrolysis of cAMP. In the time that [Co(trien)(OH_2)(OH)]Cl_2 produces 50% cleavage of cAMP, [Co$(en)_2(NH_3)$(OH)]Cl_2 or $ZnCl_2$ has no observable effect on the hydrolysis of cAMP. A detailed mechanism is presented for the cobalt complex promoted hydrolysis of the phosphodiester.

JIK CHIN et XIANG ZOU. Can. J. Chem. **65**, 1882 (1987).

Le [Co(trien)(OH_2)(OH)]Cl_2 est très efficace pour catalyser l'hydrolyse de la cAMP en adénosine dans l'eau neutre ($6 \times 10^{-6} M^{-1}\,s^{-1}$ à 50°C). On évalue que l'hydrolyse de la cAMP qui est favorisée par le complexe de cobalt est environ cent million de fois plus rapide que l'hydrolyse non-catalysée de la cAMP. Alors que le [Co(trien)(OH_2)(OH)]Cl_2 provoque 50% de clivage de la cAMP, le [Co$(en)_2(NH_3)$(OH)]Cl_2 ou le $ZnCl_3$ ne provoque aucun effet sur l'hydrolyse de la cAMP. On propose un mécanisme pour l'hydrolyse du phosphodiester qui est favorisée par le complexe de cobalt.

[Traduit par la revue]

Introduction

Adenosine 3′,5′-monophosphate (cAMP) is a key molecule that functions as an intracellular hormone in both bacterial and animal cells (1–3). The level of cAMP in the cell is regulated in part by cAMP phosphodiesterase which catalyzes the hydrolysis of cAMP to adenosine 5′-monophosphate (AMP). cAMP phosphodiesterase is a metalloenzyme as are most other phosphodiesterases that cleave phospholipids or DNA (4). A major problem in studying phosphodiesterase model reactions is that the hydrolysis of phosphodiesters such as dimethyl phosphate and cAMP in neutral water is extremely slow even at elevated temperatures. In contrast, phosphomonoesters such as *p*-nitrophenyl phosphate (5), methyl phosphate (6), and ATP (7, 8) are relatively reactive. Numerous studies have been published on simple catalytic hydrolysis of phosphomonoesters. However, prior to this work, only enzymes had been used to hydrolyze unactivated phosphodiesters such as dimethyl phosphate or cAMP in neutral water. We report here on the non-enzymic hydrolysis of cAMP in neutral water.

Experimental

[Co(trien)(OH_2)(OH)]Cl_2 ("trien": triethylenetetramine) was prepared (9) according to known procedures. In a typical experiment, the hydrolysis of 10 m*M* cAMP in 0.5 mL D_2O buffered at pD 7.0 (0.2 *M* [Co(trien)(OH_2)(OH)]Cl_2/[Co(trien)$(OH_2)_2$]Cl_3) and 50°C was monitored by the ^1H nmr (Varian XL 300) method. During the hydrolysis reaction, the ^1H nmr signal due to the $C_{1'}$-H of cAMP (6.09 s) decreased and the signal due to the $C_{1'}$-H of adenosine (6.01 d, J = 0.03 Hz) increased (Fig. 1). At 10 m*M* cAMP there is negligible stacking of cAMP. The product was confirmed by addition of a genuine sample of adenosine to the reaction mixture. Three other systems were tested as controls (0.2 *M* phosphate; 0.2 *M* [Co$(en)_2(NH_3)$(OH)]Cl_2; 0.1 *M* $ZnCl_2$). The pD values did not drop below 6.5 during any of the hydrolysis reactions.

Results and discussion

The phosphodiester bond of cAMP did not hydrolyze to any observable extent in phosphate buffer even when the reaction solution was heated at 100°C for one month. During the extensive heating of cAMP, some unidentified decomposition reactions occurred, resulting in the formation of some precipitates. In [Co(trien)(OH_2)(OH)]Cl_2/[Co(trien)$(OH_2)_2$]Cl_3 solution, the half-life for hydrolysis of cAMP is 6 days at 50°C (Fig. 1). In [Co$(en)_2(NH_3)$(OH)]Cl_2/[Co$(en)_2(NH_3)(OH_2)$]Cl_3 or $ZnCl_2$ solutions, cAMP did not hydrolyze to any observable extent during 10 days of heating at 50°C. No precipitate formed at 50°C.

[Co(trien)$(OH)_2$(OH)]Cl_2 (0.2 *M*) promotes the hydrolysis of cAMP efficiently at pD 7 and 50°C ($k_{obs} = 1.2 \times 10^{-6}\,s^{-1}$). In order to estimate the rate of the uncatalyzed hydrolysis of cAMP in neutral water, we studied the hydrolysis of sodium ethylene phosphate (10). At pD 7 and 100°C the pseudo first order rate constant for hydrolysis of ethylene phosphate is $3.0 \times 10^{-7}\,s^{-1}$. The rate was reduced to 40% for a temperature decrease of 10°C. Therefore at 50°C the rate constant should be $3.0 \times 10^{-9}\,s^{-1}$. Ethylene phosphate is 10^5 times more reactive than cAMP under basic conditions (11). If we assume that this ratio is maintained in neutral water, the rate constant for the hydrolysis of cAMP in neutral water at 50°C should be $3.0 \times 10^{-14}\,s^{-1}$ (P—O bond cleavage). This corresponds to a half-life for the hydrolysis reaction of about a million years. Therefore we estimate that [Co(trien)(OH_2)(OH)]Cl_2 (0.2 *M*) promoted hydrolysis of cAMP is 10^8 times faster than the uncatalyzed hydrolysis of cAMP.

A variety of interesting phosphodiesterase models have been studied (12–15) Zn^{2+} or Mg^{2+} (0.2 *M*) increases the rate of hydrolysis of catechol cyclic phosphate (14) by a factor of about 10. Various metal ions (Zn^{2+}, Pb^{2+}, La^{3+}, Ba^{2+}) had been used (15, 16) to promote the hydrolysis of RNA. Among the metal ions studied, Zn^{2+} had been found to be highly efficient in cleaving phosphodiesters. It had also been shown that the hydrolysis of adenosine 2′,3′-monophosphate is four times more rapid in the presence of two equivalents of Zn^{2+} than in the absence of the metal ion (16). The present study indicates that [Co(trien)(OH_2)(OH)]Cl_2 is by far the most efficient in promoting the hydrolysis of phosphodiesters.

Phosphatases (ATPase, alkaline phosphatase) are activated by divalent metal ions as are phosphodiesterases (4). There have been many reports on cobalt complex promoted hydrolysis of phosphomonoesters (5–8) but none on that of phosphodiesters. Phosphatase models cannot be used directly as phos-

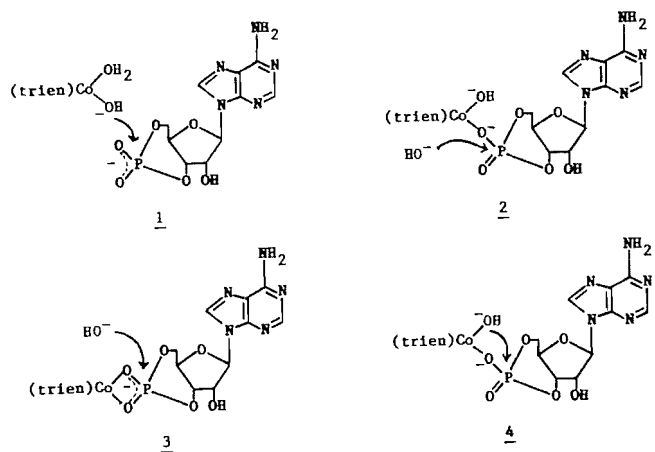
phodiesterase models since in neutral water, hydrolysis of phosphomonoesters occurs by the metaphosphate intermediate whereas phosphodiesters are generally hydrolyzed by nucleophilic attack of the water molecule on the phosphoryl group. In an interesting study, Spiro *et al.* (6) showed that $[Co(trien)(OH_2)(OH)]Cl_2$ (0.5 *M*) increases the rate of hydrolysis of methyl phosphate by a factor of 130. Attempts at hydrolyzing dimethyl phosphate with $[Co(trien)(OH_2)(OH)]Cl_2$ (6) or $[Co(NH_3)_5(OH)]Cl_2$ (17) failed. The greater rate enhancement obtained for $[Co(trien)(OH_2)(OH)]^{2+}$-promoted hydrolysis of cAMP over the rate enhancement obtained for the cobalt complex promoted hydrolysis of methyl phosphate can be explained by the fact that the uncatalyzed hydrolysis of the phosphomonoester is rapid in neutral water due to the availability of the metaphosphate mechanism. Since $[Co(trien)(OH_2)(OH)]Cl_2$ greatly increases the rate of hydrolysis of cAMP, it may do the same for dimethyl phosphate. However, dimethyl phosphate is 100 times more stable than cAMP in basic solutions (11). Therefore, even if the cobalt complex increases the rate of hydrolysis of dimethyl phosphate by a factor of 10^8, it should be difficult to detect the hydrolysis reaction.

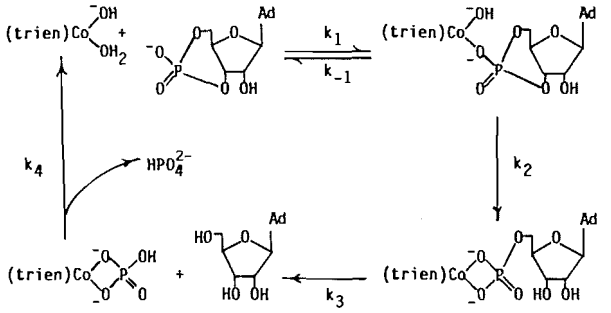
There are several possible mechanisms for $[Co(trien)(OH_2)(OH)]Cl_2$ promoted hydrolysis of cAMP (Scheme 1). Two cobalt complexes can be involved in the hydrolysis of ATP (7, 8) and *p*-nitrophenyl phosphate (18) since in these cases there are four and two anionic oxygen centers, respectively. Since phosphodiesters have only one anionic oxygen center it is likely that only one cobalt complex is involved. The basicities of the cobalt hydroxides $[Co(trien)(OH_2)(OH)]Cl_2$ and $[Co(en)_2(NH_3)(OH)]Cl_2$ are comparable ($pK_b = 8$). Under our experimental conditions, the Co—O bond of $[Co(en)_2(NH_3)(OH_2)]Cl_3$ is labile (19). The lack of activity of $[Co(en)_2(NH_3)(OH)]Cl_2$ suggests that mechanisms 1 and 2 are not important. Mechanisms 3 and 4 are kinetically indistinguishable. Mechanism 3



SCHEME 1

is unlikely to occur since binding of phosphoryl oxygen to Co(III) is very weak (17). The most probable mechanism is mechanism 4. Sargeson and co-workers (5) showed that the hydrolysis of a highly activated phosphomonoester, *p*-nitrophenyl phosphate can take place by this last mechanism.

A mechanism for the $[Co(trien)(OH_2)(OH)]Cl_2$-promoted hydrolysis of cAMP is proposed in Scheme 2. Anation (20) of $[Co(trien)(OH_2)(OH)]Cl_2$ (k_1) and its reversion (k_{-1}), hydrolysis of bidentate phosphomonoesters (k_3), and expulsion of phosphate from the cobalt complex (k_4) (20) are fast compared to the overall $[Co(trien)(OH_2)(OH)]Cl_2$ promoted hydrolysis of cAMP. Therefore the rate-determining step for the catalytic cycle should be the k_2 step. For *cis*-$[Co(en)_2(OH)(OH_2)]$-promoted hydrolysis of *p*-nitrophenyl phosphate (5) and $[Co(trien)(OH)(OH_2)]$-promoted hydrolysis of *p*-nitrophenyl methyl phosphonate (21) the rate-determining step is the anation step. The hydrolysis of the phosphodiester bond could result in



SCHEME 2

either the 3′O—P bond cleavage as shown in Scheme 2 or the 5′O—P bond cleavage. Either of the resulting phosphomonoester should hydrolyze rapidly (6). There is a linear free energy relationship between the equilibrium constant for anation on Co(III) and the basicity of the anionic ligand (22). From this relationship k_1/k_2 can be estimated ($1\,M^{-1}$). Since $k_{obs} = k_1 k_2/k_{-1}$, k_2 is estimated at $6 \times 10^{-6}\,s^{-1}$.

Recently, there has been a lot of progress in designing catalysts that cleave DNA sequence specifically (23). These catalysts are generally based on Fe(II)/O_2 and cleave DNA oxidatively rather than hydrolytically. Although the mechanism of the oxidative cleavage reaction is not clear it is believed that a hydroxyl radical is involved. Since the hydroxyl radical is highly reactive and diffusable, it is practically impossible to control the cleavage reaction with precision (24). Functional groups that promote the hydrolysis of phosphodiesters efficiently will be of great value in developing artificial sequence specific DNase and RNase.

In conclusion, it has been shown for the first time that the highly stable phosphodiester, cAMP can be hydrolyzed efficiently in neutral water with a simple catalyst ([Co(trien)-(OH_2)(OH)]Cl_2). Furthermore, the cobalt complex gives a far greater rate enhancement for the hydrolysis of cAMP ($\sim 10^8$) compared to the rate enhancement for the hydrolysis of methyl phosphate ($\sim 10^2$). We propose that the cobalt(III) ion not only stabilizes the phosphodiester anion but also activates the water molecule. The hydrolysis reaction is effected by an intramolecular nucleophilic attack of the metal hydroxide on the metal bound phosphodiester. Such double activation by a metal ion may play an important role in the enzymatic hydrolysis of cAMP and DNA. Highly efficient catalysts that hydrolyze phosphodiesters will be important in developing artificial restriction enzymes.

Étude de l'action des organomagnésiens sur les dérivés carboxyliques de la pyridine

P. CANONNE ET M. BELLEY
Département de chimie, Université Laval, Québec (Qué.), Canada

Reçu le 2 décembre 1986

Cet article est dédié au Professeur John T. Edward

P. CANONNE et M. BELLEY. Can. J. Chem. **65**, 1885 (1987).

La réaction de Grignard avec les esters pyridinecarboxyliques **1**, **2**, l'acide pyridinecarboxylique-2 (**3**), et l'anhydride pyridinedicarboxylique-2,3 (**5**) a montré une régiosélectivité au niveau du groupe carbonyle rattaché à la position 2 de l'ester ou de l'anhydride. Ceci nous a permis de développer une nouvelle voie de synthèse des dialkyl-7,7 (7*H*) furo(3,4-*b*) pyridinones-5.

P. CANONNE and M. BELLEY. Can. J. Chem. **65**, 1885 (1987).

Reactions of Grignard reagents with pyridinecarboxylic esters **1**, **2**, pyridine-2-carboxylic acid (**3**), and 2,3-pyridinedicarboxylic acid anhydride (**5**) show regioselectivity at the carbonyl in position 2. This is exemplified by an efficient synthesis of 7,7-dialkylated-7*H*-furo[3,4-*b*]-substituted pyridin-5-ones.

Dans le cadre général de l'utilisation des anhydrides d'acides dicarboxyliques pour la préparation des lactones dialkylées (1) et monoalkylées (2), nous avons entrepris le présent travail afin de démontrer que la réaction des organomagnésiens constitue une méthode générale qui peut être appliquée pour la synthèse des lactones hétéroaromatiques. Ceci nous a aussi semblé intéressant car l'examen de la littérature a montré qu'aucune étude systématique n'a été effectuée sur les dérivés de la pyridine. De plus, il apparaît que les lactones mono- et bisubstituées sont difficilement accessibles par d'autres méthodes et surtout les (7*H*) furo[3,4-*b*] pyridinones-5 (3).

En effet, récemment (4) il a été observé que l'ortholithiation du *N*,*N*-diisopropylpyridinamide-2 conduit aisément au composé lithié en position 3 lequel à son tour réagit avec un aldéhyde ou cétone pour donner la lactone correspondante. Cependant, l'ortholithiation du *N*,*N*-diisopropylpyridinamide-3 fournit uniquement le composé lithié en position 4 sans aucune trace du composé lithié en position 2. Toute tentative d'introduction, d'une fonction en position 2, n'a pu donné les résultats escomptés. D'autre part, les rendements obtenus lors de l'action des organomagnésiens sur l'ester acide issu de l'anhydride pyridinedicarboxylique-2,3 sont peu concluants et très faibles (5).

Il nous a donc semblé intéressant d'entreprendre l'étude de l'action des organomagnésiens sur les esters pyridinecarboxyliques (**1** et **2**), sur l'acide (**3**) et aussi sur l'anhydride pyrazinedicarboxylique (**4**) et l'anhydride pyridinecarboxylique-2,3 (**5**) afin d'étudier systématiquement leurs réactions avec les organomagnésiens et mettre en évidence l'influence de la position de l'azote sur les rendements réactionnels (6).

En premier lieu, nous avons étudié les facteurs qui influencent les réactions organomagnésiennes (addition, réduction et énolisation). Pour ce faire, nous avons étudié l'action du bromure de propylmagnésium avec les deux esters **1** et **2**, car cet organomagnésien favorise les réactions compétitives (7) à celle de l'addition et notamment lorsque le solvant utilisé est le THF.

Nous avons opéré avec un excès d'organomagnésien[1] aussi bien dans l'éther, dans le THF, et avons trouvé que le produit de la réaction de diaddition n'est le produit principal de la réaction que lorsque le solvant utilisé est l'éther. Nous supposons que la réaction est plus rapide dans le solvant le moins basique. Dans les deux solvants, nous n'avons observé aucune réaction de dimérisation.

En revanche, nous avons observé le propyl-4 pyridinecarboxylate-3 d'éthyle **11** (12%) qui correspond à la réaction d'alkylation du noyau pyridinique. Cependant, ceci n'est obtenu que lorsque la réaction est effectuée dans l'éther diéthylique et à la température ambiante. Il est à noter que cette réaction s'effectue moins facilement que dans le cas de la cyano-3 pyridine (9) et de la cyano-3 quinoline (10).

Les deux esters fournissent les alcools tertiaires correspondants par un processus de diaddition et les deux alcools secondaires par un processus d'addition–réduction. On note également la formation de la (pyridinyl-2)-1 butanone-1 (**6**) qui correspondrait à un processus d'addition–énolisation plutôt qu'à un processus de non réaction de la cétone intermédiaire. Il semble qu'une telle cétone se forme plus difficilement dans le cas de la réaction avec l'ester **2**. On constate généralement que le solvant joue un rôle important dans la distribution des produits de ces réactions. Il est fort probable que cette différence soit due au fait que les organomagnésiens aux concentrations utilisées sont monomères dans le tétrahydrofuranne et dimères dans l'éther diéthylique (11). Cette différence est très grande entre la réaction de diaddition et la réaction d'addition–réduction. Le tétrahydrofuranne favorise la formation de l'alcool secondaire (47% contre 16% dans l'éther). Les résultats obtenus sont rassemblés au tableau 1.

Il en résulte donc de ces expériences que les alcools secondaires ou tertiaires peuvent être obtenus selon le choix du solvant. Une expérience réalisée avec l'acide pyridinecarboxylique-2 dans le tétrahydrofuranne montre que la (pyridinyl-2)-1 butanone-1 peut être obtenue avec un rendement de 55%.

Nous décrivons ainsi une méthode importante de synthèse de cétones sans passer par les chlorures d'acide ou encore les anhydrides en utilisant des organocadmiens (12) ou les composés organiques du manganèse (13).

Les résultats obtenus avec les réactions sur les esters suggèrent que les anhydrides pyrazinedicarboxylique (**4**) et pyridinedicarboxylique (**5**) conduiraient, selon le solvant utilisé, à l'obtention spécifique des lactones monoalkylées et des lactones dialkylées.

Aussi nous avons été intéressés à synthétiser les spirolactones correspondantes en faisant réagir le di(bromomagnésio)-1,4 butane avec les deux anhydrides **4** et **5** afin de démontrer l'influence de l'azote. Nous avons constaté alors que l'anhydride **4**

1. Nous avons observé une grande sensibilité de ces substrats vis-à-vis des organomagnésiens à 25°C se traduisant par la formation d'une quantité importante des composés à haut poids moléculaire.

SCHÉMA 1

fournit la lactone correspondante **12** difficilement même à basse température, et que l'anhydride **5** conduit toutefois à la formation de la spiro[cyclopentane-1,7′ (5′*H*) furo[3,4-*b*] pyridin]-one-5′ (**13**) avec un rendement de (45%) (schéma 1). En outre, cette réaction montre une régiosélectivité très marquée. En effet la spiro[cyclopentane-1,5′ (7′*H*) furo[3,4-*b*] pyridin]one-7′ (**14**) isomère n'est obtenue qu'en faible quantité (8%). Nous supposons que cette régiosélectivité peut être attribuée à la proximité de l'atome de l'azote qui forme une liaison de coordination avec l'atome de magnésium, favorisant ainsi l'attaque préférentielle du carbonyle rattaché à la position 2 de l'anhydride **5** (schéma 2). Ainsi, le carboxylate formé réagit à son tour avec une seconde fonction organomagnésienne et conduit après hydrolyse à la lactone **13** (schéma 3).

Nous avons en premier lieu réalisé une étude dans le tétrahydrofuranne à différentes températures et nous avons observé qu'à basse température (−20 à −60°C) le rendement global en lactones est supérieur à celui trouvé à la température ambiante. Ceci peut être attribué à une réactivité plus faible du groupement carboxylate intermédiaire aux températures comprises entre −20 et −60°C. Cette réactivité semble être plus accusée dans le cas du carboxylate rattaché à la position 2 de la pyridine que dans le cas du carboxylate situé en position 3. En effet, les rendements en lactones **21** et **22** ne varient pas avec la température de la réaction alors que le rendement de la lactone **23** passe de 0 à 13%. De plus, on constate une forte augmentation de la propyl-7 (7*H*) furo[3,4-*b*] pyridinone-5 (**22**) (de 10 à 28%). Cette lactone est probablement formée par un processus d'addition–réduction (schéma 4). Comme nous n'avons pas isolé la propyl-5 (5*H*) furo[3,4-*b*] pyridinone-7, nous supposons encore que la formation de lactone **22** peut être attribuée à la présence de l'azote. Enfin une étude réalisée dans le mélange de solvants éther–toluène montre que la formation des lactones **21** et **22** est favorisée au détriment de la lactone **23** (tableau 2). Ces observations sont en accord avec la grande réactivité de l'acide pyridinecarboxylique-2 (**3**) (tableau 1).

De l'ensemble de ces résultats, il apparaît que les réactions secondaires sont favorisées en un moindre degré lorsque les conditions ci-dessous sont respectées :

1. Préparation et réaction des organomagnésiens dans un solvant hydrocarboné en présence de l'éther diéthylique.
2. Utilisation d'une température de réaction comprise entre −20 et −60°C.

Nous constatons ainsi que l'anhydride **5** est un substrat de choix pour la synthèse de (7*H*) furo[3,4-*b*] pyridinones-5 difficilement accessibles par d'autres voies de synthèse.

Partie expérimentale

Les spectres ir ont été enregistrés à l'aide d'un appareil Beckman IR 4250, et les spectres de rmn ^{1}H sur un appareil Bruker (90 MHz) et sur un appareil Varian XL-200 (200 MHz). Les spectres rmn ^{13}C ont été enregistrés sur un appareil Bruker MP-80 (20 MHz). Les spectres de masse ont été effectués sur un appareil Hewlett–Packard 5992 (GS/MG). Les séparations chromatographiques sur colonne ont été effectuées sur gel de silice (Woelms 32–63). Le nicotinate d'éthyle, l'acide picolique, le picolinate d'éthyle et l'acide pyridinedicarboxylique-2,3 sont commercialement accessibles chez Aldrich. Les microanalyses ont été effectuées par Galbraith Laboratories Inc.

Matériel de départ

Le tétrahydrofuranne a été distillé sur sodium et gardé sous atmosphère d'azote, les anhydrides pyridinedicarboxylique-2,3 et pyrazinecarboxylique-2,3 ont été préparés selon la méthode classique en utilisant l'anhydride acétique (14). Les organomagnésiens ont été préparés selon les modes opératoires précédemment décrits (1, 8).

Réaction du bromure de n*-propylmagnésium avec le pyridinecarboxylate-2 d'éthyle ou picolinate d'éthyle (1)*

On prépare dans l'éther un excès de bromure de *n*-propylmagnésium (4 équivalents), et on ajoute l'ester (7,603 g) à 0°C, puis on laisse réagir sous agitation pendant 16 h à la température ambiante. Après hydrolyse et traitement habituel, on sépare les produits par chromatographie sur gel de silice en utilisant le mélange d'éluants acétate d'éthyle – éther de pétrole 1:99 – 20:80. On isole respective-

(Pyridinyl-2)-1 butanone-1 (6): Rdt : 10% (0,153 g) liquide; ir ν_{max} : (film) 2960, 2930, 2870, 2851, 2802, 1715, 1455, 1293, 1270, 1160, 1140, 1116, 1008, 871 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,02 (3H, *t*, *J* = 7 Hz, CH_3CH_2), 1,78 (2H, q, *J* = 7 Hz, CH_3CH_2), 1,78 (2H, q, *J* = 7 Hz, $CH_3CH_2CH_2$), 3,33 (2H, t, *J* = 7 Hz, CH_2CO), 7,35–8,33 (3H, m), 8,77 (1H, dd) ppm; rmn ^{13}C ($CDCl_3$) δ : 202,1, 154,0, 149,1, 136,9, 127, 121,8, 39,7, 17,6, 13,9 ppm. *Anal.* calc. pour $C_9H_{11}NO$: C 72,46, H 7,43, N 9,38; tr. : C 72,38, H 7,31, N 9,30.

(Pyridinyl-2)-1 butanol-1 (7): Rdt : 48% (0,763 g) liquide; ir ν_{max} (film) : 3380, 2968, 2933, 2871, 1599, 1575, 1468, 1439, 1128, 1069, 1040, 751 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 0,73–2,00 (7H, m), 4,77 (1H, t, *J* = 6 Hz, —C*H*OH), 5,17 (1H, s, OH), 7,03–7,90 (3H, m), 8,53 (1H, dd) ppm; rmn ^{13}C ($CDCl_3$) δ : 163,2, 148,4, 136,8, 122,3, 120,5, 73,1, 40,7, 18,7, 14,0 ppm. *Anal.* calc. pour $C_9H_{13}NO$: C 71,49, H 8,66, N 9,36; tr. : C 71,58, H 8.72, N 9,11.

(Pyridinyl-2)-4 heptanol-4 (8): Rdt : 30% (0,604 g) liquide; ir ν_{max} (film) : 3403, 2958, 2934, 2872, 1599, 1574, 1471, 1440, 1403, 1166, 1031, 798, 756 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 0,67–2,00 (14H, m, $CH_3CH_2CH_2$), 5,40 (1H, s), 7,07–7,90 (3H, m), 8,60 (1H, d, *J* = 5 Hz) ppm; rmn ^{13}C ($CDCl_3$) δ : 164,5, 147,3, 136,8, 121,6, 119,8, 76,2, 44,9, 16,8, 14,5 ppm. *Anal.* calc. pour $C_{12}H_{19}NO$: C 74,57, H 9,91, N 7,24; tr. : C 74,43, H 9,80, N 7,19.

Réactions du bromure de n*-propylmagnésium avec le pyridinecarboxylate d'éthyle ou nicotinate d'éthyle (2)*

1. Dans le THF

On utilise 4 équivalents de réactif de Grignard par équivalent d'ester (**2**) (3,063 g) et on procède comme précédemment. On sépare les composés obtenus par chromatographie sur gel de silice à l'aide du mélange éluant éther de pétrole – acétate d'éthyle.

(Pyridinyl-3)-1 butanol (9): Rdt : 47% (1,421 g) liquide; ir ν_{max} (film) : 3330, 2949, 2862, 1423, 1028, 711 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 0,70–1,90 (7H, m), 4,68 (1H, t, *J* = 6 Hz, C*H*OH), 5,32 (1H, s, OH), 7,23 (1H, dd, *J* = 5 et 8 Hz), 7,77 (1H, dd, *J* = 1,5 et 8 Hz), 8,23–8,50 (2H, m) ppm; rmn ^{13}C ($CDCl_3$) δ : 148,1, 147,7, 141,4, 134,2, 123,6, 71,5, 41,3, 18,9, 13,9 ppm. *Anal.* calc. pour $C_9H_{13}NO$: C 71,49, H 8,66, N 9,26; tr. : C 71,58, H 8,71, N 9,18.

(Pyridinyl-3)-4 heptanol-4 (10): Rdt : 46% (1,775 g) liquide; ir ν_{max} (film) : 3250, 2960, 2932, 2873, 1470, 1420, 718 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 0,60–1,97 (14H, m), 3,97 (1H, s, OH), 7,20 (1H, dd,

J = 5 et 8 Hz), 7,80 (1H, dd), 8,40 (1H, dd), 8,61 (1H, d) ppm; rmn ^{13}C ($CDCl_3$) δ: 147,3, 142,7, 133,8, 123,1, 75,7, 45,4, 16,8, 14,4 ppm. *Anal.* calc. pour $C_{12}H_{19}NO$: C 74,57, H 9,91, N 7.24; tr. : C 74,37, H 9,80, N 7,20.

2. *Dans l'éther diéthylique*

À une solution éthérée de bromure de *n*-propylmagnésium (4 équivalents) on ajoute goutte à goutte 1,603 g (10,6 mmol) de nicotinate d'éthyle dilué dans le même solvant et on procède suivant le même mode opératoire que précédemment. Après chromatographie sur colonne de gel de silice on obtient 63% (1,287 g) de (pyridinyl-3)-4 heptanol-4 (**10**), 16% (0,257 g) de (pyridinyl-3)-1 butanol (**9**), 2% (0,033 g) de pyridinyl-3 butanone-1 et 12% (0,250 g) de propyl-4 pyridinylcarboxylate d'éthyle (**11**).

*Propyl-4 pyridinylcarboxylate-3 d'éthyle (**11**)* : Rdt : 12% (0,250 g) liquide; ir ν_{max} (film) : 2951, 2950, 2862, 1861, 1721, 1587, 1271, 1101 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 0,97 (3H, t, J = 7 Hz), 1,40 (3H, t, J = 7 Hz), 1,20–1,90 (2H, m), 2,97 (2H, t, J = 7 Hz), 4,40 (2H, q, J = 7 Hz), 7,20 (1H, d, J = 5 Hz), 8,60 (1H, d, J = 5 Hz), 9,10 (1H, s) ppm; rmn ^{13}C ($CDCl_3$) δ: 166,5, 153,4, 152,2 151,8, 126,4, 125,4, 61,2, 35,8, 24,0, 14,3, 14,0 ppm; sm *m/e*: 194,30 (M + 1, 6,3), 193,20 (M^+, 56,6), 150,2 (35), 148,20 (100%), 135,25 (54), 119,15 (38), 118,15 (36), 91,20 (31), 65,10 (32). *Anal.* calc. pour $C_{11}H_{15}NO_2$: C 68,37, H 7,82, N 7,24; tr. : C 68,30, H 7,75, N 7,20.

*Réaction du bromure de propylmagnésium avec l'acide pyridine-carboxylique-2 ou picolique (**3**)*

À 3,013 g (24,5 mmol) d'acide **3** en suspension dans le THF anhydre, on ajoute goutte à goutte le réactif de Grignard préparé à partir de 18,733 g (152 mmol) de bromopropane et 4,102 g de Mg dans 150 mL de THF, puis on laisse réagir 20 h. Après hydrolyse avec une solution saturée de chlorure d'ammonium, on ramène la phase aqueuse à pH 7, puis on extrait au dichlorométhane. Après chromatographie sur colonne de gel de silice du produit brut de réaction, on isole 2,011 g (55%) de (pyridinyl-2)-1 butanone-1 (**6**).

Réaction des dibromomagnésiens avec les anhydrides

*Réaction du di(bromomagnésio)-1,4 butane avec l'anhydride pyrazinedicarboxylique (**4**)*

À une solution de 64 mL de THF contenant 15,3 mmol de (dibromomagnésio)-1,4 butane (8), on ajoute à −5°C 2,255 g (15,2 mmol) d'anhydride **4** dissous dans 14 mL de THF. Après 10 min d'agitation à −20°C, on hydrolyse le mélange réactionnel. Par chromatographie sur colonne de gel de silice, en utilisant le mélange d'éluants acétate d'éthyle – benzène 3:97, on isole 0,275 g de spirolactone **12** (Rdt 10%). Le dosage par chromatographie en phase gazeuse donne 13% de spiro-[cyclopentane-1,5′ (7′*H*) furo[3,4-*b*] pyrazin]one-7′ (**12**); ir ν_{max} (CH_2Cl_2) : 1777 (C=O) cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,90–2,35 (8H, s, H), 8,93 (2H, s) ppm. Ce composé semble être sensible à l'air et donc n'a pu être analysé de façon satisfaisante.

*Réactions du di(bromomagnésio)-1,4 butane avec l'anhydride pyridinedicarboxylique-2,3 (**5**)*

À une solution de 29 mmol de di(bromomagnésio)-1,4 butane dans 89 mL de THF maintenue à 0°C, on ajoute 2,88 g (19,3 mmol) d'an-

hydride **5** dissous dans 30 mL de THF anhydre, puis on laisse réagir sous agitation pendant 16 h. Après chromatographie sur colonne de gel de silice en utilisant un mélange acétate d'éthyle – éther de pétrole 75:25 comme éluant, on obtient 1,443 g de spirolactone **13**, Rdt 45% (0,252 g), et 8% de la lactone isomère **14**.

*Spiro[cyclopentane-1,7′ (5′*H*)furo[3,4-*b*] pyridin]-one-5 (**13**)* : F = 102,8–103,3°C; ir ν_{max} (CH_2Cl_2) : 1762 (C=O), 1609, 1590, 1108, 1093, 966 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,85–2,45 (8H, s), 7,50 (1H, dd, J = 5 et 8 Hz), 8,23 (1H, dd, J = 2 et 8 Hz), 8,93 (1H, dd, J = 2 et 5 Hz) ppm; rmn ^{13}C ($CDCl_3$) δ : 171,4, 168,0, 155,5, 133,8, 123,9, 119,9, 96,4, 38,2, 25,4 ppm; sm *m/e* : 190,10 (M + 1, 4,7%) 189,20 (M^+, 27,5%). *Anal.* calc. pour $C_{11}H_{11}NO_2$: C 76,27, H 6,40, N 8,08; tr. : C 76,40, H 6,51, N 7,98.

*Spiro[cyclopentane-1,5 (7*H*)furo[3,4-*b*] pyridin]-one-7 (**14**)* : F = 84–86°C; ir ν_{max} (CH_2Cl_2) : 2958, 2859, 1770, 1599, 1585, 1470, 1342, 1306, 1102, 988, 959, 801 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,93–2,30 (8H, s), 7,67 (1H, dd, J = 5 et 8 Hz), 7,99 (1H, dd, J = 2 et 8 Hz), 8,97 (1H, dd, J = 2 et 5 Hz) ppm; rmn ^{13}C ($CDCl_3$) δ : 167,6, 152,5, 146,8, 144,8, 130,0, 127,6, 93,7, 39,6, 25,0 ppm; sm *m/e* : 190,10 (M + 1, 15), 189,20 (M^+, 100%) 166,15 (140), 160,05, 147,05 (94), 133,10 (42), 132,10 (78), 106,05 (56), 105,05 (84), 104,05 (43), 78,05 (35), 77,05 (67), 51,10 (36). *Anal.* calc. pour $C_{11}H_{11}NO_2$: C 76,27, H 6,40, N 8,08; tr. : C 76,20, H 6,38, N 7,90.

*Réaction du bromure de phénylmagnésium avec l'anhydride pyridinedicarboxylique-2,3 (**5**)*

Une solution de bromure de phénylmagnésium préparée dans le THF (29,5 mmol) est ajoutée à une solution de l'anhydride **5** (13,4 mmol) dans le THF à −70°C et on laisse agiter 20 h à −10°C avant d'hydrolyser. Après chromatographie sur gel de silice du produit brut en utilisant comme éluant le mélange acétate d'éthyle – éther de pétrole 11:89, on recueille 1,910 g de la lactone **15** (Rdt 50%) et 1,862 g de son isomère **16** impur que l'on recristallise pour obtenir 1,456 g (Rdt 40%). À la température ambiante on obtient 31% (1,264 g) de lactone **15**.

*Diphényl-7,7 (7*H*)furo[3,4-*b*] pyridinone-5 (**15**)* : F = 162–163°C; ir ν_{max} (CH_2Cl_2) : 1768, 1600, 1586, 1491, 1160, 1126, 1076, 967, 953 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 7,20–7,70 (11H, m), 8,27 (1H, dd, J = 2 et 8 Hz), 8,97 (1H, dd, J = 2 et 5 Hz) ppm; rmn ^{13}C ($CDCl_3$) δ : 170,8, 167,6, 155,3, 139,9, 134,4, 128,6, 127,0, 124,2, 119,7, 90,7; sm *m/e* : 288,25 (M + 1, 11), 287,15 (M^+, 60,7), 286,15 (21), 243,20 (24), 242,20 (20), 210 (100%), 182,10 (32), 154,25 (22), 105,00 (28), 77,15 (52), 51,10 (25).

*Diphényl-5,5 (5*H*) furo[3,4-*b*] pyridinone-7 (**16**)* : F = 126,2–126,6°C; ir ν_{max} (CH_2Cl_2) : 1780, 1600, 1161, 1125, 1110, 968 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 7,43 (10H, s), 8,13 (1H, dd, J = 2 et 8 Hz), 9,00 (1H, J = 2 et 5 Hz) ppm; rmn ^{13}C ($CDCl_3$) δ : 167,3, 152,9, 146,4, 144,1, 140,2, 132,8, 129,0, 128,9, 127,5, 127,0, 89,9 ppm; sm *m/e* : 288,15 (M + 1, 3,3), 287,15 (M^+, 18,7), 244,20 (18), 243,20 (100%), 242,20 (34), 241,20 (21), 210,05 (48), 182,10 (11), 154,25 (23), 127,10 (31), 120,60 (10), 105 (17), 77,15 (31), 51,10 (22).

Réaction du bromure de p*-tolymagnésium avec l'anhydride pyridinecarboxylique-2,3 (**5**)*

À une solution de 2 g (13,4 mmol) de l'anhydride **5** dans 30 mL de THF, on ajoute goutte à goutte la solution organomagnésienne (4 équivalents) préparée dans le THF à −60°C, puis on laisse agiter pendant 20 h à −10°C, puis on hydrolyse. Après chromatographie flash sur gel de silice en utilisant le mélange acétate d'éthyle – benzène 5:95 et 8:92 on recueille 2,075 g (49%) de di(*p*-tolyl)-7,7 (7*H*) furo-[3,4-*b*] pyridinone-5 (**17**) et 1,439 g (34%) de di(*p*-tolyl)-5,5 (7*H*) furo[3,4-*b*] pyridinone-7 (**18**).

*Di(*p*-tolyl)-7,7 (7*H*)furo[3,4-*b*] pyridinone-5 (**17**)* : F = 112–113°C; ir ν_{max} (CH_2Cl_2) : 1771, 1604, 1511, 1158, 1127, 1121 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 2,33 (6H, s), 7,07–7,64 (9H, m), 8,27 (1H, dd, J = 2 et 8 Hz), 9,00 (1H, dd, J = 2 et 5 Hz) ppm; rmn ^{13}C ($CDCl_3$) δ : 170,7, 167,8, 155,3, 138,4, 137,1, 134,3, 129,2, 127,0, 124,0, 119,7, 91,0, 21,0 ppm; sm *m/e* : 317,20 (M + 2, 2), 316,20 (M + 1, 16,6), 315,20 (M^+, 75,2), 271,30 (70), 256,30 (21), 241,10 (21), 224,15 (100%), 196,20 (25), 167,25 (38), 119,20 (34), 91,15 (42), 77,15 (22), 65,10 (26). *Anal.* calc. pour $C_{21}H_{17}NO_2$: C 79,98, H 5,43, N 4,44; tr. : C 79,91, H 5,38, N 4,32.

*Di(*p*-tolyl)-5,5 (5*H*) furo[3,4-*b*] pyridinone-7 (**18**)* : Rdt : 34% (1,439 g); F = 157–158°C; ir ν_{max} (CH_2Cl_2) : 1777, 1512, 1157, 1128, 1109, 960 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 2,33 (6H, s), 7,23 (8H, s), 7,63 (1H, dd, J = 5 et 8 Hz), 8,07 (1H, dd, J = 2 et 8 Hz), 8,97 (1H, dd, J = 2 et 5 Hz) ppm; rmn ^{13}C ($CDCl_3$) δ : 167,6, 152,9, 146,9, 144,1, 139,0, 137,5, 132,8, 129,5, 127,5, 127,7, 90,1, 21,1 ppm; sm *m/e* : 316,20 (M + 1, 7,4), 315,20 (M^+, 34,5), 272,30 (21), 271,30 (100%), 270,30 (22), 257,20 (22), 256,30 (85), 254,20 (20), 224,15 (47), 167,25 (29), 91,15 (29). *Anal.* calc. pour $C_{21}H_{17}NO_2$: C 79,98, H 5,43, N 4,44; tr. : C 79,80, H 5,45, N 4,38.

*Réaction du bromure de méthylmagnésium avec l'anhydride pyridinedicarboxylique-2,3 (**5**)*

On prépare ce réactif de Grignard en faisant barboter un courant de bromométhane dans le ballon réactionnel refroidi contenant 0,757 g de magnésium et 30 mL de THF anhydre, puis on y ajoute goutte à goutte à −60°C 2,0 g (13,4 mmol) d'anhydride **5** dissous dans 50 mL de THF, et on laisse la réaction se poursuivre sous agitation pendant 16 h à 10°C. Après hydrolyse et traitement habituel, on recueille par chromatographie sur gel de silice, en utilisant comme éluant le mélange de solvants acétate d'éthyle – éther de pétrole 35:65, deux lactones **19** et **20**.

*Diméthyl-7,7 (7*H*)furo[3,4-*b*] pyridinone-5 (**19**)* : Rdt : 50%; F = 85–86°C; ir ν_{max} (CH_2Cl_2) : 1766, 1606, 1589, 1475, 1326, 1200, 1168, 1143, 1092, 1047, 950, 907, 789 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,73 (6H, s), 7,53 (1H, dd, J = 5 et 8 Hz), 8,27 (1H, dd, J = 2 et 8 Hz), 8,93 (1H, dd, J = 2 et 5 Hz) ppm; rmn ^{13}C ($CDCl_3$) δ : 1730, 167,8, 155,3, 134,3, 124,1, 119,0, 86,4, 25,7 ppm; sm *m/e* : 163,10 (17), 149,10 (8), 148,20 (100%), 105,05 (9), 92,10 (21), 77,10 (9), 65,15 (10), 51,15 (8).

*Diméthyl-5,5 (5*H*) furo[3,4-*b*] pyridinone-7 (**20**)* : Rdt : 20%; F = 104–104.5°C; ir ν_{max} (CH_2Cl_2) : 1772, 1318, 1206, 1167, 1090, 1050, 949, 900, 801 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,73 (6H, s), 7,61 (1H, dd, J = 5 et 8 Hz), 7,98 (1H, dd, J = 2 et 8 Hz), 8,92 (1H, dd, J = 2 et 5 Hz) ppm; rmn ^{13}C ($CDCl_3$) δ : 167,6, 152,6, 149,0, 144,1, 129,9, 127,7, 83,9, 27,3 ppm; sm *m/e* : 164,10 (M + 1, 4,1), 163,20 (M + 37), 148,10 (100%), 120,05 (52), 118,15 (21), 104,05 (15), 92,10 (39), 72,10 (17), 51,15 (22). *Anal.* calc. pour $C_9H_9NO_2$: C 66,25, H 5,56, N 8,58; tr. : C 66,15, H 5,48, N 8,51.

*Réaction du bromure de propylmagnésium avec la furo[3,4-*b*] pyridinedione-5,7 ou l'anhydride pyridinedicarboxylique-2,3 (**5**)*

1. THF à 25°C

À 120 mmol de bromure de propylmagnésium dans le THF on ajoute 34,3 mmol (5,119 g) d'anhydride **5**. Après agitation durant 24 h, on hydrolyse le mélange réactionnel et, par séparation chromatographique, on obtient 1,128 g (Rdt 19%) de dipropyl-7,7 (7*H*) furo[3,4-*b*] pyridinone-5 (**21**) et 0,687 g (Rdt 10%) de propyl-7 (7*H*) furo[3,4-*b*] pyridinone-5 (**22**).

2. Réaction du bromure de propylmagnésium avec l'anhydride pyridinedicarboxylique-2,3 dans un mélange éther diéthylique – toluène 1:3 à 25°C

On prépare le bromure de propylmagnésium à partir de 4,537 g (36,9 mmol) de bromopropane et 0,986 g de magnésium dans 40 mL d'éther diéthylique. À ce réactif refroidi à 0°C, on ajoute goutte à goutte 2,0 g (13,4 mmol) d'anhydride **5** dissous dans 120 mL de toluène anhydre bouillant. On laisse agiter pendant 16 h à la température ambiante avant d'hydrolyser le mélange réactionnel. Après chromatographie sur gel de silice en utilisant comme éluant les mélanges acétate d'éthyle – benzène 5:95 et acétate d'éthyle – benzène 10:90, on isole trois produits dans les proportions citées ci-dessous.

*Dipropyl-7,7 (7*H*) furo[3,4-*b*] pyridinone-5 (**21**)* : 1,150 g (Rdt 39%).

*Propyl-7 (7*H*) furo[3,4-*b*] pyridinone-5 (**22**)* : 0,272 g (Rdt 11%).

*Dipropyl-5,5 (5*H*) furo[3,4-*b*] pyridinone-7 (**23**)* : 0,096 g (Rdt 3%).

3. À basse température dans le tétrahydrofuranne

On refroidit à −60°C le réactif de Grignard obtenu à partir de 4,124 g (33,5 mmol) de bromopropane et 0,897 g de magnésium dans 28 mL de THF anhydre, puis on y ajoute goutte à goutte 0,986 g (6,61 mmol) d'anhydride **5** dissous dans 25 mL de THF en trois réactions (1–3) à différentes températures : (1) à −60°C, 10 min; (2) à −40°C, 10 min; (3) −20°C, 10 min. Après hydrolyse on dose par chromatographie en phase gazeuse les lactones obtenues en utilisant comme standard interne le phénanthrène. Les rendements correspondants obtenus dans chacune des réactions sont donnés ci-dessous.

(1) À −60°C : dipropyl-7,7 (7*H*) furo[3,4-*b*] pyridinone-5 (**21**) : 21%; propyl-7 (7*H*) furo[3,4-*b*] pyridinone-5 (**22**) : 31%; dipropyl-5,5 (5*H*) furo[3,4-*b*] pyridinone-7 (**23**) : 12%.

(2) À −40°C : dipropyl-7,7 (7*H*) furo[3,4-*b*] pyridinone-5 (**21**) : 20%; propyl-7 (7*H*) furo[3,4-*b*] pyridinone-5 (**22**) : 31%; dipropyl-5,5 (5*H*) furo[3,4-*b*] pyridinone-5 (**23**) : 13%.

(3) À −20°C : dipropyl-7,7 (7*H*) furo[3,4-*b*] pyridinone-5 (**21**) : 19%; propyl-7 (7*H*) furo[3,4-*b*] pyridinone-5 (**22**) : 28%; dipropyl-5,5 (5*H*) furo[3,4-*b*] pyridinone-7 (**23**) : 13%.

*Dipropyl-7,7 (7*H*) furo[3,4-*b*] pyridinone-5 (**21**) :* F = 59–60°C; ir ν_{max} (CCl_4) : 2910, 2876, 2812, 1776, 1612, 1592, 1288, 1184, 1096, 1074, 952 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 0,80–0,90 (6H, m), 0,90–1,55 (4H, m), 1,94–2,20 (4H, m), 7,49 (1H, dd, J = 5 et 8 Hz), 8,20 (1H, dd, J = 2 et 8 Hz), 8,89 (1H, dd, J = 2 et 5 Hz) ppm; rmn ^{13}C ($CDCl_3$) δ : 171,5, 168,4, 155,1, 133,8, 123,8, 121,0, 91,2, 39,7, 16,5, 14,0 ppm; sm *m/e* : 177,10 (71), 176,10 (95), 148,15 (29), 134,10 (100%), 130,10 (17), 106,00 (27), 78,05 (21). *Anal.* calc. pour $C_{13}H_{17}NO_2$: C 71,20, H 7,82, N 6,38; tr. : C 71,02, H 7,91, N 6,46.

2,4,6-Trinitrophenyl cellulose (picryl cellulose) was synthesized by S_NAr displacement of chloride from picryl chloride by sodium cellulosate. The cellulosate was prepared *in situ* from microcrystalline cellulose and sodium methoxide. Depending upon the procedure used, two products with different degrees of picrylation resulted; one contained one picryl ring per ca. 6.5 glucosyl units (PC-6), while the other had ca. one picryl ring per 12 (PC-12). These picryl ethers were characterized by several independent methods: 400-MHz ^1H nuclear magnetic resonance spectroscopy of the DMSO-soluble material, temperature-dependent mass spectrometry (ion pyrograms), and differential scanning calorimetry (DSC). The nuclear magnetic resonance spectrum displays peaks in the low field region (8–9.5 ppm) assigned to the picryl rings; these resonances are well separated from those for possible alternative compounds such as unreacted picryl chloride, picric acid, or 2,4,6-trinitroanisole. It is suggested that the various picryl resonances arise primarily from different microenvironments and (or) conformational preferences of the polymer chain rather than from different substitution sites. Substitution at a primary C-6 position of the glucosyl moiety is favoured. DSC shows that while cellulose undergoes an endothermic decomposition between 320 and 350°C, picryl cellulose exhibits an exothermic decomposition at ca. 230°C. This exotherm is accompanied by the liberation of picric acid, as confirmed by nuclear magnetic resonance; mass spectral results indicate concurrent chain cleavage to yield smaller polysaccharides. A mechanism for initiation of pyrolytic decomposition is proposed, in which loss of picric acid is accompanied by rupture of a glycosidic bond with concomitant formation of glucosan and enolic end groups on the remaining fragments.

MICHAEL J. STRAUSS, REUBEN TORRES, JOHN PHELAN, ANDY CRAFT, BRUCE PITNER, DEANE NASON, YVON CARIGNAN, JULIAN M. DUST et ERWIN BUNCEL. Can. J. Chem. **65**, 1891 (1987).

On a réalisé la synthèse de la trinitro-2,4,6 phényl cellulose (picryle de cellulose) en procédant à une substitution S_NAr du chlorure de picryle par le cellulosate de sodium. On a préparé le cellulosate en faisant réagir *in situ* de la cellulose microcristalline avec du méthylate de sodium. Suivant la méthode utilisée, il se forme deux produits comportant des degrés différents de picrylation : un produit qui contient un groupement picryle par 6,5 unités glucosyles (PC-6) et un autre qui contient un groupement picryle par 12 unités glucosyles (PC-12). On a caractérisé ces éthers picryles par plusieurs méthodes indépendantes dont la spectroscopie de résonance magnétique nucléaire du ^1H à 400 MHz du produit soluble dans le DMSO, la spectrométrie de masse à température variable (pyrogrammes ioniques) et la calorimétrie à balayage différentiel (CBD). Les spectres rmn présentent des bandes dans la région des bas champs (8–9,5 ppm) qui ont été attribués aux picryles; ces raies sont bien séparées de celles qui pourraient provenir d'autres composés comme le chlorure de picryle qui n'aurait pas réagi, de l'acide picrique ou du trinitro-2,4,6 anisole. On suggère que les diverses raies dues au picryles proviennent principalement de divers microenvironnements et (ou) de préférences conformationnelles des chaînes de polymères plutôt que de divers sites de substitution. La substitution au niveau du carbone primaire en position C-6 de la portion glucosyle est favorisée. La CBD permet de démontrer que la cellulose subit une décomposition endothermique entre 320 et 350°C et que le picryle de cellulose donne lieu à une décomposition endothermique à environ 230°C. Cette décomposition exothermique est accompagnée d'une libération d'acide picrique et on a confirmé cette conclusion par rmn; le donnée de la spectrométrie de masse indiquent qu'il se produit une clivage concomitant qui fournit des polysaccharides plus petits. On propose un mécanisme pour l'initiation de la décomposition pyrolytique dans lequel la perte d'aide picrique est accompagnée par la rupture d'une liaison glycosidique avec la formation concomitante de glucosane et de groupements énoliques en bout de chaîne sur les fragments qui restent.

[Traduit par la revue]

The interaction of polynitroaromatic and heteroaromatic compounds with electron-rich donors results in the formation of electron donor–acceptor (1) and (or) anionic Meisenheimer type σ-complexes (2). The σ-complexes, particularly the adducts arising from novel electron-deficient substrates, have been the subject of considerable recent interest (3–6). In this context, the reaction of polynitroaryl ether derivatives of cellulose with nucleophiles could form an interesting system of study and part of our ongoing program of research.

During the past few decades there have been several attempts to prepare and characterize the polynitroaryl ethers of cellulose (7, 8). Nitration of cellulose phenyl ether resulted in partial nitration of the hydroxyl as well as the phenyl groups (7). Avny *et al.* attempted the preparation of picryl cellulose (PC) directly from cellulose membrane (cellophane), as well as from cotton fabric, by reacting the corresponding sodium cellulosates with picryl chloride in benzene, but the material obtained was only partially characterized (8). The results of this work were interpreted on the basis of the highly coloured species, assumed to be an adduct formulated as **1**, that was isolated and neutralized with

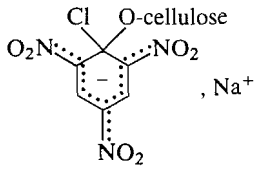
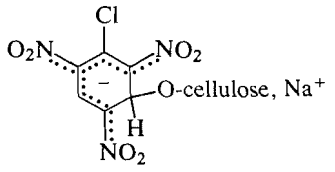
acetic acid. Two alternative neutralization routes were proposed, leading either to the cellulose and picryl chloride starting materials or to the desired picryl ether of cellulose. It was suggested that neutralization favoured reversion of adduct **1** to the starting materials, due to steric hindrance between the picryl and glucopyranoside rings in the picryl cellulose (8).

It is known that the kinetically preferred site of attack by nucleophiles on polynitroaromatic substrates such as picryl chloride or 2,4,6-trinitroanisole occurs *meta* to the substituent in the 1-position (9, 10). In the present system such a process would give rise to adduct **2**, which could only regenerate



1



2

starting material upon addition of acid. Intervention of the 1,3 adduct and its subsequent acid decomposition would result in significantly lower yield of picryl cellulose.

Since sodium cellulosate[2] is expected to be more soluble and a better nucleophile in dimethyl sulfoxide (DMSO) than in benzene, the picrylation of cellulose in DMSO should offer advantages (11). We report here our results on the synthesis of picryl cellulose in DMSO and the full characterization of the product.

Results and discussion

Synthesis of picryl celluloses, PC-6 and PC-12

In this work, various procedures were investigated in the preparation of picryl cellulose. Two representative procedures, which led to the successful preparation of products that were subsequently characterized, are described, while one procedure that did not yield desired product is also described.

In all preparations, sodium cellulosate was prepared *in situ* from microcrystalline cellulose by treating a sample of the desiccated cellulose first with DMSO, to swell it thoroughly with the solvent, and then with freshly prepared sodium methoxide. The resulting cellulosate was washed with dry DMSO to remove excess methoxide and, in the first procedure, reacted with a solution of picryl chloride in DMSO to yield PC-12 after work-up. In the second procedure, picryl chloride was added as a powdered solid to the sodium cellulosate in DMSO; this process afforded PC-6, a more highly picrylated material. In either case, the picryl cellulose was well washed with a variety of solvents, followed by Soxhlet extraction of the material for 4 days and drying under vacuum. This extensive washing and extraction procedure militates against the presence of any adsorbed or entrained picryl chloride, or picrate.

In both methods of preparation addition of the picryl chloride, whether in solution or as a solid, was relatively rapid. In one of the attempted preparations, a concentrated solution of picryl chloride in DMSO was allowed to stand for 30 min prior to addition to the cellulosate suspension. The picryl chloride solution became very hot over this period of time and in this preparation no picryl ring was incorporated into the product. These observations are in accord with the known reactivity of picryl chloride in DMSO without added nucleophile (12).

The preferred method for the synthesis of picryl cellulose in terms of yield of product and degree of picrylation (PC-6) involved rapid introduction of finely powdered picryl chloride directly into the stirred solution of sodium cellulosate in DMSO.

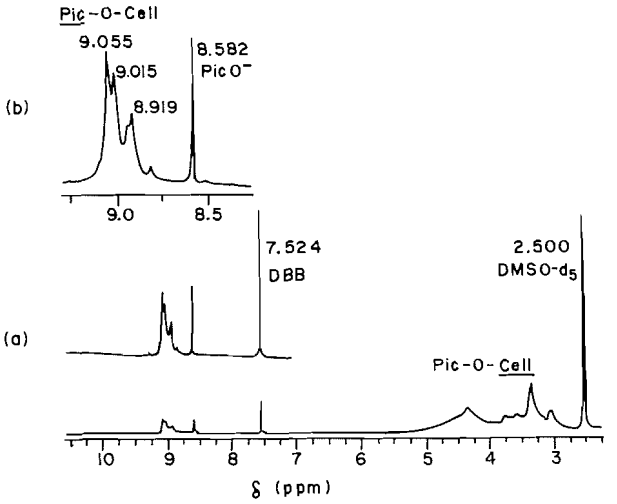


FIG. 1. The ^1H nmr spectrum of picryl cellulose (PC-6) in DMSO-d_6. Inset (a), aromatic region intensified (δ 7–10); inset (b), peaks due to picryl moieties of the picryl cellulose and of picrate ion.

Characterization of picryl celluloses, PC-6 and PC-12

1. Physical properties, elemental analysis, and hydrolytic cleavage

The picryl celluloses synthesized in this work are tan powders when dry. PC-6 and PC-12 are extremely hygroscopic and hydrate rapidly, i.e., the weight of both materials in air increases over time. Hydration is complete within 24 h, at which point the weight increase levels off at 7.3%. The hydrated products are bright yellow in colour, in contrast to the tan anhydrous powder. The process is probably accompanied by some hydrolysis (*vide infra*).

Elemental analysis (C, H, N) clearly differentiates the two picryl cellulose products. The nitrogen content and number of glucosyl units per picryl ring for PC-6 and PC-12 are given in the experimental section. Based on the requirement of 3 nitrogens per picryl ring, the PC-6 contains the larger number of picryl rings per glucosyl residue.

When finely powdered picryl cellulose is rapidly stirred in distilled water, partial dissolution occurs and the pH slowly drops while the solution turns bright yellow. An absorption maximum is noted in the ultraviolet–visible spectrum of the aqueous solution at 352 nm, corresponding to the absorption band for picric acid (13).

Picric acid adsorbed on the surface of cellulose might be expected to be released instantly into aqueous solution. It is, therefore, significant that the absorption assigned to picric acid attained a maximum value only after 30 min at room temperature.

The formation of picric acid is indicative of a hydrolytic cleavage. This hydrolysis could occur either via an S_NAr displacement of the picryl ring (pathway a) or via an S_N2-type attack of water on C-6 (pathway b; Scheme 1).

2. Evidence from ^1H nuclear magnetic resonance

An ^1H nmr spectrum of picryl cellulose in $(CD_3)_2SO$ can be

[2]The exact nature of the sodium cellulosate is not well defined. We consider sodium cellulosate to be the intermediate material derived by treatment of microcrystalline cellulose with base. In this material an equilibrium concentration of oxy-anion or activated hydroxyl sites exists for subsequent reaction with picryl chloride to give the covalently bound picryl cellulose.

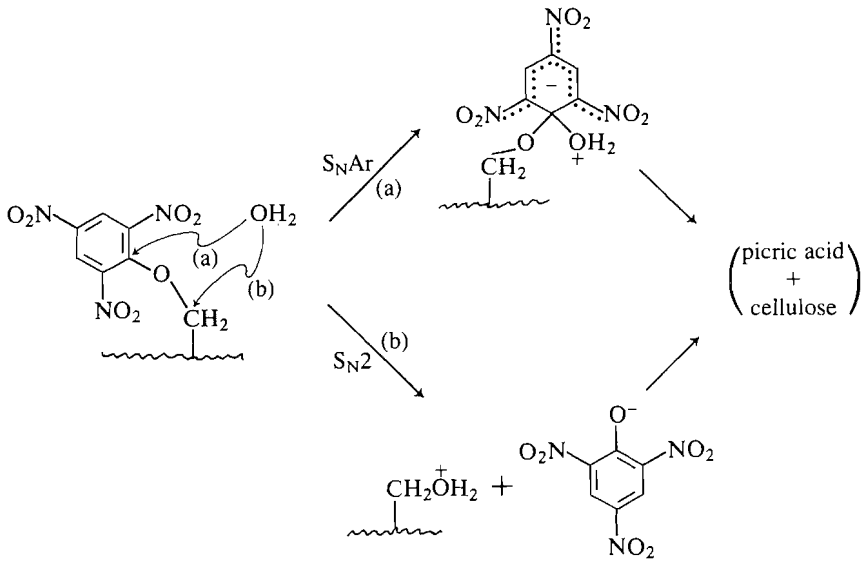

SCHEME 1

obtained using a saturated solution prepared by sonication. The ^{1}H nmr spectrum of PC-12 was identical to that of PC-6, although not as intense. Resonances for the glucosyl residues appear in the upfield region of the spectrum (Fig. 1) from 2.0 to 5.4 ppm; these are broad and not particularly well resolved, presumably due to conformational changes and slow tumbling of the cellulose chains in solution.

Resonances due to the aromatic picryl moieties of picryl cellulose, as well as free picrate, appear in the downfield region of the spectrum. The expanded spectrum of Fig. 1 shows three relatively broad peaks located at 9.055, 9.015, and 8.919 ppm, as well as a very sharp singlet at 8.582 ppm. The sharp singlet at 7.524 ppm is due to *p*-dibromobenzene (DBB), used as an internal standard. The sharp signal at 8.582 ppm results from the two equivalent protons of picrate anion, $PicO^-$. The peaks centered around 9.00 ppm result from picryl ether moieties covalently bonded to the cellulose chain.

It is significant to note that the singlet at 8.582 ppm, which is assigned to picrate anion, appears at exactly the same chemical shift as authentic picric acid in $(CD_3)_2SO$. This compound is known to be fully ionized in DMSO (11). If picrate were adsorbed on the surface of the cellulose or if some free and some adsorbed picrate existed in rapid equilibrium, an averaged signal would be observed at a position different from that for picrate in $(CD_3)_2SO$ alone (14). Similarly, the signals centered at 9.00 ppm are not due to contamination from trace amounts of unreacted picryl chloride or from 2,4,6-trinitroanisole (P-OMe). When picryl chloride or P-OMe was added to the PC sample, the spectra obtained showed sharp singlets for picryl chloride at 9.234 and for P-OMe at 9.101 ppm respectively. These signals do not overlap with those for picryl cellulose. The signals at 9.055–8.919 ppm do not shift from their previously recorded chemical shifts, as would occur if significant equilibration occurred between the free and bound picryl groups. Also, the signals for picryl chloride and P-OMe in $(CD_3)_2SO$ appear at the same chemical shift in the presence or absence of PC.

Clearly, the signals situated at 9.055, 9.015, and 8.919 ppm are assignable to picryl ring(s) covalently bonded to the cellulose polymer. There are three possible sites where bonding of the picryl ring to the glucosyl moiety might occur, namely C-2, C-3, and C-6. It is tempting to assume that the resonances centered around 9.00 ppm result from bonding at these different sites. However, the primary hydroxyl function at C-6 is expected to be the preferred nucleophilic moiety in attack on picryl chloride (15–17), in part because the C-2 and C-3 sites are much more hindered, and also because of the preferential deprotonation of the primary C-6 hydroxyl.

Thus, for reasons of both steric hindrance and relative acidity, it is likely that S_NAr displacement yields picryl moieties bonded to the oxygen on C-6. Conformational preferences in the chain would be expected to produce different microenvironments for a C-6 picryl ether, and this could give rise to the three separate picryl signals that are observed.

The "effective concentration" of the picryl ether moieties is $0.015 \pm 0.005\,M$, as determined by comparison of the integral for the resonances centered around 9.00 ppm with the integral for the protons of the DBB standard at 7.524 ppm. The concentration of picryl ether moieties is much higher than expected from the elemental analysis data.
