Two possible explanations can be considered to account for the discrepancy between the "effective concentration" of picryl units as determined by nmr, and the concentration calculated from elemental analysis data and the derived empirical formula. First, it could be argued that a range of lower molecular weight chains has preferentially dissolved in the $(CD_3)_2SO$ solvent and that such lower molecular weight material contains more highly picrylated regions than the bulk material. In this case the ^{1}H nmr spectrum may not be representative of the bulk polymer, which presumably consists of a distribution of various picryl cellulose chain lengths. In short, the process of dissolution has actually been a process of fractionation on the basis of molecular weight. The second possible explanation is that the observed solubility is directly related to the degree of picrylation. In that regard, it has been reported that increased derivatization, by reaction of the hydroxyl groups, leads to increased solubility (17, 18). As well, in the present work we have found that ca. 70 wt.% of PC-6 dissolves in DMSO whereas ca. 39 wt.% of PC-12 is soluble. Thus it is found that the bulk material that is most highly picrylated is also the most soluble in DMSO. It can be concluded that in the case of PC-6 the ^{1}H nmr spectrum obtained on the DMSO-soluble material is certainly representative of the bulk picryl cellulose. The situation in the case of PC-12 is not

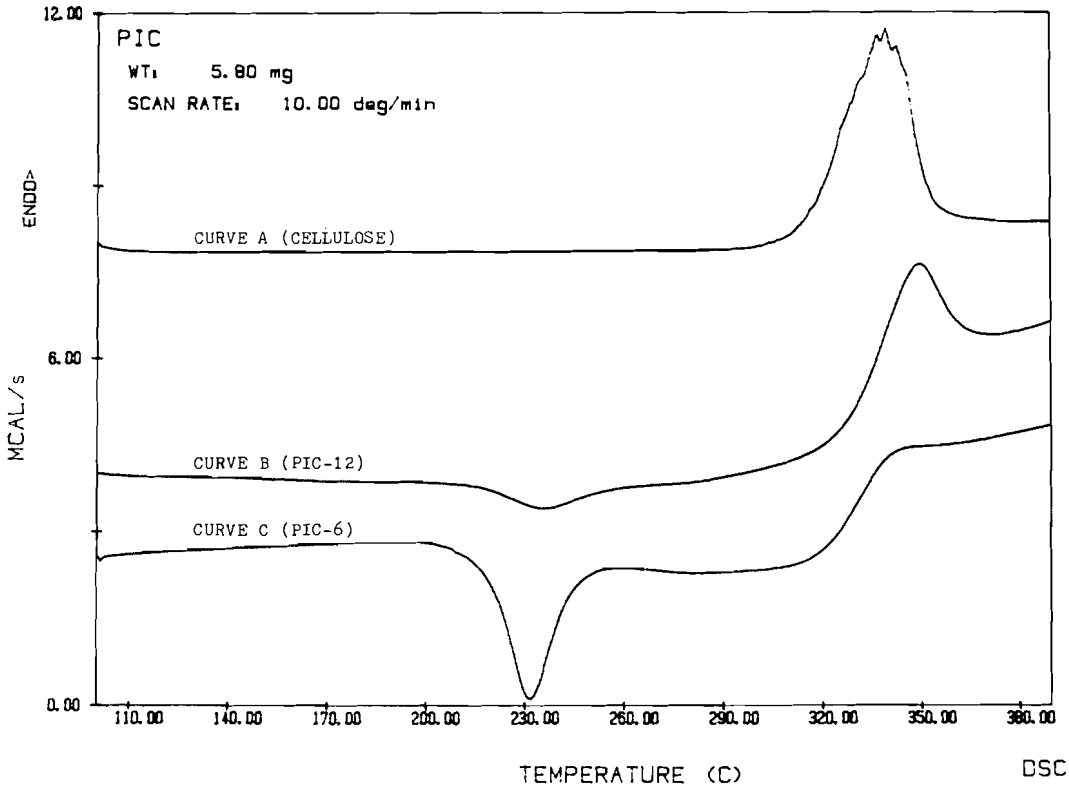

FIG. 2. Differential scanning calorimetry for picryl cellulose (PC-6 and PC-12) and cellulose. The cellulose energy axis has been rescaled to allow comparison of transition temperatures.

as well defined, although it appears that any fractionation that may have occurred on dissolution in DMSO is not extensive.

Also in accord with these observations is the ratio of integrals of the picryl ether absorption to the total glucosyl proton absorption found upfield. Based upon the bulk material, which contained 6.5 glucosyl units per picryl ring (PC-6), this integral ratio is predicted to be ca. 1:29. The measured value is 1:15, a further indication that preferential solubilization of more highly picrylated material in $(CD_3)_2SO$ has occurred.

It should be emphasized that the residual solid material that is insoluble in DMSO still contains picryl groups. Thus the infrared spectrum of the residual solid (PC-6 and PC-12), after removal of DMSO, thorough washing with diethyl ether, removal of the ether, and vacuum drying of the solid, displays ir bands at 1535 and 1340 cm^{-1}, characteristic of the asymmetric and symmetric stretching vibrations of the attached aromatic nitro groups. Clearly, both the DMSO-soluble and insoluble materials are picrylated.

Complementary to the nmr studies described above, further information was sought through differential scanning calorimetry and mass spectral analysis. Since these methods involve heating to high temperatures, it seemed desirable to monitor by ^1H nmr any changes that may occur on heating the picryl cellulose. It is found that in a standard sample (PC-6), the ratio of the integral sum of the picryl ether moieties compared to the picrate anion integral is ca. 9:1. The picrate anion may result from hydrolysis in the DMSO solution caused by small amounts of water bound in the polymer or by adventitious water in the commercial $(CD_3)_2SO$. This ratio was almost reversed (1:7) when the dry picryl cellulose was preheated to 230°C in an argon atmosphere before being dissolved in $(CD_3)_2SO$ for spectral analysis. It is concluded that hydrolysis does not account for this increase in picrate anion concentration but, rather, pyrolytic cleavage occurs in the dry solid. The differential scanning calorimetry and mass spectral studies described below confirm this conclusion.

3. Differential scanning calorimetry (DSC)

The thermal decomposition of cellulose is a complex process, which can be monitored by differential scanning calorimetry. The differential thermal analysis results have been previously found to be dependent on the temperature range studied, the period of heating, and the heating rate, as well as on the physical and chemical properties of the cellulose (19–22). For these reasons, a control DSC curve of the thermal behaviour of the microcrystalline cellulose that was the precursor of both PC-6 and PC-12 was determined (curve A, Fig. 2). The endothermic maximum, which occurs at 340°C, represents an initial depolymerization (which involves cracking and dehydration), closely followed by the competing reactions of decomposition, volatilization, polymerization, and aromatization (19, 20). The large endotherm ($\Delta H = -278$ cal g^{-1}) is indicative of the predominant depolymerization and volatilization processes; at about 350°C these reactions either cease or are masked by the competitive exothermic reactions. The latter subside and little further heat is evolved in the temperature region studied (100–400°C).

While microcrystalline cellulose and picryl cellulose show similarities in their thermal decomposition, it is clear that the latter displays thermal behaviour characteristic of C-6 substituted cellulose ethers. Upon cursory examination both PC-12 and PC-6 exhibit two thermal transitions in their DSC curves (Fig. 2; curves B and C). In the case of PC-12 (curve B), the first is a shallow exotherm that occurs between 230 and 235°C and is not present in the precursor cellulose (curve A). This initial exotherm is the dominant feature of the DSC trace for PC-6 (curve C). Note that the ratio of evolved heats for PC-6 com-

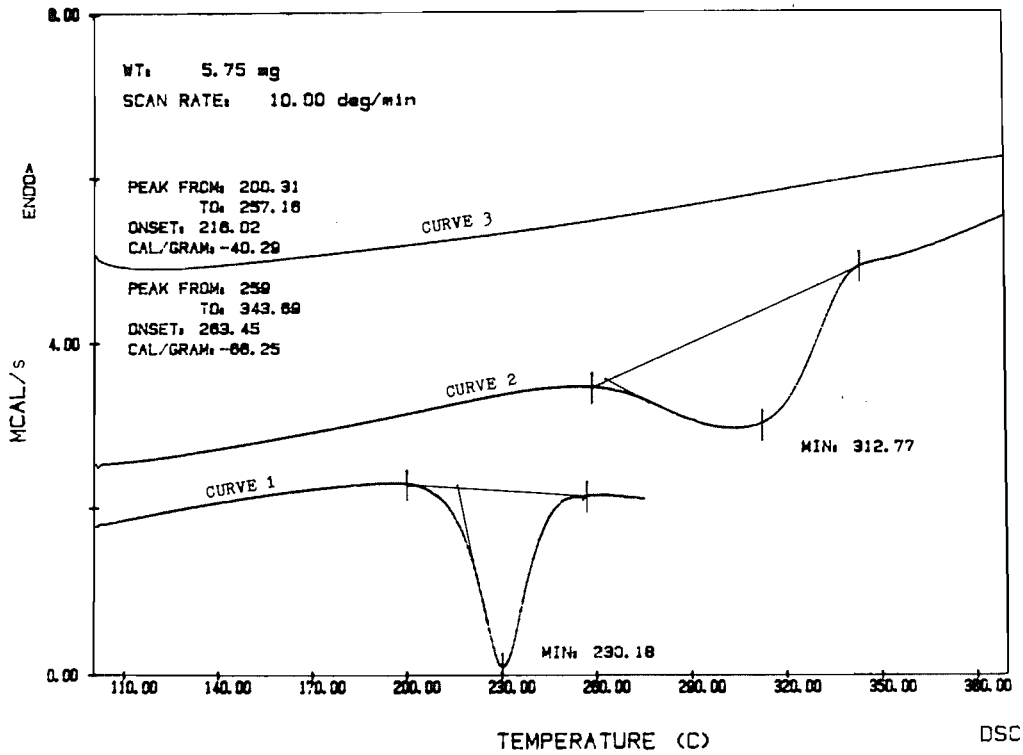

FIG. 3. Differential scanning calorimetry for PC-6. The curves represent cycled heating and recooling: Curve 1, 25–260°C; Curve 2, sample from curve 1 cooled and then heated, 25–380°C; Curve 3, sample from curve 2 cooled and then heated, 25–380°C.

pared to PC-12 ($\Delta H_{PC\text{-}6}/\Delta H_{PC\text{-}12} = -40.3\ cal\ g^{-1}/-9.2\ cal\ g^{-1}$) is 4.4 and parallels the picryl content of the samples. Hence the picryl moiety is directly involved in the exothermic reaction.

The broad and diffuse endotherm with maximum at 350°C (curve B) forms the secondary feature of the DSC plot for PC-12. This endothermic peak corresponds to the same type of decomposition processes that occur in the microcrystalline cellulose sample (curve A). It is significant to note the trend to larger exotherms at 230–235°C and diminished endotherms at 350°C as a function of the increase in the degree of picrylation (cellulose to PC-6).

The interdependence of the endothermic and exothermic features of the DSC trace is clarified in the cycling experiment shown for PC-6 in Fig. 3. First the sample was heated past the point at which the initial exothermic reaction has ceased, i.e., 280°C (curve 1, Fig. 3). The sample was permitted to return to room temperature and was then reheated; the DSC plot (curve 2, Fig. 3) exhibits no exotherm at 230°C, but a significantly broadened exothermic peak commencing at 259°C and centred at 313°C is observed. The diminished endotherms displayed by PC-12, and even more so by PC-6 (Fig. 2), are thus the result of a competing exothermic reaction revealed in this cycling experiment. The heat evolved in this exothermic process is absorbed in the endothermic decomposition of the cellulose chain in PC-6 and PC-12. Note that only in the absence of the 230°C exotherm is the corresponding 313°C exothermic maximum observable.

The disappearance of the 230°C exotherm is indicative of picryl ether bond scission coupled with another process. In this regard, it is important that the sample colour changed markedly at 250°C, in a control experiment conducted in a melting point capillary, going from tan to dark brown. Coincident with the colour change, water and a yellow oil were observed to condense on the unheated upper portions of the capillary. The water no doubt arises from the known loss of adsorbed water that occurs at ca. 80–100°C (20) and from the dehydration processes that accompany depolymerization of the cellulose chain. Thermal decomposition in a sublimation apparatus leads to the isolation of picric acid as crystals on the cold finger and thus identifies the yellow oil noted in the melting point capillary experiment.

Furthermore, in a recent study of the thermal behaviour of the C-6 substituted cellulose ethers, namely cellulose *p*-toluenesulfonate, tritylate, and phosphate, Jain *et al.* found an initial small endotherm for the tritylate and phosphate (157 and 160°C, respectively), which they attributed to cleavage of the ethers (22). In contrast, cellulose tosylate exhibited an exothermic maximum at 175°C (22). The unique behaviour of the C-6 cellulose tosylate was ascribed to a simultaneous endothermic scission of the *p*-toluenesulfonyl group, as the acid, and induced decomposition of the cellulose chain. By analogy, rupture of the C-6 picryl ether bond in PC-12 and PC-6 would be expected to result in the release of picric acid, accompanied by an exothermic cellulose decomposition. In view of these results, the relationship of the large exotherm and the broadened cellulose decomposition endotherm of PC-6 and PC-12 is straightforward. The exotherm (230°C) represents concurrent endothermic picryl ether scission and highly exothermic acid-induced cellulose decomposition. This decomposition pathway may be visualized as in Scheme 2.

4. Mass spectral analysis and ion pyrograms

Further clarification of mechanistic details of the exo- and endothermic pyrolytic reactions of cellulose and picryl cellulose can be obtained by carrying out the pyrolyses directly in the solid probe of a mass spectrometer. Ion pyrograms showing approximate amounts of both primary and secondary products of pyrolysis can be used to identify fragments evolved during the various cleavage processes. While accurate control and

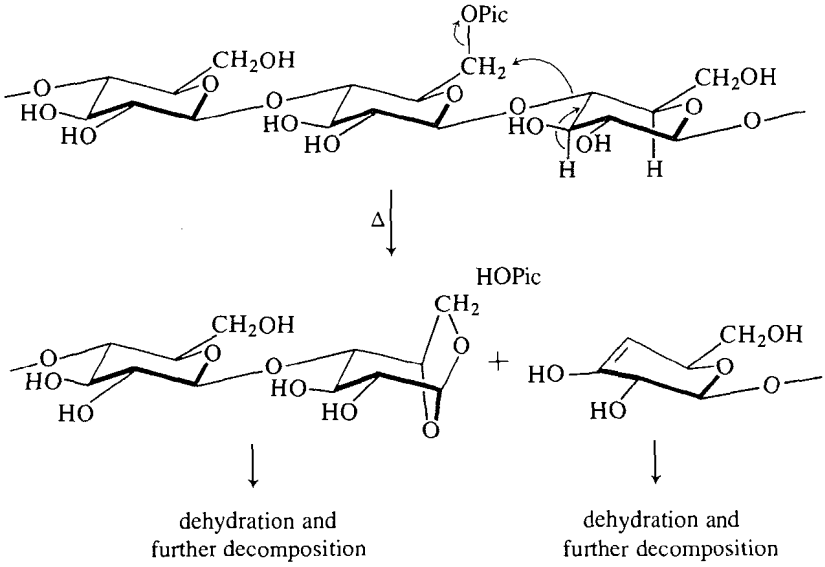

SCHEME 2

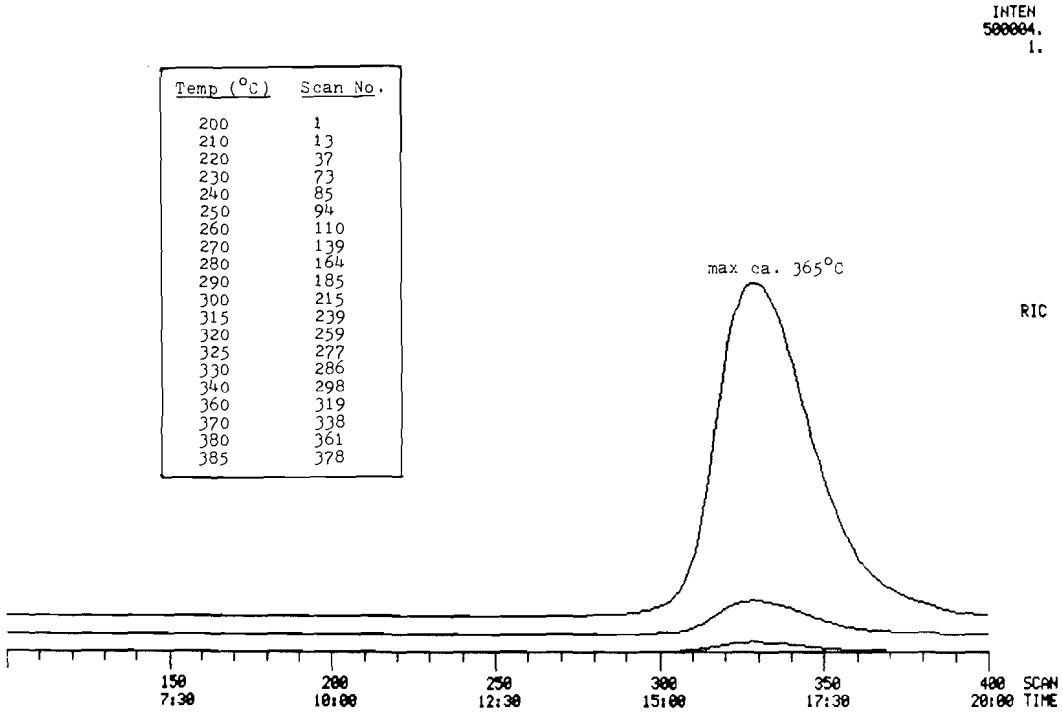

FIG. 4. Electron impact mass spectral map (total ion plot) for microcrystalline cellulose from 200 to 400°C.

measurement of the exact temperature at the point of sample pyrolysis is difficult, the overall qualitative picture is clear and informative.

The total ion spectrum map (ion pyrogram) for microcrystalline cellulose is shown in Fig. 4. Maximum ion intensity is achieved at ca. 365°C, with significant ion production from 350 to 400°C. Based upon the DSC evidence, this behaviour must correspond to the endothermic decomposition processes of cracking and dehydration.

The electron impact (70 eV) mass spectrum, measured at the onset of significant ion production at 350°C, is shown in Fig. 5. The parent ion of 1,4:3,6-dianhydro-β-D-glucopyranose is found at m/e 144. Although this ion is of low relative intensity (1.04%), it is significant in that anhydroglucoses (pyranose or furanose analogs of glucosan, for example) generally do not yield observable ions of m/e larger than 98. Other significant, albeit low intensity, fragments occur at m/e 126 (0.74%) and m/e 98 (5.28%). The former may represent either the ion of 5-hydroxymethyl-2-furfural or of 2-furylhydroxymethyl ketone, whereas the latter arises primarily from fragmentation of the furfural (23–25). The characteristic intense peaks at m/e 73 and 60 derive from anhydroglucose parent ion fragmentation (23).

As in the case of cellulose, the ion pyrogram of PC-6 (Fig. 6) shows maximum ion production at relatively high temperatures (ca. 386°C) but, in contrast, an initial ion-producing process commences at approximately 250°C and reaches a maximum at

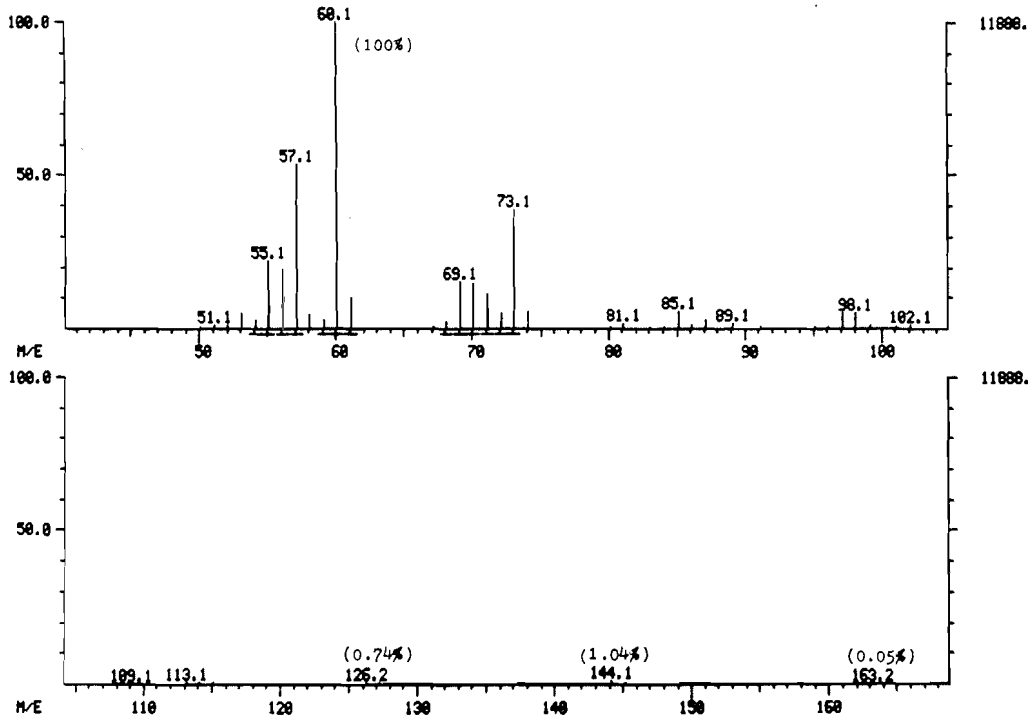

FIG. 5. Electron impact mass spectrum of microcrystalline cellulose at 350°C.

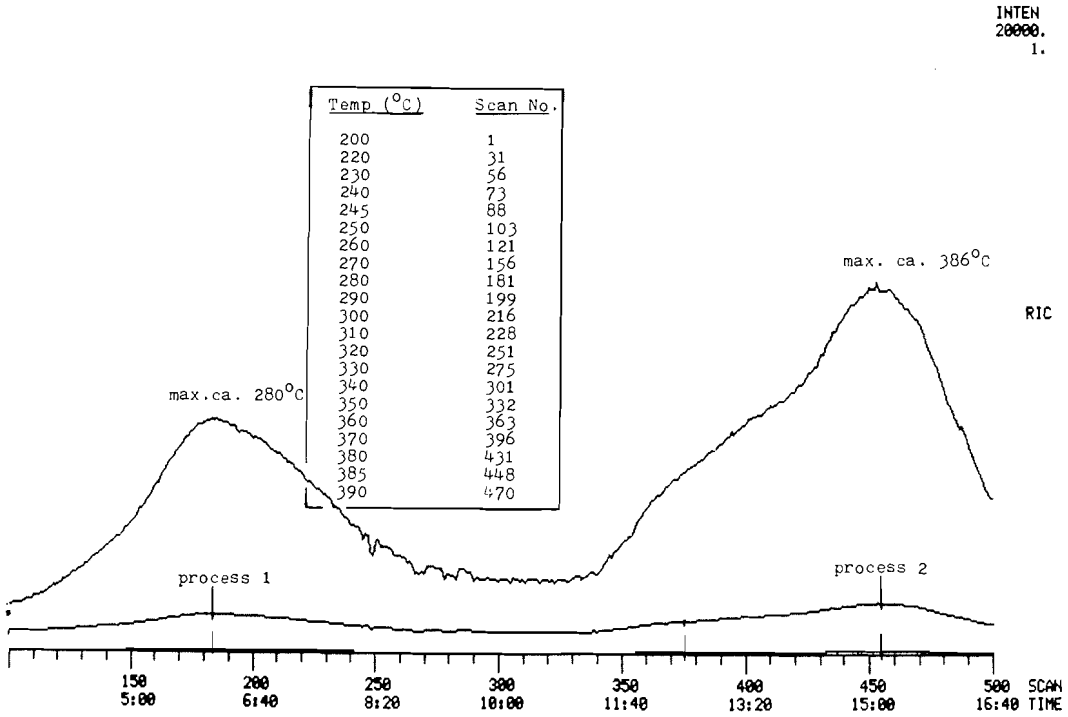

FIG. 6. Electron impact mass spectral map (total ion plot) for picryl cellulose (PC-6).

ca. 280°C. Two temperature-dependent processes appear to exist, each associated with a maximum in ion production (Fig. 6).

A mass spectrum of PC-6 measured at ca. 280°C displays two prominent peaks at m/e 229 (46%) and m/e 199 (4.0%), which are unique to the picrylated product (Fig. 7). The m/e 229 can be readily ascribed to the picric acid radical cation formed by cleavage from the cellulose chain. Loss of NO would give rise to

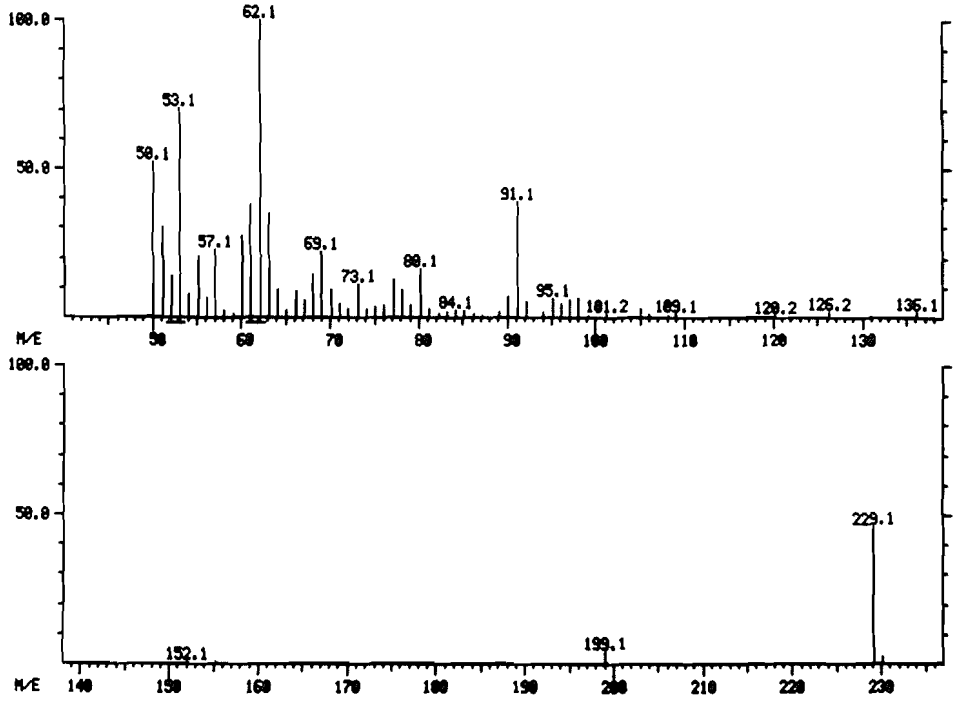

FIG. 7. The electron impact mass spectrum of picryl cellulose (PC-6) at 280°C.

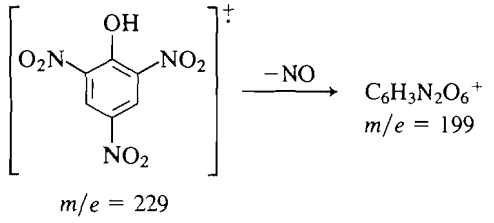
the m/e 199 ion:



The temperature-dependent behaviour of PC-6 and the pyrolytic product ions of the picryl ether can be correlated. Thus Fig. 8 shows the ion pyrogram of m/e 229, 199, 144, 126, 97, 73, and 60 ions as a function of temperature. As can be seen, maximum intensity of the m/e 229 ion correlates well with ion production at ca. 280°C, as does the intensity of m/e 199, which confirms the relationship between the two peaks. On the other hand, *maximum* intensity for the m/e 144, 126, 97, 73, and 60 ions corresponds to a probe temperature of ca. 386°C. Similar and confirmatory observations can be made from chemical ionization generated mass spectral maps and ion intensities.

Clearly, the decomposition pathways for PC-6 involve the picryl ether moieties. Picric acid is lost from PC-6 at a lower temperature than that at which decomposition is noted in the precursor microcrystalline cellulose. Further, the two temperature/ion production maxima for PC-6 are in accord with the two regions of decomposition detected by DSC.

In fact, the presence of the picryl ring in the cellulose chain promotes the cellulose cleavage, as in the mechanism proposed in Scheme 2. Thus, presuming a relatively random distribution such that approximately one picryl ring is bonded per 6–12 glucosyl residues, fragmentation to release picric acid would lead to smaller oligosaccharides with much greater volatility and mobility. These oligosaccharides would be expected to undergo even more facile pyrolytic rupture than the intact cellulose chain.

Conclusions

Two picryl celluloses were prepared, PC-6 and PC-12, differing only in the number of picryl rings incorporated into the cellulose chain. Elemental analysis, hydrolytic cleavage behaviour, ^{1}H nmr analysis in DMSO-d_6, differential scanning calorimetry, as well as mass spectrometry, identify these products as picryl ethers, distinct from cellulose containing adsorbed picryl chloride, picric acid, or trinitroanisole. The different analytical methods are complementary. Pyrolytic behaviour noted by DSC was confirmed by mass spectrometry. Evolution of picric acid was detected by mass spectrometry, and picric acid was isolated in a control experiment from the thermal decomposition of PC-6 and was also observed in ^{1}H nmr experiments (as picrate anion). The ^{1}H nmr provides evidence that the picryl ether moieties are most likely attached at C-6 of the glucosyl residues. The picryl groups noted in the ^{1}H nmr of the DMSO-soluble material derived from PC-6 or PC-12 are also present, according to ir data, in the DMSO-insoluble residure. It is concluded that the ^{1}H nmr spectral data are representative of the bulk picryl celluloses. The thermal decomposition of the cellulose C-6 tosylate noted in the recent literature (22) is analogous to the thermal behaviour of picryl cellulose and further identifies PC-6 and PC-12 as C-6 cellulose ethers, in accord with the ^{1}H nmr evidence.

Experimental

Preparation of picryl cellulose, PC-6

Microcrystalline cellulose was dried over P_2O_5 at 50°C (2 Torr; 1 Torr = 133.3 Pa) for 5 h. A sample of the desiccated cellulose (9.5 g) was added to 200 mL of dry DMSO and stirred for 20 min. To the stirred mixture was added 140 mL of freshly prepared 4 *M* sodium methoxide in methanol and the mixture was allowed to stir for another 25 min before it was rapidly filtered. The filtered solid was kept covered with dry DMSO and the cake was broken up with a spatula into granular chunks and washed with copious amounts of dry DMSO (5 separate 100 mL washes with dry DMSO). This washing procedure was performed to remove any excess sodium methoxide. The washed material

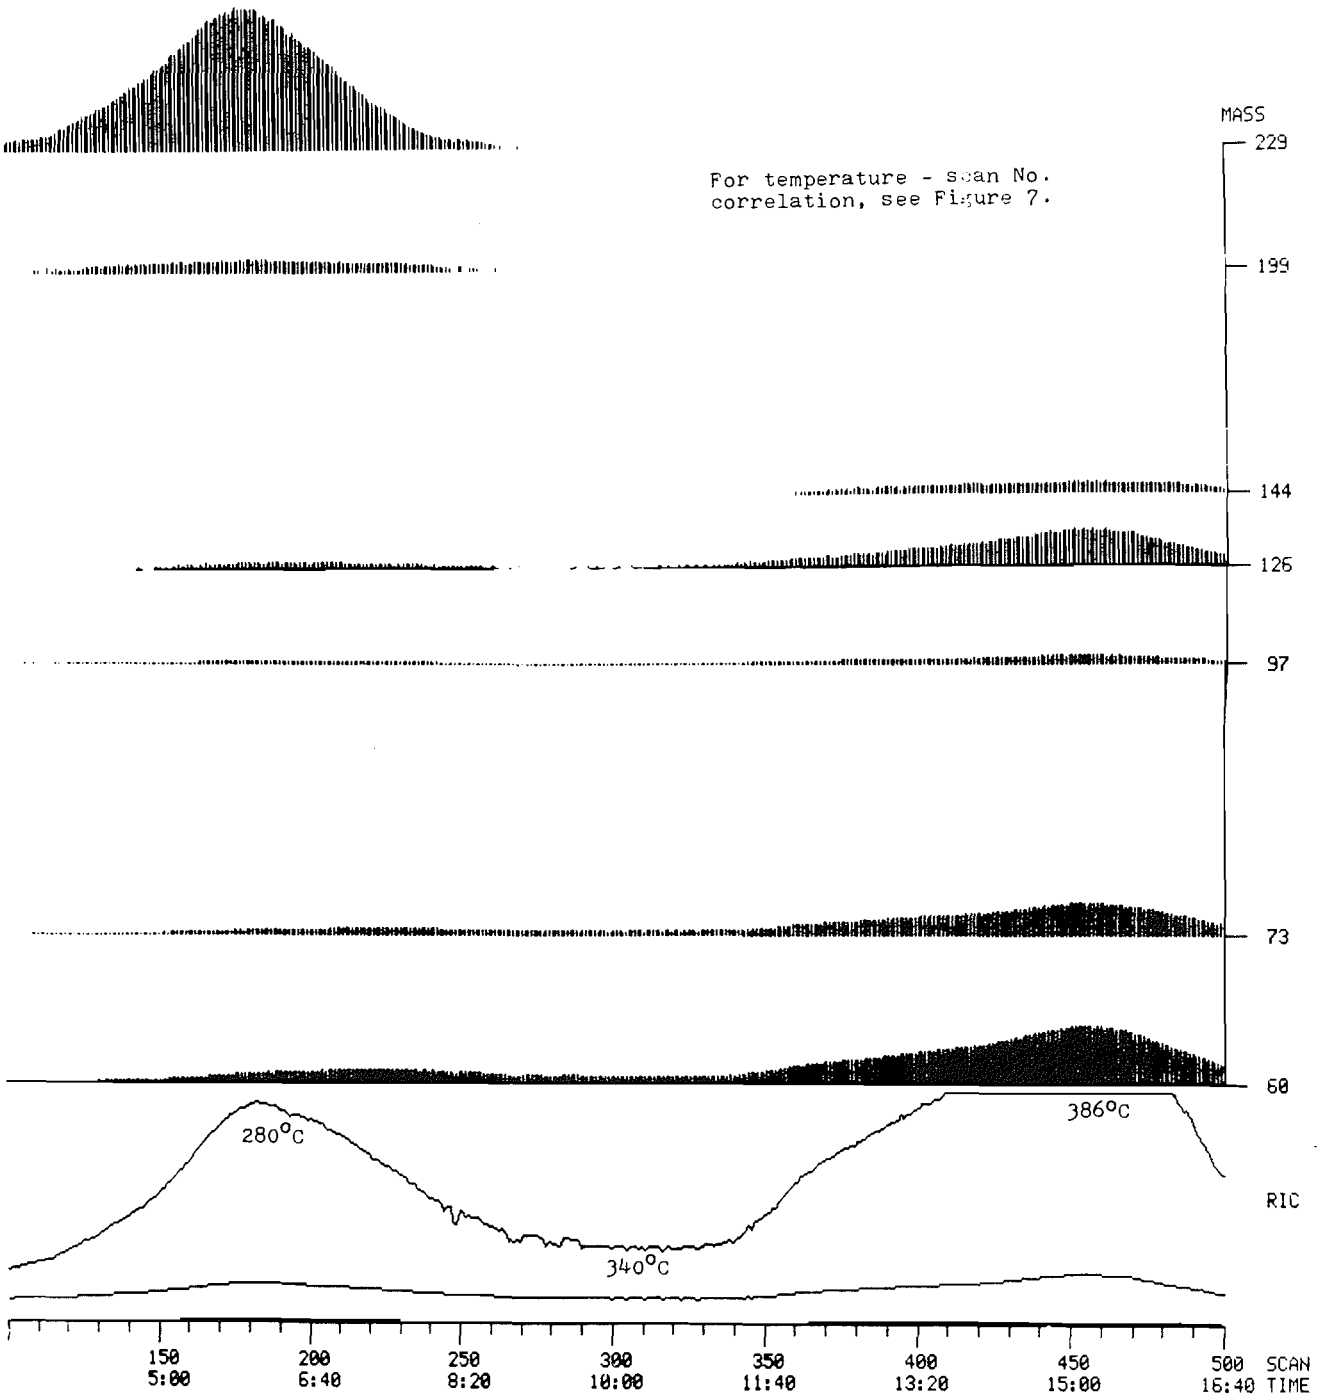

FIG. 8. Electron impact mass spectral map (total ion plot, and masses 60, 73, 97, 126, 144, 199, and 229) for PC-6 from 200 to 400°C.

was added to 300 mL of freshly distilled dry DMSO in a 1-L Erlenmeyer flask and stirred rapidly with a magnetic stirrer until the solid became finely divided. To this rapidly stirred mixture 25 g of dry powdered picryl chloride was added in small portions. During the rapid addition, another 200 mL of dry DMSO was introduced into the flask since the dark red mixture had gelled. After stirring for 7 h at room temperature the gel became less viscous and appeared dark orange-yellow. At this point the reaction was quenched by pouring the mixture into 2 L of anhydrous ether. The yellow precipitate was filtered off and washed with three successive 100 mL portions of dry acetone, followed by two successive 100 mL portions of dry ethanol. At the end of this process the ethanol filtrate was colourless. The resulting yellow powder was extracted with methanol for 4 days using a Soxhlet extractor. The purified solid was transferred to a drying pistol and dried for 2 days over P_2O_5 at 100°C (2 Torr). The total yield of pale tan powder was 7.5 g.

The material obtained is very hygroscopic. It is insoluble in water, methanol, and other organic solvents but slightly soluble in DMSO. Analysis of the tan powder shows C 41.44, H 4.85, and N 3.31%, which, basing calculations on the amount of cellulose bonded to one picryl ring (3 nitrogens), yields an empirical formula of $C_{43}H_{61}N_3O_{39}$. This corresponds to about 6.5 glucosyl moieties per picryl ring.

Preparation of picryl cellulose, PC-12

This preparation was carried out using the same quantities as in the preparation of PC-6, but the picryl chloride was dissolved in DMSO and then added to the stirred sodium cellulosate in DMSO. The product so obtained incorporated less nitrogen. It analyzed for C 42.26, H 5.49,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

N 1.93%, which corresponds to about 12 glucosyl residues per picryl ring.

Solubility studies

Weighed quantities of PC-6 and PC-12 were placed into test tubes fitted with septum caps. The transfer of material was done in an N_2-filled dry box. The sample weights were determined by difference (PC-6: 14.02 mg; PC-12: 93.51 mg). DMSO (800 μL) was injected into each tube. After sonication and centrifugation the supernatant DMSO solution was removed and replaced with diethyl ether by means of a syringe. The samples were repeatedly subjected to ether treatment followed by centrifugation. Finally, the sample was dried at reduced pressure (<1 Torr) in a drying pistol and the dried residues were weighed. Of the PC-6, 4.14 mg remained, while of PC-12, 57.34 mg remained. The weight percent of material that had dissolved is therefore PC-6, 70.5%; PC-12, 38.7%

^1H nuclear magnetic resonance spectroscopy

All nmr spectra were recorded on an AM 400-MHz Bruker spectrometer equipped with a standard $^1H/^{13}C$ probe. Standard Wilmad PP-507 nmr tubes were used. Samples were sonicated using a Bransonic ultrasonic bath. Typically, 10–25 mg of the cellulose derivative was placed in a septum-covered small volumetric flask. $(CD_3)_2SO$ (800 μL) was injected into the nitrogen-flushed vessel and the suspension was sonicated in an ultrasonic bath for 2–3 h. The resultant mixture was allowed to settle and the transparent supernatant solution, usually yellow or orange in colour, was carefully withdrawn through the septum via syringe. (Separate centrifugation of a control sample of the supernatant showed that it contained no visible insoluble material.) The contents of the syringe were injected into a dry, septum-covered, nitrogen-flushed nmr tube containing 2 μL of stock *p*-dibromobenzene (DBB) solution and the spectrum was taken. The DMSO-d_5 resonance centered at 2.500 ppm was used as the internal shift standard. Typically, the instrument was adjusted as follows: spin rate, 25 rps; relaxation delay, 3 s; acquisition time, 2.982 s; pulse width, 5 μs; pulse angle, 45°; temperature, ambient (20 ± 2°C). For most experiments, 128 transients/FID sufficed to obtain the spectra reported herein.

Differential scanning calorimetry

The DSC experiments were performed using a Perkin Elmer DSC-4 instrument equipped with the Thermal Analysis Data Station (TADS). The instrument was calibrated with an indium standard prior to use. Each sample was encapsulated in an aluminum pan. The encapsulated sample was placed in the sample holder and an empty aluminum pan was placed in the reference holder. Samples were heated at a rate of 10°C/min over the ranges shown in the various plots. In all scans nitrogen was used as purge gas. When the scan was completed, onset temperatures and energy changes were determined with the aid of the TADS system. For example, temperature limits for an on-screen peak of interest were input to the TADS. ΔH values and temperatures of maxima or minima were then obtained.

Mass spectroscopy

All spectra were obtained on a Finnegan 4610 quadrupole mass spectrometer at 70 eV and were calibrated with perfluorotributylamine. Scientific Instrument Services S-95A glass capillaries were used for the solid probe. Approximately 100 μg of each sample was placed in the capillary and secured with a plug of clean glass wool. The heating rate was controlled manually and the probe temperature was read directly from the digital display of the instrument. Chemical ionization spectra employed methane.

The heating rate for the electron impact spectra was approximately 10 ± 3°C/min between 200 and 400°C. The scan time was 2.9 s with a 0.05-s hold between scans. CI spectra employed a heating rate of approximately 30°C/min and a scan time of 1.45 s with a 0.05-s hold time.

Received December 10, 1986

This paper is dedicated to Professor John T. Edward

BYUNG CHAN EU. Can. J. Chem. **65**, 1901 (1987).

A simple heuristic method of constructing tensor operator bases for spins larger than 1/2 is presented which yields the same matrix representations as reported in the literature. By using the basis sets, we discuss the evolution of density matrices which can be put in Sylvester's form for an exponential operator. Use of quaternions is discussed for constructing tensor operator bases for half integer spins.

BYUNG CHAN EU. Can. J. Chem. **65**, 1901 (1987).

On présente une méthode heuristique simple qui permet de construire des bases d'opérateurs de tenseurs pour les spins plus grands que 1/2; cette méthode conduit aux mêmes représentations matricielles que celles rapportées dans la littérature. Utilisant des ensembles de base, on discute de l'évolution des densités matricielles qui peuvent être mises sous la forme de Sylvester pour un opérateur exponentiel. On discute de l'utilisation de quaternions pour la construction de bases d'opérateurs de tenseurs pour les spins fractionnaires.

I. Introduction

In pulsed nmr experiments the evolution of nuclear spins is an interest of study, and it is necessary to have mathematical representations of spin angular momentum operators in order to carry out analysis of their temporal evolution. It is well known in quantum mechanics how to construct such representations in the case of spin 1/2, and we know that spin angular momentum operators are given by the Pauli spin matrices. Textbooks on quantum mechanics do not discuss representations of spin matrices in the case of spins larger than 1/2. In the past attention has been paid to systems of spins larger than 1/2, particularly in connection with pulsed nmr experiments (1–4). For the cases of spins larger than 1/2 Abragam (4) suggests in his classic monograph on nmr spectroscopy to use fictitious spin-1/2 operators to describe such spin systems. If the spin is larger than 1/2, there are more than two energy levels involved, but Abragam's fictitious spin-1/2 operators are constructed by selecting two levels of interest from the whole set of levels and neglecting the rest of them. This procedure creates effectively two-level systems which can then be described by Pauli-spin-like representations for spin angular momentum operators involved. Following Abragam's idea, Vega and Pines (2) introduced fictitious spin-1/2 operators to represent the spin angular momentum and related operators for a spin larger than 1/2. In the case of spin 1 there are nine independent operators acting like Pauli spin operators while in the case of spin 3/2 there are 18 fictitious spin-1/2 operators which one can construct by embedding 2×2 Pauli matrices. However, there are in fact only 16 independent operators required since the operators for spin 3/2 are 4×4 matrices. The overcompleteness is removed by three algebraic relations which hold for the z components of fictitious spin-1/2 operators: $\mathbf{I}_z^{(rs)} + \mathbf{I}_z^{(st)} + \mathbf{I}_z^{(tr)} = 0$ where the notation is that of Vega and Pines (2). One thus obtains 16 independent operators when the unit operator is added to the 15 independent operators so constructed. The result therefore is mathematically correct, but inconvenient in practice for lack of rotation symmetry to which spin operators are generally subject.

However, it is possible to construct 16 independent operators in terms of Pauli spin matrices without using the fictitious spin-1/2 operators if we realize that for spin 3/2 the spin angular momentum operators can be represented by 4×4 matrices and any 4×4 matrix can be thought of as consisting of four 2×2 submatrices which in turn can be written in terms of the 2×2 unit matrix and three Pauli matrices. Since there are 16 elements in the 4×4 spin angular momentum matrix, one requires 16 independent bases in which the matrix can be expanded just as a 2×2 matrix can be expanded in Pauli matrices. As will be shown later, they can be easily constructed and are complete. However, like the fictitious spin-1/2 operators they are mathematical bases which are not easy to associate with readily imaginable physical entities such as the cartesian components of a spin angular momentum. Since such a basis set also is not constructed on the basis of rotational symmetry inherent to spin angular momentum, the equations of motion for spin density operators can be generally more complicated than is in the case of a symmetry-adapted basis set.

A symmetry-adapted basis set should be more suitable and practical for solving physical problems, and such a basis set can be readily constructed if the rotation group theory is applied and in particular the theory of tensor operators is applied. The usefulness of symmetry-adapted basis sets in quantum mechanics is well recognized and exploited widely. In nmr Pyper (1*a*) appears to have used for the first time the symmetry-adapted irreducible tensor operator basis set which was originally developed for nuclear physics. And he has used the tensor operator sets to expand superoperators, Hamiltonians, and the density operator, and has developed a general theory of spin relaxation by means of them. Lynden-Bell (1*b*) and Spiess (1*c*) later have used the tensor operator formalism in nmr, but in their theories it is not shown how the spin matrices can be represented for the cases of $I > 1/2$. By couching the formalism in the language of the theory of Coope *et al.* (5), Sanctuary (3) uses a representation of spherical tensor bases $\mathbf{Y}^{(k)q}(I)$ for spin operators as follows:

$$[1] \qquad \mathbf{Y}^{(k)q}(I) = i^k[(2I+1)(2k+1)]^{1/2} \times \sum_{M,M'} (-)^{I-M} \begin{pmatrix} I & k & I \\ -M & q & M' \end{pmatrix} |IM\rangle\langle IM'|$$

where I is the spin, k and q are integers, and

$$\begin{pmatrix} I & k & I \\ -M & q & M' \end{pmatrix}$$

is the $3 - j$ symbol for a Clebsch–Gordan coefficient (6*a*). He makes extensive use of these bases in his later work (7) on the evolution of isolated spins, e.g., a single spin or two spins interacting with each other through a dipolar interaction, etc. The $\mathbf{Y}^{(k)q}$ is supposedly a tensor of rank k since it is a direct product of k vector components (spin angular momenta more precisely), but its representation as given by [1] is a dyadic since it is basically given by a dyadic $|IM\rangle\langle IM'|$, or in physical terms, the density matrix. Therefore $\mathbf{Y}^{(k)q}$ appears to stand for something other than a tensor of rank k which it is supposedly meant to be. Later on we will be able to interpret it as a matrix representation of a kth rank tensor in the Hilbert space for the spin angular momentum operator. Without this interpretation the mathematical meaning of the right hand side of [1] does not jibe with the terminology "kth rank tensor" associated with the object on the left hand side of [1]. He relates $\mathbf{Y}^{(k)q}$ to spin angular momentum operators, but since the latter are not given by their own representations eq. [1] must be taken as the means for representing spin angular momentum operators. Since there is little physical content in [1], which merely stands for a set of mathematical bases, the physics of the system in hand has become rather opaque and difficult to grasp.

In this paper we present a heuristic method of constructing the spherical basis set in terms of explicitly represented spin angular momentum operators for $I > \frac{1}{2}$. The result is a basis set not only similar to, if not identical with, the one deduced from [1] but also with clear meanings, and the basis is formally uniform for both integer and half-integer spins as is in the formalism by Pyper (1*a*), Lynden-Bell (1*b*), and Spiess (1*c*). We show that the problem in essence boils down to finding representations for spin angular momentum operators $\mathbf{I}_x$, $\mathbf{I}_y$, and $\mathbf{I}_z$ and construct spherical tensor bases with the former by simply following the well established procedure in the theory of angular momentum. It requires a minimum knowledge of rotation group theory and provides a basic and simple mathematical machinery to deal with problems related to spins larger than 1/2. With the basis set so constructed, we consider the evolution of spin density matrix in the cases of $I = 1$ and 3/2 when there is a perturbation turned on by a radiofrequency wave. Calculations can be made facile if the theory of Lie groups is taken advantage of. Some exact results are presented for the density matrices for arbitrary initial conditions. If the Sylvester formula for an exponential operator is made use of for the density matrix, it can be expressed in a rather useful form amenable to facile computation. The usefulness of the Sylvester formula does not appear to be appreciated in nmr.

II. Spherical tensor bases

In quantum mechanics one can construct spherical harmonics in terms of three cartesian components x, y, and z of a vector $\boldsymbol{r}$. In complete analogy to this it is possible to construct spherical tensors in terms of three cartesian components $\mathbf{I}_x$, $\mathbf{I}_y$, and $\mathbf{I}_z$ of spin angular momentum $\mathbf{I}$ which behaves as a vector. We take the z axis as the direction of quantization. These operators obey the well-known commutation relations for angular momentum operators

[2*a*] $[\mathbf{I}_x, \mathbf{I}_y] = \mathrm{i}\mathbf{I}_z$ (cyclical)

[2*b*] $[\mathbf{I}_z, \mathbf{I}_\pm] = \pm\mathbf{I}_\pm$

[2*c*] $[\mathbf{I}_+, \mathbf{I}_-] = 2\mathbf{I}_z$

where $\mathbf{I}_\pm$ are the raising and lowering operators. Fano and Racah (8) define irreducible tensor operators $\mathbf{T}_{lm}$ by the commutation relations

[3] $$[\mathbf{I}_\pm, \mathbf{T}_{lm}] = [(l \mp m)(l \pm m + 1)]^{1/2}\mathbf{T}_{lm\pm1}$$

[4] $$[\mathbf{I}_z, \mathbf{T}_{lm}] = m\mathbf{T}_{lm}$$

That is, if the set $\mathbf{T}_{lm}$ fulfills commutation relations [3] and [4] it is an irreducible tensor set. It is useful to remark at this point that if we define the following operators

$$\mathscr{L}_\pm = [\mathbf{I}_\pm, \ ], \quad \mathscr{L}_z = [\mathbf{I}_z, \ ]$$

the commutation relations [3] and [4] are isomorphic to the well-known relations for the lowering and raising operators of an ordinary angular momentum operator and its z component acting on spherical harmonic Y_l^m. Therefore the tensor operators $\mathbf{T}_{lm}$ may be regarded as eigenoperators for $\mathscr{L}_\pm$ and $\mathscr{L}_z$ which are in fact intimately related to the Liouville operator defined below. This analogy is cogent. Indeed, according to the theory of rotation group, the spherical tensor $\mathbf{T}_{lm}$ corresponding to spherical harmonic $\mathbf{Y}_l^m(\hat{\boldsymbol{r}})$ can be generated by the relation (9)

[5] $$\mathbf{T}_{lm}(\mathbf{I}) = (\mathbf{I}\cdot\nabla)^l Z_l^m(\boldsymbol{r})$$

where Z_l^m is a solid harmonic

$$Z_l^m(\boldsymbol{r}) = r^l Y_l^m(\hat{\boldsymbol{r}})$$

The differential operator ∇ operates on $\boldsymbol{r}$ or one of its components in Z_l^m and replaces it with $\mathbf{I}$ or the component of $\mathbf{I}$ corresponding to the component of $\boldsymbol{r}$ that has been differentiated. An alternative formula for generating spherical tensors is the recurrence relation

[6] $$\mathbf{T}_{lm} = (4\pi/3)^{l/2}[l!(2l+1)!!/4\pi]^{1/2} \times \sum_\mu C(1, l-1, l; -\mu, m+\mu)\mathbf{T}_{l-1,m+\mu}\mathbf{T}_{1,-\mu}$$

where $C(j_1, j_2, j_3; m_1, m_2)$ is another form for the Clebsch–Gordan coefficient (6*a*) and $(2l+1)!! = (2l+1)(2l-1)\ldots 3.1$. The higher order tensors can therefore be constructed with [6] if $\mathbf{T}_{10}$ and $\mathbf{T}_{1,\pm1}$ are given. To construct the higher order tensors it is useful to take advantage of the commutation relations [2*a*]–[2*c*]. The tensor operator $\mathbf{T}_{lm}$ is self-adjoint in the following sense:

[7] $$\mathbf{T}_{lm}^\dagger = (-)^m\mathbf{T}_{l,-m}$$

We also define the unit operator by $\mathbf{I}_0$. It will be 3×3 unit matrix for $I = 1$ and 4×4 unit matrix for $I = 3/2$, etc.

Using [5] for generating irreducible tensors $\mathbf{T}_{lm}$ is not as elegant as using [6], but simple and straightforward. It yields a completely symmetrized set of tensors. We list tensor bases so constructed for $l \leqslant 3$ which are necessary for studying spin 1 and 3/2. The following spherical tensors are renormalized such that $N_{lm} = [\mathrm{Tr}\,(\mathbf{T}_{lm}\mathbf{T}_{lm}^\dagger)]^{-1/2}$:

[8] $$\mathbf{T}_{00} = N_{00}\mathbf{I}_0$$

[9*a*] $$\mathbf{T}_{10} = N_{10}\mathbf{I}_z$$

[9*b*] $$\mathbf{T}_{1,\pm1} = N_{1,\pm1}\mathbf{I}_\pm$$

[10*a*] $$\mathbf{T}_{20} = N_{20}(3\mathbf{I}_z^2 - \mathbf{I}^2)$$

[10*b*] $$\mathbf{T}_{2,\pm1} = \mp N_{2,\pm1}(\mathbf{I}_\pm\mathbf{I}_z + \mathbf{I}_z\mathbf{I}_\pm)$$

[10*c*] $$\mathbf{T}_{2,\pm2} = \mathbf{N}_{2,\pm2}\mathbf{I}_\pm^2$$

[11*a*] $$\mathbf{T}_{30} = N_{30}(5\mathbf{I}_z^2 - 3\mathbf{I}^2 + 1)\mathbf{I}_z$$

	$(3, \pm 3)$		$\frac{1}{6}$

TABLE 2. Solid harmonics

l, m	Z_l^m
0, 0	$1/(4\pi)^{1/2}$
1, 0	$(3/4\pi)^{1/2}z$
1, $\mp$1	$\pm(3/8\pi)^{1/2}(x \pm iy)$
2, 0	$(5/16\pi)^{1/2}(2z^2 - x^2 - y^2)$
2, $\pm$2	$(15/16\pi)^{1/2}(x \pm iy)^2$
3, 0	$(7/16\pi)^{1/2}(2z^2 - 3x^2 - 3y^2)z$
3, $\pm$1	$\mp(21/64\pi)^{1/2}(4z^2 - x^2 - y^2)(x \pm iy)$
3, $\pm$2	$(105/16\pi)^{1/2}z(x \pm iy)^2$
3, $\pm$3	$\mp(35/64\pi)^{1/2}(x \pm iy)^3$

$$[11b]\quad \mathbf{T}_{3,\pm1} = \mp N_{3,\pm1}[(5\mathbf{I}_z^2 - \mathbf{I}^2 - 1/2)\mathbf{I}_\pm + \mathbf{I}_\pm(5\mathbf{I}_z^2 - \mathbf{I}^2 - 1/2)]$$

$$[11c]\quad \mathbf{T}_{3,\pm2} = N_{3,\pm2}(\mathbf{I}_\pm^2\mathbf{I}_z + \mathbf{I}_z\mathbf{I}_\pm^2 + \mathbf{I}_\pm\mathbf{I}_z\mathbf{I}_\pm)$$

$$[11d]\quad \mathbf{T}_{3,\pm3} = \mp N_{3,\pm3}\mathbf{I}_\pm^3$$

The normalization constants N_{lm} are summarized in Table 1. The above set, apart from the normalization constants, agree with the set by Sanctuary (3) except for $\mathbf{T}_{3,\pm2}$ which is not symmetrized in his set. Pyper and Spiess (1) used a similar set. These irreducible spherical tensor operators may be contrasted with solid harmonics $Z_l^m(\boldsymbol{r})$ list in Table 2.

When appropriate spin angular momentum operators $\mathbf{I}_z$ and $\mathbf{I}_\pm$ are substituted into the tensor bases above, we obtain explicit representations for them in the Hilbert space. When that is done, the irreducible spherical tensors assume basically the same structures as the matrix representations in Sanctuary's table for $\mathbf{Y}^{(k)q}$; see ref. 3. Therefore we are now able to see that the right hand side of [1] is the matrix representation of the kth rank tensor in the Hilbert space where $\mathbf{I}_z$ is diagonal and $\mathbf{I}_\pm$ are given as below. These three operators are the building blocks of the theories for dynamical evolution of isolated spins which are larger than 1/2.

A. $I = 1$

In this case the representations of spin angular momentum operators are exactly the same as those for the ordinary angular momentum operators of magnitude unity. Since the method of finding the representations for the latter is well documented in the literature (8), we will be as brief as possible. The commutation relations [2*a*] suggest that $\mathbf{I}_x$, $\mathbf{I}_y$, and $\mathbf{I}_z$ are traceless. Since we are assuming the z axis as the axis of quantization, in the Hilbert space spanned by eigenvectors $|1\rangle$, $|0\rangle$, and $|-1\rangle$ the z component $\mathbf{I}_z$ must be in the form

$$[12]\quad \mathbf{I}_z = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix}$$

To obtain the matrix representations for $\mathbf{I}_x$ and $\mathbf{I}_y$ we assume a 3×3 matrix for $\mathbf{I}_+$: $\mathbf{I}_+ = (a_{ij})$. Since $\mathbf{I}_+ = \mathbf{I}_-^\dagger$, we then find $\mathbf{I}_- = (a_{ij}^*)$. If these matrices are substituted into the commutation relations [2*a*]–[2*c*], there follows a set of algebraic equations for matrix elements a_{ij}. Solving the set for a_{ij}, we obtain the matrix elements a_{ij} within the sign. The results are as follows:

$$[13a]\quad \mathbf{I}_x = 2^{-1/2}\begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}$$

$$[13b]\quad \mathbf{I}_y = 2^{-1/2}\begin{bmatrix} 0 & -i & 0 \\ i & 0 & -i \\ 0 & i & 0 \end{bmatrix}$$

As is obvious, $\mathbf{I}_x$, $\mathbf{I}_y$, and $\mathbf{I}_z$ are all traceless. We also find

$$\mathbf{I}^2 = \mathbf{I}_x^2 + \mathbf{I}_y^2 + \mathbf{I}_z^2 = 2\mathbf{I}_0$$

where $\mathbf{I}_0$ is the 3×3 unit matrix. This is an expected result since the eigenvalue of $\mathbf{I}^2$ is 2 in the space spanned by $|1\rangle$, $|0\rangle$, and $|-1\rangle$. If [12], [13*a*], and [13*b*] are substituted into [8] and [9], the matrix representations in the Hilbert space of nine independent, orthogonal spherical tensor operators are obtained for $\mathbf{I} = 1$. It can be easily verified that, apart from the constant multiplication factors, they agree with $\mathbf{Y}^{(k)q}$ for $\mathbf{I} = 1$ given in ref. 3. We therefore see that $\mathbf{Y}^{(k)q}$ in ref. 3 are simply the matrix representations of spherical tensor operators.

B. $I = 3/2$

The procedure for finding the representations of $\mathbf{I}_x$, $\mathbf{I}_y$, and $\mathbf{I}_z$ for $I = 3/2$ is basically the same as for the case of $I = 1$. Again by making use of the fact that $\mathrm{Tr}\,\mathbf{I}_z = 0$ is implied by the commutation relations [2*a*]–[2*c*], we infer that in the Hilbert space spanned by the eigenvectors $|3/2\rangle$, $|1/2\rangle$, $|-1/2\rangle$, and $|-3/2\rangle$ the matrix representation of $\mathbf{I}_z$ is

$$[14a]\quad \mathbf{I}_z = \begin{bmatrix} 3/2 & 0 & 0 & 0 \\ 0 & 1/2 & 0 & 0 \\ 0 & 0 & -1/2 & 0 \\ 0 & 0 & 0 & -3/2 \end{bmatrix}$$

Then by assuming a 4×4 matrix for $\mathbf{I}_+$, $\mathbf{I}_+ = (a_{ij})$, and making use of $\mathbf{I}_+ = \mathbf{I}_-^\dagger$, the commutation relations and [14*a*] we obtain a set of algebraic equations for a_{ij}. Solving these algebraic equations, we find the matrix representations for $\mathbf{I}_x$

and $\mathbf{I}_y$ for $I = 3/2$:

$$[14b] \quad \mathbf{I}_x = \begin{bmatrix} 0 & \sqrt{3}/2 & 0 & 0 \\ \sqrt{3}/2 & 0 & 1 & 0 \\ 0 & 1 & 0 & \sqrt{3}/2 \\ 0 & 0 & \sqrt{3}/2 & 0 \end{bmatrix}$$

$$[14c] \quad \mathbf{I}_y = \begin{bmatrix} 0 & -i\sqrt{3}/2 & 0 & 0 \\ i\sqrt{3}/2 & 0 & -i & 0 \\ 0 & i & 0 & -i\sqrt{3}/2 \\ 0 & 0 & i\sqrt{3}/2 & 0 \end{bmatrix}$$

These matrix representations of $\mathbf{I}_x$, $\mathbf{I}_y$, and $\mathbf{I}_z$ clearly satisfy the commutation relations. They are also traceless. It is easy to show

$$\mathbf{I}^2 = (15/4)\mathbf{I}_0$$

where $\mathbf{I}_0$ is the 4×4 unit matrix. If the representations [14*a*]–[14*c*] are inserted into [8]–[10], there follow the matrix representations of spherical tensor operator basis for $I = 3/2$ in the Hilbert space spanned by $|3/2\rangle$ $|1/2\rangle$, $|-1/2\rangle$, and $|-3/2\rangle$.

III. Quaternions and construction of linearly independent bases

The Pauli spin matrices are quaternions (10–12) and any 2×2 matrix can be expressed in terms of them. The Pauli matrices are written as

$$[15] \quad \sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

to which the unit matrix σ_0 is added:

$$\sigma_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$

These matrices obey the commutation relations

$$[\sigma_x, \sigma_y] = 2i\sigma_z, \text{ etc. (cyclical)}$$

Now consider a 4×4 matrix

$$\mathbf{S} = \begin{pmatrix} \mathbf{a} & \mathbf{b} \\ \mathbf{c} & \mathbf{d} \end{pmatrix}$$

where **a**, **b**, etc. are 2×2 submatrices. Since the submatrices can be expanded in terms of Pauli matrices (quaternions), e.g.,

$$\mathbf{a} = a_0\sigma_0 + a_x\sigma_x + a_y\sigma_y + a_z\sigma_z$$

where a_x, a_y, etc. are the expansion coefficients, the matrix **S** can be written in terms of Pauli matrices by embedding the latter in the 4×4 array for **S**. This idea motivates us to define the following set of matrices:

$$[16] \quad \begin{aligned} \mathbf{e}_1 &= \begin{pmatrix} \sigma_0 & 0 \\ 0 & \sigma_0 \end{pmatrix}, \quad \mathbf{e}_2 = \begin{pmatrix} 0 & \sigma_0 \\ \sigma_0 & 0 \end{pmatrix}, \quad \mathbf{e}_3 = \begin{pmatrix} 0 & -i\sigma_0 \\ i\sigma_0 & 0 \end{pmatrix}, \quad \mathbf{e}_4 = \begin{pmatrix} \sigma_0 & 0 \\ 0 & -\sigma_0 \end{pmatrix}, \\ \mathbf{e}_5 &= \begin{pmatrix} \sigma_x & 0 \\ 0 & \sigma_x \end{pmatrix}, \quad \mathbf{e}_6 = \begin{pmatrix} 0 & \sigma_x \\ \sigma_x & 0 \end{pmatrix}, \quad \mathbf{e}_7 = \begin{pmatrix} 0 & -i\sigma_x \\ i\sigma_x & 0 \end{pmatrix}, \quad \mathbf{e}_8 = \begin{pmatrix} \sigma_x & 0 \\ 0 & -\sigma_x \end{pmatrix}, \\ \mathbf{e}_9 &= \begin{pmatrix} \sigma_y & 0 \\ 0 & \sigma_y \end{pmatrix}, \quad \mathbf{e}_{10} = \begin{pmatrix} 0 & \sigma_y \\ \sigma_y & 0 \end{pmatrix}, \quad \mathbf{e}_{11} = \begin{pmatrix} 0 & -i\sigma_y \\ i\sigma_y & 0 \end{pmatrix}, \quad \mathbf{e}_{12} = \begin{pmatrix} \sigma_y & 0 \\ 0 & -\sigma_y \end{pmatrix}, \\ \mathbf{e}_{13} &= \begin{pmatrix} \sigma_z & 0 \\ 0 & \sigma_z \end{pmatrix}, \quad \mathbf{e}_{14} = \begin{pmatrix} 0 & \sigma_z \\ \sigma_z & 0 \end{pmatrix}, \quad \mathbf{e}_{15} = \begin{pmatrix} 0 & -i\sigma_z \\ i\sigma_z & 0 \end{pmatrix}, \quad \mathbf{e}_{16} = \begin{pmatrix} \sigma_z & 0 \\ 0 & -\sigma_z \end{pmatrix} \end{aligned}$$

This set is constructed in the following manner: Regard σ_0, σ_x, σ_y, and σ_z as numbers and form Pauli matrices with each one of them. Since there are four Pauli matrices and four super-Pauli matrices are possible to form with each one of the four Pauli matrices, there are 16 elements in all. The result is the set given in [16]. Note that there are four subsets which look like the Pauli matrices. These bases are all hermitean, orthogonal, and linearly independent as can be verified by forming the Gramm determinant which turns out to be non-zero. For the purpose of this and other calculations we define the scalar products by

$$(\mathbf{e}_i, \mathbf{e}_j) = \text{Tr}\,(\mathbf{e}_i\mathbf{e}_j^\dagger)$$

Since the Pauli matrices have the property

$$\sigma_0^2 = \sigma_x^2 = \sigma_y^2 = \sigma_z^2 = 1$$

that is, they are their own inverse (involutional), we easily see that all the elements in the set [16] have the same involution property as the Pauli matrices themselves. The elements in [16] do not generally commute with each other and, when non-commuting, they obey the same commutation relations as the Pauli matrices. To indicate such commutation relations, a commutator table is prepared in Table 3 where a numeral k stands for $2i\mathbf{e}_k$ for the commutator formed with the elements in the column and the row, and in that order.

Since the basis set is linearly independent, any 4×4 matrix can be expressed in terms of the 16 independent orthogonal basis listed above. As in the case of the set constructed with fictitious spin-1/2 operators, this set unfortunately is inconvenient owing to the lack of symmetry. For this reason we will not use it in actual calculations, but since there are some intrinsically interesting features (11, 12) in it which might be useful for study of spin dynamics in another context, it is presented here for completeness and for record.

IV. Dynamics of spins

In pulsed nmr experiments we are interested in the evolution of a spin in interaction with the rest of the system. An appropriate description for the evolution of such a system requires an irreversible relaxation equation such as the Redfield equation as described in ref. 1*a* or the Pauli master equation. In the event that such a relaxation-type equation is not required, the density matrix of a single spin may be described by the von Neumann equation.

$\mathbf{e}_{15}$	0	−16	0	14	11	0	9	0	−7	0	−5	0	0	−4	0	2
$\mathbf{e}_{16}$	0	15	−14	0	12	0	0	9	−8	0	0	−5	0	3	−2	0

[a]The commutators are constructed with the column and the row and in that order. The numeral l in the table stands for $2i\mathbf{e}_l = [\mathbf{e}_j, \mathbf{e}_k]$. For example, 4 is for $[\mathbf{e}_2, \mathbf{e}_3] = 2i\mathbf{e}_4$ and its conjugate element in the table is $[\mathbf{e}_3, \mathbf{e}_2] = -2i\mathbf{e}_4$, i.e., −4.

[17] $i(\partial\rho/\partial t) = [\mathcal{H}, \rho]$

where we have put $\hbar = 1$ and $\mathcal{H}$ is the Hamiltonian. This equation is sometimes called the quantum Liouville equation with the Liouville operator defined by the operator

[18] $\mathcal{L} = [\mathcal{H}, \ ]$

The Liouville equation [17] is considered in ref. 3, but it is solved differently in this paper. We believe the present method is simpler. Equation [17] can be formally solved in the form

[19] $\rho(t) = \exp(-it\mathcal{L})\rho(0)$

if the Hamiltonian is time-independent. Since our aim here is in illustrating an application of the spherical tensor operator set presented, we shall consider the following Hamiltonian studied by others (1–4):

[20] $\mathcal{H} = \omega_0\mathbf{I}_z + \omega_1(\mathbf{I}_x \cos\omega t + \mathbf{I}_y \sin\omega t)$

in the standard notation. The transformation to the rotating frame of reference

[21] $\bar{\rho} = \exp(-i\omega t\mathbf{I}_z)\rho \exp(i\omega t\mathbf{I}_z)$

puts the Hamiltonian in a time-independent form

[22] $\bar{\mathcal{H}} = \exp(-i\omega t\mathbf{I}_z)\mathcal{H} \exp(i\omega t\mathbf{I}_z)$
$= \Delta\omega\mathbf{I}_z + \omega_1\mathbf{I}_x = \Delta\omega\mathbf{I}_z + (1/2)\omega_1(\mathbf{I}_+ + \mathbf{I}_-)$

where $\Delta\omega = \omega_0 - \omega$. The Liouville equation then is

$i(\partial\bar{\rho}/\partial t) = [\bar{\mathcal{H}}, \bar{\rho}] \equiv \bar{\mathcal{L}}\bar{\rho}$

which is formally solved by

[23] $\bar{\rho}(t) = \exp(-it\bar{\mathcal{L}})\bar{\rho}(0)$

This formal solution must be cast in an explicit form so that it can be useful for practical study. This is discussed below.

First, we observe that the initial condition $\bar{\rho}(0)$ is a matrix whose dimension is 3 in the case of $I = 1$ and 4 in the case of $I = 3/2$, etc. Since such a matrix can be expanded in a complete set of tensor bases, we may write

[24] $\bar{\rho}(0) = \sum_{l=0}^{2I} \sum_{m=-l}^{l} \rho_{lm}\mathbf{T}_{lm}$

where ρ_{lm} is the projection of the initial condition onto the base $\mathbf{T}_{lm}$:

[25] $\rho_{lm} = \mathrm{Tr}[\bar{\rho}(0)\mathbf{T}_{lm}^{\dagger}]$

Substituting [24] into [23], we find

[26] $\bar{\rho}(t) = \sum_{l=0}^{2I} \sum_{m=-l}^{l} \rho_{lm} \exp(-it\bar{\mathcal{L}})\mathbf{T}_{lm}$

To calculate the evolution of $\mathbf{T}_{lm}$ in time, we observe the following:

$$[\mathbf{I}_z, \mathbf{T}_{lm}] = m\mathbf{T}_{lm}$$

$$[\mathbf{I}_\pm, \mathbf{T}_{lm}] = [(l \mp m)(l \pm m + 1)]^{1/2}\mathbf{T}_{lm\pm 1}$$

(cf. [3] and [4])

Since the operator $\bar{\mathcal{L}}$ generates a commutator with its operand, in the case of the Hamiltonian [22] we obtain

$$[27]\quad \begin{aligned}\bar{\mathcal{L}}\mathbf{T}_{lm} &= [\bar{\mathcal{H}}, \mathbf{T}_{lm}] \\ &= \Delta\omega[\mathbf{I}_z, \mathbf{T}_{lm}] + \tfrac{1}{2}\omega_1[\mathbf{I}_+, \mathbf{T}_{lm}] + \tfrac{1}{2}\omega_1[\mathbf{I}_-, \mathbf{T}_{lm}] \\ &= m\Delta\omega\mathbf{T}_{lm} + \tfrac{1}{2}\omega_1\{[(l - m)(l + m + 1)]^{1/2}\mathbf{T}_{lm+1} \\ &\quad + [(l + m)(l - m + 1)]^{1/2}\mathbf{T}_{lm-1}\}\end{aligned}$$

The first line is by the definition of $\bar{\mathcal{L}}$, the second line is due to the linearity of the operator $\bar{\mathcal{L}}$, and the last line is due to [3] and [4]. This calculation shows that the operator $\bar{\mathcal{L}}$ maps the subspace spanned by $\{\mathbf{T}_{lm}: m = l, l - 1, \ldots, -l\}$ onto itself. In other words, $\bar{\mathcal{L}}\mathbf{T}_{lm}$ is a linear combination of $\{\mathbf{T}_{ln}\}$ itself. Therefore we may define a matrix $\mathbf{C}^{(l)}$ such that

$$[28]\quad \bar{\mathcal{L}}\mathbf{T}_{lm} = \sum_{p=-l}^{l} C_{mp}^{(l)}\mathbf{T}_{lp}$$

That is,

$$[29]\quad \begin{aligned}C_{mp}^{(l)} &= \mathrm{Tr}\,(\mathbf{T}_{lp}^{\dagger}\bar{\mathcal{L}}\mathbf{T}_{lm}) \\ &= m\Delta\omega\delta_{pm} + \tfrac{1}{2}\omega_1[(l - m)(l + m + 1)]^{1/2}\delta_{pm+1} \\ &\quad + \tfrac{1}{2}\omega_1[(l + m)(l - m + 1)]^{1/2}\delta_{pm-1}\end{aligned}$$

Equation [28] implies the following important result for the present calculation: since the sum over p is over the multiplet of l, the operator $\bar{\mathcal{L}}$ maps $\{\mathbf{T}_{lm}\}$ onto itself. In other words, the new spherical tensor operators generated by $\bar{\mathcal{L}}$ remain within the multiplet corresponding to l. Thus we see that

$$\begin{aligned}\bar{\mathcal{L}}^2\mathbf{T}_{lm} &= \sum_{p=-l}^{l}\sum_{q=-l}^{l} C_{mp}^{(l)}C_{pq}^{(l)}\mathbf{T}_{lq} \\ &= \sum_{q=-l}^{l}(\mathbf{C}^{(l)})_{mq}^2\mathbf{T}_{lq}\end{aligned}$$

Repeating this process, we obtain

$$\bar{\mathcal{L}}^n\mathbf{T}_{lm} = \sum_{q=-l}^{l}(\mathbf{C}^{(l)n})_{mq}\mathbf{T}_{lq}$$

and thus finally the density matrix in the form

$$[30]\quad \begin{aligned}\bar{\rho}(t) &= \sum_{l=0}^{2I}\sum_{m=-l}^{l}\rho_{lm}\exp(-it\bar{\mathcal{L}})\mathbf{T}_{lm} \\ &= \sum_{l=0}^{2I}\sum_{m=-l}^{l}\rho_{lm}\sum_{n=0}^{\infty}\frac{(-it)^n}{n!}\bar{\mathcal{L}}^n\mathbf{T}_{lm} \\ &= \sum_{l=0}^{2I}\sum_{m=-l}^{l}\sum_{q=-l}^{l}\rho_{lm}\sum_{n=0}^{\infty}\frac{(-it)^n}{n!}(\mathbf{C}^{(l)n})_{mq}\mathbf{T}_{lq} \\ &= \sum_{l=0}^{2I}\sum_{m=-l}^{l}\sum_{q=-l}^{l}\rho_{lm}\exp(-it\mathbf{C}^{(l)})_{mq}\mathbf{T}_{lq}\end{aligned}$$

where $\mathbf{C}^{(l)}$ is $(2l + 1) \times (2l + 1)$ tridiagonal matrix and $\mathbf{C}^{(0)} = 0$. There now remains the task of diagonalizing the matrices $\mathbf{C}^{(l)}$ for $l = 1, 2. \ldots$ Obviously, since $\mathbf{C}^{(l)}$ are symmetric, their eigenvalues are real.

If the eigenvalues $\lambda_\alpha^{(l)}$ are all distinct as they will turn out to be in the case of $\bar{\mathcal{L}}$ given by [22], the Sylvester formula (13) puts [30] in a more useful form:

$$[31]\quad \bar{\rho}(t) = \sum_{l=0}^{2I}\sum_{m=-l}^{l}\sum_{q=-l}^{l}\sum_{\alpha\in l}\left[\exp(-it\lambda_\alpha^{(l)})\prod_{\beta\neq\alpha}\frac{(\mathbf{C}^{(l)} - \lambda_\beta^{(l)})}{(\lambda_\alpha^{(l)} - \lambda_\beta^{(l)})}\right]_{mq}\mathbf{T}_{lq}\rho_{lm}$$

where the sum over α runs over all eigenvalues for the lth multiplet. When the eigenvalues are explicitly obtained, the problem is solved and the density matrix is explicitly known for any initial condition that determines ρ_{lm}. We now turn our attention to the eigenvalues.

A. $l = 1$

In this case $\mathbf{C}^{(1)}$ is a 3×3 matrix of the form:

$$[32]\quad \mathbf{C}^{(1)} = \begin{bmatrix}\Delta\omega & \omega_1/\sqrt{2} & 0 \\ \omega_1/\sqrt{2} & 0 & \omega_1/\sqrt{2} \\ 0 & \omega_1/\sqrt{2} & -\Delta\omega\end{bmatrix}$$

The eigenvalues of this matrix are

$$[33]\quad \lambda_0^{(1)} = 0, \quad \lambda_\pm^{(1)} = \pm[\Delta\omega^2 + \omega_1^2]^{1/2}$$

They are all real and distinct. Substitution of this result into the Sylvester form [31] for the density matrix explicitly yields the density matrix for $I = 1/2$.

B. $l = 2$

The matrix $\mathbf{C}^{(2)}$ in this case is a 5×5 matrix of the form:

$$[34]\quad \mathbf{C}^{(2)} = \begin{bmatrix}2\Delta\omega & \omega_1 & 0 & 0 & 0 \\ \omega & \Delta\omega & (\frac{3}{2})^{1/2}\omega_1 & 0 & 0 \\ 0 & (\frac{3}{2})^{1/2}\omega_1 & 0 & (\frac{3}{2})^{1/2}\omega_1 & 0 \\ 0 & 0 & (\frac{3}{2})^{1/2}\omega_1 & -\Delta\omega & \omega_1 \\ 0 & 0 & 0 & \omega_1 & -2\Delta\omega\end{bmatrix}$$

The eigenvalues of this matrix are

$$[35]\quad \begin{aligned}\lambda_0^{(2)} &= 0 \\ \lambda_{\pm\pm}^{(2)} &= \pm[\tfrac{5}{2}(\Delta\omega^2 + \omega_1^2) \pm \tfrac{1}{2}(9\Delta\omega^4 + 18\Delta\omega^2\omega_1^2 \\ &\quad + \omega_1^4)^{1/2}]^{1/2}\end{aligned}$$

which are also real and distinct. These determine the $l = 2$ part of the density matrix. In the case of $I = 1$ the $\mathbf{C}^{(l)}$ up to $l = 2$ are sufficient for determining the density matrix.

C. $l = 3$

In this case the matrix is 7×7:

$$[36]\quad \mathbf{C}^{(3)} = \begin{bmatrix}3\Delta\omega & (\frac{3}{2})^{1/2}\omega_1 & 0 & 0 & 0 & 0 & 0 \\ (\frac{3}{2})^{1/2}\omega_1 & 2\Delta\omega & (\frac{5}{2})^{1/2}\omega_1 & 0 & 0 & 0 & 0 \\ 0 & (\frac{5}{2})^{1/2}\omega_1 & \Delta\omega & \sqrt{3}\omega_1 & 0 & 0 & 0 \\ 0 & 0 & \sqrt{3}\omega_1 & 0 & \sqrt{3}\omega_1 & 0 & 0 \\ 0 & 0 & 0 & \sqrt{3}\omega_1 & -\Delta\omega & (\frac{5}{2})^{1/2}\omega_1 & 0 \\ 0 & 0 & 0 & 0 & (\frac{5}{2})^{1/2}\omega_1 & -2\Delta\omega & (\frac{3}{2})^{1/2}\omega_1 \\ 0 & 0 & 0 & 0 & 0 & (\frac{3}{2})^{1/2}\omega_1 & -3\Delta\omega\end{bmatrix}$$

For personal use only.

The secular determinant of this matrix factorizes to the following form:

$$\det|\mathbf{C}^{(3)} - \lambda\mathbf{1}| = -\lambda f(\lambda^2)$$

where $f(\lambda^2)$ is a cubic polynomial of λ^2, but its coefficients are rather complicated. We present the function $f(\lambda^2)$ for completeness:

$$\begin{aligned} f(\lambda^2) = {} & (\lambda^2 - \Delta\omega^2)\mathbf{D}(\Delta\omega)\mathbf{D}(-\Delta\omega) \\ & - (25/4)\omega_1^2(9\Delta\omega^2 - \lambda^2) \\ & + 6\omega_1^2\mathbf{D}(\Delta\omega)\mathbf{D}(-\Delta\omega) + 225\omega_1^4\Delta\omega^2 \\ & - 15\omega_1^4(6\Delta\omega^2 + \lambda^2 - (3/2)\omega_1^2) \\ & + \tfrac{5}{2}\omega_1^2[(3\Delta\omega - \lambda)(\Delta\omega + \lambda)\mathbf{D}(-\Delta\omega) \\ & \qquad + (3\Delta\omega + \lambda)(\Delta\omega - \lambda)\mathbf{D}(\Delta\omega)] \end{aligned}$$

where

$$\mathbf{D}(x) = \begin{vmatrix} 3x - \lambda & (\frac{3}{2})^{1/2}\omega_1 \\ (\frac{3}{2})^{1/2}\omega_1 & 2x - \lambda \end{vmatrix}$$

and therefore $\mathbf{D}(\Delta\omega)\mathbf{D}(-\Delta\omega)$ is a function of λ^2. The last term, i.e., the term in the square brackets is also a function of λ^2. The roots of the function can be analytically found since it is a cubic function of λ^2. In any case the eigenvalues are also all real and distinct, and there are three pairs of eigenvalues which are not equal to zero, and one which is equal to zero. Since their exact forms are rather devoid of physical insight, we shall not reproduce them here. More useful and insightful solutions can be found by using a perturbation method in the region of small ω_1.

The results for $\mathbf{C}^{(l)}$ above allows to determine the density matrices for spins up to $I = 3/2$. It is useful to note that the dimension of the matrix representations for the tensor operator bases $\mathbf{T}_{lm}$ changes according to the spin values, e.g., 2 for $I = 1/2$, 3 for $I = 1$, and 4 for $I = 3/2$.

V. Concluding remarks

In this paper we have presented a simple pedestrian procedure for constructing spherical tensor operators with which one can expand operators related to spin angular momenta for all values of I. Although it may appear surprising, this simple procedure has not been used in the literature. The procedure reduces to a minimum the use of rotation group theory and complicated algebra associated with it which is difficult to master for one not practicing rotation group theory everyday. The present heuristic method is easy to handle and to apply to other higher spin values. It only takes a rather straightforward algebra. By this formalism the dynamics of one or two isolated spins of $I \geq 1/2$ is reduced to a simple quantum mechanical problem that can be even taught in a quantum mechanics class room. Dynamics of isolated spins is not sufficient for chemical problems, and many-spin problems must be solved for them. The present formalism may be applied to study the latter problems.

Solvent effects on the photoisomerization of bilirubin

B. M. SAILOFSKY AND G. R. BROWN
Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, P.Q., Canada H3A 2K6

Received January 2, 1987

This paper is dedicated to Professor John T. Edward

B. M. SAILOFSKY and G. R. BROWN. Can. J. Chem. **65**, 1908 (1987).

Studies of the photolysis of bilirubin IX-α by absorbance difference (AD) spectroscopy show that in solvents which do not interfere with the intramolecular hydrogen bonding, e.g., $CHCl_3$, *EZ/ZE* isomers and lumirubins are formed, with the former being predominant. The addition of ethanol to $CHCl_3$, either before or during photolysis, greatly changes the AD spectra, possibly because of a reaction of photoproducts with the ethanol or solvatochromism of the *EZ/ZE* isomers. Solvents which interfere with the intramolecular hydrogen bonding of bilirubin, e.g., DMSO, increase the importance of the photoreaction that forms lumirubins. The kinetics of product formation indicate that the lumirubins result from a photoreaction of *EZ/ZE* isomers. The addition of aqueous buffer to DMSO lowers the extent of photoisomerization and leads to AD spectra that resemble those obtained for the photolysis in $CHCl_3$. The addition of human serum albumin (HSA), using stopped flow techniques, to aqueous buffer solution of bilirubin immediately after photolysis gives evidence that the HSA traps the *EZ/ZE* isomers and prevents their reversion. However, in the presence of HSA the predominant pathway for photoreaction of bilirubin to *EZ/ZE* isomers is by reaction of the bound bilirubin. The AD spectra are similar to those obtained for solvents that interfere with hydrogen bonding.

B. M. SAILOFSKY et G. R. BROWN. Can. J. Chem. **65**, 1908 (1987).

Les études de spectroscopie par absorbance différentielle (AD) ont démontré que la photolyse de la bilirubine-IXα poursuivie en milieux qui ne perturbent pas les liaisons hydrogènes, tel que le chloroforme, produit principalement les isomères *EZ/ZE*, ainsi que des lumirubines. L'addition d'éthanol, par exemple au chloroforme, soit avant ou après la photolyse transforme les spectres AD, peut-être à la suite d'une réaction des photoproduits avec l'éthanol ou en raison du solvatochromisme des isomères *EZ/ZE*. Par contre, la formation des lumirubines par photoréaction est favorisée dans des solvants tel que le sulphoxyde diméthylique, c'est-à-dire dans des solvants qui perturbent les liaisons hydrogènes. Ainsi, les résultats d'études de cinétique démontrent que les lumirubines sont formées par la photoréaction des isomères *EZ/ZE*. L'addition de solutions tampons aqueuses au sulphoxyde diméthylique diminue le degré de photoisomérisation et les spectres AD obtenus ressemblent à ceux obtenus après la photolyse dans le chloroforme. L'addition de la sérum-albumine humaine (SAH), immédiatement après la photolyse, à des solutions tampons aqueuses de bilirubine en utilisant des techniques d'additions simultanées, indique que la SAH capte les isomères *EZ/ZE* et empêche leur inversion. Cependant, la photoréduction de la bilirubine en isomères *EZ/ZE* en présence de la SAH se poursuit principalement par réaction des bilirubines liées. Les spectres AD obtenus sont semblables à ceux obtenus dans des milieux qui perturbent les liaisons hydrogènes.

Introduction

During the past fifteen years the photochemistry of bilirubin has been studied extensively (1–4), particularly photoisomerization. It is related to phototherapy, used for the treatment of neonatal jaundice (5). Originally it was thought that the major mechanism leading to a lowering in the plasma bilirubin level during phototherapy involves photooxidation of bilirubin (6) but it has subsequently been shown that photoisomerization is a much faster reaction and hence precedes photooxidation (7–9).

Initial evidence suggested that the photoisomerization of bilirubin leads to only one photoproduct, first named "photobilirubin" (8). Further work showed that there are in fact a number of photoproducts, including both structural and geometric isomers (10–13). Furthermore, the photoproduct formed, and in what proportion, seems to be a function of many parameters, including the nature of the solvent and the presence or absence of oxygen or of proteins such as albumin.

The conformation of the bilirubin molecule in solution is highly solvent dependent. In aqueous solution bilirubin is folded into a configuration that has six intramolecular hydrogen bonds (14). This folded, "ridge tile" structure results in the molecule being highly hydrophobic and thus sparingly soluble in aqueous solution. The reported solubility of bilirubin in aqueous solution at physiological pH ranges from 0.007 to 100 μ*M*, with the lower value being favoured according to Brodersen (15). The bilirubin molecule assumes this tight, intramolecularly hydrogen bonded stucture in water and in chloroform (16) but in solvents which interfere with hydrogen bonding, e.g., dimethyl sulfoxide (DMSO), the molecule "opens up" as some of the hydrogen bonds are weakened (10, 17).

Certain conclusions from studies of the photolysis of bilirubin in organic solvents have been extended to phototherapy conditions. Since the ultimate goal of phototherapy is to lower the bilirubin levels in the infant's blood plasma, it is imperative that effect of solvent on the mechanisms of the photoisomerization and photodestruction of bilirubin be understood. Thus, we have studied the photoreaction in various organic and aqueous media, with and without HSA and BSA, and offer some explanation for the photoisomerization results with respect to the environment of the bilirubin.

Experimental

Solutions of bilirubin were prepared daily by dissolving the powder (from bovine gallstones, Sigma) in the appropriate solvent. The purity of the bilirubin was checked using HPLC (18). Chloroform (Spectrograde, Anachemia), triethylamine (Reagent grade, Anachemia) and dimethylsulfoxide (HPLC grade, Anachemia) were used as received, except in experiments for which the ethanol stabilizer in the chloroform was removed immediately prior to use by first distilling over P_2O_5 and then passing the distillate through a column of basic I alumina (Sigma).

Aqueous solutions were made by first dissolving the bilirubin in 0.10 *M* NaOH and adjusting the volume of KH_2PO_4/NaOH buffer to achieve a final pH of 7.8 ± 0.1. Prior to use the solvents were purged with dried nitrogen.

Aliquots of the aqueous solution were added to HSA/buffer solutions to obtain the desired ratio of [HSA]/[BR]. Human serum (Cutter Laboratories) and bovine serum (Sigma, Fraction V) albumin were

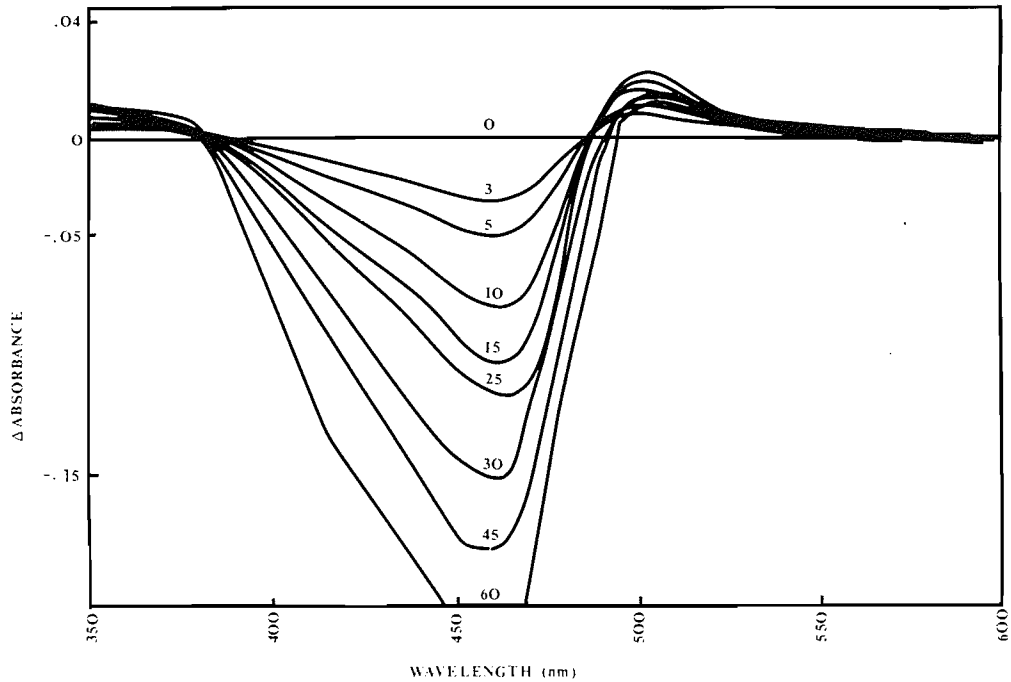

FIG. 1. Absorbance difference spectra for a solution of bilirubin in pure $CHCl_3$ after various times of irradiation. (The numbers refer to the irradiation times, in minutes.)

used as received. For all solutions the final concentration of bilirubin was 1.71×10^{-5} *M*. Studies were done at room temperature, except for those with the pure buffer solutions, which were kept in an ice bath prior to use.

The solutions (< 1 mL), contained in 1.00 cm path length cells, were irradiated directly in the cell holder of the Hewlett Packard Model 8451A Diode Array Spectrophotometer by placing the light source (Cole-Parmer Fiber Optic Illuminator Model 9745-00, fitted with a blue filter with a bandpass of 410–470 nm) over the cell, i.e., by shining the light down through the cell opening (intensity = 0.5 $\mu W/cm^2$). Since the course of bilirubin photochemistry has been shown to depend upon the excitation wavelength (19), the same light source was used throughout this study. The spectrophotometer was capable of recording a spectrum within 1 s *while* the irradiation light source was still on.

The HPLC apparatus and methods, described previously by McCarthy *et al.* (18), used reverse phase methods. The chromatograph consisted of a Waters Associates Model 590 pump, a Rheodyne 7125 injection valve and a Schoeffel Spectraflow (Kratos Analytical Instruments, Ramsay, NJ) Model SF770 variable wavelength detector. The column was a 15.0 × 0.46 cm blank packed in-house with 5 μm Spherisorb (Chromatographic Specialties Company, Town of Mount Royal, Quebec) with a guard column consisting of a 3.5 × 0.46 cm blank packed with a 30–38 μm octyldecyl silica (Whatman Inc., Clinton, NJ). The mobile phase contained 50% phosphate buffer (pH = 7.4), 25% acetonitrile, and 25% dimthylsulfoxide, and 1.5 g/L of tetrabutylammonium chloride (Sigma) as an ion-pairing agent. Prior to sample injection the sample was dissolved in the appropriate amount of phosphate buffer/acetonitrile/dimethylsulfoxide so that the solvent phase matched the mobile phase. All analyses were done at room temperature using a flow rate of 1.0 mL/min with the detector wavelength set at 455 nm.

The stopped flow experiments, made with a Model 1A Stopped-Flow Apparatus (Cantech Scientific Ltd., Winnipeg, Canada), monitored the changes in absorbance, at a fixed wavelength, with a TDI photometer and stored the data with a TDI 1024C transient recorder. The data were transferred to an IBM PC that performed the desired calculations. For these experiments, an aqueous solution of bilirubin was placed into one syringe and of HSA ([HSA]/[BR] = 10) in the second syringe. The syringe containing the bilirubin could be irradiated, using the light source described above, prior to mixing. The two syringes emptied into the observation cell, where the data points (208 points) were collected over a 20 s time span, beginning within 5 ms.

Results and discussion

(A) Photolysis in pure chloroform

When a solution of bilirubin in pure $CHCl_3$ purged with N_2 is irradiated a characteristic absorbance difference (AD) spectrum is obtained (Fig. 1), as reported previously (8, 20). During the first 25 min of irradiation two isosbestic points are obtained. The isosbestic point at 490 nm is not maintained at irradiation times >30 min, but that at 380 nm remains, suggesting two separate photoproducts. The production of *EZ/ZE* isomers of bilirubin leads to the isosbestic point at 490 nm (9). The second isosbestic point results from the formation of a second photoproduct, previously identified as "lumirubins" (12), also referred to as "cyclobilirubin" (9), "unknown pigment" (11), and "pigment 430" (21), that has an absorbance maximum around 430 nm (10). Lumirubin is a configurational isomer of bilirubin formed by an *endo*-vinyl cyclization on one end ring of the molecule (11, 13, 22).

Based on structural arguments obtained by use of molecular models, it seems likely that cyclization to form lumirubins occurs *after* a rotation about the C4—C5 bond of the bilirubin, i.e., by a reaction of *EZ/ZE* isomers. This has been the subject of considerable dispute (11, 22), and is considered more fully later. Although an induction period for the formation of lumirubins would be expected for such a mechanism, it is not detected, probably because the necessary buildup in the concentration of *EZ/ZE* isomers is fairly rapid compared to the frequency at which spectra were taken.

(B) Photolysis in chloroform/ethanol

The photolysis behaviour of bilirubin in $CHCl_3$ containing 1% ethanol stabilizer is similar to that in pure $CHCl_3$ with the exception that, at a given time of irradiation, the resulting gain

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12

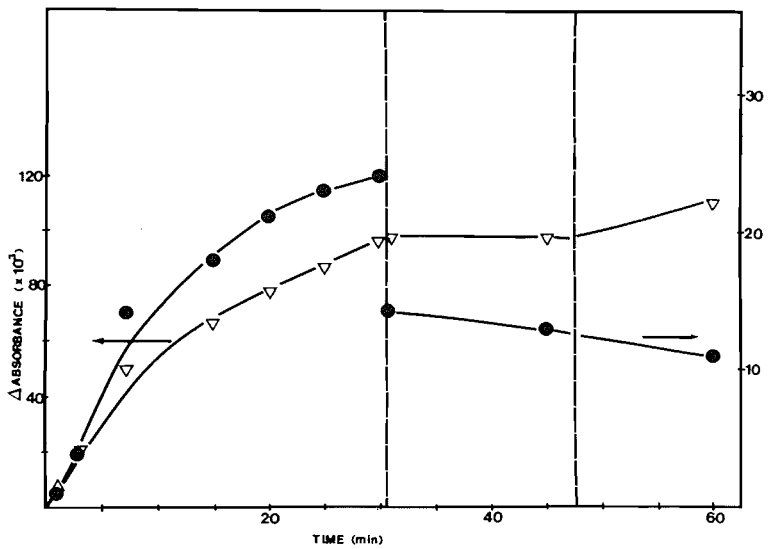

FIG. 2. The absolute values of the absorbance difference of the gain peak (500 nm) and the loss peak (460 nm) for a photolyzed solution of bilirubin in pure $CHCl_3$ as a function of irradiation time. At t = 31 min, irradiation was discontinued and ethanol was added. At t = 47 min, photolysis was continued: ●, gain peak; ▽, loss peak.

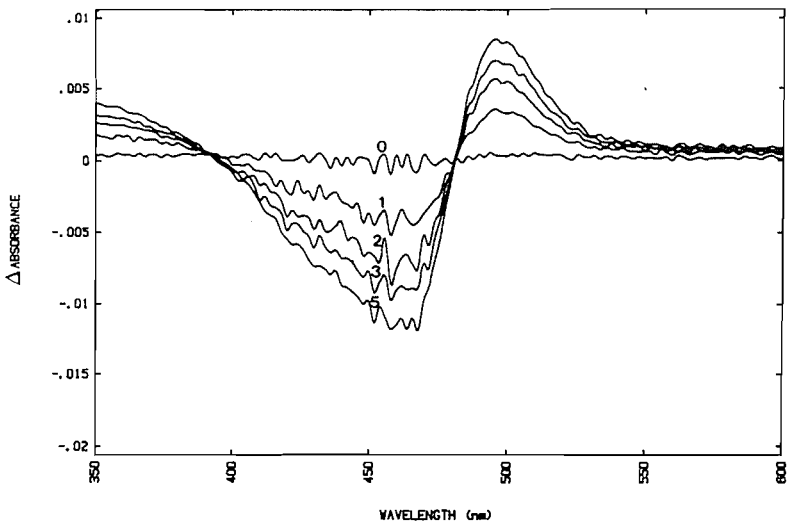

FIG. 4. Absorbance difference spectra for a solution of bilirubin in DMSO/buffer (90:10) for various irradiation times. (The numbers refer to the irradiation times, in minutes.)

peaks are less than one half the size of those using pure $CHCl_3$. However, within experimental uncertainty, the loss peaks remain unchanged. It should be noted that even 1% stabilizer in the solvent corresponds to a molar ethanol concentration that is much greater than the bilirubin concentration.

The following experiment was made to elucidate the role of ethanol: bilirubin in pure $CHCl_3$ purged with N_2 was irradiated for 30 min after which 10 μL of ethanol (1% of the total volume of the solution being irradiated) was added. The cell was gently shaken, the irradiating light was turned off, and additional spectra were taken. Possible side effects due to the addition of ethanol were accounted for by simultaneously adding an equal amount of ethanol to the reference solution. Upon addition of ethanol the height of the gain peak, due to the *EZ/ZE* isomers, immediately decreased substantially while the bilirubin loss peak remained essentially unchanged (Fig. 2). Concomitantly the isosbestic points disappeared. When irradiation of this solution was resumed the gain peak showed a further decrease while the loss peak continued to increase, and the isosbestic point at 380 nm was restored. These observations are consistent with the continued formation of lumirubins, since there is still a loss of bilirubin and an isosbestic point. Meanwhile the peak at 500 nm, corresponding to the *EZ/ZE* isomers, is decreasing slightly such that a new photostationary state is established. Interestingly, the absorbance difference at 500 nm reaches the same final value, 0.011, as in the $CHCl_3$/ethanol system discussed above.

The explanation of these results must account for a rapid decrease in the gain peak due to added ethanol that is not accompanied by any change in the size of the loss peak. A possible explanation is a reaction of ethanol with the *EZ/ZE* isomers. Photochemical addition of alcohols to the *exo*-vinyl group of bilirubin has been reported previously by Garbagnati and Manitto (23). However, the data are not consistent with Manitto's overall mechanism which requires the reaction to be light induced and irreversible. Since the *EZ/ZE* isomers are not entirely consumed, despite a large molar excess of ethanol, the reaction must be an equilibrium process. Furthermore, since the reaction occurs after the light is turned off, it is a reaction with the photoproduct. A reversible reaction of photoproducts with ethanol is consistent with a decrease in the concentration of *EZ/ZE* isomers in $CHCl_3$/EtOH solutions relative to that in pure $CHCl_3$ as well as the immediate decrease in its concentration when ethanol is added after the irradiation.

Alternatively, the changes in the height of the gain peak upon addition of ethanol may indicate solvatochromism of the photoisomers, similar to that exhibited by bilirubin dimethyl ester (24). It is well known that bilirubin dimethyl ester in dilute solution exhibits solvatochromism which has been attributed to the presence of two co-existing conformers with different orientations of the A/B and C/D pyrromethenone moieties with respect to each other (24). It seems likely that the *EZ/ZE* photoisomers can also co-exist in two orientations. Since these photoisomers have less intramolecular H-bonding than bilirubin they are more polar and should have characteristics similar to the bilirubin dimethyl ester so that the relative proportions are likely to be solvent dependent. Thus, while little solvatochromism is expected for bilirubin IX-α in weakly H-bonding solvents, it may well be significant in the case of the *EZ/ZE* photoisomers.

(C) Photolysis in dimethyl sulfoxide

A more dramatic effect on the photoisomerization due to environment can be seen when DMSO is used as solvent rather than $CHCl_3$ (Fig. 3). Similar results were obtained for both DMSO and $CHCl_3/Et_3N$. Comparison with Fig. 1 indicates a difference in shape on the short wavelength side of the loss peak. Specifically, the shoulder at ca. 430 nm seen previously for long irradiation times with $CHCl_3$ is now more distinct such that the loss peak is double humped. Furthermore, the two isosbestic points do not appear simultaneously. The isosbestic point at ca. 490 nm occurs only at short irradiation times (<7 min), while the isosbestic point at 380 nm develops only after longer irradiation times (>7 min).

These data are consistent with the two-step process presented above. The spectra for short times of irradiation indicate that production of *EZ/ZE* isomers predominates (one isosbestic point). An induction period is now evident which could not be seen when bilirubin was irradiated in $CHCl_3$. Since an initial buildup of *EZ/ZE* isomers is required before lumirubins are formed, it is now apparent that the latter results by a reaction of the former. As the time of irradiation is increased, the isosbestic

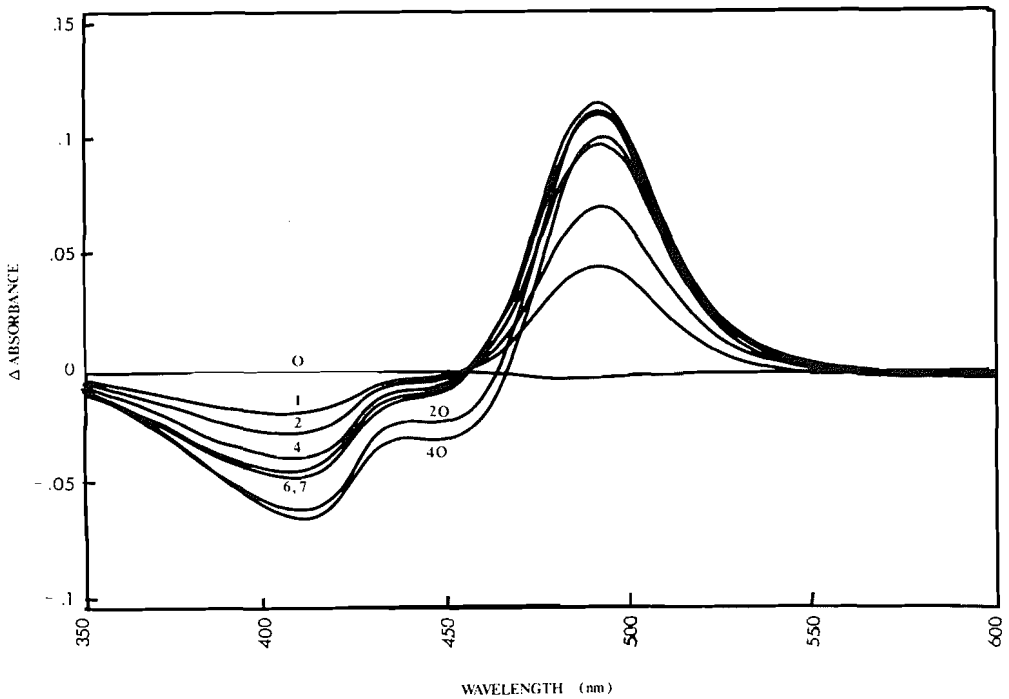

FIG. 5. Absorbance difference spectra for an aqueous buffer solution of bilirubin and human serum albumin for various irradiation times. (The numbers refer to the irradiation times, in minutes.)

point is no longer maintained, indicating that *EZ/ZE* isomers have reached an equilibrium concentration, but another isosbestic point appears at shorter wavelength, indicating that the lumirubins continue to be formed. The increased distortion of the loss peak at 430 nm for DMSO as compared to that with $CHCl_3$ is probably due to an increased concentration of this photoproduct relative to that of *EZ/ZE* isomers. Ostrow and co-workers have shown that in DMSO lumirubins can be produced in sufficient quantities to be isolated (10).

The development of a double-humped loss peak on irradiation of aqueous solutions of bilirubin containing human serum albumin (HSA) has also been attributed, by Davies and Keohane (25), to the presence of a second synthesis peak. To verify that the double-humped loss peaks in the AD spectra result from a superimposed gain peak, experiments were made using HPLC methods described previously by McCarthy *et al.* (18). Chromatograms of the DMSO solution of bilirubin after irradiation confirmed the presence of more than one photoproduct. In fact, McDonagh *et al.* (22), have also reported that irradiation of bilirubin in a $CHCl_3/Et_3N$ system results in a second photoproduct that absorbs at 434 nm. This is consistent with the hypothesis that lumirubins can be formed in solvents which interfere strongly with the intramolecular hydrogen bonding of the bilirubin.

Thus, the mechanism for the formation of photoproducts in DMSO is similar to that in $CHCl_3$ but appears to differ only in the relative quantum yields for the formation of the various photoproducts. It seems that solvents like DMSO and Et_3N permit the *EZ/ZE* isomers to attain certain orientations which favour this internal cyclization. Similar behaviour is seen during photolysis of bilirubin in aqueous solutions containing HSA. As will be shown later, the photoisomers of bilirubin are detected in aqueous solution only when HSA is added. The formation of lumirubins from *EZ/ZE* isomers is consistent with the mechanism proposed previously by Onishi *et al.* (11), rather than that of McDonagh *et al.* (22), who propose that the cyclization process takes place directly from the bilirubin, and not from *EZ/ZE* isomers.

(D) Photolysis in dimethyl sulfoxide/water

To obtain a better understanding of the effect of changes in the polarity a solution of bilirubin in DMSO/buffer (90:10) was irradiated. The AD spectra obtained during the first 5 min of irradiation are analogous to those for the $CHCl_3$ system in that there is only one loss peak with two isosbestic points (Fig. 4). As for photolysis in $CHCl_3$, with increasing time the isosbestic point at 490 nm disappears. Simultaneously, a shoulder begins to form on the loss peak, indicating that the production of *EZ/ZE* isomers has reached a photostationary state but lumirubins are still being formed.

Thus, the relative importance of the different pathways for bilirubin photoisomerization, photodegradation, and photooxidation is highly dependent upon the environment of the bilirubin molecule. The AD spectra resulting from irradiation of bilirubin in DMSO are considerably different from those for bilirubin in $CHCl_3$. Yet, if 10% aqueous phase is added to the DMSO, the spectra become very similar. The addition of water to DMSO causes the bilirubin molecule to adopt a tightly closed, hydrophobic structure, similar to that in $CHCl_3$, and not the more open structure thought to be present in DMSO. The resulting photoprocess in DMSO/buffer becomes more similar to that in the $CHCl_3$/EtOH system rather than that in pure DMSO. In fact, not only are the shapes of the AD spectra very similar, but the absorbance difference is 0.011 in the $CHCl_3$/EtOH system and 0.010 in the DMSO/H_2O.

(E) Photolysis of aqueous solutions containing albumin

The dramatic changes resulting from the addition of water to DMSO suggested that photolysis of bilirubin in aqueous medium should differ considerably from photolysis in organic solvents. Indeed, as reported previously (26), attempts to identify

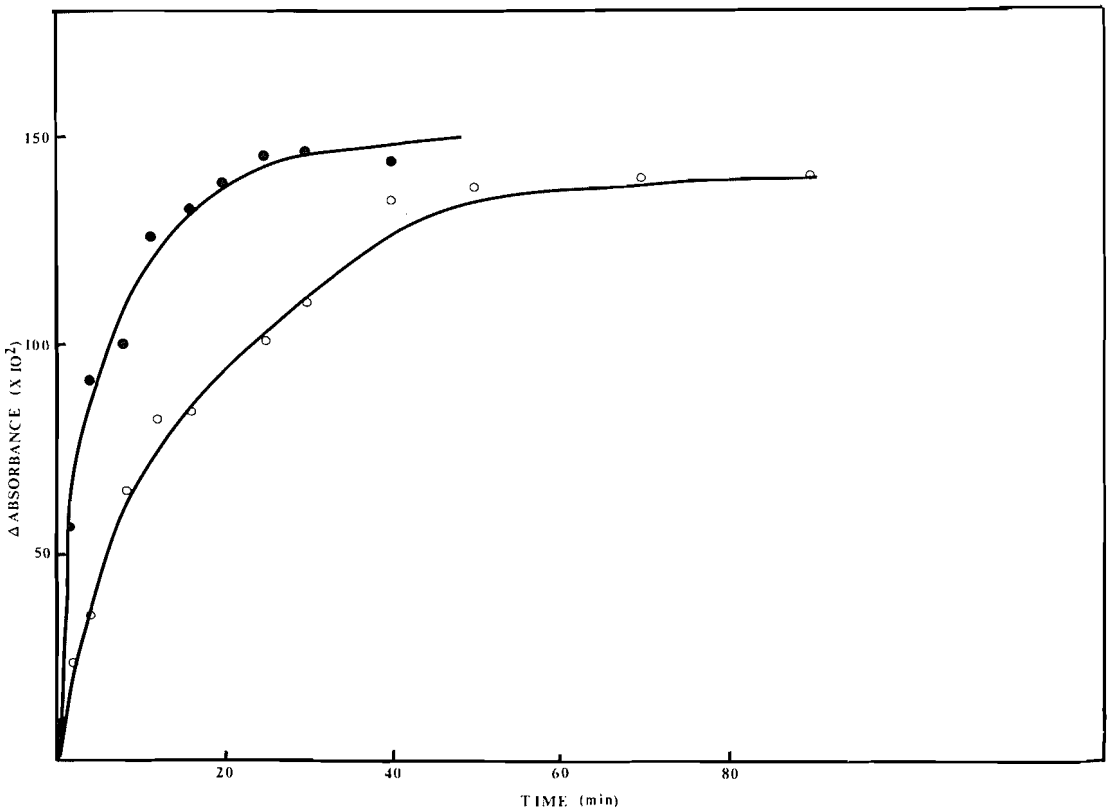

FIG. 6. The absolute values of the absorbance difference of the gain peak (490 nm) for a photolyzed aqueous buffer solution of bilirubin and human serum albumin at different light intensities: ●, high intensity; ○, low intensity.

photoproducts after irradiation of bilirubin in aqueous phosphate buffer were unsuccessful. However, photoproduct formation is readily apparent after the irradiation of the aqueous bilirubin solution containing a small amount of HSA.

When a solution of bilirubin containing HSA with a molar albumin concentration seven times that of the bilirubin is irradiated, the resulting AD spectra (Fig. 5) show three peaks: two loss peaks at 408 and 448 nm, and one large gain peak at 492 nm. In contrast, replacement of HSA with BSA results in one gain peak at ca. 508 nm and a corresponding loss peak at ca. 460 nm (20). These AD spectra show characteristics similar to those for irradiated DMSO solutions of bilirubin. That is, at short irradiation times there is only one isosbestic point, at 460 nm, indicating that initially there is only one product being formed, *EZ/ZE* isomers. As the time of irradiation is increased, this isosbestic point disappears, indicating a disruption in the equilibrium, BR ⇆ *EZ/ZE* isomers, while a second isosbestic point (360 nm) appears, indicating that a second product is now being formed. Thus, the mechanism for photoproduct formation in HSA appears to be the same as in DMSO.

When the height of the gain peak (492 nm) is plotted as a function of the time of irradiation in the presence of HSA a sharp increase is seen initially, followed by the appearance of a photostationary state (Fig. 6). Similar behaviour is seen, but with an increase in initial slope by a factor of 3, so that the photostationary state is reached more rapidly when the intensity of the irradiating light is increased approximately threefold. Thus, a direct relationship is seen between the intensity of the irradiating light and the initial rate of formation of photoproduct. The occurrence of a photostationary state indicates that the formation of *EZ/ZE* isomers from bilirubin is reversible. Furthermore, since the AD spectrum of irradiated bilirubin remains unchanged when it is left in the dark, the reverse process must also be light induced, as proposed by McDonagh and Palma (22).

As mentioned above, it has been suggested previously that the double loss peak is in fact due to the development of a synthesis peak (25). Further evidence is obtained from a plot of peak height after irradiating for 7.0 min, as a function of log {[HSA]/[BR]}, at a fixed bilirubin concentration of $1.71 \times 10^{-5} M$ (Fig. 7). The loss peak at 408 nm behaves identically with the gain peak at 492 nm, while the loss peak at 448 nm behaves differently. (The values have been corrected for the absorbance by HSA at the illuminating wavelength.) The magnitude of the loss peak at 448 nm is, within experimental error, independent of [HSA]/[BR] whereas the other two peaks go through a maximum at a ratio of ca. 1.5/1.0 and then decrease to a plateau. The limit appears to be related to the binding of the bilirubin and/or its photoproducts to the HSA. As the HSA concentration increases, more photoproduct is produced until a [HSA]/[BR] of 1.5 is reached. At higher concentrations of HSA, the amount of photoproduct decreases, perhaps because the binding of bilirubin decreases due to protein aggregation. Such a decrease in binding affinity at high concentrations of HSA has been reported previously (27). When both HSA and bilirubin concentrations are decreased by a factor of 10 a plateau without a "hump" occurs.

The apparent requirement of albumin in aqueous solution of bilirubin to bring about the production of photobilirubin suggests that: (*a*) photoisomerization requires that the albumin bind the bilirubin to facilitate the isomerization, or (*b*) unbound bilirubin can undergo photoisomerization but rapid reversion occurs in the absence of albumin. If the latter were true it should be possible to "trap" photoproducts formed by the

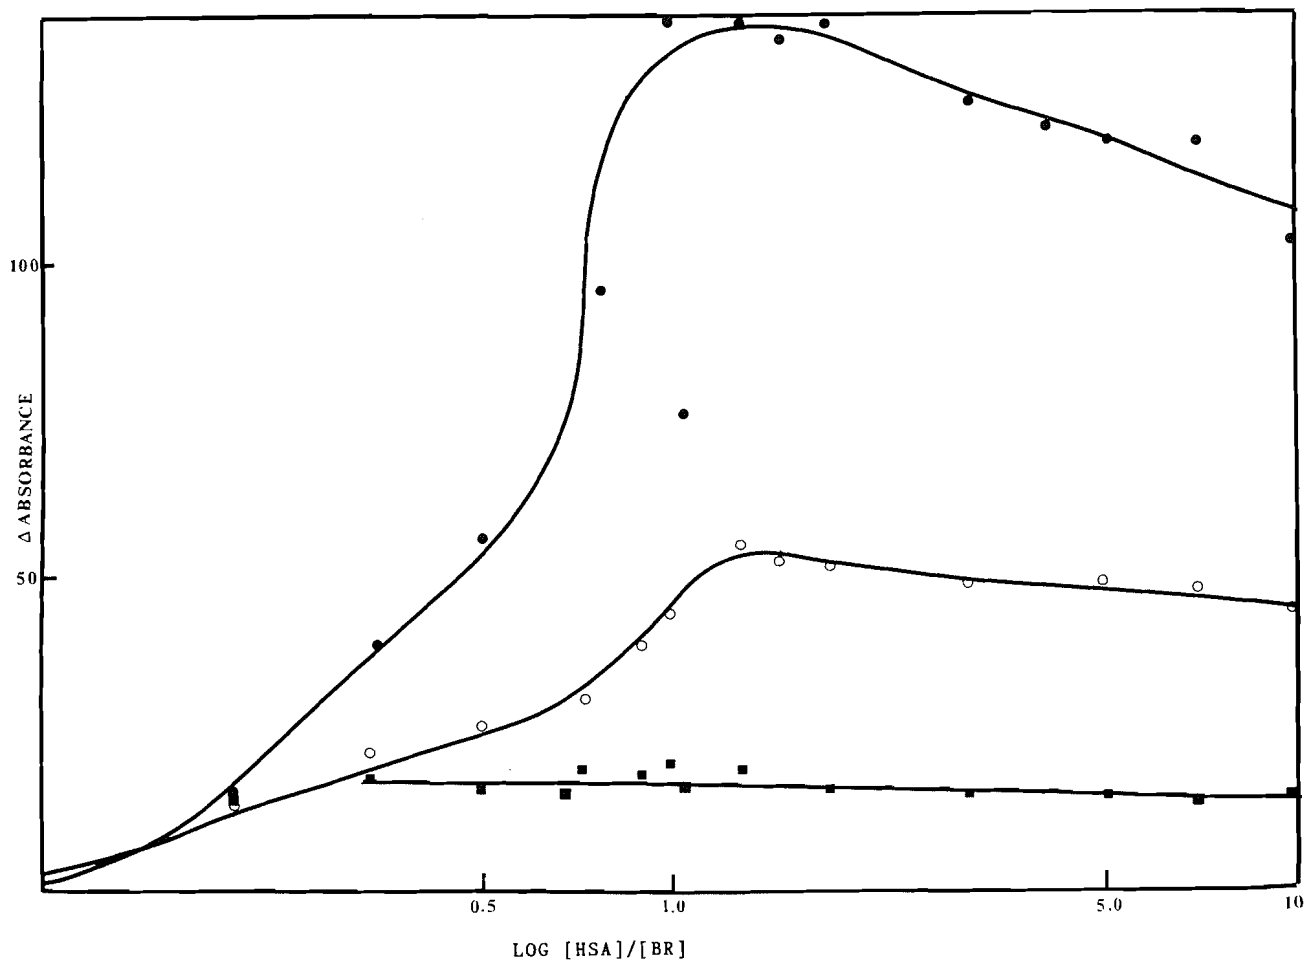

FIG. 7. The absolute values of the absorbance difference, multiplied by 100, of the gain peak (490 nm) and the two loss peaks (448 nm and 408 nm) for a photolyzed aqueous buffer solution of bilirubin and human serum albumin as a function of the log [HSA]/[BR], at 7 min of irradiation: ●, 492 nm; ○, 408 nm; ■, 448 nm.

irradiation of an aqueous solution of bilirubin by adding albumin to bind the photoproducts immediately after irradiation. This was done using the method of stopped flow analysis. The bilirubin buffer solution was irradiated for a given period of time, mixed with a solution of HSA (total mixing time of 20 ms) and the absorbance at the desired wavelength was recorded immediately. A small amount of photoproduct was formed, as evidenced by an increase in absorbance at 490 nm, that increases with time of irradiation (Fig. 8). As expected a concomitant decrease in absorbance was noted at 410 nm while, within experimental error, there was no change in absorbance at 460 nm, which corresponds to an isosbestic point in the AD spectrum of an irradiated solution of bilirubin/HSA. In contrast, no photoproduct formation was detected in an analogous experiment when an irradiated aqueous solution of bilirubin was mixed with buffer, indicating that the presence of HSA is indeed necessary to protect the photoproduct. By comparison, there was approximately a threefold increase in photoproduct formation when the irradiated solution contained both HSA and bilirubin. Thus, it would appear that it is possible for bilirubin to isomerize to form the *EZ*/*ZE* isomers in aqueous solution, but that under these conditions the reversion is too fast to permit their detection. However, when albumin is added to the solution immediately following the irradiation, the *EZ*/*ZE* isomers are bound to the albumin and do not revert to bilirubin.

The fact that more photoproduct is formed when the albumin is present during the irradiation than when it is added just after the irradiation follows from Fig. 7 which shows an increase in photoproduct formation with increasing [HSA]/[BR]. Below the [HSA]/[BR] ratio of 1/1 there is relatively little photoproduct formed. Since the first molecule of bilirubin binds strongly to HSA, with a binding constant of 10^6–10^7 (28), the fraction of free bilirubin is very small at the ratio of [HSA]/[BR] of 1/1, suggesting that it is the irradiation of bound bilirubin that gives rise to the increased formation of photoproducts. Lee and Gillispie (29) have shown that the bilirubin molecule is buried deeply within the HSA. Consequently the HSA can provide a protective environment where the photoproduct is more readily formed. It has been suggested (28) that the HSA molecule maintains the bilirubin in an environment that changes the energies of the transition states leading to the formation of photoproduct. The idea that bilirubin is protected by albumin is also discussed by Rubaltelli and Jori (30).

Summary

It is apparent that the photolysis of bilirubin is a very complex process, involving various photoisomerizations, photodestruction, and photooxidation. Although photoisomerization reactions predominate at short irradiation times under anaerobic conditions, the relative yields of isomers is highly depen-

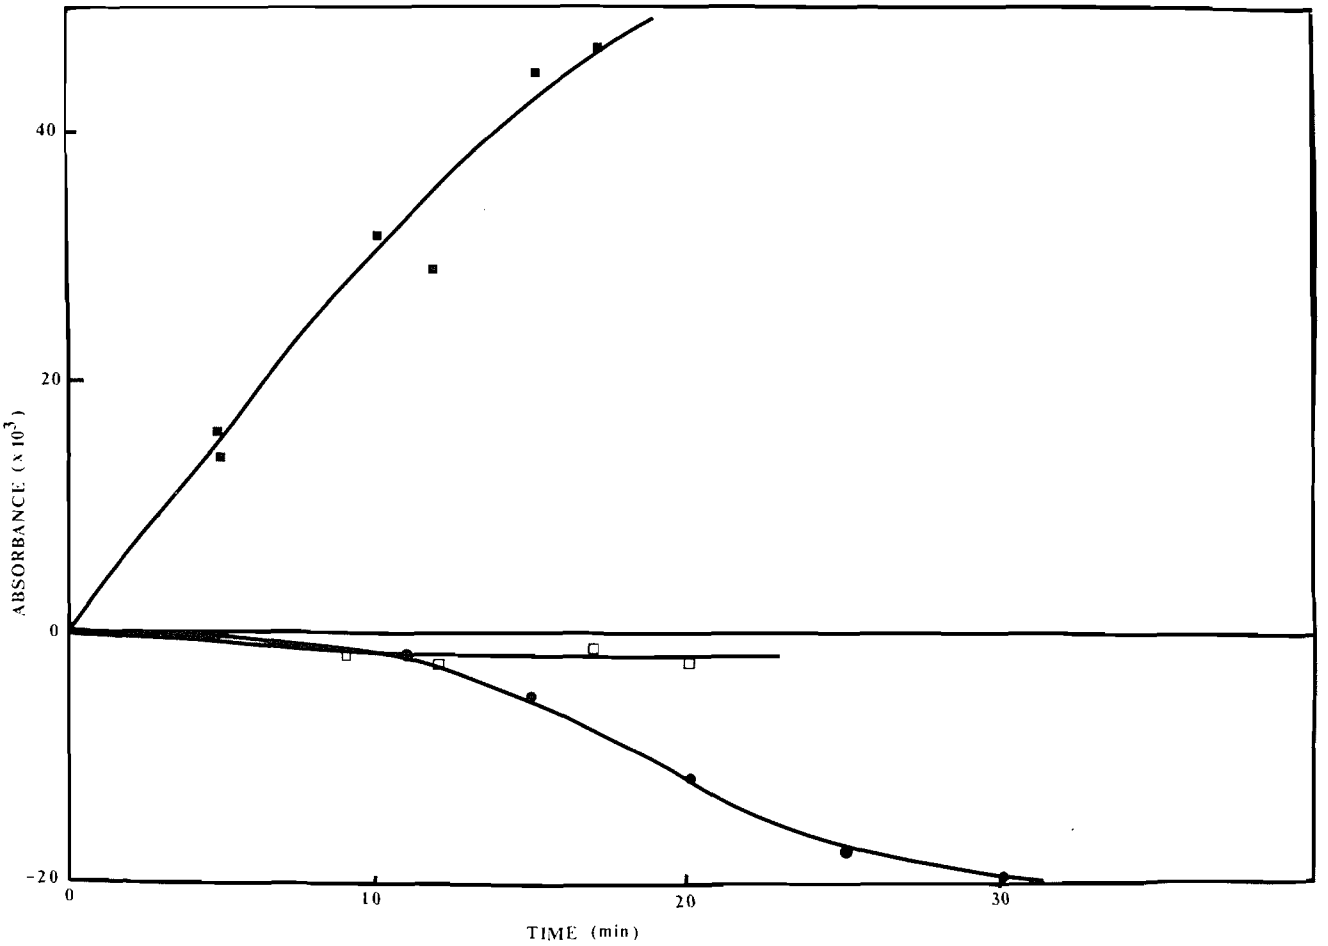

FIG. 8. The absolute values of the absorbance difference at three separate wavelengths (490 nm, 460 nm, and 410 nm) as a function of the irradiation time for a photolyzed aqueous solution of bilirubin after mixing with human serum albumin: ■, 490 nm; □, 460 nm; ●, 410 nm.

dent on the environment of the bilirubin at the time of irradiation. In solvents which interfere weakly with the intramolecular hydrogen bonds of bilirubin, solvents like water or ethanol, formation of lumirubins from *EZ/ZE* isomers is less than in stronger interfering solvents like DMSO and Et_3N. Although small amounts of photoisomers can be "trapped" in irradiated aqueous buffer solutions of bilirubin, substantially greater amounts are formed in the presence of HSA. Indeed, photoisomer production in the presence of HSA is similar to that in DMSO solutions.

A study of chiral induction in some diene additions catalyzed by chiral alkoxyaluminum dichlorides

COLLEEN J. NORTHCOTT AND ZDENEK VALENTA

Department of Chemistry, University of New Brunswick, Bag Service No. 45222, Fredericton, N.B., Canada E3B 6E2

Received November 4, 1986

This paper is dedicated to Professor John T. Edward

COLLEEN J. NORTHCOTT and ZDENEK VALENTA. Can. J. Chem. **65**, 1917 (1987)

A reliable procedure for the preparation of the chiral Lewis acid catalysts, (−)-menthoxy- ((−)-**1**) and (−)-bornyloxy-aluminum dichloride ((−)-**2**), has been established for the study of diene additions. The geometry of conformationally mobile α,β-unsaturated carbonyl compounds complexed with these catalysts has been probed using the α-methylene ketones **3** and **4** and 2,6-dimethyl-1,4-benzoquinone **5** as dienophiles of fixed geometry. The addition of the first two to cyclopentadiene and (−)-**1** yields *exo* and *endo* adducts that exhibit a range of 28–54% enantiomeric excess (ee); with **5**, only the *endo* isomer, showing 8% ee, is formed. In the corresponding additions catalyzed by (−)-**2**, adducts displaying ee in the range of 3–18% are formed.

COLLEEN J. NORTHCOTT et ZDENEK VALENTA. Can. J. Chem. **65**, 1917 (1987).

Dans le but d'étudier les additions des diènes, on a mis au point une méthode sûre de préparer les catalyseurs chiraux d'acides de Lewis, dichlorures de (−)-menthoxy- ((−)-**1**) et de (−)-bornyloxy-aluminium ((−)-**2**). Utilisant les α-méthylènes cétones **3** et **4** et la diméthyl-2,6 benzoquinone-1,4 (**5**) comme dièenophiles de géométrie définie, on a examiné la géométrie des composés carbonylés α,β-insaturés et conformationnellement mobiles lorsqu'ils sont complexés avec ces catalyseurs. L'addition des deux premiers au cyclopentadiène et au composé (−)-**1** conduit à des adduits *exo* et *endo* dans lesquels on note un excès énantiomérique (ee) allant de 28 à 54%; avec le composé **5**, il ne se forme que de l'isomère *endo* présentant 8% d'ee. Dans les additions correspondantes catalysées par le produit (−)-**2**, les adduits qui se forment présentent des ee qui vont de 3 à 18%.

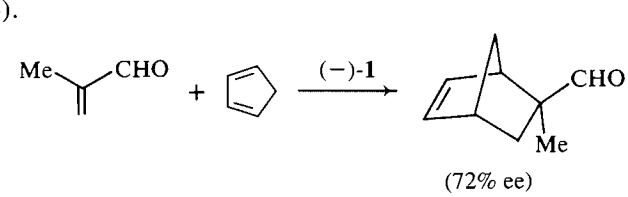
The Diels–Alder reaction has recently been the subject of many studies aimed at the achievement of high chiral induction (1), not only due to its synthetic usefulness, but also to its well-defined steric features (2). Despite the extensive work carried out on this key cycloaddition with chiral dienophiles (3), chiral dienes (4), and chiral-directing units in the connecting chain of intramolecular systems (5), the search continues for a more general means of inducing asymmetry.

In this regard, the combination of an achiral diene and dienophile with a chiral Lewis acid catalyst is particularly attractive. Independent of the question whether the transition state is "tighter" in catalyzed additions (6), a complexation of the chiral Lewis acid with one of the reaction components would yield an asymmetric reagent with a potential for guiding a selective approach of the remaining component. Also, in addition to the other established advantages of catalysis in the Diels–Alder reaction (7), the use of chiral Lewis acids would be experimentally more convenient, since the necessity for the introduction of a chiral unit into the addend(s) and the subsequent removal from the adduct would be eliminated.

Three important studies have been conducted to probe the feasibility of this combination. Danishefsky and co-workers (8) reported an enantiomeric excess (ee) of 15–58% in the products of additions of various siloxydienes to benzaldehyde in the presence of the chiral lanthanide Eu(hfc)$_3$. Kelly *et al.* (9) obtained a remarkable ee (>98%) in diene additions to juglone (8-hydroxy-1,4-naphthoquinone), which had been made highly chiral by a bidentate attachment of a chiral borate. While this very elegant work with juglone (9) shows that high induction is achievable in diene additions to olefin bonds *provided that a suitably bulky chiral catalyst is essentially fixed in a rigid conformation*, the pioneering work using a chiral lanthanide (8) indicates that, in diene additions to a carbonyl group acting as dienophile, moderate chiral induction can be achieved without a rigidly held catalyst.

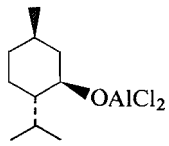
This leaves an important question. Is synthetically useful chiral induction achievable in a general case in which neither of the two addends possesses functionality that could provide additional binding to the chiral catalyst and in which the diene is adding to the olefin part of an α,β-unsaturated system? Normally, the Lewis acid catalyst binds to the carbonyl group of the dienophile; in a general case, it can therefore be expected to be further away from the site of bond formation in additions to the olefin bond, rather than the carbonyl group, of the dienophile. Based on the range of ee obtained in additions to the carbonyl group (8), the prospects for high chiral induction in additions to the olefin bond using a conformationally mobile chiral Lewis acid are thus not encouraging.

The work of Koga and co-workers (10) provides useful information and a system for a further study of this question. An encouraging ee of 72% was obtained in the major *exo* adduct from the addition of cyclopentadiene to methacrolein in the presence of (−)-menthoxyaluminum dichloride ((−)-**1**) (Fig. 1). In contrast, the reported selectivity in *exo* Diels–Alder adducts obtained from (nonchiral Lewis acid) catalyzed additions to chiral acrylates is in the range of only 3–45% ee (3). Furthermore, it was noted (10) that the reaction of methyl acrylate and cyclopentadiene, mediated by chiral catalysts (−)-**1** and (+)-**2**, yielded the *endo* adduct in low optical purity (6–9% ee); this is in dramatic contrast to the high chiral induction displayed in the *endo* adducts of (nonchiral Lewis acid) catalyzed additions of chiral acrylates to cyclopentadiene (3).

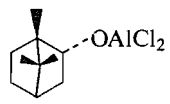


(72% ee)

FIG. 1.



(−)-**1**



(−)-**2**

These intriguing findings prompted the present investigation into the scope of chiral Lewis acid mediated Diels–Alder reactions. In addition to indicating the chiral induction achievable with conformationally mobile catalysts as discussed above, it was hoped that the study could define at least some aspects of the geometry of the reacting species at the transition state of the Diels–Alder reaction. In the case of conformationally unrestrained α,β-unsaturated carbonyl dienophiles, for example, the *s-trans* and *s-cis* conformations can exist in equilibrium (Fig. 2).[1] Furthermore, catalysts such as **1** and **2** can then bind to one of the two lone pair orbitals of the carbonyl oxygen; this leads to four possible geometries for the reacting complexed dienophile (catalyst attachments a or b in Fig. 2),[1] with further ambiguity arising from possible rotation around the two Al—O bonds and around the O–terpene bond (Fig. 2).

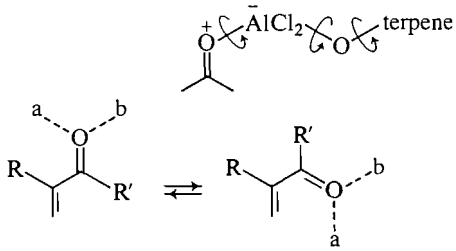


FIG. 2.

An examination of the methacrolein addition (Fig. 1) (10) in this light shows that, in any reasonable conformation of the complexed *s-trans* dienophile (e.g., that shown in Fig. 3), the

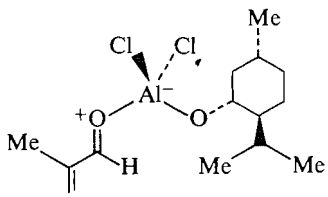

FIG. 3.

chiral moiety is probably located at too great a distance to effect any significant induction. In the case of the *s-cis* conformation of the dienophile, on the other hand, a geometry such as that depicted in Fig. 4 can be visualized in which the isopropyl group of the chiral monoterpene shields one face of the dienophile, and which correctly predicts the observed chirality of the cyclopentadiene adduct (Fig. 1). The *s-cis* conformation of (the reacting complexed) methacrolein is not unreasonable in view of the presence of the α-methyl group (see Discussion and conclusions). Although the attachment of the catalyst to the carbonyl group indicated in Fig. 4 appears sterically unfavorable, it should be noted that a stabilizing electronic interaction between the terpene O-atom and the double bond is possible in this conformation. Furthermore, the geometry of the remaining lone pair orbital of the carbonyl oxygen may well be favored stereoelectronically (11).

[1]For an important recent theoretical study of this equilibrium and many references, see ref. 15.

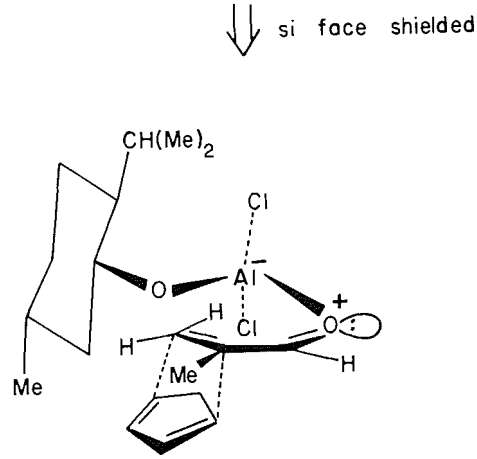

FIG. 4

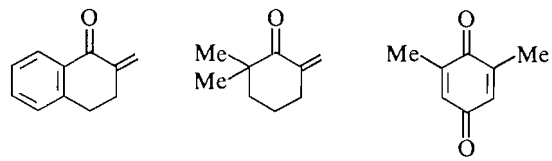
To test the hypothesis that the *s-cis* conformation of the complexed dienophile is the effective one[2] and to determine whether high chiral induction could be obtained in the more frequently observed *endo* additions, the cyclic cisoid α-methylene carbonyl dienophiles **3** and **4** and the cyclic transoid unsaturated carbonyl compound **5** have been chosen for Diels–Alder reactions with cyclopentadiene in the presence of the chiral alkoxyaluminum dichloride catalysts (−)-**1** and (−)-**2**.

The α-methylene tetralone **3** is not ideal as a model, since the chiral alkoxyaluminum dichlorides can be expected to complex with either of the two lone pair orbitals of the carbonyl oxygen (11), thus placing the chiral moiety in at least one unfavorable (distant) orientation (Fig. 5, formula b). In contrast, the steric hindrance exerted by the methyl groups of **4** should favour complexation with the chiral Lewis acid on the side of the double bond, making it a simpler model (Fig. 6). Finally, the benzoquinone **5** was tested as a check for the



3 **4** **5**

assumption that an *s-trans* conformation of the complexed dienophile is less effective for chiral induction.

The chiral analyst

The combination of chiral monoterpene alcohols with alkylaluminum halides,[3] resulting in alkoxyaluminum dihalides, first reported by Furukawa and co-workers (14), appeared to be a suitable catalytic system (10) for the study. However, when the compounds (−)-**1** and (−)-**2**, formed by the addition of (−)-menthol and (−)-borneol, respectively, to ethylaluminum dichloride, were isolated in our laboratory according to the cited procedure (14), crystalline catalysts giving little or no induction in the addition of methacrolein to cyclopentadiene were obtained.

To prevent a possible hydrolysis of the catalyst, a series of

[2]The concept of a cisoid geometry of the reactive α,β-unsaturated carbonyl dienophile has been proposed to explain results of other asymmetric induction studies (3*a*, 12).

[3]The use of alkylaluminum halides as Lewis acid catalysts has become widespread due to their availability, range of acidity and nucleophilicity of the alkyl group, and mildness (13).

X = (−)-menthyl or (−)-bornyl

FIG. 5.

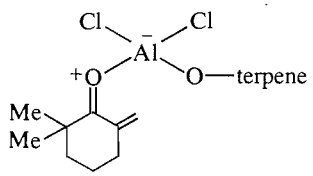

FIG. 6.

in situ preparations of (−)-**1** was run at various temperatures and times. Each of these catalyst solutions was tested in a methacrolein–cyclopentadiene reaction (see Experimental); however, a maximum of only 44% ee (compared to the reported 72% ee) was achieved. Furthermore, the inferiority of all catalysts prepared at temperatures above −15°C, for periods of time longer than 24 h or with fewer recrystallizations than the optimized procedure, suggested that a disproportionation of the catalyst occurs to an equilibrium mixture containing aluminum chloride.

A procedure was finally developed, which included repeated recrystallization of the catalyst from toluene at −78°C under anhydrous conditions and which provided a catalyst of reasonably consistent quality as determined in the methacrolein "test" reaction (Fig. 1).

Results

The relationship between chiral induction and the conformation of the complexed dienophile at the transition state was then investigated by means of the model dienophiles **3**, **4**, and **5**. The additions of these dienophiles to cyclopentadiene catalyzed by (−)-**1** and (−)-**2** were performed in anhydrous toluene at −78°C (Table 1). Chromatographic purification of each of the product mixtures yielded *exo* and *endo* adducts whose geometry was assigned on the basis of ^{1}H nmr spectra and whose optical purity was determined by chiral shift reagent [Eu(hfc)$_3$] ^{1}H nmr analysis. For correlative purposes, the racemic products for each case were obtained from additions catalyzed by boron trifluoride etherate. In addition, a concurrent thermal reaction was run at the low temperature to confirm that no addition took place without the catalyst. A range in quality of the catalysts was observed, even with the optimized preparation, so that the methacrolein–cyclopentadiene addition was also carried out along with every reaction under study (Table 1, last column).

Discussion and conclusions

The results of the investigation are summarized in Table 1. It can be seen that the observed chiral induction using catalyst (−)-**1** and cisoid models **3** and **4** is moderately high in the *exo* and *endo* adducts (entries 2 and 5; 28–54% ee range), and that the value observed with the transoid model **5** is significantly lower (8% ee). The fact that higher ee's have not been obtained indicates the limitations of restricting only the mobility of the dienophile in such systems.

Of particular note is the relatively high induction observed in the *exo* adduct of **4** and cyclopentadiene (entry 5). The catalyst almost certainly is complexed with the carbonyl oxygen orbital projected away from the two methyl groups (Fig. 6), placing the chiral terpene moiety closer to the site of bond formation. The induction obtained in the *exo* adduct, a (normalized) value of 60% ee, corresponds well to the 72% ee observed in the *exo* adduct of methacrolein. This similarity substantiates our proposal of an *s-cis* conformation in the reactive complex of (−)-**1** and methacrolein[4] (Fig. 4).

Furthermore, the benzoquinone **5**, which models the *s-trans* dienophile conformation (Fig. 3), exhibits low chiral induction; this implies that the monoterpene is too distant to effectively shield the olefin in this conformation.

A comparison of chiral inductions achieved with catalyst (−)-**1** and the two cisoid dienophiles in the *exo* and *endo* regions, respectively, shows that the observed ee is significantly higher in the *endo* adduct in the case of **3** (*endo:exo* = 54:38), while the opposite is true for dienophile **4** (*endo:exo* = 28:48)! *A priori*, a higher induction may well have been expected for both the *endo* and the *exo* adduct of **4** (as compared to those of **3**) because of the postulated more favorable attachment of the catalyst to dienophile **4** (compare Figs. 5 and 6). Clearly, other factors come into play; for example, the conformation of the O—Al—O–terpene moiety (see Fig. 2) is no doubt different in the various additions, as influenced by the structure of the dienophile and by different steric influences exerted by the diene in the *exo* and *endo* regions, respectively, during addition. Complicated as this situation may be, the results show that a reasonably useful chiral induction can be achieved in the more commonly encountered *endo* additions, *provided that the olefin bond and the carbonyl group of the dienophile are in the* cis *conformation.*[5]

Houk and co-workers calculated a slight preference for the *s-trans* form of protonated acrolein (0.2 and 1.8 kcal/mol) and a bigger preference for the *s-trans* form of lithium-complexed acrolein (1.9 and 3.2 kcal/mol) (15). If it can be assumed that the H^+ and Li^+ models are reasonable analogies for such carbonyl complexes as those formed with **1** and **2**, their conclusions are in agreement with the experimental results of Koga and co-workers (10) who, as stated above, found very low ee values in the reaction of acrolein and catalysts **1** or **2** with cyclopentadiene in the *endo* region. The carbonyl group points "away" from the cyclopentadiene and the chiral catalysts are thus too far to cause significant induction (see Fig. 3). Our results with quinone **5** (Table 1, entries 7 and 8) complete this consistent picture.

We believe, however, that the results with dienophiles **3** and **4** strongly suggest that complexed methacrolein reacts in the *s-cis* conformation, at least when adding to cyclopentadiene in the *exo* region (10). The calculated energy differences between the *s-cis* and *s-trans* forms of protonated and Li^+-complexed acrolein are sufficiently small (15) to allow a preference for the *s-cis* form when a methyl group is placed in the α position.

[4]The low chemical yield obtained with model **4** is unfortunate, due to polymerization of **4**, but irrelevant to the argument.

[5]It should be remembered, however, that all the above conclusions are strictly relevant to cyclopentadiene only. Useful chiral inductions may well be achievable with transoid dienophiles in additions to dienes that contain the necessary stereo-differentiating features in the appropriate region of space (for example, 1-vinylcyclohexene and larger).

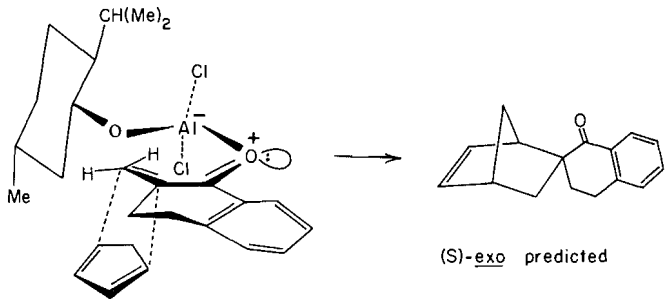

FIG. 7

Clearly, this postulate should be further tested, both by experimental and by computational methods.

Although not included in the table, the reaction of α-methylene γ-butyrolactone with (−)-**1** and cyclopentadiene was carried out in this study as a probe for understanding induction in acrylate additions. *Exo* and *endo* adducts were obtained in a 57:1 ratio. The low yields of the *endo* adduct and the inability to obtain diastereomeric signals for any proton resonance in the ^{1}H nmr analysis made quantification of the induction impossible in this case; for the *exo* product, however, 30% ee was observed. This induction is significantly higher than that observed with methyl acrylate and chiral catalysts (−)-**1** and (+)-**2** (6–9% ee) (10). The ring in α-methylene γ-butyrolactone ensures the *E*-ester–*s-cis* dienophile conformation for this model; this comparison then suggests that a conformation similar to that of α-methylene γ-butyrolactone does not play a significant role in catalyzed additions of the conformationally mobile methyl acrylate.

The Diels–Alder adducts in this study are not easily degraded into compounds of known absolute configuration, nor readily correlated to known configurations; the lack of this information does not detract from the conclusions drawn from this study concerning the magnitude of induction. Furthermore, one can speculate on the probable absolute configurations based on correlation with the defined course of the methacrolein addition as described above (Fig. 4). For example, the *exo* adduct of dienophile **3** and cyclopentadiene formed in a reaction catalyzed by (−)-**1** (Table 1, entry 2) is predicted to have the (*S*) configuration as shown in Fig. 7.

Several comments can be made about the general usefulness of chiral alkoxyaluminum dichlorides for chiral induction. Experimentation with temperatures above −78°C or with an alternate solvent such as methylene chloride, while increasing reaction rate, gave adducts with little or no chiral induction. From our experience, the chiral inducing ability of the catalyst is highly dependent upon the experimental technique in its preparation. The nature of the catalytic species in solution (whether monomeric, polymeric, or a combination) is unknown; increasing the amount of catalyst from 0.4 equivalent to 2 equivalents did not increase ee in the adducts, although amounts lower than 0.4 equivalent gave lower induction. This suggests a possibility of different percentages of the most effective chiral-inducing species with each preparation—a distinct disadvantage of these catalysts.

(−)-**2** exhibited substantially less chiral induction relative to (−)-**1** in all cases. As has been demonstrated in numerous studies with chiral acrylates (3), the diastereo-differentiating moiety may be modified to improve shielding of one face of the reacting species; however, our findings indicate that, despite a possible electronic interaction between the catalyst's oxygen and the dienophile olefin, very high induction is unlikely due to the mobile oxygen–monoterpene bond.

Experimental

The ^{1}H nmr spectra were recorded in $CDCl_3$ on a Varian T60 or Varian XL-200 spectrometer. Anhydrous Eu(hfc)$_3$ (Aldrich) was used in the ^{1}H nmr shift studies. The ir spectra of samples in $CHCl_3$ were obtained on a Perkin–Elmer 727B spectrophotometer with 0.5-mm NaCl cells. Low resolution electron impact (70 eV) mass spectra were recorded with a Hitachi Perkin–Elmer RMU-6D spectrometer. The gas chromatography was carried out on a Varian 6000 capillary gc with flame ionization detector, helium as the carrier gas, and both injection port and detector temperatures at 240°C. A Waters Associates 6000A high pressure liquid chromatograph in combination with a 440 uv absorbance detector at λ_{max} 254 nm and a refractive index detector was employed for analyses by hplc.

Optical rotations of samples in $CHCl_3$ were measured in either 5-mL or 1-mL glass cells at ambient temperature with a Perkin–Elmer 241 polarimeter at λ_{max} 589 nm.

Column chromatography was performed on silica gel (Kieselgel 60G, E. Merck) and preparative thin-layer chromatography was carried out on 0.25-mm silica gel 60F-254 plates (BDH) or on Kieselgel

60F-254 plates (E. Merck) of thickness 0.5 mm or 1 mm. Hexane and ethyl acetate were distilled before use in the chromatography.

(−)-Menthol was distilled from sodium at 0.2 Torr (1 Torr = 133.3 Pa) to 99% optical purity and (−)-borneol was sublimed (at 0.2 Torr) to 98% optical purity. Ethylaluminum dichloride (Alfa) was handled as a 25% w/w solution in hexane under argon. All solvents were freshly distilled under an argon atmosphere: toluene and benzene were dried over sodium, heptane over calcium hydride, and tetrahydrofuran with lithium aluminum hydride. Methacrolein and boron trifluoride etherate were distilled before use. Cyclopentadiene was obtained by cracking dicyclopentadiene at 170°C prior to reaction.

Melting points were determined with a Gallenkamp capillary tube apparatus and are uncorrected.

Preparation of (−)-menthoxyaluminum dichloride (−)-1

The procedure given by Furukawa and co-workers (14) was modified as follows.

A flame-dried 100-mL three-neck flask was equipped with a dropping funnel, a rubber septum, a magnetic stirrer, a gas inlet, and a bubbler. The 25% ethylaluminum dichloride solution in hexane (38.3 g, 0.0754 mol) was added via syringe under a slow flow of argon. This was cooled to −78°C and a solution of (−)-menthol (12.0 g, 0.0768 mol) in dry heptane (18 mL) was added dropwise over 25 min. A white precipitate formed. The mixture was carefully allowed to reach 20°C; during this time, a clear solution resulted and ethane was vigorously evolved. After 15 min at 20°C, a white solid formed and was allowed to settle over 15 min. The supernatant liquid (30 mL) was decanted via syringe under positive argon pressure. The remaining white solid was dried under vacuum (0.2 Torr) for 10 min, then was dissolved in anhydrous toluene (28 mL) at room temperature. The clear colorless solution was immediately cooled to −78°C for 24 h to give white crystals. The recrystallization was carried out by decantation as above of the mother liquor at −78°C. The remaining "wet" crystals at −78°C were washed with precooled toluene (5 mL), again followed by removal of the supernatant liquid. The crystals were dissolved in toluene (20 mL) at −10°C, then the solution was again cooled to −78°C for 24 h. This procedure was repeated five times; decreasing volumes of toluene were required to dissolve the crystals at −10°C for the successive recrystallizations. From a total volume of 35 mL of the product (−)-**1** in toluene, a 1-mL aliquot, upon evaporation of the solvent *in vacuo*, yielded white crystals of (−)-**1** (0.284 g, total yield 9.94 g, 52%); mp 87–90°C; ir ν_{max}: 3200 (br), 2950, 1450; ^{1}H nmr δ: 0.8 (3H, d, J = 7 Hz, CH_3), 0.97 (6H, d, J = 7 Hz, $2CH_3$'s), 1.6 (6H, m, —CH_2—), 2.3 (2H, m, —CH—), 4.1 (1H, m, —CH—O$AlCl_2$).

Preparation of (−)-bornyloxyaluminum dichloride, (−)-2

The procedure described for (−)-**1** was carried out, with the following modifications. The solution of (−)-borneol (5.0 g, 0.032 mol) in dry toluene (22 mL) was added dropwise over 10 min to the 25% ethylaluminum dichloride solution in hexane (16 g, 0.032 mol) at −78°C. The mixture was slowly allowed to warm to 15°C when ethane was evolved. After 45 min of stirring at this temperature, a clear solution formed. The solution was concentrated under reduced pressure (1 Torr) to an approximate volume of 20 mL, then was cooled at −78°C for 24 h. The recrystallization procedure for (−)-**1** was followed. From a final volume of 16 mL of product (−)-**2** in toluene, a 1.0-mL aliquot yielded white crystals of (−)-**2** upon evaporation of the solvent *in vacuo* (0.333 g, total yield 5.33 g, 67%); mp 97–98°C; ir ν_{max}: 3400–3100 (br), 2950, 1450; ^{1}H nmr δ: 0.9 (6H, s, $2CH_3$'s), 1.06 (3H, s, CH_3), 1.6 (6H, m, —CH_2—), 2.4 (1H, br m, —CH—), 4.7 (1H, dd, J = 10 and 4 Hz, —CH—O$AlCl_2$).

In situ *preparation of (−)-1*

Dry toluene (2 mL) and a 25% solution of ethylaluminum dichloride in hexane (2.51 g, 0.0049 mol) were added to an apparatus as described for (−)-**1**. After cooling to −78°C, the solution of (−)-menthol (0.80 g, 0.0051 mol) in toluene (3 mL) was added dropwise. The solution was stirred at −15°C for 24 h, and subsequently used as an *in situ* catalyst.

Catalyzed Diels–Alder addition of methacrolein to cyclopentadiene

The procedure cited by Koga and co-workers (10) was used in the methacrolein (0.025 mol) reaction with several modifications. After extraction of the reaction mixture with hexane and drying ($MgSO_4$), the organic phase was concentrated under reduced pressure (95 Torr) with a bath temperature of 35–40°C to one-fifth of its volume. The pale yellow toluene solution contained the aldehyde adducts in a ratio of *exo:endo* 97:3 and in 70% yield as estimated from the ^{1}H nmr spectrum. The aldehyde solution was immediately oxidized with silver oxide and the *endo* acid was removed by iodolactonization (16). The *exo* acid was obtained (0.608 g, 16% overall); mp 34–36°C; $[\alpha]_D$ +48.3° (*c* 6, EtOH, 71.6% ee);[6] ir ν_{max}: 3500–3100 (br), 2700–2500 (br), 1690; ^{1}H nmr δ: 0.90 (1H, dm, J = 12 Hz, *endo* H(3)), 1.20 (3H, s, CH_3), 1.50 (2H, m, apex H_a, H_b), 2.50 (1H, dd, J = 4 and 12 Hz, *exo* (H(3)), 2.87 (1H, m, H(4)), 3.10 (1H, m, H(1)), 6.17 (2H, m, vinylic H(5), H(6)), 11.53 (1H, br m, OH); ms m/e: 152 (M^+).

Preparation of 2-methylene-α-tetralone, 3 and 2,2-dimethyl-6-methylene cyclohexanone, 4

Dienophiles **3** and **4** were prepared from α-tetralone and 2,2-dimethylcyclohexanone (19), respectively, by Gras' method for the formation of α-methylene ketones (18). Due to their ready dimerization at temperatures as low as −15°C, freshly prepared **3** and **4** were immediately used in subsequent Diels–Alder additions without further purification.

3 (91%); tlc in hexane – ethyl acetate (4:1) indicated 80% purity, R_f 0.5; ir ν_{max}: 1670, 1610 (sh), 1600; ^{1}H nmr δ: 3.00 (4H, m, —CH_2—), 5.43 (1H, d, J = 1 Hz, C=CH_2), 6.20 (1H, d, J = 1 Hz, >C=CH_2), 7.00–7.50 (3H, m, aromatic H's), 8.07 (1H, d, J = 6 Hz, aromatic H β to carbonyl).

The product **3** upon sitting at room temperature for 24 h formed its dimer, a bright yellow oil; tlc in hexane – ethyl acetate (4:1), R_f 0.4; ir ν_{max}: 1690, 1665, 1600; uv λ_{max}: 250 (5 200), 282 (6 700); ^{1}H nmr δ: 2.23 (8H, m, —CH_2—), 2.74 (2H, m, —CH_2—aromatic), 3.06 (2H, m, —CH_2—aromatic), 7.00–7.50 (7H, m, aromatic H's), 8.03 (1H, d, J = 6 Hz, aromatic H β to carbonyl); ms m/e: 316 (M^+).

4 (91%); ir ν_{max}: 1700, 1620; ^{1}H nmr δ: 1.10 (6H, s, $2CH_3$'s), 1.73 (4H, m, —CH_2—), 2.60 (2H, br m, —CH_2—C=C), 5.07 (1H, dd, J = 1 and 2 Hz, —C=CH_2), 5.67 (1H, dd, J = 1 and 2 Hz, —C=CH_2).

Diels–Alder additions with cyclopentadiene. General procedure

The apparatus for all of the Diels–Alder reactions comprised a flame-dried 100-mL three-neck flask with a rubber septum, magnetic stirrer, a gas inlet, and a bubbler, and was maintained under an argon atmosphere. In the trials catalyzed by $BF_3 \cdot Et_2O$, the amount of catalyst indicated in Table 1 was added to the dienophile in dry toluene at −78°C, followed by the dropwise addition of two equivalents of cyclopentadiene in toluene (total solvent ratio 28:1), unless otherwise described.

For reactions catalyzed by (−)-**1** or (−)-**2**, a solution of the dienophile in dry toluene was added by syringe to an aliquot of the catalyst in toluene (cf. Table 1 for equivalents) at −78°C. Cyclopentadiene (2 equivalents, unless otherwise stated) in toluene was added dropwise via syringe (total solvent ratio 20:1). The reactions were stirred at −78°C for the times recorded in Table 1. The adducts were isolated by the following extraction procedure. Water (2–5 mL) was added at −78°C, then at ambient temperature the mixture was diluted with water and extracted with hexane. The organic layers were washed with water and brine, dried ($MgSO_4$), and concentrated *in vacuo* to give the crude product mixture. For each reaction catalyzed by (−)-**1** or (−)-**2**, a concurrent methacrolein–cyclopentadiene addition was carried out with the same batch of catalyst and its optical purity was determined by conversion to the *exo* acid as described above. Also, a

[6]The reported rotation of the optically pure *exo* acid is +67.4° (EtOH) and its absolute configuration is reported to be (+)-(2*S*) (17).

For personal use only.

noncatalyzed reaction was performed at −78°C for each dienophile–diene combination.

*Addition of **3** with $BF_3 \cdot Et_2O$*

A crude orange oil (0.30 g) was obtained from the reaction of **3** (0.20 g, 0.0013 mol) with cyclopentadiene (0.16 g, 0.0025 mol) and $BF_3 \cdot Et_2O$ (0.18 g, 0.0013 mol). It was purified by preparative tlc (1-mm plates, hexane – ethyl acetate 9:1) to give the following:

Exo adduct-**3**, yellow oil (0.150 g); tlc, R_f 0.7 (hexane – ethyl acetate 9:1); ir ν_{max}: 1680, 1605; uv λ_{max}: 245 (11 900), 290 (1 200); ^{1}H nmr δ: 0.62 (1H, dd, J = 3 and 11 Hz, *endo* H(3)), 1.30 (1H, d, J = 9 Hz, apex H_a), 1.70 (1H, d, J = 9 Hz, apex H_b), 1.83 (2H, m, —CH_2—), 2.60 (1H, half of dd, J = 4 Hz, *exo* H(3)), 2.80 (4H, m, H(1), H(4), —CH_2—aromatic), 6.20 (2H, m, vinylic H(5), H(6)), 7.30 (3H, m, aromatic), 8.03 (1H, dd, J = 2 and 6 Hz, aromatic H β to carbonyl); ms m/e: 224 (M^+). The addition of Eu(hfc)$_3$ (17 mg) to racemic *exo* adduct-**3** (10 mg) shifted the signal at δ 8.03 to δ 9.5, where the enantiomeric shifts were displayed as two doublets (integration of peak areas 1:1).

Endo adduct-**3**, colorless oil (0.075 g); tlc, R_f 0.63 (hexane – ethyl acetate 9:1); ir ν_{max}: 1680, 1605; uv λ_{max}: 245 (10 000), 287 (2 400); ^{1}H nmr δ: 1.27 (1H, dd, J = 12 and 3 Hz, *exo* H(3)), 1.70 (2H, t, —CH_2—), 2.20 (1H, half of dd, J = 2 Hz, *endo* H(3)), 2.30 (2H, m, apex H_a, H_b), 3.04 (4H, m, —CH_2—aromatic), 5.70 (1H, dd, J = 6 and 3 Hz), and 6.27 (1H, dd, J = 6 and 3 Hz) representing the vinylic H(6) and H(5), 7.30 (3H, m, aromatic), 7.93 (1H, dd, J = 7 and 2 Hz, deshielded aromatic H); ms m/e: 224 (M^+). The signal at δ 7.93 was shifted to δ 8.6, upon addition of Eu(hfc)$_3$ (17 mg) to *endo* adduct-**3** (10 mg), and was exhibited as two doublets of equal density.

*Addition of **3** with (−)-**1***

The addition of **3** (1.10 g, 0.0069 mol) and cyclopentadiene (0.83 g, 0.013 mol) catalyzed by (−)-**1** (3.52 g, 0.014 mol) yielded a crude product mixture as a yellow oil (2.76 g). A portion (0.180 g) was purified by preparative tlc (0.5-mm plates, developed twice in hexane – ethyl acetate 9:1) to yield the following:

Exo adduct-**3**, yellow oil (0.102 g); tlc, R_f 0.7 (hexane – ethyl acetate 9:1, developed twice); $[\alpha]_D$ −14.1° (*c* 10, $CHCl_3$); ir, ^{1}H nmr, uv, and ms confirmed the structure. Addition of Eu(hfc)$_3$ (16 mg) to *exo* adduct-**3** (10 mg) shifted the signal at δ 8.03 (1H, d) to δ 9.25, where two doublets (integration 69:31) were displayed, representing 38% ee.

Endo adduct-**3**, colorless oil (0.008 g); tlc, R_f 0.63 (hexane – ethyl acetate 9:1, developed twice); $[\alpha]_D$ +147° (*c* 0.8, $CHCl_3$); ir, ^{1}H nmr, uv, and ms identified the adduct. Addition of Eu(hfc)$_3$ (20 mg) to *endo* adduct-**3** (10 mg) shifted the signal at δ 7.93 (1H, d) to δ 9.00, where it was exhibited as two doublets (integration 23:77), corresponding to 54% ee.

*Addition of **3** with (−)-**2***

Similarly, the Diels–Alder reaction was carried out, but with 4 equivalents of cyclopentadiene added at 1-, 3-, 5-, and 8-h intervals. Column chromatography (silica gel, hexane – ethyl acetate 9:1), followed by preparative tlc (1-mm plates, developed twice in hexane – ethyl acetate 9:1), yielded the purified adducts, *exo* adduct-**3** and *endo* adduct-**3**, in the chemical and optical yields recorded in Table 1. Spectral data confirmed the structures.

*Addition of **4** with $BF_3 \cdot Et_2O$*

Due to the ready polymerization of **4**, the $BF_3 \cdot Et_2O$ (1.20 mL, 0.0098 mol) was added to the mixture of **4** (3.00 g, estimated 0.017 mol) and cyclopentadiene (4.59 g, 0.069 mol) at −78°C. This temperature was maintained for 6 h, then stirring was continued at −15°C for 14 h. The crude product was partially purified by column chromatography (silica gel, hexane – ethyl acetate 100:3) to yield a yellow oil (0.826 g). A portion (0.226 g) was further purified by preparative tlc (0.5-mm plates, developed twice in hexane – ethyl acetate 100:3) to give:

Exo adduct-**4**, yellow oil (0.054 g); tlc, R_f 0.5 (hexane – ethyl acetate 100:3, developed twice); ir ν_{max}: 1685; ^{1}H nmr δ: 0.90 (1H, dd, J = 12 and 2 Hz, *endo* H(3)), 1.17 (6H, s, 2CH_3's), 1.38 (1H, d, J = 8 Hz, apex H_a), 1.60 (3H, m, apex H_b and —CH_2—), 1.70 (4H, t, —CH_2—), 2.20 (1H, dd, J = 12 and 4 Hz, *exo* H(3)), 2.83 (1H, m, H(4)), 3.00 (1H, m, H(1)), 6.12 (1H, dd, J = 6 and 2 Hz) and 6.22 (1H, dd, J = 6 and 2 Hz) representing vinylic H(5) and H(6); ms m/e: 204 (M^+). When *exo* adduct-**4** (2 mg) was complexed with Eu(hfc)$_3$ (2 mg), the singlet at δ 1.17 of the coincident methyl resonances was split into two singlets at δ 1.24 and δ 1.25, representing the two CH_3 groups; with additional Eu(hfc)$_3$ (3 mg total), the δ 1.25 signal was split into two singlets (integration 1:1) at δ 1.33 and δ 1.34 corresponding to the enantiomers.

Endo adduct-**4**, yellow oil (0.038 g); tlc, R_f 0.45 (hexane – ethyl acetate 100:3, developed twice); ir ν_{max}: 1695; ^{1}H nmr δ: 1.06 (3H, s, CH_3), 1.15 (1H, dd, J = 12 and 4 Hz, *exo* H(3)), 1.20 (3H, s, CH_3), 1.47 (1H, bd, J = 8 Hz, apex H_a), 1.70 (5H, m, apex H_b and —CH_2—), 2.00 (2H, m, —CH_2—), 2.17 (1H, dd, J = 12 and 2 Hz, *endo* H(3)), 2.82 (1H, m, H(4)), 3.16 (1H, m, H(1)), 5.77 (1H, dd, J = 6 and 3 Hz) and 6.20 (1H, dd, J = 6 and 3 Hz) representing vinylic H(6) and H(5); ms m/e: 204 (M^+). The methyl singlet at δ 1.06 of *endo* adduct-**4** (1 mg) appeared as two singlets at δ 1.13 and δ 1.14 of equal intensity, upon addition of Eu(hfc)$_3$ (0.8 mg).

Dimeric **4**, clear crystals (0.055 g); tlc, R_f 0.51 (hexane – ethyl acetate 100:3, developed twice); ir, ^{1}H nmr confirmed its structure; ms m/e: 276 (M^+); glc indicated rt 12.6 min (GSCOT, SP 1000, 44 m, id = 0.5 mm, 160°C, 18 psi (1 psi = 6.9 kPa)).

*Addition of **4** with (−)-**1***

The reverse addition was carried out, with **4** (2.77 g, 0.02 mol) added to the mixture of cyclopentadiene (5.28 g, 0.08 mol) and (−)-**1** (5.06 g, 0.02 mol) in dry toluene. The crude product mixture (3.56 g) was partially purified by column chromatography (silica gel, hexane – ethyl acetate 50:1). The major fraction (1.05 g) was further purified by preparative tlc (0.5-mm plates, developed three times in hexane – ethyl acetate 100:3) to yield *exo* adduct-**4** (0.665 g) and *endo* adduct-**4** (0.079 g). Each of these was prepared for hplc separation by dilution in hexane and passage through Porisil Sep-Packs to remove polar impurities. Then, elution of each with 3% ethyl acetate in hexane on a Porisil M20 column at pressure 1100 psi and flow rate of 5 mL/min, and recycling of the major peaks several times, gave the purified adducts:

Exo adduct-**4**, colorless oil (0.035 g); characterized by tlc, ir, ^{1}H nmr; ms m/e: 204 (M^+); hplc: rt 11.0 min; glc (160°C, 18 psi); rt 4.9 min; $[\alpha]_D$ +39°C (*c* 2, $CHCl_3$). The addition of Eu(hfc)$_3$ (1.8 mg) to *exo* adduct-**4** (1 mg) shifted the signal at δ 1.17 (6H, s) to δ 1.22 (3H, s) and δ 1.23 (3H, s) representing the axial and equatorial methyl resonances. With a total of 5.4 mg of Eu(hfc)$_3$, the δ 1.23 singlet was split into two singlets at δ 1.605 and δ 1.615 (integration 26:74) for one enantiomeric methyl, representing 48% ee.

Endo adduct-**4**, yellow oil (0.009 g); characterized by tlc, ir, ^{1}H nmr; ms m/e: 204 (M^+); hplc: rt 12.0–13.1 min; glc (160°C, 18 psi); rt 5.15 min, also impurities at rt 3.3, 4.4, and 6.0 (~50%); $[\alpha]_D$ not available. The methyl singlet at δ 1.06 of *endo* adduct-**4** (1 mg) appeared as two singlets at δ 1.64 and δ 1.72 (peak area 65:35), upon addition of Eu(hfc)$_3$ (1.6 mg), which corresponded to 30% ee.

*Addition of **5** with $BF_3 \cdot Et_2O$*

The addition of **5** (0.50 g, 0.0037 mol) and cyclopentadiene (0.48 g, 0.0073 mol) catalyzed by $BF_3 \cdot Et_2O$ (0.20 mL, 0.0015 mol) yielded a yellow oil (0.700 g), which was purified by preparative tlc (1-mm plates, hexane – ethyl acetate 4:1) to give the pure *endo* adduct (0.65 g, 92%); tlc R_f 0.5 (hexane – ethyl acetate 4:1); ir ν_{max}: 1660; ^{1}H nmr δ: 1.40 (3H, s, —CH_3), 1.57 (2H, m, apex H_a and H_b), 1.90 (3H, d, J = 1 Hz, C=C—CH_3), 2.80 (1H, d, J = 4 Hz, ring junction H(2)), 3.06 (1H, m, H(4)), 3.37 (1H, m, H(1)), 6.00 (2H, m, vinylic H(5) and H(6)), 6.47 (1H, bs, quinone C=C—H); ms m/e: 202 (M^+). The addition of Eu(hfc)$_3$ (16 mg) to the racemic *endo* adduct (10 mg) caused a diastereomeric shift difference of the quinone vinylic proton at δ 6.47, which was exhibited as two signals of equal intensity at δ 9.2 and δ 9.3.

*Addition of **5** with (−)-**1***

The Diels–Alder reaction of **5** (0.50 g, 0.0037 mol) and cyclopentadiene (0.48 g, 0.0073 mol) catalyzed by (−)-**1** (0.37 g, 0.0015 mol) in anhydrous toluene yielded, after preparative tlc (1-mm plates,

hexane – ethyl acetate 4:1), the pure *endo* adduct (0.65 g, 65%); $[\alpha]_D$ +4.6° (*c* 7, $CHCl_3$); ir, ^1H nmr, ms confirmed the structure. Addition of Eu(hfc)$_3$ (20 mg) to the *endo* adduct (10 mg) gave two diastereomeric quinone vinyl hydrogen signals (peak areas 54:46) at δ 10.0 and δ 10.1, corresponding to 8% ee.

Addition of 5 with (−)-2

The Diels–Alder addition of **5** (0.50 g, 0.0037 mol) and cyclopentadiene (0.48 g, 0.0073 mol) catalyzed by (−)-**2** (0.92 g, 0.0037 mol) was carried out at −78°C for 1 h, then additional cyclopentadiene (0.048 g, 0.0073 mol) was added and stirring was continued for 3 h. The product was purified by preparative tlc (1-mm plates, hexane – ethyl acetate 4:1) to give pure *endo* adduct (0.39 g, 53%); $[\alpha]_D$ +5.7° (*c* 9, $CHCl_3$); ir, ^1H nmr, ms confirmed the structure. Addition of Eu(hfc)$_3$ (20 mg) to the *endo* adduct (10 mg) produced two diastereomeric quinone vinyl hydrogen signals (peak areas 53:47) at δ 9.7 and δ 9.8, representing 6% ee.

Partial molar volumes of phenalkylamines and their physiologically active derivatives in water

FEREIDOON SHAHIDI

Department of Biochemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X9

Received January 10, 1987

This paper is dedicated to Professor John T. Edward

FEREIDOON SHAHIDI. Can. J. Chem. **65**, 1924 (1987).

The partial molar volumes at infinite dilution, V^0, for a number of phenalkylamines, their physiologically active derivatives, and their hydrochloride salts have been measured and related to their van der Waals volumes. Results indicate a value of 13.8 mL mol^{-1} for the electrostriction of water molecules by the terminal $\overset{+}{N}H_3$ group. Volumes of proton ionization in these compounds vary between 2.90 and 6.26 mL mol^{-1}.

FEREIDOON SHAHIDI. Can. J. Chem. **65**, 1924 (1987).

On a mesuré les volumes molaires partiels à dilution infinie, V^0, d'un certain nombre de phénylalkylamines, de leurs dérivés physiologiquement actifs et de leurs chlorhydrates et on a établi une corrélation avec leurs volumes de van der Waals. Les résultats indiquent que l'électrostriction des molécules d'eau par les groupements $\overset{+}{N}H_3$ terminaux est égale à 13,8 mL mol^{-1}. Dans ces composés, les volumes d'ionisation des protons varient de 2,90 à 6,26 mL mol^{-1}.

[Traduit par la revue]

Introduction

One of the most exciting fields in experimental medicine and medicinal chemistry which has advanced over the past thirty years is the work done by neurochemists for the discovery of the chemical messengers or brain chemicals (1–5). The simplest of these neurotransmitters are dopamine, noradrenaline, etc. They are products of enzymatic conversion of tyrosine and are stored in the vesicles of nerve cells. Deficiency of dopamine is found to result in Parkinson's disease and its over-firing causes some forms of paranoid schizophrenia. Dopamine deficiency may be treated with L-dihydroxyphenylalanine (L-DOPA) which appears to indirectly provide dopamine and is over-firing may be treated using dopamine blocking agents such as phenothiazines and other antipsychotic drugs. Although a lot of work has recently been concentrated on the medicinal aspects of these chemicals and their analogues, there has been no attempt to investigate their physicochemical and thermodynamic properties.

In this paper we report on our results for the partial molar volumes for a number of phenalkylamines and their physiologically active derivatives, both as free amines and their hydrochloride salts in water.

Experimental

All the compounds used in this work were reagent-grade commercial products and phenalkylamines were further purified by distillation. Solutions of the corresponding hydrochlorides were prepared just prior to use by titration with stoichiometric amounts of standardized HCl solution.

Density measurements were carried out at 25.00 ± 0.01°C using a Paar digital precision densimeter model DMA 02C. At least eight measurements at concentrations of 0.2–2.0% were carried out for each compound.

The apparent molar volumes, ϕ_v, were obtained from eq. [1] in each case.

$$[1] \quad \phi_v = M(1/d - W_1/d^0)W_2$$

where M is the molecular weight of the solute, W_2 its weight fraction, W_1 the weight fraction of the solvent, and d and d^0 are the densities of the solution and of water, respectively.

The hydrochlorides of the amines studied dissociate in aqueous solution to a very limited extent and the maximum corrections required to account for such processes are <0.1 mL mol^{-1}, thus within the experimental error and were ignored (6).

The partial molar volumes at infinite dilution for phenalkylamines and their derivatives were obtained from least-squares fit of the experimental ϕ_v's against molar concentration ($\phi_v = V^0 + hC$) and the V^0 values and b_v, the deviation constants, for their corresponding hydrochlorides were calculated using equation (2) (7, 8).

$$[2] \quad \phi_v = V^0 + 1.868\sqrt{C} + b_vC$$

The molar concentrations, C, were deduced from weight fraction and density data.

Results and discussion

Limiting partial molar volumes for phenalkylamines, Ph—$(CH_2)_n$—NH_2, and their hydrochlorides in water are reported in Table 1, together with the deviation constants, b_v, and the calculated V^0 values based on the equation

[3] $V^0 = aV_w + b$

where V_w is the van der Waals volume (9) and a and b are empirical constants derived from the least-squares fit of V^0 against V_w (10), and depend on the type of solute molecules and the nature of the solvent. The calculated values of V^0 are in excellent agreement with the experimental results. From the b values of eq. [3] for phenalkylamines and their hydrochlorides a value of 13.8 mL mol^{-1} may be calculated for the electrostriction of water molecules by the terminal $\overset{+}{N}H_3$ group. This is in accord with values of 12.8–14.5 mL mol^{-1} obtained for $\overset{+}{N}H_3$ in diamines (6), amino acids (11, 12), and their derivatives (13). The b_v values in eq. [2] are all negative for phenalkylamines hydrochlorides and descend with increasing chain length, as observed for other homologous series (6, 13, 14). The h values for phenalkylamines and phenethylamine derivatives were close to zero (in the concentration ranges studied) and did not follow any discernible trends.

The volume increment for methylene groups are all about 16.0 ± 0.4 mL mol^{-1} except for that of benzylamine hydrochloride. The smaller $V^0(CH_2)$ in benzylammonium ion is due to the changes in electrostriction of water molecules by $\overset{+}{N}H_3$ and changes in hydrophobic hydration of the benzene ring. It has been suggested that substitution of a hydrogen atom on $\overset{+}{N}H_3$ or on the carbon atoms adjacent to it by an alkyl group excludes

Ephedrine	2.90 ± 0.74	9.52

[a] Values from ref. 20.

some of the electrostrictive water molecules surrounding the $\overset{+}{N}H_3$ group (15). Removal of the alkyl substituent further away from the vicinity of the $\overset{+}{N}H_3$ group is therefore responsible for the observed $V^0(CH_2)$ in benzylammonium ion. (There are two β carbon atoms adjacent to $\overset{+}{N}H_3$ group in anilinium ion, whereas only one β carbon atom is present for $\overset{+}{N}H_3$ group in benzylamine.) Similar differences were observed for the V^0 values of isomeric butylamines hydrochlorides (16). The extent of the first hydration shell around $\overset{+}{N}H_3$ group for anilinium and phenbutylammonium ions are shown in Fig. 1, indicating that only small electrostatic changes may be expected in the volumic effects by introduction of intervening methylene groups between the phenyl and $\overset{+}{N}H_3$ groups for phenalkylamines. Partial removal of the fourth intervening methylene group from within the $\overset{+}{N}H_3$ hydration shell of phenbutylamine lends further support to this view.

In Table 2, the V^0 values for phenethylamine derivatives are assembled. From the data presented, an average volume increment, $V^0_{(H\rightarrow OH)}$, of 1.9 ± 0.5 mL mol^{-1} may be calculated for the replacement of a hydrogen atom by an OH group. This agrees well with a value of 2.1 ± 0.4 mL mol^{-1} obtained for hydroxy-containing amino acids (12). Replacement of a hydrogen atom on the α-carbon by a methyl group, $V^0_{(H\rightarrow CH_3)}$, results in a volume increase of 16.3 and 17.3 mL mol^{-1} for phenalkylamines and their hydrochlorides, respectively. A volume change of 18.1 mL mol^{-1} may be obtained when the substitution occurs on a $\overset{+}{N}H_3$ group. These larger volume increments in amine hydrochlorides are caused by the effect of the charge on the orientation of water molecules around the methyl substituent, as well as its effects on reducing the electrostriction of water molecules by the charged group (15, 17). The b_v values for phenethylamine derivatives of Table 2 do not follow any discernible trend.

Volumes of proton ionization, ΔV^0_I, together with the pK_a values for the protonated amines tabulated in Tables 1 and 2 are shown in Table 3. Results indicate that except for epinephrine, ephedrine, and amphetamine, ΔV^0_I values are almost constant for the amines studied in this work. Methylation on α-carbon atom or the nitrogen centre reduces the volumes of proton ionization (epinephrine, ephedrine, and amphetamine), in support of our previous findings for other systems (12, 17) and in agreement with the general expectation that secondary amines have lower ΔV^0_I values than primary amines.

Immobilized replicates of sequence 136–148 of human serum albumin as adsorbents for bilirubin

M. BOUVIER, G. R. BROWN, AND L. E. ST-PIERRE
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received January 2, 1987

This paper is dedicated to Professor John T. Edward

M. BOUVIER, G. R. BROWN, and L. E. ST-PIERRE. Can. J. Chem. **65**, 1927 (1987).

Strategic peptide sequences, patterned on the sequence 136–148 of the primary structure of human serum albumin, have been immobilized on a cross-linked polyacrylamide support using the solid phase peptide synthesis technique. Certain of the resulting materials proved to be efficient adsorbents for bilirubin from aqueous phosphate buffer solution. Amino acids such as lysine and arginine favour the binding of the ligand, whereas glutamic acid reduces it markedly. From Scatchard plots, first and second equilibrium binding constants, in the range of $(0.3–9.6) \times 10^4\ M^{-1}$, were obtained using a site treatment. These binding constants are comparable to that for the binding of bilirubin by a larger fragment of bovine serum albumin that contains the synthesized sequence.

M. BOUVIER, G. R. BROWN et L. E. ST-PIERRE. Can. J. Chem. **65**, 1927 (1987).

Des chaînes peptidiques identiques à la séquence 136–148 de la structure primaire de l'albumine humaine ont été immobilisées sur un support de polyacrylamide réticulé en utilisant la synthèse en phase solide des peptides. Certains des polymères à contenu peptidique ainsi obtenus se sont avérés être d'excellents adsorbants pour la bilirubine lorsque testés en milieu tampon. La présence d'acides aminés tels que l'arginine et la lysine dans la séquence peptidique favorisent l'adsorption du ligand tandis que l'acide glutamique la réduit appréciablement. Des constantes d'associations de l'ordre de $(0{,}3–9{,}6) \times 10^4\ M^{-1}$ ont été obtenues pour ces adsorbants directement des courbes de Scatchard à l'aide d'un traitement mathématique basé sur les sites d'adsorption. Ces constantes d'associations sont comparables à celle pour l'association de la bilirubine sur un fragment de l'albumine bovine qui contient la séquence synthétisée.

Introduction

The tetrapyrrole bile pigment bilirubin (Fig. 1*a*) is a product of the catabolism of hemoglobin from aged red blood cells. It is bound, in the blood, to human serum albumin (HSA) with each protein molecule having a capacity for strong binding of two bilirubin molecules (1). A number of pathologies exist in which the concentration of bilirubin is in excess of that which the HSA can accommodate (2). This results in an elevated free bilirubin concentration that is toxic and can cause a number of disorders, including some that are life threatening.

The removal of excess bilirubin from the blood has been the subject of much research and a number of techniques have been developed to this end. Included in these are certain photoirradiation and hemoperfusion methods.

Hemoperfusion treatments require the use of adsorbents that can bind bilirubin. These include cholestyramine (3, 4), a polymer with quaternary ammonium functional groups, and similar materials (4, 5) that are thought to act as ion-exchange resins by interacting with the two carboxyl groups of bilirubin. However, none of the existing adsorbents is entirely satisfactory for clinical use, their main shortcomings being nonspecificity and low capacity. Indeed, the most selective adsorbent thus far investigated, in terms of plasma components, has been immobilized HSA (6). However, the utility of this material is severely limited because of a low capacity, binding only two bilirubin molecules on a molecule of molecular weight in excess of 66 000.

The ideal adsorbent for bilirubin would exhibit high specificity, biocompatibility, and high capacity. With knowledge of the primary structure of HSA (7, 8) and information available concerning the possible location of the binding sites for bilirubin on that molecule (9–13), it is possible to synthesize onto a suitable polymer support peptide sequences that are replicates of corresponding sections of the primary structure of HSA and to test these materials as adsorbents for bilirubin.

Previous studies from this laboratory have demonstrated that peptide chains consisting of the basic amino acids, arginine or lysine, attached to a cross-linked polyacrylamide support are good adsorbents for bilirubin (14, 15). The binding capacity was shown to depend markedly on the number and arrangement of amino acids in the sequence. This paper describes the synthesis of a series of peptide resins replicating sections of HSA and their properties as adsorbents. A secondary goal was to attempt to shed light on the location of the binding sites for bilirubin on HSA and, to this end, site binding constants have been calculated and compared to those for the binding of bilirubin on the protein.

Experimental

1. Syntheses of peptide resins

The peptide resins were synthesized onto 11% cross-linked polyacrylamide support (Chemalog), which is a copolymer of dimethylacrylamide and *N*-acryl-1,6-diaminohexane reticulated with bisacrylyl-1,2-diaminoethane. The polymer substitution as determined by potentiometric titration with $AgNO_3$ was 0.22 mmol/g. Amino acids were purchased from Vega Biotechnologies as the L form of the Boc-α-amino acids with the side-chain groups protected as follows: Arg(nitro), Glu-(γ-benzyl ester), Tyr(*O*-benzyl), His-(N^{im}-tosyl), Lys-(ε-2-chloro-benzyloxycarbonyl). (Three letter symbols are used for designations of the amino acids as recommended by the Joint Commission on Biochemical Nomenclature of IUPAC-IUB.) Solvents used for synthesis were distilled, except dichloromethane (DCM), which was dried over molecule sieves, Type 4A.

Syntheses were done using a Vega 250 Synthesizer according to a previously published program (14):

"The resin was initially neutralized with 40% diisopropylethylamine (DIEA)/DCM for 20 minutes. Activated amino acids in the form of symmetrical anhydrides were used for coupling reactions. The anhydrides were pre-formed as follows: 6 equivalents of Boc-α-amino acid were dissolved in DCM (dimethylformamide (DMF) for Arg(nitro)) at 0°C. To this solution 3 equivalents of 10% dicyclohexylcarbodiimide (DCC)/DCM (10% DCC/DMF for Arg(nitro)) were slowly added.

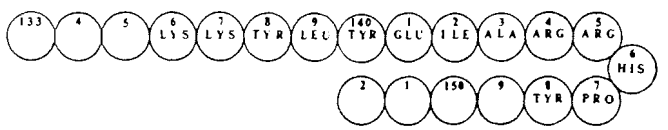
(b)



(c)

FIG. 1. (*a*) Structure of bilirubin. (*b*) Illustration of human serum albumin structure displaying the location of the replicated sequence. (*c*) Primary structure of the replicated sequence 136–148, which was immobilized on a polyacrylamide support.

After allowing the mixture to stir for about 30 minutes at 0°C, dicyclohexylurea was filtered off and the filtrate added directly to the flask containing the resin. The reaction was left until satisfactory coupling was obtained, as indicated by a positive ninhydrin test (16). After completion of the coupling step, Boc amino protecting groups were removed using 40% trifluoroacetic acid/DCM followed by neutralization with 5% DIEA/DCM. Deprotection steps were also monitored by the ninhydrin test."

Samples of the peptide resins were removed at strategic points during the course of the synthesis. At the completion of the syntheses, the protecting groups on the side chains of the amino acids were removed by treating the dried peptide resins with anhydrous hydrogen fluoride in the presence of anisole for 60 min at 0°C (30 min at −20°C followed by 30 min at 0°C for peptide resins containing glutamic acid residues). A spacer made of one alanine residue was incorporated at the beginning of the sequence to keep the active portion of the peptide away from the polymer backbone.

2. Amino acid analysis

Peptide resins 10 mg (1–2 μmol of peptide) were hydrolyzed at 110°C for 48 h in a vacuum reaction tube using degassed propionic acid (Gold label, Aldrich), 0.29 mL, and hydrochloric acid 11.90 *M* (Suprapur, BDH), 0.5 mL. After hydrolysis, the acidic solution was filtered and the remaining resin was washed several times with a small portion of water. The filtrate was collected in a test tube and evaporated to dryness under vacuum. The amino acids were then dissolved with sodium citrate dilution buffer pH 2.2, 0.20 *N* (Pierce) in a 10-mL volumetric flask to which 1 mL of 5 m*M* nitrotyrosine solution had been added as an internal standard. Amino acid analyses were performed using a Varian 5500 Analyzer.

3. Adsorption experiments

To determine the times required for equilibrium adsorption data, kinetic studies were done with each of the synthesized peptide resins using a degassed bilirubin (from bovine gallstones, Sigma) solution, 10 mg/dL in a 0.050 *M* KH_2PO_4/NaOH buffer at pH 7.80. An aliquot of 25 mL of that solution was added to 10 mg of a peptide resin and the mixture was stirred at 0°C under nitrogen, as described previously (14). Using a Beckman 25 spectrophotometer, absorbance values for free bilirubin were taken at 438 nm with aliquots withdrawn at 15-min intervals during the first hour and every 30 min thereafter until a constant absorbance was obtained.

Adsorption experiments were then performed with bilirubin solutions of different initial concentrations, up to a maximum of 10 mg/dL in a 0.050 *M* degassed phosphate buffer at pH 7.80. An aliquot of 25 mL of one of the above solutions was added to 10 mg of a peptide resin and the mixture stirred at 0°C under nitrogen for as long as required for the system to reach equilibrium.

Results and discussion

1. Rationalization for choice of sequence

The sequence selected for synthesis is the fragment 136–148 (Fig. 1*c*). Its location in the protein is illustrated in Fig. 1*b*, which exhibits the structure of human serum albumin as determined by Brown and co-workers (7).

The rationale involved in the choice of this fragment is as follows: First, the sequence consists of five basic, five hydrophobic, and three polar amino acid residues, as shown in Table 1. Therefore various types of interactions between bilirubin and these residues are possible. Furthermore, this sequence has an overall basic character at the pH used for the adsorption experiments, with the net charge being +3. This particular feature of the sequence is of interest for the binding of a dianion such as bilirubin. The sequence contains all of the active amino acids, arginine, histidine, tyrosine, and lysine, suggested by Jacobsen to be at or near the strong binding site for bilirubin on HSA (17, 18). Interestingly enough, this fragment also seems to be the only one in the entire protein that, over a short range of amino acids, contains these four residues. It is noteworthy that bovine serum albumin (BSA) and α-fetoprotein, two other proteins which also bind bilirubin, both have very similar primary structures in the region of the selected fragment. Furthermore, the choice of this sequence is based on its particular location in HSA. It forms the tip of loop no. 3 (Fig. 1*b*) and, according to Brown's model for the tertiary structure of albumin (19), the tips of loops form the entrance to narrow channels proposed to be suitable binding locations for bulky ligands like bilirubin. Therefore, the selected sequence within loop no. 3 could very well represent a binding site for bilirubin, owing to its location, and its attachment to a polymer support could produce an efficient adsorbent for bilirubin.

2. Amino acid analysis

Results from peptide resin hydrolysis are given in Table 2 in the form of ratios based on the recovery of the alanine residue of resin 1. The data indicate a loss in the number of growing peptide chains as each succeeding fragment of the sequence is added, with the exceptions of resins 2 and 4. Peptide chain terminations through mechanisms such as resistance of Boc protecting groups to deprotection reagents, amino groups buried in the porous polymer matrix and thus not accessible to the activated amino acids for coupling, can account for failure in the growth of some of the peptide chains (20). The percentage of cross-links in the support used is relatively high and therefore diffusion of the reagents through it is made more difficult than in supports regularly used in solid phase peptide synthesis.

3. Adsorption isotherms

The kinetic studies demonstrated that the peptide resins have saturation times varying between 1 and 2 h. The peptide resins that showed greater binding capacities required between 1.5 and 2 h to reach equilibrium, with the largest change in adsorption occurring within the first hour. Times necessary to obtain equilibrium adsorption isotherms for the peptide resins were based on this information.

Figure 2 shows the equilibrium adsorption isotherms, obtained at 0°C, for the seven synthesized adsorbents that describe in a systematic way the adsorption behaviour of the growing replicate sequence 136–148 of HSA. The parameter r represents the equilibrium molar ratio of bound bilirubin per peptide pendant in the polymer and [A] is the equilibrium concentration of free bilirubin. The curves drawn through the experimental points are derived from a nonlinear iterative computer program, NLIN from SAS (SAS Institute, 1982), using a method described previously (21).

As indicated by the amino acid analyses, a substantial fraction of the pendants terminated at various stages of the synthesis. Consequently, in certain cases the material used for adsorption contained a mixture of pendant lengths. The composition of the mixture can be defined on the basis of the analyses, assuming that a terminated sequence cannot be extended by subsequent syntheses. Adsorption isotherms obtained by normalizing the curves from Fig. 2, in accordance with the hydrolysis data in Table 2, are shown in Fig. 3. This normalization process assumes that the binding behaviour of each type of pendant is not influenced by the presence of other types of pendants. That is, those peptide chains that lacked the amino acids added to form the subsequent peptide resin retain an adsorption capacity that is unaffected by the presence of the other successfully synthesized pendants. Consequently, each normalized isotherm represents the adsorption behaviour of an adsorbent having identical peptide sequences.

The isotherms show that the trend in adsorption, within the range of concentrations used, is not related in a simple manner to the length of the peptide chains. This is in agreement with results obtained previously in this laboratory (15). After the addition of the sequence His-Pro-Tyr-Ala- to the polymer support to form resin 1, the binding capacity remains similar to that of the polymer itself, as shown in Fig. 3. This peptide sequence consists of four different amino acids, of which

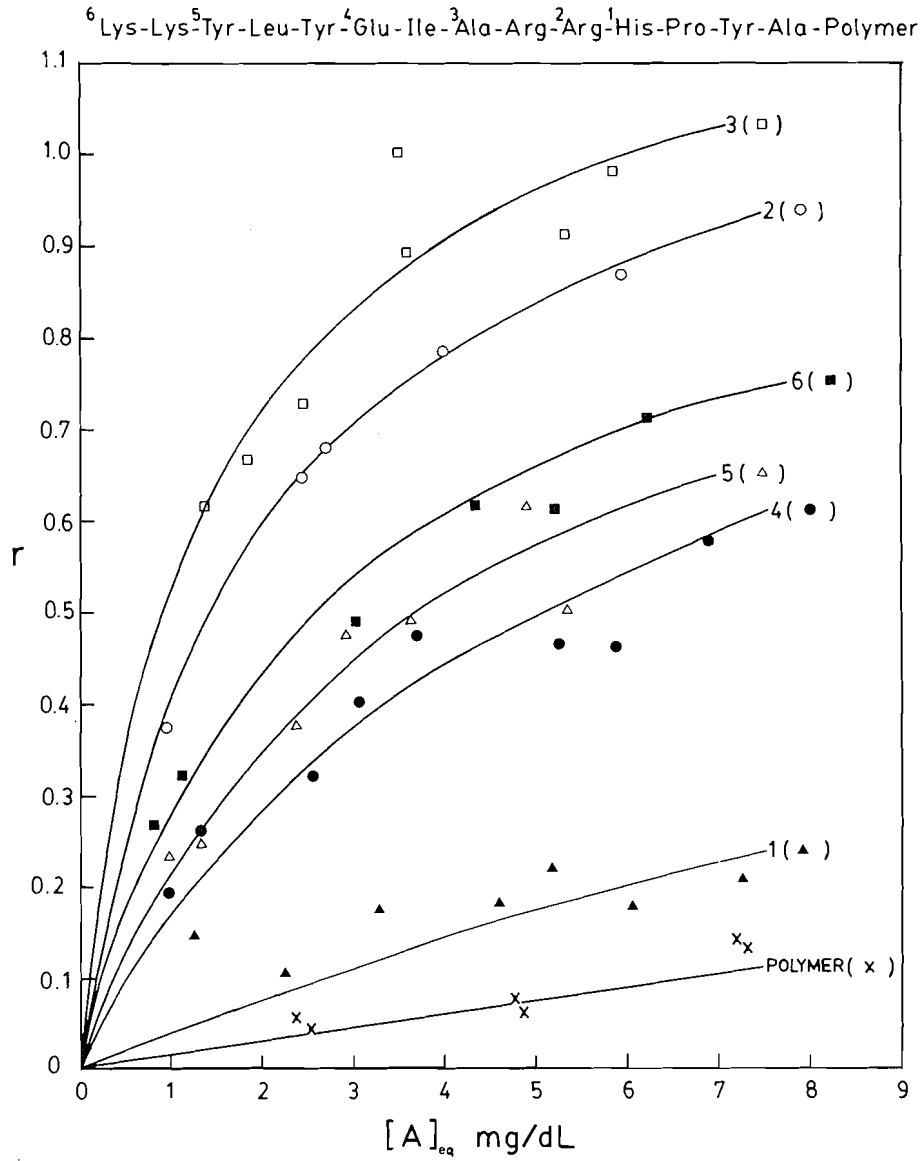

FIG. 2. Experimental equilibrium isotherms for the adsorption of bilirubin on peptide resins that replicate the sequence 136–148 of HSA.

histidine and tyrosine were proposed to be active in the binding of bilirubin on albumin (17). The combination of these two residues with alanine and proline forms an adsorbent that is only moderately active in binding bilirubin.

A large increase in binding capacity occurs following the coupling of one arginine residue to the previous fragment, resin 2. This behaviour reinforces the results of C. Jacobsen regarding the importance of arginine for the binding of bilirubin. The addition of a second arginine, resin 3, has a modest beneficial effect, the increase being much less than that due to the first arginine.

Addition of isoleucine and glutamic acid to form resin 4 results in a sharply diminished binding capacity. This can be attributed to the presence of the negatively charged glutamic acid. The addition of the Tyr-Leu-Tyr- segment, resin 5, causes a small increase in binding capacity over that of the previous peptide resin, probably due to the tyrosine, as indicated by resin 1.

Finally, the replicate sequence 136–148 ends with the addition of two lysine residues, resin 6, resulting in a considerable increase in binding capacity, especially at low bilirubin concentrations. These two basic residues have negated the effect of the glutamic acid residue. However, the adsorption isotherm fails to return to the maximum level exhibited by the sequence containing the first 7 amino acids, i.e., resin 3.

From the adsorption isotherms it is apparent that resins 2 and 3 will exhibit saturation at levels in excess of 1 mole of bound bilirubin per mole of pendant, while resins 1, 4, and 5 saturate at 1 mole, or less, of bound bilirubin per mole of pendant. Within the experimental range of concentration, resin 6 is the only adsorbent that definitely attains saturation (at $r = 1.1$). Thus, resin 6 will be considered similar to resins 1, 4, and 5 in terms of binding capacity, and will hereafter be considered as an adsorbent that has, within experimental error, one binding site per pendant.

These adsorption results support a binding mechanism that involves electrostatic interactions between the positively charged functional groups of the constituent amino acids and the negatively charged carboxyl groups on the bilirubin molecule. Previous results with peptide resins that have arginine and lysine

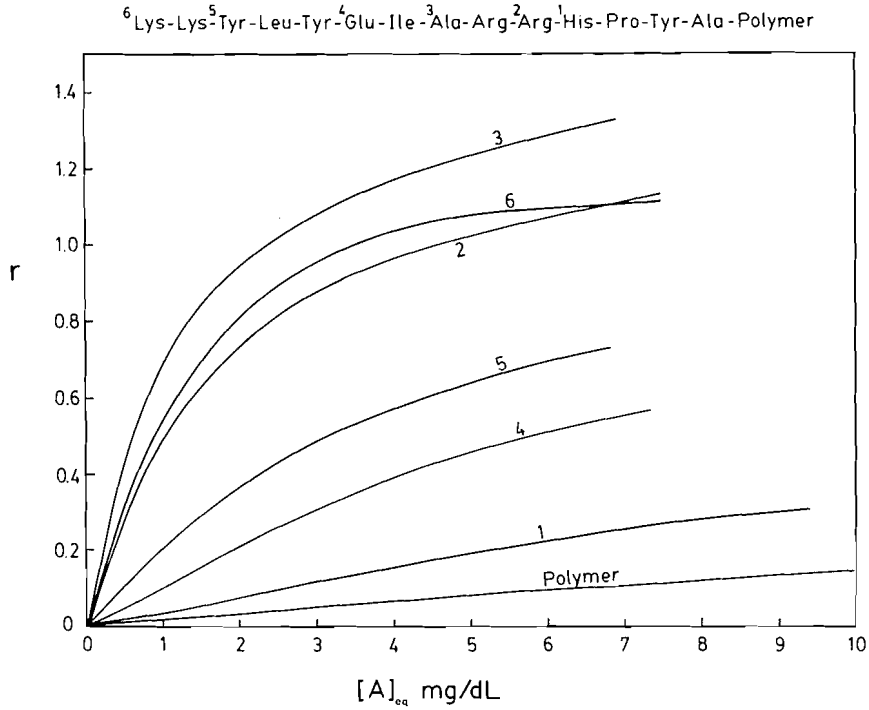

FIG. 3. Normalized equilibrium isotherms for the adsorption of bilirubin.

containing pendants (15) are explicable on the same basis. Furthermore, direct evidence for the interaction of the COOH groups of bilirubin with free NH_2 groups of lysine residues has been obtained from studies of nmr relaxation times (22). However, the results obtained for resins 2 and 3 demonstrate that, as might be expected, there is no simple linear relationship between the number of basic residues in the pendant and its binding capacity. Related factors, such as the length of the resulting sequence, the conformation of the peptide chains, and the position of the basic residues in the sequence, are also expected to influence the adsorption results.

4. Binding constants

The equilibrium isotherms reflect an expression of the binding affinity between bilirubin and the pendants of the peptide resins. Absolute values indicating the strength of these affinities can be expressed in the form of binding constants.

Resin 1 is the classical case of an adsorbent with a single binding site, as shown by a linear Scatchard plot (Fig. 4) that extrapolates to an intercept on the x-axis close to $r = 1$. For an adsorbent with one binding site per pendant, the Scatchard equation (23) has the form

$$[1] \quad r/[A] = k(1 - r)$$

where the parameters r and [A] are as defined previously and k is the binding constant. The binding constant, derived directly from the ordinate intercept, is equal to $0.3 \times 10^4\ M^{-1}$ (Table 3). This binding constant can be viewed as either a stoichiometric or site constant, since for adsorbents with a single site these are equivalent.

The Scatchard plots for resins 2 and 3 are very different than that for resin 1, with both exhibiting similar concave upward behaviour and tending toward an intercept of $r > 1$ (Fig. 4), indicating more than one binding site per pendant but no more than two. Indeed, the size of a molecule of bilirubin, with respect to the length of the peptide pendants considered, precludes a capacity greater than two for these systems. Upward concavity reflects an adsorption isotherm for which r rises rapidly at low [A], after which it increases very slowly so that saturation is reached only at high values of [A]. This behaviour is usually associated with a first binding constant that is larger than the second.

From a molecular point of view, two interpretations are possible for cases when $k_1 > k_2$: (*a*) negative cooperativity is developed between binding sites as a result of the binding of the first bilirubin molecule to a pendant; and (*b*) the binding sites are independent and nonequivalent, with a second binding constant being markedly smaller than the first. From a consideration of binding constant values only, it is not possible to get direct insight into the nature of the binding behaviour. However, due to the relatively short length of the pendants on these peptide resins the two binding sites must be in close proximity. For these particular sequences and placements of amino acids, relatively limited secondary and tertiary structures are expected. This precludes the formation of two classes of sites having different initial affinities. Therefore it seems probable that interactions exist between initially equivalent binding sites, so that the first explanation is more plausible.

For adsorbents with two initially equivalent, interaction sites, binding constants can be derived using a graphical method based on a modified Scatchard equation (21):

$$[2] \quad r/[A] = \frac{k_2 r(2 - r)}{r - 1 + \delta}$$

where

$$\delta = \{1 + 2(\xi - 1)r - (\xi - 1)r^2\}^{1/2}$$

$$\xi = k_2/k_1$$

The constants k_1 and k_2 are first and second *site* binding constants. It can be shown from eq. [2] that as r approaches 0,

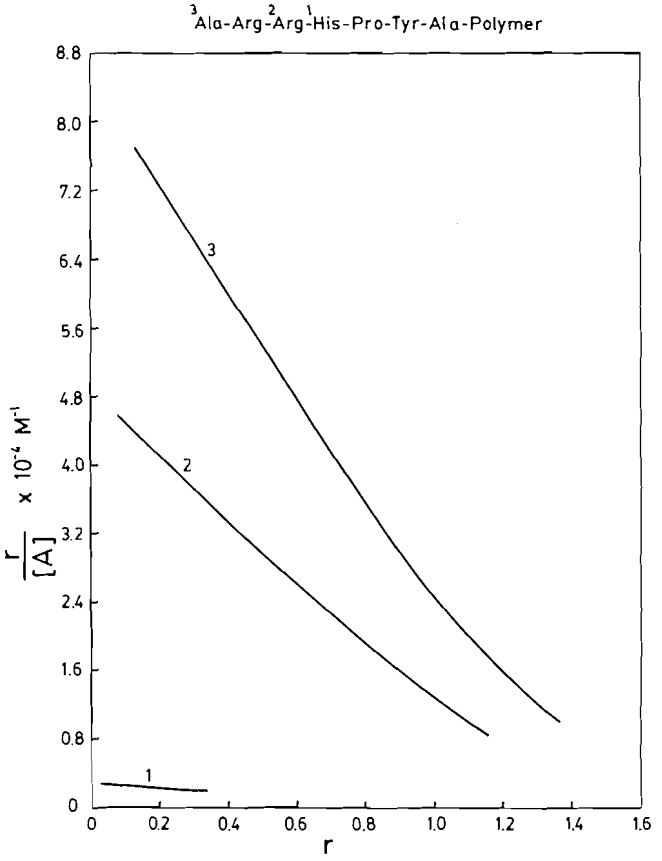

FIG. 4. Scatchard plots for peptide resins representing a portion of the sequence 136–148 of HSA.

TABLE 3. Site equilibrium constants for binding of bilirubin by peptide resins describing the replicate fragment 136–148 of human serum albumin

Peptide resins	Site binding constant $\times 10^{-4} M^{-1}$ k_1	k_2
1 -His-Pro-Tyr-Ala-polymer	0.3	0
2 -Arg-	2.4	0.7
3 -Ala-Arg-	4.3	1.5
4 -Glu-Ile-	0.3	3.3
5 -Tyr-Leu-Tyr-	1.3	2.8
6 Lys-Lys-	4.8	9.6

$r/[A] = 2k_1$, and when $r = 1$, i.e., at half saturation, $r/[A] = (k_1k_2)^{1/2}$.

The intercepts on the ordinate of Fig. 4 are $4.8 \times 10^4\ M^{-1}$ and $8.5 \times 10^4\ M^{-1}$ for resins 2 and 3, respectively, and correspond to k_1 of $2.4 \times 10^4\ M^{-1}$ and $4.3 \times 10^4\ M^{-1}$ (Table 3). The $r/[A]$ values at half saturation are $1.3 \times 10^4\ M^{-1}$ and $2.5 \times 10^4\ M^{-1}$ for resins 2 and 3, respectively, corresponding to values for k_2 of $0.7 \times 10^4\ M^{-1}$ and $1.5 \times 10^4\ M^{-1}$ (Table 3). The importance of arginine in binding bilirubin is clearly demonstrated by the larger value of k_1 for resin 2 as compared to the binding constant for resin 1. Furthermore, k_1 is approximately doubled by the addition of a second arginine to form resin 3. For resin 2 the negative cooperativity is shown by the fact that $k_2/k_1 = 0.29$, so that the binding of the first bilirubin apparently interferes with subsequent binding at the second site. Similarly, $k_2/k_1 = 0.35$ for resin 3, so that the degree of negative cooperativity is decreased somewhat. This might be expected since the increase in length affords more space for the second bilirubin molecule.

The first binding constant of resin 3 is larger than that of resin 2 and reflects the steeper slope of the isotherm at low concentrations. Furthermore, due to the relatively large values of both k_1 and k_2, the adsorption isotherm associated with resin 3 should saturate at a lower concentration, as Fig. 3 indicates.

Scatchard plots with concave downward behaviour (Fig. 5) are obtained as the last three fragments are added to complete the replicate peptide sequence, resins 4, 5, and 6. This pattern is associated with an adsorption isotherm for which, as [A] increases, r rises slowly at low concentration, then increases rapidly, and finally attains saturation, i.e., a sigmoidal isotherm. Such plots manifest positive cooperativity between binding sites, i.e., after filling the first site there is an increase in the affinity of the other binding site. This behaviour is also associated with a second binding constant that is larger than the first.

These three peptide resins are very interesting cases of peptide–ligand interactions in that their Scatchard plots (Fig. 5) manifest positive cooperativity even though r is less than or equal to one. Indeed, as indicated by the adsorption isotherms (Fig. 3), resins 4, 5, and 6 appear to have only one binding site per pendant. Consequently, the cooperative nature of the binding must be between adjacent peptide pendants, each having only one binding site, rather than between two sites on the same pendant, as for resins 2 and 3.

A plausible explanation is obtained from a consideration of the nature of the amino acids making up the peptide pendants of these adsorbents. The introduction of the glutamic acid residue with a negative charge to form resin 4 introduces the possibility of electrostatic interactions with arginine residues on other pendants since, at the pH of these adsorption experiments, both arginine and glutamic acid should be fully ionized. Binding of the first bilirubin molecule could disturb these interactions between pendants and result in the development of a more favourable second binding site on the unoccupied pendant. In terms of binding constants this behaviour would thus be reflected by a larger value of the second binding constant, k_2.

The mathematical treatment required to derive site binding constants for these peptide resins is obtained by extending the model presented previously (21) for adsorbents with two initially equivalent, interacting sites. That model is based on an expression for r in terms of [A] and the site binding constants k_1 and k_2 in the form

$$[3a] \quad r = \frac{2k_1[A] + 2k_1k_2[A]^2}{1 + 2k_1[A] + k_1k_2[A]^2}$$

The binding model for resins 4, 5, and 6 requires that the parameter r, which is the molar ratio of bound bilirubin per pendant, be doubled owing to interactions between two pendants that effectively decrease the substitution on the polymer support by half. Consequently, eq. [3*a*] becomes

$$[3b] \quad r = \frac{k_1[A] + k_1k_2[A]^2}{1 + 2k_1[A] + k_1k_2[A]^2}$$

Equation [3*b*] can be expressed as a quadratic in [A] in the form:

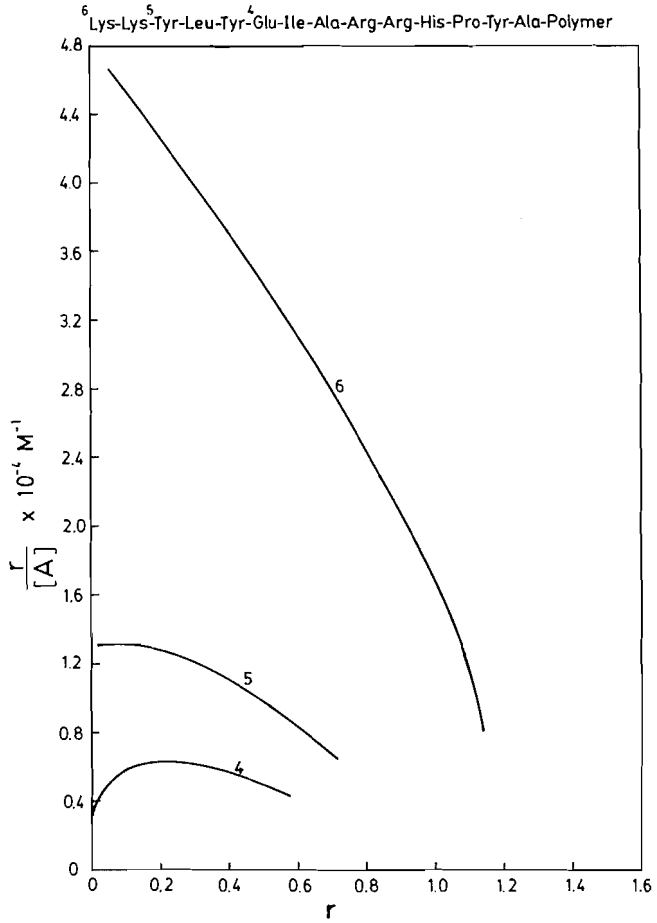

FIG. 5. Scatchard plots for peptide resins describing the sequence 136–148 of HSA.

$$[4a] \quad [A]^2 + [A](1 - 2r)/\{k_2(1 - r)\} - r/\{k_1k_2(1 - r)\} = 0$$

The positive root of eq. [4*a*], which is the only solution that results in positive [A], is

$$[4b] \quad r = \frac{2r - 1 + \delta'}{2k_2(1 - r)}$$

where

$$\delta' = \{1 + 4(\xi - 1)r - 4(\xi - 1)r^2\}^{1/2}$$

$$\xi = k_2/k_1$$

Thus the modified Scatchard equation used for resins 4, 5, and 6 is

$$[5] \quad r/[A] = \frac{2k_2r(1 - r)}{2r - 1 + \delta'}$$

Using the binomial theorem it can be shown that in the limit as r approaches 0, $r/[A] = k_1$, and when $r = 0.5$, or at half saturation, $r/[A] = 1/2(k_1k_2)^{1/2}$. Site binding constants k_1 and k_2 can thus be obtained graphically from a Scatchard plot in a manner analogous to that used for the previous adsorbents.

Binding constants for resins 4, 5, and 6 derived in this manner are given in Table 3. Ordinate intercepts on Fig. 5 yield k_1 equal to $0.3 \times 10^4\ M^{-1}$, $1.3 \times 10^4\ M^{-1}$, and $4.8 \times 10^4\ M^{-1}$ for resins 4, 5, and 6, respectively. The corresponding values of $r/[A]$ at half saturation are $0.5 \times 10^4\ M^{-1}$, $1.0 \times 10^4\ M^{-1}$, and $3.4 \times 10^4\ M^{-1}$, respectively, corresponding to k_2 values of $3.3 \times 10^4\ M^{-1}$, $2.8 \times 10^4\ M^{-1}$, and $9.6 \times 10^4\ M^{-1}$. As expected, second binding constants higher than the first are obtained in all cases. Resin 4 demonstrates the strongest positive cooperativity, having the largest ratio of k_2/k_1, corresponding to an elevenfold enhancement. Resins 5 and 6 have lower, but very similar, ratios of k_2/k_1 (equal to 2.2 and 2, respectively).

These results correlate well with the binding model introduced for these three adsorbents. It is with resin 4 that the glutamic acid was introduced and this adsorbent possesses the largest enhancement. The binding behaviour suggests that the binding of the first bilirubin molecule in some manner either balances or shields the negative charge of the glutamic acid so that the second bilirubin molecule binds more strongly. The introduction of the subsequent amino acids, among which are the strongly basic lysine residues, serve to further attenuate the role of the negative charge and this is reflected by the diminished k_2/k_1 ratio for resins 5 and 6.

As mentioned previously, binding with positive cooperativity is generally reflected by a sigmoidal shape in the adsorption isotherm. In the case of resins 4 and 5, the relatively low slope of the isotherm (Fig. 3) at low adsorbate concentrations is the only sign of such cooperativity. However, the corresponding Scatchard plots (Fig. 5) demonstrate the positive cooperativity binding, in a more obvious way, by the concave downward shape.

The adsorption isotherm of resin 6 (Fig. 3) has a relatively steep slope at low concentrations and also shows saturation, but gives no evidence of a sigmoidal shape. Again, the corresponding Scatchard plot is more appropriate in this regard. The high value for the first binding constant reflects the rapid increase in r at low equilibrium concentrations. Furthermore, combined with this first binding constant is a second binding constant that is twice the first. Consequently, the maximum loading occurs at a relatively low adsorbate concentration.

Resin 6 has several of the characteristics required of a good adsorbent. It has a high binding capacity at low adsorbate concentrations, in part because of positive cooperativity combined with a large first binding constant. At concentrations above 7 mg/dL, resin 2 has a higher binding capacity than does resin 6. It could be concluded that resin 3 would be the best candidate for clinical purposes since it has the highest binding capacity as well as a relatively large k_1. However, this ignores the question of specificity of interactions. The adsorption behaviour of other biological adsorbates will be reported in the near future.

It is of interest to compare the equilibrium binding constants of these peptide resins with those of HSA for the binding of bilirubin. Numerous studies indicate that the first molecule of bilirubin binds to HSA with a binding constant in the region of 10^6–$10^8\ M^{-1}$ (24). The large range in reported values indicates a sensitivity to experimental conditions and methods. Nonetheless, they are larger by a factor of ca. 10^2–10^4 than that for any of the synthesized peptide resins. Similarly, the binding constants for the second site on HSA have been reported to be 10^5–$10^6\ M^{-1}$ (24), i.e., only slightly larger than those of these peptide resins.

It is noteworthy that a binding constant of $1.8 \times 10^5\ M^{-1}$ was obtained by Reed *et al.* (25) for the binding of bilirubin by the fragment 115–184 of BSA. As previously mentioned, HSA and BSA have very similar primary structures in this region, loop no. 3 in Fig. 1*b*, and should therefore have similar binding constants. Reed's value is only slightly higher than the binding

constants of some of the present peptide resins, which are structurally simpler and consist of shorter sequences composed in this region of HSA.

As postulated previously by many researchers (9–11, 17, 18), bilirubin binding sites on human albumin may be in the amino terminal half of the protein, more specifically in the region of loops no. 3 and no. 4 (Fig. 1*b*). The similarity in binding constants for the peptide resins with that for the BSA fragment offers supporting evidence that the binding location for bilirubin on the protein is in the vicinity of the sequence of the synthesized peptide resins. The existing discrepancy may reflect the flexibility of the albumin, which allows it to adopt conformations that form binding sites that are specifically shaped for a given ligand, as has been suggested by Brodersen (24). Accordingly, a more developed secondary and tertiary structure of HSA, as compared to that of the peptide pendants of the synthesized adsorbents, may contribute to enhance the unique binding character of albumin in terms of affinity, capacity, and specificity.

Conclusion

This work demonstrates that a strategic replicate sequence, patterned after the primary structure of HSA, when immobilized onto a cross-linked polymer support results in a material that can be used as adsorbent for bilirubin. Results show that the introduction of the basic amino acids into the sequence tends to produce adsorbents with a relatively strong binding affinity for bilirubin. Binding constants, comparable to that of a larger fragment of BSA surrounding the replicated sequence, were obtained with these much simpler adsorbents.

Surface adsorption at low coverage of *n*-alkanes on bleached kraft papers using gas chromatography

N. GURNAGUL AND D. G. GRAY

Pulp and Paper Research Institute of Canada, and Department of Chemistry, McGill University, 3420 University St., Montreal, P.Q., Canada H3A 2A7

Received January 13, 1987

This paper is dedicated to Professor John T. Edward

N. GURNAGUL and D. G. GRAY. Can. J. Chem. **65**, 1935 (1987).

The adsorption at low surface coverage of a series of *n*-alkanes on various bleached kraft paper surfaces was measured by gas chromatography. Differences in surface area of the paper samples were readily measured from the gas chromatographic retention volumes. The standard free energy, the enthalpy, and the entropy of adsorption varied linearly with the number of carbon atoms in the *n*-alkanes. The heats of adsorption were close to the heats of liquefaction, indicating the non-specific interactions of the hydrocarbons with the bleached kraft surfaces. The London component of the surface free energy was estimated from the gas chromatographic results to be 47.9 mN/m.

N. GURNAGUL et D. G. GRAY. Can. J. Chem. **65**, 1935 (1987).

Utilisant la chromatographie en phase gazeuse et opérant avec des surfaces qui sont relativement peu couvertes, on a mesuré l'adsorption d'une série de *n*-alcanes sur diverses surfaces de papier kraft blanchi. Grâce aux volumes de rétention en chromatographie en phase gazeuse, on peut facilement mesurer les différences dans les superficies des surfaces des échantillons de papier. L'énergie libre standard, l'enthalpie et l'entropie d'adsorption varient d'une façon linéaire avec le nombre d'atomes de carbone dans les *n*-alcanes. Les chaleurs d'adsorption sont semblables à celles des chaleurs de liquéfation et ce résultat indique que les interactions des hydrocarbures avec les surfaces du papier kraft blanchi ne sont pas spécifiques. En se basant sur les résultats de la chromatographie en phase gazeuse, on a évalué que la composante de London à l'énergie libre de surface est égale à 47,9 mN/m.

Introduction

In its simplest form, paper is made from a dilute (0.2–1% by weight) aqueous suspension of wood pulp fibres by draining the water through a fabric mesh which retains the fibres (1). As the water is removed, surface tension forces bring the fibres into intimate contact, resulting after pressing and drying in a fibrous sheet held together primarily by interfibre hydrogen bonds between polysaccharide components on the surface of the wood pulp fibres. Thus paper sheets, unless specially treated, remain sensitive to moisture, changing dimensions with changes in relative humidity and disintegrating when re-immersed in water.

The strength and optical properties of paper sheets depend on many variables in fibre and sheet preparation. In most papermaking processes, the pulp fibres are treated mechanically prior to sheet formation. The operation is known as "beating" or "refining" the pulp. This mechanical treatment of the fibres renders them more flexible and fibrillated. The increase in flexibility was explained by Emerton (2) who suggested that the flexing of the fibres during beating caused the breakdown of the fibre wall into separate lamellae, particularly in the secondary wall layers. This internal fibrillation results in increased amounts of water sorption by the hydrophilic hemicelluloses and the amorphous fraction of cellulose. The water incorporated into the amorphous polysaccharide phase exerts a plasticizing effect on the composite structure which deforms more readily (2). Beating also results in external fibrillation where "fibrils", sometimes aggregated into membranes, extend from, and are attached to, the surfaces of fibres (3). The enhanced flexibility and collapse of fibrillation leads to a denser, stronger, sheet on drying.

The surface area of a paper sheet may be defined as the surface area of the constituent fibres minus the "bonded" area, where fibres are in contact. (This area is of course much larger than the geometric or "purchased" area of a paper sheet because of the porous structure of the sheet.) The surface area is smaller for a beaten sheet than for an unbeaten sheet, because the beaten fibres are more flexible, and they pack together in a denser sheet during drying.

A gas chromatographic (GC) method has been adapted to measure the surface area of pulp fibres and paper (4) and the response of surface area to changes in relative humidity (5). Recently, the responses to changes in relative humidity of a series of paper samples, prepared by beating a sample of bleached kraft wood pulp to different levels, have been followed by this method (6). In essence, (*i*) the gas chromatographic retention of hydrocarbon vapours on a paper stationary phase packed into a column conditioned at a given relative humidity is measured; (*ii*) adsorption isotherms are derived from the GC data (7); (*iii*) surface areas and the thermodynamics of adsorption are determined from the adsorption isotherms. However, measurement of adsorption isotherms by the methods of finite concentration gas chromatography is rather laborious. In favourable situations, a much more rapid indication of vapour–substrate interactions can be derived from gas chromatographic retention data in the infinite dilution or "Henry's law" limit, where the high inherent sensitivity of GC detectors is used to measure the retention of very small concentrations of vapour on the substrate. The retention time is readily related to the slope of the adsorption isotherm if the slope approaches a limiting value at very low surface coverage (7). The gas chromatographic measurements at finite concentration on kraft paper samples prepared from pulp beaten to different degrees (6) are extended in this paper to measurements made at very low coverage. Some indication of the interactions of *n*-alkanes with the paper surface are derived from the measurements, and a facile method for estimating changes in surface area of paper samples is presented. The experimental methods and interpretation follow

previous results on cotton filter paper (8). Briefly, the technique of infinite dilution GC involves the introduction of very low probe vapour concentrations in the carrier gas phase. The GC peak shapes in favorable cases are symmetrical and the adsorption isotherms are linear. In this so-called "Henry's law" region, adsorbate–adsorbate interactions are negligible and the net retention volume V_N is independent of the injection size and is related to the limiting slope at zero concentration of the adsorption isotherm (7) by:

$$[1] \quad V_N = A(d\Gamma/dc)_{c\to 0} = AK_s$$

where V_N is the corrected net retention volume at infinite dilution, A is the total surface area of adsorbent in the column, Γ is the concentration of adsorbate on the adsorbent expressed in mol/m^2, c is the gas phase concentration of the adsorbate, and K_s is a surface coefficient. Due to the low adsorbate concentration in the vapour phase and the low column pressure drop, the standard GC corrections (7) are not necessary.

Thermodynamic quantities are derived from the partition coefficients. The standard free energy of adsorption, ΔG_A^0 is given by (9),

$$[2] \quad \Delta G_A^0 = -RT \ln (BK_s)$$

where R is the gas constant, T is the column temperature, and B is a constant that is the ratio of the standard reference states in the gas phase and on the surface:

$$[3] \quad B = p_{s,g}/\pi_s$$

where $p_{s,g}$ is the adsorbate vapour pressure in the gaseous standard state and π_s is the two-dimensional spreading or surface pressure of the adsorbed gas. The values of the standard reference states are taken as $p_{s,g} = 101\ kN/m^2$ (1 atm) and $\pi_s = 0.338\ mN/m$. This value of π_s has been suggested by de Boer such that the standard surface pressure may be defined as the pressure where the average distance of separation between molecules in the adsorbed phase equals that in the standard gas state (9).

At zero surface coverage, the temperature dependence of the partition coefficient, K_s, allows one to calculate the differential heat of adsorption, q_d, which may be identified with $-\Delta\bar{H}_A$ (9), the enthalpy of adsorption,

$$[4] \quad \frac{d(\ln K_s)}{d(1/T)} = \frac{q_d}{R} = \frac{-\Delta\bar{H}_A}{R}$$

The slope of a plot of $\ln K_s$ as a function of T^{-1} will yield the differential heat of adsorption. From the difference between $\Delta\bar{G}_A^0$ and $-q_d$, the standard entropy of adsorption of the probe at zero coverage, $\Delta\bar{S}_A^0$ can be calculated,

$$[5] \quad \Delta\bar{S}_A^0 = -(q_d + \Delta\bar{G}_A^0)/T = \frac{\Delta\bar{H}_A - \Delta\bar{G}_A^0}{T}$$

An empirical method has been proposed to calculate the differential free energy of adsorption from the vapour phase for a —CH_2— segment of an n-alkane chain, at effectively zero surface coverage (8):

$$[6] \quad \Delta\bar{G}_{A(CH_2)}^0 = -RT \ln (K_s^{n+1}/K_s^n)$$

where $\Delta\bar{G}_{A(CH_2)}^0$ is the incremental standard free energy of adsorption per mole of —CH_2— group at zero coverage, R is the gas constant, T is the absolute temperature, and K_s^{n+1}, K_s^n are the partition coefficients for n-alkanes with $n + 1$ and n carbons, respectively. When measurements are made at constant temperature and carrier gas flow rate, assuming gas phase ideality,

$$[7] \quad \frac{K_s^{n+1}}{K_s^n} = \frac{V_R^{n+1}}{V_R^n} = \frac{t_R^{n+1}}{t_R^n}$$

where V_R^{n+1}, V_R^n are the net retention volumes for alkanes with $n + 1$ and n carbon atoms, respectively, and t_R^{n+1}, t_R^n are the corresponding peak retention times (measured from the elution time of a non-interacting vapour). Therefore, it is possible to measure $\Delta\bar{G}_{A(CH_2)}^0$ by simply making an injection of a mixture of a homologous series of n-alkanes and measuring the respective net retention times, without knowledge of the adsorbent surface area or the flow rate of carrier gas.

The adsorption of hydrocarbons on the cellulosic bleached kraft surface is non-specific, and the attractive forces between the adsorbate molecules and the adsorbent surface are essentially dispersive. According to Fowkes, the work of adhesion, W_A, between a nonpolar liquid and surface is given by the geometric mean of the surface tensions of the two components (10),

$$[8] \quad W_A = 2(\gamma_1\gamma_2^L)^{1/2}$$

where γ_1 is the surface tension of the nonpolar liquid and γ_2^L is the London component of the surface tension of the second component.

If the work of adhesion, W_A, is replaced by the free energy of adsorption per mole of CH_2 group (8), then,

$$[9] \quad \frac{-\Delta\bar{G}_{A(CH_2)}^0}{Na_{CH_2}} = 2(\gamma_{CH_2}\gamma_2^L)^{1/2}$$

where $a_{(CH_2)}$ is 0.06 nm^2, the cross-sectional area of a methylene group, $\gamma_{(CH_2)}$ is the surface tension of a surface comprised only of CH_2 groups (from extrapolation of the surface tension of low molecular weight alkanes to infinite chain length). The value of $\gamma_{(CH_2)}$ is about 35 mN/m (11). As stated, γ_2^L is the London component of the surface free energy of the adsorbent and N is the Avogadro number. The GC method provides an alternate route to surface free energies which avoids some of the problems of contact angle measurements on paper.

Experimental

The simple gas chromatographic apparatus with flame ionization detector and thermostatted water-bath has been described in detail previously (5).

Most of the experiments were performed with a commercial bleached kraft pulp (Domtar Q90, 100% black spruce, northern Quebec, 42% yield). The initial pulp samples were in the form of $8\frac{1}{2} \times 11$ dried lap sheets. The edges of the sheets were cut off and the sheets were soaked for 4 h, then disintegrated and beaten to several standard freeness values in a laboratory PFI mill. Five samples were used: the initial unbeaten pulp (Q90) and samples beaten for 3000, 6000, 9000, and 11000 revolutions (Q90-3M, Q90-6M, Q90-9M, and Q90-11M respectively).

Handsheets were prepared from these pulps with a British Standard Handsheet apparatus (12). The handsheets were cut into small (1.8 mm diameter) pieces and packed into 1 m copper columns of 5 mm o.d. previously washed with acetone. All the paper samples had an initial moisture content of about 7–8%, determined by drying small amounts to constant weight. The paper samples were packed directly into the columns without drying, conditioned at 90% RH, then dried overnight at 105°C in a stream of dry nitrogen.

Infinite dilution measurements were made at several temperatures (20°C, 25°C, 30°C, 40°C) on the bleached kraft samples after exposure to 90% relative humidity and drying. The temperatures of the columns

were maintained to within ±0.05°C by means of a water circulating bath.

The *n*-alkanes (Aldrich gold label) were distilled and passed through a column of activated alumina to remove polar impurities. The *n*-alkanes were injected into the column by drawing in and expelling the vapour over the liquid into Hamilton 10 μL and 1 μL syringes. The vapour remaining in the needle (corresponding to about 10^{-5} mm^3 of liquid hydrocarbon) was expelled when the needle was heated in the injection port. The dead volumes of the columns were determined by simultaneously injecting methane, which was not retained by the bleached kraft stationary phases. The external surface areas of the bleached kraft samples after drying from 90% RH are listed in Table 1. These were measured from finite concentration GC results for *n*-decane (6).

Results and discussion

The peak shapes for all the hydrocarbons on the various bleached kraft papers were symmetrical, with net retention volumes that were independent of sample concentration. This indicates that the Henry's law region was attained.

The partition coefficients at different temperatures, calculated from the net retention volumes and the bleached kraft surface areas (Table 1) according to eq. [1] are listed in Table 2.

TABLE 3. Comparison of chromatographic routes to measure relative surface areas

[b]From data in Table 1, from ref. 6.

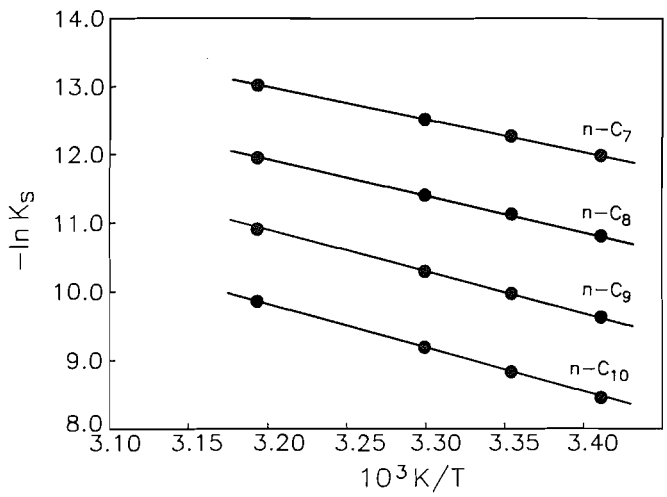

FIG. 1. The variation of the surface partition coefficient with temperature for the *n*-alkanes on Q90 unbeaten bleached kraft at 20°C.

The reproducibility of the coefficients was about 2% for each column. The accuracy of the coefficients depends on the net retention volume and the surface area determined by finite concentration GC. Although the reproducibility in retention volumes for different columns is ~3%, the errors in estimating the surface areas by finite concentration GC are rather large (~5%).

For surfaces with the *same surface composition*, eq. [1] indicates a simple approach for the determination of relative surface areas. The ratio of the specific retention volumes at infinite dilution for two separate columns yields the relative surface areas; these may be compared with relative areas from finite concentration GC (Table 3). The two independent methods give reasonable agreement. Thus the infinite dilution method provides a quick way of determining surface areas with a single injection.

Thermodynamics of adsorption

The temperature dependence of the surface partition coefficient is illustrated for the hydrocarbon probes on the unbeaten Q90 bleached kraft sample in Fig. 1. The differential heats of adsorption, q_d, were obtained from the least-squares determination of the slopes, according to eq. [4]. The standard deviations of the slopes were 2% to 3%.

The standard free energies of adsorption were calculated from eq. [2] using the de Boer standard state for spreading pressure. From the difference in ΔG_A^0 and $-q_d$, standard entropies of adsorption at zero coverage were calculated (eq. [5]). These

TABLE 5. Free energies of adsorption per mole of methylene group $\Delta G^0_{A(CH_2)}$ (kJ mol^{-1}) on bleached kraft papers at 20°C

Adsorbent	$\Delta G^0_{A(CH_2)}$ (kJ mol^{-1})
Q90	2.87 ± 0.01
Q90-3M	2.87 ± 0.02
Q90-6M	2.90 ± 0.01
Q90-9M	2.92 ± 0.02
Q90-11M	2.92 ± 0.03

thermodynamic parameters are tabulated in Table 4 for the unbeaten Q90 and the beaten Q90-9M sample at 20°C. The table also includes the heats of liquefaction, ΔH^0_L, for the alkane probes (14). The low heats of adsorption at zero coverage indicate a virtual absence of high-energy sites; the fact that these heats approach the heats of liquefaction indicates the weak physical adsorption of the *n*-alkanes. Thus the bleached kraft surfaces are energetically homogeneous towards saturated alkane adsorption. The values for K_s and the thermodynamic functions on the different paper surfaces are rather scattered, but no significant trend with beating is observed as only the surface area changes and not the chemical composition. The values are similar to those for *n*-alkane adsorption on cellophane (regenerated cellulose) (13) and pure cotton cellulose (8). This is expected as the bleached kraft paper surface is predominantly also almost pure cellulose.

The loss of one translational degree of freedom during the adsorption process results in a decrease in the entropy of the gas molecules. For an ideal gas adsorbate, the magnitude of the entropy loss may be estimated from the simple de Boer model (9). The predicted entropy changes for adsorption of heptane, octane, nonane and decane at 20°C are −52.4, −53.0, −53.5, and −53.9 J K^{-1} mol^{-1}, respectively. The experimental $\Delta\bar{S}_A$ values for Q90 samples are numerically larger than these values. The additional loss of entropy may be attributed to some hindered vibrational and rotational motions of the adsorbed alkanes.

Incremental thermodynamic quantities

The values of the thermodynamic functions (Table 4) vary linearly with the number of carbon atoms. For example, for the Q90-9M sample there is a constant increase of 5.5 ± 0.1 kJ mol^{-1} for the differential heat of adsorption. Constant increments of −2.9 kJ mol^{-1} and −9.0 ± 0.3 J K^{-1} mol^{-1} are observed for $\Delta\bar{G}^0_A$ and $\Delta\bar{S}^0_A$, respectively. The linear variation in $\Delta\bar{G}^0_A$ with

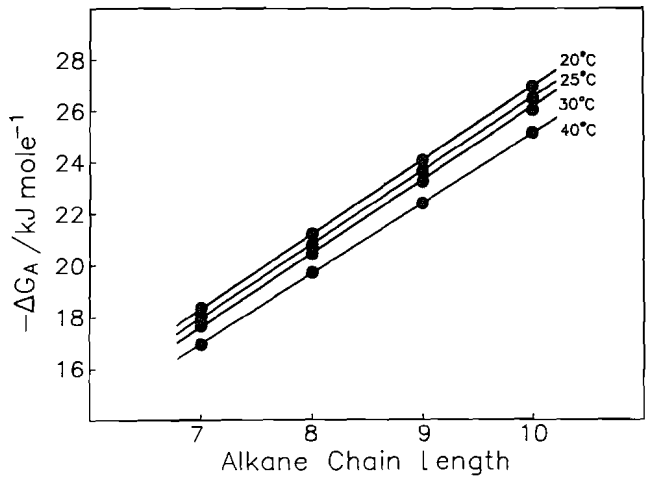

FIG. 2. The standard free energy of adsorption for *n*-alkanes on Q90 unbeaten bleached kraft at four column temperatures as a function of the number of carbon atoms in the hydrocarbon chain.

the number of carbon atoms *n* is illustrated for the unbeaten sample in Fig. 2. This behaviour is analogous to Traube's rule, and the constant increments with carbon number are consistent with a flat orientation on the surface. However, these measurements are made at extremely low surface coverage on dry paper, which has a low surface area (Table 1) and is therefore relatively non-porous. The adsorption process may be quite different at high coverages or on highly porous cellulose surfaces.

The free energies of adsorption per methylene group were calculated according to eq. [6] and are tabulated for the kraft samples at 20°C in Table 5. The values correspond to the constant increments in $\Delta\bar{G}^0_A$ in Table 4.

The London nonpolar component of the surface free energy at 20°C, γ^L_s, was calculated from eq. [9] employing the values of $\Delta\bar{G}^0_{A(CH_2)}$. The average value for all samples was 47.9 ± 2.4 mN m^{-1}. This is close to the value for cotton cellulose (49.9 mN m^{-1}) (8) and somewhat larger than the value for a less dense regenerated cellulose (42.0 mN m^{-1}) (13).

The barriers to molecular rotations in the low temperature crystal phase of ferrocenecarbaldehyde, (η^5-C_5H_5)Fe(η^5-C_5H_4CHO), have been measured using proton spin-lattice relaxation methods and assigned to different motions, based on the results of non-bonded atom–atom potential calculations. The principal relaxation is interpreted in terms of a Cole–Davidson distribution of correlation times, and assigned to rotation of the unsubstituted ring, with an activation energy of 15.3 kJ mol^{-1}. Other relaxation processes, observed via T_{1D} measurements, include rotation of the aldehyde group and oscillations of the whole molecule, with barriers of 42.4 and 25.6 kJ mol^{-1}, respectively.

RICHARD J. PAZUR, D. F. R. GILSON, PIERRE D. HARVEY et IAN S. BUTLER. Can. J. Chem. **65**, 1940 (1987).

Utilisant des méthodes de relaxation de réseau spin–proton, on a mesuré les barrières à la rotation moléculaire dans la phase cristalline de basse température du ferrocènecarbaldéhyde, (η^5-C_5H_5)Fe(η^5-C_5H_4CHO), et, en se basant sur les résultats de calculs de potentiels atome–atome non-liés, on les a attribuées aux divers mouvements qui se produisent dans le cristal. On interprète la relaxation principale en fonction d'une distribution de Cole–Davidson des temps de corrélation et on l'attribue à la rotation du noyau qui n'est pas substitué; une énergie d'activation de 15,3 kJ mol^{-1} lui est associée. Parmi les autres processus de relaxation qui ont été observés grâce à des mesures de T_{1D}, on note la rotation du groupement aldéhydique et les oscillations de la molécule dans son ensemble auxquels sont associés des barrières respectives de 42,4 et 25,6 kJ mol^{-1}.

[Traduit par la revue]

Introduction

The bonding and stereochemistry of compounds of unique structure has always been of interest to chemists (1). A particular example is that of ferrocene, where the initial problem of determining the molecular structure (2) has evolved to one of understanding the behaviour of the different crystal forms (3–7). Molecular dynamics are important, since rotation of the cyclopentadienyl rings plays a large role in determining the interactions in the solid phase (8–10). Surprisingly, the introduction of a carbonyl group to give ferrocenecarbaldehyde results in a material that undergoes an order–disorder phase transition at 317 K, with a high entropy of transition of 37.4 J K^{-1} mol^{-1}. Thus the behaviour resembles that of some organic molecular crystals rather than other metallocene derivatives (11). Studies of the crystal structures of both the high- and low-temperature phases have been reported (12–14). According to Leadbetter and co-workers (12, 13), the low-temperature phase is orthorhombic and the high temperature one is face-centered-cubic, but a later study (14) concluded that while the room temperature structure was basically correct, there is a disorder whereby 15% of the molecules are twisted by 36° about the molecular axis. The structure of the high-temperature phase has also been disputed, and Sato and co-workers (14) have claimed that, while the orthorhombic symmetry is maintained, there is an expansion along one crystal axis by 50%.

The molecular dynamics of ferrocenecarbaldehyde have been studied using quasielastic and inelastic neutron scattering methods (15) and interpreted in terms of a hindered rotation of the unsubstituted ring in the ordered phase, and a variety of motions with barriers ranging from less than 6 kJ mol^{-1} to ca. 20 kJ mol^{-1} in the high-temperature phase. However, different treatments of the quasielastic neutron scattering in the ordered phase gave different values for the barrier to rotation: 15 ± 2 kJ mol^{-1} and 22 ± 2 kJ mol^{-1}. By analogy with ferrocene itself, the inelastic neutron scattering peak at 57 cm^{-1} was assigned to the torsional vibration of the ring, leading to a barrier height of 8 kJ mol^{-1}, or, alternatively, if a peak at 80 cm^{-1}, observed in the inelastic scattering spectra at lower temperatures was assigned to this mode, then a barrier of 16 kJ mol^{-1} was obtained.

A determination of the activation energies for molecular motions in ferrocenecarbaldehyde by a different technique seemed appropriate. A study of the behaviour of ferrocenecarbaldehyde by proton spin-lattice relaxation time measurements complements our other studies of ring dynamics in π-arene complexes (16–19) and Raman (20) and XPS (21) studies of a series of ferrocenyl compounds. The properties of substituted ferrocene derivatives are of current interest in the development of chemically derivatised electrodes for photoelectric energy conversion systems (22). At the time that our results were complete, Nakamura and co-workers (23) reported the results of a proton spin-lattice relaxation time study in which they determined activation energies for three different processes in the low-temperature phase. These were assigned to rotation of the unsubstituted ring and to a small angle rotation of the whole molecule. The experimental results are confirmed in the present study, but our interpretation of the results is, however, different.

Experimental

Ferrocenecarbaldehyde was obtained from Aldrich Chemicals and was purified by slow sublimation under reduced pressure (0.1 Torr, 25°C). Proton spin-lattice relaxation times were measured, by the inversion recovery method (180°–t–90°) for T_1 and the Jeener–Broekarts (24, 25) sequence (90°–t_1–45°–t_2–45°) for T_{1D}, using a Spin-Lock CPS2 spectrometer operating at 33 MHz. Sample temperature was controlled by a stream of heated or cooled nitrogen and measured with a digital thermometer. Potential energy calculations were done with the program POTENT, and a SIMPLEX algorithm used to fit the temperature dependence of the spin-lattice relaxation times, both programs were written in TurboPascal.

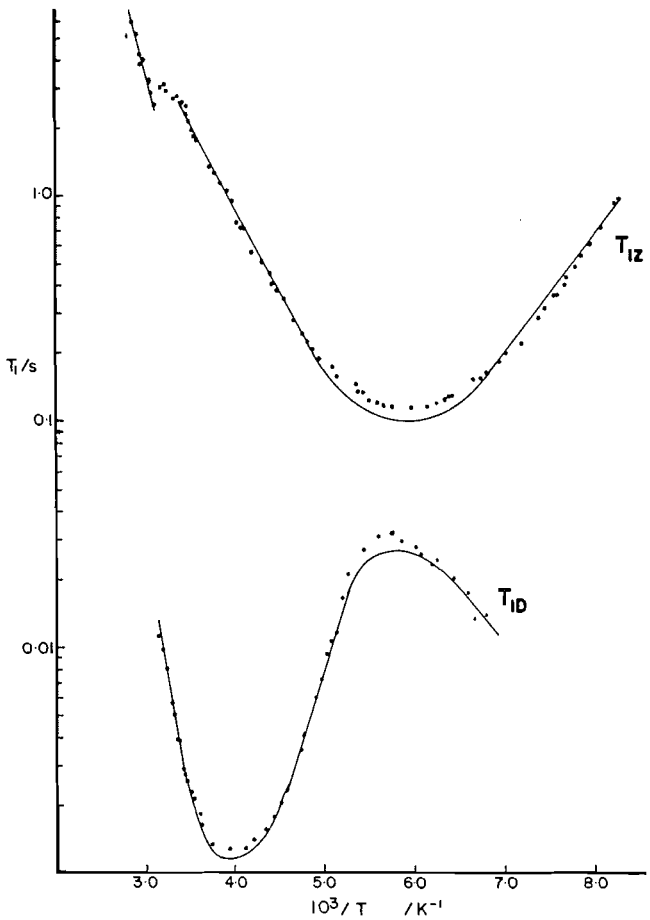

FIG. 1. Temperature dependence of the spin-lattice relaxation times, T_{1Z} and T_{1D}. The solid lines are the theoretical curves based on eqs. [3] and [4].

times is shown in Fig. 1. The phase change at 317 K is shown quite clearly by the discontinuity in T_{1Z}, and there is a change in the slope in the vicinity of 294 K. The results are in good agreement with those reported by Nakamura *et al.* (23), including the proposed second order phase change at 294 K. The existence of this phase change was not reported in two other studies (12, 26).

The usual equation for spin-lattice relaxation by a dipole–dipole mechanism is given by eq. [1];

$$[1] \quad 1/T_{1Z} = (2/3)C\tau\{1/(1 + \omega^2\tau^2) + 4/(1 + 4\omega^2\tau^2)\}$$

where $\tau = \tau_0 \exp(E/RT)$ is the correlation time for molecular reorientation, ω is the measurement frequency, and C is a constant related to the change in second moment resulting from the motion. A plot of $\ln(T_1)$ versus reciprocal temperature should give a V-shaped curve with a minimum value of T_1 occurring at $\omega\tau = 0.6158$. The high temperature limit, $\omega\tau \ll 1$, leads to a straight line with slope $-E/RT$, while the low temperature side, with $\omega\tau \gg 1$, gives a line of slope $+E/RT$. Thus the slopes on either side of the T_1 minimum should be equal. However, in the ferrocenecarbaldehyde case, while the two slopes are linear, they were not the same. This was interpreted by Nakamura and co-workers to be due to two different barriers resulting from cyclopentadienyl rings occupying different sites in the unit cell (23). This implies that different local environments must exist for two distinct sets of molecules, but the two crystallographic structure studies (13, 14) agreed that the space group is $P2_12_12_1$, in which the molecules all occupy equivalent sites. However, Sato *et al.* (14) refined their structure to include two possible molecular orientations (in the ratio 0.85:0.15) with the disordered molecules rotated by 36°. In such a case, there could be a second activation energy, but since a large contribution to the barrier arises from nearest neighbour interactions, the disordering should affect not only the disordered molecules, which, presumably, are random in position in the lattice, but also those surrounding them. Thus, there should be a distribution of barrier heights rather than two discrete barriers.

An alternative approach to the interpretation of the T_1 versus temperature behaviour assumes that a distribution of correlation times exists, $G(\tau)$, such that eq. [1] becomes

$$[2] \quad 1/T_1 = (2/3)C\left\{\int_0^a \tau G(\tau)d\tau/(1 + \omega^2\tau^2) + 4\int_0^a \tau G(\tau)d\tau/(1 + 4\omega^2\tau^2)\right\}$$

The effects of such distributions on the spin-lattice relaxation time have been investigated by Connor (27) and reviewed by Noack (28). Distribution functions such as Gaussian, log-exponential, Fuoss–Kirkwood, and Cole–Cole distributions are symmetric and, therefore, lead to the same slopes on either side of the minimum, although the shape around the minimum is changed. Since an asymmetric function is required in the present case, we have used the empirical Cole–Davidson function

$$G(\tau) = \{\sin(\alpha\pi)/\pi\}(\tau/\tau_0 - \tau) \qquad \tau < \tau_0$$
$$G(\tau) = 0 \qquad \tau > \tau_0$$

where α is a width parameter and τ_0 the mean jump time. With this distribution, T_1 is given by eq. [3]:

$$[3] \quad 1/T_1 = C\alpha\tau\left\{\frac{1}{(1 + \omega^2\tau^2)^{\alpha/2}(1 + \alpha^2\omega^2\tau^2)^{1/2}} + \frac{4}{(1 + 4\omega^2\tau^2)^{\alpha/2}(1 + 4\alpha^2\omega^2\tau^2)^{1/2}}\right\}$$

In the high temperature limit, the slope of the $\ln(T_1)$ plot remains equal to $-E/R$, but for the low temperature side, the slope is $+\alpha E/R$. Thus the value of the width parameter can be obtained from the ratio of the two slopes. Two computer fits to the experimental data were made, using a Simplex algorithm fit to eq. [3]. First, with τ_0, E, and the constant C as variables and the value of α fixed by the ratio of the slopes, and, second, with α as an additional variable parameter. The fit to the slopes is excellent, Fig. 1, with the activation energy being the same in both cases, and reasonable agreement with the two α values (Table 1). The fit to the experimental values of T_1 around the minimum is less satisfactory. The standard deviation in the Simplex fit is the same for eq. [3] and the combination of two spin-lattice relaxation times, even though more variable parameters were used in the latter case. The value of the activation energy, 15.3 kJ mol^{-1}, is in excellent agreement with the values obtained by Leadbetter and co-workers (15) from one set of quasielastic neutron scattering measurements.

In the high-temperature phase a barrier of 26.7 kJ mol^{-1} was determined from a least-squares fit. No T_1 minimum was observed, and, therefore, neither the constant C nor the pre-exponential factor could be evaluated. The barrier is somewhat higher than that determined by the neutron scattering study, and lower than the values given by Nakamura *et al.* (23), who assigned various different barriers to uniaxial rota-

tion (32 kJ mol^{-1}), self-diffusion and/or overall rotation (67 kJ mol^{-1}), and spin-rotation relaxation (11 kJ mol^{-1}).

Spin-lattice relaxation in the dipolar field

The spin-lattice relaxation time in the dipolar field is given by eq. [4];

$$[4]\quad 1/T_{1D} = C_1\tau/(1+\omega^2\tau^2) + C_2\tau/(1+4\omega^2\tau^2) + C_3\tau/(1+\omega_D^2\tau^2)$$

where C_1, C_2, and C_3 are constants and ω_D is the dipolar field (29). The observed temperature dependence shows a change of slope at 294 K (Fig. 1), which is the temperature of the second order phase transition. The T_{1D} temperature dependence between 294 and 317 K was, therefore, treated as a separate process. The activation energy of 42.4 kJ mol^{-1} is in good agreement with a barrier of 41 ± 2 kJ mol^{-1} obtained by Nakamura and co-workers (23) from T_1 measurements and assigned to a small angle reorientation about the molecular axis.

Fitting the remainder of the curve is more complicated since there are two different processes involved and, using eq. [4], a total of twelve different parameters could be varied. The minimum in T_{1D} at about 250 K was assumed to arise from the third term in eq. [3] only and a fit obtained to the experimental points in the temperature range 190 to 290 K. The calculated T_{1D} values were then subtracted from the experimental data for temperatures below 185 K and these points fitted to eq. [4] with the further assumption that $\tau \ll 1$. This fit gave an activation energy of 14.3 kJ mol^{-1} and pre-exponential term of 3.92×10^{-13} s. These values are very close to those obtained from the T_{1Z} fit using the Cole–Davidson distribution and thus the T_{1D} behaviour in the lowest temperature region was identified with the rotation of the unsubstituted cyclopentadienyl ring. Therefore the final fitting procedure involved varying only C_1 and C_3, with the activation energy and pre-exponential term at those values obtained from the T_{1Z} study (14.83 kJ mol^{-1} and 1.42×10^{-13} s, respectively). Thus the number of variable parameters was reduced to six. The values of the various parameters are given in Table 1. The present studies give activation energies for various motions in the low-temperature phase that are in good agreement with the results of Nakamura and co-workers (23). The assignment of the different activation energies to particular molecular motions is not immediately apparent, except for the obvious case of the rotation of the unsubstituted ring.

Non-bonded atom–atom potential energies

In our earlier studies on the barriers to rotation in π-arene metal tricarbonyl complexes (17–19), non-bonded atom–atom potential calculations proved to be very useful in examining the different contributions to the overall barrier. In these cases, the internal barriers are extremely small, and, therefore, the hindrance to ring rotation is due almost entirely to intermolecular contacts. Similar calculations for ferrocenecarbaldehyde seemed appropriate in order to assign the observed barriers in the ordered phase. The known crystal structure (13, 14) was used as the input data for these non-bonded atom–atom potential calculations.

The Buckingham exp-6 potential, eq. [5], was used, with the A, B, and C parameters taken from Mirsky's compilation (30).

$$[5]\quad U(r) = Ar^{-6} - B\exp(-Cr)$$

The energy is calculated as a function of the angle of rotation of a "probe" molecule (or part of a molecule), by summing $U(r)$ over all atom pairs within a given cut-off distance. The difference between the minimum and maximum values gives the barrier height. Since we are not attempting to calculate lattice energies as such, but "potential energy environments" (31), the summation was cut-off at 10 Å, and contributions from the metal atom were omitted, as this atom lies on the molecular (rotational) axis and does not contribute to the angular dependence. The calculation is based upon a single molecule or group rotating in a rigid lattice of surrounding molecules and possible effects of cooperative motions must be examined by considering specific interactions. Furthermore, since the parameters are derived from total lattice energy calculations, heats of sublimation, elastic constants, etc., and not from fitting barriers to rotation, the choice of the parameters for the potential function is quite empirical, with the justification that these terms are considered to be transferable from one system to another (30).

First, we calculate the barrier height for the simplest mode — the rotation of the unsubstituted ring in a rigid lattice. The results are shown in Fig. 2. The contributions to the total energy are shown for ring A – ring A and ring A – ring B contributions (where ring A is the unsubstituted ring and ring B bears the carbonyl substituent). The total calculated barrier height is 14.2 kJ mol^{-1}, with the major contribution, 13.5 kJ mol^{-1}, arising from ring A – ring B interactions. The ring A – ring A contribution is less than 1 kJ mol^{-1}, which means that cooperative rotations between unsubstituted rings are unlikely, but might be important for ring A – ring B motions. The internal barrier is 0.25 kJ mol^{-1} with the minimum at about 36°, i.e. out-of-phase with the total potential. Thus the non-bonded potential minimum for an isolated molecule would be at the staggered conformation, in contrast to the crystal where the rings are nearly eclipsed (12). These calculations do not, of course, include the electronic contribution to the internal barrier. Theoretical calculations (32) showed the eclipsed conformation of ferrocene to be 2.8 kJ mol^{-1} more stable than the staggered form, in reasonable agreement with the value estimated from electron diffraction of 3.8 kJ mol^{-1} (33). The total barrier should be 17 to 18 kJ mol^{-1}, which compares reasonably well with the measured value.

The persistence of the 57 cm^{-1} peak in the inelastic neutron

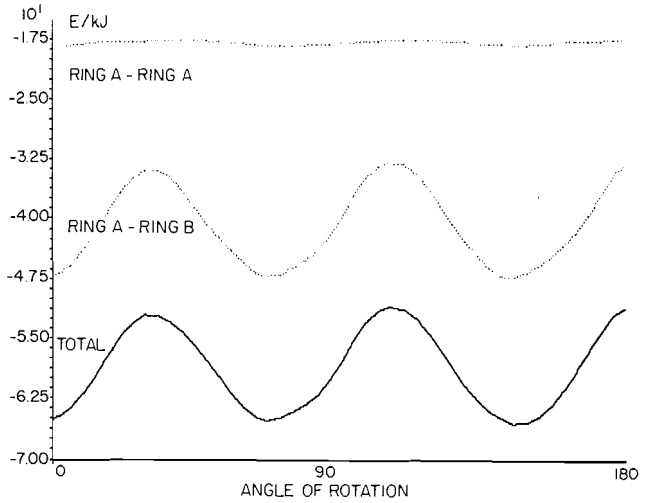

FIG. 2. Potential energy environment as a function of rotation angle of ring A.

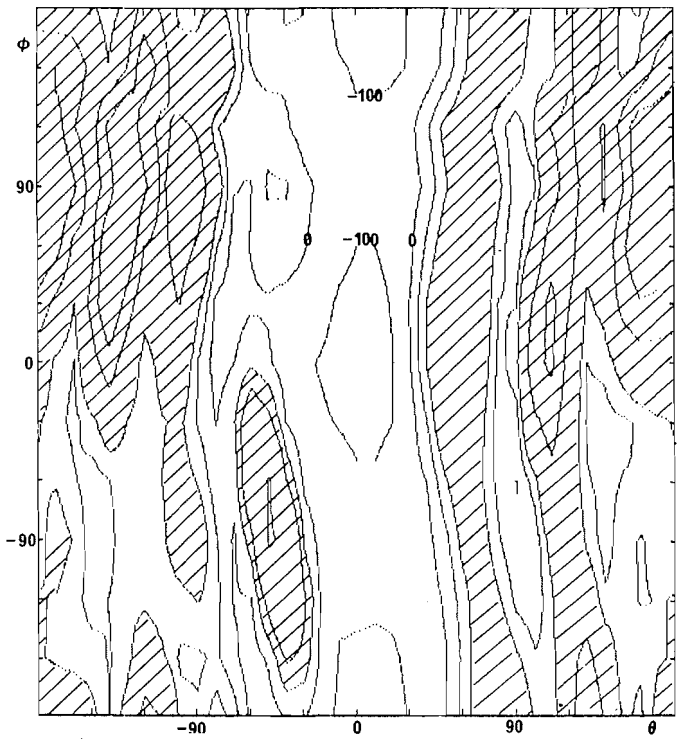

FIG. 3. Contour plot of the potential energy environment for rotations of the whole molecule, angle θ, and the carbaldehyde group, angle ϕ. Positive values of ϕ correspond to a rotation with the hydrogen atom position above the plane of the ring. The contour lines are at −100, 0, 100, 200, 400, and 1000 kJ mol^{-1}. The hatched areas are at potential energies above 200 kJ mol^{-1}.

scattering spectra of both phases led to the conclusion that the observed barrier must arise principally from internal sources (11). However, the present calculations show that the internal barrier is only 16–20% of the total and, therefore, the 57 cm^{-1} peak in the inelastic scattering spectrum should not be assigned to the torsional mode.

The two simplest possibilities for the remaining barriers are (*i*) rotation of the substituent aldehyde group and (*ii*) rotation of the whole molecule. In order to explore the possibility of a cooperative motion between whole molecule and substituent group rotations the potential energy environment was calculated for whole molecule motion at different angles of rotation of the —CHO group. The results are shown in the form of a contour plot in Fig. 3. Rotation of the carbaldehyde group corresponds to variation of the angle ϕ, with θ fixed, and rotation of the whole molecule to ϕ = 0, with θ varied. The non-bonded potential does not include electronic, i.e., bonded, contributions, but the enthalpy for substituent rotation in ferrocenecarbaldehyde in solution has been measured by proton and carbon magnetic resonance to be 31.2 kJ mol^{-1} (34) and this contribution has been added to the non-bonded potential (with the assumption that the internal barrier is a cosine function). Potential minima occur at the crystallographic coordinates and at ϕ = 180°. The latter has a total energy that is 6 kJ mol^{-1} above the true minimum with a barrier of 56 kJ mol^{-1} between the two positions. The calculated barrier to rotation of the carbaldehyde substituent should be somewhat lower since the rest of the molecule can oscillate and the actual equilibrium positions occur at non-zero values of θ. The activation energy of 41 kJ mol^{-1} observed in the T_{1D} measurements above 294 K is, therefore, assigned to the aldehyde group rotation and not to small angle motion of the whole molecule.

For the whole molecule rotation there is a very broad region around the equilibrium position in which the energy increases only slowly over an angle of ±20°. A small angle motion of the whole molecule about a pseudo C_5 axis may be most probable candidate for the small second moment change between 210 and 290° (23) and the motion with an activation energy of 26 kJ mol^{-1}. Also, there are several different minima in the angular dependence at ϕ = 0, with the lowest occurring at −75°. This is actually part of a trough with a negative calculated potential energy environment and a minimum located at θ = −65° and ϕ = 26°. The presence of the second minimum is significant since it can trap the molecule in a second site, and thus provides an alternative molecular orientation in a metastable state. Other minima occur at higher potential energies (the unshaded regions in Fig. 3) and population of these could provide a mechanism whereby the disordering process can occur when ordered crystal is heated and, furthermore, it is possible that molecules could be trapped in these positions if the sample is cooled rapidly from the plastic phase. This may account for the difficulties associated with the Dsc and Dta studies (12, 26).

The products of the reaction of thiiranium ions with competing nucleophiles

GEORGE H. SCHMID,[1] MARK STRUKELJ, AND SNEZANA DALIPI
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received January 15, 1987

This paper is dedicated to Professor John T. Edward

GEORGE H. SCHMID, MARK STRUKELJ, and SNEZANA DALIPI. Can. J. Chem. **65**, 1945 (1987).

The reaction of the stable thiiranium ion, prepared by the reaction of trifluoromethanesulfonic acid and methyl-3-(4-chlorophenylthio)propene with tetraethylammonium chloride in either 3.5 or 36% v/v methanol/dichloromethane with urea as a buffer, forms 2-methoxy-2-methyl-1-propyl 4-chlorophenyl sulfide, 2-chloro-2-methyl-1-propyl 4-chlorophenyl sulfide, and 1-chloro-2-methyl-2-propyl 4-chlorophenyl sulfide as products. While these same products are formed by the addition of 4-chlorobenzenesulfenyl chloride to methylpropene in the same solvents, their proportions differ. This is one of the rare examples in which there is a difference in the product composition of thiiranium ions formed in different ways and allowed to react under identical conditions. One possible explanation for this difference may be that the two thiiranium ions form products by different paths involving different kinds of ion pairs.

GEORGE H. SCHMID, MARK STRUKELJ et SNEZANA DALIPI. Can. J. Chem. **65**, 1945 (1987).

La réaction de l'acide trifluorométhanesulfonique avec le méthyl-3 (chloro-4 phénylthio) propène fournit l'ion thiiranium stable qui, par réaction avec le chlorure de tétraéthylammonium dans un mélange à 3,5 ou à 36% v/v de méthanol dans le dichlorométhane et en présence d'urée comme tampon, conduit à la formation de (chloro-4 phénylthio)-1 méthoxy-2 méthyl-2 propane, de (chloro-4 phénylthio)-1 chloro-2 méthyl-2 propane et de (chloro-4 phénylthio)-2 chloro-1 méthyl-2 propane. L'addition du chlorure de chloro-4 benzènesulfényle au méthylpropène conduit aux mêmes produits; toutefois, leurs proportions diffèrent. Ce cas représente un des rares exemples dans lesquels on note une différence dans la composition des produits qui se forment à partir d'ions thiiranium produits de façons différentes, mais que l'on a fait réagir dans des conditions identiques. Pour expliquer ces différences, on peut imaginer que les deux ions thiiranium forment des produits par des voies différentes impliquant des formes différentes de paires d'ions.

[Traduit par la revue]

Thiiranium ions[2] are postulated as intermediates in the (*i*) solvolysis of β-chloroalkyl aryl sulfides, (*ii*) alkylation of thiiranes, and (*iii*) addition of alkane- or arenesulfenyl derivatives to alkenes (2). They can be prepared and isolated by variations of the reactions in which thiiranium ions are proposed as intermediates (3). The difference is that to form a stable thiiranium ion, the counterion must be a very poor nucleophile to ensure that it will not react with the thiiranium ion. Despite claims to the contrary (4), the products of the reaction of these stable thiiranium ions with nucleophiles are similar in many respects to those formed in the addition reactions of alkane- and arenesulfenyl chlorides to alkenes.

Both are capable of undergoing reactions that involve skeletal rearrangements. For example, the stable thiiranium ion **1** reacts with nucleophiles to form products of 1,5 hydride shift (5). Rearranged products are formed after allowing the stable ion **2** to stand for 1.5 h before it is reacted with chloride ion (6). Rearranged products are also formed by the addition of arenesulfenyl chlorides to alkenes. The reaction of 2,4-dinitrobenzenesulfenyl chloride and norbornene in formic acid forms rearranged solvent-incorporated products (7). Clearly there are examples in the literature where both stable thiiranium ions and intermediates involved in the addition of sulfenyl halides to alkenes form rearranged and (or) solvent-incorporated products.

A second similarity is that nonstereospecific products are formed in both the reaction of stable thiiranium ions with nucleophiles and the addition of arenesulfenyl chlorides to alkenes. The reaction of the isomeric stable ions **4** and **5**

[2]The term "thiiranium ion" has been and is used to designate the positively charged three-member sulfur containing ring irrespective of the location of the counter ion. This is analogous to the original practice of Winstein *et al.* (1) who referred to the carbocation portion of all ion pairs as varieties of carbonium ions.

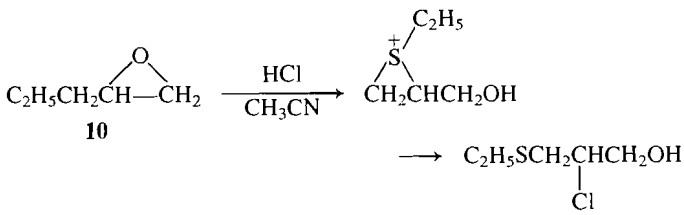
8

with acetic acid at room temperature gives the same mixture of *erythro*-(**6**) and *threo*-(**7**) products (8). Nonstereospecific products are also formed by the addition of 2,4-dinitrobenzenesulfenyl chloride to *E*- and *Z*-anethole (9) and 4-methoxy-β-deutereostyrene (10).

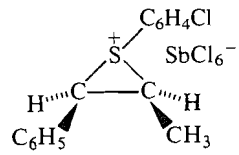
A third similarity is the regiochemistry of the products formed in the two reactions. The stable thiiranium ion **8** forms the same proportion of regioisomers as formed by the addition of 4-chlorobenzenesulfenyl chloride to methylpropene when the two reactions are carried out in the same solvent and at the same temperature (11).

The fourth similarity is the ability of a thiiranium ion, either a stable one or one postulated as an intermediate, to react with chloride ion rather than the solvent. The absence of solvent-incorporated products in the addition of arenesulfenyl chlorides to alkenes has been recognized (4) but the fact that stable thiiranium ions can also discriminate between chloride ion and solvents as nucleophiles seems to have escaped notice. Thus, lithium chloride reacts with the stable thiiranium ion **3** in acetonitrile/dichloromethane to form products of attack by both chloride ion (80%) and acetonitrile (5%) (12). Only products of the reaction of chloride ion are reported for the reaction of the stable ion formed by the reaction of the epoxysulfide **10** with HCl in acetonitrile (13). Thus stable ions, like their counterparts in the addition reaction, react preferentially with the stronger nucleophile.



10

However, differences between the reactions of stable thiiranium ions and those proposed as intermediates have been cited (4). It has been stressed that the reaction of 4-chlorobenzenesulfenyl chloride with *E*- and *Z*-2-butene gives different products by *anti*-stereospecific addition (14) while the reaction of stable ions **4** and **5** with acetic acid gives the same product mixture. While this is a clear difference, it must be pointed out in all fairness that the two reactions occur under very different conditions. The addition reaction occurs instantly in 1,1,2,2-tetrachloroethane at 25°C.[3] In contrast, the stable ions **4** and **5** were allowed to stand for 1.5 h at 20°C before reacting them with acetic acid. A thiiranium ion that is allowed to stand for long periods of time in the absence of a good nucleophile has a high kinetic stability (16) and it can undergo reactions that are not available to a thiiranium ion intermediate formed in the presence of a good nucleophile. This has been demonstrated by the reaction of the thiiranium ion **10** (17). The time between formation of **10** and its reaction with added chloride ion has a great effect on the stereochemistry of the product even at −70°C. Thus allowing **10** to stand for a short time before reacting it with chloride ion results in products formed predominantly via a thiiranium ion. When the ion is allowed to stand for longer times before reacting it with chloride ion, products are formed via an open β-chloroalkyl carbocation. Thus the reactions of stable thiiranium ions are not necessarily good models for the intermediates in the addition of arenesulfenyl chlorides to alkenes.



10

The major problem in making comparisons between the reactions of stable thiiranium ions and those proposed as intermediates is the paucity of data available under identical conditions. It is our contention that meaningful conclusions about differences and (or) similarities of the reactions of stable thiiranium ions and thiiranium ion intermediates cannot be reached unless comparisons are made from reactions carried out under identical experimental conditions. The purpose of this paper is to determine if there really is a difference in the product composition of the reaction, *under identical conditions*, of two competing nucleophiles, chloride ion and methanol, with both a stable thiiranium ion and one formed as an intermediate in the addition of arenesulfenyl chlorides to alkenes.

Results and discussion

The thiiranium ion *S*-(4-chlorophenyl)-2,2-dimethylthiiranium trifluoromethanesulfonate, **11**, was prepared by dissolving methyl 3-(4-chlorophenylthio)propene, prepared by the reaction of sodium 4-chlorothiophenoxide and methallyl chloride in methanol, in hexane and adding the resultant solution slowly to trifluoromethanesulfonic acid (11). A solution containing tetramethylammonium chloride, urea, and methanol (3.5 or 36 v/v%) in dichloromethane was added to the stable ion. The product composition of this reaction was compared to that obtained by the addition of 4-chlorobenzenesulfenyl chloride to methylpropene under the same conditions of solvent composition, added urea, and temperature. The data are given in Table 1.

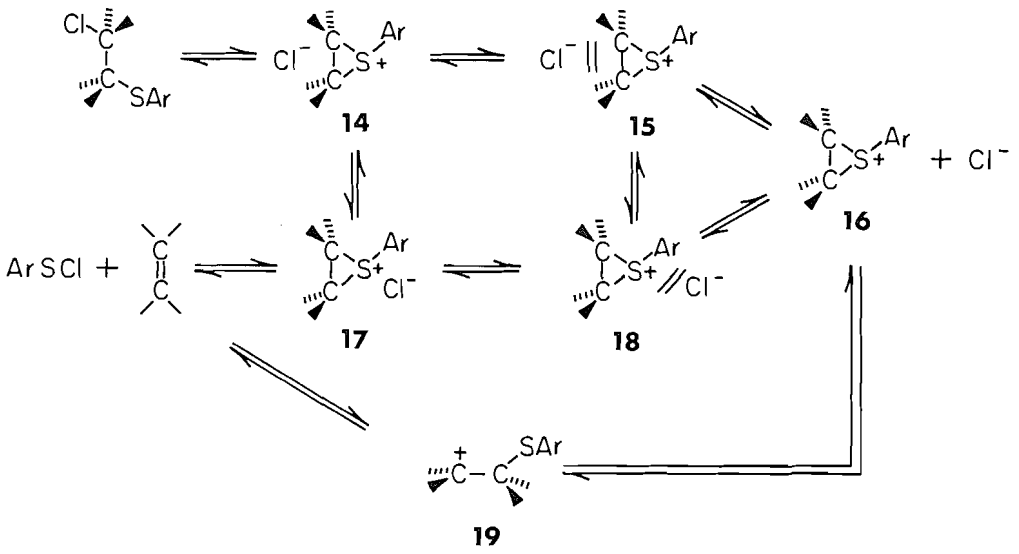
The first point to notice about the data in Table 1 is that the addition of 4-chlorobenzenesulfenyl chloride to methylpropene forms substantial amounts of the solvent-incorporated product 2-methoxy-2-methyl-1-propyl 4-chlorophenyl sulfide (**12**) even at low methanol concentrations. Before concluding that the intermediate thiiranium ion does indeed react with the solvent, it is necessary to consider other possible routes to **12**. One way that **12** could be formed is by methanolysis of the normal chloro adducts. To eliminate this path, it is necessary to know how rapidly methanolysis of the normal adducts occurs. The product compositions of methanolysis of the chloro adducts as a function of time are given in Table 2. After 5 min of methanolysis in 36 v/v% methanol only 4% **12** is formed. Clearly the rate of methanolysis of the adducts is much slower than the rapid addition of 4-chlorobenzenesulfenyl chloride to methylpropene.

Another way that **12** could be formed is by the addition to the double bond of the sulfenate ester ($ArSOCH_3$), known to be formed by the reaction of sulfenyl halides and methanol (18). This seems unlikely for the following reasons. The rate constant for the reaction of 4-chlorobenzenesulfenyl chloride and methanol in dichloromethane at 25°C for concentrations of methanol of 6.4% or lower is $1.48 \pm 1.3 \times 10^{-4}$ s^{-1} (19). This rate constant is much slower than that for the addition of 4-chlorobenzenesulfenyl chloride to methylpropene in dichloromethane at 25°C ($k_2 = 551$ M^{-1} s^{-1}). Therefore under these conditions a carbon–carbon double bond is a much better nucleophile than methanol towards bivalent sulfur (21). Consistent with these rate data is the fact that the reaction of arenesulfenyl chlorides with alkenols occurs only at the double bond (22). Therefore the only logical conclusion is that the intermediate thiiranium ion reacts with methanol to form **12**.

A second point to notice about the addition reaction is that the Markownikoff isomer **12** is the only solvent-incorporated product formed. Rapid acid-catalyzed isomerization of the anti-Markownikoff to the Markownikoff solvent-incorporated product **12** is probably not an explanation of this fact since in our work the addition reaction was carried out in the presence of an excess of urea to capture the HCl generated. It is also known that the reaction of stable thiiranium ion **11** with methoxide ion forms only **12** (23). Thus the Markownikoff isomer seems to be the kinetically controlled product.

It is surprising to find that a thiiranium ion reacts with methanol at only the most substituted carbon. One possible explanation for the formation of only **12** is that different nucleophiles react with thiiranium ions at different sites. Thus hard nucleophiles such as methanol react with the harder, more substituted, carbon while softer nucleophiles react with the softer, less substituted, carbon of **11**. It is also possible that **12** is formed via the open β-arylthio carbocation **13** rather than **11**. The products of addition to methylpropene cannot provide the necessary stereochemical information about the products that would prove the presence of an open ion in the mechanism of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.



SCHEME 1

this reaction. But whatever the reason, the fact remains that the reaction of methanol with either the stable ion **11** or the intermediate in the addition reaction forms the *same* product.

The product compositions given in Table 1 for the addition of 4-chlorobenzenesulfenyl chloride to methylpropane are those of kinetic control. This was established by carrying out the following experiment. A solution of the alkene in 36 v/v% methanol/dichloromethane containing a fivefold excess of urea was divided into equal halves. To one half was added a 3:1 mixture of the anti-Markownikoff/Markownikoff adducts. An equal quantity of sulfenyl chloride was added to each solution and the products were analyzed by glc. The ratio of anti-Markownikoff/Markownikoff adducts in the solution to which adducts were added was found to be equal within experimental uncertainty to that expected if no isomerization of the added adducts occurred.

While **12** is formed in both reactions, the amount of this product depends on the reaction. The reaction of **11** with 36 v/v% methanol/dichloromethane forms 64.6% **12** while only 25% of **12** is formed in the addition reaction in the same solvent. Similarly, the relative amounts of 1-chloro-2-(4-chlorophenylthio)-2-methylpropane depend on the reaction. Furthermore, the regiochemistry of the chlorine-containing products is predominately Markownikoff in both reactions. This is in contrast to the usual addition of arenesulfenyl chlorides to methylpropene where the kinetically controlled product has the anti-Markownikoff orientation. The data presented here, obtained for both reactions under identical conditions, provide one of the few examples of a difference between the reactions of stable thiiranium ions and those proposed as intermediates.

What is the cause of this difference? One possible explanation may be that different types of ions or ion pairs are involved in the two reactions. The importance of ion pairs in the mechanism of many reactions is well documented (24). Electrophilic additions are no exception. A number of people have proposed that the mechanism of an electrophilic addition reaction could involve ion-pair intermediates (25). Subsequent work by Rolston and Yates (26) and Garnier and Dubois (27) established the importance of ion pairs in the bromination of alkenes. In 1973, Fitzgerald provided evidence that the mechanism of the electrophilic addition of arenesulfenyl chlorides to alkenes and the mechanism of neighboring sulfur participation in the reaction of β-chloroalkyl aryl sulfides both involve the same series of thiiranium ions (28). The major features of the mechanism that we proposed is shown in Scheme 1 (2). The upper sequence of reactions involving ion pairs **14** and **15** and ion **16** is the general solvolysis scheme proposed by Winstein.[4] The lower sequence of ion pairs is similar to that proposed by Poutsma and Kartch (25*c*) and applied to additions of arenesulfenyl chlorides by Zefirov and co-workers (4). The ion pairs **14** and **17** are contact ion pairs and **15** and **18** are solvent-separated ion pairs that differ only in the location of the counterion. Also included in this scheme is the open ion **19**. Our contribution to this mechanism was to provide evidence that these two paths are linked by ion pairs **14** and **17**, **15**, and **18**, and (or) the dissociated ion **16**. We propose in this scheme that electrophilic addition of arenesulfenyl chlorides to alkenes, isomerization of Markownikoff–anti-Markownikoff adducts, and solvolysis of β-chloroalkyl aryl sulfides all occur by means of a common mechanism (2).

While there is evidence in the literature for all of these ion pairs, this does not mean that they are all involved in every reaction. For example, the anti-Markownikoff to Markownikoff isomerization of the adducts of arenesulfenyl chlorides to alkenes is known to occur much faster than their acetolysis (15). A similar conclusion can be reached from the methanolysis data given in Table 2. Similarly, anti-Markownikoff to Markownikoff isomerization occurs faster than the transfer of ArSCl from one alkene to the other in the nonpolar solvent 1,1,2,2-tetrachloroethane (20). From these data we can conclude that internal return from ion pair **14** is faster than formation of **15**. Thus the mechanism of isomerization of the adducts involves ion pair **14** while their solvolysis occurs by means of ion pair **15** and (or) ion **16**. We can also conclude from these data that ion pairs **14** and **17** play an important mechanistic role in the isomerization, exchange, and addition reactions in non-

[4]For a summary and complete references to Winstein's work on ion pairs see ref. 29.

hydroxylic nonpolar solvents. Therefore the contact ion pairs **14** and **17** are the important intermediates in the addition of arenesulfenyl chlorides to alkenes in nonpolar solvents such as acetic acid and dichloromethane. The reaction of **11** with chloride ion in dichloromethane forms a similar product mixture to that formed by the addition of 4-chlorobenzenesulfenyl chloride to methylpropene (11). Thus the contact ion pairs **14** and **17** are the important intermediates involved in the mechanism of these two reactions in dichloromethane.

As methanol or other polar solvent is added to dichloromethane, the importance of solvent-separated ion pairs increases in the mechanism of both addition of arenesulfenyl chlorides and the reaction of stable thiiranium ions. It is clear from the data in Table 1 that more of the solvent-incorporated product **12** is formed in the reaction of the stable ion **11** than in the addition reaction. From these data, we can conclude that solvent-separated ion pairs **15** and **18** and (or) ion **16** are the predominant intermediates in the mechanism of the reaction of the stable ion **11** while they play a lesser role in the mechanism of the addition reaction. The data in Table 1, data obtained from the literature, and the mechanism given in Scheme 1 allow us to explain the difference in product composition between the reaction of stable thiiranium ions and those proposed as intermediates in the addition of arenesulfenyl chlorides to alkenes. The addition of arenesulfenyl chloride to alkenes even in 36 v/v% methanol/dichloromethane occurs by a mechanism involving predominantly contact ion pairs **14** and **17**. In contrast, the reaction of stable thiiranium ions such as **11** occurs in methanol/dichloromethane predominantly by means of the solvent-separated ion pair **15**. While both reactions give the same products, their proportions are different because of the differences in their product determining steps.

In conclusion, our data provide a rare example in which there is a clear difference in the product composition of thiiranium ions formed in different ways and allowed to react under identical conditions. This difference is not in the kind but only in the relative amounts of the products, which may be due to their formation by different paths involving different kinds of thiiranium ion pairs.

Experimental

The ^{1}H nmr spectra were recorded on Varian T-60, XL-100, or XL-200 spectrometers. All chemical shifts are relative to TMS. Gas–liquid chromatography was carried out on a Varian 2700 Aerograph equipped with a flame ionization detector using a Varian CDS 111 digital integrator to obtain peak areas. Analysis was carried out using a 5% QF-1 on Chromosorb in a 2 m × 2 mm silanized glass column at 120°C with a flow rate of 24 mL/min.

All solvents used were ACS grade. Dichloromethane was further purified by distillation after refluxing over P_2O_5. Methanol was purified by distilling from magnesium turnings. All solvents were shielded from light and stored over 3 Å molecular sieves that had been activated by heating at 220–300°C for 8–12 h. All reactions were carried out under an atmosphere of argon.

Methyl-3-(4-chlorophenylthio)propene was prepared as previously reported (11).

*S-(4-Chlorophenyl)-2,2-dimethylthiiranium trifluoromethanesulfonate, **11***, was prepared as previously reported (11).

Methanolysis of Markownikoff and anti-Markownikoff adducts

To a solution of 22.5 mL of dry dichloromethane containing 0.0448 g (7.48 mmol) of urea and 0.3515 g (1.50 mmol) of *anti*-Markownikoff and Markownikoff adducts (ratio 3:1) was added 12.5 mL of dry methanol. Each reaction was then stirred at 25°C for the appropriate time before it was quenched by the addition of 35 mL of distilled water. The layers were separated and the organic layer was washed with water (3 × 25 mL). The layers were separated and the organic layer was dried over $MgSO_4$, filtered, and the solvent removed by rotary evaporation. The resulting liquid was analyzed by either nmr (solvent $CDCl_3$) or glc.

*Reaction of thiiranium ion **11** with chloride ion and methanol*

To 30 mL of a methanol/dichloromethane solution containing 36% methanol by volume was added 3.40 g (56.7 mmol) of urea and 0.570 g (3.45 mmol) of tetramethylammonium chloride. This solution was stirred at 25°C for several minutes and then **11**, prepared as previously reported, was added. The reaction was immediately quenched by the addition of 30 mL of water. The layers were separated and the organic layer was washed with water (3 × 20 mL). The organic layer was dried over $MgSO_4$, filtered, and the solvent removed by rotary evaporation. The resulting liquid was analyzed by either nmr (solvent $CDCl_3$) or glc.

Hydration of acylimidazoles: tetrahedral intermediates in acylimidazole hydrolysis and nucleophilic attack by imidazole on esters. The question of concerted mechanisms for acyl transfers

J. Peter Guthrie[1] and David C. Pike

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received November 17, 1986

This paper is dedicated to Professor John T. Edward

J. Peter Guthrie and David C. Pike. Can. J. Chem. **65**, 1951 (1987).

Heats of hydrolysis have been measured for three acylimidazole acetals. From these results free energies of formation in aqueous solution have been calculated for the acetals and the corresponding tetrahedral intermediates. Having free energies of formation for the tetrahedral intermediates allows a detailed analysis of the energetics of both the unobservable nucleophilic reaction of imidazole with ethyl acetate and also the observable reaction of imidazole with *p*-nitrophenyl acetate. pK_a values of 1-(3-aminopropyl)-imidazole and 1-(2-aminoethyl)-imidazole have been determined to allow calculation of the σ^* value for the imidazolyl substituent. The dependence of imidazole pK_a values on the electron-withdrawing properties of the 1-substituent was also determined. There is a linear free energy relation between the free energy change for replacement of OH in a carbonyl hydrate by imidazolyl and the sum of the σ^* values for the other substituents. The implications of these results for the question of concerted versus stepwise mechanisms for the reactions of imidazole with aryl acetates have been examined. An equilibrium constant has been calculated for the addition of imidazole to *p*-nitrophenyl acetate. A simple extension of Marcus theory allows the free energy surface for a three-dimensional reaction coordinate diagram to be calculated using the energy levels of the tetrahedral intermediate determined in this work, the energy level of the acylium ion derived from literature data, and intrinsic barriers for the edge reactions. It is shown that the reaction of imidazole with *p*-nitrophenyl acetate probably follows a concerted path. General conclusions from this theory of concerted reactions are discussed.

J. Peter Guthrie et David C. Pike. Can. J. Chem. **65**, 1951 (1987).

On a mesuré les chaleurs d'hydrolyse de trois acétals d'acylimidazoles. À partir de ces données, on a calculé les énergies libres de formation, en solutions aqueuses, des acétals et de leurs intermédiaires tétraédriques correspondants. À l'aide des énergies libres de formation des intermédiaires tétraédriques, on peut effectuer une analyse détaillée des énergies impliquées tant dans la réaction nucléophile de l'imidazole avec l'acétate d'éthyle (réaction qui n'est pas observée) que dans la réaction observée de l'imidazole avec l'acétate de *p*-nitrophényle. Afin de permettre le calcul de la valeur σ^* du substituant imidazolyle, on a déterminé les valeurs de pK_a de l'(amino-3 propyl)-1 imidazole et de l'(amino-2 éthyl)-1 imidazole. On a aussi déterminé la relation qui existe entre les valeurs de pK_a de l'imidazole et les propriétés électroaffinitaires du substituant en position 1. Il existe une relation linéaire entre le changement d'énergie libre pour le remplacement d'un OH d'un hydrate de carbonyl par le groupement imidazolyle et la somme des valeurs σ^* des autres substituants. On a examiné les implications de ces résultats sur la question des mécanismes concertés par opposition aux mécanismes par étapes pour les réactions de l'imidazole avec les acétates d'aryles. On a calculé une constante d'équilibre pour l'addition de l'imidazole à l'acétate de *p*-nitrophényle. En se basant sur les niveaux d'énergie des intermédiaires tétraédriques qui ont été déterminés dans ce travail, sur le niveau d'énergie de l'ion acylium que l'on peut dériver des données de la littérature et sur les barrières intrinsèques des réactions se produisant aux arêtes et faisant appel à une extension simple de la théorie de Marcus, on peut calculer le diagramme de coordonnées de la surface d'énergie libre d'une réaction tridimensionnelle. On démontre que la réaction de l'imidazole avec l'acétate de *p*-nitrophényle se produit probablement par une voie concertée. On discute des conclusions générales que l'on peut tirer à partir de cette théorie des réactions concertées.

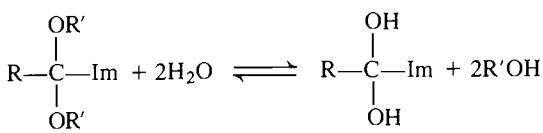
[Traduit par la revue]

Introduction

Imidazole is well known as a nucleophilic catalyst for the hydrolysis of active esters (1–4); the acylimidazole formed as an intermediate is itself rapidly hydrolyzed (2, 3). We have previously reported a thermochemical approach to determining free energies of formation of tetrahedral intermediates in aqueous solution, as well as of other reactive intermediates (5, 6).

In this paper we wish to report the results of three closely linked investigations aimed at improving understanding of the mechanisms of these reactions. We have studied the thermochemistry of acylimidazole acetals and hence determined free energies of formation in solution of the corresponding tetrahedral intermediates. We developed indirect procedures allowing the estimation of free energies of formation for tetrahedral intermediates involved in reactions of imidazole with some nitrophenyl acetates. Finally, in considering the question of whether the reactions of imidazole with active esters are concerted or stepwise, we have developed a theory of such processes, showing how criteria for "concertion" can be phrased in terms of the characteristics of the limiting stepwise reactions.

We have applied the thermochemical approach, which we previously employed for other systems, to the tetrahedral intermediates involved in hydrolysis of acylimidazoles and the nucleophilic attack of imidazoles on esters. For three acylimidazoles, acetyl, formyl, and benzoyl, we have prepared the acetals, determined the free energies of formation, and then calculated the free energies of formation of the tetrahedral intermediates by means of the hypothetical hydrolysis reaction:



This was accomplished using the previously reported linear free energy relationship (6) for the reaction:

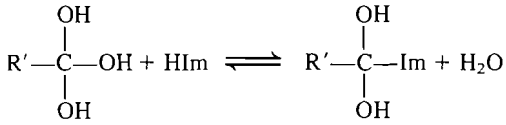
We now find that there is a similar relationship for replacement of OH by imidazolyl:



With free energies of formation of the tetrahedral intermediates formed in imidazole-catalyzed hydrolyses now in hand we can investigate the detailed energetics of these reactions. By an extension of our thermochemical calculations we can estimate the free energies of formation of the tetrahedral intermediate formed by the addition of imidazole to *p*-nitrophenyl acetate. This allows us to address the question of the mechanism of this acyl transfer reaction.

Results

Calorimetry

The starting point for the determination of the free energies of formation of tetrahedral intermediates was the determination of the heats of formation of the acylimidazole acetals, based on the calorimetric measurement of the heats of hydrolysis of the acylimidazole acetals.

Heats of reaction were measured with a simple calorimeter using the procedure previously described (7). Stoichiometries were verified by nmr analysis of product solutions and showed that in all cases hydrolysis of acylimidazole acetals in dilute acid led to the ester, one mole of alcohol, and the imidazole in its protonated form.

Our results are summarized in Table 1, which gives both the directly measured heats of reaction and the heats of reaction corrected to pure compound standard states (pure liquid or solid) for all reactants and products. The derived heats of formation are given in Table 2, which includes the other thermodynamic quantities employed in this paper.

Free energies of formation

Calculation of free energies of formation in the gas phase from the heats of formation in condensed phase required heats of vaporization and also standard entropies for the gaseous compounds. Heats of vaporization for the acylimidazole acetals were estimated by a procedure that we developed using the boiling points at reduced pressures (8), in the present case interpolated or extrapolated boiling points at 1 Torr (1 Torr = 133.3 Pa). All of the values of $\Delta H_{\text{vaporization}}$ estimated as just described are found in Table 2. Entropies were estimated by several procedures based on additivity and disproportionation (9). These calculations are found in the Appendix; the entropy values are in Table 2.

Free energies of transfer

The free energy of transfer from the gas phase (at 1 atm; 1 atm = 101.3 kPa) to aqueous solution (1 *M* with an infinitely dilute reference state) could sometimes be measured directly or indirectly and sometimes calculated from the solubility and vapor pressure. For benzoylimidazole dimethyl acetal it was possible to determine the solubility in aqueous sodium hydroxide solution, although there was a slow hydrolysis reaction. Extrapolation to zero time allowed calculation of the actual solubility. From the boiling point data gathered to evaluate the heat of vaporization, the vapor pressure at 25°C could be calculated by a procedure that we recently reported (8). This procedure uses the available vapor pressure data and values of the heat of vaporization and heat capacity of vaporization (estimated using our atomic additivity parameters (10)). The value so obtained was $p_{25°C} = 6.22 \times 10^{-4}$ Torr. We could then calculate the free energy of transfer as -5.73 ± 0.30, with the error limits based on an estimated uncertainty of 50% in the vapor pressure.

For formylimidazole diethyl acetal, the solubility was too high for ideality to be assumed, and was in fact critically dependent on temperature and ionic strength. A solution of 1.54 *M* formylimidazole diethyl acetal in 0.1 *M* NaOH at about 4°C separated into two phases upon warming to room temperature, while at 0.075 *M* NaOH the same proportions of acetal and water gave a homogenous solution from 4 to 25°C. The free energy of transfer for formylimidazole diethyl acetal was estimated indirectly as follows. The solubility was difficult to measure experimentally because of the phase separation behavior with small changes in temperature or salt concentration; this implies that we are dealing with a pair of nearly miscible liquids, with considerable deviations from ideality. To estimate the ideal solubility, we used the relationship reported by Hansch *et al.* (11) between solubility and the partition constant between water and 1-octanol. We have in fact measured the partition constant between water and heptane, but Leo and Hansch have shown (12) that there are linear free energy relations among partition constants for various solvents

TABLE 1. Heats of solution and reaction used in determining heats of formation

[a]Experimental heats of reaction or solution measured in this work; all at 25°C, in 0.1 *M* aqueous HCl, unless otherwise noted. For water, alcohols, and esters, the quantity measured is the heat of solution (pure liquid to dilute solution). For imidazole the quantity measured is the heat of reaction (pure solid to dilute solution of protonated compound). For the acylimidazole acetals the quantity measured is the heat of reaction (pure compound to dilute solution of stoichiometric amounts of protonated imidazole, alcohol, and ester).

[b]All reactants and products in pure compound standard states, i.e., pure liquid acylimidazole acetal plus pure liquid water going to pure crystalline imidazole, pure liquid alcohol, and pure liquid ester.

and water. Thus we can calculate a partition constant from water to 1-octanol from our measured partition constant from water to heptane, and thence calculate the solubility; the value so obtained was 0.77 *M*. The vapour pressure, determined by extrapolation from our measurements, was 8.38×10^{-3} Torr. These values lead to a free energy of transfer of −6.79 kcal/mol.

We prepared formylimidazole dipropyl acetal and measured its solubility and vapor pressure. The solubility was low enough, 0.062 *M*, to ensure ideality; the vapor pressure, determined by extrapolation, was 2.4×10^{-3} Torr. From these data we obtain a free energy of transfer of −5.86 ± 0.14 kcal/mol. By subtracting twice the $[CH_2(C)_2]$ group contribution (13) we can calculate the free energy of transfer of formylimidazole diethyl acetal as −5.45 ± 0.14 kcal/mol; this value was used for further calculations.

For acetylimidazole diethyl acetal we could neither determine the solubility nor directly determine the free energy of transfer from gas to aqueous solution because of rapid breakdown of the acetal in water even at high pH. However, it was possible to determine an apparent partition coefficient between water and heptane as a function of stirring time and then extrapolate to zero time to correct for the hydrolysis. The value so obtained was $K = c_{water}/c_{heptane} = 0.98$. Estimation of the ideal aqueous solubility, by the same process as for formylimidazole diethyl acetal, led to a value of 0.25 *M*. This value, with the vapor pressure, 6.54×10^{-3} Torr, leads to a free energy of transfer of −5.95 kcal/mol.

In addition, the free energy of transfer from gas to water was estimated by an additivity calculation, assuming that the change in ΔG_t is the same on going from formylimidazole diethyl acetal to acetylimidazole diethyl acetal as from trimethyl orthoformate ($\Delta G_t = -2.52$ (14)) to trimethyl orthoacetate ($\Delta G_t = -2.48$(14)). The estimate so obtained was −5.49 ± 0.50 kcal/mol. This value was used for further calculations.

The free energy of transfer of imidazole itself has recently been reported by Wolfenden *et al.* (15) as −7.91 kcal/mol.

pK_a values and σ values*

To carry out calculations of the free energy changes for hypothetical hydrolyses it was necessary to have a σ* value for imidazole as a substituent. There appeared to be no such value in the literature, so we prepared two ω-aminoalkylimidazoles and determined their pK_a values. The values so obtained were, for *N*-(2-aminoethyl)-imidazole, pK_1 = 5.90 ± 0.02, pK_2 = 8.45 ± 0.02; for *N*-(3-aminopropyl)imidazole, pK_1 = 6.50 ± 0.02, pK_2 = 9.63 ± 0.02. Then, by interpolation from plots of pK_a vs. σ* for suitable sets of substituted alkyl ammonium ions, we could determine σ* values; see Fig. 1. The values that we used for these correlations are found in Table 3. The values so determined for σ* were 2.61 ± 0.07 and 2.84 ± 0.26, for which the weighted average is 2.63 ± 0.06.

These data can also be used to determine the dependence of the pK_a of an N-substituted imidazole on the nature of the substituent; our new pK_1 values give two additional points, which with the available values from the literature are found in Table 3.[2] The best line fitting these points for $X—CH_2—ImH^+$ is pK_a = (6.84 ± 0.13) − (0.302 ± 0.068)σ_x*; see Fig. 1. The fit is less than ideal and in fact there are indications that substituents with and without hydrogen bond donor groups may constitute separate families, but in view of the limited number of values available it seems better to use a general equation fitting all the data and accept larger error limits than to try to develop restricted correlations based on very few points.

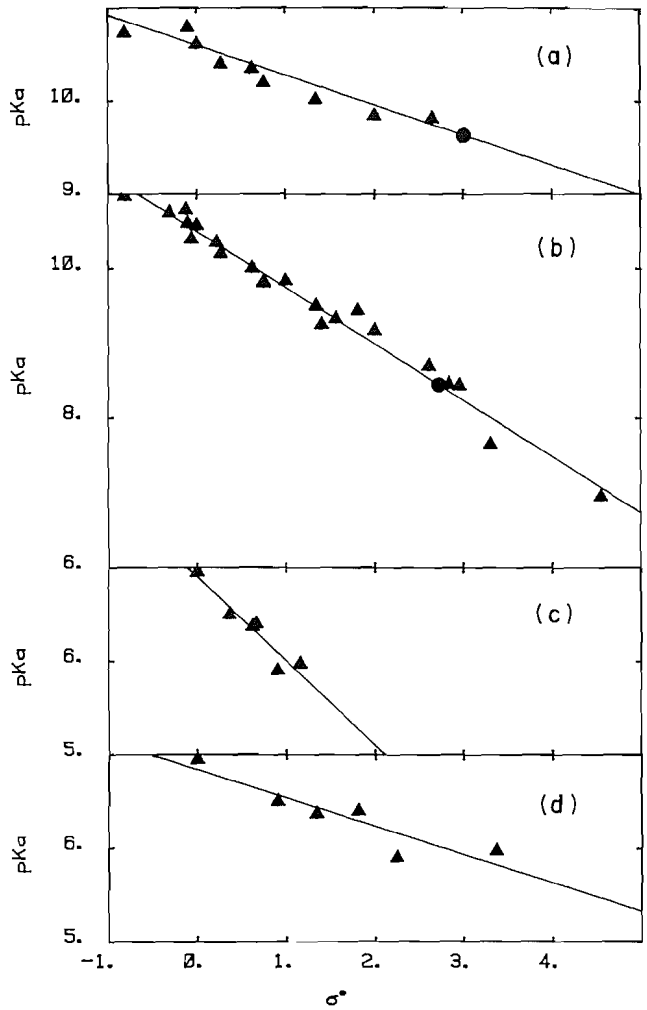

FIG. 1. Relation of pK_a to σ* for ammonium ions. (▲) experimental pK_a and known σ*; (●) experimental pK_a used to define σ* from the correlation line. (*a*) $X—CH_2—CH_2—CH_2—NH_3^+$; (*b*) $X—CH_2—CH_2—NH_3^+$; (*c*) $X—ImH^+$; (*d*) $X—CH_2—ImH^+$.

We also require a value of σ* for imidazolium as a substituent. A value can be calculated from the first pK_a of imidazoleacetic acid (16) by using the equation relating pK_a for RCH_2COOH recommended by Barlin and Perrin (17). The pK_a value of 2.19 leads to a σ* value of 3.84.

Free energies of formation of acylimidazole acetals and tetrahedral intermediates

Now it is possible to calculate the quantities of greatest interest for the rest of this paper, namely the free energies of formation in aqueous solution. The calculation of these values for the acylimidazole acetals is straightforward (5) and leads to the values given in Table 2.

The calculation of the free energies of formation of the tetrahedral intermediates is also straightforward, except for the problem of estimating strain release during the hypothetical hydrolyses. Our approach relies upon fitting the molecule to a diamond lattice and using additive parameters for each interaction, following Pihlaja and Kankare (18). This approach does not work for aryl substituents. Examination of models suggests that there will be only small interactions of the alkyl

[2]We thank Professor R. A. McClelland for kindly communicating a value for the pK_a of 2-imidazolyl-2-methoxypropane prior to publication.

TABLE 3. pK_a values used for linear free energy relations[a]

(*a*) N-substituted imidazolium ions

substituents on oxygen with imidazolyl or phenyl substituents and that these may be safely ignored.

The free energies of formation for the acylimidazole hemiacetals and hydrates in Table 2 now permit the calculation of the free energy changes for addition of imidazole to the esters or of water to the acylimidazoles. These equilibrium constants are given in Table 4. The latter set of equilibria is more directly related to observable chemistry because the acylimidazoles undergo ready hydrolysis by way of the hydrate while addition of imidazole to esters with poor leaving groups, as in the present cases, does not lead to any net reaction but simply to loss of imidazole and regeneration of starting material.

Equilibrium constant for addition of imidazole to acetone

To extend our calculations to other tetrahedral intermediates, it will be necessary to have as many examples as possible of equilibrium constants for addition of imidazole to carbonyl compounds. One key value, which we realized should be measurable but which had not been reported, is that for addition to acetone. We have measured this equilibrium constant directly by determining the ^{1}H nmr spectrum of a solution 1 *M* in each of imidazole and acetone. No additional peaks could be seen at 60 MHz, but at 200 MHz it was possible to see a new peak, comparable in size to that assigned to acetone hydrate (19). The intensity of this peak was dependent upon the concentration of imidazole for fixed acetone concentration, and became undetectably low when the concentration of acetone was lowered 1000-fold. The position of the new signal was very similar to that of the signal assigned to the *C*-methyl groups in 2-methoxy-2-imidazolylpropane. We conclude that the new peak corresponds to 2-hydroxy-2-imidazolylpropane; the equilibrium constant for addition of imidazole to acetone can be evaluated as 2.6 ± 1.1 × 10^{-3} M^{-1} at 20 ± 3°C. We obtain an equilibrium constant for hydration of acetone of (2.0 ± 0.9) × 10^{-5} M^{-1} at 20 ± 3°C; Hine and Redding reported a value of (2.5 ± 0.7) × 10^{-5} M^{-1} at 33°C (19).

pK_a values for tetrahedral intermediates

To include various protonation states of the tetrahedral intermediates, which are important in the actual reaction mechanisms, it was necessary to have values for the various pK_a values of these compounds. These pK_a values were estimated using the procedures previously described (20, 21); the pK_a values that we employ in this paper are found in Table 5. These estimates made use of the σ^* values shown in Table 6.

Discussion

We wish first to test the equilibrium constants that we have derived for hydration of acyl imidazoles, by seeing if they are consistent with other data. One such test is to see if the new points fall on the Marcus curves previously found for hydroxide and water addition to carbonyl groups (20).

Those rate constants for the hydrolysis of the acyl imidazoles that were available from the literature are collected in Table 7. Using these values we can examine the correlation of rate and equilibrium constants: unfortunately only for acetylimidazole is the equilibrium constant for formation of the acylimidazole known. Figure 2 shows that the points for the attack of hydroxide and water on acetylimidazole fall very near the same lines (7) that correlate data for a wide range of acyl compounds (20).

Since, in general, protonation and methylation of imidazole on the remote nitrogen have very similar effects, we can examine the reaction of hydroxide with acetylimidazolium ion by using the observed rate constant for *N*-acetyl-*N'*-methylimidazolium ion and an equilibrium constant calculated for acetylimidazolium ion using estimated pK_a values. This point also falls near the correlation line for other acyl compounds; see Fig. 2.

By inverting the procedure we can estimate the equilibrium constants for addition of water or hydroxide to an acylimidazole from the corresponding rate constants. This is possible for benzoylimidazole, for which the kinetics of hydrolysis have been studied (22). Since all classes of compound fall near a common Marcus correlation line (20), we use the most recent and best-defined line that we have obtained, that for esters (7). This line was derived taking explicit account of diffusion-limited encounter complex formation. From the rate constant for hydroxide attack, we calculate an observable equilibrium constant for addition of hydroxide to give an anionic adduct, $\log K = -1.31$. In the same way we calculate an observable equilibrium constant for addition of hydroxide to *N*-benzoylimidazolium ion (making the assumption that the rate and equilibrium constants for this process will be similar to those for *N*-benzoyl-*N'*-methylimidazolium ion), $\log K = 4.45$. Finally for the reaction of water with benzoylimidazole, which we assume goes through the zwitterion (20, 7), we calculate an equilibrium constant for addition of water to give the zwitterion, and then from the zwitterion content (estimated as previously

[o]Calculated using $pK_a(OH) = 17.03 - 1.32\Sigma\sigma^*$ (20).

[p]Estimated assuming that the pK_a of R—CO—ImH^+ is linear in σ_R^*; alternatively one might assume that the pK_a would be the same as for R = Me. The error limits are based on the difference between the results of these assumptions.

described (20)) we calculate the equilibrium constant for formation of the neutral adduct as $\log K = -3.57$.

Now we may compare these values, using pK_a values from Table 5 to relate them. For hydroxide addition, estimates derived from the reactions of hydroxide with benzoylimidazole, water with benzoylimidazole, and hydroxide with benzoylimidazolium are -1.32, 0.70, and 0.74 respectively, for an average of 0.04 ± 1.17. Similarly the estimates for water addition are -5.58, -3.57, and -3.53 respectively, for an average of -4.23 ± 1.17.

$$\text{Ph—CO—OH + HIm} \underset{}{\overset{-14.19\pm1.35}{\rightleftharpoons}} \text{Ph—C(OH)}_2\text{—Im} \overset{4.23\pm1.17}{\rightleftharpoons} \text{Ph—CO—Im + H}_2\text{O}$$

$$\overset{-9.96\pm1.79}{\rightleftharpoons}$$

As a test of this procedure we can ask how it would have worked for acetylimidazole. From the rate data in Table 7 (23) we calculate equilibrium constants for addition of hydroxide to acetylimidazole of -1.25, 0.01, and 1.02 respectively, for an average of -0.08 ± 1.13, and for addition of water of -4.52, -3.29, and -2.27 respectively, for an average of -3.36 ± 1.13. This may be compared to the thermochemical value of -3.73 ± 1.08 for the addition of water to acetylimidazole. The values are in satisfactory agreement.

For formylimidazole no rate or equilibrium data could be found; to obtain an initial estimate we note that $\log K_{hydration}$ is very similar for acetylimidazole (-3.73 ± 1.08) and benzoylimidazole (-4.22 ± 1.19). The values are indistinguishable. Thus we take $\log K_{hydration}$ for formylimidazole as the average of the values for acetylimidazole and benzoylimidazole, -4.0. Rather arbitrarily we assign limits of ± 2.0 to this value. We may now calculate the equilibrium constant for hydrolysis of formylimidazole. From this equilibrium constant it is possible to calculate a free energy of formation in aqueous solution for formylimidazole: see Table 2.

It is now possible to make predictions (necessarily very approximate) of the rate constants for hydrolysis of formylimidazole. For hydroxide plus the acylimidazole we predict $\log k = 3.1 \pm 0.9$; for water plus the acylimidazole, $\log k = -4.4 \pm 1.6$.

We can attempt to estimate the rate of nucleophilic catalysis by imidazole, eq. [1], of the hydrolysis of the methyl or ethyl esters corresponding to our acylimidazole acetals in the following way. We have the equilibrium constants for the addition of imidazole to the esters, calculated from the free energies of formation. We have rate constants for addition of water to the acylimidazoles, and therefore rates for the expulsion of water from the acylimidazole hydrate. If we assume that the rate constants for the analogous steps involving methanol or ethanol would be very similar, we can estimate the overall rates of the nucleophilic catalysis reactions as $k_1k_2/(k_{-1} + k_2) \cong k_1k_2/k_{-1} = K_1k_2$. Using the above assumption and the rate and equilibrium constants for the hydrolysis of acetylimidazole we estimate that $k_2 = 3.9\ s^{-1}$. To support the assumption that k_{-1} is much larger than k_2 we carried out the following

$$\text{H—CO—Im + H}_2\text{O} \underset{}{\overset{-4.0\pm2.0}{\rightleftharpoons}} \text{H—C(OH)}_2\text{—Im} \overset{9.08\pm1.11}{\rightleftharpoons} \text{HCOOH + HIm}$$

$$\overset{5.1\pm2.3}{\rightleftharpoons}$$

estimation of k_{-1} for acetylimidazole. Kirsch and Jencks (2) have shown that there is a linear relation between rates of imidazole- and hydroxide-catalyzed hydrolyses for acetate esters with good leaving groups for which k_1 is the rate-determining step; we extrapolated this relationship to obtain a rate constant for nucleophilic attack of imidazole on ethyl acetate, obtaining an estimated value of $3 \times 10^{-3}\ M^{-1}\ s^{-1}$. This, in combination with the equilibrium constant for addition of imidazole to ethyl acetate, leads to a rate constant for expulsion of imidazole, k_{-1}, of $1.3 \times 10^9\ s^{-1}$. Although there are undoubtedly considerable uncertainties associated with this estimate, there is no doubt that $k_{-1} \gg k_2$. The value estimated for the apparent rate constant for imidazole-catalyzed hydrolysis of ethyl acetate is then $9.1 \times 10^{-12}\ M^{-1}\ s^{-1}$; the reported (24) value for the water rate is $2.5 \times 10^{-10}\ s^{-1}$, so that

$$\text{[1]}\quad \text{CH}_3\text{—CO—OEt + HIm} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{CH}_3\text{—C(OH)(OH)—OEt} \xrightarrow{k_2} \text{CH}_3\text{—CO—Im + HOEt}$$

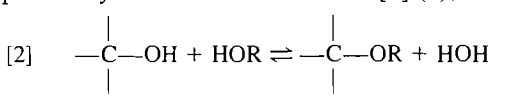
(*a*) Hydroxide addition to give the anionic tetrahedral speices, $b = 8.99$. (*b*) Water addition to give the zwitterion, $b = 8.81$.

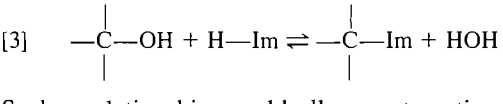
nucleophilic catalysis could only make a contribution equal to the water rate at 27 *M* imidazole. These calculations are in complete accord with the experimental observation that nucleophilic catalysis by imidazole is not observed for simple alkyl esters, and that only general base catalysis by imidazole is detectable (2).

Free energy changes for replacement of hydroxyl by imidazolyl

In calculating the free energies of formation of the tetrahedral intermediates we used a relationship between the free energy change, corrected for steric and symmetry factors, and the sum of the σ* values for the central carbon, which has been previously established for reaction [2] (6),



It was of interest to see if a similar relationship would hold for replacement of hydroxyl by imidazolyl, reaction [3],



Such a relationship would allow us to estimate free energies of formation for some interesting tetrahedral intermediates for which the corresponding acetals are expected to be very unstable, so that the thermochemical procedures used for the simple acetals described above would be impossible.

Figure 3 shows that there is indeed a relationship but that the number of hydrogens on the central carbon (aldehydic hydrogens on the corresponding carbonyl compound) is an important variable, in addition to the electronic effects of the substituents. The data on which this figure is based are found in Table S1.[3] The results based on thermochemistry are not sufficiently precise to demand different ρ* values for different numbers of hydrogens on the central carbon. The ΔG value for formaldehyde is anomalous because it differs from that for

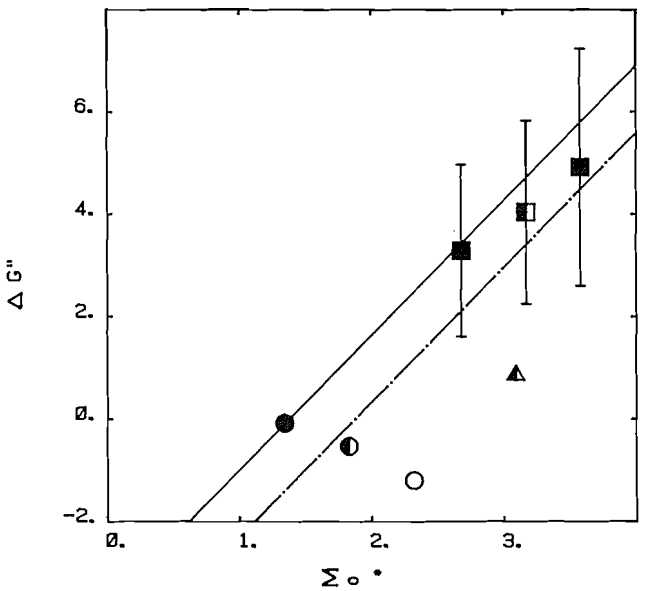

FIG. 3. Free energy change, corrected for symmetry effects, for replacement of OH by imidazolyl, as a function of $\Sigma\sigma^*$ for the remaining substituents on the central carbon, and of the number of hydrogens on the central carbon. Filled symbols, no hydrogens on the central carbon; half-filled symbols, one hydrogen on the central carbon; open symbol, two hydrogens on the central carbon. (○) Equilibrium constants used; (□) thermochemically derived values; (△) pyridine-4-carboxaldehyde adduct, for which only a limit could be placed on the equilibrium constant for addition of imidazole.

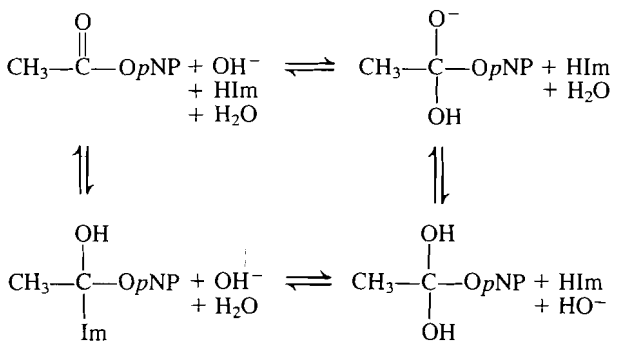

SCHEME 1

acetaldehyde by more than ΔG for acetaldehyde differs from that for acetone. This behavior is puzzling but not unique. Examination of comparable data for replacement of OH by CN, using the equilibrium constants collected in ref. 75, shows a similar anomaly for formaldehyde. Thus the available data for replacement of OH by imidazolyl, excluding the point for formaldehyde, can be fitted by eq. [4], in which Δ is the number of hydrogens on the central carbon:

$$[4] \quad \Delta G = -(3.62 \pm 0.44) + (2.63 \pm 0.30)\Sigma\sigma^* - (1.31 \pm 0.2)\Delta$$

The central feature of this analysis is that electron-withdrawing substituents on the central carbon strongly disfavor the replacement of OH by imidazolyl, i.e., make imidazole less effective relative to water as a nucleophile for equilibrium addition to the corresponding carbonyl compound. There is independent evidence for this proposition in that Sander and Jencks were unable to detect any adduct formation from imidazole and pyridine-4-carboxyaldehyde for which the equilibrium constant for addition of water was readily measured (25). Their detection limits lead to a $\Delta G'' > 0.86$ kcal/mol for replacement of OH by imidazolyl; this is markedly more positive than the value, −0.53, for acetaldehyde.

Equilibrium constants for addition of imidazole to nitrophenyl acetates

Using this relationship we can explore the energetics of the imidazole-catalyzed hydrolysis of *p*-nitrophenyl acetate. If we can calculate the free energy of formation of the covalent hydrate of *p*-nitrophenyl acetate, then we can calculate the free energy change for replacement of one of the hydroxyl groups by an imidazolyl group, and hence the free energy change for addition of imidazole to the ester; see Scheme 1. The free energy change for the addition of water to *p*-nitrophenyl acetate can be estimated from the Marcus curves relating rate and equilibrium for the hydroxide-catalyzed hydrolysis reactions, using the equation previously reported for a variety of esters (7). The calculation involves estimation of the pK_a of the covalent hydrate (20, 26). The equilibrium constant so derived for the addition of water to *p*-nitrophenyl acetate is $\log K_{H_2O} = -7.86 \pm 2.0$. (Most of the equilibrium data for the rate equilibrium correlation were derived from thermochemistry and had uncertainties of ca. ±2.0 in $\log K$, so it is unlikely that interpolated values are better defined.)

The equilibrium constant for replacement of a hydroxyl group in the covalent hydrate of *p*-nitrophenyl acetate by an imidazolyl group may now be calculated as $\log K = -6.64 \pm 1.25$. By combining the equilibrium constants for hydration and for replacement of one hydroxyl by imidazole, we can calculate the equilibrium constant for addition of imidazole to *p*-nitrophenyl acetate as $\log K_{Im} = -13.39 \pm 2.34$. This equilibrium constant is calculated for the addition of neutral imidazole to the neutral ester to give the neutral adduct. Mechanistically it seems clear that the immediate product is the zwitterionic adduct; *N*-methylimidazole is known to be essentially as effective as imidazole as a nucleophilic catalyst for the hydrolysis of active esters (4, 27). The zwitterion content can be calculated from estimates of the pK_a values for the OH and the imidazolium moieties in the cationic form of the tetrahedral intermediate. Using the value of $\sigma^* = 3.84$ for imidazolium estimated above, we calculate the pK_a of the hydroxyl to be 8.12 and the pK_a of the imidazolium to be 5.57; we assume that these estimated pK_a values are uncertain by ±0.3 log units. Then the zwitterion content is given by $\log K_Z = -2.56$, and the equilibrium constant for addition of imidazole to *p*-nitrophenyl acetate to give the zwitterion is -15.95 ± 2.30. The corresponding free energy change, relative to separated reagents, is 21.79 ± 3.14 kcal/mol.

If we assume that the reaction of imidazole with *p*-nitrophenyl acetate to give acetylimidazolium ion and *p*-nitrophenoxide follows a stepwise mechanism, and addition of imidazole is rate limiting with expulsion of *p*-nitrophenoxide a fast second step (2), then we should now be able to calculate the intrinsic barrier for the attack of imidazole. (Jencks and Kirsch did not distinguish between a stepwise mechanism and a one-step mechanism with a skewed transition state, but showed that for *p*-nitrophenyl acetate the rate-determining step involves principally bond formation with little bond breaking (2).) From the equilibrium constant derived above and the rate constant for imidazole attack on *p*-nitrophenyl acetate, $\log k = -0.239$ (2), we may substituent into the Marcus equation (7, 28–30) and attempt to solve for the intrinsic barrier. When we do this we find that no real value can be found because the observed rate is

too fast relative to the energy level of the putative intermediate. The free energy of activation, relative to separated reagents, is 17.78 kcal/mol, which is lower than the energy level of the intermediate. This suggests that the reaction may in fact be concerted, and that the tetrahedral species may not be on the reaction coordinate.

This may be compared to the situation for other aminolyses where an intrinsic barrier can be calculated. For the aminolysis of methyl formate, where an equilibrium constant is available for addition of dimethyl amine to give the zwitterion (31), a rate constant may be estimated (31) from the work of Blackburn and Jencks (32). Using $\log K = 7.8 \times 10^{-11}$ (31) and $\log k = 1.60$ (31) we obtain $b = 4.50$ (b is the intrinsic barrier in log k units (33, 7)). From work of Cox and Jencks (34) we obtain rate and equilibrium constants for the addition of methoxyamine to phenyl acetate; their values are $\log k = 2.55$ and $\log K = -7.75$. From these values we obtain $b = 5.26$. This should be larger than the intrinsic barrier for imidazole because methoxyamine has two NH protons that will undergo a major change in solvation as reaction proceeds, while imidazole has only one. Arnett and Wolf have shown that amine NH's are only weakly hydrogen bonded to water, whereas ammonium NH's are strongly hydrogen bonded (35). Thus the available information concerning amine addition to esters requires relatively small intrinsic barriers.

Concerted vs. stepwise reactions

The question of whether a tetrahedral intermediate is on the reaction coordinate or whether a concerted path is preferred is of current interest (36–41) and it seems worthwhile to explore the implications of our thermochemical calculations and of Marcus theory (28–30). A method of presentation frequently used to examine the energetic consequences of structural change is the three-dimensional reaction coordinate diagram first employed by Albery (42–44). We wish to calculate plausible values for all points on the surface and for this purpose need an analytical expression for the energy at any point as well as energies for the four corner points and intrinsic barriers for the four edge reactions. We have three of the corner energies because the equilibrium constants for the overall hydrolysis (45) and addition to give the tetrahedral intermediate are known. The fourth corner is the acylium ion, corresponding to the elimination–addition mechanistic competitor; the energy of this species will be estimated below.

It is quite common to express the reaction coordinate for a single chemical step in terms of two intersecting parabolas (46–49). Kurz (50) has shown that an equivalent representation is a single, inverted parabola, eq. [5]:

$$[5] \quad G = \alpha x + \beta x^2$$

where x is the reaction coordinate, and the free energy at $x = 0$ is defined as 0.0 for convenience. This approximation has been shown to be consistent with Marcus theory (50). We generalize the inverted parabola to three dimensions as eq. [6][4]

$$[6] \quad G = \alpha x + \beta x^2 + \gamma y + \delta y^2 + \epsilon xy$$

where x and y are the reaction coordinates of the "edge reactions" and the free energy at $(x,y) = (0,0)$ has been defined as 0.0, and impose the constraints that the four "edge parabolas" for $x = 0,1$ and $y = 0,1$ must satisfy the Marcus equation for the edge reactions. These constraints and the overall thermodynamics specify all of the parameters in terms of the free energy changes and intrinsic barriers for the edge reactions. When $y = 0$, $G = \alpha x + \beta x^2$. For this reaction, $\Delta G^0 = \alpha + \beta$, where ΔG^0 is the overall free energy change from $x = 0$ to $x = 1$. It is easily seen that $x^{\ddagger} = -\alpha/2\beta$, and hence $\Delta G^{\ddagger} = -\alpha^2/4\beta = \tilde{G}(1 + \Delta G^0/4\tilde{G})^2$, where $\tilde{G}$ is the intrinsic barrier expressed in terms of free energy. These expressions may be solved to give $\alpha = \Delta G^0 + 4\tilde{G}$ and $\beta = -4\tilde{G}$. Similarly, one may express γ and δ in terms of the free energy change and intrinsic barrier for the $x = 0$ edge reaction. It is an unavoidable logical consequence of eq. [6] that the intrinsic barriers for $x = 0$ and $x = 1$, and for $y = 0$ and $y = 1$, must be identical. The final parameter, ϵ, is determined by the thermodynamic requirement that the overall free energy change from starting material to product, $\Delta G_{rxn} = \alpha + \beta + \gamma + \delta + \epsilon$.

The question of whether a reaction is concerted or not can now be phrased in terms of whether there is a path, from starting material to product, that has a maximum free energy less than for either path along two edge parabolas.

We may solve for the coordinates and energy of the transition state in terms of eq. [6] by finding the values of $x^{\ddagger}$ and $y^{\ddagger}$ that make $\partial G/\partial x = 0$ and $\partial G/\partial y = 0$. When this is done we obtain:

$$[7] \quad \begin{aligned} x^{\ddagger} &= (2\alpha\delta - \gamma\epsilon)/(\epsilon^2 - 4\beta\delta) \\ y^{\ddagger} &= (2\beta\gamma - \alpha\epsilon)/(\epsilon^2 - 4\beta\delta) \\ \Delta G^{\ddagger} &= (\alpha^2\delta + \beta\gamma^2 - \alpha\gamma\epsilon)/(\epsilon^2 - 4\beta\delta) \end{aligned}$$

It is also useful to examine the behavior of the energy surface in terms of an alternative pair of coordinates (51), one running from starting material (0) to product (1) ("progress variable" (51), here called p) and the other running from one of the intermediates (0) to the other (1) ("disparity variable" (51), here called q). Following Grunwald (51), we transform and renormalize the coordinates using

$$[8] \quad \begin{aligned} p &= (x + y)/2 & x &= p + q - 1/2 \\ q &= (x - y)/2 + 1/2 & y &= p - q + 1/2 \end{aligned}$$

In terms of p and q we may derive

$$[9] \quad \begin{aligned} G = {} & (\alpha - \beta + \gamma + \delta)p + (\alpha - \beta - \gamma - \delta + \epsilon)q \\ & + (\beta + \delta + \epsilon)p^2 + (\beta + \delta - \epsilon)q^2 + 2(\beta - \delta)pq \\ & + (-2\alpha + \beta + 2\gamma + \delta - \epsilon)/4 \end{aligned}$$

$$p^{\ddagger} = [(\alpha\delta + \beta\gamma) - \epsilon(\alpha + \gamma)/2)]/(\epsilon^2 - 4\beta\delta)$$

$$q^{\ddagger} = 1/2 + [(\alpha\delta - \beta\gamma) + \epsilon(\alpha - \gamma)2]/(\epsilon^2 - 4\beta\delta)$$

A necessary and sufficient condition for a concerted reaction is that the section through the energy surface at $p = 1/2$ be concave upward. Equation [6] defines either a paraboloid or a hyperbolic paraboloid. If a section of $p = 1/2$ is concave downward then the surface is a paraboloid, and there will be an energy mountain in the reaction square; if a section at $p = 1/2$ is concave upward, then the surface is a hyperbolic paraboloid and there is a saddle point, though it may not be at $p = 1/2$.

When we impose the condition that $p = 1/2$, the equation for G as a function of q alone is

$$[10] \quad G = (\gamma + \delta) + (\alpha - \gamma - 2\delta + \epsilon)q + (\beta + \delta - \epsilon)q^2$$

If $(\beta + \delta - \epsilon) > 0$ and $0 < q^{\ddagger} < 1$, then the reaction is concerted.

[4]Throughout our discussion of the three-dimensional reaction surface we will use free energies calculated for the encounter complex, using an equilibrium constant for encounter complex formation assuming no attraction or repulsion, but requiring the nucleophile to be on one or the other face of the planar ester electrophile (7, 33). The reference point is the encounter complex of ester and imidazole.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

A logical consequence of the above analysis is that a reaction is either concerted or stepwise, but that there cannot be coexisting competitive concerted or stepwise paths. This is a consequence of the mathematical simplicity of our model, which does not allow any ridge-like barrier on the surface between a concerted and a stepwise path. If experimental evidence were to demand that concerted and stepwise paths can coexist, then one would have to conclude that our model is, at least, oversimplified. The conclusion, that reactions are either concerted or stepwise but not both, is almost, but not quite, equivalent to saying that concertedness is "enforced", as proposed by Jencks (36), by a lifetime of the intermediate that is less than a single vibration. It is not impossible that one could have a situation such that the kinetic barriers to both breakdown paths of an intermediate (i.e. β and δ) were both large enough in absolute magnitude to correspond to a finite lifetime, while still satisfying the criterion for a concerted process (i.e., $(\beta + \delta - \epsilon) > 0$).

Another interesting case is for the identity reaction where nucleophile and leaving group are the same. In this case $\Delta G^0 = 0$, and $\beta = \delta$ because the intrinsic barriers for addition or expulsion of the nucleophile are necessarily the same. We define Γ_0 to be the energy of the intermediate at $q = 0$, and Γ_1 to be the energy of the intermediate at $q = 1$. Then $\alpha = \Gamma_0 - \beta$, $\gamma = \Gamma_1 - \beta$, $p^{\ddagger} = 1/2$, $q^{\ddagger} = 1/2 + (\Gamma_0 - \Gamma_1)/2(\Gamma_0 + \Gamma_1 + 2\beta)$, and

$$\Delta G^{\ddagger} = \Gamma_1 - (\Gamma_1 + \beta)^2/(\Gamma_1 + \Gamma_0 + 2\beta)$$

and this may be converted into a quadratic in β,

$$[11] \quad \beta^2 + [2\Delta G^{\ddagger}]\beta + [\Delta G^{\ddagger}(\Gamma_1 + \Gamma_0) - \Gamma_1\Gamma_0] = 0$$

which may be solved for β.

Similar ideas have been used by other authors (52–55) but we believe that we have carried the analysis farther than previous workers. Albery and Kreevoy (52) derived expressions relating experimentally determined quantities to positions along the "progress" (51) or "symmetry" (52) (α) and "disparity" (51) or "tightness" (52) (τ) coordinates. Jencks and Jencks (53) used an equation analogous to eq. [6] but did not impose the constraints of Marcus theory (28–30). Gajewski (54) used an analog of eq. [6] with no x^2 or y^2 terms. Dunn (55) explored the implications of two-dimensional reaction surfaces, but had a less satisfactory derivation of the surface.

Acylium ion formation

The equilibrium constant for formation of this ion may be estimated from the nmr studies of Deno *et al.* (56) who found that $[CH_3COOH] = [CH_3COOH_2^+]$ at 77% H_2SO_4 and $[CH_3COOH_2^+] = [CH_3—C{\equiv}O^+]$ at 15% SO_3. 77% H_2SO_4 corresponds to $H_0 = -6.56$ (57) and 15% SO_3 corresponds to $H_0 = -13.23$ (58). To estimate H_R for 15% SO_3 we extrapolated a linear relationship between H_0 and H_R, which holds for aqueous sulfuric acid. Such relationships are general (59) but it is clearly an extrapolation to extend the line into fuming sulfuric acid; this approach leads to an H_R value of -23.92 for 15% SO_3. Now we make the assumption that protonation and dehydration of the acid follow these simple acidity functions and calculate that for $H_0 = -13.23$, $\log([CH_3COOH]/[CH_3COOH_2^+]) = -6.67$; then $pK_R = -17.25$. Assuming that this value can be used in water, we can then calculate the equilibrium constant for reaction [12]

$$[12] \quad CH_3—COOH + p\text{NPOH} \rightleftharpoons CH_3—C{\equiv}O^+ + p\text{NPO}^- + H_2O$$

$$K = \frac{[CH_3—C{\equiv}O^+][p\text{NPO}^-][H^+]}{[CH_3—COOH][H^+][p\text{NPOH}]} = 10^{-17.25} \times 10^{-7.14} = 10^{-24.38}$$

The equilibrium constant for the hydrolysis of *p*-nitrophenyl acetate is $\log K = 6.90$ (45); thus the equilibrium constant for the heterolytic cleavage of *p*-nitrophenyl acetate is $\log K = -17.48$. This value is clearly subject to large uncertainties, because we do not have proper acidity functions for RCOOH in H_2SO_4/SO_3 mixtures either for protonation or protonation/dehydration, and the extrapolations used in the calculation are very long.[5]

Intrinsic barrier for the addition or expulsion of p*-nitrophenoxide*

In addition to an intrinsic barrier for the addition of imidazole to give a tetrahedral intermediate, we need to know the intrinsic barrier for the expulsion of *p*-nitrophenoxide ion from this intermediate. This turns out to be a more difficult problem, because in all of the many studies of *p*-nitrophenoxide replacement, it is the attack of a nucleophile that is rate limiting, and thus the rate of the expulsion is unknown. An estimate may be obtained as follows. We have already estimated the equilibrium constant for the addition of water to *p*-nitrophenyl acetate (*vide supra*); $\log K_{H_2O} = -7.86 \pm 2.0$. Since we have found linear free energy relations for the replacement of OH by OR (6) and by imidazolyl, it seems plausible to postulate that there should be such a relationship for replacement of OH by *p*-nitrophenoxy. Unfortunately there are not sufficient data to test this assumption. From the equilibria for addition of water to acetic acid (61) and to *p*-nitrophenyl acetate and for addition of imidazole to acetic acid and to *p*-nitrophenyl acetate we can determine the slope of a plot of ΔG for replacement of OH by *p*-nitrophenoxy vs. $\Sigma\sigma^*$ for the substituents on the central carbon, and thence calculate the free energy change for the process:

$$[13] \quad CH_3—\underset{\displaystyle OpNP}{\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}}—OH + p\text{NPOH} \rightleftharpoons CH_3—\underset{\displaystyle OpNP}{\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}}—OpNP + H_2O$$

The uncertainty in this free energy change or in the associated equilibrium constant will be essentially the same as for the replacement of OH by *p*-nitrophenoxy in the imidazole adduct of acetic acid, because $\Sigma\sigma^*$ is very similar. Thus we arrive at $\log K = -10.4 \pm 3.1$ for reaction [13]. Then by estimating the pK_a of this intermediate we can calculate the equilibrium constant for the attack of *p*-nitrophenoxide on *p*-nitrophenyl acetate to give the anionic tetrahedral intermediate; the value we obtain is $\log K = -20.5 \pm 3.7$. The rate constant for this reaction can be estimated by interpolation from data given by Fersht and Jencks (62); the value we obtain is $\log k = -1.15 \pm 0.61$. When we compare the free energy change for addition, 28.0 ± 5.1 kcal/mol, with the free energy of activation for the exchange process, 19.02 ± 0.83 kcal/mol (both calculated with respect to the separated reagents), we find that the free energy

[5] Arnett *et al.* (60) used a similar extrapolation (with similar reservations about the uncertainties involved) to estimate H_R for magic acid.

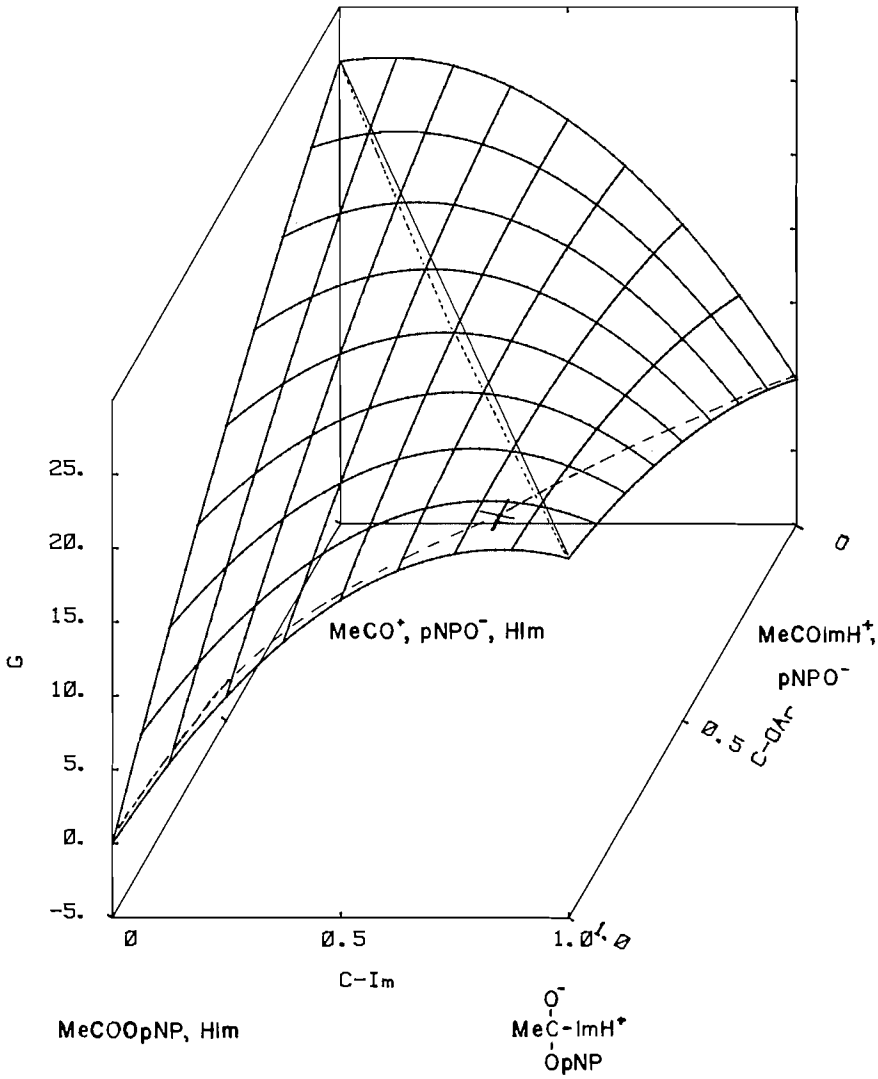

FIG. 4. Three-dimensional reaction coordinate surface for the reaction of imidazole with *p*-nitrophenyl acetate. The surface is calculated using eq. [6], with the thermodynamic and kinetic barriers described in the text. (---) Minimum energy path from starting material to product; (----) section through the energy surface at $p = 1/2$; (—) straight line joining the energies of the two intermediates, for ease of visualization.

of activation is markedly less than the free energy change for forming the intermediate. The difference is large enough that it is outside even the considerable uncertainty of our estimates, so that one must consider the possibility that this reaction is concerted. If we make this assumption, then we may solve eq. [11] and obtain a value of $b = 1.35 \pm 0.38$. (Two roots are obtained but only one corresponds to $0 < q^{\pm} < 1$.)

Reaction surface for imidazole plus p-*nitrophenyl acetate*

The intrinsic barrier for the addition of imidazole to *p*-nitrophenyl acetate will be taken as 5 (*vide supra*). The barrier for the expulsion of *p*-nitrophenoxide is taken as 1.3 (*vide supra*). The thermodynamic barriers for formation of the "corner intermediates" have been calculated above. For use in eq. [6] these values must be corrected to apply to the encounter complexes of starting materials and products. We use the estimate for the equilibrium constant for encounter complex formation suggested by Hine (33). For acylium ion formation there is an unknown contribution from ion pairing. We will assume that this is negligible for the moment; ion pairing is normally not strongly favored for 1:1 electrolytes in water, and in the present case the relevant ion pair, with O^- next to $-C{\equiv}O^+$, has probably lost hydrogen-bonded solvation at O^- relative to the separated ions, with no good compensating interaction. The three-dimensional surface so derived is shown in Fig. 4. The implications of this diagram are that the tetrahedral species is no longer an obligatory intermediate, and that a concerted reaction path is favored. The value of $\Delta G^{\pm}$ implied by Fig. 4 is actually greater than the observed value. If we assume that the errors in the energies of both intermediates are ± 4.3 kcal/mol, then the largest value of b for imidazole addition compatible with the thermodynamics, the observed free energy of activation, and $b = 1.35$ for *p*-nitrophenoxide expulsion is 3.4. This is distinctly smaller than the values established for other aminolyses, although as we argued above there is a basis for expecting a value for imidazole that is smaller than the value for a primary amine. Given the imperfect state of our present knowledge of the thermodynamic and kinetic barriers for the edge reactions, we can only conclude that in terms of the theory given above a concerted reaction is allowed. In fact we may ask what is the upper limit on the intrinsic barrier for *p*-nitrophenoxide expulsion for the overall reaction to be

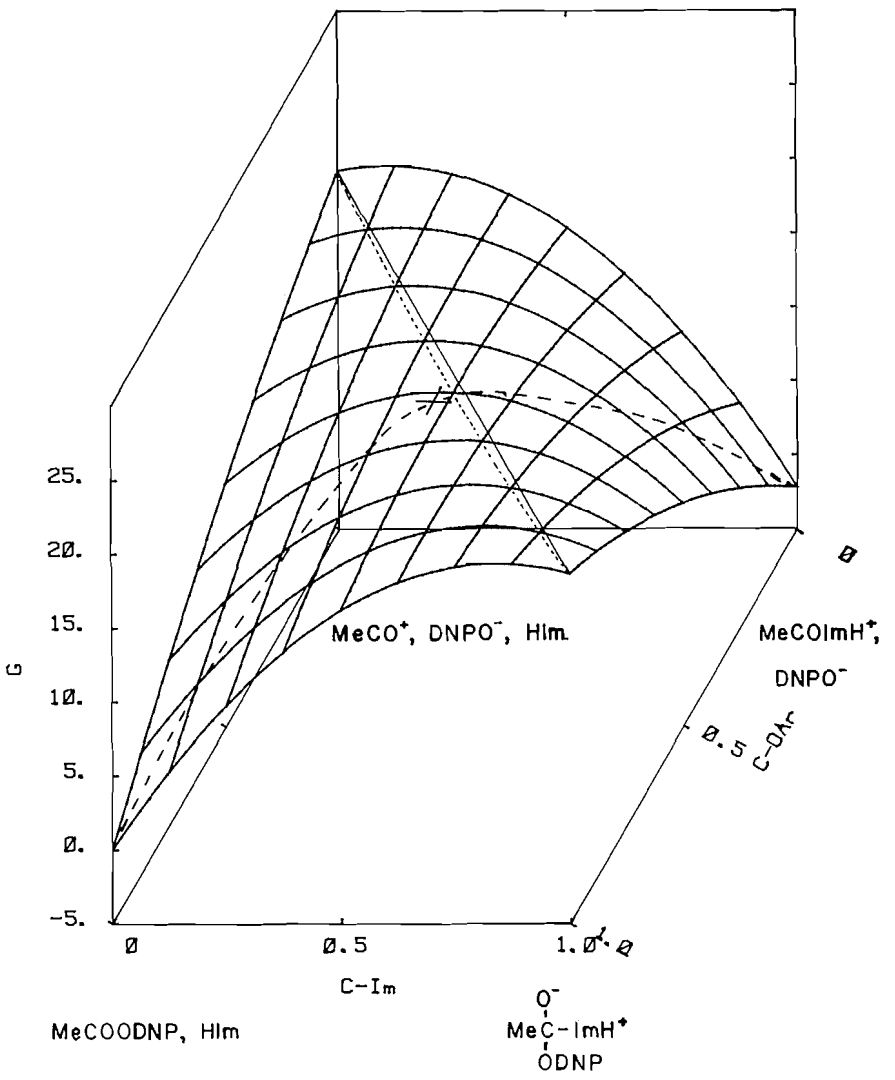

FIG. 5. Three-dimensional reaction coordinate surface for the reaction of imidazole with 2,4-nitrophenyl acetate. The surface is calculated using eq. [6], with the thermodynamic and kinetic barriers described in the text. (---) Minimum energy path from starting material to product; (----) section through the energy surface at $p = 1/2$; (—) straight line joining the energies of the two intermediates, for ease of visualization.

concerted, assuming an intrinsic barrier of 5 for imidazole addition and the energy levels of the intermediates derived above. Using the condition, $(\beta + \delta - \epsilon) > 0$, the answer is that the reaction is concerted if the intrinsic barrier for phenoxide expulsion is $b < 2.5$. Since the observed free energy of activation is less than the free energy change for formation of either of the corner intermediates, our calculations require a concerted mechanism. This in turn says that both intrinsic barriers must be small, which as we have seen is consistent with what is known.

For the corresponding case of 2,4-dinitrophenyl acetate, the overall equilibrium constant for hydrolysis is distinctly more favorable, at $\log K = 9.06$ (63), than for *p*-nitrophenyl acetate; the equilibrium constant for tetrahedral intermediate formation by imidazole addition is estimated in the same way as for *p*-nitrophenyl acetate as $\log K = -13.29 \pm 2.39$. The equilibrium constant for imidazole addition to give the zwitterionic tetrahedral intermediate is estimated to be $\log K = -15.44 \pm 2.35$. The equilibrium constant for cleavage of dinitrophenyl acetate to give acetylium ion and dinitrophenoxide is estimated to be $\log K = -12.3 \pm 3.0$. The equilibrium constant for reaction of dinitrophenyl acetate with imidazole to give acetylimidazolium dinitrophenoxide is $\log K = 1.6$. We have no information allowing estimation of the intrinsic barriers for 2,3-dinitrophenoxide expulsion, so we will use the same intrinsic barriers as for *p*-nitrophenoxide. Figure 5 shows the surface calculated using these values. Once again a concerted reaction is predicted, but once again the prediction is not rigorous. In fact the conditions for a concerted reaction, using the same assumptions as for *p*-nitrophenyl acetate, turn out to be stricter here. The intrinsic barrier for expulsion of 2,4-dinitrophenoxide must be $b < 2.3$ for the reaction to be concerted if the intrinsic barrier for imidazole attack is $b = 5$.

Although it is not possible at this time to give a clear statement of whether or not the theory of concerted reactions outlined above demands a concerted mechanism for the reactions of imidazole with *p*-nitrophenyl acetate and 2,4-dinitrophenyl acetate, it is possible to see why these reactions have become likely candidates for such a mechanism. The intrinsic barriers for leaving group expulsion have become small, and the nucleophile has a small intrinsic barrier for addition. In both cases the demands for new solvation by the attacking or leaving groups are modest and the lone pair basicities are such as to confer high, though not extremely high, reactivity. The energy

For personal use only.

levels of the two corner intermediates have become matched because of the improved leaving group abilities of the nitrophenoxides. Because addition of imidazole becomes relatively less favorable as the substituents on the carbonyl carbon become increasingly more electron withdrawing, we find that the equilibrium constant for addition of imidazole becomes slightly less favorable in the sequence ethyl acetate, *p*-nitrophenyl acetate, 2,4-dinitrophenyl acetate. In the same sequence the equilibrium constant for heterolysis to the acylium ion becomes dramatically more favorable. To our surprise, in the course of asking whether the reaction of imidazole with *p*-nitrophenyl acetate might be concerted, we found not only evidence that this might be so, but that an even stronger case could be made for the virtual reaction of *p*-nitrophenoxide with *p*-nitrophenyl acetate. We can state the assumptions involved in our assertion that the acyl transfer reaction of imidazole with nitrophenyl acetates and the virtual reaction of *p*-nitrophenoxide with *p*-nitrophenyl acetate are concerted:

1. That the energetics of tetrahedral intermediate formation are approximately correct.
2. That the energetics of acylium ion formation are approximately correct.
3. That the assignment of intrinsic barriers is approximately correct.
4. That Marcus theory can be applied to calculate barriers not just at the edges of the diagram, but in the interior as well.
5. That the intrinsic barrier for a given reaction coordinate in a three-dimensional reaction coordinate diagram is independent of the value of the other reaction coordinate.

The value of the picture that we have developed for concerted reactions is that it gives a strong criterion for when a reaction will and will not be concerted. A fully concerted reaction, one where reaction from starting material to product has the disparity variable always close to 1/2, is only possible when the intrinsic barriers for the edge reactions are low and the thermodynamic barriers for formation of the potential intermediates are high.

This new theory of concerted reactions should be quite general. The major impediment to applying it to other reactions is the need for free energies of the two intermediates and for the two intrinsic barriers for the edge reactions. It seems clear that it will be possible, with some effort, to test our ideas on several reactions where there is experimental evidence bearing on the question of a stepwise vs. a concerted path. These investigations are being undertaken, and will be reported in due course.

Experimental

Materials

Acetylimidazole diethyl acetal and formylimidazole diethyl acetal were prepared by distilling off the by-product ethanol from a mixture of imidazole and a catalytic amount of *p*-toluenesulfonic acid in a large excess of triethyl orthoformate or triethyl orthoacetate as solvent over a 2-h period. Excess solvent was removed at room temperature and reduced pressure and the remaining product purified by distillation. Formylimidazole diethyl acetal: bp 82–84°C, 0.3 Torr; lit. (64) bp 52°C, 0.02 Torr; 60-MHz ^{1}H nmr spectrum ($CDCl_3$), δ: 7.8 (s, 1H, imidazole), 7.1 (s, 2H, imidazole), 6.1 (s, 1H, $HC(O)_2(N)$), 3.6 (q, 4H, $CH_2(O)(C)$), 1.2 (t, 6H, CH_3) ppm. Acetylimidazole diethyl acetal: bp 66–69°C, 0.1 Torr; 200-MHz ^{1}H nmr spectrum ($CDCl_3$), δ: 7.44 (s, 1H, imidazole), 7.06, 7.02 (2s, 2H, imidazole), 3.31–3.61 (m, 4H, $CH_2(O)(C)$), 1.74 (s, 3H, $CH_3C(O)_2(N)$), 1.22 (t, 6H, CH_3CH_2) ppm. *Exact Mass* calcd. for $C_9H_{16}N_2O_2$: 184.12116; found: 184.12094.

Formylimidazole dipropyl acetal

Tripropyl orthoformate was prepared by exchange, heating trimethyl orthoformate with excess *n*-propanol in the presence of a catalytic amount of *p*-toluenesulfonic acid. To drive the reaction to completion it was necessary to distill off the propanol and then add and distill off more propanol. Formylimidazole dipropyl acetal was prepared from tripropyl orthoformate by the same procedure used for formylimidazole diethyl acetal; bp 100°C at 0.5 Torr; 200-MHz ^{1}H nmr ($CDCl_3$), δ: 0.99 (t, 6H, CH_3), 1.68 (sextet, 4H, $CH_2(C)_2$), 3.53 (t, 4H, $CH_2(C)(O)$), 6.13 (s, 1H, $HC(O)_2(N)$), 8.1, 8.3, 8.9 (3s, 3H, imidazole) ppm. *Exact Mass* calcd. for $C_{10}H_{18}N_2O_2$: 198.13681; found: 198.13691.

Benzoylimidazole dimethyl acetal was prepared from imidazole with a catalytic amount of *p*-toluenesulfonic acid in trimethyl orthobenzoate as solvent. After heating in a 130°C oil bath for 14.5 h, with periodic addition of more catalyst, an nmr spectrum of the reaction mixture indicated that more than 90% of the imidazole had been consumed. Excess solvent was removed under reduced pressure and the last traces of imidazole were removed from the residue by extracting a diethyl ether solution three times with a 0.05 *M* pH 10.0 sodium carbonate/bicarbonate buffer. After drying, the ether was removed and the residue purified by distillation; bp 108–110°C, 0.1 Torr; 200-MHz ^{1}H nmr spectrum ($CDCl_3$), δ: 7.85 (s, 1H, imidazole), 7.45, 7.31 (2m, 5H, phenyl), 6.98, 6.88 (2s, 2H, imidazole), 3.11 (s, 6H, CH_3O) ppm. *Exact Mass* calcd. for $C_{12}H_{14}N_2O_2$: 218.10551; found: 218.10548.

1-(3'-Aminopropyl)-imidazole dihydrochloride (ref. 65)

N-(3-Bromopropyl)-phthalimide (Aldrich), 25 g (93.2 mmol), and imidazole, 12.7 g (186.5 mmol), were dissolved in acetone (60 mL) and refluxed for 4 h. After evaporation of the solvent under reduced pressure the syrupy yellow residue was redissolved in chloroform (100 mL) and the excess imidazole extracted with aqueous base. The organic layer was dried, the solvent removed, and the solid residue redissolved in ethanol (95%, 100 mL). Hydrazine hydrate (85%, 6 mL) was added and the mixture refluxed for 1.5 h. The solution was then filtered, evaporated, and the syrupy yellow residue dissolved in water, acidified (HCl), and filtered again. It was then made basic (NaOH) and extracted several times with chloroform. The contents of the organic phase were distilled (103–104°C, 500 mTorr), and converted to the dihydrochloride salt by evaporation from aqueous acid. Yield 3.24 g (16.4 mmol, 18%); 60-MHz nmr, free amine in $CDCl_3$ with TMS, δ: 1.3 (br s, NH_2), 1.8 (quintet, —C—CH_2—C—), 2.7 (t, —CH_2—N), 4.0 (t, Im—CH_2—C), 6.9, 7.0, 7.4 (3s, imidazole) ppm.

1-(2'-Aminoethyl)-imidazole dihydrochloride (ref. 65)

N-(2-Bromoethyl)-phthalimide (Aldrich), 25 g (98.4 mmol), and imidazole, 13.4 g (196.8 mmol), were refluxed in acetone (60 mL) for 4 h. Thin-layer chromatography (tlc) (5% methanol in chloroform on silica gel) indicated that the reaction was only about 50% complete so heating was continued for another 4 h. Solvent was then evaporated and excess imidazole was removed by dissolving the residue in chloroform (100 mL) and extracting it with aqueous base. The reaction product, *N*-(2-imidazolylethyl)-phthalimide, was separated from the unreacted *N*-(2-bromoethyl)-phthalimide by crystallizing the contents of the organic phase from acetone. Unreacted starting material was returned, with an excess of imidazole, to acetone solution and refluxed for a further 6 h, resulting in a second crop of product. The combined *N*-(imidazolylethyl)-phthalimide (14.7 g, 60.9 mmol) was dissolved with 4 mL hydrazine hydrate (85%, 183 mmol) in ethanol (95%, 100 mL) and refluxed for 1.5 h. The reaction mixture was then made acidic (HCl), filtered, and solvent removed under reduced presure. Product was recovered from the residue by dissolving it in aqueous base (75 mL), saturating with sodium chloride, and extracting several times with chloroform. The contents of the organic phase were distilled (80–82°C, 200 mTorr) and converted to the dihydrochloride salt by evaporation from aqueous acid. Yield 5.57 g (30.3 mmol, 31%); 60-MHz nmr, free amine in $CDCl_3$ with TMS, δ: 1.2 (br s, NH_2), 3.0 (t, C—CH_2—N), 4.0 (t, Im—CH_2—C), 7.0, 7.1, 7.5 (3s, imidazole) ppm.

TABLE 8. Boiling point measurements

	Boiling point (°C at 1 Torr)	Parameters[b] from least squares		ΔH_{vap}[c]	ΔC_{vap}[d]	$p_{25°C}$[c] (Torr)
		A	B			
Dimethyl phthalate	103.9	21.4 ± 0.92	8.07 ± 0.38			
Benzoylimidazole dimethyl acetal	114.7	26.3 ± 1.19	10.2 ± 0.46	20.45 ± 0.28	−37.2 ± 1.1	8.7×10^{-4}

Methods

Heats of hydrolysis

Calorimetry was carried out using the apparatus and procedure previously described (31). The results are summarized in Table 1. For each reaction the stoichiometry was determined by injecting a suitable amount of the compound into the deuterated analog of the calorimetry solvent (using relatively larger amounts of compound to allow nmr analysis), and then recording the ^{1}H nmr spectrum. The acylimidazole acetals invariably gave the corresponding alkyl ester, alcohol, and imidazole as products within the time required to make up the solution and run a spectrum.

Boiling point measurements on dimethyl phthalate, benzoylimidazole dimethyl acetal, formylimidazole diethyl acetal, formylimidazole dipropyl acetal, and acetylimidazole diethyl acetal

The boiling points of these compounds were determined at various pressures using the boiling point apparatus designed by Hoover *et al.* (66). The boiling point at a pressure of 1 Torr was then determined by interpolation, using a least-squares fit of $\ln(p) = A + B(1000/T)$ to the data. The values so obtained are found in Table 8.

The interpolated value for dimethyl phthalate is in good agreement with the accepted value of 100.3°C (67). We require vapor pressures at 25°C for these compounds; the extrapolations were carried out by a method we developed (8), which requires heats and heat capacities of vaporization. The estimated values that we used for this purpose are given in Table 8, as are the estimated vapor pressures.

Pauly assay for imidazole (ref. 68)

A sample, with water added if necessary to give 2 mL, was treated with 1% sulfanilic acid in 1.0 *M* HCl (0.4 mL) and 0.72 *M* $NaNO_2$ (0.4 mL). After 300 s 1.9 *M* sodium carbonate solution (1.2 mL) was added and the volume made up to 10.0 mL with water. At 800–900 s after the addition of $NaNO_2$ solution the absorbance at 498 nm was read. Calibration standards using known amounts of imidazole were run at the same time. The absorbance at 498 nm reaches a maximum and then slowly declines.

Solubility of formylimidazole dipropyl acetal

Portions of formylimidazole dipropyl acetal were stirred at 25°C with 0.1 *M* aqueous sodium hydroxide for 1.5 h in 50-mL centrifuge tubes. The tubes were centrifuged, and 2.0-mL samples were taken and diluted to 25.0 mL with 1.0 *M* HCl and let stand at room temperature. The imidazole content was analyzed by the Pauly procedure, using the absorbance at 498 nm 800–900 s after adding carbonate. The average of four samples was $(60.6 \pm 1.6) \times 10^{-3}$ *M* formylimidazole dipropyl acetal in the original saturated solutions.

Solubility of benzoylimidazole dimethyl acetal

A small quantity of benzoylimidazole dimethylacetal (50–100 μL) was added to 25 mL of a stirred solution of 0.1 *M* NaOH in a large test tube (3 × 20 cm) and the tube placed in a 25°C water bath. The end of the tube was sealed with Parafilm. After one day the mixtures containing 50 μL of benzoylimidazole dimethylacetal appeared homogeneous, while those with 100 μL still contained undissolved material after 3 days. Periodically, over three days, 30-μL aliquots of the supernatant solution from the experiment with 100 μL of benzoylimidazole dimethyl acetal were added to 5 mL 0.1 *M* aqueous HCl and the optical absorbance of this solution measured at 231 nm. The molar extinction coefficient for methylbenzoate in 0.1 *M* aqueous HCl was measured as 11 780 ± 20 M^{-1} cm^{-1}. A plot of the absorbance vs. time (after about 15 h) was best fitted by a straight line of slope 5.022×10^{-3} (absorbance units/h) and an intercept on the absorbance axis of 0.906. Thus the concentration of a saturated solution of benzoylimidazole dimethyl acetal in 0.1 *M* NaOH at 25°C is = 12.9 m*M*. The increase in absorbance at 231 nm with time is interpreted as being due to the slow hydrolysis of benzoylimidazole dimethyl acetal in 0.1 *M* NaOH to methyl benzoate, imidazole, and methanol. This increase of 5.022×10^{-3} absorbance units/h corresponds to a pseudo-first-order rate constant of 1.5×10^{-6} s^{-1} for hydrolysis. In a separate set of fairly crude experiments a small quantity of benzoylimidazole dimethyl dissolved in THF was injected into aqueous phosphate or carbonate buffered solution and the half-life for the hydrolysis of the acetal observed at 254 nm. The results of these experiments as well as the one above are found in Table 9.

TABLE 9. Crude kinetics of hydrolysis for benzoylimidazole dimethyl acetal[a]

	pH	$t_{1/2}$ (s)	log k
	8	28	−1.6
	9.2	400	−2.8
	10	4800	−3.8
0.1 *M* NaOH	13	450000	−5.8

[a]In aqueous solution at 25°C.

The rate observed at pH 13 is about 10 times faster than would have been expected from extrapolation of the data at lower pH; we conclude that there is an uncatalyzed rate of hydrolysis in addition to the acid-catalyzed path that dominates at low pH.

Determination of pK values for aminoethyl- and aminopropyl-imidazole

Solutions for titration of aminoethyl- and aminopropyl-imidazole were prepared by dissolving about 180 mg of the hydrochloride salts, along with sufficient KCl so that the total salt concentration was 0.1 *M*, in 100.0 mL water. This solution was then transferred to a 125-mL

(b) Titration of aminopropylimidazole					
185.60	9.37	605.80	0.934 ± 0.001	0.326 ± 0.002	0.240 ± 0.002
186.15	9.40	605.40	0.944 ± 0.001	0.313 ± 0.002	0.235 ± 0.002
187.25	9.45	604.55	0.948 ± 0.001	0.313 ± 0.002	0.234 ± 0.002
		pK_1 = 6.50 ± 0.02		pK_2 = 9.63 ± 0.02	

Erlenmeyer flask with stirring bar and placed in a water bath at 25°C. A pH electrode, which had been calibrated to standard buffers at pH 7.0 and 10.0, was immersed in the solution and it was titrated with 1.0 M NaOH using a Gilmont Ultraprecision micrometer buret, which could be read to 0.0001 mL.

The volume measurements for the background titration of 0.1 M KCl were subtracted from the volume measurements at the corresponding pH for the titration of the samples using a simple computer program. The data were then fitted to the equation

$$X = C(1/(1 + H/K_1) + 1/(1 + H/K_2))$$

where X is the volume of NaOH solution added, C is the volume of NaOH solution required to titrate one equivalent of the sample, H is the hydrogen ion concentration (10^{-pH}), and K_1 and K_2 are acid dissociation constants for the aminoethyl- and aminopropyl-imidazoles, by use of the least-squares program RIGLSQ47. This program takes as input the corrected values of titrant volume and pH, and estimates of C, K_1, and K_2. The results are shown in Table 10.

Equilibrium constant for the addition of imidazole to acetone

Samples were made up in a total volume of 5.0 mL, containing 0.5 mL of D_2O to provide a lock for the nmr spectrometer, 0.37 mL of acetone, 170 or 340 mg imidazole, and 0–0.45 mL 0.98 M HCl to adjust the pH. The 200-MHz nmr spectra showed, in addition to the major peak due to the CH_3 of acetone at 2.04 δ, a ^{13}C satellite signal at 1.72 δ, a signal at 1.26–1.34 δ attributed to the covalent hydrate of acetone (intensity 20.3 ± 8.7% of the ^{13}C satellite), and a peak at 1.44–1.73 δ attributed to the imidazole adduct of acetone (intensity related to imidazole concentration, and absent when no imidazole was present). The data that we obtained are found in Table S2.[3] A least-squares fit of the ratio of imidazole adduct to hydrate signal intensities to the equation $r = a[\text{Imidazole}]_{\text{free base}}$ gave a = 2.33 ± 0.09.

Appendix

The standard entropy of imidazole in the ideal gas standard state was estimated starting from the entropy of pyrrole, which is the closest model compound for which an entropy has been reported (69, 70). After suitable correction for the lower symmetry of imidazole, the entropy of pyrrole should be a good estimate for the entropy of imidazole. (The intrinsic[6] entropies of benzene and pyridine are very similar, 69.3 (72) and 69.0 (73) respectively.)

We can estimate entropies for the acylimidazole acetals by a variant on the Atom level method of Benson and Buss (9), with the groups attached to the central atom in the imidazolyl derivatives of interest treated as compound "atoms". For imidazolyl, the entropy contribution, 46.4, is obtained from the intrinsic entropy of imidazole by subtracting the contribution for a hydrogen atom, i.e., 21 (9). For methyl we calculated an average value based on the entropies of ethane, propane, isobutane, and neopentane (73) using suitable atomic parameters from ref. 9; the value was 30.22 ± 0.24. (The group level parameter for methyl is 30.41 (72).) For phenyl we calculated an average value based on the entropies for toluene, fluorobenzene, chlorobenzene, bromobenzene, and iodobenzene (73) using suitable atomic parameters from ref. 9; the value was 47.0 ± 2.0. (The value calculated using group level parameters was 49.96 (72).)

For methoxy and ethoxy, we derived parameters starting from the entropies of dimethyl ether and ethyl methyl ether (73) and the value for methyl derived above; the values so obtained were 39.2 for methoxy (calculated value from group level parameters was 39.09 (72)) and 48.6 for ethoxy (calculated value from group level parameters was 48.89 (72)).

These parameters permit the estimation of intrinsic entropies for the acylimidazole acetals and the 2-alkoxy-2-imidazolylpropanes; the values so calculated are found in Table 11.

We then tried an alternative estimation procedure, starting with the assumption that there is no net change in the intrinsic entropy for the exchange reaction shown:

$$R—C(OR')_2—Ph + H—Im \rightleftharpoons R—C(OR')_2—Im + H—Ph$$

The entropies of R—C(OR′)$_2$—Ph were estimated using Benson's group additivity values (72). No value was available

[6]Intrinsic entropies do not contain the contributions due to symmetry (71).

for the group $[C(C_B)_2(O)_2]$ needed for R—$C(OR')_2$—Ph with R = Ph or for $[C(C_B)_2(C)_2]$ needed for the analogous hydrocarbon. Accordingly we had to derive a reasonable value for $[C(C_B)_2(C)_2]$ before proceeding. No data allowing direct evaluation could be found, so an indirect approach was necessary. We determined the effect on related group contributions of replacing two tetrahedral carbons by two aromatic carbons and so estimated $[C(C_B)_2(C)_2]$ from $[C(C)_4]$.

We began by determining some of the unknown group contributions from literature data. $[CH_2(C_B)_2]$ was determined from the entropy of diphenylmethane, for which Stull *et al.* (73) report a value of 72.1 for $S^0(l)$. Vapor pressure data (67) lead to $p(25°C) = 0.038$ Torr by a short extrapolation using the Clausius–Clapeyron equation. The heat of vaporization of the liquid has been reported as $\Delta H_v(25°C) = 16.13 \pm 0.07$ (74). From $S^0(l)$, ΔH_{vap}, and $p(25°C)$ we calculate the standard entropy $S^0(g) = 106.52$. When the symmetry contribution is removed, $S^* = 110.66$.[7] Using Benson's values for $[C_BH]$ and $[C_B(C)]$ we can calculate that $[CH_2(C_B)_2] = 10.73$. This value is somewhat larger than the analogous contributions with C in place of C_B: $[CH_2(C)_2] = 9.42$, and $[CH_2(C)(C_B)] = 9.34$.

$[CH(C)(C_B)_2]$ was determined from the entropy of 1,1-diphenylethane for which Stull *et al.* report an $S^0(l) = 80.28$. Using vapor pressure data from Beilstein (75) we could calculate the vapor pressure by a short extrapolation using the Clausius–Clapeyron equation; $p(25°C) = 0.0132$ Torr. From the boiling point at 1 Torr, $\Delta H_v = 17.51 \pm 1.00$ (8). From the vapor pressure at 25°C, ΔH_v, and $S^0(l)$ we can calculate $S^0(g) = 117.22 \pm 3.35$. Removing the symmetry correction, $S^* = 122.17$. Then using Benson's group parameters for $[C_BH]$, $[C_B(C)]$, and $[CH_3(C)]$ we can calculate $[CH(C)(C_B)_2] = -8.16 \pm 3.35$. For comparison, $[CH(C)_3] = -12.07$ and $[CH(C)_2(C_B)] = -12.15$. The vapor pressure data used to estimate ΔH_{vap} and $p(25°C)$ were not of high precision, so that we must assign an uncertainty of 1 kcal/mol to ΔH_{vap}; this leads to an error of 3.35 in $S^0(g)$.

No data could be found for 2,2-diphenylpropane, so an analogous evaluation of $[C(C)_2(C_B)_2]$ was not possible. Instead we estimated the effect of replacing two C's by two C_B's. This effect is seen to be small; on going from $[CH_2(C)_2] = 9.42$ to $[CH_2(C_B)_2] = 10.73$ the change in the group contribution is seen to be 1.31. On going from $[CH(C)_3] = -12.07$ to $[CH(C)(C_B)_2] = -8.16 \pm 3.35$ the change in the group contribution is 3.91 ± 3.35. Thus the second estimate is less precise, but indistinguishable. Consequently we should use the value of 1.31 in estimating the group contribution for $[C(C)_2(C_B)_2]$. Under the circumstances, the best guess for $[C(C)_2(C_B)_2]$ is -35.10 (the value for $[C(C)_4]$ (72)) + 1.31 = -33.79.

We can now estimate the standard entropies for the hydrocarbon analogs of the acylimidazole acetals with $-CH_2-$ in place of -O- and phenyl in place of imidazolyl. From these values we can estimate the standard entropies of the corresponding acetals using the correction from $-CH_2-$ to -O- suggested by Stull *et al.* (73). The values so obtained are, for $(EtO)_2CH$—Ph, $S^*(g) = 133.78$; for $(EtO)_2C(Me)$—Ph, $S^*(g) = 141.17$; for $(MeO)_2C(Ph)_2$, $S^*(g) = 143.27$. Using the disproportionation assumption we may then calculate the entropies of the acylimidazole acetals, obtaining: $(EtO)_2CH$—Im, $S^0(g) = 130.0$; $(EtO)_2C(Me)$—Im, $S^0(g) = 132.7$; $(MeO)_2C(Ph)$—Im, $S^0(g) = 135.62$.

Finally we tried an atomic level calculation starting from the standard entropies of the corresponding orthoesters, and correcting for the difference in contributions between the appropriate alkoxyl group and imidazolyl. It was first necessary to estimate the standard entropies of the orthoesters, because none of these values have been measured. We did this by starting with the closest hydrocarbon analogs for which entropy data were available. For triethyl orthoformate we start with the analogous hydrocarbon, 4-propylheptane, for which $S^0(g) = 125.56$ (73). Correcting for symmetry and replacement of $-C_2-$ and -O-, we get $S^0(g) = 121.78$ for the orthoester and $S^0(g) = 123.9$ for formylimidazole diethyl acetal. For trimethyl orthoacetate the hydrocarbon analog is 4-methyl-4-propylheptane; the standard entropy of this compound has not been reported but a value is available for 3-ethyl-3-methylpentane, $S^0(g) = 103.48$ (73). By adding three times the group contribution for $[CH_2(C)_2]$ we obtain $S^0(g) = 127.96$ for triethyl orthoacetate and $S^0(g) = 130.1$ for acetylimidazole diethyl acetal. For trimethyl orthobenzoate the hydrocarbon analog is 1,1-diethylpropylbenzene. The standard entropy for this compound is unknown, but it can be estimated from that of *tert*-butylbenzene, which can be calculated from the available data: $S^0(l) = 66.6$ (73), $\Delta H_{vap} = 11.50 \pm 0.05$ (76), $p(25°C) = 2.18$ Torr (calculated from data in ref. 67). These values lead to $S^0(g) = 93.53$ for *tert*-butylbenzene, and thence to $S^0(g) = 121.79$ for 1,1-diethylpropylbenzene. Finally we calculate $S^0(g) = 118.01$ for trimethyl orthobenzoate and $S^0(g) = 129.3$ for benzoylimidazole dimethyl acetal.

These values are not in full agreement, but the various estimates are not very different. We use the average of the estimates, with uncertainty limits based on the scatter.

[7]We follow Stull *et al.* (73) and use S^* to mean the entropy not corrected for symmetry, and S^0 to mean the standard entropy, including the symmetry corrections.

Electronegativity in density functional theory: diatomic bond energies and hardness parameters

A. R. ORSKY AND M. A. WHITEHEAD
Department of Chemistry, McGill University, 801 Sherbrooke St. West, Montreal, P.Q., Canada H3A 2K6

Received January 5, 1987

This paper is dedicated to Professor John T. Edward

A. R. ORSKY and M. A. WHITEHEAD. Can. J. Chem. **65**, 1970 (1987).

New definitions of the rate of change of electronegativity with charge, the hardness η, of an atom, are developed for acids A and bases B, where $\eta_A = 1/4(I_{(A^+)} - A_{(A^0)})$ and $\eta_B = 1/4(I_{(B^0)} - A_{(B^-)}) \approx 1/4(I_{(B^0)})$. These definitions reproduce the experimental ordering of hard and soft acids and bases, and produce good trends in diatomic bond energies.

A. R. ORSKY et M. A. WHITEHEAD. Can. J. Chem. **65**, 1970 (1987).

Pour les acides A et les bases B, on a développé de nouvelles définitions du taux de changement de l'électronégativité avec la charge et la dureté η d'un atome; dans cette définition, $\eta_A = 1/4(I_{(A^+)} - A_{(A^0)})$ et $\eta_B = 1/4(I_{(B^0)} - A_{(B^-)}) \approx 1/4(I_{(B^0)})$. Ces définitions permettent de reproduire l'ordre expérimental des acides et des bases durs et mous et elles fournissent de bonnes tendances pour les énergies des liaisons diatomiques.

[Traduit par la revue]

I. Introduction

Pauling postulated the energy of *covalent bonds* to be additive. Thus for two atoms, A and B, the bond energy E_{AB} should be the arithmetic mean of the bond energy E_{A_2} in A_2 and E_{B_2} in B_2,

$$[1] \qquad \frac{E_{A_2} + E_{B_2}}{2} = E_{AB}$$

For a covalent bond with polar character, the *ionic* character of the bond AB reflects the additional stabilization caused by the coulomb energy, and

$$[2] \qquad E^i_{AB} = E_{AB} - 1/2(E_{A_2} + E_{B_2})$$

where E^i_{AB}, the ionic component of the bond energy, increases as the difference in the ability of A and B to attract electrons increases in the *molecule* AB.

This qualitative property of an atom to attract electrons in a molecule is the *chemical electronegativity* (3), $\bar{\chi}$. Mulliken (4) developed an equation to represent $\bar{\chi}$ for an atom, in terms of I and A, the isolated atom ionization energy and electron affinity,

$$[3] \qquad \bar{\chi} = 1/2(I + A)$$

It if is assumed (5, 6) that $\bar{\chi}$ is orbital dependent, then

$$[4] \qquad \bar{\chi}_S = 1/2(I_{jS} + A_{jS})$$

where $\bar{\chi}_S$ is the chemical electronegativity of atom S, I_{jS} is the ionization energy, and A_{jS} is the electron affinity of the jth orbital of S. The chemical electronegativity represents the average binding energy of electrons in an atom and the corresponding negative ion (7),

$$[4a] \qquad X + Y \rightarrow X^+ + Y^- \qquad \Delta E = I_X - A_Y$$

$$[4b] \qquad X + Y \rightarrow X^- + Y^+ \qquad \Delta E = I_Y - A_X$$

because the energy changes of reactions [4*a*] and [4*b*] are equal only if $\bar{\chi}_X = \bar{\chi}_Y$.

The energy of an atom can be expanded as a function of the charge $q = Z - N$, where N is the number of electrons about a nucleus of charge Z. Using a polynomial expansion of q (7),

$$[5] \qquad E(q) = aq + bq^2 + cq^3 + dq^4$$

This function is useful if $E(q)$ is differentiable, leading to *differential electronegativity* (3), $\chi_S(q)$,

$$[6] \qquad \chi_S(q) = \left[\frac{\delta E_S(q)}{\delta q}\right]_q$$

and from [5] and [6] the chemical and differential electronegativities are equal for neutral atoms,

$$[7] \qquad \chi_{q=0} = \bar{\chi}$$

Assuming that $E(q)$ is a differentiable function of q gives a functional definition to χ.

However, this assumption has not been fully proved, and remains a real problem for non-integer q, when $E(q)$ has no clear physical meaning. When the total energy, $E(q)$, is expressed within density functional theory (8), and is assumed differentiable (8),

$$[8] \qquad \chi_S(q) = \left[\frac{\delta E_S(q)}{\delta q}\right]_q = -\mu_S$$

where μ is the *chemical potential* (5).

Consequently when two atoms A and B form a molecule AB, they take on an equilibrium χ-value, $\chi_{AB}(q')$, because of electronegativity equalization (9):

$$[9] \qquad A + B \rightarrow AB$$

and

$$[10] \qquad \chi_A(q_A) + \chi_B(q_B) \rightarrow \chi_{AB}(q_{AB})$$

thus

$$[11] \qquad \chi_{AB}(q_{AB}) = \chi_A(q'_A) = \chi_B(q'_B)$$

and

$$[12] \qquad q'_A - q_A = q_B - q'_B = \Delta q = i$$

where i is the *ionic character* of the bond and primes indicate equilibrium charge values. The initial and equilibrium electron negativities of A and B are given by $\chi_A(q_A)$ and $\chi_A(q'_A)$, and $\chi_B(q_B)$ and $\chi_B(q'_B)$ respectively. In molecular formation, all the valence atomic orbitals determine χ_{AB}, because I, A, and $\chi(q)$ are all functions of the occupancy of all the orbitals in the valence shell.

For the reaction in eq. [9] E_{AB} is given by [13] or [14] where E^c_{AB} and E^i_{AB} are the covalent and ionic components of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

E_{AB}, and $E_{AB}(i)$ is a function of the ionic character

[13] $$E_{AB} = E^c_{AB} + E^i_{AB}$$

and

[14] $$E_{AB} = 1/2(E_{A_2} + E_{B_2}) + E_{AB}(i)$$

which can be rearranged to give covalent and ionic components of the bond energy,

[15] $$E^c_{AB} = 1/2(E_{A_2} + E_{B_2})$$

[16] $$E^i_{AB} = E_{AB}(i)$$

Using the change in energy with respect to the number of electrons in [6] gives

[17] $$E^i_{AB} = E_{AB}(i) \approx \frac{\delta E_{AB}(q)}{\delta q}\Delta q$$

or

[18] $$E^i_{AB} = \chi_{AB}(q)i$$

since $\Delta q = i$ by [12],

[19] $$E^i_{AB} = \chi(q)i = E_{AB} - 1/2(E_{A_2} + E_{B_2})$$

II. Hardness

The second derivative of the energy (10) with respect to charge q was first called the hardness parameter η by Parr and Pearson (2)

[20] $$\eta_S = \left[\frac{\delta^2 E(q)}{\delta q^2}\right]_q = 1/2\left[\frac{\delta \chi}{\delta q}\right]_q$$

and from the finite difference formula that hardness was expressed in terms of the ionization potential and electron affinity as

[21] $$\eta_S = 1/2(I_S - A_S)$$

identical with the c parameter in traditional electronegativity theory (10, 11). The electronegativity is also derivable from the finite difference formula. However, there are two distinct derivations of the electronegativity: one assumes that the dependence of the electronegativity on the charge is linear between A^+ and A^-; the other assumes a distinct discontinuity at A^0 between the $A^+ \rightarrow A^0$ and $A^0 \rightarrow A^-$ lines (8). The present derivation uses the finite difference formula and applies it to a discontinuous electronegativity curve.

The change in energy going from a neutral atom to the positive or negative ion is calculated from the energies of these states:

[22] $$S^- \leftrightarrow S^0 \leftrightarrow S^+$$

$$\textit{Energy:} \quad (E_0 - A_{S^0}) \leftrightarrow E_0 \leftrightarrow (E_0 + I_{S^0})$$

where I_{S^0} and A_{S^0} are the energies necessary to remove an electron from S^0 and S^- respectively. The energy of S in the neutral state is E_0.

To calculate the charge transfer from S^0 to $S^\pm$ it is necessary to calculate the electronegativity at $q = 0$, $\chi_{q=0}$, namely $q'_S = q_S + \Delta q$ ([12]). Combining the electronegativity from [18] with the ionic energy E^i from [17] and the relation of ionic character and change in electronegativity in [12]

[23] $$\chi(q) = \frac{\delta E(q)}{\delta q} \approx \frac{\Delta E}{\Delta q}$$

Therefore

[24] $$\left[\frac{\Delta E}{\Delta q}\right]_{q=0} = \frac{(E_0 + I_{S^0}) - (E_0 - A_{S^0})}{2}$$

where the energies of $S^\pm$ are $E_{S^\pm}$ respectively and $\Delta E = E_{S^+} - E_{S^-}$ with $\Delta q = 2$. Substituting the approximate equality in [23]

[25] $$\left[\frac{\delta E}{\delta q}\right]_{q=0} \approx \frac{(I_{S^0} + A_{S^0})}{2}$$

Therefore

[26] $$\bar{\chi}_{q=0} = 1/2(I_{S^0} + A_{S^0})$$

The equality holds in [23] and [24] in the limit where Δq goes to zero.

This gives a new definition for an acid and a base. Consider an acid–base reaction $A^+ + B^- \rightarrow A^{\delta+}B^{\delta-}$. There will be charge transfer from the base B^- to the acid A^+ until the electronegativity is equalized, giving molecular atoms with charges $A^{\delta+}$ and $B^{\delta-}$. It is assumed that the change in $\chi(q)$ between A^0 and $A^{\delta+}$ is the same as that between A^0 and A^+, so that the change in $\chi(q)$ and charge transfer in the final molecule can be calculated from the covalent state A^0B^0. $\chi(q)$ is defined by the straight line connecting $\chi(A^0)$ and $\chi(A^+)$, and $\chi(B^0)$ and $\chi(B^-)$ for the acid and base, respectively. Therefore $\chi(q)$ is differentiable with respect to charge q and well defined in the region of charge transfer.

The electronegativity of the kth orbital is

[27] $$\chi_k(q_k) = \tfrac{1}{2}(I_k(q_k) + A_k(q_k))$$

where

[28] $$I_k(q_k) = E(q_k) - E(q_k - 1)$$

and

[29] $$A_k(q_k) = E(q_k + 1) - E(q_k)$$

for orbital occupany q_k where A_k and I_k are the electron affinity and ionization potential of the kth orbital respectively, and $E(q_k)$ is the energy of the system as a function of q_k. The finite difference approximation is now applied to the electronegativity line to give the hardness η,

[30] $$\frac{\delta^2 E(q)}{\delta q^2} = \frac{\delta \chi}{\delta q} \approx \frac{1}{2}\left[\frac{\Delta I_k(q_k)}{\Delta q} + \frac{\Delta A_k(q_k)}{\Delta q}\right]$$

For an acid in the reaction $A^+ + B^- \rightarrow A^{\delta+}B^{\delta-}$ the energy changes in going from A^0 to A^+ and B^0 to B^- are used to evaluate the terms in [29], where $q_{A^0} = q_{(A^+)} + \Delta q$, so that

[31] $$\Delta q = 1$$

The change in the ionization potential with charge is

[32] $$\Delta I_k(q_k) = I_k(A^+) - I_k(A^0)$$

In terms of charge this change in ionization potential is

[33] $$\Delta I_k(q_k) = I_k(q_k - 1) - I_k(q_k)$$

and in terms of energies of the atoms and ions is

[34] $$\Delta I_k(q_k) = [(E(q_k - 1) - E(q_k - 2)) - (E(q_k) - E(q_k - 1))]$$

Therefore

[35] $$\Delta I_k(q_k) = -E(q_k) + 2E(q_k - 1) - E(q_k - 2)$$

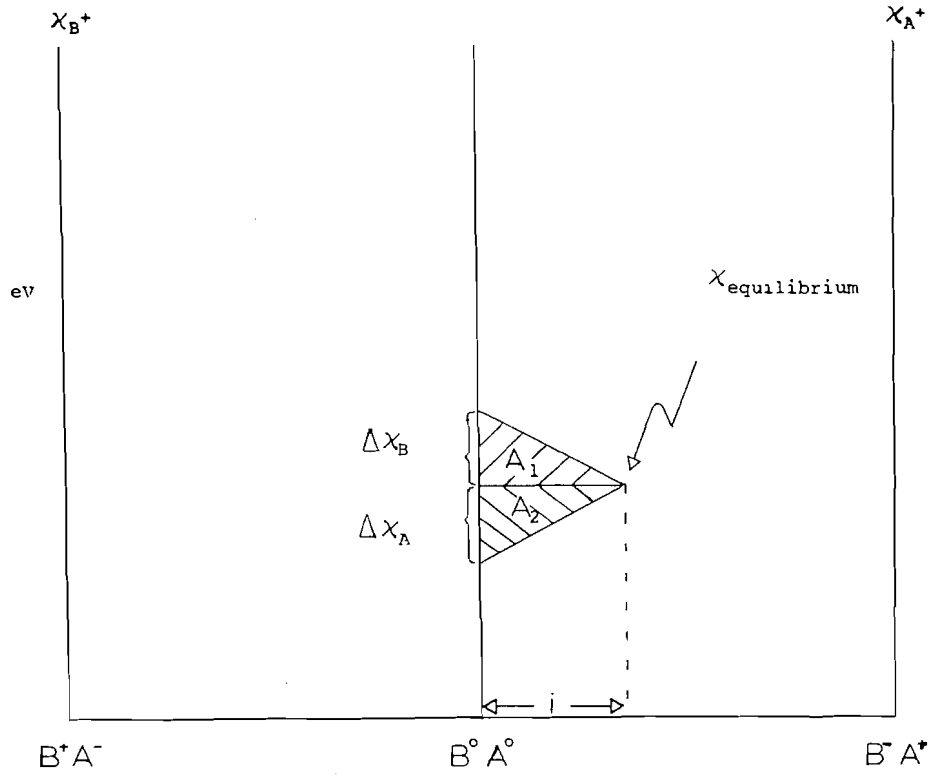

FIG. 1. Graphical intersection of the acid and base electronegativity lines $\chi_A(q)$ and $\chi_B(q)$, the slopes of which are η_A and η_B respectively. The equilibrium electronegativity $\chi_{AB} = \chi_{equilibrium}$ gives the charge transfer i, and the difference in areas $A_2 - A_1$ is the charge transfer energy, ΔE_{ct}.

Similarly the change in the electron affinity with charge, A^0 going to A^+, is

[36] $\Delta A_k(q_k) = A_k(A^+) - A_k(A^0)$

giving

[37] $\Delta A_k(q_k) = A_k(q_k - 1) - A_k(q_k)$

expanding to

[38] $\Delta A_k(q_k) = [(E(q_k) - E(q_k - 1)) - (E(q_k + 1) - E(q_k))]$

and therefore

[39] $\Delta A_k(q_k) = -E(q_k + 1) - 2E(q_k) - E(q_k - 1)$

Using [35] and [39] in [30]

[40] $2\eta_{Acid} = \dfrac{\delta\chi}{\delta q} \approx \frac{1}{2}[E(q_k - 1) - E(q_k - 2) - E(q_k + 1) + E(q_k)]$

reducing to

[41] $2\eta_{Acid} = \dfrac{\delta\chi}{\delta q} \approx -\frac{1}{2}[I_k(q_k - 1) - A_k(q_k)]$

Consequently η_{Acid} is

[42] $\eta_A = \dfrac{1}{2}\dfrac{\delta\chi}{\delta q} \approx \dfrac{1}{4}[I_k(q_k - 1) - A_k(q_k)]$

Similarly the base in the reaction $A^+ + B^- \rightarrow A^{\delta+}B^{\delta-}$ has its terms calculated ([31]) from the transfer B^0 to B^- where $q_{B^0} = q_{(B^-)} - \Delta q$,

[43] $\Delta I_k(q_k) = -E(q_k + 1) + 2E(q_k) - E(q_k - 1)$

and

[44] $\Delta A_k(q_k) = -E(q_k + 2) + 2E(q_k + 1) + E(q_k)$

Using [43] and [44] in [30] gives

[45] $2\eta_{Base} = \dfrac{\delta\chi}{\delta q} \approx \frac{1}{2}[E(q_k) - E(q_k - 1) - E(q_k + 2) + E(q_k + 1)]$

hence

[46] $2\eta_{Base} = \dfrac{\delta\chi}{\delta q} \approx \frac{1}{2}[I_k(q_k) - A_k(q_k + 1)]$

Assuming $A_k(q_k + 1) \approx 0$, which is reasonable because a negative ion has zero or a small negative electron affinity, η_{Base} is

[47] $\eta_B = \dfrac{1}{2}\dfrac{\delta\chi}{\delta q} \approx \dfrac{1}{4}I_k(q_k)$

Within the usual assumptions of electronegativity equalization (8) and the differentiability of the electronegativity with charge, these expressions for the hardness of acids η_{A^+} and bases η_{B^-} are self consistent.

The electronegativity difference of A^+ and B^- indicates which atom in a reaction is the acid and which the base; the hardness shows the rate of change of the electronegativity with charge and governs the charge transfer in the polar covalent bond. The electronegativity variation is that developed by Gopinathan and Whitehead (8) and subsequently discussed by Parr (2), in which there is a discontinuity in the energy as a function of charge at the uncharged atom S^0. This gives rise to two different slopes for η between S^0 and S^+ and between S^0 and S^-.

The expression for $E(q)$ can be used to calculate the change in energy in going from the free atom towards the acid A^+ or base B^- (9, 10),

$$[48a] \quad \Delta E_A = E_{(A^{\delta+})} - E_{A^0} = \chi_{A^0}\Delta q + \eta_A \Delta q^2$$

and

$$[48b] \quad \Delta E_B = E_{(B^{\delta-})} - E_{B^0} = -\chi_{B^0}\Delta q + \eta_B \Delta q^2$$

Equalization in the electronegativity gives a total energy change

$$\Delta E = \Delta E_A + \Delta E_B$$

or

$$[49] \quad \Delta E = (\chi_{A^0} - \chi_{B^0})\Delta q + (\eta_A + \eta_B)\Delta q^2$$

where η_A is the slope of the $\chi(q)$ line between $q = 0$ and $q = 1$, and η_B is for $q = 0$ to $q = -1$. Differentiating,

$$[50] \quad \chi_{AB} = \chi'_A = \chi'_B = \chi_{A^0} + 2\eta_A \Delta q = \chi_{B^0} - 2\eta_B \Delta q$$

However, the ionic character is given by the charge transfer

$$[51] \quad i = \Delta q = \frac{(\chi_{B^0} - \chi_{A^0})}{2(\eta_A + \eta_B)}$$

Substituting this expression into the energy expression

$$[52] \quad \Delta E = -\frac{(\chi_{A^0} - \chi_{B^0})^2}{4(\eta_A + \eta_B)}$$

This is the charge transfer energy

$$[53] \quad \Delta E_{ct} = -\frac{(\Delta\chi_i)^2}{4\sum_i \eta_i}$$

This scheme predates any concepts of hardness. The present hardness parameter was simply a constant c in the parabolic expansion of the energy in terms of charge (10, 11, 16),

$$[54] \quad E(q) = a + bq + cq^2$$

$$[55] \quad \chi(q) = b + 2cq$$

where

$$[56] \quad b = 1/2(3I_S - A_S)$$

and

$$[57] \quad c = 1/2(A_S - I_S)$$

which is identical with Parr's definition of hardness (2). Consequently the results in Tables 2 and 3 from Parr are similar to those in Baird and Whitehead (10). The group orbital electronegativities (11) make the Parr and present formulations immediately applicable to large molecules (12), while the wealth of BEEM–π calculations (12, 14, 15) should open the theory to conjugated acids and bases.

The fundamental change in the theory of hardness is caused by the fundamental change in the charge dependence of the electronegativity introduced by Gopinathan and Whitehead (8) within the density functional theory. The present extension of this theory gives the discontinuity of the electronegativity at the unit occupancy of the atom, which insures that the rate of change of the electronegativity is different in going from S^+ to S^0 and from S^0 to S^-, so that two hardness parameters are required.

In Fig. 1, the χ-dependence on q is shown graphically. Where the acid and base lines cross is $\chi_{equilibrium} = \chi_{molecular}$ and this gives the ionic character as the distance from χ^0 in χ–q space.

The energy stabilization caused by charge transfer is

$$[58] \quad \Delta E = -\int_0^i \chi_B(q_B)dq_B + \int_0^i \chi_A(q_A)dq_A$$

This is the difference in areas $A_2 - A_1$ in Fig. 1.

III. Hard and soft acids and bases

Chemical hardness and softness (17) explained the behaviour of Lewis acids and bases. Depending on the stability of the complex, AB, Lewis acids and Lewis bases were divided into two kinds, hard and soft. The generalized characteristics and behaviour are

Soft base	*Hard base*
low electronegativity	high electronegativity
high polarizability	low polarizability
easily oxidized	hard to oxidize
low energy empty orbitals	high energy empty orbitals
Soft acid	*Hard acid*
low valence	high valence
large size	small size
several easily excited electrons	no easily excited electrons

while the HSAB (17) principle states that hard acids prefer hard bases and soft acids prefer soft bases.

Without even inventing hardness parameters the sequence above can be easily described in terms of electronegativity (10) of the uncharged atom:

hard acid → soft acid → soft base → hard base

low electronegativity → high electronegativity

Obviously $A^0 \rightarrow A^+$ raises the electronegativity and $B^0 \rightarrow B^-$ lowers the electronegativity; the lower the electronegativity, the higher it becomes, and vice versa. Thus the pattern for the ions is

hard acid → soft acid → soft base → hard base

high electronegativity → low electronegativity

This is obviously true: [52] shows that charge transfer is driven by differences in electronegativity, and inhibited by the sum of hardnesses.

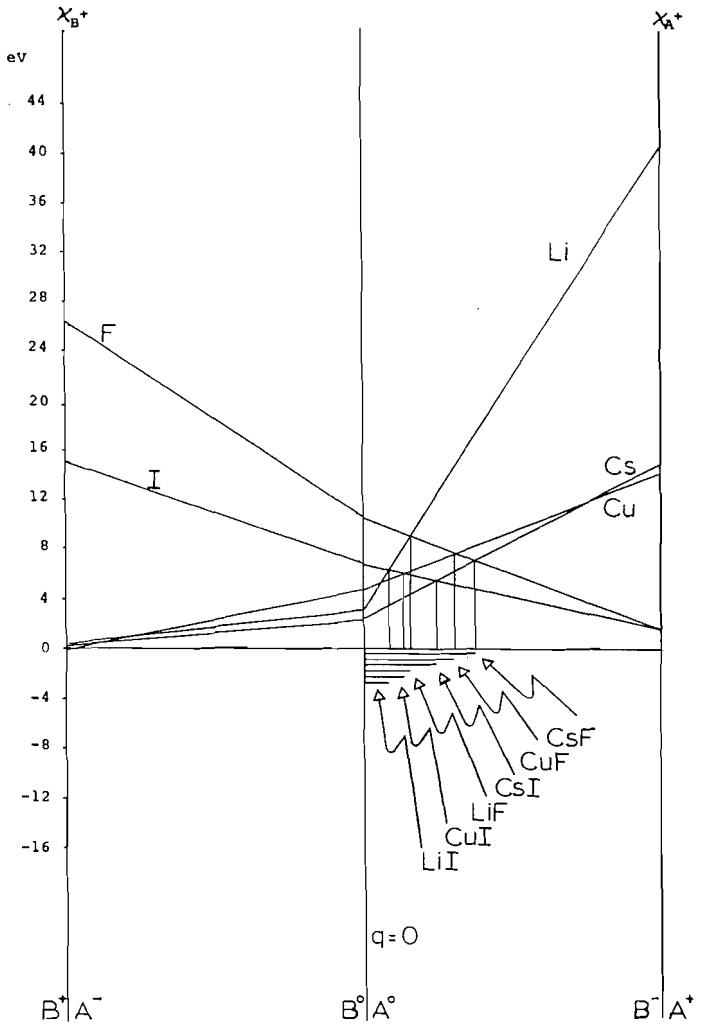

FIG. 2. Illustrative plots of $\chi(q)$ versus $q = Z - N$, which determine the charge transfer and charge transfer energy in the present theory of some typical bases. The discontinuity at $q = 0$ gives two $\chi(q)$ lines: one from $q = 0$ to $q = 1$ and the other from $q = 0$ to $q = -1$ with slopes $\eta_A = 1/4(I_{(A^+)} - A_{(A^0)})$ and $\eta_B = 1/4(I_{(B^0)} - A_{(B^-)})$ corresponding to an acid and base.

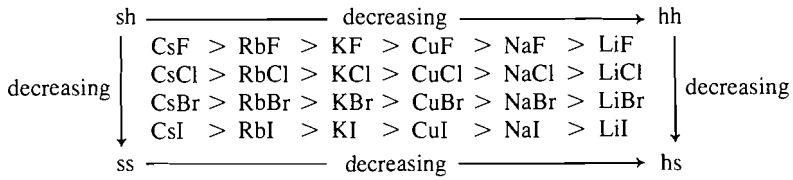
IV. Calculated hardness and charge transfer

To compare the present theory with that of Parr (2) the electronegativities χ and hardnesses η were calculated for the same set of alkali and copper halogen compounds. The charge transfer energy ΔE_{ct} and numerical charge transfer, i, were calculated from the data in Tables 1 through 3. The graphs for combining three acids and two bases as selected illustrations are given in Figs. 2 and 3 while the overall trends in Figs. 2 through 6 are discussed in the text.

The new definitions of the hardness η_A and η_B give results whose trend in ΔE_{ct} and i parallel the experimental sequences except for the copper halogenides, which occur between potassium and sodium instead of after lithium, Table 4:



The hardness parameters agree with the sequence expected within the HSAB theory; thus copper is the softest acid,

η_A: acids: Li > Na > K > Rb > Cs > Cu

η_B: bases: F > Cl > Br > I

The hardness of a base behaving as an acid, and vice versa, is well described by the appropriate hardness definition, η_{Acid} or η_{Base}. Thus lithium is a hard acid as Li^+, and a soft base as Li^-. Interhalogen molecules and alkali metal halides are also well described. Figure 2 gives the graphical results.

The calculated charge transfers, Table 3, are quite small and the difference in charge transfer between any pair of compounds is large. The interhalogens are well described. The charge transfer energies, Table 4, are small. The hardness difference is inversely related to the charge transfer,

$$[59] \quad i = \left[\frac{2\chi_{eq} - \Sigma\chi_{A,B}}{2}\right]\frac{1}{\Delta\eta}$$

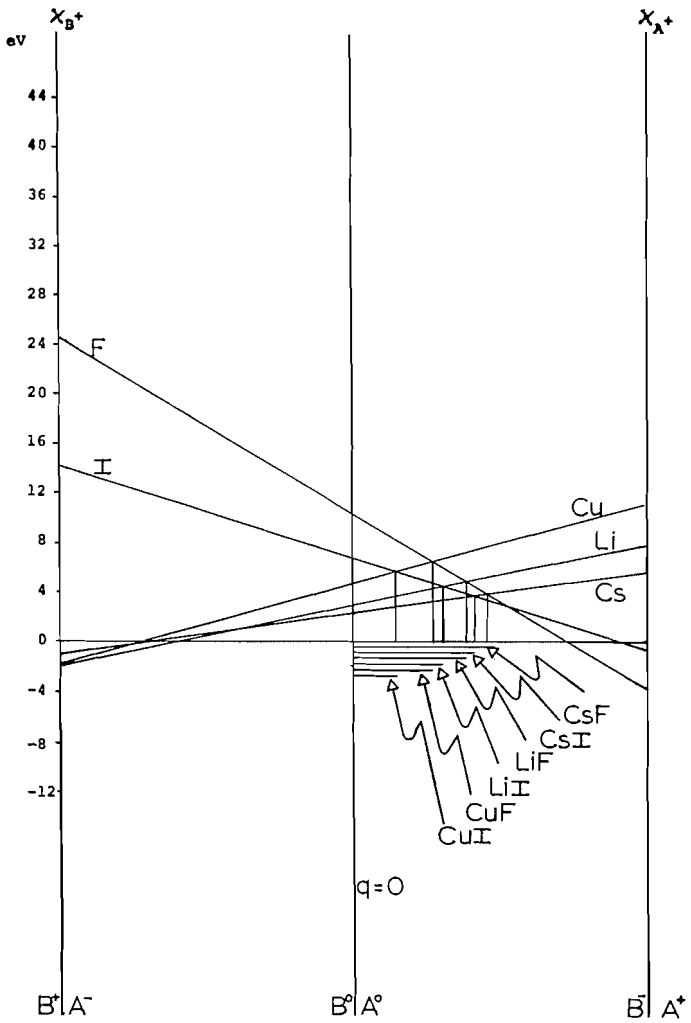


FIG. 3. Illustrative plots of $\chi(q) = Z - N$ using Parr's definition of the hardness, $\eta = 1/2(I - A)$.

and comes from [50]. Therefore the dependence of charge transfer on hardness difference $\Delta\eta$ is the result of [59] and not of

$$[60] \quad I_{B'} - I_{A'} = \eta_B - \eta_A$$

where the primes mean after charge transfer and before bond formation (2). It is dependent on $\Delta\eta$ relative to the sum of the electronegativities of the acid and base, $\Sigma_{AB}\chi$.

The bonding is poorly described quantitatively except for the interhalogens, but the trends are excellent, as shown by the dipole moment μ plot against the calculated charge transfer i, Fig. 4. The plot of hardness sum against the molar polarizability P shows the expected trend: η is proportional to $1/P$ where $P = \frac{4\pi}{3}N(\alpha + \mu^2/3kT)$. The polarizability, α, is the induced moment per molecule from the temporary distortion of the electron orbit by an applied field, Fig. 5.

V. Discussion

From Fig. 2 and the trends above, it can be seen that the new definitions η_A and η_B give different results from the earlier definition. While the earlier definition was also dependent on

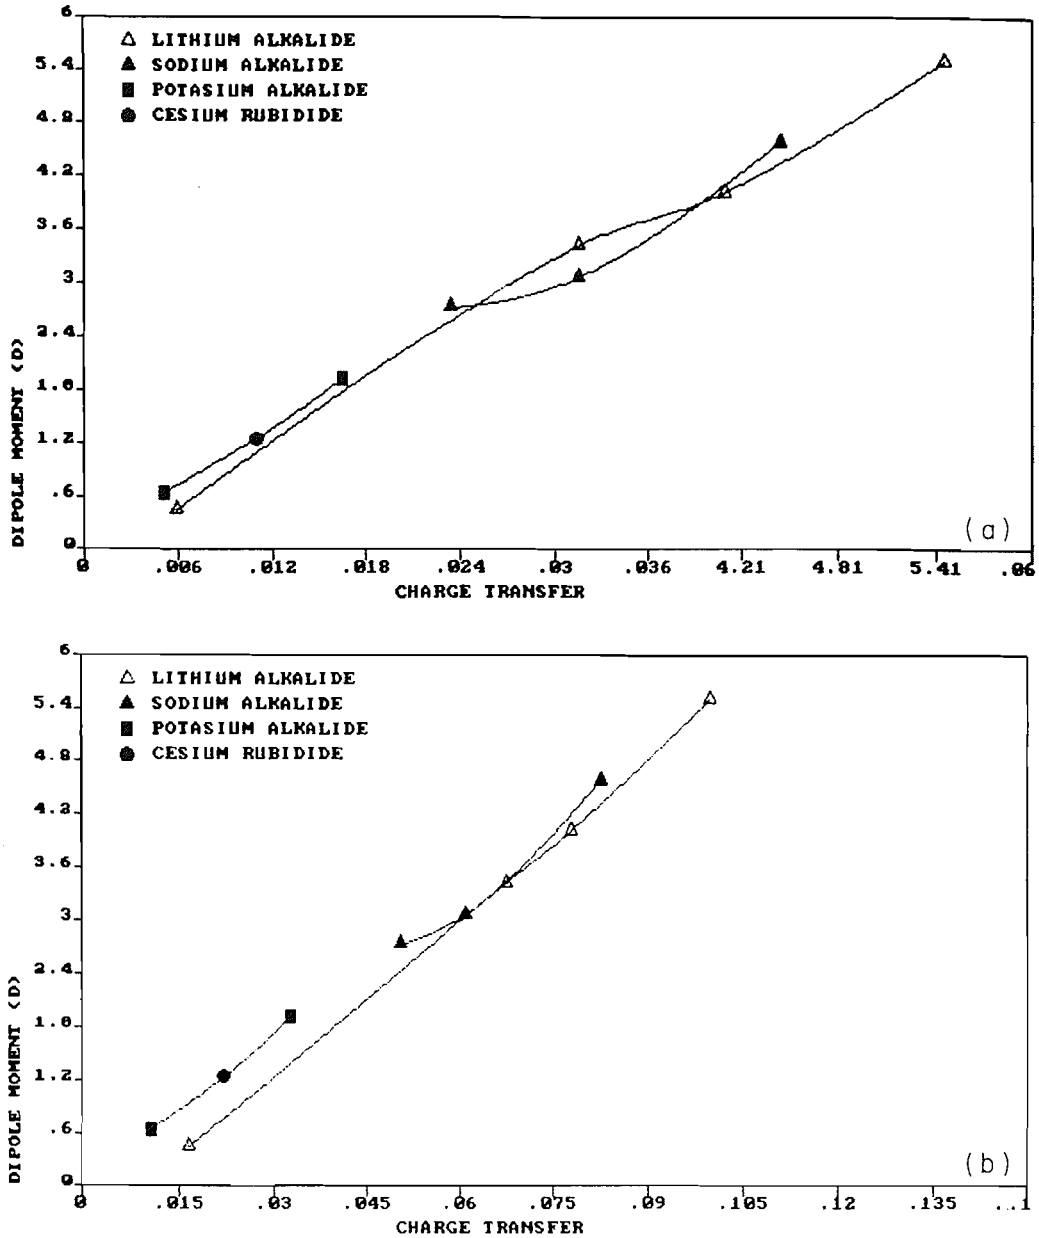

FIG. 4. (*a*) Experimental interalkali dipole moments are related to the calculated charge transfers using the present definitions of hardness $\eta_A = 1/4(I_{(A^+)} - A_{(A^0)})$ and $\eta_B = 1/4(I_{(B^0)} - A_{(B^-)})$ and the charge transfer $i = \dfrac{\Delta\chi_{A,B}}{2\Sigma_{A,B}\eta}$ (from Table 3). (*b*) Experimental interalkali dipole moments are related to the calculated charge transfers using Parr's definition (2) of hardness, $\eta = 1/2(I - A)$ and $i = \dfrac{\Delta\chi_{A,B}}{2\Sigma\eta}$ (Table 3).

whether the hardness was for an acid or base

[61] $\eta_B = \eta(B^+) = 1/2(I_{B^+} - A_{B^+})$

[62] $\eta_B = \eta(B) = 1/2(I_B - A_B)$

and

[63] $\eta_A = \eta(A) = 1/2(I_A - A_A)$

These equations do not fit the definition of η, [20], that hardness is "the resistance of the chemical potential (minus electronegativity) to change in the number of electrons" (2). It would be difficult to imagine that the hardness would not change on adding an electron to a base. Similarly, [6] relates ionization potentials *after charge transfer* to hardnesses *before charge transfer*, which is illogical.

The comparison of the dipole moments and polarizabilities from these equations with the present results, Figs. 4 and 5, shows similar trends although the spread in polarizabilities with the present results are more reasonable.

The trends in the HSAB theory are not predicted by the definitions, [61] through [63]. The hard–soft combination CsF has the most charge transfer, while the hard–hard and soft–soft combinations, LiF and CsI, have moderate charge transfer: they should have the least. Also copper is predicted a harder acid than lithium; HSAB theory requires copper to be a model soft and lithium a model hard acid, Fig. 3 (compare with Fig. 2). The charge transfers, Table 3, are much larger, and the difference in charge transfer is much less by the definitions, [61] through [63]; the alkali halides are, however, better fitted with the new hardness definition. The relations between the

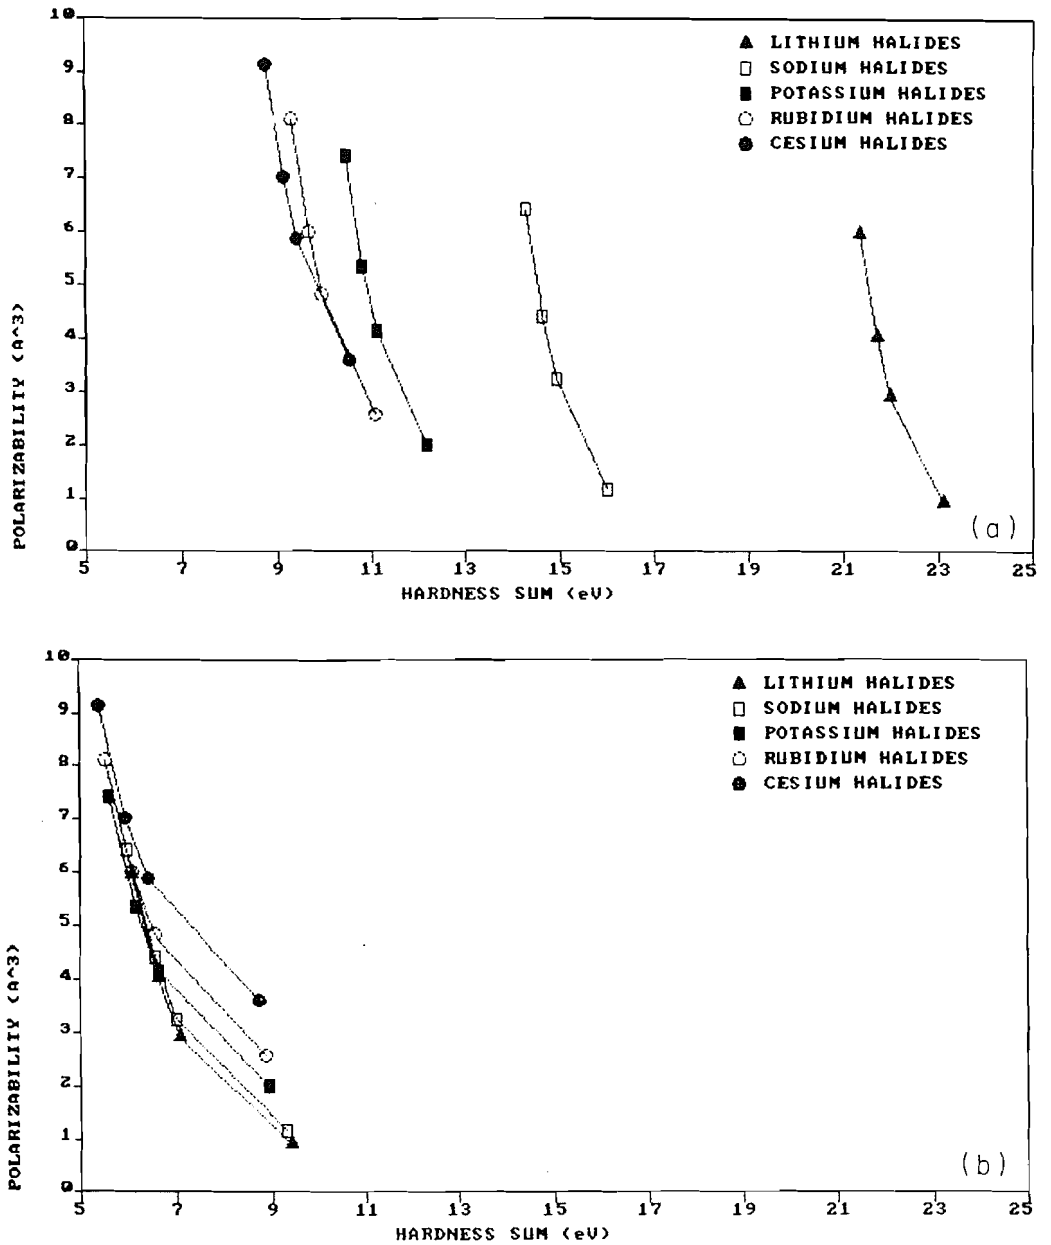

FIG. 5. (*a*) Experimental polarizabilities are related to the sum of the calculated hardness using the definitions of the present theory: $\eta_A = 1/4(I_{(A^+)} - A_{(A^0)})$ and $\eta_B = 1/4(I_{(B^0)} - A_{(B^-)})$ (from Table 3). (*b*) Experimental polarizabilities are plotted against the sum of the calculated hardness using Parr's definition (2), $\eta = 1/2(I - A)$ (from Table 3).

parameters, the experimental results, the charge transfer, and the charge transfer energies are the same for both the old and new definitions.

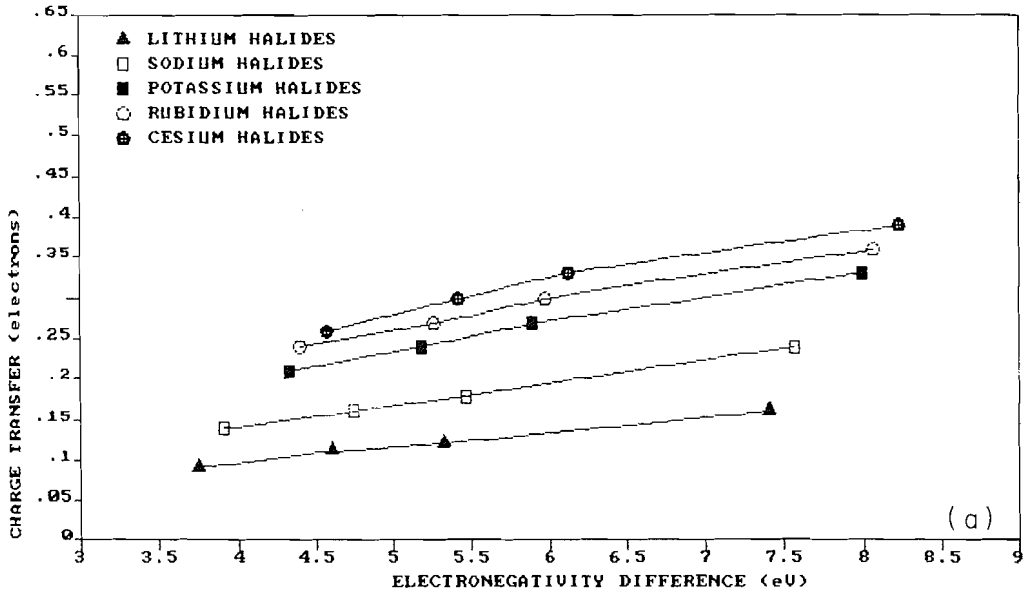
Equation [51] predicts charge transfer proportional to the difference in electronegativities of the acid and base. The experimental charge transfer, the calculated charge transfer using Parr's hardness, η_P, and the present η_A and η_B for the alkali halogenides are plotted in Fig. 6. There is a linear dependence of the experimental charge transfer in the lithium halogenides on differences in electronegativity, and no consistent trends or relations within or between any other alkali halogenide group. The equations result in a fairly regular dependence of the charge transfer on differences in electronegativity except for the last two points in Parr's results, which have almost constant charge transfer. Hence the calculated trends are not reflected by experimental results except in the lithium halogenides.

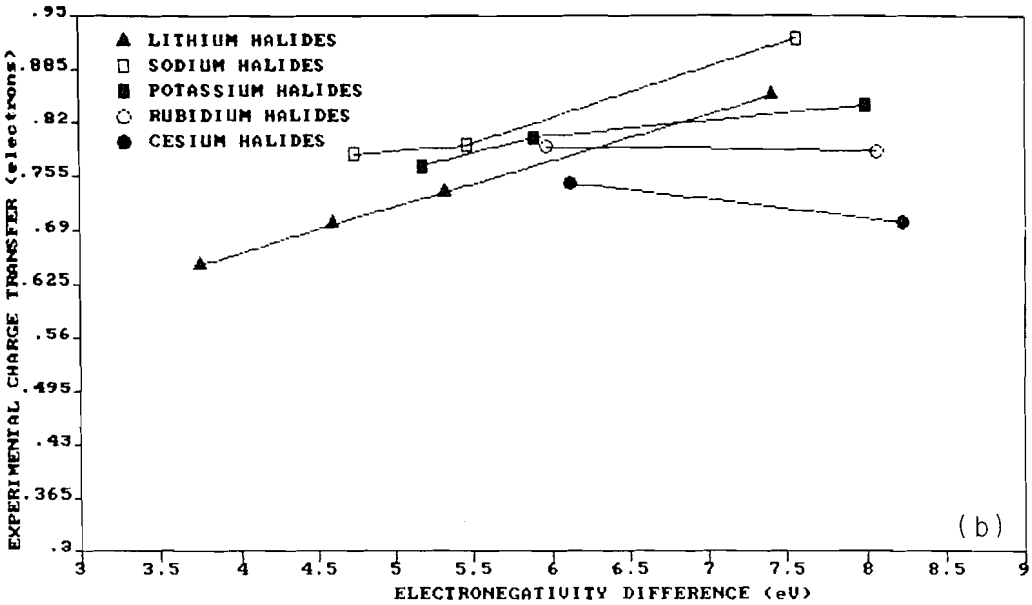
To compare the calculated values with other experimental results the ionic component of bond energies was estimated. Using eq. [53], experimental and theoretical bond energies were calculated for the alkali and copper halogenides and are collected in Table 4. Most charge transfer energies are very low compared to the experimental estimates, which is consistent with the low theoretical charge transfers with respect to the experimental ones in Table 3 for this group of compounds. The experimental trends from the results in Table 4 are

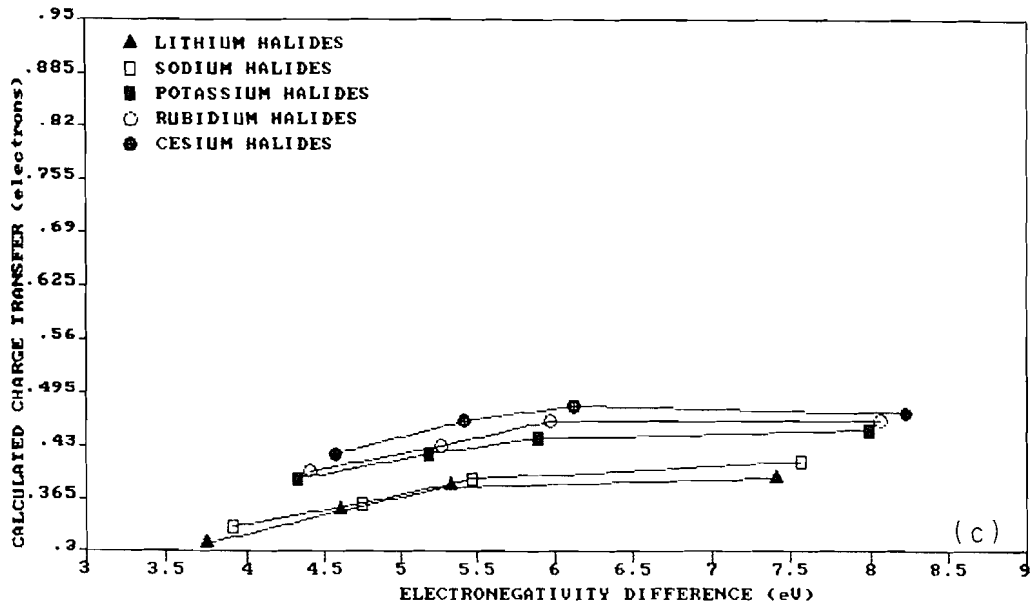
$$\begin{aligned}
&\text{LiF} \sim \text{CsF} \sim \text{RbF} \geq \text{KF} > \text{NaF} > \text{CuF}\\
&\text{RbCl} \sim \text{CsCl} \sim \text{LiCl} \sim \text{KCl} > \text{NaCl} > \text{CuCl}\\
&\text{CsBr} \sim \text{LiBr} \sim \text{RbBr} \geq \text{KBr} > \text{NaBr} > \text{CuBr}\\
&\text{CsI} \sim \text{RbI} \sim \text{LiI} > \text{KI} > \text{NaI} > \text{CuI}
\end{aligned}$$

where the bond energies generally decrease moving down the columns. Parr's hardness trends do not match these; the lithium halogenide series is predicted as having a smaller charge

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.







transfer than any other alkali halogenide series, whereas the experimental charge transfer indicates the lithium series has one of the greatest charge transfers.

VI. Conclusions

The new definitions of η, $\eta_A = 1/4(I_{(A^+)} - A_{(A^0)})$ and $\eta = 1/4(I_{(B^0)} - A_{(B^-)})$, in the context of the charge transfer model with equalization of electronegativities, gives a self-consistent theory. Comparing the theoretical charge transfer with experimental and calculated parameters proves Parr's (2) interpretation of bonding in terms of the hardness, $\eta_P = 1/2(I - A)$, to be less than ideal.

The new definitions for hardness, $\eta_A = 1/4(I_{(A^+)} - A_{(A^0)})$ and $\eta_B = 1/4(I_{(B^0)} - A_{(B^-)})$ for an acid and base, improve the continuity and results of this bonding model. Most results correlate qualitatively well with experimental bond energy data, unlike the HSAB. There are still problems in unifying the quantitative hardness theory with the hardness concept in HSAB theory.

The bonding polarity is qualitatively well described, although quantitatively the model breaks down, as illustrated by the small predicted charge transfers. Huheey suggested (18, 19) that this is caused by unequal cancelling of the covalent and electrostatic interactions. However, there are many factors unaccounted for in the model, including the atomic sizes, and the change in nuclear charge, $\Delta Z = |Z_A - Z_B|$, where Z_A and Z_B are the atomic numbers of A and B. This can be accounted for in a full second-order expansion of the energy, $E(N,Z)$. This may correct the anomalous charge transfer predictions for lithium and copper seen in this model, since these two atoms have the highest and lowest field gradients at the nuclei respectively. Many attempts (20–26) have been made to improve the original formulation of $\eta = 1/2(I - A)$. They are not considered here because it is the initial definition of the hardness η which has been changed.

This paper is dedicated to Professor John T. Edward

FRANÇOIS TERRIER, JACQUES LELIÈVRE, ALAIN-PIERRE CHATROUSSE, ROBERT SCHAAL, and PATRICK G. FARRELL. Can. J. Chem. **65**, 1980 (1987).

Rates of deprotonation of 2,2′,4,4′-tetranitrodiphenylmethane (**1**) by a variety of bases B^- and of protonation of the resulting carbanion (**2**) by the conjugated acids BH in methanol have been measured at 20°C. The Brönsted α^{BH} coefficients for protonation of **2** by phenol and carboxylic acid buffers are equal to 0.58 and 0.43, respectively, as compared with α^{BH} values of 0.59 and 0.52 respectively, for the same reactions in 50% H_2O – 50% DMSO. On the other hand, a comparison of the intrinsic rate constants k_0^{BH} (in the Marcus sense) in the two solvents reveals that the effect of going from 50% H_2O – 50% DMSO to methanol is to lower k_0^{ArOH} for the phenol reactions by a factor of 2 but to increase k_0^{RCOOH} for carboxylic acid reactions by a factor of 5. It is shown that the solvent effects on α^{BH} and k_0^{BH} can all be understood in the context of the Principle of Imperfect Synchronisation (PIS) recently proposed by Bernasconi. In addition, a fast equilibrium protonation of the carbanion **2** is found to precede its conversion to **1** at low pH, i.e., pH < 5. The resulting protonated species is suggested to be the nitronic acid **2**,*H* arising from fast protonation of a *para* NO_2 group of **2**. The pK_a' value associated with the ionization of **2**,*H* is ~4.25.

FRANÇOIS TERRIER, JACQUES LELIÈVRE, ALAIN-PIERRE CHATROUSSE, ROBERT SCHAAL et PATRICK G. FARRELL. Can. J. Chem. **65**, 1980 (1987).

Les vitesses de déprotonation du tétranitro-2,2′,4,4′ diphénylméthane (**1**) par diverses bases B^- ainsi que les vitesses de protonation du carbanion correspondant (**2**) par les acides conjugués BH ont été mesurées à t = 20°C dans le méthanol. Les coefficients de Brönsted α^{BH} relatifs à la protonation de **2** par les phénols et les acides carboxyliques sont respectivement égaux à 0,58 et 0,43 alors que des valeurs de α^{BH} de 0,59 et 0,52 ont été trouvées pour ces mêmes réactions dans 50% H_2O – 50% DMSO. Une comparaison des constantes de vitesse intrinsèques k_0^{BH} (définies selon Marcus) mesurées dans les deux solvants montre qu'un transfert du milieu H_2O–DMSO 50:50 au méthanol a pour effet de diminuer la constante k_0^{ArOH} relative aux phénols d'un facteur 2 mais d'augmenter la constante k_0^{RCOOH} relative aux acides carboxyliques d'un facteur 5. Il est montré que les effets de solvants sur α^{BH} et k_0^{BH} sont parfaitement compatibles avec le Principe de Synchronisation Imparfaite (PIS) récemment proposé par Bernasconi. De plus, un équilibre de protonation rapide du carbanion **2** a été observé préalablement à sa conversion en la molécule **1** aux pH < 5. L'espèce acide formée est considérée comme l'acide nitronique **2**,*H* qui résulte d'une protonation de l'un des groupes paranitrés de **2**. Le pK_a' associé à l'ionisation de **2**,*H* est voisin de 4,25 dans le méthanol.

Despite the absence of an electron-withdrawing group directly bonded to the exocyclic ionizable carbon, 2,2′,4,4′-tetranitrodiphenylmethane **1** has a noteworthy acidity in methanol (1). The pK_a^{MeOH} value for formation of the very stable carbanion **2** is 15.30 at 20°C, i.e., **2** is half-formed in a potassium methoxide solution ~0.03 *M*.

We have taken advantage of the stability of **2** to carry out a comprehensive kinetic study of the reactions shown in eq. [1] over the pH range of 3–14.86 at 20°C in methanol. k_p^{MeOH}, k_p^{MeO}, and k_p^B are the rate constants for deprotonation of **1** by methanol, methoxide ion, and any buffer base, respectively, while $k_{-p}^{H^+}$, k_{-p}^{MeOH}, and k_{-p}^{BH} refer to the rates of reprotonation of the carbanion **2** by the solvated proton, methanol, and any buffer acid, respectively. Our results allow the determination of the intrinsic reactivity of **1** in methanol and reveal the existence of a fast equilibrium between **2** and a new species in the most acidic solutions (pH < 5). This species is postulated as a nitronic acid resulting from the protonation of a NO_2 group of **2**. The dependence of the protonation rates of **2** upon the acidity and the nature of the protonating agent is also discussed.

[1] 
1 **2**

Results

Rates of proton transfer in methanol were measured using buffer solutions or dilute CH_3OK or benzene sulfonic acid solutions, always under pseudo-first-order conditions. The ionic strength was kept constant at 0.01 *M* by adding NaBr as needed. In such conditions, ion pairing effects are negligible and the H^+ concentration of the methanolic solutions can be deduced from the measured pH values ($[H^+] = 10^{-pH}/\gamma^{\pm}$ with $\gamma^{\pm}$ = 0.66 at 20°C) (2, 3). The rates were measured in a

stopped-flow spectrophotometer by monitoring the appearance or the disappearance of the absorption of the carbanion at or near its λ_{max} (680 nm; ε = 28 000 L mol^{-1} cm^{-1}).

The deprotonation of **1** was first studied using potassium methoxide solutions in the concentration range 0.002–0.01 *M* (I = 0.01 *M*). As expected, the observed rates for the approach to equilibrium [1] fitted nicely eq. [2], allowing a facile determination of the rate constant k_p^{MeO} for deprotonation of **1** by methoxide ion and of the rate constant k_{-p}^{MeOH} for reprotonation of **2** by the solvent: k_p^{MeO} = 24.8 L mol^{-1} s^{-1}; k_{-p}^{MeOH} = 0.75 s^{-1}. These values compare well with those previously determined without maintaining constant ionic strength (k_p^{MeO} = 26.2 L mol^{-1} s^{-1}; k_{-p}^{MeOH} = 0.73 s^{-1}) (1) and confirm the value of the equilibrium constant K_p for the reaction **1** + $MeO^- \rightleftharpoons$ **2** + MeOH: $K_p = k_p^{MeO}/k_{-p}^{MeOH}$ = 33 L mol^{-1}.

$$[2] \quad k_{obsd} = k_p^{MeO}[MeO^-] + k_{-p}^{MeOH}$$

The conversion of **2** to **1** was investigated by carrying out pH-jump experiments. These were performed by mixing a slightly basic solution of **1** with appropriate BH/B^--type buffers made up from various carboxylic acids and phenols. A few experiments were also conducted with benzenesulfonic acid solutions (5×10^{-4} – 8.71×10^{-4} *M* after mixing). Because of the low ionic strength chosen, the concentration of the basic buffer species B^- was varied between 0.001 and 0.01 *M* in the final solutions. Concomitant changes in the BH concentration were between 0.001 and 0.03 *M* since different buffer ratios were used. Although the changes in the buffer concentrations were relatively small, they resulted in appreciable variations in the observed rates of equilibrium at a given pH, as shown in Table 1. The need to work at low B^- concentrations also implied the use of very dilute methoxide solutions of the carbon acid **1** and, depending upon the buffer solution required after the pH jump, only CH_3OK concentrations in the range 0.002–0.02 *M* could be employed. Under such experimental conditions, the concentration of the carbanion **2**, generated from a 10^{-4} *M* solution of **1**, was in the approximate range 5×10^{-6} – 3.7×10^{-5} *M*. However, in view of the high absorbance of **2**, these concentrations made it possible to record reliable kinetic data in all pH-jump experiments.

The general expression for the pseudo-first-order rate constant k_{obsd} associated with the equilibrium between **1** and **2** is given by

$$[3] \quad k_{obsd} = k_p^{MeOH} + k_p^{MeO}[MeO^-] + k_p^{B}[B^-] + k_{-p}^{H^+}[H^+] + k_{-p}^{BH}[BH] + k_{-p}^{MeOH}$$

TABLE 2. Observed rate constants k_{obsd}^0 for protonation of the carbanion **2** at zero buffer concentration and different pH in methanol[a]

pH	$[H^+]^b$	k_{obsd}^0, s^{-1}	pH	$[H^+]^b$	k_{obsd}^0, s^{-1}
3.24	8.71×10^{-4}	363	6.26	8.32×10^{-7}	7.00
4	1.51×10^{-4}	200	6.44	5.5×10^{-7}	4.97

4.48	5×10^{-5}	126	7.42	5.75×10^{-8}	1.18
4.76	2.63×10^{-5}	79.5	7.61	3.71×10^{-8}	1.02
4.96	1.66×10^{-5}	58.5	7.99	1.55×10^{-8}	0.89
5.18	1×10^{-5}	38.5	8.10	1.20×10^{-8}	0.79
5.48	5×10^{-6}	36	8.56	4.37×10^{-9}	0.79
5.66	3.31×10^{-6}	25.1	8.75	2.69×10^{-9}	0.72
5.96	1.66×10^{-6}	12.60	9.04	1.38×10^{-9}	0.75

[a] t = 20°C; I = 0.01 mol L^{-1}.
[b] Calculated from log $[H^+]$ = −pH + 0.18.

but the pH range covered by the buffer and benzenesulfonic acid solutions studied (3–14, 31) lies far below the pK_a value for formation of **2**. Thus, eq. [3] can be safely reduced to

$$[4] \quad k_{obsd} = k_{-p}^{H^+}[H^+] + k_{-p}^{BH}[BH] + k_{-p}^{MeOH}$$

The various rate constants of eq. [4] were evaluated as follows. In carboxylic acid and phenol buffer solutions of pH > 8.5, plots of k_{obsd} vs. [BH] were linear with points determined at different pH falling on the same straight line (Fig. S_1).[2] Results are therefore consistent with the equation:

$$[5] \quad k_{obsd} = k_{-p}^{MeOH} + k_{-p}^{BH}[BH]$$

which is a special case of eq. [4] where $k_{-p}^{H^+}[H^+] \ll k_{-p}^{MeOH}$. The slopes of the k_{obsd} vs. [BH] plots afforded the k_{-p}^{BH} values for the different buffers studied, while the intercepts were all equal to k_{-p}^{MeOH} = 0.73 ± 0.03 s^{-1}, in good agreement with the k_{-p}^{MeOH} value previously determined from eq. [2].

With carboxylic acid buffer solutions in the pH range 5.5–8.5, the contribution of the hydronium ion to the acid catalysis was no longer negligible, as evidenced by the observation that plots of k_{obsd} vs. [BH] were linear with pH-dependent intercepts (Fig. S_2).[2] In this case, eq. [4] applies and determination of k_{-p}^{BH} from the slopes of the buffer plots obtained at constant pH was straightforward. On the other hand, a plot of the intercepts (denoted k_{obsd}^0) of these plots vs. $[H^+]$

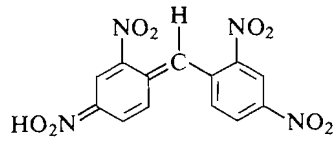
afforded a straight line (not shown) consistent with eq. [6]. We thus obtain $k_{-p}^{H^+} = 7.12 \times 10^6$ L mol^{-1} s^{-1} and $k_{-p}^{MeOH} = 0.75$ s^{-1}, again in good agreement with previous determinations of k_{-p}^{MeOH}. The experimental k_{obsd}^0 values are summarized in Table 2.

$$[6] \quad k_{obsd}^0 = k_{-p}^{H^+}[H^+] + k_{-p}^{MeOH}$$

In the relatively acidic trichloroacetic acid buffer solutions, very strong catalysis by BH was observed, as expected, but this catalysis cannot be accounted for in terms of eq. [4]. As shown in Fig. S_3,[2] plots of k_{obsd} vs. [BH] at constant pH remain linear but they have slopes that decrease with decreasing pH. This suggests that the decomposition of **2** becomes complicated by another process at pH < 5 (4). The concomitant observation that the k_{obsd}^0 values determined from the intercepts (Table 2) level off at low pH, as shown by the bilogarithmic plot of Fig. 1, confirms this suggestion and indicates in fact that the carbanion **2** is involved in a fast equilibrium protonation prior to its conversion to **1**. As will be discussed later, there is little doubt that the resulting protonated species arises from protonation at a NO_2 group of **2**, most likely at the 4-position, and is therefore the nitronic acid **2**,*H*.



2,*H*

Considering the fast initial formation of **2**,*H*, the conversion of **2** to **1** is now described by eq. [7] where K_a' is the acidity constant of the nitronic acid functionality. Based on this,

$$[7] \quad \mathbf{2},H \rightleftharpoons \mathbf{2} + H^+ \xrightarrow{k_{-p}^{H^+}[H^+] + k_{-p}^{MeOH} + k_{-p}^{BH}[BH]} \mathbf{1}$$

$$[8] \quad k_{obsd} = (k_{-p}^{H^+}[H^+] + k_{-p}^{MeOH})\frac{K_a'}{K_a' + [H^+]} + k_{-p}^{BH}[BH]\frac{K_a'}{K_a' + [H^+]}$$

$$[9] \quad k_{obsd}^0 = (k_{-p}^{H^+}[H^+] + k_{-p}^{MeOH})\frac{K_a'}{K_a' + [H^+]}$$

the values of the observed rate constant k_{obsd} for carbanion protonation should fit eq. [8], accounting for the observed decrease in the slopes of the k_{obsd} vs. [BH] plots with increasing H^+ concentration. Equation [8] simplifies to eq. [9] when no buffer acid is present in the solutions. At pH > 5.5, the formation of **2**,*H* does not occur to significant extent, so that $K_a' \gg [H^+]$ and eq. [9] further reduces to eq. [6]. This situation is consistent with the plateau and the straight line of slope −1 that are observed at pH > 8 ($k_{-p}^{MeOH} \gg k_{-p}^{H^+}[H^+]$) and between pH 5.5 and 6.5 ($k_{-p}^{H^+}[H^+] \gg k_{-p}^{MeOH}$), respectively, in Fig. 1. In contrast, at very low pH where $K_a' \ll [H^+]$, eq. [9] becomes

$$[10] \quad k_{obsd}^0 = k_{-p}^{H^+}K_a'$$

giving rise to the second plateau observed in Fig. 1. From measurements in benzenesulfonic acid solutions, one can estimate $k_{-p}^{H^+}K'_a \sim 350\,s^{-1}$ but this value has a large experimental error because rates at low pH are very close to the time resolution of the stopped-flow apparatus. Using this value and the previously determined $k_{-p}^{H^+}$ value (7.12×10^6 L mol^{-1} s^{-1}), one calculates $K'_a = 4.9 \times 10^{-5}$ mol L^{-1} for the acidity constant of **2**,*H*, i.e., $pK'_a \sim 4.30$. Another estimate of K'_a could also be obtained from measurements in the pH range 3.24–5.5. At these pH values, k_{-p}^{MeOH} is negligible in eq. [9], which may be rewritten in the form of eq. [11]. In accordance with this equation, a plot of $1/k^0_{obsd}$ vs. $1/[H^+]$ affords a straight line

$$[11]\quad \frac{1}{k^0_{obsd}} = \frac{1}{k_{-p}^{H^+}[H^+]} + \frac{1}{k_{-p}^{H^+}K'_a}$$

(Fig. S_4),[2] allowing the calculation of $k_{-p}^{H^+}$ and $k_{-p}^{H^+}K'_a$ from the slope and the intercept, respectively: $k_{-p}^{H^+} = 4.27 \times 10^6$ L mol^{-1} s^{-1}, $k_{-p}^{H^+}K'_a = 294\,s^{-1}$. Although the values thus obtained are only in rough agreement with those determined from eq. [6] in the pH range 5.5–8.5 ($k_{-p}^{H^+}$) or at very low pH ($k_{-p}^{H^+}K'_a$), the interesting point is that they confirm the order of magnitude of the acidity of **2**,*H*: $K'_a = 6.88 \times 10^{-5}$ mol L^{-1}; $pK'_a = 4.17$. The knowledge of K'_a allows the calculation of the k_{-p}^{BH} value for trichloroacetic acid buffer from the slopes of the k_{obsd} vs. [BH] plots of eq. [8] (see Fig. S_3).

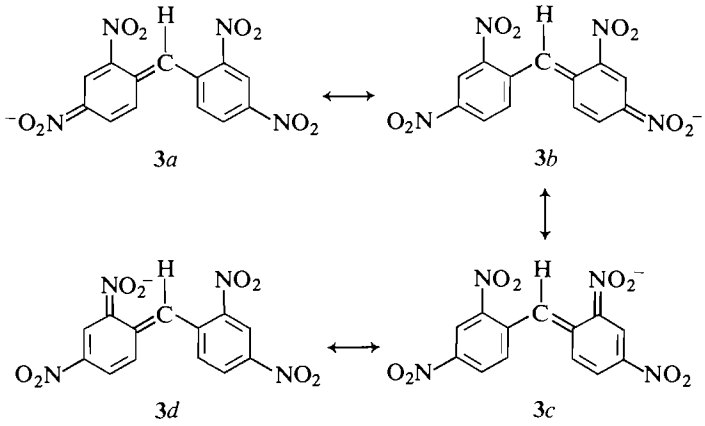
The various rate parameters associated with the interconversion of **1** and **2** are summarized in Table 3. With the exception of the rate constant associated with the deprotonation of **1** by MeO$^-$ ($k_p^B = k_p^{MeO}$), all k_p^B values were calculated: $k_p^B = k_{-p}^{BH}K_a^1/K_a^{BH}$ (buffer species) or $k_p^B = k_{-p}^{H^+}K_a^1$ (B = MeOH).

Discussion

Nitronic acid formation

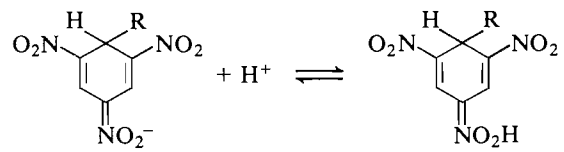
The most interesting result of this work is undoubtedly our observation that the carbanion **2** is susceptible to fast reversible protonation in acidic methanol, but our proposal (*vide supra*) that the resulting protonated species is presumably the nitronic acid **2**,*H* needs justification.

We have previously demonstrated that the carbanion **2** is essentially planar and has a highly delocalized negative charge (5). Thus, ^{13}C nmr spectra show that the chemical shift of the exocyclic carbon is strongly shifted to low field on conversion of **1** to **2**: $\delta\ C_\alpha = 35.0$ ppm for **1** and 100.9 ppm for **2** in DMSO. Such values clearly indicate that the bonding to the exocyclic carbon of **2** is essentially olefin-like (6), and that the negative charge is necessarily delocalized over the nitrophenyl rings, as shown in structures **3***a*–**3***d*. A consequence is that the ionization of **1** to give **2** involves an extensive structural–electronic–solvational reorganization, a situation that is typical for many carbon acids and is generally reflected by the finding that the corresponding proton transfer reactions have high intrinsic energy barriers and strongly imbalanced transition states (7–11). Significantly, a kinetic analysis carried out in 50% H_2O – 50% DMSO has revealed that the intrinsic energy barriers for deprotonation of **2** by various bases are among the highest so far measured for carbon acids (5, 11). Similarly, the results obtained have given evidence for a high degree of charge imbalance in the transition states corresponding to the various reactions of eq. [1] (5, 11). The kinetic data therefore support the nmr conclusion that **2** is a planar delocalized carbanion.



Considering the resonance structures **3***a*–**3***d*, it is clear that the *fast* protonation of **2** in acidic methanol can only occur at a nitro group and hence the protonated species at low pH is a nitronic acid. Furthermore, it is also well known that a *p*-NO_2 group is significantly more effective at resonance stabilization of charge than is an *o*-NO_2 group (12, 13). On this basis, one can reasonably expect that the negative charge of **2** lies preferentially on the 4- and 4′-NO_2 groups, as visualized in structures **3***a* and **3***b*, and that one of these groups will be preferentially protonated to give the nitronic acid **2**,*H*. Some support for this conclusion is provided by our previous observation of a negative transition state imbalance effect for the deprotonation of **1** in 50% DMSO – 50% H_2O (5). As then discussed, this effect is better understood in terms of structures **3***a* and **3***b* rather than in terms of structures **3***c* and **3***d* for the carbanion **2**.

Further support for the identification of the protonated species **2**,*H* as a nitronic acid is that the pK'_a value measured for the ionization of this derivative is in the same range as those reported for nitronic acids resulting from the protonation of a number of nitrocyclohexadienylide rings (13–16). Typical examples are the nitronic acids **4***a*,*H*–**4***d*,*H*, which have been



4 **4**,*H*

a, R =  OH; *b*, R =  ;

c, R =  ; *d*, R = H

characterized by nmr and result from the protonation of the trinitrobenzene σ-adducts **4***a*–*d*. Thus, the equilibrium formation of **4***a*,*H* from the parent phenoxide adduct has been spectrophotometrically studied and pK'_a values of −1 and +3 have been derived for the ionization of **4***a*,*H* in aqueous and ethanolic solutions, respectively (16). Since the acidity of oxygen acids usually decreases on going from water to methanol to ethanol (17), these results suggest pK'_a values of ~1–2 for nitronic acids of the type **4**,*H* in methanol. More significantly, we have recently reported pK'_a values in the order of 4.2–4.5 for the ionization of the nitronic acids **5***a*–*d*,*H* resulting from the protonation of the benzofurazan and benzofuroxan adducts **5***a*–*d* in methanol (4). The fact that these values, which refer

to the protonation of a *para*-like NO_2 group, are essentially the same as that found for protonation of **2** under similar experimental conditions lends additional support to our assignment of **2**,*H* as a nitronic acid.[3]

Rate constants for proton transfer

Figure 2 shows that carboxylic acid and phenol buffers obey different Brönsted relationships. For a given $\Delta pK + \log(p/q)$ value ($\Delta pK = pK_a^{BH} - pK_a^1$ and p and q are the usual statistical factors used for Brönsted plots), phenols appear to be more efficient oxygen-acid catalysts than carboxylic acids. This behaviour is qualitatively the same as that found in the study of reactions [1] in 50% H_2O – 50% DMSO (5), and in the study of the ionization of acetylacetone and 1,3-indandione in various H_2O–DMSO mixtures (18, 19).

A noteworthy feature of Fig. 2, however, is that the slopes of the Brönsted lines are markedly different for the two classes of buffers. Thus, the α^{BH} value is equal to 0.58 for the phenols and 0.43 for the carboxylic acids. In this respect, the situation contrasts with that observed in 50% H_2O – 50% DMSO where $\alpha^{ArOH} = 0.59$, a value that is essentially the same as that found in methanol, and $\alpha^{RCOOH} = 0.52$ (5). Using the classical definition of the intrinsic rate constant, i.e., $k_0 = k_{-p}^{BH}/p = k_p^B/q$ where $\Delta pK + \log(p/q) = 0$ (7, 21, 22), the $\log k_0^{RCOOH}$ and $\log k_0^{ArOH}$ values can be readily determined from the Brönsted plots (11). They are equal to 0.15 ± 0.1 and 0.18 ± 0.2, respectively, at 20°C in methanol. These low $\log k_0$ values confirm that high intrinsic energy barriers are associated with reactions [1] (5). The more interesting result, however, is that the intrinsic rate constant for the phenol reactions in methanol is lower by a factor of 2 than that found in 50% H_2O – 50% DMSO solution, while that for the carboxylic acid reactions is greater by a factor of about 5. Since the temperature used in this work (t = 20°C) is lower than that used in 50% H_2O – 50% DMSO (t = 25°C), the observed decrease in k_0^{ArOH} may be the result of a temperature effect rather than of a solvent effect although the temperature difference is extremely small. However, it is clear that this explanation cannot be invoked to account for the increase observed in k_0^{RCOOH} and this latter change must be the reflection of a solvent effect.

Considering the effect of the solvent transfer from 50% H_2O – 50% DMSO (t = 25°C) to methanol (t = 20°C) on the reactions of eq. [1], it is of interest to note that the pK_a's of the buffer carboxylic acids increase by about 3.8 pK units while that for the ionization of **1** increases by 4.40 pK units (5). It thus appears that the protonation of **2** by carboxylic acids is thermodynamically more favorable in the methanolic than in the aqueous DMSO system. The concomitant decrease observed in the α^{RCOOH} value would therefore appear consistent with the reactivity–selectivity principle (RSP) (23). However, the same solvent transfer also increases the pK_a's of the buffer phenols, but to a lesser extent than that of carboxylic acids ($\Delta pK^{ArOH} \sim 3$). As a result, the thermodynamics of the protonation of **2** by phenols is favored to a greater degree than that by carboxylic acids and the RSP would predict a greater decrease in the α^{ArOH} than in the α^{RCOOH} value. This is clearly not the case since α^{ArOH} is essentially the same in the two solvents and thus the reaction is no longer understandable in terms of the RSP.

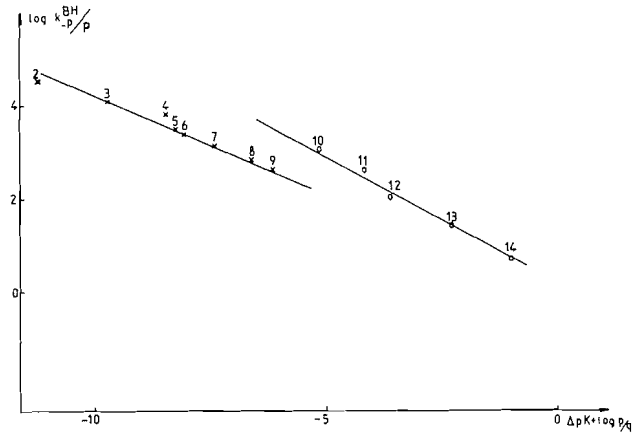

FIG. 2. Brönsted plots for the catalysis of the protonation of the carbanion **2** by carboxylic acids and phenols in methanol; t = 20°C; I = 0.01 mol L^{-1}. The numbering of the catalysts is given in Table 3.

That the RSP fails to account for the situation observed is not surprising since it is now well known that reactions which involve resonance stabilized carbanions, and which are therefore subject to large transition state imbalances, cannot be treated by common formalisms (7, 9, 11, 18, 19, 24). In particular, it has been shown that the effect of a solvent change on the intrinsic rate constant k_0 for the deprotonation of a carbon acid (or reprotonation of the corresponding carbanion) is closely related to specific stabilizing or destabilizing factors of reactants and products (11, 18, 19, 25). For reactions involving an anionic base B^- like those of eq. [1], for example, solvation of the base is a reactant stabilizing factor while solvation of the resulting carbanion C^- is a product stabilizing factor and, to a first approximation, the changes in k_0 can be described by eq. [12] (11, 18, 19). ${}^{S_1}\gamma_B^{S_2}$ and ${}^{S_1}\gamma_C^{S_2}$ are the solvent activity coefficients of the base B^- and the carbanion C^-, respectively, for the transfer from a solvent S_1 to a solvent S_2, $\alpha_d^{B^-}$ and $\alpha_s^{C^-}$ measure the progress of desolvation of B^- and of solvation of C^- at the transition state, respectively, while β is the measured Brönsted β value for deprotonation of the carbon acid by various bases of the B^- type. The presence of the negative sign in front of $\log {}^{S_1}\gamma_C^{S_2}$ but not in front of $\log {}^{S_1}\gamma_B^{S_2}$ is because C^- is a product whereas B^- is a reactant (11). For proton transfer reactions involving carbanions, desolvation of the base B^- is always ahead of proton transfer, i.e., $(\alpha_d^{B^-} - \beta) > 0$, while solvation of C^- is always delayed, i.e., $(\alpha_s^{C^-} - \beta) < 0$ (11, 18,

[12] $$\delta \log {}^{S_1}k_0^{S_2} = (\alpha_d^{B^-} - \beta) \log {}^{S_1}\gamma_B^{S_2} + (\alpha_s^{C^-} - \beta)(-\log {}^{S_1}\gamma_C^{S_2})$$

[3]To obtain an accurate spectrum of the nitronic acid **2**,*H* a concentrated solution of **2** is required. From the pK_a of **1**(15.3 at 20°C in MeOH) it can be calculated that a ca. 0.5 *M* solution of methoxide ion is needed for almost complete conversion to **2**, and reliable pH-jump experiments to produce solutions with final pH ~ 3 cannot be made on such solutions. In spite of numerous attempts, we were unable to overcome the experimental problems and could not obtain a spectrum of **2**,*H*.

19).[4] Equation [12] therefore predicts that k_0 will vary, depending upon whether the solvent transfer stabilizes or destabilizes, simultaneously, B^- and C^- or has a different effect on each of these two species. Several situations have been recently discussed and reviewed by Bernasconi, where observed changes in k_0 due to solvent effects were found to agree with the $\delta \log k_0$ values estimated from eq. [12] (11, 18, 19).

In view of the large imbalance effects associated with eq. [1], it is interesting to look at whether the changes in k_0 found for the reactions involving $RCOO^-$ and ArO^- ions on going from 50% H_2O – 50% DMSO (a mixture now denoted as D) to methanol (M) can be understood in terms of eq. [12]. In this respect, let us first note that our studies of eq. [1] have been essentially carried out in the reverse direction so that it is probably more appropriate to discuss our results with reference to the reprotonation of the carbanions **2** by phenols and carboxylic acids and therefore to use eq. [13]. α is the measured Brönsted coefficient for k_{-p}^{BH} while $\alpha_s^{B^-}$ and $\alpha_d^{C^-}$ measure the progress in the solvation of the developing base B^- ($\alpha_s^{B^-} < \alpha$) and of the desolvation of the carbanion C^- ($\alpha_d^{C^-} > \alpha$) at the transition state, respectively. That eq. [13] is equivalent to eq. [12] can be readily seen since we have $\alpha + \beta = 1$ and $\alpha_d + \alpha_s = 1$ (18).

$$[13] \quad \delta \log {}^{D}k_0^{M} = (\alpha_s^{B^-} - \alpha)(-\log {}^{D}\gamma_{B^-}^{M}) + (\alpha_d^{C^-} - \alpha) \log {}^{D}\gamma_{C^-}^{M}$$

Based on eq. [13], the effect of changing solvent from 50% H_2O – 50% DMSO (D) to methanol (M) on the intrinsic rate constant k_0 for reactions [1] with carboxylic acids is given by

$$[14] \quad \delta \log {}^{D}k_0^{M} = (\alpha_s^{RCOO^-} - \alpha)(-\log {}^{D}\gamma_{RCOO^-}^{M}) + (\alpha_d^{C^-} - \alpha) \log {}^{D}\gamma_{C^-}^{M} = 0.70$$

with

$$\alpha = 0.47 \text{ (see footnote 4)}$$

and

$$\log {}^{D}\gamma_{RCOO^-}^{M} = -0.18 \ (\log {}^{D}\gamma_{RCOO^-}^{H_2O} = -3.08 \text{ (ref. 19)}; \ \log {}^{H_2O}\gamma_{RCOO^-}^{M} = 2.9 \text{ (ref. 26)}$$

Since $(-\log {}^{D}\gamma_{RCOO^-}^{M})$ is positive (0.18) and the value of $(\alpha_s^{RCOO^-} - \alpha)$ varies from $-\alpha$ to 0 ($\alpha_s^{RCOO^-} = 0$ corresponds to the hypothetical situation where solvation of the developing carboxylate ion has made no progress in the transition state), we see that the contribution of the first term in eq. [14] is negative, and has values between -0.08 ($\alpha_s^{RCOO^-} = 0$) and zero ($\alpha_s^{RCOO^-} = 0.47$). These values require a positive value between 0.70 and 0.78 for the second term and, since $\alpha_d^{C^-} > \alpha$, a positive value for $\log {}^{D}\gamma_{C^-}^{M}$. Assuming complete desolvation of the carbanion C^- prior to proton transfer, i.e., $\alpha_d^{C^-} \sim 1$, a minimum value of 1.32 can be estimated for $\log {}^{D}\gamma_{C^-}^{M}$. This result suggests that the carbanion **2** is somewhat destabilized on going from the aqueous DMSO mixture to methanol. This conclusion looks quite reasonable since delocalized anionic species are known to be better stabilized in aqueous or alcoholic DMSO mixtures than in protic solvents (13, 26, 27, 28).

Let us now assume that the decrease in k_0^{ArOH} may also be related to the solvent change and not only to the temperature effect. Applying eq. [13] to the phenol reactions gives

$$[15] \quad \delta \log {}^{D}k_0^{M} = (\alpha_s^{ArO^-} - \alpha)(-\log {}^{D}\gamma_{ArO^-}^{M}) + (\alpha_d^{C^-} - \alpha) \log {}^{D}\gamma_{C^-}^{M} = -0.32$$

Qualitatively, we can see that the first term of eq. [15] must be appreciably negative to account for a decrease in k_0. This is because the second term is positive ($\alpha_d^{C^-} - \alpha) > 0$, $\log {}^{D}\gamma_{C^-}^{M} > 0$, *vide supra*) even though the larger α value found for ArOH (0.58) tends to attenuate its contribution compared to that in carboxylic acids. Since, again, we expect that solvation of the developing ArO^- ion is delayed, i.e., $(\alpha_s^{ArO^-} - \alpha) \leqslant 0$, it follows that $\log {}^{D}\gamma_{ArO^-}^{M}$ must be more negative than $\log {}^{D}\gamma_{RCOO^-}^{M}$ and therefore that phenoxide anions are much more stabilized than carboxylate anions on transfer from 50% H_2O – 50% DMSO to methanol. Interestingly, this conclusion is consistent with experimental results obtained by Juillard (29) and Abraham *et al.* (30), who found that changing from water to methanol causes a notable destabilization of carboxylate anions but increases the stabilization of phenoxide anions. It thus appears that both temperature and solvent effects are in accord with the observed decrease in k_0^{ArOH}.

Notwithstanding any possible temperature effect upon k_0 in the case of the phenol reactions, we can conclude from the above discussion that the different behaviour of reactions [1] with carboxylic acids and phenols is qualitatively in agreement with eq. [13]. This further confirms that the ionization of polynitrodiphenylmethanes constitutes a remarkable example of strongly imbalanced proton transfers.

Experimental

Materials

2,2′,4,4′-Tetranitrodiphenylmethane was prepared according to literature procedure and recrystallized in acetic acid; mp 182°C (31). Potassium methoxide solutions were made up as described previously. Buffers were purified commercial products.

Measurements

Kinetic studies were made using a Durrum stopped-flow spectrophotometer with a thermostatted cell compartment (±0.5°C).

pH determinations in methanol were carried out at 20°C using the same procedure as that previously used for other kinetic studies. A Tacussel Isis 20000 electronic pH meter was used.

[4] As noted by Bernasconi and Bunnell (18), a quantitative application of eq. [14] requires α to be solvent independent. For the purposes of a qualitative discussion, an average α value from the two solvents being compared is a satisfactory approximation (11, 18).

Received February 23, 1987

This paper is dedicated to Professor John T. Edward

MARTINO PAVENTI. Can. J. Chem. **65**, 1987 (1987).

Arguments are presented against the accepted notion that multiple rate constants may be obtained from observed singular or pooled kinetic runs. For any competitive consecutive second-order reaction, the particular solution satisfying the total differential equation, derived from $(n + 1)$ simultaneous differential equations, is $S = (aA_0 - S_0)\{(aA_0/S_0)[\exp(aA_0 - S_0)kt] - 1\}^{-1}$, where S is the concentration of reactant common for all the steps, A is the concentration of the substrate with a reactive sites, A_0 and S_0 are the concentration of reactants at zero time, k is the observed rate constant, and t is the time. This equation is shown to reproduce the experimental reported data and yields $k = \min(k(1), \ldots, k(n))$, where $k(i)$ is the rate constant assigned to step i. It is also shown that the initial conditions need not be known. For experiments with the initial condition $(aA_0 = S_0)$, with only species A and S are present at zero time, the expression $(S_0\{\int_0^\infty (S - \alpha)^2 dt\}^{-1})$ may be useful for an approximate evaluation of k when values of S do not approach zero after an infinite time (i.e., $S_\infty = \alpha \neq 0$, where α is the asymptote for the data).

MARTINO PAVENTI. Can. J. Chem. **65**, 1987 (1987).

On présente des arguments contre la notion généralement acceptée que les constantes de vitesse des réactions multiples peuvent être déduites d'études cinétiques uniques ou combinées. Pour toute réaction consécutive et compétitive du deuxième ordre, la solution particulière qui satisfait à l'équation différentielle totale et qui est dérivée de $(n + 1)$ équations différentielles simultanées est la suivante : $S = (aA_0 - S_0)\{(aA_0/S_0)[\exp(aA_0 - S_0)kt] - 1\}^{-1}$ dans laquelle S est la concentration du réactif commun à chacune des étapes, A est la concentration du substrat avec a sites réactifs, A_0 et S_0 sont les concentrations des réactifs au temps zéro, k est la constante de vitesse observée et t est le temps. On démontre que cette équation permet de reproduire les données expérimentales qui ont été rapportées et qu'elle conduit à $k = \min(k(1), \ldots, k(n))$ dans laquelle $k(i)$ est la vitesse attribuée à l'étape i. On démontre aussi qu'il n'est pas nécessaire de connaître les conditions initiales. Pour les expériences particulières dans lesquelles les conditions initiales satisfont à la relation $aA_0 = S_0$ et dans lesquelles seules les espèces A et S sont présentes au temps zéro, on peut utiliser l'expression $(S_0\{\int_0^\infty (S - \alpha)^2 dt\}^{-1})$ pour évaluer k d'une façon approximative, lorsque les valeurs de S ne s'approchent pas de zéro après un temps infini (c'est à dire que $S_\infty = \alpha \neq 0$ lorsque α est une asymptote pour les données).

[Traduit par la revue]

1. Introduction

Exact solutions for nonlinear differential equations are of paramount importance since all natural processes and laws are best described by these equations. For example, the *approximate* solutions of the Schrödinger equation are the backbone of modern chemistry and physics. In recent years, however, the emphasis has shifted from more classical mathematical goal of finding exact (i.e., analytical) solutions to integral equations and differential equations to the more realistic attempts at the quantitative characterization of solutions (1). This change in approach follows necessarily from an increasing preoccupation with nonlinear problems for which exact analytical solutions are unlikely (1). In agreement with Somorjai (1), there is no single best "recipe" for solution (even if a unique solution does exist), and inspired guessing combined with perseverance plays an important role.

Papers have been written advancing the approximate (2), graphical (3–13), and iterative (14–19) methodologies to evaluate *all* the rate constants for a competitive second-order reaction and parasitic papers have resulted as an extension (20, 21) of these concepts. All have irreconcilable mathematical differences between the solutions found and the experimental data. An attempt will be made here to surface some oddities and artifacts of approximate methodologies and to present a clear, simple, particular solution of the total differential equation resulting from the kinetic process. Without recourse to a steady-state treatment, the complete non-linear differential equations, derived below, have been obtained by a process similar to that described by Benson (22).

2. Deduction of the particular solution

Consider the very simple case of a second order irreversible reaction which takes analogy from the one-electron system, of the Schrödinger equation for which an exact solution exists.

$$A + S \xrightarrow{k_1} B$$

SCHEME 1

The differential equations[1] describing this process are:

[1] $A' = -k_1AS$

[2] $S' = -k_1AS$

From formal integration between limits the mass balance is obtained:[2]

[3] $\int_{S_0}^{S} dS = \int_{A_0}^{A} dA$

and therefore

[1]The definition of one operator is helpful for this and other derivations, in writing the equations more succinctly. For a general function f the operator $(')$ defines the derivative of the function with respect to time: $(f)' = (f') = df/dt$ and for the nth derivative with respect to time, the operator is written n times (i.e., $(f''') = d^3f/dt^3$). Also the letters $A, B, \ldots, S$ in the differential equations represent the instantaneous concentrations of species $A, B, \ldots, S$ in the schemes. The subscript 0 relates to the respective concentrations at zero time. The k_i are the individual rate constants described in the schemes.

[2]For more complex schemes, information of the mass-balance equation is also contained in the differential equations.

[4] $A = S + A_0 - S_0$

Substitution of eq. [4] into eq. [2] and integrating yields the general solution[3] (23):

[5] $S = (A_0 - S_0)\{(A_0/S_0)[\exp(A_0 - S_0)k_1t] - 1\}^{-1}$

Consider the linear[4] consecutive second-order reaction:

$$A + S \xrightarrow{k_1} B$$

$$B + S \xrightarrow{k_2} C$$

SCHEME 2

This process is mathematically described as:

[6] $A' = -k_1AS$

[7] $B' = k_1AS - k_2BS$

[8] $S' = -k_1AS - k_2BS$

The total differential equation may be derived as follows. Equation [8] is divided by S, differentiated, and A' and B' from eqs. [6] and [7] are substituted to yield:

[9] $$\left(\frac{S'}{S}\right)' = ZAS + (k_2)^2BS$$

where $Z = (k_1^2 - k_1k_2)$. Dividing eq. [9] by k_2 and adding the resultant to eq. [8], one obtains:

[10] $$\left(\frac{1}{k_2}\right)\left(\frac{S'}{S}\right)' + S' = Z_1AS$$

where $Z_1 = (Z/k_2 - k_1)$. Dividing eq. [10] by S, differentiating, and substituting for A' (eq. [6]) gives:

[11] $$\frac{1}{k_2}\left(\frac{1}{S}\left(\frac{S'}{S}\right)'\right)' + \left(\frac{S'}{S}\right)' = -Z_1k_1AS$$

Dividing eq. [11] by k_1 and adding the resultant to eq. [10] yields:

[12] $$\frac{1}{k_1k_2}\left(\frac{1}{S}\left(\frac{S'}{S}\right)'\right)' + \left(\frac{1}{k_1} + \frac{1}{k_2}\right)\left(\frac{S'}{S}\right)' + S' = 0$$

Analogously to the Schrödinger equation for two or more electrons where the hydrogen-like wavefunction is used to solve the Hamiltonian, the equation

[13] $S = (2A_0 - S_0)\{(2A_0/S_0)[\exp(2A_0 - S_0)kt] - 1\}^{-1}$

which is deduced from eq. [5], where k is the observed rate constant, is appropriately differentiated and substituted in eq. [12], giving:

[14] $$\frac{k^2}{k_1k_2} - \left(\frac{1}{k_1} + \frac{1}{k_2}\right)k + 1 = 0$$

[3]This general solution is indicative of all cases: for $S_0 \ll A_0$ (pseudo-first order) eq. [5] reduces to

$$S = S_0 \exp(-A_0k_1t)$$

The case where $A_0 = S_0$ can be shown by application of L'Hôpital's rule (24) to be:

$$S = S_0 \lim_{S_0 \to A_0} A_0(A_0 - S_0)\{(A_0/S_0)[\exp(A_0 - S_0)k_1t] - 1\}^{-1} = S_0(S_0k_1t + 1)^{-1}$$

[4]This is not to be confused with linear differential equations, but meant to illustrate reactions in series (25*a*).

Therefore eq. [12] is satisfied for all the time domain with the condition of eq. [14] that $(k = k_1)$ or $(k = k_2)$ and eq. [13] is a particular solution for the total differential equation [12].

Combination of the mass-balance equation (i.e., $(S_0 - 2A_0) = (S - 2A - B)$ for $B_0 = C_0 = 0$), eqs. [6] and [8] yields:

[15] $$S' + k_2S^2 - k_2(S_0 - 2A_0) = \frac{(2k_2 - k_1)}{-k_1}A'$$

for the case where $(S_0 = 2A_0)$ the limits of integration are known, simplifying eq. [15] to:

[16] $$\int_0^\infty S^2\,dt = S_0\frac{(2k_2 + k_1)}{2k_1k_2}$$

If the function of S is the limiting value[3] (i.e., $S = S_0(S_0kt + 1)^{-1}$) then eq. [16] integrates to:

[17] $$\frac{1}{k} = \frac{2k_2 + k_1}{2k_2k_1}$$

For a realistic solution of the process in Scheme 2, both eq. [14] and eq. [17] must be satisfied simultaneously. Also the reaction will not take place if $(k_1 = 0)$ or stops at species B if $(k_2 = 0)$. Combination of the roots for the two equations give:

[18] if $k = k_1$ (root of eq. [14]) then $k_2 = \infty$ (root of eq. [17])

[19] if $k = k_2$ (root of eq. [14]) then $k_1 = 2k_2$ (root of eq. [17])

and therefore $k = \min(k_1, k_2)$. The question of which of these two cases (roots) applies to the consecutive second order reaction of Scheme 2 may be answered by analysis of the kinetics of the individual steps under pseudo-first-order conditions.

Frost and Schwemer (4) have expressed the essence of eqs. [18] and [19] as the reaction corresponding to simple second order for $(k_2/k_1) = 0, 0.5$, or ∞. But $(k_2/k_1) = 0$ is tantamount to $k_1 = \infty$ (since $k_2 \neq 0$) and $B_0 = A_0$: an imaginary state since $B_0 = 0$ (see condition for deriving eq. [16]). Although k can mathematically equal k_2 for k_1 exactly equal to $2k_2$, this is experimentally improbable. Yet this *must be so* (i.e., $k_1 = 2k_2$) because the data (4) (Table 1) are reproduced by eq. [13], but the numbers obtained for k_1 and k_2 do not reflect this. These two opposing issues may be reconciled if only *one* rate constant is calculated from the data and not two or more.

Consider the parallel consecutive second-order process:

$$A + S \xrightarrow{k_1} B$$

$$A + S \xrightarrow{k_2} C$$

$$B + S \xrightarrow{k_3} D$$

$$C + S \xrightarrow{k_4} D$$

SCHEME 3

The differential equations describing this system are:

[20] $A' = -(k_1 + k_2)AS$

[21] $B' = k_1AS - k_3BS$

[22] $C' = k_2AS - k_4CS$

[23] $S' = -(k_1 + k_2)AS - k_3BS - k_4CS$

Employing the same mathematical manipulation as shown for

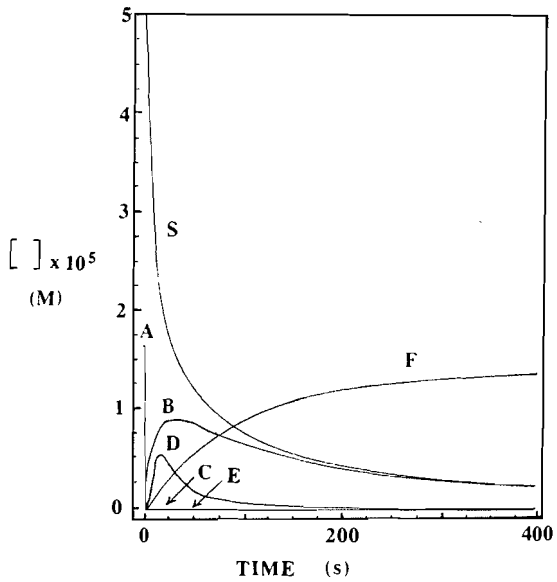

FIG. 1. Concentrations of species (letter symbols: A, B, C, D, E, F, S in Scheme 4) for the simulated tribromination of phenol from RMCHS (27). For the value of rate constants and concentration of the species see text.

the process in Scheme 2 above, we obtain the total differential equation

$$[24]\quad \frac{1}{(k_1+k_2)k_3k_4}\left(\frac{1}{S}\left(\frac{1}{S}\left(\frac{S'}{S}\right)'\right)'\right)' + \left\{\frac{1}{(k_1+k_2)k_3}+\frac{1}{(k_1+k_2)k_4}+\frac{1}{k_3k_4}\right\}\left(\frac{1}{S}\left(\frac{S'}{S}\right)'\right)' + \left\{\frac{1}{(k_1+k_2)}+\frac{1}{k_3}+\frac{1}{k_4}\right\}\left(\frac{S'}{S}\right)' + S' = 0$$

Again appropriate differentiation and substitution of the particular solution (eq. [13]) gives:

$$[25]\quad \frac{k^3}{(k_1+k_2)k_3k_4} - \left\{\frac{1}{(k_1+k_2)k_3}+\frac{1}{(k_1+k_2)k_4}+\frac{1}{k_3k_4}\right\}k^2 + \left\{\frac{1}{(k_1+k_2)}+\frac{1}{k_3}+\frac{1}{k_4}\right\}k - 1 = 0$$

and so $k = (k_1 + k_2)$, k_3, or k_4. Experiments and simulations (see Fig. 1) (26) show that $k = \min((k_1 + k_2), k_3, k_4)$.

The processes of Schemes 2 and 3 may be combined and extended to $(n + 1)$ differential equations. In a similar manner it can be shown that a particular solution[5] is

$$[26]\quad S = (aA_0 - S_0)\{(aA_0/S_0)[\exp(aA_0 - S_0)kt] - 1\}^{-1}$$

where a is the number of reactive sites of species A, k is the observed rate constant, and $k = \min(k(1), \ldots, k(n))$.

To elucidate that this solution is reasonable, computer simulations[6] (27) were done for a more complicated second-order consecutive reaction: tribromination of phenol (26) outlined in Scheme 4.

$$A + S \xrightarrow{k_1} B \qquad S = \text{bromine}$$
$$A + S \xrightarrow{k_2} C \qquad A = \text{phenol}$$
$$B + S \xrightarrow{k_3} D \qquad B = \text{4-bromophenol}$$
$$C + S \xrightarrow{k_4} D \qquad C = \text{2-bromophenol}$$
$$C + S \xrightarrow{k_5} E \qquad D = \text{2,4-dibromophenol}$$
$$D + S \xrightarrow{k_6} F \qquad E = \text{2,6-dibromophenol}$$
$$E + S \xrightarrow{k_7} F \qquad F = \text{2,4,6-tribromophenol}$$

SCHEME 4

Pseudo-first-order kinetics for the aqueous bromination of phenol, object of a different paper,[7] at pH = 1, 25°C in 1 M KBr gave $k(1) = (k_1 + k_2) = 1.33 \times 10^5$, $k(2) = k_3 = 7.74 \times 10^3$, $k(3) = (k_4 + k_5) = 2.24 \times 10^3$, $k(4) = k_6 = 871$, $k(5) = k_7 = 6.02 \times 10^3\ M^{-1}\ s^{-1}$ and assumed that $k_4/k_5 = k_1/k_2 = 50$. The initial conditions for the simulation were $S_0 = 3A_0 = 5 \times 10^{-5}\ M$ and $(B_0 = C_0 = D_0 = E_0 = F_0 = 0)$. When these parameters are input in the program, it generates concentration values for each of the species, by differential solution of the simultaneous equations[8] at different times and these are plotted in Fig. 1. Analysis clearly shows $S = (894t + 2 \times 10^{-4})^{-1}$ correlation coefficient (hereafter denoted as c-c) (0.99994) demonstrating that $k = 894 \simeq k(4) = 871\ M^{-1}\ s^{-1}$: the value of the rate-determining step. The small difference in the magnitude may be attributed, in part, to rounding off errors in the iterations.

Combination of the mass-balance equation (where $(aA_0 = S_0)$, and B_0, C_0,... $= 0$) and the simultaneous differential equations for any consecutive process leads to:

$$[27]\quad k = \frac{S_0}{\int_0^\infty S^2\,dt}$$

identical to eq. [16] but where the expression for k varies with the process.[9]

3. Discussion

3.1. Initial conditions

Initial conditions have been a source of difficulty for all the authors. Frost and Schwemer (4) and Svirbely *et al.* (14–18) dismiss this difficulty by explaining that for $S_0 = aA_0$, where a is the number of reactive sites on species A, the mathematical equations simplify. Wen (20), Khan and Khan (11), and Kubin *et al.* (21) apparently wrote their papers so that the restriction $S_0 = aA_0$ could be lifted. However, these last authors show conflicting arguments within their own papers. Citing (11, 20) the work of Goldfinger *et al.* (28) that stoichiometric concentrations of reactants may be difficult to prepare, particularly when the reactants are gases and the reactions are rapid, they overlook their own analytical solution which requires known initial conditions. If it is difficult to prepare stoichiometric concentra-

[5]The terms $(aA_0 - S_0)$ and (aA_0/S_0) differentiate eq. [5] from eq. [26] where the first term evolves from the mass-balance equation of the reaction scheme. The factor a is justified in eq. [26] because it concatenates earlier observations (4, 14–18) with the shown case[3] that for $(aA_0 = S_0)$ then $S = S_0(S_0kt + 1)^{-1}$.

[6]We acknowledge the guidance of Dr. R. T. Rye to the use and logic of the program: RMCHS (27).

[7]O. S. Tee and M. Paventi, manuscript in preparation.

[8]The differential equations are set up by a subroutine from the input chemical equations.

[9]The expression for k for the process in Scheme 3 is

$$k = \frac{2(k_1 + k_2)k_3k_4}{k_1k_4 + k_2k_3 + 2k_3k_4}$$

tions of reactants then it is similarly difficult to know the precise initial conditions. Wen then does not avoid (20), as he claims, the restriction to prepare stoichiometric amounts but merely generalizes the work of Frost and Schwemer (4). It will be shown below that valuable information about initial conditions may be obtained by analysis of the data by eq. [26].

Consider that the experimental data may be reproduced by eq. [26]. The initial conditions need not be known. The pertinent parameters may be found thusly. Equation [26] is rearranged:

$$[28] \quad \ln\left\{\frac{(aA_0 - S_0)}{S} + 1\right\} = (aA_0 - S_0)kt + \ln(aA_0/S_0)$$

To find the individual parameters in Table 1, the left-hand side of eq. [28] is plotted versus t. The unknown constant $(aA_0 - S_0)$ is varied so as to get a maximum correlation coefficient. This task is easily accomplished with a pocket calculator. At maximum correlation, the optimized parameters: $(aA_0 - S_0)$, the slope: $\{(aA_0 - S_0)k\}$, and the intercept: $\{\ln(aA_0/S_0)\}$ are known. Therefore, k is simply the ratio of the slope and $(aA_0 - S_0)$, and A_0 and S_0 can be evaluated from $(aA_0 - S_0)$ and the intercept. These various constants are reported in Table 1 along with the published values. The initial conditions thus calculated compare favourably with the experimental initial conditions. Thus, no prior knowledge of initial conditions or ratio of reactants need be known. The exception to this agreement between the calculated and experimental initial conditions comes from the work of Ritchie (12) on the alkaline hydrolysis of the monoethyl and diethyl succinate, as shown in Table 1. Analysis using eq. [28] leads to a concentration of the diethyl ester approximately half of the initial experimental value. This difference may be explained if the value of a (the "effective" number of reactive sites on A) is one, so that the reaction is not consecutive but stops at the monoester stage. This is plausible since the rate of alkaline hydrolysis of the half-ester of succinic acid would be expected to be much smaller than the rate of hydrolysis of the diester because of the electrostatic effect of the ionized carboxyl group. This electrostatic effect is manifest in the ratio $(k_1/k_2 > 100)$ (12, 13) for diethyl malonate. In the work of Svirbely and Kuchta (7) with diethyl succinate, the electrostatic effect is minimized (so that $k_1/k_2 \approx$ unity) because in the solvent dioxane–water 76.3% (7) ion-association of Na^+ with CO^- will be extensive.

It can be seen from Fig. 1 that immediately after mixing, the original concentration of phenol has totally reacted to form intermediate products. From this simulation it can be deduced that beginning with *any ratio* of reactants it should be possible to obtain the minimum rate constant for the reaction. This statement has a consequence: it is not required for the original reactant to be absolutely pure, as long as the impurities are part of the kinetic scheme. This exposes the futility of the experimental work to obtain very pure substances (6, 16–18). Ingold (2) would seem to have implicitly accepted this fact in obtaining one of the rate constants for the hydrolysis of dimethyl glutarate.

3.2. Closeness of fit

The rate constants are assumed to be a reliable set when the original data are regenerated from the equations employed (2, 14–18, 21) or when a certain shift of a given plot (4) gives coincidence with a calculated family of curves. But degeneracy may occur for certain ratios $(k_2{:}k_1 = 0, 0.5, \infty)$ (4), $(k_1{:}k_2{:}k_3 = 3{:}2{:}1)$ (5, 6), or $(k_1{:}k_2{:}k_3{:}k_4 = 4{:}3{:}2{:}1)$ (16) making the reactions appear simple second order. In cases where the denominator is equal (or close to) zero, extended (16) or quickly-converging (21) power series or differential approximations (14) are used. These particulars and predeterminations of $k(i)$'s (5, 6), make the methodology of solution semi-empirical, confusing, and not as general as claimed.

In fact, closeness of fit cannot be a measure of reliability of the solutions (29) for the rate equations, as has been suggested (11, 16–18, 21). This is illustrated with an example below. Furthermore, the multiple rate constants, however obtained, indicate that a predetermined number of parameters (rate constants) multiplied by a particular function can reproduce the data. But mathematically *any* function can be approximated by *any* number of terms of a power series. Thus, this criterion fails on two counts. Firstly, it forces an arbitrary and finite set of constants to regenerate the function when another more numerous set may improve the "closeness of fit". This is illustrated in section 3.4. Secondly, it fails the test for uniqueness as discussed by Svirbely *et al.* (18) or by inspection of Table 1. For instance the entry for the alkaline hydrolysis of 1,3,5-tri-(4-carbomethoxyphenyl)-benzene reads (k_1, k_2, k_3): 0.0890, 0.0593, 0.0297 $M^{-1}\,s^{-1}$ (6) and 0.0721, 0.0540, 0.0375 $M^{-1}\,s^{-1}$ (21), respectively, for the identical kinetic run.

In one case Kubin *et al.* (21) try to explain the difference in one of their evaluated rate constant versus that reported (see their Fig. 2 (21)), by arguing that it is necessary to measure the reaction course at least up to 70–75% conversion. The deduction was based mainly on their favourable results (graphically represented in their Fig. 1 (21)) using the data of Frost and Schwemer (4) (up to 66% conversion). This explanation cannot be correct because if the function[10] $(\lambda = \int_0^t S\,dt)$ can be determined accurately, then it little matters how its values vary from $t = 0$ to $t = \infty$ (i.e., $\lambda = \int_t^\infty S\,dt$). Regardless of the range of λ: $(\int_0^{t_{30\%}} S\,dt)$ as used in their iteration (21) or $(\int_0^{t_{75\%}} S\,dt)$ as claimed for optimum results, mathematically an identical set of rate constants ought to be produced. In fact, Svirbely *et al.* (14) use values of time very close to zero to avoid the failure of their general eq. [14] when its denominator approaches zero. Likewise it is shown by Radhakrishnamurti *et al.* (9) that in the interval $(0 \leqslant t \leqslant t_{20\%})$ similar values of the rate constants may be obtained as when evaluated over the interval $(0 \leqslant t \leqslant t_{60\%})$. Also application of eq. [27] requires 100% conversion, yet can be solved if the function S is known accurately within a finite time interval.

Although it is not necessary to follow a reaction up to large conversion values, it is a necessary condition that the data for S have zero as their asymptote and no other value no matter how small. Differently stated, it is necessary that the integral (eq. [27]) be finite. For example, consider the smoothed data of Frost and Schwemer (4) (their Table IV (ref. 4) or Table 4 (ref. 25*b*)) where $S = [OH^-]$, $A = [\text{diethyladipate}]$, $S_0 = 2A_0 = 0.00996\,M$. These data may be represented by the two equations below:

$$[29] \quad S = (0.045689t + 107.23)^{-1} + 5.5178 \times 10^{-4} \qquad (\text{c-c} = 0.9999993)$$

where $S_0 = (107.23)^{-1} = 0.009326\,M$, and by

$$[30] \quad S = (0.0365t + 104)^{-1} \qquad (\text{c-c} = 0.9997)$$

[10]Evaluation of such a function was originally introduced by French (3) and then appeared to gain general acceptability with Svirbely *et al.* (14–18), Kubin *et al.* (21), and Saville (30).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

where $S_0 = (104)^{-1} = 0.00961\ M$.[11] Substituting S from eq. [29] (i.e., the most closely fitting data) in eq. [27], no mathematical solution is obtained because ($\int_0^\infty S^2 dt = \infty$). However, the more poorly correlated data from eq. [30], with a zero asymptote, yield $\int_0^\infty S^2 dt = 0.263\ M^2$. Therefore, from eq. [27], $k = (0.00961/0.263) = 0.0365\ M^{-1}\ s^{-1}$ or $k = (0.00996/0.263) = 0.0379\ M^{-1}\ s^{-1}$ depending on the value of S_0 used. Compare these values with the minimum reported (4): $0.0307\ M^{-1}\ s^{-1}$. The foregoing example then illustrates that a close fit should not necessarily be the aim in deciding the reliability of the equations.

3.3. The nonzero asymptote and variation of initial conditions

Problems of initial conditions arise in eq. [30] if a zero asymptote is forced upon the data which are ultimately reflected in the value of k, but as discussed in section 3.1, initial condition problems are resolved by analysis using eq. [28]. In fact this equation also incorporates the nonzero asymptote, provided it is small, by allowing variations of the terms ($aA_0 - S_0$) and $\ln(aA_0/S_0)$.

Reconsider the smoothed data above (4) and the same data, in its raw form, given in Table III of ref. 4. Analysis of the massaged data via eq. [28] gives the following parameters: $k = 0.0372\ M^{-1}\ s^{-1}$, $S_0 = 0.00973\ M$, $A_0 = 0.00486\ M$, and the optimum c-c = 0.99949. Although the terms ($aA_0 = S_0$) and $\ln(aA_0/S_0)$ are allowed to vary, the calculated values S_0 and A_0 are significantly closer to the experimental values than when evaluated from eq. [29] or eq. [30]. Analysis of the raw data using eq. [28] yields (see Table 1): $k = 0.0367\ M^{-1}\ s^{-1}$, $S_0 = 0.00967\ M$, $A_0 = 0.00480\ M$, and the optimum c-c = 0.99953. From these parameters one immediately concludes that the smoothed data are biased, since the constants do not agree and biased in the wrong direction, since the correlation coefficient from the analysis of the raw data is greater than that evaluated from the smoothed data. Similar bias may exist for pooled data if care is not exercised.

Apparently, no difficulty exists in the analysis of the data if the asymptote is small. However, such compensation via eq. [28] cannot be made if the value of the asymptote is large. Three examples from the literature (15, 17, 18) are shown in Fig. 2. The reason for this experimental abnormality (i.e., high limiting value) may be due, in part, to interferences of intermediate products in the determination of S causing markedly different curvature during the initial stages (see Fig. 2) when intermediate product build-up is fastest. The intersections, shown in Fig. 2, of the apparently bi-phasic plots, numbered **1** and **3**, correspond precisely to the time 8.6 min and 16 min, respectively, at which rate, intermediate product formation has reached a maximum (see Fig. 1 for both refs. 17 and 18). The method for an approximate evaluation of k for these cases is

$$[31] \quad k = \frac{S_0}{\int_0^\infty (S - \alpha)^2 dt}$$

[11]As pointed by a referee, the use of correlation coefficients should not be misconstrued as an adequate (or the only) criterion for goodness of fit. It is offered as a familiar (as opposed to quadratic mean error of fit (17, 18)) one-number quantity that measures the magnitude of the deviation from the data. This number avoids tables of percent differences between calculated and observed values used in earlier papers (15–18), but by itself does not measure the randomness of these differences. To represent a close fit, a correlation coefficient close to unity must be accompanied by such a measure of randomness.

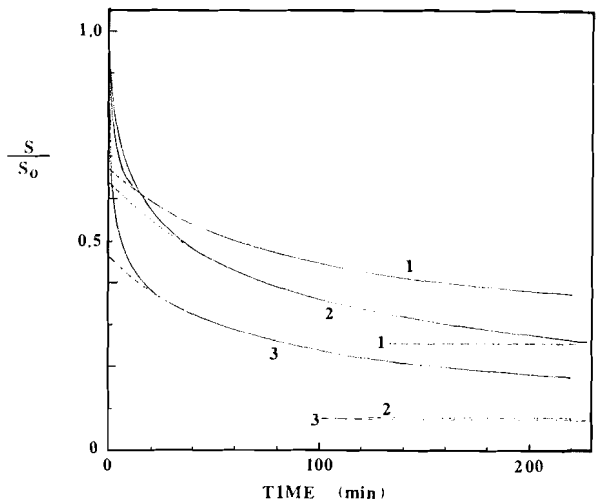

FIG. 2. Ratio of $[HO^-] = S$ to $[HO^-]_0 = S_0$ versus time for the hydrolysis of **1**: triethyl citrate (18), **2**: 1,3,5-tricarbomethoxybenzene (15), and **3**: diethyl malate (17). The numbered dotted segments are the asymptotes (α/S) (see Table 1) for the respective curves. The equations of the dotted lines extrapolating the curves to zero time are given in the footnotes of Table 1. Note that for **2** the data extend to 501 min but the curve was truncated for clarity.

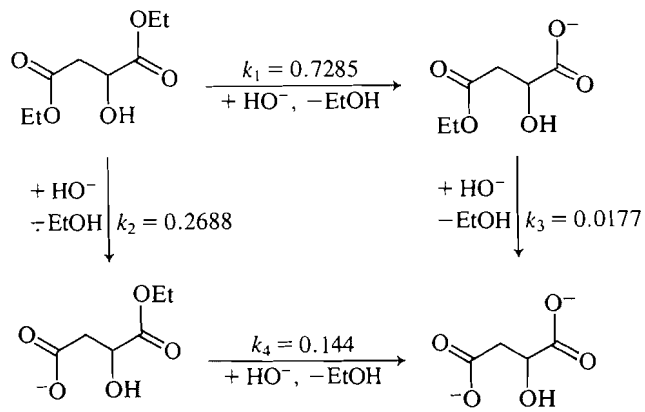
which is deduced from eq. [27] where α is the value of the asymptote.[12] This technique was employed to evaluate the rate constants for the alkaline hydrolysis of 1,3,5-tricarbomethoxybenzene (15), diethyl malate (17), and triethyl citrate (18) shown in Table 1.

3.4. The rate constants

The value of the rate constant calculated from a single set of data must be unique. The wrong assumption made in the literature, cited in this paper, is that two or more rate constants can be evaluated. Firstly, this presupposes a particular mechanism. Secondly, completely false solutions and arguments result. We will point out one.

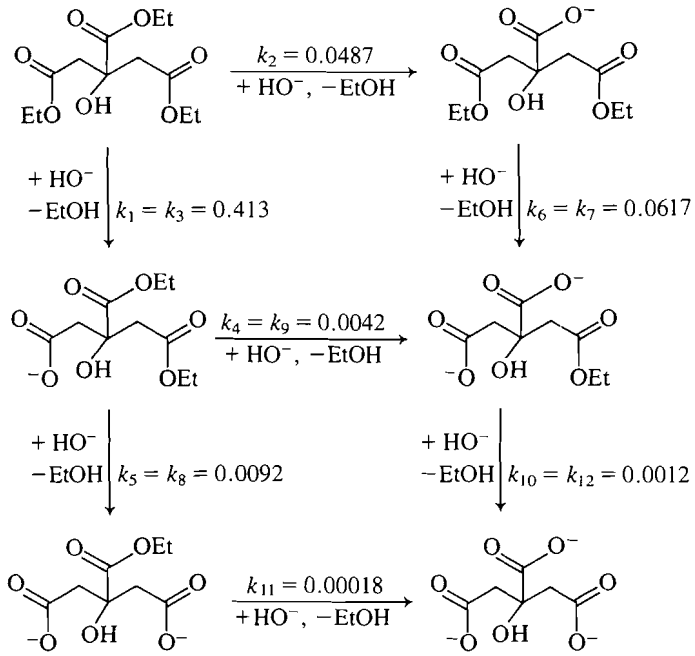
For the alkaline hydrolysis of diethyl malate, Svirbely and Kundell (17) list the following results (k_i's expressed in $M^{-1}\ s^{-1}$):



SCHEME 5

[12]The value of α was calculated from analysis of the data via the equation $(S - \alpha)^{-1} = (bt + c)$ where b and c are constants (by analogy to the limiting equation[5] where $\alpha = 0$: b = k and $c = (S_0)^{-1}$. The data for S are analyzed for different time intervals (see footnotes of Table 1). Also the correlation coefficients reported in the footnotes of Table 1 is that resulting from these analyses.

From the Taft reaction constant for the basic hydrolysis of esters (2.48), they calculate that an α-hydroxy substituent should increase the rate of basic hydrolysis of an ester by 25-fold and that for a β-hydroxy substituent by about 3.1-fold, agreeing with their experimental result (17). However, results for the alkaline hydrolysis of triethyl citrate, under the same conditions as for diethyl malate, show different substituent effects. The data of Svirbely *et al.* (18) (k_i's in $M^{-1}\,s^{-1}$) are shown below:



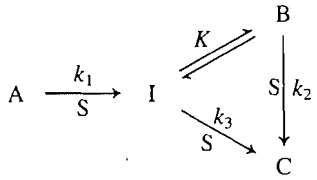
SCHEME 6

This difference is in part dismissed as an effect of steric hindrance (cf. $k_1 = 0.7285\ M^{-1}\,s^{-1}$ for diethyl malate and $k_2 = 0.0487\ M^{-1}\,s^{-1}$ for triethyl citrate) but an opposite effect appears in the second hydrolysis step (cf. $k_3 = 0.0177\ M^{-1}\,s^{-1}$ for diethyl malate and $k_6 = k_7 = 0.0617\ M^{-1}\,s^{-1}$ for triethyl citrate). The answer is that the rate constants for these two reactions are wrong. The apropos mathematical reason for this statement is expounded by Rodriguin and Rodriguina[13] that the assignment of the rate constant to a particular step is haphazard since the rate constants can be interchanged (31*c*). Thus, the literature values reported in Table 1 for a particular step of any reaction cannot be taken seriously!

All the substrates in Table 1, with the exception of 1,3,5-tri-(4-carbomethoxyphenyl)-benzene and 1,3,5-tricarbomethoxy-benzene, may undergo an intramolecular assisted displacement of alkoxide, yet no mention of this is made anywhere. This brings up the second reason why the rate constant must be unique: what if the mechanism also involves a reactive intermediate? The method outlined above by solving eq. [28], independently of the mechanism, gives the rate constant of the rate-limiting step. In combination with pseudo-first-order kinetics, information about a reactive intermediate may be drawn.

[13]The equations shown by Rodriguin and Rodriquina, for instance eq. II.12 (31*a*), are similar to eqs. [2], [3], and [4] reported by Svirbely and Blauer (14) where the values of t, for the case where one component is in large excess (31*b*), is replaced by the value $\lambda = \int_0^t Sdt$. Thus, any argument (31*c*) which is valid for eq. II.12 is also valid for the equations of the papers cited here.

This is illustrated with an example. Let us assume that the processes $A + S \xrightarrow{k_1} B$ and $B + S \xrightarrow{k_2} C$ have been studied independently under pseudo-first-order conditions and the constants k_1 and k_2 are known for different conditions. In particular, it is known that $B + S \xrightarrow{k_2} C$ is the slow step (i.e. $k_2 = \min(k_1, k_2)$). However, analysis of the second-order consecutive reaction, under the same particular conditions, reveals that $k = k_1$. The explanation for such situation may be as follows:



SCHEME 7

where I is an intermediate and K is the tautomeric constant. The applicable equilibrium, mass balance, and differential equations for Scheme 7 are:

[32] $B = KI$

[33] $A_0 = A + (1 + K)I + C$

[34] $A' = -k_1AS$

[35] $C' = (Kk_2 + k_3)IS$

[36] $S' = k_1AS - (Kk_2 + k_3)IS$

By differentiation of eq. [33] and substitution of C' and A' into the resultant equation one obtains:

[37] $$I' = \frac{k_1}{(1 + K)}AS - \frac{(Kk_2 + k_3)}{(1 + K)}IS$$

Assuming that the data are represented by eq. [28], then by the same methodology shown above for Scheme 2, the ultimate equation in k has the form

[38] $$\frac{(1 + K)}{k_1(Kk_2 + k_3)}k^2 - \left(\frac{1}{k_1} + \frac{(1 + K)}{(Kk_2 + k_3)}\right)k + 1 = 0$$

which is satisfied when $k = k_1$ or $k = (Kk_2 + k_3)/(K + 1)$. Now, since it is given that $k = k_1$ and $k_2 < k_1$ then $(Kk_2 + k_3)/(K + 1) > k_1$. Thus, we have a handle in evaluating upper or lower limits of k_3 or K if one of these can be estimated. This example was evident for two kinetic processes studied by the author (26) and are the object of an upcoming paper. These cases can *only* arise from the study of consecutive second-order reactions and explained in conjunction with pseudo-first-order kinetics of the individual processes.

One last point concerning rate constants as determined from the conventional pseudo-first-order analysis and those obtained from eq. [28]. For a substrate A, with a reactive sites, reacting with species S, the second-order rate constant k, for reaction conditions of pseudo-first-order, has been erroneously evaluated from the simple exponential equation: $S = S_0(\exp A_0kt)^{-1}$ or a variant $S = \{S_0(A_0 - S_0)/A_0\}\{\exp\ (A_0 - S_0)kt\}^{-1}$. However, the quaesitum[14] for k must be evaluated from eq. [26] (or eq. [28]) with the pseudo-first-order condition (i.e.,

[14]The Webster dictionary defines quaesitum as the actual value of a quantity.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 118.98.75.50 on 09/07/12
For personal use only.

$S_0 \ll aA_0$). The limiting functions[3] for eq. [26] are $S = \{S_0(\exp aA_0kt)^{-1}\}$ or $S = \{S_0(aA_0 - S_0)/aA_0\}\{\exp(aA_0 - S_0)kt\}^{-1}$. Thus the conventional second-order rate constant may be up to a times larger than that evaluated from eq. [26].[15] This factor is usually treated as a statistical correction which may be correct if all the reactive sites on species A are symmetrical but obviously wrong if no symmetry exists between the reactive sites.

4. Conclusion

We have shown that experimental data are well reproduced by eq. [26] (or eq. [28]), whose cheaper[16] and faster analysis yields $k = \min(k(1), \ldots, k(n))$ and also the initial conditions (i.e., S_0 and A_0). For data with a large non-zero asymptote eq. [31] may be applied to find the approximation for k. The literature rate constants listed in Table 1 have no scientific significance and appear to be mathematical artifacts[17,18] of the non-linear integral equations used. These constants when introduced into these equations reproduce the data, but because the total number has been predetermined by the chosen mechanism, their significance is on very shaky footing. More pseudo-first-order kinetics need be done with the compounds listed in Table 1 to get a clearer overall picture of the mechanism. Such kinetics should also better demonstrate the validity of eq. [26] as applied to second-order competitive reactions and the significance of k.

[15]This has also been shown to be the case (26) by allowing all the species, derived from A after reaction with S, to account for the disappearance of S. Then assuming the steady state on all these species except that of the rate-determining step, the rate constant works out to be larger than the quaesitum by the number of reactive sites of the species in the rate-determining step.

[16]The acknowledgements of the various papers (14, 16–18) divulge that grants have been required to cover the costs of computer expenses.

[17]Rephrasing the words of Dr. B. C. Eu whose consultation for the nonlinear differential equations is acknowledged, the mathematical iterations can be equated to the chasing of a ghost.

[18]Note that Svirbely *et al.* (14) mention that the guess to the value of the rate constant must be good (close to 100%) for the iteration to converge.

A theoretical insight into the insertion reaction of singlet methylene to the hydrogen molecule

M. ORTEGA, J. M. LLUCH, A. OLIVA, AND J. BERTRAN
Departamento de Química Física, Universidad Autónoma de Barcelona, Bellaterra, Barcelona, Spain

Received June 20, 1986[1]

M. ORTEGA, J. M. LLUCH, A. OLIVA, and J. BERTRAN. Can. J. Chem. **65**, 1995 (1987).

The least-motion and non-least-motion energy profiles for the insertion reaction of singlet methylene into the hydrogen molecule have been calculated using the 6-31G* basis set and introducing the correlation energy with the Møller–Plesset perturbation theory and with the MC-SCF technique. From the results obtained the effect of geometry optimization including electron correlation on the shape of the energy surface is discussed. The building up of a bidimensional biconfigurational energy surface has permitted one to interpret the opening of the methylene angle during the least-motion process as a direct consequence of the change in the electronic configuration. The TC-SCF/6-31G* second order transition structure for this forbidden process has been directly located using gradient minimization methods.

M. ORTEGA, J. M. LLUCH, A. OLIVA et J. BERTRAN. Can. J. Chem. **65**, 1995 (1987).

En utilisant des ensembles de base 6-31G* et en introduisant l'énergie de corrélation dans la théorie perturbationnelle de Møller–Plesset et dans la technique des OM en champ auto-cohérent, on a calculé les profils d'énergie, impliquant et n'impliquant pas un minimum de mouvement, pour la réaction d'insertion du méthylène singulet dans la molécule d'hydrogène. A partir des résultats obtenus, on discute de l'effet de l'optimisation de la géométrie, y compris de la corrélation électronique, sur la forme de la surface énergétique. En construisant une surface énergétique biconfigurationnelle et bidimentionnelle, on a pu affirmer que l'ouverture de l'angle du méthylène, au cours du processus impliquant un minimum de mouvement, est une conséquence directe du changement dans la configuration électronique. Utilisant des méthodes de minimisation des gradients, on a pu localiser directement la structure de transition du deuxième ordre TC-SCF/6-31G* de ce processus défendu.

[Traduit par la revue]

1. Introduction

It is now well established that Hartree–Fock molecular orbital theory leads to equilibrium structures that show systematic deviations from the experimental results (1). In recent studies of a wide range of molecules, Pople *et al.* (2, 3) have demonstrated that the introduction of electron correlation is essential in order to obtain equilibrium geometries which are in good agreement with experimental data. In spite of these interesting results, most theoretical calculations on chemical reactivity have been done until the present by assuming that the geometries of the critical points of the potential hypersurface remain unchanged when one takes into account electron correlation. So, critical points of a reaction hypersurface are determined at the Hartree–Fock level and the correlation energy is then added, keeping invariant the previously found geometries.

Because of its small size, the insertion of singlet methylene to the hydrogen molecule has been extensively studied at different levels of calculation (4–13). This process is a prototype for reactions where a symmetry-forbidden least-motion path and an allowed non-least-motion path of lower symmetry can compete.

In order to introduce electron correlation in the least-motion path, Bauschlicher *et al.* (9) have calculated a series of contour maps showing several cuts of the potential energy hypersurface which correspond to the initial approach of both reactants, using the configuration interaction method with a double ζ basis set. They have found that the methylene bond angle at the saddle point is much larger than that for either the reactants or products, since it takes a value quite close to 180°. The authors believe that this surprising result can be attributed to the fact that this almost linear arrangement of singlet methylene will substantially decrease the unfavourable interaction between its lone pair and the doubly occupied $1\sigma_g$ orbital of H_2.

In a similar way, the same authors have studied (10) the non-least motion approach. Their CI results lead to no barrier at all for this type of approach. They conclude that the single determinant self-consistent field method does not properly describe several of the main features of the non-least motion pathway, since its results are not only quantitatively, but as well qualitatively different from the CI ones. A different conclusion is reached by Zurawski *et al.* (12). These authors use the reaction coordinate method with complete optimization at the SCF level and then introduce electron correlation in the IEPA, CI, and CEPA schemes, keeping unchanged the SCF geometries. In all cases they find that the minimum energy path does not noticeably change when electron correlation is added. The discrepancy with the results of Bauschlicher is attributed by the authors to the complete geometry optimization carried out by them. However, Schlegel *et al.* (13) have recently studied the same problem with direct location of the stationary points at the HF/3-21G and HF/6-31G* levels and using the Møller–Plesset perturbation theory in order to estimate the effect of the electron correlation energy. They have found a minute energy barrier at the Hartree–Fock level, this barrier disappearing when electron correlation is added. This result seems to show again that electron correlation substantially changes the energy profile of the non-least motion approach.

None of the above mentioned papers have studied the effect of the correlation energy on the geometry optimization process when the reaction coordinate method is used. We believe that it would be very interesting to discuss its effect on the shape of the reaction surface and, therefore, on the reaction path. In order to achieve this aim we have studied the least-motion and the non-least-motion pathways using the reaction coordinate method and optimizing all the geometrical parameters both at the Hartree–Fock level and with inclusion of electron correlation.

This work will also permit discussion on the opening of the methylene angle in the least-motion approach, quite a striking result which, undoubtedly, merits some further consideration.

2. Method of Calculation

Ab initio molecular orbital calculations were performed with the GAUSSIAN 82 (14) and MONSTERGAUSS (15) programs, using the 6-31G* basis set (16), since it is one of the simplest for which the introduction of correlation effects leads to a net improvement in structural predictions (2). Electron correlation energy was estimated by using the Møller–Plesset partition (MP) in the many-body perturbation theory (MBPT) up to second order (17). Multiconfigurational calculations using the ground and the lowest biexcited configurations were also done. These multiconfigurational calculations have been indicated throughout this work with the symbol TC-SCF.

All equilibrium geometries and transition structures were fully optimized with analytical gradient methods (18), both at the Hartree–Fock level and with inclusion of electron correlation.

3. Results and discussion

We will sequentially present the results corresponding to the allowed non-least-motion and the forbidden least-motion pathways. They have been studied with the reaction coordinate method, using the R distance between the carbon atom of methylene and the midpoint of the hydrogen molecule as independent variable. C_{2v} symmetry has been imposed for the study of the least-motion process.

Figure 1 presents the energy profiles obtained at three different levels of calculation for the beginning of the non-least-motion process. At the Hartree–Fock level, one intermediate and one transition state appear, although the resulting energy barrier is quite small. It is interesting to note that the direct location of these stationary points almost does not change the geometry and the energy of them, thus indicating the goodness of the reaction coordinate we have used. The values of R for the intermediate and the transition state are, respectively, 2.50 and 1.84 Å. When electron correlation is added, with the Møller–Plesset perturbation theory, keeping unchanged the Hartree–Fock geometries, an important stabilization of the energy profile can be observed and the energy barrier disappears. These results are in good agreement with those previously obtained by Schlegel (13). Finally, we have recalculated the energy profile with a new geometry optimization which already includes electron correlation. This leads to a new noteworthy stabilization of the energy profile although no important changes in the shape of the energy profile are now produced.

Let us now analyze the effect of electron correlation on the geometry optimization. Table 1 presents the values of the energy and of the different geometrical parameters of the system obtained both at the Hartree–Fock level and with inclusion of electron correlation, for some of the points which we have calculated. These points have been chosen in such a way that the values of R correspond to the Hartree–Fock stationary points. The presented geometrical parameters are defined in Fig. 2. The comparison between HF and MP2 values clearly shows that electron correlation produces only slight changes in the geometry of the system, the most important being the one corresponding to the angle α which measures the inclination of the hydrogen molecule with respect to the plane of methylene. In both levels of calculation the angle θ increases monotonically from its initial value in methylene to the value it has in methane. It is also interesting to note that the angle β is initially very close to 90° in good agreement with the prediction of previous calculations (10, 11, 13). Finally, the energy values of the reactants ($R = \infty$) and of methane ($R = 0.63$ Å) permit the calculation of the exothermicity of the process at both levels of calculation. One obtains 123.0 and 137.4 kcal mol^{-1}, respectively, in satisfactory agreement with the best available value, 122 kcal mol^{-1}, found in the literature (9).

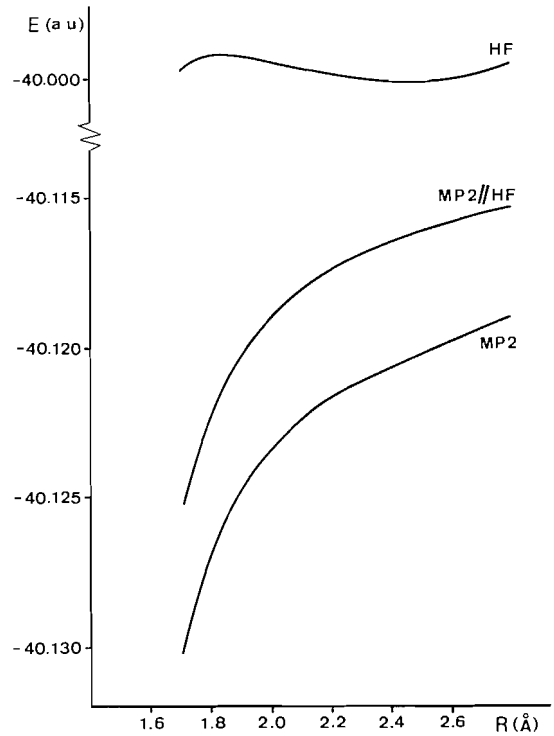

FIG. 1. Energy profiles for the non-least-motion insertion of singlet methylene to the hydrogen molecule.

Let us now present the results obtained for the least-motion pathway. Figure 3 shows the energy profiles for this approach corresponding to the same different levels of calculation which have been used for the non-least-motion pathway. One can observe that the 6-31G* Hartree–Fock energy profile presents an important energy barrier, 35.5 kcal^{-1}, whose maximum is situated at about $R = 2.0$ Å. Such a large barrier is consistent with the forbiddenness of the process, our value being something higher than the CI value found by Bauschlicher and co-workers (9). As in the case of the non-least-motion pathway, a great stabilization of the energy profile is obtained when electron correlation is added at the MP2//HF level. However, the position of the maximum along the reaction coordinate scarcely changes and the value of the energy barrier only slightly decreases to the value of 32.9 kcal mol^{-1}. One can also observe that geometry optimization already including electron

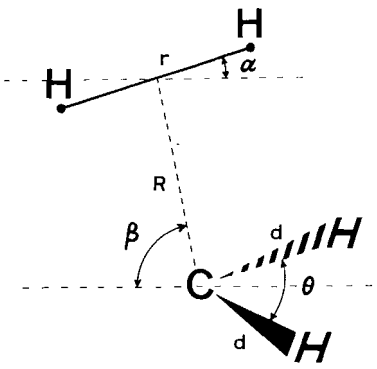

FIG. 2. Geometrical parameters used to describe the reaction system.

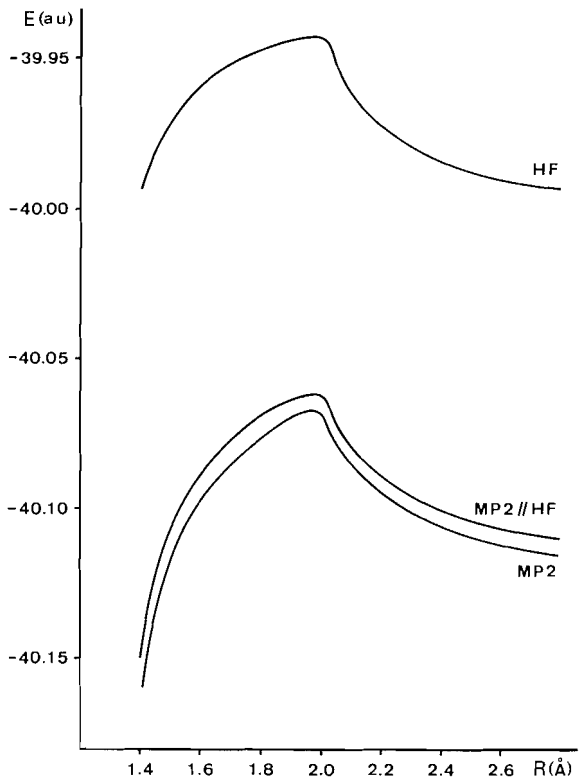

FIG. 3. Energy profiles for the least-motion insertion of singlet methylene to the hydrogen molecule.

correlation at the MP2 level leads again to a noticeable change of the energy profile, the energy barrier being now 32.6 kcal mol^{-1}. It is also interesting to remark that the three energy profiles have a rather curious shape, the slope of the curve being very much greater before than after the energy maximum. The appearance of these kinks will be discussed later.

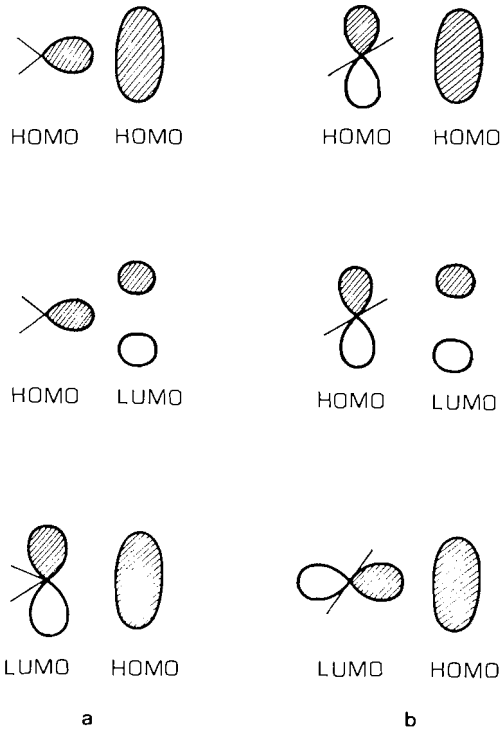

FIG. 4. Schematic representation of the frontier orbital interactions for the insertion of bent (a) and linear (b) singlet methylene to the hydrogen molecule.

The geometries obtained at the HF and MP2 levels of calculation for the structure corresponding to the maximum of the energy profiles are presented in Table 2. Obviously, only four geometrical parameters must now be specified in order to completely determine the geometry of the system, since C_{2v} symmetry has been imposed in the least-motion approach. It has to be emphasized that the values of the methylene angle θ corresponding to the maximum energy point are always rather close to 180°. As mentioned in the introduction, this almost linear arrangement of singlet methylene in the energy maximum was explained by Bauschlicher *et al.* (9) through a decrease of the unfavourable interaction between the lone pair of methylene and the doubly occupied $1\sigma_g$ orbital of the hydrogen molecule. This simple explanation seems reasonable. In the language of the frontier orbital theory, it corresponds to the diminution of the repulsive HOMO–HOMO interaction. This can be easily visualized in Fig. 4 where the different frontier orbital interactions are schematically presented for the bent and linear configurations of methylene. The symmetry of the two frontier orbitals for the linear structure has been deduced by considering the correlation diagram for the least-motion insertion of linear singlet methylene into the hydrogen molecule. Although they are strictly degenerate when the methylene molecule is isolated, the degeneracy is broken down once the process has just begun. The correlation diagram shows that the HOMO and the LUMO of the interacting system have, respectively, b_1 and a_1 symmetries in the point group C_{2v}. One can observe in Fig. 4 that the linear arrangement is not only favoured by the decrease of the repulsive interaction between the lone pair of methylene and the doubly occupied $1\sigma_g$ orbital of H_2, but also by the simultaneous increase of both stabilizing HOMO–LUMO interactions. So, the consideration of HOMO–HOMO and HOMO–LUMO interactions permits an interpretation of the

opening of the methylene angle which is produced during the process.

Let us now analyze the variation of the geometrical parameters along the reaction coordinate. Table 3 presents this variation at the HF and MP2 levels. In both cases the most important fact to be remarked is the sudden change in geometry which is exactly produced at the energy maximum. Specially interesting is the behaviour of the methylene angle θ. At the energy maximum, this angle suddenly changes from the value it has in the reactants to the value rather close to 180° and, then, it begins to decrease until the tetrahedral value of methane is reached. The sudden change in geometry at the energy

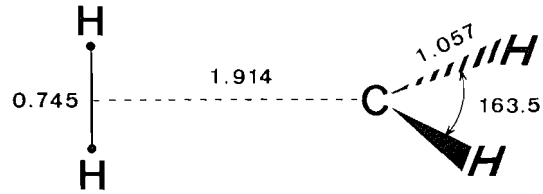

FIG. 6. Geometry of the transition structure of the least-motion path. Bond lengths in Å and angles in deg.

maximum is accompanied by a discontinuous change from the a_1^2 electronic configuration to the b_1^2 one. These results suggest that the angle θ must play an important role in the reaction coordinate and that biconfigurational calculations which take into account the a_1^2 and the b_1^2 configurations have to be done. So the building up of a bidimensional biconfigurational energy surface seems necessary in order to understand the actual mechanism of the least-motion process.

Figure 5 presents this bidimensional energy surface which has been obtained by taking as independent variables of the reaction coordinate the distance *R* and the methylene angle θ. The dotted line represents the points of the surface in which the two configurations have the same weight. Consequently, the a_1^2 configuration predominates for the points situated below the dotted line, while the b_1^2 configuration is dominant for the structures situated above this line. The most interesting fact one can observe in Fig. 5 is the existence of a saddle point situated at about $R = 1.9$ Å and $\theta = 160°$. This saddle point leads to an energy barrier of about 41 kcal mol^{-1}. Given its situation with respect to the dotted line, the dominant configuration at this point is the b_1^2 one, i.e. the change of configuration has already been produced. All these results are consistent with the ones which have been found from the energy profiles of Fig. 3, although the methylene angle and the distance *R* are now smaller and the energy barrier is noticeably higher. However, it has to be reminded that those energy profiles lead to a sudden change of both the methylene angle and the electronic configuration. That this sudden change is a direct consequence of the methodological limitations can now be clearly understood. Starting from the approximate situation of the saddle point we have tentatively drawn, in dashed line, the reaction path which links this point with the valleys of reactants and product. At the beginning of the process, the reaction coordinate is mostly formed by the distance *R* between the two reactants. In a second stage, the methylene angle θ greatly intervenes in the reaction coordinate, since it varies from the value it has in isolated methylene to a value of about 160° at the saddle point. At the same time the weight of the initially dominant a_1^2 configuration monotonically decreases from the reactants to the saddle point, the value of 50% having been reached at about $R = 2.2$ Å where the reaction path crosses the dotted line. The variations of θ and of the electronic configuration are rather fast, but continuous. Figure 5 clearly shows that the above mentioned discontinuity in the energy profiles is essentially due to the use of only the parameter *R* as independent variable of the reaction coordinate.

Starting from the approximate situation of the saddle point in the bidimensional energy surface, we have looked for the actual existence of a stationary point in the biconfigurational hypersurface through analytical gradient minimization. We do have found a stationary point, whose geometry is presented in Fig. 6. The characterization of this stationary point shows that it is a second order saddle point, since its force constant matrix has two negative eigenvalues. This was to be expected, given

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

that the least-motion path is not an actual reaction path, the C_{2v} symmetry having been imposed throughout. In fact, the eigenvector corresponding to the most negative eigenvalue corresponds to the breaking of this symmetry, thus leading to the non-least-motion process. On the other side the eigenvector corresponding to the other negative eigenvalue is directly associated to the least-motion approach at the saddle point since its most important components correspond to the shortening of the R distance between the two reactants. The examination of the geometrical parameters R and θ of the located saddle point shows that they are very similar to the ones previously estimated on Fig. 5, thus indicating that the choice of R and θ as the independent variables of the reaction coordinate was very adequate. The energy of the located saddle point leads to a value of 41.1 kcal mol^{-1} for the least-motion energy barrier, this value being again very close to the estimated one.

4. Conclusions

The examination of the effect of electron correlation in geometry has permitted the calculation of the least-motion and of the non-least motion MP2/6-31G* energy profiles. In this way we have found that the non-least-motion approach takes place without any energy barrier, thus confirming the results previously obtained by other authors (10–13) from more restricted studies of the energy surface. In the least-motion pathway we have shown that geometry optimization including electron correlation does not appreciably change the shape of the energy surface at the MP2 level of calculation.

This work has also permitted one to give an interpretation of the sudden opening of the methylene angle which is obtained in all the theoretical calculations carried out until the present on the least-motion path (8, 9). The building up of a bidimensional biconfigurational energy surface has shown that this opening is produced in a continuous, rather than discontinuous, way and that it is intimately related to a simultaneous change in the electronic configuration of the system. The approximate saddle point obtained in this way has permitted the direct location of a second order stationary point for this forbidden process. The results obtained in this work clearly show that the introduction of static correlation is essential in order to give a correct description of the least-motion process.

X-ray single crystal analysis sheds further light on the structure of this new iminium salt. ATABNEP crystallizes in the monoclinic system, space group $P2_1$ and shows a very short value for the C—N distance in the iminium group, thus suggesting that the contribution of the carbonium ion form in this particular case is much lower than usual, a fact that can be considered a rationale for the reluctance of ATABNEP to undergo hydrolysis.

H. R. VITURRO, B. E. RIVERO, O. E. PIRO, J. A. CARAM, M. E. MARTINS et C. M. MARSCHOFF. Can. J. Chem. **65**, 2000 (1987).

L'analyse par diffraction des rayons X d'un monocristal de ATABNEP montre que ce nouveau sel d'iminium cristallise dans le système monoclinique et appartient au groupe d'espace $P2_1$. La très courte distance observée pour la liaison C—N dans le group iminium suggère que dans ce cas la contribution de l'ion carbonium est bien moindre que dans la plupart de sels d'iminium connus et, donc, fournit une possible interprétation à la résistance de ce sel à la reaction d'hydrolyse.

Iminium salts have received increasing attention during the last fifteen years because of their potential as reaction intermediates in preparing different organic compounds, both directly (1) and by photochemical excitation (2). Nevertheless, and probably because of the difficulties involved in preparing good single crystals, X-ray diffraction data are not abundant for these compounds (ref. 1, p. 89).

Recently, a new iminium salt, $C_{14}H_{25}N_2O^+.ClO_4^-$ with f.w. = 336.5, whose structure was determined by means of usual spectroscopic techniques to be 8-acetamido-2,4,4,8-tetramethyl-3-azanium-bicyclo[3.3.1]non-2-ene perchlorate (ATABNEP), was prepared by reaction of some terpenes (limonene, β-pinene, and terpinolene) with dilute solutions of perchloric acid in acetonitrile (3). The bicyclic cation of ATABNEP (Fig. 1) shows remarkable properties with respect to the ususal behaviour of iminium salts: thus, it is very stable, as seen from its high melting point (252–252.5°C) and, more important, the solid can be handled and stored without special cares, since it is unaffected by humidity at ambient conditions. This fact gives ATABNEP a particular interest because potential applications of this compound would not require working in controlled environments. It is of interest to note, in this respect, that iminium salts are usually very sensitive to water, undergoing a hydrolysis reaction which yields a ketone and an ammonium salt as products (ref. 1, p. 156), while ATABNEP does not show chemical change when dissolved in water (in fact, it can be recrystallized from aqueous solutions) and, also, does not react when refluxed in 10% H_2SO_4. Reaction with water occurs only in alkaline media but, then, the usual reaction does not take place and an imine that retains the bicyclic structure of the cation is precipitated (4).

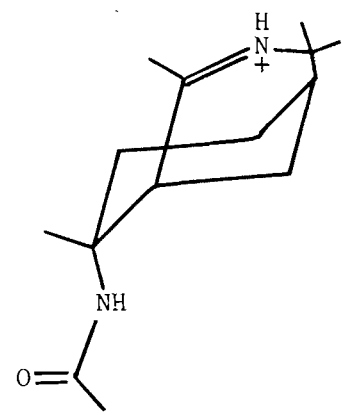

FIG. 1. Schematic drawing of the organic cation in ATABNEP.

Taking all this into account, it was concluded that a complete X-ray study of this compound would be worthwhile.

Experimental

ATABNEP was prepared from (+)limonene and from (−)β-pinene as previously described (3) and recrystallized from ethanol at room temperature. Good colourless crystals were obtained after one month. It has not been possible, up to now, to isolate crystals from the terpinolene-generated ATABNEP adequately to undertake the crystal structure determination of this solid, which has no optical activity. No differences in the diffraction pattern of the salt generated from limonene with respect to samples obtained from pinene were observed.

A complete X-ray diffraction data set was obtained from a prismatic crystal of limonene-derived ATABNEP of approximate dimensions $0.45 \times 0.45 \times 0.60$ mm with an Huber four circle diffractometer, used with graphite monochromated MoK_α radiation ($\lambda = 0.7093$ Å). The unit cell dimensions and orientation matrix for data collection were produced from 15 centered reflections by least-squares refinement. The 3543 reflections in the $\pm h, +k, -l$ reciprocal space quadrant having θ in the range 0–25° were measured by the ω-scan technique, working in the constant precision mode. Intensities of two standard reflections were monitored every 180 min and showed to be essentially constant throughout the experiment (within 1%).

For the calculations, the 961 independent reflections having $I > 2.5\sigma(I)$ were used. Data were corrected for Lorentz, polarization, and extinction effects, but not for absorption. The atomic dispersion scattering factors of Cromer and Waber (5) and the anomalous dispersion coefficients of Cromer and Ibers (6) were employed in the calculations. Most of these were performed on a PDP 11/34 computer with the SHELX program (7). The projection shown below was drawn with the program ORTEP (8).

Results

Crystal data are as follows:

Monoclinic, space group $P2_1$, with $a = 7.902(5)$ Å, $b = 8.837(2)$ Å, $c = 12.779(3)$ Å, $\gamma = 110.32(2)°$, $V = 838.1$ Å^3, $Z = 2$, $\rho_c = 1.33$ g/cm^3, $\rho_m = 1.26$ g/cm^3, $\mu(MoK_\alpha) = 2.07$ mm^{-1}, $F(000) = 360$ electrons.

The chlorine atom was readily located from a Patterson map and its position confirmed by the highest peak in the best symbolic addition map for the centrosymmetric projection of the structure along its screw axis (crystal c axis). All other non-hydrogen atoms were subsequently found by alternate difference Fourier synthesis and isotropic least-squares refinement, which converged to an R-factor of 10.7%.

The subsequent difference Fourier synthesis showed peaks corresponding to 17 out of the 25 hydrogen atoms of the molecule. These atoms were positioned at the corresponding positive electron density regions on stereochemical grounds and kept fixed during further isotropic refinement. The eight missing atoms were positioned as follows: two of them, belonging to a methylenic carbon, were also fixed stereochemically, while the remaining six hydrogen atoms, which pertain to two methyl substituents, were refined as rigid groups. The overall vibrational B value for all hydrogen atoms was fixed to be 6.3 Å^2. The final refinement was carried out by anisotropic full-matrix least-square methods keeping all hydrogen atoms fixed at the previously obtained positions. This procedure converged to agreement factors $R = 6.7\%$ and $R_w = 7.1\%$, with the minimization function defined by $M = \Sigma w[|F_0| - |F_c|]$ with weights $w = [\sigma^2(F_0) + 0.0006F_1^2]^{-1}$. At this stage, the number of independent reflections per parameter is 4.8 and the difference Fourier synthesis is essentially flat (maximum and minimum peaks were 0.25 and -0.3 e/Å^3, respectively.)

The difference between the R-factors for both molecular stereoisomers was not statistically significant to afford the determination of the absolute configuration for the limonene-generated ATABNEP. The assignment of the (1S, 5R, 8R) configuration for the employed crystal and (1R, 5S, 8S) for the product obtained from pinene was made on the grounds of chemical path stereospecificity (3).

Final positional parameters and equivalent isotropic temperature factors computed following Hamilton (9) for all non-hydrogen atoms are given in Table 1. An ORTEP projection of the content of one asymmetric unit of the limonene derived ATABNEP, down the a axis, displaying the conformational features of the molecule and atom numbering is shown in Fig. 2. A projection of the crystal packing is presented in Fig. 3.

As it can be readily seen, the obtained structure confirms the previous proposal (3). Bond distances and bond angles for the

perchlorate anion and the organic cation are listed, respectively, in Tables 2 and 3.[7]

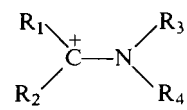
Discussion

In the perchlorate anion the four oxygen atoms form a slightly distorted tetrahedron with mean Cl—O distance 1.39(1) Å and mean O—Cl—O angle 109(4)°, a value that compares well with the perfect tetrahedron (109.5°). The relatively high thermal parameters associated with the oxygen atoms (see Fig. 2 and Table 1) could be due to large rotational dynamic and/or static disorder of the anion around its center.

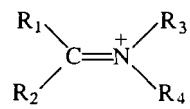
In the organic cation the six carbon ring has a well defined chair configuration with mean C—C distance equal to 1.54(2) Å and a mean C—C—C angle of 111(3)°, being the largest deviation from perfect sp^3 hybridization 5°. The other ring, which contains the iminium group, has five of its atoms, C(1), C(2), N(3), C(4), and C(5) as well as the substituting atom on the iminium carbon, i.e. C(10), almost in the same plane (within 0.05 Å).

Bond lengths and bond angles in the acetamido residue are in good agreement with data in the literature (10), and the group is in axial position with respect to the chair, as should be expected from the Ritter mechanism (3).

It must also be noticed that the C—N distance in the iminium group, 1.28(1) Å, is shorter than what theoretical arguments would suggest for this particular bond. In this connection, it is to be recalled that, as pointed out by Kollman (ref. 1, chap. 1) iminium ions considered from the point of view of valence bond theory contain significant contributions from the two resonance structures **1** and **2**:



1



2

their relative importance being dependent on the nature of the substituents. Thus, for the hypothetical $[H_2CNH_2]^+$ ion, the carbon–nitrogen distance has been calculated to be 1.28 Å (ref. 1, chap. 1) while for $[(CH_3)_2CN(CH_3)_2]^+$ the theoretical value is 1.30 Å (ref. 1, chap. 1) which compares well with the experimental datum of 1.302 Å (12). The last figure is theoretically justified because methyl substitution on the carbon stabilizes structure **1** through methyl hyperconjugation with the carbonium center and, thus, leads to longer carbon–nitrogen bonds, while methyl substitution on the nitrogen atom should have an opposite (i.e. iminium stabilizing) though weaker effect, a fact that is confirmed when carbon–nitrogen bond lengths for $[(CH_3)_2NCR_2]^+$ and $[H_2NCR_2]^+$ are compared.

We have, then, that the observed carbon–nitrogen distance in the iminium group of ATABNEP is shorter than what one should expect, particularly if it is considered that there is a methyl substituent on the carbon. This, in turn, suggests that the steric hindrance due to the bicyclic structure enhances the contribution of resonance form **2**, a fact that is confirmed when it is noted that bond angles for C(1)—C(2)—C(10),

N(3)—C(4)—C(11)	102.0(8)	C(13)—C(8)—N(16)	108.6(8)
N(3)—C(4)—C(12)	104.9(8)	C(1)—C(9)—C(5)	108.9(8)
C(5)—C(4)—C(11)	110.7(9)	C(14)—C(15)—N(16)	116(1)
C(5)—C(4)—C(12)	116.9(9)	C(14)—C(15)—O(17)	121(1)
C(11)—C(4)—C(12)	109.7(9)	N(16)—C(15)—O(17)	124(1)
C(4)—C(5)—C(6)	116.1(9)	C(8)—N(16)—C(15)	124.2(9)
C(4)—C(5)—C(9)	109.2(8)		

C(1)—C(2)—N(3), and C(10)—C(2)—N(3) are very near the theoretical value for sp^2 hybridization.

This feature affords a rationale for the reluctance of this compound to undergo hydrolysis, since this reaction should occur through the attack of a water molecule on the carbonium ion. The fact that reaction with water in alkali media proceed via direct proton abstraction from the iminium form (7) reinforces this interpretation.

Electroionization study of ethane: structures in the ionization and appearance curves[1]

PIERRE PLESSIS AND PAUL MARMET

Herzberg Institute of Astrophysics, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received January 23, 1987

PIERRE PLESSIS and PAUL MARMET. Can. J. Chem. **65**, 2004 (1987).

Ionization efficiency curves of very high signal-to-noise ratio are presented for ethane and most fragment ions containing at least one carbon atom. These curves, which are produced by monoenergetic electron impact, extend up to 10 eV above the initial onsets. Novel structures are observed in most curves. Certain features appear at the same energy in several of the curves indicating that they belong to a common progenitor, either $C_2H_6^-$ * or $C_2H_6^*$, and not directly to the detected ions. These sets of structure are attributed to negative ion states (Feshbach resonances) and/or to Rydberg autoionizing states.

PIERRE PLESSIS et PAUL MARMET. Can. J. Chem. **65**, 2004 (1987).

Des courbes de section efficace d'ionisation de très grand rapport signal sur bruit sont présentées pour l'éthane et ses fragments ioniques composés d'au moins un atome de carbone. Ces courbes sont produites par impact d'électrons monoénergétiques et s'étendent jusqu'à 10 eV au-dessus des seuils initiaux. De nouvelles structures sont observées dans la plupart des courbes. Certaines structures apparaissent aux mêmes énergies dans plusieurs courbes, ce qui indique qu'elles n'appartiennent pas directement aux ions détectés mais à une particule qui est à l'origine de tous ces ions, soit le $C_2H_6^-$ * ou le $C_2H_6^*$. Ces groupes de structures sont attribués à des états d'ions négatifs (résonances Feshbach) et/ou à des états de Rydberg autoionisants.

1. Introduction

Ethane and its fragment ions have been studied fairly extensively by various methods in the ionization and appearance threshold regions. Our data for these regions have been presented in a recent paper (1). Much less work has been done at energies above the immediate onset regions. Ionization efficiency curves at higher energies are reported by Suzuki and Maeda (2) using a monoenergetic electron beam, Selim (3) using the (pseudo-monoenergetic) electron impact energy distribution difference technique, and Berkowitz (4) using photoionization mass spectrometry. In this paper very high signal-to-noise ratio electroionization efficiency (EIE) data extending up to 10 eV above onset are presented for ethane and all fragment ions containing at least one carbon atom, except CH_4^+. Numerous low intensity features are observed for the first time in most curves. Assignments are proposed for many of these structures.

2. Apparatus and method

More complete descriptions of the apparatus have been given elsewhere (5, 6). It consists of two 127° electrostatic selectors in series producing a monoenergetic electron beam. In this work the full width at half maximum (FWHM) resolution of the beam is approximately 60 meV for a current of 3×10^{-8} A. The molecular beam is bombarded by the electrons; the ions produced are mass analysed by a large quadrupole mass filter and the transmitted ions are detected by a dynode type electron multiplier. Data acquisition is computer controlled. An individual EIE curve takes about 10 s to obtain and the final curves consist of thousands of individual curves summed over periods of about 130 h. The energy scale of the curves is calibrated typically every 24 h using the clear threshold structure of argon (15.760 eV). The energy drift per 24 h period was usually no greater than 20 meV and this was taken into account in adding the data.

Most structures in EIE curves appear as narrow (high frequency) and relatively weak perturbations on an intense, broad (low frequency), and smoothly varying ionization continuum. Filtering out the intense low frequency components allows the high frequency features to be seen much more readily. This is accomplished by a specialized Fourier filtering technique (7–9) whose transmission factor for the mth frequency component is given by

$$[1] \quad T_{m,S} = 1 - \left(\cos\frac{\pi m}{N}\right)^{2S}$$

where S is a parameter controlling the amount of low frequency component that is eliminated and N is the number of channels used. For the special case of $S = 1$ and using the transmission factor $-T_{m,S}$, the result is identical to the second derivative. It has been shown qualitatively that for small values of S ($S \leq 100$) the result is similar to the second derivative but contains a larger amount of low frequency components (10). The vertically inverted filtered curves ($-T_{m,S}$) are presented in this paper in order to have direct resemblance with the second derivative.

3. Results and discussion

The raw data EIE curves of ethane and of the fragments studied in this work are presented in Figs. 1 and 2. The data points, originally taken at an interval of 20 meV per channel, are added 5 by 5 to give 100 meV per channel in order to improve the signal-to-noise ratio and allow weaker features to be detected. Very little structure of detectable intensity narrower than 300 meV could be seen in the curves, so virtually no information was lost by increasing the energy interval. The intensity of the curves of Figs. 1 and 2 increases uniformly with energy and, apart from the initial onset regions that have been analysed previously (1), they show no apparent narrow distinct features. At the vertical scale shown, the general shape of the curves of Fig. 2 differs from that of the Fig. 1 curves in that the intensity of the former increases significantly only several eV above onset. The CH_2^+ curve has an intermediary form to these two groups of curves. From Fig. 2 it is clear that the probability for producing these fragment ions and their respective reaction products with minimal internal and kinetic energy is very small. The relative peak height intensities of the ethane ions are given in Table 1 where it is seen that the most abundant ion at 35 eV is the $C_2H_4^+$ fragment.

Once the low frequency continuum of the Figs. 1 and 2 curves is removed, by using the aforementioned high pass filter, numerous structures can be seen. The filtered curves are presented in Figs. 3 to 5. The data of Fig. 3 are shown at 20 meV per channel. The energies of the indicated structures are given in Table 2. The intensities of these structures are small compared with the ionization continuum, and therefore are not apparent on the original curves. For example, structure E at 13.28 eV of the $C_2H_6^+$ curve and structure H_2 at 18.8 eV of the $C_2H_4^+$ curve have amplitudes of only 0.06% and 0.01% of their respective ionization continuum. Most of the features observed in the

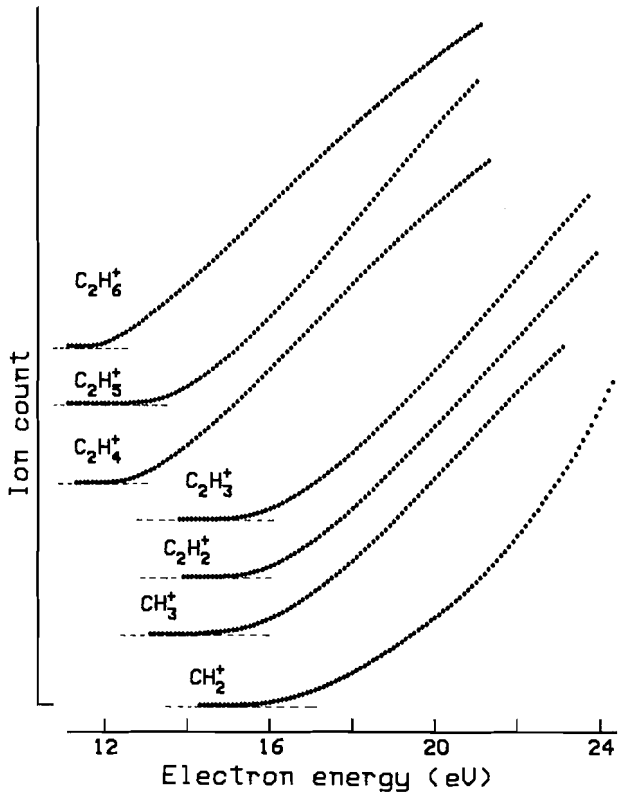

FIG. 1. EIE curves of ethane and of several fragment ions. The zero of the curves have been displaced for clearer presentation. The ion count in the last channel of each curve is given in Table 1 (100 meV per channel).

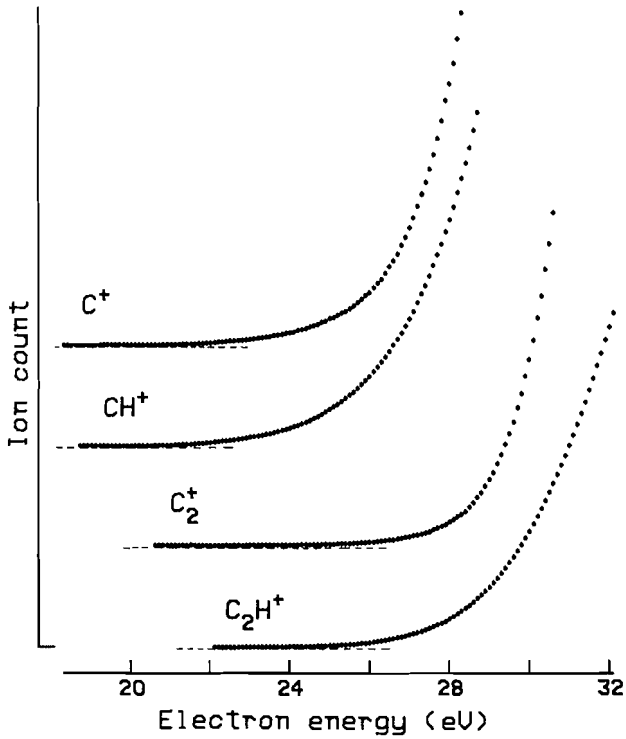

FIG. 2. EIE curves of the weaker intensity ethane fragments. As in Fig. 1.

filtered curves are reported here for the first time. Because of the complexity of the transitions involved and the lack of pertinent experimental and theoretical work on ethane, it is presently not possible to give unequivocal assignments to these features.

TABLE 1. Relative peak height intensities of the ethane ions for 35.0 eV electrons

Ion	Relative intensity	N^a
$C_2H_6^+$	46.33	2.884×10^9

CH^+	0.070	2.884×10^6
C^+	0.020	4.660×10^5

[a] N is the number of counts in the last channel of the curves of Figs. 1 and 2.

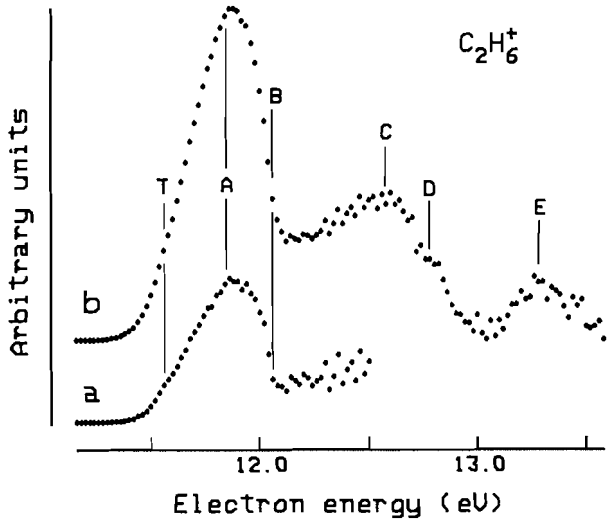

FIG. 3. $C_2H_6^+$ EIE curve high pass filtered using $S = 7$ (curve a) and $S = 30$ (curve b). Energy interval per channel = 20 meV.

However, plausible general interpretations for many of the structures are proposed below. These are summarized in Table 3.

A remarkable aspect of the Figs. 4 and 5 curves is that a number of features having similar profiles appear at the same energy in several of the curves, as listed in Table 3. It is evident that these structures cannot be attributed to states of the detected ions since such series of coincidences are essentially impossible given the great differences in the detected ions. Each set of features must have a common origin. Previous work on methane (11), acetylene (12), and ethylene (13), in which similar sets of structures are observed in the ionization and appearance curves, indicate that negative ion states (Feshbach resonances) and autoionizing states are the major processes responsible for producing these sets of structures as well as most of the features observed in EIE data.

In the present case $C_2H_6^{-*}$ is the source species resulting from the initial collision of an electron on C_2H_6. During the interaction of the electron with the target molecule, quantum transitions take place in which the number of charges is conserved. Thus, at this stage, only negative ion states are involved which correspond to continua, Feshbach resonances or shape resonances. When transitions occur new states of the

negative ion are formed which can either (directly or indirectly) autoionize, dissociate into fragments, or emit photons. The variations in cross section as a function of energy of the electrons interacting with the ethane molecules to form different states of $C_2H_6^-$* will be reflected in the ionization and various fragment ion cross sections, as seen in the curves of Figs. 4 and 5. It follows that when a structure is common to several ethane ions, it is caused by a configuration of the parent negative ion. Furthermore, the $C_2H_6^-$* cross section can be perturbed by the probability of forming excited neutral states ($C_2H_6^*$ + e^-), consequently the perturbations due to these neutral states will also manifest themselves in the ionization and ionic fragmentation cross sections.

Structures *T*, *A*, and *B* of the $C_2H_6^+$ curve (Fig. 3) have been analysed in detail and at higher resolution in the previous paper on ethane (1). The corresponding interpretations are given in Table 3. All other structures listed in Table 3 are considered to be caused by members of negative ion states series, $^2X\ nl\ n'l'$, or of Rydberg autoionizing states series, $^2X\ nl$, where *X* represents a particular $C_2H_6^+$ state, or to a mixture of these which converge to the different electronic states of the ethane ion. The ethane ground state configuration is generally accepted as being $(1a_{1g})^2(1a_{2u})^2(2a_{1g})^2(2a_{2u})^2(1e_u)^4(3a_{1g})^2(1e_g)^4$, $^1A_{1g}$ (4). The ionization energies for the ethane valence electrons, obtained by photoelectron spectroscopy (14), are

reproduced in Table 4. It is assumed in the interpretations given in Table 3, that a series limit can occur in the region starting from the adiabatic ionization energy to just above the vertical ionization energy.

The basic considerations taken into account in assigning the sets of structures listed in Table 3 were the energies of the expected series limits (ethane ion states) and the general shape of the filtered curves. Evidently, a member of a series must appear at an energy below the series limit. From the work on methane (11), members of a series may be found down to about 4 eV below the ionization limit. The interpretation of structures D, E, and C_2 is somewhat ambiguous as these could belong to series converging to either the $^2A_{1g}$ or the ^2E_u state of $C_2H_6^+$. However, since the general shape and intensities of the $C_2H_6^+$ and $C_2H_4^+$ filtered curves above and below 13.5 eV ($^2A_{1g}$ vertical ionization energy) are quite different, this suggests that the structures below 13.5 eV converge to the $^2A_{1g}$ state and not to the ^2E_u state near 15 eV. Structures between 13.5 and 15.8 eV can be confidently assigned to series converging to the ^2E_u state as this is the only energetically plausible limit in this region. Similarly, structures between 16.0 and 19.6 eV are assigned to series which have the $^2A_{2u}$ state as their limit. It is seen in the $C_2H_5^+$, $C_2H_3^+$, $C_2H_2^+$, and CH_2^+ filtered curves that starting from 19.6 eV, the slope of the curves changes and the amplitude of the structures above this energy increases, suggesting the start of a new set of series which must converge to the $^2A_{1g}$ state of the ethane ion.

The C_2H^+, C_2^+, CH^+, and C^+ filtered curves (not shown here) vary gradually with energy and show few distinct features. Little significant information can be drawn from them.

4. Other results

The electron impact works of Suzuki and Maeda (2) and Selim (3) also report structures in the ethane EIE curve and in some of the more intense fragment ion curves. Both detect features in their direct EIE curves. This indicates that the relative intensities of their structures are much larger than those observed in this study. Also, the energies of these structures are not consistent with those reported here. The direct EIE curves of Figs. 1 and 2 show no apparent structures above threshold and it is only when the intense continuum is removed that the weak intensity features are seen. Given that the signal-to-noise ratio of their curves is considerably less than that of our data, it is clear to us that their results are incompatible with ours.

The photoionization mass spectrometric study of ethane by Berkowitz (4) yields little pertinent information in the energy region considered in this work.

5. Conclusion

Numerous clear structures are observed for the first time in the EIE curves of ethane and ethane fragment ions. Several of the features occur at the same energy in these curves and are certainly caused by the common progenitor $C_2H_6^{-}$*. The structures of the Figs. 4 and 5 curves are tentatively assigned to series of negative ion states and/or to autoionizing Rydberg states. Our present knowledge of the $C_2H_6 + e^-$ system is limited. However, we trust that these new results will be helpful in stimulating further experimental and theoretical work on this system.

R. N. O'BRIEN and K. S. V. SANTHANAM. Can. J. Chem. **65**, 2009 (1987).

The electrodeposition of cupric ferrocyanide from a solution of potassium ferrocyanide with the convection-free parallel plane horizontal electrodes with the cathode over the anode was followed by multiple beam laser interferometry as well as the conventional electrochemical instrumentation. It is considered that the cupric ion generated immediately reacts with ferrocyanide ion to form a conducting adhering precipitate layer. The initial resistance of this layer is low. Its resistance is constant with thickness until about 5×10^{-8} C mm^2 has been passed probably representing $\sim 10^5$ molecular layers when the resistance begins to rise. A magnetic field of 0.47 T caused a slight decrease in the resistance of the cell probably due to slow rotation of the inhomogeneous paramagnetic solution. This coating may be useful as an electrode.

R. N. O'BRIEN et K. S. V. SANTHANAM. Can. J. Chem. **65**, 2009 (1987).

Utilisant l'interférométrie à rayons laser multiples ainsi que des méthodes instrumentales électrochimiques conventionnelles, on a étudié l'électrodéposition du ferrocyanure cuivrique à partir d'une solution de ferrocyanure de potassium, à l'aide d'électrodes parralèles, à plan horizontal et sans convection alors que la cathode est au-dessus de l'anode. On considère que l'ion cuivrique qui est généré réagit immédiatement avec l'ion ferrocyanure pour former une couche de précipité qui adhère et qui est conductrice. Jusqu'à environ 5×10^{-8} C mm^2, sa résistance est constante avec l'épaisseur; ceci représente environ 10^5 couches moléculaires avant que la résistance commence à augmenter. Un champ magnétique de 0,47 T provoque une faible diminution dans la résistance de la cellule qui est probablement due à une rotation lente de la solution paramagnétique qui n'est pas homogène. Ce revètement peut s'avérer utile comme électrode.

[Traduit par la revue]

Introduction

A previous paper (1) from our laboratories reported the growth of concentration gradients in the galvanostatic electrodeposition of Cu from a solution of $CuSO_4$ by using two copper disc electrodes (Cu anode and Cu cathode) with parallel, plane working surfaces in the usual interferometric cell arrangement. In the present work early experiments using the electrolyte $K_4Fe(CN)_6$ at vertical electrodes showed that there was a negative refractive index gradient at both electrodes, i.e. decreasing from the bulk solution to the electrode. These gradients increased from the beginning of the electrolysis till a steady state of concentration gradient was reached as convective flow at the electrodes became the limiting factor to growth. The orientation of the electrodes used in the work to avoid convection was the cathode over anode (C/A) position. We have investigated the concentration gradients that are developed using $K_4Fe(CN)_6$ as the electrolyte in the above electrode configuration. The galvanostatic electrolysis produces a reddish brown film of copper ferrocyanide on the anode, and gas on the cathode. Interestingly this anode film shows electronic conduction and changes color upon oxidation and may therefore be useful as an electrode material (2–4). We wish to report here the results of a comparative study of the two types of cells, $Cu|CuSO_4|Cu$ and $Cu|K_4Fe(CN)_6|Cu$ using multiple beam laser interferometry. These results provide insight into the growth of diffusion layers at the two anodes in the two electrolytes.

Experimental

The electrodeposition of copper ferrocyanide was carried out in a cell of 1.39 mm thick with two almost semicircular Cu electrodes, 3 cm long, cut from either side of a disc (Fig. 1) which when the area obscured by the retaining arrangements were subtracted gave a working surface of 30 mm^2. The electrodes were separated by 2.5 mm. The electrodes were cleaned in concentrated HCl for a few minutes and then washed very thoroughly with double distilled water. All sides of the Cu electrodes were coated with an insulating paint (glyptol) except the working sides (parallel to the axis of the disc) now set parallel and horizontal in the cell, leaving only the long side electroactive. The cell (Fig. 1) is similar in design to the one previously employed (1), that is the Teflon body, glass flats, electrolyte, and electrodes could be described as a thin slice of a cylinder of 6 cm outside diameter and the whole electrochemical cell is inside a Fabry-Perot type multiple beam interferometer. The electrical contact to the Cu electrodes was made through a Cu wire inserted through the Teflon holder. The other experimental arrangements consisted of a Spectra physics Model 122, He–Ne laser as light source, a R.C.A. CC030 video camera, a Hitachi VHS portable VTR model VT7A, and a 20″ Hitachi color monitor. The entire experiment has been videotaped for later observations through the viewing optics of a 35 mm Nikon camera and the 35 mm negatives (of pictures taken at desired elapsed times) were projected onto a plotting table. The interferometric cell was mounted on a brass support with three adjustable screws for adjusting the wedge-angle between the 90% reflecting glass flats.

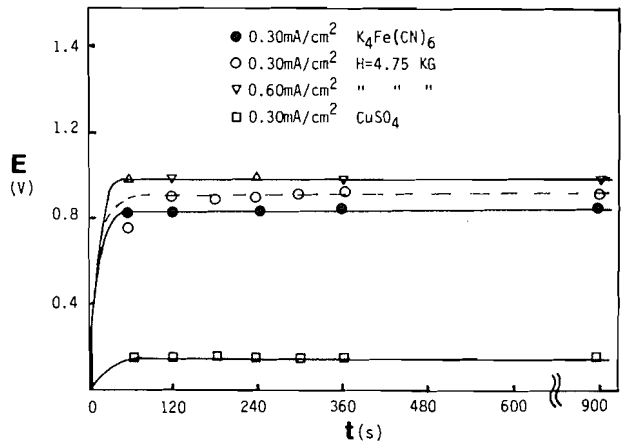

FIG. 2. The impressed voltage vs. time plot in the electrolysis of $K_4Fe(CN)_6$ and $CuSO_4$ at current densities of 0.30 mA cm^{-2} and 0.60 mA cm^{-2}. The effect of magnetic field on the above curve is also shown in the figure.

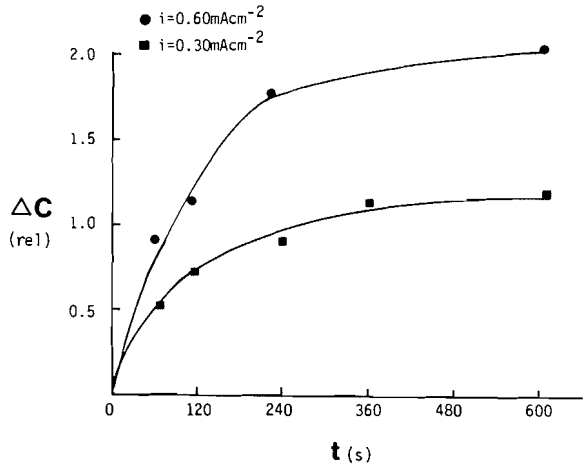

FIG. 3. The plot of ΔC_{max} as a function of the electrolysis time in the electrolysis of $K_4Fe(CN)_6$.

Results and discussion

The galvanostatic electrolysis of 0.1 *M* $K_4Fe(CN)_6$ generated a curve of impressed voltage as a function of the electrolysis duration as did 0.1 *M* $CuSO_4$ as shown in Fig. 2. Due to differences in the conductivities of $K_4Fe(CN)_6$ and $CuSO_4$, and the filming that occurs at the anode by ferrocyanide, the cell voltages in the two cases are significantly different. The other features of the *E*–*t* plots are very similar and the progress of the electrolysis in ferrocyanide was very smooth except for some gas outbursts in the electrolyte adjacent to the cathode which we believe can only be due to the evolution of H_2 gas. It is, however, possible that some ferricyanide ion, if any were present, was also reduced. The effect of current density upon the impressed voltage is also shown in Fig. 2. In $CuSO_4$ electrolysis copper is transferred across the cell by the essentially equivalent dissolution of the Cu anode and the deposition of Cu at the cathode. No difference in electrode efficiencies were detected interferometrically. In the contrasting situation, the electrolysis of $K_4Fe(CN)_6$ results in the deposition of Cu ferrocyanide[1] on the anode and at the cathode evolution of H_2 though as previously mentioned, possibly some reduction to ferrocyanide

[1]A saturated solution of cupric ferrocyanide in water contains 1.0×10^{-5} g-ions of Cu^{2+} per liter (5).

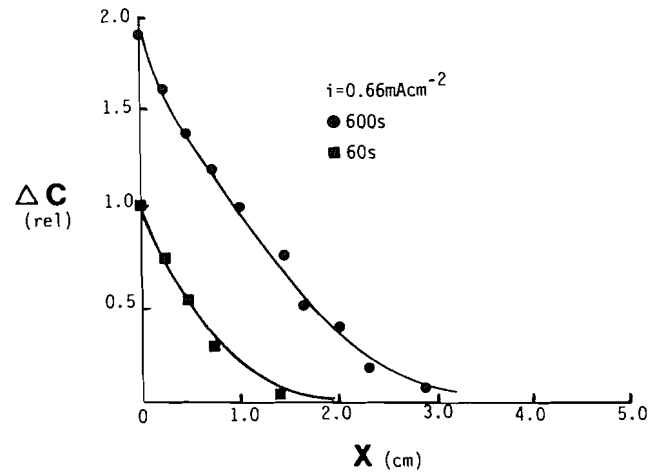

FIG. 4. The concentration–distance profile during the electrolysis of $K_4Fe(CN)_4$ at Cu anode and Cu cathode the X-axis is increased to 50 times the real value.

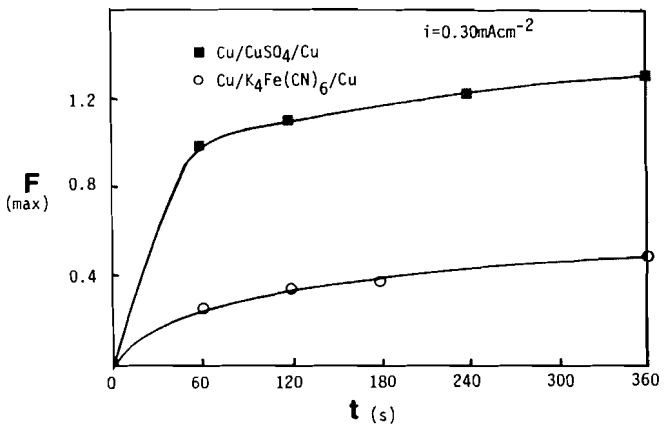

FIG. 5. The fringe shift during the progress of the electrolysis of $CuSO_4$ and $K_4Fe(CN)_6$ at identical current density of 0.30 mA cm^{-2}.

ion. Figure 3 shows the development of the fringe bend (a refractive index increase denoting a concentration change of one or more components) at the Cu anode due to the deposition of the film. The most likely changes in concentration of the solution components to cause this change in refractive index are considered below after introduction of other relevant data. The progressive movement of the fringes during the electrolysis has been followed for over 900 s. Considering the plot of this maximum concentration change (at the anode–electrolyte interface), ΔC_{rel}, vs. elapsed duration of electrolysis, the shape and smoothness of the curves is evidence for the absence of any convection of a magnitude which need be considered during this part of the electrolysis. Figure 4 shows the plot of the concentration profiles at 60 and 600 s (an apparently unlimited growth of the refractive index profile) indicative of diffusion (and the absence of convection) as the dominant transport mode (6, 7). While the above results are similar to those with $CuSO_4$ between the same two electrode materials (1), there were some significant deviations noted relating to the fringe shift or concentration polarization. The calculated fringe shift (*F*) during the electrolysis at the anode is much higher with $K_4Fe(CN)_6$ for an identical current density. In the plot of *F* vs. *t* (Fig. 5) during the electrolysis of $CuSO_4$ and $K_4Fe(CN)_6$; the difference is very obvious between the two electrolytes (see also Fig. 3) and also from the calculated values. The *F* values in

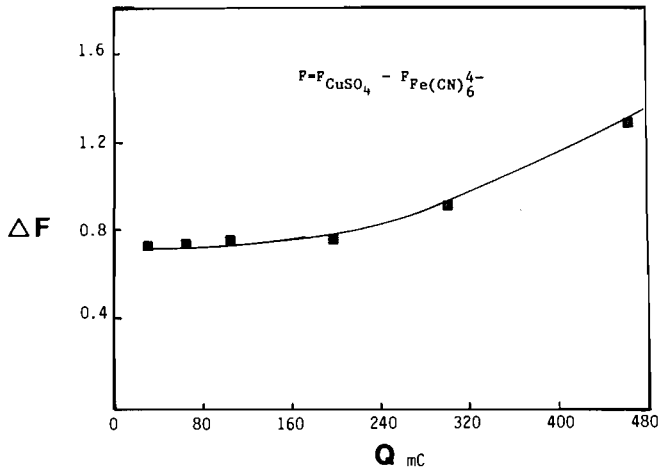

FIG. 6. A plot of fringe shift differences in the electrolysis of $CuSO_4$ and $K_4Fe(CN)_6$ as a function of the charge passed.

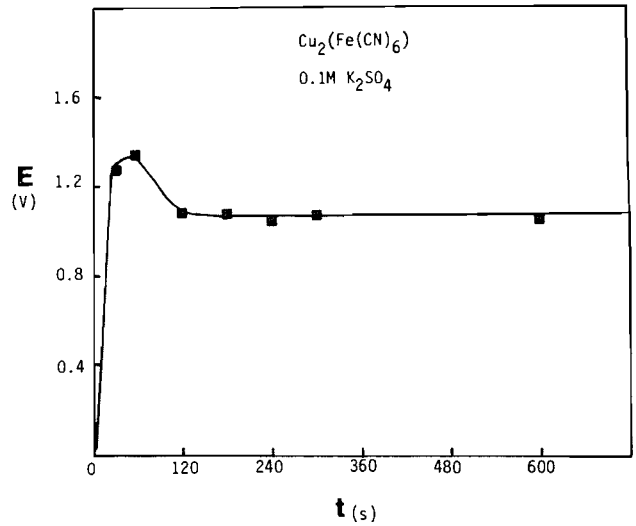

FIG. 7. The impressed voltage vs. time curve in the electrolysis of 0.1 M K_2SO_4 between Cu ferrocyanide anode and Cu cathode.

$K_4Fe(CN)_6$ are always smaller, presumably because four K^+ are in excess as $Fe(CN)_6^{4-}$ is precipitated as $(Cu^{2+})_4[FeCN_6^{4-}]_2$ and a suitable anion such as OH^- diffuses in to maintain electrical neutrality. This KOH has a much lower refractive index in solution than $K_4Fe(CN)_6$. If the difference in fringe shifts ($F_{CuSO_4} - F_{K_4Fe(CN)_6}$) is plotted as a function of the coulombs passed in the electrolysis (Fig. 6), we observe a constancy up to about 200 mC or about 60 $\mu C\ mm^{-2}$ or thicknesses in the range of 10^5 molecular layers. Then a divergence from linearity begins, ΔF rising with a slope of about two fringe shifts per coulomb. Since the oxidation of $Fe(CN)_6^{4-}$ cannot occur at the Cu anode ($E_{Cu_2^{2+}/Cu} = 0.02$ V (in the presence of $Fe(CN)_6^{4-}$) and $E_{Fe(CN)_6^{3-}|Fe(CN)_6^{4-}} = 0.27$ V (5, 7) at the roughly calculated concentrations using the relevant equilibria) the initial reaction can therefore be attributed to the dissolution of the Cu anode. The Cu^{2+} reacts with $Fe(CN)_6^{4-}$ forming a mixed complex (8) via a reaction $4Cu^{2+} + 2Fe(CN)_6^{4-} \rightarrow Cu_4^{2+}[Fe(CN)_6^{4-}]_2$ with perhaps (but unlikely) intermediate formation of $K_2Cu[Fe(CN)_6]$. There may be some incorporation of Cu^+ since the red-brown color of the deposit on the anode is different from the red-brown colour of cupric ferrocyanide or it may reflect the electrochemical mode of formation with the necessary attendant imperfections of a semi-conductor. This deposition results in slowing down the rate of Cu^{2+} escaping to the surface at long times (as the film thickens) but as may be seen from Fig. 5, this film is conducting and the anodic process proceeds. We attribute the anodic fringe shift (where fringe shift is the deviation from the straight fringe condition in the bulk usually measured in fringe separation or fringes for more than one fringe separation distance) observed to the depletion of $Fe(CN)_6^{4-}$ near this electrode. The refractive index (n) measurements on $K_4Fe(CN)_6$ solutions of different concentrations in an Abbé refractometer give a plot of Δn vs. C, and from this a fringe shift is calculated to correspond to $6.7 \times 10^{-3}\ M$ which is greater than for $CuSO_4$ under the same circumstances, or during the electrolysis the refractive index in the anode region should decrease. The possibility of Cu^{2+} escaping into the solution and being involved in an increased fringe shift difference has been considered but was ruled out because of the extremely low solubility of the ferrocyanide product.

Experiments conducted using a mixture of 0.1 M $K_4Fe(CN)_6$ and 0.1 M $K_3Fe(CN)_6$ instead of 0.1 M $K_4Fe(CN)_6$ alone, produce a difference in the cathodic reaction; the H_2 evolution does not occur, otherwise the other results were identical to the simple $K_4Fe(CN)_6$ electrolyte.

Effect of magnetic field

The magnetic field effect was mainly investigated on this system to improve the smoothness of the deposition. The cell was inserted into the cavity of a strong (up to 1.0 T) electromagnet. The laser was removed to 1.2 m to avoid magnetic effects on the plasma. Care was taken to have no Fe or Fe alloys in the field. The impresed voltage vs. time curve in the field deviates from the zero field result in a way shown in Fig. 2. The higher impressed voltages in the field have been attributed to the increased resistances offered by the cell for the same current density as a result of uniform deposition of the Cu ferrocyanide. A more uniform film would be expected to have smaller pores and no pinholes and a generally decreased surface area. With vertical electrodes the magnetic field acts on the hydrodynamic flow and the velocity of the fluid flow increases with increasing magnetic field (1, 9). In the present series of experiments a magnetic field of about 0.5 T has been applied externally. The effect observed was actually a smoother film. This result is similar to that obtained with polycarbazole deposition in a magnetic field (10). Another and expected observation was that the concentration gradients were much more extended at zero field than in the magnetic field; for example at 60 s of electrolysis the diffusion layer extended up to 0.16 mm at B = 0.475 T and up to 0.20 mm at zero field. These results are very similar to those obtained in a 0.1 M $CuSO_4$ solution where the mild convective effects were attributed to differences in the paramagnetism of two concentrations of Cu^{2+} (a $3d^9$ ion) in a strong field (11) causing slow rotation of the electrolyte, which limits the diffusion layer.

Finally, the suitability of electrodeposited Cu ferrocyanide as an electrode was briefly examined by using the filmed electrode as the anode in the electrolysis of 0.1 M K_2SO_4 along with a Cu cathode. This cell was used with current densities ranging from 0.12 mA cm^{-2} to 0.60 mA cm^{-2} and the interference fringes patterns were recorded. Fringe shifts (F_{max}) of 1.1 and 1.4 were noted at 240 s and 360 s in the electrolysis at a current density of 0.12 mA cm^{-2} at the filmed electrode confirming that it is a conducting electrode. The impressed voltage–time curve during this electrolysis is shown in Fig. 7. In view of the

reported use of $Cu_2Fe(CN)_6$ precipitated into porous pottery in the older chemistry books, e.g., Latimer and Hildebrand (12), to make semi-permeable membranes this material should probably be studied further as an electrode coating.

Unusual spectral shifts in the prototropic reactions of 2,7-diaminofluorene

R. MANOHARAN AND SNEH K. DOGRA[1]

Department of Chemistry, Indian Institute of Technology, Kanpur-208016, India

Received July 7, 1986[2]

R. MANOHARAN and SNEH K. DOGRA. Can. J. Chem. **65**, 2013 (1987).

The red shift observed in the absorption spectrum of 2,7-diaminofluorene (DAF) in ether and acetonitrile is either due to the proton-donating capacity of the solute or due to its dispersive interactions with the solvent and a blue shift in methanol and water is due to the proton-accepting nature of DAF. DAF acts as a proton donor in S_1 state in all solvents. The red shift in the fluorescence spectrum of the monocation of DAF relative to that of DAF is not because of the —NH_2 group becoming more basic but because of the large solvent relaxating in aqueous medium. On the other hand, the monocation of DAF in cyclohexane follows the normal blue shift in the fluorescence spectrum. pK_a values for the various prototropic reactions in S_0 and S_1 states are determined and discussed.

R. MANOHARAN et SNEH K. DOGRA. Can. J. Chem. **65**, 2013 (1987).

Lorsqu'on détermine les spectres d'absorption du diamino-2,7 fluorène (DAF) dans l'éther et dans l'acétonitrile, on observe un déplacement vers le rouge; ce résultat est dû soit à la capacité du soluté à donner des protons ou aux interactions dispersives du solvant. Par ailleurs, on observe un déplacement vers le bleu lorsque les spectres sont déterminés dans le méthanol et dans l'eau; ces résultats sont dus à la nature du DAF qui a tendance à accepter des protons. Dans tous les solvants, le DAF agit comme donneur de proton dans l'état S_1. Si on compare le spectre de fluorescence du monocation du DAF avec celui du DAF, on observe un déplacement vers le rouge qui n'est pas dû au fait que le groupement —NH_2 devient plus basique mais plutôt à la relaxation importante du solvant dans le milieu aqueux. Par ailleurs, le spectre de fluorescence du monocation du DAF dans le cyclohexane subit le déplacement normal vers le bleu. On a déterminé et on discute des valeurs de pK_a pour diverses réactions prototropiques dans les états S_0 et S_1.

During electronic transitions, the charge density changes at each atom of the molecule. Depending upon the nature of the transition as well as the nature of the molecule itself, the molecule may become less polar or more polar in the excited state as compared to the ground state. Due to this, the solvent molecules rearrange themselves in the S_1 state, which is different from the ground state. Since the rearrangement of the solvent molecules involves bond breaking or bond formation, the time taken for this phenomenon can be compared with the period of vibrational motion and this is much smaller than the fluorescence lifetime. In other words, the fluorescence always occurs from the thermally equilibrated excited state even though the molecule, to begin with, is in the Franck–Condon state. The equilibrated state is of lower energy than the Franck–Condon state provided the polarity of the molecule changes (increases or decreases) and the solvent is polar (1, 2). Sometimes the stabilisation of the states, called solvent relaxation, is so large that either reversal of states takes place or large Stokes' shifts are observed. For example, if a $\pi \rightarrow \pi^*$ state is the lowest energy transition, a pyridinic-like nitrogen atom becomes more basic upon excitation and protonation in general will lead to red shift in the absorption and fluorescence spectra (3). The absorption spectrum of *O*-phenanthroline (4), which contains two nitrogen atoms at positions 9, 10 is red-shifted upon protonation of both the nitrogen atoms. However, the fluorescence spectrum behaves differently under the above conditions, i.e. a large red shift is observed in the fluorescence spectrum of the neutral molecule on protonation, but upon the second protonation a blue shift is observed. Schulman *et al.* (4) showed that this abnormal spectral shift in the fluorescence spectrum of the monocation is due to a large solvent relaxation in aqueous medium whereas the normal red shift is observed when the fluorescence spectrum of the monocation is taken in hydrocarbon as a solvent.

In the fluorene molecule, electrophilic attack can take place at position 2. If the electron-donating groups are present at positions 2 and 7, the spectral behaviour can be abnormal on protonation. The present study of 2,7-diaminofluorene (DAF) was carried out with the above aim in mind. The absorption and fluorescence spectra are recorded at different pH and in different solvents. The pK_a values have been calculated for the following prototropic reactions both in the ground and excited states.

[1] $DAF \rightleftharpoons DAF^- + H^+$

[2] $DAFH^+ \rightleftharpoons DAF + H^+$

[3] $DAFH_2^{2+} \rightleftharpoons DAFH^+ + H^+$

Experimental

2,7-Diaminofluorene (DAF) was obtained from Aldrich Chemical Co. and recrystallised from benzene. The purity of the compound was checked by noting its melting point, electronic spectrum, and similar fluorescence spectra when excited with different wavelengths. Spectrograde methanol (BDH), analytical grade sulphuric acid, sodium hydroxide, and trifluoroacetic acid (TFA) were used as such. Cyclohexane, ether, and acetonitrile were further purified according to a procedure suggested in the literature (5). Triply distilled water was used for aqueous solutions. Solutions in the pH range of 3 to 10 were prepared by adding appropriate amounts of NaOH and H_3PO_4. A modified Hammett's acidity scale (6) for the H_2SO_4–H_2O mixtures and Yagil's basicity scale (7) for NaOH–H_2O mixtures were used below pH 1 and above pH 13, respectively. Hammett's acidity function (H_0) serves specifically as a measure of the tendency for the solution in question to transfer a proton to an uncharged or charged base molecule, increasingly negative values corresponding to higher acidity.

Absorption spectra were recorded on a Shimadzu 190 UV spectrophotometer, equipped with a U 135 recorder. Fluorescence measurements were carried out on a recording spectrofluorimeter, fabricated in our laboratory and the details are available elsewhere (8). Both monochromators were calibrated from time to time using a low pressure mercury lamp. The excitation source bandwidth was 8 nm. The fluorescence spectra were corrected according to the procedure suggested by Parker (9). The quantum yields were calculated, using quinine sulphate in 0.1 *N* H_2SO_4 as a standard (10) and the wavelength

[a]ϵ is in cubic decimeters per mole per centimeter. s is shoulder.

used for excitation was 313 nm. The concentrations used were in the range of 1.5×10^{-5} *M*. The solutions for absorptiometric and fluorometric titrations were prepared just before taking measurements. The isosbestic wavelengths were used for measuring the fluorescence intensities at any analytical wavelength. The values for dication–monocation, monocation–neutral, and neutral–monoanion couples are 270 nm, 324 nm, and 345 nm, respectively. The pH of the solutions in the range 1–13 were measured on a Toshniwal pH meter, model CL 44A.

Results and Discussion

Effect of solvents

The absorption and fluorescence spectra of DAF were observed in different solvents and the relevant data are compiled in Table 1. The absorption data are depicted in Fig. 1 and the fluorescence data in Fig. 2. When compared to fluorene (11), the absorption maxima of all DAF bands are largely red-shifted in any one solvent. The structures of the ~300 nm and ~200 nm bands of the fluorene molecule are completely destroyed whereas the structure of the middle band (~264 nm) is not affected that much in less polar solvents. All these band maxima are red-shifted (300 to 340 nm, 264 to 290 nm, and 200 to

215 nm) in any one particular solvent. The structure of the middle band is also lost in more polar solvents. The absorption spectrum is red-shifted from cyclohexane to acetonitrile, a more polar solvent and blue-shifted in methanol and water. On the other hand, the fluorescence spectrum is a large red-shifted broad band as compared to the structured fluorescence spectrum of fluorene (11). The fluorescence maximum is regularly red-shifted as the polarity and proton-donor capacity of the solvent increases. Under similar environments the fluorescence quantum yield remains nearly constant except in water, at pH 8.

The structure of the fluorene molecule can be compared with

For personal use only.

O-, O'-condensed biphenyl system (12) and its transitions can be compared with those present in the benzene molecule, although this kind of notation is not applicable to the biphenyl system. Thus, the 300, 260 and 220 nm band systems of fluorene can be assigned to the $^1A_g \rightarrow {}^1L_b$, $^1A_g \rightarrow {}^1L_a$, and $^1A_g \rightarrow {}^1B_b$ transitions, respectively (12). The first and the third transitions are thus long-axis polarised and the second one is short-axis polarised. Since both the amino groups are present on the long axis of fluorene, the interaction is maximum with the ring and the first and the third band will be affected more than the second one. Thus the structure of the long wavelength band of fluorene is completely lost. Though the bathochromic shift is observed in the ~260 nm band system of fluorene, the structure in non-polar solvents is observed. The loss in the structure in more polar solvents is due to the stronger interaction of the solute and solvent molecules. The spectral shifts observed in the absorption spectrum of DAF in more polar or hydrogen bonding solvents are consistent with the characteristic behaviour of amino (13) or hydroxyl groups (14), i.e. it acts as a proton donor to the proton-acceptor solvents but preferably as a proton acceptor if the solvent possesses both proton-donor and proton-acceptor properties in the S_0 state. Ether is acting as a proton acceptor and acetonitrile a dispersive, whereas methanol and water are proton-donor solvents. In the excited singlet state, since the charge migration increases from the $—NH_2$ group to the ring, it will reduce the charge density at the nitrogen atom and thus behave as a proton-donor group. This is further manifested from the increased acidity of the $—NH_2$ group on excitation (*vide infra*). The Stokes shift $[\bar{\nu}_{abs}(max) - \bar{\nu}_{flu}(max)]$ increases with increase in the polarity or hydrogen bonding ability of the solvents, indicating that dipole moment of the molecule increases upon excitation. The decrease in the fluorescence quantum yield of the neutral DAF in water suggests the stronger interactions with water, thereby increasing the rate of radiationless processes.

Effect of pH

The absorption and fluorescence spectra of DAF have been studied in the H_0/pH/H_- range of −10 to 16. The relevant data are compiled in Table 1. Absorption data are shown in Fig. 3 and fluorescence data in Fig. 4. The changes observed in the absorption spectrum of DAF are consistent with the decrease of pH. The absorption spectrum of DAF is blue-shifted around pH 5, indicating the formation of monocation by protonating one of the amino groups and the long wavelength absorption band of this species resembles that of 2-aminofluorene (15). A further blue shift is observed at H_0 −4, suggesting the formation of dication by protonating the second amino group also. This is further confirmed by the resemblance of the absorption spectrum of the latter species to that of fluorene (11), i.e. the band structure of the ~300 nm band system is clearly visible. No further change in absorption spectrum is noticed even at H_0 −10. After pH 12, the maxima of the 329 and 207 nm bands start red shifting and the shift is not complete even at H_- 16; the most strongly basic solution used. The middle band is not much affected until H_- 15 and its intensity is reduced drastically at H_- 16, becoming a flat band, without any change in band maximum. The first change is due to the formation of monoanion, obtained by the deprotonation of one of the $—NH_2$ groups. This is further confirmed by the fact that the major changes in the absorption spectrum are only produced in the long axis polarised bands. The pK_a value for this proton transfer reaction could not be calculated because of the reason

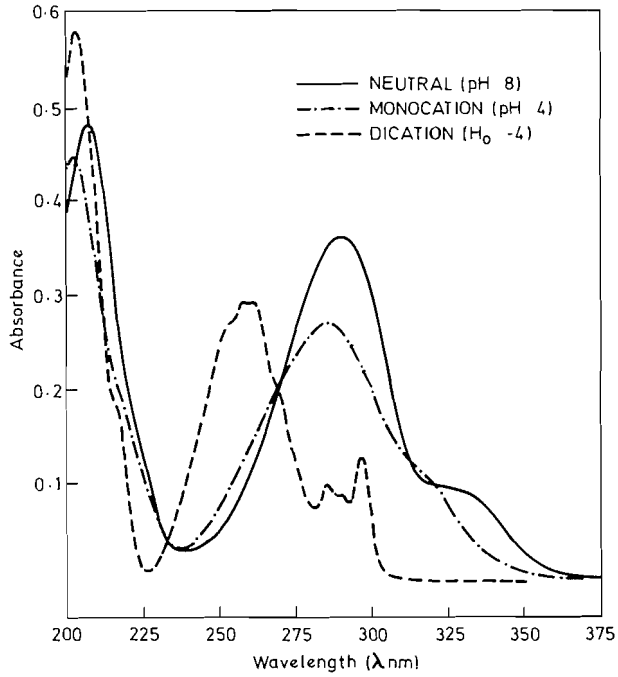

FIG. 3. Absorption spectra of different prototropic species of DAF at 298 K: —, neutral (pH 6.7); ·····, monocation (pH 4); ---, dication (H_0 −4).

mentioned above, but its value will be certainly lower than the pK_a value for other aromatic amines (>16 (13)). This can be explained on the same lines as will be done to explain the high value of pK_a [2].

The effect of pH on the fluorescence spectrum is very different from that of pH on the absorption spectrum. The behaviour of DAF at pH 12 in the excited state is in agreement with the earlier results on similar groups, in the sense that the monoanion formed by the deprotonation of $—NH_2$ group is generally non-fluorescent (16) with few exceptions (17). The pK_a^* calculated from fluorimetric titration curves is 13.9. This is in the same range as the observed pK_a^*'s for other aromatic amines, indicating that the $—NH_2$ group becomes strongly acidic on excitation (16).

The fluorescence characteristics of the cationic species of DAF, with the decrease of pH are different from the absorption characteristics. DAF is weakly fluorescent (395 nm) in basic and nearly neutral solution. In the region near pH 5, the intensity of the weak 395 nm fluorescent band decreases with the decrease of pH while the intensity of the slightly red-shifted (410 nm) fluorescent band increases. The excitation spectra monitored at both wavelengths resemble exactly the absorption spectra of the two species formed in the S_0 state. The intensity of the 410 nm band decreases to nearly 10% of its maximum value at pH 0.5, when a very large blue-shifted, structured fluorescent band (310 nm, 300 nm) starts appearing. The blue-shifted band attains its maximum intensity by H_0 −4. The intensity of the ~310 nm band starts decreasing on increasing the acid concentration without the appearance of any other new fluorescent band and at highest H_0 value, it is 5% of its maximum intensity (I_0). This fluorescence spectrum exactly resembles that of the parent fluorene molecule. The excitation spectrum monitored at the 310 nm band resembles the absorption spectrum of the ground state species as well as that of the fluorene molecule. The excitation spectra, recorded at pH 5, H_0 −1 and below H_0 −1 resemble the absorption spectra of the

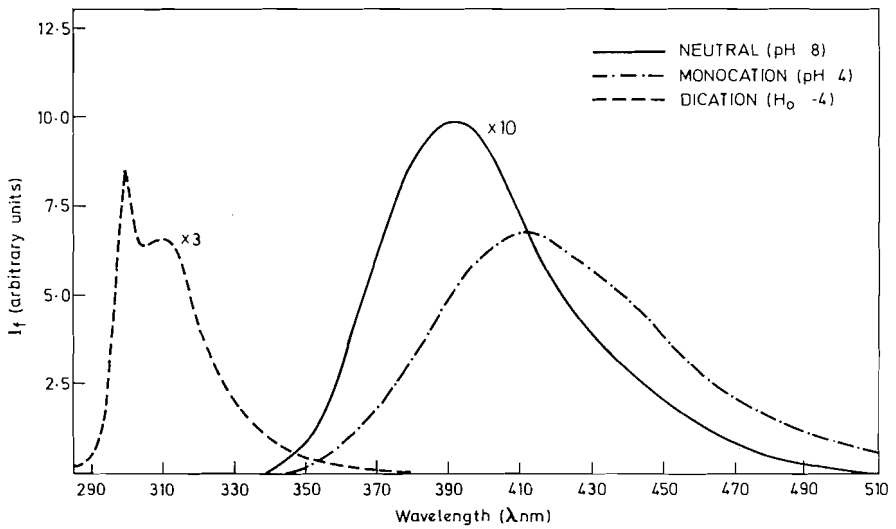

FIG. 4. Fluorescence spectra of different prototropic species of DAF at 298 K: —, neutral; ·····, monocation (pH 4); ---, dication (H_0 −4).

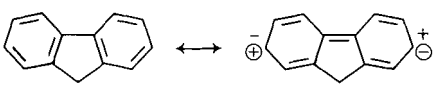
species present in the ground state at these acid concentrations. Thus the species present in the excited singlet state at these conditions are neutral, monocation, and dication, respectively.

As previously mentioned the lowest energy transition in DAF is a $\pi \rightarrow \pi^*$ transition which is long-axis polarised. Since the trend observed in the absorption spectra on addition of protons is similar to that observed in other amines (16), it suggests that the nature of the lowest energy state in these ions remains the same. The mirror image relationship observed between the absorption and fluorescence spectra of the neutral and dication species clearly indicate that fluorescence in these species is taking place from the state polarised along the longer axis. Though the mirror image relationship is not observed in the case of the monocation, it can be concluded that the emitting state is still the same as that observed in other species. This is because the difference between the absorption maxima of the two bands in neutral and monocation remains the same and thus the reverse cannot take place. Also, the proximity of the excitation and fluorescence bands infers that they both arise from the long-axis polarised band.

The ground state pK_a values for the monocation–neutral and dication–monocation equilibria, calculated spectrophotometrically, are 5.8 and 3.6, respectively. These values are listed in Table 2. The pK_a values reported in the literature (18) for the corresponding equilibria are 4.96 and 3.6, respectively. Since the latter values are obtained in 70% ethanol/water (v/v) solutions, these values cannot be compared with our values, which are determined in water. Similarly the pK_a values for these equilibria in the S_1 state are determined from fluorimetric titrations, as well as with the help of the Förster cycle method (17), using absorption, fluorescence, and the average of the absorption and fluorescence maxima. The data are compiled in Table 2. The pK_a [2] value is higher than observed for the aromatic amine protonation reaction (~4.5, ref. 14) and pK_a [3] is lower than ~4.5. This clearly suggests that the charge density at one of the amino group is higher than what is normally present in a monoaromatic amine. This can be explained from the following canonical structure of the fluorene molecule, i.e., it is well known that electrophilic attack in the case of fluorene takes place at position 2, followed by attack at position 7 (1). If the electron-donating group is present at position 7, the charge density at position 2 will increase further. The average charge density at the $—NH_2$ groups will be the same, because of the symmetric nature of DAF. But at any particular instant, one of the $—NH_2$ groups will be a little more basic than the other. This will lead to an increase in the pK_a [2] value for this equilibrium. The opposite is true for the behaviour of the other amino group and the pK_a [3] will be lower than the normal amino group protonation.



The agreement between the pK_a^* values obtained by various methods is not very good. The value of equilibrium constant for the monocation–neutral equilibrium obtained with the help of fluorimetric titration method has only given the ground-state value. This could be due either to the short lifetimes of the conjugate acid–base pair or the concentration of hydrogen ions are so small that the rate of protonation or deprotonation cannot compete with the rate of emission. The difference between the pK_a^* values for reactions [2] and [3], calculated by the Förster cycle method and using the absorption and fluorescence data, is due to very different solvent relaxation of the various species in these equilibria. The Stokes shift observed for neutral, monocation, and dication in water, i.e., 5120, 7100, 340 cm^{-1}, respectively, further proves the point.

The Förster cycle method, using the fluorescence data, has clearly indicated that the amino group become more basic on excitation, which is completely opposite to the normal behaviour of the aromatic amines. As stated earlier, it is due to the very large solvent relaxation of DAF^+ as compared to that observed for neutral or dication species in water. This can be tested if one records the spectral changes of these three species in a non-polar and non-hydrogen bonding medium. An example is cyclohexane, because in this medium the solvent relaxation effects of three species derived from DAF are expected to be very small compared to those in aqueous or acidic medium. Table 3 depicts the absorption and fluorescence spectrum of neutral DAF, monocation, and dication of DAF. The latter two species were obtained by the addition of different amount of TFA in cyclohexane. The absorption spectra of the ionic species matched with those species derived by the addition of sulphuric acid in aqueous medium but the fluorescence spectra were

different under the similar environments. The results obtained in fluorescence were similar to the normal behaviour of the aromatic amines, thereby confirming the above explanation i.e. a blue shift (324 nm) is observed in the fluorescence spectrum of DAF. The greater polarity of the monocation can also be noted from the Stokes' shifts observed in non-polar and polar media. For example, in cyclohexane, the Stokes' shifts of the neutral, monocationic, and dicationic species are 2670, 1920, and 770 cm^{-1}, respectively, whereas in water are 5120, 7100, and 340 cm^{-1}, respectively. The large discrepancy between the Stokes' shifts for DAF^+ in cyclohexane and water must be due to solvent relaxation because the change in solvent cannot change the vibrational relaxation or a change in the energy of the excited state by such a large amount. Further, the large Stokes' shift of DAF^+ in water suggests that this species is stabilised in the excited state much more than in the ground state relative to the species with which it is in prototropic equilibrium. Thus, as suggested by Schulman *et al.* (4), the Förster cycle method, using the average of the absorption and fluorescence maxima, will not be useful in these equilibria.

Fluorimetric titrations between dication–monocation indicate that there is no correspondence between the decrease in fluorescence intensity of the monocation and the increase in fluorescence intensity of the dication. This is similar to the normal behaviour observed for the protonation reaction of aromatic amine, i.e., proton-induced fluorescence quenching of the base is observed before it is being protonated (14, 18). In these cases the pK_a^* value is calculated from the formation curve of the dication, rather than from the decrease in intensity of the monocation and the pK_a^*(3) value is −3.0. The agreement between this value and that obtained by the Förster cycle method with absorption data is quite reasonable. The

TABLE 3. Absorption and fluorescence maxima of DAF in the presence of TFA

	285	305
	260	

difference may be due to the structured absorption spectrum of dication and the broad band of the monocation. The pK_a^* value obtained using fluorescence maxima cannot be compared with other values due to reasons mentioned earlier. Anyway, the pK_a^*(3) values so obtained do indicate that ammonium ions become more acidic in the excited singlet state.

The proton-induced fluorescence quenching mechanism can be compared with that proposed by Shizuka *et al.* (19) and can be described by the simple Stern–Volmer equation

$$\frac{I_0}{I} = 1 + k_q\tau[H^+]$$

where I and I_0 are the fluorescence intensities of monocation with and without the presence of $[H^+]$, k_q is the proton-induced fluorescence quenching constant, and τ is the lifetime of the

For personal use only.

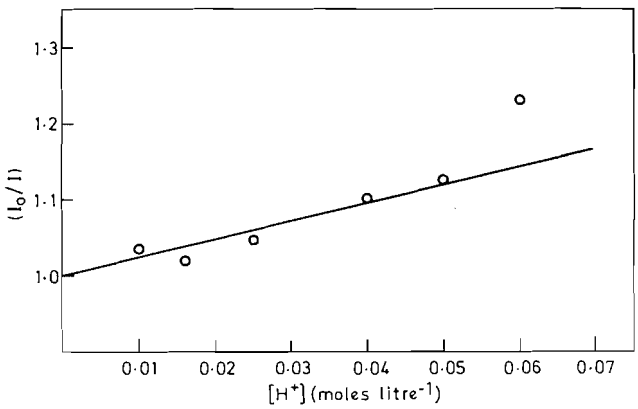

FIG. 6. Plot of I_0/I versus $[H^+]$.

monocation. $k_q\tau$ is calculated from Fig. 6 and is 2.4 dm^3 mol^{-1}. The natural lifetime (τ_{FM}) is calculated by using Strickler-Berg's equation (20), whereas τ is obtained from the relation $\tau = \tau_{FM}\phi_f$. The error involved in the calculation of τ_{FM} is large because the long wavelength absorption band of DAF^+ is not well resolved. This band has been created assuming that the distribution is Gaussian. This assumption is based on the fact that the other absorption bands are Gaussian. The value of k_q thus obtained is 4×10^8 dm^3 mol^{-1} s^{-1} and is less than the value of k_q generally observed for neutral amines (15, 19). This is due to the positive charge already existed on the molecule.

Conclusion

The above study has clearly indicated that the red shift in the fluorescence spectrum of the monocation as compared to the neutral DAF is due to the large solvent relaxation in its excited singlet state. Thus the fluorescence data cannot be used to calculate the pK_a^* values for both prototropic equilibria using the Förster cycle method.

ortho Iodophenoxy crotonates **3***e*–**7***e* cyclize to dihydrobenzo[*b*]furans **1** and **9**–**12** when subjected to lithium–iodine exchange at −100°C. Naphtho[2,1-*b*]furan **13** can be similarly obtained from α-iodonaphthoxy crotonate **8***e*. Methylation of this reaction mixture *in situ* provides a single diastereomer **14**; its relative configuration is assigned by ^{1}H nuclear magnetic resonance, and its formation rationalized by steric arguments. Diastereoselective deuteration is also observed in this case.

GAMINI WEERATUNGA, ALINA JAWORSKA-SOBIESIAK, STEPHEN HORNE et RUSSELL RODRIGO. Can. J. Chem. **65**, 2019 (1987).

Lorsqu'on soumet les crotonates d'*ortho*-iodophénoxyles (**3***e*–**7***e*) à un échange lithium–iode, à 100°C, ils se cyclisent en dihydro benzo[*b*]furannes (**1**, **9**–**12**). De la même manière, le crotonate d'α-iodonaphthoxyle (**8***e*) conduit au naphto[2,1-*b*]furanne (**13**). La méthylation *in situ* de ce mélange réactionnel ne conduit qu'à un seul diastéréoisomère, le composé **14**; on a attribué sa configuration relative en se basant sur son spectre de résonance magnétique nucléaire du ^{1}H et on a rationalisé sa formation en se basant sur des arguments stériques. Dans ce cas, on observe aussi une deutération diastéréosélective.

A current project in natural product synthesis in our laboratory required an efficient method for the preparation of a 4-methyl-7-methoxybenzo[*b*]furan (or the 2,3-dihydro derivative thereof) substituted at C-3 by a functionalized one- or two-carbon unit (e.g. **1** or **2**). Versatile syntheses of such compounds (for a recent review see ref. 1) from easily available starting materials are not commonplace but the subject has attracted some recent attention, and methods of forming the 3–3a bond through anionic (2, 3) or radical (4) intermediates have been employed. Processes involving 1–2 bond formation (5) (from phenols) and the more traditional 2–3 bond formation (6) from phenoxyacetic acids have also been reported. Nevertheless the problem at hand still resisted a satisfactory solution, although a small amount of **2** was prepared by the Bradsher–Parham (3) epoxide cyclialkylation procedure. The main drawback of this synthesis, in our hands, was the sluggish epoxidation of the *O*-allyl phenol, the precursor of the desired epoxide.

In seeking a solution to the problem we attempted to combine the economy of Parham's cyclialkylation with the *ortho*-directing potential of the phenolic hydroxyl group. Thus, after the methoxymethyl ether (**3***b*) of the phenol (**3***a*) was used to effect (7) *ortho*-iodination, an intramolecular 5-*exo*-*trig* Michael addition triggered by lithium–iodine exchange in a subsequent intermediate (**3***e*) was envisaged as depicted. Although the exchange reaction might be very fast, the cyclization still has many obvious pitfalls, the acidity of the γ-hydrogen atoms of the ester for one; we were encouraged to explore it, however, by the recent report of a similar cyclialkylation with some vinyl sulfones (8). We now report the successful realization of these plans, and the development of an efficient, general synthesis of 3-substituted dihydrobenzofurans (e.g. **1** and **9**–**13**).

In these six examples the disposition of the substituents in the benzenoid moiety is controlled by the iodination step. Considerable flexibility is available and can be exercised by judicious choice of starting materials. Phenols **3***a*–**7***a* are converted into their methoxymethyl ethers (**3***b*–**7***b*) in the usual manner (NaH, $ClCH_2OMe$, DMF), deprotonated (7) (*n*-BuLi, ether, O°C), quenched with five equivalents of iodine in dry tetrahydrofuran, and the resultant iodo compounds **3***c*–**7***c* treated with aqueous methanolic hydrochloric acid. The iodophenols **3***d*–**7***d* were produced in overall yields ranging from 50% (**4***d*) to 63% (**7***d*) by this three-step sequence. We note that the iodination sequence with **5***a* produces a contiguously substituted iodophenol (**5***d*) whereas with **6***a* a 1,2,4,5 substitution pattern results (9), a consequence, probably, of differing steric constraints and acidities of the protons in the two benzenoid ring systems. The availability of *ortho* iodophenols from other sources (10) will shorten the synthesis and this is demonstrated here by the direct iodination of 2-naphthol (**8***a*) to provide **8***d* in 90% yield.

Iodophenols **3***d*–**8***d* are then alkylated with ethyl γ-bromocrotonate (acetone – potassium carbonate) and the crotonates **3***e*–**8***e* subjected to metal–halogen exchange at −100°C (in THF–ether–hexane 4:1:1) with *n*-butyl lithium, and quenched with water after 1 h at that temperature. Dihydrobenzofurans **1** and **9**–**12** and dihydronaptho[2,1-*b*]furan **13** produced in the intramolecular Michael addition (cyclialkylation) step were isolated in yields ranging from 60 to 71% and overall yields of 25–44%.

The ^{1}H nmr spectra of the products are summarized in Table 1. Certain features of these spectra provide useful clues for the assignment of the individual A and B components of the two ABX systems (—O—CH_2—CH—CH_2—CO_2Et) and thereby the conformation of the C-3 ethyl acetate side chain. The invariant position of the ethyl ester signals in all six compounds suggests a conformation (Fig. 1), in which the ester is far removed from the structural changes in the aromatic region of the molecule. This is supported by *gauche* (3–5 Hz) and *anti*

[a]Benzofuran numbering used for consistency; aromatic coupling constants ranged from 8 to 8.8 Hz.

(9.5–11 Hz) couplings for the nonequivalent methylene protons of the side chain and by the fact that the more shielded proton is coupled *anti* to H-3. The presence of a carbon substituent at C-4 (as in **1** and **13**) reduces $\Delta\nu$ for the C-2 methylene group from 0.5 to 0.2 ppm and reduces the smaller 2β-3 (*trans*) coupling from about 6.5 to 3 Hz. This is accompanied by a reduction of the *gauche* coupling in the side chain methylene group from ca. 5 Hz to 3 Hz. The changes are satisfactorily rationalized by proposing that steric interaction between the C-4 substituent and the *gauche*-coupled proton of the methylene group enlarges that dihedral angle slightly and thereby brings the *anti*-coupled proton closer to H-2β. Twisting of the C2—C3 bond, which has

FIG. 2

been previously observed in dihydrobenzofurans (11), moves H-2β outwards and away in response to this interaction, thus producing the changes in H-2 resonances described above.

Evidence for the ionic character of the cyclialkylation (as opposed to similar radical processes (4)) was sought by *in situ* methylation and deuteration of the enolate (**8***e* → **13**). Quenching this reaction mixture with an excess of the electrophile (methyl iodide or *d*-acetic acid) at −100°C, a mere 30 s after addition of the *n*-butyl lithium, and allowing it to reach room temperature overnight provided satisfactory yields of the desired methylated and deuterated products. The cyclialkylation thus appears to be an extremely rapid process even at −100°C. The methyl derivative **14** so obtained was diastereomerically pure (250-MHz ^{1}H nmr) and its configuration and conformation assigned as in Fig. 2 by interpretation of the spectrum in comparison with that of **13**. The new methyl doublet at 0.93 ppm (J = 7.2 Hz) is at a somewhat higher field than expected,[2] betraying its shielded location *anti* to H-3. The proton remaining appears as an octet at 3.2 δ, *gauche* coupled (J = 3.3 Hz) to H-3, and the ethyl ester resonances are again essentially unchanged (1.29 and 4.20 δ). Very significantly, the usual pattern of H-2 absorptions (Table 1) is reversed in **14**, the quartet for H-2β is now downfield (4.75 δ, J_{gem} = 9.7, $J_{2\beta,3}$ = 3.2 Hz) of the "triplet" for H-2α (4.66 δ, $J_{2\alpha,3}$ = 9.0 Hz), almost certainly because of the increased distortion at C-2 caused by the H2β-methyl interaction. The signal for the central proton H-3 appears at 4.33 and as two triplets with vicinal couplings of 3.2, 3.3, and 9.0 Hz. These assignments and coupling constants are supported by decoupling. The spectra of **13** and **14** are unchanged when run at −20°C. The deuterated product **15** was obtained with similar diastereoselectivity. The ^{1}H and ^{2}H nmr spectra of **15** indicated that, again, the upfield *anti*-coupled proton of **13** is replaced by deuterium with a ca. 7:1 diastereoselectivity (Fig. 2).

[2]The absorption of the *gem*-dimethyl group in methyl 2-methyl propanoate (methyl isobutyrate) is found at 1.2 δ (Aldrich Library of NMR Spectra, Vol. III, spectrum 22D).

The high diastereoselectivity observed in several examples of methylation of acyclic ester enolates has been attributed to the conformation adopted by the enolate and direction of the approaching electrophile by the neighbouring asymmetric substituent antiperiplanar to it for steric (12, 15) or electronic (13) reasons or both (14). In the case at hand a low energy eclipsed (15) conformation and electrophilic attack from the less hindered face of the double bond appears to be reponsible for the exclusive formation of diastereomers **14** and **15** as shown in Fig. 2.

Application of the benzofuran synthesis to natural product chemistry and further investigations of the stereochemistry of the methylation and deuteration are continuing and will be reported in due course.

Experimental

General methods

Melting points were determined on a Fischer Mel Temp apparatus and are uncorrected. Infrared spectra were obtained on a Perkin–Elmer 983 spectrophotometer. Nuclear magnetic resonance spectra were obtained on a Bruker WP-80 or AM 250 spectrometer in deuteriochloroform unless otherwise indicated. Mass spectra were measured on a VG 7070 instrument and are reported in the order m/z (intensity, assignment). Combustion analyses were performed by the Guelph Chemical Laboratories, Guelph, Ontario.

General procedure for the preparation of methoxymethyl esters **3**b–**7**b

The phenol (**3***a*–**7***a*, 40 mmol) was dissolved in dry dimethyl formamide (15 mL) and this solution added dropwise to a suspension of sodium hydride (60 mmol) in dimethyl formamide (25 mL) at 80°C under a nitrogen atmosphere. After 1 h at this temperature the mixture was cooled to 0°C, chloromethyl methyl ether (60 mmol) added, and the solution allowed to reach ambient temperature overnight. Water was added and most of the liquids removed by distillation under reduced pressure. The residue was extracted into ether and the extracts washed successively with 10% aqueous sodium hydroxide and brine and dried (Na_2SO_4). The solvent was removed and the residual oil distilled to provide the desired products.

3*b* (82.5%); bp 60°C (0.1 Torr; 1 Torr = 133.3 Pa); δ (80 MHz): 2.28 (s, 3H, $ArCH_3$), 3.50 (s, 3H, OMe), 3.85 (s, 3H, Ar-OMe), 5.20 (s, 2H, OCH_2O), 6.80, 6.98 (3H, ArH); ms: 182 (100, M^+), 152 (94, $M^+ - CH_2O$), 137 (31, $M^+ - CH_3OCH_2$). *Anal.* calcd. for $C_{10}H_{14}O_3$: C 65.91, H 7.74; found: C 65.68, H 8.10.

4*b* (75%); bp 60–64°C (0.1 Torr).

5*b* (85%); bp 65–70°C (0.05 Torr).

6*b* (81%); bp 44–46°C (0.1 Torr).

7*b* (94%); bp 65–70°C (0.1 Torr).

All compounds had spectroscopic properties consistent with their structures and similar to those reported for **3***b*.

General procedure for preparation of iodophenols **3**d–**7**d

The methoxymethyl derivative (**3***b*–**7***b*) dissolved in anhydrous ether (1 g in 10 mL) was cooled to 0°C and a solution of *n*-butyllithium (1.6 *M* in hexane, 2.2 equiv.) added dropwise, under an atmosphere of nitrogen. After 1 h at this temperature a solution of iodine in dry THF (6 equiv.) was added and the mixture allowed to reach ambient temperature overnight. A saturated aqueous solution of sodium thiosulfate was added, the organic solvents removed under reduced pressure, and the aqueous layer extracted with ether. The extracts were washed and dried (Na_2SO_4) and the solvent removed. The dark residual oil was filtered through a column of silica gel in ethyl acetate – hexane. Iodo compounds **3***c*–**7***c* had the expected spectroscopic properties (nmr, ms) and were used without further purification.

A solution of the above iodo derivative (12.4 mmol) in methanol–THF (20 mL, 1:1) was stirred at room temperature under nitrogen with 2 *M* HCl (8 mL) for 22 h and monitored by tlc. The organic solvents were removed under reduced pressure, the residue extracted with methylene chloride, washed, and dried (Na_2SO_4). The solvent was removed to leave a solid, which was crystallized to provide iodophenols **3***d*–**7***d*.

General procedure for the preparation of γ-phenoxycrotonates ***3****e*–***8****e*

The iodophenol (1 g) was dissolved in dry acetone (15 mL) and ethyl-4-bromocrotonate (1.1 equiv.) added, followed by anhydrous potassium carbonate (1.2 equiv.). The mixture was refluxed for 24 h, the acetone removed, water added, and the aqueous mixture extracted with methylene chloride. The organic extracts were washed, dried (Na_2SO_4), and the solvent removed. The residue was chromatographed on silica gel in the appropriate solvent system (see below).

3*e* (70%), purified by chromatography in ethyl acetate – hexane (1:9). Oil could not be crystallized or distilled without extensive decomposition; ir ($CHCl_3$): 1725, 1664 cm^{-1}; δ (80 MHz): 1.3, 4.2 (t, q, 3H, 2H, CO_2Et), 2.39 (s, 3H, ArMe), 3.80 (s, 3H, OMe), 4.6 (m, 2H, -OCH_2-), 6.32 (br d, 1H, J = 15.6 Hz, =*CH* CO_2Et), 7.11 (dt, 1H, J = 15.6, 4.4 Hz, CH_2—C*H*=), 6.80, 6.95 (q, 2H, J = 8.2 Hz, ArH); ms: 376 (24, M^+), 263 (100, M^+ – CH_2CH=*CH* CO_2Et). *Anal.* calcd. for $C_{14}H_{17}O_4I$: C 44.70, H 4.55; found: C 44.81, H 4.75.

4*e* (98%), purified by chromatography as above. Oil could not be crystallized or distilled; ir (neat): 1719, 1663 cm^{-1}; δ (250 MHz): 1.3, 4.22 (t, q, 3H, 2H, CO_2Et), 3.82 (s, 3H, OMe), 4.64 (m, 2H, -OCH_2-), 6.31 (br d, 1H, J = 15.7 Hz, =*CH* CO_2Et), 7.11 (dt, 1H, J = 15.7, 4.4 Hz, CH_2CH=), 6.83 (m, 2H, ArH), 7.33 (d, 1H, J = 7.7 Hz, ArH); ms: 362 (31, M^+), 249 (100, M^+ – $C_6H_9O_2$). *Anal.* calcd. for $C_{13}H_{15}O_4I$: C 43.11, H 4.17; found: C 42.93, H 4.31.

5*e* (86%), purified by chromatography in ethyl acetate – hexane (1:4) and crystallized from hexane–ether, mp 82–83°C; ir (Nujol): 1712, 1649 cm^{-1}; δ (250 MHz): 1.31, 4.25 (t, q, 3H, 2H, CO_2Et), 4.66 (m, 2H, -OCH_2-), 6.01 (s, 2H, -OCH_2O-), 6.22, 6.66 (q, 2H, J = 8.4 Hz, ArH), 6.35 (br d, 1H, J = 15.7 Hz, =*CH* CO_2Et), 7.06 (dt, 1H, J = 15.7, 3.7 Hz, CH_2CH=); ms: 376 (18, M^+), 263 (100, M^+ – $C_6H_9O_2$). *Anal.* calcd. for $C_{13}H_{13}O_5I$: C 41.51, H 3.48; found: C 41.27, H 3.38.

6*e* (84%), purified by filtering through a silica gel column in hexane–ether (19:1) and crystallized from hexane, mp 68–69°C; ir ($CHCl_3$): 1711, 1664 cm^{-1}; δ (80 MHz): 1.30, 4.22 (t, q, 3H, 2H, CO_2Et), 2.15, 2.19 (s, 3H each, ArMe), 4.69 (m, -OCH_2-), 6.32 (br d, 1H, J = 15.8 Hz, =*CH*CO_2Et), 6.56 (s, 1H, ArH), 7.07 (dt, 1H, J = 15.8, 3.7 Hz, CH_2CH=), 7.51 (s, 1H, ArH); ms: 360 (89, M^+), 247 (100, M^+ – $C_6H_9O_2$). *Anal.* calcd. for $C_{14}H_{17}O_3I$: C 46.68, H 4.76; found: C 46.83, H 4.99.

General procedure for cyclialkylation of iodocrotonates; the preparation of ***1*** *and* ***9–13***

The iodocrotonate (0.5 g) dissolved in dry THF–ether–hexane (18 mL, 4:1:1) under a nitrogen atmosphere was cooled to −100°C (liquid nitrogen, ligroin, acetone, isopropanol bath), *n*-BuLi (1.6 *M* in hexane, 1.1 equiv.) was added dropwise, and the mixture maintained at −100°C for 1 h with stirring. Water was added, the solution allowed to reach room temperature, the organic solvents removed, and the aqueous residue extracted with ether, washed, and dried (Na_2SO_4). The ether was removed and the residual oil chromatographed on a silica gel column in the appropriate solvent system (see below).

1 (71%), chromatographed in ethyl acetate – hexane (1:4) and crystallized from hexane; mp 41°C; ir (neat): 1730 cm^{-1}; ms: 250 (62, M^+), 163 (100, M^+ – CH_2CO_2Et). *Anal.* calcd. for $C_{14}H_{18}O_4$: C 67.18, H 7.25; found: C 67.30, H 7.67.

9 (68%), chromatographed in hexane–ether (4:1) and obtained as an oil that resisted crystallization; ir (neat): 1730 cm^{-1}; ms: 236 (64, M^+), 149 (100, M^+ – $C_4H_7O_2$). *Anal.* calcd. for $C_{13}H_{16}O_4$: C 66.08, H 6.83; found: C 65.95, H 7.22.

10 (68%), chromatographed in hexane – ethyl acetate (4:1) and obtained as an oil that resisted crystallization; ir (neat): 1730 cm^{-1}; ms: 250 (100, M^+), 163 (87, M^+ – $C_4H_7O_2$). *Anal.* calcd. for $C_{13}H_{14}O_5$: C 62.39, H 5.64; found: C 62.84, H 6.03.

11 (60%), chromatographed in hexane–ether (4:1) and crystallized from hexane, mp 36–37°C; ir (Nujol): 1739 cm^{-1}; ms: 234 (38, M^+), 147 (100, M^+ – $C_4H_7O_2$). *Anal.* calcd. for $C_{14}H_{18}O_3$: C 71.77, H 7.74; found: C 71.98, H 7.79.

12 (69%), chromatographed in hexane–ether and obtained as an oil that resisted crystallization; ir (neat): 1729 cm^{-1}; ms: 250 (98, M^+), 163 (100, M^+ – $C_4H_7O_2$). Correct analytical figures could not be obtained for this compound in spite of several efforts.

13 (68%), chromatographed in ethyl acetate – hexane (1:4) and crystallized from ether–hexane, mp 48–49°C; ir ($CHCl_3$): 1727 cm^{-1}; ms: 256 (28, M^+), 169 (100, M^+ – $C_4H_7O_2$). *Anal.* calcd. for $C_{16}H_{16}O_3$: C 74.98, H 6.29; found: C 75.24, H 6.74.

*Methylation and deuteration experiments (****14*** *and* ***15****)*

The reactions carried out with **8***e* on a 0.5-mmol scale (191 mg) were quenched with excess methyl iodide or acetic acid-*d* after 0.5 min at −100°C, allowed to reach room temperature overnight, and worked up as described for **13**.

14, ms: 270 (11, M^+), 169 (100, M^+ – $C_5H_9O_2$).

15, ^2H nmr ($CHCl_3$, 38.4 MHz): 2.59, 3.00 in the intensity ratio of 20.005:2.991; ^1H nmr ($CDCl_3$, 250 MHz) shows virtually total disappearance of the quartet at 2.58 δ and broadening (H–C–D coupling) of the quartet at 2.99 δ (Table 1); ms: 257 (24, M^+), 169 (100, M^+ – $C_4H_6O_2D$). A small M − 1 peak at m/z 256 (2.06), not found in the mass spectrum of **13**, represents nondeuterated material. If such an assumption is made and the corresponding M + 1 component is subtracted, the extent of deuteration is calculated to be 92%.

Received November 26, 1986

TEODORO S. KAUFMAN, MIRTA P. MISCHNE, MANUEL GONZALEZ-SIERRA, and EDMUNDO A. RUVEDA. Can. J. Chem. **65**, 2024 (1987).

The synthesis of the cleistanthane-type diterpene **13** (8-β(H),14-β-ethyl, 13-methylene podocarpane), a dihydro epimer of the natural product **6**, is described. By comparison of the ^{13}C nuclear magnetic resonance spectral data of **13** and related compounds with those reported for **6**, the stereochemistry of the C-14 side chain of the latter was confirmed.

TEODORO S. KAUFMAN, MIRTA P. MISCHNE, MANUEL GONZALEZ-SIERRA et EDMUNDO A. RUVEDA. Can. J. Chem. **65**, 2024 (1987).

On décrit la synthèse du diterpène **13** (l'éthyl-14β méthylène-13 podocarpane-8β(H)) du type cléistanthane, un épimère dihydrogéné du produit naturel **6**. Par comparaison des données spectrales de la résonance magnétique nucléaire du ^{13}C du composé **13** et de celles de composés apparentés au produit **6**, on a pu confirmer la stéréochimie de la chaîne latérale de ce dernier composé.

For personal use only.

The cleistanthane type of diterpenoids represents a small group of natural products formally derived from the parent hydrocarbon 14-ethyl-13-methyl podocarpane (**1**), including cleistanthol (**2**) (1), veadeirol (**3**) (2), veaderoic acid (**4**) (2), and the tetracyclic lactone **5** (3), all of them containing an aromatic ring C.

More recently, a new member of this group, the hydrocarbon **6**, was isolated from *Amphibolis antarctica*, one of the major sea grasses of Shark Bay (Western Australia). Structure **6** was established on the basis of its ^1H and ^{13}C nmr spectral data and comparison with those of **7**, **8**, and **9** (4). Interestingly enough, the structure of **6** is reminiscent of that suggested for the cleistanthane framework **12**, biogenetically derived by the pimarane–cleistanthane rearrangement (**10** → **11** → **12**) (5).

A careful analysis of the spectral data reported for **6** showed us that the ^1H nmr coupling constants, from which the stereochemistry of the C-14 side chain was suggested, were not in agreement with the ^{13}C nmr signals assignment. In fact, as the side chain at C-14 is axial, and assuming that the substituent at C-13 will have practically no effect on C-9 in structure **6**, the signal corresponding to C-9 should appear at higher field than those of the same site of **7** and **8**, due to the γ effect imposed by C-15.

To solve this problem and also to obtain spectral information on this type of diterpenoids, we decided to carry out an exhaustive ^{13}C nmr analysis of synthetic compounds related to **6**, such as its dihydro epimer **13** and some of its derivatives.

For the synthesis of **13**, the ketone **14**, readily prepared from manool (6, 7), appeared to be an ideal precursor, since it possesses the required tricyclic skeleton with the necessary functional groups for building up the two-carbon side chain with the required stereochemistry at C-14 and for the transformation of the C-13 carbonyl into the *exo*-methylene group.

Our initial approach to the synthesis of **13** was the lithium in liquid ammonia reduction of **14** with simultaneous trapping of the corresponding enolate with ethyl iodide (8). Unfortunately, under these conditions, compound **8** was obtained as the major product. However, by using the α-alkyation conditions described by Atwater (9), the desired monoethyl-α,β-unsaturated ketone **15** was obtained in 61% yield together with a small amount of the corresponding α,α-diethyl-β,γ-unsaturated ketone **16**. Lithium in liquid ammonia reduction of **15** produced the expected thermodynamically more stable, equatorially substituted, saturated ketone **17** in good yield.

From **17**, by a standard Wittig reaction (triphenylmethylphosphonium bromide, methyl lithium) or thioketalization followed by Raney nickel desulfurization, the desired hydrocarbons **13** and **18** were obtained.

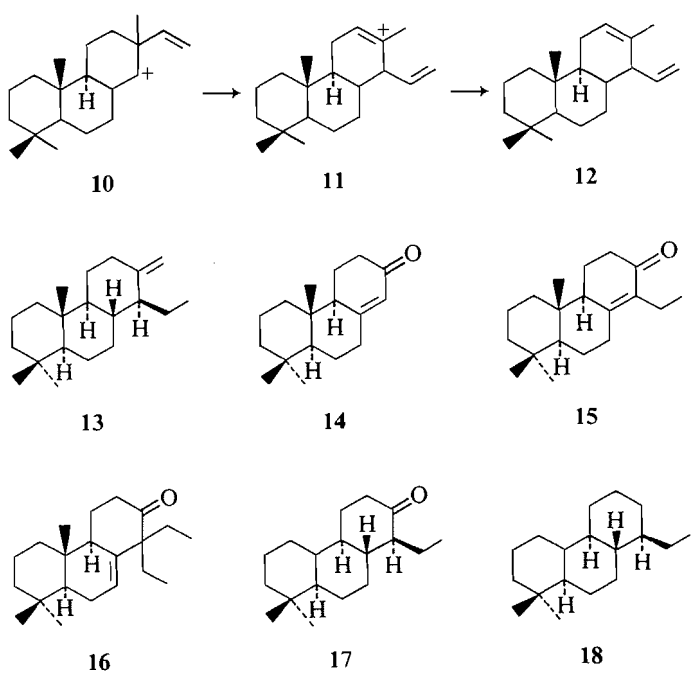
*Assignments may be interchanged.

At this point, a comparative analysis of the ^{13}C nmr spectra obtained for compounds **13**, **17**, and **18**, together with the reported data for compounds **7** and **8** (4) and the calculated chemical shifts obtained by using the substituent parameters proposed by Beierbeck *et al.* (10), allowed the complete shift assignment for **13**, **17**, and **18**.

Comparison of the chemical shifts assigned to **13** and **17** shows that C-12 and C-14, in compound **13**, are shielded, while C-15 is deshielded, as expected for a carbonyl to exocyclic double-bond change (11). The chemical shifts for C-9 in compounds **13**, **17**, and **18** are similar to those observed for the same site in **7** and **8**, and are in agreement with an equatorial orientation of the side chain at C-14.

With this information in hand, together with the data reported by Grover and Stothers (11) on the effects of axial and equatorial methyl groups on their neighboring carbons in methylenecyclohexanes, and assuming that the effect induced by a sp^3 carbon is similar in magnitude to that produced by the C-15 sp^2 of **6**, the reported ^{13}C nmr data for the natural product were reanalyzed. We have found that by reversing the signals previously attributed to C-9 and C-14, an assignment in agreement with the axial position for the C-14 side chain is obtained. Comparison of the C-12 chemical shift for compounds **6** and **13** confirms the above observations. In fact, due to the axial position of the side chain in the natural product, the signal of C-12, suffering a γ effect, resonates at 29.6 ppm, a value very close to the calculated one (30.58 ppm). The upfield shift observed for C-17 in going from **6** to **13** is also in agreement with the different position of the C-14 side chain in both compounds.

In conclusion, the ^{13}C nmr data indicate, in agreement with the ^{1}H nmr coupling constants reported, that the suggested stereochemistry for the side chain in **6** is the correct one (4). The carbon shifts of **18** (observed and calculated), **17**, **13**, and **6** (reported and calculated), with the reassigned signals for C-9 and C-14, are listed in Table 1.



Experimental

Melting points were determined on an Ernst Leitz hot-stage microscope and are uncorrected. Infrared spectra were recorded on a Beckman Acculab 8 spectrometer. The ^{1}H and ^{13}C nmr spectra were recorded at 80.13 and 20.15 MHz on a Bruker WP 80 SY spectrometer in deuteriochloroform, and chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. The carbon shifts of **13**, **17**, and **18** were assigned by comparison with the reported data of **7** (4) and analysis of the generated CH/CH_3 and CH_2/q subspectra by spin-echo sequence utilizing the attached proton test method (APT) (12).

All solvents were purified and dried by standard techniques. All reactions were performed under dry nitrogen atmosphere. Column chromatography was performed on silica gel 60H, slurry packed, run under low pressure of nitrogen, and employing increasing amounts of ethyl ether in hexane as solvent.

14-Ethyl podocarp-8(14)-en-13-one ***15***

To a boiling solution of potassium *tert*-butoxide (prepared from

0.6 mg-atom of K) in 1.35 mL of anhydrous *tert*-butyl alcohol was added 100 mg (0.407 mmol) of the enone **14** dissolved in 2.65 mL of hot *tert*-butyl alcohol. After 10 min, 0.052 mL (0.65 mmol) of dry ethyl iodide in 6.75 mL of *tert*-butyl alcohol was added dropwise with stirring, over a 2.5-h period, to the refluxing solution. The mixture was stirred and refluxed for 0.5 h, cooled, and acidified with concentrated hydrochloric acid. After addition of water to dispel the turbidity, *tert*-butyl alcohol was removed under reduced pressure. The organic material was extracted with ether (3 × 50 mL) and dried (Na_2SO_4). Removal of the solvent under reduced pressure gave an oil, which after chromatography afforded 34 mg (28%) of **16** as an oil; ir (film): 2940, 2860, 1715 (C=O), 1460, 1386, 1230, 1200, 1140, 1050, 980, 840 (>C=C—H), and 770 cm^{-1}; ^{1}Hmr ($CDCl_3$): 0.71 (t, 6H, C14 side chain methyl groups J = 8 Hz), 0.84, 0.90, and 0.93 (s, 3H each, C4 and C10 Me), 0.93 (s, 3H), 5.58 (m, $w_{1/2}$ = 8 Hz, 1H, H-C7); mass spectrum *m/e* (relative intensity): 302 (100) M^+, 287(14), 273(62), 255(7), 245(7), 231(8), 215(10), 189(9), 177(10), 166(74), 149(15), 138(20), 123(22), 109(72), 95(23), 85(21), 69(30), 55(26).

Increase in solvent polarity furnished 68 mg (61%) of **15**, which after crystallization from hexane gave crystals, mp 85.0–85.5°C; ir (KBr): 2949, 2860, 1660 (conj. C=O), 1620, 1450, 1320, 1120, 1050, and 960 cm^{-1}; ^{1}Hmr ($CDCl_3$): 0.76, 0.87, and 0.93 (s, 3H each, C4 and C10 Me), 0.91 (t, 3H, H-C16, J = 8 Hz), 2.29–2.42 (m, 2H, H-C15), 2.70–3.25 (m, 1H, H-C9). Irradiation of the triplet at δ 0.91 collapsed the 2.29–2.42 multiplet to a singlet, while irradiation at δ 2.37 simplified the δ 0.91 triplet to a singlet; ms *m/e* (relative intensity): 274(28) M^+, 259(3), 245(2), 205(4), 189(4), 175(5), 163(15), 151(14), 138(100), 137(68), 123(22), 107(12), 95(19), 91(15), 81(23), 69(21), 55(20). *Exact Mass* (M^+) calcd. for $C_{19}H_{30}O$: 274.2385; found: 274.2371.

8-β(H),14-β-Ethyl podocarpan-13-one ***17***

To 20 mL of stirred dry liquid ammonia (distilled from lithium) was added 15 mg (2.16 mg-atom) of lithium wire. After 15 min, a solution of 380 mg (1.387 mmol) of **15** and 0.103 mL (1.387 mmol) of *tert*-butyl alcohol in 5 mL of anhydrous ether was added, and the mixture was refluxed for 50 min. Then an excess of ammonium chloride was added, and the ammonia was removed with a nitrogen stream. Water (20 mL) was added to the remaining solid and then the organic material was extracted with 3 × 40 mL of ether. The combined extracts were washed with brine (1 × 20 mL) and dried over Na_2SO_4. On evaporating the solvent, the residue solidified. After chromatography it gave 340 mg (89%) of **17** as a solid, followed by 11 mg (3%) of **15**. Crystallization of **17** from methanol afforded white crystals, mp 62.5–63.5°C; ir (KBr): 2950, 2880, 1720 (C=O), 1460, and 1380 cm^{-1}; ^{1}Hmr ($CDCl_3$): 0.83 and 0.86 (s, 6 and 3H, C4 and C10 Me), 0.83 (t, 3H, H-C16, J = 8 Hz), 2.28–2.40 (m, 1H, H-C14); ms *m/e* (relative intensity): 276(99) M^+, 261(14), 248(100), 233(11), 215(7), 205(4), 190(7), 177(35), 163(24), 151(19), 136(46), 133(51), 109(34), 95(43), 81(50), 69(58), 67(64), 55(55). *Exact Mass* (M^+) calcd. for $C_{19}H_{32}O$: 276.2453; found: 276.2452.

8-β(H),14-β-Ethyl podocarpane ***18***

1,2-Ethanedithiol (0.15 mL), followed by 0.05 mL of boron trifluoride etherate, was added to 80 mg (0.290 mmol) of **17** dissolved in 5 mL of anhydrous Cl_2CH_2. The mixture was left overnight at room temperature, then 5 mL of 1.5 *M* aqueous NaOH was added. After stirring for 30 min the organic material was extracted with 4 × 30 mL of ether. The ethereal extracts were washed with 2 × 10 mL brine and dried (Na_2SO_4). After removing the solvent under reduced pressure, the remaining solid was crystallized from ether, affording white crystals of the dithioketal derivative in nearly quantitative yield; mp 94.0–96.0°C; ir (KBr): 2900, 2840, 1430, 1370, 1200, 970, 910, 850, 780, and 730 cm^{-1}; ^{1}Hmr ($CDCl_3$): 0.81, and 0.84 (s, 6 and 3H, C4 and C10 Me), 2.07–2.19 (m, 1H, H-C14), 3.22 (s, 4H, $-S(CH_2)_2S-$); ms *m/e* (relative intensity): 352(18) M^+, 324(5), 259(5), 221(6), 177(3), 165(91), 151(11), 137(16), 131(100), 123(24), 118(65), 109(26), 95(34), 81(33), 69(48), 55(32), 41(34).

The above-mentioned compound (100 mg), dissolved in 5 mL of absolute ethanol, was added to 1.5 g of Raney nickel, suspended in 15 mL of anhydrous ethanol. After a 12-h reflux, the catalyst was filtered and washed four times with hot ethanol (10 mL each). After solvent evaporation and chromatography, 52 mg (69% yield from **17**) of **18** as an oil was obtained; ir (film): 2940, 2860, 1460, and 1380 cm^{-1}; ^{1}Hmr ($CDCl_3$): 0.81, and 0.84 (s, 6 and 3H, C4 and C10 Me), 0.68–2.12 (m, 25 H); ms *m/e* (relative intensity): 262(32) M^+, 247(12), 177(72), 165(7), 149(100), 136(35), 123(77), 109(91), 95(69), 81(78), 69(65), 67(67), 55(69). *Exact Mass* (M^+) calcd. for $C_{19}H_{34}$: 262.2661; found: 262.2657.

8-β(H),14-β-Ethyl, 13-methylene podocarpane ***13***

MeLi solution in hexane (0.57 mL of 1.516 *M*) was added dropwise to a stirred suspension of 334 mg (0.93 mmol) of methyltriphenylphosphonium bromide in 2 mL of anhydrous ether. After 2 h at room temperature, 60 mg (0.22 mmol) of ketone **17** in 1 mL of ether was added and the mixture was stirred 24 h; after addition of water (10 mL), the organic material was extracted with 4 × 30 mL of ether, washed with 2 × 10 mL of brine, and dried (Na_2SO_4). The residue was chromatographed and then sublimed to afford 284 mg (85%) of **13**, mp 39.0–39.5°C; ir (KBr): 2940, 2860, 1650 (C=C), 1450, 1390, and 900 ($C=CH_2$) cm^{-1}; ^{1}Hmr ($CDCl_3$): 0.80, 0.82, and 0.85 (s, 3H each, C4 and C10 Me), 0.89 (t, 3H, H-C16, J = 6.4 Hz), 2.41 (m, 1H, H-C14), 4.56 and 4.69 (br s, 1H each, H-C17); ms *m/e* (relative intensity): 274(15) M^+, 259(25), 245(5), 231(4), 218(5), 203(4), 189(8), 177(23), 163(15), 149(22), 136(80), 121(32), 109(43), 107(50), 93(56), 81(80), 69(71), 55(81), 41(100). *Exact Mass* (M^+) calcd. for $C_{20}H_{34}$: 274.2710; found: 274.2695.

NOTE ADDED IN PROOF: While this manuscript was in press, auricularic acid, a cleistanthane diterpene very related to **6**, was isolated from *Pogostemon auricularis* Hassk (Prakash *et al.*, Tetrahedron Lett. **28**, 685 (1987)).

Reçu le 16 octobre 1986

EMILE BISAGNI, MARILYS RAUTUREAU, MARTINE CROISY-DELCEY et CHRISTIANE HUEL. Can. J. Chem. **65**, 2027 (1987).

La lithiation de l'acétyl-4 chloro-2 pyridine éthylène glycol acétal, effectuée au moyen du diisopropylamidure de sodium (LDA) fournit le dérivé lithié en 3 correspondant. Celui-ci réagit avec les aldéhydes aromatiques en donnant les alcools secondaires attendus qui sont réduits par le triéthylsilane dans l'acide trifluoroacétique. Les acétyl-4 arylméthyl-3 chloro-2 pyridine éthylène glycol acétals résultants sont directement hydrolysés et cyclisés en milieu acide pour donner les systèmes polycycliques comportant une chloro-1 méthyl-5 isoquinoléine fusionnée par sa liaison [*g*] au noyau aromatique correspondant à l'aldéhyde mis en oeuvre.

EMILE BISAGNI, MARILYS RAUTUREAU, MARTINE CROISY-DELCEY, and CHRISTIANE HUEL. Can. J. Chem. **65**, 2027 (1987).

Lithiation of 4-acetyl 2-chloro pyridine ethylene glycol ketal by exchange with lithium diisopropylamine (LDA) led to 4-acetyl 2-chloro 3-lithio pyridine ethylene glycol ketal. This lithio derivative was reacted with aromatic aldehydes giving the expected alcohols, which were reduced by triethylsilane and trifluoroacetic acid at room temperature. The resulting 4-acetyl 3-arylmethyl 2-chloro pyridine ethylene glycol ketals were hydrolysed and cyclized in acidic medium, leading to polycondensed heterocyclic systems that have a 1-chloro 5-methyl isoquinoline nucleus fused by its [*g*] bond to the starting aromatic aldehyde.

Dans un travail récent (1), nous avons montré que les méthyl-5-2*H*-isoquinolones-1 fusionnées à divers systèmes aromatiques par leur liaison [*g*], puis les dérivés chlorés correspondants, sont accessibles au départ de la [(méthoxy-2 pyridyl)-4]-2 diméthyl-4,4 oxazoline-2 **1**. Ce composé est toutefois préparé en 5 étapes à partir de l'acide chloro-2 isonicotinique et le schéma de synthèse utilisé comporte 5 transformations supplémentaires, ce qui rend la méthode assez laborieuse (schéma 1).

Compte tenu de l'intérêt biologique avéré (2, 3) ou potentiel, des nombreux composés susceptibles d'être obtenus par substitution des chloro-1 méthyl-5 isoquinoléines fusionnées aux systèmes aromatiques hétérocycliques les plus variés, et du fait que la synthèse convergente resumée par le schéma 1 paraissait intéressante malgré certaines limitations pour les composés qui comportent une position facilement échangeable par les lithiens (1), nous avons donc cherché à en appliquer le principe en utilisant des intermédiaires différents, capables de le rendre à la fois plus simple et applicable de manière générale.

Dans le présent article, nous décrivons nos résultats à ce sujet.

Au cours du travail déjà mentionné (1), nous avions constaté qu'à l'exception de certains cas particuliers de la transformations **5** → **6**, toutes les étapes du schéma 1 conduisent aux composés attendus avec de bons rendements. Dans le cas du diméthoxy-2,5 benzaldéhyde nouvellement étudié, le bilan global **1** → **7** s'élève d'ailleurs à 35,5% et le principal problème posé était bien de rendre la synthèse applicable dans tous les cas.

Pour cela, il fallait pouvoir introduire directement le groupement acétyl, en le protégeant pour permettre l'utilisation des lithiens, tout en maintenant par ailleurs une fonction sur le sommet 2 de la pyridine. De préférence, celle-ci devait être inerte vis-à-vis des organo-métalliques et devait limiter le problème de l'éventuelle addition de ces derniers en 1,2 de cet hétérocycle. Enfin, le nouveau composé de départ choisi devait être succeptible d'être lithié en 3, au même titre que l'oxazoline **1**.

L'acetyl-4 chloro-2 pyridine éthylène glycol acétal **8** déjà décrit (4) paraissant réunir les conditions ainsi définies, nous avons étudié sa lithiation par échange au moyen du diisopropylamidure de lithium (LDA), lui-même utilisé dans les conditions précisées par Quéguiner et coll. (5) pour lithier d'autres dérivés de la pyridine.

Après 4 h à −70°C dans le tétrahydrofuranne (THF) l'échange LDA – composé **8** conduit effectivement au lithien attendu **9** dont l'hydrolyse par D_2O fournit le dioxolanne de l'acétyl-4 chloro-2 deuterio-3 pyridine **10** avec un rendement supérieur à 60% (dosage rmn).

Nous avons donc poursuivi notre étude par des essais de condensation du diméthoxy-2,5 benzaldehyde, du β-naphthaldéhyde, du formyl-3 thiophène et du *p*-chlorobenzaldéhyde, pris comme exemples d'aldéhydes aromatiques, sur le dérivé lithié **9**. Cela fournit normalement les dioxolannes des acetyl-4 chloro-2(α-aryl α-hydroxy)méthyl-3 pyridines correspondantes **11***a*, **11***b*, **11***c* et **11***d*, avec des rendements de 72, 73, 61 et 76%, respectivement. Ces alcools secondaires étant apparentés au benzhydrol, ils devaient pouvoir être réduits par le triethylsilane dans l'acide trifluoroacétique, suivant les conditions décrites pour la réduction des alcools benzyliques (6, 7). C'est bien ce que nous avons observé pour **11***a*, **11***b* et **11***c* mais, du fait de la présence du groupement dioxolanne aisément hydrolysable, cette réduction en dérivés arylméthylés **12** s'accompagne toujours de l'apparition des produits cyclisés correspondants, probablement formés par cyclodéshydratation des cétones intermédiaires **13**. L'hydrolyse–cyclisation est toutefois incomplète dans les conditions de la réaction et afin d'améliorer les rendements en produit cyclisé, dont l'obtention dans des conditions aisées constituait le but du travail, nous avons traité directement le mélange réactionnel brut dans l'acide chlorhydrique 6 *M* à 50–60°C pour compléter les transformations. La chloro-1 diméthoxy-6,9 methyl-5 benzo[*g*]isoquinoléine **14** (65%), la chloro-1 methyl-5 naphtho[1,2-*g*]isoquinoléine **15** (40%) et la chloro-1 methyl-5 thiéno[2,3-*g*]isoquinoléine **16** (60%), qui sont bien identiques aux composés que nous avons déjà décrits dans les cas de **15** et de **16** (1), ou à celui formé à partir de **7** pour le composé **14**, ont ainsi été obtenus, avec les rendements indiqués calculés par rapport aux alcools **11** et sans qu'il soit nécessaire d'isoler les intermédiaires **12** et **13** (schéma 2).

Cependant, la suite des transformations décrites ci-dessus

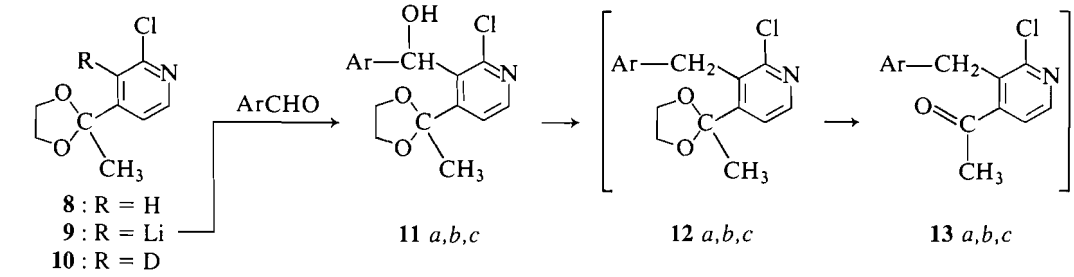
SCHÉMA 1



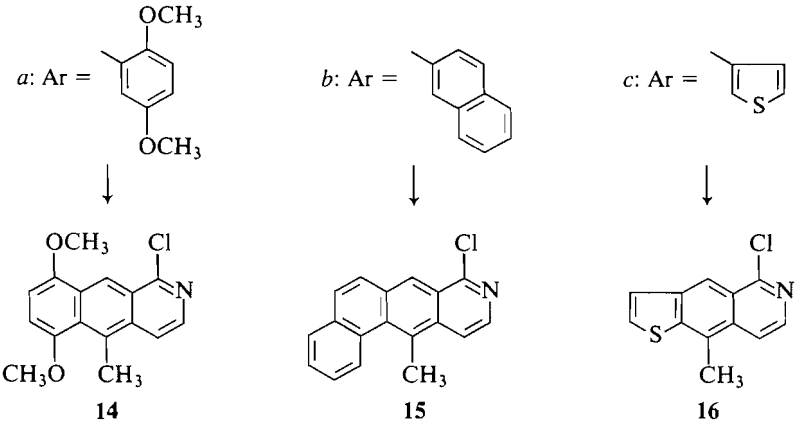


SCHÉMA 2

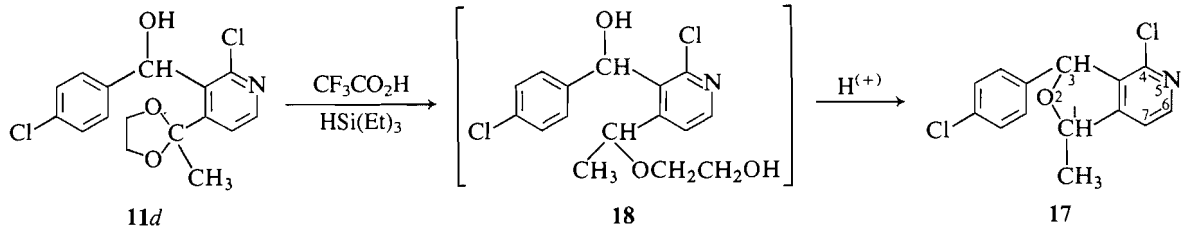

SCHÉMA 3

implique la réduction sélective de la fonction alcool secondaire par le couple triéthylsilane – acide trifluoroacétique alors que la fonction acétal est elle-même réductible dans les conditions utilisées (7).

Lorsque la fonction dioxolanne est affectée en priorité, la réaction suit donc un cours différent, comme nous l'avons observé dans le cas du composé **11***d*. En effet, celui-ci ne conduit pas à la benzoisoquinoléine attendue, mais seulement à la chloro-4 dihydro-1,3 méthyl-1 (*p*-chlorophényl)-3 furo[3,4-*c*]pyridine **17**, très probablement par l'intermédiaire du composé **18**, suivant le schéma 3.

Il est donc évident que tous les alcools de type **11** ne peuvent pas subir la suite des réactions décrites précédemment et que, pour rendre celle-ci applicable dans tous les cas, il sera nécessaire de préciser les conditions pour réduire sélectivement la fonction alcool, au besoin en ajoutant une étape spécifique.

Les transformations résumées par le schéma 2 constituent néanmoins une nouvelle méthode de synthèse des chloro-1 méthyl-5 isoquinoléines fusionnées par leur liaison [*g*] à divers systèmes aromatiques.

Le composé de départ utilisé est le dioxolanne de l'acétyl-4 chloro-2 pyridine facile à préparer (4) et bien que cette méthode implique 4 types différents d'intermédiaires, elle s'effectue en réalité en seulement 2 étapes, ce qui la rend facile et rapide. Par ailleurs, le petit nombre de transformations impliquées se traduit naturellement par une amélioration des rendements. C'est ainsi que le bilan global des préparations de **14**, **15** et **16** est de 31,6, 27,5 et 4,7% par la méthode au départ de **1** (1) alors qu'il s'élève à 48,75, 40 et 36,6% au départ du dioxolanne **8**.

Partie expérimentale

(Méthoxy-2' ((α-hydroxy α-(diméthoxy-2",5" phényl)-méthyl))-3' pyridyl-4']-2 diméthyl-4,4 oxazoline-2 **3**

À une solution de l'oxazoline **1** (1) (2,26 g, 11 mmol) dans le THF sec (25 mL), le méthyllithium (9,54 mL d'une solution 1,1 *M* dans l'éther diethylique, 10,5 mmol) est ajouté sous argon, à −5°C. Le mélange se colore rapidement en jaune et après 1 h d'agitation à 0°C, le dimethoxy-2,5 benzaldehyde (1,66 g, 10 mmol) en solution dans le THF (10 mL) est ajouté goutte à goutte. Le mélange est agité à la température ambiante pendant 18 h, décomposé en le versant dans l'eau et extrait au chlorure de méthylène. Le résidu de l'évaporation de ce dernier est repris dans le toluène et recristallisé dans le même solvant pour donner des aiguilles incolores (2,2 g, 68%), F = 161°C; ^{1}H rmn ($(CD_3)_2SO$) δ : 1,31 (s, 2 × 3H, $(CH_3)_2$), 3,43, 3,74, 3,79 (3s, 3 × 3H, OCH_3), 4,08 (q, 2H, CH_2, J_{H-H} = 8,7 Hz), 5,99 (d, 1H, CH—O*H*, J = 8,5 Hz), 6,54 (d, 1H, C*H*—OH), 6,76 (d, 2H, H-3" + H-4" Ar), 7,12 (d, 1H, H-5 py, J_{5-6} = 5 Hz), 7,24 (s élargi, 1H, H-6" Ar), 8,14 (d, 1H, H-6 py). *Anal.* calc. pour $C_{20}H_{24}N_2O_5$: C 64,50, H 6,50, N 7,52; trouvé : C 64,81, H 6,55, N 7,82.

*(Diméthoxy-2',5' phényl)-3-3*H,*5*H*-furo[3,4-*c*]pyridin dione-1,4* **4**

L'oxazoline **3** (4,1 g) est chauffée dans l'acide chlorhydrique 4 *M* (300 mL) au reflux pendant 3 h et le mélange est évaporé à sec, sous pression réduite. Le résidu est recristallisé dans le dioxanne pour donner 2,8 g (89%) de la lactone **4** sous la forme de microcristaux incolores, F = 236°C; ^{1}H rmn ($(CD_3)_2SO$) δ : 3,71 + 3,73 (2s, 2 × 3H, OCH_3), 6,61 (d, 1H, H-7, J_{7-6} = 6,5 Hz), 6,61 (d, 1H, CH), 6,73 (m, 1H, H-6' Ar), 7,04 (m, 2H, H-3' + H-4' Ar), 7,67 (dd, 1H, H-6). *Anal.* calc. pour $C_{15}H_{13}NO_3$: C 62,71, H 4,56, N 4,9; trouvé : C 62,62, H 4,58, N 5,1.

Acide (diméthoxy-2',5' benzyl)-3 hydroxy-2 pyridine carboxylique-4 **5**

La lactone **4** (2,8 g) est réduite en la chauffant pendant 24 h à reflux dans 140 mL d'ammoniaque concentré en présence de 14 g de zinc en poudre, préalablement activé, et de 70 mg de sulfate de cuivre. Le mélange refroidi est filtré, le solide essoré est lavé à l'eau et l'ensemble du filtrat est acidifié par l'acide chlorhydrique. Le précipité obtenu est recristallisé dans l'éthanol pour donner 2,3 g (81%) de microcristaux incolores, F environ 260°C, correspondant à l'acide **5** attendu, légèrement hydraté; ^{1}H rmn ($(CD_3)_2SO$) δ : 3,63 + 3,75 (2s, 2 × 3H, OCH_3), 3,96 (s, 2H, CH_2), 6,35 (d, 1H, H-5 py, J_{5-6} = 6,6 Hz), 6,43 (d, 1H, H-6' Ar, $J_{6'-4'}$ = 2,9 Hz), 6,70 (q, 1H, H-4' Ar), 6,86 (d, 1H, H-3' Ar, $J_{3'-4'}$ = 8,9 Hz), 7,37 (d, 1H, H-6 py). *Anal.* calc. pour $C_{15}H_{15}NO_5$: C 62,28, H 5,23, N 4,83; calc. pour $C_{15}H_{15}NO_5 \cdot 0{,}25H_2O$: C 61,33, H 5,28, N 4,77; trouvé : C 61,48, H 5,07, N 5,09.

*Acétyl-4 (diméthoxy-2,5 benzyl)-3-1*H*-pyridone-2* **6**

À la suspension de l'acide **6** (867 mg, 3 mmol) dans le THF sec (115 mL) «refroidie» à 10°C et maintenue sous agitation, le méthyllithium (27,3 mL d'une solution 0,55 *M* dans l'éther diéthylique, 5 équivalents) est ajouté en une seule fois. Le mélange est agité à la température ambiante pendant 18 h et versé dans 160 mL d'eau. Après évaporation du THF, la solution résiduelle est acidifiée à pH 4 par addition de 2 mL d'acide acétique et saturée par du chlorure de sodium. Le précipité obtenu après 24 h d'abandon à la température ambiante est recristallisé dans le toluène ou l'acétate d'éthyle pour donner 483 mg (56%) de paillettes jaunâtres correspondant à la cétone attendue **6**, F = 141–142°C; ^{1}H rmn ($(CD_3)_2SO$) δ : 2,38 (s, 3H, $COCH_3$), 3,64 (s, 2H, CH_2), 3,74 (s, 2 × 3H, OCH_3), 6,32 (d, 1H, H-5 py, J_{5-6} = 6,6 Hz), 6,51 (d, 1H, H-6' Ar, $J_{6'-4'}$ = 2,6 Hz), 6,72 (q, 1H, H-4' Ar), 6,88 (d, 1H, H-3' Ar, $J_{3'-4'}$ = 8,8 Hz), 7,42 (d, 1H, H-6 py), 11,75 (s large, 1H, NH). *Anal.* calc. pour $C_{16}H_{17}NO_4$: C 66,88, H 5,96, N 4,88; trouvé : C 66,62, H 5,98, N 4,72.

*Méthyl-5 diméthoxy-6,8 benzo[*g*]-2*H*-isoquinolone-1* **7**

Le mélange formé par la cétone précédente **6** (102 mg) dans l'acide chlorhydrique 6 *M* (10 mL) est agité à la température ambiante pendant 1 h et refroidi à 0°C. Le solide formé, filtré et séché, recristallise dans le toluène pour donner 95 mg (91,5%) de microcristaux, F = 256°C, correspondant à l'isoquinolone **7**, hydratée avec 0,25H_2O; ^{1}H rmn ($(CD_3)_2SO$) δ : 3,05 (s, 3H, CH_3), 3,92 + 4,01 (2s, 2 × 3H, OCH_3), 6,84 (d, 1H, H-4, J_{4-3} = 7,7 Hz), 6,88 + 7,03 (2d, 2H, H-7 + H-8, J_{7-8} = 8,9 Hz), 7,16 (dd, 1H, H-3, J_{3-NH} = 5,8 Hz), 9,08 (s, 1H, H-10), 11,04 (s large, 1H, NH). *Anal.* calc. pour $C_{16}H_{15}NO_3 \cdot 0{,}25H_2O$: C 70,20, H 5,66, N 5,11; trouvé : C 69,93, H 5,65, N 5,43.

Remarque : Lorsque la cétone **6** résultant de la transformation de l'acide **5** par le méthyllithium est directement traitée par l'acide chlorhydrique, sans être isolée, le rendement global de la transformation **5** → **7** s'élève à 72,4%.

Dioxolanne de l'acétyl-4 chloro-2 pyridine **8**

Ce composé a été préparé comme indiqué par Lamattina (4) qui le décrit comme un liquide. Distillé à Eb_{10} = 128°C, il cristallise en donnant un solide qui fond aux environs de 30°C.

Acétyl-4 chloro-2 (α-aryl α-hydroxy)méthyl-3 pyridines éthylène glycol acetals **11**a, **11**b, **11**c *et* **11**d

Dans un tricol de 250 mL séché à 120°C et maintenu sous argon, on introduit le tetrahydrofuranne (THF, 50 mL) fraichement distillé sur le mélange benzophénone + sodium. Après avoir refroidi à 0°C, le butyllithium (6,9 mL de la solution commerciale 1,6 *M*, 11 mmol) et la diisopropylamine distillée sur hydrure de calcium (1,54 mL, 11 mmol) sont ajoutés successivement. L'ensemble est agité à 0°C pendant 1 h puis refroidi à −70°C. En continuant à refroidir à cette dernière température, le dioxolanne **8** (1,995 g, 10 mmol) en solution dans le THF (10 mL) est alors ajouté, goutte à goutte. Trente minutes après la fin de l'addition, on observe l'apparition d'un précipité jaune et le mélange hétérogène se transforme progressivement en un gel. Après 4 h à −70°C, l'aldéhyde choisi (10 mmol) en solution dans le THF (10 mL) est ajouté goutte à goutte et le nouveau mélange est agité à la même température pendant 1 h puis abandonné à la température ambiante pendant 15 h. L'ensemble est versé dans l'eau, extrait au chlorure de méthylène, et les phases organiques réunies sont séchées sur sulfate de sodium et évaporées. Le résidu huileux cristallise progressivement dans l'hexane ou le cyclohexane et le solide obtenu est recristallisé dans le même solvant pour fournir le composé attendu, sous la forme de cristaux incolores.

11*a* : Rendement 72%; F : 92°C (cyclohexane); ^{1}H rmn ($CDCl_3$) δ : 1,73 (s, 3H, CH_3), 3,72 (s, 2 × 3H, OCH_3), 3,8–4,6 (m, 4H, CH_2CH_2), 4,29 (d, 1H, OH, J_{CH-OH} = 8,2 Hz), 6,66–6,84 (m, 4H, C*H*OH + 3H-Ar), 7,57 (d, 1H, H-5 py, J_{5-6} = 5 Hz), 8,31 (d, 1H, H-6 py). *Anal.* calc. pour $C_{18}H_{20}ClNO_5$: C 59,10, H 5,51, N 3,83, Cl 9,69; trouvé : C 58,82, H 5,47, N 4,02, Cl 9.67.

11*b* : Rendement 73%; F = 146°C (cyclohexane); ^{1}H rmn ($CDCl_3$) δ : 1,77 (s, 3H, CH_3), 3,58–3,93 (m, 4H, CH_2—CH_2), 4,35 (d, 1H, O*H*, J_{OH-CH} = 11,2 Hz), 6,81 (d, 1H, C*H*—OH), 7,41–7,50 (m, 5H, 5H-Ar), 7,61 (d, 1H, H-5 py, J_{5-6} = 5 Hz), 7,78–7,87 (m, 2H, 2H-Ar), 8,41 (d, 1H, H-6 py). *Anal.* calc. pour $C_{20}H_{18}ClNO_3$: C 67,51, H 5,10, N 3,94, Cl 9,96; trouvé : C 67,71, H 5,16, N 3,96, Cl 9,89.

11*c* : Rendement 61%; F = 105°C (hexane); ^{1}H rmn ($CDCl_3$) δ : 1,75 (s, 3H, CH_3), 3,2–4,02 (m, 4H, CH_2—CH_2), 4,52 (d, 1H, OH, J_{OH-CH} = 11,5 Hz), 6,62 (dd, 1H, C*H*OH, $J_{CH-H\text{-}2\,th}$ = 2 Hz), 6,88–7 (m, 2H, H-2 th + H-4 th), 7,26–7,34 (m, 1H, H-5 th), 7,56 (d, 1H, H-5 py, J_{5-6} = 5 Hz), 8,37 (d, 1H, H-6 py). *Anal.* calc. pour

$C_{14}H_{14}ClNO_3S \cdot 0{,}25H_2O$: C 53,16, H 4,58, N 4,43, S 10,12, Cl 11,23; trouvé : C 53,21, H 4,45, N 4,41, S 10,13, Cl 11,21.

11*d* : Rendement 76%; F = 125°C (cyclohexane); ^{1}H rmn ($CDCl_3$) δ : 1,74 (s, 3H, CH_3), 3,3 (m, 4H, CH_2—CH_2), 4,13 (d, 1H, OH, J_{OH-CH} = 11,7 Hz), 7,13 (d, 2H, H-2′ + H-6′ Ar, $J_{H-3'-H-2'}$ = 8,2 Hz), 7,31 (d, 2H, H-3′ + H-5′ Ar), 7,58 (d, 1H, H-5 py, J_{5-6} = 5 Hz), 8,38 (d, 1H, H-6 py). *Anal.* calc. pour $C_{16}H_{15}Cl_2NO_3$: C 56,49, H 4,44, N 4,12, Cl 20,84; trouvé : C 56,63, H 4,18, N 4,01, Cl 21,07.

*Réduction–hydrolyse–cyclisation des composés **11** : formation des dérivés polycycliques **14**, **15**, **16***

Le composé choisi (**11***a*, **11***b* ou **11***c*, 1 mmol) est ajouté à l'acide trifluoroacétique (2 mL) et à la solution résultante agitée à la température ambiante (20–25°C), le triethylsilane (0,18 mL, 1,1 mmol) est ajouté en une seule fois. L'agitation est poursuivie pendant 18 h à la température ambiante et l'excès d'acide trifluoroacétique est évaporé sous pression reduite. L'acide chlorhydrique 6 *M* (20 mL) est ajouté au résidu et le mélange est agité à 55–60°C pendant 4 h pour former les composés **14** et **15** et seulement pendant 45 min pour préparer la thiénoisoquinoléine **16**. Le mélange refroidi est alcalinisé par l'ammoniaque, extrait au chlorure de méthylène et la phase organique séchée sur sulfate de sodium est filtrée et évaporée. Le résidu obtenu cristallise dans le minimum de méthanol (**14** et **16**) ou dans l'hexane (**15**) et les produits obtenus sont recristallisés dans le même solvant.

14 : F = 170°C; Rdt 65%.

15 : F = 151°C; Rdt 37%.

16 : F = 138°C; Rdt 60%.

Pour les composés **15** et **16**, les points de fusion, les R_f sur plaque de silice, avec plusieurs mélanges de solvants comme éluants, de même que les spectres de ^{1}H rmn sont en tous points identiques à ceux des mêmes produits déja décrits dans la référence 1.

*Chloro-1 dimethoxy-6,9 methyl-5 benzyl[g]isoquinoléine **14***

Méthode A : voir ci-dessus.

Méthode B : le mélange formé par le composé **7** (500 mg) et l'oxychlorure de phosphore (20 mL) est chauffé au reflux pendant 1 h et l'excès d'oxychlorure est évaporé sous pression réduite. Le résidu est décomposé par addition d'eau glacée, alcalinisé par l'ammoniaque et extrait au chlorure de méthylène. La phase organique séchée est filtrée, évaporée, et le résidu est recristallisé dans l'hexane pour fournir 478 mg (89%) d'aiguilles jaunes, F = 170°C, identique au composé formé par la méthode A; ^{1}H rmn ($CDCl_3$) δ : 3,26 (d, 3H, CH_3, $J_{CH_3-H_4}$ = 0,7 Hz), 3,95 + 4,06 (2s, 2 × 3H, OCH_3), 6,7 + 6,84 (2d, 2H, H-7 + H-8, J_{7-8} = 8 Hz), 8,0 (dd, 1H, H-4, J_{4-3} = 6,5 Hz), 8,19 (d, 1H, H-3), 9,3 (s, 1H, H-10). *Anal.* calc. pour $C_{16}H_{14}ClNO_2$: C 66,79, H 4,90, N 4,87, Cl 12,32; trouvé : C 66,52, H 4,75, N 4,97, Cl 12,59.

*Chloro-4 dihydro-1,3 méthyl-1 (p-chlorophenyl)-3 furo[3,4-c]pyridine **17***

Le composé **11***d* (680 mg, 2 mmol) est ajouté à l'acide trifluoroacétique (4 mL) refroidi à 0°C et le triethylsilane (0,64 mL, 4 mmol) est ajouté aussitôt en une seule fois, en maintenant le mélange sous agitation. Après 6 h d'agitation à 0°C et 15 h à la température ambiante, le mélange est versé dans l'eau, aussitôt alcalinisé par l'ammoniaque et extrait au chlorure de méthylène. L'évaporation du solvant fournit un résidu qui est repris dans l'hexane pour donner, après 2 recristallisations dans le même solvant, 190 mg (34%) de microcristaux incolores correspondant au composé **17**, F = 130°C; ^{1}H rmn ($CDCl_3$) δ : 1,63 (d, 3H, CH_3-1, J_{CH_3-H-1} = 6,5 Hz), 5,4 (m, 1H, H-1), 6,1 (d, 1H, H-3, J_{3-1} = 2 Hz), 7,17 (d, 1H, H-7, J_{7-6} = 5 Hz), 7,22 (d, 2H, H-2′ + H-6′ Ar, $J_{2'-3'}$ = 8,3 Hz), 7,35 (d, 2H, H-3′ + H-5′ Ar), 8,4 (d, 1H, H-6). *Anal.* calc. pour $C_{14}H_{11}Cl_2NO$: C 60,01, H 3,96, N 5,00, O 5,71, Cl 25,30; trouvé : C 59,74, H 3,71, N 4,78, O 5,85, Cl 25,26.

Remarque : les eaux mères de la recristallisation du composé précédent, évaporées et traitées par l'acide chlorhydrique (et par l'acide sulfurique) n'ont fourni aucune trace de la benzoisoquinoléine qui aurait pu se former suivant les transformations résumées par le schéma 2.

Réactivité des α-halobutyrolactones à halogènes tertiaires vis-à-vis des nucléophiles faiblement basiques

JOSYANE GHARBI-BENAROUS, MOUNIR M. ESSAYEGH ET GILBERT DANA[1]

Laboratoire de stéréochimie réactionnelle, Bât. F, Université Pierre et Marie Curie, 4 Place Jussieu, 75252 CEDEX 05, France

Reçu le 11 juillet 1986[2]

JOSYANE GHARBI-BENAROUS, MOUNIR M. ESSAYEGH et GILBERT DANA. Can. J. Chem. **65**, 2031 (1987).

Le méthyl-2 phényl-4 buténolide **5** est préparé quantitativement par élimination de HBr à partir des bromolactones correspondantes **3**. La réaction, obtenue par action des ions halogénures à 100°C dans des solvants polaires aprotiques (DMF, DMSO) est accompagnée d'une substitution nucléophile bimoléculaire. Dans ces réactions, le solvant semble jouer un rôle actif. S'il est assez polaire, il provoque une activation du substrat (forte polarisation préalable de la liaison C—Br) nécessaire au déclenchement de la réaction. En l'absence d'ions halogénures une réaction de type solvolytique intervient pour le démarrage de la réaction. Mais dès que la production des ions halogénures par élimination devient notable, les mécanismes bimoléculaires deviennent prépondérants. L'activation des chlorolactones **4** s'avère beaucoup moins aisée que celle des bromolactones **3**, mais dans les deux cas l'élimination est du type E_2ip avec semble-t-il, une approche du type E_2C.

JOSYANE GHARBI-BENAROUS, MOUNIR M. ESSAYEGH, and GILBERT DANA. Can. J. Chem. **65**, 2031 (1987).

2-Methyl-4-phenylbutenolide (**5**) is prepared in a quantitative manner by an elimination of HBr from the corresponding bromolactones **3**. This reaction, induced by halide ions at 100°C in polar aprotic solvents (DMF, DMSO), is accompanied by a bimolecular nucleophilic substitution. In these reactions, the solvent seems able to play an active role. A polar solvent induces the necessary activation of the substrate (by a prior strong polarization of the C—Br bond). In the absence of halide ions, a solvolytic reaction takes place. As soon as the elimination reaction produces enough halide ions, the bimolecular reaction takes over. The activation of the chlorolactones **4** is much more difficult than that of the bromolactones **3**; however, each elimination is of the E_2ip type with some E_2C type.

Dans un précédent mémoire (1), nous avons proposé une nouvelle voie d'accés au méthyl-2 phényl-4 buténolide-2,3. La méthode utilise des dérivés dihydro-2,3 furanniques (2–4) et fait intervenir une réaction d'élimination d'hydracide sur les α-bromobutyrolactones correspondantes. L'intérêt que suscite le motif buténolide pour les nombreuses propriétés physiologiques qui lui sont attachées (5, 6) nous a encouragés à examiner plus en détail ses possibilités de formation à partir des halolactones.

La déshydrohalogénation est effectuée par une base faible en milieu aprotique (LiBr, DMF, 100°C) dans des conditions qui se sont révélées épimérisantes pour le brome (schéma 1).

Cette réaction de substitution peut jouer un rôle important dans la réaction d'élimination, dans la mesure où, entraînant un changement de stéréochimie du brome, elle permet éventuellement de former les stéréoisomères **1** susceptibles de subir l'élimination *anti*.

En fait, deux types de mécanismes reconnus peuvent être envisagés pour ces réactions d'élimination/substitution. Le premier, assez généralement admis, est un *mécanisme bimoléculaire* de type E_2C (en raison de la faible basicité du nucléophile mis en jeu) (7, 8) ou de type E_2ip, mécanisme par paire d'ions (en raison de la forte polarité du solvant) (9, 10). L'autre possibilité est un *mécanisme solvolytique* par formation d'un carbocation en α du carbonyle. Des carbocations de ce type ont été observés et étudiés aussi bien en α d'une cétone (11) que d'un ester (11*d*, 12). Ils sont généralement plus réactifs dans le cas des esters (11*d*). Il nous a semblé intéressant d'envisager le cas d'un substrat lactonique plus propice à l'hypothèse du mécanisme solvolytique que les lactones **1**.

Dans le présent mémoire, nous examinerons le cas des stéréoisomères *a* et *b* des α-méthyl-halolactones **3** et **4**. L'utilisation de tels substrats tertiaires devrait privilégier les mécanismes solvolytique ou par paire d'ions au détriment du mécanisme E_2C. Nous montrerons que des considérations cinétiques de nature semi-quantitative et que des observations stéréochimiques simples permettent, notamment par comparaison du comportement dans divers solvants, de proposer un schéma réactionnel assez détaillé. Nous tiendrons compte également de l'orientation de la réaction vers le buténolide **5** plutôt que vers la méthylène-lactone **6**.

11	**3***b*	60°C; 1 h	LiBr, 2 équiv.	7	72(**3***a*)	21	21/72 = 0,29

[a]Dans les mêmes conditions, mais au bout de 3 h, la transformation en buténolide est totale. Le rendement en buténolide purifié est alors de 94%.
[b]Trace non dosable par rmn.
[c]Au bout de 3 h, on peut également isoler après traitement (lavage à l'eau, extraction à l'éther...) 10% de α-hydroxylactones (13).
[d]Valeur mesurée en fin d'expérience. L'équilibre correspond à une valeur de l'ordre de 0,16 à 60°C.
N.B. Les dosages sont effectués par intégration en rmn et confirmés par ccm préparative. Les expériences ont été répétées (2–3 fois) de façon indépendante avec obtention d'écarts inférieurs à 3%. Les résultats obtenus dans les expériences préliminaires et dans des conditions intermédiaires (ou plus sévères) sont cohérents avec le reste du tableau et ne sont pas mentionnés. La nature de l'halogène présent dans les produits de substitution est confirmée par spectrographie de masse et par analyse centésimale.

TABLEAU 2. Étude de la bromolactone **3***a* dans des solvants de différentes polarités

16	DMSO	80°C; 3 h	0	31	10(**3***b*)	59	10/59 = 0,169

[a]Même résultat avec et sans LiBr.
[b]Même résultat avec et sans LiCl.
[c]Deux équivalents de sel (0,8 mmol LiBr ou LiCl) dans 10 mL de solvant pour 1 équivalent (0,4 mmol) de bromolactone **3***a*.
N.B. Voir tableau 1.

L'isomère majoritaire **3***a* correspond à l'attaque électrophile du brome par la face la moins encombrée du dihydrofuranne (face α) (1).

Les chlorolactones **4** sont obtenues de façon analogue en trois étapes. L'isomère **4***a* est alors initialement obtenu pur et son épimère **4***b* est préparé par isomérisation dans la présente étude.

Les quatre lactones sont aisément identifiables par rmn du proton et par chromatographie en couche mince sur silice (ccm). Les dosages réalisés au cours de l'étude qui suit (tableaux 1–4) ont été effectués par intégration en rmn pour la mise au point des conditions expérimentales jusqu'à obtention de résultats reproductibles à 2 ou 3% près. Les dosages sont alors confirmés par ccm préparative et les échantillons purifiés envoyés à l'analyse et à la spectrographie de masse pour vérifier notamment la nature de l'halogène présent (voir partie expérimentale).

D'une façon générale, les halolactones **3** et **4**, à halogène tertiaire, sont moins réactives (en ce qui concerne l'élimination) que les bromolactones **1**. Dans les conditions où ces dernières réagissent totalement pour former le buténolide **2** (isolé avec un rendement de 95% (1)), les taux de transformation des bromolactones **3** et des chlorolactones **4** en buténolide **5** sont seulement de 80 et 24% respectivement (action des sels LiBr ou LiCl, dans le DMF, 1 h à 100°C, tableaux 1 et 3, expériences n° 1). Dans ces conditions, on peut observer l'équilibration des

[a]Même résultats avec et sans LiCl.

[b]Deux équivalents de sel (0,8 mmol LiBr ou LiCl) dans 10 mL de solvant pour 1 équivalent (0,4 mmol) de chlorolactone **4***a*.

N.B. Voir tableau 1.

stéréoisomères *a* et *b* sur les lactones résiduelles. Contrairement au cas des lactones **1**, l'expérience montre que, pour les lactones à halogène tertiaire, on ne peut pas trouver de conditions d'équilibration (substitution) sans élimination (abaissement de la température, absence de nucléophile, changement de solvant...). Toutefois, par abaissement de température, l'élimination peut être suffisamment ralentie pour que la composition d'équilibre des bromolactones soit approximativement observée (K(**3**) = (**3***b*)/(**3***a*) = 0,162 ± 0,002, expériences n° 2 et 10, tableau 1). Pour les chlorolactones, bien que la vitesse d'élimination soit notablement plus faible que pour les bromolactones, la vitesse d'épimérisation du chlore reste toujours du même ordre de grandeur que la vitesse d'élimination et le rapport (**4***b*)/(**4***a*) stationnaire approximativement atteint (0,4–0,6) ne correspond pas forcément à la constante d'équilibre (expériences n° 2, 13 et 14, tableau 3).

Ces équilibrations sont étudiées sur des solutions de 10 mL de DMF contenant 0,4 mmol d'halolactone et 2 équivalents (0,8 mmol) du nucléophile (LiBr ou LiCl respectivement) à 60°C pour les bromolactones et à 100°C pour les chlorolactones. En l'absence du nucléophile, dans les mêmes conditions, aucune réaction n'est observée (tableau 2, expérience n° 7, et tableau 4, expérience n° 5). Pour développer l'étude de ces réactions, nous avons d'abord modifié la nature et la concentration du nucléophile.

Au point vue préparatif, signalons qu'on peut obtenir de façon optimum le buténolide **5** à partir de la bromolactone **3***a*, en 3 h à 100°C, dans les mêmes conditions (tableau 1, note *a*).

Changement de nucléophile

L'utilisation des ions chlorures (LiCl) au lieu de bromure (LiBr) avec les lactones bromées **3** accélère la réaction d'élimination (tableau 1, expériences n° 2 et 3 et expériences n° 9 et 10). On n'observe plus l'épimérisation du brome et

For personal use only.

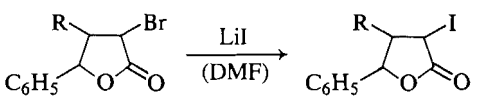
le seul produit de substitution trouvé est la chlorolactone de configuration inverse (**4***b* à partir de **3***a* et **4***a* à partir de **3***b*) comme le montrent la chromatographie en couche mince préparative (ccm), l'analyse centésimale, la rmn du proton et la spectrographie de masse. La comparaison des expériences n° 4 et 5 (tableau 1) montre que la vitesse de formation de la chlorolactone **4***b* à partir de la bromolactone **3***a* est proportionnelle à la concentration des ions chlorures : on obtient autant de chlorolactone **4***b* (10%) en 1 h avec 1 équivalent de Cl^- qu'en 30 min avec 2 équivalents. *Aussi bien par sa stéréochimie que par son ordre, la réaction est du type* S_N2. Notons que les deux chlorolactones **4***a* et **4***b* sont stables dans les conditions de la réaction (tableau 3, expériences n° 5 et 11).

L'utilisation des ions iodures (LiI au lieu de LiBr) ralentit au contraire la réaction d'élimination qui reste tout de même plus rapide qu'en l'absence de sel (tableau 1, expériences n° 6 et 7, et tableau 2, expériences n° 7 et 13). La réaction de substitution principalement observée est une lente épimérisation du brome, sans formation de lactones iodées. On observe en outre l'apparition d'une faible quantité d'α-hydroxylactones (5–10%) (lactols stéréoisomères déjà décrits (13)).

En ce qui concerne les lactones chlorées **4**, elles sont moins réactives que les lactones bromées **3**. En présence de LiCl dans le DMF, il faut attendre plusieurs heures à 100°C, pour approcher d'une composition stationnaire **4***a* ⇄ **4***b*. En présence de LiBr, la formation des lactones bromées ne peut être espérée que dans des conditions où ces dernières perdent rapidement HBr (tableau 3, expériences n° 8, 9 et 10). Dans ces circonstances, on comprend qu'*il n'est possible de changer l'halogène d'une halolactone que pour un halogène plus léger*, l'halolactone à halogène plus lourd étant notablement plus réactive que le produit de départ.

Notons que ce résultat est particulier aux halolactones tertiaires puisque les bromolactones **1**, à brome secondaire, nous ont permis d'accéder par cette méthode aux iodo-lactones correspondantes.[3]



Influence de la polarité du solvant

Dans le DMF pur, lorsqu'on chauffe une solution de bromolactone **3***a* à 80°C ou de chlorolactone **4***a* à 100°C, on observe dans un premier temps une lente apparition du buténolide et de la lactone *b* isomère (tableau 2, expérience n° 10, et tableau 4, expérience n° 8). De la même façon qu'en présence de sel, les deux réactions apparaissent simultanément vers ces températures (tableaux 2 et 4). Toutefois, les vitesses de réactions sont très ralenties par rapport aux résultats observés dans les conditions de réactions bimoléculaires (présence d'ions Br^-, Cl^-, I^-). Nous avons donc entrepris l'étude de l'influence de la polarité du solvant sur le déclenchement de cette réaction de type solvolytique.

L'étude a été effectuée sur les lactones **3***a* et **4***a* dans des solvants purs ou en présence d'un nucléophile (0,4 mmol dans 10 mL de solvant, avec éventuellement 2 équivalents de sel, tableaux 2 et 4).

Dans les solvants peu polaires (toluène, éther, acétonitrile), à reflux, aucune réaction n'est observée, même en présence de sels.

Dans les solvants plus polaires (DMF, DMSO) les réactions d'élimination et de substitution ont lieu, avec ou sans réactifs nucléophiles, à des températures suffisamment élevées. À température ambiante aucune réaction n'est observée. Il existe enfin des températures intermédiaires pour lesquelles les réactions se produisent, mais seulement en présence de sels. C'est le cas par exemple des réactions dans le DMF à 80°C pour la chlorolactone ou à 60°C pour la bromolactone.

L'acétone se classe de ce point de vue parmi les solvants peu polaires pour la chlorolactone (pas de réaction, avec ou sans sel) et comme solvant plus polaires pour la bromolactone (tableau 2, expériences n° 4, 5 et 6), mais en raison de sa basse température d'ébullition, nous n'avons pu observer la réaction en l'absence de sel.

Avec la γ-collidine, solvant basique, le milieu reste exempt d'ions halogènures puisque le bromhydrate et le chlorhydrate de collidine sont insolubles. Dans ces conditions nous avons observé que la chlorolactone **4***a* donne lieu à une élimination lente sans épimérisation (formation de 10% de buténolide **5** en 3 h à 100°C) alors qu'avec la bromolactone **3***a*, l'épimérisation du brome est rapide par rapport à l'élimination (22% d'élimination en 3 h à 100°C, avec un rapport (**3***b*)/(**3***a*) final = 0,15).

Discussion

Il apparaît que les réactions effectuées dans le DMF correspondent à un mécanisme complexe mettant en jeu, suivant les conditions, des réactions de type solvolytique ou (et) des réactions bimoléculaires :

$$[1] \quad v = k_S(RX) + k_2(Y^-)(RX)$$

Pour rendre compte d'une substitution typiquement bimoléculaire sur un substrat tertiaire (15), nous envisageons l'hypothèse de la formation d'une paire d'ions sur laquelle s'effectue l'attaque du nucléophile (16). Dans la paire d'ions, présentant une liaison C—Br (ou C—Cl) activée, fortement polarisée, la stéréochimie de la molécule de départ reste inchangée (10).

En effet, dans les solvants peu polaires (toluène, éther, acétonitrile), aucune réaction n'est observée, même en présence d'un nucléophile. Dans de tels solvants, l'activation du substrat ne se produit pas ($k_1 = 0$, schéma 2). Ni le mécanisme bimoléculaire ni le mécanisme solvolytique ne peuvent être déclenchés.

Dans les solvants plus polaires comme le DMF ou le DMSO, la paire d'ions **3***c* se forme ($k_1 \neq 0$). Selon la température, elle peut réagir selon un mécanisme bimoléculaire (à condition qu'il y ait un sel présent) ou par voie solvolytique. Aux basses températures (vers 50 ou 60°C pour la bromolactone **3***a*) et en l'absence de sel, il n'y a pas de solvolyse, donc $k_S \simeq 0$ et aucune réaction ne se produit malgré l'activation du substrat en paire d'ions **3***c*. À la même température, mais en présence du sel Li^+Y^-, $[Y^-]$ est différent de zéro, et les réactions bimoléculaires apparaissent. Donc k_2 et k'_2 sont différents de zéro à une température où k_S est encore pratiquement nul. Les produits observés dans ces conditions (**3***a* $\xrightarrow{Cl^-}$ **4***b* par exemple), correspondent bien aux critères cinétiques et stéréochimiques d'une réaction bimoléculaire et il faut admettre que le mécanisme bimoléculaire se fait sur la paire d'ions **3***c* et non sur la molécule **3***a* de départ puisqu'il ne se produit pas dans le toluène ou l'acétonitrile.

Toujours dans les solvants polaires, et en l'absence de sel ($[Y^-] = 0$, la voie bimoléculaire est barrée), on peut déclencher les réactions de substitution et d'élimination par la voie solvolytique en augmentant la température (k_S devient alors différent de zéro).

Toutefois la formation du buténolide, à partir de **3***a* par

3. G. Dana et J. Gharbi-Benarous. Travaux non publiés.

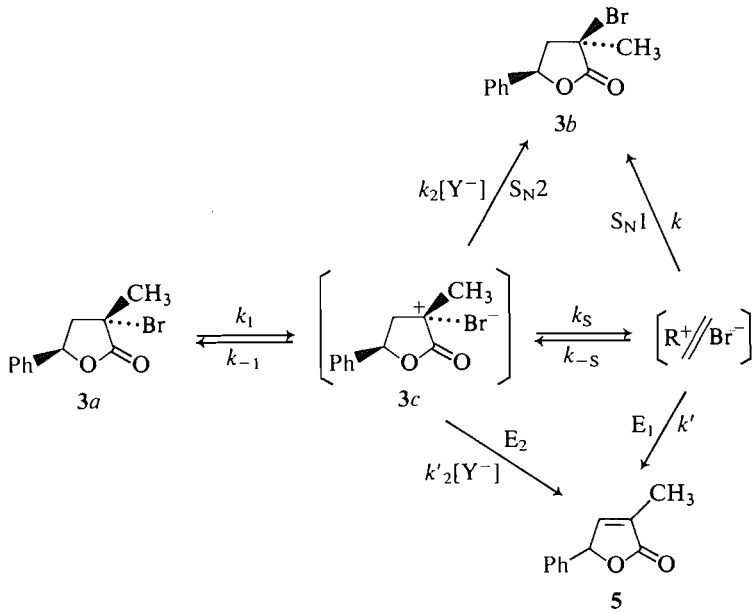


SCHÉMA 2

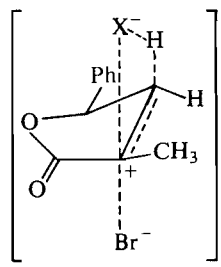
exemple (schéma 2), entraîne la libération d'une quantité équivalente d'ions bromures, et, très rapidement, les mécanismes bimoléculaires entrent en compétition avec la solvolyse et deviennent prépondérants, $k_2[Br^-] \gg k_S$: la paire d'ions **3***c* réagit beaucoup plus vite avec les réactifs nucléophiles qu'avec le solvant. Il suffit qu'il y ait très peu de base Y^- dans le milieu réactionnel pour que cette constante solvolytique soit masquée par les constantes k_2 et k'_2, plus grandes. Dans les expériences de solvolyse (en l'absence de sel), on observe, en effet, qu'après une période d'induction (au cours de laquelle les produits apparaîssent lentement) l'élimination s'accélère de façon considérable, et la réaction prend une allure autocatalytique (tableau 2, expériences 10, 11 et 12) : il se forme plus de buténolide en 4 h entre la 8^e et la 12^e heure (+23%, expériences 11 et 12) qu'en 5 h, entre la 3^e et 8^e heure (+9%, expériences 10 et 11) dans le DMF à 80°C, malgré la diminution de concentration du substrat. Cette solvolyse ne semble pourtant pas produire de carbocation libre puisque nous n'avons jamais mis en évidence de produits de substitution électrophile sur l'anisole ou le toluène, en ajoutant ces réactifs (avec une concentration de 10%) dans le DMF, dans les conditions de la solvolyse. Dans le schéma 2, nous avons donc représenté l'intermédiaire réactionnel de la solvolyse sous forme d'une paire d'ions intersolvatée $R^+//X^-$ (10).

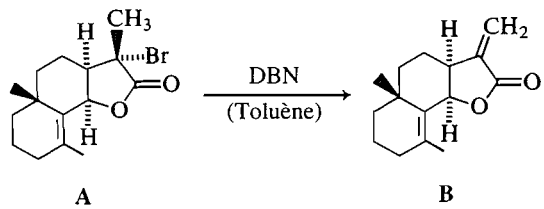
On voit que malgré la simplicité de l'idée de départ (éq. [1]) une étude cinétique précise du schéma 2 n'est pas aisée d'autant plus que l'isomère **3***b* formé à partir de **3***a* va donner lieu aux mêmes réactions que **3***a*, mais avec des constantes de vitesses propres. Ceci explique le point de vue semi-quantitatif adopté dans cette étude dans laquelle nous avons mis en évidence la participation du solvant dans le processus bimoléculaire, au cours d'une étape préliminaire d'activation réversible des halolactones. Cependant le mécanisme du transfert d'hydrogène dans l'état de transition reste à discuter. Compte tenu du faible caractère basique des réactifs nucléophiles Y^- (Cl^- ou Br^-), on peut a priori envisager une approche de type E_2C sur la paire d'ions préformée **3***c* (schéma 3).

Une telle structure de l'état de transition permet de rendre compte de la grande différence de réactivité entre les ions Cl^-, Br^- et I^- pour des raisons évidentes de difficulté d'approche dûe à la présence du méthyle.



3*c*

SCHÉMA 3



A **B**

SCHÉMA 4

De la même façon, les résultats obtenus suggèrent que les règles de Saitzeff contrôlent l'orientation de l'élimination de HBr. En effet, conduisant de préférence aux oléfines les plus substituées (17), un état de transition E_2C privilégie la formation du buténolide **5** par rapport à la méthylène lactone **6**, dont la double liaison est moins substituée (18).

Une orientation exocyclique de l'élimination sur un substrat analogue a été observé (19) pour la méthyl bromolactone **A**. En utilisant le DBN comme réactif, G. Ourisson et coll. ont obtenu la méthylène-lactone **B** correspondante (schéma 4).

Or, une étude sur la réaction d'élimination avec LiBr dans le DMF ou avec le DBN dans le DMF pour les haloesters de type $ArCH_2—CX(R)—COOEt$ (20) a prouvé que l'état de transition avec le DBN est bien du type E_2C sans variation notable de géométrie par rapport à LiBr. En fait dans le cas de la molécule **A**, on ne pouvait escompter d'élimination antipériplanaire de HBr que du côté du méthyle, conduisant obligatoirement à la lactone insaturée exocyclique **B**. La réaction conduite de façon similaire sur notre substrat **3***a*, a donné en 30 min, à 100°C, 40% de buténolide **5** sans apparition de méthylène-lactone **6**.

[a]Le méthyle en 2 donne un singulet fin. Les trois protons H3 et H4 forment un système ABX. Les déplacements chimiques et les couplages affichés sont les valeurs obtenues par ajustement des paramètres (programme PANIC).

NOTA : La discussion des valeurs de ce tableau et l'étude conformationnelle des lactones sera développée dans un prochain mémoire.

Conclusion

En conclusion, on peut dire, pour ce substrat tertiaire, que l'activation de la liaison C—X en α du carbonyle en paire d'ions peut avoir lieu sous l'effet de solvants suffisamment polaires. Elle rend alors possible (avec des nucléophiles faiblement basiques) des mécanismes bimoléculaires S_N2, normalement peu probables sur des substrats tertiaires, et E_2. En l'absence de nucléophile, le mécanisme solvolytique peut intervenir pour le déclenchement de la réaction qui se poursuit alors selon le processus bimoléculaire de façon autocatalytique. On peut noter qu'avec les lactones bromées, cette activation est favorisée par un meilleur groupe partant (Br^- par rapport à Cl^-) et on observe une grande différence de réactivité entre les deux lactones tertiaires, chlorée et bromée (**3***a* et **4***a*).

Signalons enfin, que les deux substrats **3** et **1** présentent le même intérêt préparatif pour les buténolides **5** ou **2**, la réaction d'élimination conduisant dans les deux cas avec des rendements presque quantitatifs à un buténolide pur à partir d'un mélange de lactones bromées stéréoisomères.

Partie expérimentale

Les études spectroscopiques de ce travail et les microanalyses ont été effectuées au Centre de spectrochimie de Paris-Centre.

Les spectres rmn ^{1}H sont enregistrés sur spectrographe Bruker WP-80, en solution dans $CDCl_3$ ou dans C_6D_6; les déplacements chimiques sont exprimés en δ par rapport au tétraméthylsilane utilisé comme référence interne. Les constantes de couplage sont exprimées en hertz.

Les spectres de masse ont été réalisés avec le spectromètre Kratos MS50 et les spectres ir en film liquide à l'état pur ou en pastille KBr, sur un spectrographe Perkin–Elmer modèle 357. Les points de fusion ont été déterminés sur bloc Kofler.

Les différents produits sont purifiés ou séparés par chromatographie en couche mince (ccm) sur silice (gel de silice, Merck 60 PF 254). Le système de solvant utilisé comme éluant est le mélange éther de pétrole – éther (EP:E), et la visualisation est effectuée par uv.

Préparation des bromolactones 3

Elles sont obtenues en trois étapes.

1. On prépare le *méthyl-4 phényl-2 dihydro-2,3 furanne* selon un procédé déjà décrit, par réduction duplicative de l'aldéhyde benzoïque et de l'α-méthyl acroléine, en présence de magnésium et d'acide acétique (2*c*). La deshydratation de l'hydroxytétrahydrofuranne formé par distillation en présence d'un cristal d'iode conduit au DHF correspondant. L'analyse spectroscopique, en particulier la rmn, est en accord avec la description de ce produit déjà publié (2*b*).

2. *Les bromhydrines* sont obtenues quantitativement à partir du dihydrofuranne selon une méthode précédemment utilisée (1, 21). On traite 500 mg de DHF avec 1,1 g de NBS en solution dans le DMSO (10 mL) humide, à froid (bain de glace). On ajoute une solution d'eau bicarbonatée et on extrait à l'éther. Par évaporation du solvant on obtient 810 mg de bromhydrines cristallisées. Les deux bromhydrines stéréoisomères **8***a* et **8***b* sont séparées par ccm (EP:E = 80:20, 2 élutions), R_f (**8***a*) = 0,36 (88%) et R_f (**8***b*) = 0,23 (12%), et cristallisées dans un mélange EP:E = 90:10.

Hydroxy-2β bromo-3α méthyl-3β phényl-5β tétrahydrofuranne (**8***a*), F = 98°C; ir (KBr) : 3300 cm^{-1}; rmn ^{1}H (C_6D_6) : 5,5 (H2α, s), 1,54 (H(Me), s), 2,17 (H4α), 1,82 (H4β), 5,4 (H5α), 7 (H(Ph)), J (H4αH4β) = −14; J (H5H4α) = 5,8; J (H5H4β) = 10,2. *Anal.* calc. pour $C_{11}H_{13}O_2Br$: C 51,36, H 5,06; tr. : C 51,17, H 5,07%.

Hydroxy-2 bromo-3β méthyl-3α phényl-5β tetrahydrofuranne (**8***b*), F = 81°C; ir (KBr) : 3320 cm^{-1}; rmn ^{1}H (C_6D_6) : la bande de R_f = 0,23 correspond à deux isomères en solution (anomérisation au niveau du carbone C2), 5,46 et 4,52 (H2, s), 1,58 et 1,34 (H(Me), s), 2,12 (H4, m), 5,05 et 4,52 (H5α, t), 7,1 (H(Ph)), J (H5H4α) + J (H5H4β) = 14,5 et 16. Le même dédoublement du spectre apparaît dans le chloroforme. *Anal.* calc. pour $C_{11}H_{13}O_2Br$: C 51,36, H 5,06; tr. : C 51,65, H 5,12%.

3. L'oxydation à l'aide du réactif de Jones du mélange brut des bromhydrines (1) (800 mg dans 20 mL d'acétone), refroidi à 0°C, conduit au mélange des deux lactones bromées **3***a* (88%) et **3***b* (12%) cristallisées (782 mg) (dosées par rmn) : rendement 97% par rapport au dihydrofuranne de départ. Les deux bromolactones **3***a* et **3***b* sont séparables par ccm (EP:E = 80:20; R_f (**3***a*) = 0,49, R_f (**3***b*) = 0,26). Ces deux isomères cristallisent dans un mélange EP:E = 90:10.

Bromo-2α méthyl-2β phényl-4β butyrolactone (**3***a*), F = 63°C; ir (KBr) : 1780 cm^{-1}; rmn ^{1}H (C_6D_6) et ($CDCl_3$) : tableau 5. Cet isomère est facilement dosable en rmn, par son proton H4α à 4,94 ppm dans C_6D_6; mass m/e : 254 et 256 ($M^{\ddagger}$). Ce doublet permet au cours de cette étude de discerner sans ambiguité cet isomère **3***a* de son homologue chloré **4***a*. *Anal.* calc. pour $C_{11}H_{11}O_2Br$: C 51,76, H 4,32; tr. : C 51,72, H 4,52%.

Bromo-2β méthyl-2α phényl-4β butyrolactone (**3***b*), F = 61°C; ir (KBr) : 1780 cm^{-1}; rmn ^{1}H (C_6D_6) et ($CDCl_3$) : tableau 5. Cet isomère est dosable (et aisément discernable de **3***a*) en rmn par la position de son proton H4α à 4,53 ppm dans C_6D_6. La différenciation entre **3***b* et le dérivé chloré correspondant **4***b* s'effectue aisément par effet de solvant.

Notons en effet (tableau 5) que la partie AB du système ABX à même aspect pour **3***b* et **4***b* dans C_6D_6, mais se présente de façon très différente dans $CDCl_3$: $\nu_B - \nu_A$ est très petit pour **3***b* (2,8 Hz à 80 MHz) et grand pour **4***b* (16 Hz). En fait, nous avons indiqué un croisement des déplacements chimiques de H3α et H3β entre ces deux solvants. Ce croisement est observé pour un mélange $CDCl_3$–C_6D_6 = 70:30 pour **3***b* et 50:50 pour **4***b* (fig. 1). Masse m/e : 254 et 256 ($M^{\ddagger}$). Ce doublet confirme la présence du brome dans **3***b* par rapport à son homologue chloré **4***b*. *Anal.* calc. pour $C_{11}H_{11}O_2Br$: C 51,76, H 4,32; tr. : C 51,85, H 4,49%.

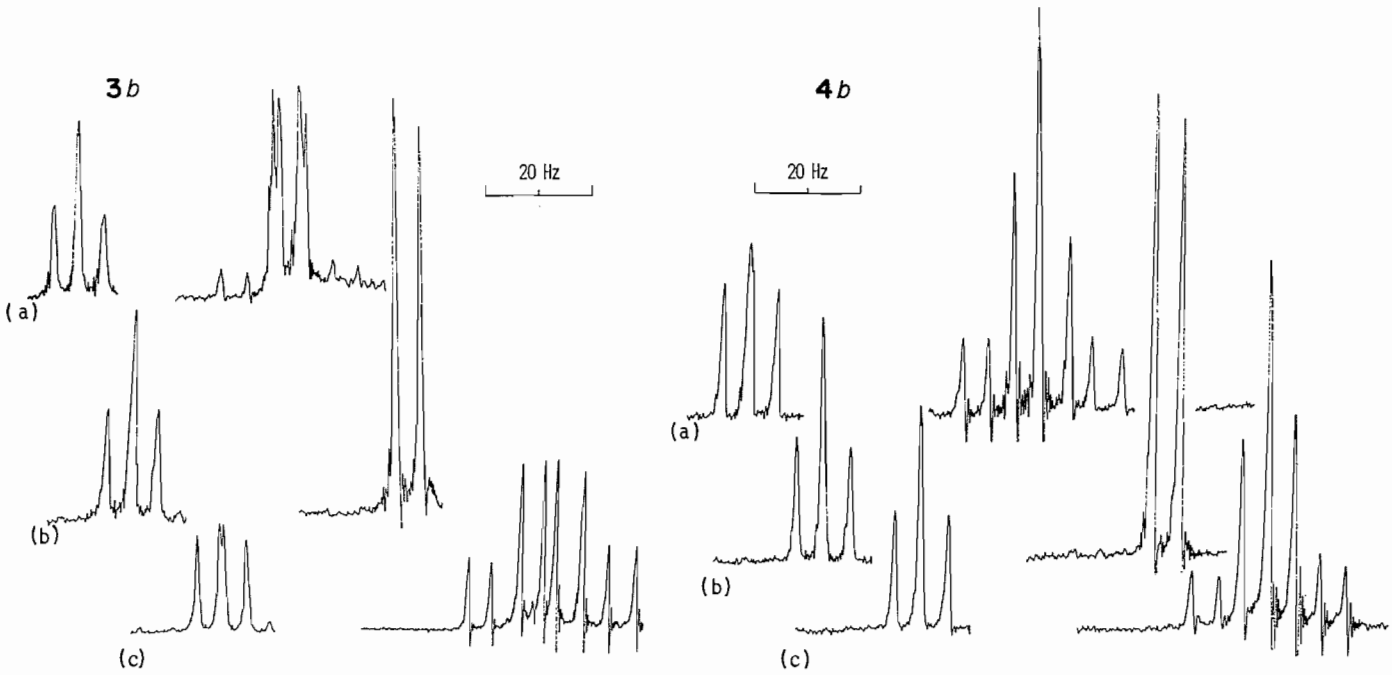

FIG. 1. Croisement des déplacements chimiques des protons H3α et H3β des isomères **3***b* et **4***b* selon le solvant (80 MHz). Aspect du système ABX de **3***b* (a) dans $CDCl_3$: ν_A = 231,10; ν_B = 228,28; ν_X = 432,07 Hz; (b) dans le mélange $CDCl_3$–C_6D_6 = 70:30 : $\nu_{A,B}$ = 211,34; ν_X = 410,12 Hz; (c) dans C_6D_6 : ν_A = 146,69; ν_B = 169,05; ν_X = 362,48 Hz. Aspect du système ABX de **4***b* (a) dans $CDCl_3$: ν_A = 229,65; ν_B = 213,75; ν_X = 426 Hz; (b) dans le mélange $CDCl_3$–C_6D_6 = 50:50 : $\nu_{A,B}$ = 187,75; ν_X = 392 Hz; (c) dans C_6D_6 : ν_A = 156,17; ν_B = 171,83; ν_X = 368 Hz. *N.B.* Le mélange (b) correspond au croisement (système AA′X).

Préparation des chlorolactones **4**

La chloration du phényl-2 méthyl-4 dihydro-2,3 furanne a été effectuée à froid (bain de glace) par le chlore gazeux (22), en atmosphère déchargée d'oxygène par passage préalable d'un courant d'azote. On a utilisé une solution de 1 g du composé dihydrofurannique dilué à 10% dans CCl_4. Le dérivé dichloré formé est directement hydrolysé par simple agitation dans l'eau bicarbonatée pendant 1 h à température ambiante et conduit à l'hémiacétal chloré que l'on extrait à l'éther. L'oxydation du mélange brut (1,26 g) par le réactif de Jones (1) conduit à la chlorolactone **4***a* sous forme d'une huile jaune clair. Une purification par ccm (EP:E = 70:30) nous a permis d'obtenir 706 mg de produit pur : R_f (**4***a*) = 0,46; rendement 54%.

Chloro-2α méthyl-2β phényl-4β butyrolactone (**4***a*), ir : 1775 cm^{-1}; rmn ^1H (C_6D_6) et ($CDCl_3$) : tableau 5. Cet isomère a été dosé au cours de cette étude grâce à son proton H4α (δ = 5,01 ppm, C_6D_6); masse *m/e* : 210 et 212 ($M^{\ddagger}$) (doublet caractéristique d'un produit monochloré). *Anal.* calc. pour $C_{11}H_{11}O_2Cl$: C 62,71, H 5,22; tr. : C 62,83, H 5,32%.

Deshydrohalogénation des halolactones **3** *et* **4**

On opère en milieu anhydre, sous azote, avec 2 équivalents de LiBr (ou LiCl) pour 1 équivalent de bromolactone **3** (ou de chlorolactone **4**). À une solution de 108,5 mg (0,4 mmol) de la bromolactone isomère pur **3***a* (ou 87,5 mg de la chlorolactone **4***a*) dans 8 mL de DMF, on ajoute, sous agitation magnétique, une solution de 72,5 mg de LiBr (0,8 mmol) ou (35,5 mg LiCl) dans 2 mL de DMF. Le mélange est porté à la température de 100 ± 1°C (bain thermostaté) et agité pendant 1 h (3 h pour **4***a*). On laisse alors revenir à température ambiante puis on ajoute 5 mL d'eau avant d'extraire à l'éther. La phase organique est lavée à l'eau puis séchée sur sulfate de sodium. L'éther est alors évaporé sous vide au rotavapor (température du bain : 40°C). Le produit brut est alors analysé par rmn à 80 MHz, puis les différents constituants sont séparés par ccm (EP:E = 60:40), et purifiés. À partir de **3***a*, on obtient 58 mg de buténolide **5**, liquide jaune, R_f (**5**) = 0,35 (rendement 80%), en même temps qu'on récupère 21,5 mg de cristaux de la lactone résiduelle (**3***a*). Signalons que la réaction **3***a* → **5** est totale en 3 h dans les mêmes conditions. Le buténolide **5** est alors isolé pur (68,5 mg) avec un rendement de 94%. À partir de **4***a*, le produit brut obtenu est constitué de trois produits (séparation par ccm, EP:E = 70:30, 2 élutions) : 40 mg de buténolide **5** (rendement 54%), 10 mg de chlorolactone **4***b* (R_f (**4***b*) = 0,23) et 30 mg de l'isomère **4***a* résiduel.

L'étude du comportement de chaque isomère pur **3***a*, **3***b* et **4***a*, **4***b* a été réalisée dans les mêmes conditions (2 équivalents de sels : 35,5 mg de LiCl ou 72,5 mg de LiBr ou 111,5 mg LiI pour 0,4 mmol de lactone), mais à des températures et pour des durées différentes (tableaux 1 et 3).

La proportion des différents constituants des mélanges obtenus est évaluée par un dosage en rmn du proton H4α pour les halolactones isomères : **3***a* ou **4***a*, **3***b* ou **4***b* et du proton H3 pour le buténolide. Leur identification est ensuite confirmée par analyse, par spectrométrie de masse et par effet de solvant en rmn; de même, leur proportion sera confirmée après purification par ccm.

Chloro-2β méthyl-2α phényl-4β butyrolactone **4**b

Cet isomère ne peut être obtenu que par réaction d'isomérisation de la chlorolactone **4***a*; ir (liq.) : 1775 cm^{-1}; rmn ^1H (C_6D_6) et ($CDCl_3$) : tableau 5; dosé dans le mélange réactionnel par la position de H4α (δ = 4,6 ppm, C_6D_6); masse *m/e*: 210 et 212 ($M^{\ddagger}$). *Anal.* calc. pour $C_{11}H_{11}O_2Cl$: C 62,71, H 5,22; tr. : C 62,85, H 5,31%.

Méthyl-2 phényl-4 $\Delta^{2(3)}$ *butyrolactone* (**5**), ir (liq.) : 1775 et 1660 cm^{-1}; rmn ^1H ($CDCl_3$) : 1,90 (H(Me), t), 5,77 (H4, quintuplet), 7,60 (H3, quintuplet), 7,25 (H(Ph)), *J* (H3H(Me)) ≃ *J* (H4H(Me)) ≃ *J* (H3H4) = 1,9 Hz.

Ce produit a déjà été obtenu par d'autres procédés (13, 14). Masse *m/e* : 174 ($M^{\ddagger}$). *Anal.* calc. pour $C_{11}H_{10}O_2$: C 75,86, H 5,74; tr. : C 75,85, H 5,65%.

Elimination par la collidine

On chauffe 100 mg de bromolactone **3***a* (ou chlorolactone **4***a*) dans 10 mL de collidine pendant 3 h (ou 6 h) à 100°C. Le bromhydrate (ou chlorhydrate) de collidine formé est filtré, lavé avec de l'éther anhydre. La collidine restant est diluée dans l'éther et la phase éthérée est très soigneusement lavée par HCl 10% jusqu'à la neutralité (le buténolide est détruit en milieu acide), puis par un peu d'eau. La solution éthérée est séchée sur Na_2SO_4 et évaporée. Le produit brut, dosé par rmn (proton H4α pour les halolactones **3** et **4** et proton H3 pour

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

le buténolide **5**) est constitué principalement du substrat de départ et du buténolide, à partir de la chlorolactone **4***a* (10% **5** + 90% **4***a* en 3 h et 24% **5** + 76% **4***a* en 6 h); mais à partir de **3***a*, on isole de plus son isomère **3***b* (22% **5** + 10% **3***b* + 68% **3***a* en 3 h et 44% **5** + 8% **3***b* + 48% **3***a* en 6 h).

Elimination par le DBN

Une solution de 108,5 mg bromolactone **3***a* (0,4 mmol) dans 4 mL de toluène anhydre est traitée avec 300 mL de DBN (diazo-1,5 bicyclononène) et chauffée à 100°C pendant 30 min sous azote. Après addition d'éther la phase organique est lavée avec une solution froide de HCl à 10% saturée en sel. Toutes les phases aqueuses réunies sont ensuite extraites à l'éther. Les phases organiques séchées sur sulfate de sodium, évaporées sous vide, fournissent après séparation sur silice, 30 mg du buténolide **5** (rendement : 40%).

Treatment of nitrones (**1***a–d*, **26***a,b*, **34**, **49**) with potassium in tetrahydrofuran (THF) gives rise to radical anion (**2***a–d*, **27***a,b*, **35**, **50**) and dianion intermediates (**3***a–d*, **28***a,b*, **36**) through electron transfer reactions. These intermediates undergo further transformations to give a variety of products. Thus, the aldehydonitrones (**1***a–d*) give the corresponding aldehydes (**10***a–c*), carboxylic acids (**25***a–c*), and azobenzenes (**19***a,d*), whereas the ketonitrones (**26***a,b*) give deoxygenation products (**31***a,b*). The nitrone **34** gave a mixture of products consisting of benzoic acid (**25***a*), dibenzyl (**48**), the dimeric product **38**, and tetraphenylpyrazine (**46**), whereas **49** did not give any isolable product. Cyclic voltammetric studies have been employed to measure the reduction potentials for both one-electron and two-electron transfer processes, leading to the radical anions and dianions respectively. These intermediates have been characterized through their electronic spectra and they were quenched by oxygen. Pulse radiolysis of the nitrones **1***a–d*, **26***a,b*, **34**, and **49** also gave the corresponding radical anions **2***a–d*, **27***a,b*, **35**, and **50**, characterized by their spectra.

KONDA ASHOK, PALLIKKAPARAMBIL M. SCARIA, PRASHANT V. KAMAT et MANAPURATHU V. GEORGE. Can. J. Chem. **65**, 2039 (1987).

La réaction des nitrones **1***a–d*, **26***a,b*, **34** et **49** avec le potassium dans le tétrahydrofuranne (THF) conduit, grâce à des réactions de transfert d'électrons, aux radicaux anions **2***a–d*, **27***a,b*, **35** et **50** et aux intermédiaires dianioniques **3***a–d*, **28***a,b* et **36**. Ces intermédiaires subissent d'autres transformations qui donnent lieu à la formation de plusieurs autres produits. Ainsi, les aldéhydonitrones **1***a,d* conduisent aux aldéhydes **10***a–c*, aux acides carboxyliques **25***a–c* et aux azobenzènes **19***a,d* correspondants; par ailleurs, les cétonitrones **26***a,b* conduisent aux produits de déoxygénation **31***a,b*. La nitrone **34** conduit à un mélange de produits qui est formé d'acide benzoïque (**25***a*), de dibenzyle (**48**), du produit dimère **38** et de tétraphénylpyrazine (**46**); par ailleurs, avec le composé **49**, on ne peut isoler aucune produit. On a utilisé des études de voltammétrie cyclique pour mesurer les potentiels de réduction des processus de transfert, tant à un qu'à deux électrons, qui conduisent respectivement à la formation des radicaux anions et dianions. On a caractérisé ces intermédiares grâce à leurs spectres électroniques et on les a piégés avec de l'oxygène. La radiolyse pulsée des nitrones **1***a–d*, **26***a,b*, **34** et **49** conduit aussi aux radicaux anions correspondants **2***a–d*, **27***a,b*, **35** et **50** que l'on a caractérisé par leurs spectres.

[Traduit par la revue]

Introduction

Alkali metals are known to add to unsaturated organic substrates, giving rise to radical anion and dianion intermediates through electron transfer reactions (for some pertinent reviews, see ref. 1). These intermediates, in turn, can undergo a variety of reactions that include disproportionation, fragmentation, dimerization, oxidation, and rearrangements. Also, these intermediates are very susceptible to air oxidation, which results in a variety of oxidative products.

Of the different organic substrates, nitrones have been of particular interest in view of the deoxygenation reactions, which are reported to occur in presence of metals and other reagents (2–5). Only very few examples of the reaction of alkali metals with nitrones have been reported so far (6–8). The reaction of α,*N*-diphenylnitrone (**1***a*) with sodium in ethanol, for example, has been reported to give *N*-benzylamine, the reduction product. The object of the present investigation has been to examine the potassium-induced transformations of a few representative nitrones, with a view to studying the nature of products formed in these reactions and also to understanding the mechanism of these transformations.

Results and discussion

In the present studies, we have examined the reactions of α,*N*-diphenylnitrone (**1***a*), α,*o*-hydroxyphenyl-*N*-phenylnitrone (**1***b*), *N*-phenyl-α-*p*-tolylnitrone (**1***c*), α-phenyl-*N*-*p*-tolylnitrone (**1***d*), triphenylnitrone (**26***a*), α-diphenylene-*N*-phenylnitrone (**26***b*), *N*-benzyl-α-phenylnitrone (**34**), and 1,1,3-triphenylisoindole-*N*-oxide (**49**) with potassium in THF.

The reaction of **1***a* with potassium in THF, for example, gave a mixture of *trans*-stilbene (**13***a*, 8%), *trans*-azobenzene (**19***a*, 82%), benzaldehyde (**10***a*, 42%), and benzoic acid (**25***a*, 47%). The reaction of **1***b* under analogous conditions gave a mixture of **19***a* (58%), salicylaldehyde (**10***b*, 25%), and salicyclic acid (**25***b*, 30%), along with a 20% recovery of the starting material (**1***b*). When the reaction of **1***b*, however, was carried out in presence of excess of potassium (four equivalents), better yields of **19***a* (69%), **10***b* (37%), and **25***b* (45%) were obtained. Similarly, the reaction of **1***c* with potassium in THF gave a

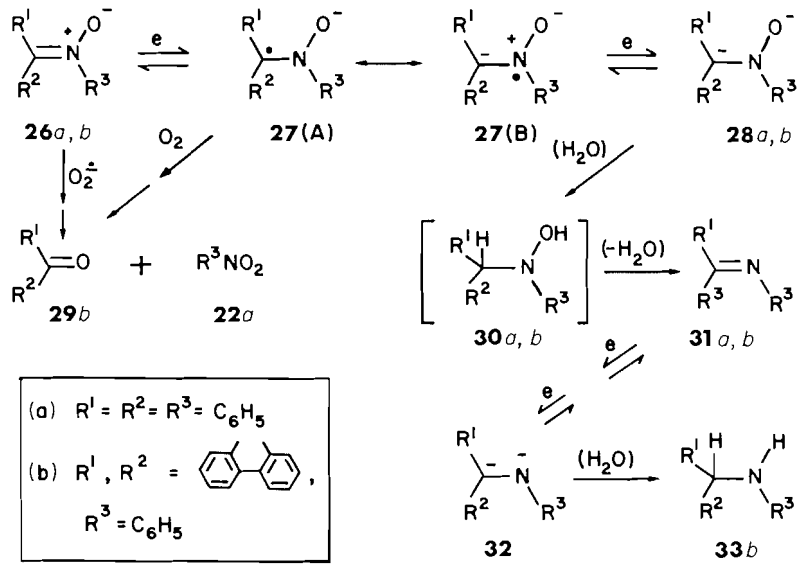
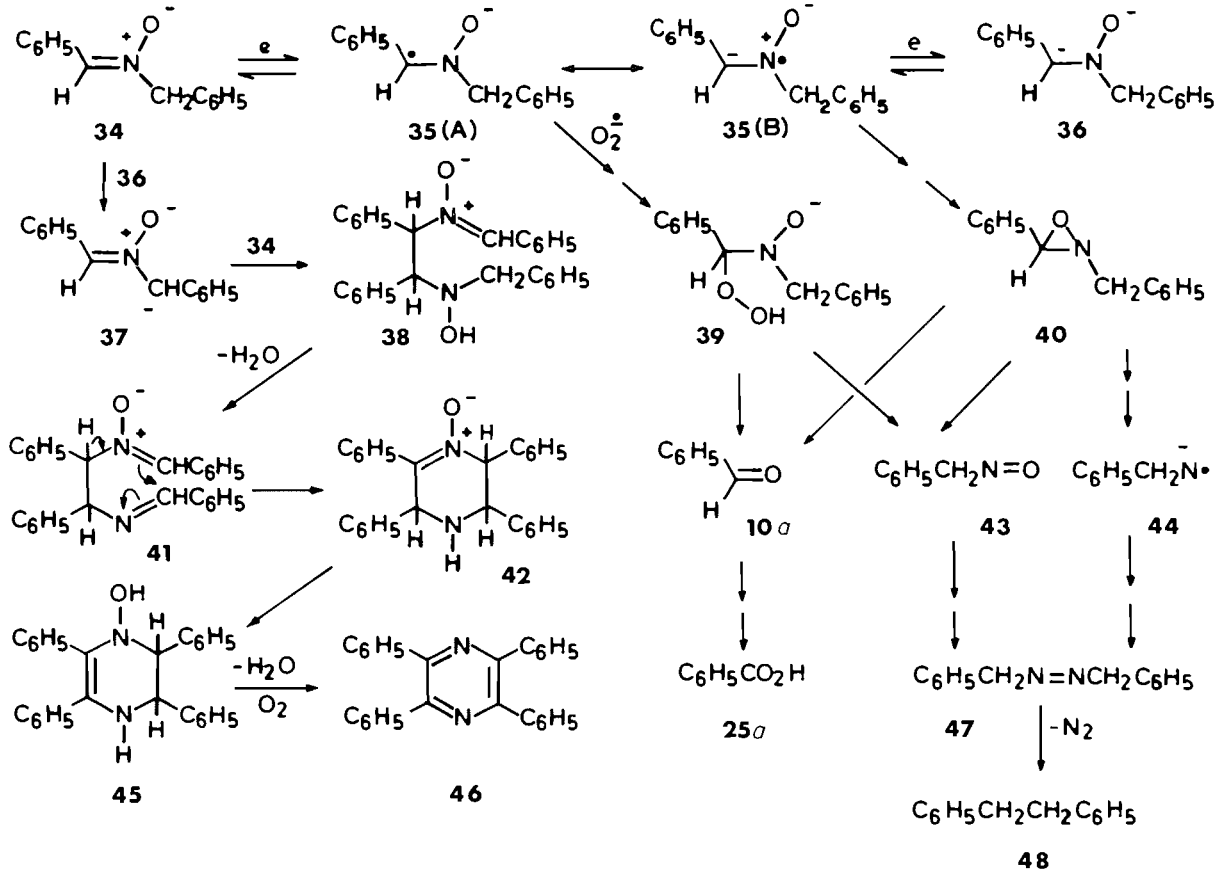


SCHEME 2

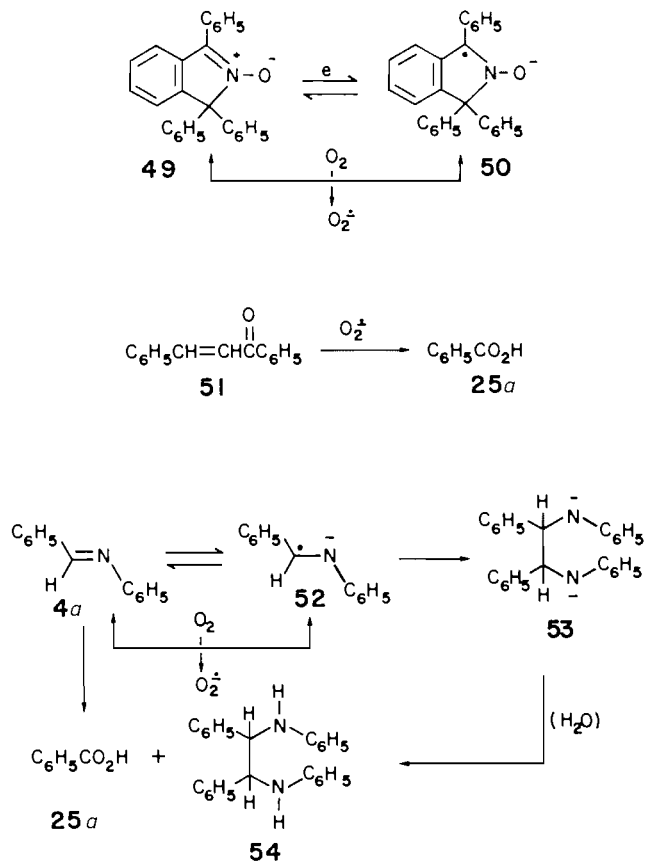
mixture of *trans*-1,2-di-*p*-tolylethylene (**13***c*, 6%), **19***a* (80%), *p*-tolualdehyde (**10***c*, 40%), and *p*-toluic acid (**25***c*, 44%), whereas **1***d* under similar conditions gave a mixture of **13***a* (4%), *trans*-*p*-azotoluene (**19***d*, 88%), **10***a* (40%), and **25***a* (49%) (Scheme 1). In contrast to the reactions of **1***a–d*, the reaction of triphenylnitrone (**26***a*) with potassium in THF gave benzhydrylidene aniline (**31***a*, 81%) (Scheme 2). Similarly, the reaction of **26***b* under analogous conditions gave an 81% yield of 9-fluorenylidene aniline (**31***b*). When the reaction of **26***b*, however, was carried out in presence of excess of potassium (four equivalents), a mixture of **31***b* (71%) and 9-anilinofluorene (**33***b*, 8%) was obtained. On the other hand, the reaction of *N*-benzyl-α-phenylnitrone (**34**) with potassium in THF gave a mixture of benzoic acid (**25***a*, 18%), *N*-(2-



SCHEME 3

benzylhydroxylamino-1,2-diphenylethano)-α-phenylnitrone (**38**, 21%), dibenzyl (**48**, 18%), and 2,3,5,6-tetraphenylpyrazine (**46**, 17%), along with an 8% recovery of the unchanged starting material (**34**) (Scheme 3). The reaction of 1,1,3-triphenylisoindole-*N*-oxide (**49**) with potassium in THF, however, did not lead to any isolable product; most of the starting material (**49**) could be recovered unchanged (69%) (Scheme 4).

The formation of the different products in the reaction of the aldehydonitrones **1***a–d* with potassium can be understood in terms of the reaction pathway shown in Scheme 1.[4] It is assumed that the initial step in the reaction of **1***a–d* with potassium is an electron transfer reaction, leading to the radical anion intermediate **2***a–d*[5] which, in turn, can accept a second electron to give the dianion intermediate **3***a–d*, depending on the ease with which **2** can be converted to **3**. These dianion intermediates (**3***a–d*) could lead to deoxygenated Schiff bases **4***a–d* or products derived from them. To examine the involvement of such Schiff bases **4***a–d* or their further transformation products in these reactions, we have examined the reaction of *N*-benzylideneaniline (**4***a*) with potassium in THF. Treatment of **4***a* with excess of potassium in THF under analogous conditions gave a mixture of benzoic acid (**25***a*, 28%) and *d,l-N,N'*-1,2-tetraphenylethylenediamine (**54**, 55%) (Scheme 4). The fact that we have not been able to isolate the ethylenediamines (**54**) in the reaction of **1***a–d* would indirectly



SCHEME 4

[4]The reactions are quite complex and other plausible pathways for the formation of some of the products cannot be excluded.

[5]Several resonance structures can be written for the intermediate radical anion **2**. Two of these structures, **2**(A) and **2**(B) are indicated here.

rule out the involvement of the corresponding Schiff bases **4***a–d* in these reactions.

A second possible mode of reaction of **2***a–d*, although not very likely under our reaction conditions, is its interaction with adventitious oxygen[6] to give back the starting nitrone **1***a–d* and potassium superoxide. Several examples of superoxide formation by electron transfer to oxygen from radical anions and also by electrochemical methods are reported in the literature (9). Subsequent reaction of superoxide with **1***a–d* or **2***a–d* will lead to the hydroperoxy intermediate **5**, which can fragment to the aldehyde **10***a–c* and the nitroso compound **11***a,d*. Further reaction of the aldehyde **10***a–c* with potassium will give the radical anion **15** and the dianion **20**, which can ultimately lead to the corresponding carboxylic acid **25***a–c*. The nitroso compound **11***a,d* in the presence of excess of potassium will lead to the azo compound **19***a,d*, or in the presence of excess of oxygen give the corresponding nitro compound **22**. It may be mentioned in this connection that nitrosobenzene, formed as an intermediate in the reaction of nitrobenzene with lithium in THF, is converted to azobenzene in the presence of excess of lithium (10).

A more likely pathway for the reaction of **2***a–d* would be its conversion to the oxaziridine **6**, which can fragment to give the nitroso compound **11***a,d* and the carbene **12**. The formation of small amounts of *trans*-stilbene (**13***a*) from **1***a* and *trans*-1,2-di-*p*-tolylethylene (**13***c*) from **1***c* can be explained in terms of the dimerization of **12**. The oxaziridine **6** can also react further with potassium to give the radical anion **7** and the dianion **8** and ultimately products derived from them. Fragmentation of **7** can lead to the intermediate **14** and the aldehyde **10***a–c*. Further transformations of **14** will ultimately give rise to the azo compound **19***a,d*.

To examine whether or not the involvement of oxygen in the reaction of **2***a–d*, as implicated earlier (Scheme 1), can be justified, we have carried out, in a separate experiment, the reaction of **1***a* with potassium in THF that has been previously saturated with oxygen. The reaction of **1***a*, under these conditions, gave a mixture of *trans*-stilbene (**13***a*, 8%), benzaldehyde (**10***a*, 38%), benzoic acid (**25***a*, 47%), and nitrobenzene (**22***a*, 72%). The fact that there is no appreciable difference in the yields of benzaldehyde (**10***a*) and benzoic acid (**25***a*), when the reaction of **1***a* with potassium is carried out in the absence and in the presence of oxygen, would suggest that the pathway involving the hydroperoxy intermediate **5** in Scheme 1 is not justified. Perhaps the more likely pathway involves the oxaziridine **6**, as stated earlier. The high yield of nitrobenzene (**22***a*) in the reaction of **1***a* with potassium in presence of oxygen would suggest that it is formed from nitrosobenzene (**11***a*) or other precursors such as **7**, **8**, and **14** through their reaction with oxygen.

To examine the type of products encountered in the reaction of the nitrones **1***a–d* with potassium superoxide, we have treated **1***a* with potassium superoxide in benzene containing 18-crown-6 at room temperature, obtaining a mixture of **25***a* (82%) and **22***a* (89%). The formation of both **25***a* and **22***a* in this reaction could be accounted for in terms of the **5** and its subsequent fragmentation to **10***a* and **11***a*. Further reaction of **10***a* and **11***a* with potassium superoxide will give **25***a* and **22***a*, respectively[7] (11). In a separate experiment, we have shown that nitrosobenzene (**11***a*) actually undergoes oxidation to nitrobenzene (**22***a*, 61%) on treatment with potassium superoxide in benzene, justifying our assumption that **11***a*, formed through the fragmentation of **5**, is being converted to **22***a*.

In Scheme 1, we have indicated the involvement of several radical anion and dianion intermediates in the transformation of the nitrones **1***a–d* to the observed products, on treatment with potassium in THF. In an attempt to intercept some of these intermediates, we have treated the reaction mixture from **1***a* and potassium in THF, before work-up, in separate experiments, with moist THF and benzoyl chloride respectively. Treatment of the reaction mixture from **1***a* with moist THF before work-up gave a mixture of **13***a* (7%), **19***a* (78%), **10***a* (32%), **25***a* (25%), and benzyl alcohol (**23***a*, 25%). The formation of **23***a* under these conditions would suggest the involvement of the dianion intermediate **20** in the transformations of **10***a* to **25***a*. Further, it is to be inferred that the dianion **20** is converted to the hydroperoxy anion **21**, a possible precursor of **25***a*, during work-up, through its reaction with oxygen. This fact is further confirmed by the observation that the reaction of **10***a* with potassium in THF, followed by treatment with moist THF, in a separate experiment, gave a mixture of benzyl alcohol (**23***a*, 46%) and benzoic acid (**25***a*, 41%). In contrast, the reaction of **10***a* with potassium in THF, followed by the usual work-up procedure employed in the case of the nitrones **1***a–d*, gave a 75% yield of **25***a*. It is therefore to be inferred that under the conditions of work-up, which involve exposure of the reaction mixture from **10***a* (or **1***a*) to air, most of the dianion **20** is converted to the hydroperoxy intermediate **21** and ultimately to **25***a*. This is further substantiated by the observation that the reaction of **10***a* with potassium in THF, saturated with oxygen, gave a 77% yield of **25***a*.

When the reaction mixture from **1***a* (after treatment with potassium in THF) was treated with benzoyl chloride, a mixture of *trans*-stilbene (**13***a*, 6%), *trans*-azobenzene (**19***a*, 75%), benzaldehyde (**10***a*, 39%), benzoic acid (**25***a*, 5%), benzoic anhydride (**24**, 50%), and benzanilide (**9**, 17%) was obtained. The formation of **24** in this reaction can be explained in terms of the reaction of the intermediates **20** and **21** with benzoyl chloride. In support of this view, it has been observed that treatment of the reaction mixture obtained from the reaction of benzaldehyde (**10***a*) with potassium in THF with benzoyl chloride, in a separate experiment, gave a 81% yield of benzoic anhydride (**24**). The fact that some benzaldehyde (**10***a*) could be isolated from the reaction of **1***a* with potassium in THF, followed by treatment with benzoyl chloride, would suggest that all of **10***a* is not converted to **20** and, ultimately, to other products under our reaction conditions. The formation of small amounts of benzanilide (**9**) in this reaction, however, can be rationalized in terms of the reaction of the dianion intermediate **8** with benzoyl chloride. This would suggest that in the reaction of **1***a* with potassium in THF, at least part of the reaction proceeds through **6** → **7** → **8** (Scheme 1).

In contrast to the reactions of the aldehydonitrones **1***a–d*, the ketonitrones **26***a* and **26***b* with potassium give mostly the deoxygenated products **31***a* and **31***b*, respectively. It is evident that in these cases, the reaction pathway involving the dianion intermediates **28***a,b* becomes important. These dianions, under the conditions of work-up, could be converted to the *N*-hydroxy

[6]Although THF, freshly distilled over sodium, has been employed for these reactions, it has not been possible to completely exclude oxygen under our experimental conditions, which involved shaking the reagents in a stoppered flask for several hours.

[7]For some recent reviews on the chemistry of superoxide, see ref. 11.

For personal use only.

derivatives **30***a*,*b*, which will then undergo dehydration to give the Schiff bases **31***a*,*b* (Scheme 2). This difference in behavior between the aldehydonitrones (**1***a*–*d*) and ketonitrones (**26***a*,*b*) could in part be due to the greater stability of the dianions **28***a*,*b* and also due to the difficulty of forming oxaziridines from the radical anions **27***a*,*b*. It may be pointed out that in the reaction of **26***b* with potassium in oxygen-saturated THF, under conditions analogous to those of the aldehydonitrone **1***a*, only a small amount of fluorenone (**29***b*, 28%) could be isolated; nearly 65% of the unchanged starting material (**26***b*) could be recovered from this reaction. However, when the reaction of **26***b* was carried out in presence of potassium superoxide in benzene containing 18-crown-6, fluorenone (**29***b*) could be obtained in better yields. Thus, the treatment of **26***b* with excess of potassium superoxide in a mixture of benzene and 18-crown-6 for 42 h at room temperature gave a 78% yield of **29***b* and a 24% yield of nitrobenzene (**22***a*), in addition to the recovery of a small amount (19%) of the starting material (**26***b*).

The formation of a small amount of 9-anilinofluorene (**33***b*, 8%), besides the major product **31***b* (71%), in the reaction of **26***b* with excess of potassium could be understood in terms of the further reaction of **31***b* with potassium to give the corresponding dianion intermediate **32***b*, which under the conditions of work-up will lead to **33***b*. In support of this view, it has been observed that treatment of **31***b* with potassium in THF under analogous conditions gave a 73% yield of 9-anilinofluorene (**33***b*), along with a 10% recovery of the starting material, **26***b*.

The formation of the different products such as benzoic acid (**25***a*), dibenzyl (**48**), the nitrone **38**, and the tetraphenylpyrazine **46** in the reaction of **34** with potassium in THF could be understood in terms of the reaction pathway shown in Scheme 3. The oxaziridine **40**, formed from the radical anion intermediate **35**, could fragment to benzaldehyde **10***a* and the nitroso compound **43**. Further reaction of **10***a* will lead to benzoic acid **25***a*, whereas the subsequent reaction of **43** with potassium would give the corresponding azo compound **47**. Nitrogen loss from either **47** or one of its precursors involving intermediates **40** and **44** could give dibenzyl (**48**). The formation of the nitrone **38** and tetraphenylpyrazine (**46**), however, could be rationalized in terms of the anionic intermediate **37**, which may be formed through the abstraction of one of the benzylic protons by superoxide anion or any other base (**36**). This anionic species **37** can combine with the starting nitrone **34** to give **38**. In this connection it may be pointed out that **38** has been reported to be formed in moderate yields, on treatment of **34** with lithium dimsylate (12). Subsequent transformations of **38**, involving the loss of two molecules of water and air oxidation, will ultimately give **46**, as shown in Scheme 3.

In contrast to the reaction of the aldehydonitrones, **1***a*–*d* and ketonitrones, **26***a*,*b*, the reaction of 1,1,3-triphenylisoindole-*N*-oxide (**49**) with potassium in THF did not give rise to any product. It is assumed that **49** initially accepts an electron from potassium to give the radical anion intermediate **50** (as evidenced by color changes), which then reverts to the starting material, on exposure to air, under work-up conditions. To substantiate this view we have, in a separate experiment, bubbled oxygen gas through the reaction mixture obtained by the treatment of **49** with potassium in THF and subsequently treated this mixture with benzalacetophenone (**51**) to give a 70% yield of benzoic acid (**25***a*) and 69% yield of the unchanged starting material (**49**). This clearly shows that the superoxide, generated on reaction of **49** with oxygen, reacts with **51** to give benzoic acid. Mention may be made in this connection that **51** is known to undergo oxidation with potassium superoxide to give benzoic acid (13). The absence of any reaction product, other than the generation of **50**, in the reaction of **49** with potassium would imply the nonreactivity of superoxide with the starting nitrone **49**. This is supported by the observation that the reaction of **49** with potassium superoxide in benzene in presence of 18-crown-6, under conditions analogous to the oxidation of **1***a* and **26***b*, did not give rise to any product; most of the starting material (**49**, 69%) was recovered unchanged.

Cyclic voltammetric studies

It has been reported earlier that aromatic amine *N*-oxides undergo electrochemical reduction to give the corresponding radical anions (14, 15). To examine whether the radical anions **2***a*–*d*, **27***a*,*b*, **35**, and **50** and the dianions **3***a*–*d*, **28***a*,*b*, and **36** are actually involved in the reaction of the starting nitrones **1***a*–*d*, **26***a*,*b*, **34**,and **49** with potassium, an attempt was made to generate these reactive intermediates electrochemically and to characterize them through their reduction potentials and electronic spectra. In this connection, we have recorded the cyclic voltammograms of the nitrones **1***a*–*d*, **26***a*,*b*, **34**, and **49**, and Fig. 1 shows the cyclic voltammograms of three representative nitrones **1***a*, **34**, and **49**. The values for the peak potential for the one-electron (E_p^1) and two-electron (E_p^2) reductions for these quasi-reversible systems were evaluated and are listed in Table 1. It is pertinent to observe that in the cathodic sweep cyclic voltammograms of all the nitrones except **49**, the backward sweep waves, which should correspond to the oxidation of the dianions and radical anions, were not observed. In the case of **49**, however, the backward sweep corresponding to the one-electron redox system could be observed, suggesting thereby that the radical anion **50** and its oxidation are fully reversible.

To characterize the radical anions and dianions generated from the nitrones **1***a*–*d*, **26***a*,*b*, **34**, and **49**, we have electrochemically reduced these substrates in acetonitrile in a specially designed cell, applying the requisite potentials in each case, and have recorded their electronic spectra. The spectral details are summarized in Table 1. Examination of Table 1 reveals that the starting nitrones are characterized by an absorption maximum around 298–353 nm, whereas the corresponding radical anions showed a red shifted absorption maximum around 320–450 nm; the corresponding dianions, however, showed an absorption maximum around 280–295 nm. These observations are in tune with the spectral data reported for the radical anions and dianions derived from azobenzene and nitroaromatics through their reaction with lithium in THF (17–19). An interesting observation was that the radical anions **2***a*–*d*, **27***a*,*b*, **35**, and **50** and the dianions **3***a*–*d*, **28***a*,*b*, and **36** were quenched by oxygen, as evidenced by the disappearance of their absorption bands, on bubbling oxygen gas through their solutions in acetonitrile. It is likely that they react with oxygen to give superoxide anion, as implicated in Schemes 1–4.

Pulse radiolysis studies

Earlier studies from this laboratory have shown that radical anions of unsaturated substrates such as retinal polyenes, for example, can be generated through the attachment of the solvated electron e_{sol}^- in polar solvents such as methanol under pulse radiolysis conditions (16). In the present studies, we have observed that the nitrones **1***a*–*d*, **26***a*,*b*, **34**, and **49** undergo electron attachment in methanol to give the corresponding radical anions **2***a*–*d*, **27***a*,*b*, **35**, and **50**, respectively, characterized through their absorption spectra (Fig. 2). These radical

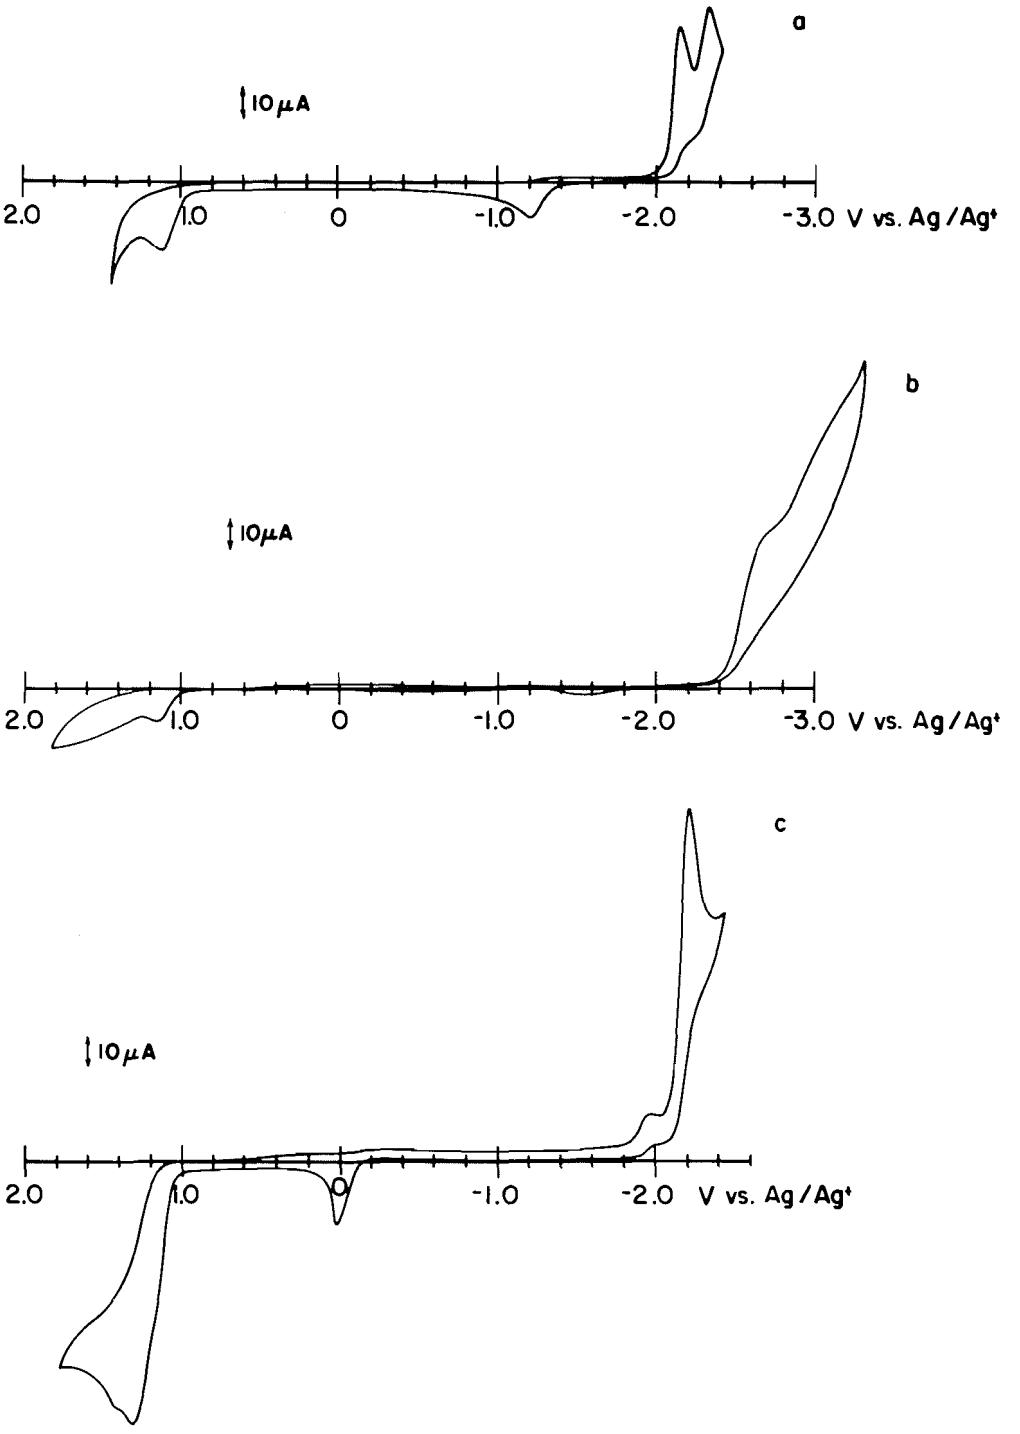

FIG. 1. Cyclic voltammograms of **1***a* (a), **34** (b), and **49** (c) in acetonitrile containing 0.1 *M* tetrabutylammonium perchlorate (TBAP). Sweep rate was 100 mV/s. Working electrode was Pt microelectrode and reference electrode was Ag/Ag^+.

anions showed strong absorption maxima in the 320–450 nm region, similar to the transients formed under electrochemical conditions, and were quenched by oxygen, as evidenced by their enhanced decay at higher concentrations of oxygen. The close similarity in the spectra of the intermediates, generated under both electrochemical and pulse radiolysis conditions, justifies our assumption that radical anions are the primary intermediates formed through electron transfer processes in the reaction of nitrones with potassium.

Experimental

All melting points are uncorrected and were determined on a Mel-Temp melting point apparatus. The ir spectra were recorded on Perkin–Elmer Model 377 or Model 580 infrared spectrophotometers. The electronic spectra were recorded on Cary 17D, Cary 219, or Beckman DB spectrophotometers. The nmr traces were recorded on a Varian EM-390 spectrometer using TMS as internal standard.

Starting materials

α,*N*-Diphenylnitrone (**1***a*) (20), mp 112–113°C; α,*o*-hydroxy-

[a]Both radical anions and dianions were stable under nitrogen atmosphere during the recording of the spectra.
[b]Measured from pulse radiolysis experiments (solvent methanol).
[c]Measured from electrochemical experiments (solvent acetonitrile, 0.1 *M* TBAP).
[d]At the absorption maximum (error ±25%).
[e]Measurements could not be made due to the absorption of the starting nitrone.

phenyl-*N*-phenylnitrone (**1***b*) (21), mp 115°C; *N*-phenyl-α-*p*-tolylnitrone (**1***c*) (22), mp 92–93°C; α-phenyl-*N*-*p*-tolylnitrone (**1***d*) (6), mp 123°C; triphenylnitrone (**26***a*) (3), mp 217–218°C; α-diphenylene-*N*-phenylnitrone (**26***b*) (23), mp 191–192°C; *N*-benzyl-α-phenylnitrone (**34**) (24), mp 82–83°C; 1,1,3-triphenylisoindole-*N*-oxide (**49**) (25), mp 198°C; *N*-benzylideneaniline (**4***a*) (26), mp 89°C; and 9-fluorenylideneaniline (**31***b*) (27), mp 89°C were prepared by reported procedures. Petroleum ether used was the fraction with bp 60–80°C. Gold Label acetonitrile was used for cyclic voltammetric studies.

*Reaction of nitrones (**1**a–d, **26**a,b) with potassium in THF*

A general procedure was to shake a mixture of 3 mmol of the appropriate nitrone (**1***a–d*, **26***a,b*) and finely cut potassium (6 mg-atom) in THF (125 mL) in a stoppered round-bottomed flask for several hours. A few clean, broken glass pieces were added to the mixture to ensure a fresh surface of metal throughout the reaction. In general, the reaction mixture underwent pronounced color changes due to the formation of radical anion and dianion intermediates. On completion of the reaction, the mixture was poured into moist THF (100 mL) to destroy any unchanged potassium and then the solvent was removed under vacuum to give a residual solid. This material was treated with water (10 mL) and extracted with methylene chloride (100 mL). Acidification of the aqueous layer with dilute hydrochloric acid and extraction with methylene chloride (100 mL) gave the carboxylic acid fraction, which was recrystallized from suitable solvents.

Work-up of the nonaqueous fraction (methylene chloride extract), by removal of the solvent under vacuum and fractional crystallization from suitable solvents, gave the nonacidic products.

*Reaction of **1**a*

Treatment of 590 mg (3 mmol) of **1***a* with potassium (235 mg, 6 mg-atom) in THF for 16 h and work-up in the usual manner gave 170 mg (47%) of benzoic acid (**25***a*), mp 121°C (mixture melting point). The non-aqueous fraction (methylene chloride extract) was worked up by removal of the solvent under vacuum and chromatographing over alumina. Elution with petroleum ether gave 20 mg (8%) of *trans*-stilbene (**13***a*), mp 124°C (mixture melting point). Further elution with a mixture (1:4) of benzene and petroleum ether gave 220 mg (82%) of *trans*-azobenzene (**19***a*), mp 68°C (mixture melting point). Subsequent elution with a mixture (1:1) of benzene and petroleum ether gave 130 mg (42%) of benzaldehyde (**10***a*) (superimposable ir spectrum with that of an authentic sample). Treatment of **1***a* (1.77 g, 9 mmol) with potassium (0.7 g, 18 mg-atom) in THF (triply distilled over sodium) for 16 h, under complete exclusion of oxygen (positive nitrogen pressure), and work-up as in the earlier case gave a mixture of **25***a*, **13***a*, **19***a*, and **10***a* in 48, 9, 81, and 40% yields, respectively.

In a repeat run, **1***a* (590 mg, 3 mmol) was treated with potassium (235 mg, 6 mg-atom) in THF (125 mL), saturated with oxygen, for 16 h. Work-up as in the earlier case gave 170 mg (47%) of benzoic acid (**25***a*), mp 121°C (mixture melting point), from the aqueous fraction. The nonaqueous fraction was chromatographed over alumina and eluted with petroleum ether to give 20 mg (8%) of **13***a*, mp 124°C (mixture melting point). Further elution with a mixture (1:9) of benzene and petroleum ether gave 260 mg (70%) of nitrobenzene (**22***a*) (superimposable ir spectrum with that of an authentic sample). Subsequent elution with a mixture (1:1) of benzene and petroleum ether gave 120 mg (38%) of benzaldehyde (**10***a*) (superimposable ir spectrum with that of an authentic sample). In a repeat experiment, the same amount of **1***a* (3 mmol) was treated with potassium (6 mg-atom) in oxygen-saturated THF for 16 h, under identical conditions, and worked up to give a mixture of **25***a*, **13***a*, **22***a*, and **10***a* in 53, 8, 73 and 38% yields, respectively.

In yet another run, **1***a* (590 mg, 3 mmol) was treated with potassium (235 mg, 6 mg-atom) in THF (125 mL) for 16 h. Moist THF (25 mL) was injected into the reaction mixture and the shaking was continued for an additional 5 h. Work-up of the mixture as in the earlier cases gave 90 mg (25%) of benzoic acid (**25***a*), mp 121°C (mixture melting point); 19 mg (7%) of **13***a*, mp 124°C (mixture melting point); 210 mg (78%) of *trans*-azobenzene (**19***a*), mp 68°C (mixture melting point); 80 mg (25%) of benzyl alcohol (**23***a*) (superimposable ir with that of an authentic sample); and 100 mg (32%) of benzaldehyde (**10***a*) (superimposable ir with that of an authentic sample). In a repeat run, **1***a* (3 mmol) was treated with potassium (6 mg-atom) in THF (triply distilled over sodium) for 16 h under the complete exclusion of oxygen (positive nitrogen pressure) and worked up as in the earlier case by treatment with moist THF to give a mixture of **25***a*, **13***a*, **19***a*, **23***a*, and **10***a* in 25, 8, 82, 30, and 29% yields, respectively.

In another run, **1***a* (590 mg, 3 mmol) was treated with potassium (235 mg, 6 mg-atom) in THF (125 mL) for 16 h. A solution of benzoyl chloride (425 mg, 3 mmol) in THF (25 mL) was injected into the reaction vessel and the shaking was continued for an additional 5 h. Work-up of the mixture in the usual manner gave 18 mg (5%) of benzoic acid (**25***a*), mp 121°C (mixture melting point), from the aqueous fraction. The nonaqueous fraction was chromatographed over alumina. Elution with petroleum ether gave 15 mg (6%) of **13***a*, mp 124°C (mixture melting point). Further elution with a mixture (1:9) of benzene and petroleum ether gave 200 mg (75%) of **19***a*, mp 68°C (mixture melting point). Subsequent elution with a mixture (3:7) of

For personal use only.

benzene and petroleum ether gave 330 mg (50%) of benzoic anhydride (**24**), mp 42°C (mixture melting point). Elution with a mixture (1:1) of benzene and petroleum ether gave 123 mg (39%) of benzaldehyde (**10***a*) and, finally, elution with benzene gave 100 mg (17%) of benzanilide (**9**), mp 163–164°C (mixture melting point).

*Reaction of **10**a*

Treatment of **10***a* (636 mg, 6 mmol) with potassium (235 mg, 6 mg-atom) in THF (125 mL) for 15 h and work-up in the usual manner gave 550 mg (75%) of benzoic acid (**25***a*), mp 121°C (mixture melting point).

In a repeat run, **10***a* (636 mg, 6 mmol) was treated with potassium (235 mg, 6 mg-atom) in THF (125 mL), saturated with oxygen. Work-up of the mixture as in the earlier cases gave 565 mg (77%) of **25***a*, mp 121°C (mixture melting point).

In yet another run, **10***a* (636 mg, 6 mmol) was treated with potassium (235 mg, 6 mg-atom) in THF (125 mL) for 15 h. Moist THF (25 mL) was injected into the reaction vessel and the shaking was continued for an additional 5 h. Work-up of the mixture as in the earlier cases gave 300 mg (41%) of benzoic acid (**25***a*), mp 121°C (mixture melting point), and 300 mg (46%) of benzyl alcohol (**23***a*) (superimposable ir spectrum with that of an authentic sample).

In a repeat run, **10***a* (636 mg, 6 mmol) was treated with potassium (235 mg, 6 mg-atom) in THF (125 mL) for 15 h. A solution of freshly distilled benzoyl chloride (840 mg, 6 mmol) in THF (25 mL) was injected into the reaction flask and the shaking was continued for an additional 5 h. Work-up in the usual manner gave 1.1 g (81%) of benzoic anhydride (**24**), mp 42°C (mixture melting point).

*Reaction of **1**b*

Treatment of 640 mg (3 mmol) of **1***b* with 235 mg (6 mg-atom) of potassium in THF for 10 h and work-up in the usual manner gave 125 mg (30%) of salicylic acid (**25***b*), mp 159°C (mixture melting point), from the aqueous fraction. Work-up of the nonaqueous fraction gave a residual solid, which was chromatographed over alumina. Elution with petroleum ether gave 160 mg (58%) of *trans*-azobenzene (**19***a*), mp 68°C (mixture melting point), after recrystallization from ethanol. Further elution with a mixture (1:1) of benzene and petroleum ether gave 90 mg (25%) of salicylaldehyde (superimposable ir spectrum with that of an authentic sample). Subsequent elution with a mixture (4:3) of benzene and petroleum ether gave 130 mg (20%) of unchanged starting material (**1***b*), mp 118°C (mixture melting point), after recrystallization from benzene.

In a repeat run, 640 mg (3 mmol) of **1***b* was treated with 470 mg (12 mg-atom) of potassium in THF (125 mL) for 15 h and worked up as in the earlier cases to give 185 mg (45%) of **25***b*, mp 159°C (mixture melting point); 190 mg (69%) of **19***a*, mp 68°C (mixture melting point); and 135 mg (37%) of **10***b*.

*Reaction of **1**c*

A solution of **1***c* (640 mg, 3 mmol) in THF (125 mL) was shaken with potassium (235 mg, 6 mg-atom) for 15 h. The colorless solution became yellow at first, later brown, and finally black. Work-up of the mixture as in the earlier cases gave 180 mg (44%) of *p*-toluic acid (**25***c*), mp 182°C (mixture melting point), after recrystallization from benzene. Work-up of the nonaqueous fraction gave a residual solid, which was chromatographed on alumina. Elution with petroleum ether gave 20 mg (6%) of *trans*-1,2-di-*p*-tolylethylene (**13***c*), mp 176°C (mixture melting point). Further elution with a mixture (1:9) of benzene and petroleum ether gave 220 mg (80%) of *trans*-azobenzene (**19***a*), mp 68°C (mixture melting point), after recrystallization from ethanol. Subsequent elution of the column with a mixture (1:1) of benzene and petroleum ether gave 145 mg (40%) of *p*-tolualdehyde (**10***c*) (superimposable ir spectrum with that of an authentic sample).

*Reaction of **1**d*

A solution of **1***d* (640 mg, 3 mmol) in THF (125 mL) was shaken with potassium (235 mg, 6 mg-atom) for 12 h. Work-up of the mixture as in the earlier cases gave 180 mg (49%) of benzoic acid (**25***a*), mp 121°C (mixture melting point). The nonaqueous fraction was chromatographed over alumina and eluted with petroleum ether to give 10 mg (4%) of *trans*-stilbene (**13***a*), mp 124°C (mixture melting point). Further elution with a mixture (1:9) of benzene and petroleum ether gave 280 mg (89%) of **19***d*, mp 144°C (mixture melting point), after recrystallization from ethanol. Subsequent elution with a mixture (1:1) of benzene and petroleum ether gave 130 mg (40%) of benzaldehyde (**10***a*) (superimposable ir spectrum with that of an authentic sample).

*Reaction of **26**a*

Treatment of **26***a* (1.37 g, 5 mmol) with potassium (390 mg, 10 mg-atom) in THF for 3.5 h and work-up as in the earlier cases gave 1.05 g (82%) of benzhydrylideneaniline (**31***a*), mp 113–114°C (mixture melting point), after recrystallization from methanol.

*Reaction of **26**b*

Treatment of **26***b* (1.08 g, 4 mmol) with potassium (315 mg, 8 mg-atom) in THF for 10 h and work-up as in the earlier cases gave 820 mg (81%) of 9-fluorenylideneaniline (**31***b*), mp 89°C (mixture melting point), after recrystallization from a mixture (1:3) of chloroform and ethanol.

In a repeat run, 1.36 g (5 mmol) of **26***b* was treated with excess of potassium (780 mg, 20 mg-atom) in THF for 10 h, under analogous conditions, and worked up to give 100 mg (8%) of 9-anilinofluorene (**33***b*), mp 123–124°C (mixture melting point), and 900 mg (71%) of 9-fluorenylideneaniline (**31***b*), mp 89°C (mixture melting point).

In yet another run, **26***b* (108 mg, 0.37 mmol) was treated with potassium (30 mg, 0.77 mg-atom) for 10 h in THF (125 mL), which was previously saturated with oxygen. Work-up of the reaction mixture as in the earlier cases gave 20 mg (28%) of 9-fluorenone (**29***b*), mp 84°C (mixture melting point), and 70 mg (65%) of the unchanged starting material (**26***b*), mp 191–192°C (mixture melting point).

Reaction of N*-Benzyl-α-phenylnitrone (**34**) with potassium in THF*

A solution of **34** (950 mg, 4.5 mmol) in THF (125 mL) was shaken with potassium (180 mg, 4.5 mg-atom) for 10 h. The solution, which was colorless initially, changed to yellow, red, and finally brown. The reaction mixture was poured into moist THF (100 mL) and then the solvent was removed under vacuum. The residual solid thus obtained was treated with water (10 mL) and extracted with methylene chloride. The aqueous layer, on acidification with dilute hydrochloric acid and extraction with methylene chloride, gave 100 mg (18%) of **25***a*, mp 121°C (mixture melting point). Removal of the solvent from the earlier methylene chloride extract gave a product mixture, which was chromatographed over alumina. Elution with petroleum ether gave 75 mg (18%) of dibenzyl (**48**), mp 52°C (mixture melting point). Further elution with a mixture (1:4) of benzene and petroleum ether gave 150 mg (17%) of 2,3,5,6-tetraphenylpyrazine (**46**), mp 249°C (mixture melting point). Further elution of the column with a mixture (2:3) of benzene and petroleum ether gave 200 mg (21%) of α-phenyl-*N*-(2-benzylhydroxylamino-1,2-diphenylethano)nitrone (**38**), mp 196°C (mixture melting point). Subsequent elution of the column with benzene gave 75 mg (8%) of the unchanged starting material (**34**), mp 82–83°C (mixture melting point).

*Reaction of 1,2,3-triphenylisoindole-*N*-oxide (**49**) with potassium in THF*

A solution of **49** (360 mg, 1 mmol) in THF (125 mL) was shaken with potassium (78 mg, 2 mg-atom) for 12 h. The solution, which was initially colorless, changed to yellow and finally to orange. Exposure of the reaction mixture to air destroyed the color. Work-up of the reaction mixture in the usual manner gave 250 mg (69%) of the unchanged starting material (**49**), mp 198°C (mixture melting point), as the only isolable product.

In a repeat run, 360 mg (1 mmol) of **49** was treated with 78 mg (2 mg-atom) of potassium in THF (125 mL) for 12 h. Oxygen gas was bubbled through the reaction mixture and afterwards a solution of benzalacetophenone (**51**) (210 mg, 1 mmol) in benzene (25 mL) was added and the mixture was shaken for a further period of 2 h. Work-up of the reaction mixture as in the earlier cases gave 250 mg (69%) of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

unchanged nitrone **49**, mp 198°C (mixture melting point), and 170 mg (70%) of benzoic acid (**25***a*), mp 121°C (mixture melting point).

*Reaction of benzylideneaniline (**4**a) with potassium in THF*

A solution of **4***a* (1.36 g, 7.5 mmol) in THF (125 mL) was shaken with potassium (1.17 g, 30 mg-atom) for 9 h. The solution, which was initially colorless, became yellow, then brown, and finally colorless again. Work-up in the usual manner gave 260 mg (28%) of **25***a*, mp 121°C (mixture melting point), after recrystallization from hot water, and 760 mg (55%) of *d,l-N,N'*,1,2-tetraphenylethylenediamine (**54**), mp 150–151°C (mixture melting point).

*Reaction of 9-fluorenylideneaniline (**31**b) with potassium in THF*

A solution of **31***b* (1.02 g, 4 mmol) in THF (125 mL) was shaken with potassium (315 mg, 8 mg-atom) for 10 h. The reaction mixture was treated with moist THF (10 mL) and the solvent was later removed under vacuum. The residual solid was extracted with ether to give a product mixture that was then triturated with ethanol (2 mL). The ethanol-insoluble product gave 750 mg (73%) of 9-anilinofluorene (**33***b*), mp 124°C (mixture melting point), after recrystallization from ethanol. The ethanol-soluble fraction was evaporated under vacuum to give 100 mg (10%) of the unchanged starting material (**31***b*), mp 89°C (mixture melting point), after recrystallization from a mixture (1:3) of chloroform and ethanol.

*Reaction of α,N-diphenylnitrone (**1**a) with potassium superoxide*

A mixture of **1***a* (390 mg, 1.98 mmol), potassium superoxide (290 mg, 4 mmol), and 18-crown-6 (530 mg, 2 mmol) in benzene (100 mL) was stirred at room temperature for 24 h, protected from sunlight. The reaction mixture became yellow at first and later turned orange and finally red. On completion of the reaction, the mixture was washed several times with aqueous sodium chloride solution. Removal of the solvent from organic layer under vacuum gave 220 mg (89%) of nitrobenzene (superimposable ir with an authentic sample).

The combined aqueous washings were acidified with dilute hydrochloric acid and extracted with benzene. Removal of the solvent from the benzene extract under vacuum gave 200 mg (82%) of benzoic acid, **25***a*, mp 121°C (mixture melting point).

*Reaction of α-diphenylene-N-phenylnitrone (**26**b) with potassium superoxide*

A mixture of the nitrone **26***b* (270 mg, 1 mmol), potassium superoxide (420 mg, 6 mmol), and 18-crown-6 (530 mg, 2 mmol) in benzene (100 mL) was stirred at room temperature for 42 h, protected from sunlight. The reaction mixture became initially yellow and later red. The mixture was washed several times with aqueous sodium chloride solution. Removal of the solvent from the organic layer under vacuum gave a product mixture that was chromatographed over alumina. Elution with petroleum ether gave 30 mg (24%) of nitrobenzene (**22***a*) (superimposable ir spectrum with that of an authentic sample). Elution with a mixture (1:4) of benzene and petroleum ether gave 130 mg (72%) of 9-fluorenone (**29***b*), mp 84°C (mixture melting point). Further elution with a mixture (3:1) of benzene and petroleum ether gave 50 mg (19%) of the unchanged starting material (**26***b*), mp 191–192°C (mixture melting point). Work-up of the aqueous washings by acidification with dilute hydrochloric acid and extraction with benzene, as in the earlier case, did not give rise to any isolable product.

*Attempted reaction of 1,1,3-triphenylisoindole-N-oxide (**49**) with potassium superoxide*

A mixture of **49** (180 mg, 0.5 mmol), potassium superoxide (70 mg, 1 mmol), and 18-crown-6 (135 mg, 0.5 mmol) in benzene (100 mL) was stirred at room temperature for 12 h, protected from sunlight. Work-up of the reaction mixture as in the earlier cases gave 125 mg (69%) of the unchanged starting material (**49**), mp 198°C (mixture melting point), as the only isolable product.

*Reaction of nitrosobenzene (**11**a) with potassium superoxide*

A mixture of **11***a* (428 mg, 4 mmol), potassium superoxide (288 mg, 4 mmol), and 18-crown-6 (530 mg, 2 mmol) in benzene (100 mL) was stirred at room temperature for 6 h. Work-up of the mixture as in the earlier cases gave 300 mg (61%) of nitrobenzene (**22***a*) (superimposable ir spectrum with that of an authentic sample).

Cyclic voltammetry

Cyclic voltammetric measurements were made with a Princeton Applied Research (PAR) Model 173 potentiostat/galvanostat, a PAR Model 175 universal programmer, and a Kipp and Zonen X–Y recorder. Experiments were performed in a standard three-compartment cell equipped with a Pt-disc working electrode, Pt-wire counter electrode, and Ag/Ag^+ reference electrode. For spectroelectrochemical measurements, a specially designed cell was employed, which consists of an extended 10-mm quartz cuvette, equipped with a Pt-gauze working electrode, a Pt-foil counter electrode, and an Ag/Ag^+ reference electrode. The electrolysis was carried out in acetonitrile solutions (~0.05 m*M*) under nitrogen atmosphere at controlled potentials and the absorption spectra of the electrochemically generated radical anions and dianions were recorded directly in a Cary 219 Spectrophotometer. Both one-electron and two-electron reduction processes were monitored directly using a PAR 179 digital coulometer.

Pulse radiolysis

The computer controlled pulse radiolysis apparatus, which allows determination of transient spectra at various times after the pulse, and kinetic measurements of the spectral changes have been described elsewhere (28). The solutions of the nitrones in methanol (~0.5 m*M*) were deaerated before pulse radiolysis by bubbling nitrogen for at least half an hour. The deaeration was continued in the reservoir from which the solution was allowed to flow slowly and continuously through the pulse radiolysis cell. The irradiation was carried out with 5-ns electron pulses from the Notre Dame 7-MeV ARCO LP-7 linear accelerator using dose rates of $\sim 2 \times 10^{16}$ eV/g per pulse.

Acknowledgments

BENITO ALCAIDE, CARMEN L. MARDOMINGO, JOAQUÍN PLUMET, CARLOS CATIVIELA, and JOSÉ A. MAYORAL. Can. J. Chem. **65**, 2050 (1987).

Twelve *para*-substituted benzylideneanilines selected according to the optimality criteria of experimental matrices were prepared in order to study the influence of the substituents on the cycloaddition rate with benzonitrile oxide. The results obtained indicate that the cycloaddition is a concerted process with a high degree of synchrony.

BENITO ALCAIDE, CARMEN L. MARDOMINGO, JOAQUÍN PLUMET, CARLOS CATIVIELA et JOSÉ A. MAYORAL. Can. J. Chem. **65**, 2050 (1987).

Dans le but de mesurer l'influence des substituants sur leurs vitesses de cycloaddition avec l'oxyde de benzonitrile, on a préparé douze benzylidèneanilines substitués en position *para* qui avaient été choisis d'après des critères d'optimalité de matrices expérimentales. Les résultats obtenus indiquent que la cycloaddition est un processus concerté possédant un degré élevé de synchronisme.

Introduction

Mechanistic studies concerning 1,3-dipolar cycloaddition reactions with all carbon dipolarophiles constitute a well-documented field of research (1). However, the mechanism of 1,3-dipolar cycloaddition processes with heterodipolarophiles has attracted less attention. The reaction between benzonitrile oxide and the azomethinic double bond is a well-known process, and provides an excellent synthetic route to Δ^2-1,2,4-oxadiazolines (2)[3] (Fig. 1).

To the best of our knowledge no systematic study aimed at clarifying the mechanism of this process has been made. The only published antecedent is the measurement of the rate of cycloaddition of benzonitrile oxide (BNO) to benzylidenemethylamine (3) relative to the cycloaddition to ethyl crotonate.

Huisgen (4) has proposed a "concerted but not synchronous" transition state for 1,3-dipolar cycloadditions involving nitrilium betaines and all-carbon dipolarophiles. This is represented by a group of resonance structures that contribute to a different degree to the real structure of the transition state (2).

The study of the influence of different substituents in the aromatic rings of benzylideneanilines on the rate of cycloaddition with BNO represents our contribution to the clarification of the mechanism of this process.

Selection of substrates

The selection of molecules suitable for the kinetic study was effected by an exchange algorithm (5) from a set of 45 4,4′-disubstituted benzylideneanilines (Table 1), assuming a linear model function of the parameters σ_I and σ_R^0 (6), of the type:

$$[1] \quad k_r = a_0 + a_1\sigma_R^0(X) + a_2\sigma_I(X) + a_3\sigma_R^0(Y) + a_4\sigma_I(Y)$$

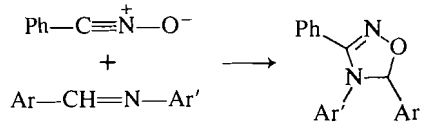

FIG. 1.

The 12 points selected by the optimum *D* criterion (7) (Fig. 2) are also set out in Table 1.

Experimental

(a) Materials and methods

Column chromatography separations were performed on silica gel 60 (Merck) with activity II–IV (Brockmann). Analytical tlc was performed on silica gel 60 F_{254} (Merck).

Gas–liquid chromatographies (competition measurements) were carried out on a Perkin–Elmer Sigma 300 apparatus fitted with a Sigma 10 chromatographic data station using the following conditions: column VCC 10% on Chromosorb W (AW-DCMS, 80–100 mesh); column dimensions, 3 m × 0.32 cm; carrier gas, N_2 (40–45 mL/min); detector temperature (flame ionization), 220°C.

(b) Spectroscopic procedures

The ir spectra were recorded on a Perkin–Elmer 781 spectrophotometer in KBr. The ^{1}H nmr spectra (analytical) were recorded on a Varian T-60 apparatus at 60 MHz. The ^{1}H nmr spectra (competition measurements) were recorded on a Bruker WP 80 spectrometer. The uv spectra were recorded on a Perkin–Elmer Lambda 3 apparatus in $CHCl_3$, at concentrations between 10^{-4} and 10^{-5} *M*.

(c) Melting points were determined in a Büchi 510 apparatus and are not corrected.

(d) Azomethines were prepared using the following general procedure: equimolecular amounts of amine and aldehyde were mixed together in a Dean–Stark device, in benzene, toluene, or xylene as solvent. The system was heated at reflux for 1–2 h and the solvent was then distilled *in vacuo*.

Except for imine no. **22**, the remaining imines have been previously described, e.g., imines **1**, **19**, and **37** by Hall and co-workers (8) and imines **4**, **8**, **9**, **26**, **27**, **37**, **39**, **43**, and **44** by Tokumaru and

[1]Author to whom correspondence may be addressed.

[2]Revision received February 17, 1987.

[3]The observed regioselectivity agrees with that observed in similar cases (2) and may be rationalized by the application of the FMO (Frontier Molecular Orbital) theory.

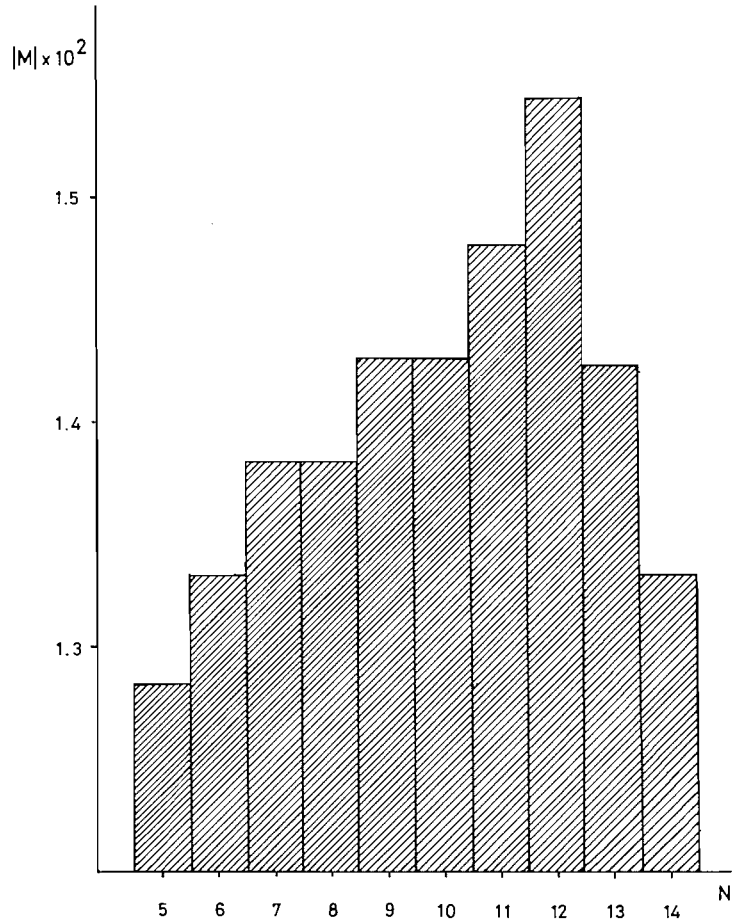

FIG. 2. Value of the determinant $|M|$ as a function of the number of experiments N.

co-workers (9). Contrary to the comments of Hall (8), all imines can be crystallized from ethanol with the exception of the *p*-nitroaniline derivatives (**8**, **26**, and **43**), which afford crystalline ethoxyamino derivatives ArCH(OEt)NHAr′. These azomethines were crystallized from benzene. Yields are expressed as % crystalline product.

p-*Methoxybenzylidene*-p-*fluoraniline* (*22*)

In benzene as solvent, mp 70–72°C; yield, 50%; ν_{max}: 1620 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 3.76 (s, 3H, CH_3—O), 8.27 (s, 1H, CH=N), 6.7–7.9 (m, 8H, aromatics). *Anal.* calcd.: C 73.36, H 5.24, N 6.11; found: C 73.51, H 5.06, N 6.16%.

(e) 3,4-Diaryl-5-phenyl-4,5-dihydro-1,2,4-oxadiazoles

Method A

To a mixture of imine and benzhydroximoyl chloride (10) in chloroform, a solution of freshly distilled triethylamine in chloroform was added. The molar ratio imine:chloride:Et_3N was approximately 1:1.5:1.5. The reaction was stirred at room temperature for between 3 and 7 h. After filtration of triethylamine hydrochloride, the reaction crude was chromatographed on a column (10 g silica gel/1 g crude) using benzene as eluent.

Method B

To a solution of imine in carbon tetrachloride, a solution of benzhydroximoyl chloride and a solution of freshly distilled triethylamine in carbon tetrachloride were simultaneously added. The molar ratio imine:chloride:Et_3N was approximately 1:2.2:2.2. The reaction was continued as in Method A.

3,4,5-Triphenyl-4,5-dihydro-1,2,4-oxadiazol (**1**): 500 mg (2.76 mmol) of **1** was treated with 640 mg (4.11 mmol) of benzhydroximoyl chloride and 420 mg (4.16 mmol) of triethylamine according to Method A. Reaction time, 7 h. Yield, 190 mg (0.63 mmol), 23%; mp 75–76°C (EtOH); ^1H nmr (CCl_4), δ: 6.30 (s, 1H), 6.6–7.5 (m, 15H). *Anal.* calcd.: C 80.00, H 5.33, N 9.33; found: C 79.95, H 5.40, N 9.56%. This product was described by Fabbrini and de Sarlo. (64%) (11), Lauria *et al.* (64%) (12), and Huisgen and co-workers (71%) (13).

*3,5-Diphenyl-4-(*p-*fluorphenyl)-4,5-dihydro-1,2,4-oxadiazol* (**2**): 500 mg (2.51 mmol) of **4** was treated with 570 mg (3.66 mmol) of benzhydroximoyl chloride and 380 mg (3.77 mmol) of triethylamine according to Method A. Reaction time, 7 h. Yield, 160 mg (0.50 mmol), 20%; mp 119–120°C (EtOH); ^1H nmr (CCl_4), δ: 6.30 (s, 1H), 6.6–7.8 (m, 14H). *Anal.* calcd.: C 75.47, H 4.72, N 8.81; found: C 75.52, H 4.78, N 8.80%.

*3,5-Diphenyl-4-(*p-*nitrophenyl)-4,5-dihydro-1,2,4-oxadiazol* (**3**): 340 mg (1.50 mmol) of **8** was treated with 520 mg (3.34 mmol) of benzhydroximoyl chloride and 340 mg (3.37 mmol) of triethylamine according to Method B. Reaction time, 7 h. Yield, 350 mg (1.01 mmol), 67%. The resulting oil (one pot in tlc) could not be crystallized; ^1H nmr (CCl_4), δ: 6.53 (s, 1H), 6.6–8.1 (m, 14H). *Anal.* calcd.: C 69.56, H 4.35, N 12.17; found: C 69.70, H 4.35, N 12.13%.

*3,5-Diphenyl-4-(*p-N,N-*dimethylaminophenyl)-4,5-dihydro-1,2,4-oxadiazol* (**4**): 170 mg (0.76 mmol) of **9** was treated with 180 mg (1.16 mmol) of benzhydroximoyl chloride and 120 mg (1.18 mmol) of triethylamine according to Method A. Reaction time, 2 h. Yield, 140 mg (0.41 mmol), 54%; mp 140–142°C (EtOH); ^1H nmr ($CDCl_3$), δ: 2.83 (s, 6H), 6.33 (s, 1H), 6.5–6.8 (m, 14H). *Anal.* calcd.: C 79.67, H 6.12, N 12.24; found: C 79.62, H 6.05, N 12.21%.

*3,4-Diphenyl-5-(*p-*methoxyphenyl)-4,5-dihydro-1,2,4-oxadiazol* (**5**): 170 mg (0.81 mmol) of **19** was treated with 190 mg (1.22 mmol) of benzhydroximoyl chloride and 120 mg (1.13 mmol) of triethylamine according to Method A. Reaction time, 5 h. Yield, 210 mg (0.64 mmol), 79%. The resulting oil (one pot in tlc) could not be crystallized; ^1H nmr ($CDCl_3$), δ: 3.80 (s, 3H), 6.40 (s, 1H), 6.6–7.8 (m, 15H). *Anal.* calcd.: C 76.36, H 5.45, N 8.48; found: C 76.51, H 5.39, N 8.40%.

[a]Natural variables (NV) were not standardized in the usual way but following the formula

$$x_{ij} = \frac{NV_{ij} - (\text{center})_i}{(\text{range of variation})_i}$$

where $(\text{centre})_i = (NV_{max} + NV_{min})/2$ and $(\text{range of variation})_i = (NV_{max} - NV_{min})/2$. This method of standardization leads the variables to have values between +1 and −1 (see ref. 7).

*3-Phenyl-4-(*p*-fluorphenyl)-5-(*p*-methoxyphenyl)-4,5-dihydro-1,2,4-oxadiazol* (**6**): 340 mg (1.48 mmol) of **22** was treated with 350 mg (2.25 mmol) of benzhydroximoyl chloride and 220 mg (2.18 mmol) of triethylamine according to Method A. [a]Biphenyl as internal standard in all cases.

[b]Initial temperature – time the initial temperature is maintained/rates of temperature increase of °C/min/final temperature – time the final temperature is maintained.

[c]In this case, considering the similarity of the retention times, the reference imine was **9**; the relative rate measured was subsequently corrected with respect to imine **1**.

*3-Phenyl-4-(*p-N,N-*dimethylaminophenyl)-5-(*p-*methoxyphenyl)-4,5-dihydro-1,2,4-oxadiazol* (**8**): 340 mg (1.33 mmol) of **27** was treated with 350 mg (2.25 mmol) of triethylamine according to Method A. Reaction time, 4 h. Yield, 80 mg (0.21 mmol), 16%; mp 118–120°C (CCl_4); ^1H nmr ($CDCl_3$), δ: 2.70 (s, 6H), 3.63 (s, 3H), 6.10 (s, 1H), 6.2–7.6 (m, 13H). *Anal.* calcd.: C 73.99, H 6.17, N 11.26; found: C 74.11, H 6.21, N 11.24%.

*3,4-Diphenyl-5-(*p-*nitrophenyl)-4,5-dihydro-1,2,4-oxadiazol* (**9**): 170 mg (0.75 mmol) of **37** was treated with 180 mg (1.16 mmol) of benzhydroximoyl chloride and 110 mg (1.09 mmol) of triethylamine according to Method A. Reaction time, 3 h. Yield, 100 mg (0.29 mmol), 39%; mp 104–108°C (EtOH); ^1H nmr ($CDCl_3$), δ: 6.57 (s, 1H), 6.7–8.5 (m, 14H). *Anal.* calcd.: C 69.56, H 4.34, N 12.17; found: C 69.55, H 4.33, N 12.20%.

*3-Phenyl-4-(*p-*fluorphenyl)-5-(*p-*nitrophenyl)-4,5-dihydro-1,2,4-oxadiazol* (**10**): 170 mg (0.70 mmol) of **39** was treated with 160 mg (1.03 mmol) of benzhydroximoyl chloride and 110 mg (1.09 mol) of triethylamine according to Method A. Reaction time, 3 h. Yield, 100 mg (0.28 mmol), 40%; mp 90–92°C (EtOH); ^1H nmr ($CDCl_3$), δ: 6.53 (s, 1H), 6.7–8.5 (m, 13H). *Anal.* calcd.: C 66.12, H 3.86, N 11.57; found: C 66.10, H 3.87, N 11.59%.

*3-Phenyl-4,5-bis(*p-*nitrophenyl)-4,5-dihydro-1,2,4-oxadiazol* (**11**): 340 mg (1.25 mmol) of **43** was treated with 470 mg (3.02 mmol) of benzhydroximoyl chloride and 300 mg (2.97 mmol) of triethylamine according to Method B. Reaction time, 2 h. Yield, 300 mg (0.77 mmol), 62%. The resulting oil (one pot in tlc) could not be crystallized; ^1H nmr ($CDCl_3$), δ: 6.5–8.4 (m, 13H). *Anal.* calcd.: C 61.54, H 3.59, N 14.36; found: C 61.41, H 3.62, N 14.43%.

*3-Phenyl-4-(*p-N,N-*dimethylaminophenyl)-5-(*p-*nitrophenyl)-4,5-dihydro-1,2,4-oxadiazol* (**12**): 340 mg (1.26 mmol) of **44** were treated with 430 mg (2.77 mmol) of benzhydroximoyl chloride and 280 mg (2.77 mmol) of triethylamine according to Method B. Reaction time, 3 h. Yield, 180 mg (0.46 mmol), 37%; mp 170–172°C (EtOH); ^1H nmr ($CDCl_3$), δ: 2.85 (s, 6H), 6.43 (s, 1H), 6.3–8.3 (m, 13H). *Anal.* calcd.: C 68.04, H 5.15, N 14.43; found: C 68.01, H 5.03, N 14.46%.

(f) Competition measurements

Competition measurements corresponding to imines **4**, **8**, **9**, **19**, **22**, **37**, and **39** were carried out by gas–liquid chromatography. The measurements of the areas of the peaks corresponding to the reference imine (**1**) and the internal standard (biphenyl in all cases), both prior to the addition of the reagent ($t = 0$) and when all of the reagent had been consumed (time $t = t$) (14), gave the expression corresponding to the relative cycloaddition rate through the application of eq. [2]:

$$[2] \quad \log \frac{S_{nt}}{S_{n0}} \cdot \frac{S_0}{S_t} = \frac{k_n}{k_1} \log \frac{S_{1t}}{S_{10}} \cdot \frac{S_0}{S_t}$$

where: S_{n0} = area of the peak corresponding to imine n when time $t = 0$; S_{10} = area of the peak corresponding to the reference imine when $t = 0$; S_0 = area of the peak corresponding to biphenyl when time $t = 0$; S_{nt} = area of the peak corresponding to imine n when time $t = t$; S_{1t} = area of the peak corresponding to the reference imine when time $t = t$; S_t = area of the peak corresponding to biphenyl when time $t = t$.

TABLE 3. Experimental conditions for ^1H nmr measurements

Imine no.	δ CH=N	Reference imine	δ CH=N
26	8.32	**9**	8.51
27	8.43	**1**	8.45
43	8.52	**27**	8.43
44	8.62	**27**	8.43

The imine whose relative ratio was to be measured, the reference imine, and the internal standard were dissolved in the minimum, amount of chloroform in a molar ratio of approximately 5:5:1.

Several samples were analyzed by glc and the ratio of the areas relative to the internal standard was determined. Then a chloroform solution of benzhydroximoyl chloride and a solution of freshly distilled triethylamine were added simultaneously. The molar ratio imine:reagent was in all cases 2:1. The reaction mixture was stirred at room temperature for between three and four hours and the samples to be analyzed were then withdrawn. Table 2 shows the retention time for each compound and the optimum temperature programs for each chromatographic analysis.

A typical procedure was the following: benzylideneaniline (**1**) (49.9 mg, 0.276 mmol), *N*-(*p*-*N*,*N*-dimethylaminophenyl)benzylideneamine (**9**) (62.0 mg, 0.277 mmol), and biphenyl (10.2 mg, 0.066 mmol) were mixed together in 8.0 mL of chloroform. Three samples were analyzed by glc under the previously mentioned conditions. The retention times and the areas of **1**, **9**, and biphenyl were the following (see eq. [2]):

Retention times (min)			Areas		
1	**9**	Biphenyl	S_{90}	S_{10}	S_0
7.47	20.95	3.07	6.21	19.84	5.90
7.47	21.09	3.07	6.49	21.36	6.24
7.47	21.00	3.10	8.64	26.39	7.60

A solution of benzhydroximoyl chloride (43.8 mg, 0.282 mmol) in 7.0 mL of chloroform and a solution of triethylamine (30.3 mg, 0.300 mmol) in 7.0 mL of chloroform were simultaneously added to the imine and biphenyl solution. After 3 h 23 min a sample was withdrawn. The chlorhydrate of the amine was removed by filtration and washed with chloroform (3 × 5 mL). The solvent was partially

TABLE 4. Relative rate constants for the selected benzylideneanilines

Compound no.	**27**	**9**	**22**	**19**	**4**	**1**	**44**	**26**	**37**	**39**	**8**	**43**
k_{rel}	2.3	2.0	1.5	1.4	1.2	1.0	1.4	1.2	1.1	1.0	0.4	0.9

eliminated to a volume of solution of ca. 10 mL and the mixture was analyzed with the following results:

Retention times (min)			Areas		
1	**9**	Biphenyl	S_{9t}	S_{1t}	S_t
7.47	21.12	3.06	5.75	23.92	9.16
7.47	21.12	3.09	6.42	29.76	12.26

Evaluation of three independent experiments by eq. [2] afforded k_9/k_1. Mean value $k_9/k_1 = 2.0$; estimated error ± 0.1.

Competition measurements corresponding to the imines **26**, **27**, **43**, and **44** were carried out by ^{1}H nmr spectroscopy. No internal standard was used. Equimolar amounts of the imine whose relative rate was to be measured and of the reference imine were weighed. Both imines were then dissolved in $CDCl_3$ and the ^{1}H nmr spectrum of the mixture was recorded. The ratio of imines was determined from multiple integration of the signals corresponding to the aldiminic proton on a conveniently expanded spectrum. Subsequently, an equimolar mixture of benzhydroximoyl chloride and triethylamine (ratio imine:reagents approximately 2:1.5) was added and the spectrum was recorded after three hours; the ratio of unreacted imines was then measured. The relative rate was determined by means of a modified eq. [2]. Table 3 shows the experimental conditions used.

A typical procedure was the following: 50.0 mg (0.276 mmol) of imine **1** and 70.2 mg (0.276 mmol) of imine **27** were dissolved in 7.0 mL of $CDCl_3$ and the ^{1}H nmr spectrum of the mixture was then recorded. The integral corresponding to aldiminic protons of each compound was 24.0 mm. To the above solution were added simultaneously a solution of 42.9 mg (0.276 mmol) of benzhydroximoyl chloride in 2 mL of $CDCl_3$ and a solution of 27.9 mg (0.276 mmol) of Et_3N in 2 mL of $CDCl_3$. The reaction was maintained at room temperature for 3 h. The chlorhydrate of the amine was then removed by filtration and washed with $CDCl_3$ (2 × 3 mL). The solution was analyzed by ^{1}H nmr. The areas of the aldiminic protons (multiple integration) were $S_{27t} = 15.1$ mm; $S_1 = 19.5$ mm.

Substitution in eq. [2] yielded

$$k_{27}/k_1 = 2.23$$

The experiment was repeated three times. Mean value $k_{27}/k_1 = 2.3$. Estimated error ± 0.2.

Results and discussion

The competition rate constant values based on 1.0 for X = Y = H (imine **1**) are collected in Table 4.

The total range of k_{rel} covers 5.7 units. The slowest value corresponds to the imine with X = H, Y = NO_2 (**8**), whereas the fastest representative is imine **27**, with X = OCH_3, Y = $N(CH_3)_2$.

The regression obtained with the 12 selected experiments led to the eq. [3]

$$[3] \quad k_r = 1.3 - 0.3(\pm 0.24)x_1 + 0.1(\pm 0.26)x_2 - 0.4(\pm 0.25)x_3 - 0.2(\pm 0.25)x_4$$

$$r^2 = 0.82; \; r_A^2 = 0.72; \; n = 12; \; s = 0.27; \; F_{4,7;0.95} = 4.12$$

This equation is acceptable, though not completely satisfactory from a statistical point of view, if the magnitude of the confidence interval and the small F values are taken into account. The use of more complex models, such as the additive model that takes into account interactions between X and Y through the azomethinic bond, does not improve the results.

TABLE 5. FMO energies for the selected benzylideneanilines

Compound no.	Fully minimized		Planar structure	
	E_{HO}	E_{LU}	E_{HO}	E_{LU}
27	−8.58	−0.07	−8.53	−0.60
9	−8.57	−0.10	−8.58	−0.55
22	−9.19	−0.21	−8.82	−0.82

4	−9.20	−0.23	−8.98	−0.78
1	−9.05	−0.01	−8.84	−0.54
44	−8.75	−1.15	−8.80	−1.30
26	−9.36	−0.60	−9.21	−1.31
37	−9.39	−0.73	−9.36	−1.31
39	−9.53	−0.83	−9.50	−1.45
8	−9.81	−0.65	−9.55	−1.30
43	−10.43	−0.99	−10.34	−1.76

An examination of the relative rates of cycloadditions (Table 4) indicates a small development of charged species in the transition state. Thus, for the cycloaddition of benzonitrile oxide to substituted styrenes (15) (a concerted process with a high degree of synchrony) the maximum ratio of rates is 2, the fastest representative corresponding to the 4-nitro derivative and the slowest to the unsubstituted one. However, for the cycloaddition of tetracyanoethylene to *p*-substituted styrenes (a typical zwitterionic process) the rate constant presents a variation in the range of 500 from the *p*-methoxy to the *p*-cyclopropyl substituent (16).

Sustmann (17) has collected data for the reactivity of a large number of 1,3-dipolar cycloaddition reactions and the reactivity of the 1,3-dipoles is classified in three groups according to the separation between FMOs of dipoles and dipolarophiles and, therefore, with frontier orbital control for these reactions.

In view of this, we tried to know the electronic configuration of the 1,3-dipole and of the dipolarophiles, to explain the observed reactivity scale by using the FMO theory (18).

The electronic structure for the different benzylideneanilines in their *E* configuration[4] was calculated using an SCF semi-empirical molecular orbital (MO) method MNDO (20). The geometrical features obtained when the azomethinic structures were fully minimized show that both aromatic rings are out of the C=N bond plane, displaying unusually high torsion angles (of between 64° and 83° for both aromatic rings), which are of similar value in every case.

However, it is well known that the aromatic ring attached to the imine carbon is planar or practically planar (21), whereas the ring attached to the nitrogen is twisted in such a way that the loss of π−π conjugation (22) is made up for by the increase in $n-\pi$ conjugation. The lack of planarity may be due to the MNDO

[4]All these benzylideneanilines exist in their more stable *E* configuration; assignments were made in a straightforward way by considering their spectroscopic data and the bibliography on the subject (8, 19).

39	348	10 000	45.3	−9.50	−1.43	8.50	8.57
8	345	17 400	21.9	−9.58	−1.27	8.58	8.73
43	340	17 200	22.7	−10.36	−1.73	9.36	8.27

[a]Represents E_{HO}(dipolarophile) − E_{LU}(dipole).
[b]Represents E_{HO}(dipole) − E_{LU}(dipolarophile). The values for the FMO of benzonitrile oxide were established by Houk *et al.* (25): $E_{HO} = -10$ eV; $E_{LU} = -1.0$ eV.

tendency to twist groups possessing π-delocalization with phenyl rings (23), a tendency probably due to the overestimation of short nonbonded interactions in this semiempirical method (20).

To test the influence of the geometrical features on the electronic structure of the selected 12 benzylideneanilines the FMO energies were recalculated for a planar structure (Table 5). The values obtained show that this influence is noticeable in particular in the LUMO energy and in the coefficients of both frontier orbitals.

In view of this, it was considered necessary to recalculate the FMO energy levels assuming the aromatic moiety attached to the iminic carbon to be planar; considering a torsion angle, calculated from data, for the aromatic ring attached to the nitrogen atom; and fixing the corresponding dihedral angles.

Equation [4] used by Minkin *et al.* (22*h*) relates the torsion angle θ of a compound to the extinction coefficient (ε) for its conjugation band and the extinction coefficient (ε_0) of a coplanar system.

$$[4] \quad \cos^2\theta = \frac{\varepsilon}{\varepsilon_0}$$

In Table 6 are collected the uv data (λ_{max} and ε of the conjugation band) for the benzylideneanilines considered.

In accordance with Doubt and Vandembert's observations (24), the presence of substituents of complementary electronic demand (attractor–donor) on both rings favours a shift of the azomethinic conjugation band with respect to benzylideneaniline, increasing the system conjugation and therefore the coplanarity. So compound no. **44**, which has a maximum complementary substitution, is taken as the reference system (coplanar, $\theta = 0$) for the evaluation of the torsion angles of the ring attached to the nitrogen atom in our benzylideneanilines. The new values of θ introduced in the molecular geometry for MNDO calculations, as well as the values of E_{HOMO}[5] and E_{LUMO} obtained, are indicated in Table 6.

The ΔE values, set out in Table 6, show that the range studied cannot be satisfied solely by a type of orbital control (HOMO dipole – LUMO dipolarophile or LUMO dipole – HOMO dipolarophile), as was to be expected for a type II dipole (17). This accounts for our difficulty in finding a mathematical model that reproduces the observed rates of cycloaddition for the 12 selected imines. In fact, when the regression is performed with the seven cases with an ΔE value more favourable for the interaction LUMO dipole – HOMO dipolarophile using σ_p(X) and σ_p(Y), an excellent result is obtained (eq. [5]).

$$[5] \quad k_r = 1.19 - 0.88(\pm 0.43)\sigma_p(X) - 1.03(\pm 0.35)\sigma_p(Y)$$
$$r^2 = 0.95;\ r^2_A = 0.92;\ n = 7;\ s = 0.13;\ F_{1,4;0.95} = 4.26$$

The use of σ_p instead of σ^0_R and σ_I is statistically necessary to have an acceptable number of degrees of freedom, and the correlation existing among the variables makes it suitable. When σ_p(X) and σ_p(Y) are used with the 12 imines, r^2 decreases to 0.75.

[5]To our knowledge, the only experimental data in the literature concerning the HOMO of benzylideneaniline (22*i*) agree with the determined value.

Growing interstellar cyanopolyacetylenes with ion/molecule reactions

DIETHARD K. BOHME, STANISŁAW WŁODEK, AND ASIT B. RAKSIT
Department of Chemistry and Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received December 15, 1986

DIETHARD K. BOHME, STANISŁAW WŁODEK, and ASIT B. RAKSIT. Can. J. Chem. **65**, 2057 (1987).

New and recent results of laboratory measurements are presented which allow an assessment of four ion/molecule reaction schemes which have been proposed for the gas-phase synthesis of interstellar cyanopolyacetylenes. The schemes are scrutinized in terms of the manner of growth of the carbon backbone and the manner in which nitrogen is entrained in the formation of ions of the type $H_2C_{2n+1}N^+$ which may neutralize by proton transfer or electron–ion recombination to form cyanopolyacetylenes.

DIETHARD K. BOHME, STANISŁAW WŁODEK et ASIT B. RAKSIT. Can. J. Chem. **65**, 2057 (1987).

On rapporte des résultats nouveaux et récents relatifs à des mesures de laboratoires qui permettent d'évaluer quatre schémas réactionnels ions/molécules qui ont été proposés pour la synthèse en phase gazeuse de cyanopolyacétylènes interstellaires. On a examiné les divers schémas en fonction de la croissance de la chaîne carbonée ainsi que de la façon par laquelle l'azote est entraîné dans la formation d'ions du type $H_2C_{2n+1}N^+$ qui peuvent être neutralisés par un transfert de proton ou par une recombinaison ion/électron conduisant à des cyanopolyacétylènes.

Introduction

Perhaps the most remarkable aspect of the known chemical composition of the interstellar medium is the abundance of the homologous series of cyanopolyacetylene molecules which have been identified by radioastronomers (1). The higher members of this family of chain-like carbon molecules with terminal cyanogen (CN) substituents are not found naturally on earth, but their rotational transitions have been detected at radio frequencies in all types of molecular clouds in interstellar space as well as in circumstellar envelopes. There is now a need to understand the mechanisms of their formation in these environments. Several synthetic pathways have been suggested. These include the fragmentation of grains or very large molecules (2), catalytic surface reactions (3), and homogeneous gas-phase reactions between ions and molecules. Here we examine the various schemes which have been proposed for the latter pathway of gas-phase synthesis by ion chemistry, many elements of which have been included in detailed modelling studies of interstellar clouds. New and recent results of laboratory measurements are presented which advance our understanding of several of these schemes, allow their assessment, and permit some discrimination between them.

Four ion/molecule reaction schemes will be considered. In all of them formation of the cyanopolyacetylene is achieved ultimately by the neutralization of $H_2C_{2n+1}N^+$ through the electron-ion recombination reaction [1].

[1] $H_2C_{2n+1}N^+ + e \rightarrow HC_{2n+1}N + H$

or by a proton-transfer reaction with a molecule having a proton affinity higher than the cyanopolyacetylene. The schemes differ in the manner of growth of the carbon backbone and the manner in which nitrogen is entrained in the formation of $H_2C_{2n+1}N^+$.

The earliest models put forward by Winnewisser and Walmsley (4) and by Schiff and Bohme (5) allow for the buildup of the cyanopolyacetylenes in two ways. In one scheme (Scheme A) the acetylenic chain is conceived to grow two carbon atoms at a time by reactions between acetylene and its ions and then to be substituted by reaction with HCN or CN as indicated in reactions [2] and [3].

[2] $C_{2n}H_{2,3}^+ + HCN \rightarrow H_2C_{2n+1}N^+ + H,H_2$

[3] $C_{2n}H_{2,3}^+ + CN \rightarrow H_2C_{2n+1}N^+ + h\nu,H$

Alternatively (Scheme B), substitution is achieved first, followed by growth of the carbon backbone by reactions with acetylene ions as in reaction [4].

[4] $C_2H_{2,3}^+ + HC_{2n+1}N \rightarrow H_2C_{2n+3}N^+ + H,H_2$

Growth by one carbon atom at a time is the distinguishing feature of the scheme proposed by Woods (6) (Scheme C). The two essential steps in this scheme are given in reactions [5] and [6].

[5] $C^+ + HC_{2n+1}N \rightarrow C_{2n+2}N^+ + H$

[6] $C_{2n+2}N^+ + CH_4 \rightarrow H_2C_{2n+3}N^+ + H_2$

Finally, several authors (7–9) recently have postulated a mechanism (Scheme D) in which build-up of the carbon chain is followed by reactions with N atoms as in reactions [7] and [10]. Depending on the degree of hydrogenation of the carbonaceous reactant ion, secondary hydrogenation reactions may be required as in reactions [8] and [9] before neutralization can yield the cyanopolyacetylene.

[7] $C_{2n+1}H^+ + N \rightarrow C_{2n+1}N^+ + H$

[8] $C_{2n+1}N^+ + H_2 \rightarrow HC_{2n+1}N^+ + H$

[9] $HC_{2n+1}N^+ + H_2 \rightarrow H_2C_{2n+1}N^+ + H$

[10] $C_{2n+1}H_3^+ + N \rightarrow H_2C_{2n+1}N^+ + H$

Reactions with N atoms are attractive in the chemistry of dark interstellar clouds because of the relatively high abundance of these atoms.

Experimental

Several new reactions were measured as part of this more general evaluation of the gas-phase synthesis of cyanopolyacetylenes by ion chemistry. The measurements were performed with the Selected-Ion Flow Tube (SIFT) apparatus in the Ion Chemistry Laboratory (10, 11). Ions were generated in an axial electron impact ionizer (Extranuclear Model 0413) at ca. 50 eV from the pure parent gas or the parent gas diluted with helium: C^+ (cyanogen), C_3^+ (methylacetylene), C_5^+ (*n*-pentane), $C_4H_2^+$ (diacetylene), and C_4N^+ (allyl cyanide). The ions were injected into helium carrier gas at ca. 10 to 50 V. The total pressure was in the range from 0.30 to 0.35 Torr and the ambient temperature was 296 ± 2 K. The reagent gases and helium carrier gas were of high purity (≥99.5 mol%). Hydrogen cyanide was prepared according to the procedure described by Glemser (12). Rate constants and product distributions were derived in the usual manner (13, 14).

Results and discussion

In this section we provide a detailed and comprehensive assessment of the four ion/molecule reaction schemes which have been advanced for cyanopolyacetylene synthesis. Our new results together with recent results are integrated into the discussion as appropriate. An attempt is made throughout to project the chemistry to higher members of the homologous series for which new measurements are not available.

Series A

Scheme A rests on the likelihood of growing polyacetylene cations. Two obvious routes for the growth of polyacetylene cations involve the sequential addition of C_2 units either directly to the ion as follows:

$$[11]\quad C_2H_{2,3}^+ \xrightarrow{C_2} C_4H_{2,3}^+ \xrightarrow{C_2} C_6H_{2,3}^+ \xrightarrow{C_2} C_8H_{2,3}^+ \xrightarrow{C_2}$$

or indirectly by repeated reaction with the polyacetylene formed through the neutralization of the polyacetylene cations as follows:

$$[12]\quad \begin{array}{ccccccc} C_2H_{2,3}^+ & & C_4H_{2,3}^+ & & C_6H_{2,3}^+ & & C_8H_{2,3}^+ \\ \downarrow & \overset{C_2^+}{\nearrow} & \downarrow & \overset{C_2^+}{\nearrow} & \downarrow & \overset{C_2^+}{\nearrow} & \downarrow \\ C_2H_2 & & C_4H_2 & & C_6H_2 & & C_8H_2 \end{array}$$

Both schemes may also operate with polyatomic carbon units containing an even number of carbon atoms, such as neutral or ionized C_4 or C_6 units. At the low pressures of the interstellar medium the addition of the carbon unit in each step may occur either by radiative association or by condensation as indicated in reactions [13] to [16] for diatomic carbon units:

$$[13]\quad C_{2n}H_{2,3}^+ + C_2 \rightarrow C_{2n+2}H_{2,3}^+ + h\nu$$

$$[14]\quad C_{2n}H_{2,3}^+ + C_2H_{1,2} \rightarrow C_{2n+2}H_{2,3}^+ + H, H_2$$

$$[15]\quad C_{2n}H_2 + C_2H_{0,1}^+ \rightarrow C_{2n+2}H_{2,3}^+ + h\nu$$

$$[16]\quad C_{2n}H_2 + C_2H_{2,3}^+ \rightarrow C_{2n+2}H_{2,3}^+ + H, H_2$$

Only a very few of these reactions have actually been explored in the laboratory. The available measurements provide insight primarily into the kinetics of the initiation steps.

There is no information on the reactions of the acetylenic ions with the molecules C_2 and C_2H, but it is well known that the ions $C_2H_2^+$ and $C_2H_3^+$ react with acetylene to etablish $C_4H_2^+$ and $C_4H_3^+$ (15). Figure 1 displays results of SIFT measurements which show how the reaction of $C_2H_2^+$ with C_2H_2 establishes $C_4H_2^+$ and $C_4H_3^+$ as well as the adduct ion $C_4H_4^+$. The adduct is likely to be collisionally stabilized at the pressures of the SIFT experiments; it is not observed at low pressures in ICR experiments (15). In contrast, the ions $C_4H_2^+$ and $C_4H_3^+$ form adduct ions with acetylene under SIFT conditions (16) as well as at the low pressures of the ICR technique (15, 17). There has been one report of a minor channel at low pressures which leads to $C_6H_3^+$ from $C_4H_2^+$ and C_2H_2 (15). The observation of adducts at low pressures implies the occurrence of radiative association, although both collisional and radiative association have been advanced as the mechanism for the association of $C_4H_2^+$ and $C_4H_3^+$ with C_2H_2 at low pressures (15, 17).

The reactions of acetylene with $C_2H_2^+$ and $C_2H_3^+$ also initiate the reaction sequence [12] and it is known that C_2H^+ reacts rapidly with C_2H_2 to produce $C_4H_2^+$ exclusively (15). SIFT measurements have shown that the chain-lengthening reaction of diacetylene with $C_2H_2^+$ to form $C_6H_3^+$ must compete with a predominant charge transfer channel (16). This may also be the case for reactions of $C_2H_2^+$ with higher polyacetylenes as the ionization energy decreases with chain length. For the reactions with $C_2H_3^+$ proton transfer will be the competitive channel since the proton affinity of C_2H_2 is expected to be lower than that of the polyacetylenes.

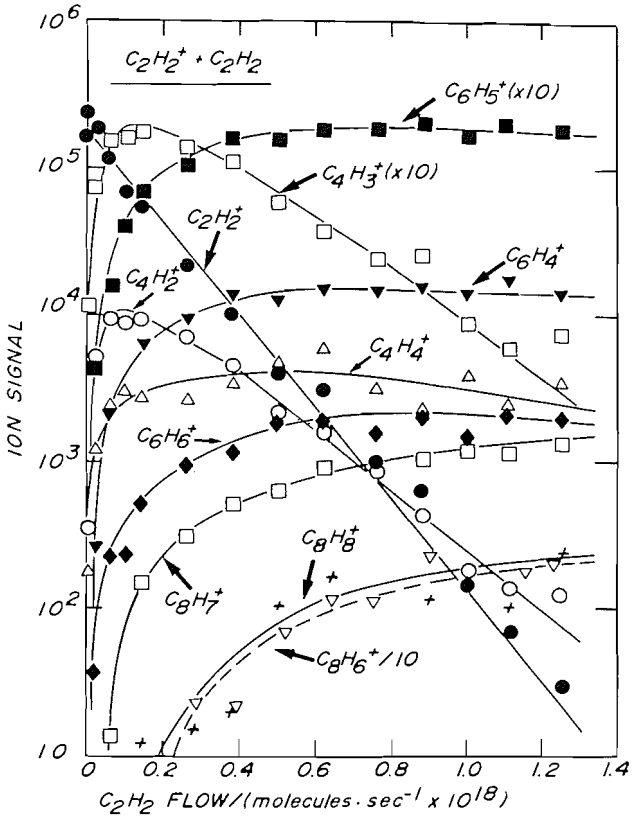

FIG. 1. Observations of the sequential acetylene chemistry initiated by $C_2H_2^+$ in the reaction region of a SIFT apparatus. Three steps are seen to lead to the connection of four C_2 units with overall complete retention of acetylenic hydrogen ($C_8H_8^+$) and with loss of H ($C_8H_7^+$) and H_2 ($C_8H_6^+$). The buffer gas is helium. $P = 0.34$ Torr, $\bar{v} = 7.4 \times 10^3$ cm s^{-1}, $L = 46$ cm, and $T = 296$ K. The $C_2H_2^+$ is derived from acetylene by electron impact at 20 eV.

Some information is also available for reactions between neutral and ionic C_4 units. Recent SIFT measurements have indicated that the reactions of $C_4H_2^+$ and $C_4H_3^+$ with diacetylene can establish $C_6H_2^+$ and $C_6H_3^+$ but that they are dominated by adduct formation, as are the reactions of $C_6H_2^+$ and $C_6H_3^+$ with diacetylene (16). The situation is different at lower pressures where collisional stabilization is less influential. For the reaction of $C_4H_2^+$ with C_4H_2 recent ICR measurements have indicated the formation of the products $C_6H_2^+$ (83%), $C_8H_2^+$ (17%), and $C_8H_3^+$ (1%) (18). Also the reaction of $C_4H_3^+$ with acetylene was observed to produce $C_6H_3^+$ exclusively (18). Other ICR measurements have shown that the $C_6H_2^+$ produced from $C_4H_2^+$ and C_4H_2 reacts with diacetylene to produce $C_8H_2^+$ and $C_{10}H_2^+$ (19). Finally, it has also been shown that C_4H^+ reacts with diacetylene to produce $C_8H_2^+$ exclusively (18).

In summary, the results of laboratory measurements available at this time indicate that polyacetylenic ions are readily generated by sequential reactions involving C_2 or C_4 units. SIFT measurements suggest that collisional association reactions begin to predominate at moderate pressures as the ionic complexity increases, and ICR measurements indicate that ionic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

growth at the low pressures of interstellar environments may proceed by bimolecular condensation reactions, or possibly radiative association reactions.

For Scheme A to succeed in the ultimate formation of cyanopolyacetylenes, the growth of polyacetylene cations must be followed by the entrainment of CN according to reactions of type [2] and [3]. Experimental observations are unavailable for reactions with CN, but some measurements have been reported for reactions with HCN. ICR measurements (15) indicate a fast reaction of $C_2H_2^+$ with HCN to produce two ions as indicated in reaction [17]:

$$[17]\quad C_2H_2^+ + HCN \xrightarrow{0.65} H_2CN^+ + C_2H$$
$$\xrightarrow{0.35} H_2C_3N^+ + H$$

Both product ions have also been observed in SIFT experiments at a branching ratio of 0.05 each, but the predominant product observed at the higher pressures of the SIFT was the ionic adduct (5). $C_2H_3^+$ was observed with both techniques to react with HCN by proton transfer (11, 15). Recent ICR measurements indicate that both $C_4H_2^+$ and $C_4H_3^+$ do not react rapidly with HCN at low pressures, $k < 2 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} (15). SIFT experiments carried out in this study indicate rapid association in helium at a total pressure of 0.335 Torr and a helium density of 1.1×10^{16} atoms cm^{-3} at 296 ± 2 K. Reaction [18] was observed to have an effective bimolecular

$$[18]\quad C_4H_2^+ + HCN + He \rightarrow H_3C_5N^+ + He$$

rate constant of 2.2×10^{-10} cm^3 molecule^{-1} s^{-1} under these conditions. The structure of the adduct ion is uncertain, but it may be a source for neutral cyanodiacetylene if it loses molecular hydrogen upon recombination with electrons. In the interstellar environment the association must proceed radiatively. The upper limit to the rate constant for this reaction determined with the ICR method does not preclude this possibility, and the high rate of collisional association certainly is suggestive of a relatively efficient radiative association.

Scheme B

Scheme B relies on the build-up of the cyanopolyacetylenes by their repeated reaction with the acetylenic ions $C_2H_2^+$ and $C_2H_3^+$ in which the CN substituent is retained. While experiments have shown that this is achieved for one of the first members of the family of reactions, viz. the reaction of HCN with $C_2H_2^+$, it is not for the next higher member. As indicated earlier, ICR and SIFT measurements have shown that HCN reacts with $C_2H_2^+$ to produce some $H_2C_3N^+$ while the $C_2H_3^+$ ion reacts with HCN only by proton transfer. In contrast, recent SIFT experiments in our laboratory indicate that elimination of HCN and association dominate in the reaction of $C_2H_2^+$ with HC_3N for which $k = 3.2 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} (20):

$$[19]\quad C_2H_2^+ + HC_3N \xrightarrow{0.5} C_4H_2^+ + HCN$$
$$\xrightarrow{0.5} C_5H_3N^+$$

A similar result has been reported recently by Knight *et al.* (21) who suggest that the ionic adduct which must be formed by radiative association at the low pressures of interstellar clouds may yield some HC_5N by electron/ion recombination. $C_2H_3^+$ is known to react with cyanoacetylene only by proton transfer (20, 21).

Scheme C

The scheme proposed by Woods has as its foundation the atomic carbon ion. Growth is achieved by adding single carbon units through sequential reactions with C^+ and methane. No laboratory data were available for the reactions [5] and [6] involving cyanoacetylenes when this scheme was originally conceived by Woods. However, recent SIFT measurements in our laboratory have shown that this scheme is indeed credible. We have shown that C^+ reacts with the first member of the series of cyanopolyacetylenes extremely rapidly, $k = 6.1 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}, to produce the C_4N^+ cation 20% of the time as shown in reaction [20] (20):

$$[20]\quad C^+ + HC_3N \xrightarrow{0.8} C_3H^+ + CN$$
$$\xrightarrow{0.2} C_4N^+ + H$$

We report here the results for the subsequent reaction of C_4N^+ with CH_4 which establishes some $H_2C_5N^+$. The latter ion may neutralize to form cyanodiacetylene.

With C^+ as the source ion for C_4N^+, sufficient cyanoacetylene was added into the flow tube of the SIFT apparatus to deplete most of the C^+. The major ion in the flow tube under these conditions was C_3H^+ but addition of methane did provide an assessment of the products of the C_4N^+ reaction since the products of the reaction of C_3H^+ with methane had been characterized previously in our laboratory (10). Experiments performed at low resolution identified product ions at m/z = 51 + 52 ($C_4H_3^+$ or C_3HN^+ and $C_4H_4^+$ or $C_3H_2N^+$), 27 + 28 ($C_2H_3^+$ or CHN^+ and $C_2H_4^+$ or CH_2N^+), and 76 ($C_5H_2N^+$). The rate constant for the decay of C_4N^+ at 296 ± 2 K was determined to be 5.5×10^{-10} cm^3 molecule^{-1} s^{-1}. Further experiments were performed to elucidate the product yields by generating C_4N^+ from allyl cyanide by electron impact (22). The observed product ions with their relative yields were as follows:

$$[21]\quad C_4N^+ + CH_4 \xrightarrow{0.35} C_3H_2N^+ + C_2H_2$$
$$\xrightarrow{0.30} C_4H_3^+ + CHN$$
$$\xrightarrow{0.25} C_2H_3^+ + C_3HN$$
$$\xrightarrow{0.05} CH_2N^+ + C_4H_2$$
$$\xrightarrow{0.05} C_5H_2N^+ + H_2$$

The overall rate constant in this case was 5.7×10^{-10} cm^3 molecule^{-1} s^{-1}. Experiments with CD_4 excluded $C_4H_4^+$, CHN^+, and $C_2H_4^+$ as possible product ions. C_3HN^+ was shown to contribute less than 5% to the total product ions. The results of one experiment with CD_4 are shown in Fig. 2.

Two pairs of the product ions in reaction [21] are related by intramolecular proton transfer. Thus neutral and protonated cyanoacetylene (or isocyanoacetylene) appear to contribute 60% to the total product ions, while neutral and protonated diacetylene appear to contribute 35%. The remaining 5% of the reaction appears to lead to protonated cyanodiacetylene or an isomer of cyanodiacetylene.

Scheme C presumes similar reactions of C^+ with the higher members of the homologous series of cyanopolyacetylenes and similar reactions of the derivative $C_{2n+2}N^+$ ions with CH_4 as indicated by reactions [5] and [6]. Figure 3 projects the

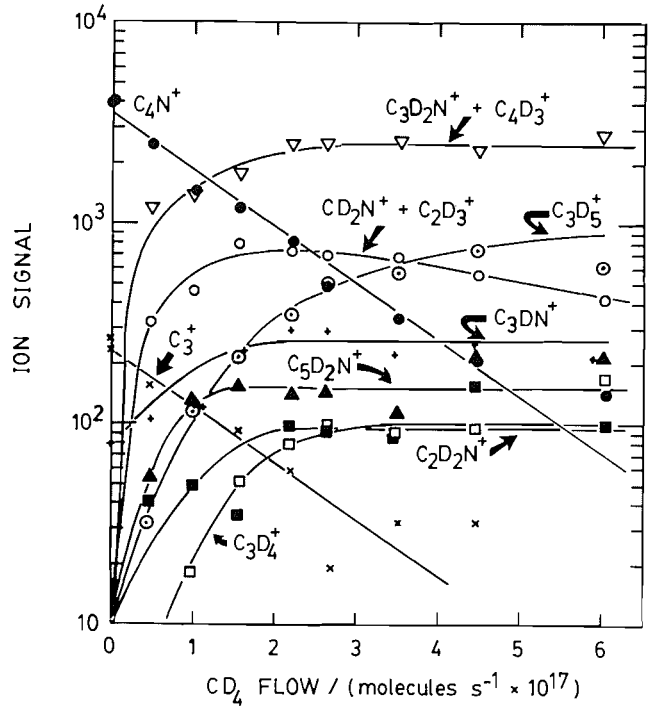

FIG. 2. The variations in ion signals observed for the addition of deuterated methane into the reaction region of the SIFT apparatus in which C_4N^+ is initially established in helium buffer gas. P = 0.35 Torr, $\bar{v} = 6.7 \times 10^3$ cm s^{-1}, L = 46 cm, and T = 294 K. The C_4N^+ is derived from allyl cyanide by electron impact at 55 eV.

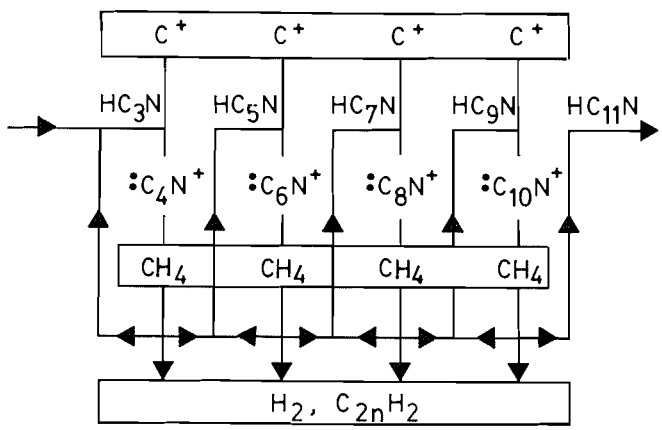

FIG. 3. Hypothetical scheme for the synthesis of cyanopolyacetylenes.

chemistry established in this study for the production of cyanodiacetylene to the production of higher cyanopolyacetylenes. The scheme provides a plausible route to the synthesis of the higher cyanopolyacetylenes. An important feature of this scheme is the chemical feedback of the lower cyanopolyacetylene(s) which may be formed in the reactions of $C_{2n+2}N^+$ with CH_4. In the interstellar chemistry the latter reactions must compete with those involving H_2. In a separate study we have shown that C_4N^+ reacts with H_2 only slowly, $k = 2.2 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} at 296 K, to produce C_3H^+ (22).

Other reactions of $C_{2n+2}N^+$ which may lead to growth of cyanopolyacetylenes in interstellar chemistry are also possible as is indicated, for example, by reactions [22] and [23]:

[22] $C_{2n+2}N^+ + CH_3 \rightarrow H_2C_{2n+3}N^+ + H$

[23] $C_{2n+2}N^+ + CH_2 \rightarrow H_2C_{2n+3}N^+ + h\nu$

These reactions involve radicals as neutral reactants and would be much more difficult to measure in the laboratory.

Scheme D

The hydrocarbon ions required for reactions [7] and [10] contain an odd number of carbon atoms. There are a number of possible sources for $C_{2n+1}H^+$ ions in the interstellar environment. These include the protonation of odd carbon clusters as illustrated by reaction [24], the hydrogenation of odd carbon ion

[24] $XH^+ + C_{2n+1} \rightarrow C_{2n+1}H^+ + X$

clusters as indicated by reaction [25], or the reactions of C^+

[25] $C^+_{2n+1} + H_2 \rightarrow C^+_{2n+1}H^+ + H$

with polyacetylenes as in reaction [26]. Reactions of type [24]

[26] $C^+ + C_{2n}H_2 \rightarrow C_{2n+1}H^+ + H$

have not yet been observed in the laboratory. Also, the proton affinities of neutral carbon clusters are not known. Nevertheless, these reactions are expected to occur in interstellar clouds because of the presence of likely proton donors such as H_3^+, N_2H^+, and CHO^+. Reactions of type [25] have recently been investigated with the SIFT technique. For the reaction of C_3^+ a rate constant of 3.0×10^{-10} cm^{-3} molecule^{-1} s^{-1} has been reported (23). We can report here new results for our observations of the following two deuteration reactions:

[27] $C_3^+ + D_2 \rightarrow C_3D^+ + D$

[28] $C_5^+ + D_2 \rightarrow C_5D^+ + D$

Reactions [27] and [28] were found to have room temperature rate constants of (1.3 ± 0.4) and $(5 \pm 2) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}, respectively. Reactions of type [26], important in interstellar clouds because of the relatively high abundance of C^+ ions, have been observed with acetylene and diacetylene for which rate constants of 2.2 and 1.5×10^{-9} cm^3 molecule^{-1} s^{-1}, respectively, have been reported (16, 24).

Still another source of C_nH^+ ions has become apparent in a recent study of the chemistry of C_4N^+. This latter ion was observed to react with acetylene and diacetylene to produce C_5H^+ and C_7H^+ respectively through reactions of type [29] (22):

[29] $C_4N^+ + C_{2n+2}H_2 \rightarrow C_{2n+5}H^+ + HCN$

Possible direct sources of $C_{2n+1}H_3^+$ ions which are likely in dense interstellar clouds involve reactions of CH_3^+ with acetylene and polyacetylenes. The kinetics of the reactions with acetylene and diacetylene have now been characterized in the laboratory. The reaction with acetylene produces $C_3H_3^+$ exclusively according to reaction [30] (5):

[30] $CH_3^+ + C_2H_2 \rightarrow C_3H_3^+ + H_2$

while the reaction with diacetylene produces some $C_5H_3^+$ according to reaction [31] (16).

[31] $CH_3^+ + C_4H_2 \xrightarrow{0.9} C_3H_3^+ + C_2H_2$

$$\xrightarrow{0.1} C_5H_3^+ + H_2$$

There is little experimental information on the reactions of $C_{2n+1}H^+$ and $C_{2n+1}H_3^+$ with N atoms and on the subsequent hydrogenation of the $C_{2n+1}N^+$ ions. Only one member of reactions [7] and [10] has been studied in the laboratory. Recent flow-drift experiments have provided a rate constant of 1.3×10^{-10} cm^{-3} molecule^{-1} s^{-1} for the reaction near thermal ener-

For personal use only.

gies (0.1 to 0.2 eV) of $C_3H_3^+$ derived by electron impact on C_3H_7Br (25):

[32] $C_3H_3^+ + N \rightarrow H_2C_3N^+ + H$

Data for hydrogenation reactions of type [8] is also sparse. SIFT experiments have shown that C_3N^+ rapidly hydrogenates at 300 K according to reaction [33] with a rate constant of 9.1 ×

[33] $C_3N^+ + H_2 \xrightarrow{0.90} HC_3N^+ + H$

$$\xrightarrow{0.10} H_2C_3N^+$$

10^{-10} cm^3 molecule^{-1} s^{-1} at ca. 0.3 Torr in helium buffer gas (21). The further hydrogenation of HC_3N^+ is much slower at 300 K and competes with a dissociative channel in the manner expressed by reaction [34] (21, 26):

[34] $HC_3N^+ + H_2 \xrightarrow{0.5(0.76)} H_2C_3N^+ + H$

$$\xrightarrow{0.5(0.24)} C_2H_2^+ + HCN$$

Rate constants at 300 K of 1.9 and 7 × 10^{-12} cm^3 molecule^{-1} s^{-1} have been reported for this reaction (21, 26). The temperature dependence of this slow reaction is not known but it is conceivable that the rate constant for this reaction increases as the temperature drops in analogy with the reaction of NH_3^+ with H_2 (17).

Conclusions

Some progress has been made in this study and others carried out over the past few years in the characterization of the ion/molecule reactions which constitute the four reaction schemes proposed for the gas-phase synthesis of interstellar cyanopolyacetylenes. Substantial gaps still exist, but there is now sufficient data to allow some discrimination between the four schemes.

The polyacetylenic ions required for Scheme A are readily generated by sequential reactions involving C_2 and C_4 units. But the entrainment of nitrogen through an eventual bimolecular reaction with HCN appears to succeed only with $C_2H_2^+$ and thus only for the formation of cyanoacetylene. The four-carbon ions do not react with HCN in a bimolecular fashion at 300 K; $C_4H_2^+$ was observed to react with HCN in a rapid termolecular association reaction. The success of this scheme must therefore rest on the reactions with CN for which there is no information.

Scheme B relies on the build-up of cyanopolyacetylenes by their repeated reaction with acetylenic ions. However, measurements with cyanoacetylene suggest that this growth may be short-circuited by proton transfer or by elimination of HCN.

Growth by repeated addition of single carbon units to cyanopolyacetylenes through sequential reactions with C^+ ions and CH_n neutrals as described in Scheme C appears to be quite feasible. Results are presented for the critical reaction of C_4N^+ with CH_4 which provides the bridge from cyanoacetylene to cyanodiacetylene. The scheme is projected to higher members of the cyanopolyacetylenes and is attractive especially in view of the chemical feedback that is possible. More information is required for the higher members of the homologous series.

There is still little laboratory evidence for Scheme D in which nitrogen entrainment by slightly hydrogenated hydrocarbon ions occurs through reaction with nitrogen atoms. Nevertheless this route remains an attractive option unless hydrogenation reactions with H_2 are required to build up the hydrogen content before neutralization to form the cyanopolyacetylene. The efficiency of hydrogenation appears variable and unpredictable. New results are presented for the hydrogenation of odd-numbered carbon ions which leads to the slightly hydrogenated hydrocarbon ions which can initiate Scheme D.

Electrochemical and modulated specular reflectance spectroelectrochemical (MSRS) investigations were performed on 1-(diphenylmethylene)cyclopropabenzene in nominally dry acetonitrile solution. The results indicate the formation of a stable anion radical (λ_{max} = 587 nm) and a quasi stable cation radical (λ_{max} = 473 nm). The first order homogeneous rate constant for the decay of the cation radical was computed.

On a effectué des études électrochimiques et spectroélectrochimiques de réflectance spéculaire modulée (SRSM) sur le diphénylméthylène-1 cyclopropabenzène en solution dans de l'acétonitrile qui est théoriquement sec. Les résultats indiquent qu'il y a formation d'un anion radical complexe (absorption maximale à 587 nm) et d'un cation radical qui est pratiquement stable (absorption maximale à 473 nm). On a évalué la constante de vitesse homogène du premier ordre pour la décomposition du cation radical.

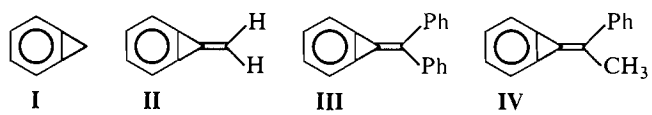
Introduction

The unusual properties and reactivity of highly strained molecules have interested chemists for quite some time (1). Presently there is a great deal of interest and research activity in cycloproparene chemistry. Cycloproparenes possess some of the highest strain energies known (2); the parent compound **I** has a strain energy of 68 kcal/mol (3). As a result, the electrochemical oxidation and reduction potentials of the neutral molecules are lower than those of most other electroactive hydrocarbons.

Even more highly strained and unusual alkylidene derivatives of **I** have been reported (4): the diphenylmethylene (**III**) and the 1-phenylethylidene (**IV**) derivatives have been synthesized, as well as the corresponding naphthalene analogs **V** and **VI**.



I **II** **III** **IV**

V **VI**

Compounds **III** and **V** are stable in air and in aprotic solvents against rapid oxidation. The methylenecycloproparene parent compound **II** has not been successfully isolated, but attempts to synthesize this species continue.

The possibility of charge separated resonance forms contributing to the stability of the neutral molecule **V** was suggested by an initial spectral characterization. We have recently reported the results of an electrochemical and spectroelectrochemical study of **V** (5), and in an effort to further characterize and understand the nature of the special properties of these molecules we have undertaken an electrochemical and spectroelectrochemical investigation of **III**. One question is how large a role does the aromatic moiety of the cycloproparene ring play in the stability of the ion radicals compared to the substituents on the methylene group. The naphthalene analog in the previous study was shown to form a stable anion radical (on the timescale of the experiment) when electrochemically reduced in oxygen-free acetonitrile solution. When oxygen is present the anion radical reacts rapidly with O_2 at a rate approaching the diffusion limit. Additionally, the compound was shown to form a quasi stable cation radical when electrooxidized. In the present study, compound **III** has been found to behave similarly. In addition, the homogeneous rate constant for the decay of the cation radical in acetonitrile solution has been computed from spectroelectrochemical transient data.

Experimental

Chemicals and reagents

The preparation of **III** has been described in detail (4, 14). A stirred solution of cyclopropabenzene in dry THF was cooled to −70°C under

oxygen-free nitrogen; *n*-butyllithium in hexane was added slowly, while the bath temperature was allowed to rise to −40°C. After 1.5 h the solution was again cooled to −70°C, and trimethylsilyl chloride was added dropwise until the deep orange solution had become colorless. The reaction mixture was allowed to warm slightly for 1 h and then cooled again to −70°C, at which time the above metallation procedure with *n*-butyllithium was repeated. Quenching of the generated α-silyl carbanion was attained with benzophenone in THF, and the resulting clear yellow solution was allowed to warm to room temperature. After 1.5 h aqueous sodium bicarbonate was added after which the mixture was extracted with dichloromethane. The combined organic extracts were washed with water, dried with magnesium sulfate, and concentrated to an orange oil under reduced pressure. This oil was then passed through a silica gel column (petroleum ether:ethyl acetate, 9:1) and fractions of the most mobile component, 1-(diphenylmethylene)cyclopropabenzene, were collected as a yellow oil which solidified on standing at −20°C. Recrystallization from petroleum ether gave yellow needle-like crystals, mp 89–91°C.

The preparation of tetra-*n*-butylammonium tetrafluoroborate (TBAF) has been described previously (6). This supporting electrolyte was prepared from the metathesis of sodium tetrafluoroborate and tetra-*n*-butylammonium hydrogen sulfate. The crude product was washed with ice water, dissolved in a minimum amount of methylene chloride, and precipitated with cold diethyl ether. After a second recrystallization, the product was air dried and stored in a vacuum oven at 75°C for 24 h before use.

Acetonitrile was hplc grade (Baker Chemicals, 0.001% nominal water content) and was used as received. Deoxygenation of the reaction mixture was accomplished by purging with dry helium gas immediately prior to the experiments.

The reference electrode was a silver wire immersed in 0.01 *M* silver nitrate and 0.10 *M* TBAF in acetonitrile. We report all potentials with respect to this reference.

Electrochemistry and spectroelectrochemistry

A three electrode potentiostat and a waveform generator (JAS Instrument Systems, Inc.) provided the control of electrode potential. Cyclic voltammetry was conducted in a three-electrode kinetic cell wherein a platinum wire working electrode surrounded by a cylindrical platinum foil secondary electrode was mounted. A Luggin capillary reference electrode tip was situated within about 1 mm of the working electrode. Although the geometry of the setup is cylindrical, the experiments were carried out on a timescale where linear diffusion is observed. See ref. 7 for precise details. For spectroelectrochemical experiments, a cell was used that held a 7 mm diameter platinum mirror disk working electrode with a planar Pt foil counter electrode situated opposite, providing good linear diffusion characteristics for up to 10 s. Two quartz windows were mounted to enable passage of incoming and outgoing uv/vis radiation at a 45° angle of incidence and reflectance. A Luggin reference probe was positioned close to the working electrode so as not to obstruct the optical path. Exact details have been described previously (8).

The spectroelectrochemical cell was mounted on an optical bench, and the optical beam from a monochromator (GCA McPherson model 302) was directed onto the electrode surface, and reflected onto a photomultiplier tube (RCA model 31000A). The signal from the PMT was digitized by an oscilloscope (Tektronix model 5223): this datum was transmitted over a GPIB interface to a computer (IBM PC/AT). The computer signal averaged digitized data from single reflectance transients: the background intensity was controlled so that the value of the relative reflectance could be calculated as described in ref. 8. The MSRS technique used in this work was implemented by first maintaining the potential at a value where no electrochemical reaction occurred. The potential was then stepped to a value where electrooxidation or electroreduction was forced into diffusion control, and the spectroelectrochemical reflectance transient response of the electrogenerated species was recorded on the digitizing oscilloscope as a function of time after the potential pulse was applied. Alternately, the potential was also modulated at a high frequency (40 Hz) and the resulting ac reflectance change monitored with a lock-in amplifier: scanning wavelength simultaneously provided uv-vis difference spectra of the reactants, intermediates, and products (8).

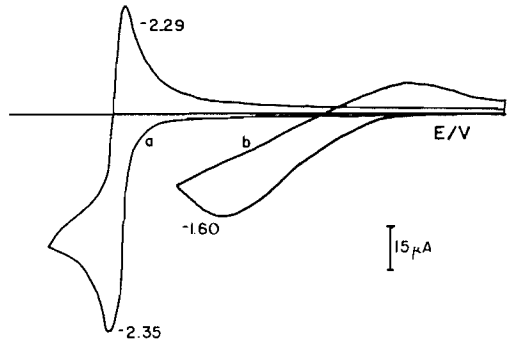

FIG. 1. Cyclic voltammetry for (*a*) 1 m*M* **III** and for (*b*) dioxygen in 0.15 *M* TBAF/acetonitrile solution at a platinum electrode. The sweep rate was 50 mV s^{-1}. Potentials are vs. the Ag/Ag^+ (0.01 *M* $AgNO_3$ in 0.1 *M* TBAF in acetonitrile) reference electrode.

Results and discussion

Voltammetry

A. Anions

At a platinum electrode, the voltammetric reduction of a blank solution containing only supporting electrolyte showed no faradaic current (<0.1 μA cm^{-2}) over the range of potentials studied. Cyclic voltammetry of **III** at negative potentials in oxygen-free acetonitrile solution is shown in Fig. 1*a*. A one-electron wave due to the reduction of the neutral molecule to the anion radical at the platinum working electrode is observed. The voltammetric response indicates electrochemical reversibility at this (50 mV s^{-1}) and faster sweep rates: the voltammetric peak separation is 60 mV, and the ratio of cathodic to anodic peak currents is unity. The half-wave potential is −2.32 V vs. Ag/Ag^+. There is no evidence of anion radical decay on the experimental timescale (ca. 1 min); the anion radical is quite stable, as is that of the naphthyl cycloproparene analog (5).

When only oxygen is present in solution a voltammogram such as that in Fig. 1*b* results. The first cathodic wave at −1.60 V (vs. Ag/Ag^+) corresponds to the reduction of oxygen to superoxide, which is a kinetically slow electron transfer (5). On the return excursion an anodic peak at −0.78 V due to the reoxidation of superoxide is seen. The diffusion-controlled peak for the formation of superoxide is thus 750 mV less negative than the peak potential for the formation of the anion radical of **III** at a sweep rate of 50 mV/s. (At glassy carbon the reduction of oxygen is kinetically more reversible: the separation between the cathodic peak due to the formation of superoxide and the corresponding oxidation peak is reduced from about 820 mV at platinum at 240 mV on carbon at these sweep rates.)

Plots of cathodic peak current versus square root of sweep rate for both dioxygen and isolated **III** are linear for sweep rates of up to 500 mV/s; the plots intersect the origin. This is the expected result for an electrochemical reaction where there are no complicating side reactions involving reactants or products, and where there are no complications due to adsorption of species undergoing electron transfer. Uncomplicated electrochemical formation of the anion radical of **III** and of superoxide is thus consistent with observations; both reductions are simple one-electron transfers.

However, solutions containing both **III** and oxygen demonstrate more complicated voltammetry than that of the individual systems described above (Fig. 2). As in Fig. 1, the first reduction wave at −1.60 V corresponds to the formation of

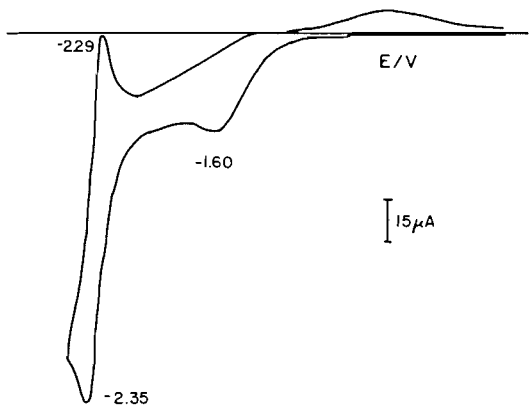

FIG. 2. Cyclic voltammetry of the mixed system of the components in Fig. 1. Parameters the same as in Fig. 1.

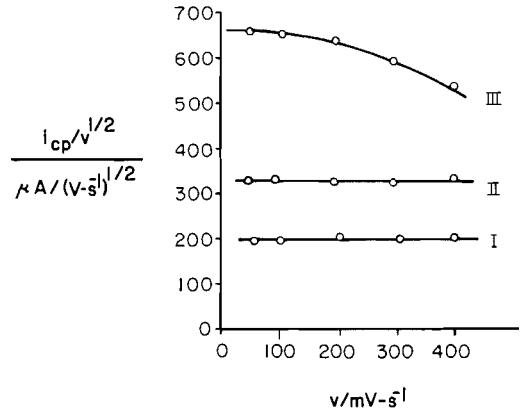

FIG. 3. Plots of the normalized peak current vs. sweep rate for the data in Figs. 1 and 2. (I) is that for the reduction peak in Fig. 1*b*; (II) is that for the reduction peak in Fig. 1*a*; (III) is for the reduction peak at −2.35 V in Fig. 2. Except for the sweep rate, the parameters are the same as those in Fig. 1.

superoxide. We observe, however, that the magnitude of the current in the second wave at −2.35 V, due to the formation of the anion radical of **III** is larger than that for the simple one electron transfer as was observed in the single component **III** system. There are several possible explanations for this behavior.

One possibility is the case where an electroactive product is formed whose reduction potential is less negative than that of **III**. In the present case, this would most likely be due to the reaction of the anion radical of **III** with diffusing oxygen or superoxide:

$$\mathbf{III}^{\cdot -} + O_2 \rightarrow W$$

$$W + ne^- \rightarrow X$$

or

$$\mathbf{III} + O_2^- \rightarrow Y$$

$$Y + ne^- \rightarrow Z$$

(The second reaction is unlikely, as it is unfavorable energetically.) However, bulk electrolysis of **III** at potentials up to and less negative than −2.35 V yielded no evidence of the expected products of either of the proposed reaction schemes. Additionally, if such an electron transfer — chemical step — electron transfer scheme were indeed occurring, the height of the second cathodic wave would imply the involvement of more than one electron in the reduction of W or Y which, though possible, is unlikely.

Voltammetric experiments revealed no evidence of the reaction of unreduced **III** with oxygen. Upon deoxygenation with helium purging of the mixed (both **III** and O_2 present) solution, the uncomplicated electrochemical behavior shown in Fig. 1*a* could be reproduced. Also, if in the mixed system, a cyclic voltammogram was run to a switching potential past the peak for oxygen reduction but prior to the cathodic wave corresponding to reduction of **III**, the reverse sweep yielded an oxidation peak for superoxide which was uncomplicated, as per Fig. 1*b*. This is evidence that superoxide does not react chemically to any appreciable extent with **III**, although Fig. 2 shows a depletion of available total radical anion of **III** in the diffusion layer; the oxidation peak at −2.29 V is reduced in magnitude when O_2 is present. All of the above possibilities suggest that a product of the addition of **III** and oxygen should be observed, but exhaustive electrolyses at or beyond the second reduction wave gave no significant yields of any product of **III** except the anion radical.

Another possible explanation for the unusually high current seen in the second reduction wave (in the mixed system) is the catalytic regeneration of **III** by reaction of oxygen with the anion radical to form **III** and superoxide:

$$\mathbf{III}^{\cdot -} + O_2 \rightleftharpoons \mathbf{III} + O_2^-$$

In turn, superoxide reacts with the anion radical to form **III** and peroxide in the presence of a proton donor:

$$HS + \mathbf{III}^{\cdot -} + O_2^- \rightleftharpoons S^- + \mathbf{III} + HO_2^-$$

Whereas O_2^- is not a strong enough base to react with HS in dry acetonitrile (O_2^- is stable in dry acetonitrile for about 40 min), electron transfer from $\mathbf{III}^{+\cdot}$ to O_2^- would form a base (5) such as O_2^{2-} that is now strong enough to react with HS (the solvent). These results imply that electrochemical reduction of superoxide to peroxide is thermodynamically feasible at potentials where **III** is reduced, but that the electrode reaction is very slow. The formation of peroxide in acetonitrile has been previously observed (9), where superoxide in the presence of any available proton donor was reported to disproportionate to peroxide and oxygen. Bulk electrolysis of the mixed system at a potential of −2.40 V did indeed give rise to solutions which were found to contain peroxide ion, as evidenced by testing with Fenton's reagent. Thus, if **III** is regenerated continuously in the presence of oxygen, the cathodic current at the electrode, which is diffusion limited, will be expected to increase as observed, without the production of any other organic product of **III** (except the anion radical).

Figure 3 shows a plot of the normalized (to the square root of the sweep rate) current magnitude as a function of the sweep rate for the aromatic hydrocarbon–oxygen system. The lowest plot (I) is that for the oxygen reduction peak. Plot II is that for the uncomplicated one electron reduction peak of **III** to its anion radical in the absence of oxygen. Plot III is for the cathodic peak at −2.35 V when both **III** and oxygen are present in comparable amounts. The reduction peak in plot III is the sum of the currents for the reduction of **III** to its anion radical and the reduction of electroactive products formed from the reaction of the anion radical with oxygen and superoxide, which the data suggest to be more regenerated **III** as proposed in the preceding paragraph.

It should be noted that in the mixed system, a subsequent cathodic excursion following cyclic voltammetry from 0 to −2.5 V vs. Ag/Ag^+ gave rise to no additional reduction waves

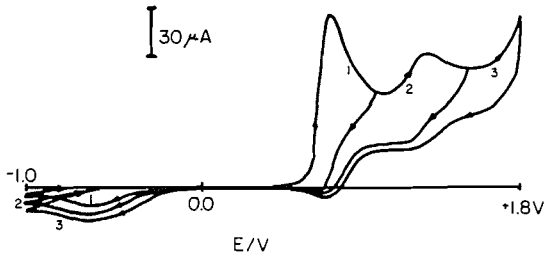

FIG. 4. Cyclic voltammetry of 1 m*M* **III** in acetonitrile. Potential program was 0.0 V to positive potentials, then reversing to negative potentials, then returning to zero. Parameters the same as in Fig. 1.

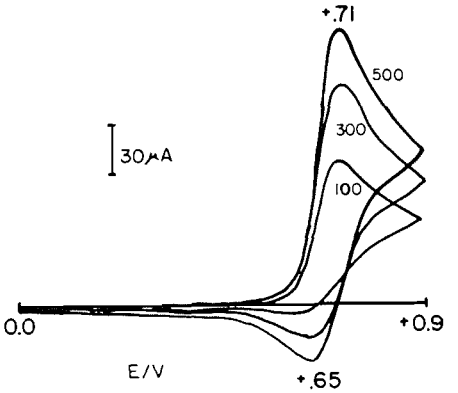

FIG. 5. Cyclic voltammetry of 1 m*M* **III** in acetonitrile as a function of sweep rate. Parameters the same as in Fig. 1.

at lower potentials than that for **III** reduction. This is further evidence that no long-lived organic products of the reaction of the anion radical with O_2 and superoxide other than **III** are generated. Though short-lived products of this reaction cannot be ruled out, the fact that the cathodic peak at −2.35 V grows in comparison with the anodic peak at −2.29 V is certainly consistent with regeneration of additional **III**.

The half wave potential for the reduction of **III** is 400 mV more negative than that for the reduction of **V** (5). This is the expected result in view of the greater delocalization of the extra electron possible in the larger π orbital system: the stability of the naphthyl anion is greater than that of the benzyl analog, just as it is known to be in naphthalene and benzene. We have performed simple Hückel calculations on **III** and **V** and find that this assumption is in line with the results of those calculations.

B. Cations

In deoxygenated acetonitrile solution, a voltammetric sweep to positive potentials gives rise to single electron oxidations of **III** to its radical cation and of its radical cation to dication (Fig. 4). The second reduction is irreversible: the lifetime of the dication is very short on the experimental timescale. On the other hand, the anodic and cathodic peak potential separation (corresponding to oxidation of **III** and reduction of $\mathbf{III}^{+\cdot}$, respectively), approach 60 mV when sweep rates are increased to 500 mV s^{-1}, suggesting electrochemical reversibility at this sweep rate; the half-wave potential there is +0.68 V. However, up to 500 mV s^{-1}, the anodic peak current (oxidation of **III**) is greater than the cathodic peak current (reduction of $\mathbf{III}^{+\cdot}$), and the ratio of cathodic to anodic peak current increases with sweep rate (Fig. 5). These observations are consistent with a reversible electron transfer followed by kinetic decomposition of the resulting cation radical (5). If the potential is swept immediately to more negative values following the oxidation of **III** to its cation radical, a new peak appears at about −0.7 V (Fig. 4); this peak is due to the reduction of protons formed in the decomposition of the cation radical. If the potential is swept positive enough to form the dication, and then immediately swept negative to potentials where the anion radical is formed, no peak for the reduction of the dication is observed; only the reduction due to the protrons is evident.

At a glassy carbon electrode, virtually identical behavior was observed for **III** at all applied potentials except the cathodic peak at −0.7 V disappeared, which confirms that this wave corresponds to the reduction of protons formed in the first anodic wave. Also, oxygen had no effect on the electrochemistry of the cation radical or dication; the very same voltammetry as described above was observed even if oxygen was present in solution.

It is interesting to note that the half wave potential for the oxidation of the benzyl derivative **III** is about 130 mV *less* positive than the half wave potential for the oxidation of the naphthyl derivative **V** (5). This surprising result is not explained by simply considering the stabilities of the ions as was possible in the case of the reduction of these two compounds. The result can be explained for both oxidation and reduction if one assumes that there is a large difference in the ground state energies of the two neutral compounds **III** and **V**, and lesser differences in the electronic energies of their respective cation radicals. If neutral **V** is energetically more stable than **III**, it will be more difficult to oxidize than **III**, given that the cations of each are closer in energy than are the neutral species. This trend was indeed indicated in the Hückel calculations; the overall stabilization energy of **V** was predicted to be greater than that of **III**, whereas the electronic energy difference between the cation radicals is less than the energy difference between the neutral species.

C. Structural considerations

The consideration of the possible structures of the electrochemically formed ion radicals is of interest. The reversible behavior of **III** upon oxidation and reduction indicates that no opening of the three-membered ring occurs when either the cation radical or the anion radical is formed. The compound is reduced at slightly less negative potentials than many other aromatic hydrocarbons in acetonitrile. The half-wave potential for the reduction of **III** was seen to be −2.32 V vs. Ag/Ag^+. This value compares with half-wave potentials of −2.9 V for naphthalene, −2.5 V for tetraphenylethylene, −2.5 V for pyrene, −2.4 V for diphenylanthracene, and −1.93 V for diphenylmethylenecyclopropa[*b*]naphthalene. Compound **III** is oxidized at somewhat less positive potentials than many other aromatic hydrocarbons in this solvent. It has a half-wave potential of +0.68 V for oxidation to the cation radical. For naphthalene this value is +1.40 V, for pyrene +1.06 V, for tetraphenylethylene +1.0 V, for diphenylanthracene +0.92 V, for anthracene +0.91 V, for diphenylmethylenecyclopropa[*b*]-naphthalene +0.81 V, and for perylene +0.66 V.[3]

On formation of the radical ions, it is most likely that the olefinic double bond is broken. This release of strain would yield a reduced free energy of ion formation. The anion would be then formed at less negative potentials and the cation formed

[3]These half-wave potentials were obtained from refs. 5, 10, and 11, assuming where necessary that the potential of the Ag/Ag^+ reference electrode is 0.3 V more positive than that of the saturated calomel electrode.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

at less positive potentials than what might be predicted from half-wave potentials of other aromatic hydrocarbons. Proposed structures for the anion radical are:

while possible structures for the radical cation might be:

It is not possible from our voltammetric data to conclude for either species which resonance structure contributes most to the lowest overall energy state.

Spectroelectrochemistry

A. The anion radical

Modulated specular reflectance spectroscopy (MSRS) in the visible range was performed on solutions containing **III** (1 m*M*) in acetonitrile in the absence of oxygen. The potential was stepped from 0 to −2.50 V and the frequency of modulation was 40 Hz. The MSRS technique is described more explicitly in refs. 8 and 12. A single peak (λ_{max} = 587 nm) due to absorption by the radical anion was observed. Reflection spectroelectrochemical transients for the formation of the anion radical were then obtained at this wavelength using the same potentials. Figure 6 shows the transient for radical anion formation of **III** at the platinum mirror electrode in the absence of oxygen. Composite transient data from 100, 200, 400, and 1000 ms transients were combined to examine the linearity of the optical response with the square root of time over an extended period. Linearity indicates anion radical stability over the examined timescale, if the amplitude of $\Delta R/R$ is kept small. The plots of $-\Delta R/R$ vs. $t^{1/2}$ were indeed linear with a correlation coefficient of 0.99885, showing the radical anion to be very stable for times of at least 1 s. This also demonstrates the reproducibility and accuracy of this transient technique.

Figure 7 shows the transient that results when oxygen is present in solution together with **III**. MSRS data data of this system at the same potentials of modulation still revealed a single peak at the same wavelength as that for the oxygen-free system, demonstrating that superoxide does not absorb at this or at any nearby frequency. We still observe the formation of the radical anion during the forward potential step although the reflectance is somewhat less. When the potential is reversed to its base value, however, to where only neutral **III** and O_2 are stable, the reflectance, which is proportional to absorbance at low values of $\Delta R/R$, is observed to decay rapidly to zero. Clearly, the anion radical of **III** reacts rapidly with oxygen.

Regeneration of **III** is suggested by the observed reflectance–time profile during the forward applied potential pulse; the shape of the transient is still a linear function of the square root of time. $\mathbf{III}^+$ diffuses from the electrode surface into the oxygen and superoxide rich solution, neutral **III** is formed and can therefore diffuse back to the electrode and undergo another reduction.

The results are consistent with the following proposed mechanism for the cathodic reduction of **III**:

IN THE ABSENCE OF OXYGEN

$$\mathbf{III} + e^- \rightleftharpoons \mathbf{III}^{\cdot-} \qquad E^{\circ} = -2.32 \text{ V}$$

In oxygen-free solution a simple electron transfer occurs reversibly to form the anion radical from neutral **III**.

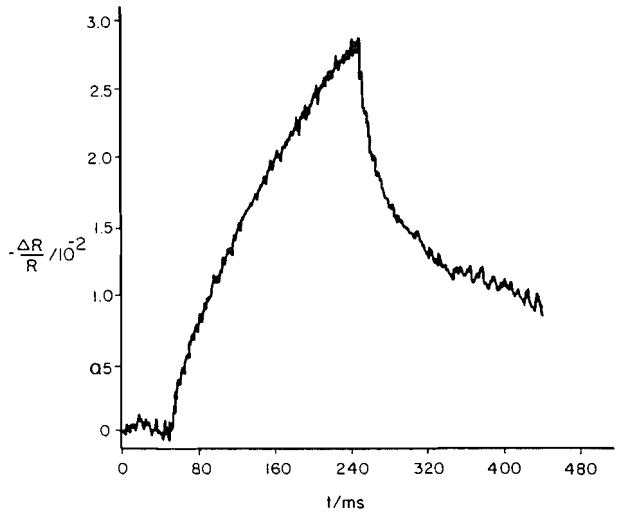

FIG. 6. Reflectance spectroelectrochemical transient at 587 nm for the anion radical of **III** in the solution described in Fig. 1*a*. (The solution is oxygen-free.)

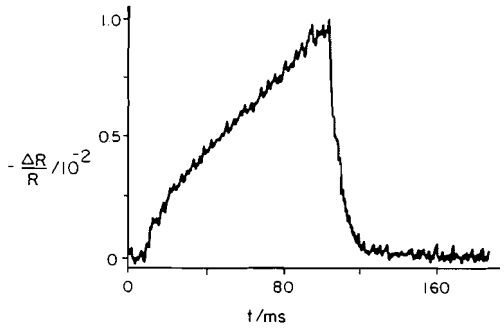

FIG. 7. Reflectance spectroelectrochemical transient at 587 nm for the anion radical of **III** in the solution described in Fig. 2. (The solution contains oxygen.)

IN THE PRESENCE OF OXYGEN

$$O_2 + e^- \rightleftharpoons O_2^{\cdot-} \qquad E^{\circ} = -1.18 \text{ V}$$

$$\mathbf{III} + e^- \rightleftharpoons \mathbf{III}^{\cdot-} \qquad E^{\circ} = -2.32 \text{ V}$$

$$O_2 + \mathbf{III}^{\cdot-} \rightleftharpoons O_2^- + \mathbf{III}$$

$$HS + O_2^{\cdot-} + \mathbf{III}^{\cdot-} \rightleftharpoons S^- + HO_2^- + \mathbf{III}$$

Here the mean of the oxidation and reduction peak potentials for dioxygen have been taken to be the standard potential. During the forward potential step, the rate of production of the anion at the electrode is limited by the diffusion of the neutral species to the surface. Reaction of anion with oxygen and superoxide regenerates the neutral molecule, so more of **III** is available to diffuse to the interface. Because of this, the absorbance of the radical anion in oxygen-containing solution is not much lower than it is in the solution in which oxygen is not present. During the reverse potential pulse, however, the oxygen consumes the anion while the regenerated starting material cannot react electrochemically to form more anion to replace that which is consumed. The reflectance therefore fails rapidly in comparison to the case in an oxygen-free environment.

The supporting electrolyte cation, TBA^+, probably acts as a proton donor in the proposed scheme. The peroxide dianion most likely abstracts a proton from the background electrolyte.

Further studies on this possibility are underway and will appear elsewhere.

Evidence for the greater stability of the anion radical of **V** than that of **III** is apparent from the MSRS experiment. The wavelength of maximum absorption for the anion radical of **III** appears at 587 nm, while that for the anion radical of **V** is observed at 529 nm (5); the energy of the electronic transition for the naphthyl derivative anion radical is higher than that for the benzyl derivative anion radical. Energy levels predicted from the Hückel calculations appeared at relative energies which are consistent with these data.

B. The cation radical

A reflectance transient spectrum was obtained as before for the cation radical formation from **III**, by stepping the electrode potential (chronoamperometric experiment) from 0 to +0.9 V, which causes diffusion-controlled mass transport of neutral **III** to the electrode. The current response indicated a simple one-electron transfer. The wavelength of maximum $\Delta R/R$ was found at 473 nm for the formation of the radical cation. Identical spectra resulted whether O_2 was present or absent in the solution. Spectroelectrochemical transients for the anodic oxidation of **III** to its radical cation were then taken at the above λ_{max} for pulse lengths of 20, 40, 100, 200, and 400 ms duration; a typical transient is shown in Fig. 8. Such transients were identical whether O_2 existed in solution or did not, suggesting no cation radical reaction with oxygen. The composite data from the above transients of different length were plotted as before ($\Delta R/R$ vs. $t^{1/2}$) (Fig. 9). The plot is linear up to times of about 100 ms, and thereafter we see a fall-off region; the cation radical is stable for a short period before it undergoes decay.

Whether this decay involves an electron transfer or not, a chemical step is certainly involved; it is the product of this decay which appears at cathodic potentials upon reverse sweep to negative values in the cyclic voltammetry described earlier. Assuming first or pseudo first order kinetic behavior, we can compute the homogeneous rate constant for the decay of the radical cation from the spectroelectrochemical data utilizing the technique described in refs. 12 and 13, where the rate constant

$$k = \frac{\left[-\frac{\Delta R}{R}\right]_0 - \left[-\frac{\Delta R}{R}\right]}{\int_0^t \left[-\frac{\Delta R}{R}\right]_k dt}$$

Here $[-\Delta R/R]_0$ is the change in reflectance which would be obtained at time t if the absorbing species does not decay, and $[-\Delta R/R]_k$ is the change in reflectance where decay occurs with a first order rate constant k. Computation of this k value was performed from data from various transients in excess of 100 ms length, and a mean homogeneous first order rate constant of 1.99 s^{-1} was determined for the degradation of the cation radical.

The data are consistent with the following mechanism for the oxidation of **III**, either in the presence or absence of oxygen:

$$\mathbf{III} \rightleftharpoons \mathbf{III}^{+\cdot} + e^-$$

$$\mathbf{III}^{+\cdot} \xrightarrow{k} P$$

$$(P + ne^- \rightleftharpoons Q)$$

It was not possible from the spectroelectrochemical data to determine between an EC or an ECE mechanism where the second electron transfer could not be observed (*vide infra*).

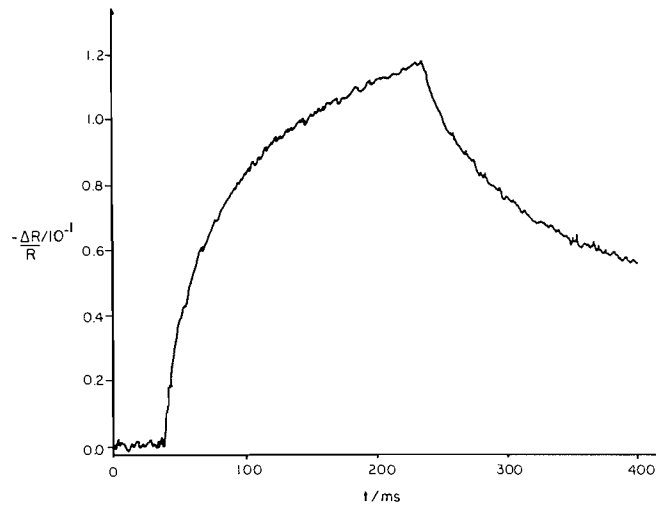

FIG. 8. Reflectance spectroelectrochemical transient at 473 nm for the cation radical of **III** in the solution described in Fig. 4.

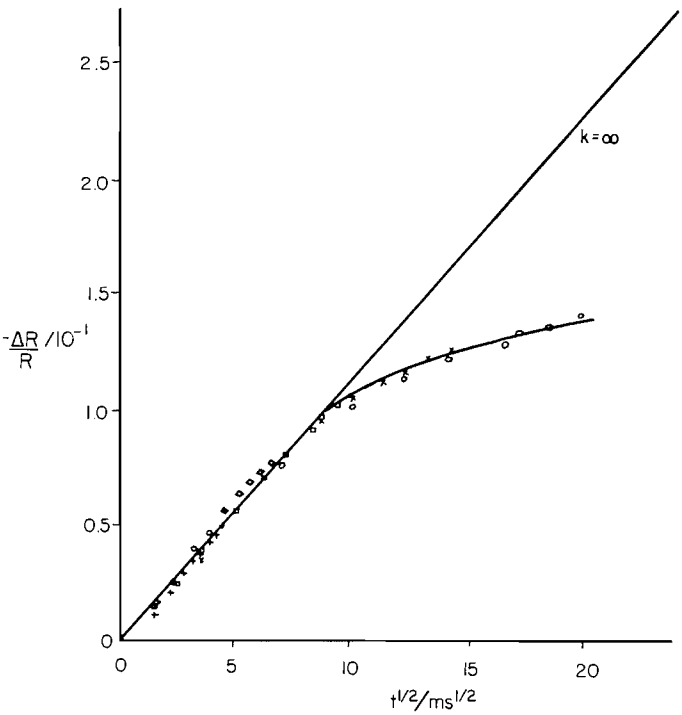

FIG. 9. Reflectance vs. square root of time plot for the formation of the cation radical from transients of duration: +, 20 ms; □, 40 ms; ◇, 100 ms; ×, 200 ms; ○, 400 ms. Solution is that described in Fig. 4.

The electrochemical and spectroelectrochemical (*vide infra*) evidence is for an EC type of reaction mechanism: subsequent electron transfer reactions are not indicated after the initial chemical reaction product is formed. If the concentration of the hydrocarbon is increased, the rate constant for reaction of the cation radical does not increase when the solution is very dry, indicating that in this solvent of low nucleophilicity, dehydrodimerization reactions to form the biphenyl or other dimer products with starting material or other cation radicals is not the major chemical reaction of the cation radical. The reaction also is not dependent on the nature or concentration of supporting electrolyte as long as the solutions are of sufficient conductivity to allow for reliable electrochemical measurements; lithium perchlorate, tetrabutylammonium tetrafluoro-

borate, and tetraethylammonium perchlorate all gave similar results at 0.05, 0.10, and 0.25 *M* concentrations. Water addition at the 1–20 m*M* level in all of these solutions did not lead to changes in the rate of cation radical reaction.

Other possible pathways (13, 15) for hydrocarbon cation radical reactions are well known. They proceed generally by an ECE type reaction, such as loss of proton to give the free radical with subsequent loss of another electron to give the carbenium species, which reacts with any nucleophile to give stable products. Disproportionation reactions occur much less frequently, and these are also overall two electron transfer reactions. The most plausible reaction is that there is a proton loss (*vide supra*) to form the free radical of **III**, which is (*a*) either electrochemically more difficult to oxidize than the starting material (this is indicated by the Hückel calculation), and/or (*b*) because of the slow rate of production from the cation the free radical species will be concentrated at a distance far from the electrode compared to the size of the reaction layer of the radical. The radical reacts away (probably by radical–radical dimerization) before it can be transported back to the electrode to undergo another electron transfer (cf. (*a*)).

MSRS spectra for the cation radicals of **III** and **V** gave similar wavelengths of maximum absorption: 473 and 480 nm, respectively. This indicates that the cation radicals have similar ground state electronic energies. The HOMO–LUMO electronic transition energies calculated with the Hückel programs were also consistent with these observations.

Conclusion

The voltammetric and spectroelectrochemical studies of the title compound suggest significant electronic differences in both **III** and **V** as well as their respective anion radicals, while indicating that the cation radicals of the two species are energetically similar. Studies on neutral alkylidene cyclopropabenzenes (14) have shown the stability of the cyclopropabenzene derivatives to be less than that of their naphthyl homologs. Simple Hückel molecular orbital calculations gave results which were consistent with these observations.

The hex-5-enose degradation: cleavage of glycosiduronic acid linkages in modified methylated *Sterculia* gums[1,2]

GERALD OLIVER ASPINALL,[3] LEV KHONDO, AND BRUCE ALAN WILLIAMS
Department of Chemistry, York University, North York, Toronto, Ont., Canada M3J 1P3

Received October 17, 1986

GERALD OLIVER ASPINALL, LEV KHONDO, and BRUCE ALAN WILLIAMS. Can. J. Chem. **65**, 2069 (1987).

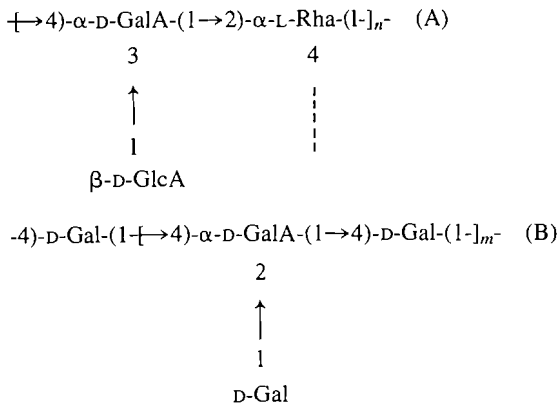
Reduction of uronic acid residues in permethylated polysaccharides from *Sterculia urens* and *S. caudata* gums, followed by transformation of the resulting hexose into 6-deoxy-6-iodohexose residues, affords modified polysaccharides that undergo depolymerization on treatment with zinc dust. The main products after reduction with sodium borohydride are hexenitol-terminated oligosaccharides. Their structures have been assigned as members of a series of *O*-[α-L-rhamnopyranosyl]-(1→3)-1,2-dideoxyhex-1-enitol derivatives, with and without attendant β-D-galactopyranosyl substituents, on the basis of nuclear magnetic resonance and mass spectral data and compositional analysis of trideuteriomethylated derivatives. The structures of the polysaccharides have been reassessed in the light of these and other experiments, and may now be formulated as containing a backbone of alternating 4-linked α-D-galacturonic acid and 2-linked α-L-rhamnopyranose residues bearing a minimum of three types of side chains attached at specific sites. Characterization of some of the degradation products provides evidence that limited degradation had occurred during methylation of the glycuronans.

GERALD OLIVER ASPINALL, LEV KHONDO et BRUCE ALAN WILLIAMS. Can. J. Chem. **65**, 2069 (1987).

La réduction de résidus d'acide uronique de polysaccharides perméthylés provenant de gommes de *Sterculia urens* et de *S. caudata*, suivie d'une transformation de l'hexose qui en résulte en résidus déoxy-6 iodo-6 hexose, fournit des polysaccharides modifiés qui subissent une dépolymérisation lorsqu'on les traite par de la poudre de zinc. Les produits principaux provenant d'une réduction par le borohydrure de sodium sont des oligosaccharides se terminant par un hexènitol. En se basant sur des données de résonance magnétique nucléaire et de spectre de masse ainsi que sur des analyses de composition des dérivés trideutérométhylés, on a attribué leurs structures aux membres d'une série de dérivés *O*-[α-L-rhamnopyrannosyl]-(1→3)-didéoxy-1,2 hexène-1 itols qui pouvaient aussi porter des groupements β-D-galactopyrannosyles. On a réévalué les structures des polysaccharides à la lumière de ces expériences ainsi que d'autres et on peut maintenant affirmer qu'elles contiennent une unité de base formée d'acide α-D-galacturonique lié par la position 4 qui alterne avec un résidu du α-L-rhamnopyrannose lié par la position 2; cette unité répétitive porte un minimum de trois types de chaînes latérales qui sont attachées à des sites spécifiques. La caractérisation de quelques produits de dégradation fournit des données permettant d'affirmer qu'il s'est produit une dégradation limitée au cours de la méthylation des glycuronanes.

[Traduit par la revue]

Exudate gums from the *Sterculia* genus contain structurally similar, partially acetylated polysaccharides with residues of D-glucuronic acid, D-galacturonic acid, D-galactose, and L-rhamnose (1–5). The most detailed studies have been carried out on *S. urens* gum and led to the formulation of two structural regions: (A) repetitive 4-linked *O*-α-D-galactopyranosyluronic acid-(1→2)-L-rhamnopyranose units bearing β-D-glucopyranosyluronic acid residues at O-3 of galacturonic acid and undefined side chains at O-4 of rhamnose residues; and (B) branched trisaccharide units that are probably not present in repetitive sequences. Indirect evidence suggested that these latter units were continuous with and interrupted the rhamnogalacturonan regions at intervals (**1**). Other neutral sugar residues were not placed with certainty. Acid hydrolysis or acetolysis was used for partial fragmentation and took advantage of the relative resistance to acid-catalyzed cleavage of glycosiduronic acid linkages. A reversal of these preferences was effected by partial acetolysis of the carboxyl-reduced polysaccharide, which permitted the isolation of a more random selection of oligosaccharides, but it was not always possible to distinguish between galactose residues originally present and those formed from the reduction of galacturonic acid units. The recently developed hex-5-enose degradation (6, 7) provides an alternative fragmentation procedure in which selective cleavage takes place at former glycosiduronic acid linkages with the formation of hexenose-terminated oligosaccharides containing unaltered neutral glycosyl substituents. We describe here the application of this degradation to permethylated derivatives of *S. caudata* and *S. urens* gums with the formation of oligosaccharides that throw fresh light on the detailed structures of these polysaccharides.



1: previously formulated structural regions in *Sterculia urens* gum

The hex-5-enose degradation as applied to glycuronans (Scheme 1, **I**) involves methylation (**I** → **II**), followed by reduction (**II** → **III**) of hexuronic acid residues, iodination (**III** → **IV**), analysis by reductive deiodination (**IV** → **V**), and zinc dust degradation (**IV** → **VI**) to generate hexenoses

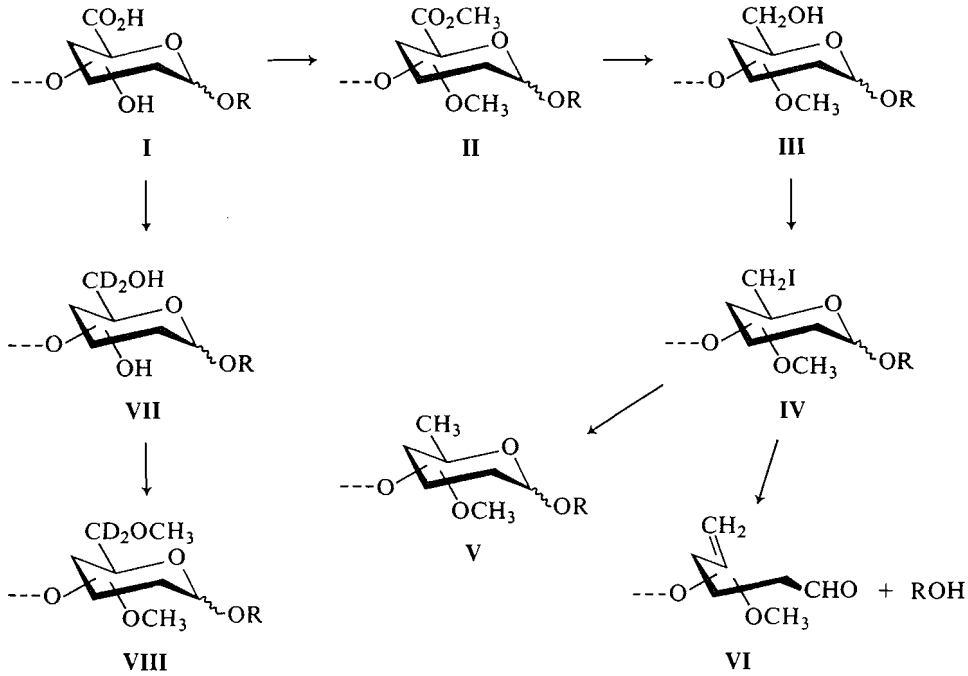

SCHEME 1. Modifications of *Sterculia* gums showing generalized structures for glycosiduronic acid residues undergoing change as described in the text.

with liberation of aglycons. Reduction of the methylated gum samples prepared in earlier investigations (1, 2) with lithium aluminum hydride afforded some material that was mobile on tlc plates, and the material of higher molecular weight that was required was separated by gel permeation chromatography on Sephadex LH-20. The methylated glycans after carboxyl reduction (**III**) were treated with *N*-iodosuccinimide and triphenylphosphine (8) to give iodinated derivatives. Since previous studies had established the presence of at least three types of uronic acid residues it was necessary to demonstrate completeness of reaction at each type of unit. This was achieved by treatment of samples of the iodinated glycans (**IV**) with tributylstannane (9) followed by hydrolysis and normal methylated sugar analysis by glc–ms of the derived partially methylated alditol acetates (10). In this manner newly formed 6-deoxyhexose residues (in **V**) were recognized as originating from the corresponding methylated uronic acid residues (in **II**). The results for both gums (Table 1) showed that a satisfactory degree of structural modification had occurred in the iodination step through disappearance of hexose (in **III**) and appearance of the related 6-deoxyhexose derivatives. Table 1 also presents the results of a different analysis of uronic acid residues in which deuterium-labelled carboxyl-reduced polysaccharides (**VII**), formed by treatment of polysaccharide 2-hydroxyethyl esters (1) with sodium borodeuteride, were converted into their methylated derivatives (**VIII**). Although reduction was not complete after two esterification–reduction cycles, a sufficiently high degree of modification had been achieved for methylation to be performed with the retention of potentially base-sensitive residues (*vide infra*). The glc–ms analysis of deuterium-labelled methylated sugar devivatives (Table 1) confirmed the presence of terminal glucuronic acid and two types of galacturonic acid residues as branch points, as required in the previously formulated structure (**1**). In addition, the results showed that *S. urens* gum contained some unbranched 4-linked galacturonic acid residues, as did *S. caudata* gum together with some galacturonic acid end groups.

Iodinated methylated *S. caudata* gum (**IV***a*) was heated with zinc dust in 95% ethanol and the whole reaction mixture was reduced with sodium borohydride. That a high degree of depolymerization had occurred was indicated by trideuteriomethylation of exposed hydroxyl groups in otherwise unaltered neutral sugar components, in which process most of the 3-*O*-methylrhamnose was alkylated at O-2, some of the 2,3,6-tri-*O*-methylgalactose was alkylated at O-4, but the highly volatile derivatives of alkylated alditol and hexenitol terminal units were not detected. Direct analysis of the peralkylated degradation products by glc–ms showed the presence of five separable oligosaccharide derivatives (**2**–**6**) for which partial structural assignments could be made. With minor exceptions, fragment ions from individual glycosyl units showed that these were uniformly substituted with respect to isotopic labels.

For preparative purposes the mixture of products formed

[a]**III***a*, methylated *S. caudata* gum after carboxyl reduction; **V***a*, iodinated methylated *S. caudata* gum after treatment with tributylstannane; **VIII***a*, carboxyl-reduced ($NaBD_4$) *S. caudata* gum after methylation. **III***b*, **V***b*, and **VIII***b* are the corresponding derivatives of *S. urens* gum.

[b]Sugars characterized by conversion into partially methylated alditol acetates for analysis by glc–ms.

[c]It is assumed that the proportions of inseparable derivatives of 2,3,4-Me_3Rha and 2,3,4-Me_3 6-*d*Glc in **V***a* and **V***b* are unchanged from those in **III***a* and **III***b*.

[d]Since derivatives of 2,3-Me_2Fuc and 2,3,4,6-Me_4Gal were not separated it is assumed that the relative proportions of these two sugars in **V***a* and **V***b* are the same as those of 2,3-Me_2Gal and 2,3,4,6-Me_4Gal in **III***a* and **III***b*.

[e]Since derivatives of 2,3,4-Me_3Glc and 2,3,6-Me_3Gal were not separated it is assumed that the proportions of the latter in **III***a* and **III***b* were the same as those in **V***a* and **V***b*.

*The glc–ms showed at least 80% incorporation of label in $-CD_2OCH_3$ groups in relevant fragment ions. Allowance is made for nonlabelled components where there is evidence for their formation from neutral sugars.

**The glc–ms showed 20–25% incorporation of label in $-CD_2OCH_3$ groups. These are apportioned between neutral and uronic acid-derived sugars.

from modified methylated *S. caudata* gum on zinc degradation followed by reduction was chromatographed on silica gel plates to give 1,2-dideoxy-3,4,5-tri-*O*-methyl-L-*xylo*-hex-1-enitol[4] and fractions containing oligosaccharides, mainly as 2- or 3-component mixtures. Each fraction was converted into trideuteriomethylated derivatives, and the identities and relative proportions of the components were determined by glc–ms (Table 2) so that the configurations of glycosidic linkages, even for compounds in admixture, could be unambiguously assigned from the anomeric signals of corresponding intensity in the nmr spectra (Table 3). Substitution patterns of terminal 1,2-dideoxyhex-1-enitol or alditol residues were evident from simple fragment ions in the ms and, where necessary, the positions of trideuteriomethyl substituents in glycosyl residues were confirmed by conversion of the hydrolysis products into partially methylated alditol acetates for glc–ms analysis. The results established the presence of six oligosaccharides (**2***a*–**6***a* and **2***c*) in the original mixture, and the structures of the corresponding trideuteriomethylated derivatives (**2***b*–**6***b* and **2***d*) are shown with *m/z* values for significant fragment ions in their mass spectra.

Four of the oligosaccharides contain 1,2-dideoxyhex-1-enitol termini. Since acid residues in internal chains are those of D-galacturonic acid only, it is assumed without further proof that all glycosylated hexenitols have the L-*lyxo* configuration. The disaccharide derivatives **2***a* and **2***c* differ only in the degree of methylation and, after trideuteriomethylation, give chromatographically indistinguishable compounds. The nature of the two different glycosyl substituents of the hexenitol residue in the branched trisaccharide **5***b* is apparent from the mass spectral fragment ions at *m/z* 192 and 219 together with those of the corresponding aglycons at *m/z* 380 and 353, and the location of the hexopyranosyl substituent at O-5 of the hexenitol (O-2 of the parent galacturonic acid) is shown from the fragment

[4]Systematic nomenclature requires that reduction of 5,6-dideoxyhex-5-enoses gives 1,2-dideoxyhex-1-enitols with consequent changes in configurational prefixes and the numbering of substituents.

[a]Determined by glc as in Table 2.
[b]Consistent data were obtained for the same compounds in different fractions but are reported only where the designated (†) compound is the major component of the mixture. All spectra of relevant compounds showed signals at δ 1.27 (d, 3H, $J_{1,2}$ = 6.22 Hz, H-6 of α-L-Rha), 5.21–5.35 (m, 2H, -CH=CH_2), and 5.84–5.96 (m, 1H, -CH=CH$_2$).
[c]Glycosyl (but not hexenitol/alditol) substituents in designated (†) compounds were characterized on hydrolysis and methylated sugar analysis.
[d]Although a minor component, the anomeric signal was unambiguously assigned in the two-component mixture. The methylation pattern was inferred from ms data.
[e]These fractions also contained some chromatographically mobile material, which would not be estimated by glc analysis of fully alkylated derivatives.

ions at *m/z* 340 and 305. The presence in the mass spectrum of a **V** ion (11) at *m/z* 190 supports the branched structure, and the relatively low abundance of this ion suggests that the glycosyl substituents are not vicinal. Mass spectral data likewise define the second trisaccharide **6***b* as having a linear structure in which locations of trideuteriomethyl groups indicate former points of attachment of glycosyl substituents. The rhamnitol-terminated disaccharide **3***b* is related to the linear trisaccharide **6***b*, and evidence that it is the product of inadvertent breakdown was obtained from deuterium incorporation into the rhamnitol

moiety when the products of zinc degradation were treated with sodium borodeuteride. Acid lability of 4-*O*-glycosylhex-5-enoses under the conditions of the zinc degradation was observed previously (6). The disaccharide derivative **4***a* was characterized as a methyl glycoside in which the fragment ion at *m/z* 311 (**7**) from the trideuteriomethylated derivative **4***b* is characteristic of a (1→4)-linked disaccharide, a conclusion supported by the identities of the hydrolysis products, 2,3,4*,6-

tetra-*O*-methylgalactose[5] and 2*,3-di-*O*-methylrhamnose. The nmr data showed that all the neutral glycosyl residues in the oligosaccharides were those of β-D-galactopyranose and α-L-rhamnopyranose.

Modified methylated *S. urens* gum (**IV***b*) was degraded in the same way and reduction of products from the zinc treatment gave oligosaccharides that were shown by glc–ms of the trideuteriomethylated derivatives to be qualitatively similar to those formed from *S. caudata* gum. The relatively large excess of fully alkylated trisaccharide **5***b* over other components in the mixture may reflect incomplete reaction during the zinc degradation, and is probably not representative of the parent methylated polysaccharide since compositional analyses of methylated polysaccharides (e.g. **III***a* and *b*, and **VIII***a* and *b*) from the two gums showed smaller differences (Table 1). However, the mass spectrum of fully alkylated trisaccharide **5** from *S. urens* gum showed that the rhamnose residues were not uniformly labelled with trideuteriomethyl groups. Although an attempt to separate chromatographically the oligosaccharide mixture, **2***a*, **3***a*, etc., was only partly successful, samples of differently labelled trisaccharides **5***a* and **5***c* were isolated and these were converted into the corresponding fully alkylated derivatives **5***b* and **5***d* for individual examination.

Revised by still incomplete structures for the two closely related polysaccharides from *S. urens* and *S. caudata* gums may be considered in the light of the oligosaccharides isolated from partial acid hydrolysis or acetolysis in earlier studies (1, 2), the new degradation products, and the compositional analyses of modified methylated polysaccharides (Table 1). The results show that the backbone consists exclusively of chains of 4-linked α-D-galacturonic acid and 2-linked L-rhamnopyranose residues with all other sugar residues present in side chains. Oligosaccharides **2***a*, **5***a*, and **6***a*, isolated as degradation products from both gums, are derivatives of 1,2-dideoxy-3-*O*-α-L-rhamnopyranosyl-L-*lyxo*-hex-1-enitol, and confirm earlier conclusions from the acetolysis of carboxyl-reduced *S. urens* gum (1) that residues of the two sugars are in alternating sequence, and also provide evidence for the anomeric configuration of rhamnose residues. In the case of *S. urens* gum, independent evidence for this assignment has now been obtained from the degraded rhamnogalactan, formed on Smith degradation of the carboxyl-reduced gum (1), whose Cmr spectrum shows two main resonances in the anomeric region at δ_C 99.3 ($^1J_{^{13}C_1,^1H_1}$ = 174.5 Hz, α-Gal) and 97.5 ($^1J_{^{13}C_1,^1H_1}$ = 170.4 Hz, α-Rha). Trideuteriomethylation at O-4 of 1,2-dideoxyhex-1-enitol residues in **6***b* (corresponding to O-3 of galacturonic acid residues in the parent glycan) indicates the site of former attachment of β-D-glucuronic acid residues. Oligosaccharides **5***b* and **6***b* contain β-D-galactopyranose residues of different types, nonreducing end groups linked (1→2) to galacturonic acid and 4-linked residues attached (1→4) to rhamnose residues. The disaccharide **2***b* arises from an unbranched segment of the rhamnogalacturonan chain. The conclusions so far necessitate a revision of the earlier formulation (**1**) in that the 4-linked galactose residues must now be accommodated in side chains rather than as part of the sequences interrupting the regular backbone, and the following partial structure **8** may be proposed. The only contiguous neutral sugar residues are those giving rise to the two glycosyl residues in trisaccharide **6**. Support for this aspect of the structure was obtained when the only oligosaccharide product

[5]The asterisk (*) designates trideuteriomethyl substituents.

8: rhamnogalacturonan backbone (**A–D**) in *Sterculia* gums showing side-chain attachments of β-D-galactopyranose residues (not necessarily in sequence), based on the characterization of oligosaccharides **5***b* (with glycosyl residues corresponding to **C** and **D**′) and **6***b* (with glycosyl residues corresponding to **A** and **A**′).

detected on treatment of *S. urens* gum with lithium in 1,2-diaminoethane (12) was characterized as 4-*O*-β-D-galactopyranosyl-L-rhamnitol. Although not fully understood, this degradation results in destruction of uronic acid residues by base-catalyzed β-elimination with exposure of reducing sugar residues, which, during this treatment or on subsequent reaction with sodium borohydride, are reduced to alditols (13).

Structure **8** contains two types of galacturonic acid residues as branch points. Although a high degree of accuracy should not be placed on the compositional analyses of these complex methylated polysaccharide derivatives, there is a reasonable correspondence in both methylated glycans after carboxyl reduction (**III***a* and **III***b*) between the proportions of 2- and 3-*O*-methylgalactoses formed from these branch points and those of 2,3,4-tri-*O*-methylglucose and 2,3,4,6-tetra-*O*-methylgalactose respectively, which are attached as side chains. It is therefore no longer possible to associate these branched galacturonic acid residues with the 4-linked galactose residues now located in side chains. On the other hand, the proportion of 2,3,4-tri-*O*-methylgalactose formed on hydrolysis of methylated glycan derivatives (**III**), and originating from galacturonic acid end groups, is insufficient to account for all of the units of the aldobiouronic acid, 4-*O*-α-D-galactopyranosyluronic acid-D-galactose, which is a significant partial acid hydrolysis product (1–4) from each of the *Sterculia* gums so far examined. A possible explanation for this discrepancy is that a substantial proportion of side-chain galacturonic acid residues was lost by base-catalyzed β-elimination during methylation by the classical Haworth and Purdie procedures. Assuming that the base-catalyzed β-elimination of 4-*O*-substituents from uronic esters has some E2 character and occurs more readily with, but is not restricted to, galacturonates with leaving groups in the anti-periplanar orientation, loss of outer chain galacturonic acid residues at a late stage in the alkylation process could expose new terminal 2,3,6-tri-*O*-methylgalactose residues. With reagent largely spent, further alkylation at the axially oriented hydroxyl group might not occur. A second observation that is consistent with the susceptibility of galacturonate esters to base degradation is the isolation of the disaccharide glycoside **2***a*, which can only represent reducing termini of the rhamnogalacturonan chain. The formation of such a disaccharide accounting for ~10% of the degradation products would suggest a degree of polymerization in the region of 20–30 residues for the supposedly least degraded and chromatographically immobile fraction of the methylated gums after carboxyl reduction (**III**). We have no information on the molecular weight of our sample(s) of *Sterculia* gums, but a value 9×10^6 for *S. urens* gum has been reported from ultracentrifuge data (14). We regard it as highly probable that most of the units of disaccharide **2** originate from the glycosidation of reducing rhamnose residues inadvertently exposed with accompanying chain scission by β-elimination under the basic conditions necessarily used during the methylation. McNeil *et al.* (15) have reported the formation of methyl glycosides from the partial depolymerization of a methylated rhamnogalacturonan. A recent paper by Sømme reports degradation of a glucuronan during methylation using dimsyl base (16).

Analyses (Table 1) performed on methylated derivatives (**VIII**) of deuterium-labelled carboxyl-reduced polysaccharides confirmed the presence of the known uronic acid components in structure **8**, and showed in addition that *S. urens* gum contained some unbranched 4-linked galacturonic acid residues, as did *S. caudata* gum, together with some galacturonic acid end groups. These observations do not fully account quantitatively for side-chain galacturonic acid residues or define their complete structural environments. In *S. caudata* gum some galacturonic acid end groups were also indicated by the detection of 2,3,4-tri-*O*-methylfucose in the analysis of the iodinated methylated glycan after treatment with tributylstannane (**V***a*), but there is no evidence yet for the identity of residues external to the 4-linked uronic acid units. In *S. urens* gum the presence of rhamnopyranose end groups, together with the detection of some rhamnose-terminated disaccharide **2***f* from the hexenose degradation, points to some α-L-Rha*p*-(1→4)-α-D-Gal*p*A-(1→4)-β-D-Gal*p*- sequences. However, rhamnopyranose end groups in disaccharide **2***f* could also, as presumably do those in the branched trisaccharide **5***f*, arise from main chain nonreducing termini resulting from depolymerization during methylation.

Revision of the previously proposed structure (**1**) for *Sterculia* gums requires exclusively a rhamnogalacturonan backbone with residues of other sugar constituents attached in side chains. Tomoda *et al.* (17) have carried out a series of studies on plant mucilages of the Malvaceae family and have shown that these polysaccharides are of a closely related type in which rhamnogalacturonan chains carry β-D-glucuronic acid residues linked in the same manner as in the *Sterculia* gums. Some of these glycans also contain β-D-galactopyranose residues whose attachment (1→4) to rhamnose is inferred rather than directly proven. However, the absence of the aldobiouronic acid,

4-*O*-α-D-galactopyranosyluronic acid-D-galactose, from the products of partial acid hydrolysis suggests that side-chain galacturonic acid residues do not occur in these mucilages. Rhamnogalacturonans of great complexity occur widely as cell wall constituents of dicots (13, 18). Since they are liberated by the action of *endo*-α-D-galacturonanase, it has yet to be ascertained whether they occur as independent molecular species or originate from the excision of rhamnogalacturonan domains from more extended structures in which galacturonan regions are also present.

Our results show that the hex-5-enose degradation may be used to probe aspects of structure through the isolation of oligosaccharide derivatives from otherwise inaccessible structural regions. The differentiation of residues of the same sugar, e.g. D-galactose, in different locations is only possible when the degradation is performed on a polysaccharide containing stable methyl ether substituents. However, the results point to an inherent limitation of the methylation procedure when applied to glycuronans, often suspected but rarely documented, that the basic conditions necessarily used may be accompanied by degradation. For many purposes, limited depolymerization with retention of the essential repetitive structure may be of little consequence. It is a much more substantial matter if loss of certain sugar residues gives rise to methylated glycans whose structures are no longer representative of the parent polysaccharides.

Experimental

Samples of *Sterculia urens* and *S. caudata* gums and the derived methylated polysaccharides were those used in the earlier series of investigations (1–5). The ^1H and ^{13}C nmr spectra were recorded on a Bruker AM 300 spectrometer in deuteriochloroform with tetramethylsilane as internal standard. Gas–liquid chromatography was performed on a Perkin–Elmer Sigma 3B chromatograph using (A) a packed column of 3% of silicone gum Silar 10 CP on Chromosorb W-HP (100/200 mesh), (B) a capillary column of DB-225, or (C) a capillary column of DB-17. For glc – mass spectrometry, columns (B) or (C) were attached by a jet separator to a VG Micromass 16F mass spectrometer operated with an inlet temperature of 250°C, an ionization potential of 70 eV, and an ion source temperature of ~250°C.

Unsubstituted polysaccharides and their methylated derivatives were hydrolysed by the methods of Albersheim *et al.* (19) and the resulting sugars were converted into alditol acetates for glc analysis (20). Iodinated methylated polysaccharides (**IV**) were boiled in dry oxolane for 1 h with tributylstannane in the presence of a trace quantity of 2,2′-azobis(2-methylpropionitrile) as radical initiator (9, 21), to furnish the corresponding 6-deoxy-methylated polysaccharides (**V**). Uronic acid determinations were by the method of Blumenkrantz and Asboe-Hansen (22). Zinc dust was activated by the method of Frank and Smith (23). Preparative tlc was conducted on a Chromatotron (Model 7924, Harrison Research, Palo Alto, CA, U.S.A.).

Iodination of carboxyl-reduced methylated S. caudata *gum (**III**)*

Carboxyl-reduced methylated *S. caudata* gum (**III***a*) was prepared as described for the corresponding derivative of methylated *S. urens* gum (5) by reduction of methylated gum (**II***a*) with lithium aluminum hydride in oxolane. Chromatographically mobile (tlc in benzene–methanol, 6:1) material, which presumably contained severely degraded products, was separated by gel filtration on Sephadex LH-20 in dichloromethane–methanol (2:1) and a sample of the immobile fraction, which contained no uronic acid and was used in further experiments, was hydrolysed for methylated sugar analysis (Table 1). Carboxyl-reduced methylated polysaccharide (192 mg) in dry pyridine (30 mL) containing *N*-iodosuccinimide (666 mg) and triphenylphosphine (778 mg) was heated at 60°C for 16 h. Methanol (1 mL) was added to quench the reaction, the mixture was concentrated, the residue was dissolved in dichloromethane, and the solution was washed with aqueous sodium thiosulfate, dried, and concentrated. Residual material was twice fractionated by passage through a column (450 × 40 mm) of Sephadex LH-20, using dichloromethane–methanol (2:1) as eluant to ensure the complete removal of triphenylphosphine oxide, and afforded iodinated methylated polysaccharide (**IV***a*) (173 mg). A sample of the modified polysaccharide was deiodinated and hydrolysed for sugar analysis (Table 1).

Zinc degradation of iodinated methylated S. caudata *gum (**IV**a)*

Iodinated methylated polysaccharide (**IV***a*) (170 mg) was heated in boiling ethanol–water (19:1, 10 mL) with freshly activated zinc dust for 6 h. Thin-layer chromatography in benzene–methanol (6:1) showed the formation of mobile oligosaccharides together with a substance with the mobility of 5,6-dideoxy-2,3,4-tri-*O*-methyl-D-*xylo*-hex-5-enose. The cooled reaction mixture was filtered, and the filtrate was diluted with water, reduced with sodium borohydride, and processed to give the corresponding alditol/hexenitol-terminated derivatives (165 mg). Completeness of deiodination was confirmed by (*i*) analysis of sugars formed on direct hydrolysis and (*ii*) analysis of sugars formed on hydrolysis after treatment with tributylstannane, which showed no products that could have arisen from unchanged 6-deoxy-6-iodohexose constituents. A further quantity of the oligosaccharide mixture was trideuteriomethylated and hydrolysis of the product showed that 2,3,6-tri-*O*-methylgalactose had been largely replaced by 2,3,4*,6-tetra-*O*-methylgalactose, and 3-*O*-methylrhamnose by 2*,3-di-*O*-methylrhamnose. Direct examination of the fully alkylated oligosaccharide mixture by glc–ms showed the presence of five components in only one of which was there appreciable nonuniformity of isotopic labelling (Table 2). Reduction of the zinc degradation products with sodium borodeuteride, followed by trideuteriomethylation and glc–ms analysis, showed deuterium incorporation into all derivatives except **4***b*.

The oligosaccharide alditol/hexenitol mixture (33 mg) was separated by preparative tlc on a 1-mm silica gel plate preequilibrated with benzene, and elution with mixtures of benzene and methanol (1–10%) gave 8 fractions. Fraction 1 (5 mg) was indistinguishable (glc, tlc, and ^1H nmr) from 1,2-dideoxy-3,4,6-tri-*O*-methyl-L-*xylo*-hex-1-enitol prepared from methyl 6-deoxy-6-iodo-2,3,4-tri-*O*-methyl-α-D-glucopyranoside by treatment with zinc dust followed by reduction with sodium borohydride. Oligosaccharide fractions 2–8 contained mixtures of components and were individually trideuteriomethylated; the fully alkylated products were examined by glc (Table 2 for conditions) to determine the proportions of components and, by their relative intensities, to assign signals of anomeric protons in the ^1H nmr spectra (Table 3). From another preparative tlc separation a chromatographically homogeneous sample of disaccharide methyl glycoside **4***a* was isolated and converted into the trideuteriomethylated derivative **4***b*, which was hydrolyzed to give 2,3,4*,6-tetra-*O*-methylgalactose and 2*,3-di-*O*-methylrhamnose.

Zinc degradation of iodinated methylated S. urens *gum (**IV**b)*

Iodinated methylated *S. urens* gum was prepared from the methylated gum via the carboxyl-reduced methylated polysaccharide in the same way as the corresponding derivative of *S. caudata* gum, and compositional analyses are given in Table 1. Degradation with zinc was carried out as described previously and, after treatment with sodium borohydride, a sample of the mixture of alditol/hexenitol-terminated oligosaccharides was trideuteriomethylated and analyzed by glc–ms (Table 2). Attempted preparative separation of the oligosaccharide mixture was only partially successful, but chromatographically pure samples of oligosaccharides **5***a* and **5***c* were isolated, and these were converted into the corresponding fully alkylated derivatives **5***b* and **5***d*, which differed only in the proportion of OCD_3 substituents. Anomeric configurations in **5***b* were assigned from ^{13}C resonances at δ_C 105.1 ($^1J_{^{13}C_1,^1H_1}$ = 157 Hz, β-Gal) and 96.7 ($^1J_{^{13}C_1,^1H_1}$ = 168 Hz, α-Rha), and in both **5***b* and **5***d* from ^1H nmr resonances at δ 5.07 (br s) and 4.27 ($J_{1,2}$ = 7.7 Hz). Hydrolysis of both oligosaccharides gave 2,3,4,6-tetra-*O*-methylgalactose with 2*,3,4-tri- and 2,3,4-tri-*O*-methylrhamnose from **5***b* and **5***d* respectively.

Deuterium-labelled carboxyl-reduced Sterculia *gums (VII)*

Deacetylated *S. caudata* gum (900 mg, as ammonium salt) in water (60 mL) was treated with Dowex 50(H^+) resin and ethylene oxide was passed through the solution to give a concentration of ~20% (w/w). The solution was kept for 5 days with a pH change from 2.9 to 6, and the addition of ethanol (2 vol) in the presence of a small amount of potassium acetate to effect coagulation of the precipitate afforded polysaccharide glycol ester (700 mg), which was redissolved in water and freeze-dried. A suspension of the glycol ester (680 mg) in aqueous 2 *M* sodium borodeuteride (40 mL) was stirred gently and the resulting viscous solution was left overnight. Polysaccharide (590 mg) isolated by precipitation with an equal volume of ethanol contained 22% of uronic acid residues. Repetition of the esterification–reduction sequence (24) gave deuterium-labelled carboxyl-reduced *S. caudata* gum (**VII***a*) (400 mg) containing 10% of uronic acid residues, and giving on hydrolysis rhamnose (27%), galactose (48%), and glucose (15%). A similarly prepared sample of deuterium-labelled carboxyl-reduced *S. urens* gum (**VII***b*) contained 7% of uronic acid residues and gave on hydrolysis rhamnose (30%), galactose (51%), and glucose (7%). Samples of both carboxyl-reduced polysaccharides were methylated (10) and methylated sugar derivatives were analyzed by glc–ms (Table 1).

Degradation of S. urens *gum with lithium in 1,2-diaminoethane*

Dry deacetylated *S. urens* gum (500 mg, as ammonium salt) was stirred under argon in dry 1,2-diaminoethane for 30 min. Lithium was added in portions until the suspension became blue, and further lithium was added for 5 h until most of the suspended polysaccharide had dissolved. When complete reaction of lithium had taken place, ice was added in portions during 30 min, the solution was concentrated with repeated additions of toluene, and the residue in water was passed through Dowex 50(H^+) resin to remove lithium ions and the remaining diaminoethane, and concentrated to a residue (190 mg). To ensure complete conversion of reducing sugars to alditols the residue was treated with sodium borohydride and the resulting solution was applied to a column of charcoal–Celite (1:1). Elution of the column with water gave rhamnitol as the sole product detected by tlc, and elution with water containing 0.5% of butanone gave a fraction (50 mg) containing a single disaccharide (tlc in ethyl acetate – acetic acid – formic acid – water, 18:3:1:4). The disaccharide was converted into the fully methylated derivative **3***c*, nmr δ: 4.26 (d, 1H, $J_{1,2}$ = 7.72 Hz, H-1′), 3.31–3.57 (8s, 8 × OMe), 1.26 (d, 3H, $J_{5,6}$ = 6.22 Hz, H-6); δ_C: 104.6 (C-1′), 55.6–61.2 (8 × OCH_3), 16.0 (C-6). The glc–ms gave a single peak and showed fragment ions at m/z 395 (M − CH_2OCH_3), 307, 305, 275, 265, 219, 205, 187, 173, 155, 133. No other chromatographically mobile oligosaccharides were detected on elution of the charcoal–Celite column with water containing up to 5% of butanone.

Smith degradation of carboxyl-reduced S. urens *gum*

Carboxyl-reduced *S. urens* gum with a residual uronic acid content of ~3% was prepared by the method of Taylor and Conrad (25) and modified polysaccharide from the Smith degradation was isolated as described previously (1). Methylation analysis confirmed the identity of the glycan by the formation of derivatives of 2,3,6-tri-*O*-methylgalactose and 3,4-di-*O*-methylrhamnose as the major products.

A nuclear magnetic resonance relaxation study of liquid hydrogen cyanide

RODERICK E. WASYLISHEN
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received December 15, 1986

RODERICK E. WASYLISHEN. Can. J. Chem. **65**, 2077 (1987).

The rates of ^2H, ^{13}C, and ^{14}N spin-lattice relaxation for liquid deuterium cyanide have been studied as a function of temperature. The quadrupolar nuclei relax exclusively by the quadrupolar relaxation mechanism while the rate of ^{13}C and ^{15}N relaxation is completely dominated by the spin-rotation mechanism. The apparent activation energy that describes the temperature dependence of spin-lattice relaxation for all nuclei studied is approximately 1.6 kcal mol^{-1}. The temperature dependence of the rate of ^{13}C relaxation in liquid HCN was also investigated. Although the determination of very accurate rotational and angular momentum correlation times is hampered by intermolecular effects on the nuclear quadrupolar coupling constants and the appropriately averaged C—H bond separation, the derived correlation times for DCN and HCN are in reasonable agreement (± 15%).

RODERICK E. WASYLISHEN. Can. J. Chem. **65**, 2077 (1987).

On a étudié les vitesses de relaxation spin-réseau ^2H, ^{13}C et ^{14}N du cyanure de deutérium liquide, à diverses températures. Le mécanisme de relaxation du noyau quadrupolaire n'implique qu'une relaxation quadrupolaire alors que la vitesse de relaxation du ^{13}C et du ^{14}N est complètement dominée par un mécanisme spin-rotation. L'énergie d'activation apparente qui décrit la relation entre la température et la relaxation spin-réseau de chacun des noyaux étudiés est d'environ 1,6 kcal mol^{-1}. On a aussi étudié la relation entre la température et la vitesse de relaxation du ^{13}C, dans le HCN liquide. Même si la détermination de valeurs très précises pour les temps de corrélation des moments rotationnel et angulaire est rendue difficile par les effets intermoléculaires sur les constantes de couplages nucléaires quadrupolaires et par la séparation de la liaison C—H qui est approximativement moyenne, on obtient un accord raisonnable (± 15%) pour les temps de corrélation que l'on a dérivé pour le DCN et le HCN.

Introduction

At atmospheric pressure hydrogen cyanide, HCN, exists as a liquid over a relatively narrow temperature range, 39 degrees between 259.8 and 298.8 K (1). Many of the liquid state properties of HCN such as its unusually high dielectric constant are best interpreted in terms of the formation of linear polymeric hydrogen-bonded chains (2). Indeed, such one-dimensional hydrogen-bonded chains are the dominant structural feature of the solid (3–6). In the gas phase, the linear dimer is known to exist and its structure has recently been investigated using rotational microwave spectroscopy (7–10).

The objective of this study is to probe the rotational motion of HCN in the liquid phase using the results of nmr relaxation measurements (11–21). Hydrogen cyanide is a particularly attractive molecule for nmr study because there are potentially five different stable nmr active isotopes: ^1H, ^2H, ^{13}C, ^{14}N, and ^{15}N. Another advantage of HCN is that its structure is accurately known (3, 22–26) and, as well, a number of spectroscopic constants such as nuclear quadrupolar couplings (8, 9, 22–29), nuclear spin rotation constants (22, 24, 26, 30), and chemical shielding anisotropies (31–35) are available. These constants are essential in the interpretation of the nmr relaxation data.

Previous nmr studies on HCN include a comprehensive study of the temperature dependence of the ^1H, ^{13}C, and ^{15}N nuclear magnetic shielding by Jameson *et al.* (36). The only nmr relaxation measurement on HCN of which we are aware is a ^{13}C measurement of HCN in chloroform, which led the authors to suggest that the ^1H,^{13}C dipole–dipole, spin-rotation, and chemical shielding anisotropy mechanisms all contribute to ^{13}C relaxation (37). No attempt was made to analyze the data to obtain information about the rotational dynamics of HCN. In fact, we have been unable to find any reports of rotational correlation times for HCN in the liquid phase. In contrast, considerable information is available for molecules such as water (13, 17, 38–41), ammonia (17, 42–44), and acetonitrile (12, 20, 45–53). In the present study we obtain rotational correlation times, τ_2, and angular momentum correlation times, τ_J, for hydrogen cyanide as a function of temperature.

Theory

In this section a brief summary of the relationships between ^2H, ^{14}N, ^{13}C, and ^{15}N nmr relaxation times and the rotational and angular momentum correlation times, τ_2 and τ_J respectively, is presented.

Deuterium and nitrogen-14 are both quadrupolar nuclei with spin $I = 1$, which almost always relax by the quadrupolar mechanism. For a small molecule such as HCN, the extreme narrowing condition applies and the rate of quadrupolar relaxation, R_1^Q, is given eq. [1], where T_1 is the spin-lattice

$$[1] \quad R_1^Q = 1/T_1 = 1.5\pi^2\chi^2(1 + \eta^2/3)\tau_2$$

relaxation time, χ is the nuclear quadrupolar coupling constant, e^2qQ/h, in Hz, η is the asymmetry parameter, and τ_2 is the rotational correlation time.

The relaxation of a first row spin 1/2 nucleus such as ^{13}C or ^{15}N is generally governed by the dipole–dipole interaction with neighbouring protons. In general, the rate of I-spin relaxation due to I,S dipole–dipole relaxation is given by eq. [2], where

$$[2] \quad R_1^{DD}(I,S) = 1/T_1 = (4/3)\gamma_I^2\gamma_S^2 r_{IS}^{-6}\hbar^2 S(S + 1)\tau_2$$

γ_I and γ_S are the gyromagnetic ratio of I and S respectively, r_{IS} is the I-nucleus, S-nucleus separation, and S is the spin of nucleus S.

In small molecules where τ_2 is of the order of 10^{-12} s or less, the spin-rotation relaxation mechanism often dominates the relaxation of a spin 1/2 nucleus. For a linear molecule, where I is the moment of inertia, k is the Boltzmann constant, T is the absolute temperature, $C_\perp$ is the spin-rotation constant in Hz, and τ_J is the angular momentum correlation time, eq. [3] applies.

$$[3] \quad R_1^{SR} = 1/T_1 = (16\pi^2/3)(IkT/h^2)(2\pi C_\perp)^2\tau_J$$

TABLE 1. Nitrogen-14 T_1's and τ_2 values for liquid deuterium cyanide. The τ_2 values are calculated assuming $\chi(^{14}N) = 4707.9$ kHz (24, 26)

Temperature (K)	T_1 (ms)[a]	τ_2 (ps)
295	9.29	0.328
288	8.81	0.346
280	8.06	0.378
272	7.35	0.415
266	7.00	0.435
261	6.39	0.477

[a]Estimated error is less than 5%.

TABLE 2. Deuterium T_1's and τ_2 values for liquid deuterium cyanide. The τ_2 values are calculated assuming $\chi(^2H) = 202.23$ kHz (24, 26)[a]

Temperature (K)	T_1 (s)[a]	τ_2 (ps)
297	5.38	0.307
290	5.01	0.330
275	4.35	0.380
270	4.14	0.399
265	3.87	0.427
260	3.65	0.453

[a]Estimated error is less than 5%.

For a molecule undergoing small-step diffusion, τ_2 and τ_J are related by the Hubbard relationship (14–21, 54), eq. [4], where

$$[4] \quad \tau_2^*\tau_J^* = 1/6$$

$\tau_2^* = \tau_2(kT/I)^{1/2}$ and $\tau_J^* = \tau_J(kT/I)^{1/2}$ are dimensionless.

Experimental

A mixture of $D^{13}CN/D^{12}CN$ (45:45) and $H^{13}CN/H^{12}CN$ (5:5) was prepared by adding an aqueous NaCN (50% ^{13}C enriched) solution to a sulfuric acid solution (55); 90% of all the hydrogen was deuterium. The evolved hydrogen cyanide was passed through a series of $CaCl_2$ drying tubes and condensed directly into an nmr tube designed to restrict liquid vapor interchange (56). Deuterium, ^{13}C, and ^{14}N nmr relaxation measurements were performed on this sample. A second sample of hydrogen cyanide in which 20% of all nitrogens present were ^{15}N and 20% of all hydrogens present were ^2H was prepared, as described above, for ^{15}N measurements. All labelled compounds were obtained from Merck Sharp & Dohme, Canada, Limited. Finally, an unlabelled sample of HCN was prepared from a cylinder of HCN and helium supplied by Matheson. All samples were degassed and sealed under vacuum.

The nmr spectra were recorded at 9.40 and at 5.875 T on Bruker WH-400 and WM-250 spectrometers, respectively. All nmr measurements on hydrogen cyanide were carried out at 8.48 T on a Nicolet 360 nmr spectrometer. Spin-lattice relaxation times were measured using the inversion–recovery technique (56) and calculated using a 3-parameter fitting procedure (57, 58).

Results and discussion

1. Deuterium cyanide

Measured ^{14}N, ^2H, and ^{13}C spin-latice relaxation times for deuterium cyanide are summarized in Tables 1–3, respectively.

(a) Nitrogen-14 relaxation

The temperature dependence of the ^{14}N spin-lattice relaxation times in liquid deuterium cyanide are represented by eq. [5]; the slope indicates an Arrhenius activation energy, E_a,

$$[5] \quad \ln T_1 = -0.8182(10^3/T) - 1.896$$

of 1.62 kcal mol^{-1}. This value for E_a is much smaller than the value reported for water, which varies from about 5 kcal mol^{-1} at 0°C to approximately 3.5 kcal mol^{-1} in the temperature range 40–100°C (13). The E_a value observed here for DCN is comparable to the value of 1.9 kcal mol^{-1} observed for ammonia (42) and the value of 1.7 kcal mol^{-1} reported for rotations of the CN axis in acetonitrile (12).

To calculate the rotational correlation times, τ_2 values, from the data in Table 1 one requires a value of the ^{14}N quadrupolar coupling constant. In molecules such as HCN there is considerable variation in $\chi(^{14}N)$ depending on the intermolecular interactions (41, 59). In the gas-phase monomer the value is 4707.9 kHz (22, 24, 26), while in the solid state a value of 4018.3 kHz (28) has been reported. In the gas-phase dimer, **1**,

$$H_1—C\equiv N_1\cdots H_2—C\equiv N_2$$

1

Buxton *et al.* (9) recently found the two nitrogens N_1 and N_2 have χ values of 4097.3 kHz and 4440 kHz, respectively. In a detailed study of liquid acetonitrile, Böhm *et al.* (45) have found that τ_2 values from ^{14}N nmr relaxation data are consistent with those from Raman experiments only if the gas-phase nuclear quadrupolar coupling constant is used. In the present study further evidence is presented for using the value obtained for the gas-phase monomer (see discussion on HCN that follows). The τ_2 values given for DCN in Table 1 were calculated using $\chi(^{14}N) = 4707.9$ kHz and thus represent a lower limit on τ_2 at any given temperature. Rotational correlation times calculated using the χ value obtained in the solid state would result in τ_2 values that are longer by a factor of 1.37.

(b) Deuterium relaxation

The temperature dependence of the ^2H relaxation times is indicated in Table 2; the best linear fit is given by eq. [6]. The

$$[6] \quad \ln T_1 = -0.8081(10^3/T) + 4.400$$

value of E_a, 1.61 kcal mol^{-1}, is in excellent agreement with the value obtained from the temperature dependence of the ^{14}N data.

For the gas-phase monomer the ^2H nuclear quadrupolar coupling constant in DCN is 202.23 kHz (22, 24, 26). In the gas-phase hydrogen-bonded dimer $\chi(^2H_1) = 182.9$ kHz and $\chi(^2H_2) = 175.6$ kHz (8). The value of the deuterium nuclear quadrupolar coupling constant in the solid state has not been reported but is probably between 170 and 175 kHz. Reduction of nuclear quadrupole coupling constants on hydrogen bonding is well known (41, 59); for example, in water the gas-phase monomer values are $\chi(^2H) = 318.6$ kHz and $\chi(^{17}O) = 10.17$ MHz while in ice the values are $\chi(^2H) = 215$ kHz and $\chi(^{17}O) = 6.41$ MHz (38–41). The problems associated with obtaining accurate single-molecule reorientational correlation times in these systems have been previously discussed (40, 41, 59).

The τ_2 values in Table 2 were calculated using the $\chi(^2H)$ value obtained for the gas-phase monomer; at any given temperature τ_2 is within experimental error of the value obtained from the ^{14}N T_1 data.

[a]All measurements were carried out at 8.48 T; the error in the observed T_1's is less than 5% while the error in η is ± 0.05.
[b]$\eta_{max} = \gamma(^1H)/2\gamma(^{13}C) = 1.988$.
[c]In this case $R_1^{other} = R_1^{CSA} + R_1^{DD}(^{13}C,^{14}N)$.
[d]τ_2 values of 0.291, 0.356, and 0.450 ps were obtained from ^{14}N nmr measurements on this same sample at 300, 279, and 260 K respectively.

(c) Carbon-13 relaxation

The variations in carbon-13 T_1 values with temperature for $^2H^{13}C^{14}N$ are given in Table 3. The observed increase in the ^{13}C T_1 values with decreasing temperature is an indication that the spin-rotation mechanism dominates. Other mechanisms that may make a contribution to the observed rate of carbon relaxation include the chemical shielding anisotropy mechanism (11, 16, 17, 19, 21) and the dipole–dipole mechanism with the directly bonded ^{2}H and ^{14}N nuclei. The efficiency of each of these mechanisms was evaluated using eqs. [7] and [2], respectively.

$$[7] \quad R_1^{CSA} = 1/T_1 = (2/15)\omega_C^2(\Delta\sigma)^2\tau_2$$

In eq. [7] ω_C is the carbon resonance frequency in angular units and $\Delta\sigma = \sigma_\parallel - \sigma_\perp$ is the ^{13}C chemical shielding anisotropy, 334 ppm (32). At any given temperature the value of τ_2 was taken to be the average of the values obtained from the ^{14}N and ^{2}H nmr data given in Tables 1 and 2. The r_{CN} and r_{CD} bond lengths required to evaluate the efficiency of the dipole–dipole mechanism were taken as 1.1532 and 1.0655 Å, respectively (22). Even at 9.4 T the chemical shielding anisotropy mechanism contributes less than 12% to the total rate of carbon relaxation. The ^{14}N,^{13}C and ^{2}H,^{13}C dipole–dipole mechanisms are much less efficient. The results in Table 3 indicate that the spin-rotation mechanism accounts for about 93% of the total rate of carbon spin-lattice relaxation at 300 K, and about 86% at 260 K. A plot of $\ln R_1^{SR}$ vs. $1/T$ results in a straight line with a slope corresponding to $E_a = 1.5 \pm 0.3$ kcal mol^{-1}.

From the rate of spin-rotation relaxation, one can use the experimental spin-rotation constant, $C_\perp = 15.0 \pm 1.0$ kHz (22, 30), to obtain the τ_J values listed in Table 3. Because of the uncertainty in $C_\perp$ the error in the τ_J values is about ±15%. The final values of τ_2 and τ_J for DCN are summarized in Table 3. At any given temperature the product $\tau_2^*\tau_J^*$ is within experimental error of the value expected for small-step rotational diffusion, 0.167.

2. Hydrogen cyanide

Carbon-13 spin-lattice relaxation times and nuclear Overhauser enhancement factors for a sample of hydrogen cyanide are given in Table 4. All isotopes are present in natural abundance. Measurement of the nOe permits one to obtain the rate of ^{13}C,^{1}H dipole–dipole relaxation, from which it is possible to calculate τ_2 (eq. [8]). In calculating the τ_2 values

$$[8] \quad R_1^{DD}(^{13}C,^1H) = (\eta_{obs}/\eta_{max})R_1^{obs}$$

in column 5 of Table 4 we have substituted the equilibrium carbon–hydrogen bond length, 1.0655 Å, in eq. [2]. The values obtained for τ_2 from the ^{13}C nmr measurements are within experimental error of those obtained from ^{14}N T_1's on this same sample (see footnote *d* of Table 4). The rates of CSA and ^{14}N,^{13}C dipole–dipole relaxation were evaluated using eqs. [7] and [2] as already described for DCN; however, the τ_2 values in Table 4 were used.

Plots of $\ln R_1^{DD}(^{13}C,H)$ and $\ln R_1^{SR}(^{13}C)$ as a function of $10^3/T$ have slopes of $+2.1 \pm 0.5$ kcal mol^{-1} and -1.4 ± 0.3 kcal mol^{-1}, respectively. The slope of the ^{13}C,^{1}H dipolar contribution is within experimental error of the slope obtained for an analogous plot involving the relaxation of the quadrupolar nuclei (^{14}N and ^{2}H). The values of E_a obtained from the temperature dependence of T_1^{SR} in DCN and HCN are in excellent agreement.

The τ_J values in Table 4 were calculated assuming the value of the product $C_\perp I_\perp$ for $^2H^{13}C^{14}N$ is equal to this same product

in $^1H^{13}C^{14}N$. The resulting τ_2 and τ_J values for hydrogen cyanide are summarized in Table 4. In general, the τ_2 values for HCN appear to be slightly less than those for DCN, as one would intuitively expect, since $[I(DCN)/I(HCN)]^{1/2} = 1.10$. At any given temperature, the τ_2^* and τ_J^* values obtained for DCN and HCN are within 15% of one another.

There has been considerable debate in the literature concerning the value of r that one should substitute into eq. [2] to calculate accurate rotational correlation times from dipolar relaxation data (60–62). Harris and Newman (60) argue that one should use r_{-3} where

$$[9] \quad r_k = \langle r^k \rangle^{1/k} = r_1 + (k-1)\mu^2/2r_1$$

and r_1 is the mean bond length (vibrational average) and μ the root-mean-square amplitude of the ground state vibration (63). Using this notation, r_{-1} and r_{-2} are the averages generally obtained from diffraction and rotational spectroscopy, respectively (60). If one applies eq. [9] to any given molecule, r_{-3} is usually about 1% less than r_1 and this results in a 6% change in τ_2. However, in the case of a hydrogen-bonded liquid such as hydrogen cyanide there is no guarantee that the mean bond length in the liquid state will be the same as it is in the gas-phase monomer. Qualitatively one would expect the average C—H bond length to increase when the hydrogen is involved in intermolecular hydrogen bonding.

The above mentioned problems of vibrational averaging and molecular structure in a hydrogen-bonded system lead to considerable uncertainty (perhaps, ±15%) in the rotational correlational times derived here.

3. Nitrogen-15 relaxation

Nitrogen-15 nmr measurements were performed on a sample of hydrogen cyanide that contained 20% deuterium. Because of a two-bond isotope effect the ^{15}N resonance of $^2HC^{15}N$ was 0.960 ppm to low frequency of the corresponding resonance in $^1HC^{15}N$, permitting the measurement of separate T_1 values for each isotopomer.

For HCN the ^{15}N T_1 was 50.0 ± 5 s at 5.875 T and 52.9 ± 3 s at 9.4 T. For DCN the ^{15}N T_1 at 9.4 T was 55.0 ± 5 s. All measurements were carried out at 297 ± 2 K. The ^2H T_1 for this same sample was 5.15 ± 0.3 s, in good agreement with the value obtained for $^2HC^{14}N$ (Table 2).

The similar ^{15}N T_1's observed for HCN at the two different applied fields indicate that the CSA mechanism makes a negligible contribution to the rate of ^{15}N relaxation. Also, the similar $T_1(^{15}N)$ values observed for HCN and DCN indicate that the $^1H,^{15}N$ dipole–dipole mechanism plays a minor role. The spin-rotation mechanism completely dominates the rate of ^{15}N relaxation and, following the procedure previously outlined for ^{13}C relaxation, one finds that T_1^{SR} is 52.9 s for HCN and 57.7 s for DCN. The value of the nitrogen-14 spin rotation constant in HCN is 10.13 kHz (23, 24, 26) and, using eq. [10]

$$[10] \quad (C_\perp I_\perp)/\gamma_N = (C'_\perp I'_\perp)/\gamma'_N$$

for two isotopomers of hydrogen cyanide, one finds that $C_\perp(^{15}N)$ is 13.80 and 11.21 kHz in $HC^{15}N$ and $^2HC^{15}N$ respectively. Substitution into eq. [3] results in τ_J^* values of 0.116 and 0.124 for HCN and DCN, respectively. For HCN the τ_J^* values obtained from the ^{15}N relaxation data are about 20% shorter than the value obtained from the ^{13}C measurements (at 300 K); however, considering the errors in our measurements, the errors associated with the spin-rotation constants, and the assumptions made, we consider this agreement satisfactory. The agreement of τ_J^* values from ^{13}C and ^{15}N relaxation measurements on DCN is much better, approximately 7%.

Conclusions

The most important mechanism for ^{13}C and ^{15}N spin-lattice relaxation in liquid hydrogen cyanide is the spin-rotation mechanism. At 300 K, analyses of ^2H, ^{14}N, ^{13}C, and ^{15}N spin-lattice relaxation times indicate $\tau_2^* = 1.3 \pm 0.2$ and $\tau_J^* = 0.13 \pm 0.02$. For $\tau_2^* = 1.3$, the J-diffusion model (15) predicts $\tau_J^* = 0.15$, while for small-step rotational diffusion $\tau_J^* = 0.13$. It is hoped this investigation of HCN will stimulate investigation by other techniques.

Acknowledgements

I would like to thank Drs. Robert Lenkinski and Charles Rodger for making spectrometer time available at the Southwestern Ontario NMR Centre (9.40 T) and at Bruker Spectrospin Canada (5.875 T), respectively. The nmr measurements on HCN (8.48 T) were carried out at the Atlantic Regional NMR Centre, Dalhousie University. I wish to thank NSERC for financial support in establishing and maintaining the regional centre, and also for operating grants. Finally I would like to thank Kenneth J. Friesen for his assistance in preparing some of the samples and Professors Cynthia Jameson and Brian Pettitt for several stimulating discussions.

Received October 28, 1986

RICHARD J. BARTON, KEITH E. JOHNSON, BEVERLY E. ROBERTSON, F. WAYNE YERHOFF and SHENGZHI HU. Can. J. Chem. **65**, 2082 (1987).

The structures of reaction products between 4-amino-2,3-dimethyl-1-phenyl-3-pyrazolin-5-one and *o*-cresol, *p*-cresol, and *p*-ethylphenol are reported. The reaction of the former compound with phenols is used to estimate the concentration of phenol in potable water supplies. The reaction products are 2,3-dimethyl-4-[4-oxo-2,5-cyclohexadien-1-ylidene)amino]-1-phenyl-3-pyrazolin-5-one (monoclinic, $P2_1/c$, red, $Z = 4$, $a = 7.092(1)$, $b = 26.616(2)$, $c = 8.644(2)$ Å, $\beta = 79.17(3)°$, 1432 reflections, $R = 0.083$, $R_w = 0.040$), 1,9*a*-dihydro-1,6,9*a*-trimethyl-2-phenylpyrazolo[3,4-*b*][1,4]benzoxazin-3(2*H*)-one (orthorhombic, *Pbca*, yellow, $Z = 8$, $a = 18.943(3)$, $b = 12.749(5)$, $c = 13.223(2)$ Å, 2122 reflections, $R = 0.067$, $R_w = 0.038$), and 6-ethyl-1,9a-dihydro-1,9a-dimethyl-2-phenylpyrazolo[3,4-*b*][1,4]benzoxazin-3(2*H*)-one (orthorhombic, *Pbca*, yellow, $a = 18.895(11)$, $b = 12.737(5)$, $c = 14.041(6)$ Å, $Z = 8$, 1126 reflections, $R = 0.068$, $R_w = 0.061$), respectively. The latter two compounds rearrange to form 1,2,4,10-tetrahydro-1,6-dimethyl-2-phenyl-3*H*-pyrazolo[3,4-*c*][1,5]benzoxazepin-3-one (monoclinic, $P2_1/c$, white, $Z = 8$, $a = 15.072(4)$, $b = 14.491(4)$, $c = 15.505(3)$ Å, $\beta = 111.15(1)°$, 3416 reflections, $R = 0.101$, $R_w = 0.046$) and 6-ethyl-1,2,4,10-tetrahydro-1-methyl-2-phenyl-3*H*-pyrazolo[3,4-*c*][1,5]benzoxazepin-3-one (monoclinic, $C2/c$, white, $Z = 8$, $a = 33.768(3)$, $b = 6.678(1)$, $c = 15.836(2)$ Å, $\beta = 115.41(1)$, 2805 reflections, $R = 0.076$, $R_w = 0.043$), respectively. The rearrangement is consistent with the observation that the pyrazolone rings of benzoxazinones are strained, as manifested by enlarged perimeters.

RICHARD J. BARTON, KEITH E. JOHNSON, BEVERLY E. ROBERTSON, F. WAYNE YERHOFF et SHENGZHI HU. Can. J. Chem. **65**, 2082 (1987).

On a déterminé les structures des produits de la réaction de l'amino-4 diméthyl-2,3 phényl-1 pyrazoline-3 one-5 avec l'*o*-crésol, le *p*-crésol et le *p*-éthylphénol. On utilise la réaction de ce produit hétérocyclique avec les phénols pour déterminer la concentration des phénols dans les sources d'eau potable. Les produits de la réaction sont respectivement la diméthyl-2,3 [(oxo-4 cyclohexadiène-2,5 ylidène-1)-1 amino]-4 phényl-1 pyrazoline-3 one-5 (monoclinique, $P2_1/c_0$ rouge, $Z = 4$, $a = 7{,}092(1)$, $b = 26{,}616(2)$ et $c = 8{,}644(2)$ Å, $\beta = 79{,}17(3)°$, 1432 réflexions, $R = 0{,}083$ et $R_w = 0{,}040$), la dihydro-1,9a triméthyl-1,6,9a phényl-2 2*H*-pyrazolo[3,4-*b*][1,4]benzoxazinone-3 (orthorhombique, *Pbca*, jaune, $Z = 8$, $a = 18{,}943(3)$, $b = 12{,}749(5)$ et $c = 13{,}223(2)$ Å, 2122 réflexions, $R = 0{,}067$ et $R_w = 0{,}038$) et l'éthyl-6 dihydro-1,9a diméthyl-1,9a phényl-2 2*H*-pyrazolo[3,4-*b*][1,4]benzoxazinone-3 (orthorhombique, *Pbca*, jaune, $a = 18{,}895(11)$, $b = 12{,}737(5)$ et $c = 14{,}041$ Å, $Z = 8$, 1126 réflexions, $R = 0{,}068$ et $R_w = 0{,}061$). Les deux derniers composés se transposent pour former respectivement la tétrahydro-1,2,4,10 diméthyl-1,6 phényl-2 3*H*-pyrazolo[3,4-*c*][1,5]benzoxazépinone-3 (monoclinique, $P2_1/c$, blanc, $Z = 8$, $a = 15{,}072(4)$, $b = 14{,}491(4)$ et $c = 15{,}505(3)$ Å, $\beta = 111{,}15(1)°$, 3416 réflexions, $R = 0{,}101$, $R_w = 0{,}046$) et l'éthyl-6 tétrahydro-1,2,4,10 méthyl-1 phényl-2 3*H*-pyrazolo[3,4-*c*][1,5]benzoxazépinone-3 (monoclinique, $C2/c$, blanc, $Z = 8$, $a = 33{,}768(3)$, $b = 6{,}678(1)$ et $c = 15{,}836(2)$ Å, $\beta = 115{,}41(1)°$, 2805 réflexions, $R = 0{,}076$ et $R_w = 0{,}043$). La transposition est en accord avec l'observation qui a été faite, par le biais de leurs périmètres agrandis, que les cycles pyrazolones des benzoxazinones sont tendus.

[Traduit par la revue]

Introduction

A standard procedure (1) for the estimation of phenols at low (ng/mL) concentrations in potable water supplies consists of measuring the intensity of the red colour formed when the phenol is oxidized in the presence of excess 4-aminoantipyrine (4-amino-2,3-dimethyl-1-phenyl-3-pyrazolin-5-one). Several papers (2–7) suggested that the reaction product was a *p*-quinoneimide and that the reaction could not proceed when the position *para*- to OH was occupied by alkyl, aryl, nitroso, nitro, benzoyl, ester, or aldehyde groups but would take place when that position was substituted by halo, carbonyl, alkoxyl, and sulfonic acid groups. It was reported (6) that although the colour reaction did not occur with certain *p*-substituted phenols, a white reaction product could be isolated and this material was purported to be the result of an *ortho* coupling process.

Investigations in this laboratory by ^{1}H nmr spectroscopy (8, 9) confirmed the formation of *p*-quinoneimides. *p*-Alkylphenols gave an orange solution from which a yellow product, assigned the structure of an *o*-quinoneimide, was isolated. The yellow product underwent thermal and base-catalysed rearrangement to a white benzodihydrooxazepine. ^{13}C nuclear magnetic resonance spectroscopy subsequently indicated the yellow product was a benzoxazinone (10).

In this paper we report on the X-ray crystallographic structures of the red product obtained from *o*-cresol, the yellow products obtained from *p*-cresol and *p*-ethylphenol, and the white rearrangement products from the latter two.

Experimental

The compounds were prepared as described previously (9). Methyl and ethyl benzoxazinone were recrystallized thrice by dissolving in a minimum of boiling *n*-pentane, filtering, and cooling slowly to 5°C. Methyl and ethyl benzoxazepinone were recrystallized thrice by dissolving in boiling 95% ethanol and cooling slowly to 5°C. Densities

were measured by flotation. Crystal data and refinement parameters for the five compounds are given in Table 1. Data were collected using MoKα radiation, $\lambda = 0.70926$ Å, in the θ–2θ scan mode and a graphite monochromator on a modified Picker diffractometer at 291 K. The intensities of three standard reflections were monitored after every 47 reflections were recorded. In all cases their intensities did not change significantly. Standard deviations of the intensities of the reflections were calculated from counting statistics with an additional contribution from the excess scatter in the intensities of the standard reflections. Data were reduced to structure amplitudes in the usual manner. Corrections for absorption and extinction were not applied. Structures were solved by direct methods and Fourier methods using the National Research Council of Canada program package (11) and the XRAY-76 system of programs (12). There are two independent molecules in the asymmetric unit of the rearrangement product of *p*-ethylphenol. All structures were refined with anisotropic non-hydrogen atoms and isotropic hydrogen atoms by full-matrix least squares, using $\sigma^{-2}(F)$ weights. Scattering factors for all atoms were taken from the XRAY-76 system (12).

Results

The red product obtained from *o*-cresol is 2,3-dimethyl-4-[4-oxo-2,5-cyclohexadien-1-ylidene)amino]-1-phenyl-3-pyrazolin-5-one (*p*-quinoneimide). The yellow products obtained from *p*-cresol and *p*-ethylphenol are 1,9a-dihydro-1,6,9a-trimethyl-2-phenylpyrazalo[3,4-*b*][1,4]benzoxazin-3(2*H*)-one (methyl benzoxazinone) and 6-ethyl-1,9a-dihydro-1,9a-dimethyl-2-phenylpyrazolo[3,4-*b*][1,4]benzoxazin-3(2*H*)-one (ethyl benzoxazinone), respectively. Their rearrangement products are 1,2,4,10-tetrahydro-1,6-dimethyl-2-phenyl-3*H*-pyrazolo-[3,4-*c*][1,5]benzoxazepin-3-one (methyl benzoxazepinone) and 6-ethyl-1,2,4,10-tetrahydro-1-methyl-2-phenyl-3*H*-pyrazolo[3,4-*c*][1,5]benzoxazepin-3-one (ethyl benzoxazepinone).

Figure 1 shows the structures of the three product types. Figure 2 contains stereoscopic views of the *p*-quinoneimide molecule, the methyl benzoxazinone molecule, and one of the methyl benzoxazepinone molecules. The labelling of the atoms for the *p*-quinoneimide molecule is given in Fig. 3.[1] In the ethyl benzoxazinone and ethyl benzoxazepinone molecules C(19) replaces H(7,3). In both benzoxazinone molecules O(1) bridges atoms C(5) and C(9). In the three benzoxazepinone molecules, O(1) bridges atoms C(5) and C(11). In methyl benzoxazinone, the atoms belonging to the two independent molecules in the asymmetric unit are labelled 1 and 2.

Bond lengths and angles not involving hydrogen atoms for all

[1]Structure amplitude tables, tables of atomic parameters, isotropic temperature factors for hydrogen atoms, and anisotropic temperature factors for non-hydrogen atoms are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

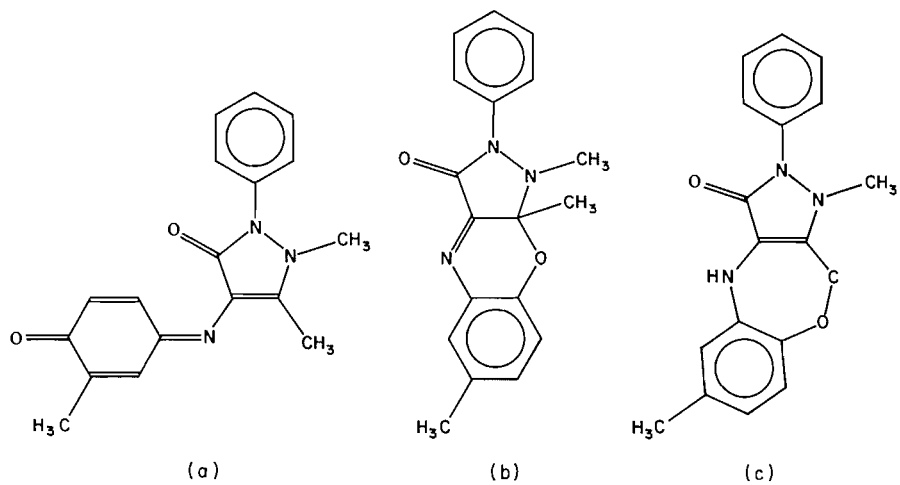

FIG. 1. The structure of (*a*) the *p*-quinoneimide molecule derived from *o*-cresol, (*b*) the methyl benzoxazinone molecule, (*c*) the methyl benzoxazepinone molecule.

compounds are given in Table 2. The angles between the planar rings of the molecules, as defined in Fig. 4, are given in Table 3. The torsional angles in the antipyrine ring and the torsional angles in the rings involving N(1) are given in Table 4. Hydrogen bond parameters for the benzoxazepinone structures are given in Table 5.

Discussion

The bond lengths in *p*-quinoneimide are consistent with its formula; in particular, [C(1)—C(2)], [C(4)—C(5)], and [C(6)—N(1)] are short in this molecule, consistent with the assignment of the quinonoid group. Within the pyrazolone ring in *p*-quinoneimide [C(10)—N(3)] is long, [N(3)—N(2)] short, and [N(2)—C(9)] very short, compared to their lengths in the other five molecules. The [N(1)—C(8)] distance in this molecule is also short (1.362(6) Å), supporting the notion of some delocalization through the C(8)—N(1)—C(6) group. If the bond distances in *p*-quinoneimide are compared with those in antipyrine (13), in the former the bonds from C(8) to C(9) and to C(10) are longer by 0.04(1) Å and that from C(9) to N(2) is shorter by 0.05(1) Å. The C(8)—N(1) bond length is reduced by 0.07(1) Å compared to that in amidopyrone (14). The N(2)—N(3)—C(10) linkage changes little but [N(2)—C(12)] is longer in the *p*-quinoneimide than in the antipyrine and amidopyrone molecules.

The benzoxazinones are conceptually the intramolecular Michael condensation products of *o*-quinoneimides. So far we have not isolated the latter from the *p*-alkylphenol–amino-

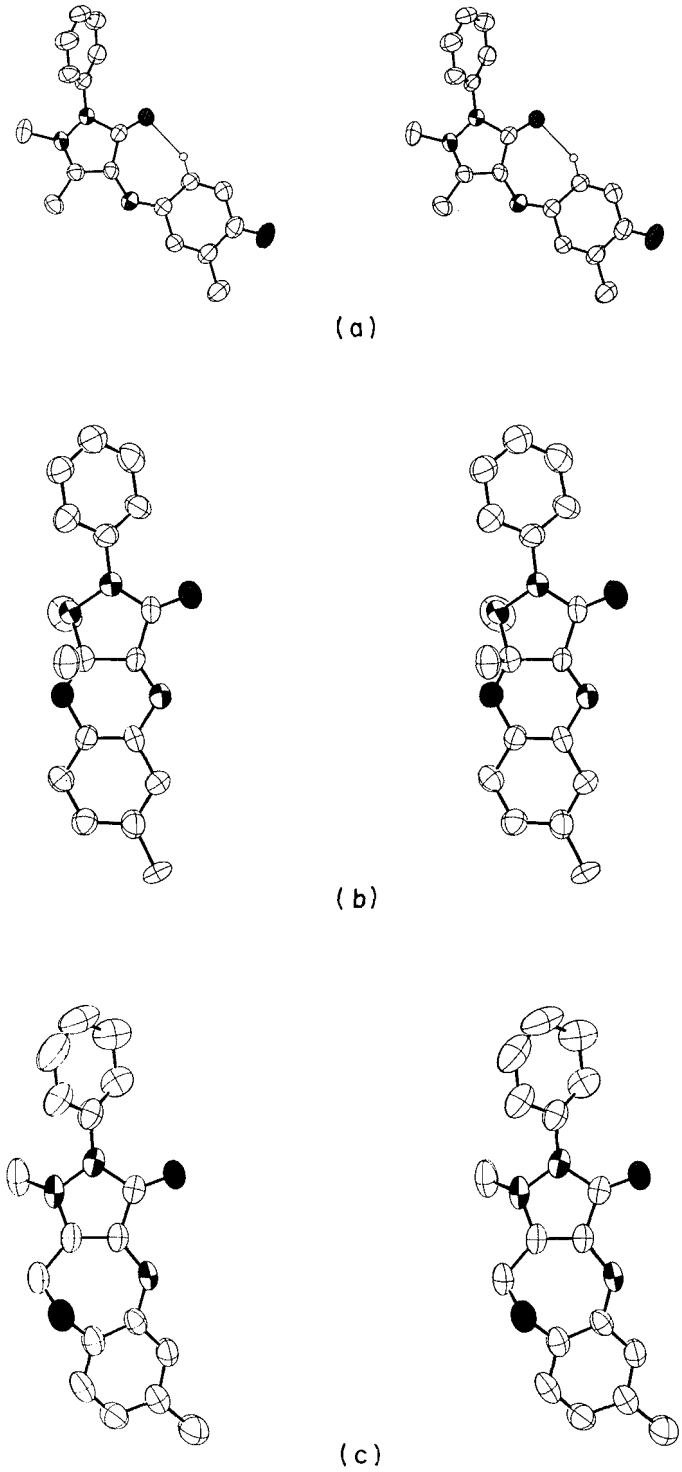

FIG. 2. Stereoscopic views of (*a*) the *p*-quinoneimide molecule, (*b*) the methyl benzoxazinone molecule, (*c*) a methyl benzoxazepinone molecule. The oxygen atoms are filled, the nitrogen atoms partially filled.

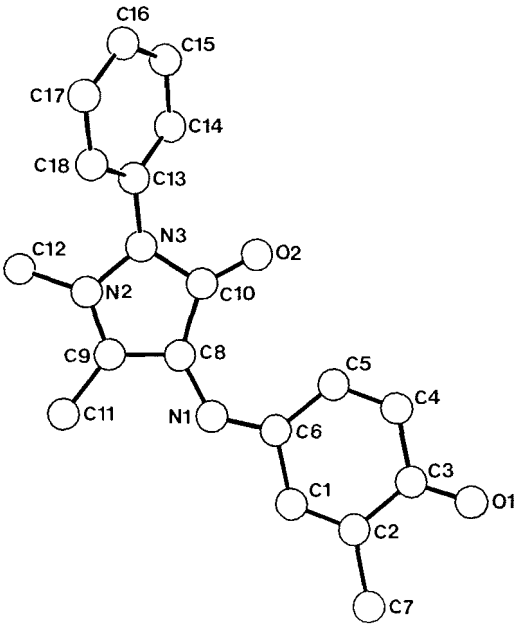

FIG. 3. Labelling of the atoms in the *p*-quinoneimide molecule. See text for labelling of the other compounds.

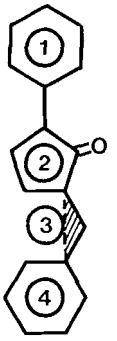

FIG. 4. Definition of the molecular planes.

antipyrine–ferricyanide mixtures. Within the benzoxazinone molecules we find [N(1)—C(8)] to be even shorter than [N(1)—C(6)] in *p*-quinoneimide while [N(1)—C(6)] in the former is the distance of a single bond; conjugation in the C(8)—N(1)—C(6) linkage is reduced and the shift in λ_{max} from 455 to 335 nm and reduction in ϵ_{max} corroborate this. In the pyrazolone rings [C(8)—C(9)], [C(9)—C(11)], [N(2)—C(9)], and [N(2)—N(3)] are lengthened while [C(10)—N(3)] is shortened. Since C(9) is common to two rings and bonded to a methyl group the distances of other atoms from it are long merely because of the congestion.

The benzoxazepinones possess the appropriate bond lengths relative to the benzoxazines: [C(8)—C(10)], [C(8)—C(9)], [C(9)—C(11)], [C(9)—N(2)], [N(2)—C(12)], and [N(2)—N(3)] are shorter while [C(10)—N(3)] is longer. The C(8)—N(1)—C(6) group is different in that the nitrogen atom carries a hydrogen atom: [N(1)—C(6)] is close to a single bond distance although it is shorter than that in the benzoxazinones and [N(1)—C(8)] is shorter than that in amidopyrone. The new seven-membered rings are decidedly puckered.

In the *p*-quinoneimide molecule, the hydrogen atom H(5) on C(5) is only 2.06(3) Å removed from the oxygen atom O(2) and the possibility that carbon atoms in quinone rings may act as donors of hydrogen bonds cannot be *a priori* eliminated. Therefore, the possibility that the H(5)...O(2) interaction has some hydrogen bond character must be considered. Other relevant parameters are the [C(5)—O(2)] distance at 2.973(5) Å, the [C(5)—H(5)] distance at 1.01(3) Å and the C(5)—H(5)—O(2) angle at 148(3)°.

As is clear from Table 5, the three atoms labelled O(2) in the two benzoxazepinone structures are hydrogen bonded, but the atoms O(2) in the two benzoxazinone molecules are not.

TABLE 5. Hydrogen bond distances (Å) and angles (deg)

Compound	A—H.....B		[A—H]	[H...B]	[A...B]	∠AHB
Methyl benzoxazepinone(1)	N(1,1)	O(2,2)	0.81(2)	2.26(3)	3.034(4)	160(7)
Methyl benzoxazepinone(2)	N(2,1)	O(1,2)	0.83(3)	2.19(3)	2.998(4)	161(7)
Ethyl benzoxazepinone	N(1)	O(2)	0.89(2)	2.05(2)	2.875(3)	154(5)

TABLE 6. Perimeters of the pyrazolone rings (Å)

Compound	Perimeter
Antipyrine (14)	6.97
Amidopyrone (15)	7.03
p-Quinoneimide	7.00
Methyl benzoxazinone	7.28
Ethyl benzoxazinone	7.20
Methyl benzoxazepinone, mol. 1	6.99
Methyl benzoxazepinone, mol. 2	6.98
Ethyl benzoxazepinone	6.99
Several metal complexes (21, 22)	6.89–7.06

Nevertheless, the average [C(10)—O(2)] distances are very similar for the hydrogen bonded and non-hydrogen bonded O(2) atoms and are similar to the [C(10)—O(2)] distance of 1.227(6) Å in *p*-quinoneimide. The closure of the seven-membered heterocyclic ring in the former case and closure of the six-membered ring in the latter case lead to variations in the bonding of the antipyrine ring which change the environment of the C(10)—O(2) bond. In the antipyrine (13) and amidopyrone (14) molecules, the equivalent atom O(2) is not hydrogen bonded and the [C(10)—O(2)] length is 1.237(6) Å. The average [C(10)—O(2)] distance in complexes of amidopyrone with barbital (15) and cyclobarbital (16), in which the O(2) atoms is hydrogen bonded, is 1.244(3) Å. In view of the similarity of these molecules to the *p*-quinoneimide molecule, the [C(10—O(2)] distance here is short, even for the non-hydrogen bonded case. A further indication that the O(2)...H(5) interaction is essentially repulsive is that the ring O(2), H(5), C(5), C(6), N(1), C(8), C(10) is not planar. The torsional angles C(8)—C(10)—O(2)—H(5), C(10)—O(2)—H(5)—C(5), and O(2)—H(5)—C(5)—C(6) are 8(4)°, −19(3)°, and 16(3)°, respectively. Finally, the quinone ring is bent at the bridge-head carbon atom, C(6), 6.8(4)° away from O(2) with respect to the position that would leave the angles N(1)—C(6)—C(5) and N(1)—C(6)—C(1) equal. Therefore we conclude that O(2) is not the acceptor of a hydrogen bond from C(5).

The perimeters of the pyrazolone rings in the various

structures are listed in Table 6. The distortion in the benzoxazinones shows as the enlarged "perimeters" for these molecules, where the atoms are not coplanar. Otherwise, the perimeter of a pyrazolone ring appears to be 7.00 ± 0.02 Å, giving an average bond length of 1.40 Å. Pyrazolones as a class are considered to be π-excessive aromatics, intermediate between benzene and pyridine in degree of aromaticity (17). In benzene the average bond length is 1.40 Å; in a selection of pyridine compounds and complexes the average bond length is 1.37 ± 0.01 Å (18). Pyrazole, the parent of pyrazolones, has a perimeter of 6.77 Å (19), giving an average bond length of 1.354 Å and the complex $Ni(pyrazole)_4Cl_2$ (20) has pyrazole perimeters of 6.74 and 6.80 Å. In pyrazolone complexes we find a range of perimeters from 6.89 to 7.06 Å (21, 22). It appears then that the perimeter of a potentially aromatic molecule can act as a measure of its aromaticity; experimental errors and alterations in bond lengths due to local short range effects involving the position of a single atom will have a minimal effect on the value of the perimeter in such a system.

LEO H. KOOLE, HENK M. BUCK, AGNES NYILAS, and JYOTI CHATTOPADHYAYA. Can. J. Chem. **65**, 2089 (1987).

A variable temperature high resolution ^{1}H nuclear magnetic resonance study (at 300 or 500 MHz) of the two modified nucleosides 9-(2′-deoxy-β-D-*threo*-ribofuranosyl)-adenine (**1**) and 9-(3′-deoxy-β-D-*threo*-ribofuranosyl)-adenine (**2**) has been performed. It was found that the furanose conformation in **1** and **2** can be best described as a rapid North (N) ⇄ South (S) equilibrium that is biased toward the N-form. For **1**, a marked temperature dependence of the N ⇄ S equilibrium was found, whereas the furanose conformation in **2** is virtually insensitive to temperature changes. Comparison of these results with the well-known conformational properties of the natural nucleosides 2′-deoxyadenosine (2′-dA) and 3′-deoxyadenosine (3′-dA) revealed that the net result of the *gauche* effect and the anomeric effect is of major importance in determining the furanose conformation. A brief discussion in terms of the thermodynamic parameters that govern the N ⇄ S equilibria in the investigated nucleosides is given.

LEO H. KOOLE, HENK M. BUCK, AGNES NYILAS et JYOTI CHATTOPADHYAYA. Can. J. Chem. **65**, 2089 (1987).

On a effectué une étude de résonance magnétique nucléaire à haute résolution (à 300 ou 500 MHz) et à température variable de deux nucléosides modifiés, soit la (déoxy-2 β-D-*thréo*-ribofurannosyl)-9 adénine (**1**) et la (déoxy-3 β-D-*thréo*-ribofurannosyl)-9 adénine (**2**). On a trouvé que la meilleure façon de décrire la conformation du furannose des composés **1** et **2** fait appel à un équilibre rapide nord (N) ⇄ sud (S) dans lequel la forme N est favorisée. Dans le cas du composé **1**, on a observé que l'équilibre (N) ⇄ (S) est soumis à une dépendance marquée sur la température; par ailleurs, la conformation du furannose de la molécule **2** est virtuellement insensible aux changements de température. Une comparaison de ces résultats avec les propriétés conformationnelles bien connues des nucléosides naturels déoxy-2′ adénosine (d-2′ A) et déoxy-3′ adénoside (d-3′ A) révèle que le résultat net de l'effet *gauche* et de l'effet anomérique est important dans la détermination de la conformation du furannose. On présente une brève discussion en fonction des paramètres thermodynamiques qui influencent l'équilibre (N) ⇄ (S) dans les nucléosides étudiés.

Introduction[2]

Naturally occurring nucleic acids display a marked structural versatility, which is essential to their function of storing and transmitting genetic information in the living cell (1). In particular, the backbone chain, in which negatively charged phosphate groups alternate with furanose sugar units (ribose in RNAs, 2′-deoxyribose in DNAs), is capable of adopting a variety of distinct conformations. It has been shown that the overall structural flexibility of DNA and RNA is largely determined by the furanose rings in the backbone, and this insight has stimulated extensive experimental (2–4) and theoretical (5–13) research on furanose puckering in nucleosides and nucleotides. We report herein a detailed ^{1}H nmr conformational study on the modified deoxyadenosine systems (14, 15) 9-(2′-deoxy-β-D-*threo*-ribofuranosyl)-adenine (**1**) and 9-(3′-deoxy-β-D-*threo*-ribofuranosyl)-adenine (**2**). Both structures (Fig. 1) have the hydroxyl group on the furanose ring in the unnatural *endo* position.

It should be noted that Mengel and Wiedner (14), as well as Lüdemann *et al.* (16), have previously reported ^{1}H nmr studies on **1** and **2**. However, the work of Mengel and Wiedner does not mention a conformational analysis of the furanose moieties in **1** and **2**. The conformational studies as reported by Lüdemann *et al.* refer exclusively to the solvent ND_3 and a sample temperature of 213 K. In the present work, we determined the conformational properties of **1** and **2** as a function of the sample temperature in the solvents D_2O or dimethyl formamide-d_6. Comparison with the natural nucleosides 2′-deoxyadenosine (2′-dA) and 3′-deoxyadenosine (3′-dA), also called cordycepin, provided new details on the nature of furanose puckering. It is found that the net effect of two stereoelectronic factors (i.e., the *gauche* effect and the anomeric effect) is of major importance in determining the conformational preferences of the sugar unit in solution.

Experimental

Preparation

The preparation of the modified nucleosides **1** and **2** has been described previously (14, 15). The essential step in the synthesis route for both compounds involves the $LiAlH_4$ reduction of a (6*N*,5′) doubly protected 2′,3′-*lyxo*-anhydroadenosine structure. Using $LiAlD_4$ in the reduction step, the synthesis route can be used to introduce deuterium in a stereospecific way (15). After this reaction, one obtains **1** with a deuterium in the *exo* position at $C_{2'}$ ($C_{2'}$(*R*) configuration), and **2** with a deuterium in the *exo* position at $C_{3'}$ ($C_{3'}$(*S*) configuration). The natural nucleosides 2′-dA and 3′-dA were purchased from Sigma.

Nuclear magnetic resonance spectroscopy

The ^{1}H nmr spectra were recorded at different sample temperatures on a Bruker CXP 300 nmr spectrometer[3] (^{1}H frequency: 300.13 MHz),

or on a Bruker AM 500 nmr spectrometer[4] (^{1}H frequency: 500.1 MHz). In all cases, the field-frequency lock was provided by the solvent (D_2O or dimethyl formamide-d_6). At 300 MHz, we used a spectral window of 3000 Hz; at 500 MHz this was 5000 Hz. Before Fourier transformation, the spectra were zero-filled to 32 or 64 K, and resolution enhanced by an appropriate Gaussian multiplication. In some cases, a standard computer simulation–iteration procedure was employed to obtain accurate values for spin–spin couplings and chemical shifts.

Furanose conformation

The description of the puckered conformation in furanose rings is greatly facilitated by the pseudorotation concept (5, 17), in which the conformations of the five ring torsions are mathematically related to a puckering amplitude (ν_m), and a phase angle of pseudorotation (P). The puckering amplitude identifies the deviation from planarity of the furanose ring. From the large number of X-ray crystallographic studies of nucleosides and nucleotides (18) it is known that ν_m is confined to a narrow range around $\nu_m = 39°$. Potential energy calculations have clearly shown that the stability of the furanose systems decreases sharply when ν_m is varied (2). The phase angle of pseudorotation actually indicates which part of the ring is bent. P lies in the range 0–360°, thus encompassing an entire pseudorotation cycle. Also from crystallographic studies, it is known that P values occur in two distinct and relatively narrow ranges (18). The first range is centered around $P = 18°$ ($C_{3'}$-*endo* ring conformation), and is designated as N (North). The N pucker is characteristic for all RNAs and, for example, the A form of DNA (4). The second range is centered around $P = 162°$ ($C_{2'}$-*endo* ring conformation), and is called S (South). This pucker is found, for example, in B DNA. Conformational studies on nucleosides and nucleotides in solution have shown that the furanose ring is generally involved in a rapid N ⇄ S equilibrium, which is an approximate 1:1 blend for ribose rings, and clearly biased toward the S form for 2′-deoxyribose rings (2, 19–21).

A rationale for this different conformational behavior of ribose vs. 2′-deoxyribose has been given by Olson (2). She stated that the preferred conformation in solution is determined by the so-called *gauche* effect, i.e., the tendency of vicinal oxygen atoms to adopt a *gauche* rotational arrangement (12, 22, 23). For furanose units, this means that the oxygens $O_{2'}$ and $O_{3'}$ are preferentially located in an axial position.

Looking at the N and S forms of ribose, it is seen that the N form corresponds with $O_{2'}$ axial and $O_{3'}$ equatorial, whereas the reverse situation occurs in the S form. Consequently, ribose shows a 1:1 distribution over N and S in solution. 2′-Deoxyribose, on the other hand, has $O_{3'}$ axial in the S form, and $O_{3'}$ equatorial in the N form, which leads to a preference for S in solution. The theory also correctly predicts the experimentally observed preference of 3′-deoxy nucleosides (e.g. cordycepin) for the N pucker (24–26). At first sight, the *gauche* effect theory seems to account for all experimental data that have been obtained on nucleosides and nucleotides in solution. However, a substantial shortcoming is obvious, since the theory does not explain why the N ⇄ S conformational equilibrium in 2′-deoxy nucleosides is virtually temperature independent (25). This experimental fact indicates that the free energy difference between the N and S states is in fact solely determined by entropy factors. Apparently, the entropy is 1–2 eu larger in the S form than in the N form. In contrast, the N ⇄ S equilibrium for 3′-deoxy nucleosides is clearly temperature sensitive (*vide infra*). In this case, raising the temperature leads to increased populations of the S pucker, i.e., the N form is associated with the lowest enthalpy.

In the present work, we have specifically focused on the temperature dependence of the conformational equilibria of **1**, **2**, 2′-dA, and 3′-dA. A brief discussion of the thermodynamic parameters governing the N ⇄ S equilibria is given. It appears to be necessary to account explicitly for the so-called anomeric effect (27), i.e. the preference of the nucleobase to be axially located on the furanose unit.

Results

We have recorded 300- and 500-MHz ^{1}H nmr spectra of **1**, **2**, 2′-dA, and 3′-dA in the temperature range of −40 to 95°C. In the experiments at sample temperatures higher than 0°C, we used D_2O as the medium; all other experiments refer to the solvent dimethyl formamide-d_6. Table 1 summarizes the ^{1}H nmr parameters that were obtained on **1** and **2** at 25°C. The data obtained at other sample temperatures are listed as supplementary material.[5]

*9-(2′-Deoxy-β-D-*threo*-ribofuranosyl)-adenine (**1**)*

The conformation of the furanose ring in **1** was determined from the relationship between the coupling constants of the vicinal ring protons (i.e., $J_{1'2'}$, $J_{1'2''}$, $J_{2'3''}$, $J_{2''3''}$, and $J_{3''4'}$) and the pseudorotational parameters of the ring. The assignment of the protons $H_{2'}$ and $H_{2''}$ was based on a comparison with the analogue of **1**, in which $H_{2''}$ was substituted by deuterium (15). From this, it follows that $\delta(2'') > \delta(2')$. Using the generalized Karplus equation of Altona and co-workers (28), we calculated the variation of the five ring-coupling constants over the full pseudorotation circuit.[6] A convenient qualitative representation of the conformational equilibrium of the furanose ring in **1** is

[4]Dutch National 500/200 hf NMR facility at Nijmegen, The Netherlands.

[5]Tables of nmr spectral parameters obtained on **1**, **2**, 2′-dA, and 3′-dA may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[6]Analogous calculations have recently been performed for 5-methoxymethyl-1-(2′-deoxy-β-D-*lyxo*-furanosyl uracil). See Fig. 3 in ref. 29.

given in Fig. 2, which shows the variation of $J_{1'2'}$ and $J_{3''4'}$ with P. Note that $J_{1'2'}$ is a transoidal coupling, showing a large variation of 9.4 Hz (from 1.2 to 10.6 Hz) over the pseudorotation cycle. The cisoidal coupling $J_{3''4'}$, on the other hand, shows a much smaller variation of 5.9 Hz (from 1.9 to 7.8 Hz). The experimental data points are found in the lower left part of the cycle, close to $P = 0°$. From the plot, it is evident that the conformation of the furanose ring is strongly biased toward the N form. Also, it is seen that the ring conformation varies with the sample temperature in such a way that increasing the temperature results in an enhanced population of an S form, which is found in the upper right region of the graph. A quantitative picture of the furanose conformation could be obtained by application of the PSEUROT method (30), after correct parametrization for the *endo* orientation of the 3′-OH group on the ring.

The PSEUROT algorithm calculates the best fit of P_N, P_S (the phase angles of pseudorotation in the N and S forms), $\nu_{m,N}$, $\nu_{m,S}$ (the puckering amplitudes in the N and S forms), and the mol fraction of the participating conformers, to the experimental spin–spin couplings between the ring protons.

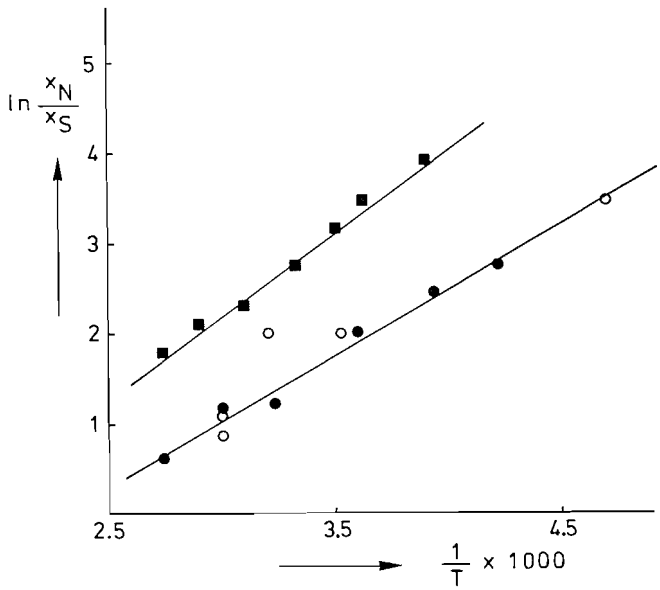

FIG. 3. Van't Hoff plot, based on the experimental data on **1** (black squares) and 3′-dA (black circles). The open circles refer to nmr measurements on 3′-dA, described in ref. 25.

The program was run under the reasonable assumption that the N and S forms have the same puckering amplitude. Based on our data, it was found that the furanose conformation in **1** is best described by a dominant N form with $P = 0°$, $\nu_m = 33°$, and a minor S form with $P = 208°$, $\nu_m = 33°$. Table 2 lists the calculated populations of the N form (x_N) as a function of the sample temperature. Interestingly, these data can be used to estimate the thermodynamic parameters of the N ⇄ S conformational equilibrium in **1**. In the van't Hoff plot ($\ln x_N/x_S$ vs. $1/T$) of Fig. 3, the data on **1** correspond with the black squares. From the slope of the best-fit line through the data points, it follows that the conversion from N toward S is associated with an increase of the standard enthalpy of 17 kJ/mol. The estimated inaccuracy in this number is ±3 kJ/mol. The intercept with the vertical axis reveals that the standard entropies of the N and S forms differ by approximately 1.5 eu, in favor of S. In addition, the conformation of the exocyclic $C_{4'}$—$C_{5'}$ bond in **1** was analyzed on the basis of the vicinal proton–proton coupling constants $J_{4'5'}$ and $J_{4'5''}$ (28, 31, 32). At a sample temperature of 25°C, it was found that $J_{4'5'}$ = 4.2 Hz, and $J_{4'5''}$ = 7.3 Hz. From this, it was calculated that the populations of γ^+, γ^t, and γ^- are 0.20, 0.60, and 0.20, respectively. Thus, γ^t is the preferred $C_{4'}$—$C_{5'}$ conformation in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12

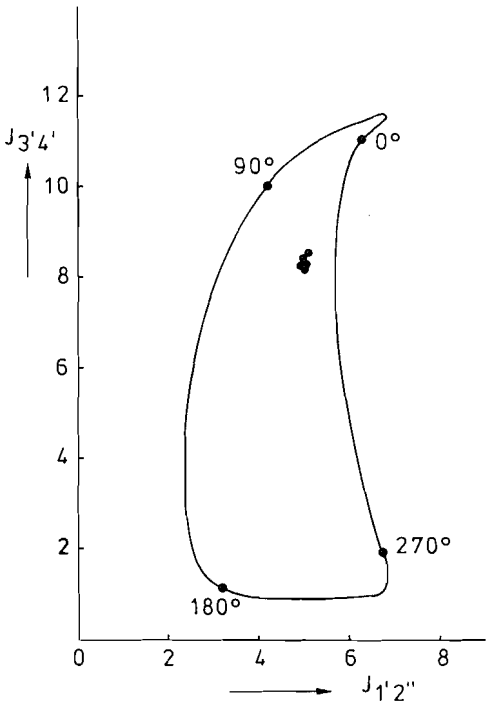

FIG. 4. Calculated variation of $J_{1'2''}$ and $J_{3'4'}$ in **2** with the phase angle of pseudorotation (P). The experimental data obtained on **2** at different sample temperatures are clustered in the midregion of the graph (see text).

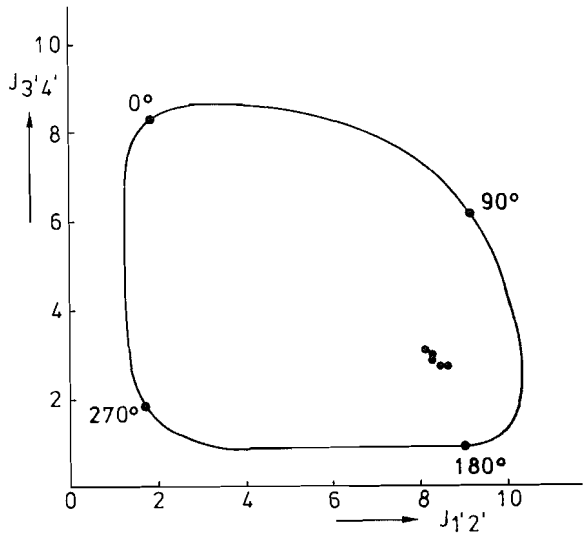

FIG. 5. Calculated variation of $J_{1'2'}$ and $J_{3'4'}$ in 2′-dA with the phase angle of pseudorotation (P).

1, whereas γ^+ always dominates in unmodified nucleosides. Most likely, the cisoidal orientation of the 3′- and 5′-hydroxyl groups in **1** strongly destabilizes γ^+ because of unfavorable electrostatic and (or) steric interactions. Therefore the $C_{4'}$—$C_{5'}$ conformation is strongly biased toward γ^t. We also observed a marked temperature dependency of the $C_{4'}$—$C_{5'}$ conformational equilibrium. Lowering the temperature results in a more pronounced preference for γ^t. Details are given in the supplementary material.

*9-(3′-Deoxy-β-D-*threo*-ribofuranosyl)adenine (2)*

For this compound, the furanose conformation was determined from the vicinal coupling constants $J_{1'2''}$, $J_{2''3'}$, $J_{2''3''}$, $J_{3'4'}$, and $J_{3''4'}$. The assignment of the protons $H_{3'}$ and $H_{3''}$ was based on a comparison with the analogue structure of **2** in which $H_{3''}$ was replaced by deuterium (15). It is found in this way that $\delta(3'') > \delta(3')$. After calculating the dependence of the ring-coupling constants on the phase angle of pseudorotation (28), we could construct Fig. 4, showing the variation of $J_{1'2''}$ and $J_{3'4'}$ with P. Note that $J_{1'2''}$ is a cisoidal coupling with a variation of only 4.5 Hz (from 2.3 to 6.8 Hz) over the entire pseudorotation cycle. A much greater variation of 10.8 Hz (from 0.8 to 11.6 Hz) was calculated for the transoidal coupling $J_{3'4'}$. The experimental data are clustered in the upper region of the graph, close to the line that connects the calculated points for $P = 0°$ and $P = 180°$. Figure 4 immediately shows that the N ⇄ S equilibrium in **2** is virtually temperature independent. Therefore it can be concluded that the enthalpy difference between the N and S forms in **2** is close to zero. Also, it is seen that the distribution over N and S is biased toward N, i.e., the entropy of the N form slightly exceeds that of the S form. In the case of **2**, we confined ourselves to the qualitative description of the furanose conformation as given above. This is due to the fact that the five ring couplings are practically constant over the temperature range of −45 to 95°C. With respect to the $C_{4'}$—$C_{5'}$ conformation it was found that $J_{4'5'} = 3.0$ Hz, and $J_{4'5''} = 5.2$ Hz. From this, we calculated that γ^+, γ^t, and γ^- have the relative populations of 0.53, 0.41, and 0.06, respectively at a sample temperature of 25°C. Lowering the temperature results in a pronounced preference for the γ^+ rotamer. All relevant data are given in the supplementary material.

2′-Deoxyadenosine (2′-dA)

The conformational properties of 2′-dA, an essential building block of DNA, have been studied extensively by means of X-ray crystallography (33) and nmr spectroscopy (25, 34–36). In the crystal structure, 2′-dA shows an N-type furanose ring ($P = 14°$, $\nu_m = 35.5°$). The conformations around the $C_{1'}$—N_9 and $C_{4'}$—$C_{5'}$ bonds are *anti* and γ^+, respectively. From the nmr data, it was concluded that the conformation of the furanose ring in 2′-dA is best described as a rapid N ⇄ S equilibrium. The best-fit pseudorotational parameters for the N form are $P = 10°$, $\nu_m = 35.5°$; for the S form, $P = 167°$, $\nu_m = 35.5°$ (30). In Fig. 5, we have plotted both $J_{1'2'}$ and $J_{3'4'}$ as a function of P (*vide supra*). The calculations were performed for a puckering amplitude of 35.5°. The data points in the graph refer to literature data (25), as well as to our own experiments in D_2O in deuterated dimethyl formamide (see supplementary material). Clearly, the data points are clustered in the lower right region of the plot, indicating that the S form of the furanose ring is slightly preferred in solution. Remarkably, the N ⇄ S equilibrium is virtually insensitive to temperature changes, i.e., the enthalpy difference between the N and S forms is close to zero.

3′-Deoxyadenosine (3′-dA)

The conformation of 3′-dA in the solid state and in solution has also received considerable attention (25, 26). The interest in 3′-dA stems from its pronounced antibiotic properties (37). The X-ray structure shows an N-type furanose ring with $P = 12.7°$, and $\nu_m = 32°$. Westhof *et al.* (25) have recorded nmr spectra of 3′-dA at different temperatures (ranging from −60 to 80°C), and in different solvents (e.g., D_2O, ND_3, and deuterated pyridine). They have shown that the furanose conformation in 3′-dA is heavily biased toward N, and also that the N ⇄ S equilibrium is strongly temperature dependent. Raising the temperature results in an enhanced population of the S form. In

this work, we have estimated the thermodynamic parameters governing the N ⇄ S equilibrium in 3′-dA on the basis of our own data (which were obtained in D_2O or in deuterated dimethyl formamide), as well as on Westhof's data. Application of the PSEUROT method revealed that the conformation of the furanose moiety is best described as a rapid equilibrium between a dominant N form with $P = 13°$, $\nu_m = 32°$, and an S form with $P = 169°$, $\nu_m = 32°$. Table 3 summarizes the calculated population of the N form as a function of the temperature. From the van't Hoff plot in Fig. 3 it was calculated that the N ⇄ S transition in 3′-dA is associated with an increase of the standard enthalpy by approximately 14 kJ/mol. The estimated inaccuracy of this number is again 3 kJ/mol. The entropy change of the N → S transition is again approximately +1.5 eu.

Discussion

From the results, it is evident that **1** and 3′-dA have highly similar conformational properties with respect to the furanose rings. In both cases, a pronounced preference for the N form is found. Also, the N ⇄ S equilibria in **1** and 3′-dA show a highly comparable variation with the sample temperature, since the enthalpy differences between N and S (17 ± 3 kJ/mol for **1**; 14 ± 3 kJ/mol for 3′-dA) are essentially similar. A tentative explanation for these findings is derived on the basis of Fig. 6, which shows the N and S forms for both structures. In both cases, the N form is associated with a favorable axial orientation of the adenine base (anomeric effect), as well as a favorable axial orientation of the hydroxyl group on the furanose ring (3′-OH in **1**, or 2′-OH in 3′-dA). The conversion from N toward S results in undesirable equatorial locations of the base and the hydroxyl group in either case. Clearly, the anomeric effect and the *gauche* effect are cooperative, since both effects drive the N ⇄ S equilibrium toward the N form. Logically, the N form has the lower enthalpy, which explains the experimentally observed temperature dependence of the N ⇄ S equilibria in both structures.

For model compound **2** and 2′-dA it holds that the sugar ring is involved in an N ⇄ S equilibrium that is insensitive to temperature changes. Figure 7 offers a tentative explanation for these results. The N conformation for **2** and 2′-dA has a favorable axial location of the base, combined with unfavorable equatorial furanose OH groups, whereas the reverse situation (equatorial base and axial furanose hydroxyl) is found in the corresponding S form. Evidently, the anomeric effect and the *gauche* effect are counteractive in these cases, which apparently results in cancelling of the enthalpy differences between the N and S forms. For 2′-dA, this reasoning is further substantiated by the experimental finding that structure **3**, in which the base is in fact replaced by hydrogen, shows a temperature-dependent N ⇄ S equilibrium with a preference for S.[7] The anomeric effect is eliminated in this case, i.e., the furanose conformation in **3** is solely determined by the *gauche* effect. Variable temperature measurements on **3** have shown that the enthalpy is approximately 8 kJ/mol lower in the S form than in the N form.[7]

The results show that both the *gauche* effect and the anomeric effect should be taken into account for the description of the conformation of the furanose ring in nucleosides and nucleotides. It goes without saying that other factors, such as chemical

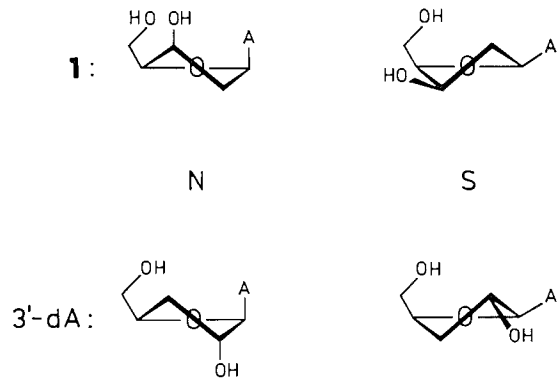

FIG. 6. N and S forms of **1** and 3′-dA. Clearly, the N forms have axial orientation of the adenine base, and axial orientation of the furanose OH. In the corresponding S forms, both the base and the OH group are equatorial.

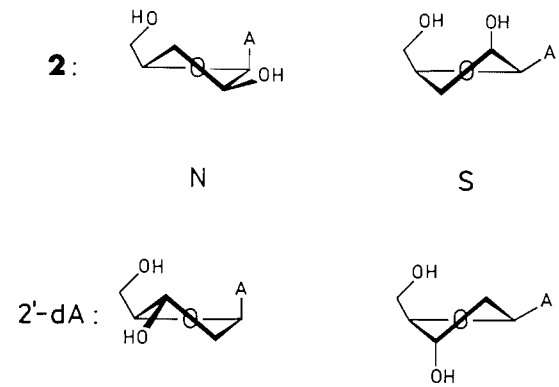

FIG. 7. N and S forms of **2** and 2′-dA. The N forms have axial orientation of the adenine base, combined with an equatorial OH group. The corresponding S forms have an equatorial base, and an axial OH group.

modifications of the base or the introduction of bulky groups on the furanose ring, may also have an important impact on the conformation. However, the present theory may offer an explanation for the well-known polymorphism of oligomeric and polymeric DNA structures, since it is clear that the individual 2′-deoxyribose units may occur in N or S without substantially affecting the enthalpy content of the structure. On the other hand, RNA structures are uniform with N-type conformations of the ribose rings. This is consistent with the fact that the anomeric effect actually determines the enthalpy preference for the N form of ribose.

FARUK NOME, MARCOS CAROLI REZENDE, CLAUDIA MARIA SABÓIA, and ARLINDO CLEMENTE DA SILVA. Can. J. Chem. **65**, 2095 (1987).

The thermolysis of five *para*-substituted benzylcobalamins was studied at different temperatures. In the presence of KCN the observed rates increase with the cyanide concentration until a constant value is attained at high [CN^-]. In both series the homolytic cleavage of the Co—C bond is slightly dependent on the *para*-substituent of the benzyl moiety, with ρ values of −0.1 and −0.2 when 5,6-dimethylbenzimidazole (Bzm) and cyanide are the axial ligands respectively. The Co—C bond is weakened by electron-donating axial ligands and the homolytic cleavage rates increase in the order H_2O < Bzm < CN.

FARUK NOME, MARCOS CAROLI REZENDE, CLAUDIA MARIA SABÓIA et ARLINDO CLEMENTE DA SILVA. Can. J. Chem. **65**, 2095 (1987).

La thermolyse de cinq benzylcobalamines *para*-substituées a été étudiée à diverses températures. Les constantes de vitesse observées augmentent avec la concentration de cyanure jusqu'à une valeur constante à haute [CN^-]. Dans les deux séries, la rupture homolytique de la liaison Co—C dépend légèrement du *para*-substituant de la moitié benzylique, les valeurs de ρ étant respectivement −0,1 et −0,2 pour les ligands axiaux 5,6-dimethylbenzimidazole (Bzm) et cyanure. Les ligands axiaux affaiblissent la liaison Co—C et les constantes de vitesse de rupture homolytique augmentent dans l'ordre H_2O < Bzm < CN.

Introduction

The chemistry of the Co(III)—C bond plays a central role in the biochemistry of vitamin B_{12} (1, 2). As a consequence, the formation and cleavage of the Co—C bond of alkylcobalamins and cobinamides in various chemical processes have been topics of continuous interest in the vitamin B_{12} chemistry (1–14). Examples are found of homolytic and heterolytic cleavages and it is not always an easy task to decide which is the preferred pathway in many thermal decompositions. Even when a homolytic pathway is firmly established, the charge distribution in the transition state remains a subject of speculation. Although large kinetic effects arising from electronic factors are not to be expected in these homolytic processes, such effects do exist and can shed more light on the nature of the transition state of these cleavages. Changes in the ease of the Co—C bond breaking may be observed by either changing the charge of the Co atom, or of the alkyl moiety. Schrauzer and Grate (10) studied the thermolysis of benzylcobalamin and showed, on the basis of the products formed under aerobic and anaerobic conditions, that this is a homolytic process. We decided to study other substituted benzylcobalamins and evaluate the effect of these substituents on the rate of the Co—C bond cleavage. We were also interested in the effects of axial ligands on the cobalt atom, and how they might affect this thermolysis process. Such a *trans* effect should be larger than the result of altering the benzyl moiety, as the ligand is directly attached to the cobalt atom.

Experimental

Vitamin B_{12a} (aquocobalamin) and vitamin B_{12} (cyanocobalamin) were purchased from Merck, Sharp and Dohme. Diaquocobinamide was obtained from vitamin B_{12} following the procedures reported by Pratt and co-workers (14) and Friedrich and Bernhauer (15). The benzyl- and *p*-methylbenzylcobinamide and the various substituted benzylcobalamins **1** employed were prepared following Schrauzer's procedure (9). The products obtained were spectroscopically identical with those reported in the literature.

The spectroscopic characterization of all cobalamins and cobinamides prepared and the kinetic measurements were performed with a Shimadzu UV-210A spectrophotometer equipped with thermostatted water-jacketted cell compartments. The analysis of the organic products of the reactions was carried out with a gas chromatograph CG 370, equipped with an OV-17 column, retention times being identical with those of authentic samples.

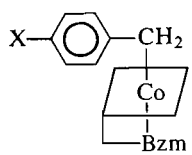
The aerobic decomposition of benzylcobalamins and cobinamides was studied in aqueous buffered solution at pH 7.0 by following the change of absorbance at 350 and 425 nm respectively. The spectral changes observed were identical with those reported by Schrauzer and Grate (10) with isobestic points at 370 and 480 nm. The decomposition of benzylcobalamins **1** in the presence of KCN was studied in aqueous buffered solution at pH 11, by monitoring the formation of the products at 367 nm. The spectral changes observed were similar to those described by Jencks and co-workers (11) for the thermolysis of (methoxycarbonyl)methylcobalamin in the presence of excess cyanide, which yields a mixture of cyano- and dicyanocobalamins (λ_{max}: 575, 540, and 370 nm).

Rate constants were obtained from linear plots of $\ln(A_\infty - A_t)$ vs. time. All plots were linear for at least 90% of the reaction, with correlation coefficients greater than 0.99. The activation parameters were calculated from Arrhenius plots of the rate constants at different temperatures.

Results and discussion

Benzylcobalamin decomposes in the presence of oxygen to form benzaldehyde and vitamin B_{12a} (9). The reaction is much slower under nitrogen because of recombination of the benzyl radical and the Co(II) species formed by the homolytic cleavage of the Co—C bond.

We have studied the thermolysis of five *p*-substituted benzylcobalamins **1** at pH 7.0 and different temperatures.



X = H, Me, MeO, Br, CO_2^-

1

The observed rate constants are given in Table 1. The activation parameters for the thermolysis process for each benzylcobalamin were calculated from the observed pseudo-first-order rate constants and are given in Table 2. For the sake of comparison and the discussion below, activation parameters for the benzyl- and *p*-methylbenzylcobinamide are also included in Table 2.

We have also followed the decomposition of cobalamins **1** in the presence of cyanide anion. As with the experiments in the absence of CN^-, the thermolysis is considerably slower

under nitrogen. Similarly to the reaction in the absence of CN^- the products were the corresponding benzaldehyde and 1,2-diarylethane in aerobic and anaerobic conditions respectively. Toluene, a product that could be formed by homolysis of the Co—C bond followed by electron transfer, was not detected under our experimental conditions. However, in this case, the spectral analysis of the products revealed the formation of a mixture of cyano- and dicyanocobalamin, both under aerobic and anaerobic conditions. The formation of a cobalt(III) species in a homolytic process can be explained by the disproportionation of the Co(II) species initially formed in the presence of excess cyanide, the Co(I) species being consumed by trace oxygen (16).

[1] $2Co(II) + 2CN^- \overset{K_D = 0.28}{\rightleftharpoons} Co(III)(CN^-)_2 + Co(I)$

As shown by Savéant and co-workers, this disproportionation is not as important when the axial ligand is water, hydroxide, or benzimidazole (16).

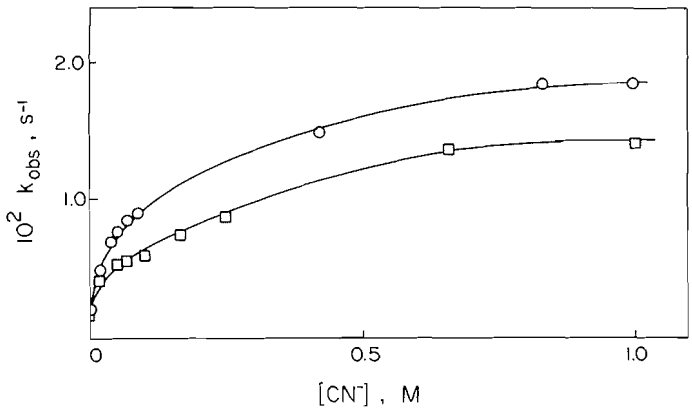

FIG. 1. Variation of k_{obs} as a function of the concentration of cyanide ion for the thermolysis of *p*-methoxybenzylcobalamin (○) and benzylcobalamin (□) at 25.0°C.

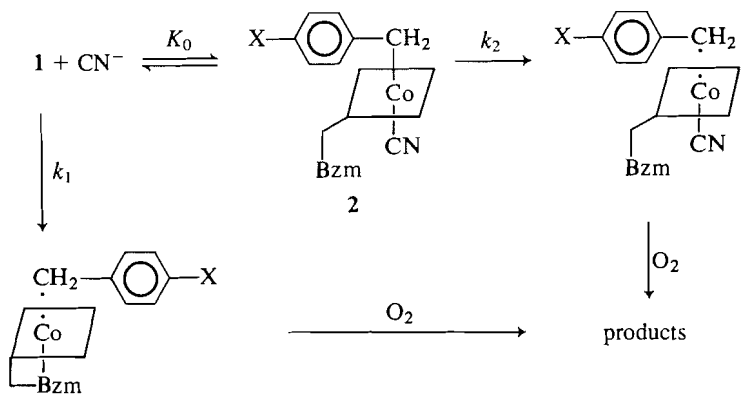
Table 3 lists the observed rate values for the decomposition of cobalamins **1** at 25°C, pH 11, and increasing concentrations of cyanide anion. The thermolysis rate is found to increase with $[CN^-]$ until a constant value is reached. Such behaviour is illustrated for the benzyl- and the *p*-methoxybenzylcobalamin in Fig. 1, and has been described by Jencks and co-workers (11) in the decomposition of (methoxycarbonyl)methylcobalamin in the presence of cyanide. Our data can be rationalized by a mechanism that involves a preequilibrium between two cobalt species with different axial ligands, -CN and 5,6-dimethylbenzimidazole (Bzm), which undergo thermolysis at different rates.

[2]



At high cyanide concentrations the benzimidazole ligand is completely displaced by CN^-, the observed rate becoming constant and equal to k_2. Equation [3] relates the observed rate constant to the cyanide concentration.

[3] $k_{obs} = (k_1 + k_2 \cdot K_0[CN^-])/(1 + K_0 \cdot [CN^-])$

Since $k_{obs} = k_1$ when $[CN^-] = 0$, and $k_{obs} = k_2$ for sufficiently high concentrations of cyanide, the preequilibrium constant K_0 can be estimated by proper adjustment of eq. [3] to the experimental values. For the five cobalamins studied, the average K_0 value was $12 \pm 6\ M^{-1}$, not very different from the value of $22.7\ M^{-1}$ for a similar equilibrium involving the (methoxycarbonyl)methylcobalamin (11).

The observed rate values for the thermolysis of the five cobalamins in the presence of a high concentration of cyanide ($[CN^-] = 0.83\ M$) at various temperatures are given in Table 4. Under these conditions, these rates are equal to the rate values k_2, and the activation parameters derived from them (Table 5) correspond to the homolytic cleavage of the Co—C bond when -CN is the axial ligand. We can thus compare the two homolytic processes that differ in the nature of the axial ligand. Figure 2 is a Hammett plot of the thermolysis rate constants for all *p*-substituted benzylcobalamins. The ρ values are −0.1 and −0.2, in the absence and presence of cyanide respectively. The small values were expected for a homolytic process, but the negative sign in both cases is an indication of a slight nucleophilic character of the incipient benzyl radical in the transition state.

The nature of the axial ligand was expected to play an important role in the homolytic cleavage of the Co—C bond. In fact, for the reaction in which water was the axial ligand (Table 2), the values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for the compounds studied are in the range of 27.2–28.6 kcal mol^{-1} and 10.1 – 14.4 eu respectively. When benzimidazole is the axial ligand, a slight decrease in $\Delta H^{\ddagger}$ (21.7–25.0 kcal mol^{-1}) is observed (Table 2). This trend is maintained when cyanide is the ligand, the range of $\Delta H^{\ddagger}$ values being 15.1–11.3 kcal mol^{-1}, but in this case a strong decrease in $\Delta S^{\ddagger}$ (−15.6 to −29.3 eu) is also observed (Table 5).

The changes observed in both enthalpy and entropy of activation are noteworthy and, as should be expected for reactions occurring through the same mechanism, a linear dependence of $\Delta H^{\ddagger}$ on $\Delta S^{\ddagger}$ is observed (graph not shown), implying a partial compensation of both factors. It is clear from Table 2 that the variations of $\Delta H^{\ddagger}$ predominate in the overall changes of $\Delta G^{\ddagger}$ for the reaction series.

It may be argued in the case of cobalamins that these activation parameters do not correspond solely to the homolytic cleavage of the Co—C bond. In fact, as pointed out by Schrauzer and Grate (10), the activation parameters for the thermolysis of the organocobalamins include a contribution from the base-on/base-off benzimidazole coordination equilibria. A comparison between benzylcobalamins and other related systems where these contributions are absent should be valid only if the benzimidazole coordination equilibria for all benzylcobalamins studied do not vary with the temperature, being cancelled in the calculation of the activation parameters. This was in fact observed by us with the *p*-substituted benzylcobalamins studied in this work. As was the case of benzylcobalamin itself (10), our cobalamins showed very small spectral changes in the temperature range of our experiments, indicating that variations of coordination equilibria with temperature are negligible.

The pronounced entropic change from positive (benzimida-

zole and water as axial ligands) to negative values when cyanide is coordinated to the cobalt(III) atom is, to the best of our knowledge, unprecedented. Following Schrauzer's tentative arguments (10), we may regard such an entropic change as the result of two opposing trends, an entropic gain due to the departure of the benzyl groups, and an entropy loss, when -CN is the axial ligand. Thus, the order imposed on the benzylcobalamin and benzylcobinamide by the benzyl group is lost in the transition state, which should be very nearly cobalt(II) in nature. When CN^- is the axial ligand, the order imposed by axial cyanide coordination is increased in going from the Co(III) to the Co(II) species and more than compensates the entropy gain due to the benzyl group departure. The overall result is then a net entropy decrease of the cyanide coordinated system.

Table 6 lists the rate constants at 25°C for the Co—C bond cleavage reaction of the benzyl and *p*-methylbenzylcobalamins in the presence and absence of cyanide ion, and the dissociation energies of the corresponding Co—C bond, estimated, according to Halpern (12), to be 2.0 kcal mol^{-1} less than the homolysis activation enthalpies. For the sake of comparison we also include the Co—C bond dissociation energies estimated from the thermolysis of the benzyl- and *p*-methylbenzylcobinamide at 25°C. Inspection of this table shows that the homolysis is facilitated by the increasing electron-donating ability of the axial ligand. By reducing the charge of the cobalt atom, the electron-donating axial cyanide weakens the Co—C bond considerably, as compared to the more stable cobalamin and cobinamide systems. This ground-state effect is much more important than an eventual transition state destabilization by the cyanide ligand, which renders more difficult the transition from Co(III) to Co(II) by increasing the electron density around the cobalt atom.

In conclusion, the present work extends Schrauzer's original studies on the homolytic cleavage of benzylcobalamin (10) by varying both the benzyl moiety and the substituent in the fifth coordination position. As anticipated, the homolytic fission is only slightly dependent on the nature of the *para* substituent of the benzyl moiety, but the negative values obtained argue for some small degree of nucleophilic character of the incipient benzyl radical in the transition state. Changing the axial substituent results in considerable changes in the rates of homolytic Co—C cleavage, such rates increasing in the order H_2O < Bzm < CN. It is noteworthy that, in spite of the large changes brought about by the replacement of the 5,6-dimethylbenzimidazole ligand by water or cyanide, the reaction mechanism and the mode of cleavage of the Co—C bond are essentially the same.

It is important to emphasize that, because of the particular steric and electronic labilization of the Co—C bond in benzylcobalamins, any mechanistic extension of our results to other organocobalamins should be made with caution.

Received December 9, 1986

R. H. JUDGE, D. C. MOULE, and J. D. GODDARD. Can. J. Chem. **65**, 2100 (1987).

The 270 nm absorption spectra of thioformamide, $CHSNH_2$ and $CHSND_2$, have been photographically recorded under conditions of long path length (88 m) and moderate resolution (7.5 Å/mm). The absorption was assigned to the electron promotion, $n_S \rightarrow \pi^*$ (CS), and to the electronic transition, $\tilde{A}\,^1A'' \leftarrow \tilde{X}\,^1A'$. The spectra proved to be complex, highly congested and somewhat diffuse which limited the extent of the vibrational assignments. Progressions in five members were observed in both $CHSNH_2/CHSND_2$ in intervals of 516/496 cm^{-1} which were assigned to ν_{10}, the out-of-plane aldehyde wagging mode. It was concluded on Franck–Condon grounds that the $\tilde{A}\,^1A''$ molecule was non-planar at the aldehyde center. Structures and vibrational frequencies were calculated for the $\tilde{X}\,^1A'$ and the $\tilde{a}\,^3A''$ electronic states at the 3-21G* SCF level. The calculations confirmed that the lower state was strictly planar and predicted that both the aldehyde and amino groups were pyramidal in the upper electronic state.

R. H. JUDGE, D. C. MOULE et J. D. GODDARD. Can. J. Chem. **65**, 2100 (1987).

Utilisant des conditions de grandes longueurs de passage (88 m) et de résolutions modérée (7,5 Å/mm), on a procédé à un enregistrement photographique des spectres d'absorption à 270 nm du thiformamide, du $CHSNH_2$ et du $CHSND_2$. On a attribué l'absorption à une promotion électronique $n_S \rightarrow \pi^*$ (CS) et à une transition électronique $\tilde{A}\,^1A'' \leftarrow \tilde{X}\,^1A'$. Il s'avère que le spectre est complexe, qu'il est très congestionné et assez diffus; ceci limite le degré des attributions vibrationnelles. Tant dans le $CHSNH_2$ que dans le $CHSND_2$, on a observé des progressions dans cinq membres, à des intervalles de 516/496 cm^{-1}, que l'on a attribué à la vibration ν_{10}, le mode d'oscillation hors-plan du groupement aldéhyde. En se basant sur la théorie de Franck–Condon, on en conclut que la molécule $\tilde{A}\,^1A''$ n'est pas planaire au niveau du carbone aldéhydique. On a calculé les structures et les fréquences vibrationnelles des états électroniques $\tilde{X}\,^1A'$ et $\tilde{a}\,^3A''$ au niveau de champ auto-cohérent 3-21G*. Les calculs ont permis de confirmer que l'état d'énergie le plus bas est strictement plan et de prédire que le groupement aldéhyde ainsi que le groupement amino sont de nature pyramidale à l'état électronique élevé.

[Traduit par la revue]

Introduction

The electronic spectra which result from excitations within the amide chromophore have been extensively studied (1). A disappointing feature of these spectra is that the band systems lie in the far and vacuum uv regions. Moreover, they are diffuse and thus not amenable to detailed vibronic analyses. When the oxygen is replaced by sulphur, the situation improves considerably. In the case of thioformamide, Tsuboi *et al.* (2) found three absorption systems in the accessible region of the spectrum. The first absorption which they observed at 190 nm was assigned as a $\pi(C{=}S) + n_N \rightarrow \pi^*(C{=}S)$ electron promotion. A second system at 230 nm which contained discrete vibrational fine structure was analyzed in some detail and assigned to n_N-$\pi(C{=}S) \rightarrow \pi^*(C{=}S)$ excitation. The third system at 270 nm was described as weak and very broad and was given the assignment $n_S \rightarrow \pi^*(C{=}S)$. When the thioformamide molecule is considered from the viewpoint that it represents an extension in a series of thiocarbonyl molecules, which begins with the prototype CH_2S, an immediate complication to the electronic configuration is the presence of an a'' electron pair formally on the nitrogen atom. In the simplest of localized orbital pictures, these electrons would be contained in a second nonbonding orbital, in this case, n_N-$\pi(C{=}S)$. The photoelectron spectrum (2) of thioformamide shows that the ease of ionization of the two nonbonding pairs n_S and n_N-$\pi(C{=}S)$ is nearly the same, 8.70 and 9.30 eV, respectively. The lack of extensive Franck–Condon activity associated with the first photoelectron transition shows that n_S is essentially nonbonding. Promotion of an electron from either of the orbitals to the $\pi^*(C{=}S)$ orbital would give rise to two $n \rightarrow \pi^*(C{=}S)$ transitions. The first of these would be the $\tilde{A}\,^1A''$ (n_S, $\pi^*(C{=}S)$) $\leftarrow \tilde{X}\,^1A'$ transition which occurs at 270 nm, the second $\tilde{B}\,^1A'$ (n_N-$\pi(C{=}S)$, $\pi^*(C{=}S)$) $\leftarrow \tilde{X}\,^1A'$ at 230 nm. We decided to make a study of the system at 270 nm since the $n_S \rightarrow \pi^*$ transitions in thiocarbonyl molecules often generate spectra which are vibrationally discrete. As the compound is a solid at room temperature, its vapour pressure is relatively low and long path lengths of the vapour are required. In order to obtain a better understanding of the electronic assignments and particularly as an aid to the assignments of the vibronic intervals, the geometries of the $\tilde{X}\,^1A'$ and $\tilde{a}\,^3A''$ states (Fig. 1) and the vibrational frequencies were evaluated by *ab initio* techniques at the 3-21G* SCF level.

The molecular structure of thioformamide has been fully determined in the lower $\tilde{X}\,^1A'$ state by microwave spectroscopy. From a study of seven isotopic species, Sugisaki *et al.* (3) demonstrated that the thioformamide molecule is planar. Vibrational frequencies for the NCS bending and amino wagging modes were also established from relative intensity measurements of the satellite microwave lines. Infrared measurements

have been made on crystal samples of $CHSNH_2$ and $CHSND_2$ by Susuki (4). The complete assignment of the twelve normal modes of vibration was aided by a normal coordinate analysis in which the Urey–Bradley force constants were transferred from similar molecules.

Experimental methods

Thioformamide was prepared by the method of Willstäter and Werth (9). To 100 g of formamide in an ice–salt bath, 50 g of powdered P_2S_5 was added slowly with vigorous stirring over a 2 h period. At the end of this time, 500 mL of absolute ether was added and the mass stirred for an additional 24 h at room temperature. The ethereal solution was decanted and the sticky residue repeatedly washed with ether. The extracts were combined and the solvent was stripped off under reduced pressure (water aspirator). The thioformamide remained as a red–orange oil.

The raw thioformamide was dissolved in H_2O (thus forming the hydrate) and any suspended sulphur removed by filtration. Ether was added and the hydrated thioformamide salted out by saturating the water layer with $(NH_4)_2SO_4$. Addition of P_2O_5 to the ether solution converted the hydrated thioformamide to free thioformamide, the solution was filtered, concentrated, and then cooled to −25°C. When cold petroleum ether (−25°C) was added, white crystals precipitated from solution. These crystals were filtered, washed with cold solvent, and dried in a vacuum desiccator for 30 min. The yield was 10 g of pure thioformamide, mp 26–27°C. The product was stored at −20°C until required.

A small amount of solid thioformamide was placed in a 2 m glass multiple reflection cell set to 44 traversals. The cell was evacuated and then allowed to reach saturation vapour pressure of the solid at 20°C. Spectra were recorded on Kodak Spectrum Analysis No. 1 film using a 1.5 m Bausch & Lomb Spectrograph with a dispersion of 15Å mm. A 1000 W Xe arc supplied the continuum and lines from a Fe/Ne hollow cathode tube were used for calibration. A Joyce–Lobel microdensitometer was used to obtain the tracings displayed in Fig. 2. Frequencies were obtained from the tenfold enlargements of the photographic films.

The deuterated thioformamide was obtained by the lyophilization of thioformamide in D_2O. The spectrum of $CHSND_2$ was obtained by conditioning the absorption cell with D_2O before introducing the sample of $CHSND_2$.

Computational methods

All computations were performed with the GAUSSIAN82 program system (10). Geometries for the ground and lowest excited triplet electronic states were optimized at the SCF level (UHF for the triplet state) using analytic gradient methods and the 3-21G* basis set (11, 12). Although it is the singlet $n_S \rightarrow \pi^*(C{=}S)$ state which has been observed in the experiments, the calculations focussed on the companion triplet principally due to the computational ease of an UHF approach. The modelling of the structures and vibrational frequencies of a $^1n\pi^*$ state by the $^3n\pi^*$ companion cannot produce results of extraordinarily high accuracy. However, the conclusion that such a model is certainly a very reasonable one is supported by experimentally based comparisons of the $^1n\pi^*$ and $^3n\pi^*$ states of formaldehyde or thioformaldehyde (13). For example, the structural parameters for H_2CO ($^1n\pi^*//^3n\pi^*$) are r(CO) 1.323//1.307, r(CH) 1.098//1.084, ∝(HCH) 118.4°//121.8° and ρ(oop) 34.0°//41.1°. For H_2CS the vibrational frequencies (cm^{-1}) in the $\tilde{A}\,^1A_2$ state in comparison with the $\tilde{a}^3A_2$ state are ($^1n\pi^*//^3n\pi^*$) (13): $\nu_2(a_1)$ 1316//1320, $\nu_3(a_1)$ 861.6//820, and $\nu_6(b_2)$ 799//762.3. Harmonic vibrational frequencies were computed using analytical second derivatives (14*a*) and then scaled by 0.90 (to approximately correct for both the SCF method and anharmonicity (14*b*)) prior to comparisons with experiment. The vertical excitation energies to the lowest $^3A'$ and $^3A''$ states at the ground state geometry as well as the

[a]From ref. 3.

adiabatic energy difference to the nonplanar ^3A state derived from the $^3A''$ one were computed using the 6-31G* basis set (12, 15) and including electron correlation effects by full fourth order Moller–Plesset perturbation theory (MP4SDTQ) (16).

Results and assignments

The equilibrium structure and vibrational frequencies of ground state $CHSNH_2$ and $CHSND_2$ were calculated by *ab initio* methods at the 3-21G* SCF level. Table 1 presents the results of the structural calculations for the $\tilde{X}\,^1A'$ state along with the bond lengths and bond angles derived from microwave analyses (3). The calculated values are strictly r_e quantities where each of the nuclei are at the bottoms of their potential wells while the results of the microwave analyses are r_s substitution quantities (20) and usually $r_e < r_s$. The agreement is satisfactory with the largest difference in a bond length being 0.027 Å for C—N. At this level of computation, thioformamide was found to be strictly planar at the nitrogen centre. The computed total dipole moment is ~25% greater than experiment as is often the case with such calculations (e.g. ref. 17).

Table 2 gives the calculated vibrational frequencies for $CHSNH_2$ and $CHSND_2$ and makes a comparison to the observed crystal phase ir data and the vibrational frequencies derived from microwave intensities (3, 4). When the calculated SCF harmonic vibrational frequencies are scaled by 0.90 to approximately correct for the SCF method and for anharmonicity, the agreement with the observed data is reasonable for the small amplitude vibrations. For 21 comparisons the average absolute deviation is 47 cm^{-1}. As would be expected the torsional frequencies, ν''_{12} = 551 cm^{-1} $CHSNH_2$ or 410 cm^{-1} $CHSND_2$, are too high relative to the observed frequencies (393/293 cm^{-1}) since the torsional functions should be highly anharmonic and not adequately described by the harmonic oscillator approximation.

The weak absorption system observed at 270 nm proved to have a complex vibrational fine structure and could not be assigned without some assistance from theory. Clearly, it would be most desirable to have a knowledge of the $\tilde{A}\,^1A''$ excited state geometry. The vibrational modes active in the spectrum would be those which have coordinates (bond lengths and bond angles) undergoing the greatest changes upon electronic excitation. In order to employ the UHF method, the properties of the companion state $\tilde{a}^3A''$ were calculated rather than those of the $\tilde{A}\,^1A''$ state. These states are expected to be close in energy and should be rather similar in their structure and dynamics. At the geometry of the ground state molecule, restricted open shell SCF calculations indicated that the $^1n\pi^*$–$^3n\pi^*$ splitting was only about 1300 cm^{-1}.

A number of higher level calculations were carried out at the 3-21G* SCF geometries to determine the vertical and adiabatic excitation energies to the lowest triplet state. The best calculations involved the 6-31G* basis set and included electron correlation effects (MP4SDTQ). The vertical excitation energy to the $\tilde{a}^3A''$ state was calculated to be 28183 cm^{-1} and the adiabatic energy gap 23596 cm^{-1}. Thus relaxation of the geometry in the triplet state lowers the energy by 4587 cm^{-1} or 13.1 kcal mol^{-1}.

CNH_2	119.71
HNHoop	11.0
CSoop	33.10
μ_{tot}(D)	2.336 D

Table 3 gives the equilibrium geometry for the upper state and Table 4, the vibrational frequencies. In the $\tilde{a}^3A$ state derived from the lowest $^3A''$ state, thioformamide is predicted to be nonplanar at both the nitrogen and carbon centres. The angle formed between the CHN frame and the CS bond is calculated to be 33.10°. For comparison, the calculated CS out-of-plane angle in triplet HFCS is 35.2° (18). (The structures of $CHSNH_2$ in the two combining states are illustrated in Fig. 1.) In thioformamide, inversion motion in the ν_{10} wag between the two nonplanar equilibrium configurations should be possible. The calculated height of the potential barrier at the 6-31G* MP3 level (with planarity imposed at C but other geometrical parameters relaxed at the 3-21G* SCF level) relative to the equilibrium structure of Table 3 is calculated to be 992 cm^{-1}. On Franck–Condon grounds ν'_{10} should be very active in forming strong progressions in the spectrum. Tables 2 and 4 predict that the frequency of this mode should drop from 1001 to 599 cm^{-1} upon electronic excitation of $CHSNH_2$. In $CHSND_2$, the decrease is from 988 to 596 cm^{-1}. The dynamics of the nitrogen centre are also of interest. Upon excitation, the two low-lying out-of-plane vibrational modes described as nitrogen wagging, ν''_{11} = 725 cm^{-1}, and NH_2 torsion, ν''_{12} = 551 cm^{-1} decrease to ν'_{11} = 280 cm^{-1} and ν'_{12} = 257 cm^{-1}. These changes could be the result of a broadening and flattening of these potentials in the upper state perhaps to the extent that they can no longer be described well in the harmonic approximation. Both ν'_{11} and ν'_{12} would be better treated as coupled large amplitude motions and would be expected to be active. The other significant structural change is the elongation of the CS bond. The calculation indicates that the CS bond in the excited triplet state is longer than that in the ground state by 0.139 Å. The magnitude of this lengthening is probably somewhat overestimated (19). However, the thiocarbonyl stretch, ν'_8, also should be active in the spectrum.

Microdensitometer traces of the many banded spectra of $CHSNH_2$ and $CHSND_2$ are given in Fig. 1. The observed bandheads are collected together in Table 5. It is clear that the spectra are highly congested and that the $CHSNH_2$ traces are more complex than those of $CHSND_2$. For this reason we turn first to the $CHSND_2$ spectra. The foregoing theoretical discussion indicates that the major change in structure occurs at the thiocarbonyl end of the molecule where the thiocarbonyl bond is distorted by 33.1° from the molecular plane. This is accompanied by a reduction in frequency of ν'_{10} from 988 to 596 cm^{-1}. The most prominent feature in the spectrum should be a progression in a frequency of about 600 cm^{-1}. This is precisely what is observed in the $CHSND_2$ spectra: namely, a progression of bands which form intervals of 496, 497, 490, and 496 cm^{-1}. These bands can immediately be assigned to the activity of the out-of-plane sulphur wagging mode. The assignment of the lower vibrational quantum number $v'' = 0$ follows from the large value of ν''_{10} (hot bands in this mode can be excluded.) The assignment for the numbering of ν' is more difficult. At this time only a provisional assignment is possible and this comes from the value of the origin isotope shift calculated from the theoretical vibrational frequencies (of the triplet) and from a comparison of the spectra of the two isotopes.

	36398		

A set of bands in the spectrum of the other isotope, $CHSNH_2$, can be grouped into a progression in intervals of 516, 518, 514, and 503 cm^{-1}. These bands show a small but uniformly decreasing shift of 41, 19, 2.1, and -10.3 cm^{-1} with respect to the bands of the major progression in $CHSND_2$. The calculated origin isotope effect from Tables 2 and 4 is 69.5 cm^{-1} which places the X_0^1 suborigin one further quantum of ν'_{10} to lower energies. In $CHSNH_2$ this band is clearly observed at 34222 cm^{-1}. The assignments given to the two main progressions are shown in Table 5. The remaining bands in the two spectra are more difficult to assign. Part of the reason for this is that the band patterns in $CHSNH_2$ and $CHSND_2$ are so different that vibrational correlations cannot be easily made. As the effect of deuterating at the nitrogen end of the molecule grossly changes the vibrational fine structure it follows that the ν_{11} and ν_{12} wagging and torsional modes must be active in the spectrum. On Franck–Condon grounds this would be a consequence of a non-planar distortion of thioformamide at the nitrogen centre. Indeed, the calculations show that while the ground state is strictly planar, the nitrogen is pyramidal in the $\tilde{a}$ state. The angle between the plane defined by the CSN and the line bisecting the HNH angle is calculated to be 11.0°. The calculated vibrational frequencies also demonstrate that a distortion occurs at the nitrogen centre. For example, $\nu'_{12}/\nu''_{12} =$ 551/257 cm^{-1} is calculated for $CHSNH_2$ and 410/195 cm^{-1} for $CHSND_2$. Since the excited state potential for this mode undoubtedly contains a double minimum it follows that the harmonic approximation used in the calculations is not particularly reliable. For this reason the complex structure which was attributed to out-of-plane wagging or torsion was not assigned.

The underlying continuum absorption results from several factors. The output of the Xe arc source decreases rapidly with decreasing wavelength as does the response of the film. In addition, the calculations suggest that the gross structural changes lead to long Franck–Condon induced progressions. Such progressions are expected to be complex and highly conjested and could create a quickly rising background continuum.

Discussion

Three absorption systems are observed in the vapour phase spectra of $CHSNH_2/CHSND_2$: a weak system at 270 nm, a moderately intense and structured system at 230 nm and a very strong continuum at 190 nm. Tsuboi *et al.* (2) assigned these spectra, respectively to the electronic promotions $n_S \rightarrow \pi^*$ (CS), $n_N \rightarrow \pi^*$ (CS), and π (CS) $\rightarrow \pi^*$ (CS). Their analyses of the vibrational structure which is contained in the 230 nm system are consistent with the assignment $n_N \rightarrow \pi^*$ (CS). This system is found to have a strong O_0^0 origin band, and only moderate activity in the in-plane stretching and bending modes. In particular, the spectrum does not display bands which can be attributed to conformational distortion. That is, the symmetry of the $\tilde{B}\,^1A'$ state is that of the $\tilde{X}\,^1A'$ ground state and the molecule is strictly planar in both equilibrium configurations. This is to be expected for a transition which involves the removal of an electron from the n_N (a'') orbital and its insertion into a π^* (a'') orbital. The electron configuration for the excited state could be described as $H_2N^+CHS^-$. The positive charge stabilizes the nitrogen center in the planar form.

Experimental difficulties prevented us from obtaining a definitive assignment of the vibrational fine structure in the $n_S \rightarrow \pi^*$ (CS) system. The major problem was a lack of (pressure × path length) and as a consequence the weak bands at longer wavelengths were poorly defined. This is partly because the sample is unstable in the vapour phase. Moreover, $CHSNH_2$ is a solid at room temperature and must be observed at its sublimation vapour pressure. The other difficulty is the spectrum. While the transition is allowed by electric dipole selection rules (out-of-plane polarized), it is forbidden by the local symmetry of the molecule. The excitation process may be considered to be a rotational displacement of the electron from the n_S to the π^* (CS) orbital rather than a translation. While this gives the transition a high magnetic dipole strength, the electric dipole strength is low. The other factor which complicates the analysis is that the origin is expected to be weak. This is a consequence of the formation of long progressions in the out-of-plane vibrational modes. Indeed, the bands which lie in the region of the vertical transition could be several orders of magnitude stronger than the 0_0^0 origin band. The 6-31G* MP4SDTQ calculations predict that the electronic origin in the $\tilde{a}^3A$ state is some 4587 cm^{-1} below the position of the vertical transition.

The bands in the thioformamide–H_2 spectra can be grouped into intervals of 516 cm^{-1} which drop to 496 cm^{-1} in the D_2 compound. The assignment to ν'_{10}, the hydrogen out-of-plane wagging mode follows from the calculated values for the two species 599/596. Activity in an out-of-plane wagging mode is only possible if the CHS group in the upper state is nonplanar. As a consequence, the potential function governing out-of-plane motion would contain double minima. Quanta of ν_{10} would be arranged into a state of +, − inversion doublet levels which are degenerate for energies well below the top of the barrier. As the intervals in $CHSNH_2$ are grouped into a progression of 516, 518, 514, 503 cm^{-1} which does not display any gross effects of inversion doubling, it follows that the height of the barrier governing aldehyde wagging is large. A high barrier height is not unexpected. In the series of molecules (5–8) $CHOCl/CHOF/CCl_2O$ and CF_2O the barrier heights to molecular inversion are 1609/2550/3170/8200 cm^{-1}, respectively. The variation in the barrier heights has been attributed to the inductive effect of the attached halogen atom. The NH_2 group is electronegative and would pull electron density onto the carbon atom, thereby destabilizing the planar form of the $\tilde{A}\,^1A''$ molecule.

Detailed experimental information about the dynamics and structure of the NH_2 group was limited by the diffuse and congested nature of the spectrum. Both the microwave and the *ab initio* calculations demonstrate that the $\tilde{X}\,A'$ ground state is rigidly planar. The calculated values of the ν_{11} and ν_{12} NH_2 wagging and torsional frequencies are 725 and 551 cm^{-1}. In the excited state $\tilde{A}\,^1A''$ state, the hydrogen atoms are predicted to be distorted from the plane of the molecule by 11°. As a result, the ν_{11} hydrogen wagging mode would be a molecular inversion. The barrier height for NH_2 inversion (6-31G* MP3), other variables relaxed at the 3-21G* SCF level, is calculated to be 792 cm^{-1}. That the spectra of $CHSNH_2$ and $CHSND_2$ are very different is an indication that NH_2 wagging and torsion are active in the spectrum. The calculated values for these modes are 280 and 257 cm^{-1} respectively.

Effets de solvant sur les complexes par transfert de charge iode – composés thiocarbonylés

GEORGES GUIHENEUF,[1] JOSÉ-LUIS M. ABBOUD[2] ET WIDDED BOUAB
Laboratoire de chimie physique organique, Université Cadi Ayyad, BP S 15, Marrakech, Maroc

Reçu le 25 août 1986[3]

GEORGES GUIHENEUF, JOSÉ-LUIS M. ABBOUD et WIDDED BOUAB. Can. J. Chem. **65**, 2106 (1987).

Les effets de solvant sur divers complexes par transfert de charge iode – bases thiocarbonylées de stabilité variable ont été déterminés et sont comparés aux effets de solvant sur les complexes iode – composés carbonylés. L'inversion de l'effet des solvants donneurs de liaison hydrogène en passant d'une série à l'autre résulte du caractère dur des bases carbonylées et mou des bases thiocarbonylées.

GEORGES GUIHENEUF, JOSÉ-LUIS M. ABBOUD, and WIDDED BOUAB. Can. J. Chem. **65**, 2106 (1987).

The effects of solvents on different iodine – thiocarbonyl base charge-transfer complexes of variable stability have been examined and these are compared with the effects of solvents of the iodine – carbonyl compound complexes. There is an inversion of the effect of those solvents that can form hydrogen bonds on going from one series to the other, which is attributed to the fact that the carbonyl compounds are hard bases while the thiocarbonyl compounds are soft bases.

[Journal translation]

Introduction

Parmi les multiples facteurs qui gouvernent la stabilité des complexes par transfert de charge, le milieu : phase gazeuse ou solution exerce une influence déterminante (1). La nature du solvant, elle-même, modifie notablement les constantes de complexation. En général, ces valeurs diminuent lorsque la polarité du solvant augmente; c'est le cas, par exemple, pour les complexes entre un donneur d'électron et un accepteur π (2). Lorsque l'accepteur d'électron est la molécule d'iode, un changement de solvant peut, selon le donneur considéré, conduire aussi bien à un accroissement (3–7) qu'à une diminution (8–11) des constantes K_c de complexation. Ainsi pour le complexe entre l'iode et la *N,N* diméthylacétamide, K_c diminue de 15 $dm^3\ mol^{-1}$ (12) lorsque le solvant est l'heptane, à 1,4 $dm^3\ mol^{-1}$ avec le dichlorométhane (8). Au contraire, si l'on considère la complexation de l'iode avec la tétraméthylthiourée, la constante subit une forte augmentation de 13 000 $dm^3\ mol^{-1}$ dans l'heptane (3) à 49 000 $dm^3\ mol^{-1}$ dans CH_2Cl_2 (3).

Pour expliquer ces divergences dans les variations de K_c avec le solvant, Augdahl et coll. (3) ont émis l'hypothèse que le sens de l'effet de solvant dépend du pourcentage de transfert de charge dans l'état fondamental et donc de la grandeur de la constante de formation du complexe. Si le transfert de charge est faible (*N,N* diméthylacétamide par exemple) la constante décroît lorsque la polarité du solvant augmente (11). À l'inverse, si le complexe correspond à un transfert de charge élevé (tétraméthylthiourée) un solvant polaire stabilise le complexe et entraîne une forte augmentation de la constante d'équilibre. Le sens de variation de K_c avec la polarité du solvant dépendrait donc uniquement de la stabilité du complexe et par conséquence, pour un accepteur donné, de la basicité du donneur d'électron. Il est possible de tester la validité de ce modèle en étudiant l'effet des solvants sur les complexes de l'iode avec des composés thiocarbonylés dont la basicité est voisine de celle de la diméthylacétamide. Si l'hypothèse d'Augdahl et coll. est justifiée, on doit alors observer le même sens d'effet de solvant pour les bases carbonylées et thiocarbonylées.

o-$C_6H_4Cl_2$	9,93	31 ± 2	—
CH_2ClCH_2Cl	10,36	29 ± 1	474 ± 50

[a]En $dm^3\ mol^{-1}$, à 25°C, la reproductibilité correspond à un degré de confiance de 95%.

Résultats

Deux bases thiocarbonylées ont été retenues : le thiocamphre et le dithioester $C_4H_9CSSCH_3$. Les constantes de complexation du tableau 1 ont été calculées à partir des absorbances des bandes de l'iode libre et complexé qui se trouvent entre 400 et 520 nm. Les deux bases absorbent également dans ce domaine de longueur d'onde; une correction a été effectuée pour chaque solution. La méthode de calcul est celle de Rose et Drago ou une méthode dérivée (13).

Nous avons vérifié qu'il n'y avait pas précipitation du complexe dans les solvants apolaires et que les spectres n'évoluaient pas pendant la durée de l'expérience. Nous nous sommes également assurés de l'absence des ions I_3^- qui apparaissent fréquemment dans les milieux polaires et entraînent des erreurs importantes sur les valeurs des constantes.

Discussion

Parmi les solvants, aucun ne possède un caractère basique suffisant pour entrer en compétition avec les bases thiocarbonylées. La présence d'un ou deux atomes de chlore sur le noyau abaisse sensiblement la basicité du cycle aromatique du chloro ou de l'*ortho*-dichlorobenzène. Les constantes mesurées dans ces deux solvants ne révèlent pas une présence significative de complexe iode–solvant analogue au complexe iode–benzène (8).

Avec les bases thiocarbonylées étudiées nous constatons, comme pour les thioamides et les thiourées, une augmentation des valeurs de K_c avec la polarité du solvant, caractérisée par sa

constante diélectrique. Nous pouvons donc immédiatement en conclure que le modèle d'Augdahl et coll. n'est pas satisfaisant : «*le sens de l'effet de solvant, diminution ou augmentation de la constante de complexation, n'est pas lié uniquement au pourcentage de transfert de charge dans l'état fondamental et à la grandeur de la constante d'équilibre*». Il apparaît au contraire comme une propriété qui dépend de la nature chimique du site donneur d'électron. Pour tous les donneurs d'électrons thiocarbonylés le sens de l'effet de solvant est identique, quel que soit la valeur de la constante d'association avec l'iode. Il faut donc rechercher ailleurs les raisons de l'inversion des effets de solvant entre les bases carbonylées et thiocarbonylées.

Il est indispensable, auparavant, de préciser la notion, souvent ambigüe, de polarité des solvants. Nous distinguerons les effets liés réellement à la polarité–polarisabilité de ceux qui dépendent des interactions spécifiques (14). Ces interactions, par liaison hydrogène ou transfert de charge, sont fonction de la basicité (ou de l'acidité) du solvant d'une part, de l'acidité (ou de la basicité) de l'accepteur et du donneur d'électron, d'autre part. Or les basicités relatives d'une série de donneurs d'électron dépendent de l'acide choisi comme référence; il est impossible de caractériser la basicité par un paramètre unique qui établirait une échelle intrinsèque des basicités (15, 16). Pour pallier cette difficulté, Pearson a proposé de distinguer entre acidité et basicité dures et molles (17). Ce modèle permet de prévoir les interactions privilégiées entre acides et bases possédant des caractères durs ou mous semblables. Nous avons pu expliquer, de cette façon, que les constantes d'association de l'iode (acide mou) avec les bases thiocarbonylées (bases molles) sont beaucoup plus grandes que les constantes d'association avec les bases carbonylées (bases plus dures) (18). L'inverse est observé avec les donneurs de liaison hydrogène (acides relativement durs) : par exemple, à 20°C, dans CCl_4, la constante d'association du phénol avec la diméthylacétamide est de 152 $dm^3\ mol^{-1}$ alors qu'elle n'est que de 12 $dm^3\ mol^{-1}$ avec la diméthylthioacétamide (19).

Jusqu'à présent, ces paramètres de dureté, ou de mollesse, n'ont pas été pris en considération lors de la comparaison des effets des solvants étudiés bien que ceux-ci soient donneurs de liaison hydrogène (CH_2Cl_2, $CHCl_3$) ou accepteur d'électron (CCl_4) (20). Compte tenu des observations précédentes nous prévoyons, dans le cadre de ce modèle, que les interactions par liaison hydrogène de CH_2Cl_2 et $CHCl_3$ sont privilégiées avec les bases les plus dures, c'est-à-dire les composés carbonylés. Elles sont, en revanche, faibles avec les bases thiocarbonylées. En conséquence, la composante prédominante de l'effet de CH_2Cl_2 ou $CHCl_3$ sur la stabilité des complexes iode – bases carbonylées est l'interaction par liaison hydrogène du solvant avec la base. Il en résulte, par rapport à l'heptane, une diminution de la constante de complexation avec l'iode. Au contraire, dans le cas des bases thiocarbonylées, l'incidence des liaisons hydrogène est négligeable; ce sont les effets de polarité–polarisabilité qui vont déterminer le sens de variation de la constante. Or le complexe avec l'iode possède, en raison du transfert de charge, un moment dipolaire plus important que celui du donneur libre ce qui conduit, puisque la polarité du solvant s'accroît de l'heptane à CH_2Cl_2 ou $CHCl_3$, à un terme énergétique favorable qui stabilise le complexe et augmente la constante. L'inversion du sens des effets de solvant est donc une conséquence de la dualité du caractère basique, mou et dur, des donneurs d'électron.

Plusieurs résultats confirment cette interprétation et la validité du modèle :

(*i*) Le chloroforme est un donneur de liaison hydrogène plus fort que le dichlorométhane, l'abaissement de la constante d'association iode – base carbonylée doit être plus importante avec le chloroforme. Conformément à cette précision, la constante de formation du complexe iode–diméthylacétamide est de 1,4 $dm^3\ mol^{-1}$ dans le dichlorométhane (8) et seulement de 0,6 $dm^3\ mol^{-1}$ dans le chloroforme (tableau 2).

(*ii*) CH_2Cl_2 ($\varepsilon = 8{,}93$) est plus polaire que $CHCl_3$ ($\varepsilon = 4{,}8$); la stabilisation des complexes iode–diméthylthioacétamide et iode–thiocamphre doit donc être plus forte dans CH_2Cl_2. Les valeurs expérimentales vérifient cet ordre : les constantes sont plus élevées dans CH_2Cl_2 que dans $CHCl_3$.

(*iii*) Les abaissements des constantes en passant de l'heptane au tétrachlorure de carbone sont importants avec les bases carbonylées; dans le cas des bases thiocarbonylées, les valeurs diffèrent peut entre les deux solvants. Ici encore, les résultats corroborent pleinement le modèle proposé. Le chlore, atome accepteur du CCl_4, est un site relativement dur, les complexes carbonyle–CCl_4 sont donc plus stables que les complexes thiocarbonyle–CCl_4. La compétition entre les deux complexes base–I_2 et base–CCl_4 est plus marquée dans le cas des bases carbonylées d'où les variations plus importantes qu'avec les bases thiocarbonylées.

(*iv*) Avec les solvants non donneurs de liaison hydrogène (CH_3CCl_3, ClC_6H_5, o-$Cl_2C_6H_4$, ...) les interactions polaires sont seules présentes, quel que soit la base. Elles conduisent à des augmentations des constantes de formation avec la polarité du milieu, indépendantes de la stabilité des complexes iode–thiocarbonyles.

Dans le cadre de ce modèle des effets de solvant et en se limitant aux solvants non donneurs de liaison hydrogène, nous attendons également une augmentation des constantes de complexation de l'iode avec la diméthylacétamide et la diméthylformamide lorsque la polarité du solvant s'accroît. Nous avons, pour ces deux amides, élargi la gamme de polarité

For personal use only.

des solvants aux chloro et *ortho*-dichlorobenzène (tableau 2). Nous observons effectivement un accroissement régulier des valeurs K_c en passant de CCl_4 à ClC_6H_5 et o-$Cl_2C_6H_4$. Cependant, même dans ce dernier solvant, la valeur K_c est inférieure à celle de l'heptane. Il faudrait, pour retrouver une valeur identique, accroître encore la polarité du solvant, ce qui est difficile à réaliser expérimentalement : les ions I_3^- se forment alors très rapidement et interdisent une détermination significative de la constante. Lors de la formation du complexe, une molécule d'iode se substitue à une molécule de solvant dans la couche de solvatation, ce qui introduit sur le plan énergétique un terme de déstabilisation du complexe. Pour avoir une augmentation de la constante, il faut que la stabilisation due à l'interaction dipolaire du solvant avec le complexe compense le terme défavorable. Le pourcentage de transfert de charge peut alors intervenir; il doit être suffisant pour que l'interaction supplémentaire complexe–solvant l'emporte sur l'effet résultant de l'approche de l'iode. Ces deux facteurs antagonistes peuvent expliquer les variations observées dans le cas des bases carbonylées : diminution puis augmentation des constantes lorsque la polarité des solvants s'accroît. En l'absence de modèle autorisant une évaluation quantitative des diverses contributions nous devons nous limiter à l'interprétation qualitative fondée sur la dualité des caractères acides et basiques.

Nous retiendrons que les solvants polaires non donneurs de liaison hydrogène (*o*-dichlorobenzène, par exemple) stabilisent, en règle générale, les complexes par transfert de charge avec l'iode. Les solvants polaires donneurs de liaison hydrogène ($CHCl_3$), qui sont des acides durs au sens de Pearson, stabilisent également les complexes par transfert de charge de l'iode avec les bases molles (thiocarbonylées) car ils interviennent quasi exclusivement par leurs effets non spécifiques de polarité. En revanche, ces solvants déstabilisent les complexes de iode avec les bases dures (carbonylées) puisqu'ils entrent en compétition avec l'iode pour se complexer avec la base.

Partie expérimentale

Les mesures d'absorbance ont été réalisées sur un spectromètre Cary 219 équipé de cellules quartz de 1 cm. La température était maintenue constante, à 25°C, par une circulation d'eau à partir d'un cryostat Lauda K2R.

Le thiocamphre, préparé par action de P_4S_{10} sur le camphre (22) a été recristallisé dans un mélange eau–alcool puis chromatographié sur colonne de gel de silice (éluant : hexane). Il a ensuite été séché sous vide sur P_2O_5. Le dithioester $C_4H_9CSSCH_3$, obtenu par la méthode de Meijer *et al.* (23), a été purifié par distillations répétées.

Tous les solvants ont été purifiés avant usage (24) et séchés sur tamis moléculaires 4 Å.

Nous avons étudié l'influence de l'ion F^- sur la dissolution anodique du cuivre dans des solutions aqueuses acides (pH 1,6–6), principalement à pH 5, en présence de KF 0,1 *M*. La nature des changements se produisant sur l'électrode durant l'oxydation a été mise en évidence par la voltampérométrie cyclique ainsi que par différentes techniques d'analyse de surface (SEM, XPS, AES). Afin d'établir le mécanisme d'oxydation électrochimique du cuivre à pH 5, des études avec l'électrode tournante à disque ont été menées dans des conditions où la dissolution du cuivre est généralisée. Aux pH 1,6–6, l'électrode de cuivre se dissout uniformément i.e. sans qu'il y ait de zones préférentielles sur la surface lorsqu'elle subit une polarisation potentiodynamique (10 mV s^{-1}) à des potentiels supérieurs à 0 V_{ECS}. À pH faiblement acide (pH 5, KF 0,1 *M*), lorsque le balayage du potentiel va jusqu'à +0,5 V, l'oxydation du cuivre débute par la corrosion généralisée de l'électrode suivi de la formation d'un film de Cu_2O non passivant; au fur et à mesure que le temps d'oxydation augmente, le courant diminue et l'électrode devient passivée. Un modèle de dissolution anodique est présenté pour les résultats obtenus à pH 5. Lorsqu'il y a corrosion uniforme de l'électrode tournante, le cuivre s'oxyde en ions Cu^{2+}. Lorsque $\omega \rightarrow 0$, la vitesse de dissolution de l'électrode est limitée par la diffusion de l'ion Cu^{2+} de l'électrode vers le coeur de la solution alors que lorsque $\omega \rightarrow \infty$, le processus de transfert de charge limite la cinétique de la dissolution.

E. POTVIN, M. DROGOWSKA, H. MÉNARD, and L. BROSSARD. Can. J. Chem. **65**, 2109 (1987).

The influence of F^- ions on the anodic dissolution of copper in aqueous acidic solutions (pH 1.6–6), mainly at pH 5 with 0.1 *M* KF, has been studied. The nature of the changes that occur on the electrode during the oxidation has been examined by cyclic voltamperometry as well as by different techniques of surface analysis (SEM, XPS, AES). To determine the mechanism of the electrochemical oxidation of copper at pH 5, studies with rotating disk electrodes have been carried out under conditions giving rise to a general dissolution of copper. At pH 1.6–6, the copper electrode dissolves uniformly, i.e., without preferential zones on the surface, when it is submitted to a potentiodynamic polarization (10 mV s^{-1}) at potentials above 0 V_{ECS}. At slightly acidic pH (pH 5, KF 0.1 *M*), with a sweep of potential up to +0.5 V, the oxidation of copper begins with a generalized corrosion of the electrode and it is followed by the formation of a film of Cu_2O that is not passivating; as the oxidation proceeds, the current drops and the electrode becomes passivated. One model for the anodic dissolution is presented for the results obtained at pH 5. When a uniform corrosion develops on the rotating electrode, the copper is oxidized to Cu^{2+} ions. When $\omega \rightarrow 0$, the rate of dissolution of the electrode is limited by the diffusion of the Cu^{2+} ions from the electrode to the solution, whereas when $\omega \rightarrow \infty$ the process of charge transfer is the limiting factor to the kinetics of the dissolution.

[Journal translation]

Introduction

Les travaux rapportés dans la littérature concernant la dissolution anodique du cuivre en solution aqueuse acide ont surtout été réalisés en présence des anions Cl^- (1–7) et SO_4^{2-} (8–16). Ces études ont démontré l'influence déterminante de l'anion en solution ainsi que la rôle clé joué par les complexes du cuivre dans les procédés d'oxydation de ce métal.

En ce qui concerne les ions fluorures, l'oxydation électrochimique du cuivre a été étudiée dans le HF anhydre (17). L'oxydation se produit en deux étapes soient la dissolution du cuivre en ion Cu^{2+} et la précipitation du CuF_2 sur l'électrode. À notre connaissance, la dissolution anodique du cuivre dans des solutions aqueuses légèrement acides contenant des ions F^- n'a pas été abordée dans la littérature.

De façon plus générale, la forme stable du cuivre dissous dans des solutions non complexantes comme les sulfates, les nitrates et les perchlorates est le Cu(II) alors que les espèces du Cu(I) sont stables dans des solutions complexantes comme les Cl^-, Br^-, I^- et l'ammoniaque (18). La dismutation de l'espèce Cu^+ est largement favorisée lorsque l'ion n'est pas stabilisé par la formation d'un complexe.

L'ion fluorure est peu complexant pour le cuivre. À la différence des autres halogénures, la thermodynamique prévoit que les composés et complexes du fluor avec le cuivre bivalent seront favorisés par rapport à ceux du cuivre monovalent (19–22).

Au cours de ce travail, nous avons étudié le comportement anodique du cuivre en solutions aqueuses acides (pH 1,6–6) en présence de KF 0,1 *M*, principalement à pH 5. La nature des changements se produisant sur l'électrode durant l'oxydation a été mise en évidence par la voltampérométrie cyclique, ainsi que par différentes méthodes d'analyse de surface (SEM, XPS et AES). Des essais avec l'électrode tournante à disque ont été menés à pH 5 dans des conditions où la dissolution du cuivre est généralisée afin d'établir le mécanisme d'oxydation électrochimique du cuivre.

Partie expérimentale

Une cellule électrochimique conventionnelle de verre, à trois compartiments, a été utilisée pour les pH 5 et 6 et une cellule de matériaux inertes au HF, à deux compartiments, pour les pH allant de 1,6 à 5.

L'électrode de travail est constituée d'un cylindre de cuivre (diamètre ~ 0,56 cm) coupé à partir d'une tige de cuivre polycristallin (Alpha-Ventron Corporation 99,99%) et scellé dans un tube de verre avec de la colle époxy ou dans une gaine de Kel F (pour l'électrode tournante). De cette manière une surface circulaire en position horizontale (~0,25 cm^2) est en contact avec la solution. La surface de l'électrode de cuivre a été polie mécaniquement sur une polisseuse

Leco avec une suspension de particules d'alumine de 5 à 0,3 μm puis nettoyée abondamment avec de l'eau triplement distillée.

Avant chaque essai, l'électrode est plongée en solution à un potentiel de −0,4 V pour réduire les oxydes se trouvant sur la surface; lorsque le courant atteint −0,4 μA cm^{-2}, l'électrode est jugée prête pour l'essai proprement dit.

L'électrode de référence est l'électrode au calomel saturé Hg/HgCl/KCl (sat) (E = 0,24 V_{ESH}); elle est séparée du compartiment principal par un pont qui est relié à un capillaire de Luggin. Aux pH inférieurs à 5, l'électrode de référence a été séparée du compartiment principal par un capillaire de Lugin de matériau inerte au HF. Les potentiels sont indiqués par rapport à cette électrode. L'électrode auxiliaire est une tige de carbone ou une grille de platine placée dans un 2e compartiment.

Pour les analyses de surface, les échantillons de cuivre ont été lavés après l'essai avec de l'eau tridistillée et du méthanol distillé puis scellés dans un tube de verre sous atmosphère d'azote pour être analysés. La pression résiduelle durant les analyses était de 5 × 10^{-8} Torr (1 Torr = 133,3 Pa). Les analyses par XPS ont été faites avec une source de Mg Kα de 480 W de puissance. Un canon à électrons de 10 kV a servi aux analyses par AES; le courant était de 4 nA.

Les solutions acides ont été préparées par un mélange de KF et de HF. Avant chaque essai, la solution a été désaérée par un barbottage d'azote. Les expériences ont été menées à 25°C.

Les essais en balayage linéaire de la tension ont été réalisés avec un potentiostat PAR modèle 173, contrôlé par un programmeur universel PAR modèle 175. Les charges ont été mesurées avec un coulomètre intégré PAR modèle 179 et le courant avec un ampèremètre Keithley modèle 177.

Résultats et discussion

La figure 1 montre un voltampérogramme réalisé dans une solution de HF 1 M (pH = 1,6) à une vitesse de balayage en tension de 10 mV s^{-1}. Le courant d'oxydation du cuivre est négligeable de −0,8 V jusqu'à ~0 V où la dissolution généralisée du cuivre est observée. En balayage inversé, le processus de réduction commence à un potentiel de ~0 V et un pic cathodique est formé. La charge anodique, Q_{ox} (~300 mC cm^{-2}), est beaucoup plus grande que la charge cathodique, Q_{red} (~20 mC cm^{-2}), ce qui est compatible avec la dissolution du cuivre en solution. Au cours de l'oxydation, la surface de l'électrode passe d'un éclat brillant à mat. La microscopie optique a révélé que ce changement est dû à une augmentation de la rugosité de la surface.

Un essai dans une solution de KF 0,1 M additionnée de HF (pH = 5), à une vitesse de balayage de 10 mV s^{-1}, est effectué sur une échelle de potentiel allant du dégagement de H_2 (~ −1,8 V) jusqu'à +2,8 V sans qu'il y ait formation apparente de O_2 (fig. 2). Le courant d'oxydation est négligeable jusqu'à ~0 V puis la dissolution généralisée commence. Au cours du balayage anodique, on voit apparaître un film sur l'électrode sans constater une baisse significative du courant d'oxydation. On observe la présence de deux zones de réduction distinctes; la première débute à ~ −0,1 V et la seconde à ~ −0,9 V.

Lorsque l'électrode est polarisée jusqu'à +0,5 V dans les mêmes conditions (fig. 3, ligne pleine), on voit à l'oeil nu qu'un film anodique se forme et un pic de réduction est présent; il débute autour de −0,8 V.

Dans une solution de KF 0,1 M (pH = 5) tamponnée avec le phtalate de potassium (P.P.) (fig. 3, ligne pointillée), un pic anodique est présent autour de +0,2 V; au-delà de ce potentiel, la dissolution généralisée de l'électrode a lieu. Aucun produit visible à l'oeil nu n'est observé sur le cuivre et l'électrode qui avait initialement un éclat métallique est devenue terne. Aucun pic cathodique n'est présent en balayage de retour avant le dégagement d'hydrogène. Ces courbes montrent une différence significative du comportement de l'anode de cuivre en solution

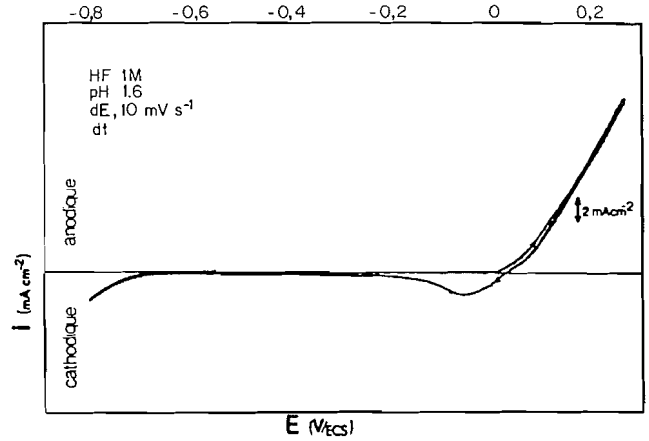

FIG. 1. Voltampérogramme dans une solution de HF 1 M, pH 1,6. dE/dt = 10 mV s^{-1}.

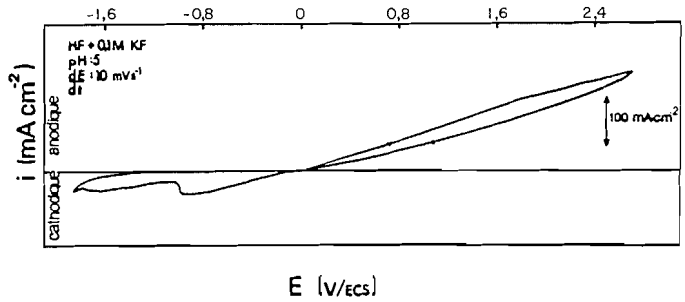

FIG. 2. Voltampérogramme dans une solution de KF 0,1 M à pH 5. dE/dt = 10 mV s^{-1}.

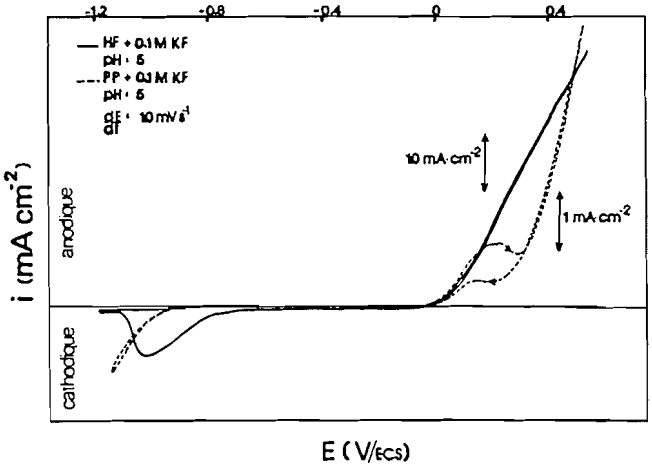

FIG. 3. Voltampérogrammes à pH 5, dans une solution de KF 0,1 M (—) et dans une solution de KF 0,1 M additionnée du tampon phtalate de potassium (---).

fluorurée selon qu'il y ait ou non du phtalate de potassium dissous. Il est en effet admis que le pouvoir complexant de l'ion phtalate par rapport au cuivre est supérieur à celui de l'ion fluorure (22). Pour cette raison, les analyses ont été effectuées dans des solutions de KF 0,1 M titrées avec HF aux pH désirés.

Dans une solution de KF 0,1 M (pH = 5), l'électrode a subi un balayage en tension de −0,8 à +0,5 V à une vitesse de 10 mV s^{-1}, suivi d'un arrêt du potentiel à +0,5 V durant plusieurs minutes. L'électrode de cuivre se recouvre peu à peu d'un film. En prolongeant l'oxydation au-delà d'une heure, la

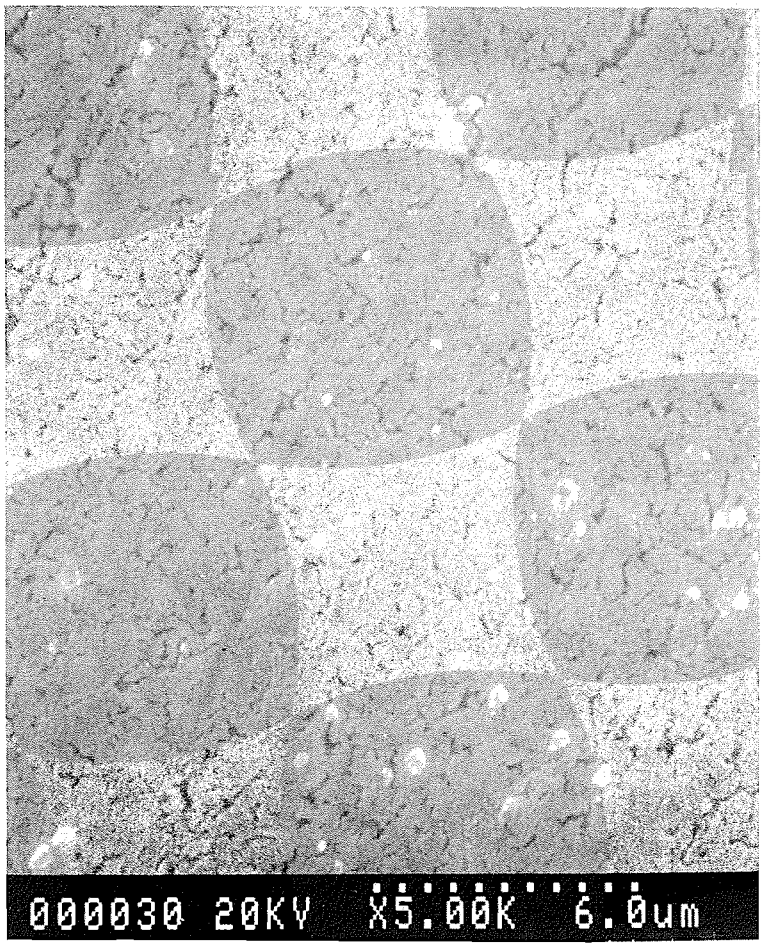

FIG. 4. Photographie par microscopie électronique à balayage du film anodique formé sur l'électrode de cuivre dans une solution de KF 0,1 *M* à pH 5. $dE/dt = 10\,mV\,s^{-1}$. Balayage de −800 à +580 mV; arrêt à +580 mV, 10 min.

surface est entièrement recouverte et la vitesse de dissolution du cuivre devient considérablement réduite.

La microscopie électronique à balayage (SEM) a été utilisée pour étudier la morphologie du film anodique généré sur une électrode qui a subi un balayage (10 mV s^{-1}) de −800 à +580 mV, avec un arrêt à ce dernier potentiel durant 10 min, dans une solution de KF 0,1 *M* à pH 5. Le film est poreux et il est composé d'un produit qui conduit mal le courant (fig. 4). Une analyse en spectroscopie des photoélectrons X (XPS) et en spectroscopie des électrons Auger (AES) a révélé que le film se compose de Cu_2O mais ne contient pas le composé fluoruré qui peut exister dans ces conditions à pH 5, i.e. le $3CuF_2 \cdot Cu(OH)_2$ (23).

Afin d'établir le mécanisme d'oxydation électrochimique du cuivre à pH 5, des études avec l'électrode tournante à disque ont été menées dans des conditions où la dissolution du cuivre est généralisée.

L'électrode est plongée dans une solution de KF (a_{F^-} = 0,074) ayant un pH de 5, avec un potentiel imposé de −0,4 V. Le courant est lu pour chaque vitesse de rotation allant de 81 à 4 rotations par seconde (rps). Une plage de potentiel de −0,05 à +0,05 V est couverte en effectuant des sauts de potentiel de +0,01 V. Les courbes i vs. $\omega^{1/2}$ (ω, vitesse de rotation angulaire de l'électrode en s^{-1}) sont montrées à la figure 5. Les courbes s'écartent d'une droite et ne passent pas par l'origine, ce qui indique que l'oxydation du cuivre est quasi réversible (24), i.e. limitée à la fois par le transfert de masse et par une réaction de surface.

Dans ce cas où le système est quasi réversible, il est possible de décomposer le courant total en deux termes associés à chaque processus lent comme suit :

$$[1] \quad i^{-1} = i_\infty^{-1} + i_{d,a}^{-1}$$

i_∞ : composante du courant indépendante de $\omega^{1/2}$-réaction de surface; et $i_{d,a}$: courant de diffusion-convective anodique qui obéit à l'équation de Levich, [2] :

$$[2] \quad i_{d,a} = 0{,}62nFAD^{2/3}\omega^{1/2}\gamma^{-1/6}(C^s - C^*) = B\omega^{1/2}$$

(réf. 24)

n : nombre d'électron; F : constante de Faraday; A : aire géométrique de l'électrode; D : coefficient de diffusion de l'espèce oxydée ($cm^2\,s^{-1}$); γ : viscosité cinématique ($cm^2\,s^{-1}$); ω : vitesse de rotation angulaire de l'électrode (s^{-1}); C^* : concentration de l'espèce qui diffuse dans la solution ($mol\,cm^{-3}$); C^s : concentration de l'espèce qui diffuse à la surface de l'électrode ($mol\,cm^{-3}$).

Les relations [1] et [2] conduisent à

$$[3] \quad i^{-1} = i_\infty^{-1} + B^{-1}\omega^{-1/2}$$

Les courbes i^{-1} en fonction de $\omega^{-1/2}$ doivent donner une droite pour chaque potentiel appliqué (fig. 6), dont les valeurs B^{-1} et i_∞^{-1} sont déterminables à partir de la pente et de l'ordonnée

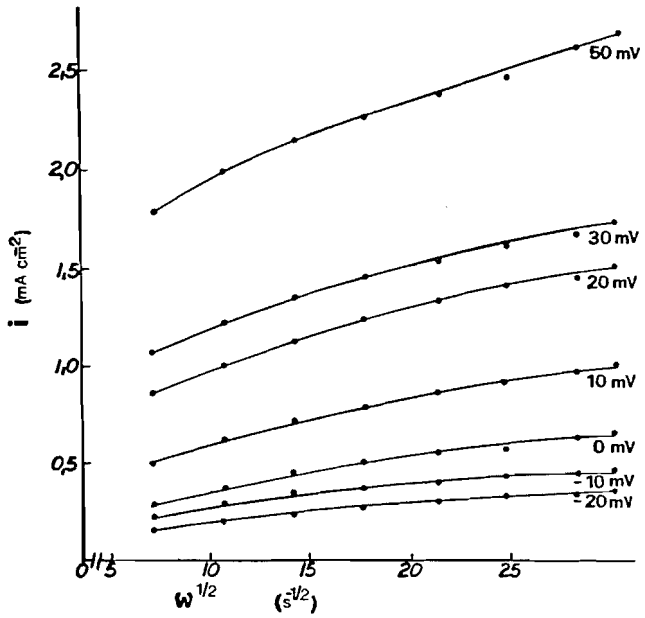

FIG. 5. Courbes $i = f(\omega^{1/2})$ pour différents potentiels appliqués. Solution KF–HF: $a_{F^-} = 0{,}074$, pH = 5.

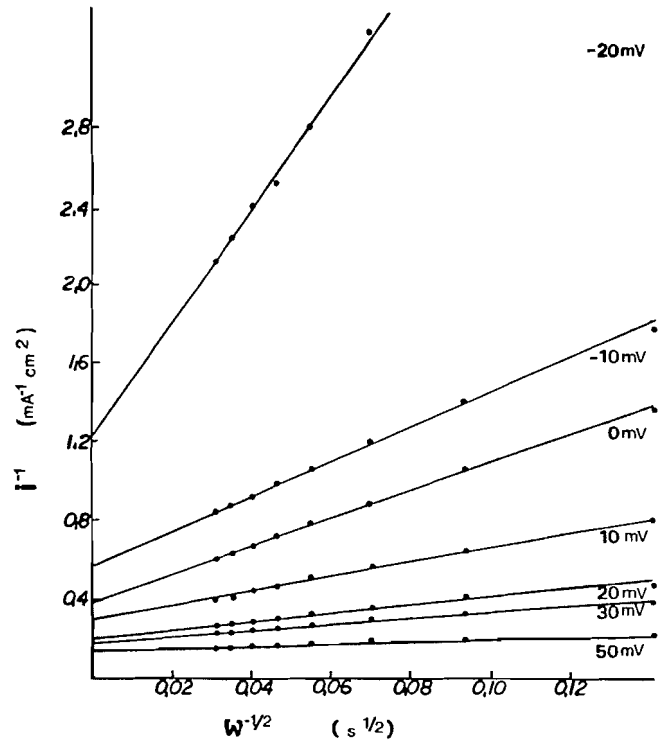

FIG. 6. Courbes $i^{-1} = f(\omega^{-1/2})$ pour différents potentiels appliqués. Solution KF–HF: $a_{F^-} = 0{,}074$, pH = 5.

à l'origine respectivement. L'inverse de la pente du graphique i^{-1} en fonction de $\omega^{-1/2}$ correspond à B, c'est-à-dire au produit, $i_{d,a}\omega^{-1/2}$ alors que i_∞^{-1} est obtenu par extrapolation de la droite jusqu'à $\omega^{-1/2}$ égale zéro. Les valeurs de B ou $i_{d,a}\omega^{-1/2}$ ont été déterminées pour différents potentiels. La relation log $i_{d,a}\omega^{-1/2}$ vs. E est linéaire (fig. 7, ligne pleine) et la pente moyenne obtenue pour plusieurs essais dans une solution de KF ($a_F = 0{,}074$) à pH 5 est de 29,2 ± 0,5 mV. La relation log i_∞ vs. E est linéaire ce qui indique que la réaction de surface

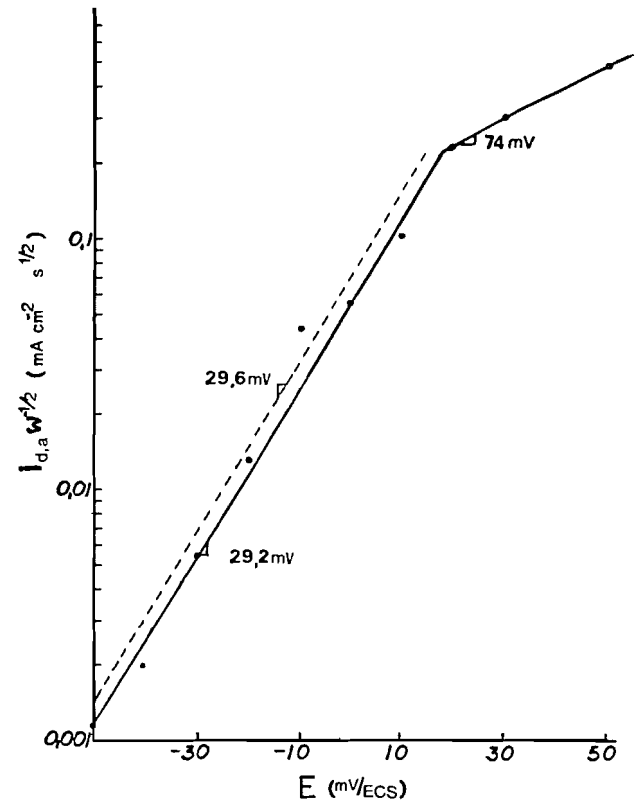

FIG. 7. Courbes log $i_{d,a}\omega^{-1/2} = f(E)$. Solution KF–HF: $a_{F^-} = 0{,}074$, pH = 5. (—) courbe expérimentale; (---) courbe calculée.

est une réaction de transfert d'électron. Nous obtenons avec la relation log i_∞ vs. E une courbe de Tafel dont la pente moyenne est de 32 ± 6 mV.

Le pouvoir peu complexant de l'ion fluorure favorise la formation de l'ion Cu^{2+} (18). Considérons le cas où le cuivre se dissout sous forme de Cu^{2+} et où le transfert de masse fait intervenir la diffusion du Cu^{2+} formé à l'électrode. Nous pouvons résumer la réaction globale d'oxydation du cuivre en deux étapes : (1) l'étape globale de transfert d'électron conduisant à la formation de Cu^{2+}, i.e. $Cu = Cu^{2+} + 2e^-$; (2) la diffusion du Cu^{2+} de l'électrode vers la solution.

Lorsque $\omega \to 0$, l'étape (2) est lente et l'étape (1) rapide; le terme $B^{-1}\omega^{-1/2}$ de l'équation [3] devient le terme dominant et $i \sim i_{d,a}$.

Le courant de diffusion de l'ion Cu^{2+} est donné par l'équation de Levich :

$$[4] \quad i_{d,a} = 0{,}62nFAD_{Cu^{2+}}^{2/3}\omega^{1/2}\gamma^{-1/6}(C^s_{Cu^{2+}} - C^*_{Cu^{+}})$$

où $C^s_{Cu^{2+}}$: concentration de Cu^{2+} à la surface de l'électrode et $C^*_{Cu^{2+}}$: concentration de Cu^{2+} en solution.

Puisque la vitesse de transfert de masse est lente par rapport à la vitesse de transfert d'électron lorsque $\omega \to 0$, l'équation de Nernst s'applique ce qui nous permet de calculer la concentration de Cu^{2+} à la surface de l'électrode :

$$[5] \quad E = E^0_{Cu/Cu^{2+}} + \frac{RT}{nF} \ln C^s_{Cu^{2+}} \cdot f_{Cu^{2+}}$$

$f_{Cu^{2+}}$: coefficient d'activité du Cu^{2+}.

En combinant les équations [4] et [5] et en tenant compte du fait que $C^*_{Cu^{2+}} \lessapprox C^s_{Cu^{2+}}$, on obtient la relation du courant de diffusion :

[6] $$i_{d,a} = 0{,}62nFAD^{2/3}_{Cu^{2+}}\omega^{1/2}\gamma^{-1/6}(1/f_{Cu^{2+}}) \times \exp\left[\frac{nF}{RT}(E - E^0_{Cu/Cu^{2+}})\right]$$

Pour une réaction procédant d'un échange de 2 électrons comme l'oxydation du cuivre sous forme de Cu^{2+}, la relation $\log i_{d,a}\omega^{-1/2}$ vs. E tirée de l'équation [6] donne une pente de 29,6 mV (25°C). La courbe expérimentale représentée à la figure 7 (ligne pleine) a deux pentes différentes, 29,2 mV et 74 mV. La cassure des droites a lieu à $\sim +15$ mV. Nous considérons dans l'analyse des résultats uniquement la partie de la courbe allant de -50 à $+15$ mV parce que la cassure apparaît près du potentiel pour lequel un dépôt noir commence à se former sur l'électrode. Les composés prévus à partir de la thermodynamique dans ces conditions expérimentales sont le Cu_2O et le $3CuF_2 \cdot Cu(OH)_2$ (23). Nous avons obtenu à partir de nos mesures une pente moyenne de 29,2 ± 0,5 mV. Les résultats expérimentaux concordent très bien avec la réaction d'oxydation du cuivre sous forme Cu^{2+}.

À partir de l'équation [6], on a tracé la courbe calculée de la relation $\log i_{d,a}\omega^{1/2}$ en fonction de E (fig. 7, ligne pointillée), en utilisant les valeurs suivantes : $E^0_{Cu/Cu^{2+}} = 0{,}105\ V_{ECS}$ (18), $f_{Cu^{2+}} = -0{,}40$ (25), $D_{Cu^{2+}} = 0{,}83 \times 10^{-5}\ cm^2\ s^{-1}$ (26), $\gamma = 0{,}01\ cm^2\ s^{-1}$ (24), $A = 0{,}20\ cm^2$.

Les droites expérimentale et calculée (fig. 7) sont séparées par un faible écart; il y a donc harmonie entre les résultats expérimentaux obtenus à pH 5 et le modèle proposé pour l'oxydation du cuivre. On explique l'écart par la différence entre les valeurs $D_{Cu^{2+}}$, $f_{Cu^{2+}}$, $E^0_{Cu/Cu^{2+}}$ utilisées pour le calcul et les valeurs réelles du système expérimental et possiblement par une faible différence de potentiel dans la jonction liquide.

La réaction de transfert d'électron peut être déterminée par l'analyse de la courbe de Tafel, $\log i_\infty$ vs. E. Lorsque $\omega \rightarrow \infty$, le terme i^{-1} de l'équation [3] devient dominant et $i \sim i_\infty$, c'est-à-dire que le transfert d'électron est l'étape déterminante.

Un mécanisme conduisant à la formation de Cu^{2+} peut être envisagé (12). Il fait intervenir deux étapes d'oxydation électrochimique successives pour lesquelles la deuxième étape est déterminante (l'espèce Cu^+ reste adsorbée sur l'électrode) :

[7] $Cu \rightleftarrows Cu^+ + 1e$ rapide

[8] $Cu^+ \rightleftarrows Cu^{2+} + 1e$ lente

Pour un tel mécanisme, la pente de la courbe de Tafel a une valeur théorique de 40 mV. Étant donné que la pente expérimentale de la relation $\log i_\infty$ vs. E est comprise entre 26 et 38 mV, le mécanisme procédant des étapes [7] et [8] est envisageable. Par ailleurs, la dismutation de l'espèce intermédiaire Cu^+ est aussi probable (27), ce qui conduit dans ce cas à une valeur pour la pente de Tafel de 30 mV.

Conclusion

Cette étude nous a permis de mettre en évidence l'influence de l'ion F^- sur la dissolution anodique du cuivre dans des solutions aqueuses acides (pH 1,6–6), principalement à pH 5, en présence de KF 0,1 *M*. Aux pH 1,6–6, l'électrode de cuivre se dissout uniformément, i.e. sans qu'il y ait de zones préférentielles sur la surface lorsqu'elle subit une polarisation potentiodynamique (10 mV s^{-1}) à des potentiels supérieurs à $0\ V_{ECS}$. À pH faiblement acide (pH 5, KF 0,1 *M*), lorsque le balayage du potentiel va jusqu'à +0,5 V, l'oxydation du cuivre débute par la dissolution généralisée de l'électrode suivi de la formation d'un film de Cu_2O non passivant; au fur et à mesure que le temps d'oxydation augmente, le courant diminue et l'électrode devient passivée. À pH 5, dans les conditions où la dissolution de l'électrode tournante est généralisée, les courbes $i = f(\omega^{1/2})$ sont caractéristiques d'un système quasi réversible. Lorsque $\omega \rightarrow 0$, l'oxydation est limitée par l'étape de diffusion du Cu^{2+} de l'électrode jusqu'au coeur de la solution, alors que lorsque $\omega \rightarrow \infty$, l'oxydation du cuivre est limitée par le processus de transfert de charge conduisant à la formation de Cu^{2+}.

Remerciements

Ce travail a été supporté par l'Institut de recherche de l'Hydro-Québec (IREQ) et par le Conseil de recherches en sciences naturelles et en génie du Canada (CRSNG). Nous tenons à remercier Monsieur A. Adnot du «Laboratoire d'analyse de surface du GRAPS» (Université Laval) pour les analyses de XPS et AES.

Assisted hydrolysis of the nitrile group of 2-aminoadamantane-2-carbonitrile

MARTINO PAVENTI, FRANCIS L. CHUBB, AND JOHN T. EDWARD
Department of Chemistry, McGill University, 801 Sherbrooke Street West, Montreal, P.Q., Canada H3A 2K6

Received February 10, 1987

MARTINO PAVENTI, FRANCIS L. CHUBB, and JOHN T. EDWARD. Can. J. Chem. **65**, 2114 (1987).

Attempts to hydrolyse the nitrile group of 2-aminoadamantane-2-carbonitrile by mineral acid or alkali have been unsuccessful. However, treatment of the aminonitrile with benzaldehyde in alkaline solution gives the benzal derivative of the α-aminoamide, readily hydrolysed to the α-aminoamide. Alternatively, benzoylation of the amino group followed by acid hydrolysis gives successively the α-benzamido acid and the α-amino acid. Possible mechanisms for these facilitated hydrolyses are advanced.

MARTINO PAVENTI, FRANCIS L. CHUBB et JOHN T. EDWARD. Can. J. Chem. **65**, 2114 (1987).

Des essais menés en vue d'hydrolyser le groupement nitrile de l'amino-2 adamantanecarbonitrile-2 par les acides minéraux ou par les hydroxydes alcalins se sont avérés infructueux. Toutefois, si on traité l'aminonitrile par du benzaldéhyde en solution alcaline, on obtient un dérivé benzal de l'α-aminoamide qui peut facilement être hydrolysé en α-aminoamide. Une méthode alternative implique une benzoylation du groupement aminé qui est suivie d'une hydrolyse acide pour conduire avec succès à l'acide α-benzamido et à l'acide α-aminé. On propose des mécanismes possibles pour ces hydrolyses rendues faciles.

2-Aminoadamantane-2-carbonitrile **2** is readily prepared from adamantanone **1** (1), but attempts to hydrolyse it to the amino acid **5** have been unsuccessful (2). This is not totally surprising, since the nitrile group of **2** is constrained into an axial position, in which it is known to resist hydrolysis (3). The amino acid **5** was eventually obtained by Nagasawa *et al.* (2) by preparing first the hydantoin **4** by reaction of the ketone **1** with cyanide and ammonium carbonate (the Bucherer–Bergs reaction) in a pressure vessel at 120°C and 170 psi (1 psi = 6.9 kPa), and then hydrolysing the hydantoin to the amino acid by heating it with 1.25 *M* aqueous sodium hydroxide in a pressure vessel at 195°C and 250 psi (Scheme 1).

The severity of these conditions challenged us to devise an easier preparation. The most obvious was the aldehyde- or ketone-assisted hydrolysis of the α-aminonitrile in alkaline solution to give the Schiff base (e.g. **8**) of the α-aminoamide (4–12); this is usually hydrolysed with extreme ease to the α-aminoamide (e.g. **9**) and then, with more difficulty, to the α-amino acid (e.g. **5**). The mechanism of this reaction has been studied by Commeyras and co-workers (4–6); in the present instance the reaction steps would be **2** → **6** → **7** → **8**. However, the procedure of Commeyras (who worked with simple α-aminonitriles in aqueous solution) was judged unsuitable for our water-insoluble compound **2**, and so we used the earlier procedure of Cook *et al.* (7–12) in which the α-aminonitrile was treated with sodium methoxide in neat ketone (e.g. acetone). This reaction yielded only adamantanone, from the base-catalysed decomposition of **2** (13). However, reaction of **2** with benzaldehyde and KOH in aqueous ethanol[1] gave the Schiff base **8** (R^1 = Ph, R^2 = H), although reaction with cyclohexanone under these conditions gave nothing. Evidently steric hindrance to the formation of the five-membered ring intermediate **7** becomes excessive if R^2 is larger than hydrogen.

The aminoamide **9** was readily obtained from the benzal derivative **8** (R^1 = Ph, R^2 = H) by treatment with dilute acid or with phenylhydrazine in benzene containing a trace of acetic acid. However, its further hydrolysis to **5** by strong acid or alkali was extremely slow, and so other routes were investigated.

One of these was the ketone-assisted thiohydrolysis of the nitrile group (9, 15) with cyclohexanone as the ketone. This would be expected to yield the imidazolidine-4-thione **10** by the mechanism shown in Scheme 2 (15). In fact, this compound was obtained, but in small yield, along with the compounds **11** and **13** (15). Evidently steric hindrance at the cyclization step leading to **10** is sufficient to allow the competing hydrolysis of the intermediate to yield **11**, and steric hindrance at an earlier stage causes **2** to react so slowly that the competing breakdown of **2** to adamantanone, NH_3, and HCN (13) can result in the formation of significant amounts of **12** and thence of **13**.[2]

In the end of the most practical route to the amino acid **5** was found to start with the α-benzamidonitrile **14** (Scheme 3). Our previous experience with α-benzamidonitriles[3] led us to expect a rapid hydrolysis of the nitrile **14** to the amide **16** in concentrated hydrochloric acid, probably by way of the oxazoline intermediate **15** (16), followed by a slower hydrolysis of the amide **16** to the acid **17**. In fact, both stages of the acid hydrolysis seem to be accelerated by the benzamido group, the nitrile **14** readily giving the acid **17**. More prolonged acid treatment is required to hydrolyse the benzamido group of **17** to give the hydrochloride of the amino acid **5**. This last hydrolysis, which contrasts with the resistance of the amido group of **9** to aqueous acid, probably takes place because of the greater distance of the amido carbonyl of **17** from the crowding adamantane moiety.

It may be noted that the anchimerically assisted attacks on the nitrile group in the four routes depicted in Schemes 1–3 are all basically similar, but that the route via the hydantoin **4** suffers from the disadvantage of the excessive stability of this intermediate. Anchimeric assistance by the α-benzamido group to the hydrolysis of nitriles seems not to have been recognized previously, and is under active investigation in this laboratory.

[1]We had previously found that this reaction converted α-amino-α-phenylacetonitrile to the Schiff base of α-amino-α-phenylacetamide. The experiment was suggested by the observation of Clarke and Francis (14) that treatment of benzaldehyde cyanohydrin with ammonia and benzaldehyde in aqueous ethanol containing KOH gave the Schiff base of α-amino-α-phenylacetamide.

[2]This experiment was repeated with the addition of varying amounts of aqueous ammonia, and the crude product analysed by thin-layer chromatography. A rough estimate of the relative amounts of **10**, **11**, and **13**, based on the intensity of the spots, was 20:15:65; this ratio was not appreciably affected by the amount of ammonia present.

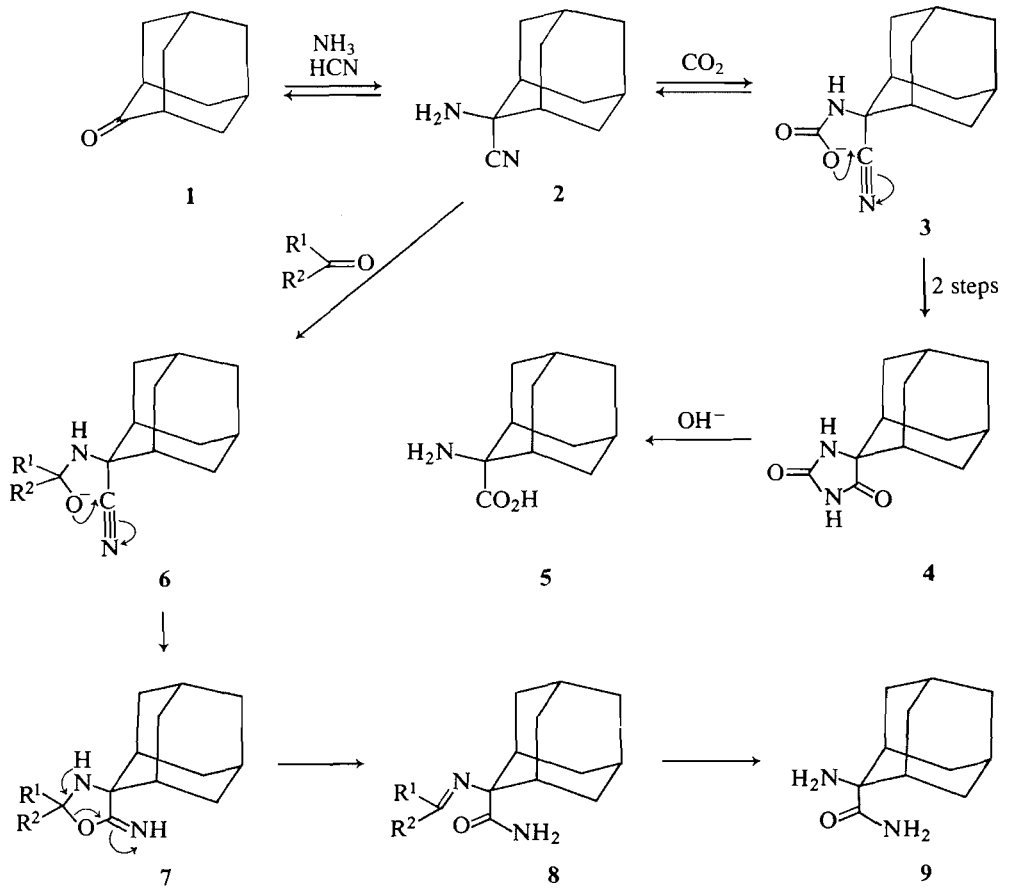

SCHEME 1

Experimental

α-Benzylideneamino-α-phenylacetamide

α-Amino-α-phenylacetonitrile (10 g) in ethanol (20 mL) was added dropwise to a stirred mixture of benzaldehyde (7 g), 15% aqueous potassium hydroxide (10 mL), concentrated aqueous ammonia (10 mL), and ethanol (4 mL). A first crop (12.5 g) of crystalline solid was removed by filtration after 1 h, and a second crop (1.5 g) from the filtrate after it had stood overnight. The combined crops were recrystallized from ethyl acetate – light petroleum (1:1 v/v) to yield α-benzylideneamino-α-phenylacetamide (13 g, 72%), mp 125–127°C (lit. (14) mp 126°C); ν_{max} (Nujol): 3380, 3290, 3180, 1660, 1640 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.92 (1H, S, =NC*H*Ph—CO—), 6.33 (1H, s, NH), 6.90 (1H, s, NH), 7.07–7.90 (10H, m, aromatic), 8.18 (1H, s, PhC*H*=N—).

2-Aminoadamantane-2-carbonitrile (2) hydrochloride

The reaction of adamantanone with sodium cyanide, ammonium chloride, and aqueous ammonia in ethanol–water was carried out following ref. 1, after which the reaction mixture was extracted with ether (200 mL). The extract was dried, and HCl gas was passed through the solution. The precipitated hydrochloride was filtered, washed with water (68% yield), and recrystallized from acetonitrile, charring above 300°C.

2-Benzylideneaminoadamantane-2-carboxamide (8; R^1 = Ph, R^2 = H)

A solution of 2-aminoadamantane-2-carbonitrile (6.0 g) and benzaldehyde (3.6 g) in ethanol (13 mL), concentrated aqueous ammonia (4.6 mL), and 15% aqueous potassium hydroxide (4.6 mL), stirred at room temperature, deposited a white solid. After 2.5 h, filtration removed 3.85 g, mp 185–186°C, and after standing overnight, 1.1 g, mp 186–187°C (total yield 52%); ν_{max} (KBr): 3390, 3350, 3310, 3210 (NH), 3030 (aromatic CH), 2940–2850 (aliphatic CH), 1685, 1655 (amide), 1630 (C=N) cm^{-1}; ^1H nmr (DMSO-d_6) δ: 1.33–2.20 (12H, m, adamantane), 2.37 (2H, m, adamantane), 5.80 (2H, s, $CONH_2$, removed by D_2O), 7.20–7.53 (3H, m, aromatic), 7.53–7.87 (2H, m, aromatic), 8.40 (1H, s, PhC*H*=N—).

2-Aminoadamantane-2-carboxamide (9)

A solution of 2-benzylideneaminoadamantane-2-carboxamide (2.0 g) and phenylhydrazine (0.8 g) in benzene (60 mL) containing two drops of acetic acid was heated under reflux for 1.5 h. The solution after concentration and cooling deposited colourless platelets (1.2 g, 88%), mp 184–186°C; ν_{max} (KBr): 3350, 3270, 3100 (NH), 2900, 2820 (aliphatic CH), 1670 (amide) cm^{-1}; ^1Hmr (DMSO-d_6) δ: 1.3–2.5 (14H, m), 1.87 (2H, s, NH_2, removed by D_2O), 6.73 (2H, br s, $CONH_2$, removed by D_2O). *Anal.* calcd. for $C_{11}H_{18}N_2O$: C 68.01, H 9.34, N 14.42; found: C 67.89, H 8.75, N 14.37.

2-Benzamidoadamantane-2-carboxamide (16)

Benzoyl chloride (0.52 g) was added gradually to a stirred solution of 2-aminoadamantane-2-carboxamide (0.60 g) and potassium carbonate (0.64 g) in water (10 mL) – tetrahydrofuran (10 mL). The mixture was left overnight and the insoluble product then removed and recrystallized from ethyl acetate: prisms (0.80 g, 87%), mp 232–234°C; ν_{max} (KBr): 3463, 3328, 3207, 3243 (NH), 3168, 3055 (aromatic CH), 2928, 2903, 2853 (aliphatic CH), 1686, 1659, 1636 (amide); ^1Hmr (DMSO-d_6) δ: 1.66 (12H, m), 2.43 (1H, m, amide), 2.66 (2H, m), 6.55 (2H, br d, amide), 7.00–7.50 (5H, m, aromatic). *Anal.* calcd. for $C_{18}H_{22}N_2O_2$: C 72.46, H 7.43, N 9.39; found: C 72.62, H 7.61, N 8.80.

Adamantane-2-spiro-5'-imidazolidin-4'-thione-2'-spirocyclohexane (10)

Hydrogen sulfide was bubbled for 1.5 h into an ethanolic solution (20 mL) at 0°C containing 2-aminoadamantane-2-carbonitrile hydro-

chloride (2.12 g, 0.010 mol), triethylamine (1.03 g, 0.010 mol), and cyclohexanone (1.0 g, 0.010 mol), and the reaction vessel was then stoppered and left at room temperature for 2 h. The solution was then purged of excess H_2S by a stream of N_2 for 1.5 h at room temperature, and left at room temperature for 48 h. Slender yellow needles were removed by filtration and washed with ethanol. The dried product (0.12 g, 4%) was recrystallized from acetonitrile to give needles, mp 235–237°C, shown by thin-layer chromatography to be contaminated with a small amount of the compound **13**. This was removed by chromatography on Florisil and elution with chloroform, the less polar **10** being removed first. It was recrystallized from acetonitrile: needles, mp 236–238°C; ν_{max}: 3285 (N—H), 3145 (thioamide N—H), 2915, 2895, 2850, 1495, 1458, 1443 cm^{-1}; uv (95% ethanol) λ_{max}: 274 nm (ε 13 500); uv (0.9 *M* ethanolic KOH) λ_{max}: 258 nm (ε 10 200; uv (3.6 *M* ethanolic HCl) λ_{max}: 277 nm (ε 13 000); ^{1}Hmr (DMSO-d_6) δ: 1.67–1.93 (22H, m), 2.30 (2H, m), 3.47 and 3.67 (1H, NH),[4] 10.67 (1H, s, thioamide); electron impact ms *m/z* (formula, intensity, fragment): 290 ($C_{17}H_{26}N_2S$, 27, M^+), 256 ($C_{17}H_{24}N_2$, 22, M − H_2S), 231 ($C_{16}H_{25}N$, 97, M − HNCS), 149 ($C_{10}H_{15}N$, 92), 134 ($C_{10}H_{14}$, 31). *Anal.* calcd. for $C_{17}H_{26}N_2S$: C 70.30, H 9.02, S 11.04; found: C 70.63, H 9.14, S 11.33.

*2-Aminoadamantane-2-thionamide (**11**)*

2-Aminoadamantane-2-carbonitrile hydrochloride (1.06 g) was allowed to react with H_2S and cyclohexanone in ethanol according to the procedure above, and the crude product was chromatographed on Florisil. Elution with chloroform removed the less polar materials **1**, **10**, and **13**; elution with chloroform–methanol 9:1 (v/v) removed 2-aminoadamantane-2-thionamide, which crystallized from chloroform was white plates, mp 164–166°C; ν_{max} (KBr): 3381, 3335, 3263, 3171, 2931, 2897, 2847, 2323 (w br), 1620, 1571, 1560, 1418 cm^{-1}; uv (water) λ_{max}: 273 nm (ε 8350); ^{1}Hmr (DMSO-d_6) δ: 1.82 (10H, m), 2.40 (6H, m, CH + NH_2), 7.8 (~2H, br s, $CSNH_2$); ms *m/z* (formula, intensity, fragment): 176 ($C_{11}H_{16}N_2$, 32, M^+ − H_2S), 151 ($C_{10}H_{17}N$, 250, M^+ − HNCS), 150 ($C_{10}H_{16}N$, 922, M^+ − H_2NCS), 149 ($C_{10}H_{15}N$, 1000, M^+ − H_2NCSH). *Anal.* calcd. for $C_{11}H_{18}N_2S$: C 62.81, H 8.62, N 13.32; found: C 62.78, H 8.68, N 13.25.

The nitrate salt was prepared by adding 70% nitric acid to a chloroform solution of the free base, and was recrystallized from water: yellow needles, mp 225–226°C; ν_{max}: 3305, 3285, 3135, 2985, 2910, 2855, 1640, 1630, 1587, 1525, 1495, 1475, 1465 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 2.0 (10H, m), 2.77 (4H, s), 8.20 (3H, br s, $—\overset{+}{N}H_3$), 10.9 (2H, br s, thioamide).

*2-Benzamidoadamantane-2-carbonitrile (**14**)*

Benzoyl chloride (1.70 g) was added slowly with stirring to a solution of 2-aminoadamantane-2-carbonitrile hydrochloride (2.13 g) and potassium carbonate (2.10 g) in water (30 mL) – tetrahydrofuran (20 mL). After 1 h the precipitated solid was removed by filtration and recrystallized from ethyl acetate: slender needles (2.4 g, 86% yield), mp 241–243°C; ν_{max} (KBr): 3365 (N—H), 2227 (C≡N), 1650 (NHCO) cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 0.87–2.20 (12H), 2.73 (2H, s), 7.42–7.92 (5H, m, Ph), 8.53 (1H, br s, amide). *Anal.* calcd. for $C_{18}H_{20}N_2O$: C 77.11, H 7.19, N 9.99; found: C 77.05, H 7.85, N 10.37.

*2-Benzamidoadamantane-2-carboxylic acid (**17**)*

2-Benzamidoadamantane-2-carbonitrile (0.10 g) in tetrahydrofuran (4 mL) and concentrated aqueous hydrochloric acid (10 mL) was kept overnight at room temperature[5] and then diluted with water (40 mL), giving the acid **17** (0.10 g, 93%), mp 240–241°C after recrystallization from chloroform; ν_{max} (KBr): 3495 (N—H), 1738 (CO_2H), 1625 (amide) cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 1.47–2.41 (14H, m), 2.63 (2H, m), 7.42–7.91 (5H, m, Ph), 8.08 (1H, s, amide). *Anal.* calcd. for $C_{18}H_{21}NO_3$: C 72.22, H 7.07, N 4.68; found: C 72.12, H 6.98, N 4.65.

*2-Aminoadamantane-2-carboxylic acid (**5**)*

A solution of 2-benzamidoadamantane-2-carboxylic acid (0.50 g) in acetic acid (200 mL), concentrated aqueous hydrochloric acid (8.0 mL), and water (8.0 mL) was boiled under reflux for 30 h and then concentrated under reduced pressure. The solid residue was extracted with hot diethyl ether (2 × 50 mL) and with hot acetonitrile (2 × 50 mL), and then dissolved in methanol (5 mL) and filtered. Addition of diethyl ether (100 mL) to the filtrate, and scratching, induced crystallization of the hydrochloride (0.25 g, 65%), mp 269–270°C (lit. (2) mp ≥280°C); ν_{max} (KBr): 3230, 3180 (NH_3^+), 1722 (CO_2H) cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 1.83 (10H, m), 2.27 (4H, br, m), 7.97–9.97 (3H, NH_3^+). An aqueous solution of the hydrochloride was filtered, and the pH of the filtrate adjusted to ca. 5 with sodium bicarbonate. Fine white plates crystallized out, mp 303–305°C, raised to 308–311°C (lit. (2) mp 308–310°C) on recrystallization from water; ν_{max} (KBr): 3470, 3360, 3260 (NH_3^+), 1642 (CO_2^-) cm^{-1}. *Anal.* calcd. for $C_{11}H_{17}NO_2$: C 67.66, H 8.77, N 7.17; found: C 67.65, H 8.94, N 7.35.

[4]The two broad peaks for N(1′)—H, each of equal area and adding up to one proton, are puzzling. A referee has suggested that the peaks are singlets from axial and equatorial NH. The ^{1}Hmr spectrum of cyclohexane-spiro-5′-imidazolin-4′-thione-2′-spirocyclohexane shows only one singlet for this NH (15), but possibly the more rigid spiroadamantane raises the barrier to axial–equatorial interconversion of the spirocyclohexane.

[5]Later experiments showed this time to be unnecessarily long; in fact, thin-layer chromatography showed that hydrolysis of **14** to **17** was complete in about 5 min, with no appreciable amount of the intermediate **16** present.

Topsentins, new toxic bis-indole alkaloids from the marine sponge *Topsentia genitrix*[1]

Three new bis-indole alkaloids, topsentin-A (**1**), -B1 (**2**), and -B2 (**3**) have been isolated from the Mediterranean sponge *Topsentia genitrix* and their structure determined by spectroscopic methods. These compounds are weakly toxic for fish and for dissociated cells of the freshwater sponge *Ephydatia fluviatilis* and thus might be partially responsible for the chemical defense of the sponge.

Trois alcaloïdes bis-indoliques nouveaux, les topsentines-A (**1**), -B1 (**2**) et -B2 (**3**), ont été isolés de l'éponge méditerranéenne *Topsentia genitrix*, et leurs structures déterminées par des méthodes spectroscopiques. Ces composés, qui sont faiblement toxiques vis-à-vis des poissons et des cellules dissociées de l'éponge d'eau douce *Ephydatia fluviatilis*, sont donc probablement responsables de la défense chimique de cette éponge.

[Traduit par la revue]

Introduction

Among marine organisms, sponges appear to be one of the richest phylum in toxicogenic species. They are also remarkable for their ability to synthesize a wide variety of secondary metabolites (1, 2) that, in several cases, have been demonstrated to be responsible for the observed toxicity (3, 4). It is now generally admitted that these noxious compounds may act to minimize predation by mobile animals and (or) to reduce settlement and overgrowth of fouling organisms (5).

In the course of our search for compounds involved in the defense mechanism of sponges, we observed that the methanolic extract of the sponge *Topsentia genitrix* (Halichondriidae) is weakly toxic to the fish *Lebistes reticulatus* (LD: <50 mg/L) and to mice (LD_{50}: 10 mg/kg), kills dissociated cells of the freshwater sponge *Ephydatia fluviatilis* before early aggregation (<100 mg/L) (6), and shows antibacterial activities. We wish to report here on the isolation and structure determination of three new bis-indole alkaloids partially responsible for these activities.

Results and discussion

A large specimen of *Topsentia genitrix*, a rarely encountered Mediterranean sponge, was collected near Banyuls (France) by scuba diving. The three major compounds of the active fraction, named topsentin-A (**1**), topsentin-B1 (**2**), and topsentin-B2 (**3**), were separated by droplet counter current chromatography (DCCC: $CHCl_3$, CH_3OH, H_2O, 13:7:8) and further purified by flash chromatography on silica gel ($CHCl_3$, CH_3OH, NH_3 25%, 19:0.5:1 or 9:1:1).

Topsentin-A (1)

The pattern of the uv (CH_3OH, λ_{max} at 209 (43 000) sh 228, 253 (21 200) sh 270, 373 nm (17 930)) and ir spectra (KBr, no aliphatic ν C—H, aromatic out-of-plane bending band at 735 cm^{-1}), together with the absence in the ^1H nmr spectrum of topsentin-A of signals between 0 and 7 ppm, are indicative of an aromatic skeleton. The EI mass spectrum shows an intense molecular ion at m/z 326 and high resolution measurements provide the molecular formula $C_{20}H_{14}N_4O$ (*Exact Mass* calculated: 326.1168; measured: 326.1169). Although the behaviour of topsentin-A, both in tlc and hplc, suggests that it is a pure compound, its ^1H nmr spectrum, recorded in CD_3COCD_3, shows signals ($2 \times 14H$) attributable to a mixture of two closely related derivatives in a ratio 60:40. Four peaks amounting to a total of 6 protons (3H per derivative) disappear on treatment with D_2O and the addition of a few drops of CF_3COOD induces a dramatic simplification of the spectrum, which under these conditions shows signals integrating for 11 protons only. Such behaviour is reminiscent of the existence of two slowly interconverting compounds whose protonated forms are identical.

The ^{13}C nmr spectra of **1** (CD_3COCD_3–D_2O–CF_3COOD; BBD and DEPT) ascertain the presence of 20 carbon atoms (9 quaternary and 11 tertiary). The $^1H/^1H$ correlated 2D nmr spectrum of the protonated form of **1** shows that the four protons absorbing at 8.35, 7.65, 7.36, and 7.35 ppm and the four protons absorbing at 7.96, 7.60, 7.28, and 7.25 ppm form two separated 4-spin systems attributable to two 1,2-disubstituted benzene rings. The simulation of the two 4-spin systems using the PANIC program (7) confirms this attribution and allows accurate determination of the chemical shifts and coupling constants. The assignment of the carbon–proton connectivities of these protons was deduced from the $^1H/^{13}C$ correlated 2D nmr spectrum. SPI experiments (8) showed that the 1H singlet at δ 8.72 undergoes long range heteronuclear coupling

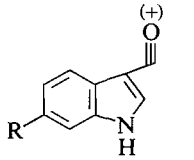
3	OH	Br

with the ^{13}C signals at δ 114.8, 126.9, and 138.0, while the 1H singlet at δ 8.15 is long-range coupled with the ^{13}C signals at δ 125.4, 137.6, and 103.1. All these data, together with the presence of a deshielded carbon atom at δ 172.1, are consistent with the presence in topsentin-A of both a 3-ketoindole and a 3-substituted indole chromophore. The comparison of the ^1H and ^{13}C chemical shifts with those of model compounds (9–15) strongly supports this hypothesis. Thus, all signals in the ^1H and ^{13}C nmr spectra of **1** have been assigned, except for a 1H singlet at 8.08 ppm and 3 peaks corresponding to 1 tertiary (116.6) and two quaternary (141.5 and 132.5) carbon atoms in the ^{13}C nmr spectra. That these signals are attributable to a C-disubstituted imidazole ring follows from comparison with reported values (16) and from SPI experiments, which showed that the proton at δ 8.08 is long-range coupled with the ^{13}C signal at δ 141.5 and 132.5. The presence of an imidazole ring explains the modifications observed in the ^1H nmr spectrum of topsentin-A on addition of CF_3COOD. In neutral solution, asymmetrically C-disubstituted imidazoles exist as mixtures of slowly interconverting tautomers, and protonation yields a symmetrical imidazolium cation (17). It is known that, of the three carbon atoms of imidazole derivatives, the C-2 (imidazole numbering) is the most deshielded (δ ~ 140) (16). Since in topsentin-A this signal (δ 141.5) corresponds to a quaternary carbon atom, the imidazole ring is necessarily substituted at the carbon bearing the two nitrogen atoms. Moreover, further SPI experiments indicated that the signal at δ 8.15, attributable to the proton H-17 α to the nitrogen atom of the indole chromophore, is coupled (^3J) with the C-4 (or C-5) of the imidazole ring (δ 132.5). It follows from all these data that the protonated form of topsentin-A may be represented by structure **1***a*.

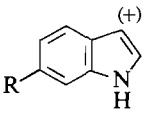
A careful analysis of the ^1H nmr spectrum of topsentin-A measured in CD_3COCD_3 permits us to assign the signals of both tautomers. Interestingly, the two signals at 7.62 and 7.70 ppm attributable to H-14 show different NH/CH coupling constants (2.2 and 1.5 Hz respectively). Since it is reasonable to assume that the larger *J* infers coupling between adjacent protons (17), the signal at 7.7 ppm may be assigned to tautomer **1***b*, which is thus the most abundant. The mass spectrum of topsentin-A entirely corroborates the proposed structure. It shows characteristic fragments corresponding to cleavages α to the carbonyl group. Cleavage of the C10—C11 bond gives rise to fragments *a* (*m/z* 144), *a* + H• (*m/z* 145), and *d* + H• (*m/z* 183), while cleavage of the C3—C10 bond gives rise to fragments *c* (*m/z* 210) and *c* − H• (*m/z* 209). Subsequent loss of a molecule of carbon monoxide leads to fragments *b* (*m/z* 116; *a* − CO), *b* + H• (*m/z* 117; *a* + H• − CO), and *d* − H• (*m/z* 181; *c* − H• − CO) respectively. The composition of all these fragments was confirmed by high resolution measurements. The parent–daughter relationships $M^{+\bullet} \rightarrow c - H^\bullet \rightarrow d - H^\bullet$ and $a \rightarrow b$ are ascertained by the presence of metastable peaks at *m/z* 134, 157, and 94 respectively.

Topsentin-B1 (2)

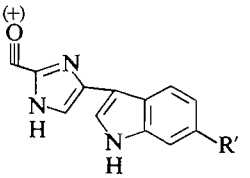
The spectroscopic properties of topsentin-B1 are closely related to those of topsentin-A. The EI mass spectrum shows an intense molecular ion at *m/z* 342 and high resolution measurements provide the molecular formula $C_{20}H_{14}N_4O_2$ (*Exact Mass* calculated: 342.1117; measured: 342.1129). Thus, topsentin-B1 possesses one more oxygen atom than topsentin-A. Moreover, in the ms of **2**, the peaks corresponding to fragments *a*, *a* + H•, *b*, and *b* + H• in the ms of **1** are shifted to *m/z* 160 (*a*′), *m/z* 161 (*a*′ + H•), *m/z* 132 (*b*′), and *m/z* 133 (*b*′ + H•), respectively, while those corresponding to fragments *c*, *c* − H•, *d* − H•, and *d* + H• are unchanged. This suggests that the extra oxygen atom is located on the 3-ketoindole moiety of the molecule. The presence in the ^1H nmr of 4 exchangeable protons implies that this oxygen atom is involved in an hydroxyl group. Further examination of the ^1H nmr data shows that the 4-spin system attributable to protons H-5 to H-8 in topsentin-A



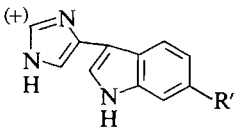
a R = H *m/z* 144
a′ R = OH *m/z* 160



b R = H *m/z* 116
b′ R = OH *m/z* 132



c R′ = H *m/z* 210
c′ R′ = Br *m/z* 288/290



d R′ = H *m/z* 182
d′ R′ = Br *m/z* 260/262

is replaced, in the spectrum of topsentin-B1, by a 3-spin system whose pattern indicates a 1,2,4-benzene substitution. The positioning of the hydroxyl group at C-6 follows from comparison of the chemical shifts of these three protons and their adjacent carbon atom in the ^1H and ^{13}C nmr spectra of topsentin-B1 with the chemical shifts calculated from the shielding effects[2] induced by the introduction of an hydroxyl group at C-6 or C-7 in topsentin-A, taken as reference compound. It follows that topsentin-B1 is 6-hydroxytopsentin-A. This structure is fully confirmed by the $^1H/^1H$ and $^1H/^{13}C$ correlated 2D nmr spectra.

In CD_3COCD_3, topsentin-B1 behaves as topsentin-A, existing as a mixture of two tautomeric forms (55:45) in slow interconversion. Again the *b* tautomer is the most abundant.

*Topsentin-B2 (**3**)*

Topsentin-B2 has the same R_f as topsentin-B1 in tlc and the two compounds can only be separated by DCCC. Their spectroscopic properties are closely related and suggest that topsentin-B2 is a monobromo derivative of topsentin-B1. The EI mass spectrum of **3** shows an intense molecular ion cluster at *m/z* 420–422 (50:50) which analyzes for $C_{20}H_{13}N_4O_2Br$ (measured: 420.0237/422.0215; calculated: 420.0222/422.0203) by high resolution mass spectrometry. Moreover, the peaks corresponding to fragments *c*, $c - H^\cdot$, and $d + H^\cdot$ in **1** and **2** are shifted 78–80 daltons to the high masses in the mass spectrum of **3** while those corresponding to fragments *a'* and *b'* are unchanged. These data demonstrate that the bromine atom is attached to the indole moiety of the molecule. Additional support for this hypothesis is provided by the ^1H nmr spectrum, which shows two 3-spin systems characteristic of the presence of two 1,2,4-trisubstituted benzene rings. The locations of the OH and Br substituents in **3** are based, as discussed above, on calculations of the ^1H and ^{13}C shielding effects taking **1** and **2** as reference compounds. Thus, topsentin-B2 is 21-bromotopsentin-B1. The $^1H/^1H$ and $^1H/^{13}C$ correlated 2D nmr spectra are in complete agreement with the proposed structure. As **1** and **2**, topsentin-B2 exists in neutral solution as a mixture of two tautomeric forms (67:33) in slow interconversion, with tautomer *b* being preponderant.

The LD of these three bis-indole alkaloids, for the fish *Lebistes reticulatus*, is between 15 and 20 mg/L, indicating that they are, at least in part, responsible for the toxicity of the methanolic extract of the sponge *Topsentia genitrix*. From a biogenetic point of view, the topsentins most probably derive from the combination of 2 tryptamine (or tryptophane) units.

Until now, only a few tryptamine-derived indole compounds have been isolated from marine invertebrates in general, and from sponges in particular (1, 2, 19, 20). Most of the marine indoles are rather simple compounds, presumably representing small deviations or sidelines in tryptophane metabolism. The topsentins fit nicely into this scheme and reinforce the idea that the complex indole alkaloid metabolic pathways that have appeared in higher plants probably have no counterpart in the marine environment.

Experimental

Thin-layer chromatographic analyses (tlc) were realized on SilG UV_{254} (Macherey Nagel) and visualized by using uv light at 254 nm. Silica gel column chromatographies were performed by the flash technique (21) on MN-Kieselgel 60 (0.04–0.063 mm) and droplet counter current chromatographies (DCCC) on a Büchi B670 (288 tubes, l = 40 cm, i.d. = 2.7 mm).

The ^1H and ^{13}C nmr spectra were recorded at 250 and 62.8 MHz respectively, using a Bruker WM 250 spectrometer. Chemical shifts are quoted in δ values downfield from TMS as internal standard. The 2D experiments were performed using the Bruker microprograms. EI hrms were recorded on a Micromass 7070 F mass spectrometer.

Extraction and purification procedures

The fresh animal, collected by scuba diving near Banyuls (France), was preserved in MeOH and transported to the laboratory in Brussels. The sponge was cut into small pieces and exhaustively extracted with MeOH. Evaporation of the organic solvent under reduced pressure led to an aqueous solution that was extracted with dichloromethane (fraction A: 1.5 g) and dichloromethane–ethanol 3:2 (fraction B: 8.1 g) respectively. The residual aqueous solution was evaporated to dryness and the resulting solid was treated with ethanol (fraction D: 18 g). This latter fraction was percolated on silica gel (eluent:hexane–acetone 6:4 to 0:10).

The less polar fraction (3.1 g) contained mainly topsentin-A, -B1, and -B2, which were separated by DCCC (descending mode; solvent: $CHCl_3$–CH_3OH–H_2O, 13:7:8; flow 7 mL/h; fractions of 10 mL). Fractions 4–11 yielded crude topsentin-A (~500 mg), fractions 35–52 crude topsentin-B1 (~350 mg), and fractions 65–85 crude topsentin-B2 (~100 mg). All three derivatives were purified by silica gel flash chromatography ($CHCl_3$–CH_3OH–NH_3 25%, 19:0.5:1). They were found to be homogenous by hplc (CH_3OH–H_2O, 1:1; RP-18 5μm).

Topsentin-A: mp 290–292°C; uv (CH_3OH) λ_{max}: 209 (43 000), 253 (21 200), 373 nm (17 930) shoulders at 228 and 270 nm; ir (film): characteristic bands at 3250 (br), 1700, 1230, 845, and 735 cm^{-1}; EI ms: 326 (M^+, 100), 210 (13), 209 (78), 183 (23), 181 (7), 163 (15), 154 (13), 144 (56), 117 (16), 116 (21), 89 (15). *Exact Mass* calcd. for $C_{20}H_{14}N_4O$: 326.1168; found (hrms): 326.1169.

We have studied the vibrational spectra and thermal behaviour of *ortho*-dinitrotetramethylbenzene (*o*-DNTMB) to learn more about its molecular and lattice dynamics. The molecule undergoes two solid–solid phase transitions, close to the melting point, which could be explained by the relaxation of forces hindering the methyl-group and nitro-group free rotations. We have deduced the nature of the solid state vibrational motions, particularly those of lattice phonons, using group theory.

Dans le but d'obtenir de l'information sur ses dynamiques moléculaire et de réseau, on a étudié les spectres vibrationnels et le comportement thermique de l-*o*-dinitrotétraméthylbenzène (*o*-DNTMB). Près du point de fusion, la molécule subit deux transitions de phase solide–solide; on peut les expliquer par la relaxation des forces qui empêchent respectivement les rotations libres du groupement méthyle et celle du groupement nitro. On a déduit la nature des mouvements vibrationnels à l'état solide, spécialement en ce qui a trait aux phonons.

[Traduit par la revue]

1. Introduction

In this paper we report the results of a study of the vibrational spectra of *ortho*-dinitrotetramethylbenzene (*o*-DNTMB) in the crystalline state. The analysis of the spectroscopic properties of this type of crystal is interesting in that recent report shows that (1) similar molecules have a centre of inversion in the Bravais cell, in spite of the absence of this symmetry element in the molecule itself (2–5).

Studies of the dielectric relaxation properties of similar compounds (6, 7) and of the calorimetric behaviour of *o*-DNTMB (8), have been performed in our laboratory, but the information derived needs to be confirmed by spectroscopic technique where symmetry characteristics of molecules and crystals determine decisively the validity of certain selection rules.

With this in mind, we studied the vibrational spectra of the title molecule using one-phonon ir absorption and Raman scattering. We paid special attention to the low frequency region of the crystal spectra, as from the results we could be able to determine with certainty if the propagated or scattered photons originated from lattice phonons.

2. The model

Crystals of *o*-DNTMB are triclinic at room temperature and belong to the centrosymmetric $P\bar{1}$ (C_i^1) space group, as established by X-ray diffractometry in our laboratory (9). There are two molecular units in the Bravais cell, they couple appreciably, probably through strong dipolar interactions to produce the separation of the doubly degenerate molecular vibrational states of the lattice. Since the molecules have low symmetry, at the most planar C_s, all the fundamental molecular vibrations are active both in the infrared as well in the Raman spectra. The molecular vibrations give rise to Davidov's doublets, through coupling of the quasi degenerate vibrational states of the two interacting molecules of the unit cell. However, with a centrosymmetric crystal, one component (a_u) of the crystal splitting should be active in the infrared spectrum only and the other one (a_g) in the Raman only. This is well featured in the whole mid-frequency region (see Table 1), and also in the region of the lattice vibrations as per Table 2. The centrosymmetric C_i unit cell will give 12 lattice phonons distributed into three acoustical branches and nine optical branches having nine non-zero frequencies at the γ point of the first Brillouin zone. These will involve both translational and librational components to the eigenvectors and, at zero value of the wavevector $\boldsymbol{K}$, those motions having a high translational component can be of LO or TO character.

3. Experimental part

o-DNTMB was prepared in our laboratory following standard procedures, and was purified by a series of crystallization from $C_2H_5OH/CHCl_3$ mixtures. It was finally obtained from $CHCl_3$.

The mid-ir spectra were measured by a Perkin-Elmer, model 983 grating spectrometer, and the far-ir spectra (250–20 cm^{-1}) with a Bruker FT-IR spectrometer, with a resolution in this range of 2 cm^{-1}. Raman spectra were obtained with a Jobin-Yvon RAMANOR HG 2S grating double monochromator. The scattered photons were detected by a thermoelectrically cooled RCA C31034A phototube, coupled with a photon counting chain by Strumentazioni Elettroniche Avanzate (S.E.A., Rome). The exciting source was a Spectra-Physics argon ion laser, model 164-O9, of 5W (all lines power), the power collimated on the samples being at 514.5 nm, ca. 400 mW for the solutions in $CHCl_3$ and ca. 250 mW for the powders. The spectral slit width was 3 cm^{-1} for the solutions and 2 cm^{-1} for the solid samples. Depolarization ratios on the solution spectra were measured with conventional half-wave polarization rotors, standardised on the Raman lines of CCl_4.

4. Results

The results of our vibrational measurements are collected in Tables 1 and 2. The most important crystallographic data are reported in Table 3. Molecular bond distances are shown in

[a]ω_3, ω_5, and ω_8 are taken from the far infrared spectrum (Fig. 3).

Fig. 1. Figure 2 shows the one-phonon Raman scattering at low frequency of the crystals at room temperature. The corresponding region of the infrared absorption is shown in Fig. 3.

Thermal behaviour of solid *o*-DNTMB was followed with scanning calorimetry in a temperature range from 298 K to the solid–liquid transition (451.5 K), to confirm that the solid phase that is stable from 77 to 298 K, remains the only form stable above room temperature, or if phase transitions are possible before fusion occurs.

In Table 4 we have collected the results of the calorimetric

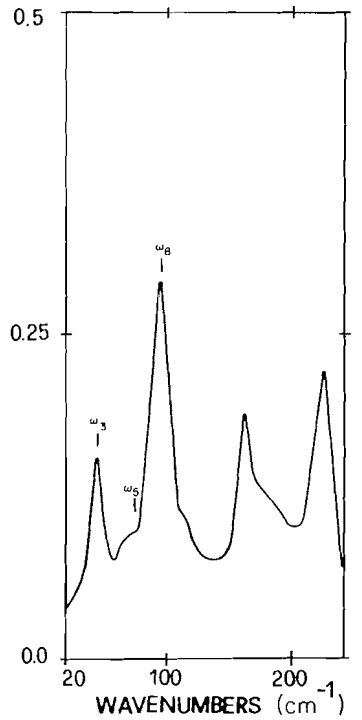

FIG. 3. Low-frequency FTIR spectrum of *o*-DNTMB crystals (polyethylene matrix) at room temperature.

measurements. The data show that two solid–solid phase transitions are present in a restricted temperature range near the melting point. The broadening of the ir and Raman peaks and the temperature dependence of the thermodynamic functions allows us (8) to establish the nature of these phase transitions in the solid state, which, on these grounds, seem to be first-order transitions (10). These might be due to the relaxation, by effect of temperature, of the forces which prevent the free rotation of the methyl- and nitro-groups. The interaction energy among the two different types of substituents should, in fact, be quite different and one could confidently assume that, in the case of the strongly polar NO_2 groups, only very close to the solid–liquid transition the dipole–dipole forces may be overcome.

As appears from Table 1, frequency values of molecular motions are higher in solid state spectra than in solution, except for a few modes. This fact is somewhat surprising, especially because, for stretching vibrations, the intermolecular coupling in the solid state always produces frequency lowering, due to the intramolecular force field variation caused by anharmonicity factors of the crystal field. We shall discuss this point in the following section.

5. Discussion

The vibrational assignment of the fundamental vibrations of *o*-DNTMB was made following previous studies on *ortho*-dinitrobenzene (*o*-DNB) (11), and disubstituted hexamethylbenzenes (1). It is not difficult to attribute the intense infrared peak at 1542 cm^{-1} (the corresponding Raman line is at 1537 cm^{-1}, of medium intensity), to the antisymmetric N—O stretching mode of the —NO_2 groups. The symmetric N—O stretching mode is at 1356 cm^{-1} in the infrared and the depolarization ratio of the Raman line in solution supports

this assignment. The remaining vibrations of the NO_2 group (scissor, rock, wag, and twist modes) are found at frequencies near those of *o*-DNB (11). Each of these modes gives rise to four ir frequencies, because there are two nitro groups per molecule and two molecules per unit cell.

Methyl group vibrations are assigned in a straightforward manner, since their frequency values are found in the regions expected according to classic group frequency correlations. Thus, besides the C—H stretchings around 2900 cm^{-1}, there are the well-known internal CH_3 bending vibrations δ_a at 1458 and 1446 cm^{-1} (this mode is probably strongly coupled with the ν_{19} mode of the benzenic ring) and δ_s at 1389 cm^{-1}. The rocking modes of the CH_3 groups fall in the region around 1000 cm^{-1} (12, 13). For assignment of the ring modes we have studied extensive literature (1, 11–13) and found many frequencies near those of relevant similar molecules. However, it should be noted that some frequencies have not been assigned with certainty, since we have not performed a normal coordinate calculation.

One peculiar aspect of the lattice properties of *o*-DNTMB in its internal phonon spectrum is the anomalous shift of its vibrational frequencies to the red in going from crystal to solution phase. We can explain this by assuming that the interactions of the solute and solvent molecules to be very strong. This can be true since both the solvent ($CHCl_3$) and the solute are highly polar. Thus, an intimate contact between solute and solvent molecules — as it happens in solution phase — can produce frequency lowerings of dipolar nature much more effectively than the crystalline field acting on the dipoles of the two *o*-DNTMB molecules alone. This interpretation could be supported by the fact that the amount of the crystal splitting, i.e. the frequency difference between a_g and a_u components of the Davidov's doublets is never more than 6–7 wavenumbers.

Table 2 lists some vibrational data for the lattice phonons at three temperatures. It shows a systematic trend towards higher frequencies in all these motions on going from room to liquid nitrogen temperature. Since it is known (14, 15) that cooling changes the molecular packing in crystals, because of the contraction of the unit cell constants, such a systematic increase in frequency at the lower temperatures is attributed to anharmonicity factors on the effective force constants and to an increase of the interaction force constants among the molecules in the lattice potential energy function.

The nine lattice motions having nonzero frequencies at the centre of the first Brillouin zone are, of course, mixed modes. Three of these have the character of nonpure translations of the two molecules out-of-phase (those in-phase constitute the three acoustical branches), and six are nonpure librations due to factor group coupling. The Raman modes have gerade representations and thus, with $Z = 2$, can have translation components with change of polarizability of the unit cell. The three molecular nonpure librations are separated into three a_g (Raman active) and three a_u (infrared active) representations, leading to the tentative pairing of the relevant frequencies: ω_2 with ω_3, ω_5 with ω_6, and ω_7 with ω_8. The frequency separation between infrared and Raman modes is, for all three pairs, of 8 wavenumbers, in quite good agreement with the average frequency separation of motions observed in the mid-frequency region.

The last point we wish to discuss is that connected with parameters such as intensities and half-band widths of these modes. We must expect this latter parameter to decrease systematically from room to liquid nitrogen temperature, as a result of a better definition of the energy values of the excited vibrational states (uncertainty principle). However, we do not observe a regular decrease of the half-band widths, whereas the variation with temperature of the peak intensities seems to be quite regular, being proportional to $(v + 1)$ and increases with temperature. This behaviour might be connected to the systematic variations of the band areas. The freezing, in this case, of the lattice type motions will produce a decrease in the mode amplitudes and consequently in the polarizability variations. This can provide a good explanation of the systematic reduction of the band areas of the Raman lines.

The siderophore pyochelin, identified for the first time as a metabolite of *Pseudomonas fluorescens*, was isolated in highly pure form as a dimeric complex with two zinc atoms. The ^{1}H and ^{13}C magnetic resonance data for the two pyochelin moieties of the complex differ significantly from each other and from those of free pyochelin. The complex also exhibits unusual solubility and stability properties. Since it is easily isolable and can be readily converted into highly pure, free pyochelin, it offers an excellent entry to further biological studies on this important metabolite.

DIANE A. CUPPELS, ROBERT D. STIPANOVIC, ALBERT STOESSL et J. B. STOTHERS. Can. J. Chem. **65**, 2126 (1987).

La pyochéline sidérophore a été identifiée pour la première fois comme un métabolite du *Pseudomonas fluorescens*; on l'a isolée à l'état pur sous la forme d'un complexe dimère contenant deux atomes de zinc. Les données de la résonance magnétique nucléaire du ^{1}H et du ^{13}C pour chacune des deux portions du complexe de la pyochéline ainsi que pour la pyochéline libre diffèrent beaucoup entre elles. Le complexe présente aussi des propriétés inhabituelles tant au point de vue de la solubilité que de la stabilité. Puisqu'on peut facilement l'isoler et qu'on peut facilement le retransformer en pyochéline très pure, ce complexe offre une excellente porte d'entrée vers d'autres études biologiques de ce métabolite important.

During the course of a recent biosynthetic study (1) of the antibiotic and phytotoxic pyoluteorin (**1**) from a culture of *Pseudomonas fluorescens*, we obtained another highly fluorescent substance in microcrystalline form and in relatively substantial yield. After extensive ^{1}H and ^{13}Cmr studies of this material, the various carbon–hydrogen part structures were identified and, with additional evidence concerning functional groups, it became apparent that the substance was a metal complex of pyochelin (**2***a*), a recently reported siderophore from *Pseudomonas aeruginosa* (2, 3). This conclusion was confirmed by the ready conversion of the complex into **2***a* and its methyl ester **2***b*. The complex itself, however, is inherently interesting and we wish to describe its properties and our structural studies in some detail in this paper.[3]

The complex separated as a granular powder on concentration of vividly fluorescent fractions eluted after **1**, from a column of TLC grade silica by MeOH–$CHCl_3$–HOAc (10:90:1). After trituration with MeOH, the product was essentially pure as judged by comparison of its ir and nmr spectra with those obtained for a more extensively purified analytical sample. The latter gave combustion results that were in excellent agreement with the values for C, H, and N calculated for $C_{28}H_{28}N_4O_6S_4M_x$ or $C_{28}H_{30}N_4O_6S_4M_x$; values for O and S were within acceptable limits. By difference, these figures also indicated an approximate value for M_x as 17%; ashing, determination of the equivalent weight by titration with 0.1 *M* HCl, paper chromatography, and the volatility of the resulting chloride at red heat tentatively identified M_x as Zn_2. Atomic absorption spectrometry of the complex confirmed this conclusion both qualitatively and quantitatively.

The ^{1}Hmr spectrum of the complex contained separately resolved patterns for 15 protons, two multiplets arising from three and four protons, respectively, and two methyl singlets, δ 2.62, 2.64, ascribable to N-Me groups. The ^{13}C spectrum

exhibited signals for 28 nonequivalent carbons and the number of protons bonded to each was revealed by a DEPT spectrum (5), which also clearly revealed the two methine signals, δ_C 77.6, 77.9, partially obscured by the solvent absorption in the normal spectrum. A ^{1}H–^{1}H correlation (COSY) spectrum (6) permitted a complete analysis of the proton patterns and a ^{13}C–^{1}H correlation spectrum (7) led directly to six part structures. These consist of two aryl fragments **A** and **B** and four saturated units **C**–**F** with the N-Me carbons at δ_C 45.8 and 46.1 and four additional fully substituted carbons at δ_C 174.1, 176.2, 177.6, and 178.4.

Attempted methylation of the complex with CH_2N_2 gave an intractable product but treatment with methanolic HCl under mild conditions afforded two crystalline compounds. One, obtained in high yield (ca. 2 mol based on a molecular weight of 774 for the complex), was an amino acid hydrochloride, identified as either *N*-methylcysteine methyl ester hydrochloride or its autoxidation product, *N*,*N*′-dimethylcystine dimethyl ester hydrochloride, from its ^{1}Hmr spectrum (see Experimental). This substance decomposed before it could be studied further and a second attempt to isolate it failed, for

[a]Shieldings in ppm from internal TMS for $CDCl_3$ solutions: columns A from ref. 3, columns B this work; similar values in parentheses may be interchanged. ^1H–^1H couplings in Hz listed in square brackets.
[b]Signal masked by $CDCl_3$ absorption.

reasons that are unclear. Unfortunately this precluded determination of its configuration. As models, L-*N*,*N*′-dimethylcystine and L-*N*-methylcysteine were prepared according to literature procedures (8) and their proton data strongly favored formulation of the degradation product as the monomer. However, attempts to convert the authentic compounds into their methyl ester hydrochlorides by treatment with methanolic HCl gave only ill-defined products. In the meantime, other evidence had rendered a rigorous identification of the degradation product unnecessary and these problems were not pursued further.

The second methanolysis product, obtained in only small quantity, had the constitution $C_{10}H_7NO_2S$ according to precise mass measurements and its structure was readily shown to be that of aeruginaldehyde (**3***a*) from its uv, ^1H, and ^{13}C spectra. The uv and proton data were in close agreement with those for aeruginoic acid (**3***b*), which has been described as a metabolite of *P. aeruginosa* (9). In further confirmation of structure **3***a*, the compound gave an intensely yellow spot on tlc with 2,4-dinitrophenylhydrazine as spray reagent and was readily reduced by sodium borohydride to furnish, upon acetylation, the diacetate **3***c* with the requisite ^1Hmr spectrum (see Experimental).

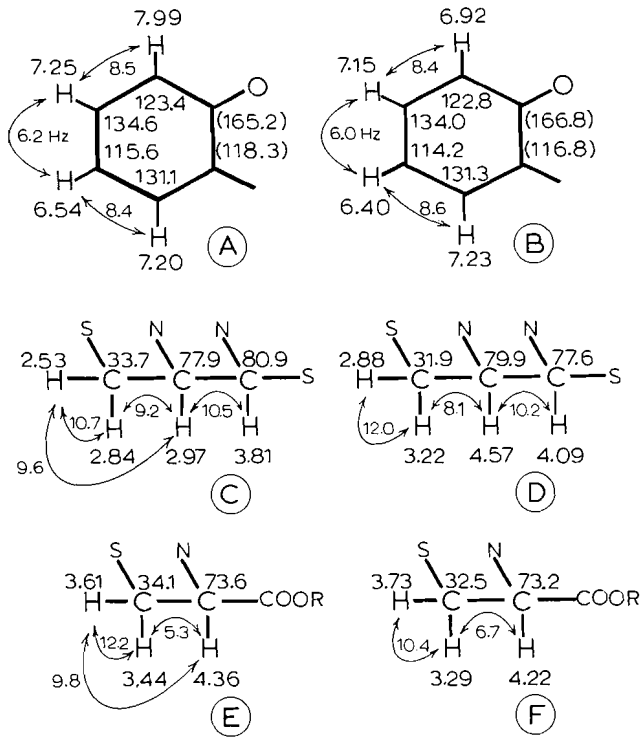
When a solution of the complex in $CHCl_3$ was briefly shaken with 0.01 *M* HCl, the organic phase furnished a syrup with the uv, ^1H, and ^{13}C spectra corresponding to those reported for pyochelin (2, 3). Methylation of this product with CH_2N_2 gave a methyl ester whose ^1H and ^{13}Cmr parameters agreed closely with those reported for **2***b* (3). Our nmr data are collected in Table 1 together with those reported previously for **2***a* and **2***b*. In the earlier report, no ^1H–^1H coupling constants were given for **2***a*, which also contained an unidentified contaminant. However, we found that the components of the various multiplets could be clearly resolved and the coupling constants readily determined; the coupling interactions were confirmed with a ^1H–^1H COSY spectrum and a decoupling experiment. With a complete analysis of the ^1H spectrum, the ^{13}C assignments listed in Table 1 were definitively determined from a ^{13}C–^1H heteronuclear correlation spectrum. A complete analysis of the proton spectrum of **2***b* was straightforward and a ^{13}C–^1H correlation spectrum led to the unequivocal ^{13}C assignments listed in Table 1.

A sample of the zinc-free product obtained by treatment of the complex with dilute HCl was passed through a column of silica as in the original isolation of the complex and found to yield the original complex as judged by the ^1H spectrum of the eluted material. In a supplementary experiment, a small amount of the complex in chloroform was shaken with a 1% solution of HOAc in water. The product from the organic phase was a 2:5 mixture of the complex and free **2***a*, as estimated from the proton spectrum. The constitution of the complex as $(pyochelin)_2Zn_2$ was therefore established beyond doubt but several additional points merit discussion.

The ready conversion of pyochelin into the complex on SiO_2 indicated that the original isolate was probably an artifact of chromatography. This was confirmed by extracting a fresh batch of bacterial cultures with EtOAc both before and after acidification. Both extracts exhibited uv spectra characteristic of a mixture of **1** (λ_{max} 255, 310 nm) and free **2***a* (λ_{max} 250, 310 nm) without detectable peaks or shoulders ascribable to the complex (λ_{max} 264, 359 nm), but the latter was obtained upon chromatography of the combined extracts over SiO_2. The source of the zinc is almost certainly a zinc salt, the supposedly inert but otherwise unspecified phosphor, incorporated into the silica by the manufacturers. Elution of a sample of the silica with a volume of solvent approximately equivalent to that used in the isolation of the complex furnished only about 20% of the zinc eluted as the pyochelin complex in the main experiment, thereby implying a high affinity of pyochelin for this metal.

A more difficult question is the manner in which the part structures **A**–**F** are combined to form two pyochelin moieties since no long-range proton interactions were resolved in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.



^{1}H spectrum. However, the COSY spectrum of the complex revealed weak cross-peaks (off-diagonal elements) for the pair of protons at δ 3.81 and 4.36 and for those at δ 4.09 and 4.22 signalling weak long-range interactions between H-2″ and H-4″ in each of the thiazolidine rings, thereby correlating part structure **C** with **E**, **D** with **F**, and identifying the linked pairs of thiazolidine and thiazoline rings in the two moieties; but no evidence was available through which we could assign **A** or **B** to the **C**–**E** or **D**–**F** fragments.

Thirdly, it remained to determine the nature of the binding of zinc to the pyochelin units. At this stage, only a partial answer to this question can be presented. The ir spectrum of the complex, in $CHCl_3$, shows no strong absorption in the 1650–1800 cm^{-1} region that could be attributed to free carboxyl or ester. On the other hand, strong absorption at 1592 cm^{-1} indicated that both carboxyl groups are present in ionized form. This does not necessarily imply that the zinc atoms are in close proximity thereto. In the uv spectrum, the band at 359 nm undergoes a hypochromic shift on acidification, clearly because of liberation of pyochelin, but no significant bathochromic shift is observed on addition of alkali.[4] This implies that at least one of the phenolic hydroxyls is ionized while the other is either ionized or coordinately bonded to zinc. The ^{1}Hmr spectrum does not resolve this question. The proton *ortho* to oxygen in the aryl fragment **A** absorbs at anomalously low field, δ 7.99, which is 1 ppm downfield from the corresponding protons in **2***a*, **2***b*, **3***a*, and the second pyochelin moiety of the complex. Direct comparison with a model phenol and its phenolate was not possible with the $CDCl_3$ solvent used. The only readily available information from the literature indicated that ionization of phenols produces a small upfield shift of the *ortho* protons (10). In a model experiment, we found pronounced upfield shifts for all aryl protons of salicyl alcohol in DMSO-d_6 – 1 *M* NaOH (4:1) relative to its equimolar solution in DMSO-d_6–H_2O (4:1) (see Experimental). A direct comparison with the complex and pyochelin in these solvents was not possible because of apparent decomposition of the complex, even in DMSO-d_6–H_2O alone. Fortunately, the ^{13}C spectrum was more informative. The shieldings of both oxygen bearing carbons of the complex are similar (δ_C 165.2, 166.8), and both absorb distinctly downfield from the corresponding signals for **2***a* (δ_C 159.0) and **2***b* (159.0). Similar differences are found for the protonated aryl carbon *ortho* to oxygen (C-3) while the C-5 signals, *para* to oxygen, are shielded by 3–5 ppm in the complex relative to **2***a* and **2***b*. These trends are similar to those recently reported for the *ipso*, *ortho*, and *para* carbons in a series of phenols upon deprotonation (11). It is interesting that only one of the substituted carbons *ortho* to oxygen in the complex exhibits an appreciable downfield shift relative to the shielding of this carbon (C-1) in **2***a*. Furthermore, the imino and carboxyl carbons in the complex, δ_C 174.0, 176.1, 177.4, and 178.4, are downfield from the corresponding signals in **2***a*, δ_C 172.1, 173.8. The most probable explanation of the sum of these data is that the hydroxyl and carboxyl groups are ionized and the *ortho* hydrogen of part structure **A** is strongly and differentially shielded by spatial proximity to zinc or other functional group. It may be noted that the relative orientations of the thiazolidine and thiazoline rings in the two pyochelin moieties in the complex must differ from that in pyochelin itself since the vicinal couplings between H-2″ and H-4′ are 10.2 and 10.5 Hz in the complex but only 7.7 Hz in **2***a* (5.1 Hz in **2***b*). It seems curious that no vicinal coupling was resolved for one of the methylene protons in each of the rings containing fragments **D** and **F** while significant vicinal interactions were apparent for each of the corresponding methylene protons in **C** and **E** as well as **2***a* and **2***b*.

During the final stages of preparation of this manuscript, a report appeared (12) describing the formation, upon SiO_2 chromatography, of an aluminum complex of 2-hydroxy-4-methoxy-5-methylpyridine-*N*-oxide, a siderophore of *Pseudomonas cepacia*. The authors comment, as we have (4), that the binding of siderophores to cations other than Fe^{3+} may have biological significance.

Experimental

Mass spectra were obtained with a Varian MAT 311A system, uv spectra on EtOH solutions with a Shimadzu 240 uv, and ir spectra on $CHCl_3$ solutions with a Pye–Unicam PU9516 spectrophotometer. The ^{1}Hmr spectra were recorded with Varian XL-200 and -300 systems on $CDCl_3$ solutions with TMS as internal reference while ^{13}C spectra were determined with the XL-300 system employing $CDCl_3$ solutions. The number of protons on individual carbons was assessed using the DEPT sequence (5) whereby the signals for methylene carbons are 180° out of phase with the methine and methyl peaks and those for fully substituted carbons are nulled. The ^{1}H and ^{13}C nmr spectra were independent of concentration over a 5-fold range, 5–25 mg/0.4 mL. Homonuclear ^{1}H–^{1}H correlation spectra were obtained using the HOMCOR sequence of the XL software with a 1024 × 512 data point matrix transforming 1024 points in both domains using a spectral width of 1 kHz (**2***a*, XL-200) and 1.8 kHz (Zn complex, XL-300) in both domains. The heteronuclear ^{13}C–^{1}H correlation spectra were recorded with the XL-300 utilizing the HETCOR sequence of the XL software using a 2048 × 128 data matrix, transforming 2048 and 512 points across spectral widths of 8.2 kHz for ^{13}C and 1.8 kHz for ^{1}H, respectively.

Unless otherwise indicated, all solvents were redistilled before use; EtOH was the 95% product. Macherey–Nagel Polygram Sil G/UV_{254} 0.25-mm sheets were used for tlc and SiO_2 (Camag DFO) for column chromatography, with MeOH–$CHCl_3$–HOAc (10:90:1) as solvent.

[4]However, a significant bathochromic shift was observed on rendering the acidified solution alkaline.

Evaporations were done at water aspirator pressures. Melting points were determined on a Kofler apparatus and are uncorrected. Microanalyses were carried out by Guelph Chemical Laboratories Ltd.

Isolation and properties of the pyochelin–zinc complex

Pseudomonas fluorescens Pf5 was grown for two days on King's B broth (16 × 40 mL) and harvested as described previously (1) except that the cultures were not amended with sodium acetate. The EtOAc extracts obtained from four batches of the centrifuged and acidified culture media were combined (800 mg) and chromatographed (25-mL fractions) over SiO_2 (500 g) that had been packed from ca. 1 L and then prewashed with another 4 L of the standard solvent. Pyoluteorin (**1**) was eluted in fractions 40–45 and the pyochelin–zinc complex in fractions 58–72 (tlc). The latter were combined, the solvent evaporated, and the solid residue triturated with MeOH (10 mL). The product was removed by filtration and washed with several small portions of MeOH to give practically pure complex (117 mg), identical by ^{1}H and ^{13}Cmr with material initially isolated in the biosynthetic experiments (1).[5]

An analytical specimen was prepared by washing the above material (34 mg) in $CHCl_3$ (10 mL) with water (2 × 2 mL) and reextracting the aqueous phase with $CHCl_3$ (10 mL). The material obtained from the combined filtered $CHCl_3$ layers by evaporation was precipitated from $CHCl_3$ (0.2 mL) by dropwise addition of MeOH (2 mL) to give pure complex (26 mg after drying *in vacuo* at room temperature for 24 h).

Ultraviolet spectrum, λ_{max} (ϵ): 359 (13 800), 264 (19 800), and 244 (44 600) nm; λ_{max} (EtOH/$^+$H): 311 (10 200), 250 (22 900), and 210 (46 200); λ_{max} (EtOH/$^-$OH): 361 (12 900), 262 (19 700), and 221 (46 200) when determined immediately but after 1 h, following the addition of alkali, λ_{max}: 354 (12 000), 252 (19 700), and 220 (sh) (40 900). Similar values were obtained for the alkaline solution after 3.5 h but very extensive decomposition was apparent when the spectrum was examined 3 days later. After treatment of the acidified solution (1 drop of 0.1 *M* HCl) with a small excess of 0.1 *M* NaOH (2 drops), λ_{max}: 368 (10 900), 255 (18 200), and 220 (40 200). Infrared spectrum ($CHCl_3$): 2840 (w), 2700–2800 (vw), 1670 (m), 1657 (sh), 1608, 1592 (vs), 1573, 1463, 1440, 1402, 1400, 1361, 1331, 1310, 1152, 1143, 1134, 1090, 1035, 976, 964, and 952 cm^{-1}. *Anal.* calcd. for $C_{28}H_{28}N_4O_6S_4Zn_2$: C 43.36, H 3.64, N 7.22, O 12.38, S 16.53, ash (as ZnO) 20.99, Zn 16.86; calcd. for $C_{28}H_{30}N_4O_6S_4Zn_2$: C 43.25, H 3.89, N 7.21, O 12.35, S 16.49, ash 20.93, Zn 16.81; found: C 42.98, H 3.83, N 7.23, O 13.75, S 15.13, ash 18.3, Zn (atomic absorption) 16.67.

The complex was readily soluble in $CHCl_3$ when obtained by evaporation of a water-washed solution but, when dry, required a small drop of MeOH for complete solution. It was precipitated on addition of more MeOH and was practically insoluble in EtOH, Me_2CO, and C_6H_6. Dilute solutions for uv measurements were effected only by prolonged heating. The complex dissolved in hot EtOAc but, on cooling, separated in amorphous form that was not further investigated.

Methanolysis of the complex

A solution of the complex (16 mg, 0.02 mmol) in MeOH (5 mL) containing HCl (3.8%) was evaporated after standing at room temperature for 1 day. After repeated reevaporation from MeOH–$CHCl_3$, the product was dissolved in $CHCl_3$ (ca. 2 mL) on addition of just sufficient MeOH. After standing in an open flask for ca. 2 h, a crystalline substance separated (product **A**, 7.8 mg). The residue obtained by evaporation of the mother liquors was dissolved in $CHCl_3$, washed with water, reevaporated, and chromatographed over SiO_2 (15 g) with $CHCl_3$ (2-mL fractions). Fraction 18 (2.8 mg) crystallized from MeOH upon addition of water to turbidity and refrigeration (product **B**, 2 mg, mp 60–63.5°C).

Product A

After washing with $CHCl_3$, this methyl ester (see text) had mp 174–175°C; R_f 0.34 on Whatman No. 1 paper in *n*-BuOH–H_2O–HOAc (4:5:1) (weak purple to ninhydrin); only end absorption in the uv spectrum; ^{1}Hmr (D_2O) δ: 4.37 (t, $J \sim 5$ Hz, 1H), 3.75 (s, 3H, OMe), 3.44 (dd, $J = 4.6$, 15.6 Hz, 1H), 3.26 (dd, $J = 5.5$, 15.6 Hz, 1H), and 2.68 (s, 3H, N-Me). On standing three days in D_2O the substance had decomposed to several products (deposition of solid, paper chromatography). A portion of the residue obtained upon evaporation of the solvent was ignited with sodium, the product giving strongly positive reactions in the standard tests for N, S, and Cl^-.

L-*N*,*N*′-Dimethylcystine, prepared from L-thiazolidine carboxylic acid (1.66 g) as described in the literature (8), had mp 221°C (dec.) (capillary inserted at 210°C, lit. (8) mp 217–219°C); ^{1}Hmr (D_2O) δ: 3.80 (t, $J \sim 6$ Hz, 1H), 3.19 (d, $J = 6$ Hz, 2H), 2.61 (s, 3H).

L-*N*-Methylcysteine, prepared from the cystine derivative (8), had mp 233–233.5°C (dec.) (capillary inserted at 220°C, lit. (8), mp 228–229°C); ^{1}Hmr (D_2O) δ: 4.11 (dd, $J = 4.4$, 6.1 Hz, 1H), 3.43 (dd, $J = 4.4$, 15.4 Hz, 1H), 3.34 (dd, $J = 6.1$, 15.4 Hz, 1H), 2.65 (s, 3H).

Product B

Recrystallization from cyclohexane gave aeruginaldehyde, mp 135–135.5°C; ir ($CHCl_3$): 3120, 3050, 3020, 2050, 1701 (s), 1622, 1582, 1481 (s), 1270, 1160, 1138, 1012, 946 cm^{-1}; λ_{max} (EtOH): 321 (7 800), 280 (8 500), 212 sh (13 000), and 203 (14 300); (EtOH/$^-$OH): 367 (10 300), 278 (10 600), 237 (22 500), 206 (75 000); ^{1}Hmr ($CDCl_3$) δ: 10.03 (s, 1H, -CHO), 8.12 (s, H-5), 7.62 (dd, $J = 1.5$, 7.9 Hz, H-6), 7.37 (ddd, $J = 1.5$, 7.4, 8.4 Hz, H-4′), 7.09 (dd, $J = 1.2$, 8.4 Hz, H-3′), 6.94 (ddd, $J = 1.2$, 7.4, 7.9 Hz, H-5′; ^{13}Cmr ($CDCl_3$) δ_C: 183.3 (CHO), 118.2, 119.8, 125.1, 127.6, 132.9 (5 × aryl CH), 116.0, 153.5, 156.8, 163.0 (4 × aryl C). *Exact Mass* calcd. for $C_{10}H_7NO_2S$: 205.0197; found: 205.0192.

The compound (0.5 mg) in MeOH (0.5 mL) was treated with a few crystals of $NaBH_4$ at room temperature and reaction was complete almost immediately (tlc). After the addition of water and a drop of HOAc, the product was extracted into $CHCl_3$, the solvent evaporated, and the residue acetylated with a few drops of Ac_2O–C_5H_5N (2:3) overnight. Preparative tlc (precoated plate, Baker 1007-4) in MeOH–$CHCl_3$–HOAc (5:95:1) gave the diacetate of the reduction product as an oil, homogeneous on tlc; ^{1}Hmr ($CDCl_3$) δ: 8.22 (dd, $J = 1.8$, 7.5 Hz, H-3′), 7.46 (dt, $J = 1.8$, 7.5 Hz, H-5′), 7.38 (t, $J = 0.8$ Hz, H-5), 7.35 (dt, $J = 1.5$, 7.5 Hz, H-4′), 7.22 (dd, $J = 1.5$, 7.5 Hz, H-6′), 5.30 (d, $J = 0.8$ Hz, -CH_2O-), 2.44 (s, 3H, ArOAc), 2.15 (s, 3H, OAc). Assignments were confirmed by irradiation at δ 8.22, which produced doublets of doublets at δ 7.46 ($J = 7.5$, 7.8 Hz), 7.35 ($J = 1.5$, 7.5 Hz), and 7.22 ($J = 1.5$, 7.8 Hz).

Interconversions of the complex and pyochelin

The complex (10.9 mg) in $CHCl_3$ (10 mL) was shaken for 2 min with 0.01 *M* HCl (10 mL). The aqueous layer was extracted with more $CHCl_3$ (2 × 4 mL), and the organic phases were washed in turn with water (2 × 2 mL), combined, and evaporated to furnish a fluorescent syrup (9.6 mg) identified as pyochelin (**2***a*) by the spectral data; ir ($CHCl_3$): 1767 (vs), 1725 (sh), 1620, 1590, 1564, 1490, 1452, 1355, 1295, 1152, 1118, 949, 904 cm^{-1}; λ_{max} (EtOH): 312 (9 900), 250 (22 200), 210 (48 100); λ_{max} (EtOH/$^-$OH): 348 (14 600), 250 (26 700), 220 (55 500); ^{1}Hmr and ^{13}Cmr (see Table 1).

Methylation of the product (4.8 mg) as reported (3) gave **2***b*, the ^{1}H and ^{13}Cmr data for which are collected in Table 1.

Another portion (2.9 mg) of **2***a* obtained above was chromatographed in 5-mL fractions over SiO_2 (4 g) packed in 20 mL and prewashed with 25 mL of the standard solvent. The material (~3 mg) eluted in fractions 4 and 5 was substantially pure complex as judged by its ^{1}Hmr spectrum. In a second experiment, the centrifugate obtained from a fresh batch of cultures (16 × 40 mL) was divided into two equal portions; one (pH 7.2) was extracted with EtOAc (3 × 300 mL) while the second was acidified with 2 *M* HCl (40 mL) before extraction. After evaporation, dissolution in EtOH, and dilution to 1 L, the two extracts exhibited λ_{max} 310 (d 0.205), 250 (0.335), and 222 (0.78) and λ_{max} 310, 290 (sh), 250, 211 (d 0.63, 0.56, 1.20, 2.92), respectively. The extracted centrifugate, pH 7.2, was then acidified with HOAc and reextracted similarly, to give a solution (1 L) with λ_{max} 310, 250, 209 (d 0.092, 0.68, 1.92). Further acidification with 2 *M* HCl and extraction gave material with only ill-defined absorption bands. The

[5]Both in the biosynthetic and several other runs, the highly pure complex separated directly on concentration of the appropriate fractions.

first pair of extracts were combined and chromatographed over SiO_2 (100 g) in the usual way to furnish the complex (8.8 mg after washing in, and precipitation from, $CHCl_3$), identified by the ^{1}Hmr spectrum.

A solution of pure complex (3.6 mg) in $CHCl_3$ (4 mL) was shaken for 2 min with 0.1 *M* Na_2CO_3 (2 mL) and then water (2 × 2 mL) and the aqueous layers were extracted in sequence with $CHCl_3$ (3 × 2 mL). The material obtained upon evaporation of the solvent from the combined $CHCl_3$ layers exhibited the ^{1}Hmr spectrum of the complex.

Another sample of the pure complex (3.5 mg) was shaken with 1% HOAc (2 mL) and worked up as described above. The proton spectrum of the product (3.1 mg) corresponded to that of a mixture of complex and free **2***a* in a 2:5 ratio.

In a control experiment, a column of SiO_2 (50 g) was packed in, and washed with, the standard solvent until 400 mL had been collected. Another 200 mL of solvent was then percolated through the column and collected separately. The first eluate, after washing and reevaporation from 2 *M* HCl, contained only a barely detectable trace of zinc (paper chromatography). The material (ca. 5 mg) similarly obtained from the second eluate contained 0.35 mg of Zn (atomic absorption).

Formation of ferripyochelin

The complex (1 mg) was distributed between EtOAc (3 × 5 mL) and aqueous $FeCl_3$ (0.1%, 3 × 5 mL). The EtOAc layers were washed with water (3 × 0.8 mL), combined, and evaporated to give free **2***a* (0.16 mg) as estimated from the uv spectrum. The extracted $FeCl_3$ layers and washings were combined, strongly acidified (0.8 mL, 2 *M* HCl), and extracted with EtOAc (4 × 10 mL). On attempted washing with water (2 × 0.8 mL), much of the red color of the extracts passed into the water but was reextracted on acidification (0.05 mL, 2 *M* HCl) of the combined washings. After washing with another portion of HCl (1 mL, 0.1 *M*), the EtOAc extracts were combined, diluted with EtOH, and evaporated. The product exhibited an uv spectrum (λ_{max} 520, 420 sh, 320, 255, 232, and 213 nm) very similar to that reported for ferripyochelin (λ_{max} 520, 425, 325, 255, and 237 nm), in an amount corresponding to 0.38 mg as estimated from the published data (2).

Alkali-induced ^{1}Hmr shifts in salicyl alcohol

Salicyl alcohol (**4**) (12.4 mg, 1.0 mmol) exhibited a spectrum in DMSO-d_6 (0.4 mL)/H_2O (0.1 mL) solution containing signals at δ 8.28 (dd, J = 1.7, 7.2 Hz, H-6), 8.09 (dt, J = 1.7, 7.5 Hz, H-4), 7.82 (dt, J = 1.1, 7.5 Hz, H-5), 7.79 (dd, J = 1.1, 7.8 Hz, H-3), and 5.28 (s, 2H, CH_2O) and, in DMSO-d_6 (0.4 mL)/NaOH (0.1 mL, 1 *M*), these signals appeared at δ 7.76 (m, 2H, H-4, -6), 7.30 (dd, J = 1.2, 8.4 Hz, H-3), 7.14 (dt, J = 1.2, 7.2 Hz, H-5), and 5.35 (s, 2H, -CH_2O-).

The proton spectrum of the complex (3 mg) in DMSO-d_6–H_2O showed only a few broad absorption bands that bore little, if any, resemblance to the features of the $CDCl_3$ spectrum.

Photochemistry of dibenzylketone in Nafion membranes[1]

V. WINTGENS AND J. C. SCAIANO

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received January 14, 1987

V. WINTGENS and J. C. SCAIANO. Can. J. Chem. **65**, 2131 (1987).

Photolysis of dibenzyl ketone in vacuum-dried Nafion membranes leads to the detection of fluorescence from the protonated ketone and formation of modest yields of benzyl cations characterized using laser photolysis techniques. Exchange of the acid sites in Nafion by cationic surfactants leads to decreased environmental polarity and a change in mechanism towards the benzyl radical chemistry which is common in organic solvents. The decay of benzyl radicals in Nafion membranes shows magnetic field dependence which indicates that geminate processes play an important role.

V. WINTGENS et J. C. SCAIANO. Can. J. Chem. **65**, 2131 (1987).

La photolyse de la dibenzyl cétone, adsorbée sur membranes Nafion déshydratées sous vide, conduit à la détection de la fluorescence de la cétone protonée et à la formation en faible quantité de cations benzyliques, caractérisés par l'intermédiaire de techniques de photolyse laser. Lorsque les sites acides de la membrane Nafion sont échangés avec des surfactants cationiques, la polarité du milieu diminue, et le mécanisme change pour la chimie du radical benzylique, habituellement observée dans les solvants organiques. La décroissance du radical benzylique dans les membranes Nafion dépend du champ magnétique appliqué, indiquant que les processus géminés jouent un rôle important.

Introduction

The photochemistry of dibenzylketone (DBK) has been examined in several solvents (1) and leads to the efficient formation of 1,2-diphenylethane as the only major product. The product is formed by reaction of the benzyl radicals, which are generated in two ways, in the Norrish type I reaction from the triplet state of DBK, and in the decarbonylation of the phenylacetyl radicals, i.e.:

[1] $PhCH_2COCH_2Ph \xrightarrow{h\nu} {}^3PhCH_2COCH_2Ph^*$

[2] ${}^3PhCH_2COCH_2Ph^* \rightarrow PhCH_2^{\cdot} + PhCH_2CO^{\cdot}$

[3] $PhCH_2CO^{\cdot} \rightarrow PhCH_2^{\cdot} + CO$

[4] $PhCH_2^{\cdot} + PhCH_2^{\cdot} \rightarrow PhCH_2CH_2Ph$

The decarbonylation reaction is a very fast process (2, 3); the lifetime of $PhCH_2CO^{\cdot}$ is 190 ns at 300 K in methanol (3). In homogeneous solution, this reaction is usually quantitative, but instances of intermolecular reactions of the phenylacetyl radical are common in micellar and zeolite systems (4–6) where the geminate radical pairs tend to be relatively long lived. These reactions have also been used to study the influence of a solid matrix on the photochemistry of DBK (5, 7).

In a recent paper, two ketones, benzophenone and xanthone (8), have been used as probes for polarity and acidity of Nafion membranes. We report here the results of a study of the DBK photochemistry in Nafion membranes in their acid form and in membranes exchanged with cationic surfactants.

Nafion membranes provide a very peculiar type of environment. They consist of a perfluorinated carbon backbone with pendant chains terminated in sulfonate head groups which are responsible for their ion exchange and swelling properties. The photochemistry of several other systems has been reported in Nafion membranes, including pyrene (9), $Ru(bpy)_3^{2+}$ (10), semiconductors (11), and other organic substrates (12).

This work on the photochemistry of DBK incorporated into Nafion membranes clearly shows that the process leads to chemical consequences quite different from those observed in homogeneous or micellar solution, or in zeolite systems (1–7).

[1]NRC No. 27493.

Experimental

Nafion 117 membranes (0.007 in.) and Nafion powder (10–35 mesh) were purchased from Aldrich. They were washed by refluxing with methanol, and then dried at room temperature under vacuum.

The membranes were swollen with 5×10^{-2} *M* DBK in water–methanol (1:1) solution, or with 0.01 *M* DBK in a 0.1 *M* aqueous solution of surfactant. Several hours are necessary to get enough adsorption by DBK in the Nafion membranes. Then, they were washed with methanol, dried in air, and positioned in 7×7 mm^2 Suprasil cells. The samples were deaerated by a nitrogen stream, or under vacuum.

Ultraviolet–visible and fluorescence spectra were recorded using an HP-8451-A diode array spectrometer and a Perkin-Elmer LS-5 spectrofluorimeter, respectively.

The laser flash photolysis experiments were carried out using the pulses (308 nm, ~4 ns, ≤60 mJ/pulse) from a Lumonics TE-860-2 excimer laser filled with Xe–HCl–He mixtures; the samples were positioned at 45° with respect to both the excitation and monitoring beams. Further details on the experimental set-up have been reported elsewhere (13). Transient spectra were recorded using an E.G.&G. gated intensified optical multichannel analyzer equipped with a model 1420 detector.

The preparative experiments were carried out using both the Nafion membrane (prepared as described before) and Nafion powder. The pellets were swollen with only the necessary volume of 5×10^{-3} *M* DBK solution in methanol to get a gel-like material. They were gently outgassed by a nitrogen stream, or under vacuum. The excitation light used was centered around 300 nm (RPR-300 lamps). After desorption by methanol the products were detected by GC using a Perkin-Elmer 8320 capillary instrument. We noted in all cases a small percentage of products with short retention time, but high molecular weight, probably due to perfluorinated fragments released by the photo-irradiated membrane.

Pyrene was used as a probe to study the surfactant exchanged membrane Nafion. The ration (I_3/I_1) for the fluorescence bands depends on the medium polarity, and can give interesting information about the microenvironment (9). The detailed description of this well-known technique is beyond the scope of this paper.

The membranes were swollen in saturated pyrene–water solution, or in 5×10^{-6} *M* pyrene in surfactant solution (1×10^{-2} *M* dodecyltrimethylammonium chloride = DTAC). They were then rinsed with methanol, dried in air, and positioned in 7×7 mm^2 Suprasil cells. The fluorescence spectra were recorded before and after the samples were degassed under vacuum.

For the pyrene–Nafion membranes, the I_3/I_1 ratios are of the order of 0.85 and 1.2 for wet and dried samples, respectively; these values

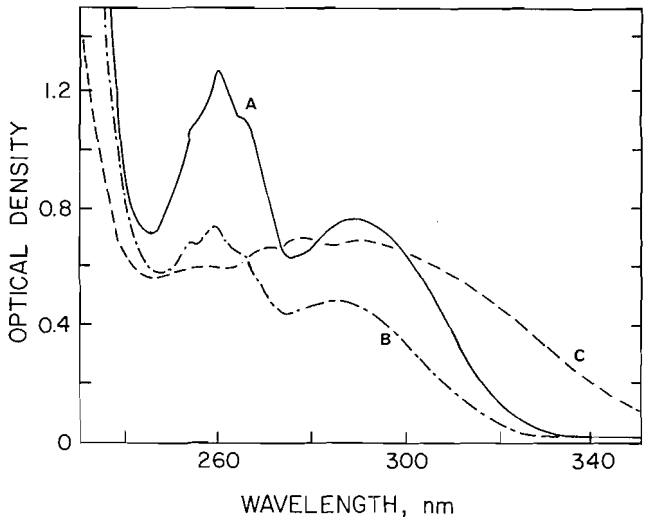

FIG. 1. Ground state absorption of DBK in methanol (*A*), H-Nafion (*B*), and H_2SO_4 (*C*).

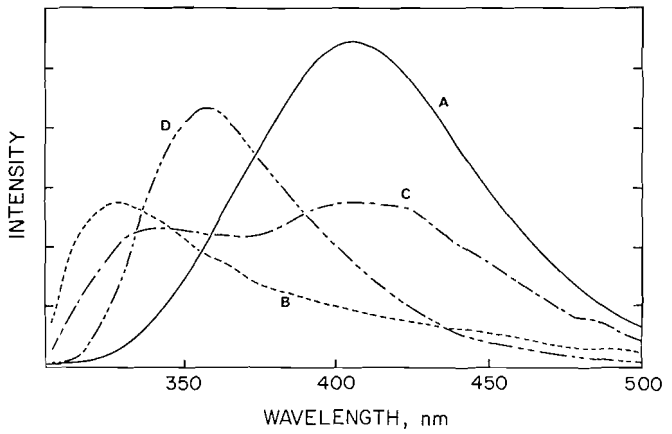

FIG. 2. Fluorescence spectra of DBK in methanol (*A*), H-Nafion (*B*), DTAC exchanged Nafion (*C*), and H_2SO_4 (*D*).

are close to those reported in the literature (9). The I_3/I_1 increase reflects the decrease of the microenvironment polarity after the loss of water. However, in the case of the system pyrene–DTAC–Nafion, the ratio remains constant at 0.9, even after several hours under vacuum. The probe does not see any change in its microenvironment; it seems that it is "protected" by the surfactant, which acts as a "shelter". Interestingly, the I_3/I_1 value compares well with that obtained independently in DTAC micelles.

Results and discussion

Absorption spectra

The absorption spectrum of DBK on the acid form of Nafion (H-Nafion) is very similar of those recorded in organic solvents; a red shift is observed in sulfuric acid (see Fig. 1). This result is similar to those for xanthone and benzophenone (8), where the acidity of the membrane is not enough to protonate the ground state of the ketone.

Fluorescence spectroscopy

The weak fluorescence emission from DBK in H-Nafion is quite different from that typically observed in homogeneous solution. This is a clear indication of protonation of the DBK excited singlet state; similarly, xanthone and benzophenone are also protonated (and fluoresce) under these conditions (8). Figure 2 shows a comparison of the fluorescence from DBK in

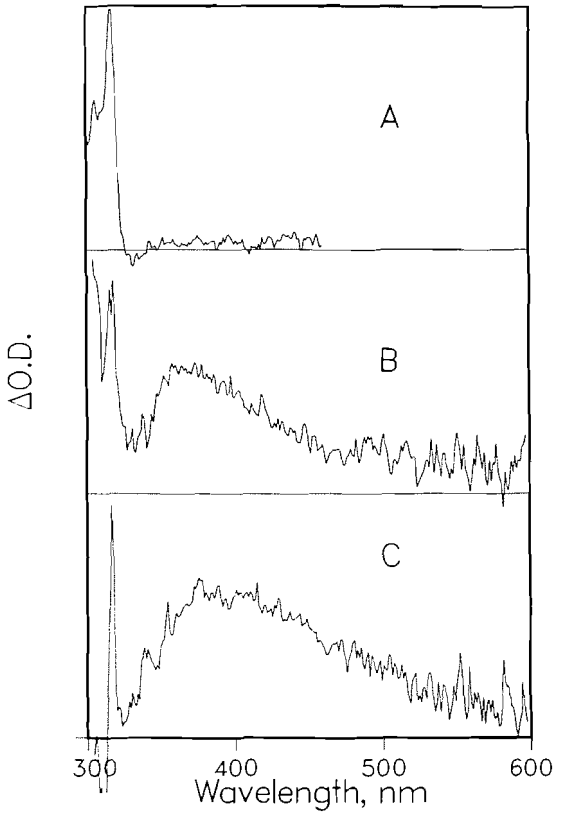

FIG. 3. Transient absorption from DBK in methanol solution (delay: 1 μs) (*A*) and from DBK on DTAB/Nafion 1 μs (*B*) or 10 μs (*C*) after 308 nm laser excitation.

H-Nafion (protonated singlet) and in methanol (unprotonated singlet). The maximum in H-Nafion is 330 nm and can be compared with solution values of 355 nm in sulfuric acid (protonated) and 405 nm in methanol (unprotonated).

It is now well established that the properties of polyelectrolytes as media for photochemical reactions can be significantly modified by addition of surfactants (14, 15). We have tried a similar approach in the case of Nafion membranes, by partially exchanging the protons with cationic surfactants. By using dodecyltrimethylammonium halides (DTAC = chloride, DTAB = bromide) the organic substrates can be "protected" from the acidic environment. Indeed, in the case of DBK–surfactant–Nafion system, we observe the fluorescence from both forms, protonated at ~340 nm, and unprotonated at ~400 nm (see Fig. 2). This property of the surfactant to provide a "shelter" from the polar and acidic H-Nafion medium has also been confirmed using pyrene as a fluorescent probe (see Experimental).

Laser flash photolysis

Pulsed laser excitation (308 nm) of DBK in homogeneous solution leads to strong and readily characterized transient absorption signals due to benzyl radicals (λ_{max} = 317 nm) (16). On short time scales the production of the radical by two separate processes (i.e. reactions [2] and [3]) can be easily identified (2, 3).

The photochemical behaviour of DBK in H-Nafion and in surfactant-exchanged membranes is quite different from that observed in homogeneous solution. Thus, in H-Nafion, no signal at or around 317 nm was detected; the only observable

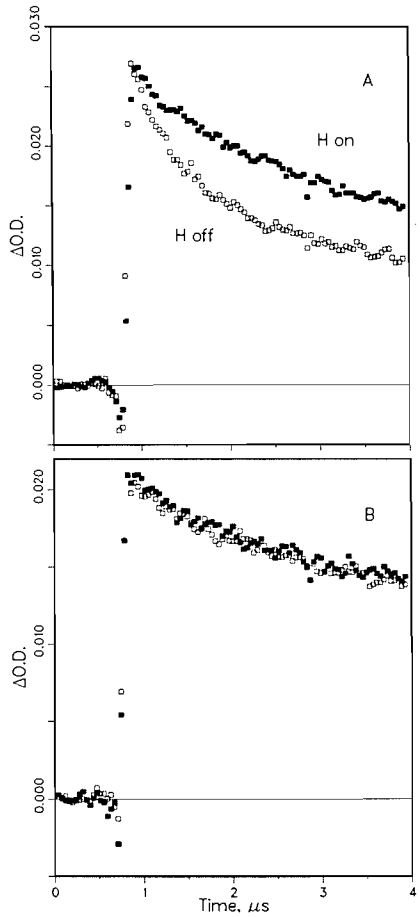

FIG. 4. Magnetic field effect for DBK on DTAB/Nafion monitored at 317 nm (*A*) and 370 nm (*B*). Filled points correspond to data under a 4000 G field.

transient was a very weak and long-lived broad absorption band centered around 370 nm (complex decay kinetics, $t_{1/2} \sim 3$ μs).

In surfactant-exchanged Nafion, two bands at 317 and 370 nm were observed. The corresponding transient spectra are illustrated in Fig. 3. The sharp 317 nm band can be readily assigned to the benzyl radical (compare with Fig. 3, spectrum *A*). The broad 370 nm is tentatively assigned to the benzyl cation by analogy with the reported spectrum for this species (17, 18). The decay of both bands followed complex kinetics, a feature which is not uncommon in solid heterogeneous systems (19). The decay at 317 nm could be adequately fitted by a biexponential function and led to lifetimes of ~0.6 μs and ~7 μs. The 370 nm band was longer-lived than the 317 nm band ($\tau \simeq 9$ μs).

Magnetic field effects

Several studies in the last few years have clearly demonstrated that triplet radical-pairs in organized media frequently show substantial magnetic field dependence (6, 20, 21). The effect at moderate fields is due to Zeeman splitting of the triplet sublevels which leads to the slow down, or eventually the shut-off of some intersystem crossing channels.

In order to test the radical-pair behaviour, we examined the photolysis of DBK in the surfactant exchanged membrane at fields of around 4000 G. The effect is illustrated in Fig. 4; the decay of the 317 nm band clearly depends on the magnetic field, which further supports the assignment of this transient to the benzyl radical, and suggests that the geminate radical-pair is held in close proximity for a considerable time. The magnitude of this effect is, however, smaller than those typically observed in micellar systems. (The effect is outside the experimental uncertainty at ~900 G.) On the other hand, the 370 nm band does not show magnetic field dependence (see Fig. 4). This observation provides strong support for our assignment of this band to the benzyl cation, rather than to a radical species, since no magnetic field effect is expected for a closed shell species.

Preparative experiments

Preparative experiments were carried out on H-Nafion films, surfactant exchanged Nafion films, and H-Nafion pellets.

In the case of samples deaerated by a stream of nitrogen, the only significant product is 1,2-diphenylethane, produced very slowly by comparison with homogeneous systems. The quantum yield for photodecomposition must be extremely small, as could be anticipated from the failure to detect benzyl radicals in the laser photolysis experiment. It is apparent that small residual amounts of solvent (water or methanol) affect the polarity of the membrane and lead to the slow formation of 1,2-diphenylethane. In the case of vacuum-dried samples no photoproducts were detected following extraction of the irradiated samples.

The behaviour of the DBK–surfactant–Nafion membranes under irradiation is quite different. Even with vacuum-dried samples, the formation of 1,2-diphenylethane can be readily observed. For example, under the same conditions that the H-Nafion system leads to no photoproducts, a conversion of ~50% is observed in the surfactant-exchanged membrane. This result is in good agreement with the observation of both radical and cation species in the laser photolysis experiments. Comparison of the exchanged membrane with homogeneous solution (methanol) led to slightly smaller (75%) conversion to diphenylethane in the membrane, although problems in matching the irradiation dose of solid and liquid samples cast some doubts on the significance of this small difference.

After exhaustive extraction of the irradiated Nafion film with refluxing methanol, a new ground state absorption was detected ($\lambda_{max} \sim 260$ nm) in the usually transparent Nafion films. Since the absorption is produced in the same conditions under which the benzyl cation is detectable it is probably due to an aromatic chromophore covalently bonded to the membrane. The most likely bonding site in the membrane is the SO_3^- group, thus leading to $—SO_3CH_2Ph$.

Thus, our results suggest that protonation of the excited state of DBK leads to the photogeneration of benzyl cations and that the Nafion membrane behaves as a chemical scavenger for these cations. Of course, trapping of the benzyl cation leaves unanswered the question of the fate of the rest of the molecule. An obvious candidate would be phenylacetaldehyde. Unfortunately, our attempts to detect it were unsuccessful. On the other hand, when in a separate experiment phenylacetaldehyde was adsorbed on H-Nafion, the uv–visible spectra recorded before and after irradiation showed that the sample was not stable under these conditions, and led to a new absorption at 260 nm, which also did not disappear completely after desorption. We suggest that the aldehyde undergoes polymerization and/or oligomerization and that, in the case of DBK–H–Nafion (where the phenylacetaldehyde would be generated in situ) this process is responsible for the failure to extract and/or detect this product.

No $PhCH_2OCH_3$ (the expected methanol scavenging product) was detected among the products even when the membrane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

contained some residual methanol. This may indicate that only benzyl radicals are produced at the methanol-containing sites, with the benzyl cations being the preferred products in the "dry" or methanol-deficient sites.

Conclusion

The photolysis of DBK on vacuum dried membranes leads to a transient absorption at 370 nm that has been tentatively assigned to the benzyl cation. Under these conditions no benzyl radicals are formed, and fluorescence studies indicate that the only important excited intermediate is the protonated singlet state.

In air-dried samples, deaerated by a steam of nitrogen, the residual amount of solvent (water or methanol) is enough to affect the polarity of the membrane and to lead to the formation of 1,2-diphenylethane in small amounts.

The Nafion environment can be further modified by exchange with cationic surfactants. Thus, in the DBK–DTAB–Nafion system, both absorptions, attributed to benzyl radicals (317 nm) and benzyl cations (370 nm) have been detected in laser photolysis experiments. Quite clearly, decreased acidity leads to a transition from the cationic mechanism toward the typical "organic media" behaviour with benzyl radical formation. Magnetic field effects show that benzyl radicals are distributed in local cages, a requirement for the observation of magnetic field effects on the geminate radical-pair. The 370 nm transient did not show any effect with fields of up to 5000 G, as expected for the benzyl cation.

Product studies indicate that while benzyl radicals lead to easily extractable 1,2-diphenylethane, the benzyl cations appear to be efficiently scavengered within the Nafion matrix, leading to permanent incorporation of aromatic moieties.

3′-Azido-3′-deoxythymidine (AZT), an inhibitor of HIV (human immunodeficiency virus) replication, was recently found to improve the condition of patients suffering from AIDS (acquired immunodeficiency syndrome) or ARC (AIDS-related complex). An X-ray analysis of AZT was undertaken in order to determine the three-dimensional structure of this thymidine analogue. The crystals belong to the monoclinic space group $P2_1$ and the cell dimensions are a = 5.6282(4), b = 12.0130(7), c = 17.5072(10) Å, β = 95.946(5)°. The structure was determined by direct methods and refined to R = 0.028 for 2029 observed reflections. Two crystallographically independent molecules were found in the asymmetric unit. One of them, molecule A, adopts a conformation which is fairly common in nucleosides, viz. a C2′ *endo*/C3′ *exo* pucker of the furanose ring and a glycosidic torsion angle χ_{CN} = 53.4°. However, the conformation of molecule B is highly unusual. The sugar ring pucker is C3′ *exo*/C4′ *endo* and χ_{CN} = 2.3°. This high-energy conformation may represent the biologically active form of AZT. Its determination may therefore assist in the design of other inhibitors of HIV.

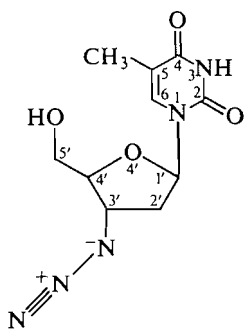
GEORGE I. BIRNBAUM, JERZY GIZIEWICZ, ERIC J. GABE, TAI-SHUN LIN et WILLIAM H. PRUSOFF. Can. J. Chem. **65**, 2135 (1987).

Il a été récemment découvert que l'azido-3′ déoxy-3′ thymidine (AZT), un inhibiteur de la réplication du VIH (virus immunodéficitaire humain), améliore la condition des patients soufrant du SIDA (syndrome de l'immuno-déficience acquise) ou du SAS (syndrome associé au SIDA). On a entrepris une étude par diffraction des rayons-X du AZT dans le but de déterminer la structure tridimensionnelle de cet analogue de la thymidine. Les cristaux appartiennent au groupe d'espace monoclinique $P2_1$ et les dimensions de la maille sont a = 5,6282(4), b = 12,0130(7) et c = 17,5072(10) Å et β = 95,946(5)°. On a déterminé la structure par des méthodes directes et on l'a affinée jusqu'à une valeur de R = 0,028 pour 2029 réflexions observées. On a trouvé que l'unité asymétrique contient deux molécules qui sont indépendantes d'un point de vue cristallographique. L'une d'elles, la molécule A, adopte une conformation qui est assez commune dans les nucléosides, soit un plissement C2′ *endo*/C3′ *exo* du noyau furannose et un angle de torsion glycosidique χ_{CN} = 53,4°. Toutefois, la conformation de la molécule B est assez inusitée. Le noyau de sucre subit un plissement C3′ *exo*/C4′ *endo* et χ_{CN} = 2,3°. Cette conformation de haute énergie pourrait s'avérer être la forme biologiquement active de l'AZT. La détermination de la configuration de l'AZT peut donc aider au développement d'autres inhibiteurs du VIH.

[Traduit par la revue]

Introduction

3′-Azido-3′-deoxythymidine (AZT, BW A509U) was first synthesized by Horwitz *et al.* (1) and later, by a modification of this procedure, by Lin and Prusoff (2). The antiviral activity of AZT was first reported by Ostertag *et al.* (3) and Dube *et al.* (4) who found a dramatic decrease of Friend virus (FV) in murine erythroleukemia cells previously transformed by the FV complex, whereas AZT had only a minimal effect on the replication of the host cell. They suggested that AZT could possibly be used to inhibit viral DNA replication by interfering with DNA chain elongation, without significantly affecting cellular viability. Krieg *et al.* (5) also reported the inhibition of Friend virus by AZT. More recently Mitsuya *et al.* (6) reported the inhibitory effect of AZT on the infectivity and cytopathic effect of HIV *in vitro*. This virus is considered to be responsible in humans for the development of acquired immunodeficiency syndrome (AIDS) or AIDS-related complex (ARC). Mitsuya *et al.* found that the triphosphate of AZT competitively inhibits



reverse transcriptase encoded by the HIV virus. Infected H9 cells exposed to AZT were prevented, in a dose-dependent fashion, from expressing reverse transcriptase as well as the viral p24 *gag* protein (6). AZT behaves like an analog of thymidine, since the inhibitory effect of AZT is prevented in a dose-dependent manner by thymidine.

Since 1981, about 52 000 individuals have been diagnosed as having AIDS and about 5 to 10 million are believed to be infected with HIV. Of those who developed AIDS, about half

[a]The x and y coordinates were multiplied by 10^4 and the z coordinates by 10^5.

are now dead, and the number who will develop AIDS is expected in the next four years to increase to 400 000 in the United States alone. Yarchoan *et al.* (7), in a Phase I clinical trial of several regimes of AZT in 19 patients with AIDS or ARC, found it to be well absorbed from the gastrointestinal tract, to cross the blood brain barrier, to produce some immunological improvement and — most important — it appeared that some of the patients improved. These encouraging findings have resulted in its current licensing for treatment of AIDS patients in the United Kingdom and the United States.

In view of the strong interest in this useful drug for the therapy of AIDS and ARC, we consider it important to learn more about its physical and chemical properties. In this report we describe the three-dimensional structure of AZT determined by an X-ray analysis.

Experimental

Crystalline clusters of AZT were grown from a mixture of ethanol and acetone. A wedge-shaped fragment, measuring 0.3 × 0.5 × 0.6 mm, was cut off and mounted on a Picker diffractometer equipped with a copper tube and a graphite monochromator. The following data were obtained:

$C_{10}H_{13}N_5O_4$ fw = 267.15

Monoclinic, a = 5.6282(4), b = 12.0130(7), c = 17.5072(10) Å, β = 95.946(5)°, V = 1177.3 Å^3, ρ_c = 1.51 g cm^{-3}, Z = 4 (150 K; CuKα_1, λ = 1.54056 Å); $F(000)$ = 560, μ(CuKα) = 9.7 cm^{-1}.

The crystal was cooled to 150 K and the intensity data were measured with $\theta/2\theta$ scans and profile analysis (8). Of the 2037 unique reflections accessible to the diffractometer ($2\theta \leqq 127°$), only 8 had $I < 3\sigma(I)$ and were considered unobserved.

The intensities were corrected for Lorentz and polarization factors; absorption corrections were considered unnecessary. The crystal structure was determined by direct methods (9). All hydrogen atoms were located on difference Fourier maps. Atomic parameters were refined by full-matrix least squares with anisotropic temperature parameters for nonhydrogen atoms and isotropic parameters for hydrogens. After the final least-squares cycle the largest parameter shift equalled 0.25σ. The refinement converged at R = 0.028 and R_w = 0.035. All calculations were performed with the NRCVAX system of programs (10). The coordinates and equivalent isotropic temperature parameters of nonhydrogen atoms are listed in Table 1. Their anisotropic temperature parameters as well as lists of hydrogen atom parameters and of observed and calculated structure factors are available.[3]

Results and discussion

Molecular geometry

The conformations of the two independent molecules in the asymmetric unit are quite different (Fig. 1). In molecule A, the glycosidic torsion angle χ_{CN} [C6—N1—C1′—O4′] is 53.4(3)°, the pucker of the furanose ring is C2′ *endo*/C3′ *exo* (^2_3T, P = 175.2°, τ_m = 32.3°) and the side chain is *gauche*$^+$. In molecule B, χ_{CN} = 2.3(4)°, the ring pucker is C3′ *exo*/C4′ *endo* (^4_3T, P = 214.5°, τ_m = 36.6°) and the side chain is *trans*. Stereoscopic views of the two molecules are shown in Fig. 2. The conformation of molecule A is quite normal for a 2′-deoxynucleoside (11). The ring pucker is dictated by the *gauche* effect (12): the ^2_3T conformation places the polar C3′—N3′ bond approximately *gauche* to C4′—O4′. The χ_{CN} value is within the range usually associated with such a ring pucker (11) and the *gauche*$^+$ conformation of the side chain is stabilized by an intramolecular C6—H···O5′ hydrogen bond, a fairly common phenomenon (13).

On the other hand, the conformation of molecule B is highly unusual. The most recent Cambridge Crystallographic Database (14), containing almost 600 nucleosides and nucleotides, lists only two structures with a furanose ring in a similar conformation (P = 215 ± 9°). In deoxycytidine 5′-phosphate, 5′-dCMP (15), and in 5′-methylthioadenosine, TMA (16), the ring pucker is also ^4_3T, the phase angles of pseudorotation, 213° and 216°, respectively, being almost identical to that in molecule B in AZT. Interestingly, a low value of χ_{CN} (−6.0°) was found in 5′-dCMP as well. The small torsion angle χ_{CN} means that

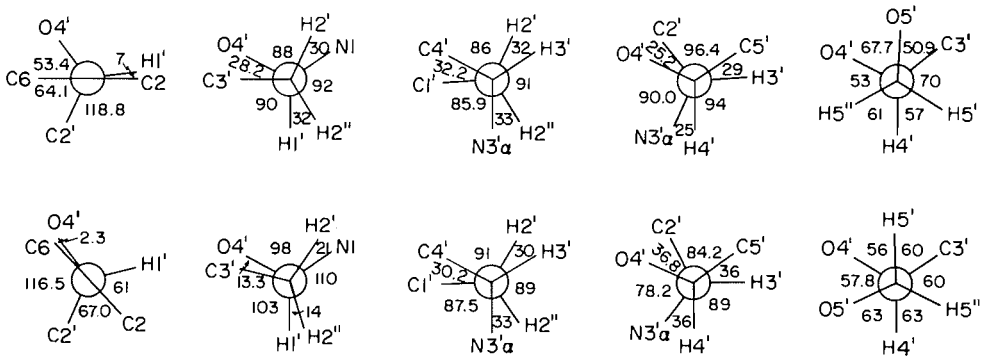

FIG. 1. Newman projections along (left to right) N1—C1′, C1′—C2′, C2′—C3′, C3′—C4′, and C4′—C5′, in molecules A (top) and B (bottom).

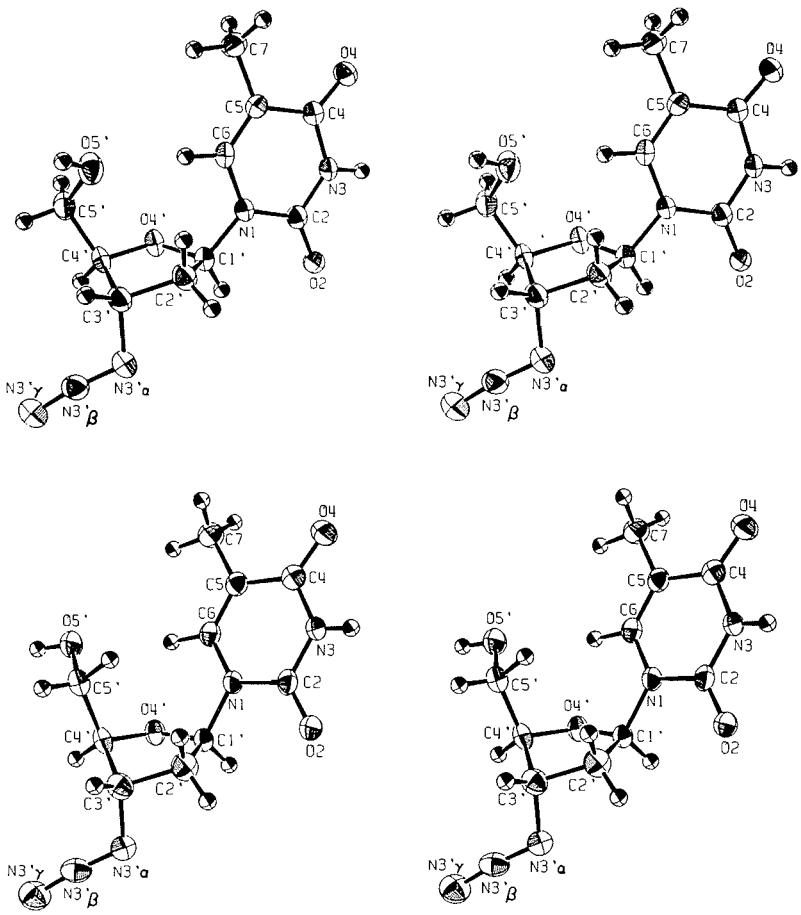

FIG. 2. Stereoscopic views of molecule A (top) and molecule B (bottom); the thermal ellipsoids correspond to 70% probability.

the N1—C6 bond eclipses C1′—O4′. This, in turn, imposes significant changes in the geometry of molecule B. Thus, the glycosidic bond N1—C1′ (1.505(4) Å) is much longer than the one in molecule A (1.468(4) Å). The strain also causes an increase of the bond angle C6—N1—C1′ to 123.0(2)°, as compared to 118.7(2)° in molecule A. Bond lengths and bond angles are listed in Tables 2 and 3, respectively.

The conformation of the azido group is similar in molecules A and B, the torsion angles C2′—C3′—N3′α—N3′β being 178.1(3) and 175.8(3)°, respectively. This places the terminal nitrogen atom N3′γ as far away from the aglycon as possible. The C—N and N—N bond lengths indicate that the C—$\overset{+}{N}$—$\overset{+}{N}$≡N resonance form predominates and that there is also some contribution of the C—N=$\overset{+}{N}$=$\overset{-}{N}$ resonance form.

Hydrogen bonding and packing

As mentioned above, there is an intramolecular hydrogen bond involving H6 in molecule A. After normalizing the C6—H6 distance to the nominal value of 1.09 Å, we obtained a corrected H6···O5′ distance of 2.06 Å (Table 4). This distance corresponds to a relatively strong C—H···O hydrogen bond (13*c*). In molecule B, H6 also participates in intramolecular hydrogen bonding, being donated to both O4′ and O5′. The distances and angles, while less favorable than those in molecule A, are well within the range of such interactions tabulated by Taylor and Kennard (13*c*). The O—H and N—H distances in the intermolecular hydrogen bonds listed in Table 4 were normalized to 0.97 and 1.04 Å, respectively.

The packing of the molecules in the crystal is shown in Fig. 3.

One of the interesting features is the base pairing of molecules A and B via N3—H···O2 hydrogen bonds. There are also some stacking interactions between molecules A and B. The C2—O2 bond in molecule B and the N3—C4 bond in molecule A are almost superimposed, thus being stabilized by a dipole–dipole interaction. Some short inter-stack distances are C4(A)···C2(B) 3.191(5) Å, C4(A)···O2(B) 3.365 (4) Å. There is also a short inter-stack distance of 3.327(5) Å between two carbonyl carbon atoms C2(A) and C4(B).

Biological considerations

The rare occurrence of the ${}^{4}_{3}T$ sugar ring pucker, found in molecule B of AZT, reflects the potential energy of this conformation which is approximately 1.7 kcal/mol higher than the global minimum corresponding to a C2′ *endo* (${}^{2}E$) pucker (17). This energy difference is similar to the 1.8 kcal/mol energy barrier which hinders free pseudorotation of 2′-deoxyribose along the ${}^{2}E$—${}^{0}E$—${}^{3}E$ pathway. In fact, very few nucleosides have been found with an O4′ *endo* (${}^{0}E$) conformation of the sugar ring in the solid state, although this pucker may contribute to the equilibrium population in solution (18). The eclipsing of N1—C6 and C1′—O4′ bonds, as evidenced by

O5′(B)—H···O4(A)	1 − *x*, ½ + *y*, 1 − *z*		2.830	1.99	1.88	167

[a]The esd's are 0.003–0.004 Å and 0.03–0.06 Å for *D*···*A* and H···*A* distances, respectively, and 3° for *D*—H···*A* angles.

the low value of χ_{CN}, further increases the potential energy of molecule B. Since substrates often adopt a high-energy transition state upon binding to an enzyme or receptor, it is possible that the conformation of molecule B represents the biologically active form of AZT. In this conformation, the binding of AZT—triphosphate to its target enzyme may be enhanced by a more favorable geometry of hydrogen bonds involving O2 and N3, resulting from the 51° rotation of the base about the glycosidic bond. The azido group is most likely responsible for the antiviral properties of AZT, and it is reasonable to assume that its terminal nitrogen atom Nγ, with its partial negative charge, is involved in the binding of AZT—triphosphate to the retroviral DNA polymerase. The following intramolecular distances were calculated in molecule B: N′γ···O2 7.373(3) Å, N′γ···N3 8.836(4) Å, N′γ···O4 10.625(4) Å. Such geometrical considerations may assist in the design of new and more effective drugs.[4]

Syntheses of chiral intermediates of 1-β-methylcarbapenems: (3*S*,4*R*)-3-[1(*R*)-*tert*-butyldimethylsilyloxyethyl]-4-chloroazetidin-2-one and (3*S*,4*S*)-3-[1(*R*)-*tert*-butyldimethylsilyloxyethyl]-4-[1(*R*)-*tert*-butylthiocarbonylethyl]azetidin-2-one

MASAKI ENDO

Chemical Process Development, Bristol-Myers Pharmaceutical Research and Development Division, 100 Industrial Blvd., Candiac, P.Q., Canada J5R 1J1

Received March 30, 1987

MASAKI ENDO. Can. J. Chem. **65**, 2140 (1987).

The 4-chloroazetidinone **10**, a very reactive chiral intermediate for 1-β-methylcarbapenems (**1***b*), was easily prepared and isolated as a solid crystalline compound from the corresponding sulfide **5**. Another chiral intermediate (**16***d*) bearing the 1-β-methyl moiety was prepared by stereoselective aldol type condensation of either azetidinone **4** or **10** with metal enolates **14** (R = S—Bu^t, M = $ZrCp_2Cl$,  , and SnBr). The β/α ratios were 9:1, 3:1, and 2:1 respectively.

MASAKI ENDO. Can. J. Chem. **65**, 2140 (1987).

On a préparé facilement la chloro-4 azétidinone (**10**), un intermédiaire chiral très réactif dans la synthèse des méthyl-1β carbapénèmes (**1***b*); on l'a isolé sous la forme d'un composé cristallin solide à partir du sulfure **5** correspondant. On a aussi préparé un autre intermédiaire chiral (**16***d*) qui porte une portion méthyle-1β; pour ce faire, on a utilisé une condensation de type aldolique stéréosélective des azétidinones **4** ou **10** avec les énolates métalliques **14** (R = S—*tert*-Bu, M = $ZrCp_2Cl$, $B(OCH_2)_2$ ou SnBr). Les rapports β/α sont respectivement de 9:1, de 3:1 et de 2:1.

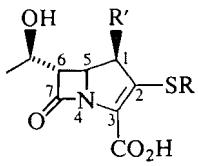
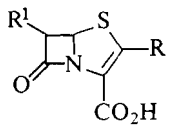
Since the discoveries of the highly active β-lactam antibiotics, carbapenem (**1***a*) (R =  , thienamycin) (1) and 1-β-methylcarbapenem (**1***b*) (2), and the synthesis of penems (**2**) by Woodward (3), much attention has been directed toward the syntheses of these compounds and their analogs (4).

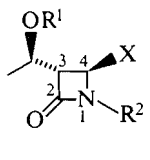
The most commonly used chiral intermediates for both penem and carbapenem syntheses are azetidinones **3**, where



1 *a*: R′ = H
b: R′ = CH_3



2

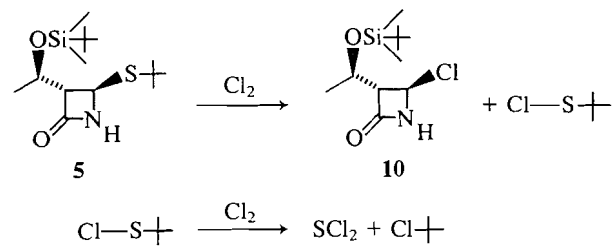


3

particularly 4-acetoxyazetidinone **4** has been widely used as an important intermediate (6). Although compound **4** is a stable solid easily available both from well-described procedures (5, 7) and from a commercial source,[1] its reactivity is limited, particularly at low temperature. It is such low temperature reaction conditions that are required for kinetic control, for example to control the stereochemistry in the syntheses of 1-β-methylcarbapenems (**1***b*). Thus, the more reactive 4-chloroazetidinone **10** might better serve as the substrate for such kinetically controlled reactions.

Karady *et al.* (8) reported the *N*-protected 4-chloroazetidinone **3** ($R^1 = R^2 = Si\!\!\leftarrow\!\!\rightarrow$; X = Cl), and demonstrated it to be a useful intermediate. However, because the nitrogen was protected with a *tert*-butyldimethylsilyl group, the reactivity of **3** ($R^1 = R^2 = Si\!\!\leftarrow\!\!\rightarrow$; X = Cl) at the C-4 position is dramatically

[1]Kanegafuchi Chemical Industry Company, Osaka, Japan.

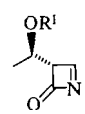


SCHEME 1

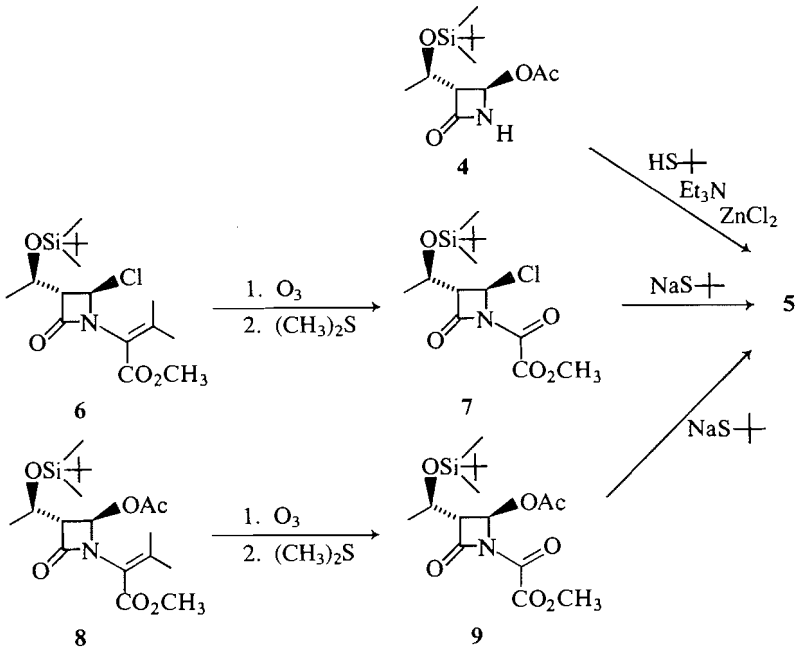
reduced compared to that of **10** without nitrogen protection.[2] Synthesis of the 4-chloroazetidinone **10** has been briefly reported by Perrone and co-workers (9), but these workers do not describe its isolation.

Herein is reported an easy preparation of the title compound **10**. Compound **10** was prepared by chlorinolysis of sulfide **5** with two equivalents of chlorine at −15°C (Scheme 1). Although one equivalent of chlorine is theoretically enough to produce **10**, a nonvolatile by-product produced with one equivalent of chlorine contaminates the product. The by-product, *tert*-butylsulfenyl chloride, reacts with an additional equivalent of chlorine to give volatile products. The crude

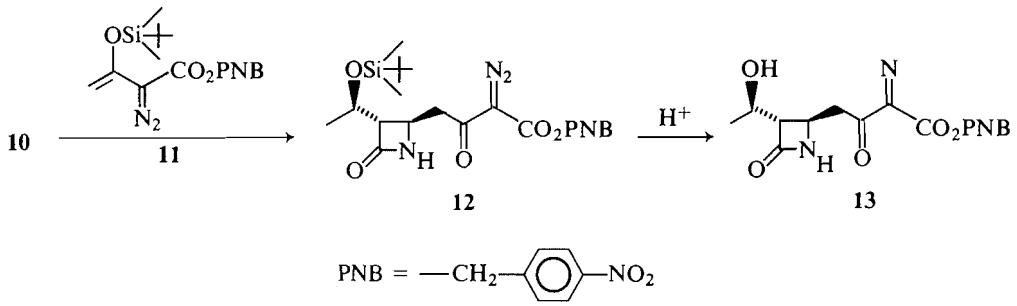
[2]It has been proven that the displacement reactions of 2-azetidinone **3** ($R^1 = Si\!\!\leftarrow\!\!\rightarrow$; R^2 = H; X = OAc) at the C-4 position go via a reactive intermediate



(10). It is more difficult to form the corresponding iminium salt of the *N*-protected azetidinone.



SCHEME 2



SCHEME 3

product was easily recrystallized from cold pentane, affording white crystalline solid **10** in 76% yield (Scheme 1). This product is rather unstable at room temperature but reasonably stable at −20°C. Compound **5**, the precursor of **10**, may be prepared from three different starting materials (Scheme 2). Treatment of 4-acetoxyazetidinone **4** (5) with *tert*-butylmercaptan, triethylamine, and zinc chloride gave compound **5** in 70% yield. The other two starting materials **7** (11) and **9** (11) (prepared quantitatively from the corresponding secopenams **6** (11) and **8** (11) by ozonolysis) reacted with sodium *tert*-butylmercaptide in ethanol, affording the sulfide **5** in good yields.

Chiral 4-chloroazetidinone **10** was converted to a known intermediate **13** (6*c*) for carbapenem syntheses (Scheme 3). Compound **10**, as expected, demonstrated its high reactivity, undergoing reaction with the *tert*-butyldimethylsilylenol ether **11** (6*c*) at low temperature to afford azetidinone **12** (6*c*). Deprotection of the hydroxy moiety (6*c*) was carried out by treating **12** with 1 *M* aqueous hydrochloric acid in methanol to give **13** in 64% overall yield.

Compound **10** also showed its usefulness for kinetically controlled reactions in 1-β-methylcarbapenem synthesis by reacting with metal enolates **14** at −78°C to give compound **16** (described below).

1-β-Methylcarbapenems (**1***b*) have been shown to be chemically and metabolically more stable than 1-unsubstituted carbapenems (**1***a*), and also to retain high antimicrobial activity (2). However, a stereoselective introduction of the β-methyl group into the carbapenem precursors has been a major problem (2, 12). Recently, several research groups have discovered means to overcome the problem. Fuentes *et al.* (13) reported that Evans type enolates **14***a* (14) undergo stereoselective aldol type condensation with 4-acetoxyazetidinone **4** in the presence of Lewis acid to afford **16***a* in good yields with predominantly the β-isomer. Similar results on **16***b*, using tin(II) enolates of thiazolidine-2-thiones and oxazolidine-2-thiones, have been reported by other groups (15, 16). As well, Iimori and Shibasaki (17) reported a stereoselective introduction of the β-methyl group by reducing an olefinic ester **15***a* with L-Selectride (β/α 8:1, 77% yield). Kim *et al.* (18) similarly achieved a stereoselective hydrogenation of **15***b* to give **16** (R = OCH_3, β/α 3:1) (Scheme 4).

In the search for a new way to introduce the β-methyl group, we conducted a series of coupling reactions of azetidinones **4** or **10** with the metal enolates **14** (R = OBz and S—Bu^t).

The enolates **14** were prepared by three known methods (19–21) depending on the reagent used (Scheme 5).

As mentioned earlier, 4-chloroazetidinone **10** has an advantage over 4-acetoxyazetidinone **4** in dealing with unstable metal enolates **14** that require low reaction temperature. The required low reaction temperature, as well, fulfils the kinetic condition to

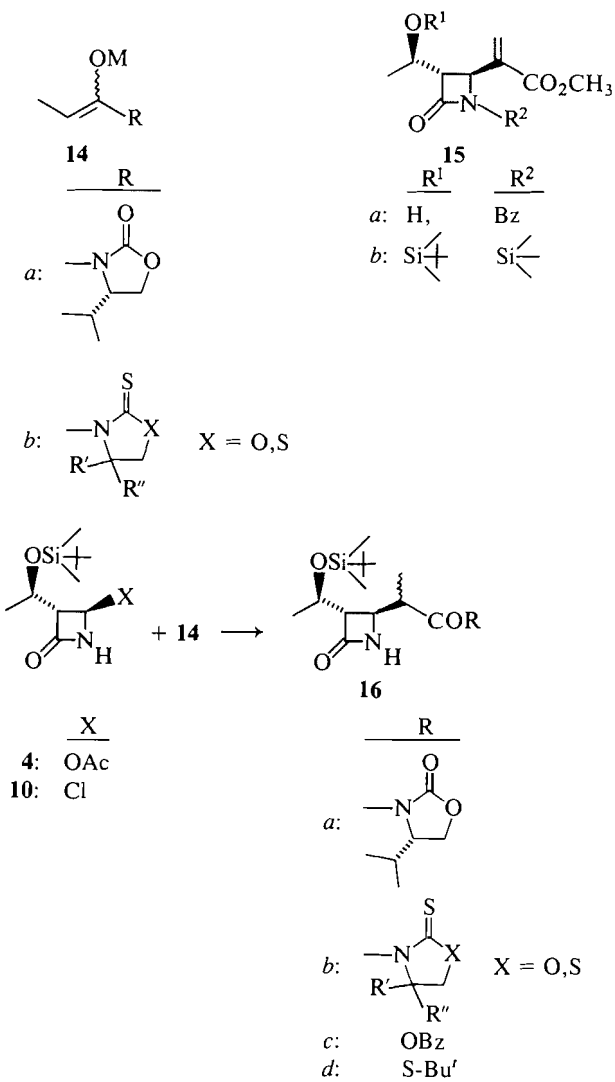
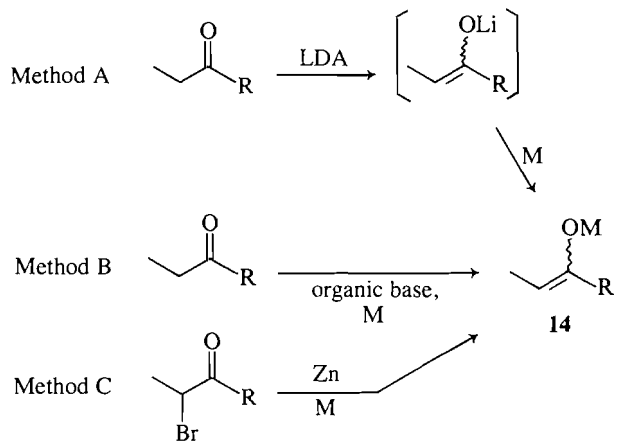
		Reaction temperature (°C)	0	−5 to 0	23	−78	23	−5 to 0	−10 to −5
		Reaction time (h)	1/3	2	72	2	48	2/3	5/6

[a]The ratio was determined by hplc (column: Hypersil, column length: 200 × 2.1 mm, solvent: 10–20% EtOAc/hexane, detection: uv 260 nm).
[b]**4** was used for all cases except the one indicated.
[c]Tin powder (3 equiv.) was used instead of zinc dust and $AgBF_4$ (10 mol%) was added to activate metal tin.
[d]**10** was used. This gives slightly better yield than **4**.



SCHEME 4



SCHEME 5

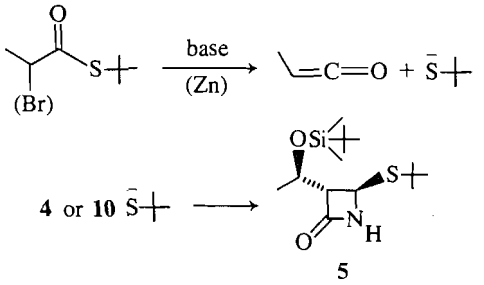
control the stereochemistry. The 4-chloroazetidinone **10** reacts at temperatures as low as −78°C, while 4-acetoxyazetidinone **4** does not react at a significant rate below −10°C.

The results are shown in Table 1. When R = OBz, product **16***c* was obtained, for which there was little stereoselectivity observed favoring the β-isomer regardless of the metal enolate used. The β/α ratio was more or less in a range of 1:1, or weighted towards the α-isomer. On the other hand, *tert*-butyl thiopropionate (R = S—Bu^t), giving product **16***d*, showed greater stereoselectivity, either favoring the α-isomer or the β-isomer. Thus, zirconium, boronyl, and tin(II) enolates were found to be good reagents to introduce the β-methyl group stereoselectivity.

It is not yet known which factors determine the stereochemical outcome in the coupling reaction with azetidinones **4** or **10**. Therefore it is rather difficult to predict the result, while the stereochemistry of analogous aldol condensations is generally well predicted (22).

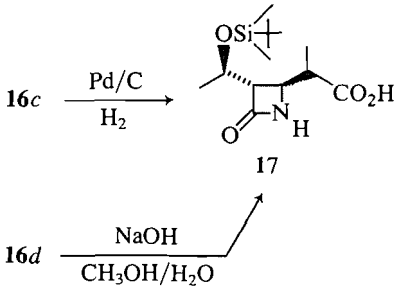
One of the causes of the low yields in the series of *tert*-butyl thio(bromo)propionate reactions seems to be ketene formation,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.



particularly under strongly basic conditions where more by-product **5** was isolated.

The structures **16***c* and **16***d* were confirmed by converting them to the known acid **17** (2*a*). Thus, the benzyl ester **16***c* was subjected to hydrogenolysis to give crystalline **17** as a β/α mixture in 76% yield. The α-isomer crystallized out from an ethyl acetate solution and was isolated pure. The thioester **16***d*



(β/α 94:6) was hydrolyzed under basic conditions to **17** (90%). However, the ^{1}H nmr spectrum indicated partial epimerization of the β-methyl group (β/α 70:30). Intermediate **17** has been converted to 1-β-methylcarbapenems (2*a*).

Experimental

*(3S,4R)-3-[1(R)-*tert*-Butyldimethylsilyloxyethyl]-4-chloro-1-(1-methoxycarbonyl-2-methyl-1-propenyl)azetidin-2-one (6)*

Compound **6** was prepared as described in ref. 11 except that the *tert*-butyldimethylsilyl function served to protect the hydroxy group instead of the trichloroethyl carbonate group. The crude solid (100% yield) was used without further purification; ^{1}H nmr (60 MHz, $CDCl_3$) δ: 0.03 (s, 6H, CH_3), 0.83 (s, 9H, CH_3CSi), 1.23 (d, J = 6 Hz, 3H, CH_3CHO), 1.93, 2.22 (2s, 6H, $=C(CH_3)_2$), 3.32 (dd, J = 1.5 Hz, 1H, H-3), 3.71 (s, 3H, CO_2CH_3), 4.18 (m, 1H, CH_3CHO), 5.86 (d, J = 1.5 Hz, H-4).

*(3S,4R)-4-Acetoxy-3-[1(R)-*tert*-butyldimethylsilyloxyethyl]-1-(2-methoxy-1,2-dioxyethyl)azetidine-2-one (9)*

A solution of compound **8** (5) (7.98 g, 0.02 mol) in dichloromethane (80 mL) was cooled to −78°C and ozone gas was bubbled in until a blue color persisted. The cooling bath was removed and the excess ozone was expelled by bubbling nitrogen gas. The ozonide solution was treated at room temperature with dimethyl sulfide (3 mL) for 1.5 h. The clear, colorless solution was washed with water (3×), dried over anhydrous magnesium sulfate, and concentrated *in vacuo* to give the white crystalline title compound (7.7 g, 98%), which was recrystallized from ether/petroleum ether (1:1), mp 54–55°C; ir (Nujol): 1700, 1760, 1828 cm^{-1}; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.01, 0.06 (2s, 6H, CH_3Si), 0.81 (s, 9H, CH_3CSi), 1.29 (d, J = 6.4 Hz, 3H, CH_3CHO), 2.11 (s, 3H, $OCOCH_3$), 3.26 (dd, J = 1.9 and 2.0 Hz, 1H, H-3), 3.90 (s, 3H, CO_2CH_3), 4.31 (m, 1H, CH_3CHO), 6.73 (d, J = 2.0 Hz, 1H, H-4). *Anal.* calcd. for $C_{16}H_{27}NO_7Si$ (373.447): C 51.46, H 7.29, N 3.75; found: C 51.44, H 7.37, N 3.71.

*(3S,4R)-3-[1(R)-*tert*-Butyldimethylsilyloxyethyl]-4-chloro-1-(2-methoxy-1,2-dioxyethyl)azetidin-2-one (7)*

Compound **7** was prepared in 97% yield as described in ref. 11 except that the *tert*-butyldimethylsilyl group served as protection for the hydroxy group instead of the trichloroethyl carbonate group. The crystalline solid was pure enough to be used in the next step without further purification; mp 69–71°C (recrystallized from petroleum ether); ir (Nujol): 1715, 1760, 1825 cm^{-1}; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.01, 0.06 (2s, 6H, CH_3Si), 0.81 (s, 9H, CH_3CSi), 1.28 (d, J = 6.3 Hz, 3H, CH_3CHO), 3.53 (overlapping dd, 1H, H-3), 3.92 (s, 3H, CO_2CH_3), 4.32 (m, 1H, CH_3CHO), 6.01 (d, J = 1.9 Hz, 1H, H-4). *Anal.* calcd. for $C_{14}H_{24}ClNO_5Si$ (349.856): C 48.06, H 6.91, N 4.00, Cl 10.13; found: C 47.94, H 7.03, N 3.95, Cl 9.89.

*(3S,4R)-3-[1(R)-*tert*-Butyldimethylsilyloxyethyl]-4-*tert*-butylthioazetidin-2-one (5)*

Method A: via 4-acetoxyazetidinone 4

To a solution of compound **4** (57.4 g, 0.2 mol) in dichloromethane (600 mL) under nitrogen atmosphere was added *tert*-butylmercaptan (24.6 mL, 0.22 mol) followed by addition of triethylamine (30.6 mL, 0.2 mol). The solution was cooled to 0°C and zinc chloride (27.2 g, 0.2 mol) was added. The resulting milky solution was stirred at room temperature for 2 days. The reaction mixture was successively washed with 1 *M* aqueous hydrochloric acid (500 mL), saturated sodium bicarbonate (500 mL), and water (500 mL), dried over anhydrous magnesium sulfate, and concentrated to give a wet crystalline solid (70 g). The crude product was triturated in isopropyl alcohol (150 mL) and then diluted with water (150 mL). The slurry was cooled to 5°C and the solid was collected by filtration. The cake was washed with cold (5°C) isopropyl alcohol – water (1:2, 100 mL) and dried *in vacuo* to give the title compound **5**. Yield 44.3 g (70%); mp 152–154°C; $[\alpha]_D^{23}$ +85.0° (*c* 0.57, $CHCl_3$); ir (Nujol): 1715, 1762 cm^{-1}; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.06, 0.07 (2s, 6H, CH_3Si), 0.87 (s, 9H, CH_3CSi), 1.20 (d, J = 6.3 Hz, 3H, CH_3CHO), 1.36 (s, 9H, $S(CH_3)_3$), 3.03 (m, 1H, H-3), 4.25 (m, 1H, CH_3CHO), 5.00 (d, J = 2.6 Hz, 1H, H-4), 6.06 (br s, 1H, NH). *Anal.* calcd. for $C_{15}H_{31}NO_2SSi$ (317.563): C 56.73, H 9.84, N 4.41, S 10.10; found: C 56.74, H 9.91, N 4.37, S 10.09.

Method B: via 4-chlorooxamate (7)

To an ice-cooled solution of compound **7** (0.349 g, 1 mmol) in ethanol (5 mL) under nitrogen atmosphere was added dropwise sodium *tert*-butylmercaptide (1.1 mL of 1 *M* solution in ethanol–water 6:1). The resulting solution was stirred at 5–10°C for 15 min. The reaction mixture was diluted with diethyl ether (70 mL), washed with brine (4×), dried over anhydrous magnesium sulfate, and concentrated to give crystalline **5** (0.31 g, 98%).

Method C: via 4-acetoxyoxamate (9)

To a solution of compound **9** (0.389 g, 1.04 mmol) in ethanol (6 mL) under nitrogen atmosphere was added sodium *tert*-butylmercaptide (1.1 mL of 1 *M* solution in ethanol–water 6:1). The hazy solution was stirred at room temperature for 2 h. The reaction mixture was diluted with diethyl ether (70 mL), washed with brine (4×), dried over anhydrous magnesium sulfate, and concentrated to dryness, affording the white crystalline product **5** (0.32 g, 96%).

Compound **5** produced by methods B and C showed identical spectral values to compound **5** produced by method A.

*(3S,4R)-3-[1(R)-*tert*-Butyldimethylsilyloxyethyl]-4-chloroazetidin-2-one (10)*

Chlorine gas (2.24 g, 31.54 mmol) was gently bubbled into a solution of compound **5** (5.0 g, 15.77 mmol) in dichloromethane (50 mL) while maintaining the temperature at −5 to −15°C. The yellow solution was concentrated (*in vacuo*, <20°C) to give a crystalline solid, which was recrystallized from cold (−70°C) pentane to give the title compound **10**. Yield 3.12 g (76%), white crystals; mp 84–85°C; $[\alpha]_D^{23}$ +23.5° (*c* 0.49, $CHCl_3$); ir (Nujol): 1736, 1775 cm^{-1}; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.03, 0.05 (2s, 6H, CH_3Si), 0.84 (s, 9H, CH_3CSi), 1.26 (d, J = 6.4 Hz, 3H, CH_3CHO), 3.41 (m, 1H, H-3), 4.21 (m, 1H, CH_3CHO), 5.67 (d, J = 1.3 Hz, 1H, H-4), 6.25 (br s, 1H, NH). *Anal.* calcd. for $C_{11}H_{22}ClNO_2Si$ (263.810): C 50.08, H 8.41, N 5.30, Cl 13.43; found: C 50.11, H 8.50, N 5.22, Cl 13.24.

*(3S,4R)-3-[1(R)-*tert*-Butyldimethylsilyloxyethyl]-4-(3-*p*-nitrobenzyloxycarbonyl-2-oxo-3-diazopropan-1-yl]-azetidin-2-one (**12**) and (3S,4R)-3-[1(R)-hydroxyethyl]-4-(3-*p*-nitrobenzyloxycarbonyl-2-oxo-3-diazopropan-1-yl]-azetidin-2-one (**13**)*

To a solution of compound **10** (0.264 g, 1 mmol) in dichloromethane (6 mL) at −40°C under nitrogen atmosphere was added silver tetrafluoroborate (0.195 g, 1 mmol), followed by addition of a solution of enol ether **11** (0.57 g, 1.5 mmol) (6*c*) in dichloromethane (6 mL) over 20 min. The resulting solution was stirred at −30 to −40°C for 2 h. The reaction mixture was diluted with ethyl acetate (40 mL), then washed successively with saturated sodium bicarbonate (30 mL) and brine (2 × 40 mL). Concentration of the organic phase gave a mixture of oil and solid that was dissolved in methanol (10 mL). Insoluble solids were filtered off and washed with methanol (5 mL). The combined filtrate (containing compound **12**) was treated at room temperature with 1 *M* aqueous hydrochloric acid (2.5 mL) for 18 h. The reaction mixture was diluted with water (30 mL), then extracted with ethyl acetate (60 mL and 40 mL respectively). The organic phase was washed successively with saturated sodium bicarbonate (40 mL) and brine (2 × 50 mL), dried over anhydrous magnesium sulfate, and concentrated to give a wet solid. The product (**13**) was isolated by triturating in ether (10 mL). Yield 0.24 g (64%), mp 149–150°C (lit. (6*c*) mp 151–152°C). The ^{1}H nmr spectrum was identical to that reported (6*c*).

Metal enolate/azetidinone coupling reactions

A typical procedure for each method is described.

Method A (ref. 19)

To a lithium diisopropylamine (2.5 mmol) solution in dry tetrahydrofuran (6 mL) at −78°C was added a solution of *tert*-butyl thiopropionate (0.365 g, 2.5 mmol) in tetrahydrofuran (2 mL) over 10 min. The resulting lithium enolate solution was stirred at −78°C for 0.5 h. Then, a solution of zirconocene dichloride (0.73 g, 2.5 mmol) in tetrahydrofuran (10 mL) was added dropwise over 15 min and the mixture was stirred for 0.5 h. To this was added all at once 4-chloroazetidinone **10** (0.264 g, 1 mmol). The resulting solution was stirred at −78°C for 2 h. The reaction mixture was diluted with ether (60 mL), washed successively with 1 *M* hydrochloric acid (20 mL), saturated sodium bicarbonate (20 mL), and brine (2 × 30 mL), dried over anhydrous magnesium sulfate, and concentrated to give an oil (0.248 g), which was chromatographed on silica gel (ether – petroleum ether 1:1), yielding 56 mg (15%) of **16***d* with a β/α ratio of 94:6; mp 109–113°C (recrystallized from petroleum ether); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.04, 0.05 (2s, CH_3—Si, αβ), 0.84, 0.85 (2s, CH_3—C—Si, αβ), 1.14, 1.24 (2d, J = 6.4 and 7.0 Hz, CH_3—CH—OSi and CH_3—CH—C=O, β), 1.20 (2 overlapping d, J = 6.2 and 7.2 Hz, CH_3—CH—OSi and CH_3—CH—C=O, α), 1.43 (s, *t*-BuS, β), 1.44 (s, *t*-BuS, α), 2.61 (m, CH_3—*CH*—C=O, α), 2.73 (m, overlapping, H-3, α, and CH_3—*CH*—C=O, β), 2.94 (dd, J = 2.2 and 3.5 Hz, H-3, β), 3.68 (dd, J = 2.1 and 9.5 Hz, H-4, α), 3.82 (dd, J = 2.2 and 6.2 Hz, H-4, β), 4.15 (m, CH_3—*CH*—OSi, αβ), 5.86 (br s, NH, β), 5.93 (br s, NH, α). *Anal.* calcd. for $C_{18}H_{35}NO_3SSi$ (373.601): C 57.87, H 9.44, N 3.75, S 8.58; found: C 58.11, H 9.50, N 3.70, S 8.42.

Method B (ref. 20)

To an ice-cooled solution of *tert*-butylthiopropionate (0.584 g, 4 mmol) in dry methylene chloride (10 mL) was added diisopropylethylamine (0.75 mL, 4.3 mmol), followed by dropwise addition of a solution of ethylenechloroboronate (4 mmol) in methylene chloride (3 mL). The resulting solution was stirred at room temperature for 3.5 h. To this solution was added **4** (5) (0.574 g, 2 mmol) and it was stirred at room temperature for 2 days. The reaction mixture was washed successively with 1 *M* hydrochloric acid, saturated sodium bicarbonate, and water, dried over anhydrous magnesium sulfate, concentrated, and chromatographed on silica gel (ether – petroleum ether 1:1), giving 0.23 g of **16***d* (30%, β/α 77:23). The ^{1}H nmr spectrum was identical to that of compound **16***d* produced by method A.

Method C (ref. 21)

To a slurry of activated zinc dust (0.5 g, 7.7 mmol) in dry tetrahydrofuran (10 mL) at −10°C was added diethylaluminum chloride (3.8 mmol, in hexane). A solution of **4** (0.574 g, 2 mmol) and benzyl 2-bromopropionate (1.46 g, 6 mmol) in tetrahydrofuran (10 mL) was added dropwise over 0.5 h. The resulting slurry was stirred at −10°C for 1 h. The reaction mixture was filtered on Celite and the filtrate was diluted with ether (70 mL), washed successively with 1 *M* hydrochloric acid (25 mL), saturated sodium bicarbonate (25 mL), and brine (2 × 30 mL), dried over anhydrous magnesium sulfate, and concentrated to give an oil, which was chromatographed on silica gel (ether – petroleum ether 1:1), yielding 0.57 g of **16***c* (73%, β/α 52:48); mp 61–62°C (recrystallized from petroleum ether); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.04, 0.06 (2s, CH_3—Si, αβ), 0.84, 0.85 (2s, CH_3—C—Si, αβ), 1.12, 1.23 (2d, J = 6.3 and 7.0 Hz, CH_3—CH—OSi and CH_3—CHC=O, β), 1.22 (2 overlapping d, J = 6.2 and 7.2 Hz, CH_3—CH—OSi and CH_3—CH—C=O, α), 2.55 (m, CH_3—*CH*—C=O, α), 2.71 (m, overlapping H-3, α, and CH_3—*CH*—C=O, β), 2.96 (dd, J = 2.2 and 4.3 Hz, H-3, β), 3.69 (dd, J = 2.0 and 9.4 Hz, H-4, α), 3.90 (dd, J = 2.2 and 5.4 Hz, H-4, β), 4.42 (m, CH_3—*CH*—OSi, αβ), 5.11 (CH_2Ph, β), 5.13 (s, CH_2Ph, α), 5.82 (br s, NH, β), 5.92 (br s, NH, α), 7.33 (s, Ph, αβ). *Anal.* calcd. for $C_{21}H_{33}NO_4Si$ (391.553): C 64.42, H 8.50, N 3.58; found: C 64.65, H 8.83, N 3.54.

*Hydrogenolysis of **16**c*

Compound **16***c* (β/α 52:48, 0.41 g, 1.05 mmol) was dissolved in methanol (30 mL). To this were added 10% Pd/C (200 mg), water (1.5 mL), and pH 7 phosphate buffer (3 mL). This mixture was placed in an hydrogenation bottle that was shaken at room temperature under 7 psi/H_2 (1 psi = 6.9 kPa) for 1.5 h. The reaction mixture was filtered on Celite and the Celite was washed with methanol (10 mL). The filtrate was concentrated to give a white solid (0.33 g), which was dissolved in a mixture of saturated sodium bicarbonate (8 mL) and water (8 mL), and washed with ether (2 × 10 mL). The aqueous phase was acidified with 2 *M* hydrochloric acid and extracted with ether (2 × 15 mL). The ether extract was washed with brine (20 mL), dried over anhydrous magnesium sulfate, and concentrated to give crystalline **17** as a β/α mixture (0.24 g, 76%, β/α 1:1, mp 130–134°C). The pure α-isomer was isolated by crystallization from ethyl acetate; mp 160–162°C, $[\alpha]_D^{23}$ −2.7° (*c* 0.11, CH_3OH); ir (Nujol): 2190, 2800–2400 (br), and 1712 (br) cm^{-1}; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.06, 0.07 (2s, 6H, CH_3—Si), 0.87 (s, 9H, CH_3—C—Si), 1.24, 1.27 (2 overlapping d, J = 5.7 and 7.0 Hz, 6H, CH_3—CH—OSi and CH_3—CH—C=O), 2.55 (m, 1H, CH_3—CH—C=O), 2.78 (dd, J = 1.0 and 5.2 Hz, 1H, H-3), 3.68 (dd, J = 1.9 and 9.8 Hz, 1H, H-4), 4.18 (m, 1H, CH_3—CH—OSi), 6.59 (br s, NH). *Anal.* calcd. for $C_{14}H_{27}NO_4Si$ (301.428): C 55.78, H 9.03, N 4.65; found: C 55.63, H 9.20, N 4.61. The reported ^{1}H nmr spectrum of the β-isomer (2*a*) supports the structure as well.

*Hydrolysis of **16**d*

Compound **16***d* (β/α 94:6, 31 mg, 0.083 mmol) was dissolved in methanol (1.7 mL). To this were added water (0.25 mL) and 2.5 *M* sodium hydroxide (0.1 mL). The resulting solution was stirred at room temperature for 2 days. The reaction mixture was diluted with water (20 mL) and washed with ether (2 × 20 mL). The aqueous phase was then acidified with concentrated hydrochloric acid (0.5 mL) and extracted with ethyl acetate (2 × 25 mL). The organic phase was washed with brine (2 × 25 mL), dried over anhydrous magnesium sulfate, and concentrated to give crystalline **17** as a white solid (23 mg, 90%). Although the ^{1}H nmr spectrum showed the expected product, it indicated partial epimerization of the methyl group (β/α 70:30).

The binding energies of trialkylgermanium cations to water molecules studied by high pressure mass spectrometry

JOHN ALFRED STONE AND WILHELMUS JOHANNES WYTENBURG
Chemistry Department, Queen's University, Kingston, Ont., Canada K7L 3N6

Received February 5, 1987

JOHN ALFRED STONE and WILHELMUS JOHANNES WYTENBURG. Can. J. Chem. **65**, 2146 (1987).

The binding energies of H_2O to R_3Ge^+ have been measured using pulsed electron beam, high pressure mass spectrometry. van't Hoff plots have yielded thermodynamic data (ΔH^0, ΔS^0) for the reactions, [5], $R_3Ge^+ + H_2O \rightleftharpoons R_3GeOH_2^+$ (R = CH_3, C_2H_5, C_3H_7, C_4H_9) and [7], $R_3GeOH_2^+ + H_2O \rightleftharpoons R_3Ge(OH_2)_2^+$ (R = CH_3, C_2H_5). ΔH_5^0 decreases with increasing size of R (CH_3 28.6 ± 0.5 kcal mol^{-1}, C_4H_9 20.6 ± 1.2 kcal mol^{-1}) while ΔS_5^0 shows much less change (34.4 ± 0.9 to 30.3 ± 2.8 cal K^{-1} mol^{-1}). Comparison with data for $(CH_3)_3M^+$ (M = Si, Sn) shows that binding energy decreases with increasing size of M.

JOHN ALFRED STONE et WILHELMUS JOHANNES WYTENBURG. Can. J. Chem. **65**, 2146 (1987).

On a mesuré les énergies de liaison du H_2O au R_3Ge^+ en faisant appel à la spectrométrie de masse à haute pression et à faisceau d'électrons pulsés. Les courbes de van't Hoff ont permis d'obtenir les données thermodynamiques (ΔH^0 et ΔS^0) pour les réactions $R_3Ge^+ + H_2O \rightleftharpoons R_3GeOH_2^+$ (5) (R = CH_3, C_2H_5, C_3H_7 et C_4H_9) et $R_3GeOH_2^+ + H_2O \rightleftharpoons R_3Ge(OH_2)^+$ (7) (R = CH_3 et C_2H_5). Le ΔH_5^0 diminue avec une augmentation de la taille du groupement R (CH_2, 28,6 ± 0,5 kcal mol^{-1}, C_4H_9, 20,6 ± 1,2 kcal mol^{-1}) alors que le ΔS_5^0 varie beaucoup moins (34,4 ± 0,9 à 30,3 ± 2,8 cal K^{-1} mol^{-1}). Une comparaison des données pour $(CH_3)_3M^+$ (M = Si, Sn) démontre que l'énergie de liaison diminue avec une augmentation de la taille de M.

[Traduit par la revue]

Introduction

The adducts formed between trimethylgermylium ($(CH_3)_3Ge^+$) and Lewis bases are reported to be considerably more stable than those formed between trimethylsilylium ($(CH_3)_3Si^+$) and the same bases. For example at low pressure ($\sim 10^{-4}$ Torr (1 Torr = 133 Pa)) under ion cyclotron resonance (ICR) conditions the adducts formed by the addition of $(CH_3)_3Ge^+$ to a wide variety of N, O, or S containing bases (alcohols, amines, esters etc.) generally do not decompose. By contrast the adducts formed by the addition of $(CH_3)_3Si^+$ to the same bases decompose to a very great extent under the same experimental conditions. The only $(CH_3)_3Ge^+$ adducts which decompose to a considerable extent are those of carboxylates and thio-esters and even these show much less fragmentation than the analogous $(CH_3)_3Si^+$ adducts (1). This increased stability of the germanium adducts cannot be ascribed to a greater Lewis acid–base interaction since under ICR conditions the increased reaction exothermicity would lead to enhanced decomposition. The explanation must lie in a much reduced exothermicity of adduct formation and/or to the larger germanium centre closing off decomposition channels which are readily accessible in the silicon complexes. A first determination of the thermochemistry of adduct formation by $(CH_3)_3Ge^+$ is the subject of this study.

We have previously reported the enthalpies of binding of $(CH_3)_3Si^+$ to a variety of aromatic and oxygen-containing bases (2, 3). The enthalpy values are based on an absolute measurement obtained from the temperature coefficient of the equilibrium constant for reaction [1].

[1] $(CH_3)_3Si^+ + H_2O \rightleftharpoons (CH_3)_3SiOH_2^+$

In this paper we report a similar measurement for the analogous reaction [2]

[2] $(CH_3)_3Ge^+ + H_2O \rightleftharpoons (CH_3)_3GeOH_2^+$

In addition, the ready availability of other germanium tetraalkyl compounds allowed the measurement of the enthalpy of binding of water to other R_3Ge^+ ions (R = C_2H_5, n–C_3H_7, butyl).

Experimental

The pulsed electron beam mass spectrometer with ion source operable at pressures up to 5 Torr, and the method of obtaining equilibrium data have been described previously (4). Premixed samples are made up in a heated 5 L flask from which they are bled into the ion source via a heated leak valve. A typical sample contained <0.3 mol% R_4Ge (R = CH_3, C_2H_5, n-C_3H_7, butyl), 0.02 mol% sulfur hexafluoride, >99 mol% methane, and water vapour whose amount was always small and optimized to give best precision for each equilibrium measurement.

All the tetraalkyl germanium compounds were from Morton Thiokol Inc., Alfa Products, and were used as received except for $(CH_3)_4Ge$. This compound was found to be contaminated with more than 1 mol% tetrahydrofuran which forms a much more strongly bonded complex with $(CH_3)_3Ge^+$ than does water and hence prevents the study of reaction [2]. Gas liquid chromatography was used to remove this impurity. The tetrapropylgermanium contained n-propyl groups but the tetrabutylgermanium, with butyl groups whose structure was not identified by the manufacturer, was found to contain a mixture of butyl isomers. Its nmr spectrum was complex and no attempt was made to characterize it further.

The sulfur hexafluoride was present in each sample to capture electrons and decrease the rate of positive ion diffusion to the ion source walls and hence increase the ion residence times in the source (4).

Results and discussion

The ion chemistry of $R_4Ge/SF_6/CH_4$ (0.002/0.0002/0.99) mixtures was studied briefly at ion source pressures in the range 2–4 Torr and temperatures in the range 350–600 K. The reactions observed are analogous to those reported for $(CH_3)_4Si/SF_6/CH_4$ mixtures under similar ion source conditions (3).

R_3Ge^+ is the only initial ion resulting from the reaction of R_4Ge with the major reagent ions CH_5^+ and $C_2H_5^+$ present in methane under chemical ionization (CI) conditions. R_3Ge^+ then reacts with R_4Ge giving $R_7Ge_2^+$.

[3] $CH_5^+(C_2H_5)^+ + R_4Ge \rightarrow R_3Ge^+ + RH + CH_4(C_2H_4)$

Reaction [4] is assumed to be, and is written as, an equilibrium although this was not ascertained. The assumption is justifiable since $(CH_3)_7Si_2^+$ and $(CH_3)_3Si^+$ are found to participate in the analogous equilibrium in $(CH_3)_4Si/CH_4$ mixtures (2). The formation of $(CH_3)_7M_2^+$ seems to be a common characteristic for all members M except carbon of Group IV A; the formation of $(CH_3)_7Sn_2^+$ in $(CH_3)_4Sn/CH_4$ mixtures has been previously reported (5).

The addition of small amounts of water to the $R_4Ge/CH_4/SF_6$ system results in the appearance of three new ions, a drastic reduction in the abundance of $R_7Ge_2^+$, and a significant reduction in R_3Ge^+. Two of the new ions are the water adducts $R_3GeOH_2^+$ and $R_3Ge(OH_2)_2^+$. $R_3GeOH_2^+$ is formed by addition of water to R_3Ge^+ and probably also by displacement of R_4Ge from $R_7Ge_2^+$.

[5] $R_3Ge^+ + H_2O \rightleftharpoons R_3GeOH_2^+$

[6] $R_7Ge_2^+ + H_2O \rightleftharpoons R_3GeOH_2^+ + R_4Ge$

$R_3GeOH_2^+$ is further solvated by water

[7] $R_3GeOH_2^+ + H_2O \rightleftharpoons R_3Ge(OH_2)_2^+$

Reactions [5], [6], and [7] are written as equilibrium reactions; [5] and [6] were examined in detail and proved to be so. No such study was made for reaction [6] but if reactions [4] and [5] are equilibrium reactions then reaction [6], if it occurs, must also be.

The third new ion which was formed upon addition of water to the sample had an isotopic pattern showing the presence of two germanium atoms and six R groups, leading to the formula $R_6Ge_2OH^+$. We suggest that this is a protonated germoxane which is analogous to protonated hexamethyl disiloxane observed in $(CH_3)_4Si/CH_4/H_2O$ mixtures (2).

[8] $R_3GeOH_2^+ + R_4Ge \rightarrow R_3GeO(H)GeR_3^+ + RH$

The formation of this ion is an irreversible process and at long reaction times under suitable conditions, it can become the dominant ion. However, equilibria [5] and [7] are set up very rapidly and the measured equilibrium constants are not perturbed by the much slower reaction [8].

The equilibrium constants K_5 and K_7 for reactions [5] and [7] are defined as

$$K_5 = \frac{i_{R_3GeOH_2^+}}{i_{R_3Ge^+}(P_{H_2O}/P^0)} \qquad K_7 = \frac{i_{R_3Ge(OH_2)^+}}{i_{R_3GeOH_2^+}(P_{H_2O}/P^0)}$$

where i is an ion current at long ion residence time when equilibrium has been attained, P_{H_2O} is the pressure (Torr) of water vapour in the ion source, and P^0 is standard pressure (760 Torr). K_5 was measured over a range of temperatures for R = CH_3, C_2H_5, C_3H_7, and C_4H_9 while K_7 was measured under similar conditions only for R = CH_3 and C_2H_5. The van't Hoff plots are shown in Figs. 1 and 2 while the ΔH^0 and ΔS^0 values obtained from the slopes of these plots are given in Table 1. Also shown in this table are data for some analogous reactions of $(CH_3)_3M^+$ (M = C, Si, Sn).

The data for the addition of one molecule of water to R_3Ge^+ show that the binding energy decreases as the size of R increases i.e. in the order $CH_3 > C_2H_5 > n\text{-}C_5H_7 > C_4H_9$. The decrease from CH_3 to C_4H_9 is 8 kcal mol^{-1}, a 30% change. This is understandable in terms of an increasing stabilization of R_3Ge^+ due to electron transfer from R to Ge with increasing size of R. As the electron density on Ge increases the interaction energy with H_2O correspondingly decreases. The decrease in enthalpy

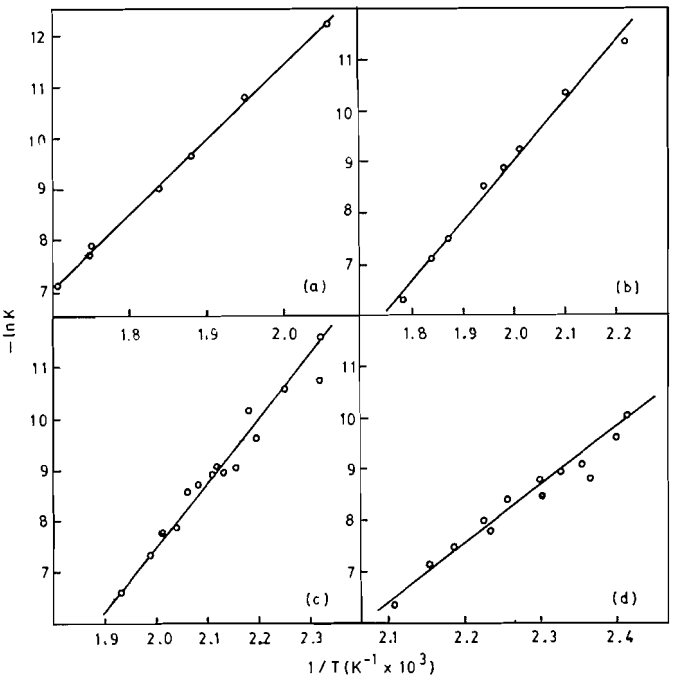

FIG. 1. van't Hoff plots for the reaction $R_3Ge^+ + H_2O \rightleftharpoons R_3GeOH_2^+$: (*a*) R = CH_3, (*b*) R = C_2H_5, (*c*) R = n-C_3H_7, (*d*) R = C_4H_9.

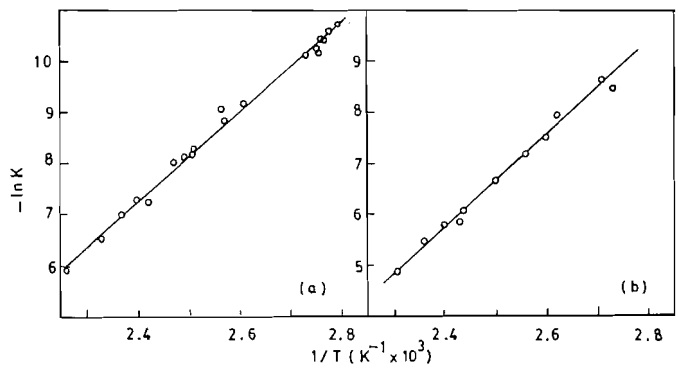

FIG. 2. van't Hoff plots for the reaction $R_3GeOH_2^+ + H_2O \rightleftharpoons R_3Ge(OH_2)_2^+$: (*a*) R = CH_3, (*b*) R = C_2H_5.

of binding from R = CH_3 to R = C_2H_5 (3.7 kcal mol^{-1}) is considerably greater than that from R = C_2H_5 to R = n-C_3H_7 (~1.5 kcal mol^{-1}) in line with the rapid attenuation of electron-releasing ability with length of an alkyl chain (6). The significantly larger increase from R = n-C_3H_7 to R = C_4H_9 (~2.8 kcal mol^{-1}) is consistent with the presence of branched, isomeric butyl groups in $(C_4H_9)_3R^+$.

The decreases in entropy shown in Table 1 for reaction [6] are large and show only small changes with change of R. These values imply the formation of products by condensation, i.e., covalent bond formation, rather than the formation of cluster ions for which entropies of formation are usually considerably smaller (7). The reaction products are therefore equivalent to those obtained by protonation of the germanols R_3GeOH. The absence of appropriate thermodynamic data for such compounds prevents the calculation of their proton affinities from the enthalpies of binding as was done for trimethylsilanol (3). The additions of the second water molecule to $(CH_3)_3GeOH_2^+$ and to $(C_2H_5)_3GeOH_2^+$ are much less exothermic processes

TABLE 1. Thermodynamic data for reactions [3] ($R_3M^+ + H_2O \rightleftharpoons R_3MOH_2^+$) and [4] ($R_3MOH_2^+ + H_2O \rightleftharpoons R_3M(OH_2)_2^+$)

M	R	$-\Delta H_5^0$ (kcal mol^{-1})	$-\Delta S_5^0$ (cal K^{-1} mol^{-1})	$-\Delta H_7^0$ (kcal mol^{-1})	$-\Delta S_7^0$ (cal K^{-1} mol^{-1})
Ge	CH_3	28.6 ± 0.5	34.4 ± 0.9	17.2 ± 0.3	26.7 ± 0.8

than the addition of the first molecules. The exothermicity is slightly greater for the latter ion than for the former while the entropy change is much more negative for latter. These changes suggest a lessening influence of the alkyl groups as the number of water molecules increases in line with the suggestion of Hiraoka and Kebarle (8) who studied $(CH_3)_3C(OH_2)_2^+$ that the positive charge becomes largely located on the hydroxyl hydrogens and the thermochemistry approaches that for $H(H_2O)_2^+$. For example, for reaction [9], $-\Delta H^0$ is ~21 kcal mol^{-1} and $-\Delta S^0$ has values between 20 and 28 cal K^{-1} mol^{-1} (9), values very similar to those for $(CH_3)_3MOH_2^+$.

[9] $H^+(H_2O)_2 + H_2O \rightleftharpoons H(H_3O)_3^+$

This argument is strengthened by the enthalpy and entropy changes shown in Table 1 for hydration of $(CH_3)_3SiOH_2^+$, the values being closely similar to those for the germanium compounds.

Stabilization of $(CH_3)_3X^+$ by hyperconjugation appears to be much more important for X = C than for X = Si, Ge, or Sn (10). This can be associated with the very small size of C and is in line with its higher electronegativity. The assigned electronegativities of the other elements have very similar values (11) and Table 1 shows that their enthalpies of binding for $(CH_3)_3X^+$ to one molecule of water are grouped together but are very different from the value for carbon. The order of decrease in binding energy, Si > Ge > Sn, presumably reflects the normal decrease in binding energy with increasing atomic weight in a column of the periodic table which is usually associated with the size of the atom.

We have previously shown that the H_2O in $(CH_3)_3SiOH_2^+$ is readily displaced in exothermic reactions by oxygen bases such as alcohols, ethers, esters, etc. (2). We determined that such reactions also occur with $(CH_3)_3GeOH_2^+$. The only quantitative data obtained in this study are for reaction [10].

[10] $(CH_3)_3GeOH_2^+ + CH_3OH \rightleftharpoons (CH_3)_3GeO(H)CH_3^+ + H_2O$

Here $\Delta H^0 = -6.4 \pm 0.1$ kcal mol^{-1} and $\Delta S^0 = -1.6 \pm 0.1$ cal K^{-1} mol^{-1} while ΔH^0 for the silicon compound was -9.1 kcal mol^{-1} (2). The latter was obtained from a standard free energy measurement at 468 K and a calculated entropy. The binding energies of alcohols to $(CH_3)_3Ge^+$ are therefore in line with those for water in being significantly lower than the binding energies to $(CH_3)_3Si^+$.

PETER JAMES SMITH and KENNETH CHARLES WESTAWAY. Can. J. Chem. **65**, 2149 (1987).

The secondary α-deuterium kinetic isotope effect has been measured for the thermal reaction of 2-phenylethyldimethylamine oxide in 90 mol% DMSO–H_2O at 60.0°C. A large secondary α-deuterium isotope effect of 1.158 per α-D was found, which indicates significant C—$\overset{+}{N}$ bond rupture and very little double bond formation at the transition state for this concerted *syn*-elimination process. The observed large normal value for $(k_H/k_D)_\alpha$ is discussed in terms of the use of secondary α-D isotope effects for the determination of stereochemistry for a concerted elimination process. Various isotope effects found for the *syn* elimination of the above amine oxide and those for the *anti* elimination of 2-arylethyltrimethylammonium salts with ethoxide are considered with respect to the relative transition state structures for *syn*- and *anti*-elimination reactions.

PETER JAMES SMITH et KENNETH CHARLES WESTAWAY. Can. J. Chem. **65**, 2149 (1987).

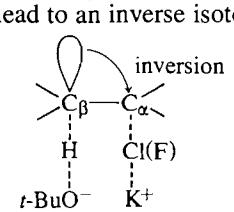
Opérant à 60,0°C, dans un mélange à 90 mol% de DMSO–H_2O, on a mesuré l'effet isotopique cinétique secondaire du deutérium en α sur la réaction thermique de l'oxyde de la phényl-2 éthyl diméthyl amine. On a observé un effet isotopique secondaire élevé (1,158) pour le deutérium en α et ce résultat indique que, dans l'état de transition de cette élimination *syn* concertée, il se produit beaucoup de rupture de la liaison C—$\overset{+}{N}$ et très peu de formation de double liaison. On discute de cette valeur normale, mais élevée, qui a été observée pour le $(k_H/k_D)_\alpha$ en fonction de l'utilisation des effets isotopiques secondaires des deutérium en α pour la détermination de la stéréochimie d'un processus concerté d'élimination. Divers effets isotopiques qui ont été observés pour l'élimination *syn* de l'oxyde d'amine mentionnée plus haut et d'autres effets rapportés pour l'élimination *anti* des sels d'aryl-2 éthyl triméthyl ammonium par l'éthylate ont été considérés en relation avec les structures relatives des états de transition des réactions d'éliminations *syn* et *anti*.

[Traduit par la revue]

Introduction

In a recent study (1, 2) on the E2 reaction of the 2-phenylethyl halides with *tert*-butoxide in *tert*-butyl alcohol it was found that the magnitude of the secondary α-deuterium kinetic isotope effect was dependent on the concentration of the abstracting base when chlorine and fluorine were the leaving groups. The secondary isotope effect, $(k_H/k_D)_\alpha$, was inverse at "low" base concentrations and normal at "high" base concentrations. These and other results were discussed in terms of both *syn*- and *anti*-elimination pathways promoted by various associated and dissociated base species. It was suggested that the $(k_H/k_D)_\alpha$ effect may be useful as a criterion for determining the stereochemistry of E2 elimination reactions.

At low *tert*-butoxide concentrations, it was suggested that the reaction of both the chloro and fluoro substrates proceed via a *syn*-elimination pathway where the loss of the leaving group and the β-hydrogen is assisted by the *t*-BuOK ion pair. For such a transition state, **1**, which is expected to have considerable carbanionic character (3), it was considered that sufficient negative charge could develop on the β carbon so that inversion occurs at both C_β and C_α. It was proposed that attack of the incipient lone pair of electrons from the backside of C_α would increase the $\overset{H}{C}$—X out-of-plane bending frequencies at the transition state and lead to an inverse isotope effect (4–7).



1

To investigate whether the observation of inverse secondary α hydrogen–deuterium kinetic isotope effects for reactions via the concerted one-step elimination pathway can be used as a test for *syn* stereochemistry we decided in the present study to examine the thermolysis reaction of 2-phenylethyldimethylamine oxide in 90 mol% dimethyl sulfoxide in water at 60°C, eq. [1], by determining the secondary α-deuterium kinetic isotope effect. The thermal decomposition of amine oxides has been established to be a concerted intramolecular *syn*-elimination process (8–12).

[1] $PhCH_2CH_2\overset{+}{N}(CH_3)_2$ (with O^-) $\xrightarrow[60°C]{90\ mol\%\ DMSO\text{–}H_2O}$ $PhCH{=}CH_2 + N(CH_3)_2$ (with OH)

The nature of the transition state for the thermal decomposition of amine oxides has been recently investigated. Chiao and Saunders (13) determined the primary hydrogen–deuterium kinetic isotope effect for reaction of 2-phenylethyldimethylamine and 2-phenylpropyldimethylamine oxides in various binary solvent mixtures. They found that the $(k_H/k_D)_\beta$ values varied very little with changes in solvent composition and were small in magnitude (14), between 2 and 3.[1] Their results were interpreted in terms of a nonlinear proton transfer, as required for the intramolecular *syn* elimination of amine oxides, transition state **2**, to avoid strain.

On the other hand, Kwart and Brechbiel (15) measured the primary β-deuterium kinetic isotope effect over a 70°C temperature

[1]The small kinetic hydrogen isotope effects are consistent with theoretical predictions (14).

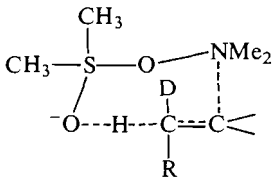
2

range for the thermolysis reaction of n-$C_6H_{11}CHDCH_2\overset{+}{N}Me_2$ with O^-

in dimethyl sulfoxide and found a significant temperature dependence. They interpreted their results in terms of a linear proton transfer to the oxygen of the dimethyl sulfoxide in a seven-membered ring via a product-like transition state where Me_2SO is coordinated to the amine oxide oxygen, transition state **3**. However, it has been recently pointed out (16) that the temperature dependence of the primary β-deuterium kinetic isotope effect should not be used as a mechanistic tool in differentiating between linear and bent transition states.

Carbon-14 kinetic isotope effects and a ρ value for the reaction of several ring substituted 2-phenylethyldimethylamine oxides in 10% water – 90% Me_2SO at 65°C have recently been determined (17). The large carbon isotope effects at both the α and β carbons, $(k_{12}/k_{14})_\alpha = 1.061 \pm 0.006$ and $(k_{12}/k_{14})_\beta = 1.036 \pm 0.005$, respectively, together with the calculated ρ value of +2.11 led the authors to conclude that there was some buildup of negative charge at C_β and extensive rupture of both the C_β—N and C_β—H bonds with relatively little double bond formation at the transition state.



3

The results of the present study will be considered in terms of the use of the magnitude of secondary α-deuterium isotope effects as a criterion for the determination of the stereochemistry of concerted one-step elimination processes. As well, our results and those of other workers (13, 17) will be used to shed light on the transition state structure for the thermal *syn*-elimination reaction of amine oxides.

Results and discussion

The thermal elimination reaction of 2-phenylethyldimethylamine oxide was investigated in the present study in 90 mol% DMSO–H_2O solution to compare our results with those of previous workers (13, 17). Rate measurements were carried out spectrophotometrically using amine oxide samples containing some water, as the anhydrous form is unstable (13). The rate constants for reaction of a pair of undeuterated and α-dideuterated substrates were determined simultaneously to minimize possible effects due to temperature fluctuations in the constant temperature bath. The rate constants determined for each of the four pairs of kinetic runs are given in Table 1, as well as the calculated secondary α-deuterium kinetic isotope effects, $(k_H/k_D)_\alpha$.

The rate constants determined for reaction of the undeuterated amine oxide at 60.0°C, k_H(ave.) = 15.40 s^{-1}, are in good agreement with the literature value (13) of 13.0 s^{-1} determined in the same solvent conditions at 59.8°C. The small discrepancy between the rate constants could be due to the temperature difference and (or) to a slight solvent effect, as it has been shown (13) that the presence of water sharply decreases the rate, presumably due to a decrease in the basicity of the oxide oxygen through increased hydrogen bonding with water.

TABLE 1. The rate constants and secondary α-deuterium kinetic isotope effects for the *syn*-elimination reaction of 2-phenylethyldimethylamine oxide and its α-d_2 analogue in 90 mol% DMSO–water at 60.0°C

Run no.	$k_H \times 10^5$ s^{-1}	$k_D \times 10^5$ s^{-1}	$(k_H/k_D)_\alpha$
1	14.34[a] ±0.04[b]	10.53[a] ±0.03[b]	1.362[a]
2	15.72 ±0.02	11.66 ±0.04	1.348
3	15.03 ±0.02	11.35 ±0.04	1.324
4	15.46 ±0.02	11.65 ±0.03	1.327
		Average	1.340±0.018[c] (1.158 per α-D)

[a]Measured at a lower temperature of 59.9°C.
[b]Standard deviation within a kinetic run.
[c]Standard deviation.

The average of the four α-deuterium kinetic isotope effect determinations, $(k_H/k_D)_\alpha$ (ave.) = 1.340 ± 0.018 ($(k_H/k_D)_{\alpha\text{-D}}$ = 1.158 per α-D), is large and normal, indicating a significant decrease in the out-of-plane bending vibration involving the α C—H bonds at the transition state (6). The conclusion is reached from the results of the present study, where *syn* elimination in amine oxide pyrolysis did not give rise to an inverse secondary α-deuterium kinetic isotope effect, that the magnitude of $(k_H/k_D)_\alpha$ cannot be used as a criterion for the determination of the stereochemistry of a one-step elimination process (1, 2).[2] The large kinetic isotope effect of 1.34 may be compared with the small value of $(k_H/k_D)_\alpha$ = 1.02 found for the E2 reaction of 2-phenylethyltrimethylammonium ion with ethoxide at 40°C, which has been shown to proceed via an *anti*-elimination pathway (18) with a carbanionic transition state where C_β—H bond rupture has progressed to a greater degree than C—$\overset{+}{N}$ bond weakening (19). As well, the S_N2 reaction of thiophenoxide ion with benzyldimethylanilinium ion in *N*,*N*-dimethylformamide at 0°C gave a secondary α-deuterium isotope effect of 1.18 (20).

Although the magnitude of the secondary α-deuterium isotope effect is dependent on the nature of the leaving group, it is reasonable to qualitatively compare the magnitude of the secondary isotope effects above since in all cases the leaving group is a tertiary amine. Clearly the isotope effect found in the present study is much larger than those found for the E2 and S_N2 processes and is close to the theoretical maximum predicted for carbocation formation.[3] To our knowledge, $(k_H/k_D)_\alpha$ = 1.340 is the largest value found for a one-step concerted elimination process. Such a large value must arise due to an extensive decrease in the C_α—H out-of-plane bending vibrations at the transition state. This suggests that there is considerable C—$\overset{+}{N}$ bond rupture and very little carbon–carbon double bond formation at the activated complex.

The observation of the large normal secondary α-deuterium isotope effect, therefore, indicates that the transition state for the intramolecular *syn* elimination of the amine oxide cannot have significant S_N2 character, as illustrated in transition state **1**. Interaction of the developing electron density at C_β with C_α

[2]This conclusion will be considered in a full paper currently in preparation, concerning the reaction of *tert*-butoxide in *tert*-butyl alcohol with the 2-phenylethyl halides.

[3]Hartshorn and Skiher (21) found a value of $(k_H/k_D)_\alpha$ = 1.19 per α-D for the reaction, $CH_3\overset{+}{N}H_3 \rightarrow \overset{+}{C}H_3 + NH_3$.

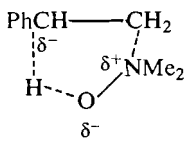
would be expected to give rise to a small or inverse secondary α-deuterium isotope effect (6).

Accordingly, it is proposed that the transition state for the amine oxide decomposition has extensive C_β—H and C_α—N bond rupture but negligible interaction between the orbital developing at C_β with the α carbon (very little double bond formation), **4**, and a nonlinear proton transfer (13). Such a transition state could be described as carbanionic since there is significant charge buildup at C_β that can be stabilized by delocalization into the aromatic ring. This is consistent with the observed ρ value of +2.1 found for the reactions of the 2-arylethyldimethylamine oxides (17).



4

Substantial negative charge buildup at C_β at the transition state is expected for *syn* eliminations, particularly when the leaving group is a poor nucleofuge like dimethylhydroxylamine (23). For reactions involving competing *syn*- and *anti*-elimination pathways, ρ_{syn} was found to be significantly greater than ρ_{anti}, indicating greater carbanionic character at the transition state for *syn* as compared with *anti* elimination. This conclusion receives support from the molecular orbital approach of Bach *et al.* (24) who considered that the S_N2-like reaction, as illustrated in **1**, can be viewed as interaction of the C_β—H bonding electrons with the vacant σ* orbital of the C—$\overset{+}{N}$ bond. For this to occur effectively, considerable electron density at C_β must be generated *anti* to the C—$\overset{+}{N}$ bond, **1**.

The conclusion that there is significant C—N bond rupture at the transition state, based on the observation of the large normal α-D isotope effect, receives support from the study on the pyrolysis reaction of several 1-arylethyldimethylamine oxides (9) where a ρ value of +0.77 was found, which indicates a decrease in the induced positive charge at C_α in the activated complex.

Reaction proceeding by way of a true carbanion intermediate, either short or long lived, can be ruled out. For a long lived carbanion intermediate, inversion and rotation prior to the loss of the leaving group would lead to both *syn* and *anti* elimination, contrary to observation (12). The large secondary α-deuterium isotope effect and the large carbon isotope effect, $(k_{12}/k_{14})_\alpha$, which both indicate considerable C—$\overset{+}{N}$ bond weakening at the transition state, are not in accord with rate limiting carbon–hydrogen bond rupture to form a high energy carbanion intermediate.

It is interesting to compare the transition state structure for the reaction of 2-phenylethyltrimethylammonium ion with ethoxide, a concerted *anti* elimination, with the transition state geometry for reaction of 2-phenylethyldimethylamine oxide, a concerted *syn* elimination, since the structure of the two substrates is similar. Isotope effects determined for the two reactions are given in Table 2.

A comparison of the primary hydrogen–deuterium isotope effects, $(k_H/k_D)_\beta$, obtained for the two reactions is difficult since they were determined under different reaction conditions via transition states of different geometry (linear vs. nonlinear proton transfer). The comparison is further complicated by the possibility of different tunneling contributions for the two reactions.

A comparison of the carbon isotope effects (17) determined at both C_β and C_α, $(k_{12}/k_{14})_\beta$ and $(k_{12}/k_{14})_\alpha$, respectively, for the two reactions indicates that both transition states, *syn* and *anti*, have extensive C—H and C—$\overset{+}{N}$ bond rupture. The nitrogen isotope effect, $[(k_{14}/k_{15}) - 1]100 = 1.33$, determined for the ammonium salt reaction confirms that there is significant C—$\overset{+}{N}$ bond weakening at the transition state.

It appears, however, that C—$\overset{+}{N}$ bond rupture is *more* advanced at the transition state for the *syn* elimination of the amine oxide, $(k_{12}/k_{14})_\alpha = 1.061$, as compared with the *anti* elimination of the ammonium salt, $(k_{12}/k_{14})_\alpha = 1.044$. This receives support from the relative magnitude of the secondary α-deuterium isotope effects determined for the two systems, $(k_H/k_D)_\alpha = 1.34$ and 1.02 for the amine oxide and ammonium salt reactions, respectively.

In conclusion, it appears that the transition state for both the *anti* and *syn* processes has considerable C—H and C—$\overset{+}{N}$ bond weakening. They differ significantly, however, in the degree of double bond formation. While the *anti* process has considerable π bond formation at the transition state, as indicated by the small $(k_H/k_D)_\alpha$ value, the activated complex for the *syn* reaction has very little double bond character. This conclusion is reasonable in the light of the theoretical treatments of Bach *et al.* (24) and More O'Ferrall (25) since *anti* elimination is the more favoured process for stereochemical reasons.

Experimental

Melting points are uncorrected. The proton nmr spectra were determined on a Varian T-60 spectrometer. All reagents and solvents were reagent grade and were dried and purified by the usual procedures. The dimethyl sulfoxide solvent (Baker Analyzed) was refluxed over calcium hydride for 6 h and distilled.

Methyl phenylacetate

After a mixture of 55 g (0.40 mol) of phenylacetic acid, 125 mL (3.1 mol) of methanol, and 5 mL of concentrated sulfuric acid had refluxed overnight, the methanol was removed on a rotary evaporator. The residue was mixed with 250 mL of water and 10 mL of carbon tetrachloride in a separatory funnel. The organic layer was separated and washed with water, a 20% sodium hydrogen carbonate solution, and finally with water. The organic layer was dried with 5 g of anhydrous magnesium sulfate and the carbon tetrachloride was removed under reduced pressure. Distillation gave 39.9 g (66.5%) of methyl phenylacetate, bp 68–70°C/2 Torr (1 Torr = 133.3 Pa) (lit. (26) bp 218°C).

2-Phenylethyl-1,1-d_2*-alcohol*

This compound was synthesized by the procedure described by Westaway and Ali (27). A mixture of 24 g (0.16 mol) of methyl phenylacetate in 25 mL of dry (distilled from lithium aluminum hydride) ether was added dropwise to a solution prepared by dissolving 4 g (0.095 mol) of lithium aluminum deuteride (Merck) in 600 mL of dry ether in a 3-L three-necked flask. When the addition was complete, the mixture was refluxed overnight. Then the excess lithium aluminum deuteride was destroyed by carefully adding 150 mL of 10% sulfuric acid. The ether layer was removed and the aqueous layer was washed three times with 100-mL aliquots of ether. The ether layers were combined and washed with a 5% sodium hydrogen carbonate solution until all the acid had been removed. Finally the ether layer was washed with 100 mL of water and dried over anhydrous magnesium sulfate. Removal of the ether on the rotary evaporator and distillation gave 17.6 g (87.5%) of 2-phenylethyl-1,1-d_2-alcohol, bp 100°C/6 Torr (lit. (28) bp 110°C/20 Torr). An nmr analysis indicated that the product was at least 99% deuterated at the one position.

2-Phenylethyl-1,1-d_2*-p-toluenesulfonate*

The tosylate was prepared by the method developed by Tipson (29). 2-Phenylethyl-1,1-d_2-alcohol, 18.0 g (0.145 mol) was dissolved in 175 mL of pyridine and cooled to 0°C in an ice–salt bath. Then, 30 g of purified[4] *p*-toluenesulfonyl chloride was added and the mixture was stirred at 0°C for 2.5 h. Then, 3-, 3-, 6-, and 15-mL portions of cold water were added at 5-min intervals so that the temperature did not rise. Then, 150 mL of cold water was added and the product was extracted with five 75-mL portions of chloroform. The pyridine was removed from the product by extraction with several 100-mL portions of 10% sulfuric acid and one 250-mL portion of water. Most of the chloroform was removed on the rotary evaporator and the remaining solution was dried over anhydrous sodium sulfate. Removal of the chloroform left 33.6 g of an orange liquid that eventually crystallized to give white needles. These needles were recrystallized from ether–pentane to give 30.3 g (74.4%) of 2-phenylethyl-1,1-d_2-*p*-toluenesulfonate, mp 37–38°C (lit. (22) mp 37.5–38.2°C).

2-Phenylethyldimethylamine-1,1-d_2

This substance was prepared by the method described by Saunders and Edison (28). Twelve grams (0.27 mol) of anhydrous dimethylamine (Matheson) was bubbled into a solution prepared from 30.3 g (0.109 mol) of 2-phenylethyl-1,1-d_2-*p*-toluenesulfonate and 225 mL of ether. After the mixture had stirred overnight, the reaction mixture was diluted with 150 mL of water. The ether layer was separated and the remaining product was extracted with five 50-mL portions of ether. The amine was purified by extracting it with four 50-mL portions of 10% HCl. The acid extracts were made basic with 40% sodium hydroxide and the amine was extracted with five 50-mL portions of ether. The ether solution was reduced to 50 mL on the rotary evaporator, dried over anhydrous sodium sulfate, and distilled to give 7.8 g (47%) of 2-phenylethyldimethylamine-1,1-d_2, bp 62–64°C/4.5 Torr (lit. (13) bp 50–51°C/0.8 Torr). An nmr analysis indicated that the compound was at least 99% deuterated at the one position.

2-Phenylethyldimethylamine-1,1-d_2 *oxide*

The amine oxide was prepared by the method described by Dohner and Saunders (12). Approximately 1.6 mL of a 30% hydrogen peroxide solution was added to a mixture of 73.0 mg (4.83 mmol) of 2-phenylethyldimethylamine-1,1-d_2 in 95 mL of methanol that had been cooled in an ice bath. Then, 50.4 mg of 10% platinum on activated carbon (Aldrich) was weighed accurately into a 250-mL round-bottomed flask and the flask was flushed with dry nitrogen for 2 min. The hydrogen peroxide – amine solution was poured rapidly onto the activated carbon and the resulting mixture was stirred for 3.5 h at room temperature. The carbon particles were removed by filtering the reaction mixture through a fine sintered glass filter. Removing the methanol on the rotary evaporator left a pale yellow solution that contained a small amount of water (13). The nmr spectrum was consistent with the expected product and indicated that the compound was at least 99% deuterated at the α carbon.

2-Phenylethyldimethylamine oxide

The undeuterated analogue of 2-phenylethyldimethylamine-1,1-d_2 oxide was prepared using the procedures described above. Comparable yields and physical properties were found for the deuterated and undeuterated products.

Kinetic measurements

All but one set of the kinetic experiments were carried out at 60.0 ± 0.1°C. In one experiment, the kinetic isotope effect was measured at a slightly lower temperature. In all cases, however, the kinetic isotope effects were calculated from rate constants determined for reaction of the deuterated and undeuterated substrates, which were measured simultaneously. This procedure eliminated the effect of any possible fluctuations in temperature that occurred in the constant temperature bath.

Each kinetic run was initiated by weighing approximately 20 mg of the amine oxide accurately in a small Erlenmeyer flask fitted with a serum cap. The 90 mol% DMSO–water solvent used in these experiments was prepared from purified DMSO (*vide supra*) and distilled water. Each run was begun by pipetting 15 mL of the 90 mol% DMSO–water solution, which had been temperature equilibrated for at least 1 h, into the Erlenmeyer flask containing the amine oxide. The serum cap was replaced and 100-μL aliquots were withdrawn from the reaction flask at appropriate times with a Hamilton gas-tight fixed needle syringe. Each sample was diluted to 5.00 mL with 95% ethanol and the absorbance at 248 nm was recorded against a blank prepared by diluting 100 μL of 90 mol% DMSO–water to 5.00 mL with 95% ethanol on a Hewlett–Packard Model HP 8451A diode array uv–vis spectrophotometer. This removed the small absorbance due to the solvent at 248 nm. Each absorbance was the average of at least three separate readings on the spectrophotometer. The rate constant was determined from the slope of the least-squares line of the plot of $\ln (OD_\infty - OD_t)$ against time. The correlation coefficient for each kinetic run was at least 0.999. The kinetic isotope effect was calculated from rate constants for a pair of deuterated and undeuterated substrates that were determined simultaneously.

[4]*p*-Toluenesulfonyl chloride, 50 g, was dissolved in 125 mL of chloroform and 375 mL of petroleum ether (bp 35–55°C). Decolourizing carbon was added and the solution was filtered via a suction filtration. The filtrate was heated to boiling, sufficient chloroform was added to dissolve any precipitated product, and the solution was allowed to cool. Filtration gave 43 g of pure *p*-toluenesulfonyl chloride.

pK_a values for substituted acetophenones: values determined by study of rates of halogenation

J. Peter Guthrie,[1] John Cossar, and Alex Klym

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received November 11, 1986

J. Peter Guthrie, John Cossar, and Alex Klym. Can. J. Chem. **65**, 2154 (1987).

pK_a values in aqueous solution have been determined for seven *p*-substituted acetophenones. The determinations are based on the diffusion-controlled reaction of an enolate with hypochlorous acid. The values determined for the acetophenones are as follows: substituent, value; H, 18.4; *p*-MeO, 19.0; *p*-F, 18.5; *p*-Cl, 18.1; *p*-Br, 18.0; *p*-NO_2, 16.7; *p*-Me_3N^+, 17.1. ρ for these pK_a values is −1.95. Using literature values for the enol content we show that most of this ρ value reflects substituent effects upon enolization. With relatively high hydroxide and low hypochlorite concentrations the major products from chlorination of acetophenones are the corresponding mandelic acids. Under similar conditions bromination of acetophenone gives benzoic acid.

J. Peter Guthrie, John Cossar et Alex Klym. Can. J. Chem. **65**, 2154 (1987).

Opérant dans des solutions aqueuses, on a déterminé les valeurs de pK_a de sept acétophénones substituées en para. Ces déterminations sont basées sur la réaction, contrôlée par la diffusion, d'un énolate avec l'acide hypochloreux. Pour les diverses acétophénones, les valeurs déterminées sont (substituants, valeurs) : H, 18,4; *p*-MeO, 19,0; *p*-F, 18,5; *p*-Cl, 18,1; *p*-Br, 18,0; *p*-NO_2, 16,7; *p*-Me_3N^+, 17,1. La valeur de ρ pour ces valeurs de pK_a est de −1,95. Utilisant les valeurs trouvées dans la littérature pour la quantité d'énol présente dans ces systèmes, on démontre que cette valeur de ρ est un reflet des effets des substituants sur l'énolisation. Avec des concentrations relativement élevées d'hydroxyde de sodium et relativement basses d'hypochlorite, les produits majeurs de la chloration des acétophénones sont les acides mandéliques correspondants. Dans des conditions semblables, la bromation de l'acétophénone conduit à de l'acide benzoïque.

Introduction

We have developed a method for determining pK_a values of simple ketones (1, 2). Such pK_a values are useful in our investigations of the aldol condensation (3–9). Some of the simple aldol reactions which we have been investigating involve acetophenone as reactant; examples are the retroaldol cleavages of chalcone (7) and dypnone. For detailed analysis of these reactions it would be useful to have a pK_a value for acetophenone itself. With a method for determining pK_a's in hand it seemed worthwhile to investigate a series of substituted acetophenones, as a convenient series for mapping out the effects of substituents upon the equilibrium constant for enolate formation. Accordingly we wish to report the results of our investigations on a set of *p*-substituted acetophenones.

We have already reported (10) the results of a detailed investigation of the path of halogenation of acetone, which with hypochlorite at low concentrations at room temperature leads not to acetic acid as textbooks might suggest, but to lactic acid as major product. Various *p*-substituted acetophenones lead to the corresponding substituted mandelic acids; we have not performed detailed studies of the analogous intermediates, but presume that the qualitative pattern of the reaction is the same for these derivatives. A simplified form of the mechanism is shown in Scheme 1. Bromination gives the textbook product in the expected fashion.

Results and discussion

Product studies

We have shown that for *p*-methoxy-, *p*-fluoro-, *p*-chloro-, *p*-bromo-, and *p*-nitroacetophenone the corresponding mandelic acids can be prepared by hypochlorite oxidation. In the case of *p*-nitroacetophenone the conditions are critical because further slow oxidation to nitrobenzoic acid takes place. Even with only a slight excess of hypochlorite over the amount required by stoichiometry, and slow addition of hypochlorite to keep the instantaneous concentration low, we obtained only a 1:1 mixture of *p*-nitromandelic acid and *p*-nitrobenzoic acid. Although we doubt that this reaction will be of practical significance as a preparative route to mandelic acids, it does demonstrate very clearly that with low hypochlorite and high hydroxide concentrations the haloform reaction does not occur because competing hydrolysis diverts the reaction path. At this time we have not established whether the diversion takes place at the monochloroketone stage, as was found for acetone (10), or at the dichloroketone stage. Experiments to settle this point are in progress.

Kinetics

The results of our kinetics investigations on *p*-substituted acetophenones are found in Tables 1–7. Except for a few experiments with acetophenone all of these kinetics were carried out using hypochlorite in excess. All kinetics were carried out under pseudo-first order conditions. With hypochlorite in excess,

$$v = k_{obs}[\text{ketone}]$$

$$k_{obs} = k_{II}[OCl^-]_{total}$$

$$k_{II} = k_{II}^0 + k_{II}^-[OH^-]$$

The k_{II}^0 term represents reaction of the enolate ion with hypochlorous acid; thus it depends only on the rate constant for a diffusion-controlled reaction and the pK_a of the ketone and of hypochlorous acid (2). The k_{II}^- term represents reaction of the enolate ion with hypochlorite ion (2). The dependence of the apparent second order rate constants, k_{II}, upon the hydroxide concentration is shown in Fig. 1. These experiments were done at a constant ionic strength of 1 *M*, maintained with KCl. However, we found that for $[OH^-] > 0.5$ *M* these plots of k_ψ vs. $[OH^-]$ showed upward curvature. We attribute these deviations from linearity to imperfect matching of solvent properties between aqueous KCl and NaOH, and used only experiments with $[OH^-] \leq 0.5$ *M* for the final least-squares fits. [a]In water at 25°C, ionic strength = 1.00 (KCl).
[b]Observed pseudo-first order rate constant.
[c]Apparent second order rate constant: $k_{II} = k_\psi/[OCl^-]$.
[d]Not included in the least squares fit; see text.

the intercepts, k_{II}^0 of these plots, the pK_a values found in Table 8 could be calculated, using relationship [1]; we use $\log k_{diffusion} = 9.23 \pm 0.5$ (2),[2] and $pK_a^{HOCl} = 7.53$ (11),

[1] $\quad pK_a = \log k_{diffusion} + pK_{diffusion} + pK_a^{HOX} - \log k_{II}^0$

When pseudo-first order kinetics are carried out with ketone in excess, it may be shown that the pseudo-first order rate constant depends on the stoichiometry number for the reaction,

[2]The rate constant for a diffusion-controlled reaction is insensitive to the exact nature of the reactants (12); the difficulty in choosing an appropriate value is in making proper allowance for the non-spherical nature of the reactants (2).

[a]In water at 25°C, ionic strength = 1.00 (KCl).
[b]Observed pseudo-first order rate constant.
[c]Apparent second order rate constant: $k_{II} = k_\psi/[OCl^-]$.

while the pseudo-first order rate constant for kinetics with hypochlorite in excess is independent of the stoichiometry.

[2] $k_{pseudo} = nk_{II}[ketone]$ ketone in excess

$k_{pseudo} = k_{II}[OCl^-]$ hypochlorite in excess

Thus we must know the actual stoichiometry of the reaction under the conditions employed if k_{II} is to be calculated from the observed pseudo-first order rate constant. However, since the hypochlorite concentration is changing and the stoichiometry depends on the hypochlorite concentration, one must expect that the ratio of k_{pseudo} to k_{II} will change during a reaction. It is in fact surprising that one observes apparently good first order kinetics; it is quite possible that an average, effective, value of n is required.

TABLE 7. Kinetics of chlorination of *p*-trimethylammonioacetophenone[a]

[Ketone] 10^3 *M*	[OCl^-] 10^3 *M*	[OH^-] *M*	k_ψ[b] 10^4 s^{-1}	k_{II}[c] M^{-1} s^{-1}

Figure 2 shows a Hammett plot for the pK_a values of the substituted acetophenones; the slope of this plot is -1.95 ± 0.19. This is distinctly more negative than the value of -1.0 which might have been anticipated by analogy with the corresponding benzoic acids. However, the process for which we might expect an analogy with ionization of benzoic acids is not really ionization of the acetophenones, but ionization of the acetophenone enols, since ionization of acetophenones involves a tautomerization as well. The equilibrium constants for enolization of acetophenones (13, 14) give a ρ value of -1.39 ± 0.11 when log K is plotted against σ (Table 9). Thus we are left with the surprising finding that the actual ionization of the enols is in fact quite *insensitive* to substituents.

$$\rho_{pK_a}^{Keto} = \rho_{enolization} + \rho_{pK_a}^{Enol}$$

$$\rho_{pK_a}^{Enol} = -0.56 \pm 0.22$$

Given the sizeable uncertainties in pK_a values determined by assumption of a value for the rate constant of a diffusion-controlled reaction (2) this is not a strong conclusion. Nonetheless it seems likely that ionization of the enols is less sensitive to substituents than ionization of the corresponding benzoic acids.

There is also the interesting question of why there is a large ρ for enolization. A possible rationalization is that tautomerization from the keto to the enol is accompanied by a significant decrease in the partial positive character of the carbon bonded to the aromatic ring because of the change from sp^3 carbon and sp^2 oxygen as substituents on this carbon to sp^2 carbon and sp^3 oxygen. The decrease in electronegativity on going from sp^2 to sp^3 oxygen is much larger than the increase on going from sp^3 to sp^2 carbon; using the values suggested by Gasteiger (15) the decrease for oxygen is -2.89 and the increase for carbon is $+0.81$ (electronegativities, on the Mulliken scale, for the neutral atoms (15)). Thus the central atom sees a decrease in electron-withdrawing power of the atoms to which it is bonded, and becomes less positive itself.

Kresge and Wirz have recently (16) reported a pK_a value for acetophenone. Their value, 18.24 ± 0.03, is in good agreement with ours, 18.38 ± 0.52. The method of Kresge and Wirz is inherently precise, but requires synthesis of a suitable precursor which will give the desired enol on flash photolysis. Our method is inherently imprecise, but requires neither preparation of precursors nor the use of specialized apparatus.

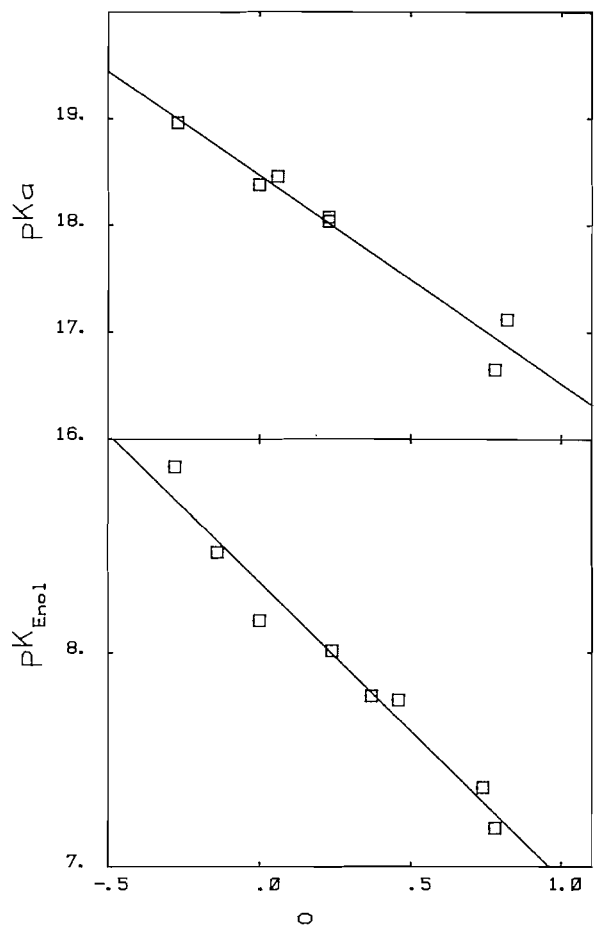

FIG. 2. pK_a values (this work) and enol contents (13, 14) for *m*- and *p*-substituted acetophenones as a function of Hammett σ values.

Experimental

Materials

All of the ketones used for kinetics were purified before use and purity was checked by running 200 MHz nmr spectra. In all cases negligible amounts of impurities were detectable except for traces of water in the liquid ketones.

Acetophenone, BDH "99%", was freshly distilled; bp 102–103°C (30 Torr), mp 20°C, lit. 20.5°C (17). p-*Bromoacetophenone*, Aldrich "98%", was purified by Kugelrohr distillation; mp 50–52°C, lit. 50–51°C (17). p-*Chloroactophenone*, Aldrich "97%", was purified by sublimation, 45°C at 0.02 Torr; mp 19°C, lit. 20°C (17). p-*Chloromandelic acid* was prepared by way of the intermediate α,α-dibromoacetophenone (18); mp 119–120°C; lit. (19) 120–121°C. p-*Fluoroacetophenone*, Aldrich "99%", was purified by gas chromatography on SE30 at 150°C; purity was confirmed by analytical gas chromatography (same conditions); only one peak was observed. p-*Fluoromandelic acid* was prepared by hydrolysis of the cyanohydrin derived from *p*-fluorobenzaldehyde (20), mp 135–136°C; lit. 137°C (20). p-*Methoxyacetophenone*, Aldrich "98%", was purified by Kugelrohr distillation; mp 37–38°C, lit. 38–39°C (17). p-*Nitroacetophenone*, Aldrich "97%", was purified by Kugelrohr distillation; mp 78–80°C, lit. 80–81°C (17).

p-*Nitromandelonitrile* was prepared from *p*-nitrobenzaldehyde and sodium cyanide (21). The literature procedure was modified by using a volume of dioxane equal to that of acetic acid to dissolve the *p*-nitrobenzaldehyde before the reaction. *p*-Nitrobenzaldehyde (2.0 g) yielded 0.91 g of a mixture which by ^{1}H-nmr appeared to be 25% *p*-nitrobenzoic acid and 75% *p*-nitromandelonitrile (35% crude yield). The α-proton appeared at δ = 5.77 ppm in 50:50 $CDCl_3/CD_3OD$. Crystallization, first from 80:20 CCl_4:$CHCl_3$, and then from toluene, gave 319 mg (13.5%) of purified material, mp 112–113°C; lit. mp (21) 114–116°C with decomposition. Exact mass calculated for $C_8H_6N_2O_3$: 178.03782; found: 178.0377 ± 0.0001. 200 MHz ^{1}H-nmr (1:1 $CDCl_3$:CD_3OD); δ = 4.80 (s, 1H) O*H*; 5.77 (s, 1H) C*H*(OH)(CN), 7.75, 7.79, 8.27, and 8.31 (1H multiplets), aromatic C*H*.

p-*Nitromandelic acid* was prepared by hydrolysis of the nitrile in 6 *M* HCl (21). The reaction mixture was extracted with ether, and the residue after evaporation was purified by column chromatography on silica gel, eluting with EtOAc:hexanes:acetone:formic acid 25:64:10:1.

p-NO_2	0.78	7.18

[a]In water at 25°C. For the substituted acetophenones, least squares gives $pK_{Enol} = 8.33 \pm 0.49 - (1.39 \pm 0.11)\sigma$.
[b]Reference 27.
[c]References 13, 14.

Chromatographically purified material was crystallized once from toluene and once again from $CHCl_3$:CCl_4 to yield 105 mg of needle-like crystals, mp 128–130°C, lit. (21) mp 131–132°C. 200 MHz ^{1}H-nmr (80:20 $CDCl_3$:CD_3OD): δ = 4.65 (b, 2H) O*H*; 5.30 (s, 1H) C*H*(OH)(COOH); 7.70, 7.75, 8.20, and 8.25, (1H multiplets) aromatic C*H*. Exact mass calculated for $C_8H_7NO_5$: 197.0334; found: 197.0326. Ultraviolet (water): λ_{max} = 280 nm, ε = 9300; shoulder at 214, ε = 6300; also ϵ_{292} = 8300, ϵ_{274} = 9100. There was little or no change upon addition of NaOH.

p-*Dimethylaminoacetophenone*. *p*-Aminoacetophenone (Aldrich), 2.3 g (0.017 mol); 98% formic acid, 5.3 mL (0.14 mol); and 37% formalin, 3.4 mL (0.037 mol HCHO) were heated on a steam bath for 2.5 h. Reaction progress was followed by TLC using 20% ethanol in hexanes. The reaction mixture was partitioned between 100 mL 1 *M* NaOH and 100 mL ether, and the aqueous phase was then extracted with ether (2 × 100 mL). The pooled ether solutions were dried (Na_2CO_3) and evaporated to yield a yellow, partially crystalline mixture. This was dissolved in boiling petroleum ether (100–110°C) containing 10% 1-propanol. On cooling in dry ice, darker impurities settled out; the solution was filtered, evaporated, and purified by Kugelrohr distillation to give material containing about 10% mono-*N*-methylaminoacetophenone and 90% di-*N*-methylacetophenone. This material was further purified by column chromatography on silica gel, eluting with 10% ethyl acetate in hexanes to give 180 mg *p*-di-*N*-methylaminoacetophenone, mp 103-105°C; lit. (17) mp 105.5°C.

p-*Trimethylammonioacetophenone*. *p*-Dimethylaminoacetophenone, 180 mg (1.1 mmol), was dissolved in benzene, 5 mL, treated with 0.34 mL (4.4 mmol) of dimethyl sulphate and allowed to stand at room temperature for 10 days. Crystals, 250 mg, were collected and washed with CCl_4; mp 128–131°C. This material was used without further purification. ^{1}H-nmr, 200 MHz (D_2O, DSS as reference) δ = 2.74 (3H, s) C*H*$_3$—CO; 3.77 (s) C*H*$_3$—OSO_3^- and 3.79 (s) $(CH_3)_3N^+$, (combined integral 12H); 8.16, (4H, AB pattern) aromatic C*H*. Lit. (22) δ 3.68 for $(CH_3)_3N^+$ at infinite dilution in D_2O containing 1% DSS. A sample of our material gave δ 3.69 for a 0.0012 *M* solution in D_2O containing 1% DSS.

Product studies were carried out by preparing aqueous solutions containing hydroxide, hypochlorite, and ketone at known concentration, allowing reaction at room temperature for a period approximately equal to that for a kinetics run, then destroying excess hypochlorite by adding sodium bisulphite, extracting the basic solution with three equal volumes of ether, acidifying (concentrated HCl) and extracting with three equal volumes of ether to obtain the organic acids. In some cases, repeated additions of small amounts of hypochlorite were used to simulate kinetics concentrations. Products were identified by 60 MHz ^{1}H-nmr and, where possible, by melting point and TLC comparison with authentic compounds.

p-*Methoxyacetophenone*, 0.0027 *M*; OH^-, 0.53 *M*; and OCl^-, 0.027 *M*, were allowed to react for 1 h. Workup gave *p*-anisic acid in 94% yield, mp 181–183°C; lit. (17) 185°C, mixture mp with an authentic sample (Matheson, Coleman and Bell) 181–183°C. *p*-Methoxyacetophenone, 0.0007 *M*; OH^-, 0.25 *M*; and OCl^-, 0.00025 *M*, in a volume of 2 L, were allowed to react over a period of 20 days; the hypochlorite concentration was maintained by seven additions at one day intervals of 0.5 *M* stock hypochlorite, 1 mL. The first five additions of hypochlorite were fully consumed within 1 day. *p*-Anisic acid (30%), and *p*-anisaldehyde (10%) were identified by TLC and nmr comparison with authentic standards: *p*-methoxymandelic acid, (60%) by nmr analysis, was isolated by preparative TLC. Two Kugelrohr distillations gave material of mp 103–105°C; lit. (23) 108°C. The mass balance based on the product ratio was 92%.

We suspect that the anisaldehyde was generated by oxidation of the mandelic acid by chlorine generated from chlorate plus chloride during and after extraction from acid. Chlorate is produced by disproportionation of hypochlorite (24). Bromine is known to bring about oxidative decarboxylation of mandelic acid (25) so it seems likely that chlorine could do so.

p-*Fluoroacetophenone*, 0.0013 *M*; OH^-, 0.2 *M*; and OCl^-, 0.005 *M*, were allowed to react for 20 h. Workup and crystallization from water gave *p*-fluorobenzoic acid, mp 183°C, lit. (17) 185°C, mixture mp with authentic sample 183°C. ^{1}H-nmr analysis of the initial extract showed that the product mixture contained 5% *p*-fluoromandelic acid as well as *p*-fluorobenzoic acid. When *p*-fluoroacetophenone, 0.00018 *M*; OH^-, 0.25 *M*; and OCl^-, 0.0002 *M* in a volume of 1 L were allowed to react for 3 days, with the hypochlorite concentration maintained by three additions of 0.5 *M* stock hypochlorite, 0.4 mL; final concentration was 0.0001 *M*. The extract of the acidified product mixture gave a spectrum almost identical to that of *p*-fluoromandelic

acid. Spectrum integrals indicated 5–10% *p*-fluorobenzoic acid and 90–95% *p*-fluoromandelic acid as products.

p-*Bromoacetophenone*, 0.00025 *M*; OH^-, 0.50 *M*; and OCl^-, 0.0005 *M* were allowed to react for 3 days, with the hypochlorite concentration maintained by three additions of stock hypochlorite. ^{1}H-nmr analysis of the extract from the acidified product mixture showed 90% *p*-bromomandelic acid and 10% *p*-bromobenzoic acid with 94% mass recovery.

p-*Chloroacetophenone*, 0.001 *M*; OH^-, 1.0 *M*; and OCl^-, $\leq$0.003 *M*, were allowed to react over a 3-h period with slow addition of hypochlorite, and then for a further 3 days. Workup gave a mixture identified by ^{1}H-nmr analysis as 10% *p*-chlorobenzoic and 90% *p*-chloromandelic acid. Crystallization from CH_2Cl_2 gave *p*-chloromandelic acid mp 120–121°C; lit. (19) 120–121°C.

p-*Nitroacetophenone*, 0.002 *M*; OH^-, 1.0 *M*; and OCl^-, 0.007 *M*, were allowed to react for 2 h. Workup gave *p*-nitrobenzoic acid in 76% yield as the only acidic product found: mp 240–241°C, lit. (17) 242°C.

p-*Nitroacetophenone*, 0.0005 *M*; OH^-, 0.4 *M*; and OCl^-, 0.002 *M*, were allowed to react for 24 h, and samples were taken at intervals and analyzed by HPLC. At 11 min after the start of the reaction, no more starting material could be detected, and the product ratio, *p*-nitrobenzoic acid:*p*-nitromandelic acid, was 1:1. After 24 h, only *p*-nitrobenzoic acid could be detected.

p-*Nitroacetophenone*, 0.0013 *M*; OH^-, 1.0 *M*; and OCl^-, 0.005 *M*, were allowed to react for 20 h, and samples were taken at intervals and analyzed by HPLC. At 6 min after the start of the reaction, no more starting material could be detected, and the product ratio, *p*-nitrobenzoic acid:*p*-nitromandelic acid, was 1.4:1. After 20 h, this ratio had become 5.5:1.

p-*Nitromandelic acid by hypochlorite oxidation of* p-*nitroacetophenone*. *p*-Nitroacetophenone, 165 mg (1.00 mmol), was dissolved in 1 L of boiling water and allowed to cool before dissolving NaOH, 20 g (0.5 mol). Sodium hypochlorite, 27.5 mL of 0.08 *M* solution (2.2 mmol), was added slowly over a period of 90 min with vigorous stirring at room temperature. After an additional 30 min, sodium bisulphite, 200 mg, was added to stop the reaction. The basic solution was extracted with ether (3 × 100 mL), acidified cautiously with 6 *M* H_2SO_4, 44 mL, and extracted again with ether (3 × 100 mL). The acid extract yielded 84 mg of yellow solid. Analysis of this material by ^{1}H-nmr revealed both *p*-nitrobenzoic and *p*-nitromandelic acids in almost equal amounts. TLC showed only two uv-active spots.

Bromination of acetophenone

Acetophenone, 0.00030 *M*; OH^-, 0.30 *M*; and OBr^-, 0.005 *M*, were allowed to react in aqueous solution 0.70 *M* in KBr (total volume 100 mL) at room temperature for 15 min. The reaction was quenched with 10 mL of a solution 0.05 *M* in bisulfite and 0.3 *M* in phosphoric acid, and adjusted to pH 7 with 6 *M* HCl (ca. 4 mL). The solution was analyzed by HPLC, with a Waters radial-PAK C8 reverse phase column, eluting with 24% methanol:76% aqueous 0.001 *M* H_3PO_4, 0.0001 *M* NH_3. Peaks were detected by uv absorption at 225 nm. The products, identified by comparison of retention times with authentic standards were mandelic acid, 2.6 ± 1%, and benzoic acid 97 ± 5%.

Methods

For ^{1}H-nmr spectra, all chemical shifts are relative to TMS as internal standard unless otherwise stated.

HPLC analyses were carried out using C8 or C18 reverse phase columns, with mixtures of aqueous buffers and methanol as eluting solvent and uv detection.

Kinetics procedures

All reactions were studied in aqueous solution at 25°C and ionic strength 1.0 *M* (KCl) using apparatus and procedures previously described (10). Hydroxide and hypochlorite solutions were titrated against standards as before (10). With acetophenone, *p*-chloro-, *p*-methoxy-, *p*-nitro-, *p*-trimethylammonio-, reactions were initiated as before (10) by injection of aqueous ketone solution. With *p*-fluoro- and *p*-bromoacetophenone, reactions were initiated by injection (Hamilton syringe) of aqueous hypochlorite, titrated just before use, into ketone solutions containing known hydroxide concentrations at 1 *M* ionic strength (KCl). All kinetics reactions were run with hypochlorite in large (ca. 20-fold) excess.

Influence of steric hindrance in molecules of substituted 2-phenyl-1,1,3,3-tetramethylguanidines on the kinetics and isotope effects of their proton transfer reactions with 4-nitrophenylnitromethane in acetonitrile solvent

PRZEMYSLAW PRUSZYNSKI[1]

Department of Chemistry, A. Mickiewicz University, Poznan, Poland

Received January 17, 1987

PRZEMYSLAW PRUSZYNSKI. Can. J. Chem. **65**, 2160 (1987).

Rate constants have been determined for the proton and deuteron transfer reactions of 4-nitrophenylnitromethane, $NO_2C_6H_4CH_2NO_2$, with three phenyl substituted derivatives of 2-phenyl-1,1,3,3-tetramethylguanidine, $X—C_6H_4—N=C[N(CH_3)_2]_2$, where X = 4-Cl, 2-Cl, and 2-Br, in the temperature range 278–308 K in acetonitrile solvent. In the concentration ranges used, the reaction to form an ion-paired product is first order in acid and first order in base. The reaction was followed spectrophotometrically using the stopped-flow technique. The reaction is fastest for the 4-Cl substituted base and slowest for the 2-Br analogue. The observed deuterium kinetic isotope effects show a clear dependence on the position and the size of the substituent in the base molecule. Kinetic isotope effects at 25°C, $k_H/k_D = 9.7 \pm 0.3$, 12.5 ± 0.3, and 15.6 ± 0.3, were observed for 4-Cl, 2-Cl, and 2-Br substituted bases respectively. The appropriate ratios of Arrhenius preexponential factors, $A_H/A_D = 0.98 \pm 0.10$, 0.87 ± 0.10, and 0.77 ± 0.10, may indicate increasing importance of tunnelling of the proton when the substituent is moved from the *para* to the *ortho* position or when the size of *ortho* substituent increases. Values of tunnelling correction factors were calculated using Bell's equation by means of the Caldor and Saunders method.

PRZEMYSLAW PRUSZYNSKI. Can. J. Chem. **65**, 2160 (1987).

Opérant dans l'acétonitrile comme solvant et à des températures allant de 278 à 308 K, on a déterminé les constantes de vitesse des réactions de transfert de proton et de deutéron du nitro-4 phénylnitrométhane, $NO_2C_6H_4CH_2NO_2$, vers trois dérivés, portant des groupements phényles substitués, de la phényl-2 tétraméthyl-1,1,3,3 guanidine, $X—C_6H_4—N=C[N(CH_3)_2]_2$ dans lequel X = les substituants Cl-4, Cl-2 et Br-2. Aux concentrations utilisées, la réaction conduisant à la formation d'une paire d'ions est du premier ordre en acide et du premier ordre en base. On a suivi la réaction en faisant appel à la spectrophotométrie et à la technique du flux stoppé. La vitesse de réaction de la base substituée par un Cl-4 est la plus rapide alors que celle de la base substituée par un Br-4 est la plus lente. Les effets isotopiques cinétiques du deutérium qui ont été observés démontrent clairement qu'il existe une relation avec la position et la taille du substituant dans la molécule basique. Pour les bases portant les substituants Cl-4, Cl-2 et Br-2, les effets isotopiques cinétiques à 25°C, k_H/k_D, sont respectivement de $9,7 \pm 0,3$, $12,5 \pm 0,3$ et $15,6 \pm 0,3$. Les rapports appropriés des facteurs préexponentiels d'Arrhénius, $A_H/A_D = 0,98 \pm 0,10$, $0,87 \pm 0,10$ et $0,77 \pm 0,10$, pourraient éventuellement indiquer que l'effet tunnel du proton augmente lorsqu'on déplace le substituant de la position *para* à la position *ortho* ou lorsqu'on augmente la taille du substituant *ortho*. On a calculé les facteurs de correction pour l'effet tunnel en faisant appel à l'équation de Bell et en appliquant la méthode de Caldor et Saunders.

[Traduit par la revue]

Introduction

The kinetics of the reaction between 4-nitrophenylnitromethane (4-NPNM) and 1,1,3,3-tetramethylguanidine (TMG) have been studied in several aprotic solvents by Caldin and Mateo (1). The large kinetic isotope effect values and anomalous Arrhenius parameters found for nonpolar solvents were explained in terms of participation of tunnelling to the reaction pathway (2–6). The strong solvent dependance of the kinetic isotope effect and the manifestation of the tunnelling effect were interpreted in terms of increase of effective mass of the transferred proton in polar solvents, when changes in solvation during the course of the reaction accompanied the translational movement of solvent molecules. The change in steric structure of tertiary amines caused by their protonation could also be considered as a factor increasing the effective mass of the transferred proton. Caldin and co-workers (7–10) compared the isotope effect for the reaction of 4-NPNM with tertiary amines (NEt_3 and NBu_3) with that measured for the more rigid quinuclidine. Their results were consistent with that for solvent dependance in the case of TMG, but the isotope effect was much smaller for tertiary amines than for TMG. These differences were explained in the terms of a greater curvature of the energy barrier in the case of imine bases. They suggested that the sp^2 nitrogen lone pair in TMG is more spherical, because of the greater contribution of the *s* orbital, than the lone pair of sp^3 hybridized nitrogen in amines, demanding closer approach of the reacting acid and base in the reaction complex. The values of volume of activation $\Delta V^{\neq}$ for the reaction of 4-NPNM and TMG in several solvents of low polarity were also measured (11). Other reactions of 4-NPNM with bases containing sp^2 hybridized nitrogen were then examined. Alkylimidamides (10), cyclic imidamide-DBU (12), and pentamethylguanidine (13) gave results confirming the need for a tunnelling correction; however, the values of the isotope effects were much lower than in the case of TMG as a base (1). Hubbard *et al.* (14) in a later paper reported k_H/k_D = 20–30 for the reaction of 4-NPNM with dialkylbenzamidamides in a series of solvents of low polarity. Rogne and co-workers (15–17), in a series of papers, discussed the influence of exchangeable hydrogen present in the TMG molecule on the kinetics of the deuteron transfer reaction. The "isotopic scrambling" effect, more important when the equilibrium constant is small, i.e., in the case of the reaction studied in solvents of low polarity, creates spurious values of the kinetic isotope effect. TMG and other imine bases are very difficult to dry, so the influence of residual water on the kinetics of the deuteron transfer reaction was also examined (18–20). This residual water can especially affect the deuteron transfer reaction when the concentration of the TMG solution is high (18), the condition used for reactions with low equilibrium constants. The influence of extraneous water was studied in the reaction of 4-NPNM with pentamethylguanidine (19) and with TMG in toluene (20). In both cases no such influence was observed, which must not be in contrast with the calculated

influence of TMG residual water as there were no data for water-free systems (18).

This work adds some further data to the widely studied kinetics and isotope effects of 4-NPNM. The synthesis of various phenyl substituted derivatives of 2-phenyl-1,1,3,3-tetramethylguanidine (21) was also accomplished earlier by Kessler and Leibfritz (22) and Oszczapowicz and Osek (23). Bases used in these studies, 2-(4′-chlorophenyl)-1,1,3,3-tetramethylguanidine, 2-(2′-chlorophenyl)-1,1,3,3-tetramethylguanidine, and 2-(2′-bromophenyl)-1,1,3,3-tetramethylguanidine, do not have the exchangeable hydrogens and are much less hygroscopic than TMG, so the measurements should not be affected either by isotopic scrambling or by water brought into the reaction mixture with the solution of base. These bases are also weaker than most of the imidine bases used before (21, 23), so one can expect a more symmetrical energy barrier and therefore a higher isotope effect arising from bigger loss of the zero-point energy difference between initial and transition states and from higher probability of tunnelling (4, 5). Results of Lewis and Funderberk (24, 25) and our previous measurements (26, 27) showed the strong dependance of the observed isotope effects on the presence of the substituent group close to the acidic or basic sites in the reactants. Changing the position and the size of the substituent on the phenyl ring creates the possibility of further observing the relation between the structure of the reactants and the isotope effects.

Experimental

Materials

4-Nitrophenylnitromethane and its deuterated analogue were prepared as previously reported (1). 2-(4′-Chlorophenyl)-1,1,3,3-tetramethylguanidine, 2-(2′-chlorophenyl)-1,1,3,3-tetramethylguanidine, and 2-(2′-bromophenyl)-1,1,3,3-tetramethylguanidine were synthesized using the condensation reaction of an appropriate derivative of aniline with 1,1,3,3-tetramethylurea in the presence of $POCl_3$ (21). The purity of these bases was checked by means of spectroscopic methods as described in ref. 21. The elemental analyses of these compounds, in good agreement with the calculated elemental content (21), confirm that they are not very hygroscopic. Acetonitrile was purified by the method of O'Donnell *et al.* (28), distilled through the 1.5-m column from P_2O_5, and only the middle fraction (about 60%) was collected. Its purity was checked by means of uv spectroscopy.

Measurements

The equilibrium measurements were performed using the Specord M-40 spectrophotometer equipped with a thermostating device by the method described in ref. 29. Values of the absorbance for solutions of 4-NPNM and base, with known initial concentration, were determined. Two millilitres of both acid and base solution were placed in the cuvette and thermostated for about 5 min in the spectrophotometer. The particular absorbance measurements could be affected by a slow decolorizing process, which might be a reason for some discrepancy between the equilibrium constants found from these measurements and those from the kinetic data. The decolorization is slow (half-life time of about 1 h or more) but it may lead to some errors in the equilibrium measurements. This effect cannot affect the kinetic runs, which are completed within seconds, especially as the Guggenheim method of calculation of the observed rate constant was used (30). The kinetic measurements were done spectrophotometrically using a stopped-flow apparatus. The kinetic runs were performed under pseudo-first-order conditions with base always in large excess. The kinetic curves were exactly exponential in the case of the proton transfer reaction. In the case of the deuteron transfer reaction the early part of the kinetic curve (about 10%) showed some contribution of the proton transfer reaction. This part showed a tendency to increase with time. Fresh solutions of deuterated 4-nitrophenylnitromethane were always used. After neglecting the beginning part of the curve (usually about 30%) the remainder was exactly exponential, giving a Guggenheim plot with a correlation coefficient similar to that for the proton transfer reaction. The observed rate constants k_{obs} for five base concentrations (b) were determined at each temperature. Then the least-squares method was used to fit the k_{obs} values against the base concentration, and the second-order rate constant for forward reaction k_2 and rate constant for backward reaction k_b were determined from the slope and the intercept of eq. [1]:

$$[1] \quad k_{obs} = (k_2 \times b) + k_b$$

The temperature dependance of the second-order rate constants in the temperature range 278–308 K allowed the activation parameters to be calculated. Calculations of the tunnelling correction factors were done using Bell's equation (4, 5) and the program of Kaldor and Saunders (31).

Results and discussion

The reaction of 4-nitrophenylnitromethane with three phenyl substituted derivatives of 2-phenyl-1,1,3,3-tetramethylguanidine: 2-(4′-chlorophenyl)-1,1,3,3-tetramethylguanidine, (**1**, 4-ClPhTMG), 2-(2′-chlorophenyl)-1,1,3,3-tetramethylguanidine (**2**, 2-ClPhTMG), 2-(2′-bromophenyl)-1,1,3,3-tetramethylguanidine (**3**, 2-BrPhTMG), in acetonitrile gives the red product, $\lambda_{max} = 500$ nm.

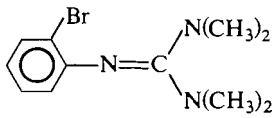
2



3

The equilibrium measurements gave a linear plot of a/A (a, the initial concentration of acid; A, the equilibrium absorbance of the reaction mixture) with $1/b$ (b, initial concentration of base), a relation expected for products existing in the form of ion pairs (29). The relation of a/A against A/b, expected to be linear when the product is in the form of separate ions (29), shows a distinct upward curvature so that the form of product is certain and in agreement with previous measurements (1, 29). A molecular extinction coefficient of the order of magnitude 2×10^4 dm^3 mol^{-1} cm^{-1} and equilibrium constants 600 ± 200, 400 ± 200, and 300 ± 140 dm^3 mol^{-1} for 4-ClPhTMG, 2-ClPhTMG, and 2-BrPhTMG respectively were calculated. The pK_a values measured in water at 25°C at ionic strength 0.1 mol dm^{-3} (21) are 11.70 ± 0.02 for 4-ClPhTMG, 11.16 ± 0.10 for 2-ClPhTMG, and 10.97 ± 0.04 for 2-BrPhTMG. The pK_a of 4-NPNM in water is 6.49 ± 0.01 (32). Kolthoff *et al.* (33) measured the pK_a values for various types of acids in acetonitrile. For tetramethylguanidine pK_a values of 23.3 in acetonitrile and 13.6 in water were found ($\Delta pK_{a(W-AN)} = 9.7$) (33). For uncharged acids, which during the dissociation process form an anion strongly solvated by water, the $\Delta pK_{a(W-AN)}$ value changes between 10.7 for picric acid and 17.5 for acetic acid (33). This value is lower when the extent of the delocalization of the negative charge in the anion increases. The anion of 4-NPNM resembles the picric acid anion much more than the acetic acid anion with negative charge localized at the oxygen. The difference in the pK_a for 4-NPNM and derivatives of Ph-TMG, 4–5 in water, decreases to about 2–3 when the system is transferred to acetonitrile, which is in

TABLE 2. Activation parameters for the proton and deuteron transfer reactions from 4-NPNM to 4-ClPhTMG, 2-ClPhTMG, and 2-BrPhTMG in acetonitrile solvent

Parameter	4-ClPhTMG	2-ClPhTMG	2-BrPhTMG
$\Delta H_H^{\ddagger}$ (kJ mol^{-1})	27.2 ± 1.1	29.3 ± 0.5	28.5 ± 0.5
$\Delta H_D^{\ddagger}$ (kJ mol^{-1})	32.8 ± 0.2	35.9 ± 0.7	35.9 ± 0.5
$\Delta S_H^{\ddagger}$ (J mol^{-1} deg^{-1})	−97.8 ± 4.0	−102.4 ± 1.7	−105.7 ± 1.7
$\Delta S_D^{\ddagger}$ (J mol^{-1} deg^{-1})	−97.8 ± 0.8	−101.2 ± 2.1	−103.7 ± 3.3
A_H (dm^3 mol^{-1} s^{-1})	(1.26 ± 0.59) × 10^8	(7.43 ± 1.59) × 10^7	(4.75 ± 0.99) × 10^7
A_D (dm^3 mol^{-1} s^{-1})	(1.29 ± 0.10) × 10^8	(8.50 ± 2.31) × 10^7	(6.11 ± 0.12) × 10^7

good agreement with the equilibrium constants observed for the reactions studied.

The value of the molecular extinction coefficient, about 2 × 10^4 dm^3 mol^{-1} cm^{-1}, is in good agreement with values found in previous measurements for reactions with 4-NPNM as an acid (1).

Table 1 presents the rate constants measured for the reactions studied. The second-order rate constants k_{2H} for 4-ClPhTMG, 2-ClPhTMG, and 2-BrPhTMG at 25°C are 810 ± 28, 202 ± 9, and 176 ± 3 dm^3 mol^{-1} s^{-1} respectively. The respective backward rate constants at 25°C are 0.7 ± 0.1, 0.4 ± 0.1, and 0.3 ± 0.1. The ratio of forward and backward rate constants gives the equilibrium constants 1100 ± 200, 500 ± 50, and 550 ± 100 for 4-Cl, 2-Cl, and 2-Br derivatives respectively. These values are in satisfactory agreement with those found from equilibrium measurements in the light of problems explained in the experimental section.

This reaction is fastest for the strongest base 4-ClPhTMG and is much slower for both *ortho*-substituted bases. Table 2 gives the activation parameters for the reactions studied.

These values show that the enthalpy of activation increases in the order 4-ClPhTMG, 2-BrPhTMG, and 2-ClPhTMG showing that the bond-forming–bond-breaking process on the way to the transition state is becoming more endoergic in this sequence. This is not in full agreement with the pK_a values in the case of 2-Cl and 2-Br derivatives. Nevertheless the difference of the pK_a in water for these two bases is small, and might be easily reversed in acetonitrile. The activation parameters in the case of 2-BrPhTMG and 2-ClPhTMG are comparable within the experimental error but, if their mean values are considered, it is the entropy of activation that makes reaction of 2-BrPhTMG slower. The more negative value of the entropy of activation and the lower value of the Arrhenius preexponential factor for 2-BrPhTMG than for 2-ClPhTMG may be explained in terms of greater steric inhibition in forming the transition state for reaction when larger bromine is present in the position *ortho* to the basic site of the reactant. Such a case is an interesting model for studying the influence of steric hindrance on the values of kinetic isotope effects. The strength of the bases used differs so slightly that, especially in the case of carbon acids, it should not

TABLE 3. Isotope effects for the proton transfer reactions from 4-NPNM to 4-ClPhTMG, 2-ClPhTMG, and 2-BrPhTMG in acetonitrile

	4-ClPhTMG	2-ClPhTMG	2-BrPhTMG
k_{2H}/k_{2D} at 5 (°C)	11.5 ± 0.5	15.4 ± 0.5	18.6 ± 1.2
10	11.0 ± 0.7	13.8 ± 0.8	18.4 ± 0.5
15	10.9 ± 0.2	13.4 ± 0.9	17.2 ± 0.4
20	9.6 ± 0.3	12.6 ± 0.8	16.1 ± 0.3
25	9.7 ± 0.3	12.5 ± 0.7	15.6 ± 0.3
30	8.9 ± 0.4	11.6 ± 0.6	15.1 ± 0.2
35	9.5 ± 0.4	11.6 ± 0.5	13.5 ± 0.2
$\Delta\Delta H^*$ (kJ mol^{-1})	5.7 ± 1.6	6.6 ± 0.8	7.4 ± 0.7
$\Delta\Delta S^*$ (J mol^{-1} deg^{-1})	0.0 ± 3.8	1.3 ± 2.7	2.1 ± 3.8
A_H/A_D	0.98 ± 0.46	0.87 ± 0.19	0.77 ± 0.16
$Q_{t,H}/Q_{t,D}$	—	1.12 ± 0.12	1.22 ± 0.19

affect the symmetry of the transition state, and the variation in the isotope effects can be entirely attributed to the steric conditions of the reactions.

Table 3 presents the values of kinetic isotope effects k_{2H}/k_{2D}, differences in the activation parameters, and the calculated tunnelling correction factors. The kinetic isotope effect increases when the Cl substituent is moved from the *para* to the *ortho* position and increases further when Cl is replaced by the larger Br substituent (Table 3). In the case of 4-ClPhTMG the observed isotope effects, both on the rate constants and on the activation parameters, are within the range predicted from the zero-point energy difference for C—H and C—D bonds. The A_H/A_D value is often used as an indicator of the occurrence of a tunnelling effect in proton transfer reactions (4–6). In the present results a part of the increase in the isotope effect can be attributed to the increasing importance of proton tunnelling. The value $A_H/A_D = 0.98 \pm 0.46$ for 4-ClPhTMG is close to the classical value $A_H/A_D = 1$, and decreases smoothly to $A_H/A_D = 0.87 \pm 0.19$ for 2-ClPhTMG and to 0.77 ± 0.16 for 2-BrPhTMG, although the mean values are still within the so-called "classical" range (4, 5). Also, the standard deviation values indicate that the tunnelling effect explanation should be treated as an alternative. For the last two bases the tunnelling correction factors were calculated using Bell's equation (4, 5) and the Kaldor and Saunders computing procedure (31). The values of the ratio of tunnelling correction factors for the proton and deuteron transfer reactions, $Q_H/Q_D = 1.12 \pm 0.12$ for the 2-ClPhTMG and 1.22 ± 0.19 for 2-BrPhTMG, indicate a small participation of tunnelling in these reactions that increases smoothly with steric crowding around the basic site. These results are in good agreement with those of Lewis and Funderburk for the reaction of 2-nitropropane with pyridine bases (24, 25) and with our previous results (26, 27).

ANGEL GUZMÁN, ELFIDA MARTINEZ, ESPERANZA VELARDE, MICHAEL L. MADDOX, and JOSEPH M. MUCHOWSKI. Can. J. Chem. **65**, 2164 (1987).

The synthesis of 4-oxo-9-deoxy-9-azaprostaglandin I_2 (**23***a*) and two ω-chain analogues thereof (**23***c* and **23***e*) is described. The most salient features of the synthetic process used were (*a*) introduction of the nitrogen functionality at C-9 by [3,3] sigmatropic rearrangement of the trichloroacetamidate **5***b* to the trichloroacetamide **6**, (*b*) transformation of **6** into the bicyclic lactam **7** with sodium borohydride, (*c*) stereospecific introduction of the 11α-hydroxyl group via the bromohydrin **8***a*, and (*d*) attachment of the α chain by extrusion of sulfur from the thioimidates **20** by the Eschenmoser sulfide contraction process.

ANGEL GUZMÁN, ELFIDA MARTINEZ, ESPERANZA VELARDE, MICHAEL L. MADDOX et JOSEPH M. MUCHOWSKI. Can. J. Chem. **65**, 2164 (1987).

On décrit la synthèse de l'oxo-4 déoxy-9 aza-9 prostaglandine I_2 (**23***a*) et de deux de ses analogues avec une chaîne ω (**23***c* et **23***e*). Les caractéristiques principales du processus de synthèse utilisé sont (*a*) l'introduction d'une fonction azotée en C-9 par une transposition sigmatropique [3,3] du trichloroacétamidate **5***b* en trichloroacétamide **6**, (*b*) l'utilisation du borohydrure de sodium pour transformer le composé **6** en la lactame bicyclique **7**, (*c*) l'introduction stéréospécifique du groupement hydroxyle en 11α par le biais de la bromohydrine **8***a* et (*d*) l'attache de la chaîne α par une extrusion de soufre à partir des thioimidates **20** en faisant appel au processus d'Eschenmoser pour la contraction des sulfures.

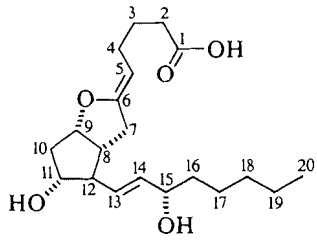
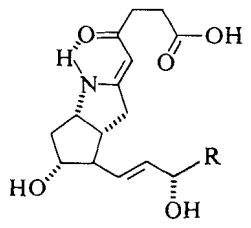
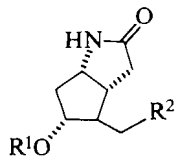
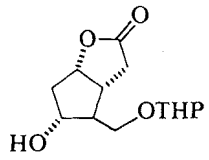
Prostacyclin (PGI_2, **1**) is the most powerful endogenous inhibitor of platelet aggregation discovered to date (1, 2). The endocyclic enol ether moiety present in this molecule renders it exceedingly sensitive to acidic conditions and even at physiological pH its half-life is only ca. 3 min. It is thus ineffective orally and when it is administered by intravenous infusion its physiological effects disappear rapidly after termination of the infusion. Considerable effort has been devoted to the synthesis of prostacyclin analogues with reduced acid sensitivity and improved metabolic stability. The acid sensitivity problem has been solved by stratagems such as replacement of the enol ether oxygen by other atoms (e.g., sulfur, nitrogen, or carbon), resonance stabilization in the vinylogous sense (for example, with an oxo group at C-4 (3) or a nitrile moiety at C-5 (4)), inductive stabilization by suitably placed electron attracting substituents (e.g. fluorine at C-7 (5) or C-10 (6)), etc. (for reviews on this subject, see refs. 7–9). Metabolic stability has been conferred upon prostacyclin derivatives by the incorporation of a wide variety of structural modifications into the upper (α) and lower (ω) side chains (7–9). It occurred to us that the prostacyclin analogue **2** was a particularly attractive synthetic target because of the minimal acid sensitivity, good chemical stability, and marked preference for the hydrogen bonded *Z* isomeric form associated with the vinylogous amide functionality (10, 11).

It was our intention of effect the introduction of the vinylogous amide moiety of **2** by the Eschenmoser sulfide contraction reaction (10) and thus the lactam **3** was an obvious starting material. One such compound (**3**, R^1 = Ac, R^2 = OTHP) had already been synthesized by Bartmann *et al.* (12) in seven steps from the Corey lactone **4** (13). In our hands,









this reaction sequence was not easily reproducible and therefore another synthetic route to lactams of this class was devised. Thus, the readily available unsaturated ester **5***a* (ref. 14, Scheme 1) was converted into the trichloroacetamidate **5***b*, which underwent [3,3] sigmatropic rearrangement (15) to the allylic trichloroacetamide **6** (54% yield from **5***a*) in boiling xylene (133°C in Mexico City!). This compound was transformed directly into the unsaturated bicyclic lactam **7** (80%) on reductive deacylation with ethanolic sodium borohydride at 60°C (16). The structure on this compound is fully supported by the 300-MHz nmr spectrum (Table 1). *N*-Bromosuccinimide in wet dimethylsulfoxide (17) effected the conversion of **7** into a single bromohydrin **8***a* in 72% yield. The stereo- and regiochemistry shown in **8***a* was originally assigned by analogy to that observed for the products obtained from the very closely related bicyclic unsaturated systems **10**, **11**, and **12** with *N*-bromoacetamide in aqueous acetone (18), iodine acetate in

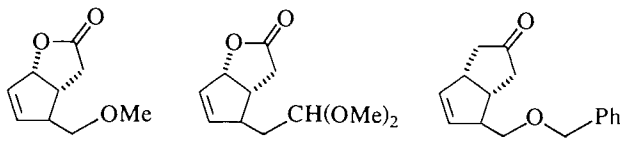
SCHEME 1

dry acetic acid (19), and *N*-bromosuccinimide in wet dimethylsulfoxide (14), respectively. In addition, the proton coupling constants (Table 1) were similar to those reported for a closely related model system (20). The structure of **8***a* was verified by reductive debromination of the derived acetate **8***b* with tri-*n*-butyltin hydride followed by hydrogenolytic debenzylation (Pd–C) of **9***a*, thus obtained, to the known (12) diol monoacetate **9***b*.[3]

For the synthesis of the desired prostacyclin derivatives, the bromohydrin **8***a* was converted into the *p*-phenylbenzoate ester **8***c* or the *tert*-butyldimethylsilyl ether **8***d*, which, on reductive debromination (to **9***c* and **9***e*) and subsequent catalytic hydrogenolysis, as described above, gave the primary alcohols **9***d* and **9***f*. Oxidation of these alcohols with Collins reagent (21) and immediate condensation of the crude, unstable aldehydes **13***a* and **13***b* (Scheme 2) with the sodium salts of the appropriate ketophosphonates provided the enones **14***a–d*. In general, considerably better overall yields of the enones **16** were



10 **11** **12**

obtained when the silylated alcohol **9***f* was used as the aldehyde precursor for the Wadsworth–Emmons (22) reaction. Reduction of the enones with methanolic sodium borohydride containing cerous chloride (23) produced mixtures of epimeric alcohols, the ratios of which depended on the nature of the alcohol protecting group at C-11 (prostaglandin numbering). The *p*-phenyl benzoate esters **14***a* and **14***c* gave rise to nearly equal amounts of the 15α and 15β isomers[4] **15***a,c* and **15***b,d* whereas a 2:1 ratio of epimers **17***a,c* and **17***b,d* was formed from the silyl ethers **14***b,d*. These alcohols (separable by flash chromatography or preparative tlc on silica gel) were then transformed into the bis-*tert*-butyldimethylsilyl ethers **18***a–f*, either directly, in the case of **17***a–d*, or after conversion into the diols **16***a–d*. Reaction of **18** with Lawesson's reagent (24) in hot benzene provided the thiolactams **19** (Scheme 3) in ca. 70–80% yield. The stage was now set for the introduction of the upper (α) side chain by the sulfide contraction process. Alkylation of the sodium salts of the thiolactams with methyl 5-bromolevulinate gave the unstable thiaimino compounds **20**, which, without purification, were heated with potassium-*tert*-butoxide in a xylene–*tert*-butanol mixture containing triphenylphosphine. The silylated vinylogous amides (**21***a–f*), formed in 55–70% yield, showed the expected infrared absorptions at 3280, 1625, and 1545 cm^{-1} and, in the case of **21***f*, the broad band at 3280 cm^{-1} did not shift on dilution (0.1–0.01 *M*). In addition, the compounds had a singlet nmr absorption at ca. δ 5.0 for the lone olefinic hydrogen atom (at C-5), a broad peak for a strongly H-bonded NH at δ 9.9 ± 0.2, and an intense uv absorption near 306 nm (ε ~ 19 000) for the vinylogous amide chromophore. These spectroscopic properties are virtually identical to those reported (10) for the monocyclic vinylogous amide **24**. Desilylation of **21** was effected with tetra-*n*-butylammonium fluoride in tetrahydrofuran (25) at 40°C and the methyl esters **22**, so produced, were hydrolysed with potassium carbonate in methanol–water solution. Both the methyl esters **22** and the carboxylic acids **23** could be kept for long periods of time at ambient temperature without appreciable decomposition. The carboxylic acids exhibit considerable stability under acidic conditions. Indeed, tlc purification thereof was carried out using an acetic acid containing solvent system.

The carboxylic acids were tested as inhibitors of ADP induced aggregation of human platelet rich plasma in vitro by a modification of the method of Born (26). The 15-cyclopentyl compound **23***e* was the most active member of this series of compounds (see Table 2) with a potency ca. one-quarter that of PGE_1. This low level of activity (~0.01 × prostacyclin sodium salt) was surprising in view of the fact that, where comparisons were possible, the nmr spectral parameters of **23***b* (Table 1), and by implication **23***a*, and prostacyclin (27) showed considerable

[3]We thank Dr. W. Bartmann, Hoechst, A. G. Frankfurt am Main, for providing us with a copy of the nmr spectrum of **9***b*, which was identical to that obtained by us (see Table 1).

[4]The α stereochemistry was assigned to the less polar 15-hydroxy compounds **15***a,c* and **17***a,c* (see Table 3) because, in each case, these gave rise to the azaprostacyclin epimer, which was the more potent inhibitor of adenosine diphosphate (ADP) induced aggregation of human platelet rich plasma (HPRP; see below).

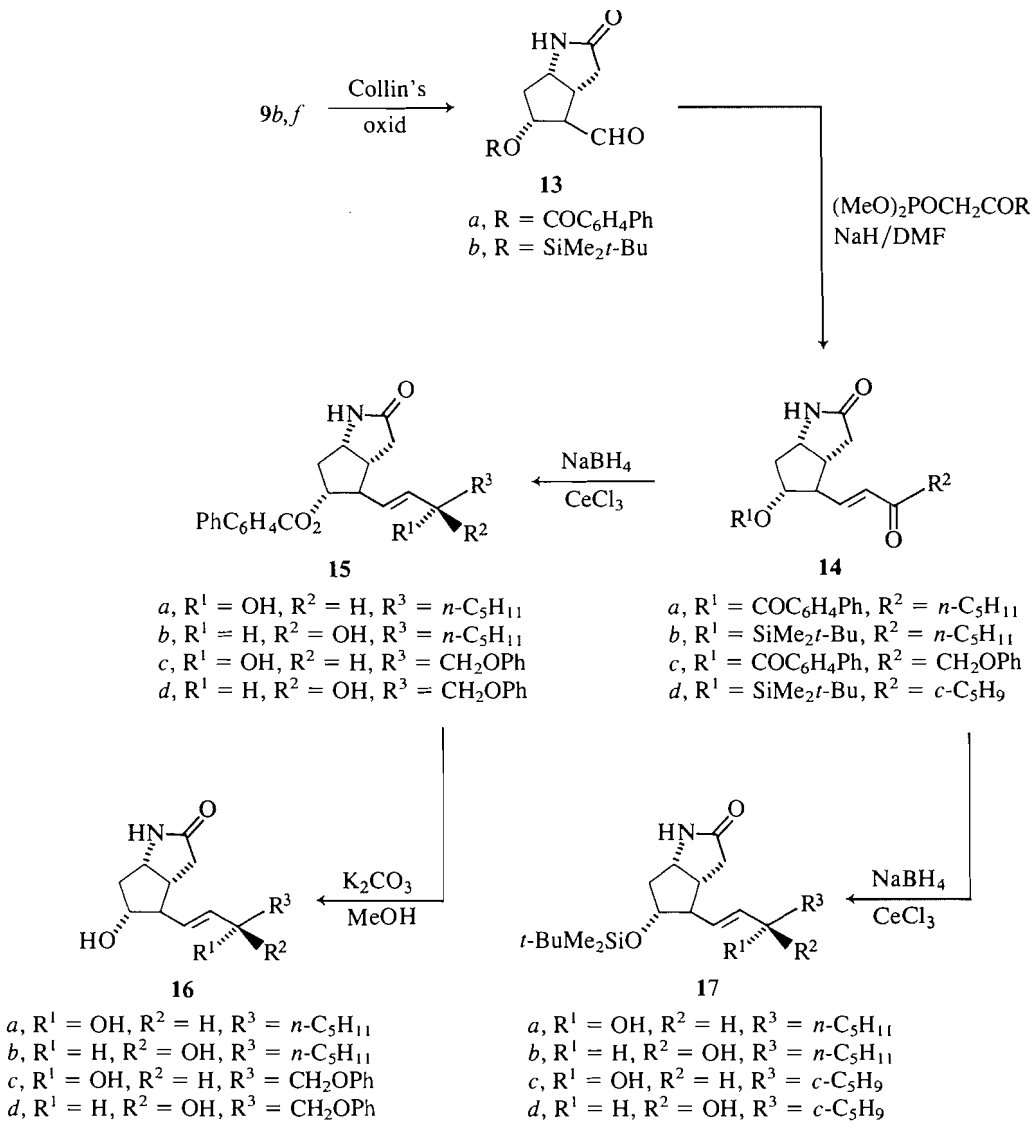

SCHEME 2

similarity, indicating a significant conformational congruence between these compounds. It is conceivable that the weak activity of these compounds is a consequence of the rigidity of the vinylogous amide system, which may not permit the carboxyl group to reach the required PGI_2 receptor binding site,[5] but other explanations are possible.

Experimental

The melting points were determined in a Mel-Temp melting point apparatus and are not corrected. The infrared spectra were measured in chloroform solution, unless specified otherwise, with a Perkin–Elmer Model 237 grating spectrophotometer. The ultraviolet spectra were recorded in methanol solution with a Perkin–Elmer Model 402 ultraviolet visible spectrometer. The nmr spectra were obtained with a Varian EM-390 or a Bruker WM 300 nmr spectrometer and are expressed as parts per million (δ) from internal tetramethylsilane. The high resolution mass spectra were measured with a Varian-MAT 311A mass spectrometer.

The terms "worked up in the usual manner" or "the usual work-up" signify that the extract was washed successively with water and saturated sodium chloride solution, then it was dried over magnesium sulfate, and the solvent was removed *in vacuo*.

[5]We thank a referee for this suggestion.

Methyl ω-bromolevulinate

Monomethyl succinate (87 g, 724 mmol) and thionyl chloride (103 mL) were heated together at 40°C for 2 h. The excess thionyl chloride was removed *in vacuo* and the residual oil was distilled at 77–80°C/4 Torr (1 Torr = 133.3 Pa) (95% yield). The acid chloride (6 g) was added dropwise at 0°C to ethereal diazomethane (2.5 equiv. in ether (58 mL)). One half hour after the addition was completed a stream of argon was passed through the solution to remove the excess diazomethane. The solvent was then removed *in vacuo* at room

24

temperature and the residue was dissolved in ether (85 mL) and cooled to 0°C. An ethereal solution of 1.17 *M* hydrogen bromide (14.2 mL) was added and stirring was maintained for 1 h. The ether was washed with saturated sodium carbonate solution and then worked up as usual. The crude product was distilled at 66–70°C/0.3 Torr (85% yield). This oil solidifies (lit. (10) mp 4°C) in the refrigerator.

Synthesis of the trichloroacetamide **6**

A solution of the unsaturated alcoholic ester **5***a* (12.8 g, 82.6 mmol) in anhydrous ether (100 mL) was added at room temperature to a stirred suspension of sodium hydride (0.328 g, 8.2 mmol; 60% dispersion in mineral oil) in anhydrous ether (90 mL). When hydrogen evolution had terminated (20 min), the solution was cooled to −30°C and a solution of trichloroacetonitrile (8.3 mL, 11.9 g, 82 mmol) in dry ether (15 mL) was added slowly to the stirred solution. The reaction temperature was allowed to reach −10°C and after 25 min at this temperature methanol (1.5 mL) and pentane (750 mL) were added, the mixture was filtered to remove a small amount of a solid, and the filtrate was evaporated *in vacuo*. The crude[6] trichloroacetamidate **5***b* was dissolved in xylene

[6]If the crude trichloroacetamidate was subjected to flash chromatography on silica gel (50 g/g mixture) using hexane – ethyl acetate (4:1) as the eluting solvent, a sample of the pure imidate **5***b* could be isolated, in about 30% yield, as an oil; ir: 3350, 1735, 1665 cm^{-1}; nmr δ: 2.32 (m, 1H, H-12), 2.47 (dd, 1H, $J_{7A,8}$ = 8.0 Hz, $J_{7A,7B}$ = 20.4 Hz, H-7A), 2.57 (dd, 1H, $J_{7B,8}$ = 7.0 Hz, $J_{7A,7B}$ = 20.4 Hz, H-7B), 2.93 (m, 1H, H-8), 3.61 (d, 2H, *J* = 7.5 Hz, 13-CH_2), 3.66 (s, 3H, OMe), 4.54 (s, 2H, OCH_2), 5.66 (m, 1H, H-11), 5.95 (m, 1H, H-10), 6.08 (m, 1H, H-9), 7.32 (m, 5H, C_6H_5), 8.28 (s, 1H, NH); ms *m/e* (CI NH_3): 439, 437 (MNH_4^+), 420 (MH^+), 386 (MH^+ − Cl + H), 352 (386 − Cl + H). This material was not characterized further. Continued elution of the column gave an apparent mixture (3:1) as judged by tlc and nmr (ca. one-half, in weight terms, of the pure imidate), as an oil; ir: 3350, 1735, 1665 cm^{-1}; nmr δ: 2.14, 2.33, 2.46 (multiplets, total 3H), 2.89 (m, 1H), 3.55 (d, 1.5H, *J* = 6.3 Hz), 3.59 (d, 0.5H, *J* = 6.4 Hz), 3.64 (s, 1H, OCH_3), 4.51, 4.53 (singlets, total 2H, OCH_2), 5.54 (bs, 0.75H), 5.66 (bs, 0.25H), 5.75 (m, 0.75H), 5.94 (m, 1H), 6.06 (m, 0.25H), 7.29 (m, 5H, C_6H_5), 8.27

(250 mL) and the solution was heated at reflux temperature (133°C in Mexico City) for 6 h. The solvent was removed *in vacuo* and the residue was dissolved in anhydrous methanol (328 mL) and anhydrous potassium carbonate (18.7 g, 135 mmol) was added thereto. The mixture was stirred at room temperature for 2.5 h, it was then cooled to 0°C and 1 *M* hydrochloric acid was added until a neutral solution was obtained. The methanol was removed *in vacuo* and the aqueous phase was extracted with ethyl acetate. After the usual work-up the crude product was subjected to column chromatography on silica gel. Elution with hexane – ethyl acetate (9:1) gave the crystalline trichloroacetamide **6** (18.7 g). Elution with hexane – ethyl acetate (85:15) gave the starting ester **5***a* (7.1 g, 33%). The yield of the trichloroacetamide, based on trichloroacetonitrile, was 54%. After crystallization from dichloromethane–hexane the amide **6** had mp 81–82°C; ir: 3460, 1730 cm^{-1}; nmr δ: 2.40–3.15 (m, 4H, 7-CH_2, H-8,12[7]), 3.43 (d, 2H, J = 6 Hz, 13-CH_2), 3.63 (s, 3H, OMe), 4.50 (s, 2H, OCH_2), 5.13 (m, 1H, H-9), 5.70 (m, 1H, H-10), 5.98 (m, 1H, H-11), 7.05 (bs, 1H, NH), 7.30 (s, 5H, C_6H_5). *Anal.* calcd. for $C_{18}H_{20}Cl_3NO_4$: C 51.38, H 4.79, Cl 25.28, N 3.33; found: C 51.65, H 4.72, Cl 25.13, N 3.30.

Sodium borohydride induced reductive cyclization of **6** *to bicyclic lactam* **7**

A solution of sodium borohydride (3.39 g, 95 mmol) in anhydrous ethanol (118 mL) was added to a stirred solution of **6** (10.0 g, 23.7 mmol) in ethanol (115 mL) maintained in a heating bath at 60°C in an argon atmosphere. The rate of addition was controlled so that the reaction temperature did not exceed 70°C. When the addition was completed, stirring was continued for a further 0.5 h and then the mixture was cooled to 0°C. Acetone (225 mL) was added and after stirring for 15 min the mixture was evaporated to dryness and the residue was extracted with ethyl acetate. The extract was worked up as usual and the crude product was purified by preparative tlc on silica gel using dichloromethane–ether (1:1) as the developing solvent. The crystalline bicyclic lactam **7** (4.6 g, 80%) was obtained, which after crystallization from ether had mp 56–57°C; ir: 3450, 1690 cm^{-1}; nmr (see Table 1). *Anal.* calcd. for $C_{15}H_{17}NO_4 \cdot 0.33H_2O$: C 72.26, H 7.14, N 5.62; found: C 71.84, H 6.84, N 5.58.

Synthesis of the bromohydrin **8**a

N-Bromosuccinimide (13.2 g, 74 mmol) was added to a cooled (10°C) stirred solution of the unsaturated lactam (9.0 g, 36.9 mmol) in dimethylsulfoxide (162 mL) containing water (18 mL). The reaction mixture was stirred at 20°C for 1 h, the dimethylsulfoxide was removed *in vacuo* (40°/0.4 Torr), and the residue was diluted with saturated aqueous sodium potassium tartarate solution (40 mL). The product was extracted into a 1:1 ether – ethyl acetate solution, the extract was worked up as usual, and the product was purified by tlc on silica gel using ethyl acetate – dichloromethane (9:1) as the developing solvent. The bromohydrin **8***a* was obtained as a solid (5.2 g, 72%) that, after crystallization from ether–hexane, had mp 89–90°C; ir: 3450, 3300, 1700 cm^{-1}; nmr (see Table 1). *Anal.* calcd. for $C_{15}H_{18}BrNO_3 \cdot 0.5H_2O$: C 51.78, H 5.48, Br 22.88, N 4.01; found: C 51.71, H 5.38, Br 22.58, N 4.07.

Conversion of the bromohydrin **8**a *to the diol monoacetate* **9**b

A solution of the bromohydrin **8***a* (0.750 g, 2.2 mmol) in pyridine (1.8 mL) and acetic anhydride (0.8 mL) was stirred at room temperature for 2 h. The solution was diluted with water, the product was extracted into ethyl acetate, and the extract was washed with 2% aqueous sodium bicarbonate solution, dried, and evaporated *in vacuo*. The residue was purified by preparative tlc on silica gel using ethyl acetate – dichloromethane (1:1) as the developing solvent. The acetate **8***b* (0.600 g, 72%) was obtained as an oil; ir: 3430, 1745, 1710 cm^{-1}; nmr δ: 1.90–3.15 (m, 4H), 2.06 (s, 3H, CH_3), 3.36–3.73 (m, 2H, CH_2O), 3.86–4.30 (m, 2H), 4.50 (s, 2H, OCH_2Ph), 5.37 (m, 1H, H-11), 6.80 (bs, 1H, NH), 7.33 (s, 5H, Ph). This material was used without further characterization as follows. A solution of the acetate **8***b* (0.600 g, 1.6 mmol) in toluene (15 mL) containing tri-*n*-butyltin hydride (0.727 g, 2.5 mmol) and azobisisobutyronitrile (0.003 g) was heated at 60°C for 1 h. The solvent was removed *in vacuo*, the residue was dissolved in acetonitrile and this solution was extracted with hexane. The acetonitrile phase was evaporated *in vacuo* and the residue was purified by tlc on silica gel using ethyl acetate as the developing solvent. The debrominated acetate **9***a* (0.370 g, 78%) was isolated as an oil; ir: 3440, 1730, 1690 cm^{-1}; nmr δ: 1.60–2.83 (m, 6H), 2.00 (s, 3H, CH_3), 3.50 (d, 2H, J = 4.5 Hz, CH_2O), 4.50 (s, 2H, OCH_2Ph), 5.03 (m, 1H, H-11), 6.53 (bs, 1H, NH), 7.33 (s, 5H, Ph). This compound was used without further characterization. A solution of **9***a* (0.350 g, 1.15 mmol) in ethyl acetate (20 mL) containing suspended 10% palladium on charcoal catalyst (0.070 g) was stirred under hydrogen at atmospheric pressure until 1 equivalent of hydrogen was absorbed (2.5 h). The mixture was filtered through Celite, the filtrate was evaporated *in vacuo*, and the residue was purified by tlc on silica gel using ethyl acetate – methanol (9:1) as the developing solvent. After crystallization from hexane–dichloromethane the diol monoacetate **9***b* (0.200 g, 82%) had mp 74–76°C; ir: 3400, 1730, 1700 cm^{-1}; nmr δ (see Table 1); *m/e*: 213.1001 (calcd. for $C_{10}H_{15}NO_4$: 213.1000).

Synthesis of the p*-phenylbenzoate* **8**c

4-Phenylbenzoyl chloride (6.65 g, 30.6 mmol) was added to a solution of the bromohydrin **8***a* (8.7 g, 25.6 mmol) in dry pyridine (31 mL). After stirring for 2 h at room temperature water (3 mL) was added and the mixture was stirred for a further 1 h. The pyridine was removed *in vacuo*, dichloromethane was added to the residue, and the mixture was filtered through a pad of Celite. The filtrate was washed with 10% hydrochloric acid and then worked up in the usual way. The crude product was subjected to column chromatography on neutral alumina (Fluka, Act. II) using dichloromethane as the eluant. The pure material (9.5 g, 71%) was obtained as a solid that, after crystallization from dichloromethane, had mp 131–133°C; ir: 3420, 1710 cm^{-1}; nmr δ: 2.10–3.16 (m, 4H, H-8,12), 3.60 (m, 2H, 13-CH_2), 4.00–4.33 (m, 2H, H-9,10), 4.47 (s, 2H, OCH_2Ph), 5.60 (t, 1H, J = 6 Hz, H-11), 6.80 (s, 1H, NH), 7.30 (s, 5H, Ph), 7.33–8.26 (m, 9H, C_6H_4–C_6H_5). *Anal.* calcd. for $C_{28}H_{26}BrNO_4$: C 64.61, H 5.03, Br 15.35, N 2.69, found: C 64.53, H 5.05, Br 15.38, N 2.60.

Synthesis of the tert*-butyldimethylsilyl ether* **8**d

tert-Butyldimethylsilyl chloride (1.60 g, 10.6 mmol) and imidazole (1.86 g, 27.4 mmol) were added to a stirred solution of the bromohydrin (1.00 g, 2.94 mmol) in dry dimethylformamide (14 mL). After 3 h at room temperature the solution was diluted with water and extracted with ethyl acetate. After the usual work-up the crude material was purified by tlc on silica gel using dichloromethane – ethyl acetate (1:1) as the developing solvent. The product (0.866 g, 65%) was obtained as a solid that, after crystallization from dichloromethane–hexane, had mp 106–108°C; ir: 3450, 1700 cm^{-1}; nmr δ: 0.07 (s, 3H, MeSi), 0.16 (s, 3H, MeSi), 0.86 (s, 9H, Me_3CSi), 1.70–3.06 (m, 4H, 7-CH_2, H-8,12), 3.55 (d, 2H, J = 4.5 Hz, 13-CH_2), 3.78 (m, 1H, H-11), 3.96–4.26 (m, 2H, H-9,10), 4.48 (s, 2H, OCH_2Ph), 6.60 (s, 1H, NH), 7.30 (s, 5H, Ph). *Anal.* calcd. for $C_{21}H_{32}BrNO_3Si$: C 55.49, H 7.19, Br 17.58, N 3.08; found: C 55.58, H 7.39, Br 17.69, N 3.06.

Reductive debromination of the p*-phenylbenzoate* **8**c *to* **9**c

A solution of the bromo compound **8***c* (8.50 g, 16.3 mmol) in dry benzene (140 mL) containing tri-*n*-butyltin hydride (5.82 g, 20 mmol) and azobisisobutyronitrile (0.028 g) was heated at 60°C for 4 h. The solvent was removed *in vacuo* and the residue was dissolved in acetonitrile (400 mL). The solution was washed several times with hexane (discarded) and then evaporated *in vacuo*. The residue was subjected to column chromatography on neutral aluminia (Fluka, Act

(s, 0.25H, NH). Meaningful mass spectra could not be obtained for this material. It was not characterized further.

When the pure imidate **5***b* was heated in dry xylene as described in the body of the experimental section, the pure trichloroacetamide **6** was obtained directly in 80% yield. When the above mixture was subjected to the same conditions, it was transformed into the trichloroacetamide **6** (40%) and the starting ester **5***a* (30%), but only after treatment with methanolic potassium carbonate.

[7]Prostaglandin numbering system.

For personal use only.

II) using dichloromethane as the eluant. The product **9***c* was isolated as a solid (6.10 g, 85%) that on crystallization from dichloromethane–hexane, had mp 145–146°C; ir: 3460, 1695 cm^{-1}; nmr δ: 2.10–2.86 (m, 4H, 7-CH_2, H-8,12), 3.51 (d, 2H, J = 6 Hz, 13-CH_2), 4.13 (m, 1H, H-9), 4.50 (s, 2H, OCH_2Ph), 5.35 (dd, 1H, $J \simeq 4.5$ Hz, H-11), 6.50 (s, 1H, NH), 7.28 (s, 5H, Ph), 7.20–8.50 (m, 9H, $C_6H_4C_6H_5$). *Anal.* calcd. for $C_{28}H_{27}NO_4$: C 76.06, H 6.16, N 3.17; found: C 75.88, H 6.17, N 3.08.

Reductive debromination of the tert*-butyldimethylsilyl ether 8*d *to 9*e

The debromination of **8***d* was effected in the same manner as described for **8***c* except that the reaction was carried out at 70°C for 2 h and the product, obtained in 95% yield, was purified by crystallization from dichloromethane–hexane. It had mp 108–110°C; ir: 3460, 1695 cm^{-1}; nmr δ: 0.10 (s, 6H, Me_2Si), 0.86 (s, 9H, Me_3CSi), 1.20–2.73 (m, 4H, 7-CH_2, H-8,12), 3.44 (d, 2H, J = 4.5 Hz, 13-CH_2), 3.80–4.20 (m, 2H, H-9,11), 4.46 (s, 2H, OCH_2Ph), 5.53 (s, 1H, NH), 7.30 (s, 5H, Ph). *Anal.* calcd. for $C_{21}H_{33}NO_3Si$: C 67.15, H 8.85, N 3.72; found: C 67.03, H 8.71, N 3.60.

*Hydrogenolysis of 9*c *to 9*d

A stirred solution of the benzyl ether **9***c* (8.70 g, 19.7 mmol) in dimethyoxyethane (75 mL) containing 70% perchloric acid (1.3 mL) and suspended 10% palladium on charcoal catalyst (3.1 g) was hydrogenated at room temperature and atmospheric pressure until hydrogen absorption ceased (10 h). The mixture was filtered through Celite, the filtrate was evaporated *in vacuo*, and the residue was dissolved in dichloromethane. This solution was worked up in the usual way to give the alcohol **9***d* as a solid (6.50 g, 94%) that, on crystallization from ethyl acetate – methanol, had mp 175–178°C; ir: 3480, 1695 cm^{-1}; nmr δ: 2.00–2.96 (m, 6H), 3.60 (m, 2H, 13-CH_2), 4.20 (m, 1H, H-9), 5.36 (q, $J \simeq 6$ Hz, H-11), 5.80 (s, 1H, NH), 7.33–7.66 (m, 5H, Ph), 7.89 (q, 4H, J_o = 7.5 Hz, C_6H_4). *Anal.* calcd. for $C_{21}H_{21}NO_4 \cdot 0.5H_2O$: C 69.98, H 6.15, N 3.89; found: C 70.00, H 5.87, N 3.89.

*Hydrogenolysis of 9*e *to 9*f

A stirred solution of the benzyl ether **9***e* (0.750 g, 2 mmol) in ethyl acetate (40 mL) containing suspended 10% palladium on carbon catalyst (0.15 g) was hydrogenated as described for the synthesis of **9***d* (18 h). After filtration of the mixture through Celite and evaporation of the filtrate *in vacuo*, the residue was purified by tlc on silica gel using ethyl acetate – methanol (98:2) as the developing solvent. The solid product (0.432 g, 76%), on crystallization from dichloromethane–hexane, had mp 80–82°C; ir: 3440, 3250, 1690 cm^{-1}; nmr δ: 0.07 (s, 6H, Me_2Si), 0.86 (s, 9H, Me_3CSi), 1.20–2.73 (m, 4H), 3.55 (d, 2H, J = 6 Hz, 13-CH_2), 3.80–4.20 (m, 2H, H-9,11). *Anal.* calcd. for $C_{14}H_{27}NO_3Si$: C 58.90, H 9.53, N 4.90; found: C 58.65, H 9.86, N 4.72.

Synthesis of the enones 14

(a) n*-Amyl enone 14*a

Collins reagent (22.7 g) and a suspension of the alcohol **9***d* (3.50 g, 10 mmol) in dry dichloromethane (100 mL) were added successively to a stirred suspension of Celite (45.4 g, dried at 125°C for 24 h) in anhydrous dichloromethane (300 mL) at 0°C. The reaction mixture was stirred at 5°C for 15 min, sodium bisulfate dihydrate (45.4 g) was added, and agitation was continued for a further 10 min at 5°C. The mixture was filtered through a pad of anhydrous magnesium sulfate, the filtrate was evaporated *in vacuo*, and the residual aldehyde **13***a* (~3.5 g) was used directly as follows. Dimethyl 2-oxoheptylphosphonate (2.09 g, 9.4 mmol) dissolved in dry dimethoxyethane (47 mL) was added to a stirred suspension of sodium hydride (obtained from a 60% dispersion in mineral oil (0.378 g, 9.4 mmol) washed with dry hexane) in anhydrous dimethoxyethane (112 mL). After 0.5 h at room temperature a solution of the above aldehyde (3.5 g) in dry dimethoxyethane (50 mL) was added and the mixture was stirred at room temperature for 2.5 h. Acetic acid (0.54 mL) was added, the solvent was removed *in vacuo*, and ethyl acetate was added to the residue. The mixture was filtered through Celite, the filtrate was dried, and the solvent was removed *in vacuo*. The residue was purified by the process indicated in Table 3. The yield, mp, solvent of crystallization, and elemental analysis are also found in this table.

*(b) Silylated enone 14*b

The synthesis of this compound was carried out as described for **14***a* except that the quantities of the phosphonate (0.490 g, 1.9 mmol), 60% sodium hydride (0.070 g, 1.75 mmol), and the crude aldehyde **13***b* (derived from 1.4 mmol (0.400 g) of the alcohol **9***f*) were slightly different and the reaction time was 1 h. See Table 3 for purification and physical constants; uv: 236 (10 700) nm; ir: 3460, 1700, 1670 cm^{-1}; nmr δ: 0.03 (s, 6H, Me_2Si), 0.73–1.03 (m, 12H), 1.16–2.80 (m, 14H), 3.77–4.20 (m, 2H, H-9,11), 6.15 (d, 1H, $J_{13,14}$ = 16 Hz, H-14), 6.63 (dd, 1H, $J_{12,13}$ = 7.5 Hz, $J_{13,14}$ = 16 Hz, H-13), 6.80 (s, 1H, NH).

*(c) 16-Phenoxy enone 14*c

The synthesis of this enone was carried out as described for **14***b* except that the phosphonate was dimethyl-2-oxo-3-phenoxypropylphosphonate and the reaction time was 3 h.

*(d) Cyclopentyl enone 14*d

This enone was prepared in the same manner as described for **14***b* except that dimethyl 2-oxo-2-cyclopentylethylphosphonate was used and the reaction time was 1.5 h.

Sodium borohydride reduction of the enones 14

*(a) Synthesis of 15*a *and 15*b

Methanolic cerous chloride hexahydrate (1.35 mL of a 0.4 *M* solution; 0.54 mmol) was added, at 0°C, to a stirred solution of the enone **14***a* (1.30 g, 2.9 mmol) in tetrahydrofuran (25 mL). Immediately thereafter, sodium borohydride (0.133 g, 3.5 mmol) was added in four equal portions at 1-min intervals. Stirring was continued for 7 min and then water (15 mL) was added and the reaction mixture was extracted with ethyl acetate. After the usual work-up, the crude product was purified as indicated in Table 3. The physical constants of the less polar 15α alcohol **15***a* and the more polar **15**β alcohol **15***b* are also found in Table 3.

*(b) Synthesis of 17*a *and 17*b *from 14*b

This reduction was effected as described above for **14***a* except that the enone (0.300 g, 0.79 mmol) was dissolved in methanol (28 mL) and was reacted with 0.4 *M* methanolic cerous chloride hexahydrate (0.3 mL) and sodium borohydride (0.030 g, 0.79 mmol). The mixture was separated by tlc as indicated in Table 3 to give the 15α (less polar) and 15β (more polar) alcohols **17***a* and **17***b*. Compound **17***a* had the following spectroscopic properties: ir: 3610, 3460, 1695 cm^{-1}; nmr δ: 0.03 (s, 6H, Me_2Si), 0.73–1.00 (m, 12H), 1.13–2.66 (m, 14H), 3.66–4.23 (m, 3H, H-9,11,15), 5.40–5.63 (m, 2H, H-13,14), 6.73 (bs, 1H, NH).

*(c) Synthesis of 15*c *and 15*d *from 14*c

This reduction was carried out as described for **14***a* except that the enone was dissolved in a tetrahydrofuran (30 mL/g enone) – methanol (10 mL/g enone) solvent mixture. The mixture of alcohols produced was separated by tlc on silica gel using the solvent system indicated in Table 3.

*(d) Reduction of 14*d *to 17*c *and 17*d

This reduction was carried out as described for **14***c* except that the enone **14***d* (3.6 g, 9.65 mmol) in methanol (100 mL) was reacted with 0.4 *M* methanolic cerous chloride hexahydrate (25 mL, 10 mmol) and sodium borohydride (0.377 g, 9.9 mmol). The mixture of alcohols obtained was separated by flash chromatography on silica gel (Merck, no. 9385) using hexane – ethyl acetate (1:1) as the eluting solvent.

Hydrolysis of the esters 15 to the diols 16

The conversion of **15***a* to **16***a* was typical. A solution of the *p*-phenylbenzoate **15***a* (0.500 g, 1.12 mmol) in absolute methanol (10 mL) containing anhydrous potassium carbonate (0.154 g, 1.12 mmol) was stirred at room temperature for 3 h. The solution was cooled

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

to 0°C, neutralized with 1 *M* hydrochloric acid (2.2 mL), and the methanol was removed *in vacuo*. The residue was mixed with ethyl acetate, and the organic phase was washed with 10% sodium bicarbonate solution and then worked up in the usual way. The crude diol was purified as indicated in Table 3. After crystallization, the less polar diol **16***a* had the following spectroscopic properties: ir: 3620, 3450, 1680 cm^{-1}; nmr δ: 0.88 (t, 3H, J = 6 Hz, 20-CH_3), 1.03–2.66 (m, 14H), 3.97 (m, 3H, H-9,11,15), 5.53 (m, 2H, H-13,14), 7.04 (bs, 1H, NH).

The diols **16***b*, **16***c*, and **16***d* were prepared as described above for **16***a* except that a mixture of methanol (10 mL) and tetrahydrofuran (2 mL) was used as the solvent for a reaction carried out on a 1-mmol scale.

*Synthesis of the bis-*tert*-butyldimethylsilyl compounds **18***

Imidazole (10 mmol) and *tert*-butyldimethylsilyl chloride (5 mmol) were added to a stirred solution of the diol **16** or monosilylated diol **17** (1 mmol) in anhydrous DMF (25–35 mL/g alcohol). After reaction for 1–3 h, the solution was diluted with water and the product was extracted with ethyl acetate or a 1:1 benzene – ethyl acetate mixture (for **18***e* and **18***f*). After the usual work-up, the crude products were purified as indicated in Table 2. Compound **18***a* had the following spectroscopic properties: ir: 3450, 1698 cm^{-1}; nmr δ: 0.03 (s, 12H, Me_2Si), 0.86 (m, 21H, Me_3CSi, 20-CH_3), 1.13–2.60 (m, 14H), 3.93 (m, 3H, H-19,11,15), 5.43 (m, 2H, H-13,14), 6.50 (s, 1H, NH).

*Synthesis of the thiolactams **19***

A solution of the lactam (2 mmol) and Lawesson's reagent (1–1.4 mmol); 2,4-bis(4-methoxyphenyl)-1,3-dithia-2,4-diphosphetane-2,4-disulfide, Aldrich Chem. Co.) in anhydrous benzene (25–50 mL/g of lactam) was heated at reflux temperature for 0.5–1 h. The solvent was removed *in vacuo*, the residue was mixed with dichloromethane, and the mixture was filtered. The filtrate was evaporated *in vacuo* and the residue was purified by preparative tlc on silica gel using the solvent system indicated in Table 3. The tlc pure 15α compound **19***a* had the following spectroscopic properties: ir: 3420, 1500 cm^{-1}; nmr δ: 0.03 (s, 12H, Me_2Si), 0.88 (m, 21H, 20-Me, Me_3CSi), 1.06–3.26 (m, 14H), 4.05 (m, 3H, H-9,11,15), 5.43 (m, 2H, H-13,14), 8.72 (s, 1H, NH).

*Synthesis of the bis-*tert*-butyldimethylsilyl vinylogous amides **21***

Sodium hydride in mineral oil (50% suspension, 1 mmol) was washed with dry hexane, layered with anhydrous tetrahydrofuran (10–20 mL), and the thiolactam (1 mmol) dissolved in dry tetrahydrofuran (10–20 mL) was added thereto with stirring. After 1 h at room temperature the mixture was cooled to 0°C and a solution of methyl 5-bromolevulinate (1.1 mmol) in dry tetrahydrofuran (10–20 mL) was added slowly and then the reaction mixture was stirred for 0.25–0.5 h. Ethyl acetate, or ethyl acetate – ether (1:1) in the case of **20***e* and **20***f*, and water were added and the reaction was then worked up as usual to give the thioimidates **20**. The crude thioimidates (ir absorption of 1740–1750 cm^{-1}) were used immediately in the next step.

*(a) Synthesis of **21***a–d

Triphenylphosphine (1.5 mmol) and potassium-*tert*-butoxide (0.2 mmol) were added to the crude thioimidate dissolved in 1:1 xylene–*tert*-butanol solution (7 mL, anhydrous) and the mixture was heated at reflux temperature for 2–3 h. The mixture was diluted with water and worked up in the usual way. The crude products were purified in the manner described in Table 3. The tlc-pure, oily **21***a* had the following spectroscopic properties: uv: 270 (1590), 308 (20 000) nm; ir: 3260, 1740, 1625, 1540 cm^{-1}; nmr δ: 0.03 (s, 12H, Me_2Si), 0.66 (m, 21H, 20-Me_3CSi), 1.03–3.00 (m, 14H), 2.56 (s, 4H, 2-CH_2, 3-CH_2), 3.93 (m, 3H, H-9,11,15), 3.63 (s, 3H, OMe), 4.96 (s, 1H, H-5), 5.24 (m, 2H, H-13,14), 9.88 (bs, 1H, NH).

*(b) Synthesis of **21***e,f

Triphenylphosphine (0.16 mmol) and potassium-*tert*-butoxide (0.2 mmol) were added to the crude thioimidate from above dissolved in 10:1 xylene–*tert*-butanol (10 mL) and the reaction was effected as described for **21***a–d*.

*Hydrolysis of the bis-*tert*-butyldimethylsilyl ethers **21** to the 11,15-diols **22***

A solution of tetra-*n*-butylammonium fluoride (4 mmol) in anhydrous tetrahydrofuran (5 mL) was added to a stirred solution of the disilyl ether (1 mmol) in the same solvent (10–25 mL). The resulting solution was heated at 40°C for 18–24 h and the solvent was then removed *in vacuo*. The residue was partitioned between water and ethyl acetate and worked up in the usual way. The product was purified in the manner described in Table 3. Pure **22***a* had the following spectroscopic properties: uv: 215 (1660), 317 (19 600) nm; ir: 3620, 3390 (br) 1740, 1625, 1540 cm^{-1}; nmr δ: 0.88 (m, 3H, 20-CH_3), 1.16–3.33 (m, 18H), 3.95 (m, 3H, H-9,11,15), 5.01 (s, 1H, H-5), 5.46 (m, 2H, H-13,14), 9.77 (bs, 1H, NH).

*Hydrolysis of the azaprostacyclin methyl esters **22** to the carboxylic acids **23***

A solution of the ester (1 mmol) in methanol (15 mL) containing water (1 mL) and potassium carbonate (3 mmol) was stirred at room temperature for 38–64 h. The methanol was removed *in vacuo*, water was added to the residue, and the solution was extracted with dichloromethane. The aqueous phase was cooled to 0°C and brought to pH 4 by the addition of a saturated aqueous oxalic acid solution. The product was extracted into ethyl acetate and worked up in the usual way.

The conformational properties of some phenyl esters. Molecular orbital and nuclear magnetic resonance studies

TED SCHAEFER AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 13, 1987

TED SCHAEFER and GLENN H. PENNER. Can. J. Chem. **65**, 2175 (1987).

Extensive, geometry-optimized, STO-3G MO computations on phenyl formate imply a strongly nonplanar *Z* conformer (C=O bond *cis* to the phenyl group) at ambient temperatures. The internal barrier to rotation about the C(1)—O bond in this conformer is computed as $V/\text{kJ mol}^{-1} = (-5.17 \pm 0.27) \sin^2\theta - (2.42 \pm 0.27) \sin^2 2\theta$, θ being zero for the planar conformer; the twofold is nearly twice as large as the fourfold component. The expectation value of θ is 58° at 300 K. The spin–spin coupling constants over six bonds between ^{13}C and ^{19}F nuclei in 4-fluorophenyl formate, acetate, propionate, and isobutyrate, as well as in the 2,6-dichloro-4-fluorophenyl acetate, are adduced as evidence for nonplanar conformers of these molecules. The magnitudes of these six-bond coupling constants are consistent with internal barriers to rotation about the C(1)—O bonds, which are similar in magnitude to those given by the computations on the *Z* conformer of phenyl formate. The energies of the planar and nonplanar *E* conformers, as well as the interconversion energies for $E \rightleftharpoons Z$ isomerization, are computed. Small amounts of the nonplanar *E* conformer are predicted at ambient temperatures. The ^{13}C chemical shifts and the one-bond ^{13}C, ^{19}F coupling constants are consistent, respectively, with only minor variations in the conformational behavior of the ester moieties caused by the fluorine substituent and by changes in the structures of these moieties themselves.

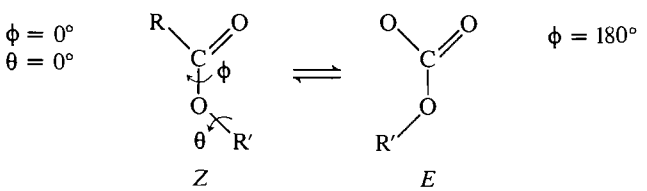
TED SCHAEFER et GLENN H. PENNER. Can. J. Chem. **65**, 2175 (1987).

Des calculs étendus d'OM effectués au niveau STO-3G sur du formate de phényle optimisé pour la géométrie laissent fortement supposer que le conformère *Z* non-plan (la liaison C=O est *cis* par rapport au groupement phényle) est privilégié à la température ambiante. On a calculé que la barrière interne à la rotation autour de la liaison C(1)—O de ce conformère peut être exprimée par l'équation $V/\text{kJ mol}^{-1} = (-5{,}17 \pm 0{,}27) \sin^2\theta - (2{,}42 \pm 0{,}27) \sin^2 2\theta$ dans laquelle θ est égal à zéro pour le conformère plan; la composante binaire est deux fois plus importante que la composante quaternaire. À 300 K, la valeur attendue pour θ est de 58°. On a aussi utilisé les constantes de couplage spin–spin à travers six liaisons entre les noyaux de ^{13}C et de ^{19}F des formate, acétate, propionate et isobutyrate de fluoro-4 phényle de même que de l'acétate du dichloro-2,6 fluoro-4 phényle comme preuve de l'existence des conformères non-plans de ces molécules. Les amplitudes de ces constantes de couplage à travers six liaisons sont en accord avec des barrières à la rotation autour des liaisons C(1)—O qui sont semblables en amplitude à celles obtenues par calculs sur la conformère *Z* du formate de phényle. On a aussi calculé les énergies des conformères *E* plan et non-plan ainsi que les énergies d'interconversion pour l'isomérisation $E \rightleftharpoons Z$. À la température ambiante, on prédit que de faibles proportions du conformère *E* non-plan existeront. Le déplacements chimiques en résonance magnétique nucléaire du ^{13}C et les constantes de couplage ^{13}C–^{19}F sont respectivement en accord uniquement avec des variations mineures dans le comportement conformationnel des portions esters qui sont causées par le substituant fluor et par des changements dans les structures de ces portions elle-mêmes.

[Traduit par la revue]

Introduction

Alkyl esters are usually discussed in terms of planar or nearly planar *Z* and *E* conformers (1–7). In the formates (R = H), small amounts of *E* have been detected at low temperatures when R′ = CH_3, C_2H_5, and $CH(CH_3)_2$ (6). Rather larger populations of *E* occur for R′ = $C(CH_3)_3$ (4–6). The free energy barriers to interconversion of *E* and *Z* are available from dynamic nmr measurements (4–6).



Z *E*

A combination of diffraction and spectroscopic data for vinyl formate in the gas phase, supplemented by 4-21G MO and molecular mechanics computations, indicate the planar *Z* conformer at room temperature (8). It is at least 9.6 kJ/mol more stable than the *E* form.

It has been suggested that phenyl formate exists in the *Z* form, nearly planar because of conjugation involving the aromatic π electrons (3). Phenyl thiolformate, however, displays almost equal stabilities of the *Z* and *E* conformers at 193 K in solution (9). There is some evidence that the phenyl group in the latter molecule is not coplanar with the S—C(H)=O moiety, that is, θ ≠ 0° and is perhaps as large as 90° in structures analogous to those above (9).

In this paper, MO calculations and long-range ^{13}C, ^{19}F spin–spin coupling constants are found to be consistent with severely nonplanar *Z* conformations of phenyl formate and 4-fluorophenyl—O—C(=O)R (R = H, CH_3, C_2H_5, and $CH(CH_3)_2$). Appreciable populations of planar forms at 300 K are unlikely.

Experimental

The 4-fluorophenyl formate was made by the Vilsmeier reaction from 4-fluorophenol exactly as described (10). The other esters were prepared in the usual way by reaction of 4-fluorophenol with the appropriate acid anhydrides in the presence of some pyridine. Samples for nmr spectra were prepared as solutions in acetone-d_6, concentrations being given in Table 1 below, which also contained some tetramethyl silane (TMS). The solutions were transferred to 10-mm od nmr sample tubes and were degassed by the freeze–pump–thaw procedure prior to flame-sealing of the tubes. The $^{13}C\{^1H\}$ nmr spectra were accumulated on an AM300 Bruker spectrometer at a probe temperature of 300 K in a manner described before (11). Peak widths at half height were typically 0.1 Hz, so that splittings due to coupling with ^{19}F nuclei could be determined with satisfactory precision (Table 1).

STO-3G MO computations employed the computer program MONSTERGAUSS (12) on an Amdahl V7 system. Rather extensive geometry optimization was demanded during the computations, with, how-

ever, the constraint that the aromatic carbon atoms remain in a plane. INDO MO FPT calculations (13) were also performed on the Amdahl.

Results and discussion

STO-3G MO structure of phenyl formate

The planar *Z* form has φ = 0° (see structure above) and θ = 0°, where the latter angle gives the angle of twist about the C(1)—O bond; C(1) is an aromatic carbon atom. As θ increases, the total energy decreases. The relative energies, computed at 15° intervals in θ, are reproduced by eq. [1]. The quoted

$$[1]\quad V/\text{kJ mol}^{-1} = -(5.17 \pm 0.27)\sin^2\theta - (2.42 \pm 0.27)\sin^2 2\theta = V_2\sin^2\theta + V_4\sin^2 2\theta$$

errors are calculated at the 95% confidence level. Figure 1 displays the computed energies and the twofold and fourfold components as θ goes from 0 to 180°, φ being 0° (C=O *cis* to the benzene plane). At 300 K the expectation or average value of θ is 58.1° and that of $\sin^2\theta$ is 0.685. The minimum energy occurs for θ near 60° and for φ = 0°, the total energy being −412.974 198 au. Figure 2 displays the computed geometry for phenyl formate at θ = 60°, where the energy is 0.4 kJ/mol higher.

Table 2 presents the energies at 15° intervals in θ between 0° and 90° and at 30° intervals in φ between 0° and 180°. Symmetry arguments then yield the energies for θ and φ values lying in other quadrants. Direct conversion of the most stable, nonplanar, *Z* conformer to the *E* conformer requires about 31 kJ/mol, although there are other pathways somewhat less energetically demanding. At 300 K the most stable *E* conformer would be present to the extent of less than 3% on the assumption of similar entropies for the various conformers. Dynamic nmr experiments are contraindicated by these computations because, even if the interconversion barriers are large enough to observe, the required low temperatures would reduce the *E* populations

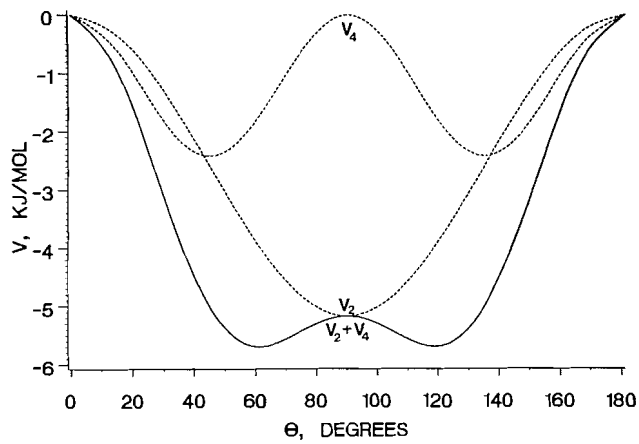

FIG. 1. The solid line represents the geometry-optimized STO-3G MO relative energies for the *Z* conformer of phenyl formate (C=O bond pointing towards the phenyl group) as a function of the twist angle, θ, about the C(1)—O bond. When θ is 0°, the molecule is planar; that is, the C=O bond lies in the benzene plane. The dashed lines represent the twofold and fourfold components of the computer barrier about the C(1)—O bond. The relative energies are given by $V/\text{kJ mol}^{-1} = (-5.17 \pm 0.27)\sin^2\theta - (2.42 \pm 0.27)\sin^2 2\theta$. See the text for a fuller discussion and Fig. 2 for the computed geometry at θ = 60°.

even further. To our knowledge such experiments have not been reported for phenyl esters.

In summary, the nonplanar *Z* form of phenyl formate, the C=O bond pointing towards the phenyl group, is computed as much the most stable at ambient temperatures. These predictions for the isolated molecule are compared below with long-range coupling constants for some derivatives of phenyl formate. These yield information about θ preferences but not about φ values.

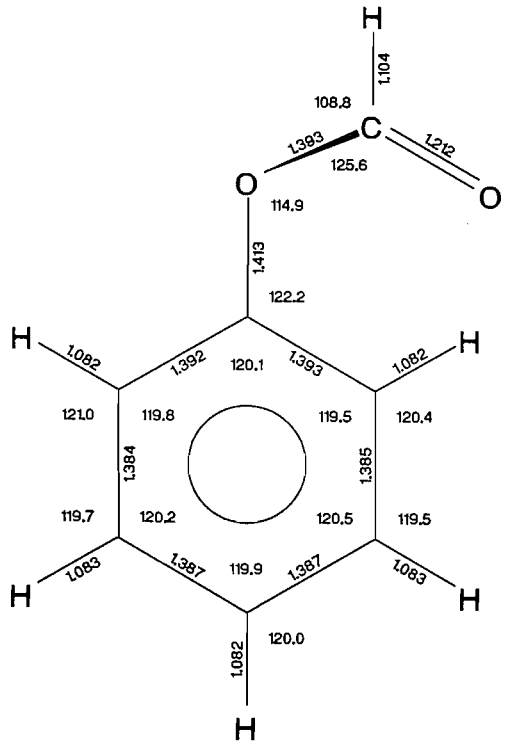

FIG. 2. The geometry-optimized STO-3G structure of phenyl formate. It has the *Z* conformation (see text) and is nonplanar. The side chain is twisted out of the benzene plane by 60°, that is, about the C(1)—O bond. The computed energy is −412.974 027 au and is 5.9 kJ/mol lower than that for the planar *Z* conformer (see text for energies of other conformations). In the planar form the C(1)—O—C angle is computed as 121.0°, indicating a reason for its instability. The O—C=O angle in this figure is computed as 0.7° larger than in vinyl formate (8) using 4-21G. The present geometry provides a starting point for higher level MO computations.

Conformational indications from $^6J(^{13}C, ^{19}F) \equiv {}^6J$

In previous work on 4-fluorophenyl derivatives of methane, ethene, and cyclohexane, $^6J(^{13}C, ^{19}F) \equiv {}^6J$ was established as a σ–π coupling. Such a coupling constant is proportional to $\sin^2\theta$ and is therefore a valuable indicator of the conformational behaviour of the side chain (14). Again, in anisole derivatives (15), ^6J also appears as σ–π coupling constant. In both instances, INDO MO FPT computations appear to confirm the $\sin^2\theta$ dependence of ^6J, although they underestimate the magnitude of $^6J_{90}$, the maximum value of ^6J. Similar behaviour was found here for 4-fluorophenyl formate. The previous work also implied (14) that ^6J is not very sensitive to the hybridization state of the carbon atom containing the coupled ^{13}C nucleus.

$^6J_{90}$ in 4-fluoroanisole was assessed as 1.48 Hz, from its value in the 2,6-dibromo derivative (15), and as 1.42 Hz in 4-fluorophenyl acetic acid (14). In 2,6-dichloro-4-fluorophenyl acetate (Table 1), ^6J is 1.19 Hz. For a hypothetical rigid conformation of this molecule, that is, for $\theta = 90°$, this number would represent $^6J_{90}$. Of course, the molecule is not rigid, so that 1.19 Hz represents a lower limit of $^6J_{90}$ in 4-fluorophenyl acetate. An upper limit will be taken as 1.42 Hz, implying $^6J_{90}$ as 1.30 ± 0.12 Hz. In 4-fluorophenyl acetate, $^6J_{90}$ is 0.88(1) Hz, and $\langle\sin^2\theta\rangle$ follows as 0.88(1)/1.30(12) or 0.68 ± 0.07, perhaps in accidental agreement with the value of 0.685 implied by the STO-3G MO energies for phenyl formate.

The ^6J values in Table 1 do not vary drastically from compound to compound. This behavior is expected if the *Z* conformer is predominant (R pointing away from the phenyl plane). ^6J in the formate is 0.08 ± 0.02 Hz larger than in the isopropyl derivative. One possible reason is that $^6J_{90}$ varies from molecule to molecule, substitution of the aldehydic hydrogen atom in the formate by an alkyl group causing a reduction in $^6J_{90}$. An indirect and supportive piece of evidence for such a reduction comes from the ^6J of 1.37(2) Hz in 2,6-dibromo-4-fluoro phenyl ethyl ether (unpublished work in this laboratory). Replacement of a hydrogen atom by a methyl group in the corresponding anisole therefore leads to a reduction of nearly 0.1 Hz in ^6J. However, it is also conceivable that, in the esters, the alkyl groups aid conjugation with the aromatic π electrons, thereby causing somewhat lower values of $\langle\sin^2\theta\rangle$; in the planar form the latter vanishes.

TABLE 2. The STO 3G MO relative energies[a] of phenyl formate

	φ						
θ	0	30	60	90	120	150	180
0	0.00[b]	4.81	15.35	20.05	15.91	12.41	11.91[c]
15	−0.67	3.35	14.91	21.13	19.04	14.78	10.27
30	−2.89	1.69	15.26	23.05	21.21	14.28	6.40

60	−5.88	2.00	18.69	25.75	20.23	9.12	2.99
75	−5.43	3.60	20.08	25.88	19.25	9.02	4.84
90	−4.93[d]	4.44	20.14	25.42	19.08	9.86	5.99[e]

[a]Energies in kJ/mol and angles in degrees.
[b]The relative energy of the planar *Z* conformer (see structures in the text).
[c]The relative energy of the planar *E* conformer.
[d]The relative energy of the perpendicular *Z* conformer.
[e]The relative energy of the perpendicular *E* conformer.

Furthermore, the fluorine substituent is a weak π electron donor. Its presence will favor somewhat the nonplanar *Z* conformers for the esters in Table 1 (see below). Hence the ^6J values and the $\langle\sin^2\theta\rangle$ values derived from them cannot be rigorously compared with $\langle\sin^2\theta\rangle$ given by the MO calculations. Additionally, the latter refer to the free molecule and the measurements in Table 1 were made in acetone-d_6 solution. However, the computed moment of phenyl formate varies by only 0.02 D as θ goes from zero to 90°. To a first approximation, therefore, the influence of the solvent on the stability of the conformers is expected to be small. Indeed, in CS_2 solution, ^6J in 4-fluorophenyl formate is 0.85 Hz, 0.06 Hz smaller than in acetone-d_6 solution. This decrease implies a reduction of 0.05 in $\langle\sin^2\theta\rangle$ and therefore one of less than 3° in arc sin $\langle\sin^2\theta\rangle^{1/2}$ for the nonpolar solution.

The ^6J values are sensitive to the conformational angle θ but their dependence on φ is not known. The MO computations imply negligible populations of the *E* conformers at 300 K. Furthermore, the computed energies imply that dynamic nmr measurements would be uninformative. It is concluded that the ^6J values in solution are consistent with nonplanar conformers having $\langle\theta\rangle \sim 55°$. However, the *J* values cannot exclude the presence of *E* conformers at these θ values.

The ^{13}C chemical shifts

The ^{13}C chemical shifts in Table 1 are consistent with the idea that the *para* fluorine substituent does not alter substantially the conformational behaviour of the ester groupings. Using the chemical shifts known for fluorobenzene and phenyl acetate (16) and assuming additivity, the aromatic ^{13}C chemical shifts predicted for 4-fluorophenyl acetate deviate by an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

average of only 0.4 ppm from those in Table 1. By way of contrast, in the 2,6-dichloro derivative, an additive scheme yields chemical shifts deviating by about 4 ppm at C-4, for example. In this compound, of course, there must exist a much stronger preference for a perpendicular conformation of the ester moiety than in 4-fluorophenyl acetate.

Conformational evidence from $^1J(^{13}C, ^{19}F) \equiv {}^1J$

The $OCOCH_3$ group causes increased shielding at the *para* position (16), but to a much smaller extent than a methoxy group, of course, and, in fact, to an extent similar to alkyl groups. Because ^1J is proportional to the mesomeric properties of the *para* substituent in fluorobenzene derivatives (17, 18), it is therefore reasonable that ^1J in 4-fluorotoluene is -241.4 Hz (14) and is -241.9 Hz in 4-fluorophenyl acetate (Table 1), both measured in acetone solution (^1J ranges from -233 Hz in the 4-amino compound to -257 Hz in the 4-nitro derivative (18)). The ^1J values in Table 1 appear consistent with only minor changes in the side-chain conformation from compound to compound. ^1J in fluorobenzene derivatives is known to vary by as much as 10 Hz in various solvents (18). In a recent study of ^{13}C chemical shifts of 1,4-disubstituted benzenes (19), it was concluded that the $OCOCH_3$ group may be characterized as a noninteracting substituent, that is, interacting very weakly with a *para* substituent. This conclusion is consistent with the results of the present study.

Anhydropenicillin: a key intermediate for the stereocontrolled introduction of the 6-*R*-hydroxyethyl side chain of the penem and carbapenem antibiotics

ALAIN MARTEL,[1] JEAN-PAUL DARIS, CAROL BACHAND, AND MARCEL MENARD
Groupe Pharmaceutique Bristol-Myers, 100 Boulevard de l'Industrie, Candiac (Que.), Canada J5R 1J1

Received March 23, 1987

ALAIN MARTEL, JEAN-PAUL DARIS, CAROL BACHAND, and MARCEL MENARD. Can. J. Chem. **65**, 2179 (1987).

Aldol condensation of the magnesium enolate derived from anhydro-6,6-dibromopenicillin with acetaldehyde allows for the stereospecific introduction of a 1-*R*-hydroxyethyl substituent at C-6. Protection of the hydroxy group followed by reductive dehalogenation provides anhydro-6(α)-[(1-*R*)-(*tert*-butyldimethylsilyloxy)-ethyl]-penicillin, an intermediate in the synthesis of thienamycin. A high yield conversion of this anhydro derivative to (4-*R*)-acetoxy-(3-*S*)-[(1-*R*)-(*tert*-butyldimethylsilyloxy-ethyl]-azetidin-2-one (**5**) is also reported.

ALAIN MARTEL, JEAN-PAUL DARIS, CAROL BACHAND et MARCEL MENARD. Can. J. Chem. **65**, 2179 (1987).

La condensation aldolique de l'acétaldéhyde avec l'énolate magnésien dérivé de l'anhydro dibromo-6,6 pénicilline permet d'introduire d'une façon stéréospécifique un substituant hydroxyéthyle-1(*R*) au niveau du carbone-6. La protection du groupement hydroxyle, suivie d'une déshalogénation réductrice, conduit à l'anhydro [(*tert*-butyldiméthylsilyloxy)-1(*R*) éthyl]-6α pénicilline, un intermédiaire dans la synthèse de la thiénamycine. On rapporte aussi une méthode de transformer ce dérivé anhydro en acétoxy-4(*R*) [(*tert*-butyldiméthylsilyloxy-1(*R*) éthyl]-3(*S*) azétidinone-2 (**5**), avec un excellent rendement.

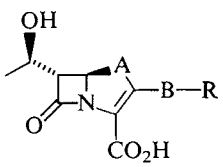
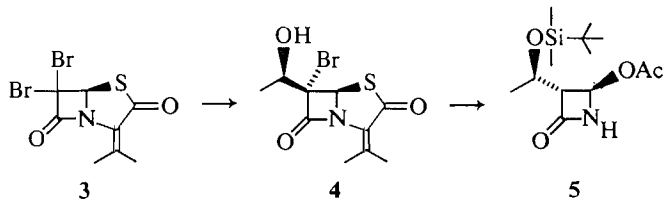
Penems **1** (1) and carbapenems **2** (2) are highly potent β-lactam antibiotics whose structural features differ considerably from the classical β-lactams (i.e., penicillins and cephalosporins). The most notable difference is the presence of a 6-*R*-hydroxyethyl side chain, which confers chemical as well as enzymatic stability to these molecules (3). The synthesis of chiral azetidinones that possess a hydroxyethyl side chain having the proper configuration, and which can be readily transformed into either penems or carbapenems, has been the subject of numerous reports (4). We have previously described the synthesis of key intermediates such as (4*R*)-(tritylthio)azetidinone and the corresponding silver mercaptide (5) as well as (3*S*)-bromo-(4*R*)-chloro-2-azetidinone (6), and their conversion to penems or to carbapenem precursors. This paper describes the stereoselective introduction of the *trans*-*R*-hydroxyethyl side chain onto anhydro-6,6-dibromopenicillin[2] and the subsequent conversion of this adduct to the very useful carbapenem precursor 4-acetoxyazetidinone **5** (7).



1: A = S, B = CH_2
2: A = CH_2, B = S

Since the initial report of DiNinno *et al.* (8) on the regiospecific hydroxyethylation of the C-6 position of penicillinates, many research groups have used this approach to prepare penem and carbapenem precursors (7). This method proved to be very useful even though the aldol condensation suffered from a lack of stereospecificity. Subsequent work by Kellogg and co-workers (9*a*, *b*) suggested that complete stereoselectivity in the aldol reaction could be achieved if a metal enolate of the penicillin nucleus could chelate with β-face selectivity, and if the steric effect of the 2-β-methyl group was eliminated.[3]



3 **4** **5**

SCHEME 1

Indeed, we have found that an anhydropenicillin (10) ring fulfilled these requirements, since the aldol condensation of the enolate derived from anhydro-6,6-dibromopenicillin **3** with acetaldehyde proceeded with 100% stereoselectivity and only the *cis* 6-*R* derivative **4** was obtained.

Anhydro-6,6-dibromopenicillin **3** (Scheme 2) was prepared by the treatment of an activated ester of dibromopenicillin **6** with base. Specifically, treatment of the triethylamine salt of 6,6-dibromopenicillin with trifluoroacetic anhydride gave a mixed anhydride that, on standing in pyridine, rearranged to give the anhydro ring (85% yield). The physical and spectral characteristics of **3** were identical to those reported by Clayton (11).

The magnesium enolate (8) of derivative **3** (Scheme 2) was reacted with acetaldehyde to give a single aldol adduct, presumably the *cis* *R*-hydroxyethyl derivative **4**, in essentially a quantitative yield (see Table 1). However, the structural assignment of **4** was unambiguously confirmed by the single crystal X-ray analysis of its *tert*-butyldimethylsilyl ether derivative **7** (see Fig. 1).

Reduction of **4** with zinc–silver couple at −15°C (12) gave a mixture of the two expected isomers from which crystalline **8** (R = H) was isolated in 42% yield. This was not unexpected since it has been shown (7) that the α/β ratio of 6-hydroxyethyl isomers that are obtained by reduction of such 6-α-bromo derivatives is influenced by both the temperature of the reduction and the steric bulk of the hydroxyethyl protecting group. When the reduction of **4** was carried out at −50°C the yield of crystalline **8** (R = H) was increased to 57%. Almost complete stereoselection was achieved when the TBDMS ether **7** (80.6%) of **4** was reduced at −45°C; the 6-α-hydroxyethyl derivative **8** was formed in 96.8% yield, contaminated only with starting material (0.7%) and the undesired β isomer (2.5%).

Further manipulation of derivative **8** gives a precursor that is

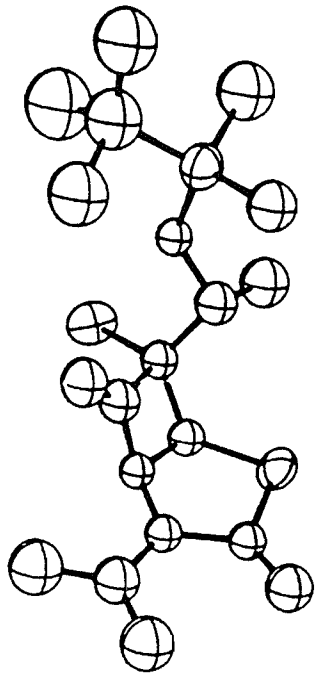

FIG. 1. ORTEP stereoview of compound **7**.

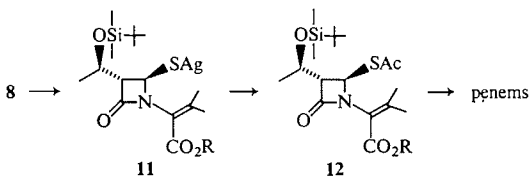
common to both the penems[4] and the carbapenems. This is illustrated by the conversion of **8** to the 4-acetoxyazetidinone **5** via a two-step process that is modeled after one which has been used (*7b,c*) to degrade the penicillin molecule to an azetidinone. Thus treatment of **8** with excess $Hg(OAc)_2$ in CH_3CO_2H (Scheme 2) afforded the crystalline *N*-substituted 4-acetoxyazetidinone **9** in excellent yield (95%).

Oxidative cleavage of the *N*-β-methylcrotonic acid portion was carried out either by treatment with ozone or permanganate. To avoid side reactions ($KMnO_4$ oxidation) or to facilitate the base catalyzed solvolysis of the intermediate oxamate (ozonolysis), the carboxylic acid **9** was first protected. Thus, reaction of **9** with EEDQ gave the anhydride **10** (X = CO_2Et), which was then treated with ozone. Reduction of the ozonide (Me_2S) and methanolysis of the resulting oxamate yielded the desired 4-acetoxyazetidinone **5** (95%), for which physical and spectral data were identical to those previously reported (7). It was subsequently found that ozonolysis of **9** in MeOH followed by silica gel treatment of the resulting oxamic acid gave the free 4-acetoxyazetidinone **5** directly (75%).

[4]The thiolactone **8** can be transformed easily to a silver mercaptide **11** in an alcoholic solvent. Acylation of the latter gave an intermediate **12** already reported for the preparation of penems (see ref. 13).



Similarly, permanganate oxidation of the methyl ester **10** (X = Me) gave the acetoxyazetidinone **5** in good yield (85%).

Acknowledgments

We would like to thank Professor B. Belleau, McGill University, and Drs. H. Mastalerz, R. Vanga, and E. Ruediger for helpful discussions. We would like also to thank Professor A. Michel, Université de Sherbrooke, for the X-ray structure determination.

M. P. Bueno, C. Cativiela, C. Finol, J. A. Mayoral, and C. Jaime. Can. J. Chem. **65**, 2182 (1987).

A study has been made of the Diels–Alder reaction of methyl-*N*-acetyl (and benzoyl)-α,β-dehydroalaninates with cyclopentadiene. In the reaction of methyl-*N*-acetyl-α,β-dehydroalaninate total conversion is obtained under several conditions, while the *N*-benzoyl derivative shows a lower reactivity. The stereoselectivity of the reaction is determined by ^{1}H nuclear magnetic resonance spectroscopy. Perturbation MO calculations, using wave functions generated by the MNDO method, are used to rationalize the relative reactivity of the dienophiles and the stereoselectivity observed.

M. P. Bueno, C. Cativiela, C. Finol, J. A. Mayoral et C. Jaime. Can. J. Chem. **65**, 2182 (1987).

On a réalisé une étude sur la réaction de Diels–Alder entre les *N*-acétyl (et benzoyl) α,β-déhydroalaninates de méthyle et le cyclopentadiène. Utilisant diverses conditions, la réaction du *N*-acétyl α,β-déhydroalaninate de méthyle conduit toujours à une conversion totale alors que la réactivité du dérivé *N*-benzoylé est beaucoup plus faible. On a déterminé la stéréosélectivité de la réaction par résonance magnétique nucléaire du ^{1}H. On a utilisé des calculs d'OM, faisant appel à des fonctions d'ondes générées par la méthode MNDO, pour rationaliser la réactivité relative des dièndophiles ainsi que la stéréosélectivité observée.

Cycloaliphatic amino acids such as those having a norbornane skeleton are known to possess interesting biological properties that affect the transport of ions through biological membranes (1). These amino acids have usually been synthesized from the corresponding carbonyl compounds by Strecker or Bucherer synthesis. To the best of our knowledge there is only one reference dealing with their preparation from *N*-acyl-α,β-dehydroalaninates by means of Diels–Alder reactions (2). In conjunction with the biological interest of these amino acids we have studied the Diels–Alder reaction between methyl-*N*-acetyl (or benzoyl)-α,β-dehydroalaninates (Fig. 1) and cyclopentadiene. The results obtained encouraged us to make a theoretical study by means of the MNDO method (3). There is a good correlation between the calculations and the experimental results.

Synthesis of dienophiles and Diels–Alder reactions

Methyl *N*-acetyl (and benzoyl)-α,β-dehydroalaninates (**1***a*,*b*) were prepared by methylation with methyl iodide of the corresponding acids, which were obtained by condensation of pyruvic acid and acetamide or benzamide (4). While methyl *N*-acetyl-α,β-dehydroalaninate (**1***a*) is a stable product, the *N*-benzoyl derivative (**1***b*) is a rather oily unstable one (5) and a pure sample could only be obtained by means of column chromatography.

Methyl *N*-acetyl-α,β-dehydroalaninate (**1***a*) was allowed to react with cyclopentadiene under several conditions. The results (Table 1) show that total conversion can be obtained by using a moderate excess of cyclopentadiene, $TiCl_4$ as a catalyst, or high reaction temperatures. The adducts were separated by column chromatography and the structural assignments were made on the basis of the ^{1}H nmr signals of the substituents at C-2. The shielding of the double bond of 2-substituted-5-norbornene derivatives leads the signals of the protons in the *endo* substituents to a higher field than those in the *exo* substituents (2); thus the *exo*/*endo* ratio could be directly estimated from the ^{1}H nmr spectrum of the mixture. The *exo*/*endo* ratio does not change noticeably according to the conditions of reaction. Methyl *N*-benzoyl-α,β-dehydrolaninate (**1***b*) shows a lower reactivity (Fig. 1).

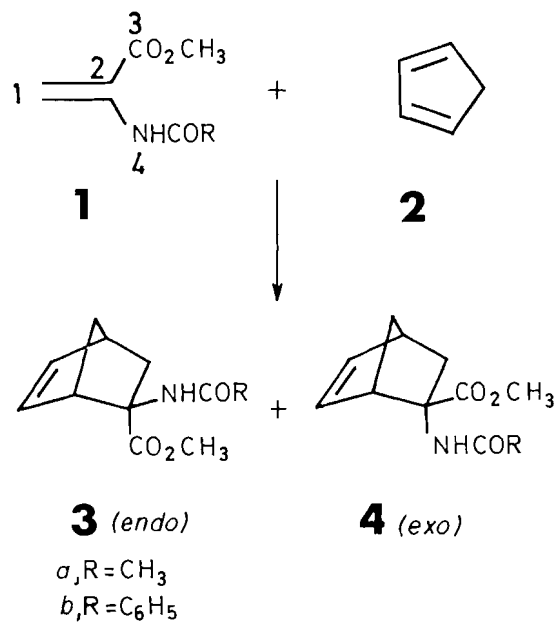

FIG. 1. Reaction between cyclopentadiene and methyl-*N*-acyl-α,β-dehydroalaninates.

Study of the reactivity and stereochemistry of the Diels–Alder reactions

The perturbational treatment leads to three different types of Diels–Alder reactions (6): normal, inverse, and neutral,

depending on which HOMO–LUMO interaction is the dominant stabilizing factor.

To evaluate the different interactions, the electronic structures of dienophiles **1***a* and **1***b* and cyclopentadiene (**2**) were calculated by the MNDO method (3). Compounds **1***a* and **1***b* show a considerable mobility around their σ bonds, but fortunately Ajò *et al.* (7) have studied the structure of several α,β-unsaturated acetylamino acid ethyl esters, and found that dehydroalanine derivatives are planar or quasiplanar. Thus, we have only considered planar conformations for **1***a* and **1***b* (8).

Only conformations *s-cis* and *s-trans* regarding the C2—C3 bond in **1***a* were considered. Calculations showed conformer *s-trans* to be more stable than *s-cis* by 0.6 kcal/mol, consequently only the results of the calculations for the *s-trans* conformer were taken into account (Table 2). A schematic representation of the MNDO calculated HOMO and LUMO for *s-trans* **1***a* and **2** is shown in Fig. 2 together with their atomic electron densities (Σc^2).

The reaction occurs between C1 and C4 of cyclopentadiene (**2**), and C1 and C2 of the dienophile **1**, respectively. The following simplified equation expresses the main orbital interactions (9).

$$[1]\quad E = \frac{2[(c_1^{HO})^2(c_1^{LU})^2 + (c_4^{HO})^2(c_2^{LU})^2 + (c_3^{HO})^2(c_3^{LU})^2]\beta_{C-C}^2}{E_{diene}^{HO} - E_{dienophile}^{LU}} + \frac{2[(c_1^{LU})^2(c_1^{HO})^2 + (c_4^{LU})^2(c_2^{HO})^2]\beta_{C-C}^2 + [(c_3^{LU})^2(c_4^{HO})^2]\beta_{C-N}^2}{E_{dienophile}^{HO} - E_{diene}^{LU}}$$

According to the energy gaps between HOMO's and LUMO's, the reaction between **1***a* and **2** can be classified as normal, although nearly neutral ($E_2^{HOMO} - E_{1a}^{LUMO} = -8.985$ eV, $E_{1a}^{HOMO} - E_2^{LUMO} = -9.724$ eV).

The *endo*/*exo* selectivity of Diels–Alder reactions is generally explained by additional overlap between orbitals of atoms not directly intervening in bond formation, secondary interactions. In our case, we must focus attention on the N atom in the acylamino group and on the carbonyl carbon in the ester moiety (Fig. 2).

If the $HOMO_{diene}$–$LUMO_{dienophile}$ pair is considered, the only relevant secondary interaction occurs between C3 of both diene and dienophile, leading to a preference for the *endo* stereoisomer. However, in the $LUMO_{diene}$–$HOMO_{dienophile}$ pair the only relevant secondary interaction occurs between C3–diene and N4–dienophile, so this orbital pair favours the formation of the *exo* adduct (Fig. 3).

Introducing the atomic coefficients and MO energies for **1***a* and **2**, and taking the resonance integrals, β_{C-X}, as the geometric average of individual β values (9), we obtain a

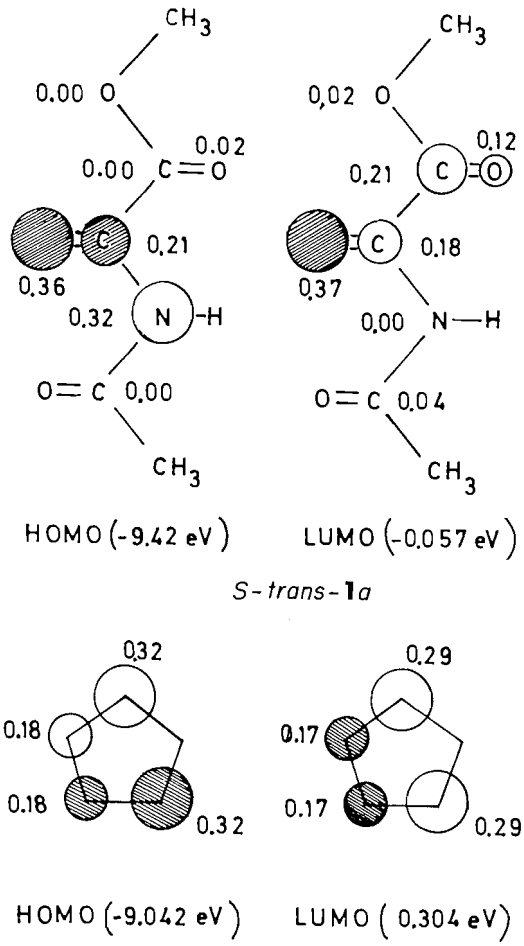

FIG. 2. Schematic representation of MNDO calculated HOMO and LUMO for **1***a* and **2**. Figures denote electron densities on each atom.

$\Delta E_{endo} = -0.082\beta_C^2$ and a $\Delta E_{exo} = -0.089\beta_C^2$. From these values we can infer that the *exo* isomer is slightly favoured over the *endo*, being in qualitative agreement with the experimentally observed preference for the *exo* over the *endo* isomer (Table 1).

With regard to compound **1***b*, the only relevant torsion angle to be determined in the MNDO calculations is the one formed by the phenyl ring plane and the amido unit plane, "ω", whose calculated value under geometry optimization is ω = 90°. This lack of planarity may, however, be due to the MNDO tendency to twist groups with π-systems conjugated to phenyl rings (10), a tendency probably due to the overestimation of short nonbonded contacts in this semiempirical method (3). This situation can affect the electronic structure of **1***b*, and the calculation was repeated fixing ω = 0°.

The electronic structures of planar (ω = 0°) and perpendicular (ω = 90°) **1***b* show no difference in their atomic orbital contributions from those of $C1^{LUMO}$ and $C2^{LUMO}$, because the LUMO of the perpendicular conformation is aromatic-like, while that of the planar structure is ethylenic-like (Table 2). Consequently only the planar conformation will be considered.

The HOMO − LUMO energy gaps are $E_{diene}^{HOMO} - E_{dienophile}^{LUMO} = -8.605$ eV and $E_{dienophile}^{HOMO} - E_{diene}^{LUMO} = -9.634$ eV. Again the reaction can be classified as normal or neutral. The only important secondary interactions are those coming from the N atom of the benzamido group, since the carbonyl carbon of the ester moiety has no significant coefficients at all (Table 2). The application of eq. [1] to the present case allows us to obtain $\Delta E_{endo} = -0.040\beta_C^2$ and $\Delta E_{exo} = -0.054\beta_C^2$, so the *exo* stereoisomer must be favoured again.

It is remarkable that although several approximations have been made in the calculation of ΔE's, the results agree qualitatively with the experiments. Moreover, the low reactivity of **1***b* can be explained by considering the lower values for its calculated ΔE's compared to those of **1***a*, or by a possible contribution of the nonplanar conformation leading to steric hindrance in the transition state.

The lower *exo*/*endo* ratio obtained when $TiCl_4$ is used as a catalyst is difficult to account for. The catalyst can coordinate at several sites within **1***a*. To simulate this coordination in the simplest possible way, a proton was attached to the carbonyl oxygen of the ester and acetamido units of **1***a*. Calculations show that coordination at the acetamido group is more favoured, by 10.9 kcal/mol, so only this possibility is considered. The LUMO of this protonated species has no significant coefficients at C1 and C2, the effective LUMO then being LUMO + 1 (Table 3). The energy gap between frontier orbitals of the reactants is now clearly shifted to the $HOMO_{diene}$ – $(LUMO + 1)_{dienophile}$ pair, and the reaction can be classified as normal. Figure 4 shows a schematic representation of this interaction.

In this simple model for $TiCl_4$ coordination, only the *endo* adduct is favoured by secondary interactions, so it is reasonable to expect a lower experimental *exo*/*endo* ratio.

Discussion

While methylacrylate reacts with cyclopentadiene giving an *endo/exo* ratio of about 70:30 (11), the reverse is found with **1***a* (*exo/endo* ratio of about 70:30) (Table 1). Formally, the reason for this is the replacement of an H atom by an acetamido group. Methylacrylate has ethylene π-type frontier orbitals with contribution of the carbonyl carbon atom; consequently only the *endo* approach shows stabilizing secondary interactions in the $HOMO_{diene}$–$LUMO_{dienophile}$ pair. Compound **1***a* also has ethylene π-type frontier orbitals, but the presence of the acetamido group gives rise to the existence of a new secondary interaction, which favours the obtention of the *exo* isomer. The application of eq. [1] shows the importance of secondary interaction in this particular case.

The replacement of the acetamido group in **1***a* by a methyl group, leading to methyl methacrylate, does not change the observed *exo/endo* ratio, 68:32 (11). In this case secondary interaction cannot be invoked, and the reason for this remains controversial, to say the least. While some authors propose destabilizing van der Waals interactions (12), others suggest attractive van der Waals interactions (11).

Although a simple model enables us to rationalize the lower *exo/endo* ratio obtained when $TiCl_4$ is used, we cannot explain the experimental result. Seven-membered chelate complexes where $TiCl_4$ is coordinated to two carbonyl oxygens are known, which suggests that species with the catalyst coordinated to both carbonyl oxygen atoms may exist in our case.

In summary, we can conclude that in the Diels–Alder reaction between **1** and **2**, in the absence of a catalyst, the secondary interactions play an important role in determining the experimental *exo/endo* ratios.

Experimental

Melting points were determined on a Büchi apparatus and are uncorrected; ir spectra were registered on a Perkin–Elmer 283 spectrophotometer, and ^1H nmr spectra on a Bruker WP 80 CW apparatus.

Synthesis of methyl N*-acetyl-α,β-dehydroalaninate (**1**a)*

CH_3I (11.36 g, 80 mmol) and 12.15 g (88 mmol) of anhydrous K_2CO_3 were added to a solution of 5.16 g (40 mmol) of *N*-acetyl-α,β-dehydroalanine in dry acetone. The mixture was refluxed for 3 h and then an additional 5.68 g (40 mmol) of CH_3I was added and the reflux was maintained for another 3 h. The solution was then cooled and the solid was separated by filtration and washed with acetone. The acetone was removed by distillation under reduced pressure and the oily residue was extracted with chloroform. The removal of the chloroform by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

distillation under reduced pressure afforded 4.60 g (80%) of methyl *N*-acetyl-α,β-dehydroalaninate (**1***a*), which can be recrystallized from *n*-pentane. The mp and the ^{1}H nmr spectrum were in accordance with those given in the literature; mp 50–52°C (lit. (13) mp 50–52°C).

Synthesis of methyl N-*benzoyl-α,β-dehydroalaninate (1*b*)*

CH_3I (11.36 g, 80 mmol) and 12.15 g (88 mmol) of anhydrous K_2CO_3 were added to a solution of 7.64 g (40 mmol) of *N*-benzoyl-α,β-dehydroalanine in dry acetone and the mixture was refluxed for 3.5 h. The solution was then cooled and the solid was separated by filtration and washed with acetone. The removal of the acetone by distillation under reduced pressure afforded 7.0 g (85%) of crude material whose main component is the methyl *N*-benzoyl-α,β-dehydroalaninate (**1***b*). A pure oily sample was prepared by column chromatography on silica gel using CCl_4/AcOEt = 15:1 as eluent. The ir and ^{1}H nmr spectra were in accordance with those given in ref. 4.

Diels–Alder reactions

Without a catalyst

To a solution of 2 mmol of the corresponding methyl *N*-acyl-α,β-dehydroalaninate and a little hydroquinone in the appropriate dry solvent, the amount of freshly distilled cyclopentadiene previously chosen was added, and the solution was refluxed for 5 h. The solvent was then removed by distillation under reduced pressure and the residue analyzed by ^{1}H nmr.

The adducts were separated by means of column chromatography using Et_2O/Me_2CO = 9:1 as eluent.

Methyl 2-*exo*-acetylamino-5-norboren-2-*endo*-carboxylate (**3***a*): mp 131–133°C (lit. (2) mp 132–133°C); ir (Nujol) ν: 3270 (NH), 1755 (CO), 1650 (CO) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.75 (m, 1H), 6.29 (m, 1H), 5.84 (m, 1H), 3.63 (s, 3H), 2.93 (m, 3H), 2.69–2.13 (m, 2H), 1.98 (s, 3H), 1.88–1.39 (m, 2H).

Methyl 2-*endo*-acetylamino-5-norboren-2-*exo*-carboxylate (**4***a*): mp 148–150°C (lit. (2) mp 148–149°C); ir (Nujol) ν: 3290 (NH), 1740 (CO), 1650 (CO) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.38 (m, 2H), 6.07 (m, 1H), 3.75 (s, 3H), 3.31 (m, 1H), 2.89 (m, 1H), 2.75–2.48 (m, 1H), 1.91 (s, 3H), 1.72–1.10 (m, 3H).

With a catalyst

Under nitrogen, 2.2 mmol of $TiCl_4$ in dry CH_2Cl_2 was added at the appropriate temperature to a stirred solution of **1***a* (2 mmol) in dry CH_2Cl_2. Then a solution of the amount of cyclopentadiene previously chosen in dry CH_2Cl_2 at the same temperature was added. The mixture was stirred for 5 h, treated with a saturated solution of aqueous Na_2CO_3, and washed with a saturated solution of aqueous NaCl. Evaporation of the organic phase yielded a residue that was analyzed by ^{1}H nmr.

MNDO calculations

The dienophiles were considered planar and to have the conformation represented in Fig. 3. In two different calculations the planarity of the phenyl ring and carbonyl group of the amide in **1***b* was fixed, or the dihedral angle "ω" (Fig. 4) was optimized. The other geometrical parameters were optimized, except those of the phenyl ring, which were fixed as follows: C—C = 1.3970 Å, C—H = 1.048 Å, C—C—C = 120.0°, C—C—H = 120.0°; endocyclic C—C—C—C = 0.0° and H—C—C—H = 0.0°.

The crystal structure of $Sn_6O_2(CF_3CO_2)_8.CF_3CO_2H$

R. J. BATCHELOR, T. BIRCHALL,[1] AND J. P. JOHNSON

Department of Chemistry and Institute for Materials Research, McMaster University, 1280 Main Street West, Hamilton, Ont., Canada L8S 4M1

Received February 24, 1987

R. J. BATCHELOR, T. BIRCHALL, and J. P. JOHNSON. Can. J. Chem. **65**, 2187 (1987).

The X-ray crystal structure of $Sn_6O_2(CF_3CO_2)_8.CF_3CO_2H$ has been determined: $R_1 = 0.0519$. The crystals were orthorhombic, space group $Pna2_1$, $a = 18.327(4)$ Å, $b = 12.209(3)$ Å, $c = 19.218(3)$ Å, $f_w = 1762.29$, and $Z = 4$. The structure consists of two sets of three tin(II) atoms, each set linked by a μ_3-oxo bridge. The tin atoms are further linked by trifluoroacetate groups to form an extended structure in which the tin atoms can be described as having either SnX_4E or SnX_5E coordination.

R. J. BATCHELOR, T. BIRCHALL et J. P. JOHNSON. Can. J. Chem. **65**, 2187 (1987).

On a déterminé la structure cristalline du $Sn_6O_2(CF_3CO_2)_8.CF_3CO_2H$ par diffraction des rayons-X : $R_1 = 0{,}0519$. Les cristaux sont orthorhombiques, groupe d'espace $Pna2_1$, $a = 18{,}327(4)$, $b = 12{,}209(3)$ et $c = 19{,}218(3)$ Å, masse = 1762,29 et $Z = 4$. La structure comporte deux ensembles de trois atomes d'étain(II), chacun des ensembles étant relié par un pont oxo-μ_3. Les atomes d'étain sont de plus reliés par les groupements trifluoroacétates pour former une structure importante dans laquelle la coordination des atomes d'étain peut être décrite comme étant soit SnX_4E ou SnX_5E.

[Traduit par la revue]

Introduction

A number of tin(II) carboxylates have been prepared, studied by a variety of spectroscopic techniques and were inferred to have trigonal-pyramidal stereochemistry about tin (1, 2). However, relatively few of these carboxylates have been obtained in a pure form. Recently we were able to isolate tin(II) trifluoroacetate and characterize it spectroscopically (3). Our spectroscopic results seemed to indicate that the tin environment was unlikely to be that of a trigonal pyramid. These spectroscopic data were more consistent with the trigonal-bipyramidal tin environment found in tin(II) formate (4). In an attempt to obtain crystals of tin(II) trifluoroacetate, suitable for analysis by X-ray crystallography, we sublimed some of the original compound in a sealed tube and obtained crystals of $Sn_6O_2(CF_3CO_2)_8.CF_3CO_2H$ whose crystal structure we now report.

Experimental

Preparation

A sample of $Sn(CF_3CO_2)_2$ was prepared according to the literature method (3). Since none of this material was suitable for X-ray crystallographic analysis, some of the material was placed in a dry 6 mm diameter Pyrex tube, evacuated, sealed and the tube laid horizontally on top of a 150°C oven so that a temperature gradient was set up across the diameter of the tube. After several days small crystals had formed on the coolest side of the tube. These were removed in a dry atmosphere box and a crystal suitable for X-ray analysis was mounted in a capillary tube which was then sealed and the analysis performed on a Nicolet P3 diffractometer. The methods of selection of scan rates and initial data treatment have been described (5, 6). Details of the crystal data, acquisition and structure refinement are summarized in Table 1.

Computations were carried out on a Cyber 17/730 computer. Data reduction employed programs from the XRAY 76 package (7). Lorentz, polarization and empirical absorption corrections were applied (8–10). The intensity-weighted reciprocal lattice indicated the space groups *Pnma* or $Pna2_1$. The eventual choice of $Pna2_1$ was justified by the successfully refined structure. The coordinates of the tin atoms were obtained using the program MULTAN (11) and a series of full-matrix least-squares refinements, followed by three-dimensional electron density difference syntheses, using the program SHELX 76 (12), revealed all of the C, O, and F atoms. Because of the large number

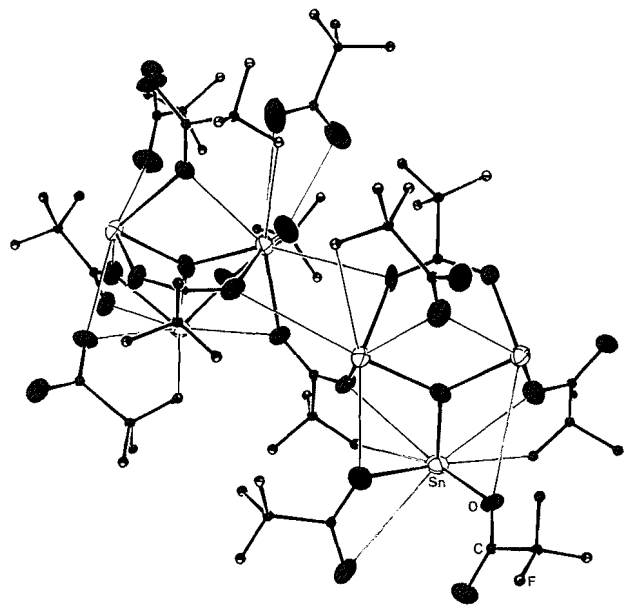

FIG. 1. The structure of $Sn_6O_2(CF_3CO_2)_8.CF_3CO_2H$ showing all interatomic distances smaller than the sum of van der Waals radii.

of atoms in this structure it was necessary to refine it using a large block approximation to the normal matrix. Two blocks were refined alternately. The first included all parameters for the tin atoms as well as for O(1) to O(18) inclusive. The second included the parameters for the remaining atoms. The scale, and in the final stages the "extinction" parameter (see Table 1) were included as variables in each cycle. Using this method, final refinement of a total of 391 variables, including anisotropic atomic temperature factors for Sn, O, and F, minimized $\Sigma_w(|F_o|-|F_c|)^2$ for the 4577 observed reflections, yielding a final residual of $R_1 = 0.0519$. The H atom was not located in the final difference Fourier map.

The final atomic positional coordinates are given in Table 2, interatomic distances (Sn—O) and bond angles (O—Sn—O) in Table 3(*a*). Other bond distances and angles (Table 3(*b*)), anisotropic temperature factors for the Sn, O, and F atoms (Table 4) and the observed and calculated structure factors (Table 5) have been deposited as Supplementary Information and are available on request.[2] Plots were generated using ORTEP II (13).

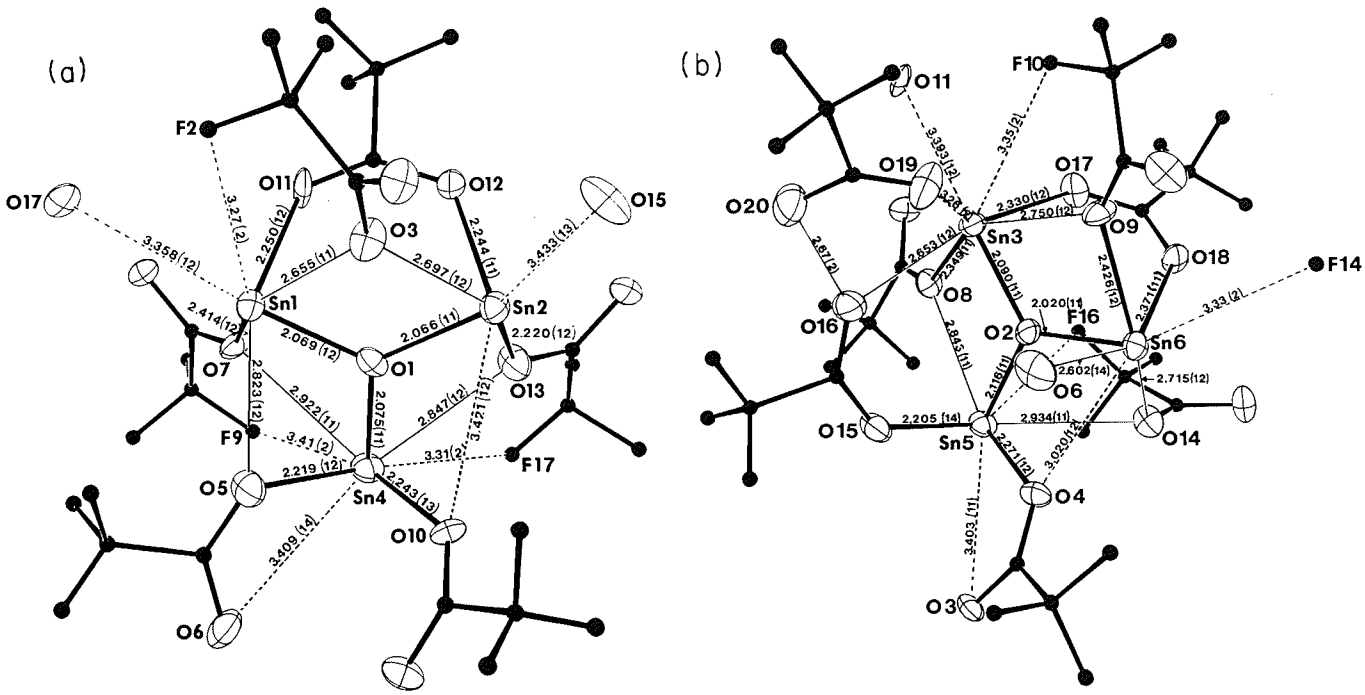

FIG. 2. The two Sn_3O units, *a* and *b*, together with their most closely associated carboxylate ligands. Thick lines represent strong bonds, thin lines represent weak but significant interactions, while hatched lines represent very weak interactions, or non-bonding contacts.

Results and discussion

Preliminary spectroscopic data obtained on the sublimed material revealed that the compound could not be the expected $Sn(CF_3CO_2)_2$. The X-ray solution shows that the structure consists of two sets of three tin(II) atoms, each set being linked by a μ_3-oxo bridge. Two crystallographically independent Sn_3O units are linked by trifluoroacetate groups to form an extended structure. The two Sn_3O units and their surrounding trifluoroacetate groups are shown in Fig. 1. In addition to the trifluoroacetate ligands which link the Sn_3O units, there are trifluoroacetate groups which are bonded to each tin in order to satisfy its charge and coordination requirements. One trifluoroacetic acid molecule completes the asymmetric unit. This results in there being six different tin environments in the structure. Although each of the trifluoroacetate groups is crystallographically different, there are three basic types. These are, monodentate with one strong O—Sn bond, bidentate-chelating two different tin atoms in a symmetric fashion, and bidentate-chelating two different tin atoms in an asymmetric fashion. The trifluoroacetic acid molecule is hydrogen bonded to an oxygen of one of the trifluoroacetate ligands, O(20)—O(16), 2.67(2) Å and has a long contact O(19)—Sn(3), 3.26(2) Å. Not one of the carboxylate ligands forms a bidentate chelating link to a single tin atom.

For convenience the two Sn_3O units together with their most closely associated carboxylate ligands have been represented in Fig. 2*a* and *b* with all interatomic distances less than the sum of the Van der Waals radii being indicated. A number of these distances which are close to the Van der Waals separations are almost certainly non-bonding interactions, however they are included for completeness. Nevertheless, the Sn—O distances displayed range from 2.02 Å out to the Van der Waals separation of 3.45 Å and it is difficult to draw a clear distinction between bonding and non-bonding interactions. Each of the Sn_3O units is almost planar, with plane *1*, (Sn(1), Sn(2), Sn(4), O(1)) defined by $0.5840x - 0.6179y - 0.5265z + 9.3489 = 0$, while plane 2 (Sn(3), Sn(5), Sn(6), O(2)) is defined by $0.5167x - 0.5024y - 0.6933z + 8.4461 = 0$. The deviation of O(1) from plane *1* is −0.05(1) Å while O(2) is +0.06(1) Å out of plane 2: the dihedral angle between these two planes is 12.3°.

The unit containing Sn(1), Sn(2), Sn(4), O(1), shown in Fig. 2(*a*), is the more symmetric of the two, the tin—μ_3O distances being essentially equal, with the Sn—O—Sn angles close to 120° (Table 3). There is a variation in Sn—O bond lengths in the second unit ranging from O(2)—Sn(6), 2.020(11) Å through O(2)—Sn(3), 2.090(11) Å to 0(2)—Sn(5), 2.116(11) Å, though the Sn—O—Sn angles again remain close to 120°. These μ_3 oxo—tin bonds are shorter than those found recently in mixed valence tin caboxylates (3, 14, 15) and are among the shortest Sn(II)—O bond lengths measured to date (16), with O(2)—Sn(6) at 2.020(11) Å being the shortest known. Each tin has two relatively short Sn—O interactions in addition to the short bond to the μ_3 oxygen atom giving a pyramidal arrangement at the tin atoms. This arrangement, however, is not a trigonal one since the Sn—Oμ_3 bond is always significantly shorter than the other tin–oxygen interactions and furthermore the O—Sn—O angles vary from 74.3 to 90.6° (Table 3), presumably to accommodate the other longer tin—oxygen interactions and the non-bonding electron pair.

In the Sn(1)Sn(2)Sn(4)O(1) unit tin atoms (1) and (2) are symmetrically bridged by one trifluoroacetate group through O(11) and O(12) and these are strong interactions. These two tin atoms also are weakly μ-bridged via O(3) of a trifluoroacetate whose other oxygen O(4) forms a strong bond to Sn(5) of another Sn_3O unit. The Sn(1)—O(3) and Sn(2)—O(3) distances are 2.655(11) and 2.697(12) Å, respectively, clearly interactions of a weaker type but still significant being only

0.25 Å longer than the sum of the ionic radii (16). This bridging interaction gives these two tin atoms a coordination represented as SnX_4E rather than as SnX_3E, where E represents the non bonding electron pair (17). The situation at Sn(4) is slightly different in that there are two longer secondary interactions at 2.847(12) and 2.922(11) Å, giving it a SnX_5E coordination. There are longer Sn—O,F interactions also listed in Table 3 and shown in the figures but these are obviously of marginal significance. Of the six trifluoroacetate ligands bonded to the tin atoms in this unit, only one forms an essentially symmetric bidentate bridge (see O(11)—Sn(1), O(12)—Sn(2)). The other five trifluoroacetates interact to varying degrees with both Sn_3O units or symmetry related ones.

As indicated earlier the second unit is not as symmetric as the one just described. Figure 2(*b*) shows all the interactions to Sn less than Van der Waals separations. There is again one trifluoroacetate which symmetrically bridges Sn(3) and Sn(6). The atom O(9) forms a μ-oxo bridge between these tin atoms but this is quite asymmetric, unlike the O(3) bridging Sn(1) and Sn(2). The coordination about each tin in this unit can be represented as SnX_5E, if the very long interactions are discounted. There are six trifluoroacetate groups associated with this unit, as in the previous case, but in addition a trifluoroacetic acid molecule is hydrogen bonded to O(16) and weakly coordinating to Sn(3), O(20)—O(16) and O(19)—Sn(3), respectively. This may be one reason for the more distorted geometry of this unit compared to the other, pushing O(9) away from Sn(3) towards Sn(6) to give distances of 2.759(12) and 2.426(12) Å compared to 2.655(11) and 2.697(12) Å for Sn(1)—O(3) and Sn(2)—O(3), respectively.

Figure 3 summarizes the bonding interactions for each trifluoroacetate group. No two are identical though in the broadest sense there are three types, monodentate, bidentate (symmetrically bridged), and bidentate (asymmetrically bridged), with the trifluoroacetic acid molecule, of course, being unique. Little can be said about the internal geometry of the carboxylate

units in these trifluoroacetate ligands since the errors on the C—O bonds are rather high.

Conclusions

Sublimation of $Sn(CF_3CO_2)_2$ results in the production of $Sn_6O_2(CF_3CO_2)_8.CF_3CO_2H$. This has two groups of three tin(II) atoms each connected by a μ_3-oxo bridge. The tin atoms are further coordinated by trifluoroacetate ions and one trifluoroacetic acid molecule. This latter presumably arises from the presence of small quantities of water adsorbed on the surface of the glass tube used for the sublimation, or picked up when the original $Sn(CF_3CO_2)_2$ was introduced into the tube, although this was carried out in a dry atmosphere glove box. The oxo-bridges arise either from surface moisture or by the

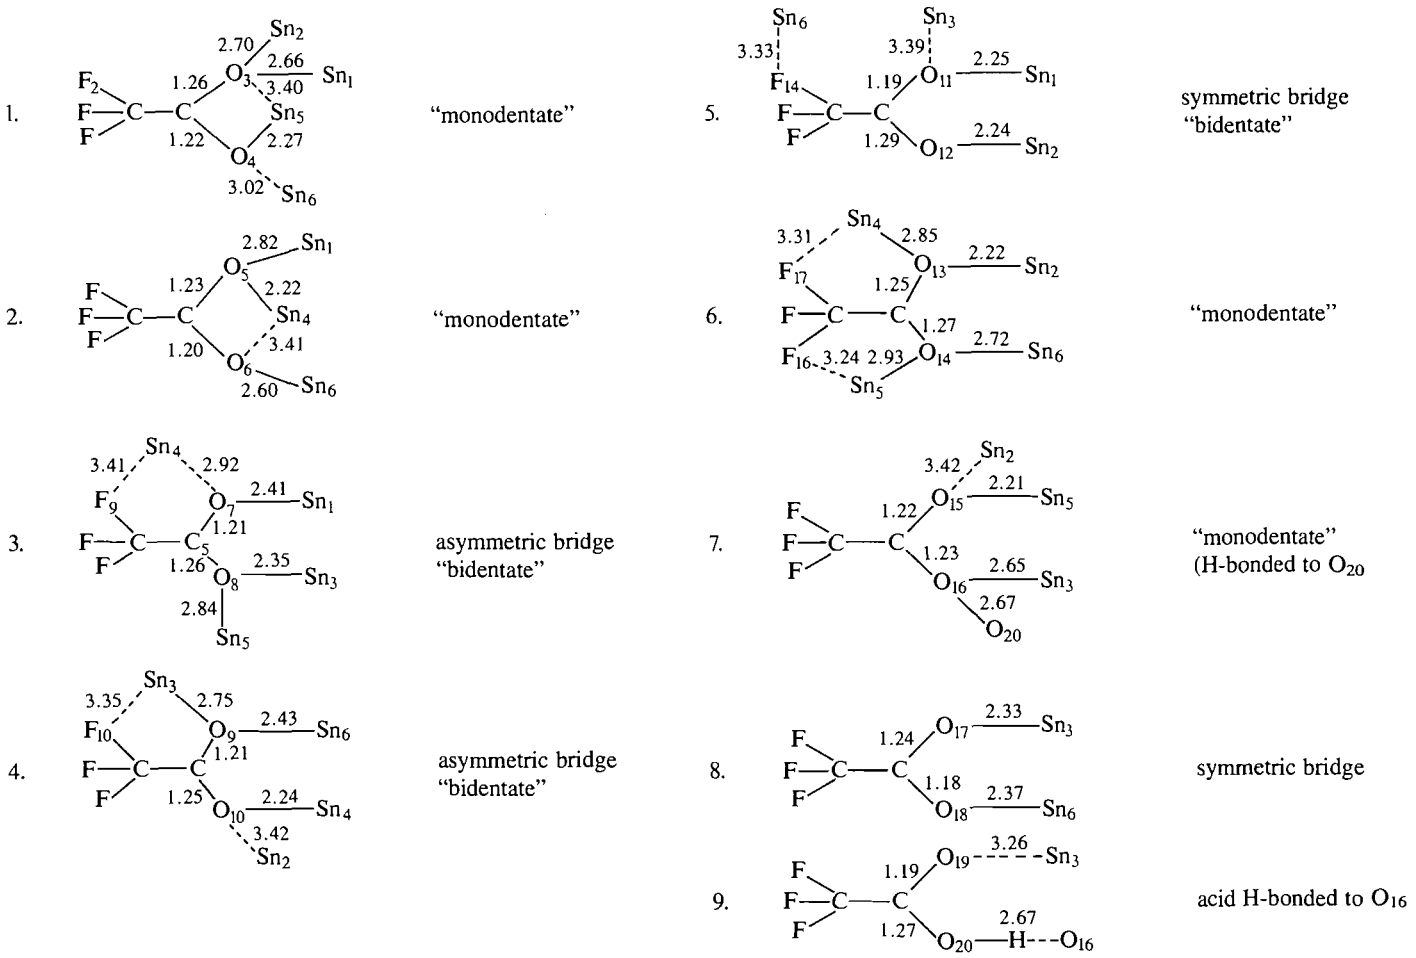

FIG. 3. Bonding interactions for each trifluoroacetate group.

elimination of O^{2-} from two trifluoroacetate ligands.

We are continuing our efforts to obtain crystals of $Sn(CF_3CO_2)_2$ suitable for X-ray crystallographic analysis.

Radical reactions of *N*-haloamides with olefins. XIII.[1] Quantum yields for the photochemical addition of *N*-halo-*N*-hydroamides and *N*-chlorosuccinimide to 3,3-dimethyl-1-butene

JACQUES TUAILLON,[2] YVON COUTURE, AND JEAN LESSARD[3]

Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received October 20, 1986

JACQUES TUAILLON, YVON COUTURE, and JEAN LESSARD. Can. J. Chem. **65**, 2194 (1987).

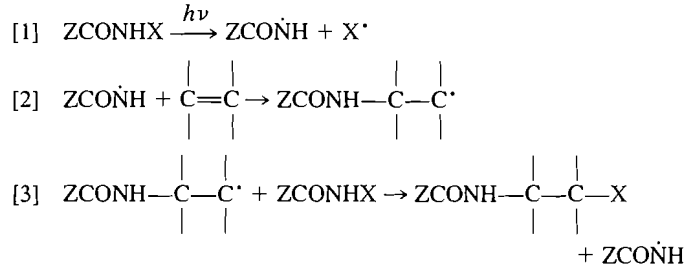
The quantum yield of the photochemically initiated radical chain addition of ZCONHX to 3,3-dimethyl-1-butene increases with Z in the order $CH_3 < ClCH_2 < C_2H_5O < CCl_3 < CF_3$ and is governed by the transfer step. The quantum yields are similar for *N*-chloroacetamide and *N*-chlorosuccinimide but the yield of addition is lower with the latter due to photodecomposition of the 1,2-adduct.

JACQUES TUAILLON, YVON COUTURE et JEAN LESSARD. Can. J. Chem. **65**, 2194 (1987).

Le rendement quantique de l'addition radicalaire en chaîne de ZCONHX au diméthyl-3,3 butène-1, initiée par dissociation photochimique, augmente avec Z dans l'ordre $CH_3 < ClCH_2 < C_2H_5O < CCl_3 < CF_3$ et dépend essentiellement de l'efficacité de l'étape de transfert. Le *N*-chloroacétamide et le *N*-chlorosuccinimide donnent des rendements quantiques semblables, mais le rendement d'addition est plus faible avec le dernier dû à la photodécomposition de l'adduit-1,2.

Introduction

We reported that in the photochemically initiated radical chain addition of *N*-chloro-*N*-hydroamides (ZCONHCl, **1**) to cyclohexene, the yield of 1,2-addition increases with the electron-withdrawing power of Z (2): CH_3 (53%) < C_2H_5O (84%) < $ClCH_2$ (89%) < Cl_2CH (94%) < CCl_3 (99%) ≃ CF_3 (100%). Thus, as the ZCO moiety becomes more electronegative, the 1,2-addition chain (steps [2] and [3]) competes more effectively with other processes such as halogenation (hydrogen abstraction).

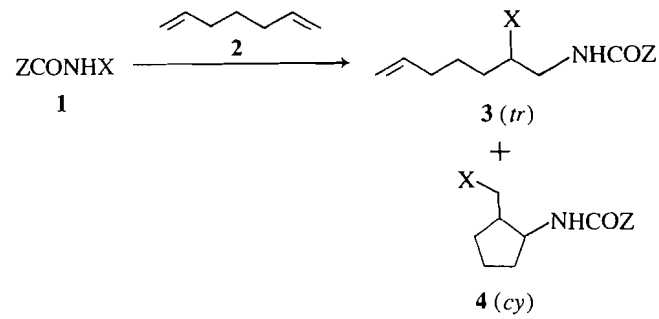


By studying the addition of ZCONHCl to 1,6-heptadiene (**2**), we have shown that the **3**-to-**4** ratio (*tr*ansfer-to-*cy*clization ratio) (Scheme 1), and hence the reactivity of ZCONHCl as chlorine atom donor towards a carbon radical (transfer step [3], X = Cl), increases with the electron-withdrawing power of Z (3): $CH_3 < ClCH_2 < C_2H_5O < CCl_3 \simeq CF_3$.

We now report the quantum yields for the photochemical addition of *N*-haloamides **1** and *N*-chlorosuccinimide (NCS) (**7**) to 3,3-dimethyl-1-butene (**5**) (Schemes 2 and 3), chosen as olefin to minimize the importance of hydrogen abstraction (no allylic hydrogen), and compare them with the transfer-to-cyclization ratios (**3**/**4**) for the addition to 1,6-heptadiene (**2**) (Scheme 1).

Results and discussion

The irradiations were carried out at 254 nm in a Vycor cell under conditions similar to those used in ref. 2 (see footnote *a* of Table 1). Cyclohepta-1,3-diene in ethanol was used as actinometer (4). The quantum yields for the addition process and the yields of addition are recorded in Table 1 and were measured at 15–20%, 30–35%, and 50–55% conversion (determined by iodometry) for each *N*-haloamide; no significant differences were noted with the extent of conversion up to 55% conversion. The material balance based on the amide moiety of **1** and **7** (1,2-adduct plus parent amide) was better than 95% in all cases. The identification and characterization of the 1,2-adducts **6** and **8** have already been described (5). The transfer-to-cyclization (*tr*/*cy*) (**3**/**4**) ratios for the additions of *N*-haloamides **1** to 1,6-heptadiene (**2**) taken from ref. 3 are also included in Table 1.



SCHEME 1

The 1,2-adducts **6***c* and **8** underwent photodecomposition, to the extent of 10 and 30% respectively, when irradiated over the time required for complete conversion of the *N*-haloamide. The other 1,2-adducts **6** showed no sign of photodecomposition. The photodecomposition of **6** and **8**[4] did not result in any significant change in the yield of addition or in the material balance based on the amide moiety up to 55% conversion.

With NCS (**7**), we studied the effect of the NCS-to-olefin (**7**/**5**) molar ratio and the effect of the number of photons per unit of time on the chemical and quantum yield of addition up

[1]For part XII, see ref. 1.

[4]The photodecomposition of **8** gives succinimide. No attempt was made to detect and identify other products from the photodecomposition of **8** or any product from the photodecomposition of **6***c*. The literature contains reports on the photochemical addition of NCS (6) and *N*-bromosuccinimide (6–8) to 3,3-dimethyl-1-butene (**5**) but no mention is made that **8** or its bromo analogue were photolabile under the reaction conditions.

SCHEME 3

to 55% loss of NCS. Both yields increase (*i*) as the **7**/**5** molar ratio decreases: from 20%, Φ = 0.4 mol einstein^{-1} (Φ for loss of NCS = 1.9), for a molar ratio of 3, to 61%, Φ = 4 mol einstein^{-1} (Φ for loss of NCS = 6.5), for a molar ratio of 0.67 (case reported in Table 1, entry 6); (*ii*) as the number of photons decreases: from 38%, Φ = 1.7 mol einstein^{-1} (Φ for loss of NCS = 4.5) with 7×10^{-7} einstein s^{-1}, to 61%, Φ = 4 mol einstein^{-1} (Table 1, entry 6) (Φ for loss of NCS = 6.5) with $(0.5–1.8) \times 10^{-7}$ einstein s^{-1}. The irradiations of Table 1 were consequently carried out with 1.8×10^{-7} einstein s^{-1} or less, using an *N*-haloamide-to-olefin molar ratio of 0.59 to 0.67.

We determined the material balance based on chlorine for the addition of NCS (**7**), which gave the lowest yields of addition. The chlorine balance consists of 1,2-adduct **8** and 1,2-dichloro-3,3-dimethylbutane. The yield of the latter was determined by vpc: 33% (chlorine balance ≃ 53%) for a **7**/**5** molar ratio of 3; 6% (chlorine balance ≃ 61–70%) for a **7**/**5** molar ratio of 0.67 (Table 1, entry 6). No 4-chloro-3,2-dimethyl-1-butene, resulting from hydrogen abstraction on **5**, was detected in the 250-MHz ^{1}Hmr spectrum of the crude reaction mixture (no singlet at 3.30 ppm (9)) and only a trace amount of chloroform resulting from hydrogen abstraction on methylene chloride was detected (≃1% by vpc). This is surprising since in the radical photochlorination of **5**, 4-chloro-3,2-dimethyl-1-butene represents 12–13% of the chlorinated products and since the photolysis of NCS in methylene chloride in the presence of neopentane and ethylene was reported to give neopentyl chloride (81%) and chloroform (15%) plus a small amount (5%) of 1,2-adduct (**8**). Thus, hydrogen abstraction does not appear to be an important process under the conditions we used unless 4-chloro-3,3-dimethyl-1-butene underwent photodecomposition (e.g. dehydrochlorination). Two to three other products were present in small amounts in the crude reaction mixture according to the ^{1}Hmr spectrum and vpc analysis. They are fairly volatile and could result from dehydrochlorination of chlorinated products but they were not identified.

When NCS (**7**) is in excess with respect to the olefin (**7**/**5** = 3), 1,2-dichloro-3,3-dimethylbutane is a major product together with the 1,2-adduct **8**. Considering the low material balance based on chlorine (53%), any discussion concerning the process(es) responsible for the formation of the dichloro adduct would be highly speculative. The photodecomposition of 1,2-adduct **8** can be partly responsible for the relatively low chlorine balance (the dichloro adduct is stable under the photolysis conditions).

It is interesting to compare the photolysis of NCS (**7**) and *N*-bromosuccinimide (NBS) in the presence of 3,3-dimethyl-1-butene (**5**). Skell and co-workers (8) reported that, for a NBS/**5** molar ratio of 3.5, the quantum yield for the loss of NBS in methylene chloride is 67 mol einstein^{-1} for a 82% conversion. The main products are β-bromopropylisocyanate and the 1,2-adduct, and the bromine balance is quite good. The different product distribution and the longer chain of the NBS reaction result from the fact that NBS is a better halogen atom donor (better transfer agent) than NCS, an N—Br bond being weaker than an N—Cl bond (10).

The results of Table 1 show that the yield of addition increases as Φ increases, that is, as the 1,2-addition chain

becomes longer and thus competes more and more effectively with other processes. When comparing an *N*-bromoamide with its *N*-chloro analogue, the relative chain lengths for the addition, and hence the relative quantum yields, depend solely on the relative rates of the transfer step [3] since the same amidyl radical is involved in the addition step [2]. The transfer step [3] should be faster with the *N*-bromoamide because an N—Br bond is weaker than an N—Cl bond (10) as stated above. Indeed, the entries 6 and 4 of Table 1 show that the quantum yield is 18 times larger for *N*-bromotrichloroacetamide (**1***f*) than for the *N*-chloro analogue **1***d*. The agreement between this figure and the relative rate of the transfer step [3] (19 times faster with **1***f* than with **1***d*) obtained from the addition to 1,6-heptadiene (**2**) (3) is excellent.

As shown in entries 1 to 5 of Table 1, the increase of the quantum yield of addition, and hence of the 1,2-addition chain length with the electron-withdrawing power of Z, parallels the reactivity of ZCONHCl as chlorine atom donor towards a carbon radical (transfer step [3])[5] as determined by the *tr* (**3**)/*cy* (**4**) ratio for addition to 1,6-heptadiene (**2**) (Scheme 1) (3). Thus, the chain length of the 1,2-addition process is governed by the transfer step [3], which implies that chain termination involves the adduct radical, and *N*-chloramides are good transfer agents resulting in high yields of addition.

NCS (**7**), with two acyl (electron-attracting) groups attached to the nitrogen, should be a better chlorine atom donor than *N*-chloroacetamide (NCA (**1***a*) (LUMO = σ* (N—Cl) lower in energy or more polar transition state for NCS than for NCA).[5] Therefore Φ(NCS) (addition of NCS: Table 1, entry 6) should be larger (longer 1,2-addition chain) than Φ(NCA) (entry 1). The 1,2-adduct **8** being photolabile, the value of Φ in entry 6 is a minimum value and the true Φ(NCS) is probably larger than Φ(NCA).

If we compare the yields of 1,2-addition of *N*-haloamides to 3,3-dimethyl-1-butene (**5**) and to cyclohexene, they are usually higher with **5**. For instance, the yield of addition of NCA (**1***a*) to **5** is 72% after complete conversion of NCA (5) and that to cyclohexene is 55% (1). This is due to the fact that in the case of cyclohexene, which possesses reactive allylic hydrogens, hydrogen abstraction, a chain process competing with 1,2-addition (2, 13),[6] is more effective than the process(es) competing with 1,2-addition in the case of **5**. With NCS, the yield of addition to **5** (48%) (5) is somewhat lower than that to cyclohexene (54%) (1) due to the photodecomposition of the 1,2-adduct **8**. No such photodecomposition of the 1,2-adduct of NCS to cyclohexene was observed (1). When 1,2-addition accounts for 90% or more of the reaction, there is no difference in the yields of addition to cyclohexene and to **5** (2, 5) as expected. As for the chlorine balance, the situation is much better in the case of cyclohexene where the chlorinated products could be clearly identified (2, 13). The chlorine balance (1,2-adduct + dichlorocyclohexane + 3-chloro- and 4-chlorocyclohexene) is better than 90% in most cases (13).[6]

Conclusion

The close parallel between the variation of the quantum yield in the photochemical addition of ZCONHX (**1**) to 3,3-dimethyl-1-butene (**5**) and the variation of the rate of halogen atom transfer (eq. [3]) as evaluated from the addition of ZCONHX to 1,6-heptadiene (**2**) (3) with the electronegativity of Z, shows that the transfer step [3] is governing the 1,2-addition chain length. Thus *N*-haloamides are good transfer agents and good to excellent yields of 1,2-addition are obtained. The implication of this on the competition between 1,2-addition and hydrogen abstraction and on the mechanism of hydrogen abstraction in the case of cyclohexene will be discussed in a forthcoming paper, together with the results of a study of the halogenated products.[6]

In the case of 3,3-dimethyl-1-butene (**5**), which has no reactive allylic hydrogen, hydrogen abstraction, even from the solvent, does not appear to be an important process competing with 1,2-addition, and the nature of the main competing process(es) is unknown at present.

Experimental

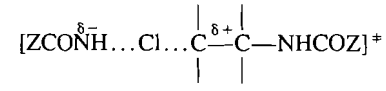
Vapor phase chromatographic (vpc) analyses were performed with a Hewlett Packard chromatograph model 5710A equipped with a flame ionization detector on a DB-5 (95% dimethyl – 5% diphenylpolysiloxane) fused silica capillary column 30 m long using an internal standard (phthalimide or methyl benzoate). Merck silica gel $60F_{254}$ was used for preparative layer chromatography (CH_2Cl_2 or ether–hexane 50:50 containing 4% CH_3OH saturated with NH_3 as eluent). Ultraviolet spectrophotometric determinations were carried out on a Varian Techtron spectrophotometer model 635 or a Beckman uv spectrophotometer model 5230. The ^{1}Hmr spectra were recorded on a Bruker WM-250 spectrometer.

The preparation of the *N*-haloamides (2) and the isolation and characterization of the 1,2-adducts **6** and **8** from preparative photolyses (5) have been described. *1,2-Dichloro-3,3-dimethylbutane* was prepared by chlorination of a CCl_4 solution of 3,3-dimethyl-1-butene in the dark at 0°C (14). The product was purified by fractional distillation and its purity checked by vpc and ^{1}Hmr: bp 60–61°C/21 Torr (lit. (15) bp 63.5°C/20 Torr) (1 Torr = 133.3 Pa).

Quantum yield determinations

The irradiations were carried out at 254 nm in a Rayonnet RPR reactor equipped with a merry-go-round using 14 × 170 mm Vycor test tubes fitted with a 19/40 ground quartz female joint and, as stopper, a two-way Teflon stopcock on a 19/40 ground glass male joint. A test tube (A) containing the solution of the *N*-haloamide and the olefin was followed by a test tube (B) containing the actinometer in succession: $A^1B^1A^2B^2$... At a given time, the merry-go-round was stopped and a test tube A and a test tube B were quickly removed together. Concentrations were chosen to ensure that all the light hitting the cell was absorbed by the actinometer and by the *N*-haloamide (up to 80% conversion). Cyclohepta-1,3-diene (CHD) in 95% ethanol (10 mL of a 30 m*M* solution) was used as actinometer (4). The quantum yield for the disappearance of CHD was determined to be 0.50 ± 0.05 (lit. (4) 0.48 ± 0.01) with ferrioxalate actinometry (16). The CHD solution was diluted (1 mL to 250 mL with 95% ethanol) and the absorbance was measured at 250 nm; the concentration of remaining CHD was obtained from an absorbance vs. concentration graph (ε = 7835). The solution of *N*-haloamide and 3,3-dimethyl-1-butene (passed through alumina)

[5]The increase of the reactivity of ZCONHCl in the transfer step [3] with the electronegativity of Z has been explained in terms of a polar effect stabilizing the transition state (3) (a polar transition state has been proposed for the attack of carbon radicals on carbon–halogen bonds (11)):



In terms of frontier orbital (12) ([3] is an exothermic reaction), such a polar effect corresponds to a dominant SOMO (carbon radical)–LUMO (the σ* (N—Cl) orbital of ZCONHCl) interaction: as the electron-attracting power of Z increases, the energy of σ* (N—Cl) diminishes (12) and the perturbation energy (the reactivity) should increase accordingly.

[6]D. Touchard, Y. Couture, M. Mondon, and J. Lessard. Unpublished results.

(10 mL of a 200 m*M* solution in *N*-haloamide containing the required amount of olefin) in CH_2Cl_2 (freshly distilled over P_2O_5) was freed from oxygen (three successive freeze–thaw cycles under argon). After irradiation, the amount of *N*-haloamide consumed was determined by iodometry from a 3-mL aliquot. To the remaining solution, solid sodium bisulfite (~200 mg) and water (~0.2 mL) were added. After a few minutes (negative starch–iodide paper test), the solution was dried over $MgSO_4$, filtered, then transferred into a 25-mL volumetric flask with CH_2Cl_2 for quantification by vpc and (or) preparative layer chromatography. The results are recorded in Table 1.

In the experiments with NCS, the reaction solution from 25–30% conversion of NCS was distilled through a Vigreux column to remove CH_2Cl_2 and 3,3-dimethyl-1-butene. The residue and the liquid remaining in the Vigreux column were analyzed by ^{1}Hmr. *Excess of olefin*: *residue*: two singlets of very low intensity at 1.57 and 2.17 ppm besides the absorptions due to 1,2-adduct **8** and succinimide, and no absorptions corresponding to 1,2-dichloro-3,3-dimethylbutane (formed in 6% yield according to vpc analysis); *liquid in the column*: three singlets at 1.24, 1.57, and 2.17 ppm besides the absorptions due to 3,3-dimethyl-1-butene and CH_2Cl_2. *Excess of NCS*: *residue*: two singlets of low intensity at 1.59 and 2.17 ppm besides the absorptions due to 1,2-adduct **8**, succinimide, and 1,2-dichloro-3,3-dimethylbutane; *liquid in the column*: two singlets at 1.57 and 2.17 ppm besides the absorptions due to 3,3-dimethyl-1-butene and CH_2Cl_2.

The products in the liquid from the Vigreux column contained no chlorine according to the mass spectrum. They were not investigated further. In none of the above ^{1}Hmr spectra was singlet at 3.30 ppm detectable, due to the presence of 4-chloro-3,3-dimethyl-1-butene.

Received September 18, 1986[1]

MARÍA ASUNCIÓN GALLARDO, JOSÉ MARÍA MELENDO, JOSÉ SANTIAGO URIETA, and CELSO GUTIERREZ LOSA. Can. J. Chem. **65**, 2198 (1987).

Solubility measurements of several non-polar gases (He, Ne, Ar, Kr, Xe, H_2, D_2, N_2, O_2, C_2H_4, C_2H_6, CF_4, SF_6, and CO_2) in cyclohexanone at 273.15 to 303.15 K and a partial pressure of gas of 101.32 kPa, are reported. Gibbs energy, enthalpy, and entropy of solution at 298.15 K and 101.32 kPa partial pressure of gas were evaluated. Effective hard-sphere diameter temperature dependence has been studied and its effect on the calculated SPT (Scaled Particle Theory) solubilities, and enthalpies and entropies of solution was also examined.

MARÍA ASUNCIÓN GALLARDO, JOSÉ MARÍA MELENDO, JOSÉ SANTIAGO URIETA et CELSO GUTIERREZ LOSA. Can. J. Chem. **65**, 2198 (1987).

Opérant à des températures allant de 273,15 à 303,15 K et à des pressions partielles de gaz de 101,32 kPa, on a mesuré les solubilités de plusieurs gaz non polaires (He, Ne, Ar, Kr, Xe, H_2, D_2, N_2, O_2, C_2H_4, C_2H_6, CF_4, SF_6 et CO_2) dans la cyclohexanone. On a évalué l'énergie libre de Gibbs, l'enthalpie ainsi que l'entropie de solution à 298,15 K et à une pression partielle de gaz de 101,32 kPa. On a étudié la relation entre le diamètre effectif des sphères solides et la température et on a aussi étudié son effet sur les solubilités calculées sur la base de la théorie de la particule graduée; de plus, on a aussi examiné les enthalpies et les entropies de solution.

Introduction

Apart from their practical usefulness, solubility measurements of non-polar gases in liquids are of great interest in the theoretical study of liquids.

In spite of the various approaches proposed up to now, no general method exists for rigorous gas solubility predictions. While it is true that some successful calculations of solubility and of thermodynamic properties for simple systems, using either perturbation or variation methods, were performed (1–8) when more complex molecules are involved, a strict explanation of solubility at molecular level is unattainable, specially when anisotropy effects are important.

While lacking the strictness of the above-mentioned methods, Pierotti's "Scaled Particle Theory" (SPT) (1963) (9) shows an outstanding consistency and was extensively used for estimating molecular pair-potential parameters of liquids from gas solubility data. The main simplifications introduced into the original cavity theory for solutions are as follows: (*a*) solutions are made up of "hard-sphere" molecules; (*b*) the radial distribution function is independent of temperature and therefore $G_i = E_i$; and (*c*) solvent molecules are uniformly distributed around each solute molecule, that is to say, the radial distribution function, $g(\sigma,r)$, is unity.

In the first steps of the development of the cavity theory the effect of temperature on the "effective hard-sphere diameter" of solvent molecules was ignored. However, more recent works (10–15) have revealed that a hard-sphere temperature dependence must be taken into account if an adequate theoretical explanation of solubility results is to be given. In 1981, Cosgrove analysed in depth the effect of the effective hard-sphere diameter temperature dependence on solution enthalpies of rare gases in some non-polar organic solvents (benzene, cyclohexane, tetrachloromethane, and *n*-hexane) and in water, too (15).

In the present paper, the effect of temperature on effective hard-sphere diameter, a_1, is studied for a polar molecule, cyclohexanone ($\mu = 9.34 \times 10^{-30}$ m C), and solubility data of fourteen gases in this solvent, between 273.15 and 303.15 K and at a gas pressure of 101.32 kPa, are given.

Experimental

The equipment used for solubility measurements and the associated experimental technique were similar to those described in previous papers (16, 17).

The purity of the gases (all from Sociedad Española de Oxígeno except Ne and CF_4 which were from Baker) was He 99.995%, Ne 99.9%, Ar 99.9990%, Kr 99.95%, Xe 99.995%, H_2 99.99%, D_2 99.4%, N_2 99.998%, O_2 99.98%, C_2H_4 99.90%, C_2H_6 99.0%, CF_4 99%, SF_6 99.5%, and CO_2 99.998%. Cyclohexanone (Carlo Erba: ≧99%) was used as solvent; its purity was checked by GLC and by refractive index measurement (experimental value, n_D (293.15 K) = 1.45071; literature, 1.4507 (18)). Vapour pressure data of the solvent were taken from the literature (18).

The uncertainty on about the reported solubilities is estimated in ±0.7%, or less, except for gases with low solubilities (He and Ne) for which it is approximately ±2.0%.

Results

In Table 1, the experimental results for the solubilities of He, Ar, Kr, Xe, H_2, D_2, N_2, O_2, C_2H_4, C_2H_6, CF_4, SF_6, and CO_2 in cyclohexanone in terms of the equilibrium mole fraction, x_2, are given at temperatures ranging from 273.15 to 303.15 K, and at 101.32 kPa partial pressure of gas. The results were fitted by least squares to an equation of the form:

$$[1] \quad -\ln x_2 = a \ln T + b$$

In Table 1 the values of a and b for each system are set out together with the standard deviations

$$\sigma = \left\{ \sum_{i=1}^{n} (\ln x_{2,1} + a \ln T_i + b)^2/(n-2) \right\}^{1/2}$$

Table 2 shows the values of partial molar Gibbs energy, $\Delta G^0_{m,2}$, partial molar enthalpy, $\Delta H^0_{m,2}$, partial molar entropy, $\Delta S^0_{m,2}$, and partial molar Hildebrand entropy, ΔS^0_H, for the

[1]Revision received April 3, 1987.

TABLE 1. Solubility of gases ($x_2 \times 10^4$) in cyclohexanone, at 101.32 kPa partial pressure of gas between 273.15 and 303.15 K, coefficients of the equation $-\ln x_2 = a \ln T + b$, and standard deviations as defined in the text

solution process calculated from our experimental results, and using the adequate relations (20).

Discussion

The scaled particle theory formalism of gas solubility has been explained so many times that we consider unnecessary to do it again; we will just summarize the pertinent equations instead. The changes in Gibbs energy and enthalpy for the solution process are given by equations (9, 12):

$$[2]\quad \Delta G^0_{m,2} = -RT \ln K_H = G_c + G_i + RT \ln (RT/v^0_1)$$

$$[3]\quad \Delta H^0_{m,2} = |\partial(\Delta G^0/T)/\partial(1/T)|_p = H_c + H_i - RT + \alpha_p RT^2$$

where R is the gas constant, T is the absolute temperature, $K_H = p_2/x_2$ is the Henry's law constant, p_2 is the partial pressure of the gas, x_2 is the gas mole fraction in the solution, v^0_1 is the molar volume of the solvent, α_p is the thermal expansion coefficient of the solvent; the subscripts 1 and 2 refer to the solvent and the solute, respectively, and c and i refer to cavity formation and interaction steps, respectively.

In the present paper we are interested in the temperature dependence of the effective hard-sphere diameter. It can be seen (Fig. 1) that Henry's law constant decreases regularly with the polarizability of the rare gases; from this plot, the extrapolated value of ln K_H to zero polarizability leads to the solubility of a hard sphere of 0.258 nm diameter. This diameter is obtained from the extrapolation to zero polarizability of the plot of diameter of the rare gases against the corresponding polarizabilities. Introducing such a value in eq. [2] with $\alpha_2 = 0$, the effective hard-sphere diameter of the solvent, a_1, can be calculated (9). As solubility data of rare gases were available for several temperatures, we were able to evaluate the linear coefficient of expansion of a_1, at 298.15 K and 101.32 kPa, namely:

$$l_1 = (1/a_1)(\partial a_1/\partial T)_p = -2.07 \times 10^{-4}\ \text{K}^{-1}$$

The necessary data used in the calculations are given in Table 3.

Recently, Cosgrove and Walkley have proposed a method for calculating l_1 from enthalpy of solution data (15). If the enthalpies of solution of rare gases in a given solvent are available, the enthalpy of solution of a hard sphere (a_2 = 0.258 nm), $\Delta H_{2,0}$, can be obtained from extrapolation of $\Delta H^0_{m,2}$ vs. α_2 to zero polarizability; then l_1 can be calculated by means of eq. [3] and also the corresponding expression for H_c which depends on the linear coefficient of expansion of a_1. The value of $\Delta H_{2,0}$ found for cyclohexanone was 12.24 kJ mol^{-1}. Likewise, the value of l_1 obtained for cyclohexanone at 298.15 K and 101.32 kPa was -1.87×10^{-4} K^{-1}, in good agreement with that calculated from ln K_H at several temperatures.

In order to study the effect of the effective hard-sphere diameter temperature dependence, solubility and thermodynamic functions associated to the solution process were calculated by means of the scaled particle theory either assuming a constant a_1 ($l_1 = 0$) or admitting its temperature dependence ($l_1 \neq 0$).

Table 2 contains also the theoretical values for $\Delta H^0_{m,2}$ and $\Delta S^0_{m,2}$, both when $l_1 = 0$ or $l_1 \neq 0$. In Figs. 2 and 3 the differences between experimental and calculated values are plotted against the effective hard-sphere diameter of the solute. The following observations are worth making: (*i*) for He and Ne (that is to say, the gases with the shallowest energy well)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

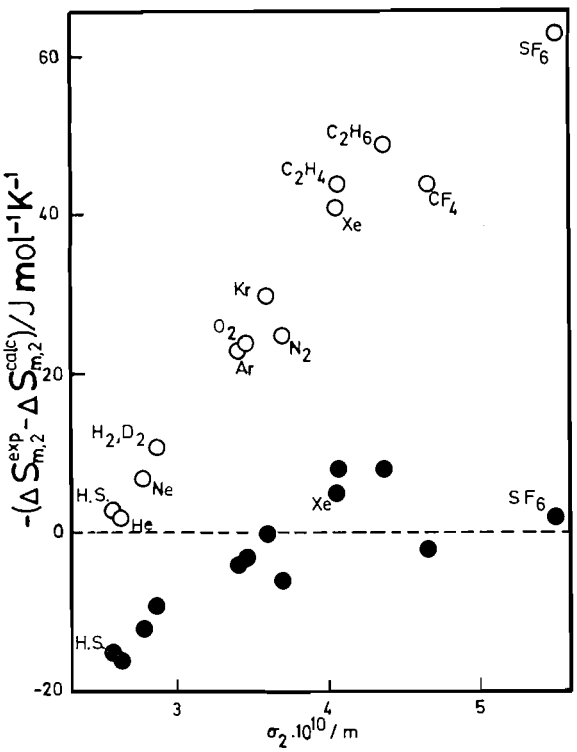

FIG. 3. Difference between experimental and calculated (SPT) values of the partial molar entropy of solution, $-(\Delta S^{exp}_{m,2} - \Delta S^{calcd}_{m,2})$, of gases dissolved in cyclohexanone at 298.15 K, versus the effective hard sphere diameter of solutes: ○, values calculated with $l_1 \neq 0$; ●, values calculated with $l_1 = 0$.

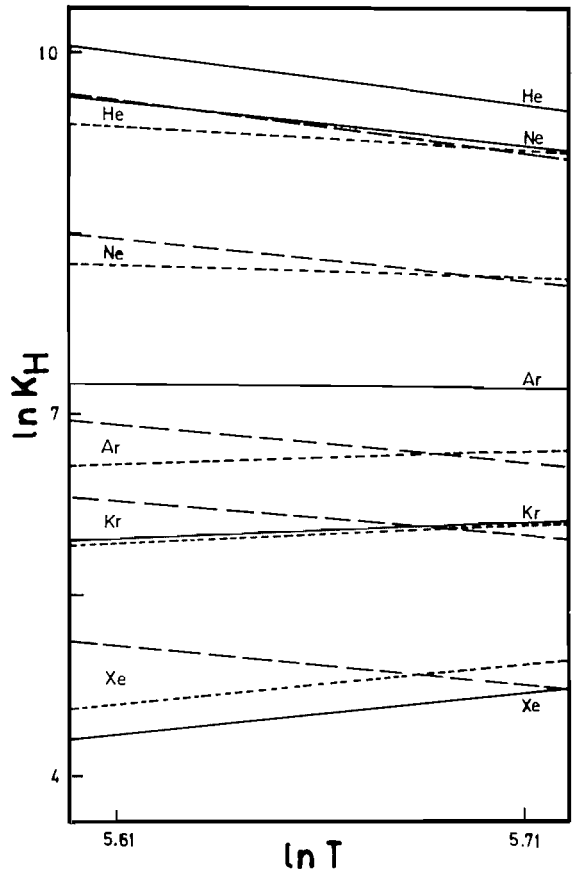

FIG. 4. ln K_H of inert gases in cyclohexanone as a function of ln T: the unbroken line are experimental values; the broken lines are calculated (SPT) values using G_i temperature independent, – – – with $l_1 = -2.07 \times 10^{-4}\,K^{-1}$ and - - - with $l_1 = 0$.

experimental and calculated $\Delta H^0_{m,2}$ and $\Delta S^0_{m,2}$ are in good agreement when $l_1 = -1.87 \times 10^{-4}\,K^{-1}$ is used; with $l_1 = 0$ the calculated values differ greatly from the experimental ones; (*ii*) for gases whose potential energy curves are similar in depth to that of Kr, only the values of $\Delta H^0_{m,2}$ and $\Delta S^0_{m,2}$ obtained with $l_1 = 0$ agree with the experimental ones. Cosgrove and Walkley found similar concordance pattern for the calculated enthalpies of solution for other solvents (15).

When the values of solution enthalpy obtained from eq. [3] (Table 2) are compared with those deduced from the slope of the plot of the theoretical ln K_H against ln T, one can observe that the two ways only agree when G_i is temperature independent. This is because the theory assumes the entropy of interaction to be equal to zero. However, the predicted values of ln K_H are better if G_i is assumed to be temperature dependent in eq. [2]. Figure 4 shows the plot of ln K_H against ln T for the rare gases with G_i = constant.

Following Cosgrove and Walkley (15), we have checked the thermodynamic consistency of equations [2] and [3] for a hypothetical solute of hard-sphere molecules for which $G_i = H_i = 0$. The diameters used were the hard-sphere effective diameters for the rare gases (see Table 3). Enthalpy of solution at 298.15 K was calculated from [3], either with $l_1 = 0$ or with $l_1 = 1.87 \times 10^{-4}\,K^{-1}$. Once the values of ln K_H were obtained from eq. [2] at 293.15 and 303.15 K, the enthalpy of solution was calculated by means of:

$$[4] \quad \Delta H^0_{m,2}(\ln K_H) = -RT^2[\ln K_H(303) - \ln K_H(293)]/10$$

both supposing a_1 = constant = $a_1(298.15)$, $\Delta H^P(\ln K_H)$, and $a_1 = a_1(T)$, $\Delta H^1(\ln K_H)$. The results obtained (Table 4) show

TABLE 4. Enthalpies of solution of rare gases as hard spheres ($G_i = H_i = 0$)

Gases	ΔH^P / kJ mol^{-1}	ΔH^1 / kJ mol^{-1}	$\Delta H^P(\ln K_H)$ / kJ mol^{-1}	$\Delta H^1(\ln K_H)$ / kJ mol^{-1}
He	7.3	12.6	7.6	12.6
Ne	8.1	13.9	8.5	14.1
Ar	11.8	19.9	12.2	19.9
Kr	13.1	21.9	13.5	22.0
Xe	16.4	27.2	17.2	27.2

that [2] and [3] lead to similar values when the same criterion about hard-sphere temperature dependence is used in both cases (either with $l_1 = 0$ or with $l_1 \neq 0$). This confirms that the disagreement between the values for $\Delta H^0_{m,2}$ calculated using both ways should be ascribed to the interaction term, G_i.

Studies of the synthesis of 5-hydroxy 6-keto steroids and related 6-keto steroids

PETER YATES AND SHIRLEY STIVER
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received March 17, 1987

PETER YATES and SHIRLEY STIVER. Can. J. Chem. **65**, 2203 (1987).

Syntheses of 5-hydroxy-5α- and 5β-cholestan-6-one (**11** and **13**) and their 3β-acetoxy (**10** and **21**) and 3β-benzyloxy derivatives (**12** and **19**) are described, as are syntheses of the 7α-deutero derivatives of **10** and **21**. Related investigations of the syntheses of the 5-methoxy and 5-methyl analogues of these compounds are also discussed. Treatment of **12** with potassium *tert*-butoxide has been shown to give 5-hydroxy-5β-cholest-3-en-6-one (**14**) and its Δ^2 isomer **15**. Reaction of 6-nitrocholesteryl acetate (**50**) with lithium dimethylcuprate gives 3α,5-cyclo-5α-cholestan-6-one (*E*)-oxime (**51**) as the major product.

PETER YATES et SHIRLEY STIVER. Can. J. Chem. **65**, 2203 (1987).

On décrit la synthèse des hydroxy-5 5α- et 5β-cholestanones-6 (**11** et **13**) et de leurs dérivés acétoxy-3β (**10** et **21**) et benzyloxy-3β (**12** et **19**) ainsi que celle des dérivés deutéro-7α des composés **10** et **21**. On discute aussi des études apparentées orientées vers la synthèse des analogues méthoxy-5 et méthyl-5 de ces composés. On a démontré que la réaction du composé **12** avec le *tert*-butylate de potassium conduit à l'hydroxy-5 5β-cholestène-3 one-6 (**14**) et à son isomère Δ^2 (**15**). Le produit principal de la réaction de l'acétate de nitro-6 cholestéryle (**50**) avec le diméthylcuprate de lithium est l'oxime-(*E*) de la cyclo-3α,5 5α-cholestanone (**51**).

In the course of our work on the photochemistry of cyclic α-hydroxy ketones (1), we have had occasion to investigate the synthesis of a number of 5-hydroxy 6-keto steroids and their 7-deutero derivatives together with related 6-keto steroids with other C-5 substituents. Since these studies were extensive and gave results of intrinsic interest, we discuss them separately here and plan to give a detailed account of the photochemical results separately.

Synthesis of steroidal ketols

5α-Hydroxy 6-keto steroids **10–12** were synthesized by the general sequence shown in Scheme 1. Treatment of cholest-5-enes **1–3** with *m*-chloroperoxybenzoic acid gave in each case a mixture of α- and β-epoxides **4–6** that was not separated, since the mixtures gave solely the 5α,6β-diols **7–9** upon treatment with aqueous acid. *p*-Toluenesulfonic acid in aqueous dioxane proved particularly useful for this transformation. Preferential *trans* diaxial ring opening accounts for the observed stereoselectivity (2). Oxidation of the 5α,6β-diols to the 5α-ketols **10–12** was achieved with several reagents; pyridinium chlorochromate is favored as the most reliable and easiest to use. *N*-Bromosuccinimide, the work-horse reagent in these systems (3), gave in our hands variable results.

Spectral data for the compounds in Scheme 1 are in accord with expectation. In the ^{1}H nmr spectra of the ketols **10–12** a triplet (J = 13 Hz) at δ 2.7–2.8 is assigned to the 7α proton. Deshielding of protons situated in a 1,3-diaxial relationship to electronegative substituents such as hydroxyl has been documented (9).

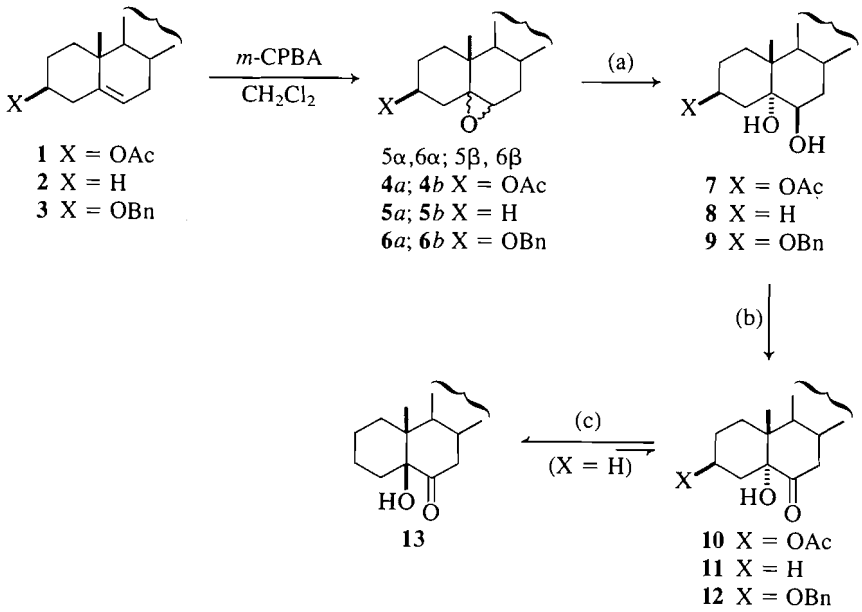
5α-Hydroxy 6-keto steroids have long been recognized to equilibrate under basic conditions with their 5β counterparts (10). Preponderance of the 5β epimer in these equilibria has been attributed to intramolecular hydrogen bonding between the hydroxyl and carbonyl groups in the 5β-ketols where it is geometrically favored. Epimerization of 5-hydroxy-5α-cholestan-6-one (**11**) with methanolic 10% potassium hydroxide (10) gave a ~9:1 mixture of the 5β-ketol **13** and **11**, which were separated chromatographically. The 5β-ketol **13** was also obtained from hydrogenation of the Δ^3-5β-ketol **14** (*vide infra*).

Treatment of the 3β-benzyloxy-5α-ketol **12** with methanolic potassium hydroxide as above did not effect epimerization; largely unconsumed starting material was recovered even after 56 h. Attempted epimerization of **12** with potassium *tert*-butoxide in *tert*-butyl alcohol resulted instead in a facile synthesis of 5-hydroxy-5β-cholest-3-en-6-one (**14**) (Scheme 2). In the ^{1}H nmr spectrum of **14** the hydroxyl proton signal appears as a sharp singlet at δ 4.20, indicative of intramolecular hydrogen bonding (11) and strongly suggesting the 5β configuration. This was confirmed by hydrogenation of **14** to the 5β-ketol **13**. The ^{1}H nmr spectrum of **14** displays two one-proton multiplets at δ 5.42 (width = 13 Hz) and 6.00 (width = 17 Hz), consistent with the Δ^3 position assigned to the olefinic bond. Based on observed correlations between the vicinal coupling constant in H—C—C—H systems and the allylic coupling constant in H—C=C—C—H systems with dihedral angles (12, 13), the multiplet at δ 6.00 is assigned to the C-3 vinyl proton and that at δ 5.42 to the C-4 vinyl proton.

Treatment of **12** with potassium *tert*-butoxide in *tert*-butyl alcohol also gave rise to a minor product, considered to be 5-hydroxy-5-cholest-2-en-6-one (**15**) (Scheme 2). The Δ^2- and Δ^3-5β-ketols **14** and **15** were separated by flash chromatography on a silver nitrate impregnated silica gel column. A sharp singlet at δ 4.05 in the ^{1}H nmr spectrum of **15** again signaled the 5β configuration. A narrow two-proton multiplet ($W_{1/2}$ = 4 Hz) at δ 5.67 arising from the vinyl protons (14) and a peak in its mass spectrum at m/z 346 (80) (M − C_4H_6), considered to originate from a retro Diels–Alder fragmentation, distinguished the Δ^2-5β-ketol **15** from the Δ^3-5β-ketol **14**.

The Δ^3-ketol **14** is postulated to arise by elimination of benzyloxy anion from the enolate of the *A*-homo *B*-nor ketol **16** to give **17** (Scheme 3). Mazur and Nussim (10) have provided evidence to support their postulate that such an *A*-homo *B*-nor ketol is an intermediate in the epimerization of 5-hydroxy-5α-cholestan-6-one (**11**) to its 5β epimer **13**. The presence, under the basic reaction conditions, of a small amount of the Δ^2-ketol **18** in equilibrium with its Δ^3 isomer **17** accounts for the formation of the Δ^2-ketol **15**.

In continuing pursuit of the conversion of **12** to its 5β epimer we next investigated its reaction with Grignard reagents, which can induce rearrangements of α-hydroxy ketones, albeit with the complication of addition to the carbonyl group (15, 16). We found that the very sterically congested 2-mesitylmagnesium



(a) **4**: 70% $HClO_4$/aq. acetone (4); **5**, **6**; *p*-TSA/aq. dioxane, 1.5 h

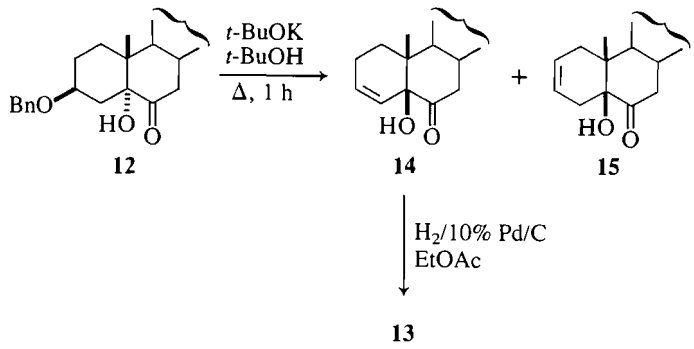
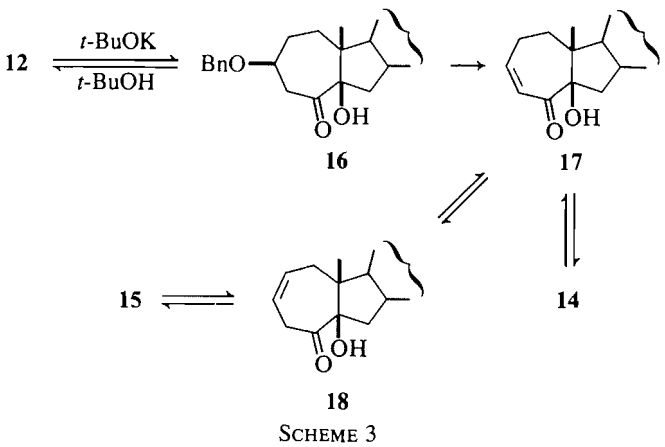
SCHEME 1



SCHEME 2



SCHEME 3

bromide cleanly epimerized the 3β-benzyloxy-5α-ketol **12** to its 5β epimer **19**, the only other component of the reaction product being unconsumed **12** (~30%) (Scheme 4). Care in the preparation of the Grignard reagent was critical to the success of this reaction. We found that it was important that Grignard reagent formation be initiated as early as possible during addition of 2-bromomesitylene to magnesium. Failure to ensure this often resulted in a delayed, exothermic reaction between the magnesium and halide, which was detrimental to the capability of the reagent to effect epimerization. We thus found it advantageous to ensure smooth formation of the reagent by entrainment of the magnesium with 1,2-dibromoethane.

Hydrogenolysis of **19** gave 3β,5-dihydroxy-5β-cholestan-6-one (**20**), which on acetylation afforded 3β-acetoxy-5-hydroxy-5β-cholestan-6-one (**21**) in high yield. Interestingly, the mass spectra of the 3-acetoxy- and 3-deoxy-5β-ketols **21** and **13** each exhibit a base peak at m/z 318, which is an ion of low relative abundance in the spectra of the corresponding 5α epimers **10** and **11**. This fragment, assigned the composition $C_{22}H_{38}O$ on the basis of an accurate mass measurement, can be envisioned to arise as depicted in Scheme 5.[1] The reason for the divergent fragmentation behaviour observed for the 5α- and 5β-ketols is not apparent.

Synthesis of 7α-deutero steroidal ketols

The reaction sequence used for the synthesis of the 7α-deutero-3β-acetoxy 5α- and 5β-ketols **23** and **25** is shown in Scheme 6. Bromination of **10** with bromine in acetic acid and chloroform, according to the method of Rodewald *et al.* (18), gave the 7α-bromo-5α-ketol **22** in high yield. Application of this procedure to **21** proved equally successful, yielding solely the 7α-bromo-5β-ketol **24**. The stereochemistry at C-7 in **22** and **24** was witnessed by the narrow multiplets observed for the C*H*Br proton signals at δ 4.18 and 4.42, respectively, in their ^1H nmr spectra (19).

Reduction of **22** and **24** with zinc and *O*-deuteroacetic acid (19, 20) provided an excellent method for the stereoselective

[1]A similar fragmentation pattern has been suggested to account for the intense m/z 318 ions observed in the mass spectra of a number of 3-substituted 6-oxa-*B*-homo-5a-cholestan-7-ones (17).

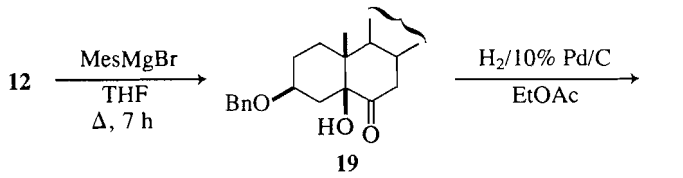
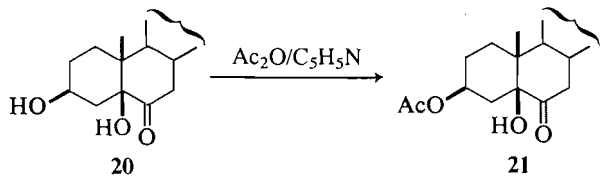
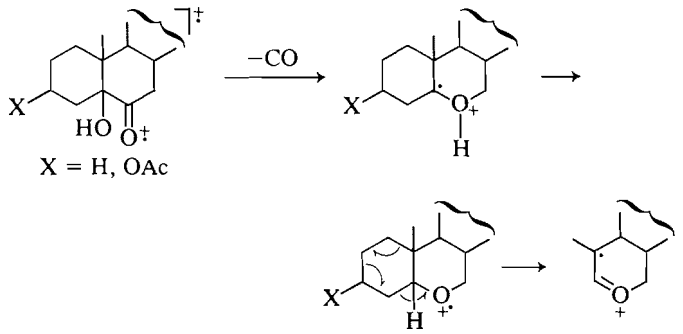
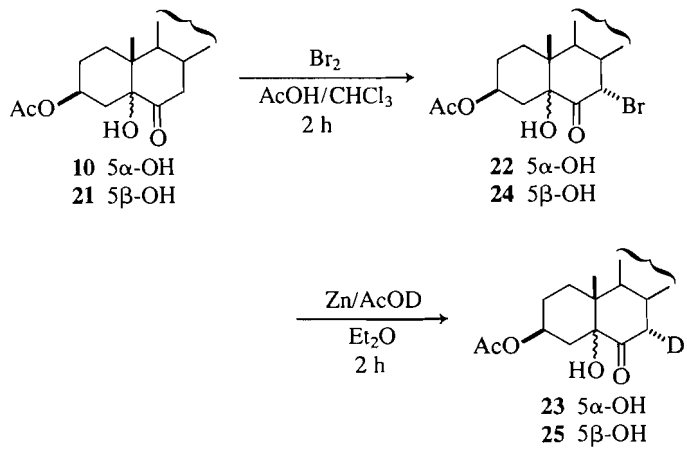




SCHEME 4



SCHEME 5



SCHEME 6

introduction of deuterium into the 7α site. The deuterated ketols **23** and **25** were thus obtained in high chemical yield as well as with good incorporation of deuterium label. The deuterium content, d_0, d_1, and d_2, was calculated from the mass spectra according to the method of Budzikiewicz, Djerassi, and Williams (21). The intensities of the molecular ions were relatively weak, and the low signal-to-noise ratios that resulted led to wide scatter in the values calculated for the deuterium content. Therefore, calculations of the deuterium content were based on the more abundant (M − AcOH) fragments. These calculations, which are considered to be valid since the loss of acetic acid from the molecular ions is not expected to involve the C-7 methylene group, gave d_0 15%, d_1 80%, and d_2 5% for **23**.

The deuterium content of **23** and **25** was also calculated from their ^{1}H nmr spectrum. In the spectrum of the undeuterated 3β-acetoxy-5α-ketol **10**, the axial 5-hydroxyl group deshields the 7α proton, whose signal appears at δ 2.76, downfield of the steroidal envelope. Upon deuteration, this signal almost completely disappeared; the weak intensity residual signal for **23** had an area that was 12% of that observed for the C*H*OAc proton at δ 5.03 and thus established that the deuterium content at the 7α site was 88%. Calculations based on the mass spectrum gave a d_1 value of 80% and a maximum deuterium content of 85%. Both of these values were lower than that obtained from the ^{1}H nmr analysis, showing that all of the deuterium label in **23** resided in the 7α site. In the light of the margins of error accompanying deuterium content calculations from the mass and ^{1}H nmr spectra (22 (also pp. 218–221), 23, 24), differences between the two of 5–10% were routinely observed and are considered acceptable.

The situation for **25** is somewhat more complex. The ^{1}H nmr spectrum of the undeuterated ketol **21** exhibits a two-proton multiplet at δ 2.17–2.30 and a one-proton doublet of doublets at δ 2.42 (J = 14, 4 Hz). The latter signal is readily assignable to the 7β proton on the basis of the coupling constants. Upon deuteration, the signal at δ 2.42 collapsed to a doublet (J = 3 Hz) showing that the 14-Hz coupling is attributable to a geminal interaction, as expected. In addition, a doublet of doublets at δ 2.24 (J = 15, 4 Hz) was revealed, thereby demonstrating that the multiplet at δ 2.17–2.30 in the spectrum of **21** is composed of two doublets of doublets, one at δ 2.23 (J = 14, 12 Hz) and the other at δ 2.24 (J = 15, 4 Hz). The former is assigned on the basis of the 12-Hz coupling constant, indicative of an axial–axial interaction, to the 7α proton, while the latter is tentatively ascribed to either the 4α or the 4β proton. In the spectrum of **25** the areas of the δ 2.24 doublet of doublets and of the doublet at δ 2.42 assigned to the 7β proton were observed to be equal. This established that the 7β site was completely protonated and that all the deuterium label again was present in the 7α configuration. From the mass spectrum of **25**, the deuterium content was calculated to be 80–85%.

Studies of the synthesis of 5-methoxy 6-keto steroids

Despite the seeming simplicity of the approach, *O*-methylation of the 3β-acetoxy-5α- and 5β-ketols **10** and **21** under a variety of conditions did not provide a useful synthesis of the corresponding 5-methoxy 6-keto steroids. In the 5α series, a route from the 5β,6β-epoxide **4*b*** to the methoxy ketone **32** was therefore devised (Scheme 7). Since the 5α,6α-epoxide **4*a*** is known to afford the 5-hydroxy 6-methoxy regiochemistry upon acid-catalyzed addition of methanol (25), the mixture of α- and β-epoxides **4*a*** and **4*b*** described previously could not be used in the synthesis of **32**. The required stereoselective synthesis of the β-epoxide **4*b*** was achieved via the 5α-bromo-6β-acetate **26**. This was formed as the major product, together with its stereoisomer **27**, from the reaction of cholesteryl acetate (**1**) with *N*-bromoacetamide and lithium acetate in acetic acid (cf. ref. 26). The structural assignments for **26** and **27** were based on comparison of their ^{1}H nmr spectra with the spectrum of 5-bromo-5α-cholestane-3β,6β-diol 3-acetate **28**, prepared by bromination of cholesteryl acetate (**1**) in aqueous medium (27).

The 5β-bromo-6α-acetate **27** can be conjectured to arise via attack of bromine on the β face of olefin **1** followed by attack of acetate ion at C-6 in the intermediate bromonium ion, thus avoiding an unfavorable 1,3-diaxial bromine–methyl interaction that would have resulted from addition in the opposite regiochemical sense.

Treatment of the 5α-bromo 6β-acetoxy isomer **26** with ethanolic sodium ethoxide at room temperature gave the

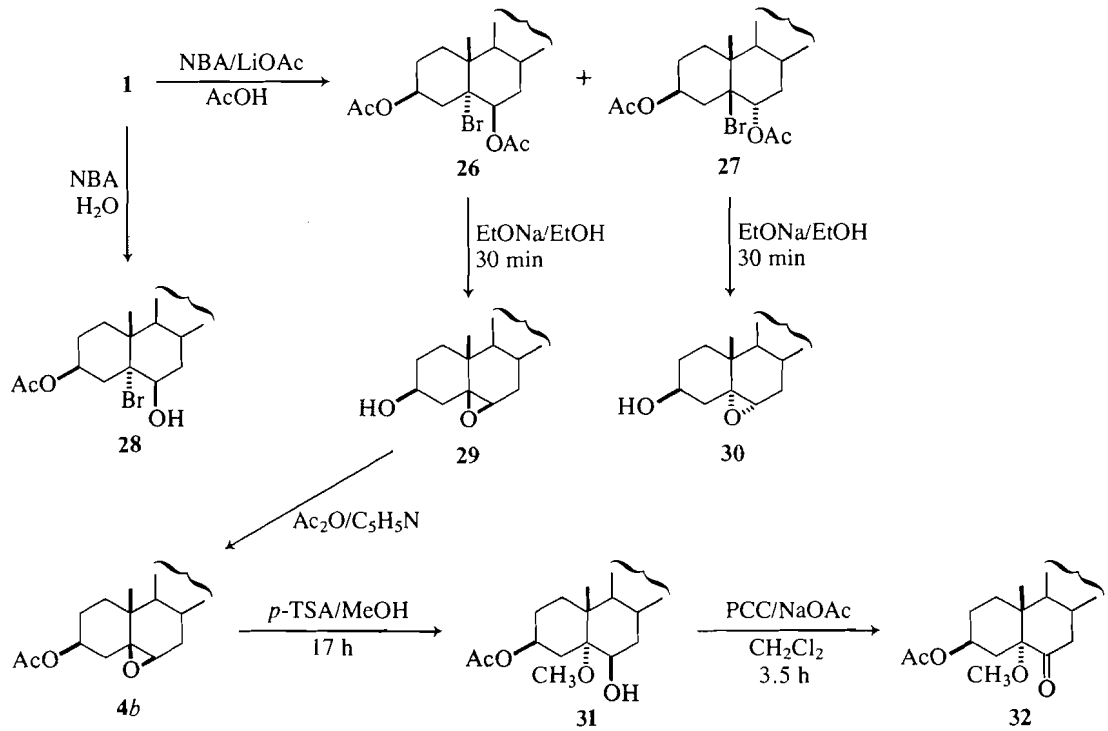
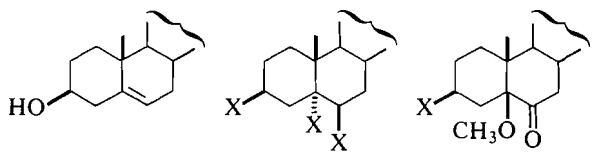


SCHEME 7

3-hydroxy-5β,6β-epoxide **29**. Similar reaction with a mixture of **26** and **27** gave both **29** and the α-epoxide **30**, demonstrating the necessity for separation of **26** and **27** for a stereoselective synthesis of the β-epoxide. The structures of the α- and β-epoxides **30** and **29** were assigned on the basis of the higher field chemical shift of the C-19 methyl signal and the smaller coupling constant for the C-6 methine proton in the ^{1}H nmr spectrum of the β- relative to the α-epoxide (28). The α-epoxide appears to originate from the 5β-bromo 6α-acetate **27**, although the substituents are not aligned for an *anti*-periplanar displacement of bromide by the alkoxide formed from attack of ethoxide on the 6α-acetoxy group. However, participation of a boat form of ring B would permit an *anti*-periplanar transition state for displacement.

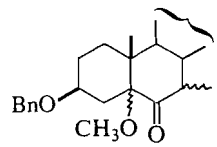
Epoxide **29** was also prepared by treatment of the triacetate **35** (29), obtained from cholesterol (**33**) via the triol **34** (30), with



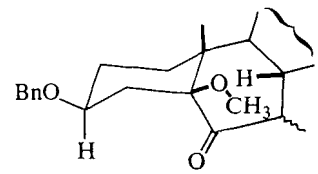
33 **34** X = OH, **35** X = OAc, **36** X = OBn, **37** X = OH

ethanolic sodium ethoxide. Acetylation of **29** gave the acetoxy β-epoxide **4*b***. Acid-catalyzed, regioselective opening of the epoxide ring of **4*b*** with methanol and oxidation of the resulting 5α-methoxy 6β-alcohol **31**, gave the desired 5α-methoxy ketone **32**.

It was envisioned that synthesis of the 5β-methoxy ketone **37** could be accomplished by *O*-methylation of the 3β-benzyloxy-5β-ketol **19** to give the ether **36** followed by hydrogenolysis and acetylation. In the event, methylation of **19** gave a dimethylation product. The presence in its ^{1}H nmr spectrum of a doublet (J = 7 Hz) at δ 1.06 (CH_3CH) and a doublet of quartets (J = 7,



38 5α-OCH_3
39 5β-OCH_3



39*A*

42 X = Y = OCH_3

7 Hz) at δ 2.32 (CH_3CHCH) in addition to an *O*-methyl signal at δ 3.60 indicated that both *O*-alkylation and *C*-alkylation α to the carbonyl group had occurred. The 5α configuration as in **38** was initially suggested by the appearance of the C*H*OBn proton signal at δ 3.60 as a broad multiplet. However, other features of the ^{1}H nmr spectrum of the methylation product were not readily accommodated by the 5α-methoxy assignment **38**.[2]

This circumstance and results from methylation of the C-5 hydroxyl group in systems in which the C-6 carbonyl group was protected (*vide infra*) led us to consider the possibility that the product from methylation of **19** had the 5β stereochemistry as in **39** and that the broad multiplet assigned to the C*H*OBn proton

[2]The possibility that methylation had occurred at C-4 via an *A*-homo *B*-nor intermediate was excluded by the observation that the C*H*OBn signal at δ 3.60 was unaffected by irradiation at δ 2.32, the chemical shift of the signal assigned to the C*H*CH_3 proton.

arose from an axial conformation of this proton resulting from the preference of either ring A or B in **39** to exist in a boat-like conformation. A conformation with ring A in a chair and ring B in a boat form as in **39***A* appears to be the most favorable conformation available to **39** consistent with an axial disposition of the C-3 methine proton. This conformation also reconciles the unusual chemical shifts observed in the ^{1}H nmr spectrum of the methylation product. In this conformer, the C-19 methyl group (δ 1.04) resides in a completely different environment from that in the 3β-benzyloxy-5β-ketol **19** (C-19 Me at δ 0.83), and a large difference in their chemical shifts is not unexpected. The unusually deshielded resonance at δ 2.67 for the C-8 methine proton is consistent with the propinquity of this proton to the methoxyl substituent (ref. 11, pp. 71, 72; ref. 31), as in **39***A*. Models demonstrate that the 4α proton is situated in the deshielding cone of the C-6 carbonyl group, and the unusually low field resonance for this proton at δ 2.60 provides further evidence for the existence of **39** in the ring B boat conformation and its assignment to the methylation product. The coupling of 7 Hz between the C-7 and C-8 methine protons did not permit an unambiguous assignment of the configuration at C-7 (ref. 9, p. 51; ref. 32).

We proceeded to protect the 6-keto group in **19** to inhibit *C*-methylation. The oxime **40** and oxime methyl ether **41** were prepared following standard procedures. In their ^{1}H nmr spectra they both exhibited broad doublets (J = 12 Hz) at δ 3.3, assigned to the 7β proton and indicative of the *E* geometry (33–36). Methylation of either **40** or **41** gave the 5β-methoxy 6-oxime methyl ether **42**. The ^{1}H nmr spectrum of **42** exhibited two three-proton singlets at δ 3.10 and 3.87. The former was assigned to the C-5 methoxyl protons and the latter to the oxime methyl ether protons, based on reported chemical shifts of oxime methyl ether signals (35). Since both **40** and **41** would be extremely unlikely to undergo epimerization under the mild methylation conditions employed, the 5-methoxy 6-oxime methyl ether **42** was assigned the 5β configuration. As in the case of the analogous 5β-methoxy ketone **39**, the ^{1}H nmr spectrum of **42** was consistent with the 5β stereochemistry with ring B existing in a boat conformation, resulting in an axial disposition of the C*H*OBn proton and a broad multiplet for its proton signal. The chemical shift of the C-19 methyl singlet of the oxime **42** at δ 1.03 reflects its similarity to that of **39**. Compound **42** was assigned the *E* configuration since oximes with an α quaternary center are known to prefer this geometry (37). The *E* geometry in **42**, unlike that in **40** and **41**, was not evident from its ^{1}H nmr spectrum: neither of the C-7 methylene protons was shifted downfield from the steroidal envelope. The deshielding for α protons *syn* to an oxime group has been attributed to the anisotropy of the lone pairs on oxygen (38), and has been observed to decrease as the dihedral angle between the relevant C—H bond and the C=N—OH plane increases (36). Since in the ring B boat conformer of **42** both of the C-7 methylene protons are out of the C=N—OMe plane, the fact that they do not give rise to signals usually associated with the *E* geometry of the oxime derivative is readily explicable.

Attempted hydrolysis of the oxime methyl ether group in **42** with aqueous perchloric acid and methyl pyruvate (39) gave, following chromatography, a major fraction comprising a ~70:30 mixture of two compounds containing a single methoxyl group. The ir and ^{1}H nmr spectra of this mixture indicated that the C-5 methoxyl group had been removed while the oxime methyl ether moiety had remained intact. With this result, the synthesis of the 5β-methoxy ketone **37** was not pursued further.

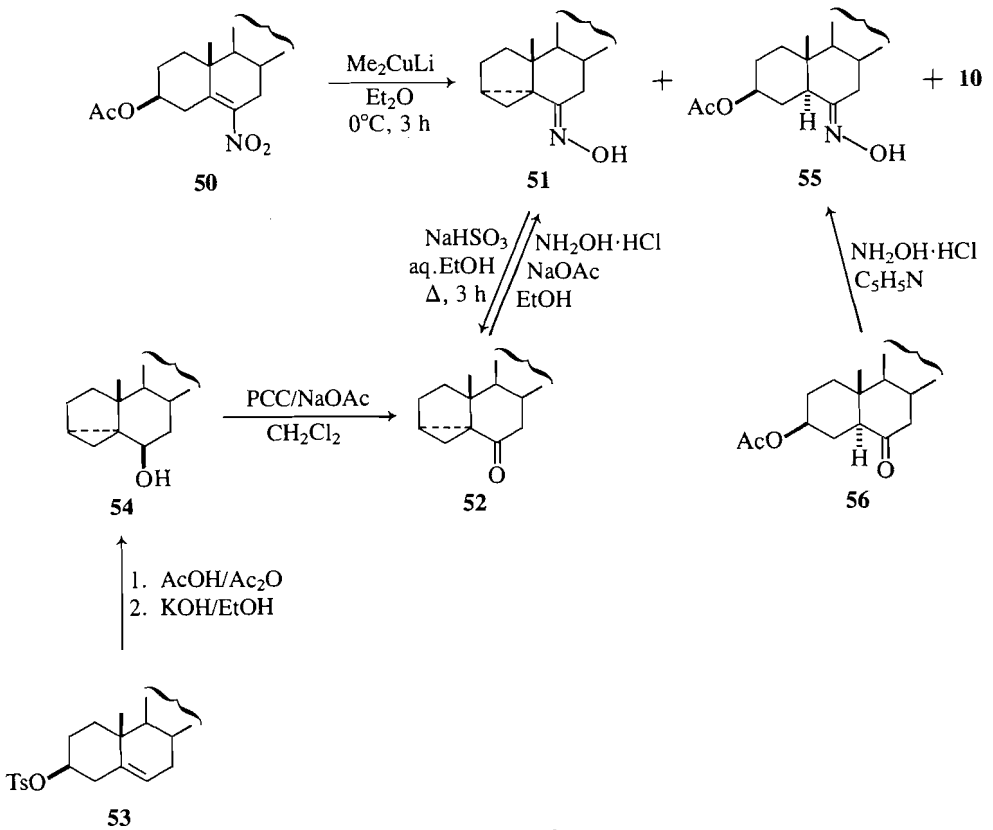
Approaches to the synthesis of 5-methyl 6-keto steroids

Direct methylation of 6-keto steroids has been reported to require vigorous reaction conditions, under which 5-methyl 6-keto steroids were obtained in poor yield (40). Addition of methylmagnesium iodide to the β-epoxide **29** has been claimed to give the 5α-methyl 6β-alcohol **43** (41), but Julia *et al.* (42) concluded that the product had structure **44**, and was formed via rearrangement of **29** (43). Our own investigation of the reaction has confirmed this conclusion (see Experimental) and also led to the isolation of a minor product to which we assign the structure **45**. It is considered to originate from initial isomerization of **29** to the *A*-homo *B*-nor 4a-ketone and subsequent Grignard addition. The 5β configuration was assigned based on analogy to the boron trifluoride catalyzed rearrangement of the 6α-methyl 5β,6β-epoxide **46**, which is reported to give the *A*-homo *B*-nor 5β-methyl 4a-ketone **47** together with the ketone **48** (44).

Lithium dialkylcuprate reagents also react with epoxides to give alkyl alcohols and have the advantage that they do not, in general, induce epoxide-to-ketone isomerizations; furthermore, reactions of cuprate reagents with epoxy esters have been observed to occur with chemoselective attack at the oxirane ring (45). However, reaction of the 3β-acetoxy β-epoxide **4***b* with lithium dimethylcuprate gave none of the desired 5-methyl 6-alcohol, but two other products—the 3-hydroxy β-epoxide **29** and its acetoacetic ester **49**. Bands at 5.73 and 5.81 μm in its ir spectrum and a broad two-proton singlet in its ^{1}H nmr spectrum at δ 3.42, which slowly disappeared upon treatment with deuterium oxide, indicated that the acetoacetic ester **49** exists largely as the keto ester tautomer, in accord with expectation (46). Abstraction of a proton α to the carbonyl moiety of the acetoxy group and acylation of the resulting enolate by another molecule of **46** accounts for the formation of both products.

In another approach to the synthesis of 5-methyl 6-keto steroids, we investigated the conjugate addition of lithium dimethylcuprate to 6-nitrocholesteryl acetate (**50**).[3] We hoped that this might provide a method for regioselective introduction of a methyl substituent at the C-5 site. Subsequent Nef reaction of the resulting 5-methyl 6-nitrocholestane would then afford a route to 5-methyl 6-keto steroids. Although reports of reactions between lithium dialkylcuprates and α,β-unsaturated nitro compounds are rare, conjugate addition has been observed in the reactions of 1-(4-chlorophenyl)-2-nitropropene with both lithium dimethyl- and diphenylcuprate (48). However, the reaction between **50**, prepared by nitration of cholesteryl acetate (**1**) (49), and lithium dimethylcuprate followed a different

[3]This study has been the subject of a preliminary communication (47).



SCHEME 8

course, giving 3α,5-cyclo-5α-cholestan-6-one (*E*)-oxime (**51**) in 65% yield (Scheme 8). In the single frequency off-resonance decoupled ^{13}C nmr spectrum of **51**, a triplet at δ 8.0 and a singlet at δ 160.5 signaled cyclopropyl and oximino functions, respectively. The presence in its ^1H nmr spectrum of a broad doublet at δ 3.30 (J = 11 Hz) evidenced the *E* geometry about the C=N bond (33, 34, 36) and a high field multiplet at δ 0.49 is ascribed to the C-4 methylene protons of the cyclopropane ring. In the mass spectrum of **51**, a relatively abundant ion (40%) at m/z 383 is assigned to an ion formed by loss of an oxygen atom from the molecular ion. This type of fragmentation has been observed in the mass spectrum of cyclohexanone oxime (50). The structural assignment **51** was confirmed by treatment of the product with sodium bisulfite in aqueous ethanol to give the 3α,5α-cyclo ketone **52** (51).

The structural assignment was further verified by an independent synthesis. 3α,5-Cyclo-5α-cholestan-6β-ol (**54**) formed by solvolysis of cholesteryl tosylate (**53**) (ref. 2*a*, pp. 236–248; ref. 52) was oxidized with pyridinium chlorochromate (PCC) in the presence of sodium acetate (2 equiv./mol PCC) to give the cyclopropyl ketone **52**. The amount of sodium acetate employed was critical to the success of this oxidation, since the product obtained following the recommended conditions (0.2 equiv. NaOAc/mol PCC) (53) contained olefinic and aldehydic side products presumed to arise from acid-initiated opening of the cyclopropyl ring. Oximination of ketone **52** gave the *E* oxime; the formation of the *E* geometrical isomer is considered to be due to the presence of the quaternary center at C-5 (37). A number of minor products were formed in the reaction between lithium dimethylcuprate and **50** (Scheme 8). We have identified 3β-acetoxy-5α-cholestan-6-one (*E*)-oxime (**55**), isolated in a mixture with the acetoxy 5α-ketol **10**, by direct comparison with a sample prepared by oximination of the parent ketone **56** (54).

A possible mechanism for the formation of oxime **51** from the reaction of lithium dimethylcuprate with **50** is detailed in Scheme 9. Introduction of an electron into the α,β-unsaturated nitro system would lead to a radical anion **57**. House and Umen (55) have reported that unsaturated systems with reduction potentials less negative than −2.4 V (in *N*,*N*-dimethylformamide) will accept an electron from lithium dimethylcuprate, and Sato *et al.* (56) have reported that the reduction potential of the nitro olefin **50** lies in the range −1.35 to −1.37 V (in *N*,*N*-dimethylformamide). Intramolecular nucleophilic displacement of the acetoxy group in **57** would generate the cyclopropane ring with the 3α,5α geometry.[4] The ability of anions at C-5 to displace good leaving groups in the β orientation at C-3 leading to 3α,5α-cyclo steroids is well documented (54), although this may be the first example in which an acetoxy group has been so displaced. Sato *et al.* (56) have observed that while electrolysis of the tosylate **61** gave a 43% yield of the cyclo nitro compound **62**, no evidence of any 3,5-cyclo products derived from internal displacement of the acetoxy group could be detected from similar electrolysis of the analogous acetate **50**, which gave the bimolecular product **63**. In the case of the cuprate reaction of **50**, displacement of the acetoxy group may be facilitated by complexation with lithium or copper species. To account for further reduction of **58** to oxime **51** (Scheme 9), complex **59** is postulated to form and undergo methyl insertion (55) to give the nitronate ester **60**.

[4]While a two-electron transfer mechanism cannot be excluded, related studies lead us to favor internal displacement from a radical anion formed by a one-electron process (56, 57).

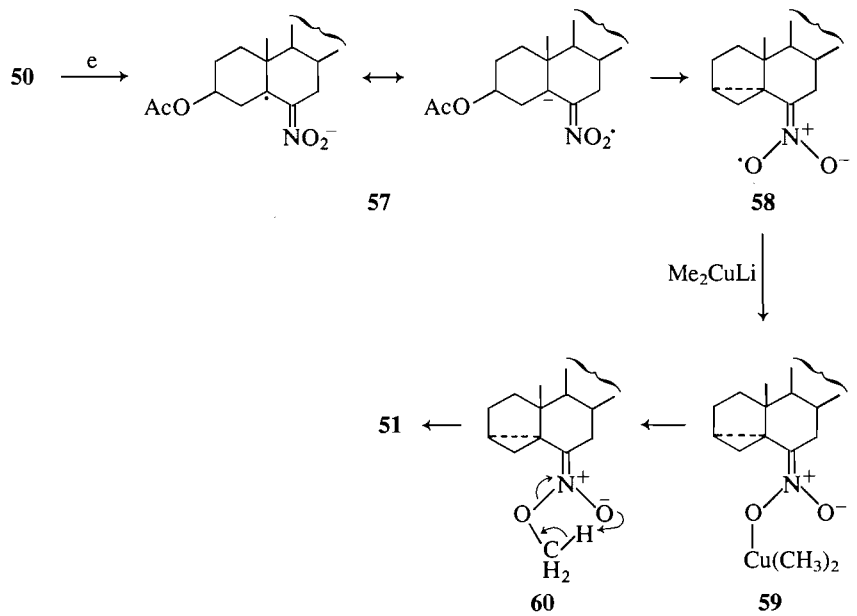
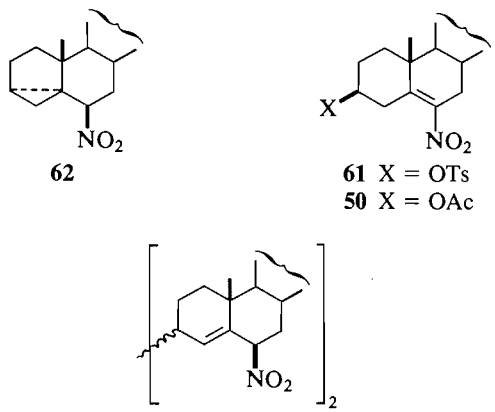


SCHEME 9



This postulate is not without precedent, for in the reduction of nitroalkanes to oximes by carbon monoxide and copper salts Knifton (58) has suggested that carbon monoxide insertion into a copper–oxygen bond occurs in a related copper-bound nitronate anion. Decomposition of the nitronate ester **60** to afford the oxime **51**, as depicted, is well documented (58, 59). The stereochemical consequences for the oxime generated by the mechanism outlined in Scheme 9 are undefined; however, equilibration of the *Z* to the *E* isomer during work-up would account for isolation of only the latter from the reaction mixture. Oxime **51** was recovered unchanged following resubjection to lithium dimethylcuprate treatment.

Experimental[5]

Melting points were recorded on a Fisher–Johns melting point apparatus and are uncorrected. The ir spectra were recorded in chloroform and the ^{1}H nmr spectra at 60 MHz in deuterochloroform unless otherwise specified. For symmetrical multiplets in the latter the width at half-height ($W_{1/2}$) is recorded while for unsymmetrical multiplets the total width is given. Low resolution mass spectra were recorded with a Bell and Howell CEC 21-490 mass spectrometer. For the deuterium content calculations, 10–20 scans of the region of the spectrum containing the isotopic cluster associated with the molecular ion or, where appropriate, of the (M − CH_3CO_2H) fragment were obtained at a high signal-to-noise ratio and averaged. Accurate mass measurements were made with an AEI MS-3074 spectrometer with a DS-50 data system.

Organic solutions were concentrated on a rotary evaporator under water aspirator pressure. Column chromatography was carried out on silica gel (Grace Davison, grade 923, 100–200 mesh), neutral alumina (Merck, activity 1, 70–230 mesh, 90 Å mean pore diameter), or Florisil (Aldrich, 100–200 mesh). Flash chromatography was performed on 40–60 μm silica gel (Merck, grade 60, 230–400 mesh, 60 Å mean pore diameter) under air, nitrogen, or argon pressure so that the drop in solvent height was 5 cm/min.

Several compounds described here have been obtained previously. Full experimental details for their preparation in the present work are given only when a new method or a significant variation of an earlier method has been used.

*5,6α-Epoxy-5α- and 5,6β-epoxy-5β-cholestan-3β-yl acetate (**4**a and **4**b)*

Oxidation of cholesteryl acetate (**1**) (60) with *m*-chloroperoxybenzoic acid in dichloromethane gave a mixture of **4***a* and **4***b* (99%) as a white solid. Crystallization from aqueous 90% acetone gave a 50:50 mixture of **4***a* and **4***b* as white crystals, mp 103–109°C; ir λ_{max}: 5.78 μm; ^{1}H nmr δ: 0.62 (s, C-18 Me α-epoxide), 0.65 (s, C-18 Me β-epoxide), 1.03 (s, C-19 Me β-epoxide), 1.10 (s, C-19 Me β-epoxide), 2.03 (s), 2.83 (d, J = 4 Hz, α-epoxide) and 3.07 (d, J = 3 Hz, β-epoxide) (1H), 4.83 (br m, $W_{1/2}$ = 24 Hz, 1H); ms m/z: 444 (6), 384 (100).

*5,6α-Cholestane-3β,5,6β-triol 3-acetate (**7**)*

Perchloric acid (70%; 0.35 mL) was added dropwise to a solution of a 50:50 mixture of **4***a* and **4***b* (1.14 g, 2.57 mmol) in acetone (50 mL) and water (3 mL), and after the solution was stirred at room temperature for 5 h, water was added to precipitate the product. The collected product was washed with water and crystallized from aqueous 90% acetone to give **7** (1.02 g, 86%) as white crystals, mp 206.5–208.5°C (lit. (61) mp 207–208°C); ir λ_{max}: 3.02 (sh, w), 3.14 (br, w), 5.79 μm; ^{1}H nmr δ: 0.68 (s, C-18 Me), 1.20 (s, C-19 Me), 1.93 (br s, OH, absent after treatment with deuterium oxide), 2.03 (s), 3.53 (nar m, $W_{1/2}$ = 8 Hz, 1H), 5.13 (br m, $W_{1/2}$ = 20 Hz, 1H); ms m/z: 462 (20), 384 (100).

*3β-Acetoxy-5-hydroxy-5α-cholestan-6-one (**10**)*

*(i) Oxidation of **7** with pyridinium chlorochromate*

A solution of **7** (0.984 g, 2.13 mmol) in dichloromethane (55 mL) was added all at once to a stirred suspension of pyridinium chlorochromate (Aldrich; 1.15 g, 5.33 mmol) and neutral, activity I, 70–230 mesh alumina (Merck; 4.45 g) in dichloromethane (30 mL) under an argon atmosphere. The reaction mixture was stirred at room temperature for 2 h, and ether (25 mL) was added to the resulting brown suspension. The mixture was filtered through a Florisil column (2 × 12 cm) and the column was eluted with ether (100 mL). The combined organic solutions were concentrated to give **10** (0.86 g, 88%) as a white solid. Crystallization from methanol gave **10** as white needles, mp 231.5–233.5°C. Flash chromatography of the product on silica gel (2 × 14 cm) with chloroform – ethyl acetate (9:1 v/v) as eluent gave **10** (0.78 g, 79%), which crystallized from methanol as white needles, mp 235.5–238°C (lit. (30) mp 232–233°C); ir λ_{max}: 2.81 (sh, w), 2.95 (br, w), 5.83 μm; ^{1}H nmr (400 MHz) δ: 0.64 (s, C-18 Me), 0.81 (s, C-19 Me), 0.86 (d, J = 6 Hz, C-26,27 Me), 0.91 (d, J = 7 Hz, C-21 Me), 2.01 (s), 2.10 (dd, J = 13, 4 Hz), 2.76 (dd, J = 13, 13 Hz, 1H), 3.11 (br s, OH, 1H), 5.03 (br m, $W_{1/2}$ = 24 Hz, 1H); ms m/z: 460 (20), 400 (100).

*(ii) Oxidation of **7** with silver carbonate on Celite*

Silver carbonate precipitated on Celite was prepared following the method of Balogh, Fetizon, and Golfier (6). The Ag_2CO_3/Celite reagent was assumed to contain approximately 1 mmol of silver carbonate for every 0.57 g of reagent (6). A stirred suspension of **7** (216 mg, 0.47 mmol) and Ag_2CO_3/Celite (2.85 g, ~5 mmol) in anhydrous benzene (25 mL) under a nitrogen atmosphere was heated under reflux for 96 h with azeotropic removal of water by means of a Dean–Stark apparatus. The resultant dark green reaction mixture was filtered and concentrated to give a brownish colored solid. This was dissolved in chloroform, and the solution was filtered through Celite. The filtrate was concentrated to give **10** (210 mg, 98%) as a white solid, which on crystallization from methanol gave **10** as white needles, mp 233–235°C.

*5,6α-Epoxy-5α- and 5,6β-epoxy-5β-cholestane (**5**a and **5**b)*

Oxidation of 5-cholestene (**2**) (62) with *m*-chloroperoxybenzoic acid in dichloromethane gave a ~70:30 mixture of **5***a* and **5***b* (2.95 g) in quantitative yield as a pale yellow solid; ir λ_{max}: 3.47 μm; ^{1}H nmr δ: 0.60 (s, C-18 Me α-epoxide), 0.63 (s, C-18 Me β-epoxide), 1.00 (s, C-19 Me β-epoxide), 1.05 (s, C-19 Me α-epoxide), 2.83 (d, J = 4 Hz, α-epoxide) and 2.97 (d, J = 3 Hz, β-epoxide) (1H); ms m/z: 386 (90), 55 (100).

*5α-Cholestane-5,6β-diol (**8**)*

A solution of a 70:30 mixture of **5***a* and **5***b* (2.38 g, 6.17 mmol) and *p*-toluenesulfonic acid monohydrate (65 mg, 0.34 mmol) in dioxane–water (9:1 v/v; 43 mL) was stirred and heated under reflux for 1.5 h. The solution was allowed to cool to room temperature and poured into aqueous 10% Na_2CO_3 (20 mL). The dioxane was removed under water aspirator pressure on a rotary evaporator equipped with a cold trap condenser. The residue was extracted with ether (4 × 25 mL), and the combined ethereal extracts were washed with water (4 × 25 mL), dried (Na_2SO_4), and concentrated to give **8** (2.17 g, 87%) as a yellow oil that partially crystallized on standing; ir λ_{max}: 2.75 (sh, w), 2.88 (br, w) μm; ^{1}H nmr δ: 0.70 (s, C-18 Me), 1.17 (s, C-19 Me), 1.50 (m, OH, absent after treatment with D_2O), 3.48 (nar m, $W_{1/2}$ = 6 Hz, 1H); ms m/z: 404 (10), 386 (100).

*5-Hydroxy-5α-cholestan-6-one (**11**)*

Oxidation of **8** in dioxane–water with purified (63) *N*-bromosuccinimide gave **11** as a white solid (61%), which exhibited a ^{1}H nmr spectrum in accord with expectation. However, thin-layer chromatography indicated the presence of a very small amount of impurity, and a solution of the compound became darker yellow in color during attempted crystallization from methanol. The methanolic solution was concentrated, and flash chromatography of the yellow solid on silica gel (2 × 15 cm) with hexanes – ethyl acetate (9:1 v/v) gave **11** (284 mg, 44%). Crystallization from methanol gave **11** as fine white needles, mp 150–153°C (lit. (7) mp 152–153°C); ir λ_{max}: 2.75 (sh, w), 2.96 (br, w), 5.82 μm; ^{1}H nmr δ: 0.65 (s, C-18 Me), 0.78 (s, C-19 Me), 1.77 (br s, OH), 2.77 (dd, J = 12 Hz, 12 Hz); ms m/z: 402 (100).

*Cholesteryl benzyl ether (**3**)*

Benzylation of cholesterol (**33**) (64) in anhydrous benzene and anhydrous dimethyl sulfoxide with NaH (50% dispersion in oil) followed by purified benzyl bromide (65) gave a yellow solid, which on crystallization from acetone gave **3** (76%) as white needles, mp 115–116°C. The melt solidified on cooling, and the solid remelted at 119–121.5°C (lit. (66) mp 118.5°C). Compound **3**: ir λ_{max}: 6.19 (vw) μm; ^{1}H nmr δ: 0.70 (s, C-18 Me), 1.03 (s, C-19 Me), 3.25 (br m, $W_{1/2}$ = 20 Hz, 1H), 4.57 (s, 2H), 5.33 (nar m, $W_{1/2}$ = 8 Hz, 1H), 7.33 (s, 5H); ms m/z: 476 (2), 370 (100), 91 (98).

*5,6α-Epoxy-5α- and 5,6β-epoxy-5β-cholestan-3β-yl benzyl ether (**6**a and **6**b)*

Oxidation of **3** with *m*-chloroperoxybenzoic acid in dichloromethane gave an 80:20 mixture of **6***a* and **6***b* (94%) as a white solid, mp 102–113°C; ir λ_{max}: 3.55 μm; ^{1}H nmr δ: 0.60 (s, C-18 Me), 1.00 (s, C-19 β-epoxide), 1.07 (s, C-19 Me α-epoxide), 2.87 (d, J = 4 Hz, α-epoxide) and 3.00 (d, J = 3 Hz, β-epoxide) (1H), 3.60 (br m, $W_{1/2}$ = 24 Hz, 1H), 4.50 (s, 2H), 7.30 (s, 5H); ms m/z: 492 (5), 91 (100).

*5α-Cholestane-3β,5,6β-triol 3-benzyl ether (**9**)*

A suspension of an 80:20 mixture of **6***a* and **6***b* (79.7 g, 0.162 mol) and *p*-toluenesulfonic acid monohydrate (1.65 g, 0.009 mol) in dioxane (1 L) and water (100 mL) was stirred and heated under reflux under an argon atmosphere for 1.5 h. The resulting solution was allowed to cool to room temperature and was added to aqueous 10% Na_2CO_3 (500 mL). The dioxane was removed under water aspirator pressure on a rotary evaporator equipped with a cold trap condenser. The residue was dissolved by adding ether (550 mL), dichloromethane (200 mL), and water (150 mL), and the aqueous layer was extracted with ether (2 × 100 mL) and ether–dichloromethane (70:30 v/v; 1 × 100 mL). The combined organic phases were washed with water (300 mL, 5 × 50 mL), dried ($MgSO_4$), and concentrated to give **9** (77 g, 93%) as a white solid. Crystallization from hexanes–acetone (75:25 v/v; 650 mL) gave white needles, mp 185–187°C; (lit. (67) mp 185–186°C); ir λ_{max}: 2.88 (sh, w), 3.01 (br, w) μm; ^{1}H nmr δ: 0.67 (s, C-18 Me), 1.18 (s, C-19 Me), 1.57 (m, OH, absent after treatment with D_2O), 3.43 (nar m, $W_{1/2}$ = 5 Hz, 1H), 3.78 (br m, $W_{1/2}$ = 20 Hz, 1H), 4.53 (s, 2H), 7.30 (s, 5H); ms m/z: 510 (0), 91 (100).

*3β-Benzyloxy-5-hydroxy-5α-cholestan-6-one (**12**)*

*(i) Oxidation of **9** with pyridinium chlorochromate in the presence of molecular sieves and alumina*

A solution of **9** (20.0 g, 39.2 mmol) in anhydrous dichloromethane (100 mL) was added over a period of 5 min to a mechanically stirred mixture of pyridinium chlorochromate (Aldrich; 16.1 g, 74.6 mmol), 3 Å molecular sieves (BDH; 60 g), activated by crushing the $\frac{1}{8}$-in. pellets with a mortar and pestle and heating over a flame under a flow of argon for 2 h, and neutral, activity I, 70–230 mesh alumina (Merck; 57 g) in anhydrous dichloromethane (35 mL) under an argon atmosphere. Initially, the brown reaction mixture became warm, causing the dichloromethane to boil gently. After the mixture was stirred for 1 h, ether (100 mL) was added, and the mixture was filtered through a Florisil column (54 g, 4 × 10 cm). The column was eluted with ether (800 mL), and the combined organic solutions were concentrated to give a brown solid. A solution of the solid in ether (600 mL) was filtered through an alumina column (65 g, 4 × 8 cm), and the column was eluted with ether (800 mL). The combined ethereal solutions were concentrated to give **12** (13.9 g, 70%) as a white solid, mp 180.5–184°C. Crystallization from cyclohexane gave **12** as white needles, mp 189.5–190°C (lit. (68) mp 186–188°C); ir λ_{max}: 2.84 (sh, w), 3.00 (br, w), 5.82 μm; ^{1}H nmr δ: 0.65 (s, C-18 Me), 0.83 (s, C-19 Me), 2.13 (br s, OH, absent after treatment with D_2O), 2.70 (dd, J = 12, 12 Hz, 1H), 3.72 (br m, $W_{1/2}$ = 20 Hz, 1H), 4.53 (s, 2H), 7.32 (s, 5H); ms m/z: 508 (14), 91 (100).

For personal use only.

(ii) Oxidation of ***9*** *with pyridinium chlorochromate in the presence of alumina*

A solution of **9** (6.10 g, 12.0 mmol) in anhydrous dichloromethane (310 mL) was added to a stirred suspension of pyridinium chlorochromate (Aldrich; 6.50 g, 30.2 mmol) and neutral, activity I, 70–230 mesh alumina (Merck; 25 g) in anhydrous dichloromethane (170 mL) under an argon atmosphere. The mixture was stirred at room temperature for 1.5 h, and ether (140 mL) was added to the resulting brown mixture. The mixture was filtered through a Florisil column (57 g, 4 × 14 cm), and the column was eluted with ether (300 mL); the organic solutions were concentrated to give a yellow solid. A solution of the solid in ether (200 mL) was passed through an alumina column (30 g, 2 × 12 cm), and the column was eluted with ether (50 mL). The combined ethereal solutions were concentrated to give **12** (5.76 g, 95%). Crystallization from cyclohexane gave **12** (5.05 g, 83%) as white needles, mp 179–181.5°C.

Treatment of ***12*** *with potassium* tert*-butoxide. Formation of 5-hydroxy-5β-cholest-3-en-6-one (****14****) and 5-hydroxy-5β-cholest-2-en-6-one (****15****)*

Compound **12** (3.01 g, 5.93 mmol) was added to a solution of potassium *tert*-butoxide (Aldrich; 13.9 g, 124 mmol) in anhydrous *tert*-butyl alcohol (75 mL), and the suspension was heated to give a red solution. The solution was boiled under reflux for 1 h, allowed to cool to room temperature, and poured into water (50 mL). The *tert*-butyl alcohol was removed under water aspirator pressure on a rotary evaporator equipped with a cold trap condenser, and the residue was extracted with ether (3 × 50 mL, 1 × 25 mL). The combined ethereal extracts were washed with saturated aqueous NaCl and water, dried ($MgSO_4$), and concentrated. Medium pressure liquid chromatography of the residual orange oil (2.73 g), in three portions, on a size B (3 × 25 cm) silica gel column (Merck) with hexanes – ethyl acetate (95:5 v/v) gave the Δ^3-ketol **14** as a white solid (1.55 g, 65%). The ^{13}C nmr spectrum suggested that the product contained a small amount of the Δ^2-ketol **15**. The mixture (1.30 g) of the two olefinic isomers was separated in 350-mg portions by flash chromatography with hexanes – ethyl acetate (95:5 v/v) on a column (2.5 × 14 cm) of silica gel containing 7% (w/w) $AgNO_3$. This was prepared by shaking 40–60 μm silica gel (Merck; 60 g) with a solution of $AgNO_3$ (4.3 g) in water (20 mL) and drying the adsorbent in an oven at 140°C overnight. Compound **15** (61 mg, 3%) was eluted first as a white solid that was crystallized from methanol to give white needles, mp 125–126.5°C (lit. (14, 69)[6] mp 122–124.5°C); ir λ_{max}: 2.96 (br, w), 5.85, 5.99 (w) μm; ^1H nmr δ: 0.67 (s, C-18 Me), 0.76 (s, C-19 Me), 4.05 (s, OH, 1H), 5.67 (nar m, $W_{1/2}$ = 4 Hz, 2H); ms *m/z*: 400 (38), 55 (100). *Accurate Mass* calcd. for $C_{27}H_{44}O_2$: 400.3341; found: 400.3349.

Further elution gave **14** (1.2 g, 58%) as a white solid. Crystallization from methanol gave **14** as white needles, mp 92–93.5°C; the melt was cooled, and the solid was remelted, mp 95–96.5°C. Compound **14**: ir λ_{max}: 2.95 (sh, w), 5.86 μm; ir λ_{max}(KBr): 2.89 (sh, m), 5.86, 6.05 (v w), 14.59 (w) μm; uv λ_{max} (ε) (ethanol): 283 (83); ^1H nmr (200 MHz) δ: 0.65 (s, C-18 Me), 0.77 (s, C-19 Me), 0.86 (d, *J* = 6 Hz, C-26,27 Me), 0.91 (d, *J* = 7 Hz, C-21 Me), 4.20 (s, OH, absent after treatment with D_2O, 1H), 5.42 (dt, *J* = 10, 2 Hz, 1H), 6.00 (dt, *J* = 10, 3.5 Hz, 1H); ms *m/z*: 400 (21), 55 (100). *Accurate Mass* calcd. for $C_{27}H_{44}O_2$: 400.3341; found: 400.3351. *Anal.* calcd. for $C_{27}H_{44}O_2$: C 80.86, H 11.02; found: C 80.94, H 11.07.

*5-Hydroxy-5β-cholestan-6-one (****13****)*

(i) Hydrogenation of ***14***

A solution of **14** (86 mg, 0.22 mmol) in ethyl acetate (3 mL) was stirred with 10% palladium on carbon (11 mg) in a Morton flask under an atmosphere of hydrogen for 48 h. The reaction mixture was filtered through anhydrous $MgSO_4$, and the solution was concentrated to give **13** (80 mg, 93%) as a white solid. Crystallization from methanol gave white needles, mp 104–105°C (lit. (69) mp 103–104°C); ir λ_{max}: 2.84 (w), 5.86 μm; ^1H nmr δ: 0.65 (s, C-18 Me), 0.70 (s, C-19 Me), 3.83 (s, OH, absent after treatment with D_2O, 1H); ms *m/z*: 402 (22), 318 (100).

(ii) Epimerization of ***11***

A solution of **11** (108 mg, 0.27 mmol) in methanolic 10% KOH (3 mL) was heated under reflux for 8 h. The solution was allowed to cool, and the methanol was removed. The residue was added to water (10 mL), and the mixture was extracted with ether (30 mL, 2 × 10 mL). The combined ethereal extracts were washed with saturated aqueous NaCl (4 × 10 mL), dried (Na_2SO_4), and concentrated. The resulting yellow oil (110 mg) was flash chromatographed on silica gel with hexanes – ethyl acetate (95:5 v/v) as eluent to afford **13** (83 mg, 77%) as a white solid that was crystallized from methanol as white needles, mp 103–104.5°C. Further elution gave **11** (9 mg, 8%) as a white solid.

Epimerization of ***12****. Formation of 3β-benzyloxy-5-hydroxy-5β-cholestan-6-one (****19****)*

1,2-Dibromoethane (0.17 mL, 1.97 mmol) was added dropwise to a stirred mixture of magnesium turnings (1.67 g, 68.9 mmol) in anhydrous tetrahydrofuran (11 mL) under an argon atmosphere. The reaction mixture warmed to approximately 40°C, and the edges of the magnesium turnings became tinged with black. After 10 min the mixture had cooled to room temperature, and a solution of a mixture of 2-bromomesitylene (5.92 mL, 38.7 mmol) and 1,2-dibromoethane (3.17 mL, 36.8 mmol) in anhydrous tetrahydrofuran (44 mL) was added dropwise over a period of 6 h. With this slow addition the temperature of the reaction mixture did not increase during the addition. After the addition, the mixture was stirred for an additional 30 min to ensure complete consumption of the magnesium. The resulting grey solution, containing a white precipitate, was devoid of any yellow color.[7] It was treated dropwise over a period of 30 min with a solution of **12** (5.00 g, 9.84 mmol) in anhydrous tetrahydrofuran (65 mL). The resulting grey solution, which contained less white precipitate than before the addition of **12**, was heated under reflux for 7 h. A gold-colored solution containing a very small amount of white precipitate resulted. This was poured into cold (0°C) water (40 mL), and the tetrahydrofuran was removed. Benzene (100 mL) and 2 *M* aqueous HCl (25 mL) were added to the residue and the mixture was filtered through Celite. The Celite was washed with benzene (2 × 25 mL), and the washings were combined with the filtrate. The benzene layer was separated and washed with saturated aqueous $NaHCO_3$ (25 mL) and water (3 × 15 mL), dried, and concentrated. The ^1H nmr spectrum of the residue suggested that it contained mesitylene or 2-bromomesitylene, and it was pumped under high vacuum (0.25 Torr; 1 Torr = 133.3 Pa) in a water bath at 80°C to give an oil. Preparative high performance liquid chromatography of the oil was performed on a PrePak-500 silica gel column (Waters Associates; 5.7 × 30 cm) with chloroform–hexanes – ethyl acetate (65:34:1 v/v/v) as eluent. Compound **19** was eluted first as a white solid (3.50 g, 70%). Crystallization from aqueous methanol gave white crystals, mp 113–114°C; the melt solidified on cooling, and the solid remelted at 124–125°C; ir λ_{max}: 2.98 (m), 5.83, 8.57 (m) μm; ir λ_{max} (KBr): 2.87 (sh, m), 5.84, 6.68 (w), 8.56 (sh, m), 13.68 (br, m), 14.40 (m) μm; ^1H nmr δ: 0.67 (s, C-18 Me), 0.83 (s, C-19 Me), 3.83 (nar m, $W_{1/2}$ = 8 Hz, 1H), 4.35 (s, OH, 1H), 4.53 (s, 2H), 7.28 (s, 5H); ms *m/z*: 508 (1), 402 (100). *Anal.* calcd. for $C_{34}H_{52}O_3$: C 80.26, H 10.30; found: C 80.29, H 10.37.

Further elution gave **12** (1.5 g, 30%) as a white solid.

Hydrogenolysis of ***19****. Formation of 3β,5-dihydroxy-5β-cholestan-6-one (****20****)*

A solution of **19** (1.54 g, 3.03 mmol) in ethyl acetate (65 mL) was stirred with 10% palladium on carbon (160 mg) under hydrogen at atmospheric pressure for 5 h. The reaction mixture was filtered through anhydrous $MgSO_4$, and the filtrate was concentrated to give **20** (1.27 g) in quantitative yield as a colorless oil; ^1H nmr δ: 0.67 (s, C-18 Me),

[6]Compound **15** was originally structure **14** (69).

[7]Grignard solutions that developed a yellow color did not effect epimerization.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

0.77 (s, C-19 Me), 4.03 (m), 4.43 (br s, OH). It was not purified further, but was acetylated directly.

3β-Acetoxy-5-hydroxy-5β-cholestan-6-one (21)

A solution containing **20** (1.21 g, 2.90 mmol), anhydrous pyridine (6.8 mL, 84 mmol), and freshly distilled acetic anhydride (5.6 mL, 59 mmol) was allowed to stand under an argon atmosphere for 68 h. The resulting orange solution was added to ice-water (50 mL), and the yellow solid that precipitated was filtered, washed with water (25 mL), and dissolved in ether (125 mL). The ethereal solution was washed with 2 *M* aqueous HCl (2 × 5 mL), saturated aqueous $NaHCO_3$ (25 mL), and water (3 × 10 mL), dried (Na_2SO_4), and concentrated. The yellow solid obtained (1.22 g) was flash chromatographed on silica gel (2.5 × 17 cm) with chloroform as eluent to give **21** (1.18 g, 89%) as a white solid. Crystallization from methanol gave white needles, mp 143.5–145°C (lit. (70) mp 142.5–144.5°C); ir λ_{max}: 2.95 (br, w), 5.78, 5.84, 7.26 (m), 8.58 (m) μm; ir λ_{max} (KBr): 2.90 (sh, m), 5.80, 5.89, 8.74 (w), 8.98 (m) μm; ^{1}H nmr (200 MHz) δ: 0.66 (s, C-18 Me), 0.76 (s, C-19 Me), 0.87 (d, J = 6 Hz, C-26,27 Me), 0.92 (d, J = 6 Hz, C-21 Me), 2.07 (s), 2.17–2.30 (m, 2H), 2.42 (dd, J = 14, 4 Hz, 1H), 3.92 (s, OH, 1H), 5.07 (nar m, $W_{1/2}$ = 8 Hz, 1H); ms m/z: 460 (2), 318 (100). *Accurate Mass* calcd. for $C_{22}H_{38}O$ (M − $C_7H_{10}O_3$): 318.2923; found: 318.2921.

3β-Acetoxy-7α-bromo-5-hydroxy-5α-cholestan-6-one (22)

Compound **22** was prepared from **10** by the method (procedure d) of Rodewald *et al.* (18). The crude product was flash chromatographed on silica gel with chloroform – ethyl acetate (97:3 v/v) as eluent to give **22** in 84% yield as a colorless oil that solidified on standing. Crystallization from methanol gave **22** as a white powder, mp 172.5–174.5°C (lit. (18) mp 170–172°C); ir λ_{max}: 2.78 (sh, w), 2.98 (br, w), 5.79, 5.83 μm; ir λ_{max} (CCl_4): 2.72 (sh, w), 2.98 (br, w), 5.74, 5.82 μm; ^{1}H nmr δ: 0.68 (s, C-18 Me), 0.83 (s, C-19 Me), 2.02 (s), 3.08 (s, OH, 1H), 4.18 (nar m, $W_{1/2}$ = 5 Hz, 1H), 5.12 (br m, $W_{1/2}$ = 20 Hz, 1H); ms m/z: 400 (42), 43 (100).

3β-Acetoxy-7α-deutero-5-hydroxy-5α-cholestan-6-one (23)

In a separatory funnel, a solution of **22** (110 mg, 0.20 mmol) in ether (10 mL) was treated with D_2O (99.8%, Aldrich; 4 × 1 mL), and the organic phase was added via cannula to zinc dust (307 mg, 4.69 mmol) in a D_2O-pretreated flask under argon. The mixture was stirred, and (*O*-D) acetic acid (98%, Aldrich; 550 μL, 9.45 mmol) was added dropwise over a period of 1 min. The suspension was stirred at room temperature for 2 h, and solid Na_2CO_3 (~8 g) was added. The mixture was filtered, and the zinc and Na_2CO_3 solids were washed with ether (7 × 10 mL). The combined filtrate and washings were washed with a solution of 5% $NaHCO_3$ in D_2O (1 mL) and saturated aqueous NaCl (2 × 10 mL), dried (Na_2SO_4), and concentrated to give **23** (76 mg, 81%) as a white solid. Crystallization from methanol gave white needles, mp 231–233°C; ir λ_{max}: 3.08 (br, w), 5.83 μm; ^{1}H nmr (200 MHz) δ: 0.64 (s, C-18 Me), 0.81 (s, C-19 Me), 0.86 (d, J = 7 Hz, C-26,27 Me), 0.91 (d, J = 7 Hz, C-21 Me), 2.00 (s), 2.76 (dd, J = 12, 12 Hz, 0.12H), 3.20 (br s, OH, 1H), 5.03 (br m, $W_{1/2}$ = 19 Hz, 1H); ms m/z: d_0 15%, d_1 80%, d_2 5% (based on M − AcOH); d_0 15%, d_1 82%, d_2 3% (based on M).

3β-Acetoxy-7α-bromo-5-hydroxy-5β-cholestan-6-one (24)

A solution of **21** (215 mg, 0.47 mmol) in chloroform (3.3 mL) was treated with 1.42 mL of a solution of bromine (0.40 mL) and acetic acid (1.0 mL) in chloroform (20 mL). The red solution was allowed to stand at room temperature for 2 h, and the resulting yellow solution was poured into aqueous 10% Na_2SO_3 (5 mL). The mixture was extracted with benzene (25 mL, 2 × 10 mL), and the combined organic extracts were washed with saturated aqueous $NaHCO_3$ (5 mL) and water (3 × 5 mL), dried (Na_2SO_4), and concentrated to give **24** as a pale yellow solid (256 mg) in quantitative yield. Flash chromatography on silica gel (2.5 × 17 cm) with dichloromethane–ether (98:2 v/v) gave **24** (230 mg, 91%) as a white solid. Crystallization from methanol gave white needles, mp 139–139.5°C (lit. (71) mp 137–138°C); ir λ_{max} (KBr): 2.89 (m), 5.76, 5.85 μm; ^{1}H nmr δ: 0.70 (s, C-18 Me), 0.80 (s, C-19 Me), 2.07 (s), 3.07 (dd, J = 16, 4 Hz, 1H), 3.65 (s, OH, 1H), 4.42 (nar m, $W_{1/2}$ = 5 Hz, 1H), 5.07 (nar m, $W_{1/2}$ = 8 Hz, 1H); ms m/z: 400 (30), 318 (100).

3β-Acetoxy-7α-deutero-5-hydroxy-5β-cholestan-6-one (25)

A solution of **24** (120 mg, 0.22 mmol) in ether (11 mL) was reduced with zinc dust (333 mg, 5.09 mmol) and (*O*-D) acetic acid (600 μL, 10.2 mmol) at room temperature for 2.5 h following the procedure for **23** (*vide supra*). The reaction mixture was neutralized with solid Na_2CO_3 (12 g), and work-up as for **23** gave **25** (79 mg, 77%) as a white solid. Crystallization from methanol gave transparent square plates, mp 143.5–144.5°C; ir λ_{max} (KBr): 2.90 (sh, w), 5.81, 5.88, 8.91 (w) μm; ^{1}H nmr (200 MHz) δ: 0.66 (s, C-18 Me), 0.76 (s, C-19 Me), 0.87 (d, J = 7 Hz, C-26,27 Me), 0.92 (d, J = 6 Hz, C-21 Me), 2.07 (s), 2.24 (dd, J = 15, 4 Hz, 1H), 2.40 (d, J = 3 Hz, 1H), 3.92 (s, OH, 1H), 5.07 (nar m, $W_{1/2}$ = 8 Hz, 1H); ms m/z: 461 (2), 319 (100); d_0 16%, d_1 78%, d_2 6% (based on M − AcOH).

Bromination of cholesteryl acetate (1) in acetic acid. Formation of 5-bromo-5α-cholestane-3β,6β-diol diacetate (26) and 5-bromo-5β-cholestane-3β,6α-diol diacetate (27)

Cholesteryl acetate (**1**) was treated with *N*-bromoacetamide in a solution of lithium acetate in acetic acid to give **26** accompanied by ~10–20% of **27**. The crude product was crystallized from methanol to give **26** (34%) as white needles, mp 91.5–93°C (lit. (72) mp 89–91°C). A second crop of crystals, found to be a mixture of **26** and **27**, was recrystallized from methanol to give a further amount of **26** (total 39%). The crystallized **26** was chromatographed on silica gel with cyclohexane–ether (9:1 v/v) as eluent; recrystallization from methanol raised the melting point to 95.5–96°C. Compound **26**: ir λ_{max}: 5.76 μm; ^{1}H nmr δ: 0.70 (s, C-18 Me), 1.30 (s, C-19 Me), 2.03 (s), 2.10 (s), 5.35 (nar m) and 5.47 (br m) (2H); ms m/z: 384 (82), 368 (95), 43 (100).

A portion of the mother liquor from the first crystallization was applied to a silica gel preparative thin-layer chromatography plate, and the plate was eluted twice with hexanes – ethyl acetate (4:1 v/v). The upper band (R_f 0.65) gave **27**; ir λ_{max}: 5.77 μm; ^{1}H nmr (100 MHz) δ: 0.70 (s, C-18 Me), 0.85 (d, J = 6 Hz, C-26,27 Me), 0.94 (d, J = 6 Hz, C-21 Me), 1.37 (s, C-19 Me), 2.00 (s), 2.06 (s), 2.86 (br dd, J = 14, 5 Hz, 1H), 4.66 (br m, $W_{1/2}$ = 20 Hz, 1H), 5.24 (nar m, $W_{1/2}$ = 8 Hz, 1H); ms m/z: 384 (80), 368 (80), 43 (100). The lower band (R_f 0.57) gave **26**.

Bromination of 1 in aqueous medium. Formation of 28

Cholesteryl acetate (**1**) in acetone, ether, and water was treated with *N*-bromoacetamide to give a yellow solid, shown by ^{1}H nmr spectroscopy to contain at least two major products. Crystallization from hexanes gave **28** (15%) as a white powder, mp 167–170°C (lit. (73) mp 168–170°C); ir λ_{max}: 2.76 (sh, w), 2.90 (br, w), 5.78 μm; ^{1}H nmr δ: 0.67 (s, C-18 Me), 1.30 (s, C-19 Me), 1.77 (m, OH, absent after treatment with D_2O), 2.02 (s), 4.18 (nar m, $W_{1/2}$ = 7 Hz, 1H), 5.47 (br m, $W_{1/2}$ = 20 Hz, 1H); ms m/z: 384 (100).

5α-Cholestane-3β,5,6β-triol (34)

Compound **34** was prepared from cholesterol (**33**) according to the method of Fieser and Rajagopalan (30). Crystallization from methanol gave **34** in 79% yield as white needles, mp 229–232°C (lit. (30) mp 237–239°C); ir λ_{max}: 2.94 (sh, w), 3.07 (br, w) μm; ^{1}H nmr (dimethyl sulfoxide-d_6) δ: 0.63 (s, C-18 Me), 1.03 (s, C-19 Me), 3.50–4.40 (m), 3.57 (s, OH, absent after treatment with D_2O, 1H), 4.12 (d, J = 5 Hz, OH, absent after treatment with D_2O, 1H), 4.32 (d, J = 4 Hz, OH, absent after treatment with D_2O, 1H); ms m/z: 420 (2), 384 (100).

5α-Cholestane-3β,5,6β-triol triacetate (35)

Compound **35** was prepared in 98% yield by acetylation of **34** with acetic anhydride and *p*-toluenesulfonic acid monohydrate in acetic acid (28). Crystallization from methanol gave **35** (78%) as white needles, mp 149.5–151.5°C (lit. (28) mp 151.2–151.8°C); ir λ_{max}: 5.76 μm; ^{1}H nmr δ: 0.70 (s, C-18 Me), 1.20 (s, C-19 Me), 1.97 (s, one Ac), 2.07 (s, two Ac), 2.83 (br dd, J = 13, 5 Hz, 1H), 4.73 (br m, $W_{1/2}$ = 18 Hz, 1H), 5.83 (nar m, $W_{1/2}$ = 6 Hz, 1H); ^{1}H nmr (benzene) δ:

0.65 (s, C-18 Me), 1.17 (s, C-19 Me), 1.62 (s), 1.68 (s), 1.73 (s), 3.17 (dd, J = 14, 5 Hz), 5.08 (br m), 6.28 (nar m); ms m/z: 384 (100).

*5,6β-Epoxy-5β-cholestan-3β-ol (**29**)*

*(i) From **26** and ethanolic sodium ethoxide*

To a solution of sodium ethoxide in ethanol, prepared by the addition of sodium (5.90 g, 0.256 mol) to absolute ethanol (300 mL), **26** (7.50 g, 0.013 mol) was added, and the colorless solution was stirred at room temperature under nitrogen for 0.5 h. Water (30 mL) was added to the resulting pale yellow solution and the ethanol was removed on the rotary evaporator under water aspirator pressure. The residue was extracted with ether, and the combined organic extracts were washed with water, dried ($MgSO_4$), and concentrated to give **29** (6.33 g) as a white solid in quantitative yield. Two crystallizations from methanol gave **29** (4.1 g, 77%) as white needles, mp 139–140°C (lit. (28) mp 130–133.5°C (from acetone–methanol); ir λ_{max}: 2.72 (sh, w), 2.85 (br, w) μm; ^{1}H nmr δ: 0.65 (s, C-18 Me), 1.00 (s, C-19 Me), 1.83 (br s, OH, absent after treatment with D_2O), 3.03 (d, J = 3 Hz, 1H), 3.63 (br m, $W_{1/2}$ = 18 Hz, 1H).

*(ii) From **35** and ethanolic sodium ethoxide*

Treatment of **35** with sodium ethoxide in refluxing ethanol following the method of Rowland and Nace (29) gave **29** in 84% yield.

*5,6β-Epoxy-5β-cholestan-3β-yl acetate (**4**b) from **29***

Compound **29** was acetylated with acetic anhydride and pyridine (28) to give **4***b* in 70% yield; ir λ_{max}: 5.78 μm; ^{1}H nmr δ: 0.65 (s, C-18 Me), 1.02 (s, C-19 Me), 2.02 (s), 3.05 (d, J = 3 Hz, 1H), 4.73 (br m, $W_{1/2}$ = 22 Hz, 1H).

*5-Methoxy-5α-cholestane-3β,6β-diol 3-acetate (**31**)*

A solution of **4***b* (1.00 g, 2.25 mmol) and *p*-toluenesulfonic acid monohydrate (36 mg, 0.19 mmol) in methanol (250 mL) was allowed to stand at room temperature for 17 h. The solution was poured into saturated aqueous $NaHCO_3$ (100 mL) and the methanol was removed. The residue was extracted with ether (100 mL, 2 × 25 mL), and the combined organic extracts were washed with water (3 × 10 mL), dried (Na_2SO_4), and concentrated to give **31** (1.01 g, 94%) as a white solid. Crystallization from methanol gave white needles, mp 161–162°C (lit. (74) mp 152.5–154°C); ir λ_{max}: 2.83 (sh, w), 2.94 (br, w), 5.79 μm; ^{1}H nmr δ: 0.68 (s, C-18 Me), 1.18 (s, C-19 Me), 1.45 (m, OH, absent after treatment with D_2O), 2.02 (s), 3.18 (s, 3H), 3.85 (nar m, $W_{1/2}$ = 8 Hz, 1H), 4.85 (br m, $W_{1/2}$ = 20 Hz, 1H); ms m/z: 476 (3), 366 (100).

*3β-Acetoxy-5-methoxy-5α-cholestan-6-one (**32**)*

A solution of **31** (678 mg, 1.42 mmol) in dichloromethane (5 mL) was added to a stirred suspension of pyridinium chlorochromate (Aldrich; 503 mg, 2.34 mmol) and anhydrous sodium acetate (29 mg, 0.36 mmol) in dichloromethane (5 mL) under a nitrogen atmosphere, and the mixture was stirred at room temperature for 3.5 h. Ether (5 mL) was added, and the brown mixture was applied to a Florisil column (18 g, 2 × 10 cm). The column was eluted with ether (40 mL), and the combined eluents were concentrated to give **32** (678 mg) as a white solid in quantitative yield. Crystallization from methanol gave white needles, mp 152–153°C (lit. (74) mp 149–150°C); ir λ_{max}: 5.78, 5.82 μm; ^{1}H nmr δ: 0.63 (s, C-18 Me), 0.80 (s, C-19 Me), 2.00 (s), 3.13 (s, 3H), 4.80 (br m, $W_{1/2}$ = 20 Hz, 1H); ms m/z: 474 (42), 414 (100). *Accurate Mass* calcd. for $C_{30}H_{50}O_4$: 474.3709; found: 474.3723.

*3β-Benzyloxy-5-methoxy-7α-methyl-5β-cholestan-6-one (**39**)*

Sodium hydride (80% dispersion in oil; 42.0 mg, 1.40 mmol) was added in three portions over a period of 30 min to a stirred solution of **19** (32.8 mg, 0.064 mmol) and iodomethane (1.0 mL, 16 mmol) in anhydrous tetrahydrofuran (5 mL) under argon. The reaction mixture was stirred at room temperature for a further 3.5 h and added cautiously to water (5 mL). The mixture was extracted with ether, and the combined ethereal extracts were washed with aqueous 10% Na_2SO_3 and water, dried (Na_2SO_4), and concentrated to give a colorless oil (42 mg). Flash chromatography of the oil on silica gel (1.5 × 12 cm) with chloroform–hexanes (4:1 v/v) as eluent gave **39** (25 mg, 73%) as a white solid. Crystallization from methanol gave white crystals shaped like fir trees, mp 107.5–109°C; ir λ_{max}: 5.85 μm; ^{1}H nmr (200 MHz) δ: 0.71 (s, C-18 Me), 0.87 (d, J = 7 Hz, C-26,27 Me), 0.91 (d, J = 7 Hz, C-21 Me), 1.04 (s, C-19 Me), 1.06 (d, J = 7 Hz), 2.32 (dq, J = 7, 7 Hz, 1H), 2.60 (dd, J = 12, 5 Hz, 1H), 2.67 (br m, $W_{1/2}$ = 20 Hz, 1H), 3.16 (s, 3H), 3.60 (br m, $W_{1/2}$ = 20 Hz, 1H), 4.58 (s, 2H), 7.33–7.36 (m, 5H); ms m/z: 536 (6), 91 (100). *Anal.* calcd. for $C_{36}H_{56}O_3$: C 80.55, H 10.52; found: C 80.38, H 10.51.

3β-Benzyloxy-5-hydroxy-5β-cholestan-6-one (E)*-oxime (**40**)*

Compound **19** was treated with hydroxylamine hydrochloride in 95% ethanol and pyridine to give **40** as a colorless oil (61 mg, 88%). Crystallization from methanol–hexanes gave **40** as colorless needles, mp 157.5–159°C; ir λ_{max}: 2.78 (sh, w), 2.88 (br, w), 6.12 (v w) μm; ^{1}H nmr δ: 0.67 (s, C-18 Me), 0.93 (s, C-19 Me), 3.37 (br d, J = 12 Hz, 1H), 3.80 (nar m, $W_{1/2}$ = 8 Hz, 1H), 4.50 (m, OH, absent after treatment with D_2O, 1H), 4.52 (s, 2H), 7.30 (s, 5H); ms m/z: 523 (1), 91 (100).

3β-Benzyloxy-5-hydroxy-5β-cholestan-6-one (E)*-oxime methyl ether (**41**)*

Compound **19** was treated with methoxylamine hydrochloride in anhydrous pyridine to give a pale yellow oil, which was flash chromatographed on silica gel (2 × 19 cm) with dichloromethane–ether (99:1 v/v) as eluent to give **41** (478 mg, 85%) as a colorless oil that resisted crystallization; ir λ_{max}: 2.99 (sh, m), 6.24 (w), 8.58 (m) μm; ^{1}H nmr δ: 0.67 (s, C-18 Me), 0.90 (s, C-19 Me), 3.27 (d, J = 12 Hz, 1H), 3.83 (nar m) and 3.93 (s) (4H), 4.43 (s, OH, 1H), 4.53 (s, 2H), 7.33 (s, 5H); ms m/z: 537 (<1), 91 (100). *Anal.* calcd. for $C_{35}H_{55}O_3N$: C 78.16, H 10.31, N 2.60; found: C 77.72, H 10.11, N 2.61.

3β-Benzyloxy-5-methoxy-5β-cholestan-6-one (E)*-oxime methyl ether (**42**)*

*(i) From methylation of **41***

Sodium hydride (80% dispersion in oil; 159 mg, 5.29 mmol) was added in portions to a stirred solution of **41** (452 mg, 0.84 mmol) and iodomethane (1.5 mL, 24 mmol) in anhydrous tetrahydrofuran (25 mL) under an argon atmosphere. The mixture was stirred at room temperature overnight and added cautiously to water (25 mL). The tetrahydrofuran was removed and the residue was extracted with ether (50 mL, 2 × 25 mL). The combined ethereal layers were washed with water (2 × 15 mL), dried (Na_2SO_4), and concentrated. The residual oil (488 mg) was flash chromatographed on silica gel (2 × 13 cm) with chloroform–hexanes (85:15 v/v) as eluent to give **42** (412 mg, 89%) as a colorless oil that resisted crystallization; ir λ_{max}: 6.12 (w) μm; ^{1}H nmr δ: 0.73 (s, C-18 Me), 1.03 (s, C-19 Me), 2.70 (dd, J = 12, 4 Hz, 1H), 3.10 (s, 3H), 3.73 (br m) and 3.87 (s) (4H), 4.60 (s, 2H), 7.37 (m, 5H); ms m/z: 551 (1), 460 (95), 91 (100). *Anal.* calcd. for $C_{36}H_{57}O_3N$: C 78.35, H 10.41, N 2.54; found: C 78.30, H 10.27, N 2.55.

*(ii) From methylation of **40***

Treatment of **40** (31 mg, 0.06 mmol) with NaH (80% dispersion in oil; 25 mg, 0.83 mmol) and iodomethane (0.20 mL, 3.2 mmol) in anhydrous tetrahydrofuran (3 mL) for 12 h and work-up as in (*i*) gave a colorless oil (32 mg), shown by ^{1}H nmr spectroscopy to be **42**.

*Reaction of **29** with methylmagnesium iodide. Formation of 6α-methyl-5α-cholestane-3β,6β-diol (**44**) and 4aξ-methyl-*A*-homo-*B*-nor-5β-cholestane-3β,4aξ-diol (**45**)*

An ethereal solution of methylmagnesium iodide was prepared by the addition of a solution of freshly distilled iodomethane (10.1 mL, 162 mmol) in anhydrous ether (4 mL) to a stirred mixture of purified magnesium turnings[8] (0.802 g, 33.0 mmol) in anhydrous ether (1 mL) under a nitrogen atmosphere. Grignard formation was self-initiated and the mixture was stirred at room temperature for 3 h. Anhydrous ether

[8]Magnesium turnings were washed with aqueous 2 *M* HCl (25 mL), water (×5), ethanol (×10), and anhydrous ether (×5), and pumped under high vacuum overnight.

For personal use only.

(10 mL) was added, and the resulting slightly cloudy, grey mixture was transferred via cannula to an addition funnel, added dropwise over a period of 1 h to a stirred solution of **29** (2.48 g, 6.17 mmol) in a mixture of anhydrous benzene (25 mL) and ether (15 mL) under a nitrogen atmosphere, and heated at reflux. Following the addition, solvent (20 mL) was removed by distillation at atmospheric pressure, bp 40–51°C, and the residual solution was heated under reflux for a further 9 h. The resulting colorless, slightly cloudy reaction mixture was poured into ice, and saturated aqueous NH_4Cl was added. The organic phase was separated and washed with aqueous 5% $Na_2S_2O_3$, saturated aqueous $NaHCO_3$, and water, dried ($MgSO_4$), and concentrated to give a white solid (2.56 g). The ^1H nmr spectrum of the product indicated the presence of two major components, **44** and **45**, in a ~60:40 ratio. The solid was triturated with acetone, and **44** was obtained as the residual white powder, mp 184–186°C (lit. (42) mp 194°C); ir λ_{max}: 2.82 (sh, w), 2.95 (br, w) μm; ^1H nmr δ: 0.67 (s, C-18 Me), 1.02 (s, C-19 Me), 1.15 (s), 1.57 (m, OH, absent after treatment with D_2O), 3.53 (br m, $W_{1/2}$ = 20 Hz, 1H); ms *m/z*: 418 (3), 403 (100), 400 (68). *Accurate Mass* calcd. for $C_{27}H_{47}O_2$ (M − CH_3), $C_{28}H_{48}O$ (M − H_2O): 403.3576, 400.3705; found: 403.3563, 400.3698.

The acetone solution from the trituration was concentrated, and the residual solid was crystallized from ethyl acetate to give **45** (0.14 g, 5%) as white crystals, mp 86.5–88.5°C; ir λ_{max}: 2.83 (sh, w), 2.93 (br, w) μm; ^1H nmr δ: 0.67 (s, C-18 Me), 0.98 (s, C-19 Me), 1.22 (s), 1.90 (m, OH, absent after treatment with D_2O), 3.98 (nar m, $W_{1/2}$ = 12 Hz, 1H); ms *m/z*: 418 (5), 87 (100). *Accurate Mass* calcd. for $C_{28}H_{50}O_2$: 418.3811; found: 418.3787.

Reaction of ***4b*** *with lithium dimethylcuprate. Formation of 5,6β-epoxy-5β-cholestan-3β-yl 3-oxobutyrate (**49**) and 5,6β-epoxy-5β-cholestan-3β-ol (**29**)*

A stirred suspension of CuI (147 mg, 0.77 mmol) in anhydrous ether (10 mL) under a nitrogen atmosphere and cooled in an ice–salt bath was treated dropwise with a solution of methyllithium–LiBr complex in ether (1.2 *M*; 1.25 mL, 1.50 mmol). To the ethereal solution of lithium dimethylcuprate, a solution of **4*b*** (172 mg, 0.39 mmol) in anhydrous ether (5 mL) was added dropwise over a period of 15 min. A yellow precipitate slowly began to fall from solution, and the mixture was stirred in the ice–salt bath for 3 h. The resulting yellow suspension was treated with saturated aqueous NH_4Cl (10 mL), and the two-phase mixture was stirred at room temperature overnight. The ethereal layer was separated, washed with saturated aqueous $Na_2S_2O_3$ and water, dried ($MgSO_4$), and concentrated to give a white solid (130 mg). The ^1H nmr spectrum of the product evidenced a ~40:60 mixture of **49** and **29**. An ethereal solution of the solid was applied to a 1-mm silica gel plate, and the plate was eluted with ether. The upper band (R_f 0.66) gave **49** (40 mg, 21%) as a white solid; ir λ_{max}: 5.73, 5.81 μm; ^1H nmr (100 MHz) δ: 0.64 (s, C-18 Me), 1.00 (s, C-19 Me), 2.25 (s, 3H), 3.07 (d, *J* = 3 Hz, 1H), 3.42 (br s, exchanges slowly with D_2O, 2H), 4.84 (br m, $W_{1/2}$ = 24 Hz, 1H); ms *m/z*: 486 (2), 384 (100). The lower band (R_f 0.41) gave **29** (65 mg, 42%) as a white solid.

*6-Nitrocholesteryl acetate (**50**)*

Nitration of cholesteryl acetate (**1**) (49) gave **50** in 68% yield as white needles, mp 103.5°C–105°C (from methanol) (lit. (49) mp 102.5–103°C); ir λ_{max}: 5.75, 6.62 (m) μm; ^1H nmr δ: 0.70 (s, C-18 Me), 1.15 (s, C-19 Me), 2.02 (s), 4.60 (br m, $W_{1/2}$ = 18 Hz, 1H); ms *m/z*: 473 (6), 413 (100).

Reaction of ***50*** *with lithium dimethylcuprate. Formation of 3α,5-cyclo-5α-cholestan-6-one (*E*)-oxime (**51**), 3β-acetoxy-5α-cholestan-6-one (*E*)-oxime (**55**), and 3β-acetoxy-5-hydroxy-5α-cholestan-6-one (**10**)*

An ethereal solution of lithium dimethylcuprate was prepared by the dropwise addition of a solution of methyllithium–LiBr complex in ether (1.7 *M*; 17.4 mL, 29.6 mmol) to a stirred suspension of purified (75) CuI (2.93 g, 15.4 mmol) in anhydrous ether (125 mL) under an argon atmosphere and cooled in an ice bath. A solution of **50** (1.39 g, 2.94 mmol) in anhydrous ether (15 mL) was added dropwise over a period of 30 min, and the resulting yellow suspension was stirred at 0°C for 3 h and subsequently added via cannula to a stirred solution of saturated aqueous NH_4Cl (250 mL) buffered to pH 8 with aqueous 28% NH_3. The two-phase mixture was stirred overnight, and the blue aqueous layer was extracted with ether (3 × 50 mL). The combined ethereal layer and extracts were washed with saturated aqueous NaCl (4 × 10 mL), dried (Na_2SO_4), and concentrated to give a yellow oil (1.32 g). Preparative thin-layer chromatography of the oil (134 mg) on silica gel with hexanes – ethyl acetate (4:1 v/v) gave **51** (77 mg, 65%) as a white solid. Crystallization from aqueous ethanol gave white crystals, mp 126–126.5°C (lit. (76) mp 125–126°C). A mixture mp taken with a sample of **51**, mp 124.5–125.5°C, prepared by oximination of ketone **52** (*vide infra*) was 125–126°C. Compound **51**: ir λ_{max}: 2.78 (sh, m), 3.06 (br, m), 6.07 (w) μm; ^1H nmr δ: 0.49 (m, 1H), 0.68 (s, C-18 Me), 0.91(s, C-19 Me), 3.30 (br d, *J* = 11 Hz, 1H), 8.67 (v br m, OH, 1H); ms *m/z*: 399 (12), 135 (100). *Accurate Mass* calcd. for $C_{27}H_{45}ON$: 399.3501; found: 399.3505. *Anal.* calcd. for $C_{27}H_{45}ON$: C 81.14, H 11.35, N 3.50; found: C 80.79, H 11.31, N 3.55.

A portion (411 mg) of the crude oil was purified by medium pressure liquid chromatography on a 3 × 25-cm silica gel column (Merck) with hexanes – ethyl acetate (85:15 v/v) as eluent. Compound **51** (176 mg, 48%) was eluted first, and further elution gave a white solid (46 mg) and a colorless oil (22 mg). Flash silica gel chromatography of the solid with dichloromethane – ethyl acetate (9:1 v/v) gave a mixture (30 mg) of **55** and **10** as a white solid; ir λ_{max}: 2.88 (sh, w), 3.06 (br, w), 5.79, 6.20 (w) μm; ^1H nmr δ: 0.63 (s, C-18 Me), 0.75 (s, C-19 Me, **55**), 0.80 (s, C-19 Me, **10**), 2.00 (s), 3.33 (br d, *J* = 11 Hz, **55** 7β-H), 4.67 (br m, **55** C*H*OAc), 5.05 (br m, **10** C*H*OAc); ^{13}C nmr (δ > 60 ppm) δ: 70.8, 73.4, 80.3, 159.8, 170.6, 171.0, 212.2; ms *m/z*: 460 (10), 459 (5), 43 (100).

Hydrolysis of ***51***. *Formation of 3α,5-cyclo-5α-cholestan-6-one (**52**)*

A mixture of **51** (58 mg, 0.15 mmol) and $NaHSO_3$ (311 mg) in absolute ethanol (14 mL) and water (2.7 mL) was stirred and heated under reflux for 3 h. The mixture was allowed to cool and the ethanol was removed. The residue was extracted with ether (25 mL, 3 × 10 mL), and the ethereal extract was washed with saturated aqueous $NaHCO_3$ (10 mL) and water, dried (Na_2SO_4), and concentrated to give **52** (49 mg, 87%) as a white solid. Crystallization from methanol gave white crystals, mp 97–98°C (lit. (77) mp 97.2–97.6°C). A mixture mp taken with a sample of **52**, mp 99–99.5°C, prepared by oxidation of **54** (*vide infra*) was 97.5–99.5°C. Ketone **52**: ir λ_{max}: 5.94 μm; ^1H nmr δ: 0.70 (s, C-18 Me), 1.00 (s, C-19 Me); ms *m/z*: 384 (100). *Accurate Mass* calcd. for $C_{27}H_{44}O$: 384.3392; found: 384.3398.

*3α,5-Cyclo-5α-cholestan-6β-ol (**54**)*

Cholesteryl *p*-toluenesulfonate (**53**) was treated with a mixture of potassium acetate and acetic anhydride, and the resulting mixture of acetates was hydrolyzed with ethanolic KOH (78) to give **54** (62%) as a white solid, mp 64.5–68°C (lit. (78) 74–75°C); ir λ_{max}: 2.77 (sh, w), 2.90 (br, w) μm; ^1H nmr δ: 0.17–0.57 (m), 0.72 (s, C-18 Me), 1.07 (s, C-19 Me), 1.50 (m, OH, absent after treatment with D_2O), 3.22 (nar m, $W_{1/2}$ = 6 Hz, 1H); ms *m/z*: 386 (1), 368 (100).

Oxidation of ***54***. *Formation of 52*

A stirred suspension of pyridinium chlorochromate (Aldrich: 97 mg, 0.45 mmol) and anhydrous sodium acetate (69 mg, 0.84 mmol) in dichloromethane (1 mL) under a nitrogen atmosphere was treated with a solution of **54** (112 mg, 0.29 mmol) in dichloromethane (1 mL). The mixture was stirred at room temperature for 25 h, and ether (2 mL) was added to the resulting olive-colored suspension. The reaction mixture was applied to a Florisil column (5 g, 2 × 4 cm), and the column was eluted with ether (100 mL). The eluent was concentrated to give **52** (105 mg, 94%) as a white solid. Crystallization from methanol gave white crystals, mp 99–99.5°C (lit. (77) mp 97.2–97.6°C). The spectra of this product were identical to those of **52** prepared by hydrolysis of **51**.

Oximation of ***52***. *Formation of 51*

Compound **52** was treated with hydroxylamine hydrochloride and anhydrous sodium acetate in ethanol to give **51** (91%) as a colorless oil.

Crystallization from aqueous ethanol gave white crystals, mp 124.5–125.5°C (lit. (78) mp 125–126°C). The ir, ^{1}H nmr, ^{13}C nmr, and mass spectra were identical to those of **51** obtained by reaction of **50** with lithium dimethylcuprate.

3β-Acetoxy-5α-cholestan-6-one (56)

Reduction of 6-nitrocholesteryl acetate (**50**) with zinc and acetic acid (54) gave **56** in 88% yield as white needles, mp 128–131.5°C (lit. (54) mp 127–128°C); ir λ_{max}: 5.77, 5.82 μm; ^{1}H nmr δ: 0.68 (s, C-18 Me), 0.80 (s, C-19 Me), 2.03 (s), 4.67 (br m, $W_{1/2}$ = 20 Hz, 1H).

3β-Acetoxy-5α-cholestan-6-one (E)*-oxime (55)*

Compound **56** was treated with hydroxylamine hydrochloride and sodium acetate in ethanol to give **55** (83%) as a white solid. Crystallization from methanol–hexanes gave colorless plates, mp 198–199°C (lit. (79) mp 206–208°C (from methanol)); ir λ_{max}: 2.90 (sh, w), 3.11 (br, w) 5.77, 6.00 (w) μm; ^{1}H nmr δ: 0.67 (s, C-18 Me), 0.75 (s, C-19 Me), 2.00 (s), 3.32 (br d, J = 11 Hz, 1H), 4.65 (br m, $W_{1/2}$ = 22 Hz, 1H), 9.33 (v br m, OH, 1H); ms m/z: 459 (15), 399 (100).

Étude radiocristallographique comparée de quelques Δ-2 imidazolines substituées

PIERRE BROUANT ET JACQUES BARBE[1]

Groupe d'études et de recherches en chimie thérapeutique organique et physique, Faculté de pharmacie, 27 boul. Jean-Moulin, 13385 Marseille CEDEX 5, France

ET

ALAIN MARSURA, CATHERINE SOULA ET CUONG LUU-DUC

Groupe de pharmacochimie, Faculté de pharmacie, Domaine de la Merci, 38700 La Tronche, France

Reçu le 7 janvier 1987

PIERRE BROUANT, JACQUES BARBE, ALAIN MARSURA, CATHERINE SOULA et CUONG LUU-DUC. Can. J. Chem. **65**, 2217 (1987).

La comparaison des configurations de trois composés de la série des Δ-2 imidazolines fonctionnalisées, montre une géométrie spatiale constante. Tous les substituants sont en position *trans* les uns par rapport aux autres et contribuent ainsi à une minimisation des gênes stériques. D'apprès cette étude, il semble également que la nature du substituant à l'azote N(3) influe de manière importante sur la position du carbonyle. Les résultats confortent ceux d'une étude en résonance magnétique nucléaire antérieure.

PIERRE BROUANT, JACQUES BARBE, ALAIN MARSURA, CATHERINE SOULA, and CUONG LUU-DUC. Can. J. Chem. **65**, 2217 (1987).

The solid state structures of three compounds belonging to the Δ-2 imidazoline series have been compared. X-ray data and molecular parameters are given. It is noteworthy to point out that substituents are *trans* to one another in these structures. Moreover, the spatial orientation of the carbonyl group attached to C(4) depends on the nature of the substituent attached to nitrogen N(3). In addition, results are in close agreement with those of nuclear magnetic resonance spectroscopy.

Introduction

Les Δ-2 imidazolines sont des substances dont l'intérêt thérapeutique déjà ancien s'est encore affirmé récemment. En effet, ce sont des antidépresseurs (1), des antiparasitaires (2), des bactériostatiques (3), mais ces composés possèdent aussi des propriétés hypotensives dont exemple est donné par la clonidine et ses homologues (4). Cependant, à ce jour, peu de dérivés fonctionnalisés ont été décrits. Le travail présenté concerne l'analyse structurale par radiocristallographie de molécules nouvelles dont la formule générale est donnés sur la figure 1 et qui ont été obtenues par action de cétones α-bromées α,β-éthyléniques avec des amidines N-substituées (5). Il s'agit plus particulièrement de la benzyl-1 diphényl-2,4 acétyl-5 Δ-2 imidazoline (**2**) et de l'isopropyl-1 diphényl-2,4 benzoyl-5 Δ-2 imidazoline (**3**) qui ont été choisies comme témoins. Les résultats, discutés en se référant à ceux d'une étude préliminaire (6) consacrée à l'isopropyl-1 diphényl-2,4 pivaloyl-5 Δ-2 imidazoline (**1**), permettent une discussion comparative des configurations.

Partie expérimentale

Les données cristallines comparées pour les deux composés sont rapportées dans le tableau 1.

Les monocristaux des deux composés ont été obtenus par simple évaporation à température ambiante de leurs solutions saturées dans le chloroforme (**2**) ou dans un mélange équimolaire d'acétate d'éthyle et d'ether éthylique (**3**). Les densités ont été mesurées par flottaison.

La détermination des mailles et l'enregistrement des intensités diffractées ont été effectués sur un diffractomètre automatique 4 cercles CAD-4 Enraf Nonius à monochromateur de graphite : $\lambda(\text{Mo K}\bar{\alpha}) = 0{,}7107$ Å. Les paramètres des mailles ont été obtenus par moindres carrés à partir des positions angulaires de 25 réflexions pour les deux composés.

Les conditions expérimentales d'enregistrement des intensités peuvent être considérées comme identiques (T = 293 K) pour les deux composés. La technique de balayage en $\theta-2\theta$ a été utilisée. On a réalisé des contrôles d'orientation toutes les 300 mesures et des contrôles d'intensité toutes les 10 000 secondes. La déviation angulaire maximum acceptée était de 0,12 et les variations d'intensité ont toujours été inférieures à 3% (**2**) ou 2% (**3**).

Aucune correction particulière d'absorption n'a été effectuée. Les structures ont été déterminées par les méthodes directes (7). Elles ont été ensuite précisées par une succession de synthèses de différences-Fourier et de cycles d'affinements par moindres carrés.

Les atomes d'hydrogène, en partie localisés sur les cartes de densités-différences et construits géométriquement pour les autres, ont été inclus mais non affinés dans les deux derniers cycles d'affinement qui ont eu lieu en matrice entière. Tous les atomes ont été affectés d'un facteur d'agitation thermique anisotrope sauf les atomes d'hydrogène affectés d'un facteur d'agitation fixé à 5 Å^2 pour les deux composés. La fonction à minimiser était $\Sigma w(|F_o| - |F_c|)^2$ avec $w = 1$. Les facteurs de diffusion atomique proviennent de la réf. 8. Tous les calculs ont été effectués sur ordinateur DEC PDP 11/44 sous logiciel SDP (9).

L'enregistrement et les calculs ont été réalisés dans le Service de cristallochimie de l'Université d'Aix-Marseille III, rue Henri Poincaré 13397 Marseille Cedex 13.

Les tableaux 2 et 3 donnent les coordonnées atomiques.[2] Dans les tableaux 4 et 5 sont portés les paramètres angulaires et de liaison. Les valeurs des angles de torsion les plus significatives sont présentées dans le tableau 6.

On doit noter ici que la présence dans chacune des molécules considérées de centres asymétriques implique l'existence d'images non superposables. Les structures ont été résolues dans des groupes d'espace centrosymétriques. Cependant, les coordonnées atomiques ont été transformées pour se rapporter toutes au même conformère.

Les représentations géométriques de ces conformères sont données sur la figure 2.

*Les atomes affinés anisotropiquement sont donnés sous la forme d'équivalents isotropiques définis ainsi au moyen des paramètres de la maille :

$$B_{eq} = 4/3[a^2B(1,1) + b^2B(2,2) + c^2B(3,3) + ab(\cos\gamma)B(1,2) + ac(\cos\beta)B(1,3) + bc(\cos\alpha)B(2,3)]$$

Discussion

Les trois composés adoptent une conformation du cycle imidazoline en forme d'enveloppe. Cela ressort du tableau 7, qui donne les distances des atomes du cycle et celles du premier atome de chaque substituant au plan moyen défini par les atomes coplanaires N(1), C(2), N(3) et C(5). La position de C(4) est nettement hors du plan moyen chez **1** et **2** mais, les cotes étant opposées par rapport à ce plan, les conformations sont inversées. En revanche, le composé **3** est à ce niveau plus plan que les précédents, la tendance au pliage ayant lieu, dans ce cas, de part et d'autre d'un axe imaginaire C(2)–C(4) avec un atome N(3) qui ne s'élève qu'à 0,05 Å au dessus d'un plan formé par C(4), C(5), N(1) et C(2). Quant aux substituants, leurs cotes sont de même signe pour les trois composés et ils conservent ainsi une même orientation *trans*, ce qui s'accorde avec les mesures antérieures des constantes de couplage ^3J(H4–H5) (10). On peut également évaluer la planéité du cycle en s'intéressant aux plans des moindres carrés formés par N(1), C(2), N(3), C(4) et C(5). Il apparaît alors que les distances maximales au plan moyen sont de 0,089 Å (**1**), 0,069 Å (**2**) et 0,021 Å (**3**).

En ce qui concerne les différences dans les longueurs de liaison, elles sont relativement faibles entre liaisons de nature identique : 0,018 Å en moyenne, avec un maximum de 0,053 Å pour la liaison C(4)—C(7). La liaison N(1)—C(2) est en moyenne de 1,28 Å, les liaisons N(3)—C(4), C(3)—C(6) et N(1)—C(5) sont de 1,48 Å, celle entre C(2)—N(3) étant de 1,38 Å. Ces valeurs peuvent être comparées aux valeurs théoriques d'une double liaison carbone–azote (1,29 Å) ou d'une simple liaison carbone–azote (1,48 Å). On en déduit que si la liaison N(1)—C(2) est bien une liaison double N_{sp^2}—C_{sp^2}, si les liaisons N(3)—C(4), N(3)—C(6) et N(1)—C(5) sont bien des liaisons simples N_{sp^3}—C_{sp^3}, la liaison C(2)—N(3), en revanche, présente un caractère partiel de double liaison N_{sp^3}—C_{sp^2}. On notera, en outre, que ces valeurs concordent avec celles de 1,27(1) et 1,33(1) données pour la dihydro-7,8 diphényl-2,5 imidazo [1,2-*f*] [1,3,4,6] triazépine (11) ou avec celles de 1,28(3) et 1,37(2) données pour la (dihydro-4,5 imidazolyl-2)-2 benzophénone (12) ou encore avec celles de 1,28(7) et 1,38(2) données pour les *N*,*N*-diméthylamidoximes (13).

D'autre part, la moyenne des variations des angles n'est que de 2,04°. L'angle C(2)—N(3)—C(4) a une valeur moyenne de 106,8°. Ce résultat s'accorde avec ceux de Beagley *et al.* (11) et ceux de MacKechnie et Paul (12) qui, dans le cas des composés déjà cités, donnent la valeur 105,8°. De plus le substituant C(6) porté par l'azote N(3) est situé nettement hors du plan comme cela apparait dans le tableau 7. Tout ceci, compte tenu par ailleurs du caractère partiel de double liaison pour la liaison C(2)—N(3), est en faveur d'un état intermédiaire d'hybridation de l'azote N(3).

Pour ce qui est des substituants portés par le cycle en position 2, 3, 4 et 5, on peut relever les observations suivantes liées aux

valeurs des angles de torsion présentées dans le tableau 6 :

(*i*) Le phényle en 2 prend chez les trois composés une angulation voisine afin de s'éloigner au maximum du substituant greffé en N(3). Donc il n'y pas de conjugaison entre ce groupement et la liaison imine intracyclique comme en témoigne la valeur moyenne de l'angulation qui est égale à 41,5°.

(*ii*) On note également une angulation assez voisine pour les substituants isopropyle ou benzyle greffés en N(3). Le cycle phényle du substituant benzyle dans le composé **2** prend la place d'un des groupements méthyles de **1** ou **3**. Les angulations de **2** et **3** autour de la liaison N(3)—C(6) sont très proche de 60° et donc de la valeur théorique pour une conformation décalée. D'autre part dans le cas de **3** le calcul des distances entre l'hydrogène porté par C(4) et les hydrogènes respectivement portés par C(61) et C(62) : 2,37 Å et 2,42 Å, révèle une proximité entre ces atomes conforme aux résultats observés en rmn par effet Overhauser (10) et s'accorde avec l'état d'hybridation de N(3) mentionné précédement. De même, la distance de 2,55 Å entre l'hydrogène porté par C(6) et l'hydrogène porté par C(22) confirme aussi les résultats de rmn (10).

(*iii*) La projection de l'angle C(4)—N(3)—C(2) dans un plan perpendiculaire à la liaison N(3)—C(6), qui serait de 180° pour un azote N(3) purement sp^2 ou de 120° pour un azote purement sp^3, vaut respectivement 156,2(9)° pour **1**, 136,0(5)° pour **2** et 131,1(5)° pour **3**. On en déduit 40% de caractère sp^3 pour **1**, 73% pour **2** et 81% pour **3**.

(*iv*) La liaison C(7)—O(70) est, dans les trois cas, située dans le même quadrant que la liaison C(4)—N(3) ce qui correspond à une forme cisoide, **3** ayant en outre même

TABLEAU 7. Distances au plan moyen défini par les atomes C(5)—N(1)—C(2)—N(3)

Atomes	Composé **1**	Composé **2**	Composé **3**
N(1)	−0,021(7)	−0,019(3)	−0,011(5)
C(2)	0,023(8)	0,016(3)	0,012(7)
N(3)	−0,013(7)	−0,009(3)	−0,006(5)
C(4)	−0,243(8)	0,188(3)	0,045(7)
C(5)	0,011(9)	0,008(3)	0,006(7)
C(21)	0,059(8)	0,023(3)	0,025(6)
C(6)	0,546(9)	0,622(3)	0,658(7)
C(7)	−1,694(9)	−0,732(4)	−1,267(7)
C(51)	1,320(8)	1,076(3)	1,198(6)
χ^2	22,694	74,478	10,458

conformation que **1**. On doit souligner, à ce propos, que par nOe-différence entre les atomes d'hydrogène portés par C(5) et C(72) on avait abouti à la même conclusion (10).

(*v*) Enfin, le phényle greffé en 5 est toujours presque quasiment perpendiculaire au plan du cycle imidazoline comme le montre la distance entre l'atome d'hydrogène porté par C(5) et celui porté par C(52). Cette valeur (2,36 Å) est proche du minimum observable par simulation de rotation autour de la liaison C(5)—C(51) (2,13 Å). Ce résultat concorde avec l'interaction notée par nOe-différence (10).

Conclusion

La différence structurale essentielle relevée dans cette étude tient à une inversion d'enveloppe chez **2**. Néanmoins, la similitude conformationnelle est particulièrement marquée entre

Photochemistry of halogenated benzene derivatives. Part VIII.[1] Photoformation of 2-methyl-4,5,6,7-tetrachlorobenzoxazole from pentachlorophenol in water–acetonitrile

GHULAM GHAUS CHOUDHRY,[2] NORMA JEAN GRAHAM, AND G. R. BARRIE WEBSTER
Pesticide Research Laboratory, Department of Soil Science, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received September 3, 1986[3]

GHULAM GHAUS CHOUDHRY, NORMA JEAN GRAHAM, and G. R. BARRIE WEBSTER. Can. J. Chem. **65**, 2223 (1987).

Photolysis of a solution of pentachlorophenol (**1**) in H_2O–CH_3CN (2:3 v/v) was conducted on a synthetic scale using wavelengths ≥ 290 nm. After changing the pH of the photolyzate of **1** to ≥ 12, the photoproduct 2-methyl-4,5,6,7-tetrachlorobenzoxazole (**2**) was extracted with *n*-hexane. The product **2** was crystallized from methanolic solution. Ultraviolet, IR, FT-^{1}H-NMR, proton-decoupled normal FT-^{13}C-NMR, and proton-decoupled DEPT (distortionless enhancement by polarization transfer) sequence FT-^{13}C-NMR spectroscopy were used to identify photoproduct **2** as 2-methyl-4,5,6,7-tetrachlorobenzoxazole. A mechanism for the photoformation of benzoxazole **2** from **1** is proposed. 3,4,5,6-Tetrachlorocyclohexa-3,5-diene-1,2-ketocarbene formed from 2-hydroxy-3,4,5,6-tetrachlorophenyl radical is suggested as key intermediate involved in the generation of oxazole **2** from phenol **1**. The chemical yield of **2** on the basis of **1** was ca. 1%. A mechanism is proposed to explain the mass spectral fragmentation of **2** via the losses of Ċl, :C=O, Cl—Ċ=O, CH_3—Ċ=O, CH_3CN, and $\dot{C}_3H_3ClNO$ species from the parent molecular ion.

GHULAM GHAUS CHOUDHRY, NORMA JEAN GRAHAM et G. R. BARRIE WEBSTER. Can. J. Chem. **65**, 2223 (1987).

Utilisant des longueurs d'onde ≥ 290 nm et opérant à une échelle synthétique, on a procédé à une photolyse d'une solution de pentachlorophénol (**1**) dans le H_2O/CH_3CN (2/3 v/v). Après avoir ajusté le pH de la solution à une valeur supérieure à 12, on a extrait le photoproduit, le méthyl-2 tétrachloro-4,5,6,7 benzoxazole (**2**), par de l'hexane. On a recristallisé le produit **2** à partir du méthanol. L'identification du produit **2** comme le méthyl-2 tétrachloro-4,5,6,7 benzoxazole a été réalisée grâce aux spectres UV et IR, aux spectres rmn ^{1}H par transformation de Fourier et à une séquence de spectres rmn du ^{13}C normalement découplés du proton et découplés des protons grâce à un rehaussement sans distorsion effectué par transfert de polarisation (RDTP). On propose un mécanisme pour la photoformation du benzoxazole **2** à partir du composé **1**. Dans la génération de l'oxazole **2** à partir du phénol **1**, on suggère que l'intermédiaire clé est le tétrachloro-3,4,5,6 cyclohexadiène-3,5 céto-1 carbène-2, qui se forme à partir du radical hydroxy-2 tétrachloro-3,4,5,6 phényle. Le rendement chimique du composé **2**, sur la base de la quantité de **1** mise en jeu, est de 1%. On propose un mécanisme pour expliquer pourquoi la fragmentation du composé **2** en spectrométrie de masse se produit avec des pertes de .Cl, :C=O, Cl—Ċ=O, CH_3CN et .C_3H_3ClNO à partir de l'ion moléculaire de base.
[Traduit par la revue]

Introduction

The contamination of soil and aquatic environments by chlorinated aromatic pollutants (CAPs) such as polychlorophenols (PCPs) is well known. PCPs includingg several other chloroorganics have been recently identified in the flue gas and fly ash emitted from some municipal and industrial incinerators located in Canada, Japan, Switzerland, and the Netherlands (2–4). Likewise, PCPs have been widely found in surface waters and in wastewaters, in particular, in pulp mill effluents (5–7). In the environment, PCPs originate from pulp bleaching and the disinfection of waters, but are also contaminants and degradation products of pesticides (8). Furthermore, pentachlorophenol (P_5CP) (**1**) itself has been widely used in agriculture and industry as a fungicide, bactericide, herbicide, molluscicide, algicide, and insecticide (9, 10). Presently, CAP **1** is utilized mainly as a wood preservative, which has led to its widespread presence in the environment (9).

Photochemical transformation caused by sunlight is an important environmental process for chemicals present in air, water, and soils (11). Several authors have reported solution phase as well as solid phase environmental photochemistry of P_5CP (**1**) (12–21). Recently, we (22) have reported our investigations on the environmental photochemistry of several PCPs, namely tetra- and pentachlorophenols in H_2O–CH_3CN (2:3 v/v) at λ ≥ 290 nm concluding that the process of reductive dechlorination is dependent not only upon the position of the OH group but also upon the relative positions of the Cl substituents on the benzene nucleus. In aqueous acetonitrile, for instance, **1** also gave rise to the generation of a photoproduct of molecular formula $C_8H_3Cl_4NO$ (22).

In view of our continuing interest in the environmental photolytic fate of pollutants, viz., halogenated benzene derivatives (see ref. 1; and the preceding articles of this series cited therein), we decided to further investigate the photochemistry of **1** dissolved in water-acetonitrile (2:3 v/v) at λ ≥ 290 nm. This paper presents the structural elucidation of the photoproduct $C_8H_3Cl_4NO$ (**2**) arising from pentachlorophenol (**1**) in aqueous acetonitrile along with the proposed mechanisms for the formation and mass fragmentation pattern of compound **2**.

Experimental

(a) Substrates and solvents

Pentachlorophenol (P_5CP) (**1**) and 1,2,3,4-tetrachlorobenzene (internal standard) were supplied by Aldrich Chemical Co., Inc. Solvents such as methanol and *n*-hexane were purchased from Caledon Laboratories Ltd., Ont., Canada, while spectrograde acetonitrile was supplied by Aldrich Chem. Co., Inc. The source of water was same as previously described (23).

(b) Preparation of solution of P_5CP (1) in water-acetonitrile (2:3)

A stock solution of P_5CP (**1**) was prepared by heating 0.7 g **1** in 250 mL CH_3CN at 45°C and filtering through a medium porosity sintered glass filter. To 50 mL of the stock solution in a 500 mL volumetric flask, 250 mL acetonitrile were added. With continuous manual shaking, 200 mL water was then added to this diluted acetonitrile solution of **1**. The concentration of P_5CP (**1**) in H_2O–CH_3CN

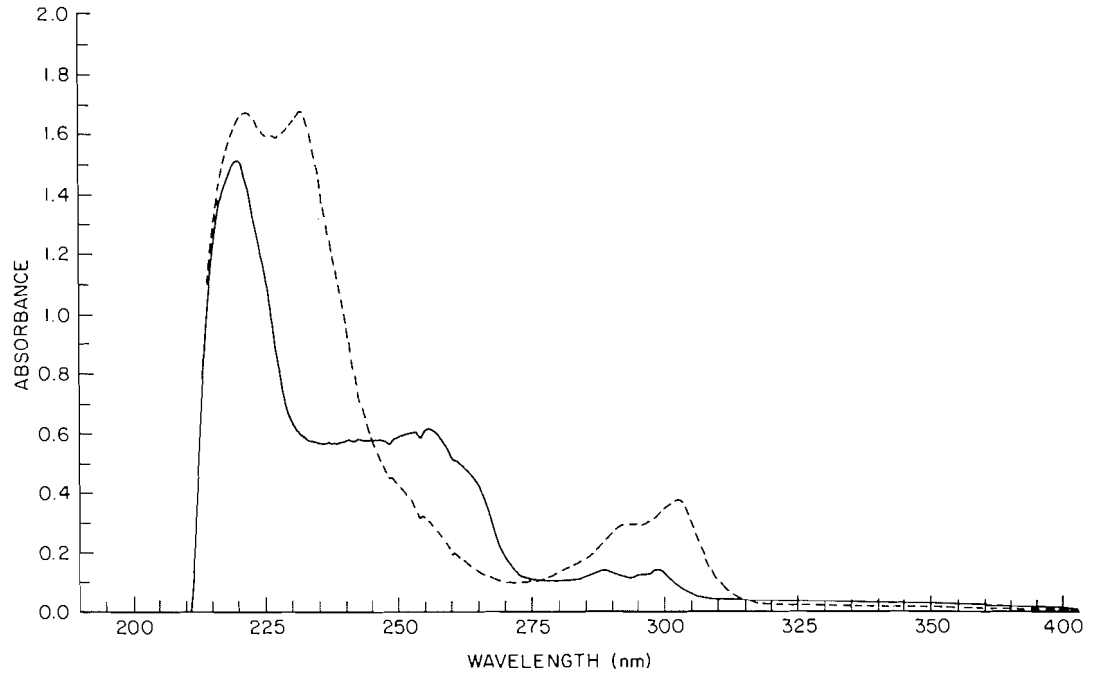

FIG. 1. UV absorption spectra of solutions of 0.25×10^{-3} *M* pentachlorophenol (**1**) (---) and 0.62×10^{-4} *M* 2-methyl-4,5,6,7-tetrachlorobenzoxazole (**2**) (—) in *n*-hexane.

(2:3 v/v) was determined by HPLC to be 1.000 m*M*; utilizing a 1.124 m*M* solution of **1** in methanol as an analytical standard. In this manner, 6.5 L of 1.00 m*M* solution of the starting material **1** was prepared in H_2O–CH_3CN (2:3 v/v).

(c) Irradiation experiments

The solution-phase photoreactions of pentachlorophenol in water–acetonitrile (2:3 v/v) were carried out using previously reported (22–25) Rayonet Photochemical Reactor (The Southern New England Ultra Violet Company) equipped with 16 RPR-3000 Å lamps having an energy output of 90% in the wavelength range 290 to 310 nm. In order to determine the optimum UV light photolytic exposure time as well as the retention time of the desired photoproduct $C_8H_4Cl_3NO$ (**2**) from **1**, analytical scale photolysis experiments were conducted in Pyrex glass tubes containing 2 mL sample solution each. On synthetic scale, 6.5 L of 1.000 m*M* solution of P_5CP (**1**) were photolyzed in 250 mL aliquots contained in a 1-litre Pyrex glass conical flask, photoreaction time for each aliquot being 30 h.

(d) High performance liquid chromatography (HPLC) analysis

The formation of the photoproduct **2** was monitored using a Waters Model 4000 HPLC equipped with Model 6000A pump, U6K injector, and an M440 UV absorbance detector. Separations were obtained with a 30 cm × 3.9 mm μBondapak C_{18} column (reverse phase). The UV detector wavelength used for these analyses was 254 nm. The photolyzates of P_5CP (**1**) were analyzed with the eluting solvent system CH_3CN–H_2O (3:2 v/v) at a flow rate of 1 mL/min. Under these conditions, the retention times of P_5CP (**1**), photoproduct $C_8H_3Cl_4NO$ (**2**), and 1,2,3,4-tetrachlorobenzene (internal standard) were 1.98, 15.30, and 18.65 min, respectively.

(e) Extraction and crystallization of the photoproduct $C_8H_3Cl_4NO$ (2)

The synthetic scale photolyzate (250 mL) of PCP **1** in H_2O–CH_3CN (2:3 v/v) was equally divided into two portions. Each portion was treated with 62.5 mL of 0.590 *M* aqueous solution of NaOH (the resultant pH being ≥12) and was subsequently extracted with 125 mL *n*-hexane. The *n*-hexane extracts of both portions of the photolyzate of **1** which contained the photoproduct $C_8H_3Cl_4NO$ (**2**) were evaporated to a few mL with a rotary evaporator and were then transferred to a 15 mL centrifuge tube. To this tube, similar *n*-hexane extracts of four additional 250 mL photolyzates of **1** were also added and the solvent was evaporated to dryness with nitrogen gas. The compound **2** was redissolved in the minimal amount of methanol by heating the centrifuge tube in a hot water bath maintained at 35°C. The conventional procedures were unsuccessful for crystallizing the product **2**. The technique and apparatus consisting of Teacup, sintered glass filter tubes, recrystallization Craig tubes, and centrifuge tubes, previously described by Martin-Smith (26) for the small scale crystallization of biological organic compounds, were utilized for crystallizing the photoproduct **2** from its methanolic solution.

The remaining 5250 mL of the photolyzate of PCP **1** in H_2O–CH_3CN (2:3 v/v) was also subjected to the above cited methods for the isolation and crystallization of the photoproduct $C_8H_3Cl_4NO$ (**2**). Total amount of the pure crystallin compound **2** synthesized photochemically from 6.5 L solution of P_5CP (**1**) (1.000 m*M*) was 0.01175 g thereby indicating that the chemical yield of **2** from phenol **1** was 0.667%.

(f) Melting point determination

Melting points for P_5CP (**1**) and $C_8H_3Cl_4NO$ (**2**) were 185–188 and 133°C; where as the literature values of such data were 188–191 (27) and 140.5–141.5°C (28) for **1** and 2-methyl-4,5,6,7-tetrachlorobenzoxazole (**2**) (designation of this structure to the compound $C_8H_3Cl_4NO$ **2** is discussed below), respectively.

(g) Spectroscopy

The spectroscopic instrumentations and techniques utilized for the elucidation of structure of the photolytic product $C_8H_3Cl_4NO$ (**2**), which was isolated in the crystalline form as cited above, are as follows:

(i) UV light absorbing

Light absorption spectra (Fig. 1) of the starting material **1** and the desired photoproduct **2** dissolved in *n*-hexane were recorded using Unicam Spectrophotometer. Quartz glass cuvets used were of 1-cm pathlength.

(ii) Infrared (IR)

Infrared spectrum (Fig. 2) of the product **2** in KBr was recorded on a Perkin Elmer 457 Grating IR Spectrophotometer.

(iii) Nuclear magnetic resonance (NMR)

All the NMR spectra of the compound **2** shown in Figs.3–5 were recorded on a Bruker AM-300 Spectrophotometer using tetramethylsilane (TMS) as an internal standard and $CDCl_3$ as a solvent. Chemical

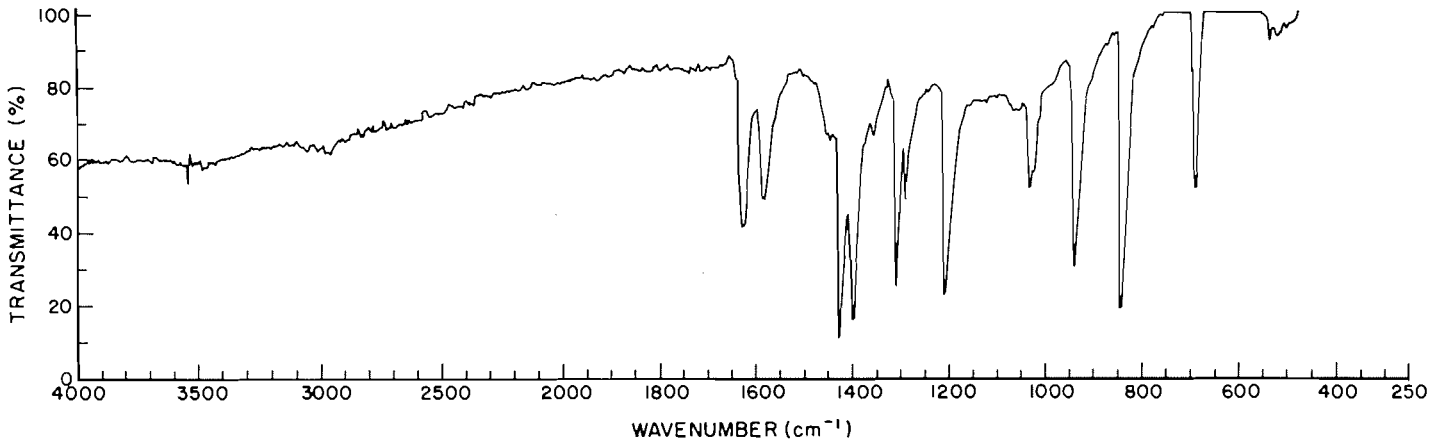

FIG. 2. IR spectrum of 2-methyl-4,5,6,7-tetrachlorobenzoxazole (**2**) in KBr.

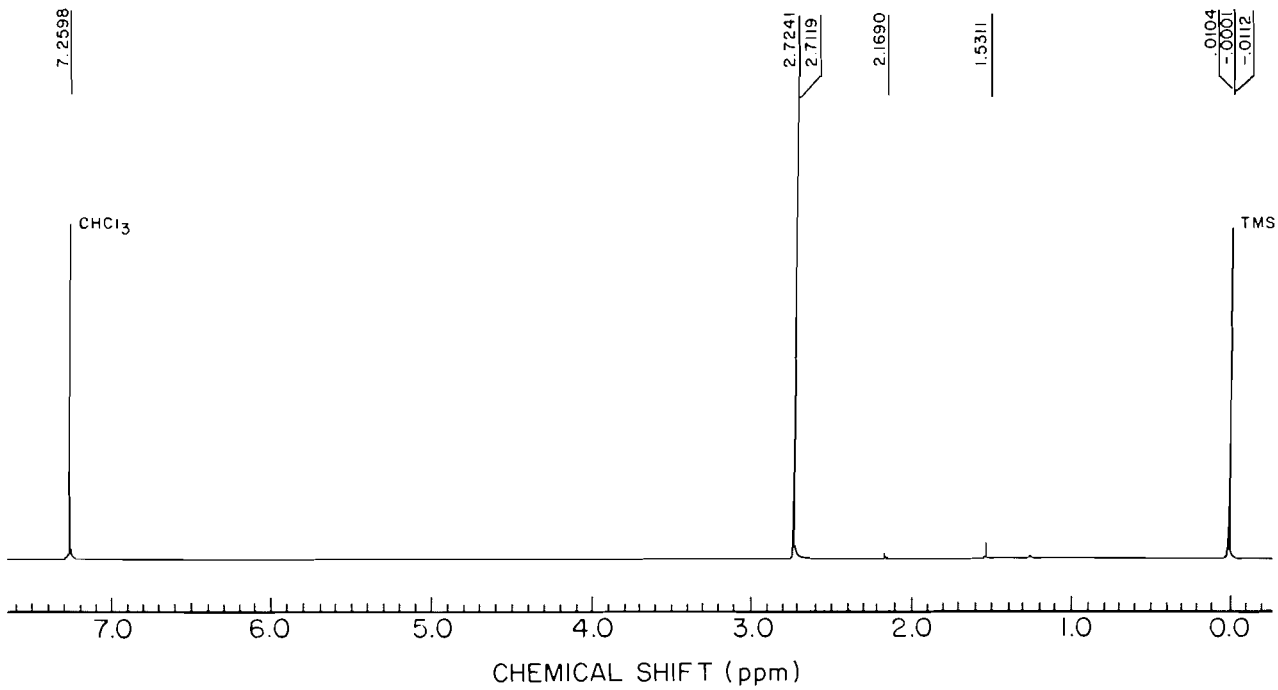

FIG. 3. ^{1}H-NMR spectrum (300.13 MHz) of 2-methyl-4,5,6,7-tetrachlorobenzoxazole (**2**) in deuterated chloroform.

shifts, quoted as δ values (units being ppm), were measured in relation to TMS.

The ^{1}H-NMR (Fig. 3) and ^{13}C-NMR (Figs. 4 and 5) spectra of **2** were run at 300.13 and 75.40 MHz, respectively. Due to the limited amount of **2** available, all NMR spectra were obtained by averaging multiscan runs; the total number of scans were 32, 2718, and 2048 in the case of ^{1}H-NMR (Fig. 3), proton-decoupled normal ^{13}C-NMR (Fig. 4), and proton-decoupled distortionless enhancement by polarization transfer (DEPT) sequence ^{13}C-NMR (Fig. 5), respectively.

The DEPT spectra of **2** (Fig. 5) were recorded by the techniques recently published by Doddrell and co-workers (29). The spectra (*a*), (*b*), and (*c*) (see Fig. 5) were determined with pulse (θ) of values $\pi/4$, $\pi/2$, and $3\pi/4$, respectively. In these DEPT spectra, which are the consequence of the transfer of polarization of protons to C, signals from non-protonated carbon atoms did not appear. It should be pointed out that in the context of polarization transfer ^{13}C-NMR spectroscopy, the DEPT sequence overcomes several important limitations of the INEPT (insensitive nuclear enhanced polarization transfer) pulse sequence (29). The technique of INEPT was originally developed by Morris and Freeman (30), and later was modified and used by several investigators (cf. refs. 31, 32).

(h) Gas chromatography – mass spectrometry

A Hewlett-Packard 5894 A gas chromatograph mass spectrometer (GC–MS) operating in the electron-impact mode at 70 eV was utilized for recording the mass spectrum (MS) of $C_8H_3Cl_4NO$ compound (**2**) (Fig. 6). Other conditions for the operation of this GC–MS were the same as previously described by Choudhry *et al.* (22).

Results and discussion

Spectroscopic analysis of the product $C_8H_3Cl_4NO$ (2)

The pure crystalline 2-methyl-4,5,6,7-tetrachlorobenzoxazole (**2**) (structure assigned to the compound $C_8H_3Cl_4NO$ **2** as discussed below), synthesized on large scale by photolyzing P_5CP (**1**) in water-acetonitrile (2:3 v/v), viz., reaction [1] was subjected to several analytical methodologies. Figures 1–5 record UV absorption, IR, FT 300 MHz ^{1}H-NMR, normal proton decoupled FT 75 MHz ^{13}C-NMR, and DEPT sequence proton decoupled FT 75 MHz ^{13}C-NMR spectra of benzoxazole **2**, respectively. Previously reported electron impact mode MS of compound **2** is reproduced in Fig. 6.

[1] 
1 **2** ~1%

The comparison of UV spectrum of oxazole **2** with phenol **1** shows that the photoproduct **2** has acquired absorption maxima (λ_{max}) at 219, 253, 255.5, 261, 288.5, 295, and 298.5 nm, the values of molar extinction coefficients (ϵ_λ) being 24516, 9839, 9919, 8145, 2177, 1936, and 2258 l mol^{-1} cm^{-1}, respectively. The IR spectral data of **2** in KBr (see Fig. 2) provide the evidence for the possible presence of CH_3 (absorption at 2980 cm^{-1} (w)), aromatic C=C and C=N (1630 (m), 1590 (m) cm^{-1}), conjugated C—O (1310 (s), 1290 (m), 1210 (vs), 1034 (m), 1025 (m) cm^{-1}), and aromatic C—Cl (692 cm^{-1} (m)) groups in the product **2**. The symbols such as w, m, s, and vs shown in the parentheses indicate weak, medium, strong, and very strong intensity of the peaks, respectively.

The interpretations of ^{1}H- and ^{13}C-NMR spectra of tetrachlorobenzoxazole **2** are documented in Table 1. The presence of CH_3 group is also evident from the ^{1}H-NMR spectrum of the product **2** (see Fig. 3), which possesses a peak with δ = 2.17 ppm. In this proton NMR, the other peaks at 0.00, 1.53, 2.72, and 7.26 ppm are attributable to the protons of TMS (added to the sample solution as an internal standard), water, acetone, and chloroform, respectively; the latter three chemicals being present as impurities in $CDCl_3$ used as dissolving solvent (Table 1, Section I).

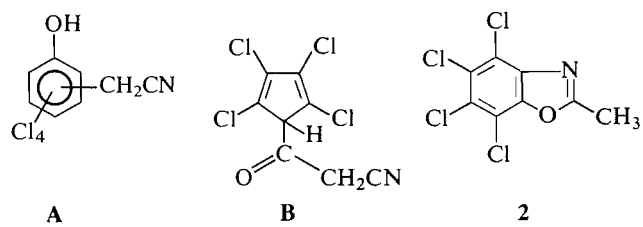
The normal proton decoupled ^{13}C-NMR spectrum of benzoxazole **2** (Fig. 4) displays, in addition to the resonance absorptions at 0.00 and 77.02 ppm due to the carbons of TMS and $CDCl_3$, respectively, eight carbon resonance absorptions arising from compound **2**. The interpretation of this spectrum, conducted with the aid of inductive effect theory and possible resonance structures of **2** (not shown herein), is included in Table 1 (Section II).

The proton decoupled DEPT sequence ^{13}C-NMR of **2**, which were recorded at 45°, 90°, and 135° pulse, are documented in Fig. 5. According to Doddrell and co-workers (29), the enhancement by polarization transfer in the case of methine (CH), methylene (CH_2), and methyl (CH_3) carbon will depend upon mathematical relations, viz. sin θ, sin 2θ, and sin θ + sin 3θ, respectively; whereby indicating that at $\theta = \pi/4$, methine, methylene, and methyl resonances should appear as positive (↑) signals. At $\theta = \pi/2$, only methine C resonance as positive signal should appear, and at $\theta = 3\pi/4$, methine and methyl C resonances should appear as positive signal, whereas methylene C resonance should appear as negative (↓) signal. Thus following these investigators (29), Fig. 5(*a*) records all protonated carbons, i.e., CH, CH_2 (if it is present), and CH_3 groups, while Fig. 5(*b*) provides only absorption due to CH group. Likewise, Fig. 5(*c*) is expected to display a negative absorption arising from the CH_2 carbon resonance (if it is present); whereas CH and CH_3 resonances have appeared as positive peaks. In conclusion, it is apparent from the DEPT sequence ^{13}C-NMR (Fig. 5) as well as from the Section III in Table 1, that only one sort of proton absorption is seen in Fig. 3, and that this absorption indicates the presence of methyl group in **2**.

Structural elucidation of the photoproduct $C_8H_3Cl_4NO$ (2)

Mass spectrum of the photoproduct **2** (Fig. 6) suggests that the molecular weight of this compound is 269 (calculated on the basis of fragments containing ^{35}Cl only), which is an odd number, thereby indicating that **2** contains an odd number of nitrogen atoms. Furthermore, in this MS, the ion clusters for the parent molecular ion ($M^{+\cdot}$) possess relative abundances characteristic of 4 Cl atoms (33). Thus a likely molecular formula for the compound **2** is $C_8H_3Cl_4NO$. Among several structures attributable to **2** of molecular formula $C_8H_3Cl_4NO$, the following ones are attractive to consider.

Structure **A**, namely hydroxytetrachlorophenylacetonitrile(s)



A **B** **2**

is (are) expected to be formed through the combination of the photolytically generated hydroxytetrachlorophenyl radicals from P_5CP (**1**) with $^{\cdot}CH_2$-CN species (which may have been generated via abstraction of H atoms from the cosolvent acetonitrile by intermediate free radical species). Structure **A** has been ruled out as described elsewhere (22). In addition this structure can also be rejected on the basis of its IR, ^{1}H-NMR, and ^{13}C-NMR spectral data (see Figs. 2–5 and Table 1) described above. In particular, DEPT sequence ^{13}C-NMR spectrum (Fig. 5) clearly provides evidence that CH_2 and CH units are absent.

TABLE 1. Proton and carbon-13 NMR spectral data of 2-methyl-4,5,6,7-tetrachlorobenzoxazole (**2**) in deuterated chloroform

I. 300 MHz ^{1}H-NMR spectral data[a]

Chemical shift, δ_H (ppm)	Protons
0.00	Protons of the CH_3 groups of tetramethylsilane (TMS) used as a reference compound
1.53	Protons of H_2O present as an impurity
2.17	Protons of the CH_3 groups of acetone present as an impurity
2.72	Protons of the CH_3 group of oxazole **2**
7.26	Proton of $CHCl_3$ present as an impurity in deuterated chloroform used as a solvent

II. 75 MHz ^{13}C-NMR spectral data[b]

Chemical shift, δ_C (ppm)	Carbon-13 atoms
0.00	Carbons of TMS used as a reference compound
14.59	Carbon of the methyl group of oxazole **2**
77.02	Carbon of the solvent $CDCl_3$
114.93	7-C of oxazole **2**
122.61	4-C of oxazole **2**
128.92	5-C of oxazole **2**
129.12	6-C of oxazole **2**
139.03	7a-C of oxazole **2**
146.67	3a-C of oxazole **2**
166.44	2-C of oxazole **2**

III. DEPT sequence 75 MHz ^{13}C-NMR spectral data[c]

Figure No. (type of carbons observed)	Chemical shift, δ_C (ppm)	Remarks
5a (All protonated carbons)	0.0	Signal from the protonated C of the TMS
	14.6	Signal from the protonated C of oxazole **2**
	77.4	Signal from the protonated C of the chloroform (an impurity in $CDCl_3$) (see below also)
5b (CH units only)	77.4	Signal from the CH unit of the chloroform present as an impurity in $CDCl_3$
5c (CH, CH_3 and CH_2 units)	0.0	The absence of a negative peak expected to originate from the CH_2 group indicates that the peak centered at 14.6 ppm δ_C is due to the protonated C of the methyl group of the oxazole **2** (compare these data with those of Figs. 5*a* and 5*b*)
	14.6	
	77.4	

[a]Spectrum is plotted in Fig. 3.
[b]Spectrum is mentioned in Fig. 4.
[c]Spectra are shown in Fig. 5.

Similarly, structure **B** (cyanomethyl 2,3,4,5-tetrachloro-2,4-cyclopentadien-1-yl ketone) for **2**, a product anticipated to be yielded through the pathways shown in reaction [2], can be ruled out due to the following reasons: (*a*) IR spectrum (Fig. 2) does not show any evidence for the presence of a carbonyl group, (*b*) ^{1}H-NMR spectrum (Fig. 3) displays only one type of protons, (*c*) DEPT sequence ^{13}C-NMR spectrum (Fig. 5) provides evidence for the absence of methine and methylene carbon atoms, and (*d*) MS does not show the expected losses of $^{\bullet}CH_2$—CN and O=Ċ—CH_2CN species from $M^{+\bullet}$. The rejection of the structure (**B**) evidently reflects that the ring contraction process,

$$\mathbf{4} \not\longrightarrow \mathbf{C}$$

does not occur in the present circumstances. However, it should be mentioned that previously Lemaire and his associates (16, 34, 35) during their photochemical investigations on 2-chlorophenol (in anionic form) have invoked the concept of 1,2-ketocarbene **4** (non-chlorinated) and its contraction to a five member ring, i.e. ketene (C) (non-chlorinated).

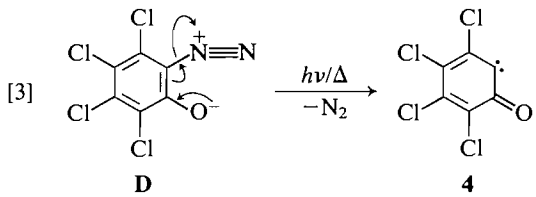
After discarding structures **A** and **B**, the most appropriate and logical structure, which can be assigned to the product $C_8H_3Cl_4NO$ is 2-methyl-4,5,6,7-tetrachlorobenzoxazole (**2**). As discussed above, the supporting facts from the spectral analysis are following: (*a*) IR spectrum (Fig. 2) shows absorption due to aromatic C—O, C=C, and C=N groups, (*b*) ^{1}H-NMR spectrum (Fig. 3) indicates resonance from only one type of proton CH_3 group, (*c*) Normal ^{13}C-NMR spectrum (Fig. 4) displays resonances from one aliphatic carbon and seven aromatic carbons, (*d*) DEPT pulse ^{13}C-NMR spectrum (Fig. 5) yields conclusive evidence for the presence of methyl carbon and the absence of methylene and methine carbons, and (*e*) MS (Fig. 6) reveals fragmentation pattern (discussed below) favoring structure **2**.

Mechanism for the photogeneration of 2-methyl-4,5,6,7-tetrachlorobenzoxazole (2)

The photoformation of 2-methyl-4,5,6,7-tetrachlorobenzoxazole (**2**) from pentachlorophenol (**1**) in water–acetonitrile (2:3 v/v) solution wavelength ~ 300 nm can be explained by the proposed Scheme 1. Accordingly, absorption of UV light by molecules of **1** would result in the production of 2-hydroxy-3,4,5,6-tetrachlorophenyl radicals (**3**) through the homolytic cleavage of the C—Cl bond at position 2 of compound **1** (step *i*), which subsequently would lose H atoms to yield 3,4,5,6-tetrachlorocyclohexa-3,5-diene-1,2-ketocarbene (**4**) (step *ii*). Another mechanism for the formation of carbenes **4** is discussed below (see reaction [6]). Nucleophilic attack of the cosolvent acetonitrile at position 1 of carbenes **4** accompanied by ring closure would then take place (step *iii*), thereby producing benzoxazole **2**. In addition, ketocarbenes **4** could yield the 1,3-dipolar species **4***a*, which could react with CH_3CN to give rise to oxazole **2** (step *iv*).

Evidence for the production of the intermediate 2-hydroxyphenyl radical **3** is provided by the appearance of the photoproduct 2,3,4,5-tetrachlorophenol (2,3,4,5-T_4CP) which is formed as the result of the abstraction of H atoms from the cosolvent and from other hydrogen donors by species **3** (22). Likewise, the intermediate involvement of the radical species **3** in the production of chlorinated 1,2-ketocarbenes **4** is supported by the fact that in H_2O–CH_3CN (2:3 v/v) the photolysis of 2,3,4,5-T_4CP did not yield product of the type **2**, i.e. $C_8H_4Cl_3NO$, while the other two tetrachlorophenols provided such products (22). It is noteworthy that the former CAP also did not yield 3,4,5-T_3CP anticipated to be formed through the photohomolysis of the C—Cl bond at position 2 and the subsequent abstraction of H atoms from the hydrogen donors (22). However, 1,2,4,5- and 1,3,4,5-T_4CP produced trichlorophenols via such photoprocesses, thereby revealing that 2-hydroxypolychlorophenyl radicals are key intermediates for the generation of 1,2-ketocarbenes and eventually of the benzoxazole type products. It should be mentioned that 1,3-dipolar cycloaddition of intermediate **4** and **4***a* species generated photochemically and thermally from 3,4,5,6-tetrachlorobenzene-2-diazo-1-oxide (**D**) (reaction [3]) to several nitriles



such as acetonitrile, benzonitrile, etc. is a well known phenomenon (28). When the photoreaction of **D** was carried out in CH_3CN, oxazole **2** was produced (28); these investigators analyzed **2** with the support of elemental analysis, melting point determination, and IR spectroscopy.

Moreover, Husigen and co-workers (28) reported that 2-methoxy-3,4,5,6-tetrachlorophenol is formed, when chemical D is subjected to photolysis in CH_3OH; the final product being the consequence of the nucleophilic attack of the solvent on the intermediates **4** (see reaction [3]). Thus in our present studies 3,4,5,6-tetrachlorocatechol is expected to be yielded via the chemical reactions of intermediate species **4** and **4***a* with water. However, as reported earlier (22), among the photoproducts of **1** in H_2O–CH_3CN (2:3 v/v), tetrachlorocatechol as well as lower chlorinated catechols were not observed. The reason for the failure to detect such catechol(s) on GC–MS may be that these compounds face deep secondary photodegradation on the benzene nucleus (e.g. ref. 20). In the case of the pyrolytic reactions of the sodium salt of *o*-halogenophenoxides at 260°C leading to the generation of substituted dibenzo-*p*-dioxins, trapping of the intermediary substituted 1,2-ketocarbenes using sodium salts of phenol and benzene thioalcohol as well as benzamide is well known (see pp. 78–80 of ref. 3).

Furthermore, the likelihood that the molecules of **1** in the photoexcited state are converted into radical pairs, i.e. [(**3**) Ċl], which may be responsible for the formation of the ultimate photoproducts, is not ruled out. Such radical pairs may be generated within the solvent cage. Those which escape the solvent cage would yield reductively dechlorinated phenol as the primary product; whereas in the case of those pairs staying within the cage, conversion of radicals **3** into 1,2-ketocarbenes **4** would occur (see step *ii* in Scheme 1), the loss of H atoms from **3** being facilitated by the chlorine radicals present in the cage.

It is interesting to mention that in the past several authors have reported nucleophilic photosubstitution reactions of unsubstituted (36–39) and substituted (40–47) aromatic hydrocarbons in aqueous and non-aqueous organic solvents at $\lambda < 266$ nm. For example, Lemmetyinen *et al.* (40) and Liu and Weiss (41) have demonstrated the intermediate involvement of radical cations (formed from the starting aromatic hydrocarbons) in the photohydrolysis and photocyanation of 4-chloro- and 4-fluoroanisole and 2-fluoroanisole, respectively. Likewise, Previtali and Ebbesen (42) observed the photo-ionization of chlorobenzene in polar solvents leading to the intermediate formation

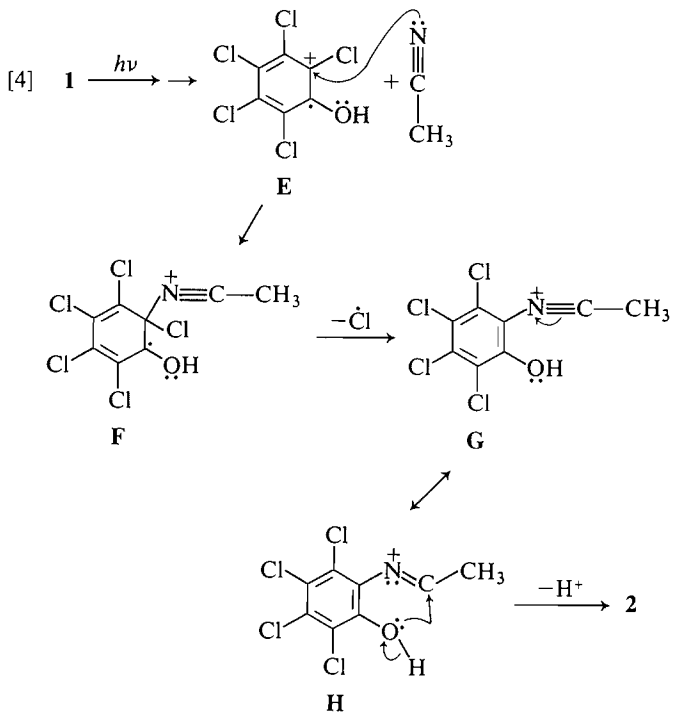
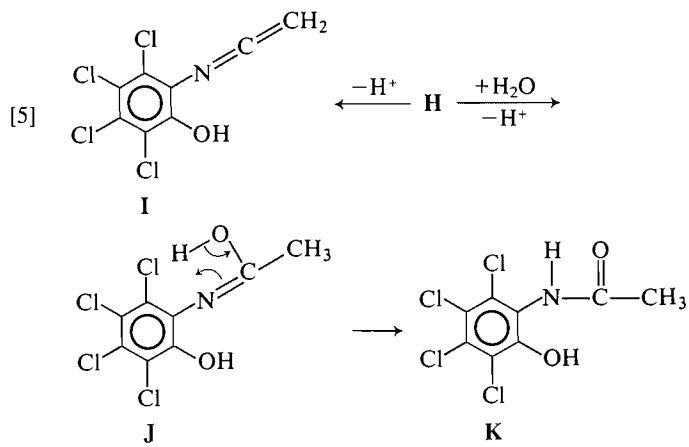
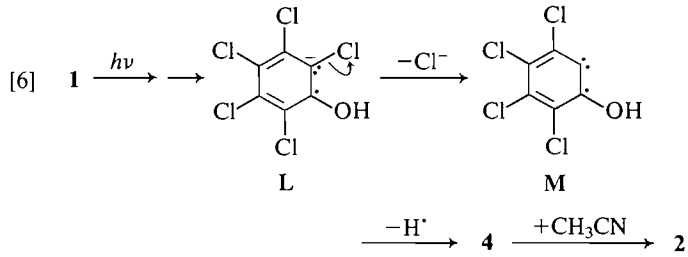
of radical cations during laser flash photolysis studies. Furthermore, Bunce and co-workers (36) have recently reported the mechanism of the photohydroxynitration of biphenyl by nitrate ions involving radical cation species. Thus, in the present studies, one may consider to invoke the intermediate involvement of tetrachloro radical cations, e.g., species **E** which might have undergone the nucleophilic attack of acetonitrile to yield the tetrachlorobenzoxazole **2** via the intermediates **F**, **G**, and **H** (see reaction [4]). However, this pathway for the photo-



generation of the oxazole **2** can be discarded due to the facts that the intermediate cation species **H** did not produce other photoproducts such as phenols **I** and **J** and **K** expected to be formed through the loss of H^+ ions from **H** and nucleophilic attack of water on **H**, respectively (reaction [5]).



Previously, Siegman and Houser (43) explained the photoproduction of 1,4-dimethoxybenzene from 4-chloroanisole in methanol by invoking the concept of the formation of radical anions from the substrate and radical cations from the solvents molecules as intermediates. Following these authors' (43) concept, an alternative plausible mechanism involving intermediary anion species, viz. **L** could be considered for the



photogeneration of the oxazole **2** from phenol **1** (reaction [6]). In reaction [6], the anions **L** may lose Cl^- ions to give species **M** which subsequently yield 1,2-ketocarbene **4** via the loss of H atoms and eventually producing **2**. Species **M** may also abstract H atoms from the solvent system to yield 2,3,4,5-tetrachlorophenol. Contrary to reaction [4], the anticipated reaction [6] would proceed via the ejection of Cl substituent prior to the introduction of the acetonitrile molecule (see discussion described above). We do not have any apparent argument to reject the mechanism shown in reaction [6].

Mechanistic interpretation of the MS of the benzoxazole 2

Table 2 records the *m/e* values of the fragments seen in the MS of the benzoxazole **2** along with their corresponding molecular formulae and sources. The mechanism given in Scheme 2 is proposed to explain the fragmentation pattern for the oxazole **2** upon electron impact. Loss of an electron from **1** would result in formation of carbonium radical ions **5** and **27**. Carbonium species **5** would lead to the oxonium radical ions **6**, which subsequently would undergo simultaneous ring contraction and expansion of the benzene and oxazole nuclei of **6**, respectively; whereby oxonium radical ions **7** would be produced. Alternatively, species **6** could be generated via the ejection of an electron from the non-bonding lone pair of electrons on the oxygen atom of **2** and the conversion of the resulting radical ions into **6** (not shown in Scheme 2). The oxonium radical ions **7** would then undergo scission of the appropriate C—C, C—O, C—N, and C—Cl bonds as well as 1,2-shift of chlorine substituents on the cation species leading to the generation of positively charged species **8**–**22** with the losses of molecular acetonitrile and radicals, viz. $^{\bullet}Cl$, Cl—$\dot{C}$=O, and $\ddot{C}$=O. In addition, positively charged species **23** and **24** together with **25** and **26** are yielded from carbonium radicals **5** through the respective loss of CH_3CN and chlorine radicals. Similarly, azonium radical species **29** are produced from carbonium radicals **27** via the intermediate species **28**; which then lose acetyl radicals to give rise to the formation of azonium carbenes **30**. Species **30** can be transformed into cations **31** and **32**. The processes depicted in Scheme 2 are supported by the fragmentation pattern in the mass spectrum of product **2**, although in this spectrum some fragments are of rather low relative intensity (Fig. 6).

Miscellaneous

Choudhry and Hutzinger (24) have also reported the photogeneration of compounds with empirical formulae $C_8H_5Cl_2NO$ and $C_8H_4Cl_3NO$ (two isomers of each) in the case of the UV irradiation of 1,2,3,4-tetrachlorobenzene and pentachlorobenzene in water–acetonitrile mixtures, respectively. Likewise, compounds $C_8H_5Cl_2NO$ (three isomers) and C_8H_6ClNO were also seen in the acetone-sensitized photolysis of 1,2,3,4-tetrachlorobenzene in aqueous acetonitrile; whereas, such photoreaction of 1,2,3,5-tetrachlorobenzene provided one isomer of $C_8H_5Cl_2NO$ (24). It can be speculated with the support of discussions given above that all these products are 2-methyl-

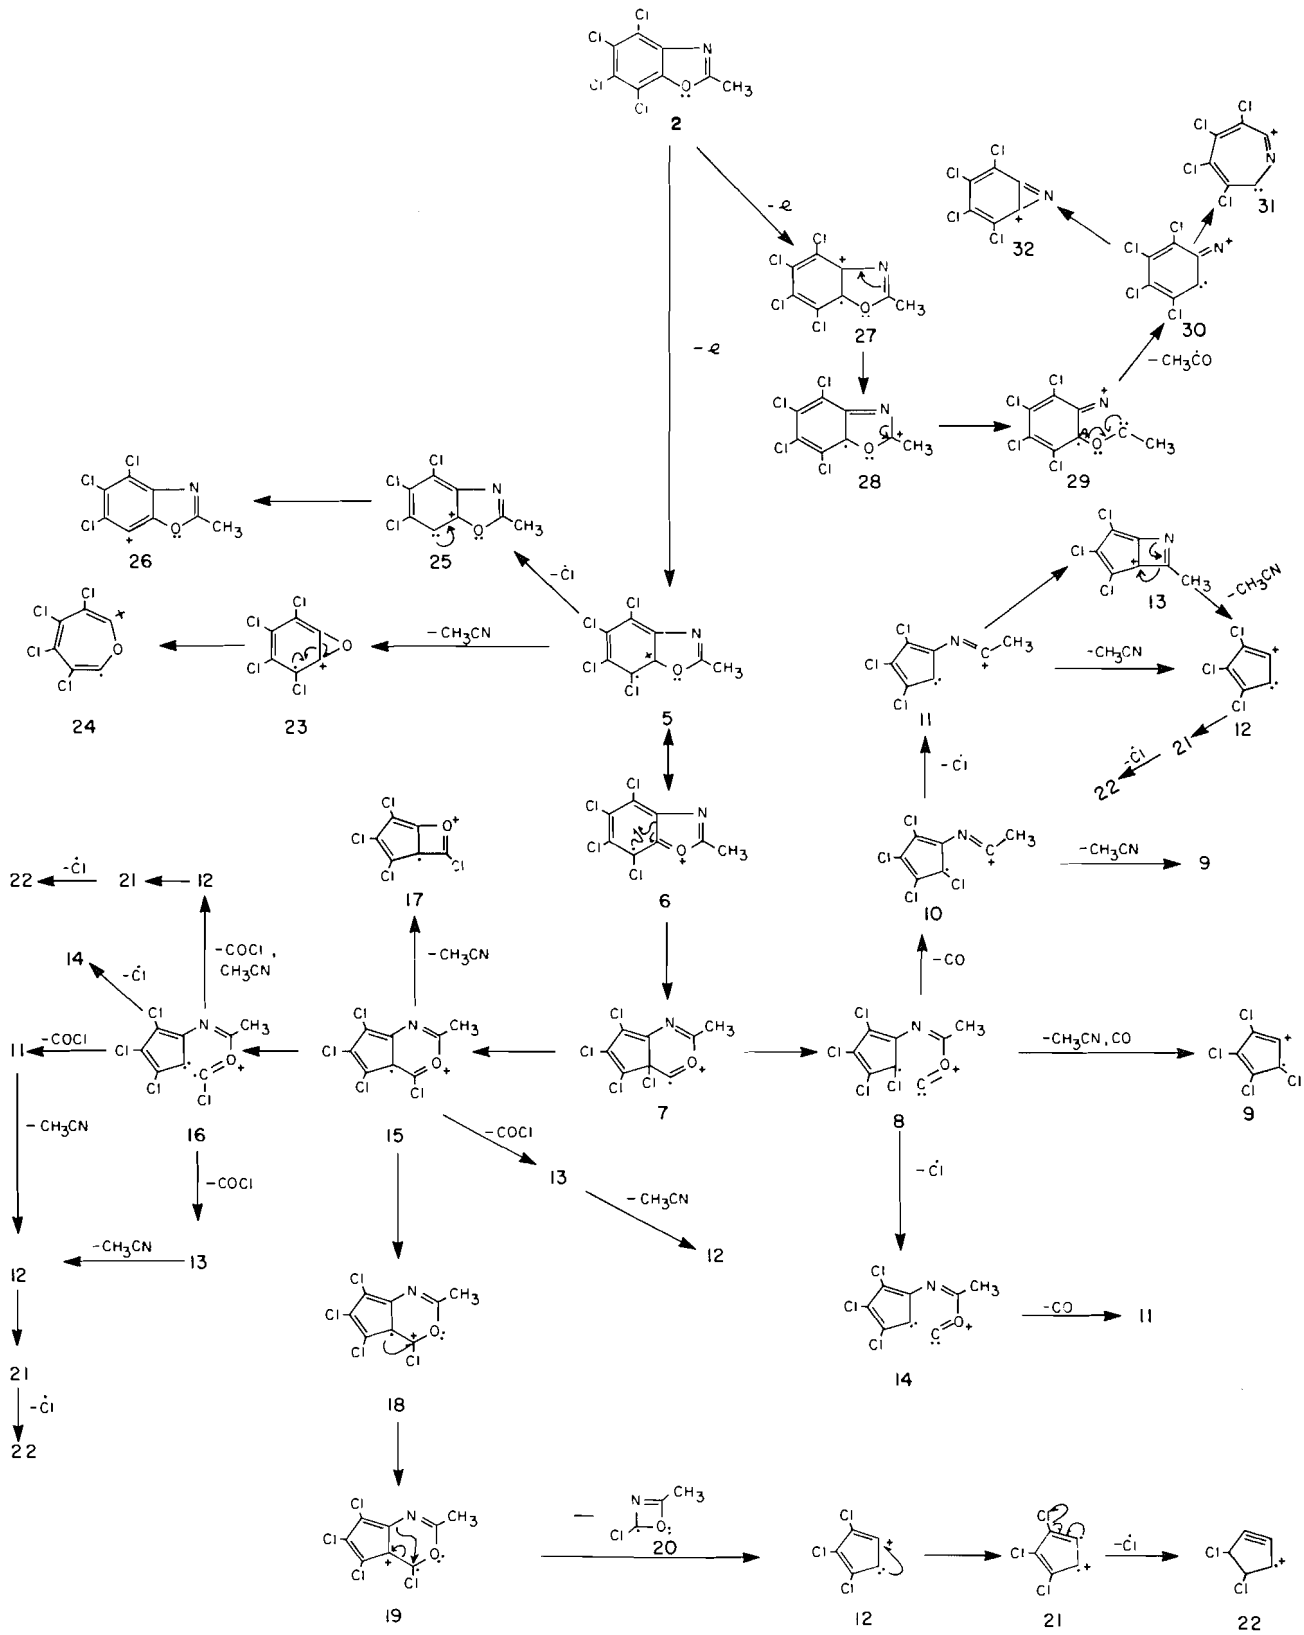

SCHEME 2

benzoxazoles having various numbers of chlorine substituents at the benzene nucleus presumably yielded via the secondary photoreactions of the appropriate polychlorophenols, which may be the photoproducts of the polychlorobenzenes.

The synthetic yield of photoproduct benzoxazole **2** from pentachlorophenol (**1**) was ca. 1% (see reaction [1]), thereby indicating that this photochemical process is undoubtedly of little synthetic applicability. However, it is notable that the analytical yield of oxazole **2**, calculated from the amount of photoconverted starting material **1**, was 11%, when 4.11 m*M*

solution of **1** in CH_3CN–H_2O (2:3 v/v) was exposed to UV light of $\lambda \geq 290$ nm for 6 h (22). Although natural water bodies contaminated with phenol **1** are not expected to contain acetonitrile which could result in the sunlight photolytic generation of oxazole **2**, the results of present and previous (22) investigations clearly reflect that other natural organics of similar or greater nucleophilicity to that of CH_3CN are likely to react with the intermediate species **4** and **4***a* produced from the sunlight photolysis of **1** in natural aquatic systems.

Finally, acetonitrile is strongly recommended and is therefore frequently utilized as cosolvent for investigations aiming for the determination of aquatic (photo)chemical fate of pesticides and other pollutants. Our results presenting the photoincorporation of cosolvent acetonitrile into pentachlorophenol (**1**) are of significant importance, which are anticipated to assist the investigators to interpret their experimental photolytic data in the context of photoproducts identifications.

Conclusions

Spectral data, especially NMR and MS, lead us to conclude that the compound $C_8H_3Cl_4NO$ (**2**) synthesized through the photolysis of pentachlorophenol (**1**) in H_2O–CH_3CN (2:3 v/v) at $\lambda \geq 290$ nm is 2-methyl-4,5,6,7-tetrachlorobenzoxazole. This photoproduct can only be yielded *if* the homolysis of the C—Cl bond at the *ortho* position with respect to hydroxy group on **1** has occurred; the resulting *o*-hydroxytetrachlorophenyl radicals play a key role of utmost importance for the reaction leading to the eventual generation of benzoxazole **2**. In the environment, natural water bodies may contain several other nucleophiles which may react with the sunlight photolytically generated intermediate 1,2-ketocarbens (cf. structure **4**) and 1,3-dipolar species (cf. structure **4***a*) from CAPs, viz. polychlorophenols.

Determination of the intercarbonyl dihedral angle of 1,2-diketones by ^{17}O nmr

HANS CERFONTAIN,[1] COR KRUK, ROEL REXWINKEL, AND FRANK STUNNENBERG
Laboratory for Organic Chemistry, The University of Amsterdam, Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands

Received March 5, 1987

HANS CERFONTAIN, COR KRUK, ROEL REXWINKEL, and FRANK STUNNENBERG. Can. J. Chem. **65**, 2234 (1987).

This study describes a method using ^{17}O nmr to determine the intercarbonyl dihedral angle in a homologous series of seven 1,2-diketones. It is shown that the ^{17}O nmr shifts of the 1,2-diketones are linearly dependent on both the electron density at the oxygen atoms and the $n \rightarrow \pi^*$ excitation energy of the 1,2-diketo chromophore. Reduction of the overlap in the π system of the 1,2-diketo moiety leads to a gradual upfield shift of the ^{17}O nmr signal, due to the increase in both the π-electron density at the oxygen atoms q_O^π and the mean transition energy ΔE.

HANS CERFONTAIN, COR KRUK, ROEL REXWINKEL et FRANK STUNNENBERG. Can. J. Chem. **65**, 2234 (1987).

Cette étude décrit une méthode qui fait appel à la rmn du ^{17}O pour déterminer l'angle dièdre intercarbonyles dans un série homologue de sept dicétones-1,2. On démontre que les déplacements des dicétones-1,2 en rmn du ^{17}O dépendent d'une façon linéaire à la fois sur la densité électronique des atomes d'oxygène que sur l'énergie d'excitation $n \rightarrow \pi^*$ du chromophore dicéto-1,2. La réduction dans le recouvrement du système-π de la portion dicéto-1,2 conduit à un déplacement graduel vers les hauts champs du spectre rmn du ^{17}O; ce résultat provient d'une augmentation tant de la densité des électrons-π au niveau des atomes d'oxygène (q_O^π) que de l'énergie de transition moyenne (ΔE).

[Traduit par la revue]

Introduction

Since the first detection of the ^{17}O isotope in 1951 (1), there has not been much research towards direct application of ^{17}O in chemistry, compared to other nuclei like ^1H, ^{13}C, ^{31}P, and ^{19}F. This is partly caused by the very much lower natural abundance of the ^{17}O nucleus (0.037%) (2) but also by the more limited importance of ^{17}O in elucidation of chemical structures as compared with ^1H and ^{13}C. In the 35 years following its first nmr detection the techniques of measuring ^{17}O have improved enormously. Nowadays ^{17}O spectra are easily obtained, even of natural, i.e. ^{17}O non-enriched, compounds and the very large ^{17}O chemical shift range (800 ppm) compensates sufficiently for the inevitable line-broadening.

In this study we have used ^{17}O nmr measurements as a method for the conformational analysis of the 1,2-dicarbonyl chromophore in 1,2-diketones, with special reference to the intercarbonyl dihedral angle θ, i.e. the angle of twist around the C—C bond between the two carbonyl groups, defined in the Newman Projection of Fig. 1. So far the dihedral angles of 1,2-diketones were determined by time-consuming dipole-moment measurements (3) and very occasionally by crystallographic X-ray determination (4).

The origin of our interest in the 1,2-diketo chromophore stems from our photochemical studies of 1,2-diketones (5, 6), in particular by the observation that the photochemical behaviour of (cyclic) 1,2-diketones depends on the size of the dihedral angle of the 1,2-diketo chromophore.

^{17}O nmr chemical shifts

The local magnetic field B at a nucleus N is not the same as the applied magnetic field. As a result of electronic movements the nucleus is shielded and senses a magnetic field B, which differs from the applied field B^0 according to eq. [1] in which

$$[1] \quad B = B^0(1 - \sigma_N)$$

σ_N is the shielding constant for nucleus N. According to Pople (7) σ_N is the sum of three intramolecular contributions, viz. the local diamagnetic electron ring current term (σ_N^d), the term due to the paramagnetic anisotropic local electron effects (σ_N^p),

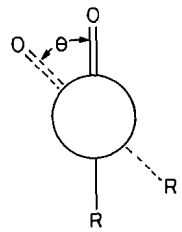

FIG. 1. Newman projection of the 1,2-diketo chromophore along the central C—C bond.

and the term accounting for the shielding effects caused by the neighbouring groups ($\Sigma\sigma_{NB}$):[2]

$$[2] \quad \sigma_N = \sigma_N^d + \sigma_N^p + \Sigma\sigma_{NB}$$

σ_N^d is always positive and works against the applied field, σ_N^p is negative and contributes to the applied field, while the other term can be positive or negative in sign. It has been established that the main term of σ_N for ^{17}O nmr is σ_N^p (8, 9). In the present series of symmetric 1,2-diketones θ covers the full range from 0 to 180°. Given the similarity of the environment of the 1,2-diketo moiety in the 1,2-diketones of the present study, the shielding effect $\Sigma\sigma_{NB}$ will be constant.[3] Accordingly, the first and third contribution to σ_N (cf. eq. [2]) will, in first approximation, be constant and the changes in the ^{17}O chemical shift will depend only on changes in the paramagnetic contribution σ_N^p as a result of variations in the dihedral angle θ. According to Karplus and Pople σ_N^p is determined by eq. [3]

$$[3] \quad \sigma_N^p = k(\Delta E^{-1})\langle r^{-3}\rangle_{2p_N}\{Q_{NN} + \Sigma Q_{NB}\}$$

(10, 11) in which k is a constant and $\langle r^{-3}\rangle_{2p_N}$ stands for the observable of the reciprocal cube of the mean radius of the $2p$ orbital on atom N which depends upon the actual charge on that

[1]Author to whom correspondence may be addressed.

[2]For the sake of simplicity the external contributions from solvents and other intermolecular interactions are neglected. The dependence of the ^{17}O chemical shift on the solvent was obviated by performing all the nmr experiments in the same solvent and at the same temperature.

[3]Camphorquinone (**8**) does not fit in this series. The asymmetrical methyl substituent in this molecule renders the two oxygens non-equivalent, as illustrated by two ^{17}O nmr signals.

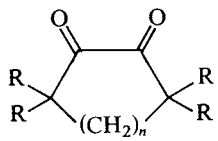
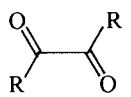
atom. The terms Q_{NN} and ΣQ_{NB} contain the bond orders of the *p* orbitals at atom N and the bond orders between the *p* orbitals of the atom in question and its neighbours B, respectively. For the homologous series of the present structurally related 1,2-diketones the term in parentheses is taken to be constant.[4] The most problematic factor in eq. [3] is the mean excitation energy ΔE. This arbitrary term is generally replaced by an average excitation energy and is in first approximation equal to the lowest excitation energy (12). For 1,2-diketones that transition is of $n\rightarrow\pi^*$ character and its energy varies strongly with variations in θ (3); the factor ΔE^{-1} can therefore not be taken to be constant (see also Discussion).

Results and discussion

The ^{17}O chemical shift data of the 1,2-diketones **1–7** have



1 *n* = 1, R = Me
2 *n* = 2, R = Me
3 *n* = 3, R = Me
6 *n* = 8, R = H



4 R = *t*-Bu
5 R = Me
9 R = H

been determined in dry acetonitrile as solvent at 70°C at natural abundance. The results are collected in Table 1. The ^{17}O signal shifts to higher field upon increasing θ from 0 to 90° to decrease again upon further increasing θ from 90 to 180° (Fig. 2A). Twisting of the π system of the 1,2-diketo chromophore away from coplanarity (θ = 0 or 180°) leads to a reduction of

[4]MNDO studies on glyoxal (**9**) as model compound showed that the terms Q_{NN} and ΣQ_{NB} are both independent of the dihedral angle θ. Upon varying θ (the selected values being 12, 42, 82, 122, and 158°), the charge at the oxygen atom changes, but the terms Q_{NN} and ΣQ_{NB} remain constant at values of 1.69 (sd 0.01) and 0.449 (sd 0.001), respectively.

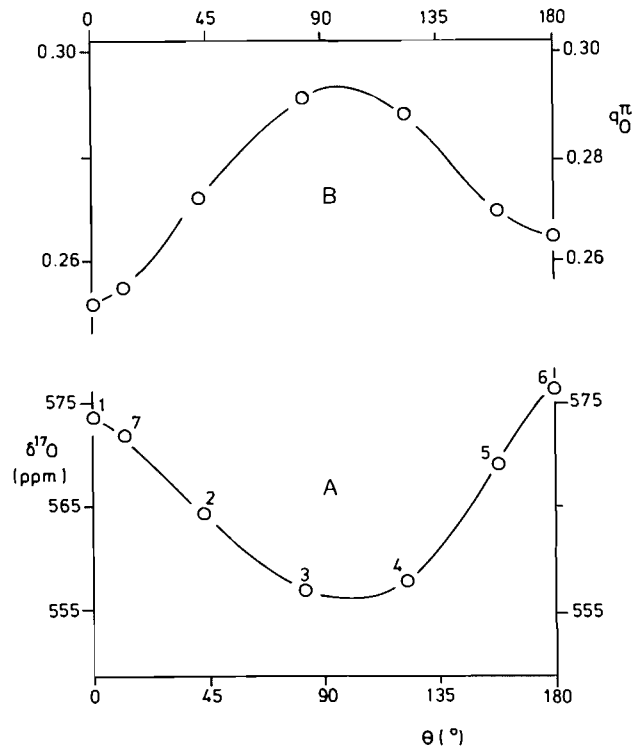

FIG. 2. Variation of $\delta\ ^{17}O$ of a series of 1,2-diketones (A) and of the MNDO calculated π-electron densities at the oxygen atoms of glyoxal (**9**) (B) with the dihedral angle θ of the O=C—C=O moiety.

the overlap integral S_{ij} of the central C—C bond and since —according to Mulliken's approximation (13)—the resonance integral H_{ij} is proportional to the overlap integral (eq. [4]),

[4] $S_{ij} = \langle\Psi_i|\Psi_j\rangle \sim \langle\Psi_i|H|\Psi_j\rangle = H_{ij}$

also to a reduction of the resonance integral. This is illustrated qualitatively in a simplified MO-scheme for the 1,2-diketo moiety (Fig. 3). The overlap integral S_{ij} is proportional to cos θ and, using (second order) perturbation theory, the resonance integral H_{ij} follows a $\cos^2\theta$ dependence (14). Thus at θ = 90° there is no interaction between the two C=O chromophores: they are degenerate.

[5] $S_{ij}(\theta) = S^0_{ij}\cos\theta$

[6] $H_{ij}(\theta) \simeq H^0_{ij}\cos^2\theta$

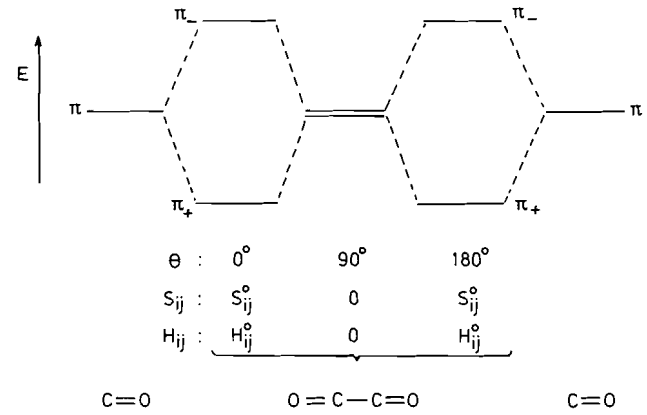

FIG. 3. Simplified MO-scheme for the π-MO's of the C=O and O=C—C=O chromophores: $\pi = \pi[\Psi_{CO}]$; $\pi_+ = \pi + \pi$; $\pi_- = \pi - \pi$.

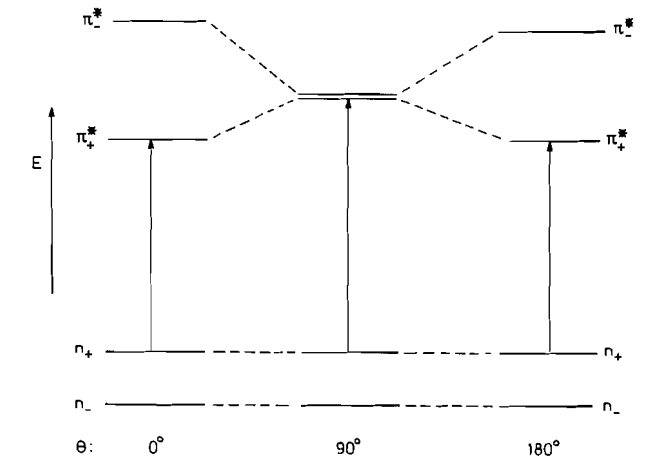

FIG. 4. Simplified MO-scheme of the 1,2-diketo chromophore at varying dihedral angles, illustrating the increase of $\Delta E(n \rightarrow \pi^*)$ upon twisting.

Changes in θ, and thus in both S_{ij} and H_{ij}, lead to a change in the electron density on the oxygen atoms q^{π}_{O}. This change has a dramatic effect on the chemical shift of the ^{17}O nucleus (15). An increase of the electron density on oxygen results in a spatial expansion of the 2*p* orbitals and this to a reduction of the term $\langle r^{-3} \rangle_{2p_N}$ in eq. [3]. A reduction in this term implies a reduction in the paramagnetic contribution to the shielding constant σ^{P}_{N} and thus an upfield shift of the ^{17}O resonance signal.

In order to obtain information on the effect of the π-electron density at the oxygen atom (q^{π}_{O}), the charge densities were calculated for glyoxal (**9**) as model compound, using semi-empirical SCF-MO calculations (the MNDO semi-empirical SCF-MO theory was developed by Dewar and Thiel (16)). The thus calculated π-electron densities at the oxygen atoms are shown in Fig. 2B as a function of θ. Clearly, the π-electron density at oxygen increases as the overlap in the π system decreases and *vice versa*. However, not only the term $\langle r^{-3} \rangle_{2p_N}$ in eq. [3] changes upon varying θ, but also the mean excitation energy ΔE is liable to depend on θ. For the series of the presently studied 1,2-diketones ΔE is not constant, as was sometimes assumed (for a discussion on the contribution of ΔE to the ^{17}O chemical shifts, see ref. 17), but varies considerably. Again, upon varying θ from both 0 and 180° to 90° the integral S_{ij} decreases to become zero at θ = 90°. The lowest vacant MO of the 1,2-diketo chromophore, which is a π* level (cf. Fig. 4),

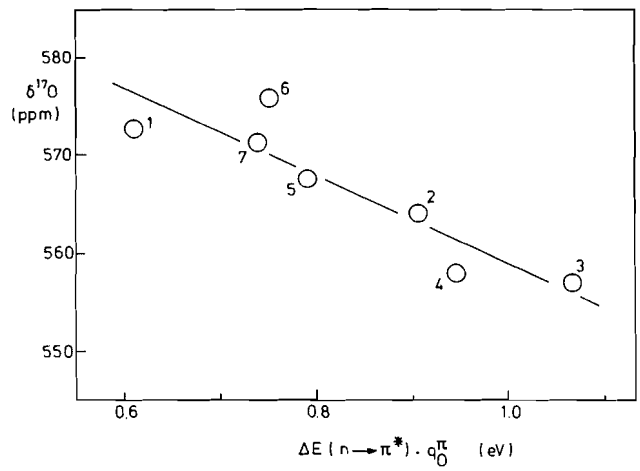

FIG. 5. Relationship between δ ^{17}O and $\Delta E(n \rightarrow \pi^*).q^{\pi}_{O}$ (n = 7, coefficient of correlation, $r = -0.90$).

increases in energy, while the highest occupied n-orbital is not affected.

The values of ΔE, calculated from the uv band maxima are compiled in Table 1. The effects of ΔE and q^{π}_{O} on σ^{P}_{N} (cf. eq. [3]) work in the same direction, both leading to an upfield shift due to the reduction in the overlap of the π system in the O=C—C=O chromophore. So, the relation between the product $\Delta E.q^{\pi}_{O}$ and the ^{17}O chemical shift should be linear, as is in fact observed (Fig. 5). The deviations from linearity are thought to be due in part to the use of uv-band maxima instead of the O–O transitions.

Performing least-square curve fitting methods on the data of the Figs. 2A and B give the best fits for a $\cos^4 \theta$ dependence for δ ^{17}O and a $\cos^2 \theta$ dependence for the π-electron density at the oxygen atoms with coefficients of correlation of 0.99 and −0.94, respectively. These results closely agree with the $\cos^2 \theta$ dependence for $\Delta E(n \rightarrow \pi^*)$, found theoretically (14), and support the linear relationship between δ ^{17}O and $\Delta E(n \rightarrow \pi^*).q^{\pi}_{O}$.

Experimental

The preparation of the 1,2-diketones was described before (5, 19). Homoadamantane-4,5-dione (**12**) was a gift from Philips Duphar B.V. The ^{17}O nmr spectra were recorded on a Bruker WM 250 spectrometer, operating at 33.905 MHz with a 10 mm broad band probe. The spectra were obtained at natural abundance on about 0.5 *M* solutions at 343 K in dry acetonitrile. The ^{17}O chemical shifts are relative to the absorption signal of water as external reference. The instrument settings are as follows: 25 kHz spectral width, 4K data points, 15 μs pulse width, corresponding to a 30° pulse angle, 82 ms acquisition time and no relaxation delay. The signal-to-noise ratio (s/n) was improved by a 25 Hz exponential broadening factor. Number of scans = 25 000. Data point resolution was improved by zero filling to 8K data points.

The dihedral angle of dodecane-1,2-dione (**6**) was obtained from Stuart molecular model studies (this method was described in ref. 18); the other values for θ were taken from ref. 3. The semi-empirical MNDO calculations (16) were performed on a DEC VAX 11/785 computer of the K. U. Nijmegen CAOS/CAMM calculating facility, using the QCPE Nr. 455 MOPAC program (20). The calculations were performed on glyoxal (**9**) as model compound for chosen fixed dihedral angles, using full geometry optimization.

Deuterium isotope effects on nuclear shielding constants and spin–spin coupling constants in the ammonium ion, ammonia, and water

RODERICK E. WASYLISHEN[1] AND JAN O. FRIEDRICH
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received April 1, 1987

RODERICK E. WASYLISHEN and JAN O. FRIEDRICH. Can. J. Chem. **65**, 2238 (1987).

Deuterium isotope effects on ^{15}N chemical shifts have been investigated for the ammonium ion, ammonia, and aniline; $^1\Delta^{15}N(^{2/1}H)$ equals −293.3, −622.9, and −714.6 ppb respectively. Deviations from additivity are noted for $NH_{4-n}D_n^+$ and $NH_{3-n}D_n$; these deviations follow the predictions of Jameson and Osten. For ammonia, examination of the proton nuclear magnetic resonance spectrum yields $^1\Delta^1H(^{15/14}N) = -2.0 \pm 0.4$ ppb and $^2\Delta^1H(^{2/1}H) \simeq -28.6$ ppb. An accurate value of -1545 ± 5 ppb was obtained for $^1\Delta^{17}O(^{2/1}H)$ in water. Derivatives of the heavy atom shielding constants with respect to extensions in the equilibrium bond length have been estimated for NH_4^+, NH_3, and H_2O; these derivatives are compared with the recent calculations of Chesnut. Deuterium isotope effects on $^1J(^{15}N,H)$ in ammonia and aniline have been measured for the first time. For the ammonium ion, deuterium isotope effects on $^1J(^{15}N,H)$ are in good agreement with the less accurate values we previously observed on $^1J(^{14}N,H)$. In the case of water, both primary and secondary deuterium isotope effects on $^1J(^{17}O,H)$ are less than 2%. The isotope effects on the spin–spin coupling constants observed here are compared with those previously reported for other hydrides in the literature.

RODERICK E. WASYLISHEN et JAN O. FRIEDRICH. Can. J. Chem. **65**, 2238 (1987).

On a étudié les effets isotopiques du deutérium sur les déplacements chimiques du ^{15}N dans l'ion ammonium, dans l'ammoniac et dans l'aniline; les valeurs des $^1\Delta^{15}N(^{2/1}H)$ sont respectivement égales à −293,3, −622,9 et −714,6 ppb. On a noté des déviations de l'additivité pour les antités $NH_{4-n}D_n^+$ et $NH_{3-n}D_n$; ces déviations suivent les prédictions de Jameson et Osten. Pour l'ammoniac, l'examen du spectre en résonance magnétique nucléaire du proton permet de déduire les valeurs suivantes; $^1\Delta(^{15/14}N) = -2{,}0 \pm 0{,}4$ ppb et $^2\Delta^1H(^{2/1}H) \simeq -28{,}6$ ppb. Dans l'eau, on a déterminé que la valeur précise de $^1\Delta^{17}O(^{2/1}H)$ est égale à -1545 ± 5 ppb. Pour le NH_4^+, le NH_3 et le H_2O, on a évalué les dérivés des constantes de blindage de l'atome lourd par rapport aux extensions de la longueur de la liaison à l'équilibre; on a comparé ces dérivés avec les calculs récents de Chesnut. On a aussi mesuré pour la première fois les effets isotopiques du deutérium sur les constantes $^1J(^{15}N,H)$ de l'ammoniac et de l'aniline. Dans le cas de l'ion ammonium, les effets isotopiques du deutérium sur la constante $^1J(^{15}N,H)$ sont en bon accord avec les valeurs beaucoup moins précises que nous avons observées sur la constante $^1J(^{14}N,H)$. Dans le cas de l'eau, les effets isotopiques du deutérium, tant primaire que secondaire, sur la constante $^1J(^{17}O,H)$ sont plus faibles que 2%. On a comparé les effets isotopiques sur les constantes de couplage spin–spin observées dans ce travail avec celles rapportées antérieurement dans la littérature pour d'autres hydrures.

[Traduit par la revue]

Introduction

Deuterium isotope effects on nuclear shielding constants have been actively investigated for more than 20 years. The results of this work have been summarized in three recent reviews (1–3). The following are some general observations pertinent to the present study.

1. Replacement of hydrogen by deuterium results in greater shielding of a neighbouring nucleus; the magnitude of this isotope shift depends on the remoteness of the nucleus from the site of isotopic substitution and the chemical shift range of the nucleus under observation.

2. To a very good approximation, isotope shifts are additive; that is, the magnitude of observed isotope shifts is generally directly proportional to the number of equivalent protons that have been replaced by deuterium.

One object of the present study was to determine whether $^{2/1}H$ isotope effects on ^{15}N and ^{17}O nuclear shielding constants in ammonia and water are strictly additive. Deuterium isotope effects in these molecules have been previously reported (4, 5); however, for ammonia the deviations from additivity were zero within experimental error. In the case of water only the value of $\sigma(H_2O) - \sigma(D_2O)$ is available (5).

The replacement of hydrogen by deuterium has provided a means of measuring spin–spin coupling constants between equivalent protons. For example, in ammonia, $^2J(H,D) = -1.54 \pm 0.12$ Hz (6); hence the value quoted for $^2J(H,H)$ is (γ_H/γ_D) (−1.54 Hz) or -10.0 ± 0.8 Hz. This procedure has recently been questioned by Raynes and co-workers (7–9), who argue that vibrational effects on J due to isotopic substitution may be significant. Recently Jameson and Osten (10) have summarized isotope effects on spin–spin coupling constants and provided an explanation for some of the observed effects. Unlike isotope effects on shielding constants, which are invariably of the same sign, isotope effects on J can be of either sign. For example, the primary isotope effect on J (defined by eq. [1]) is only positive in molecules where A has an electron lone pair.

$$[1] \quad {}^1\Delta_p{}^nJ(A,{}^{2/1}H) \equiv |{}^nJ(A,D)|(\gamma_H/\gamma_D) - |{}^nJ(A,H)|$$

Secondary deuterium isotope effects on J (defined by eq. [2])

$$[2] \quad \Delta_s{}^nJ(A,B) \equiv |{}^nJ(A,B)_D| - |{}^nJ(A,B)_H|$$

are also of either sign and at this time there appears to be no simple criterion for predicting the sign of Δ_s in a particular molecule. A second objective of the present study was to provide further accurate experimental data of isotope effects on J in a few relatively simple molecules and determine if the reuslts are consistent with the general trends recently summarized in ref. 10.

Theory

Here we will use the notation introduced by Gombler (11) and used extensively by Jameson and Osten (3). The isotope shift observed for a nucleus A upon substitution of a hydrogen by

deuterium is expressed by eq. [3],

$$[3]\quad {}^{n}\Delta A(^{2/1}H) = \sigma^{A}(A—{}^{1}H) - \sigma^{A}(A—{}^{2}H)$$

where n is the number of bonds between A and the position of substitution. Jameson and Osten (12–14) have shown that one-bond isotope shifts can be estimated using eq. [4],

$$[4]\quad {}^{1}\Delta A(^{2/1}H) \simeq (\partial\sigma^{A}/\partial\Delta r_{AH})_{e}\Delta_{H}$$

where $(\partial\sigma^{A}/\partial\Delta r_{AH})_{e}$ is the shielding derivative of A with respect to bond extension at the site of substitution. This derivative is generally negative (3, 15, 16) and independent of mass. The last term in eq. [4] is the *difference* in the mean bond displacement between the light isotopomer and the heavy isotopomer and is often referred to as the dynamic factor (12). For a single substitution of an end hydrogen the dynamic factor is given by eq. [5] (13),

$$[5]\quad \Delta_{H} = [\langle\Delta r_{AH}\rangle - \langle\Delta r_{AD}\rangle] \simeq \langle\Delta r_{AH}\rangle\tfrac{1}{2}((m_{D} - m_{H})/m_{D})(m_{A}/(m_{A} + m_{H})) \simeq \tfrac{1}{4}\langle\Delta r_{AH}\rangle$$

For hydrides the mean bond displacement, $\langle\Delta r_{AH}\rangle$, will depend on A but is in the range of 15–21 $\times 10^{-3}$ Å (14). A more complete analysis of isotope shifts is generally difficult because one must consider differences in mean bond angle deformations $\langle\Delta\alpha\rangle$ and terms such as $\langle(\Delta\alpha)^2\rangle$ and $\langle(\Delta r)^2\rangle$ (3, 17, 18).

In the special case of highly symmetrical molecules such as a simple tetrahedral molecule or ion, AH_4, Jameson and Osten (3, 13) have shown that the isotope shift is given by eq. [6],

$$[6]\quad \sigma^{A}(AH_{4-n}D_{n}) - \sigma^{A}(AH_{4-n'}D_{n'}) = (\partial\sigma^{A}/\partial\Delta r_{AH})_{e}[(n' - n)\Delta_{H} + \delta(n) - \delta(n')]$$

where δ is a secondary effect related to the extent a bond is perturbed by isotopic substitution in an adjacent bond. Because the difference, $\delta(n) - \delta(n')$, is much less than Δ_{H}, isotope shifts generally show small deviations from additivity. Detailed analysis indicates that for the series AH_4, AH_3D, AH_2D_2, AHD_3, and AD_4 deviations from additivity should be in the ratios 0:3:4:3:0 (13). In the case of A ≡ carbon, Bigeleisen and Goldstein (19) have shown that deviations in the zero-point energies vs. n are also in the ratios 0:3:4:3:0.

Isotope effects on spin–spin coupling constants can also be interpreted in terms of differences in dynamical averaging upon isotopic substitution (10). The primary isotope effect on the one-bond coupling constant is given by eq. [7],

$$[7]\quad \Delta_{p}{}^{1}K(A,^{2/1}H) = (\partial K/\partial\Delta r_{AH})_{e}[\langle\Delta r_{AD}\rangle - \langle\Delta r_{AH}\rangle] + \ldots$$

where ${}^{1}K$ is the reduced spin–spin coupling constant defined by eq. [8],

$$[8]\quad K(A,B) = 4\pi^{2}J(A,B)/h\gamma_{A}\gamma_{B}$$

and all other terms have been defined. Note that, as written, the dynamical factor in eq. [7] is negative.

Secondary isotope effects on spin–spin coupling constants are more complex and the interested reader should consult ref. 10.

Experimental

Nuclear magnetic resonance spectra were obtained at 20°C on a Nicolet 360 operating at a proton frequency of 361.05 MHz. All isotopically labelled compounds used in this study were obtained from Merck, Sharp and Dohme.

A 4 *M* aqueous solution of $NH_{4-n}D_{n}{}^{+}NO_{3}{}^{-}$ in 2 *M* HCl was prepared for ^{15}N nmr measurements; approximately 55% of the ammonium ions were ^{15}N labelled.

A sample of $NH_{3-n}D_{n}$ was prepared by mixing $^{15}NH_3$ and ND_3. The resulting mixture was dried over Na metal, distilled into a thick walled 10-mm o.d. nmr tube, and then sealed under vacuum.

Approximately 35% of the amino hydrogens of aniline-^{15}N were replaced by deuterium by adding a precalculated amount of D_2O to aniline-^{15}N. The solution was dried over solid KOH, and dissolved in chloroform-*d* containing 4A molecular sieves. The final concentration of aniline in chloroform was approximately 1 *M*; the sample was degassed and sealed in a 10-mm o.d. nmr tube.

A sample containing oxygen-17 labelled H_2O, HDO, and D_2O was prepared by mixing approximately 3 parts H_2O (20% ^{17}O) with 2 parts D_2O. A small quantity of this mixture was added to cyclohexane-d_{12}.

Results and discussion

1. $^{2/1}H$ isotope effects on ^{15}N and ^{17}O shielding constants

(a) ${}^{1}\Delta^{15}N(^{2/1}H)$ in the ammonium ion, ammonia, and aniline

Deuterium/proton isotope effects on the ^{15}N chemical shifts in the ammonium ion, ammonia, and aniline are summarized in Tables 1–3 respectively. The ^{15}N nmr spectrum of $NH_{3-n}D_{n}$ is shown in Fig. 1. The isotope shifts, ${}^{1}\Delta^{15}N(^{2/1}H)$ in ammonia and aniline, −623 and −715 ppb/D, respectively, are more than twice the magnitude of the corresponding value (−293 ppb/D) in the ammonium ion. The relatively small isotope shift observed for the ammonium ion compared to that in ammonia apparently arises primarily because of the reduced electron density about the nitrogen nucleus of $NH_4{}^{+}$. If one assumes that eqs. [4] and [5] apply we obtain $\partial\sigma(N)/\partial\Delta r_{NH}$ values of −60 and −124 ppm/Å for $NH_4{}^{+}$ and NH_3, respectively. These values are in excellent agreement with theoretical values of −67.9 and −130.3 ppm/Å recently reported by Chesnut (15). In the above calculations we have used Δr_{NH}

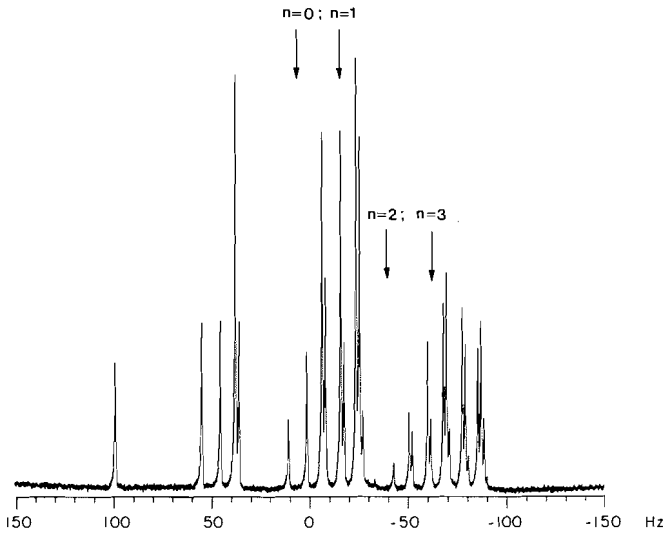

FIG. 1. Nitrogen-15 nmr spectrum of neat $NH_{3-n}D_n$ at 36.585 MHz.

values of 20.34×10^{-3} Å (12) and 20.2×10^{-3} Å (18) for the ammonium ion and ammonia. The good agreement in the experimental and theoretical shielding derivatives suggests that terms involving partial derivatives of σ with respect to changes in bond angle, such as $\partial\sigma/\partial\alpha$, must make a small contribution to $^1\Delta^{15}N(^{2/1}H)$. Recently calculations of Chesnut and Foley (16) also indicate that the bond angle derivatives in ammonia are relatively small.

The second point evident from the data in Tables 1–3 is that the isotope shifts in the ammonium ion and ammonia are *not* perfectly additive. Although we previously observed non-additivity in the ^{14}N chemical shifts of the ammonium ion (20) the ^{15}N results in Tables 1 are slightly more accurate. Deuterium isotope shifts on nitrogen shielding in the ammonium ion have been previously reported by numerous workers (21–24); however, due to the experimental errors, deviations from strict additivity were not observed. As mentioned in the theoretical section, Jameson and Osten (13) predict that the deviations from perfect additivity in $AH_{4-n}D_n$ should be in the ratio 0:3:4:3:0, in excellent agreement with our experimental results. For stannane, $SnH_{4-n}D_n$, we recently found that the deviations from strict additivity are also in the ratio 0:3:4:3:0 (25). Deviations from perfect additivity have not been observed in an earlier ^{15}N nmr study of ammonia (4). Following the arguments of Jameson and Osten (13) the ratio of the deviations in $AH_{3-n}D_n$ should be 0:1:1:0, in excellent agreement with the observations in Table 2. Any deviations from strict additivity in aniline are too small to be observed. We would like to point out that in the case of aniline we observed all three species, ϕNH_2, ϕNHD, and ϕND_2, in the same solution under conditions of slow exchange; previous workers (24) have utilized coaxial tubes to observe separate resonance signals for ϕNH_2 and ϕND_2.

(b) $^1\Delta^{17}O(^{2/1}H)$ in water and the hydronium ion

A part of the ^{17}O nmr spectrum of the various isotopomers of water immersed in cyclohexane-d_{12} is shown in Fig. 2. This portion of the spectrum is attributed to cyclohexane-solvated water molecules. If water clusters (e.g., dimers or trimers) are responsible for this part of the ^{17}O nmr spectrum it is clear that O—H and O—D exchange is relatively slow since $\nu_{1/2}(^{17}O) <$ 4 Hz. At about 14.8 ppm to high frequency of the $H_2{}^{17}O$ resonance shown in Fig. 2 we observed a broad intense peak

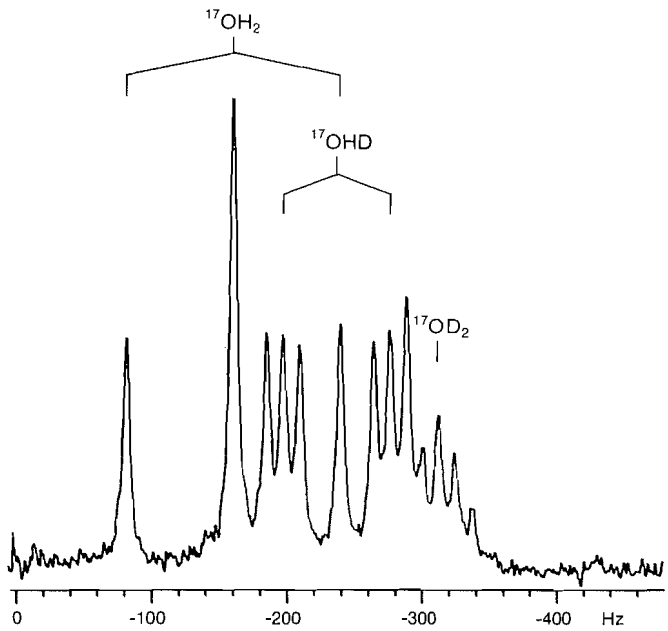

FIG. 2. Oxygen-17 nmr spectrum of $H_{2-n}D_nO$ dissolved in cyclohexane-d_{12} at 48.946 MHz.

NHD_2	−56.28	−61.33	−1.43 (−9.35)

[a] The protons of $^{14}NH_3$ resonante at 2.0 ± 0.4 parts per billion to high frequency of those in $^{15}NH_3$; i.e., $^1\Delta^1H(^{15/14}N) = -2.0 \pm 0.4$ ppb.

[b] In parts per billion (±0.05) relative to NH_3; negative shifts are to low frequency (high field).

[c] In Hz (±0.02), values in brackets are $^2J(H,H) = 6.51440\ ^2J(H,D)$.

($\nu_{1/2} \simeq 140$ Hz), not shown, which is attributed to suspended drops of water (water-solvated water). A similar observation for water immersed in CCl_4 has been reported by Mateescu and Benedikt (26). The downfield shift (high frequency) with increased association is consistent with the direction of the gas to liquid shift observed for H_2O, but is only about half this value, +36 ppm (5*b*, 27).

The total isotope shift that we observe for water, −3.090 ± 0.005 ppm (i.e., $^1\Delta^{17}O(^{2/1}H) = 1.550$ ppm/D, see Table 4) is in excellent agreement with the early value of Lutz and Oehler (5*a*), −3.08 ± 0.2 ppm, and the recent value of −2.9 ppm of S. Aime *et al.* (28). The value of Lutz and Oehler (5*a*) was obtained by measuring the ^{17}O resonance of various D_2O/H_2O mixtures, while the value of S. Aime *et al.* (28) was determined

by simultaneously measuring the ^{17}O resonance of D_2O and H_2O in concentric 5- and 10-mm nmr tubes. Interestingly, the isotope shift we measured in cyclohexane is within experimental error of the values reported in aqueous solution but substantially smaller than the gas-phase value of 4.04 ± 0.35 ppm (5*b*).

Mateescu *et al.* have apparently measured $^1\Delta^{17}O(^{2/1}H)$ values for H_2O and H_3O^+; however, only their value for the hydronium ion has been reported in the literature (29), $^1\Delta^{17}O(^{2/1}H) = -0.3$ ppm/D. Using $\langle \Delta r_{OH} \rangle = 20.0 \times 10^{-3}$ Å for both H_2O (18) and H_3O^+ we calculate $\partial\sigma(O)/\partial\Delta r$ values of −296 and −60 ppm/Å, respectively. The value of $\partial\sigma(O)/\partial\Delta r$ obtained for water is essentially the same value obtained by Osten and Jameson (18) and is in good agreement with values of −270.9 ppm/Å (30) and −267 ppm/Å (15, 16) calculated using molecular orbital theory. Qualitatively, the smaller magnitude of the isotope shift and of $\partial\sigma(O)/\partial\Delta r$ observed for H_3O^+ compared to H_2O can be accounted for in terms of the charge density argument used to account for differences between NH_4^+ and NH_3 (15). It is of interest to point out that we also observed very small isotope shifts in the stannonium cation, $^1\Delta Sn(^{2/1}H) = -0.05$ ppm/D compared to a value of $^1\Delta Sn(^{2/1}H) = -0.403$ ppm/D for stannane (25).

Finally, the much larger negative value of $^1\Delta O(^{2/1}H)$ observed for water compared to the value of $^1\Delta N(^{2/1}H)$ observed for ammonia is part of a general trend for all hydrides, AH_n. As one moves across any row of the periodic table the isotope effect, $^1\Delta A(^{2/1}H)$, becomes more negative because of the behaviour of $\partial\sigma(A)/\partial\Delta r$ (15).

2. *The ^1H nmr spectrum of $^{15/14}NH_{3-n}D_n$*

The proton nmr spectrum of $^{15/14}NH_{3-n}D_n$ is rather complex (Fig. 3) because it arises from the overlapping spectrum of six different isotopomers. For the three isotopomers containing ^{14}N ($^{14}NH_3$, $^{14}NH_2D$, and $^{14}NHD_2$) the main feature in each of their ^1H nmr spectra is a broad 1:1:1 triplet due to spin–spin coupling ($J \simeq 43.8$ Hz) with a rapidly relaxing ^{14}N ($I = 1$). This is a classic example of ^1H scalar relaxation (T_2) of the second kind (31). The principal feature in the ^1H nmr spectra of the three other isotopomers is of course a doublet due to $^1J(^{15}N,H)$. All isotope shifts and spin–spin coupling constants are summarized in Table 5.

We observed a very small isotope shift, $^1\Delta^1H(^{15/14}N) = -2.0 \pm 0.4$ ppb; this is within experimental error of the value recently observed in NH_4^+ (32), and is comparable to the value of $^1\Delta^1H(^{13/12}C)$, −2.4 ± 0.2 ppb (33), in methane. The value of $^1\Delta^1H(^{18/16}O)$ in water is approximately −12 ± 3 ppb (34); however, the fractional change in mass here is also larger. As well, $\partial\sigma(^1H)/\partial\Delta r$ shows increasing negative values on going from methane to water (15, 16).

The two-bond isotope shift, $^2\Delta^1H(^{2/1}H)$ shows small deviations from strict additivity; this was not evident in an earlier study (6).

The value of $^2J(H,D)$ in $^{15}NH_2D$, −1.475 ± 0.02 Hz, leads to a more accurate value of $^2J(H,H)$, −9.6 ± 0.2 Hz, compared

[b]These values of J involve ^{15}N and a hydrogen that is 1.02 Å from the central nitrogen atom. These values would correspond to J(N,D) γ_H/γ_D.

to the earlier result, −10.0 ± 0.8 Hz (6). The values of $^1J(^{15}N,H)$ obtained from the ^{1}H nmr spectrum are within experimental error of those measured in the ^{15}N nmr spectrum (see discussion to follow).

3. Isotope effects on J

Isotope effects on spin–spin coupling constants are generally difficult to measure because typically they are less than 0.5 Hz (10). Spin–spin coupling constants in the various isotopomers of the ammonium ion, ammonia, aniline, and water are summarized in Tables 6–9, respectively. Both primary and secondary isotope effects on $^1J(^{15}N,H)$ are apparent for the ammonium ion, ammonia, and aniline; however, for water Δ_p $^1J(^{17}O,^{2/1}H)$ and Δ_s $^1J(^{17}O,H)$ [$^{2/1}$H] are both less than the experimental error. In the case of hydrogen selenide, the primary and secondary deuterium isotope effects on $^1J(^{77}Se,H)$ are approximately 2.5 Hz (4%) and 1.0 Hz (1.6%), respectively (36); thus it is not surprising that isotope effects on J in water are not observed (*vide infra*).

For ammonia Δ_p $^1J(^{15}N,^{2/1}H)$ and Δ_s $^1J(^{15}N,H)$ [$^{2/1}$H] are 0.46 ± 0.13 Hz (0.75%) and −0.07 ± 0.02 Hz (0.11%), respectively. These primary and secondary isotope effects are of the same sign as those observed for phosphine (37); however, the values for ammonia are approximately an order of magnitude smaller than those observed for phosphine. Interestingly, the relative magnitudes of the $^{2/1}$H induced one-bond isotope effect on the ^{15}N and ^{31}P chemical shifts in these two molecules are comparable (37). The primary and secondary isotope effects on J(N,H) in aniline are within experimental error of those measured for ammonia.

Jameson and Osten found primary isotope effects to be positive in molecules where one of the coupled nuclei had one or more lone pairs; otherwise the primary isotope effect was negative (10). Thus for the ammonium ion one would expect Δ_p $^1J(^{15}N,^{2/1}H)$ to be negative; the observed value, however, appears to be positive, +0.28 ± 0.2 Hz. To determine whether or not a positive value is consistent with theory, we carried out semiempirical MO calculations at the INDO level of approximation (38). We assumed a tetrahedral geometry for NH_4^+ and carried out the finite perturbation calculations of $J(^{15}N,H)$ for five different combinations of N—H bond lengths. To simulate the effect of deuterium substitution we used an N—H bond length of 1.02 Å as opposed to 1.03 Å for a regular N—H bond. The results (Table 10) predict $^1\Delta_p$ $^1J(^{15}N,^{2/1}H)$ to be negative (−1.2 Hz) and the secondary isotope effect to also be negative (≃ −0.10 Hz) as observed (−0.07 ± 0.03 Hz). Although the actual values of these calculated isotope effects are not accurate we believe their calculated signs and relative magnitudes are relevant. The results of analogous semiempirical calculations for methane (39) agree with experimental (10). The ammonium ion also exhibits an unusual positive isotope shift $^2\Delta^1H(^{2/1}H)$ (32, 40), which has been attributed to intermolecular effects (32); also see ref. 24. It is likely that these effects are also responsible for the unexpected sign of Δ_p $^1J(^{15}N,H)$ in the ammonium ion.

In summary, our results indicate that in the first row hydrides,

For personal use only.

NH_4^+, NH_3, and H_2O substitution of hydrogen by deuterium results in a very small change in the average value of the various spin–spin coupling constants investigated in this study. Nevertheless, in comparing theoretical calculations of J with experiment it is important to consider the influence of vibrational averaging (see refs. 7–10, 41–43).

Terpenoid metabolites from skin extracts of the dendronotid nudibranch *Tochuina tetraquetra*

DAVID E. WILLIAMS AND RAYMOND J. ANDERSEN[1]

Departments of Chemistry and Oceanography, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received March 10, 1987

DAVID E. WILLIAMS and RAYMOND J. ANDERSEN. Can. J. Chem. **65**, 2244 (1987).

The skin chemistry of specimens of the dendronotid nudibranch *Tochuina tetraquetra* collected at Port Hardy and Bamfield, British Columbia, has been examined. Port Hardy animals yielded tochuinyl acetate (**1**) and dihydrotochuinyl acetate (**2**), two new cuparane sesquiterpenoids, as well as rubifolide (**3**) and pukalide (**4**), two previously known cembrane diterpenoids. Bamfield animals yielded the known briarein-type diterpenoid ptilosarcenone (**5**) and the previously unreported butanoate analogue **6**. The *T. tetraquetra* metabolites are sequestered from coelenterates in the nudibranch's diet.

DAVID E. WILLIAMS et RAYMOND J. ANDERSEN. Can. J. Chem. **65**, 2244 (1987).

On a étudié la chimie de la peau de spécimens de dendronotides nudibranches *Tochuina tetraquetra* recueillis à Port Hardy et Bamfield, Columbie britannique. Les animaux de Port Hardy fournissent de l'acétate de tochuinyle (**1**) et de l'acétate de dihydrotochuinyle (**2**), deux nouveaux sesquiterpénoïdes du cuparane, ainsi que du rubifolide (**3**) et du pukalide (**4**), deux diterpénoïdes antérieurement connus du cembrane. Les animaux de Bamfield fournissent la ptilosarcénone (**5**), un diterpénoïde connu du type de la briaréine, et l'analogue buténoate **6** qui était antérieurement inconnu. Les métabolites du *T. tetraquetra* sont séquestrés des coélentérates dans la diète de la nudibranche.

The cold temperate waters of coastal British Columbia are inhabited by more than 100 species of subtidal and intertidal nudibranchs (1). Many of these species are abundant and easily collected by SCUBA. We have found that the skin extracts of a number of British Columbia nudibranchs contain interesting secondary metabolites (2). The majority of the compounds isolated to date have been sesquiterpenoids or diterpenoids. We have also found that many of the metabolites are of dietary origin (3). A variation in skin chemistry from one collecting site to the next, reflecting a change in the nudibranch's diet, provides strong evidence for a dietary origin (3, 4). It has been shown by us and others that nudibranchs can sequester secondary metabolites, sometimes selectively, from dietary sponges (4), bryozoans (5), soft corals (6), and hydroids (7).

Tochuina tetraquetra is a large (up to 30 cm) orange-yellow dendronotid nudibranch that is commonly found from the Kuril Islands, USSR, to the Santa Cruz Islands, California (8). We have made collections of *T. tetraquetra* from two British Columbia sites and we wish to report the isolation of tochuinyl acetate (**1**), dihydrotochuinyl acetate (**2**), rubifolide (**3**), and pukalide (**4**) from Port Hardy animals, and the isolation of ptilosarcenone (**5**) and its butanoate analogue **6** from Barkley Sound animals.

Specimens of *T. tetraquetra* were collected by hand using SCUBA at depths of −3 to −15 m. Freshly collected whole animals were immersed in methanol as soon as they were brought to the surface. After extraction at room temperature for at least 48 h, the methanol was decanted, concentrated *in vacuo*, and partitioned between brine and ethyl acetate. The ethyl acetate soluble materials were fractionated by silica gel preparative tlc and reverse phase hplc to give pure metabolites.

Port Hardy animals

Tochuinyl acetate (**1**) was obtained as a colorless oil that gave a parent ion at m/z 260.1777 daltons in the EIMS, appropriate for a molecular formula of $C_{17}H_{24}O_2$ (deviation 0.0 mmu). A carbonyl stretching band at 1735 cm^{-1} in the ir, in combination with a methyl singlet resonance at 1.94 ppm in the ^1H nmr and a carbonyl resonance at 171.2 ppm in the ^{13}C nmr, identified an acetate residue. Additional methyl singlets at 1.13, 1.33, and 2.30 ppm in the ^1H nmr suggested that the remaining 15 carbon atoms of tochuinyl acetate were part of a sesquiterpenoid fragment.

The ^1H nmr resonances at 2.30 (s, 3H), 7.08 (d, J = 8 Hz, 1H), and 7.22 (d, J = 8 Hz, 1H) ppm, ^{13}C nmr resonances at 20.8 (CH_3), 126.7 (2CH), 128.6 (2CH), 135.3 (C), and 142.9 (C) ppm, and a ms fragment at m/z 91 (C_7H_7) were assigned to a 4-methylphenyl moiety. A pair of ^1H nmr signals at 3.36 (d, J = 11 Hz, 1H) and 3.59 (d, J = 11 Hz, 1H) ppm were assigned to the geminal protons of a tertiary acetoxymethyl group. The molecular formula of tochuinyl acetate required six degrees of unsaturation, which could be satisfied by the phenyl ring, the acetate carbonyl, and an additional carbocyclic ring.

Structure **1**, based on a cuparene sesquiterpenoid skeleton, effectively accounted for all the spectral features of tochuinyl acetate. Two SINEPT (9) experiments, optimized for polarization transfer through 7-Hz coupling, confirmed the proposed constitution. Irradiation of the methyl resonance at 1.13 ppm (Me15) showed transfer to carbon resonances at 34.8 (C10), 47.4 (C7 or C11), 49.8 (C7 or C11), and 70.6 (C14) ppm; irradiation of the methyl resonance at 1.33 (Me13) ppm showed transfer to carbon resonances at 37.6 (C8), 47.4 (C7 or C11), 49.8 (C7 or C11), and 142.9 (C6) ppm. A series of difference nOe (nuclear Overhauser enhancement) experiments established that the relative stereochemistry about the cyclopentane ring was as shown in **1**. Irradiation of the methyl resonance at 1.13 ppm (Me15) induced nOe's into the methyl resonance at 1.33 (Me13), the geminal methylene protons at 3.36 and 3.59 (H14 and H14a), and into the aromatic protons at 7.22 (H1 and H5) ppm. Irradiation of the methyl resonance at 1.33 (Me13) ppm induced nOe's into the methyl resonance at 1.13 (Me15) and the aromatic resonance at 7.22 (H1 and H5) ppm.

Dihydrotochuinyl acetate (**2**) was also obtained as a colorless oil that gave a parent ion at m/z 262.1926 daltons in the EIMS, appropriate for a molecular formula of $C_{17}H_{26}O_2$ (deviation −0.7 mmu). A fragment ion at m/z 260 in the ms of **2** indicated a facile loss of H_2 from the parent ion, and the ^1H and ^{13}C nmr

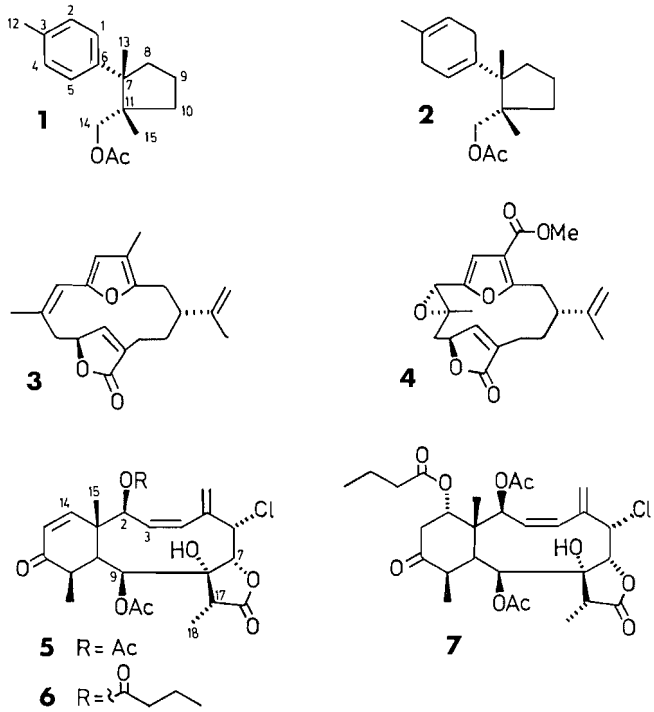
spectra of **2** suggested that it was the 1,4-dihydro derivative of **1**. Thus, the ^{1}H and ^{13}C resonances assigned to the 4-methylphenyl fragment in the nmr spectra of **1** (Tables 1 and 2), were replaced in the nmr spectra of **2** with ^{1}H resonances at 1.65 (s, 3H), 2.61 (m, 2H), 2.70 (m, 2H), 5.39 (bs, 1H), and 5.53 (bs, 1H) ppm, and ^{13}C resonances at 28.4 (CH_2), 31.9 (CH_2), 119.0 (CH), 119.1 (CH), 130.5 (C), and 138.5 (C) ppm, which could be assigned to a 1-alkyl-4-methyl-1,4-cyclohexadiene residue. Dihydrotochuinyl acetate (**2**) was quantitatively converted to tochuinyl acetate (**1**) by dehydrogenation with palladium on charcoal in refluxing ethanol in accordance with the proposed structure.



We subsequently isolated tochuinyl acetate (**1**) and dihydrotochuinyl acetate (**2**) as minor constituents from extracts of the soft coral *Gersemia rubiformis*. *Tochuina tetraquetra* is often found feeding on *G. rubiformis*. To the best of our knowledge, **1** and **2** represent the first examples of cuparane sesquiterpenoids isolated from a soft coral.

The two final components of the Port Hardy *T. tetraquetra* extracts were the known diterpenoids rubifolide (**3**) (10) and pukalide (**4**) (11). Rubifolide was shown to be identical to an authentic sample by spectroscopic and tlc comparison. Pukalide was identified by comparison of its spectral data to literature values.

Bamfield animals

Skin extracts of the Bamfield specimens of *T. tetraquetra* contained only the known diterpenoid ptilosarcenone (**5**) (12) and its butanoate analogue **6**, which has not been previously reported. Ptilosarcenone was identified by comparing its ^{1}H nmr spectrum to the ^{1}H nmr spectrum of authentic material.

Butanoate **6** was obtained as a colorless oil that showed a weak parent ion in the EIMS at 508.1873 daltons, corresponding to a molecular formula of $C_{26}H_{33}ClO_8$. The ^{1}H nmr spectrum indicated that **6** was closely related to ptilosarcenone (**5**); however, one of the acetate resonances in the spectrum of **5** was replaced in the spectrum of **6** by resonances at 0.99 (t, J = 7 Hz, 3H), 1.71 (m, 2H), 2.38 (t, J = 7 Hz, 2H) ppm assigned to a butanoate ester. A series of difference nOe experiments demonstrated that the butanoate ester in **6** was attached to C2, while the acetate ester was attached to C9. Irradiation of the acetate methyl resonance at 2.20 ppm induced nOe's into Me15 (1.17), H3 (5.60), and H7 (4.98), while simultaneous irradiation of the butanoate α-methylene (H24 and H24a) proton resonance and the H17 resonance, which both occur at 2.38 ppm, induced nOe's into H7 (4.98, from H17), H9 (5.46, from H17), Me18 (1.20, from H17), and H14 (6.58, from butanoate α-CH_2).

Ptilosarcenone was reported to be generated by facile elimination of butanoic acid from ptilosarcone (**7**) (12). To

[a]Signals lie partially on top of one another.

discount the possibility that **5** and **6** were isolation artifacts, we carried out a rapid work-up of a $CHCl_3$ extract of freshly collected *T. tetraquetra* specimens. We found only diterpenes **5** and **6** with no trace of the putative parent compounds, for example ptilosarcone (**7**). It appears that ptilosarcenone (**5**) and its butanoate analogue **6** are the metabolites actually present in the skin extracts of *T. tetraquetra*.

Discussion

All of the metabolites present in the skin extracts of *T. tetraquetra*, with the exception of pukalide, can be directly traced to the coelenterates that make up its diet. Tochuinyl acetate (**1**), dihydrotochuinyl acetate (**2**), and rubifolide (**3**) are all metabolites of the soft coral *Gersemia rubiformis*, which is one of the major dietary organisms of Port Hardy animals (10). Pukalide has been reported as a metabolite of the tropical soft coral *Sinularia abrupta* (11*a*) and the tropical gorgonian *Lophogorgia rigida* (11*b*); however, *G. rubiformis* is the only species of soft coral or gorgonian reported to grow in the same habitat as *T. tetraquetra* (1) and we have not been able to find pukalide in *G. rubiformis* extracts. Thus, the exact origin of pukalide remains unknown. It could be an extremely minor metabolite of *G. rubiformis* that has eluded us thus far, it could be a metabolite of an as yet unreported soft coral, or it could result from chemical transformations carried out by the nudibranch on some *G. rubiformis* metabolite. Ptilosarcenone (**5**) has been reported as one of the major metabolites of the sea pen *Ptilosarcus gurneyi* (12), which is a component of the diet of Bamfield specimens of *T. tetraquetra*. An exhaustive study of the metabolites of *P. gurneyi* collected at Seattle, Washington, and Sidney, B.C, failed to uncover the butanoate analogue **6** or any metabolite that could be viewed as a precursor to it (13). Probably the chemistry of the Bamfield population of *P. gurneyi* differs slightly from the Strait of Georgia and Puget Sound populations.

Experimental

The ^{1}H nmr spectra were recorded on Varian XL-300 and Bruker WH-400 spectrometers. The ^{13}C nmr spectra were recorded on a Varian XL-300 spectrometer. TMS was used as an internal standard. Low resolution mass spectra were recorded on an AEI MS902 spectrometer and high resolution mass spectra on an AIE MS50 spectrometer. The ir spectra were recorded on a Perkin–Elmer 1710 Fourier Transform spectrometer. Ultraviolet–visible spectra were recorded on a Bausch and Lomb Spectronic-2000 instrument. Optical rotation measurements were recorded on a Perkin–Elmer 141 polarimeter.

Merck silica gel 230–400 mesh was used for flash and preparative thin-layer chromatography and a Whatman Magnum-9 Partisil-10 column was used for preparative hplc.

Specimens of *Tochuina tetraquetra* were collected by hand using SCUBA in several exposed rocky channels (−5 to −15 m) located within the Gordon Group of Islands, Port Hardy, British Columbia (found feeding on or sitting nearby *Gersemia rubiformis*—two animals were collected), and within the Deer Group of Islands, Barkley Sound, British Columbia ("Bamfield animals"—three animals were collected).

Freshly collected animals were immediately immersed in methanol and extracted at room temperature for 2–3 days before decanting the methanol to give a first skin extract. Fresh methanol was added to the animals and they were left for a further 2 days. The second methanol extract was decanted and the two skin extracts were combined.

Port Hardy animals

The methanol extract (1000 mL) was concentrated *in vacuo* to 50 mL and partitioned between brine (100 mL) and ethyl acetate (4 × 150 mL). The combined ethyl acetate layers were dried over sodium sulphate for 2 h and then reduced *in vacuo* to yield 0.5 g of an orange oil.

The oil was fractionated by preparative thin-layer silica gel chromatography (2% methanol/98% methylene chloride) to yield two short wave uv active bands. The least polar band contained 10.7 mg of a mixture of rubifolide (**3**), tochuinyl acetate (**1**), dihydrotochuinyl acetate (**2**), and fats (R_f 0.66). The more polar band contained pukalide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

(**4**) and fats (R_f 0.28). The polar band was further purified via reverse phase hplc (70% methanol/30% water) to yield 15.7 mg of pukalide (**4**) as a white solid (powdery).

The less polar band was further fractionated on reverse phase hplc (80%/15%/5% methanol/water/methylene chloride) to yield crude samples of rubifolide (**3**), tochuinyl acetate (**1**), and dihydrotochuinyl acetate (**2**). Repetitive reverse phase hplc purifications (80%/15%/5% methanol/water/methylene chloride) on these crude samples yielded pure rubifolide (**3**) as a white crystalline solid (4.2 mg), and pure samples of tochuinyl acetate (**1**) (1.4 mg) and dihydrotochuinyl acetate (**2**) (0.7 mg), both as clear oils.

Bamfield animals

The methanol extract (1000 mL) was worked up as described above to yield 0.6 g of an orange oil.

The oil was fractionated by preparative thin-layer silica gel chromatography (2% methanol/98% methylene chloride) to yield a uv active (254 nm) band (R_f 0.25). This band was further purified on reverse phase hplc (70% methanol/30% water) to yield ptilosarcenone (**5**) (7.2 mg) as an amorphous solid, and its butanoate analogue (**6**) (5.1 mg) as a glass.

In the rapid work-up, freshly collected animals were immediately immersed in chloroform and left standing at room temperature for 1 day. The chloroform (600 mL) was decanted off and reduced *in vacuo* to 200 mL before being partitioned between brine (200 mL) and ethyl acetate (4 × 200 mL). The combined ethyl acetate layers were dried over sodium sulphate and reduced to dryness *in vacuo* to give an orange oil. The oil was fractionated by preparative thin-layer chromatography using nonactivated silica gel (i.e., cured at room temperature) (eluent 8% ethyl acetate/92% methylene chloride). A uv active band (R_f 0.23) was further fractionated on normal phase hplc (15% ethyl acetate/85% methylene chloride) to yield only ptilosarcenone (**5**) and its butanoate analogue **6**. Total work-up took less than 3 days.

*Tochuinyl acetate (**1**)*: $[\alpha]_D^{25}$ −42.5° (*c* 1.09, CH_2Cl_2); R_f 0.80 (5% MeOH/95% CH_2Cl_2); ir (CH_2Cl_2): 2963, 2882, 1734, 1516, 1480, 1466, 1379, 1245, and 1034 cm^{-1}; ^1H nmr (Table 1); ^{13}C nmr (Table 2); ms, *m/z* (rel. intensity): 260 (23), 217 (3), 200 (12), 185 (13), 171 (9), 158 (51), 143 (61), 132 (100), 119 (77), 105 (48), 91 (39), 77 (13), 65 (10), 55 (12). *Exact Mass* calcd. for $C_{17}H_{24}O_2$: 260.1777; found (hrms): 260.1777.

*Dihydrotochuinyl acetate (**2**)*: $[\alpha]_D^{25}$ −29.3° (*c* 1.11, CH_2Cl_2); R_f 0.84 (5% MeOH/95% CH_2Cl_2); ir (CH_2Cl_2): 2963, 2882, 2820, 1731, 1653 (very weak), 1468, 1379, 1238, 1034, 985, and 952 cm^{-1}; ^1H nmr (Table 1); ^{13}C nmr (Table 2); ms, *m/z* (rel. intensity): 262 (24), 260 (7), 219 (2), 217 (1), 202 (21), 200 (10), 187 (26), 185 (11), 173 (17), 171 (6), 159 (31), 145 (55), 132 (85), 119 (100), 105 (78), 91 (70), 77 (39), 67 (33), 61 (41), 55 (42). *Exact Mass* calcd. for $C_{17}H_{26}O_2$: 262.1934; found (hrms): 262.1926.

*Oxidation of dihydrotochuinyl acetate (**2**)*

Dihydrotochuinyl acetate (**2**) (3.8 mg) was refluxed for 18 h in 95% ethanol (3 mL) containing a catalytic amount of palladium on activated charcoal. The palladium catalyst was filtered off (on fine sintered glass) and the ethanol filtrate was reduced to dryness to yield 3.5 mg of **1**.

*Butanoate **6***: $[\alpha]_D^{25}$ −49.2° (*c* 0.41, CH_2Cl_2); R_f 0.71 (5% MeOH/95% CH_2Cl_2); uv (MeOH) λ_{max}: 220 nm (4857); ir (CH_2Cl_2) 3590, 2940, 2880, 1790, 1735, 1689, and 1371 cm^{-1}; ^1H nmr (Table 3); ms, *m/z* (rel. intensity): 508 (0.2), 438 (5), 422 (3), 402 (3), 378 (4), 360 (4), 342 (4), 324 (4), 307 (4), 297 (4), 287 (4), 279 (5), 271 (4), 269 (7), 255 (5), 253 (5), 251 (7), 231 (14), 219 (12), 203 (10), 191 (18), 175 (15), 147 (17), 135 (32), 123 (72), 107 (27), 95 (17), 81 (14), 71 (95), 55 (13), 43 (100). *Exact Mass* calcd. for $C_{26}H_{33}ClO_8$: 508.1865; found (hrms): 508.1873.

Additivity of the partial molar volumes of organic compounds

NORIO NISHIMURA, TOHRU TANAKA, AND TAKUSHI MOTOYAMA
Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700, Japan

Received December 5, 1986

NORIO NISHIMURA, TOHRU TANAKA, and TAKUSHI MOTOYAMA. Can. J. Chem. **65**, 2248 (1987).

A critical test of additivity for partial molar volume has been made at 25°C in CCl_4 with polyethylene glycol dimethyl ethers, crown ethers, cycloalkanes, *n*-alkanes, and others. Plots of partial molar volume at infinite dilution ($\bar{V}^0$) against the properly chosen number of repeating unit (n) are linear except for small cyclic molecules, and the slopes of homologous straight chain and ring compounds are the same. The values of $\bar{V}^0$ extrapolated to $n = 0$ for cycloalkanes and crown ethers support the validity of the contribution due to the translational kinetic energy that has been predicted recently on a theoretical basis. The importance of packing efficiencies around the solute molecules has been examined by means of simple models.

NORIO NISHIMURA, TOHRU TANAKA et TAKUSHI MOTOYAMA. Can. J. Chem. **65**, 2248 (1987).

Opérant à 25°C, dans des solutions de CCl_4, on a effectué une évaluation critique de l'additivité des volumes molaires partiels pour des éthers diméthyliques du polyéthylène glycol, des éthers couronnes, des cycloalcanes, des *n*-alcanes et d'autres composés. A l'exception des molécules contenant des petits cycles, on a trouvé qu'il existe une relation linéaire entre les volumes molaires partiels à dilution infinie ($\bar{V}^0$) et le nombre choisi approprié d'unités periodiques (n); de plus, les pentes des courbes pour les composés homologues aliphatiques sont les mêmes que celles pour les composés cycliques. Pour les cycloalcanes et pour les éthers couronnes, les valeurs de ($\bar{V}^0$) extrapolées à $n = 0$ sont en accord avec la prédiction qui a récemment été faite sur une base théorique et selon laquelle on prévoit une contribution de la part de l'énergie cinétique de translation. Utilisant des modèles simples, on a étudié l'importance des efficacités d'empilement autour des molécules de solutés.

[Traduit par la revue]

Introduction

Volume additivity has been assumed since the end of the 19th century. For example, Traube (1) considered the molar volume as consisting of a covolume (ϕ) that corresponds to the free volume term in the van der Waals equation, and the sum of atomic volumes based on the constituent atoms:

$$[1] \quad V = \phi + \Sigma n^i V^i$$

Here n^i is the number of, and V^i is the volume associated with, atoms of type i. A similar equation that does not involve the ϕ terms was proposed by Exner (2).

Recently, Edward and co-workers (3–5) measured a vast number of compounds in various solvents. They concluded that the partial molar volume of alkanes at infinite dilution ($\bar{V}^0$) can be expressed by

$$[2] \quad \bar{V}^0 = V_c + n^k I^k + Z_g^l \delta^l + C$$

where the first term is a constant covolume; n^k is the number of, and I^k the volume increment associated with, atomic groups of type k; Z_g^l is the average number of *gauche* interactions of type l and δ^l the volume change associated with the interaction; C is a cyclization parameter the magnitude of which depends on the number of skeletal atoms in the ring. Using eq. [2], they estimated the value of V_c and I^k by means of a least-squares fitting of their experimental data. Citing Stillinger's theory (6), they advocated that the estimated V_c of 11.61 cm^3/mol (in CCl_4 at 25°C) is the volume increase that would result even for a point particle on account of its kinetic contribution (5). However, the kinetic contribution predicted by Stillinger on the basis of the scaled-particle theory is $\kappa_T RT$ (2–3 cm^3/mol for most solvents). It is curious that they made no comment on this large discrepancy.

Another important contribution has been made by Teresawa and co-workers (7) who showed that the partial molar volume of a series of homologous compounds can be related to their van der Waals volume:

$$[3] \quad \bar{V}^0 = aV_w + b$$

where a and b are constants for the series of interest at constant temperature and pressure. At first sight, one might think that the b term corresponds to the covolume V_c, since b is the volume at $V_w = 0$. However, it is not the case, as will be shown later.

Very recently, Yoshimura and Nakahara (8) derived expressions for the volume change accompanying contact-complex formation in hard-sphere fluids. They pointed out that the volume change is composed of two terms related to (*i*) molecular packing and (*ii*) thermal motion of molecules. Their ideas are of great significance for high pressure kineticists since they have not been taken into account for the activation volume ($\Delta V^{\ddagger}$) and reaction volume (ΔV). They further developed the additivity rule of the partial molar volume (9, 10). Based on the virial theorem, they have derived the following equation:

$$[4] \quad \bar{V}^0 = \bar{V}^0_{conf} + \kappa_T RT$$

where $\bar{V}^0_{conf}$ denotes the volume contribution due to the configurational interaction between solute and solvent molecules, and κ_T the isothermal compressibility of the solvent used. The second term arises from the translational motion of a solute in solution. This term is completely in accord with the one derived by Stillinger. They have shown that the additivity rule for *n*-alkanes consisting n methylene units can be expressed as

$$[5] \quad \bar{V}^0_{conf} = \alpha n + \beta$$

and that this equation is obeyed quite accurately.

Their work has motivated us to examine the additivity scheme for a series of compounds in various solvents. In this work, we have estimated the translational contribution by using large ring compounds composed of the same repeating unit. The aspects of the volume additivity were examined by comparing ring compounds with similar chain compounds. In order to understand the essential feature of the volume additivity, branched alkanes for which vicinal steric effects may exist were avoided. The packing efficiencies around atomic groups having different size and shape have also been examined.

Experimental

Materials

Cycloalkanes $C_{15}H_{30}$ and $C_{16}H_{32}$ were prepared by reducing the corresponding cycloketones according to the modified Wolff–Kishner method (11). For $C_{15}H_{30}$: mp 65.8–66.0°C, lit. 62.3–63.5°C (12); for $C_{16}H_{32}$: mp 62.8–63°C, lit. 60–61°C (12).

Reagent grade *n*-alkanes were used as received, and the purity checked by VPC. Pure 21-crown-7 and 24-crown-8 were kindly supplied by Professor T. Iwachido. Other substances were purified either by recrystallization, distillation, or sublimation, and dried in the usual manner.

Density measurements

A Kyoto Denshi digital precision density meter DA-101B placed in an air-thermostated box was used. Solutions of different molalities were prepared and deaerated with an ultrasonic cleaner. The solution was transferred into a measurement cell by means of an air-baffle. After measurement, the solution was purged by replacing in the measurement cell the next, more concentrated solution. This process was repeated until the end. From the relationship between molality and specific volume, the partial molar volume at infinite dilution were estimated in the usual manner.

Results

The partial molar volumes of polyethylene glycol dimethyl ethers (PEGDE), crown ethers (CE), *n*-alkanes (NA), cycloalkanes (CA), and other kinds of compounds in CCl_4 at 25°C are given in Table 1. Figure 1 shows the relationship between $\bar{V}^0$ and n, the number of repeating units properly chosen (for example, $n = 8$ for decane). The linear regression equations for these series of compounds are

[6] $\bar{V}^0/\text{cm}^3\ \text{mol}^{-1} = (16.6 \pm 0.1)n + (66.5 \pm 0.6)$

for *n*-alkanes ($n = 6, 7, 9, 11, 12, 13$; $r = 0.999943$).

[7] $\bar{V}^0/\text{cm}^3\ \text{mol}^{-1} = (16.4 \pm 0.2)n + (1.5 \pm 2.3)$

for cycloalkanes ($n = 10, 12, 15, 16$; $r = 0.99976$).

[8] $\bar{V}^0/\text{cm}^3\ \text{mol}^{-1} = (38.5 \pm 0.0)n + (66.4 \pm 0.1)$

for PEGDE (repeating unit = —O—CH_2—CH_2—; $n = 1, 2, 3, 4$; $r = 0.99999$).

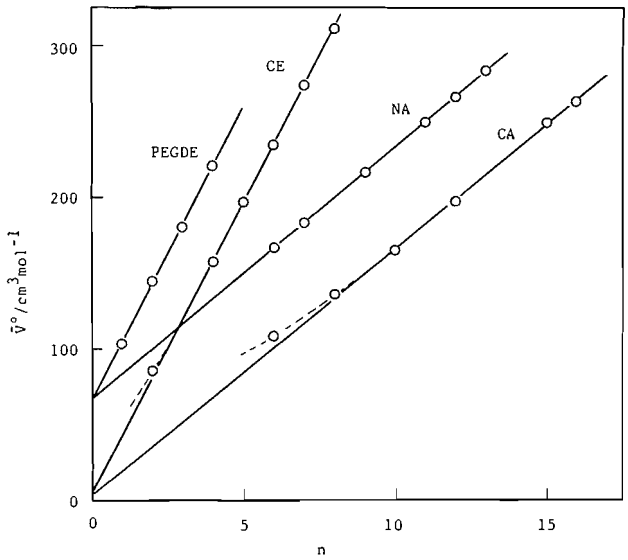

FIG. 1. Plots of the partial molar volume against the number of repeating unit for polyethylene glycol dimethyl ethers (PEGDE), crown ethers (CE), *n*-alkanes (NA), and cycloalkanes (CA).

[9] $\bar{V}^0/\text{cm}^3\ \text{mol}^{-1} = (38.6 \pm 0.4)n + (3.3 \pm 0.3)$

for crown ethers ($n = 4, 5, 6, 7, 8$; $r = 0.999996$).

A similar but modified treatment can be done by using eq. [3]. For example,

[10] $\bar{V}^0/\text{cm}^3\ \text{mol}^{-1} = (1.33 \pm 0.01)V_w + (25.5 \pm 0.6)$

for aromatics ($r = 0.99996$), and

[11] $\bar{V}^0/\text{cm}^3\ \text{mol}^{-1} = (1.25 \pm 0.02)V_w + (35.2 \pm 1.9)$

for chloroalkanes ($r = 0.9996$). This is shown in Fig. 2. The van der Waals volumes were estimated by using Bondi's data (13).

Discussion

Contribution of translational motion to $\bar{V}^0$ and the validity of additivity rule

On the basis of the scaled-particle theory, Stillinger (6)

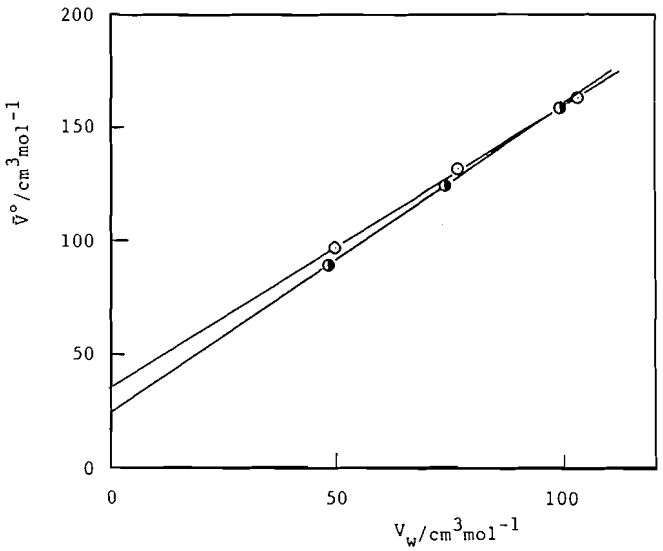

FIG. 2. $\bar{V}^0$ versus V_w plots for aromatics (—●—) and chloroalkanes (—○—).

pointed out that one of the distinct contributions to $\bar{V}^0$ is the volume increase ($= \kappa_T RT$) that would result even for a point particle on account of its kinetic contribution to pressure. The same expression has been derived by Yoshimura *et al.* (8, 9) on the basis of the virial theorem for classical fluids. However, the experimental verification of this term is difficult. As far as we are aware, no such trial has yet been made. We have undertaken to tackle the problem by using large ring compounds consisting of the same repeating unit. The reason is as follows: for normal alkanes, $\bar{V}^0_{conf}$ in eq. [5] can be written as (10)

$$[12]\quad \bar{V}^0_{conf} = n\bar{V}^0(\text{—}CH_2\text{—}) + 2\bar{V}^0(CH_3\text{—})$$

$$[13]\quad = na_1V_w(\text{—}CH_2\text{—}) + 2a_2V_w(CH_3\text{—})$$

where $\bar{V}^0(\text{—}CH_2\text{—})$ and $\bar{V}^0(CH_3\text{—})$ denote the contributions of the methylene and methyl groups to $\bar{V}^0_{conf}$, respectively; a_1 and a_2 denote the ratios $\bar{V}^0(\text{—}CH_2\text{—})/V_w(\text{—}CH_2\text{—})$ and $\bar{V}^0(CH_3\text{—})/V_w(CH_3\text{—})$, respectively, and are the partial molar volumes normalized to their van der Waals volumes. The a terms measure how loosely the molecular moiety (or molecule) in question is packed. From eqs. [4] and [12], we have

$$[14]\quad \bar{V}^0 = n\bar{V}^0(\text{—}CH_2\text{—}) + 2\bar{V}^0(CH_3\text{—}) + \kappa_T RT$$

For cycloalkanes we have

$$[15]\quad \bar{V}^0 = n\bar{V}^0(\text{—}CH_2\text{—}) + \kappa_T RT$$

In this case, if we plot $\bar{V}^0$ against n, and extrapolate to $n = 0$, the intercept should be $\kappa_T RT$. This equation can be applied to any cyclocompounds consisting of the same repeating unit. The intercepts for CA and CE are (1.5 ± 2.3) cm^3/mol and (3.3 ± 0.3) cm^3/mol, respectively (eqs. [7] and [9]). These values may be compared with the reported values of $\kappa_T RT/cm^3\ mol^{-1}$ = 2.64 (14), 2.62 (15), and 2.67 (16) for CCl_4 at 25°C and 1 atm. If the number of measurement points, experimental accuracy for estimating $\bar{V}^0$, and inevitable uncertainties involved in the estimation of the intercept are taken into account, the intercepts of such compounds could be regarded as the $\kappa_T RT$ term. Indeed, if $\kappa_T RT$ = 2.64 cm^3/mol is fixed, the average slopes of the $\bar{V}^0$ vs. n plot only change from 16.4 (eq. [7]) to 16.3 for CA, and from 38.6 (eq. [9]) to 38.7 for CE. It is noted that the covolume of 11.61 cm^3/mol proposed by Edward *et al.* (3–5) has no theoretical background in spite of that the arbitrariness of the value of covolume appeared in the literature was discussed by them.

The second remarkable point in Fig. 1 is that the strictly linear relationship between $\bar{V}^0$ and n holds for each series of compounds and that, if we eliminate the data for small-membered ring compounds (*vide infra*), the slopes of the plots for NA and CA, and PEGDE and CE are virtually the same (eqs. [6]–[9]). The above findings means that all the repeating units, irrespective of their positions, contribute equally to $\bar{V}^0$. In other words, the solvent CCl_4 as a probe for tracing volumes cannot distinguish the position and/or conformations with respect to neighbours (*trans* and *gauche*) of these repeating groups.

The third notable point is that for small-membered ring compounds, deviations from linearity can be observed. According to Edward *et al.*, an additional cyclization parameter C (eq. [2]) which varies with the number n of ring atoms for alkanes, from C = 5.3 cm^3/mol (n = 3) to C = −21.0 cm^3/mol (n = 10). Judging from features in Fig. 1, it is clear that this way of correction is upside down. The reason for the upward deviations for small-membered ring compounds has been discussed (10) using and comparing cylindrical and torus models for the linear alkanes and cycloalkanes, respectively.

Generalized form of the additivity rule

Let us consider a chain molecule of the type A—(B)$_n$—A. Equation [14] can be generalized as

$$[16]\quad \bar{V}^0 = n\bar{V}^0(\text{—}B\text{—}) + 2\bar{V}^0(A\text{—}) + \kappa_T RT$$

$$[17]\quad = na_1V_w(\text{—}B\text{—}) + 2V_wa_2(A\text{—}) + \kappa_T RT$$

The van der Waals volume can be written as

$$[18]\quad V_w = nV_w(\text{—}B\text{—}) + 2V_w(A\text{—})$$

From eqs. [17] and [18], it is deduced that if we plot $\bar{V}^0$ against V_w for a series of the A—(B)$_n$—A type of molecules, then the trajectory of $P(\bar{V}^0, V_w)$ on the V_w–V^0 vector plane constitutes two straight lines as shown in Fig. 3. It is clear that the point b (see eq. [3]) has no physical meaning. Alternatively, such aspects can be explained in terms of two kinds of operations: addition and substitution. An increase in the chain number for n-alkanes, for example, is a kind of addition operation. Introduction of C in place of A for A—(B)$_n$—A type of molecules is a kind of substitution operation. Generally, the volume change $\Delta\bar{V}^0$ upon substitution of an atomic group or an atom Y— in place of X— can be expressed as

$$[19]\quad \Delta\bar{V}^0 = \bar{V}^0(Y\text{—}) - \bar{V}^0(X\text{—})$$

Repetition of these operations constitutes a network. An example is shown in Fig. 4. It must be noted that the above additivity rule would hold strictly only when mesomeric and vicinal steric effects or special interactions such as hydrogen bonding can be neglected. If it is not so, corrections would be necessary as in the case of van der Waals volume calculations (13).

Significance of molecular packing around atomic groups of different sizes and shapes

By using the data in Table 1 and eqs. [6]–[12] and [14], we can allot the partial molar volumes for any atomic groups. For example, $\bar{V}^0(\text{—}CH_2\text{—})$ = 16.5 cm^3/mol (average of the

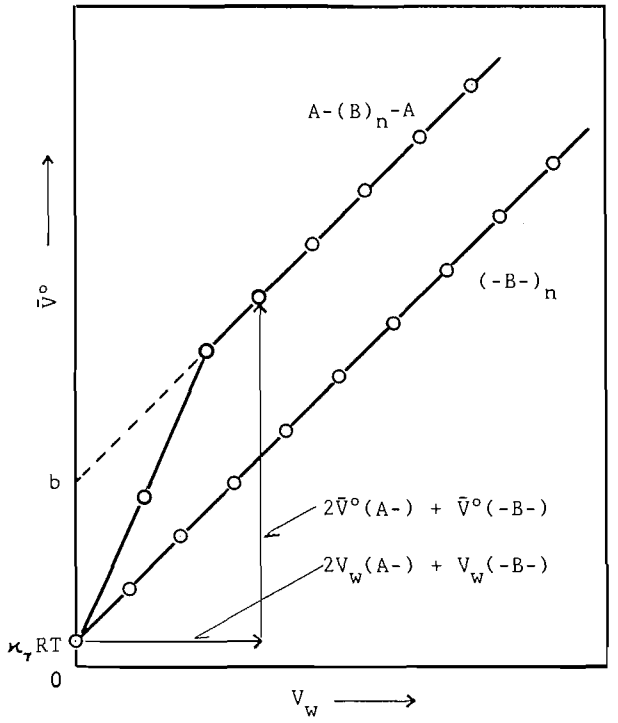

FIG. 3. Schematic representation of the relationship between $\bar{V}^0$ and V_w for a series of compounds of the type A—(B)$_n$—A and (—B—)$_n$.

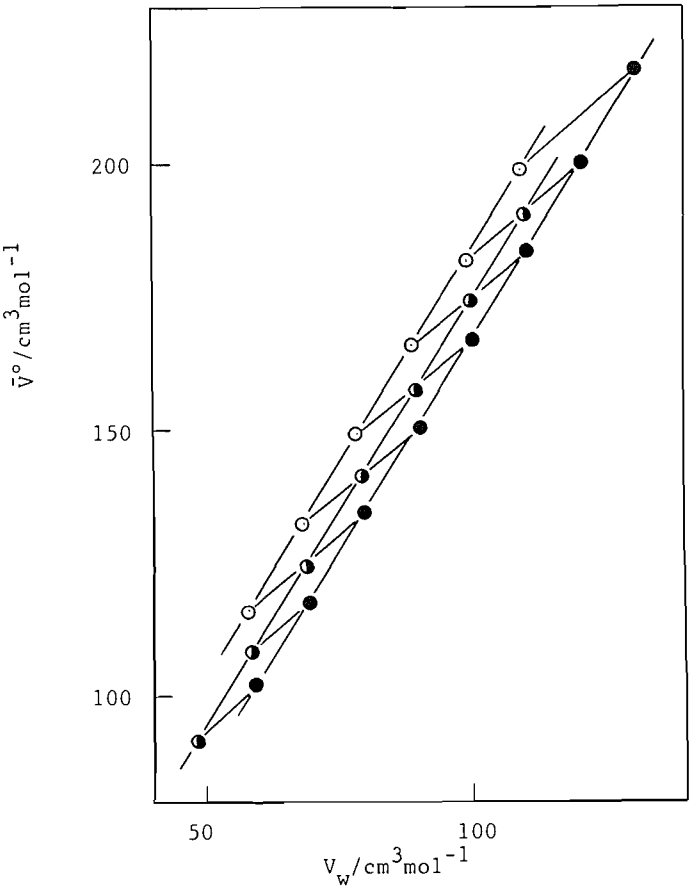

FIG. 4. Example of a network as a result of addition and substitution operation. (—○—): CH_3—$(CH_2)_n$—CH_3; (—◑—): $BrCH_2$—$(CH_2)_n$—CH_3; (—●—): $BrCH_2$—$(CH_2)_n$—CH_2Br. Data cited from ref. 4.

slopes of the straight lines in eqs. [6] and [7]). Once it is fixed, then $\bar{V}^0(CH_3—) = 32.0\,cm^3/mol$ can be estimated by using eqs. [6] and [14], and so on. The partial molar volumes allotted for several atomic groups are given in Table 2, together with their van der Waals volumes calculated by using Bondi's data (13). The *a* term in the table denotes the partial molar volumes reduced to their van der Waals volumes, and the value measures how loosely the atomic group in question is packed. The data for benzene, naphthalene, anthracene, carbon tetrachloride, and adamantane are also given for the sake of discussion in this section.

Inspection of the data in Table 2 reveals some interesting points. First of all, the partial molar volume allotted for atomic groups is not always proportional to their van der Waals volume. For example, $\bar{V}^0(H—)$ is as large as $\bar{V}^0(—CH_2—)$. Further, $\bar{V}^0(\text{—}\underset{|}{C}\text{—})$ has a negative volume of $-14.5\,cm^3/mol$. It was pointed out (3) that Exner's scheme has no covolume term, which leads to a very large $\bar{V}^0(H—)$ (14.90 cm^3/mol) and a negative increment ($-13.22\,cm^3/mol$) for carbon. These values are very near to those in Table 2. Edward *et al.* do not object to a negative increment since the additive scheme works fairly well, but this is hard to comprehend intuitively. In our opinion, the partial molar volumes in Table 2 are calculated using the empirical equations and as long as we use these values we have no problems. One must keep in mind that the "carbon" is never faced to solvents. Since $\bar{V}^0$ is determined by the interaction of a solute with the surrounding solvent molecules, the formally negative value of $\bar{V}^0(\text{—}\underset{|}{C}\text{—})$ itself bears no physical meaning.

Secondly, the reduced partial molar volume clearly reflects

TABLE 2. Partial molar volumes, van der Waals volumes allotted for atomic groups or molecules (cm^3/mol), and reduced partial molar volumes

Atomic group	$\bar{V}^0$	V_w	$a\,(=\bar{V}^0/V_w)$

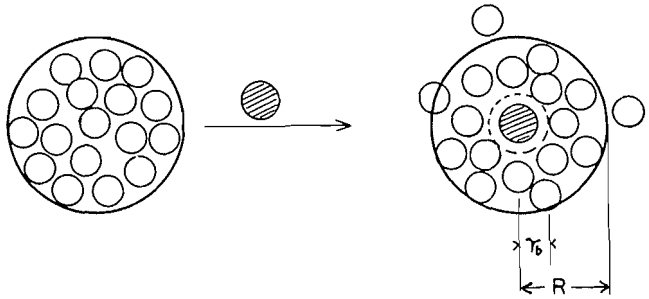

FIG. 6. Schematic representation of the physical meaning of the partial molar volume at infinite dilution ($\bar{V}^0$).

the size and shape of molecular moieties. On the molecular basis, the following sets of atomic groups or molecules having different van der Waals volumes could be regarded as similar in shape to each other: (—CH_2—, —CCl_2—), (CH_3—, CCl_3—), (H—, Cl—), and (CH_4, CCl_4, adamantane). Within these sets, the a value is always larger for the atomic group which has a smaller van der Waals volume. Thirdly, if we compare $\bar{V}^0$(CH_3—) with $\bar{V}^0$(—CH_2—), the former is unexpectedly larger than the latter. The same is true for $\bar{V}^0$(CCl_3—) and $\bar{V}^0$(—CCl_2—). We could say that the geometrical differences between "hemispherical" CH_3— and "cylindrical" —CH_2— moieties are responsible for the above findings.

Interpretation of the partial molar volume

We have seen that the size as well as shape of the atomic groups are the important factors in determining the a term. On the assumption that solute molecules are spherical, Edward and Farrell (17) have given an expression for the partial molar volume of the solute molecule of effective van der Waals radius r_w.

$$[20] \quad \bar{V}^0 = (4/3)\pi L(r_w + \Delta)^3$$

where L is the Avogadro number and Δ denotes a parameter adjusting for the void where solvent molecules are excluded (Fig. 5). By using the volume data of aliphatic and aromatic hydrocarbons in water, they examined eq. [20], and found that the average separation of the solute molecules from the solvent as a continuum is 5.3 nm.

Recently, Lee (18) developed a theory for the partial molar volume of the solute in infinitely dilute hard-sphere binary mixtures. The expression for $\bar{V}^0$ is formally the same as eq. [20]. However, Δ is not constant but a slowly varying function of r_w and depends primarily on the size of solvent molecule and the packing density of the pure solvent. According to his calculation, Δ gradually increases as the solute-to-solvent radius ratio decreases. Therefore, this theory predicts that if we measure $\bar{V}^0$ for a series of spherical solutes of varying r_w in a fixed solvent, the thickness Δ will become larger the smaller the solute molecule is. This must be kept in mind for the sake of later discussion.

Let us consider a space enveloped by a spherical surface of radius R, centered by a solute molecule. The number of solvent molecules N within the sphere is given by

$$[21] \quad N = \int_0^R 4\pi r^2 \rho_0 g(r) \mathrm{d}r$$

where ρ_0 is the number density of the pure solvent molecule and $g(r)$ is the radial distribution function at the distance r from the solute molecule. In the absence of the solute molecule, the number of solvent molecule N_0 is given by

$$[22] \quad N_0 = \int_0^R 4\pi \rho_0 r^2 \mathrm{d}r$$

If R is large enough compared with molecular dimensions, and the solution is sufficiently dilute, the partial molar volume of the solute in question at infinite dilution can be given by

$$[23] \quad \bar{V}^0 = (N_0 - N)V_0 = 4\pi L \int_0^R r^2\{1 - g(r)\}\mathrm{d}r$$

where V_0 is the molar volume of the solvent. Therefore, $\bar{V}^0$ is interpreted as the number of "solvent" molecules excluded from the space, multiplied by the solvent molar volume, as depicted in Fig. 6.

In real solutions, it is difficult to estimate the radial distribution function. In the simplest case, we assume that $g(r) = 0$ in the region $r < r_b$, and $g(r) = 1$ in the region $r > r_b$. Then it follows from eq. [23],

$$[24] \quad \bar{V}^0 = (4/3)\pi L r_b^3$$

If we set $r_w + \Delta = r_b$, eq. [24] becomes identical to eq. [20]. Therefore, this oversimplified model calculation is virtually the same as that of Edward and Farrell (Fig. 5), based on the sphere-in-continuum model. The success of their treatment for comparatively small molecules suggests that the proposed model is reasonable. Since the shapes of most of real molecules and atomic groups are far from spherical, more realistic models will be needed. We have seen that the a term depends on the size and shape of the atomic groups concerned. As the simplest models, we could regard CH_3—, CCl_3—, H—, and Cl— as hemispherical, —CH_2— and —CCl_2— as cylindrical with a height of 12.6 nm (estimated from the C—C bond length and C—C—C bond angle). Based on these models, the radius r and r_w of the sphere, hemisphere, and cylinder models can be estimated from the data in Table 2. If Δ is defined as

$$[25] \quad \Delta = r - r_w$$

as in the case of the sphere model (18), then Δ can be regarded as the thickness of the zone where the solvent molecules are excluded. In Table 3, r, r_w, and Δ are given. If a liquid consists of hard spheres and has a randomly closest packing structure (19), the radius of the sphere r could be calculated by using the following equation:

$$[26] \quad 1.56(4/3)\pi r^3 L = V - \kappa_T RT$$

where V is the molar volume of the liquid. Based on this

TABLE 3. Model calculation of r, r_w, and Δ (nm) for atomic groups and molecules

Atomic group	r	r_w	Δ	Assumed model
Adamantane	38.2	32.2	6.0	Spherical
CCl_4	33.8	27.0	6.8	
CH_4	27.1	19.0	8.1	
CCl_3—	37.2	31.2	6.0	Hemispherical
CH_3—	29.4	22.1	7.3	
Cl—	29.6	21.0	8.6	
H—	23.1	13.9	9.2	
—CCl_2—	36.5	33.4	3.1	Cylindrical
—CH_2—	26.3	20.7	5.6	

equation, r is calculated to be 28.8 nm for CCl_4, which agrees fairly well with $r_w = 27.0$ nm in Table 3.

If the data in Table 3 are inspected, we notice that the Δ values also depend on the molecular size and shape. One might think the Δ should be independent of the size and shape, since these have already been taken into account. According to our view, this dependency of the Δ value on the molecular size and shape reflects the significance of the molecular packing. In the above treatment, the solvent molecules have been regarded as continuum medium. In fact, it is not the case. In principle, if an explicit expression for $g(r)$ in eq. [23] is given for a specified system, $\bar{V}^0$ could be estimated.

A new framework for the understanding of the partial molar volume on the molecular level has also been put forward by Yoshimura and Nakahara (8). Their conclusion is essentially the same as that of Lee (18); it involves the solute to solvent size ratio, and this involvement overwhelms the classical picture of the sphere-in-continuum model. According to both theories, the solvent molecules can be packed more closely on a flat surface than on a surface of large curvature. Indeed, we can see in Table 3 that the Δ value increases in the order of increasing curvature of the surface of solute molecules or moieties. The above findings support the validity of their prediction, at least on the CPK model level.

Concluding remarks

The additive scheme we have put forward indicates the significance of molecular packing in solution. So far, however, the intrinsic volume changes ($\Delta V^{\ddagger}_{int}$, $\Delta \bar{V}^{0}_{int}$) accompanying chemical reactions have often been discussed and interpreted in terms of van der Waals volume changes. Therefore, it seems necessary to make a new framework for the intrinsic volume change for various types of chemical reactions. In this respect, the additivity rule seem to have a potential importance for the prediction of volume profile for chemical reactions, though in a limited scope for the time being. We also suggest that the contribution of translational motion to volume change will become very important, for instance, for aggregation reactions for which a great number of solute molecules aggregate to form a micelle.

An ^{1}H nuclear magnetic resonance study of derivatives of 3-hydroxy-12,13-epoxytrichothec-9-enes[1]

MARC E. SAVARD, BARBARA A. BLACKWELL, AND ROY GREENHALGH[2]
Plant Research Centre, Agriculture Canada, Ottawa, Ont., Canada K1A 0C6

Received March 18, 1987

MARC E. SAVARD, BARBARA A. BLACKWELL, and ROY GREENHALGH. Can. J. Chem. **65**, 2254 (1987).

The 250-MHz ^{1}H nuclear magnetic resonance spectra of 36 natural and synthetic trichothecenes have been analyzed and the chemical shifts as well as the vicinal and long-range coupling constants determined. Knowledge of the 16-CH_3 chemical shift enables the substitution pattern of the A ring to be defined. Similarly, oxygenation in the C ring results in easily identifiable resonances. The $J_{2,3}$ and $J_{3,4}$ values define the configuration of substituents at C-3 and C-4, while the configuration at C-7 and C-8 can be defined by the $J_{7,8}$, $J_{7\alpha,11}$, and $J_{7\beta,15}$ values. The trichothecene ring system adopts the most stable A-half-chair, B-chair conformation in solution. The correlations obtained allow easy structural determination of unknown trichothecenes.

MARC E. SAVARD, BARBARA A. BLACKWELL et ROY GREENHALGH. Can. J. Chem. **65**, 2254 (1987).

On a déterminé les spectres en résonance magnétique nucléaire du ^{1}H à 250 MHz de 36 trichothécènes naturels et de synthèse et on a déterminé les déplacements chimiques ainsi que les constantes de couplage tant vicinales qu'à longue distance. La connaissance du déplacement chimique du CH_3 en position 16 permet de définir le patron de substitution du cycle A. De la même manière, l'oxygénation du cycle C conduit à des résonances qui sont facilement identifiables. Les valeurs des constantes $J_{2,3}$ et $J_{3,4}$ permettent de définir la configuration des substituants dans les positions C-3 et C-4 alors que les configurations dans les positions C-7 et C-8 peuvent être définies par les valeurs des constantes $J_{7,8}$, $J_{7\alpha,11}$ et $J_{7\beta,15}$. En solution, le système de cycles des trichothécènes adopte la conformation la plus stable, impliquant un cycle A en demi-chaise et un cycle B en forme chaise. Les corrélations obtenues permettent d'attribuer facilement des structures à des trichothécènes inconnus.

Introduction

Mycotoxins are common contaminants of grains in temperate climates, and result in significant economic losses in the agro-food sector. In Canada, an epidemic infestation of *Fusarium* in wheat and corn in recent years resulted in high levels of mycotoxin-contaminated grains, which, when used for feed, produced emesis in pigs (1). The causative factor was identified as 3α,7α,15-trihydroxy-12,13-epoxytrichothec-9-en-8-one (4-deoxynivalenol, DON, vomitoxin, **24**) (see Fig. 1 for the basic skeleton and numbering system of trichothecenes). A process was developed for the large-scale production of DON (2), which was required for toxicological testing and feeding trials. In addition to DON, a large number of other trichothecenes were isolated in trace amounts (2–7). These compounds are of interest because of the diverse antifungal, cytotoxic, and phytotoxic properties they exhibit.

The first trichothecene was reported by Freeman *et al.* in 1959 (8), and was followed by the characterization of several other trichothecenes (9–11). In these studies, an incorrect structure was proposed in that a reactive oxygen was misinterpreted as being part of an oxetane ring instead of an epoxide (12, 13). Most trichothecenes contain a double bond at C-9 and an epoxide ring at C-12, and are oxygenated at one or more positions. These oxygen functions can occur as esterified or free hydroxyl groups or as ketones.

Some ^{1}H nmr characteristics of the trichothecene skeleton have been reported (14–16). However, the substitution patterns of these compounds are not always readily discerned. As a result of the large number of trichothecenes isolated in our laboratory (2–7), an extensive nmr data base has been developed. The present study attempts to correlate structural features with chemical shift, and the coupling constants with the conformation of the substituents. This knowledge will facilitate the characterization of new trichothecenes.

Experimental

Instruments

The ^{1}H nmr spectra were recorded at 250 MHz on a Bruker WM 250 spectrometer. Spectra were acquired with 16K data points, a 2200-Hz spectral window, 60° pulses, and an 8-s repetition rate. Chemical shifts were referenced to deuterochloroform at 7.24 ppm and reported (ppm) relative to tetramethylsilane (Me_4Si). Confirmation of ^{1}H chemical shift assignments was made for several compounds by ^{1}H homonuclear correlation spectroscopy. The (90–t_1–45 FID) pulse sequence (COSY-45) was accumulated by using 512 × 1K FID's of 16 scans each. Sine bell windows (shifted $\pi/4$ in F_1) were employed in data processing. The spectral resolution was 1.4 Hz/point. These 2D spectra were especially useful in resolving overlapping AB systems.

Melting points were determined on a Fisher–Johns heating stage apparatus and are uncorrected. Mass spectra were obtained on either a Finnigan MAT 312 mass spectrometer or a Finnigan MAT 4500 gc/ms system. Accurate mass measurements were determined by peak matching with an ion in the spectrum of perfluorokerosene.

Chemicals

Most trichothecenes were isolated from fermentations of *Fusarium sporotrichioides* (5), *F. roseum* (3), *F. graminearum* (4), *F. culmorum* (2), or *F. crookwellense* (6). The synthesis of the T-2 analogues **16**, **17**, **18**, and **19** has been reported elsewhere (17). Other trichothecenes synthesized include:

*7,15-Diacetyl-4-deoxynivalenol (**29**) and 7-acetyl-4-DON (**26**)*

Triacetyl-DON (**30**) (7) (500 mg) was dissolved in a 100:1 solution (50 mL) of methanol and concentrated HCl and stirred overnight at room temperature. The reaction was neutralized with sodium methoxide (325 mg), concentrated, and the residue partitioned between water and ethyl acetate. The organic phase was washed with brine, dried over sodium sulfate, concentrated, and chromatographed on silica gel (50 g) with 25:75 EtOAc/hexane (200 mL) followed by 50:50 EtOAc/hexane (300 mL). Three compounds were isolated: (*a*) the starting material **30** (114 mg); (*b*) 7,15-diacetyl-4-deoxynivalenol (**29**) (230 mg, 51%), mp 142–144°C; ^{1}H nmr: see Table 2; ms: 380 (5), 338 (13), 320 (10), 278 (33), 260 (38), 248 (52), 136 (90), 108 (80), 98 (100), 79 (91), 55 (85). *Exact Mass* (ms) calcd. for $C_{19}H_{24}O_8$: 380.1471; found: 380.1481 (M^+); and (*c*) 7-acetyl-4-deoxynivalenol (**26**) (64 mg, 16%), mp: 218–220°C; ^{1}H nmr: see Table 2; ms: 338 (4),

278 (11), 249 (40), 137 (49), 107 (56), 98 (100), 79 (88), 55 (87). *Exact Mass* (ms) calcd. for $C_{17}H_{22}O_7$: 338.1365; found: 338.1317 (M^+). The yield of compound **26** was not maximized.

*3-Keto-4-deoxynivalenol (**31**), 3,15-diketo-4-DON (**33**), and 15-keto-4-DON (**32**)*

Oxalyl chloride (30 μL, 0.32 mmol) in freshly distilled dichloromethane (2 mL) was cooled to −60°C. DMSO (50 μL) in CH_2Cl_2 (2 mL) was slowly added, under N_2 (18). DON (**24**) (85 mg, 0.29 mmol) in CH_2Cl_2 (2 mL) and DMSO (100 μL) were added over 5 min. The resulting solution was stirred at −60°C for 15 min and triethylamine (0.2 mL) was added. After a further 5 min, the solution was warmed to room temperature, water (10 mL) added, and the mixture extracted with CH_2Cl_2 (3 × 10 mL). The organic fractions were combined, washed with water, then with brine, dried over Na_2SO_4, concentrated, and chromatographed on silica gel (3 g) with 50:50 EtOAc/hexane to yield three compounds: (*a*) 3,15-diketo-4-deoxynivalenol (**33**) (52 mg, 62%); ^{1}H nmr: see Table 2; ms: 292 (4), 277 (1), 263 (5), 245 (23), 231 (56), 221 (49), 204 (84), 175 (40), 124 (91), 123 (96), 43 (100). *Exact Mass* (ms) calcd. for $C_{15}H_{16}O_6$: 292.0947; found: 292.0935 (M^+); (*b*) 3-keto-4-deoxynivalenol (**31**) (7 mg, 8.3%); ^{1}H nmr: see Table 2; ms: 294 (4), 279 (2), 276 (3), 264 (2), 246 (29), 231 (39), 204 (94), 175 (37), 136 (70), 124 (100), 108 (91), 77 (62), 55 (55), 43 (90). *Exact Mass* (ms) calcd. for $C_{15}H_{18}O_6$: 294.1103; found: 294.1111 (M^+); and (*c*) 15-keto-4-deoxynivalenol (**32**) (12 mg, 14.2%); ^{1}H nmr: see Table 2; ms: 294 (9), 279 (2), 276 (2), 265 (45), 248 (41), 208 (22), 179 (22), 167 (29), 151 (23), 137 (32), 123 (41), 105 (32), 98 (45), 95 (45), 77 (47), 55 (49), 43 (100). *Exact Mass* (ms) calcd. for $C_{15}H_{18}O_6$: 294.1103; found: 294.1083 (M^+).

*7,8-Dihydroxycalonectrin 7,8-boronate ester (**9**)*

7,8-Dihydroxycalonectrin (**8**) (50 mg, 0.13 mmol) and phenylboronic acid (23 mg, 0.19 mmol) in dry acetone were refluxed for 4 h, then cooled and concentrated to give a white oily solid. When washed with hexane, it yielded a white crystalline solid (60 mg, 98%), mp 119–120°C. ^{1}H nmr: see Table 1; ms: 468 (26), 426 (6), 408 (10), 395 (28), 304 (50), 262 (100), 223 (74). *Exact Mass* (ms) calcd. for $C_{25}H_{29}O_8B$: 468.1955; found: 468.1923 (M^+).

*3-Acetyl-4-deoxynivalenol 7,15-boronate ester (**35**)*

The same procedure as above with 3-acetyl-4-DON (**25**) gave a

quantitative yield; mp 209–210°C; ^{1}H nmr: see Table 2; ms: 424 (12), 327 (6), 267 (22), 163 (32), 98 (100), 79 (54). *Exact Mass* (ms) calcd. for $C_{23}H_{25}O_7B$: 424.1693; found: 424.1710 (M^+).

4-Deoxynivalenol 7,15-boronate ester (34)

The same procedure as above with 4-DON (**24**) gave a quantitative yield; mp 221–223°C; ^{1}H nmr: see Table 2; ms: 382 (29), 241 (55), 98 (100), 79 (49). *Exact Mass* (ms) calcd. for $C_{21}H_{23}O_6B$: 382.1587; found: 382.1592 (M^+).

3-Keto-4-deoxynivalenol 7,15-boronate ester (36)

The same oxidation conditions used for **31**, **32**, and **33** were followed with 4-DON boronate ester (**34**) as a substrate. The product consisted of a 50:50 mixture of the desired **36** and 3-keto-DON (**31**). This mixture was then boronated as above to yield the product **36** in 97% yield; mp 174–176°C; ^{1}H nmr: see Table 2; ms: 380 (100), 281 (16), 241 (24), 173 (50), 108 (93), 97 (89), 79 (70). *Exact Mass* (ms) calcd. for $C_{21}H_{21}O_6B$: 380.1430; found: 380.1414 (M^+).

Results and discussion

The most recognizable feature in the ^{1}H nmr spectrum of 12,13-epoxytrichothec-9-enes is a quartet for the C-13 methylene protons of the epoxy moiety. This AB system occurs between 2.70 and 3.40 ppm, with a coupling constant of 3.5–4.5 Hz, $\Delta\delta$ = 0.05–0.32 ppm. In some derivatized trichothecenes, this AB system collapses to a singlet. Other spectral characteristics are a sharp singlet for the C-14 methyl protons and a broad singlet for the C-16 methyl protons.

(A) C-13 methylene protons

The epoxide moiety projects upwards from the middle of the β face of the trichothecene molecule, hence it would be expected that its resonance would be affected by any structural variation. However, oxygenation at C-3, C-4, C-8, or C-15 has essentially no effect (Tables 1 and 2). The basic chemical shifts for the C-13 AB system are 2.80 and 3.05 ppm. For trichothecenes hydroxylated at C-7, these resonances are shifted downfield to 3.06–3.10 and 3.09–3.23 ppm, respectively. All the 7-OH trichothecenes reported to date have an α orientation.

That the H-13 chemical shifts are affected by substitution on the opposite face of the molecule can be rationalized using 3-dimensional models. In the most stable conformation of the trichothecene molecule (3*a*, 13, 19, 20), the A ring assumes a half-chair and the B ring a chair conformation (Fig. 2A). It can be clearly seen that C-13 is closer to the 7α-OH than other hetero substituents. In other possible conformations of the trichothecene molecule (i.e., A half-chair, B boat (Fig. 2B) and A boat, B boat), the 7α-OH group will be farther from the H-13 protons, resulting in minimal effect on their chemical shift.

(B) 16-Methyl group

These protons appear as a broad singlet in the range 1.65–1.89 ppm. Although this range is small, it is indicative of the substitution pattern of the A ring. Thus, for trichothecenes not substituted in the A ring, the 16-CH_3 chemical shift ranges from 1.65 to 1.71 ppm (**1–4**). The range is similar for compounds with a 7-OH (**5**, **6**); however, an 8-OH induces a downfield shift to 1.82–1.86 ppm (**10–14**). As expected, hydroxylation at both C-7 and C-8 induces no further shift (**7**, **8**). Acylation of the 8-OH returns the chemical shift upfield to 1.71–1.73 ppm (**15–19**) while oxidation of 8-OH to a ketone results in a slight upfield shift to 1.80–1.82 ppm (**20–22**). Hydroxyl or acetyl moieties at C-7 of the 8-ketotrichothecenes result in an even further downfield shift to 1.84–1.89 ppm (**23–33**).

(C) 14-Methyl group

The basic chemical shift for the 14-CH_3 is 0.80 ± 0.05 ppm (**1**). Hydroxylation of C-7 causes no significant change, and

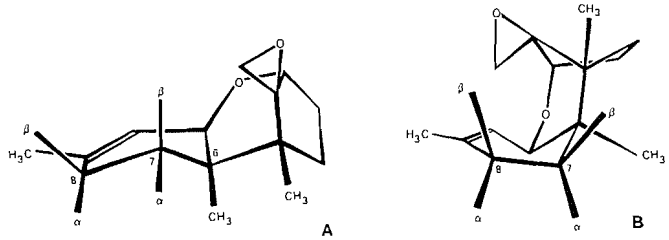

FIG. 2. Conformations of trichothecene ring system. (A) A half-chair, B chair; (B) A half chair, B boat.

hydroxylation of C-8 or C-15 results only in a minor downfield shift (0.01–0.1 ppm) (**3**, **13**, **14**, **22**). However, if both C-7 and either C-8 or C-15 are hydroxylated, the 14-CH_3 resonance is shifted downfield to 1.04–1.14 ppm (**7**, **24**, **25**). Acylation of the 15-OH has little effect (**5**, **8**, **23**, **27**, **28**), while acylation of the 7-OH produces an upfield shift to ~0.95 ppm (**26**, **29**, **30**). Oxidation of the 15-OH to an aldehyde or the 8-OH to a ketone, such as in **32**, **33** and **23**, **27**, **28**, has no effect on the 14-CH_3 chemical shift.

This dependence on C-8 or C-15 for an effect of C-7 substitution on the chemical shift of 14-CH_3 may be due more to steric than electronic factors as hydroxylation of C-8 or C-15 forces the 7-OH closer to the 14-CH_3.

An alternative explanation for the change in the 14-CH_3 chemical shift would invoke the less stable conformation in which ring A is in a half-chair and ring B in a boat conformation (Fig. 2B). This conformation would relieve the strain involved with both the 8-OH and the 15-CH_2OH being in axial positions (Fig. 2A). However, this implies a downfield effect on the chemical shift of H-14 for compounds hydroxylated at C-8 and C-15 but not at C-7, as in **13** (0.89 ppm), which is not observed.

(D) A ring

(a) C-7

When the A ring is not substituted, the H-7α resonance occurs at 1.7–1.8 ppm, and H-7β is at approximately 2.00 ppm (**2**, **4**). Hydroxylation at C-8 shifts these resonances slightly downfield to 1.7–2.1 ppm and 2.2–2.3 ppm (**10**, **13**), respectively, while acetylation of the 8-OH shifts the H-7β signal further to 2.3–2.4 ppm (**15–19**). No significant change is observed for the H-7α resonance. A ketone at C-8 results in an H-7β chemical shift of 2.85 ± 0.05 ppm, and H-7α resonance in the range 2.26–2.46 ppm.

Hydroxylation of C-7 (α position) shifts the H-7β resonance downfield to 4.5 ± 0.05 ppm (**5**, **6**). Hydroxylation of C-8 to give a dihydroxy compound has no further effect (**7**, **8**). Oxidation of C-8 to a ketone results in a chemical shift for H-7β of 4.8–4.9 ppm (**23**, **24**, **25**, **27**, **28**, **31**, **32**) and acetylation of the 7-OH of the resulting compounds shifts H-7β downfield to 6.05 ppm (**26**, **29**, **30**).

The H-7α and H-7β assignments are based on the $J_{7\alpha,8\beta}$ and $J_{7\beta,8\beta}$ coupling constants for the 8α-OH compounds. A value of $J_{7\alpha,8\beta}$ = 1.4–1.8 Hz is typical of an equatorial–equatorial dihedral angle $\Phi_{e,e}$ of 80°–90°, while $J_{7\beta,8\beta}$ = 5–6 Hz is typical for a $\Phi_{a,e}$ of 30°–40°. The lower field position of H-7β as compared to H-7α can be ascribed to its proximity to the oxygens at position 1 and in the epoxide moiety (16). Assignment of the higher field resonance to H-7α is aided by its coupling to H-11 observable in compounds **10–14**, **20**, and **21** ($J_{7\alpha,11}$ = 1.4–1.8 Hz). Only H-7α can achieve a "W" relationship with H-11 to show this long-range coupling (see Fig. 5). This necessitates an A half-chair, B chair conformation (Fig. 2A) for trichothecenes.

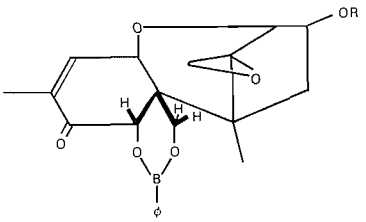

FIG. 3. Conformation of DON-boronate showing the 7,15-pro-*R* "W" relationship.

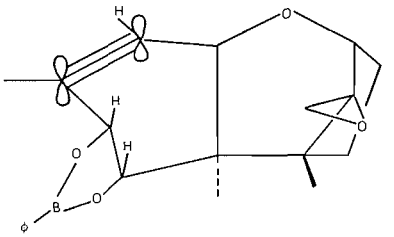

FIG. 4. Conformation of 7,8-dihydroxycalonectrin-boronate showing the steric relationship between the axial 8-H and the 9,10 π electron system.

W coupling is also observed in COSY spectra between H-7β and one of the H-15 protons but is measurable only for 8-keto-isotrichodermin (**20**) ($J_{7\beta,15}$ = 1.2 Hz) and some trichothecene derivatives such as the 7,15-boronates of DON (**34**) and 3-AcDON (**35**), where the H-7β and pro-*R*-H-15 are locked in a W conformation (Fig. 3). This rigid structure causes the H-7β signal to be a doublet (5.22–5.23 ppm) coupling with one H-15 ($J_{7\beta,15}$ = 2.2 Hz).

(b) C-8

The chemical shifts of the methylene protons at C-8 range from 1.7 to 2.4 ppm and exhibit small AB character. In addition to coupling to the H-7 methylene protons, the H-8 protons show long-range coupling with the 16-CH_3 and H-10 methine protons, which broadens the H-8 resonances, occasionally resulting in the dispersion of the H-8 signal beneath other peaks.

Hydroxylation at C-8 induces a downfield shift to 4–4.15 ppm (**7**, **8**, **10**–**14**), and acetylation of the resulting alcohols shifts the H-8 resonance further downfield to 5.2–5.3 ppm (**15**–**19**). These shifts permit easier assignment of the H-8 resonance, which appears as a broadened doublet (triplet when C*H*—O*H* coupling is present).

The 8-OH moiety in naturally occurring trichothecenes normally has the α configuration, which the exception of the 8β-hydroxytrichothecene isolated by Corley *et al.* (21) and two synthetic compounds, **14** (17) and its 15-Ac analogue (22). The *cis* coupling constant $J_{7\beta,8\beta}$ of 8α-OH trichothecenes is ~5 Hz, while the *trans* $J_{7\alpha,8\beta}$ is only 0–1.8 Hz. This result is consistent with the Karplus relationship for the stable conformation of the A ring (Fig. 2A and ref. 1). The *J* values of the synthetic 8β-OH epimer of 15-deacylneosolaniol (**14**) are 6 Hz (*cis*) and 10.2 Hz (*trans*), in agreement with the other reported values (21, 22). This sharp distinction in *J* values facilitates the assignment of the proper configuration at C-8.

(c) C-10

The H-10 resonance is also very characteristic of trichothecenes. It is usually a multiplet at 5.4–5.8 ppm but high field analysis with resolution enhancement shows this resonance to be a doublet of quartets, as originally postulated (23), which may be complicated by long-range coupling to the H-8. If $J_{10,8}$ is of the same order as $J_{10,16}$ (1.5 Hz), H-10 appears as a doublet of pentets as for compound **14**, which has an 8β-OH. In this case the axial C8—H bond is coplanar with the C9—C10 π orbital system thus maximizing the long-range coupling between H-8 and H-10.

The H-8β may also be forced into an axial position by acylation (**15**–**19**) or by boronation of 7,8-dihydroxycalonectrin (**8**) yielding the boronate **9**. In this derivative, $J_{7\beta,8\beta}$ has increased from the usual 5.5 Hz to 8.8 Hz as the C7—Hβ and C8—Hβ bonds are almost parallel. This reduction of the dihedral angle (Fig. 4) forces the H-8β into a pseudo-axial position parallel to the C9—C10 π-system, thus increasing the $J_{8\beta,10}$ to 1.5 Hz.

The H-10 chemical shift is significantly affected only by substitution at C-8 and C-3. Hydroxylation at C-8 moves the H-10 resonance from 5.4 to 5.6 ppm; acetylation of this alcohol moves it further downfield to 5.78 ppm, and oxidation to a ketone shifts it to 6.5–6.6 ppm. Since all compounds studied were oxygenated at C-3, the value of 5.27 ppm reported for 8β-hydroxytrichothecene may be used as a reference (21). The corresponding 3-hydroxylated compound, **14**, shows an increase in the H-10 chemical shift to 5.62 ppm as compared to 5.65 ppm for the 8α-OH isomer **13**, and acetylation of the 3-OH shifts it slightly to just under 5.6 ppm. Similar considerations about the effects of C-3 substitution are applicable to the 8-ketotrichothecenes.

(d) C-11

The H-11 resonance may be confused with that of H-8 when C-8 is hydroxylated since both are broad doublets in the same spectral region. The H-11 chemical shift ranges from 3.9 to 4.4 ppm and from 4.3 to 5.0 ppm for 8-ketotrichothecenes. The chemical shift is affected by oxidation at all ring positions and is therefore unsuitable for structure determination.

The broadness of this signal is due to long-range coupling to the 16-CH_3 and occasionally H-7α (see section *D* (*a*)), as shown by COSY experiments.

(E) C ring

(a) C-2

The H-2 resonance is a simple doublet due to coupling to H-3 and is observed at 3.6–3.9 ppm. The H-2 resonance occurs at a slightly lower field with a C-3 acetoxy group (3.72–3.75 ppm) than with a C-3 hydroxyl moiety (3.60–3.67 ppm). A C-8 keto group also affects the H-2 chemical shift of the 3-acetoxy compounds appreciably (3.8–3.9 ppm) but has apparently little effect in the case of 3-hydroxytrichothecenes.

(b) C-3

In this study, all compounds are oxygenated at C-3. The H-3 chemical shifts can be classified into three groups based on three structural variations: 3-OH-4-OAc-trichothecenes (4.15 ± 0.05 ppm), 3-OAc-trichothecenes (5.15 ± 0.05 ppm), and 3-OH-8-ketotrichothecenes (4.5 ± 0.1 ppm). Substitution at C-15, C-7, and C-8 has little effect (0.2 ppm) on the H-3 chemical shift.

All C-3 hydroxy or acetoxy trichothecenes isolated have in common the α configuration as deduced from $J_{2,3}$ = 4.4–5 Hz, typical of a Φ = 20°–30°. The $J_{3\beta,4\alpha}$ of trichothecenes is dependent on whether C-4 is oxygenated or not; if not substituted, $J_{3\beta,4\alpha}$ ranges from 4.5 to 8 Hz and is approximately 3 Hz if C-4 is substituted, as steric crowding appreciably reduces the 120° dihedral angle.

(c) C-4

If C-4 is not substituted, H-4α and H-4β range from 2.0 to 2.4 ppm, with H-4β usually at the higher field. The H-4

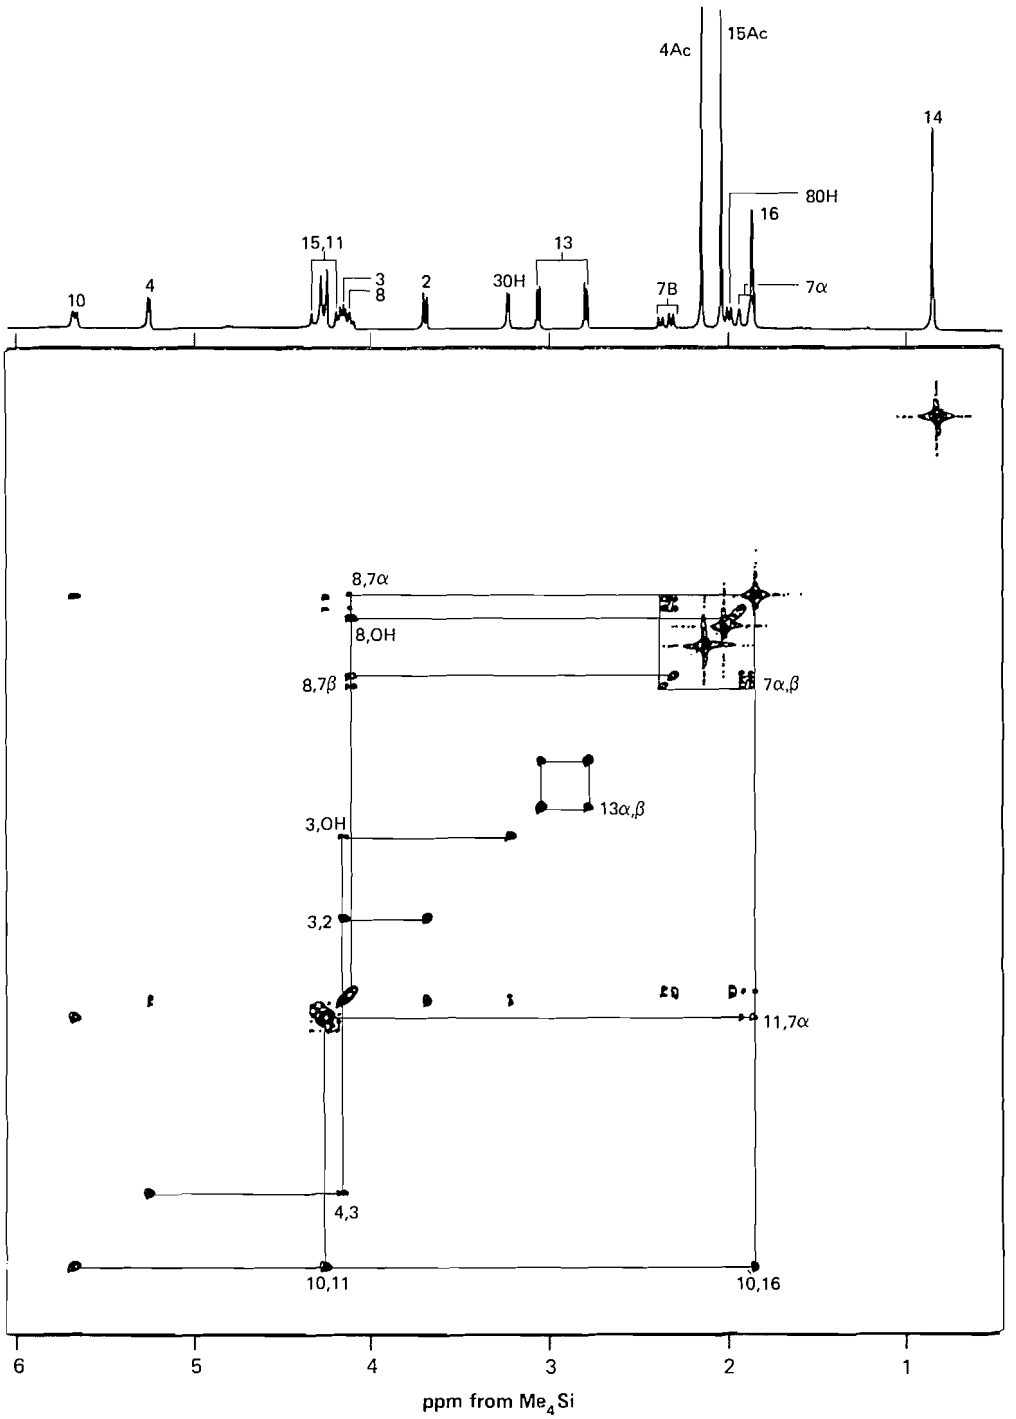

FIG. 5. $^1H/^1H$ correlation spectrum of neosolaniol (**12**), illustrating the first-order and long-range coupling typical for trichothecenes. The single pulse spectrum is shown at the top of the figure.

resonances are not resolved from H-7 and H-8 when these positions are unsubstituted. When resolved, the H-4 resonances can be easily identified by their $J_{3,4}$ coupling. Their geminal coupling constant $J_{4\alpha,4\beta}$ is approximately 15 Hz, while $J_{3\beta,4\beta}$ is about 10 Hz ($\Phi \sim 0°$) and $J_{3\beta,4\alpha}$ can vary from 4.5 to 8 Hz ($\Phi \sim 120°$) (20, 24). The large variation in the latter is due to the sensitivity of J to small changes in Φ at this angle as predicted by the Karplus relationship.

Acetylation of 4-OH gives H-4 resonances ranging from 5.0 to 5.4 ppm. The small values of $J_{3,4}$ (2.8–3.4 Hz) indicate a *trans* relationship (3α,4β) between the C-3 and C-4 substituents for all naturally occurring trichothecenes.

The H-4α resonance is affected by the acetylation of the C-3, C-7, C-8, and C-15 hydroxyl groups, all of which cause a slight downfield shift of the H-4α resonance but have a minimal effect on H-4β. Acetylation of the 3-OH has the greatest effect, as can be more clearly seen in synthetic derivatives (17). Compounds **15–19** provide another interesting series since the only variation is in the size of the C-8 substituent. The H-4 resonance occurs at 5.19 ppm when a C-8 acetoxy group is present, whereas a propionoxy group moves it to 5.25 ppm. Further increases in the straight-chain length of the C-8 substituent have no effect on H-4; however, branching at C-2′ (**17**) produces a further downfield shift of H-4 to 5.36 ppm (17).

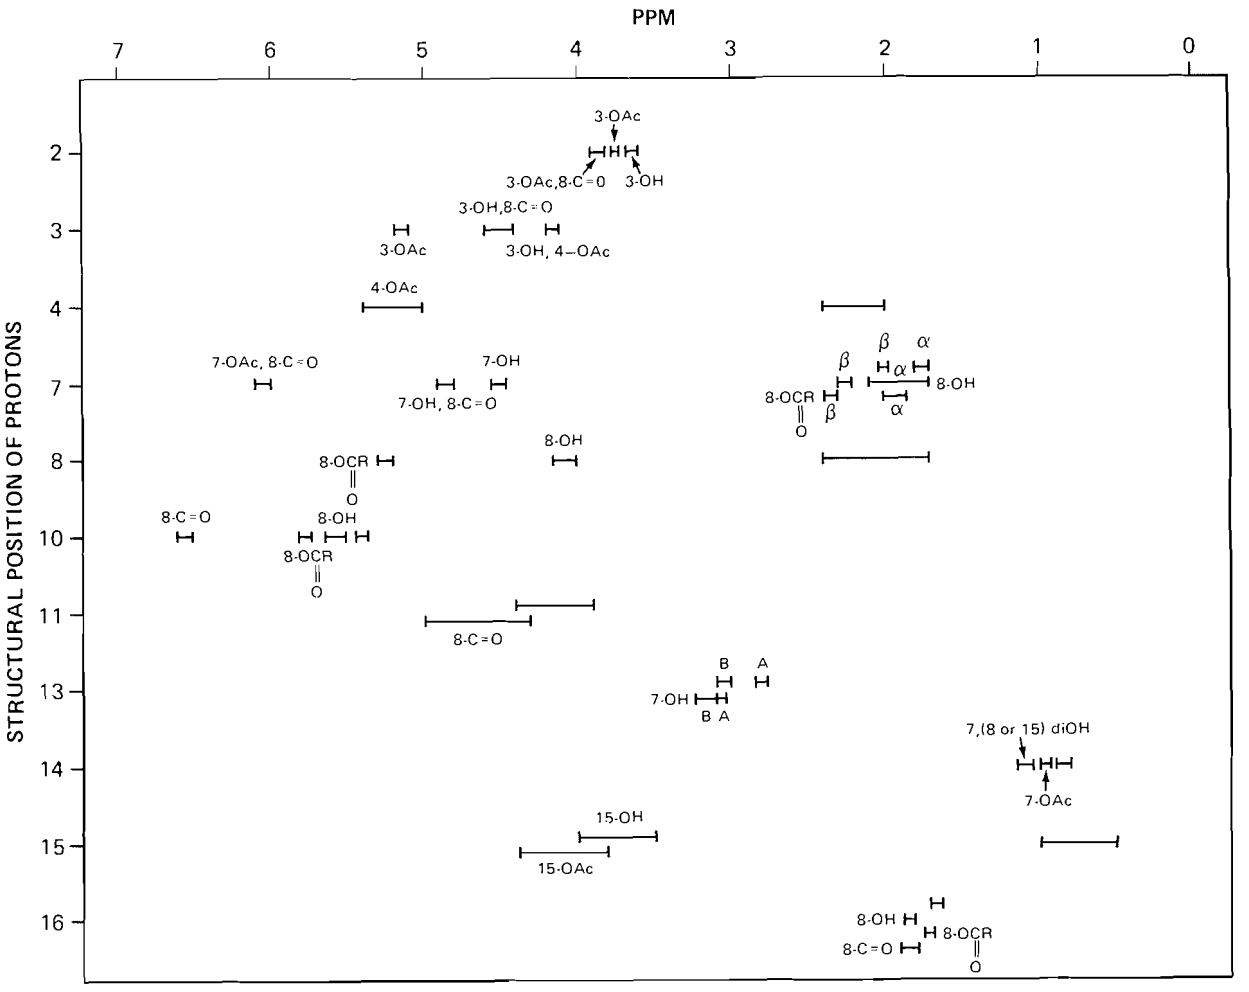

FIG. 6. Characteristic chemical shifts for trichothecene protons.

(F) C-15

For the isotrichodermin-type compounds (**1**, **6**, **7**, **10**, **20**), the 15-CH_3 resonance occurs as a singlet between 0.74 and 1.0 ppm. This resonance can be differentiated from the 14-CH_3 singlet by its long-range coupling to H-7β as observed in COSY spectra. When C-15 is oxygenated, the H-15 methylenic protons appear as an AB system ($\Delta\delta$ = 0–0.3 ppm) centered between 3.5 and 4.0 ppm for the free OH and between 3.9 and 4.4 ppm for the C-15 acetylated compounds. Occasionally further coupling to the 15-OH is observed.

The chemical shift of both methyl and methylenic H-15 protons is moved downfield by hydroxylation at either C-7 or C-8, the shift being greater for the 7-OH. Further downfield shift is induced by acetylation of the 7-OH, but acetylation or oxidation of the 8-OH to a ketone shows little effect.

Conclusion

Knowledge of the effect of the bonded and nonbonded interactions of trichothecenes on their nmr spectra facilitates the characterization of unknown compounds. The chemical shifts of the 16-CH_3, H-10, 14-CH_3, and H-15 protons provide information on the degree and type of oxygenation in ring A. The vicinal coupling constants $J_{7,8}$ and $J_{3,4}$ provide information on the orientation (α or β) for the various substituents. Long-range coupling observed between H-7 and H-15, between H-8 and H-16, and between H-8 and H-10 also offers specific information on the conformation of the trichothecene ring system. All these data are consistent with the stable conformation in solution having the A ring in a half-chair and the B ring in a chair conformation. The data are summarized in Fig. 6.

Kinetics of hydrolysis of aromatic mono- and disulfonyl chlorides

PRZEMYSLAW SANECKI AND EDWARD ROKASZEWSKI
Faculty of Chemistry, I. Lukasiewicz Technical University, 35-959 Rzeszów, Poland

Received October 29, 1986[1]

PRZEMYSLAW SANECKI and EDWARD ROKASZEWSKI. Can. J. Chem. **65**, 2263 (1987).

A continuous polarographic method of recording instantaneous concentrations of —SO_2Cl groups in an aqueous acetic acid system containing CH_3CO_2Na has been elaborated. Ten model monosulfonyl chlorides underwent hydrolysis according to pseudo-first order kinetics (20% H_2O, 80% v.v. CH_3CO_2H, 0.5 mol × dm^{-3} CH_3CO_2Na). Plots of hydrolysis for seven disulfonyl dichlorides with different number of —CH_3 groups have been determined. Pseudo-first order rate constants for two consecutive reactions of hydrolysis (k_1 and k_2) have been computed and the influence of —SO_2Cl and —SO_3^- groups on the reactivity of the second group —SO_2Cl has been discussed. The mechanism of nucleophilic substitution has also been discussed.

PRZEMYSLAW SANECKI et EDWARD ROKASZEWSKI. Can. J. Chem. **65**, 2263 (1987).

On a développé une méthode polarographique continue qui permet d'enregistrer instantanément la présence de groupements —SO_2Cl dans des systèmes aqueux d'acide acétique contenant du CH_3CO_2Na. Dix chlorures modèles de monosulfonyles ont subi une hydrolyse suivant une cinétique de pseudo-premier ordre (20% H_2O, 80% v/v de CH_3CO_2H et 0,5 mol × dm^{-3} de CH_3CO_2Na). On a déterminé les courbes d'hydrolyse de sept dichlorures de disulfonyles qui diffèrent par le nombre de groupements CH_3. On a calculé les constantes de pseudo-premier ordre pour les deux réactions d'hydrolyse consécutives (k_1 et k_2) et on discute de l'influence des groupements —SO_2Cl et —SO_3^- sur la réactivité du deuxième groupement —SO_2Cl. On discute aussi du mécanisme de la substitution nucléophile.

[Traduit par la revue]

Introduction

The solvolysis and hydrolysis of sulfonyl halogenides are subject of many papers (refs. 1–23 and references therein). The character of the investigations is closely linked with advances in knowledge on reaction mechanism as reported by Arrhenius, Bodenstein, Ingold, Winstein, Brønsted, and Hammett and co-workers. The titrimetric or conductometric methods were used in the determination of instantaneous concentrations of reagents or products, and spectral uv was used only in two cases.

It has been found that monosulfonyl chlorides hydrolyze according to the S_N2 mechanism (e.g. refs. 9, 10):

$$(R)Ar—SO_2Cl + H_2O \rightarrow (R)Ar—SO_3H + HCl$$

At a constant concentration of the nucleophilic agent such as H_2O (2, 8, 12, 14, 16, 17), OH^- (8, 22), $CH_3CO_2^-$ (12, 19, 22), the reaction is described by a pseudo-first order kinetic equation.

Only one paper (6) on the hydrolysis of bifunctional sulfonyl chlorides has been published so far but it does not attempt to determine separate rate constants (k_1 and k_2). The hydrolysis was investigated in a dioxane–water (30% by vol.) medium at an initial concentration of sulfonyl chloride 0.006–0.0125 mol dm^{-3} and temperatures of 303, 313, and 323 K. Five monofunctional sulfonyl chlorides were investigated: X—C_6H_4—SO_2Cl, X— = H—, C_6H_5—, C_6H_5—CH_2—, C_6H_5—O—, C_6H_5—CO—, and seven bifunctional derivatives: 4,4′-ClO_2S—Ar—X—Ar—SO_2Cl X = (—, good, biphenyl), CH_2, $(CH_2)_2$, O, CO, SO_2 (2,2′), and *m*-$C_6H_4(SO_2Cl)_2$. It was found that most bifunctional derivatives hydrolyze according to the first order kinetics (6). For *m*-benzenedisulfochloride we observed a continuous decrease in the rate constant as the reaction progressed (6).

This paper is, therefore, to determine the hydrolysis rate constant for each group of disulfonyl chlorides and to discuss some possible changes in the hydrolysis mechanism. The polarographic method enables us to register the instantaneous concentration of the —SO_2Cl groups in a detailed and continuous (or semi-continuous) manner.

Experimental

Chemicals

Seventeen sulfonyl and disulfonyl chlorides were used. The compounds were synthesized and purified by classical methods (24–26). The other substances used here (CH_3COOH, CH_3COONa) were p.p.a. Acetic acid was further purified by distillation over $KMnO_4$. Twice distilled water was used.

Apparatus

LP-60 polarograph with EZ-2 recorder and MLW-U-7^c ultrathermostat (±0.05 K) were used.

Rate measurements

The rate of hydrolysis in CH_3CO_2H containing H_2O medium in the presence of CH_3CO_2Na was determined by a polarographic method in a cell of 7 cm^3 capacity. The cell was connected to an external reference electrode (the saturated aqueous acetate electrode) by a reservoir filled with the same solution as that used for dissolving the substrates. The reservoir was separated from the reaction mixture and the reference electrode by a glass sinter G-5. Deaerated solution of the substrate in glacial acetic acid was introduced into deaerated solution of the other components in the polarographic cell and stirred with a stream of nitrogen at 298 ± 0.05 K for 3 s. Then, the polarographic circuit was closed and current intensity as a function of time was recorded, the nitrogen or argon atmosphere over the reaction mixture being continuously maintained. The current intensity ($i_{l,obs}$) − time (t) was continuously recorded at a constant potential corresponding to the potential of the limiting current. The latter was determined earlier for each compound from the polarographic wave. Initially, the concentration of —SO_2Cl was always 1.7×10^{-3} mol dm^{-3}. Paper feed rate was 8.0 cm h^{-1} (1 cm = 450 s), for *p*-$N(CH_3)_2C_6H_4SO_2Cl$ 4.0 cm min^{-1} (1 cm = 15 s). The measurement was terminated when ratio i_l/i_{l0} was smaller than or equal to 0.1. A slight adjustment (less than 0.3%) was made for residual current (i_{res}) using $i_l = i_{l,obs} - i_{res}$. The value of i_{res} did not change after all compound had reacted.

Kinetics

Compounds containing two —SO_2Cl groups should under-

For personal use only.

go two consecutive irreversible reactions of hydrolysis in accordance with the scheme

$$\underset{\text{A}}{\text{ClO}_2\text{S—Ar—SO}_2\text{Cl}} + \text{H}_2\text{O} \xrightarrow{k_1} \underset{\text{A}_1}{\text{ClO}_2\text{S—Ar—SO}_3\text{H}} + \text{HCl}$$

$$\underset{\text{A}_1}{\text{ClO}_2\text{S—Ar—SO}_2\text{H}} + \text{H}_2\text{O} \xrightarrow{k_2} \underset{\text{A}_2}{\text{HO}_3\text{S—Ar—SO}_3\text{H}} + \text{HCl}$$

It follows from statistical data that at identical reactivities of $—SO_2Cl$ groups in A and A_1 the ratio of constants $k_2/k_1 = r$ should be 0.5.

A system of two irreversible consecutive first order reactions

$$[1] \quad \text{A} \xrightarrow{k_1} \text{A}_1 \xrightarrow{k_2} \text{A}_2$$

is described by the known set of differential equations (27)

$$[2] \quad -\frac{da}{dt} = k_1 a$$

$$[3] \quad \frac{da_1}{dt} = k_1 a - k_2 a_1$$

$$[4] \quad \frac{da_2}{dt} = k_2 a_1$$

where $a = c_A/c_{0A}$, $a_1 = c_{A_1}/c_{0A}$, $a_2 = c_{A_2}/c_{0A}$; c_A, c_{A_1}, c_{A_2} are the instantaneous concentrations of compounds A, A_1, A_2, and c_{0A} is the initial concentration of substrate A. A solution to this problem is the following set of equations:

$$[5] \quad a = \exp(-k_1 t)$$

$$[6] \quad a_1 = (a - a^r)/(r - 1)$$

$$[7] \quad a_2 = 1 + ra/(1 - r) - a^r/(1 - r)$$

where $r = k_2/k_1$ and $a + a_1 + a_2 = 1.0$. An exact determination of constants k_1 or k_2 is possible by means of recording instantaneous concentrations of A, A_1, or A_2. It is also possible to record instantaneous concentrations of functional groups such as c_{SO_2Cl}.

In accordance with the reaction scheme, during hydrolysis we may expect two polarographically active compounds, A and A_1. The limiting current (i_l) measured at a given moment must be the sum of limiting currents of both forms A and A_1 which, in accordance with Ilkovič's equation, may be written as

$$[8] \quad i_l = \text{constant} \times n_A D_A c_A + \text{constant} \times n_{A_1} D_{A_1} c_{A_1}$$

where n is the number of electrons transferred during the reduction, D is diffusion coefficient, and c is concentration in mol dm^{-3}. For the reduction of both forms A and A_1 the numbers of transferred electrons are 4 and 2, respectively. A polarographic method does not produce a noticeable decrease in the concentration of $—SO_2Cl$ groups. We can assume that $D_A = D_{A_1}$. Hence from eq. [8] we get

$$[9] \quad i_l = 2\,\text{constant}_1 \times c_A + \text{constant}_1 \times c_{A_1}$$

For $t = 0$ eq. [9] takes the form

$$[10] \quad i_{l,0} = 2\,\text{constant}_1 \cdot c_{0A}$$

Dividing the members of eqs. [9] by [10] we get

$$[11] \quad i_l/i_{l,0} = c_A/c_{0A} + c_{A_1}/(2c_{0A})$$

or, having taken into consideration formulas for a, a_1, and a_2

$$[12] \quad i_l/i_{l,0} = a + a_1/2$$

From [5], [6], and [12] we get [13]:

$$[13] \quad p = i_l/i_{l,0} = \exp(-k_1 t) + \frac{\exp(-k_1 t) - \exp(-k_2 t)}{2(k_2/k_1 - 1)}$$

Rate constants were computed from the final non-linear equation [13] in which k_1 and k_2 are unknown. Equation [13] were utilized here for computing constants k_1 and k_2 on the basis of continuous recording of instantaneous concentrations of $—SO_2Cl$ groups, i.e., $p = f(t)$. We used a polarographic method which makes this recording possible.

The method of least squares was used in accordance with the condition

$$[14] \quad S = \sum_{j=1}^{n} \left[1 - \frac{p_j}{(i_l/i_{l,0})_j}\right]^2 = \text{minimum}$$

where p_j was a value computed on the basis of an assumed pair of values k_1 and k_2, but $(i_l/i_{l0})_j$ was measured at time t_j. From the continuous course $i_l = f(t)$ values $(i_l)_j$, differing by a constant step, at $n \geqslant 20$, were chosen.

Results and discussion

The suitability of the polarographic method was tested for the model compound $C_6H_5—SO_2Cl$ and for nine substituted derivatives $X—C_6H_4—SO_2Cl$ for which the following dependence was expected:

$$[15] \quad i_l/i_{l0} = \exp(-kt)$$

The results showed that in media presented in Fig. 1 and in Table 1 $\ln(i_l/i_{l0})$ is a linear function of time and that the rate constants of a pseudo-first order reaction do not change up to the reaction degree of 95 ± 5%.

The rate of hydrolysis of $C_6H_5SO_2Cl$ is a complex function of the electrolyte concentration (CH_3CO_2Na) and of the used solvents (H_2O, CH_3CO_2H), Fig. 1. With a constant concentration of solvents (80% CH_3CO_2H, 20% v.v. H_2O) an increase in acetate concentration from 0.1 to 0.3 mol dm^{-3} causes a slight increase in the hydrolysis rate-constant, curve *1*. This medium is characterized by an approximately equimolar ratio of the acid to water ($c_{CH_3CO_2H}/c_{H_2O} = 1.15/1.0$) and the hydrolysis reactions in it run more slowly than those in aqueous solutions (2, 8, 12). Probably the active concentration of water is lower than its computed value because of its co-association with acetic acid molecules. From extrapolation it follows that in the case of electrolyte shortage $k = 1.4 \times 10^{-5}$ s^{-1}; however, experimental determination of the constant by means of polarographic method cannot be done.

Simple nucleophiles such as H_2O, OH^-, $CH_3CO_2^-$ and complex nucleophiles such as hydrated ions, ion pairs, and larger aggregates may be present in the medium. However, we consider the participation of free OH^- groups improbable. When the acetate concentration increases in the range 0.1 to 0.3 mol dm^{-3}, a mixed hydrolysis involving water and a form of acetic anion may take place. When the acetate concentration increases in the range 0.3 to 0.5 mol dm^{-3} (Fig. 1, curve 1), an approximately linear increase in the hydrolysis rate is observed. This suggests the participation of acetic anions or the anions in complex nucleophiles.

Further increase in acetate concentration no longer causes a

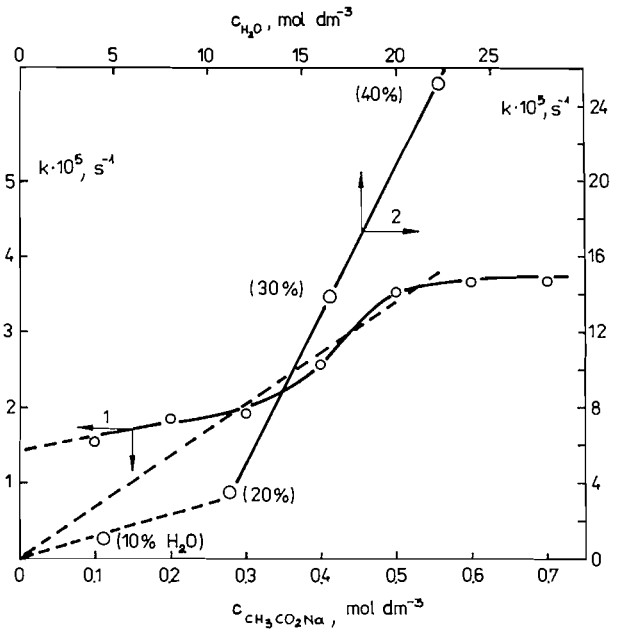

FIG. 1. Influence of sodium acetate concentration (curve *1*) at constant concentration of the solvents (80% CH_3CO_2H, 20% v.v. H_2O), and of water concentration (curve 2) at constant concentration of sodium acetate (0.5 mol × dm^{-3}) on the rate of hydrolysis of $C_6H_5SO_2Cl$ (c_0 = 1.7 × 10^{-3} mol × dm^{-3}), T = 298.15 K.

visible increase in the hydrolysis rate (Fig. 1, curve 1). In solutions with more water (20–40% v.v. H_2O, Fig. 1, curve 2), the investigated reaction is very sensitive to water concentration and the relationship $k = f(c_{H_2O})$ is linear. The increase in water concentration is accompanied by an increase in the concentration of acetate ions and within this range of water concentrations the hydrolysis probably involves "free" $CH_3CO_2^-$ ions as mentioned in refs. 12 and 19.

For comparison a solution 20% H_2O, 80% v.v. CH_3CO_2H, 0.5 mol dm^{-3} CH_3CO_2Na was used as a model medium. The results of hydrolysis of ten monosulfonylchlorides X—C_6H_4—SO_2Cl have been presented in Table 1.

Using the nine values of constants k (compounds **1** to **9**) a Hammett correlation [16] was determined:

$$[16]\quad \log (k_X/k_H) = \rho\sigma_X + \delta$$

ρ = 1.34 ± 0.25; δ = −0.091 ± 0.097, n = 9, r = 0.9788, s_0 = 0.097, for $t_{0.05,7}$. The probable reaction scheme is

$$[17]\quad Ar—SO_2Cl + CH_3CO_2^- \xrightarrow{k} Ar—SO_2—O—COCH_3 + Cl^-$$

$$[18]\quad Ar—SO_2—O—COCH_3 + CH_3CO_2^- + H_2O \xrightarrow{\text{fast}} Ar—SO_3^- + 2CH_3CO_2H$$

Of the ten investigated derivatives *p-N,N*-dimethylaminebenzenesulfonylchloride hydrolyzes exceptionally fast. One observes here a change in the character of the substituent from a donor to a strong acceptor and the estimated value of σ_X from [16] is as high as 1.66, greater than the value for *p*-$(CH_3)_2NH^+$ (32). The possible explanation is an elimination–additive mechanism such as those described in refs. 19, 22, 23:

$$[19]\quad (CH_3)_2N—C_6H_4—SO_2Cl \rightarrow (CH_3)_2\overset{+}{N}=\langle\bigcirc\rangle=SO_2 + Cl^-$$

This reaction is confirmed since the hydrolysis rate is independent of acetate concentration: $c_{CH_3CO_2Na}$ = 0.1; 0.3; 0.5 mol dm^{-3}, k = (4.67; 5.11; 4.95 ± 0.1) × 10^{-3} s^{-1}, respectively.

Using hyperchloric acid instead of sodium acetate (c_{HClO_4} = 0.5 mol × dm^{-3}) gives k = (1.38 ± 0.12) 10^{-3} s^{-1}. This medium allows the equilibrium —$N(CH_3)_2$ + H^+ ⇌ —$NH(CH_3)_2H^+$ to occur. The 3.6-fold rate reduction (from 4.95 × 10^{-3} to 1.38 × 10^{-3} s^{-1}) suggests a significant decrease in —$N(CH_3)_2$ concentration.

Our procedure enables us to study the hydrolysis kinetics of seven disulfonyl compounds $C_6H_{4-n}(CH_3)_n(SO_2Cl)_2$ where n = 0, 1, 2, 3, to determine their k_1 and k_2 values. Our results are presented in Table 2.

The rate constant ratio $r = k_2/k_1$ suggests a change in the reactivity of the second —SO_2Cl group after the charged SO_3^- group has appeared. Despite the negative charge, the group shows an acceptor character and the rate constants of the investigated derivatives are greater than the hydrolysis rate constant of the model compound $C_6H_5SO_2Cl$. For *meta* and *para* disulfonyldichlorides they are, on average, one order lower than the corresponding values of k_1 ($r = k_2/k_1$ = 0.066 ÷ 0.28).

On the other hand, for two compounds (11, 14) with —SO_2Cl groups in the *ortho position* $k_2 \cong k_1$. Here there is probably a change in the reaction mechanism from S_N2 to S_Ni for the second reaction [21]:

$$[20]\quad o\text{-}(ClO_2S)_2C_6H_4 + CH_3CO_2^- + H_2O \xrightarrow{k_1} 4\text{-}HO_3S—C_6H_4—SO_2Cl + CH_3CO_2H + Cl^-$$

$$[21]\quad C_6H_4(SO_2Cl)SO_3H \xrightarrow{k_2 \cong k_1} C_6H_4\langle{}^{SO_2}_{SO_2}\rangle O + H^+ + Cl^-$$

$$[22]\quad C_6H_4(SO_2)_2O + CH_3CO_2^- + H_2O \xrightarrow{\text{fast}} C_6H_4(SO_3H)SO_3^- + CH_3CO_2H$$

In the hydrolysis reaction of the second —SO_2Cl group (S_Ni mechanism) —OH group from SO_3H or —O^- from SO_3^- becomes an internal nucleophilic agent. From a statistical viewpoint, the second reaction is two times faster than the first one.

We have gathered below some σ_X constants for —SO_2Cl and —SO_3^- substituents calculated from eq. [16] and the data

TABLE 2. Pseudo-first order rate constants of consecutive hydrolysis (k_1, k_2) of benzenedisulfonylchlorides $C_6H_{4-n}(CH_3)_n(SO_2Cl)_2$, $c_{SO_2Cl} = 1.7 \times 10^{-3}$ mol dm^{-3}, $T = 298.15$K

No.	Compound	$k_1 \times 10^5$ (s^{-1})	$k_2 \times 10^5$ (s^{-1})	$r = k_2/k_1$	sd 100%*

17	3-ClO_2S-2,4,6-$(CH_3)_3$—C_6H_1—SO_2Cl	135 ±2	13.2 ±0.50	0.098	3.4

*sd = $[S/(n-1)]^{1/2}$, eq. [14].

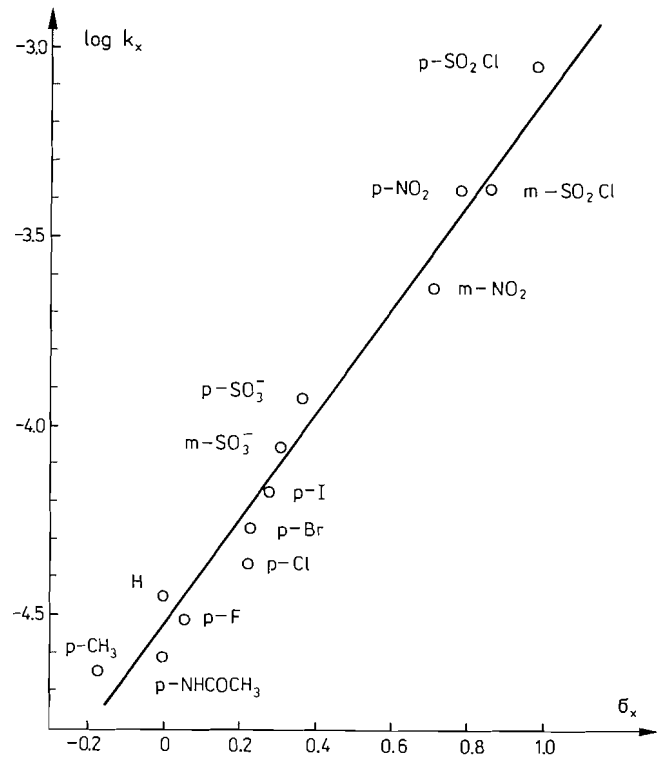

FIG. 2. Hammett correlation for the hydrolysis of substituted benzenesulfonylchlorides in the solution 80% CH_3CO_2H, 20% v.v. H_2O; $c_{CH_3CO_2Na} = 0.5$ mol × dm^{-3}, $c_{0,SO_2Cl} = 1.7 \times 10^{-3}$ mol × dm^{-3}, $T = 298.15$ K.

in Table 2, after taking the statistical data into account: $k_{SO_2Cl} = k_1/2$, $k_{SO_3^-} = k_2$.

o-SO_2Cl	*m*-SO_2Cl	*p*-SO_2Cl
0.43	0.87	1.11
o-SO_3^-*	*m*-SO_3^-	*p*-SO_3^-
0.66	0.37	0.46

*indicates a change in hydrolysis mechanism

For *meta* and *para* substituents these values are within the range given in the literature (28–34).

Compound **14** (Table 2) may undergo a parallel two step hydrolysis since it contains two unidentical groups —SO_2Cl. The actual summary hydrolysis rate should thus be described by four constants. The same is true for compound **15**. The other compounds (**16** and **17**) contain —SO_2Cl groups which are identical because of their symmetrical structures and it is of no significance which of these hydrolyzes first. The presence of methyl groups in *ortho* position increases the hydrolysis rate.

By adding four points for hydrolysis *m*- and *p*-disulfonyldichlorides and their intermediates ($k_1/2$ and k_2, Table 2) to correlation [16] we get a more general and accurate Hammett correlation (Fig. 2):

$$\log (k_X/k_H) = (1.42 \pm 0.16)\sigma_X - (0.087 \pm 0.082)$$

$$n = 13,\ r = 0.9852,\ s_0 = 0.094, \quad \text{for } t_{0.05,11}$$

The literature substituent constants were taken into account: $\sigma^m_{SO_3^-} = 0.31$, $\sigma^p_{SO_3^-} = 0.37$ (35), $\sigma^m_{SO_2Cl} = 0.86$ (36, 37), and $\sigma^p_{SO_2Cl} = 0.98$ (38). The value $\sigma^p_{SO_2Cl} = 0.98$ was also computed from Exner's equation (39). The value 1.11 determined from the correlation [16] is close to the value computed from the data given by Taft *et al.* (36, 37): $\sigma^p_{SO_2Cl} = 1.14$ ($\sigma_I = 0.86$, $\sigma_R = 0.28$) as well as to the value given by Bray and Barnes (29): $\sigma^p_{SO_2Cl} = 1.114$.

Acknowledgements

The authors would like to thank a referee for pointing out that our present results show a good correlation with Rogne's k_{OH^-} values (8), indicating the ionic character of the reaction.

Received January 26, 1987

JALEH KHORAMI, ALAIN LEMIEUX, and DENIS NADEAU. Can. J. Chem. **65**, 2268 (1987).

Magnesium hydroxide and silica, which are at the base of the chemical composition of chrysotile asbestos fibers, have been treated with phosphorus oxychloride vapors and compared to chrysotile asbestos treated similarly. Thermogravimetric, evolved gas analyses, and Fourier Transform infrared spectroscopy techniques were used to identify the compounds formed and (or) adsorbed on the surface of the minerals phosphorylated at room temperature and after a heat post-treatment at 300°C. The results obtained show that the reaction of silica with phosphorus oxychloride can be considered negligible. However, the modifications induced on magnesium hydroxide and chrysotile asbestos fibers are similar. After the chemical treatment at room temperature, it was possible to identify the presence of hydrochloric acid, phosphorus oxychloride, magnesium chloride (nH_2O), and acid orthophosphate salts. In comparison, the compounds formed after the 300°C heat post-treatment were only hydrated polyphosphate salts and magnesium chloride (nH_2O). It is postulated that a polyphosphorus coating is formed at the surface of the chrysotile asbestos fibers when these are treated with phosphorus oxychloride at room temperature and then treated at 300°C after the phosphorylation process.

JALEH KHORAMI, ALAIN LEMIEUX et DENIS NADEAU. Can. J. Chem. **65**, 2268 (1987).

L'hydroxyde de magnésium et la silice, qui constituent la base de la composition chimique de l'amiante chrysotile, ont été traitées avec des vapeurs d'oxychlorure de phosphore pour être ensuite comparées avec des fibres d'amiante chrysotile traitées de façon similaire. Des techniques telles que les analyses thermogravimétriques, les gaz dégagés et la spectroscopie infrarouge ont été utilisées pour identifier les composés formés et (ou) adsorbés sur la surface des minéraux phosphorylés à la température ambiante, et après un post-traitement à la chaleur (300°C). Les résultats obtenus montrent que la réaction de la silice avec l'oxychlorure de phosphore peut être considérée comme négligeable. Cependant, les modifications induites sur l'hydroxyde de magnésium et les fibres d'amiante chrysotile sont similaires. Après traitement chimique à la température ambiante, on a pu identifier la présence d'acide chlorhydrique, d'oxychlorure de phosphore, de chlorure de magnésium (nH_2O) et des sels d'orthophosphates acides. Comparativement, les composés retrouvés après le post-traitement à 300°C sont uniquement des sels hydratés de polyphosphate et le chlorure de magnésium. Il est postulé que, lorsque la réaction de l'amiante chrysotile avec l'oxychlorure de phosphore à la température de la pièce est suivie d'un post-traitement à 300°C, le traitement chimique conduit à la formation d'un revêtement de polyphosphate sur la surface des fibres.

Introduction

It has been repeatedly demonstrated that one of the factors responsible for the biological activity of chrysotile asbestos fibers is related to its chemical structure, particularly in relation to the surface reactivity of the mineral (1, 2). Several methods have been devised to study the effect of a chemical modification on the biological reactivity of chrysotile asbestos. These methods include acid leaching (3, 4) and metal deposition (5). One of the methods selected by Lalancette and co-workers (6, 7) for inducing a chemical modification of this mineral was phosphorylation with phosphorus oxychloride ($POCl_3$). Chrysotile fibers thus treated showed successful reduction of biological activity without losing their main industrial properties.

Previously we characterized these chemically modified fibers using thermogravimetric methods (TG/DTG), infrared spectroscopy (IR), surface charge or zeta potential (ZP), and specific surface area (SSA) measurements (8, 9). From these studies it was concluded that, after the treatment with $POCl_3$ vapours and a post-treatment at 300°C, the chrysotile fibers were coated with phosphorus compounds. Nevertheless, none of these previous methodologies could clearly establish the chemical composition of the phosphorus compounds deposited at the surface of the chrysotile fibers. For example, IR spectra of the treated fibers revealed several modifications, but it was concluded that the vibration bands of the phosphorus compounds were overlaying the Si—O bands of the crystalline structure of chrysotile (9).

Chrysotile asbestos fibers belong to the serpentine family. The basic structure of this mineral group is a sheet of silica

TABLE 1. Physicochemical properties of the minerals before and after the $POCl_3$ treatment

Sample	ZP (mV)	SSA (m^2/g)	Percentage phosphorus retained
SiO_2	−51	1.0	0
SiO_2 + $POCl_3$ (room temp.)	−51	1.0	0.1
SiO_2 + $POCl_3$ + Δ 300°C	−51	1.0	0.1
$Mg(OH)_2$	+9	20.0	0
$Mg(OH)_2$ + $POCl_3$ (room temp.)	−10	*	1.5
$Mg(OH)_2$ + $POCl_3$ + Δ 300°C	−15	14.0	1.9
Chrysotile very short fibers (VSF)	+40	38.0	0
VSF + $POCl_3$ (room temp.)	−20	*	3.2
VSF + $POCl_3$ + Δ 300°C	−26	24.0	3.6

*The presence of volatile materials in these products did not allow us to determine the exact SSA for these samples.

TABLE 2. Thermogravimetric profiles of the magnesium hydroxide sample before and after the phosphorylation process

Compound	Percentage of weight loss between 30 and 300°C	Percentage of weight loss between 300 and 600°C	Total percentage of weight loss up to 1000°C
$Mg(OH)_2$	1.7	25.5	30.4
$Mg(OH)_2 + POCl_3$ (room temp).	15.6	25.2	43.1
$Mg(OH)_2 + POCl_3 + \Delta$ 300°C	1.5	31.0	33.8

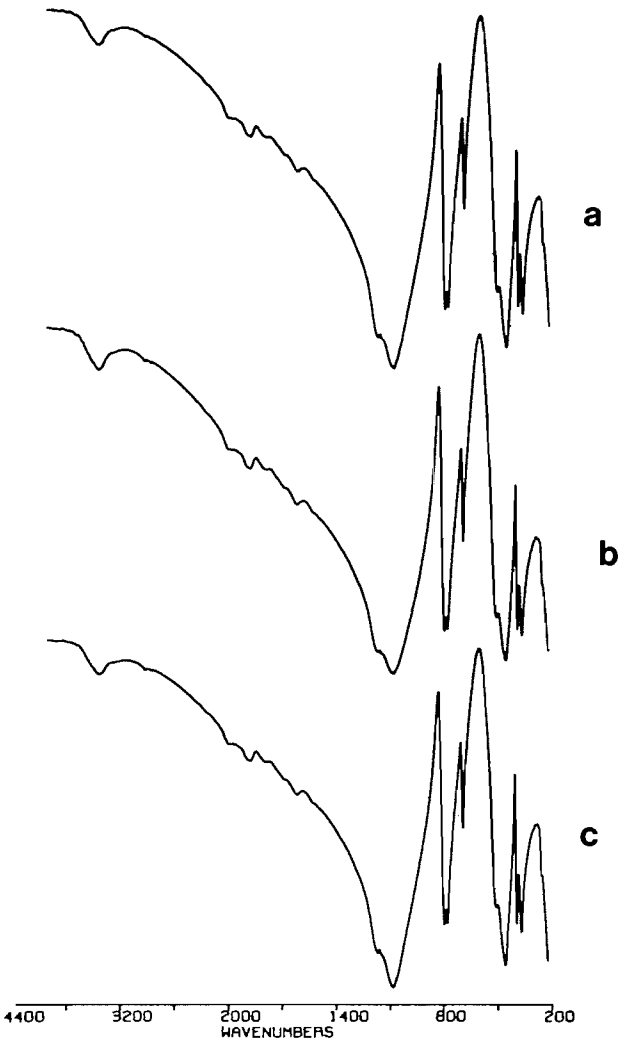

FIG. 1. FTIR spectra of SiO_2 before and after the $POCl_3$ treatment. (*a*) SiO_2; (*b*) $SiO_2 + POCl_3$; $SiO_2 + POCl_3 + \Delta$ 300°C.

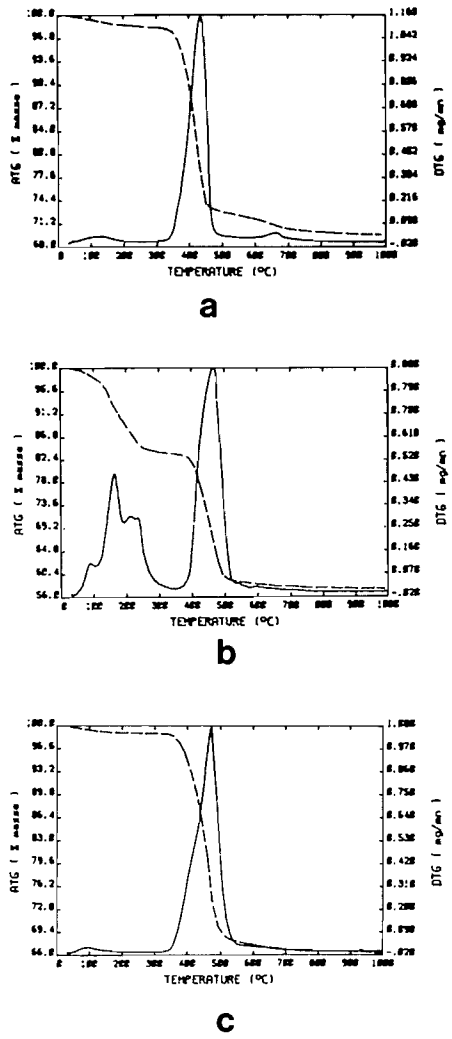

FIG. 2. TG/DTG profiles of magnesium hydroxide before and after the $POCl_3$ treatment. (*a*) $Mg(OH)_2$; (*b*) $Mg(OH)_2 + POCl_3$; (*c*) $Mg(OH)_2 + POCl_3 + \Delta$ 300°C.

tetrahedra, overlaid with a sheet of magnesium hydroxide (Mg—OH). With chrysotile, the differences in the lattice parameters of the silica and magnesium hydroxide layers induce the composite to adopt a curvature, with the Mg—OH groups on the external surface (10).

In this study two compounds, magnesium hydroxide ($Mg(OH)_2$) and silica (SiO_2), which are the basis of the chemical composition of chrysotile asbestos, have been phosphorylated in the same manner as the chrysotile fibers. These two composites were selected mainly to determine which of the hydroxyl (O—H) groups, situated on the surface, or the silica sheet, from the inner layer of the chrysotile structure, show the strongest reactivity with $POCl_3$.

From the IR spectra of $Mg(OH)_2$ before and after treatment with $POCl_3$, we could identify the chemical composition of the phosphorus compounds that were formed during reaction at room temperature and after the post-treatment at 300°C. Finally, from the comparison of the IR spectra of the powders, the thermal curves, the IR spectra of the evolved gases from the thermal decompositions, and from the ZP and SSA measurements on $Mg(OH)_2$, SiO_2, and chrysotile asbestos before and after the

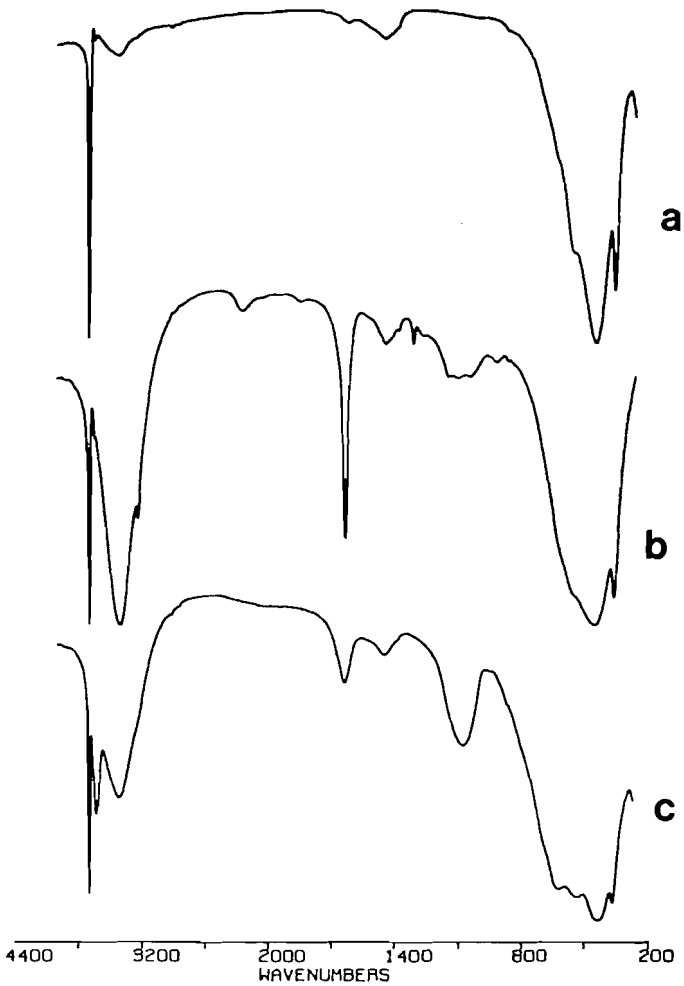

FIG. 3. FTIR spectra of magnesium hydroxide before and after the $POCl_3$ treatment. (*a*) $Mg(OH)_2$; (*b*) $Mg(OH)_2$ + $POCl_3$; (*c*) $Mg(OH)_2$ + $POCl_3$ + Δ 300°C.

$POCl_3$ treatment, we were able to elucidate the nature of the phosphorus compounds retained on the surface of the chrysotile fibers.

Experimental

The chemicals used in this study are as follows: (*a*) $POCl_3$ (from BDH Chemicals code No. B29536); (*b*) $Mg(OH)_2$ (from Fluka AG, BUCHS SG purum p.a. code no. 63078); (*c*) SiO_2 (from Fisher No. S-153 Floated powders 240 mesh); (*d*) chrysotile asbestos. (Very short fibers from the commercial grade 4T30 were isolated by a method based on the procedure of Jolicoeur *et al.* (11).)

Each sample was characterized before and after the $POCl_3$ treatment, with the following methods:

(a) Fourier Transform Infrared (FTIR) spectroscopy (Model MX-1, Nicolet Instrument Corp., Madison, WI).

(b) TG/DTG (Model TGS-2, Perkin–Elmer Canada Ltd, Montréal, Québec, Canada).

(c) ZP in 1 m*M* KCl, pH 7.0 (Zeta-reader, model ZR-11, Komline–Sanderson, Noram, Pointe Claire, Québec).

(d) SSA by nitrogen (N_2) adsorption (Quantasorb, model QS-10, Quantachrome Corp., Syosset, NY).

Twenty-four hours before the treatment with $POCl_3$, a known amount of each sample was dried at 110°C. The dried samples were then treated according to the procedure outlined by Lalancette and Dunnigan (7), by circulating N_2 gas saturated with $POCl_3$ vapors at 14°C through a reaction vessel held at ambient temperature. Finally, the $POCl_3$-treated samples were withdrawn and heated in an oven at 300°C for 2.5 h (8).

Results and discussion

In this study we will examine the SiO_2, $Mg(OH)_2$, and chrysotile asbestos before the chemical treatment, after treatment in the gas phase with $POCl_3$ at room temperature, and after the heat post-treatment at 300°C. The physicochemical analyses performed on these samples are summarized in Table 1.

Reaction of $POCl_3$ with SiO_2

Silicates are known to have a high thermal stability; the thermal trace TG/DTG (not illustrated) of untreated SiO_2 and $POCl_3$-treated SiO_2 did not show any significant thermal decomposition between 30 and 1000°C. Infrared spectra of SiO_2 treated with $POCl_3$ at room temperature and heated are compared with those of untreated SiO_2 (Fig. 1). No striking changes occurred during treatment of SiO_2 with $POCl_3$ either at room temperature or after the 300°C post-treatment. In Table 1 it is shown that, for SiO_2, ZP and SSA measurements are comparable before and after the treatments. Nevertheless, a small percentage of phosphorus is retained on the surface of the mineral (0.1%).

Reaction of $POCl_3$ with $Mg(OH)_2$

The thermal curves TG/DTG as well as the IR spectra of $Mg(OH)_2$, before and after the treatment with $POCl_3$, are given in Figs. 2 and 3. The thermogravimetric results (weight losses) are given in Table 2 and the physicochemical properties before and after the chemical treatment are presented in Table 1. From these results, one can see that $Mg(OH)_2$ has reacted more strongly with $POCl_3$ than has SiO_2 and that the composition of the phosphorus compounds formed during the treatment at room temperature and after the 300°C heat treatment are different.

(a) Treatment of $Mg(OH)_2$ with $POCl_3$ at room temperature

The thermogravimetric analyses show a 15.6% total weight loss between 30 and 300°C. The weight losses in this temperature range indicate the existence of volatile compounds absorbed, and (or) the presence of physisorbed and crystallization water.

From the FTIR spectra of gases evolved between 30 and 300°C and 300 and 600°C (Figs. 4 and 5), one can characterize these volatile compounds by evolved gas analyses (EGA). Gases like H_2O, HCl, CO_2, and $POCl_3$ evolved between 30 and 300°C. Between 300 and 600°C, TG/DTG and EGA data indicate a decomposition of the $Mg(OH)_2$. However, we cannot rule out the possible formation of $MgCl_2 \cdot nH_2O$ during the reaction. Todor (12) showed that a partial hydrolysis of the type shown in eq. [1], as well as some decomposition of $Mg(OH)_2$, can occur in this range of temperature.

[1] $MgCl_2 + H_2O \rightarrow MgO + 2HCl$

The spectra of the gases evolved between 300 and 600°C, showing traces of HCl, confirm the overlapping of the decomposition of $Mg(OH)_2$ and the partial hydrolysis of $MgCl_2 \cdot nH_2O$ occurring in this temperature range. The FTIR analyses of $Mg(OH)_2$ treated with $POCl_3$ at ambient temperature are given in Table 3 and Fig. 3. From these results, it is believed that the major phosphorus compounds formed during the phosphorylation at ambient temperature are acid orthophosphate salts.

In summary, from the TG/DTG, EGA, and FTIR analyses, it was possible to identify the presence of the following compounds formed and (or) adsorbed during the reaction: HCl, $POCl_3$, $MgCl_2 \cdot nH_2O$, and acid orthophosphate salts.

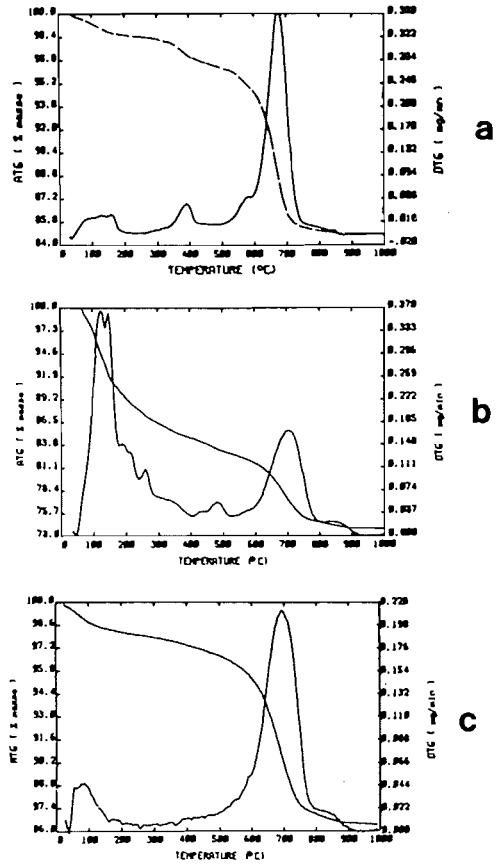

FIG. 6. TG/DTG profiles of chrysotile before and after the $POCl_3$ treatment. (*a*) Chrysotile (VSF); (*b*) VSF + $POCl_3$; (*c*) VSF + $POCl_3$ + Δ 300°C.

heated at 300°C (Fig. 2 and Table 2) indicate a slight percentage of weight loss between 30 and 300°C. Nevertheless, as judged by the percentage of weight loss and the DTG curve profile in the range 300–600°C, we can predict the superimposition of several decomposition products (Fig.2 and Table 2). The IR spectra of the gases evolving between 300 and 600°C (Fig. 5) show the presence of H_2O, CO_2, and HCl. From these results we can conclude that the following decompositions are overlapping in this range of temperature:

[2] $Mg(OH)_2 \rightarrow H_2O + MgO$

[3] $MgCl_2 + H_2O \rightarrow MgO + 2HCl$

The IR spectra of the phosphorylated $Mg(OH)_2$ sample after the 300°C heat treatment (Fig. 3 and Table 3) show significant changes when compared to the $Mg(OH)_2$ treated only with $POCl_3$ at room temperature. We observe the disappearance of absorption bands related to the presence of acid orthophosphate salts and the appearance of a broad band between 1200 and 980 cm^{-1}, with a maximum at 1080 cm^{-1}. This is interpreted as P—O—P stretching bands, while the P—O—P bending band is observed as a shoulder at 630 cm^{-1}. We also notice the absence of bands due to HCl vibrations (linked to the $Mg(OH)_2$ by H-bonds) at 2260 and 1860 cm^{-1}. The presence of the bands at 3625 and 3408 cm^{-1} (O—H stretching) indicates the presence of more than one type of water of crystallization and (or) free water (physisorbed water).

The appearance of CO_2 vibrations in the spectra of evolved gases from $Mg(OH)_2$ can be due to CO_2 impurities in the gas cell and (or) the atmosphere, as well as to traces of CO_2 adsorbed on the surface of the mineral.

TABLE 4. Thermogravimetric profiles of the chrysotile asbestos fibers before and after the phosphorylation process

Compound	Percentage of weight loss between 30 and 300°C	Percentage of weight loss between 300 and 600°C	Percentage of weight loss between 600 and 1000°C	Total percentage of weight loss up to 1000°C
Chrysotile VSF	1.8	3.6	9.9	15.3
VSF + $POCl_3$ (room temp.)	13.6	4.8	7.7	26.5
VSF + $POCl_3$ + Δ 300°C	2.0	2.2	9.3	13.5

before and after treatment with $POCl_3$ at room temperature and after the 300°C heat post-treatment, respectively, are presented in Fig. 6 and Table 4. The EGA for the thermal decomposition of the three samples of chrysotile in the temperature ranges 30–300°C, 300–550°C, and 550–1000°C are respectively illustrated in Figs. 7, 8, and 9. While the IR results are reported in Fig. 10 and Table 3, in Fig. 11 is found the comparison between the IR spectra of chrysotile asbestos and of $Mg(OH)_2$ treated with $POCl_3$ at room temperature and after the 300°C heat post-treatment.

One can observe the similarity of the compounds formed during the treatment with $POCl_3$ at room temperature and after the heat post-treatment of the two minerals. As can be seen from Fig. 11, the silicate vibrations of the chrysotile fibers overlap those of the phosphate compounds (between 1200 and 800 cm^{-1}; also between 800 and 400 cm^{-1}). Due to the superimposition of these bands, it was not possible to clearly identify by IR the characteristic bands of the different phosphorus compounds formed during the phosphorylation of chrysotile asbestos. However, as schematized in Fig. 12, it is strongly suspected that the

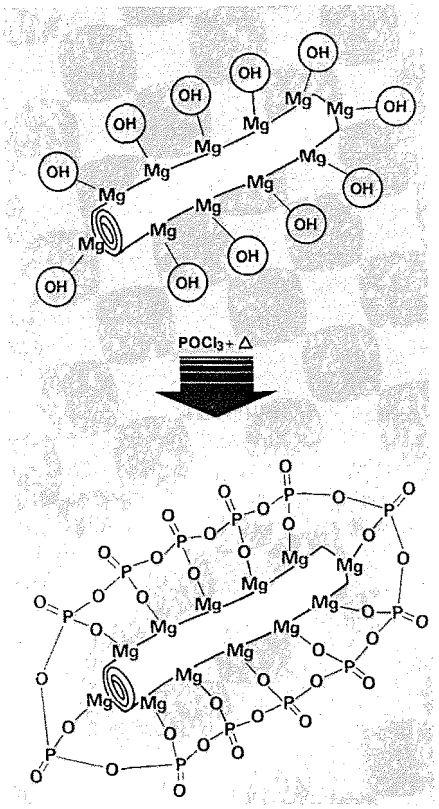

FIG. 12. Schematic representation of a chrysotile asbestos monofibril before and after the $POCl_3$ process and post-treatment at 300°C.

modification of chrysotile asbestos fibers by $POCl_3$ involved a coating of the fibers with polyphosphate compounds, implicating the structural O—H groups at the surface of the mineral fibers.

Conclusion

From the data of this study, one can summarize the following points:

(*a*) The results obtained with SiO_2 and $Mg(OH)_2$ after the treatment with $POCl_3$ at ambient temperature and after the 300°C heat post-treatment show that the reaction of $POCl_3$ with silica can be considered negligible.

(*b*) The modifications induced by the $POCl_3$ treatment on $Mg(OH)_2$ and chrysotile asbestos fibers are similar.

(*c*) The phosphate compounds formed during the chemical treatment at room temperature are mostly hydrated acid orthophosphate salts, while those formed after the 300°C heat post-treatment are hydrated polyphosphate salts.

(*d*) $MgCl_2 \cdot nH_2O$ salts are formed either during the $POCl_3$ treatment at room temperature or after the heat post-treatment, while the presence of $POCl_3$, HCl, and H_2O adsorbed on the surface were only observed after the $POCl_3$ treatment at room temperature.

Therefore one can conclude that between the silica and the magnesium sheets of the structure of chrysotile asbestos fibers, the magnesium sheet and, more especially, the O—H layer on the external surface of the fibers possess the strongest reactivity with $POCl_3$ vapors.

Reactivity and photophysical behavior of chromone triplet. A laser flash photolysis study

S. RAJADURAI AND P. K. DAS[1]

Radiation Laboratory, University of Notre Dame, Notre Dame, IN 46556, U.S.A.

Received February 9, 1987

S. RAJADURAI and P. K. DAS. Can. J. Chem. **65**, 2277 (1987).

The chromone triplet (λ^T_{max} = 620 nm, $\varepsilon^T_{max} = 2.5 \times 10^3 M^{-1}\,cm^{-1}$ in acetonitrile) is produced in quantitative yields upon 308- or 337.1-nm laser pulse excitation and is characterized by submicrosecond lifetimes in solutions at room temperature. The short-lived nature of the triplet is attributable to intrinsically fast $T_1 \rightsquigarrow S_0$ intersystem crossing, nearly diffusion-limited self-quenching, and facile interactions with solvents in the form of charge and hydrogen-atom transfer. The unusually high self-quenching rate constants, $(0.9–4.0) \times 10^9 M^{-1}\,s^{-1}$, are related in a major part to the presence of the ene double bond at which the photocycloaddition of the triplet may occur; this is supported by large bimolecular rate constants (k_q^T) observed for chromone triplet quenching by various alkene derivatives. Although, based on low-temperature photophysical behaviors, the lowest triplet state of chromone in polar solvents is expected to be of reduced n,π^* character, the reactivity of the triplet toward hydrogen donors is very pronounced in acetonitrile (for example, $k_q^T = 1.7 \times 10^9$ and $7.4 \times 10^6 M^{-1}\,s^{-1}$ for tri-*n*-butylstannane and 2-propanol, respectively). Carbon tetrachloride and benzene prove to be facile quenchers of chromone triplet; the quenching interactions probably involve charge transfer, the carbonyl triplet acting as a donor and an acceptor, respectively. The electrophilic role of chromone triplet in the quenching by benzene derivatives is supported by a good correlation between k_q^T and quencher oxidation potential.

S. RAJADURAI et P. K. DAS. Can. J. Chem. **65**, 2277 (1987).

Utilisant une excitation par laser pulsé à 308 ou 337,1 nm, on a produit le triplet de la chromone (λ^T_{max} = 620 nm; $\varepsilon^T_{max} = 2{,}5 \times 10^3 M^{-1}\,cm^{-1}$, dans l'acétonitrile) et on l'a caractérisé, en solutions, à la température ambiante, en faisant appel à des temps de demi-vie plus courts que les microsecondes. On attribue les temps de demi-vie très courts du triplet à un passage intersystème $T_1 \rightsquigarrow S_0$ qui est intrinsèquement rapide, à un auto-piégeage qui est pratiquement limité par la diffusion ainsi qu'à des interactions faciles avec les solvants sous la forme de transfert de charges et d'atomes d'hydrogènes. On a établi que les constantes de vitesses d'auto-piégeage qui sont inhabituellement élevées, $(0{,}9–4{,}0) \times 10^9 M^{-1}\,s^{-1}$, sont principalement reliées à la présence de la double liaison ène à partir de laquelle la photocycloaddition du triplet peut se produire; cette conclusion est supportée par les constantes de vitesses bimoléculaires élevées (k_q^T) qui ont été observée pour le piégeage du triplet de la chromone par divers dérivés des alcènes. Même si, sur la base des comportements photophysiques à basses températures, on s'attend à ce que le caractère n,π^* de l'état triplet le plus bas de la chromone soit réduit dans les solvants polaires, la réactivité du triplet vis-à-vis des donneurs d'hydrogène est très prononcée dans l'acétonitrile (par exemple, $k_q^T = 1{,}7 \times 10^9$ et $7{,}4 \times 10^6 M^{-1}\,s^{-1}$ respectivement pour le tri-*n*-butylstannane et le propanol-2). Le tétrachlorure de carbone et le benzène s'avèrent de bons pièges pour le triplet de la chromone; les interactions de piégeage impliquent probablement des transferts de charges dans lesquels le triplet du carbonyle agissant suivant le cas soit comme donneur soit comme accepteur. Le rôle électrophile du triplet de la chromone dans le piégeage des dérivés du benzène est supporté par une bonne corrélation entre les valeurs de k_q^T et les potentiels d'oxydation des pièges.

[Traduit par la revue]

Introduction

Interactions of proximate n,π^* and π,π^* states in both singlet and triplet manifolds of heteroatom-containing π-systems have long been topics of interest to spectroscopists, photochemists, and photophysicists. Vibronic mixing and occasional inversion of the relative location of these two states, when lying close to each other as the lowermost singlet excited states, are easily affected by variation of substituent, solvent, and temperature, and result in dramatic changes in the fluorescence properties of a molecule (1–3). Quite often such a molecule serves as a useful probe for micropolarity in multiphase systems. Vibronic interactions and (or) thermal equilibria involving lowest-lying n,π^* and π,π^* triplet states determine the radical-like behavior of carbonyl compounds in hydrogen-abstraction photoreactions (4–6). Finally, the rate of intersystem crossing between two electronic states of different multiplicity depends strongly on whether or not these two states are of the same orbital origin (7–9).

For several reasons we have been interested in a laser flash photolysis study of chromone (**1**) in solutions at room temperature. First, several studies (10–12) based on EPR (electron paramagnetic resonance) and phosphorescence spectra in low temperature matrices have shown the low-lying n,π^* and π,π^* triplet states of chromone to be essentially isoenergetic. It is of interest to know if a similar situation prevails at room temperature and manifests itself in the photophysical and photochemical behavior of the triplet in fluid solutions. Second, chromone has been shown to undergo facile photoaddition reactions in which olefins or acetylenes are added along the ene double bond and, in some cases, at the carbonyl group (13, 14). The products of coupling of radicals derived from hydrogen abstraction are also observed (14). The sustained interest in the photocycloaddition of chromone is borne out by the fact that it has formed the subject of a recent theoretical study (15). Although the triplet has been implicated as the photoexcited species participating in chromone photochemistry, very little is known about the kinetics of its decay and bimolecular interactions under reaction conditions. To the best of our knowledge, all the time-resolved studies of chromone photophysics have so far focused only on the decay of triplet absorption or phosphorescene over milliseconds in grassy matrices at 77 K (10, 11, 16) or the picosecond buildup of triplet absorption giving intersystem crossing rates over picoseconds at room temperature (16). Third, in a recent report (17) based on evidence from triplet quenching behavior we have suggested that in fluid solutions 2,3-diphenylchromone (**2**) undergoes considerable structural relaxation in the triplet state, probably in the form of twisting about the ene double bond (to relieve the steric hindrance between the neighboring phenyl

groups). Obviously, it is important to establish if such a relaxation occurs in the triplet state of the parent molecule in the absence of the steric crowding.

Experimental

Chromone (**1**) and 4-chromanone (**3**) were supplied by Aldrich. The former was recrystallized from aqueous ethanol while the latter was used as received. Since the authenticity of the chromone sample was not guaranteed by the vendor, this was checked by mass and ^{1}H nmr spectra (18) recorded in a Finnigan–Mat Model 8430 mass spectrometer and a Nicolet NB-300 nmr spectrometer, respectively. Acetonitrile and chloroform, both of spectral grade from Aldrich, were distilled before use. The other solvents were also of spectral grade and were used as received from commercial sources (mostly Fisher and Aldrich). For some experiments, benzene and CCl_4 were purified in the following manner (19). The solvent (400 mL) containing 5 g benzophenone in a Pyrex flask was photolyzed for 12 h under argon saturation in a Rayonet reactor fitted with 16 RPR-3500 lamps and was then fractionally distilled. The procedure was repeated once with the distillate. The reagents used in the quenching studies were of best grades commercially available and were subjected to standard purification procedures (recrystallization, vacuum sublimation, or fractional distillation under reduced pressure). Toluene-d_8 (Aldrich, 100.0 at.% D) was used as received.

Most of the laser flash photolysis experiments were performed with 308-nm laser pulses (~20 ns, 10–100 mJ/pulse) from a Lambda-Physik EMG-100 MSC excimer unit (filled with Xe/HCl gas mixture). For some experiments use was also made of 248-nm laser pulses (~20 ns, 10–100 mJ/pulse) from the same excimer laser unit (filled with Kr/F_2 mixture) and 337.1-nm nitrogen laser pulses (~8 ns, 2–3 mJ/pulse) from a Molectron UV-400 source. The kinetic spectrophotometer and the data collection system have been described in previous publications (20, 21) from the Radiation Laboratory. Except for triplet self-quenching studies, a front-face configuration was used for laser excitation, the direction of the latter being at 20°–30° with respect to that of the analyzing light. The path lengths of the quartz cells were 1–3 mm; those used in experiments involving comparisons of transient absorbances for yield measurements were of optically flat surfaces and 2-mm path lengths. The kinetics of chromone triplet quenching by its ground state were studied in 1 cm × 1 cm square cells with a right angle geometry between the laser excitation pulse (308 nm) and the monitoring light. The intensity of the laser pulse in these experiments was so attenuated that the end-of-pulse triplet concentration was less than 5% of the ground-state concentration in each kinetic measurement. The deoxygenation of solutions was effected by saturation with high-purity argon.

Results

Triplet state photophysical properties

The preliminary flash photolysis experiments on chromone were carried out with nitrogen laser pulses at 337.1 nm. At this wavelength, the light absorption occurs into the lowest-lying weak $^1(n,\pi^*)$ band system ($\varepsilon = 22 M^{-1}\,cm^{-1}$ at 337 nm in acetonitrile). For sufficient absorbance (~0.1 in a 2-mm cell) at the laser excitation wavelength, the solutions of chromone have

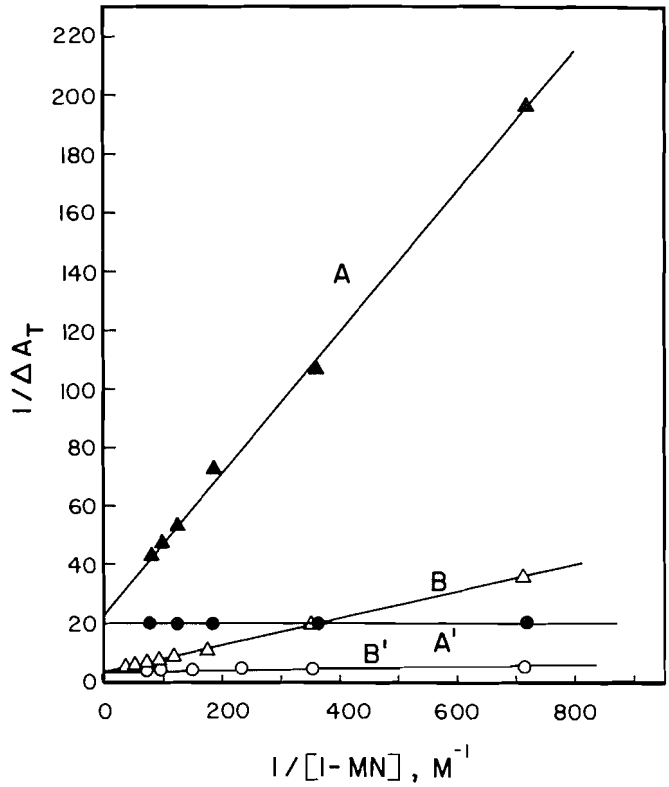

FIG. 1. Double reciprocal plots based on eq. [3], with 1-methylnaphthalene as the quencher in (A,A′) benzene and (B,B′) acetonitrile. The solutions of (A,B) chromone and (A′,B′) benzophenone were optically matched at the laser excitation wavelength, 337.1 nm (absorbance = 0.2 in 2-mm cells).

to be concentrated (40–60 m*M*). Upon laser pulse excitation, chromone solutions at these high concentrations in various solvents, namely, benzene, acetonitrile, methanol, 2-propanol, *tert*-butanol, and carbon tetrachloride, give a fast-decaying transient ($\tau \leq 30$ ns) characterized by absorption maxima at 620–640 nm. The short lifetimes of the transient preclude any study of its diagnostic quenching behaviors. However, that a short-lived triplet is produced in high yields under 337.1-nm laser excitation is shown by experiments in the presence of 1-methylnaphthalene and biphenyl. The triplets of the latter with characteristic transient absorption spectra (λ^T_{max} = 420–425 and 355–360 nm, respectively) are produced, presumably as a result of energy transfer from the flash-photolytic chromone triplet. With 1-methylnaphthalene in benzene and acetonitrile and biphenyl in benzene, the absorbance changes due to their triplets monitored at the respective maxima were measured as functions of the acceptor concentrations. Based on triplet excitation transfer from chromone triplet (^{3}CH*) in competition with its decay (eq. [1] and [2]), a double-reciprocal relationship is expected between the acceptor triplet absorbance (ΔA_T) and its ground-state concentration, [A], see eq. [3]. In this equation ϕ_T represents the triplet yield of chromone.

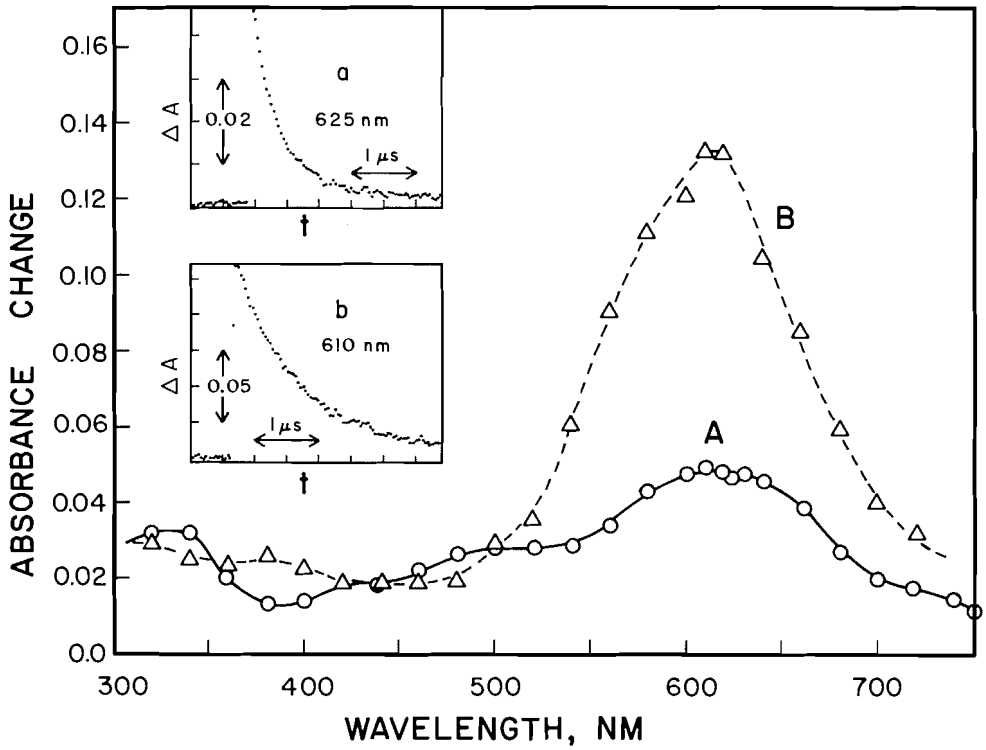

FIG. 2. Triplet–triplet absorption spectra of chromone observed at 0.1 μs following 308-nm laser excitation in (A) acetonitrile and (B) 2,2,2-trifluoroethanol. Insets: representative kinetic traces for chromone triplet decay in (a) acetonitrile and (b) 2,2,2-trifluoroethanol containing 0.19 and 0.84 m*M* chromone, respectively.

these plots gave 20 and 16 M^{-1} for $k_q^T\tau_T$ values in the two solvents, respectively. A similar value, i.e., 17 M^{-1} was obtained for biphenyl as acceptor in benzene. Assuming a value of $5 \times 10^9 M^{-1} s^{-1}$ for k_q^T under diffusion control (see later), we estimate lifetimes (τ_T) of 3–4 ns for chromone triplet under the conditions of the measurements. It will be shown later that the short triplet lifetimes are due to efficient self-quenching and interactions with solvent.

Also in Fig. 1 are shown the plots based on eq. [3] for 1-methylnaphthalene as acceptor of energy from benzophenone triplet in benzene and acetonitrile. The benzophenone solutions were optically matched with those of chromone at the laser excitation wavelength (337.1 nm). The comparison of the reciprocal of the intercept for chromone with that for benzophenone under the same condition led to the determination of ϕ_T. We obtained values of 0.86 ± 0.15 and 1.0 ± 0.15 for ϕ_T of chromone in benzene and acetonitrile, respectively.

The use of 308- and 248-nm laser pulses enabled us to conduct flash photolysis experiments on chromone solutions of submillimolar concentrations. In Fig. 2 is shown the transient absorption spectrum upon 308-nm laser pulse excitation of 0.19 m*M* chromone in acetonitrile. As evident from the kinetic trace in the inset, the transient (λ_{max} = 620 nm) observed in this dilute solution is relatively long-lived (τ = 0.6 μs). Quenching behaviors (*vide infra*) combined with sensitization of triplets of typical acceptors of lower energy, e.g., 1-methylnaphthalene and biphenyl, establish the identity of the 620-nm transient as chromone triplet (^{3}CH*). A comparison of end-of-pulse transient absorbance at 620 nm due to ^{3}CH*, observed in acetonitrile in the absence of biphenyl, with that at 360 nm due to biphenyl triplet, produced in the chromone solution containing ~10 m*M* biphenyl, suggests that the maximum extinction coefficient (ε_{max}^T) of ^{3}CH* is 1/16 of that of biphenyl triplet. Assuming that ε_{max}^T of biphenyl in acetonitrile is not very different from that in cyclohexane ($\varepsilon_{max}^T = 4.3 \times 10^4 M^{-1} cm^{-1}$ at 361 nm (22)), we estimate ε_{max}^T of ^{3}CH* to be (3 ± 1) × $10^3 M^{-1} cm^{-1}$ (at 620 nm). A similar value, (2.5 ± 0.3) × $10^3 M^{-1} cm^{-1}$, is obtained through a comparison of end-of-pulse triplet absorbances (at respective maxima) observed upon 308-nm laser excitation of optically matched solutions of chromone and benzophenone ($\varepsilon_{max}^T = 6.5 \times 10^3 M^{-1} cm^{-1}$ at 520 nm (23) in acetonitrile). The comparative measurements were carried out in the linear region over a tenfold change in laser pulse intensity (ca. 1–10 mJ/pulse) and ϕ_T's were taken to be unity for both ketones in acetonitrile.

The rate constant (k_{obs}^T) for the decay of chromone triplet is found to be strongly dependent on the ground state concentration, [CH]. In several solvents, the intrinsic triplet lifetime (τ_T^0), determined by the $S_0 \leftrightsquigarrow T_1$ process as well as interactions with solvent (eqs. [4*a*,*b*]), and the self-quenching rate constant (k_{SQ}^T, eq. [5]) were obtained from the intercept and slope of the linear plots of k_{obs}^T vs. [CH] (see eq. [6]).

$$[4a] \quad {}^3CH^* \xrightarrow{1/\tau_T^0} {}^1CH$$

$$[4b] \quad {}^3CH^* + S \rightarrow {}^1CH \text{ or products}$$

$$[5] \quad {}^3CH^* + {}^1CH \xrightarrow{k_{SQ}^T} 2\,{}^1CH \text{ or products}$$

$$[6] \quad k_{obs}^T = 1/\tau_T^0 + k_{SQ}^T[CH]$$

Some representative plots based on eq. [6] are shown in Fig. 3. The data concerning τ_T^0 and k_{SQ}^T are presented in Table 1.

From the location of the 0–0 band of the phosphorescence spectrum of chromone in 2-methyltetrahydrofuran glass at 77 K, its triplet energy (E_T) is measured to be 75.1 kcal/mol (14). Thus chromone is not expected to be an efficient quencher of the triplets of benzophenone (E_T = 69 kcal/mol (24)) or *p*-methoxyacetophenone (E_T = 72 kcal/mol (24)). Employing chro-

mone at 0–5 mM in benzene, its effect on the decay of benzophenone and *p*-methoxyacetophenone triplet was studied. The quenchee triplets were monitored at 532 and 375 nm, respectively. In these experiments (λ_{ex} = 337.1 nm), the absorption of laser photons by chromone at its highest concentration was negligible and, because of short lifetime in benzene (see later), chromone triplet (if any) formed as a result of endothermic energy transfer did not interfere with the measurement of the decay rate constant (k_{obs}^T) of the triplets of the two aromatic ketones. From the dependence of k_{obs}^T on [CH], we obtained 8.7×10^7 and $1.6 \times 10^8 M^{-1} s^{-1}$ for the bimolecular rate constants for the quenching of benzophenone and *p*-methoxyacetophenone triplet, respectively. This result establishes the triplet energy (E_T) of chromone at room temperature to be higher than that of *p*-methoxyacetophenone (E_T = 72 kcal/mol). It should be noted that the quenching of the two ketone triplets can occur

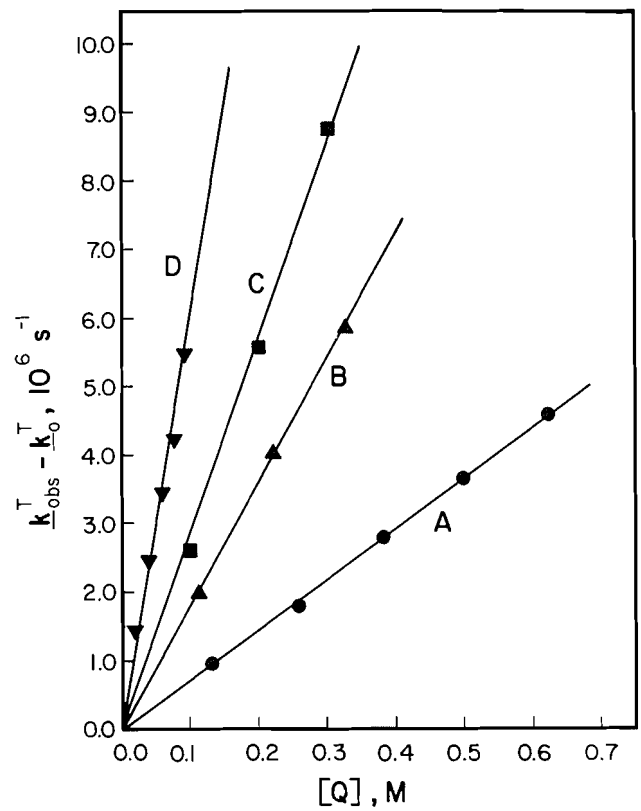

FIG. 4. Linear plots, based on eq. [7], for the quenching of chromone triplet in acetonitrile by (A) 2-propanol, (B) benzene, (C) carbon tetrachloride, and (D) toluene.

not only by energy transfer (endothermic but essentially irreversible because of short chromone triplet lifetime in benzene), but also via oxetane formation with the ene double bond of chromone.

Triplet quenching studies

The kinetics of the quenching of chromone triplet by a variety of quenchers capable of interacting with the triplet by chemical as well as physical mechanisms were studied in detail. Dilute solutions of chromone (0.15–0.25 mM) in acetonitrile were used and the triplet, produced by 308-nm laser excitation, was monitored at 600–620 nm. In all cases, the pseudo-first-order rate constant (k_{obs}^T) for the triplet decay was measured as a function of quencher concentration, [Q], and the quenching rate constant (k_Q^T) was obtained from the slope of the linear plot of k_{obs}^T against [Q], based on eq. [7].

$$[7] \quad k_{obs}^T = 1/\tau_T + k_Q^T[Q]$$

Some representative plots are presented in Fig. 4 and the k_q^T data are compiled in Table 2.

Though non-hydrogen-donating, benzene and carbon tetrachloride proved to be "reactive" solvents for chromone triplet. Although in benzene no residual absorption could be observed following the rapid triplet decay, this was not the case with carbon tetrachloride. In the later solvent, a broad long-lived transient absorption at 350–700 nm ($\lambda_{max} \sim$ 550 nm) was noted on the microsecond time scale and the decay of this absorption was found to be oxygen insensitive. We have also examined benzene and carbon tetrachloride as specific quenchers for chromone triplet in acetonitrile, and k_q^T's were found to be significantly high (1.8×10^7 and $3.0 \times 10^7 M^{-1} s^{-1}$, respectively). Since the observed quenching could be due to

impurities (namely, olefin derivatives) in the two solvents, the experiments were repeated with samples of benzene and carbon tetrachloride that were subjected to special purification procedures (see the experimental section). k_q^T's obtained with purified samples were essentially the same as those with untreated samples.

To ascertain the direction of charge transfer, if any, in the interaction of chromone triplet with benzene, k_q^T's were measured for a series of methylated benzenes (Table 3). It is noted that k_q^T's increase progressively as the electron-donating nature of the benzene derivatives increases. Furthermore, the rate constant for quenching by toluene-d_8 ($k_q^T = 5.6 \times 10^7 M^{-1} s^{-1}$) is found to be practically identical to that for toluene ($k_q^T = 5.5 \times 10^7 M^{-1} s^{-1}$).

Transient photoproduct spectra and efficiencies of hydrogen abstraction

In hydrogen-donating solvents (e.g., 2-propanol) as well as in the presence of hydrogen donors (e.g., tri-*n*-butylstannane) as quenchers, the decay of chromone triplet leads to a long-

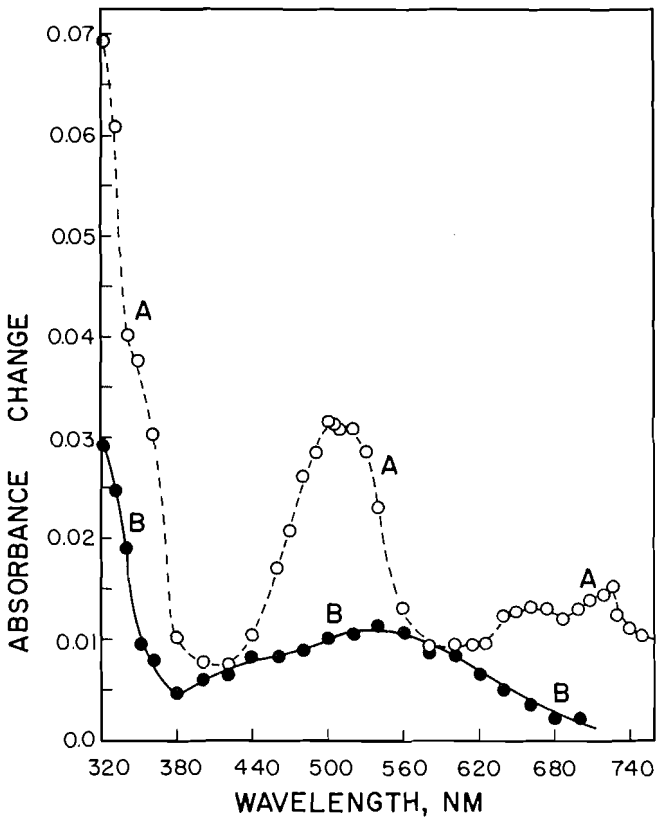

FIG. 5. The transient absorption spectra of (A) ketyl radical from chromone in neat 2-propanol and (B) product(s) of the quenching of chromone triplet by carbon tetrachloride (1.0 *M*) in acetonitrile (observed at 3.2 and 0.50 μs, respectively, following 308-nm laser pulse excitation). [Chromone] = 0.21 m*M* in both cases.

lived residual absorption (λ_{max} = 520 nm) attributable to the ketyl radical (**4**) formed as a result of hydrogen atom transfer (eq. [8]). The transient spectrum in neat 2-propanol is shown in Fig. 5A. Note that the longest-wavelength band system (600–750 nm) is unusual for a ketyl radical and may be due to its deprotonated form (radical anion). However, we found the spectrum of the long-lived transient in 2-propanol containing 13 m*M* trifluoroacetic acid to be identical to that in the absence of the acid. Based on this, the assignment of the long-wavelength band to the radical anion seems unlikely (unless the ketyl radical has an abnormally low pK_a value). The decay of the transient is very oxygen sensitive; from the observed lifetime (128 ± 5 ns) in air-saturated 2-propanol, the rate constant for oxygen quenching is calculated to be $3.5 \times 10^9 M^{-1} s^{-1}$. The similarity of decay kinetics at various wavelength maxima suggests that the observed band systems belong to either one single species, or more than one species in fast equilibrium. Assuming that the quenching of chromone triplet by 2-propanol or tetrahydrofuran in acetonitrile occurs solely by hydrogen abstraction, we determined the extinction coefficient of the radical to be $2.1 \times 10^3 M^{-1} cm^{-1}$ (at 510 nm). This was based on the comparison of the end-of-pulse absorbance due to ^{3}CH* in acetonitrile (λ_{ex} = 308 nm) in the absence of a quencher with the maximum transient absorbance due to the ketyl radical produced under extensive triplet quenching (≥80%) by 2-propanol and tetrahydrofuran.

Practically no residual absorbance changes are noted at 320–700 nm following the quenching of chromone triplet (in acetonitrile) by its ground state and by the olefin derivatives (Table 2) having no easily abstractable H atom. As noted earlier for the neat solvent, ^{3}CH* quenching by CCl_4 added to an acetonitrile solution leads to the formation of an oxygen-insensitive transient species, the spectrum of which is shown in Fig. 5B. Very probably, this is the radical cation (**5**) of chromone formed as a result of electron transfer from the triplet to CCl_4 (eq. [9]).[2]

[8] $^3\mathbf{1}^* + SH \rightarrow \mathbf{4} + S\cdot$

[9] $^3\mathbf{1}^* + CCl_4 \rightarrow \mathbf{5} + \cdot CCl_3 + Cl^-$

For many of the reagents under consideration (Tables 2 and 3), hydrogen atom transfer is feasible in competition with other modes of quenching. The efficiencies of hydrogen abstraction in the course of the quenching processes have been determined in acetonitrile in terms of yields (ϕ_{ketyl}) of the ketyl radical (**4**) monitored at 520 nm. The transient absorbances due to the radical, kinetically corrected to values corresponding to the total quenching of ^{3}CH*, were compared with those observed with 2-propanol or tetrahydrofuran as the quencher. The relative ϕ_{ketyl} values obtained in this manner in several cases are given in Tables 2 and 3.

Photophysical and quenching behaviors of 4-chromanone triplet

For comparison, 4-chromanone (**3**) was also subjected to a limited number of laser flash photolysis experiments. The triplet and ketyl radical absorption spectra, obtained upon 308-nm laser pulse excitation in acetonitrile and 2-propanol respectively, are presented in Fig. 6. The long-wavelength maximum at 430 nm in the triplet–triplet spectrum agrees with the maxima reported by Hamanoue *et al.* (16). From the concentration dependence of triplet decay rate constant in acetonitrile, benzene, and carbon tetrachloride, k_{SQ}^T's are estimated to be smaller than $2 \times 10^8 M^{-1} s^{-1}$ in these solvents and τ_T^0's are measured to be 5.0, 1.2, and 1.3 μs, respectively. Employing techniques similar to those in the case of chromone (*vide supra*), we obtained values of unity for ϕ_T and of $3.7 \times 10^3 M^{-1} cm^{-1}$ for ε_T^{max} at 430 nm (in acetonitrile, λ_{ex} = 337.1 nm). 1-Methylnaphthalene was used as the triplet energy acceptor in these experiments.

The kinetics of the quenching of 4-chromanone triplet (monitored at 430 nm) were studied in acetonitrile using a number of selected reagents. The k_q^T data obtained from linear plots based on eq. [7] are included in Table 2. The most notable difference in the quenching behavior of chromone and 4-chromanone triplets lies in that toward alkenes and hydrogen donors, chromone triplet being much more reactive. The relative inefficiency of 4-chromanone triplet to abstract hydrogen atoms is also evident from the fact that the triplet is quite long-lived in neat 2-propanol (observed τ_T = 520 ns for 0.34 m*M* 4-chromanone).

[2]A similar transient spectrum ascribable to **5** formed as a result of charge transfer from solvent-derived radical cation is also observed upon pulse radiolysis of **1** in 1,2-dichloroethane. Furthermore, the aqueous extract from a carbon tetrachloride solution of chromone (1.3 m*M*) that has been subjected to continued photolysis by repetitive 308 nm laser pulses slowly forms a white precipitate upon addition of an $AgNO_3$ solution. This test proves negative with similarly photolyzed carbon tetrachloride (alone) and with unphotolyzed chromone solution. These qualitative results suggest that the cleavage of CCl_4 is sensitized by chromone, leading to product(s) capable of forming AgCl upon reaction with $AgNO_3$ in the aqueous medium. The fact that the precipitation is not instantaneous indicates that Cl^- or HCl does not accumulate as an initial photoproduct.

Discussion

As noted in the Introduction, the excited-state properties of chromone and 4-chromanone have been examined (10–12) by various spectroscopic methods including phosphorescence emission/excitation spectra, phosphorescence polarization/lifetimes, oxygen and heavy-atom perturbed singlet–triplet absorption, and triplet-state esr (electron spin resonance). Both of these carbonyl compounds have weak lowest-lying singlet states with properties consistent with an n,π^* orbital character (10). For chromone, the low-temperature spectroscopic data indicate that the low-lying n,π^* and π,π^* triplet states are nearly isoenergetic, strongly mixed, and subject to reordering upon changing the nature of solvent (11). In comparison, for 4-chromanone, a greater energy gap is suggested between the lowest-lying n,π^* and the proximate π,π^* triplet states (11). These state orders in chromone and 4-chromanone have been claimed to be consistent with the picosecond intersystem crossing rates at room temperature (16). Interestingly, for chromone at 77 K, the appearance of multiple components in phosphorescence decay curves (e.g., in 2-methyltetrahydrofuran glass) and the concentration dependence of phosphorescence spectra in nonpolar solvents (e.g., 3-methylpentane glass) have been explained in terms of involvement of several different lowest triplet conformations of chromone and conglomeration of solute molecules, respectively (10).

Since the environmental effect on an electronic transition resulting from dispersive interaction is determined by the oscillator strength of the transition, the lowering of density and refractive index of the medium upon going from glassy matrices at 77 K to room-temperature solutions is not expected to bring about dramatic changes in the state order in the triplet manifold of chromone and 4-chromanone. Thus, to begin with, it is reasonable to assume that in solutions at room temperature chromone possesses low-lying n,π^* and π,π^* triplet states, close to each other, with relative location sensitive to the polarity and hydrogen-bonding nature of the medium, and the 4-chromanone has the lowest triplet state of predominantly n,π^* character. It is of interest to examine whether and to what extent the photophysical and photochemical behaviors of the two aromatic carbonyl systems at room temperature reflect these state orders.

Perhaps the best photochemical criterion of an n,π^* carbonyl triplet is its radical-like behavior in hydrogen abstraction reactions. As the k_q^T data for the quenching of chromone triplet by tri-n-butyl stannane, 2-propanol, and tetrahydroguran (Table 2) suggest, even in the polar solvent (acetonitrile) this carbonyl triplet is an efficient hydrogen abstractor. In particular, the reactivity of chromone triplet toward tri-n-butylstannane in acetonitrile ($k_q^T = 1.7 \times 10^9 M^{-1} s^{-1}$) is as high as that of xanthone triplet in carbon tetrachloride ($k_q^T = 1.5 \times 10^9 M^{-1} s^{-1}$ (6)). The triplet of xanthone is recognized to be of predominantly n,π^* character in nonpolar solvents and the bimolecular rate constant for its reaction with 2-propanol exhibits a dramatic decreasing trend, attributable to $^3(n,\pi^*)$–$^3(\pi,\pi^*)$ inversion, upon going from a nonpolar solvent to a polar one (e.g., $k_q^T = 1.1 \times 10^8 M^{-1} s^{-1}$ in carbon tetrachloride vs. $2.2 \times 10^5 M^{-1} s^{-1}$ in neat propanol (6)). Since the triplet energy of xanthone (E_T = 74 kcal/mol (24)) is similar to that of chromone (E_T = 75 kcal/mol), it is tempting to make an attempt to determine the n,π^* character of chromone triplet by consideration of its hydrogen abstraction reactivity relative to that of xanthone triplet. However, this would be misleading because of the fact that the resonance stabilization (25) of the ketyl radical and the enthalpy change in the course of hydrogen atom transfer are different in the two cases. Unfortunately, we could not find a suitable unreactive nonpolar solvent for use to determine an upper limit of the hydrogen abstraction reactivity of chromone triplet in a predominantly n,π^* configuration. Nevertheless, the facts that the k_q^T's for various hydrogen donors in acetonitrile are relatively high and that in neat 2-propanol the hydrogen abstrac-

tion rate is higher, by one order of magnitude, for chromone ($k_q^T > 3 \times 10^6 M^{-1} s^{-1}$, based on $\tau_T < 25$ ns) than for xanthone triplet ($k_q^T = 2.2 \times 10^5 M^{-1} s^{-1}$) suggest that even in polar solvents the lowest triplet state of chromone has a substantial contribution from the n,π^* configuration (either through vibronic mixing or in thermal equilibrium). This conclusion suggests that the theoretical treatment of the cycloaddition reactivity of chromone triplet would be more relevant in terms of an n,π^* configuration than a π,π^* configuration (as considered in the recent study (15)).

At low temperature (77 K) the lowermost triplet state of 4-chromanone is recognized to be of n,π^* nature; the $^3(\pi,\pi^*)$ state is located at an energy too high for its contribution to the lowest-energy state to be significantly influenced by solvent (10–12). Thus, compared to chromone in a given solvent at room temperature, 4-chromanone is expected to have a higher n,π^* character and hence a greater hydrogen abstraction reactivity in its lowest triplet state. Surprisingly, however, as the data in Table 2 show, the rate constants for the quenching of 4-chromanone triplet by various hydrogen donors are considerably smaller than those for the chromone triplet. This is explainable by the facts that the triplet energy (E_T) of the former is lower than that of the latter by about 2 kcal/mol (10, 11) and that the resonance stabilization of the ketyl radical is higher in the case of chromone (because of participation of the double bond in delocalizing the unpaired electron). Thus, the enthalpy change associated with hydrogen abstraction would be more favorable for chromone triplet.

The high rate constants for chromone triplet quenching by many of the molecules containing multiple bonds (Table 2) are explainable in terms of cycloaddition at the ene double bond. In several cases, namely, cyclohexene, 2,3-dimethyl-2-butene, and methyl acrylate, this is supported by the fact that the quenching of 4-chromanone triplet by these molecules is much less efficient. The photocycloaddition reaction of chromone involving the ene double bond is established as its major photoreaction under steady-state irradiation in the presence of alkene/alkyne derivative (13, 14). As a matter of fact, the order of k_q^T for cyclohexane, 2,3-dimethyl-2-butene, and 2-butyne is in agreement with that of the reactivity of cyclopentene, 2,3-dimethyl-2-butene, and 2-butyne observed in the steady-state study (14). Chromone triplet has been considered to be an electrophile in its photocycloaddition reactions (14). Interestingly, however, the k_q^T's for electron-poor olefins, namely, maleic anhydride, methyl acrylate, and acrylonitrile, are found to be higher than the electron-rich ones, namely, 2,5-dimethoxydihydrofuran, 2,3-dimethyl-2-butene, and cyclohexene (Table 2). It would, however, be premature to take this as evidence against the electrophilic character of chromone triplet because the observed k_q^T's contain contributions of the various processes, namely, cycloaddition at the ene double bond, oxetane formation, energy transfer, and hydrogen abstraction. The relative importance of these contributions has to be sorted out before a meaningful conclusion can be drawn regarding the trend of a given type of photoreaction.

The behavior of chromone triplet as an electrophile is, however, evident in its quenching by benzene and methylated benzenes (Table 3). Figure 7 shows the logarithmic plot of k_q^T vs. oxidation potential of the benzene derivatives. Evidently there is a good correlation between the quenching rate constant and the electron-donating capability of these quenchers. The fact that the k_q^T for benzene fits well into the correlation can be taken to mean that its interaction with chromone triplet involves

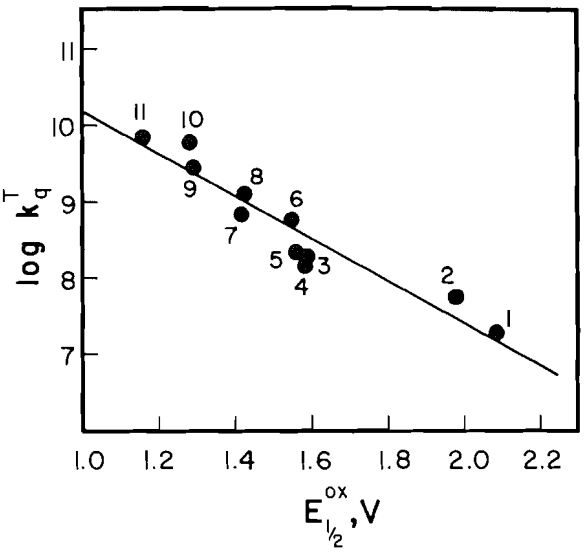

FIG. 7. The logarithmic plot of bimolecular rate constant for chromone triplet quenching vs. oxidation potential of benzene and methylated benzenes. For the numbers identifying the quenchers, see Table 3. The least-squares best-fit straight line (correlation coefficient = 0.948) is given by: $\log(k_q^T) = -2.79\,(E^{ox}_{1/2}) + 12.98$.

charge transfer. Interestingly, the rate constant for chromone triplet quenching by diphenylmethanol ($1.0 \times 10^8 M^{-1} s^{-1}$) is almost what is expected from k_q^T for the toluene ($5.5 \times 10^7 M^{-1} s^{-1}$), after taking into account the presence of two phenyl groups in the former. This suggests that the quenching by the aromatic alcohol is dominated by charge transfer interaction at the aromatic nucleus, rather than by direct hydrogen abstraction. This is also supported by less than quantitative yield (0.38) of ketyl radical formation and by the absence of isotope effect in the quenching by toluene and toluene-d_8. It should be noted that the ketyl radical in the case of diphenylmethanol may originate from intra-ion-pair proton transfer following the charge transfer interaction, rather than from direct hydrogen atom transfer (26).

The most plausible mechanism for the facile quenching of chromone triplet by CCl_4 appears to be the one involving charge transfer in which the triplet acts as a donor. The formation of oxygen-insensitive transient product, most probably chromone radical cation, as a result of the quenching shows that the charge transfer is not totally reversible (as in the case of benzene). Lissi and Encina (27) have observed the reaction of acetone and 2-pentanone triplets with CCl_4, the rate constant for 2-pentanone triplet being $1.2 \times 10^7 M^{-1} s^{-1}$ (in *n*-hexane). Chromone appears to be the rare example of an aromatic carbonyl system the triplet of which shows high reactivity toward CCl_4. The enhanced reactivity is attributable to the relatively high triplet energy and the structural feature of chromone (i.e., ether linkage) giving rise to a favorable oxidation potential.

The self-quenching rate constants (k_{SQ}^T) of chromone triplet in different solvents (Table 1) are all close to the limit of diffusion control. As far as we know, among aromatic carbonyl triplets, chromone is characterized by the highest k_{SQ}^T's in polar solvents. For xanthone, k_{SQ}^T's have been found to range from $4.2 \times 10^7 M^{-1} s^{-1}$ in 1:1 water:acetonitrile to $4 \times 10^9 M^{-1} s^{-1}$ in *n*-heptane. The solvent dependence of the self-quenching in the case of xanthone triplet has been attributed to interaction at the oxygen bridge. While a similar interaction is

also possible in the case of chromone, it is more likely that chromone in the ground state acts as an olefin, leading to photocycloaddition with the triplet (i.e., dimerization). The difference in the mechanism of the self-quenching of xanthone and chromone triplets becomes apparent when one considers the fact that, on going from neat acetonitrile to 1:1 water:acetonitrile, k_{SQ}^{T} for xanthone drops by a factor of ten (6) while that for chromone remains practically unchanged (Table 1).

Finally, it should be pointed out that with quenchers such as ferrocene, biphenyl, 1-methylnaphthalene, and 2,5-dimethyl-2,4-hexadiene having triplet energies lower than E_T of chromone by at least 10 kcal/mol, k_q^T's are all in the limit of diffusion control (Table 2). In particular, with ferrocene ($E_T \cong$ 40 kcal/mol), for which both energy and electron transfer are feasible, the value of $1.7 \times 10^{10} M^{-1} s^{-1}$ for k_q^T in acetonitrile is very close to the theoretical diffusion rate (k_{diff}). Also, as expected for the energy transfer quenching of a triplet by a radical, the spin-statistically limited maximum value of $1/3k_{diff}$ is achieved in the case of quenching by DTBN. These large rate constants for energy transfer quenching are evidence against any extensive structural relaxation in the lowest triplet state of chromone (for example, in the form of twisting about the ene double bond). On the contrary, in the case of 2,3-diphenylchromone (**2**), the triplet quenching by 1-methylnaphthalene, 2,5-dimethyl-2,4-hexadiene, ferrocene, and DTBN occurs at considerably slower rates (17) suggesting extensive triplet state relaxation in **2** (possibly in the form of partial twisting about the double bond to relieve the steric hindrance between the two adjacent phenyl substituents).

Interaction between bromothymol blue and antipyrine in dichloromethane

ALBERTO HERNANDEZ GAINZA AND LUISA PUERTA JIMENEZ
Departamento de Quimica Fisica, Facultad de Farmacia, Universidad de Granada, 18001 Granada, España

Received June 11, 1986[1]

ALBERTO HERNANDEZ GAINZA and LUISA PUERTA JIMENEZ. Can. J. Chem. **65**, 2286 (1987).

Antipyrine (AT) reacts with bromothymol blue (BTB) in dichloromethane (DCM), forming an ion pair of 1:1 stoichiometry. Chemical equilibrium has been demonstrated and the formation constants of the ion pair at various temperatures have been calculated spectrophotometrically. The thermodynamic parameters of the reaction are $\Delta H^0 = -6994$ cal/mol, $\Delta S^0 = -11.05$ cal/K mol, and $\Delta G^0_{25°C} = -3703$ cal/mol.

ALBERTO HERNANDEZ GAINZA et LUISA PUERTA JIMENEZ. Can. J. Chem. **65**, 2286 (1987).

La antipyrine (AT) réactionne avec le bleu de bromothymol (BTB) dans chlorure de méthylène formant une paire d'ions d'estequiométrie 1:1. C'est évident une équilibre chimique et on a calculé les constantes de formation de la paire d'ions à différentes températures et le coefficient d'extinction molaire à partir de mésures spectrophotométriques. Les parametres thermodynamiques de la réaction sont $\Delta H^0 = -6994$ cal/mol, $\Delta S^0 = -11{,}05$ cal/K mol et $\Delta G^0_{25°C} = -3703$ cal/mol.

Introduction

Bromothymol blue is the most widely used dye for the determination of amines of pharmaceutical interest by photometric titration in two phases (1–7). The amine – bromothymol blue reaction has been described as a non-specific acid–base process in one non-polar phase (8, 9), and in two non-miscible phases (1–7). However, the reaction is not totally non-specific because some amines give practically no reaction either in one or two phases, such as the benzodiazepines medazepam and bromazepam (9, 10). There are many other amines, for which the reaction has not been described, and in view of the great deal of work published on this topic, it is easy to conclude that most amines give no reaction with bromothymol blue (BTB), or that the reaction is so weak that it can not be studied with conventional methodology.

In this work the reaction of bromothymol blue (free acid) with an analgesic derivative of pyrazolone, antipyrine (free base), has been studied. Conventional methods of study and quantification of this interaction in dichloromethane can not, because of its weak character, be studied by the classic methods described for strong associations. Therefore the methods of Benesi–Hildebrand (11, 12) and Rosseinsky (13) have been used to calculate equilibrium constants and molar absorptivity. The values of the thermodynamic quantities ΔG^0, ΔH^0, and ΔS^0, which are not known for the strong complexes of bromothymol blue, have been evaluated. This work also presents a comparison between strong and weak types of associations and of the interaction that generates them. It suggests that the one-phase interaction has the same chemical nature for amines that form strong associates (8, 9) as that for antipyrine (AT), the only amine known that forms both a weak associate with BTB and a quantifiable reaction.

In previous studies (9) it has been demonstrated that an identical BTB – amine ion pair is obtained from extraction in two-phase systems (water/chloroform) as from direct reaction between BTB (free acid) and the amine (free base) in chloroform. In this study the properties of the BTB–AT ion pair are investigated only for the reaction of BTB (free acid) with AT (free base) in a one-phase dichloromethane system. In two-phase systems the identical BTB–AT ion pair obtained by extraction is difficult to study, given its low stability in organic solvents, and that its pK_a value is inadequate ($pK_a = 1.5$) for extraction as an ion pair with BTB (1, 2).

[1]Revision received May 11, 1987.

Experimental

Apparatus

The spectrophotometer used was a Perkin-Elmer Lambda 5 with B. Braun Melsungen AG models Frigomix 1.495 and Thermomix 1.441 (±0.2°C) thermostats. Quartz cells of 1-cm path length were employed. Other apparatus included a Hewlett-Packard 9825 A microcomputer and a Radiometer model CDM 83 conductimeter.

Reagents

1,2-Dihydro-1,5-dimethyl-2-phenyl-3*H*-pyrazol-3-one (antipyrine) Merck, analytical grade, was stored in desiccator over phosphorus pentoxide. Dichloromethane, DCM (Carlo Erba, spectrophometric grade), with water content less than 0.02% and bromothymol blue (Merck, analytical grade) were used without further purification.

Results

Spectrophotometry and conductimetry of antipyrine and bromothymol blue solutions

Upon mixing of solutions of antipyrine (free base) with bromothymol blue (free acid) a new band of absorption appears with a maximum at 410 nm that is not observed in separate spectra of the reagents. In Fig. 1 a spectrum of an antipyrine – bromothymol blue mixture is shown, along with spectra of the reagents separately. Job's method (14) of continuous variation was used to determine the stoichiometric ratio of bromothymol blue to antipyrine. For this method, solutions of amine and dye whose concentration sum is constant were prepared at mole ratios between 0.01 and 0.99 (dye–amine), and the absorbances of the resulting solutions were recorded at 410 nm against pure dichloromethane. A Job's representation is shown in Fig. 2.
