5.0 ± 0.2	0.18	26.0
5.0 ± 0.2	0.22	31.0

[a]μ = 1.0 ($NaCF_3CO_2$); $C_{Ru(II)} = 3.5 \times 10^{-3}$; 0.010 *M* $NaHCO_3$.
[b]Each value is a mean of at least three independent determinations whose agreement is better than 95%.

[2] *trans*-$[Ru(NH_3)_4P(OEt)_3(H_2O)]^{2+} + X^-$ $\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}}$ *trans*-$[Ru(NH_3)_4P(OEt)_3X]^+ + H_2O$

where X indicates N_3^-, SCN^-, and CN^-, respectively.

The characteristics of the electronic spectra of the products of reaction [2] are listed in Table 1.

The kinetic data obtained for the above reaction are summarized in Tables 2–4.

There is no evidence in the plots of k_{obsd} versus $[X^-]$ for rate saturation even with pseudo-halide concentrations as high as 0.22 *M*.

The second order specific rates k_1 for the substitution of the water molecule in *trans*-$[Ru(NH_3)_4P(OEt)_3(H_2O)]^{2+}$ for CN^-, N_3^-, and SCN^- are $(3.1 \pm 0.3) \times 10^2$, $(1.7 \pm 0.1) \times 10^2$, and $(1.4 \pm 0.1) \times 10^2$ M^{-1} s^{-1}, respectively, at 25°C, μ = 1.0 ($NaCF_3COO$ 0.90 *M*/$NaHCO_3$ 0.10 *M*). Under the same experimental conditions the aquation of the pseudo-halide derivatives, *trans*-$[Ru(NH_3)_4P(OEt)_3X]^+$, proceeds at specific rates k_{-1} of $(1.2 \pm 0.1) \times 10^{-1}$, $(1.8 \pm 0.1) \times 10$, and $(2.8 \pm 0.1) \times 10$ s^{-1} for $X^- = CN^-$, N_3^-, and SCN^-, respectively.

Since the intercept of the plot k_{obsd} versus $[X^-]$ for the cyanide system is very close to the origin the rate for CN^- loss from *trans*-$[Ru(NH_3)_4P(OEt)_3CN]^+$ was estimated from a least-squares treatment of the experimental data; therefore, the values of 1.2×10^{-1} s^{-1} and 2.6×10^3 M^{-1} must be considered as the upper and lower limits for k_{-1} and K_{eq}, respectively.

Discussion

The reactions between Ru(II) centers and CN^-, SCN^-, and N_3^- are not simple substitution processes (10–15). The decomposition observed even in the solid state of the $[Ru(NH_3)_5N_3]^{2+}$ ion or of the $[Ru(trien)(N_3)_2]^+$ ion to the corresponding $[Ru(NH_3)_5N_2]^{2+}$ and the $[Ru(trien)N_3N_2]^+$ ions illustrates such reactivity (16).

For the azide ion, a strong oxidizing agent in acidic media the specific second order rates for these reactions show dependence

on the driving force of the Ru(III)/Ru(II) couple in these complexes (17).

Since triethyl phosphite stabilizes Ru(II) with respect to Ru(III) in *trans*-$[Ru(NH_3)_4P(OEt)_3(H_2O)]^{2+}$ ($E^0 = +0.46$ V versus s.c.e.) and the monophosphite complex (1) is weaker acid than aquopentaammine-ruthenium(II), it was expected that the reaction between the monophosphite complex with N_3^- and the other pseudo-halides could be studied without further complications.

The activation parameters for the N_3^- system, calculated from values in Table 2 are $\Delta H_1^{\ddagger} = 3.4 \pm 1.8$ kcal mol^{-1}, $\Delta H_{-1}^{\ddagger} = 6.0 \pm 2.0$ kcal mol^{-1}, $\Delta S_1^{\ddagger} = -37 \pm 6$ cal mol^{-1} deg^{-1}, $\Delta S_{-1}^{\ddagger} = -32 \pm 6$ cal mol^{-1} deg^{-1}. The net replacement of the water in the *trans*-$[Ru(NH_3)_4P(OEt)_3(H_2O)]^{2+}$ by N_3^- is exothermic by 2.8 ± 2.0 kcal mol^{-1} and the entropy change is $\Delta S_{eq}^{\ddagger} = -5 \pm 6$ cal mol^{-1} deg^{-1}.

The stability constants for the *trans*-$[Ru(NH_3)_4P(OEt)_3X]^+$ complexes, calculated from the quotient k_1/k_{-1} are $2.6 \times 10^3\ M^{-1}$, $10 \pm 1\ M^{-1}$, and $5.0 \pm 0.5\ M^{-1}$ for CN^-, N_3^-, and SCN^-, respectively. The position of CN^-, N_3^-, and SCN^- arranged in order of decreasing affinity for the monophosphite complex in the series of the ligands studied (1) is

$$SO^{2-} \sim P(OEt)_3 > CN^- > imN > isn > pyr > Mepyr^+ > N_3^- > SCN^-$$

where imN, isn, pyr, and $Mepyr^+$ are imidazol, isonicotinamide, pyrazine, and methylpyrazinium respectively.

CN^- and SCN^- are both ambidentate ligands and no structural work has been carried out on these systems. However, based on the literature data (10, 18) for similar Ru(II) complexes, it seems reasonable to expect the carbon and sulphur atoms to be the coordination sites for CN^- and SCN^-, respectively, in the monophosphite complexes.

The position of CN^- in the series above, close to $P(OEt)_3$ and SO_3^{2-} can be understood on the basis of its biphilic character. A synergistic effect between the π and σ components of the $(OEt)_3P$—Ru—CN^- bonds must be operative, strengthening the Ru—CN^- linkage. For the azide ion, a weak π acid and moderate σ base, and for the thiocyanate, a weak π acid and weak σ base, the synergism between the π and σ components of the $(OEt)_3P$—Ru—SCN^- and $(EtO)_3P$—Ru—N_3^- bonds should be very weak if not absent.

The formation constants for monoazide and monothiocyanate complexes for divalent metal ions where back-bonding is not significant and those for the *trans*-$[Ru(NH_3)_4P(OEt)_3N_3]^+$ and *trans*-$[Ru(NH_3)_4P(OEt)_3(SCN)]^+$ are of the same order of magnitude. The increase in stability (19–21) of these complexes follow the order

$$Mn^{2+} < Fe^{2+} < Co^{2+} < Ni^{2+} < Zn^{2+} < Ru(II) < Cd^{2+}$$

For electrophilic substituents such as isonicotinamide, pyrazine, and methylpyrazinium, a tendency to rate saturation has been observed on the plots of k_{obsd} versus ligand concentration (1). This behavior is explained by a mechanism of the type:

[3] $[Ru(NH_3)_4P(OEt)_3(H_2O)]^{2+} + X^- \xrightarrow{K_{os}} [[Ru(NH_3)_4P(OEt)_3(H_2O)]^{2+}.X^-]$

[4] $[Ru(NH_3)_4P(OEt)_3(H_2O)]^{2+}.X^- \underset{k'_{-1}}{\overset{k_{1'}}{\rightleftharpoons}} [Ru(NH_3)_4P(OEt)_3X]^{1+} + H_2O$

where X^- represents the entering ligand regardless of its formal charge.

The plots of k_{obsd} versus $[X^-]$ for N_3^-, SCN^-, and CN^- exhibit the same patterns as those observed for good nucleophilic substituents such as imidazole and sulphite ion. The dependence of k_{obsd} upon $[X^-]$ is first order in all the range of ligand concentration and no tendency for rate saturation has been observed.

The overwhelming evidence for the substitution reactions of ruthenium(II) complexes favours a dissociative process (1, 2, 4, 6, 10, 11, 22). Although this mechanism is governed principally by dissociative activation, it is unlikely from the above data that the behavior of N_3^-, SCN^-, and CN^- could be interpreted assuming the formation of the outer-sphere type complexes $[[Ru(NH_3)_4P(OEt)_3(H_2O)^{2+}].X^-]$. It should also be noted that the stability of the outer-sphere complexes is directly related to the extent of charge transfer from Ru(II) to the π acid ligand. Therefore the outer-sphere association of the monophosphite complex with N_3^-, SCN^-, CN^-, imN, and SO^{2-} — weak π acids — should be very weak if it exists (1).

A linear relationship could be found between $\log k_1$ versus $\log K_{eq}$, and $\log k_{-1}$ versus $\log 1/K_{eq}$ for reaction [2] (X = SO^{2-}, CN^-, N_3^-, imN, and SCN^-). For anation reaction the slope is about 0 (indeed 0.05), which implies a transition state resembling the reactants. In the aquation reaction the observed slope for the free energy relationship is 0.89, suggesting that the departing group X^- is only weakly bound in the transition state that resembles the products (23, 24). These results suggest a dissociative activation and are in agreement with our previous observation (1) that the activated complex contains one metal complex and one ligand with some degree of bond making.

It is well known that the extension of bond making relative to bond breaking in the activated complexes changes continuously from one extreme to the other as a function of the experimental conditions, ligands and of the metal center. Small changes could sometimes modify the reaction mechanism (23–25).

In spite of the chemical similarity between phosphite (1) and sulphite systems, no experimental evidence for rate saturations has been reported for substitution reactions on *trans*-$[Ru(NH_3)_4SO_3(H_2O)]$ and related complexes (3, 4). The monophosphite complex seems to be the first reported example on Ru(II) chemistry where the same metal center is able to discriminate through a different mechanism between electrophilic and nucleophilic entering ligands.

Minor metabolites of the marine hydroid *Garveia annulata*

EOIN FAHY AND RAYMOND J. ANDERSEN[1]

Departments of Chemistry and Oceanography, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received June 5, 1986

EOIN FAHY and RAYMOND J. ANDERSEN. Can. J. Chem. **65**, 376 (1987).

Garvalones A (**8**) and B (**18**), garvins A (**11**) and B (**13**), garveatin D (**20**), garveatin A quinone (**29**), 2-hydroxygarveatins A (**21**) and B (**26**), and 2-hydroxygarvin B (**16**) have been isolated from methanol extracts of the marine hydroid *Garveia annulata*. The structures of all nine metabolites were inferred from their spectral data and chemical derivatization reactions. 2-(3-Oxobutyl)garveatin A (**10**) was synthesized as a model compound for the garvalones and the same methodology was applied to the synthesis of garvalone B (**18**). Dimeric compounds **30** and **32**, formed from 2,2′ coupling of two molecules of garveatin B (**2**) or one molecule of garveatin B (**2**) and one molecule of garvin B (**13**) respectively, were also isolated and shown to be artifacts.

EOIN FAHY et RAYMOND J. ANDERSEN. Can. J. Chem. **65**, 376 (1987).

Les garvalones A (**8**) et B (**18**), les garvines A (**11**) et B (**13**), la garvéatine D (**20**), la garvéatine A quinone (**29**), les hydroxy-2 garvéatines A (**21**) et B (**26**) et l'hydroxy-2 garvine B (**16**) ont été isolées des extraits méthanoliques de l'hydroïde marin *Garveia annulate*. On a déduit les structures des neuf métabolites à partir de leurs données spectrales et de réactions de dérivatisations chimiques. On a synthétisé la (oxo-3 butyl)-2 garvéatine A (**10**) comme composé modèle pour les garvalones et on a appliqué la même méthodologie à la synthèse de la garvalone B (**18**). On a aussi isolé les composés dimères **30** et **32**, qui se forment respectivement par le couplage 2,2′ de deux molécules de garvéatine B (**2**) ou d'une molécule de garvéatine B (**2**) et d'une molécule de garvine B (**13**), et on a démontré qu'il s'agit là de produits qui ne sont pas d'origine.

[Traduit par la revue]

Garveia annulata is a small orange hydroid[2] that is reasonably abundant in the rocky subtidal habitats of Barkley Sound, British Columbia, during the late winter months. Methanol extracts of *G. annulata* are very rich in metabolites that display potent in vitro antimicrobial activity. We have recently reported the isolation of garveatin A (**1**) (2), garveatin B (**2**), garveatin C (**3**), 2-hydroxygarvin A (**4**), garvin A quinone (**5**) (3), annulin A

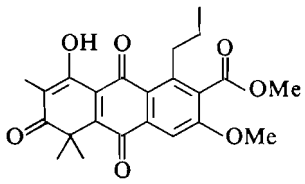
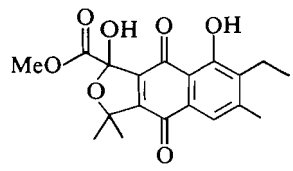
24 R = Ac



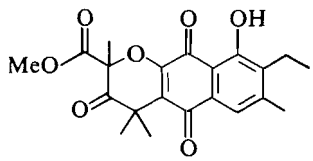
5

(**6**), and annulin B (**7**) (4) from these extracts. Our continuing investigations of *G. annulata* have resulted in the isolation of a number of minor metabolites whose structures we report herein.

Garvalone A (**8**) was obtained as an optically inactive pale yellow oil that gave a parent ion in the hrms (high resolution mass spectrum) appropriate for a molecular formula of $C_{27}H_{32}O_7$. A close relationship between the aromatic portion of the previously reported 2-hydroxygarvin A (**4**) and a fragment of **8** was immediately apparent from a comparison of their spectral data. The uv spectrum (λ_{max} 228, 279, 317, 330, and 382 nm) of **8** was virtually identical to that of **4** (λ_{max} 226, 278, 318, 332,



6



7

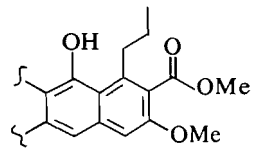
and 385 nm) and its ^1H (Table 1) and ^{13}C (Table 2) nmr spectra contained resonances that could be assigned to the naphthalenic substructure **i**.



i

Functionality, which accounted for the remaining atoms ($C_{11}H_{16}O_3$) of garvalone A (**8**), could be readily identified upon further consideration of its ^1H and ^{13}C nmr spectra. Four methyl singlets at 1.47, 1.55, 1.59, and 2.04 and a complex multiplet at 2.23 (4H) ppm located the remaining hydrogen atoms. Carbon

*, #, and & indicate that the assignments may be interchanged.

resonances at 39.1 (t) and 31.4 (t) required that the protons resonating at 2.23 ppm be attached to two methylene carbons. Carbonyl resonances at 211.9, 207.0, and 203.9 showed that the three oxygens were present as ketone functionalities and resonances at 58.3 (s) and 47.9 (s) ppm identified quaternary carbons.

The carbon resonances at 203.9, 58.3, 211.9, and 47.9 ppm in the spectrum of **8** were very similar to the resonances exhibited by carbons 1 to 4 in garveatin C (**3**) (C1, 204.9; C2, 55.3; C3, 211.6; C4, 48.1) (3), suggesting that both metabolites had the 1-oxo, 2-dialkyl, 3-oxo, 4-dialkyl functionalities in common. Demonstration of an nOe (nuclear Overhauser enhancement) between the aromatic proton resonance at 7.13 (H10) and two methyl resonances at 1.55 and 1.59 ppm in the ^1H nmr of **8** provided evidence for a *gem*-dimethyl group at C4. The ^1H nmr resonance at 1.47 (s, 3H) was assigned to a methyl substituent at C2 by analogy with the other *Garveia* metabolites, and a methyl ketone residue was indicated by the ^1H nmr resonance at 2.04 (s, 3H) and the ^{13}C nmr resonances at 207.0 (s) and 30.5 (q) ppm. Insertion of the two methylene carbons between the carbonyl carbon of the methyl ketone residue and the remaining unsatisfied valence at C2 of the anthracenone skeleton gave the proposed structure **8** for garvalone A. In the mass spectrum, **8** shows intense fragment ions at 398 ($M^+ + H - (CH_3COCH_2CH_2$-): 100%) and 397 ($M^+ - (CH_3COCH_2CH_2$-): 89%) as would be expected.

2-(3-Oxobutyl)garveatin A (**10**), a model for **8**, was obtained from a Michael reaction (5) between garveatin A (**1**) and methyl vinyl ketone (benzene, room temperature, K_2CO_3, 18-crown-6). The ^1H nmr, ^{13}C nmr, and mass spectra of **10** were in complete accord with the structure assigned to garvalone A (**8**) (see Tables 1 and 2).

Three of the new minor metabolites from the *Garveia* extracts belong to the garvin family. Garvin A (**11**) was obtained as a bright yellow solid that gave a parent ion in the mass spectrum at m/z 398 appropriate for a molecular formula of $C_{23}H_{26}O_6$. Its ^1H nmr spectrum showed resonances (Table 1) assignable to the *n*-propyl, methyl ester, and methyl ether functionalities found in the substructure **i** of 2-hydroxygarvin A (**4**) (3). Additional resonances at 1.64 (s, 6H), 1.99 (s, 1.5H), 1.50 (d, J = 7 Hz,

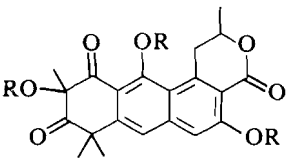
1.5H), and 4.01 (q, $J = 7$ Hz, 0.5H) ppm corresponded closely to the signals assigned to the two tautomeric forms of the alicyclic ring in garveatin B (**2**) (3). A simple combination of the two fragments led to the assignment of structure **11** to garvin A. Treatment of garvin A (**11**) with diazomethane gave monomethyl garvin A (**12**) as the major product.

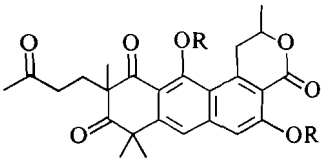
Garvin B (**13**) was obtained as an optically active yellow solid that was shown by hrms to have a molecular formula of $C_{21}H_{20}O_6$. Methyl resonances at 1.54, 1.58, and 1.85 ppm in the ^{1}H nmr (DMSO-d_6; Table 1) of garvin B showed a strong resemblance to the resonances for the methyl groups in the alicyclic ring of garveatin A (**1**) (2) (DMSO-d_6; 1.59, 6H; 1.90, 3H), indicating that the two molecules had this substructure in common. Aromatic resonances at 7.16 (s, 1H) and 7.35 (s, 1H) could be assigned to protons on C5 and C10 of an anthracenone skeleton by analogy with other *Garveia* metabolites. A six-proton spin system (1.50 (d, $J = 7$ Hz, 3H), 4.77 (m, 1H), 3.23 (dd, $J = 19$, 13 Hz, 1H), 4.35 (dd, $J = 19$, 3 Hz, 1H)) could be assigned to a propyl residue that contained an oxygen substituent at the central carbon and an aryl substituent at one of the terminal carbons. Carbon resonances at 20.4, 75.4, and 34.0 ppm were assigned to the substituted propyl residue. The remaining substituents on the aromatic nucleus were shown to be two phenols by methylation and acetylation reactions that gave **14** and **15** respectively, and an ester carbonyl by the observation of a ^{13}C nmr resonance at 170.6 ppm. Modification of the structure of garvin A (**11**) by replacing the methoxy substituent at C6 with a phenol, and formation of a delta (δ) lactone between an alcohol at C16 and the carboxyl at C14, leads to a new structure **13**, which effectively accounts for all the properties of garvin B.

2-Hydroxygarvin B (**16**) was obtained as a yellow solid, which showed a parent ion in its mass spectrum at m/z 384 appropriate for a molecular formula of $C_{21}H_{20}O_7$. A preliminary examination of the ^{1}H nmr spectrum of **16** (Table 1) revealed that a number of the resonances were doubled (ratio approximately 1:1), indicating that a mixture of two diastereomers was present. It was readily apparent from both the ^{1}H and ^{13}C nmr spectra of **16** (Tables 1 and 2) that each of the diastereomers contained an alicyclic ring identical to that found in 2-hydroxygarvin A (**4**), and a naphthalenic fragment identical to that found in garvin B (**13**). Acetylation of **16** gave a mixture of the diastereomeric triacetates **17** in good yield. We have not determined which of the two chiral centers in 2-hydroxygarvin B (**16**) is epimeric in the two naturally occurring diasteromers; however, the observation that garvin B (**13**) is optically active implies that **13** occurs as a single enantiomer and suggests that biological hydroxylation at C2 has occurred in a nonstereospecific fashion.

Garvalone B (**18**), an extremely minor component of the crude extracts, was isolated as a light yellow oil. In the mass spectrum, **18** showed a parent ion at m/z 328, consistent with a molecular formula of $C_{26}H_{28}O_6$. The ^{1}H nmr of **18** (Table 1) also showed a number of resonances that were doubled, again indicating the presence of two diastereomers (ratio 2:3), which we were unable to separate. The major isomer displayed signals (Table 1) that corresponded to the ^{1}H nmr resonances displayed by the functionality in the alicyclic ring of garvalone A (**8**). The remaining ^{1}H nmr resonances in the spectrum of **18** showed a close correspondence to the observed ^{1}H nmr resonances for the aromatic and lactonic portions of garvin B (**13**). Garvalone B (**18**) was quantitatively converted to the diacetate **19** in accordance with the proposed structure.



16 R = H
17 R = Ac



18 R = H
19 R = Ac

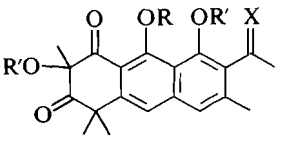
A synthesis of a mixture of garvalone B diastereomers (**18**) (ratio 2:3) was achieved via a Michael reaction between garvin B (**13**) and methyl vinyl ketone. The major isomer formed in the Michael reaction was the minor, naturally occurring isomer. Once again, since garvin B (**13**) occurs as a single enantiomer, it seems reasonable to assume that it is the chiral center at C2 that is epimeric in the natural garvalone B stereoisomers. This assignment is consistent with the lack of optical activity found for garvalone A (**8**) and it implies a nonstereospecific alkylation at C2 in both molecules.

Four of the new minor metabolites belong to the garveatin family. Garveatin D (**20**) was obtained as a yellow oil that showed a parent ion in its mass spectrum at m/z 354 appropriate for a molecular formula of $C_{21}H_{20}O_5$. Its ^{1}H nmr spectrum (Table 1) showed a striking resemblance to the spectrum of garveatin C (**3**) (3). The only noticeable differences were the absence of a methyl ether resonance in the region of 3.9 ppm, an upfield shift in the position of the H5 signal (**3**: 7.35; **20**: 7.05 ppm) reflecting the lack of methylation on the C8 phenol, and the appearance of two phenolic resonances (10.20, 16.15) instead of just one. These observations are consistent with the proposed structure **20** for garveatin D.

An extremely polar metabolite, 2-hydroxygarveatin A (**21**), was obtained as an orange solid that was difficult to purify and gave poor spectral data due to its low solubility in organic solvents. It was most conveniently characterized as its triacetate **22**, a colorless solid that had a molecular formula of $C_{26}H_{26}O_9$. The structure of **22** could be directly assigned by comparing its ^{1}H nmr spectrum (Table 1) to the ^{1}H nmr spectra of triacetyl garveatin A (**23**) (1) and 2-hydroxygarvin A diacetate (**24**) (3).

2-Hydroxygarveatin B (**26**) was obtained as a yellow solid that was shown by hrms to have a molecular formula of $C_{20}H_{22}O_5$. The chemical shifts of three methyl groups in the ^{1}H nmr spectrum of **26** (1.50, 1.65, 1.78) closely corresponded to the shifts of the methyl groups in the alicyclic ring of 2-hydroxygarvin A (**4**) (1.52, 1.66, 1.81) (3) and the remaining proton resonances mimicked those for the aromatic nucleus and its substituents in garveatin B (**2**), allowing a routine assignment of the structure as **26**. 2-Hydroxy garveatin B (**26**) could be converted to a mixture of the triacetate **27** (Table 1) and the diacetate **28**.

Garveatin A quinone (**29**) was isolated as a red oil that was shown by mass spectrometry to have a molecular formula of $C_{20}H_{18}O_6$. The ^{1}H nmr spectrum (Table 1) of **29** immediately



21 R = R′ = H X = O
22 R = R′ = Ac X = O

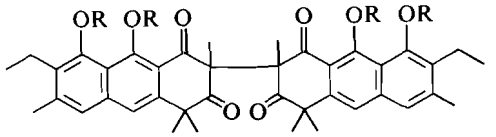
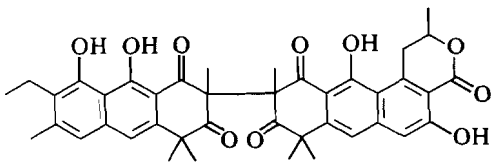
suggested a close relationship to garveatin A (**1**). However, in contrast to the ^{1}H nmr spectrum of 1, only one aromatic proton resonance was observed in the ^{1}H nmr of **29**, and the similarity of its chemical shift (7.55 ppm) to that observed for H5 in garvin A quinone (**5**) (7.56 ppm) (3) suggested that **29** might also be a quinone. The ^{13}C nmr resonances at 193.0 and 180.4 ppm in the spectrum of **29** confirmed the presence of the quinone functionality, and the remainder of the spectrum was in good agreement with the proposed structure. Phenolic and enolic proton resonances at 11.45 and 11.66 ppm indicated that in chloroform solution garveatin A quinone (**29**) exists as the 3-keto tautomer shown.

Garveatin A quinone (**29**) was present in fresh extracts (<48 h) of *Garveia annulata*, and we found that garveatin A (**1**) was not readily converted to the quinone by aerial oxidation in either acidic or basic solutions. Therefore, it seems likely that the quinone **29** is a true metabolite and not an oxidation artifact.

The first evidence for the presence of dimers in the *G. annulata* extracts came from the observation that ^{1}H nmr samples ($CDCl_3$) of garveatin B (**2**) developed a new set of resonances on standing and that these new resonances increased in intensity with time. Repurification of an "aged" garveatin B (**2**) nmr sample yielded, in addition to garveatin B (**2**), a less polar compound **30** whose ^{1}H nmr spectrum contained signals corresponding to the new resonances in the spectrum of "aged" **2**. Compound **30** was not formed when garveatin B (**2**) was



30 R = H
31 R = Ac



32

allowed to stand in C_6D_6 or acetone-d_6 solutions, but it was detected as a very minor constituent of the flash fraction from which garveatin B (**2**) was originally isolated.

The ^{1}H nmr spectrum of **30** (Table 3) contained resonances that could be assigned to the aromatic ethyl, aromatic methyl, H5, H10, and phenolic protons of a naphthalenic fragment identical to that found in garveatin B (**2**). All the above resonances showed small upfield shifts (range: 0.03 (C14-CH_3) – 0.40 (C9-OH) ppm) relative to the corresponding resonances in garveatin B (**2**). Methyl singlets at 1.38, 1.66, and 1.88 ppm indicated that **30** had an alicyclic ring containing an asymmetric center fused to the naphthelinic fragment. The ^{13}C nmr spectrum of **30** contained carbonyl resonances at 202.4 and 209.0 ppm that were similar in chemical shift to the resonances assigned to the C1 (205.8 ppm) and C3 (211.6 ppm) ketone functionalities in garveatin C (**3**), suggesting that the two molecules contained similarly substituted alicyclic rings. A ^{13}C nmr resonance at 63.0 ppm in the spectrum of **30** was assigned to a dialkylated carbon at C2 of the anthracenone skeleton.

The highest mass ion in the electron impact mass spectrum (EI ms) of **30** appeared at m/z 326 daltons. Acetylation of **30**, however, gave a major product **31** that gave a weak molecular ion at m/z 818 daltons in its EI ms. We concluded that **30** was a dimer formed by a 2,2′ linkage of garveatin B (**2**) monomers and that **31** was its 8,8′,9,9′ tetraacetate.

TABLE 3. ^{1}H nuclear magnetic resonance data. Chemical shifts are in ppm from TMS. All spectra were run in $CDCl_3$

All resonances are singlets unless indicated otherwise. * indicates assignment may be reversed.

The mixed dimer **32** was obtained as an orange oil in the course of a routine work-up of a *G. annulata* crude extract. A FAB (fast atom bombardment) mass spectrum of **32** showed a molecular ion at m/z 693 (M + 1) daltons, appropriate for a molecular formula of $C_{41}H_{40}O_{10}$, and fragment ions at m/z 326/327 and 368/369 corresponding to the garveatin B (**2**) and garvin B (**13**) monomers respectively. The ^{1}H nmr spectrum of **32** (Table 3) contained resonances that could be assigned to both the garveatin B and garvin B-like fragments of the dimer, allowing a routine assignment of the structure. Once again, many of the observed ^{1}H nmr resonances of **32** show upfield shifts relative to the corresponding resonances in the ^{1}H nmr spectra of the individual monomers. Mixtures of dimers **30** and **32** form slowly in chloroform solutions containing equal parts of garveatin B (**2**) and garvin B (**13**), with or without added silica gel. It seems likely, therefore, that both the mixed dimer **32** and the symmetrical dimer **30** are artifacts formed during fractionation of the *G. annulata* extracts.

One interesting feature of the dimerization reactions leading to **30** and **32** is the apparent formation of only a single relative stereochemistry at the two new chiral centers in the products. In principle, dimerization at C2 of either of the monomers **2** or **13** can lead to the formation of either the *meso* isomer or a racemic mixture of the *R,R* and *S,S* isomers. The *meso* dimer should be separable from the *R,R* and *S,S* dimers and the two types should exhibit different spectral features. We have found no evidence for the formation of more than one type of stereoisomer. Cameron *et al.* have used chiral nmr shift reagents to identify the diasteromers of a series of 10,10′ emodin bianthrones (6). We attempted to apply this methodology to the tetraacetates of our dimers, but excessive line broadening prevented any definite conclusions. Therefore it is still not clear whether the *Garveia* monomers dimerize to give only the *meso* or a mixture of *R,R* and *S,S* isomers.

None of the other *G. annulata* metabolites spontaneously dimerize as readily as garveatin B (**2**) upon standing at room

temperature in $CDCl_3$. Garveatin A (**1**) does not dimerize at all, while garvin A (**11**) gives only a very low yield of dimer after a period of a week or longer. It is possible that the spontaneous dimerization of garveatin B (**2**) and garvin A (**11**) in chloroform solutions is related to the high percentage of diketo tautomer present for both these compounds in this solvent. In contrast, the ^1H nmr spectrum of garveatin A (**1**) ($CDCl_3$) shows it to be present exclusively as the keto-enol tautomer.

The minor *G. annulata* metabolites reported in this manuscript can be grouped into three families, the garveatins (compounds **20**, **21**, **26**, and **29**), the garvins (compounds **11**, **13**, and **16**), and the garvalones (compounds **8** and **18**). The anthracene based ring system found in all the compounds is a common feature of polyketide derived metabolites.[3] We have previously proposed that a single nonaketide precursor could lead to both the garveatins and the garvins by simply adopting different folding patterns prior to cyclization and aromatization (3). The garvalones are simply C2 alkylated garvins, although the nature of the alkylation pathway is not immediately apparent. Hydroxylation at C2 and anthraquinone formation are secondary biogenetic transformations observed in both the garveatin and garvin families.

Experimental

The ^1H nmr spectra were recorded on Bruker WP-80, Nicolet–Oxford 270, Varian XL-300, and Bruker WH-400 spectrometers. The ^{13}C nmr spectra were recorded on a Varian XL-300 spectrometer. TMS was used as an internal standard. Low resolution mass spectra were recorded on an AEI MS902 spectrometer and high resolution mass spectra on an AEI MS50 instrument. The ir spectra were recorded on a BOMEM Fourier transform spectrometer. Ultraviolet–visible spectra were recorded on a Bausch and Lomb Spectronic-2000 spectrometer. Optical rotation measurements were recorded on a Perkin–Elmer 141 polarimeter.

Merck silica gel 230–400 mesh was used for flash and preparative thin-layer chromatography and Whatman Magnum-9 Partisil-10 and Partisil-10 ODS 3 columns were used for preparative hplc. Sephadex LH-20 resin was used for molecular exclusion chromatography. The R_f values are listed for compounds in an analytical tlc system using a 1:49:49 acetic acid – ethyl acetate – hexane eluent.

Collection data

Garveia Annulata was collected by hand using SCUBA (−2 to −9 m) on exposed rocky reefs in Barkley Sound, British Columbia, during the winter and spring months.

Extraction and chromatography

Freshly collected whole specimens were immediately placed in methanol and stored at room temperature. The methanol extract was decanted and filtered. The filtrate was rotary evaporated to give an aqueous suspension that was diluted to 400 mL with distilled water and extracted successively with hexane (3 × 400 mL), methylene chloride (3 × 400 mL), and ethyl acetate (2 × 400 mL).

The hexane (600 mg) and methylene chloride (4 g) extracts were fractionated separately by step-gradient vacuum flash chromatography using a 3.5 cm thick silica pad in a sintered glass funnel (10 cm diameter). Fractions eluting with the same solvent composition from each separation were combined. Elution with 20% ethyl acetate – hexane, 50% ethyl acetate – hexane, 100% ethyl acetate, and 20% methanol – ethyl acetate gave fractions A (140 mg), B (500 mg), C (1.5 g), and D (700 mg) respectively. Chromatography of fraction B on Sephadex LH-20 (90% methanol – methylene chloride) yielded a fraction that was further purified by preparative tlc (50% ethyl acetate – hexane, 10% ethyl acetate – chloroform, and 20% ethyl acetate – hexane) to give garvalone A (**8**) (20 mg), 2-hydroxygarvin B (**16**) (9 mg), and garveatin B dimer (**30**) (3 mg). Another LH20 fraction contained a component that was purified by preparative tlc (10% ethyl acetate – hexane) and reverse phase hplc (95% acetonitrile–water) to yield garveatin B – garvin B dimer (**32**) (6 mg).

LH-20 purification of fraction C yielded garvin B (**13**) (100 mg) and 2-hydroxygarveatin B (**26**) (40 mg) as well as two other fractions that were chromatographed on preparative tlc (10% ethyl acetate – chloroform, 25% ethyl acetate – hexane, and 5% methanol–chloroform) to yield garvin A (**11**) (45 mg), garveatin D (**20**) (8 mg), and garvalone B (**18**). Fraction D contained a complex mixture of relatively polar compounds, which were separated on reversed phase tlc plates (80% methanol–water) to yield 2-hydroxygarveatin A (**21**) as the major component.

The ethyl acetate phase was subjected to vacuum flash chromatography using a 3.5-cm silica gel pad in a sintered glass funnel (10 cm diameter). Elution with an ethyl acetate – methylene chloride gradient yielded a fraction that was deep red. This fraction was further purified by preparative tlc (methanol – methylene chloride, 2:98) to give garveatin A quinone (**29**) (11 mg).

*Garvalone A (**18**):* obtained as a light yellow oil, R_f 0.42; uv (MeOH): 228 (15 000), 279 (20 100), 317 (4 900), 330 (4 100), 382 (4 400) nm; ir ($CHCl_3$): 1570, 1610, 1718, 1737 cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$): 1.11 (t, 3H, J = 7 Hz), 1.47 (s, 3H), 1.55 (s, 3H), 1.59 (s, 3H), 1.75 (m, 2H), 2.04 (s, 3H), 2.23 (m, 4H), 3.15 (m, 2H), 3.93 (s, 3H), 3.96 (s, 3H), 6.93 (s, 1H), 7.13 (s, 1H), 15.10 (s, 1H) ppm; ^{13}C nmr (75 MHz, $CDCl_3$): 211.90 (s), 207.04 (s), 203.88 (s), 168.61 (s), 166.59 (s), 157.35 (s), 142.97 (s), 142.50 (s), 141.82 (s), 126.45 (s), 116.78 (s), 115.28 (d), 108.70 (s), 104.96 (d), 58.30 (s), 55.94 (q), 52.49 (q), 47.85 (s), 39.06 (t), 36.14 (t), 31.43 (t), 30.52 (q), 29.86 (q), 27.01 (q), 25.42 (t), 24.21 (q), 14.80 (q) ppm; ms m/z (relative intensity): 468 (M^+, 94), 453 (14), 437 (14), 398 (100), 397 (89), 383 (43). *Exact Mass* calcd. for $C_{27}H_{32}O_7$: 468.2149; found: 468.2162.

*Preparation of methyl garvalone A (**9**)*

Garvalone A (**8**) (20 mg), K_2CO_3 (150 mg, anhydrous), and methyl iodide (0.6 mL) were dissolved in 10 mL of acetone and the mixture was stirred at reflux overnight under an atmosphere of N_2. The reaction mixture was rotary evaporated and partitioned between water and methylene chloride. The methylene chloride phase yielded methyl garvalone A (**9**) (20 mg). Compound **9** was obtained as a pale yellow oil, R_f 0.39; uv (MeOH): 225, 263, 314 nm; ^1H nmr (400 MHz, $CDCl_3$): 0.94 (t, 3H, J = 7 Hz), 1.36 (s, 3H), 1.52 (s, 3H), 1.57 (s, 3H), 1.6 (m, 2H), 1.95–2.10 (m, 2H), 2.05 (s, 3H), 2.24 (m, 2H), 2.48 (m, 2H), 2.87 (m, 1H), 3.14 (m, 1H), 3.95 (s, 3H), 3.97 (s, 3H), 7.02 (s, 1H), 7.49 (s, 1H) ppm; ms m/z (rel. intensity): 482 (M^+, 57), 467 (11), 451 (9), 426 (23), 412 (38), 411 (37), 397 (62), 383 (18).

*Preparation of 2-(3-oxobutyl)garveatin A (**10**)*

To a solution of garveatin A (**1**) (15 mg) in benzene (7 mL) was added anhydrous K_2CO_3 (100 mg), methyl vinyl ketone (50 μL), and 18-crown-6 (one crystal). The mixture was refluxed under N_2 for 24 h after which it was filtered and the filtrate was concentrated *in vacuo*. Preparative tlc of the residue (silica gel; acetic acid – methanol–chloroform, 1:5:94) gave 2-(3-oxobutyl)garveatin A (**10**) (12 mg) and unreacted garveatin A (2 mg). Compound **10**: ^1H nmr ($CDCl_3$, 400 MHz): 1.48 (s, 3H), 1.54 (s, 3H), 1.58 (s, 3H), 2.04 (s, 3H), 2.24 (m, 4H), 2.34 (s, 3H), 2.55 (s, 3H), 6.65 (s, 1H), 7.12 (s, 1H), 10.13 (s, 1H), 16.29 (s, 1H); ^{13}C nmr ($CDCl_3$): 20.7, 24.1, 27.1, 29.9, 30.7, 31.3, 32.3, 38.9, 47.9, 58.0, 107.8, 110.8, 115.5, 120.2, 125.3, 139.5, 141.2, 142.5, 156.0, 166.1, 204.1, 204.2, 206.9, 211.3 ppm; ms m/z: M^+ 410, 341, 340, 326, 325 (100%).

*Garvin A (**11**):* obtained as a yellow solid, R_f 0.41; uv (MeOH): 220, 247, 274, 321, 383 nm; ^1H nmr (300 MHz, $CDCl_3$): 1.03 (t, 3H, J = 7 Hz), 1.64 (s, 3H), 1.73 (m, 2H), 1.99 (s, 3H), 3.18 (m, 2H), 3.95 (s, 3H), 3.97 (s, 3H), 6.91 (s, 1H), 7.17 (s, 1H), 15.14 (s, 1H), also 1.50 (d, 3H, J = 7 Hz), 4.01 (q, 1H, J = 7 Hz) due to diketo tautomer; ms m/z (rel. intensity): 398 (M^+, 100), 383 (30), 367 (21), 351 (17).

Preparation of monomethyl garvin A (12)

Garvin A (**11**) (14 mg) was dissolved in diethyl ether (3 mL, anhydrous) and treated with diazomethane (generated by adding 0.6 mL 5 *M* NaOH to 100-mg *N*-methylnitronitrosoguanidine). After standing overnight, the reaction mixture was purified by preparative tlc (80% $CHCl_3$–hexane) to give monomethylgarvin A (**12**) (6.4 mg) as the major product. *Compound (12):* R_f 0.60; uv (MeOH): 220, 250, 275, 283 (sh), 322, 334 (sh), 390 nm; ^{1}H nmr (300 MHz, $CDCl_3$): 1.02 (t, 3H), 1.55 (s, 6H), 1.73 (m, 2H), 2.06 (s, 3H), 3.19 (m, 2H), 3.93 (s, 3H), 3.96 (s, 3H), 3.99 (s, 3H), 6.90 (s, 1H), 7.14 (s, 1H), 15.87 (s, 1H) ppm; ms *m/z* (rel. intensity): 412 (M^+, 44), 397 (32), 381 (15), 365 (24), 337 (10).

Garvin B (13): obtained as a yellow solid, R_f 0.43; uv (MeOH): 229, 256, 289, 327, 389 nm; ^{1}H nmr (300 MHz, DMSO-d_6): 1.50 (d, 3H, J = 7 Hz), 1.54 (s, 3H), 1.58 (s, 3H), 1.85 (s, 3H), 3.23 (dd, 1H, J = 19, 13 Hz), 4.35 (dd, 1H, J = 19, 3 Hz), 4.77 (m, 1H), 7.16 (s, 1H), 7.35 (s, 1H), 11.14 (s, 1H), 17.85 (s, 1H) ppm; ^{13}C nmr (75 MHz, DMSO-d_6): 191.05, 177.97, 170.58, 166.33, 159.05, 149.09, 145.56, 142.55, 115.00, 114.40, 110.53, 110.50, 107.70, 107.65, 75.40, 48.24, 33.97, 29.24, 28.93, 20.43, 7.60 ppm; ms *m/z* (rel. intensity): 368 (M^+, 6), 353 (3), 325 (3), 311 (3). *Exact Mass* calcd. for $C_{21}H_{20}O_6$: 368.1260; found: 368.1269.

Preparation of trimethyl garvin B (14)

A solution of garvin B (**13**) (15 mg), K_2CO_3 (100 mg), and methyl iodide (0.5 mL) in 10 mL acetone was refluxed under a stream of N_2 for 6 h and then partitioned between water and methylene chloride. The methylene chloride soluble material was chromatographed on silica (50% ethyl acetate – hexane) to yield trimethylgarvin B (**14**) (10 mg) as the major reaction product. *Compound (14):* obtained as a pale yellow solid, R_f 0.27; $[\alpha]_D^{22}$ +172.69° (*c* 0.26, $CHCl_3$); uv (MeOH): 232, 275, 330 nm; ^{1}H nmr (300 MHz, $CDCl_3$): 1.37 (s, 3H), 1.42 (s, 3H), 1.54 (s, 3H), 1.55 (d, 3H, J = 7 Hz), 1.57 (s, 3H), 3.27 (dd, 1H, J = 19, 13 Hz), 3.89 (s, 3H), 4.04 (s, 3H), 4.13 (dd, 1H, J = 19, 3 Hz), 4.45 (m, 1H), 7.13 (s, 1H), 7.50 (s, 1H) ppm; ms *m/z* (rel. intensity): 410 (M^+, 100), 395 (11), 377 (13), 367 (12), 340 (49), 339 (40).

Acetylation of garvin B

Garvin B (**11**) (30 mg) was acetylated at room temperature with pyridine (0.5 mL) and acetic anhydride (0.5 mL). After evaporation of the reagents, the residue was purified by preparative tlc (10% ethyl acetate – methylene chloride) and hplc (10% ethyl acetate – hexane) to give garvin B diacetate (5 mg) and garvin B triacetate (**13**) (15 mg). *Diacetate:* obtained as a light yellow oil, R_f 0.38; uv (MeOH): 245, 286, 389 nm; ^{1}H nmr (80 MHz, $CDCl_3$): 1.55 (s, 3H), 1.57 (s, 3H), 1.58 (d, 3H, J = 7 Hz), 1.88 (s, 3H), 2.38 (s, 3H), 2.41 (s, 3H), 3.40 (dd, 1H, J = 19, 13 Hz), 4.32 (dd, 1H, J = 19, 3 Hz), 4.60 (m, 1H), 7.25 (s, 1H), 7.30 (s, 1H), 15.75 (s, 1H) ppm; ms *m/z* (rel. intensity): 452 (M^+, 2), 451 (5), 409 (15), 367 (76), 352 (23). *Triacetate (15):* obtained as a pale yellow oil, R_f 0.24; uv (MeOH): 222, 237, 281, 292, 305 (sh), 345, 365 (sh), 384 nm; ^{1}H nmr (400 MHz, $CDCl_3$): 1.57 (d, 3H, J = 7 Hz), 1.58 (s, 3H), 1.64 (s, 3H), 1.81 (s, 3H), 2.36 (s, 3H), 2.40 (s, 3H), 2.57 (s, 3H), 3.28 (dd, 1H, J = 19, 13 Hz), 3.85 (dd, 1H, J = 19, 3 Hz), 4.58 (m, 1H), 7.48 (s, 1H), 7.86 (s, 1H) ppm; ms *m/z* (rel. intensity): 494 (M^+, 1), 493 (1), 451 (13), 409 (22), 367 (68), 352 (16).

2-Hydroxygarvin B (16): obtained as a yellow solid, R_f 0.35; uv (MeOH): 234, 287, 386 (neutral), 253, 310, 417 (basic) nm; ^{1}H nmr (400 MHz, $CDCl_3$): 1.50, 1.54 (s, 3H), 1.64, 1.65 (d, J = 7 Hz, 3H), 1.65, 1.66 (s, 3H), 1.80, 1.82 (s, 3H), 3.41, 3.44 (dd, J = 12, 19 Hz, 1H), 4.02 (br s, 1H), 4.38 (dd, J = 3, 19 Hz, 1H), 4.74 (m, 1H), 7.11 (s, 2H), 11.44, 11.45 (s, 1H), 14.61, 14.62 (s, 1H) ppm; ^{13}C nmr (75 MHz, $CDCl_3$): 209.83, 199.71 (199.55), 169.85 (169.80), 167.39 (167.17), 161.27 (167.16), 145.40 (145.26), 144.58 (144.54), 143.84, 116.03, 115.94, 111.81, 110.81 (110.77), 107.00 (106.88), 81.64 (81.57), 75.43 (75.35), 47.14 (47.05), 34.60 (34.36), 30.70 (30.44), 29.15 (29.04), 28.43 (27.99), 20.83 ppm; ms *m/z* (rel. intensity): 384 (M^+, 32), 368 (22), 353 (9), 342 (90), 341 (100), 327 (61), 309 (26).

Garvalone B (18): obtained as a light yellow oil (3:2 mixture of diastereomers), R_f 0.44; $[\alpha]_D$ +136.92° (*c* 0.39, $CHCl_3$); uv (MeOH): 236, 290, 385 nm; ^{1}H nmr (300 MHz, $CDCl_3$): 1.464, 1.470 (s, 3H), 1.566, 1.533 (s, 3H), 1.584, 1.611 (s, 3H), 1.646 (d, J = 7 Hz, 3H), 2.063, 2.042 (s, 3H), 2.234 (m, 4H), 3.419, 3.424 (dd, J = 18, 12 Hz, 1H), 4.387 (dd, J = 18, 3 Hz, 1H), 4.732 (m, 1H), 7.060 (s, 1H), 7.102 (s, 1H), 11.503 (s, 1H), 15.442 (s, 1H) ppm; ms *m/z* (rel. intensity): 438 (M^+, 12), 368 (10), 353 (5), 325 (3). *Garvalone B diacetate (19):* ^{1}H nmr (300 MHz, $CDCl_3$): 2.40 (s, 3H), 2.47 (s, 3H), 7.53 (s, 1H), 7.75 (s, 1H) ppm.

Synthesis of garvalone B (18)

Garvin B (**13**) (15 mg) was dissolved in benzene (8 mL) containing 100 mg of K_2CO_3 (anhydrous) and a crystal of 18-crown-6. Excess methyl vinyl ketone (100 μL) was added and the mixture was stirred at reflux overnight, under N_2. The reaction mixture was then filtered and the filtrate concentrated *in vacuo*. Preparative tlc (5% MeOH–$CHCl_3$) purification gave garvalone B (**18**) (8 mg) as a 2:3 mixture of diastereomers and unreacted garvin B (4 mg).

Garveatin D (20): obtained as a yellow solid, R_f 0.40; uv (MeOH): 238, 269, 417 nm; ^{1}H nmr (300 MHz, $CDCl_3$): 1.50 (s, 6H), 1.58 (s, 6H), 2.41 (br s, 3H), 2.63 (s, 3H), 7.05 (br s, 1H), 7.12 (s, 1H), 10.20 (s, 1H), 16.15 (s, 1H) ppm; ms *m/z* (rel. intensity): 354 (M^+, 53), 339 (59), 321 (30), 311 (15), 297 (13), 293 (16).

Preparation of 2-hydroxygarveatin A triacetate (22)

Fraction D (200 mg) obtained from flash chromatography of the methylene chloride phase of the extract was dissolved in pyridine (3 mL) and acetic anhydride (7 mL) and stirred at room temperature for 48 h. After evaporation of the reagents, the residue was purified by flash chromatography (methanol – methylene chloride gradient) and preparative tlc (50% ethyl acetate – hexane) to give 2-hydroxygarveatin A triacetate (**22**) (90 mg). *Triacetate (22):* obtained as a colourless solid, R_f 0.25; uv (MeOH): 226, 260, 303, 355 nm; ^{1}H nmr (400 MHz, $CDCl_3$): 1.45 (s, 3H), 1.57 (s, 3H), 1.79 (s, 3H), 2.20 (s, 3H), 2.34 (s, 3H), 2.41 (br s, 3H), 2.50 (s, 3H), 7.61 (s, 1H), 7.79 (s, 1H) ppm; ms *m/z* (rel. intensity): 482 (M^+, 3), 440 (25), 398 (100), 356 (20), 338 (32), 314 (83), 313 (77). *Exact Mass* calcd. for $C_{26}H_{26}O_9$: 482.1577; found: 482.1567.

Preparation of diacetate (25)

On standing in pyridine-d_6 in an nmr tube overnight, triacetate (**22**) partially decomposed to diacetate (**25**) (yield 40%) which was purified via flash chromatography (ethyl acetate – hexane gradient). *Diacetate (25):* R_f 0.40; uv (MeOH): 226, 272, 306 (sh), 385 nm; ^{1}H nmr (80 MHz, $CDCl_3$): 1.58 (s, 3H), 1.63 (s, 3H), 1.74 (s, 3H), 2.24 (s, 3H), 2.40 (s, 3H), 2.45 (br s, 3H), 2.55 (s, 3H), 7.26 (1H), 7.47 (s, 1H), 9.26 (s, 1H) ppm; ^{13}C nmr (75 MHz, $CDCl_3$): 206.5, 202.7, 198.4, 169.7, 163.7, 145.0, 142.8, 139.6, 137.9, 134.1, 126.9, 116.3, 115.1, 108.1, 82.6, 47.4, 32.0, 31.2, 29.3, 23.4, 21.1, 20.0, 19.7 ppm; ms *m/z* (rel. intensity): 440 (M^+, 14), 398 (71), 356 (9), 340 (14), 338 (25), 314 (90), 313 (100), 295 (13).

2-Hydroxygarveatin B (26): obtained as a yellow solid, R_f 0.28; uv (MeOH): 224, 275, 423 nm; ^{1}H nmr (80 MHz, $CDCl_3$): 1.18 (t, 3H, J = 7 Hz), 1.50 (s, 3H), 1.65 (s, 3H), 1.78 (s, 3H), 2.47 (br s, 3H), 2.80 (q, 2H, J = 7 Hz), 4.60 (bs, 1H), 7.08 (br s, 1H), 7.13 (s, 1H), 9.68 (s, 1H), 15.15 (s, 1H) ppm; ms *m/z* (rel. intensity): 342 (M^+, 15), 327 (5), 300 (26), 299 (30), 285 (13). *Exact Mass* calcd. for $C_{20}H_{22}O_5$: 342.1468; found: 342.1467.

Preparation of 2-hydroxygarveatin B acetates

A solution of 2-hydroxygarveatin B (**26**) (16 mg), pyridine (0.25 mL), and acetic anhydride (0.5 mL) was stirred overnight at room temperature. After removal of the reagents *in vacuo*, the residue was chromatographed on silica (2% methanol – methylene chloride) to give 2-hydroxygarveatin B diacetate (3 mg), and 2-hydroxygarveatin B triacetate (**27**) (11 mg).

Diacetate (28): R_f 0.30; uv (MeOH): 213, 250, 307 (sh), 319, 363 nm; ^{1}H nmr (80 MHz, $CDCl_3$): 1.15 (t, 3H, J = 7 Hz), 1.26 (s, 3H), 1.40 (s, 3H), 1.83 (s, 3H), 2.45 (s, 3H), 2.47 (s, 3H), 2.52 (br s, 1H), 2.71 (q, 1H, J = 7 Hz), 4.63 (br s, 1H), 7.62 (br s, 1H),

7.66 (s, 1H) ppm; ms *m/z* (rel. intensity): 426 (M^+, 10), 384 (19), 342 (47), 326 (18), 324 (33), 300 (84), 299 (100), 282 (77).

Triacetate (27): R_f 0.40; uv (MeOH): 217, 260, 304, 316, 359 nm; ^{1}H nmr (80 MHz, $CDCl_3$): 1.13 (t, 3H, J = 7 Hz), 1.44 (s, 3H), 1.55 (s, 3H), 1.78 (s, 3H), 2.22 (s, 3H), 2.45 (s, 6H), 2.50 (br s, 3H), 2.70 (q, 2H, J = 7 Hz), 7.55 (br s, 1H), 7.70 (s, 1H) ppm; ms *m/z* (rel. intensity): 468 (M^+, 4), 426 (20), 384 (100), 342 (19), 324 (28), 300 (44), 299 (82), 282 (26). *Exact Mass* calcd. for $C_{26}H_{28}O_6$: 468.1784; found: 468.1776.

Garveatin A quinone (29): obtained as a red oil, R_f 0.49; uv (MeOH): 218, 265, 280 (sh) and 410 nm; ^{1}H nmr ($CDCl_3$, 80 MHz): 1.63 (s, 6H), 1.98 (s, 3H), 2.41 (bs, 3H), 2.60 (s, 3H), 7.55 (bs, 1H), 11.45 (s, 1H), 11.66 (s, 1H); ^{13}C nmr ($CDCl_3$, 75 MHz): 202.1, 200.0, 193.0, 180.4, 159.5, 159.1, 156.2, 147.2, 136.3, 131.9, 127.7, 123.0, 118.6, 112.4, 48.3, 31.9, 26.4 (2 carbons), 20.5, 8.1. *Exact Mass* (ms) calcd. for $C_{20}H_{18}O_6$: 354.1103; found: 354.1108.

Preparation of garveatin B dimer

A solution of garveatin B (**2**) in $CDCl_3$ was allowed to stand overnight in a closed nmr tube at room temperature. The sample was then chromatographed on preparative tlc (20% ethyl acetate – hexane) to give garveatin B dimer **30** in approximately 30% yield. *Dimer 30:* obtained as an orange oil, R_f 0.66; uv (MeOH): 225, 275, 320 sh, 434 nm; ^{1}H nmr (270 MHz, $CDCl_3$): 1.07 (t, J = 7 Hz, 3H), 1.38 (s, 3H), 1.66 (s, 3H), 1.88 (s, 3H), 2.43 (s, 3H), 2.53 (m, 1H), 2.70 (m, 1H), 6.98 (s, 2H), 9.37 (s, 1H), 15.79 (s, 1H) ppm; ^{13}C nmr (75 MHz, C_6D_6): 208.9, 202.4, 167.3, 155.6, 143.5, 140.0, 137.7, 126.4, 119.9, 115.7, 110.9, 107.9, 63.0, 48.6, 33.6, 25.9, 21.2, 20.4, 19.8, 13.8 ppm; ms *m/z* (rel. intensity): 326 (57), 311 (100), 283 (20), 269 (11) (molecular ion not seen in EI spectrum).

Preparation of garveatin B dimer tetraacetate 31

Garveatin B dimer **30** (2 mg) was treated overnight with 100 μL of acetic anhydride and 100 μL of pyridine. The reaction mixture was then chromatographed on preparative tlc (50% ethyl acetate – hexane) to give the tetraacetate **31** in quantitative yield. *Tetraacetate 31:* obtained as a light yellow oil, R_f 0.60; ^{1}H nmr (300 MHz, $CDCl_3$): 1.15 (t, J = 7 Hz, 3H), 1.56 (s, 3H), 1.71 (s, 3H), 1.85 (s, 3H), 2.30 (s, 3H), 2.42 (s, 3H), 2.52 (s, 3H), 2.55 (m, 1H), 2.75 (m, 1H), 7.61 (s, 1H), 7.75 (s, 1H) ppm; ms *m/z* (rel. intensity): 818 (M^+, 0.02), 776 (0.30), 734 (0.31), 716 (0.44), 674 (2), 410 (3), 368 (12), 326 (100), 311 (67).

Garveatin B – garvin B dimer 32

Obtained as an orange oil, R_f 0.65; uv (MeOH): 283, 400 (neutral), 282, 305 (sh), 414 (basic) nm; ^{1}H nmr (400 MHz, $CDCl_3$): 1.00 (t, J = 7 Hz, 3H), 1.20 (s, 3H), 1.24 (s, 3H), 1.51 (d, J = 7 Hz, 3H), 1.78 (s, 3H), 1.80 (s, 3H), 1.81 (s, 3H), 1.82 (s, 3H), 2.35 (dd, J = 19, 12 Hz, 1H), 2.42 (s, 3H), 2.42 (m, 1H), 2.77 (m, 1H), 3.83 (dd, J = 19, 3 Hz, 1H), 4.40 (m, 1H), 6.90 (s, 2H), 6.92 (s, 1H), 7.02 (s, 1H), 9.10 (s, 1H), 14.85 (s, 1H), 15.70 (s, 1H) ppm; ms *m/z* (rel. intensity): 368 (100), 353 (53), 326 (53), 311 (88), 297 (20) (no molecular ion was seen in the EI spectrum); FAB ms (MeOH solution in thioglycerol) *m/z*: 693 (M + 1 ion), 649, 369, 368, 327, 326, 311, 297.

Raman spectra of tri-*n*-butylamine show pairs of bands whose temperature-dependent intensities clearly suggest their assignment to different conformers in simultaneous equilibria. These spectroscopic data are interpreted and correlated with structural information obtained from statistical analysis of gauche skeletal arrangements in tri-*n*-butylamine. The average numbers of *gauche* interactions in various tri-*n*-alkylamines are used to evaluate partial molal volumes which show excellent agreement with experimental data, thus imparting statistical meaning and usefulness to the concept of "average conformation".

As the temperature decreases, the band at 904 cm^{-1} in pure liquid tri-*n*-butylamine increases in intensity at the expense of the band at 880 cm^{-1}. Both of these bands are ascribed to CH_2 and CH_3 rocking vibrations. In solution, the conformer represented by the band at 904 cm^{-1} is favoured by polar solvents, whereas the conformer represented by the 860 cm^{-1} band is favoured by non-polar solvents.

The relative intensity changes with increasing temperature of the bands at 1456 and 1440 cm^{-1} is explained by an increase in the number of CH_2 groups adjoining two *gauche* bonds and a decrease in the number of CH_2 groups adjoining a *trans* and *gauche* bond.

Temperature dependence of the relative intensities of bands in the CH stretching region suggest, by comparison with mono- and di-*n*-butylamine, that the increase in the number of alkyl chains around the nitrogen atom makes molecular packing less restrictive and unique, giving rise to mesophases, as the overall shapes of the molecules become more spherical.

A. M. Amorim da Costa, L. A. E. Batista de Carvalho, J. J. C. Teixeira-Dias, Ester F. G. Barbosa et Isabel M. S. Lampreia. Can. J. Chem. **65**, 384 (1987).

Les spectres Raman de la tri-*n*-butylamine présentent des paires de bandes dont les intensités dépendent de la température; ces observations suggèrent clairement que l'on doit les attribuer à différents conformères dans équilibres simultanés. On interprète ces données spectroscopiques et on établit une corrélation avec les informations structurales obtenues à partir d'une analyse statistique des arrangements *gauches* du squelette de la tri-*n*-butylamine. On utilise les nombres moyens d'interactions gauches dans diverses tri-*n*-alkylamines pour évaluer les volumes molales partiels qui sont en bon accord avec les données expérimentales; cette corrélation permet d'attribuer une signification statistique et de démontrer l'utilité du concept de «conformation moyenne».

Dans le cas de la tri-*n*-butylamine à l'état de liquide pur, une diminution de la température provoque une augmentation de l'intensité de la bande à 904 cm^{-1}, au détriment de la bande à 880 cm^{-1}. On attribue ces deux bandes aux vibrations de balancement des CH_2 et CH_3. En solution, le conformère représenté par la bande à 904 cm^{-1} est favorisé dans les solvants polaires alors que le conformère représenté par la bande à 860 cm^{-1} est favorisé par les solvants non polaires.

On explique les changements d'intensités relatives des bandes à 1456 et 1440 cm^{-1}, qui sont associés à une augmentation de la température, par une augmentation du nombre de groupements CH_2 dans les positions qui sont jointes directement à deux liaisons *gauches* et par une diminution du nombre de groupements CH_2 dans les positions qui sont jointes à une liaison *trans* et à une liaison *gauche*.

La relation qui existe entre la température et les intensités relatives des bandes de la région de l'élongation du CH suggère, par comparaisons avec les mono- et di-*n*-butylamines, que l'augmentation du nombre de chaînes alkyles autour de l'atome d'azote rend l'empilage moléculaire moins restrictif et moins unique; cette situation donne lieu à des mésophases au fur et à mesure que les formes globales des molécules deviennent plus sphériques.

[Traduit par la revue]

1. Introduction

Vibrational spectra have been widely used in conformational analysis (1). However, the assignment of infrared and Raman spectral lines relating to a specific molecular geometry often cannot be decided uniquely from spectra alone. Corroborative chemical or other physical evidence is usually necessary for the understanding of conformational spectral features. Moreover, assumptions regarding conformations and their relative energies cannot generally be avoided.

The role of various intramolecular effects governing conformational stability, including steric hindrance, intramolecular hydrogen bonding, the *gauche* effect and the *trans* lone-pair effect, has been experimentally considered in the conformational analysis of alcohols, amines, and their substituted derivatives (2–7).

Using the statistical thermodynamic treatment of molecular spectra, Scott (8) was able to show the statistical distribution of five conformers of *n*-propylamine in the vapour phase and reported that the observed infrared spectrum of ethylamine arose solely from the conformation with C_1 symmetry, which assumed the *gauche* orientation of the CCN group. Radom and co-workers (9) applied *ab initio* molecular orbital theory to study internal rotations in methylamine and ethylamine and

found that the staggered conformation was preferred and conformers with the vacant corner of the nitrogen tetrahedron *gauche* to C_α—C_β were the most stable. Eggert and Djerassi (10) used ^{13}C nuclear magnetic resonance to estimate the equilibrium distribution of conformers for *n*-propylamine and isobutylamine in solution and found that the rotamer distribution was quite different from that of the corresponding alkanes.

Conformational studies by Raman spectroscopy and statistical analysis of *gauche* interactions in *n*-butylamine have been previously reported by the authors (11). Also, temperature-dependent intensities of Raman bands of di-*n*-butylamine (12) suggest the occurrence of different conformers in simultaneous equilibria.

Microwave studies of tri-methylamine have shown that the molecular skeleton adopts a C_{3v} equilibrium configuration in the vapour phase with one CH bond of each methyl group *trans* to the nitrogen lone pair (13). Using this model for tri-ethylamine, Kumar (4) obtained vibrational evidence for the existence of at least two rotational isomers differing in their relative proportions between the solid, liquid, and vapour phases. Green (5) has also concluded, from vibrational spectra, that at least three forms of tri-ethylphosphine are present in the liquid. Conformational studies of other tri-alkylamines, namely NMe_2Et and $NMeEt_2$ (6, 7), were carried out by vibrational spectroscopy using the tri-methylamine model with success. In principle, there are two vibrationally distinguishable conformations of NMe_2Et (7), six of $NMeEt_2$ (6), and seven of NEt_3 (4). Conformational analysis becomes more complex with increasing number of CH_2 units. For instance, to distinguish pentane conformers, it is necessary to include six one-to-four and thirteen one-to-five different non-bonded interactions (14).

The main purpose of the present study is to interpret Raman spectra and thermodynamic information on molecular conformations of tri-*n*-butylamine (Bu_3N) in the liquid phase. Due to the existence of three butyl chains in this compound, the number of possible different conformers in equilibrium is very large, and can be determined only by systematic building of molecular models. In this work, all the vibrationally distinguishable conformations were constructed, and the average number of *gauche* interactions of each type, at various temperatures, calculated by statistical thermodynamic methods (15–17). Significant changes observed in the Raman spectra of the liquid at different temperatures and in different solvents are reported and their correlations with the average number of *gauche* interactions of each type is considered.

2. Experimental

All the compounds used in this study were of purum grade. Even so, the samples were dried and distilled by repeated fractional distillation as previously described (18), before recording the spectra and taking density measurements. Partial molal volumes were obtained from the densities of solutions. These were determined at 25 ± 0.001°C with a digital density meter Anton Parr 02D. For C_6H_6, the density was obtained with a precision of $\pm 2 \times 10^{-6}$ g cm^{-3}.

Raman spectra were recorded on a Cary 82 spectrometer using an Ar^+ Spectra Physics laser (model 164-05) whose output at 514.5 nm was adjusted to provide 200–250 mW at the sample position.

We used the photon counting mode with sensitivities adjusted in the 10^3 to 10^5 counts s^{-1} range to provide reasonable signal-to-noise ratios. The spectrometer operated with spectral slitwidths (w) of 4 cm. The pen period (τ) was set at 2.0 s and the scanning speed of the monochromator (v/cm^{-1} s^{-1}) adjusted so that $v \leq w/(4\tau)$.

Temperature variation was carried out with a continuous flow cryostat (Oxford Instruments, model CF 100) operating with liquid nitrogen. Samples were contained in 0.5 cm^3 cylindrical cells and temperature values recorded on a temperature controller.

3. Results and discussion

Conformational analysis of a compound such as Bu_3N is of great importance for the structural interpretation of its thermodynamic properties. A good example of this type of investigation was carried out by Mann and co-workers (15, 16), who related macroscopic properties, molal volumes, refractive index, and heat of combustion, with a structural parameter representing the average number of *gauche* interactions of a series of straight and branched chain alkanes. Later, Edward and co-workers (19) applied and extended these ideas to partial molal volumes.

(i) Statistical analysis of gauche *interactions in Et_3N, Pr_3N, and Bu_3N*

The evaluation of the average number of *gauche* interactions of a specific type requires the determination of all possible molecular conformations. As the number of possible conformations increases rapidly with chain length, a genealogical building of molecular models is required. Starting with three stable and spectroscopically distinguishable molecular conformations of Et_3N suggested by Kumar (4), Table 1 presents a "genealogic tree" of all possible molecular conformations, from Et_3N to Bu_3N, after the sterically hindered conformations were excluded with the help of molecular models. The statistical weight of a conformation, s, having a definite number of *gauche* interactions of a particular type, N_g, is represented by the product of statistical weights of "parent" and "son" molecules. The average numbers of *gauche* interactions, $\bar{N}_g$, can be calculated as described in ref. 15, after evaluating the mole fraction of each conformer, γ_i, using the following expression:

$$[1] \quad \gamma_i = s_i \exp(-\Delta H_i/RT)/\sum_i s_i \exp(-\Delta H_i/RT)$$

The temperature dependence of $\bar{N}_g$ is now easily evaluated as $\bar{N}_g$ is a sum of *gauche* interactions weighted by the temperature-dependent γ_i values. In particular, for Bu_3N, $\bar{N}_g$(CCNC) decreases with temperature from 3.3 at 298 K to its minimum value of 3, as ΔH(CCNC) = H(*gauche*-CCNC) − H(*trans*-CCNC) is positive (14). $\bar{N}_g$(CCCN) increases with decreasing temperature from 1.1 at 298 K to its limiting value of 3, as ΔH(CCCN) = H(*gauche*-CCCN) − H(*trans*-CCCN) is negative (14). Although the ΔH values for amines used in these calculations involve large uncertainties (14), both the above mentioned variations are consistent with the increasing influence, at lower temperatures, of the lone pair of electrons on the nitrogen atom, through the *trans* effect, with respect to the α-carbon hydrogen atoms, and the *gauche* effect, relative to the slightly polar C_α—C_β bond. Morever, $\bar{N}_g$(CCCC) decreases with temperature from 1.0 at 298 K to zero, at low temperatures, thus confirming the well-known stability of all-*trans* alkylic chains at low temperatures (20). $\bar{N}_g$(CCCN) is greater at room temperature for Pr_3N (1.4) than for Bu_3N (1.1).

In estimating the average number of *gauche* interactions in a few tri-*n*-alkylamines at 298 K, we have assumed that the $\bar{N}_g$(CCNC) and $\bar{N}_g$(CCCN) for all tertiary amines larger than tri-*n*-butylamine are equal to those of Bu_3N. For CCCC interactions $\bar{N}_g$ values were obtained by multiplying by 3 the values reported in ref. 19, for the corresponding *n*-alkanes, yielding the following results: Bu_3N, 1.0; Hex_3N, 2.9; Oct_3N, 4.6; Dec_3N, 6.4; and Dod_3N, 8.2. The value for Bu_3N has been obtained directly from the molecular models.

TABLE 1. "Genealogic tree" of most probable molecular conformations from Et_3N to Bu_3N showing the total number of *gauche* interactions, N_g, of each particular type (CCNC, CCCN, or CCCC) and the corresponding total statistical weights (s_i)

(ii) Relation between partial molal volume $\bar{V}^0$ and $\bar{N}_g$ values

A relationship between $\bar{V}^0$ and $\bar{N}_g$ was proposed by Edward and co-workers (19, 21)

$$[2] \quad \bar{V}^0 = V_c + \sum_i n_i I_i + \sum_k \delta(k)\bar{N}_g(k)$$

where V_c is the covolume (volume of the solvent molecule cavity required to accommodate a point kinetic particle of no intrinsic volume), I_i is the volume increment associated with group of type i, and n_i is the number of such groups. $\bar{N}_g(k)$ is the average number of *gauche* interactions of type k and $\delta(k)$ is the volume change associated with such an interaction.

The application of this equation to a series of compounds interacting weakly with the solvent was done with success by the same authors (21, 22). In the case of a series of tertiary amines in benzene the application of eq. [2] revealed that the volume increment associated with the amine group is not constant. The n–π specific interaction between the pair of electrons of this group and the delocalized electrons in benzene (18, 23, 24) seem to vary regularly along the series. Thus in order to evaluate this term more correctly we added to the van der Waals volume of the tertiary amine group a term proportional to its surface area fraction:

$$[3] \quad I_{:N\leq} = V_w + C(A_w/A_t)$$

V_w and A_w are the van der Waals volume and surface area (25) of the tertiary amine group, respectively, A_t is the total van der Waals surface area, and C is a constant.

In the present study, the constant C and the parameters δ(CCNC) and δ(CCCN) were obtained by a least-squares fitting of eq. [2] to the experimentally determined $\bar{V}^0$ values (18), for a few tertiary amines in benzene, using the previously determined $\bar{N}_g$ values. The CH_3 and CH_2 group contributions (I_{CH_3} = 27.40 cm^3 mol^{-1}; I_{CH_2} = 17.15 cm^3 mol^{-1}) were evaluated relating expression (2) with the linear equation $\bar{V}^0$ vs. n_C (number of carbon atoms) for the best set of experimental results of straight-clean hydrocarbons in benzene (18, 26).

The values of V_c and δ(CCCC) were taken from Edward and co-workers (26) (V_c = 11.4 cm^3 mol^{-1} and δ(CCCC) = −1.1 cm^3 mol^{-1}), although these solvent-dependent parameters were not obtained from an extensive study in benzene (26).

The $\bar{V}^0$ values for the tri-*n*-alkylamines in benzene studied at 298 K were then calculated and showed excellent agreement with experimental results (Table 2).

TABLE 2. Calculated and experimental partial molal volumes (V^0/cm^3 mol^{-1}) for a few tri-*n*-alkylamines in benzene, at 298 K

Molecule	V^0_{exp}	V^0_{calc}	$V^0_{calc} - V^0_{exp}$

(iii) Spectral studies of temperature variation and solvents effects

Figure 1 shows the Raman spectrum of liquid tri-*n*-butylamine at room temperature. It is expected that some of the observed Raman bands arise from modes originating in specific conformations, whereas others result from contributions of more than one conformation.

Table 3 shows the observed Raman frequencies and their approximate descriptions based on available vibrational assignments for similar molecules.

The 650–1300 cm^{-1} region

Most of the band in this region cannot be ascribed to individual vibrational modes with a reasonable level of confidence. In fact, these vibrational modes are highly mixed, as can be inferred from previous vibrational calculations (11).

The 950–1200 cm^{-1} region contains important frequencies involving the C—C and the C—N stretching vibrations. These vibrations are expected to have very similar frequencies with appreciable coupling between C—C and C—N neighbouring oscillators. Little systematic work has yet been done to identify the bands due to these vibrational modes. However, considering the existing data, the bands at 1172 and 1185 cm^{-1} should arise mainly from C—N stretching while the bands in the 950–1128 cm^{-1} frequency region are expected to be essentially due to C—C stretching vibrations. Both C—C and C—N

vibrational motions should mix appreciably with methylene, methyl, and skeletal deformations.

Figure 2 shows the Raman spectra of tri-*n*-butylamine in the 700–1000 cm^{-1} region, at different temperatures. Temperature-dependent intensities of pairs of bands occurring at 880 and 860 cm^{-1} and at 880 and 904 cm^{-1} suggest that these bands pertain to different conformers and yield the same ΔH 2.0 kJ mol^{-1}.

As the temperature decreases, the intensity of the band at 904 cm^{-1} increases at the expense of the band at 880 cm^{-1}. At 100 K, the latter is still recognized among various neighbouring bands. However, it is clear that the band at 904 cm^{-1} dominates the bands at 880 and 860 cm^{-1} and so should probably be ascribed to the low temperature form.

In solution, the simultaneous equilibria between conformers are dependent on environmental polarity. Other things being equal, the ratio of more-polar to less-polar conformers should increase with solvent polarity. In order to assess this effect, we have determined the intensity ratios $I(880)/I(904)$ and $I(880)/I(860)$ in 1:1 solutions of tri-*n*-butylamine in various solvents (carbon tetrachloride, carbon disulphide, benzene, and chloroform). The solvent polarities were measured on the E_T scale which uses the "solvatochromic band" shifts of 4-(2,4,6-triphenylpyridinium)-2,6 diphenylphenoxide or its trimethyl derivative to probe solvent polarities (27) (E_T/kJ mol^{-1}: CCl_4 = 136.0; CS_2 = 136.4; C_6H_6 = 144.3; $CHCl_3$ = 163.6). As the medium becomes more polar, the band at 904 cm^{-1} dominates relative to the band at 860 cm^{-1}. This suggests that the conformer whose band occurs at 904 cm^{-1} is favoured by polar solvents, whereas the conformer represented by the 860 cm^{-1} band is favoured by non-polar solvents.

The 1300–1700 cm^{-1} region

The assignment of some of the observed bands in this region, where most of the CH_2 deformations occur, is fairly well

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

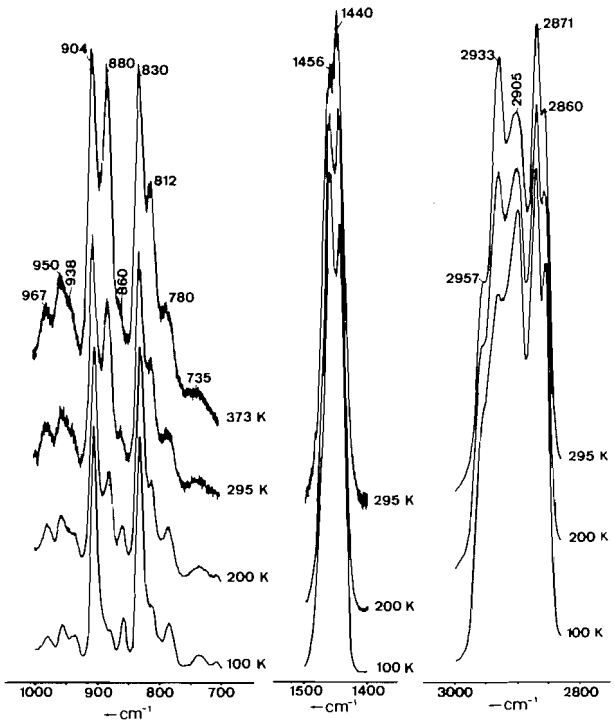

FIG. 2. The Raman spectra of tri-*n*-butylamine, at different temperatures in the liquid state.

established for hydrocarbons (28). The CH_2 scissoring vibrations occur near 1463 cm^{-1} in alkanes and are independent of the number or sequence of methylenes (29). These vibrational modes are sometimes shifted by the CH_2 wagging modes, which occur also in this region and are quite sensitive to the environment, namely, to the number of methylene sequences and to *trans* or *gauche* arrangements. The same kind of sensitivity is also known to occur for CH_2 twisting and rocking modes (29). The methyl symmetric deformation in alkanes occurs around 1350–1400 cm^{-1}.

Taking this evidence on hydrocarbons as a basis for the present assignments, the band at 1300 cm^{-1} is ascribed to the CH_2 wagging mode and the band at 1380 cm^{-1} to the symmetric deformation of the methyl groups. Bands at 1456 and 1440 cm^{-1} are associated with CH_3 and CH_2 scissoring deformations and are temperature dependent, as we shall see. On the other hand, bands at 1690 and 1645 cm^{-1} may be interpreted as combination bands involving C—C stretching modes.

Figure 2 shows also Raman spectra in the 1400 to 1500 cm^{-1} region, at different temperatures. At low temperatures, the dominating peak occurs at 1456 cm^{-1}. At about 200 K both peaks are of equal height. At higher temperatures the prominent intensity maximum occurs at 1440 cm^{-1}.

It is a striking spectral feature that the CH_2 scissoring modes have a well-defined structure which has been reported for a series of *n*-paraffins, namely for liquid *n*-paraffins longer than *n*-pentane as well as for non-crystalline solid and molten polyethylene (30). It has been previously suggested that the band at 1440 cm^{-1} should be considered as an overtone of the methylene rocking fundamental, which occurs at 720 cm^{-1} in polyethylene (31). However, the increase in the intensity of the 1440 cm^{-1} band with temperature does not conform with the expected behaviour for an overtone band. Also, the possible involvement of *gauche* methylene wagging modes should be ruled out as the 1440 cm^{-1} band would then be much weaker than the methylene wagging at 1300 cm^{-1}, which is not the case. On the other hand, the assignment of the 1440 cm^{-1} band to the scissoring vibrations of methylene groups adjoining two central bonds of *gauche* arrangements is consistent with known experimental facts (30). Namely, the temperature dependence of the band suggests that it should be associated with conformations having a higher energy than a planar chain.

Comparing the 1400–1500 cm^{-1} region in various tertiary amines, we note that the corresponding pairs of bands occur at about 1454 and 1476 cm^{-1}, for liquid tri-*n*-ethylamine, at 1448 and 1468 cm^{-1}, for liquid tri-*n*-propylamine, and at 1440 and 1456 cm^{-1}, for liquid tri-*n*-butylamine and longer alkylic chain amines. At room temperature, the higher frequency component of these pairs of bands is less intense. With increasing number of CH_2 units the high frequency component becomes more pronounced and the frequency shift of these pairs of bands reveals a small change in the force constant associated with the scissoring vibrations. On this basis, the higher frequency component of these pairs of bands should have a contribution of the scissoring mode of a methylene group adjoining a *trans* bond and a *gauche* bond, whereas, in the lower frequency component, the CH_2 oscillator should adjoin two *gauche* bonds (30). As the temperature increases, the alkylic chains become more and more fluid with an increasing number of *gauche* arrangements. Therefore, there will be an increase in the amount of CH_2 groups adjoining two *gauche* bonds and a decrease in the amount of CH_2 groups adjoining a *trans* and a *gauche* bond. This explains the relative intensity changes with increasing temperature of the 1456 and 1440 cm^{-1} bands.

The 2600–3000 cm^{-1} region

The carbon–hydrogen stretching modes of tri-*n*-butylamine can be readily assigned on the basis of group frequencies for similar molecules (6, 7, 32). The symmetric and antisymmetric stretching modes of CH_2 can be assigned to Raman lines at 2860 and 2905 cm^{-1}, respectively. The 2957 and 2871 cm^{-1} bands are assigned to CH_3 stretching vibrations, the latter frequency being ascribed to the symmetric motion. The band at 2933 cm^{-1} is essentially explained in terms of a Fermi resonance interaction between the symmetric methylene C—H stretching fundamental and binary combinations of the methylene bending vibrations of the extended chain (32).

The additional bands in this spectral region, below 2800 cm^{-1}, are believed to be due to overtones or combinations of the C—H deformations. Their intensities are largely accounted for in terms of Fermi resonance interactions with the carbon–hydrogen stretching motions.

As temperature increases, the intensity of the band at 2933 cm^{-1} increases and the intensity of the band at about 2905 cm^{-1} decreases. At about 200 K they display equal peak heights (Fig. 2). These intensity changes are consistent with a progressive elimination of extensive *trans* structure and a greater fluidity of the hydrocarbon chains. Hence, by increasing the temperature, the number of conformations increases for which the opportunity for Fermi resonance exists. Therefore, the 2933 cm^{-1} band intensity increases. On the other hand, it is known that the intensity of the CH_2 antisymmetric stretching mode is reduced when lateral interactions between hydrocarbon chains are disrupted, namely, by formation of *gauche* rotamers (32). In tri-*n*-alkylamines, lateral interactions are expected to be important, especially at low temperatures, due to antiparallel molecular alignment (33). The increase of temperature reduces these interactions drastically.

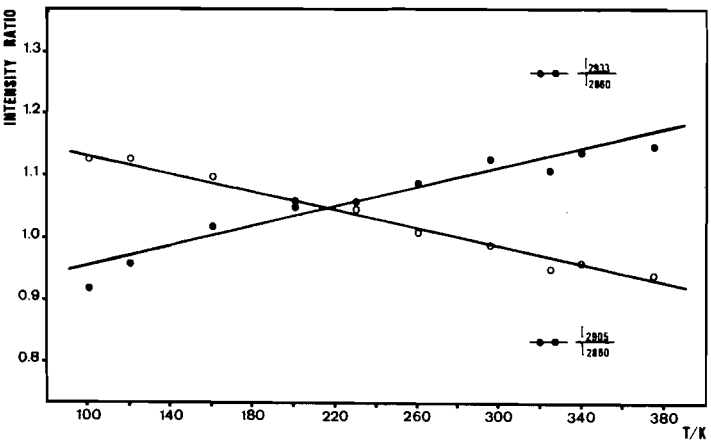

FIG. 3. Ratio of intensities vs. temperature, for pairs of Raman bands in the CH stretching region of tri-*n*-butylamine.

We have recorded Raman spectra of tri-*n*-butylamine at ten different temperatures between 100 and 373 K. At the expected solidification temperature (179 K), the crystalline solid was not obtained: the spectral lines were neither sharp nor did they show any crystal field splittings. Tri-*n*-butylamine just formed a glassy solid.

It is well known that the peak heights ratio of the methylene antisymmetric and symmetric vibrations, i.e., the ratio $I(2905)/I(2860)$, can be used to estimate the degree of order of the chains, giving intermediate values to those of the liquid and of the crystalline states after micellization (34, 35). On the other hand, the intensity ratio $I(2933)/I(2860)$ can be used as an environmental polarity parameter correlated with the polar character of the chains (34, 35).

Figure 3 shows the variation of these two parameters with temperature, for liquid tri-*n*-butylamine. As the temperature increases, the hydrocarbon chains become more disordered, as expected, with an increase in mobility of the methyl and methylene groups. At the same time, there is an increase in environmental polarity of the chains which, in turn, corresponds to a decrease in direct chain-to-chain contact. While these temperature-dependent features are expected, they nevertheless support the interpretation advanced for the relative intensity changes in the bands at 2933 vs. 2905 and 1456 vs. 1440 cm^{-1}.

When the order and polarity parameters were plotted against temperature a smooth "transition" was found below the expected solidification temperature (179 K). This is shown in Fig. 3.

4. Conclusion

Raman spectra of amines exhibit a number of features whose temperature-dependent intensities clearly sugest the occurrence of different conformers in simultaneous equilibria. These spectra provide useful vibrational information to monitor conformational changes.

In the case of tri-*n*-butylamine, where experimental data were available, the Raman spectra at different temperatures were interpreted and correlated with structural information obtained from statistical analysis of *gauche* skeletal arrangements. The average numbers of *gauche* interactions are correlated with temperature-dependent intensities of Raman bands and with the increasing influence, at lower temperatures, of the lone pair of electrons on the nitrogen atom, through the *trans* effect with respect to the α-carbon hydrogen atoms, and the *gauche* effect relative to the slightly polar $C_\alpha—C_\beta$ bond. The bands at 904 and 1456 cm^{-1} were ascribed to the low temperature form as these bands dominate at low temperatures. On the other hand, the conformer whose band occurs at 904 cm^{-1} was also favoured by polar solvents.

The introduction of the $\sum_k \delta(k)\bar{N}_g(k)$ as an additive term in eq. [2] and the correct evaluation of the volume increment associated with the amine group (eq. [3]) lead to an excellent agreement between calculated and experimental $\bar{V}^o$ values.

Temperature dependence of the relative intensities of bands in the CH stretching region suggest, by comparison with mono- (11) and di-*n*-butylamine (12), that the increase in the number of alkyl chains around the nitrogen atom makes molecular packing less restrictive and unique, giving rise to mesophases, as the overall shapes of the molecules become more spherical.

Reçu le 7 juillet 1986

GUY J. COLLIN, HÉLÈNE DESLAURIERS et GEORGE R. DE MARÉ. Can. J. Chem. **65**, 391 (1987).

On a utilisé la photochimie directe à 147 nm pour générer les radicaux vinyliques C_4H_7, méthyl-1- et méthyl-2-propène-1 yles, ainsi que le radical C_5H_9, diméthyl-1,2-propène-1 yle, à partir des tri- et tétraméthyléthylènes. Dans les deux cas, la fragmentation primaire d'une liaison α(C—C) est suffisamment importante. L'excédent énergie du photon est suffisamment important pour que ces radicaux vinyliques C_4H_7 et C_5H_9 soient vibrationnellement très chauds pour pouvoir s'isomériser vers des structures allyliques avant de se fragmenter. On montre qu'à des pressions de l'ordre de quelques Torr, la majorité des radicaux vinyliques C_4H_7 (≅70%) ont atteint une structure allylique avant fragmentation et que leur temps de vie, evalué dans les présentes conditions, est inférieur à la nanoseconde. La situation est moins claire bien que très similaire dans le cas du radical vinylique C_5H_9.

GUY J. COLLIN, HÉLÈNE DESLAURIERS, and GEORGE R. DE MARÉ. Can. J. Chem. **65**, 391 (1987).

Direct photolysis at 147 nm of tri- and tetramethylethylenes has been used to produce highly excited vinylic 1-methyl- and 2-methyl-1-propene-1-yl radicals (C_4H_7), as well as the 1,2-dimethyl-1-propen-1-yl radical (C_5H_9). In both cases, the primary fragmentation of the photoexcited molecules involved the split of an α(C—C) bond with high yields. The excess energy is sufficiently important that the majority of the vinylic radicals are very hot, and are able to isomerize towards an allylic structure before the occurrence of fragmentation. At a pressure of a few Torr, most of the vinylic C_4H_7 radicals (ca. 70%) isomerize to an allylic structure, and its lifetime is estimated to be less than one nanosecond under the present conditions. Although the mechanism is less simple, the excited vinylic C_5H_9 radical exhibits similar behaviour.

Introduction

Dans les trois précédentes publications de cette série, nous avons observé l'interconversion, l'isomérisation mutuelle de radicaux allyles diversement substitués par des groupes méthyles (1). Dans ces systèmes, des radicaux allyliques vibrationnellement excités ont la possibilité de transférer un atome d'hydrogène entre les positions 1 et 4 via un intermédiaire à cinq côtés. Nous n'avons pas pu observer l'isomérisation de ces radicaux allyles vers des structures vinyliques. Par contre, dans un travail un peu plus ancien, lors de la photolyse du triméthyléthylène (3ME), nous avions proposé que les deux radicaux C_4H_7, nommément les radicaux méthyl-1- et méthyl-2-propène-1 yles, doivent s'isomériser au moins partiellement vers les formes allyliques pour rendre compte de la formation de certains produits (2, 3)

Le présent rapport constitue une étude systématique de l'effet de pression dans les photolyses des tri- et tétraméthyléthylènes (3ME et 4ME) à 147,0 nm afin de mesurer l'importance de ces isomérisations : processus [4] et [8], ainsi que celle impliquant le radical diméthyl-1,2-propène-1 yle.

Méthode expérimentale

Matériaux

Les 3ME et 4ME sont des produits A.P.I. contenant respectivement 0,06 ± 0,04% et 0,03 ± 0,02% d'impuretés. L'analyse chromatographique de l'échantillon de 3ME montre la présence de méthyl-2-butène-1 : 160 ppm, d'isoprène : 93 ppm, de pentène-2 (*cis* + *trans*) : 230 ppm. Quant à l'échantillon de 4ME, il ne contient que des traces de propane : 45 ppm. L'hexafluorure de soufre provient de chez

Matheson Gas Products Canada (C.P. 99,8% min) et l'oxygène (99,995%) est acheté chez Liquid Carbonic Canada. Ces deux produits ne laissent pas voir de traces d'impuretés sur les chromatographies.

Photolyses, actinométrie, analyses

Toutes ces informations ont été récemment précisées dans la littérature (1).

Résultats

Cas du 3ME

La photolyse du 3ME à 147 nm et en présence de 10% d'oxygène moléculaire montre la formation de divers hydrocarbures. Ce sont l'isoprène, le butyne-2, les butadiène-1,3 et -1,2, le propyne et l'allène. Les rendements quantiques de ces produits décroissent avec l'ajout de quantités croissantes d'hexafluorure de soufre (figures 1 et 2). Lorsque la photolyse est réalisée en l'absence d'oxygène, d'autres produits apparaissent. Ce sont principalement l'éthane, le méthyl-2-butène-1, le méthyl-3-butène-1, l'isopentane et le diméthyl-2,2-butane (tableau 1). La formation de ces produits ainsi que celle d'autres aux rendements plus faibles a déjà été expliquée ailleurs (7).

Cas du 4ME

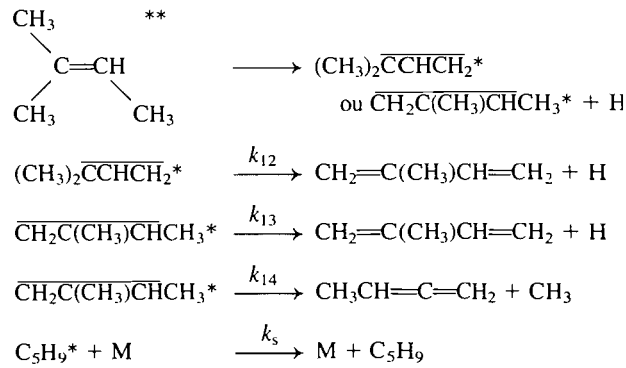
La photolyse du 4ME à 147 nm et en présence de 10% d'oxygène moléculaire montre la formation de diméthyl-2,3-butadiène-1,3, de méthyl-3-butadiène-1,2, de butyne-2, d'isoprène, de butadiène-1,2, de diméthyl-2,3-butène-1 et de propène avec des rendements quantiques qui décroissent avec l'augmentation de pression de l'hexafluorure de soufre (voir plus loin les figures 4 et 5).

En l'absence d'oxygène, ou d'oxyde nitrique, on observe à nouveau une formation importante d'éthane, de diméthyl-2,3- et de triméthyl-2,2,3-butane ainsi que d'un peu de divers isomères en C_6H_{12} de même qu'une formation appréciable de diméthyl-2,3-butène-1 (tableau 2).

Discussion

La photolyse du triméthyléthylène (3ME)

La photostabilité du 3ME sous rayonnement uv n'est pas inconnue. Plusieurs études partielles ont montré la complexité des mécanismes de formation des produits (2, 3, 7, 8). En plus de la double liaison, la molécule contient une liaison C—H située en position α par rapport à cette double liaison -α(C—H)-, trois liaisons α(C—C) et neuf liaisons β(C—H). Avec ce type de molécules ne disposant pas de liaisons β(C—C), la photofragmentation implique soit l'une ou l'autre des deux liaisons α(C—C) et β(C—H) avec une probabilité similaire (9). Compte tenu de l'énergie du photon à 147 nm (E = 811 kJ Einstein^{-1}), le mécanisme retenu implique les réactions [1]–[10] relatives à la scission primaire de l'une des trois liaisons α(C—C). La rupture primaire d'une liaison β(C—H) implique les réactions suivantes



où k_{12}, k_{13} et k_{14} sont les constantes de vitesse des réactions monomoléculaires de fragmentation des radicaux activés, et k_s est la constante de vitesse de stabilisation par collision des radicaux allyles C_5H_9. Quant aux réactions engendrées par la rupture primaire de la liaison α(C—H), elle sera discutée plus en détail dans le cas de la photolyse du tétraméthyléthylène. Notons seulement que le butyne-2 sera le résultat de cette rupture α(C—H). Les réactions [1]–[15] rendent compte de la formation du propyne, de l'allène, des butadiène-1,3 et -1,2 et

de l'isoprène. Compte tenu des stabilisations éventuelles par collision des intermédiaires M*, le rendement quantique de chacun de ces produits est susceptible d'un comportement de type Stern–Volmer (10, 11) : l'inverse du rendement quantique du produit X est une fonction linéaire croissante de la pression.

$$[16] \quad [\Phi(X)]^{-1} = [\Phi_0(X)]^{-1}(1 + k_s[M]/k_d)$$

où $\Phi(X)$ et $\Phi_0(X)$ sont respectivement les rendements quantiques du produit X mesuré à une pression M et extrapollé à pression nulle, k_s et k_d sont les constantes de vitesse de stabilisation (ordre deux) et de dissociation (ordre un) des intermédiaires radicalaires chauds.

La figure 1 montre l'excellente linéarité obtenue dans le cas de trois produits. La figure 2 par contre indique clairement une courbure plus ou moins négative dans le cas des rendements en propyne, butyne-2 et butadiène-1,2. Il existe plusieurs explications à ces courbures (10–12). Parmi ces explications, il y a le fait les radicaux primaires ne sont pas activés de façon monoénergétique. Les deux fragments primaires issus des réactions [2], [6] et [11] emportent chacun une part de l'énergie excédentaire. Dans le cas des fragments qui ont pour complément l'atome d'hydrogène (réaction [11]), on peut penser qu'ils ont une distribution de population en énergie plus étroite que si ce complément est le radical méthyle (réactions [2] et [6]). La courbure sera ainsi moins prononcée dans les cas de l'isoprène et du butadiène-1,2 comparativement aux cas du propyne et de l'allène. Une deuxième raison réside dans le fait que deux intermédiaires différents peuvent être à l'origine d'un même produit, mais avec des constantes de vitesse différente (cas du propyne : réactions [3] et [7]). Enfin, un produit peut être le résultat de la chimie de deux intermédiaires ou plus intervenant successivement. Par exemple, réactions [6]–[9], l'allène est le résultat de l'isomérisation du radical méthyl-2-propène-1 yle et de la fragmentation du radical β-méthallyle. Toutes ces raisons peuvent s'additionner ou se soustraire, de telle sorte que les apparentes linéarités ou courbures ne permettent pas de pousser plus avant la discussion.

On peut cependant mesurer l'importance de l'isomérisation des radicaux méthyl-1- et -2-propène-1 yles vers les structures allyliques. En effet à pression nulle, le propyne est le résultat

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

de la fragmentation directe de ces radicaux chauds alors que les formations d'allène et de butadiène-1,3 réclament d'abord leur isomérisation vers les formes allyliques. Si γ représente le pourcentage des radicaux vinyles isomérisés vers les formes allyliques, alors

$$[17] \quad \gamma = \frac{\Phi(\text{allène}) + \Phi(\text{butadiène-1,3})}{\Phi(\text{propyne}) + \Phi(\text{allène}) + \Phi(\text{butadiène-1,3})}$$

Cette valeur mesurée à 5 Torr de monomère est de 0,53 (colonne 1, tableau 1).

Cette relation fait cependant la supposition qu'à cette pression tous les radicaux méthyl-1- et méthyl-2-propène-1 yles d'une part et également tous les radicaux α- et β-méthallyles se fragmentent. Cela est loin d'être sûr. En effet en absence d'oxygène (tableau 1), il y a formation de quantités importantes de méthyl-2-butène-1 ($\Phi \cong 0{,}18$) via la combinaison des radicaux méthyles et β-méthyllyles et de traces de méthyl-3-butène-1 et de pentène-2 ($\Phi \cong 0{,}01$) par combinaison des radicaux méthyles et α-méthallyles. Cette observation requiert que tous les radicaux β-méthallyles ne se fragmentent pas à pression nulle, et si l'on peut admettre comme approximation que tous les radicaux α-méthallyles se décomposent à cette pression, c'est loin d'être le cas pour les radicaux β-méthallyles. Ce comportement différent des radicaux α-méthallyles se comprend aisément si l'on se souvient que dans le cas présent ils proviennent de l'isomérisation partielle des radicaux chauds méthyl-1-propène-1 yles. Il apparaît que les radicaux qui ont franchi la barrière de potentiel relative au processus [4] ont l'énergie suffisante pour se fragmenter en butadiène + H. Ce n'est pas le cas des radicaux β-méthallyles. En effet, seulement une fraction de ces radicaux issus de l'isomérisation des radicaux méthyl-2-propène-1 yles, processus [8], ont l'énergie suffisante pour donner lieu à la formation de l'allène et de radicaux méthyles. L'étude des diagrammes d'énergie potentielle est convaincante : voir figures 3 et 4 de la réf. 13. De ces considérations, il ressort que l'expression [17′] doit remplacer la précédente :

$$[17'] \quad \gamma_{corr} \cong \frac{\Phi(\text{allène}) + \Phi(\text{butadiène-1,3}) + \Phi(C_5H_{10})}{\Phi(\text{propyne}) + \Phi(\text{allène}) + \Phi(\text{butadiène-1,3}) + \Phi(C_5H_{10})}$$

Cette valeur γ_{corr} est de 0,70 sous une pression de 5 Torr (tableau 1). On peut donc conclure que les processus d'isomérisation des radicaux vinyliques vers les structures allyliques sont très importants.

La reformation du monomère par la combinaison des radicaux méthyles avec les radicaux méthylpropène-1 yles empêche l'évaluation directe de leur stabilité. Par contre le bilan complet de la fragmentation de la molécule photoexcitée incite à penser qu'il n'y en a pas, ou peu de stabilisés dans les conditions expérimentales présentes. Naturellement, si certains radicaux vinyliques sont stabilisés et, par exemple, reforment le monomère par combinaison avec les radicaux méthyles, le rapport γ_{corr} tout juste établi devrait être revue à la baisse.

Cette importante isomérisation des radicaux vinyliques chauds vers les structures allyliques doit être mise en parallèle avec le fait que les réactions inverses, les isomérisations des radicaux allyles vers les structures vinyliques, n'ont jamais été invoquées pour expliquer les formations de produits dans les photolyses de plusieurs alcènes (voir par exemple la réf. 14). La présence d'une énergie de résonance allylique de quelque 50 kJ mol^{-1} dans les radicaux allyles (5) augmente d'autant la barrière de

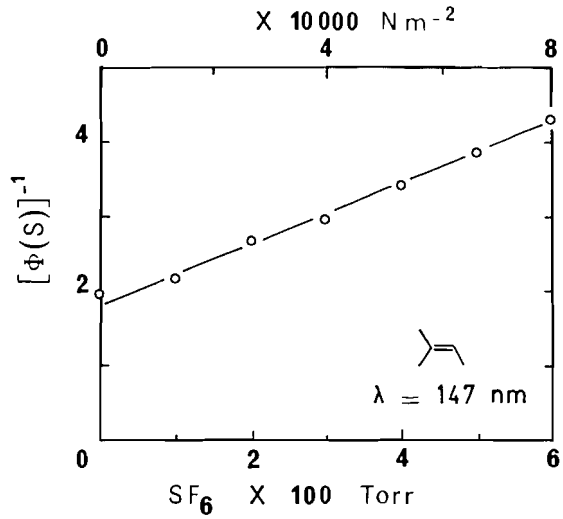

FIG. 3. Voir fig. 1; $S = \Phi(\text{propyne}) + \Phi(\text{allène}) + \Phi(\text{butadiène-1,3}) + \Phi(\text{méthyl-3-butène-1}) + \Phi(\text{méthyl-2-butène-1})$ ($r^2 = 0{,}99$; $\Phi_0 = 0{,}56$; interception axe de la pression : −420 Torr).

potentiel et que, si équilibre il y a, au facteur pré-exponentiel près, l'équilibre est nettement déplacé vers la formation des radicaux allyles (13). La variation de la valeur γ_{corr} qui semble diminuer avec l'augmentation de pression (tableau 1) est de peu d'intérêt puisque à haute pression, il y a aussi stabilisation par collision des radicaux vinyles.

Il est par contre intéresssant de noter que si l'on confond les radicaux méthyl-1- et méthyl-2-propène-1 yles, et que l'on regarde le comportement Stern–Volmer de la somme

$$[18] \quad S = \Phi(\text{propyne}) + \Phi(\text{butadiène-1,3}) + \Phi(\text{méthyl-2-butène-1}) + \Phi(\text{méthyl-3-butène-1}) + \Phi(\text{allène})$$

on obtient une linéarité presqu'exemplaire (fig. 3). Aux remarques précédentes déjà faites sur ces linéarités, on en déduit que le rapport $k_M/(k_{isom} + k_{diss})$ des radicaux vinyles C_4H_7 est voisin de 450 Torr, ou encore en traduisant en terme de fréquence de collision, le temps de vie «moyen» de ces radicaux est de l'ordre de $0{,}3–0{,}4 \times 10^{-9}$ s. Cette donnée, bien que très spéculative compte tenu des approximations faites et de la méthodologie utilisée, est quand même intéressante. En effet, on peut penser les molécules photoexcitées, M**, sont elles-mêmes susceptibles de stabilisation par collision. En supposant que toute l'énergie du photon incident réside dans le tissu vibrationnel de la molécule, nous avons déjà montré qu'en utilisant des calculs RRKM (Rice–Ramsperger–Kassel–Marcus) appropriés, le temps de la molécule pentène-1 photoexcitée à 147 nm correspond à une pression de stabilisation de 130 atm (1 atm = 101.3 kPa). Ce résultat tient compte d'un transfert d'énergie de 21 kJ mol^{-1} (5 kcal mol^{-1}) à chaque collision et une énergie de la liaison β(C—C) de 301 kJ mol^{-1} (15). Compte tenu des énergies plus rigides des liaisons individuelles du 3ME, un temps de vie «RRKM» beaucoup plus long doit être retenu pour le 3ME. Des calculs similaires ont montré que la pression de stabilisation est plutôt de l'ordre de 7 atm.[2] Il s'ensuit que l'on peut raisonnablement ignorer la réaction de stabilisation par collision du 3ME photoexcité à 147 nm.

Finalement, il est pertinent d'estimer l'importance de chacun des processus primaires de fragmentation sous faible pression (tableau 3). Bien qu'un peu d'isoprène soit aussi formé suite à la

TABLEAU 3. Photofragmentation du triméthyléthylène à 147 nm

Processus primaire	Produits	Φ^a	Note
β(C—H)	Isoprène	0,32	fig. 1
	Butadiène-1,2	0,05	fig. 2
α(C—C)	Propyne Butadiène-1,3 Allène (C_5H_{10})	0,56[b]	fig. 3
α(C—H)	Butyne-2	0,08	fig. 2
	Isoprène[b]	(0,07)	
	Total	1,08	

[a]Valeurs obtenues par extrapolation des rendements à pression nulle de SF_6, donc sous une pression de TME de 5 Torr (665 N m^{-2}).
[b]Voir texte.

rupture primaire α(C—H) (voir plus loin) il est évidemment impossible ici de distinguer cette formation de celle consécutive à la rupture primaire β(C—C). On peut raisonnablement estimer que cette formation résiduaire d'isoprène est au plus similaire à celle du butyne-2 (voir plus loin). Le total des processus de fragmentation est légèrement supérieur à l'unité. Ce dépassement traduit en partie l'incertitude expérimentale ainsi que certaines subtilités de mécanismes non-discutées ici.

La photolyse du tétraméthyléthylène (4ME)

La photofragmentation du 4ME à 147 nm est relativement plus simple. Étant donné la structure symétrique de la molécule, et en l'absence d'une isomérisation de la molécule photo-excitée, celle-ci ne dispose que de deux types de liaisons disponibles pour la fragmentation. Ce sont les 12 liaisons C—H situées en position β par rapport à la double liaison -β(C—H)- et quatre liaisons α(C—C). Avec ce type de molécules ne disposant pas de liaisons β(C—C), la photofragmentation implique soit l'une ou l'autre des deux liaisons α(C—C) et β(C—H) avec une probabilité similaire (9). Compte tenu de l'énergie du photon à 147 nm ($E \cong 811$ kJ Einstein^{-1}), le mécanisme retenu est le suivant :

[19] $(CH_3)_2C{=}C(CH_3)_2 + h\nu \rightarrow (CH_3)_2C{=}C(CH_3)_2{}^{**}$

[20] $(CH_3)_2C{=}C(CH_3)_2{}^{**} \rightarrow (CH_3)_2\overline{CC(CH_3)CH_2}{}^{*} + H$
$\Delta H \cong 326$ kJ mol^{-1} (4)

[21] $(CH_3)_2\overline{CC(CH_3)CH_2}{}^{*} \rightarrow CH_2{=}C(CH_3)C(CH_3){=}CH_2 + H$
$\Delta H = 217$ kJ mol^{-1}

[22] $(CH_3)_2\overline{CC(CH_3)CH_2}{}^{*} \rightarrow (CH_3)_2C{=}C{=}CH_2 + CH_3$
$\Delta H = 222{,}5$ kJ mol^{-1}

[23] $C_6H_{11}{}^{*} + M \rightarrow M + C_6H_{11}$

[24] $(CH_3)_2C{=}C(CH_3)_2{}^{**} \rightarrow CH_3 + (CH_3)_2C{=}\dot{C}CH_3{}^{*}$

[25] $(CH_3)_2C{=}\dot{C}CH_3{}^{*} \rightarrow CH_3 + CH_3C{\equiv}CCH_3$

[26] $(CH_3)_2C{=}\dot{C}CH_3{}^{*} \rightarrow \overline{CH_2C(CH_3)CH}CH_3{}^{*}$

suivies des réactions [13]–[15]. Comme on le voit, ce mécanisme explique aisément la formation des produits observés dans la photolyse du 4ME. Il explique aussi la formation du butyne-2 dans celle du 3ME, et y ajoute de l'isoprène et du butadiène-1,2. Quantitativement, les rendements sont en accord avec le comportement de type Stern–Volmer avec les remarques déjà faites sur les courbures des droites Stern–Volmer (figures 4 et 5). En outre, dans le cas présent, il n'est pas sûr que l'on puisse ignorer la stabilisation par collision de la molécule photoexcitée. Cette dernière remarque est pertinente puisque même en présence d'oxygène moléculaire, on a toujours observé une formation de diméthyl-2,3-butène-1, un isomère

dont la formation a déjà été reportée dans la photolyse du 4ME à plus longues longueurs d'onde (16). Sans entrer dans le détail du mécanisme impliqué dans l'isomérisation, celle-ci peut bien entendu être le résultat de l'état électronique fondamental vibrationnellement chaud, mais aussi faire intervenir des états électroniques excités Rydberg (12). En l'absence de preuves suffisantes, il y a lieu seulement de ne pas écarter la possibilité de la stabilisation de la molécule fondamentale vibrationnellement très chaude.

Remerciements

Nous voulons remercier très vivement la Division des Affaires Scientifiques de l'OTAN (#85/0484) pour l'aide généreuse qu'elle a apportée à ce projet.

Electrochemical oxidation of squaric and croconic acids on Pt and Pt surfaces modified by underpotential heavy metal monolayers in acid solutions

D. SAZOU AND G. KOKKINIDIS

Aristotelian University of Thessaloniki, Department of Chemistry, Laboratory of Physical Chemistry, Thessaloniki 54006, Greece

Received June 16, 1986

D. SAZOU and G. KOKKINIDIS. Can. J. Chem. **65**, 397 (1987).

The electrochemical oxidation of squaric and croconic acids on platinum in aqueous perchloric acid solutions has been investigated by means of cyclic voltammetry, rotating disc electrode, potentiostatic transients and controlled-potential electrolysis. The kinetic parameters (Tafel slopes, reaction orders) have been determined on the foot of the wave by varying the sweep rate, the angular velocity, depolarizer concentration, and perchloric acid concentration. A probable mechanism has been proposed for the overall oxidation processes. It involves two charge-transfer steps followed by the desorption of product, which is the rate-determining step. The oxidation product is immediately deactivated by a rapid hydration reaction. Also, the effect of underpotential Tl, Pb, and Bi monolayers on the electrochemical behaviour of squaric and croconic acids has been examined.

D. SAZOU et G. KOKKINIDIS. Can. J. Chem. **65**, 397 (1987).

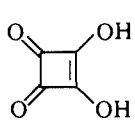
Faisant appel à la voltamétrie cyclique, à l'électrode à disque tournant, aux espèces transitoires potentiostatiques et à l'électrolyse à potentiel contrôlé, on a étudié l'oxydation électrochimique des acides squarique et croconique sur le platine, dans des solutions aqueuses d'acide perchlorique. On a déterminé les paramètres cinétiques (pentes de Tafel, ordres de réaction) au pied de la vague en faisant varier la vitesse de balayage, la vitesse angulaire, la concentration du dépolarisant et la concentration de l'acide perchlorique. On propose un mécanisme probable pour l'ensemble des processus d'oxydation. Il implique deux étapes de transfert de charge qui sont suivies par la désorbtion du produit, qui est l'étape déterminante de la réaction. Le produit d'oxydation est rapidement désactivé par une réaction rapide d'hydration. De plus, on a examiné l'effet des monocouches de Tl, Pb et Bi n'ayant pas le potentiel approprié sur le comportement électrochimique des acides squarique et croconique.

[Traduit par la revue]

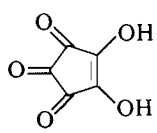
Introduction

Many studies have been carried out on the electrochemical oxidation of different enediol compounds like L-ascorbic, D-araboascorbic, dihydroxyfumaric and dialuric acids because of their biological importance (1–6). The oxidation studies of these enediols show a two-electron transfer followed by a pseudo-first order chemical reaction due to the carbonyl group hydration of the oxidation product.

However, the electrochemical oxidation of squaric acid (H_2SQ) and croconic acid (H_2CR) — which are also two enediols, members of a series of cyclic oxocarbon dibasic acids — has not been discussed so far. Polarographic studies were reported in the literature only for electrochemical reduction of croconic acid, as well as for the characterization of its reduction products (7–9).



(H_2SQ)



(H_2CR)

The aim of this work was first to give a detailed analysis of the kinetics of H_2SQ and H_2CR oxidation on platinum electrode in acid solutions.

On the other hand, in our previous paper (10) the influence of underpotential deposited (upd) layers of Tl. Pb, and Bi on the electrochemical behaviour of tetrahydroxy-1,4-benzoquinone and rhodizonic acid (also an enediol) on a Pt electrode has been studied in acid solutions. It was observed that the upd layers improve the reversibility of the redox system tetrahydroxy-1,4-benzoquinone/hexahydroxybenzene, as well as the oxidation of rhodizonic acid.

Thus the second purpose of this paper is to see if the electrochemical oxidation of H_2SQ and H_2CR is also catalysed by upd monolayers of certain heavy metal atoms.

The study was carried out in aqueous $HClO_4$ solutions using cyclic voltammetric and rotating disc techniques in combination with controlled-potential electrolysis and potential-step transients.

Experimental

The general experimental procedure, the activation of electrodes and the experimental set-up used have been described previously (11).

However, it must be mentioned that the roughness factor of the Pt electrodes was 1.15; this value was estimated by integration of the hydrogen adsorption–desorption current potential curves in 0.5 *M* $HClO_4$ solution, assuming that 210 $\mu C\ cm^{-2}$ of hydrogen is adsorbed on a perfectly smooth platinum electrode. The electrode potentials, E_H, given in various voltammograms and plots are referred to the normal hydrogen electrode. All the experiments were carried out at a constant temperature of 298 ± 0.1 K.

The supporting electrolyte was prepared from triply distilled water and $HClO_4$ 70% (Merck, "suprapure"). Squaric acid obtained from Fluka (Pract) was recrystallized twice from water (decomposition point, 293°C) (12). Potassium croconate was prepared according to the method of Nietzki–Benckiser (13) as reported in ref. 7. Perchlorate salts were prepared from the respective oxides or carbonates (Merck, "suprapure" or "p.a.") dissolved into the solution which contains stoichiometric quantity of $HClO_4$. Before starting any experiment, a sufficient amount of pure nitrogen was bubbled in the electrolyte solution to remove the dissolved oxygen, while during the measurements a nitrogen stream was passed above the solution.

Results

1. *Characteristics of the squaric and croconic acids oxidation on Pt electrode*

Cyclic voltammograms at different scan rates showing the oxidation of H_2SQ on Pt in 0.5 *M* $HClO_4$ are given in Fig. 1.

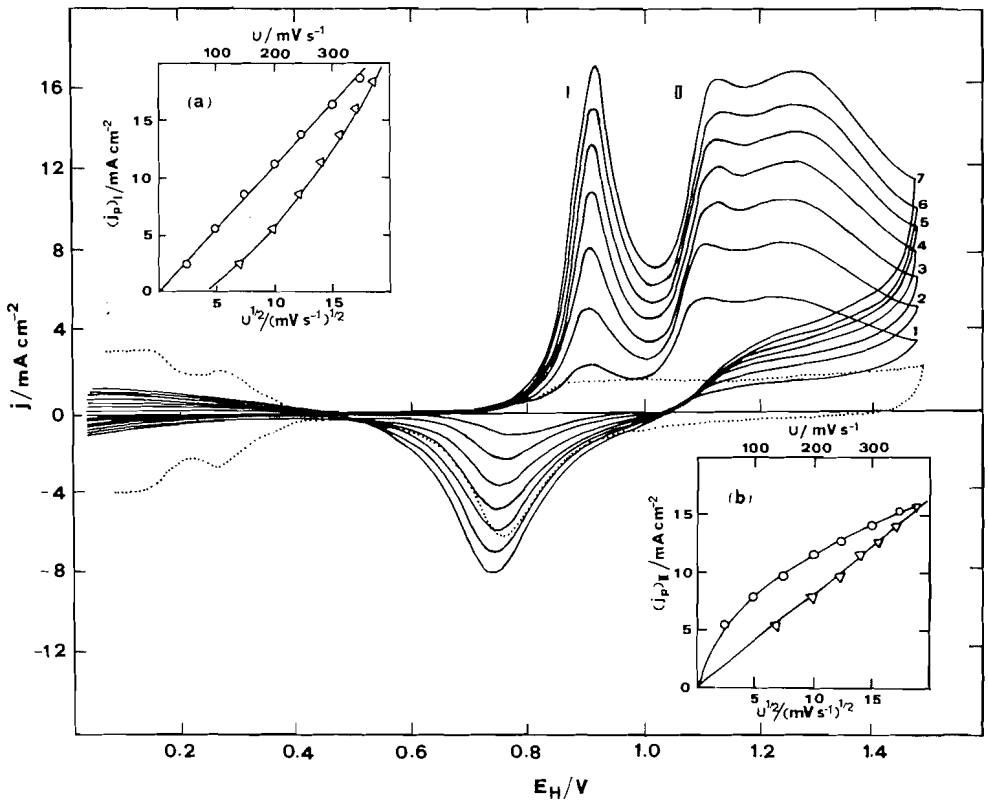

FIG. 1. Cyclic voltammograms of H_2SQ (10^{-3} *M*) on a Pt sheet in 0.5 *M* $HClO_4$ at different scan rates: (*1*) 50; (*2*) 100; (*3*) 150; (*4*) 200; (*5*) 250; (*6*) 300; (*7*) 350 mV s^{-1}. (·····) Voltammogram of the supporting electrolyte at υ = 100 mV s^{-1}. Insets: (*a*) plot of the first peak current vs. υ, (○) and $\upsilon^{1/2}$, (△); (*b*) plot of the second peak current vs. υ, (○) and $\upsilon^{1/2}$, (△).

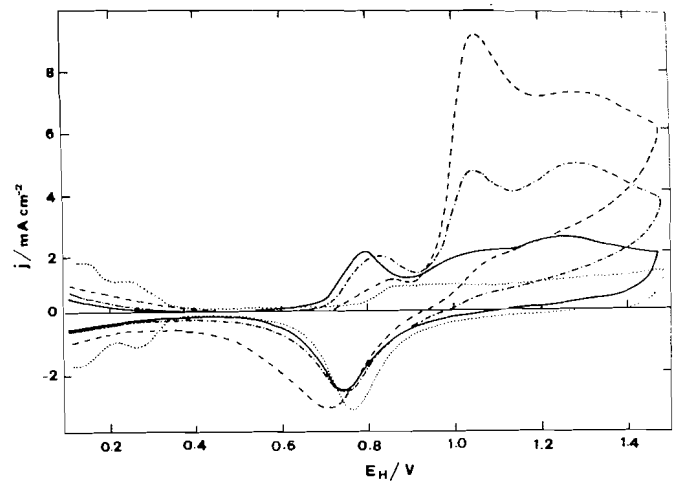

FIG. 2. Cyclic voltammograms of H_2CR (potassium croconate) on a Pt sheet in 0.5 *M* $HClO_4$ at different H_2CR concentrations: (—) 2×10^{-4} *M*; (-·-·-) 10^{-3} *M*; (---) 2.5×10^{-3} *M*; (·····) voltammogram of the supporting electrolyte; υ = 100 mV s^{-1}.

The H_2SQ oxidation commences at potentials where the electrode begins to be covered by the oxides. It is observed that two oxidation waves during the anodic sweep are obtained: a prewave (I) followed at more positive potentials by the main oxidation wave (II). Adsorption control of the prewave and diffusion control of the main wave were verified by scan rate dependence studies. The peak current density of the first wave, $(j_P)_I$, increases linearly with the scan rate, while the peak current density of the second wave, $(j_P)_{II}$, is directly proportional to the square root of the scan rate, as it is shown in the inset diagrams of Fig. 1.

The *j*–*E* curves obtained at these low scan rates ($\upsilon < 0.5$ V s^{-1}) shows an irreversible oxidation. By comparing these curves with those obtained in the same bulk solution without H_2SQ present, it can be seen that the cathodic wave at about 0.75 V is due to the reduction of formed oxides on the surface of platinum.

The other enediol, H_2CR, displays the same oxidation profile (Fig. 2) to that recorded in the case of H_2SQ differing only by the magnitude of their current densities. The current densities obtained are about twice greater for H_2SQ than for H_2CR.

The appearance of an adsorption peak at potentials more negative than the potential of the main diffusion peak indicates the strong adsorption of the reaction product (14). According to the theory of Wopschall and Shain (14), we examined only qualitatively the dependence of the scan rate on the half-peak width, ΔE_W, of the adsorption peak and the ratio, ρ, of the adsorption peak height to the diffusion peak height.

With increase of the scan rate the shape of the prepeak changes and more sharp adsorption prepeaks are obtained (Fig. 1). Also the ratio ρ varies linearly on the square root of the scan rate (Fig. 3) for different bulk concentrations of H_2SQ and H_2CR, indicating the strong adsorption of product of the oxidation process. The small deviations from the linearity of the ρ vs. $\upsilon^{1/2}$ plots observed at high concentrations of H_2SQ and H_2CR and high scan rates seem to be attributed to the small contribution of the weak adsorption of the reactants themselves.

The oxidation of H_2SQ and H_2CR has also been studied on the rotating disc electrode. Figures 4 and 5 show the current density–potential curves of H_2SQ and H_2CR, respectively, obtained on a Pt rotating disc electrode in 0.5 *M* $HClO_4$. A single oxidation wave for both H_2SQ and H_2CR appears. Note that, under rotating conditions, the adsorption prewave is very

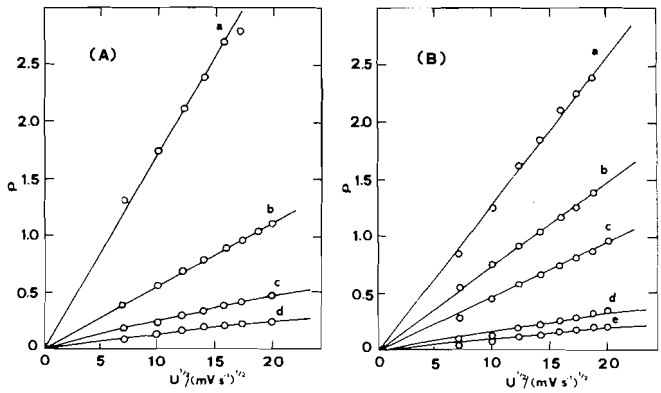

FIG. 3. Ratio of adsorption peak to diffusion peak, ρ, as a function of $v^{1/2}$ for the cyclic voltammograms at different bulk concentrations of H_2SQ (*A*): (*a*) 5×10^{-4}; (*b*) 10^{-3}; (*c*) 2.5×10^{-3}; (*d*) $5 \times 10^{-3}\,M$, and H_2CR (*B*): (*a*) 2×10^{-4}; (*b*) 5×10^{-4}; (*c*) 10^{-3}; (*d*) 2.5×10^{-3}; (*e*) $4 \times 10^{-3}\,M$.

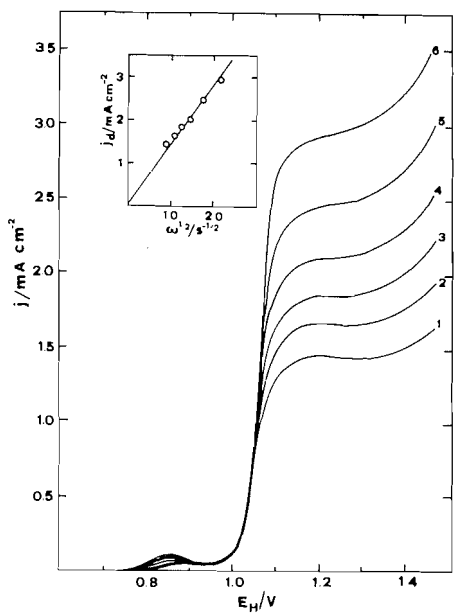

FIG. 4. Current density – potential curves for H_2SQ ($10^{-3}\,M$) oxidation on a Pt rotating disc electrode in $0.5\,M$ $HClO_4$. $|dE/dt| = 20\,mV\,s^{-1}$; rotation frequency *f*: (*1*) 12.5; (*2*) 18.3; (*3*) 25; (*4*) 35; (*5*) 50; (*6*) 75 Hz. Inset: limiting diffusion current density j_d vs. $\omega^{1/2}$ ($\omega = 2\pi f$).

small. However, it becomes more evident when the potential sweep rate increases.

The limiting current density of the oxidation waves of the two acids increases linearly with $\omega^{1/2}$ ($\omega = 2\pi f$). From the slope $dj_d/d\omega^{1/2}$ of the inset plots of Figs. 4 and 5, the diffusion coefficients of H_2SQ and H_2CR were determined by means of the corrected Levich–Riddiford equation (15, 16), after substituting for the kinematic viscosity the value $\nu = 8.929 \times 10^{-3}$ $cm^2\,s^{-1}$ and for the number of electrons consumed per molecule the value $n = 2$. The latter was estimated by controlled-potential electrolysis experiments. The calculated values are: $D_{H_2SQ} = 1.30 \times 10^{-5}\,cm^2\,s^{-1}$ and $D_{H_2CR} = 0.55 \times 10^{-5}\,cm^2\,s^{-1}$. These values agree reasonably well with those obtained from the slope of the j–$t^{1/2}$ diagrams; the j–t curves are recorded using potential-step transients (17).

Although the size of the molecules of the two compounds is about the same, comparing the values of D_{H_2SQ} and D_{H_2CR} it is

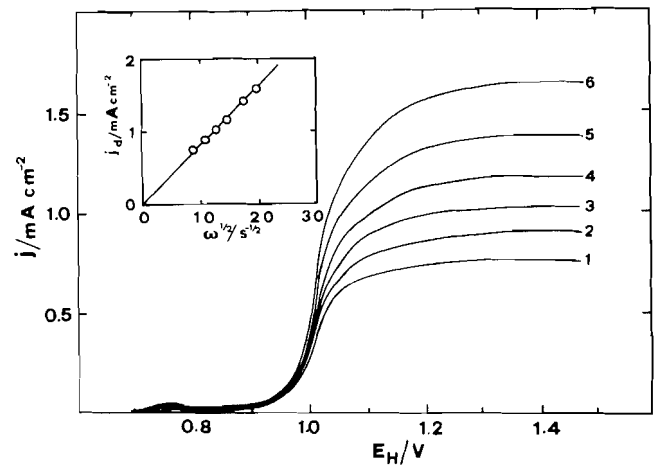

FIG. 5. Current density – potential curves for H_2CR (kalium croconate, $10^{-3}\,M$) oxidation on a Pt rotating disc electrode in $0.5\,M$ $HClO_4$. $|dE/dt| = 20\,mV\,s^{-1}$; rotation frequency *f*: (*1*) 12.5; (*2*) 18.3; (*3*) 25; (*4*) 35; (*5*) 50; (*6*) 75 Hz. Inset: limiting diffusion current density j_d vs. $\omega^{1/2}$ ($\omega = 2\pi f$).

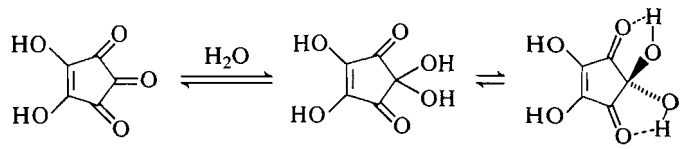
obvious that the value of D_{H_2SQ} is about twice that of D_{H_2CR}. This difference in the diffusion coefficients may be due to the fact that H_2CR exists in aqueous solutions in its hydrated form which favors a voluminal structure of the molecule through two intramolecular hydrogen bonds, thus resulting in a lower mobility. Generally, it is known that in the case of tricarbonyl compounds, the hydration occurs in the central carbonyl group because of its high reactivity (18, 19).



The calculated values of D allow us to evaluate the value of αz, the apparent transfer coefficient. The j_p vs. $v^{1/2}$ plots (for example Fig. 1, inset (*b*)) for low v values show a behaviour of pure diffusion, the slope of which is expressed by the following equation:

$$\frac{dj_p}{dv^{1/2}} = 3.1 \times 10^5 n(\alpha z)^{1/2} D^{1/2} c$$

In this way a value of $\alpha z = 1.42$ for H_2SQ and $\alpha z = 0.84$ for H_2CR is obtained by substituting $n = 2$, the total number of transferred electrons per depolarizer molecule.

Curves of the type shown in Figs. 4 and 5 were used to obtain $\log[j/(j_d - j)]$ vs. E plots, examples of which are given in Figs. 6 (*A*) and (*B*) for H_2SQ and H_2CR, respectively. From these diagrams the role of reactant or product adsorption becomes obvious mainly in the case of H_2CR. The slope of the $\log[j/(j_d - j)]$ vs. E plot changes with the H_2CR concentration. At low concentrations two linear parts with different slopes appear:

$$\left(\frac{dE}{d\log[j/(j_d - j)]}\right)_I = 55\,mV\,decade^{-1}$$

and

$$\left(\frac{dE}{d\log[j/(j_d - j)]}\right)_{II} = 130\,mV\,decade^{-1}$$

(for $c = 10^{-3}\,M$).

The slope of the first part in the potential range of the foot of

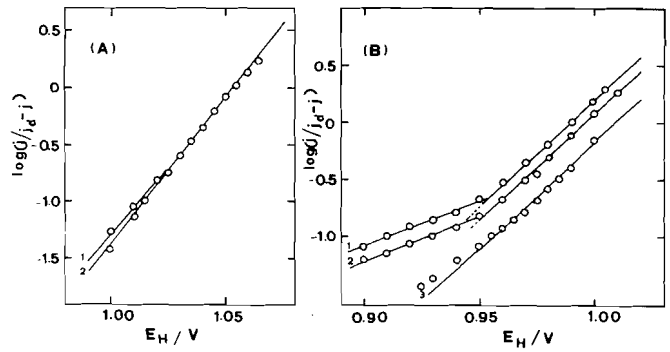

FIG. 6. $\log [j/(j_d - j)]$ vs. E plot of H_2SQ (A) and H_2CR (B) oxidation on a Pt rotating disc electrode in 0.5 M $HClO_4$. (A): (1) 10^{-3} M at 12.5 Hz; (2) 5×10^{-3} M at 12.5 Hz. (B): (1), (2) 10^{-3} M at 12.5 Hz and 25 Hz, respectively; (3) 4×10^{-3} M at 12.5 Hz.

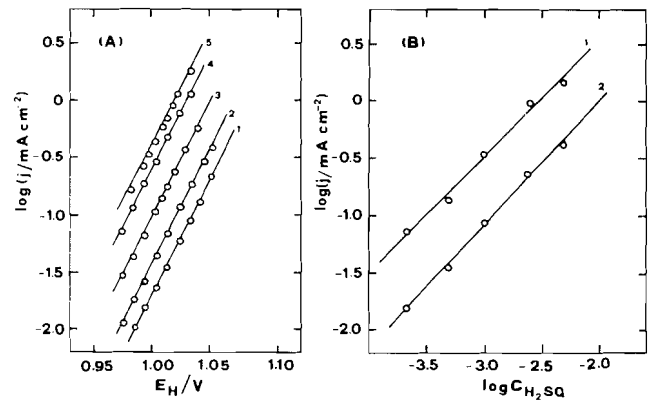

FIG. 7. (A): log j vs. E plot of H_2SQ oxidation on Pt in 0.5 M $HClO_4$ for different concentrations of H_2SQ: (1) 2×10^{-4}; (2) 5×10^{-4}; (3) 10^{-3}; (4) 2.5×10^{-3}; (5) 5×10^{-3} M. f = 25 Hz. (B): Plot of log j vs. log c_{H_2SQ} at E_H = 1.03 V (1) and E_H = 1.00 V (2).

the wave changes with the increase of H_2CR concentration, while that of the second segment remains constant. In the case of relatively low concentrations (up to 2.5×10^{-3} M) the change is negligible but at $c_{H_2CR} \simeq 4 \times 10^{-3}$ M almost one straight line with slope about equal to that of the second linear part is obtained

$$\left(\frac{dE}{d \log [j/(j_d - j)]} \simeq 65 \text{ mV decade}^{-1}\right)$$

In the case of H_2SQ (Fig. 6(A)), the change in the slope is very slight even in low concentrations of H_2SQ and it reasonably can be considered as one straight line with slope independent on H_2SQ concentration.

2. Reaction orders

Influence of H_2SQ and H_2CR concentration: From the logarithmic analysis of the raising part of the current density – potential curves under quasi-stationary conditions (dE/dt = 2 mV s^{-1}) the Tafel plots were obtained for different concentrations of H_2SQ (Fig. 7(A)). The corresponding Tafel slope is independent of the H_2SQ concentration having an average value of 40 mV $decade^{-1}$. This value is in excellent agreement with the value 42 mV $decade^{-1}$ calculated from the value of αz reported previously. The current density values at E = constant increase proportionately to the concentration of H_2SQ. The quotient (d log j/d log c) is independent of the potential at which it was measured (Fig. 7(B)), as well as of pH; it was found equal to 1.05 ± 0.1, which means first order reaction with respect to H_2SQ concentration.

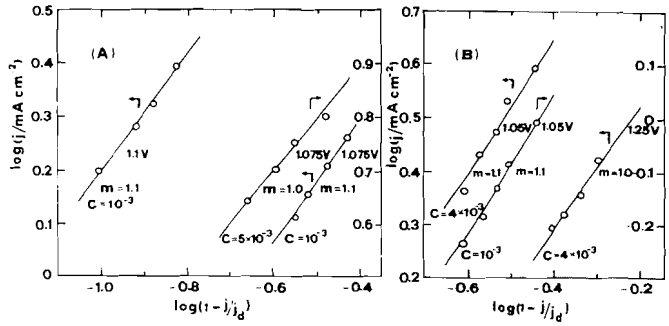

FIG. 8. Plot of log j vs. log $(1 - j/j_d)$. Data were obtained from r.d.e. experiments for H_2SQ (A) and H_2CR (B) oxidation on Pt in 0.5 M $HClO_4$. (The concentrations are expressed in molarities.)

In the case of H_2CR, the above analysis under quasi-stationary conditions also was carried out and the $(d \log j/d \log c)_E$ was found equal to 0.8 ± 0.1. The observed deviation from the unit may be attributed to the effect of H_2CR concentration on the Tafel slope value obtained at the foot of the wave. However, the reaction order with respect to H_2CR concentration can also be determined using the equation (20, 21):

$$j = kc_{Dep}^m [1 - j/j_d]^m$$

where k is the rate constant, c_{Dep} the concentration of the depolarizer in the solution, m the reaction order, j the current density at a constant potential value for different rotation frequencies and j_d the corresponding limiting current density at every rotation frequency.

According to the above equation, a plot of log j vs. log $(1 - j/j_d)$ should be linear with a slope equal to m. The reaction order obtained from this type of plots (Fig. 8(B)) for different H_2CR concentrations was equal to about 1.1.

The same equation was also applicated in the case of H_2SQ and the obtained diagram is demonstrated in Fig. 8(A). The reaction order obtained from these plots was about 1.1, which is consistent with the previous observations.

Influence of $HClO_4$ concentration: from the current density – potential curves of H_2SQ and H_2CR under quasi-stationary conditions for different $HClO_4$ concentrations at constant ionic strength, the Tafel plots were obtained which are demonstrated in Figs. 9(A) and 10(A), respectively. In these experiments the ionic strength was held constant (I = 1) by adding into the solution $NaClO_4$ the appropriate concentration. The Tafel lines shift to more positive potentials as the H^+ concentration increases. The Tafel slope obtained at the raising part of the wave is independent of pH having an average value of about 40 mV $decade^{-1}$ for H_2SQ and 110 mV $decade^{-1}$ for H_2CR. The log j vs. log c_{H^+} plots (Figs. 9(B) and 10(B)) at different constant potential values give the following reaction orders with respect to the H^+ concentration:

TABLE 1. Reaction order with respect to H^+ concentration

Substance	$\left[\frac{d \log j}{d \log c_{H^+}}\right]_{E, c_{Dep}, I=1}$
H_2SQ	−1.1 (for pH < 0.5) −0.3 (for 0.5 < pH < 2)
H_2CR	−1.1 (for pH < 0.4) −0.6 (for 0.4 < pH < 2)

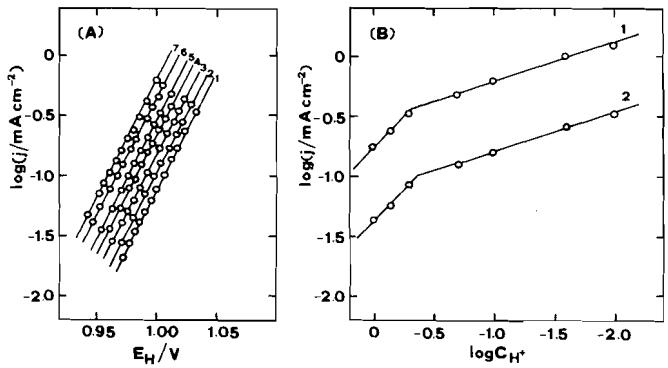

FIG. 9. (*A*): log j vs. E plot of H_2SQ ($10^{-3}M$) oxidation in different $HClO_4$ concentrations: (*1*) 1.0; (*2*) 0.7; (*3*) 0.5; (*4*) 0.2; (*5*) 0.1; (*6*) 0.02; (*7*) 0.01M and constant ionic strength (I = 1); f = 25 Hz. (*B*): plot of log j vs. log c_{H^+} at E_H = 1.03 V (*1*) and E_H = 1.00 V (*2*).

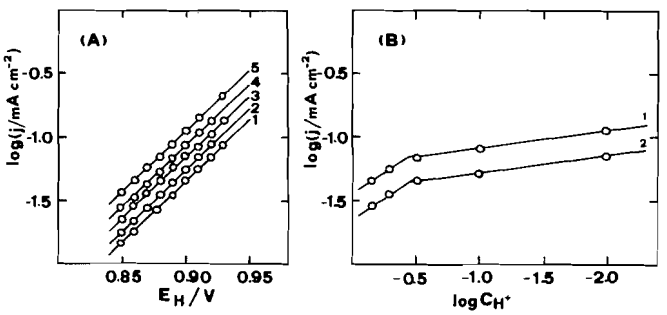

FIG. 10. (*A*): log j vs. E plot of H_2CR ($10^{-3}M$) oxidation in different $HClO_4$ concentrations: (*1*) 0.7; (*2*) 0.5; (*3*) 0.3; (*4*) 0.1; (*5*) 0.01M and constant ionic strength (I = 1); f = 25 Hz. (*B*): plot of log j vs. log c_{H^+} at E_H = 0.90 V (*1*) and E_H = 0.87 V (*2*).

The intersection of the two linear segments (Figs. 9(*B*) and 10(*B*)) reasonably coincides with the pK_{a_1} values of the two acids obtained potentiometrically: $pK_{a_1}(H_2SQ)$ = 0.52 (22, 23) and $pK_{a_1}(H_2CR)$ = 0.32 (23).

3. Mechanism proposed in acid solutions

The data collected demonstrate that the oxidation of H_2SQ and H_2CR corresponds to a two electron-transfer. Considering all the experimental results for the two electrode processes the oxidation mechanism proposed in the acid media ($pH < pK_{a_1}$) must be consistent with the following:

(*a*) Reaction order with respect to depolarizer:

$$\left(\frac{d\log j}{d\log c_{H_2SQ}}\right)_{E,c_{H^+}} = 1.1, \quad \left(\frac{d\log j}{d\log c_{H_2CR}}\right)_{E,c_{H^+}} = 1.1$$

(*b*) Reaction order with respect to H^+ for two compounds:

$$\left(\frac{d\log j}{d\log c_{H^+}}\right)_{E,c_{Dep},I=1} = -1.1$$

(*c*) Tafel slope:

40 mV for H_2SQ and 110 mV for H_2CR.

All the experimental parameters are in agreement with the theoretical ones except the reaction order with respect to H^+. The reaction orders,

$$\left(\frac{d\log j}{d\log c_{H^+}}\right)_{E,c_{Dep}}$$

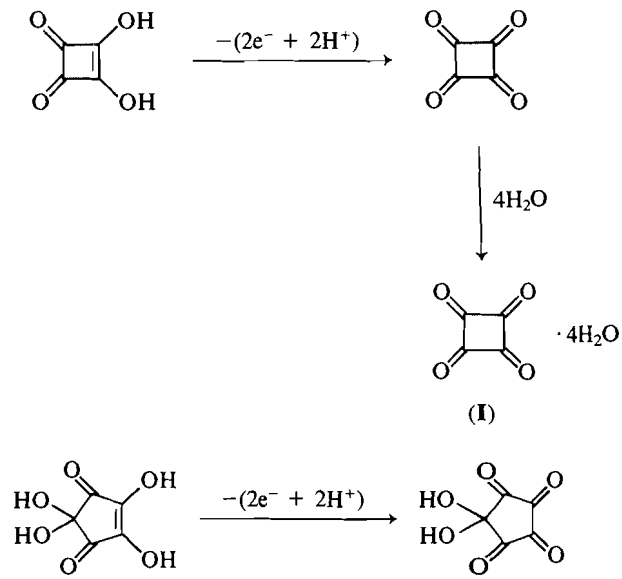
measured imply that one proton intervene in the pH range where $pH < pK_{a_1}$, whereas two protons are theoretically predicted to involve in the reaction process up to the rate-determining step. This effect may be attributed to the fact that the dehydrogenation of different fuels on Pt is not an electrochemical reaction. For this phenomenon some experimental evidence exists (24) and this type of reaction seems to be plausible in light of the high adsorption enthalpy of H_{ads} on Pt. The reaction can be visualized as follows:

$$H_2SQ + 2Pt \rightarrow Pt\text{-}HSQ + Pt\text{-}H$$

$$H_2CR + 2Pt \rightarrow Pt\text{-}HCR + Pt\text{-}H$$

The adsorbed H-atom is oxidized very fast at sufficiently positive potentials.

On the other hand, the voltammetric data show the absence of a cathodic peak at low scan rates, which can be explained by the deactivation of the oxidation product caused by the hydration chemical reaction. The isolated oxidation products from the electrolyzed solution were in the case of H_2SQ the tetrahydrate of cyclobutantetrone (**I**), whereas in the case of H_2CR the leuconic acid pentahydrate (**II**). Thus the overall oxidation reactions are as follows:



The following scheme presents a probable reaction mechanism for the oxidation of H_2SQ and H_2CR, which seems to be consistent with our experimental results.

[3] 
[4] 
[5] 
Assuming reaction [4] as being the rate-determining step and using the quasi-equilibrium approximation and a Langmuir type isotherm for depolarizer adsorption ($\vartheta \rightarrow 0$) the value of the anodic current density on the raising part of the wave can be expressed as:

$$j = 2FK_1K_2k_3c_{Dep}c_{H^+}^{-1} \exp(fE)$$

where c_{Dep} is the total concentration of H_2SQ or H_2CR in the bulk of the solution, c_{H^+} is the concentration of the H^+ ions, K_1 and K_2 are the equilibrium constants of reactions [2] and [3], k_3 is the rate constant of the r.d.s. and $f = \alpha zF/RT$. The experimental values of the Tafel slope and reaction orders are in agreement with those derived from the postulated mechanism.

4. Influence of the upd of Tl, Pb, and Bi on H_2SQ and H_2CR oxidation

The effect of the underpotential deposition of Tl on Pt on the anodic oxidation of H_2SQ is shown in Fig. 11, where the cyclic voltammograms of H_2SQ are given with and without Tl^+ ions present in the solution of the supporting electrolyte. Some change in the Pt electrode for H_2SQ oxidation is observed when Tl^+ ions are added to the solution and discharged to form the upd layer on the substrate. The adsorption peak is almost suppressed, while the peak potential of the diffusion wave appears at less positive potentials. The upd of Pb and Bi does not affect in any way the electrochemical behaviour of H_2SQ on platinum electrode.

Analogous behaviour is observed in the case of H_2CR. In Fig. 12 the cyclic voltammograms of H_2CR on Pt and Pt/M(upd) (M = Tl, Pb, and Bi) are given. For comparison the inset figure represents the cyclic voltammograms of the upd of Pb, Tl, and Bi on Pt. The concentration of Tl^+ was $10^{-3}M$, while those of Pb^{2+} and Bi^{3+} were $5 \times 10^{-5}M$. At higher concentrations complexation of H_2CR with Pb^{2+} and Bi^{3+} becomes significant. The upd of Pb and Bi causes a partial suppression of the adsorption wave and simultaneously a small increase of the current density of the diffusion wave. On the other hand, the upd of Tl causes a complete suppression of the adsorption wave with respective increase of the height of the diffusion wave. Taking into account the bounded area of the j–E curves, the increase of the diffusion wave seems to be analogous to the decrease or disappearance of the adsorption prewave.

This behaviour described above is different to that observed in the case of rhodizonic acid (10), a similar compound with six-member ring. The oxidation wave of rhodizonic acid on Pt also corresponds to a two-electron transfer. The upd ad-layers of Tl, Pb, and Bi catalyze the oxidation of this compound shifting the polarization wave towards less positive potentials and improving the reversibility of the wave not only under cyclic voltammetric conditions, but also on the Pt rotating disc electrode. Also, similar positive catalytic effect of the upd of Tl, Pb, and Bi has been reported for the oxidation of ascorbic acid (also an enediol) on the Pt electrode (25).

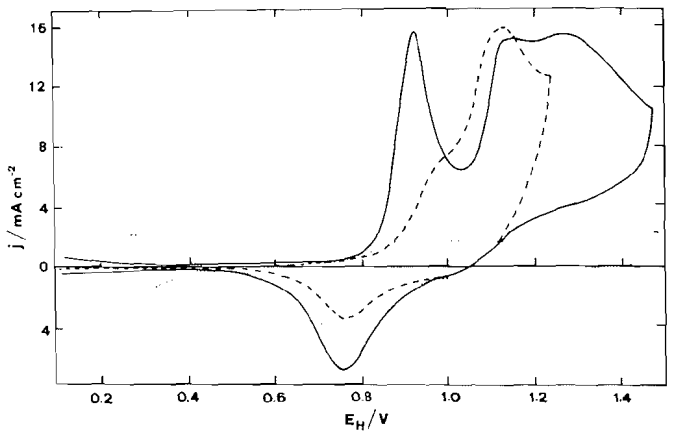

FIG. 11. Cyclic voltammograms of H_2SQ ($10^{-3}M$) on a Pt sheet in $0.5M$ $HClO_4$ in the absence (—) and presence (---) of $10^{-3}M$ $TlClO_4$. $v = 200$ mV s^{-1}. (· · · · ·) Voltammogram of the supporting electrolyte at $v = 200$ mV s^{-1}.

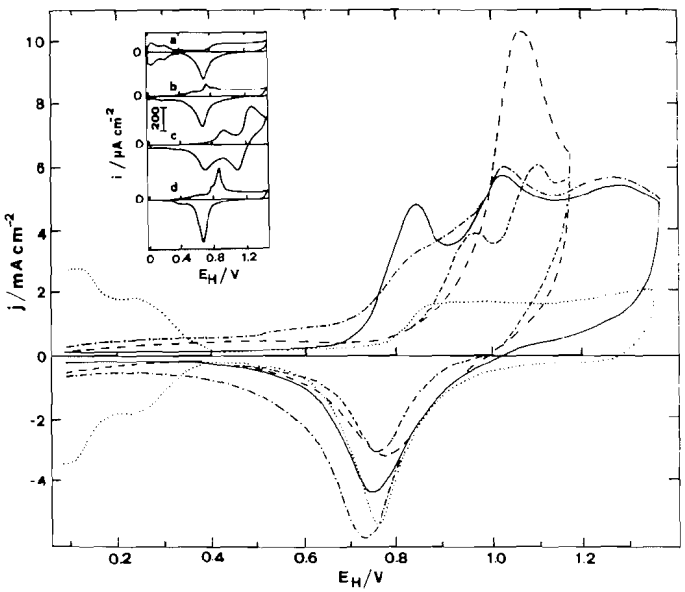

FIG. 12. Cyclic voltammograms of H_2CR (potassium croconate, $5 \times 10^{-4}M$) on a Pt sheet in $0.5M$ $HClO_4$ in the absence (—) and presence of: (---) $10^{-3}M$ $TlClO_4$; (· · · · ·) $5 \times 10^{-5}M$ $Pb(ClO_4)_2$;

The upd ad-layers of Tl, Pb, and Bi do not result in a notable increase of the catalytic activity of the Pt electrode for H_2SQ and H_2CR oxidation as in the case of rhodizonic and ascorbic acids. This difference seems to be attributed to the fact that the standard oxidation potentials of H_2SQ and H_2CR are located at more positive potentials — compared to those of rhodizonic and ascorbic acids — just on the positive boundaries of the upd ranges of the above metals on Pt, where the upd of the metals is superimposed by the upd of oxygen.

MARIE-PAULE SIMONNIN, JEAN-CLAUDE HALLE, MARIE-JOSÉ POUET, FRANÇOIS TERRIER, and DANIEL DAVOUST. Can. J. Chem. **64**, 404 (1986).

Low temperature ^{1}H nuclear magnetic resonance spectra of the zwitterionic and anionic carbon-bonded adducts resulting from the addition of 4,6-dinitrobenzofuroxan (DNBF) or 4,6-dinitrobenzofurazan (DNBZ) to 1,8-bis(dimethylamino)naphthalene, the proton sponge PS, have been recorded at 500 MHz in DMF-d_7. They reveal the presence of two conformers due to restricted rotation around the C_{sp^2}—C_{sp^3} bond between C-4 of PS and the sp^3 carbon C-7′ of the negatively charged $DNBF^-$ or $DNBZ^-$ moiety. The geometry of these conformers was deduced from nuclear Overhauser enhancement difference spectra. The results show that in all systems there is a large preference for the less strained *s-trans* type of conformation, whose population lies between 80 and 90%. An interesting feature is the dependence of the chemical shift of the *peri* H5 proton on the conformation. In accordance with previously reported *peri* effects, a significant deshielding of H5 is observed in the major conformers, where this proton is spatially close to H7′. In contrast, H5 moves upfield in the minor conformers, in which it lies in the vicinity of the $DNBF^-$ or $DNBZ^-$ moiety.

MARIE-PAULE SIMONNIN, JEAN-CLAUDE HALLE, MARIE-JOSÉ POUET, FRANÇOIS TERRIER et DANIEL DAVOUST. Can. J. Chem. **64**, 404 (1986).

Les spectres rmn ^{1}H des C adduits zwitterioniques et anioniques résultant de l'addition du dinitro-4,6 benzofuroxanne (DNBF) ou du dinitro-4,6 benzofurazane (DNBZ) au bis(dimethylamino)-1,8 naphthalène, l'éponge à proton PS, ont été enregistrés, à 500 MHz, à basse température, dans le DMF-d_7. Ils indiquent la présence de deux conformères en raison d'une rotation restreinte autour de la liaison C_{sp^3}—C_{sp^2} entre le carbone C-4 de l'éponge à proton et le carbone sp^3 C-7′ de l'entité $DNBF^-$ ou $DNBZ^-$ chargée négativement. La géométrie de ces conformères a été déduite des effets nOe. Les résultats montrent que, dans tous les systèmes, une grande préférence existe pour les conformations moins encombrées de type *s-trans*, dont la population est comprise entre 80 et 90%. Le déplacement chimique du proton *peri* H5 dépend de la conformation : dans les conformères majoritaires où ce proton est proche de H7′, la résonance de H5 est déplacée vers les champs faibles, en accord avec les effets *péri*. Par contre, la résonance de ce proton est déplacée vers les champs forts dans les conformères minoritaires, dans lesquels H5 est situé au voisinage de l'entité $DNBF^-$ ou $DNBZ^-$.

Introduction

We have recently reported that 1,8-bis(dimethylamino)naphthalene, commonly known as the proton sponge (1–3),[2] behaves as a carbon nucleophile towards heteroaromatic super-electrophiles like 4,6-dinitro-benzofuroxan (DNBF) and -benzofurazan (DNBZ), yielding quantitatively the zwitterionic adducts **1**,*H* and **2**,*H* respectively in acetonitrile or dimethyl sulfoxide (Me_2SO) according to eq. [1] (5). The structure of **1**,*H* and **2**,*H* has been unambiguously established on the basis of 100-MHz ^{1}H nmr data. A particular feature was, however, the finding that the resonances of the naphthalenic H-3 and H-5 protons were broad when the nmr spectra were recorded at probe temperature, but became sharper and sharper with increasing temperature. This observation suggested restricted rotation around the C4—C7′, bond of **1**,*H* and **2**,*H* due to steric hindrance (5).

In view of the large but rather uncommon structure of **1**,*H* and **2**,*H*, we found it of interest to inspect in detail the conformations of these species at low temperature by high frequency ^{1}H nmr spectroscopy (500 MHz). During the course of this work, we observed that it was possible to deprotonate the

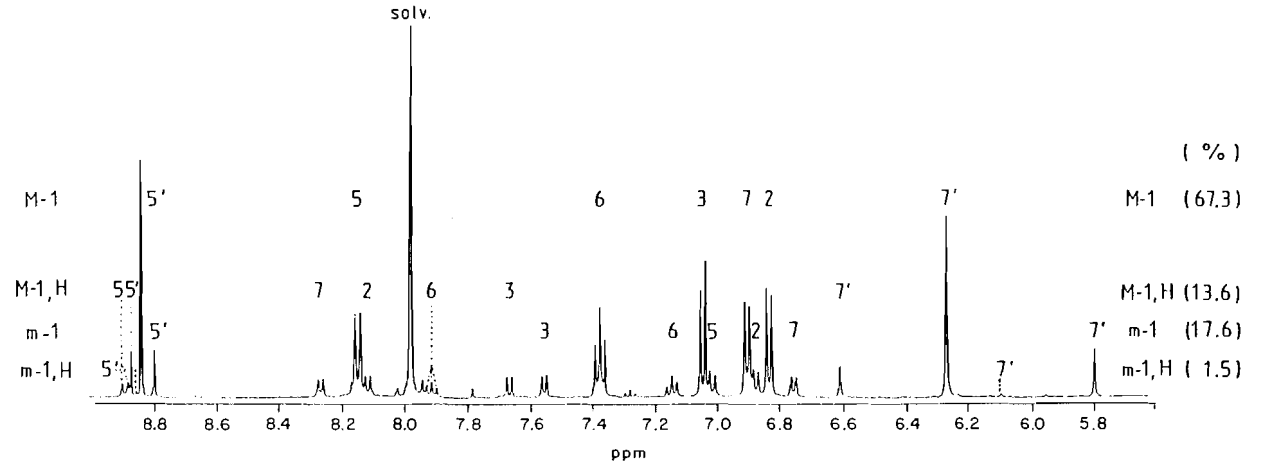

FIG. 1. The 500-MHz ^{1}H nmr spectrum (low field region) recorded at −55°C of the PS–DNBF adduct in DMF-d_7 in the presence of DABCO; the sample contains a mixture of **1** (85%) and **1**,*H* (15%). The assignments of signals belonging to each conformer are indicated on the same horizontal line.

N,*N*-dimethylamino moieties of **1**,*H* and **2**,*H*, which allowed us to extend our study to the anionic species **1** and **2**. In all cases, a full characterization of the conformers has been made by performing low temperature nOe (nuclear Overhauser enhancement) experiments. We now report our results, which also provide new data relative to rotational isomerism around a C_{sp^3}—C_{sp^2} bond in strained naphthalenic derivatives, a problem that has received particular attention in the past few years (6–11).

Results

Syntheses of **1**,*H* and **2**,*H* employed in this study have been previously detailed (5). The isolated zwitterionic adducts were dissolved in deuterated dimethylformamide (DMF-d_7). Conversion of **1**,*H* and **2**,*H* into the anionic forms **1** and **2** was achieved by *in situ* addition of diazabicyclooctane (DABCO) as the base reagent. Evidence for this conversion was provided by nmr spectra, which showed that addition of DABCO results in a decrease in the intensity of the N...$\overset{+}{\text{H}}$...N signal around 19 ppm as well as of other signals of **1**,*H* or **2**,*H*, and the appearance of a new set of signals at higher field. These are consistent with the formation of the anionic adducts **1** and **2**. In particular, the shift variations of the various protons of the naphthalenic moieties are comparable to those observed in a study of the equilibrium between the protonated and neutral forms of PS itself (1). After addition of one equivalent of DABCO to DMF-d_7 solutions of **1**,*H* or **2**,*H*, only the signals due to the anions **1** or **2** were observed.

That DABCO is a sufficiently strong base to deprotonate the proton sponge moieties of the adducts may be surprising in view of the well-known higher basicity of the proton sponge relative to DABCO in protic solvents. Significantly, nmr spectra also reveal that DABCO is more basic than the proton sponge itself in DMF-d_7 and Me_2SO-d_6, indicating that there is an inversion in the relative basicities of these two amines on transfer from water to dipolar aprotic solvents. On this ground and since the nitrogen basicity of **1**,*H* and **2**,*H* is probably lower than that of PS, due to the well-known acidifying effect exerted by the anionic moieties of DNBF and DNBZ adducts (12–14), the conversion of **1**,*H* or **2**,*H* into **1** or **2** by DABCO may be readily understood.

The 500-MHz ^{1}H nmr spectra of **1**,*H*, **2**,*H*, **1**, and **2** recorded at probe temperature (21°C) in DMF-d_7 exhibit broad signals that sharpen on decreasing the temperature. Well-resolved spectra were obtained below −50°C. These showed the presence of two sets of signals with very different intensities, which suggest the existence of two unequally populated conformers for each of the adducts (Fig. 1).

The spectrum of each conformer is expected to exhibit two singlets due to the H5′ and H7′ protons of the DNBF or DNBZ moiety, an AB and an AMX system for the H2, H3 and H5, H6, and H7 protons, respectively, of the naphthalenic ring. Two N-methyl resonances are also expected in the high field region. All these signals were actually observed and fully assigned for the major conformers that we will denote **M-1**,*H*, **M-2**,*H*, **M-1**, and **M-2**. As well, the resonances of the various protons of the minor conformers **m-1** and **m-2** of the anionic adducts could be identified, with the exception of those for the N-methyl groups. This suggests that these resonances are either the same as those for the major conformers or that they overlap with the signals due to the solvent. In the case of the minor conformers **m-1**,*H* and **m-2**,*H* of the zwitterionic adducts, only the signals of the protons belonging to the DNBF or DNBZ moiety could be observed, despite the high frequency used for this study.

Assignment of the signals was deduced from double resonance experiments. Thus, irradiation of the triplet due to the H6 proton allowed the identification of the two doublets belonging to the AMX naphthalenic system. Similarly, the AB system due to the H2 and H3 protons was identified by irradiating the A or B doublet.

Identification of the conformers was deduced from low temperature nOe experiments. The nOe difference spectra of the major conformers of the zwitterionic adducts **M-1**,*H* and **M-2**,*H* recorded while irradiating the H7′ resonance exhibited a 30% enhancement of the A part of the AMX system. Similarly, irradiation of the H7′ resonance of the major conformers of the anionic adducts **M-1** and **M-2** gave a 20% nOe enhancement of the A part of the AMX system. These results demonstrate that the low field A part of the AMX systems is due to H5 and that this proton is spatially close to H7′ in the conformers **M-1**,*H*, **M-2**,*H*, **M-1**, and **M-2**.

Despite the low population of the minor conformers **m-1** and **m-2**, nOe difference spectra show that irradiation of H7′ results in an appreciable enhancement of the low field part of the AB

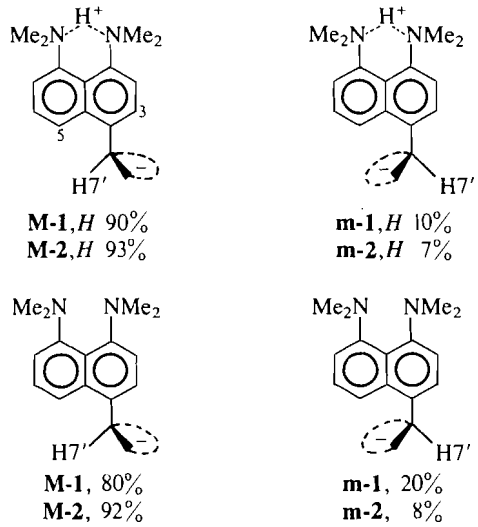
For personal use only.



system. This effect indicates that H3 is deshielded relative to H2 and reveals that H3 lies in the vicinity of H7′ in the minor conformation of the anionic adducts.

Although the nOe experiments were carried out at −55°C, the temperature was not low enough to avoid spin saturation transfer, and small enhancements due to this effect were also observed. Thus, in the case of the conformer **M-1**, a small enhancement (~4%) was observed on the A part of the AB system, indicating that H3 is less shielded than H2, as found in the corresponding minor conformer **m-1**. Similarly, experiments involving **m-1** or **m-2** resulted in a small enhancement of one of the doublets belonging to the AMX system, which was therefore assigned to H5. This spin saturation transfer was also very useful to confirm the assignment of the H7′ signal of the minor conformers **m-1**,*H* and **m-2**,*H* whose naphthalenic protons could not be identified.

The various nmr data are summarized in Tables 1 and 2, which refer to the DNBF and DNBZ systems, respectively. For purpose of comparison, the nmr spectra of neutral and protonated forms of the proton sponge, i.e., PS and PSH^+, were recorded under similar experimental conditions as those used for the adducts. The results are given in Table 3.

Discussion

Preferred conformations around the C4—C7′ bond

The low temperature spectra indicate the presence of only two conformers in the anionic and zwitterionic adducts formed in both the DNBF–PS and DNBZ–PS systems. All major conformers have the same geometry, with the H5 proton located in the vicinity of the H7′ proton bonded to the sp^3 carbon of the adducts. This means that the negatively charged DNBF or DNBZ moiety is removed from the naphthalenic system. By analogy with the situation found in enol ethers, such a geometry can be referred to an *s-trans* conformation. In contrast, the geometry of the minor anionic conformers would be of the *s-cis* type since the $DNBF^-$ or $DNBZ^-$ moiety lies on the same side as the naphthalenic ring relative to the C4—C7′ bond. Although the naphthalenic protons of the minor zwitterionic conformers **m-1**,*H* and **m-2**,*H* could not be identified, it is reasonable to assume that they adopt a geometry similar to that of their anionic analogs.

The 180° rotation around the C4—C7′ bond has a marked influence on the chemical shifts of the naphthalenic protons. It is generally observed that the H8 proton in the *peri* position is deshielded in 1-substituted naphthalenic derivatives (15, 16). Such a situation is actually observed in the major conformers **M-1**,*H*, **M-2**,*H*, **M-1**, and **M-2**, in which the *peri*-like proton H5 is spatially close to H7′. In contrast, H5 undergoes a significant upfield shift (>1 ppm) in the minor conformers **m-1** and **m-2**, in which it is far away from the H7′ proton but close to the $DNBF^-$ or $DNBZ^-$ moieties. An opposite sequence is observed for H3; this proton is more shielded in the *s-trans* major conformers than in the *s-cis* minor ones: in these instances, H3 is the naphthalenic proton, which is the most deshielded. Finally, it is interesting to point out that an upfield shift is observed for

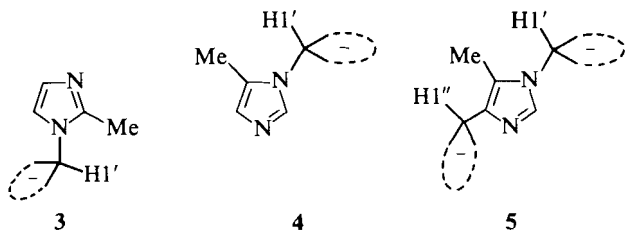
H5 or H3 only in the conformers where H5 or H3 is located above the $DNBF^-$ or $DNBZ^-$ moieties; this suggests a significant ring current in the negatively charged heterocyclic systems.

Significant nuclear Overhauser enhancements were observed for H5 in the *s-trans* major conformers and for H3 in the *s-cis* minor conformers, i.e., for the deshielded naphthalenic proton located in the vicinity of H7′. This situation is somewhat reminiscent of that observed in a recent study of imidazole adducts of 1,3,5-trinitrobenzene (TNB) (17). In this series, it was observed that the imidazolic and methyl protons are more shielded in the adducts than in the imidazoles, except for the methyl groups adjacent to a $N\text{-}TNB^-$ or $C\text{-}TNB^-$ moiety, which are deshielded relative to the parent imidazole. On the basis of nOe experiments, the deshielded methyl groups were shown to be spatially close to the H1′ or H1″ protons bonded to the sp^3 carbon of the TNB^- moiety, as depicted in structures **3**, **4**, and **5**. As previously suggested, such a deshielding effect is probably related to a proximity effect (18, 19).



3 4 5

Although X-ray structure determinations have shown that the deformation of the naphthalenic system is greater in the neutral than in the protonated form of PS (20–22), there is no marked difference in the population of the major and minor conformers of the various anionic and zwitterionic DNBF and DNBZ adducts. In all systems, there is a large preference for the less-strained *s-trans* conformation whose population lies between 80 and 93%.

Hindered rotation around a $C_{sp^3}—C_{sp^2}$ bond has been reported in 9-(1-naphthyl) fluorenes and 1-neopentyl naphthalene and found to result in barriers of 18 and 5.15 kcal mol^{-1}, respectively (6, 7, 11). Clearly, there is some structural similarity between these molecules and our adducts but, due to the very different populations of the major and minor conformers involved in the coalescence process, a reliable estimation of the corresponding barriers is not straightforward, even at 500 MHz. To be noted, however, is that molecular mechanics calculations carried out by Anderson and Barkel (11) have shown that the *peri* interaction is of crucial importance in the barrier measured for 1-neopentyl naphthalene. It is likely that this factor also plays a significant role in the PS adducts as well as in 9-(1-naphthyl) fluorenes.

Protonation shifts

The coupling constants observed for the naphthalic protons in the various adducts show a similar trend, i.e., $J_{56} > J_{67}$. This is consistent with literature data for naphthalene (23, 24) and monosubstituted naphthalenes (25) as well as with predictions based on bond order. This also implies that J_{34} is greater than J_{23} in the case of PS and PSH^+, which agrees with results reported by Alder *et al.* for PS but not for PSH^+ (1).

The effect of protonation of the dimethylamino groups on the chemical shift of the naphthalenic protons may be measured by the equation:

$$\Delta\delta_i = \delta_i^{BH^+} - \delta_i^{B}$$

where BH^+ refers to PSH^+ or the zwitterionic adducts and B refers to PS or the anionic adducts. Comparison of the $\Delta\delta$ values in Tables 1–3 shows that the protonation shifts are very similar for PS and the major conformers of the adducts **1** and **2**. Although the positive charge is shared between two NMe_2 groups in our systems, the effect of the protonation on the *ortho* and *meta* protons is comparable to that observed by Castellano *et al.* in a study of the quaternization of *N,N*-dimethylaniline (4): $\Delta\delta_{ortho} \sim 1.39$ ppm, $\Delta\delta_{meta} \sim 0.57$ ppm. In contrast, our $\Delta\delta$ values for the *para* protons ($\Delta\delta_{para} \sim 0.7$ ppm) are weaker than the $\Delta\delta$ value reported in the *N,N*-dimethylaniline system ($\Delta\delta_{para} \sim 1$ ppm). Since the effect of the positive charge on the NR_3^+ groups is essentially to induce an inductive polarization of the π electrons in the aromatic ring(s) (4), this result is in accord with the weaker interaction between the nitrogen lone pairs and the naphthalenic ring in the neutral proton sponge moieties and therefore a weaker change in electron density at the *para* position on protonation of the N atoms. This conclusion is consistent with the known geometry of PS in the solid state (20).

Conclusion

The study has shown that the various carbon-bonded adducts resulting from the addition of the highly electrophilic DNBF and DNBZ to the C-4 carbon of the proton sponge exist as a mixture of two unequally populated conformers. Low-temperature nmr spectra indicate the existence of a twofold barrier, likely due to steric interaction between the naphthalenic *peri* proton and the negatively charged $DNBF^-$ or $DNBZ^-$ moiety. The trisubstituted nature of the naphthalenic rings in the adducts has allowed a complete assignment of the naphthalenic protons in the various conformers.

Experimental

Samples of **1**,*H* and **2**,*H* were prepared as previously described (5). About 5 mg of **1**,*H* or **2**,*H* was dissolved in 0.5 mL of DMF-d_7 (Aldrich, 99% ^2H or SST, 99.5% ^2H). These solutions were centrifuged and deoxygenated by bubbling argon just before running the nmr spectra.

Diazabicyclo octane, DABCO (Aldrich), was sublimed before use. About 12 mg of DABCO was dissolved in 0.5 mL of DMF-d_7. Increasing amounts of this DABCO solution were added to those of the zwitterionic adducts of **1**,*H* or **2**,*H* to generate the anionic adducts **1** or **2**.

The nmr spectra were run at 500 MHz on a Bruker WM 500 spectrometer equipped with an ASPECT 2000 computer. Acquisition parameters: pulse width, 4 μs (30°); spectral width, 10 000 Hz; memory size, 32 K; digital resolution, 0.6 Hz/point.

The nOe difference spectra were run using the following parameters: relaxation delay, 3.0 s; irradiation time, 1.0 s; acquisition time without irradiation, 1.6 s.

Peak positions were measured relative to the traces of CH_3CN or THF used during the synthesis of **1**,*H* or **2**,*H*, and TMS was added to the nmr tube after the low temperature experiments to determine the δ values of these solvents relative to internal TMS.

Uranium(IV) trifluoromethanesulfonate and some ternary uranium(IV) trifluoromethanesulfonates

MADANMOHAN S. GILL, ANIL K. SETHI, AND RAJENDRA D. VERMA[1]
Department of Chemistry, Panjab University, Chandigarh-160 014, India

Received February 17, 1986[2]

MADANMOHAN S. GILL, ANIL K. SETHI, and RAJENDRA D. VERMA. Can. J. Chem. **65**, 409 (1987).

$U(SO_3CF_3)_4$ and $M^{II}U^{IV}(SO_3CF_3)_6$, M = Mg, Mn, Fe, Zn, have been prepared by the reaction of their respective trifluoroacetates with HSO_3CF_3 acid in CF_3COOH medium at room temperature. Infrared data indicate bidentate bridging $—SO_3CF_3$ groups in these compounds. Magnetic moments show the presence of uranium(IV) species. Diffuse reflectance spectra suggest six coordinate uranium(IV) although the presence of possible eight or higher coordinate uranium(IV) cannot be ruled out. X-ray diffraction studies reveal them to be definite entities.

MADANMOHAN S. GILL, ANIL K. SETHI et RAJENDRA D. VERMA. Can. J. Chem. **65**, 409 (1987).

Operant à température ambiante et dans un milieu de CF_3COOH, on a préparé les dérivés $U(SO_3CF_3)$ et $M^{II}U^{IV}(SO_3CF_3)_6$, dans lesquels M = Mg, Mn, Fe, Zn, en faisant réagir leurs trifluoroacétates respectifs avec du HSO_3CF_3. Les données de l'infrarouge indiquent que, dans ces composés, les groupements $—SO_3CF_3$ forment des ponts bidentates. Les moments magnétiques démontrent la présence d'espèces uranium(IV). Les spectres de réflectance diffuse suggèrent que l'uranium(IV) est hexacoordonné; toutefois, on ne peut pas éliminé la possibilité que les degrés de coordination de l'uranium(IV) soient égaux à huit ou plus. Des études par diffraction des rayons-X révèlent qu'il s'agit d'entités bien definies.

[Traduit par la revue]

Introduction

Trifluoromethanesulfonic acid and fluorosulfuric acid are isostructural and of comparable strength. The exact order of their acid strength is, however, the subject of discussion. A large number of derivatives are known for both acids (1–4). Uranium(IV) (5, 6) and uranium(V) fluorosulfates (7, 8) have been reported. $UO_2(SO_3F)_2$ and $UO(SO_3F)_2$ are also known (6). Whereas a large number of ternary fluorosulfates, such as $MU(SO_3F)_6$, M = Mg, Zn (6), $KAu(SO_3F)_4$ (9, 10), $K_2Pt(SO_3F)_6$ (11), $Ag^{II}Pt^{IV}(SO_3F)_6$ and $Ag^{II}Sn^{IV}(SO_3F)_6$ (12), $M_2[Mn(SO_3F)_5]$, M = K, Cs (13), $M_2[Pd(SO_3F)_6]$, M = Cs^+, NO^+, ClO_2^+, $M[Pd(SO_3F)_6]$, M = Ba^{II}, Pd^{II}, and $Pd^{II}[M(SO_3F)_6]$, M = Pt^{IV} and Sn^{IV} (14) are known, only a few trifluoromethanesulfonates, viz., $M^{II}UO_2(SO_3CF_3)_4$, M^{II} = Mg, Ba, Zn (15), and $K_2[Sn(SO_3CF_3)_6]$, $K[Sn(SO_3CF_3)_5]$, $Cs_2[Pt(SO_3CF_3)_6]$, $Pd^{II}[Pd^{IV}(SO_3CF_3)_6]$, and $Mn[Sn(SO_3CF_3)_6]$ (16), $Cs[Au(SO_3CF_3)_4]$ (17), and $Sn^{II}[Sn^{IV}(SO_3CF_3)_6]$ (18) have been reported. In this article, we report the preparation and characterization of $U(SO_3CF_3)_4$ and $M^{II}U^{IV}(SO_3CF_3)_6$, M = Mg, Mn, Fe, and Zn.

Experimental

$U(O_2CCH_3)_4$ and $M^{II}U^{IV}(O_2CCH_3)_6$, M = Mg, Mn, Fe, Zn were prepared according to literature methods (19). AR grade $UO_2(O_2CCH_3)_2$, $Zn(O_2CCH_3)_2$, $Mg(O_2CCH_3)_2$ and the metals were used as such. Solvents were dried and distilled before use. Trifluoromethanesulfonic acid (Aldrich) was distilled in an atmosphere of dry nitrogen. $U(O_2CCF_3)_4$ and $M^{II}U^{IV}(O_2CCF_3)_6$ were prepared by refluxing the corresponding acetates with trifluoroacetic acid.

In a typical preparation, a slight excess of trifluoromethanesulfonic acid than required on the basis of stoichiometry was added to a known amount (2–3 mmol) of the corresponding trifluoroacetate in trifluoroacetic acid (8–10 mL) and the contents were stirred at room temperature under dry N_2 atmosphere for 3–5 h. In case of $U(SO_3CF_3)_4$ and $Zn^{II}U^{IV}(SO_3CF_3)_6$ clear light green solutions were obtained, which on keeping overnight resulted in the separation of green solids. In case of $Mn^{II}U^{IV}(SO_3CF_3)_6$, a viscous light green jelly-like mass was obtained, which was triturated with petroleum ether to obtain a crystalline compound. In case of $Mg^{II}U^{IV}(SO_3CF_3)_6$ and $Fe^{II}U^{IV}(SO_3CF_3)_6$, solids remained. In all these cases, solids obtained were filtered under positive pressure of dry N_2 gas, washed with trifluoroacetic acid, followed by dry petroleum ether and finally dried *in vacuo*. The yields in all cases exceed 90%.

TABLE 1. Analytical data

Compound	% Found (calcd.) M	U	S	F	C
$U(SO_3CF_3)_4$	—	28.39 (28.53)	15.27 (15.34)	27.24 (27.33)	5.68 (5.75)
$Mg^{II}U^{IV}(SO_3CF_3)_6$	1.97 (2.10)	20.49 (20.58)	16.52 (16.60)	29.49 (29.57)	6.18 (6.22)
$Mn^{II}U^{IV}(SO_3CF_3)_6$	4.55 (4.62)	19.97 (20.05)	16.09 (16.17)	28.75 (28.81)	6.01 (6.06)
$Fe^{II}U^{IV}(SO_3CF_3)_6$	4.66 (4.70)	19.94 (20.03)	16.10 (16.16)	28.72 (28.29)	5.98 (6.06)
$Zn^{II}U^{IV}(SO_3CF_3)_6$	5.33 (5.45)	19.76 (19.87)	15.94 (16.03)	28.49 (28.56)	5.93 (6.01)

Sulfur was determined as $BaSO_4$ after fusing a known weight of the compound with fusion mixture. Fluorine was determined as described (20). Uranium, magnesium, manganese, iron, and zinc were estimated as described (19). Carbon and hydrogen were determined microanalytically by the microanalyst of the department. The analytical results are given in Table 1.

The ir spectra of the compounds were recorded as Nujol and hexachlorobutadiene mulls between silver chloride plates using a Perkin-Elmer 621 spectrophotometer. Diffuse refluctance spectra of powdered compounds were recorded on a Unicam SP-735 spectrophotometer using freshly sublimed MgO as a reflecting reference (courtesy I.I.T., New Delhi). X-ray powder diffraction data were obtained from a Philips X-ray diffraction apparatus model PW 1729 using CuK radiation and Ni filter with incorporated facilities for scintillation counting. The samples were run from 4° to 70° with 10°/min rotation. Magnetic susceptibilities were determined at room temperature using Gouy's method. $Hg[Co(NCS)_4]$ was used as calibrant. All manipulations were carried out in a dry box having dry N_2 gas atmosphere.

Results and discussion

Inorganic trifluoromethanesulfonate derivatives have largely been prepared by solvolysis (17, 21, 22) of the general type:

$$MX_n + nHSO_3CF_3 \rightarrow M(SO_3CF_3)_n + nHX$$

X = F, Cl, Br, SO_3F, carboxylates etc.

To a lesser extent, salts like $AgSO_3CF_3$ in metathetical reactions have also been used. We have observed (6, 15) the facile displacement of trifluoroacetate group at ambient temperature by SO_3X group, X = F, CF_3; in the preparation of ternary fluorosulphates or trifluoromethanesulfonates. Trifluoroacetates on the other hand are easily obtainable from the corresponding acetates by "acid exchange" method. In our opinion, solvolysis of trifluoroacetates in trifluoroacetic acid medium is a convenient method for the preparation of simple inorganic and ternary fluorosulphates as well as trifluoromethanesulfonates.

The reactions of $M^{II}U^{IV}(O_2CCF_3)_6$ with HSO_3CF_3 in trifluoroacetic acid medium may be represented as

$$M^{II}U^{IV}(O_2CCF_3)_6 + 6HSO_3CF_3 \rightarrow M^{II}U^{IV}(SO_3CF_3)_6 + 6CF_3COOH$$

These compounds are light green, hygroscopic solids and are insoluble in usual non-coordinating organic solvents. The compounds do not melt up to 200°C.

X-ray powder diffraction spectra of $Mg^{II}U^{IV}(SO_3CF_3)_6$, $Mg(SO_3CF_3)_2$, and $U(SO_3CF_3)_4$ gave well-defined diffraction lines (Table 2). The observed d(Å) values of $Mg^{II}U^{IV}(SO_3CF_3)_6$ are found to be different from those of $Mg(SO_3CF_3)_2$ or $U(SO_3CF_3)_4$. This excludes the possibility of the presence of free $Mg(SO_3CF_3)_2$ or $U(SO_3CF_3)_4$ in $Mg^{II}U^{IV}(SO_3CF_3)_6$ and suggests that the latter is real compound rather than a 1:1 stoichiometric mixture of the components. Similar X-ray diffraction studies were carried out on $M^{II}U^{IV}(O_2CCF_3)_6$, which were used as precursors for the corresponding trifluoromethanesulfonates.

Infrared spectra of $U(SO_3CF_3)_4$ and $Mg^{II}U^{IV}(SO_3CF_3)_6$ along with those of $Ag(SO_3CF_3)_2$ (17) and $(CH_3)_3SnSO_3CF_3$ (24) with their tentative assignments are given in Table 3. Six fundamental modes of vibrations ($3A'$ and $3E$ modes, all ir and Raman active) are observed for SO_3X anion (X = Cl, F, CH_3, CF_3, or CF_3SO_3) of C_{3v} symmetry. Covalent interactions result

in splitting of all E modes. As a consequence, the number of fundamental modes increase from six to nine for covalently bonded SO_3X group. Vibrational assignments in trifluoromethanesulfonates follow the same pattern as that in fluorosulfates, but some ambiguity does exist in certain vibrational assignments due to the fact that sulfur–oxygen and carbon–fluorine vibrations of identical symmetry (A' and E) are found in the same spectral region (23) resulting in coupling. In interpreting the ir spectra of $M^{II}U^{IV}(SO_3CF_3)_6$ emphasis has been placed on the identification of the functionality of SO_3CF_3 group recognizable from the number and position of sulfur–oxygen stretching frequencies. The number of bands in the ir spectra of these compounds indicate lowering of the symmetry of SO_3CF_3 group from C_{3v} to $\hat{c}_s$. The νS—O modes around 1300 sb, 1125 s, and 1030 cm^{-1} suggest the presence of bridging bidentate SO_3CF_3 groups when compared to the corresponding SO_3CF_3 stretching bands in $Ag(SO_3CF_3)_2$ (17), $(CH_3)_3SnSO_3CF_3$ (24), and $(CH_3)_2Sn(SO_3CF_3)_2$ (25). In $(CH_3)_3SnSO_3CF_3$ and $(CH_3)_2Sn(SO_3CF_3)_2$ bridging bidentate SO_3CF_3 groups have been proposed on the basis of ^{119}Sn Mössbauer spectra and X-ray diffraction studies and a structural study on the analogous compound $(CH_3)_2Sn(SO_3F)_2$ (26). Bands around 1170–1235 cm^{-1} may be attributed to νCF_3. Weak bands around 760–775 cm^{-1} are due to νS—C. The δSO_3 (510 and 625 cm^{-1}) and δCF_3 (570 cm^{-1}) also agree with the corresponding modes in $Me_3SnSO_3CF_3$.

Diffuse reflectance spectra of uranium(IV) complexes have been studied (27) and the complexes have been divided into three classes on the basis of band intensities on the arbitrary Beckman scale of 0–2. The "weak" intensity spectra occur in six coordinate uranium(IV) complexes, whereas a "strong" and "medium" intensity spectra appear where the coordination number is higher than six. The diffuse reflectance spectra of $U(SO_3CF_3)_4$, $Mg^{II}U^{IV}(SO_3CF_3)_6$, and $Zn^{II}U^{IV}(SO_3CF_3)_6$ have been recorded. The spectra are usually not well resolved. Almost similar but not completely identical bands (28) have been observed around 400, 450, 525, 575, 700, and 1300 nm. Octahedral uranium(IV) complexes exhibit weak bands in the region 400, 590, and 630 nm as well as a weak band at 450 nm (29). The latter also appears in the spectra of 8-coordinate uranium(IV) species (30). Bands observed in the present compounds suggest six coordinate uranium(IV) species although the possibilities of eight or higher coordinate uranium(IV) cannot be ruled out because a band at 450 nm also appears in the spectra of eight coordinate uranium(IV) complexes.

The magnetic moments of the compounds having uranium(IV) centers are reported in the range 3.0–3.8 BM, having $5f^2$ configuration (31–33). The magnetic moments of the compounds at 297 K ($U(SO_3CF_3)_4$ = 3.73, $Mg^{II}U^{IV}(SO_3CF_3)_6$ = 3.80, $Mn^{II}U^{IV}(SO_3CF_3)_6$ = 9.58, $Fe^{II}U^{IV}(SO_3CF_3)_6$ = 7.38, $Zn^{II}U^{IV}(SO_3CF_3)_6$ = 3.65 BM) confirm the presence of uranium(IV) species in these compounds and also the presence of Mn^{2+} and Fe^{2+} in $Mn^{II}U^{IV}(SO_3CF_3)_6$ and $Fe^{II}U^{IV}(SO_3CF_3)_6$ according to Pascal's law of additive magnetic susceptibilities (34). Whereas the magnetic moments of these compounds at room temperature confirm the presence of uranium(IV) species, the diffuse reflectance spectra of the compounds studied suggest hexa- or higher coordination around uranium(IV).

In conclusion it may be remarked that conversion of trifluoroacetates to trifluoromethanesulfonates in trifluoroacetic acid medium at room temperature is a convenient synthetic method for the preparation of metal trifluoromethanesulfonates.

The rapid synthesis of deoxyfluoro sugars using tris(dimethylamino)sulfonium difluorotrimethylsilicate (TASF)[1]

BOGDAN DOBOSZEWSKI, GEORGE W. HAY, AND WALTER A. SZAREK[2]
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received March 4, 1986[3]

BOGDAN DOBOSZEWSKI, GEORGE W. HAY, and WALTER A. SZAREK. Can. J. Chem. **65**, 412 (1987).

Deoxyfluoro sugars were synthesized rapidly by the reaction of trifluoromethanesulfonyl derivatives of partially protected sugars with tris(dimethylamino)sulfonium difluorotrimethylsilicate (TASF) under mild conditions. The displacements occurred with inversion of configuration; fluorine has been introduced stereospecifically at each of the secondary alcoholic sites of aldohexopyranosides and in one example of a furanoid system. In some instances unsaturated compounds that contained no fluorine were produced.

BOGDAN DOBOSZEWSKI, GEORGE W. HAY et WALTER A. SZAREK. Can. J. Chem. **65**, 412 (1987).

On a réalisé une synthèse rapide de sucres désoxyfluorés en faisant réagir des dérivés trifluorométhanesulfonylés de sucres partiellement protégés avec du difluorotriméthylsilicate de tris(diméthylamino)sulfonium (TASF), utilisant des conditions douces. Les réactions de déplacement se font avec inversion de configuration; on a pu introduire d'une façon spécifique des atomes de fluor au niveau de chacun des sites alcooliques secondaires des aldohexopyrannosides et dans un exemple de système furannoïde. Dans quelques cas, on a obtenu des composés insaturés qui ne contenaient pas de fluor.

Introduction

The expanding application of deoxyfluoro sugars for the study of carbohydrate metabolism and transport in both normal (1–5) and pathological (6–10) states has stimulated interest in their chemical (11) and biological (1*a*, 2) properties. Furthermore, it has actuated intensive efforts to develop improved methods of synthesis, and especially procedures suitable for the preparation of ^{18}F-labeled carbohydrates for use in medical imaging (12). Included in the approaches taken to this end are addition reactions of such reagents as molecular fluorine (10, 13, 14), xenon difluoride (15–17), and acetyl hypofluoride (18–22), reaction of free hydroxyl groups with (diethylamino)-sulfur trifluoride (23–25), nucleophilic ring-openings with potassium hydrogen fluoride (26–28), and nucleophilic displacement of good leaving groups by a range of fluoride salts (29–34).

We recently reported (35) in preliminary form the rapid, fluoride-ion displacement of carbohydrate triflates using tris-(dimethylamino)sulfonium difluorotrimethylsilicate (TASF) (36), a reagent that previously had been utilized (37) for the synthesis of 1-deoxy-1-fluoro-D-fructose. TASF is a hygroscopic solid, which is freely soluble in a variety of organic solvents in which it acts as an effective fluoride-ion donor when employed under rigorously anhydrous conditions; the relatively brief reaction times (35) are such that it may be of interest for the potential synthesis of ^{18}F-labeled radiopharmaceuticals for positron emission tomography. The scope and utility of the reagent are further delineated in the present report, which provides full details of the results of both the previous (35) and later studies in which TASF has been used to effect the displacement, with inversion of configuration, of triflate groups at each of C-2, C-3, C-4, and C-6 of suitably protected aldohexopyranosides, at C-6 of 1,2:3,4-di-*O*-isopropylidene-α-D-galactose (**10**), and at C-3 of 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose (**12**).

Results and discussion

The synthetic results have been summarized in Table 1. In most cases the displacement of triflate anion occurred rapidly (≦30 min) at or below reflux temperature; however, in two examples (see Table 1, compounds **4** and **13**) an elimination reaction was found to predominate.

Methyl 4,6-*O*-benzylidene-3-*O*-methyl-β-D-mannopyranoside (**1***a*) (38) was converted into the 2-*O*-triflyl derivative (**1***b*) by reaction with trifluoromethanesulfonic anhydride (39). The reaction of **1***b* with TASF[4] in dichloromethane occurred rapidly in cold solution. Examination of the reaction solution by thin-layer chromatography (tlc) 10 min after the addition of TASF failed to detect the presence of **1***b*. The reaction afforded a 64% yield of methyl 4,6-*O*-benzylidene-2-deoxy-2-fluoro-3-*O*-methyl-β-D-glucopyranoside (**14**), which was identified on the basis of its ^{13}C and ^{19}F nuclear magnetic resonance (nmr) spectra. Of particular diagnostic importance was the observation that the values of the coupling constants $J_{F,1}$ (4.2 Hz), $J_{F,2}$ (49.5 Hz), and $J_{F,3}$ (14.0 Hz) agreed closely with those reported by Adamson *et al.* (40) for 2-deoxy-2-fluoro-β-D-glucose.

The preparation of methyl 3-*O*-benzyl-4,6-*O*-benzylidene-β-D-glucopyranoside was achieved in 20% yield by benzylation of methyl 4,6-*O*-benzylidene-β-D-glucopyranoside (see ref. 41) using tetra-*n*-butylammonium hydrogen sulfate (42) under phase-transfer conditions (41, 43). Oxidation of the product, followed by reduction using sodium borohydride, afforded a high yield of methyl 3-*O*-benzyl-4,6-*O*-benzylidene-β-D-mannopyranoside (**2***a*), from which the 2-*O*-triflyl derivative **2***b* was readily obtained by reaction with triflic anhydride. Compound **2***b* underwent a rapid reaction with TASF at reflux temperature to give two compounds in an approximate ratio of 2.4:1. The main product, obtained in 45% yield, was identified as methyl 3-*O*-benzyl-4,6-*O*-benzylidene-2-deoxy-2-fluoro-β-D-glucopyranoside (**15**) on the basis of the ^{1}H, ^{13}C, and ^{19}F nmr data. The ^{1}Hmr spectrum of **15** exhibited $J_{1,2}$ = 7.5 Hz, and $J_{2,3}$ = 8.0 Hz, values indicative of a *trans* relative configuration of the protons on carbons 1, 2, and 3. Furthermore, as with compound **14**, the values for $J_{F,1}$, $J_{F,2}$, and $J_{F,3}$ corresponded to those reported by Adamson *et al.* (40) for the *gluco* configuration. The minor product (19% yield) tentatively was

assigned the structure of methyl 3-*O*-benzyl-4,6-*O*-benzylidene-2-deoxy-β-D-*erythro*-hex-2-enopyranoside on the basis of its ^{1}Hmr spectrum; this substance was unstable and underwent some decomposition during tlc. Base-catalyzed elimination reactions with triflyl derivatives are uncommon (44, 45), but have been observed in certain furanoid (44, 46) and, very recently, in pyranoid (34*a*,*c*) ring systems (see also Table 1). Eliminations in glycopyranosides occurred (34*a*,*c*) under conditions that decreased the ease of nucleophilic substitution (34*a*, 47).

The reaction of benzyl 3,4,6-tri-*O*-benzyl-2-*O*-trifluoromethanesulfonyl-β-D-mannopyranoside (**3***b*) with TASF, below room temperature, was complete in less than 5 min, to give a low (11%) yield of benzyl 3,4,6-tri-*O*-benzyl-2-deoxy-2-fluoro-β-D-glucopyranoside (**16**), whereas the isomeric α-D-mannopyranoside **4***b* reacted relatively slowly with TASF at room temperature to give a product that did not contain fluorine. The product obtained from **4***b* was unstable and underwent some decomposition during thin-layer or flash chromatography; the ^{1}Hmr spectrum of the product was consistent with the occurrence of an elimination reaction, and the compound was tentatively assigned the structure of **17**. The instability of this product obviated the acquisition of an elemental analysis. The reaction of **3***b* with TASF, which gave rise to **16**, was accompanied by the formation of an unidentified compound; this, by analogy with the reaction of TASF with **2***b* and **4***b*, may possibly be an unsaturated product from a competing elimination reaction.

The reactions of the β-D-glucopyranosides **5***b*, **6***b*, and **7***b* with TASF yielded results that were very different in each case, but which were fully consistent with the current understanding of nucleophilic displacements in carbohydrates (45, 47–49). The less rapid and efficient displacement of triflate anion from **6***b*, as compared with that from **5***b*, may be attributable to the increased steric hindrance occasioned by the introduction of benzyl and 2,2,2-trichloroethyl groups in place of methyl groups. Furthermore, the facile displacement of triflate from C-3 of **7***b* reflects the diminution of the steric and electronic effects that render the displacement of C-2 sulfonates in β-D-glucopyranosides much more difficult (47*b*). It is noteworthy that the product of the relatively difficult reaction of TASF with **6***b* was found to contain, in addition to **19**, two unidentified components, a result that indicates the relative increase in competing reactions as nucleophilic substitution is impeded.

The reaction of methyl 2,3,6-tri-*O*-benzyl-4-*O*-trifluoromethanesulfonyl-β-D-glucopyranoside (**8***b*) with TASF in dichloromethane at reflux temperature was monitored by tlc and was judged to be complete after 20 min, at which point the starting compound (**8***b*) no longer was detectable. The assignment of the *galacto* configuration to the product **21** was based on the nmr data; the values of the coupling constants observed for H-3 and H-4 (2.8 Hz), H-4 and H-5 (~0 Hz) (see ref. 50), H-3 and F-4 (27.5 Hz), H-4 and F-4 (49.8 Hz), and H-5 and F-4 (22.3 Hz) (see ref. 51) were in agreement with those reported in the literature for derivatives of methyl 4-deoxy-4-fluoro-β-D-galactopyranosides.

Methyl 2,3,6-tri-*O*-benzyl-4-*O*-trifluoromethanesulfonyl-α-D-galactopyranoside (**9***b*) was prepared from **9***a* (52) in the manner described for **1***b*. Compound **9***b* reacted with TASF much more rapidly than did **8***b*; the conversion was complete within 10 min after the addition of TASF to a cold solution of **9***b*. The product, methyl 2,3,6-tri-*O*-benzyl-4-deoxy-4-fluoro-α-D-glucopyranoside (**22**), was isolated in 67% yield by flash chromatography. The assignment of the *gluco* configuration to **22** followed from the nmr data. The enhanced ease of displacement of the axially oriented trifloxy group of **9***b*, as compared to that of the equatorially oriented one of **8***b*, is consistent with the suggestion (48) that a *galacto* isomer has a higher ground-state energy than the corresponding *gluco* compound.

The nucleophilic displacement by TASF of a trifloxy group located on a primary carbon atom occurred with great rapidity under mild conditions. Thus, the reaction of 1,2:3,4-di-*O*-isopropylidene-6-*O*-trifluoromethanesulfonyl-α-D-galactopyranose (**10***b*) with TASF was complete in less than 10 min at 0–20°C and afforded a 71% yield of 6-deoxy-6-fluoro-1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose (**23**) (53). In a similar manner, methyl 2,3-di-*O*-benzyl-4,6-bis-*O*-(trifluoromethanesulfonyl)-β-D-glucopyranoside (**11***b*) reacted rapidly with TASF at reflux temperature to give a 39% yield of methyl 2,3-di-*O*-benzyl-4,6-dideoxy-4,6-difluoro-β-D-galactopyranoside (**24**); this, however, was accompanied by the formation of a slightly smaller amount of a less polar, unidentified compound.

The selective introduction of fluorine into a furanose ring was demonstrated by the reaction of TASF with 1,2:5,6-di-*O*-isopropylidene-3-*O*-trifluoromethanesulfonyl-α-D-allofuranose (**12***b*), which gave a 66% yield of 3-deoxy-3-fluoro-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**25**) (54). The isomeric triflate **13***b*, having the D-*gluco* configuration, reacted with TASF under the same conditions to give an 83% yield of the elimination product, 3-deoxy-1,2:5,6-di-*O*-isopropylidene-α-D-*erythro*-hex-3-enofuranose (**26**) (55), but no fluorine-containing product was detected.

The above examples have demonstrated the utility of TASF as a useful reagent for the rapid introduction of fluorine into a variety of monosaccharide triflates.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 automatic polarimeter using chloroform as solvent in a 1-dm tube at 23 ± 3°C. The ^{1}Hmr spectra were recorded on a Bruker AM400 spectrometer at 400 MHz; ^{13}Cmr and ^{19}Fmr spectra were recorded on the same instrument at 100.6 and 476.5 MHz, respectively. Tetramethylsilane (TMS) was used as the internal standard for ^{1}Hmr and ^{13}Cmr spectra; trichlorofluoromethane was used as the external standard for the ^{19}Fmr spectra. All ^{13}Cmr spectra employed the SEFT pulse sequence (56). Thin-layer chromatography was performed on plates coated with Merck GF-254 silica gel. Flash chromatography was carried out using Merck silica gel G (230–400 mesh).

All reactions employing triflic anhydride or TASF were performed under rigorously anhydrous conditions under a constant flow of argon.

Starting compounds prepared by methods described in the literature had physical constants in agreement with the published data.

Methyl 3-O-benzyl-4,6-O-benzylidene-β-D-mannopyranoside (2a)

Methyl 4,6-*O*-benzylidene-β-D-glucopyranoside (19.2 g, 68 mmol), benzyl bromide (9.7 mL, 81.6 mmol), and tetra-*n*-butylammonium hydrogen sulfate (2 g, 5.9 mmol) in dichloromethane (150 mL) were stirred vigorously with a 10% aqueous solution of sodium hydroxide (200 mL). After 5 h the aqueous phase was replaced with a fresh solution of 10% aqueous sodium hydroxide to which tetra-*n*-butylammonium hydrogen sulfate (2 g) was added, and rapid stirring was continued overnight. The organic phase was evaporated; the residue was shown by tlc (hexanes – ethyl acetate, 2:1 (v/v)) to consist of 3 components having R_f values of 0.24, 0.48, and 0.66. The component having R_f 0.24 was isolated by flash chromatography (hexanes – ethyl acetate, gradient solution 2:1–1:1 (v/v)) and identified as methyl

3-*O*-benzyl-4,6-*O*-benzylidene-β-D-glucopyranoside (5.0 g, 19.7%): mp 179–181°C (lit. (57) mp 181–183°C).

The product (0.3 g, 0.80 mmol) was treated with dimethyl sulfoxide (10 mL) and acetic anhydride (5 mL) for 24 h at room temperature. The solution was evaporated at ~85°C, and the residue dissolved in tetrahydrofuran (5 mL). The solution was diluted with methanol (20 mL) and sodium borohydride (0.5 g) was added in small portions. After 30 min the solvent was evaporated and the residue resolved by flash chromatography. The component having R_f 0.43 (hexanes – ethyl acetate 1:2 (v/v)) was identified as **2***a* (0.248 g, 82.7%): mp 117–118.5°C; $[\alpha]_D$ −29.8° (*c* 1.25, chloroform) (lit. (58) mp 119.5–121°C; $[\alpha]_D$ −32° (*c* 0.8, chloroform)).

*Benzyl 3,4,6-tri-*O*-benzyl-β-D-mannopyranoside (**3**a)*

3,4,6-Tri-*O*-benzyl-1,2-*O*-(1-ethoxyethylidene)-α-D-glucopyranoside (59) (0.79 g, 1.5 mmol) was treated with acetyl chloride (0.1 mL) and benzyl alcohol (10 mL) at 90°C for 4 h. Flash chromatography of the reaction product afforded benzyl 3,4,6-tri-*O*-benzyl-β-D-glucopyranoside (60) (0.33 g, 40%): mp 88–89.5°C (hexanes–ether); $[\alpha]_D$ −26.5° (*c* 0.8, chloroform). This glucopyranoside (0.253 g, 0.468 mmol) was dissolved in dichloromethane (5 mL) and dimethyl sulfoxide (0.067 mL), the solution cooled in a solid CO_2 – acetone bath, and trifluoroacetic anhydride (0.4 mL, 0.6 mmol) added dropwise during 10 min. The reaction was held in the cooling bath for 40 min. Triethylamine (0.4 mL) was added and, after 10 min, the solution was diluted with dichloromethane, washed with water, dried ($MgSO_4$), and the solvent evaporated. The residue was dissolved in ethyl ether (3 mL) and methanol (20 mL); sodium borohydride (0.5 g) was added in small portions and allowed to react for 40 min at room temperature. The solution was evaporated, the residue suspended in dichloromethane, and the mixture washed with water. The organic phase was dried ($MgSO_4$), evaporated, and the residue purified by flash chromatography using hexanes – ethyl ether (5:6 (v/v)) to give **3***a* (0.186 g, 73.5%): $[\alpha]_D$ −48.2° (*c* 4.6, chloroform) (lit. (33) $[\alpha]_D^{22}$ − 43° (*c* 1.3, chloroform); ^{1}Hmr ($CDCl_3$) δ: 4.96–4.51 (m, 8H, CH_2Ph), 4.42 (d, 1H, $J_{1,2}$ = 0.6 Hz, H-1), 4.09 (br d, 1H, $J_{2,3}$ = 2.6 Hz, H-2), 3.88 (t, 1H, $J_{4,3}$, $J_{4,5}$ = 9.5, 9.4 Hz, H-4), 3.76 (doubled AB, 2H, AB *J* = 23.0, 10.5, $J_{5,6}$ = 5.4, $J_{5,6'}$ = 2.0 Hz, H-6, H-6′), 3.52 (dd, 1H, $J_{3,2}$ = 3.2, $J_{3,4}$ = 9.0 Hz, H-3), 3.42 (dd, 1H, $J_{4,5}$ = 9.5, $J_{5,6}$ = 5.3, $J_{5,6'}$ = 2.0 Hz, H-5), 2.53 (s, 1H, OH); ^{13}Cmr ($CDCl_3$) δ: 97.97 ($J_{C\text{-}1,H\text{-}1}$ = 156.90 Hz, C-1). *Anal.* calcd. for $C_{34}H_{36}O_6$: C 75.53, H 6.71; found: C 75.11, H 6.74.

*2,2,2-Trichloroethyl 3-*O*-benzyl-4,6-*O*-benzylidene-β-D-glucopyranoside (**6**a)* (see ref. 60*a*)

2,2,2-Trichloroethyl 4,6-*O*-benzylidene-β-D-glucopyranoside (3.0 g, 7.5 mmol) was stirred with benzyl bromide (1.6 g, 9.35 mmol), tetra-*n*-butylammonium bromide (0.6 g, 1.9 mmol), and a 10% aqueous solution of sodium hydroxide (8 mL) at room temperature. After 8 h the aqueous phase was exchanged and stirring was continued for 5 h. The organic phase was separated, washed with water, evaporated, and the residual mixture resolved by flash chromatography to give **6***a* (0.48 g, 13.0%): mp 101.5–102.5°C (hexanes – ethyl ether); $[\alpha]_D$ −38.9° (*c* 1.6, chloroform). The major product has been reported (60*a*) to be the 2-*O*-benzyl isomer.

*Methyl 4,6-*O*-benzylidene-2-deoxy-2-fluoro-3-*O*-methyl-β-D-glucopyranoside (**14**)*

Methyl 4,6-*O*-benzylidene-3-*O*-methyl-β-D-mannopyranoside (38) (**1***a*) (0.133 g, 0.45 mmol) was dissolved in dichloromethane (5 mL) and pyridine (0.11 mL, 1.3 mmol) and the solution cooled in an ice–salt bath. Trifluoromethanesulfonic anhydride (0.20 mL, 1.2 mmol) was added dropwise; tlc indicated that the reaction was complete in less than 10 min. The reaction mixture was washed sequentially with ice-cold, dilute hydrochloric acid and water, dried ($MgSO_4$), and evaporated, to give the 2-*O*-triflyl derivative **1***b*, which was used immediately in the next step without further purification. TASF (0.42 g, 1.37 mmol)[5] was added in one portion to a cold (salt bath) solution of **1***b* in dichloromethane (5 mL). The reaction flask was removed from the cooling bath and after 10 min the reaction mixture was washed with water, dried ($MgSO_4$), evaporated, and purified by flash chromatography (hexanes – ethyl ether, 2:1 (v/v)) to give **14** (0.086 g, 64%): mp 107–108°C; $[\alpha]_D$ −39.6° (*c* 0.79, chloroform) (lit. (61) mp 108°C).

*Methyl 3-*O*-benzyl-4,6-*O*-benzylidene-2-deoxy-2-fluoro-β-D-glucopyranoside (**15**)*

To a cold (salt bath) solution of **2***a* (0.248 g, 0.66 mmol) in dichloromethane (7 mL) and pyridine (0.4 mL), triflic anhydride (0.45 mL, 2.7 mmol) was added dropwise during 2 min. The reaction solution was removed from the cooling bath and the reaction was monitored by tlc. After 15 min, the reaction solution was washed sequentially with ice-cold, 0.1 *M* HCl, and water (2×), dried ($MgSO_4$), evaporated, and dried under vacuum (1.33 Pa) for 1 h, to give **2***b*: ^{1}Hmr ($CDCl_3$) δ: 5.62 (s, 1H, PhCHO_2), 5.11 (d, 1H, $J_{2,1}$ = 3.0 Hz, H-2), 4.80 (AB, 2H, *J* = 13.0, 22.5 Hz, CH_2Ph), 4.51 (s, 1H, H-1), 4.33 (dd, 1H, $J_{6,5}$ = 4.7, $J_{6,6'}$ = 10.5 Hz, H-6_{eq}), 4.00 (t, 1H, $J_{4,3}$ = $J_{4,5}$ = 9.5 Hz, H-4), 3.90 (t, 1H, $J_{6',5}$, $J_{6',6}$ = 10.2, 10.5 Hz, H-6_{ax}), 3.76 (dd, 1H, $J_{3,2}$ = 3.0, $J_{3,4}$ = 9.7 Hz, H-3), 3.55 (s, 3H, OCH_3), 3.38 (ddd, 1H, $J_{5,4}$ = 9.4, $J_{5,6}$ = 5.0, $J_{5,6'}$ = 9.8 Hz, H-5). This compound was used immediately in the succeeding step.

Compound **2***b* was dissolved in cold (salt bath) dichloromethane (10 mL); TASF (0.55 g, 1.8 mmol) was added, and the solution was heated at reflux temperature for 10 min. The reaction solution was washed with water, dried ($MgSO_4$), and evaporated. The residue was shown by tlc (hexanes – ethyl ether, 1:1 (v/v)) to consist of two components having R_f values of 0.61 and 0.51. The mixture was resolved by flash chromatography (hexanes – ethyl acetate, 4:1 (v/v)) to give **15** (0.112 g, 44.9%): mp 155–158°C; $[\alpha]_D$ −45.6° (*c* 0.55, chloroform) (lit. (34*c*) mp 156–158°C; $[\alpha]_D$ −42° (*c* 0.85, chloroform)); ^{1}Hmr ($CDCl_3$) δ: 5.56 (s, 1H, PhCHO_2), 4.85 (AB, 2H, *J* = 12.0, 18.0 Hz, CH_2Ph), 4.48 (dd, 1H, $J_{1,2}$ = 7.5, $J_{1,F}$ = 4.0 Hz, H-1), 4.36 (dd, 1H, $J_{5,6'}$ = 5.0, $J_{6,6'}$ = 10.6 Hz, H-6_{eq}), 4.33 (dt, 1H, $J_{2,1}$ = $J_{2,3}$ = 8.0, $J_{2,F}$ = 49.5 Hz, H-2), 3.84 (dt, 1H, $J_{3,2}$ = 8.6, $J_{3,4}$ = 9.0, $J_{3,F}$ = 15.0 Hz, H-3), 3.78 (t, 1H, $J_{6',5}$ = 10.0, $J_{6',6}$ = 10.5 Hz, H-6_{ax}), 3.67 (t, 1H, $J_{4,3}$ = $J_{4,5}$ = 9.5 Hz, H-4), 3.57 (s, 3H, OCH_3), 3.43 (dt, 1H, $J_{5,4}$ = $J_{5,6}$ = 9.5, $J_{5,6'}$ = 5.0 Hz, H-5); ^{13}Cmr ($CDCl_3$) δ: 102.14 ($J_{C\text{-}1,F}$ = 23.8 Hz, C-1), 101.31 (PhCHO_2), 92.85 ($J_{C\text{-}2,F}$ = 186.9 Hz, C-2), 80.46 ($J_{C\text{-}4,F}$ = 8.9 Hz, C-4), 78.85 ($J_{C\text{-}3,F}$ = 19.4 Hz, C-3), 74.35, 68.56 (C-6, CH_2Ph), 66.16 (C-5), 57.37 (OCH_3); ^{19}Fmr φ: 198.27 (ddd, $J_{F,1}$ = 4.2, $J_{F,2}$ = 49.6, $J_{F,3}$ = 15.0 Hz). The second component tentatively has been designated methyl 3-*O*-benzyl-4,6-*O*-benzylidene-2-deoxy-β-D-*erythro*-hex-3-enopyranoside (0.045 g, 19.1%): ^{1}Hmr ($CDCl_3$) δ: 5.63 (s, 1H, PhCHO_2), 5.40 (t, 1H, $J_{2,1}$, $J_{2,4}$ < 1 Hz, H-2), 4.88 (AB, 2H, *J* = 12.5, 21.0 Hz, PhCH_2), 4.70 (bs, 1H, H-1), 4.50 (dt, 1H, $J_{4,2}$, $J_{4,1}$ < 1, $J_{4,5}$ = 8.4 Hz, H-4), 4.33 (dd, 1H, $J_{6,5}$ = 4.5, $J_{6,6'}$ = 10.3 Hz, H-6_{eq}), 4.00 (t, 1H, $J_{6',5}$ = 10.0, $J_{6',6}$ = 10.5 Hz, H-6_{ax}), 3.82 (ddd, 1H, $J_{5,4}$ = 8.5, $J_{5,6}$ = 4.2, $J_{5,6'}$ = 9.6 Hz, H-5).

*Benzyl 3,4,6-tri-*O*-benzyl-2-deoxy-2-fluoro-β-D-glucopyranoside (**16**)*

Compound **3***a* (0.270 g, 0.499 mmol) was converted into the corresponding triflate, **3***b*, by reaction with triflic anhydride (0.3 mL, 1.8 mmol) and pyridine (0.4 mL) in the manner described for **1***b*. TASF (0.471 g, 1.71 mmol) was added to a solution of **3***b* in cold dichloromethane (8 mL); the solution was heated at reflux temperature and the reaction was judged to be complete (tlc) after 30 min. Flash chromatography (hexanes – ethyl ether, 72:28 (v/v)) of the reaction product afforded a more polar, unstable, unidentified compound, and **16** (0.030 g, 11%): $[\alpha]_D$ −21.5° (*c* 1.57, chloroform) (lit. (33) $[\alpha]_D^{22}$ −13° (*c* 0.85, chloroform)); ^{1}Hmr ($CDCl_3$) δ: 4.98–4.51 (m, 9H, CH_2Ph, H-1), 4.43 (dt, 1H, $J_{2,1}$ = $J_{2,3}$ = 8.0, $J_{2,F}$ = 50.1 Hz, H-2), 3.80–3.61 (m, 4H, H-3, -4, -6, -6′), 3.46 (ddd, 1H, $J_{5,4}$ = 9.6, $J_{5,6}$ = 4.3, $J_{5,6'}$ = 2.0 Hz, H-5); ^{13}Cmr ($CDCl_3$) δ: 99.21 ($J_{C\text{-}1,F}$ = 22.1 Hz, C-1), 93.34 ($J_{C\text{-}2,F}$ = 187.3 Hz, C-2), 83.42 ($J_{C\text{-}3,F}$ = 15.7 Hz, C-3); ^{19}Fmr ($CDCl_3$) φ: 195.82 (ddd, $J_{F,2}$ = 50.1, *J* = 15.2, 2.0 Hz).

[5]The molar quantities of TASF reported are based on an assumed purity of 90%, as reported by the manufacturer.

*The reaction of benzyl 3,4,6-tri-O-benzyl-2-O-trifluoromethanesulfonyl-α-D-mannopyranoside (**4**b) with TASF to produce **17***

Compound **4***a* (62) (0.413 g, 0.764 mmol) was converted into **4***b* by reaction with triflic anhydride (0.45 mL, 2.7 mmol) and pyridine (0.5 mL) in dichloromethane (8 mL) in the manner described for **2***b*. The triflate **4***b*, in dichloromethane (5 mL), was treated with TASF (0.630 g, 2.29 mmol) for 50 min in the manner described for **15**. Flash chromatography of the residue from the reaction solution, using hexanes – ethyl ether (3:1 (v/v)), afforded 0.31 g (~77%) of a product that underwent some decomposition during chromatography to give two new compounds having greater polarity than the original product. The reaction product had $[\alpha]_D$ +73.90° (*c* 1, chloroform); ^{1}Hmr ($CDCl_3$) δ: 5.30 (d, 1H, $J_{2,1}$ = 3.5 Hz, H-2), 4.89 (d, 1H, $J_{1,2}$ = 3.5 Hz, H-1), 4.88–4.39 (m, 8H, C*H*$_2$Ph), 4.29 (d, 1H, $J_{4,5}$ = 9.2 Hz, H-4), 4.19 (ddd, 1H, $J_{5,4}$ = 9.2, $J_{5,6}$ = 3.8, $J_{5,6'}$ = 2.1 Hz, H-5), 3.64 (doubled AB, 2H, AB *J* = 10.5, 41.5, $J_{6,5}$ = 4.0, $J_{6',5}$ = 2.0 Hz, H-6, H-6'). These data are consistent with the product having the structure represented by **17**.

*Methyl 4,6-O-benzylidene-2-deoxy-2-fluoro-3-O-methyl-β-D-mannopyranoside (**18**)*

Methyl 4,6-*O*-benzylidene-3-*O*-methyl-β-D-glucopyranoside (**5***a*) (62) (0.273 g, 0.92 mmol) in dichloromethane (5 mL) was converted into **5***b* by reaction with triflic anhydride (0.5 mL, 3.0 mmol) and pyridine (0.7 mL) in the manner described for **1***b*. The product (**5***b*) was dissolved in cold, 1:1 (v/v) dichloromethane–acetonitrile (10 mL), TASF (0.815 g, 2.96 mmol) was added, and the solution heated at reflux temperature for 1 h. The reaction product was obtained in the manner described for **14** and was purified by flash chromatography (hexanes – ethyl acetate, 64:36 (v/v)) to give an unidentified compound (0.043 g), and **18** (0.179 g, 65.1%): mp 177–178°C (from hexanes – ethyl ether); $[\alpha]_D$ −64.8° (*c* 1.24, chloroform) (lit. (34*b*) mp 180–182°C; $[\alpha]_D$ −30° (*c* 0.3, chloroform)); ^{1}Hmr ($CDCl_3$) δ: 5.58 (s, 1H, PhC*H*O$_2$), 4.87 (dd, 1H, $J_{2,3}$ = 2.5, $J_{2,F}$ = 50 Hz, H-2), 4.45 (d, 1H, $J_{1,F}$ = 19.0 Hz, H-1), 4.35 (dd, 1H, $J_{6,5}$ = 4.8, $J_{6,6'}$ = 10.5 Hz, H-6$_{eq}$), 4.00 (dt, 1H, $J_{4,3}$, $J_{4,5}$ = 9.3, 9.6, $J_{4,F}$ = 1.6 Hz, H-4), 3.88 (t, 1H, $J_{6',5}$ = 10.2, $J_{6',6}$ = 10.5 Hz, H-6$_{ax}$), 3.58 (s, 3H, OCH_3), 3.56 (s, 3H, OCH_3), 3.48 (ddd, 1H, $J_{3,2}$ = 2.5, $J_{3,4}$ = 8.6, $J_{3,F}$ = 26.0 Hz, H-3), 3.40 (dt, 1H, $J_{5,4}$ = 10.0, $J_{5,6}$ = 5.0, $J_{5,6'}$ = 10.0 Hz, H-5); ^{13}Cmr ($CDCl_3$) δ: 101.68 (PhC*H*O$_2$), 100.37 ($J_{C\text{-}1,F}$ = 15.6 Hz, C-1), 87.50 ($J_{C\text{-}2,F}$ = 189.6 Hz, C-2), 78.38 (C-4), 72.28 ($J_{C\text{-}3,F}$ = 20.6 Hz, C-3), 68.42 (C-6), 66.99 (C-5), 58.60, 57.54 (OCH_3); ^{19}Fmr ($CDCl_3$) φ: 219.447 (ddd, $J_{F,1}$ = 18.9, $J_{F,2}$ = 50.25, $J_{F,3}$ = 26.25 Hz). *Anal.* calcd. for $C_{15}H_{19}FO_5$: C 60.39, H 6.42, F 6.37; found: C 60.20, H 6.37, F 6.25.

*2,2,2-Trichloroethyl 3-O-benzyl-4,6-O-benzylidene-2-deoxy-2-fluoro-β-D-mannopyranoside (**19**)*

Compound **6***a* (0.267 g, 0.545 mmol) was converted into the triflate **6***b* by reaction with triflic anhydride (0.25 mL, 1.5 mmol) and pyridine (0.5 mL) in dichloromethane (7 mL) in the manner described for **1***b*. The product (**6***b*) was dissolved in cold dichloromethane (7 mL), TASF (0.470 g, 1.71 mmol) was added, and the reaction solution was heated at reflux temperature for 5 h. The reaction products were isolated in the manner described for **14** and the mixture was resolved by flash chromatography (hexanes – ethyl ether, 3:1 (v/v)) to give two unidentified products, and **19** (0.061 g, 22.7%): $[\alpha]_D$ −24.6° (*c* 1.45, chloroform); ^{1}Hmr ($CDCl_3$) δ: 5.65 (s, 1H, PhC*H*O$_2$), 4.96 (dd, 1H, $J_{2,3}$ = 2.5, $J_{2,F}$ = 49.8 Hz, H-2), 4.85 (d, 1H, $J_{1,F}$ = 18.6 Hz, H-1), 4.84 (AB, 2H, *J* = 22.5, 12.0 Hz, C*H*$_2$Ph), 4.37 (dd, 1H, $J_{6,5}$ = 4.8, $J_{6,6'}$ = 10.0 Hz, H-6$_{eq}$), 4.34 (AB, 2H, *J* = 12.0, 94.5 Hz, CH_2CCl_3), 4.14 (dt, 1H, $J_{4,3}$ = $J_{4,5}$ = 9.5, $J_{4,F}$ = 1.5 Hz, H-4), 3.93 (t, 1H, $J_{6',5}$ = $J_{6',6}$ = 10.0 Hz, H-6$_{ax}$), 3.71 (ddd, 1H, $J_{3,2}$ = 2.5, $J_{3,4}$ = 9.5, $J_{3,F}$ = 25.8 Hz, H-3), 3.43 (dt, 1H, $J_{5,4}$ = $J_{5,6'}$ = 10.0, $J_{5,6}$ = 5.0 Hz, H-5); ^{13}Cmr ($CDCl_3$) δ: 101.65 (PhC*H*O$_2$), 99.55 ($J_{C\text{-}1,F}$ = 16.5 Hz, C-1), 96.06 (CH_2CCl_3), 87.89 ($J_{C\text{-}2,F}$ = 190.4 Hz, C-2), 80.43 (C*H*$_2$CCl$_3$), 77.97 (C-4), 75.60 ($J_{C\text{-}3,F}$ = 16.5 Hz, C-3), 72.60, 68.23 (C*H*$_2$Ph, C-6), 67.42 (C-5); ^{19}Fmr ($CDCl_3$) φ: 218.82 (ddd, $J_{F,1}$ = 18.5, $J_{F,2}$ = 50.0, $J_{F,3}$ = 26.0 Hz). *Anal.* calcd. for $C_{22}H_{22}Cl_3FO_5$: C 53.73, H 4.51; found: C 53.34, H 4.55.

*Methyl 4,6-O-benzylidene-3-deoxy-3-fluoro-2-O-methyl-β-D-allopyranoside (**20**)*

Methyl 4,6-*O*-benzylidene-2-*O*-methyl-β-D-glucopyranoside (**7***a*) (63) (0.27 g, 0.91 mmol) was converted into the triflate **7***b* by reaction with triflic anhydride (0.5 mL, 3.0 mmol) and pyridine (0.7 mL) in the manner described for **1***b*. The triflate **7***b* was dissolved in cold dichloromethane (8 mL) and TASF (0.75 g, 2.7 mmol) was added. The reaction flask was removed from the cooling bath and the reaction was judged (tlc) to be complete in less than 10 min. After the usual isolation procedure the product was purified by flash chromatography (hexanes – ethyl ether, 45:55 (v/v)) to give **20** (0.176 g, 64.7%): mp 157–158°C (hexanes – ethyl ether); $[\alpha]_D$ −87.2° (*c* 1.0, chloroform); ^{1}Hmr ($CDCl_3$) δ: 5.52 (s, 1H, PhC*H*O$_2$), 5.16 (dt, 1H, $J_{3,2}$ = $J_{3,4}$ = 1.5, $J_{3,F}$ = 54.0 Hz, H-3), 4.68 (dd, 1H, $J_{1,2}$ = 7.9, $J_{1,F}$ = 1.0 Hz, H-1), 4.41 (dd, 1H, $J_{6,5}$ = 5.0, $J_{6,6'}$ = 10.0 Hz, H-6$_{eq}$), 3.94 (ddt, 1H, $J_{5,4}$ = $J_{5,6'}$ = 10.0, $J_{5,6}$ = 5.0, $J_{5,F}$ = 1.0 Hz, H-5), 3.74 (dt, 1H, $J_{6',5}$ = $J_{6',6}$ = 10.0, $J_{6',F}$ = 1.5 Hz, H-6$_{ax}$), 3.61–3.49 (m, 7H, OCH_3, H-4), 3.15 (ddd, 1H, $J_{2,1}$ = 8.0, $J_{2,3}$ = 2.0, $J_{2,F}$ = 27.0 Hz, H-2); ^{13}Cmr ($CDCl_3$) δ: 102.02 (PhC*H*O$_2$), 86.90 ($J_{C\text{-}5,F}$ = 183.3 Hz, C-3), 78.99 ($J_{C\text{-}2,F}$ = 17.0 Hz, C-2), 77.30 ($J_{C\text{-}4,F}$ = 17.2 Hz, C-4), 69.01 (C-6), 62.88 ($J_{C\text{-}5,F}$ = 2.5 Hz, C-5), 58.41, 57.32 (OCH_3); ^{19}Fmr ($CDCl_3$) φ: 213.99 (quintet, $J_{F,2}$ = $J_{F,4}$ = 27.0, $J_{F,3}$ = 54.0 Hz). *Anal.* calcd. for $C_{15}H_{19}FO_5$: C 60.39, H 6.42, F 6.37; found: C 60.21, H 6.40, F 6.01.

*Methyl 2,3,6-tri-O-benzyl-4-deoxy-4-fluoro-β-D-galactopyranoside (**21**)*

A solution of methyl 2,3,6-tri-*O*-benzyl-β-D-glucopyranoside (**8***a*) (64) (0.257 g, 0.55 mmol) in pyridine (0.7 mL) and dichloromethane (6 mL) was converted into the 4-*O*-triflyl derivative **8***b* by treatment with triflic anhydride (0.3 mL, 1.78 mmol) in the manner described for **1***b*. To a solution of **8***b* in cold dichloromethane (8 mL) was added TASF (0.494 g, 1.79 mmol). The reaction was performed as described for **16** and was judged (tlc) to be complete after 20 min. The reaction product was obtained in the usual manner and purified by flash chromatography (hexanes – ethyl acetate, 3:1 (v/v)) to give **21** (0.198 g, 76.7%): $[\alpha]_D$ −10.1° (*c* 5.94, chloroform); ^{1}Hmr ($CDCl_3$) δ: 4.82 (dd, 1H, $J_{4,3}$ = 2.8, $J_{4,F}$ = 49.5 Hz, H-4), 4.91–4.69 (m, 4H, C*H*$_2$Ph), 4.56 (s, 2H, C*H*$_2$Ph), 4.29 (d, 1H, $J_{1,2}$ = 8.0 Hz, H-1), 3.77–3.59 (m, 4H, H-2, -5, -6, -6'), 3.56 (s, 3H, OCH_3), 3.49 (ddd, 1H, $J_{3,2}$ = 9.5, $J_{3,4}$ = 2.5, $J_{3,F}$ = 28.5 Hz, H-3); ^{13}Cmr ($CDCl_3$) δ: 104.52 (C-1), 85.86 ($J_{C\text{-}4,F}$ = 183.4 Hz, C-4), 78.99 (C-2), 78.89 ($J_{C\text{-}3,F}$ = 18.9 Hz, C-3), 72.06 ($J_{C\text{-}5,F}$ = 17.5 Hz, C-5), 67.74 ($J_{C\text{-}6,F}$ = 5.8 Hz, C-6), 75.22, 73.66 and 72.34 (C*H*$_2$Ph), 57.04 (OCH_3); ^{19}Fmr ($CDCl_3$) φ: 217.23 (dt, $J_{F,3}$ = 27.5, $J_{F,4}$ = 49.8, $J_{F,5}$ = 27.6 Hz). *Anal.* calcd. for $C_{28}H_{31}FO_5$: C 72.08, H 6.70, F 4.07; found: C 71.94, H 6.78, F 3.96.

*Methyl 2,3,6-tri-O-benzyl-4-deoxy-4-fluoro-α-D-glucopyranoside (**22**)*

Methyl 2,3,6-tri-*O*-benzyl-α-D-galactopyranoside (**9***a*) (52) (0.633 g, 1.36 mmol) was treated with triflic anhydride (0.55 mL, 3.3 mmol) in pyridine (0.7 mL) in the manner described for **1***b*, to form **9***b*. The product (**9***b*) was dissolved in cold dichloromethane (~15 mL) and TASF (1.061 g, 3.85 mmol) was added. The flask was removed from the ice–salt bath and allowed to warm at ambient temperature. The reaction was stopped after 10 min by the addition of water. The reaction product was isolated in the manner described for **14** and purified by flash chromatography (hexanes – ethyl ether 2:1 (v/v)) to give **22** (0.427 g, 67.1%): $[\alpha]_D$ +18.8° (*c* 3.52, chloroform);[6] ^{1}Hmr ($CDCl_3$) δ: 4.86–4.54 (m, 7H, C*H*$_2$Ph, H-1), 4.52 (dt, 1H, $J_{4,3}$, $J_{4,5}$ = 8.6, 8.5, $J_{4,F}$ = 50.2 Hz, H-4), 4.01 (dt, 1H, $J_{3,2}$ = $J_{3,4}$ = 9.0, $J_{3,F}$ =

[6]Compound **22** has been reported (1*c*) to have $[\alpha]_D^{23}$ +48.8° (*c* 1.23, chloroform); however, repetition of the reported procedure by us afforded a product established to be **22**, which has $[\alpha]_D$ +19.0° (*c* 2.3, chloroform).

15.5 Hz, H-3), 3.84 (m, 1H, H-5), 3.67 (m, 2H, H-6, H-6′), 3.50 (dd, 1H, $J_{2,1}$ = 3.3, $J_{2,3}$ = 9.5 Hz, H-2), 3.39 (s, 3H, OCH_3); ^{13}Cmr ($CDCl_3$) δ: 98.14 (C-1), 89.68 ($J_{C\text{-}4,F}$ = 183.4 Hz, C-4), 79.74 ($J_{C\text{-}3,F}$ = 17.0 Hz, C-3), 78.41 ($J_{C\text{-}2,F}$ = 8.0 Hz, C-2), 68.06 ($J_{C\text{-}5,F}$ = 24.0 Hz, C-5), 75.18, 73.64 and 73.56 (CH_2Ph), 68.02 (C-6), 55.38 (OCH_3); ^{19}Fmr ($CDCl_3$) ϕ: 194.81 (dd, $J_{F,3}$ = 15.5, $J_{F,4}$ = 50.5 Hz). *Anal.* calcd. for $C_{28}H_{31}FO_5$: C 72.08, H 6.70, F 4.07; found: C 72.05, H 6.69, F 4.12.

*6-Deoxy-6-fluoro-1,2:3,4-di-*O*-isopropylidene-α-*D*-galactopyranose (**23**)*

1,2:3,4-Di-*O*-isopropylidene-α-D-galactopyranose (**10***a*) (65) (0.481 g, 1.85 mmol) was converted into the 6-*O*-triflyl derivative **10***b* by reaction with triflic anhydride (0.77 mL, 4.63 mmol) and pyridine (0.44 mL, 5.56 mmol) in the manner described for **1***b*. Compound **10***b*, in dichloromethane (10 mL), was treated with TASF (1.79 g, 5.84 mmol) under the conditions used for **14**. The reaction product was purified by flash chromatography (toluene – ethyl ether, 19:1 (v/v)) to give **23** (0.345 g, 71%): $[\alpha]_D$ −54.8° (*c* 3.18, chloroform) (lit. (53) $[\alpha]_D$ −51.4° (*c* 1.28, chloroform); ^{13}Cmr ($CDCl_3$) δ: 95.95 (C-1), 81.84 ($J_{C\text{-}6,F}$ = 168.2 Hz, C-6), 70.39, 70.31, 70.22 (C-2, C-3, C-4), 66.49 ($J_{C\text{-}5,F}$ = 22.0 Hz, C-5); ^{19}Fmr ($CDCl_3$) ϕ: 226.57 (dt, $J_{F,5}$ = 13.0, $J_{F,6}$ = 47.5 Hz).

*Methyl 2,3-di-*O*-benzyl-4,6-dideoxy-4,6-difluoro-β-*D*-galactopyranoside (**24**)*

Methyl 2,3-di-*O*-benzyl-β-D-glucopyranoside (**11***a*) (66) (0.187 g, 0.499 mmol) was converted into the corresponding ditriflate **11***b* by treatment with triflic anhydride (0.5 mL, 3.0 mmol) and pyridine (0.5 mL) in dichloromethane (7 mL) in the usual manner. Compound **11***b* was reacted with TASF (0.850 g, 3.09 mmol) in dichloromethane (8 mL) at reflux temperature for 30 min. Flash chromatography (hexanes – ethyl ether, 60:28 (v/v)) of the reaction product afforded a less polar, unidentified compound (0.060 g), and **24** (0.074 g, 39.1%): mp 74–75°C (hexanes – ethyl ether); $[\alpha]_D$ − 13.8° (*c* 2.89, chloroform); ^{1}Hmr ($CDCl_3$) δ: 4.81 (AB, 2H, *J* = 11.1, 53.7 Hz, CH_2Ph), 4.74 (dd, 1H, $J_{4,3}$ = 2.4, $J_{4,F}$ = 49.9 Hz, H-4), 4.73 (s, 2H, CH_2Ph), 4.57 (dd, 2H, $J_{6,5}$ = 6.3, $J_{6,F}$ = 46.0 Hz, H-6, H-6′), 4.30 (d, 1H, $J_{1,2}$ = 7.7 Hz, H-1), 3.74–3.58 (m, 2H, H-2, H-5), 3.56 (s, 3H, OCH_3), 3.50 (ddd, 1H, $J_{3,2}$ = 9.5, $J_{3,4}$ = 2.5, $J_{3,F}$ = 28.5 Hz, H-3); ^{13}Cmr ($CDCl_3$) δ: 104.47 (PhCHO_2), 85.44 ($J_{C\text{-}4,F\text{-}4}$ = 181.2, $J_{C\text{-}4,F\text{-}6}$ = 4.0 Hz, C-4), 80.45 ($J_{C\text{-}6,F\text{-}4}$ = 5.9, $J_{C\text{-}6,F\text{-}6}$ = 169.1 Hz, C-6), 78.69 (C-2), 78.47 ($J_{C\text{-}3,F\text{-}4}$ = 17.7 Hz, C-3), 75.21, 72.43 (CH_2Ph), 71.29 (*J* = 17.8, 23.8 Hz, C-5); ^{19}Fmr ($CDCl_3$) ϕ: 216.86 (dt, $J_{F\text{-}4,H\text{-}3}$ = 27.8, $J_{F\text{-}4,H\text{-}4}$ = 50.3, $J_{F\text{-}4,H\text{-}5}$ = 27.7 Hz, F-4), 231.20 (dt, $J_{F\text{-}6,H\text{-}5}$ = 10.6, $J_{F\text{-}6,H\text{-}6,\text{-}6'}$ = 46.3 Hz, F-6). *Anal.* calcd. for $C_{21}H_{24}F_2O_4$: C 66.65, H 6.39, F 10.04; found: C 66.50, H 6.40, F 9.10.

*3-Deoxy-3-fluoro-1,2:5,6-di-*O*-isopropylidene-α-*D*-glucofuranose (**25**)*

1,2:5,6-Di-*O*-isopropylidene-α-D-allofuranose (**12***a*) (67) (0.428 g, 1.85 mmol) in dichloromethane (6 mL) was treated with triflic anhydride (0.76 mL, 4.54 mmol) and pyridine (0.45 mL, 5.56 mmol) as described for **1***b*. The reaction was complete in <10 min to give **12***b*, which was immediately dissolved in cold dichloromethane (10 mL) and treated with TASF (1.76 g, 5.74 mmol) in the manner described for **14**. The reaction product was purified by flash chromatography (hexanes – ethyl ether, 4:1 (v/v)) to give **25** (0.321 g, 66%): $[\alpha]_D$ −21.4° (*c* 1.15, chloroform) (lit. (54) $[\alpha]_D$ −22° (*c* 1.0, chloroform)); ^{13}Cmr ($CDCl_3$) δ: 105.15 (C-1), 93.79 ($J_{C\text{-}3,F}$ = 183.4 Hz, C-3), 82.54 ($J_{C,F}$ = 32.9 Hz, C-2 or C-4), 80.65 ($J_{C,F}$ = 19.0 Hz, C-2 or C-4), 71.88 ($J_{C\text{-}5,F}$ = 7.5 Hz, C-5), 67.16 (C-6); ^{19}Fmr ($CDCl_3$) ϕ: 207.97 (ddd, $J_{F,2}$ = 10.6, $J_{F,3}$ = 49.8, $J_{F,4}$ = 29.0 Hz).

*3-Deoxy-1,2:5,6-di-*O*-isopropylidene-α-*D*-erythro-hex-3-enofuranose (**26**)*

1,2:5,6-Di-*O*-isopropylidene-α-D-glucofuranose (**13***a*) (68) (0.114 g, 0.44 mmol) in dichloromethane (5 mL) was converted into the 3-*O*-triflyl derivative **13***b* by reaction with triflic anhydride (0.18 mL, 1.09 mmol) and pyridine (0.11 mL, 1.36 mmol) in the usual manner. Compound **13***b* was dissolved in dichloromethane (5 mL) and reacted with TASF (0.42 g, 1.37 mmol) as described for **14**. Flash chromatography (hexanes – ethyl ether, 4:1 (v/v)) of the residue from the reaction solution afforded **26** (0.088 g, 83%): $[\alpha]_D$ +15.3° (*c* 1.1 ethanol) (lit. (55) $[\alpha]_D$ +19.8° (*c* 3.03, ethanol)).

Received July 14, 1986

JOHN S. HAYNES, STEVEN J. RETTIG, JOHN R. SAMS, ROBERT C. THOMPSON, and JAMES TROTTER. Can. J. Chem. **65**, 420 (1987).

Crystals of poly-bis(pyrazine)bis(methanesulfonato-*O*)copper(II) are orthorhombic, $a = 8.199(1)$, $b = 13.130(1)$, $c = 6.913(1)$ Å, $Z = 2$, space group *Pnnm*. The structure was solved by conventional heavy atom methods and was refined by full-matrix least-squares procedures to $R = 0.025$ and $R_w = 0.033$ for 1226 reflections with $I \geq 3\sigma(I)$. The complex contains parallel sheets, each sheet consisting of a square array of copper(II) ions bridged by two types of bidentate pyrazine ligands. The CuN_4O_2 chromophore is tetragonally elongated; the equatorial plane contains two pyrazine nitrogen atoms (Cu—N(1) = 2.058(2) Å) and two oxygen atoms from monodentate methanesulfonate ligands (Cu—O(1) = 1.956(1) Å); the axial sites are occupied by bridging pyrazine groups with significantly longer Cu—N bond lengths (Cu—N(2) = 2.692(2) Å). Magnetic susceptibility studies (82 to 4.2 K) reveal antiferromagnetic behaviour with a susceptibility maximum at about 6.2 K. Exchange coupling in the complex is considered to take place primarily via the more strongly bound, equatorially coordinated pyrazine ligands. Analysis of the magnetic susceptibility data according to a Heisenberg linear chain of interacting $S = 1/2$ spins yields best fit values of $J = -3.82\ cm^{-1}$ and $g = 2.13$. Vibrational and electronic spectroscopic and differential scanning calorimetric studies on the title compound and, for comparison, on the related mononuclear pyridine complex, bis(methanesulfonato)-tetrakis(pyridine)copper(II), are also reported.

JOHN S. HAYNES, STEVEN J. RETTIG, JOHN R. SAMS, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **65**, 420 (1987).

Les cristaux du poly-bis(pyrazine)bis(méthanesulfonato-*O*)cuivre(II) sont orthorhombiques et ils cristallisent dans le groupe d'espace *Pnnm* avec $a = 8{,}199(1)$, $b = 13{,}130(1)$ et $c = 6{,}913(1)$ Å et $Z = 2$. On a résolu la structure par les méthodes conventionnelles aux atomes lourds et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de $R = 0{,}025$ et $R_w = 0{,}033$ pour 1226 réflexions avec $I \geq 3\sigma(I)$. Le complexe comporte des feuilles parallèles et chaque feuille comprend un arrangement carré d'ions de cuivre(II) qui sont pontés par deux types de ligands pyrazines bidentates. Le chromophore CuN_4O_2 est un tétragone allongé; le plan équatorial contient deux atomes d'azote de la pyrazine (Cu—N(1) = 2,058(2) Å) et deux atomes d'oxygène des ligands méthanesulfonates monodentates (Cu—O(1) = 1,956(1) Å); les sites axiaux sont occupés par des groupements pyrazines formant des ponts et ces longueurs des liaisons Cu—N sont beaucoup plus longues (Cu—N(2) = 2,692(2) Å). Des études de susceptibilité magnétique (de 82 à 4,2 K) révèlent l'existence d'un comportement antiferromagnétique avec une susceptibilité maximale à environ 6,2 K. On considère que, dans le complexe, le couplage d'échange se produit principalement par le biais des ligands pyrazines qui sont coordonnés d'une façon équatoriale et qui sont liés plus fortement. Une analyse des données de susceptibilité magnétique, en faisant appel d'une chaîne linéaire de Heisenberg des spins $S = 1/2$ qui interagissent, conduit à des valeurs de $J = -3{,}82\ cm^{-1}$ et $g = 2{,}13$. On rapporte aussi les études spectroscopiques, tant au niveau vibrationnel qu'électronique, ainsi que les études calorimétriques à balayage différentiel qui ont été faites sur le compos mentionné dans le titre et, pour fins de comparaison, sur le complexe pyridine mononucléaire apparenté, bis(méthanesulfonato)tétrakis(pyridine)cuivre(II).

[Traduit par la revue]

Introduction

Pyrazine-bridged complexes of the transition metals are of particular interest because of the potential for the propagation of magnetic exchange over extended distances, and some of the most fruitful investigations in this area have involved complexes of copper(II). Extensive structural and magnetic studies on complexes such as $Cu(pyz)_2(ClO_4)_2$ (1, 2), $Cu(pyz)(NO_3)_2$ (3) and the hexafluoroacetylacetonate analogue, $Cu(pyz)(hfac)_2$ (4) have shown that the magnitude of the exchange coupling in these systems is significantly affected by structural variations involving the bridging pyrazine network (5–7).

We report here the synthesis, X-ray structure determination, and characterization of the bis(pyrazine) complex of copper(II) methanesulfonate, $Cu(pyz)_2(CH_3SO_3)_2$. This compound bears a superficial structural resemblance to $Cu(pyz)_2(ClO_4)_2$ as both are two-dimensional pyrazine-bridged polymers, with unidentate coordinated anions. In the perchlorate, however, the anions occupy axial sites with all pyrazines in equivalent equatorial positions (1), while in the methanesulfonate the anions are bound in the equatorial plane and there are two distinct types of pyrazine bridges. In one dimension the pyrazines occupy equatorial positions with relatively short Cu—N bonds as in $Cu(pyz)(NO_3)_2$ (3) while in the other dimension the bridging pyrazines occupy more weakly bound axial positions as in $Cu(pyz)(hfac)_2$ (4). This novel pyrazine-bridge system makes $Cu(pyz)_2(CH_3SO_3)_2$ a particularly important candidate for cryomagnetic studies. To aid in the evaluation of the spectroscopic and magnetic properties of this compound we have also prepared and characterized the analogous pyridine derivative, $Cu(py)_4(CH_3SO_3)_2$.

Experimental

Syntheses

The bis(pyrazine) complex of copper(II) methanesulfonate was prepared by the reaction of anhydrous copper(II) methanesulfonate (8) with an excess of pyrazine (Aldrich Chemicals, gold label) in methanol. $Cu(CH_3SO_3)_2$ (2.11 mmol) was dissolved in hot methanol (3 mL) and the solution was then added to a hot solution of pyrazine (28.7 mmol) in methanol (5 mL). A pale blue precipitate formed immediately and was removed by filtration. Overnight the filtrate yielded further product in crystalline form. Total yield 81%. *Anal.* calcd. for $CuC_{10}H_{14}N_4S_2O_6$: C 29.02, H 3.41, N 13.54; found: C 28.98, H 3.60, N 13.63. Samples left exposed to the atmosphere for several hours were found

to undergo some hydration (typically less than half a mole of water per mole of complex) as indicated by the appearance of a weak, broad absorption in the 2800 to 3500 region of the infrared spectrum and by microanalysis.

The tetrakis(pyridine) complex was made by the addition of an excess of pyridine (62 mmol) to a solution of $Cu(CH_3SO_3)_2$ (4.14 mmol) in hot methanol (8 mL). Overnight, dark blue crystals formed and these were subsequently isolated by filtration in 73% yield. *Anal.* calcd. for $CuC_{22}H_{26}N_4S_2O_6$: C 46.35, H 4.60, N 9.83; found: C 46.60, H 4.70, N 9.80.

Physical measurements

Infrared and electronic spectra and differential scanning calorimetry measurements were obtained using equipment and procedures previously described (9). Magnetic susceptibilities were measured using a P.A.R. Model 155 vibrating sample magnetometer (10) and were corrected for the diamagnetism of all atoms. These corrections were (in 10^{-6} cm^3 mol^{-1}): copper, −11; $CH_3SO_3^-$, −35; pyridine, −49; pyrazine, −45. A value of 60×10^{-6} cm^3 mol^{-1} was used to correct for the temperature-independent paramagnetism of copper(II). Analyses for C, H, and N were performed by P. Borda of this department.

X-ray crystallographic analysis of poly-bis(pyrazine)bis-(methanesulfonato-O)copper(II)

A crystal bounded by the nine faces (followed by their distances in mm from a common origin): {1 1 0}, 0.213, {0 1 1}, 0.219, (−1, −1, −3), 0.150 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 47–62°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{10}H_{14}CuN_4O_6S_2$ f.w. = 413.91

Orthorhombic, a = 8.199(1), b = 13.130(1), c = 6.913(1) Å, V = 744.2(1) Å^3, Z = 2, ρ_c = 1.847 Mg m^{-3}, $F(000)$ = 422, μ(Mo-$K\alpha$) = 17.74 cm^{-1}. Absent reflections: $0kl$, $k + l$ odd, and $h0l$, $h + l$ odd, space group $Pnnm$ (D_{2h}^{12}, No. 58) from structure analysis.

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.01–10.06° min^{-1} over a range of (0.60 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 65°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 2%. After data reduction,[2] an absorption correction was applied using the Gaussian integration method (11, 12). Transmission factors ranged from 0.521 to 0.588 for 102 integration points. Of the 1447 independent reflections measured, 1226 (84.7%) had intensities greater than or equal to 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The systematic absences allow space groups $Pnn2$ and $Pnnm$, the latter being suggested by both the E-statistics and the Patterson function. The coordinates of the Cu and S atoms (which both occupy special positions) were determined from the Patterson function and those of the remaining atoms were determined from subsequent difference maps. In the final stages of refinement the non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. The scattering factors of ref. 13 were used for non-hydrogen atoms and those of ref. 14 for hydrogen atoms. Anomalous scattering factors from ref. 15 were used for the Cu and S atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 82 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (16–18). The final value of g was 1.3(2) × 10^4. Convergence was reached at R = 0.025 and R_w = 0.033 for 1226 reflections with $I \geq 3\sigma(I)$. For all 1447 reflections R = 0.034. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, $S = [\Sigma w\Delta^2/(m - n)]^{1/2}$ = 1.503.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.006 and 0.07σ, respectively. A final difference map showed maximum fluctuations of −0.93 to +0.38 e Å^{-3} (near C(4) and the midpoint of the C(2)—C(2)^1 bond, respectively). The final positional and thermal parameters appear in Tables 1 and 5, respectively.[3] Measured and calculated structure factors have been placed in the Depository for Unpublished Data.[3] Bond lengths, bond angles, and possible weak C—H···O interactions appear in Tables 2–4, respectively. Bond lengths and angles involving hydrogen (Tables 6, 7) have been deposited.

*Superscripts refer to symmetry operations: $^5x-1/2, 1/2-y, 1/2-z$; $^6x, y, z$. Other geometrical data: H(1b)···O(2)^5···H(2) = 83.1(6)°, H(2)···O(1)···H(4) = 70.5(4)°, O(1)···H(2)···O(2)^5 = 94.9(6)°.

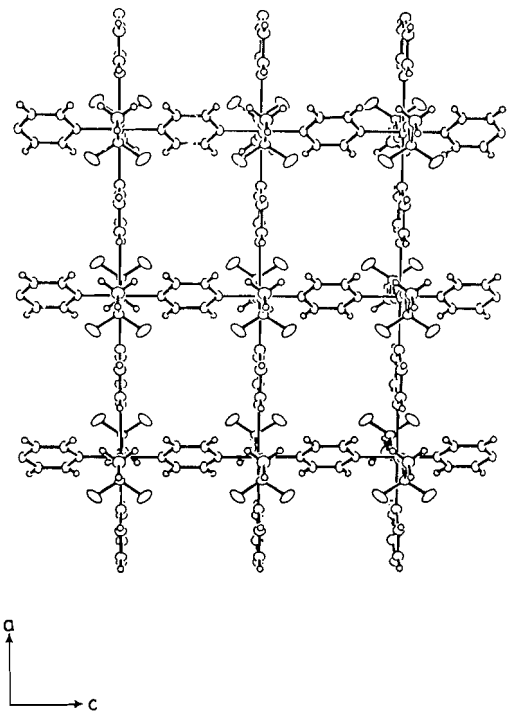

FIG. 1. View of a single layer in $Cu(N_2C_4H_4)_2(CH_3SO_3)_2$.

has tetragonally-elongated octahedral coordination (Fig. 2), the equatorial plane containing two pyrazine nitrogen atoms (Cu—N(1) = 2.058(2) Å) and two oxygen atoms from monodentate methanesulfonate ligands (Cu—O(1) = 1.956(1) Å); the axial coordination sites are occupied by bridging pyrazine groups with significantly longer Cu—N bond lengths (Cu—N(2) = 2.692(2) Å). The Cu—O bond distance is typical of an oxygen atom bound to copper in the equatorial plane; for example, in $Cu(pyz)(NO_3)_2$ the equatorial Cu—O bond distance is 2.010(4) Å (3). The Cu—N(1) distance is almost identical to the value of 2.062(3) Å found in $Cu(pyz)_2(ClO_4)_2$ (1) and only slightly longer than the Cu—N distance of 1.98 Å found in $Cu(pyz)(NO_3)_2$ (3); whereas the Cu—N(2) distance is much longer. This axial pyrazine group is even more weakly bound to copper than the axial pyrazine groups in $Cu(pyz)(hfac)_2$ (4) (Cu—N of 2.529(9) Å) and the acetate complex, $Cu_2(OAc)_4(pyz)$ (19) (Cu—N of 2.171(6) Å).

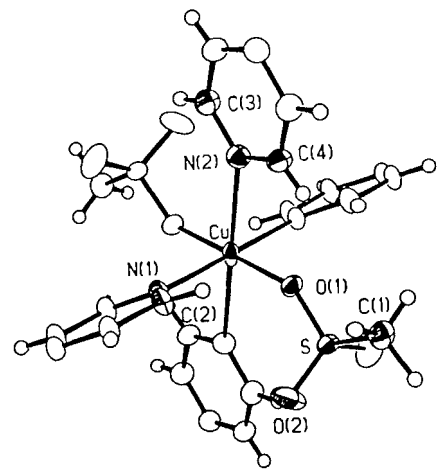

FIG. 2. Inner coordination sphere about the copper(II) ion in $Cu(N_2C_4H_4)_2(CH_3SO_3)_2$; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms; crystallographically unique atoms are shaded and labelled.

In spite of being coordinated to copper at different distances, the pyrazine rings in $Cu(pyz)_2(CH_3SO_3)_2$ have similar internal bonding parameters. Both types of pyrazine ring are planar within experimental error and the bond lengths and angles within the pyrazine rings are similar to those found in free pyrazine (20). The dimensions of the pyrazine rings compare well with those reported for other metal complexes containing bidentate bridging pyrazine ligands. For example, in the Creutz–Taube (21, 22) complex the mean C—N bond length is 1.348(9) Å and the C—C distance is 1.382(10) Å; in $Cu(pyz)_2(CH_3SO_3)_2$ these distances are 1.341(2) and 1.390(3) Å, respectively. The pyrazine rings involved in the stronger bonding to copper are canted at an angle of 28.50(8)° to the $CuN_2O_2(xy)$ plane;

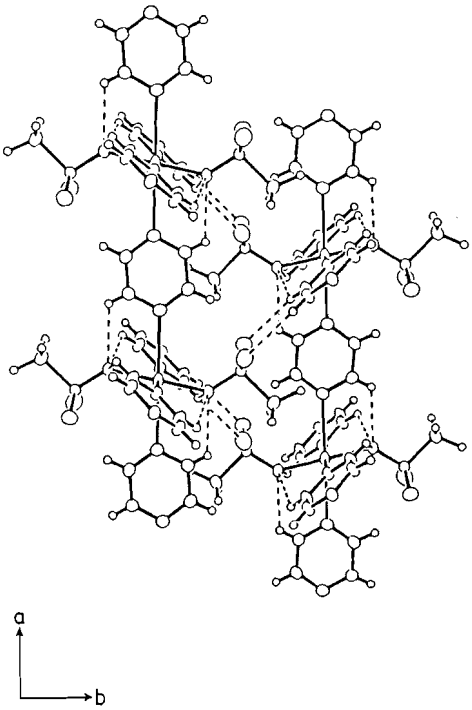

FIG. 3. Two adjacent layers in $Cu(N_2C_4H_4)_2(CH_3SO_3)_2$ viewed along the *c*-axis; hydrogen bonding interactions shown by broken lines.

whereas the pyrazine rings bonded axially lie in the $CuN_2O_2(xz)$ plane.

The $CH_3SO_3^-$ anion in $Cu(pyz)_2(CH_3SO_3)_2$ assumes a staggered-ethane configuration about the S—C bond. Repulsions between oxygen atoms on sulfur are greater than those between oxygen atoms and the methyl group; as a result, the O—S—O angles are consistently greater than the C—S—O angles. The effect of monodentate coordination on the geometry of the anion is most evident in the range of S—O bond distances observed. The S—O(1) bond involving the oxygen coordinated to copper is longest at 1.483(1) Å while the terminal S—O bonds are 1.442(1) Å. The rather long S—O(1) bond observed here compared to S to coordinated O bonding distances of 1.429–1.456 Å in $Ca(CH_3SO_3)_2$ (23), 1.445–1.462 Å in $Cu(CO)(C_2H_5SO_3)_2$ (24), 1.441 Å in $Cu(H_2O)_4(CH_3SO_3)_2$ (25), and 1.460–1.463 Å in $Cd(H_2O)_2(CH_3SO_3)_2$ (26) attest to the strength of the in-plane coordination of the $CH_3SO_3^-$ group in the pyrazine complex.

There are several C—H···O interactions which may play a role in determining the overall structure of $Cu(pyz)_2(CH_3SO_3)_2$ (Fig. 3). Intralayer C—H···O interactions between the sulfonate oxygen atom O(1) and the hydrogen atoms attached to the pyrazine rings appear to influence the canting of the pyrazine rings; H(4)···O(1) and H(2)···O(1) distances are 2.50 and 2.46 Å, respectively. The first of these interactions appears to hold the axial pyrazine group in the CuN_2O_2 plane; whereas, the second interaction may be at least partially responsible for the fact that the equatorially bound pyrazine ligand is canted at an angle of 28.5° to the CuN_2O_2 plane.

In $Cu(pyz)_2(CH_3SO_3)_2$, the layers are separated by a distance of 6.565 Å. In comparison, the interlayer separation in $Cu(pyz)_2(ClO_4)_2$ (1) is 7.012 Å. The proximity of adjacent layers in the methanesulfonate complex may result from interlayer C—H···O interactions. There appear to be two such interactions, H(1b)···O(2) (2.38 Å) and H(2)···O(2) (2.50 Å) which may be significant. Both involve the terminally bound sulfonate oxygen atom, O(2), which interacts with a hydrogen atom of a methanesulfonate anion and a hydrogen atom of the equatorially bound pyrazine ligand on an adjacent layer.

Differential scanning calorimetry (DSC)

To characterize more fully the title compound in terms of its thermal stability, particularly in view of the fact that the X-ray studies showed one of the pyrazine ligands to be relatively weakly bound, we examined the compound and the related pyridine complex, $Cu(py)_4(CH_3SO_3)_2$ by DSC. $Cu(pyz)_2(CH_3SO_3)_2$ shows an endothermic event at 188°C (ΔH = 62 kJ mol^{-1}) which, according to an approximate weight loss measurement (27), corresponds to the loss of one mole of pyrazine, presumably the more weakly bound axial ligand. Loss of the second mole of pyrazine occurs at approximately 300°C near which temperature the onset of exothermic oxidative decomposition takes place. In comparison, $Cu(py)_4(CH_3SO_3)_2$ shows two closely spaced endothermic events at 180 and 196°C. While enthalpy changes associated with these events were estimated at ~90 and 50 kJ mol^{-1}, respectively, it was not possible to establish weight changes associated with each event. Heating a sample of the compound to a temperature slightly above 196°C gave a weight loss intermediate between that expected for the loss of 2 and 3 mol of pyridine. Exothermic oxidative decomposition takes place, in this case, at temperatures above approximately 257°C. In summary, in spite of the presence of axially bound pyrazine groups, $Cu(pyz)_2(CH_3SO_3)_2$ is at least as thermally stable as its pyridine analogue, showing no measurable decomposition up to temperatures of about 167°C (onset of the first endothermic event).

Spectroscopic studies

By comparing the infrared spectra of $Cu(pyz)_2(CH_3SO_3)_2$ and $Cu(py)_4(CH_3SO_3)_2$ with those of the neutral ligands and related complexes (28–31) it is possible to identify those bands arising primarily from internal vibrations of the methanesulfonate groups. These bands are listed in Table 8. Monodentate coordination by the anion results in a lowering in symmetry of the CSO_3 moiety and a consequent splitting of the doubly degenerate (in C_{3v} symmetry) SO_3 asymmetric stretching and deformation modes, ν_4 and ν_5, are expected. In $Cu(pyz)_2(CH_3SO_3)_2$, ν_4 is split by 95 cm^{-1} and the appearance of three medium to strong bands in the deformation region ($\nu_3(A_1)$, $\nu_5(E)$) clearly indicates a splitting of ν_5. In contrast, $Cu(py)_4(CH_3SO_3)_2$ exhibits a splitting of only 49 cm^{-1} in ν_4 and there is no observable splitting of ν_5 in this complex. We interpret these differences as being a consequence of the fact that while the sulfonate anion is coordinated strongly in an equatorial position in the pyrazine complex, it is coordinated more weakly in an axial

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

position in the pyridine complex. Axial sulfonate coordination was proposed earlier for $Cu(py)_4(FSO_3)_2$, a complex in which ν_4 is split by 50 cm^{-1} (29). Infrared absorptions assignable to pyridine vibrations occur as expected in $Cu(py)_4(CH_3SO_3)_2$. In particular, the 8*a*, 6*a*, and 16*b* vibrations, at 1606, 641, and 440 cm^{-1} respectively, show the expected shifts to higher frequencies on coordination (29). Many of the pyrazine fundamentals are obscured by the broader and generally more intense sulfonate absorptions in the infrared spectrum of $Cu(pyz)_2(CH_3SO_3)_2$. However, little interference between anion and neutral ligand bands occurs below 900 cm^{-1} and it is possible to assign medium to strong intensity bands at 846, 813, 494, and 440 cm^{-1} to pyrazine vibrations. Pure liquid pyrazine has only two corresponding bands at 804 and 417 cm^{-1} (22, 23) and the apparent doubling of fundamentals in the complex is likely a consequence of the presence of two structurally distinct bridging pyrazine ligands in this compound.

The electronic spectrum of $Cu(py)_4(CH_3SO_3)_2$ shows a broad absorption with a maximum at 16 800 cm^{-1}. This compares favorably with the spectra reported (29, 32) for the complexes $Cu(py)_4(XSO_3)_2$ (X = CF_3, F, *p*-$CH_3C_6H_4$; abs. max. = 17 400, 17 200, and 16 900 cm^{-1}) and is consistent with all four complexes having elongated tetragonal octahedral CuN_4O_2 chromophores with axially bound sulfonates. A recent X-ray crystal structure determination has confirmed this structure for $Cu(py)_4(CF_3SO_3)_2$ (32). In contrast, the X-ray diffraction studies in the present work have revealed a rhombic distorted $CuO_2N_2N'_2$ chromophore in $Cu(pyz)_2(CH_3SO_3)_2$ and this structural difference is manifested in a shift in the electronic spectrum to lower energies. $Cu(pyz)_2(CH_3SO_3)_2$ exhibits a broad absorption with a maximum at 14 000 cm^{-1}.

Magnetic studies

Magnetic susceptibilities of both $Cu(py)_4(CH_3SO_3)_2$ and $Cu(pyz)_2(CH_3SO_3)_2$ were measured from 82 to 4.2 K; data are listed in Table 9 (deposited) and plotted as magnetic moment versus temperature in Fig. 4. Although there appears to be a slight increase in μ_{eff} with decreasing temperature for the pyridine complex, the variation with temperature is not large, and the values of μ_{eff} are of the same magnitude as reported previously for analogous fluorosulfate and paratoluenesulfonate complexes (29). In contrast, μ_{eff} for the pyrazine complex shows a strong temperature dependence with the value decreasing from 1.78 BM at 82 K to 0.85 BM at 4.2 K, suggesting the presence of relatively strong antiferromagnetic coupling in this material. The effect of magnetic concentration is more clearly seen in the magnetic susceptibility data, which exhibits a maximum at approximately 6.2 K (Fig. 5). Rather long Cu···Cu distances (6.9134(2) and 8.1991(4) Å along the *c* and *a* cell edges, Fig. 1) tend to rule out direct exchange between metal centres and the presence of pyrazine bridges suggests superexchange through the bridging ligands.

Particularly relevant to this work are the studies on $Cu(pyz)_2(ClO_4)_2$ (1, 2) where X-ray crystallography has revealed important structural similarities and differences with the compound studied here. The magnetic susceptibility of $Cu(pyz)_2(ClO_4)_2$ exhibits a maximum value at 12.1 K (2), and Darriet *et al.* (1) successfully modelled these data by using Lines' high-temperature series-expansion expression for a two-dimensional square-planar antiferromagnet in the Heisenberg limit (33). The parameters obtained by fitting the magnetic susceptibility data were $J = -5.3\ cm^{-1}$ and $g = 2.107$. Fitting the magnetic susceptibility data for $Cu(pyz)_2(CH_3SO_3)_2$ to this two-dimensional model,

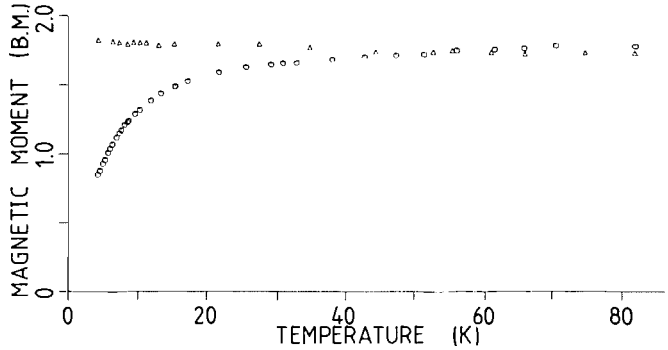

FIG. 4. Magnetic moment versus temperature for $Cu(NC_5H_5)_4(CH_3SO_3)_2$ (△) and $Cu(N_2C_4H_4)_2(CH_3SO_3)_2$ (□).

yields a best fit[4] with the parameters $J = -2.48\ cm^{-1}$ and $g = 2.15$ ($F = 0.0118$). As measured by the exchange coupling parameter, *J*, the magnitude of the magnetic exchange in the methanesulfonate complex is approximately one half of that calculated for $Cu(pyz)_2(ClO_4)_2$. Several possibilities exist to explain this relative diminution of *J* in $Cu(pyz)_2(CH_3SO_3)_2$. The first is that the methanesulfonate anion, by acting as a stronger Lewis base than the perchlorate anion towards copper, effectively decreases the acidity of the copper(II) ions towards the bridging pyrazine groups and hence, lowers the intralayer exchange interaction. A second alternative explanation is related to the fact that in the perchlorate derivative the pyrazine groups are equivalent and oriented in a way so as to interact effectively with the unpaired electron density on the copper(II) ions, resulting in an equal contribution from each pyrazine ligand to the overall exchange interaction. In $Cu(pyz)_2(CH_3SO_3)_2$, however there are two distinct pyrazine ligands and the exchange integral for each bridging pyrazine is likely to be dependent upon two factors: the degree of separation of the two copper ions (length of the bridge) and the orientation of the pyrazine π-system with respect to the copper *d*-orbitals. In $Cu(pyz)_2(CH_3SO_3)_2$ adjacent copper(II) ions are separated by either 6.9134(2) Å when the intervening pyrazine group is strongly bound in the equatorial plane, or 8.1991(4) Å, when the intervening pyrazine group is weakly bound in an axial position. Considering distances alone, it would be expected that the shorter the Cu···Cu separation is, the greater would be the magnetic exchange effect. Thus, the equatorially bound pyrazine groups may be expected to transmit exchange coupling effects more efficiently than the axially bound pyrazine groups.

It has been shown previously that for pyrazine groups bound in the equatorial, *xy*, plane the orientation of the plane of the ligand with respect to the *xy* plane of the copper chromophore also plays an important role in determining the effectiveness of exchange. Earlier research (7) has demonstrated that for copper–pyrazine complexes in which the unpaired electron is in the $d_{x^2-y^2}$ orbital (as the tetragonally elongated pseudo-octahedral environment suggests it is in $Cu(pyz)_2(CH_3SO_3)_2$) the magnitude of the antiferromagnetic exchange is determined from the overlap of the $d_{x^2-y^2}$ orbital and the pyrazine π-system. This

[4]A least-squares fitting procedure allows both *J* and *g* to vary until a minimum value is obtained for the function *F*;

$$F = \left[\frac{1}{n}\Sigma\left(\frac{\chi_i^{calcd} - \chi_i^{obs}}{\chi_i^{obs}}\right)^2\right]^{1/2}$$

where *n* is the number of data points and χ_i^{obs} and χ_i^{calcd} are the experimental and calculated molar magnetic susceptibilities.

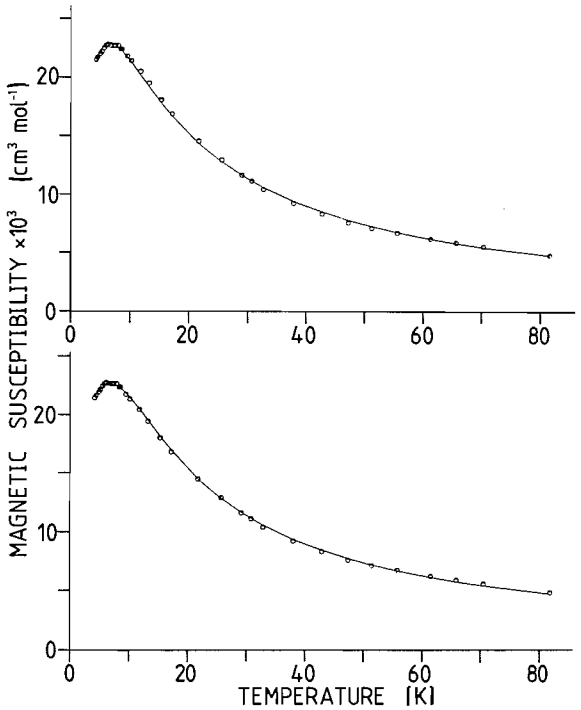

FIG. 5. Magnetic susceptibility versus temperature for $Cu(N_2C_4H_4)_2(CH_3SO_3)_2$. Upper: two-dimensional model; solid line generated with $J = -2.48\,cm^{-1}$ and $g = 2.15$. Lower: linear chain model; solid line generated with $J = -3.82\,cm^{-1}$, $g = 2.13$.

interaction, however, is only possible when the pyrazine ring is canted out of the *xy* plane. For example, the pyrazine rings in $Cu(pyz)_2(ClO_4)_2$ (1) and $Cu(pyz)(NO_3)_2$ (3) are canted out of the *xy* plane by angles of 66.1 and 50°, respectively, and significant magnetic exchange interactions are observed (1, 5). On the other hand, in $Cu(pyzA)_2(ClO_4)_2$ (where pyzA is pyrazine-2-carboxamide), the pyrazine rings lie in the *xy* plane (34) resulting in orthogonal overlap and a magnetically-dilute system (35). These previous studies and the X-ray structure results for $Cu(pyz)_2(CH_3SO_3)_2$ suggest that the equatorially bound pyrazine group in the methanesulfonate compound, which is canted out of the *xy* plane by 28.5°, is suitably oriented to present a π-pathway for magnetic interactions between copper centres.

The axially coordinated pyrazine in $Cu(pyz)_2(CH_3SO_3)_2$ is structurally similar to the bridging pyrazine group in the hexafluoroacetylacetonate complex $Cu(pyz)(hfac)_2$ (4). In both instances the Cu—N bonds are long and the plane of the pyrazine ring lies in the *xz* plane of the molecule. It was argued (7) that both the length of the Cu—N bonds and the orientation of the pyrazine ring, which did not permit effective d–π overlap with copper, accounted for the fact that no significant magnetic exchange was seen in the hfac complex. This suggests that the axial pyrazines may also be ineffective in propagating magnetic exchange in $Cu(pyz)_2(CH_3SO_3)_2$.

The above comparison of pyrazine group coordination modes in $Cu(pyz)_2(CH_3SO_3)_2$ with those in other copper(II)–pyrazine complexes suggests that the magnetic exchange interaction in the methylsulfonate derivative may proceed via two different routes, with the exchange interaction through the equatorially bound pyrazine, J_{eq}, significantly stronger than the exchange, J_{ax}, through the axially bound pyrazine. In the extreme case where $J_{eq} \gg J_{ax}$, the magnetic properties may be more closely represented by a one-dimensional linear chain model. A model has been proposed for the analysis of the magnetic susceptibility of a Heisenberg linear chain for $S = 1/2$ ions. Hall (36) and Hatfield and co-workers (37) developed the model proposed by Bonner and Fisher (38); this resulted in an expression for the molar susceptibility of a linear chain of interacting $S = 1/2$ spins as a polynomial expansion. The best fit of the data for $Cu(pyz)_2(CH_3SO_3)_2$ to this model is equally as good as the best fit to the two-dimensional model; for the one-dimensional model the parameters obtained from the best fit are $J = -3.82$ cm^{-1} and $g = 2.13$, with $F = 0.0118$. The best fit is represented by the solid line in Fig. 5. Unfortunately the magnetic exchange in $Cu(pyz)_2(CH_3SO_3)_2$ is not sufficiently strong to enable one to distinguish between one- and two-dimensional pathways on the basis of magnetic properties alone. On the basis of structural considerations discussed above, however, it seems most reasonable to consider the compound to consist of linear chains of —Cu—pyz—Cu— units, in which there are relatively strong intrachain magnetic exchange interactions and although these linear chains are crosslinked through the weakly bound axial pyrazine groups the interchain interactions are of a much smaller magnitude.

Total synthesis of the ravidomycin aglycone (defucogilvocarcin V)

JOHN A. FINDLAY, ANAND DALJEET, PETER JOHN MURRAY, AND RABINDRA N. REJ
Chemistry Department, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received July 24, 1986

JOHN A. FINDLAY, ANAND DALJEET, PETER JOHN MURRAY, and RABINDRA N. REJ. Can. J. Chem. **65**, 427 (1987).

The synthesis of 1-hydroxy-10,12-dimethoxy-8-vinyl-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one **7**, starting from vanillin and 1,5-dihydroxynaphthalene is described. This compound is the aglycone of the antitumor antibiotic ravidomycin and is identical with the recently reported antimicrobial agent, defucogilvocarcin V.

JOHN A. FINDLAY, ANAND DALJEET, PETER JOHN MURRAY et RABINDRA N. REJ. Can. J. Chem. **65**, 427 (1987).

Utilisant la vanilline et le dihydroxy-1,5 naphtalène comme produits de départ, on a synthétisé l'hydroxyl-1 diméthoxy-10,12 vinyl-8 6*H*-benzo[*d*]naphto[1,2*b*]pyrannone-6 (**7**). Ce produit est l'aglycone de l'antibiotique antitumoral, ravidomycine, et il est identique à l'agent antimicrobien rapporté récemment, défucogilvocarcine V.

[Traduit par la revue]

Introduction

Members of the chrysomycin family of antibiotics are produced by several strains of *Streptomycetes*. These compounds are yellow in colour and possess a common benzonaphthopyranone system attached to different C-glycoside moieties. The members of this family reported to date are toromycin (gilvocarcin V) **1** (1), gilvocarcin M **2** (2), and gilvocarcin E **3**, chrysomycin V **4**, chrysomycin M **5** (3), and ravidomycin **6** (4). The letters V, M, and E signify vinyl, methyl, and ethyl, respectively, the single, but important, variation in the aglycone structure among members of a category within the family. Toromycin from *Streptomyces collinus* was shown to be identical to gilvocarcin V isolated from *S. gilvotanareus* (2*e*).

This class of compounds has aroused considerable interest in view of the antibiotic and antitumor activity of its members (5). In particular, chrysomycin V **4**, gilvocarcin V **1**, and ravidomycin **6** have been shown to possess potent antitumor activity and it has been concluded, by Elespuru and Gonda (6), that the C4 vinyl group is essential for potent antitumor properties.

7

When we embarked on structural studies on ravidomycin in early 1980, the structures of the chrysomycins and gilvocarcins had not been published. Since ravidomycin and derivatives were not amenable to solution by X-ray methods, we deduced the complete structure and stereochemistry principally by chemical degradation studies and ^{1}H and ^{13}C nmr spectroscopy (4). A key degradation product in our work was the aglycone **7** obtained by fusion of ravidomycin **6** with potassium hydroxide. Very recently Misra *et al.* (8) have isolated **7** from the acetone extract of the mycelia of *Streptomyces arenae* 2064. They have shown it to possess antimicrobial activity and have designated it defucogilvocarcin V and suggested that its presence in the fermentation broth indicates that in the biogenesis of gilvocarcins the sugar moiety is probably attached to the chromophore **7** after it has been assembled.

In view of the importance of the aglycone in our structural elucidation of ravidomycin and the increasing interest in the chrysomycin family of antibiotics, we undertook synthetic studies targeted at 1-hydroxy-10,12-dimethoxy-8-vinyl-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one **7** and now present our work.

The key step in our synthetic approach involves the union of the appropriately functionalized Grignard reagent of naphthalene **10** with the protected substituted benzoic acid derivative **16** via a nucleophilic aromatic substitution producing the phenyl naphthalene **17**. The previously described (7) 5-acetoxy-2-bromo-1,4-naphthoquinone **9**, obtained in 92% yield from 1,5-dihydroxynaphthalene **8**, was reduced with sodium dithionite and immediately methylated with dimethyl sulfate/potassium hydroxide to provide the Grignard precursor **10** (43%). 3-Bromo-4,5-dimethoxybenzaldehyde **12** was prepared in 95% yield from vanillin by bromination to **11** (9), followed by methylation with iodomethane in refluxing acetone containing anhydrous potassium carbonate. A Wittig reaction on **12** afforded **13** (96% yield), which was transformed via Grignard reaction with carbon dioxide to the acid **14** in 55% yield. Attempts to protect the carboxyl group by introduction of a Δ^2-oxazoline using conditions developed by Meyers *et al.* (10) gave rise to mixtures of products, apparently due to the sensitivity of the vinyl group to the acidic medium. It was necessary then to reintroduce the vinyl group at a later stage. Catalytic reduction of the vinyl group and protection of the carbonyl group afforded the key intermediate Δ^2-oxazoline **16** in 80% yield from **14**. Thus the appropriately functionalized and protected naphthalene

18 R^1, R^2 = H, R^3 = CH_2CH_3
19 R^1, R^2 = Ac, R^3 = CH_2CH_3
20 R^1 = Ac, R^2 = CH_3, R^3 = CH_2CH_3
21 R^1 = CH_3, R^2 = Ac, R^3 = CH_2CH_3
22 R^1, R^2 = CH_3, R^3 = CH_2CH_3
23 R^1 = Ac, R^2, R^3 = CH_3
24 R^1 = Ac, R^2 = CH_3, R^3 = $CHCH_3$ (Br)
25 R^1 = Ac, R^2 = CH_3, R^3 = $CH{=}CH_2$

10 and benzoic acid derivative **16** were prepared in simple and efficient pathways from readily available inexpensive precursors.

The convergent coupling reaction producing the phenylnaphthalene **17** in 81% yield was accomplished by adding the Δ^2-oxazoline **16** to the Grignard reagent of **10** using conditions pioneered by Meyers *et al.* (10) in other endeavours. Treatment of **17** with refluxing glacial acetic acid – hydriodic acid (1:1) effected deprotection of the carbonyl group, demethylation at three sites, and lactonization, giving **18** in 77% yield in one step.

The site of the remaining methoxyl in **18** was ascertained by comparison of the ^{1}H nmr spectra with those in its diacetate **19** (11). Thus acetylation shifts of δ +0.38, +0.46, and +0.61 ppm were noted for signals due to C11H, C2H, and C4H, while virtually no difference was noted for signals assigned to C9H and C7H. Thus the phenolic groups in **18** must be placed at C1 and C12.

Methylation of phenolic lactone **18** using one equivalent of iodomethane and anhydrous potassium carbonate in dimethylsulfoxide–acetone afforded a mixture of **20** and **21** (3:2) in 86% yield, separable by preparative thin-layer chromatography. Location of the acetate moiety in these isomers was readily accomplished by comparison of chemical shifts for the aromatic protons with those in compound **18** and its trimethoxy derivative **22**. The chemical shift assignments for monoacetate **21** are in close agreement with those for the homologous compound **23** obtained by Takahashi *et al.* (2*b*) upon treatment of the tetraacetate of gilvocarcin M **2** with HCl in refluxing methanol followed by acetylation.

Introduction of the vinyl group in **20** was effected by bromination with one equivalent of *N*-bromosuccinimide, giving the monobromide **24** in 75% yield. The latter was converted in 40% yield to the aglycone **7** via the phenyl selenoxide derivative using methodology developed by Sharpless *et al.* (12). Alternatively, the vinyl group can be introduced by treatment of **20** with two equivalents of *N*-bromosuccinimide in refluxing carbon tetrachloride containing a catalytic amount of dibenzoyl peroxide to give the acetate **25**.

1-Hydroxy-10,12-dimethyl-8-vinyl-6*H*-benzo[*d*]naphtho-[1,2*b*]pyran-6-one **7** prepared via this route was identical in all physical and spectroscopic properties with those of the aglycone obtained by alkali fusion of ravidomycin, and was consistent with those reported (8) for the antibiotic defucogilvocarcin V.

Experimental

General

All melting points were determined on a Kofler hot stage apparatus and are uncorrected. High resolution mass spectra were recorded on an AEI MS-50 spectrometer at the Mass Spectrometry Lab, University of Alberta. The infrared spectra were recorded on Perkin–Elmer 727B or 598 spectrophotometers and ultraviolet spectra were obtained with a Beckman 25 instrument.

Nuclear magnetic resonance spectra were recorded on a Varian XL-200 spectrometer using tetramethylsilane (TMS) as internal standard. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was also used as an internal standard when DMSO-d_6 was employed as a solvent.

Column chromatograms were prepared using silica gel G or Kieselgel 60 (230–400 mesh) packed in chloroform or hexane. Analytical thin-layer chromatography (tlc) was done on precoated silica plates (silica gel 60-F-254) 20 cm × 20 cm and 0.5, 1, or 2 mm thickness.

*2-Bromo-1,4,5-trimethoxynaphthalene **10***

2-Bromo-5-acetoxy-1,4-naphthaquinone **9** (5) (1.3 g, 4.4 mmol)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12

dissolved in ethyl acetate – ether (1:10, 100 mL) was shaken vigorously with freshly prepared saturated aqueous sodium dithionite solution (2 × 50 mL) in a separatory funnel. The ether layer was washed with water (50 mL), saturated sodium chloride solution (50 mL), dried, and filtered immediately. The solvent was removed *in vacuo* below 15°C and the resulting dry solid dissolved in absolute ethanol (25 mL) and treated with dimethylsulfate (2.5 g). To this vigorously stirred, ice-cooled solution sodium hydroxide solution (10 mL, 40%) was added dropwise over one hour. After one more hour additional sodium hydroxide (3 mL, 40%) was added to ensure basicity and the mixture was stirred overnight. Ethanol was then removed *in vacuo* at 15°C and the resulting solution dissolved in water (200 mL) and extracted with ether (3 × 30 mL). The combined ether extract was washed with aqueous sodium hydroxide (20 mL, 20%), water (2 × 75 mL), and saturated sodium chloride solution (50 mL), and dried. After evaporation of solvent, the residue was flash chromatographed yielding 2-bromo-1,4,5-trimethoxynaphthalene **10** (0.56 g, 43%), which was recrystallized from hexane–ether to provide a white crystalline solid, mp 109–112°C; uv (CH_3OH) λ_{max} nm (log ε): 231 (4.92), 305 (4.05), 323 (4.03), 338 (4.05); ir ($CHCl_3$) ν_{max}: 1610, 1580 (aromatic) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.91 (s, 6H, 2 × OCH_3), 3.99 (s, 3H, OCH_3), 6.86 (dd, 1H, J = 1.0 Hz, J = 7.9 Hz, C6H), 6.90 (s, 1H, C3H), 7.42 (dd, 1H, J = 7.9 Hz, J = 8.4 Hz, C7H), 7.68 (dd, 1H, J = 1.0 Hz, J = 8.5 Hz, C8H). *Exact Mass* calcd. for $C_{13}H_{13}O_3Br$: 298.0027; found: 298.0020 (M^+, 76).

3-Bromo-4,5-dimethoxybenzaldehyde 12

3-Bromo-4-hydroxy-5-methoxybenzaldehyde **11** (9) (1.0 g, 4.33 mmol) in anhydrous acetone (30 mL) was treated with anhydrous potassium carbonate (1.5 g) and excess iodomethane and the mixture was refluxed for 20 h. The solution was cooled, filtered, and evaporated, and the resulting oil dissolved in ether, washed with water and with saturated sodium chloride solution, dried, and evaporated to yield crystalline 3-bromo-4,5-dimethoxybenzaldehyde **12** (1.01 g, 95%), mp 53–54°C; uv (CH_3OH) λ_{max} nm (log ε): 210 (4.8), 218 (4.5), 272 (3.78), 302 (3.40); ir ($CHCl_3$) ν_{max}: 1690 (C=O), 1600 (aromatic) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.95 (s, 3H, OCH_3), 3.96 (s, 3H, OCH_3), 7.40 (d, 1H, J = 1.8 Hz), 7.66 (d, 1H, J = 1.8 Hz), 9.86 (s, 1H, C*H*O). *Exact Mass* calcd. for $C_9H_9O_3Br$: 245.9715; found: 245.9716.

1-Bromo-2,3-dimethoxy-5-ethenyl benzene 13

Sodium hydride (24.6 mg, 0.82 mmol, 80% oil dispersion) and dry tetrahydrofuran (5 mL) were added to a dry three-necked flask equipped with a condenser and dry nitrogen flow. To this suspension was added methyl triphenyl phosphonium bromide (0.146 g, 0.41 mmol) and the mixture was stirred for 10 min. Then 3-bromo-4,5-dimethoxy benzaldehyde **12** (100 mg, 0.41 mmol) in tetrahydrofuran (2 mL) was added and the mixture was gently refluxed for 1.5 h, after which time tlc indicated that all starting material had been transformed. After addition of methanol (2 mL) the reaction mixture was filtered, and then poured into distilled water and extracted with ether (4 × 50 mL). The ether extract, following usual treatment, yielded a solid suspended in oil, which was taken up in hexane and introduced onto a pad of coarse silica gel in a sintered glass funnel. Elution with hexane – ethyl acetate (95:5) yielded the light-sensitive product 1-bromo-2,3-dimethoxy-5-ethenyl benzene **13** (94.3 mg, 96%), which was stored in the cold under argon until further use; uv (CH_3OH) λ_{max} nm (log ε): 218 (4.36), 256 (3.97), 296 (3.29), 306 (3.16); ir ($CHCl_3$) ν_{max}: 1630, 1590 (C=C, aromatic conj.) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.78 (s, 3H, OCH_3), 3.79 (s, 3H, OCH_3), 5.17 (d, 1H, J_{cis} = 10.8 Hz), 5.97 (d, 1H, J_{trans} = 17.5 Hz), 6.50 (dd, 1H, J_{cis} = 10.8 Hz, J_{trans} = 17.5 Hz), 6.19 (d, 1H, J = 1.8 Hz), 7.10 (d, 1H, J = 1.8 Hz). *Exact Mass* calcd. for $C_{10}H_{11}O_2Br$: 241.9918; found: 241.9942.

2,3-Dimethoxy-5-ethenyl benzoic acid 14

To magnesium turnings (20 mg, 0.82 mmol) in dry tetrahydrofuran (3 mL) in a three-necked flask under nitrogen was added a small crystal of iodine and the mixture refluxed for 3 min with a heat gun. After cooling, the tetrahydrofuran was removed by pipette and 1-bromo-2,3-dimethoxy-5-ethenyl benzene **13** (100 mg, 0.41 mmol) in tetrahydrofuran (5 mL) was added. This mixture was refluxed for short periods with a heat gun and when there was no sign of Grignard reagent formation, a catalytic amount of iodomethane was added and refluxing initiated again. After a cloudy precipitate formed, the reaction was cooled and stirred vigorously at room temperature for 2 h. The flask was then filled cautiously with crushed Dry Ice and, after 10 h, saturated ammonium chloride solution (10 mL) was added, the solution was filtered, and the residue washed with water and then ether. The organic layer was diluted with ether (20 mL) and extracted with water (6 × 15 mL). The combined aqueous extract was washed with ether (20 mL) and then acidified with dilute sulfuric acid (5%) and extracted with ether (4 × 30 mL). The ether extract, after washing, drying, and evaporation, yielded 2,3-dimethoxy-5-ethenyl benzoic acid **14**, a solid (47 mg, 55%), mp 73–76°C; uv (CH_3OH) λ_{max} nm (log ε): 220 (3.96), 257 (3.64), 300 (3.10); ir ($CHCl_3$) ν_{max}: 3400 (OH), 1740 (COOH), 1600, 1590 (C=C, aromatic) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.88 (s, 3H, OCH_3), 4.00 (s, 3H, OCH_3), 5.25 (d, 1H, J_{cis} = 11.0 Hz), 5.70 (d, 1H, J_{trans} = 17.5 Hz), 6.60 (dd, 1H, J_{cis} = 11.0 Hz, J_{trans} = 17.5 Hz), 7.12 (d, 1H, J = 2.0 Hz), 7.67 (d, 1H, J = 2 Hz). *Exact Mass* calcd. for $C_{11}H_{12}O_4$: 208.0735; found: 208.0731.

2,3-Dimethoxy-5-ethyl benzoic acid 15

2,3-Dimethoxy-5-ethenyl benzoic acid **14** (100 mg, 0.48 mmol) in ethanol (1.5 mL) was hydrogenated at 1 atmosphere (101.3 kPa) and room temperature in the presence of palladium-on-carbon (10 mg) overnight. The mixture was filtered through Celite and evaporated, yielding 2,3-dimethoxy-5-ethyl benzoic acid **15** as an oil (101 mg, 100%); uv (CH_3OH) λ_{max} nm (log ε): 208 (4.39), 279 (3.52); ir ($CHCl_3$) ν_{max}: 3420 (OH), 1735 (C=O), 1610, 1590 (C=C, aromatic) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.23 (t, 3H, J = 7.6 Hz, CH_2CH_3), 2.64 (q, 2H, J = 7.6 Hz, CH_2CH_3), 3.92 (s, 3H, OCH_3), 4.04 (s, 3H, OCH_3), 7.00 (d, 1H, J = 1.7 Hz), 7.53 (d, 1H, J = 1.7 Hz). *Exact Mass* calcd. for $C_{11}H_{14}O_4$: 210.0892; found: 210.0894.

2-(2,3-Dimethoxy-5-ethylphenyl)-4,4-dimethyl-4,5-dihydro-oxazole 16

Thionyl chloride (7.6 g, 0.064 mol) was added to 2,3-dimethoxy-5-ethyl benzoic acid **15** (4.5 g, 0.0213 mol) and the mixture was refluxed for 8 h under nitrogen. Excess thionyl chloride was removed *in vacuo* yielding the acid chloride of **15** (4.6 g), which was dissolved in methylene chloride (50 mL) and added dropwise to a stirred solution of 2-amino-2-methyl-1-propanol (3.6 g, 0.04 mol) in methylene chloride (25 mL) cooled to 0°C. The reaction was stirred at room temperature overnight, then filtered and the filtrate concentrated to give a brown oil that was treated with thionyl chloride (2.64 g), by slow addition, and the solution was stirred for 2 h at room temperature. Removal of excess thionyl chloride *in vacuo* afforded an oily product that was treated with ether (75 mL) and water (150 mL). The aqueous layer was made basic by addition of aqueous sodium hydroxide (20%) and extracted with ether (3 × 100 mL). The ethereal extraction yielded a crude product (4.85 g), which was flash chromatographed affording 2-(2,3-dimethoxy-5-ethylphenyl)-4,4-dimethyl-4,5-dihydro-oxazole **16** (4.58 g, 80%); uv (CH_3OH) λ_{max} nm (log ε): 209 (4.36), 246 (3.65), 2.90 (3.32); ir ($CHCl_3$) ν_{max}: 1645 (C=N), 1580 (C=C, aromatic) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.24 (t, 3H, J = 7.5 Hz, CH_2CH_3), 1.41 (s, 6H, $(CH_3)_2CH$), 2.62 (q, 2H, J = 7.6 Hz, CH_2CH_3), 3.85 (s, 3H, OCH_3), 3.89 (s, 3H, OCH_3), 4.14 (s, 2H, CH_2O), 6.86 (d, 1H, J = 2.2 Hz), 7.17 (d, 1H, J = 2.2 Hz). *Exact Mass* calcd. for $C_{15}H_{21}O_3N$: 263.1521; found: 263.1520.

2-[4'-Ethyl-2'-methoxy-1'-(2-{1,4,5-trimethoxynaphthalene})-phenyl]-4,4-dimethyl-2,3-dihydro-oxazole 17

To a dry three-necked flask under dry nitrogen was added magnesium (30 mg, 1.23 mmol) and 2-bromo-1,4,5-trimethoxynaphthalene **10** (108 mg, 0.36 mmol) in dry tetrahydrofuran (12 mL); the mixture was stirred vigorously and heated with a heat gun. Formation of Grignard reagent was induced by addition of a catalytic amount of iodine and the solution was then refluxed gently for 0.25 h. After

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

cooling to room temperature, 2-(2,3-dimethoxy-5-ethylphenyl)-4,4-dimethyl-4,5-dihydro-oxazole **16** (100 mg, 0.38 mmol) in dry tetrahydrofuran (6 mL) was added over 5 min and the solution was then stirred for 15 h at room temperature, since thin-layer chromatography (tlc) (hexane – ethyl acetate 60:40, developed twice) indicated absence of starting material and appearance of a new spot of low R_f. The reaction mixture was filtered, suspended in water, and extracted with ether (3 × 30 mL), which, after the usual treatment, afforded the product (146 mg). This product was chromatographed on a silica gel column yielding 2-[4′-ethyl-2′-methoxy-1′-(2-{1,4,5-trimethoxynaphthalene})phenyl]-4,4-dimethyl-4,5-dihydro-oxazole **17** (138 mg, 81%); uv (CH_3OH) λ_{max} (log ε): 210 (4.43), 227 (4.56), 244 (3.98), 296 (3.89), 324 (3.71), 340 (3.71); ir ($CHCl_3$) ν_{max}: 1630 (C=N), 1600, 1580 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.15 (s, 3H, $(CH_3)_2C$), 1.16 (s, 3H, $(CH_3)_2C$), 1.32 (t, 3H, J = 7.6 Hz, CH_2CH_3), 2.74 (q, 2H, J = 7.6 Hz, CH_2CH_3), 3.57 (s, 3H, OCH_3), 3.55 (d, 1H, J = 8.0 Hz, OCH_2), 3.64 (d, 1H, J = 8 Hz, OCH_2), 3.77 (s, 3H, OCH_3), 3.90 (s, 3H, OCH_3), 4.00 (s, 3H, OCH_3), 6.68 (s, 1H, C3H), 6.90 (d, 1H, J = 7.6 Hz, C6H), 6.96 (bs, 1H, C3′H), 7.28 (bs, 1H, C5′H), 7.42 (t, 1H, J = 7.6 Hz, C7H), 7.78 (d, 1H, J = 7.6 Hz, C8H). *Exact Mass* calcd. for $C_{27}H_{31}O_5N$: 449.2202; found: 449.2207 (M^+, 46).

*1,12-Dihydroxy-10-methoxy-8-ethyl-6*H*-benzo[*d*]naphtho[1,2*b*]-pyran-6-one* ***18***

A solution of 2-[4′-ethyl-2′-methoxy-1′-(2-{1,4,5-trimethoxynaphthalene})phenyl]-4,4-dimethyl-4,5-dihydro-oxazole **17** (100 mg, 0.22 mmol) in glacial acid acid (1.5 mL) and hydriodic acid (1.5 mL, 47%), was refluxed for 2 h, whence a solid precipitated from the solution. Acetic acid (1 mL) and hydriodic acid (1 mL) were added and refluxing continued for 7 h. After cooling, the mixture was filtered to provide the solid product 1,12-dihydroxy-10-methoxy-8-ethyl-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one **18** (60 mg, 77%), mp 289–290°C (dec.); uv (CH_3OH) λ_{max} nm (log ε): 242 (4.59), 264 (4.40), 273 (4.48), 314 (4.10), 324 (4.08), 340 (3.97), 380 (3.90); ir (KBr) ν_{max}: 330 (phenolic OH), 1660 (C=O), 1610, 1580 (C=C, aromatic) cm^{-1}; ^1H nmr ($(CD_3)_2SO$) δ: 1.33 (t, 3H, J = 7.6 Hz, CH_2CH_3), 2.84 (q, 2H, J = 7.6 Hz, CH_2CH_3), 4.15 (s, 3H, OCH_3), 6.96 (dd, 1H, J = 7.6 Hz, J = 1.0 Hz, C2H), 7.51 (dd, 1H, J = 8.4 Hz, J = 7.7 Hz, C3H), 7.53 (d, 1H, J = 1.7 Hz, C9H), 7.87 (d, 1H, J = 1.7 Hz, C7H), 7.88 (dd, 1H, J = 8.5 Hz, J = 1.0 Hz, C4H), 8.38 (s, 1H C11H). *Exact Mass* calcd. for $C_{21}H_{18}O_5$: 350.1154; found: 350.0996.

*1,12-Diacetoxy-10-methoxy-8-ethyl-6*H*-benzo[*d*]naphtho[1,2*b*]-pyran-6-one* ***19***

A solution of 1,12-dihydro-10-methoxy-8-ethyl-6*H*-benzo[*d*]-naphtho[1,2*b*]pyran-6-one **18** (5 mg, 0.01 mmol) in pyridine (0.5 mL) and acetic anhydride and a catalytic amount of dimethylaminopyridine was stirred overnight. Preparative thin-layer chromatography (ptlc) following evaporation of solvents provided 1,12-diacetoxy-10-methoxy-8-ethyl-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one **19** (6 mg, 100%), mp 211–213°C; uv (CH_3OH) λ_{max} (log ε): 224 (3.76), 243 (3.78), 263 (3.40), 272 (3.70), 315 (3.08), 335 (3.03), 357 (3.19), 365 (3.24); ir ($CHCl_3$) ν_{max}: 1762 (acetate C=O), 1725 (lactone C=O), 1615 (C=C, aromatic); ^1H nmr ($(CD_3)_2SO$) δ: 1.33 (t, 3H, J = 7.6 Hz, CH_2CH_3), 2.45 (s, 3H, $OCOCH_3$), 2.46 (s, 3H, $OCOCH_3$), 2.85 (q, 2H, J = 7.6 Hz, CH_2CH_3), 4.13 (s, 3H, OCH_3), 7.42 (dd, 1H, J = 1.1 Hz, J = 7.6 Hz, C2H), 7.55 (d, 1H, J = 1.6 Hz, C9H), 7.75 (dd, 1H, J = 7.6 Hz, J = 8.5 Hz, C3H), 7.90 (d, 1H, J = 1.6 Hz, C7H), 8.49 (dd, 1H, J = 1.1 Hz, J = 8.5 Hz, C4H), 8.76 (s, 1H, C11H); ^1H nmr ($CDCl_3$) δ: 1.35 (t, 3H, J = 7.7 Hz, CH_2CH_3), 2.43 (s, 3H, $OCOCH_3$), 2.45 (s, 3H, $OCOCH_3$), 2.86 (q, 2H, J = 7.6 Hz, CH_2CH_3), 4.07 (s, 3H, OCH_3), 7.22 (d, 1H, J = 1.0 Hz, C9H), 7.26 (d, 1H, J = 7.5 Hz, C4H), 7.62 (dd, 1H, J = 7.7 Hz, J = 8.3 Hz, C3H), 8.00 (d, 1H, J = 1.0 Hz, C7H), 8.61 (d, 1H, J = 8.2 Hz, C4H), 8.70 (s, 1H, C11H). *Exact Mass* calcd. for $C_{24}H_{20}O_7$: 420.1208; found: 420.1214.

*1-Acetoxy-10,12-dimethoxy-8-ethyl-6*H*-benzo[*d*]naphtho[1,2*b*]-pyran-6-one* ***20*** *and 12-acetoxy-1,10-dimethoxy-8-ethyl-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one* ***21***

1,12-Dihydroxy-10-methoxy-8-ethyl-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one **19** (5 mg, 0.01 mmol) in dry acetone (4 mL) and dimethylsulfoxide (2 mL) was treated with potassium carbonate (10 mg) and iodomethane and stirred at room temperature for 2 h. After filtration and removal of solvent the residue was stirred overnight with acetic anhydride (1.5 mL) and pyridine (1 mL) and a catalytic amount of dimethylaminopyridine. Evaporation followed by ptlc on silica gel (4 × chloroform) afforded the compounds **20** (3 mg), mp 223–225°C and **21** (2 mg), mp 232–238°C. 1-Acetoxy-10,12-dimethoxy-8-ethyl-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one **20**: uv (CH_3OH) λ_{max} nm (log ε): 241 (4.82), 265 (4.62), 273 (4.75), 298 (4.23), 311 (4.19), 324 (4.14), 331 (4.12), 368 (4.19); ir ($CHCl_3$) ν_{max}: 1750 (acetate C=O), 1720 (lactone C=O), 1610, 1590 (C=C, aromatic) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.31 (t, 3H, J = 7.6 Hz, CH_2CH_3), 2.74 (q, 2H, J = 7.6 Hz, CH_2CH_3), 3.92 (s, 3H, OCH_3), 3.96 (s, 3H, OCH_3), 7.08 (bs, 1H, C9H), 7.17 (dd, 1H, J = 1.1 Hz, J = 7.5 Hz, C2H), 7.56 (dd, 1H, J = 7.5 Hz, J = 8.6 Hz, C3H), 7.90 (bs, 1H, C7H), 8.28 (s, 1H, C11H), 8.47 (dd, 1H, J = 1.1 Hz, J = 8.6 Hz, C4H); ^{13}C nmr ($CDCl_3$) δ: 14.97 (q, CH_3CH_2), 20.93 (q, CH_3CO), 28.8 (t, CH_2CH_3), 55.93 (q, OCH_3), 56.03 (q, OCH_3), 104.12 (d, C11), 113.68 (s, C10b), 116.92 (d, C9), 120.56 (d, C7), 120.74 (s, C12a), 120.93 (d, C4), 121.38 (d, C3), 121.71 (s, C6a), 123.03 (s, C10a), 126.23 (s, C4a), 126.66 (d, C2), 140.30 (s, C4b), 146.12 (s, C8), 146.12 (s, C1), 150.62 (s, C12), 157.06 (s, C10), 161.18 (s, C6), 170.11 (s, acetate C=O). *Exact Mass* calcd. for $C_{23}H_{20}O_6$: 392.1260 found: 392.1259. 12-Acetoxy-1,10-dimethoxy-8-ethyl-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one **21**: uv (CH_3OH) λ_{max} nm (log ε): 24 (4.82), 265 (4.62), 273 (4.75), 298 (4.23), 311 (4.19), 324 (4.14) 331 (4.12), 368 (4.19); ir ($CHCl_3$) ν_{max}: 1750 (acetate CO), 172((lactone C=O), 1610, 1590 (C=C, aromatic) cm^{-1}; ^1H nmr ($CDCl_3$ δ: 1.33 (t, 3H, J = 7.7 Hz, CH_2CH_3), 2.41 (s, 3H, $OCOCH_3$), 2.7 (q, 2H, J = 7.7 Hz, CH_2CH_3), 3.99 (s, 3H, OCH_3), 4.03 (s, 3H OCH_3), 6.95 (d, 1H, J = 7.6 Hz, C2H), 7.15 (bs, 1H, C9H), 7.5 (t, 1H, J = 8.2 Hz, C3H), 7.95 (bs, 1H, C7H), 8.24 (d, 1H, J = 8.3 Hz, C4H), 8.54 (s, 1H, C11H). *Exact Mass* calcd. for $C_{23}H_{20}O_6$ 392.1260; found: 392.1252.

*8-Ethyl-1,10,12-trimethoxy-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one* ***22***

To a solution of 1,12-dihydroxy-10-methoxy-8-ethyl-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one **18** (5 mg, 0.01 mmol) in dry acetone (4 mL) and dimethylsulfoxide (1 mL) was added potassium carbonate (20 mg) and the mixture was stirred at room temperature for 24 h. After the customary work-up the product was purified by ptlc, giving 8-ethyl-1,10,12-trimethoxy-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one **22** (5 mg 96%), mp 240–245°C; uv (CH_3OH) λ_{max} nm (log ε): 242 (4.79), 26 (4.51), 273 (4.67), 300 (4.19), 310 (4.16), 320 (4.06), 340 (4.01) 370 (4.21); ir ($CHCl_3$) ν_{max}: 1720 (lactone C=O), 1600 (C=C aromatic) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.35 (t, 3H, J = 7.7 Hz, CH_2CH_3) 2.83 (q, 2H, J = 7.7 Hz, CH_2CH_3), 4.03 (t, 3H, OCH_3), 4.06 (s, 3H OCH_3), 4.12 (s, 3H, OCH_3), 7.01 (dd, 1H, J = 1.2 Hz, J = 7.9 Hz C2H), 7.23 (d, 1H, J = 1.3 Hz, C9H), 7.53 (dd, 1H, J = 7.9 Hz, J = 8.5 Hz, C3H), 8.03 (d, 1H, J = 1.3 Hz, C7H), 8.26 (dd, 1H, J = 1.2 Hz, J = 8.5 Hz, C4H), 8.48 (s, 1H, C11H). *Exact Mass* calcd for $C_{22}H_{20}O_5$: 364.1310; found: 364.1309.

*1-Acetoxy-10,12-dimethoxy-8-(bromoethyl)-6*H*-benzo[*d*]naphtho-[1,2*b*]pyran-6-one* ***24***

A mixture of 1-acetoxy-10,12-dimethoxy-8-ethyl-6*H*-benzo[*d*]-naphtho[1,2*b*]pyran-6-one **20** (20 mg, 0.05 mmol) in dry carbon tetrachloride was treated with *N*-bromosuccinimide (5 mg, 0.03 mmol) and a catalytic amount of dibenzoyl peroxide, and was then refluxed for 3 h. Since tlc showed the presence of starting material, additional *N*-bromosuccinimide (5 mg, 0.03 mmol) was added and refluxing was continued for 3 h, after which all starting material appeared, from tlc scrutiny, to be consumed. Evaporation of solvent and recrystallization

from chloroform–ether gave 1-acetoxy-10,12-dimethoxy-8-(bromoethyl)-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one **24** (18 mg, 75%), mp 178–180°C; uv (CH_3OH) λ_{max} nm (log ε): 242 (4.88), 264 (4.06), 275 (4.77), 302 (4.41), 316 (4.32), 328 (4.28), 375 (4.38); ir ($CHCl_3$) ν_{max}: 1750 (acetate C=O), 1720 (lactone C=O), 1610, 1590 (C=C, aromatic) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.15 (d, 3H, J = 6.9 Hz, CH_3CHBr), 2.41 (s, 3H, CH_3COO), 2.77 (s, OH), 3.98 (s, 3H, OCH_3), 4.09 (s, 3H, OCH_3), 5.31 (q, 1H, J = 6.9 Hz, CH_3CHBr), 7.21 (dd, 1H, J = 1.2 Hz, J = 7.5 Hz, C2H), 7.42 (d, 1H, J = 1.7 Hz, C9H), 7.60 (dd, 1H, J = 7.5 Hz, J = 8.6 Hz, C3H), 8.16 (d, 1H, J = 1.6 Hz, C7H), 8.38 (s, 1H, C11H), 8.51 (dd, 1H, J = 1.1 Hz, J = 8.6 Hz, C4H). *Exact Mass* calcd. for $C_{23}H_{19}O_6Br$: 472.0364; found: 472.0334.

*1-Hydroxy-10,12-dimethoxy-8-vinyl-6*H*-benzo[*d*]naphtho[1,2*b*]-pyran-6-one* **7**

Sodium borohydride (3 mg) was added to diphenyl diselenide (11.8 mg) in absolute ethanol (2 mL) under a flow of argon. Diphenyl diselenide (2 mg) was added to destroy any excess sodium borohydride and the solution turned yellow. 1-Acetoxy-10,12-dimethoxy-8-(bromoethyl)-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one **24** (8 mg, 0.02 mmol) in dry tetrahydrofuran was added and the reaction mixture was refluxed for 2.5 h. The solution was cooled in an ice bath, hydrogen peroxide (2 mL, 30%) was added over 20 min, and the mixture was stirred for 3 h at 0°C. Dilution with water (10 mL) and extraction with ether (3 × 20 mL) provided a crude product that was purified by ptlc to give 1-hydroxy-10,12-dimethoxy-8-vinyl-6*H*-benzo[*d*]naphtho[1,2*b*]pyran-6-one **7** (2.3 mg, 40%), mp 263–265°C, identical in all physical and spectroscopic properties with compound **7** obtained by alkali fusion of ravidomycin (4).

*1-Acetoxy-10,12-dimethoxy-8-vinyl-6*H*-benzo[*d*]naphtho[1,2*b*]-pyran-6-one* **25**

1-Acetoxy-10,12-dimethoxy-8-ethyl-6*H*-benzo[*d*]naphtho[1,2*b*]-pyran-6-one **20** (16 mg, 0.04 mmol) in carbon tetrachloride (30 mL) was refluxed with *N*-bromosuccinimide (7.3 mg) and a catalytic amount of dibenzoyl peroxide for 4 h. Thin-layer chromatography showed the presence of starting material and so additional *N*-bromosuccinimide (7.3 mg) was added and refluxing was continued for 4 h, after which tlc showed the absence of starting material. After evaporation of solvent the products were purified by ptlc on silica gel (chloroform). Fractional crystallization (chloroform–hexane) of the main band gave 1-acetoxy-10,12-dimethoxy-8-vinyl-6*H*-benzo[*d*]naphtho[1,2*b*]-pyran-6-one **25** (5 mg, 31%), mp 215–218°C (the mother liquor contained the acetate monobromide **24** together with **25**); uv (CH_3OH) λ_{max} nm (log ε): 242 (4.85), 276 (4.69), 282 (4.72), 306 (4.47), 319 (4.38), 330 (4.30), 346 (4.27), 380 (4.36); ir ($CHCl_3$) ν_{max}: 1750 (acetate C=O), 1720 (lactone C=O), 1605, 1590 (C=C, aromatic) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.42 (s, 3H, CH_3COO), 4.03 (s, 3H, OCH_3), 4.14 (s, 3H, OCH_3), 5.47 (d, 1H, J = 10.7 Hz, vinyl H), 5.98 (d, 1H, J = 17.8 Hz, vinyl H), 6.84 (dd, 1H, J = 17.8 Hz, J = 10.7 Hz, vinyl H), 7.22 (dd, 1H, J = 1.0 Hz, J = 7.5 Hz, C2H), 7.40 (d, 1H, J = 1.4 Hz, C9H), 7.61 (dd, 1H, J = 7.6 Hz, J = 8.5 Hz, C3H), 8.21 (d, 1H, J = 1.4 Hz, C7H), 8.49 (s, 1H, C11H), 8.55 (dd, 1H, J = 1.0 Hz, J = 8.5 Hz, C4H). *Exact Mass* calcd. for $C_{23}H_{18}O_6$: 390.1103; found: 390.1101.

The Dufour's gland secretion of *C. scutellaris* contains a series of C_{23} long chain derivatives characterized by the presence of a cross-conjugated dienone linked to either a primary acetate, an aldehyde, or a carboxylic acid function. These compounds further differ from each other by the degree of unsaturation and (or) the position of an isolated double bond in the carbon atom chain. A combination of spectroscopic data and chemical degradations led to structures **1***a–c*, **2***a–c*, and **5***a–c* for the major components of the secretion. The highly electrophilic character of these compounds accounts for their efficiency as contact poisons.

D. DALOZE, J. C. BRAEKMAN, P. VANHECKE, J. L. BOEVÉ et J. M. PASTEELS. Can. J. Chem. **65**, 432 (1987).

La sécrétion de la glande de Dufour de *C. scutellaris* contient une série de dérivés à longue chaîne en C_{23} qui sont caractérisés par la présence d'une dièнone conjugée croisée liée à une fonction acétate primaire, aldéhyde ou acide carboxylique. Ces composés diffèrent aussi les uns des autres par le degré d'insaturation et (ou) par la position d'une double liaison isolée dans la chaîne carbonée. En se basant sur une combinaison de données spectroscopiques et de dégradations chimiques, on a pu attribuer les structures **1***a–c*, **2***a–c* et **5***a–c* aux principaux composants de la sécrétion. Le caractère électrophile élevé de ces composés explique leur efficacité comme poisons de contact.

[Traduit par la revue]

Introduction

The composition of the Dufour's gland secretion of ants has been the subject of several investigations. Aliphatic linear hydrocarbons in the range C_9–C_{27} are generally present, but branched-chain hydrocarbons and oxygenated compounds can also be encountered (for review see ref. 1). Among the subfamily Myrmicinae, the Dufour's gland contents of several species of the genus *Myrmica* have been investigated (2–8). Besides the linear, odd-numbered hydrocarbon theme, traces of highly volatile alcohols, aldehydes, and ketones in the C_1–C_4 range have also been reported (9). Most species of *Myrmica* also possess terpenoid hydrocarbons, identified as (*Z*,*E*)-α-farnesene, homofarnesene, and bishomofarnesene (8). Farnesene derivatives have also been identified in the Dufour's gland of several species of the genera *Atta* (10), *Solenopsis* (11–13), *Aphaenogaster* (14), and *Pheidole* (15).

Ethological studies have shown that ants of the genus *Myrmica* use their Dufour's gland contents as recruitment and home-range marking pheromone (4). In addition, some ant species utilize trace components of the Dufour's gland secretion as trail pheromone (e.g., the sesquiterpenoid aldehyde faranal in *Monomorium pharaonis* (16) and farnesene derivatives in several *Solenopsis* species (11–13)).

Ants of the genus *Crematogaster* are unique among the myrmicines in that they use their Dufour's gland secretion as a contact defensive secretion (17), instead of injecting, by stinging, a venom produced by the poison gland as in most primitive ant species.

Crematogaster species are able to swing their gasters up and over the thorax and head so that the sting is presented in a cephalad direction (18). Furthermore, while their spatulate sting is not a suitable injection device, it would function ideally as an organ for topically applying venom (18). This interpretation is supported by the observation that the venom of *Crematogaster lineolata* is very toxic when topically administered to termite workers (ref. 1*b*, p. 809). We have similarly observed that the venom of *C. scutellaris*, an aggressive Mediterranean species, is toxic to other ants. These observations prompted us to examine the chemical composition of this venom.

Results and discussion

When workers of *C. scutellaris* are immobilized with tweezers, a droplet of venom is emitted and accumulates on the spatulate portion of the sting. This secretion can be collected on bits of filter paper and stored in hexane. In this manner, the secretion of 250 ants afforded about 15 mg of a light yellow oil, after removal of the solvent (about 60 μg/ant).

Preliminary observations have shown that the constituents of the secretion are unstable and must be kept in dilute solutions under N_2, at −30°C, to avoid extensive decomposition. A tlc analysis of freshly collected material (SiO_2; eluent, hexane–acetone 8:2) indicated the presence of five spots corresponding to at least five components, numbered CS1 to CS5 in order of increasing polarity. The relative proportions of these five components vary from one collection to another.

All attempts to separate the venom constituents by adsorption chromatography on either silica gel, alumina, or Florisil failed, since most of the material (≥75%) remained on the column and could not be recovered. However, repetitive partition chromatographies on Sephadex LH-20 columns, using heptane–$CHCl_3$–MeOH (10:10:1) as eluent (20), allowed us to resolve the mixture in five fractions, corresponding to the above-mentioned tlc spots. As will be shown below, these fractions are not pure compounds but rather mixtures of derivatives differing by the number and (or) position of the double bond(s).

We first turned our attention to CS2, whose stability looked more promising than that of its companions.

Fraction CS2

The EI (electron impact) ms (mass spectrum) of CS2 shows at least three peaks attributable to molecular ions, at *m/z* 388,

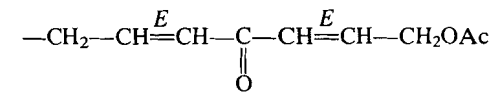
390, and 392 (the intensity of the latter being very small), thus indicating that this fraction is still a mixture of compounds differing by their degree of unsaturation. High performance liquid chromatography (hplc) analysis (SiO_2, 5 μm, hexane–dioxane 99:1) of CS2 demonstrated the presence of at least six components (in order of increasing polarity): A (3.5%); B (2.5%); C (14.0%); D (44%); E (9.0%), and F (27%). These values are approximate since some of the peaks (e.g., C and D) are poorly resolved. Preparative hplc afforded very small samples of C and D (as a mixture) and of F. Interestingly, the ms of the C and D mixture displays only a small M^+ peak at m/z 390, suggesting that these compounds are isomers. High resolution ms measurements on the most intense fragment ions gave the following results: m/z 362.28244 ($C_{23}H_{38}O_3$); 330.29172 ($C_{23}H_{38}O$); 320.27248 ($C_{21}H_{36}O_2$); 302.26095 ($C_{21}H_{34}O$). This suggests that C and D have the empirical formula $C_{25}H_{42}O_3$. In the ms of F, the molecular ion (M^+ 388), and all the characteristic fragment ions appear two mass units lower than in the ms of C and D, thus indicating the molecular formula $C_{25}H_{40}O_3$ for F. The ir and uv spectra of CS2 ($\nu_{C=O}$ 1745 and 1670 cm^{-1}; $\nu_{C=C}$ 1640 and 1620 cm^{-1}; ν_{C-O} 1230 cm^{-1}; λ_{max} 235 nm, ε 30 000 (CH_3OH)) indicated the presence of acetoxy group(s) and of a conjugated ketone, probably of the cross-conjugated dienone type (21).

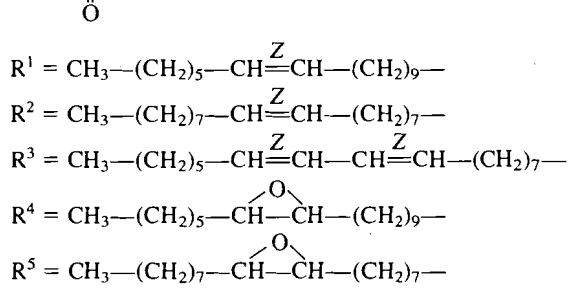
The ^1H nmr spectrum (Table 1, column **2***a*,*b*) fully confirmed these assignments. In particular, it showed the presence of a primary allylic acetoxy group (4.78 ppm, dd, J = 4.8 and 1.6 Hz; 2H) linked to a cross-conjugated dienone. Extensive decoupling experiments and comparison of the ^1H nmr spectrum of CS2 with those of reference cross-conjugated dienones (21, 22) established the presence of partial structure **X**:



X

Bearing in mind the empirical formula $C_{25}H_{42}O_3$ for C and D, structural moiety **X** contains all the oxygen atoms and four out of the five unsaturations of the molecules. It follows that, to complete the structure of C and D, a $C_{16}H_{31}$ moiety must be linked to **X**. The ^1H nmr spectrum unambiguously demonstrated that this moiety is an unbranched carbon atom chain bearing one isolated double bond (1.25 ppm, bs, methylenes; 0.89 ppm, distorted t, 3H, methyl; and 5.34 ppm, t, 2H, olefins).

	R^0	R
1*a*	CHO	R^1
1*b*	CHO	R^2
1*c*	CHO	R^3
2*a*	CH_2OAc	R^1
2*b*	CH_2OAc	R^2
2*c*	CH_2OAc	R^3
3*a*	CH_2OAc	R^4
3*b*	CH_2OAc	R^5
5*a*	COOH	R^1
5*b*	COOH	R^2
5*c*	COOH	R^3



Combination of these structural elements led to the structural hypothesis **Y** for C and D, which must only differ by the location and (or) the geometry of the isolated double bond.

Y ($m + n = 13$)

This was proved as follows. Microozonolysis (23) of both CS2 and of the crude secretion, followed by treatment of the resulting ozonide with $P\phi_3$, afforded *n*-heptanal and *n*-nonanal in a 3:1 ratio (glc). On the other hand, treatment of CS2 with *m*-chloroperbenzoic acid yielded chiefly a monoepoxide fraction (**3***a*,*b*) which, after purification by preparative tlc, showed only one molecular ion at m/z 406 in its EI ms. This result, together with the ^1H nmr of **3***a*,*b*, demonstrated that the latter are derived from C and D and are not contaminated by any epoxide coming from the dehydro derivative F. The ms of **3***a*,*b* displays strong peaks at m/z 279.19672 ($C_{17}H_{27}O_3$) and 251.16393 ($C_{15}H_{23}O_3$) arising from cleavage α to the epoxide group in **3***a* and **3***b*, respectively.

Cleavage of **3***a*,*b* with HIO_4 (24) again led to the identification of *n*-heptanal and *n*-nonanal in a 3:1 ratio (glc). These results demonstrated that, in the major compound D, the double bond is located between C-16 and C-17, and between C-14 and C-15 in its isomer C.

Finally, the geometry of these double bonds was assigned as *Z*, on the basis of a $^1H/^{13}C$ nmr heterodecoupling experiment, allowing us to assign the signals of the allylic carbon atoms at 27 ppm (25). Since this experiment was performed on the crude secretion, the geometry of the isolated double bond must also be *Z* in all other Δ^{16} and Δ^{14} derivatives whose structures will be discussed shortly.

Compound D is thus (2*E*,5*E*,16*Z*)-4-oxotricosa-2,5,16-trien-1-ol acetate (**2***a*), whereas C is (2*E*,5*E*,14*Z*)-4-oxotricosa-2,5,14-trien-1-ol acetate (**2***b*).

In addition to the signals attributed to **2***a* and **2***b*, the ^1H nmr spectrum of CS2 also contains three signals at 5.38 ppm (dt, 2H), 6.24 ppm (bd, J = 9 Hz, 2H), and 2.12 ppm (m, 4H) attributable to a conjugated *Z*,*Z*-diene in a long chain (26). This was fully confirmed by double irradiation experiments. Consequently, compound F possess a conjugated diene, which should be located either in the $\Delta^{14,16}$ or in the $\Delta^{12,14}$ position,

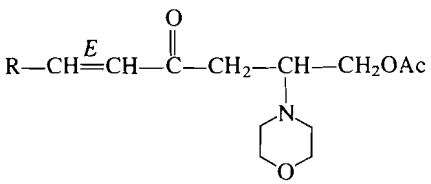
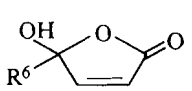
according to the results of the ozonolysis reaction of CS2. On the basis of the double bond position in the monoenes, we tentatively propose that compound F could be (2*E*,5*E*,14*Z*,16*Z*)-4-oxotricosa-2,5,14,16-tetraen-1-ol acetate (**2***c*).

The structural assignments of compounds **2***a*–*c* were confirmed as follows. Treatment of CS2 with morpholine (27) in EtOH led, after silica gel column chromatography, to a mixture of adducts **6***a*–*c*. The spectral properties of the latter (EI



6*a* R = R^1
6*b* R = R^2
6*c* R = R^3



4*a* R^6 = CH_3—$(CH_2)_5$—CH=CH—$(CH_2)_{11}$— (Z)
4*b* R^6 = CH_3—$(CH_2)_7$—CH=CH—$(CH_2)_9$— (Z)

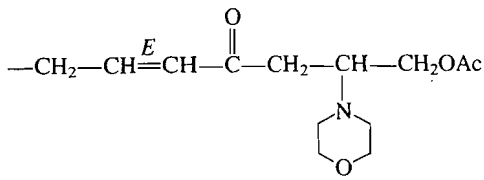
7 R^6 = CH_3—

ms: M^+ at *m*/*z* 475 and 477, CI (NH_3) ms: $(M+H)^+$ at *m*/*z* 476 and 478, leading to empirical formulae $C_{29}H_{49}NO_4$ and $C_{29}H_{51}NO_4$, respectively; ir: $\nu_{C=O}$ 1745, 1700, and 1670 cm^{-1}; $\nu_{C=C}$ 1620 cm^{-1}; uv λ_{max} 228 nm) are in agreement with the addition of one morpholine molecule to the conjugated chromophore of **2***a*–*c*. Indeed, the presence of partial structure **Z** in **6***a*–*c* was clearly demonstrated by the ^{1}H nmr spectrum (Table 1) and by extensive double irradiation experiments.



Z

The structures of the three major components of CS2 (C, D, and F) are thus unambiguously established. The three minor ones (A, B, and E) have not yet been identified. However, the presence of a small peak at *m*/*z* 392 in the ms of CS2 (*vide supra*) points to the existence of one or several dihydro derivatives of **2***a* and **2***b*, whose structures could not be more accurately defined.

Several attempts were made to correlate compounds **2***a*–*c*, in particular by homo- or heterogeneous catalytic hydrogenation, but without success, since only intractable mixtures were obtained.

Fraction CS1

This very unstable fraction also displays three molecular ions at *m*/*z* 344, 346, and 348, in a 1:3:1 ratio.

An intense fragment ion is observed at *m*/*z* 318.25534 ($C_{21}H_{34}O_2$, hrms, $M^+ - C_2H_4$). In the CI ms (isobutane) of CS1, $(M+H)^+$ peaks appear at 345, 347, and 349 with $(M+C_4H_9)^+$ peaks at *m*/*z* 401, 403, and 405. It follows from these data that

For personal use only.

the major component of CS1 has a molecular weight of 346 daltons, and a molecular formula $C_{23}H_{38}O_2$. As in CS2, it is clearly accompanied by one (or more) dehydro (M^+ at m/z 344) and dihydro derivative(s) (M^+ at m/z 348). The ir spectrum shows the presence of conjugated carbonyl groups ($\nu_{C=O}$ 1695, 1675 cm^{-1}; $\nu_{C=C}$ 1625 cm^{-1}), whereas the ^1H nmr of CS1 (Table 1, column **1***a*,*b*) clearly shows the presence of an aldehyde function linked to the usual cross-conjugated dienone (CHO, 9.80 ppm, d, 7.3 Hz coupled to H-2; 6.83 ppm, dd, 16.0 and 7.3 Hz), and of the same mixture of monoenic (5.30 ppm, t) and dienic (5.45, dt and 6.20 ppm, bd) components. These ms and nmr data, together with our results on CS2, indicated that CS1 is a mixture of at least four derivatives, the structures of three of which may be represented by **1***a*–**1***c*. Thus, the major compound of CS1 (**1***a*) is, most probably, (2*E*,5*E*,16*Z*)-4-oxotricosa-2,5,16-trienal.

Fraction CS5

The more polar fraction of the secretion follows the same EI ms pattern as the others, with molecular ions at m/z 360, 362, and 364 (confirmed by D/CI (NH_3) ms). The most intense peak, at m/z 362, gives rise to prominent fragment ions at m/z 334.2502 ($C_{21}H_{34}O_3$, hrms, $M^+ - C_2H_4$) and 316.23925 ($C_{21}H_{32}O_2$, hrms, $M^+ - C_2H_4 - H_2O$), and corresponds to the molecular formula $C_{23}H_{38}O_3$. The uv (λ_{max} 235 nm) and ir spectra (ν_{OH} 3500–2400 cm^{-1}; $\nu_{C=O}$ 1710, 1685, 1665 cm^{-1}; $\nu_{C=C}$ 1625 cm^{-1}) suggest the presence of a carboxylic acid function and of the cross-conjugated dienone.

Two C=O groups are evident in the ^{13}C nmr spectrum of CS5 (CO, 188.5 and COOH, 170.0 ppm), whereas the ^1H nmr spectrum (Table 1) fully supports structures **5***a*–**5***c* for the major components of CS5. The major compound (**5***a*) is thus formulated as (2*E*,5*E*,16*Z*)-4-oxotricosa-2,5,16-trienoic acid. Again, all our attempts to chemically correlate **5***a*–**5***c* with other derivatives of the series failed. Esterification of the carboxylic acid was also attempted under various experimental conditions (CH_2N_2, CH_3OH/H^+, Meerwein salts), but only led to degraded material.

Fraction CS3

This minor yellow fraction suffered extensive degradation as soon as it came out of the Sephadex LH-20 column, and could not be investigated.

Fraction CS4

The EI ms spectrum of this minor fraction is very similar to that of CS5 (M^+ at m/z 360, 362, 364, 366, and 368; intense fragment ions at m/z 334 and 316), thus suggesting a close relationship between both fractions.

The ir spectrum (ν_{OH} 3350 cm^{-1}; $\nu_{C=O}$ 1775 and 1750 cm^{-1}; $\nu_{C=C}$ 1670 cm^{-1}) indicated the presence of an hydroxyl group and of an α,β-unsaturated lactone (28). After several LH-20 chromatographies, we obtained a sample of CS4, whose ^1H nmr is reported in Table 1 (column **4***a*,*b*). Comparison of this spectrum with that of pseudo *cis*-β-acetylacrylic acid (**7**) (29) points to the presence of the same structural elements in both derivatives. Further, the sole olefinic signals that appear in this spectrum are those of the $\Delta^{2(Z)}$ (*cis*) and the $\Delta^{14/16}$ double bonds. These observations lead us to propose structures **4***a*–**4***c* for the major components of CS4. These compounds probably arise by addition of the COOH group to the unsaturated C=O function of $\Delta^{2(Z)}$ dihydro isomers of **5***a*–**5***c*. Although no attempt was made to investigate this reaction in detail, we have observed that uv irradiation of CS5 (254 nm) yielded a less polar fraction with an R_f in tlc identical to that of fraction CS4.

Careful dissection of Dufour's and poison glands, followed by CH_2Cl_2 extraction and tlc analyses, have demonstrated that the compounds we have discussed originate from the Dufour's gland.

The structure and chemical reactivity of *C. scutellaris* derivatives suggest that their toxicity stems from their electrophilic character, allowing them to react with biologically important nucleophilic sites containing hydroxyl, sulfhydryl, or amino groups. Similar contact poisons from termites of the subfamilies Prorhinotermitinae and Rhinotermitinae (30) have been described, and include nitroalkenes, vinylketones, and β-ketoaldehydes. Conjugated ketoaldehydes have also been reported from defensive secretions of bugs (31) and sawflies (19).

However, to the best of our knowledge, this is the first report of this type of derivative in the defensive secretion of an ant.

Experimental

The following instruments were used to measure the physical data: ir, Pye unicam SP1000; uv, Cary 14; ^1H and ^{13}C nmr, Bruker WM 250; ms, Finnigan 3000 D and Micro-mass 7070 F. The nmr spectra were recorded in $CDCl_3$ solution. Chemical shifts are quoted in δ values downfield from TMS as internal standard. The tlc were performed on Polygram Sil G precoated plates (Macherey Nagel).

Collection of the secretion

C. scutellaris workers were seized by tweezers and the defensive secretion that appears at the tip of the sting was collected on bits of filter paper and stored in hexane at −30°C under N_2.

Thin-layer chromatography of the secretion (hexane–acetone 8:2) shows the presence of 5 well-resolved spots numbered from CS1 to CS5 in order of increasing polarity.

Isolation of the compounds

Twenty-two milligrams of the crude secretion of *C. scutellaris* were submitted to partition chromatography on a Sephadex LH-20 column (1 m) using heptane–$CHCl_3$–MeOH (10:10:1) as eluent (20). Flow rate: 0.2 mL/min. Fractions of 3 mL were collected and combined after analysis by tlc (hexane–acetone 8:2). In this manner were obtained (in order of elution from the Sephadex LH-20 column) CS3 (2.5 mg), CS2 (5.0 mg), CS1 (4.5 mg), CS4 (2.5 mg), and CS5 (7.5 mg).

Fraction CS1

Oil; ir: $\nu_{C=O}$ 1695, 1675 cm^{-1}; $\nu_{C=C}$ 1625 cm^{-1}; uv: λ_{max} 234 nm (hexane); ^1H nmr: see Table 1; EI ms: M^+ at m/z 348, 346, 344 (1:3:1); fragment ions at m/z 320, 318.25534 ($C_{21}H_{34}O_2$), 316, 304, 302, 263, 261, 123, 121, 109, 107, 97, 95. CI ms (isobutane): 405, 403, 401 $(M + C_4H_9)^+$, 349, 347, 345 $(M + H)^+$, 319 $(346 - 28 + H^+)$.

Fraction CS2

Oil; ir and uv spectra: see text; ^1H nmr: Table 1; EI ms: M^+ at m/z 392, 390, 388; fragment ions at m/z 364, 362.28244 ($C_{23}H_{38}O_3$), 360, 350, 348, 346, 330.29172 ($C_{23}H_{38}O$), 328, 320.27248 ($C_{21}H_{36}O_2$), 318, 304, 302.26095 ($C_{21}H_{34}O$), 263, 261, 163, 161, 123, 121, 109, 107.

The hplc analysis of CS2: hplc analysis of CS2 (SiO_2, 5 μm, hexane–dioxane 99:1, uv and refractive index detectors) shows the presence of six components, A–F (see text). EI ms of C–D mixture: M^+ at m/z 390; fragment ions at m/z 362, 348, 330, 320, 302, 263 ... 177, 175, 163, 161, 123, 121, 109, 107; EI ms of F: M^+ at m/z 388; fragment ions at m/z 360, 346, 328, 318, 300, 284, 256 ... 175, 163, 161, 123, 121, 109, 107.

Ozonolysis of CS2

CS2 (2 mg) in 50 μL pentane and 250 μL MeOH was ozonolyzed according to Beroza and Bierl (23) at −60°C during 5 min. Addition of $P\phi_3$ and glc analysis on a capillary OV-1 column (115°C) allowed us to identify *n*-heptanal and *n*-nonanal in a 3:1 ratio, by coinjection

with authentic samples. The same result was obtained by glc analysis on a packed 10% Carbowax 20 M column (80 and 105°C).

Ozonolysis of the crude secretion also yielded *n*-heptanal and *n*-nonanal in roughly the same ratio.

Epoxides **3**a,b

CS2 (3 mg) in CH_2Cl_2 was treated at 0°C with an excess of MCPBA under stirring for 2 h. The reaction mixture was concentrated under N_2 and purified by preparative tlc (SiO_2, 0.25 × 5 × 10 cm, hexane–acetone 7:3) affording 1.5 mg of a mixture of **3***a* and **3***b*. **3***a*,*b*: oil; ^1H nmr: see Table 1; EI ms: M^+ at *m/z* 406 ($C_{25}H_{42}O_4$); fragment ions at *m/z* 378, 364, 346, 336, 333, 318, 305, 279.19672 ($C_{17}H_{27}O_3$), 251.16393 ($C_{15}H_{23}O_3$), 249, 247, 223.16956 ($C_{14}H_{23}O_2$) and 223.13343 ($C_{13}H_{19}O_3$), 221, 219, 191, 163.

Cleavage of **3**a,b *with* HIO_4

Treatment of **3***a*,*b* in hexane–Et_2O with HIO_4 (24) followed by glc analysis under the same conditions as above allowed the identification of *n*-heptanal and *n*-nonanal in a 3:1 ratio.

Treatment of CS2 with morpholine

Fraction CS2 (5 mg) in EtOH was treated with 5 drops of freshly distilled morpholine and left at 4°C for 1 h. After evaporation of the solvent and silica gel column chromatography (hexane–dioxane 9:1), the adducts **6***a*, **6***b*, and **6***c* were obtained as a mixture giving only one spot on tlc in several solvent systems.

6*a*, **6***b*, **6***c*: oil; ir and uv spectra: see text; ^1H nmr: Table 1; EI ms: M^+ at *m/z* 479 (small), 477, and 475; fragment ions at *m/z* 449, 447, 404, 402, 390, 389, 376, 362, 350, 348, 330, 320, 302, 263; CI ms (NH_3): $(M+H)^+$ at *m/z* 478 and 476.

Fraction CS4

Oil; ir and uv spectra: see text. This sample was further purified by Sephadex LH-20 chromatography ($CHCl_3$–hexane, 7:3) affording a fraction whose ^1H nmr is described in Table 1; EI ms: M^+ at *m/z* 368, 366, 364, 362, and 360; fragment ions at *m/z* 334, 332, 317, 316, 314, 303, 289, 288, 250.

Fraction CS5

Oil; ir and uv spectra: see text; ^1H nmr: Table 1; EI ms: M^+ at *m/z* 364, 362, and 360; fragment ions at *m/z* 336, 334.2502 ($C_{21}H_{34}O_3$), 332, 316.23925 ($C_{21}H_{32}O_2$), 284, 256; CI ms (NH_3): $(M+NH_4^+)$ at *m/z* 384, 382, 380, 378; fragment ions at *m/z* 356, 354, 352 and 350 $(M+NH_4^+ - C_2H_4)$, 337, 335 and 333 $(M+H^+ - C_2H_4)$.

Acknowledgments

We thank Prof. J. F. Normant (Paris) for sending us spectroscopic data of dienone systems, Dr. R. Ottinger for the nmr spectra, and Mr. C. Moulard for the mass spectra.

KANTA KUMAR, MORTON H. LITT, RAJ K. CHADHA, and JOHN E. DRAKE. Can. J. Chem. **65**, 437 (1987).

The coupling reaction between $PhMeSiCl_2$ and Me_2SiCl_2 in the presence of Na/K alloy resulted in a variety of phenylated permethylcyclohexasilanes of which only *trans*-1,4-$Ph_2Me_{10}Si_6$ could be obtained in pure form by repeated recrystallizations. It was studied by means of nmr (^1H, ^{13}C, and ^{29}Si) and X-ray crystallography. The crystals are monoclinic, $P2_1/c$ with $a = 10.105(6)$, $b = 14.77(1)$, $c = 9.973(6)$ Å, $\beta = 94.08(5)°$, $V = 1485(2)$ Å^3, and $Z = 2$ for 1922 unique "observed" reflections and the structure refined to an R index of 0.036. The molecule has site symmetry $\bar{1}$ and the chair conformation of cyclohexane, with the two phenyl rings occupying the equatorial positions.

KANTA KUMAR, MORTON H. LITT, RAJ K. CHADHA et JOHN E. DRAKE. Can. J. Chem. **65**, 437 (1987).

La réaction de couplage du $PhMeSiCl_2$ et du Me_2SiCl_2, en présence d'un alliage de Na/K, conduit à un mélange de perméthylcyclohexasilanes phénylés duquel, des cristallisations fractionnées répétées, n'ont permis d'isoler à l'état pur que le diphényl-1,4-*trans* $Me_{10}Si_6$. On l'a étudié par rmn du ^1H, du ^{13}C et du ^{29}Si ainsi que par diffraction des rayons-X. Les cristaux sont monocliniques, $P2_1/c$, avec $a = 10{,}105(6)$, $b = 14{,}77(1)$ et $c = 9{,}973(6)$ Å, $\beta = 94{,}08(5)°$, $V = 1485(2)$ Å^3 et $Z = 2$ pour 1922 réflexions uniques observées : on a affiné la structure jusqu'à une valeur de R de 0,036. La molécule possède un site de symétrie $\bar{1}$; le cyclohexane adopte une conformation chaise et les deux groupements phényles occupent des positions équatoriales.

[Traduit par la revue]

Introduction

Phenylated permethylcyclohexasilane derivatives are generally prepared by the reaction of PhMgCl with chloropermethylcyclohexasilanes (1–3). The method is basically used to purify the chloro derivatives because the phenyl compounds are much easier to handle in air and can be quantitatively converted back to the chloro derivatives (1). For this reason we decided to prepare phenylated permethylcyclohexasilanes directly from monosilane precursors, following the procedures of Helmer and West (1). In this paper, we report the preparation of one such compound, namely *trans*-1,4-diphenyldecamethylcyclohexasilane, along with an X-ray crystallographic study which confirms the *trans* geometry and establishes the orientation of the phenyl rings in the compound.

Results and discussion

The method used to synthesize the phenyl-substituted permethylcyclohexasilanes was that of alkali metal co-condensation of one equivalent of $PhMeSiCl_2$ with two equivalents of Me_2SiCl_2.

$$PhMeSiCl_2 + 2Me_2SiCl_2 \xrightarrow[THF]{Na/K} Ph_xMe_{12-x}Si_6 + MCl$$

$x = 0$–6; M = Na or K

Though the method gave compounds with every degree of phenyl substitution, only $Me_{12}Si_6$, $PhMe_{11}Si_6$, and $Ph_2Me_{10}Si_6$ derivatives were isolated and characterized. The yield of the diphenyl derivatives was optimized by the slow addition of the mixed dihalosilanes to Na/K alloy in refluxing THF. The maximum yield of the mixture of various isomers of $Ph_2Me_{10}Si_6$ thus obtained was 32%. Table 1 shows the percent yield of various isolated derivatives. The theoretical yields were obtained by assuming that the coupling of the dimethyl and methylphenyl silyl groups was random, and by using a binomial expansion to calculate the values. There is good agreement between theory and experiment (Table 1) showing that the slow addition results in establishing a random product distribution, probably by ring opening and reshuffling reactions subsequent to coupling. In reactions where the silanes were added to the reaction flask rapidly, large amounts of $Me_{12}Si_6$ and higher phenylated compounds were obtained.

TABLE 1. Percent yield of various isolated derivatives

$Ph_xMe_{12-x}Si_6$ x	Yield wt%	Yield mol%	Theoretical yield mol%
0	8	11	8.8
1	24	27	26.3
2	32	32	32.9
3	36	30	21.9
4			8.2
5			1.6
6			0.1

The isomeric mixture of diphenyl derivatives obtained from the optimum yield reaction was further separated into the solid (A) and liquid (B) fractions by the addition of ethanol. The ^1H nmr spectra of these two fractions are shown in Fig. 1 and an hplc run showed that the solid fraction (A) was a mixture of more than five isomers. Repeated recrystallizations of the solid fraction were carried out until its chromatogram showed only a single peak. Thus, this diphenyldecamethylcyclohexasilane (mp 168–170°C) was isolated only in a small yield. Its ^1H nmr

*$U_{eq} = \frac{1}{3}\Sigma_i\Sigma_j a^*_i a^*_j a_i \cdot a_j$.

spectrum is shown in Fig. 1 and ^1H, ^{13}C, and ^{29}Si nmr data are given in the Experimental section.

If the two phenyl substituents in a 1,4-disubstituted hexasilane ring are either both equatorial or both axial, there would be two non-equivalent silicon atoms (ratio 2:4), three non-equivalent methyl groups (2:4:4), and three non-equivalent methyl protons (6:12:12). The observed number of signals clearly indicate that the diphenyl derivative possesses *trans* geometry, i.e., the two phenyl rings are indeed either both equatorial or both axial. However, it is expected that the bulkier phenyl groups, in order to minimize non-bonding interactions, should probably occupy the equatorial positions. The following assignment of the nmr signals are based on this assumption.

In the ^1H nmr spectrum, the methyl groups attached to the 1,4 silicon atoms being axial appear downfield at 0.530 ppm. As the equatorial methyl groups at positions 2, 3, 5, and 6 lie in the deshielding region of the phenyl rings, they appear at 0.330 ppm, while the axial methyl groups are shielded and appear to highfield at 0.198 ppm. In contrast with the ^1H nmr spectra, an upfield shift was observed for the 1,4 methyl groups

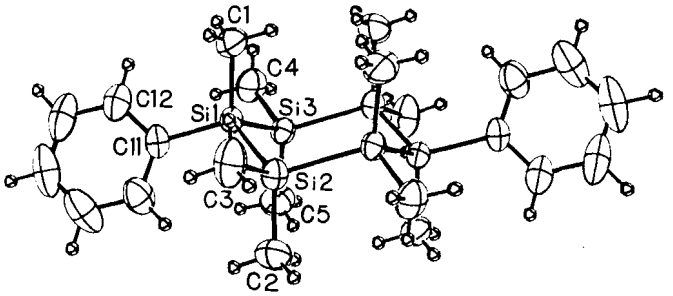

FIG. 2. ORTEP plot of *trans*-1,4-$Ph_2Me_{10}Si_6$. The atoms are drawn with the 50% probability ellipsoids. The labeling scheme is defined, unlabeled atoms are related to labeled ones by a centre of inversion at 0, 0, ½. Hydrogen atoms are drawn arbitrarily small.

in the ^{13}C nmr spectrum (−6.49 ppm). The methyl groups which are *cis* to the phenyl groups appear downfield at −4.32 ppm and those which are *trans* to the phenyl groups appear upfield at −6.71 ppm. These assignments are consistent with the results of Helmer and West (1). The 1,4-silicon resonances appear at −41.40 ppm while other silicon resonances appear at −41.08 ppm. This assignment of peaks is based on the results of Sharp *et al.* (4).

The single crystal X-ray structure determination confirms the *trans* geometry of 1,4-diphenyldecamethylcyclohexasilane. The final atomic coordinates for Si and C atoms are given in Table 2 and important distances and angles in Table 3. The compound exists as discrete molecules as shown in Fig. 2. The cyclohexasilane ring adopts a regular chair conformation with $\bar{1}$ site symmetry at 0, 0, ½. The two phenyl rings which are present at the 1,4 positions occupy equatorial sites. The average Si—Si distance of 2.350(3) Å is close to that in elemental silicon, 2.352 Å (5), $Me_{12}Si_6$, 2.338(4) Å (6), and $Ph_6Me_6Si_6$, 2.359(2) Å (7). These distances agree well with the Si—Si covalent bond length of 2.34 Å (8). The average Si—Si—Si bond angle is 110.6(6)° and average SiSiSiSi torsion angle is 57.1°. These and other torsion angles (Table 4) are closer to the ideal angles of 109.5°, 60°, and 180° for a six-membered chair conformation than the respective angles in other hexasilane structures studied so far (6, 7, 9). This indicates that the structure of *trans*-1,4-$Ph_2Me_{10}Si_6$ has the least distorted cyclohexasilane ring relative to those of $Me_{12}Si_6$ (6), all *trans*-$Ph_6Me_6Si_6$ (7), and $Ph_{12}Si_6.7C_6H_6$ (9).[2]

The average Si—C bond length is 1.890(8) Å and there is very little or no difference between the average Si—C(ax) (1.890(9) Å) and Si—C(eq) (1.889(9) Å) bond lengths. Here, the structure differs from $Me_{12}Si_6$ where a difference of 0.033 Å is reported between axial and equatorial Si—C bond distances (6). However, the difference between averaged Si—C(Me), 1.888(8) Å and Si—C(Ph) 1.897(3) Å is of the same magnitude as has been observed in $Ph_6Me_6Si_6$ (7).

Experimental

Starting materials

Me_2SiCl_2 and $MePhSiCl_2$ were obtained from Aldrich Chemical Co., and were distilled before use. Tetrahydrofuran (THF) was predried over $LiAlH_4$ and distilled from Na/benzophenone.

Preparation of 1,4-diphenyldecamethylcyclohexasilane

Typically, K (22.9 g) and Na (3.82 g; 78% K by weight) (10) were placed in a 3-necked, 1-L round bottom flask along with THF (300 mL) and then warmed and stirred for 1 h. A mixture of $PhMeSiCl_2$ (20 g, 0.105 mol) and Me_2SiCl_2 (27 g, 0.210 mol) in THF (50 mL) was then added dropwise over 2 h. The solution was refluxed overnight, cooled, and hexane (approx. 250 mL) added. Excess of Na/K was destroyed by slow and careful addition of water. The organic layer was separated, washed with aqueous NaCl, and dried over anhydrous Na_2SO_4. After evaporation of the solvent, 24.5 g of viscous liquid was obtained.

Thin layer chromatography (silica) using hexane as solvent showed the liquid to be a mixture of at least five products. Three products, $Me_{12}Si_6$, $PhMe_{11}Si_6$, and $Ph_2Me_{10}Si_6$ were isolated with the help of flash column chromatography (6 × 18 cm, packed with 40–63 μ silica gel 60) (11) using hexane as eluent. Fractions of 125 mL were collected, which on evaporation afforded the following compounds:

Fractions 4–6: $Me_{12}Si_6$ (3.2 g, 8%); ^1H nmr ($CDCl_3$, δ ppm) 0.182 (s); mp 251–253°C (lit. (7) 254–257°C).

Fractions 14–16: $PhMe_{11}Si_6$, recrystallized from ethanol (6.2 g, 24%); mp 109–110°C (lit. (5) 110–111°C).

Fractions 17–28: The isomeric mixture of 2,3-, 1,3-, and 1,4-*cis* and *trans* derivatives of $Ph_2Me_{10}Si_6$ (8.3 g, 32%). The mixture became semi-solid after standing overnight at room temperature. A small amount of ethanol was added to it and the solid (A) and liquid (B) fractions were separated by filtration.

Repeated recrystallizations of the solid fraction (A) gave 1.2 g of pure *trans*-1,4-$Ph_2Me_{10}Si_6$ (mp 168–170°C). High performance liquid chromatography showed a single peak. *Anal.* calcd. for $Si_6H_{40}C_{22}$: C 55.85, H 8.52, Si 35.62; found: C 55.70, H 8.53, Si 35.83. Mass spectrum (m/z): 472 (M^+). ^1H nmr ($CDCl_3$, δ ppm): 0.198 (s, 12H); 0.330 (s, 12H), 0.530 (s, 6H); 7.42 (m, 10H). $^{13}C\{^1H\}$ nmr ($CDCl_3$, δ ppm): −4.32, −6.49, −6.71, 134.68(*o*), 127.86(*p*), 127.71(*m*), 146.98(*ipso*). ^{29}Si nmr ($CDCl_3$, δ ppm): −41.08, −41.40. absorbance detector was set at 254 nm. ^{1}H nmr spectra were run using $CDCl_3$ as solvent and CH_2Cl_2 as internal reference (δ 5.35). ^{13}C nmr spectra were referenced to the central peak of the $CDCl_3$ triplet (δ 77.0). TMS was the internal standard for ^{29}Si nmr spectra. $Cr(acac)_3$ was added for the ^{29}Si and ^{13}C nmr. Infrared spectra were recorded on a Digilab Model FT-IRS-14. Mass spectra were obtained on a Finnigan mass spectrometer. Melting points were uncorrected. Elemental analyses were done by Galbraith Laboratory. Density was measured by the flotation method in C_6H_{12}/CCl_4.

X-ray crystallographic analysis

A crystal of dimensions 0.18 × 0.27 × 0.34 mm was mounted along the largest dimension and aligned on a Syntex $P2_1$ automated diffractometer. The unit cell dimensions were calculated from the setting angles of 15 strong reflections having $15° < 2\theta < 30°$. The data were collected and processed following the procedure described previously (12). The intensities of three monitor reflections checked every 60 reflections changed only by 2% during data collection. Of the 3068 reflections measured ($3° < 2\theta < 50°$, h, $0 \rightarrow 12$; k, $0 \rightarrow 17$, l, $-11 \rightarrow 11$), 1922 independent reflections had $I > 3\sigma(I)$ and only these were used in subsequent calculations. The intensities were corrected for Lorentz and polarization effects and not for absorption, since μ was only 2.48 cm^{-1}. Systematic absences ($0k0$, $k = 2n + 1$; $h0l$, $l = 2n + 1$) indicate the space group $P2_1/c$. Details of X-ray data and refinement parameters are summarized in Table 5.

The positions of Si(1), Si(2), and Si(3) atoms were obtained from the E-map (direct methods) using SHELX, while those of carbon atoms were determined from a difference Fourier map. The structure was refined anisotropically by the full-matrix least-squares methods. A difference map at this stage showed peaks at plausible hydrogen positions. Hydrogen atoms were included in subsequent refinements in ideal positions (C—H 0.95 Å, ∠CCH 120°, ∠HCH 109.5°). Methyl hydrogen atoms were refined as a group with isotropic thermal parameters assigned 0.01 Å^2 greater than the atoms to which they are attached. Refinement gave final values of $R = 0.036$ and $R_w = 0.041$. The function $(|F_o| - |F_c|)^2$ was minimized during least-squares refinement and in the final cycles, a weighting scheme of the form $w = 1/[\alpha^2(F) + pF^2]$ was employed with a final p value of 0.0006. No evidence of secondary extinction was found. Sources of scattering factors and computer programs used have been given elsewhere (12).

Received June 13, 1986

N. BANAIT, M. HOJATTI, P. FINDLAY, and A. J. KRESGE. Can. J. Chem. **65**, 441 (1987).

The rates of conversion of $C_6H_5C{\equiv}COCH_3$ to $C_6H_5CH_2CO_2CH_3$ were measured in dilute $HClO_4/H_2O$, $DClO_4/D_2O$, and H_3PO_4–$H_2PO_2^-/H_2O$ buffer solutions, and the rates of conversion of $C_6H_5C{\equiv}CSCH_3$ to $C_6H_5CH_2COSCH_3$, $C_6H_5C{\equiv}CH$ to $C_6H_5COCH_3$, 2,4,6-$(CH_3)_3C_6H_2C{\equiv}CH$ to 2,4,6-$(CH_3)_3C_6H_2COCH_3$, and p-$CH_3OC_6H_4C{\equiv}CCH_3$ to p-$CH_3OC_6H_4COCH_2CH_3$ were measured in concentrated $HClO_4/H_2O$ solutions, all at 25°C. The reaction of $C_6H_5C{\equiv}COCH_3$ showed general acid catalysis and gave the isotope effect $k_{H^+}/k_{D^+} = 1.59$, which indicates that it proceeds through rate-determining proton transfer from catalyst to substrate. The hydronium ion catalytic coefficient for this reaction is $k_{H^+} = 8.8 \times 10^{-2}\ M^{-1}\ s^{-1}$, and those for the other four, in the order given above, are $k_{H^+} = 1.2 \times 10^{-3}$, 2.9×10^{-7}, 1.2×10^{-4}, and $8.5 \times 10^{-6}\ M^{-1}\ s^{-1}$. Relative reactivities based on these rate constants are discussed.

N. BANAIT, M. HOJATTI, P. FINDLAY et A. J. KRESGE. Can. J. Chem. **65**, 441 (1987).

Opérant à 25°C, on a mesuré les vitesses de conversion du $C_6H_5C{\equiv}COCH_3$ en $C_6H_5CH_2CO_2CH_3$ dans des solutions diluées de $HClO_4/H_2O$ et de $DClO_4/D_2O$ et dans des solutions tampons de H_3PO_4–$H_2PO_2^-/H_2O$; on a aussi mesuré les vitesses de conversion du $C_6H_5C{\equiv}CSCH_3$ en $C_6H_5CH_2COSCH_3$, du $C_6H_5C{\equiv}CH$ en $C_6H_5COCH_3$, du $(CH_3)_3$-2,4,6 $C_6H_2C{\equiv}CH$ en $(CH_3)_3$-2,4,6 $C_6H_2COCH_3$ et du p-$CH_3OC_6H_4C{\equiv}CCH_3$ en p-$CH_3OC_6H_4COCH_2CH_3$ dans des solutions concentrées de $HClO_4/H_2O$. La réaction du $C_6H_5C{\equiv}COCH_3$ est soumise à une catalyse acide générale et l'effet isotopique $k_{H^+}/k_{D^+} = 1{,}59$; ce dernier résultat indique que la réaction procède par une étape déterminante impliquant un transfert de proton du catalyseur vers le substrat. Le coefficient catalytique de l'ion hydronium, pour cette réaction, est $k_{H^+} = 8{,}8 \times 10^{-2}\ M^{-1}\ s^{-1}$ et pour les quatre autres, dans l'ordre mentionné plus haut, ces coefficients sont respectivement $1{,}2 \times 10^{-3}$, $2{,}9 \times 10^{-7}$, $1{,}2 \times 10^{-4}$ et $8{,}5 \times 10^{-6}\ M^{-1}\ s^{-1}$. On discute des réactivités relatives en se basant sur ces constantes de vitesses.

[Traduit par la revue]

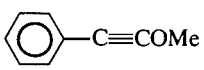
In an extensive series of investigations, Drenth and his students examined the acid-catalyzed addition of water to acetylenic ethers and thioethers (1). That work showed that these reactions occur through protonation of the triple bond in the β-position to give a vinyl cation, reaction [1] X = O, S,

$$[1]\quad CH{\equiv}CXR \xrightarrow[-A^-]{HA} CH_2{=}\overset{+}{C}XR$$

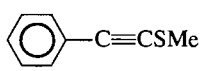
followed by hydration of this cation and tautomerization of the ensuing ester enol, reaction [2].

$$[2]\quad CH_2{=}\overset{+}{C}XR \xrightarrow[-H^+]{H_2O} CH_2{=}\overset{OH}{\overset{|}{C}}XR \rightarrow CH_3\overset{O}{\overset{\|}{C}}XR$$

We hope to use the photochemical analog of this thermal reaction to prepare ester enols in aqueous solution and to examine their chemistry in that medium. We have found it necessary for this purpose to know the stability of 1-methoxy-2-phenylethyne, **1**, and 1-methylthio-2-phenylethyne, **2**, in



1



2

aqueous acids, and we have consequently measured the rates of acid-catalyzed hydration of these substances in aqueous solution. We report the results of that study here together with some information on the kinetics of acid-catalyzed hydration of the related acetylenes phenylethyne, **3**, mesitylethyne, **4**, and 1-(*p*-methoxyphenyl)-propyne, **5**.

Experimental section

Materials

1-Methoxy-2-phenylethyne was prepared by treating 1-chloro-2-phenylethyne with sodium methoxide (2), and 1-methylthio-2-phenylethyne was prepared by treating sodium phenylacetylide first with sulfur and then with methyl iodide (3). A portion of the latter substance was converted to methyl phenylthioacetate by heating in acetic acid solution (4). Mesitylethyne was synthesized by dehydrohalogenating 1-chloro-1-mesitylethene, which in turn was obtained by treating 2,4,6-trimethylacetophenone with phosphorous pentachloride (5). 1-(*p*-Methoxyphenyl)-propyne (6) was prepared by alkylating sodium *p*-methoxyphenylacetylide with methyl iodide, and *p*-methoxyphenylacetylene (7) was made from *p*-methoxyacetophenone in a manner similar to that used for mesitylethyne. All of these substances had physical properties similar to literature values and gave spectra consistent with their structures. Other materials used in this research were best available commercial grades. Samples used for kinetic determinations were purified by gas chromatography.

Solutions were prepared from deionized H_2O purified further by distillation or from D_2O (MSD Isotopes 99.8 atom % D) as received.

Kinetics

Rates of reaction were determined spectroscopically by monitoring the decrease in absorbance of the strong uv band characteristic of

arylacetylenes with $\lambda_{max} \cong 240$ nm. Measurements were made with a Cary 118 spectrometer whose cell compartment was thermostatted at 25.0 ± 0.02°C. Runs were performed by first allowing 3.0 mL of aqueous acid or buffer solution to come to temperature equilibrium with the spectrometer cell compartment and then adding a few μL of stock solution of substrate dissolved in acetonitrile; initial substrate concentrations in the reaction mixtures were $2–6 \times 10^{-5}$ *M*. Reactions were followed to completion. The data so obtained conformed to the first-order rate law well, and observed first-order rate constants were calculated by least-squares fitting of absorbance and time values to an expontential function (8).

Results

Gas chromatographic examination of a spent reaction mixture indicated that only one product is formed in the acid-catalyzed hydration of 1-methoxy-2-phenylethyne in aqueous solution, and comparison of the uv spectrum of this product with that of an authentic sample showed this substance to be the methyl ester of phenylacetic acid, as expected. Similar spectral comparisons likewise showed the product of the hydration of 1-methylthio-2-phenylethyne to be the methanethiol ester of phenylacetic acid, and the products of the hydrolysis of phenylethyne, mesitylethyne, and 1-(*p*-methoxyphenyl)-propyne to be the corresponding aryl ketones.

Measurements of the rate of hydration of 1-methoxy-2-phenylethyne were made in perchloric acid solutions over the concentration range 0.02–0.1 *M* in H_2O solution and over the range 0.01–0.06 *M* in D_2O; these data are summarized in Table S1.[2] Observed first-order rate constants determined in both solvents were accurately proportional to acid concentration, and linear least-squares analysis gave the catalytic coefficients $k_{H^+} = (8.81 \pm 0.18) \times 10^{-2}\ M^{-1}\ s^{-1}$ and $k_{D^+} = (5.54 \pm 0.07) \times 10^{-2} M^{-1} s^{-1}$; these provide the isotope effect $k_{H^+}/k_{D^+} = 1.59 \pm 0.04$.

Rates of hydration of 1-methoxy-2-phenylethyne were also measured in phosphoric acid buffer solutions. Two series of solutions of constant buffer ratio ($[H_3PO_4]/[H_2PO_4^-] = 0.47$ and 0.92) and constant ionic strength (0.10 *M*, maintained with NaCl) were used. Within each series, buffer concentrations were varied by a factor of five. These data are summarized in Table S2.[2]

Because H_3PO_4 is a moderately strong acid, hydronium ion concentrations failed to remain constant within these buffer solution series. This "buffer failure" (9) was treated by adjusting observed first-order rate constants to values expected for a common hydronium ion concentration within each series (10); values of $[H_3O^+]$ needed for this purpose were obtained by calculation using $K_a = 7.14 \times 10^{-3}$ *M* (11) and ionic activity coefficients (for $H_2PO_4^-$ and H_3O^+) recommended by Bates (12).

Observed first-order rate constants adjusted in this way increased with increasing phosphoric acid concentration, indicating that the hydration of 1-methoxy-2-phenylethyne is subject to general acid catalysis. The relationship between k_{adj} and $[H_3PO_4]$ was accurately linear, and least-squares analysis gave $k_{H_3PO_4} = (6.00 \pm 0.15) \times 10^{-3} M^{-1} s^{-1}$ (buffer ratio = 0.47) and $(7.36 \pm 0.15) \times 10^{-3} M^{-1} s^{-1}$ (buffer ratio = 0.92). These values are in reasonable agreement with each other, and that indicates that there is no catalysis by the general base ($H_2PO_4^-$) present in these buffer solutions. The intercepts of these linear relationships provided the hydronium ion catalytic coefficients $k_{H^+} = (9.19 \pm 0.09) \times 10^{-2} M^{-1} s^{-1}$ (buffer ratio = 0.47) and $(9.06 \pm 0.08) \times 10^{-2} M^{-1} s^{-1}$ (buffer ratio = 0.92), each of which is in good agreement with the value measured directly in perchloric acid solutions, $k_{H^+} = (8.81 \pm 0.18) \times 10^{-2} M^{-1} s^{-1}$.

TABLE 1. Summary of hydrogen-ion catalytic coefficients for the hydration of acetylenes in dilute aqueous solution at 25°C

Substrate	$k_{H^+}/M^{-1} s^{-1}$
	$(8.81 \pm 0.18) \times 10^{-2}$
	$(1.21 \pm 0.01) \times 10^{-3}$
	$(2.86 \pm 0.09) \times 10^{-7}$
	$(1.21 \pm 0.03) \times 10^{-4}$
	$(8.45 \pm 0.27) \times 10^{-6}$

All of the other acetylenes examined here were considerably less reactive than 1-methoxy-2-phenylethyne, and their rates of hydration were consequently measured in concentrated acid solutions: 0.5–24 wt. % $HClO_4$ for 1-methylthio-2-phenylethyne, 30–50 wt. % $HClO_4$ for 1-(*p*-methoxyphenyl)-propyne. These data are summarized in Table S3.[2] For all four substrates, observed first-order rate constants increased with increasing medium acidity much more rapidly than in direct proportion to hydronium ion concentration, and an acidity function had to be used to extrapolate the data to dilute solution. The Cox–Yates X_0 function (13) appears to be the best currently available quantity for this purpose (14), and each of the four present sets of data gave good linear relationships when treated in this way. The dilute solution hydronium ion catalytic coefficients obtained by extrapolating these relationships to $X_0 = 0$ are listed in Table 1.

The rate of hydration of one of these actylenes, phenylethyne, has been measured before in concentrated aqueous sulfuric acid solutions in two different laboratories (15), and extrapolation of those data to dilute solution using the Cox–Yates *X* function (16) gives $k = (2.31 \pm 0.15) \times 10^{-7}\ M^{-1}\ s^{-1}$ and $k = (1.77 \pm 0.32) \times 10^{-7}\ M^{-1}\ s^{-1}$. Although these values are broadly consistent with the present result, $k_{H^+} = (2.86 \pm 0.09) \times 10^{-7} M^{-1} s^{-1}$, differences in the direction of faster rates in sulfuric acid might have been expected: sulfuric acid at the concentrations used contains the additional acidic species HSO_4^-, and this is known to cause the rates of some acid-catalyzed reactions to be faster in this medium than in solutions of completely dissociated monobasic acids such as $HClO_4$ (17). In order to determine whether this unexpected behavior could be the result of unintentional differences in reaction conditions between the present and the previous studies, we made a few rate measurements in sulfuric acid solutions at three different concentrations, all in the range used by the previous studies. These data, summarized in Tables S4,[2] show good agreement with the previous results. It seems likely, therefore, that the

[2]Tables S1–S4 of rate data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

discrepancy comes rather from a difference in the acidity functions employed for the sulfuric acid (X) and perchloric acid (X_0) correlations, for use of the X function for perchloric acid (16) gives $k_{H^+} = (1.93 \pm 0.17) \times 10^{-7} M^{-1} s^{-1}$, which differs in the expected sense from at least one of the sulfuric acid results.

Discussion

We have found that the hydration of 1-methoxy-2-phenylethyne is a general-acid-catalyzed reaction with a hydronium-ion isotope effect in the normal ($k_H/k_D > 1$) direction. This is evidence for a rate-determining proton transfer process, which indicates that the mechanism of this reaction is the same as that established for the hydration of purely aliphatic acetylenic ethers (1), namely, slow proton transfer from the catalyst to the substrate, reaction [3] followed by rapid hydration of the vinyl

[3] $$PhC{\equiv}COMe + HA \rightarrow PhCH{=}\overset{+}{C}OMe + A^-$$

cation thus formed and tautomerization of the resulting enol of methyl phenylacetate, reaction [4]. This mechanistic assignment is supported by the fact that vinyl cations react with water rapidly, at rates near the encounter-controlled limit (18), as well as by the expectation that ester enols should be at least as reactive as the closely related ketene acetals, which are normally very labile substances (19).

[4] $$PhCH{=}\overset{+}{C}OMe \xrightarrow[-H^+]{H_2O} PhCH{=}\overset{OH}{\overset{|}{C}}OMe \rightarrow PhCH_2\overset{O}{\overset{\|}{C}}OMe$$

The fact that methyl phenylacetate and not α-methoxyacetophenone, **6**, is the product of this hydration reaction indicates that the direction of addition is as shown in reaction [3], and that a methoxyl group is better than phenyl at stabilizing the adjacent developing carbocationic center. Similarly, thiomethyl is also better than phenyl in this respect, for methyl phenylthioacetate, **7**, and not α-methanethioacetophenone, **8**, is the product of

$PhC(=O)CH_2OMe$ **6** $\quad$ $PhCH_2C(=O)SMe$ **7** $\quad$ $PhC(=O)CH_2SMe$ **8**

acid-catalyzed hydration of 1-methanethio-2-phenylethyne, **2**. This regioselectivity is similar to that found in the hydration of arylalkylthioacetylenes catalyzed by mercuric ion (3*b*, 20), and it is also consistent with the fact that the σ^+ constants of methoxy (−0.78) and methylthio (−0.60) are both stronger than that of phenyl (−0.18).

The present results show PhC≡COMe to be 70 times more reactive to carbon protonation by the hydronium ion than is PhC≡CSMe. This is an order of magnitude less than the superiority of oxygen over thio acetylenic ethers found in purely aliphatic systems (1), and the difference could be the result of initial state stabilization in the aryl systems through conjugation of the ether function with the phenyl group; the latter would be expected to be stronger in the oxygen than in the thio ether. Such conjugation may also be responsible for the much lower (900-fold) reactivity of PhC≡COMe as compared to HC≡COMe; similar effects have been found in the hydrolysis of corresponding vinyl ethers (21).

The influence of a β-methyl group on the rate of carbon-protonation of acetylenic ethers is also rate retarding, but the effect is weaker than that of phenyl. A factor of 25–40 may be estimated for this retardation from the rate constant measured here for *p*-$MeOC_6H_4C{\equiv}CMe$ and those reported for *p*-$MeO_6H_4C{\equiv}CH$ (15); this factor is similar to those found for aliphatic acetylenic ethers (1) and also for other acetylenes (22) as well as vinyl ethers (23) and alkenes (24).

Methyl substitution in the phenyl ring of arylacetylenes which are not acetylenic ethers, on the other hand, raises the rate of acid-catalyzed hydration, as expected, for now the positive charge is generated on the carbon atom adjacent to the aryl group, reaction [5]. A 17- to 20-fold rate acceleration has been

[5] $$ArC{=}CH \xrightarrow[-A^-]{HA} Ar\overset{+}{C}{=}CH_2$$

found for one methyl group in the *para* position (15), and the rate constants for phenyl- and mesitylacetylene measured here give a 420-fold acceleration for methyl substitution in all three *ortho* and *para* positions. The latter factor is similar to the rate acceleration found for mesityl- over phenylacetylene in sulfuric acid – acetic acid media at 50°C (7); it shows that the electrical effect of an *ortho* methyl group is not unlike that of a *para* methyl and that *ortho*-group steric effects are not important in the hydration of mesitylacetylene.

Ternary charge transfer complexes. IV.[1] Complexes with Fe, Nb, Ta, Mo, W, or U in the anion[2]

SYDNEY BROWNSTEIN, ERIC GABE, BRIDGET IRISH, FLORENCE LEE, BRENDA LOUIE, AND ANDREJ PIOTROWSKI
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received May 22, 1986

SYDNEY BROWNSTEIN, ERIC GABE, BRIDGET IRISH, FLORENCE LEE, BRENDA LOUIE, and ANDREJ PIOTROWSKI. Can. J. Chem. **65**, 445 (1987).

$NOMX_6$·aromatic charge transfer complexes are formed from NOX and NbX_5 or TaX_5, where X may be F or Cl and the aromatic portion is a methyl-substituted benzene. $NOMoF_6$, $NOUF_6$, $NOUF_7$, and $NOWCl_7$·aromatic complexes have been identified but only oxyfluoro species have been isolated when M is Mo, W, or U. $NOTaCl_6$·hexamethylbenzene crystallizes in the trigonal space group $P3_2$, with a = 9.822(3), c = 17.469(7) Å. $NOFeCl_4$·hexamethylbenzene·½benzene crystallizes in the orthorhombic space group *Ccmb*, with a = 14.8009(20), b = 15.7683(10), c = 17.3913(14) Å. High conductivity in these complexes appears to depend upon a long N—O bond.

SYDNEY BROWNSTEIN, ERIC GABE, BRIDGET IRISH, FLORENCE LEE, BRENDA LOUIE et ANDREJ PIOTROWSKI. Can. J. Chem. **65**, 445 (1987).

Partant de NOX et de NbX_5 ou TaX_5, on peut former des complexes de transfert de charge $NOMX_6$·aromatique dans lesquels X = F ou Cl alors que la portion aromatique = benzènes substitués par des groupements méthyles. On a pu identifier les complexes $NOMoF_6$, $NOUF_6$, $NOUF_7$ et $NOWCl_7$·aromatique; toutefois, seules les espèces oxyfluorées dans lesquelles M est égal à Mo, W ou U ont pu être isolées. Le composé $NOTaCl_6$·hexaméthylbenzène cristallise dans le groupe d'espace trigonal $P3_2$, avec a = 9,822(3) et c = 17,469(7) Å. Le composé $NOFeCl_4$, hexaméthylbenzène·½benzène cristallise dans le groupe d'espace orthorhombique *Ccmb*, avec a = 14,8009(20), b = 15,7683(10) et c = 17,3913(14) Å. La conductivité élevée de ces complexes semble dépendre de la longue liaison N—O.

[Traduit par la revue]

Introduction

The nature of the anion is found to have a large effect on the properties of charge transfer complexes of type $NO^+ \cdot MX_n^- \cdot$ aromatic, where X may be F or Cl, n may be 4 or 6, M may be B, Al, Ga, Tl, P, As, or Sb and aromatic may be benzene or a methyl substituted benzene (1, 2). In this article the properties of such complexes will be presented where the halogen is chlorine or fluorine and M is niobium or tantalum. In addition, complexes with the anion $FeCl_4^-$ and with some anions MX_n^-, where M may be Mo, W or U, n may be 6 or 7, and X may be chlorine or fluorine, as well as complexes with anions $M_2O_2F_9^-$ where M may be Mo or W, will also be discussed.

Following is a brief history of the nitrosyl salts which were used in this study. Infrared and Raman spectra have been previously recorded for $NOMCl_6$ (M = Nb, Ta) (3), $NOMF_6$ (4–7) (M = Mo, U), $NOMF_7$ (M = Mo, W, U) (6, 8), $NOM_2O_2F_9$ (M = Mo, W) (9); and $NOFeCl_4$ (10). Mixed chloro–fluoro anions have been observed for both niobium and tantalum, but not with the nitrosyl cation (11). The reaction of NOCl with $MoCl_5$ and WCl_6 has not been reported previously. $NOMF_7$ (M = Mo, W, U) is prepared from NOF and MF_6 (8). Nitric oxide itself reacts with MF_6 (M = Mo, U) to give $NOMF_6$ (7) while another route is by reduction with nitrosyl chloride (8).

Experimental

Chemicals

Nitrosyl chloride and molybdenum, tungsten, and uranium hexafluorides were used directly from the supplier's cylinders. Nitric oxide was passed through a silica gel trap in "Dry Ice", to remove NO_2, just before use. Nitrosyl fluoride was synthesized by the direct reaction of nitric oxide and fluorine at low temperature (7). Niobium and molybdenum pentachloride, ferric chloride, niobium and tantalum pentafluoride, tungsten hexachloride, hexamethylbenzene, mesitylene, *p*-xylene and toluene were used as purchased. Tantalum pentachloride was vacuum sublimed before use. Sulfur dioxide, methylene chloride, and neopentane were purified and stored as previously described (12). All manipulations were carried out under an atmosphere of dry nitrogen.

$NOTaCl_6 \cdot C_6(CH_3)_6$

An equimolar quantity of hexamethylbenzene was added, in a dry box, to $TaCl_5$ in a reaction vessel closed with a "Teflon" stopcock. One equivalent of nitrosyl chloride and sulfur dioxide as solvent were added by vacuum transfer and a reaction occurred immediately upon warming to room temperature. An equal volume of methylene chloride was added and the sulfur dioxide was very slowly pumped away while the solution was kept at 0°C. Black crystals of the $NOTaCl_6$·hexamethylbenzene adduct precipitated from the CH_2Cl_2 solution.

$NOFeCl_4 \cdot C_6(CH_3)_6 \cdot 0.5(C_6H_6)$

To 46.2 mg of $FeCl_3$ in one arm of a two armed reactor was condensed 3 mL of NOCl. After warming to room temperature all volatile materials were pumped away under vacuum to give a residue of 62.4 mg of $NOFeCl_4$ (yield = 96%). In a nitrogen-filled dry box, 41.3 mg of hexamethylbenzene was added directly onto the $NOFeCl_4$. SO_2 (3 mL) was condensed onto these solids which dissolved completely to give a clear, intensely colored brown solution. All volatile materials were pumped away under vacuum and 3 mL of CH_2Cl_2 was condensed onto the black solid. Most of the material went into solution which was carefully decanted from the residual solid into the other arm of the reactor. Approximately 1 mL of benzene was condensed onto the CH_2Cl_2 solution. After warming to room temperature and mixing, approximately half of the liquid was slowly distilled into the original arm of the reactor by cooling it gradually. Black, glossy crystals appeared on the walls of the reactor. The remaining solution was decanted into the original arm of the reactor to isolate the crystalline solid. This arm was evacuated and sealed under vacuum for storage.

$NOMF_x \cdot C_6(CH_3)_6$ (M = Mo or U, x = 6; M = Mo, W or U, x = 7)

In a typical reaction sequence 1.00 mmol of NO or NOF and an equimolar amount of MF_6 (M = Mo, W, or U) were condensed into a Monel reactor at −196°C. The reactor was gradually warmed to room temperature over a period of 0.5–1 h and then opened in a dry box. Samples of the resulting $NOMF_x$ (x = 6 or 7) salts were sealed in capillary tubes and checked for purity by Raman spectroscopy.

[a]The transformation matrix to turn the axes of the space group $Ccmb$ into the standard setting $Cmca$ is 0,0,1/1,0,0/0,0,−1.
[b]$R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.
[c]$R_w = \Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2$.

Assuming a 100% yield of the nitrosyl salt, a 0.5 equivalent of hexamethylbenzene was added to the reactor in the dry box. The reactor was subsequently evacuated and ~5 mL of SO_2 or CH_2Cl_2 condensed onto the reactants at −196°C. The reactor was warmed to −78°C and shaken gently at this temperature for ~5 min. The solvent was then removed *in vacuo* while keeping the reactor at −78°C. After all the volatiles were removed at this temperature, the reactor was warmed to room temperature with continual pumping and then opened in a dry box revealing red–brown (M = Mo or W) or purple (M = U), air- and moisture-sensitive powders.

Magnetic resonance spectra were obtained on a Bruker AM400 spectrometer at a magnetic field strength corresponding to 400 MHz for protons. Carbon and proton chemical shifts are reported with respect to tetramethylsilane, although neopentane was used as an internal reference since it is inert with respect to the compounds studied. A correction of 0.92 ppm was applied for protons and 31.4 ppm for ^{13}C. Fluorine resonance shifts are reported with respect to internal $CFCl_3$.

Ultraviolet–visible spectra, in CH_2Cl_2 as solvent, were obtained on a Cary 210 Spectrometer. Infrared spectra were obtained for KBr pellets by Beckman Acculab 4 and Perkin–Elmer 683 Infrared Spectrometers. Samples for conductivity measurements were prepared as pressed pellets with the same die used for KBr infrared pellets. The resistance was measured between the parallel, adjustable plates of a General Radio type 1690A conductivity cell with a 1673A automatic capacitance bridge operating at 1 kHz.

X-ray reflection intensities were measured with monochromatized MoKα radiation, (λ(MoKα_1) = 0.70932 Å). Reflections were considered significant with $I_{net} > 2.5\sigma(I_{net})$. X-ray structural data for $NOTaCl_6$·hexamethylbenzene and $NOFeCl_4$·hexamethylbenzene·½benzene are listed in Table 1.

The diffraction intensities of a crystal of $NOTaCl_6$·hexamethylbenzene were collected at 115 K using a Picker diffractometer and the $\theta/2\theta$ scan technique with profile analysis (13). The data for $NOFeCl_4$·hexamethylbenzene·½benzene were collected at room temperature using a Nonius CAD-4 diffractometer with the ω scan technique. Both structures were solved with MULTAN (14) and refined by full-matrix least-squares. All calculations were performed with the NRCVAX system of programs (15). Scattering factors including anomalous dispersion were taken from the International tables for X-ray crystallography (16).

The final atomic positional parameters, bond lengths and angles, and mean temperature factors for $NOTaCl_6$·hexamethylbenzene are given in Table 2. The anisotropic thermal parameters and the structure factors are deposited as supplementary material.[3] It is not possible to unambiguously assign the nitrogen and oxygen atoms as shown. Reversing their relative positions causes an insignificant change in the agreement indices. The present assignment is preferred since it agrees with our previously reported results (2).

The structure consists of three entities $TaCl_6$, NO, and $C_6(CH_3)_6$ as shown in Fig. 1. The Ta atom is co-ordinated to six Cl atoms to form a distorted octahedron (maximum deviation from the ideal octahedral angle is 2.1°). The distances of Ta—Cl are 2.302(4) to 2.342(4) Å. The N—O distance is 1.10(1) Å. The distances from the plane of the ring to the N atom and the O atom are 2.12(1) and 2.94(2) Å, respectively. The arrangement of the three entities in the unit cell as in Fig. 2 shows no ordered sheet or layer of any molecule, probably owing to the 32 symmetry element in the space group.

The final atomic positional parameters, bond lengths and angles, and mean temperature factors for $NOFeCl_4$·hexamethylbenzene·½benzene are listed in Table 3. The anisotropic thermal parameters and final structure factors are included as supplementary material.[3] During data collection the crystal decayed as shown by an intensity drop to 72% on the standard reflections. Sets of three standard reflections were measured after each 100 regular measurements and the average intensity ratio for each set was used in a five point smoothing process to establish an intensity correction curve. Corrections were then obtained by linear interpolation between adjacent points. It is probably because of this decay, despite the attempt to correct for it, that the thermal parameters are high and that attempts to locate hydrogen atoms from the difference Fourier synthesis were unsuccessful. The structure consists of four entities, $FeCl_4$, NO, $C_6(CH_3)_6$, and ½C_6H_6, shown in Fig. 3 as a whole molecule. The Fe atom is co-ordinated to four Cl atoms to form a distorted tetrahedron with the distances of Fe—Cl from 2.170(4) to 2.171(4) Å. The N—O distance is 1.09(2) Å. The distances and angles of $C_6(CH_3)_6$ and C_6H_6 molecules are normal. The distances from the plane of the $C_6(CH_3)_6$ ring to the N and O atoms are 2.02(3) and 2.87(3) Å, respectively.

Results and discussion

Both the pentachlorides and pentafluorides of niobium and tantalum react with the corresponding nitrosyl halide and a methyl-substituted benzene to give a charge transfer compound of formula $NOMX_6$·aromatic. These have been identified by the physical properties listed in Table 4. The chloro compounds are thermally unstable, those of $NbCl_5$ decomposing in solution above approximately 0°C. From the characteristic red–brown color, the proton resonance spectra at −10°C, and the sharpening of the ^{93}Nb resonance from the broad lines found for $NbCl_5$ and $NONbCl_6$, the formation of charge transfer complexes is confirmed for the chloro–niobium system. Similar results are found for the niobium–fluorine complexes, with the additional evidence from fluorine resonance spectroscopy of the classical ten line pattern for NbF_6^- (17). Although $NONbF_6$ itself is insoluble in liquid SO_2 it is brought into solution upon complexing with the aromatic species. These adducts are thermally stable, in contrast to the chloro compounds. The proton resonance spectra of the aromatic portion of the fluoro compounds display somewhat smaller displacements than the chloro species relative to the uncomplexed aromatic species, suggesting less transfer of charge. With the mixed halide aromatic complexes NOCl + NbF_5 and NOCl + TaF_5 the only fluorine signals observed were from the hexafluoroanions showing that halogen disproportionation has occurred.

Vanadium trichloride with NOCl does not appear to form

charge transfer complexes. The solvents and aromatic compounds used in this study were rapidly fluorinated by VF_5 and VF_5 + NOF. Niobium and tantalum pentachlorides with $POCl_3$ also do not form charge transfer complexes. Niobium pentachloride and $SOCl_2$ or NSCl chlorinate hexamethylbenzene. There is some spectral evidence for a ternary charge transfer complex of NOCl, $MoCl_5$, and hexamethylbenzene, stable at low temperature, listed in Table 2. However, in the corresponding system with mesitylene the aromatic compound is chlorinated. The system WCl_6, NOCl, and hexamethylbenzene forms a slightly more stable complex but this too decomposes rapidly at room temperature.

Mixing $NOMF_7$ (M = Mo or W) with hexamethylbenzene in a Monel reactor at −78°C using CH_2Cl_2 or SO_2 as solvent results in the formation of the corresponding ternary complex where the anion is the fluorine-bridged species $OMF_4 \cdot F \cdot MF_4O$. This has been identified by the characteristic M—O and M—F absorptions in the infrared region. Similarly, in solution in a glass nmr tube at −78°C only the fluorine resonance of the oxyfluoroanion is observed. There is no evidence for the initial formation of $NOMF_7 \cdot$ hexamethylbenzene followed by a disproportionation. Pertinent spectral data are listed in Table 4. A freshly prepared KBr pellet of the reaction product of $NOUF_7$ and hexamethylbenzene initially had a single strong N—O stretching frequency at 1870 cm^{-1}. This changed with time to yield the same spectrum as previously assigned to the

$UO_2F_2X_2^{2-}$ anion (X = NO_3 or F) (18, 19). No fluorine resonance signals were observed in the uranium systems.

$NOMF_6$ (M = Mo or U) reacts with hexamethylbenzene at −78°C to immediately give the adduct with the MF_6^- anion. The change in the infrared (Mo and U) and fluorine resonance (Mo) spectra with time show that these adducts again

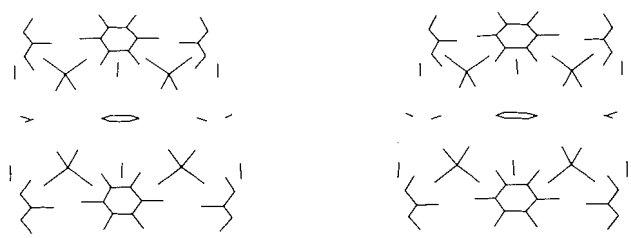

FIG. 4. A stereo drawing of the arrangement of the various entities of $NOFeCl_4$·hexamethylbenzene·½benzene. Only one half of the benzene, hexamethylbenzene, and NO entities are shown on each side of the central region.

quickly decompose to give the oxofluoroanions $Mo_2O_2F_9^-$ and $UO_2F_2X_2^{2-}$ (X = NO_3 or F), respectively.

The adduct of $NOFeCl_4$ and hexamethylbenzene is quite reactive to traces of moisture and an infrared spectrum could not be obtained without decomposition. The paramagnetic nature of the complex prevents acquisition of proton or carbon resonance spectra. The characteristic intense red–brown colour and ultraviolet spectrum, listed in Table 4, readily identify the fact that charge transfer has occurred. The crystal structure, as partially presented in the stereo drawing of Fig. 4, is rather unusual in that the benzene molecules are quite far from the other entities, suggesting negligible interaction between benzene and NO^+ in this structure. The overall structural arrangement consists of sheets perpendicular to the *Z* axis. At approximately $Z = 0 + \frac{1}{2}$ there are sheets of hexamethylbenzene and benzene moieties and at $Z = \frac{1}{4}$ and $\frac{3}{4}$ there are sheets of $FeCl_4$ anions. The NO groups are sandwiched between the two types

of layers in an arrangement which is too complex to present clearly in a diagram. Figure 4 is a simplified stereo diagram, viewed down the *Z* axis, showing the spatial relationship of the various structural elements. From an investigation of the uv spectrum of the system $NOFeCl_4$ and benzene in methylene chloride as solvent it appears that there is negligible charge-transfer complex formation between them.

It is interesting to note that both the group V and group VI transition elements form less stable complexes than the main group V elements (2). In every case where complex formation occurs the ultraviolet spectra are essentially independent of the anion. The proton and carbon resonance shifts upon charge transfer formation are somewhat anion dependent, being largest for the strongest complexes. Except for $NOSbCl_6 \cdot$ hexamethylbenzene the N—O stretching frequencies and N—O bond lengths do not vary greatly for the different anions. The conductivity varies markedly in those complexes where it may be measured. From the limited data it appears that high conductivity requires a very long N—O bond, as found previously (2).

The dynamics of the reaction of F atoms with *trans*-diimide[1]

R. A. BACK, P. S. NEUDORFL, J. J. SLOAN, AND P. T. WASSELL
Division of Chemistry, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R6

Received June 5, 1986

R. A. BACK, P. S. NEUDORFL, J. J. SLOAN, and P. T. WASSELL. Can. J. Chem. **65**, 451 (1987).

Emission from the HF product of the reaction F + N_2H_2 has been measured in an arrested-relaxation infrared chemiluminescence experiment. The vibrational distribution is inverted, peaking in HF($v' = 2$). This energy partitioning indicates that the reaction occurs without the formation of a long-lived intermediate species. The detailed shape of the primary energy distribution could not be determined due to severe difficulties in the production of N_2H_2.

R. A. BACK, P. S. NEUDORFL, J. J. SLOAN et P. T. WASSELL. Can. J. Chem. **65**, 451 (1987).

Au cours d'une expérience de chemiluminescence infrarouge par relaxation stoppée, on a mesuré l'émission de HF provenant de la réaction de F + N_2H_2. La distribution vibrationnelle est inversée et elle atteint un maximum avec HF($v' = 2$). Cette énergie de partition indique que la réaction se produit sans formation d'espèces intermédiaires de longue vie. Dû aux difficultés extrêmes rencontrées dans la production de N_2H_2, on n'a pas pu déterminer la forme détaillée de la distribution de l'énergie primaire.

Introduction

Reactions of F atoms with N—H bonds have been the subject of several dynamics studies in this (1–6) and other (7, 8) laboratories. The molecular reagent, hence the molecular environment of the N—H bond, varied widely in these studies. The reagents included $HCONH_2$ and CH_3NH_2 (1), NH_3 (3, 5, 7, 8), N_2H_4 (3, 7), HN_3 (2, 8), HNCO (4), and NH_2 (6). In all cases but one, that of the NH_2 radical, the HF vibrational excitation created by the F/H—NR family of reactions is smaller than that observed for comparable F atom reactions at C—H bonds. The latter typically create HF vibrational distributions which peak sharply at a point more than half way to the maximum level permitted by the exoergicity. The F/H—NR reactions, on the other hand, produce observed HF vibrational distributions which either decrease monotonically with increasing vibrational level, as in the $HCONH_2$ and N_2H_4 cases, or peak very weakly at a low vibrational level, as in the CH_3NH_2 reaction.

These general results have been observed in many laboratories, although differences in detail exist among the various studies as to the precise extent of vibrational excitation in a few of the cases. The N_2H_4 and C_2H_4 reactions illustrate the point. The exoergicity of the N_2H_4 reaction is 237 kJ mol^{-1} whereas that of the C_2H_4 reaction is 115 kJ mol^{-1}. In the former case, the *observed* HF vibrational distribution peaks in HF($v' = 1$) (3, 7) (probably it peaks in the $v' = 0$ level) and the fraction of the exoergicity channelled into vibration, $f_v' \cong 0.34$ whereas the vibrational distribution created by the C_2H_4 reaction peaks at HF($v' = 2$), the maximum energetically-accessible level, and has $f_v' \cong 0.55$.

The N—H reactions listed above all have substantial exoergicity, ranging from 250 to about 540 kJ mol^{-1}. The observation of a low HF vibrational excitation from such a reaction implies that the energy released in the formation of the HF bond has not remained there, but has migrated elsewhere during the reactive collision. This intramolecular energy migration in the reaction intermediate can be caused, for example, by interactions between the energized fragment (the HF) and either the nuclei or nearby orbitals of the substrate molecule, which prolong the reaction and provide a pathway for energy flow. The duration and intensity of these interactions determine the amount of the exoergicity lost to the polyatomic fragment during the product-separation phase of the reaction. In particular, if a statistical HF vibrational distribution is observed (characterized by rapidly-decreasing populations with increasing vibrational level), it can be assumed that the exoergicity was distributed equally among the product degrees of freedom via the transient formation of a reaction intermediate having a relatively long lifetime. This is because statistical energy partitioning favours product modes having the highest state densities. Since translational and rotational state densities are much higher than the vibrational state density of a small diatomic such as HF, it is impossible for a reaction forming a long-lived intermediate to produce vibrational inversion in HF.

Conversely, the observation of vibrational inversion in a product such as HF indicates unequivocally that the reaction time is very short. Dynamical calculations imply that the timescale in this case is in the order of one vibrational period. The reasons for the differences in the lifetimes of the reaction intermediates have been the subject of many publications. On the simplest level, short-lived reactions occur via reaction geometries for which there is no strong bonding in the intermediate. For the F/NH_2 reaction (6), for example, short-time (direct) dynamics occur because the barrier to reaction on the lowest triplet surface is approximately zero (6), hence the reaction can occur via an F—HNH geometry without sampling the deep FNH_2 potential well on the singlet surface.

Even if a strongly-bound intermediate is formed, however, its lifetime may be short if the potential energy released is large and the reduced masses for the collision and product separation are small. This is the case with the reaction O($^1D_2$) + H_2 for which the mechanism is predominantly an insertion to form vibrationally-excited H_2O. The consequent release of about 770 kJ mol^{-1} of potential energy causes the immediate dissociation of the intermediate with the formation of vibrationally-inverted OH (9).

The F + NH_3 reaction appears to be a case where the circumstances of geometry and bonding prolong the reactive collision and produce HF which is vibrationally colder than that created by comparable F/H—CR reactions. *Ab initio* computations of the F/NH_3 potential energy surface indicate that there is a hydrogen bonded species of the form F—H—NH_2 in the exit channel which is stable with respect to the separated products by 46 kJ mol^{-1} or about one third of the exoergicity of the reaction (10). Although the analysis of the calculations is still under way, it appears that this bound species facilitates

[1]NRC No. 25869.

the intramolecular vibrational energy transfer process by which the NH_2 radical receives part of the exoergicity which would otherwise have led to vibrational inversion in the HF product.

In the present paper, we carry these studies further by measuring the energy distribution in the reaction of fluorine atoms with *trans*-diimide:

[1] $F + N_2H_2 \rightarrow HF(v') + N_2H \qquad \Delta H_0^0 = -73$ kcal mol^{-1}

In this case, the H—N_2H bond energy is low (60 kcal mol^{-1}) and the N—N bond is essentially olefinic (11). These energetics are based on the reported heat of formation of N_2H_2, $\Delta H_{f(298)}^0 = 212 \pm 8$ kJ mol^{-1} (12), combined with a calculated value for the H—NN· bond energy of -38 kJ mol^{-1} (13). The weak N—H bond and the olefinic N=N bond of N_2H_2 make it similar in these respects to N_2H_4 which produces, on reaction with F atoms, vibrationally cold HF (3, 7). We find, however, that the HF produced in reaction [1] is vibrationally inverted.

Experimental

These experiments were carried out in a conventional low pressure arrested-relaxation infrared chemiluminescence apparatus (14). The reaction chamber was a stainless steel cylinder 25 cm diameter × 30 cm high containing liquid-nitrogen-cooled vertical chevron baffles arranged radially to completely enclose the interior of the chamber except for a rectangular volume containing a multipass optical cell (Welsh cell). The cryobaffle was designed to ensure that molecules escaping from the reaction volume (at the centre of the chamber) would be efficiently trapped and would have a very small probability of re-entering the observation zone subtended by the Welsh cell. The Welsh cell mirrors were freshly gold-coated before each experiment. The infrared emission collected by this cell was focussed into a Fourier transform spectrometer by an f/2 CaF_2 lens mounted in a flange in the reaction chamber wall.

The atomic fluorine reagent was generated by a 2450 MHz plasma discharge in CF_4 flowing in a 10 mm diameter quartz tube mounted in the centre of the reaction chamber lid. The lower end of the discharge tube was located slightly above the Welsh cell mirrors on the central axis of the reaction chamber. The N_2H_2 was admitted through a second tube mounted in the wall of the reaction chamber perpendicular to the discharge tube and located slightly below it. This configuration provided good reagent mixing and had the added advantage that the molecular reagent was directed across the stream of F atoms, towards the vertical chevron cryobaffle on the opposite side of the reaction chamber. As a result, the molecules which failed to collide with F atoms in the reaction zone immediately below the F-atom inlet tube, passed through this region and entered the liquid-nitrogen-cooled cryobaffle, where they were trapped very efficiently. The average pressure in the reaction zone was in the 10^{-4} Torr range but the pressure immediately below the F-atom discharge tube could have been an order of magnitude higher than this.

The N_2H_2 was produced by the thermal decomposition of solid Na-tosylhydrazide at temperatures between about 60°C and 120°C (11, 15) and admitted to the reaction vessel via a short thermostatted tube. It has previously been shown that this method produces almost pure *trans*-N_2H_2 in the gas phase (16). This is a very unstable molecule, however, and the possibility remains for heterogeneous decomposition on surfaces such as those of the reagent inlet tube. The tube carrying the N_2H_2 was kept as short as possible in order to minimize this problem, but for this reason, no direct measurement of the flowrate was attempted. As a result, the flowrate of the N_2H_2 and hence its concentration in the reaction zone were assumed to be proportional to the temperature of the decomposition. This uncertainty precluded the unequivocal determination of the shape of the initial energy distribution, as will be described in the next section.

Before each experiment, the F-atom discharge was run for approximately one hour until this system had become stable. Then the temperature of the solid Na-tosylhydrazide was increased slowly while monitoring the reaction zone for emission. Detectable emission began when the temperature reached about 60°C: its intensity increased with the temperature of the decomposition thereafter until either the solid reagent had been consumed (a few hours) or the heater was turned off and the temperature allowed to decrease again. Spectra were recorded for various temperature ranges — hence N_2H_2 flows — at known, constant F-atom flows. Two series of observations were carried out: one at low temperatures and one at high temperatures. The CF_4 flows for these two experiments were 5.2 and 4.0 μmol s^{-1}, respectively. These flows gave a signal-to-noise ratio in the measured spectra of 50–70 for N_2H_2-generator temperatures above about 90°C. The only spectrum observed during these experiments was the $\Delta v' = -1$ fundamental of HF. Emission from all vibrational levels up to $v' = 5$ was obtained. The spectra were assigned and measured by spectral analysis programs written here for this purpose. The vibrational and rotational populations were obtained from these spectra using a standard data analysis, which has been described previously (17). In the following, the results of both series of experiments will be reported and the initial distribution which these imply will be identified.

Results

Although emission was detected from the observation zone at temperatures above about 65°C, the spectral signal-to-noise was inadequate to obtain a distribution until a temperature of about 80°C was reached. Thereafter, measurements were carried out over a temperature range from about 80 to 124°C in two separate experiments. The results are listed in Table 1. All distributions in the table are normalized to $\Sigma_{v'} P(v') = 1.0$.

Runs 67 to 70 represent the lower-temperature group of measurements. In this case, the decomposition temperature was permitted to rise only to 95°C. The heater was then switched off and the data acquisition continued while the temperature decreased (see run 70). The flowrates and consequently the signal-to-noise for these low temperature experiments were smaller than those of the high-temperature runs. The uncertainty in all vibrational populations, however, was less than ±0.03 per v' level. Table 1 shows that all the low-temperature distributions are the same within this uncertainty. Runs 33 to 45 were done in a separate experiment in which the temperature was permitted to rise to 124°C before the heater was turned off. Observations in the lower part of this temperature range gave the same distributions as listed for runs 67 to 70. As the temperature rose above 100°C, however, the population of $v' = 2$ began to increase with respect to the other levels, and some population was detected in $v' = 5$.

The absence of population in $v' = 5$ for the low-temperature runs could be attributed to poorer signal-to-noise due to the lower flowrates but the markedly higher relative population in $v' = 2$ at the higher temperature cannot be created by a change in flowrates or intensity. It is not possible to attribute the $v' = 2$ population increase to vibrational deactivation from higher levels either, since this process would cause a strong increase in the population of $v' = 1$ as well. Table 1 shows that after the temperature reaches about 105°C the distribution does not change with increasing flow, even up to the highest temperature, 124°C. (Temperatures above this were not used in order to avoid dissociating the N_2H_2 on the hot surfaces.) It must be assumed that the flowrate increased with the temperature in this range and hence that the distribution observed in runs 34, 35, and 45 is not dependent on the N_2H_2 flow. The two different distributions into which the data fall can be seen more clearly from Fig. 1, in which runs from each temperature range are plotted.

The rotational distributions observed in experiment 69 are shown in Fig. 2. These are typical of the rotational excitation

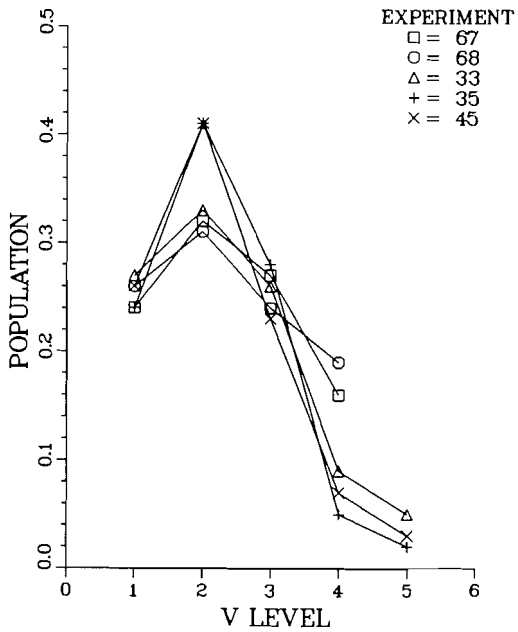

FIG. 1. The vibrational energy distributions obtained in the experiments listed in Table 1.

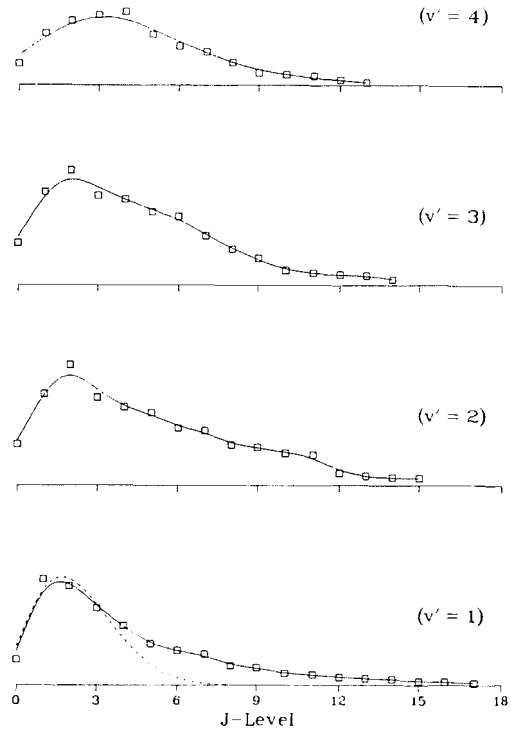

FIG. 2. The rotational distributions created in experiment 69. The dashed curve is a room-temperature Boltzmann distribution for comparison.

observed in all experiments. The solid curves are cubic splines which approximate the experimental observation (the points) to enhance the visibility of the latter. The dashed curve in the lower panel is a room-temperature Boltzmann distribution for comparison with the experimental data. This shows that all of the observed distributions have suffered partial rotational relaxation, but residual non-Boltzmann populations remain in all cases. The height of the latter suggests that the initial rotational excitation (before the partial relaxation) was not large, considering that the exoergicity of the reaction is sufficient to population $J' = 27$ of the $v' = 4$ level.

The extreme difficulty in producing stable flows of N_2H_2 which were high enough for this experimental technique, coupled with our inability to measure the flows directly, introduce unavoidable uncertainties in the interpretation of these data. The similarity of the distributions in each temperature range and the incompatibility of the observed differences with normal vibrational deactivation patterns suggest that a second process, separate from reaction [1], is responsible for these differences. In particular, the strong maximum in the population of $v' = 2$ which appears in the high-temperature experiments introduces the suspicion that a second process begins to contribute to the emission at high temperature. The simplest candidate for this process is the reaction of F atoms with H_2, which is well known to produce an HF vibrational distribution peaking in $v' = 2$. The H_2 could presumably come from the thermal decomposition of N_2H_2 before it reached the reaction zone. Although previous work (16) has suggested that the N_2H_2 produced by this method is quite pure, a contribution to the HF($v \leq 3$) populations at the highest temperature cannot be ruled out.

On the other hand, if there is no contribution from impurities such as H_2, it must be assumed that a secondary reaction is the source of the differences between the high- and low-temperature distributions. We have previously observed several primary/secondary reaction sequences of the form: $F + RH_2 \rightarrow HF_p(v') + RH$, followed by $F + RH \rightarrow HF_s(v') + R$ in this laboratory and have measured the product energy distributions in the systems: $F/H_2O/OH$ (18), $F/C_2H_4/C_2H_3$ (19), and $F/NH_3/NH_2$ (5, 6). The general behaviour observed in such cases is a change in the vibrational distribution when conditions are changed from those favouring only the primary reaction to those favouring *both* reactions. A complete discussion of this is given in ref. 6, including a numerical model of the $F/NH_3/NH_2$ system.

The most important condition for observation of a secondary reaction is a very large rate constant for the primary reaction. This ensures the creation of a high concentration of the intermediate radical and hence adequate opportunity for the secondary reaction to occur before the mixture leaves the observation zone. In the present system, the rate constant for reaction [1] (the primary reaction) is unknown, but would be expected to be at least as large as that for the reaction of F atoms with NH_3 — 3×10^{-11} cm^3 $molecule^{-1}$ s^{-1} (20). In addition to this, it is necessary for the secondary reaction to have a large rate constant as well, so the HF product will be produced in the observation zone. A simple kinetic analysis of the two-step primary/secondary sequence above, with the intermediate radical RH in steady state, shows that the rate of production of HF_s has the form:

$$k_1[F][RH_2]\cdot\frac{k_2[F]}{k_2[F] + k_p} - k_p[HF_s]$$

where k_1 and k_2 are the rate constants for the primary and secondary reactions and k_p is the rate constant for removal of all species from the observation zone by pumping. If the pumping rate is very large with respect to all other processes, the first term becomes very small and the secondary reaction cannot be observed. If $k_p \ll k_2[F]$, however, this rate expression shows that the secondary process can become appreciable with respect to the primary one.

The relative sizes of these terms is a sensitive function of the local conditions in the experiment and it is not possible to accurately determine the factors necessary for their calculation. It is possible, however, to make some rough estimates. These experiments were carried out using a 6″ diffusion pump (since replaced with a 15″ pump) which had a baffled pumping speed of about 1000 l/s. The volume of the observation zone is somewhat less than 1 L, but k_p may be taken to be about 10^3 s^{-1}. Although the average pressure observed in the reaction chamber was 10^{-4} Torr for these experiments, it is possible for the *local* pressure in the reaction zone immediately below the quartz inlet tube to be an order of magnitude higher than that. It is reasonable to assume that, on the average, about 50% of the CF_4 flow is converted to CF_2 + 2F in the discharge and thus 33% of the gas in the CF_4 reagent inlet is atomic fluorine (6). Since the observed total pressure in these experiments depended almost completely on the CF_4 flow (presumably because the N_2H_2 efficiently cryopumped on the liquid-nitrogen-cooled baffles), this indicates that the $[F] \cong 3 \times 10^{-4}$ Torr. If k_2 is approximately gas kinetic ($\cong 3 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}), the value of $k_2[F]$ would therefore be about 10^3. This shows that under conditions of very high N_2H_2 flow, large F atom concentration *and* large k_2, it is possible to have seen the product of the secondary process $F + N_2H \rightarrow HF_s(v') + N_2$.

In the case where the N_2H_2 flow is low, the production rate of primary HF, given by the first term in the above expression, will be small and the pumping terms will dominate. The steady-state concentration of the radical intermediate, given by

$$[RH] = \frac{k_1[F][RH_2]}{k_2[F] + k_p}$$

will also be very small in this case. Using the rate constant for the F/NH_3 reaction with the other values estimated above, the average value of $[RH]/[RH_2]$ in the observation zone is found to be about 0.08. Under these conditions, the products of the secondary reaction might not be observable. If the higher temperature runs produced an order of magnitude increase in the N_2H_2 flow, then the production rate for HF_s will increase by the same amount, and the secondary reaction might be expected to make a detectable contribution.

The preceding paragraphs have shown that the increase in the $HF(v' = 2)$ population in the high-temperature experiments could be due to a contribution from either the $F + H_2$ reaction or the secondary $F + N_2H$ reaction. The NN—H bond energy is thought to be negative (13), although it may have a substantial barrier to dissociation (11). If the N_2H dissociates immediately after the primary reaction, the source of the added $HF(v' = 2)$ would have to be the $F + H_2$ reaction. In any case, it is clear that the distributions recorded at low temperature (and hence low N_2H_2 concentration) are least likely to be contaminated by either of these interfering reactions. Thus we regard the average of the distributions measured in runs 67–70 as the initial distribution from the N_2H_2 reaction.

Discussion

This reaction conforms to the energy partitioning patterns of other F/H—NR reactions inasmuch as it does not channel a large amount of energy into HF vibration or rotation. The suggested initial vibrational distribution — $P(v' = 1:2:3:4) = 0.25:0.31:0.26:0.18$ — represents only about 35% of the available energy. In this respect it is very similar to the F/N_2H_4 reaction, for which we have obtained $f_v' = 0.19$.[2] This may be contrasted with the F/H—CR reactions, mentioned earlier, for which this fraction (f_v') is typically in the range of 0.45–0.55. The latter reactions have similar exoergicity and the same mass combination (the transfer of a light atom between two heavier species), so the difference in the energy partitioning must be due to differences in the potential energy surface sampled during the reactive event.

The large HF vibrational excitation created by the F/H—CR reactions is understood to indicate simple abstraction dynamics in which the H atom is transferred rapidly (during approximately one C—H vibrational period) at a relatively large distance, thus preventing the migration of the exoergicity from the newly-formed HF bond back to the polyatomic product. Any influence on the reaction dynamics which facilitates this energy flow causes a reduction in the HF vibrational excitation. Thus, for example, if the F atom bonds first to the molecular reagent, forming a chemically-activated intermediate complex, the excitation of the internal modes of the reaction products from the subsequent (unimolecular) decomposition of the complex is statistical, depending only upon the density of states of each mode. In this event, the HF vibrational populations decrease rapidly and monotonically with increasing vibrational level.

The vibrational distribution from the $F/H—N_2H$ reaction does not have this extreme shape, so it must be concluded that it does not involve a long-lived intermediate complex. Its (slightly-inverted) distribution is more characteristic of a short-lived reaction, dynamically similar to the F/H—CR reactions. Its reduced f_v' and less strongly-peaked vibrational distribution suggest there are dynamical influences which enhance the energy flow from the HF back to the N_2H fragment. These could be, for example, hydrogen-bonded species such as F··H··NR, which could prolong the interaction slightly. Alternately, the F atom could preferentially interact with some part of the molecule other than the H atom, forming a transient

[2]D. W. Setser. Private communication.

bond there before reacting with the hydrogen. If this interaction were very abbreviated, the HF vibrational distribution, while inverted, would be less strongly-peaked than that from a single abstraction.

Whatever the dynamical cause, this reaction does not channel energy efficiently into the HF internal mode. The maximum vibrational excitation possible on the basis of the exoergicity is $HF(v' = 7)$ — substantially above the highest level observed in the experiment. The excess energy remaining after creation of the most-probable HF level ($v' = 2$) is 200 kJ mol^{-1}. It is likely that a large part of this energy remains in the N_2H fragment, which probably dissociates as a result of this excitation.

In the recent work of Anantaraman (Can. J. Chem. **64**, 46 (1986)) the conversion from kinematic viscosity to dynamic viscosity was incorrect. We calculated correct values from the tabulated data. We also give corrected values of the ideal mixture viscosity, the Grunberg–Nissan deviation parameter, and the Hind interaction parameter.

NORMAN GEE, GORDON R. FREEMAN et A. V. ANANTARAMAN. Can. J. Chem. **65**, 456 (1987).

Dans le travail récent de Anantaraman (Can. J. Chem. **64**, 46 (1986)), la conversion de la viscosité cinématique à la viscosité dynamique était incorrecte. On a recalculé les valeurs correctes à partir des données présentées dans les tableaux. On rapporte aussi les valeurs corrigées pour la viscosité du mélange idéal, pour le paramètre de déviation de Grunberg–Nissan et pour le paramètre d'interaction de Hind.

In a recent work (1) values of the dynamic viscosity η were calculated from measured values of the kinematic viscosity ν and the mass density ρ using the incorrect equation [1].

[1] $\eta = \nu/\rho$

That this was done can be verified by comparing (ν/ρ) calculated from data in Table 3 of ref. 1 to η values in Fig. 4 and Table 6 of ref. 1. The correct equation is:

[2] $\eta = \nu \times \rho$

as kinematic viscosity is defined as fluid viscosity divided by fluid density (2). Values of the observed experimental viscosity η_{obs} in ref. 1 are incorrect. Correct ones calculated from the tabulated values of ν and ρ in ref. 1 are given in Table 1.

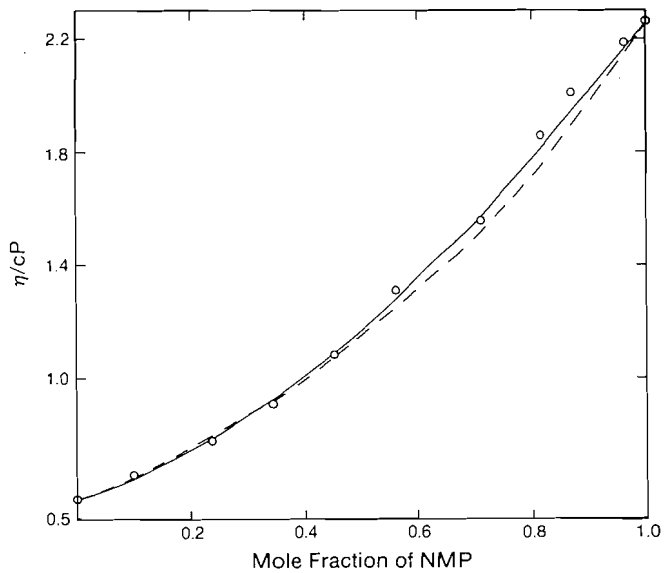

FIG. 1. Dynamic viscosity as a function of composition. System: NMP—THF; temperature: 5.0 ± 0.05°C. ○ Measured; --- ideal eq. [3]; — empirical.

The previous work analyzed η values using the Grunberg–Nissan model (3) and the Hind model (4). The ideal mixture viscosity in the Grunberg–Nissan model η_{GN} was that of Arrhenius (5) as modified by Kendall and Monroe (6) from volume to mole fraction:

[3] $\ln \eta_{GN} = x_1 \ln \eta_1 + x_2 \ln \eta_2$

where 1 and 2 refer to the two components. Values of η_{GP}

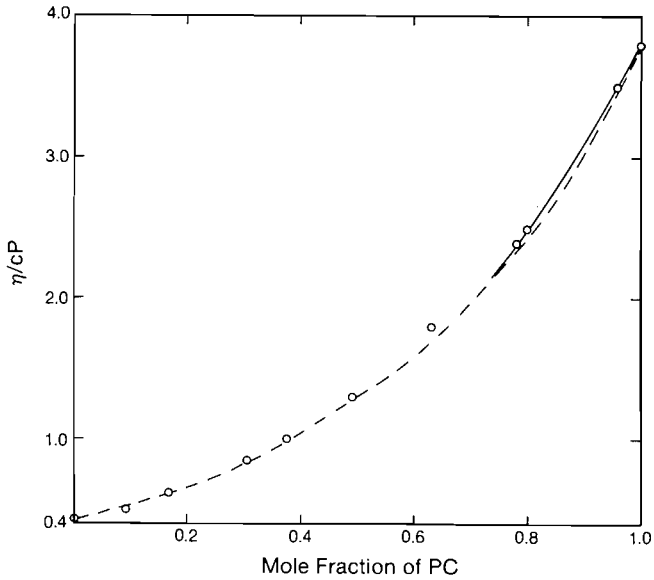

FIG. 2. Dynamic viscosity as a function of composition. System: PC—AN; temperature: 5.0 ± 0.05°C. ○ Measured; --- ideal eq. [3]; — empirical.

based on the correct η are given in Table 1; Figs. 4 and 5 of ref. 1 are redrawn in Figs. 1 and 2, respectively. Viscosities of both the binary mixtures NMP–THF and PC–AN follow the empirical Arrhenius expression, eq. [3], suggesting the absence of specific intermolecular interactions during the process of momentum transfer in these systems. Values of the Grunberg–Nissan deviation parameter ϵ defined as

$$[4] \quad \epsilon = (\ln \eta_{obs} - \ln \eta_{GN})/x_1 x_2$$

and the Hind interaction parameter η_{12} from

$$[5] \quad \eta_{12} = [\eta_{obs} - (x_1^2 \eta_1 + x_2^2 \eta_2)]/2x_1 x_2$$

for the corrected η_{obs} are also given in Table 1.

Organometallic aspects of cytochrome P-450 metabolism

J.-I. SETSUNE
Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka 591, Japan
AND
D. DOLPHIN
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received April 14, 1986

J.-I. SETSUNE and D. DOLPHIN. Can. J. Chem. **65**, 459 (1987).

Carbeneiron porphyrins, (*N,Fe*)-bridged methyleneiron porphyrins, *N*-alkyliron porphyrins and σ-alkyliron porphyrins have all been shown to occur in nature and to be interconvertible via redox reactions. The chemistry of the naturally occurring iron porphyrins and model iron, cobalt, and ruthenium porphyrins is reviewed emphasizing their organometallic chemistry.

J.-I. SETSUNE et D. DOLPHIN. Can. J. Chem. **65**, 459 (1987).

On a démontré que les porphyrines liées au carbène-fer, des porphyrines liées au méthylène-fer par une liaison *N–Fe*, les porphyrines liées à des *N*-alkyl-fer et les porphyrines liées à des σ-alkyl-fer se retrouvent toutes dans la nature et qu'elles se transforment les unes dans les autres par des réactions rédox. On passe en revue la chimie des porphyrines liées au fer ainsi que celle de porphyrines modèles liées au fer, au cobalt et au ruthénium en faisant ressortir leur chimie organométallique.

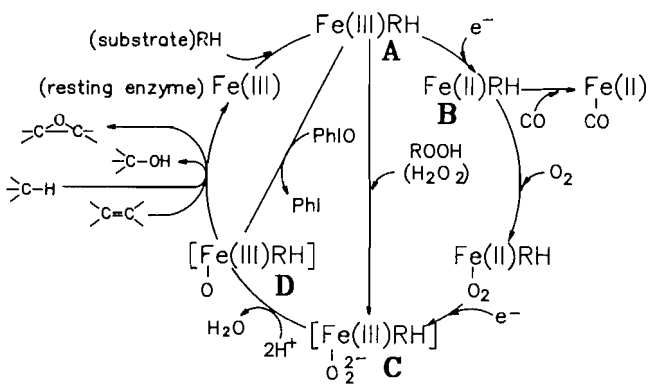
I. Introduction

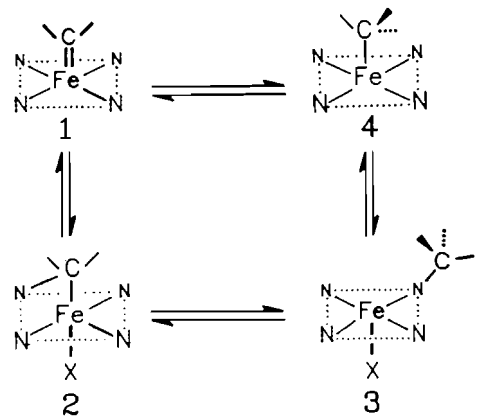
Until recently the only major organometallic chemistry of biological significance was that associated with coenzyme B_{12} and related systems containing cobalt–carbon bonds (1). However, the importance of organometallic chemistry of iron porphyrins and heme proteins is now being recognized.

The cytochromes P-450 (2) activate molecular oxygen by using prosthetic heme at the active site and NADPH as an electron source. One atom of dioxygen is reduced to water and the other used for the monooxygenation reactions such as hydroxylation of alkanes and arenes, epoxidation of olefins, and *N*-oxide and *S*-oxide formation of amino and sulfur compounds (2–4). Cytochrome P-450 also plays a key role in the reductive dehalogenation of polyhalogenated compounds (5–8). The oxoiron (IV) π-cation radical complex (**D**, Scheme 1), or some equivalent, is the key intermediate of the monooxygenation reaction in the catalytic cycle shown in Scheme 1 while the iron(II) complex (**B**) seems to interact directly with halogenated compounds during their reductive metabolism.

Recent studies on iron porphyrins have elucidated the chemical properties of, and the mutual relationships between,



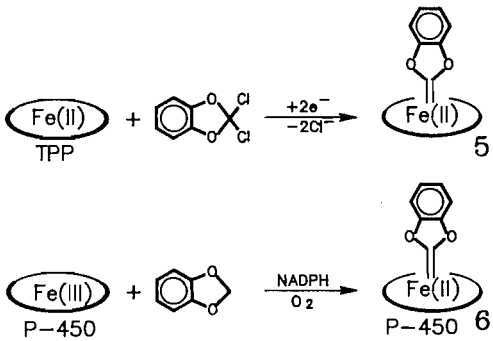
SCHEME 1



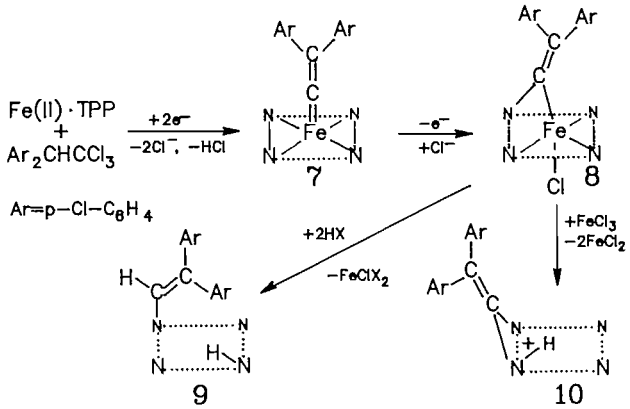
SCHEME 2

carbeneiron(II) porphyrins[1] (**1**), (*N,Fe*)-bridged methyleneiron(III) porphyrins (**2**), *N*-alkyliron(II) porphyrins (**3**), and σ-alkyliron(III) porphyrins (**4**) (Scheme 2). These four complexes may be regarded as models which can explain much of the *in vivo* chemical and biochemical reactions of cytochrome P-450. The complex (**1**) is a carbon analogue of compound II of catalases and peroxidases (3), while complex (**2**) is isoelectronic with an Fe—O—N bridged structure which is one of several structures proposed for compound I of catalase (9). Hepatic green porphyrins generated as a result of suicidal inactivation of cytochrome P-450 were shown to be *N*-alkylporphyrins (**3**) (10), and formation of a protein-stabilized σ-alkylporphyrin (**4**) has been postulated in the reaction of hemoglobin and myoglobin with phenyl hydrazine, ultimately giving rise to *N*-phenylheme (cf. **3**) (11). The carbeneiron(II) structure (**1**) was postulated for the stable 455 nm-absorbing complex of cytochrome P-450 which was observed upon oxidative metabolism of 1,3-benzodioxole known to be a potent insecticide

[1] We name these complexes as iron(II) carbene complexes cognizant of the fact that we have called the isoelectronic complexes in schemes 20 and 23 oxoiron(IV) species.



SCHEME 3



SCHEME 4

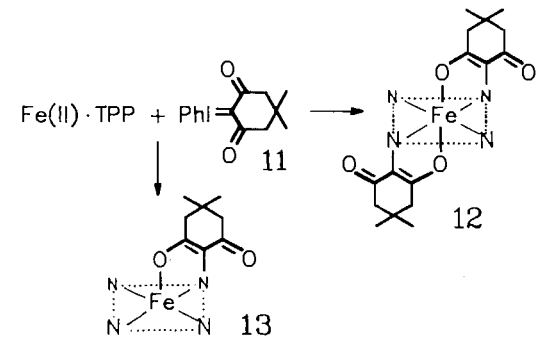
synergist (12). A 470 nm-absorbing intermediate was observed during the reductive metabolism of halothane, an inhalation anaesthetic, and ascribed to the formation of a carbeneiron(II) complex (**1**) or a σ-alkyliron(III) complex (**4**) (5–8).

In view of these observations, the organometallic chemistry of iron porphyrins may serve as an excellent basis for elucidating the mechanism of the catalytic reactions in which the cytochromes P-450 play important roles. We present here, recent advances in the field of organometalloporphyrin chemistry which will be surveyed emphasizing their biological relevance.

II. Carbeneiron(II) and σ-alkyliron(III) porphyrins

The first carbeneiron(II) porphyrin, dichlorocarbeneiron(II) tetraphenylporphyrin, was reported in 1977 (13). Various carbeneiron(II) porphyrins were prepared through the reaction of iron(II) porphyrins with polyhalogenated compounds in the presence of a reducing agent (14). The 1,3-benzodioxole-2-carbene complex (**5**) was synthesized from Fe(II)TPP (**4**) and 2,2-dichloro-1,3-benzodioxole to provide spectroscopic evidence in support of the formation of a 1,3-benzodioxole-2-carbene complex (**6**) (Scheme 3) of cytochrome P-450. These observations may explain the inhibitory action of 1,3-benzodioxole, as an insecticide synergist, on the enzymes responsible for insecticide detoxification (12).

The insecticide DDT, 2,2-bis(*p*-chlorophenyl)-1,1,1-trichloroethane, when reacted as above, followed by β-elimination of HCl, afforded a diaryl vinylidene carbene complex, $Ar_2C{=}C{=}Fe(II)TPP$ (**7**) (Scheme 4), which was found to be exceptionally stable (15) and was therefore conveniently used to investigate the general behavior of carbeneiron(II) porphyrins. Upon a one-electron oxidation of the vinylidene carbene complex (**7**), the electrophilic vinylidene ligand is no longer



SCHEME 5

stabilized by iron in the ferric state and nucleophilic attack of the pyrrole nitrogen leads to the formation of the (*N*,*Fe*)-bridged vinylidene complex (**8**) which is transformed into the *N*-vinylporphyrin (**9**) upon protonolysis of the iron–carbon bond. The *N*,*N'*-bridged vinylidene porphyrin (**10**) is generated upon a further one-electron oxidation with $FeCl_3$ (9, 16–18).

Although it has been reported that a green porphyrin absorbing at 595 nm was transiently observed when chloro-iron(III) protoporphyrin IX dimethyl ester was allowed to react with diazomethane (19), iron carbene complexes of the type (**1**) and (**2**) have never been successfully obtained through the action of iron porphyrins with diazo compounds. Instead, the reaction of Fe(II)TPP with a phenyliodonium ylide (**11**), which is structurally analogous to iodosylbenzene, PhIO, afforded the bis(*N*-alkyl)porphyrin Fe(II) complex (**12**) which can be regarded as an analog of the bridged methylene complex (**2**) (20) (Scheme 5). The carbeneiron(II) structure and the (*N*,*Fe*)-bridged methyleneiron(III) structure were confirmed by single crystal X-ray determinations (9, 21). Under more carefully controlled conditions the mono(*N*-alkyl) complex (**13**) has also been prepared (22) (Scheme 5).

Electrochemical reduction of complex (**7**) was accompanied by spectral changes indicating the formation of a σ-vinyl-iron(II) porphyrin (**14**) which was alternately produced by a one-electron reduction of the σ-vinyliron(III) porphyrin (**15**) (23, 24). The redox relationship between the complexes (**7**) and (**15**) are shown in Scheme 6 (25).

σ-Alkyliron(III) porphyrins are obtained classically by the reaction of iron(III) porphyrins with Grignard reagents (26–28). Two other routes to σ-alkyliron(III) porphyrin reported recently are the reaction of Fe(II) porphyrins with alkyl radicals generated under pulse radiolysis conditions (29) and the reaction of an electrochemically generated Fe(I) porphyrin with alkyl halides in an S_N2 type nucleophilic substitution, oxidative addition, reaction (24, 30).

The σ-alkyliron(III)TPP complex (**16**) was detected during the catalytic reduction of *p*-nitrobenzyl chloride to *p*-nitrotoluene using a H_2O–toluene biphasic system with a phase transfer catalyst, sodium ascorbate, and Fe(III)TPP(Cl) (31). This supports the mechanism shown in Scheme 7 and also suggests that σ-alkyliron(III) complexes could be intermediates in the formation of carbeneiron(II) complexes, emphasizing the role of σ-alkyliron(III) intermediates in the metabolic reduction of halogenated compounds by cytochrome P-450. In fact, formation of the σ-alkyliron(III) porphyrin (**17**) was demonstrated when $CF_3CHClBr$, an inhalation anaesthetic, was allowed to react under the same conditions as when the carbeneiron(II)·tetraphenylporphyrin (**18**) was formed (8, 32). A unifying reaction mechanism is presented in Scheme 8 for these reactions.

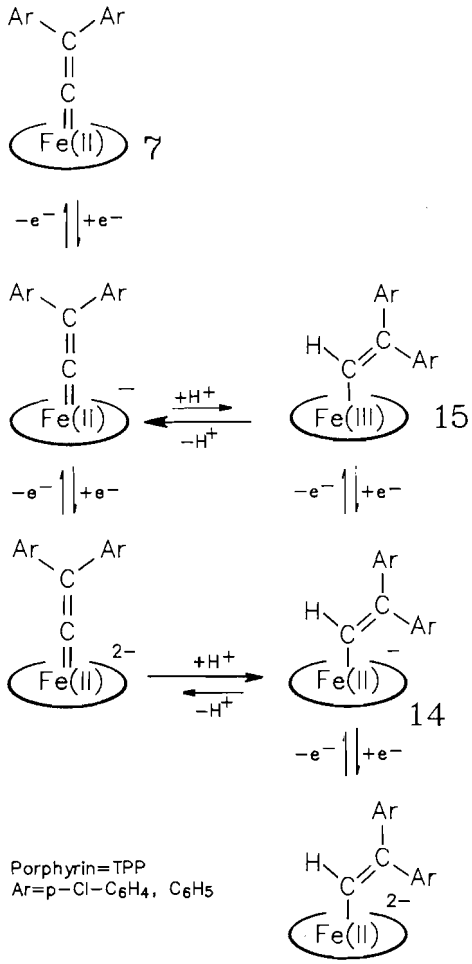
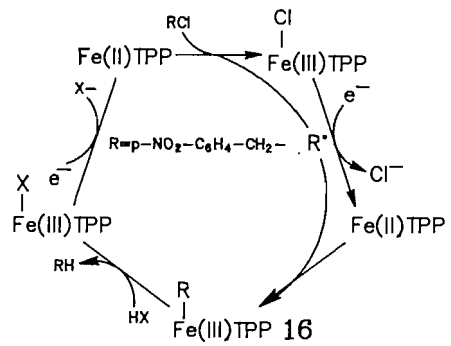
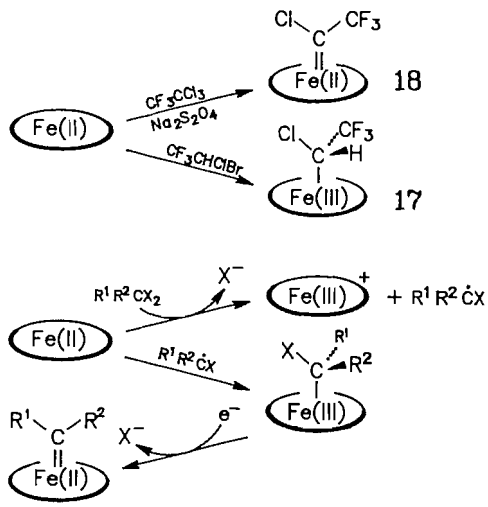


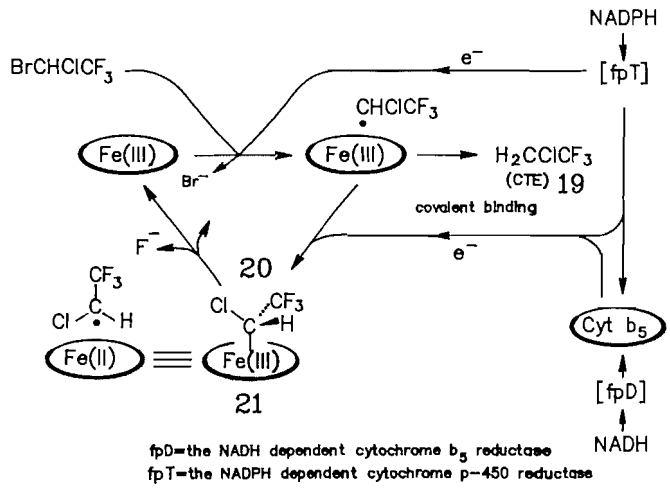
SCHEME 6



SCHEME 7



SCHEME 8



SCHEME 9

Although $CF_3CHClBr$ is metabolized in man to trifluoroacetic acid via a monooxygenase pathway, debrominated metabolites, 2-chloro-1,1,1-trifluoroethane (CTE, **19**) and 2-chloro-1,1-difluoroethylene (CDE, **20**), were detected *in vitro* accompanied by an increased covalent binding of the labelled substrate to the enzyme with decreasing dioxygen tension (5). Since the CTE/CDE ratio is shifted by addition and inhibition of cytochrome b_5, which is responsible for the second electron donation in the catalytic cycle of cytochrome P-450 system (**B** → **C**, Scheme 1), it follows that a $CF_3CHCl^{\bullet}$ radical is formed upon the first one-electron reduction which then abstracts a hydrogen atom to give CTE or attacks an amino acid residue. The Fe(III)$CHClCF_3$ σ-complex (**21**) is formed upon the second one-electron reduction and decomposes to CDE by a β-elimination mechanism (Scheme 9).

Hemoglobin and myoglobin are inactivated during the catalytic oxidation of aryl hydrazines to arenes, hydrogen peroxide, and dinitrogen (11). Nuclear magnetic resonance signals of the aryl group, which is thought to be bound directly to iron(III), are observed both with the inactivated hemoglobin and with the prosthetic heme extracted under anaerobic conditions (33). Aerobic work-up, with acid, of the inactivated hemoglobin gave *N*-arylprotoporphyrin IX dimethyl ester. Ethyl hydrazine is also oxidatively decomposed by hemoproteins to give *N*-ethylation of the prosthetic heme. Predominant *N*-ethylation on ring C of the protoporphyrin IX was observed. The globin is not necessary for *N*-arylation and *N*-alkylation to take place since hemin itself reacts analogously (34), however the protein may stabilize the intermediates which are thought to be aryl and σ-alkyliron(III) complexes.

A reversible iron-to-nitrogen shift (**22**–**23**) of alkyl, aryl, and vinyl groups was demonstrated upon a one-electron redox step with iron TPP complexes (35). The iron-to-nitrogen shift can be interpreted formally in terms of an oxidation of iron(III) to iron(IV) followed by the reductive elimination of the C and N ligands to form a C—N bond and iron(II), although earlier experiments with cobalt porphyrins (see below) have shown the involvement of the porphyrin macrocycle (37). A similar

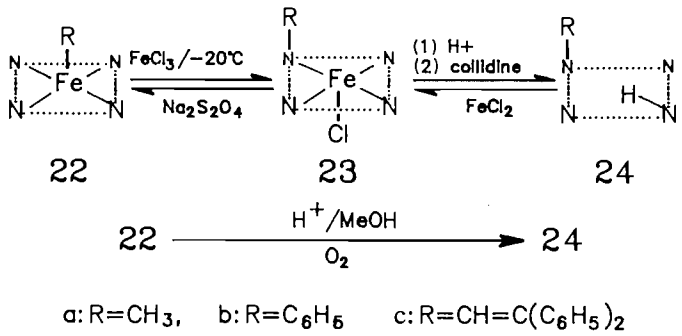
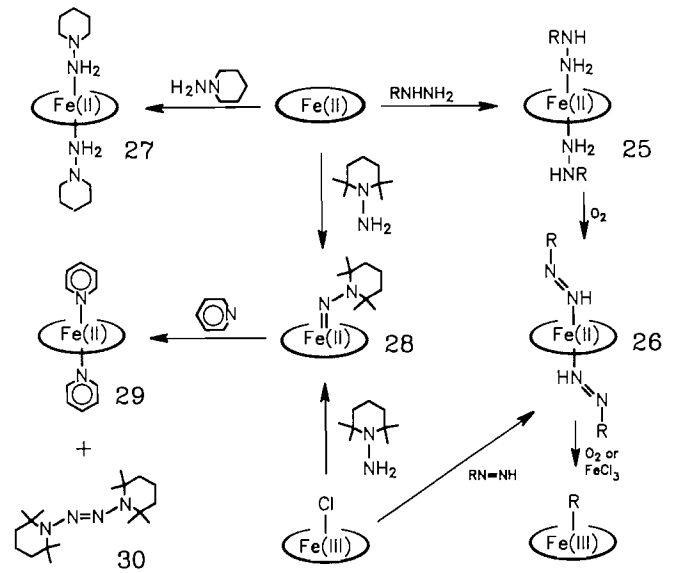


SCHEME 10



SCHEME 11

iron-to-nitrogen rearrangement of a phenyl group was shown by treatment of σ-phenyliron(III) tetraphenylporphyrin (**22***b*) with acidic methanol under aerobic conditions (36). These findings provide a rationale for the formation of σ-alkyliron(III) complexes and their transformation into *N*-alkylhemes (**24**) in the reaction of hemoproteins with alkyl hydrazines (Scheme 10).

Methyl hydrazine reduces ferric tetraphenylporphyrin to the corresponding bishydrazine hemochrome, TPP·Fe(II)$(RNHNH_2)_2$ (**25**), under anaerobic conditions, which is then oxidized to a bisdiazene hemochrome, TPP·Fe(II)$(RN{=}NH)_2$ (**26**), which upon further oxidation by $FeCl_3$ or O_2 gives the σ-methyliron(III) TPP (**19***a*) (38). A similar reaction pathway was suggested for phenyl hydrazine although the corresponding bisdiazene hemochrome proved to be too unstable to be characterized (38). The reactions of 1,1-dialkyl hydrazines toward iron porphyrin are different from those of monoalkylhydrazines. While 1-aminopiperidine reacts with TPP·Fe(III)Cl to give only the bishydrazine hemochrome, TPP·Fe(II)$(NH_2{-}NC_5H_{10})_2$ (**27**), the iron–nitrene complex, TPP·Fe(N—NC_9H_{18}) (**28**), was obtained when 1-amino-2,2,6,6-tetramethylpiperidine was used (39). The same nitrene complex (**28**) was prepared by the direct reaction of TPP·Fe(II) with pre-generated nitrene at low temperature and shown to release the nitrene ligand upon addition of excess pyridine to give TPP·Fe(II)$(py)_2$ (**29**) and the tetrazene (**30**). These results indicate that the reactions of hydrazines with iron porphyrins are strongly dependent on the nature of the substituted hydrazine (Scheme 11).

III. Organometalloporphyrins other than iron

Treatment of the *N,N'*-bridged tetraphenylporphyrin (**31**) with $Fe_3(CO)_{12}$ gave the carbene complex (**32**) (40). Similarly reaction with $Ru_3(CO)_{12}$ gave the corresponding ruthenium carbene complex (**32**). However, reaction of (**31**) with $Ni(CO)_4$ leaves one of the C—N bonds intact with formation of a σ-C—Ni bond (**33**) (40) (Scheme 12).

Ruthenium porphyrins are beginning to exhibit some rich organometallic chemistry. Thus Collman's group (41) have reported the reactions outlined in Scheme 13 where the ruthenium(II) dimers (**34**) of OEP and TPP both undergo similar reactions. Reduction, using potassium in THF, of the dimers gives the dipotassium Ru^0 porphyrin (**35**) (42) which undergoes the reactions shown in Scheme 14. The bisalkyl complexes can also be prepared by the reaction of the ruthenium(IV)

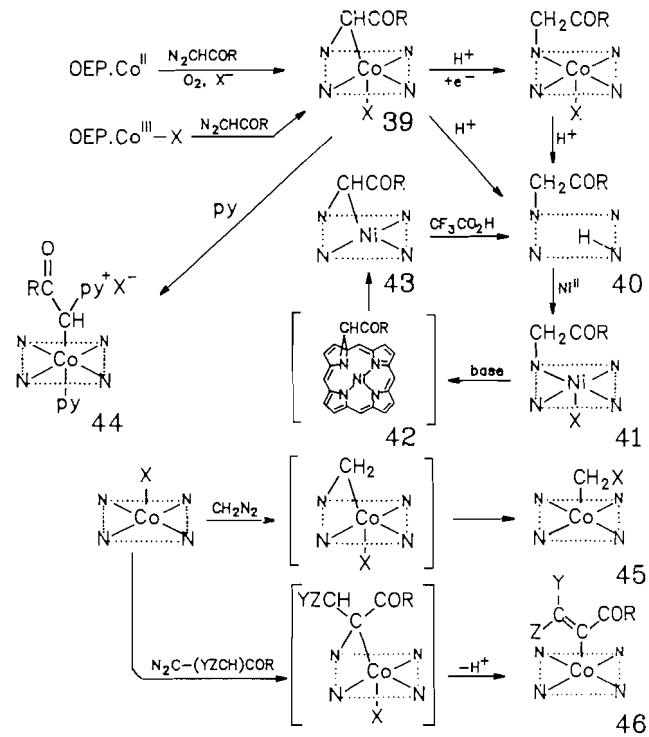
SCHEME 15

dibromide (**36**) with alkyl lithium and Grignard reagents (43) (Scheme 14).

σ-Alkyl complexes, *N*-alkyl complexes, and (*N,metal*)-bridged methylene complexes of cobalt porphyrins are known. Oxidative migration of ethyl and carboethoxy groups from cobalt to nitrogen occurs after an electrochemical oxidation to afford *N*-ethyl- and *N*-carboethoxy–TPP·Co(II) complexes (**37** ⇄ **38**, Scheme 15) (37). Spectroelectrochemical evidence showed that the initial site of oxidation was at the porphyrin ring to give a porphyrin π-cation radical intermediate. Treatment of σ-alkyl-, σ-aryl-, and σ-vinylcobalt(III) porphyrins with trifluoroacetic acid under aerobic conditions analogously brings about cobalt-to-nitrogen ligand migration (44, 45). In this case molecular oxygen, in acidic solution, seems to act as a strong oxidant to drive the reaction. Reductive nitrogen-to-metal migration of a methyl group takes place when cobalt, rhodium, and iridium complexes of *N*-methyl octaethylporphyrin are treated with sodium borohydride (46–48). These reversible metal-to-nitrogen migrations occur intramolecularly (Scheme 15), and detailed studies on the transfer of alkyl, aryl, and styryl groups between cobalt and nitrogen have been made (49, 50).

Unusual (*N,Co*)-bridged methylene complexes (**39**) of OEP·Co(III) were prepared through the reaction of divalent and trivalent cobalt OEP with ethyl diazoacetate (51, 52) and diazoacetaldehyde (53). A carbene cobalt(II) porphyrin was not detected and oxygen plays a key role in the reaction of Co(II)OEP with diazo compounds. Protonolysis of the cobalt(III)–carbon bond occurs to give *N*-substituted porphyrins (**40**) when the bridged complex (**39**) is treated with acid under conditions where Co(III) can be reduced to Co(II). The studies of Callot and Schaeffer with diazoalkanes were the first to suggest exchange of an organic fragment between metal and nitrogen proceeding via a bridged intermediate (54). Base treatment of (*N*-$CH_2CO_2C_2H_5$)Ni(II)TPPClO_4 (**41**) generates a kinetically favored (*N,C*)-bridged methylene intermediate (**42**) which gives rise to the (*N,Ni*)-bridged methylene complex (**43**) which can be further transformed into *N*-carboethoxymethyl TPP (**40**) upon addition of trifluoroacetic acid (55) (Scheme 16).

Addition of pyridine to (*N,Co*)-ethoxycarbonylmethylene Co(III)OEPCl (**39**) results in the formation of the pyridinium compound (**44**) (52). Direct formation of σ-halomethylcobalt(III) porphyrins (**45**) from the reaction of halocobalt(III) porphyrins with diazomethane involves a nucleophilic cleavage reaction of the transient bridged methylene complex, which was not isolated in this case (56). The σ-vinylcobalt(III) TPP (**46**) is generated directly when ethyl diazopropionate is allowed to react with Co(III)TPPCl (54). The N—C bond fission is facilitated if the bridgehead substituent bears a proton (56, 57).



SCHEME 16

IV. Suicidal *N*-alkylation of cytochrome P-450

It has recently been reported that the prosthetic heme of cytochrome P-450 monooxygenases is converted into abnormal green porphyrins during the metabolism of 1,4-dihydropyridine derivatives (9, 58–60), cyclopropyl amines (61, 62), alkyl hydrazines (63), 1-aminobenzotriazole (64, 65), terminal olefins (66, 67), and terminal acetylenes (68–71). The hepatic porphyrin biologically modified with 3,5-dicarboethoxy-1,4-dihydrocollidine (**47**) was characterized as *N*-methylprotoporphyrin IX dimethyl ester (**49**). The *N*-methyl group was shown to be predominantly on pyrrole ring A on the basis of chemical synthesis and hplc separation of the four possible isomers of (**49**) (10, 58) (Scheme 17). *N*-Methylation of protoporphyrin IX dimethyl ester (**48**) with methyl fluorosulfonate afforded a mixture of four isomers in approximately equal amounts. The site of *N*-methylation of the four different pyrrole rings (A, B, C, and D) was determined using nmr techniques (58). The preferential ring A alkylation in the biological process seems to be controlled by the stereochemical arrangement of the protein surrounding the prosthetic heme.

Destructive activity of various 4-substituted 3,5-bis(ethoxycarbonyl)-2,6-dimethyl-1,4-dihydropyridines (**47**) as suicidal substrates in the catalytic metabolism of cytochrome P-450 enzymes was studied by using spin trapping technique to provide evidence in support of the formation of an alkyl radical derived from the 4-substituent of the substrate, which argues for the one-electron oxidation of a nitrogen lone pair of the substrate as the initial step (60). Cyclopropyl amines as suicidal substrates for cytochrome P-450 have also been reported and an aminium cation radical intermediate was postulated to form via a one-electron oxidation mechanism (61, 62). A tracer experiment showed covalent binding of the substrate to both the protein and the prosthetic heme presumably by the action of a ring-opened carbon-centered radical (**51**) formed from the aminium cation radical intermediate (**50**). Suicidal *N*-alkylation of the prosthetic heme of cytochrome P-450 was also reported in the metabolic processing of alkyl hydrazines (63) and 1-aminobenzotriazole (64, 65). *N*-(2-Phenylethyl)protoporphyrin IX dimethyl ester (**53**) was isolated from rat liver microsomes treated with 2-phenylethyl hydrazine and analyzed spectroscopically to show that *N*-alkylation had occurred on the pyrrole ring C or D. A spin trap experiment was successfully used to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12

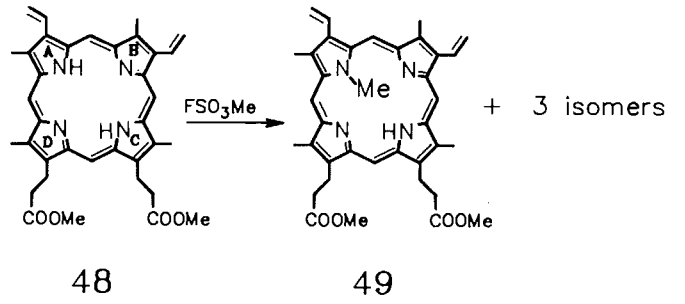
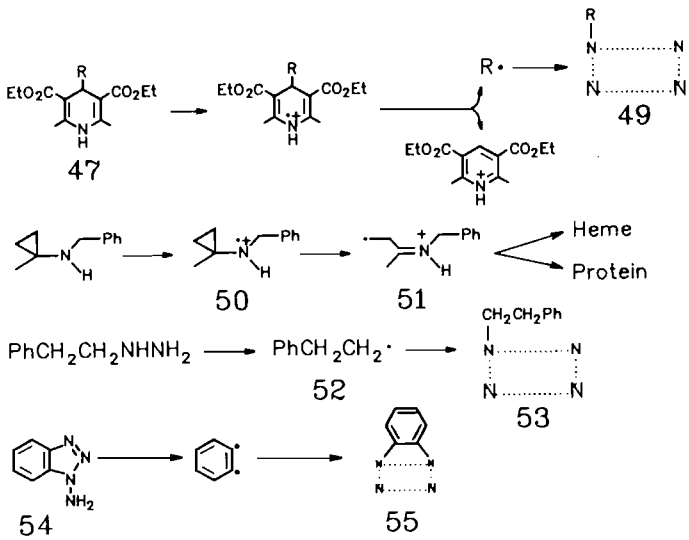


SCHEME 17



SCHEME 18

detect the 2-phenylethyl radical (**52**) in the metabolic process (63). Exceptionally high destructive ability was obtained with 1-aminobenzotriazole (**54**), which is known to yield benzyne upon mild chemical oxidation, and the hepatic porphyrin in this case was tentatively characterized as *N,N'-ortho*-phenylene bridged protoporphyrin IX dimethyl ester (**55**) on the basis of nmr, mass, and visible spectra (64, 65) (Scheme 18). More recently the total synthesis of vinylidene and phenylene bridged porphyrins have been reported (72). The catalytic metabolism of these amino compounds is believed to be initiated by a one-electron heteroatom oxidation. This parallels the cases of *N*-oxygenation and *S*-oxygenation of aminopyrine (73–75) and organosulfur compounds (76, 77) catalyzed by microsomal cytochrome P-450 enzymes. The above results indicate that suicidal inactivation by these substrates originates in the generation of a carbon-centered radical, the radical then inactivates cytochrome P-450 through an attack on either protein or the nitrogen of heme as summarized in Scheme 18. The heme alkylation can occur first at the iron atom to give a σ-bonded alkyliron complex which can rearrange to an *N*-alkylheme upon a one-electron oxidation (11, 35, 63).

The prosthetic heme of cytochrome P-450 is converted during the metabolism of terminal olefins and acetylenes into *N*-alkylporphyrins; the *N*-substituent consists of the substrate and one oxygen atom. Nuclear magnetic resonance studies showed that hydroxyethyl, 2-hydroxypropyl, and 2-hydroxyoctyl groups were bonded to the pyrrolic nitrogen of ring D of the hemes biologically modified with ethylene, propene, and 1-octene, respectively (66, 68).

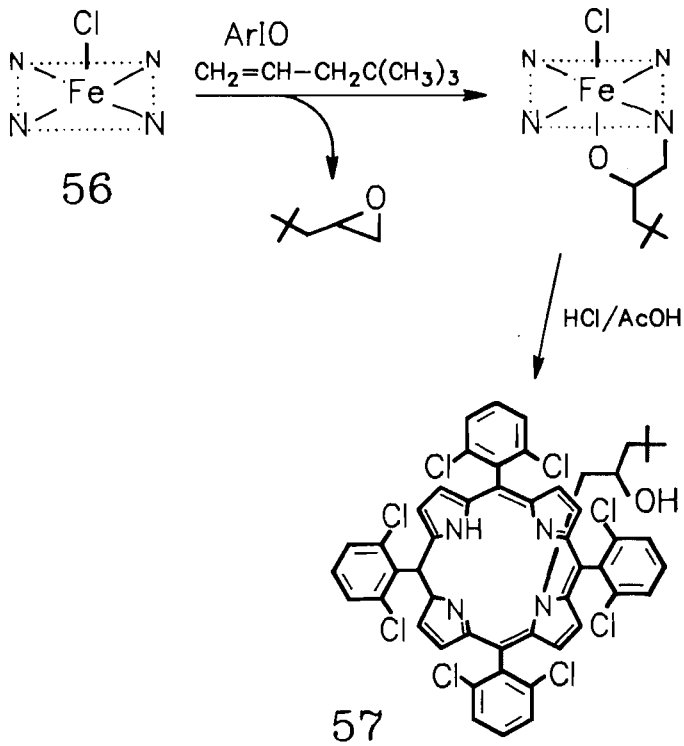
We have demonstrated suicidal *N*-alkylation of an iron porphyrin model complex of cytochrome P-450 when *N*-(4,4-dimethyl-2-hydroxypentyl)-5,10,15,20-tetrakis(2,6-dichlorophenyl)porphine (**57**) was isolated from the epoxidation reaction of 4,4-dimethyl-1-pentene with iodosopentafluorobenzene catalysed by 5,10,15,20-tetrakis(2,6-dichlorophenyl)porphinatoiron(III) chloride (**56**) (78) (Scheme 19).

We have also shown (79) that *N*-alkylation of cobalt(III) porphyrin π-cation radicals occurs with alkynes. Thus cobalt(III) octaethylporphyrin π-cation radicals, prepared by the oxidation of cobaltic OEP with ferric chloride or perchlorate, reacted with acetylene, 1-hexyne, propargyl alcohol, 2-butyne-1,4-diol, and mono- and diphenyl acetylenes, to give in good yields the *N*(21),*N*(22)–etheno bridged porphyrins (**58**) (Scheme 20).

Both of the above *N*-alkylations can be considered as occurring via an initial one-electron transfer from the unsaturated hydrocarbon to the highly oxidized metalloporphyrin (Scheme 21) to generate a radical cation of the hydrocarbon (this concept is developed in more detail below).

Intermediate **59** (Scheme 21*b*) generated after formation of an initial N—C bond contains a σ-cobalt–carbon bond and an oxidized porphyrin π-cation radical. We have shown earlier that such a species may undergo a cobalt → nitrogen ligand migration. Such a migration in this case would lead to the observed etheno bridged product (**58**).

It was reported that inactivation of cytochrome P-450 with acetylene, propyne, and 1-octyne afforded *N*-(2-oxoalkyl)pro-



SCHEME 19

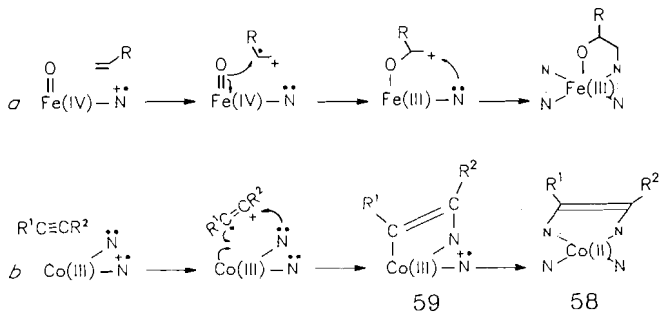


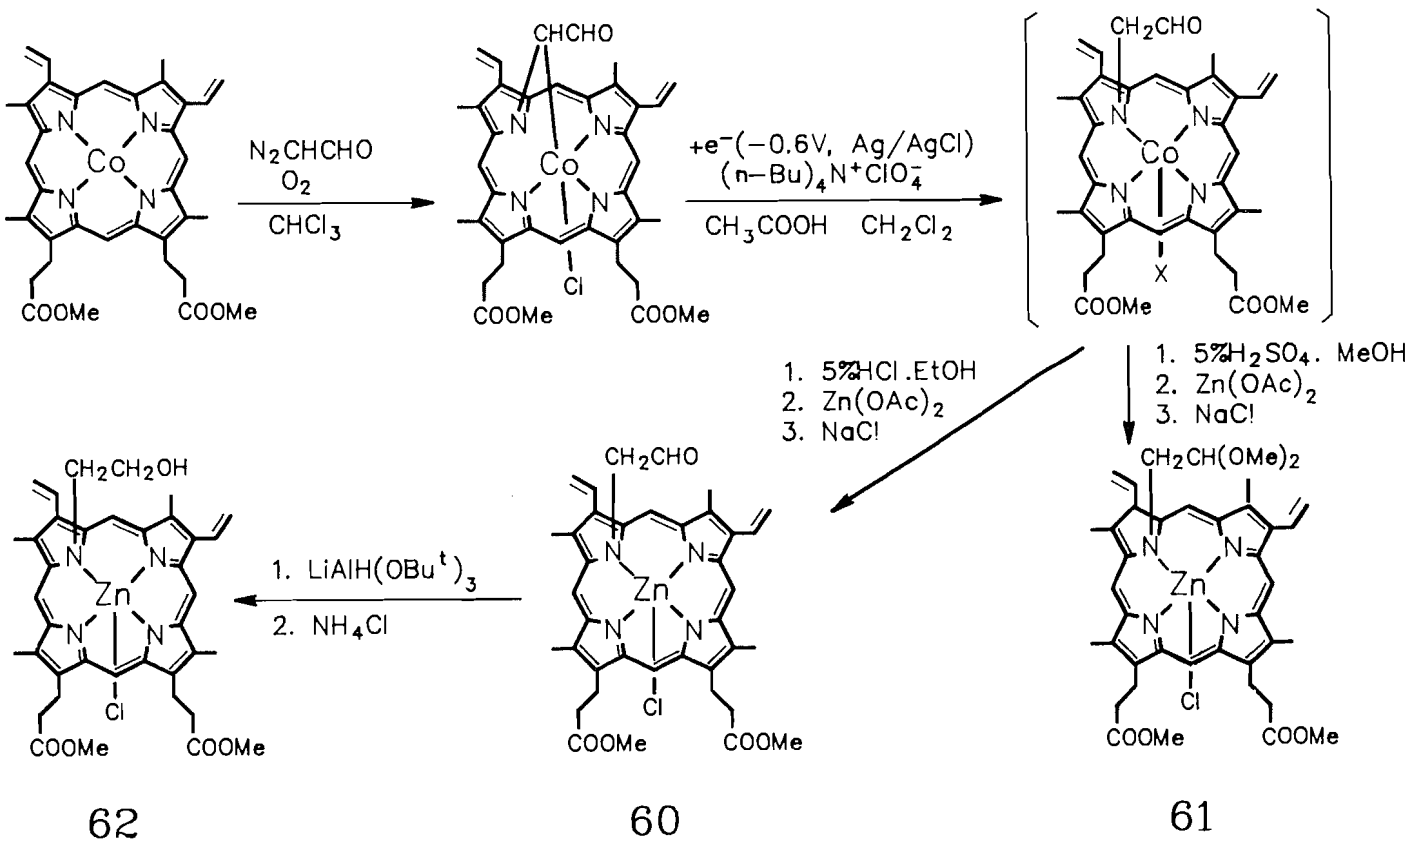
SCHEME 21

toporphyrin IX dimethyl esters with the *N*-substituents specifically on pyrrole ring A in the case of propyne and 1-octyne (68, 70). The acetylene-derived porphyrin was a mixture of two *N*-alkylprotoporphyrin IX dimethyl esters, the *N*-substituents of which were shown to be formylmethyl and the corresponding dimethyl acetal on the basis of mass spectroscopic studies. The site of the pyrrole ring bearing *N*-substituent was not determined (69). In order to provide a firm basis for the structural identification of these *N*-alkylporphyrins biologically modified with unsaturated compounds, chemical synthesis of *N*-formylmethyl- (**60**), *N*-(2,2-dimethoxyethyl)- (**61**), and *N*-(2-hydroxyethyl)protoporphyrin IX dimethyl ester (**62**) was accomplished as shown in Scheme 22 (80). Spectroscopic analysis of these synthetic *N*-alkylprotoporphyrin IX dimethyl esters showed that the site of *N*-alkylation in the biological reactions with acetylene occurred on ring C or D.

In order to isolate the hepatically modified hemes they were esterified with methanol. During this process the naturally derived and synthetic *N*-formylmethylporphyrins were partially converted into the *N*-(2,2-dimethoxyethyl)porphyrin. Unsubstituted acetylene seems to show less regiospecificity during the *N*-alkylation of cytochrome P-450 than is observed with substituted acetylenes and appears to be similar to that observed with unsubstituted ethylene.

The biological *N*-alkylation of heme takes place not only regiospecifically but also stereospecifically with respect to the plane of alkylation. The circular dichroism spectra of two ring C isomers of *N*-ethylprotoporphyrin IX dimethyl ester zinc(II) chloride, one from cytochrome P-450 inactivated with 3,5-bis(ethoxycarbonyl)-2,6-dimethyl-4-ethyl-1,4-dihydropyridine and the other from hemoglobin treated with ethyl hydrazine, are identical (81). This in combination with the hypothesis that *N*-alkylation in hemoglobin most likely occurs from the distal side of the porphyrin plane to which molecular oxygen is bound, provides a rationale for the assignment of an absolute *R*-configuration of the *N*-ethylprotoporphyrin IX obtained from hemoglobin and cytochrome P-450, since the active site geometry of hemoglobin is known X-ray crystallographically. The same absolute *R*-configuration was suggested for the *N*-alkylated porphyrins obtained with propyne and ethylene because the circular dichroism spectra of these porphyrins are virtually the same as those of the corresponding regioisomers of the biologically obtained *N*-ethyl derivative (81). The regiospecificity and stereospecificity observed in the *N*-alkylation of cytochrome P-450 with unsaturated compounds led to an active site model of the phenobarbital induced cytochrome P-450 enzymes which features the absolute orientation of the prosthetic heme, steric constraints over pyrrole ring B, and a lipophilic channel over pyrrole ring C accommodating linear alkyl substituent (68).

The stereochemical course of the catalytic epoxidation and



SCHEME 22

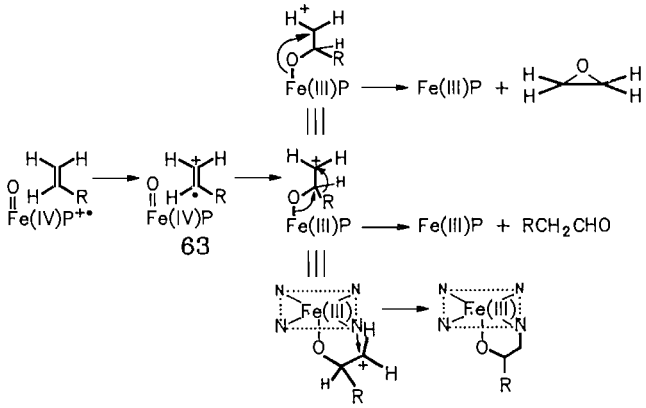
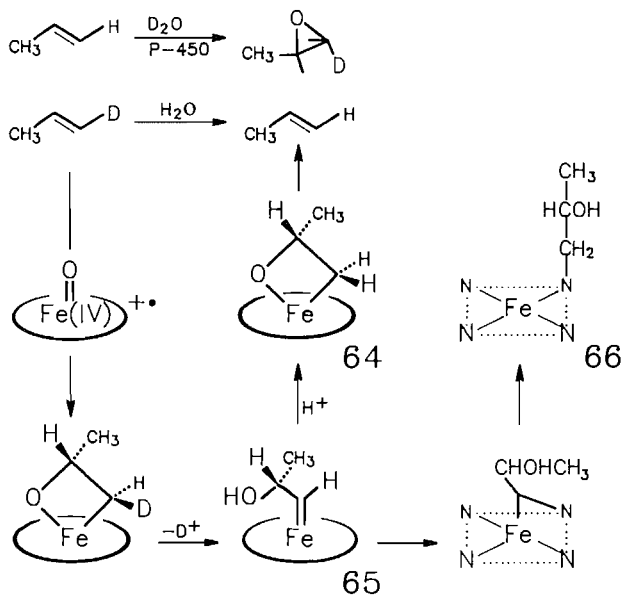


SCHEME 23



SCHEME 24

prosthetic heme alkylation during the metabolism of 1-octene has been studied to show that the olefin stereochemistry is completely retained in both transformations and that only the *re* face of the olefin undergoes *N*-alkylation whereas the *re* and the *si* face are almost equally available for epoxidation (67). The latter observation is consistent with the regiospecific ring D *N*-alkylation by 1-octene under the stereochemical control of the active site.

It is now apparent that the hemoprotein families of the catalases, peroxidases, and cytochrome P-450 are closely related and the active iron–oxygen species of cytochrome P-450 is suggested to be an oxoiron(IV) porphyrin π-cation radical (**D**, Scheme 1) comparable to that seen for catalase and horseradish peroxidase (82).

High valent oxo complexes of iron(IV) tetramesitylporphyrin (83) and ruthenium(IV) octaethylporphyrin have been prepared from the corresponding trivalent metalloporphyrins and iodosylbenzene (84). These compounds exhibit spectral properties similar to those reported for the high oxidation states of catalases and peroxidase and their reactivity towards alkanes and olefins parallels that of cytochrome P-450. Scheme 23 shows how, after an initial one electron transfer from an olefin to the electron deficient oxo-ferryl π-cation radical, an intermediate cation radical of the olefin (**63**) can account for all of the products observed both biologically (4) and in the model systems (78).

Groves *et al.* (85) have shown for the specific case of propylene, that deuterium can be both regio- and stereospecifically incorporated into the recovered alkene during a P-450 mediated epoxidation, when the reaction is run in D_2O. In addition, deuterium can be lost from deuterated propene when the reaction is carried out in water. Groves *et al.* have suggested that this reaction may proceed via a metallocycle (**64**) which reversibly gives, upon deprotonation, the metallocarbene (**65**) and which in turn would lead to the *N*-alkylheme (**66**) (Scheme 24).

Spectral studies on the interaction of iodine with thiazoles

REFAT ABDEL-HAMID, AHMED A. EL-SAMAHY, ABDEL-HAFIZ EL-TAHER, AND HUSSEIN EL-SAGHER
Department of Chemistry, Faculty of Science, Sohag, Egypt

Received May 2, 1986

REFAT ABDEL-HAMID, AHMED A. EL-SAMAHY, ABDEL-HAFIZ EL-TAHER, and HUSSEIN EL-SAGHER. Can. J. Chem. **65**, 468 (1987).

The electron donor–acceptor molecular complexes between thiazole and some of its derivatives and iodine in several solvents have been investigated spectrophotometrically at different temperatures. Spectral characteristics, equilibrium constants, K, extinction coefficients, ϵ, and thermodynamic functions of formation, ΔH^0, ΔG^0, and ΔS^0 have been determined. It was found that the data fit satisfactorily the 1:1 stoichiometric equilibrium: $D + I_2 = DI_2$ "outer complex". The EDA complexes obtained are of "n–σ*" type in which the nitrogen atom of thiazole is the donor center. Moreover, the effect of solvents on the K values is discussed in terms of the solute–solute and solute–solvent competing equilibria.

REFAT ABDEL-HAMID, AHMED A. EL-SAMAHY, ABDEL-HAFIZ EL-TAHER et HUSSEIN EL-SAGHER. Can. J. Chem. **65**, 468 (1987).

Opérant à plusieurs températures différentes et faisent appel à la spectrophotométrie, on a étudié les complexes moléculaires donneurs–accepteurs d'électrons entre le thiazole ainsi que quelques-uns de ses dérivés avec l'iode, dans plusieurs solvants. On a déterminé les caractéristiques spectrales, les constantes d'équilibre, K, les coefficients d'extinction, ϵ, ainsi que les fonctions thermodynamiques de formation, ΔH^0, ΔG^0 et ΔS^0. On a trouvé que les données s'accordent bien avec un équilibre stoechiométrique 1:1: $D + I_2$ = « complexe externe » DI_2. Les complexes que l'on a obtenus avec le EDA sont du type « n–σ* » dans lequel l'atome d'azote du thiazole est le centre donneur. De plus, on discute de l'effet des solvants sur les valeurs de K en fonction d'équilibres solutés–solutés et solutés–solvants qui sont en compétition.

Introduction

Heterocyclic compounds form 1:1 stoichiometric electron donor–acceptor molecular complexes with iodine in aprotic solvents (1–3). It has been reported that these EDA complexes are of n-donor–acceptor type and have high thermodynamic stability. Their formation constants and enthalpies of formation put them among the strongest complexes of this type. Recently, a study on the electron donor–acceptor molecular complex equilibria of iodine and thiazoles in carbon tetrachloride using the constant activity method has been performed (4).

This article reports an attempt to study the electron donor–acceptor molecular complexes of iodine with thiazole and some of its derivatives. This was undertaken to determine the spectral and thermodynamic characteristics of such complexes to give more information about such systems. Equilibrium constants and molar extinction coefficients of these complexes are computed at different temperatures. The study is extended to include the effect of solvents on such equilibria. The results are discussed in terms of the molecular structure of the compounds and the solute–solute and solute–solvent competing equilibria. The thiazoles investigated herein are thiazole, (**I**); 4-methylthiazole, (**II**); 2,4-dimethylthiazole, (**III**); and bezothiazole, (**IV**). Solvents used are *n*-heptane, cyclohexane, carbon tetrachloride, and benzene.

Experimental

Materials

The thiazoles used were all supplied by Aldrich Chemical Co. Solvents (B.D.H. or E. Merck) spectroquality were used without further purification and stored under nitrogen atmosphere over 4A Linde molecular sieves. Fisher certified iodine was resublimed under reduced pressure.

Solutions

Stock solutions of donor and iodine were prepared by dissolving a precisely measured amount in the appropriate volume of solvent and stored in the dark. Solutions for measurements were made by mixing appropriate amounts of stock donor, stock iodine, and pure solvent and kept from moisture as far as possible. The measurements were made after about 10 h of mixing. Each set contained eight to ten solutions with the same iodine concentration and varying amounts of donor. The range of concentration for the donors was 0.01 to 0.18 mol dm^{-3} and concentration of acceptor was held constant of 5.0×10^{-4} mol dm^{-3}.

Measurements

Electronic absorption spectrophotometric measurements were made on a UNICAM SP 8-100 Recording Spectrophotometer equipped with a thermostatted cell accessories. Stoppered silica cells of 1.0 cm path length were used. The temperature of solutions was controlled within ±0.1°C using a Haake Ultrathermostat.

The conductivity measurements were carried out on a YSI Conductivity bridge at 25°C.

Calculations

The calculations were performed only for solutions with absorbance changing by no more than 1% after 24 h. The computer program fitted the experimental data (the measured absorbance and concentrations) in the form of a straight line by the linear least-squares fit method (5), based on the equations (6) obtained on the rearrangment of the Bensi–Hildebrand (7) equation. The rearranged equations enable independent evaluation of the equilibrium constant, K, as well as the extinction coefficient, ϵ, of the molecular EDA complexes. These equations are:

$$[1] \quad \left(\frac{C_A^0 + C_D^0}{C_D^0}\right) d = C_A^0 \epsilon l - \frac{d}{K C_D^0}$$

$$[2] \quad (C_A^0 + C_D^0) = \epsilon l \frac{C_A^0 \cdot C_D^0}{d} - \frac{1}{K}$$

where C_A^0, C_D^0 are the initial concentration of the acceptor (iodine) and donor, respectively (in mol dm^{-3}), d is the absorbance at the wavelength of investigation, and l (the cell thickness) = 1.0 cm. The K and ϵ values were derived from the slope and the intercept of eq. [1] and from the intercept and the slope of eq. [2]. The data for every set of solutions containing a constant acceptor concentration and varying amounts of the donor were processed separately. The K and ϵ values obtained at three wavelengths (λ_{max}, $\lambda_{max} \pm 5$ nm of the perturbed iodine) for three sets were then averaged and the results are listed in Tables 1 and 2. All calculations were performed on an Apple IIe computer.

Results and discussion

In the present system, iodine–thiazoles, the electronic absorption spectra are recorded in the wavelength range of 350–625 nm. A typical example is shown in Fig. 1 for thiazole, (**I**). The absorption spectra of iodine with other thiazoles are of similar nature except the position of the perturbed iodine band and the isosbestic point of the complex. It is found that in carbon tetrachloride the iodine visible absorption spectrum shows a broad band with λ_{max} of 512 nm. The thiazoles visible absorption spectra, in the same solvent, exhibit practically no absorption at the 350–625 nm range. On addition of thiazole compounds to the iodine solution, the iodine absorption band at 512 nm is shifted towards shorter wavelengths and a decrease in its absorbance is observed. Further increase in donor concentration leads to an increase in the intensity of the blue-shifted iodine band (about 410 nm) at the expense of the longer wavelength one. Moreover, a sharp isosbestic point is observed near 470 nm for all iodine–thiazoles studied. A similar behaviour is observed in the case of imidazoles–iodine systems (8, 9). These results are indicative of the formation of one species of complex, between iodine and each of the subject thiazoles, and the complex species is in equilibrium with free iodine and thiazole in solution.

This behaviour can be interpreted on the basis of the valance-

For personal use only.

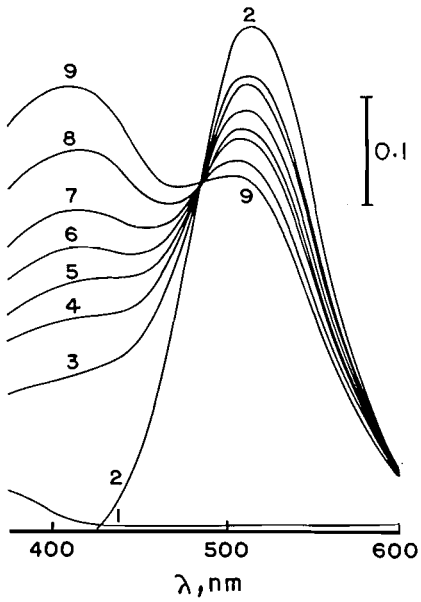

FIG. 1. Electronic absorption spectra of iodine (5.0×10^{-4} mol dm^{-3}) – thiazole – carbon tetrachloride system at different concentrations of donor: 2-C_D = 0, 3- = 0.014, 4- = 0.020, 5- = 0.027, 6- = 0.034, 7- = 0.041, 8- = 0.054, 9- = 0.068 mol dm^{-3} (1-thiazole concentration: 0.02 mol dm^{-3}).

bond theory for charge transfer interaction developed by Mulliken (10). The 512 nm band of iodine in carbon tetrachloride ($B \leftarrow X$) is mainly due to the $3\pi_{ou}^{+} \leftarrow {}^{1}\Sigma_{g}^{+}$ and $\sigma_u \leftarrow \pi_g$ transitions. The $B \leftarrow X$ transition shifts an electron from a π_g to a σ_u MO antibonding orbital. Thus, the blue-shift of the iodine band is attributed to the perturbation of iodine by repulsive interaction between the two partners of the electron donor–acceptor molecular complex (1). Herein, it seems that the complexing site of the donor is the nitrogen atom of thiazole molecule. The lone electron pair on the nitrogen atom is the most probable one, since their ionisation potential is relatively smaller than that of the sulfur atom (the ionisation potential of the lone electron pair for nitrogen is 10.40 eV and for sulfur is 12.70 eV for thiazole, (**I**) (11)). Consequently, the σ_u MO of iodine will be raised while the energy of the nonbonding orbital of the donor will be lowered. This leads to the observed blue shift of the iodine visible band (about 100 nm). This is verified from the examination of the total charge density on the nitrogen and the sulfur atoms of thiazole (−0.625 and +0.727, respectively (12)).

On plotting C_A^0/d against $1/C_D^0$, at the wavelength of the perturbed iodine band a fairly good straight line is obtained with a correlation coefficient of 0.998, in all the investigated thiazoles–iodine systems, indicating thereby the formation of 1:1 stoichiometric complexes in these systems in the concentration region of study. It is found that the thiazoles–iodine solutions show very low conductivity (below 1.0×10^{-6} ohm^{-1} cm^{-1}). These results and the observed constant isosbestic point reveal a typical equilibrium between uncharged species

[3] $D + I_2 = D—I_2$ "outer complex"

Equilibrium constants, K, and the molar extinction coefficients, ϵ, of the subject thiazoles – iodine EDA complexes in carbon tetrachloride are evaluated at three wavelengths in the range of the blue-shifted iodine band making use of eqs. [1] and [2] as described above. It is found that there is no systematic dependence of the equilibrium constants on the analytical wavelength (c.f. Tables 1 and 2). This gives a verification of the assumption that within the experimental errors, one iodine – thiazole EDA complex only is formed in the solution. The mean values of K and ϵ estimated for the three wavelengths are compiled in Table 1, along with the other spectral characteristics.

A linear least-squares fit is observed between log K and the magnitude of the blue shift, $\Delta\bar{\nu}$, except for 2,4-dimethylthiazole, with a correlation coefficient of 0.995 as with the other aza-aromatics (13) revealing that the extent of the blue shift of the iodine band is a rough measure of the strength of the complex formation between the subject thiazole and iodine.

In these systems, like the present ones the formation of I_3^- ion is inevitable, I_3^- has absorption maxima at 293 and 365 nm (14, 15). Although there is no indication of any absorption near 365 nm, slight changes of K and ϵ values with wavelength are observed as shown in Table 1. This is most likely due to I_3^- ion.

For the thiazole–iodine complexes the equilibrium constants of formation obtained (c.f. Table 1) are rather high compared with the K values for the π complexes. This supports the conclusion that these complexes are of the "n–σ^*" type.

A satisfactory linear least-squares fit is obtained between log K_{EDA} and pK_a for the iodine–thiazole system under investigation. The regression line of that fit is as follows:

$$[4] \quad \log K_{EDA} = (0.546 \pm 0.002) + (0.299 \pm 0.001)pK_a \qquad r = 0.976$$

This indicates that the complexation reaction is analogous with the protonation reaction and also that the same electrons (n electrons of the nitrogen atom) is responsible for the bond with the proton for the electron donor–acceptor interaction. This gives a further support for the conclusion that these complexes are of the "n–σ^*" type.

Introduction of a methyl group in the thiazole nucleus (compound **II**) increases the basicity of the nitrogen atom relative to the unsubstituted thiazole (compound **I**). This leads to an increase in the equilibrium constant of the EDA molecular complex. Further introduction of a methyl group (compound **III**) causes a further increase of the basicity and K value, since the effect of the electron-donating groups was noted to be additive. On the other hand, the replacement of a vinyl group in thiazole by a phenyl group (compound **IV**), decrease the basicity and hence the K value. This decrease in basicity is due to the lone pair of electrons on the nitrogen atom in benzothiazole, **IV**, being more extensively delocalized than in thiazole.

It is worth noting that the possibility of the fused phenyl group of benzothiazole acting as a π-donor to iodine is not considered since this action is much weaker than that for the nitrogen atom of the thiazole nucleus.

The equilibrium constants of the subject thiazole–iodine systems in carbon tetrachloride have been determined previously by the constant activity method (4), K_s and the values obtained are recorded in Table 1. On comparing the K_s values with that obtained herein, spectral K, it is evident that the K_s values are slightly higher than that of the spectral K values. Similar higher values of K_s have been reported by Childs *et al.* (16) for aromatic–iodine systems and by Mahmoud *et al.* (9) for imidazole-iodine systems. It has been pointed out by Christian *et al.* (17) that K_s actually includes both specific interactions (complex formation) and non-specific interactions between donor and iodine. If the correction term due to non-specific interac-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

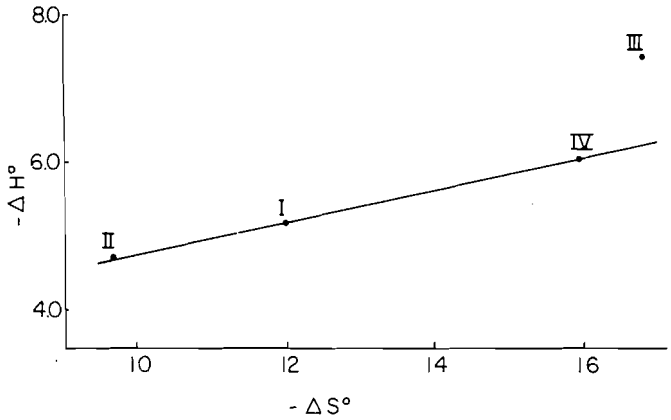

FIG. 2. The ΔH^0–ΔS^0 relationship for the thiazoles–I_2 system in CCl_4.

tions is near zero, then the K_s values may equal to the spectral K (18, 19). In the case of strong complexes like thiazole–iodine the contribution due to non-specific interaction is small.

In order to estimate the thermodynamic parameters, the enthalpy and entropy of formation, the equilibrium measurements are carried out at different temperatures. Equilibrium constants are determined and a relation between $R \ln K$ vs. $1/T$ are plotted. The enthalpies of formation, ΔH^0, and the entropies of formation, ΔS^0, are obtained from the slopes and the intercepts with abscissa, respectively, using the unweighted linear least-squares method. The values obtained are presented in Table 3. The Gibbs's free energies of formation, ΔG^0, are also calculated from eq. [5] and the values obtained are collected in Table 3.

$$[5] \quad \Delta G^0 = -RT \ln K$$

On plotting ΔH^0 versus ΔS^0, a linear relationship is obtained (Fig. 2). This behaviour is similar to the ΔS^0 dependence on ΔH^0 known for EDA complexes involving iodine. Therefore, it is evident that the most important factor affecting the magnitude of thermodynamic functions of complexation is common to ΔS^0 and ΔH^0. The increase in ΔH^0 values reflects an enhancement of the donor–acceptor interactions. This is substantiated by the examination of the values of b^2/a^2 values for such EDA complexes, where a and b are the coefficients of the dative and no-bond functions of the ground state function of the molecular electron donor–acceptor complexes (1). To get an estimate of the b^2/a^2 values, one may use the following equation (8)

$$[6] \quad b^2/a^2 = -\Delta H^0/h\bar{\nu}$$

where $\bar{\nu}$ is the wavenumber of the maximum absorption of the perturbed iodine band in cm^{-1}. The results show that the magnitude of the interaction of thiazoles as donors and iodine as acceptor is high.

Solvent effect

The electronic absorption spectra of 4-methylthiazole (**II**)–iodine solvent viz. *n*-heptane, cyclohexane, carbon tetrachloride, benzene are very similar except for the position of the λ_{max} and λ_{iso} of the complex. These spectrophotometric data are employed to calculate the equilibrium data for the 4-methylthiazole–iodine–solvent systems using the above method. The equilibrium characteristics are collected in Table 2.

The experimental results obtained for 4-methylthiazole–iodine complex in different solvents show that the values of the

*Standard deviations ΔH^0, ±2%; ΔS^0, ±5%; ΔG^0, ±3%. (ΔG^0 is calculated at 25°C.)

spectrophotometric properties are markedly affected by the variation of the solvent in which the measurements are carried out. The most striking feature of the data is that the effect of changing the medium on the equilibrium constants runs in the following sequence:

n-heptane > cyclohexane > carbon tetrachloride > benzene

The starting point for discussing the solvent effect on donor–acceptor equilibria should be the data referring to the gas phase reaction. Unfortunately, these data are not available. Therefore, the obtained data should be related to a medium which can be arbitrarily assumed to be a non-solvating one. As usual, a non-polar and non-reacting aliphatic hydrocarbon must be chosen (here *n*-heptane). It is, however, immediately seen that even within the aliphatic hydrocarbons the change in K values is as great as 13%. While the differences in equilibrium constants between subsequent members of this series of solvents are, within experimental error, parallel to the observed K variations for the isoquinoline– and lutidine–iodine systems (20, 21).

The lower value of the equilibrium constant, K, in cyclohexane relative to that in *n*-heptane could be due to the poorer solvation of the EDA complex by cyclohexane because of its rather rigid molecular structure.

It seems rather clear that the decrease in K values, as observed for carbon tetrachloride and benzene, must be ascribed to the solute–solute and solute–solvent competing equilibria. In carbon tetrachloride, which is a weak acceptor, the competing interactions would involve mainly the *n*-donor action of thiazoles towards iodine and the solvent. It would be expected that the specific interactions of thiazoles with carbon tetrachloride are rather weak; nevertheless, the excess of the solvent makes them important in decreasing amine activity. Furthermore, it has been reported that there is a specific interaction between carbon tetrachloride and iodine to form a 1:1 EDA complexes with equilibrium constant as great as 1.54 $dm^3\ mol^{-1}$ (22). Thus, the interactions between the complex and carbon tetrachloride should be of non-specific character and importance of dipole – induced dipole interaction in the solvation of the complex by CCl_4.

The solvation pattern in benzene is much more complicated. Even with the well-known classical iodine–benzene interactions, the quantitative interpretation of the measurements is far from being unequivocal. Moreover, one must take into account the interactions between the donor and benzene which, in contrast to the situation in CCl_4, do not seem to involve the n-donor of thiazoles. If this really is the case, the solvation of thiazole nucleus with benzene might be retained, at least partly, in the complex.

Received December 13, 1985[1]

MICHELINE CHARPENTIER, JACQUES FOSSEY, THOMAS T. TIDWELL, and SAUL WOLFE. Can. J. Chem. **65**, 473 (1987).

Eleven stationary points on the singlet $C_2H_2F_3^+$ potential energy surface have been calculated using the 3-21G basis set, and characterized as minima (four structures) or first-order saddle points (seven structures) by vibrational analysis. To check the reliability of this basis set, three of the structures have also been optimized at the 6-31G* level; although the geometries change somewhat, the relative energies and nature (maxima, minima) of the structures remain the same. For $CF_3CH_2^+$ the minimum energy structure has one C—F bond coplanar with the vacant *p*-atomic orbital at the cationic centre. The structure is 16.4 kcal/mol less stable than the lowest energy conformation of $FCH_2CF_2^+$, and the barrier for the 1,2 fluorine migration which connects the two structures is low. The cation F_2CHCHF^+ has a conformation that is a minimum on the potential energy surface that is 16.9 kcal/mol higher in energy than $FCH_2CF_2^+$; the two structures are separated by a barrier for 1,2 hydrogen migration of 23.5 kcal/mol. The electronic effects in the various structures have been studied using a quantitative PMO analysis of the interactions between the two carbon fragments of the ions. For $CF_3CH_2^+$ the net effect of the fluorine is highly destabilizing; the principal stabilizing interactions between CF_3^+ and CH_2 consist of π donation from CF_3^+ to CH_2 and homoconjugation of a fluorine lone pair with the cationic centre. No net stabilization attributable to fluorine bridging could be found.

MICHELINE CHARPENTIER, JACQUES FOSSEY, THOMAS T. TIDWELL et SAUL WOLFE. Can. J. Chem. **65**, 473 (1987).

Utilisant un ensemble 3-21G, on a calculé la surface d'énergie potentielle de onze points stationaires du singulet $C_2H_2F_3^+$ et, à l'aide d'une analyse vibrationnelle, on a caractérisé quatre structures comme minima et sept structures comme des maxima du premier ordre. Afin de vérifier la fiabilité de cet ensemble, on a aussi optimisé trois structures au niveau 6-31G*; même si les géométries changent un peu, les énergies relatives et la nature (maxima ou minima) des structures demeurent les mêmes. Pour l'ion $CF_3CH_2^+$, la structure présentant un minimum d'énergie possède une liaison C—F qui est coplanaire avec l'orbitale atomique *p* vacante du centre cationique. La structure est 16,4 kcal/mol moins stable que la conformation d'énergie minimale de l'ion $FCH_3CF_2^+$ et la barrière à la migration 1,2 du fluor qui relie les deux structures est faible. Le cation F_2CHCHF^+ possède une conformation qui est un minimum sur la surface d'énergie potentielle et qui est 16,9 kcal/mol plus riche en énergie que celle du $FCH_2CF_2^+$; les deux structures sont séparées par une barrière de 23,5 kcal/mol pour la migration 1,2 de l'hydrogène. On a étudié les effets électroniques sur les diverses structures en faisant appel à une analyse quantitative PMO des interactions entre les deux sections carbonées des ions. Pour le $CF_3CH_2^+$ l'effet de fluor est fort déstabilisant; les interactions stabilisantes principales entre le CF_3^+ et le CH_2 sont une donation π du CF_3^+ au CH_2 et une homoconjugaison de la paire libre du fluor avec le centre cationique. On n'a pas pu mettre en évidence de stabilisation nette attribuable à un pontage du fluor.

[Traduit par la revue]

Despite the strong σ-electron withdrawing effect of fluorine, CF_3^+ is *stabilized* relative to CH_3^+: the reaction $CH_3^+ + CHF_3 \rightarrow CF_3^+ + CH_4$ is exothermic by 13.2 kcal/mol (1). The infrared spectrum of matrix isolated CF_3^+ exhibits a high ν_3 fundamental and shows that the stabilization of this cation is associated with n_π–p_π bonding between fluorine lone pairs and the carbocationic centre (2).

The powerful *destabilizing* (3) effect of a CF_3 group upon an *adjacent* (4, 5) or nearby carbocationic centre (4*i*, 6) has been amply demonstrated experimentally by kinetic (4, 6), and spectroscopic (5) studies, and has also been applied to organic synthesis (7). Even in the gas phase the reaction $CF_3CH_2^+ + CH_4 \rightarrow CF_3CH_3 + CH_3^+$ is exothermic by 13 kcal/mol (3*a*).

The interaction of a CF_3 group with an adjacent carbocationic center has also been studied theoretically (8), but the conclusions of such calculations seem superficially to disagree with those based on experimental studies. For example, in solution the CF_3 group is found experimentally to be uniformly deactivating relative to hydrogen in the generation of an adjacent carbocation center, usually by very large factors (10^5 to 10^7) (4). A second electron-withdrawing substituent has a greatly diminished effect: $k(H)/k(CF_3) = 54$ for formation of the cations $PhCHCF_3^+$ and $PhC(CF_3)_2^+$ (9), respectively. There is no evidence for fluorine migration, and despite much effort (10), there is no definitive example of the fluorine bridging depicted in reaction [1] in solution.

[1] 
1 2

However, in the gas phase, on the basis of the isotope distribution in the fragment ions using ^2H or ^{13}C labeled precursors, a bridged ion $C_2H_4F^+$ appears to be formed (11) in the process shown in reaction [2].

[2] $p\text{-}CH_3C_6H_4OCH_2CH_2F \xrightarrow[-p\text{-}CH_3H_6H_4O]{-e^-}$ 
The theoretical studies suggest that there is both n-electron and π-electron donation by fluorine to an adjacent carbocation.

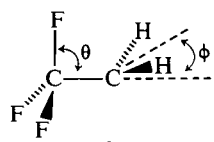
[a]Geometries in parentheses refer to 6-31G*//6-31G* calculations, others are 3-21G//3-21G.

In a calculation on $CF_3CH_2^+$ (**3**), which employed STO-3G calculations to optimize the geometries, and a single point 4-31G calculation to determine the energy, conformation **3***a* ($\theta = 101°$; $\phi = 4°$) was preferred (8*a*).



3*a*

It was argued (8*a*) that this "cation is distorted in exactly the same fashion as the ethyl cation", shows "abnormally low destabilization", and there is "no hyperconjugative stabilization by the trifluoromethyl group". Nevertheless, **3***a* shows some kind of attractive interaction between one of the fluorines and the methylene hydrogens. The origin of this effect has not been discussed.

In another study it was concluded that CF_3 could become a π-donor "in systems with relatively extreme π-electron deficiency" (8*c*).

Theoretical studies of the $C_2H_4F^+$ cation are extensive (12), and are relevant to the problem of $CF_3CH_2^+$. The best calculations (12*b*) find the bridged structure **2** to be more stable by 7.1 kcal/mol. Bridging of $C_2H_4F^+$ is also predicted by MINDO/3 (12*c*), but to an "exaggerated" (12*a*) extent.

The structures and energies of the isomeric ions $CH_3CF_2^+$, CH_2FCHF^+, and $CHF_2CH_2^+$ have been calculated recently, and used to facilitate the interpretation of the experimental photoionization of CH_3CHF_2 (12*d*); bridged structures were explicitly excluded from this latter study.

The theoretical calculations and gas phase experimental studies suggest that stabilization of an adjacent carbocation center by fluorine bridging or π-donation can be significant. This contrasts to the experimental studies in solution.

The purpose of the present work is to examine, in a more comprehensive manner, the cation **3**, and its putative rearrangement products $CH_2FCF_2^+$ (**4**) and CHF_2CHF^+ (**5**). We intend eventually to extend the study to more highly fluorinated systems. Such studies will provide a theoretical framework for ongoing experimental examinations of large polyfluorinated systems.

Method

Ab-initio molecular orbital calculations were carried out with the GAUSSIAN 80 (13) and MONSTERGAUSS (14) programs. Stationary points in the singlet $C_2H_2F_3^+$ potential energy surface were located at the Hartree–Fock (HF) level by gradient optimization techniques (15) using the 3-21G basis set (16). One point calculations were then performed on these geometries at the 6-31G* level (17) (6-31G*//3-21G). The 3-21G geometries, total energies and relative energies are displayed in Tables 1 to 3. Structures are classified as equilibrium structures or as transition structures on the basis of a vibrational analysis carried out at the HF/3-21G level.

Quantitative PMO analyses (18) were performed at the STO-3G level on standard geometries, to provide insight into the origins of the conformational preferences and the nature of the molecular distortions. In this procedure the orbitals of a molecular system A–B, which contains the functional groups A and B, are rewritten as a linear combination of the orbitals of A and B. This allows the stabilizing and destabilizing orbital interactions between A and B to be calculated explicitly. As has been discussed extensively (18), the molecular geometry relaxes so as to minimize destabilization and maximize stabilization. The standard geometries employed for the PMO analysis were, in all cases, C—C = 1.53 Å, C—H = 1.08 Å, C(+)—F = 1.26 Å, C—F = 1.35 Å, tetrahedral angle = 109.4712, trigonal angle 120°. Table 4 summarizes the total energy differences computed in this manner.

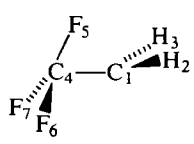
Discussion

As shown in reaction [3], **3** and **4** are related by a 1,2 F-migration; **4** and **5** are related by a 1,2 H-migration. Two transition structures connect these cations, one for the process 3 ⇄ 4 and the other for the process 4 ⇄ 5. All of these structures have been calculated.

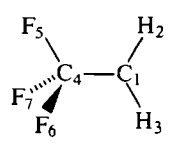
[3] $CF_3CH_2^+ \rightarrow {}^+CF_2CH_2F \rightarrow CF_2HCHF^+$
3 **4** **5**

$CF_3CH_2^+$

For the ion **3**, only the bisected conformation **3***a*, which has one C—F bond coplanar with the *p*-atomic orbital at the carbocation center, is an energy minimum. A 90° rotation about the C—C bond affords a transition structure **3***b*, in which one C—F bond is perpendicular to the *p*-atomic orbital at the carbocation center. Both these structures have been optimized fully without constraints, and are true stationary points on the 3-21G hypersurface.



3*a*



3*b*

Structure **3***a* is 1.11 kcal/mol more stable than **3***b* at the 3-21G//3-21G level. However, at the 6-31G*//3-21G level, **3***a* is found to be 1.53 kcal/mol less stable than **3***b*. Such a reversal of stabilities normally reflects a difference in geometries at the two basis set levels. Since fluorine is known to be difficult to describe adequately with a small Gaussian basis set (12*b*), it was considered desirable to extend the study of $CF_3CH_2^+$ to full optimization of the structures at the 6-31G* level (6.31G*//6-31G*). These results are included in Table 1. The C_1—C_4—F_5 angle of **3***a* increases from 83.3 to 99.2°, but **3***a* remains a minimum, more stable than **3***b* by only 0.40 kcal/mol, and **3***b* remains a first-order saddle point.

The quantitative PMO analysis of $CF_3CH_2^+$ focuses on interactions between CF_3 and CH_2 in the standard geometries **3***a*$_s$ and **3***b*$_s$. The fragment orbitals (FO's) of CF_3 are treated as linear combinations of C—F bond orbitals (i.e., σC—F, σ*C—F, and three n doublets on each F atom). In C_{3v} symmetry these linear combinations lead to three kinds of orbitals, which are shown schematically in Fig. 1.

The FO's of CH_2^+ are σCH_2, πCH_2, *p*CH_2, π*CH_2, and σ*CH_2. In Table 5, the total PMO energetic effect and the sum over all CF_3 FO's of the energetic effect associated with each CH_2 FO are given.

	$\mathbf{3}a_{st}$	$\mathbf{3}b_{st}$	−6.82
$FCH_2CF_2^+$	$\mathbf{4}a_s$	$\mathbf{4}d_s$	3.04
F_2CHCHF^+	$\mathbf{5}a_s$	$\mathbf{5}g_s$	−1.04
	$\mathbf{5}d_s$	$\mathbf{5}a_s$	−1.60
$FCH_2CH_2^+$	$\mathbf{9}a_s$	$\mathbf{9}b_s$	8.40
$F_2CHCH_2^+$	$\mathbf{10}a_s$	$\mathbf{10}b_s$	−3.85

The same PMO effect is found for $\mathbf{3}a_s$ and $\mathbf{3}b_s$. This includes the destabilizing interaction associated with the πCH_2 FO's, and the stabilizing interaction associated with the *p* orbital at the carbocation center. The individual stabilizing interactions associated with the *p*-CH_2 FO's are examined in more detail in Table 6. Stabilization is seen to arise mainly from two specific interactions of the *p*-CH_2 FO's, viz., (*i*) interaction with the πCF_3 FO's of rotamer $\mathbf{3}a_s$, or with the $\pi' CF_3$ FO's of rotamer $\mathbf{3}b_s$, corresponding to the π-donor effect of the CF_3 fragment; (*ii*) interaction with the πnF_3 FO's of the rotamer $\mathbf{3}a_s$, or with the $\pi' nF_3$ FO's of rotamer $\mathbf{3}b_s$, corresponding to the homoconjugative interaction between the fluorine lone pairs and the cationic center. The π-donor and homoconjugative effects are almost the same (−5.22 and −5.32 kcal/mol, respectively).

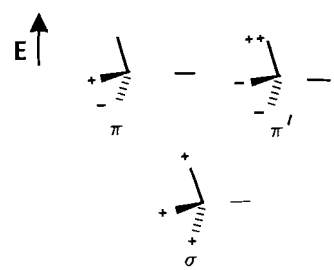

FIG. 1. The σ- and π-type orbitals of a CF_3 fragment.

The decrease in the C_1—C_4—F_5 angle seen in **3***a* parallels the observation made previously at the STO-3G level (6*a*), as does the slight bending of C_1—H_2 and C_1—H_3 towards F_5. These effects are more pronounced at the 3-21G level (83.3°) than at 6-31G* (99.2°) or STO-3G (101°).

The PMO analysis provides insights into the origins of these deformations. Structures $\mathbf{3}a_{st}$ and $\mathbf{3}b_{st}$ refer to standard geometries in which the CF_3 moiety has been tilted clockwise by 10° in the symmetry plane of the molecule (Fig. 2). This deforma-

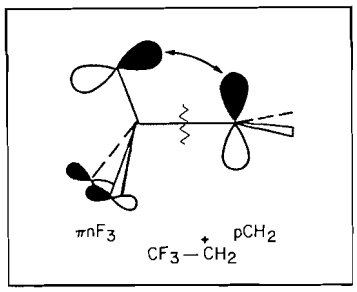

FIG. 2. An orbital interaction illustrating homoconjugation between πnF_3 and pCH$_2$ in $CF_3CH_2^+$.

tion is net stabilizing for $3a_s$ but net destabilizing for $3b_s$. The reason for this is seen in Fig. 2: $3a_{st}$ is stabilized by the interaction between the p orbital at the carbocation center and the π-combination of lone pairs on the fluorine atoms (compare interaction πnF_3–pCH$_2$ in $3a_s$ and $3a_{st}$ in Table 6).

According to the PMO formalism, the magnitude of the stabilization associated with the interaction between an unoccupied orbital (e.g., the pCH$_2$ FO) and a doubly occupied orbital (e.g., the πnF_3 FO) (see Fig. 3) is given by eq. [4], in which i = HOMO, j = LUMO, S_{ij} = overlap integral, and H_{ij} = matrix element. Equation [4] states that ΔE(PMO) is the result of three effects: (*i*) S_{ij} (overlap control); (*ii*) H_{ij} (matrix element control); (*iii*) $\Delta\epsilon = \epsilon_i = \epsilon_j$ (energy gap control).

$$[4] \quad \Delta E^{ij}_{PMO} = \frac{2S^2_{ij}(\epsilon_i - H_{ij}/S_{ij})^2}{\epsilon_i - \epsilon_j}$$

The distortion $3a_s \rightarrow 3a_{st}$ leads to net stabilization because of the overlap effect S_{ij} denoted by the double-headed arrow of Fig. 2. The corresponding deformation is unfavorable in $3b_s \rightarrow 3b_{st}$ because of the interaction between the occupied CH_2 and CF_3 fragments (cf. the interactions associated with πCH_2 in $3b_s$ and $3b_{st}$, Table 5) and the decreased stabilization associated with the pCH$_2$ FO. This analysis indicates that the deformation of the C_1—C_4—F_5 angle in $3a$ originates from homoconjugation with the lone pair on F_5.

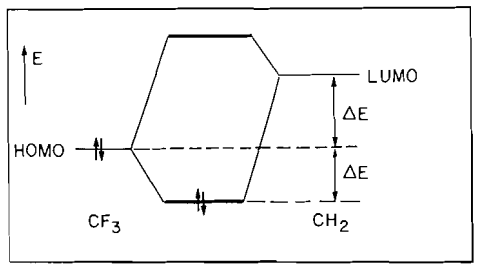

FIG. 3. The orbital interaction diagram appropriate to eq. [4].

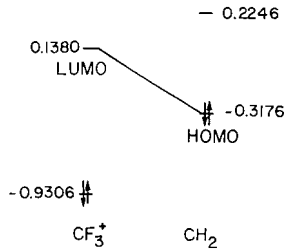

FIG. 4. Orbital interaction diagram for the reaction of CF_3^+ with CH_2 (STO-3G calculations).

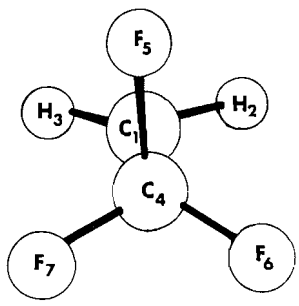
A quite different interpretation of the geometry of $3a$ can be suggested, if this structure is regarded as a complex between CF_3^+ and the carbene CH_2. As seen in the Newman projection **6**, the methylene group lies above the F_5—C_4 perpendicular,



6

and is tilted towards F_5. This implies that the most favorable geometry for a cation–carbene interaction is **7**. The interaction would lead to charge transfer from the HOMO of the carbene to the LUMO of the cation or, alternatively, from the HOMO of the cation to the LUMO of the carbene. In either case, charge transfer into antibonding C—F regions or charge transfer from bonding C—F regions will lead to lengthening of C—F bonds.

These ideas were explored by computations on CF_3^+ and CH_2 at the 3-21G and STO-3G levels. At the 3-21G level the

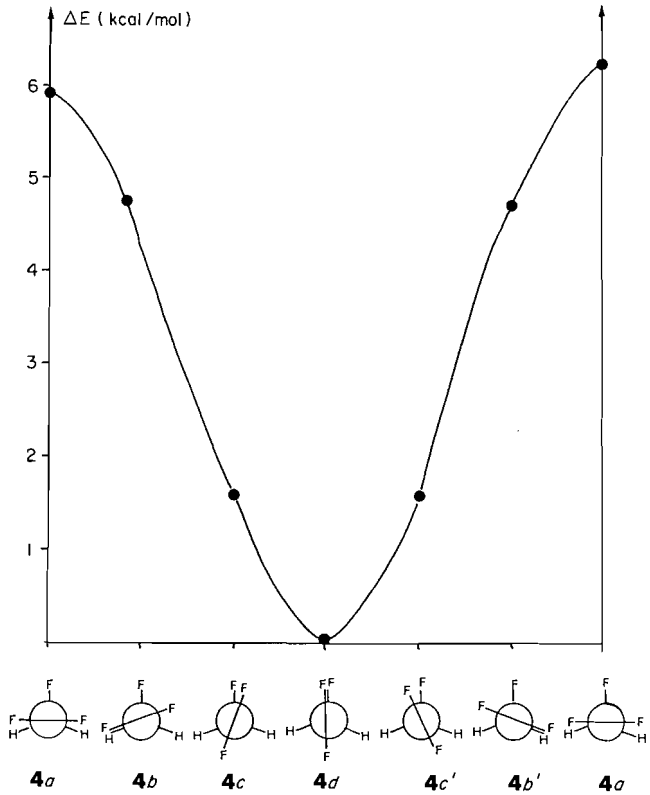

FIG. 5. Rotation about the C—C bond in $FCH_2CF_2^+$ (3-21G calculations).

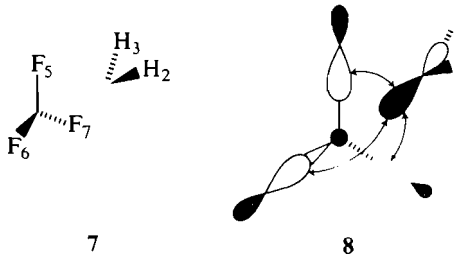
C—F bond length in CF_3^+ is 1.2507 Å. Comparison of this value with the C—F bond lengths in **3***a* reveals that the putative interaction of CF_3^+ with CH_2 lengthens all three C—F bonds, and the effect is greatest on C—F_5. The STO-3G interaction diagram is shown in Fig. 4, from which it is clear that the dominant interaction would comprise charge transfer from the HOMO of CH_2 to an unoccupied orbital of CF_3^+. This interaction is depicted in **8**; the acceptor orbital is antibonding between C and F, and the out-of-phase secondary overlap (depicted by double-headed arrows) would cause the CH_2 to move towards F_5, as in structure **7**. In summary, the CF_3 group in $CF_3CH_2^+$ is strongly destabilizing, and the conformation **3***a* which maximizes the CF_3 interactions with CH_2 is only 0.40 kcal/mol more stable than **3***b* at the 6-31G*//6-31G level.

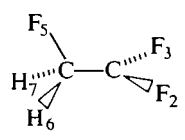


7

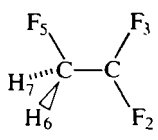
8

$FCH_2CF_2^+$

For the ion $FCH_2CF_2^+$ (**4**), four limiting conformations, **4***a*–**4***d*, were examined. To describe rotation about the C—C bond these were optimized in a subspace in which the C—C rotational angle was fixed (Fig. 5). Only **4***d* is an energy minimum, and **4***a* is an energy maximum. These stationary points were optimized fully without restriction with the 3-21G basis set, and their geometrical parameters and energies are given in Table 2. The barrier height is 5.96 kcal/mol at the 3-21G//3-21G level and 5.66 kcal/mol at the 6-31G*//3-21G level.



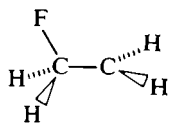
4a



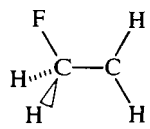
4d

In **4***a*, which has C_4—F_5 eclipsed with the vacant *p* orbital on C_1, the F_5—C_4—C_1 angle is small, as in **3***a* (**3***a*, 83.3°, **4***a*, 100.3°), but in this case no stabilization is associated with the decreased angle. That the relative stability of **4***d* is the result of hyperconjugation by H_6 and H_7 was demonstrated by a series of quantitative PMO analyses on **4**, $FCH_2CH_2^+$ (**9**) and $F_2CHCH_2^+$ (**10**). For **4** this analysis focuses on interactions between CH_2F and CF_2, and these are summarized in Table 7, for the standard structures $\mathbf{4}a_s$ and $\mathbf{4}d_s$. The FO's termed p_1CF_2, p_2CF_2, and p_3CF_2 are the result of a linear combination of the vacant *p* orbital on C_1 with the symmetry adapted *p* lone pair on the F atoms (Fig. 6).

The PMO analysis suggests that the difference in stability between $\mathbf{4}a_s$ and $\mathbf{4}d_s$ originates in the interactions associated with p_3CF_2, the lowest vacant CF_2 FO. To check this point, a PMO analysis was performed on $FCH_2CH_2^+$ (**9**) in conformations $\mathbf{9}a_s$ and $\mathbf{9}b_s$. This analysis is included in Table 8. Reference to Table 4 demonstrates that the rotational behaviour of **9** parallels that of **4**, since $\mathbf{9}b_s$ is more stable than $\mathbf{9}a_s$ (19), but the barrier is larger in **9**. According to the PMO analysis the larger barrier in **9** is associated with the interactions of the vacant pCH_2 FO.



$\mathbf{9}a_s$



$\mathbf{9}b_s$

The vacant FO's p_3CF_2 and pCH_2 of **4** and **9**, respectively, interact with all occupied orbitals of the FCH_2 fragment. These interactions are given in Table 8, and the relevant FCH_2 FO's are shown in Fig. 7. The *s*, *p*, and σ FO's are symmetric, and the π FO's are antisymmetric with respect to the plane of the molecule. The conformational preferences in **4** and **9** result from favourable interactions between the p_3CF_2 FO of **4** and the pCH_2 of **9** with π_1FCH_2 and π_2FCH_2. The interaction with π_1FCH_2 corresponds to hyperconjugation with the two C—H bonds, while the interaction with π_2FCH_2 corresponds to homoconjugation with the symmetry-adapted lone pair on the F atom of FCH_2. These interactions are more favourable in rotamers $\mathbf{4}d_s$ and $\mathbf{9}b_s$ than the homoconjugation with the lone pair (*p*F) and the hyperconjugation with the C—F bond (σC—F) in rotamers $\mathbf{4}a_s$ and $\mathbf{9}a_s$. The effects are dominated by overlap between fragment FO's (S_{ij} in eq. [4]).

We may conclude that hyperconjugation with C—H bonds controls the conformational preferences of cations adjacent to FCH_2. In the case of the cation **10**, $F_2CHCH_2^+$, conformation $\mathbf{10}a_s$, in which C—H bond hyperconjugation is operative, is more stable than conformation $\mathbf{10}b_s$ (Table 4).

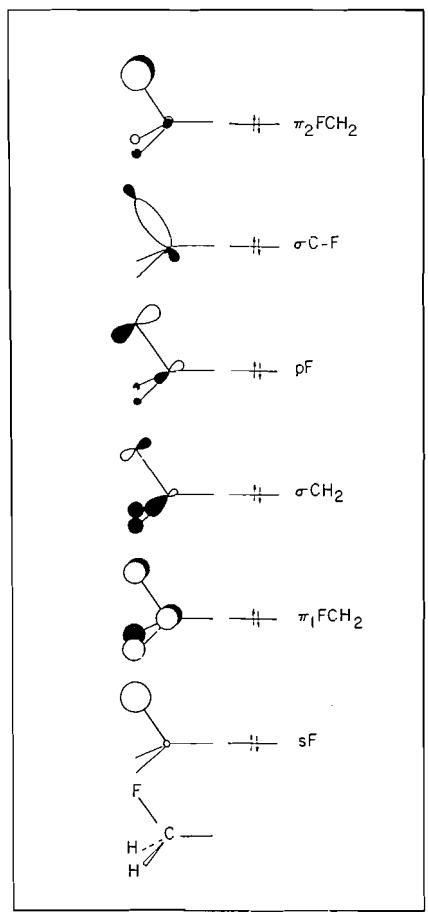

FIG. 7. The fragment orbitals of FCH_2 (see Table 8).

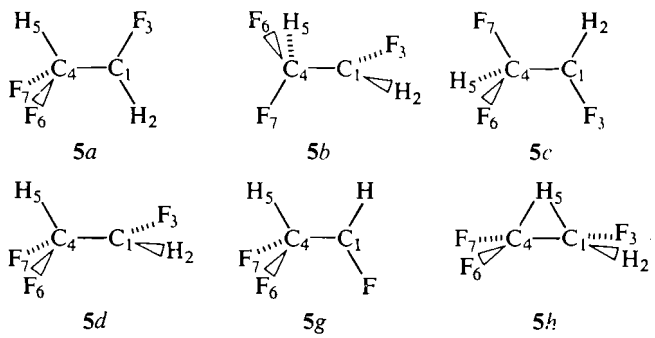
F_2CHCHF^+

For the ion F_2CHCHF^+ (**5**), the seven conformations **5***a*–**5***g* were optimized in a subspace in which the rotational angle about the C—C bond was fixed (Fig. 8).

Conformations **5***a*–**5***d* are close in energy, and **5***e*–**5***g* are progressively less stable.



On the 3-21G//3-21G hypersurface, **5***b* and **5***d* are minima, and rotamers **5***a*, **5***e*, and **5***g* are rotational transition structures. Conformation **5***d* is the global minimum. The 6-31G*//3-21G energy differences are similar (Table 3).

As in **3***a* and **4***a*, conformations of **5** having a C—F bond eclipsed with the vacant *p* orbital exhibit a small $C_1—C_4—F$ angle (**5***b*, 99.1°; **5***f*, 98.8°). However, no stabilization is reflected in these structures in comparison to **5***d*, in which the C—H bond is eclipsed with the *p* orbital. This latter structure has a normal $C_1—C_4—H$ angle (109.5°).

Interconversion of 3–5

The chemical pathway for interconversion of the $C_2H_2F_3^+$ isomers **3**–**5** is shown in Fig. 9. The most stable ion, by a considerable margin, is **4**.

The transformation of **3***a* into **4***a* is a 1,2 F-migration. At the 3-21G//3-21G level, the transition structure for this pro-

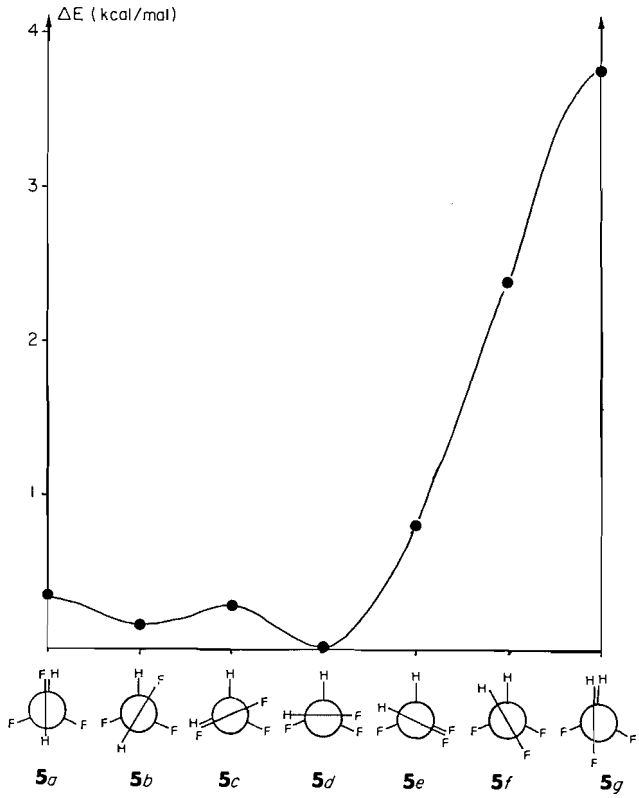

FIG. 8. Rotation about the C—C bond in F_2CHCHF^+.

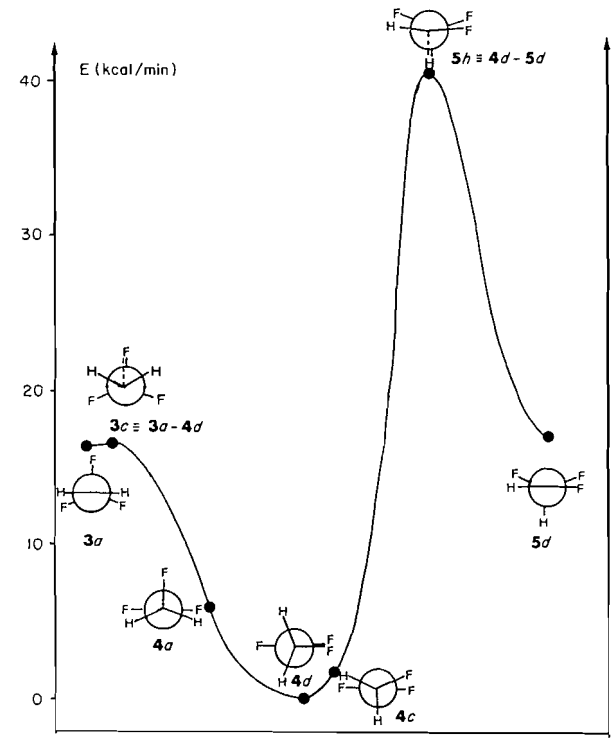

FIG. 9. Energy diagram for interconversion of $C_2H_2F_3^+$ isomers.

cess, **3***c*, is only 0.05 kcal/mol above **3***a* and the geometrical parameters of the two structures are very similar (Table 1). Moreover, **3***c* is more stable than the rotational transition state **3***b*. At the 6.31G*//3-21G level, the barrier for the rearrangement $CF_3CH_2^+ \rightarrow FCH_2CF_2^+$ is 2.79 kcal/mol. This finding is consistent with calculations on $C_2H_4F^+$, in which the bridged structure becomes relatively less stable with larger basis sets (20, 21), and with the absence of experimental evidence for fluorine migration in any well characterized system. With full optimization at 6-31G* (Table 1), **3***c* is 3.22 kcal/mol less stable than **3***a* and 2.82 kcal/mol less stable than **3***b*.

The ion **5***d* is transformed into the significantly more stable ion **4***c* by a 1,2 H-migration. At the 3-21G//3-21G level, the transition state for this process, **5***h*, is calculated to lie 23.51 kcal/mol above **5***d* (Table 3). At the 6-31G*//3-21G level, this barrier is slightly smaller (18.35 kcal/mol). The structure of **5***h* (C—C = 1.379 Å, versus C—C = 1.315 Å in ethylene at 3-21G//3-21G) resembles that of a weak $H^+\cdots CH_2{=}CHF$ complex, in contrast to **3***c* (C—C = 1.460 Å). Substitution of fluorine for hydrogen raises the barrier for 1,2 H-transfer: in $C_2H_5^+$ the bridged structure is 7.71 kcal/mol higher than the classical structure at the 3.21G//3-21G level, and is more stable than the classical structure at 6-31G**//6-31G* (20).

In conclusion the stability of $CH_2FCF_2^+$ (**4**) relative to $CF_3CH_2^+$ (**3**) and CHF_2CFH^+ (**5**) is evidently due to the stabilization associated with the CF_2^+ moiety (1, 2), and the presence of only one β-fluorine. There is strong net destabilization in **3**, but the similar energies of **3** and **5** provide evidence of some stabilizing interactions in **3**, since **5***d* benefits from both n_π–p_π donation to the cationic centre and hyperconjugative stabilization by the β-C—H bonds, but is no more stable than **3**. There is no strong conformational preference in **3**. The CF_3 group stabilizes **3** in two ways: by π-donation (hyperconjugation) and *n*-donation (homoconjugation).

The conformational preference in $FCH_2CF_2^+$ (**4**) is caused by hyperconjugation with the β-C—H bonds. The same effect explains the conformational preference in $FCH_2CH_2^+$. Hyperconjugation with a C—H bond leads to greater stabilization of a positive charge on carbon than hyperconjugation with a C—F bond combined with homoconjugation with a fluorine lone pair. In F_2CHCHF^+ the conformational preference is best explained by repulsion between the F atoms.

The absence of any reports of a solution phase fluorine migration despite the low barrier for **3***b* → **4***d* interconversion is remarkable. Even $CF_3CH_2N_2^+$ in FSO_3H gives only $CF_3CH_2O_3SF$ (22). Evidently in this system the incipient $CF_3CH_2^+$ species is so unstable that solvent capture is favoured over fluorine migration.

Preparation of 1-thio and 1-amino substituted 1,3-dihydrobenzo[*c*]thiophene 2,2-dioxides

ZAFAR KHAN AND TONY DURST

Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1S 5B6

Received April 9, 1986

ZAFAR KHAN and TONY DURST. Can. J. Chem. **65**, 482 (1987).

The 1-hydroxy substituent in 1-hydroxy-1,3-dihydrobenzo[*c*]thiophene 2,2-dioxides is readily replaced by alkoxy, alkylthio, and amino groups. These compounds serve as precursors of alkoxy, alkylthio, and amino substituted *o*-quinodimethanes. Cycloaddition reactions between a series of 1,4-disubstituted *o*-quinodimethanes bearing a phenyl group and one of the above heteroatoms, and typical dienophiles such as dimethyl fumarate and methyl crotonate were carried out. The phenyl group controlled both the regiochemistry and stereochemistry of these cycloaddition reactions, with the major products being *trans*-1-phenyl-2-carbomethoxytetrahydronaphthalenes. The amino substituted *o*-quinodimethanes were trapped only by dimethyl fumarate.

ZAFAR KHAN et TONY DURST. Can. J. Chem. **65**, 482 (1987).

Le substituant hydroxy-1 des dioxydes-2,2 de l'hydroxy-1 dihydro-1,3 benzo[*c*]thiophènes peut facilement être remplacé par des groupements alkoxy, alkylthio et amino. Ces composés servent de précurseurs pour les *o*-quinodiméthanes substitués par des groupements alkoxy, alkylthio et amino. On a effectué des réactions de cycloadditions entre, d'une part, une série de *o*-quinodiméthanes disubstitués en positions-1,4 par un groupement méthyle et l'un des hétéroatomes mentionnés ci-dessus et, d'autre part, des diénophiles typiques comme le fumarate de diméthyle et le crotonate de méthyle. Le groupement phényle contrôle tant la régiochimie que la stéréochimie de ces réactions de cycloadditions; les produits principaux sont les phényl-1 carbométhoxy-2 tétrahydronaphtalènes-*trans*. Les *o*-quinodiméthanes substitués par un groupement amino n'ont pu être piégés que par le fumarate de diméthyle.

[Traduit par la revue]

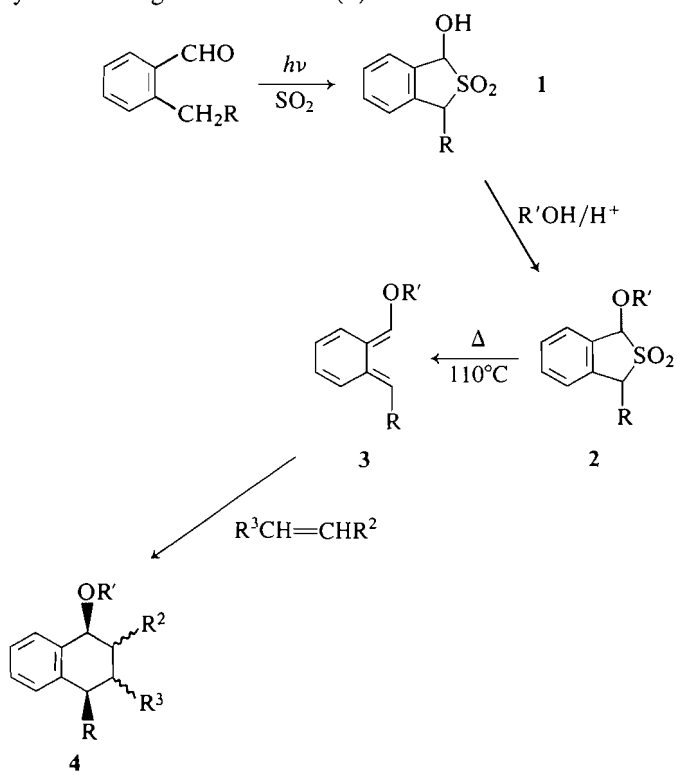
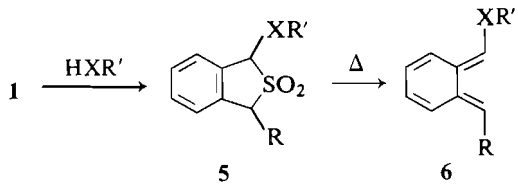
We have recently reported the preparation of 1-hydroxy-1,3-dihydrobenzo[*c*]thiophene 2,2-dioxides, **1**, via photolysis of *ortho*-substituted benzaldehydes in the presence of SO_2 (1). The hydroxyl group in **1** could readily be exchanged with a variety of alcohols leading to the formation of the alkoxy derivatives **2**. The latter have been used to generate 1-alkoxy substituted *o*-quinodimethanes **3** (2, 3), via SO_2 extrusion, and are trapped by typical dienophiles to give the tetrahydronaphthalenes **4**. Such compounds have considerable potential in the synthesis of lignan derivatives (4).



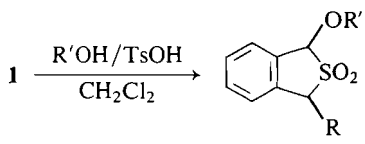
We would now like to report the preparation of derivatives of **1** in which the oxygen substituent at C-1 is replaced by other heteroatoms such as sulfur and nitrogen, e.g. **5**; the thermal extrusion of SO_2 from these derivatives to yield a new set of *ortho*-quinodimethanes, **6**; and a comparison of some cycloadditions of **6** with those of the alkoxy derivatives **3**.



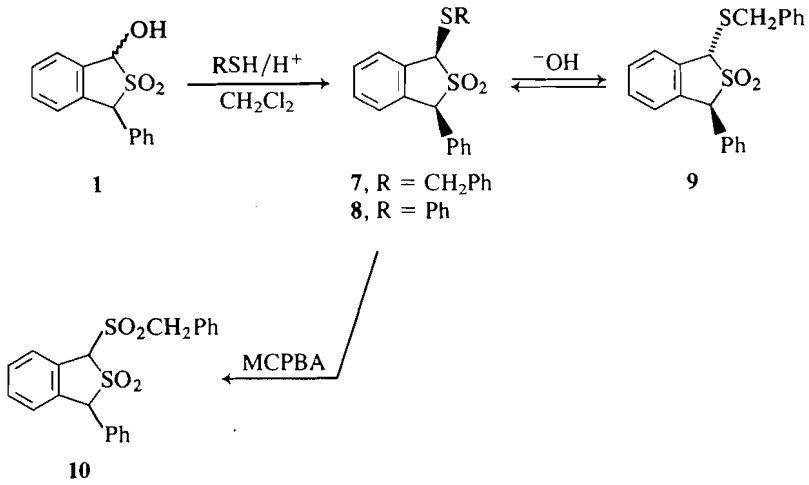
XR' = SPh, SCH_2Ph, SO_2CH_2Ph, NHPh, NPh_2, N⬭O; R = H, Ph

Preparation of 5

We had shown earlier that the hydroxyl group of **1** was readily exchanged for an alkoxy group simply by refluxing **1** in CH_2Cl_2 solution in the presence of an alcohol and a catalytic amount of TsOH (1).

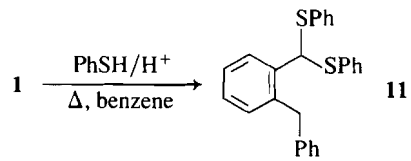


Essentially the same conditions sufficed for the preparation of the sulfides **7** and **8**. Thus, reaction of **1** (R = Ph) with an equimolar amount of benzyl of phenyl mercaptan and a catalytic amount of TsOH in CH_2Cl_2, either at reflux for several hours or room temperature for several days, afforded the sulfides **7** and **8** in about 80% crude yield (61 and 46% recrystallized yield, respectively). Under these conditions only one isomer, assigned the 1,3-*cis* configuration, was obtained. When **7***a* was exposed to 20% NaOH, isomerization to an approximately 1:1 mixture of *cis* (**7**) and *trans* (**9**) isomers occurs.

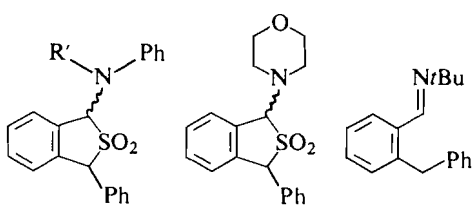


1 7, R = CH_2Ph; 8, R = Ph 9 10

The structures of **7** and **8** follow from their analytical data, spectral properties, and their reaction with dimethyl fumarate. Thus **7**, mp 124–125°C, showed two singlets at δ 5.40 and 5.18 assigned to H-1 and H-3 respectively and an AB quartet (δ_A 3.90, δ_B 4.20, J_{AB} = 13.2 Hz), in addition to 14 aromatic hydrogens. Oxidation of **7** afforded the disulfone **10** in which the proton, H-1, α to both sulfone groups, was deshielded by 0.5 ppm relative to H-1 in **7** while H-3 remained essentially unaffected. The *trans* isomer **9** was separated from the mixture of **7** and **9** by preparative tlc. Its proton nmr had peaks at δ 5.8 (H-1), 5.02 (H-3), 4.33 (d, J = 13.2 Hz), 4.01 (d, J = 13.2 Hz) in addition to a multiplet of 14 aromatic hydrogens at 7.0–7.5 ppm. The benzylic hydrogens of **8**, mp 127–128°C, were found at 5.56 and 5.44 ppm. When the reaction of **1** with PhSH and TsOH was carried out in refluxing benzene the major product was orthobenzylbenzaldehyde diphenylthioacetal **11**.

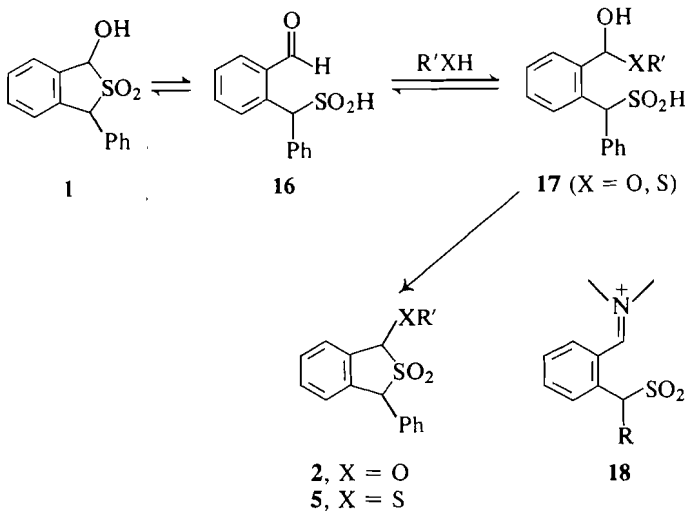


The α-aminosulfones **12–14** were formed when a solution of **1** was allowed to react with the appropriate primary or secondary amine in CH_2Cl_2 at room temperature. These aminosulfones were obtained as mixtures of isomers that were not separable on column chromatography. The isomer ratios were generally near 1:1 as determined from the integration of the pairs of singlets (H-1 and H-3) due to each isomer, appearing in the 5–6 ppm range. (See experimental section for further details.) In several cases when a primary amine was employed, e.g. *tert*-butyl amine, or when the reaction mixture was heated, desulfonylated imines, e.g. **15**, were obtained as the sole isolable product.



12, R′ = H; **14**, R′ = Ph **13** **15**

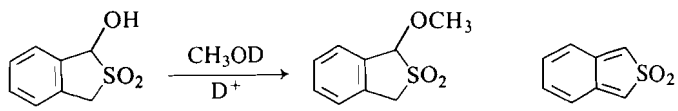
A plausible mechanism for the exchange reaction is shown below. Cyclic α-hydroxysulfones such as **1** can also exist in the open chain aldehyde – sulfinic acid tautomeric form, e.g., **16** (1). The latter compound is convertible into **2** or **5** (X = S) via acid-catalyzed hemiacetal or hemithiocetal formation giving **17**, followed by cyclization with concomitant loss of H_2O. The iminium ion **18** is a plausible intermediate in the formation of the α-aminosulfones.



1 **16** **17** (X = O, S)

2, X = O; **5**, X = S **18**

The possible intermediacy of the benzothiophene sulfone **19** in the formation of **2** (X = O, R = CH_3) from **1** was eliminated by showing that the conversion, when carried out in CH_3OD, did not result in any deuterium incorporation at C-3.



19

Cycloaddition reactions of 5

Each of the new sulfones **7**, **8**, **12–14** failed to show a molecular ion in its electron impact ms; in all cases the base peak occurred at $M^+ - 64$ suggesting a facile loss of SO_2. The exception to this behavior was the disulfone **10**, which showed a strong molecular ion peak at m/e 398 (25% of the base peak); this was reflected by the thermal stability of **10** (see below).

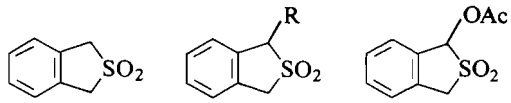
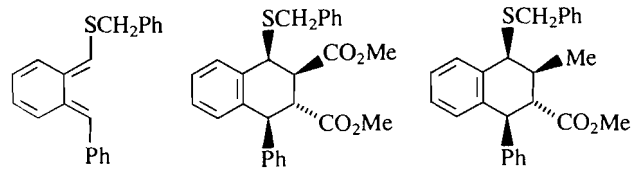
The ease of thermal extrusion from the various α-substituted 1,3-dihydrobenzo[*b*]thiophene 2,2-dioxides varies greatly with the nature of the substituent. Heteroatom substituents that can interact conjugatively with the newly generated 1,3-diene system of the *ortho*-quinodimethane lower significantly the temperature required for the extrusion reaction, when compared to the parent system **20** (5), or typical alkyl (6) or aryl (7) derivatives **21**, which are usually thermolyzed above 180°C.

Qualitatively, the amino substituted sulfones extrude SO_2 at convenient rates in refluxing $CHCl_3$ and even in refluxing CH_2Cl_2, while the thio and alkoxy substituted derivatives require 80–110°C (boiling cyclohexane or toluene). α-Acetoxy sulfones, e.g. **22**, lose SO_2 at similar rates when heated between 140 and 180°C (3). As expected from the ms data, the disulfone **10** was recovered unchanged after refluxing for 12 h in decalin.



20 **21** **22**

The trapping of the thio substituted *ortho*-quinodimethane **23** was carried out in refluxing toluene with dimethyl fumarate and methyl crotonate for about 6–8 h and yielded the adducts **24** and **25**, respectively. The purified yields were 89 and 35% (31% recovery of **8**), respectively.



23 **24** **25**

The structures of these products were assigned on the basis of their analytical and ms data and comparison of their 300-MHz proton nmr spectra with those of the corresponding 4-methoxy (8) and 4-acetoxy (3) adducts (Table 1). In particular, the large (9–11 Hz) coupling constant for H1, H2 and the small (3–4 Hz constant for H3, H4 for **24** and **25** are consistent with a *trans* diaxial and a *gauche* arrangement for H1–H2 and H3–H4, respectively. Furthermore, oxidation of **24** with MCPBA yielded the corresponding sulfone, which eliminated phenylmethanesulfinic acid upon treatment with triethylamine to form the dihydronaphthalene **26**. This product had previously been obtained by acid-catalyzed elimination of methanol from the adduct **27** (2). Thus **24** and **25** are judged to have the *trans* arrangement between the phenyl and adjacent carbomethoxy group.

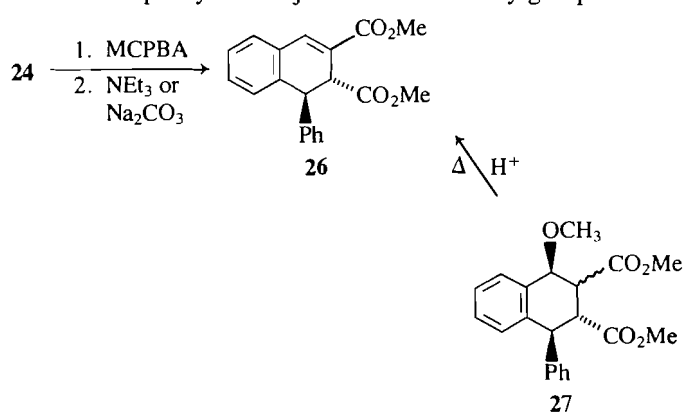


TABLE 1. Chemical shifts and coupling constants for

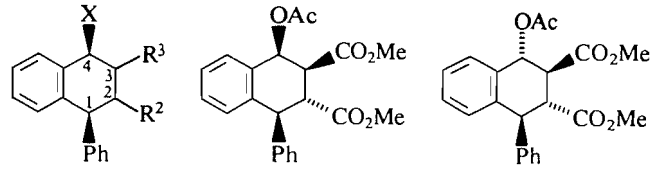
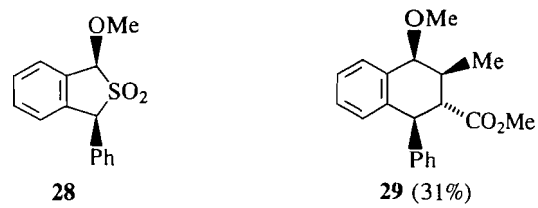


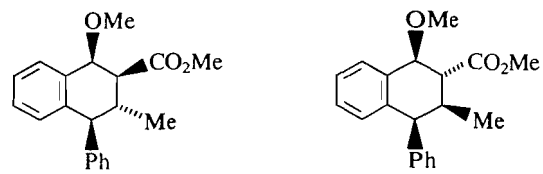
37 (ref. 3) **36** (ref. 3)

Compound	Chemical shift (δ)				Coupling constant (Hz)		
	H-1	H-2	H-3	H-4	$J_{1,2}$	$J_{2,3}$	$J_{3,4}$
24	4.08	3.45	3.55	4.33	10.8	11.8	3.5
25	4.26	3.07	2.5	3.79	11.0	11.2	3.4
27	4.09	3.61	3.30	4.70	11.0	12.1	2.9
29	4.27	3.16	2.22	3.99	11.2	11.2	2.0
34	4.02	3.3	3.31	4.32	10.6	—	3.9
35	4.37	3.31	3.49	4.35	10.5	9.3	8.3
37	4.02	3.82	3.56	6.69	11.3	12.3	3.2
36	4.37	3.48	3.60	6.80	10.7	10.8	8.9

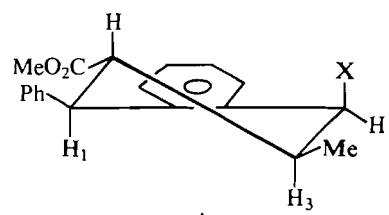
A careful investigation of the thermolysis of the methoxy derivative **28** with methyl crotonate revealed that, in addition to **29** (31%), the adducts **30** (6%) and **31** (1.2%) having the opposite regiochemistry to **29** were also obtained. In contrast, only **25**, corresponding to **29** in the methoxy series, could be isolated from the reaction of **23** and methyl crotonate, albeit in only 35% yield. Again the relative stereochemical assignments are based on the size of the relevant coupling constants (Table 1), which are consistent with these compounds existing in conformation **A**.



28 **29** (31%)



30 (6.0%) **31** (1.2%)



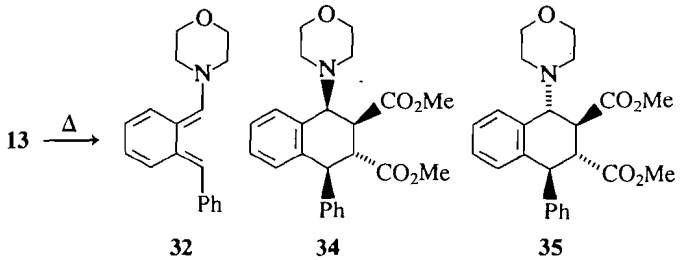
A

In agreement with the regiochemical assignment, compound **29** was converted to *trans*-2-methyl-3-carbomethoxy-4-phenyl-3,4-dihydronaphthalene in 97% yield upon heating with TsOH in benzene. In contrast, similar treatment of **30** and **31** afforded the isomeric *trans*-2-carbomethoxy-3-methyl-4-phenyl-3,4-dihydronaphthalene. Both of these naphthalenes were character-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

ized by their nmr, ms, and *Exact Mass* spectra (see Experimental). As expected, the sulfone corresponding to **25** was unaffected by treatment with triethylamine, thus confirming that this compound does not have a β-ester sulfone arrangement.

It was a considerable disappointment to us that thermolysis of the aminosulfones, e.g. **13**, in refluxing cyclohexane in the presence of the very reactive dienophile, dimethyl fumarate, gave only a modest yield of the two adducts **34** (26%) and **35** (3%), along with a 24% yield of 2-benzylbenzaldehyde. The structure of the major isomer **34** was assigned the same stereochemistry as **24**, again on the basis of the large (10.6 Hz) coupling constant between H1 and H2 and a small (3.9 Hz) coupling for H3, H4. This compound presumably arises from the *exo* addition of dimethyl fumarate to *trans–trans* diene **32**. The minor adduct **35** has similar coupling constants, as does the acetoxy derivative **36** (3) (Table 1) and may be assumed to have arisen from the trapping of a *cis–trans* diene, isomeric with **33**. Since the aminosulfone **13** was obtained as a mixture of isomers, both dienes should be formed in the thermolysis reactions thereby leading to the two adducts **34** and **35**.



32 **34** **35**

Attempts to trap the aminosubstituted *o*-quinodimethane **32** with dimethyl maleate or methyl crotonate under a variety of conditions (refluxing $CHCl_3$, cyclohexane, toluene, no solvent, 50°C) were unsuccessful. The major product isolated in all these attempts was 2-benzylbenzaldehyde. When **13** was melted and the melt examined by tlc, the above aldehyde again appeared as the major product.

In contrast to **32**, *o*-quinodimethanes bearing urethane or amide substituents have been trapped effectively, at least intramolecularly, by relatively weak dienophiles such as terminal alkenes (10) or alkynes (9).

Experimental

General

Proton nmr spectra were determined on a Varian XL-300 spectrometer in $CDCl_3$ solution. Work-up refers to partitioning the reaction mixture between H_2O and CH_2Cl_2, drying the CH_2Cl_2 layer with Na_2SO_4, and evaporating the solvent.

1-Benzylthio-1,3-dihydrobenzo[c]thiophene 2,2-dioxide, 7

Hydroxysulfone **1** (0.5 mmol), benzyl mercaptan (0.5 mmol), and TsOH (5 mg) were dissolved in 6 mL of CH_2Cl_2. The solution was stored at room temperature for 4 d, then extracted successively with 10 mL of saturated $NaHCO_3$ and 10 mL of H_2O. Crude yield: 148 mg of semi-solid material. Recrystallization afforded 111 mg (61%) of **7**, mp 124–125°C; nmr, δ: 3.89 (d, J = 13.2 Hz, 1H), 4.20 (d, J = 13.2 Hz, 1H), 5.12 (s, 1H), 5.40 (s, 1H), 7.05–7.5 (m, 14H); ms, CI/ether (relative %): 367 (1.3), 303 (32), 243 (20), 211 (40), 179 (28), 178 (16). *Anal.* calcd. for $C_{21}H_{18}O_2S_2$: C 68.82, H 4.95; found: C 68.50, H 5.00.

A solution of **7** in CH_2Cl_2 when stirred with 20% aqueous NaOH for 1 h afforded a 1:1 mixture of **7** and **9**. The mixture was separated by preparative tlc using 4:1 hexane – ethyl acetate as eluent. The nmr spectrum of **9** had peaks at δ 4.00 (d, J = 13.2 Hz, 1H), 4.33 (d, J = 13.2 Hz, 1H), 5.02 (s, 1H), 5.68 (s, 1H), and 7.0–7.45 (m, 14H).

Oxidation of 7 to 10

To a solution of 0.25 mmol of **7** in 3 mL of CH_2Cl_2 was added 0.8 mmol of MCPBA. The reaction was kept at room temperature for 14 h, then washed successively with 5 mL of 20% $NaHSO_3$, 20% $NaHCO_3$, and saturated NaCl solutions. The yield of **10**, mp 96–101°C, was quantitative; nmr, δ: 4.55 (d, J = 13.5 Hz, 1H), 5.10 (d, J = 13.5 Hz, 1H), 5.18 (s, 1H), 5.90 (s, 1H), and 6.8–8.0 (m, 14H); ms, CI/ether (relative %): 399 (25, M + 1), 335 (63), 179 (90), 91 (100).

1-Phenylthio-1,3-dihydrobenzo[c]thiophene 2,2-dioxide (8)

A solution of 0.5 mmol of hydroxysulfone **1**, 0.5 mmol of benzenethiol, and 30 mg of TsOH was heated in 10 mL of CH_2Cl_2 for 2 h. The mixture was cooled, washed with saturated sodium bicarbonate solution (15 mL), and then with 15 mL of H_2O. The organic layer was dried and evaporated. The yield of crude product was 137 mg (5:1 mixture of **8** and **11** by nmr). Recrystallization from ether afforded **8**, 46%, mp 126–128°C; nmr, δ: 5.56 (s, 1H), 5.44 (s, 1H), and 7.05–7.76 (m, 14H); ms (rel. %): 288 (42), 179 (100). *Anal.* calcd. for $C_{20}H_{16}O_2S_2$: C 68.15, H 4.58, S 18.19; found: C 68.30, H 4.99, S 18.05.

The above procedure, using benzene as solvent and refluxing the reaction mixture for 15 h, afforded the dithioacetal **11** in 61% isolated yield as a clear oil; nmr, δ: 3.85 (s, 2H), 5.30 (s, 1H), 6.8–7.8 (m, 19H); ms (rel. %): M^+ (not observed), 289 (55), 180 (60), 179 (100).

Anilinosulfone 12

Hydroxysulfone **1** (0.2 mmol) and aniline (0.4 mmol) were stirred in 1 mL CH_2Cl_2 for 0.5 h. The reaction mixture was diluted with 20 mL of CH_2Cl_2 and washed successively with 10 mL of saturated $NaHCO_3$ and 10 mL of saturated NaCl solution. Further work-up afforded a mixture of **12** and aniline. Trituration with ether gave pure **12** in 86% yield; mp 104–105°C; nmr, δ: 4.5–4.8 (b, NH), 5.33 (s, 2/3H) 5.40 (s, 1/3H), 5.87 (d, $J \approx$ 10 Hz, 1/3H), 5.98 (d, $J \approx$ 10 Hz, 2/3H), 6.8–7.5 (m, 14H); ms (rel. %): 271 (43), 270 (29), 179 (45), 178 (100), 77 (23). *Anal.* calcd. for $C_{20}H_{17}NO_2S$: C 71.62, H 5.11, N 4.18; found: C 71.43, H 5.19, N 4.11.

Morpholinosulfone 13

Sulfone **1** (632 mg, 2.43 mmol) and morpholine (212 mg, 2.43 mmol) were dissolved in 5 mL of dry CH_2Cl_2. After 2 h the solvent was evaporated, affording **13** as a crystalline substance in 95% yield (nmr). The product was recrystallized from CH_2Cl_2–hexane at −78°C; mp 62–66°C; nmr, δ: 3.2–3.3 (m, 4H), 3.7–3.8 (m, 4H), 5.25, 5.31, 5.40, 5.43 (4s, total 2H), 7.0–7.6 (m, 9H); ms (rel. %): M^+ (329, not observed), 265 (100), 264 (22), 179 (11), 178 (29). *Anal.* calcd. for $C_{18}H_{19}NO_3S$: C 65.63, H 5.81, N 4.25, S 9.73; found: C 65.79, H 6.02, N 4.09, S 9.98.

Diphenylaminosulfone 14

A solution of 0.4 mmol of hydroxysulfone **1** and 0.8 mmol of diphenylamine in 5 mL of CH_2Cl_2 was stirred at room temperature for 2.5 h, then refluxed for an additional 45 min. At this point **1** had not been completely consumed (tlc). Triethylamine (0.4 mmol) was added and the solution was refluxed for a further 4 h. Work-up as above afforded a thick oil, which was further purified by preparative tlc. The yield of **14** was 20%; nmr, δ: 6.14 (s, 1H), 6.37 (s, 1H), 6.9–8.0 (m, 19H); ms (rel. %): 411 (M^+, not observed), 347 (26), 179 (71).

Imine 15

A solution of 0.31 mmol of hydroxysulfone **1**, 0.44 mmol of *tert*-butylamine, and 0.27 mmol of triethylamine in 5 mL of CH_2Cl_2 was stirred at room temperature for 1 h. The CH_2Cl_2 layer was evaporated. Further purification via column chromatography afforded the imine **15** in 37% yield; nmr, δ: 1.40 (s, 9H), 4.38 (s, 2H), 7.1–7.8 (m, 3H), 8.00 (d, 1H), and 10.02 (s, 1H). *Exact Mass* calcd. for $C_{18}C_{21}N$: 251.1674; found: 251.1676.

Thermolysis of 7

(a) Trapping of 23 with dimethyl fumarate

Benzylthiosulfone **7** (0.3 mmol), dimethyl fumarate (0.6 mmol), and anhydrous zinc oxide were refluxed in 5 mL of toluene for 11 h.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

The zinc oxide was filtered off and the solvent evaporated. The crude product was dissolved in ether and precipitated with hexane to afford **24**, mp 46–52°C, in 89% yield; nmr, δ: 3.44 (s, 3H), 3.45 (dd, J = 10.8 and 11.8 Hz, 1H), 3.55 (dd, J = 11.8 and 3.5 Hz, 1H), 3.73 (s, 3H), 3.74 (d, J = 13.4 Hz, 1H), 4.08 (d, J = 10.8 Hz, 1H), 4.43 (d, J = 3.5 Hz, 1H), 6.70 (d, J = 7.8 Hz, 1H), 6.80 (d, J = 7.3 Hz, 1H), and 7.0–7.4 (m, 12H). *Anal.* calcd. for $C_{27}H_{26}O_4S$: C 72.62, H 5.87, S 7.18; found: C 72.49, H 6.02, S 7.38.

Compound **24** was oxidized with 3 equivalents of MCPBA in CH_2Cl_2 at room temperature for 7 h. The solution was then washed successively with saturated $NaHSO_3$, $NaHCO_3$, and NaCl solutions. Further work-up afforded a sulfone in 97% yield, mp 269–271°C. When this compound was warmed with triethylamine in CH_2Cl_2 for 1 h it was converted in quantitative yield to the alkene **26**, whose properties matched those reported by Charlton and Durst (2); nmr, δ: 3.61 (s, 3H), 3.75 (s, 3H), 4.06 (d, J = 3.0 Hz, 1H), 4.74 (d, J = 3.0 Hz, 1H), 7.0–7.4 (m, 9H), 7.72 (m, 1H). *Exact Mass* calcd. for $C_{20}H_{18}O_4$: 322.1205; found: 322.1188.

*(b) Trapping of **23** with methyl crotonate*

Benzylthiosulfone **7** (0.17 mmol), methyl crotonate (1.0 mmol), and zinc oxide (30 mg) were dissolved in 1 mL of toluene and the solution was refluxed for 16 h. The crude product, isolated after filtration and removal of most of the excess methyl crotonate, was purified by preparative tlc. The yield of **25** was 35%; in addition, 31% of **7** was recovered; nmr, δ: 1.10 (d, J = 6.6 Hz, 3H), 2.4–2.5 (m, 1H), 3.07 (t, J = 11.2 Hz, 1H), 3.49 (s, 3H), 3.78 (d, J = 3.4 Hz, 1H), 3.80 (d, J = 13.2 Hz, 1H), 3.83 (d, J = 13.2 Hz, 1H), 4.26 (d, J = 11.0 Hz, 1H), 6.68 (d, J = 7.6 Hz, 1H), 6.81 (d, J = 7.3 Hz, 1H), 7.0–7.5 (m, 12H); ms (rel. %): 412 (M^+, not observed), 311 (49), 310 (9), 279 (7), 220 (19), 219 (100), 91 (39). *Anal.* calcd. for $C_{20}H_{26}O_2S$: C 77.58, H 6.51, S 7.96; found: C 77.82, H 6.46, S 7.82.

The above sulfide was oxidized with 3 equiv. of MCPBA in CH_2Cl_2 at room temperature for 2 h. The reaction mixture was washed successively with saturated sodium sulfite, sodium bicarbonate, and sodium chloride solution. Further work-up afforded a quantitative yield of the sulfone corresponding to **25**, mp 168–171°C; nmr, δ: 1.39 (s, 3H), 2.6–2.7 (m, 1H), 3.48 (s, 3H), 3.81 (t, J = 11 Hz, 1H), 4.2–4.4 (m, 4H), 6.86 (d, J = 7 Hz, 1H), 7.0–7.6 (m, 13H). *Anal.* calcd. for $C_{26}H_{26}O_4S$: C 71.86, H 6.03, S 7.38; found: C 71.99, H 6.24, S 7.18.

The above sulfone was stable to refluxing with excess triethylamine in CH_2Cl_2 for 6 h.

*Reaction of **28** with methyl crotonate*

Methoxysulfone **28** (0.89 mmol), methyl crotonate (1.8 mmol), and zince oxide (50 mg) were refluxed in 0.5 mL of CH_2Cl_2 and 3.0 mL of cyclohexane for 3 d. The reaction mixture was diluted with an additional 30 mL of cyclohexane, filtered, and the solvents were evaporated. The crude product was separated by flash column chromatography and yielded 26% recovered **28**, 31% of **29**, 6.0% of **30**, and 1.2% of **31**.

Compound **29**: nmr, δ: 1.10 (d, J = 6.6 Hz, 3H), 2.22 (ddq, J = 11.2, 2.4, and 6.6 Hz, 1H), 3.16 (t, J = 11.2 Hz, 1H), 3.40 (s, 3H), 3.50 (s, 3H), 3.99 (d, J = 2.4 Hz, 1H), 4.27 (d, J = 11.2 Hz, 1H), 6.82 (m, 1H), 7.1–7.3 (m, J = 8 Hz); ms (rel. %): 310 (1.3, M^+), 278 (15). *Exact Mass* calcd. for $C_{20}H_{22}O_3$: 310.1569; found: 310.1557.

Compound **29** (47 mg) and TsOH (5 mg) were refluxed in 5 mL of benzene for 6 h. The reaction mixture was washed with saturated $NaHCO_3$ solution and the organic solvent dried and evaporated to yield 41 mg (97%) of *trans*-2-methyl-3-carbomethoxy-4-phenyl-3,4-dihydronaphthalene, mp 36–39°C; nmr, δ: 1.89 (s, 3H), 3.43 (d, J = 6.1 Hz, 1H), 3.59 (s, 3H), 4.54 (d, J = 6.1 Hz, 1H), 6.40 (s, 1H), 6.89 (d, J = 6.1 Hz, 1H), 7.1–7.3 (m, 8H); ms (rel. P): 278 (33), 219 (100), 218 (25). *Exact Mass* calcd. for $C_{19}C_{18}O_2$: 278.1307; found: 278.1308.

Compounds **30** and **31** were obtained as an inseparable 5:1 mixture. The major isomer **30** had nmr peaks at δ: 1.02 (d, J = 5.9 Hz, 3H), 2.69–2.73 (m, 2H), 3.36 (s, 3H), 3.49–3.51 (m, 1H), 3.76 (s, 3H), 4.50 (d, J = 2.0 Hz, 1H), 6.8 (m, 1H), 7.0 (m, 1H), 7.15–7.40 (m, 7H); ms (rel. %): 310 (6), 295 (10), 278 (83), 219 (100). *Exact Mass* calcd. for $C_{20}H_{22}O_3$: 310.1569; found: 310.1562.

The above mixture was refluxed for 0.5 h in benzene containing a catalytic amount of TsOH and yielded *trans*-2-carbomethoxy-3-methyl-4-phenyl-3,4-dihydronaphthalene in greater than 95% yield; nmr, δ: 1.12 (d, J = 7.1 Hz, 3H), 3.15 (dq, J = 1.2 and 7.1 Hz, 1H), 3.68 (s, 3H), 3.95 (bs, 1H), 6.9 (m, 2H), 7.0–7.4 (m, 7H), 7.50 (s, 1H); ms (rel. %): 278 (88), 219 (88), 218 (40), 178 (100). *Exact Mass* calcd. for $C_{19}H_{18}O_2$: 278.1307; found: 278.1314.

Evidence for the presence of a third isomer having the 3-methyl and 4-phenyl group in a *cis* relationship was also obtained from the nmr spectrum of the mixture: δ: 0.80 (d, J = 7.1 Hz, CH_3), 2.93 (quint., J ~ 7 Hz, H-3), 3.77 (OCH_3), and 4.34 (d, J ~ 6 Hz, H-4).

*Reaction of aminosulfone **13** with dimethyl fumarate*

Sulfone **13** (404 mg, 1.23 mmol), dimethyl fumarate (180 mg, 1.25 mmol), and 25 mg of ZnO were refluxed in 6 mL of cyclohexane for 8 h. The zinc oxide was filtered off, washed with additional cyclohexane, and the solvents were evaporated. The crude product was fractionated on a silica gel column to yield 26% of **34** and 3% of **35**; in addition, 15% of 2-benzylbenzaldehyde was also obtained.

The adduct **34**, mp 47–49°C, showed nmr peaks at δ: 2.45–2.55 (m, 2H), 2.65–2.75 (m, 2H), 3.3–3.4 (m, 2H), 3.41 (s, 3H), 3.5–3.6 (m, 2H), 3.6–3.7 (m, 2H), 3.71 (s, 3H), 4.02 (d, J = 10.6 Hz, 1H), 4.32 (d, J = 3.9 Hz, 1H), 6.77 (d, J = 6.9 Hz, 1H), 7.1–7.35 (m, 8H). *Anal.* calcd. for $C_{24}H_{27}NO_5$: C 70.40, H 6.65, N 3.42; found: C 70.22, H 6.97, N 3.23.

The proton nmr of **35** had key peaks at δ: 2.40–2.55 (m, 4H), 3.31 (dd, J = 9.6 and 10.5 Hz, 1H), 3.44 (s, 3H), 3.49 (t, J = 8.7 Hz, 1H), 3.64 (s, 3H), 3.6–3.7 (m, 4H), 4.35 (d, J = 8.3 Hz, 1H), 4.37 (d, J = 10.1 Hz, 1H), 6.61, (d, J = 6.9 Hz), 7.1–7.4 (m, J = 8 Hz). This compound was not further characterized.

Diozonolyses in methanol of (*E*)-4-chloro-2,3-dimethyl-1,3-hexadiene (**4***a*) and of (4*E*)-5-chloro-3,4-dimethyl-2,4-heptadiene (**4***b*) resulted in complete cleavage of the double bonds and of the single bonds of the respective diene systems. The course of these anomalous cleavage reactions has been established by step-wise ozonolyses of these dienes, and by the identification of labile methoxy hydroperoxides as intermediates.

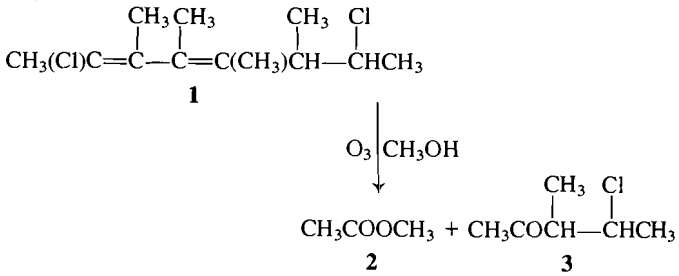
KARL GRIESBAUM et ASHIS R. BANDYOPADHYAY. Can. J. Chem. **65**, 487 (1987).

La diozonolyse du chloro-4 diméthyl-2,3 hexadiène-1,3-(*E*) (**4***a*) et du chloro-5 diméthyl-3,4 heptadiène-2,4-(*E*4) (**4***b*), dans le méthanol, conduit à une coupure complète des doubles et des simples liaisons des systèmes diéniques respectifs. On a déterminé le cours de ces réactions de coupures anormales en procédant à l'ozonolyse par étape de ces dienes ainsi qu'à l'identification des méthoxy hydroperoxydes labiles comme intermédiaires.

[Traduit par la revue]

Introduction

In previous work we obtained the chlorinated diene **1** as one of several products from the reaction of anhydrous hydrogen chloride with 2-butyne (1). In an attempt to confirm this structure by ozone degradation, we observed an anomalous ozonolysis of **1** in methanol, which resulted in the cleavage of the double bonds and of the single bond of the diene system to give fragments **2** and **3** in a ratio of 3:1 (2).



Since **1** was only available in a minute quantity, we were not in a position to follow this observation in more detail and to establish the course of this abnormal ozonolysis reaction. In the present study we have readdressed ourselves to this problem by examining the ozonolyses of the similarly structured but more readily accessible chlorinated dienes **4***a* and **4***b*.

Results and discussion

Complete ozonolysis of **4***a* and of **4***b* in methanol at ca. −60°C afforded colorless, strongly peroxidic solutions. After warming of the crude reaction products to room temperature, the peroxide contents had considerably decreased and the solutions remained colorless. Quantitative ^{1}H nmr analyses were consistent with the formation of **2** (96%), **12** (75%), **14***a* (42%), and **15** (10%) from **4***a* and with the formation of **2** (95%) and **12** (ca. 100%) from **4***b*. Compounds containing an intact $CH_3C—CCH_3$ moiety, such as **16** or **17**, could not be detected either by ^{1}H nmr or by gc (gas chromatographic) analyses. By contrast, when the freshly ozonized solutions were admixed with perdeuteriated dimethyl sulfide (DMS-d_6) and subsequently warmed up to room temperature, ^{1}H nmr and gc analyses of the yellow solutions were consistent with the formation of **16** (35%) from **4***a* and of **16** (27%) and **17** (20%) from **4***b*. Simultaneously, the yield of the abnormal cleavage product **2** was lowered from 96% after direct warm-up to 60% after DMS-d_6 treatment in the ozonolysis of **4***a* and from 95 to 18% in the ozonolysis of **4***b*.

These results demonstrated that **4***a* and **4***b* underwent anomalous ozonolysis reactions, similar to that observed for **1**, viz. by cleavage of the double bonds and of the central single bond of the respective conjugated diene systems. The fact that the extent of the abnormal cleavage could be lowered by reduction of the product mixture indicated, however, that it did not occur during the ozonolysis reaction itself, but rather by subsequent reactions of ozonolysis products in which the original central single bond of the diene system was still intact. In an attempt at identifying these ozonolysis products, we have studied the stepwise ozonolysis of **4***a* and of **4***b* with the following results:

Treatment of **4***a* in methanol with 0.8 molar equivalents of ozone afforded compounds **5***a* and **6** in yields of 93 and 87%, respectively, along with 5%, each, of **2** and of **12**. Ozonolysis of **4***b* under the same conditions gave **6** and **7** in yields of 28 and 59%, respectively, along with **8***b* and very minor proportions of **2** and **12**. The hitherto unknown hydroperoxide **6** has been isolated. In the presence of acid or triphenylphosphine it was rapidly converted into **7**, whereas in neutral media or in the presence of base, such as e.g., sodium methoxide, it was stable at room temperature.

It is apparent from these results that, in line with the known deactivating effect of chlorine substituents (3), monoozonolysis of **4***a* and of **4***b* occurred with high preference at the respective nonchlorinated double bonds to give the normal cleavage products **7** and (or) **6**, in which the central single bonds of the original diene systems were still intact. Hence, the abnormal cleavage, which was observed in the diozonolysis of **4***a* and of **4***b*, must have occurred in conjunction with the second cleavage step, i.e., the ozonolysis of the chloro substituted double bonds in **7** and (or) **6**. In an attempt at elucidating the course of this abnormal cleavage, compounds **6** and **7** have been individually ozonized in methanol/$CDCl_3$ at −60°C.

Ozonolysis of **6** and subsequent warm-up to room temperature gave a peroxidic solution, which contained **2** and **12** in yields of 82 and 79%, respectively, but no detectable amounts of compounds having an intact $CH_3C—CCH_3$ moiety. This result can be rationalized by the following sequence of reactions: In the first step the chlorinated double bond of **6** is selectively cleaved by ozone to give propionyl chloride (**10**) and the

a : R=H; *b* : R=CH_3

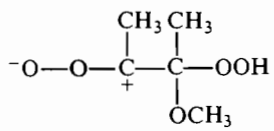
carbonyl oxide **18**. In subsequent steps, **10** is solvolyzed by methanol to give **12** and hydrogen chloride, and **18** is eventually converted into two equivalents of **2** and hydrogen peroxide. A priori, the latter conversion could occur by fragmentation of **18** itself, possibly via **19**, by intramolecular ring closure of **18** to **20** and fragmentation of the latter, or by trapping of **18** with methanol and subsequent cleavage of the resulting vicinal bismethoxyhydroperoxide **9**. As we have shown above, reduction of a fresh ozonolysis product of **6** at −60°C with DMS afforded ca. 80% of diacetyl **16** and only ca. 20% of the abnormal cleavage product **2**. This result requires that there is a peroxidic intermediate that has a finite lifetime at −60°C and in which the central single bond of the original diene system is still intact, preconditions that cannot be met by intermediates **18** or **19**. Compounds **9** and **20** had been previously postulated by us as possible intermediates in the ozonolysis of **21** in methanol (4). In that case, the transient existence of **9** or of **20** was indicated, though not rigorously proven, by ^1H nmr analysis of the fresh ozonolysis product. It is conceivable that, in the present case, the conversion of **9** or **20** into **2** was accelerated by HCl catalysis and that for this reason these intermediates evaded detection by ^1H nmr spectroscopy.

$RCH(OCH_3)_2$ **14** HCO_2CH_3 **15**

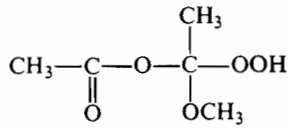
$CH_3COCOCH_3$ **16** $CH_3COC(OCH_3)_2CH_3$ **17**

a : R=H; *b* : R=CH_3

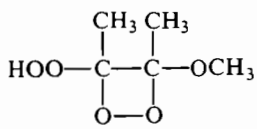
Ozonolysis of **7** and subsequent warm-up to room temperature gave a colorless solution, which was only weakly peroxidic and which contained **2** and **12** in yields of 93 and 100%, respectively. By contrast, ^1H nmr analysis of the fresh ozonolysis product at −60°C showed the presence of **10** and **11** as the single major products. Warming of the same sample to room temperature and monitoring of the reaction by ^1H nmr spectroscopy showed, besides the formation of **12**, a gradual decrease of the signals of **11** and a concurrent increase of the signals of **2** as the temperature surpassed ca. 0°C. These observations are in line with the results of previous experiments in our laboratory (4). They had shown that **11**, which had been obtained as the major product in the ozonolysis of **21**



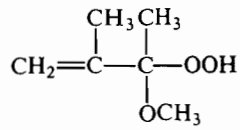
18



19



20



21

in methanol, underwent a spontaneous decomposition at temperatures above 0°C. In CD_2Cl_2 as a solvent, approximately equimolar amounts of **2** and **13** were formed, whereas in methanol **2** was the sole product, probably as the result of a post-esterification of **13**. The formation of **11** in the ozonolysis of **7** was further substantiated by reduction of the fresh ozonolysis product with DMS-d_6 at −60°C, which afforded **2**, **16**, and **17** in yields of 43, 15, and 36%, respectively, and 100% of **12**.

From the foregoing results we conclude that 1-chloro substi-

tuted conjugated dienes are bound to give solely abnormal diozonolysis products in methanol, irrespective of the nature and the position of alkyl or aryl substituents at the diene system. This is due to the fact that monochloro substituted double bonds are selectively cleaved to give acyl chloride and nonchlorinated carbonyl oxide fragments (5). As a consequence, the second cleavage step in the diozonolysis of 1-chloro substituted dienes generates vicinal bismethoxyhydroperoxides like **9** or α-oxo-methoxyhydroperoxides like **11**, both of which are thermally labile and undergo spontaneous fragmentation at room temperature with concurrent rupture of the central single bond of the original diene system. In retrospect, this reaction course now also provides an explanation for the previously observed anomalous ozonolysis of **1**, which could not be rationalized at that time.

Experimental

Materials

Chemicals, solvents, and technical gases were of commercial grades.

Methods

The ^{1}H nmr spectra were recorded in $CDCl_3$/TMS on a Bruker WP 60 and the ir spectra on a Beckman 4260 instrument. The gc analyses were carried out on a Shimadzu model 6A and gc/ms on a Hewlett Packard instrument 5985B. Analytical data that were used for the qualitative and (or) quantitative determination of ozonolysis products are compiled in Table 1.

The yields of diozonolysis products are based on the presence of a measured amount of 1,1,2,2-tetrachloroethane as a standard. The yields of products derived from **4***a* are calculated such that the maximum attainable yields of the fragments derived from the CH_2, CH_3CH_2CCl, and $CH_3C{-}CCH_3$ moieties amounted to 100% each. The yields of products derived from **4***b* are calculated such that the maximum attainable yields of the fragments derived from the CH_3CH_2CCl moiety on the one hand, and from the combined CH_3CH and $CH_3C{-}CCH_3$ moieties on the other hand, amounted to 100% each. This is based on the fact that fragments **5***b* and **8***b* are eventually converted into **2**, viz. by HCl-catalyzed dehydration of **8***b* (6) and by HCl-catalyzed conversion of **5***b* into **14***b*, followed by ozone oxidation of the latter (7).

The yields of monoozonolysis products are calculated such that the maximum attainable yields of the moieties derived from cleavage of the nonchlorinated double bond amounted to 100% each.

Diozonolysis of **4**a

A mixture of 278 mg (1.9 mmol) of **4***a* (8), 217 mg (1.3 mmol) of 1,1,2,2-tetrachloroethane, and 381 mg (11.9 mmol) of methanol was ozonized to completion at −60°C, flushed with nitrogen, and divided into two parts. The first part was warmed up to room temperature; ^{1}H nmr analysis showed the presence of **2**, **12**, **14***a*, and **15** in yields of 96, 75, 42, and 10%, respectively. The second part was immediately admixed with DMS-d_6 and slowly warmed up to room temperature; ^{1}H nmr analysis showed the presence of **2**, **12**, **14***a*, and **16**[2] in yields of 60, 63, 58, and 35%, respectively. The assignments of the above structures have been confirmed by gc/ms analyses.

Diozonolysis of **4**b

A mixture of 163 mg (1.00 mmol) of **4***b* (8), 130 mg (0.78 mmol) of 1,1,2,2-tetrachloroethane, and 215 mg (6.70 mmol) of methanol was ozonized to completion at −60°C, flushed with nitrogen, and divided into two parts. These were treated further as described above; ^{1}H nmr analysis showed the presence of **2** and **12** in yields of 95 and 100%, respectively, in the colorless product obtained after direct warm-up, and the presence of **2**, **12**, **14***b*, **16**,[2] and **17** in yields of 18, 64, 53, 27, and 20%, respectively, in the yellow product obtained after reduction with DMS-d_6. The product identification was confirmed by gc/ms analysis.

Monoozonolysis of **4**a

(a) Isolation of **6**

A solution of 1.44 g (10 mmol) of **4***a* (8) in 20 mL of methanol was treated with 8 mmol of ozone at −78°C. The crude product was admixed with 135 mg (2.5 mmol) of sodium methoxide, warmed up to room temperature, and concentrated to ca. one-half of the original volume in a rotary evaporator at 15 Torr (1 Torr = 133.3 Pa) and room temperature. Flash chromatography (column 2 × 60 cm, 105 g of silica gel, *n*-hexane/ether 9:1) of the concentrate afforded 291 mg (15%) of **6**.

[(E)-3-Chloro-1,2-dimethyl-1-methoxy-2-pentenyl]-hydroperoxide (6): Colorless liquid; ir (film): 3380 (OOH), 1630 (C=C) cm^{-1}; ^{1}H nmr (recorded in the presence of solid potassium carbonate), δ: 1.14 (t, J = 7.5 Hz, 3H), 1.47 (s, 3H), 1.89 (t, J = 0.9 Hz, 3H), 2.64 (q, J = 7.5 Hz, 2H), 3.30 (s, 3H), 7.83 (bs, 1H).

(b) Determination of product distribution

A solution of 720 mg (5 mmol) of **4***a* (8), 750 mg (4.47 mmol) of 1,1,2,2-tetrachloroethane, and 990 mg (31 mmol) of methanol in 3 mL of $CDCl_3$ was treated with 192 mg (4.0 mmol) of ozone at −60°C, admixed with 68 mg (1.25 mmol) of sodium methoxide, and warmed up to room temperature; ^{1}H nmr analysis showed the presence of **2**, **6**, **8***a*, and **12** in yields of 5, 87, 93, and 5%, respectively.

[2]Due to overlap of the CH_3CO singlet signal of **16** with the CH_2 quartet of **12**, the yield of **16** was determined by the difference between the total intensity of these two signal groups and the intensity of the $CH_3(CH_2)$ signal of **12**.

(c) Reduction of ***6***

A solution of **6** in $CDCl_3$ (previously shaken with potassium carbonate) was admixed with 35 mg of triphenylphosphine; ^1H nmr analysis after 5 min showed the signals of **7** and no residual signals of **6**.

Monoozonolysis of ***4***b

A solution of 314 mg (2.0 mmol) of ***4b*** (8), 236 mg (1.4 mmol) of 1,1,2,2-tetrachloroethane, and 234 mg (7.3 mmol) of methanol in 2 mL of $CDCl_3$ was treated with 763 mg (1.5 mmol) of ozone at −55°C, admixed with 27 mg (0.5 mmol) of sodium methoxide, and warmed up to room temperature. The ^1H nmr analysis showed the presence of **2**, **6**, **7** (8), ***8b*** (δ: 1.32 (d, J = 5.3 Hz, 3H), 3.49 (s, 3H), 4.95 (q, 1H)), and **12** in yields of 3, 28, 59, 39, and 3%, respectively.

Ozonolysis of ***6***

A solution of 190 mg (0.98 mmol) of **6**, 249 mg (1.88 mmol) of 1,1,2,2-tetrachloroethane, and 170 mg (5.31 mmol) of methanol in 2 mL of $CDCl_3$, which had been shaken with potassium carbonate, was ozonized at −60°C and divided into two parts. One part was warmed up to room temperature; ^1H nmr analysis of the strongly peroxidic solution showed the presence of **2** and of **12** in yields of 82 and 79%, respectively. The second sample was admixed with 15 drops of DMS-d_6 and warmed up to room temperature; ^1H nmr analysis showed the presence of **2**, **12**, and **16**[2] in yields of 14, 65, and 81%, respectively. The identification of the products in the second sample was confirmed by gc/ms analysis.

Ozonolysis of ***7***

A solution of 189 mg (1.30 mmol) of **7** (8), 129 mg (0.77 mmol) of 1,1,2,2-tetrachloroethane, and 249 mg (7.78 mmol) of methanol in 2 mL of $CDCl_3$ was divided into three equal parts and each part was ozonized to completion at −60°C. The first sample was warmed up to room temperature, and the second sample was admixed with 5 drops of DMS-d_6 and subsequently warmed up to room temperature. The ^1H nmr analysis showed the presence of **2** and **12** in yields of ca. 100% each, in the first sample, and the presence of **2**, **12**, **16**, and **17** in yields of 43, 100, 15, and 36%, respectively, in the second sample. The identification of the above products was confirmed by gc/ms analyses. The third sample was immediately analyzed by ^1H nmr spectroscopy at −60°C, which showed the signals of **10** (δ: 1.24, t, J = 7.0 Hz; 2.97, q) and of **11** (6). The ^1H nmr analysis of the same sample ca. 5 min after it had reached 0°C showed the presence of **2** and **12** as the single major components.

A Raman spectroscopic study of the complexation of the methylmercury(II) cation by amino acids

SERGE ALEX AND RODRIGUE SAVOIE
Département de chimie et C.R.A.M., Université Laval, Québec (Qué.), Canada G1K 7P4

Received June 23, 1986

SERGE ALEX and RODRIGUE SAVOIE. Can. J. Chem. **65**, 491 (1987).

A systematic Raman spectroscopic investigation of the complexation of CH_3Hg^+ by the standard amino acids is reported. It is shown that the vibrational bands due to the ligand—Hg and Hg—CH_3 stretching modes and to the symmetric —CH_3 bending mode of the —$HgCH_3$ unit are well suited to characterize the extent of complexation and the sites of attachment of the cation. Coordination, which occurs mostly on sulfur and nitrogen atoms by substitution of a proton on the thiol group of cysteine or on amino groups in general, is best identified by the frequency of the ligand—Hg stretching vibration in the 250–550 cm^{-1} region of the spectrum.

SERGE ALEX et RODRIGUE SAVOIE. Can. J. Chem. **65**, 491 (1987).

La complexation de l'ion CH_3Hg^+ par les acides aminés usuels a été étudiée systématiquement par spectroscopie Raman. On démontre que les bandes dues aux vibrations de valence des ensembles ligand—Hg et Hg—CH_3, de même que celle attribuable au mode de déformation symétrique du groupe CH_3, réflètent bien le degré de complexation et le site de fixation du cation. La coordination, qui implique principalement les atomes de soufre et d'azote suite à une substitution d'un proton sur le groupe thiol de la cystéine ou sur les groupes aminés en général, est la mieux identifiée par la fréquence du mode de vibration de valence ligand—Hg dans la région de 250 à 550 cm^{-1} du spectre.

Introduction

The mercury (Hg^{2+}) and methylmercury (CH_3Hg^+) cations are known to react extensively with living organisms (1). The main targets for this type of complexation are thiol ligands (2–5), such as the cysteine residues in proteins, although other sites are also involved. Complex formation through the sulfur atom is easily characterized by vibrational spectroscopy (4–9) and the substitution of a proton of an amino group by a methylmercury(II) cation also gives specific vibrational bands (10–13). We have recently studied in detail several complexes of methylmercury with some amino acids (alanine and glycine) (10), a dipeptide (glycylglycine) (11), and a small polypeptide (glutathione) (14). These studies have shown that the formation of S—Hg and N—Hg bonds by substitution of a proton on a —SH or —NH_3^+ group readily occurs in these systems. These complexation processes were followed by monitoring the frequencies and intensities of the ν(Hg—ligand), ν(Hg—CH_3), and $\delta(CH_3)$ bands (ν = stretching and δ = bending), which are particularly intense in the Raman spectra.

It became obvious in the above studies that the potential of Raman spectroscopy for determining the possible sites of complexation of the CH_3Hg^+ ion by amino acids and proteins in general had not been used to its full capacity. Also lacking in certain cases was an accurate knowledge of the conditions under which complexation could occur. The present paper gives an account of a systematic Raman spectroscopic investigation of this problem, using standard amino acids and small parent molecules.

Experimental

The amino acids in the zwitterionic or salt form were purchased from the Sigma Chem. Co. and used without further purification. The source of methylmercury(II) was the hydroxide CH_3HgOH (1 *M* aqueous solution from Alfa Inorganics). The various complexes, generally at a final concentration of 0.33 *M*, were prepared by direct mixing of appropriate quantities of aqueous solutions of the reagents. The pH was adjusted with 4 *M* NaOH or HNO_3. Reagents containing the easily oxidized —SH function were dissolved in distilled water in which nitrogen had been bubbled for ca. 15 min. Raman spectra were then recorded as soon as possible after the preparation of the complexes. The solid complexes reported here (e.g. $CH_3COOHgCH_3$) were in general prepared by mixing the appropriate amounts of the reagents (assuming a specific stoichiometry) and evaporating the solvent.

The Raman spectra, excited by the 514.5 nm line from a Spectra Physics 165 argon ion laser, were recorded on a Spex Model 1400 microcomputer-controlled spectrometer. The solutions were studied in capillary cells mounted in a copper block maintained at 10°C, except in the case of the aqueous solutions of tryptophan, where a temperature of 25°C was chosen to improve the solubility of the product (1% w/w). The spectra were typically recorded with a laser power of 300 mW at the sample. The spectral resolution was 5 cm^{-1}, one data point being recorded at each 2 cm^{-1} increment, with an integration time of 2 s per point. The spectra reproduced in this paper are original (unsmoothed) spectra.

Results and discussion

Aqueous methylmercury(II)

The methylmercury cation, CH_3Hg^+, is associated with water in aqueous solution, giving the hydroxide CH_3HgOH at high pH and the charged $CH_3HgOH_2^+$ and $(CH_3Hg)_2OH^+$ species at low pH. Note that the hydroxide can be regarded as a complex formed by the substitution of a proton of a water molecule by a CH_3Hg— group, whereas the charged species are in fact oxonium ions, resulting from a mono or disubstitution on the H_3O^+ ion. The completely substituted $(CH_3Hg)_3O^+$ ion can also exist (15), but we have had no indication of its occurrence. From the known formation constant of this species (15), it can be calculated that its concentration in the conditions that prevailed in the present study should be less than ca. 10^{-3} *M* (0.5%).

The distribution of the mercuric species as a function of pH in a 0.33 *M* aqueous solution is shown in Fig. 1. These curves were calculated using the equilibrium constants given by Libich and Rabenstein (16). The predominance of only one of the three species at certain pH values has allowed the recording of the Raman spectrum of each individually (Fig. 2). The spectra are very intense in the region shown (300–1300 cm^{-1}), with characteristic bands of the CH_3Hg moiety near 1210 cm^{-1} (symmetric bending mode, $\delta(CH_3)$) and 570 cm^{-1} (Hg—CH_3 stretching mode, ν(Hg—C)). The band due to the ν(Hg—O) vibration, which differs considerably both in intensity and frequency for each species, is particularly helpful in their

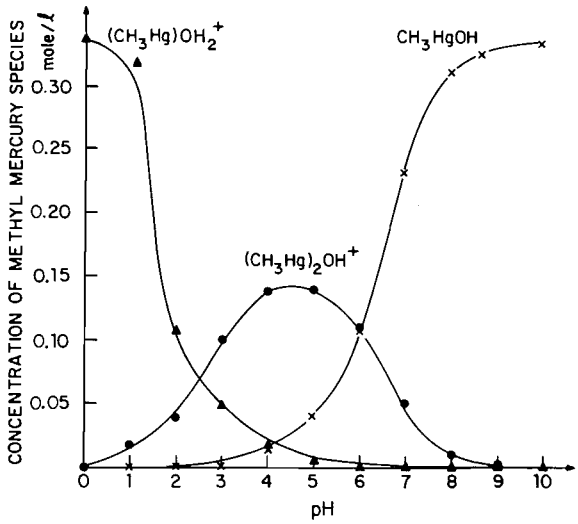

FIG. 1. Distribution of the species present in a 0.33 *M* aqueous solution of CH_3Hg^+ as a function of pH.

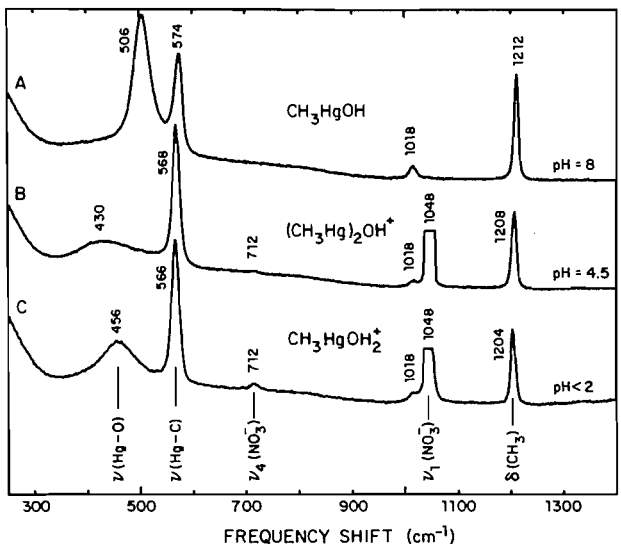

FIG. 2. Raman spectra of the species present in an aqueous solution of CH_3Hg^+ (8% w/w) as a function of pH.

identification and it can also be used to detect the presence of uncomplexed methylmercury in mixtures where complexation can occur. Also noteworthy is the hyperchromicity of the ν(Hg—C) band near 570 cm^{-1} in the charged complexes (peak-height intensity relative to the 1210 cm^{-1} band). The same effect has been found to occur following complex formation, throughout this study.

Substitution on amino groups

The charged NH_3^+ group of amino acids is a fair target for complex formation with the methylmercury cation. Rabenstein *et al.* (17) have determined by nuclear magnetic resonance spectroscopy the equilibrium constants associated with the formation of various complexes through nitrogen–mercury bonding:

$$RNH_3^+ + CH_3Hg^+ + H_2O \rightleftharpoons RNH_2HgCH_3^+ + H_3O^+$$

They showed that the complex formation constant is directly proportional to the pK_a of the NH_3^+ group, with a value of 10^7 to 10^8 at 25°C.

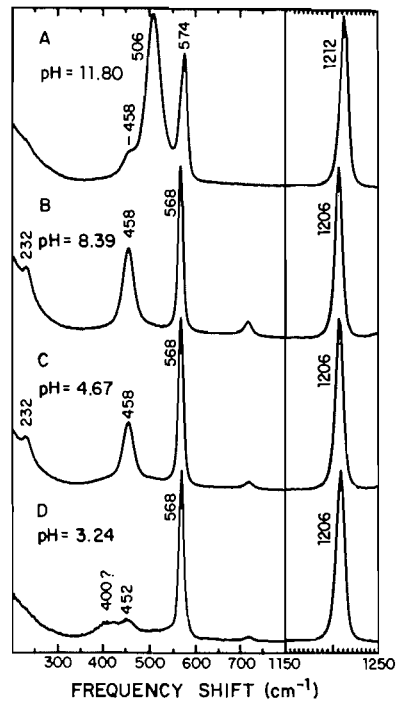

FIG. 3. Raman spectra of a 1:1 stoichiometric mixture of $CH_3NH_3^+$ and CH_3Hg^+ as a function of pH.

We have studied the simplest representative of this class of compounds, aminomethane, $CH_3NH_3^+$. The Raman spectra of equimolar aqueous mixtures of this compound and CH_3Hg^+ as a function of pH are shown in Fig. 3. The spectrum at pH 8.39 (Fig. 3 *B*) shows no sign of the 506 cm^{-1} band of CH_3HgOH, which is predominant in the spectrum of aqueous methylmercuric hydroxide at pH 8 (Fig. 2 *A*). On the other hand, a new band at 458 cm^{-1} in the spectrum can be unambiguously assigned to the ν(N—Hg) vibration of the $CH_3NH_2HgCH_3^+$ species, by comparison with similar complexes with glycine (460 cm^{-1}) (10, 12), alanine (476 cm^{-1}) (10), glycylglycine (462 cm^{-1}) (11), and even the NH_4^+ ion (468 cm^{-1}) (Table 1). This characteristic band is accompanied by a weaker peak at 232 cm^{-1}, assigned to the N—Hg—CH_3 bending mode of the complex, as this type of vibration in similar molecules has been found to occur in this region (15, 18–21).

The spectra shown in Fig. 3, together with those of aqueous methylmercuric hydroxide (Fig. 2), clearly delimitate the pH range in which complexation takes place (ca. pH 4–11). At pH ca. 3, the two bands near 400 and 450 cm^{-1} reveal the presence of uncomplexed $(CH_3Hg)_2OH^+$ and $CH_3HgOH_2^+$, with little, if any, of the complex present. At pH ca. 12, the presence of free CH_3HgOH is indicated by the strong 506 cm^{-1} band, the complex occurring in very small amount (458 cm^{-1} band). Our observations here are consistent with the nmr results (17), which showed that the methylamine complex is formed at intermediate pH values.

As can be seen in Table 1, the α-NH_3^+ group of amino acids consistently react with CH_3Hg^+, to give a complex of the —$NH_2HgCH_3^+$ type. In amino acids with no potentially reactive side chains, such as alanine, glycine, valine, leucine, isoleucine, and phenylalanine, this is the only type of complexation that should occur. The ν(N—Hg) stretching vibration of the complexes thus formed has a frequency in the range 460–475 cm^{-1} in aqueous solutions.

In the solid complexes, however, perturbations sometimes

occur and no band appears in the 470 cm^{-1} region of the spectrum. Examples of this are found in the complexes with alanine, glutamic acid, and the γ-monoethyl ester of glutamic acid (see Table 1). In these cases, it is also observed that the ν(Hg—CH_3) mode is displaced by ca. 20 cm^{-1}, at ca. 545 cm^{-1}. The likely explanation for this anomaly is an accidental coincidence of the ν(Hg—N) and ν(Hg—C) vibrations, which is likely due to structural factors in the solids. A similar effect has been observed by Wong *et al.* (6) in a complex with methionine, the spectrum of which gave a single peak at 543 cm^{-1} (ν(Hg—N) + ν(Hg—C)) in the normal compound and a doublet at 518 (ν(Hg—N)) and 534 cm^{-1} (ν(Hg—C)) in the amino deuterated compound.

The proton on the NH group of the "abnormal" amino acid proline can be substituted to some extent by CH_3Hg^+ in the pH range ca. 5–10. However, the reaction is incomplete, even in the presence of a tenfold excess of the methyl mercury cation. The weak ν(Hg—N) Raman band characterizing the complex occurs at a relatively low frequency, 452 cm^{-1}, and it is accompanied by the δ(N—Hg—C) bending mode at 186 cm^{-1}, a value which is also lower than that observed in most α-NH_3^+ substituted complexes (ca. 230 cm^{-1}).

A special effort has been made in the present study to characterize the complexation of CH_3Hg^+ by charged amino groups contained in the side chains of some amino acids (lysine, arginine, and histidine), as this type of complexation is likely to occur extensively in polypeptides and proteins containing these residues. Lysine proved to be a poor model compound for this purpose, as its charged (—NH_3^+) side chain is neutralized by a counterion which preferentially reacts with CH_3Hg^+. For example, with the bromide salt at pH ≧ 7, the spectra were dominated by strong peaks attributable to CH_3HgBr, at 118 cm^{-1} (δ(C—Hg—Br)), 206 cm^{-1} (ν(Hg—Br)), 546 cm^{-1} (ν(Hg—C)), and 1172 cm^{-1} ($\delta(CH_3)$). To circumvent this difficulty, we have used lysine derivatives in which each amino function was selectively blocked by an acetyl group. These molecules exist as zwitterionic species and do not require an extra counterion for charge neutralization. The spectra obtained with the two derivatives are shown in Fig. 4 *A* and *B*. When the side-chain amino group is blocked, complexation takes place on

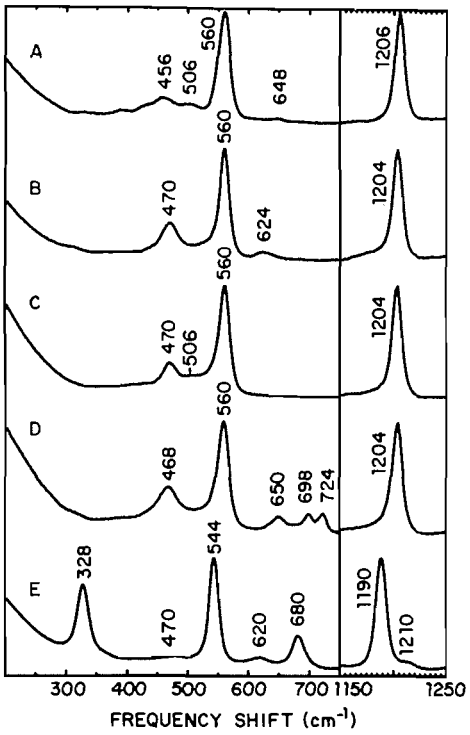

FIG. 4. Raman spectra of 1:1 stoichiometric mixtures (0.33 *M*, pH ca. 7) of CH_3Hg^+ and (*A*) *N*-α-acetyl-L-lysine, (*B*) *N*-ε-acetyl-L-lysine, (*C*) glutamic acid, (*D*) methionine, and (*E*) cysteine.

the α-NH_3^+ group and the normal ν(Hg—N) vibrational band is observed at 470 cm^{-1} (Fig. 4 *B*). On the other hand, when only the side-chain NH_3^+ group is free to react, the corresponding band is found at 456 cm^{-1} (Fig. 4 *A*). The spectrum also indicates that only partial complexation occurs, the presence of free CH_3HgOH being revealed by the 506 cm^{-1} band.

Our study of the complexation of CH_3Hg^+ by the side-chain NH_2^+ groups of arginine (hydrochloride salt) was hampered by the presence of Cl^- ions in the solutions. Although the rate constants for the formation of CH_3HgX compounds (X = Cl, Br, and I) are more important for the heavier halides (22), these constants clearly indicate that the formation of CH_3HgCl is strongly favored at low pH, whereas CH_3HgOH species should be predominant at high pH. Coordination of CH_3Hg^+ on amino groups normally occurs at intermediate pH values. Our attempts to identify specific Raman bands indicative of complexation on the side-chain —NH_2^+ groups of arginine failed, even at large CH_3Hg^+/arginine ratios. In contrast, substitution of the proton of the NH^+ group on the side chain of histidine was found to take place, giving a ν(Hg—N) vibration at 452 cm^{-1}. The negative results obtained with arginine are possibly related to the very high pK_a (ca. 12) of the side-chain group of this amino acid, which could shift the region of stability of the complex to higher pH, where the competitive reaction with OH^- species is favored.

The amide (—$CONH_2$) function on the side chain of asparagine was found to be unreactive towards the CH_3Hg^+ cation. The same conclusion is probably applicable to glutamine. On the other hand, in a solid complex obtained with tryptophan (see Table 1), complexation was indicated on the —NH group of the pyrrole unit (as well as on the α-NH_3^+ function). This was easily established from the modifications brought to the Raman spectrum of tryptophan (23), in particular from the reduced intensity of the band due to the ν(N—H) stretching mode at 3350 cm^{-1}. Only one band, at ca. 486 cm^{-1}, was found for the two expected ν(Hg—N) modes. In aqueous mixtures of tryptophan and CH_3Hg^+, the results suggested that partial complexation simultaneously occurred on both the —NH and —NH_3^+ groups, independent of the quantity of CH_3Hg^+ present. This interpretation is based on the presence in the spectra of a doublet with components at 440 and 474 cm^{-1}, respectively assigned to the ν(Hg—N) modes of the pyrrole—mercury and (α-amino)—mercury units. The value of the ν(pyrrole—Hg) vibration is comparable to that in the complex with proline (452 cm^{-1}), but it is much higher than the corresponding values proposed in similar complexes with pyridine (204–208 cm^{-1}) (24), adenine (25), and 9-methyl adenine (26) ($\nu < 300\ cm^{-1}$). The Raman spectrum of the solid complex with tryptophan also shows a band at 258 cm^{-1}, but the latter probably belongs to the δ(N—Hg—CH_3) vibration.

Coordination on carboxylate groups

The results of a proton nmr study of the complexation of the methyl mercury cation by the main organic acids (16) have indicated that the equilibrium constants of the reaction

$$RCOO^- + CH_3Hg^+ \rightleftharpoons RCOOHgCH_3$$

(10^2 to 10^3 at 25°C) are much weaker than for the substitution reaction on protonated amino groups (17). In fact, spectroscopic observations of complexes of this type have been very limited and the frequency of the ν(Hg—O) vibration is not well established. Vibrational frequencies have been reported at 279 and 295 cm^{-1} in $(CH_3COO)_2Hg$ and $(CH_3COO)_2Hg_2$, respectively (27), 300–400 cm^{-1} for Pt—glycine complexes (13), ca. 500 cm^{-1} in Zn^{2+}—glycine (28) and metal—EDTA (29) complexes, and 496 cm^{-1} for the ν(Fe—O) vibration of hemoglobin (30).

In order to better specify the frequency of the ν(Hg—O) vibration in acid—$HgCH_3$ complexes, we have studied by Raman spectroscopy the complexation of CH_3Hg^+ by formic and acetic acid. The spectra of the $CH_3COOHgCH_3$ complex in the solid phase is compared with that of the CH_3COO^- ion in Fig. 5. The interpretation of the spectrum of the solid complex is straightforward. The ν(Hg—O) vibration gives a sharp peak at 498 cm^{-1}, on the low-frequency side of the ν(Hg—C) band at 560 cm^{-1}. Also seen in the spectra are the δ(O—Hg—CH_3) band at 284 cm^{-1} and the δ(CH_3) peak at 1194 cm^{-1}. The spectrum of the ligand (31) is appreciably modified upon complex formation. In particular, one notes the disappearance of the band due to the symmetric stretching mode of the COO^- group, which is present at 1418 cm^{-1} in the spectrum of solid CH_3COONa. In aqueous solution, the spectrum (Fig. 5 *A*) shows bands due to unreacted acetic acid (894 and 1702 cm^{-1}) and to the free methylmercury ion (broad underlying band at ca. 450 cm^{-1}), which indicate that only partial complexation takes place. The characteristic bands of the complex then occur at 288, 506, 566, and 1206 cm^{-1}. The spectrum obtained upon mixing an aqueous solution of HCOOH and CH_3Hg^+ at pH 3–4 is very similar to that obtained with acetic acid, except for the ν(Hg—O) vibration which occurs at a lower frequency (400 cm^{-1}; other peaks at 274, 560, and 1205 cm^{-1}).

The ca. 500 cm^{-1} frequency for the ν(Hg—O) vibration in the complex with acetic acid is consistent with the 536 cm^{-1} value already suggested for a carboxylate-bound CH_3Hg(II) complex of glycylglycine whose structure was firmly established by X-ray diffraction (11). The fact that this vibration

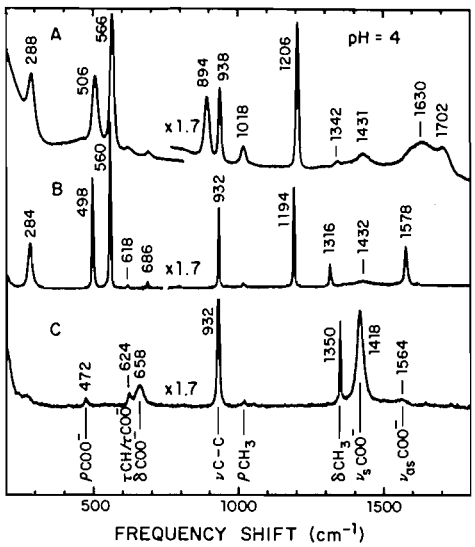

FIG. 5. Raman spectra of the $CH_3COOHgCH_3$ complex (*A*) in aqueous solution at pH 7 and (*B*) in the solid state. (*C*) Raman spectrum of CH_3COONa.

occurs at a higher frequency than that of average ν(Hg—N) vibrations (ca. 470 cm^{-1}) is unexpected as the opposite would be predicted from the relative masses of the oxygen and nitrogen atoms. The explanation for this apparent anomaly is possibly related to the relative strength of the O—Hg and N—Hg bonds, which are of different lengths (32), and to the presence of a positive charge on the nitrogen atom.

We have had no indication in the present and previous studies (10), that the α-COO^- group of amino acids reacts to any appreciable extent with CH_3Hg^+ in aqueous solution, although some solid complexes of this type have been obtained, such as the 2:1 (CH_3Hg^+:GlyGly) compound with glycylglycine (11). On the other hand, a weak band at 506 cm^{-1} in the spectrum of aqueous mixtures of glutamic acid and CH_3Hg^+ in the pH range 1 to 7 (see Fig. 4 *C*) indicates that the COO^- group on the side chain of this amino acid is slightly reactive towards the methylmercury cation. The origin of the band at 506 cm^{-1} (499 cm^{-1} in the solid complex) was ascertained from the spectra of selectively blocked glutamic acid derivatives (see Table 1). This band was not present in the spectrum of the γ-monoethyl ester of the acid, in which the side-chain carboxylate group is not available for complexation. On the other hand, in *N*-acetyl glutamic acid, where the α-NH_3^+ end is transformed into —NHC(=O)CH_3, interaction with the side-chain COO^- group took place, with resulting ν(Hg—O) band near 520 cm^{-1}. Also observed in this case was a band at 456 cm^{-1}, which had its maximum intensity at pH ca. 4, and which is believed to arise from the —$NH(HgCH_3^+)C(=O)CH_3$ complex.

It should be noted that the pK_a of the γ-COOH group of glutamic acid and of the β-COOH group of aspartic acid are quite similar (ca. 4) to that of acetic acid, which reacts appreciably with CH_3Hg^+, whereas the pK_a of the unreactive α-COOH group of amino acids are appreciably lower (ca. 2).

Coordination on sulfur atoms

Amino acids containing an OH group on their side chain (serine, threonine, and tyrosine) failed to show any side-chain complexation with CH_3Hg^+. Methionine, with —SCH_3 side group, showed the same behavior in the pH range 3 to 11 (Fig. 4 *D*). However, at very low pH (<2) metallation occurred on the sulfur atom, giving the R—$S(HgCH_3)CH_3^+$ charged species, which is characterized by the ν(Hg—S) vibrational band at 285 cm^{-1} (other peaks at 544 and 1188 cm^{-1}). Our results here are consistent with those of previous studies which indicated coordination of the thioether by Hg(II) (33) and CH_3Hg(II) (34) in very acidic solutions.

The —SH group of cysteine is known to be very reactive towards CH_3Hg^+ (35, 36), forming a very stable —$SHgCH_3$ unit (37). The vibrations of the methylmercury moiety in this complex are very characteristic on account of their relatively low frequencies: ν(Hg—S): 328 cm^{-1}, ν(Hg—C): 544 cm^{-1}, and $\delta(CH_3)$: 1190 cm^{-1} (4, 8, 9, 14). By monitoring the intensity of the ν(S—H) Raman band at 2580 cm^{-1} (38) we have confirmed that the substitution of the proton of the thiol group occurs preferentially to that on NH_3^+. The ν(S—Hg) vibrational band of the thiol-substituted complex (328 cm^{-1}) is predominant in the spectrum (Fig. 4 *E*), which also shows that both the ν(Hg—CH_3) and $\delta(CH_3)$ vibrations in this complex have frequencies which are 15 to 20 cm^{-1} lower than the usual frequencies for these modes. The very weak band at ca. 470 cm^{-1} in this spectrum indicates that some substitution has also occurred on the —NH_3^+ group in a 1:1 stoichiometric mixture of CH_3Hg^+ and cysteine. Given the much greater tendency for CH_3Hg^+ to bind to thiol groups compared to amino functions, it is unlikely that this metal ion will complex to —NH_3^+ while there are free thiol groups available. Our observations can probably be explained by a slight lowering of the concentration of cysteine in the solutions due to oxidation to cystine. A similar effect was encountered in our study of the complexation of CH_3Hg^+ by glutathione (14).

When disubstitution (—S and —N) occurred on cysteine, the resulting complex precipitated. Furthermore, when an excess of CH_3Hg^+ was present in the solutions, precipitation of L-cystine also occurred, this oxidized compound being only sparingly soluble in water at pH 1 to 8. This was followed in the Raman spectra by the appearance of a strong and sharp line at 498 cm^{-1}, attributable to the ν(S—S) vibration of the bridging unit (39). Metals are known to slowly oxidize thiols, especially at high pH (35). It is not clear, however, if the present oxidation process was due to the presence of CH_3Hg^+ alone or if it was triggered by the presence of traces of oxygen in the solution.

Summary and conclusion

Amino acids can react in a number of ways with the methylmercury cation. The reactivity of the possible coordination sites are as follows:

Terminal NH_3^+ (all amino acids): substitution of a proton readily occurs in the pH range ca. 4 to 11; ν(Hg—N): 460–475 cm^{-1} in aqueous solution, sometimes missing in solid complexes due to structural effects.

Side-chain NH_3^+ (lysine): less reactive than the α-amino end of the acid; partial substitution on this group in aqueous solution, in the same pH range as for the terminal NH_3^+ groups, but with ν(Hg—N) at a slightly lower frequency (452 cm^{-1}).

Terminal COO^- (all amino acids): no coordination detected in aqueous solution although solid complexes can be obtained; ν(Hg—O): >500 cm^{-1}.

Side-chain COO^- (glutamic acid): very slightly reactive in acid aqueous solution (aspartic acid less reactive); ν(Hg—O): >500 cm^{-1}.

Terminal NH (proline): substitution of the proton can take place to some extent in the pH range 5–10; ν(Hg—N): 452 cm^{-1}, δ(N—Hg—C): 186 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

—$NHC(NH_2)_2^+$ (arginine): no reaction of this group was detected in aqueous solution.

—NH^+ (histidine): substitution of the proton in aqueous solution; ν(Hg—N): 452 cm^{-1}.

—NH (tryptophan): the reactivity of this group in aqueous solution is comparable to that of the α-NH_3^+ group and occurs at the same time; ν(Hg—N): 440 cm^{-1}?

—OH (serine, threonine, and tyrosine): no reaction of this group detected in aqueous solution.

—$C(=O)NH_2$ (asparagine and glutamine): no reaction of this group detected in aqueous solution.

—SH (cysteine): the most reactive site in amino acids. Substitution occurs preferentially to that on NH_3^+ groups; ν(Hg—S): 328 cm^{-1}, ν(Hg—C): 544 cm^{-1}, and $\delta(CH_3)$: 1190 cm^{-1}.

—SCH_3 (methionine): no reaction in the pH range 3 to 11, but some coordination on the sulfur atom at very low (<2) pH; ν(Hg—S): 285 cm^{-1}.

The results of the present spectroscopic investigation on the coordination of CH_3Hg^+ by amino acids can probably be used in similar studies on polypeptides and proteins. Attempts along that line in our laboratory have indicated that this assumption is partly justified. However, the complexation of CH_3Hg^+ by biopolymers often cause important secondary effects, such as precipitation and conformational changes, which modify the Raman spectra in a more pronounced manner than would normally be expected from the bare complexation process.

Mécanisme des réactions du chlorite et du dioxyde de chlore. 5. Cinétique de la réaction chlorite–bromure

GUY SCHMITZ ET HENRI ROOZE
Université libre de Bruxelles, Faculté des sciences appliquées, 50 avenue F. Roosevelt, 1050 Bruxelles, Belgique

Reçu le 29 avril 1986

GUY SCHMITZ et HENRI ROOZE. Can. J. Chem. **65**, 497 (1987).

Dans les solutions acides de chlorite et de bromure on observe simultanément la dismutation du chlorite et une réaction autocatalytique conduisant à une production rapide de ClO_2. Les caractéristiques inhabituelles de cette réaction sont décrites. Dans ce système compliqué, il n'est pas possible de mesurer la vitesse de $HClO_2 + Br^- + H^+ \rightarrow HClO + HBrO$. C'est par contre possible en présence d'*ortho*-tolidine qui capte le HBrO et le HClO. Nous avons obtenu $r = k[HClO_2][Br^-][H^+]$ avec $k = 1{,}48 \times 10^{-2}\ M^{-2}\ s^{-1}$ à 25°C. En absence d'*ortho*-tolidine cette réaction initie la réaction autocatalytique pour laquelle nous proposons un modèle.

GUY SCHMITZ and HENRI ROOZE. Can. J. Chem. **65**, 497 (1987).

In acidic solutions of chlorite and bromide two processes occur simultaneously, the disproportionation of chlorite and an autocatalytic reaction leading to a rapid production of ClO_2. The unusual features of this reaction are described. In this complex system the rate of $HClO_2 + Br^- + H^+ \rightarrow HClO + HBrO$ cannot be measured. It can be, however, with added *ortho*-tolidine to remove the HBrO and HClO. We obtained $r = k[HClO_2][Br^-][H^+]$ with $k = 1.48 \times 10^{-2}\ M^{-2}\ s^{-1}$ at 25°C. Without added *ortho*-tolidine this reaction initiates the autocatalytic reaction for which we suggest a kinetic scheme.

Introduction

L'étape déterminante de la réaction chlorite–chlorure est [1]. Elle est suivie de réactions entre le chlorite et l'hypochlorite conduisant à la formation de chlorate et de dioxyde de chlore en proportions variables suivant les conditions (1).

[1] $\quad HClO_2 + Cl^- + H^+ \rightarrow 2\ HClO$

Nous avons obtenu $k_1 = 1{,}8 \times 10^{-3}\ M^{-2}\ s^{-1}$ à 25°C et une force ionique $I = 1\ M$.

Kern et Kim (2) ainsi que de Meeus et Sigalla (3) ont étudié la réaction chlorite–iodure dans la zone de pH 4–8. Sa première étape est [2].

[2] $\quad ClO_2^- + I^- + H^+ \rightarrow ClO^- + HIO$

Cette réaction est suivie d'un ensemble d'autres, faisant intervenir le chlorite, l'hypochlorite, l'iodite et l'hypoiodite, conduisant à une production autocatalytique d'iode. Le système est compliqué mais ses aspects principaux sont établis. Il peut conduire à des oscillations qui ont été étudiées par Epstein et Kustin (4).

Pour la réaction chlorite–bromure la seule étude antérieure à celle-ci est celle de Simoyi (5) que nous discuterons plus loin. Il s'agit également d'une réaction compliquée d'allure autocatalytique. Afin d'étudier isolément sa première étape, analogue de [1] et [2], nous avons utilisé la méthode à l'*ortho*-tolidine décrite dans l'article précédent de cette série (6).

Technique expérimentale

Le chlorite de sodium a été purifié par trois recristallisations successives. Ses solutions sont conservées dans le noir en milieu légèrement basique et standardisées par iodométrie. Les autres réactifs de la qualité «pour analyses» sont utilisés sans purification supplémentaire. La température est toujours fixée à 25,0 ± 0,1°C.

Lors des expériences en absence d'*ortho*-tolidine, les productions de ClO_2 sont mesurées par absorptiométrie à 360 nm comme indiqué antérieurement (1). Nous avons vérifié que dans les conditions des expériences discutées ici (faibles concentrations initiales en bromure), la contribution aux absorbances mesurées d'une éventuelle formation de brome serait totalement négligeable.

Pour les expériences faites en présence d'*ortho*-tolidine, les techniques et précautions expérimentales ont été entièrement décrites précédemment (1, 6). Rappelons que nous abrégeons la formule de l'*ortho*-tolidine en NH_2RNH_2 et celle de sa forme oxydée en NHRNH.

Les concentrations totales en chlorite de sodium seront désignée par $[NaClO_2]$ et celles des espèces effectivement présentés en solution par $[HClO_2]$ et $[ClO_2^-]$. On a donc:

$$[HClO_2] = \frac{[H^+]}{[H^+] + K_a}[NaClO_2]$$

À 25°C et pour $I = 1\ M$, $K_a = 2{,}4 \times 10^{-2}$ (7).

Caractéristiques de la réaction chlorite–bromure

Les figures 1–3 montrent des courbes caractéristiques de la formation de ClO_2 dans des mélanges acides de chlorite et de bromure. On y voit la contribution de deux groupes de réactions: (*1*) La dismutation du chlorite que nous avons étudiée antérieurement (8). Elle résulte d'une réaction catalysée par les traces de fer inévitablement présentes dans les réactifs et d'une réaction radicalaire d'ordre deux par rapport au chlorite. (*2*) La réaction due au bromure et comportant une période d'induction suivie d'une période d'allure autocatalytique. Ses principales caractéristiques sont les suivantes.

Assez curieusement, l'augmentation de la concentration du chlorite allonge la période d'induction (figure 1). Une augmentation de la concentration initiale en Br^- diminue ou augmente la période d'induction suivant que la concentration en chlorite est grande ou petite (figures 2 et 3).

Si on remplace le bromure par du brome on obtient le même genre de courbes mais la période d'induction est plus courte (figure 3, courbe 4). Si on remplace le brome par du HBrO la période d'induction est supprimée.

Si $[Br^-]_0 = 10^{-4}\ M$ la réaction se termine par consommation totale du chlorite et la stoéchiométrie correspond approximativement à [3].

[3] $\quad 4\ HClO_2 \rightarrow 2\ ClO_2 + ClO_3^- + Cl^- + 2\ H^+ + H_2O$

Par contre si $[Br^-]_0 = 10^{-6}\ M$ le type de comportement dépend de la concentration du chlorite. Si elle est grande la réaction autocatalytique ne démarre jamais et on n'observe que la dismutation du chlorite. Si elle est faible la réaction autocatalytique démarre très vite mais s'arrête alors qu'il reste du chlorite. Dans le cas de la courbe 3 de la figure 3 on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

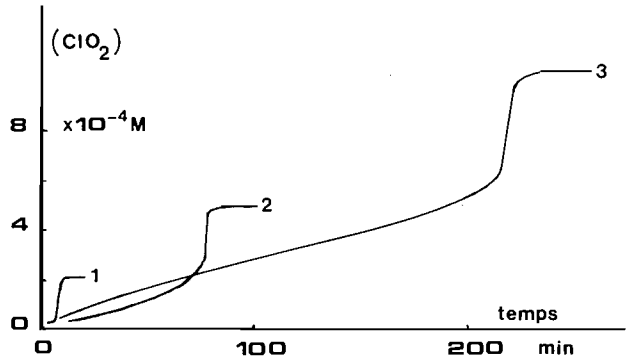

FIG. 1. La réaction chlorite–bromure : effet du chlorite. $[HClO_4] = 1\ M$; $[Br^-]_0 = 4 \times 10^{-6}\ M$; $[NaClO_2]_0 = 4{,}7 \times 10^{-4}$ (1), $9{,}4 \times 10^{-4}$ (2), $1{,}88 \times 10^{-3}\ M$ (3).

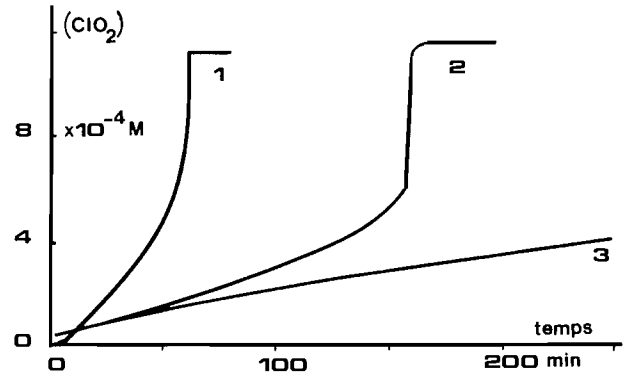

FIG. 2. La réaction chlorite–bromure : effet du bromure si $[NaClO_2]_0 = 1{,}88 \times 10^{-3}\ M$, $[HClO_4] = 1\ M$; $[Br^-]_0 = 10^{-4}$ (1), 10^{-5} (2), $10^{-6}\ M$ (3).

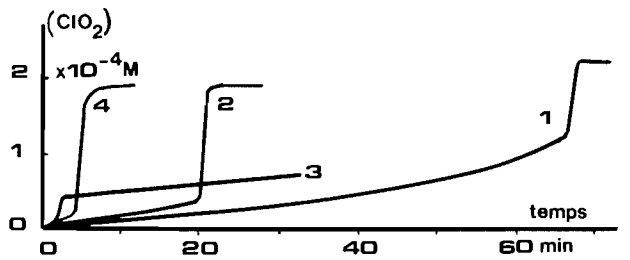

FIG. 3. La réaction chlorite–bromure : effet du bromure si $[NaClO_2]_0 = 4{,}7 \times 10^{-4}\ M$. $[HClO_4] = 1\ M$; $[Br^-]_0 = 10^{-4}$ (1), 10^{-5} (2), $10^{-6}\ M$ (3), $[Br_2] = 10^{-5}\ M$ (4).

n'a consommé que le quart du chlorite initial. Une addition de bromure fait alors redémarrer la réaction autocatalytique après une nouvelle période d'induction. Ces différents faits conduisent aux conclusions suivantes.

Des concentrations élevées en chlorite ont un effet inhibiteur sur la réaction autocatalytique.

La catalyse ne résulte pas directement du bromure et la période d'induction correspond à son oxydation en HBrO.

L'arrêt de la réaction alors qu'il reste du chlorite (figure 3) ne peut résulter que d'une oxydation totale du Br^- sous une forme inactive. Nous en déduisons qu'il est oxydé en BrO_3^-.

En milieux acides 0,1 *M* on peut également observer la réaction autocatalytique mais pour des concentrations en bromure plus élevées. Il se forme alors des quantités non négligeables de brome dont le spectre (λ_{max} = 390 nm) se superpose à celui du ClO_2 (λ_{max} = 360 nm) et il devient très difficile d'interpréter les mesures d'absorbances.

L'article de Simoyi (5) consacré à cette réaction devrait être oublié. Dans ses équations et ses calculs il confond concentrations analytiques et particulaires (avec nos notations $[NaClO_2]$ et $[ClO_2^-]$), le chlorite utilisé contenait 13% d'impuretés et surtout la stoéchiométrie n'est pas celle qu'il indique. On ne peut rien déduire de ses mesures d'absorbances. Nous avons relevé des spectres au cours de la réaction dans les conditions de sa figure 1. Ceux-ci montrent une contribution très importante du ClO_2 à 390 nm, longueur d'onde de mesures qu'il attribue au Br_2.

Étude en présence d'*ortho*-tolidine

Dans les conditions ci-dessus, il n'est pas possible d'étudier la réaction [4] :

[4] $\quad HClO_2 + Br^- + H^+ \rightarrow HClO + HBrO$

En milieux acides 1 *M* elle est masquée par la dismutation du chlorite et (ou) par la réaction autocatalytique. Diminuer l'acidité ne résoud rien car la vitesse de dismutation du chlorite augmente (8). Enfin en milieux moins acides et riches en bromure les absorbances mesurées résultent à la fois du ClO_2 et du brome.

Cette étude est par contre possible en présence d'*ortho*-tolidine. La réaction autocatalytique est supprimée et la dismutation du chlorite peut être très simplement prise en compte. La figure 4 montre qu'aux faibles conversions (inférieures à quelques pourcents), on obtient des droites dont les pentes donnent les *vitesses initiales* d'oxydation de l'*ortho*-tolidine. Nous verrons qu'elles correspondent à une somme de deux termes, l'un du à la réaction catalysée par le fer, l'autre du à la réaction [4].

D'après ce qu'on sait des réactions chlorite–chlorure et chlorite–iodure, le point de départ de la réaction autocatalytique doit être [5]. En présence d'*ortho*-tolidine cette réaction est en compétition avec [6].

[5] $\quad HClO_2 + HBrO \rightarrow BrClO_2 + H_2O$

[6] $\quad NH_2RNH_2 + HBrO \rightarrow NHRNH + Br^- + H^+ + H_2O$

Nous avons vu (1) que le HClO réagit plus rapidement avec l'*ortho*-tolidine qu'avec le chlorite. Les résultats du tableau 1 montrent qu'il en est de même du HBrO. Si on ajoute une solution de Br_2 ou de HBrO (obtenue par réaction du brome avec des ions Ag^+) à une solution acide d'*ortho*-tolidine on obtient la réaction [6], ou son homologue pour le brome. La production de NHRNH est la même que la solution d'*ortho*-tolidine contienne ou non du chlorite : le HBrO ne réagit que suivant [6] et la réaction autocatalytique est supprimée. Cette réaction apparaît par contre si on mélange le chlorite et le HBrO avant d'ajouter l'*ortho*-tolidine. La dernière ligne du tableau 1 montre que la production de NHRNH est alors nettement plus grande.

Résultats de l'étude cinétique

*Effet de l'*ortho-*tolidine*

La suppression des réactions indésirées par l'*ortho*-tolidine n'est effective que si sa concentration est suffisante. Nous avons toujours vérifié que nos vitesses sont indépendantes de cette concentration. Si $[HClO_4] = 1\ M$ et $[NaClO_2] = 5 \times 10^{-4}\ M$ cette condition est satisfaite dès $[NH_2RNH_2] = 2 \times 10^{-4}\ M$. La valeur minimale à réaliser augmente si la concentration du chlorite augmente et si l'acidité diminue.

Effet de la force ionique

Dans l'acide perchlorique 0,1 *M* les vitesses diminuent d'un facteur 1,2 si la force ionique *I* varie de 0,1 à 0,2 *M*. Entre 0,4 et

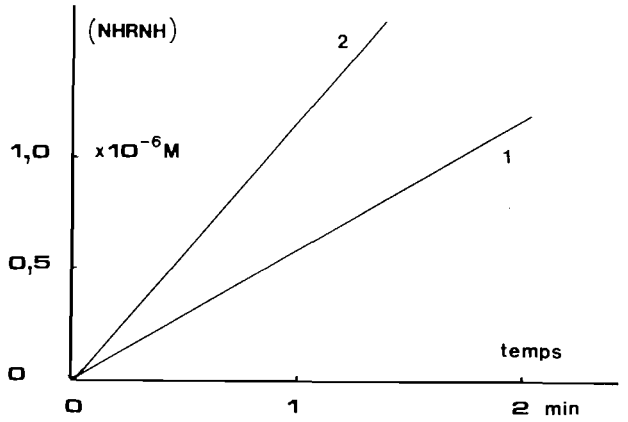

FIG. 4. La réaction chlorite–bromure en présence d'*ortho*-tolidine. $[HClO_4] = 1{,}01\ M$; $[NH_2RNH_2] = 5 \times 10^{-4}\ M$; $[NaClO_2] = 5{,}5 \times 10^{-4}\ M$; $[Br^-] = 10^{-4}$ (1), $7 \times 10^{-4}\ M$ (2).

TABLEAU 1. Oxydation de l'*ortho*-tolidine par HBrO ou Br_2 en présence de chlorite

$[NaClO_2]$ $10^{-4}\ M$	$[HBrO]_0$ $10^{-5}\ M$	[NHRNH] $10^{-5}\ M$
0	2(a)	1,93
5,5	2(a)	1,96
5,5	4(a)	3,84
0	2(b)	1,97
1,1	2(b)	1,92
1,1	2(c)	4,75

$[HClO_4] = 0{,}101\ M$; $[NH_2RNH_2]_0 = 10^{-4}\ M$. Ordre de mélange : acide, *ortho*-tolidine, chlorite, Br_2 (a) ou HBrO (b). Contre-épreuve : acide, chlorite, HBrO, *ortho*-tolidine (c).

1 *M* elles ne dépendent quasi pas de *I*. Toutes nos mesures ont été faites avec $I = 1\ M$, ajustée au besoin par du perchlorate de sodium.

Loi cinétique

La figure 4 donne un exemple de mesures des vitesses initiales d'oxydation de l'*ortho*-tolidine. Ces vitesses varient linéairement en fonction de la concentration du bromure comme le montre la figure 5.

$$\frac{d[NHRNH]}{dt} = k'[Br^-] + k''$$

Le tableau 2 donne les valeurs de k' obtenues. Elles sont proportionnelles aux concentrations $[HClO_2]$ et $[H^+]$. k'' est dû à la réaction catalysée par le fer (9). On en déduit la loi cinétique [7].

$$[7] \qquad \frac{d[NHRNH]}{dt} = k_7[HClO_2][H^+][Br^-] + r_{Fe}$$

Quelques séries de mesures ont été faites en présence d'EDTA, ce qui réduit notablement le terme r_{Fe}(9). Les valeurs de k_7 sont en parfait accord avec celles obtenues sans EDTA.

Dans l'acide 0,1 *M*, si la concentration de l'*ortho*-tolidine est inférieure à $10^{-3}\ M$ ou si celle du chlorite est supérieure à $10^{-4}\ M$ les vitesses ne sont plus indépendantes de la concentration de l'*ortho*-tolidine, ce qui explique les valeurs trop élevées du tableau 2. D'autre part si $[NH_2RNH_2]$ est supérieur à $10^{-3}\ M$ la dégradation de l'*ortho*-tolidine oxydée risque de ne plus être négligeable. Ceci limite le domaine d'acidités et de concentrations en chlorite des mesures.

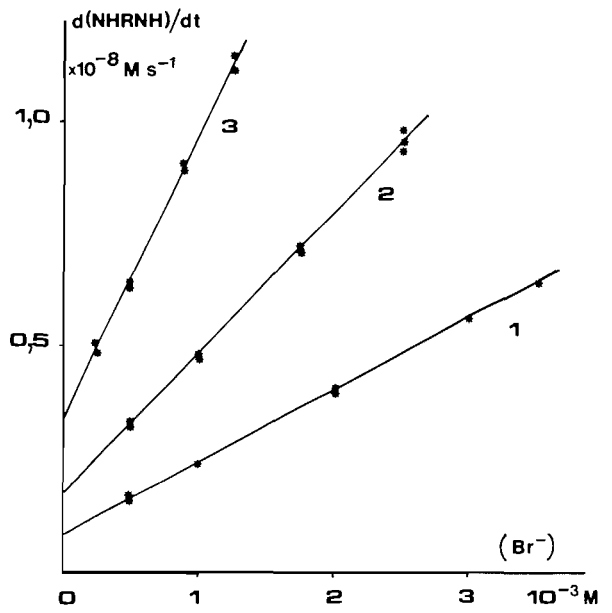

FIG. 5. Effet du bromure sur les vitesses initiales. $[HClO_4] = 1{,}01\ M$; $[NH_2RNH_2] = 5 \times 10^{-4}\ M$; $[NaClO_2] = 5{,}5 \times 10^{-5}$ (1), $1{,}1 \times 10^{-4}$ (2), $2{,}2 \times 10^{-4}\ M$ (3).

TABLEAU 2. Constantes cinétiques

$[HClO_4]$ *M*	$[NaClO_2]$ $10^{-4}\ M$	$[Br^-]$ $10^{-3}\ M$	$10^6\ k'\ s^{-1}$	$10^2\ k_7\ M^{-2}\ s^{-1}$
1,01(a)	0,55	0,5–3,5	1,62	2,99
1,01(a)	1,10	0,5–2,5	3,17	2,92
1,01(a)	2,20	0,2–1,2	6,38	2,94
1,01(a)	5,50	0,1–0,7	16,5	3,04
1,01(b)	0,55	1,0–5,0	1,57	2,90
1,01(b)	5,50	0,2–1,0	16,2	2,99
0,402(a)	0,55	4–16	0,647	3,10
0,402(a)	1,00	10–40	1,09	2,87
0,402(b)	0,55	10–50	0,594	2,85
0,201(a)	1,00	10–40	0,551	3,06
0,101(a)	0,55	10–80	0,147	3,28(c)
0,101(b)	0,275	30–100	0,064	2,85
0,101(b)	0,55	30–100	0,128	2,85
0,101(b)	1,10	10–50	0,288	3,21
0,101(b)	5,50	10–50	1,54	3,43(c)

$[NH_2RNH_2] = 5 \times 10^{-4}$ (a) ou $10^{-3}\ M$ (b). Valeurs (c) trop grandes : cf. texte.

Conclusion

En présence d'*ortho*-tolidine la réaction [4] est suivie de [6] et de son homologue pour le HClO, donnant globalement [8] :

$$[8] \qquad HClO_2 + 2\,NH_2RNH_2 \rightarrow Cl^- + H^+ + 2\,NHRNH + 2\,H_2O$$

L'étape déterminante étant [4] on obtient la loi [7] avec $k_7 = 2\ k_4$. Les valeurs du tableau 2 donnent $k_4 = (1{,}48 \pm 0{,}05) \times 10^{-2}\ M^{-2}\ s^{-1}$ à 25°C et $I = 1\ M$.

En absence d'*ortho*-tolidine le HBrO produit par [4] réagit suivant [5] et on obtient la réaction autocatalytique.

Mécanisme de la réaction autocatalytique

Idées de base

Le mécanisme que nous proposons est basé sur les faits suivants.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

1. Le catalyseur est le HBrO formé pendant la période d'induction.

2. Des concentrations élevées en chlorite inhibent la réaction autocatalytique.

3. Le sens de l'effet du bromure sur la durée de la période d'induction dépend de la concentration du chlorite.

4. La stoéchiométrie de la dismutation du chlorite est approximativement [3].

5. Le bromure et le HBrO peuvent être oxydés en bromate ne catalysant pas la décomposition du chlorite.

Plusieurs variantes de notre modèle nous ont permis de reproduire l'allure des courbes expérimentales et nous avons retenu celle qui nous a donné le meilleur accord avec les valeurs numériques des temps d'induction. Il ne faut pas accorder trop d'importance à ses détails mais bien aux idées générales suivantes, sans lesquelles il ne nous semble pas possible d'expliquer les comportements observés.

Les composés du type X_2O_2 sont des intermédiaires des réactions d'oxydo-réduction des halogènes. Ce ne sont pas des complexes activés mais de véritables composés chimiques pouvant intervenir dans au moins trois types de réactions.

$$XO_3^- + X^- + 2\,H^+ = X_2O_2 + H_2O$$

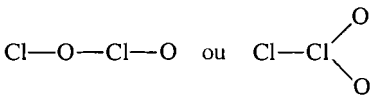
$$X_2O_2 + H_2O = HXO_2 + HXO$$

$$X_2O_2 + X^- = XO_2^- + X_2$$

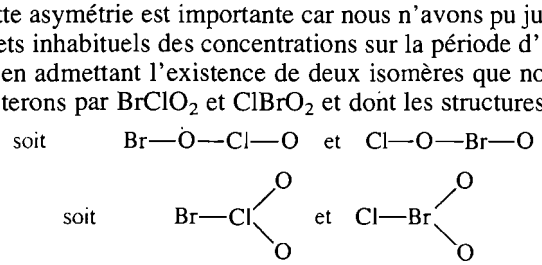
Dans le cas du chlore, il faut ajouter la formation de ClO_2 par réaction avec le chlorite (1).

$$Cl_2O_2 + HClO_2 \rightarrow 2\,ClO_2 + Cl^- + H^+$$

Le Cl_2O_2 est asymétrique (10), sa structure étant



Cette asymétrie est importante car nous n'avons pu justifier les effets inhabituels des concentrations sur la période d'induction qu'en admettant l'existence de deux isomères que nous représenterons par $BrClO_2$ et $ClBrO_2$ et dont les structures sont



La réaction HBrO + $HClO_2$ donne le premier alors que la réaction HClO + $HBrO_2$ donnerait le second.

Composantes du modèle simplifié

1. Dismutation du chlorite

En milieux 1 *M* acides et en l'absence de chlorure, elle résulte principalement d'une réaction radicalaire d'ordre deux (8). Nous ne faisons apparaître dans le modèle que la réaction globale [M1].

[M1] $2\,HClO_2 \rightarrow HClO + ClO_3^- + H^+$

2. Réactions du HClO

Nous savons qu'au cours de la dismutation du chlorite, il réagit suivant $HClO_2 + HClO \rightarrow Cl_2O_2 + H_2O$ et que le Cl_2O_2 peut donner soit du dioxyde de chlore soit du chlorate et du chlorure (1, 8). Dans les conditions étudiées ici le premier est largement prépondérant et on peut simplifier le modèle en n'écrivant que la réaction globale [M2] :

[M2] $2\,HClO_2 + HClO \rightarrow 2\,ClO_2 + Cl^- + H^+ + H_2O$

$$r_{M2} = k_{M2}[HClO_2][HClO]$$

3. Initiation

Sa première étape est la réaction étudiée ci-dessus :

[M3] $HClO_2 + Br^- + H^+ \rightarrow HClO + HBrO$

Le HBrO peut être transformé en Br_2 suivant [M4] :

[M4] $HBrO + Br^- + H^+ \rightleftharpoons Br_2 + H_2O$

Dans certaines variantes du modèle nous avons inclu la réaction $HClO + Br^- \rightarrow HBrO + Cl^-$. Elle n'en modifie guère les propriétés et est négligée ici.

4. Réactions de $BrClO_2$

Une des bases de notre modèle est sa formation suivant [M5] :

[M5] $HBrO + HClO_2 \rightleftharpoons BrClO_2 + H_2O$

Outre la réaction inverse et l'isomérisation [M6], plusieurs réactions de consommation peuvent être envisagées. L'effet du chlorite sur la période d'induction suggère que la principale soit [M7], la somme [M5] + [M7] donnant la réduction du HBrO en Br^-.

[M6] $BrClO_2 \rightarrow ClBrO_2$

[M7] $BrClO_2 + HClO_2 \rightarrow 2\,ClO_2 + Br^- + H^+$

5. Réactions du $ClBrO_2$

Cet intermédiaire formé par [M6] peut réagir suivant [M8], [M9] et [M10], analogues de réactions connues d'autres intermédiaires du type X_2O_2.

[M8] $ClBrO_2 + H_2O \rightarrow BrO_3^- + Cl^- + 2\,H^+$

[M9] $ClBrO_2 + Br^- + H^+ \rightarrow BrCl + HBrO_2$

[M10] $ClBrO_2 + HClO_2 \rightarrow BrO_2 + ClO_2 + Cl^- + H^+$

La réaction [M8] explique l'oxydation du catalyseur sous une forme inactive lorsque [Br^-] et [$HClO_2$] sont petits. La réaction [M9] est suivie de [M11] et [M12] :

[M11] $BrCl + H_2O \rightleftharpoons HBrO + Cl^- + H^+$

[M12] $HBrO_2 + HClO_2 \rightarrow HBrO + ClO_3^- + H^+$

La somme [M5] + [M6] + [M9] + [M11] + [M12] donne l'oxydation autocatalytique du Br^- en HBrO. Le BrO_2 formé par [M10] peut réagir suivant [M13] et [M14] :

[M13] $BrO_2 + HClO_2 \rightarrow ClO_2 + HBrO_2$

[M14] $BrO_2 + ClO_2 + H_2O \rightarrow ClO_3^- + H^+ + HBrO_2$

La somme [M5] + [M6] + [M10] + [M13] + [M12] donne la décomposition du chlorite suivant la stoéchiométrie [3] catalysée par le HBrO.

D'autres réactions possibles ont été négligées car elles ne faisaient que compliquer le modèle sans en modifier les propriétés, par exemple $HBrO_2 + Br^- + H^+ \rightarrow 2\,HBrO$. Nous avons également négligé les réactions du bromate, sa concentration étant toujours très faible.

6. Valeurs des constantes cinétiques

Les valeurs suivantes sont connues :

$$k_{M1} = 5{,}1 \times 10^{-3}\ M^{-1}\ s^{-1}\ (8)$$

$$k_{M3} = 1{,}48 \times 10^{-2}\ M^{-2}\ s^{-1}\ \text{(ci-dessus)}$$

$$k_{-M4} = 110\ s^{-1}\ (11)$$

$$k_{M4}/k_{-M4} = 10^8\ M^{-2}\ (\text{estimé pour } I = 1\ M)$$

$$k_{M13}/k_{M14} = 3{,}1\ (12)$$

Il semble qu'il reste un grand nombre de constantes à ajuster.

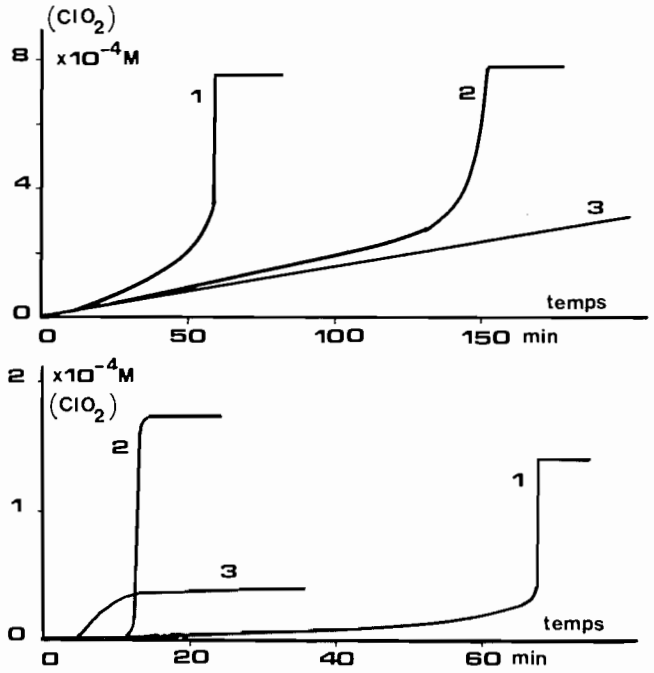


FIG. 6. Productions de ClO_2 prévues par le modèle cinétique dans les conditions des expériences des figures 2 et 3.

En fait ce nombre se réduit notablement si l'on impose que les concentrations de divers intermédiaires soient négligeables. Par exemple la valeur de k_{M2} n'est pas connue mais est certainement assez grande pour que le HClO ne s'accumule pas dans le système. Nous avons constaté que si cette condition est respectée, le choix de k_{M2} n'a aucun effet sur les consommations de $HClO_2$ et les productions de ClO_2 calculées par intégration des équations associées à notre modèle.

Cette simplification du comportement des solutions des équations différentielles est à rapprocher de l'approximation classique de la quasi-stationnarité. Considérons le cas des réactions du $ClBrO_2$. Si k_{M6} et k_{M7} sont suffisamment grands pour que $[ClBrO_2]$ soit négligeable, la valeur calculée de cette concentration est quasi-égale à celle donnée par

$$r_{M6} + r_{M7} = r_{M5}$$

Comme

$$\frac{r_{M7}}{r_{M6}} = \frac{k_{M7}}{k_{M6}}[HClO_2]$$

on voit que r_{M6} et r_{M7} ne dépendent plus des valeurs individuelles de k_{M7} et k_{M6} mais seulement de leur rapport.

Compte tenu des valeurs connues et du fait que les concentrations de HClO, $BrClO_2$, $ClBrO_2$, BrCl, $HBrO_2$ et BrO_2 sont stoéchiométriquement négligeables, il ne reste que quatre paramètres à choisir. Nous avons pris :

$$k_{M7}/k_{M6} = 500\ M^{-1}$$

$$k_{M5}k_{M6}/k_{-M5} = 3 \times 10^4\ M^{-1}\ s^{-1}$$

$$k_{M9}/k_{M10} = 400\ M^{-1}$$

$$k_{M8}/k_{M10} = 2 \times 10^{-5}\ M$$

7. Résultats

Le système d'équations différentielles associé au modèle ci-dessus a été intégré par une méthode de Gear pour les systèmes mal conditionnés. La figure 6 montre que l'accord avec les courbes expérimentales est excellent. En particulier on obtient bien une inversion du sens de l'effet du bromure sur la période d'induction pour une variation de la concentration du chlorite d'un facteur 4 seulement. Seule l'hypothèse de l'existence des deux isomères $ClBrO_2$ et $BrClO_2$ nous a permis de rendre compte de ce fait. Les détails du modèle ne pourront être précisés que quand on connaîtra mieux les réactions de $HBrO_2$ et BrO_2.

The fungus *Mortierella isabellina* can convert ethylbenzene and a number of *para*-substituted derivatives to the corresponding optically active 1-phenylethanols with enantiomeric excesses between 5 and 40% and chemical yields up to 45%. 2-Ethylnaphthalene, 2-ethylthiophene, and *n*-propylbenzene were similarly converted, as were the bicyclic compounds indane and tetralin. In most cases, the *R* absolute configuration of product predominated. The fungi *Cunninghamella echinulata* var. *elegans* and *Helminthosporium* species are also capable of performing some of these transformations. *M. isabellina* and *C. elegans* also produce 2-phenylethanols as products in some cases. The highest enantiomeric excesses during benzylic hydroxylation were obtained with *Helminthosporium* and are attributable, at least in part, to further stereoselective oxidation of the alcohol. Cross induction experiments with *M. isabellina* indicate that the same enzyme may be responsible for the benzylic hydroxylation of ethylbenzene, 2-ethylthiophene, and 2-ethylnaphthalene.

HERBERT L. HOLLAND, ELEANOR J. BERGEN, P. CHINNA CHENCHAIAH, SHAHEER H. KHAN, BENITO MUNOZ, RONALD W. NINNISS et DENISE RICHARDS. Can. J. Chem. **65**, 502 (1987).

Le champignon *Mortierella isabellina* peut transformer l'éthylbenzène et un certain nombre de ses dérivés comportant un substituant en position *para* en des phényl-1 éthanols optiquement actifs, avec des excès énantiomériques variant de 5 à 40% et avec des rendements chimiques allant jusqu'à 45%. On peut aussi transformer de la même manière l'éthyl-2 naphtalène, l'éthyl-2 thiophène, le *n*-propylbenzène ainsi que des composés bicycliques comme l'indane et la tétraline. Dans la plupart des cas, on obtient préférentiellement le produit possédant la configuration absolue *R*. Les champignons des espèces *Cunninghamella echinulata* var. *elegans* et *Helminthosporium* sont aussi capables d'effectuer les mêmes transformations. Dans quelques cas, les champignons *M. isabellina* et *C. elegans* produisent en plus des phényl-2 éthanols. Lors des hydroxylations benzyliques, les excès énantiomériques les plus élevés ont été obtenus avec le *Helminthosporium* et ces résultats sont probablement dus, au moins en partie, à une oxydation subséquente sélective de l'alcool. Des expériences d'induction croisée impliquant le *M. isabellina* indiquent que le même enzyme peut être responsable de l'hydroxylation benzylique de l'éthylbenzène, de l'éthyl-2 thiophène et de l'éthyl-2 naphtalène.

[Traduit par la revue]

Ethylbenzene, an intermediate in the manufacture of styrene, is among the highest volume organic chemicals in production, the U.S. annual output alone exceeding 2 billion kilograms. In view of its importance as an industrial chemical, ethylbenzene is a prime candidate for metabolic study. Nevertheless, data on the products of its mammalian metabolism are not extensive, being limited to reports of conversion to racemic 1-phenylethanol by rabbits (1), to predominantly *R*(+)-1-phenylethanol (ee's 33–80%) by rat liver enzymes (2–4), and to 1-phenylethanol of unspecified stereochemistry (as the first formed of a series of oxidative metabolites) in the live rat (5).

In view of the structural similarity between ethylbenzene and thioanisole, we decided to investigate the biotransformation of the former by fungi (*Mortierella isabellina* and *Helminthosporium* species) that are efficient oxidizers at the sulphur atom of thioanisole (6). The fungus *Cunninghamella echinulata* var. *elegans* was also studied, its use being suggested by the observation that it is capable of benzylic hydroxylation of methyl-substituted aromatic compounds (7). Our aim was twofold: firstly, to identify fungal systems capable of the production of benzylic alcohols directly from hydrocarbons in an asymmetric manner and, secondly, to investigate the fungal biotransformation as a model for the first step in the mammalian metabolic pathway.

There have been no reports of the fungal oxidative metabolism of ethyl benzene other than our preliminary communication (8). Studies of its bacterial metabolism have shown that oxidation occurs in the ring (9) or at the side chain terminus (10), depending on the strain of bacteria and the growth conditions. Of the substrates used in this study, only tetralin (**31**) has been previously studied as a substrate for fungal metabolism, being converted to α-tetralol (**31***a*) (of unspecified stereochemistry) and α-tetralone (**32**) by *Aspergillus niger* (11).

The results of the fungal incubations are listed in Table 1. The yields quoted are those of isolated, purified material. Absolute configurations were assigned using optical rotation data (Table 2) by comparison with literature values for compounds of known configuration (ref. 12, and references listed in Table 2). In the case of *M. isabellina*, the predominant absolute stereochemistry of hydroxylation of **1**–**4**, **6**, **8**, and **9** is the same as that observed for sulphoxidation of the analogous thioanisole derivative by this fungus (13). In two cases, **5** and **7**, however, products of opposite predominant stereochemistry were obtained. The reason for this is not clear, but may be related to the difference in steric requirements of S and $-CH_2-$, and to differences in the ways in which the reaction intermediates are influenced by the nature of the *para* substituent. The formation of 2-phenylethanols (**35**–**43**) as minor products was also observed in a number of cases.

Incubation of **1** with *M. isabellina* in the presence of the protein synthesis inhibitor cycloheximide does not lead to the production of **1***a*, indicating that the enzyme that normally carries out this transformation is inducible. By using thioanisole as an enzyme inducer during the growth period, and then subsequently performing the incubation of **1** in the presence of cycloheximide, a normal yield and stereochemistry of product was obtained. Similarly, ethylbenzene is capable of inducing an enzyme that can subsequently oxidize thioanisole in the

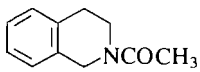
46



47

normal way (13). Cycloheximide also prevents the oxidation of thioanisole, 2-ethylthiophene, and 2-ethylnaphthalene by non-induced cells of *M. isabellina*. Successful cross-induction experiments, as described above for ethylbenzene/thioanisole, were also carried out with 2-ethylthiophene/thioanisole and 2-ethylnaphthalene/thioanisole combinations of inducer and substrate, suggesting that the same enzyme in *M. isabellina* is responsible for metabolizing all these substrates (14), although the induction of several (closely related) enzymes by a single substrate cannot be entirely excluded from consideration (15). In support of our hypothesis, however, it should be noted that the purified enzyme dopamine β hydroxylase, in addition to its normal function of producing norepinephrine from dopamine by benzylic hydroxylation, is also capable of converting a sulphide analogue of the normal substrate to sulphoxide with the same absolute configuration as the normal product (16).

In view of the stereochemical complications that could arise following possible stereoselective oxidation of the product alcohols and (or) stereoselective reductions of the resulting ketones by dehydrogenase enzymes, a situation that can obscure the mammalian hydroxylation of ethylbenzene (4), we have performed control incubations with *M. isabellina* using both enantiomers of 1-phenylethanol as substrate (see Table 1). In both cases, substrate was recovered whose absolute stereochemistry was unchanged. In the two cases in which ketones were incubated with *M. isabellina* (**14** and **32**), reduction occurs according to Prelog's rule (17) to give alcohol of predominantly *S* configuration.

The other two fungi used in this study, however, both gave acetophenone (**14**) in addition to 1-phenylethanol as product from ethylbenzene, suggesting that further oxidation of alcohol had occurred. Incubation of racemic α-tetralol (**31***a*) with *H.* species gave recovered substrate highly enriched in the *R* isomer, together with α-tetralone (**32**), and high enantiomeric excesses (e.e.'s) were observed for multiple oxidation products (e.g. **45**) of *p*-diethylbenzene with *C. echinulata*. These data suggest that these latter two microorganisms are capable of the stereoselective oxidation of secondary alcohols of *S* configuration (in accord with Prelog's rules) and that the relatively high enantiomeric excesses observed for monohydroxylated products such as **1***a* and **31***a* from *H.* species may be due in part to selective removal of the *S* enantiomer by its conversion to ketone. Transformations of α-tetralone (**32**) by *C. elegans* (a subspecies of *C. echinulata*) are reported not to involve carbonyl reduction (18). In the case of *M. isabellina* the absence of further oxidation products and the data presented above suggest, however, that benzylic alcohols, once produced, are configurationally stable under the conditions of the incubation. This is also confirmed by the results from the incubation of α,α-dideuteroethylbenzene, which will be presented at a later date.

One unexpected feature of our data is the absolute stereochemistry of benzylic hydroxylation by *H.* species. This fungus produces the opposite absolute stereochemistry of benzylic sulphoxide from that given by *M. isabellina* with the same substrate (6), but the same absolute stereochemistry of benzylic hydroxylation (Table 1). There is no doubt that our observations are the results of enzymic reactions, and cannot be attributed to autoxidation in a chiral environment; incubations performed with autoclaved fungus (inactivated enzymes) showed no evidence of 1-phenylethanol or α-tetralol formation from the corresponding substrate. We have considered the possibility that the observed enantiomeric enrichments may be the result of unequal transformation of the substrate by two different enzymes, each of which gives the opposite predominant stereochemistry of product, but have found that the enantiomeric excess in the conversion of **1** to **1***a* by *M. isabellina* is independent of temperature over the range 18–30°C, and also independent of substrate concentration over the range 0.3–1.0 mg/mL, ranges over which it is unlikely that two different enzymes would exhibit the same K_m and temperature dependence.

The range of substrates listed in Table 1 includes two whose bacterial metabolism has been reported (**12**, ref. 19), (**23**, ref. 20), but which were not metabolized by the fungi examined in this study. 1-Phenylethyl chloride (**13**) was incubated for control purposes in connection with future studies with deuterium labelled ethylbenzene, for which it is a synthetic precursor. The amines **10** and **33** were both acetylated at nitrogen during incubation, the corresponding amides being inert to further biotransformation. Cumene (**15**) gave a high yield of the benzylic alcohol with *M. isabellina*, which may be due, at least in part, to the ready autoxidation of this substrate. Although *n*-propylbenzene (**16**) gave a moderate yield of benzylic alcohol with *M. isabellina*, *n*-butylbenzene (**17**) gave a complex mixture of isomeric alcohols.

Fungal biotransformation of pyrrole (e.g. **18**) and furan (e.g. **20**) derivatives has not been reported, although furan rings are known to be degraded by several bacteria (21). Transformation of neither 2-ethylpyrrole (**18**) nor 2-ethylfuran (**20**) was observed in the present study, although 2-ethylthiophene (**19**) was hydroxylated. Previous reports of the fungal transformation of thiophene derivatives have been limited to carbonyl reduction (22) and S oxidation (23).

Phenylacetylene (**25**) and styrene (**24**) were studied in view of the reported oxidation of these substrates (to phenylacetic acid and styrene oxide, respectively) by hydroxylating enzymes (24), but neither was transformed by *M. isabellina*. Although *ortho*-diethylbenzene was not hydroxylated by the fungi used in this study, the bicyclic compounds indane (**30**) and tetralin (**31**) were, the former process serving as a comparison to the mammalian metabolism of indene (25). Although fungi are

[a] ^{1}Hnmr analysis indicated to be a complex mixture of mono-alcohols; further analysis was not undertaken.

capable of hydroxylating substituted tetrahydroisoquinolines (usually at methoxyl carbon) (26), neither of the simple tetrahydroisoquinolines **33** or **34** was hydroxylated in the present study.

The enzymes involved in the hydroxylations listed in Table 1 are almost certainly monooxygenases. We have previously shown that the enzyme in *M. isabellina* that performs sulphoxidation of thioanisole has some of the properties of this class of enzymes (27), which are common in fungi (28) and are characterized by their ability to hydroxylate unactivated hydrocarbon functionality (29). It is thought that these enzymes operate by allowing an activated oxygen species to react with a substrate radical intermediate (eq. [1]) (ref. 30, and references therein). Enzymes of this type also oxidize aromatic rings, via arene oxides, to give phenols, a reaction that fungi can perform

[1] 
efficiently on halo-substituted aromatics (31), but no evidence for phenol formation was found during the present study.

The stereochemistry of product formation is presumably controlled by the interaction between a benzylic radical intermediate and the oxygenating species (eq. [1]). However, with a single fungus (e.g. *M. isabellina*) it appears to be largely independent of the size of the substituents (cf. **1** vs. **16** and **1** vs.

[a]The "a" suffix on the arabic numeral from Table 1 is used to denote the corresponding benzylic alcohol.

19 vs. **22**) provided that they are acceptable by the enzyme, and does not exhibit the dependence upon the electronic nature of the *para* substituent (for the range **1**–**9**) shown by the stereochemistry of sulphoxides produced enzymically from the corresponding *para*-substituted thioanisoles (13). This lack of apparent correlation between ee and the size of substituent, its electronic properties (e.g. Hammett σ), or substrate polarity parameters such as the Hansch π lipophilicity term (32), precludes meaningful discussion on the magnitude of ee produced by fungal metabolism of these substrates. The observed predominance of benzylic hydroxylation with *R* absolute stereochemistry, however, may be of predictive value. A more detailed study of the hydroxylations of **1**, **3**, **30**, and **31**, using isotopically labelled substrates, is nearing completion and will be published in the near future.

Experimental

Apparatus, materials, and methods

Melting points (uncorrected) were determined on a Kofler heating stage. Infrared spectra were recorded with an Analect 6260FX spectrometer. Proton nmr spectra were recorded at 80 MHz with a Bruker WP80CW or at 200 MHz with a AC200 spectrometer, using $CDCl_3$ as solvent and TMS as internal standard. Enantiomeric ratios were determined in CCl_4 in the presence of tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato] europium(III). Mass spectra were obtained with an AEI MS30/Kratos DS55 system. Thin-layer chromatography was performed on Merck silica gel 60 F-254 and flash column chromatography on silica gel (230–400 mesh, Merck 9385). Optical rotations were determined with a Perkin–Elmer 241MC polarimeter (at McMaster University), or with a Rudolph Autopol-III polarimeter.

Maintenance of microorganisms

Mortierella isabellina NRRL 1757 was maintained on malt agar slopes. *Helminthosporium* species NRRL 4671 was maintained on V-8 juice agar slopes (ATCC medium 343), and *Cunninghamella echinulata* var. *elegans* ATCC 26269 on potato dextrose agar slopes.

Preparation of substrates

With the exception of *N*-carbomethoxy-1,2,3,4-tetrahydroisoquinoline (**34**) all the compounds used in this study were commercial samples. Their purity was checked by nmr and gc analysis, particularly for those samples (e.g. **31**) that can undergo autoxidation. Where necessary, samples were redistilled before use. Compound **34** was prepared by treatment of 1,2,3,4-tetrahydroisoquinoline (**33**) with methyl chloroformate in pyridine solution in the normal way, and gave satisfactory spectral data.

Incubations with fungi

These are summarized in Table 1. *Mortierella isabellina* NRRL 1757 was grown as previously described (27). After 3 days growth at 28°C, incubations were carried out in distilled water at substrate concentrations of 1 mg/mL in closely stoppered 1-L Erlenmeyer flasks for 72 h at 25°C. Products were isolated from the incubation medium by continuous extraction (4 days) with CH_2Cl_2, following removal of the fungus by filtration. The crude extracts were examined by tlc and submitted to flash chromatography using a benzene–ether 10% step gradient. The yields and ee values quoted in Table 1 refer to purified, isolated material, and arise from the combination of homogeneous column fractions without further purification (e.g. crystallization) that could lead to alteration of stereochemical enrichment values. In most cases, the volatility of starting material precluded its recovery after solvent evaporation, but in all cases the presence of starting material at the end of the incubation period was evident by its aroma. *Helminthosporium* species NRRL 4671 was grown in a medium consisting of V-8 juice (200 mL) and calcium carbonate (3 g), in distilled water (1 L), adjusted to pH 7.2, and *Cunninghamella echinulata* ATCC 26269 in a commercially prepared medium of Sabouraud dextrose broth (Difco). Subsequent incubations and product isolations were carried out exactly as described above.

Isolation and structure determination of products

Following chromatography as described above, products were identified by ^1H nmr, mass spectral, infrared, and optical rotation analysis. Spectral assignments were straightforward and unambiguous in all cases. Optical rotation values are listed in Table 2. Measured values were obtained in EtOH or $CHCl_3$ as appropriate. A typical procedure is outlined in full below.

Incubation of p-*diethylbenzene with* C. echinulata

para-Diethylbenzene (1.5 g) in ethanol (30 mL, 95%) was distri-

For personal use only.

buted over 15 1-L Erlenmeyer flasks, each containing a 3-day growth of *C. echinulata* suspended in distilled water (150 mL). The stoppered flasks were maintained on a rotary incubator (150 rpm) at 25°C for 72 h, and the contents filtered through a Buchner funnel. The filtrate was continuously extracted with CH_2Cl_2 for 96 h, and the extract evaporated to yield a residue (0.7 g). Chromatography of this residue gave, in order of elution: 1-(4′-ethylphenyl)ethanol, **3***a* (0.18 g), oil; ^{1}H nmr (δ): 1.25 (3H, t), 1.38 (3H, d), 2.6 (2H, q), 4.75 (1H, q), and 7.25 (2H, ABq) ppm; 2-(4′-ethylphenyl)ethanol, **36** (0.15 g), oil; ^{1}H nmr (δ): 1.3 (3H, t), 2.5–2.9 (total 4H, superimposed t+q), 3.75 (2H, t), and 7.2 (4H, s) ppm; 1-(4′-acetylphenyl)ethanol, **45** (0.04 g), oil; ^{1}H nmr (δ): 1.4 (3H, d), 2.6 (3H, s), 4.8 (1H, q), 7.4 and 7.8 (4H, ABq) ppm; 2-(4′-acetylphenyl)ethanol, **43** (0.015 g); ^{1}H nmr (δ): 2.6 (3H, s), 2.8 (2H, t), 3.8 (2H, t), 7.4 and 7.8 (4H, ABq) ppm; 1-[4′-(1″-hydroxyethyl)phenyl]ethanol, **46** (0.06 g), mp 92–94°C (lit. (39) mp 90–91°C or 114–115°C); ^{1}H nmr (δ): 1.45 (6H, d), 4.75 (2H, q), and 7.25 (4H, s) ppm; 1-[4′-(2″-hydroxyethyl)phenyl]ethanol, **41** (0.15 g), mp 78–81°C; ^{1}H nmr (δ): 1.45 (3H, d), 2.8 (2H, t), 3.8 (2H, t), 4.8 (1H, q), and 7.25 (4H, ABq) ppm; 2-[4′-(2″-hydroxyethyl)phenyl]ethanol, **42** (0.02 g), mp 83–86°C (lit. (40) mp 86°C; ^{1}H nmr (δ): 2.8 (4H, t), 3.75 (4H, t), and 7.2 (4H, s) ppm.

Cross-induction experiments

Induction of enzyme was carried out by the addition of a solution of thioanisole or ethylbenzene (12 mg) in ethanol (95%, 8 mL) to the initial fungal growth medium (1 L). After the normal growth period (see above), the fungus was resuspended in distilled water containing cycloheximide at a concentration of 0.1 mg/mL and subsequent incubations with substrate performed as described above. Experiments without induction of enzyme, but in which *de novo* protein synthesis during the incubation with substrate was stopped, were also carried out in the presence of cycloheximide (0.1 mg/mL).

Determination of enantiomeric ratios

Enantiomeric ratios were determined by observation of the benzylic hydrogen resonances in the presence of sufficient chiral shift reagent (ca. 0.8–1.2 molar equivalent) to cause baseline separation of the enantiomeric signals and a shift of those resonances to ca. 20 ppm. Under these conditions, the aromatic hydrogens *ortho* to the side chain were shifted to ca. 14 ppm, and the enantiomeric signals sufficiently well separated to permit use of these as an additional check on optical purity. In all cases studied, the signals from the *R* enantiomers were downfield for the CHOH pair and upfield for the *ortho*-hydrogen pair. This observation correlated with optical rotation data for the assignment of absolute configuration to the predominant enantiomer.

Reçu le 18 février 1986[2]

JEAN-CLAUDE TOURAY, PATRICK BAILLIF, MARIE-CLAUDE JAURAND, JEAN BIGNON et LAURE MAGNE. Can. J. Chem. **65**, 508 (1987).

L'adsorption d'acide déoxyribonucléique (ADN) sur un échantillon de chrysotile ainsi que sur deux échantillons de chrysophosphate a été étudiée par analyse chimique et par analyse de surface (spectrométrie de photoélectrons, XPS). Le chrysophosphate dérive du chrysotile par un traitement au $POCl_3$ en voie gazeuse; l'un des échantillons de chrysophosphate a été défibré par passage dans un défibreur Pallmann. L'analyse XPS des échantillons, avant traitement par l'ADN, a montré qu'une partie du phosphore fixé à la surface des fibres de chrysophosphate n'était pas stable puisqu'elle était solubilisée lorsque les fibres étaient dispersées dans l'eau distillée. Après traitement par l'ADN, la quantité d'ADN adsorbée par ces fibres était inférieure à celle adsorbée sur les fibres de chrysotile non phosphorylées (12,6 ± 1,7 μg/mg et 74,0 ± 4,0 μg/mg respectivement). L'échantillon défibré avait un comportement intermédiaire ce qui indiquerait qu'une partie des fibres a échappé à la phosphorylation (28,3 ± 5,6 μg/mg). Les résultats indiquent que l'adsorption d'ADN est une méthode sensible pour apprécier l'état de surface des fibres de chrysotile. On peut également formuler l'hypothèse que ce processus de phosphorylation masque ou bloque des sites superficiels, actifs dans l'adsorption d'ADN.

JEAN-CLAUDE TOURAY, PATRICK BAILLIF, MARIE-CLAUDE JAURAND, JEAN BIGNON, and LAURE MAGNE. Can. J. Chem. **65**, 508 (1987).

Deoxyribonucleic acid (DNA) adsorption on one sample of Canadian chrysotile and two samples of chrysophosphate has been studied using chemical analysis and a surface method of analysis (photoelectron spectroscopy, XPS). Chrysophosphate was obtained using a phosphorylation process applied to chrysotile fibres; one chrysophosphate sample was opened in a Pallmann device. XPS analysis of the samples before DNA adsorption has shown that some surface phosphorus was dissolved following suspension of the fibres in distilled water. After DNA treatment, the amount of DNA adsorbed at the surface of the chrysophosphate sample was lower than that adsorbed at the chrysotile surface (12.6 ± 1.7 μg/mg and 74.0 ± 4.0 μg/mg respectively). In addition, the opened sample adsorbed an intermediary DNA amount (28.3 ± 5.6 μg/mg), suggesting that the phosphorylation process has not reached all the bulk fibres. The results indicate that DNA adsorption is a sensitive method for investigation of the surface state of the fibre. Moreover, it seems that the phosphorylation process masks or blocks the reactive surface sites for DNA adsorption.

Introduction

L'usage commercial des fibres d'amiante fait peu à peu place à celui d'autres matériaux, le plus souvent fibreux, dont le potentiel toxique n'est pas toujours connu. Les données reportées dans la littérature ont montré que, in vitro, la toxicité des fibres d'amiante était caractérisée par une diminution de la viabilité cellulaire (1–4), une altération de la structure des chromosomes (5, 6), et une transformation des cellules (7, 8). Sur le plan physico-chimique, la réactivité de surface des fibres dans les phénomènes d'adsorption a été suggérée comme étant l'un des facteurs responsables de certains effets toxiques. Les fibres d'amiante montrent, en effet, une capacité à adsorber différentes molécules, aussi bien des cancérigènes chimiques exogènes tels que le benzo(*a*)pyrène (9) que des macromolécules endogènes. Bien que non absolue, une relation a pu être trouvée entre la capacité des minéraux à adsorber des membranes synthétiques et leur potentiel cytotoxique (10–12). L'adsorption d'acide déoxyribonucléique (ADN), macromolécule qui contient le matériel génétique, a été reportée par Chang *et al.* (12) qui, de plus, ont mis en évidence une modification de l'activité enzymatique de la DNAse après adsorption sur les fibres de chrysotile. Compte tenu de ces différents travaux, nous avons étudié les propriétés d'adsorption des fibres de chrysophosphate, fibres de chrysotile ayant subi un traitement de phosphorylation en voie gazeuse par $POCl_3$. Les études ont porté sur l'adsorption d'ADN analysée par la méthode de spectrométrie de photoélectrons (XPS) et par l'analyse chimique.

Méthodes

1. Matériel

Les fibres de chrysotile phosphorylé (chrysophosphates 3-4-5 et 3-13-5) et non phosphorylé (4-4-3) ont été fournies par la Société Nationale de l'Amiante, Sherbrooke, Quebec, Canada. La phosphorylation a été obtenue par traitement des fibres à l'oxychlorure de phosphore, $POCl_3$ (17). Un courant de gaz sec (air, azote) est chargé en $POCl_3$, par barbotage dans ce liquide maintenu à une température contrôlée. Le gaz porteur, chargé de $POCl_3$ en quantité variable, selon la température utilisée, est dirigé vers un cylindre rotatif contenant l'amiante à traiter. Un arrangement à contrecourant a été utilisé,

l'amiante arrivant par une extrémité du cylindre et le $POCl_3$ par l'autre. Les échantillons 3-4-5 et 3-13-5 se distinguent par le fait que le second échantillon a été soumis à un défibrage mécanique après phosphorylation (défibreur Pallmann).

2. Caractérisation des échantillons en XPS

Avant traitement par l'ADN, les fibres ont été caractérisées par analyse XPS. Celles-ci ont été mises en suspension dans de l'eau distillée à la température ambiante pendant 5 min, puis filtrées sur membrane Millipore. Une expérience complémentaire de plus longue durée a été réalisée en incubant les fibres à 37°C pendant 6 h dans l'eau distillée.

3. Adsorption d'ADN

Pour le traitement par l'ADN, les fibres ont été dispersées par sonication pendant 10 min (50 kHz, 20 watts); la concentration en fibres était de 2 mg/mL dans une solution de KCl/NaCl 0,145 *M*. L'ADN utilisé provenait de la Société Sigma, Saint Louis, Missouri, U.S.A. (ADN de thymus de veau). Les suspensions de fibres ont été mélangées, volume à volume, avec des solutions d'ADN à des concentrations croissantes. Le mélange était incubé à 37°C pendant 15 min.

Après incubation, le mélange était centrifugé pendant 30 min à 10 000 tours/min (12 000 × *g*) et les fibres lavées 2 fois à l'aide de la solution de KCl/NaCl 0,145 *M*. Pour l'analyse XPS, les fibres étaient recueillies, après lavage, sur un filtre, comme décrit précédemment (13).

4. Méthodes analytiques

Le tracé des isothermes d'adsorption a été effectué, pour des concentrations en ADN croissantes, par détermination de la densité optique, à 255 nm, du surnageant obtenu après centrifugation, et par référence à une courbe d'étalonnage. Les mesures ont été effectuées à l'aide d'un spectrophotomètre Beckman modèle 24 (Beckman Instruments France, Gagny, France).

L'analyse XPS a été réalisée à l'aide d'un spectromètre AEI ES 200. Les pics de photoélectrons Si_{2p} et Mg_{2s} ont été utilisés comme référence pour la matrice silicatée; les pics P_{2p} et Cl_{2p} ont été enregistrés pour mettre en évidence le traitement par $POCl_3$. Enfin, l'ADN a été caractérisé par le pic d'azote N_{1s}. La puissance de radiation (MgKα) était de 240 W. Le temps de balayage du spectre était réduit à 15 min/échantillon afin de minimiser les effets de l'irradiation sur la molécule d'ADN. Le pic N_{1s} caractéristique de la molécule d'ADN est un pic complexe qui présente 2 composantes principales qui ont pu être déterminées par ajustement en utilisant la méthode des moindres carrés à l'aide d'un microordinateur HP 85 (fig. 1).

La spectrométrie XPS, méthode d'analyse basée sur le processus photoélectronique, est quantitative lorsqu'elle est appliquée à une série d'échantillons de même nature. Pour un solide dont l'épaisseur est supérieure à 4 fois le libre parcours moyen (λ) des électrons étudiés, l'intensité du signal XPS est de la forme :

$$I = aFS\sigma C$$

où a = aire de l'échantillon, F = flux des rayons X incidents, S = facteur de transmission de l'analyseur, σ = section efficace de photoionisation, et C = concentration atomique de l'élément considéré.

Résultats et discussion

1. Analyse XPS des échantillons lessivés dans l'eau distillée

Les résultats sont présentés dans le tableau 1 où sont indiquées les intensités des pics XPS ainsi que les intensités normalisées au pic Si_{2p} qui est utilisé habituellement comme référence.

Sur les deux échantillons de chrysophosphate (3-4-5 et 3-13-5), on constate la présence de phosphore (E_l = 134,6 eV, valeur proche d'un phosphate) et de chlore (E_l = 199,2 eV, valeur observée généralement pour un chlorure). L'échantillon 3-4-5 est le plus enrichi en ces deux éléments.

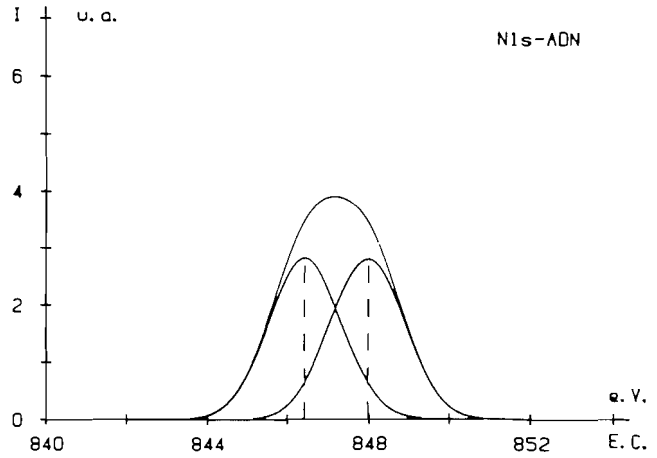

FIG. 1. Spectre N_{1s} de l'ADN. Les 2 composantes ont été déterminées par le calcul comme décrit dans le texte. u.a. : unités arbitraires; e.V. : electron volt; E.C. : Energie Cinétique.

On peut noter que l'intensité du pic Mg_{2s} normalisée au pic de silicium Si_{2p} est, pour l'échantillon 4-4-3, la même avant et après traitement dans l'eau distillée, alors que cette intensité est nettement plus faible, après lavage, pour les 2 chrysophosphates. Pour ces derniers, l'abaissement significatif du rapport Mg_{2s}/Si_{2p} s'accompagne d'une diminution importante des pics P_{2p} et Cl_{2p} ainsi que des rapports P_{2p}/Si_{2p} et Cl_{2p}/Si_{2p} qui sont diminués d'un facteur 4 et 10, respectivement. Cependant, la composition superficielle semble se stabiliser rapidement puisque l'essai 6 h à 37°C fournit des résultats très voisins de ceux obtenus après quelques minutes à la température ambiante.

Les intensités des pics Si_{2p} des échantillons avant traitement par l'ADN sont indiquées dans le tableau 2. On peut remarquer que les valeurs sont voisines pour les trois échantillons étudiés. En outre, les valeurs du rapport Mg_{2s}/Si_{2p} montrent que la surface du chrysophosphate est appauvrie en magnésium et que l'échantillon défibré (3-13-5) présente une composition intermédiaire entre le chrysophosphate non défibré (3-4-5) et le chrysotile témoin (4-4-3). Ces résultats montrent qu'une partie du phosphore fixé à la surface des fibres de chrysophosphate l'est sous forme soluble. Par ailleurs, lors du traitement par $POCl_3$, l'extraction du magnésium sous la forme probable d'un phosphate acide, mobilise essentiellement la couche brucitique externe des fibrilles de chrysotile. Un argument est apporté par la valeur théorique du rapport XPS Mg_{2s}/Si_{2p} pour une fibrille élémentaire entièrement lixiviée sur la première couche. Ce rapport s'établit à 0,69 alors qu'il est de 0,81 pour le chrysotile de référence (13, 14). La valeur 0,63 obtenue pour le chrysophosphate (3-4-5) traité dans l'eau est donc très proche de celle qui caractérise une fibre dont la couche brucitique externe aurait été lessivée.

2. Adsorption d'ADN

2.a. Isothermes d'adsorption : analyse chimique

Les résultats sont exprimés sur la figure 2. L'affinité pour l'ADN est la plus grande pour le chrysotile témoin (4-4-3) pour lequel la quantité d'ADN adsorbée au plateau est 74,0 ± 4,0 μg/mg (n = 6); elle est plus faible pour le chrysophosphate non défibré : 12,6 ± 1,7 μg/mg (n = 6); elle est intermédiaire et moins reproductible pour le chrysophosphate défibré 28,3 ± 5,6 μg/mg (n = 7), ce qui suggère que l'intérieur des fagots de fibrilles a pu échapper au traitement par $POCl_3$. En effet, on

peut admettre que le défibrage Pallmann a, de manière plus ou moins aléatoire, ouvert les fagots de fibrilles, permettant ainsi d'exposer des fibres entières et (ou) des parties de fibres vierges.

2.b. Analyse XPS

Les résultats sont présentés sous la forme de courbes où le rapport N_{1s}/Si_{2p} a été reporté en fonction de la concentration initiale en ADN (fig. 3).

On peut constater, sur la figure 3, qu'il existe une dispersion variable des résultats, faible pour les échantillons 4-4-3 et 3-4-5, et maximale pour l'échantillon de chrysophosphate défibré. Ceci était également observé sur les isothermes (fig. 2). Par ailleurs, l'examen des courbes indique que la valeur au plateau est atteinte très rapidement pour le chrysophosphate alors qu'il faut des concentrations en ADN nettement supérieures dans le cas du chrysotile témoin. Le chrysophosphate défibré présente un comportement intermédiaire entre les deux autres. Toutefois, la comparaison des figures 2 et 3 montre que le rapport des hauteurs des plateaux relatifs aux échantillons 4-4-3 et 3-4-5 est d'environ 6 pour les isothermes d'adsorption alors qu'il est d'environ 3 pour les courbes XPS. Nous n'avons pas d'explication simple de ce fait qui, selon nous, pourrait traduire une différence dans la configuration des molécules adsorbées. Cette hypothèse repose sur un calcul simple qui compare les données de l'analyse XPS et de l'analyse chimique; elle est basée sur les résultats montrant que le chrysophosphate fixait 6 fois moins d'ADN que le chrysotile témoin, alors que le taux de recouvrement ne diminuait pas dans les mêmes proportions.

Si nous faisons l'hypothèse que les macromolécules d'ADN adsorbées à la surface des fibres ont une épaisseur $l > 4\lambda$, le

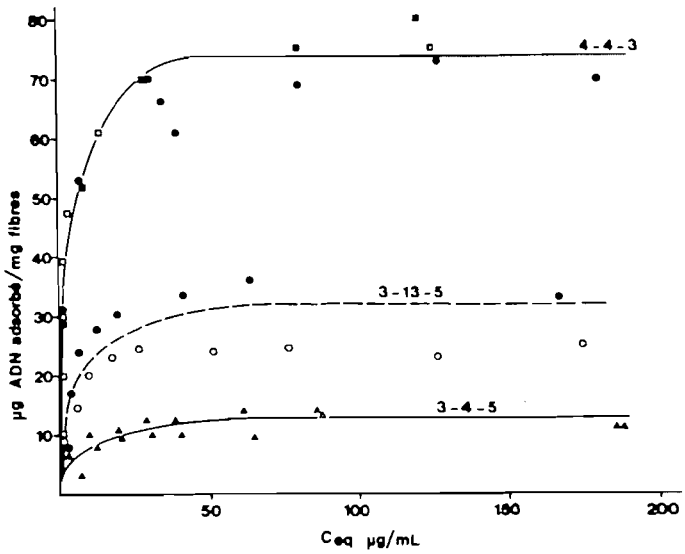

FIG. 2. Isothermes d'adsorption de l'ADN sur les différents échantillons. 4-4-3 Chrysotile non traité. 3-4-5 Chrysophosphate. 3-13-5 Chrysophosphate défibré Pallmann.

signal N_{1s}, caractéristique de l'adsorbat, sera proportionnel au taux de recouvrement θ de l'ADN, tandis que le signal Si_{2p}, caractéristique du substrat, sera proportionnel à $(1 - \theta)$. Le paramètre $R = I(N_{1s})/I(Si_{2p})$ (fig. 3) sera alors proportionnel à $\theta/(1 - \theta)$.

Par ailleurs, on peut supposer que les molécules d'ADN adsorbées sur le chrysophosphate et sur le chrysotile témoin ont le même volume moléculaire; soit n, le nombre de molécules d'ADN adsorbées sur le chrysophosphate et n', le nombre de molécules d'ADN adsorbées sur le chrysotile témoin, on aura, d'après les résultats de l'analyse chimique, $n' = 6n$. L'analyse XPS nous indique par ailleurs que $R' = 3R$; ou encore

$$[1] \quad \theta'/(1 - \theta') = 3\theta/(1 - \theta)$$

Le taux de recouvrement du chrysophosphate par l'ADN est égal au nombre n de molécules par unité de surface multiplié par s, aire d'une molécule projetée sur la surface. Il vient :

$$[2] \quad \theta = ns$$

De même pour le chrysotile témoin :

$$[3] \quad \theta' = n's' = 6ns'$$

La combinaison des relations [1], [2] et [3] permet d'obtenir une

For personal use only.

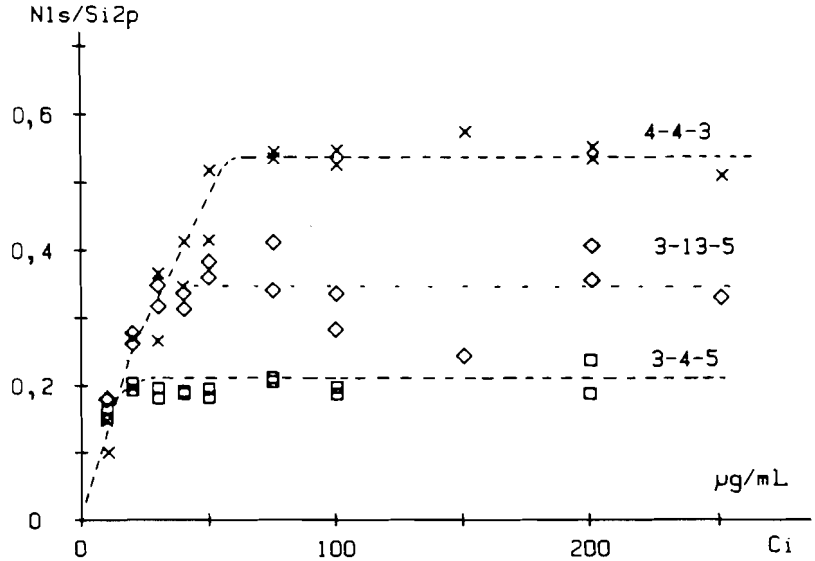

FIG. 3. Analyse XPS. Evolution du rapport d'intensité des pics N_{1s}/Si_{2p} (aire des pics) en fonction de C_i, concentration initiale en ADN. 4-4-3 Chrysotile non traité. 3-4-5 Chrysophosphate. 3-13-5 Chrysophosphate défibré Pallmann.

relation qui relie s, s' et θ' : $6s'/s + 2\theta' = 3$; par exemple, pour $\theta' = \frac{1}{2}$, on obtient $s = 3s'$ et, d'après [1], $\theta = \frac{1}{4}$.

Ce calcul simple ne permet pas de résoudre le système mais les résultats de l'analyse chimique et ceux de l'analyse XPS conduisent finalement à formuler l'hypothèse d'un plus grand étalement des macromolécules d'ADN à la surface du chrysophosphate qu'à celle du chrysotile témoin.

Conclusion

Les expériences effectuées montrent que l'adsorption d'ADN est un test sensible pour apprécier l'état de surface des fibres de chrysotile. L'interprétation complète des résultats suppose des comparaisons avec l'adsorption de molécules biologiques de plus petite taille et de forme non fibrillaire. À l'heure actuelle, les résultats relatifs à l'ADN conduisent cependant à formuler l'hypothèse d'un blocage des sites superficiels actifs par le phosphore ou par un composé phosphaté. On soulignera qu'il n'est pas indispensable que tous les sites actifs aient été bloqués par la phosphorylation pour expliquer les résultats obtenus : la possibilité de fixation d'une macromolécule organique est, en particulier, fonction de sa dimension et de sa forme. Un effet de barrière stérique (15) peut jouer un rôle pour contrôler l'adsorption de macromolécules fibrillaires telles que l'ADN.

La présence de phosphore fixé superficiellement diminue les propriétés sorptives du matériau vis-à-vis des molécules biologiques telles que l'ADN; il a été également observé une diminution des capacités d'adsorption de certains phospholipides du surfactant pulmonaire (résultats non publiés). Ces différents résultats peuvent être en relation avec la diminution de l'effet cytotoxique des fibres de chrysotile phosphaté (16). On peut par ailleurs se demander si la diminution du pouvoir clastogène (cassures de chromosomes) de ces fibres (16), comparativement au chrysotile non phosphaté, a un lien avec la diminution de l'adsorption d'ADN reportée ici.

Electrical breakdown voltage studies on Nb_2O_5 films in aqueous solutions of weak organic acid as a function of concentration, temperature, and applied field are carried out under galvanostatic conditions. Electronic conduction measurement through the Nb_2O_5 film as a function of temperature and applied field are also determined so as to examine the validity of Ikonopisov theory of electrical breakdown quantitatively.

R. K. NIGAM, K. C. SINGH et SANJEEV MAKEN. Can. J. Chem. **65**, 512 (1987).

Opérant dans des conditions galvanostatiques, on a examiné l'influence de la concentration, de la température et du champ appliqué sur le voltage lors de pannes électriques d'acides organiques. Dans le but d'évaluer quantitativement la validité de la théorie d'Ikonopisov sur les pannes électriques, on a aussi déterminé la conduction électronique à travers le film de Nb_2O_5 en fonction de la température et du champ appliqué.

Introduction

A considerable interest has been witnessed in recent years in the studies of electrical breakdown during the anodization of valve metals. The phenomenon is important both for electrolytic capacitor industry (1–3) and for anodization in general. But the difficulties lie both in the definition of breakdown and in the interpretation of the process.

A number of criteria (4), namely, the appearance of visible sparking, the slowing down of the potential rise, the reaching of a maximum voltage, the occurrence of audible crackling, the rapid voltage fluctuation, and the abrupt increase in the number of high frequency pulses in the anode circuit have been used for detecting breakdowns. Local crystallization (5) or fissure formation in oxide or electronic impact ionization and avalanching (6) are some of the breakdown mechanisms proposed by a number of investigators (7). Kardary and Klein (8) have interpreted the breakdown process by applying the stochastic succession of avalanche breakdown (9) while Ikonopisov (10) based his avalanche breakdown theory on the Forlani and Minnaja (11) model. The latter has been further supported by the experimental observations of Van Geel *et al.* (12), Fritzsche (13), and Montero and co-workers (14, 15).

In this paper a systematic study of the electrical breakdown on Nb_2O_5 film as a function of temperature, concentration, and composition of electrolyte, and current density and other experimental conditions has been made. Electronic current measurements through the oxide film as a function of temperature and applied field are also carried out. The Ikonopisov's theory of electrical breakdown has been examined critically.

Experimental

Niobium specimens (2 cm^2 in area) with a short tag were cut by a die from a sheet of niobium (99.9% purity). The edges of the specimens were abraded with fine emery paper to make them smooth. The specimen was then dipped in KOH melt to clean the surface and finally washed with distilled water. The chemical polishing of the specimen was done by dipping in a freshly prepared etching mixture of 98% H_2SO_4 + 70% HNO_3 + 48% HF (5:2:2, v/v) for 3–5 s and then washed with distilled water. It was then placed in boiling water for about 10 min to remove thin film of unknown compound from the surface of specimen. The tag of the specimen was covered with a thick anodic film formed in 0.1 *N* citric acid at room temperature. The specimen thus prepared was placed in a glass cell and was surrounded by a platinum gauze which served as a cathode during the production of oxide. The glass cell was placed in water thermostat (controlled to ±0.01 K).

Anodic polarization of the specimen was carried out at constant current, adjusted through an electronically operated constant current generator (General Electronics, Ambala Cantt.) designed specially for this purpose. The supply of current was cut off by an electronic control after the desired voltage of formation was reached. The time for the passage of current for film formation through successive intervals of voltages was recorded by an electronic timer (ET5302, Electronics Corporation of India Limited, Hydrabad) which could read ±0.01 s. The experiments under galvanostatic conditions were carried up to the breakdown voltage with A.R. grade tartaric, citric, and oxalic acids as electrolytes at temperatures ranging from 273.15 to 348.15 K and at different concentrations. Current density employed for anodic growth was varied from 1 to 100 mA/cm^2. Each reading was repeated at least five times and the breakdown voltage data show a very good reproducibility as mean values of breakdown voltage (U_B) for each set is not very much different from the lowest and the highest value of breakdown.

Thickness of the oxide film was determined by the Faraday law method. The density of niobium oxide (Nb_2O_5) was taken to be 4.36 g/cm^2 as suggested by Holtzberg *et al.* (16) and the temperature coefficient of density between 0 to 70°C has been assumed zero. The thickness was also measured using ellipsometer (Model Gaertner Production Ellipsometer L117 manufactured in USA). In electronic current (J_e) measurements, "adapted" electrolytes (17) were used. The method for the determination of stationary electronic current was the same as described by Ikonopisov *et al.* (17, 18). The film formation and the measurements of J_e as a function of temperature and applied field (E) were done under identical conditions in all electrolytes. The anodization was carried out in two stages. Initially through galvanostatic anodization at a current density of 10 mA/cm^2, a formation voltage of 200 V was reached and then maintained for 4 h. The highest values of the applied field strength were low enough (electropotentials less than 75% of the voltage at which the film was formed), thus ensuring a negligible ionic component of the current through the film. It was further supported by a negligible change in the thickness of the oxide film (measured with ellipsometer) at different intervals of time (say 1 h).

Results and discussion

Criteria of breakdown voltage

A number of criteria are used by different workers to define breakdown quantities. The particular phenomenon appearing at

[1]To whom all correspondence should be addressed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

breakdown depends upon the nature of the metal, concentration, composition, and temperature of electrolyte and the current applied for the anodic growth of the film. In case of niobium metal, breakdown is observed by the evolution of gas at the surface. Rate of gas evolution goes on increasing with time and the voltage becomes static for sometime (say 100 s). This particular voltage is taken as the breakdown voltage (U_B) for our investigations. No sparking or crackling sounds are observed at low current densities but at high current densities, say at 50 to 100 mA/cm^2, visible sparks are observed on the film. If the current is passed for a longer period the white crystalline solid is formed on the film. Once the solid is formed the voltage suddenly falls by 100 to 150 V below the breakdown voltage, then rises gradually to any maximum value. This maximum value is dependent on the quantity of the white solid formed. The formation of white solid is easier at higher concentrations of electrolyte and for larger applied current densities.

Effect of concentration

The dependence of U_B on the electrolyte resistivity ($\rho, \Omega m$) can be represented by a well known relation (1–3, 6, 19)

[1] $$U_B = a_B + b_B \log \rho$$

Here a_B and b_B are empirical constants, depending on the nature of the electrolyte. These are calculated by the method of least squares.

Electrolyte	a_B, V	b_B, V
Tartaric acid	212	46
Citric acid	160	60
Oxalic acid	143	56

In all observations, temperature of each electrolyte was set at 298.15 K and current density employed for anodization was 10 mA/cm^2. The data have been plotted in Fig. 1. The variation of log ρ from 2 to 4 was achieved by varying the molar concentrations of oxalic, citric, and tartaric acids from 0.04 to 0.0003 *M*, 0.482 to 0.00030 *M*, and 0.574 to 0.00030 *M*, respectively.

Effect of stirring

A considerable effect of stirring on U_B in fairly dilute solutions of electrolytes has been observed. This is in contradiction with the observation of many investigators (1, 2, 7, 20) who found U_B values independent of stirring. We could not explore the effect in concentrated solutions because of the formation of a white crystalline solid on the film. The values of U_B were (Fig. 2) always found to be higher when the solution was stirred than when the experiment was carried without stirring. As the concentration of solution increases the effect of stirring on U_B decreases. It seems possible that under the influence of field (when solution was not stirred) the anions density of electrolyte near the film surface becomes higher than their density in bulk. Thus the value of log ρ near the film surface will be lower than the experimentally measured value. Therefore, the measured U_B will be lower than the U_B corresponding to the bulk concentration (log ρ). But because of stirring, the concentration of anions near the surface of film and in bulk remains the same, and thus higher values of U_B are obtained in stirring solution. In concentrated solution, the number of ions near film surface become more or less maximum

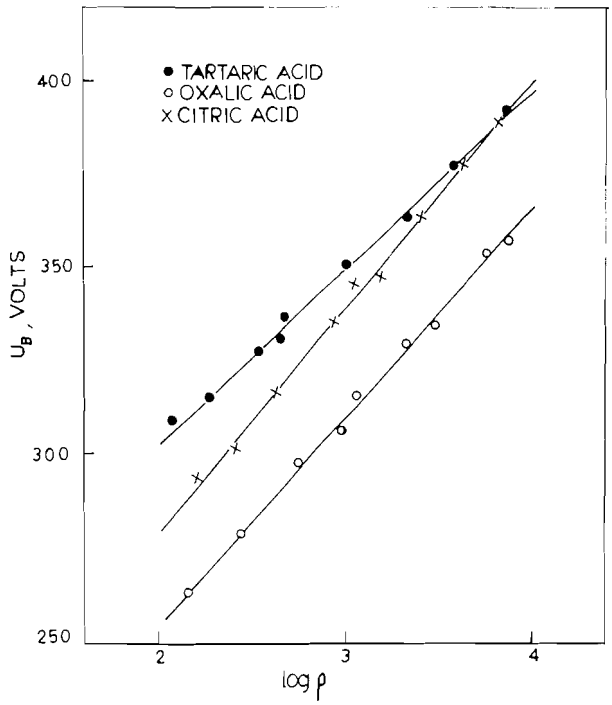

FIG. 1. Variation of breakdown voltage (U_B) with resistivity of electrolyte (ρ) at 288.15 K.

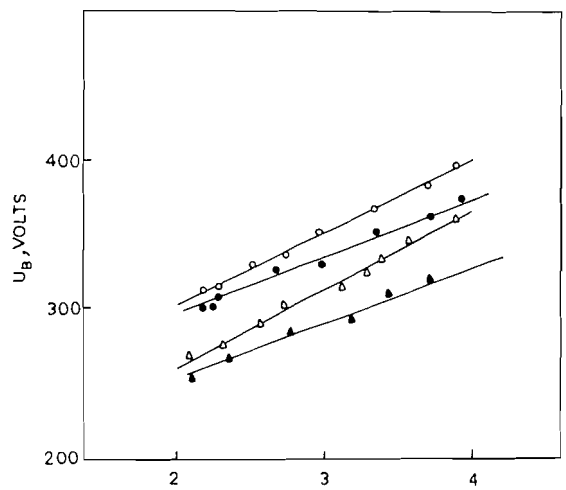

FIG. 2. Plot of U_B vs. log ρ at 298.15 K: ○ tartaric acid and △ oxalic acid (with stirring) and ● tartaric acid and ▲ oxalic acid (without stirring).

and the ions attracted by applied field do not find sufficient space near the surface. Thus further increase of concentration will not increase the ion concentration near the surface. Therefore, the effect of stirring goes on decreasing with the increase of concentration (Fig. 2).

Effect of current density (j)

The effect of current density (j) on U_B could only be measured between 1 to 100 mA/cm^2 due to experimental restrictions. The anodization at very low current densities proceeds so slowly that U_B can not be reached for a reasonable duration of the experiment. On the other hand, the abrupt potential rise and the formation of white solid at the surface of the film at sufficiently high current densities impede the accurate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

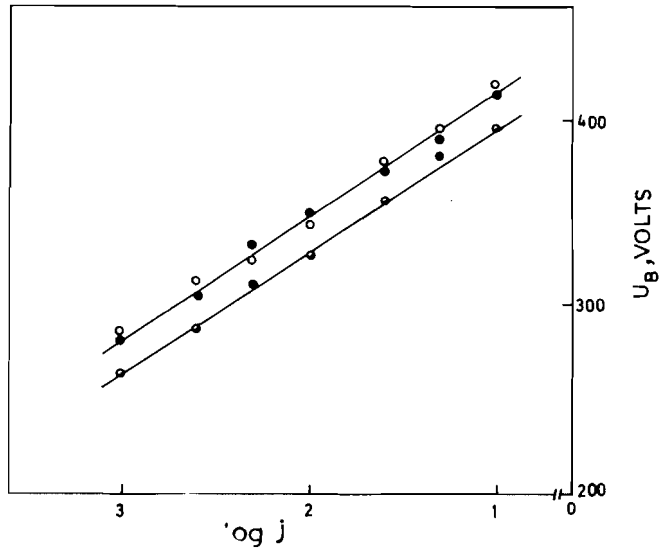

FIG. 3. Plot of U_B vs. log j, j in A/cm^2: ◒ oxalic acid, ● tartaric acid, ○ citric acid.

detection of U_B. Nevertheless, a reliable measurements of U_B can be carried out for the above stated range of current densities. At low current densities, the criterion for observation of U_B was the evolution of gas and at high current densities the evolution of gas was accompanied by the sparks at the film surface. Plots of U_B vs. log j are found to be linear (Fig. 3). With a 100-fold increase of j the increase in U_B for all three systems studied is 120 V. The 100-fold change of j changes the field strength ($E^{1/2}$) only to 18%. Thus U_B is very sensitive to the applied field. This observation is in contradiction with the observations of other workers (1, 2, 21–23). In tantalum and aluminium oxide film, the effect of current density on U_B is very small (21, 23, 24). Our data can be fitted well to the equation

$$[2] \quad U_B = A_B + B_B \log j$$

where A_B and B_B are the empirical constants dependent on the nature of metal, and the composition and concentration of the electrolyte in contact.

The following values of constants A_B and B_B are obtained:

Electrolyte	A_B, V	B_B, V
Tartaric acid	483.3	66.6
Citric acid	483.3	66.6
Oxalic acid	461.6	65.7

Here the electrolyte temperature was maintained at 298.15 K and the resistivity of solution was set at log $\rho = 3.0$ in each case. Approximately the same value of B_B in all the three electrolytes predicts that B_B is independent of the composition of electrolyte and it is only a function of the nature of metal. A_B, however, depends on the nature and concentration of the electrolyte.

Effect of temperature

Effect of temperature on U_B has been explored between the temperatures 273.15 to 348.15 K in electrolytes tartaric, oxalic, and citric acid. The resistivity of each electrolyte was set (log $\rho = 3.0$) at 298.15 K and the current density was 10 mA/cm^2. As the experimental temperature changes so does the resistivity of the solution. Thus the observed U_B values at

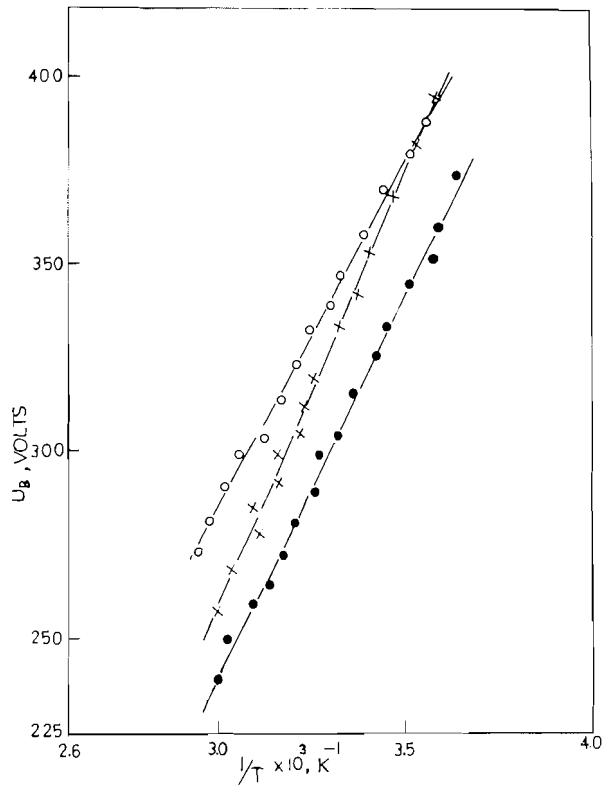

FIG. 4. Plot of U_B vs. $1/T$, ● oxalic acid, × citric acid, ○ tartaric acid.

different temperatures not only reflect the effect of temperature but also that of resistivity. In order to obtain the effect of temperature on U_B, the experimental values of U_B were corrected as follows:

$$[3] \quad U_T = U_B(T,\rho_2) - U_B(\rho_2) + U_B(25, \rho)$$

where U_T = calculated breakdown voltage at temperature T when log $\rho = 3$; $U_B(T, \rho_2)$ = experimentally measured breakdown voltage at temperature T, with solution resistivity ρ_2; $U_B(\rho_2)$ = breakdown voltage calculated from eq. [1] with resistivity ρ_2; $U_B(25, \rho)$ = breakdown voltage at temperature 25°C and log $\rho = 3.0$. Clearly the last two terms in the right hand side of eq. [3] give the change in breakdown voltage at 25°C when the resistance of solution changes from (log $\rho = 3$) to log ρ_2. Data before and after applying correction have been plotted in Figs. 4 and 5 and can be represented by the equation

$$[4] \quad U_B = \alpha_B + \beta_B/T$$

Here α_B and β_B are constants. Their values are calculated and given below:

Electrolyte	α_B, V	β_B, V K
Oxalic acid	−461.8	230.8×10^3
Tartaric acid	−366.05	214.3×10^3
Citric acid	−533.15	260.9×10^3

Here a change in temperature from 273.15 to 343.15 K changes U_B to 134, 115, 146 V in oxalic, tartaric, and citric acid, respectively. The change in field (E) within the film with the same change of temperature is calculated by employing eq. [16] and the change of E corresponding to the change in U_B was

calculated from eq. [15] and presented below

Electrolyte	Temperature changes	Change in $E^{1/2}$	Change in U_B
Oxalic acid	From 273.15 to 343.15 K	10.65%	27.62%
Citric acid	"	10.71%	36.47%
Tartaric acid	"	9.82%	26.63%

Thus the temperature change affects U_B in many ways: it changes the resistivity of the solution, field "E" within the film, and perhaps other characteristic breakdown parameters such as impact-ionization constant, primary electronic current density etc.

Ikonopisov's theory of breakdown voltage

According to Ikonopisov (10), during anodization the electrolytic contact not only provides ions for the oxidation, but also injects electrons into the conduction band of the oxide. The high field strength in it can accelerate these electrons to an energy which is sufficient to free other electrons by impact ionization so that an avalanche multiplication occurs. The avalanching effect causes the density (j_e) of the electronic current to increase with distance (x) within the anodic film.

$$[5] \quad j_e(x) = j_e(0)P \exp\left[\frac{eE}{\epsilon_m}\left(\frac{1}{x} - \frac{1}{x_r}\right)^{-1}\right]$$

where $j_e(0)$ = primary current density, injected at the electrolyte/oxide interface (at $x = 0$); e = electronic charge; x_r = recombination length; P = probability for an electron to reach the unstable energy required for surmounting the phonon scattering.

The general equation for breakdown voltage is given by

$$[6] \quad U_B = \frac{\epsilon_m}{re}[\ln j_B - \ln j_e(0)]$$

where U_B = breakdown voltage, r = recombination constant.

$$r = \frac{a_r}{a_r + 1} < 1$$

ϵ_m = difference between the mean energy of an electron necessary for ionization and the mean energy of the electrons emerging from an ionization event.

The temperature dependence of $j_e(0)$ can be described by the expression (25)

$$[7] \quad \ln j_e(0) = \ln \alpha_e + \beta_e/T$$

where α_e and β_e are constants. Substituting eq. [7] in eq. [6] and putting

$$[8] \quad \frac{\epsilon_m}{re}[\ln j_B - \ln \alpha_e] = \text{constant} = \alpha_B$$

$$[9] \quad \frac{\epsilon_m}{re}\beta_e = \text{constant} = \beta_B$$

we obtain eq. [4]

$$U_B = \alpha_B + \beta_B/T$$

The validity of above equation has already been proved

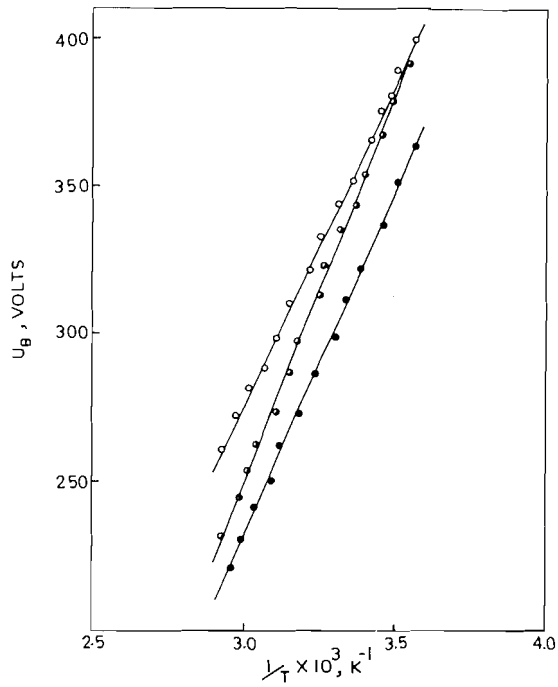

FIG. 5. Variation of U_B with $1/T$ after applying correction for log ρ: ● oxalic acid, ◒ citric acid, ○ tartaric acid.

(Fig. 5). A more intrinsic test to the theory can be derived from eq. [9].

$$[10] \quad \left(\frac{\beta_B}{\beta_e}\right) = \frac{\epsilon_m}{re}$$

Here e is the electronic charge ϵ_m and r are constants specific only for the anodized metal, and β_e is a quantity which characterizes the electron injection from the electrolyte into the oxide and depends on the electrolyte composition and nature of metal.

Consequently, the ratio β_B/β_e is determined only by the nature of the anodized metal.

For a given metal and two electrolytes with different compositions (ϵ_1 and ϵ_2) at the same conductivity

$$[11] \quad \left(\frac{\beta_B}{\beta_e}\right)_{\epsilon_1} = \left(\frac{\beta_B}{\beta_e}\right)_{\epsilon_2} = \frac{\epsilon_m}{re}$$

β_e values for all the three electrolytes are calculated from the electronic conduction experiments (Fig. 6). The slope of the line gives value of β_e; the ratio β_B/β_e for all three electrolytes are as follows:

Electrolyte	β_B	β_e	β_B/β_e
Oxalic acid	230.8	4.3×10^3	53.67
Tartaric acid	214.3	3.70	57.92
Citric acid	260.9	3.23	80.77

Similarly the dependence of $j_e(0)$ on the field strength can be described by the relation (25–27)

$$[12] \quad j_e(0) = A_e \exp[\beta_e E^{1/2}]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

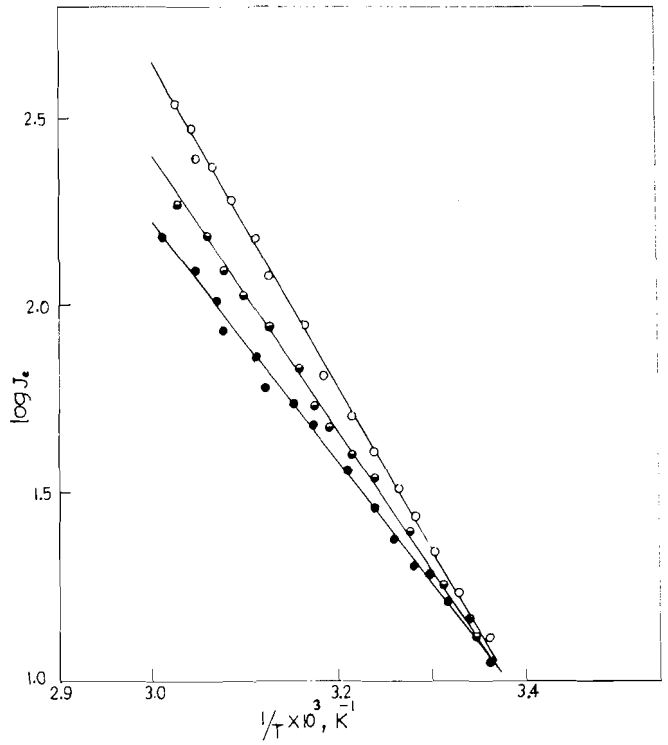

FIG. 6. Variation of electronic current (log j_e) with temperature ($1/T$): ○ oxalic acid, ◒ tartaric acid, ● citric acid.

Substituting eq. [12] in eq. [6] and putting

$$[13] \quad \frac{\epsilon_m}{re}[\ln j_B - \ln A_e) = \text{constant} = A_B'$$

$$[14] \quad \frac{\epsilon_m}{re}\beta_e = \text{constant} = B_B'$$

we obtain,

$$[15] \quad U_B = A_B' - B_B' E^{1/2}$$

The calculations of E were done using the equation of Young (28, 29)

$$[16] \quad j_i = A_i \exp\left(-\frac{B_i}{kT}\right) \exp\left(\frac{\alpha_i E - \beta_i E^2}{kT}\right)$$

where k is the Boltzmann constant, and the constants A_i, B_i, α_i, and β_i are determined only by the nature of anodized metal.

Plots of U_B vs. $E^{1/2}$ (Fig. 7) are linear, when the contacting electrolytes were tartaric, oxalic, and citric acids. A similar relation of type [11] can be obtained from eq. [14].

$$[17] \quad \left(\frac{B_B'}{B_e}\right)_{\epsilon_1} = \left(\frac{B_B'}{B_e}\right)_{\epsilon_2}$$

Again the values of B_e are obtained from the plot of $\ln j_e$ vs. $E^{1/2}$ (Fig. 8), the ratio B_B'/B_e are compared below:

Electrolyte	B_B'	B_e	B_B'/B_e
Oxalic acid	2.35×10^{-3}	0.73	3.196×10^{-3}
Tartaric acid	2.35×10^{-3}	0.78	3.008×10^{-3}
Citric acid	1.95×10^{-3}	0.80	2.418×10^{-3}

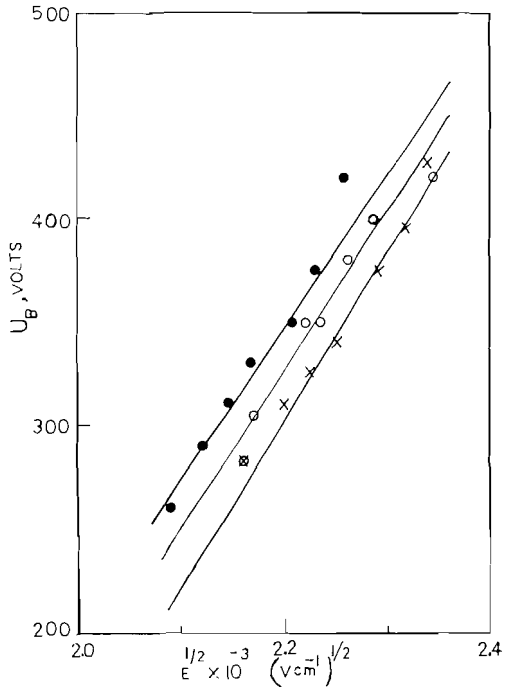

FIG. 7. Plot of U_B vs. $E^{1/2}$: ● oxalic acid, ○ tartaric acid, × citric acid.

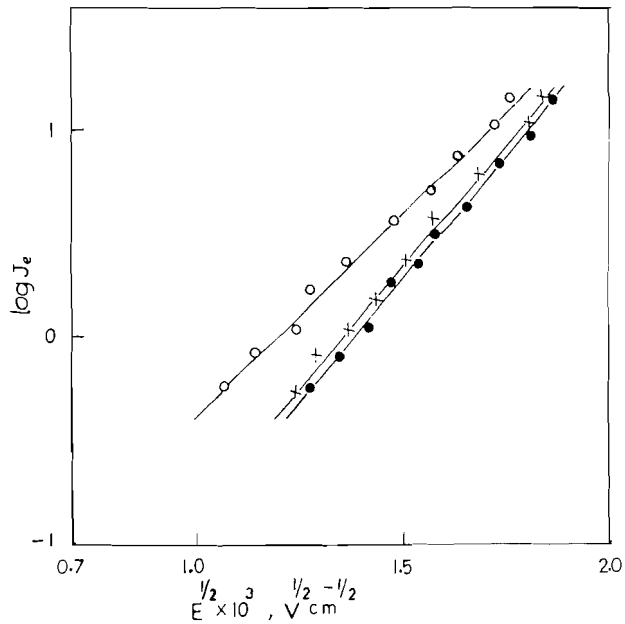

FIG. 8. Plot of j_e vs. $E^{1/2}$ at 298.15 K for various conducting electrolytes: ○ citric acid, × oxalic acid, ● tartaric acid.

Here again the ratio for oxalic and tartaric acids are the same but that for citric acid is different. Thus Ikonopisov's theory of breakdown voltage provides a theoretical justification to the effect of temperature, concentration, composition, and applied field on the breakdown voltage. However, the quantitative estimation of the various constants from experiments are different from those calculated. This may be due to the fact that the dependence of $J_e(0)$ on E, T, M, ρ have been studied at sufficiently low electric fields and the same relations have been used at high electric fields. The main limitation of the theory

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

is for not knowing the exact mechanism of the introduction of electron from the electrolyte to the oxide film. Recently Montero *et al.* (14, 15) have suggested that electron injection into the conduction band of oxide takes place from the anions incorporated in the film lattice. Thus the higher the concentration of anions in the film, the higher the primary electron current density ($J_e(0)$) and field (E); and therefore the lower the breakdown voltage. Incorporation of oxalate ions in film are known to be negligible. It has further been shown that the $J_e(0)$ and E remain almost constant during the concentration variation of oxalic acid electrolyte, but the impact ionisation coefficient changes, which is further responsible for the change of U_B with concentration.

As U_B in citric and tartaric electrolyte at particular concentration is always higher than the U_B values in oxalic acid electrolyte at the same concentration. This indirectly suggests that the concentration of citrate and tartrate ions incorporated in the film is less than that of oxalate ions. It is also obvious that the size of citrate and tartrate ions are quite large compared to the size of the oxalate ions. Thus a smaller number of larger ions will be able to penetrate in the film as compared to small-sized ions. The results of the above discussion can now be summarized. U_B depends upon the concentration, composition, and temperature of the contacting electrolyte and the current density employed for anodization. The criteria for observing U_B is the evolution of gas at the oxide film surface which makes the applied voltage static for some time. The Ikonopisov theory of electrical breakdown is able to explain all the observed effects qualitatively but its quantitative success is not certain.

New nitrogenous sesquiterpenes based on alloaromadendrane and *epi*-eudesmane skeletons from the marine sponge *Axinella cannabina*[1]

PATRIZIA CIMINIELLO, ERNESTO FATTORUSSO,[2] SILVANA MAGNO, AND LUCIANO MAYOL

Dipartimento di Chimica delle Sostanze Naturali, Università di Napoli, Via L. Rodinò 22, I-80138 Napoli, Italy (081-207014)

Received August 8, 1986

PATRIZIA CIMINIELLO, ERNESTO FATTORUSSO, SILVANA MAGNO, and LUCIANO MAYOL. Can. J. Chem. **65**, 518 (1987).

Six new nitrogenous sesquiterpenes (**1–6**), which form two new isocyanide-isothiocyanate-formamide series, have been isolated from the marine sponge *Axinella cannabina*. The structure elucidation of these compounds is based upon spectral data, including 2D-nmr, and chemical interconversions. The complete assignment of all proton and carbon resonances in nmr spectra of axisonitrile-2 (**7**), an isonitrile previously isolated from the same source, is also reported, along with its complete relative stereochemistry.

PATRIZIA CIMINIELLO, ERNESTO FATTORUSSO, SILVANA MAGNO et LUCIANO MAYOL. Can. J. Chem. **65**, 518 (1987).

De l'éponge marine *Axinella cannabina* ont été isolés six nouveaux sesquiterpènes azotés (**1–6**) qui constituent deux nouvelles séries de trois composés voisins : isonitrile, isothiocyanate et formamide. Se basant sur leurs intercorrélations chimiques et faisant appel à la rmn, y compris la rmn ^{1}H-2D, on a déterminé les structures. On a aussi donné l'attribution complète des résonances de tous les protons et de tous les carbones, dans la rmn du composé axisonitrile-2, un isonitrile déjà isolé de la même éponge, avec sa complète configuration relative.

Numerous bioactive natural products carrying rare functionalities have been isolated from marine sponges. Among these, novel sesqui- and di-terpenoid isocyanides, isothiocyanates, and formamides represent a group of closely related compounds, none of which is yet known to be produced by any other marine organism (1). Undoubtedly, the mediterranean *Axinella cannabina* is the most prolific source of these unusual metabolites since its chemical investigation resulted in the isolation of isocyanides always accompanied by the corresponding isothiocyanates and formamides (2), most likely biogenetically deriving from them (3, 4).

In this paper we amplify on our earlier work by reporting the presence in this organism of two further isocyanide-isothiocyanate-formamide series based on the *epi*-eudesmane (**1–3**) and alloaromadendrane (**4–6**) carbon skeletons. Compound **4** is epimeric at C-1 to the co-occurring axisonitrile-2 whose structure had been previously established devoid of the chirality of the 10-carbon atom (5), which is here described.

Isolation of sesquiterpenes **1–6** from the $CHCl_3$ soluble material of the methanolic extract of the animals was carried out by chromatography on SiO_2 columns followed by reversed phase high performance liquid chromatographies.

Spectral (nmr and ms) examination of the pure constituents thus obtained made it apparent that each of the two terpenoid series was based on a single carbon skeleton and that the members of each series differed only in the nature of the functional groups. This was confirmed by conversion of the isocyanides into the formamides, by treatment with aqueous AcOH, and into the isothiocyanates, by heating with sulphur.

epi-*Eudesmane compounds (1–3)*

Compound **1** (11-isocyano-7β*H*-eudesm-5-ene), an oil, showed $[\alpha]_D$ −85.7 and was analyzed for $C_{16}H_{25}N$ by high resolution mass spectroscopy. The ir spectrum showed the typical absorption for the -N⁺≡C⁻ functionalities (ν_{max} 2135 cm^{-1}). Consideration of ^{1}H and ^{13}C nmr data (Table 1) indicated that the five degrees of unsaturation inherent in the molecular formula consisted of a trisubstituted double bond and two rings in addition to the isonitrile group. The ^{1}H nmr spectrum ($CDCl_3$) indicated the presence in **1** of a secondary (δ 1.14) and a tertiary (δ 1.10) methyl. Two further CH_3 existed as a $(CH_3)_2C(\text{—}N^+\equiv C^-)$ group as seen by a 6H broad singlet at δ 1.36. The structural hypothesis for compound **1** was supported by an accurate analysis of the 500-MHz ^{1}H nmr spectrum, involving double resonance techniques and by the ^{13}C–^{1}H correlated 2D-nmr spectrum. Comparison of the ^{1}H nmr spectrum of **1** in C_6D_6 vs. $CDCl_3$ revealed that the proton resonances were more resolved in C_6D_6 and hence these values (Table 1) are recorded around structure **1** for discussion. The ^{13}C nmr spectrum revealed the presence in **1** of only two methine carbons (δ 39.25 and 44.12), the pertinent protons resonating at δ 2.42 and 1.90 as indicated by the 2D-correlated spectrum. These two methine groups were shown to delimit the segment C4 to C7 by

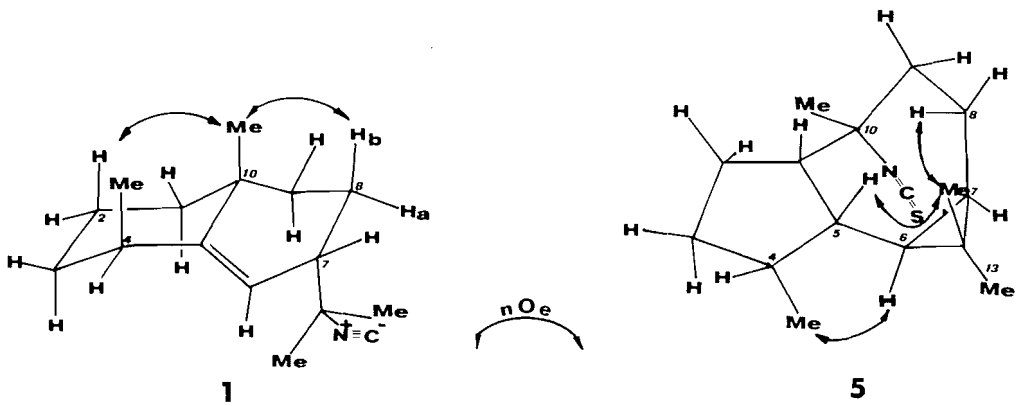

FIG. 1

the proton interactions shown by the following decoupling experiments. Irradiation at δ 5.38 (6-H) simplified the signal at δ 1.90 (7-H) into a bdd, whereas irradiation at δ 2.42 (4-H) removed the long range coupling between 4-H and 6-H and caused the doublet at δ 1.14 (15-H3) to collapse into a singlet. The extension of the above partial structure from C7 to C9 and from C4 to C1 was accomplished by further double resonance experiments assisted by 2D-correlation and spin decoupling difference techniques, which allowed us to assign all the proton resonances in **1** as reported in Table 1. At this stage the only way to accommodate the quaternary carbon atom (C-10) resonating at δ 34.78 was its incorporation among C14, C1, C9, and C5 and consequently the -$\overset{+}{N}\equiv\overset{-}{C}$ carrying isopropyl group must be located at C7.

To determine the relative spatial arrangements of all substituents we employed ^1H nmr data including nuclear Overhauser enhancement (nOe) difference spectroscopy. The equatorial nature of 4-H was established from the value of the coupling constant with 3-H_{ax} (deduced after irradiation at δ 1.14, which simplified the 4-H signal into a double doublet (J = 3.6 and 3.6 Hz)). On the other hand, the coupling constant values (J_{7-8a} and J_{7-8b}) required a *gauche* relationship of 7-H to both the C8 protons, thus indicating that the substituted isopropyl group should be either pseudo-axial α or pseudo-axial β. The latter possibility could be discarded on the grounds that the bulky β-substituent is sterically incompatible with the C-10 β-Me group. Furthermore the stereostructure **1** fully accounts for the observed nOe's between 10-Me and 2-H_{ax} and between 10-Me and 8-H_b (Fig. 1).

The molecular formula of the compound **2** (11-isothiocyano-7β*H*-eudesm-5-ene) was determined as $C_{16}H_{25}NS$ from hrms on the molecular ion at m/z 263. The presence of an

*Submerged by other signals.

[a]Overlapped with other signals in the region 2.10–1.65 δ.

J values (Hz) for **4** and **5**: 1–2a = 7; 1–2b = 7; 1–5 = 7; 2a–3a = 7; 2b–3a = 7; 3a–3b = 13.5; 3a–4 = 7; 3b–4 = 7; 4–5 = very small; 4–15 = 7; 5–6 = 9.5; 6–7 = 9.0; 7–8a = 11.5; 7–8b = 6.0; 8a–9a = 7.5; 8b–9a = 12.0; 8a–9b = 3.0; 8b–9b = 7.5; 9a–9b = 15.0.

J values (Hz) for **7**: 1–2a = 8; 1–2b = 8; 1–5 = 8; 2a–3b = 5.5; 2b–3b = 5.5; 3a–3b = 12; 3b–4 = 5.5; 4–15 = 7.

isothiocyanate function was indicated by a strong absorption at ν_{max} 2100 cm^{-1} in the ir spectrum. A clear structural relationship between **1** and **2** exists, as indicated by comparison of their ^1H and ^{13}C nmr spectra (Experimental). This was proved by conversion of **1** into **2** by treatment with sulphur at 120°C.

The third *epi*-eudesmane sesquiterpene was the formamide **3** (11-formamido-7β*H*-eudesm-5-ene, $C_{16}H_{27}NO$ from hrms), which exists as a mixture of the two rotational isomers of the NHCHO group in the ratio 2(*cis*):3(*trans*) as indicated by ^1H nmr features in $CDCl_3$ (*trans* isomer: δ 8.20 (d, *J* = 12.0 Hz, H—C(=O)), 5.33 (d, *J* = 3.5 Hz, 6-H), 1.30 (s, 12-H3 or 13-H3), 1.29 (s, 13-H3 or 12-H3), 1.12 (d, *J* = 7.0 Hz, 14-H3), 1.06 (s, 15-H3); *cis* isomer: δ 8.06 (d, *J* = 2.0 Hz, H—C(=O)), 5.33 (d, *J* = 3.5 Hz, 6-H), 1.35 (s, 12-H3 or 13-H3), 1.32 (s, 13-H3 or 12-H3), 1.12 (d, *J* = 7.0 Hz, 14-H3), 1.06 (s, 15-H3)).

Its structure was rapidly assigned by the synthesis starting from **1** with aqueous AcOH in Et_2O.

Alloaromadendrane compounds (4–6)

A minor metabolite **5** (10α-isothiocyanoalloaromadendrane) was isolated from fraction A by reversed phase hplc. This new compound was analyzed for $C_{16}H_{25}NS$ (by hrms) and this formula was substantiated by its ^{13}C nmr features (Table 2). The presence of an isothiocyanate group was concluded on the basis of an ir band at ν_{max} 2100 cm^{-1} and of a facile loss of HNCS (*m/z* 204) from the molecular ion in the mass spectrum. The determination of the gross structure of **5** was made by ^1H nmr decoupling experiments supported by ^{13}C–^1H shift-correlated 2D spectroscopy, which allowed all protons and carbons to be assigned. These data clearly indicated that **5** must possess an aromadendrane-like skeleton with the isothiocyanate group linked to C-10; therefore the compound under investigation should differ only for stereochemical details from axisothiocyanate-2 (**8**), a sesquiterpene isothiocyanate previously isolated from the same source (5).

Proof for the stereostructure **5** was obtained from nOed data and by using a shift reagent ($Eu(fod)_3$) (5, 6) in obtaining a series of nmr spectra of the corresponding isocyanide **4** (10α-isocyanoalloaromadendrane), isolated from fraction B by hplc, which gave **5** by treatment with sulphur at 120°C.

The cyclopropyl hydrogens experience a large paramagnetic shift (80% of 10-Me) on complexation with $Eu(fod)_3$. Inspection of molecular models showed that the close proximity of these atoms with the $\overset{+}{N}\equiv\overset{-}{C}$ group can occur only if compound **4** is based on an alloaramodendrane skeleton with the isocyanide function in a *cis* relationship with 6-H and 7-H. On the other hand, the intramolecular nuclear Overhauser effects observed in **5** between 6-H and 4-Me, as well as between 12-H3 and the protons linked to C-5 and C-8, accord with this postulation and indicate the relative stereochemistry at C-4 in the above related compounds (Fig. 1).

The remaining metabolite **6** (10α-formamidoalloaromadendrane), isolated from fraction C by hplc, was identified as the amide corresponding to the isocyanide and isothiocyanate described above. Amide **6** was analyzed for $C_{16}H_{27}NO$ by high

For personal use only.

resolution mass measurement of its parent ion at m/z 263. Structure **6** was assigned as the more plausible by studies of ^{1}H nmr features including decoupling experiments, which revealed a 2(*trans*):1(*cis*) ratio of the rotational isomers at the formylamino group (*trans* isomer, δ: 8.22 (d, J = 12.0 Hz, H—C(=O)—NH), 5.20 (bm, NH), 1.33 (s, 15-H3), 1.01 (s, 12-H3 or 13-H3), 0.94 (s, 13-H3 or 12-H3), 0.89 (d, J = 7.0 Hz, 14-H3), 0.69 (ddd, J = 11.5; 9.0; 6.0 Hz, 7-H), 0.25 (dd, J = 9.5; 9.0 Hz, 6-H); *cis* isomer, δ: 8.00 (d, J = 2 Hz, H—C(=O)—NH), 5.47 (bm, NH), 1.46 (s, 15-H3), 1.00 (s, 12-H3 or 13-H3), 0.92 (s, 13-H3 or 12-H3), 0.88 (d, J = 7.0 Hz, 14-H3), 0.63 (ddd, J = 11.5; 9.0; 6.0 Hz, 7-H), 0.16 (dd, J = 9.5; 9.0 Hz, 6-H)).

This attribution was secured by conversion of **4** into **6** by hydration following the usual work-up.

Axisonitrile-2 (**7**) and the related compounds **8–9** were isolated about ten years ago from the same source and their structures, including the relative stereochemistries apart from the chirality at C-10, were determined (5).

The assignment of the stereochemistry of the above chiral center has been now determined by an accurate analysis of ^{1}H and ^{13}C nmr spectra, including extensive ^{1}H decoupling studies and two-dimensional ^{13}C–^{1}H shift-correlated spectroscopy, which led to the assignment of all proton and carbon atoms in **7**, as reported in Table 2.

The ^{13}C nmr frequency of 10-Me (δ 19.54) established the *trans* relationship between this group and 1-H when compared with the corresponding carbon atom in aromadendrane derivatives (7). Further proof was obtained by the ^{1}H nmr spectrum of **7** measured in the presence of varying amounts of Eu(fod)$_3$. The 1-H proton suffered a remarkable europium shift, thus confirming its *cis* relationship with the isocyanide group.

The correct assignment of stereostructure **7** to axisonitrile-2 was secured by nOed data, which showed that 1-H and 6-H are in the nOe proximity, whereas no detectable effect was observed, as expected, between 10-Me and the cyclopropyl protons.

Experimental

The ^{1}H nmr spectra, including spin decoupling and nOe difference experiments, were recorded on a Bruker 500 WM spectrometer. The ^{13}C spectra and 2D-nmr experiments were recorded on a Bruker WM 250 spectrometer; all chemical shifts are reported in ppm, using TMS as internal standard (δ = 0). Nuclear Overhauser effects were determined with the aid of an Aspect 2000 microprogram using samples previously degassed by bubbling argon through the solution for 40 min. ^{13}C–^{1}H shift-correlated 2D-nmr spectra were obtained using a Bruker microprogram. The shift correlation with polarization transfer via J-coupling experiments were performed by adjusting the fixed delays to give maximum polarization for J_{C-H} = 135 Hz.

Low resolution mass spectra were recorded at 70 eV on an AEI MS 30 instrument. High resolution mass spectra were obtained on a Kratos spectrometer.

Optical rotations were measured in $CHCl_3$ using a Perkin Elmer 141 polarimeter with a 10-cm microcell.

The ir spectra were measured on a Perkin Elmer 157 spectrophotometer.

The hplc separations were carried out using Lichrosorb Si60 5-μm silica gel and μ-Bondapak C_{18} preparative columns (1.0 × 25 cm) with a Varian 5000 apparatus equipped with a differential refractometer detector.

Extraction

The sponge (*Axinella cannabina*) was collected in the spring of 1984, off the coast of Taranto near Porto Cesareo (Italy). The fresh material (600 g dry weight after extraction) was homogenized and extracted with MeOH (3 L × 3) and then with $CHCl_3$ (2 L × 2) at room temperature. The methanolic extracts were evaporated *in vacuo* to give an aqueous phase, which was extracted with Et_2O. Evaporation of the combined Et_2O and $CHCl_3$ extracts afforded 25 g of an oily residue, which was chromatographed under a slight N_2 pressure, on an SiO_2 column (using as eluent solvent of increasing polarity from hexane to Et_2O through C_6H_6). Early fractions (eluent hexane–C_6H_6 8:2) gave a mixture (2 g) of isothiocyanates (fraction A); middle fractions (eluent hexane–C_6H_6 2:8) yielded a mixture (11 g) of isonitriles (fraction B), and the later fractions (eluent Et_2O) afforded a mixture (700 mg) of amides (fraction C). Fractions A–C were used for the isolation of compounds **1–6** as described below.

Isolation of 2 and 5

Fraction A, obtained as above, was further separated by a silica gel column (500 g) under pressure, eluent *n*-hexane, to give an oily residue (600 mg) containing **2** and **5**. Pure **2** and **5** were obtained by hplc by using a 5-μm C_{18} reversed phase column with MeOH–H_2O 95:5 as eluent.

2, 22 mg, $[\alpha]_D$ −89.7 (*c* 0.8 in $CHCl_3$); ν_{max}: 2100 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 5.34 (d, J = 3.5 Hz, 6-H), 2.43 (m, 4-H), 1.38 (s, 12-H3 or 13-H3), 1.36 (s, 13-H3 or 12-H3), 1.13 (d, J = 7.0 Hz, 14-H3), 1.09 (s, 15-H3); ^{13}C nmr ($CDCl_3$) δ: 158.33 (C-16), 152.66 (C-5), 119.69 (C-6), 64.83 (C-11), 45.07 (C-7), 40.93 (C-1), 39.19 (C-9), 39.06 (C-4), 34.65 (C-10), 33.32 (C-3), 27.28 (C-14), 27.18 (C-12 and C-13), 22.24 (C-15), 20.64 (C-8), 17.70 (C-2); hrms, m/z calcd. for $C_{16}H_{25}NS$: 263.1709; found: 263.1704.

5, 35 mg, $[\alpha]_D$ −6.95 (*c* 0.9 in $CHCl_3$); ν_{max}: 2100 cm^{-1}; ^{1}H nmr and ^{13}C nmr data are reported in Table 2; hrms, m/z calcd. for $C_{16}H_{25}NS$: 263.1709; found: 263.1703.

Isolation of 1 and 4

Fraction B, obtained as above, was chromatographed over silica gel (900 g), again with *n*-hexane–C_6H_6 (2:8) as eluent.

The fractions containing **1** and **4** were pooled and resolved into the single components by hplc by using a 5-μm C_{18} column (eluent 10% aqueous MeOH).

1, 31 mg, $[\alpha]_D$ −85.7 (*c* 0.8, $CHCl_3$); ν_{max}: 2135 cm^{-1}; ^{1}H nmr and ^{13}C nmr are reported in Table 1; hrms, m/z calcd. for $C_{16}H_{25}N$: 231.1988; found: 231.1986.

4, 28 mg, $[\alpha]_D$ −17.21 (*c* 0.7, $CHCl_3$); ν_{max}: 2135 cm^{-1}; ^{1}H nmr and ^{13}C nmr data are reported in Table 2; hrms, m/z calcd. for $C_{16}H_{25}N$: 231.1988; found: 231.1989.

Isolation of 3 and 6

Fraction C, obtained as above, permeated through an SiO_2 column (200 g), *n*-hexane eluent, to give 200 mg of an oil containing **3** and **6**. Final purification of amides **3** and **6** was achieved by hplc (silica gel column, eluent EtOAc–*n*-hexane 9:1).

3, 6 mg; ν_{max}: 3440 and 1680 cm^{-1}; hrms, m/z calcd. for $C_{16}H_{27}NO$: 249.2094; found: 249.2090. *cis* Isomer δ: 8.06 (d, J = 2.0 Hz, H—C(=O)—), 5.33 (d, J = 3.5 Hz, 6-H), 1.35 (s, 12-H3 or 13-H3), 1.32 (s, 13-H3 or 12-H3), 1.12 (d, J = 7.0 Hz, 14-H3), 1.06 (s, 15-H3); *trans* isomer δ: 8.20 (d, J = 12.0 Hz, H—C(=O)—), 5.33 (d, J = 3.5 Hz, 6-H), 1.30 (s, 12-H3 or 13-H3), 1.29 (s, 13-H3 or 12-H3), 1.12 (d, J = 7.0 Hz, 14-H3), 1.06 (s, 15-H3).

6, 5 mg; ν_{max}: 3440 and 1680 cm^{-1}; hrms, m/z calcd. for $C_{16}H_{27}NO$: 249.2094; found: 249.2089. *cis* Isomer δ: 8.00 (d, J = 2.0 Hz, H—C(=O)—), 5.47 (bm, NH), 1.00 (s, 12-H3), 0.92 (s, 13-H3), 0.88 (d, J = 7.0 Hz, 15-H3), 0.63 (ddd, J = 11.5; 9.0; 6.0 Hz, 7-H), 0.16 (dd, J = 9.5; 9.0 Hz, 6-H); *trans* isomer δ: 8.22 (d, J = 12.0 Hz, H—C(=O)—), 5.20 (bm, NH), 1.01 (s, 12-H3), 0.94

(s, 13-H3), 0.89 (d, J = 7.0 Hz, 15-H3), 0.69 (ddd, J = 11.5; 9.0; 6.0 Hz, 7-H), 0.25 (dd, J = 9.5; 9.0 Hz, 6-H).

*Treatment of **1** with sulphur to obtain **2***

A mixture of **1** (6 mg) and excess of sulphur was heated at 120°C for 16 h. After addition of 40–70° light petroleum and filtration, the solution, taken to dryness, was purified by tlc (silica gel, *n*-hexane, uv). The band with R_f 0.6, scraped and eluted with Et_2O, afforded 4 mg of an oily product, identical to the natural **2** on the basis of their chromatographic and spectral properties.

*Treatment of **4** with sulphur to obtain **5***

Compound **4** (8 mg) was treated with sulphur by the procedure used for **1**, thus obtaining 4.5 mg of **5**, identical to the natural **5**.

*Hydration of **1** to obtain **3***

To **1** (6 mg) in anhydrous Et_2O (6 mL), glacial AcOH was added and the solution allowed to stand at room temperature for 2 h. After washing with 10% Na_2CO_3 solution and then with H_2O, the organic phase, dried and taken to dryness, was purified by tlc (SiO_2, Et_2O) to give 3.5 mg of **3**, identical to **3** isolated from *A. cannabina*.

*Hydration of **4** to obtain **6***

Compound **4** (6 mg) was treated in the analogous way used for the synthesis of **3**, thus obtaining 4 mg of **6**, identical to natural **6** on the basis of their chromatographic and spectral properties.

*Dehydrogenation of **4***

A mixture of 15 mg of **4** and 30 mg of Se was heated at 280°C for 30 min. After cooling, 40–70° light petroleum was added and the filtered solution was extracted with 60% aqueous H_2SO_4. The acid phase was diluted with water and extracted with 40–70° light petroleum. After washing with H_2O the organic phase was taken to dryness to give guaiazulene, identified by comparison of its properties with those of an authentic specimen.

Acknowledgments

The authors wish to thank Professor M. Sarà (University of Genova) for identifying the sponge. Mass spectra were provided by "Servizio di Spettrometria di Massa del C.N.R. e dell'Università di Napoli". The assistance of the staff is gratefully acknowledged.

Hydrodésazotation de l'indole sur catalyseur fer supporté sur amiante

ROGER ZALMA, LIONEL BONNEAU, JEANINE FOURNIER, JOËLLE GUIGNARD, FRANÇOISE BORG[1] ET HENRI PEZERAT[2]

Laboratoire de réactivité de surface et structure, Unité associée 1106, Centre national de la recherche scientifique, Université Pierre et Marie Curie, 4 Place Jussieu, Tour 54–55, 75252 Paris CEDEX 05, France

Reçu le 15 juillet 1986

ROGER ZALMA, LIONEL BONNEAU, JEANINE FOURNIER, JOËLLE GUIGNARD, FRANÇOISE BORG et HENRI PEZERAT. Can. J. Chem. **65**, 523 (1987).

Dans ce travail, la réaction de désazotation de l'indole a été testée en présence de deux variétés d'amiante (chrysotile et crocidolite) sous pression d'hydrogène. Cette réaction s'effectue suivant deux voies compétitives dont les principales étapes ont été déterminées. Les produits de désazotation sont essentiellement l'éthylcyclohexane et le méthylcyclohexane. L'augmentation de la température et de la pression et la préréduction des matériaux favorisent la désazotation. La présence de particules de Fe^0 en surface de fibres, formées à partir du matériau de départ, joue un rôle dans la première coupure des liaisons C—N et dans l'hydrogénation des cycles.

ROGER ZALMA, LIONEL BONNEAU, JEANINE FOURNIER, JOËLLE GUIGNARD, FRANÇOISE BORG, and HENRI PEZERAT. Can. J. Chem. **65**, 523 (1987).

The aim of this study is to examine hydrodenitrogenation (HDN) of indole on asbestos catalysts (chrysotile and crocidolite) under hydrogen pressure. HDN is carried out according to two competitive pathways, either via *ortho*-ethylaniline or via *ortho*-toluidine. This reaction is assisted by increase of temperature and pressure and by pre-reduction of the asbestos. Particles of Fe^0 on the fibre surface are formed from the original material. Their presence plays a role in the initial breaking of the C—N bond and in the hydrogenation reaction.

Le processus d'hydrotraitement catalytique a pour but d'éliminer les hétéroatomes (S, N, O) à partir des fractions lourdes du pétrole en effectuant l'hydrodésulfuration (HDS) et l'hydrodésazotation (HDN) qui s'avère être l'étape la plus difficile.

L'hydrodésazotation des hydrocarbures azotés est un processus catalytique entraînant la formation de NH_3 dont la présence conduit à un empoisonnement des sites actifs des catalyseurs acides utilisés en craquage, réformage et isomérisation.

Actuellement, l'HDN est effectuée à partir de catalyseurs hétérogènes tels CoMo, NiMo sulfurés supportés sur alumine. Plusieurs auteurs étudiant les mécanismes des réactions d'HDN sur ces catalyseurs (1, 2) ont avancé l'intervention de plusieurs espèces de sites actifs.

Nos précédents travaux sur les amiantes ont mis en évidence la présence dominante de sites donneurs d'électrons sur ces matériaux. Ces sites sont des groupements OH en basse coordination, situés en frontière de la phase solide (3, 4). De plus, nous avons révélé le caractère catalytique des amiantes, notamment dans l'oxydation d'un hydrocarbure polyaromatique, le fluorène (5). Aussi, était-il intéressant de tester ces solides comme catalyseurs en HDN.

Pour cette étude, nous avons utilisé deux minéraux, le chrysotile et la crocidolite (une amphibole ferrifère) représentatifs des deux familles d'amiante. Ces deux minéraux contiennent de la magnétite comme impureté principale (3–4%). Lors des opérations de réduction, la magnétite est réduite en Fe^0 ce qui conduit à un solide qu'on peut considérer comme un catalyseur fer supporté sur amiante. Dans la majorité de nos travaux, l'indole a été choisi comme molécule de départ.

Le but de ce travail n'est pas de fournir des mécanismes détaillés des réactions en cause, mais plutôt de mettre en évidence l'activité catalytique de matériaux simples pour l'HDN de certains hétérocycles.

Méthodes expérimentales

Les réactions ont été réalisées dans un autoclave Prolabo (volume de 250 mL) avec un système d'agitation oscillant (environ une oscillation par seconde, non modulable). Le volume de solution est inférieur à 100 mL et la vitesse maximale de montée en température est de 4°C/min. L'inertie du four est telle que le refroidissement s'effectue avec une vitesse de l'ordre de 1°C/min. Un tube central muni d'une crépine et d'un robinet permet des prises d'essai au cours du temps.

Le solvant utilisé est l'hexadécane, sauf dans quelques expériences où nous avons employé l'hexane.

Les matériaux testés sont un chrysotile et une crocidolite commerciaux. Le chrysotile est très proche des échantillons canadiens, en particulier parce qu'il contient les mêmes contaminants minéraux : magnétite et némalite (brucite fibreuse). Le taux de fer total exprimé en Fe_2O_3 est de 5,85%, celui de Fe^{2+} exprimé en FeO, de 1,58%. La crocidolite, en provenance d'Afrique du Sud, a une composition proche de la formule théorique, soit $Na_2Fe_3Si_8O_{22}(OH)_2$, avec à peu près le même taux de Fe^{2+} et de Fe^{3+}.

Ces amiantes ont d'abord été séchés à 60°C puis broyés 30 s dans un broyeur à anneau. Ils sont ensuite lavés deux fois avec du benzène à l'ébullition pour éliminer les impuretés susceptibles d'être préadsorbées, puis séchés sous courant d'azote à 70°C. Ces matériaux, suivant les expériences, peuvent ensuite subir d'autres traitements que nous préciserons ultérieurement.

La réaction est effectuée avec 75 mL de solvant, 2,25 g d'amiante et 225 mg de produit organique à désazoter. Certaines expériences ont été réalisées avec une préréduction du solide, consistant en un traitement dans l'autoclave avec 50 mL de solvant sous une pression d'hydrogène de 7 MPa et à une température de 350°C pendant 6 h. Après refroidissement on ajoute 25 mL de solvant et le produit organique à traiter.

Les produits de la réaction sont analysés en chromatographie phase vapeur (cpv) sur un chromatographe Girdel E 330 (colonne Chromosorb W à 10% de silicone OV 17).

Après réaction, les fibres sont séparées par filtration et la solution est analysée.

Nos résultats sont exprimés en pourcentage par rapport à l'ensemble des produits provenant de la réaction d'HDN de l'indole. L'analyse chromatographique et, dans quelques cas, la spectrographie de masse ont permis de déterminer les produits formés.

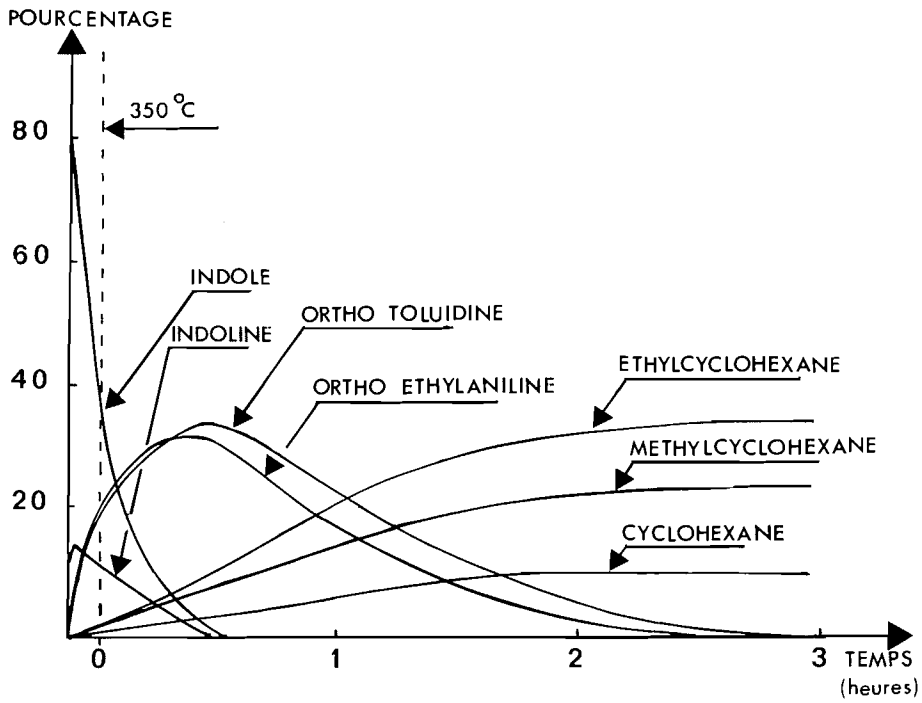

FIG. 1. Evolution du pourcentage des différents produits en fonction du temps à partir du chrysotile préréduit (350°C, 7 MPa H_2).

L'inertie du four utilisé ne permet pas de considérer comme négligeable l'intervalle de temps nécessaire à l'établissement des conditions expérimentales choisies. Ceci nous a conduit à utiliser trois modes opératoires afin de mieux appréhender les processus réactionnels :

(a) Des réactions avec palier de température

Un temps de 6 h est compté entre l'instant de mise en marche du four et celui de son arrêt. La vitesse de montée en température est de 4°C/min. L'analyse des produits contenus dans le réacteur a lieu après refroidissement complet. Le choix d'un temps relativement long de 6 h permet de négliger les éventuels problèmes de diffusion. Nous verrons d'ailleurs (fig. 1) que l'équilibre réactionnel est atteint pour un temps de 3–4 h.

(b) Des réactions sans palier de température

L'expérience est menée comme dans le cas précédent si ce n'est que le four est arrêté dès qu'il atteint la température choisie.

(c) Des réactions avec prélèvements (1 mL) au cours du temps réalisées dans les mêmes conditions opératoires qu'en (*a*). Dans ce cas le refroidissement est très rapide ce qui permet d'admettre que les réactions sont stoppées instantanément.

Dans les trois cas, la pression d'hydrogène annoncée est la pression initiale à froid, la pression finale étant évidemment plus élevée compte tenu de l'augmentation de la température.

Nous avons limité volontairement la température maximale à 380°C pour éviter une altération structurale des solides utilisés.

Le chrysotile et la crocidolite utilisés contiennent en faible quantité de la magnétite Fe_3O_4 que l'on met en évidence par diffraction des rayons X après extraction à l'aide d'un barreau aimanté (agitation dans le benzène). La formation de particules de Fe^0 lors des opérations est suivie par le même méthode.

Résultats

(a) Etudes préliminaires

À 350°C sous 7 MPa d'hydrogène et en absence des catalyseurs, nous avons constaté la formation de 0,8% d'indoline, 99% de l'indole étant conservé. Dans une expérience effectuée en palier de température à 380°C sous 7 MPa d'hydrogène et sans catalyseur, 1% de l'indole est consommé. Seulement des traces de produits désazotés ont pu être décelées.

En présence d'amiante et en absence d'indole on observe un début de craquage du solvant, l'héxadécane, à 350°C sous pression d'hydrogène. Huit *n*-alcanes (de C_5 à C_{12}) sont mis en évidence. On les retrouve dans toutes les réactions et on ne les prend pas en considération dans les résultats.

Quelques expériences en palier de température à 250, 300 et 350°C, avec chrysotile et crocidolite, permettent d'identifier, dans tous les cas, les trois grandes étapes ci-dessous :

$$\text{Indole} \xrightarrow{\text{(I)}} \text{indoline} \xrightarrow{\text{(II)}} \begin{matrix}\textit{ortho}\text{-éthylaniline}\\ \textit{ortho}\text{-toluidine}\end{matrix}$$

$$\xrightarrow{\text{(III)}} \begin{matrix}\text{éthylcyclohexane}\\ \text{méthylcyclohexane}\\ \text{cyclohexane}\end{matrix}$$

(b) Evolution des produits formés en fonction du temps

Cette étude, en palier de température, a été réalisée à partir de chrysotile préréduit et en effectuant des prélèvements au cours du temps.

Nous avons représenté sur la figure 1 l'évolution du pourcentage des différents produits de la réaction en fonction du temps. Sur le graphique nous avons choisi comme origine des temps l'instant où le four atteint 350°C. Les réactions en cause débutent aux environs de 250°C, donc avant le point choisi comme origine des temps.

Nos conditions expérimentales ne nous permettent pas d'accéder aux constantes de vitesse de chacune des réactions, mais on peut cependant observer que les vitesses apparentes de disparition de l'indoline, de l'*ortho*-éthylaniline et de l'*ortho*-toluidine sont plus lentes que celles d'apparition.

Au delà de 30 min, à chaque instant la somme S_E de l'*ortho*-éthylaniline et de l'éthylcyclohexane d'une part et la somme S_T de l'*ortho*-toluidine, du méthylcyclohexane et du cyclohexane sont sensiblement constantes.

Les chemins réactionnels probables sont donnés dans la figure 2.

Au début de la réaction, l'indole est réduit en indoline, qui,

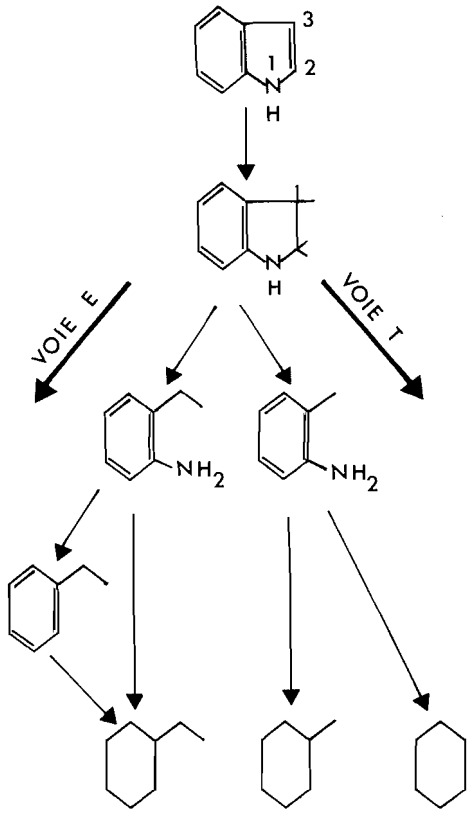

FIG. 2. Schéma des chemins réactionnels.

au delà d'une demi-heure, est totalement transformée en *ortho*-éthylaniline et en *ortho*-toluidine selon des réactions compétitives comme nous le montrerons ci-dessous. L'*ortho*-éthylaniline conduit ensuite à l'éthylcyclohexane (avec peut-être l'éthylbenzène comme phase intermédiaire) d'où la quasi-constance de la somme S_E. De même, nous pouvons déduire que l'*ortho*-toluidine est désazotée en méthylcyclohexane. Le cyclohexane provient directement de l'*ortho*-toluidine sans passer par le méthylcyclohexane, comme nous le montrerons ci-après.

(c) Influence de divers paramètres

Influence de la pression

Les expériences H_{33} et H_{26} (tableau 1) ont été réalisées à 380°C sans palier (notées ↗380°C↘) sous des pressions de 3 et 7 MPa, avec du chrysotile préréduit.

L'examen du tableau 1 révèle que la diminution de la pression (de 7 à 3 MPa) abaisse le taux de désazotation de l'indole. À faible pression on obtient une teneur élevée en *ortho*-éthylaniline et *ortho*-toluidine, ce qui confirme qu'il s'agit bien de produits intermédiaires dans la formation de l'éthylcyclohexane et du méthylcyclohexane. Sur ce même tableau on observe aussi qu'une diminution de pression favorise la voie T au détriment de la voie E. Par exemple, la somme *ortho*-toluidine plus méthylcyclohexane (voie T) passe de 25,6 à 41% alors que la somme *ortho*-éthylaniline plus éthylcyclohexane (voie E) passe de 54 à 33%.

Nous avons désigné par G un produit non identifié qui a un temps de rétention en chromatographie gazeuse proche de celui de l'éthylbenzène. Il apparaît en faible quantité et les expériences complémentaires ci-dessous nous font penser qu'il s'agit de l'éthylcyclohexène, composé déjà mis en évidence par Stern (6) dans l'HDN de l'indole. Ce composé serait intermédiaire, dans la voie E, entre éthylbenzène et l'éthylcyclohexane.

Ethylcyclohexane	20,1	53,5
Méthylcyclohexane	17	25,1
Cyclohexane	17,5	14,1

[a]% : pourcentage par rapport à la somme des produits issus de l'indole.

Influence de la température

L'influence de la température a été étudiée d'une part avec le chrysotile préréduit (H_{25}, H_{27}, H_{26}) sans palier de température, d'autre part avec la crocidolite (H_{18}, H_{21}) sans préréduction et avec palier de température (noté $\overrightarrow{300°C}$ et $\overrightarrow{380°C}$).

L'examen du tableau 2 dans le cas du chrysotile préréduit fait apparaître, d'une part que le taux de désazotation varie dans le même sens que la température (37% à 350°C, 60,6% à 365°C, 99% à 380°C), et d'autre part que la variation de température ne favorise pas sélectivement une voie de désazotation (E ou T).

Dans le cas de la crocidolite, à 300°C (H_{18}) sans préréduction du catalyseur, on observe une hydrogénation de l'indole en indoline et formation d'éthylaniline. À 350°C (H_{21}) l'indole est complètement transformé en produits désazotés. La voie T est très favorisée par rapport à la voie E quand on passe de 300 à 350°C.

Influence de la préréduction

Le tableau 3 permet de mettre en évidence le rôle de la préréduction à diverses températures (250, 350 et 380°C). À 250°C, sans préréduction, la transformation de l'indole est faible (<5%). À cette température, la préréduction entraîne la transformation de 93% de l'indole avec prédominance de la voie E (58% d'*ortho*-éthylaniline). À 350°C, les expériences effectuées sans préréduction montrent que la désazotation reste faible (10%). La transformation de l'indole est cependant quasi totale avec prédominance de la voie T (60% contre 30% pour la voie E). Par contre, lors de l'utilisation de catalyseurs préréduits, on observe que la désazotation (>35%) et la voie E (60%) sont nettement favorisées.

Les expériences H_{29} et H_{30} réalisées avec la crocidolite à 380°C sans et avec préréduction font apparaître une évolution dans le même sens. En effet, sans préréduction on a 21,3% pour la voie E contre 30% pour la voie T alors qu'avec préréduction on obtient 65,3% pour la voie E contre 23,6% pour la voie T.

Il est nécessaire de préciser que nos conditions expérimentales entraînent l'apport de particules de Fe^0 en surface de nos matériaux dès la température de 300°C en particulier dans les expériences de préréduction à 350°C. Ce Fe^0 provient de la réduction des contaminants minéraux des deux variétés d'amiante (en particulier de la magnétite) et peut être d'une fraction des couches octaèdriques de surface des « I-beam » dans le cas de la crocidolite. Les expériences rapportées dans le tableau 3

montrent que la présence de Fe^0 et la température élevée favorisent l'étape hydrogénante.

(d) Expériences complémentaires

En vue de préciser les étapes de transformation de l'indole, nous avons réalisé des expériences en partant de différents produits intermédiaires. Toutes ces réactions, en palier de température, ont été effectuées à 350°C sous une pression de 7 MPa d'hydrogène avec du chrysotile préréduit comme catalyseur et en effectuant plusieurs prélèvements au cours du temps. Sur la figure 2 nous avons noté les différents produits mis en évidence au cours de nos analyses. Il est possible sinon probable qu'il existe d'autres produits intermédiaires mais trop instables pour qu'on ait pu les caractériser.

Afin de vérifier que la formation de l'indoline est une étape intermédiaire dans la réaction de désazotation de l'indole, qu'elle se fasse par la voie E ou la voie T, nous avons réalisé une réaction en partant de l'indoline. Un prélèvement, effectué dès que la température de l'autoclave atteignait 350°C, montrait la formation d'*ortho*-éthylaniline et d'*ortho*-toluidine, dans des proportions voisines de celles obtenues à partir de l'indole dans des conditions comparables.

Par ailleurs, afin de vérifier que l'*ortho*-toluidine n'était pas formée à partir de l'*ortho*-éthylaniline, nous avons réalisé une réaction en partant de l'*ortho*-éthylaniline. Des prélèvements effectués toutes les heures ont montré que la désazotation a bien lieu sans formation ni d'*ortho*-toluidine, ni de méthylcyclohexane, ni de cyclohexane. Seuls apparaissent l'éthylcyclohexane, un peu d'éthylbenzène et un peu de produit G qui apparaît bien comme un composé se formant dans la voie E. La quantité de G diminue en fonction du temps.

Une réaction effectuée, dans les mêmes conditions, à partir de l'éthylbenzène ne produit que de l'éthylcyclohexane.

En partant de l'*ortho*-toluidine, on forme essentiellement du méthylcyclohexane, et un peu de cyclohexane. Par contre, en partant du méthylcyclohexane on n'observe pas de transformation. Il semble donc que le cyclohexane puisse être obtenu à partir de l'*ortho*-toluidine sans passer par le méthylcyclohexane.

Afin d'examiner ce qui se passe dans le cas où le carbone en α de l'azote appartient à un cycle, nous avons essayé la réaction sur l'acridine avec le chrysotile et la crocidolite comme catalyseurs. Les produits de la réaction ont été identifiés par spectrographie de masse.

Les seuls produits mis en évidence sont des produits d'hydrogénation de l'acridine : les octahydroacridine et les tétradécahydroacridines. Des prélèvements successifs au cours de la réaction ont montré que les octahydroacridines sont une étape intermédiaire de la formation des tétradécahydroacridines. Nous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

n'avons observé aucune coupure de la molécule. Le chrysotile et la crocidolite ne semblent pas être capables d'assurer la désazotation de l'acridine dans nos conditions expérimentales.

Discussion

Les étapes de l'HDN de l'indole sur amiante révèlent des points communs et des différences avec celles présentées par l'HDN de la même molécule sur des catalyseurs à base de sulfure de molybdène et de sulfure de cobalt ou de nickel supportés sur alumine ou silice (6–8).

Les points communs sont : (*i*) le passage par l'indole, c'est-à-dire l'hydrogénation de la liaison 2–3, C_α–C_β, à peu près dans les mêmes conditions de température et de pression. Ceci confirme les observations faites par de nombreux auteurs (par exemple, réf. 9) sur la nécessité d'hydrogéner cette liaison avant de pouvoir réaliser la désazotation; (*ii*) le passage probable par l'éthylbenzène entre les étapes *ortho*-éthylaniline et éthylcyclohexane (6, 8).

La différence principale entre la catalyse sur amiante et la catalyse sur sulfures de Mo et Ni, est l'existence, dans le premier cas, d'une seconde voie d'hydrogénolyse de l'indoline (voie T sur la figure 2), puisque nous avons montré que l'*ortho*-toluidine ne provenait pas de l'éthylaniline. Cette voie conduit à la formation de méthylcyclohexane et de cyclohexane.

La présence de cette seconde voie de dégradation de l'indoline (voie T) nous amène à discuter sur la nature des sites responsables de la coupure de la liaison C_α—C_β, non constatée avec d'autres catalyseurs classiques d'HDN. Si les fibres d'amiantes sont à l'origine, du moins pour une part, de cette coupure, nous ne pouvons pas exclure le rôle du Fe^0. En effet, nous avons testé comme catalyseur, un oxyde de fer noir Prolabo qui est un mélange d'hématite et de magnétite. Préréduit dans les conditions habituelles (350°C), il donne également du Fe^0. Testé en palier à 350°C sous 7 MPa d'hydrogène, après réduction, il conduit à 43% d'indoline, 22% d'*ortho*-éthylaniline et 7% d'*ortho*-toluidine. Dans cette expérience, on n'arrive pas au stade de la désazotation proprement dite. On constate donc que le Fe^0 seul est capable d'une part de permettre la première coupure des liaisons C—N et d'autre part de conduire aux deux voies d'hydrogénolyse en favorisant la voie E par rapport à la voie T.

Le fait que la première coupure de la liaison C—N soit liée à la présence de Fe^0 dans nos matériaux tendrait à confirmer les propositions de Laine (10) sur le rôle des métaux. Cet auteur fait appel à la formation transitoire de complexes où le métal M se lie à l'azote et au carbone situé en α. Ce mécanisme est voisin de celui proposé par Guttieri et Maier (11) qui utilise le platine supporté sur silice comme catalyseur d'HDN.

À partir de toutes les expériences où nos matériaux sont préréduits, nous avons constaté que la présence du Fe^0 favorise la formation de phases hydrogénées. Aussi est-il quasi certain que le Fe^0 joue également un rôle dans l'hydrogénation du cycle benzénique pouvant conduire à partir de l'éthylaniline et de l'*ortho*-toluidine aux amines saturées correspondantes, très réactives.

Si l'on se réfère aux mécanismes catalytiques proposés par Nelson et Levy (9), la coupure des liaisons C—N sur les catalyseurs NiMo et CoMo sulfurés serait un mécanisme basique. Cette proposition est cohérente avec le fait que Ni_3S_2 est l'une des phases actives dans les catalyseurs NiMo (12) et avec le fait que cette phase a un caractère donneur d'électrons (12, 13). De même, Laine (10) fait appel à ce mécanisme pour expliquer la très nette augmentation d'activité des catalyseurs CoMo et NiMo en présence de H_2S et même d'H_2O. En effet, il fait référence à une attaque nucléophile sur le carbone situé en α, ce qui revient à faire jouer un rôle important à des entités à caractère donneur.

Dans notre cas, les sites en cause peuvent être ceux des deux variétés d'amiante puisque nous avons montré précédemment que ces matériaux avaient essentiellement un caractère donneur d'électrons (3, 4).

Conclusion

Les présents travaux indiquent que le chrysotile et la crocidolite réduits constituent des catalyseurs d'HDN avec l'indole. Par contre, avec des molécules azotées où les deux carbones en α de l'azote sont engagés dans des cycles, l'hydrogénolyse de l'hétérocycle devient très difficile.

À 380°C, sans palier de température et sous 7 MPa d'hydrogène, l'HDN de l'indole est quasi complète avec les deux minéraux préréduits. Les premières étapes confirment le fait déjà noté (6, 7) que les carbones en α et en β de l'azote doivent être saturés avant qu'il y ait hydrogénolyse. Par rapport aux catalyseurs sulfurés de molybdène et de nickel, nos catalyseurs présentent l'originalité d'une voie particulière dans l'hydrogénolyse du cycle à cinq atomes, avec perte d'un méthane, cette voie intéressant environ 50% des molécules d'indole de départ.

Les sites donneurs de l'amiante peuvent jouer un rôle dans la coupure des liaisons C—N des amines intermédiaires, les sites des particules de Fe^0 participant selon le plus probable aussi bien à la coupure des liaisons C—N qu'à celle des liaisons C—C. Si les catalyseurs bifonctionnels contenant des métaux supportés sur des solides présentant des sites acides ont été bien étudiés, il n'en est pas de même pour les catalyseurs ayant des supports à caractère basique. La présente étude est un exemple de réactivité catalytique mettant en jeu ces deux types de sites.

Comme on pouvait s'y attendre, notre étude a montré que pression et température favorisaient l'HDN, la pression semblant également favoriser la voie passant par l'*ortho*-éthylaniline par rapport à celle passant par l'*ortho*-toluidine.

Remerciements

Les auteurs tiennent à remercier la Société TOTAL-CFR pour son aide financière et technique, et notamment Mr Philippe Doligez pour les analyses en spectrographie de masse.

Étude des complexes fluorés et chlorés du plomb dans les mélanges eau–HF

RÉJEAN BEAUDOIN ET HUGUES MÉNARD

Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Reçu le 24 juin 1986

RÉJEAN BEAUDOIN et HUGUES MÉNARD. Can. J. Chem. **65**, 528 (1987).

L'étude des complexes fluorés et des complexes chlorés du plomb dans les mélanges eau–HF a été effectuée par polarographie. La diminution de l'ordre des complexes fluorés de PbF_2 à PbF^+ est en accord avec la diminution de l'activité en ions fluorure, $R_0(F)$, mesurée en augmentant la concentration en HF. L'obtention de deux formes cristallines du PbF_2 selon le domaine de concentration en HF vient appuyer l'existence de deux complexes fluorés. L'observation du PbFCl confirme la présence de complexe mixte fluorure–chlorure dans les mélanges eau–HF.

RÉJEAN BEAUDOIN and HUGUES MÉNARD. Can. J. Chem. **65**, 528 (1987).

The polarographic study of lead fluoride and of lead chloride complexes has been done in water – hydrogen fluoride solutions. The successive formation of PbF_2 and of PbF^+ is in agreement with the reduction of the fluoride ion activity, $R_0(F)$, measured with the augmentation of the HF content of the solution. The formation of two crystalline structures of PbF_2 is in accord with the existence of two complexes in solution. The formation of PbFCl shows the existence of mixed fluoride–chloride complexes in water–HF solutions.

Introduction

La polarographie dans des milieux extrêmement corrosifs pour le verre, comme les mélanges HF–H_2O, est maintenant accessible à l'aide de capillaires protégés du milieu (1). Il est possible par cette technique d'analyser la formation de complexes métalliques. Une bonne connaissance des espèces dans les mélanges HF–H_2O (2–5) permet de calculer les constantes de formation des divers complexes du fluor en solution. L'utilisation d'un système de référence indépendant du solvant est une condition (6) nécessaire car il ne s'agit plus de solutions aqueuses diluées mais de mélanges de force ionique variable et d'acidité très élevée.

Mesaric et Hume (7) ont étudié les complexes fluorés du plomb en solution aqueuse. Le complexe PbF^+ se forme à faible concentration en ions fluorure ($\beta_1 = 18$) et le PbF_2 ($\beta_2 = 356$) existe à plus grande concentration en ions fluorure dans l'eau. D'autres auteurs (8) ont obtenu les mêmes résultats avec l'ion fluorure et ont démontré que le plomb forme trois complexes avec le chlore et le brome (9, 10).

La formation de complexes chlorés en solution aqueuse a été étudiée par Bond et Hefter (8, 9). Ils ont observé trois complexes avec l'ion chlorure alors que l'ion fluorure ne conduit qu'à deux complexes dans les mêmes conditions.

Nous allons déterminer les complexes fluorés du plomb dans les mélanges eau–HF jusqu'à une concentration de 55% en poids et nous allons examiner la formation des complexes chlorés dans ces mêmes solutions. Le calcul des constantes de formation permettra de préciser les zones où on retrouve les différents complexes.

Partie expérimentale

Appareils

Un potentiostat modèle PAR174A (Princeton Applied Research) a été utilisé avec un système à trois électrodes. L'électrode au calomel saturé est séparée de la solution par une jonction en Teflon poreux. Le capillaire polarographique est recouvert de polyéthylène (1) et l'électrode auxiliaire est faite d'un fil de platine. La cellule a été fabriquée dans nos ateliers à partir de Ke1F et de Teflon. La diffraction des rayons-X a été effectuée avec un appareil Philips PW1140/1139.

Produits

Les solutions ont été préparées à partir de HF 48% en poids (J. T. Baker) et à partir de HF 100% (Matheson) dilué à la concentration voulue avec de l'eau distillée. Les autres produits utilisés sont le grade ACS.

La méthode expérimentale consiste à mesurer le potentiel de demi-vague du plomb par rapport à l'électrode de référence au calomel saturé. Le potentiel de demi-vague du système de référence indépendant du solvant, le système ferricinium/ferrocène, est ensuite mesuré dans la même solution lorsque c'est possible. Si les vagues polarographiques sont trop près l'une de l'autre, on prend les mesures séparément mais l'une après l'autre.

L'étude du plomb en présence d'ions chlorure se fait en ajoutant du KCl à une solution de 10^{-3} *M* en plomb. L'activité en ions chlorure est mesurée à l'aide d'une électrode sélective Ag/AgCl, de façon à s'assurer que l'activité est près de la concentration. Jusqu'à 55% en HF, la correspondance est suffisamment bonne pour assumer l'activité égale à la concentration.

Résultats et discussion

Pour faire les calculs concernant les complexes fluorés, nous avons besoin des mesures de l'activité en ions fluorure, $R_0(F)$, et du potentiel de l'électrode au trifluorure de lanthane E_{F^-} mesuré par rapport au système de référence ferricinium/ferrocène (Fc^+/Fc). Les valeurs de $R_0(F)$ et E_{F^-} sont les mêmes que celles publiées par Vaillant *et al.* (3).

Les complexes fluorés évoluent en fonction de l'activité en ions fluorure libres. Du point de vue expérimental, on observe un déplacement du potentiel de demi-vague, $E_{\frac{1}{2}}$, selon le milieu fluoré. On peut calculer à partir de l'équation de Nernst, les pentes que l'on devrait mesurer pour des complexes fluorés d'ordre croissant. Les calculs sont faits par rapport à l'électrode réversible aux ions fluorure libres.

Le potentiel de l'électrode réversible aux ions fluorure s'exprime selon l'équation [1]

$$[1] \quad E_{F^-} = E^0_{F^-} - E_{ECS} - 0{,}059 \log a_{F^-}$$

où a_{F^-} est l'activité des ions fluorure libres. Si on mesure l'écart $\Delta E_{\frac{1}{2}}$ entre le potentiel de demi-vague du plomb et le potentiel de l'électrode réversible aux ions fluorure, on peut définir les équations suivantes pour les complexes fluorés du plomb. On choisit comme exemple un complexe bifluoré :

$$[2] \quad PbF_2 + 2e \leftrightarrows Pb_{Hg} + 2F^-$$

$$[3] \quad E_{Pb} = E^{0\prime}_{Pb} - E_{ECS} - \frac{0{,}059}{2} \log \frac{(a_{F^-})^2}{K_d[PbF_2]}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

En combinant les équations [1] et [3]:

$$[4] \quad \Delta E_{\frac{1}{2}} = E^{0\prime}_{Pb} - E^{0}_{F^-} + 0{,}059 \log a_{F^-} - \frac{0{,}059}{2} \log \frac{(a_{F^-})^2}{K_d}$$

$$[5] \quad \Delta E_{\frac{1}{2}} = \text{cte} + 0{,}059 \log a_{F^-} - 0{,}059 \log a_{F^-}$$

$$[6] \quad \Delta E_{\frac{1}{2}} = \text{cte} + 0 \log a_{F^-}$$

L'équation [6] montre clairement que pour le complexe PbF_2, la pente du potentiel de demi-vague en fonction du log a_{F^-} est de 0 volt. De la même façon on peut démontrer que le complexe PbF^+ produira une pente de +0,029 volt et le PbF_3^- produira une pente de −0,029 volt.

Les constantes de formation obtenues en présence d'ions chlorure ont été calculées à partir de la théorie de DeFord et Hume (11). Pour un ion métallique complexé dont le métal est soluble dans le mercure, la réduction à l'état métallique peut s'exprimer par l'équilibre suivant, [7]:

$$[7] \quad MX_J^{+(n-Jb)} + ne \leftrightarrows M_{Hg} + JX^{-b}$$

Le terme X^{-b} représente l'espèce complexante et J représente le nombre de ligands sur le métal.

Les constantes de formation cumulatives peuvent être évaluées à partir des équations [8] et [9].

$$[8] \quad F_0(X) = \Sigma \beta_J C_X^J$$

$$[9] \quad F_0(X) = \text{antilog} \left\{ 0{,}434 \frac{nF}{RT} (E_{\frac{1}{2}})_S - (E_{\frac{1}{2}})_c + \log \frac{(i_d)_S}{(i_d)_c} \right\}$$

Le terme $F_0(X)$ est introduit pour représenter la quantité mesurable du côté droit de l'équation. Le terme β_J représente la constante de formation du complexe J et C_X la concentration de l'espèce complexante. Les termes $(E_{\frac{1}{2}})$ et $(i_d)_S$ font référence au potentiel de demi-vague et au courant de diffusion de l'ion en solution sans l'espèce complexante alors que $(E_{\frac{1}{2}})_c$ et $(i_d)_c$ réfèrent à l'ion en présence de l'espèce complexante.

On introduit par la suite la fonction $F_1(X)$, [10], où

$$[10] \quad F_1(X) = (F_0(X) - \beta_0)/c_X$$

β_0 est la constante de formation du complexe zéro. Sa valeur est donc de l'unité. Si on porte en graphique $F_1(X)$ en fonction de la concentration en ligand, c_X, l'extrapolation à $c_X = 0$ de la fonction $F_1(X)$ nous donne la constante de formation β_1. De la même façon, on peut obtenir les autres constantes de formation par l'équation générale suivante, [11]:

$$[11] \quad F_n(X) = (F_{n-1}(X) - \beta_{n-1})/c_X$$

Pour le dernier complexe, le graphique de $F_n(X)$ en fonction de c_X donnera une droite parallèle à l'abscisse. Ceci permet de déterminer le nombre de complexes possible dans le mélange.

Shaap et McMaster (12) ont mis au point une méthode pour l'étude de complexes mixtes. On peut calculer les constantes de formation des complexes mixtes en autant que l'on connaisse les constantes de formation de chacun des complexes simples à la même force ionique et dans le même solvant. Dans notre étude, il n'est pas possible de faire ce calcul car le solvant est lui-même une espèce complexante. On connaît les constantes de formation des complexes fluorés sur le domaine de concentration en HF jusqu'à 60%. Il n'est cependant pas possible de connaître les constantes de formation des complexes chlorés pour chaque concentration en HF. La force ionique change peu avec l'addition de KCl, mais d'une concentration en HF à l'autre la différence devient très importante. Les concentrations en HF varient de 2 à 40 mol/L.

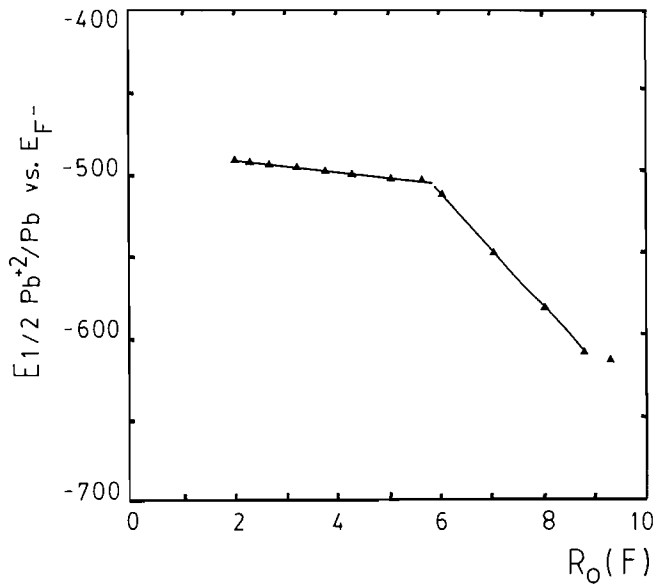

FIG. 1. Potentiel de réduction du plomb vs. E_{F^-} en fonction de l'activité en ions fluorures libres.

On ne peut pas calculer les constantes de formation des complexes mixtes contenant l'ion fluorure et l'ion chlorure mais on peut intuitivement comprendre qu'en solution l'ion chlorure remplacera successivement les ions fluorure sur le métal. Si on considère un mélange où on a le complexe MF_2, l'addition d'ions chlorure conduira aux complexes MFCl, $MFCl_2^-$ et MCl_3^-, selon la concentration en ions chlorure.

Les potentiels de réduction du plomb en fonction de la concentration en HF sont présentés au tableau 1. Le tableau 1 montre les mesures par rapport au système ferricinium/ferrocène et les résultats calculés par rapport au potentiel de l'électrode réversible aux ions fluorure.

La figure 1 présente le graphique du potentiel de demi-vague réversible aux ions fluorure en fonction de $R_0(F)$. On peut calculer la pente de $E_{\frac{1}{2}}$ versus $R_0(F)$ et déterminer les complexes fluorés en solution.

TABLEAU 2. Pentes tirées du graphique de la réduction du plomb

Domaine de % en HF (Poids)	Pente (Volt)	Complexe	Pente calculée (Volt)
2–35	+0,003	PbF_2	0
35–55	+0,032	PbF^+	+0,029

	log K	log β
PbF^+	9,3	9,3
PbF_2	5,8	15,1

Les complexes fluorés du plomb

L'interprétation des résultats se fait à partir de la pente du graphique de $E_{\frac{1}{2}}$ versus $R_0(F)$ ($R_0(F) = -\log a_{F^-}$). Le tableau 2 donne les résultats pour les complexes du plomb obtenus en solution.

La pente du potentiel de demi-vague en fonction de l'activité en ions fluorure nous permet de dire que dans le domaine de 2 à 35% en HF, le complexe en solution est le PbF_2. Dans le domaine de 35 à 55% en HF, le complexe est le PbF^+. On peut écrire les équilibres [12] et [13]:

[12] $PbF_2 + 2é \leftrightarrows Pb_{Hg} + 2F^-$

[13] $PbF^+ + é \leftrightarrows Pb_{Hg} + F^-$

Dans les solutions aqueuses, le complexe existant est PbF_2. Lorsque la concentration diminue, on passe à PbF^+. On observe le même comportement dans les solutions aqueuses de HF. On peut noter que le changement de PbF_2 à PbF^+ se fait entre 35 et 40% en HF.

Il est possible d'évaluer les constantes de formation des complexes fluorés à partir du changement de pente du potentiel de demi-vague réversible aux ions fluorure en fonction de l'activité en ions fluorure, $R_0(F)$ (13). Si on établit l'équilibre suivant:

[14] $PbF^+ \overset{K_1}{\rightleftarrows} Pb^{+2} + F^-$ et $PbF_2 \overset{K_2}{\rightleftarrows} PbF^+ + F^-$

la constante d'équilibre K_2 s'établit comme suit:

$$[15] \quad K_2 = \frac{[a_{F^-}][a_{PbF^+}]}{[a_{PbF_2}]}$$

Au point d'inflection, à la figure 1, on peut faire l'approximation que la concentration des deux complexes fluorés est équivalente. L'équilibre est alors contrôlé par l'activité en ions fluorure du milieu. La constante d'équilibre du complexe peut alors être exprimée de la façon suivante:

[16] $K_2 = 1/a_{F^-}$

[17] $\log K_2 = -\log a_{F^-} = R_0(F)$

Une approche similaire nous permet de calculer K_1. Le tableau 3 montre les constantes d'équilibre K_1 et K_2 et le log des constantes de formation β_1 et β_2.

La figure 2 présente la distribution des complexes fluorés du plomb jusqu'à 60% en HF calculée à partir des constantes successives de formation.

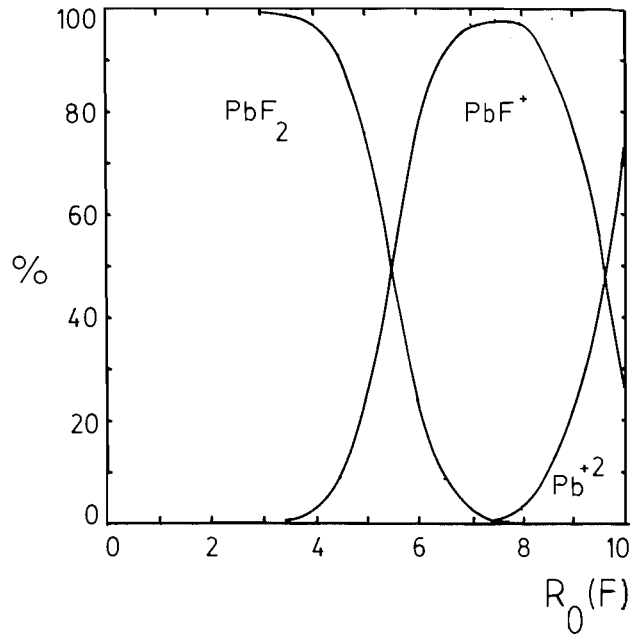

FIG. 2. Distribution des complexes fluorés du plomb en fonction de l'activité en ions fluorure libres.

D'autre part, en diffraction des rayons-X, on a analysé l'espèce formée à la surface d'une plaque de plomb oxydée dans les mélanges eau–HF. Le fluorure de plomb PbF_2 a la particularité de cristalliser sous deux formes dont les plans de diffraction sont très différents.

On a la forme orthorhombique appelée αPbF_2 et la forme cubique appelée βPbF_2 (14). La forme orthorhombique a la même structure que le $PbCl_2$ et le $PbBr_2$. Il y a quatre groupements PbF_2 par maille. La distance Pb—F varie de 2,49 à 2,85 Å. Cette structure est stable à basse température. Le αPbF_2 (orthorhombique) est préparé en dissolvant du PbO dans du HF 39%. La solution est évaporée puis le résidu est séché sous atmosphère inerte à une température de 80 à 100°C. L'analyse par rayons-X a démontré que l'échantillon n'est pas contaminé par du βPbF_2 cubique (15). Kennedy *et al.* (16) ont rapporté que la précipitation rapide de PbF_2 à partir d'une solution de $Pb(NO_3)_2$ et NH_4F donne majoritairement du αPbF_2. Cependant, si la précipitation se fait lentement, la forme cubique sera prédominante. Ceci implique que la forme cubique est la plus stable à la température de la pièce.

La forme cubique a la même structure que le CaF_2. Il y a deux groupements PbF_2 par maille. La distance Pb—F est de 2,57 Å. Cette structure est stable à haute température. Le PbF_2 sous forme cubique est transparent à température et pression normale. La phase cubique se transforme en phase orthorhombique sous l'influence de la pression. La phase orthorhombique a un volume environ 10% inférieur à la phase cubique. Cette transition avec la pression est non réversible (17, 18).

Nos mesures de diffraction des rayons-X ont montré que le PbF_2 sur les plaques de plomb oxydées dans les mélanges eau–HF se retrouve sous les deux formes cristallines. À faible concentration en HF, on trouve du αPbF_2 comme dans les solutions aqueuses concentrées en ions fluorure (7). Les analyses montrent que dans les mélanges jusqu'à 30% en HF on retrouve du αPbF_2. À 5, 10 et 20% en HF, on note la présence d'une très petite quantité de βPbF_2. La hauteur des pics est dans un rapport de 1 à 100. À 30% en HF, le αPbF_2 et le βPbF_2 sont présents en quantité comparable. À 40% en HF, on retrouve exclusivement la forme cubique du PbF_2.

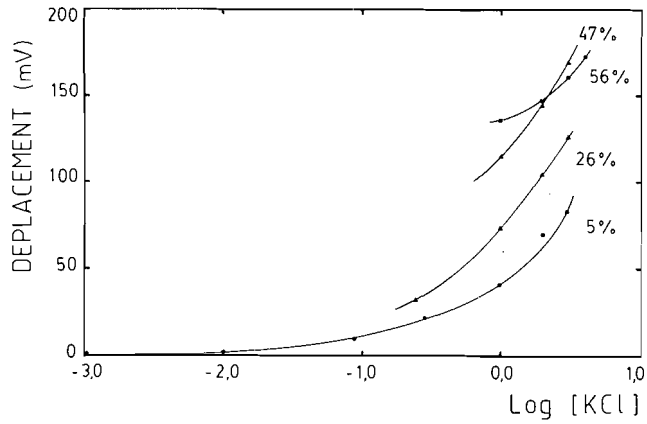

FIG. 3. Déplacement du potentiel de demi-vague du plomb en fonction du log de la concentration en KCl pour différentes concentrations en HF.

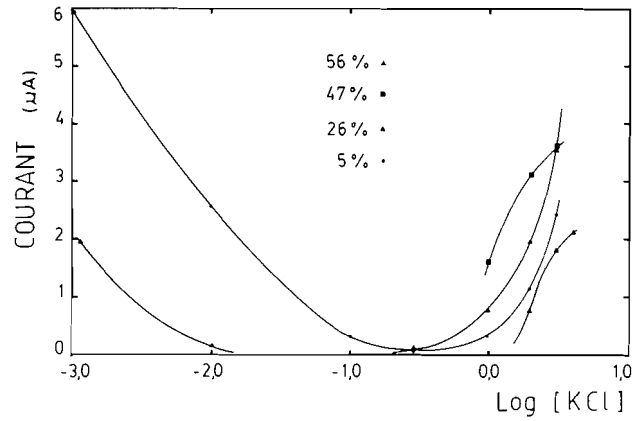

FIG. 4. Evolution du courant de diffusion du plomb en fonction du log de la concentration en KCl pour différentes concentrations en HF.

La transition de αPbF_2 à βPbF_2 aux concentrations entre 30 et 40% en HF correspond très bien à la brisure dans la relation du potentiel de demi-vague en fonction de l'activité en ions fluorure R_0(F). La relation à la figure 1 change de pente à R_0(F) d'environ 5,5. Ceci correspond à une concentration en HF de 35%. À moins de 35% en HF, le PbF_2 cristallise sous la forme orthorhombique, comme en solution aqueuse. On peut donc conclure que le complexe en solution est PbF_2 et la précipitation ou cristallisation est rapide. La pente à la figure 1 est de 0,0 volt, ce qui avait permis de conclure au complexe PbF_2 en solution.

À 40% en HF, on retrouve seulement du βPbF_2. Pour toutes les concentrations subséquentes, l'espèce cubique est la seule retrouvée à la surface du plomb.

La forme cubique du PbF_2 occupe un volume environ 10% plus élevé que la forme orthorhombique. Dans le domaine de concentration en HF entre 35 et 55%, l'espèce en solution est PbF^+. Cette espèce chargée est sûrement stabilisée par le solvant. Dans les solutions concentrées en HF, il y aura aussi stabilisation par le solvant. Il est donc raisonnable de penser que le complexe chargé est stabilisé en solution par le solvant et que l'évaporation ou la désolvatation soit responsable de la cristallisation lente sous la forme la plus volumineuse. Dans ce cas, on obtient la forme cubique du PbF_2.

Les complexes chlorés de plomb

Le déplacement anodique du potentiel de demi-vague a été relié à la formation de complexes chlorés en solution. Nous

TABLEAU 4. Constantes de formation successives des complexes chlorés du plomb

% HF (Poids)	β_1	β_2	β_3
56	30 000±10 000	10 000±3000	~4 000
47	3 700±200	5 000±200	10 000±2000

allons calculer les constantes de formation à partir de la théorie de DeFord et Hume (11). Les déplacements du potentiel de demi-vague sont présentés à la figure 3 et l'évolution du courant de diffusion est montrée à la figure 4.

La diminution du courant de diffusion est due à la précipitation du plomb sous forme du complexe mixte PbFCl. Le précipité a été identifié par diffraction des rayons-X.

Les écarts entre nos valeurs et celles fournies par ASTM sont à l'intérieur des limites de l'appareil que nous avons utilisé.

À partir des constantes de formation données au tableau 4, on peut calculer la proportion de chaque complexe chloré dans les mélanges eau–HF. Les figures 5–8 montrent les proportions de chaque complexe en fonction de la concentration en KCl dans la solution. La figure 9 montre la distribution des complexes chlorés en solution aqueuse calculée à partir des constantes de formation de Bond et Hefter (9).

En solution aqueuse, le plomb donne trois complexes chlorés. Dans les mélanges eau–HF on a aussi trois complexes chlorés. À 5 et 26% en HF, le complexe fluoré en solution est le PbF_2. La distribution des complexes chlorés ressemble beaucoup à ce qu'on observe en solution aqueuse. Le complexe $PbCl_3^-$ apparaît à des concentrations en KCl élevées et dans la même région que $PbCl_2$. Les constantes de formation dans l'eau et dans HF 5% sont du même ordre de grandeur. Dans HF, le complexe $PbCl^+$ forme le PbFCl qui est non soluble et on

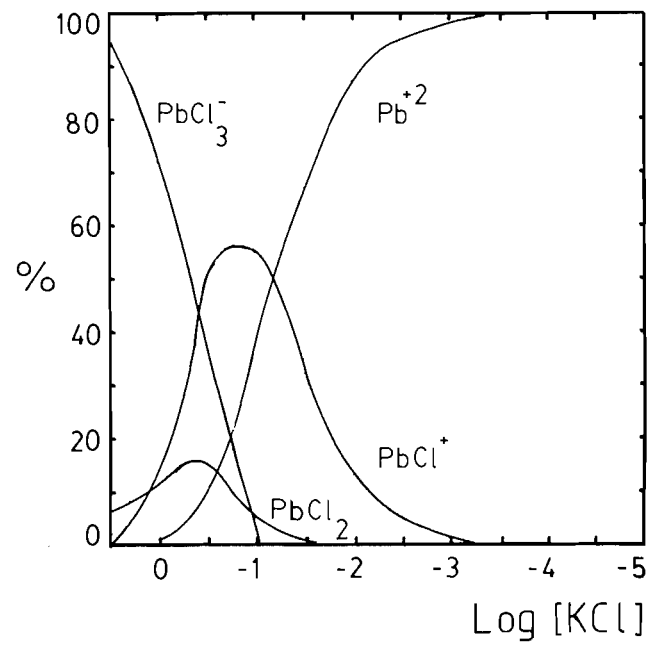

FIG. 9. Distribution des complexes chlorés en solution aqueuse en fonction de la concentration en KCl.

observe une diminution importante du courant de diffusion en polarographie.

[18] $PbF^+ + Cl^- \rightleftarrows PbFCl$ (précipité)

À 47 et 56% en HF, le complexe fluoré en solution est le PbF^+. L'addition d'un ion chlorure à cette espèce devrait être facile. En effet, la constante de formation β_1 augmente de façon très importante et le courant de diffusion chute à zéro à cause de la formation de PbFCl insoluble. Aux figures 7 et 8, on voit que le plomb est totalement sous forme de complexe $PbCl^+$ pour un important domaine de concentrations en ions chlorure.

La formation du complexe insoluble PbFCl vient appuyer l'hypothèse de la formation de complexes mixtes. Dans le domaine de concentration en HF où le complexe fluoré est PbF_2, on a remplacement des ions fluorure par des ions chlorure mais de façon successive. Dans la région où on a PbF^+, l'addition d'un ion chlorure est largement facilitée. Cependant le remplacement de l'ion fluorure semble aussi difficile qu'à plus faible concentration en HF, si on considère la proportion de complexes chlorés de degrés supérieurs. En effet, le complexe $PbCl_3^-$ apparaît toujours vers un molaire en ion chlorure. Le complexe $PbCl_2$ est peu représenté à toutes les concentrations en HF de même qu'en solution aqueuse.

Conclusion

L'étude de la vague polarographique du plomb à différentes concentrations en HF a permis de déterminer la présence de deux complexes fluorés. Le PbF_2 est présent jusqu'à 35% en poids de HF et le PbF^+ est présent de 35 à 60% en HF. L'ion chlorure déplace l'ion fluorure et on a formation de complexes mixtes chlorure–fluorure.

Solvent and α-substituent perturbations of the $^2H/^1H$ isotope shifts in the ^{13}C nuclear magnetic resonance of toluene-α-d_3

TED SCHAEFER, JAMES PEELING,[1] AND RUDY SEBASTIAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received August 12, 1986

TED SCHAEFER, JAMES PEELING, and RUDY SEBASTIAN. Can. J. Chem. **65**, 534 (1987).

The $^2H/^1H$ isotope effect on ^{13}C nmr chemical shifts, $^n\Delta$, n being the number of intervening bonds between ^2H and ^{13}C nuclei, in toluene-α-d_3 is solvent dependent. For example, $^1\Delta$ ranges from 817 ppb in CD_3OH to 869 ppb in acetone-d_6 solutions, a positive number indicating increased shielding in the deuterated species. $^1\Delta$ is linearly dependent on a function of the refractive index, n_D, of the solvent, allowing extrapolation to $n_D = 1$. The hyperconjugative model, in which the C—D bond is a poorer electron donor to the aromatic system than is a C—H bond, is tested for the substituents CH_2D, CHD_2, CD_3, $CHDCH_3$, CD_2CH_3, $CD(CH_3)_2$, C_6H_5CHD, and $(C_6H_5)_2CD$. For these substituents, the negative $^5\Delta$ is linearly related to the expectation value of $\sin^2\theta$; θ is the angle by which the C—D bond twists out of the benzene plane. The model fails quantitatively for $C_6H_5CD_2X$ (X = Cl, COOH, CN, OH). For X = OH, very large negative $^5\Delta$ and $^3\Delta$ values are observed. $^n\Delta$ is also reported for 4-ethyltoluene-α-d_3 and benzaldehyde-α-d_1. For the latter, all $^n\Delta$ values are positive other than $^5\Delta$, which vanishes in acetone-d_6 solution.

TED SCHAEFER, JAMES PEELING et RUDY SEBASTIAN. Can. J. Chem. **65**, 534 (1987).

Dans le toluène-α-d_3, l'effet isotopique $^2H/^1H$ sur les déplacements chimiques en rmn du ^{13}C, $^n\Delta$, dans lequel n est égal au nombre de liaisons intervenant entre les noyaux de ^2H et de ^{13}C, dépend du solvant. Par exemple, la valeur de $^1\Delta$ varie de 817 ppb pour des solutions dans de CD_3OH à 869 ppb pour des solutions dans l'acétone-d_6; une valeur positive indique une augmentation du blindage dans les espèces deutérées. La valeur de $^1\Delta$ varie d'une façon linéaire avec l'indice de réfraction, n_D, du solvant; cette propriété permet d'extrapoler jusqu'à une valeur de $n_D = 1$. On a vérifié l'efficacité du modèle comportant de l'hyperconjugaison, dans lequel la liaison C—D donne moins facilement des électrons au système aromatique qu'une liaison C—H pour les substituants CH_2D, CHD_2, CD_3, $CHDCH_3$, CD_2CH_3, $CD(CH_3)_2$, C_6H_5CHD et $(C_6H_5)_2CD$. Pour ces substituants, la valeur négative de $^5\Delta$ présente une corrélation linéaire avec la valeur attendue de $\sin^2\theta$; θ est l'angle de torsion de la liaison C—D par rapport au plan du benzène. D'un point de vue quantitatif, le modèle n'est pas approprié pour $C_6H_5CD_2X$ (X = Cl, COOH, CN, OH). Pour X = OH, on observe des valeurs de $^3\Delta$ et $^5\Delta$ qui sont très importantes et négatives. On rapporte aussi les valeurs de $^n\Delta$ pour l'éthyl-4 toluène-α-d_3 et pour le benzaldéhyde-α-d_1. Dans ce dernier composé, toutes les valeurs de $^n\Delta$ sont positives, à l'exception de $^5\Delta$ qui disparait en solution dans l'acétone-d_6.

Introduction

In general, nuclear shielding (a low frequency shift in nmr) increases with decreasing bond distances in polyatomic molecules (1). Because of anharmonic vibrations and centrifugal distortion a shorter average bond length ensues on replacement of a lighter by a heavier atom in a bond (2). In particular, it becomes qualitatively clear why $^1\Delta$, the $^2H/^1H$ isotope effect on ^{13}C nmr chemical shifts, is positive (increasing shielding) when ^2H replaces ^1H in the C—H bond.[2] For longer range isotope effects $^n\Delta$, n being the number of bonds intervening between ^{13}C and ^2H, complexities arise. According to Jameson (2), there is a primary dynamic effect at the substitution site, which is transmitted by a secondary electronic effect on the shielding at ^{13}C. In addition, there is a secondary dynamic effect on the bond lengths at the ^{13}C site with a concomitant primary electronic effect on the shielding. The computation of such long-range isotope shifts in larger molecules is not easy (8) and various models have been proposed to account for the observed shifts, which can be of either sign.

For conjugated systems, the hyperconjugative model is useful in some instances (9). The model entails a breakdown of the Born–Oppenheimer approximation and assumes less efficient hyperconjugative electron donation by a C—D than a C—H bond.

An additional complication comes from possible solvent-induced changes in isotope effects on nuclear shielding. Intrinsic effects are characteristic of an isolated molecule (10). Extrinsic contributions to isotope shifts should be quite general in solution because, for example, the hydrogen atom in a C—H bond has a larger amplitude of motion than the deuterium atom in a C—D bond. Therefore a difference in their interactions with solvent molecules should be present. Solvent-induced changes in isotope effects on nuclear shielding are thought (6) to be important where inter- or intramolecular hydrogen bonding occurs or, more generally, when isotopic substitution shifts the position of an equilibrium and the latter is solvent dependent.

In this paper we reexamine $^n\Delta$ values for some α-deuterated toluene derivatives in terms of the hyperconjugative model, show that solvent induced changes in $^n\Delta$ can be important for a molecule as inert as toluene-α-d_3, and demonstrate that the hyperconjugative model is of limited quantitative utility when applied to toluene derivatives with polar substituents on the side chain.

Results and discussion

The hyperconjugative model

The original suggestion (11), that $^5\Delta$ for the *para* ^{13}C nucleus in toluene-α-d_1, ethylbenzene-α-d_1, and cumene-α-d_1 depends on the angle θ, was elaborated (12) to eq. [1]. In [1], $\langle\sin^2\theta\rangle$ is the expectation value of $\sin^2\theta$, which can be obtained from

$$[1] \quad {}^5\Delta\ (\text{ppb}) = a\langle\sin^2\theta\rangle + b$$

$^6J_p^{H,CH}$ (13). The latter is the long-range spin–spin coupling constant between the α proton on the side chain and the *para* proton. Knowing $\langle\sin^2\theta\rangle$, it follows that the preferred conformation of the side chain and the barrier to internal rotation

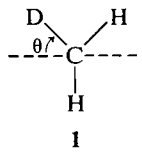
[2]See refs. 3–7 for early discussions, as well as for recent tabulations and descriptions of isotope effects on chemical shifts.



I

about the exocyclic C_{sp^2}—C_{sp^3} can be ascertained (13). Now, the measurement of $\langle \sin^2 \theta \rangle$ via $^5\Delta$ is easier than via $^6J_p^{H,CH}$ because the latter has to be extracted from complex ^{1}H nmr spectra arising from large spin systems. If relationships like [1] hold in general, then quantitative information about internal rotational barriers is available via an easy chemical shift measurement (given a high-field instrument, of course, and the requisite deuterated molecule).

Table 1 contains the observed and calculated $^5\Delta$ values for eight side chains, all measured in $CDCl_3$ solution. The calculated values come from eqs. [2] or [3], which are equivalent, of course.

$$[2] \quad {}^5\Delta \text{ (ppm)} = -13.1n\langle \sin^2 \theta \rangle + 5.1n\langle \cos^2 \theta \rangle$$

$$[3] \quad {}^5\Delta \text{ (ppm)} = -18.2n\langle \sin^2 \theta \rangle + 5.1n$$

In these equations, n is the number of α C—D bonds and $\langle \sin^2 \theta \rangle$ is 0.5 for toluene, containing a negligible internal barrier (16). For ethylbenzene, $\langle \sin^2 \theta \rangle$ is 0.385, as derived from $^6J_p^{H,CH}$ (13). A recent unpublished analysis of the ^{1}H nmr spectrum of cumene in this laboratory gave $\langle \sin^2 \theta \rangle$ as 0.229, the value used in Table 1. For diphenylmethane, $\langle \sin^2 \theta \rangle$ is taken as 0.39 ± 0.03, also deduced in this laboratory from $^6J^{H,CH}$, $^6J^{F,CH}$, and $^6J^{F,CC}$ for a number of its derivatives.

The agreement between calculated and observed $^5\Delta$ values is rather good, given the precision of about 0.4 ppb in the measurements. Note that $^5\Delta$ contains negative, presumably arising from the hyperconjugative mechanism, as well as positive components. The latter, having the same sign as $^1\Delta$, could be considered "normal," perhaps arising from the primary dynamic effect mentioned above. Equation [2] implies that this effect depends on $\langle \cos^2 \theta \rangle$, does not prove this, of course, and may be erroneous.

Solvent perturbations of $^n\Delta$ in toluene-α-d_3

Table 2 displays solvent-dependent $^n\Delta$ numbers for toluene-α-d_3, illustrating the importance of a common solvent when making comparisons of the kind given in Table 1. $^1\Delta$ increases by 51 ppb in passing from CD_3OH to CH_2I_2 as solvent. The larger $^1\Delta$ values in the more polarizable solvents are plausibly attributable to larger van der Waals interactions, which, however, cause larger deshielding in the undeuterated molecule. Solvent effects (17) for toluene display the largest deshielding of the ^{13}C nuclei in CH_2I_2 solution and are assigned to repulsive intermolecular orbital overlap effects occurring during molecular collisions. In that event, it appears sensible that C—H bonds, with their larger vibrational amplitudes, undergo larger perturbations due to collisions with solvent molecules than do C—D bonds and, therefore, that the apparent upfield shift of ^{13}C in the deuterated molecule is a consequence of the larger downfield shift in the toluene molecule itself.

Whatever the merits of the postulate (17) of a repulsive interaction as a cause of ^{13}C deshielding by solvent molecules, it may be noted that for the solvents in Table 1 a linear relation, eq. [4], exists between $^1\Delta$ and $\{(n^2 - 1)/(2n^2 + 1)\}^2 \equiv W$. The latter quantity is a measure (18) of the average squared

$$[4] \quad {}^1\Delta \text{ (ppb)} = 946.3W + 789.1$$

TABLE 1. Observed[a] and calculated[b] ^{2}H/^{1}H isotope effects on ^{13}C-4 chemical shifts in some toluene derivatives in $CDCl_3$ solution

	$^5\Delta$/ppb			$^5\Delta$/ppb	
Side chain	obsd.	calcd.	Side chain	obsd.	calcd.
CH_2D	−3.9	−4.0	CD_2CH_3	−3.8	−3.8
CHD_2	−8.0	−8.0	$CD(CH_3)_2$[c]	0	0.9
CD_3	−12.1	−12.0	C_6H_5CHD	−2.6	−2.0(5)
$CHDCH_3$	−2.1	−1.9	$(C_6H_5)_2CD$	0	0.5[d]
					−0.2[d]

[a] All but CD_2CH_3 are from refs. 9 and 11; $^5\Delta$ for CD_2CH_3 was measured in this laboratory.

[b] Calculated from $^5\Delta = -13.1n\langle \sin^2 \theta \rangle + 5.1n\langle \cos^2 \theta \rangle$ or, equivalently, from $^5\Delta = -18.2n\langle \sin^2 \theta \rangle + 5.1n$; $\langle \sin^2 \theta \rangle$ is the expectation value for $\sin^2 \theta$, θ being the angle by which the C—H bond twists out of the benzene plane; n is the number of α C—D bonds.

[c] For CH_2D, CHD_2, CD_3, $\langle \sin^2 \theta \rangle = 0.5$; for $CHDCD_3$ and CD_2CH_3, $\langle \sin^2 \theta \rangle$ is 0.385; $\langle \sin^2 \theta \rangle$ is 0.229 for $CD(CH_3)_3$ and is 0.39(3) for C_6H_5CHD (21).

[d] Deduced from $\sin^2 \theta$ for θ values given from Kerr constants (15) and infrared intensities (14); but note that these are not expectation values.

[i] Not observed.

electrical fields at the solute molecule, used in models for the van der Waals contribution to gas-to-liquid medium ^{1}H nmr shifts, particularly for hydrocarbons. Equation [4] implies a $^1\Delta$ of 789.1 ± 1.5 ppb for the isolated molecule if a reasonably short extrapolation is made to a refractive index, n_D, of unity. Because of the additivity observed for successive deuterations, $^1\Delta$ values for isolated toluene-α-d_1 and toluene-α-d_2 molecules can be estimated from the available data (11) as 263 and 526 ppb, respectively.[3]

The trend in $^2\Delta$ in Table 2 is quite similar to that of $^1\Delta$, with the exception of CD_3OH as solvent, and is presumably indicative of the same mechanism as postulated for $^1\Delta$ above. The longer range Δ values are harder to rationalize. $^5\Delta$ displays a rough trend towards more *positive* values in the solvents of *lower* polarizability (refractive indices). According to eqs. [2] or [3], $^5\Delta$ consists of two contributions, so that a solvent

[3] It is anticipated that $^1\Delta$ values for deuterated methanes in the gas phase could be estimated by procedures of this kind, of obvious interest in their computation from first principles.

[o]$^6\Delta$ to CH_2 is −0.3 ppb.
[p]Depending on how the partially resolved multiplet structure in the deuterated molecule is interpreted.

perturbation of either one or both of them is possible. It is interesting that $^4\Delta$, previously observed as zero for the compounds in Table 1 in $CDCl_3$ solution, becomes as large as 6.4 ppb for toluene-α-d_3 in acetone-d_6 solution. It is reasonable to hypothesize that $^4\Delta$ consists of terms similar in nature and equal in sign[4] to those in eqs. [2] and [3] for $^5\Delta$. Such a statement appears to hold for $^3\Delta$, in which the hyperconjugative term is nearly cancelled by the "normal" positive term (20). The latter is ca. 55 ppb for toluene-α-d_3, compared to the +15.3 ppb for $^5\Delta$. However, the data in Table 2 do not allow a decision as to the solvent dependence of either of such terms of opposite sign (see Table 3 for negative $^4\Delta$ values). Similar remarks apply to $^3\Delta$ in Table 2.

Polar α substituents

The importance of a common solvent if $^n\Delta$ values are to be compared for a set of related molecules can also be inferred from the data in Table 3. These data also demonstrate that, in the presence of polar substituents on the side chain, $\langle\sin^2\theta\rangle$ values are not ascertainable in the straightforward way found to be successful for alkyl groups in Table 1.

For the CD_2Cl, CD_2CN, and CD_2COOH side chains in Table 3, values of $\langle\sin^2\theta\rangle$ are available in acetone solution (21–23) and are 0.318, 0.51(1), and 0.33(2), respectively. It is immediately clear that eq. [3] will not reproduce the $^5\Delta$ values in acetone solution. However, on the arbitrary assumption that the hyperconjugative contribution is reduced by a factor of 9.7/12.1 (the ratio of $^5\Delta$ values for toluene-α-d_3 in acetone-d_6 and $CDCl_3$ solutions), and that the positive "normal" term is also reduced, one may write eq. [5]. This equation reproduces

$$[5]\quad {}^5\Delta\ (\text{ppb}) = -14.7n\langle\sin^2\theta\rangle + 0.7n \qquad (n = 2)$$

the observed $^5\Delta$ values to within an average deviation of 0.4 ppb. Although somewhat encouraging, this result also demonstrates that quantitative values for the internal rotational potential are not available directly from $^5\Delta$ values for arbitrary substituents on the α methyl group. A striking value of near −24 ppb is found for the CD_2OH group, for which data from this laboratory yield a $\langle\sin^2\theta\rangle$ of 0.54 in acetone solution. This value is accompanied by an equally striking $^3\Delta$ of −56.5 ppb in acetone-d_6 solution. In terms of the hyperconjugative model, the hydroxyl group causes an extraordinary decrease in the electron-donating ability of the C—D bond relative to the C—H bond.[5] Another peculiarity of $^3\Delta$ values in Table 3 is the +39 ppb observed for the CD_2COOH group, accompanied by a relatively large $^4\Delta$ of −6.4 ppb. No simple model appears to meet the requirements of such diverse values of these long-range isotope effects.

A comparison of $^n\Delta$ values for 4-ethyltoluene-α-d_3 and toluene-α-d_3 (compare for the same solvents in Table 3) suggests the rationalization that the ethyl group, being a hyperconjugative donor to the aromatic ring, decreases the donation by the methyl group and therefore leads to smaller negative (hyperconjugative) components of $^n\Delta$.

Finally, $^1\Delta$–$^4\Delta$ are all positive for benzaldehyde and $^5\Delta$

[4]Note that all ring protons in toluene are more shielded than those in benzene (19), although the *meta* protons *are* less shielded than the *ortho* and *para* protons, as expected.

[5]Of course, self-association in $CDCl_3$ solution and hydrogen bonding to solvent molecules in acetone-d_6 solution occur for benzyl alcohol, but it appears unlikely that these large values of $^3\Delta$ and $^5\Delta$ are solely attributable to such causes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

vanishes, compatible with a "normal" isotope effect that drops off rapidly as n increases. Because the barrier to internal rotation of benzaldehyde in solution is at least 30 kJ/mol (24), $\langle \sin^2 \theta \rangle$ is very small, ca. 0.05 at 300 K, so that the C—D or C—H bonds spend very little time out of the benzene plane. Furthermore, there is evidence (25) that the C=O group strongly inhibits hyperconjugative interactions of the C—H bond. These considerations are compatible with the $^n\Delta$ values in Table 3.

Experimental

Small quantities of toluene-α-d_3, benzyl alcohol-α-d_2, benzyl chloride-α-d_2, benzyl cyanide-α-d_2, phenylacetic acid-α-d_2, 4-ethyltoluene-α-d_3, ethylbenzene-α-d_2, and benzaldehyde-α-d_1 were obtained from MST Isotopes. The concentrations of undeuterated and their isotopically substituted derivatives in various solvents are given in Tables 1–3. Samples were degassed by the freeze–pump–thaw procedure and were flame-sealed. $^{13}C\{^1H\}$ nmr spectra were accumulated on an AM300 nmr spectrometer at a probe temperature of 300 K. ^1H decoupling involved the WALTZ16 pulse sequence (26). In a typical experiment, 32 FIDS were stored in 64K of memory, using a spectral window of 1064 Hz, an acquisition time of 30.8 s, and a digital resolution of 0.03 Hz/point. The precision of measurement of $^n\Delta$ was 0.4 ppb.

Caveat

A referee points out that the linear correlation between $^5\Delta$ and $^6J_p^{H,CH}$ does not necessarily support a hyperconjugative mechanism for $^5\Delta$. It may simply means that $^6J_p^{H,CH}$ and the dependence of $^5\Delta$ on the change in bond length (C—D versus C—H), at the methyl site, both depend on the same electronic transmission mechanisms. Thus, it has been shown (27, 28) that some long-range Δ values for ^{13}C and ^{19}F nuclei can be interpreted as arising from a change in electron density at the carbon and fluorine atoms, caused by a change in the bond length of the remote C—H bond. This is an interesting suggestion, although it should be noted that, while $^6J_p^{H,CH}$ in toluene is transmitted via the π electrons, it is insensitive to the presence of ring substituents (19, 29), whereas the electron densities at the various sites in the ring are markedly dependent on the nature of the substituents.

Conformational preference and internal rotation about the C_1—C_α bond in phenylacetaldehyde and some benzyl alkyl ketones from ^1H nuclear magnetic resonance and *ab initio* molecular orbital calculations

GLENN H. PENNER

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received August 20, 1986

GLENN H. PENNER. Can. J. Chem. **65**, 538 (1987).

Analysis of the ^1H nuclear magnetic resonance spectra of the benzyl moieties in phenylacetaldehyde, benzyl methyl ketone, benzyl ethyl ketone, benzyl isopropyl ketone, and 3,5-dichlorobenzyl *tert*-butyl ketone yields the long-range couplings between ring and α protons. These stereospecific couplings change very little upon replacement of the aldehydic hydrogen by various alkyl groups. The couplings for all the molecules studied fall within the ranges $^4J(CH_2, H_o) = -0.566 \pm 0.008$ Hz, $^5J(CH_2, H_m) = 0.278 \pm 0.002$ Hz, and $^6J(CH_2, H_p) = -0.409 \pm 0.010$ Hz, suggesting that in the ketones the alkyl group prefers to be *trans* to the phenyl ring and does not interfere with rotation about the C_1—C_α bond. The long-range couplings are consistent with a potential function $V(\theta) = 8.4 \pm 1.2 \sin^2\theta$ for two-fold rotation about the C_1—C_α bond; θ is the angle between the carbonyl and benzene ring plane. *Ab initio* molecular orbital calculations on phenylacetaldehyde at the STO-3G level with the C=O bond *cis* to the phenyl group yield a potential of $V(\theta) = (8.65 \pm 0.73) \sin^2\theta + (1.27 \pm 0.80) \sin^2 2\theta$, rather close to the experimental potential but with a small fourfold component. The spin–spin coupling constant between the aldehydic and α protons displays a solvent dependence consistent with previously reported values. The insensitivity of $^4J(CH_2, H_o)$, $^5J(CH_2, H_m)$, and $^6J(CH_2, H_p)$ to solvent suggests that $\langle\sin^2\theta\rangle$ is very weakly dependent on the rotation of the aldehyde group.

GLENN H. PENNER. Can. J. Chem. **65**, 538 (1987).

Une analyse des spectres rmn du ^1H de la portion benzylique du phénylacétaldéhyde, de la benzyl méthyl cétone, de la benzyl éthyl cétone, de la benzyl isopropyl cétone et de dichloro-3,5 benzyl *tert*-butyl cétone permet de déterminer les couplages à longue distance entre les protons du cycle et ceux en α. Ces couplages stéréospécifiques ne varient que peu lorsqu'on change l'hydrogène aldéhydique pour divers groupements alkyles. Les couplages pour chacune des molécules étudiées se situent tous dans les intervalles $^4J(CH_2, H_o) = -0{,}566 \pm 0{,}008$ Hz, $^5J(CH_2, H_m) = 0{,}278 \pm 0{,}002$ Hz et $^6J(CH_2, H_p) = -0{,}409 \pm 0{,}010$ Hz; ces résultats suggèrent que, dans les cétones, le groupement alkyle préfère la conformation *trans* par rapport au noyau phényle et qu'il n'interfère pas avec la rotation autour de la liaison C_1—C_α. Les couplages à longue distance sont en accord avec une fonction de potentiel qui serait exprimé par l'équation $V(\theta) = 8{,}4 \pm 1{,}2 \sin^2\theta$ pour une rotation binaire autour de la liaison C_1—C_α; θ est l'angle formé par le groupement carbonyle et le plane du cycle benzénique. Si l'on effectue des calculs OM *ab initio*, au niveau STO-3G, sur le phénylacétaldéhyde en faisant l'hypothèse que la liaison C=O est *cis* par rapport au groupement phényle, le potentiel est alors représenté par l'équation $V(\theta) = (8{,}65 \pm 0{,}73) \sin^2\theta + (1{,}27 \pm 0{,}80) \sin^2 2\theta$; cette équation est assez proche du potentiel expérimental, mais elle comporte une petite composante quaternaire. Il existe une corrélation entre la constante de couplage spin–spin du proton aldéhydique avec les protons en α, et le solvant, qui est en accord avec les données rapportées anterieurement. Le fait que les valeurs de $^4J(CH_2, H_o)$, $^5J(CH_2, H_m)$ et $^6J(CH_2, H_p)$ ne varient pas avec la nature du solvant suggère que $\langle\sin^2\theta\rangle$ ne dépend que faiblement sur la rotation du groupement aldéhydique.

[Traduit par la revue]

Introduction

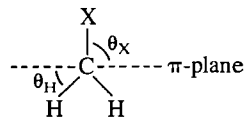
The vicinal spin–spin coupling constants between the aldehydic and α protons in phenylacetaldehyde and several of its derivatives have been reported as a function of temperature and solvent (1). The observed coupling provides information on the conformational preference of the aldehydic group in phenylacetaldehyde.

The long-range spin–spin coupling constants between the ring and α protons in α-substituted toluene derivatives have afforded much useful information on the conformational preference of the CH_2X moiety and the rotational barrier about the C_1—C_α bond (2–4). In particular, the six-bond coupling constant between the α and the *para* ring protons takes the form

[1] $$^6J(CH_2, H_p) = {}^6J_{90}\langle\sin^2\theta\rangle_H$$

where $\langle\sin^2\theta\rangle_H$ is the expectation value of $\sin^2\theta_H$, θ_H being the angle between the C—H_α bond and the phenyl ring plane. The observed ^6J in toluene (X = H), where $\langle\sin^2\theta\rangle_H$ is 0.5, yields a $^6J_{90}$ value of −1.20 Hz (5) and eq. [1] becomes

[2] $$^6J\,(\text{Hz}) = -1.20\langle\sin^2\theta\rangle_H$$



1

The relationship between $\langle\sin^2\theta\rangle$ for the X nucleus (see **1**) and $\langle\sin^2\theta\rangle$ for the α protons is

[3] $$\langle\sin^2\theta\rangle_X = 1.5 - 2\langle\sin^2\theta\rangle_H$$

The expectation value of $\sin^2\theta$ can be related to the barrier to rotation about the C_1—C_α bond by a hindered rotor model (2).

With the availability of a high-field nmr spectrometer in this laboratory, analysis of the rather tightly coupled spectra of benzylic systems has become possible (3, 4). In this paper the long-range couplings between the ring and α protons in phenylacetaldehyde, **2**, and several benzyl alkyl ketones, **2**, **4**, **5**, and **6**, are measured and related to the conformation of the side chain and to the barrier to rotation about the C_1—C_α bond.

Results and discussion

Molecular orbital calculations

Molecular orbital calculations at the STO-3G level were performed with geometry optimization on phenylacetaldehyde as a model compound. The internal angles discussed below are shown in Fig. 1.

First, the angle θ was held at 0° while φ was rotated through 180° by 30° intervals. This was repeated for θ = 90°. The lowest energy was found for that conformation in which θ = 90° and φ = 120°, with local minima at φ = 0 and 60°, φ = 0° having the lower of the latter two energies. Energies were then calculated for rotation of θ from 0 to 90° by 15° increments while φ was held at 120°. The calculations were repeated with φ held at 0 and 180°. The energies for the last three rotations were fit to potentials of the form

[4] $V(\theta) = V_2 \sin^2 \theta + V_4 \sin^2 2\theta$

The V_2 and V_4 values, together with calculated values of $\langle \sin^2 \theta \rangle_C$, are given in Table 1. The classical expectation values are calculated, numerically, using the expression

$$[5] \quad \langle \sin^2 \theta \rangle_C = \frac{\int_{-\pi}^{\pi} (\sin^2 \theta) \exp\left[\frac{-V(\theta, \phi)}{RT}\right] d\theta}{\int_{-\pi}^{\pi} \exp\left[\frac{-V(\theta, \phi)}{RT}\right] d\theta}$$

Although $V(\theta, 120°)$, $V(\theta, 180°)$, and $V(\theta, 0°)$ are different, they yield very similar $\langle \sin^2 \theta \rangle_C$ values, suggesting that, for phenylacetaldehyde, the conformation of the aldehyde group has very little effect on $\langle \sin^2 \theta \rangle_C$, the quantity obtainable from $^6J(CH_2, H_p)$.

$^3J(CH_2, CHO)$

Reported measurements of $^3J(CH_2, CHO)$ in phenylacetaldehyde range from 2.48 Hz in *trans*-decalin to 2.09 Hz in dimethylformamide (1). The coupling appears to increase as the solvent dielectric constant increases, indicating a concomitant increase in the stability of the rotamer in which the phenyl group eclipses the C=O bond (φ = 0°). The values of $^3J(CH_2, CHO)$ given in Table 2 follow this trend.

$^6J(CH_2, H_p)$

Equations [2] and [3] yield $\langle \sin^2 \theta \rangle_H$ and $\langle \sin^2 \theta \rangle_C$ values for the molecules of interest. These values are collected in Table 2. All the ^6J values fall in the range $^6J(CH_2, H_p) = -0.409 \pm 0.010$ Hz and the corresponding $\langle \sin^2 \theta \rangle_C$ values satisfy 0.818 ± 0.017. Assuming the potential function for internal rotation about the C_1—C_α bond is twofold, a hindered rotor model (2) yields V_2 as 8.4 ± 1.2 kJ/mol.

Although STO-3G calculations for phenylacetaldehyde yield potential functions, $V(\theta)$, which are not purely twofold, the expectation values of $\sin^2 \theta_C$ derived from the calculated potentials are rather close to those deduced from ^6J.

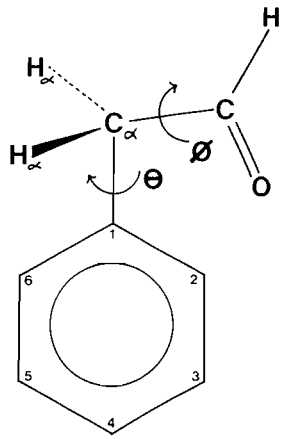

FIG. 1. The numbering system for phenylacetaldehyde. The conformation shown has θ = 0° and φ = 0°.

TABLE 1. The potential functions and $\langle \sin^2 \theta \rangle_C$ values obtained for rotation about the C_1—C_α bond in phenylacetaldehyde using the STO-3G basis set

φ[a](deg)	V_2[b](kJ/mol)	V_4[b]	$\langle \sin^2 \theta \rangle_C$
0	−11.15(33)	−1.96(33)	0.829
120	−8.65(73)	−1.27(80)	0.849
180	−14.90(15)	−4.36(15)	0.829

[a]θ and φ are defined in Fig. 1. φ is fixed at these angles as θ is varied.
[b]From a statistical best fit of the energies (seven values) to eq. [4]. The errors given in parentheses are at the 95% confidence level.
[c]$\langle \sin^2 \theta \rangle_C$ values are obtained from $V(\theta)$ using eq. [5].

The fact that $^3J(CH_2, CHO)$ changes with solvent, whereas $^6J(CH_2, H_p)$, does not, suggests that $\langle \sin^2 \theta \rangle_C$ is not strongly dependent on the conformation of the aldehyde group. *Ab initio* MO calculations agree with this suggestion.

Turning to the benzyl alkyl ketones, the independence of $^6J(CH_2, H_p)$ (and hence of $\langle \sin^2 \theta \rangle_C$) of the size of the alkyl substituent implies a conformation in which the alkyl group lies *trans* to the phenyl ring (φ = 0°) and therefore does not interfere with rotation about the C_1—C_α bond.

$^4J(CH_2, H_o)$ and $^5J(CH_2, H_m)$

The four-bond coupling constant between the α and the *ortho* protons has been written as (5, 6)

[6] $^4J(CH_2, H_o)/\text{Hz} = -1.08\langle \sin^2 \theta \rangle_H - 0.32\langle \cos^2 \theta \rangle_H$

The equation may be recast into the form

[7] $^4J(CH_2, H_o)/\text{Hz} = -0.76\langle \sin^2 \theta \rangle_H - 0.32$

It has been proposed (7) that ^5J is given by eq. [8].

[8] $^5J(CH_2, H_m)/\text{Hz} = 0.336\langle \sin^2 \theta \rangle_H + 0.322\langle \sin^2 \theta/2 \rangle_H$

For molecules with $2n$-fold barriers to internal rotation, $\langle \sin^2 \theta/2 \rangle_H$ is 0.5 (8) and eq. [8] becomes

[9] $^5J(CH_2, H_m)/\text{Hz} = 0.336\langle \sin^2 \theta \rangle_H + 0.161$

The $\langle \sin^2 \theta \rangle_H$ value obtained from $^6J(CH_2, H_p)$, using eq. [2], can be substituted into eqs. [7] and [8] to yield $^4J(CH_2, H_o) =$

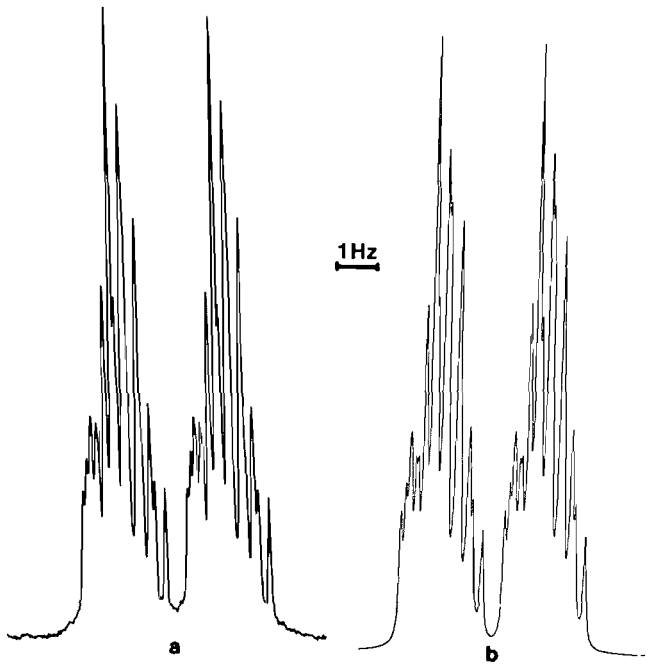

FIG. 2. The experimental (a) and computer simulated (b) spectrum of the α-protons of phenylacetaldehyde in C_6D_6 solutions. Note that the second-order nature of the spectrum does not allow simple measurement of the splittings due to long-range couplings.

-0.579 ± 0.006 Hz and $^5J(CH_2, H_m) = 0.278 \pm 0.002$ Hz. The measured values fall into the ranges $^4J(CH_2, H_o) = -0.566 \pm 0.008$ Hz and $^5J(CH_2, H_m) = 0.278 \pm 0.002$ Hz. The agreement is quite good considering the possible effects of the α carbonyl group on the coupling mechanisms involved.

Experimental

Compounds **2**, **3**, **4**, and **5** were commercially available. Compound **6** was made by reaction of the 3,5-dichlorobenzylmagnesium chloride Grignard with *tert*-butylcyanide (trimethylacetonitrile) followed by hydrolysis of the imine (9). Compound **6** was prepared with *meta* chlorine substituents to simplify the initial 90-MHz spectrum.

Samples (5.0 mol%) of the compounds together with a small amount of TMS were transferred to 5-mm od nmr tubes, were degassed by the freeze–pump–thaw method, and were flame-sealed under vacuum.

Spectra were recorded on a Bruker AM300 spectrometer at a probe temperature of 300 K. Typically 8–32 scans were acquired. Sweep-widths and data regions were adjusted to give acquisition times of approximately 30 s. The digital resolution was typically 0.03 Hz/point. After a small amount of Gaussian multiplication to improve resolution, the FID's were then transformed.

The benzyl portions of the spectra were analyzed as an AA'BB'CM_2R system for **2** and as AA'BB'CM_2 systems for **3**, **4**, **5**, and **6** using the program NUMARIT (10). Due to many small couplings to the alkyl group protons in compounds **3**, **4**, **5**, and **6**, transitions for the M_2 part of the spectra were not assigned. Linewidths of the ring proton peaks were usually less than 0.12 Hz. The experimental and simulated spectra of the M_2 part of the spectrum of phenylacetaldehyde in C_6D_6 solution are shown in Fig. 2.

Molecular orbital calculations on phenylacetaldehyde at the STO-3G level employed the program MONSTERGAUSS (11) and were run on an Amdahl 470 system. During the calculations the benzene ring nuclei were held coplanar and the ring carbons were constrained to a hexagonal geometry while allowing all ring C—C bond lengths to vary simultaneously. All other bond lengths and angles were allowed to vary independently while holding angles θ and φ constant to define a given conformation.

THOMAS N. BELL, KATHRYN A. PERKINS, and PETER G. PERKINS. Can. J. Chem. **65**, 541 (1987).

Calculations have been made on the enthalpies of the singlet and triplet N_2O_2 species generated from $^2\pi NO + {}^4\pi NO$, and the exciplexes which result from reaction of N_2O_2 with some methyl fluorosilanes. Both the ground-state singlet and the first excited triplet of the latter systems have been studied and are discussed in relation to the mechanism for the decomposition of NO after initial excitation with $Hg(6^3P_1)$ atoms.

THOMAS N. BELL, KATHRYN A. PERKINS et PETER G. PERKINS. Can. J. Chem. **65**, 541 (1987).

On a effectué des calculs sur les enthalpies des espèces singulet et triplet du N_2O_2 qui sont générées par la réaction $^2\pi NO + {}^4\pi NO$ ainsi que sur les exciplex qui proviennent de la réaction du N_2O_2 avec quelques méthyl fluorosilanes. On a aussi étudié tant l'état singulet fondamental que le premier triplet excité de ces derniers systèmes et on en discute en relation avec le mécanisme de décomposition du NO après une excitation initiale avec des atomes de $Hg(6^3P_1)$.

Introduction

The mercury-photosensitized decomposition of NO leading to N_2O, NO_2, N_2, and O_2 has been proposed (1) to occur through the intermediate N_2O_2 formed by:

$$NO^4\pi + NO \rightarrow N_2O_2 \rightarrow \text{products}$$

Silanes of general formula Me_xSiF_{4-x} enhance the rate of decomposition of NO. Mechanistic proposals involving the intial formation of the exciplexes Si—NO and Si—ON followed by further reaction of these species with NO have been advanced (2) in order to explain the observed enhancement, i.e.

$$\begin{aligned} \text{Sil} + NO^4\pi \rightarrow \text{Sil}\,NO^{\dagger} &\xrightarrow{NO} \text{Sil} + N_2 + O_2 \\ \searrow \text{Sil}\,NO^{\dagger\dagger} &\xrightarrow{NO} \text{Sil}(NO)_2 \\ &\xrightarrow{NO} \text{Sil} + N_2O + NO_2 \end{aligned}$$

This present work is concerned with a theoretical examination of the enthalpies and geometries of the species proposed in order to develop and further illuminate the mechanistic proposals for the NO decomposition.

Methods and results

The methodology relating to the theoretical calculations of the systems of this type has been described in a previous paper (3). The present work also combines the quantitative power of the MOBI method with the geometry-optimising qualities of the MNDO approach.

In the previous paper (3), calculations of a similar type dealing with the formation of the SiNO and SiON exciplexes from silane—$^4\pi$NO were discussed. In an experimental paper (2) detailing the effect of silanes on the decomposition of NO, it was suggested that these exciplexes react further with NO leading to products, though no opinion was advanced with regard to which exciplex leads to N_2 and O_2 and which to N_2O and NO_2. An examination of these experimentally based proposals is now possible as a result of our new calculations on the energetics of the various species proposed in the mechanism.

(a) N_2O_2

Since we are concerned with molecules and exciplexes formed between silanes and N_2O_2, it was first relevant to study the N_2O_2 molecule itself. Naively, one could envisage the mutual approach of two doublet NO molecules which, at bonding distances, would form an N—N single bond using the two odd electrons present in the whole system. One might expect that, on this basis, N_2O_2 would be very stable, since the single unpaired electron of each NO molecule (which is antibonding in NO) would be brought into a bonding situation. However, it appears that, experimentally, N_2O_2, although known, is not as stable as this naive picture would predict. The heat of dimerisation (4) of two NO molecules is only 8–12 kJ mol^{-1}. Hence, the simple bonding approach is unlikely to be a correct interpretation of the experimental facts. To complicate the matter, we in the present study are concerned with the interaction of a $^4\pi$NO molecule with a doublet ground-state NO molecule which would yield either a lower triplet N_2O_2 molecule (the lower energy state generated from the spin combination) or an excited quintet N_2O_2 molecule. Even the lower energy state, the triplet, of these combinations is an excited state of N_2O_2 lying above a singlet ground state which, clearly, the molecule can assume according to its (even) total number of electrons. We shall concern ourselves in this study only with the lowest singlet and the first excited triplet of N_2O_2.

We first made a calculation of the geometry of the singlet N_2O_2 molecule by optimising its energy using the MNDO method. The geometry obtained from this method was then passed into the MOBI program in order to determine the heat of formation of the N_2O_2 molecule. In order to do this, one needs a unit bond-energy parameter for the N—N bond. That for the N—O bond was taken from the previous paper (3). One can obtain the N—N bond parameter by calibrating from the hydrazine molecule. Thermodynamic data for the heat of formation of hydrazine are available (5) and a combination of this data plus a MOBI calculation of both hydrazine and ammonia yielded a bond parameter of 220.5 kJ mol^{-1} for N—N. We can now calculate the heat of reaction for the process

$$2NO \rightarrow N_2O_2$$

$$\Delta H^0_{298} = -8.4 \text{ kJ mol}^{-1}$$

This value is in excellent agreement with that contained in the review by Heicklen and Cohen (4). The geometry of the singlet N_2O_2 molecule shows an N—O bond length equal to 1.337 Å and an N—N bond length of 1.29 Å. The molecule is cisoid and the N—N—O bond angle is 90.7°. A calculation on the transoid molecule of similar geometry showed it to be much less stable. Since the NO and N_2O_2 molecules are small, *ab initio* calculations using an ST631G gaussian basis set were carried out. The calculated energy of *cis* N_2O_2 was −258.2682 hartree whilst that for two NO molecules, using the same basis set, is −258.3498 hartree (6). Hence the dimerisation is calculated by this method to be endothermic (214.2 kJ mol^{-1}). This has the opposite sign to that of the quoted experimental value (4) and we believe that *ab initio* methods at this SCF level of sophistication are not usefully applicable to estimating small heats of reaction as in the NO/N_2O_2 system (7).

Using the MNDO program, it is also possible to optimize the geometry of the triplet state of the N_2O_2. Similar treatment of this molecule resulted in an N—O bond length of 1.162 Å, an N—N bond length of 1.768 Å, and an N—N—O angle of 106.5°. In the triplet N_2O_2 system, it is clear that the double bond has been destroyed and the N—N bond is essentially a single bond.

Next, a calculation of the excited states of the N_2O_2 singlet molecule was carried out using a configuration–interaction routine which extends the MOBI program. These states were calculated using a geometry based on that of the ground-state singlet. A total of six bonding orbitals and six antibonding orbitals was included in the configuration interaction and both singlet-excited and triplet-excited states were calculated. The results showed that the optical excitation of the lowest singlet N_2O_2 molecule to the lowest triplet state required 1.83 eV (177.0 kJ mol^{-1}). Using this linking value, it is now possible to construct a cycle for the formation and decomposition of N_2O_2 in these two different spin states. Figure 1 shows such a cycle and, using this cycle, it is possible to cross-check the thermochemistry. Hence, if we enter all the figures calculated for N_2O_2 states into the cycle, leaving as unknown the stage in which singlet N_2O_2 decomposes into N_2 and O_2, we obtain, from the small inner cycle, the value for this stage (shown as A in Fig. 1) as −172.1 kJ mol^{-1} whereas if it is calculated from the large outer cycle, we obtain a figure of −202.7 kJ mol^{-1}. There is only 30 kJ difference between these and this difference almost certainly stems from the error in the calculation of the singlet–triplet optical excitation energy, given as 177.0 kJ mol^{-1} in the cycle. The cycle as a whole, however, is gratifyingly self-consistent. The heat of atomisation, to the relevant states of the atoms, of the triplet N_2O_2 molecule is 1251.0 kJ mol^{-1}.

(b) Silane N_2O_2 complexes

When one considers the complexes formed between the silane and N_2O_2, one sees immediately that two types of complex can be formed, i.e., between the silane and N_2O_2 and the silane and O_2N_2. Within these two types, there are singlet complexes and triplet complexes corresponding to the singlets and triplets of N_2O_2 itself. Whilst a large number of geometries in general could be suggested for the complexes it seems reasonable, bearing in mind that the N_2O_2 complex will be formed from the NO complex, that the geometries will be based on those of the simpler NO type. Hence, the geometries selected for the silane—N_2O_2 exciplexes were based on the minimised geometry of the silane—NO exciplex which has quasi trigonal bipyramidal site symmetry around silicon. The

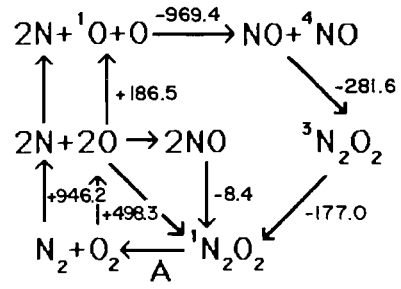

FIG. 1. Thermodynamic enthalpy cycle for $^1N_2O_2$ and $^3N_2O_2$ systems (kJ mol^{-1}).

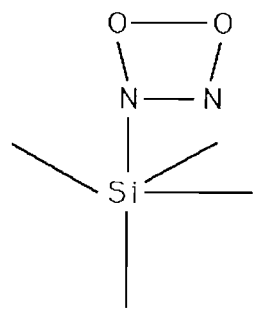

FIG. 2. Basic geometry of the Si—(N_2O_2) exciplex.

Si—NO or Si—ON axis is not exactly linear, of course, in the N_2O_2 complex, since the N—N—O angle is not 90° in either the singlet or the triplet form of N_2O_2.

The basic geometry is shown in Fig. 2. Table 1 contains heats of atomisation (to the relevant atomic states) from calculations on the singlet states of the silane—N_2O_2 species. The first three sets of data refer to the complex $SiF_4O_2N_2$ and it can be seen from the heats of atomisation that the result obtained by optimising (*i*) none of the geometrical data, (*ii*) that of the N_2O_2 moiety only, and (*iii*) all of the geometry to be optimised, affords heats of atomisation which differ only by 7.1 kJ between the extremes. Hence, in considering the rest of the singlets, only the geometry of the N_2O_2 moiety in the exciplex was optimised. The results for the heats of atomisation (to the relevant atomic states) of the triplet exciplexes are also recorded in Table 1 and in this case, there was no optimisation of any of the geometry. In the singlet complexes, the N—N link shows very strong π bond characteristics, whilst there is only an incipient O—O single bond in the complex. On this basis, we suggest that the products N_2 and O_2 stem from direct decomposition of the Si—O_2N_2 complex in the singlet state. We further suggest that N_2O and NO_2 arise from the Si—N_2O_2 complex, through reaction with a further NO molecule. These proposals are outlined in Fig. 3.

These suggestions require the decomposition of a singlet N_2O_2 complex and thus they involve the kinetics of relaxation from the triplet N_2O_2 complex or O_2N_2 complex to the singlet complexes. Hence, overall, from a mechanistic point of view, we envisage that quartet nitric oxide reacts with the silane to give the quartet silane – nitric oxide exciplex: this then interacts with a further doublet NO molecule to give the triplet N_2O_2 complex. This latter then relaxes to the singlet N_2O_2 complex which reacts to give products that depend on the orientation of N_2O_2 in the N_2O_2 exciplex. All the heats of

FIG. 4. Thermodynamic enthalpy cycle for the $Si—N_2O_2$ triplet and singlet exciplex system (kJ mol^{-1}).

atomisation calculated are shown in Table 1 and we can distill the following conclusions from that table: (*i*) There is little difference between the enthalpies of the members of a pair of singlet exciplexes derived from a particular silane, whether they be of the N_2O_2 or the O_2N_2 variety. (*ii*) For the triplet systems, the silane—O_2N_2 complex has a greater (21–38 kJ mol^{-1}, depending upon the particular silane) heat of atomisation than the corresponding triplet silane N_2O_2 isomer. Thermochemically, all species of general formula "silane—N_2O_2" for a particular silane shows that the triplet system lies some 96 kJ mol^{-1} lower in energy (i.e., less stable) than the singlet state. That is, the energy sequence is triplet silane–O_2N_2 < triplet silane–N_2O_2 < singlet silane–O_2N_2 = singlet silane–N_2O_2.

In order to construct a consistent thermochemical cycle, we also calculated the optical excitation energy of the singlet–triplet transition for each species. This was effected by using again the configuration-interaction program with six mutually interacting occupied orbitals and six antibonding orbitals. The values obtained are also shown in Table 2 and all are in the region of 2.5 eV (243 kJ). These can be correlated with the thermochemical difference in enthalpies using a cycle similar to that effective for the relationship between NO, $NO^4\pi$, and N_2O_2. This is shown in Fig. 4 and as before, we calculate the energy for stage A from an inner cycle and an outer cycle. The

TABLE 2. Excited state properties of $SiF_xMe_{4-x}N_2O_2$ or O_2N_2 complexes

System	ΔE (kJ) singlet → triplet	Orbitals* involved	Oscillator strength	Si coefficients (*d* orbitals)
$SiF_4N_2O_2$	252.3	2 ← 3	0.17	0.59; orb (3) small; orb (2)
O_2N_2	235.6	2 ← 3	0.16	No Si
$SiF_3MeN_2O_2$	250.6	1 ← 4	0.17	No Si
O_2N_2	243.9	1 ← 4	0.16	No Si
$SiF_2Me_2N_2O_2$	250.6	1 ← 6	0.17	No Si
O_2N_2	243.9	1 ← 6	0.16	No Si

*The left-hand number is the antibonding orbital and the right the bonding orbital chiefly involved in the transition. In all cases this was the dominant configuration.

difference between the two values in the exemplary case of SiF_4 is ca. 40 kJ mol^{-1} and, clearly, this difference stems mainly from error in the calculated singlet–triplet optical excitation energy of $SiF_4N_2O_2$. Actually, since the value obtained for stage A accumulates all the errors in the cycle together, then the agreement may be considered satisfactory.

Finally, we suggest that the species designated as silane—$(NO^{\dagger})$ in the experimental paper (2) corresponds to silane—(ON), whilst the species silane—$(NO^{\dagger\dagger})$ corresponds to silane—(NO).

Received December 4, 1985[1]

THOMAS N. BELL, KATHRYN A. PERKINS, and PETER G. PERKINS. Can. J. Chem. **65**, 545 (1987).

A theoretical study is presented of the relative enthalpies (calculated through heats of atomisation) of complexes of the silanes SiF_4, SiF_3Me, and SiF_2Me_2, with ground state $^2\pi$NO, and exciplexes with excited state $^4\pi$NO. The calculations favour an increasing relative stability of the complexes and exciplexes with silanes in the order $SiF_4 < F_3SiMe < F_2SiMe_2$ with, in each particular case, a geometry favouring the $\gtrless$SiON over the $\gtrless$SiNO arrangement.

THOMAS N. BELL, KATHRYN A. PERKINS et PETER G. PERKINS. Can. J. Chem. **65**, 545 (1987).

On rapporte une étude théorique sur les enthalpies relatives (calculées en faisant appel aux chaleurs d'atomisation) de complexes des silanes SiF_4, SiF_3Me et SiF_2Me_2 avec l'état fondamental du $^2\pi$NO et les exciplex de l'état excité $^4\pi$NO. Les calculs suggèrent que la stabilité relative des complexes et des exciplex avec les silanes augmente dans l'ordre $SiF_4 < F_3SiMe < F_2SiMe_2$: de plus, dans chacun des cas, la géométrie favoris $\gtrless$SiON par rapport à l'arrangement $\gtrless$SiNO.

Introduction

Sensitisation of NO by $Hg(6^3P_1)$ atoms leads to $^4\pi$NO which provides a route to decomposition into the observed (1) products N_2, O_2, and N_2O. The decomposition quantum yields are markedly enhanced (2) by the methylfluorosilanes with the order of enhancement

$$Me_2SiF_2 > MeSiF_3 \gg SiF_4$$

The mechanism proposed (2) to explain the enhancement envisaged the formation of two different distinct and non-interchangeable exciplexes (designated $SiNO^\dagger$ and $SiNO^{\dagger\dagger}$) resulting from the reaction of silane with $^4\pi$NO. It was suggested that these two types of exciplex differed as a result of either the O or N of the NO bonding to the silane, i.e., Si—ON or Si—NO. No conclusion was made as to which exciplex led to N_2 and O_2 and which to N_2O because it was extremely difficult to evince direct evidence from the experiments as to the nature and structures of such complexes, since they are of essentially transient nature. However, such a study is well suited to investigation from a theoretical point of view and, hence, we have pursued this in order to determine if, based on enthalpy considerations, complexes of the type proposed would be stable relative to the separate molecules.

Methods, results and discussion

The molecular orbital – bond index method (MOBI) has been formulated and extensively used in studies of the reactions of hydrocarbons and of the thermodynamics of silane derivatives (3–7). The technique starts from a rotationally invariant quantity, the *bond index*. This latter is compounded from the relevant elements of the Coulson bond order – density matrix, in turn obtained from some quantum mechanical self consistent field molecular calculation on the system of interest. The bond index is given by

$$B_{AB} = \sum_{\sigma \epsilon A} \sum_{\lambda \epsilon B} P_{\lambda\sigma}^2$$

where the $P_{\mu\nu}$ are the Coulson density matrix elements.

Bond indices for simple molecules such as hydrocarbons follow a pattern which correlates with the chemist's concept of multiplicity of bonds; thus, for ethane, ethylene, and acetylene the C—C bond indices are, respectively, 1.023, 2.032, and 2.998. Following this trend we have suggested that such bond indices may be used, in conjunction with experimental standard-state heats of atomisation, to obtain a set of standard energy terms for a range of bonds. These terms we call the *bond energy parameters*. Thus the bond energy parameter for a bond X—Y is the intrinsic enthalpy associated with an X—Y of unit bond index. Since the bond index reflects minor variations in the intrinsic bond strength with the environment of the bond in question, the concept should be appropriate for the direct calculation of heats of formation for molecules.

A set of bond indices may be calculated for any system and can thus afford, in principle, the heat of formation for that system in the standard state. Thus, in the case of one or more species undergoing reaction, a grid of points on an energy surface can be set up, the heat of atomisation for the system computed for each, and the reaction followed along a coordinate and over a saddle. Even without following the whole reaction hypersurface it is possible to examine a limited part of such a surface by investigating directly the geometries of transition state complexes.

The calibration process uses experimental heats of atomisation of selected compounds in the standard state at 298 K. One then takes a weighted sum of the bond indices for each interaction in the molecule and sets this equal to the experimental standard state heat of atomisation for the system. The approach depends essentially on the assumption that the energies of separate bonds in molecules and radicals are additive.

Having calibrated the bond energy parameters in this way we can then transfer them to systems of unknown thermochemistry and in our case this means the transition-state complexes in the reactions between silanes and nitric oxide. In conclusion it can be said that the MOBI method is a fast, accurate, and computer-wise efficient way of obtaining thermodynamic information on systems built from first and second row atoms. The MOBI method is thus now well established (4–7) as a quantitative tool for the investigation of the bond energies and

heats of formation of systems. Moreover, the method has been shown to be valid even when bond lengths and angles are not "normal", e.g., when the former are stretched (6). The discussion of the present implementation of the method will be carried out under several headings.

(a) The silanes

The first step was to determine heats of atomisation of the three silanes SiF_4, SiF_3Me, and SiF_2Me_2. Since the intermediate species and complexes in the Si—NO reaction were to be geometry-optimised using the MNDO method (8) (which involves Fletcher–Powell minimisation) the geometries of the silane molecules were also minimised using the same program in order to give consistency between the results. The heats of formation produced from MNDO were then discarded and the new optimised coordinates produced by the MNDO minimisation were transferred to the MOBI program which, as forestated, calculates heat of atomisation for these molecules. The SCF technique which forms the basis of the MOBI method has been fully described elsewhere (9). For molecules such as NO and the complexes a Restricted Hartree–Fock treatment was applied. Bond energy parameters are already available for F—F (3) and for the moieties involving silicon and the methyl group (4). The Si—F parameter was obtained by calibration from SiF_4. The experimental standard-state heat of formation at 298 K for SiF_4 was taken from ref. 10. A list of the bond energy parameters used is given in Table 1. The derived values of ΔH^0_{atom} are in Table 2 and it can be seen that the heat of atomisation of SiF_4 differs from its experimental value of 2387.0 kJ mol^{-1} because of the use of the "MNDO" internal coordinates.

(b) The nitric oxide molecule

The experimental heat of formation (11) of NO is 90.4 kJ mol^{-1}, which yields ΔH^0_{atom} = 631.4 kJ mol^{-1}. The NO bond index is 2.017 in nitric oxide and, hence, the unit bonding parameter for N—O is 313.0 kJ mol^{-1}. In this calculation the experimental bond length for NO was taken. If the bond length in nitric oxide is minimised with respect to the bond energy using the MNDO method, however, the optimum bond length is 1.1232 Å. Use of this "MNDO" bond length with MOBI yields a heat of atomisation for the molecule of 633.5 kJ mol^{-1}. This does not differ significantly from the standard heat of atomisation which can be deduced from experiment.

(c) Nitric oxide in the excited quartet state, $^4\pi$NO

In the series of reactions under consideration, the nitric oxide is believed to react not in its doublet ground state, but in an excited quartet state. Certainly there appears to be no decomposition of nitric oxide unless the molecule is excited by the Hg(6^3P_1) atom. The NO molecule contains eleven electrons and in the ground state, ten electrons lie in the five lowest energy levels whilst the remaining electron is described by a linear combination of the degenerate 6th and 7th π levels. We can construct a zeroth approximation configuration for the quartet state by assuming that the first four levels are filled, whilst one electron lies in each of the 5th, 6th, and 7th levels. This yields the $^4\pi$ state. The MNDO program is capable of handling calculations on quartet nitric oxide and the minimisation calculation by MNDO yields a bond length of 1.2745 Å and, directly from this method a ΔH^0_f of 377.4 kJ mol^{-1}. We can also carry out the same calculation using MOBI since the basis method for the MOBI calculation also includes an algorithm which will deal with quartet states. In this calculation, it is possible to preselect a particular configuration before performing the SCF cycles in this program. This yields an SCF solution for a single configuration determinant. If, now, the "MNDO" quartet bond length obtained as above (1.2745 Å) is used in the MOBI program, we obtain ΔH^0_{atom} = 336.8 kJ mol^{-1}, i.e., ΔH^0_f = 384.9 kJ mol^{-1} for $^4\pi$NO. This is the value we shall adopt and it concurs very well with the value obtained directly from MNDO. This implies that the bond energy parameter derived from the doublet molecule is also appropriate to the quartet state. Later, we shall confirm that this is, indeed, the case. We therefore retain the bonding parameter appropriate to a ground-state NO distance of 1.123 Å, i.e., 313.0 kJ mol^{-1}, throughout all the calculations.

In comparing ΔH^0_f values calculated as above with spectroscopically derived data on nitric oxide, it is necessary to consider the calculated atomic states of the dissociative products. The data can then be analysed by constructing a thermocycle which correlates thermodynamic and spectroscopic data. Accordingly the MOBI calculations on $^4\pi$NO were next repeated using a series of bond lengths in which the separation of the N and O atoms was increased. Thus the electron distribution throughout the orbitals of the separated atoms was determined at large N—O separation distances and it was found that these distributions correspond to the states N(^4S) and O(^1D). The NO molecule exhibits numerous excited states (12) which can be designated as Σ, Π, and Δ. Some of the potential curves for these have been calculated by Gilmore (13) and only quartet spin states can arise from a combination of the N(^4S) and O(^1D) states of the atoms. Since the ground state of oxygen is ^3P the O atom excitation energy to ^1D must be taken into account in determining ΔH^0_f from the calculated cycle. This ΔH^0_f is then compared with that estimated from the value of

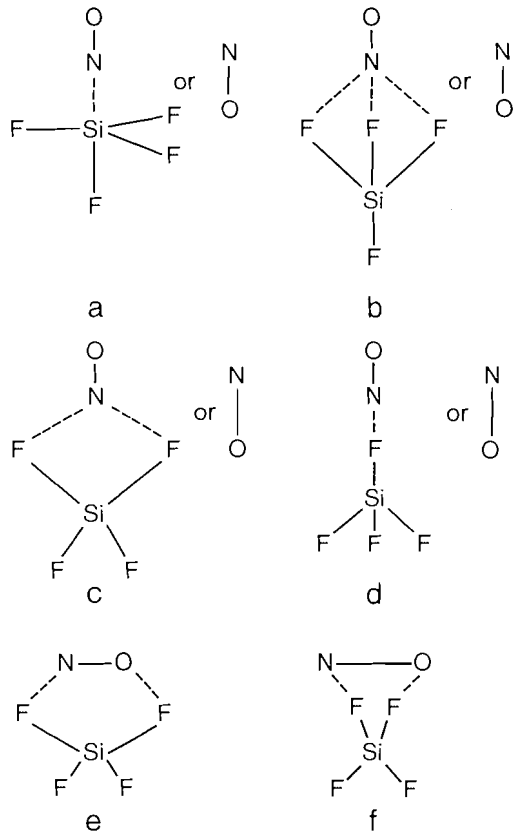

FIG. 1. Investigated geometries for Si—NO and Si—ON species.

ΔH_f^0 ($^2\pi$NO) and the spectroscopic excitation energy $^2\pi$NO → $^4\pi$NO. Thus

$$\begin{array}{ccc} N(^4S) + O(^1D) & \xrightarrow{d} & {}^4\pi NO \\ \uparrow & & \\ N(^4S) \quad O(^3P) & & \downarrow y \\ \uparrow \quad \uparrow & & \\ \tfrac{1}{2}N_2 + \tfrac{1}{2}O_2 & \xleftarrow{x} & {}^2\pi NO \end{array}$$

$$\Delta H_f^0(^4\pi NO) = a + b + c + d$$
$$= (1/2)D_{N_2} + (1/2)D_{O_2} + E_{(O^3P \rightarrow O^1D)} - D^4\pi NO$$

(Calculated) $473 \pm 4 + 249.4 + 188.7 - 336.8 = 574.3 \pm 4\,\text{kJ mol}^{-1}$

$$\Delta H_f^0(^4\pi NO) = -(x + y)$$
$$= \Delta H_f^0(^2\pi NO) + E(^2\pi NO \rightarrow {}^4\pi NO)$$

(Literature) $90.4 + 452 \pm 19 = 542.4 \pm 19\,\text{kJ mol}^{-1}$

The satisfactory agreement here confirms that the N—O bonding parameter derived for the $^2\pi$NO ground state is also appropriate for the quartet state of NO.

(d) The silane—NO doublet complexes

We first investigated the doublet complex formed by the interaction of a silane and $^2\pi$NO. It was first necessary to decide what basic geometry of approach of the NO to the silane moiety would be favoured and, having made a primary selection of the mode, then to investigate this in detail using minimisation techniques. The geometries shown in Fig. 1 were initially investigated by the MOBI method in order to decide which of them should be studied in detail. For brevity, the detailed results are not given here but we can state that five coordinate geometry around the silicon atom was favoured strongly over all other geometries and, indeed, it is intuitively reasonable that a five-coordinate geometry which is based closely on the trigonal bipyramidal symmetry around the silicon atom would be favoured. Although it is realised that a full global search using MNDO and calculation of a second derivative matrix is the most comprehensive and reliable route to a minimum, we believe that in practice our short cut to the favoured five-coordinate complex is acceptable. Many intermediates in reactions such as the hydrolysis of the silicon halides have a trigonal bipyramidal transition state, and this geometrical arrangement is invoked to explain many mechanistic processes.

TABLE 3. ΔH^0_{atom} values for the SiF_4NO complexes

Si—N (Å)	ΔH^0_{atom}(kJ mol^{-1})
5.0	3056.0
4.0	3060.6
3.7	3061.4
3.5	3061.9
2.8	3055.2
2.0	3035.5

We next investigated in detail the intermediates formulated as Si—NO by varying the Si—N distances over a range, whilst at each point optimising the remainder of the internal coordinates using the MNDO program. These optimised coordinates were then transferred to the MOBI program and the heat of atomisation calculated at each of the Si—N distances. We first studied SiF_4 and have selected (for brevity) the results for the complex SiF_4NO given in Table 3.

The figures in Table 3 show that the heat of atomisation of the SiF_4NO system leads to maximum enthalpy at Si—N = 3.5 Å. A similar series of calculations was carried out for (SiF_3Me)—NO and for (SiF_2Me_2)—NO where corresponding minima in the Si—N bond lengths occurred at 3.4 Å and 3.0 Å, respectively. Examination of the results for the above series of calculations showed that internal coordinates other than the Si—N bond length were little changed by the geometry optimisation. The optimised geometry shows that the silane moiety has a shape which is intermediate between a true trigonal bipyramid and a tetrahedron, e.g., in $^2SiF_4NO$ the bonds in the axial plane are 17.5° bent towards the NO group. Hence, in our further investigation of the complexes of type silane—ON, we did not minimise all the internal coordinates but performed calculations in which the Si—O bond lengths were taken as those for the corresponding Si—NO complexes.

From the heats of atomisation of the combined versus the non-combined systems, the enthalpy difference, $\Delta H^0_{comb} - \Delta H^0_{non\text{-}comb}$ was obtained. These results are given in Table 4, together with those for the —Si—ON systems. All show that the complexes were stable relative to the separated components, and the stabilisation enthalpies range between 10.5–18.8 kJ mol^{-1}, with Si—ON compounds showing greater stability than Si—NO compounds. The latter generalisation is weakest for the complexes of SiF_3Me and SiF_4 where the enthalpy differences are quite small.

In the ground state $^2\pi$NO the NO bond index is 2.017 (*vide supra*) and it diminishes to 2.00 in, say, the SiF_4NO complex. Thus little perturbation of this bond results from complexation of the doublet state to SiF_4.

(e) The silane—NO quartet exciplexes

The experimental work on silanes plus NO involves the $^4\pi$ state of NO and thus the silane—$^4\pi$NO exciplexes are of immediate interest. The mechanistic proposal (2) requires consideration of both exciplexes Si—NO and Si—ON. Hence, the SCF method mentioned previously, which allows quartet configurations to be selected and studied has also been used to investigate the nature, bonding, and energetics of the quartet exciplexes. These nitric oxide exciplexes with SiF_4, SiF_3Me, and SiF_2Me_2 were studied for a series of Si—N and Si—O bond lengths (i.e., both NO and ON exciplexes were studied) ranging from 1.7 to 2.5 Å. The heats of atomisation were calculated in each case using the unit bond energy parameter for NO, as described in the last section.

In order to consider the stability of the exciplexes with respect to the separated components, we must compare the heats of atomisation of these exciplexes with those of the parent silane and with the heat of atomisation of quartet NO to N(^4S) and O(^1D). The heat of formation for each exciplex as a function of Si—N or Si—O distance falls on a smooth curve and each curve can be extrapolated to a minimum point; hence, an Si—O or Si—N bond length corresponding to the maximum heat of atomisation of that exciplex can be found. The minima in the enthalpy curves for the complexes were, in all cases, found by quadratic fitting of the enthalpy versus Si—N or Si—O bond length and differentiation of the equation of the line given. All the Si—O, Si—N bond lengths thus determined fall below 3 Å. In all cases, quadratic fitting was very accurate, the points on the line being reproduced to ±0.4 kJ by the equation. All the data for the complexes calculated are given in Table 4. A measure of the complex and exciplex stability is given by the difference in the heats of atomisation, i.e., ΔH^0_{atom} (combined system) − ΔH^0_{atom} (separate components).

These results show that, in all cases, the Si—NO system is somewhat less stable than the Si—ON system. Somewhat surprisingly the ground state NO system shows that the complexes have some stability. With the exciplex system resulting from $^4\pi$NO, the Me_2SiF_2 system shows considerable stability with both configurations, that for Si—ON being more stable than Si—NO. It is interesting that only in this case is the calculated Si—O bond length (1.7 Å) near to that of a normal Si—O bond length and it is this feature which adds considerably to the stability of this particular complex. In all other cases both the Si—ON and Si—NO lengths are considerably greater than those for normal covalent bonds. With SiF_4 and $MeSiF_3$, the SiNO exciplex systems have a stability similar to the separated molecules, while the corresponding SiON systems show stabilities of 10 and 21 kJ, respectively. Promotion of NO to the excited quartet level diminishes the NO bond index and this is further lowered, e.g., in the SiF_2Me_2—ON complex, to 1.18. Excitation and complex formation therefore brings about a considerable weakening of the NO bond and produces an incipient tendency in that moiety to bonding with a second molecule of NO to give the N_2O_2 complex. This latter complex, as we will show, constitutes the next step in the decomposition of NO.

The calculations reported support the mechanistic proposal (2) that exciplexes of $^4\pi$NO with the methyfluorisilanes may indeed be formed and participate in providing a means for enhancement of the decomposition of NO. In this regard, the greatest enhancement is observed with Me_2SiF_2, i.e., the silane where exciplex formation is calculated to be most stable. Further work will examine the thermodynamics of the subsequent exciplexes which are proposed to account for the decomposition products.

Réduction électrochimique de dérivés carbonylés en milieu non aqueux en présence de $EuCl_3 \cdot 6H_2O$

JAMAÂ DOUCH ET GUY MOUSSET

Laboratoire d'électrochimie organique, Unité Associée Centre national de la recherche scientifique, 434 Université de Clermont II, 24, Avenue des Landais, BP 45, 63170 - Aubière, France

Reçu le 13 mai 1986

JAMAÂ DOUCH et GUY MOUSSET. Can. J. Chem. **65**, 549 (1987).

Dans ce travail, nous avons réalisé l'étude de la réduction électrochimique en milieu non aqueux (DMF) de cétones aromatiques ou α,β éthyléniques aromatiques en présence de $EuCl_3 \cdot 6H_2O$. Une étude préalable par infra-rouge et par voltammétrie cyclique a mis en évidence l'échange de ligands H_2O–DMF et la libération de trois ions Cl^-. Un examen détaillé des interactions entre le cation métallique et le dérivé carbonylé met en évidence la formation de complexes de type 1–1 ou 1–2 selon le site de complexation. La stéréochimie des produits d'hydro-dimérisation est en accord avec la formation à l'électrode d'un complexe de stoechiométrie 1 Eu(II) – 2 >C=O.

JAMAÂ DOUCH and GUY MOUSSET. Can. J. Chem. **65**, 549 (1987).

The electrochemical reduction of aromatic or α,β ethylenic aromatic ketones in nonaqueous solvent (DMF) has been performed in the presence of $EuCl_3 \cdot 6H_2O$. Ligand exchange between DMF and water molecules of the europium salt was first studied. A voltammetric study shows that complexation involving electrogenerated Eu(II) and ketone may occur at the electrode interface or in solution, leading respectively to 1 Eu(II) – 2 >C=O and 1 Eu(II) – 1 >C=O stoichiometries. The stereochemistry of hydrodimerization products is studied.

Le chrome(II) a été fréquemment utilisé en chimie organique comme agent réducteur, par exemple, dans le cas de dérivés nitrés, halogénés ou carbonylés (1, 2). Sa génération « *in situ* » par voie électrochimique en milieu non aqueux et son rôle dans les processus de réduction ont fait l'objet de quelques travaux (3–7). Le comportement électrochimique des cétones aromatiques simples ou substituées a été très étudié aussi bien en milieu aqueux (8–10) qu'en milieu organique (11–14). Leur réduction dans le diméthyl formamide (DMF) en présence de cations métalliques et la stéréosélectivité de la réaction d'hydrodimérisation ont été particulièrement développées récemment (15, 16) en relation avec la nature du cation présent dans le milieu, son caractère acide selon Lewis et son pouvoir complexant.

Les complexes de l'europium sont très utilisés en spectroscopie (17) ou en synthèse organique (18). Dans le cadre du travail que nous avions réalisé avec les sels de chrome et dans un but comparatif, nous avons consacré cet article à l'étude de la réduction électrochimique de dérivés carbonylés en présence d'europium(II) électrogénéré. Les sels d'europium hexahydratés (en particulier $EuCl_3 \cdot 6H_2O$) présentent deux étapes cathodiques séparées par un intervalle de potentiel beaucoup plus important que pour le chrome. Ce fait peut être avantageux pour l'étude de substrats difficilement réductibles (aryl alkyl cétones) si on désire s'affranchir de processus mettant en cause une réduction par un film de métal colloïdal déposé sur l'électrode (7) ou la formation d'amalgames avec le mercure (19) lorsque l'étape M(II)/M(0) est présente. Pour qu'une interaction entre l'europium(II) et la fonction carbonyle puisse être observée, il faut que la première étape de réduction de la cétone aromatique se situe entre les potentiels $E(A_1)$ de l'étape Eu(III)/Eu(II) et $E(A_2)$ de Eu(II)/Eu(0). Nous nous sommes volontairement limités, afin de comparer la nature et la stéréochimie des produits formés, à l'étude de la réduction des cétones **1–5** qui avaient fait l'objet de travaux antérieurs en présence de sels de chrome ou d'autres métaux.

Résultats expérimentaux et discussion

1. Réduction de $EuCl_3 \cdot 6H_2O$

La réduction électrochimique de sels d'europium en milieu aqueux ou non aqueux a été décrite dans quelques travaux (20–23). Dans le DMF, les courbes intensité–potentiel de $EuCl_3 \cdot 6H_2O$ montrent la présence de deux étapes de réduction $E_{1/2}(A_1) = -0{,}250$ V et $E_{1/2}(A_2) = -1{,}530$ V (référence $Ag/AgI/I^-$ 0,1 *M* DMF) correspondant respectivement à des échanges de 1 et 2 électrons par molécule. En voltammétrie cyclique (fig. 1) on peut noter la présence de deux pics cathodiques (A_1 et A_2) et de deux pics anodiques (A_1') correspondant à la réoxydation de l'espèce formée en A_1 ($\Delta E_p = 95$ mV) et A_2' assez mal défini en relation avec les espèces formées en A_2. Il est généralement admis (24, 25) qu'un amalgame peut se former à la seconde étape de réduction selon :

[1] $Eu^{II} + Hg + 2e^- \rightarrow Eu\,(Hg)$

La différence de potentiel ($\Delta E_p \simeq 1$ Volt) existant entre A_2 et A_2' laisse penser que ce dernier traduit la réoxydation d'espèces formées par action de l'amalgame sur des impuretés du milieu plutôt que celle de l'amalgame lui-même. Nous nous sommes toujours efforcés d'éviter la formation de Eu(0) et nous n'avons pas cherché à élucider l'origine de A_2'.

La mise en solution dans un solvant donneur S, d'un sel hexahydraté, entraîne des échanges de ligands au niveau de la sphère interne de complexation se traduisant par l'équation

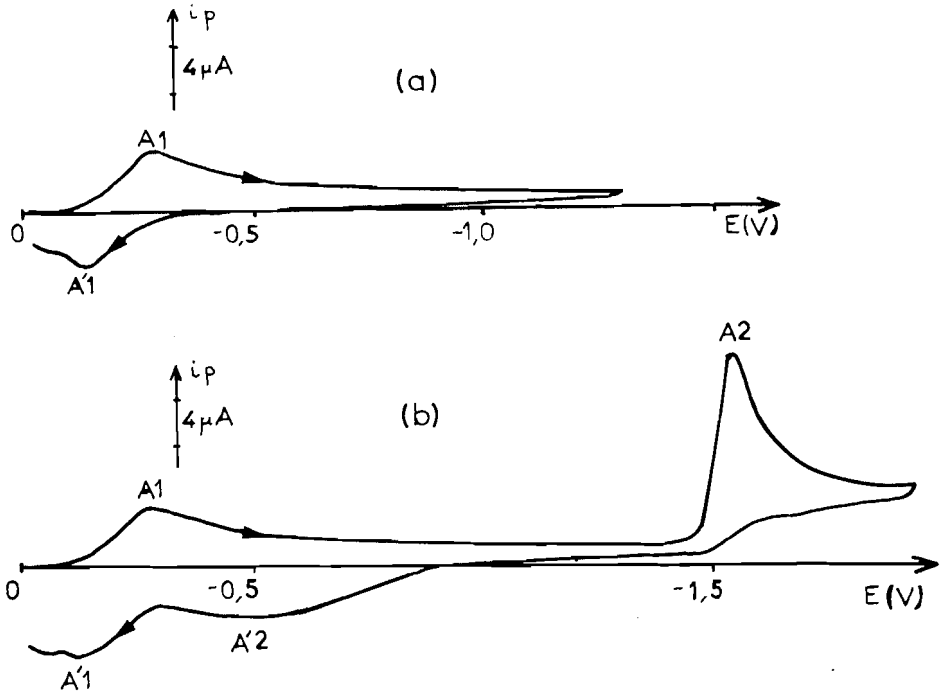

FIG. 1. Réduction voltammétrique du $EuCl_3 \cdot 6H_2O$ ($c = 2 \times 10^{-3} M$) sur électrode à goutte de mercure stationnaire $v = 0{,}1\ V\ s^{-1}$. (*a*) : Balayage 0–1,3 V. (*b*) : Balayage 0–2,0 V.

générale :

[2] $(M(H_2O)_{6-n}Cl_n)^{(3-n)^+} + mS \rightarrow (M(S)_m(H_2O)_{6-(m+n)}Cl_n)^{(3-n)^+} + mH_2O$

Afin de définir la nature du complexe final, nous avons réalisé une étude spectroscopique et voltammétrique sur $EuCl_3 \cdot 6H_2O$. La vibration dans l'infra-rouge de la liaison OH de l'eau « libre » dans le DMF fournit une bande d'absorption présentant un maximum situé à $3545\ cm^{-1}$ alors que les molécules complexées absorbent entre 3100 et $3200\ cm^{-1}$ (26). Le DMF, que nous avons utilisé, a une teneur en eau initiale de 0,15% (dosage par chromatographie en phase vapeur et par infrarouge). L'échange H_2O–DMF peut être traduit par l'équation

[3] $(Eu(H_2O)_{6-n}Cl_n)^{(3-n)^+} + (6 - n)\ DMF \rightarrow (Eu(DMF)_{6-n}Cl_n)^{(3-n)^+} + (6 - n)H_2O$

Une courbe d'étalonnage réalisée pour des solutions contenant des quantités d'eau connues permet de montrer que les six molécules d'eau de $EuCl_3 \cdot 6H_2O$ sont libérées dans le milieu lors de la mise en solution dans le DMF (fig. 2). Ceci implique que dans l'équation [3] nous ayons $n = 0$ donc que la mise en solution libère également de la sphère de complexation trois ions Cl^-.

L'oxydation de l'eau libérée par la réaction d'échange, ou contenue initialement dans le solvant, est repoussée vers des valeurs de potentiel plus anodiques en raison du phénomène de solvatation par le DMF. Il est alors possible comme dans le cas du chrome(III) (27) d'enregistrer la courbe d'oxydation des ions Cl^- libres (fig. 3) et d'en déduire la quantité présente en solution grâce à un étalonnage réalisé avec LiCl ($k_{d(DMF)} = 2{,}9 \times 10^{-2} M\,L^{-1}$) (28). La courbe voltammétrique fournie par $EuCl_3 \cdot 6H_2O$ a une morphologie tout à fait semblable à celles obtenues en absence d'ions Eu^{3+}, ce qui laisse penser que ces derniers ne perturbent pas le système. Elle permet effectivement de mettre en évidence la libération de trois ions Cl^-. L'ensemble de ces résultats nous semble apporter des arguments en faveur de l'équation d'échange :

[4] $Eu(H_2O)_6Cl_3 \xrightarrow{DMF} Eu(DMF)_6^{3+} + 6H_2O + 3Cl^-$

2. Réduction de cétones aromatiques en présence de $EuCl_3 \cdot 6H_2O$

(a) Modification du processus d'électroréduction

Lorsqu'on ajoute des quantités croissantes d'une cétone activée **1–5** à une solution de chlorure d'europium on constate : (*i*) que la présence de cétone ne modifie pratiquement pas la partie cathodique du premier pic de réduction (A_1) de l'europium(III) alors que sa partie anodique disparait progressivement. De plus, il apparait une nouvelle étape (B) irréversible située à un potentiel E(B) moins cathodique que celui du premier pic de réduction de la cétone en son radical anion (C_1) (fig. 4) (tableau 1); et (*ii*) que l'intensité de B croit avec la concentration en cétone et devient maximum pour un rapport de concentrations :

$$m = \frac{[\rangle C{=}O]}{[EuIII]} = 2$$

Jusqu'à l'équimolécularité ($m = 1$) les voltammogrammes ne présentent que deux pics (A_1 et B). Au-delà, ceux correspondant à la réduction de la cétone (C_1 et C_2) apparaissent. On peut constater également que la seconde étape (A_2) relative à la réduction de Eu(II) en Eu(0) disparait dès la première addition de cétone. Des additions successives de chlorure d'europium à une solution de cétone entraînent parallèlement à l'apparition de B, une diminution des pics de réduction C_1 et C_2 du dérivé carbonylé ainsi que des pics correspondant à la réoxydation du radical anion $\rangle C{=}O^{\cdot -}$ (C_1') ou de Eu(II) en Eu(III) (A_1'). Le potentiel du pic B est nettement moins cathodique que celui correspondant à la formation de l'europium métallique. L'ensemble des faits expérimentaux suggère l'hypothèse, déjà for-

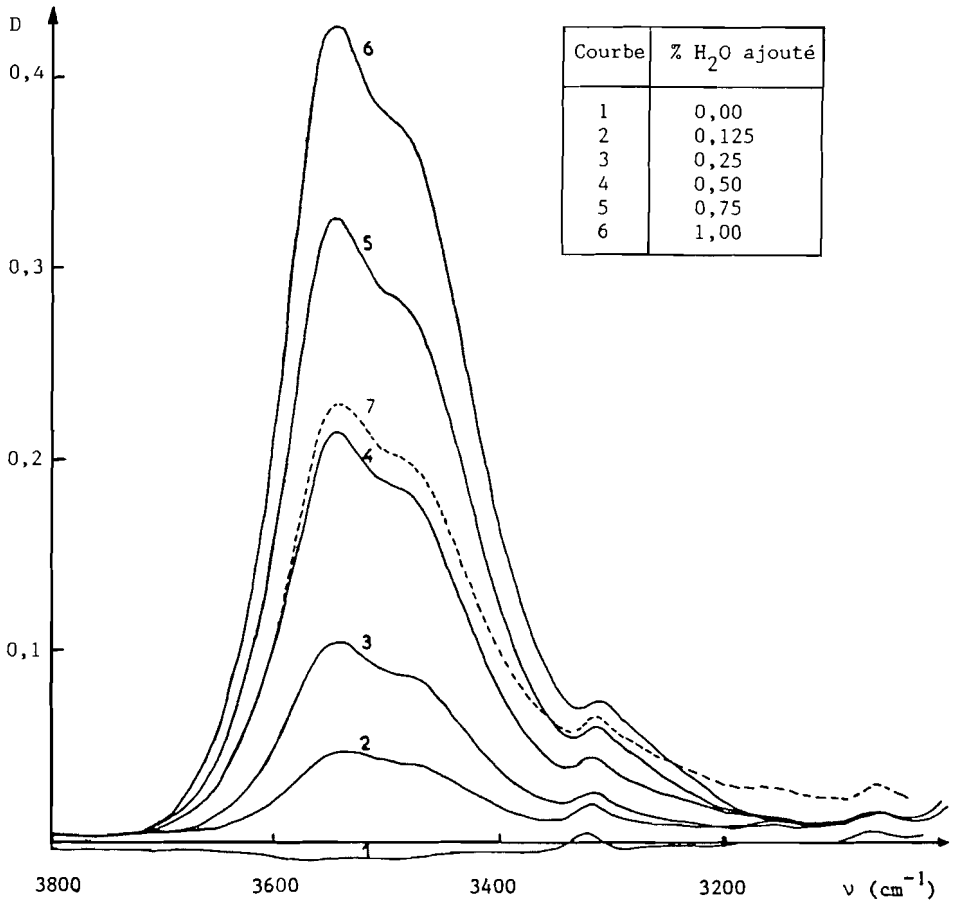

FIG. 2. Dosage de l'eau dans le DMF par spectroscopie infra-rouge. (—) (1) à (6) courbes d'étalonnage. (...) (7) DMF + $EuCl_3 \cdot 6H_2O$ ($5 \times 10^{-2} M$). Les expériences sont réalisées avec une cellule de compensation contenant du DMF.

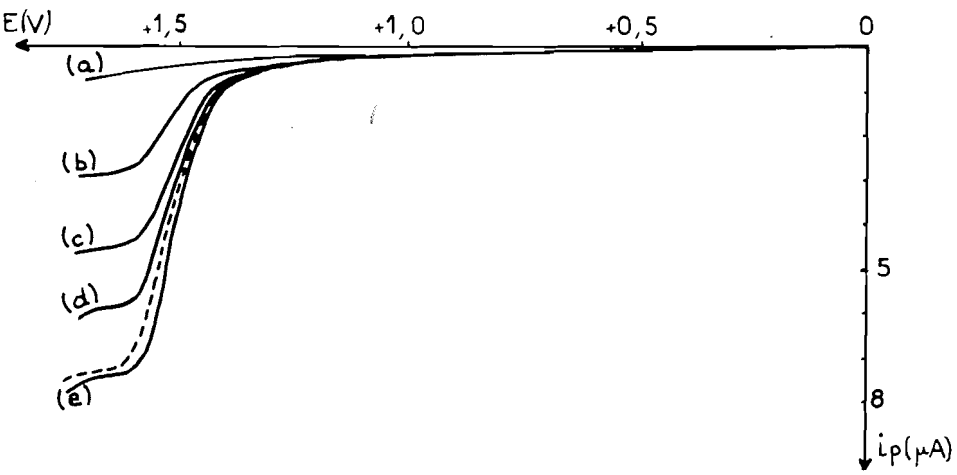

FIG. 3. Oxydation des ions Cl^- sur électrode de platine pour différentes concentrations en LiCl (—) (*a*) : 0; (*b*) : $2 \times 10^{-3} M$; (*c*) : $4 \times 10^{-3} M$; (*d*) : $6 \times 10^{-3} M$; (*e*) : $8 \times 10^{-3} M$. (---) : oxydation de $EuCl_3 \cdot 6H_2O$ $2 \times 10^{-3} M$. $v = 0{,}1\ V\ s^{-1}$. Electrolyte TBA BF_4 0,2 *M* (DMF). Electrode de référence Ag/AgI/I^- (0,1 *M* DMF).

mulée pour d'autres systèmes (4, 5), que l'espèce réduite en B résulte de l'association de molécules de cétone avec des ions divalents Eu(II).

En absence de sel métallique, des additions d'eau ou une modification de la nature de l'électrolyte support ne provoquent pas l'apparition de nouveaux pics de réduction du dérivé carbonylé. Un travail récent (29) fait état d'une possibilité de réduction indirecte de la benzophénone et du benzaldéhyde par l'ion ytterbium(II). Dans cet exemple le couple Yb^{3+}/Yb^{2+} se situe à un potentiel beaucoup plus cathodique que celui de Eu^{3+}/Eu^{2+}.

(b) Stoechiométrie du complexe et site de complexation

La figure 5 montre l'évolution de l'intensité du pic B pour une solution d'europium(III) à laquelle on ajoute des quantités croissantes de benzophénone. La proximité de la première

	1	−0,95	−1,15	0,20

étape de réduction de la cétone rend délicate, en polarographie, la mesure de l'intensité de diffusion de la vague B, aussi avons nous choisi comme pour les sels de chrome (4) d'utiliser la voltammétrie cyclique qui permet de mesurer plus facilement le courant du pic (i_p). On peut constater une augmentation rapide de i_p jusqu'à ce que le rapport des concentrations m atteigne la valeur 2, contrairement à ce que l'on observe en présence d'ions Cr^{2+} où le maximum d'intensité est atteint pour $m = 1$. La stabilisation du courant de pic observée pour $m = 2$ laisse supposer la formation d'un complexe europium–cétone de stoechiométrie 1–2. Cependant l'intensité du pic B pour $m = 2$ n'est pas exactement le double de celle observée pour $m = 1$. De plus, la réapparition des pics de réduction de la cétone dès que m est supérieur à 1 indique que la formation du complexe 1–2 n'est pas complète pour ces concentrations. Pour expliquer ce phénomène nous envisageons l'hypothèse d'une destruction partielle du sel d'europium par hydrolyse en raison du milieu rendu fortement basique au voisinage de l'électrode par l'excés de radicaux anions, ce que nous pourrons vérifier lors des électrolyses préparatives. Nous avons de plus réalisé une étude des variations de i_p (B) en fonction de la concentration en mélange sel d'europium – cétone pour une même valeur de m (fig. 6). L'intensité du pic B augmente proportionnellement à la concentration en mélange lorsque celle-ci est faible puis tend vers une limite correspondant aux concentrations de $2 \times 10^{-3} M$ en $EuCl_3 \cdot 6H_2O$ et $2 \times 10^{-3} M$ en benzophénone si $m = 1$ et de $2 \times 10^{-3} M$ en $EuCl_3 \cdot 6H_2O$ et $4 \times 10^{-3} M$ en benzophénone si $m = 2$. Cette limitation peut être due à un phénomène d'adsorption des produits de réaction (pinacol ou pinacolate) (30) à la surface de la goutte de mercure.

Afin de déterminer si la complexation peut intervenir avec l'europium(II) en solution, nous avons réalisé une réduction partielle ($0{,}8\ F\ mol^{-1}$) du sel métallique au potentiel de −0,60 V préalablement à l'introduction de la cétone. L'évolution de la solution est suivie par voltammétrie sur électrode tournante de carbone vitreux. La benzophénone **1** est ajoutée dès l'arrêt de l'électrolyse et des voltammétries de contrôle sont réalisées à divers intervalles de temps sur la même solution. Pour un rapport de concentrations $m = 0{,}5$, on observe que le pic B défini précédemment et attribué à la réduction du complexe Eu(II) – cétone est accompagné d'une étape supplémentaire (B′) située à un potentiel moins cathodique que B (fig. 7). Pour une même concentration initiale en $EuCl_3 \cdot 6H_2O$ ($4 \times 10^{-3} M$) l'intensité de B′ comparée à celle de B est fonction de la concentration en benzophénone ajoutée. Ainsi, pour une faible valeur ($10^{-3} M$) c'est le pic B′ qui est prépondérant; par contre, si la concentration augmente, l'intensité de B′ diminue par rapport à celle de B. On peut constater également que pour des conditions données, l'intensité de B′ diminue en fonction du temps au profit de B qui finalement subsiste seul. L'intensité finale est alors égale à $i_p(B') + i_p(B)$ initiales. Il est connu que les sels d'europium peuvent donner des complexes de stoechiométrie 1–1 ou 1–2 (31, 32), ces derniers étant les plus stables. Lorsque la concentration en cétone est faible comparée à celle en europium, le complexe 1–1 est favorisé. Si la concentration en dérivé carbonylé est importante, c'est le complexe 1–2 qui devient prépondérant. La modification du pic B′ avec le temps traduit l'évolution du complexe 1–1.

Si la benzophénone et le sel d'europium sont introduits simultanément, le pic B′ n'est pas observé. Les coefficients de diffusion respectifs des deux espèces étant $D_{Eu^{3+}} = 4{,}05 \times$

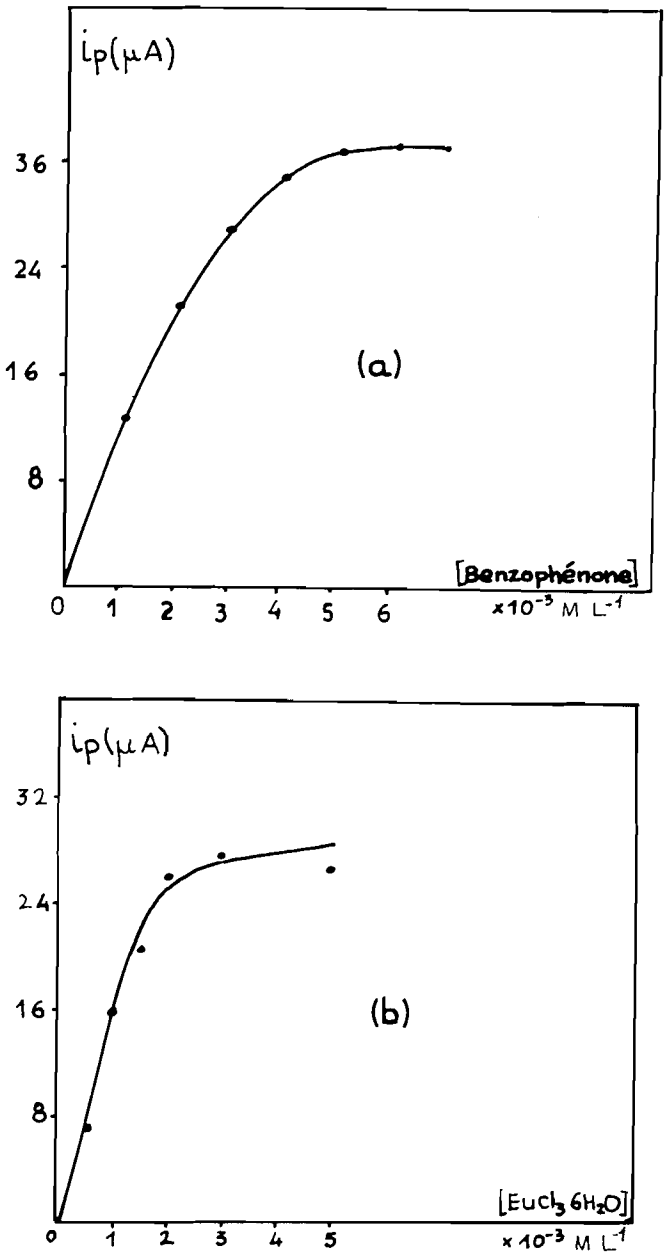

FIG. 5. Evolution de l'intensité du pic B en fonction des concentrations en $EuCl_3 \cdot 6H_2O$ ou en benzophénone. (a) $c = 2 \times 10^{-3} M$ en $EuCl_3 \cdot 6H_2O$; (b) $c = 4 \times 10^{-3} M$ en benzophénone.

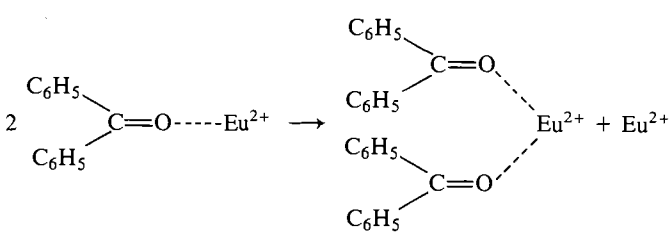
$10^6 cm^2 s^{-1}$ et $D_{>C=O} = 8{,}1 \times 10^6 cm^2 s^{-1}$, on peut penser qu'à l'électrode les conditions de concentration respectives des deux espèces seront toujours plus favorables à la formation du complexe 1–2.

Après l'électrolyse partielle de l'europium(III) à −0,6 V, la comparaison des intensités de pic obtenues en voltammétrie



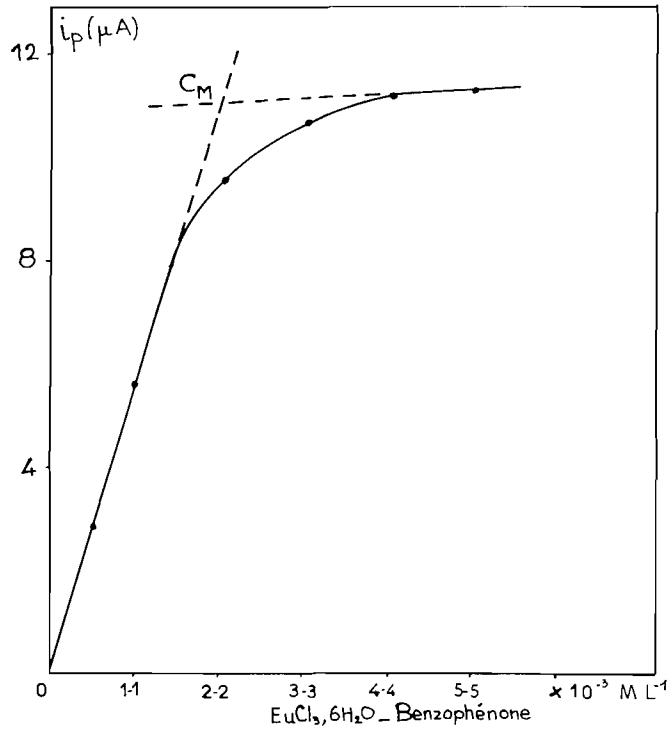


FIG. 6. Evolution de l'intensité du pic B en fonction de la concentration du mélange $EuCl_3 \cdot 6H_2O$–benzophénone pour $m = 1$.

cyclique sur goutte stationnaire de mercure donne la valeur de 3,5 pour le rapport

$$q = \frac{i_p(B') + i_p(B)}{i_p(A_1)}$$

lorsque la cétone est introduite seulement à l'arrêt de l'électrolyse. S'il y a introduction simultanée de la cétone et du sel d'europium dans la solution (sans electrolyse préalable) on obtient $q = 1{,}6$. Les mêmes expériences réalisées dans le cas de $CrCl_3 \cdot 6H_2O$ conduisent respectivement aux valeurs $q = 1{,}77$ et $q = 1{,}75$. Comme l'ont prouvé Sopher et Utley (5), ce résultat montre que l'intermédiaire clef dans le cas du chrome est Cr(III). Par contre, dans le cas de l'europium, le rapport des intensités obtenu après électrolyse préalable de Eu(III) indique que la complexation peut également intervenir avec Eu(II) en solution.

3. *Étude des produits de réduction*

Nous avons réalisé des macroélectrolyses au potentiel du pic B pour les cétones **1**, **2**, **3** et **5** afin de déterminer la nature et éventuellement la stéréochimie des produits formés. Nous distinguerons deux cas selon la valeur de m:

(i) Cas où m = *1*

Les cétones **1**, **2** et **3** donnent essentiellement les glycols par duplication. Pour l'acétophénone **3**, un seul diastéréoisomère est obtenu; il s'agit du diol racémique. Sa stéréochimie a été attribuée à partir de ses constantes physiques et de ses caractéristiques spectroscopiques (rmn ^1H des groupements méthyle) (33–35). Avec la benzalacétophénone **5**, la réduction ne fournit pas l'ε dicétone attendue mais un cétol. Là encore, la réaction est stéréospécifique et conduit au cétol chélaté *cis* (tableau 2). Sa stéréochimie a été définie par comparaison de ses constantes physiques et de sa courbe voltammétrique avec celle d'un échantillon authentique (13). La rmn ^{13}C montre un seul signal $>C=O$ à 204,9 ppm ($CDCl_3$).

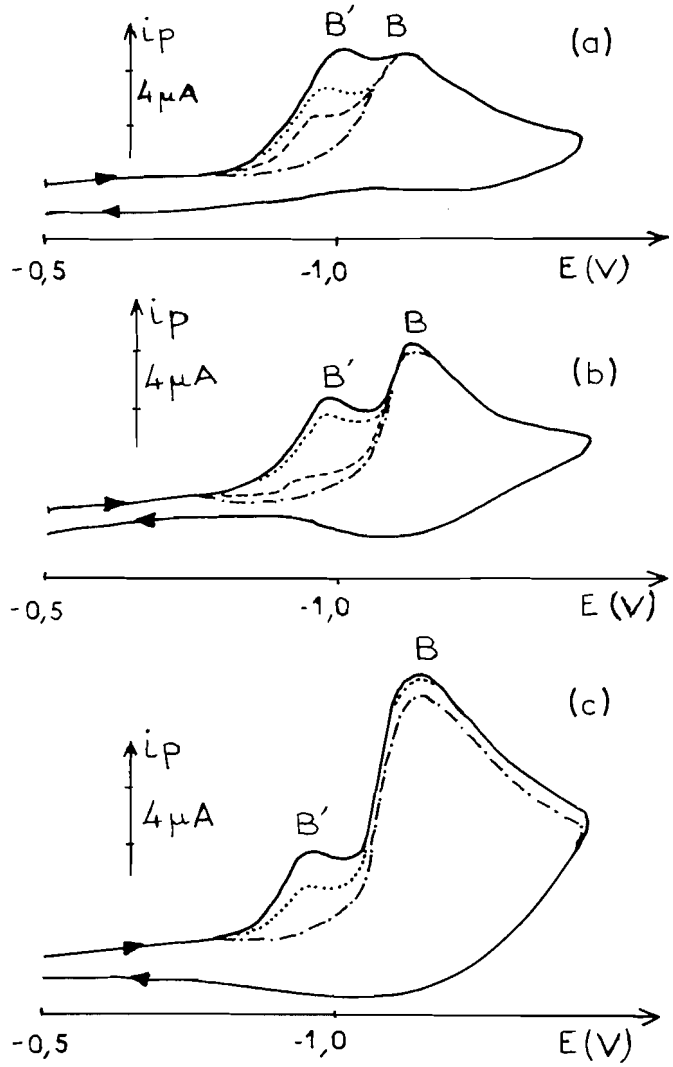

FIG. 7. Voltammogrammes obtenus après addition de benzophénone à une solution de $EuCl_3 \cdot 6H_2O$ ($c = 4 \times 10^{-3} M$) partiellement electrolysée au potentiel de $-0,6$ V, 0,8 F mol^{-1}, $v = 0,1$ V s^{-1}. Evolution en fonction du temps. (a) : (benzophénone) = $10^{-3} M$; (—) : t_0, (---) : t_0 + 60 min; (b) : (benzophénone) = $2 \times 10^{-3} M$; (—) : t_0, (---) : t_0 + 30 min; (c) : (benzophénone) = $4 \times 10^{-3} M$; (—) : t_0, (---) : t_0 + 20 min.

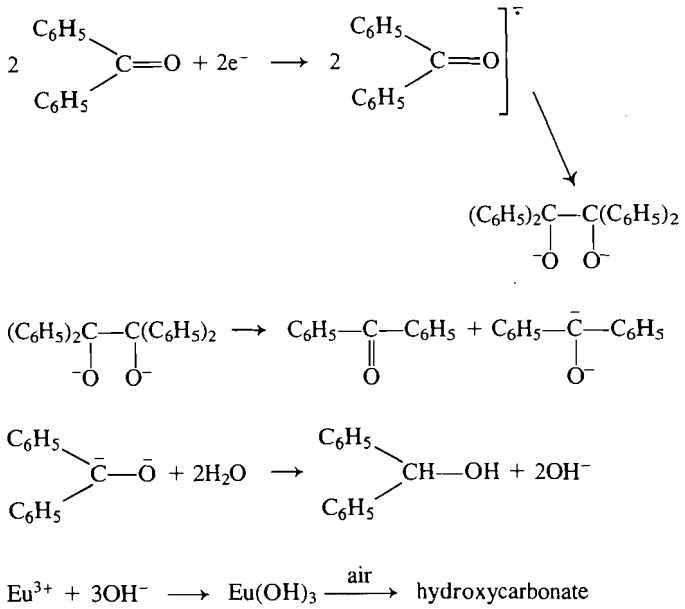
En présence de sel de chrome, la réduction de l'acétophénone est rendue délicate en raison de la proximité de l'étape Cr(II)/Cr(0). Nous avons réalisé une électrolyse au potentiel de $-1,04$ V (Ag/AgI/I$^-$ 0,1 *M* DMF). Elle nous a fourni les deux glycols diastéréoisomères dans un rapport *méso*-50%/*dl*-50% assez voisin de celui cité dans la littérature (16). Avec la benzalacétophénone, bien que le cétol *trans* s'isomérise dans $CDCl_3$ (15), deux pics sont obtenus en rmn ^{13}C à 204,9 et 205,8 ppm.

(ii) Cas où m = 2

Dans ces conditions, si des voltammétries de contrôle sont réalisées en cours d'électrolyse, on peut constater que l'intensité du pic de réduction A_1 de Eu(III) décroit rapidement pour ne plus représenter qu'environ 15% de la valeur initiale après consommation de 1 F mol^{-1}. Cette diminution qui peut correspondre à une réduction rapide de Eu(III) en Eu(II) (5, 15) est accompagnée d'une diminution importante du pic du complexe (40% de la valeur initiale) alors que les pics de réduction de la cétone libre ne sont pratiquement pas affectés. Dans le cas de la fluorénone, par exemple, une coloration rouge se développe également à la surface de l'électrode de travail. Parallèlement à ces modifications, on note l'apparition d'un précipité dans le milieu. Après filtration, celui-ci se révèle avoir les caractéristiques d'un produit minéral amorphe ne donnant pas de diffractogramme de rayons X. Les courbes thermogravimétriques mettent en évidence une première perte de masse dès 20°C suivie d'une seconde à 850°C. Nous n'avons pas fait de déterminations quantitatives en raison de difficultés rencontrées lors de la pesée initiale des échantillons (instabilité due vraisemblablement à une absorption d'eau ou de CO_2). Après chauffage à 850°C sous vide, le diffractogramme montre la présence de Eu_2O_3 sous ses deux formes cristallines (cubique : 3,13–2,71–2,56–2,31–2,20–2,13–1,92–1,80–1,76–1,70–1,63 Å; monoclinique : 3,18–3,04–2,98–2,89 Å). Le produit recueilli en cours d'électrolyse correspond certainement à la formation d'un hydroxy carbonate résultant de la fixation de gaz carbonique par l'hydroxyde d'europium (36). La première perte de masse est attribuée à un départ d'eau, la seconde à celui de CO_2. La forte coloration de la solution, dans le cas de la fluorénone, indique la formation du radical-anion ou du dianion. Ceci peut résulter soit de la présence à l'électrode de molécules de cétone non complexées (excés par rapport à Eu(II)), soit d'une réaction de rétropinacolisation rapide dans le cas où l'europium(II) est en défaut ($m = 2$). L'obtention des alcools (tableau 2) dans ces conditions serait en accord avec la seconde hypothèse.

La protonation, par les molécules d'eau, des formes réduites contribue à augmenter la basicité du milieu provoquant ainsi l'hydrolyse du sel d'europium :



Ce phénomène peut expliquer le fait que l'intensité maximum de i_p (B) pour un rapport $m = 2$ ne soit jamais le double de celle obtenue pour $m = 1$ (fig. 4). Seules les électrolyses préparatives des composés **1** et **2** ont été réalisées dans ces conditions. Elles fournissent beaucoup de cétone de départ non réduite et une faible quantité d'alcool résultant de la réaction de rétropinacolisation.

L'étude stéréochimique de la duplication de l'acétophénone a déjà donné lieu à des travaux (37, 38) mettant en évidence l'influence de la nature de l'électrolyte et des paires d'ions susceptibles de se former. En présence de sels d'europium, il parait établi que le complexe formé possède une stoechiomé-

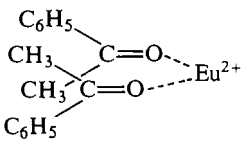
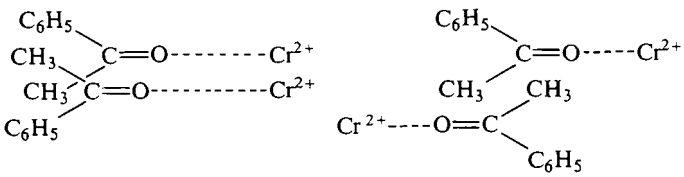
trie préférentielle correspondant à 1 Eu(II) – 2 cétones. Si on admet comme Bewick et Brown (37) que la configuration privilégiée est celle où l'encombrement stérique entre les noyaux aromatiques est minimum :

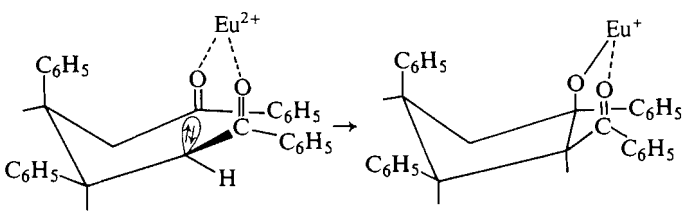


La dimérisation conduit dans ces conditions au diastéréoisomère racémique (*dl*). En présence de chrome, le complexe de stoechiométrie 1–1 peut présenter les deux configurations

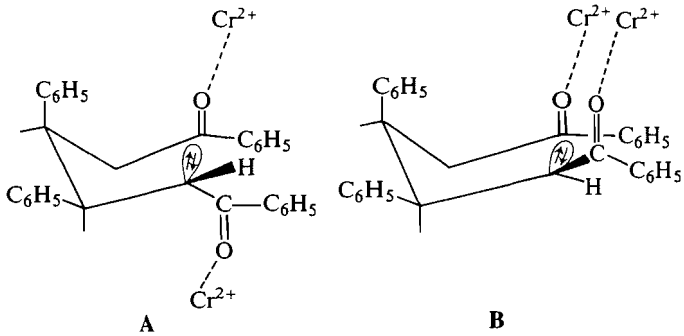


qui conduisent après duplication au mélange *méso* + racémique.

Une électrolyse au potentiel du pic B de la benzalacétophénone **5** (E_p = −0,80 V) avec m = 1 conduit à la formation d'un seul produit. La comparaison de sa température de fusion, de son spectre ir et de son voltammogramme avec les résultats obtenus pour des échantillons authentiques (13) montre qu'il s'agit du cétol *cis*. La même réaction effectuée en présence de sel de chrome conduit aux isomères *cis* et *trans* (15). À l'issue du transfert electronique intervenant au potentiel du pic B, l'addition nucléophile d'un carbanion sur l'une des fonctions carbonyles conduit au cétol *cis*.



En présence de sel de chrome, les deux structures **A** et **B** sont possibles et conduisent aux isomères *cis* et *trans*.



Une étude semblable effectuée sur la benzalacétone **4** ne nous a pas donné de résultats exploitables. Les électrolyses préparatives permettent d'isoler des produits présentant des fonctions alcool et carbonyle sans qu'il soit possible de les purifier. Il est connu (39) que dans ce cas les cétols sont instables et sujets à une réaction d'ouverture avec régénération de la dicétone.

Partie expérimentale

1. Techniques électrochimiques

Le dimethylformamide (DMF) est distillé sous pression réduite après avoir été séché sur carbonate de sodium. L'électrolyte indifférent est le perchlorate de tétrabutylammonium à la concentration de 0,1 *M*. Les tensions sont indiquées par rapport à l'électrode de référence Ag/AgI/I⁻ (Bu_4NI 0,1 *M* dans le DMF). L'électrode de travail est une goutte de mercure stationnaire. Toutes les mesures ont été réalisées à la température ambiante après désaération par un courant d'azote.

L'étude voltammétrique a été faite avec un ensemble Tacussel comprenant un potentiostat type PRT 20-2X équipé d'un générateur de signaux triangulaires et d'un amplificateur différentiel type ADTP.

Les déterminations coulométriques ont été réalisées dans une cellule contenant une nappe de mercure agitée pendant toute la durée de l'électrolyse. L'installation comprend un potentiostat PRT 100 et un intégrateur Tacussel IG5 N.

2. Electrolyses préparatives. Caractéristiques des produits

Les électrolyses préparatives ont été effectuées dans une cellule à trois compartiments. L'électrode auxiliaire est constituée dans ce cas

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

d'une plaque de graphite. Après électrolyse, le catholyte est repris par l'eau et les produits extraits à l'éther. Ces derniers sont identifiés par comparaison de leur point de fusion et de leurs caractéristiques spectroscopiques avec les données de la littérature : benzopinacol (F = 182–184°C); benzhydrol (F = 69–70°C); fluoropinacol (F = 186–187°C); fluorénol (F = 154–155°C); diphényl-2,3 butane diol-2,3 (*dl*) (F = 126°C); triphényl-1,3,4 benzoyl-2 hydroxy-1 cyclopentane *cis* (F = 196°C), *trans* (F = 210°C).

Les diffractogrammes ont été réalisés à l'aide d'un appareil Siemens composé d'un goniomètre de type 501 et d'un générateur de rayons X Kristalloplex 710. La radiation K_α du cuivre (λ = 1,5405 Å) a été utilisée. L'analyse thermogravimétrique a été faite avec une thermobalance Ugine Eyraud type 60 B commandée par un appareil de régulation et de programmation de la température RT 64. Les spectres infra-rouge ont été enregistrés sur un appareil Perkin Elmer série 18 avec des cellules en fluorure de calcium pour le dosage de l'eau.

Received January 31, 1986[2]

BYRON R. WENTZELL, TRUIS SMITH-PALMER, and JOHN C. DONINI. Can. J. Chem. **65**, 557 (1987).

The use of polarographic maximum suppression methods for determining polyacrylamides and polyacrylic acid-based polymers was investigated. Using the oxygen, Co^{2+}, and Hg^{2+} maxima these polymers were determined at the low ppm level. The effectiveness of polymers as maximum suppressors was dependent on the charge of the polymer and that of the electrode at the potential at which the polarographic wave occurred. The maximum suppression of various binary mixtures of polyacrylamides indicated that in some mixtures suppression was additive while in other mixtures, particularly those containing both anionic and cationic polymers, the suppression was greatly reduced. Aqueous extracts of chosen coals contained various interfering substances which could be removed most efficiently using Sephadex G-75, although this resin was only compatible with anionic and neutral polymers.

BYRON R. WENTZELL, TRUIS SMITH-PALMER et JOHN C. DONINI. Can. J. Chem. **65**, 557 (1987).

On a étudié la possibilité d'utiliser les méthodes de suppression polarographiques maximales pour déterminer les polyacrylamides ainsi que les polymères dérivés de l'acide polyacrylique. En utilisant les maxima de l'oxygène, du Co^{2+} et du Hg^{2+}, on a déterminé ces polymères à des niveaux de ppm. L'efficacité des polymères comme suppresseurs maximaux dépend de la charge du polymère ainsi que de celle de l'électrode au potentiel de laquelle la vague polarographique se produit. La suppression maximale de divers mélanges binaires de polyacrylamides indique que, dans quelques mélanges, la suppression est additive; toutefois, dans d'autres mélanges et particulièrement dans ceux contenant à la fois des polymères anioniques et des polymères cationiques, la suppression est fortement réduite. Les extraits aqueux de charbons choisis contiennent diverses substances qui interfèrent et qui peuvent être éliminées efficacement en utilisant du Sephadex G-75; toutefois, cette résine n'est compatible qu'avec les polymères anioniques ou neutres.

[Traduit par la revue]

Introduction

Polyacrylamides and polyacrylic acid-based polymers (pam) have many industrial applications. A variety of these polymers with cationic or anionic functional groups is commercially available in a wide range of molecular weights. One of their uses is as a flocculating agent in coal-washing operations. In these operations modern practice dictates the recycling of the wash water after sedimentation of suspended solids. Thus the residual concentration of flocculating agent should be known before additional polymer is added to the recycled water. Since these polymers are generally used at the ppm level, methods for their determination must have a low detection limit. Unfortunately there are only a few analytical methods available to determine these polymers at such low levels.

Many of the methods described in the literature are based on chemical reactions of the amide group and are not applicable to polyacrylic acid and its esters. Most of these methods are also time consuming, often involving lengthy hydrolysis steps. Scoggins and Miller (1) developed a method involving the oxidation of amide groups to a product which oxidized I^- to I_2. The I_2 was then determined spectrophotometrically as the starch–triiodide complex. Hendrickson and Neuman (2) converted the amide groups of polyacrylamide to amine groups via the Hofmann rearrangement, and then determined the polyamine fluorometrically after derivatizing with *o*-phthalaldehyde. Crummet and Hummel (3) hydrolyzed polyacrylamide in hot acid, and then distilled off the ammonia under alkaline conditions for determination with Nessler's reagent. Similarly, Hawn and Talley (4) derivatized ammonia released by alkaline hydrolysis of polyacrylamide and quantified the derivative by gas chromatography.

Several turbidimetric methods have also been described. In a method developed by Michaels and Morelos (5), and improved by Crummett and Hummell (3), benzethonium chloride, a cationic detergent, is mixed with partially hydrolyzed polyacrylamide to form a colloidally suspended complex which is determined turbidimetrically. In addition to the hydrolysis step, an ion exchange step to remove interferences and an evaporation step to concentrate dilute samples are necessary (3). Attia and Rubio (6) measured the turbidity produced when tannic acid is added to solutions of neutral and cationic polyacrylamides. While this method is relatively simple, it cannot determine strongly anionic polymers.

Electrochemical methods which measure effects due to adsorption of molecules at an electrode surface offer simple, rapid means of determining the concentration of many surface-active substances. Methods based on the measurement of changes in capacitance currents by phase-sensitive ac polarography (7) and the Kalousek commutator technique (8) have been described. Measurement of peaks due to adsorption–desorption of surfactants in ac polarography (9) and in differential pulse polarography (10) has also been used to determine surfactant concentrations. Another electrochemical method which has been used involves measuring the suppression of polarographic maxima by surfactants. In conventional dc polarography some polarographic waves are distorted by large peaks which can be many times greater than the actual diffusion current. These "maxima" are caused by convective streaming (11) and are suppressed by the addition of surface active substances such as polyacrylamide. Methods based on the suppression of the polarographic maxima of oxygen (12), Co^{2+} (13) and Hg^{2+} (14) have been described. In this paper, we describe our investigation into the use of polarographic maximum suppression as a means of determining polyacrylamides and related polymers, with particular attention being paid to determining these polymers in coal washings.

Experimental

The polyacrylamides used are listed in Table 1. They were provided by the Coal Research Lab., Energy, Mines and Resources, Edmonton, Alberta. Praestol 2810/73 is a simple polyacrylamide while in Praes-

TABLE 1. Polymers used in this study

Polymer	Charge	Charge density	Molecular weight
Praestol 2810/73	Non-ionic	—	$(0.5–1) \times 10^7$
Polyacrylamide	Non-ionic	—	—
Praestol 2900/73	Anionic	25%	$(0.5–1) \times 10^7$
Praestol 2830/72	Anionic	12.5%	—
Praestol 444k	Cationic	100%	$<5 \times 10^6$
Praestol 411k	Cationic	25%	—

tol 2900/73 approximately 25% of the amide groups of the polyacrylamide structure have been hydrolyzed to carboxyl groups, i.e., it has a charge density of 25%. Praestol 444k is a cationic polymer prepared from acrylic acid esterified with a cationic alcohol: $HOCH_2CH_2N^+R_3Cl^-$. Stock solutions of 200 ppm of these polymers were prepared in 10 megohm-cm resistivity water which was used throughout. Humic acid was purchased from Aldrich Chemical Company Inc. Polarograms were obtained using a Princeton Applied Research Model 174A Polarographic Analyzer and a Model 303 SDME. The analog output of the polarograph was digitized using an Apple IIe microcomputer with Interactive Microware software (Lab Data Manager, Scientific Plotter) and hardware (ADALAB Interface Card, ADA-AMP Instrumentation Amplifier). All potentials reported are relative to a silver – silver chloride reference electrode.

The polarograph was operated in the current-sampled dc mode with a scan rate of 2 mV/s and a drop time of 2 s. Oxygen maxima were measured in 10 m*M* KCl. Samples were bubbled with medical grade air for 4 min prior to analysis. Co^{2+} maxima were measured in solutions containing 10 m*M* KCl plus 1 m*M* Co^{2+} and samples were bubbled with N_2 for 4 min prior to analysis to remove dissolved O_2. Hg^{2+} maxima were measured in unpurged solutions containing 1 m*M* Hg^{2+} plus 0.25 *M* KCl.

Four different raw coal samples were used. Three of these, Quinsam, CRL-82-11, and Alb-X, were weathered Albertan bituminous samples. The fourth, Lingan, was a weathered Cape Breton coal. Samples were ground using a Brinkman Centrifugal Grinding Mill ZM-1 using a 0.08 mm screen size. Over 80% of the coal in these samples passed through a 200 mesh sieve. Coal extracts were prepared by shaking ground coal suspensions (10% w/v) on a wrist action shaker overnight and filtering through a sintered glass filter.

Size exclusion chromatography was performed using Sephadex G-75 gel (Pharmacia Ltd.). this gel provides an effective fractionation range for globular proteins of 5 000 to 40 000 Daltons. A 0.9 cm × 30 cm column was used and unless otherwise specified the eluent was water. A head pressure of 75 cm of water produced a flow rate of approximately 0.5 mL/min. Samples of 2.5 mL volume were chromatographed and 5.0 mL fractions were collected. Polyacrylamides (MW 5×10^6) were eluted in the void volume (fraction 2).

Amberlite XAD-2 nonionic polymeric adsorbent was cleaned by soxlet extractions with methanol. The washed and dried resin was wetted with methanol and resuspended in dilute HCl pH 2.4. Columns were packed in Pasteur pipettes and were approximately 9 cm × 0.5 cm. Samples were adjusted to pH 2.4 and 8.0 mL aliquots were chromatographed. The column was then rinsed with 2.0 mL dilute HCl.

Cation exchange chromatography was performed using Rexyn 101 strong acid cation exchanger (Fisher Scientific Company). The resin was cleaned by an 8 h soxlet extraction in methanol, followed by resuspension in 1 *N* HCl and rinsing with water. Columns were packed in Pasteur pipettes and were approximately 9 cm × 0.5 cm. Eight (8.0) mL samples were chromatographed and the columns then rinsed with 2.0 mL water. The columns were reused after regeneration with 1 *N* HCl.

Anion exchange chromatography was performed using Rexyn 201 strong anion exchange resin (Fisher Scientific Company). The resin was washed with methanol and 1 *M* KCl. Columns were packed in Pasteur pipettes. Eight (8.0 mL) samples were chromatographed and the columns then rinsed with 2.0 mL of water. The columns were regenerated by washing with 1 *M* KCl.

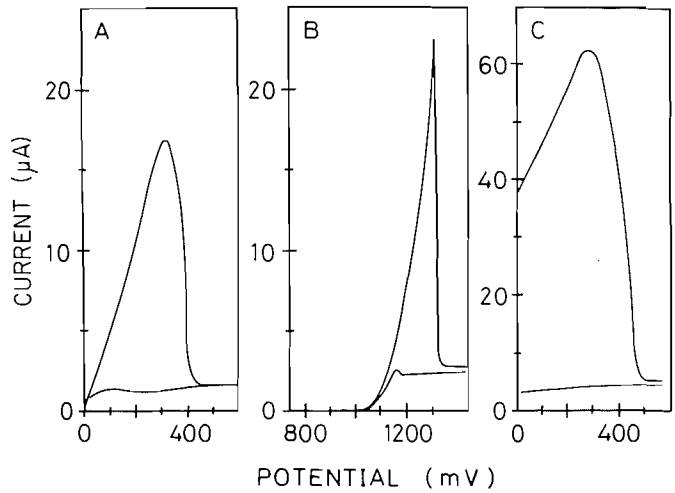

FIG. 1. Unsuppressed and suppressed polarographic waves for O_2 (*A*), Co^{2+} (*B*), and Hg^{2+} (*C*). The suppressed waves were recorded in the presence of 100 ppm polyacrylamide.

Flocculation experiments were carried out using cleaned Quinsam coal and a Kaolin powder (J. T. Baker Chemical Co.). Slurries were prepared to give a final coal concentration of 3% (w/v) and a final clay concentration of 2% (w/v) in 100 mL graduated cylinders. These slurries also contained 2 m*M* $CaCl_2$, 2 m*M* Na_2SO_4, and 2 m*M* $NaHCO_3$. Following the addition of polyacrylamides, the cylinder contents were mixed by inverting four times and the settling times then determined.

Results and discussion

In Fig. 1 are shown the unsuppressed and the suppressed polarographic waves for O_2, Co^{2+}, and Hg^{2+}. The O_2 and Co^{2+} maxima are observed only in relatively dilute salt solutions and are suppressed by increasing salt concentrations. To determine surfactants in solutions of higher or undetermined salt concentrations it would be necessary to isolate the surfactants first. By contrast the Hg^{2+} maximum is pronounced in solutions of much higher salt concentration (14). Calibration plots for the suppression of the oxygen maximum by the three Praestol polymers are shown in Fig. 2. The plots are not linear but have the general shape of adsorption isotherms, reflecting the fact that maximum suppression is due to adsorption of suppressor onto the surface of the mercury drop. This is in contrast to the standard curves reported by Dunsch *et al.* (15) which are fitted as two-piece linear graphs. The three polymers are not equally effective in suppressing the O_2 maximum. The effectiveness of a maximum suppressor depends on the strength of its adsorption onto the mercury surface and this can be influenced by such factors as polymer solubility and charge. As seen in Fig. 2, Praestol 444k is less effective than the other two polymers in suppressing the O_2 maximum. This is probably due to electrostatic repulsion of the cationic polymer from the electrode surface since the electrode is positively charged at the potential of O_2 reduction (16), or it could be due to the greater solubility of this highly charged polymer. The minimum concentrations which can be determined are approximately 2 ppm for Praestol 2810/73 and Praestol 2900/73 and 4 ppm for Praestol 444k.

Figure 3 shows the calibration plots for the suppression of the Co^{2+} maximum by the three polymers. The anionic Praestol 2900/73 is much less effective than the other two polymers.

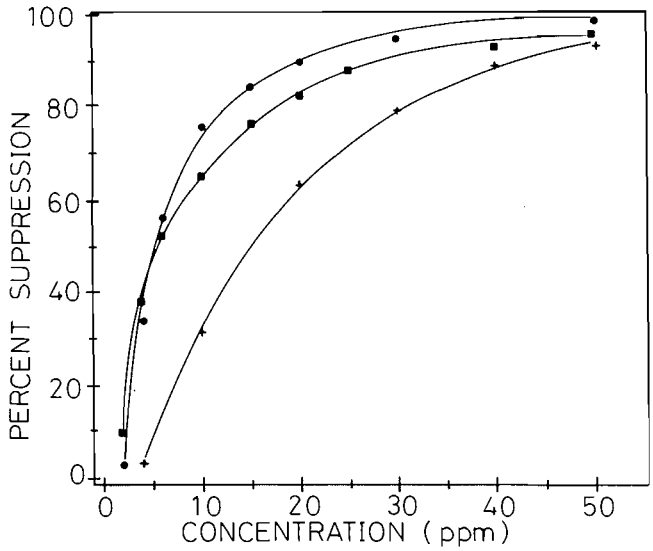

FIG. 2. Calibration curves for suppression of the O_2 maximum by Praestol 2810/73 (●), Praestol 2900/73 (■), and Praestol 444k (+).

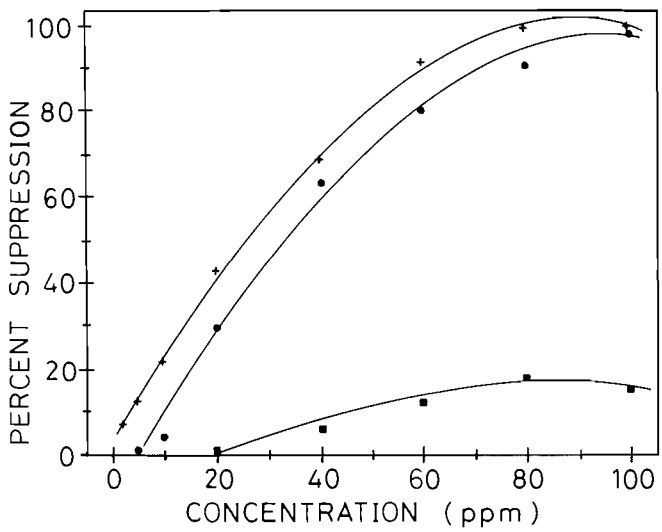

FIG. 3. Calibration curves for suppression of the Co^{2+} maximum by Praestol 2810/73 (●), Praestol 2900/73 (■), and Praestol 444k (+).

This is undoubtedly a charge effect. The mercury electrode is negatively charged at the potential of the Co^{2+} reduction and the anionic polymer should be less strongly adsorbed than the non-ionic or cationic polymers. Although these methods are basically nonspecific, a comparison of the O_2 and Co^{2+} maxima suppression should indicate whether or not a polymer is anionic.

In Fig. 4 are shown the calibration plots for the determination of the three Praestol polymers by suppression of the Hg^{2+} maximum in unpurged solutions. The minimum concentration of each polymer which can be detected is about 1 ppm. At higher concentrations Praestol 444k is the most effective while Praestol 2810/73 is the least effective. The cationic Praestol 444k would be expected to be the least effective due to its repulsion from the positively charged electrode. In samples which have been purged with N_2 to remove dissolved O_2 this is in fact observed (results not shown). The presence of O_2, however, affects the size and shape of the maxima as well as

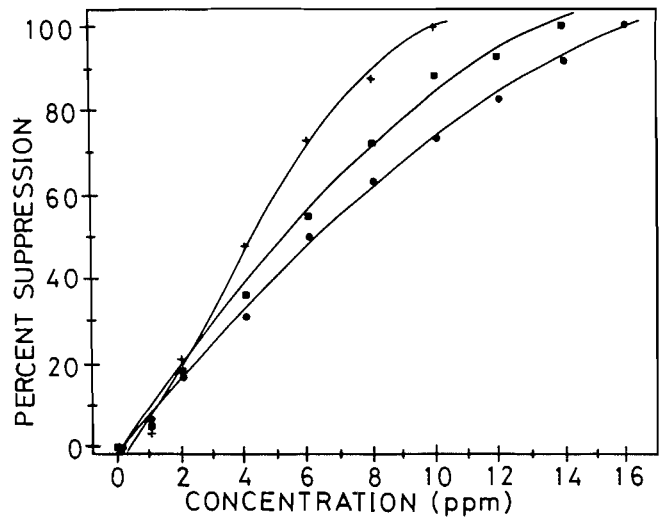

FIG. 4. Calibration curves for suppression of the Hg^{2+} maximum by Praestol 2810/73 (●), Praestol 2900/73 (■), and Praestol 444k (+).

TABLE 2. Maximum suppression by Praestol mixtures

Praestol mixture	% Suppression Obsd	Calcd
2 ppm 2810/73 + 2 ppm 2900/73	31.5	33.9
4 ppm 2810/73 + 2 ppm 2900/73	50.8	51.0
2 ppm 2810/73 + 4 ppm 2900/73	45.0	44.4
2 ppm 2810/73 + 2 ppm 444k	30.3	36.4
2 ppm 2810/73 + 4 ppm 444k	64.2	63.0
4 ppm 2810/73 + 2 ppm 444k	45.7	53.5
2 ppm 2900/73 + 2 ppm 444k	21.7	36.3
2 ppm 2900/73 + 4 ppm 444k	23.8	62.9
4 ppm 2900/73 + 4 ppm 444k	29.6	46.8

2 ppm 2900/73 + 2 ppm 444k	19.5	54.2

the relative effectiveness of the polymers in suppressing the maxima.

Experiments were carried out to observe the effect of mixtures of these polymers on maximum suppression. The concentrations used were from the lower, approximately linear portion of the calibration plots in Fig. 4. In Table 2 are listed the observed suppressions of mixtures of the polymers as well as the theoretical suppression of the mixtures, assuming strict additivity. The observed suppression of mixtures of non-ionic Praestol 2810/73 and anionic Praestol 2900/73 was very close to that predicted. For mixtures of Praestol 2810/73 and the cationic Praestol 444k, the observed suppression was somewhat less than predicted when the concentration of the former was greater than or equal to that of the latter, suggesting some interaction between these polymers resulting in reduced surface activity, perhaps through the formation of molecular aggregates. With mixtures of Praestol 2900/73 and Praestol 444k the observed suppression was much less than the predicted, indicating extensive interaction between these polymers through ion pair formation.

However, when mixtures of cationic and anionic pams are used in flocculation processes, they are not added together,

Propionic acid	10.0 ppm	34.3
Humic acid	10.0 ppm	33.5

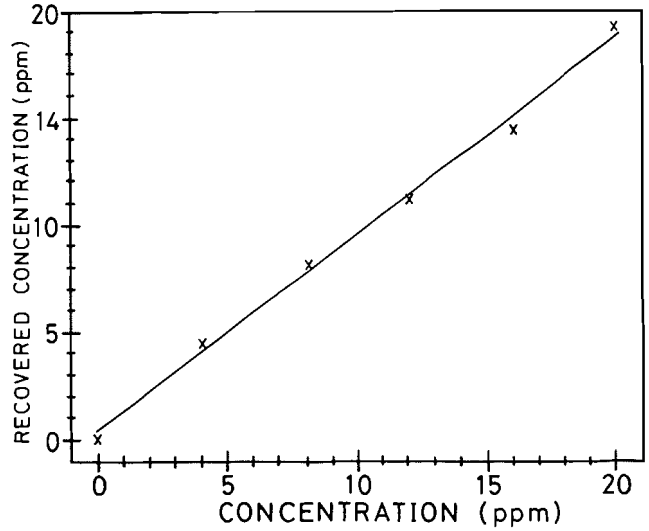

FIG. 5. Plot of measured concentration of P2830/73 in Quinsam coal washings after chromatography on Sephadex G-75, versus original concentration.

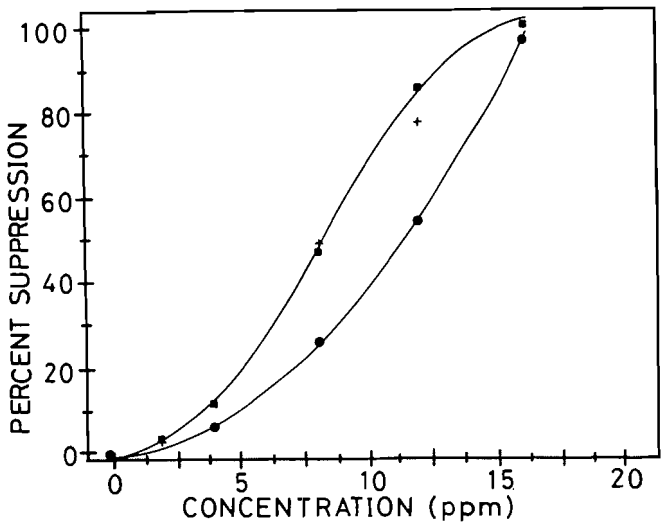

FIG. 6. Calibration curves for suppression of the Hg^{2+} maximum by P444k before chromatography (■), after chromatography in pure water (+), and after chromatography with 10 ppm humic acid (●) on XAD-2.

but, rather, sequentially (17). We have found that the cationic polymers are very strongly adsorbed onto coal/clay mixtures and thus contribute little to the final polymer mixture to be determined (see later).

These methods are not specific for polyacrylamides and other surface-active substances will interfere. Thus we investigated the determination of the pams in a number of coal washings prepared from a sampling of Canadian coals. The washings from the different coals contained different interferences. Table 3 lists these and other possible interferences along with a measure of their strength. Although none of the coal washings contained humic acid, it was felt to be worth consideration as it is often present in tap water while our coal washings were prepared with, and experiments done in, purified water. Table 4 lists the effects of various clean-up columns on the washings. A Sephadex G-75 column was the only single column able to completely remove the interferences from all of the coal washings tested and therefore was the method of choice. After passage through a Sephadex column, the recovery of the anionic polymer P2830/72 was about 90%, and a similar result was found for polyacrylamide. If the polymers were dissolved in coal washings before being passed through the column, the effect on the recovery depended on the source of the coal washings, with the greatest effect being found in washings of Quinsam coal. In this case, a plot of recovered polymer concentration (after passage through a Sephadex column) versus actual concentration yields a straight line graph with a slope of 0.92 (Fig. 5). Thus if the standards are prepared in coal washings similar to those that the unknowns are in, and are chromatographed in like fashion, analysis of neutral and anionic polymers should present no problems. However, the cationic polymers bound strongly to the Sephadex even with eluants of high salt concentration, and for their analysis in coal washings an ion exchange and/or XAD column would have to be used for the clean-up step. P444k, which is cationic with a charge density of 100%, was found to be effectively 100% recovered from XAD columns when chromatographed by itself, but in the presence of 10 ppm humic acid exhibited a markedly reduced recovery (Fig. 6). Use of this procedure would thus also require that the standards be prepared and chromatographed in the same washings that the unknowns are to be determined in. In contrast, P411k, which is also cationic but with a lower charge density, is only 90% recovered after passage through XAD, but humic acid is not found to have a significant effect on this recovery (Fig. 7). P444k was not retained on the cation exchange resin, but the recovery of P411k from it was down to about 70%.

We are using these methods in studies on flocculation rates in various systems. Some typical results are shown in Figs. 8 and 9. Cationic polymers such as P411k do not cause nearly such rapid settling as do the anionic species, but the supernatant is much clearer. Figure 8 shows that the most cost-effective concentration of P411k to use for this particular system would be approximately 10 ppm. From Fig. 9 we see that this corresponds to the point below which almost all the polymer added is bound. For the anionic polymer the situation is quite different. The settling rate curve does not show a

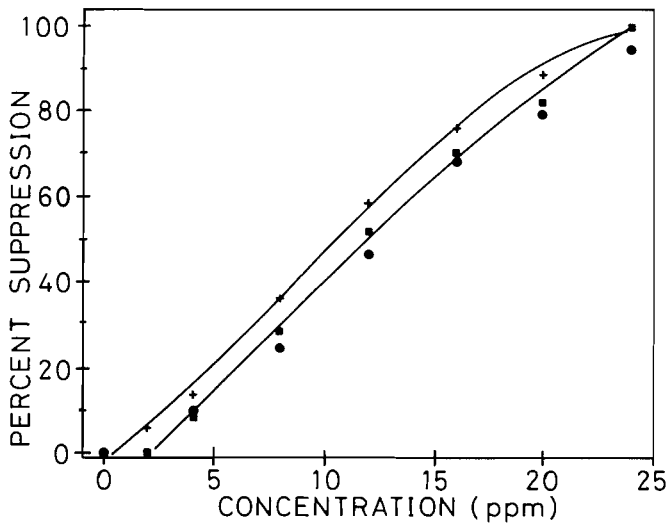

FIG. 7. Calibration curves for suppression of the Hg^{2+} maximum by P444k before chromatography (+), after chromatography (■), and after chromatography with 10 ppm humic acid (●) on XAD-2.

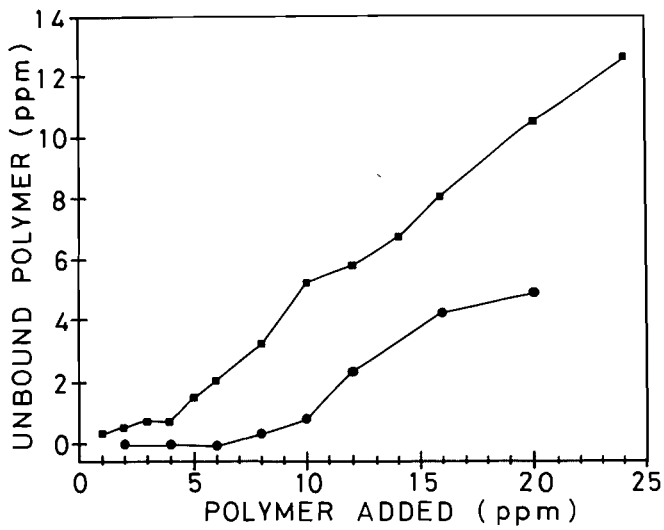

FIG. 9. Concentration of flocculant remaining in solution after flocculation versus the concentration of polymer added for P2830/72 (■) and P411k (●).

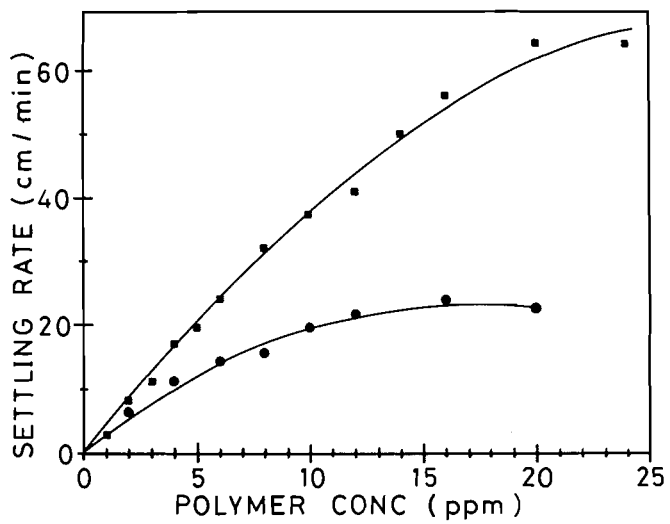

FIG. 8. Settling rate versus flocculant concentration for P2830/72 (■) and P411k (●).

plateau in the concentration region used, yet there are relatively large amounts of free polymer even for low concentrations of total added polymer.

In summary, the polarographic maximum suppression methods described here provide simple, rapid means for determining polyacrylamides and related polymers at the low ppm level. A number of common interferences have been identified and can typically be removed using a Sephadex G-75 resin before analysis of neutral or anionic polymers, or with XAD-2 and/or ion exchange resins for cationic polymers. The method involving the Hg^{2+} maximum is our method of choice as it does not require any purge time, it is the most sensitive, and it also permits the use of higher electrolyte concentrations where necessary.

The reactivity of aliphatic amines and morpholines in dioxane–water solvent systems

SABRINA KALSI, RITA LAFRAMBOISE, AND RONALD M. SCOTT[1]
Department of Chemistry, Eastern Michigan University, Ypsilanti, MI 48197, U.S.A.

Received August 18, 1986

SABRINA KALSI, RITA LAFRAMBOISE, and RONALD M. SCOTT. Can. J. Chem. **65**, 563 (1987).

Using the titration of tertiary aliphatic amines as a model a linear relationship for the log equilibrium constant versus the log dielectric constant over a broad range of dioxane–water mixtures is established. Primary and secondary amines are less responsive to changes in dielectric constant, producing linear data of shallower slope. A study of morpholine and *N*-alkylmorpholines produces curves that plateau in high dielectric constant regions and display decreasing slope as water concentrations approach zero. Similar behavior for morpholines is observed in low water mixtures where they form proton transfer complexes with *p*-nitrophenol. Possible reasons for the behavior are discussed.

SABRINA KALSI, RITA LAFRAMBOISE et RONALD M. SCOTT. Can. J. Chem. **65**, 563 (1987).

En utilisant la titration d'amines aliphatiques tertiaires comme modèle, nous avons établi une relation linéaire entre le logarithme de la constante d'équilibre et le logarithme de la constante diélectrique valable pour une large plaque des compositions de mélanges dioxan–eau. Les amines primaires et secondaires sont moins sensibles aux changements de constante diélectrique ce qui conduit une relation linéaire de pente plus faible. L'étude de la morpholine et de *N*-alkylmorpholines donne des courbes qui forment un plateau pour les constantes diélectriques élevées et dont la pente décroit lorsque la concentration de l'eau tend vers zero. Un comportement semblable est observé avec les morpholines dans les mélanges à faible teneur en eau lesquelles forment des complexes de transfert de protons avec le *p*-nitrophénol. Les raisons possibles de ce comportement sont discutées.

Introduction

The effects of the solvent on the reactions of dissolved substances can be classified into two categories. Long range solvation forces relate to the relative ability of the solvent to facilitate charge separation by virtue of the polarity of the solvent molecules. A variety of measures have been used to describe or measure this solvent property. Some such as dielectric constant are based on the measurement of a physical property of the pure solvent or solvent mixture, while others such as Taft's π value are based on the observation of the relative equilibria of model reactions in a variety of solvent systems (1). Short range solvation forces depend on a specific interaction usually by hydrogen bonding between the solute and a solvent molecule. Tendencies to interact in this fashion have been measured by such constants as the α and β values of Taft (1, 2).

Previous studies of solvation effects usually have been based on comparisons of equilibrium constants obtained in a series of different pure solvents whose polarity and possibly whose tendency to form hydrogen bonds have been independently assessed (1, 3). Mixed solvent systems are often used in studies attempting to assess the effect on some system of a change in dielectric constant, the experimental conditions being varied simply by altering the proportions of the polar and non-polar solvent component. However, such solvents clearly present a special case. For example, if one solvent component, probably the more polar one, engages in short range interactions with a solute, then the solvation shell of the reactant will be enriched in that component beyond the level of its proportion in the solvent. This circumstance has been termed preferential solvation (4). This results not only in the effect on the reactivity of the solute brought about by the short range interaction, but also in a departure from the behavior one would predict based on the long range forces due to the creation of an artificially high polarity environment.

We have selected for study the dioxane–water mixed solvent system. Because it provides a range of dielectric constant from approximately 2.2 to 78 at 25°C, it has frequently been used for studies in which the effect of dielectric constant on a system is to be assessed (5). However, it is a complex system not only for the reasons already stated, but also because water and dioxane are both proton acceptors and water is a proton donor. A pattern of hydrogen bonding between solvent molecules is therefore to be anticipated.

A first concern is whether in such a mixed solvent a reaction proceeds predictably, that is linearly, with respect to some solvent parameter. Providing a model to test effects of long range forces in isolation is difficult since the reactive centers of the model would be very likely to interact directly with dioxane, water, or both and such short range interactions distort the behavior. However, tertiary amines have only the unshared electrons of the nitrogen. By choosing a strong acid as the other reactant, and by never eliminating water from the system, our acidic species is the hydrated hydronium ion which may be reproducibly hydrated across the range of solvent mixtures. Although short range solvation has not been eliminated, it may now be considered to be non-varying across the range of study. Extending the study beyond simple tertiary aliphatic amines and observing deviation from the patterns set by these structures provides insights into the effects of short range solvation on other amines.

A system that we have studied previously in this solvent mixture involves the reacting of *p*-nitrophenol (*p*NP) and amines to form proton transfer complexes, structures in which the phenylate and ammonium ions are joined by a hydrogen bond (5). A detailed study of this reaction is only possible in the lower water content solvent mixtures, since in high water content solutions the complex tends to break into individual ions. Data from these studies are useful to confirm and extend observations of amines with strong acids.

Materials and methods

The chromophore, *p*-nitrophenol (*p*NP), was Aldrich reagent grade, and was purified twice by recrystallization from benzene. All amines were Aldrich reagent grade, were purified by fractional vacuum distillation twice, and were stored under a nitrogen atmosphere. Dioxane was Aldrich Gold Label Spectrophotometric Grade and was used

[1]To whom all correspondence should be addressed.

directly from freshly opened bottles. Water was distilled, then run through a mixed bed ion exchange resin cartridge.

Titrations were performed using a Sargent Model DG Titration apparatus employing a combination pH electrode. Dioxane–water mixtures were prepared by volume rather than by weight in order to reproduce the conditions of an earlier report (6). Accurately weighed amounts of amines in the range of 0.5 mmol were dissolved in the dioxane–water mixture, which was then titrated with 0.0100 *M* HCl dissolved in the same dioxane–water mixture.

For proton-transfer studies dioxane–water mixtures were prepared by weight. The solutions for a specific equilibrium constant determination were prepared so that the phenol concentration was constant and the amine concentration was varied. All determinations included a no amine solution and five different amine concentrations. A series of such determinations were made in solvent systems varying from 0 to 30 wt.% water in dioxane. Spectrophotometric reference solutions were prepared exactly as the sample solutions but with the phenol stock solution omitted. All solutions were made the day of use.

The spectra from 550 to 350 nm were obtained using 1 cm quartz cells in a Beckman DK-2A spectrophotometer. The sample temperature was maintained at a constant 25°C by circulating water from a constant temperature bath through a brass cell holder.

Absorbances were read at three wavelengths and were analyzed by two methods to determine the equilibrium constant. In one method the Rose–Drago equation was employed (7), generating an array of ten values for the equilibrium constant at each wavelength. These values were subjected to Chauvenet's criterion to reject extreme values, and the remaining values were averaged. In the other method of calculation, the iterative technique, a somewhat low value for the extinction coefficient of the *p*NP proton transfer complex at each specific wavelength was estimated. From the absorbance at that wavelength and the estimated extinction coefficient the concentrations of all reactants and products in the reaction mixtures were calculated, and from these five equilibrium constants were determined for each set of absorbances. The estimated value for the extinction coefficient was then incremented and the process repeated. The extinction coefficient and average equilibrium constant for the set of constants displaying the greatest self-consistency was then selected. In practice a very satisfactory convergence on a best value for the equilibrium constants is observed. This method was first used by us on this project, and is favored by us over other methods at this time. It resembles the Rose–Drago calculation in that determination of the equilibrium constant depends on first determining a value for the extinction coefficient of the complex, however the iterative testing of possible extinction coefficient values allows selection of the optimum value and provides an easy visual check as to whether the resulting values for the equilibrium constant are reasonable, reproducible, and consistent with one another. Good correspondence was obtained for the final values generated for the constants by the two methods.

The data were also treated by calculating the ratio of the concentrations of proton transfer complex to non-complexed *p*NP. The log of this ratio was plotted against the log of amine concentration. In such a plot the slope of the best straight line through the points indicates the number of amine molecules associated with each phenol in the complex, while the *X* intercept provides an approximate log *K* value. In every case the slope indicated a 1:1 complex between the participants and the estimated log *K* was close to the values obtained by the two methods described above.

Results

Figure 1 presents $-\log K$ values for the reaction of the various amines with hydrochloric acid versus solvent dielectric constant. Non-linear response is demonstrated, with values dropping sharply in the low water solutions. Similarly, in Fig. 2 decidedly non-linear plots result form plotting $-\log K$ versus the Onsager coefficient. However, in Fig. 3, $-\log K$ versus $\log \epsilon$, the data plot as a series of straight lines.

Figures 1–3 also present data for a primary and a secondary

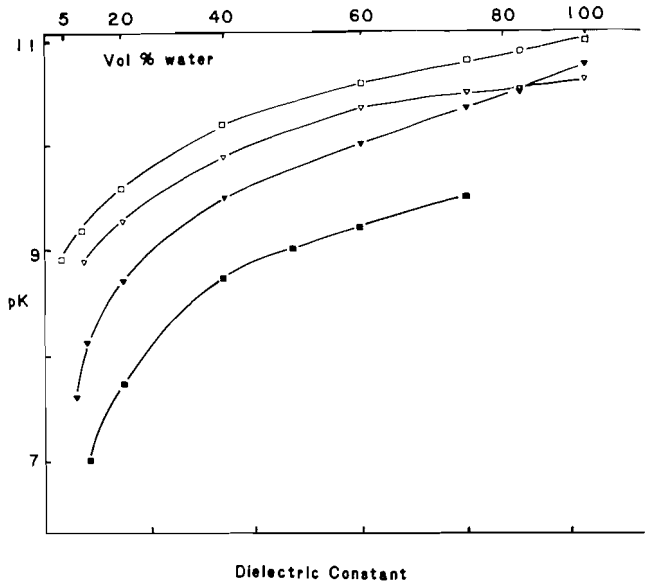

FIG. 1. The titration of aliphatic amines in mixtures of dioxane and water. Here and in Figs. 2 and 3 the solid triangles are TEA, solid squares are tributylamine, open triangles are *n*BA, and open squares are DEA. Data are plotted versus dielectric constant, with wt.% water indicated at the top of the figure.

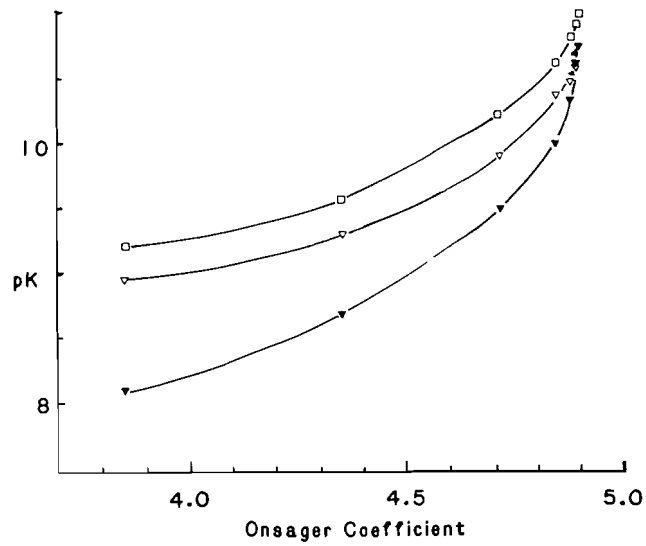

FIG. 2. These are the same data as in Fig. 1, here plotted versus Onsager coefficient $(\epsilon - 1)/(2\epsilon + 1)$.

amine. In Fig. 3 these data display linear response to $\log \epsilon$, but the slopes are more shallow. It is difficult to interpret the shallower slope as inferring other than a reduced dependence on long range forces. The linearity indicates an invariance in short range forces across the range of mixtures studied. The nitrogen protons of these amines can hydrogen bond to the oxygen unshared electrons of either dioxane or water, more likely the latter as was first predicted by Trotman–Dickenson (8). Such bonding would create an unchanging segment in the solvation shell of the amine. To the degree that this occurs the magnitude of response to changes in dielectric constant is reduced.

By contrast the data obtained when morpholine and *N*-methylmorpholine were titrated were non-linear plotting against any parameter including $\log \epsilon$ (Fig. 4). Morpholine compounds tended initially to remain at a constant equilibrium constant as

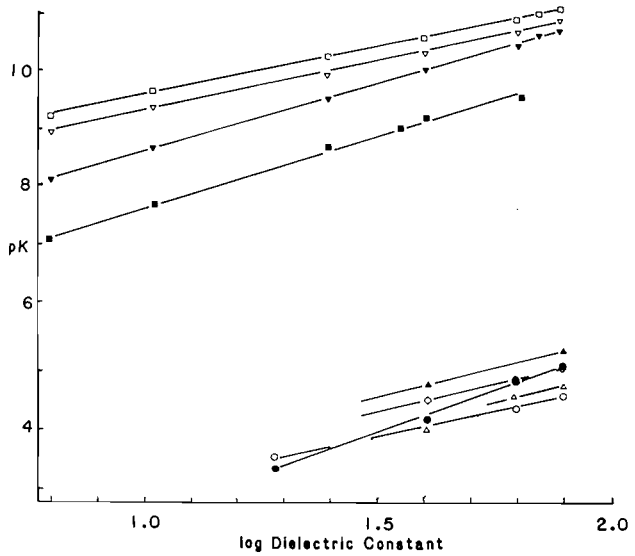

FIG. 3. These include the data in Fig. 1 plus the titration data for some aniline derivatives including aniline (open circles), *N*-methylaniline (inverted open triangles), *p*-toluidine (diamonds), *p*-anisidine (inverted solid triangles), and *N*,*N*-dimethylaniline (solid circles); aniline data from ref. 17.

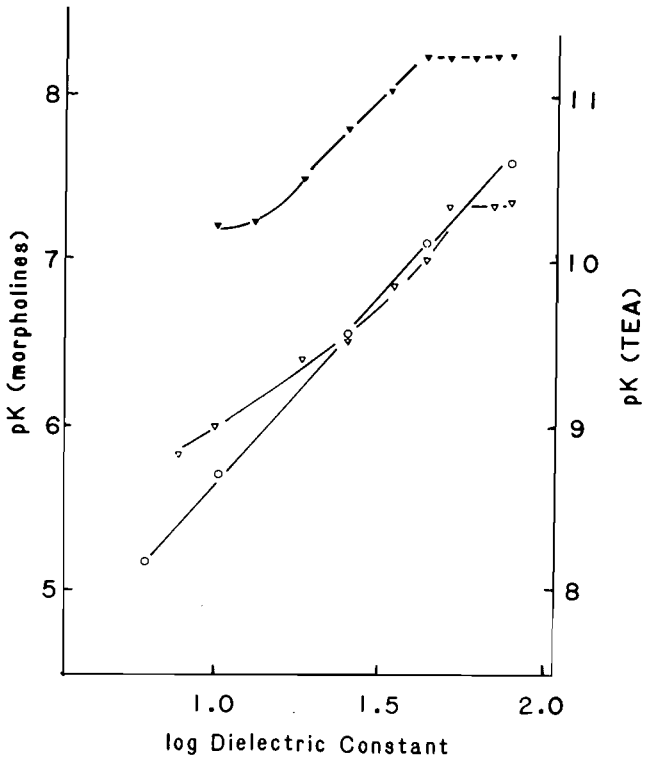

FIG. 4. The p*K* values for morpholine (solid triangles) and *N*-methylmorpholine (open triangles) as determined by titration in a variety of mixtures of dioxane and water are plotted versus log dielectric constant for the solvent mixture. Values for triethylamine are plotted for comparison (open circles).

water concentration is reduced, to drop with about the same slope as simple aliphatic amines through the middle range of water concentration, then finally to display a slower reduction in dielectric constant with loss of water at lower water concentrations than would be predicted by the behavior of simple aliphatic amines.

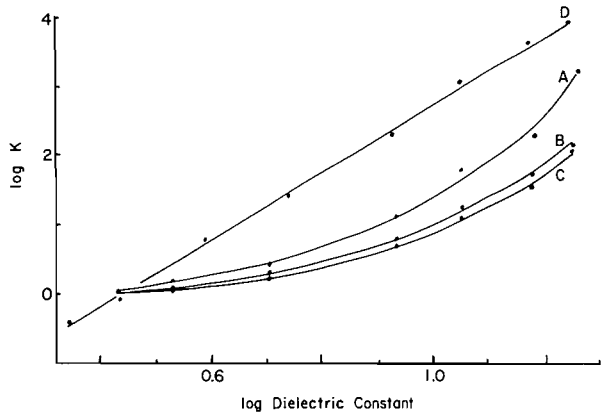

FIG. 5. The log *K* values for the formation of the proton transfer complex between *p*-nitrophenol and morpholine (*A*), *N*-methylmorpholine (*B*), and *N*-butylmorpholine (*C*) are plotted versus the log dielectric constant of the various dioxane–water solvent mixtures used. Data obtained for *n*-butylamine in the same system is plotted for comparison (*D*).

In Fig. 5 we find the log *K* for the formation of the proton transfer complex between *p*NP and various morpholines versus log ϵ. The actual values of the constants are listed in Table 1.

Discussion

Attempts to relate solvent dielectric to a number of reactions involving changes in dipole moment such as formation of quaternary ammonium ions (9), solvolysis (10), and proton transfer (11) have related a parameter of the reaction to a number of functions of dielectric constant including the constant itself, the inverse of the constant, log of the constants, and the Onsager coefficient. In previous studies using a variety of pure solvents, log ϵ was most frequently the parameter that produced linear plots. We interpret this result as an indication that under circumstances where composition-dependent interference by short range solvation forces is minimized or is invariant with solvent composition the dioxane–water mixed solvent system produces the same sort of long range solvation effects previously reported for single solvent systems.

Whether or not the linear plots obtained by the titration of tertiary amines with a strong acid in dioxane–water mixtures represent a simple response of the reaction to change in long range solvation, they certainly represent a baseline of behavior against which similar systems may be compared. With this in mind consider first the change in slope displayed by primary or secondary amines when compared to tertiary amines (Fig. 1). The only difference in the systems is the presence of hydrogen attached to the amine nitrogen in primary and secondary amines. We propose the attachment of a solvent component, probably water, to this hydrogen by a hydrogen bond, in the fashion proposed in earlier papers (12) and later validated using a dimethylsulfoxide–benzene solvent system (13). In this fashion a portion of the solvation shell of the amine becomes fixed so that the amine becomes less responsive to changes in solvent composition, finally resulting in the shallower slopes observed for primary and secondary amines in Fig. 3. In support of this concept is the observation that in very non-polar non-hydrogen bonding solvents tertiary and secondary amines are more basic than primary amines (14) while in aqueous systems the basicities of simple aliphatic amines are very similar (approximately 9.6–11.3; ref. 15). Withdrawing the proton somewhat in form-

For personal use only.

ing the hydrogen bond with the solvent raises the electron density around the amine nitrogen much as the inductive effect of the alkyl groups does in the tertiary amines.

Turning to the titration data for the morpholines (Fig. 4), two features of the curve require explanation. The plateau in the water-rich region of the data represents an almost complete insensitivity to changes in solvent composition. In the middle region log K values decrease with a slope similar to that displayed by the simple aliphatic amines and would appear to be a normal response to changing solvent composition. At the dioxane-rich end of the data, however, we see once again a leveling of the curve, indicating a lowered sensitivity to changes in solvent composition.

The special feature of the morpholine structure is the ring oxygen with its two pairs of unshared electrons. Water can hydrogen bond to these electrons, fixing a portion of the solvation shell of morpholine and rendering it less sensitive to changes in solvent composition. In water-rich mixtures long chains of water hydrogen bonded together are proposed to exist. This for example is cited as the cause of the quenching of fluorescence in this region (16). Tying the morpholine to water would lock it into this extended water chain making the solvation shell even less changeable with solvent composition. However, in the region where this structure disappears in favor of water–dioxane hydrogen-bonded complexes, the reaction begins to respond to changing solvent composition.

At the dioxane-rich end of the solvent composition continuum we present not only titration data, but also the equilibrium constants for morpholine–*p*NP proton transfer complex formation (Fig. 5). In every case we see a lowered sensitivity to the reduction of water concentration. Once again the formation of hydrogen-bonded complexes between water and the morpholine-ring oxygen unshared electrons stabilizing a portion of the increasingly rare water in the solvation shell of the morpholine. In Fig. 5 the data for the formation of an *n*-butylamine–*p*NP proton-transfer complex[2] is superimposed on the morpholine data for contrast. The similarity to the titration data is apparent.

Summary

Studies are performed on the reaction behavior of aliphatic amines and morpholines in dioxane–water solvent mixtures of varying composition. The titration of simple aliphatic amines with a strong acid is shown to produce log K values that vary linearly with log ϵ of the solvent mixture in all cases. Shallower slopes observed with primary and secondary amines as compared to tertiary amines are explained as being due to the hydrogen bonding of water to amine protons where present, making the solvation shell of the amine less responsive to changes in solvent composition. Morpholine data show a plateau in water-rich regions and a shallower slope in water-poor regions. This is ascribed to hydrogen bonding between solvent water and the unshared electrons of the morpholine-ring oxygen.

Relations entre les tungstophosphates apparentés à l'anion $PW_{12}O_{40}^{3-}$. Synthèse et propriétés d'un nouveau polyoxotungstophosphate lacunaire $K_{10}P_2W_{20}O_{70}\cdot 24H_2O$

ROLAND CONTANT

Laboratoire de physicochimie inorganique, Tours 54/55, Université Pierre et Marie Curie, 4 place Jussieu, 75252 Paris CEDEX 05, France

Reçu le 18 août 1986

ROLAND CONTANT. Can. J. Chem. **65**, 568 (1987).

Les relations entre toutes les espèces apparentées aux anions $PW_{12}O_{40}^{3-}$ et $P_2W_{21}O_{71}^{6-}$ ont été établies. Un nouveau composé $K_{10}P_2W_{20}O_{70}$ a été synthétisé et caractérisé par spectroscopie infra-rouge et Raman. L'ensemble de ses propriétés et plus particulièrement les spectres de résonance magnétique nucléaire (^{31}P et ^{183}W) permettent d'en proposer la structure. C'est une espèce lacunaire qui réagit sur le cobalt(II) pour donner deux complexes 1–1, probablement des isomères de coordination. En solution, en présence de Co^{2+}, l'isomérisation A-PW_9 → B-PW_9 se fait en plusieurs étapes qui ont été précisées. Les isomères β des tungstophosphates sont moins stables que les tungstosilicates ou germanates correspondant et β-PW_{12} n'a été identifié que sous forme réduite.

ROLAND CONTANT. Can. J. Chem. **65**, 568 (1987).

The relationship between all the polyoxotungstophosphates related to $PW_{12}O_{40}^{3-}$ and $P_2W_{21}O_{71}^{6-}$ anions was established. A new compound $K_{10}P_2W_{20}O_{70}$ was synthesized and characterized by infrared and Raman spectroscopy. These properties, and especially the ^{31}P and ^{183}W nuclear magnetic resonance spectra, allowed us to propose the structure. It is a lacunary species that reacts with Co(II) to give two 1–1 complexes, probably coordination isomers. In the presence of Co(II) the A-type → B-type PW_9 isomerization occurs in several steps, which are specified. The tungstophosphate β isomers are less stable than the corresponding tungstosilicates or germanates, and β-PW_{12} was only identified as a reduced species $PW_{12}O_{40}^{4-}$.

Introduction

Le phosphore(V) est certainement, parmi les éléments connus pour former des hétéropolyoxotungstates, celui qui donne le plus grand nombre d'espèces (1). La plupart peuvent être regroupées en « famille », une famille comprenant un polyanion « saturé » et éventuellement ses isomères, par exemple α et β $P_2W_{18}O_{62}^{6-}$, et tous les composés qui en dérivent par le départ d'un ou de plusieurs atomes de tungstène, ou par le remplacement de ces atomes de tungstène par d'autres atomes métalliques, par exemple $P_2W_{17}O_{61}^{10-}$, $P_2W_{17}MoO_{62}^{6-}$, $P_2W_{15}O_{56}^{12-}$, etc. Les trois principales familles de polyoxotungstophosphates dérivent formellement de $P_2W_{18}O_{62}^{6-}$, $PW_{12}O_{40}^{3-}$ et $P_2W_{21}O_{71}^{6-}$.

La famille de $P_2W_{18}O_{62}^{6-}$ (en abrégé P_2W_{18}) a été étudiée précédemment (2, 3). Longtemps réduite à $P_2W_{21}O_{71}^{6-}$ dont la structure a été décrite par Weakley (4), la famille de P_2W_{21} s'est enrichie récemment de $P_2W_{19}O_{69}^{14-}$ (5), de $KP_2W_{20}O_{72}^{13-}$ dont la synthèse et la structure ont été décrites par Fuchs et Palm (6) et de plusieurs composés mixtes $P_2W_{19}M_2$ et $P_2W_{18}M_3$ (7, 8). La famille de PW_{12} est plus nombreuse en raison de l'existence de plusieurs isomères. Outre α-$PW_{12}O_{40}^{3-}$ qui possède la structure bien connue, dite « de Keggin » (9), elle comprend α-$PW_{11}O_{39}^{7-}$ A,α- et A,β-$PW_9O_{34}^{9-}$ (10), γ-$PW_{10}O_{36}^{7-}$ (11) et de nombreux composés mixtes de formule générale $PW_{11}M$, $PW_{10}M_2$, PW_9M_2 (12) et PW_9M_3. Les complexes $PW_{11}M$ existent avec pratiquement tous les métaux, alors que les autres ne sont connus qu'avec des métaux à l'état d'oxydation IV, V ou VI. À cette famille, il faut ajouter B,α-$P_2W_{18}M_4O_{68}(H_2O)_2^{10-}$ (M = Co, Cu, Zn, etc.) (13) correspondant à un anion B,α-$PW_9O_{34}^{9-}$ identifié seulement à l'état solide (7).

La plupart de ces espèces ont été décrites de façon ponctuelle sans que les relations entre elles soient bien établies. Nous nous sommes attachés ici à préciser les différentes étapes conduisant du mélange tungstate–phosphate aux anions saturés $PW_{12}O_{40}^{3-}$ et $P_2W_{21}O_{71}^{6-}$. Ceci a notamment permis la synthèse d'un nouveau composé $K_{10}P_2W_{20}O_{70}\cdot 24H_2O$.

Partie expérimentale

Préparations et analyses

Les méthodes d'analyse ont été décrites dans un article précédent (2). L'acide $H_3PW_{12}O_{40}\cdot xH_2O$ (14) et $K_{14}P_2W_{19}O_{69}\cdot 24H_2O$ (5) ont été préparés suivant les méthodes décrites dans la littérature. A,β-$Na_9PW_9O_{34}\cdot 17H_2O$ a été préparée suivant la méthode décrite (12) pour la forme protonée. Ce composé n'est pas recristallisable, la précipitation est brutale et il est possible que dans certains échantillons une partie de la forme protonée en équilibre soit entraînée. B,α-$K_{10}P_2W_{18}Co_4\cdot 24H_2O$ a été préparé suivant la méthode de Weakley, Tourné et coll. (13) en augmentant légèrement l'acidité pour améliorer le rendement.

$K_{10}P_2W_{20}O_{70}\cdot 24H_2O$

Un mélange de 100 mL de tungstate de potassium molaire et 10 mL d'acide phosphorique molaire est acidifié lentement par 51 mL d'acide chlorhydrique 3 *M*. Le précipité blanc qui apparaît immédiatement est redissous en portant la solution à ébullition. La solution est abandonnée à la température ambiante et les cristaux blancs qui commencent à apparaître au bout d'une journée sont filtrés, essorés et recristallisés dans le minimum d'eau. *Anal.* calc. pour $K_{10}P_2W_{20}O_{70}\cdot 24H_2O$: K 6,88; W 64,7; P 1,09; H_2O 7,60; trouvé: K 7,08; W 64,6; P 1,09; H_2O 7,53.

La détermination de la masse molaire par ultracentrifugation a donné la valeur de 5 400, ce qui correspond à deux atomes de phosphore par mole.

$K_{14}P_2W_{20}O_{70}\cdot xH_2O$

Un mélange de 250 mL de tungstate de potassium molaire et de 25 mL d'acide phosphorique molaire est acidifié par 108 mL d'acide chlorhydrique 3 *M* et porté à ébullition. Les cristaux apparaissent au refroidissement. *Anal.* calc. pour $K_{14}P_2W_{20}O_{72}\cdot 27H_2O$: K 9,24; W 62,1; P 1,05; H_2O 8,20; trouvé: K 9,26; W 62,3; P 1,04; H_2O 8,07.

Ce composé est identique (spectres ir et Raman) à celui obtenu par Fuchs et Palm (6) à partir de $K_3PW_{12}O_{40}$. Ce sel s'effleurit facilement et l'état d'hydratation varie d'un échantillon à l'autre.

$K_6P_2W_{21}O_{71}\cdot 32H_2O$

Un échantillon de 37 g de $K_{14}P_2W_{20}O_{72}\cdot 27H_2O$ est dissous dans 70 mL d'acide chlorhydrique molaire et porté à ébullition. La partie insoluble est filtrée à chaud. Dans la solution abandonnée à température ambiante, les aiguilles blanches apparaissent au bout de 24 h et sont filtrées essorées. *Anal.* calc. pour $K_6P_2W_{21}O_{71}\cdot 32H_2O$: K 4,00;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

W 65,8; P 1,06; H_2O 9,81; trouvé : K 4,12; W 66,0; P 1,06; H_2O 9,87. On peut utiliser dans les mêmes conditions $K_{10}P_2W_{20}O_{70}\cdot 24H_2O$.

α-$K_{7-x}Na_xPW_{11}O_{39}\cdot 14H_2O$

À une solution de 181,5 g de $Na_2WO_4\cdot 2H_2O$ dans 300 mL d'eau, on ajoute successivement 50 mL d'acide phosphorique molaire et 88 mL d'acide acétique. La solution est portée une heure à reflux, puis après addition de 60 g de chlorure de potassium solide, il apparaît un fin précipité qui est filtré, essoré et séché à l'air. *Anal.* calc. pour $K_{6,4}Na_{0,6}PW_{11}O_{39}\cdot 14H_2O$: K 7,84; Na 0,43; W 63,3; P 0,97; H_2O 7,89; trouvé : K 7,90; Na 0,50; W 63,6; P 0,97; H_2O 8,06.

La proportion de sodium peut varier d'un échantillon à l'autre, et en reprécipitant plusieurs fois par le chlorure de potassium on peut obtenir le sel pratiquement exempt de sodium.

A,α-$K_9PW_9O_{34}\cdot 16H_2O$

$K_{7-x}Na_xPW_{11}O_{39}$ (64 g) est dissous dans 200 mL d'eau, puis versé dans 60 mL de solution de carbonate de potassium 2 *M*. La précipitation est instantanée. Le précipité est filtré, lavé à l'éthanol et séché à l'air. *Anal.* calc. pour $K_9PW_9O_{34}\cdot 16H_2O$: K 12,28; W 57,7; P 1,08; H_2O 10,03; trouvé : K 12,02; W 57,4; P 1,08; H_2O 9,85.

A,β-$K_8HPW_9O_{34}\cdot 18H_2O$

Un échantillon de 40 g de α-$K_9PW_9O_{34}\cdot 16H_2O$ est dissous dans 100 mL d'eau bouillante. Le précipité apparaît au refroidissement. Il est filtré, lavé à l'alcool et séché à l'air. *Anal.* calc. pour $K_8HPW_9O_{34}\cdot 18H_2O$: K 10,91; W 57,7; P 1,08; H_2O 11,30; trouvé : K 10,87; W 57,5; P 1,06; H_2O 11,33.

$K_{12}P_2W_{18}Co_3(H_2O)_3O_{68}\cdot 24H_2O$

À une solution de 1,8 g de $Co(NO_3)_2\cdot 6H_2O$ dans 80 mL d'eau sont ajoutés 11 g de α-$K_9PW_9O_{34}\cdot 16H_2O$. Le précipité bleu cristallin qui apparaît est filtré immédiatement et séché à l'air. *Anal.* calc. pour $K_{12}P_2W_{18}Co_3(H_2O)_3O_{68}\cdot 24H_2O$: K 8,39; Co 3,16; W 59,2; P 1,11; H_2O 8,69; trouvé : K 8,30; Co 3,25; W 59,0; P 1,09; H_2O 8,68.

Anions β_n-$PW_{11}O_{39}^{7-}$, β-$PW_{12}O_{40}^{4-}$ et β_n-$PW_{11}Co(OH_2)O_{39}^{5-}$

Il n'a pas été possible d'isoler des sels purs de ces complexes, mais ils peuvent être préparés en solution diluée : à 100 mL d'une solution de tungstate 2×10^{-2} mol L^{-1} sont ajoutés successivement, à froid, 2 mL d'acide chlorhydrique molaire, 2,82 g de A,β-$Na_9PW_9O_{34}\cdot 17H_2O$, puis 4 mL d'acide molaire. Le pH doit être inférieur à 5 et la formation de l'anion β_n-$PW_{11}O_{39}^{7-}$ est alors quantitative. On obtient β_n-$PW_{11}Co(H_2O)O_{39}^{5-}$ et β-$PW_{12}O_{40}^{4-}$ en ajoutant respectivement à la solution précédente 1 mL de nitrate de cobalt molaire ou 20 mL d'une solution de W(V) (5×10^{-2} mol L^{-1}) dans l'acide chlorhydrique concentré obtenue par électrolyse. Tous ces anions sont caractérisé par polarographie.

Mésures physiques

Les spectres ultraviolet et visible ont été obtenus sur un spectrophotomètre Perkin–Elmer 500, les spectres ir sur un spectrophotomètre Perkin–Elmer 283 et le spectre Raman sur un Coderg PHO utilisant la ligne à 514,5 nm d'un laser à argon Spectra Physics.

Les spectres rmn ont été obtenus sur un appareil Bruker WM 250 à 101 MHz pour ^{31}P et à 10,4 MHz pour ^{183}W. Les déplacements chimiques du ^{31}P ont été mesurés par rapport à H_3PO_4 85% externe, et ceux du ^{183}W par rapport à une solution externe de Na_2WO_4 2 *M* dans D_2O alcalinisé.

Pour la mesure de spectre de ^{183}W, la solution a été obtenue en ajoutant 6 g de $K_{10}P_2W_{20}O_{70}\cdot H_2O$ dans 10 mL de $LiClO_4$ saturé. Après filtration de perchlorate de potassium, 1 mL de D_2O a été ajouté.

Les spectres du ^{31}P ont été obtenus dans des solutions contenant 10% de D_2O de concentration $2,5\times 10^{-2}$ mol L^{-1} en phosphore. La solution de $K_6P_2W_{21}O_{71}$ est stabilisée en milieu acide (HCl 0,1 mol L^{-1}). Les autres espèces à l'exception de $K_{10}P_2W_{20}O_{70}$ sont solubilisées dans le chlorure de lithium molaire.

Les polarogrammes ont été enregistrés sur un polarographe Radiometer PO_4 avec une électrode à goutte de mercure ou une électrode de carbon tournante.

Résultats et discussion

Polarographie

Les hétéropolyanions stables en solution diluée ou dont la décomposition est suffisamment lente, peuvent être caractérisés par polarographie (tableau 1). Comme pour une protonation donnée, le processus de réduction dépend essentiellement de la structure et n'est que peu influencé par la nature de l'hétéroatome central; il est possible de comparer les tungstophosphates aux tungstosilicates (15, 16). Ainsi ont pu être identifiés A,α-PW_9 et A,β-PW_9, de même que β_n-PW_{11} et β-PW_{12} plus oxydants que les isomères α correspondants. Il existe théoriquement trois isomères β_n-PW_{11} correspondant à trois positions différentes de la lacune (15). Un seul a été observé et il s'agit probablement de l'isomère β_1, mais les polarogrammes des trois isomères β_n-SiW_{11} ne sont pas suffisamment différents pour permettre une identification sur ce seul critère.

Spectres rmn de ^{31}P

Le spectre des solutions de $P_2W_{20}O_{70}^{10-}$ présente un seul pic à −12,3 ppm, ce qui correspond à un seul type d'atome de phosphore. Le déplacement chimique est intermédiaire entre celui de $P_2W_{21}O_{71}^{6-}$ (−13,3 ppm) et celui de $PW_{11}O_{39}^{7-}$ (−11,0 ppm). Toutes les espèces plus basiques présentent en solution diluée ($P = 2,5\times 10^{-2}$ mol L^{-1}) 2 pics de hauteurs inégales. Le premier à −11,0 ppm est présent dans tous les spectres, il correspond à PW_{11}. Le second varie de +2,56 pour la solution de $KP_2W_{20}O_{72}^{13-}$ à +3,18 ppm pour la solution de α-$PW_9O_{34}^{9-}$. Ces valeurs correspondent à des mélanges en proportion variable de $H_2PO_4^-$ et HPO_4^{2-}. Pour la solution de P_2W_{19}, les deux pics sont dans le rapport 2:1 correspondant à la réaction de décomposition :

$$P_2W_{19}O_{69}^{14-} \rightarrow 4/3PW_{11}O_{39}^{7-} + 0,62W_7O_{24}^{6-} + 0,28HPO_4^{2-} + 0,39H_2PO_4^-$$

En solution très concentrée, il apparaît d'autres espèces, mais toujours en très faible proportion.

Spectres infra-rouge et Raman

Dans le tableau 2 sont présentés quelques pics sélectionnés des spectres ir des tungstophosphates. On peut noter : (*i*) une grande similitude entre les composés de la famille P_2W_{21}; (*ii*) le déplacement important de la bande P—O pour les deux isomères PW_9; (*iii*) l'absence de dédoublement de la bande P—O dans B,α-$P_2W_{18}Co_4$.

[b]Référence 6.

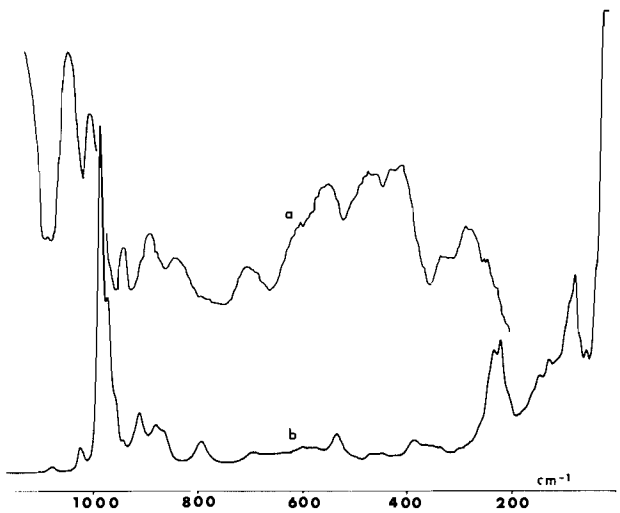

FIG. 1. Spectre infra-rouge (a) et Raman (b) de $K_{10}P_2W_{20}O_{70}\cdot 24H_2O$.

Les spectres ir et Raman de $K_{10}P_2W_{20}O_{70}$ (fig. 1) sont nettement différents de ceux de $K_{14}P_2W_{20}O_{70}$ décrits par Fuchs et Palm (6).

Action des acides et des bases : stabilité

Alors que α-$PW_{12}O_{40}^{3-}$, α-$PW_{11}O_{39}^{7-}$ et $P_2W_{20}O_{70}^{10-}$ sont stables en solution, $P_2W_{21}O_{71}^{6-}$ se décompose en quelques heures, mais peut être stabilisé par addition d'acide. Sur la courbe d'alcalinisation d'une solution fraîche de $K_6P_2W_{21}O_{71}$, il apparaît un premier saut de pH (fig. 2) correspondant à la réaction :

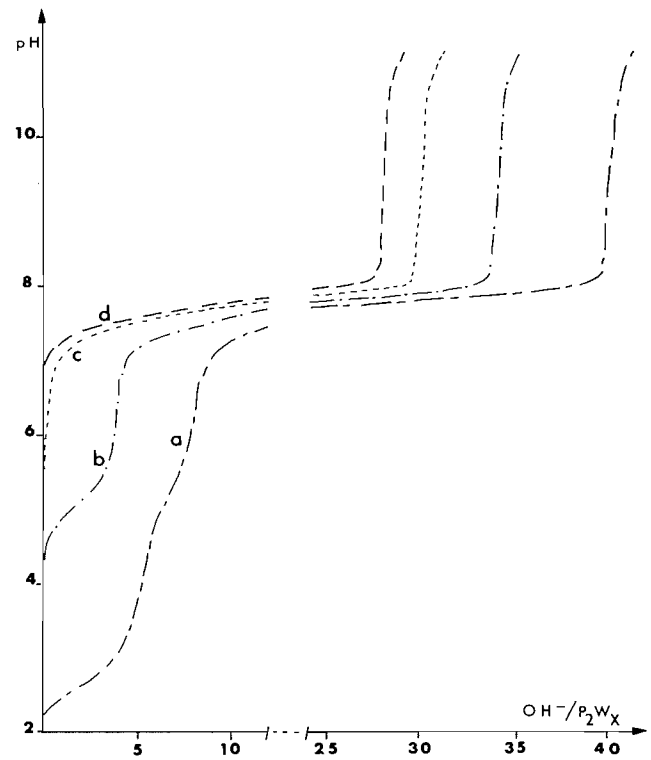

FIG. 2. Courbes d'alcalinisation de $P_2W_{21}O_{71}^{6-}$ (a), $P_2W_{20}O_{70}^{10-}$ (b), $P_2W_{20}O_{72}^{14-}$ (c) et $P_2W_{19}O_{69}^{14-}$ (d). Solutions $10^{-2}M$ dans $NaNO_3$ 0,2 M.

$$P_2W_{21}O_{71}^{6-} + 5OH^- \rightarrow 1/2P_2W_{20}O_{70}^{10-} + HPW_{11}O_{39}^{6-} + 2H_2O$$

$K_{10}P_2W_{20}O_{70}$ peut être isolé dans ces conditions à partir de $K_6P_2W_{21}O_{71}$. Le deuxième saut de pH correspond à la réaction :

$$P_2W_{20}O_{70}^{10-} + 4OH^- \xrightarrow{(1)} 3/2P_2W_{19}O_{69}^{14-} + 2/3PW_{11}O_{39}^{7-} + 2H_2O$$

$$P_2W_{20}O_{70}^{10-} + 4OH^- \xrightarrow{(2)} KP_2W_{20}O_{72}^{13-} + 2H_2O$$

$$KP_2W_{20}O_{72}^{13-} \xrightarrow{(3)} 3/2P_2W_{19}O_{69}^{14-} + 2/3PW_{11}O_{39}^{7-} + 2H_2O$$

SCHÉMA 1

P_2W_{19} se décompose ensuite rapidement sans modification du pH suivant la réaction donnée plus haut, mais sa présence instantanée peut être mise en évidence par la formation du complexe $P_2W_{19}Co_2O_{71}H_4^{10-}$ (5). Comme la réaction (3) est instantanée, il n'est pas possible de mettre en évidence $KP_2W_{20}O_{72}^{13-}$ et par conséquent de choisir entre les séquences (1) ou (2) + (3). En tout état de cause, la décomposition de $P_2W_{20}O_{70}^{10-}$ est relativement lente et ne correspond pas à une simple déprotonation.

Au dessus de pH 7, toutes les courbes d'alcalinisation sont identiques et le palier de pH correspond en solution diluée à l'équilibre de l'anion α-$PW_{11}O_{39}^{7-}$ avec le paratungstate, puis le tungstate. Toutefois, la décomposition de α-PW_{11} se fait par l'intermédiaire de α-PW_9, comme le montre la préparation de ce dernier. En effet, en acidifiant un mélange tungstate–phosphate, on peut obtenir, soit A,β-PW_9 seul, soit un mélange de A,α-PW_9 et de A,β-PW_9, mais jamais l'isomère α seul.

À partir de A,α-K_9PWO_{34}, en ajoutant les quantités stoechiométriques de tungstate de potassium et d'acide, il est possible de préparer, outre α-PW_{11} et α-PW_{12} toutes les espèces de la famille de P_2W_{21}. Comme il a été signalé pour certains d'entre eux (5, 6), la présence de potassium, ou de rubidium, est indispensable pour la formation de toutes les espèces de cette famille.

À partir de A,β-$K_8HPW_9O_{34}$ ou A,β-$Na_9PW_9O_{34}$, on obtient β_n-$PW_{11}O_{39}^{7-}$ qui s'isomérise d'autant plus rapidement qu'il est plus concentré, mais jamais β-$PW_{12}O_{40}^{3-}$. Ce dernier n'est pas stable et l'anion β-$PW_{12}O_{40}^{4-}$ se transforme instantanément en α-$PW_{12}O_{40}^{3-}$ quand il est oxydé.

Les relations entre les différentes espèces sont résumés dans le schéma 1.

Finke *et al.* (17) ont les premiers signalés que le sel A,β-$Na_9PW_9O_{34}$ se transformait, à l'état solide, sous l'action de la chaleur, en B,α-$Na_9PW_9O_{34}$. Les résultats du traitement thermique sont erratiques et pour notre part, nous n'avons jamais obtenu d'échantillons contenant plus de 30% de l'isomère B. Cette transformation ne se produit ni avec A,α-$K_9PW_9O_{34}$, ni avec A,β-$K_8HPW_9O_{34}$. Il semble donc que comme avec $P_2W_{15}O_{56}^{12-}$ (2), la présence de sodium soit indispensable pour stabiliser les espèces dans lesquelles il existe un atome d'oxygène lié seulement au phosphore.

Action du cobalt(II) sur les tungstophosphates lacunaires monovacants

Il est bien connu (1) que la plupart des hétéropolyoxotungstates lacunaires complexent de nombreux ions métalliques. Nous avons pris ici l'exemple du Co(II).

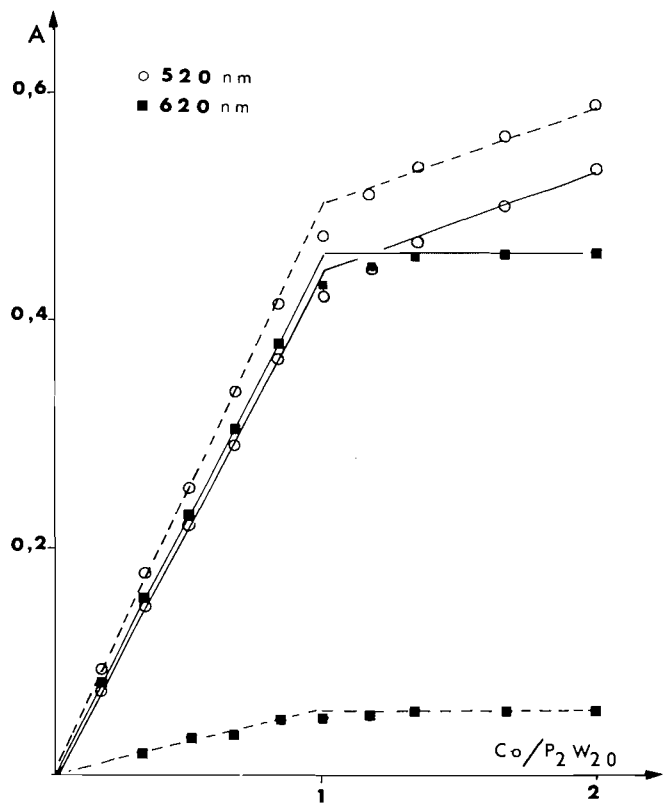

FIG. 3. Addition de Co(II) à des solutions de $P_2W_{20}O_{70}^{10-}$ $10^{-2}M$ en milieu eau–diméthylformamide à 50% : en pointillé mesures rapides de l'absorbance à 10°C; en trait plein mesures à l'équilibre à 25°C. (l = 1 cm).

Comme celle de α-$PW_{11}O_{39}^{7-}$, la solution de β_n-$PW_{11}O_{39}^{7-}$ réagit quantitativement et instantanément sur le Co(II) pour former β_n-$PW_{11}CoO_{40}H_2^{5-}$. La structure β est stabilisée, mais toutefois l'isomérisation est totale au bout de quelques jours.

L'addition de Co(II) à $P_2W_{20}O_{70}^{10-}$ montre qu'il s'agit bien d'une espèce lacunaire. Dans l'eau, il se forme un complexe peu stable rose, qui, chauffé, devient reversiblement vert entre 50 et 70°C. À partir de solutions concentrées et chaudes, il est possible d'isoler un solide de composition $P_2W_{20}Co_n$ ($n < 1$) qui redevient lentement rose lorsqu'il est refroidi. Il s'agit probablement d'un mélange de P_2W_{20} et $P_2W_{20}Co$. En utilisant un mélange eau–diméthylformamide à 50% comme solvant, il est possible de montrer (fig. 3) que le complexe rose et

le complexe vert correspondent tous les deux au rapport 1–1. Dans ces conditions, le composé rose se forme quantitativement et instantanément en dessous de 25°C, puis se transforme irréversiblement pour donner l'isomère vert en quelques heures. De tels composés intermédiaires roses avaient déjà été observés au cours de la formation de $As_2^{III}W_{20}Co$ (18) et de $P_2{}^{V}W_{19}Co_2$ (5), mais ils n'avaient pas été identifiés comme des isomères du complexe vert.

Ces deux isomères peuvent correspondre à différentes coordinations pour l'atome de cobalt. Dans le complexe rose, l'atome de cobalt serait hexacoordiné comme dans $Co(H_2O)_6^{2+}$ ou $PW_{11}CoO_{40}H_2^{5-}$ (tableau 3), tandis que dans le complexe vert, il serait pentacoordiné. L'étape lente correspondrait alors au départ d'une molécule d'eau, déshydratation favorisée par l'élévation de température ou la présence de diméthylformamide.

Action du cobalt(II) sur les tungstophosphates lacunaires multivacants

Tourné *et al.* (5) ont décrit la formation de $P_2W_{19}Co_2$ vert; cette réaction peut être utilisée pour détecter la présence de $P_2W_{19}O_{69}^{14-}$ comme l'apparition, en présence de cobalt(II), d'une coloration verte à chaud permet d'identifier $P_2W_{20}O_{70}^{10-}$. Par contre, $KP_2W_{20}O_{72}^{13-}$ ne donne pas de complexes avec les ions métalliques, ce qui est cohérent avec sa structure (6) (fig. 4*a*). En effet, il ne possède que des sites bidentés. L'addition de $K_{14}P_2W_{20}O_{72}$ solide à des solutions de cobalt(II) conduit à un mélange équimoléculaire $P_2W_{19}Co_2$–$PW_{11}Co$ ou à $PW_{11}Co$ seul, si le cobalt est en défaut.

L'action de A,α ou A,β-PW_9, ou d'une solution de synthèse équivalente, sur une solution de Co(II), conduit toujours à α-$PW_{11}Co$ ou B,α-$P_2W_{18}Co_4$ qui sont les seules espèces stables pour $Co/P < 2{,}5$, mais il existe plusieurs étapes intermédiaires qui dépendent de la nature de l'isomère ou du contre-ion.

A,α-$K_9PW_9O_{34}$ forme d'abord quantitativement A,α-$P_2W_{18}Co_3$. Cette espèce est instable en solution et évolue lentement pour conduire presque quantitativement à B,α-$P_2W_{18}Co_4$. Cette transformation dont la vitesse dépend fortement de la température et de la concentration se fait en 3 étapes, les intermédiaires (I et II) peuvent être caractérisés par leurs spectres visibles. Le premier (λ_{max} : 484 nm et 509 nm) a été isolé sous forme de sel de potassium correspondant à la formule $K_7PW_9Co_2$. Le second (λ_{max} : 510 nm et 532 nm), bien que plus stable, n'a pas été isolé. Ces deux espèces donnent α-$PW_{11}Co$ lorsqu'elles sont acidifiées. Avec A,β-$Na_9PW_9O_{34}$ il apparaît une nouvelle espèce. En effet, en mesurant immédiatement l'absorbance d'une série de solutions obtenues par addition d'une même quantité de A,β-$Na_9PW_9O_{34}\cdot 17H_2O$ dans des solutions de cobalt(II) de concentrations croissantes, on observe qu'à toute longueur d'onde elle croit jusqu'à $Co/P = 2$, ce qui indique la formation d'un complexe de formule $(PW_9Co_2)_n$ (λ_{max} : 475, 495 et 510 nm). À partir des solutions de ce complexe très

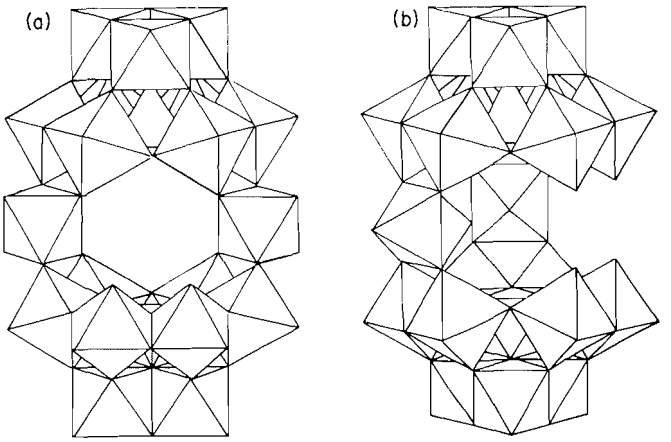

FIG. 4. Structures idéalisées des deux anions P_2W_{20}: (*a*) structure de $P_2W_{20}O_{72}^{14-}$ déterminée par Fuchs et Palm (6); (*b*) structure proposée pour $P_2W_{20}O_{70}(H_2O)_2^{10-}$.

instable, on peut obtenir : (*i*) β_n-$PW_{11}Co$ par addition de tungstate et d'acide; (*ii*) α-$P_2W_{18}Co_3$ par addition d'ions potassium, cette propriété a été utilisé pour préparer (7) ce dernier; (*iii*) α-PW_9Co_2 signalé plus haut par simple évolution. Il existerait donc deux isomères PW_9Co_2 correspondant aux formes A,α et A,β.

À partir de A,β-$K_8HPW_9O_{34}$, il se forme avec Co(II) un sel insoluble qui peut conduire à β_n-$PW_{11}Co$ par addition de tungstate et d'acide.

Les solutions de synthèse obtenues en mélangeant H_3PO_4, Co^{2+}, H_3O^+ et WO_4^{2-} ($2Na^+$) dans les proportions 2:4:18:18 conduisent dans un premier temps à un mélange des deux isomères PW_9Co_2 qui évoluent comme décrit ci-dessus pour donner principalement B,α-$P_2W_{18}Co_4$. De même, l'alcalinisation ménagée de α-$PW_{11}Co$ conduit à B,α-$P_2W_{18}Co_4$ en passant par les deux étapes intermédiaires. L'ensemble de ces relations est résumé dans le schéma 2. On peut noter qu'il existe deux voies pour la transformation A-PW_9 → B-PW_9, le traitement thermique du solide (17) ou l'isomérisation en solution en présence de Co(II) ou d'un autre ion métallique. Le cobalt(II) ne permet donc de caractériser B-PW_9 qu'à froid.

Les polyoxocobalto-tungstophosphates décrits ici ne représentent que les espèces prépondérantes. Il existe plusieurs autres complexes se formant en moindre proportion, comme par exemple $Na_{14}P_5W_{27}Co_5O_{119}H_{27}$ décrit par Weakley (19).

Considérations structurales. Résonance magnétique nucléaire de ^{183}W

Weakley (4) a déterminé la structure de $K_4P_2W_{21}O_{73}H_6\cdot 21H_2O$. Il contient deux entités A,α-PW_9 reliées entre elles par un atome de tungstène pentacoordiné et deux atomes de tungstène hexacoordinés dont les atomes d'oxygènes terminaux ou

SCHÉMA 2

les molécules d'eau de coordination sont en position *trans*. La structure de $K_{14}P_2W_{20}O_{72}\cdot xH_2O$ décrite par Fuchs et Palm (6) correspond à deux entités A,α-PW_9 reliées par deux atomes de tungstène dont les oxygènes terminaux sont en *cis* (fig. 4*a*). Étant donné la filiation entre ces deux complexes et $K_{10}P_2W_{20}O_{70}\cdot 24H_2O$, on peut raisonnablement postuler que ce dernier est formé de deux entités A,α-PW_9 reliés par deux atomes de tungstène. L'existence de complexes $P_2W_{20}M$, exclut la possibilité qu'il s'agisse d'une forme protonée du complexe de Fuchs et Palm (6). Le spectre rmn du ^{183}W présente six pics d'intensité relative 2:4:4:4:4:2 à 75,6; −116,1; −142,9; −164,3; −166,3 et −201,1 ppm. Sur les cinq premiers pics on observe les couplages $^2J_{W-P}$ avec des valeurs de 1 Hz pour le premier, 2 Hz pour le second et 1,5 Hz pour chacun des trois suivants. Seul le dernier pic à 201,1 ppm ne présente pas de couplage P–W. Ce spectre est en accord avec la structure proposée (fig. 4*b*) et permet d'attribuer le dernier pic à −201,1 ppm aux tungstènes de jonction. Ceux-ci peuvent être soit pentacoordinés, soit hexacoordinés, avec une molécule d'eau occupant la sixième position. En comparant avec $As^{III}W_{21}$ dans lequel il existe des tungstènes de jonction penta- et hexacoordiné, et où le pic correspondant au plus grand déplacement chimique a été attribué au tungstène hexacoordiné (20), ce qui est en accord avec un blindage important, nous sommes amené à proposer deux tungstènes de jonction hexacoordiné. Comme sur $As_2^{III}W_{21}$, il est probable que les atomes d'oxygènes (liaison courte) sont dirigés vers l'intérieur de la cavité (21).

On peut penser que la structure de $P_2W_{19}O_{69}(H_2O)^{14-}$ se déduit de celle de $P_2W_{20}O_{70}(H_2O)_2^{10-}$ par le départ d'un tungstène de jonction.

Dans un article récent (8), Knoth *et al.* signalent la formation, par dégradation acide des complexes $M_2P_2W_{19}$, de $K_{14}P_2W_{20}O_{72}$, un isomère *trans* du composé de Fuchs. Les seules caractéristiques données sont les spectres rmn. Les déplacements chimiques sont identiques au notre pour le ^{31}P et très légèrement différents pour le ^{183}W. Il devrait s'agir de la forme déprotonée de $P_2W_{20}O_{70}(H_2O)_2^{10-}$, mais nous avons montré qu'elle est instable. Étant donné les conditions opératoires décrites, il est possible que la solution rmn acidifiée vers pH 2 contienne notre composé, et que le solide isolé vers pH 7 soit celui de Fuchs. La même ambiguïté existe d'ailleurs entre $K_4P_2W_{21}O_{72}H_6$ (4) et $K_6P_2W_{21}O_{72}H_4$ qui est la forme usuelle (1) que nous avons préparée, le passage d'une espèce à l'autre n'étant sans doute pas un simple échange de proton.

Remerciements

L'auteur remercie Martine Richet pour sa collaboration technique et le Dr. René Thouvenot qui a enregistré les spectres rmn, pour ses conseils avisés.

A series of (*R*) acyclic and cyclic allylic alcohols was prepared by enantioselective hydrolysis of acetates using *Rhizopus nigricans*. The configurations of the alcohols formed were established by chemical methods and, in the case of 1,2-benzocyclohepta-1,3-dien-5-yl camphanate, by X-ray crystallography. In conjunction with the Harada–Nakanishi rule, the chiroptical properties of the *p*-bromobenzoate esters were used to verify configurations tentatively assigned from their method of preparation.

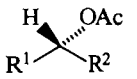
SATORU ITO, MASAJI KASAI, HERMAN ZIFFER et J. V. SILVERTON. Can. J. Chem. **65**, 574 (1987).

Faisant appel au *Rhizopus nigricans*, on a effectué des hydrolyses énantiosélectives d'acétates qui ont permis de préparer une série d'alcools allyliques cycliques et acycliques de configuration (*R*). On a déterminé ces configurations en faisant appel à des méthodes chimiques et, dans le cas du camphanate de benzo-1,2 cycloheptadiène-1,3 yle-5, à la diffraction des rayons-X. En relation avec la règle de Harada–Nakanishi, on a utilisé les propriétés chiroptiques des esters *p*-bromobenzoates pour vérifier les configurations qui avaient été attribuées provisoirement en se basant sur les méthodes de préparation.

[Traduit par la revue]

The emergence of chiral allylic alcohols as critical and versatile intermediates for the synthesis of natural products, metabolites, and drugs (1) makes this class of compounds a logical target for testing our recently developed method of preparing chiral secondary alcohols of a predictable absolute stereochemistry (2, 3). The method employs the mold, *Rhizopus nigricans*, for the hydrolysis of racemic acetates to yield chiral alcohols enriched in one enantiomer and unhydrolyzed acetates derived from the antipodal alcohol. Predictions of the absolute stereochemistry of the alcohol formed are based on a rule that the enantiomer shown in Fig. 1 is the one more rapidly hydrolyzed, where R^1 is the effectively larger substituent. The results of some 50 hydrolyses were used to assign the effective sizes of a number of substituents; the observed ordering in their sizes was found to be identical with that employed in a chemical method developed by Horeau (4) for determining the configurations of secondary alcohols.

Our earlier studies provided no information on the relative size of a carbon–carbon double bond versus a methylene group; consequently, no a priori prediction about the stereochemical course of the hydrolysis of allylic acetates was possible. We describe here the results of hydrolyzing a number of acyclic and cyclic allylic acetates using *R. nigricans* and compare the predicted configurations of the resulting alcohols with those established by chemical or crystallographic methods. While these hydrolyses have consistently yielded optically active alcohols, the absolute stereochemistry of one of the approximately ten alcohols, predicted from the above rule, was found to be in error. In an effort to identify other possible exceptions to the rule, we have determined the chiroptical properties of the allylic alcohols and their *p*-bromobenzoates. The cd (circular dichroism) curves of the latter were used in conjunction with the Harada–Nakanishi rule (5) for relating the signs of these curves to their configurations. When the configurations deduced from the optical and microbial methods differed, additional work was necessary to establish the configuration of the alcohol.



Where $R^1 > R^2$

FIG. 1. Enantiomer more rapidly hydrolyzed (where R^1 is effectively larger than R^2).

Results and discussion

Partial hydrolysis of racemic 3-cyclopentenyl (**1***b*), 3-cyclohexenyl (**2***b*), and 3-cycloheptenyl (**3***b*) acetates using the mold, *Rhizopus nigricans*, yielded alcohols enriched in the (*R*) enantiomer. The results summarized in Table 1 can be accounted for by our rule (Fig. 1) and the assumption that a carbon–carbon double bond is effectively larger than a methylene group. This assignment of the relative size of these groups agrees with that used in Horeau's chemical method (6) of assigning configurations of secondary alcohols.

The enantiomeric excesses (ee's) obtained in these hydrolyses were low; we have therefore examined two methods of increasing these values. The first approach simply involves reacetylating the chiral alcohol obtained from one hydrolysis, and subjecting the resulting ester to a second hydrolysis. There are data in the literature from the work of Sih and co-workers (7) and results by us (3) on other alcohols to indicate that this

†Optical purity unknown.

approach is successful. The second approach followed logically from an earlier observation that alcohols with large ee's were obtained from substrates in which substituents on the carbinol carbon differed greatly in their effective sizes. If the larger ee values were related to large differences in the relative sizes of substituents, then a further increase in the effective size of the double bond should result in an increase in the ee of the carbinol formed. One method of increasing the effective size of the double bond is to introduce a substituent on either olefinic carbon. To be able to prepare unsubstituted alcohols, the added substituent should be readily replaceable by a hydrogen. We therefore prepared racemic acetates of several 2- and 3-substituted allylic alcohols (see Scheme 1) and determined the configurations and ee's of alcohols obtained from their enantioselective hydrolysis. To better understand the effect of substituents on the double bond we also prepared and examined the products from the hydrolysis of 2-methyl-, 2-chloro-, 2-phenyl-, and 2-*tert*-butyl-2-cyclohexenyl acetates. Data on the results of these hydrolyses are included in Table 1; they

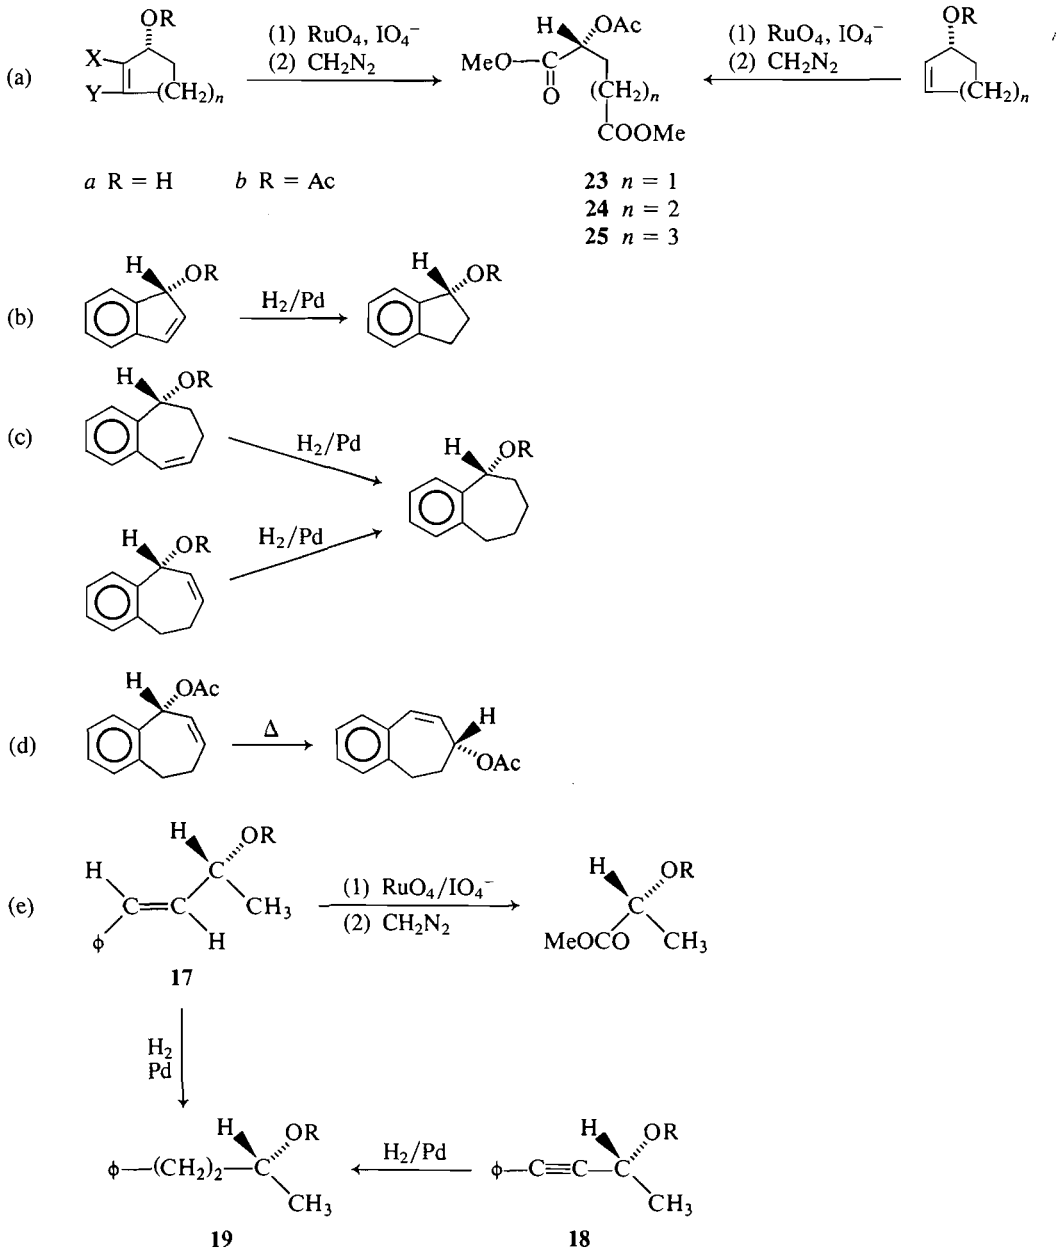

SCHEME 2

show that very bulky groups, 2-phenyl and 2-*tert*-butyl, hinder or severely retard the enzymic hydrolysis of the ester.

Each of the brominated allylic alcohols obtained in these hydrolyses had the same (*R*) configuration as the unsubstituted alcohol. The ee's of the 2-substituted five-, six-, and seven-membered cyclic compounds were equal to or greater than those of the unsubstituted ones. The presence of a substituent two bonds away from the acetate did not significantly increase the ee of the resulting alcohol.

Since the results of these hydrolyses establish that carbon–carbon double bonds are effectively larger than the methylene group and since earlier studies had shown that a fused aromatic ring was likewise larger (3), we were interested in determining the relative size of an aromatic ring and carbon–carbon double bond. Compounds **13***b* and **16***b* were prepared (Scheme 1, (c) and (f)) and the absolute stereochemistries of the alcohols formed were established as (*R*) by the reaction sequence shown in Scheme 2. While hydrolysis of **13***b* yields a small quantity of (+)-**13***a*, the major hydrolysis product was the rearranged alcohol (−)-**14***a*. In the process of establishing the configuration of the latter, the hydrolysis of **14***b* was also examined and found to yield (−)-**14***a*, i.e. the same enantiomer as was obtained from **13***b*. As converting (−)-**14***b* into a compound of established absolute stereochemistry proved to be difficult, we elected to convert (*R*)-**13***b* into **14***b*. This rearrangement was achieved by heating a sample of (−)-**13***b* at 145°C for 20 min to yield (+)-**14***b* (Scheme 2(d)). Since (−)-**13***b* has an (*R*) configuration and similar 1,3-rearrangements proceed in a suprafacial manner, the product (+)-**14***b* (which yields (+)-**14***a* on hydrolysis) should have an (*R*) configuration. The enantioselective hydrolysis of (±)-**14***b* was expected to yield the (*R*) enantiomer, (+)-**14***a*, from our rule. The observation that (−)-**14***a* was formed required its configuration to be assigned in an unequivocal manner. That assignment was made by an X-ray structure determination of the camphanate ester **14***c*, which yields (+)-**14***a* on hydrolysis. The structure determination, Fig. 2, confirmed an (*S*) configuration for (−)-**14***a*.

In addition to cyclic allylic acetates, the enantioselective

*Camphanate ester.

hydrolyses of an acyclic allylic acetate **17***b* and an acetylenic ester **18***b* were also examined. The (*R*)-alcohols (see Table 1) were obtained in each case. The result is consistent with the rule and the assumption that a carbon–carbon double or triple bond is effectively larger than a methyl group. Data on the chiroptical properties of the corresponding *p*-bromobenzoates are given in Table 2.

Data on the hydrolysis of an acyclic phenyl acetylenic acetate, **20***b*, had previously been reported (3); the configuration of the alcohol formed was accounted for by our rule and the assumption that a phenyl group was effectively larger than a carbon–carbon triple bond.

22

Synthesis of racemic substrates and determination of the absolute stereochemistry of the alcohols formed in R. nigricans *mediated hydrolyses*

Samples of the racemic substrates used in these studies were prepared by standard literature methods and by those outlined in Scheme 1.

Although the absolute stereochemistry of most of the unsubstituted cyclic allylic alcohols was known, that of the corresponding brominated derivatives was not. The groups of compounds were interrelated by oxidizing the olefinic carbons in each compound to carboxylic acid groups as shown in Scheme 2(a). A comparison of the specific rotations of the dimethyl esters, **23**–**25**, derived from the allylic acetates and their halogenated derivatives (Scheme 2(a) and Table 3), was used in assigning the absolute stereochemistry of the latter.

The configuration of (−)-**16***a* was determined by reduction to (*R*)-indanol (Scheme 2(b)).

The absolute stereochemistries of (+)-**13***b* and (−)-**15***b* were established by reducing each to (*R*)-benzocyclohepten-3-yl acetate (**15**) (Scheme 2(c)).

*X-ray crystallographic structure and stereochemical assignment of (+)-**14**c*

A sample of racemic **14***a* was converted to diastereomeric camphanate esters, which were separated by fractional crystallization. The structure and absolute stereochemistry of the (+)-camphanate, **14***c*, were determined crystallographically; the results given in the experimental section of this paper show an (*R*) configuration at the carbinol carbon. Since hydrolysis of the (+)-camphanate yields (+)-**14***a*, the configuration of (−)-**14***a* formed in the enantioselective hydrolysis of **13***b* and **14***b* was (*S*). This assignment confirms the earlier one based on the thermal rearrangement of (−)-**13***b*.

While determining absolute stereochemistry by X-ray crystallographic methods is usually unambiguous, we have found the assignment of (*R*) and (*S*) designations from visual inspection of crystallographic diagrams or display screens to be a process fraught with error. Common molecular display programs usually allow the rapid calculation of torsion angles and the calculation can be extended to nonbonded atoms for unambiguous determination of stereochemistry. If a chiral atom has four prioritized substituents 1, 2, 3, and 4 and the atoms directly attached to the chiral atom are 1a, 2a, 3a, and 4a, we define the chiral angle χ as the 1a–2a–3a–4a dihedral angle (it

TABLE 3. Summary of data on the specific rotations of dimethyl 2-acetoxydicarboxylates from 3-cycloalkenyl and 2-bromo-3-cycloalkenyl acetates

Compound	Specific rotation (ee)	Specific rotation corrected to 100% ee
23 (from **1***b*)	−1.43(6)	−24
23 (from **4***b*)	−12.6(51)	−25
23 (from **7***b*)	−5.36(23)	−23
24 (from **2***b*)	−5.14(20)	−26
24 (from **5***b*)	−7.11(27)	−26
24 (from **8***b*)	−3.64(15)	−24
25 (from **3***b*)	−6.00(25)	−24
25 (from **6***b*)	−3.00(13)	−24

is not strictly a torsion angle since the atoms are not directly connected). Since probable errors in dihedral angles are of the order of 2–3° and since the χ value for a chiral atom with substituents at the corners of a regular tetrahedron is +70.53° for an (*R*) and −70.53° for an (*S*) configuration, χ is usually definitive. In real structures, the magnitude of χ is normally 60–80°. One might also note that only the order of the substituents is required since $\chi(1\text{–}2\text{–}3\text{–}4) = \chi(4\text{–}3\text{–}2\text{–}1)$.

The chiroptical properties of p-*bromobenzoates of allylic alcohols*

Since the configuration of (−)-**14***a* obtained from **13***b* and **14***b* was not the one predicted from its method of preparation, it became important to have another method of independently assigning the configurations of small quantities of chiral allylic alcohols that were not optically pure. Since many such compounds are oils and are available in relatively small quantities, we elected to investigate an optical method developed by Harada and Nakanishi (H–N) (5*b*). Their method has proven to be reliable in assigning the absolute stereochemistry of *p*-substituted benzoates of allylic alcohols from data on the signs of their cd curves. The H–N rule states that if one looks down the carbon–carbon bond from the carbinol carbon toward the carbon–carbon double bond, a positive cd band (at approximately 240–245 nm) is predicted for the molecule if the benzoate group has to be rotated in a clockwise direction to eclipse the double bond. A counterclockwise rotation is associated with a negative cd band (see Fig. 3). For five-, six-, and seven-membered rings these predictions are independent of the conformation of the molecule. In acyclic compounds the predicted sign is dependent upon the rotamer under consideration. Thus, as a distribution of rotamers exists in solution, the observed cd band, which is the algebraic sum of the curves of all rotamers, can only be related to the absolute stereochemistry of acyclic allylic esters when there is some information on the rotamer distribution in solution along with an estimate of the rotational strengths of the various rotamers.

p-Bromobenzoates of the alcohols obtained in these studies were prepared and data on their chiroptical properties are summarized in Table 2. Inspection of the table shows that all esters of cyclic (*R*)-alcohols, except for (−)-**16***b*, exhibit positive cd bands at 240–245 nm. Thus, the negative cd curve observed for the *p*-bromobenzoate of (−)-**14***a* serves as a warning that the configuration based on its method of preparation might be incorrect.

As data for the relation between the signs of the cd curves of the acyclic allylic alcohols are limited, it is premature to interpret those data. Since the exciton chirality model relates the

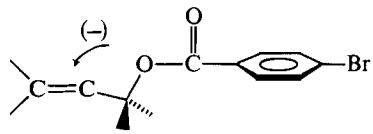

FIG. 3.

interaction of the transition moment along the carbon–carbon double bond with the transition moment of the *p*-substituted benzoate along its long axis, the presence of a halogen on the carbon–carbon double bond of cyclic allylic esters should not alter the direction of the transition moment of that carbon–carbon double bond. Indeed, the observed signs of the cd curves of the brominated derivatives are the same as those of the unsubstituted compounds. The signs of three (*R*)-alcohol derivatives in which the double bond is conjugated to an aromatic ring differ. Thus, in at least one case, the presence of a conjugated aromatic ring has changed the direction of the transition moment of the carbon–carbon double bond.

Chiroptical properties of conjugated allylic alcohols

While the cd curves of the conjugated allylic alcohols or acetate esters cannot be analyzed by the exciton chirality method, Crabbe (8*a*) suggested a relationship between the signs of the chiroptical effects of these compounds and their absolute stereochemistry. That analysis classified skewed styrenes as dissymmetric chromophores and suggested that the skew sense of the chromophore is related to the sign of the longest wavelength cd band. Our measurement of the cd curves of the camphanate and acetate esters of (−)-**14***a* shows them to have very strong positive cd bands, as would be expected from dissymmetric chromophores. The X-ray structure determination of (+)-**14***c* established a left-handed skew sense for the styrene chromophore in the crystal. Molecular models of the compounds **21** and **22**, which Crabbe reported as exhibiting positive cd bands for the longest wavelength transition, have a left-handed skew sense. The Crabbe analysis and the observed positive sign for the cd band of (+)-**14***b* are consistent with the left-handed skew sense found crystallographically. However, molecular models show that the skew sense of **14***a* and derivatives varies with their conformations. Furthermore, the critical assumption that *only* dissymmetric chromophores (e.g., skewed dienes) exhibit large cd curves for the longest wavelength transition is *not* consistent with recent observations for planar dienes. Duraisamy and Walborsky (8*b*) reported that the planar dienes that are not dissymmetric chromophores also show very strong chiroptical effects. To collect data on the chiroptical properties of additional styrene derivatives, we have measured the cd curves of compounds **9***b*, **15***b*, and **17***b* and summarized those results in Table 2.

Conclusion

Enantioselective hydrolysis of esters by *R. nigricans* can be used to prepare a wide variety of chiral allylic alcohols. The order of the effective sizes of substituents used in predicting the configurations of these alcohols is identical with that employed in Horeau's method. While the configurational assignments of allylic alcohols formed in these hydrolyses can usually be assigned from their method of preparation, they should be verified using information on the signs of the cd bands of the corresponding *p*-bromobenzoates and the Harada–Nakanishi rule. The microbially based method thus complements existing chemical methods of preparing chiral samples of this class of

molecules and provides an additional method of assigning their configurations.

Experimental

General methods

All melting points were determined using a hot-stage apparatus and are uncorrected. Proton magnetic resonance spectra were recorded on a Varian HR-220 instrument in $CDCl_3$. Chemical shifts are reported in parts per million (ppm) downfield from tetramethylsilane. Coupling constants are given in Hz. Optical rotations were recorded on a Perkin–Elmer 241MC polarimeter. Circular dichroism measurements were made using a Jasco J-500A spectropolarimeter. Preparative and analytical tlc work was performed on plates coated with silica gel F-254. The enantiomeric excesses (ee's) were usually obtained by comparing observed and reported specific rotations.

Microbial hydrolyses

The potato-dextrose medium for growing *R. nigricans* was prepared as previously described (3). A 1-L Erlenmeyer flask containing 250 mL of this medium was inoculated with *Rhizopus nigricans* (ATCC 6227b) grown in liquid culture, and shaken for 6–7 days at 25°C. The substrate (460 mg) in 1 mL of THF was added and the flask was shaken for 16–24 h. The mycelium and medium were extracted with ethyl acetate (3 × 100 mL) and the combined extracts were dried and concentrated. The area under the protons on the carbinol carbon in an nmr spectrum of the crude extract was used to determine percent hydrolysis. The recovered acetate and the alcohol formed were separated by column chromatography on silica gel with *n*-hexane and ethyl acetate as eluants. Data on recoveries, configurations of the alcohols formed, and specific rotations are summarized in Table 1.

Synthesis

Compounds **1***b*, **2***b*, and **3***b* were prepared from the corresponding unsaturated ketones by reduction with sodium borohydride in the presence of an equivalent of cerium trichloride as described by Gemal and Luche (10). The allylic alcohols were acetylated with acetic anhydride in pyridine in the usual manner. The 2-bromo derivatives **4***a* and **5***a* were prepared from the corresponding α,β-unsaturated ketones by bromination in the presence of triethylamine and purified by column chromatography on silica gel. Data on their proton nmr spectra were identical to that reported in the literature (9). The 2-bromo α,β-unsaturated ketones were reduced to allylic alcohols with sodium borohydride in the presence of an equivalent of cerium trichloride (10). A sample of **6***b* was prepared from dibromo[6.1.0]heptane by a silver acetate catalyzed solvolysis (11).

The 3-bromo α,β-unsaturated compounds **7***a* and **8***a* were prepared from the corresponding 1,3-diketone by reaction with triphenylphosphine dibromide (Scheme 1(a)) as described by Piers and Nagakura (12*a*), followed by reduction with sodium borohydride in the presence of cerium chloride as described above.

The absolute stereochemistry of compounds **1***a* (19), **2***a* (20), and **3***a* (15) is known. The corresponding acetates were oxidized, using ruthenium tetroxide (15), to the corresponding dicarboxylic acids (Scheme 2(a)), which were methylated with diazomethane. The esters were purified by column chromatography to yield known esters, and data on their specific rotations are summarized in Table 3. Compounds **4***b*, **5***b*, **6***b*, **7***b*, and **8***b* were also oxidized with ruthenium tetroxide and the resulting dicarboxylic acids esterified with diazomethane. After purification (column chromatography on silica gel), a comparison of the specific rotations of the dimethyl esters with those obtained from the unsubstituted allylic acetates showed them to have the same sign, see Table 3. A sample of racemic **9***a* was prepared by allylic bromination (NBS), in carbon tetrachloride, of 1-phenylcyclohexene followed by solvolysis of the resulting allylic bromide in aqueous THF containing sodium bicarbonate. A sample of the chiral alcohol, **9***a*, was prepared from (*R*, *S*) *trans* 2-phenylcyclohexanol, $[\alpha]_D$ −46.3° (*c* 3.1, C_6H_6), obtained by hydrolysis of the corresponding acetate by *R. nigricans*. The alcohol was reacetylated to yield **9***b*, $[\alpha]_D$ −14.0° (*c* 3.1, $CHCl_3$). Allylic bromination in CCl_4 with NBS and benzoylperoxide gave, after the standard work-up, an oil that was dehydrohalogenated with DBU in THF at room temperature. The mixture was extracted with ether, concentrated, and the acetate hydrolyzed by refluxing for 20 min in aqueous THF containing KOH. After the standard work-up, chromatography on silica gel yielded **9***a* as a colorless oil; $[\alpha]_D$ +114.5° (*c* 1.6, $CHCl_3$); ^{1}H nmr: 1.50–2.02 (m, 5H), 2.09–2.35 (m, 2H), 4.70 (br s, 1H), 6.15 (t, *J* = 4, 1H), 7.14–7.75 (m, 5H). The *p*-bromobenzoate was prepared by reaction with *p*-bromobenzoyl chloride in the usual manner.

Compounds **10***b*, **11***b*, and **12***b* were prepared by chlorinating the appropriately 2-substituted cyclohexanones with sulfuryl chloride in CCl_4 at room temperature. The reaction mixtures were then washed with water, aqueous $NaHCO_3$, saturated aqueous NaCl, dried, and distilled *in vacuo*. The 2-chloro derivatives were dehydrohalogenated with LiCl in DMF at 140°C for 1 h. The reaction mixtures were diluted with water, extracted into ether, and the ether extract was washed with dilute H_2SO_4, dried, and concentrated. The unsaturated ketones were isolated by vacuum distillation and purified by column chromatography. The unsaturated ketones were converted to allylic acetates by reduction and acetylation as described above.

An optically active sample of **10***a* was prepared by Tanno and Terashima (21) but they were unable to assign its configuration. A configuration has been assigned to the alcohol, based on the observation of a positive cd curve for its *p*-bromobenzoate and the Harada–Nakanishi rule (5). An (*R*) configuration was also assigned to (+)-**11***a*, based on the finding of a positive cd curve of the *p*-bromobenzoate ester.

*1,2-Benzocyclohepta-1,4-diene-3-ol (**13**a)*

A solution of benzosuberone in ether (8 g in 5 mL) was added dropwise to an ether solution of LDA in 60 mL of ether at −78°C (Scheme 1(c)). After 2 h, a solution of triethylamine (2.5 mL) in ether (5 mL) was added followed by a solution of trimethylsilyl chloride (10 mL) in ether (15 mL). The mixture was warmed to room temperature after 30 min and poured into water (100 mL). The solution was extracted with hexane and the hexane solution washed with aqueous sodium bicarbonate, dried, and concentrated. The trimethylsilyl enol ether was distilled as a colorless oil (10.0 g, bp 102–103°C/0.85 Torr (1 Torr = 133.3 Pa)). It was next added dropwise to a mixture of palladium acetate (3.25 g) and benzoquinone (1.23 g) in acetonitrile (50 mL) at room temperature (14), stirred for 4 h, and filtered. The filtrate was concentrated under reduced pressure and purified by column chromatography on silica gel to yield 2.41 g of 1,2-benzocyclohepta-1,4-diene-3-one as a colorless oil; ^{1}H nmr: 2.56 (td, *J* = 5.5, 5.0, 2H), 3.03 (t, *J* = 5.5, 2H), 6.25 (d, *J* = 11.5, 1H), 6.71 (td, *J* = 11.5, 5.0, 1H), 7.07–7.46 (m, 3H), 7.72 (d, *J* = 7, 1H). The unsaturated ketone was reduced with sodium borohydride (587 mg) in methanol (40 mL) containing cerium trichloride heptahydrate (5.67 g) at 0°C for 15 min. The resulting alcohol **13***a* was extracted with ether and purified by column chromatography on silica gel to yield colorless needles, mp 84–86°C; ^{1}H nmr: 2.07–2.37 (m, 2H), 2.46 (s, 1H), 2.70–3.13 (m, 2H), 5.46 (dt, *J* = 9.5, 4.0, 1H), 5.66 (s, 1H), 5.69 (dd, *J* = 9.5, 2.0, 1H), 7.02–7.25 (m, 3H), 7.30–7.43 (m, 1H). The empirical formula and molecular weight were established by mass spectroscopy as $C_{11}H_{12}O$; calcd.: 160.0888; found: 160.0887.

The acetate, **13***b*, was obtained from **13***a*, as a colorless oil; ^{1}H nmr: 2.14 (s, 3H), 2.34 (m, 2H), 2.95 (dt, *J* = 14.6, 1H), 3.17 (dt, *J* = 14.0, 6.0, 1H), 5.64 (dt, *J* = 12.0, 2.8, 1H), 5.75 (dd, *J* = 12.0, 4.2, 1H), 6.48 (dd, *J* = 1.8, 4.2, 1H), 7.07–7.31 (m, 4H).

Hydrolysis of **13***b* (543 mg) using *R. nigricans* (7 h at room temperature) yielded a crude mixture of **13***a*, **14***a*, and **14***b*. These were separated by column chromatography on silica gel to yield **13***a* (116 mg, 28%), $[\alpha]_D$ +31.2° (*c* 2.9, $CHCl_3$); **14***a* (111 mg, 26%), $[\alpha]_D$ −67.5° (*c* 2.8, $CHCl_3$); **14***b* (11 mg, 2%), $[\alpha]_D$ +63.5° (*c* 0.90, $CHCl_3$).

A sample of (−)-**13***b* (91 mg, $[\alpha]_D$ −14.5° ($CHCl_3$)) in DMSO-d_6 (1 mL) was heated to 145°C for 25 min. Chromatography of the yellow solution on silica gel ((ethyl acetate:hexane, 3:97) yielded **14***b* (17 mg, $[\alpha]_D$ +43.0° (*c* 0.60, $CHCl_3$)).

Configurational assignments

A sample of (−)-**13***a* ($[\alpha]_D$ −25.2°) was hydrogenated in ethyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12

acetate over PtO_2 to yield, after chromatography, 78 mg of (*R*) 1,2-benzocyclohepten-3-ol ($[\alpha]_D$ +33.8°) (15).

A sample of (3*S*) 1,2-benzocycloheptenol ($[\alpha]_D$ −32.2°) was acetylated in the usual manner to yield (3*S*) acetoxy-1,2-benzocycloheptene ($[\alpha]_D$ −76.8°).

*1,2-Benzocyclohepta-1,3-dien-5-ol (**14**a)*

A solution of 1,2-benzocyclohepta-1,3-diene (4.3 g) in CCl_4 (70 mL) was refluxed with NBS (6.297 g) and benzoylperoxide (596 mg) for 20 min. The crude mixture of allylic bromides was isolated and hydrolyzed with sodium bicarbonate (10.8 g) in 100 mL THF–H_2O for 6 h. The solution was extracted several times with ether and the ether solution concentrated. The crude reaction product was chromatographed on silica gel to yield **14***a* (2.52 g) as a colorless oil; ^{1}H nmr: 1.92–2.29 (m, 3H), 2.31–2.63 (m, 2H), 4.85 (br d, J = 4.5, 1H), 5.89 (td, J = 4.6, 12.4, 1H), 6.37 (d, J = 12.4, 1H), 7.08–7.30 (m, 3H), 7.38 (d, J = 6.5, 1H). *Mol. Wt.* calcd. for $C_{11}H_{12}O$: 160.0888; found: 160.0874.

The acetate, **14***b*, was prepared by acetylation of **14***a* in the usual manner. The empirical formula and molecular weight were established by mass spectroscopy as $C_{13}H_{14}O_2$; calcd.: 202.0994; found: 202.1003.

Acetylation of (−)-**14***a* ($[\alpha]_D$ −67.46°) yielded (−)-**14***b* ($[\alpha]_D$ −80.5° (*c* 0.026, $CHCl_3$).

*Preparation of **14**c, the (+)-camphanate of **14**a*

A solution of the racemic alcohol in pyridine was reacted with 1.1 equivalents of camphanic acid chloride at room temperature overnight. The camphanate was purified by column chromatography; repeated fractional crystallization from hexane – ethyl acetate yielded colorless plates, mp 120–121°C; $[\alpha]_D$ +286° (*c* 1.3, $CHCl_3$). *Anal.* calcd. for $C_{21}H_{24}O_4$: C 74.12, H 7.06; found: C 74.45, H 7.36.

The (+)-camphanate was hydrolyzed in refluxing aqueous THF (1:1) containing 2 equiv. of KOH. The solution was diluted with water and extracted with ether. The alcohol was purified by column chromatography on silica gel to yield (+)-**14***a*; $[\alpha]_D$ +361° (*c* 1.5, $CHCl_3$).

*1,2-Benzocyclohepta-1,3-dien-7-ol (**15**a)*

The crude reaction product obtained by allylic bromination of benzosuberone in carbon tetrachloride with one equivalent of NBS was dehydrohalogenated in DMF with calcium hydrogen phosphate at 80°C. The reaction mixture was poured into water, extracted into ether, and the ether solution concentrated to yield a mixture of benzosuberone and 1,2-benzocyclohepta-1,3-dien-7-one. The mixture was separated by column chromatography on silica gel; ^{1}H nmr: 2.51 (q, 2H), 2.95 (t, J = 6, 2H), 6.11–6.25 (m, 1H), 6.48 (d, J = 11, 1H), 7.16–7.30 (m, 3H), and 7.91 (d, J = 7, 1H). The empirical formula and molecular weight were established by mass spectroscopy as $C_{11}H_{10}O$; calcd.: 158.0732; found: 158.0735. Reduction of the ketone with sodium borohydride in the presence of one equivalent of cerium chloride in methanol yielded **15***a*, which was purified by chromatography on silica gel; ^{1}H nmr: 2.05–2.23 (m, 2H), 2.41–2.55 (m, 2H), 4.84 (br s, 1H), 5.84–5.98 (m, 2H), 6.39 (d, J = 11, 1H), 7.09–7.25 (m, 3H), and 7.39 (d, 1H).

Acetylation of **15***a* yielded **15***b*; ^{1}H nmr: 1.82–2.32 (m, 2H), 2.48 (m, 2H), 5.82–5.98 (m, 2H), 6.39 (br d, J = 11, 1H), 7.50–7.73 (m, 3H), and 7.72 (d, J = 7, 1H). The empirical formula and molecular weight were established by mass spectroscopy as $C_{13}H_{14}O_2$: calcd.: 202.9938; found: 202.1003.

Hydrogenation of the optically active acetate, (−)-**15***b* ($[\alpha]_D$ −14.8° ($CHCl_3$) in ethyl acetate with PtO_2 yielded (−)-(3*S*) acetoxybenzocycloheptene ($[\alpha]_D$ −6.30° (*c* 4.3, $CHCl_3$)) (15).

*Indenol (**16**a)*

Diphenyl diselenide (6.9 g) was added to a solution of bromine (3.5 g) in acetic acid (50 mL); after 30 min indene (5.2 g) was added, followed by potassium acetate (8.5 g). The mixture was stirred for 2 h, poured into water (100 mL), and extracted with ethyl acetate. The ethyl acetate solution was washed with aqueous sodium bicarbonate and water, dried over sodium sulfate, and concentrated *in vacuo*. The crude product in THF (100 mL) was cooled to 0°C and oxidized with 30% H_2O_2 (20 mL). The reaction mixture was extracted with ethyl acetate and the organic layer concentrated. Distillation yielded **16***b* as a pale yellow oil (bp 113–114°C/3.3 Torr.). The empirical formula and molecular weight of **16***b* were established by mass spectroscopy. *Mol. Wt.* calcd. for $C_{11}H_{10}O_2$: 174.06808; found: 174.06879.

A sample of (−)-**16***a*, $[\alpha]_D$ −164° (*c* 2.8, $CHCl_3$), obtained by *R. nigricans* mediated hydrolysis, was hydrogenated with PtO_2 to yield (*R*)-indanol ($[\alpha]_D$ −21.8° (*c* 3.1, $CHCl_3$)) (16).

*(E) 4-Phenyl-3-buten-2-ol (**17**a)*

The desired alcohol was prepared by the reaction of 1.1 equiv. of methyl lithium with cinnamaldehyde at −78°C. After 30 min the mixture was poured into cold 2*N* HCl and extracted with ether. The ether solution was washed with aqueous sodium bicarbonate, dried, and concentrated. The crude reaction product was acetylated in the usual way to give **17***b*; ^{1}H nmr: 1.41 (d, J = 5.5, 3H), 2.06 (s, 1H), 5.51 (qd, J = 5.5, 6.0, 3H), 6.16 (dd, J = 15.5, 6.0, 1H), 6.59 (d, J = 15.5, 1H), 7.16–7.41 (m, 5H). The empirical formula and molecular weight were established by mass spectroscopy as $C_{12}H_{14}O_2$; *Mol. Wt.* calcd.: 190.09938; found: 190.09944.

The absolute stereochemistry of the acetate recovered from the enantioselective hydrolysis using *R. nigricans* was established as (*S*) by oxidizing the acetate (131 mg, $[\alpha]_D$ −13.7°) in acetonitrile–CCl_4 (3 mL)–H_2O (6 mL) with a catalytic quantity of RuO_4 in CCl_4 in the presence of $NaIO_4$ (758 mg) at room temperature for 8 h. The mixture was poured into cold 2*N* HCl, extracted with ethyl acetate, and the organic solution was concentrated to give the crude acid (143 mg), which was methylated with excess diazomethane. Chromatography on silica gel gave (*S*)-acetoxy methyl lactate (39 mg, 48%), $[\alpha]_D$ −2.5° (*c* 2.6, $CHCl_3$)).

*4-Phenyl-3-butyn-2-ol (**18**a)*

A solution of 1.1 equiv. of methyl lithium was added to an ether solution of phenylpropargyl aldehyde at −78°C. After 30 min the mixture was poured into cold 2*N* HCl and extracted with ether. The ether solution was washed with aqueous sodium bicarbonate, dried, and concentrated. The crude alcohol was acetylated with Ac_2O in pyridine. After the usual work-up the acetate, **18***b*, was purified by column chromatography on silica gel; ^{1}H nmr: 1.58 (d, J = 6.0, 3H), 2.11 (s, 3H), 5.67 (q, J = 6.0, 1H), 7.23–7.34 (m, 3H), 7.36–7.48 (m, 2H). The empirical formula and molecular weight were established by mass spectroscopy as $C_{12}H_{12}O_2$; *Mol. Wt.* calcd.: 188.08373; found: 188.08473.

Hydrolysis of **18***b* using *R. nigricans* yielded **18**a, $[\alpha]_D$ +14.5°.

The absolute stereochemistry of the recovered acetate, **18***b*, $[\alpha]_D$ −25.7° (*c* 0.033, $CHCl_3$), was determined by hydrogenation over PtO_2 in ethyl acetate to yield (2*S*) acetoxy-4-phenylbutane, **19***b*, as a colorless oil ($[\alpha]_D$ −2.27° (*c* 0.030, $CHCl_3$)). The empirical formula and molecular weight of **19***b* were established by mass spectroscopy as $C_{12}H_{16}O_2$; *Mol. Wt.* calcd.: 192.11503; found: 192.11475.

*X-ray crystallography of (+)-**14**c*

Crystals of **14***c* were irregular plates and preliminary X-ray investigation indicated an orthorhombic unit cell. The crystal used for data collection was cut to a maximum dimension of 0.25 mm. From 15 reflections measured at ±θ angles between 20 and 30°, a least-squares refinement produced a cell with dimensions a = 9.601(1), b = 12.129(1), c = 15.854(1) Å (assumed wavelength for CuKα: 1.5418 Å). The space group was uniquely determined as $P2_12_12_1$. Assuming 4 molecules in the cell, the calculated crystal density of 1.282 g cm^{-3} was reasonable.

The phase problem was solved with MITHRIL (17). The distribution of intensities was acentric and all heavy atoms of the molecule were visible in the E map. The structure was refined by standard methods using the programs XRAY72 (18) (isotropic followed by anisotropic refinement of heavy atoms, finding H atoms in a difference map, and finally refinement of all atoms with isotropic H thermal parameters). The anisotropic temperature factor used had the form: $\exp(-(2\pi^2(\Sigma_i\Sigma(U_{ij}h_ih_ja^*_ia^*_j)))$. With 2132 observations (1483

with $I > \sigma(I)$) and a maximum sin θ/λ of 0.6233 $Å^{-1}$, the final conventional R factor was 3.9%.

The final molecular dimensions (Tables 1 through 4) are given as supplemental depository material.[4] The configuration at C-5 has been deduced as R from the known R configuration of C-4′ in the camphanate portion of the molecule and the conformation of the molecule shown in Fig. 2. There are no unusual close contacts in the crystal and no hydrogen bonds.

Acid–base behaviour of the ferrocyanide ion in perchloric acid media potentiometric and spectrophotometric study

PEDRO L. DOMINGO, BEGOÑA GARCIA, AND JOSE M. LEAL[1]

Universidad de Valladolid, Departamento de Química Física, Colegio Universitario Integrado, Burgos, Spain

Received December 9, 1985[2]

PEDRO L. DOMINGO, BEGOÑA GARCIA, and JOSE M. LEAL. Can. J. Chem. **65**, 583 (1987).

Ferrocyanide ion behaves as a tetravalent Brønsted base and can react with four protons, forming ferrocyanic acid. By potentiometric and spectrophotometric techniques it is shown that the first two protonation equilibria overlap, as do the third and fourth equilibria. The two techniques yield identical results when processed with the inclusion of non-ideality terms. The method of "separation of equilibria" is proposed to allow separate study of each of the overlapping equilibria. Values of $pK_1 = -2.54 \pm 0.10$, $pK_2 = -1.08 \pm 0.03$, $pK_3 = 2.65 \pm 0.02$, and $pK_4 = 4.19 \pm 0.02$ were obtained.

PEDRO L. DOMINGO, BEGOÑA GARCIA et JOSE M. LEAL. Can. J. Chem. **65**, 583 (1987).

L'ion ferrocyanure se comporte comme une base de Brønsted et il peut réagir avec quatre protons pour former de l'acide ferrocyanique. Faisant appel à des techniques potentiométriques et spectrophotométriques, on démontre que les deux premiers équilibres de la protonation se recouvrent comme le font les troisième et quatrième équilibres. Les deux techniques conduisent à des résultats identiques lorsqu'on les traite avec l'inclusion de termes qui tiennent compte de la non-idéalité. On propose une méthode de « séparation des équilibres » pour permettre d'étudier séparément chacun des équilibres qui se recoupent. On a obtenu les valeurs de $pK_1 = -2{,}54 \pm 0{,}10$, $pK_2 = -1{,}08 \pm 0{,}03$, $pK_3 = 0{,}02$ et $pK_4 = 4{,}19 \pm 0{,}02$.

I. Introduction

In 1820 Berzelius (1) reported the isolation of a white solid, identified as $Fe(CN)_6H_4$, from an aqueous acid solution of potassium ferrocyanide. It was later established by Kolthoff (2) that the ferrocyanide ion could be protonated as a tetravalent Brønsted base in aqueous solution. The successive protonation equilibria may be expressed in the following simplified notation:

$$[1] \quad Fe(CN)_6H_3^- + H^+ \overset{K_1}{\rightleftharpoons} Fe(CN)_6H_4$$

$$[2] \quad Fe(CN)_6H_2^{2-} + H^+ \overset{K_2}{\rightleftharpoons} Fe(CN)_6H_3^-$$

$$[3] \quad Fe(CN)_6H^{3-} + H^+ \overset{K_3}{\rightleftharpoons} Fe(CN)_6H_2^{2-}$$

$$[4] \quad Fe(CN)_6^{4-} + H^+ \overset{K_4}{\rightleftharpoons} Fe(CN)_6H^{3-}$$

Here K_4, K_3, K_2, and K_1 are the thermodynamic ionization constants of the mono, bi, tri, and tetraprotonated species, which will be designated BH^{3-}, BH_2^{2-}, BH_3^-, and BH_4; B^{4-} refers to the non-protonated species.

Kolthoff and Tomsicek (3), Nekrasov and Zotor (4), and Lanford and Kiehl (5) were the first to estimate K_3 and K_4. Jordan and Ewing (6), using a potentiometric technique, obtained values for pK_3 and pK_4 of 2.22 and 4.17. They also deduced that $K_1 > K_2 > 0.1$. Other values recently published (7) are $pK_3 = 2.57$ and $pK_4 = 4.35$. Of the four possible acid–base equilibria, only values for K_3 and K_4 have been reported. In this investigation a complete study is carried out of all four equilibria by means of potentiometric and spectrophotometric techniques.

II. Results

It has been verified that the decomposition of ferrocyanide ion in perchloric acid is negligible under the conditions of these experiments. Various authors (11–14) have studied the thermal and photochemical dissociation of the ferrocyanide ion over the 0–14 pH interval; when exposed to uv light, the pH of the solutions increases due to hydrolysis of the cyanide ion formed. In darkness, this reaction is reversible. Also, in darkness decomposition is very slow; Gaspar and Beck (14) showed that thermic and photochemical conversion is small, 0.112% and 0.045%, respectively, and that the quantum yield becomes smaller as the pH increases.

Our experiments were carried out at 25°C and with light excluded. Ultraviolet–visible measurements have shown that oxidation of ferrocyanide by perchloric acid does not occur; the ferrocyanide ion shows no noticeable absorption above 270 nm, whereas the ferricyanide ion displays absorption maxima at 301 and 416 nm regardless of the acidity of the medium. Within the acidity range 0.0 to 8.0 mol dm^{-3} of perchloric acid, no absorption bands appear above 270 nm, which provides proof of the absence of any oxidising effect. For levels above 8.0 mol dm^{-3} if the concentration of ferrocyanide is sufficiently high, a white solid consisting of a mixture of $KClO_4$ and ferrocyanic acid, $Fe(CN)_6H_4$, precipitates. Identification was carried out by means of comparison with a sample of this acid prepared according to Brauer's method (8). Figure 1 shows the most characteristic ir peaks for both samples; these coincide with those indicated in the literature (15).

(A) Potentiometric study

Equilibria [3] and [4] occur within the pH 0–14 range and overlap one another (6). The calculation of constants of overlapping equilibria from potentiometric measurements can be made by Pritz's elimination method (16) or by Speakman's method of linear extrapolation (17), the latter being used in this investigation. The thermodynamic constants of ionic dissociation for these equilibria are:

$$[5] \quad K_4 = \frac{C_{B^{4-}}}{C_{BH^{3-}}} \frac{f_4}{f_3} a_{H^+}$$

$$[6] \quad K_3 = \frac{C_{BH^{3-}}}{C_{BH_2^{2-}}} \frac{f_3}{f_2} a_{H^+}$$

where f_4, f_3, and f_2 are the activity coefficients of the B^{4-}, BH^{3-}, and BH_2^{2-} species, respectively. These two equations,

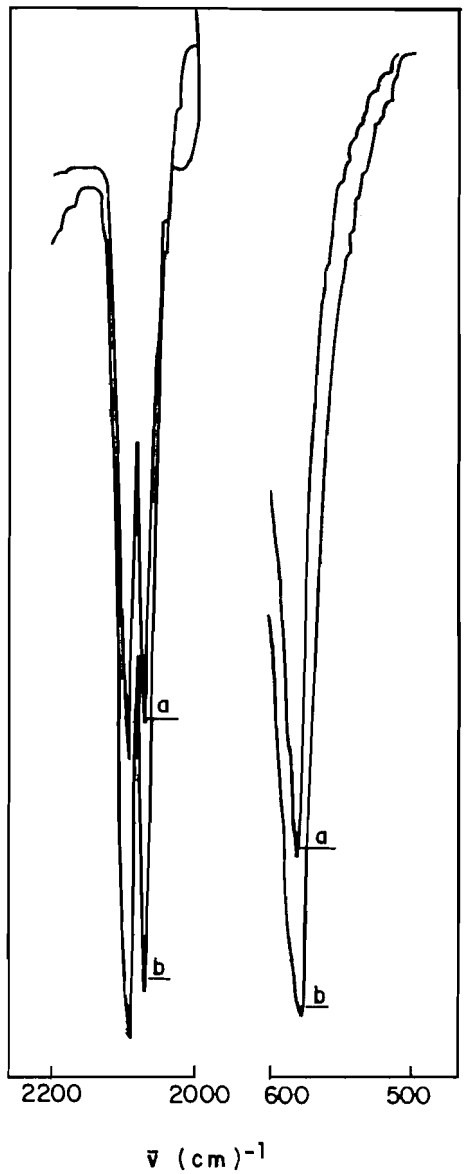

FIG. 1. Characteristic ir bands of (*a*) ferrocyanic acid prepared according to ref. 6, and (*b*) the white precipitate obtained from concentrated potassium ferrocyanide solutions (perchloric acid above 8 mol dm^{-3}).

together with a mass balance ($C_{BH_3^-} = C_{BH_4} = 0$ in this region) and a charge balance, enable us to write:

$$[7] \quad (1 - C_A/L)a_{H^+}10^{7FI_0} = 1/K_3(2C_A/L - 1)a_{H^+}^2 10^{12FI_0} - K_4$$

where C_A is the analytical concentration of potassium ferrocyanide, $L = [ClO_4^-] + [OH^-] + [H^+]$, and FI_0 is a function of the ionic strength (7), which can be calculated from

$$[8] \quad FI_0 = -\frac{AI_0^{1/2}}{1 + \mathring{a}BI_0^{1/2}}$$

where $\mathring{a} = 5 \times 10^{-8}$ cm for the ferrocyanide ion (18). Equation [7] can be written as:

$$[9] \quad y = x/K_3 - K_4$$

x and y being functions which can be determined for each pair of values V_A (the added volume of titrant)/pH. So far the treatment is analogous to that of Jordan (6), but expressions are introduced for the calculation of activity coefficients and there is also included an iterative process for a successive refining of the constants K_3 and K_4 similar to that described by Albert and Serjeant (7). This process begins by postulating initial values for K_3 and K_4; for each pair V_A/pH, the value of I_0 is postulated and, without eliminating at any time the activity coefficients, the relative concentrations C_0, C_1, and C_2 are determined for the species B^{4-}, BH^{3-}, and BH_2^{2-}, respectively. Equation [10] enables calculation of the ionic strength; if the value obtained does not coincide within a margin of ±0.1% with the postulated I_0, the process is repeated with the introduction of the calculated value of I_0, which is taken as correct, until a self-consistent value is obtained.

$$[10] \quad I_0 = ([ClO_4^-] + [OH^-] + [H^+] + C_A(16C_0 + 9C_1 + 4C_2 + 4)) \times 0.5$$

Finally, regression [9] is carried out and K_3 and K_4 are determined. If the values obtained do not coincide with those initially postulated, the process is iterated until self-consistent results are achieved. This treatment of data was programmed in BASIC. A similar, more generalized program, applicable to diacid bases, diprotic acids, and ampholites, has been developed in FORTRAN IV (7). If the program is designed so as to introduce initially the value of I_0 calculated for the first V_A/pH pair, self-consistent results are rapidly achieved. Values obtained were $K_3 = (2.22 \pm 0.04) \times 10^{-3}$, $K_4 = (6.48 \pm 0.15) \times 10^{-5}$, r_{xy} (linear correlation coeff.) = 0.9942, θ (degrees of freedom) = 18. These results are in good agreement with recent results (7).

Equilibria [1] and [2] occur at levels of acidity above 0.1 mol dm^{-3}. To obtain differential readings for a mixture of such weak bases dipolar aprotic solvents such as acetonitrile (19, 20) and acetone (21) are best; acetic anhydride also widens the range of titrations with bases as weak as the anions of strong acids (22, 23). However, potassium ferrocyanide is practically insoluble in these solvents. Dipolar aprotic solvents, such as acetonitrile, methylisobutyl ketone, etc. (24) are also best for differentiating titrations of strong acids. However, the acid $Fe(CN)_6H_4$ is very difficult to dissolve in these solvents. Dimethylsulfoxide (DMSO), which has a much higher dielectric constant, was found satisfactory. Figure 2 shows the curve obtained on titration of ferrocyanic acid in DMSO with NaOH in isopropanol. Only three inflections are observed, indicating that two of the four acid species have become leveled; this complicates quantitative treatment since each equilibrium is decomposed into at least two other equilibria:

$$[11] \quad AH + S \rightleftharpoons SH^+\text{---}A^-$$

$$[12] \quad SH^+\text{---}A^- \rightleftharpoons SH^+ + A^-$$

where AH is the acid species and S the solvent; if the solvent is water, the ion-pair cannot be detected and the dissociation is reduced to a single step.

(B) Spectrophotometric study

Figures 3 and 4 show the absorption uv spectra of the ferrocyanide ion as a function of acidity in water. The appearance of an isosbestic point indicates the presence of at least two species in equilibrium (25). A computational method for working out the number of species in equilibrium, based on the calculation of the range of a matrix of absorbances ($N \times N$), with readings at N wavelengths in N solutions of different

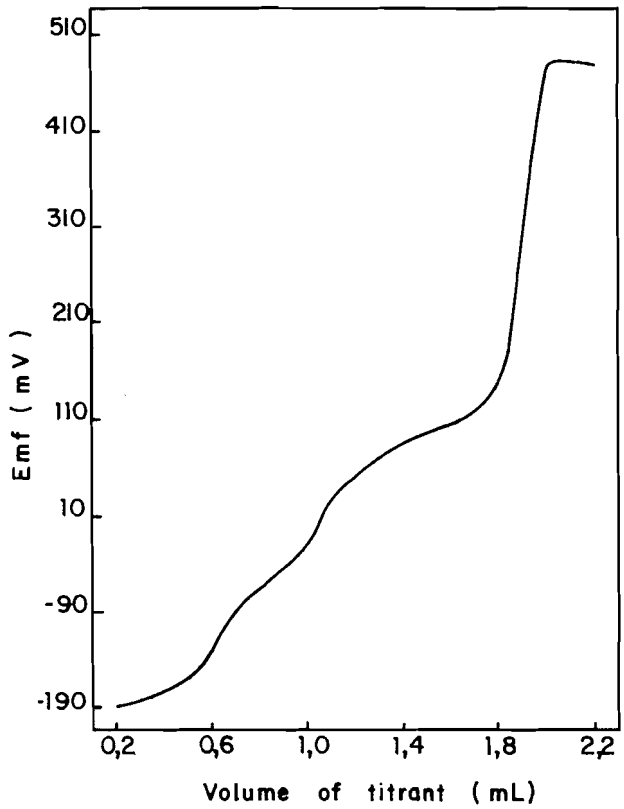

FIG. 2. Titration curve of ferrocyanic acid ($2.13 \times 10^{-3} N$) in dimethyl sulfoxide (20 mL) using NaOH ($0.022 N$) in isopropyl alcohol as titrant.

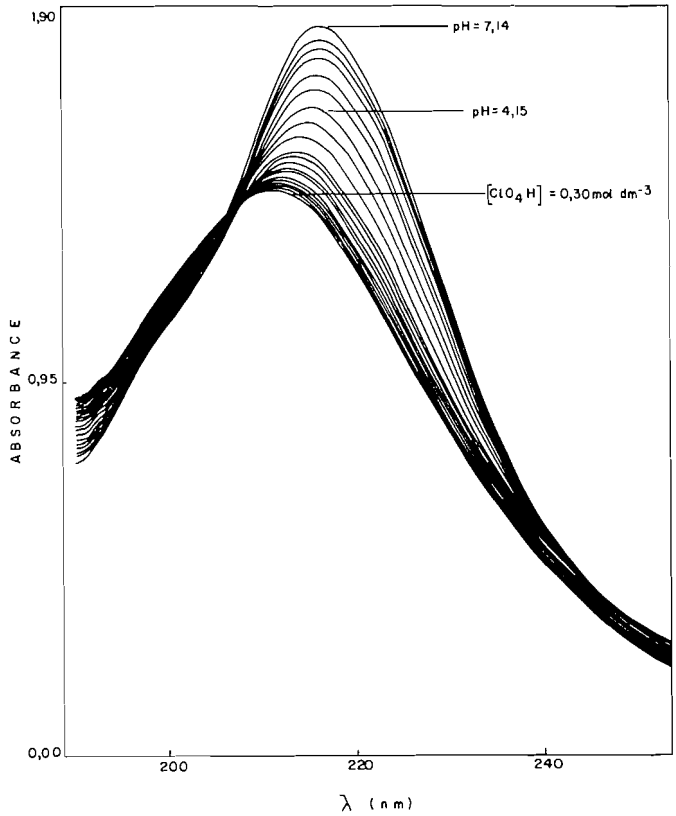

FIG. 3. Absorption uv spectra of potassium ferrocyanide (7.89×10^{-5} mol dm^{-3}) in aqueous perchloric acid solutions of pH = 7.14, 6.65, 6.20, 5.79, 4.80, 4.48, 4.15, 3.91, 3.65, 3.41, 3.33, 3.19, 3.01, 2.86, 2.55, 2.34, 2.13, 2.00, 1.85, 1.72, and $[HClO_4]$ = 0.30 mol dm^{-3}.

composition, originally written in FORTRAN (26) was rewritten in BASIC and applied separately to Figs. 3 and 4. In Fig. 3, pH range 0–14, there are three absorbing species, which match the potentiometric result: B^{4-}, BH^{3-}, and BH_2^{2-}; in Fig. 4, the high acidity region, the number of absorbing species is also three: BH_2^{2-}, BH_3^-, and BH_4. An absorbance matrix (6×6) which includes concentrations within the range 0.3–8.0 mol dm^{-3} of $HClO_4$ was used to verify this point. The error in the experimental reading of absorbances used in constructing the initial matrix of errors is estimated at 0.004. The thermodynamic constants for equilibria [1] and [2] can be written as:

$$[13] \quad pK_2 = \log I_2 - \log C_{H^+} - \log (f_{BH_2^{2-}} f_{H^+}/f_{BH_3^-})$$

$$[14] \quad pK_1 = \log I_1 - \log C_{H^+} - \log (f_{BH_3^-} f_{H^+}/f_{BH_4})$$

where I is the ionization ratio

$$(I_2 = C_{BH_3^-}/C_{BH_2^{2-}},\ I_1 = C_{BH_4}/C_{BH_3^-})$$

which, for an independent equilibrium, can be estimated by means of Gold-Hawe's equation (27):

$$[15] \quad I = \Sigma_i (1/n)(A_B - A)/(A - A_A))_{\lambda_i}$$

where A_B is the absorbance of the basic species and A_A that of the conjugate acid, each corresponding to the limits of acidity in which the equilibrium takes place; A is the absorbance value corresponding to intermediate acidity.

(1) Study in high acidity media

In media containing a high concentration of mineral acid, the terms of the activity coefficients in [13] and [14] cannot be calculated by means of the Debye–Hückel equation, so we need to resort to one of general alternative methods.

The Hammett–Deyrup general equation (28, 29) states:

$$[16] \quad \log I = -mH_x + pK$$

where H_x is Hammett's acidity function, which is particular to the type of the species under discussion. A wide collection of acidity functions have been reported (29); according to eq. [16], pK is obtained as the ordinate of the log I/H_x linear regression, and the slope, m, enables us to verify if the function H_x has been correctly chosen. If $m = 1$, then the function H_x is correct since Hammett's postulation is satisfied (28).

The Bunnett–Olsen equation (30) states:

$$[17] \quad \log I + H_0 = \Phi(H_0 + \log C_{H^+}) + pK$$

where H_0 is the Hammett acidity function for the primary aromatic amines (31, 32). As before, pK is obtained as the ordinate of a linear regression and the slope can be interpreted in terms of solvation (33).

The Cox–Yates equation (10) states:

$$[18] \quad \log I - \log C_{H^+} = m^*X + pK$$

where X, the excess acidity function, which is the same for all bases in a single system, is calculated by an iterative method based on the ionization of a large number of different bases. For aqueous perchloric acid, used in this investigation, the function X is determined by starting from the percentage of mineral acid (10). The pK is obtained as the ordinate of the linear regression $(\log I - \log C_{H^+})/X$, while from the slope we obtain the parameter m^*, which is particular to each base and can be interpreted in terms of hydration.

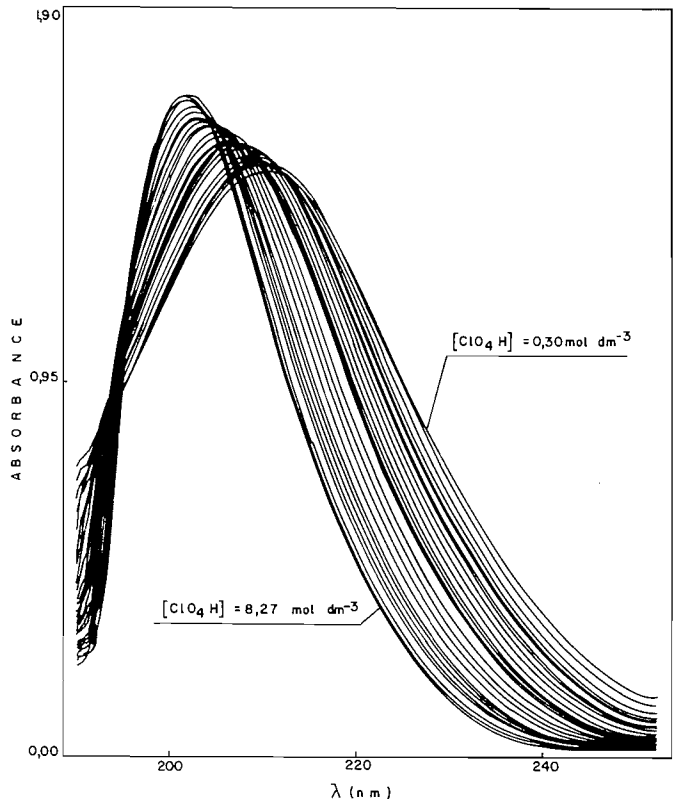

FIG. 4. Absorption uv spectra of potassium ferrocyanide (7.89×10^{-5} mol dm^{-3}) in aqueous perchloric acid solutions of concentration: 0.300, 0.810, 1.120, 1.431, 1.741, 1.974, 2.284, 2.594, 2.905, 3.215, 3.525, 3.836, 4.058, 4.379, 4.378, 5.000, 5.309, 5.619, 5.930, 6.240, 6.473, 6.783, 7.094, 7.404, 7.714, 8.000, and 8.270.

(a) Extension of Mongay's method. The isosbestic area in Fig. 4 indicates the co-existence of the species BH_2^{2-}, BH_3^-, and BH_4, that is to say, equilibria [1] and [2] overlap one another ($pK_2 - pK_1 < 3$). Mongay's method for determining constants of overlapping equilibria was developed for regions of low acidity, with activity coefficients being taken as 1 for all species (34). In this work we shall use the method without eliminating the terms related to the non-ideality of the system. Any one of the eqs. [16], [17], or [18] could be used for the investigation in strongly acid media, but we shall limit ourselves to the Cox–Yates equation for reasons which will be discussed later.

The following scheme is used. Equation [18] is applied to [1] and [2]:

$$[19] \quad K_2 = \frac{C_{BH_2^-}C_{H^+}}{C_{BH_3^-}} 10^{m_2^*X}$$

$$[20] \quad K_1 = \frac{C_{BH_3^-}C_{H^+}}{C_{BH_4}} 10^{m_1^*X}$$

These equations and those numbered [13] and [14] are equivalent (10). If we take into account the additivity of absorbances,

$$[21] \quad A = A_{BH_2^-} + A_{BH_3^-} + A_{BH_4} = A_2 + A_3 + A_4$$

and apply a mass balance:

$$[22] \quad C = C_{BH_2^-} + C_{BH_3^-} + C_{BH_4}$$

the following expression is arrived at:

$$[23] \quad A = \frac{A_2 + A_3C_{H^+}10^{m_2^*X}/K_2 + A_4C_{H^+}^2 10^{(m_1^* + m_2^*)X}/K_1K_2}{1 + C_{H^+}10^{m_2^*X}/K_2 + C_{H^+}^2 10^{(m_1^* + m_2^*)X}/K_1K_2}$$

this equation can be rearranged and written as the equation of a plane:

$$[24] \quad Z = a_0 + a_1U + a_2V$$

where Z, U, and V are functions dependent on previously known parameters and can therefore be worked out. Coefficients a_0, a_1, and a_2 contain the three values K_1, K_2, and A_3. The problem can therefore be solved using a multiple linear regression by the method of least squares. Although eq. [24] leads to several planes, for greater precision we have only chosen those appearing in Table 1. The procedure is straightforward. Using values of A/C_{H^+} such as those obtained from an expansion of Fig. 4, we look in Table V of ref. 10 for the values of m_1^* and m_2^* which are most appropriate to the type of compound being studied (since we are dealing with species of the same type it is reasonable to take $m_1^* = m_2^*$). Then for each pair of A/C_{H^+} values Z, U, and V are determined and the multilinear regression is carried out; in our case the optimum value according to ref. 10 is in the space corresponding to the anions, $m^* = 1.18 \pm 0.25$. Where this interval is narrow there is only a small error in m^*, but here the error is large and it was found advisable to develop a new method which functions in a way comparable to modern methods of iterative refining. This method is described in the next section.

(b) The separation method for overlapping equilibria. Equations [20] and [21], together with a mass balance, enable us to obtain C_2, C_3, and C_4 expressions corresponding to relative quantities of the species BH_2^{2-}, BH_3^-, and BH_4:

$$[25] \quad C_4 = (1 + (C_{H^+}10^{(m_1^*X + pK_1)})^{-1} + (C_{H^+}^2 10^{(m_1^* + m_2^*)X + pK_1 + pK_2})^{-1})^{-1}$$

$$[26] \quad C_3 = C_4(C_{H^+}10^{(m_1^*X + pK_1)})^{-1}$$

$$[27] \quad C_2 = 1 - (C_3 + C_4)$$

We postulate initial values for pK_1, pK_2, m_1^*, and m_2^* (in this case $pK_1 < pK_2 < 1$ (6) and $0.20 \leqslant m_1^* = m_2^* \leqslant 2.60$ (10)). For each acidity value the value of the function X is determined (10) as are the quantities C_2, C_3, and C_4. If we already know at the same wavelength A_2 (for 0.30 mol dm^{-3} $HClO_4$), A_4 (for 8.0 mol dm^{-3} $HClO_4$) and A (for any interme-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

diate level of acidity), by means of [28] we can obtain a value for A_3 for each value of acidity.

$$[28] \quad A_3 = \frac{A - C_2A_2 - C_4A_4}{C_3}$$

Once A_3 has been obtained it is possible to eliminate the contribution of BH_4 to the total absorbance A and to calculate by means of [29] values for A_c (corrected absorbance) which would correspond to the system if the only species existing in equilibrium were BH_2^{2-} and BH_3^-.

$$[29] \quad A_c = \frac{A - C_4A_4}{C_2 + C_3}$$

This process can be applied independently to a single wavelength or to several different ones, in such a way that by means of [15] the ionization ratio for each level of acidity can be determined, starting from the A_c values obtained previously. Equation [18] can then be used to obtain m_2^* and pK_2. In a similar fashion we eliminate the contribution made by the BH_2^{2-} species to the total absorption and, by means of [30], A_c' values can be obtained corresponding to the system where species BH_3^- and BH_4 are the only ones involved in the equilibrium.

$$[30] \quad A_c' = \frac{A - C_2A_2}{C_3 + C_4}$$

In this way equilibrium [1] can be studied independently and, by means of [15] and [18], values are obtained for m_1^* and pK_1. If the values now calculated for m_1^*, m_2^*, pK_1, and pK_2 do not match those postulated originally, the process is repeated until self-consistent results are achieved. The advantage of this method lies in the way it allows comparison of the m_1^* and m_2^* values at the end of the process. All data processing was carried out by computer. By using the data of absorbances (Fig. 4) at six different wavelengths (227, 223, 219, 204, 202, and 200 nm), the ionization ratio values of equilibria [1] and [2], (eq. [15]), as well as the values ($\log I - \log C_{H^+}$) and X (eq. [18]), were obtained (Table 2). Table 3 summarizes the average values of pK_1 and pK_2 obtained at the six wavelengths and the regression planes (Table 1) by means of Mongay's method, using $m_1^* = m_2^* = 0.85$ obtained by means of the separation method. It will be noted that the values $m_1^* = m_2^* = 0.850 \pm 0.044$ do not fall within the margin of 1.18 ± 0.25 assigned to the anions (10), a fact explained by these latter values having been obtained exclusively from anions of cyanocarbon acids, which differ in structure from the ferrocyanide ion and its protonated forms. Moreover, protonation does not affect the same atom in cyanides (35) as in cyanocarbon acids (36). The difference in the values of m^* shows that the function H_- is not able to explain the acid–base behaviour of the ferrocyanide system, and confirms that the m^* value obtained for one base is only valid for another if it is structurally similar and the functional group is the same (37).

(2) Study in low acidity media

Within the pH range 0–14, for the equilibrium

$$[31] \quad B + H^+ \rightleftharpoons BH^+$$

the thermodynamic pK_{BH^+} can be calculated empirically (31):

$$[32] \quad pK_{BH^+} = \lim_{C_{MA} \to 0} (\log I + pH) = \lim_{C_{MA} \to 0} (pK_{BH^+} + \log (f_B/f_{BH^+}))$$

with the value ($\log I$ + pH) vs. C_{MA} (mineral acid concentration) being extrapolated at infinite dilution.[3] It has recently been shown (38) that this empirical relation is not acceptable and that more satisfactory results can be obtained with the equation:

TABLE 2. Ionization ratio values for regression [18]

Equilibrium	C_{H^+} (mol dm^{-3})	I	$\log I - \log C_{H^+}$	X
[2]	1.120	0.128	−0.940	0.233

	6.240	2.237	−0.446	2.499
	6.473	3.201	−0.306	2.634
	6.783	5.395	−0.099	2.819

$$[33] \quad \log I = -n\text{p}H + n\text{p}K_{BH^+}$$

where n is a measurement of the non-ideal behaviour of the system.

The separation method

The basic equations [33] are applied to equilibria [3] and [4], with the additional introduction of mass balance. The relative quantities C_0, C_1, and C_2 are obtained for the species B^{4-}, BH^{3-}, and BH_2^{2-}:

$$[34] \quad C_0 = (1 + a_{H^+}^{n_4}K_4^{-n_4} + a_{H^+}^{(n_3+n_4)}K_3^{-n_3}K_4^{-n_4})^{-1}$$

$$[35] \quad C_1 = C_0a_{H^+}^{n_4}K_4^{-n_4}$$

$$[36] \quad C_2 = 1 - (C_0 + C_1)$$

Applying the iterative procedure for the separation of equilibria similar to that described for the high acidity region, we postulate values for n_3, n_4, pK_3, and pK_4 which, by means of equations similar to [28], [29], and [30], enable the determination of A_1 (absorbance of BH^{3-}), A_c and A_c'. Using [15] we arrive at I and n_3, n_4, pK_3, and pK_4 can be determined by means of [33]. With the data of absorbances (Fig. 3) at three different wavelengths (216, 222, and 228 nm), the ionization ratios (eq. [15]) of [3] and [4] are determined (Table 4). Table 5 shows the results obtained.

The poorer correlation in the latter case is due to three wavelengths chosen being to the right of the isosbestic point (Fig. 3); since the absorption maximum is shifted, three wavelengths should also have been chosen to the left of this point, but this did not prove to be useful because the differences are very small.

III. Discussion

Although potentiometric methods have been considered superior to spectrophotometric methods in speed, precision, and

[3]The data of absorbances used in low and high acidity media as well as the data of the titration of potassium ferrocyanide may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

	7.023	0.846	1.85

accuracy (26, 39) for the study of ionic equilibria in solution, this is only true in aqueous solutions and within the pH 0–14 range. The complexity and lack of development of theoretical models for potentiometric study in non-aqueous media mean that this technique has only a very limited use for quantitative measurements of ionic dissociation in strong acids or bases. In this investigation, the potentiometric technique yielded better results than the spectrophotometric for [3] and [4], but the opposite was true for [1] and [2].

Although the method developed for high acidity media has been based on eq. [18], also eqs. [16] or [17] could have been used just as well to design other methods. However, eq. [18] does provide a simpler way, because it is similar in form to [13] or [14] and is also more general, since the function X is valid for all bases in the same system.

TABLE 5. Thermodynamic ionization constants of equilibria [3] and [4] obtained by means of the separation method

Equilibrium	Thermodynamic ionization constant: Initial	Thermodynamic ionization constant: Final
[3]	$n_3 = 0.97$ $pK_3 = 2.65$	$n_3 = 0.97 \pm 0.13$ $pK_3 = 2.65 \pm 0.30$ $\theta = 3$ $r_{xy} = 0.9712$
[4]	$n_4 = 0.74$ $pK_4 = 4.16$	$n_4 = 0.74 \pm 0.03$ $pK_4 = 4.15 \pm 0.13$ $\theta = 4$ $r_{xy} = 0.9958$

Finally, it must be stressed that when engaged in the study of a system, it is advisable to use a real system without eliminating such terms as activity coefficients, m^*X, etc., since they provide information about non-ideal behaviour; this entails using iterative methods, which are becoming increasingly frequent in this type of calculation (7, 26). Most methods for studying overlapping equilibria are designed with the ideal model in mind and it seems clear that they can be developed with the use of a real model. Examples of the latter methods are provided by Ang (40) and Albelda *et al.* (41); because of their lesser accuracy, these methods have not proved useful in the present investigation.

IV. Experimental

Reactants

All reagents were analytical grade. Twice distilled deionized water was used throughout; in the low acidity range, water was boiled and then cooled in a closed beaker to avoid CO_2. Titrations of potassium ferrocyanide in aqueous media were carried out on 100 mL portions (0.005 mol dm^{-3}), using perchloric acid (0.999 mol dm^{-3}) as titrant. Titrations in non-aqueous media were carried out on 20 mL portions of ferrocyanic acid (0.03 mol dm^{-3}), using as titrant a solution of NaOH in isopropyl alcohol. A nitrogen atmosphere was maintained over the solutions during titrations. In the high acidity range, C_{H^+} values were calculated directly from molar concentrations of perchloric acid, since this species is fully ionized at least up to 60% w/w (9,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

10). It was not necessary to control the ionic strength since this factor is included in the excess acidity function method,[4] as stated in eq. [18].

Equipment

In the potentiometric experiments, titrant was added by microburet (±0.001 mL); pH readings were made with a Crison pH-meter (±0.01) and titration curves were plotted with a Radiometer REC 61 recorder. Spectrophotometric measurements were made with a Bodenseewerk Perkin Elmer 554 model with double beam, 1 nm slit and 1 cm optical path. The reference cell contained the same solvent as the sample under measurement. The temperature of all solutions were kept constant at 25°C ± 0.01 with a P-Selecta thermostat.

Structural studies of organoboron compounds. XXV. Synthesis and structure of (maltolato)diphenylboron

CHRIS ORVIG, STEVEN J. RETTIG, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received July 17, 1986

CHRIS ORVIG, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **65**, 590 (1987).

The reaction of maltol (3-hydroxy-2-methyl-4-pyrone) with diphenylborinic acid affords a high yield of the title compound. Crystals of (maltolato)diphenylboron are monoclinic, $a = 14.3481(6)$, $b = 8.3994(3)$, $c = 12.6657(5)$ Å, $\beta = 100.892(4)°$, $Z = 4$, space group $P2_1/n$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.041$ and $R_w = 0.052$ for 2052 reflections with $I \geq 3\sigma(I)$. The molecule contains a five-membered C_2O_2B ring having a flattened *B*-envelope conformation, the B atom being displaced 0.081(2) Å from the C_2O_2 plane. Structural and spectroscopic data are consistent with weak binding of the maltolate oxygen atoms to boron. Bond distances (corrected for libration) are O—B = 1.533(2) and 1.600(3), B—C = 1.600(3) and 1.605(3) Å.

CHRIS ORVIG, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **65**, 590 (1987).

La réaction du maltol (hydroxy-3 méthyl-2 pyrone-4) avec l'acide diphénylborinique conduit, avec un excellent rendement, au composé mentionné dans le titre. Les cristaux du (maltolato)diphénylbore sont monocliniques avec $a = 14,3481(6)$, $b = 8,3994(3)$ et $c = 12,6657(5)$ Å, $\beta = 100,892(4)°$, $Z = 4$ et groupe d'espace $P2_1/n$. On a résolu la structure par des méthodes directes et on a l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de $R = 0,041$ et $R_w = 0,052$ pour 2052 réflexions avec $I \geq 3\sigma(I)$. La molécule contient un anneau à cinq chaînons de C_2O_2B qui adopte une conformation enveloppe *B* aplatie; l'atome de B se trouve à 0,081(2) Å du plan des C_2O_2. Les données de structure et spectroscopiques sont en accord avec une liaison faible entre les atomes d'oxygène du maltolato et le bore. Les longueurs de liaison (corrigées pour la libration) sont : O—B = 1,533(2) et 1,600(3), B—C = 1,600(3) et 1,605(3) Å.

Introduction

(Maltolato)diphenylboron, **1**, has been synthesized and its molecular structure determined both as part of a continuing study of the structures of organoboron compounds[1] and in parallel with studies of neutral water-soluble aluminum complexes of neurological interest (1) and related gallium analogs (2). The neutral complex tris(maltolato)aluminum has been shown to be a potent neurotoxin (3). The natural product maltol (3-hydroxy-2-methyl-4-pyrone) is commonly used as a food additive. Since ir data indicate weak binding of the maltol oxygen atoms to boron in the title compound relative to that in the tris(maltolato) complexes of Al and Ga (2), comparison of the ligand geometries is of interest.

Experimental

(Maltolato)diphenylboron ((3-hydroxy-2-methyl-4-pyronato)-diphenylboron)

A solution of diphenylborinic acid was prepared by the acid hydrolysis (60 mL 0.10 *M* HCl) of (2-aminoethanolato)diphenylboron (1.319 g, 5.86 mmol) and extraction with diethylether (4 × 50 mL). To the organic layer was added ethanol (50 mL) followed by a solution of maltol (0.740 g, 5.87 mmol, Aldrich Chemical) in 30 mL ethanol. White flakes appeared within 10 min and the product was isolated after cooling (−20°C) overnight. Yield 1.506 g (90%). Analytically pure flakes were obtained by recrystallization from acetone/water, mp 195–196.5°C (uncorrected). *Anal.* calcd. for $C_{18}H_{15}BO_3$: C 74.52, H 5.21; found: C 74.95, H 5.28. Ir (KBr, all strong): 1640 cm^{-1} (CO); 1570, 1560 (C=C). ^1H nmr (d_6-acetone, 25°C, 80 MHz): δ 2.63 (s, 3H, CH_3); 7.25 (m, 11H, $2C_6H_5$ and $CHC(O)$); 8.62 (d, 5.4 Hz, OC*H*CH).

The ir spectrum was recorded on a Perkin-Elmer 783 from 4000–200 cm^{-1} and the ^1H nmr spectrum on a Bruker WP-80. Crystals suitable for X-ray analysis were obtained by slow evaporation of an acetone solution.

[1]For Part XXIV, see ref. 23.

X-ray crystallographic analysis

A crystal bounded by the six faces (followed by their distances in mm from a common origin): {1 0 1}, 0.12, {1 0 −1}, 0.05, (−1 ±1 1), 0.11 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 70–94°) measured on a diffractometer with Cu-*K*α radiation (λ(*K*α$_1$) = 1.540562, λ(*K*α$_2$) = 1.544390 Å). Crystal data at 22°C are:

$C_{18}H_{15}BO_3$ fw = 290.1

Monoclinic, $a = 14.3481(6)$, $b = 8.3994(3)$, $c = 12.6657(5)$ Å, $\beta = 100.892(4)°$, $V = 1498.9(1)$ $Å^3$, $Z = 4$, $\rho_c = 1.285$ Mg m^{-3}, $F(000) = 608$, μ(Cu-*K*α) = 6.52 cm^{-1}. Absent reflections: $h0l$, $h + l$ odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/n$ (alternate setting of $P2_1/c$, C_{2h}^5, No. 14).

Intensities were measured with nickel-filtered Cu-*K*α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.18–10.06° min^{-1} over a range of (0.60 + 0.14 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 150°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 4%. After data reduction,[2] an absorption correction was applied using the analytical method (4, 5). Transmission factors ranged from 0.724 to 0.896. Of the 3067 independent reflections measured, 2052 (66.9%) had intensities greater than or equal to $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, all non-hydrogen atoms being positioned from an *E*-map. Hydrogen atoms were positioned from a subsequent difference map. In the final stages of

refinement the non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. The scattering factors of ref. 6 were used for non-hydrogen atoms and those of ref. 7 for hydrogen atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix refinement of 260 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (8–10). The final value of g was $0.74(13) \times 10^4$. Convergence was reached at $R = 0.041$ and $R_w = 0.052$ for 2052 reflections with $I \geq 3\sigma(I)$. For all 3067 reflections $R = 0.073$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.009 and 0.117σ, respectively. The mean error in an observation of unit weight was 2.130. A final difference map showed maximum fluctuations of −0.40 to +0.28 e Å^{-3}, both near O(2), and was essentially featureless elsewhere. The final positional and thermal parameters appear in Tables 1 and 6[3], respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3] The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (11). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0012 Å^2. The subunits PhB and (maltolato)B were analysed separately (rms $\Delta U_{ij} = 0.0016$–0.0031 Å^2). The appropriate bond distances have been corrected for libration (11, 12), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 3. Intra-annular torsion angles defining the conformation of the five-membered chelate ring are listed in Table 4. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 7–9) are included as supplementary material.

Results and discussion

The crystal structure of (maltolato)diphenylboron consists of discrete molecules separated by normal van der Waals distances. The shortest intermolecular contact between non-hydrogen atoms is C···C = 3.295(4) Å. The molecule (Fig. 1) has as its central feature a fused-ring system which is planar to within 0.054(2) Å. Each of the three six-membered rings in the molecule is slightly, but significantly, non-planar (maximum deviation from the mean plane = 0.010(3) Å), while the five-membered C_2O_2B ring has a flattened B-envelope conformation with the boron

[3]The structure factor table, Table 6 (anisotropic thermal parameters) and other material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

atom displaced 0.081(2) Å from the C_2O_2 plane (see Table 4). The conformation of the C_2O_2B ring in **1** is intermediate between the essentially planar rings in **2** (13) and **3** (14) and the more folded envelopes observed in **4***a* and **4***b* (15).

The O—B and B—C distances in **1** are relatively long and short, respectively, when compared with those observed in other O,O-chelates of "Ph_2B^+" (compounds **2**–**9**, see Table 5), consistent with weak binding of the maltolate oxygen atoms to boron. The O(3)—B distance of 1.600(3) Å[4] is the longest O—B bond yet observed for a Ph_2BO_2 compound. Other long O—B distances occur in **4***a* (15), for the pyridinic oxygen atom in **9** (16), and for the aldehyde oxygen atom in **8** (17). In general the two O—B distances in **1**–**9** differ significantly from one another, by as much as 0.100(6) Å in **9**. Only in compound **3** are the two O—B bond lengths equal within experimental error. Despite the sometimes considerable differences between the two O—B bond lengths, the average O—B distance is a good indicator of the binding strength of the *O*,*O*-chelating ligand to the Ph_2B moiety. The B—C distances, which differ by a maximum of 0.020(7) Å in **9**, also reflect this property. In fact, the sum of all bond lengths involving the boron atom is essentially constant for a given chelate ring size: 6.328(7) Å for five-membered (**1**–**5**[5]) and 6.28(1) Å for the six-membered chelates **7**–**9**. Compounds **1**–**9** fall into three

C(3)—O(2)—B —O(3)	−4.4(2)

[4]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion of the geometry of the boron atom and are compared with similarly treated distances unless otherwise stated.

[5]Compound **6** with a distance sum of 6.283(6) Å is anomalous as a result of O—B bond shortening to compensate for a sterically lengthened intra-annular N—C bond (18).

*Average values for the two ordered ligands.

groups. The weakest O—B binding occurs for compounds **1**–**4**, which all possess unsaturated five-membered chelate rings. The longest mean O—B distances for this group occur in **1** and **4**, which both contain strained ring systems consisting of planar six-membered rings fused to nearly planar five-membered rings. Compounds **5** (19) and **6** (18) contain fully saturated five-membered chelate rings, these particular ligands being among the best donors known for the "Ph_2B^+" cation. Compounds **7** (13), **8** (17), and **9** (16) all contain less strained six-membered chelate rings.

The ν_{CO} band in the ir spectrum of **1** at 1640 cm^{-1} suggests that O(3) is less strongly bound to the boron atom than are the corresponding oxygen atoms to Al in tris(maltolato)aluminum (ν_{CO} = 1617 cm^{-1}) (1). The relative weakness of the O(3)—B bond with respect to chemically similar bonds has been discussed above. The ratios of the long and short bond distances to the maltolate O atoms in the B and Al complexes (1.044 and 1.029, respectively) further support a stronger interaction of the keto oxygen atom with aluminum. In apparent contradiction to the ir data, the (uncorrected) C(4)—O(3) distance in **1** is 0.016(4) Å longer than the corresponding mean (for the two ordered ligands) in tris(maltolato)aluminum. This may result from the greater ring strain in **1** (see below).

In general, the bond lengths in the 4-pyrone moieties in **1** and tris(maltolato)aluminum are similar to one another and to those in 2,6-dimethyl-4-pyrone hydrobromide monohydrate (20) (see Table 5), the C—O distance involving the protonated keto oxygen atom in the latter structure being slightly longer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

than the corresponding distances in the maltolate complexes. Although the structure of maltol itself has not been determined, the related structures of 4-pyrone (21) and 2,6-dimethyl-4-thiopyrone (22) indicate that upon coordination the keto C—O distance increases relative to that in 4-pyrone while the adjacent ring C—C distances decrease slightly. The remaining bond lengths are essentially unchanged.

There are some significant differences between the maltolate ligands of **1** and tris(maltolato)aluminum. The most prominent of these is the difference in the ligand bite (O(2)···O(3)) which is reduced from an average value of 2.562(8) Å in the Al complex to 2.384(2) Å in **1**. The O···O distance in the free ligand would be expected to be approximately 2.75 Å. This change is achieved primarily by angular deformations about the ring junction atoms C(3) and C(4); angles in the chelate ring decrease with compensatory increases in the exocyclic O—C—C and (to a lesser extent) the C—C—C angles in the six-membered heterocycle. Both C—O distances in the chelate ring of **1** are longer, and the C(3)—C(4) bond shorter than the corresponding mean values in tris(maltolato)aluminum. This could result from partial electron delocalization and/or the increased ring strain in **1**.

Lanostane to cucurbitane transformations[1,2]

O. E. EDWARDS[3] AND R. J. KOLT

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received June 27, 1986

O. E. EDWARDS and R. J. KOLT. Can. J. Chem. **65**, 595 (1987).

Transformation of 3,7,9,11-tetraoxygenated lanostane derivatives into 3,7,11-trioxygenated cucurbit-1(10)-enes and cucurbit-5(10)-enes has been achieved. Attempts to convert the latter in good yield into cucurbit-5-enes are documented. The steric and electronic factors influencing the course of dehydration, under Westphalen conditions, of 9α-hydroxylanostane derivatives are discussed. Unusual autooxidation and dehydrogenation promoted by rhodium trichloride and iron pentacarbonyl are described.

O. E. EDWARDS et R. J. KOLT. Can. J. Chem. **65**, 595 (1987).

On a réalisé la transformation de lanostanes tétraoxygénes en 3, 7, 9 et 11 en cucurbitènes-1(10) (ou -5(10)) trioxygénés en 3, 7 et 11. On présente des exemples d'essais de transformation, avec de bons rendements, de ces derniers en cucurbitènes-5. On discute des facteurs stériques et électroniques qui influencent le cours de la déshydratation, utilisant les conditions de Westphalen, de dérivés de l'hydroxy-9α lanostane. On décrit des réactions inhabituelles d'autooxydation et de déshydrogénation qui sont favorisées par le trichlorure de rhodium et le pentacarbonyle de fer.

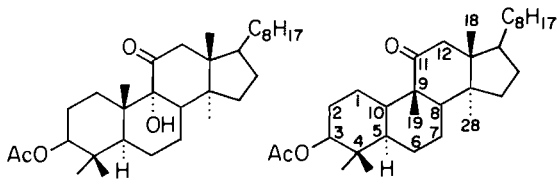
Work of Edwards and Paryzek (1) on the Westphalen-type dehydration of 3β-acetoxy-9α-hydroxylanostan-11-one **1** showed that this produced a pair of cucurbitenes[4] **2** and **3** with 1(10) and 5(10) double bonds respectively. The problem of how to convert these into the desired cucurbitacins with 5,6 double bonds (e.g., 25-deoxybryogenin acetate **4**), and the hope of improving the yields of products of migration of C-19 from C-10 to C-9, led us to place an additional carbonyl at C-7. We anticipated facile migration of any 5(10) double bond into conjugation with the 7-carbonyl. In addition, as has been pointed out by Paryzek (2) and Baddeley *et al.* (3), this carbonyl might suppress backbone rearrangement involving a transient positive charge on C-8, thus increasing the yield of 19(10→9β) *abeo*-products. On the other hand, we faced the possibility that the leaving group on C-9 might eliminate to give a large proportion of the 8-en-7-one derivatives.



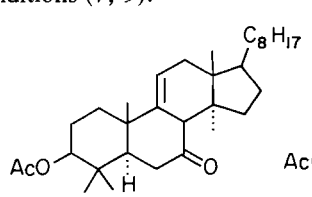
1

2 5αH, 1(10) double bond
3 5(10) double bond
4 10αH, 5(6) double bond

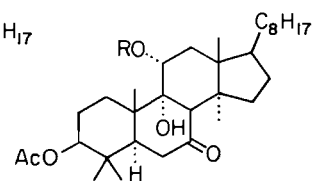
Work by Hartshorn and co-workers (4) and Jones and Marples (5) on the Westphalen dehydration–rearrangement showed that an acetoxy group on the carbon adjacent to the tertiary hydroxyl group being eliminated was effective in promoting methyl group migration. This was borne out in our earlier work (1). It also seemed possible that the electron-withdrawing action of a 7-acetoxy group might suppress backbone rearrangement (see above) without promoting simple elimination of water from a 9α-hydroxy compound. Hence the work developed into a study of Westphalen-type rearrangements of 9α-hydroxy-lanostanes with various combinations of carbonyl and acetoxy groups on C-7 and C-11.

Results

An efficient route to 3,7,9,11-tetraoxygenated lanostanes proved to be through chromic acid oxidation of the readily available 3β-acetoxy-7,9(11)-diene (dihydroagnosteryl acetate) to 3β-acetoxy-5α-lanost-9(11)-en-7-one **5** (6) followed by osmium tetroxide oxidation to the 9α,11α-diol **6*a***. Attempts to do the hydroxylation using catalytic amounts of osmium tetroxide with other oxidants (7) failed. Modified Moffatt oxidation (8) of the diol gave the 9α-hydroxy-7,11-dione **7**. However, purer **7** was obtained directly from **5** by addition of a molar equivalent of osmium tetroxide followed by oxidation of the osmate ester with hydrogen peroxide in a tetrahydrofuran–pyridine mixture. In the latter reaction full advantage was taken of the susceptibility of *cis*-diols to further oxidation under Milas-type conditions (7, 9).



5



6*a* R = H
b R = Ac
c R = CH_2SCH_3

The desired variations in functionality at C-7 and C-11 were achieved as shown in Flowsheets I and II and eq. [1] using (*a*) lithium aluminohydride reduction of the 7-carboxyl of **5** to give the 7β-alcohol, (*b*) metal hydride reduction of 11-carbonyl groups to give the 11β-alcohols, (*c*) catalytic reduction of a 7-carbonyl to give the 7α-alcohol, (*d*) lithium aluminohydride reduction of the 7,11-dione **7** giving a reasonable yield of the 3β- and 7β,11β-triol, and (*e*) selective acetylation of 3β- and 7β-hydroxyl groups in the presence of an 11β-hydroxyl group.

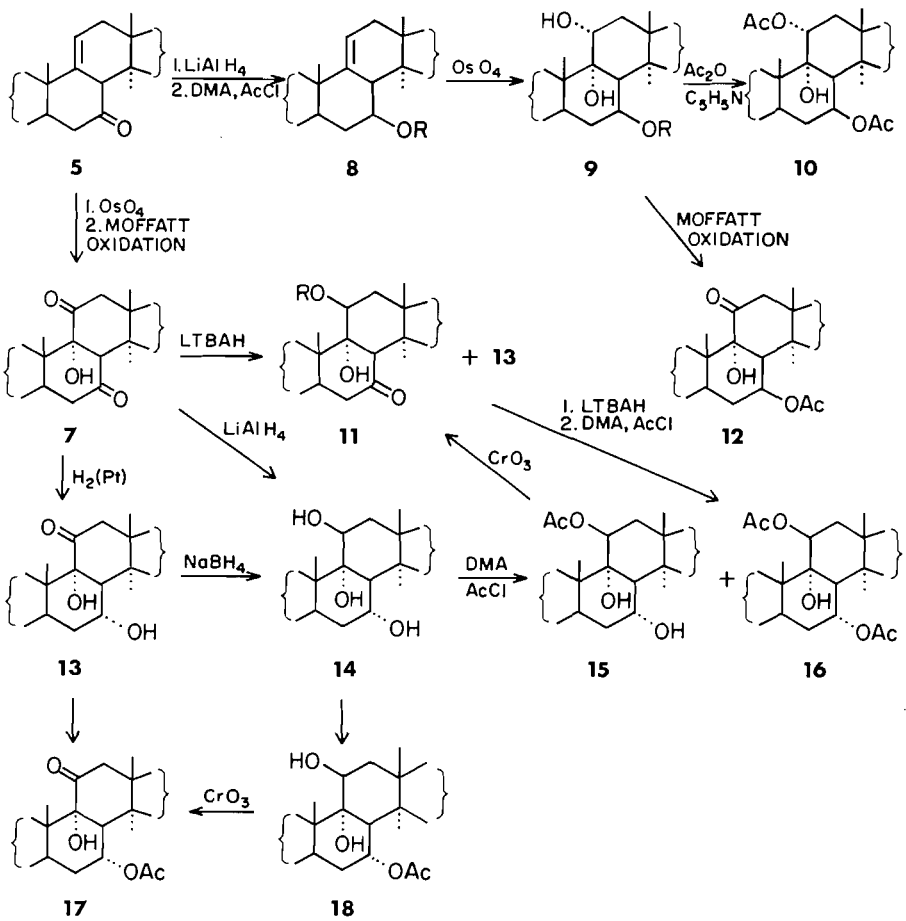
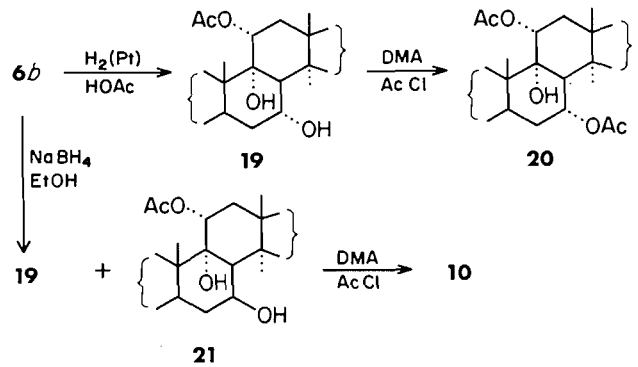
FLOWSHEET 1



The Westphalen dehydration studies were all done using the same sulfuric acid – acetic acid – acetic anhydride mixture. The results are summarized in Table 1.

It is noteworthy that the compounds with 11β-acetoxy groups gave no significant amount of cucurbitenes. The outstanding yields of 9-methyl products were in the reaction of the 7α-acetoxy-11-one **17** (78% based on unrecoverable starting material) and the 7β-acetoxy-11-one **12** (90%). A dramatic reversal of the ratios of 1(10)-ene to 5(10)-ene occurred in the change from 11-one to 11α-acetate. Since at present the 5(10)-enes are more useful for conversion to cucurbitacins, via the 5-en-7-one derivatives (2), this makes the 11α-acetoxy-7-one ***6b*** the most valuable substrate despite the lower yield (49%) of 9-methyl

FLOWSHEET 2



[1] **7** $\xrightarrow[2.\,DMA\text{-}AcCl]{1.\,LiAlH_4}$ **16** + **22**

products. Although the ratio of olefins was even better for the 7β,11α-diacetoxy compound **10**, the gain was more than offset by the extra steps needed to obtain a 5-en-7-one.

By-products in which no C-19 migration had taken place were identified for five of the substrates. These were as follows:

From ***6b***, 3β-11α-diacetoxy-5α-lanost-8-en-7-one ***24b*** (10%); 3β-acetoxy-18(13→12β) *abeo*-5α-lanosta-8,13(17)-dien-7-one **30** (5%); 3β-acetoxy-18(13→12β) *abeo*-5α-lanosta-8,11,13(17)-trien-7-one **35** (0.5%); 3β-acetoxy-5α-lanostana-7,11-dione **33** (8%); and 3β,11β-diacetoxy-5α-lanost-8-en-7-one ***24a*** (1.5%)

From **7**, 3β,9α-diacetoxy-5α-lanostana-7,11-dione **25** (23%) and 3β-acetoxy-5α-lanost-8-en-7,11-dione (12%)

From **11**, 3β,7,11-triacetoxy-5α-lanosta-7,9(11)-diene **29** (24%); 3β-acetoxy-5α-lanostana-7,11-dione **33** (32%); and 3β,11β-diacetoxy-5α-lanost-8-en-7-one ***24a*** (6%)

From **16**, 3β,7α-diacetoxy-5α-lanostan-11-one **28** (R^1 = H, R^2 = OAc) (57%)

From **22**, 3β,7α-diacetoxy-5α-lanostan-11-one **28** (R^1 = OAc, R^2 = H) (47%) and 3β,7β,11-triacetoxy-5α-lanost-9(11)-ene **43** (11%)

It was of interest to study other leaving groups at C-9. Indeed,

*Well-characterized products not involving C-19 migration.
†Based on unrecoverable starting material.

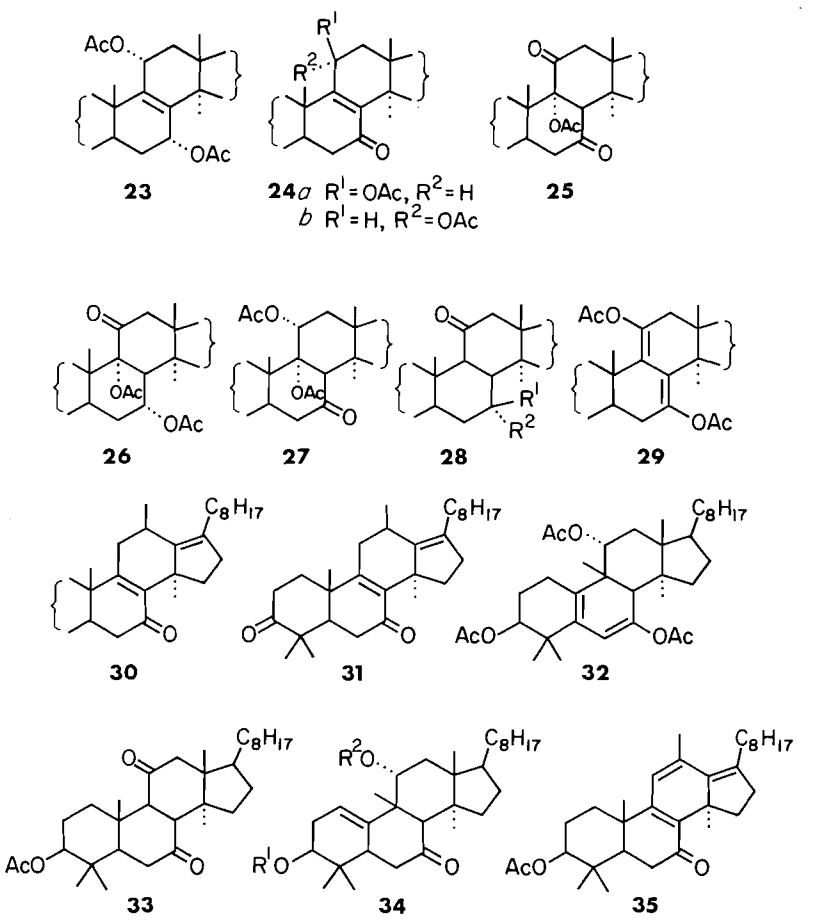
the initial intention was to prepare and deaminate 9α-amino compounds (1, 10). The 9α-acetoxy-7,11-dione **25** was obtained as a by-product of the Westphalen dehydration of **7**, and as the product of acetylation of **7** using perchloric acid in acetic anhydride. Attempts to prepare the corresponding mesylate directly using methanesulfonyl chloride, or indirectly via the methanesulfinate (11), failed.

The 9α-acetoxy compound was quite stable. Slow decomposition took place at 195°C. The only product characterized was the 8-en-7,11-dione.

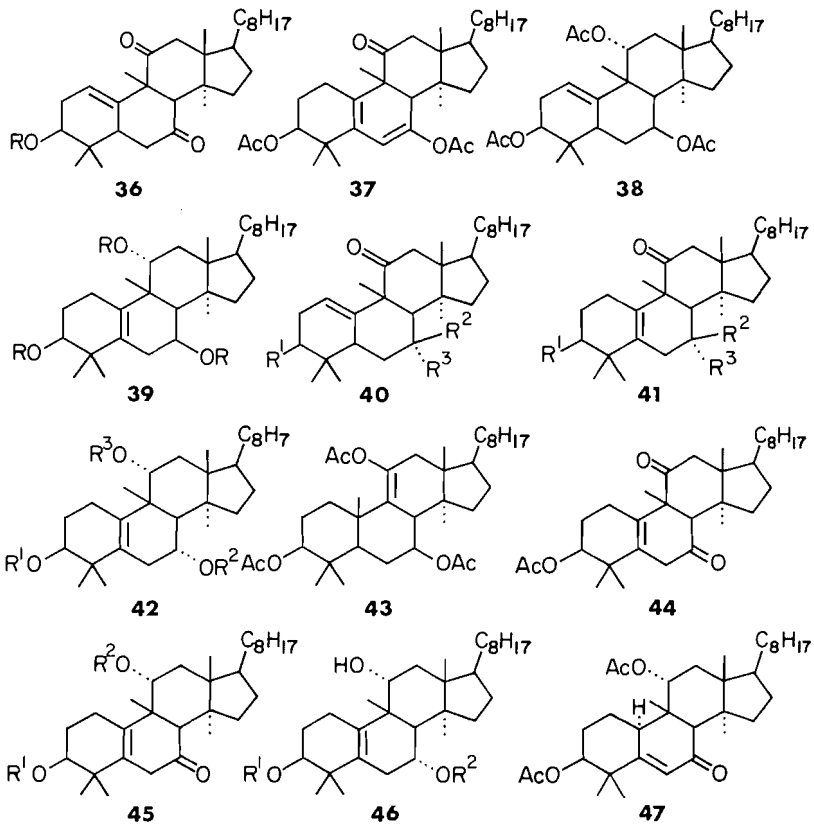
In view of the success of Paryzek (2) and Baddeley *et al.* (3) in the use of boron trifluoride in acetic anhydride, we examined its use as a dehydrating agent for our 9α-hydroxy compounds ***6a***. However, the reagent mainly acetylated the 9-hydroxyl group giving 46% of **27**. Only a small amount (9%) of the acetoxydiene **32** was produced.

Initial attempts to isomerize the 5(10)-en-7-one **45** to the conjugated 5-en-7-one **47** using potasssium hydroxide in methanol resulted in oxidation and hydrolysis to 3β,6,11α-trihydroxycucurbit-1(10),5-dien-7-one **48** (R = H). This had λ_{max} 337 nm, shifting to 383 nm in alkali. The corresponding triacetate had λ_{max} 305 nm with a weaker maximum at 240 nm and nmr spectra in accord with the assigned structure (**48**, R = Ac). A comparable 6-acetoxy dienone **49** was formed by the action of alkali on the 5(10)-en-7,11-dione **44**, followed by reacetylation.

When solutions of the enol acetate **32** or the 5(10)-en-7-one



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.



45 in 95% ethanol were degassed by boiling under argon, and a similarly degassed solution of potassium hydroxide in the same solvent was added, a maximum at 300 nm appeared followed by one at 240 nm. We attribute these to the enolate anion **48**, $R^1 = R^2 = Ac$, $R^3 = O^-$, and the 5-en-7-one **47** respectively. Again a slow development of a maximum at 380 nm occurred. After acid work-up and separation on silical gel, fractions with λ_{max} 255 and 335 nm were obtained. Thus simple conjugation had not been achieved.

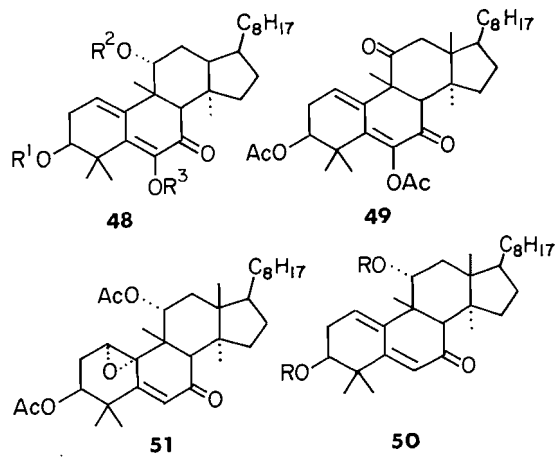
The action of dilute perchloric acid in 95% ethanol at 65°C on the enol acetate **32** or 5(10)-en-7-one **45** produced mixtures containing some product with λ_{max} near 245 nm. Since the yield of this was low, this approach was abandoned.

The best method found for producing the conjugated enone **47** from the enol acetate **32** was the use of a refluxing solution of sodium carbonate in aqueous methanol, followed by reacetylation. In this way a modest 12% conversion to **47**, identical to a previously prepared sample (12), was achieved. Two other isomers of **47** were characterized and presence of a fourth possible isomer detected.

A different approach to production of the conjugated enone **47** was based on the work of Edward and Alper (13). It was hoped that complexation of the homoannular diene of **32** with iron pentacarbonyl would mobilize the double bonds and effect isomerization to the corresponding 5,7-diene. This enol acetate would presumably hydrolyse to the 5-en-7-one **47**. In actuality, dehydrogenation and hydrolysis took place when **32** was heated with iron pentacarbonyl in diglyme, leading to 3β,11α-diacetoxycucurbita-1(10),5-dien-7-one **50** (79% based on unrecovered **32**).

The dienone **50** has recently been described as a product of the action of $BF_3 \cdot Et_2O$ in acetic anhydride on 3β-acetoxy-9α,11α-epoxy-lanost-5-en-7-one (14). Its uv, ir, and ^1H nmr spectra correspond reasonably well with those reported, as did those of the corresponding diol.

In a related attempt to rearrange the 5(10)-en-7-one to the 5-en-7-one, **45** (R = Ac) was heated in alcohol with rhodium trichloride. This reagent is known to isomerize double bonds (15). However, the same dehydrogenation resulted, producing **50** as major product. Palladium-on-charcoal in refluxing benzene also catalysed the same dehydrogenation.



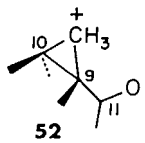
Samples of the dienol acetate **32** oxidized when left in air as a gum or froth for several months. Analysis and spectroscopic evidence showed that this was an α,β-unsaturated ketone, with the 3- and 11-acetate groups intact and a new ether oxygen. The evidence was consistent with it being 3β,11α-diacetoxy-1α,10α-epoxycucurbit-5-en-7-one **51**. Paryzek and Wydra (12) had assigned this structure to an autooxidation product of **32** obtained from 3β-acetoxy-9α,11α-epoxy-5α-lanostan-7-one, and the properties were identical.

Discussion

A good body of evidence exists that cyclic carbocations are destabilized by the presence of an adjacent carbonyl group (1,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

10, 11, 16, 17) and that they are usually only formed with the aid of charge delocalization by σ-bond participation or other neighboring group participation. It also appears that when σ-bond participation is involved, corner- and edge-protonated cyclopropanes are either intermediates or transition states on the way to products (18, 19). Thus the methyl migrations encountered in this work and other Westphalen rearrangements likely involve the methyl-bridged ion (corner-protonated cyclopropane) **52** or a transition state closely resembling this. The same applies to methyl migrations during deamination of 9α-amino- and 12α-amino-11-keto steroids (10). Our anticipation that intermediates such as **52** would lead to some cyclopropanes (in the present work, cycloartane derivatives) was not realized. This may be due to the high proton acidity of the medium, suppressing proton loss from **52**.



52

In harmony with the observations of Hartshorn and co-workers (4) and Jones and Marples (5), an α-acetoxy group on C-11 was nearly as effective as an 11-carbonyl in inducing methyl migration. However, the presence of an 11β-acetoxy group blocked methyl migration. Two factors could be involved in this. One is steric interference with methyl movement toward C-9, thus blocking formation of the methyl-bridged ion. The other is acetate participation in the ionization of the C-9 oxygen bond, taking the place of the 10-methyl group participation.

Most of the other results shown in the table can be rationalized on the basis of a few assumptions:

(*a*) That mixed anhydride (acetylsulfate) formation was rapid in all cases, as suggested by Hartshorn and co-workers (4) and that in all the cases studied except that of the 7α,11α-diacetoxy compound **20** this hydrolysed rapidly in contact with a tlc plate. Thus remaining mixed anhydride showed up as starting material.

(*b*) That the rate-determining step in the reactions was the ionization of the C(9)—O bond. This was slow in the case of the 7,11-dione **7** because of the two powerful electron-withdrawing groups, but was more rapid in the cases of **12** and **17** where one of the carbonyls had been replaced by an acetoxyl group.

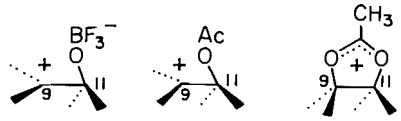
(*c*) That protonation of the mixed anhydride was needed to initiate the C—O bond rupture in the mixed anhydride. This is the only way in which we can account for the exceedingly slow rate for the 7α,11α-diacetoxy compound **20**. We argue that the two bulky acetoxy groups block approach of solvated protons to the anhydride and also act as competing bases.

(*d*) That acetylation of the 9α-hydroxy group could only occur when crowding of the α-face was minimal (e.g., for the 7,11-dione), and it results from acetic acid attack on the acetylsulfate with O—SO_2 bond rupture.

(*e*) The dramatic change in ratio 1(10)-ene to 5(10)-ene in going from the 11-one **7** to the 11α-acetate **6*b*** can be explained if the 11α-acetate blocks removal of the 1α-hydrogen by external bases, or if the 11-carbonyl acts as internal base assisting removal of the 1-hydrogen, or if both factors operate.

The most unusual observation is the slow reaction of the 7α,11β-diacetoxy compound **16**. A conformational change due to the interaction of the 11β function with the 10- and 13-methyl groups may make the 9α-substituent less accessible to solvated protons (see point (*c*)).

The opening of saturated 9,11-epoxides with boron trifluoride in any medium but acetic anhydride failed to give 10-methyl migration (2, 3, 20). This suggests that the attacking species in the anhydride medium is the acylium ion. Thus the different behavior in acetic anhydride could be a consequence of the difference between zwitterions **53** and the more isolated cations represented by **54** (see also ref. 14). We can only reconcile our observations on the 11β-acetates with the results for 9β,11β-epoxides (2, 3) if the cationic carbon of **54** is free to form a methyl bridged ion (**52**), while in our cases the ionization of the 9-O bond leads (with participation of the 11β-acetate) directly to the delocalized ion **55**. We postulate that **55** would give no methyl migration. Instead, elimination of protons on C-8 or C-11 would lead to 8-enes or 9(11)-enes respectively. Both types of product were actually observed, in addition to the 11-ketones arising by hydrolysis of the enol acetates.



53 **54** **55**

Although the yield of the β,γ-unsaturated ketone **45** was good, conversion of this to the desired conjugated stereoisomer **47** was low. Since it was accompanied, depending on the time of heating in base, by one or two stereoisomers, it appears that the rate of isomerization is comparable to that of epimerization at C-8 and C-10. It has been assumed that the first center to be inverted is C-10 (2, 3). However, this has not been rigorously established, hence we reserve judgement on the configuration of our new isomers.

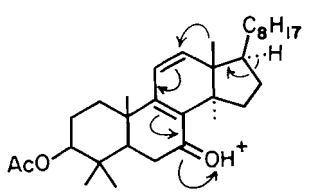
Since we were unable to form **47** by acid-catalysed isomerization of **45** or by the action of transition metals or palladium-on-charcoal on **45** or **32**, further research is needed in the Westphalen route is to be an efficient one to cucurbitacins (8β,10α-cucurbit-5-enes).

The facile dehydrogenation of the 5(10)-ene-7-one **45** to the 1(10),5-dien-7-one **50** must reflect a relief of nonbonded interactions as rings A and B are flattened. A similar dehydrogenation had been observed earlier in oxidation of cucurbitacins having a carbonyl on C-2 (21).

The very facile Barton-type oxidation (22) of the 5(10)-en-7-one derivatives **44** and **45** to 6-hydroxydienones, even in as weak a base as sodium carbonate in aqueous methanol, reflects the acidity of the proton on C-6.

The formation of the dienone **31** and trienone **35** from the 11α-acetoxy-9α-hydroxy-7-one **6*b*** was unexpected. The formation of **31** from the corresponding 9α,11α-epoxide has been described by Paryzek and Wydra (12) who have discussed possible mechanisms for its formation. Under our reaction conditions, formation of the conjugated dienone by double elimination, followed by proton-catalysed rearrangement as shown in **56**, is a plausible possibility. (See, however, ref. 12.) The dehydrogenation to **35** must be produced by oxygen.

The autooxidation of the enol acetate **32** is remarkable. Two possible mechanisms for the air oxidation are shown in Flow-



56

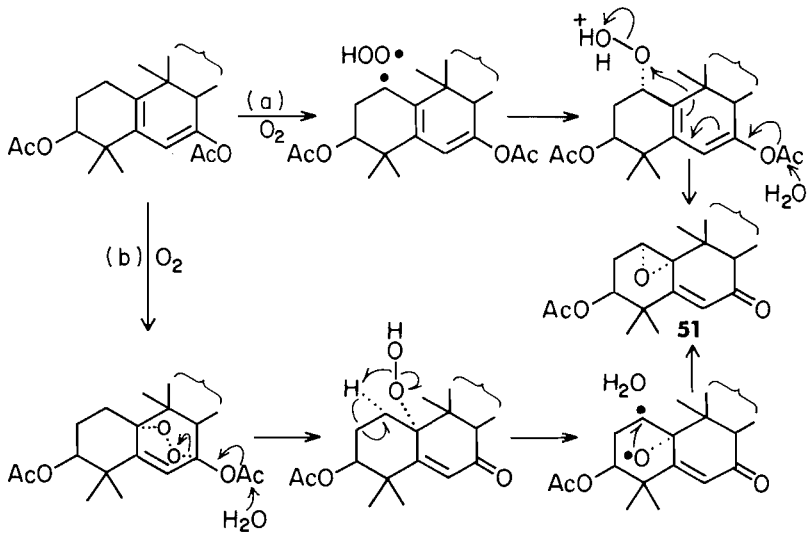
For personal use only.

FLOWSHEET 3



sheet 3. In view of the well-known epidioxide formation from ergosterol (23), mechanism (b) is attractive. Mechanism (a) has also been proposed by Paryzek and Wydra (12), who observed the same phenomenon.

Nuclear magnetic resonance spectra

The ^{13}C nmr spectra of compounds prepared in this work are listed in Tables 2–5. The assignments are based on multiplicity, known substituent effects, and assignments previously made by Baddeley and co-workers (3) and Paryzek and Wydra (12) for related compounds. However, the availability of good quantities of 3β-acetoxycucurbit-1(10)-en-7,11-dione **36** and the distinctive chemical shifts due to its functional groups prompted us to use it to check these assignments by using other nmr techniques.

It seemed likely that the proximity of the 1- and 19-hydrogens would give rise to significant nuclear Overhauser effects. However, irradiation of any of the methyl signals (δ 0.7–1.25) failed to produce a noticeable intensity change for the 1-hydrogen signal, and conversely irradiation of the 1-hydrogen gave no effect on the methyl signal intensities.

The use of ^1H COSY spectra, especially with emphasis on long range couplings ($J \sim 1$ Hz) coupled with ^1H–^{13}C correlations, made it possible to assign shifts to hydrogens on C-18 (δ 0.71, coupled to the lowest field 12-hydrogen), C-28 (δ 1.25, coupled with the 8-hydrogen and a 15-hydrogen near δ 1.42), C-29 (0.88, coupled with the 3-hydrogen), and C-30 (0.78, coupled with the 3-hydrogen). Thus the signal at δ 1.05, which had long range coupling with the 8-hydrogen, could be assigned to the 19-hydrogens. The ^1H–^{13}C correlation then gave a ^{13}C shift for C-19 of 20.2 ppm. It followed also that C-30 had the highest chemical shift (13.3) but that C-28 resonated at 30.8 ppm. Thus it appears that many of the C-19, C-28, and C-29 assignments in our tables and those of other workers (3, 12) should be revised. However, since we are unable to provide nmr evidence comparable to that for **36** we have not altered the original assignments for the other compounds.

Experimental

The instrumentation and separation techniques were as described previously (1). Abbreviations used are LAH (lithium aluminum hydride, LTBAH (lithium tri-*tert*-butoxyaluminohydride), DMA (dimethylaniline). Unless otherwise stated, rotations were of chloroform solutions, infrared spectra were taken in chloroform, and ultraviolet spectra in 95% ethanol.

Substrates and reference compounds

3β-Acetoxy-5α-lanostan-9(11)en-7-one (5). The enone **5** was prepared by chromium trioxide oxidation of either 24,25-dihydrolanosteryl acetate (**6***a*) or 24,25-dihydroagnosteryl acetate (**6***b*). The yield was better in the latter case (ca. 23%). The major impurity in both cases was 3β-acetoxy-5α-lanost-8-en-7,11-dione.

Compound **5** gave ^1H nmr signals at δ 5.41 (m, 1H, 11), 4.49 (t, J = 5 Hz, 3α), 2.87 (m, 1H, 8β), 2.35 (s, part of signals for H-6), 2.06 (s, 3H, CH_3CO), 1.12, 0.93, 0.90, 0.83, 0.76, and 0.68 (singlets, 3H, CH_3's).

3β-Acetoxy-9α,11α-dihydroxy-5α-lanostan-7-one (6a). A solution of 1.9 g of enone **5** and 1 g of osmium tetroxide in 12 mL of dry pyridine was stirred in the dark under argon for two days. A Solution of 3.6 g of sodium metabisulfate in 60 mL of water and 50 mL of pyridine was added. The dark viscous mixture was stirred for 2 h, by which time it became an orange solution. This was extracted three times with dichloromethane, then the dichloromethane solutions washed successively with water, 2*N* hydrochloric acid, saturated sodium carbonate solution, and water. The dried organic layers yielded a product that crystallized from methanol–chloroform mixtures, giving 1.7 g of dihydroxy ketone **6***a*, mp 218–220°C; $[\alpha]_D$ +33° (*c* 1.0); ν_{max}: 3610, 3520 (br), 1725 and 1710 cm^{-1}; ^1H nmr, δ: 4.41 (m, 1H, 3α), 4.24 (m, 1H, 11β), 3.28 (s, 1H, OH), 2.60 (s, 1H, 8β), 2.31 (s, 2H, 6), 2.04 (s, 3H, CH_3CO), 1.27, 1.19, 0.90, 0.86, 0.82, and 0.78 (CH_3 groups). *Anal.* calcd. for $C_{32}H_{54}O_5$: C 74.09, H 10.49; found: C 74.15, H 10.48.

Attempts to oxidize **5** using partial molar equivalents of osmium tetroxide with *N*-methylmorpholine *N*-oxide (24) or $Ba(ClO_3)_2$ (7) as oxidants only produced small amounts of **6***a*. Hydroxylation of the double bond by potassium permanganate under basic (basic potassium permanganate, ref. 25) or neutral (using water instead of 40% sodium hydroxide as the aqueous phase) phase transfer conditions, or by barium permanganate in pyridine gave mainly 3β-acetoxylanost-8-ene-7,11-dione.

3β,11α-Diacetoxy-5α-lanostan-9α-ol-7-one (6b). One gram of diol **6***a* in 5 mL of acetic anhydride and 5 mL of pyridine was left at room temperature overnight. The solution was poured into 20 mL of saturated aqueous sodium bicarbonate, then the product extracted into benzene. After removal of the benzene **6***b* crystallized from hexane, yield 1 g, mp 174–176°C; $[\alpha]_D$ +40° (*c* 1.2); ν_{max} 3600 and 1725 cm^{-1}; ^1H nmr, δ: 5.40 (dd, J_1 = 6.5 Hz, J_2 = 10 Hz, 1H, 11β), 4.42 (t, J = 6 Hz, 1H, 3α), 2.74 (s, 1H, OH), 2.64 (s, 1H, 8β), 2.31 (d, 2H, 6), 2.05 (s, 6H, CH_3CO's), 1.29, 1.22, 1.16, 0.89, 0.86, and 0.82 (CH_3's). *Anal.* calcd. for $C_{34}H_{56}O_6$: C 72.82, H 10.06; found: C 72.95, H 9.89.

Dehydration of **6***b* using thionyl chloride in pyridine gave 3β,11α-diacetoxy-5α-lanost-8-en-7-one (**24***b*).

3β-Acetoxy-9α-hydroxy-5α-lanosta-7,11-dione (7)

(a) By osmium tetroxide – hydrogen peroxide oxidation of **5** *(7, 9).* Two grams of osmium tetroxide was added to a solution of 3.8 g of 9,11-olefin **5** in 25 mL of dry pyridine. The mixture was stirred in the dark under argon for 3 days, then the bulk of the pyridine removed *in vacuo* at 50°C. The residue was dissolved in 50 mL of tetrahydrofuran, then 40 mL of 30% hydrogen peroxide was added slowly with stirring while cooling in an ice bath. After 1 h in the ice bath 5 g of sodium metabisulfite was added and the mixture stirred for 2 h at room temperature. The product was recovered as described for the hydroxylation of **5**. Crystallization from methanol–dichloromethane gave 2.4 g (59%) of hydroxy-dione **7**.

(b) By dimethylsulfonium chloride oxidation of **6***a (26).* Dimethylsulfide (0.24 mL, 3.19 mmol) was added under argon to a solution of 319 mg (2.39 mmol) of *N*-chlorosuccinimide in 10 mL of dichloromethane at −25°C. After 15 min at −25°C a solution of 331 mg (0.64 mmol) of diol **6***a* in 2 mL of dichloromethane was added. The cooling bath was removed, then after 15 min 50 mL of ether was added. The solution was washed with 0.2 *N* hydrochloric acid, water (3 times), then dried over magnesium sulfate. The 295 mg of crude product was separated on silica gel plates using 5:1 benzene – ethyl acetate, giving 151 mg of hydroxydione **7** and 102 mg of the slightly less polar methylthiomethyl ether **6***c*.

(c) By modified Moffatt oxidation of **6***a (8).* A mixture of 2.0 g of diol **6***a*, 400 mg of pyridine, 320 mg of dichloroacetic acid, 2.64 g of dicyclohexylcarbodiimide, 15 mL of dimethylsulfoxide, and 10 mL of benzene was stirred in a stoppered flask for 22 h at room temperature. A solution of 4 g of oxalic acid in 5 mL of methanol was added carefully, then the mixture stirred for 2 h. Water and benzene were added, then the precipitate removed by filtration, and the solid washed well with benzene. The benzene layers were washed with saturated aqueous oxalic acid, 5% sodium carbonate solution, dried, and distilled. The product crystallized from acetone–water giving 1.65 g (92%) of crude hydroxydione **7**, mp 195–205°C. This was contaminated with a small amount of the methylthiomethyl ether **6***c*, which could be removed by recrystallization or separation on silica gel.

The 9α-hydroxy-7,11-dione **7** had mp 215–218°C; $[\alpha]_D$ +55° (*c* 1.2); ν_{max} 3575, 3440, and 1712 cm^{-1}; ^1H nmr, δ: 4.48 (t, J = 7.5 Hz, 1H, 3α), 3.39 (s, 1H, OH), 3.25 and 3.07 (singlets, 1H, part of d of d for the 12-hydrogens), 2.88 (s, 1H, 8β), 2.4–2.1 (m, ca. 2H, 6), 2.03 (s, 3H, CH_3CO), 1.38, 1.29, 0.93, 0.90, 0.85, 0.83, and 0.76 (CH_3s). *Anal.* calcd. for $C_{32}H_{52}O_5$: C 74.37, H 10.14; found: C 74.66, H 10.34.

3β-Acetoxy-9α-hydroxy-11α(methyl thiomethoxy)-5α-lanosta-7-one (6c). Thiomethyl ether **6***c* crystallized as plates from hexane–dichloromethane. It had mp 209–212°C; $[\alpha]_D$ +6.5° (*c* 0.5); ν_{max}: 3550, 1720, and 1710 cm^{-1}; ^1H nmr, δ: 4.67 (s, 2H, S—CH_2—O), 4.47 (m, 1H, 3α), 4.09 (dd, 1H, J_1 = 6.3 Hz, J_2 = 10 Hz, 11β), 3.09 (d, 1H, J = 2 Hz, OH), 2.60 (d, 1H, J = 1.5 Hz, C-8), 2.31 (s, 2H, 6), 2.18 (s, 3H, S—CH_3), 2.05 (s, 3H, CH_3CO), 1.28, 1.21, 0.92, 0.90, 0.877, 0.83, and 0.76 (CH_3CO). *Anal.* calcd. for $C_{34}H_{58}O_5S$: C 70.55, H 10.10, S 5.53; found: C 70.55, H 10.18, S 5.71.

Dehydration of 3β-acetoxy-9α-hydroxy-5α-lanosta-7,11-dione (7)

Twenty-five microliters of thionyl chloride was added to an ice-

cold solution of 40 mg of **8** in 0.5 mL of pyridine. After 0.5 h crushed ice was added to the mixture. The resulting solid was collected on a sintered glass funnel and washed with water. It was dissolved in chloroform. The dried solution yielded 32 mg of 3β-acetoxy-5α-lanost-8-ene-7,11-dione, identical (ir, uv, ^1H nmr) with authentic material.

*3β,7β-Diacetoxy-5α-lanost-9(11)-ene (**8**, R = Ac).* This was prepared by reduction of **5** using lithium aluminum hydride in refluxing ether (27) followed by acetylation of **8** (R = H) in 1:1 acetic anhydride – pyridine at 85°C for 1 h, then 16 h at room temperature. It had mp 210–212°C (lit. (27) mp 213–214°C) and gave ^1H nmr signals at δ 5.36 (br s, $W_{\frac{1}{2}}$ = 10 Hz, 1H, 11), 4.93 (ddd, J_1 = 5 Hz, J_2 = 11 Hz, J_3 = 16 Hz, 1H, 7α), 4.47 (m, 1H, 3α), 2.03 (two CH_3CO), 1.12, 0.89, 0.83, 0.78, and 0.68 (CH_3 signals).

*3β,7β-Diacetoxy-5α-lanosta-9α,11α-diol (**9**, R = Ac).* The action of 1.2 molar equivalents of osmium tetroxide in dry pyridine on **8** (R = Ac) during 40 h and work-up as for **7** gave crude **9**. This was purified by flash chromatography on silica gel using 5:1 benzene – ethyl acetate for elution, giving a quantitative yield of **9** (R = Ac). It crystallized from acetone–hexane as fine needles, mp 118–121°C; $[\alpha]_D$ +37.5° (*c* 1.08); ν_{max}: 3500 and 1728 cm^{-1}. Its ^1H nmr spectrum had signals at δ 5.36 (ddd, J_1 = 4.5 Hz, J_2 = 10 Hz, J_3 = 15.5 Hz, 1H, 7α), 4.40 (m, 1H, 3α), 4.10 (m, 1H, 11β), 3.10 (s, 1H, OH), 2.00 and 2.02 (CH_3CO groups), 1.12, 1.00, 0.90, 0.87, and 0.81 (CH_3 groups). *Anal.* calcd. for $C_{34}H_{58}O_6$: C 72.56, H 10.39; found: C 72.70, H 10.26.

No catalytic osmylations or permanganate oxidations were attempted on substrate **8**.

*3β,11α-Diacetoxy-5α-lanosta-7β,9α-diol (**21**).* Sodium borohydride (225 mg) was added in small portions during 7 min to a solution of 113 mg of 3β,11α-diacetoxy-9α-hydroxy-5α-lanostan-7-one (**6***b*) in 6 mL of ethanol at 50°C. The solution was maintained at 50°C for 1 h, then the bulk of the solvent removed under reduced pressure. The products were distributed between 5 mL of water and dichloromethane. The dried organic layer yielded 117 mg of a mixture, which was separated on two 1000-μm silica gel plates using 6:1 benzene – ethyl acetate. A higher R_f zone yielded 32 mg of **21** while a lower R_f zone contained 68 mg of the 7α isomer **19**. In other experiments the ratio **21**:**19** varied between 1:2 and 1:3.

The diacetoxydiol **21** was not obtained crystalline. It had $[\alpha]_D$ +26.5° (*c* 1.5) and ν_{max} 3590, 3450, and 1725 cm^{-1}. Its ^1H nmr spectrum had signals at δ 5.29 (dd, J_1 = 6.5 Hz, J_2 = 10.5 Hz, 1H, 11), 4.38 (m, 1H, 3α), 4.12 (dd, J_1 = 4 Hz, J_2 = 10 Hz, 1H, 7α), 2.42 (s, 1H, OH), 2.02 and 2.04 (CH_3CO groups), 1.12, 0.90, 0.81, and 0.82 (CH_3 groups). *Anal.* calcd. for $C_{34}H_{58}O_6$: C 72.56, H 10.39; found: C 72.28, H 10.42.

*Acetylation of **21***

Acetylation of 155 mg of **21** in 10 mL of dichloromethane containing 1 mL of dimethylaniline and 0.5 mL of acetyl chloride was complete at room temperature in two days. After purification on two 500-μm silica gel plates (6:1 benzene – ethyl acetate) the product gave 151 mg of **10**, mp 212–213°C, identical to the product from **9** (R = Ac).

*3β,7β,11α-Triacetoxy-5α-lanostan-9α-ol (**10**).* Acetylation of **9** (R = Ac) in 1:1 acetic anhydride – pyridine for 16 h gave the triacetate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

10. After purification on silica gel plates it crystallized from hexane–dichloromethane mixtures; mp 212–213°C; $[\alpha]_D$ +37° (*c* 0.47); ν_{max}: 3590 and 1725 cm^{-1}. It gave ^1H nmr signals at δ 5.30 (m, 3H, 7α and 11β), 4.39 (m, 1H, 3α), 2.45 (s, 1H, OH), 2.02 (6H, CH_3CO), 2.03 (CH_3CO), 1.14, 1.04, 0.89, 0.87, and 0.82 (CH_3 groups). *Anal.* calcd. for $C_{36}H_{60}O_7$: C 71.48, H 10.00; found: C 71.26, H 10.17.

*3β-Acetoxy-9α,11β-dihydroxy-5α-lanostan-7-one (**11**, R = H).* Lithium tri-*tert*-butoxyaluminohydride (1.2 g) was added to 632 mg of hydroxydione **7** in 30 mL of ice-cold tetrahydrofuran. The mixture was then stirred at room temperature under argon for 3.5 h. The bulk of the tetrahydrofuran was removed under reduced pressure. Water (10 mL) was added cautiously to the residue (ice cooling). A precipitate was dissolved by addition of 2*N* hydrochloric acid, then the product extracted into dichloromethane. The organic layer was washed with 5% sodium carbonate solution, then with brine, dried, and distilled. The crude product was separated on 1000-μm silica gel plates using 10% ethyl acetate in dichloromethane, giving, in order of increasing R_f, 406 mg of **11** (R = H) and 132 mg of 3β-acetoxy-7α,9α-dihydroxy-5α-lanostan-11-one (**13**). 3β-Acetoxy-9α,11β-dihydroxy-5α-lanostan-7-one **11** (R = H) crystallized from methanol as needles with mp 228–230°C; $[\alpha]_D$ +36.5 (*c* 0.5); ν_{max}: 3520, 3450, 1720, and 1700 cm^{-1}; ^1H nmr, δ: 4.49 (t, *J* = 7 Hz, 1H, 3α), 3.85 (m, 1H, 11α), 2.93 (s, 1H, 8β), 2.30 (s superimposed on a mult, 2H, 12), 2.05 (s, 3H, CH_3CO), 1.47, 1.10, 0.98, 0.95, 0.90, 0.86, and 0.83 (CH_3 groups). *Anal.* calcd. for $C_{32}H_{54}O_5$: C 74.09, H 10.49; found: C 74.21, H 10.40.

*3β,11β-Diacetoxy-9α-hydroxy-5α-lanostan-7-one (**11**, R = Ac).* The ketodiol **11** (R = H) was acetylated during 5 days by a dimethylaniline – acetyl chloride mixture as described for preparation of **10**. The diacetate **11** (R = Ac) crystallized from hexane–dichloromethane as rods with mp 220–223°C; $[\alpha]_D$ +68° (*c* 0.15); ν_{max}: 3510, 1725 with shoulders at 1735 and 1700 cm^{-1}; ^1H nmr, δ: 4.86 (br d, *J* = 2 Hz, 1H, 11α), 4.48 (t, *J* = 7 Hz, 1H, 3α), 2.97 (s, 1H, 8β), 2.32 (s, 2H, 6), 2.05 and 2.07 (two CH_3CO groups), 1.88 (s, 1H, OH), 1.41, 1.12, 0.94, 0.89, 0.87, and 0.82 (CH_3 groups). *Anal.* calcd. for $C_{34}H_{56}O_6$: C 72.82, H 10.06; found: C 72.96, H 10.20.

*3β,11β-Diacetoxy-5α-lanost-8-en-7-one (**24**a).* Dehydration of **11** (R = Ac) with thionyl chloride in pyridine at 0°C gave ***24a***, which was not obtained crystalline. It had ν_{max} 1725 and 1660 cm^{-1} and λ_{max} 251 nm (ε 9400). It gave ^1H nmr signals at δ 5.64 (d, *J* = 5.5 Hz, 1H, 11α), 4.52 (m, 1H, 3α), 2.60–2.25 (m, including a singlet at 2.44, 2H, 6), 2.08, 2.05 (s, 3H, CH_3CO's), 1.35, 0.97, 0.90, 0.88, and 0.83 (CH_3 groups).

*3β,7β-Diacetoxy-9α-hydroxy-5α-lanostan-11-one (**12**).* A solution of 250 mg of diol **9** (R = Ac) and 30 mg of dicyclohexylcarbodiimide in 1 mL of benzene was prepared. To this was added 1.5 mL of dry dimethylsulfoxide followed by a solution of 50 mg of pyridine and 49 mg of dichloroacetic acid in 1 mL of benzene. After 4 h a further 190 mg of DCC was added, followed by a solution of 55 mg of pyridine and 32 mg of dichloroacetic acid in 1 mL of benzene. Thin-layer chromatography (tlc) (25% ethyl acetate in benzene) showed disappearance of most of the starting material after one more hour. The mixture was left overnight, then 0.5 g of oxalic acid in 2 mL of methanol was added cautiously. After 2 h stirring, 5 mL of hexane and 5 mL of water were added. The solid was removed by filtration and washed with 1:1 benzene–hexane mixture. The organic layer was washed with aqueous oxalic acid, then with sodium carbonate solution, dried, and distilled. More crystals were filtered from a concentrated solution of the products in 1:1 benzene–hexane. The 360 mg of residue after removal of the solvents was separated on four 1000-μm silica gel plates using 20% ethyl acetate in benzene, giving 201 mg of pure ketol **12** and 36 mg of slightly impure ketol. Ketol **12** did not crystallize. It had $[\alpha]_D$ +49.5° (*c* 0.5) and ν_{max} 3689, 3450, 1728 and 1710 (shoulder cm^{-1}. It gave ^1H nmr signals at δ 5.35 (m, 1H, 7α), 4.45 (t, *J* = 7.5 Hz, 3α), 3.19, 2.27 (pair of doublets 2H, *J* = 13 Hz, 12), 2.92 (s, 1H, OH), 2.03 (6H, CH_3CO), 1.21, 1.16, 0.89, 0.88, 0.82, and 0.77 (CH_3 groups). *Anal.* calcd. for $C_{34}H_{56}O_6$: C 72.82, H 10.05; found: C 72.53, H 9.88. A small amount of what appeared (^1H nmr) to be the methylthiomethyl ether of **9** moved on the plate just ahead of the ketol.

*3β-Acetoxy-7α,9α-dihydroxy-5α-lanostan-11-one (**13**).* A solution of 1 g of the 7,11-dione **7** and 230 mg of Adams platinum oxide catalyst in 30 mL of acetic acid was shaken under hydrogen for 1 h. The catalyst was removed by filtration through a bed of Celite, which was then washed with 200 mL of chloroform. The filtrate was shaken with enough 5% sodium carbonate solution to remove the acetic acid, then with water. The dried solution was concentrated and the residue crystallized by addition of methanol. The 853 mg of **13** had mp 231–234°C; $[\alpha]_D$ +45° (*c* 0.46), and gave ν_{max}: 3610, 3450, 1720, and 1700 cm^{-1}. It gave ^1H nmr signals at δ 4.56 (t, *J* = 7 Hz, 1H, 3α), 4.31 (s, OH), 4.24 (m, 1H, 7β), 3.05, 2.31 (pair of doublets, 2H, *J* = 15 Hz, 12), 2.40 (s, 1H, 8β), 2.05 (s, 3H, CH_3CO), 1.49, 1.08, 0.90, 0.83, and 0.77 (CH_3 groups). *Anal.* calcd. for $C_{32}H_{54}O_5$: C 74.09, H 10.49; found: C 74.23, H 10.49.

*3β-Acetoxy-5α-lanosta-7α,9α,11β-triol (**14**).* One gram of sodium borohydride was added in small portions to a refluxing solution of 370 mg of the 7α-hydroxy-11-ketone **13** in 30 mL of methanol during 4 h. The solution was cooled, then 100 mL of 1:1 benzene–ether was added. The benzene–ether layer was washed with water, dried, and distilled. The crude product was purified by repeated chromatography on silica gel plates using 4:1 benzene – ethyl acetate for development. Starting material (19 mg) was followed by a zone containing 232 mg of **14**. This had ν_{max}: 3630, 3450, and 1720 cm^{-1}; ^1H nmr, δ: 4.56 (t, *J* = 7 Hz, 1H, 3α), 4.19 (s, 2H, OH), 3.78 (m, 1H, 11α), 2.04 (s, 3H, CH_3CO), 1.32, 1.29, 0.93, 0.90, and 0.83 (CH_3 groups).

*3β,11β-Diacetoxy-5α-lanosta-7α,9-diol (**15**).* (*a*) Lithium tri-*tert*-butoxyaluminohydride (300 mg) was added to a solution of 110 mg of 3β,11β-diacetoxy-9α-hydroxy-5α-lanostan-7-one (**11**, R = Ac) in 10 mL of tetrahydrofuran. The mixture was stirred under argon for 20 h. Water (10 mL) was added, then the product extracted into dichloromethane. After purification on a 1000-μm silica gel plate using 6:1 benzene – ethyl acetate, 100 mg of **15** was obtained. It crystallized from methanol–dichloromethane as needles, mp 242–243°C; $[\alpha]_D$ +39° (*c* 0.5); ν_{max}: 3610, 3450, and 1725 cm^{-1}; ^1H nmr, δ: 4.80 (d, *J* = 3 Hz, 1H, 11α), 4.65 (s, 1H, OH), 4.65 (m, 1H, 3α), 4.27 (br s, $W_{\frac{1}{2}}$ = 10 Hz, 7β), 2.65 (s, 1H, OH), 2.26 (br d, *J* = 4 Hz, 8β), 2.04 and 2.01 (CH_3CO), 1.35, 1.23, 0.90, 0.88, and 0.83 (CH_3 groups). *Anal.* calcd. for $C_{34}H_{58}O_6$: C 72.56, H 10.56; found: C 72.32, H 10.23.

(*b*) Dimethylaniline (1.5 mL) and 0.7 mL of acetyl chloride were added to a cold solution of 108 mg of triol **14** in 11 mL of dichloromethane. The mixture was stirred under argon for 20 h, then worked up as described for **10**. Repeated separation on silica gel plates using 6:1 benzene – ethyl acetate gave 35 mg of triacetate **10** and 108 mg of diacetate **15**.

Oxidation of **15** with Jones' reagent in acetone gave a high yield of **11** (R = Ac).

*3β,7α,11β-Triacetoxy-9α-hydroxy-5α-lanostane (**16**).* (*a*) This was obtained as a by-product of acetylation of **14** to produce **15** (see above). (*b*) Reduction of 533 mg of the 7,11-dione **7** with 700 mg of lithium aluminium hydride in 40 mL of refluxing ether for 3 h under argon, followed by acetylation in dichloromethane using dimethyl aniline and acetyl chloride (see preparation of **15**), gave, after plate separation, 141 mg of **16** and 193 mg of the 7β isomer **22**.

Triacetate **10** crystallized from hexane as needles, mp 166–168°C; $[\alpha]_D$ +10° (*c* 0.5); ν_{max}: 3560, 1735, and 1725 cm^{-1}; ^1H nmr, δ: 5.34 (br s, $W_{\frac{1}{2}}$ = 6 Hz, 1H, 7β), 4.90 (br d, *J* = 4 Hz, 1H, 11α), 4.58 (t, *J* = 7.5 Hz, 1H, 3α), 3.32 (s, 1H, OH), 2.33 (m, 1H, 8β), 2.08, 2.04, 2.02 (CH_3CO), 1.24, 1.11, 0.90, and 0.81 (CH_3 groups). *Anal.* calcd. for $C_{36}H_{60}O_7$: C 71.48, H 10.00; found: C 71.48, H 9.88.

*3β,7α-Diacetoxy-9α-hydroxy-5α-lanostan-11-one (**17**).* Acetyl chloride (3 mL) was added to a cold solution of 853 mg of 7α-hydroxy-11-ketone **13** and 6 mL of dimethylaniline in 15 mL of dichloromethane. The solution, which turned violet in a few minutes, was stirred at room temperature for 5 days. It was then washed with 2*N* hydrochloric acid, 5% sodium carbonate solution, then water, dried, and distilled. The residue crystallized from methanol giving 591 mg of **17**, mp 157–160°C; $[\alpha]_D$ +3° (*c* 1.0); ν_{max}: 3670, 1738, 1725, and 1710 cm^{-1}; ^1H nmr, δ: 5.32 (br s, $W_{\frac{1}{2}}$ = 7 Hz, 1H, 7β), 4.58 (t, *J* = 7.5 Hz, 1H, 3α), 3.45 (OH), 3.07 (d, *J* = 14 Hz, half of a pair of

For personal use only.

doublets for the 12-hydrogens), 2.42 (s, 1H, 8β), 2.12 (7-CH_3CO), 2.05 (3-CH_3CO), 1.30, 1.11, 0.90, 0.82, and 0.76 (CH_3 groups).

Jones' oxidation of **18** in acetone gave a nearly quantitative yield of **17**.

3β,7α-Diacetoxy-5α-lanosta-9α-11β-diol (18). A solution of 400 mg of triol **14** in 1 mL of acetic anhydride and 1 mL of pyridine was heated at 75°C for 72 h. The mixture was cooled, then poured into 20 mL of saturated sodium bicarbonate solution. After one hour stirring, the product was extracted into dichloromethane; then the organic phase was washed with 2*N* hydrochloric acid, bicarbonate solution, dried, and distilled, giving 26 mg of **18**. This was not obtained crystalline. It had ν_{max} 3590, 1735, and 1725 cm^{-1}. It gave ^1H nmr signals at δ 5.31 (br s, $W_{\frac{1}{2}}$ = 6 Hz, 1H, 7β), 4.60 (t, J = 7.5 Hz, 1H, 3α), 3.86 (m, 1H, 11α), 3.26 (s, 1H, 11α), 2.25 (s, ca. 1H, 8β), 2.07 and 2.05 (CH_3CO), 1.30, 1.09, 0.99, 0.91, and 0.82 (CH_3 groups).

3β,11α-Diacetoxy-5α-lanostan-7α,9α-diol (19). Adam's platinum oxide catalyst (75 mg) was added to a solution of 261 mg of 11α-acetoxy-7-one **6*b*** in 15 mL of acetic acid. The mixture was shaken under hydrogen for 4 h, then worked up as described for **13**. The crude product crystallized from methanol–dichloromethane to give 185 mg of **19**, mp 224–226°C; $[\alpha]_D$ +15° (*c* 0.5); ν_{max}: 3590, 3510, and 1725 cm^{-1}; ^1H nmr, δ: 5.31 (dd, J_1 = 7 Hz, J_2 = 10 Hz, 1H, 11β), 4.46 (t, J = 7 Hz, 1H, 3α), 3.96 (m, 1H, 7β), 3.89 (s, OH), 3.19 (s, OH), 2.25 (m, ca. 1H, 8β), 2.05 and 2.07 (CH_3CO), 1.41, 1.13, 0.90, and 0.82 (CH_3 groups). *Anal.* calcd. for $C_{34}H_{58}O_6$: C 72.56, H 10.39; found: C 72.70, H 10.19.

3β,7α,11α-Triacetoxy-5α-lanostan-9α-ol (20). A solution of 147 mg of diol **19** in 3 mL of 1:1 acetic anhydride – pyridine was kept at 65°C for 6 days. The solution was concentrated *in vacuo* to a syrup. This crystallized from hexane–dichloromethane giving 127 mg of **20**, mp 201–204°C; $[\alpha]_D$ −6° (*c* 0.5); ν_{max}: 3570 and 1723 cm^{-1}; ^1H nmr, δ: 5.37 (t, J = 8 Hz, 1H, 11β), 5.27 (m, 1H, 7β), 4.53 (dd, J_1 = 6 Hz, J_2 = 9.5 Hz, 1H, 3α), 3.30 (s, OH), 3.33 (br s, ca. 1H, 8β), 2.08, 2.04, 2.04 (CH_3CO), 1.19, 1.15, 0.89, 0.85, and 0.83 (CH_3 groups). *Anal.* calcd. for $C_{36}H_{60}O_7$: C 71.48, H 10.00; found: C 71.20, H 10.10.

3β,7β,11β-Triacetoxy-5α-lanostan-7α-ol (22). This product of reduction of **7** followed by acetylation (see preparation of **16**) crystallized from hexane as needles, mp 166–168°C; $[\alpha]_D$ +57° (*c* 1.2); ν_{max}: 3510 and 1725 cm^{-1}; ^1H nmr, δ: 5.32 (m, 1H, 7α), 4.78 (br s, $W_{\frac{1}{2}}$ = 8 Hz, 1H, 11α), 4.47 (br t, $J \simeq$ 7 Hz, 1H, 3α), 2.24 (s, OH), 2.04 (two CH_3CO), 2.02 (CH_3CO), 1.25, 1.01, 0.90, and 0.82 (CH_3 groups). *Anal.* calcd. for $C_{36}H_{60}O_7$: C 71.48, H 10.00; found: C 71.53, H 10.08.

3β,7α,11α-Triacetoxy-5α-lanost-8-ene (23). Triacetate **20** was dehydrated at 0°C using thionyl chloride in pyridine. The amorphous product had ν_{max} 1725 cm^{-1} and gave ^1H nmr signals at δ 5.28 (m, 2H, 7β and 11β), 4.55 (m, 1H, 3α), 2.05 (3 × CH_3CO), 1.16, 1.02, 0.89, 0.87, 0.82, and 0.62 (CH_3 groups).

3β,11α-Diacetoxy-5α-lanost-8-en-7-one (24b). Diacetate **6*b*** was dehydrated at 0°C using thionyl chloride in pyridine. The product crystallized from methanol containing a trace of pyridine, mp 131–133°C (lit. (28) mp 133–135°C); $[\alpha]_D$ +39° (*c* 1.0); λ_{max}: 248 nm (ε 9700); ν_{max}: 1730 and 1672 cm^{-1}; ^1H nmr, δ: 5.51 (dd, J_1 = 4.5 Hz, J_2 = 9 Hz, 1H, 11β), 4.54 (m, 1H, 3α), 2.75–2.35 (2H, 6), 2.07, 2.06 (CH_3CO), 2.07, 2.06 (6H), 1.25, 1.11, 0.96, 0.90, 0.82, and 0.67 (CH_3 groups). *Anal.* calcd. for $C_{34}H_{54}O_5$: C 75.23, H 10.03; found: C 75.13; H 9.89.

3β,9α-Diacetoxy-5α-lanosta-7,11-dione (25). Perchloric acid (0.1 mL, 60%) was added to a solution of 100 mg of dione **7** in 5 mL of acetic acid and 2 mL of acetic anhydride. After 5 h of stirring at room temperature the solution was added to ice water, then the products extracted into benzene. The benzene layers were washed successively with 2*N* sodium hydroxide solution and water, dried, and distilled, giving 103 mg of **25**. This crystallized from methanol–acetone, mp 169–170°C; $[\alpha]_D$ +43° (*c* 1.1); ν_{max}: 1710 and 1725 (shoulder) cm^{-1}; ^1H nmr, δ: 4.44 (t, J = 8 Hz, 3α), 2.91 (s, 1H, 8β), 3.30 and 3.03 (singlets, part of a dd, 1H, 12), 2.47 (dd, ca. 2H, J_1 = 8 Hz, J_2 = 13 Hz, 6), 2.11 (s, 3H, 9α-CH_3CO), 2.06 (s, 3H, 3β-CH_3CO), 1.39, 1.22, 0.94, 0.89, 0.87, 0.82, and 0.73 (CH_3 groups). *Anal.* calcd. for $C_{34}H_{54}O_6$: C 73.08, H 9.74; found: C 73.21, H 9.72.

3β,7α-Diacetoxy-5α-lanostan-11-one (28, R^1 = H, R^2 = OAc). Acetylation of 3β-acetoxy-7α-hydroxy-5α-lanostan-11-one (28) R^1 = H, R^2 = OH) overnight in 1:1 acetic anhydride – pyridine gave this diacetate. It crystallized as needles from hexane with mp 182–185°C; $[\alpha]_D$ +12° (*c* 1.0); ν_{max}: 1725 and 1692 cm^{-1}; ^1H nmr, δ: 5.22 (br s, $W_{\frac{1}{2}}$ = 7 Hz, 1H, 7β), 4.56 (t, J = 7 Hz, 1H, 3α), 2.98 (br d, J = 13 Hz, 1H, 9α), 2.42 (d, J = 3 Hz, 2H, 12), 2.07 and 2.04 (CH_3CO), 1.11, 1.09, 0.90, 0.85, 0.83, 0.75, and 0.73 (CH_3 groups). *Anal.* calcd. for $C_{34}H_{56}O_5$: C 74.95, H 10.36; found: C 74.72, H 10.26.

3β,7β-Diacetoxy-5α-lanostan-11-one (28, R^1 = OAc, R^2 = H). This was prepared by acetylation of 3β-acetoxy-7β-hydroxy-5α-lanostan-11-one (29) using 1:1 acetic anhydride – pyridine at room temperature. It crystallized as prisms from hexane, mp 173–174°C; $[\alpha]_D$ +46° (*c* 1.10); ν_{max}: 1727 and 1702 (shoulder) cm^{-1}; ^1H nmr, δ: 4.97 (ddd, J_1 = 5 Hz, J_2 = 10 Hz, J_3 = 14 Hz, 1H, 7α), 4.47 (dd, J_1 = 7 Hz, J_2 = 9 Hz, 1H, 3α), 2.78 (br d, J = 14 Hz, 1H, 9α), 2.43 (d, J = 4 Hz, 2H, 12), 2.03 (two CH_3CO), 1.14, 0.90, 0.87, 0.82, and 0.73 (CH_3 groups). *Anal.* calcd. for $C_{34}H_{56}O_5$: C 74.95, H 10.36; found: C 74.70, H 10.47.

3β,7,11-Triacetoxy-5α-lanosta-7,9(11)-diene (29). Perchloric acid (0.05 mL, 60%) was added to a solution of 50 mg of 3β-acetoxy-5α-lanosta-7,11-dione (**31**) in 2 mL of acetic anhydride and 1 mL of acetic acid. The yellow solution was stirred under argon at room temperature for 6 days. Ice water was added, then the products extracted into 1:1 benzene–ether. The dark-colored residue from evaporation of the solvents was separated on two 500-μm silica gel plates using 3% ethyl acetate in dichloromethane. The main zone gave 28 mg of **29** identical to the product from Westphalen reaction of **11** (R = Ac). It was not obtained crystalline. It had $[\alpha]_D$ +73° (*c* 0.33); λ_{max}: 240 nm (ε 10 000); ν_{max}: 1735 (shoulder), 1722, and 1610 cm^{-1}. Its ^1H nmr spectrum had signals at δ 4.50 (t, J = 7 Hz, 3α), 2.85–2.30 (m, 4H, 6 and 12), 2.12 and 2.11 (singlets, 6H, CH_3CO), 2.04 (s, 3H, 3-CH_3CO), 1.17, 1.01, 0.90, 0.83, and 0.72 (CH_3 groups). *Anal.* calcd. for $C_{36}H_{56}O_6$: C 73.93, H 9.65; found: C 74.07, H 9.79.

Westphalen dehydrations and related reactions

Sulfuric acid reagent

A stock solution was prepared by diluting 5 mL of concentrated sulfuric acid to 10 mL with acetic acid. This could be kept for months without deterioration.

Westphalen reaction of 3β,11α-diacetoxy-9α-hydroxy-5α-lanostan-7-one (6b)

Sulfuric acid solution (5 mL) was added to a solution of 5 g of **6*b*** in 75 mL of acetic anhydride and 150 mL of acetic acid. The solution soon turned red. After 1 h at room temperature **6*b*** could no longer be detected by tlc (silica, 5:1 benzene – ethyl acetate). It was poured into 250 mL of water, then the products extracted into 1:1 benzene ether (2 × 250 mL). The organic layers were washed free of acetic acid using 2*N* sodium hydroxide solution, then washed with saturated brine, dried (Na_2SO_4), and distilled. The product (ca. 5 g) was separated by medium pressure liquid chromatography on silica gel using 12% ethyl acetate in hexane, giving four major fractions in order of elution. Fraction A contained 248 mg of 3β-acetoxy-18(13→12β)-*abeo*-lanosta-8,13(17)-dien-7-one **30**. Fraction B (2.73 g) was a mixture of mainly 3β,7,11α-triacetoxycucurbita-5(10),6-diene **31**, and a small amount of 3β-acetoxy-5α-lanosta-7,11-dione **33**, which could be separated on silica gel using 3% ethyl acetate in dichloromethane. Fraction C was a mixture of six components. These were roughly separated, on silica gel plates using 10:1 benzene – ethyl acetate, then completely by a second separation using 5% ethyl acetate in dichloromethane. This gave (in order of decreasing R_f), 74 mg of 7-acetoxydiene **32**, 113 mg of 3β,11α-diacetoxy-cucurbita-1(10)-en-7-one **34** (R = Ac), 69 mg of 3β,11β,5α-lanost-8-en-7-one **24*a***, 80 mg of 3β,11α-diacetoxy-5α-lanost-8-en-7-one **24*b***, and 25 mg of 3β-acetoxy-18(13→12β)-*abeo*-lanosta-8,11,13(17)-trien-7-one (**35**). Fraction D contained another 398 mg of **24*b*** for a total of 478 mg.

To confirm the role of the acetic anhydride, compound **6*b*** was left

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

in sulfuric acid in acetic acid of comparable concentration to the above Westphalen reaction. No change occurred in 17 h. Addition of acetic anhydride to reproduce the Westphalen conditions then gave complete reaction in 1 h, with product ratios comparable to those described above.

3β-Acetoxy-18(13→12β)-abeo-*5α-lanosta-8,13(17)-dien-7-one (30).* This was produced from **6*b*** in 5% yield. It crystallized from methanol as needles with mp 134°C and λ_{max} 251 nm (ε 10 000). These properties and its nmr spectra agreed with those previously reported (3).

18[13→12β]-abeo-*5α-Lanosta-8,13(17)-dien)3,7-dione (31).* The acetate **30** (29 mg) was hydrolysed by potassium hydroxide in refluxing ethanol. After purification on a 500-μm silica gel plate using 5% methanol in chloroform, 22 mg of product was isolated from the main zone (R_f 0.45). This gave 6 mg of needles from aqueous methanol, with unknown structure, and 17 mg of amorphous hydroxy ketone **30** (3β-hydroxy) with λ_{max} 252 nm (ε 9000). This was oxidized in acetone using Jones' reagent diluted with acetone. The product was purified on a 500-μm silica gel plate using 5% methanol in chloroform, giving 13 mg of the 3,7-dione **31** in Zone 1 (R_f 0.7). This had λ_{max} 248 nm (ε 7400) and ν_{max} (CH_2Cl_2) 1704 and 1661 cm^{-1}. Its ^1H nmr spectrum showed the presence of ca. 10% of impurity, giving singlets at δ 7.0 and 6.6. Aside from a 1H multiplet at δ 3.0 ($W_{\frac{1}{2}}$ = 11 Hz) the spectrum was complex.

3β,7,11α-Triacetoxycucurbita-5(10),6-diene (32). This was produced from **6*b*** in 46% yield. It was not obtained crystalline. It had $[\alpha]_D$ −34° (*c* 1.4); ν_{max}: 1740 and 1723 cm^{-1}; λ_{max}: 273 nm (ε 5550). Its ^1H nmr spectrum gave signals at δ 5.89 (s, 1H, 6), 5.22 (t, J = 8.5 Hz, 1H, 11β), 4.73 (t, J = 5 Hz, 1H, 3α), 2.30 (s, 1H, 8β), 2.12, 2.09, 2.05 (CH_3CO), 1.22, 1.02, 0.98, 0.90, and 0.83 (CH_3 groups). *Anal.* calcd. for $C_{36}H_{56}O_6$: C 73.93, H 9.65; M^+ 584.4077; found: C 73.83, H 9.69; M^+ 584.4060.

3β-Acetoxy-5α-lanosta-7,11-dione **33**. The yield from **6*b*** was 8%. Its properties corresponded to those reported (27).

3β,11α-Diacetoxycucurbit-1(10)-en-7-one (34, R = Ac). This was produced from **6*b*** in 2% yield. It crystallized from methanol as needles with mp 160–161°C; $[\alpha]_D$ −25° (*c* 1.0); ν_{max}: 1725 and 1695 cm^{-1}; ^1H nmr, δ: 6.46 (m, 1H, 1), 5.23 (dd, J_1 = 4 Hz, J_2 = 8.5 Hz, 1H, 11β), 4.83 (dd, J_1 = 8 Hz, J_2 = 10.5 Hz, 1H, 3α), 2.9–2.5 (m, 2H, 2), 2.11, 2.00 (CH_3CO), 1.14, 1.04, 0.96, 0.89, 0.86, and 0.82 (CH_3 groups). Irradiation between δ 2.65 and 2.80 made the vinyl hydrogen signal approach a singlet while simultaneously affecting the multiplet from the 3α-hydrogen.

3β-Acetoxy-18-(13→12)-abeo-*5α-lanosta-8,11,13(17)-trien-7-one (35).* This was not obtained crystalline. It had λ_{max}: 368 (ε 8250) and 232 nm (ε 10 500); ν_{max}: 1725 and 1620 cm^{-1}; ^1H nmr, δ: 6.03 (s, 1H, 11), 4.57 (dd, J_1 = 5.5 Hz, J_2 = 9.5 Hz, 1H, 3α), 2.07 (CH_3CO), 1.26, 1.22, 1.11, 1.00, 0.92, 0.88, and 0.81 (CH_3 groups).

Action of $BF_3 \cdot Et_2O$ in acetic anhydride on **6***b*

After addition of 0.25 mL of $BF_3 \cdot Et_2O$ to a solution of 121 mg of 3β,11α-diacetoxy-9α-hydroxylanostan-7-one in 3 mL of acetic anhydride, a slow reaction ensued (tlc using 6:1 benzene – ethyl acetate). Further 0.25-mL volumes of reagent were added after 70 and 120 min. The reaction was ended after 6 h by addition to 10 mL of water. The product was extracted into 1:1 benzene–ether. The organic layers were washed with sodium bicarbonate solution, then with water, dried, and distilled. The residue was separated on two 1000-μm tlc plates using 10:1 benzene – ethyl acetate, giving 15 mg of unknown, closely followed by 11 mg of dienol acetate. The main zone, with lower R_f, gave 56 mg of 9α-acetoxy compound **27**.

3β,9α,11α-Triacetoxy-5α-lanostan-7-one (27). The amorphous product from the action of $BF_3 \cdot Et_2O$ on **6*b*** had $[\alpha]_D$ +46° (*c* 0.46) and ν_{max} 1725, 1690 cm^{-1}. It gave ^1H nmr signals at δ 5.58 (t, J = 8 Hz, 1H, 11β), 4.39 (dd, J_1 = 5 Hz, J_2 = 8.5 Hz, 1H, 3α), 2.72 (s, 1H, 8β), 2.6–2.2 (m, ca. 2H, 6), 2.11 (9α-CH_3CO), 2.05 and 2.04 (CH_3CO), 1.33, 0.93, 0.89, 0.86, and 0.82 (CH_3 groups). *Anal.* calcd. for $C_{36}H_{58}O_7$: C 71.72, H 9.70; found: C 71.93, H 9.52.

Westphalen reaction of 3β-acetoxy-9α-hydroxy-5α-lanostan-7,11-dione (8)

Reaction of 1 g of **7** was carried out exactly as for **6*b***. The mixtures had become dark red after 15 min but starting material did not disappear until 5 h reaction time (tlc). The crude product was separated on eight 1000-μm silica gel plates using 10:1 benzene – ethyl acetate. Three zones, A–C (in order of decreasing R_f), were isolated, followed by a zone yielding 21 mg of unreacted **7**.

Zone A was separated on two 1000-μm plates using 2% ethyl acetate in dichloromethane, then a front zone further on two 1000-μm plates using 10% ethyl acetate in hexane. In this way 119 mg of 3β-acetoxy-5α-lanostan-8-en-7,11-dione (12%), 305 mg of 3β-acetoxy-cucurbit-1(10)-en-7,11-dione **36** (31%), 102 mg of 3β,7-diacetoxycucurbita-5(10),6-diene-11-one **37** (10%), and 284 mg of 3β,9α-diacetoxy-5α-lanostan-7,11-dione **25** (28%) were obtained in order of decreasing R_f.

3β-Acetoxycucurbit-1(10)-en-7,11-dione (36, R = Ac). This crystallized from methanol as needles with mp 104–107°C; $[\alpha]_D$ +41° (*c* 1.0); ν_{max}: 1725 and 1695 cm^{-1}; ^1H nmr, δ: 5.39 (m, 1H, 1), 4.80 (dd, J_1 = 7 Hz, J_2 = 10 Hz, 1H, 3α), 2.93 and 2.74 (singlets, 1H, part of a dd for the 12-hydrogens), 2.58 (s, ca. 1H, 8β), 2.49 (s, ca. 2H, 6) (these two signals superimposed on the other branch of the H-12 dd), 2.65–2.35 (m, 2H, 2), 2.07 (CH_3CO), 1.29, 1.09, 0.92, 0.90, 0.83, and 0.74 (CH_3 groups). *Anal.* calcd. for $C_{32}H_{50}O_4$: C 77.06, H 10.11; found: C 76.89, H 9.90.

3β,7-Diacetoxycucurbita-5(10),6-dien-11-one (37). This did not crystallize. It had $[\alpha]_D$ +35° (*c* 0.9); λ_{max}: 272 nm (ε 5610); ν_{max}: 1740 (shoulder), 1720, and 1690 cm^{-1}; ^1H nmr, δ: 5.91 (s, 1H, 6), 4.67 (dd, J_1 = 4 Hz, J_2 = 9 Hz, 1H, 3β), 2.58 (s, 2H, 12), 2.42 (s, 1H, 8β), 2.13 (s, 3H, 7-CH_3CO), 2.05 (s, 3H, 3-CH_3CO), 1.24, 1.13, 1.02, 0.99, 0.90, 0.82, and 0.72 (CH_3 groups). *Anal.* calcd. for $C_{34}H_{52}O_5$: C 75.51, H 9.69; found: C 75.33, H 9.89.

Westphalen reaction of 3β,7β,11α-triacetoxy-9α-hydroxy-5α-lanostane (10)

Stock sulfuric acid in acetic acid solution (0.1 mL) was added to a solution of 90 mg of **10** in 1 mL of acetic anhydride and 2 mL of acetic acid. The starting material was no longer evident (tlc) after 4.5 h stirring at room temperature. Work-up as for **6*b*** followed by separation on three 500-μm silica gel plates using 6:1 benzene – ethyl acetate gave 5 mg of 3β,7β,11β-triacetoxycucurbit-5(10)-ene **38**, 53 mg of 3β,7β,11α-triacetoxycucurbit-5(10)-ene **39**, and 19 mg of starting material **10**, in order of decreasing R_f.

3β,7β,11α-Triacetoxycucurbit-1(10)-ene (38). Because of the small amount isolated, this was only characterized by its ^1H nmr spectrum. This had signals at δ 5.30 (br s, $W_{\frac{1}{2}}$ = 9 Hz, 1H, 1), 5.20 (m, 2H, 7α and 11β), 4.75 (t, J = 7 Hz, 3α), 2.10, 2.06, and 2.04 (CH_3CO), 1.24, 1.03, 0.96, and 0.81 (CH_3 groups).

3β,7β,11α-Triacetoxycucurbit-5(10)-ene (39). This was not obtained crystalline. It had $[\alpha]_D$ +43.5° (*c* 0.5); ν_{max}: 1725 cm^{-1}; ^1H nmr, δ: 5.09 (m, 2H, 7α and 11β), 4.75 (t, J = 4 Hz, 1H, 3), 2.09, 2.05, and 2.04 (CH_3CO), 1.12, 1.03, 0.89, 0.82, and 0.62 (CH_3 groups). *Anal.* calcd. for $C_{36}H_{58}O_6$: C 73.68, H 9.95; found: C 73.85, H 10.08.

Westphalen reaction of 3β,11β-diacetoxy-9α-hydroxy-5α-lanostan-7-one (11, R = Ac)

A solution of 75 mg of **11** (R = Ac) in 1 mL of acetic anhydride, 2 mL of acetic acid, and 0.075 mL of stock sulfuric acid solution only developed a yellow color. Starting material could not be detected (tlc) after 90 min. Working up as for **7**, followed first by separation on silica gel plates using 6:1 benzene – ethyl acetate, then by replating of the major zones using 2% ethyl acetate in chloroform, gave (in order of decreasing R_f) 24 mg of 3β-acetoxy-5α-lanostan-7,11-dione **33** (2), 18 mg of 3β,7,11-triacetoxy-5α-lanosta-7,9(11)-diene **29**, and 4.5 mg of 3β,11β-diacetoxy-5α-lanost-8-en-7-one **24*a***.

Westphalen reaction of 3β,7β-diacetoxy-9α-hydroxy-5α-lanostan-11-one (12)

A solution of 110 mg of **12** in 1 mL of acetic anhydride, 2 mL of acetic acid, and 0.1 mL of stock sulfuric acid solution was stirred for 1 h at room temperature. It remained yellow, but the starting material was not detectable (tlc) at the end of this time. After work-up as for **7** and separation on two 1000-μm silica gel plates using 5% ethyl acetate in dichloromethane, two main products were isolated; 67 mg

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

(61%) of 3β,7β-diacetoxycucurbit-1(10)-en-11-one **40** (R^1 = R^2 = OAc, R^3 = H) and 32 mg (29%) of 3β,7β-diacetoxy-cucurbit-5(10)-en-11-one **41**, (R^1 = R^2 = OAc, R^3 = H) in order of increasing R_f.

*3β-7β-Diacetoxycucurbit-1(10)-en-11-one (**40**, R^1 = R^2 = OAc, R^3 = H).* This was not obtained crystalline. It had $[\alpha]_D$ +103° (*c* 1.5) and ν_{max} 1730 and 1690 cm^{-1}. Its ^1H nmr spectrum had signals at δ 5.25 (m, 2H, 1 and 7α), 4.73 (dd, J_1 = 6.5 Hz, J_2 = 10 Hz, 1H, 3α), 2.57 (d, *J* = 9 Hz, 2H, 12), 2.05 (2 × CH_3CO), 1.38, 1.08, 0.94, 0.90, 0.83, and 0.76. *Anal.* calcd. for $C_{34}H_{54}O_5$: C 75.23, H 10.03; found: C 75.46, H 9.80.

*3β-7β-Diacetoxycucurbit-5(10)-en-11-one (**41**, R^1 = R^2 = Ac, R^3 = H).* This was amorphous, with ν_{max} 1725 and 1693 cm^{-1}; ^1H nmr, δ: 5.18 (m, 1H, 7α), 4.65 (m, 1H, 3α), 2.72 (half a pair of doublets, *J* = 14 Hz, 12), 2.53 (s, 1H, 8), 2.05 (2-CH_3CO), 1.25, 1.01, 0.97, 0.93, 0.90, 0.82, and 0.74 (CH_3 groups); ms, *m/e* calcd. for $C_{34}H_{54}O_5$: M^+ 542; found: M^+ at 542 only 0.35% of the base peak; strong signals at *m/e* 482 (*M* − 60) and 422 (*M* − 120) (base peak).

*Westphalen reaction on 3β,7α,11β-triacetoxy-9α-hydroxy-5α-lanostane (**16**)*

A stirred solution of 46 mg of **16** in 0.5 mL of acetic anhydride, 1 mL of acetic acid, and 0.05 mL of stock sulfuric acid solution was left for 9 h at room temperature. The yellow solution was worked up as usual (see **7**), then the products separated on two 500-μm silica gel plates using 3% ethyl acetate in dichloromethane. The only product characterized was 26 mg of 3β,7α-diacetoxy-5α-lanostan-11-one **28** (R^1 = H, R^2 = OAc).

*Westphalen reaction of 3β,7α-diacetoxy-9α-hydroxy-5α-lanostan-11-one (**17**)*

A solution of 300 mg of **17** in 3.75 mL of acetic anhydride, 7.5 mL of acetic acid, and 0.3 mL of stock sulfuric acid solution was stirred at room temperature for 45 min. The red solution no longer contained starting material (tlc). It was worked up as for **7**. The products were partially separated on four 1000-μm silica gel plates using 5:1 benzene – ethyl acetate, giving 229 mg of a mixture of cucurbitenes **40** (R^1 = R^3 = OAc, R^2 = H) and **41** (R^1 = R^3 = OAc, R^2 = H) (from ^{13}C nmr evidence) and 23 mg of 3β,7α,9α-triacetoxy-5α-lanostan-11-one **26**.

The major zone was hydrolysed using 295 mg of potassium hydroxide in 10 mL of methanol and 0.5 mL of water at room temperature (11.5 h). The resulting diols were separated on three 1000-μm silica gel plates using 1:1 benzene – ethyl acetate. Two major zones were isolated, 86 mg of **40** (R^1 = R^3 = OH, R^2 = H) and 57 mg of **41** (R^1 = R^3 = OH, R^2 = H) in order of decreasing R_f. These could be acetylated in 1:1 pyridine – acetic anhydride at room temperature to the corresponding diacetates. Subsequently it was found that the original mixture of acetates from the Westphalen reaction could be separated on silica using 4% ethyl acetate in dichloromethane.

*3β,7α-Diacetoxycucurbit-1(10)-en-11-one (**40**, R^1 = R^3 = OAc, R^2 = H).* This was amorphous, with $[\alpha]_D$ +58° (*c* 0.49) and ν_{max} 1722 and 1690 cm^{-1}. Its ^1H nmr spectrum had signals at δ 5.62 (ddd, J_1 = 3 Hz, J_3 = 1 Hz, 7β), 5.24 (dd, J_1 = 3 Hz, J_2 = 7 Hz, 1H, 1), 4.77 (dd, J_1 = 6.5 Hz, J_2 = 10 Hz, 1H, 3α), 2.82, 2.44 (pair of doublets 2H, *J* = 14.5 Hz, 12), 2.55 (d, *J* = 10 Hz, 1H, 8β), 2.08 (7-CH_3CO), 2.06 (3-CH_3CO), 1.28, 0.90, 0.83, 0.75, and 0.74 (methyl groups). *Anal.* calcd. for $C_{34}H_{52}O_5$: C 75.23, H 10.03; found: C 75.26, H 9.90.

*3β,7α-Dihydroxycucurbit-1(10)-en-11-one (**40**, R^1 = R^3 = OH, R^2 = H).* This was amorphous with ν_{max} 3620, 3470, and 1685 cm^{-1}. It gave ^1H nmr signals at δ 5.22 (dd, J_1 = 3 Hz, J_2 = 8 Hz, 1H, 1), 4.58 (ddd, J_1 = 3 Hz, J_2 = 7 Hz, J_3 = 9 Hz), 3.65 (s, 1H, OH), 2.82, 2.42 (pair of doublets, 2H, *J* = 14.5 Hz, 12), 2.45 (d, *J* = 10 Hz, 1H, 8β), 1.27, 1.23, 1.04, 0.90, 0.82, 0.75, and 0.68 (methyl groups).

*3β,7α-Diacetoxycucurbit-5(10)-en-11-one (**41**, R^1 = R^3 = OAc, R^2 = H).* This was amorphous, with $[\alpha]_D$ +144° (*c* 0.16) and ν_{max} 1722 and 1695 cm^{-1}. It gave ^1H nmr signals at δ 5.57 (ddd, J_1 = 6 Hz, J_2 = 10 Hz, J_3 = 10 Hz, 1H, 7β), 4.67 (m, 1H, 3α), 2.54 (s, 2H, 12), 2.31 (d, *J* = 7 Hz, H, 8β), 2.07 (s, 3H, 7α-CH_3CO), 2.05 (s, 3H, 3β-CH_3CO), 1.31, 1.03, 0.97, 0.90, 0.83, and 0.68 (methyl groups). *Anal.* calcd. for $C_{34}H_{54}O_5$: C 75.23, H 10.03; found: C 75.38, H 10.04.

*3β,5α-Diacetoxycucurbit-5(10)-en-11-one (**41**, R^1 = R^3 = OH, R^2 = H).* This was amorphous, with ν_{max} 3620 and 1690 cm^{-1}. It gave ^1H nmr signals at δ 2.54 (s, 2H, 12), 2.17 (d, *J* = 6 Hz, 8β), 1.28, 1.25, 1.07, 0.98, 0.90, 0.83, and 0.72 (methyl groups).

*3β,7α-Triacetoxy-5α-lanostan-11-one (**26**).* This was amorphous, with ν_{max} 1725 cm^{-1}; ^1H nmr, δ: 5.26 (dd, J_1 = 3 Hz, J_2 = 6 Hz, 1H, 7β), 4.46 (dd, J_1 = 7 Hz, J_2 = 9 Hz, 1H, 3α), 2.99, 2.52 (pair of doublets, *J* = 13.5 Hz, 2H, 12), 2.18 (s, 3H, 9α-CH_3CO), 2.08 (s, 3H, 7α-CH_3CO), 2.05 (s, 3H, 3β-CH_3CO), 1.21, 0.89, 0.82, and 0.73 (methyl groups); ms *m/e* calcd. for $C_{36}H_{58}O_7$: M^+ 601.9; found: M^+ 601.9.

*Westphalen reaction of 3β,7α,11α-triacetoxy-9α-hydroxy-5α-lanostane (**20**)*

A solution of 100 mg of triacetate **20** in 1.25 mL of acetic anhydride, 2.5 mL of acetic acid, and 0.1 mL of stock sulfuric acid solution was left at room temperature. It soon became reddish-orange. After 70 h, tlc indicated that over half the material had been converted to products. In the usual work-up (as for **6*b***) a major component with R_f near that of the starting material disappeared, apparently being reconverted to **20**. Separation of the products on two 500-μm plates using 6:1 benzene – ethyl acetate gave 77 mg of recovered **20**, 8 mg of 3β,7α,11α-triacetoxycucurbit-5(10)-ene **42** (R = Ac), and 1 mg of the corresponding 1(10)-ene **38** (but 7α-acetoxy). Tripling the sulfuric acid concentration or heating at 60°C did not increase the yield of **42** and resulted in poorer recovery of starting material.

*3β,7α,11α-Triacetoxycucurbit-1(10)-ene (**42**, R = Ac).* This was amorphous, with $[\alpha]_D$ +21° (*c* 0.2); ν_{max}: 1725 cm^{-1}; ^1H nmr, δ: 5.70 (dd, J_1 = 9 Hz, J_2 = 15.5 Hz, 1H, 7β), 5.25 (t, 8 Hz, 1H, 11β), 4.71 (dd, J_1 = 4 Hz, J_2 = 7 Hz, 1H, 3α), 2.6–2.2 (m, ca. 2H, 6), 2.07 and 2.05 (CH_3CO), 1.19, 1.00, 0.90, and 0.82 (CH_3 groups). *Anal.* calcd. for $C_{36}H_{58}O_6$: C 73.68, H 9.96; found: C 73.39, H 10.02.

*3β,7α,11α-Triacetoxycucurbit-1(10)-ene (**38**, but 7α-OAc).* Because of the small quantity produced, this was only identified by its ^1H nmr spectrum. It gave signals at δ 6.17 (m, 1H, 1), 5.58 (m, 1H, 7β), 5.20 (m, 1H, 11β), and 2.07 and 2.04 (CH_3CO).

*Westphalen reaction on 3β,7β,11β-triacetoxy-9α-hydroxy-5α-lanostane (**22**)*

Triacetate **22** was treated with the same ratio of solvents and acid as for **20**. The red solution contained no starting material after 15 min at room temperature. After 0.5 h the mixture was poured into water and worked up as for **7**. The products were separated as for **20**, giving, in order of decreasing R_f, 47 mg of 3β,7β-diacetoxy-5α-lanostan-11-one **28** (R^1 = OAc, R^2 = H) and 11 mg of 3β,7β,11-triacetoxy-5α-lanost-9(11)-ene **43**.

Extending the reaction time to 2.5 h resulted in little change in the product ratio.

*3β,7β,11-Triacetoxy-5α-lanost-9(11)-ene (**43**).* This was not obtained crystalline; ^1H nmr, δ: 4.94 (m, 1H, 7α), 4.46 (br t, *J* = 7 Hz, 1H, 3α), 1.96 (α, *J* = 11.5 Hz, 1H, 8β), 2.06, 2.06, and 2.04 (CH_3CO), 1.24, 0.89, 0.82, and 0.78 (CH_3 groups).

*Thermolysis of 3β,9α-diacetoxy-5α-lanosta-7,11-dione (**35**)*

A solution of 103 mg of **24** in 1 mL of decalin was heated at 195°C for 7 h, then the bulk of the decalin removed under reduced pressure. Only 3β-acetoxy-5α-lanost-8-en-7,11-dione (29 mg) and starting material (37 mg) were recovered after separation of the product on silica gel plates using 5:1 benzene – ethyl acetate. Several minor zones were not identified.

*Action of Westphalen reagent on 3β,9α-diacetoxy-5α-lanosta-7,11-dione (**25**)*

Diacetate **25** was recovered unchanged after 3 days in the same ratio of acetic anhydride – acetic acid – sulfuric acid as was used for the Westphalen dehydrations and the normal work-up (see reaction of **6*b***). Other attempts to esterify the 9α-hydroxyl group of **7**:

1. No mesylate was obtained using methanesulfonyl chloride in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

pyridine. Methane sulfonic acid containing methanesulfonic anhydride converted **7** to the 8-en-7,11-dione. Attempts to make the 9α-methanesulfinate, following Creary (12), failed.

2. Attempts to make a 9α-triflate by the method of Blunt *et al.* (4) gave a complex mixture.

3. A carbamate appeared to form when **7** was treated in $CDCl_3$ with trichloromethyl isocyanate (30). However, this hydrolysed back to **7** when purification on silica gel plates was attempted or when the crude product was heated in xylene.

4. The action of phosgene in 100:1 benzene–pyridine at 60°C for 2 h converted **7** mainly to the 8-en-7,11-dione.

*Partial acetylation of 3β,7α-dihydroxycucurbit-1(10)-en-11-one (**40**, $R^1 = R^3 = OH$, $R^2 = H$)*

The diol **40** ($R^1 = R^3 = OH$, $R^2 = H$) (89 mg) was left in 1.5 mL of pyridine and 90 mg of acetic anhydride at 0°C for four days. Excess anhydride was destroyed using methanol, then the mixture evaporated to dryness *in vacuo*. Separation of the residue on two 500-μm plates using 6:1 benzene – ethyl acetate gave, in order of decreasing R_f, 43 mg of diacetate **40** ($R^1 = R^3 = OAc$, $R^2 = H$), 39 mg of 3β-acetoxy-7α-hydroxycucurbit-1(10)-en-11-one **40** ($R^1 = OAc$, $R^2 = H$, $R^3 = OH$), 5 mg of 7α-acetoxy-3β-hydroxycucurbit-1(10)-en-11-one **40** ($R^1 = OH$, $R^2 = H$, $R^3 = OAc$), and 3 mg of parent diol.

*3β-Acetoxy-7α-hydroxycucurbit-1(10)-en-11-one (**40**, $R^1 = OAc$, $R^2 = H$, $R^3 = OH$).* This had ν_{max}: 3620, 1720, and 1685 cm^{-1}; ^1H nmr, δ: 5.22 (dd, $J_1 = 3$ Hz, $J_2 = 8$ Hz, 1H, 1), 4.77 (dd, $J_1 = 7$ Hz, $J_2 = 10$ Hz, 1H, 3α), 4.58 (ddd, $J_1 = 3$ Hz, $J_2 = 7$ Hz, $J_3 = 9$ Hz, 1H, 7β), 2.82, 2.42 (pair of doublets, $J = 14.5$ Hz, 2H, 12), 2.45 (d, $J = 10$ Hz, 1H, 8β), 2.05 (CH_3CO), 1.28, 1.25, 0.95, 0.90, 0.83, and 0.76 (CH_3 groups).

*7α-Acetoxy-3β-hydroxycucurbit-1(10)-en-11-one (**40**, $R^1 = OH$, $R^2 = H$, $R^3 = OAc$).* This gave ^1H nmr signals at δ 5.62 (m, 1H, 7β), 5.24 (m, 1H, 1), 3.63 (OH), 3.57 (m, 1H, 3α), 2.84 and 2.42 (pair of doublets, $J = 14$ Hz, 2H, 12), 2.55 (d, $J = 10$ Hz, 8β), 2.09 (CH_3CO), 1.27, 1.26, 1.01, 0.90, 0.82, 0.72, and 0.63 (CH_3 groups).

*Oxidation of **40** ($R^1 = OAc$, $R^2 = H$, $R^3 = OH$)*

This alcohol was oxidized in acetone at 0°C using a small excess of Jones' reagent diluted with acetone. The product was 3β-acetoxycucurbit-1(10)-en-7,11-dione **36** (R = Ac), identical (^1H nmr, ir) with the product of Westphalen reaction on 9α-hydroxy-7,11-dione **7**.

*3β-Hydroxycucurbit-1(10)-en-7,11-dione (**36**, R = H).* A solution of 104 mg of 3β-acetoxycucurbit-1(10)-en-7,11-dione (**35**, R = H) in 5 mL of methanol containing 100 mg of KOH was refluxed under argon for 1 h. The recovery after work-up and purification on a 500-μm silica gel plate was only 43 mg of **36** (R = H); ν_{max}: 3620 and 1692 cm^{-1}; ^1H nmr, δ: 5.50 (m, 1H, 1), 3.53 (dd, $J_1 = 6$ Hz, $J_2 = 11$ Hz, 1H, 3α, 2H, 12), 2.52 (s, 2H, 6), 1.72 (s, OH), 1.26, 1.13, 1.02, 0.92, 0.82, and 0.73 (CH_3 groups).

Addition of $Eu(DPM)_3$ to the $CDCl_3$ solution resulted in comparable moderate downfield shifts of the vinyl hydrogen, and the 5α and 6α and 6β hydrogens.

*Hydrolysis of 3β,-11α-diacetoxycucurbit-1(10)-en-7-one (**34**, $R^1 = R^2 = Ac$)*

A solution of 34 mg of **34** ($R^1 = R^2 = Ac$) in 2 mL of 10% KOH in methanol was left under argon for 20 h at room temperature. Separation on a 500-μm silica gel plate using 6:1 benzene – ethyl acetate gave 4 mg of 11α-acetoxy-3β-hydroxycucurbit-1(10)-en-7-one (**34**, $R^1 = H$, $R^2 = Ac$) followed by 20 mg of 3β,11α-dihydroxycucurbit-1(10)-en-7-one (**34**, $R^1 = R^2 = H$).

*11α-Acetoxy-3β-hydroxycucurbit-1(10)-en-7-one (**34**, $R^1 = H$, $R^2 = Ac$).* This was not obtained crystalline. It had ν_{max} 3620 and 1695 cm^{-1} and gave ^1H nmr signals at δ 6.46 (m, 1H, 1), 5.23 (dd, $J_1 = 4$ Hz, $J_2 = 11$ Hz, 1H, 11β), 3.63 (t, $J = 9$ Hz, 1H, 3α), 2.12 (CH_3CO), 1.27, 1.20, 1.14, 0.96, 0.90, 0.83, 0.77, and 0.71 (CH_3 groups).

*3β,11α-Dihydroxycucurbit-1(10)-en-7-one (**34**, $R^1 = R^2 = H$).* This was not obtained crystalline. It had ν_{max} 3620, 3420, and 1685 cm^{-1} and gave ^1H nmr signals at δ 6.73 (m, 1H, 1), 4.00 (dd, $J_1 = 5$ Hz, $J_2 = 11.5$ Hz, 1H, 11β), 3.59 (dd, $J_1 = 7.5$ Hz, $J_2 = 10$ Hz, 1H, 3α), 2.45 (s, 2H, 6), 2.38 (5, 1H, 8β), 1.30, 0.97, 0.93, 0.90, 0.82, and 0.77 (CH_3 groups).

*3β-Acetoxy-11α-hydroxycucurbit-1(10)-en-7-one (**34**, $R^1 = Ac$, $R^2 = H$).* A solution of 20 mg of diol **34** ($R^1 = R^2 = H$) in 0.5 mL of pyridine and 30 mg of acetic anhydride was stirred at 0°C for 48 h. Another 30 mg of anhydride was added and stirring continued for 24 h. The product was separated on a 500-μm silical gel plate using 6:1 benzene – ethyl acetate, giving (in order of decreasing R_f) 5 mg of diacetate (**34**, $R^1 = R^2 = Ac$), 9 mg of monoacetate (**34**, $R^1 = Ac$, $R^2 = H$), and 5 mg of unchanged diol.

This monoacetate had ν_{max} 3620, 1720, and 1685 cm^{-1} and gave ^1H nmr signals at δ 6.73 (dd, $J_1 = 3$ Hz, $J_2 = 7.5$ Hz, 1H, 1), 4.81 (dd, $J_1 = 7.5$ Hz, $J_2 = 10.5$ Hz, 1H, 3α), 4.00 (dd, $J_1 = 3$ Hz, $J_2 = 9$ Hz, 1H, 11β), 2.8–2.3 (m, 2H, 2), 2.45 (s, 2H, 6), 2.24 (s, 1H, 8β), 2.07 (CH_3CO), 1.30, 1.25, 0.97, 0.93, 0.90, 0.86, and 0.83 (CH_3 groups).

Oxidation of monoacetate **34** ($R^1 = Ac$, $R^2 = H$) with Jones' reagent in acetone gave a high yield of 7,11-dione **36** (R = Ac), identical (^1H nmr, ir) with samples described above.

*3β,11α-Diacetoxycucurbit-5(10)-en-7-one (**45**, $R^1 = R^2 = Ac$).* 3β,7,11α-Triacetoxycucurbit-5(10),6-diene **32** (153 mg) was dissolved in 10 mL of a saturated solution of sodium carbonate in aqueous methanol (35:15 v/v) under argon. The reaction was complete in 1 h. The 142 mg of crude products was purified using three 1000-μm silica gel plates and 6:1 benzene – ethyl acetate, giving 110 mg of **45** ($R^1 = R^2 = Ac$), as a gum; ν_{max}: 1725 and 1695 (shoulder) cm^{-1}; ^1H nmr, δ: 5.15 (t, $J = 8$ Hz, 1H, 11β), 4.81 (t, $J = 3.5$ Hz, 1H, 3α), 2.89 (br s, 2H, 6), 2.44 (s, 1H, 8β), 2.11 (11α-CH_3CO), 2.05 (3β-CH_3CO), 1.07, 1.05, 0.95, 0.90, 0.82, and 0.78 (CH_3 groups); ms *m/e* calcd. for $C_{34}H_{54}O_5$: M^+ 542.4307; found: 542.4703.

*Acid hydrolysis of 3β,7,11α-triacetoxycucurbita-5(10),6-diene (**32**)*

A solution of 10 mg of **32** in 6 mL of methanol containing 1 mg of *p*-toluenesulfonic acid was left under argon for 22 h. The bulk of the methanol was evaporated, the product was extracted into dichloromethane, and this solution washed with sodium carbonate solution, dried, and distilled. The product was 9 mg of 3β,11α-diacetoxycucurbit-5(10)-en-7-one **45** ($R^1 = R^2 = Ac$) identical to the product of mild basic hydrolysis.

*3β,11α-Dihydroxycucurbit-5(10)-en-7-one (**45**, $R^1 = R^2 = H$).* A 1.4 molar solution of lithium aluminium hydride in ether (2.3 mL) was added to a solution of 200 mg of triacetoxy-diene **32** in 20 mL of ether at 0°C under argon. After 15 min at 0°C ammonia gas was used to destroy excess hydride, (22), then 8 mL of 2 *N* hydrochloric acid added cautiously. Fifty millilitres of 1:1 benzene–ether was added; the aqueous layer was separated and then washed with 50 mL of 1:1 benzene–ether. The organic layers were extracted with 5% sodium bicarbonate solution, dried, and distilled. The crude product (158 mg) was purified using three 1000-μm plates with 3:2 benzene – ethyl acetate. The 120 mg of **45** ($R^1 = R^2 = OH$) crystallized from hexane–ether mixtures with mp 156–158°C; $[\alpha]_D$ +32° (*c* 1.1); ν_{max}: 3620, 3470 and 1690 cm^{-1}; ^1H nmr, δ: 3.86 (dd, $J_1 = 6$ Hz, $J_2 = 10$ Hz, 1H, 11β), 3.53 (t, $J = 4$ Hz, 1H, 3α), 2.88 (br s, 2H, 6), 2.44 (s, 1H, 8β), 1.20, 1.00, 0.94, 0.89, 0.82, and 0.75 (CH_3 groups). *Anal.* calcd. for $C_{30}H_{50}O_3$: C 78.55, H 10.99; found: C 78.5, H 11.20.

*Vigorous reduction of 3β,11α-diacetoxycucurbit-5(10)-en-7-one (**45**, $R^1 = R^2 = Ac$)*

A mixture of 90 mg of **45** ($R^1 = R^2 = Ac$) and 90 mg of lithium aluminum hydride in 15 mL of ether was heated under reflux under argon for 2 h. After addition of a further 50 mg of hydride, refluxing was continued for 3 h. Saturated aqueous sodium sulfate was added, followed by enough anhydrous magnesium sulfate to give a filtrable solid. This was removed on sintered glass, and the solid washed with dichloromethane.

The organic layers gave 65 mg of product, which was separated on two 500-μm silica gel plates using 10% methanol in chloroform. The products obtained were 3β,11α-dihydroxycucurbit-5(10)-en-7-one (**45**, $R^1 = R^2 = H$) (11 mg), 3β,7α,11α-trihydroxy-cucurbit-5(10)-ene (**46**, $R^1 = R^2 = H$) (31 mg), and 3β,7β,11α-trihydroxy-cucurbit-5(10)-ene (**39**, R = H) (10 mg).

*3β,7α,11α-Trihydroxycucurbit-5(10)-ene (**46**, $R^1 = R^2 = H$).* This was not obtained crystalline. It had ν_{max} 3620 and 3450 cm^{-1} and gave ^1H nmr signals at δ 4.68 (dd, J_1 = 8 Hz, J_2 = 12 Hz, 1H, 7β), 3.88 (t, J = 8.5 Hz, 1H, 11β), 3.45 (dd, J_1 = 3.5 Hz, J_2 = 8 Hz, 1H, 3α), 1.29, 1.03, 1.00, 0.95, 0.90, and 0.83 (CH_3 groups).

*3β,7β,11α-Trihydroxycucurbit-5(10)-ene (**39**, R = H).* This was not obtained crystalline. It had ν_{max} 3610 and 3450 cm^{-1} and gave ^1H nmr signals at δ 3.91 (apparent t, $J \simeq$ 8 Hz, 2H, 7α and 11β), 3.49 (t, J = 3.5 Hz, 1H, 3α), 1.32, 1.16, 1.02, 1.00, 0.95, 0.89, 0.62, and 0.56 (CH_3 groups).

*Acetylation of 3β,11α-dihydroxycucurbit-5(10)-en-7-one (**45**, $R^1 = R^2 = H$)*

Ten microlitres of 60% perchloric acid was added to a stirred solution of 10 mg of diol **45** ($R^1 = R^2$ = H) in 0.5 mL of acetic anhydride and 0.25 mL of acetic acid. After 10 min at room temperature the reaction was quenched with water. The product was extracted into dichloromethane, then washed free of acid with sodium carbonate solution and the solution dried and distilled. This gave 11 mg of nearly pure 3β,7,11α-triacetoxycucurbita-5(10),6-diene **32**. Diol **45** (R = H) could not be acetylated using acetic anhydride and pyridine to give diacetate **45** (R = Ac). Instead a complex mixture containing no trace of the desired compound was obtained.

*Acetylation of 3β,7α,11α-trihydroxycucurbit-5(10)-ene (**42**, $R^1 = R^2 = R^3 = H$)*

A solution of 31 mg of triol **42** (R = H) in 1 mL of pyridine and 150 mg of acetic anhydride was kept at 0°C for 48 h. The excess anhydride was destroyed using methanol, then the solution evaporated *in vacuo*. The products were separated on two 500-μm silica gel plates using 5:1 benzene – ethyl acetate. Only the 7- and 11-monoacetates required further separation using 10% ethyl acetate in dichloromethane on a 500-μm plate. The compounds obtained, in order of decreasing R_f, and their characteristic low-field ^1H nmr shifts are collected in Table 6.

Jones' oxidation in acetone converted 3β,7α-diacetoxy-11α-hydroxycucurbit-5(10)-ene (**42***b*) into **41** (R^1 = OAc, R^2 = H, R^3 = OAc), 3β,11α-diacetoxy-7α-hydroxycucurbit-5(10)-ene (**42***c*) into **45** ($R^1 = R^2$ = Ac), and 3β-acetoxy-7α,11α-dihydroxycucurbit-5(10)-ene (**42***d*) into 3β-acetoxy-cucurbit-5(10)-en-7,11-dione (**44**), identified in each case by ir and ^1H nmr spectra with samples described above.

*Acetylation of 3β,7β,11α-trihydroxycucurbit-5(10)ene (**38**, R = H)*

This product of lithium aluminium hydride reduction of **45** ($R^1 = R^2$ = Ac) was left for 16 h in 1:1 acetic anhydride – pyridine. The product gave a ^1H nmr spectrum coincident with that of 3β,7β,11α-triacetoxycucurbit-5(10)-ene **38** (R = Ac) obtained by Westphalen reaction of **10**.

*Controlled acetylation of 3β,7α-dihydroxycucurbit-5(10)-ene-11-one (**41**, $R^1 = R^3 = OH$, $R^2 = H$)*

A solution of 41 mg of **41** ($R^1 = R^3$ = OH, R^2 = H) in 1 mL of pyridine and 40 mL of acetic anhydride was left at 0°C for three days. The excess anhydride was destroyed with methanol, then the product isolated as usual. Separation on a 500-μm silica gel plate using 6:1 benzene – ethyl acetate gave (in order of decreasing R_f) 9 mg of the 3β,7α-diacetate (**41**, $R^1 = R^3$ = OAc, R^2 = H), 11 mg of 3β-acetoxy-7α-hydroxycucurbit-5(10)-en-11-one (**41**, R^1 = OAc, R^2 = H, R^3 = OH), 6 mg of 7α-acetoxy-3β-hydroxycucurbit-5(10)-en-11-one (**41**, R^1 = OH, R^2 = H, R^3 = OAc), and 12 mg of starting diol.

*3β-Acetoxy-7α-hydroxycucurbit-5(10)-en-11-one (**41**, R^1 = OAc, R^2 = H, R^3 = OH).* This had ν_{max} 3610, 1720, and 1692 cm^{-1} and gave ^1H nmr signals at δ 4.80–4.35 (m, 2H, 3α and 7β), 2.54 (s, 2H, 12), 2.17 (d, J = 6Hz, 8β), 2.05 (CH_3CO), 1.28, 1.25, 1.03, 0.98, 0.90, 0.83, and 0.72 (CH_3 groups).

Oxidation of 11 mg **41** (R^1 = OAc, R^2 = H, R^3 = OH) in 1 mL of acetone using a small excess of Jones' reagent diluted with acetone gave 11 mg of 3β-acetoxycucurbit-5(10)-en-7,11-dione **44**.

*7α-Acetoxy-3β-hydroxycucurbit-5(10)-en-11-one (**41**, R^1 = OH, R^2 = H, R^3 = OAc).* This gave ^1H nmr signals at δ 5.56 (m, 1H, 7β), 3.38 (m, 1H, 3α), 2.52 (s, 2H, 12), 2.31 (d, J = 8 Hz, 1H, 8β), 2.07 (CH_3CO), 1.30, 1.26, 1.06, 0.96, 0.90, 0.82, and 0.68 (CH_3 groups).

*3β-Acetoxycucurbit-5(10)-en-7,11-dione (**44**).* A solution of 74 mg of **37** in 7.5 mL of a saturated solution of sodium carbonate in aqueous methanol (15:35 v/v) was stirred at room temperature for 20 min. Most of the methanol was removed under reduced pressure, then the product extracted into dichloromethane. The 57 mg of **44** so obtained did not crystallize readily; ν_{max}: 1720 and 1690 cm^{-1}; ^1H nmr, δ: 4.75 (m, 1H, 3α), 2.96 (br s, 2H, 6), 2.64 (s, 2H, 12), 2.54 (s, 1H, 8β), 2.05 (CH_3CO), 1.11, 1.03, 0.98, 0.90, 0.82, and 0.74 (CH_3 groups).

*Hydrolysis and isomerization of **32***

A saturated solution of sodium carbonate in a 35:15 v/v methanol–water mixture was prepared and degassed by boiling under argon. To 90 mL of this solution was added a solution of 180 mg of **32** in 25 mL of methanol, prepared under argon. The mixture was refluxed under argon for 16 h. The bulk of the methanol was removed under reduced pressure, then the products extracted into dichloromethane. The extracts were dried over magnesium sulfate, then distilled to give 147 mg of residue. This contained no acetoxy group (^1H nmr). It was acetylated at room temperature in 1:1 acetic anhydride – pyridine, giving 182 mg of acetates. These were separated on five 500-μm silica gel plates using 3% ethyl acetate in dichloromethane. In order of decreasing R_f the zones contained: A, 27 mg of **32**, B, 29 mg of a diacetoxy α,β-unsaturated ketone; C, 15 mg of a mixture; D, 14 mg of 3β,6,11α-triacetoxy-cucurbita-1(10),5-dien-7-one **48** (R = Ac); E, 7 mg of a conjugated ketone; F, 22 mg of 3β,11α-diacetoxycucurbit-5-en-7-one **47**; G, 2 mg of conjugated ketone. Zones E and G were incompletely characterized.

*Zone B; stereoisomer of **47**.* This amorphous acetate had ν_{max} 1725 and 1648 cm^{-1}. Its ^1H nmr spectrum had signals at δ 6.02 (s, 1H, 6), 5.24 (dd, J_1 = 6 Hz, J_2 = 12 Hz, 1H, 11β), 4.61 (m, 1H, 3α), 2.45 (s, 1H, 8), 2.11, and 2.09 (CH_3CO groups). This and its ^{13}C nmr spectrum (Table 5) are consistent with it being an isomer of **47**.

*3β,11α-Diacetoxy-10α,8β-cucurbit-5-en-7-one (**47**)*

This had ν_{max} 1725, 1650, and 1620 cm^{-1} and λ_{max} 243 nm. It gave ^1H nmr signals at δ 6.0 (s, 1H, 6), 5.18 (t, J = 7 Hz, 1H, 11β), 4.68 (br, 1H, 3α), 3.04 (br d, J = 8 Hz, 1H, 10α), 2.46 (s, 1H, 8β), 2.08 and 2.02 (CH_3CO groups). This and its ^{13}C nmr signals show it to be identical to the compound assigned this structure by Paryzek and Wydra (12). See, however, revised ^{13}C assignment in Table 5.

Briefer hydrolysis of **33** (2 h reflux) under the same conditions followed by acetylation gave, in addition to **47**, another apparent isomer of **47** with λ_{max} 242 nm; ^1H nmr, δ: 6.13 (s, 1H, 6), 5.17 (dd, J_1 = 9 Hz, J_2 = 6.6 Hz, 11β), 4.57 (m, 1H, 3α), 2.95 (br d, J = 12 Hz, 1H, 10), 2.44 (s, 1H, 8), 2.08 (two CH_3CO groups).

Attempts to induce conjugation by acid hydrolysis of **32** (*p*-toluenesulfonic acid in methanol) failed.

*Alkaline autooxidation of 3β-acetoxycucurbit-5(10)-en-7,11-dione (**44**)*

Ten milligrams of **44** was dissolved in 10 mL of methanol and 2 mL of a saturated sodium carbonate solution in 35:15 methanol–water mixture. This was refluxed under argon for 2 h. The solvent was removed under reduced pressure, then the products distributed between dichloromethane and dilute sulfuric acid. The dichloromethane solution was washed with 5% sodium carbonate solution, dried, and distilled. The residue was acetylated during 16 h in 1:1 acetic anhydride – pyridine. The usual work-up gave a product that was separated on a 500-μm silica gel plate using 6:1 benzene – ethyl acetate. The main zone yielded 6 mg of 3β,6-diacetoxycucurbita-1(10),5-dien-7,11-dione **49**.

*Alkaline autooxidation of **45** ($R^1 = R^2$ = Ac)*

(*a*) A solution of 10 mg of 3β,11α-diacetoxycucurbit-5(10)-en-7-one **45** ($R^1 = R^2$ = Ac) in 10 mL of methanol and 2 mL of a saturated solution of sodium carbonate in 35:15 methanol–water mixture was refluxed under argon for 1.5 h. The bulk of the methanol was removed under reduced pressure, then the product extracted into dichloromethane. The 9 mg of product was separated on a 500-μm silica gel plate using 1:1 benzene – ethyl acetate. The main zone gave 5 mg of the sensitive triol **48** (R = H).

(*b*) A stock solution of 1 g of potassium hydroxide in 95 mL of

methanol and 5 mL of water was prepared. One millilitre of this was added to a solution of 37 mg of **45** (R^1 = R^2 = Ac) in 3 mL of methanol. The mixture was stirred under argon for 90 min, then concentrated *in vacuo*. The products were extracted into 1:1 benzene–ether, then the organic layers washed successively with 2*N* hydrochloric acid, 5% sodium carbonate solution, then saturated brine, dried, and distilled. The residue was acetylated at room temperature in 1 mL of acetic anhydride and 1 mL of pyridine for 16 h. The acetate produced was purified on a 1000-μm silica gel plate using 10:1 benzene – ethyl acetate to give 24 mg of 3β,6,11α-triacetoxycucurbita-1(10),5-dien-7-one (**48**, R = Ac), which did not crystallize.

*Partial acetylation of **48** (R = H)*

The triol **48** (R = H) was produced as in (*a*) or by hydrolysis of **48** (R = Ac) using potassium hydroxide in methanol as in (*b*), but for 16 h at room temperature under argon. Crude triol (20 mg) was acetylated during 90 min at room temperature in 0.4 mL of pyridine and 0.4 mL of acetic anhydride. The product was separated on a 500-μm silica gel plate to give 5 mg of triacetate **48** (R = Ac) and 5 mg of 3β,6-diacetoxy-11α-hydroxycucurbita-1(10),5-diene-7-one (**48**, R^1 = R^3 = Ac, R^2 = H).

*3β,6,11α-Trihydroxycucurbita-1(10),5-dien-7-one (**48**, R = H).* This was amorphous, and gave λ_{max} 330 nm (accurate intensity not available because of decomposition) and ν_{max} 3620, 3420, 1650, and 1605 cm^{-1}. It gave ^{1}H nmr signals at δ 6.75 (s, 1H, 6-hydroxyl), 6.74 (t, J = 4.5 Hz, 1H, 1), 4.07 (dd, J_1 = 3 Hz, J_2 = 10 Hz, 1H, 11β), 3.52 (t, J = 3 Hz, 1H, 3α), 2.48 (s, 1H, 8β) superimposed on a multiplet between 2.5 and 2.3 (2H, 2), 1.43, 1.36, 1.30, 1.26, 0.96, 0.89, and 0.82 (methyl groups).

*3β,6-Diacetoxy-11α-hydroxycucurbita-1(10),5-diene-7-one (**48**, R^1 = R^3 = Ac, R^2 = H).* This was amorphous, with λ_{max}: 308 nm (ε 9000) and a weak maximum at 235 nm; ν_{max}: 3620, 1760, 1735 (shoulder), 1720, 1665, 1620, and 1585 cm^{-1}; ^{1}H nmr, δ: 6.97 (t, J = 4 Hz, 1H, 1), 4.79 (t, J = 5 Hz, 1H, 3α), 4.07 (dd, J_1 = 3 Hz, J_2 = 10 Hz, 11β), 2.43 (s, 1H, 8β) superimposed on a multiplet at 2.55–2.45 (2H, 2), 2.27 (s, 6-CH_3CO), 2.03 (s, 3H, 3β-CH_3CO), 1.42, 1.26, 1.05, 0.95, 0.89, and 0.82 (methyl groups).

*3β,6,11α-Triacetoxycucurbita-1(10),5-dien-7-one (**48**, R = Ac).* This was amorphous, with λ_{max} 306 nm (ε 8500) and a weak maximum at 1585 cm^{-1}. It gave ^{1}H nmr signals at δ 6.67 (t, J = 4.5 Hz, 1H, 1), 5.30 (dd, J_1 = 4 Hz, J_2 = 10 Hz, 1H, 11β), 4.79 (t, J = 4.5 Hz, 1H, 3α), 2.56 (s, 1H, 8β) superimposed on a multiplet at 2.6–2.35 (2H, 2), 2.28 (6-CH_3CO), 2.09 (11α-CH_3CO), 2.02 (3β-CH_3CO), 1.27, 1.26, 1.05, 0.89, and 0.82 (methyl groups). Irradiation at δ 2.53 caused the signals at 6.67 and 4.79 to collapse to singlets.

*3β,6-Diacetoxycucurbita-1(10),5-dien-7,11-dione (**49**).* This was amorphous, with ν_{max}: 1760, 1735, 1720, 1695, 1665, 1615, and 1585 cm^{-1}; ^{1}H nmr, δ: 5.56 (t, J = 4.5 Hz, 1H, 1), 4.76 (dd, J_1 = 4.5 Hz, J_2 = 6 Hz, 1H, 3α), 2.76 (s, 1H, 8β), 2.70 (s, 2H, 12), 2.30 (6-CH_3CO), 2.03 (3β-CH_3CO), 1.32, 1.20, 0.90, 0.82, and 0.78 (methyl groups); ms *m/e* calcd. for $C_{34}H_{50}O_6$: M^+ 554.3607; found: M^+ 554.3602.

*Dehydrogenation of 3β,11α-diacetoxycucurbit-5(10)-en-7-one (**45**)*

(*a*) A mixture of 21 mg of **45** (R^1 = R^2 = Ac) and 10 mg of rhodium trichloride trihydrate in 1 mL of 95% ethanol was refluxed for 2 h. A dark precipitate formed. The ethanol was evaporated, the product dissolved in dichloromethane, then this solution washed with dilute sulfuric acid followed by dilute sodium carbonate solution. The 30 mg of product was separated on a 500-μm silica gel plate using 6:1 benzene – ethyl acetate. Four zones were detected. The main product (14 mg) had R_f 0.5 and λ_{max} 296 nm, and was shown to be 3β,11α-diacetoxycucurbita-1(10),5-dien-7-one (**50**, R = Ac).

(*b*) A solution of 10 mg of diol **45** (R = H) in 5 mL of benzene containing 10 mg of 30% palladium-on-charcoal was refluxed under argon for 24 h. A further 10 mg of catalyst was added and refluxing continued for 3 days. The product (13 mg) was purified on a 500-μm silica gel plate using 1:1 benzene – ethyl acetate, giving 5 mg of amorphous dienone **50** (R = H).

Acetylation of the diol during 60 h in 1:1 acetic anhydride – pyridine at room temperature gave the amorphous diacetate **50** (R = Ac).

*Dehydrogenation of 3β,7,11α-triacetoxycucurbita-5(10),6-diene (**32**)*

The enol acetate **32** (45 mg) and 68 mg of iron pentacarbonyl in 3 mL of dry diglyme under an argon atmosphere was heated in a bath at 148°C for 26 h. The solvent was evaporated *in vacuo*, then the residue dissolved in 1 mL of ethanol. A solution of 393 mg of ferric chloride in 3 mL of 95% ethanol was added, and the mixture was stirred for 1.5 h at room temperature. The solvent was removed under reduced pressure, then the product distributed between dichloromethane and dilute sulfuric acid. The dichloromethane was washed with sodium carbonate solution, dried, and distilled. The residue gave four main zones when separated on a 1000-μm silica gel plate using 6:1 benzene – ethyl acetate. One zone (R_f 0.6) yielded 12 mg of parent **32**. The main zone (R_f 0.5) contained 26 mg (79% based on unrecovered **32**) of conjugated dienone **50** (R = Ac). This was further purified by passage of a hexane solution through a short column of Activity 1 neutral alumina. The 21 mg of amorphous product was used to obtain spectra.

*3β,11α-Dihydroxycucurbita-1(10),5-dien-7-one (**50**, R = H).* This had λ_{max} 302 nm (ε 6700) with a weak maximum at 2.35 nm, and ν_{max}: 3630, 3470, 1640, and 1585 cm^{-1}. It gave ^{1}H nmr signals at δ 6.94 (t, J = 3.5 Hz, 1H, 1), 6.02 (s, 1H, 6), 4.07 (dd, J_1 = 5 Hz, J_2 = 11 Hz, 1H, 11β), 3.62 (dd, J_1 = 7 Hz, J_2 = 9 Hz, 1H, 3α), 2.33 (s, 1H, 8β), 2.6–2.2 (m, 2H, 2), 1.28, 1.26, 1.22, 1.03, 0.95, 0.90, and 0.82 (CH_3 groups).

*3β,11α-Diacetoxycucurbita-1(10),5-dien-7-one (**50**, R = Ac).* The amorphous diacetate from acetylation of **50** (R = H) or dehydrogenation of **45** (R = H) and **32** had λ_{max} 296 nm (ε 11 300) with a weak maximum at 237 nm, and ν_{max}: 1725, 1645, and 1585 cm^{-1}. It gave ^{1}H nmr signals at δ 6.65 (br t, J = 3.2 Hz, 1H, 1), 6.03 (s, 1H, 6), 5.30 (dd, J_1 = 11.5 Hz, 1H, 11β), 4.81 (dd, J_1 = 6 Hz, J_2 = 11 Hz, 1H, 3α), 2.9–2.25 (m, 2H, 2), 2.46 (s, 1H, 8β), 2.11, 2.09 (CH_3COO groups), 1.15, 1.14, 1.10, 1.06, 0.94, 0.90, and 0.82 (CH_3 groups). Irradiation at 2.67 ppm collapsed the 1H triplet to a singlet, the signals for the 3α-H approached a singlet, and the splitting pattern for the 6-hydrogen changed. Its mass spectrum had a weak peak at *m/e* 540 (M^+) and strong peaks *m/e* 480 (M − 60) and 420 (M − 120).

*Autooxidation of 3β,7,11α-triacetoxycucurbita-5(10),6-diene (**32**)*

A 632-mg sample of the acetoxydiene **32** was stored as a froth at room temperature for 15 months. It now contained major impurities.

Separation on six 1000-μm plates using 6:1 benzene – ethyl acetate gave, in order of decreasing R_f, 296 mg of **32**, 169 mg of 3β,11α-diacetoxy-1α,10α-epoxycucurbit-5-en-7-one **51**, and 24 mg of unidentified product.

3β,11α-Diacetoxy-1α,10α-epoxycucurbit-5-en-7-one (51). This amorphous product had ν_{max}: 1730, 1655, and 1615 cm^{-1}. It gave ^1H nmr signals at δ 6.35 (s, 1H, 6), 5.10 (dd, J_1 = 3.5 Hz, J_2 = 12.5 Hz, 1H, 11β), 4.85 (t, J = 4 Hz, 1H, 3β), 4.26 (d, J = 1 Hz, 1H, 1), 3.47 (s, 1H, 8β), 2.10 (11α-CH_3COO), 2.01 (3β-CH_3COO), 1.21, 1.15, 1.06, 1.03, 0.89, and 0.82 (CH_3 groups). On irradiation at 2.30 ppm the signals for the 1-H collapsed to a singlet and the 3-H and 11-H signals became less complex. Mass spectrum, m/e calcd. for $C_{34}H_{52}O_7$: M^+ 556.3764; found: M^+ 556.3751.

FRANCIS M. F. CHEN, YOUNG LEE, RENE STEINAUER, and N. LEO BENOITON. Can. J. Chem. **65**, 613 (1987).

A study of the factors contributing to urethane formation during the coupling of *N*-alkoxycarbonylamino acids with an amino acid ester by the mixed carboxylic–carbonic acid anhydride method has been carried out, using nuclear magnetic resonance spectroscopy and high-performance liquid chromatography for the quantitation of products. Urethane formation is associated primarily with reactions of activated hindered residues such as isoleucine and *N*-methylamino acids. Of prime importance in dictating the amount of urethane generated is the tertiary amine/solvent combination. *N*-Methylpiperidine/dichloromethane is the best combination for minimizing urethane formation, *N*-methylmorpholine/tetrahydrofuran is a good combination, while triethylamine/dichloromethane is a particularly bad one. In dimethylformamide, the differences between these amines are marginal. Aqueous dimethylformamide is a good solvent for mixed anhydride generation and coupling. A small excess of substrate reduces the amount of urethane. Less racemization accompanies the coupling of peptide acids in tetrahydrofuran than in halogen-containing solvents, *N*-methylpiperidine being the superior base in these solvents, but not in dimethylformamide. Racemization is reduced by one half when menthyl chloroformate instead of isobutyl chloroformate is used in the couplings.

FRANCIS M. F. CHEN, YOUNG LEE, RENE STEINAUER et N. LEO BENOITON. Can. J. Chem. **65**, 613 (1987).

Faisant appel à la rmn et la chromatographie liquide à haute performance pour quantifier les produits formés, on a effectué une étude des facteurs qui contribuent à la formation d'uréthane lors du couplage, par la méthode des anhydrides mixtes d'acides carboxylique et carbonique, d'acides *N*-alkoxycarbonylamino avec un ester d'acide aminé. La formation d'uréthane est principalement associée avec les réactions de résidus activés empêchés, comme l'isoleucine et les acides *N*-méthylaminés. La combinaison amine tertiaire/solvant est d'importance capitale dans la quantité d'uréthane formée. Le couple *N*-méthylpipéridine/dichlorométhane correspond à la meilleure combinaison pour minimiser la formation d'uréthane; la combinaison *N*-méthylmorpholine/tétrahydropyranne est bonne alors que la combinaison triéthylamine/dichlorométhane est particulièrement mauvaise. Dans le diméthylformamide, les différences entre ces amines sont marginales. Le diméthylformamide aqueux est un bon solvant pour générer des anhydrides mixtes et pour leur couplage. Un léger excès de substrat réduit la quantité d'uréthane. Il y a moins de racémisation lors du couplage de peptides dans le tétrahydrofuranne que dans des solvants contenant des halogènes; la *N*-methylpipéridine est la base la meilleure dans ces solvants, mais pas dans le diméthylformamide. La racémisation est réduite de moitié lorsqu'on utilise du chloroformate de menthyle au lieu du chloroformate d'isobutyle hors de ces couplages.

The mixed anhydride method of coupling used in peptide synthesis involves reaction of a protected amino or peptide acid **1** with an alkyl chloroformate **2** in the presence of a tertiary amine base to give the mixed carboxylic acid – carbonic acid anhydride **3**. The anhydride is then reacted with an amine nucleophile **4**, which is either an amino acid ester **4***a* or a peptide ester, giving the protected peptide **5** (1, 2). Three side reactions may accompany the coupling reaction. An inversion of configuration may occur at the activated residue when **1** is a peptide acid, and a second acylation product, urethane **6**, may be produced by aminolysis at the carbonyl of the carbonate moiety of the anhydride or aminolysis of unconsumed chloroformate **2**, or both. Conditions for minimizing the racemization have been defined (3, 4), and protocols for obtaining maximum coupling yields have been recommended (2–4). But little is known about the urethane-forming reaction except that more urethane is generated when the activated residue is valyl or isoleucyl (5), and when the incoming nucleophile is a secondary amine (Pro, MeXxx) (2). In the course of studies on the coupling of *N*-methylamino acids (6), it became apparent to us that many questions about the mixed anhydride method of coupling remained unanswered, in particular regarding the factors contributing to the formation of the urethane side product. We therefore began a systematic investigation of this side reaction, the results of which are reported in this communication. Preliminary reports on some of the work have appeared (7, 8). Emerging from this study was the realization that mixed anhydrides are not immediately destroyed by contact with water, and consequently can be isolated from the mixture in which they are generated by washing the solution with water (9). This and the information derivable therefrom is described in the accompanying communication (10).

Results and discussion

Representative *N*-alkoxycarbonylamino acids **1***a* were coupled with an amino acid ester **4***a* under various conditions and the proportions of peptides **5***a* and urethanes **6***a* present in the neutral fractions were determined by 60-MHz ^{1}H nmr spectroscopy after the usual work-up. The combination of Boc-Ile-OH,[3] a derivative of a hindered residue, and H-Lys(Z)-OMe, which gives unique singlet resonances in the nmr spectrum, was selected as the standard system for examining the effect of parameters external to the coupling components. Reactions were carried out initially under conditions recommended for achieving optimum results except for the tempera-

ture, namely activation for 90 s in tetrahydrofuran using isobutyl chloroformate in the presence of *N*-methylmorpholine, followed by addition of the nucleophile in the same solvent (2–4). For ease of operation, −5°C instead of the recommended −15°C was chosen as temperature. After considerable data had been acquired it became obvious that an analytical method more sensitive than nmr spectroscopy was required for us to arrive at reliable conclusions. The products of the reactions were then determined by high-performance liquid chromatography (hplc). Representative results are collated in Tables 1–6, and are discussed in different sections, not necessarily in the order obtained. Only selected data from the preliminary communications (7, 8) have been reproduced. Data on racemization are given in Tables 7 and 8. In view of the novel information that has been acquired with the isolated mixed anhydrides (9), the discussion in the present communication is limited in scope to avoid duplication.

Effect of the amount of acid ***1***

One postulated source of urethane **6** is reaction of nucleophile **4** with unconsumed chloroformate **2**. The effect of using a 5% excess of **1***a* to promote complete consumption of **2***a* is shown in Table 1. The extent of the effect varied, depending on the nature of **1***a*, but it was beneficial in all cases, eliminating the formation of iBuOCO-Lyz(Z)-OMe for Boc-Pro-OH, decreasing its yield by six times for Boc-Leu-OH and by 23% for Boc-Ile-OH. These results are significant enough to conclude that the use of a small excess of **1***a* reduces the amount of urethane produced by promoting consumption of the chloroformate. Excess substrate obviously cannot be expected to eliminate the urethane generated by aminolysis at the carbonate moiety of the anhydride. Others have employed this tactic of using a small excess of substrate (11), but it has not been included in the general recommendations (2, 3, 12). In fact, it has been reported that the use of a 100% excess of substrate had no effect on the amount of **6** generated when Boc-amino acids were coupled with amino acid β-naphthylamides (5).

Effect of the nature of the base, and the activation time

Couplings were carried out using various tertiary amines selected on the basis of frequency of use and availability, bearing in mind the desirability that the amine should contain at least one *N*-methyl group (2, 3). The yields of **5***a* and **6***a* obtained are given in Table 2. The recovery of material was high

and approximately the same in all cases. There was an inverse relationship between the amount of urethane produced and the yield of peptide. Best results in terms of the amount of urethane generated were obtained with the saturated six-membered ring amines, with *N*-methylpiperidine being slightly superior to *N*-methylmorpholine. Triethylamine was definitely inferior as it gave only a 54% yield of peptide. Since all other factors were identical in the experiments, one must conclude that most of the urethane formed in the latter case, as well as with *N*-methylimidazole as base, originated from the reaction of ester **4***a* with unconsumed chloroformate. This suggests that the anhydride

is formed considerably faster in the presence of *N*-methylmorpholine than in the presence of triethylamine.[4] In support of this are the data in Table 3 showing the beneficial effects of extending the time of activation when *N*-methylpiperidine and *N*-methylpyrrolidine were used as bases. That the tertiary amine exerts its effect at the anhydride generation stage, and not at the coupling step, emerges from the results with Boc-MeLeu-OH as substrate (Table 4). When *N*-methylmorpholine was used to generate the anhydride and triethylamine was used to neutralize the hydrochloride of the ester, no urethane was detectable. But when the bases were interchanged, two thirds of the product was urethane. No peptide whatsoever was obtained from the couplings involving the two highly hindered amines. This is essentially in agreement with the literature (3).

Effect of the solvent

The course of the mixed anhydride reactions was examined in tetrahydrofuran and in dichloromethane, despite allusions to the unsuitability of the latter as a solvent (2), because of its popularity for carbodiimide-mediated reactions. The ratios of peptide to urethane obtained for several hindered substrates are given in Table 4. It is seen that when the amine was *N*-methylmorpholine or *N*-methylpiperidine, a higher ratio was obtained in dichloromethane than in tetrahydrofuran. But when the base was triethylamine, the ratio obtained in dichloromethane was much lower than in tetrahydrofuran. The conclusion is that dichloromethane is a poor solvent only when triethylamine is the base, and it is a superior solvent when *N*-methylmorpholine or *N*-methylpiperidine is used as base. On the other hand, when the solvent was dimethylformamide, there was only a slight difference in the results for the three amines. In Table 5 is shown the effect of the solvent on the yields of peptide obtained for several substrates that give rise to minimal amounts of urethane. It is seen that there was no significant difference between tetrahydrofuran, dimethylformamide, and the halogen-containing solvents. In addition, it was found that dimethylformamide to which had been added 25% of water, a solvent used successfully for couplings of symmetrical anhydrides **7***a* (13), served as well for mixed anhydride reactions as the anhydrous solvent. These results are contradictory to the generally held notions that halogen-containing solvents are poor solvents, and that anhydrous solvents are essential, for mixed anhydride reactions. The previous conclusions that halogen-containing solvents are not suitable for mixed anhydride reactions were based on results obtained using triethylamine as the base.

TABLE 5. Effect of the solvent on the yield (%) of peptide[a]

Substrate	THF	DMF	DMF–H_2O (4:1)
Boc-Val-OH	92	82	80
Boc-Pro-OH	83		91
Boc-MeLeu-OH	82	73	75
Z-Gly-Pro-OH	84		80

[a]Substrate (1.0 equiv.) coupled with H-Lys(Z)-OMe using EtOCOCl and NMM at −5°C with an activation time of 90 s; $CHCl_3$, 88%; $CHCl_2$, 84%. No urethane was detectable by nmr.

Effect of the temperature

Mixed anhydride reactions have traditionally been carried out at −15°C to minimize racemization and to avoid disproportionation of the anhydride to the symmetrical anhydride **7***a* and the dialkyl pyrocarbonate **8**. A comparison of the amounts of urethane obtained at −5°C and 23°C for our standard system in the presence of two different tertiary amines is given in Table 3. Substantially more urethane was generated at the higher temperature. This is consistent with the notion that the higher temperature promotes disproportionation, thus providing an additional source of urethane, namely the pyrocarbonate, which is a good acylating agent. An experiment with Boc-MeVal-OH at −70°C (Table 4) showed a moderate increase in urethane formation, which can be attributed to the slower formation of the anhydride. But one cannot be sure that this is the correct explanation, in view of the demonstrated effect of temperature on the aminolysis (10). Regardless, the results show that a mixed anhydride still can be coupled efficiently at a very low temperature.

Effect of the nature of the nucleophile **4**

Boc-Ile-OH was coupled with different amino acid esters **4***a* and the peptide-to-urethane ratio was determined. The results in

[4]That this is so has been unequivocally demonstrated (10).

TABLE 6. Effect of the nature of the nucleophile on urethane formation[a]

Substrate	Nucleophile	Peptide:urethane
Boc-Ile-OH	H-Gly-OBzl	97.4:2.6
Boc-Ile-OH	H-Leu-OBzl	96:4
Boc-Ile-OH	H-Val-OBzl	95:5
Boc-Ile-OH	H-Lys(Z)-OMe	93.5:6.5
Boc-Ile-OH	H-Pro-OBzl	51:49
Boc-Gly-OH	H-Gly-OBzl	>100
Boc-Leu-OH	H-Leu-OBzl	99.7:0.3
Boc-Pro-OH	H-Lys(Z)-OMe	>100
Boc-Pro-OH	H-Pro-OBzl	58:42
Boc-Pro-OH	H-Pro-OBzl	67:33[b]

[a]Substrate (1.05 equiv.) coupled using iBuOCOCl and NMM in THF at −5°C with an activation time of 90 s. Results determined by hplc.
[b]NMP in CH_2Cl_2.

Table 6 show that the side chain of **4***a* had very little influence on the extent of urethane formation except in the case of proline, for which the ratio was one. The propensity of the imino group of proline to generate urethane from the mixed anhydride reaction is well known (2). Selectivity during aminolysis is eliminated because of the higher basicity of the secondary amino group.

Effect of the addition of 1-hydroxybenzotriazole (HOBt)

A recent publication reports that the side reaction of urethane formation is suppressed when HOBt is added to the mixed anhydride before the addition of the amine nucleophile (14). The rationale is that aminolysis is preceded by transformation of the mixed anhydride into the activated ester. Boc-Ile-OH was coupled with H-Lys(Z)-OMe in an acetonitrile–dimethylformamide mixture at −15°C using isobutyl chloroformate and *N*-methylmorpholine exactly as described by Prasad *et al.* (14) with and without the addition of one equivalent of HOBt. The results were 85 and 3.0% yields of peptide and urethane, respectively, in the absence of the additive, and 90 and 2.0% yields in the presence of the additive. We conclude that the tactic of adding HOBt is beneficial, but it does not eliminate the formation of urethane.

Effect of the nature of the solvent on racemization

In view of the success achieved with the mixed anhydride reaction in dichloromethane, the extent of stereomutation accompanying the coupling of some dipeptide acids was examined in halogen-containing solvents as well as in tetrahydrofuran. A dipeptide ester, H-Lys(Z)-Gly-OBzl, was selected as the amino component. The results appear in Table 7. With alanyl and valyl as the activated residues, racemization in either tetrahydrofuran, chloroform, or dichloromethane did not exceed the limits of detection of the analytical method. With phenylalanyl as the activated residue, less racemization occurred in tetrahydrofuran than in the halogen-containing solvents. Toluene gave rise to more racemization than the other solvents. Other data in Table 8 show that more racemization occurred in dimethylformamide than in dichloromethane. Though it is stated above that anhydrous solvents are not essential for efficient coupling, the presence of water did cause considerable racemization (Table 7). The results are thus in agreement with the original contention (2, 3) that tetrahydrofuran is the best solvent for minimizing racemization.

Effect of the nature of the chloroformate on racemization

In the accompanying communication, it is reported that a 2-alkoxy-5(4*H*)-oxazolone is formed more quickly from the mixed anhydride of an *N*-alkoxycarbonylamino acid when the alkyl group is methylsulfonylethyl than when it is isobutyl, and less quickly when the alkyl group is menthyl (10). Since the racemization accompanying the coupling of peptide acids results from the formation and tautomerism of the 2-alkyl-5(4*H*)-oxazolone, it was reasoned that the racemization associated with mixed anhydride reactions might depend on the chloroformate use. Indeed this is the case. The results in Table 8 show that menthyl chloroformate (**2***c*) consistently gave rise to less racemization than isobutyl chloroformate, and in some cases less than half as much. Methylsulfonylethyl chloroformate (**2***b*) (15) led to more than 50% racemization. The results therefore can be correlated with the ease of formation of the 2-alkoxy-5(4*H*)-oxazolone from anhydride **3***a* (10). To our knowledge, this is the first time anyone has addressed the possibility that the nature of the chloroformate might have some bearing on the racemization associated with mixed anhydride reactions. The use of menthyl chloroformate can thus be considered as an option for trying to minimize racemization when coupling peptide acids. The yields of peptide product **5** were satisfactory with the model system examined (Table 8). However, the benefits of using menthyl chloroformate must be weighed against the associated disadvantages, namely that menthyl alcohol is difficult to get rid of because it is insoluble in aqueous sodium hydrogen carbonate, and the higher tendency of the mixed anhydride to generate urethane (10).

On the coupling of N*-alkoxycarbonylamino acids*

The data in Tables 1, 4, and 6 and in ref. 7 are in agreement with the notion that urethane formation is of major concern during the couplings of the hindered residues valyl and isoleucyl (2, 5) (but not leucyl as indicated in ref. 2), which led to 10–20 times more urethane than the other residues. The *N*-methylamino acid derivatives generated about five times more urethane (MeLeu vs. Leu) than the corresponding unmethylated derivatives. Whether the small amounts (0.0–0.3%) observed for the other residues resulted from incomplete consumption of chloroformate or from aminolysis at the carbonate of the anhydride cannot be established by the present approach. It should be emphasized, however, that more than minor amounts of urethane can result from the couplings of unhindered residues if an unsuitable solvent/base combination such as dichloromethane/triethylamine is used. In this regard, the results in Tables 4 and 6 and in ref. 7 indicate that the best combination for minimizing urethane formation is *N*-methylpiperidine/dichloromethane. The difficult case of Boc-Pro-OH coupled with H-Pro-OBzl improved from a peptide–urethane ratio of 58:42 for *N*-methylmorpholine/tetrahydrofuran to a ratio of 67:33 for *N*-methylpiperidine/dichloromethane (Table 6). The recommendation in the original study that *N*-methylmorpholine was the most suitable tertiary amine for mixed anhydride reactions was based on chirality considerations and on the yield of peptide without making a distinction between the two types of substrate that might be implicated (3). We suggest that careful distinction between *N*-alkoxycarbonylamino acids and peptide acids should be made in any discussion on the mixed anhydride reaction. It is not at all as critical to have a short activation time of 90 s as recommended (3) when coupling *N*-alkoxycarbonylamino acids as it is when coupling peptide acids where racemization becomes pertinent. In fact, it is probably wiser to extend the time to 2 or 3 minutes for the *N*-alkoxycarbonylamino acids to ensure complete consumption of the chloroformate, especially for the more difficult cases.

[a]% D–L isomer formed during coupling with H-Lys(Z)-Gly-OBzl at −5°C with an activation time of two min. ( ) = % yield of peptide.
[b]Couplings in THF did not work.

When prolyl is the nucleophile, or a hindered residue is activated, it is impossible to avoid urethane formation. Recognizing this, it occurred to us that one way to surmount the difficulty might to be generate a urethane that could be removed by its selective destruction before continuing on with the synthesis. The benzyloxycarbonyl groups came to mind, but using benzyl chloroformate for the coupling would not allow us to prepare our standard peptide. We therefore examined the use of methylsulfonylethyl chloroformate (**2***b*) (15), the MsOCO-*N* group being sensitive to cleavage by nucleophiles. Boc-Ile-OH was coupled with H-Lys(Z)-OMe in dichloromethane by the standard procedure using MsOCOCl instead of iBuOCOCl. A 90% yield of Boc-Ile-Lys(Z)-OMe containing 2.7% of MsOCO-Lys(Z)-OMe was obtained. The mixture was left in acetonitrile containing sodium methoxide for 5 min. Work-up gave an 80% yield of pure Boc-Ile-Lys(Z)-OMe. A small amount of deesterification had accompanied the cleavage. It should be noted that it is not possible to obtain this compound pure by the conventional mixed anhydride reaction without some form of fractionation, which could be tedious or inefficient. We recommend consideration of this approach. The alternative for circumventing the urethane problem with prolyl as the nucleophile is to insert the prolyl residue through the activated dipeptide (e.g., Boc-Xxx-Pro-OH), which is not susceptible to racemization (16).

On the coupling of peptide acids

A possible source of urethane in the coupling of peptide acids is aminolysis of unconsumed chloroformate, which accounts for the results with Z-Gly-Val-OH/TEA in Table 4. Optimum conditions to promote complete anhydride formation are therefore obviously desirable. Some indication of the amount of urethane produced during couplings under favourable conditions is given in Table 7; however, even here, one cannot be sure that all the chloroformate had been consumed before the addition of the peptide ester nucleophile. Completion of the reaction might have been assured by extending the time of activation; however, in practice, this is counter-productive as it promotes racemization (3). Consequently, the issue was not pursued, and we make no conclusions here on the generation of urethane by aminolysis at the carbonate moiety of mixed anhydrides of peptide acids. With regards to chiral preservation during couplings, the results in Table 7 are in agreement with the original contention (2, 3) that tetrahydrofuran is the best solvent for minimizing racemization. On the other hand, the results in Tables 7 and 8 suggest that the superior base for achieving the same purpose in either tetrahydrofuran or dichloromethane is *N*-methylpiperidine and not *N*-methylmorpholine. The superiority of *N*-methylpiperidine does not seem to hold in dimethylformamide (Table 8), despite our initial claim that it does (7). We have no explanation for the discrepancy in the data, and suspect that the unusually high values for racemization reported earlier (7) were obtained for couplings carried out in improperly preserved solvent.

Experimental

General

Tertiary amines and alkyl chloroformates (Aldrich products) were purchased from Terochem Laboratories, Edmonton, except for methylsulfonylethyl chloroformate, which was a gift from Professor G. I. Tesser (15). Menthyl chloroformate was the *levo* isomer. Solvents (Fisher Scientific) were dried (CH_2Cl_2 over K_2CO_3; THF over $LiAlH_4$) and distilled. Dimethylformamide was used within 72 h of distillation. Amino acid and peptide derivatives were purchased from Sigma Chemical Company or obtained by synthesis, H-Lys(Z)-OMe.HCl (17), Z-Gly-Xxx-OH (18), H-Xxx-OBzl.HCl (19), ROCO-MeXxx-

OH (20). All amino acid esters were hydrochlorides, which were neutralized by the addition of an equivalent of the pertinent tertiary amine. Solvents were removed at room temperature using a rotary evaporator. Reference compounds **6** were obtained as oils by reaction of iBuOCOCl with the appropriate amino acid ester in CH_2Cl_2 followed by aqueous washes and removal of the solvent. Proton nmr spectra were determined in deuterochloroform using a Varian EM-360 60-MHz instrument. The high-performance liquid chromatograph was a basic Waters Scientific instrument incorporating a variable-wavelength detector, a data module, and a 30 cm × 3.9 mm id stainless-steel column with 10-μm μBondapak-C_{18} packing as previously described (21).

Representative coupling procedure

To 10 mL of a stock solution of THF containing 1 mmol of *N*-methylmorpholine was added 1 mmol of H-Lys(Z)-OMe.HCl; the mixture was stirred at 23°C for 30 min and then cooled to −5°C. One or 1.05 mmol of Boc-Ile-OH was added to 10 mL of the same stock solution in a second flask, and the solution was cooled to −5°C. To this stirred solution was added 1 mmol of iBuOCOCl followed, 90 s later, by the first solution of ester. After 1 h at −5°C, and 3 or more h at room temperature, the solvent was removed and the residue was dissolved in CH_2Cl_2. The solution was washed with dilute citric acid, aqueous $NaHCO_3$, water, and dried ($MgSO_4$); the solvent was removed by evaporation and the residue was weighed. When DMF was used as solvent for couplings, it was not removed before the addition of CH_2Cl_2. In a few cases, products were separated by passage through a silica-gel column with ethyl acetate – light petroleum as solvent.

*Quantitation of peptides **5** and urethanes **6***

When not indicated, the proportions of **5** and **6** in the products were determined by comparing the intensities of appropriate signals in the nmr spectra. Otherwise, the amounts of **5** and **6** were determined by hplc using acetonitrile–water (1:1) as solvent at a flow rate of 1 mL/min with absorbance monitoring at 215 nm. The molar absorbance of Boc-Ile-Lys(Z)-OMe was 1.1% greater than that of iBuOCO-Lys(Z)-OMe. Compounds **5** and **6** for other pairs of products were assumed to have the same absorbance. The elution times (min) were: iBuOCO-Gly-OBzl, 11.2; iBuOCO-Lys(Z)-OMe, 13.4; iBuOCO-Val-OBzl, 24.5; iBuOCO-Leu-OBzl, 33.5; Boc-Pro-Lys(Z)-OMe, 9.0; Boc-Ile-Gly-OBzl, 14.0; Boc-Ile-Lys(Z)-OMe, 17.3; Boc-Leu-Lys(Z)-OMe, 18.9; Boc-Ile-Val-OBzl, 29.8; Boc-Leu-Leu-OBzl, 40.5.

Extent of racemization

This was determined by hplc of the diastereomeric H-Gly-D/L-Xxx-Lys-Gly-OH peptides on the C-18 column after deprotection of the coupling products (Z-Gly-Xxx-Lys(Z)-Gly-OBzl) by catalytic hydrogenation as described (18). The solvents, at flow rates of 1 mL/min, were 0.01 *M* ammonium acetate, pH 6.6 for Xxx = Ala, pH 4.0 for Xxx = Val, and pH 4.0 containing 4% acetonitrile for Xxx = Phe, with monitoring at 208 nm.

Preparation of H-Lys(Z)-Gly-OBzl.HCl

To an equimolar solution of Boc-Lys(Z)-OH (10 mmol), H-Gly-OBzl.HCl, 1-hydroxybenzotriazole, and *N*-methylmorpholine in CH_2Cl_2 (50 mL) at 0°C was added *N*,*N*′-dicyclohexylcarbodiimide (10 mmol) and the mixture was stirred at 0°C for 3 h. The urea was removed by filtration, the filtrate was washed with dilute citric acid and aqueous $NaHCO_3$, dried, and the solvent was removed. The residue was taken up in ethyl acetate, the solution was filtered, and the solvent was evaporated to give an oil (5.2 g, 93%). To this oil (Boc-Lys(Z)-Gly-OBzl, 4.56 g) dissolved in tetrahydrofuran at 0°C was added anhydrous diethyl ether (30 mL), which had been saturated with HCl at 0°C. After 1 h at 0°C, the solvent was removed, the residue was triturated in ether (30 mL), and the crystals that formed were collected. Recrystallizatio from ethanol–ether gave H-Lys(Z)-Gly-OBzl.HCl (3 g, 75%), m 153–154°C, $[\alpha]_D^{22}$ + 8.0° (*c* 1.0, 0.1 *N* HCl). *Anal.* calcd. fo $C_{23}H_{30}N_3O_5Cl$: C 59.40, H 6.52, N 9.06; found: C 59.26, H 6.48 N 9.04.

The preparation and reactions of mixed anhydrides of *N*-alkoxycarbonylamino acids

FRANCIS M. F. CHEN AND N. LEO BENOITON[1]

Department of Biochemistry, University of Ottawa, Ottawa, Ont., Canada K1H 8M5

Received July 3, 1986

FRANCIS M. F. CHEN and N. LEO BENOITON. Can. J. Chem. **65**, 619 (1987).

Pure mixed anhydrides $R^1OCO\text{-}Xxx\text{-}O\text{-}COOR^2$ (Xxx = NHCHRCO) have been obtained by reaction of *N*-alkoxycarbonylamino acids $R^1OCO\text{-}Xxx\text{-}OH$ with alkyl chloroformate R^2OCOCl (R^2 = methyl, ethyl, isobutyl, menthyl) in the presence of *N*-methylmorpholine or *N*-methylpiperidine (NMP) in dichloromethane at −5°C, followed by washing the mixtures with aqueous solutions and removal of the solvent. $R^1OCO\text{-}Xxx\text{-}O\text{-}COOR^2$ (R^2 = ethyl, *tert*-butyl) have been obtained by reaction of $R^1OCO\text{-}Xxx\text{-}O^-.{}^+HNMP$ with the corresponding dialkyl dicarbonates followed by the same work-up. Mixed anhydride generation is much slower when triethylamine is used as base. The initial reaction in the decomposition of mixed anhydrides is cyclization to the 2-alkoxy-5(4*H*)-oxazolone (R^1O-oxazolone) followed by release of alcohol R^2OH. Symmetrical anhydride $(R^1OCO\text{-}Xxx)_2O$ and ester $R^1OCO\text{-}Xxx\text{-}OR^2$ are also formed. The ease of cyclization depends on R^2, and is in the order methylsulfonylethyl (Ms) ≫ methyl/ethyl/isobutyl ≫ menthyl. $R^1OCO\text{-}Xxx\text{-}O\text{-}COOMs$ preparations contained a substantial amount of R^1O-oxazolone. Attempts to use this reaction as a preparative procedure for obtaining R^1O-oxazolones failed because they are too sensitive to hydrolysis and react too quickly with the product, forming the symmetrical anhydride. The effect of various parameters on the amount of urethane generated by aminolysis at the carbonate moiety of $R^1OCO\text{-}Xxx\text{-}O\text{-}COOR^2$ was examined without the uncertainty that any urethane arose from aminolysis of unconsumed chloroformate.

FRANCIS M. F. CHEN et N. LEO BENOITON. Can. J. Chem. **65**, 619 (1987).

En faisant réagir les acides *N*-alkoxycarbonylaminés $R^1OCO\text{-}Xxx\text{-}OH$ avec les chloroformates d'alkyles R^2OCOCl (R^2 = méthyle, éthyle, isobutyle et menthyle) dans le dichlorométhane, à −5°C et en présence de *N*-méthylmorpholine ou de *N*-méthylpipéridine (NMP), puis en lavant les mélanges avec des solutions aqueuses et en enlevant les solvants, on a obtenu les anhydrides mixtes $R^1OCO\text{-}Xxx\text{-}O\text{-}COOR^2$ (Xxx = NHCHRCO) à l'état pur. On a obtenu les anhydrides mixtes $R^1OCO\text{-}Xxx\text{-}O\text{-}COOR^2$ (R^2 = éthyle et *tert*-butyle) en faisant réagir $R^1OCO\text{-}Xxx\text{-}O^-.{}^+HNMP$ avec les dicarbonates de dialkyles correspondants et en les purifiant ensuite de la manière plus haut. La formation des anhydrides mixtes est beaucoup plus lente lorsqu'on utilise la triéthylamine comme base. La réaction initiale lors de la décomposition des anhydrides mixtes est la cyclisation en l'alkoxy-2 5(4*H*)-oxazolone (R^1O-oxazolone) qui est suivie par l'élimination de l'alcool R^2OH. L'anhydride symétrique $(R^1OCO\text{-}Xxx)_2O$ et l'ester $R^1OCO\text{-}Xxx\text{-}OR^2$ se forment aussi. La facilité de cyclisation dépend de R^2, dans l'ordre suivant : méthylsulfonyléthyl (Ms) ≫ méthyl/éthyl/isobutyl ≫ menthyl. Les $R^1OCO\text{-}Xxx\text{-}O\text{-}COOMs$ qui ont été obtenus contenaient des quantités importantes de R^1O-oxazolone. Des essais effectués dans le but d'utiliser cette réaction comme une méthode de préparer des R^1O-oxazolones n'ont pas donné les résultats escomptés parce que ces composés sont trop sensibles à l'hydrolyse et qu'ils réagissent trop rapidement avec le produit qui conduit à l'anhydride symétrique. On a étudié l'effet de divers paramètres sur la quantité d'uréthane qui se forme par aminolyse de la portion carbonate des $R^1OCO\text{-}Xxx\text{-}O\text{-}COOR^2$ sans se soucier de la possibilité que l'uréthane puisse provenir d'une aminolyse du chloroformate qui n'a pas réagi.

[Traduit par la revue]

A well-known method of preparing amides or phenolic esters from carboxylic acids involves activation of the acid as the mixed carboxylic–carbonic acid anhydride **3** followed by reaction with the pertinent nucleophile (1, 2). The anhydride is generated by the action of an alkyl chloroformate **2** in the presence of a tertiary amine, and is not isolated before the subsequent reaction. The activation is carried out at low temperature in anhydrous solvents, and is usually of only one or two minutes duration, to avoid decomposition of the anhydride and, when pertinent, the production of stereomuted product. In the course of a study on the side reaction of urethane formation, which is associated with mixed anhydride reactions, it was found that dichloromethane is a good solvent for mixed anhydride reactions if the tertiary amine used is *N*-methylmorpholine (3) or *N*-methylpiperidine, and that aqueous dimethylformamide could also serve as solvent for both the generation and the aminolysis steps of the reaction (4). The latter suggested to us that mixed anhydrides might be stable enough to allow their purification by washing solutions of the anhydrides in a water-immiscible solvent with water in the same way that the symmetrical anhydrides **8** of *N*-alkoxycarbonylamino acids can be purified (5). Indeed, this proved to be the case. This communication describes the preparation of mixed anhydrides of *N*-alkoxycarbonylamino acids **1** using the conventional reaction in dichloromethane, followed by washing the reaction mixture with aqueous solutions and removal of solvent. In addition, a study of the properties and reactions of mixed anhydrides is presented. A preliminary report of this work has appeared (6).

Results and discussion

Mixed anhydrides from alkyl chloroformates

Reaction of *N*-alkoxycarbonylamino acids **1** with an equivalent of methyl, ethyl, or isobutyl chloroformate in dichloromethane at −5°C in the presence of a 5% deficiency of NMM or NMP for 20 min, followed by washing the mixture with cold aqueous citric acid and sodium hydrogen carbonate and removal of solvent, gave the mixed anhydrides in 80–90% yields (eq. [1]). Some of the compounds prepared appear

in Tables 2 and 3. They were obtained as oils except for Z-DL-Ala-O-COOEt,[2] mp 50–52°C, which crystallized on evaporation of the solvent. A few anhydrides of Boc-amino acids contained a small amount of 2-alkoxy-5(4*H*)-oxazolone **5** identifiable by the unique chemical shifts of the $(CH_3)_3CO$-protons in the nmr spectra (7), Table 1. In these cases, a shorter reaction time of 2 min gave the pure anhydrides in slightly lower yields. Comparable yields were obtained from reactions effected in ethyl acetate, in which the NMP.HCl precipitated, or in moist dichloromethane. The anhydrides are identifiable by their proton nmr spectra, which resemble those of the corresponding esters **7**, i.e., Boc-Ile-O-COOR[2] vs. Boc-Ile-OR[2], except that the alkoxy protons in the anhydrides are shifted slightly downfield, Table 1. Their identities as activated forms of substrates were confirmed by their immediate reaction with amines. The compounds were stable for several hours at −5°C, or in solution in dichloromethane at 25°C. Only after 6 h did the nmr spectrum of Boc-Gly-O-COOiBu in $CDCl_3$ show a change. The solution contained 5% of 2-alkoxy-5(4*H*)-oxazolone but no other obvious contaminant after 30 h. Boc-Ile-O-COOiBu was stable in *tert*-butanol at 23°C for 24 h. There were no signs of fulvene or FmOH in the nmr curve of Fmc-Val-O-COOiBu that had been kept at −5°C for 2 weeks.

The work-up procedure destroys methyl and ethyl chloroformates, therefore an excess of reagent was used to promote complete reaction of the substrate. Moreover, any contamination of the anhydride by the chloroformate is detectible by nmr, Table 1. Isobutyl chloroformate cannot be detected by the same method, and it is more stable to hydrolysis, so it was not used in excess.

Menthyl chloroformate reacted more slowly, but produced high yields of anhydrides from Boc-Ile-OH (89%) and Boc-Val-OH (96%) after 1 h at 23°C. The products were stable for at least 2 weeks. Pure anhydrides could not be obtained from methylsulfonylethyl chloroformate (see below).

Attempts to prepare the anhydrides of derivatives of the trifunctional amino acids met with varied success depending on the reactivity of the functional group on the side chain. Z-Asp(OBzl)-OH behaved normally (see below). Z-Gln-OH, after a 4-min reaction, gave a 60% yield of anhydride containing a small amount of oxazolone and some iBuOH. Z-Asn-OH gave a 10% yield of impure anhydride. Z-Tyr-OH gave no product, but coupled efficiently when the anhydride was not isolated (Table 2). Boc-Ser-OH gave a product that decomposed, probably by polymerization. Z-Asp-OH gave the internal anhydride in moderate yield.

The accompanying communication concluded that the tertiary amine/solvent combination has a marked effect on the mixed anhydride reaction, and that the poor performance of the Et_3N/dichloromethane combination was probably due to slow generation of the anhydride (4). To prove the latter, the rate of formation of anhydride in dichloromethane in the presence of various bases was examined by isolating the anhydride at appropriate times. The results are given in Fig. 1. It is seen indeed that in the presence of Et_3N, formation of anhydride was still incomplete after 30 min. In the presence of NMM or NMP, the maximum yield of anhydride had been attained within 2 min. With diisopropylethylamine as base, the yield after 2 min was nil. This explains why the product was exclusively urethane when diisopropylethylamine had been the base in a reaction (4). The results demonstrate why the amine/solvent combination is of critical importance. It has a marked effect on the rate at which the anhydride is generated.

Mixed anhydrides from dialkyl dicarbonates

The availability of *t*BuOCO-O-COO*t*Bu (9) and the intriguing possibility that it might provide entry to mixed anhydrides that were previously inaccessible because of the unavailability of *tert*-butyl chloroformate prompted an examination of the reaction of dialkyl dicarbonates with *N*-alkoxycarbonylamino acids. Diethyl dicarbonate did not react with Boc-Ile-OH in dichloromethane at 23°C (eq. [2]), but gave a high yield of mixed anhydride after 1 h at 23°C in the presence of one equivalent of NMP (eq. [3]). A 10% excess of reagent was used. The reagent is not destroyed by the work-up, but it is readily eliminated from the product under vacuum. $(t\text{BuOCO})_2O$ reacted more slowly with the carboxylate anion, but gave a 90% yield of anhydride after 3 h. In this case an excess of reagent could not be used because the reagent is not readily eliminated under vacuum. The same yield was obtained starting from Boc-Ile-OH.$\frac{1}{2}H_2O$. No reaction occurred between $(t\text{BuOCO})_2O$ and Boc-Ile-O-$^-$.$^+$HNMP at −5°C. Compounds **3** (R = $PhCH_2$,

R^2 = Et, *t*Bu

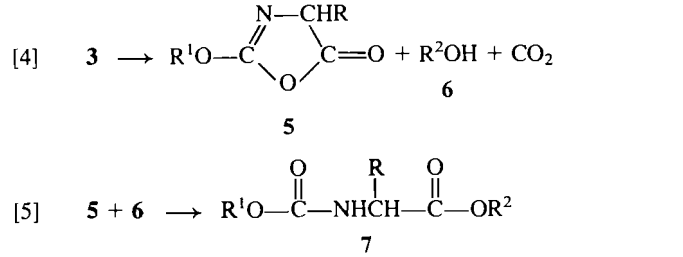
iPr) obtained from **4** were demonstrated to be stereochemically pure. This approach using dialkyl dicarbonates, eq. [3], thus allows preparation of mixed anhydrides without cooling, provides an attractive alternative to the use of ethyl chloroformate, and allows access to the heretofore undescribed mixed anhydrides containing the *tert*-butyl carbonate moiety.

Mixed anhydrides using N*-ethoxycarbonyl-2-ethoxy-1,3-dihydroquinoline (EEDQ)*

EEDQ is a peptide-bond forming reagent recognized to effect coupling through the intermediate mixed anhydride (10). The feasibility of preparing mixed anhydrides using EEDQ was examined. The addition of EEDQ to one equivalent of Boc-Val-OH in dichloromethane gave, after 2 h at 23°C and subsequent work-up, a 95% yield of Boc-Val-O-COOEt, identical with that prepared using EtOCOCl. The use of *N*-alkoxycarbonyl-2-alkoxy-1,3-dihydroquinolines (10, 11) thus allows the preparation of mixed anhydrides without the addition of a tertiary amine. Our results also demonstrate unequivocally for the first time that the mechanism proposed for the action of these reagents (10) is correct.

*Decomposition of mixed anhydrides by cyclization to the 2-alkoxy-5(4*H*)-oxazolone*

An additional source of decomposition of the mixed anhydride is cyclization to the 2-alkoxy-5(4*H*)-oxazolone **5** accompanied by release of the alkoxy group of the carbonate moiety as the alcohol (eq. [4]). The rate of this reaction depends on the nature of the two alkyl groups R and R^1, and is higher for the unpurified anhydride. The amounts of oxazolone and alcohol originating from purified Boc-Phe-O-COOMe in $CDCl_3$ at 23°C were at their maxima at 60 min, after which the nmr spectrum became complex. A pure anhydride undergoes the same reaction, but the identifiable product is the ester **7**. After 3 weeks at −5°C, 20% of Z-Val-O-COOMe had been converted to Z-Val-OMe. The nmr spectrum showed no other peaks. Formation of ester is attributed to the reaction of the alcohol with the oxazolone (eq. [5]). The cyclization is promoted by



tertiary amines, iBuOH being visible in the nmr spectrum of Z-Val-O-COOiBu within 20 min of the addition of Et_3N. The spectrum of Fmc-Ile-O-COOiBu in the presence of Et_3N showed 5–10% of FmOH, but no fulvene, at 30 min.

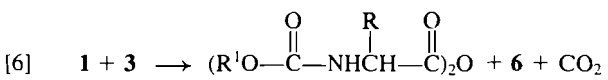
With regard to the alkyl group of the carbonate moiety, the order of stability is menthyl ≫ methyl/ethyl/isobutyl ≫ methylsulfonylethyl. Half of a sample of Boc-Ile-O-COOMn in dichloromethane remained intact after 20 h at 23°C in the presence of Et_3N. Oxazolone accounted for most of the anhydride that had disappeared. On the other hand, Boc-Ile-O-COOMs could not be obtained free of oxazolone, giving more oxazolone than anhydride. The lesser tendency of anhydrides containing menthyl to cyclize to the oxazolone suggested that less racemization would accompany the coupling of peptide acids if activation were carried out using MnOCOCl instead of iBuOCOCl. The validity of this deduction has been confirmed (4). The reaction of cyclization of the mixed anhydride promoted by base is analogous to that of the cyclization of a symmetrical anhydride (12). Together with the *O*-acylisourea generated with *N*,*N*′-dialkylcarbodiimides (7), this is the third activated form of *N*-alkoxycarbonylamino acids that has been shown to give rise to 2-alkoxy-5(4*H*)-oxazolones.

*Attempted preparation of 2-alkoxy-5(4*H*)-oxazolones from mixed anhydrides containing the methylsulfonylethyl moiety*

A previous paper reported that the reaction of *N*-alkoxycarbonylamino acids with one equivalent of soluble *N*,*N*′-dialkylcarbodiimide produced the 2-alkoxy-5(4*H*)-oxazolone **5** as well as the expected symmetrical anhydride **8** (7). The amounts were substantial only for valine and isoleucine derivatives, and only for Boc-Val-OH and Z-Val-OH could the oxazolones be isolated pure. The ease with which 2-alkoxy-5(4*H*)-oxazolones were generated by the anhydrides containing the MsOCO- moiety prompted us to examine the possibility of using them as a source of pure oxazolones. We failed, because oxazolone is generated before complete consumption of the MsOCOCl and substrate. Liberated MsOH reacts with the oxazolone producing the ester, eq. [5], and probably with unconsumed MsOCOCl, since we isolated $(MsO)_2CO$, mp 114°C, in one instance. The oxazolones from leucine and phenylalanine derivatives are formed more rapidly and are more reactive than those from valine and isoleucine derivatives. They are readily hydrolyzed, the liberated R^1OCO-Xxx-OH reacting with oxazolone to produce symmetrical anhydride **8**. Manipulation of oxazolone and symmetrical anhydride mixtures enriched the solutions with anhydride at the expense of the oxazolone. We conclude that it will be difficult to obtain pure 2-alkoxy-5(4*H*)-oxazolones from derivatives other than those of valine and isoleucine because they are sensitive to moisture and react so quickly with the product of their hydrolysis.

Reaction of mixed anhydrides with carboxylic acids. The synthesis of symmetrical anhydrides

We have previously observed that scrambling occurs when an *N*-alkoxycarbonylamino acid is added to a symmetrical anhydride (unpublished). A solution of $(Boc\text{-}Val)_2O$ and Z-Val-OH in dichloromethane, after being washed with aqueous $NaHCO_3$, contained the $PhCH_2O$- group (nmr) presumably belonging to the unsymmetrical anhydride Boc-Val-O-Val-Z. We therefore examined the reaction of a mixed anhydride **3** with its parent acid **1**, entertaining the possibility that this might be a source for symmetrical anhydrides, eq. [6]. Z-Val-O-COOMe



was left with 2 equiv. of Z-Val-OH in dichloromethane at 23°C for 20 h. After work-up, the neutral fraction contained $(Z\text{-}Val)_2O$, Z-Val-O-COOMe, and Z-Val-OMe in a ratio of 9:1:1. A similar result was obtained with Z-Val-O-COOiBu,

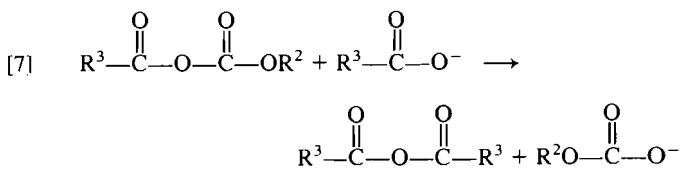
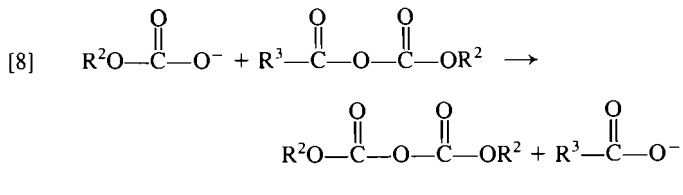
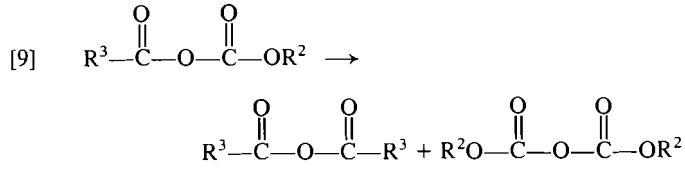
and Boc-Ile-O-COOiBu. The reaction does take place, but relatively slowly, and even more slowly with Boc-Xxx-anhydrides, and the liberated alcohol begins to esterify the parent acid before all of the anhydride has been consumed. Pure symmetrical anhydride was obtained in one case because of the fortuitous fact that it was the only one of the three products that precipitated out of light petroleum. The method therefore can be used to obtain symmetrical anhydrides; however, its efficiency depends on the ease with which the product can be separated from the ester and in some cases the starting mixed anhydride. An option for speeding up the reaction between the mixed anhydride and the parent acid is to use the carboxylate anion instead of the carboxylic acid. However, this implies the presence of a tertiary amine, which promotes cyclization of the mixed anhydride to the oxazolone (eq. [4]) thus complicating the issue further.

Decomposition of mixed anhydrides by disproportionation

Any discussion on mixed anhydrides mentions that they should be handled quickly at low temperature to avoid disproportionation to the symmetrical anhydride and the dialkyl dicarbonate, eq. [9] (2). The fate of Boc-Ile-O-COOiBu was examined by leaving a sample in dichloromethane at −5°C for 24 h. Methylamine in anhydrous ether was added and, after an hour, the Boc-Ile-O^-.$^+H_3NCH_3$ that had precipitated was collected by filtration. The yield corresponded to <1%. On the basis that the reaction of $(Boc\text{-}Ile)_2O$ with CH_3NH_2 liberates 1 equiv. of the salt, the result showed that <1% of disproportionation had occurred. A control experiment indicated that a 1% contamination could indeed be detected by this method. In a second experiment, Boc-Ile-O-COOMe was left in $CDCl_3$ at 23°C for 16 h. Inspection of the nmr spectrum revealed that the solution contained the substrate, the 2-alkoxy-5(4*H*)-oxazolone, $(Boc\text{-}Ile)_2O$, and Boc-Ile-OMe in the proportions of 21:52:23:4. In addition to the substrate and ester, the methoxy moiety was present as MeOH (53%) and MeOCO- (12%, δ = 3.77 ppm) of unestablished identity. These results are not compatible with the notion that a pure mixed anhydride undergoes simple disproportionation, eq. [9]. One could argue that if a mixed anhydride has not been purified, decomposition could be initiated by attack of a carboxylate anion, eq. [7], which in effect would result in disproportionation, eqs. [7]–[9].





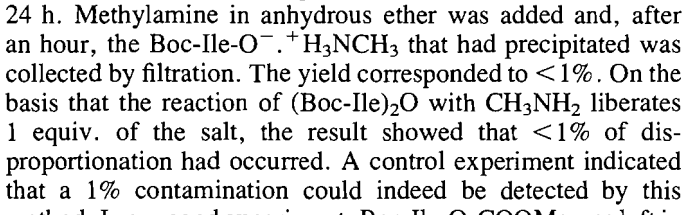


$R^3 = R^1OCO—NHCHR—$

However, we have shown above that in the presence of the tertiary amine required to initiate reaction [7], 2-alkoxy-5(4*H*)-oxazolone **5** is formed. Moreover, this oxazolone reacts quickly with the parent acid or acid anion to give symmetrical anhydride **8**. In fact, the addition of 5% of Boc-Ile-O^-.$^+$HNMP to Boc-Ile-O-COOMe in $CDCl_3$ resulted in the immediate release of MeOH (5%), with MeOH being formed continuously thereafter. We conclude that a mixed anhydride by itself does not undergo disproportionation upon storage at low temperature, and that what obtains when decomposition occurs is not disproportionation as commonly written, eq. [9], but a series of reactions subsequent to the initial cyclization to oxazolone **5**.

Aminolysis of mixed anhydrides at the carbonate moiety. Urethane formation

The major side reaction attending the coupling of *N*-alkoxycarbonylamino acids by the mixed anhydride method is the formation of urethane resulting from aminolysis at the carbonate moiety and (or) aminolysis of unconsumed alkyl chloroformate (2, 3, 14). The availability of isolated anhydrides allowed for the first time a study of the factors implicated in urethane formation by aminolysis at the carbonate moiety of the anhydride, eq. [10], without the uncertainty that some of the



$R^3 = R^1OCO—NHCHR—$

product might have originated from aminolysis of unconsumed chloroformate. The amounts of peptide **9** and urethane **10** produced from various anhydrides by the same amino acid ester under various conditions are given in Tables 2–4. Products were determined by high performance liquid chromatography (4) (hplc). Some of the results are expressed also as the ratio of the amount of urethane over the amounts of the two products. It is seen in Table 2 that the presence of NMP.HCl resulting from the use of the amino acid ester hydrochloride instead of the amino acid ester had a small positive or no effect on the generation of urethane in dichloromethane. Since it made little difference and was more convenient, all other experiments were carried out using H-Lys(Z)-OMe.HCl neutralized with NMP as the nucleophile. Dichloromethane was used as the test solvent because of its superior performance. The nature of the *N*-protector had a marked effect on the amount of urethane, benzyloxycarbonyl leading to 3–4 times as much as Boc- with Fmc- being intermediate. For the same alkyl group R^2, isoleucyl generated 12–14 times as much as leucyl. It is significant that the value for leucyl was not zero (see below).

The influence of the alkyl group R^2 of the carbonate moiety is given in Table 3. Ethyl led to slightly more urethane than isobutyl, which agrees with the generally held notion that attack at the carbonyl group is hindered by the latter. *tert*-Butyl led to three times as much as ethyl, which is inconsistent with this notion, and also contrary to what might be expected on the basis of the electron-donating property of methyl groups. Generation of urethane therefore cannot be rationalized on the basis of the size and electronic nature of the alkyl group. Methylsulfonylethyl was intermediate between the two butyl groups, and menthyl led to five times as much urethane as was obtained

from the commonly used chloroformates. This seemingly undesirable feature of the menthyl-containing anhydrides must be taken into consideration when MnOCOCl is substituted for iBuOCOCl for mixed anhydride reactions to minimize racemization (4). However, it should be considered in the proper context, that the activated moiety is a peptide acid that generates less urethane than an activated *N*-alkoxycarbonyl-amino acid.

The influence of temperature and the nature of the solvent are shown in Table 4. The solvents are listed in the order of increasing ratios, which corresponds roughly with the increase in the polarity of the solvents. The halogen-containing solvents and toluene gave the lowest ratios, but the yields of peptide in CCl_4 and $CHCl_3$ were significantly lower. The best compromise as solvent is therefore dichloromethane or toluene. Toluene has been recommended in the past, but dichloromethane has been considered an undesirable solvent for mixed anhydride reactions (2). Tetrahydrofuran performed surprisingly poorly in this test, probably in part because of the insolubility of the NMP.HCl. Diminution of the temperature from −5°C to −20°C reduced the amount of urethane formed in the halogen-containing solvents by 38–48%, but had no effect on the amount in DMF, though more was generated in DMF at 23°C. Use of low temperatures as traditionally recommended (2, 3) therefore minimizes the amount of urethane formed by aminolysis at the carbonate moiety.

Impurities in alkyl chloroformates as a minor source of urethane

In carrying out the experiments described in Table 1, it was found impossible to obtain reproducible results for the small amount of urethane generated from Boc-Leu-O-COOiBu/OEt until the chloroformates had been freshly distilled. Yields ranging from 0.25 to 1.1% were obtained. A second alkoxy peak was visible in the nmr spectra of some samples of MeOCOCl and EtOCOCl. The residue after distilling MeOCOCl was enriched in impurity, which did not react with dimethylamino-propylamine. We conclude it was dimethyl carbonate (see Table 1). EtOCOCl was enriched in impurity after being washed with aqueous acid and $NaHCO_3$. The impurity disappeared in 1 min when dimethylaminopropylamine was added, which coincided with the behavior of $(EtOCO)_2O$. The latter is more resistant to hydrolysis than is EtOCOCl. We conclude that the impurity in old samples of EtOCOCl is $(EtOCO)_2O$, which arises from the reaction of EtOCOCl with EtOCOOH that originates from the hydrolysis of EtOCOCl. It is our experience that chloroformates stored at +5°C are stable for at least one month.

Mixed anhydrides from pivaloyl chloride

An alternative to activation of an *N*-alkoxycarbonylamino acid as the anhydride R^{1}OCO-Xxx-O-COOR^2 is activation as the mixed carboxylic–carboxylic anhydride R^{1}OCO-Xxx-O-COCMe$_3$ formed by its reaction with Me$_3$CCOCl (15). These anhydrides are more reactive, and their aminolysis is considered to be more chemoselective for the -COCMe$_3$ moiety. The preparation and aminolysis of Boc-Ile-O-COCMe$_3$ (COC(CH_3)$_3$, nmr, δ = 1.28 ppm) were examined. It was found that the reaction of Boc-Ile-OH with Me$_3$CCOCl in dichloromethane at −5°C was still incomplete after 30 min. The pure anhydride was eventually obtained in 60% yield based on the amount of acid chloride by the use of an excess of Boc-Ile-OH and a reaction time of 2 h. The amounts of peptide and pivaloyl derivative generated by aminolysis of the anhydride are given in Table 2. The amount of undesired aminolysis product (10.3%) was much greater than that produced by Boc-Ile-O-COOiBu, and slightly less than that generated when the anhydride had not been isolated. We conclude that aminolysis of anhydrides containing the pivaloyl moiety is less chemoselective than aminolysis of mixed carboxylic–carbonic acid anhydrides.

Mixed anhydrides for synthetic purposes

As an example of the value of isolated mixed anhydrides for synthetic purposes, we chose the preparation of Z-Asp(OBzl)-NH$_2$, the immediate precursor of isoasparagine in a synthesis published by one of us (16). It had been brought to our attention that the method, involving coupling of Z-Asp(OBzl)-OH with ammonia via the mixed anhydride, occasionally gave erratic results. Z-Asp(OBzl)-O-COOEt was obtained in 90% yield using a 20% excess of EtOCOCl as described above. Ammonia dissolved in dichloromethane was added to the ester at −5°C. The ammonia solution had been prepared by extracting ammonium hydroxide with dichloromethane at −5°C, and adding $MgSO_4$. Filtration, evaporation of the solvent, and collection of the residue with the aid of ethyl acetate – light petroleum gave Z-Asp(OBzl)-NH$_2$ (two crops, 82%) with the appropriate nmr spectrum and the same mp as reported (16). With respect to their use for synthetic purposes, we do not suggest that isolated anhydrides are to be preferred in all cases, but the possibility that their use might prove advantageous should be kept in mind.

Miscellaneous

When the substrate in eq. [1] was an acylamino or a peptide

acid (**1**, R^1CO instead of R^1OCO), the neutral fraction after work-up contained no mixed anhydride except when the activated residue was prolyl. The major product isolated from the reactions was the 2-alkyl-5(4*H*)-oxazolone. Details will be presented in another publication. Z-Gly-Pro-O-COOiBu (Table 2) was obtained in the same yield as the anhydrides **3**. Aminolysis of this anhydride with H-Lys(Z)-OMe.HCl/NMP gave a 77% yield of peptide, 0.6% of iBuOCO-Lys(Z)-OMe, and 5% of a third unidentified product. No racemization (<0.05%; hplc as in ref. 4) accompanied the coupling. When the substrate in eq. [1] was Boc-MeVal-OH, the products were the mixed anhydride and *N*-methylvaline *N*-carboxyanhydride in a 5:1 ratio. We intend to do further work on anhydrides of this type of substrate.

Experimental

General

Tertiary amines, alkyl chloroformates, dialkyl dicarbonates, and pivaloyl chloride (Aldrich products) were purchased from Terochem Laboratories, Edmonton, except for methylsulfonylethyl chloroformate, which was a gift from Dr. G. I. Tesser (13). Menthyl chloroformate was the *levo* isomer. Solvents (Fisher Scientific) were dried (4) and distilled. Amino acid derivatives were purchased from Sigma Chemical Company. Proton nmr spectra were determined in deuterochloroform using a Varian EM-360 60-MHz instrument. With one exception, no attempt was made to secure elemental analyses for the anhydrides since it is our experience that such activated forms of amino acids are too unstable to send through the mails. The presence of contaminants in the mixed anhydrides and chloroformates and the composition of mixtures resulting from their decomposition were established by comparing the intensities and chemical shifts of the appropriate signals in the nmr spectra with those of reference compounds (Table 1). Products from the aminolysis of mixed anhydrides were determined by reversed phase hplc after washing the mixture with aqueous solutions as described in the accompanying paper (4). Me_3CCO-Lys(Z)-OMe (oil, 45% yield) was obtained by reaction of Me_3CCOCl with H-Lys(Z)-OMe.HCl/NMP in dichloromethane at 23°C for 1 h. The mixture was washed many times with aqueous solutions before removing the solvent. The absorbance of the compound at 215 nm (hplc) was 80% of that of Boc-Ile-Lys(Z)-OMe.

Preparation of mixed anhydrides 3

To acid **1** (1 mmol) and NMP or NMM (0.95 equiv.) in 10 mL of dichloromethane at −5°C was added chloroformate **2** (1.1 equiv. for R^2 = Me, Et; 1.0 equiv. otherwise), and the mixture was left at −5°C for 20 min (23°C for 1 h for R^2 = Mn). The solution was washed with cold dilute citric acid, aqueous $NaHCO_3$, and water, and the solvent was dried ($MgSO_4$) and removed at room temperature with a rotary evaporator. Z-DL-Ala-O-COOEt, mp 50–52°C. *Anal.* calcd. for $C_{14}H_{17}NO_6$: C 56.94, H 5.08, N 4.74; found: C 56.68, H 5.56, N 4.84.

In the alternative procedure, dialkyl dicarbonate **4** (1.1 equiv. for R^2 = Et, 1.0 equiv. for R^2 = *t*Bu) was added to a mixture of acid **1** (1 mmol) and NMP or NMM (1 mmol) in dichloromethane and the solution was left at room temperature for 1 h for R^2 = Et and 3 h for R^2 = *t*Bu.

Acknowledgements

We are grateful to the Medical Research Council of Canada for financial support of this research, to Dr. G. I. Tesser for the gift of methylsulfonylethyl chloroformate, to Mr. Hector Seguin of the National Research Council for the elemental analyses, and to Mrs. Y. Lee for the data in Table 3. Synthesis and properties of phenyl substituted derivatives of 2-phenyl-1,1,3,3-tetramethylguanidine

PRZEMYSLAW PRUSZYNSKI
Department of Chemistry, Adam Mickiewicz University, 60-780 Poznan, Poland

Received July 31, 1986

PRZEMYSLAW PRUSZYNSKI. Can. J. Chem. **65**, 626 (1987).

A series of 17 phenyl substituted derivatives of 2-phenyl-1,1,3,3-tetramethylguanidine was synthesized. The structure and purity of these compounds were checked by means of elemental analyses, mass spectrometry, ultraviolet spectrophotometry, and ^{1}H nuclear magnetic resonance. The pK_a values were determined and are discussed in terms of substituent effects using Hammett substituent constants. The Hammett reaction constant $\rho = 1.84 \pm 0.05$ was found to be much lower for *para* and *meta* substituted compounds than for anilines, even though the phenyl ring is attached directly to the basic centre in both cases.

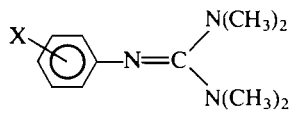
PRZEMYSLAW PRUSZYNSKI. Can. J. Chem. **65**, 626 (1987).

On a synthétisé une série de 17 phényl-2 tétraméthyl-1,1,3,3 guanidines substituées par des groupements phényles. On a vérifié la structure et la pureté de ces composés à l'aide d'analyses élémentaires, de spectrométrie de masse, de spectrophotométrie ultraviolette et de résonance magnétique nucléaire de ^{1}H. On a déterminé les valeurs des pK_a et on en discute en fonction des effets de substituants en faisant appel aux constantes de Hammett pour les substituants. On a déterminé que la constante de réaction de Hammett, $\rho = 1{,}84 \pm 0{,}05$, pour les composés substitués en positions *méta* et *para* est beaucoup plus faible que pour les anilines, même si, dans chaque cas, le groupement phényle est attaché directement au centre basique.

[Traduit par la revue]

Introduction

In most kinetic studies the opportunity of using series of closely related compounds is of great importance. The series of phenyl substituted derivatives of 2-phenyl-1,1,3,3-tetramethylguanidine (**1**) may be very useful when strong bases are



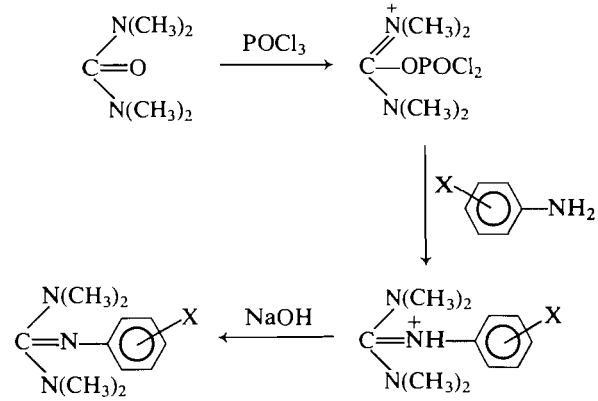
1

required. There are several papers concerned with the influence of substituent effects on the strength of guanidine bases, but they are generally concerned with substitution on one of the terminal nitrogen atoms and with alkyl substituents (1–6).

The relation between the observed pK_a values and Taft's substituent constants σ^* was found to be $pK_a = 14.0 - 3.60\sigma^*$ (1). There is no relationship present in the literature concerned with the influence of a substituent on a benzene ring that is attached to the nitrogen in a guanidine base. Values of $pK_a = 10.8$ for 1-phenyl-guanidine (2) together with $pK_a = 10.6$ for 1-(4-chlorophenyl)-guanidine (3) may give some rough idea about the sensitivity of base strength to the substituent present in the molecule. It seemed worthwhile to check the wider relationship for the case of phenyl ring attached to the nitrogen atom that undergoes protonation. Compounds presented in this paper, except for 2-phenyl-1,1,3,3-tetramethylguanidine and 2-(4′-methylphenyl)-1,1,3,3-tetramethylguanidine previously synthesized by Bredereck and Bredereck (7), have not been reported in the literature. They have been synthesized for use as bases in kinetic studies of proton transfer reactions from carbon acids. The kinetic results will be presented elsewhere.

This work gives a general procedure of synthesis, and the properties of a series of new bases. The method of Bredereck (7) is applied with some modifications. This method is based on the condensation reaction of 1,1,3,3-tetramethylurea with an appropriate aniline derivative in the presence of $POCl_3$, eq. [1], and makes it possible to synthesize various compounds by changing the aniline derivative used for synthesis.

[1]



Results and discussion

The pK_a values of the synthesized compounds together with the value for unsubstituted 2-phenyl-1,1,3,3-tetramethylguanidine are presented in Table 1, which also gives the literature values of the pK_a of the corresponding anilines and the values of Hammett's substituent constants.

Figure 1 shows a plot of the measured values of pK_a of *meta* and *para* substituted 2-phenyl-1,1,3,3-tetramethylguanidines (2-Ph-TMG) against the Hammett's $\sigma_{m,p}$ values.

The relation shown in Fig. 1 is described by eq. [2]:

[2] $$pK_{a\,\text{2-Ph-TMG}} = (12.12 \pm 0.02) - (1.84 \pm 0.05)^*\sigma_{m,p}$$

with a correlation coefficient 0.997. This equation gives the Hammett reaction constant $\rho = 1.84 \pm 0.05$. The equation for the dissociation reaction of anilinium ions is $pK_{a\,\text{aniline}} = 4.58 - 2.88\sigma$ (9). When anilines with the same substituents as reported for 2-phenyl-1,1,3,3-tetramethylguanidines are taken into account, eq. [3] is obtained, with correlation coefficient 0.998:

[3] $$pK_{a\,\text{aniline}} = (4.59 \pm 0.03) - (2.85 \pm 0.06)^*\sigma_{p,m}$$

In both correlations the special value of $\sigma = 1.26$ for the *p*-NO_2

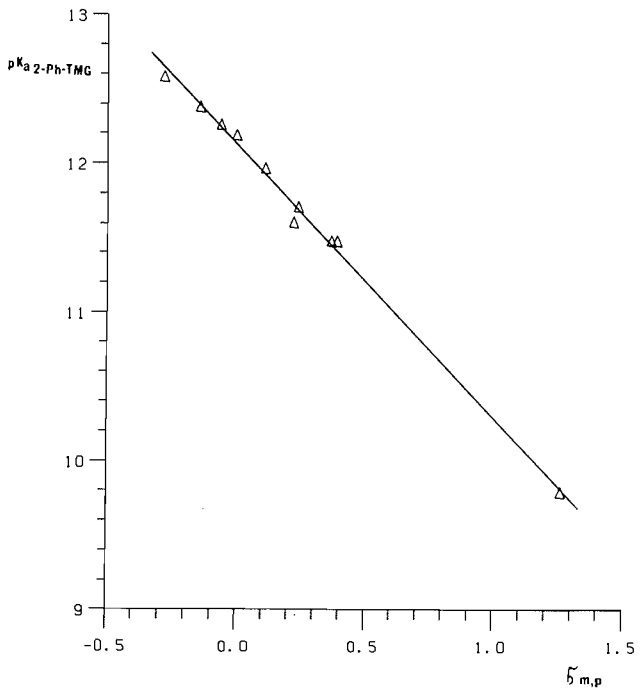

FIG. 1. The plot of the relation of pK_a of *meta* and *para* substituted derivatives of 2-phenyl-1,1,3,3-tetramethylguanidine (2-Ph-TMG) and Hammett $\sigma_{m,p}$ constants.

substituent, reported by Perrin *et al.* (1) as the best for anilines, was used. This value provides a good fit of experimental data for both series of compounds. This proves that the -N=C[$N(CH_3)_2$]$_2$ substituent is a group capable of strong resonance electron donation to the phenyl ring. It can undergo resonance interaction with the *p*-NO_2 group stabilizing the

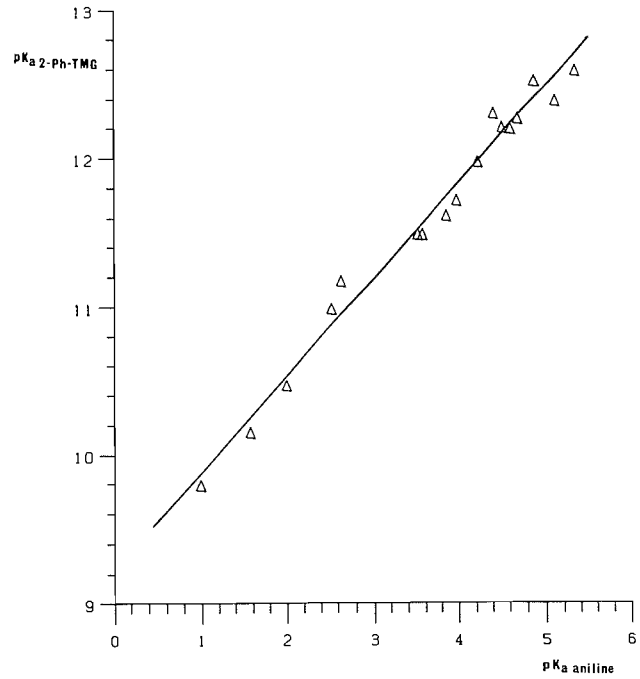

FIG. 2. The plot of pK_a of 2-phenyl-1,1,3,3-tetramethylguanidines (2-Ph-TMG) against pK_a of the corresponding anilines.

unprotonated form, which is reflected in much lower pK_a value (Table 1). This strong mesomeric interaction may be explained by the unique possibility of the -N=C[$N(CH_3)_2$]$_2$ group spreading the positive charge over all three nitrogens. According to our ^{35}Cl nqr measurements (10) this group can donate electrons mesomerically stronger than the -NH_2 group. This observation agrees with the larger bathochromic shift of the uv peak observed in the case of 2-(4-nitrophenyl)-1,1,3,3-tetramethylguanidine (λ_{max} = 400 nm) than in the case of *p*-nitroaniline (λ_{max} = 381 nm). Nevertheless the same values of σ for the *p*-NO_2 substituent show good correlations with pK_a values for anilines and 2-phenyl-1,1,3,3-tetramethylguanidines.

Equations [2] and [3] demonstrate that the base strength of aniline is more sensitive to the presence of a particular substituent than that of guanidine compounds. Figure 2 presents the relation between the pK_a value of the derivatives of aniline and the pK_a value found for the corresponding 2-phenyl-1,1,3,3-tetramethylguanidines.

Equation [4] presents the relationship between the pK_a values of anilines and appropriate derivatives of 2-phenyl-1,1,3,3-tetramethylguanidine:

$$[4]\quad pK_{a\,\text{2-Ph-TMG}} = (9.21 \pm 0.09) + (0.65 \pm 0.02) * pK_{a\,\text{aniline}}$$

with correlation coefficient 0.998.

In both cases the phenyl ring is attached directly to the nitrogen atom being protonated and the value of ρ = 2.85 for anilines is typical for such compounds. The ρ = 1.84 for guanidine derivatives indicates much lower sensitivity of their strength to the nature and position of substituent on the phenyl ring. This observation may be reasonably explained by taking into account, as mentioned above, general behaviour of the guanidines, e.g., resonance delocalization of the positive charge of their cation over three nitrogen atoms. The resonance effect causes properties of both free base and its conjugate base to be less sensitive to the substituent effect. The electron-

For personal use only.

withdrawing substituents, for example, destabilize the anilinium cation to a higher extent than they do in the case of 2-phenyl-1,1,3,3-tetramethylguanidinium cations, which bear a significant part of the positive charge on two nitrogens that are three bonds away from the benzene ring.

It is also interesting (Table 1) that a methyl group in the *ortho* position to the amino group in aniline causes a decrease of the strength of *o*-toluidine when compared to aniline (pK_a 4.42 and 4.62 respectively). In the case of guanidine derivatives this substitution leads to a small increase of the pK_a value (12.18 for the unsubstituted compound and 12.28 for 2-methyl substituted, Table 1). According to our ^{35}Cl nqr measurements (10) there is steric interaction between the *ortho* substituent and $-N{=}C[N(CH_3)_2]_2$ substituent. This interaction must lead to an increase in the energy of the unprotonated form of the base. There is a change of the hybridization of nitrogen during protonation, which allows reduced interaction of both substituents. This effect would give additional stabilization to the protonated form, leading to an increase in pK_a value.

These studies, concerned with synthesis and properties of further phenyl substituted derivatives of 2-phenyl-1,1,3,3-tetramethylguanidines, are being continued.

Experimental

The synthetic procedure was common for all compounds synthesized: a solution of 0.1 mol of 1,1,3,3-tetramethylurea (TMU, dried over molecular sieve 4A) in 100 mL of dry benzene was treated dropwise with a solution of 0.2 mol of $POCl_3$ in 20 mL of dry benzene. The reaction mixture was stirred for 1–2 h at a temperature not exceeding 25°C and left overnight at room temperature. A solution of 0.15 mol of the appropriate derivative of aniline in 50 mL of benzene was added and the reaction mixture was then stirred for 7 h at 70°C. The lower oily phase was then separated and washed several times with benzene. The pH was fixed at 7–9 with 2 *M* NaOH and the extraction with benzene was repeated. The aqueous phase was then made strongly alkaline (pH > 14) and the 2-phenyl-tetramethylguanidine derivative was extracted with benzene. These benzene extracts were collected and dried over anhydrous sodium sulphate, and the benzene was then evaporated. Usually the crude product was fractionally distilled under reduced pressure unless it solidified after removal of benzene, in which case it was recrystallized from cyclohexane. The amounts of $POCl_3$ and aniline derivative used were larger than reported by Bredereck (7). The introduction of an additional extraction at pH 7–9 allowed for easy separation of product from the unreacted aniline. An excess of $POCl_3$ and aniline increased the yield of reaction calculated against the amount of TMU used.

The picrates were obtained by mixing equimolar amounts of 2-phenyl-1,1,3,3-tetramethylguanidine derivative and picric acid in 95% ethanol. This mixture was refluxed for 15 min, cooled to room temperature, and poured into a threefold excess of water. The fine yellow crystals obtained were then recrystallized from 95% ethanol.

Melting points were measured using a Boetius apparatus and were uncorrected. The ^1H nmr spectra were obtained using a Varian EM-360 spectrometer with TMS as internal reference in $CDCl_3$. The mass spectra were recorded on a JEOL JMS D-100 spectrometer. Elemental analyses were obtained on a Perkin–Elmer 240 apparatus. In the case of oily products only very freshly distilled samples showed satisfactory results; increasing water content was observed after some time. The uv measurements were performed with a Specord M-40 spectrophotometer equipped with a thermostatic device. The pK_a measurements were done spectrophotometrically in water at 25°C and at ionic strength 0.1 mol dm^{-3} maintained by addition of KCl. Measurements were performed using NaOH solution for all compounds excepting the *p*-NO_2 derivative, where Na_2CO_3–$NaHCO_3$ buffer was used. The procedure was identical to that described by Hibbert (11) for 1,8-bis(dimethylamino)naphthalene, a base of comparable strength. The pK_a values for dichlorosubstituted compounds had to be measured in very dilute NaOH solution. This was the reason for bigger scatter of results for these two bases than in the case of other compounds. More individual measurements were done in these cases. The mean value is probably more accurate than the standard deviations show.

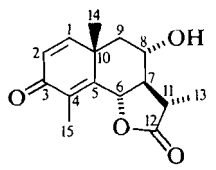
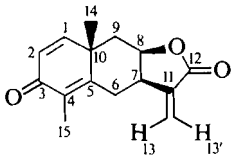
Introduction

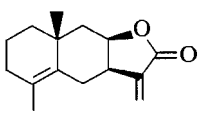
α,β-Unsaturated lactones have always aroused very much interest in medicine because of their remarkable biological properties, mainly as cytotoxic, antitumor, and bactericidal agents. Among these compounds, sesquiterpene α-methylene-γ-lactones have been intensively studied (1) from both the medicinal and chemical points of view. Numerous synthetic methods for the α-methylene-γ-lactone grouping have been designed and both total and partial syntheses of this class of compounds have been published (2, 3). Our efforts have focused on the transformation of readily available artemisin **1** into other natural sesquiterpene lactones (4). We now wish to report on our studies concerning the chemical transformation of (−)-artemisin into the natural eudesmanolides yomogin **2**, 1-deoxyivangustin **3**, and 1-deoxy-8-epiivangustin **4**.



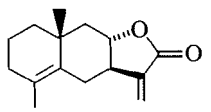
1



2



3



4

Yomogin was first isolated by Geissman from *Artemisia princeps* Pamp. (5). The racemic form has been obtained by total synthesis (6), while the natural (−)-form was prepared by Yamakawa *et al.* (7) starting from α-santonin. This last synthesis, however, implied the loss of the stereochemistry of the santonin molecule at C-7, which had to be recreated in a later step, and gave an overall yield of ca. 0.8%. On the other hand, 1-deoxyivangustin and 1-deoxy-8-epiivangustin were isolated for the first time by Bohlmann *et al.* from *Inula helenium* L. and *Artemisia pectinata* Pall., respectively (8, 9). 1-Deoxyivangustin has also been called alloalantolactone (10). Its enantiomeric (−)-form had been isolated even earlier (11) from the liverworts *Diplophyllum albicans* and *D. taxifolium*, and was named diplophyllin.

Apart from the partial conversion of isoalantolactone into **3** by acid isomerization (11), no stereodirected syntheses of **3** or **4** have been published in the literature. Artemisin **1**, which already possesses an oxygen function at C-8 and the appropriate stereochemical configuration at C-7 and C-10, should serve as a very adequate precursor for these and many other eudesman-12,8-olides with either *cis* or *trans* junction between the cyclohexane and lactone rings. According to this expectation, we have synthesized eudesmanolides **2**, **3**, and **4** from (−)-artemisin **1** in, respectively, 7, 10, and 8 steps. Overall yields were 7.5, 2, and 28%, respectively. Since artemisin had already been obtained by total synthesis (12), our syntheses can be formally considered as total syntheses of the above-mentioned compounds.

Results and discussion

A key step for the creation of the 12,8-lactone ring is the reductive cleavage of the C6—O bond in artemisin with subsequent relactonization to C-8. This reaction had already been described for α-santonin (13) and requires epimerization at C-6 prior to reduction with Zn dust. Indeed, artemisin **1** could be easily epimerized at C-6 (4*b*) by a modification of Sumi's method (14), giving **5** in ca. 60% yield. Zn reduction and esterification afforded the 8α-hydroxyester **6**, which could be lactonized almost quantitatively to lactone **7** (12*a*). By hydrogenation in the presence of Wilkinson catalyst, **7** gave **11** (15) in 95% yield. The overall yield of **11** from **1** was thus 33–35% (Scheme 1). Since epimerization at C-6 of 1,2-dihydro-α-santonin takes place with much better yields (16) than that of α-santonin, we also examined this alternative. Lactone **11** was obtained via 1,2-dihydroartemisin **8** in an overall yield of 58–60% from **1**.

Compound **11** was converted into the normal eudesmanolide **4** in a straightforward manner. By reaction with ethanedithiol, **11** gave the thioketal **12**, which yielded, by treatment with active Raney nickel, the unsaturated lactone **13** (17), contaminated with a small percentage (ca. 5%) of a double-bond isomer (16). Phenylselenylation and subsequent oxidation afforded **4** in an overall yield of ca. 49% from **11** (Scheme 2). The compound had physical and spectral properties identical with those reported by Bohlmann *et al.* (9).

For the synthesis of the eudesman-12,8β-olides **2** and **3**, an

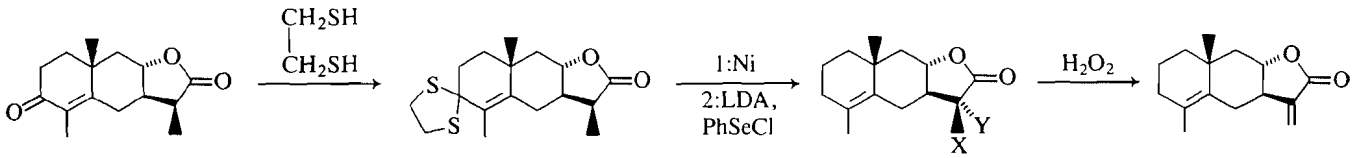
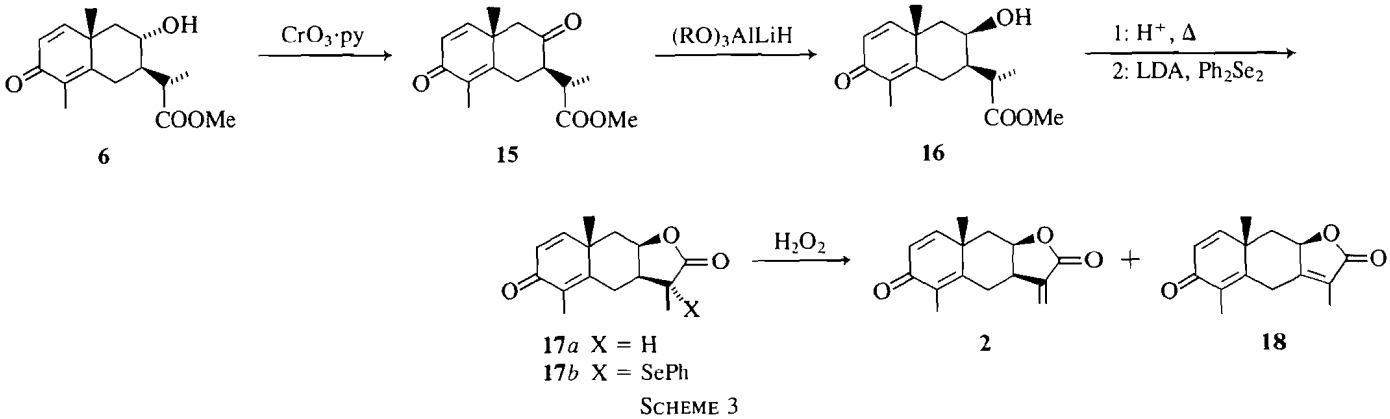


SCHEME 2



SCHEME 3

inversion of the configuration at C-8 is necessary. This was achieved via oxidation–reduction of the hydroxyester **6**. Oxidation with a modified Collins reagent (18) yielded the diketone **15**, which was subsequently reduced with $LiAlH(OBu^t)_3$. The 8β-hydroxyester **16** (80% overall yield from **6**) cyclized quantitatively to the *cis*-lactone **17***a* by brief heating in benzene with catalytic amounts of camphorsulfonic acid. Compound **17***a*, an 11,13-dihydroyomogin, had been already obtained from α-santonin by Yamakawa *et al.* (7*a*) and converted to yomogin **2** and the endocyclic double-bond isomer **18** by the phenylselenylation–oxidation procedure (Scheme 3).

The same sequence of hydrogenation, thioketalization, and desulfurization that had been utilized for the synthesis of lactone **13** proved useful for the preparation of the *cis*-isomer **21** (Scheme 4) in an overall yield of 47% from **17***a*. As in the former case (**12** → **13**), the desulfurization reaction gave not only the desired Δ^4-eudesmanolide **21** (17) but also a certain amount (ca. 13%) of the Δ^3-isomer **22**, which could be separated by chromatography. No other by-products were noted. A secure stereochemical assignment for **22** could be made from a 500-MHz ^1H nmr spectrum, in which the signals of H-5, H-6α, and H-6β were resolved. The enantiomers of compounds **21** and **22** have been described in the literature (11, 19).

By selenylation under rather strict conditions (4*b*), **21** gave **23**, in which attack of the selenylating agent proceeded from the less hindered convex α-face. As a consequence, the phenylselenyl group was located in a *syn* relationship to H-7 and the oxidative elimination step took place toward both H-7 and H-13, giving a mixture of two double-bond isomers, as in the case of yomogin (7*a*). The less abundant reaction product was shown to be identical in its spectral properties with 1-deoxy-

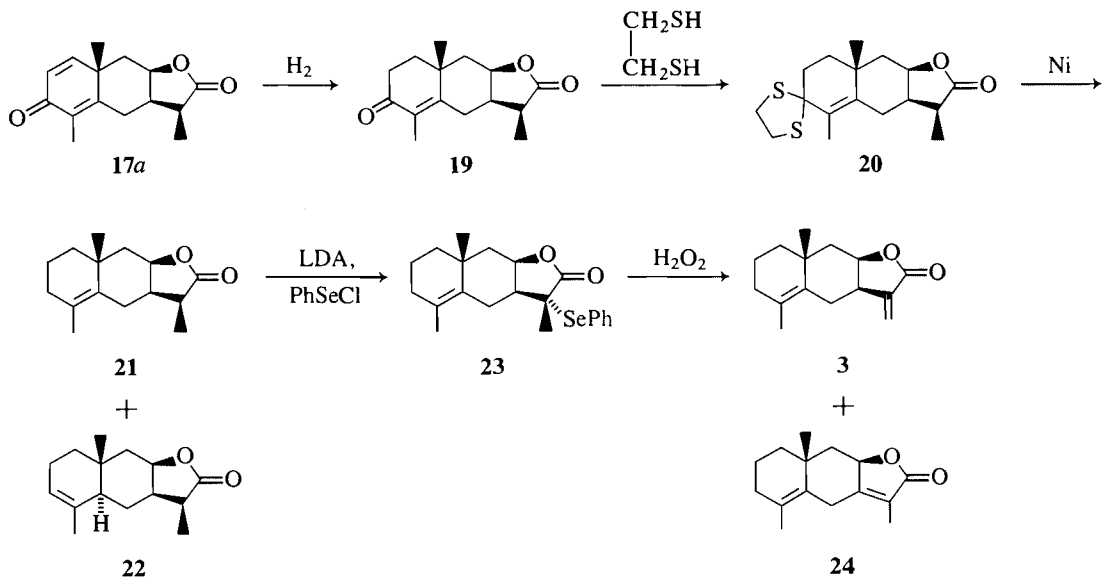

SCHEME 4

ivangustin **3** (8). The main reaction product was the unstable endocyclic double-bond isomer **24**.

Experimental

Data have been taken in part from the Ph.D. Thesis of M. Carda. Infrared spectra were recorded as KBr pellets (solids) or as films (oils) on a Perkin Elmer model 281 spectrophotometer. The uv spectra were measured in EtOH solution. Mass spectra were run by electron impact (70 eV) on a Varian MAT-311A spectrometer. The ^{1}H nmr spectra were registered, unless otherwise stated, at 200.13 MHz ($CDCl_3$ solution) on a Bruker AC-200 spectrometer. The signals of the hydrogen atoms were assigned with the aid of decoupling experiments and 2D-nmr spectroscopy (COSY). Melting points were determined on a Büchi melting point apparatus and are not corrected. Optical rotations were measured in $CHCl_3$ solutions (*c* 0.1–0.3 g/100 mL).

THF was distilled under Ar from $LiAlH_4$ and used immediately. DMF was distilled from CaH_2, benzene and CH_2Cl_2 were distilled from anhydrous $CaCl_2$, and all were kept over molecular sieves. MeOH and AcOH (Merck analytical grades) were used as received.

6-Epiartemisin, 5

Artemisin (1.3 g, ca. 5 mmol) was dissolved in 20 mL of dry DMF containing 5% hydrogen chloride. The solution was heated under Ar for 4 h at 90°C, then poured into water (50 mL) and extracted with CH_2Cl_2 (5 × 30 mL). The organic layer was then washed with 5% aqueous $NaHCO_3$ and water, dried over anhydrous Na_2SO_4, filtered, and concentrated *in vacuo*. The oily residue obtained was then chromatographed on silica gel. Elution with hexane–EtOAc 1:4 gave 728 mg (56%) of 6-epiartemisin **5** as white needles, mp 159–160°C (from hexane–CH_2Cl_2) (lit. (14) mp 156–157°C); $[\alpha]_D^{25}$ −191° (lit. (14) $[\alpha]_D^{25}$ −198°), with the expected spectroscopic properties; ^{1}H nmr, δ (ppm): 6.77 (d, *J* = 9.8 Hz, H-1), 6.27 (d, *J* = 9.8 Hz, H-2), 5.62 (d, *J* = 5.5 Hz, H-6), 3.99 (ddd, *J* = 11.7, 9.9, and 4.3 Hz, H-8), 2.99 (q, *J* = 7.7 Hz, H-11), 2.08 (s, 3H, H-15), 2.03 (dd, *J* = 12.5 and 4.3 Hz, H-9β), 2.02 (dd, *J* = 9.9 and 5.5 Hz, H-7), 1.50 (dd, *J* = 12.5 and 11.7 Hz, H-9α), 1.45 (d, 3H, *J* = 7.7 Hz, H-13), 1.32 (s, 3H, H-14).

Further elution enabled the recovery of 81 mg of unreacted artemisin. The yield of **5** thus amounts to ca. 60%, based on consumed **1**.

Methyl (11S)-3-oxo-8α-hydroxy-7αH-eudesma-1,4-dien-12-oate, 6

Activated Zn dust (1.7 g) and anhydrous AcOH (0.3 mL) were added to a solution of lactone **5** (700 mg, 2.67 mmol) in anhydrous MeOH (12 mL). After refluxing under Ar for 15 min, the reaction mixture was cooled to room temperature and directly treated with a great excess of ethereal diazomethane, until persistence of a pale yellow colour. The resulting cloudy solution was then filtered and concentrated *in vacuo*, yielding an oily residue, which was chromatographed on silica gel. Elution with hexane–EtOAc 1:1 gave 475 mg (64%) of a colorless oil, $[\alpha]_D^{25}$ −14°, which was identified as **6** by its spectral properties; ir (film), ν_{max}: 3600–3300 (br s), 1727 (s), 1655 (s) cm^{-1}; uv, λ_{max} (log ε_{max}): 240 nm (4.07); ^{1}H nmr, δ (ppm): 6.73 (d, *J* = 9.8 Hz, H-1), 6.23 (d, *J* = 9.8 Hz, H-2), 4.05 (ddd, *J* = 11, 10.5, and 4.5 Hz, H-8), 3.73 (s, 3H, COOMe), 2.96 (qd, *J* = 7.2 and 2.8 Hz, H-11), 2.82 (dd, *J* = 14.1 and 3.8 Hz, H-6α), 2.19 (ddq, *J* = 14.1, 13.6, and 1.1 Hz, H-6β), 2.10 (dd, *J* = 12.5 and 4.5 Hz, H-9β), 1.92 (d, 3H, *J* = 1.1 Hz, H-15), 1.69 (dddd, *J* = 13.6, 10.5, 3.8, and 2.8 Hz, H-7), 1.30 (d, 3H, *J* = 7.2 Hz, H-13), 1.30 (dd, *J* = 12.5 and 11 Hz, H-9α), 1.24 (s, 3H, H-14); ms *m/z* (% rel. int.): 278 (M^+, 13), 260 (28), 246 (18), 218 (10), 200 (22), 185 (44), 173 (100). *Anal.* calcd. for $C_{16}H_{22}O_4$: C 69.06, H 7.91; found: C 69.29, H 7.77.

3-Oxo-7,11α,8βH-eudesma-1,4-dien-12,8-olide, 7

A solution of hydroxyester **6** (100 mg, 0.36 mmol) and camphorsulfonic acid (CSA) (10 mg) in dry benzene (8 mL) was heated at reflux for 90 min. After evaporation of the solvent *in vacuo*, the oily residue was chromatographed on silica gel. Elution with hexane–EtOAc 1:1 gave 86 mg (97%) of lactone **7** as white needles, mp 108–109°C (from hexane–CH_2Cl_2) (lit. (12*a*) mp 151–154°C); $[\alpha]_D^{25}$ −144°; and the expected ir, uv, and mass spectra; ^{1}H nmr, δ (ppm): 6.77 (d, *J* = 9.8 Hz, H-1), 6.27 (d, *J* = 9.8 Hz, H-2), 4.49 (td, *J* = 11.6 and 4.2 Hz, H-8), 2.99 (dd, *J* = 13.6 and 3.2 Hz, H-6α), 2.79 (quintuplet, *J* = 7.6 Hz, H-11), 2.37 (dd, *J* = 11.6 and 4.2 Hz, H-9β), 2.28 (tq, *J* = 13.6 and 1.1 Hz, H-6β), 1.98 (dddd, *J* = 13.6, 11.6, 7.6, and 3.2 Hz, H-7), 1.94 (d, 3H, *J* = 1.1 Hz, H-15), 1.62 (t, *J* = 11.6 Hz, H-9α), 1.33 (s, 3H, H-14), 1.30 (d, 3H, *J* = 7.6 Hz, H-13).

1,2-Dihydro-6-epiartemisin, 9

1,2-Dihydroartemisin **8** (4*e*) (630 mg, 2.38 mmol) was treated as above (**1** → **5**) by heating for 45 min in 5% HCl/DMF. After work-up, column chromatography (elution with hexane–EtOAc 3:7) yielded 598 mg (95%) of lactone **9** as colorless needles, mp 172–173°C (from ether), $[\alpha]_D^{25}$ −71°; ir (KBr), ν_{max}: 3600–3300 (br s), 1775 (s), 1666 (s) cm^{-1}; uv, λ_{max} (log ε_{max}): 242 nm (3.96); ^{1}H nmr, δ (ppm): 5.54 (d, *J* = 5.6 Hz, H-6), 3.90 (ddd, *J* = 11.8, 9.9, and 3.8 Hz, H-8), 2.98 (q, *J* = 7.7 Hz, H-11), 2.72 (ddd, *J* = 18, 14.1, and 5.9 Hz, H-2β), 2.51 (ddd, *J* = 18, 5.1, and 2.4 Hz, H-2α), 2.00–1.90 (m, 1H, overlapped; H-1α), 2.05 (dd, *J* = 9.9 and 5.6 Hz, H-7), 1.93 (s, 3H, H-15), 1.85 (dd, *J* = 13 and 3.8 Hz, H-9β), 1.80 (ddd, *J* = 13.3, 5.9, and 2.4 Hz, H-1β), 1.45 (dd, *J* = 13 and 11.8 Hz, H-9α), 1.43 (d, 3H, *J* = 7.7 Hz, H-13), 1.28 (s, 3H, H-14); ms *m/z* (% rel. int.): 264

Methyl (11S)-3-oxo-8α-hydroxy-7αH-eudesm-4-en-12-oate, ***10***

In a similar procedure as above (**5** → **7**), 600 mg (2.27 mmol) of lactone **9** was allowed to react with activated Zn dust (1.45 g) and acetic acid (0.25 mL) in anhydrous MeOH (10 mL). After refluxing under Ar for 15 min, the reaction mixture was cooled to room temperature, treated with excess of ethereal diazomethane, filtered, concentrated *in vacuo*, and chromatographed on silica gel. Elution with hexane–EtOAc 1:1 gave **10** (410 mg, 65%) as colorless needles, mp 120–121°C (from ether); $[\alpha]_D^{25}$ +58°; ir (KBr), ν_{max}: 3600–3300 (br s), 1735 (s), 1660 (s), 1612 (m) cm^{-1}; uv, λ_{max} (log ε_{max}): 244 nm (3.95); ^1H nmr, δ (ppm): 3.93 (ddd, J = 11.1, 10.5, and 4.2 Hz, H-8), 3.71 (s, 3H, COOMe), 2.90 (qd, J = 7.2 and 2.7 Hz, H-11), 2.71 (dd, J = 14.9 and 3.6 Hz, H-6α), 2.50 (ddd, J = 17.5, 12, and 7 Hz, H-2β), 2.38 (ddd, J = 17.5, 5.3, and 3.5 Hz, H-2α), 2.03 (tq, J = 14.9 and 1.3 Hz, H-6β), 1.93 (dd, J = 12.7 and 4.2 Hz, H-9β), 1.90–1.70 (m, 3H, overlapped; H-1α/β and H-7), 1.77 (d, 3H, J = 1.3 Hz, H-15), 1.37 (dd, J = 12.7 and 11.1 Hz, H-9α), 1.25 (d, 3H, J = 7.2 Hz, H-13), 1.20 (s, 3H, H-14); ms, *m/z* (% rel. int.): 280 (M^+, 49), 262 (84), 248 (15), 247 (34), 234 (18), 219 (7), 215 (7), 202 (100), 187 (48), 175 (83), 159 (33), 147 (76). *Anal.* calcd. for $C_{16}H_{24}O_4$: C 68.57, H 8.57; found: C 68.69, H 8.43.

3-Oxo-7,11α,8βH-eudesm-4-en-12,8-olide, ***11***

(A) By hydrogenation of **7**: Freshly prepared Wilkinson catalyst (15 mg, 16.2 μmol) was suspended in dry benzene (1 mL) and stirred under H_2 atmosphere until complete dissolution (20–30 min). A solution of lactone **7** (70 mg, 0.28 mmol) in dry C_6H_6–EtOH 1:1 (4 mL) was then added via syringe. After stirring for 12 h at room temperature, the hydrogenation mixture was concentrated *in vacuo* and the brownish oily residue was chromatographed on silica gel. Elution with hexane–EtOAc 7:3 gave 67 mg (95%) of compound **11** as white needles, mp 136–137°C (from hexane–CH_2Cl_2) (lit. (15) mp 142°C); $[\alpha]_D^{25}$ +21° (lit. (15) $[\alpha]_D^{18}$ +19.4°), with the expected ir, uv, and mass spectra; ^1H nmr, δ (ppm): 4.44 (ddd, J = 11.9, 10.5, and 4 Hz, H-8), 2.90 (dd, J = 13.7 and 2 Hz, H-6α), 2.76 (quintuplet, J = 7.6 Hz, H-11), 2.58 (ddd, J = 17.5, 13.7, and 5.5 Hz, H-2β), 2.46 (ddd, J = 17.5, 5.2, and 3.1 Hz, H-2α), 2.24 (dd, J = 11.9 and 4 Hz, H-9β), 2.16 (tq, J = 13.7 and 1.2 Hz, H-6β), 2.15–1.80 (m, 3H, H-1α/1β and H-7), 1.80 (d, 3H, J = 1.2 Hz, H-15), 1.62 (t, J = 11.9 Hz, H-9α), 1.31 (s, 3H, H-14), 1.26 (d, 3H, J = 7.6 Hz, H-13).

(B) By lactonization of **10**: By the same procedure as in the transformation **6** → **7**, 56 mg of lactone **10** (0.2 mmol) and CSA (5 mg) were refluxed in dry benzene (4 mL) for 90 min. Column chromatography on silica gel (elution with hexane–EtOAc 7:3) gave 48.5 mg (98%) of compound **11**.

3,3-Ethanedithio-7,11α,8βH-eudesm-4-en-12,8-olide, ***12***

A modification of the published procedure (15) was utilized: Lactone **11** (57 mg, 0.23 mmol), ethanedithiol (0.15 mL, 1.78 mmol), and $BF_3 \cdot OEt_2$ (40 μL) were dissolved in glacial acetic acid (1 mL) and stirred for 9 h at room temperature. The reaction mixture was then poured into water (10 mL) and extracted with CH_2Cl_2 (3 × 10 mL). The organic layer was washed with 5% aqueous $NaHCO_3$ and water, dried over anhydrous Na_2SO_4, filtered, and concentrated *in vacuo*. Column chromatography on silica gel (elution with hexane–EtOAc 19:1) of the residue yielded **12** (61 mg, 82%) as white needles, mp 170–171°C (from hexane–ether) (lit. (15) mp 158°C); $[\alpha]_D^{25}$ +22° (lit. (15) $[\alpha]_D^{19}$ +43.6°), with the expected ir, uv, and mass spectra; ^1H nmr, δ (ppm): 4.37 (ddd, J = 11.7, 10.7, and 4.1 Hz, H-8), 3.50–3.15 (m, 4H, thioketal hydrogens), 2.80–2.60 (m, 1H, overlapped; H-6α), 2.68 (quintuplet, J = 7.7 Hz, H-11), 2.32 (ddd, J = 14, 12, and 3.4 Hz, H-2β), 2.21 (ddd, J = 14, 4.8, and 3.5 Hz, H-2α), 2.11 (dd, J = 11.7 and 4.1 Hz, H-9β), 1.91 (s, 3H, H-15), 1.85 (ddd, J = 13.5, 12, and 3.5 Hz, H-1α), 1.67 (ddd, J = 13.5, 4.8, and 3.4 Hz, H-1β), 1.47 (t, J = 11.7 Hz, H-9α), 1.21 (d, 3H, J = 7.7 Hz, H-13), 1.15 (s, 3H, H-14).

7,11α,8βH-Eudesm-4-en-12,8-olide, ***13***

Approximately 1 g active W-2 Raney nickel was added at once to a solution of thioketal **12** (50 mg, ca. 0.15 mmol) in MeOH (3 mL). The mixture was stirred for 8 min at room temperature and rapidly quenched by addition of ethanedithiol (0.1 mL). The reaction mixture was then filtered through a pad of silica gel (elution with EtOAc). The organic solution was then concentrated *in vacuo* and chromatographed on silica gel. Elution with hexane–EtOAc 8:2 gave **13** as a colorless oil (30 mg, 83%), homogeneous by tlc, which was shown by nmr to contain a small percentage (ca. 5%) of a double-bond isomer, probably the Δ^3-isomer (16). Elimination of this minor impurity took place in the chromatographic separation after the next step. The compound gave the expected ir and mass spectra; ^1H nmr, δ (ppm): 4.39 (ddd, J = 11.5, 10.5, and 4 Hz, H-8), 2.75–2.60 (m, 2H, H-6α and H-11), 2.06 (dd, J = 11.5 and 4 Hz, H-9β), 2.10–1.80 (m, 4H, H-3α/3β, H-6β, and H-7), 1.61 (br s, 3H, H-15), 1.70–1.40 (m, 4H, H-1α/1β and 2α/2β), 1.39 (t, J = 11.5 Hz, H-9α), 1.19 (d, 3H, J = 7.7 Hz, H-13), 1.08 (s, 3H, H-14).

11β-Phenylseleno-7α,8βH-eudesm-4-en-12,8-olide, ***14***

A solution of *n*BuLi (0.14 mL of a 1.6 *M* solution in hexane, 0.22 mmol) was added at room temperature under Ar via syringe to a solution of diisopropylamine (33 μL, 0.23 mmol) in dry THF (0.2 mL). After stirring for 15 min, the mixture was cooled to −78°C (Dry Ice – acetone bath). Lactone **13** (26 mg, 0.11 mmol) was dissolved in dry THF (0.5 mL) and added dropwise (5 min) to the cooled LDA solution. After stirring for 1 h at −78°C, a solution of Ph_2Se_2 (68 mg, 0.22 mmol) and HMPT (40 μL) in dry THF (0.5 mL) was added dropwise via syringe (5 min). The reaction mixture was stirred for 40 min at −78°C, then for a further 40 min at −40°C, and was quenched at this temperature with 0.5 *N* HCl (0.7 mL). The reaction mixture was then poured into water (5 mL) and extracted with EtOAc (3 × 5 mL), and the organic layer was washed with brine and dried over anhydrous Na_2SO_4. Filtration and evaporation *in vacuo* yielded a yellowish oil, which was chromatographed on silica gel. Elution with hexane–EtOAc 19:1 gave **14** (34 mg, 79%) as colorless needles, mp 154–155°C (from MeOH); ir (KBr), ν_{max}: 1770 (s), 1580 (m), 1475 (m), 736 (m), 689 (m) cm^{-1}; ^1H nmr, δ (ppm): 7.70–7.25 (m, 5H, aromatic hydrogens), 4.60 (ddd, J = 11.8, 10.6, and 4.2 Hz, H-8), 2.80 (dd, J = 13.5 and 3.5 Hz, H-6α), 2.07 (dd, J = 11.8 and 4.2 Hz, H-9β), 2.10–1.90 (m, 4H, H-3α/3β, H-6β, and H-7), 1.80–1.40 (m, 4H, H-1α/1β and H-2α/2β), 1.65 (br s, 3H, H-15), 1.54 (s, 3H, H-13), 1.38 (t, J = 11.8 Hz, H-9α), 1.13 (s, 3H, H-14). *Anal.* calcd. for $C_{21}H_{26}O_2Se$: C 64.79, H 6.68, Se 20.30; found: C 64.91, H 6.80, Se 20.10.

1-Deoxy-8-epiivangustin, ***4***

Hydrogen peroxide (90 μL of a 30% aqueous solution, ca. 0.8 mmol) was added at 0°C to a solution of **14** (31 mg, ca. 0.08 mmol) and AcOH (10 μL) in THF (0.5 mL). After stirring for 1 h at 0°C, the reaction mixture was poured into 5% aqueous $NaHCO_3$ (5 mL) and extracted with EtOAc (3 × 5 mL). The organic layer was washed several times with brine, dried over anhydrous Na_2SO_4, concentrated *in vacuo*, and chromatographed on silica gel. Hexane–EtOAc 8:2 eluted a colorless oil (17.5 mg, 94%), $[\alpha]_D^{25}$ −46°, with spectral properties coincident with those reported by Bohlmann *et al.* (9) for 1-deoxy-8-epiivangustin **4**; ir (film), ν_{max}: 1770 (s), 1670 (w), 983 (m) cm^{-1}; ^1H nmr, δ (ppm): 6.09 (d, J = 3.2 Hz, H-13′), 5.44 (d, J = 3 Hz, H-13), 4.11 (ddd, J = 12.1, 10.9, and 3.9 Hz, H-8), 3.00 (dd, J = 13.6 and 3.3 Hz, H-6α), 2.29 (ddq, J = 12.3, 10.9, and 3.1 Hz, H-7), 2.09 (dd, J = 11.5 and 3.9 Hz, H-9β), 2.20–1.80 (m, 3H, H-3α/3β and H-6β), 1.66 (br s, 3H, H-15), 1.70–1.40 (m, 4H, H-1α/1β and H-2α/2β), 1.51 (dd, J = 12.1 and 11.5 Hz, H-9α), 1.10 (s, 3H, H-14); ms, *m/z* (% rel. int.): 232 (M^+, 33), 217 (100), 204 (3), 199 (4), 189 (7), 123 (67). High resolution molecular weight determination, *Mol. Wt.* calcd. for $C_{15}H_{20}O_2$: 232.1463; found: 232.1456.

Methyl (11S)-3,8-dioxo-7αH-eudesma-1,4-dien-12-oate, ***15***

CrO_3 (2.57 g, 25.7 mmol) was added at 0°C portionwise (**slow addition!**) under Ar to a mixture of dry pyridine (5.5 mL) and dry CH_2Cl_2 (30 mL). After stirring this mixture for 4–5 min at 0°C, a solution of **6** (360 mg, 1.3 mmol) in dry CH_2Cl_2 (15 mL) was added. Stirring was then maintained for 6 h at 0°C, after which the reaction

For personal use only.

mixture was filtered, washed successively with 0.1 *N* HCl, water, 5% aqueous $NaHCO_3$, and brine, and dried over anhydrous Na_2SO_4. Filtration, evaporation of the solvent *in vacuo*, and column chromatography on silica gel (elution with hexane–EtOAc 1:1) yielded **15** (340 mg, 95%) as a colorless oil, lit. (*7a*) solid mp 95–97°C; $[\alpha]_D^{25}$ −100°, with the expected ir, uv, and mass spectra; ^{1}H nmr, δ (ppm): 6.67 (d, J = 9.8 Hz, H-1), 6.30 (d, J = 9.8 Hz, H-2), 3.72 (s, 3H, COOMe), 3.17 (dd, J = 13.6 and 6.2 Hz, H-6α), 3.01 (qd, J = 7.2 and 5.2 Hz, H-11), 2.83 (tq, J = 13.6 and 1 Hz, H-6β), 2.70–2.60 (m, 1H, H-7), 2.49 (d, J = 13.8 Hz, H-9β), 2.35 (d, J = 13.8 Hz, H-9α), 2.01 (d, 3H, J = 1 Hz, H-15), 1.31 (d, 3H, J = 7.2 Hz, H-13), 1.30 (s, 3H, H-14).

Methyl (11S)-3-oxo-8β-hydroxy-7αH-eudesma-1,4-dien-12-oate, ***16***

Diketoester **15** (330 mg, 1.19 mmol) was dissolved in dry THF (30 mL) and treated at 0°C with $LiAlH(OBu^t)_3$ (960 mg, 3.77 mmol). After stirring for 3 h under Ar at this temperature, the reaction was carefully quenched by addition of 0.5 *N* HCl (25 mL), diluted with brine, and extracted with EtOAc (3 × 40 mL). The organic layer was then washed with water, dried over anhydrous Na_2SO_4, filtered, concentrated *in vacuo*, and chromatographed on silica gel. Elution with hexane–EtOAc 1:1 gave **16** (280 mg, 84%) as white needles, mp 160–161°C (from hexane–CH_2Cl_2) (lit. (*7a*) oil); $[\alpha]_D^{25}$ −138°, with the expected ir, uv and mass spectra; ^{1}H nmr, δ (ppm): 6.75 (d, J = 9.8 Hz, H-1), 6.17 (d, J = 9.8 Hz, H-2), 4.20 (apparent q, average J = 2.7 Hz, H-8), 3.74 (s, 3H, COOMe), 2.74 (dq, J = 9.3 and 7 Hz, H-11), 2.60–2.40 (m, 2H, H-6α and H-6β), 2.07 (dd, J = 14.4 and 2.4 Hz, H-9β), 1.89 (br s, 3H, H-15), 1.67 (dddd, J = 11.1, 9.3, 5, and 2.7 Hz, H-7), 1.46 (dd, J = 14.4 and 3.4 Hz, H-9α), 1.44 (s, 3H, H-14), 1.23 (d, 3H, J = 7 Hz, H-13).

Further elution led to the recovery of ca. 1.5 mg (4.5%) of the 8α-hydroxyester **6**.

3-Oxo-7,8,11αH-eudesma-1,4-dien-12,8-olide, ***17***a

The hydroxyester **16** (270 mg, 0.97 mmol) was lactonized as described above (**6** → **7** and **10** → **11**) by refluxing in benzene (15 mL) in the presence of CSA (25 mg) for 90 min. Work-up and column chromatography on silica gel (elution with hexane–EtOAc 1:1) yielded ***17a*** (236 mg, 99%) as a white solid, mp 178–179°C (from hexane–CH_2Cl_2) (lit. (*7a*) mp 180–180.5°C); $[\alpha]_D^{25}$ −136° (lit. (*7a*) $[\alpha]_D^{23}$ −117.5°), with the expected ir, uv, and mass spectra; ^{1}H nmr, δ (ppm): 6.77 (d, J = 9.8 Hz, H-1), 6.22 (d, J = 9.8 Hz, H-2), 4.49 (td, J = 4.4 and 1.9 Hz, H-8), 2.92 (quintuplet, J = 6.9 Hz, H-11), 2.79 (dd, J = 13.6 and 5.8 Hz, H-6α), 2.50 (dddd, J = 13.6, 6.9, 5.8, and 4.4 Hz, H-7), 2.48 (dd, J = 15.3 and 1.9 Hz, H-9β), 2.04 (br t, J = 13.6 Hz, H-6β), 1.94 (br s, 3H, H-15), 1.58 (dd, J = 15.3 and 4.4 Hz, H-9α), 1.30 (s, 3H, H-14), 1.29 (d, 3H, J = 6.9 Hz, H-13). Several signals in the reported spectrum (*7a*) appear to have been misassigned.

3-Oxo-11α-phenylseleno-7,8αH-eudesma-1,4-dien-12,8-olide, ***17***b

The published procedure (*7a*) was exactly repeated. It yielded ***17b*** in 49% yield as colorless crystals, mp 214–215°C (from EtOAc) (lit. (*7a*) mp 215–218°C), with the expected ir, uv, and mass spectra; ^{1}H nmr, δ (ppm): 7.70–7.30 (m, 5H, aromatic hydrogens), 6.80 (d, J = 9.9 Hz, H-1), 6.25 (d, J = 9.9 Hz, H-2), 5.08 (m, 1H, H-8), 2.89 (dd, J = 13.5 and 5.7 Hz, H-6α), 2.54 (dd, J = 15.4 and 1.9 Hz, H-9β), 2.46 (ddd, J = 13.5, 5.7, and 4.1 Hz, H-7), 2.16 (br t, J = 13.5 Hz, H-6β), 1.95 (br s, 3H, H-15), 1.64 (s, 3H, H-13), 1.63 (dd, J = 15.4 and 4.7 Hz, H-9α), 1.33 (s, 3H, H-14).

Yomogin, ***2***

The oxidation of ***17b*** was carried out according to the described procedure (*7a*). After crystallization from EtOAc, yomogin **2** was obtained in 33% yield as colorless cubes, mp 206–207°C (lit. (*7a*) mp 210–211°C), with the expected ir, uv, and mass spectra; ^{1}H nmr, δ (ppm): 6.81 (d, J = 9.9 Hz, H-1), 6.28 (d, J = 1 Hz, H-13′), 6.26 (d, J = 9.9 Hz, H-2), 5.76 (d, J = 1 Hz, H-13), 4.51 (apparent q, average J = 4.2 Hz, H-8), 3.20–3.05 (m, 1H, H-7), 3.00 (dd, J = 13.6 and 7 Hz, H-6α), 2.46 (dd, J = 15.3 and 2.6 Hz, H-9β), 2.31 (ddq, J = 13.6, 11, and 1.2 Hz, H-6β), 1.98 (d, 3H, J = 1.2 Hz, H-15), 1.70 (dd, J = 15.3 and 4.7 Hz, H-9α), 1.35 (s, 3H, H-14).

3-Oxo-7,8,11αH-eudesm-4-en-12,8-olide, ***19***

Lactone ***17a*** (210 mg, 0.85 mmol) was dissolved in benzene–ethanol 1:1 (15 mL) and hydrogenated for 14 h under the same conditions as **7** in the presence of Wilkinson catalyst (40 mg). Work-up and column chromatography (elution with hexane–EtOAc 7:3) afforded **19** (201 mg, 95%) as a white solid, mp 103–104°C (from hexane–CH_2Cl_2) (lit. (*7a*) mp 111–112°C); $[\alpha]_D^{25}$ +92° (lit. (*7a*) $[\alpha]_D^{23}$ +130.4°), with the expected ir, uv, and mass spectra; ^{1}H nmr, δ (ppm): 4.52 (apparent q, average J = 2.7 Hz, H-8), 2.90 (quintuplet, J = 7 Hz, H-11), 2.67 (dd, J = 13.9 and 5.8 Hz, H-6α), 2.54 (dddd, overlapped; H-7), 2.55–2.40 (m, 2H, H-2α and H-2β), 2.30 (dd, J = 15.5 and 2.5 Hz, H-9β), 1.96 (tq, J = 13.9 and 1.3 Hz, H-6β), 1.90–1.75 (m, 2H, H-1α/1β), 1.82 (d, 3H, J = 1.3 Hz, H-15), 1.72 (dd, J = 15.5 and 4.4 Hz, H-9α), 1.30 (s, 3H, H-14), 1.28 (d, 3H, J = 7 Hz, H-13).

3,3-Ethanedithio-7,8,11αH-eudesm-4-en-12,8-olide, ***20***

A modification of the published procedure (*7b*) was utilized: Lactone **19** (180 mg, 0.72 mmol), ethanedithiol (0.45 mL, 5.34 mmol), and $BF_3 \cdot OEt_2$ (40 μL) were dissolved in glacial acetic acid (3 mL) and stirred for 4 h at room temperature. The reaction mixture was then poured into water (20 mL) and extracted with CH_2Cl_2 (4 × 10 mL). The organic layer was washed with 5% aqueous $NaHCO_3$ and water, dried over anhydrous Na_2SO_4, filtered, and concentrated *in vacuo*. Column chromatography on silica gel (elution with hexane–EtOAc 19:1) yielded **20** (206 mg, 87%) as white needles, mp 138–139°C (from hexane–CH_2Cl_2) (lit. (*7b*) mp 141–143°C); $[\alpha]_D^{25}$ +51° (lit. (*7b*) $[\alpha]_D^{23}$ +50.3°), with the expected ir and mass spectra; ^{1}H nmr, δ (ppm): 4.45 (m, 1H, H-8), 3.40–3.20 (m, 4H, thioketal hydrogens), 2.81 (qd, J = 7.2 and 6.2 Hz, H-11), 2.44 (dd, J = 14.2 and 5.8 Hz, H-6α), 2.37 (m, 1H, overlapped, H-7), 2.25–2.10 (m, 2H, H-2α/2β), 2.18 (dd, J = 15.4 and 1.8 Hz, H-9β), 1.93 (d, 3H, J = 1.1 Hz, H-15), 1.80–1.60 (m, 3H, H-1α/1β and H-6β), 1.57 (dd, J = 15.4 and 4.4 Hz, H-9α), 1.22 (d, 3H, J = 7.2 Hz, H-13), 1.14 (s, 3H, H-14).

7,8,11αH-Eudesm-4-en-12,8-olide, ***21****, and 5,7,8,11αH-eudesm-3-en-12,8-olide,* ***22***

Approximately 4 g active W-2 Raney nickel were added at once to a solution of thioketal **20** (195 mg, 0.6 mmol) in 6 mL MeOH. The mixture was stirred for 10 min at room temperature and the reaction was quenched by rapid addition of ethanedithiol (0.2 mL). Work-up as above (**12** → **14**) and column chromatography on silica gel (elution with hexane–EtOAc 9:1) yielded first **21** (81 mg, 57%) as a colorless oil, lit. (17) solid mp 59–62°C; $[\alpha]_D^{25}$ +47° (lit. (17) $[\alpha]_D^{20}$ +29.7°); its enantiomer has been reported to be an oil, $[\alpha]_D$ −53° (11, 19); ^{1}H nmr, δ (ppm): 4.45 (td, J = 4 and 2 Hz, H-8), 2.78 (qd, J = 7.2 and 6.2 Hz, H-11), 2.46 (dd, J = 13.9 and 5.8 Hz, H-6α), 2.29 (dddd, J = 12.2, 6.2, 5.8, and 4 Hz, H-7), 2.13 (dd, J = 15.3 and 2 Hz, H-9β), 2.00–1.65 (m, 3H, H-3α/3β and H-6β), 1.64 (br s, 3H, H-15), 1.54 (dd, J = 15.3 and 4 Hz, overlapped; H-9α), 1.22 (d, 3H, J = 7.2 Hz, H-13), 1.11 (s, 3H, H-14). High resolution molecular weight determination, *Mol. Wt.* calcd. for $C_{15}H_{22}O_2$: 234.1620; found: 234.1618.

Further elution with the same solvent mixture gave 18 mg (13%) of a solid compound, mp 106–107°C (from hexane–EtOAc); $[\alpha]_D^{25}$ +7°, which was assigned structure **22** on the basis of its spectral properties: ir (KBr), ν_{max}: 1765 (s), 1755 (s), 1165 (s) cm^{-1}; ^{1}H nmr at 500 MHz, δ (ppm): 5.36 (m, 1H, H-3), 4.48 (td, J = 4.3 and 1.8 Hz, H-8), 2.79 (quintuplet, J = 7.1 Hz, H-11), 2.39 (dddd, J = 12.4, 7.1, 6.2, and 4.3 Hz, H-7), 2.12 (dd, J = 15.3 and 1.8 Hz, H-9β), 2.10–1.90 (m, 2H, H-2α/2β), 1.88 (br d, $J \simeq$ 13.6 Hz, H-5), 1.74 (ddd, J = 13.6, 6.2, and 2.6 Hz, H-6α), 1.63 (br s, 3H, H-15), 1.44 (dd, J = 12.6 and 6.4 Hz, H-1β), 1.39 (dd, J = 15.3 and 4.3 Hz, H-9α), 1.30 (td, J = 12.6 and 6.5 Hz, H-1α), 1.20 (d, 3H, J = 7.1 Hz, H-13), 1.01 (td, J = 13.6 and 12.4 Hz, H-6β), 0.87 (s, 3H, H-14); ms, m/z (% rel. int.): 234 (M^+, 28), 219 (59), 173 (21), 161 (38), 145 (100). High resolution molecular weight determination, *Mol. Wt.* calcd. for $C_{15}H_{22}O_2$: 234.1620; found: 234.1612. *Anal.* calcd. for $C_{15}H_{22}O_2$: C 76.92, H 9.40; found: C 76.76, H 9.51.

11α-Phenylseleno-7,8αH-eudesm-4-en-12,8-olide, ***23***

A solution of *n*BuLi (0.75 mL of a 1.6 *M* solution in hexane,

1.2 mmol) was added at room temperature under Ar via syringe to a solution of diisopropylamine (0.18 mL, 1.26 mmol) and TMEDA (0.55 mL, 3.61 mmol) in dry THF (2 mL). After stirring for 5 min, the mixture was cooled to −23°C (Dry Ice – CCl_4 bath). Lactone **21** (70 mg, 0.3 mmol) was dissolved in dry THF (2 mL) and added dropwise (5 min) to the cooled LDA/TMEDA solution. After stirring for 1 h at −23°C, a solution of PhSeCl (230 mg, 1.2 mmol) and HMPT (0.2 mL) in dry THF (2 mL) was added dropwise (10 min) via syringe. The reaction mixture was stirred for 1 h at −23°C and quenched at this temperature with 0.5 *N* HCl (2 mL). The reaction mixture was then poured into water (15 mL) and extracted with EtOAc (4 × 15 mL). The organic layer was washed twice with brine, dried over anhydrous Na_2SO_4, filtered, and concentrated *in vacuo*. Column chromatography of the yellowish oily residue (elution with hexane–EtOAc 19:1) yielded **23** (71 mg, 66% based on recovered **21**) as almost colorless crystals, mp 134–135°C (from hexane–CH_2Cl_2); ir (KBr), ν_{max}: 1765 (s), 1170 (m), 740 (m), 690 (m); ^{1}H nmr, δ (ppm): 7.65–7.25 (m, 5H, aromatic hydrogens), 5.01 (m, 1H, H-8), 2.54 (dd, J = 13.6 and 5.9 Hz, H-6α), 2.27 (ddd, J = 12.4, 5.9, and 4.1 Hz, H-7), 2.16 (dd, J = 15.4 and 4.1 Hz, H-9β), 2.00–1.80 (m, 2H, H-3α/3β), 1.81 (dd, J = 13.6 and 12.4 Hz, H-6β), 1.62 (br s, 3H, H-15), 1.59 (dd, J = 15.4 and 4.4 Hz, H-9α), 1.55 (s, 3H, H-13), 1.10 (s, 3H, H-14). *Anal.* calcd. for $C_{21}H_{26}O_2Se$: C 64.79, H 6.68, Se 20.30; found: C 64.88, H 6.58, Se 20.12.

Further elution with the same solvent mixture led to the recovery of unreacted **21** (7 mg).

1-Deoxyivangustin, 3 and 8αH-eudesma-4,7(11)-dien-12,8-olide, 24

Hydrogen peroxide (0.18 mL of a 30% aqueous solution, ca. 1.6 mmol) was added at 0°C to a solution of **23** (63 mg, 0.16 mmol) and AcOH (20 μL) in THF (1.5 mL). After stirring for 1 h at 0°C, the reaction mixture was poured into 5% aqueous $NaHCO_3$ (8 mL) and extracted with EtOAc (4 × 5 mL). The organic layer was washed several times with brine, dried over anhydrous Na_2SO_4, filtered, and concentrated *in vacuo*. Column chromatography on silica gel (elution with hexane–EtOAc 9:1) gave first 5 mg of a colorless oil (13%), $[\alpha]_D^{25}$ +46°, identified with 1-deoxyivangustin **3** (lit. (8) $[\alpha]_D^{24}$ +35.2°); lit. $[\alpha]_D$ for the enantiomer (11) is surprisingly different in its absolute value (−119°); ir (film), ν_{max}: 1760 (s), 1260 (m), 1115 (m) cm^{-1}; ^{1}H nmr, δ (ppm): 6.23 (d, J = 2.6 Hz, H-13′), 5.60 (d, J = 2.4 Hz, H-13), 4.49 (apparent q, average J = 6.9 Hz, A-part of a strongly coupled AXX′Y-system; H-8), 3.05 (dtt, J = 10, 7.3, and 2.5 Hz, H-7), 2.80 (dd, J = 13.2 and 7.3 Hz, H-6α), 2.10–1.90 (m, 3H, H-3α/3β and H-6β), 1.74 (d, 2H, J = 6.9 Hz, XX′ part of a AXX′Y-system; H-9α/9β), 1.66 (br s, 3H, H-15), 1.08 (s, 3H, H-14); ms, m/z (% rel. int.): 232 (M^+, 36), 217 (100), 199 (12), 171 (55), 145 (53). High resolution molecular weight determination, *Mol. Wt.* calcd. for $C_{15}H_{20}O_2$: 232.1463; found: 232.1456.

Further elution with the same solvent mixture gave 23 mg (61%) of an unstable colorless oil, $[\alpha]_D^{25}$ −76°, which was assigned structure **24** on the basis of its spectral properties; ir (film), ν_{max}: 1750 (s), 1685 (m), 1680 (m), 1025 (m) cm^{-1}; uv, λ_{max} (log ε_{max}): 216 (3.99), 272 (3.76); ^{1}H nmr, δ (ppm): 4.70 (ddq, J = 9.3, 8.2, and 1.9 Hz, H-8), 3.35 (dq, J = 19.8 and 1 Hz, H-6α), 3.25 (dq, J = 19.8 and 1.9 Hz, H-6β), 2.24 (dd, J = 13.3 and 9.3 Hz, H-9β), 2.05–1.85 (m, 2H, H-3α/3β), 1.83 (td, J = 1.9 and 1 Hz, H-13), 1.65 (q, J = 1 Hz, H-15), 1.41 (dd, J = 13.3 and 8.2 Hz, H-9α), 0.94 (s, 3H, H-14); ms, m/z (% rel. int.): 232 (M^+, 39), 217 (100), 199 (9), 189 (15), 171 (12), 161 (22). High resolution molecular weight determination, *Mol. Wt.* calcd. for $C_{15}H_{20}O_2$: 232.1463; found: 232.1460.

Isomeric 6*H*,8*H*-naphthyridino-1,3-benzothiazin-8-ones

LAJOS FODOR[1] AND DAVID B. MACLEAN[2]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 21, 1986

LAJOS FODOR and DAVID B. MACLEAN. Can. J. Chem. **65**, 636 (1987).

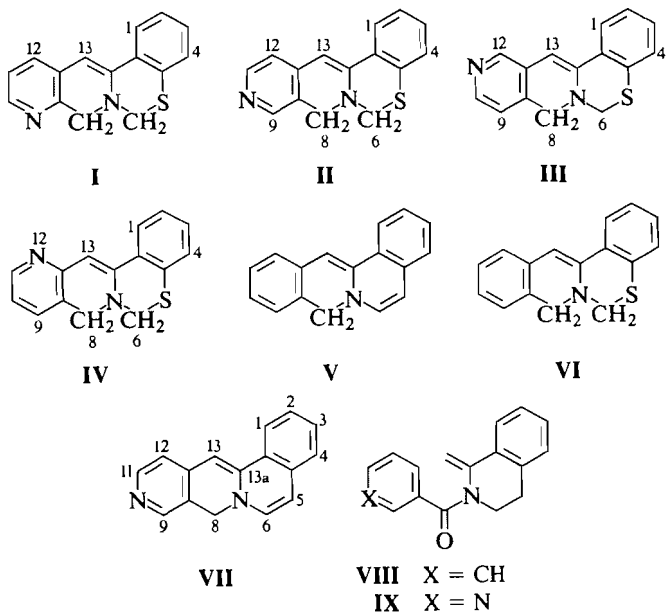
The synthesis of the ring system present in two of the four possible isomeric 6*H*,8*H*-naphthyridino-1,3-benzothiazines is reported here for the first time. 2,3-Dimethoxy-6*H*,8*H*-[2,7]naphthyridino[2,3-*c*][1,3]benzothiazin-8-one (**5**) and several related compounds have been prepared by both chemical and photochemical methods. 2,3-Dimethoxy-6*H*,8*H*-[1,6]naphthyridino[6,7-*c*][1,3]benzothiazin-8-one (**9**) has been isolated in 15% yield along with **5** in 38% yield on irradiation of 6,7-dimethoxy-3-nicotinoyl-4-methylidene-2*H*-1,3-benzothiazine (**8**).

LAJOS FODOR et DAVID B. MACLEAN. Can. J. Chem. **65**, 636 (1987).

On rapporte la première synthèse du système cyclique que l'on retrouve dans deux des quatre isomères possibles des 6*H*,8*H*-naphtyridinobenzothiazines-1,3. Utilisant des méthodes tant chimiques que photochimiques, on a préparé la diméthoxy-2,3 6*H*,8*H*-[2,7]naphtyridino-[2,3-*c*][1,3]-benzothiazinone-8 (**5**) et plusieurs composés apparentés. On a isolé la diméthoxy-2,3 6*H*,8*H*-[1,6]naphtyridino-[6,7-*c*][1,3]-benzothiazinone-8 (**9**) avec un rendement de 15% aux côtés de 38% du composé **5** lorsqu'on a effectué l'irradiation de la diméthoxy-6,7 nicotinoyl-3 méthylène-4 2*H*-benzothiazine-1,3 (**8**).

[Traduit par la revue]

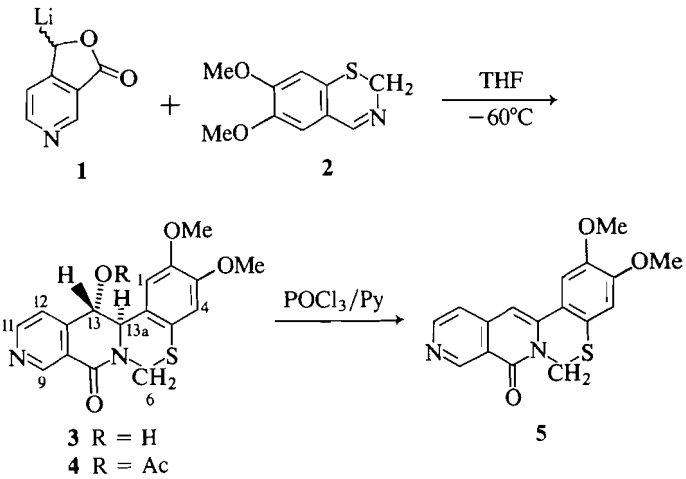
There are four possible isomeric 6*H*,8*H*-naphthyridino[1,3]-benzothiazines (**I**–**IV**) as illustrated in the accompanying formulas. To our knowledge, the synthesis of these ring systems has not been reported. The four six-membered rings present in **I**–**IV** have the same array as the 8*H*-dibenzo[*a*,*g*]quinolizines (**V**), the 6*H*,8*H*-isoquino[2,3-*c*][1,3]benzothiazines (**VI**), and the 6*H*,8*H*-isoquino[2,1-*b*][2,7]naphthyridines (**VII**). A general route to ring systems **V** (1, 2), **VI** (3), and **VII** (4, 5) has been developed in this laboratory, involving the condensation of a bicyclic imine (a 3,4-dihydro-isoquinoline in the case of **V** and **VII** and a 2*H*-1,3-benzothiazine in the case of **VI**) with a phthalide anion in the case of **V** and **VI** and an azaphthalide anion in the case of **VII**. Another general approach to ring systems **V** and **VII** has been developed by Lenz (6, 7) and by Ninomiya and co-workers (8, 9), involving the photochemical cyclization of enamides such as **VIII** and **IX**, respectively. Here we report the application of these general procedures to the synthesis of compounds containing ring systems **II** and **IV**.



I **II** **III**

IV **V** **VI**

VII **VIII** X = CH; **IX** X = N



1 **2**

3 R = H; **4** R = Ac

5

SCHEME 1

Compounds of structure **II** have been prepared as shown in Scheme 1. A solution of the lithium salt of azaphthalide **1** (4, 5) in tetrahydrofuran (THF) at −60°C was treated with a solution of 6,7-dimethoxy-2*H*-1,3-benzothiazine (**2**) in THF at −60°C for 2 h and for a longer period at 20°C. The product of reaction isolated on work-up was the racemic, crystalline lactam alcohol (**3**). The relative stereochemistry of **3** at C-13 and C-13a is similar to that observed for compounds prepared in related condensations (1–5) and was established through nmr examination of **3** and its *O*-acetate (**4**). Dehydration of **3** through treatment with $POCl_3$ in pyridine yielded **5**. The spectroscopic properties of compounds **3**–**5** are compatible with the assigned structures.

The ^1H nmr spectra of **3** and **4** show three aromatic singlets, the two at highest field being assigned to hydrogen atoms at C-1 and C-4 and that at lowest field to the hydrogen atom at C-9. An AB quartet in the aromatic region present in each spectrum is attributed to signals for hydrogen atoms at C-11 and C-12, the former being at lower field. In each spectrum the hydrogen atoms at C-6 appear as an AB quartet. In the case of the alcohol (**3**) the signals are centered at δ 4.20 and δ 5.77, and in the case of the acetate at δ 4.08 and δ 5.85; the lower field proton in each case was assigned to the equatorial proton. The signals for the methoxy groups are in the usual position for aromatic methoxy groups. The protons at C-13 and C-13a appear, respectively, at

5 (38%) 9 (15%)

SCHEME 2

δ 4.79 and 4.95 in **3** and at δ 6.24 and 5.02 in **4**. The coupling constants, $J = 9.3$ Hz for **3** and $J = 9.5$ Hz for **4**, indicate that the vicinal hydrogen atoms are *trans* to one another.

The ^{1}H nmr spectrum of **5**, aside from the signals of the two methoxy groups and the two hydrogen atoms at C-6, shows signals only in the aromatic region. Noteworthy is the presence of a signal at δ 7.24 assigned to C-13 H.

The ^{13}C nmr spectra of **3** and **5** were also recorded and agree with the structures assigned.

The mass spectrum of **3** is very similar to the spectra observed for analogous compounds of ring systems **V** (2), **VI** (3), and **VII** (5). Compound **4** suffers loss of acetic acid on electron ionization yielding an ion of m/z 326, which corresponds to the molecular ion of **5**. In the case of both **4** and **5** the ion of m/z 326 loses SH to form a fragment ion of m/z 293, which is the base peak in each spectrum. This behaviour is similar to that observed for analogous compounds of ring system **VI** (3).

We also examined a photochemical route to the preparation of compounds of ring systems **II** and **IV**. To this end we prepared the enamide **8** by condensation of 4-methyl-2*H*-1,3-benzothiazine (**6**) with nicotinoyl chloride (**7**) in the presence of triethylamine. The enamide was then irradiated in methanol solution, in a water-cooled apparatus, with a low pressure mercury lamp for 5 h. On work-up of the reaction mixture, compound **5** was isolated in 38% yield and its isomer **9** in 15% yield (see Scheme 2). In accord with previous experience in related systems (6–9), none of the dihydro derivatives of **5** and **9** were detected, although they might be expected to be the initial products of the photochemical reaction.

The structure of **9**, like that of **5**, rests upon a spectroscopic analysis. The major difference between the ^{1}H nmr spectrum of **9** and that of **5** lies in the signals associated with the hydrogen atoms of the pyridine ring. In compound **5** the three signals were observed as a singlet and an AB quartet; in **9** the three protons are contiguous and the three signals are observed as multiplets appearing at δ 7.40, 8.71, and 8.90. The lowest field signal in **5** appeared at δ 9.56, a consequence of its position adjacent to both the pyridine nitrogen and the lactam. There is no proton similarly situated in **9**, where the lowest field proton appears at δ 8.90.

In this investigation we have effected the synthesis of two (**II** and **IV**) of the four possible ring systems present in the isomeric naphthyridino-1,3-benzothiazines. The two remaining ring systems (**I** and **III**) should be obtainable by application of one or other of the general methods applied in this study provided that the requisite starting materials may be prepared. Ring system **II** is a thia analogue of the ring system present in several alkaloids of *Alangium lamarckii Thw.* (9*b*, and references therein).

Experimental

The ^{1}H nmr spectra were recorded on a Bruker AM500 at 500 MHz and the ^{13}C nmr spectra on the same instrument at 125.8 MHz. The samples were dissolved in $CDCl_3$ using tetramethylsilane (TMS) as internal standard; chemical shifts are reported in ppm (δ) downfield from TMS. The symbols, s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), and br (broadened), are used to report the multiplicity and shape of the signals. EI mass spectra were recorded either on a VG Micromass 7070F or a VG ZAB E mass spectrometer at an ionizing voltage of 70 eV. Infrared spectra were recorded on a Perkin–Elmer 283 infrared spectrometer. Melting points were determined using a Gallenkamp apparatus and are uncorrected.

6,7-Dimethoxy-2*H*-1,3-benzothiazine (**2**) (10, 11), 6,7-dimethoxy-4-methyl-2*H*-1,3-benzothiazine (**6**) (10, 11), and furo[3,4-*c*]-pyridin-3-(1*H*)-one (azaphthalide) (4, 5) were prepared as described in the literature. Nicotinic acid was obtained commercially.

*(13*R*,*13a*R*)-13,13a-Dihydro-13-hydroxy-2,3-dimethoxy-6*H,*8*H-*[2,7]naphthyridino[2,3-c][1,3]benzothiazino-8-one (3)*

A stirred solution of 1,1,1,3,3,3-hexamethyldisilazine (0.38 mL, 1.78 mmol) in dry THF (5 mL) at −20°C was treated with *n*BuLi (1.78 mmol) (1.202 mL of 1.48 *M* solution in hexane). The mixture was then cooled to −60°C and a solution of azaphthalide (0.200 g, 1.48 mmol) in dry THF (5 mL) was added dropwise, producing an orange solution that was stirred for another 15 min at −60°C. 6,7-Dimethoxy-2*H*-1,3-benzothiazine (0.30 g, 1.48 mmol) in dry THF (5 mL) was added dropwise and, when addition was complete, the stirring was continued for another 2 h. The temperature was allowed to rise to 20°C and the reaction mixture was left overnight before work-up. The solvent was evaporated, water was added, and the mixture extracted several times with $CHCl_3$. The extract was dried over Na_2SO_4 and evaporated, yielding a yellow oil that was recrystallized from ethanol (0.316 g, 62.1%), mp 259–262°C; ir, ν_{max}($CHCl_3$):

3600, 1655 cm^{-1}; ^1H nmr (500 MHz, $CDCl_3$), δ: 3.77 (3H, s, OMe), 3.80 (3H, s, OMe), 4.20 (1H, d, J = 12.3 Hz, C-6 H_{ax}), 4.79 (1H, m, C-13 H), 4.95 (1H, d, J = 9.3 Hz, C-13a H), 5.77 (1H, d, J = 12.3 Hz, H-6_{eq}), 6.28 (1H, d, J = 7.4 Hz, OH), 6.95 (1H, s, C-1 H or C-4 H), 7.06 (1H, s, C-4 H or C-1 H), 7.67 (1H, d, J = 5.0 Hz, C-1), 8.8 (1H, d, J = 5.0 Hz, C-10 H), 9.00 (1H, s, C-9 H); ^{13}C nmr (125.8 MHz, DMSO-d_6), δ: 43.2 (C-6), 55.6 and 55.7 (2 × OMe), 61.4 (C-13a), 67.6 (C-13), 112.0, 114.9, 119.8, 122.3, 123.5, 124.7, 146.1, 148.0, 148.3, 150.2, 153.1 (aromatic C's), 160.8 (C-8); ms (EI), m/z (rel. int.): 344 (44) $M^{+\cdot}$, 326 (11), 293 (15), 210 (100), 135 (13). *Mol. Wt.* (hrms) calcd. for $C_{17}H_{16}N_2O_4S$: 344.0830; found: 344.0819.

O-*Acetyl derivative (3)*

Compound (**3**) (50 mg) was dissolved in pyridine and treated with an excess of acetic anhydride (2 mL). The mixture was kept in a stoppered flask for 8 h, the excess reagent removed under vacuum, and water (5 mL) added to the residue. The aqueous suspension was extracted with $CHCl_3$, the extract dried over Na_2SO_4, and evaporated to dryness. The *O*-acetate (**4**) (49 mg, 88%) crystallized from methanol, mp 243–245°C; ^1H nmr (500 MHz, $CDCl_3$), δ: 2.10 (3H, s, CH_3CO), 3.86, 3.88 (6H, 2 × s, 2 × OMe), 4.08 (1H, d, J = 12.3 Hz, C-6 H_{ax}), 5.02 (1H, d, J = 9.5 Hz, C-13a), 5.85 (1H, d, J = 12.3 Hz, C-6 H_{eq}), 6.24 (1H, d, J = 9.5 Hz, C-13 H), 6.70 (1H, s, C-1 or C-4 H), 6.84 (1H, s, C-1 or C-4 H), 7.28 (1H, d, J = 5.0 Hz, C-12 H), 8.79 (1H, d, J = 5.0 Hz, C-11 H), 9.24 (1H, s, C-9 H); ms (EI), m/z (rel. int.): 386 (10)$M^{+\cdot}$, 326 (71), 293 (100). *Mol. Wt.* (hrms) calcd. for $C_{19}H_{18}N_2O_5S$: 386.0934; found: 386.0927.

*2,3-Dimethoxy-6*H,*8*H-*[2,7]naphthyridino[2,3-c][1,3]benzothiazin-8-one (5)*

The lactam (**3**) (150 mg), in dry pyridine (5 mL) was treated with freshly distilled $POCl_3$ (1.5 mL) and the mixture left at room temperature for 3 h. The volatile reagents were evaporated under reduced pressure, the residue taken up in H_2O (20 mL), the solution made alkaline with sodium carbonate, and the mixture extracted with $CHCl_3$. The extract was taken to dryness under reduced pressure and the last traces of pyridine removed from the residue by codistillation with benzene. The residue, freed of pyridine, was crystallized from ethanol. The product (114 mg, 80.2%) melted at 246–248°C; ir, ν_{max}($CHCl_3$): 1660; ^1H nmr (500 MHz, $CDCl_3$), δ: 3.95 (3H, s, OMe), 4.00 (3H, s, OMe), 5.35 (2H, br s, C-6 H's), 6.69 (1H, s, C-1 or C-4 H), 6.89 (1H, s, C-1 or C-4 H), 7.24 (1H, s, C-13 H), 7.39 (1H, d, J = 5.1 Hz, C-12 H), 8.69 (1H, d, J = 5.1 Hz, C-11 H), 9.56 (1H, s, C-9 H); ^{13}C nmr (125.8 MHz, $CDCl_3$), δ: 42.6 (C-6), 56.4, 56.5 (2 × OMe), 101.8, 110.6, 111.2, 119.5, 119.6, 122.5, 129.2, 142.7, 143.0, 148.8, 149.3, 150.6, 151.7 (aromatic C's), 160.4 (*C*=O); ms (EI), m/z (rel. int.): 326 ($M^{+\cdot}$) (77), 293 (100), 277 (8). *Mol. Wt.* (hrms) calcd. for $C_{17}H_{14}N_2O_3S$: 326.0715; found: 326.0720. *Anal.* calcd. for $C_{17}H_{14}N_2O_3S$: C 62.6, H 4.3, N 8.6; found: C 62.3, H 4.2, N 8.4%.

*4-Methylidene-6,7-dimethoxy-3-nicotinoyl-2*H-*1,3-benzothiazine (8)*

A mixture of nicotinic acid (1.77 g, 0.01 mol) and thionyl chloride was heated under reflux in a nitrogen atmosphere for 3 h. The excess thionyl chloride was removed by distillation. The remaining traces of $SOCl_2$ were removed by codistillation with benzene (20 mL) and the process was repeated twice more. To the white solid remaining in the flask were added CH_2Cl_2 (50 mL) and triethylamine (10 mL) and the mixture was stirred under an atmosphere of dry nitrogen. A solution of 6,7-dimethoxy-4-methyl-2*H*-1,3-benzothiazine (0.557 g, 0.0025 mol) dissolved in CH_2Cl_2 (20 mL) was then added and the solution was heated under reflux for 2 h. The solvent was removed, yielding a brown oil that crystallized from ethanol (0.762 g, 92.9%), mp 154–155°C; ir, ν_{max}($CHCl_3$): 1665 cm^{-1}; ^1H nmr (500 MHz, $CDCl_3$), δ: 3.88 (3H, s, OMe), 3.90 (3H, s, OMe), 4.52 (1H, d, J = 1.5 Hz, vinyl H), 5.20 (2H, s, C-2 H's), 5.42 (1H, d, J = 1.5 Hz, vinyl H), 6.67 (1H, s, C-5 H or C-8 H), 7.04 (1H, s, C-5 H or C-8 H), 7.29 (1H, m, C-4′ or C-5′ H), 7.76 (1H, m, C-4′ or C-5′ H), 8.61 (2H, m, C-2′ H and C-6′ H); ^{13}C nmr (125.8 MHz, $CDCl_3$), δ: 44.6 (C-2), 56.2 (2 × OMe), 108.5, 108.6, 110.4, 119.5, 123.1, 124.6, 131.5, 135.9, 141.4, 147.6, 148.9, 150.5, 150.9 (aromatic vinylic C-atoms), 166.7 (C=O); ms (EI), m/z (rel. int.): 328 (41) $M^{+\cdot}$, 327 (32), 300 (76), 299 (38), 194 (83), 106 (81), 78 (100). *Mol. Wt.* (hrms) calcd. for $C_{17}H_{16}N_2O_3S$: 328.0881; found: 328.0896. *Anal.* calcd. for $C_{17}H_{16}N_2O_3S$: C 62.2, H 4.9, N 8.5; found: C 62.5, H 5.4, N 8.3%.

*Irradiation of 6,7-dimethoxy-3-nicotinoyl-4-methylidene-2*H-*1,3-benzothiazine (8)*

A solution of compound **8** (0.566 g) in methanol (80 mL) deoxygenated with bubbling N_2 was irradiated for 5 h with a 10-watt Osram low pressure mercury lamp using a Vycor filter in a water cooled immersion well vessel. The reaction mixture was evaporated to dryness, dissolved in a minimum amount of $CHCl_3$, and chromatographed on a silica column. The column was developed with a 1% solution of MeOH in $CHCl_3$. The first compound to be eluted (0.212 g, 37.7%) was identical with **5** described above. The identity was established by a comparison of its spectroscopic properties (^1H nmr, ms), its mp, and its tlc behaviour. The second compound eluted from the column (0.083 g, 14.8%) melted at 234–237°C (ethanol); ^1H nmr (500 MHz, $CDCl_3$), δ: 3.95 (3H, s, OMe), 3.97 (3H, s, OMe), 5.37 (2H, brs, C-6 H), 6.89 (1H, s, C-1 or C-4 H), 7.15 (1H, s, C-1 or C-4 H), 7.34 (1H, s, C-13 H), 7.40 (1H, m, C-10 H), 8.71 (1H, m, C-9 H), 8.90 (1H, m, C-11 H); ^{13}C nmr (125.8 MHz, $CDCl_3$), δ: 43.0 (C-6), 56.5 (2 × OMe), 104.2, 110.5, 111.1, 120.8, 121.4, 122.7, 127.4, 138.3, 141.9, 148.9, 151.5, 152.1 (aromatic and vinylic C-atoms), 166.8 (*C*=O); ms (EI), m/z (rel. int.): 326 (85) $M^{+\cdot}$, 293 (100), 277 (7); *Mol. Wt.* (hrms) calcd. for $C_{17}H_{14}N_2O_3S$: 326.0726; found: 326.0726.

Solid state infrared and Raman data (350–100 cm^{-1}) are reported for Ph_3SnNCY (Y = O, S, Se) and their 1:1 adducts with hexamethylphosphoramide (HMPA), pyridine-*N*-oxide (pyO), 4-picoline-*N*-oxide (4-picO), triphenylphosphine oxide (Ph_3PO), and pyridine (py), as well as for $Ph_3SnNCSe \cdot L$ where L = β-pic (β-picoline) or γ-pic (γ-picoline), and assignments are given. The crystal structure of $Ph_3SnNCO \cdot pyO$ was determined by single crystal X-ray analysis. The compound crystallizes in space group *Pbca* with $a = 14.443(3)$, $b = 16.676(4)$, $c = 17.523(6)$ Å (−110°C); $Z = 8$. The structure was solved by the direct method and refined by full-matrix least-squares methods to $R = 0.024$ for 2086 observed reflections. The tin atom has distorted trigonal bipyramidal coordination with the isocyanate group and pyridine-*N*-oxide at the apices of the bipyramid and phenyl rings in the equatorial positions. Changes in ν(Sn—NCY) on adduct formation are correlated with either increased coordination at tin (Y = O) or breaking of strong chalcocyanate bridges with tin remaining five-coordinate (Y = S, Se).

IVOR WHARF, LARS PIEHLER, BRUCE M. SAILOFSKY, MARIO ONYSZCHUK et MICHEL G. SIMARD. Can. J. Chem. **65**, 639 (1987).

On a déterminé les spectres infrarouges et Raman (350–100 cm^{-1}), à l'état solide, des dérivés Ph_3SnNCY (Y = O, S, Se) et de leurs adduits 1:1 avec la pyridine, l'hexaméthylphosphoramide (HMPA) et avec les oxydes de la pyridine, de la picoline-4 et de la triphénylphosphine ainsi que des complexes $Ph_3SnNCSe \cdot L$ dans lesquels L = β-pic (β-picoline) ou γ-pic (γ-picoline) et on rapporte les attributions des bandes. On a déterminé la structure cristalline du composé $Ph_3SnNCO \cdot pyO$ par diffraction des rayons-X sur un cristal unique. Le composé cristallise dans le groupe d'espace *Pbca*, avec $a = 14{,}443(3)$, $b = 16{,}676(4)$ et $c = 17{,}523(6)$ Å (à −110°C) et $Z = 8$. On a résolu la structure par la méthode directe et on l'a affinée par les méthodes des moindres carrés jusqu'à une valeur de $R = 0{,}024$ pour 2086 réflexions observées. La coordination de l'étain est bipyramidale trigonale déformée, avec les groupements isocyanate et *N*-oxyde de la pyridine dans les positions apicales de la bipyramide et les noyaux phényles dans les positions équatoriales. On a établi une corrélation entre les changements dans les ν(Sn—NCY) qui se produisent lors de la formation de l'adduit avec soit une augmentation de la coordination au niveau de l'étain (Y = O) soit un bris des puissants ponts chalcocyanates avec l'étain penta-coordonné qui reste (Y = S, Se).

[Traduit par la revue]

Introduction

Triphenyltin compounds, principally the hydroxide and acetate, are used as agricultural fungicides (1), while Ph_3SnNCX (X = O, S, Se) and their adducts have also been tested for biological activity (2–5), following earlier studies of adducts formed by Ph_3SnNCS (6). Our knowledge of the vibrational spectra of triphenyltin pseudohalides is incomplete (7) and structures of their adducts have not yet been determined. Following our recent report on the mid-infrared spectra of $Ph_3SnNCSe$ and its adducts (8), we now present complete vibrational data (in the skeletal region) for Ph_3SnNCX (X = O, S, Se) and their adducts with some O— and N—donor ligands. In addition, one adduct, $Ph_3SnNCO \cdot pyO$, was chosen for X-ray analysis so that its structure could be compared with that of the parent Ph_3SnNCO (9). Our purpose is to obtain vibrational and structural data which would be useful in organotin chemistry, especially in evaluating the biological activity of pseudohalide derivatives.

Experimental

Solvents and liquid ligands were stored over molecular sieves before use, while solid ligands were used as received as was triphenyltin chloride (Alfa). Other experimental details, e.g. microanalyses, and Raman (powder) and infrared (Nujol mull) spectral methods were as described elsewhere (10). Triphenyltin isoselenocyanate and its adducts were those prepared earlier (8), as was triphenyltin isothiocyanate (6) and its HMPA adduct (14).

Preparations

Triphenyltin isocyanate (A)

Potassium cyanate (7.0 g; 0.086 mol) was added to a solution of triphenyltin chloride (20 g; 0.05 mol) in methanol (500 mL) and the mixture was stirred at room temperature for 2 h. The mixture was poured into ice-cold water to give a white precipitate. After further stirring (20 min) the white *product* was filtered and recrystallized from toluene; yield, 31%, mp 95–97°C (lit. 98–99°C (11), 100–103°C (12), 73–75°C (13): ν(CN) 2219 cm^{-1} (ir). *Anal.* calcd. for $C_{19}H_{15}NOSn$: C 58.2, H 3.9, N 3.7; found: C 58.0, H 3.9, N 4.1.

Triphenyltin isocyanate – pyridine-N-oxide

A mixture of pyridine-*N*-oxide (0.13 g; 1.37 mmol) and **A** (0.50 g; 1.28 mmol) was stirred in dry pentane (30 mL) for 22 h at room temperature. The *product* was filtered and recrystallized from carbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

tetrachloride; yield, 71%, mp 120–122°C; ir data, ν(CN) 2205, ν(NO) 1213 cm^{-1}. *Anal.* calcd. for $C_{24}H_{20}N_2O_2Sn$: C 59.2, H 4.1, N 5.75; found: C 59.2, H 4.2, N 5.8.

*Triphenyltin isocyanate – 4-picoline-*N*-oxide*

A mixture of 4-picoline-*N*-oxide (0.15 g; 1.37 mmol) and **A** (0.50 g; 1.28 mmol) was stirred in toluene (35 mL) at room temperature for 24 h. The fine suspension obtained was filtered and dried in a vacuum for 1 h; yield, 62%, mp 149–152°C; ir data, ν(CN) 2202, ν(NO) 1225 cm^{-1}. *Anal.* calcd. for $C_{25}H_{22}N_2O_2Sn$: C 59.9, H 4.4, N 5.6; found: C 60.0, H 4.6, N 5.3.

*Triphenyltin isothiocyanate – 4-picoline-*N*-oxide*

Triphenyltin isothiocyanate (2.0 g; 4.9 mmol) was stirred with a toluene (80 mL) solution of 4-picoline-*N*-oxide (0.75 g; 6.9 mmol) until dissolved. An oil slowly formed and this was redissolved by warming the mixture. *Slow* cooling gave crystals of the adduct; yield, 89%, mp 135–136°C; ν(CN) 2057 (ir) 2056 (R), ν(NO) 1221 cm^{-1} (ir). *Anal.* calcd. for $C_{25}H_{22}N_2OSSn$: C 58.05, H 4.3, N 5.4; found: C 58.1, H 4.1, N 5.35.

Triphenyltin isocyanate – pyridine

A mixture of **A** (1.0 g; 2.6 mmol), pyridine (14 mL), and carbon tetrachloride (15 mL) was stirred for 22 h. *Dropwise* addition of pentane to the stirred ice-cold solution precipitated the *adduct*; yield, 41%, mp 89–90°C; ir data, ν(CN) 2185, pyridine modes [8*a*] 1595, [8*b*] 1576, [14] 1405 cm^{-1}. *Anal.* calcd. for $C_{24}H_{20}N_2OSn$: C 61.2, H 4.3, N 5.95; found: C 61.0, H 4.1, N 5.8.

Procedures similar to those given above or in the literature were used to prepare *$Ph_3SnNCO \cdot HMPA$*, mp 142–145°C (lit. 130°C (3)), *$Ph_3SnNCO \cdot Ph_3PO$*, mp 142–144°C (lit. 134°C (3)), *$Ph_3SnNCS \cdot Ph_3PO$*, mp 179–180°C (lit. 180°C (6)), *$Ph_3SnNCS \cdot pyO$*, mp 164–166°C (lit. 169°C (6)), and *$Ph_3SnNCS \cdot py$*, mp 158–161°C (lit. 162°C (6)).

X-ray analysis of $Ph_3SnCO \cdot pyO$

Crystal data

$C_{24}H_{20}N_2O_2Sn$ fw = 487.13

Orthorhombic, space group *Pbca*, a = 14.444(3), b = 16.676(4), c = 17.523(6) Å, V = 4220.7 Å^3, Z = 8, ρ_c = 1.533 g cm^{-3}, (−110°C; MoK$\bar{\alpha}$, λ = 0.71069 Å, graphite monochromator) and μ(MoKα) = 12.3 cm^{-1}; crystal dimensions, 0.15 (100, $\bar{1}$00) × 0.35 (010, 0$\bar{1}$0) × 0.48 (001, 00$\bar{1}$) mm, transmission range 0.66–0.83.

A well-formed crystal was mounted on an Enraf-Nonius CAD-4 diffractometer. A set of 25 reflections was collected using the automatic SEARCH routine of the CAD4 software and the unit cell was obtained by running the INDEX program. The Niggli parameters clearly showed a primitive orthorhombic space group. Oscillation photographs, taken along the three axes, showed mirror symmetry on the three films as expected, and the layer line separations corresponded to the lengths of the chosen axes. Reflections in the range $10° \leq \theta \leq 15°$ were used for the final centering and determining the orientation matrix. Fast pre-collection over the $hk0$, $h0l$, and $0kl$ planes showed the systematic absences, $hk0$, $h \neq 2n$, $h0l$, $l \neq 2n$, and $0kl$, $k \neq 2n$, which are consistent with the space group *Pbca*.

The selenium analogue, $Ph_3SnNCSe \cdot pyO$, was also studied at room temperature using the same techniques. The crystal data[3] show the two compounds are isostructural.

The intensity data were collected using the $\omega/2\theta$ technique at low temperature to augment the intensity of high angle reflections. A fixed slit of 4.0 mm was used and the scan range was ω = (1.00 + 0.35 tan θ)°, extended 25% on either side for background measurement. All reflections were collected at the same rate of 1.7 min^{-1}. Seven standards were measured every hour and a variation of ≤2% was observed for their intensities. Crystal orientation was checked every 100 measurements. A set of 3555 reflections (hkl, $2\theta \leq 45°$) was collected and 2086 reflections with $I \geq 3\sigma(I)$ were retained for structural resolution. Net intensities and standard deviations were obtained as described elsewhere (17). The data were corrected for both Lorentz and polarisation effects and the absorption correction was done using a Gaussian integration (grid 10 × 10 × 10).

The structure was solved by the direct method (EEES) and refined by full-matrix least-squares using the SHELX programme (18). The three phenyl groups were refined as rigid groups using idealised hexagons (d(C—C) = 1.395 Å). Isotropic refinement of all nonhydrogen atoms gave $R = [\Sigma(||F_o| - |F_c||)/\Sigma|F_o|] = 0.047$; further refinement using absorption-corrected data and introduction of the hydrogen atoms at their ideal coordinates (d(C—H) = 1.08 Å and U = 0.05 Å^2) gave R = 0.041. The hydrogen parameters were not refined but the coordinates were recalculated after each cycle. In the final cycles individual weights ($w = 1/\sigma^2(F)$) based on counting statistics were applied. Convergence gave R = 0.024 with $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.027$ and a goodness-of-fit of 1.25. The last ΔF map showed only a background of 0.3e$^-$/Å^3 except for one peak of 0.5e$^-$/Å^3 at 1.2 Å from tin.

N-bonding of cyanate was assumed in the above refinement. The refinement was repeated assuming O-bonding, in which case R = 0.027, R_w = 0.037, and the goodness-of-fit was 1.42. The fact that these values are significantly higher than those for N-bonding confirms that the cyanate group is indeed N-bonded.

Scattering curves were taken from Cromer and Waber (19) except those for hydrogen (20). Anomalous dispersion factors f' and f'' were applied to the non-hydrogen scattering curves (21). Anisotropic thermal parameters (Table SI) together with observed and calculated structure factors (Table SII) and least-squares planes calculations (Table SIII), as well as the stereo view of the unit cell (Fig. SI), have been placed in the Depository of Unpublished Data.[4]

Results

(a) Vibrational spectra (350–100 cm^{-1})

(i) Ph_3SnNCY (Y = O, S, Se)

Vibrational data in the skeletal region are reported in Table 1 for Ph_3SnNCY (Y = O, S, Se) with assignments following those for the triphenyltin halides. Mössbauer data (13) suggest Ph_3SnNCO contains 4-coordinate tin in the solid state consistent with its relatively low melting point and solubility in benzene, where in solution ν(CN) is observed at 2218 cm^{-1}. Unfortunately ν(CN) values do not allow the bonding mode (Sn—N or Sn—O) of the cyanate ligand to be determined. However, the X-ray analysis of Ph_3SnNCO (9) shows it is indeed almost molecular with primary tin—nitrogen bonding and weak tin—oxygen bonding, enabling ν(Sn—NCO) and δ(Sn—NCO) to be assigned to peaks not present in the spectra of triphenyltin halides. The assignment of ν(Sn---O) to the infrared absorption at 138 cm^{-1} is consistent with the weakness of the interaction (d(Sn---O) = 2.81 Å).

Triphenyltin isothiocyanate is polymeric using thiocyanate bridges to join 5-coordinate tin atoms with strong axial primary (Sn—N) and secondary (Sn—S) bonding (23), while ν(CN) and ν(CSe) values show $Ph_3SnNCSe$ is also polymeric (8). Thus ν(Sn—NCY) is assigned to distinct infrared absorptions at ~200 cm^{-1}, while broad peaks in the region 100–130 cm^{-1} may be assigned to overlapping ν(Sn---YCN) and δ(Sn—NCY) modes. Since Ph_3SnNCS has four molecules in the asymmetric unit, crystal lattice splitting may also account for the broad character of these low frequency peaks. Where modes are

both Raman and infrared active for Ph_3SnNCS ((t), (u), and ν(Sn—NCS)), their almost complete coincidence (within experimental error, ±2 cm^{-1}) is consistent with the space group ($P2_1$–C_2^2) of this compound.

(ii) $Ph_3SnNCY \cdot L$ (L = O—donor ligand)

Tables 2(*a*)–(*d*) list vibrational data in the skeletal region (350–100 cm^{-1}) for $Ph_3SnNCY \cdot L$ (L = HMPA, Ph_3PO, pyO, and 4-picO, respectively); not included are weak-to-medium, mainly infrared-active peaks (~350, ~250 cm^{-1}) due to internal HMPA modes (14) and peaks associated with Ph_3PO (24), i.e. ~300–310 cm^{-1} (δ(P=O)), ~250–260 cm^{-1} ((u)(PPh_3)), and ~200–210 cm^{-1} ((x)(PPh_3)).[5] Assignments follow the conventional pattern with ν(Sn—NCY) and δ(Sn—NCY) modes identified by comparing the spectra with those of the analogous halide adducts[5] in the same region. No specific assignment of ν(Sn—O) is given since the axial tin—oxygen stretching mode can interact with the equatorial tin—phenyl deformations (u) in the same region.

Complete data are given for $Ph_3SnNCY \cdot L$ (L = pyO, 4-picO) with the skeletal modes, including ν(Sn—NCY) and δ(Sn—NCY), assigned after inspection of the spectra of the corresponding halide complexes.[6] Pyridine-*N*-oxide itself has an infrared peak at ~230 cm^{-1} (γ(N—O) (25, 26) while the coordinated ligand has a vibration corresponding to twisting of the ring against the donor oxygen (τ(N—O)), as well as the expected ν(Sn—O) and δ(Sn—O) modes (27, 28). The assignment of ν(Sn—O) for $Ph_3SnNCY \cdot pyO$ (~320 cm^{-1}) is consistent with that given earlier for $Ph_3SnNO_3 \cdot pyO$, 325 cm^{-1} (29) and for a number of organotin halide – pyridine-*N*-oxide adducts (30, 31).

There does not appear to be any definite assignments in the skeletal region (≤350 cm^{-1}) for 4-picoline-*N*-oxide complexes in the literature. The assignments given here by analogy with those for the pyridine-*N*-oxide adducts, must be regarded as tentative. The higher values for ν(Sn—O) may reflect the stronger donor power of 4-picoline-*N*-oxide compared with that of pyridine-*N*-oxide.

(iii) $Ph_3SnNCY \cdot L$ (L = py, β-pic, γ-pic)

Complete data for the skeletal region are given in Table 3 for the adducts with pyridine as well as for $Ph_3SnNCSe \cdot L$ (L = β-pic, γ-pic). Although most skeletal modes were readily assigned, no definite values have been given for those involving the ligands; however, assignment of ν(Sn—N_L) to 150–200 cm^{-1} (perhaps the peak of medium intensity at ~150 cm^{-1}) is consistent with the earlier assignment for $Ph_2SnX_2Py_2$ (X = Cl, Br) (32). Only by using per-deuterated ligands following Hutton *et al.* (28, 33) will it be possible to identify these tin—ligand modes clearly.

(b) Crystal and molecular structure of $Ph_3SnNCO \cdot pyO$

A conventional ORTEP drawing of the adduct is shown in Fig. 1 (top), while Fig. 1 (bottom) shows the view down the N—Sn—O axis. The refined coordinates are listed in Table 4 with bond lengths and bond angles for the non-hydrogen atoms in the adduct given in Table 5. The compound is molecular with the tin atom having a slightly distorted trigonal bipyramidal geometry in which phenyl groups occupy the equatorial positions and the isocyanate and pyridine-*N*-oxide ligands are at the apices of the bipyramid. The cell representation (Fig. S1) clearly shows the monomeric nature of the adduct and the shortest intermolecular contacts (Table 6) are consistent with only van der Waals interactions between adjacent molecules with no stacking interactions in the structure.

There is some departure from the ideal geometry as can be seen by the unequal tin—carbon bond lengths and the bond angles around the tin. The tin atom is 0.167 Å above the equatorial plane formed by C(21)—C(31)—C(41) towards the isocyanate group (2.335 Å above the plane), while the pyridine-*N*-oxide molecule is 2.182 Å below the plane. The staggered

orientation of the ligand ring with respect to the equatorial phenyl groups, as is also observed in the structure of $Ph_3SnNO_3 \cdot pyO$ (29), suggests weak inter-ring repulsions may influence the structures of these adducts. Twisting of the phenyl rings may also minimise interactions between them. These rings are differently oriented to the equatorial plane, being twisted out of the plane defined by C(21)—C(31)—C(41) by 73.0° (C(21)—C(26)), 30.2° (C(31)—C(36)), and 94° (C(41)—C(46)); reciprocal orientations of the rings are given by the dihedral angles (φ1Λφ2, 59.2°; φ1Λφ3, 80.4°; φ2Λφ3, 39.1°).

Discussion

(a) Vibrational spectra and adduct formation

The small, random changes in ν(Sn—NCY) values on adduct formation by Ph_3SnNCY (Y = S, Se) (Table 7) are consistent with the picture of strong chalcocyanate bridges being broken by the coordinating ligand with the tin atom (in the Ph_3Sn moiety) being five-coordinate in both the Lewis acids and the adducts. Mixing of axial stretching modes with each other or tin—phenyl deformations may account for the small variations observed in the ν(Sn—NCY) frequencies. It is, in fact, the chalcocyanate group which is more affected by adduct formation, with ν(CN) and ν(CY) reflecting the change from the bridging to terminal (Sn—N) bonding mode.

In contrast, the Ph_3SnNCO system shows the decrease in ν(Sn—NCO) on adduct formation that is expected with the change from mainly four to five coordination at tin. However, comparison with the change in ν(Sn—X) (X = Cl, Br) on adduct formation by Ph_3SnX (Table 7) suggests this picture is overly simplistic. For the adducts, the trend ν(Sn—NCO) ≥ ν(Sn—Cl) is consistent with other isocyanate–chloride comparisons of ν(M—X) frequencies, e.g. Me_3SiX; X = NCO, 521 cm^{-1} (34); X = Cl, 470 cm^{-1} (35); and Ph_3GeX; X = NCO, 450 cm^{-1} (36); X = Cl, 375 cm^{-1} (37), where each pair is structurally similar. The fact that Ph_3SnNCO has *ν(Sn—NCO) ≤ ν(Sn—Cl)*, and that crystalline triphenyltin

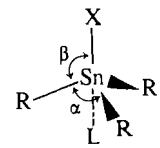
chloride is monomeric (38) implies that the weak tin–oxygen interaction (2.807 Å) in Ph_3SnNCO is sufficient to render the tin atom quasi-five-coordinate and the tin—nitrogen bond slightly weaker. Thus, Ph_3SnNCO is structurally between monomeric Ph_3GeNCO (39) and polymeric Ph_3PbNCO (40).

Since the decrease in ν(Sn—NCO) on adduct formation indicates a further weakening of the tin—nitrogen bond, the crystal structure of $Ph_3SnNCO \cdot pyO$ was determined. The structure of this adduct can also be compared with that of $Ph_3SnNO_3 \cdot pyO$ (29) which has almost trigonal bipyramidal geometry.

Formation of the pyridine-*N*-oxide adduct by Ph_3SnNCO causes an increase in d(Sn—N) from 2.122 to 2.169 Å, paralleling the change in ν(Sn—NCO) from 326 to 289 cm^{-1}, but almost no change in the cyanate group is observed. When comparing $Ph_3SnNCO \cdot pyO$ with $Ph_3SnNO_3 \cdot pyO$, the d(Sn—O_L) values, 2.355 and 2.227 Å, respectively, are consistent with the increase in ν(Sn—O_L) from 309 to 325 cm^{-1}, and suggest an order of Lewis acid strength $Ph_3SnNO_3 \geq Ph_3SnNCO$ with respect to pyridine-*N*-oxide. Although the three triphenyltin compounds considered here do not have exactly trigonal Ph_3Sn moieties, the adducts are clearly five-coordinate, but the nature of triphenyltin isocyanate requires more detailed consideration.

(b) Triphenyltin isocyanate; four- or five-coordinate?

While the degree of coordination of a metal atom or ion is often discussed in terms of the number of nearest neighbours leading to assignments of integral coordination numbers, for adduct formation by Ph_3SnX it is more appropriate to consider the changes in the angles of a trigonal unit Ph_3SnX (**I**) due to attachment of a ligand L *trans* to X.



$$\sin\beta = \sqrt{\frac{4}{3}}\sin\left(\frac{\alpha}{2}\right)$$

I

In the absence of ligand L, four-coordinate Ph_3SnX should have quasi-tetrahedral geometry with $\alpha = \beta = 109.5°$. When X and L are identical (or have equivalent donor power), the system is five-coordinate with $\alpha = 90°$ and $\beta = 120°$. These extremes may be equated with tin using sp^3 and sp^2 hybridisation schemes, respectively (10). In the solid state, no triphenyltin structure obtained to date shows ideal trigonal symmetry and tin and usually the distortion is such that all tin—carbon bonds as well as the three bond angles (α) are different. Thus, average $\angle$CSnC(α) and $\angle$CSnX(β) as well as $\angle$XSnL values are given in Table 8 for selected $Ph_3SnX \cdot L$ as a measure of the degree of coordination of tin in these compounds.

X-ray diffraction studies show Ph_3SnCl and Ph_3SnBr are monomeric having four-coordinate tin with $\alpha = 113°$ ($\beta = 106°$) indicating increased *s*-character in the tin—carbon bonds in agreement with Bent's rule. Full five coordination with both Sn—X and Sn—L bonds of equal or comparable strength is shown by $Ph_3SnNCS \cdot L^-$ (L^- = 2-pyridinium carboxylate), $Ph_3SnCl_2^-$ and Ph_3SnNCS ($\alpha = 120°$), while $Ph_3SnNO_3 \cdot L$ (L = pyO, Ph_3PO) and $Ph_3SnCl \cdot L^-$ are five-coordinate within experimental error. With $\alpha \leq 119.5°$ and $\beta \sim 95°$, $Ph_3SnNCO \cdot pyO$, as well as the adducts of Ph_3SnCl with neutral O-donor ligands, while still five-coordinate, have unequal Sn—X and Sn—L bonds with the bond order being Sn—X $\geq$ Sn—L.

Triphenyl isocyanate ($\alpha = 118°$, $\beta = 98°$) lies between the two extremes, $\alpha = 113°$, $\beta = 106°$, and $\alpha = 120°$, $\beta = 90°$. Since no exact values of α and β can be given for the boundary between four or five coordination, Ph_3SnNCO is best described as an intermediate form. However, ν(Sn—NCO) for this compound favours the description of its structure as quasi-five-coordinate with the weak tin—oxygen interaction sufficient to influence the geometry around the tin atom and weaken the *trans* tin—nitrogen bond.

The correlation of quadrupole splitting parameters (Δ mm s^{-1}) for triorganotin systems with the degree of coordination at tin

is well known (41), with Ph_3SnCl (Δ = 2.550) and Ph_3SnBr (Δ = 2.480) being quasi-tetrahedral, while Ph_3SnNCS (Δ = 3.538), $Ph_3SnNCS \cdot pyO$ (Δ = 3.144), $Ph_3SnNCS \cdot Ph_3PO$ (Δ = 3.478), and $Ph_3SnCl \cdot Ph_3PO$ (Δ = 3.228) are five-coordinate with the phenyl rings occupying the equatorial positions in a trigonal bipyramidal structure. Thus, Δ = 2.47 for Ph_3SnNCO (13) was taken to indicate a quasi-tetrahedral structure for this compound. However, Δ values are very dependent on the nature of the groups attached to the tin since alkyl and phenyl groups have large partial quadrupole splittings (pqs), e.g. alkyl, pqs(tet) = −1.37, pqs(eq) = 1.13, or phenyl, pqs(tet) = −1.26, pqs(eq) = −0.98, while anions (X) and O-donor ligands (L) such as those given in Table 8 have small pqs, e.g. Cl or Br, pqs = 0 (by definition); NCS, pqs(tet) = +0.21, pqs(ax) = +0.065; Ph_3PO, pqs(ax) = +0.12; pyO, pqs(ax) = 0.00 (42). Thus, a decrease in ∠CSnC from 120° alone will cause Δ to vary without great changes in stereochemistry

Nouveaux modèles du NADH en série oxazolyl-3 dihydro-1,4 pyridine : synthèse, réactivité, rôle de la complexation dans la réactivité

P. BINAY, G. DUPAS, J. BOURGUIGNON[1] ET G. QUEGUINER

Institut national des sciences appliquées, Institut de recherches en chimie organique fine, B.P. 08-76130 Mont-Saint-Aignan, France

Reçu le 7 avril 1986

P. BINAY, G. DUPAS, J. BOURGUIGNON et G. QUEGUINER. Can. J. Chem. **65**, 648 (1987).

Une nouvelle classe de modèles du NADH est décrite : ils contiennent la structure oxazolyl-3 dihydro-1,4 pyridine. Ils ont été préparés à la suite de l'addition régiosélective en 4 de dérivés organométalliques (dont un possède un groupe chiral), sur la (diméthyl-4,4 oxazolyl-2)-3 pyridine. La structure dihydro-1,4 pyridine est obtenue après quaternarisation et réduction par le dithionite de sodium. La quaternarisation par l'intermédiaire de la réaction de Zincke a permis d'obtenir des modèles porteurs d'une copule chirale sur l'atome d'azote pyridinique. Cette chiralité est indispensable pour induire une asymétrie au niveau du carbone en 4 dans la dihydro-1,4 pyridine correspondante. Cette asymétrie joue un rôle prépondérant dans la faible énantiosélectivité de la réduction d'un substrat prochiral tel le benzoylformiate de méthyle. La réactivité chimique des modèles préparés a été étudiée en effectuant la réduction du paranitrobenzaldéhyde en présence de perchlorate de magnésium. Tous les modèles permettent d'atteindre des rendements quantitatifs. Cependant les réactions sont plus lentes que celles effectuées, dans les mêmes conditions, avec le *N*-benzyl dihydro-1,4 nicotinamide (BNAH). Une étude en rmn de ^{13}C a montré que ce comportement est sans doute une conséquence de la forte complexation exercée par le groupe oxazolinique sur le magnésium.

P. BINAY, G. DUPAS, J. BOURGUIGNON, and G. QUEGUINER. Can. J. Chem. **65**, 648 (1987).

A new class of NADH models is described: they contain the 3-oxazolyl-1,4-dihydropyridine structure. They have been synthesized by regioselective addition at the 4 position of organometallic derivatives (one of them bearing a chiral group) on 3-(4,4-dimethyl-2-oxazolyl)pyridine. The 1,4-dihydropyridine structure is obtained after quaternarization and reduction by sodium dithionite. Quaternarization through Zincke's reaction leads to models having a chiral group at the pyridine nitrogen. This chirality is necessary to induce asymmetry at the 4 carbon in the corresponding 1,4-dihydropyridine. This asymmetry plays an important role in the low enantioselectivity of reduction of a prochiral substrate such as methyl benzoylformate. The chemical reactivity of the models has been studied by performing the reduction of *p*-nitrobenzaldehyde in the presence of magnesium perchlorate. All models gave quantitative yields. However, reactions are slower than those performed, in the same conditions, with *N*-benzyl-1,4-dihydronicotinamide (BNAH). A ^{13}C nmr study shows that this behaviour is probably a consequence of the high complexation of magnesium with the oxazoline moiety.

Le nicotinamide adénine dinucléotide est l'un des coenzymes les plus importants : il joue un rôle essentiel dans les processus d'oxydo-réduction qui se produisent dans l'organisme. Il a été établi depuis longtemps que la partie active du coenzyme sous sa forme réduite (NADH) était constituée par la fraction dihydro-1,4 nicotinamide.

Rapidement les chimistes ont préparé des «modèles» du NADH contenant la structure dihydro-1,4 pyridine, qui ont permis de développer une famille de réducteurs spécifiques, d'étudier le mécanisme des réductions biomimétiques ou de réaliser des réductions asymétriques, certaines avec des très forts excès énantiomériques. Des centaines de références rapportent les résultats obtenus dans ces divers domaines (1).

Les modèles de NADH qui ont été les plus utilisés peuvent se rattacher à deux types principaux : (*i*) ceux dérivés de la dihydro-1,4 nicotinamide tels le *N*-benzyl dihydro-1,4 nicotinamide (BNAH); (*ii*) ceux dérivés de l'ester de Hantzsch.

Ces modèles possèdent la caractéristique de comporter au moins un substituant électroattracteur en position 3, ce qui a pour conséquence de conférer une certaine stabilité à la structure dihydropyridinique (stabilité indispensable pour envisager une utilisation en synthèse) tout en lui conservant un pouvoir réducteur suffisant.

1. Auteur à qui adresser toute correspondance.

Nous décrivons ici un nouveau type de modèle du NADH comprenant le groupe oxazolinique en position 3. Ce substituant possède un bon effet électroattracteur et il est susceptible, en plus, de complexer les métaux.

Dans un premier temps nous exposerons la préparation de ces composés et de dérivés comprenant un substituant alkyle en 4. Ce substituant doit nous permettre d'étudier l'influence électronique et l'influence stérique d'un tel groupement sur le pouvoir réducteur du modèle.

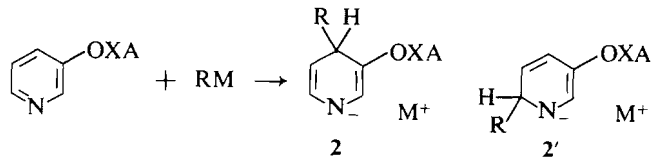
Nous avons ensuite précisé les facteurs qui gouvernent la réactivité de ces modèles (appelés par la suite en abrégé OPH pour oxazoline pyridinique hydrogénée), lors de la réduction du *p*-nitrobenzaldéhyde. Nous avons à cette occasion réalisé une étude comparative des pouvoirs réducteur et complexant de la *N*-benzyl OPH (BOPH) et du BNAH.

Dans un dernier temps, la méthode utilisée pour accéder aux dérivés du type OPH a permis d'introduire une copule chirale sur le sommet 4. Nous avons pu ainsi obtenir un modèle asymétrique qui n'est pas self-immolatif et nous l'avons testé dans la réduction de substrats prochiraux.

I. Synthèse des (dimethyl-4,4 oxazolyl-2)-3 dihydro-1,4 pyridines

Nous avons suivi le schéma suivant :

TABLEAU 1. Addition des organométalliques sur la (diméthyl-4,4 oxazolyl-2)-3 pyridine



Entrée	R–M	Solvant	Température (°C)	Durée (h)	2/2*	Rdt global (%)
1	CH_3Li	Éther	−78	2	100/0	99
2	CH_3Li	THF	+20	1	48/52	95
3	CH_3Li	THF	−78	1	100/0	99
4	CH_3MgI	Éther	−78	1	100/0	99
5	CH_3MgI	THF	−78	1	100/0	99
6	C_4H_9Li	THF	−78	15	100/0	94
7	CH_3, C_2H_5 $CHCH_2MgCl$†	THF	−78	15	100/0	90

*Le pourcentage d'intermédiaires **2** et **2'** a été déterminé par examen du spectre de rmn ^1H du mélange brut enregistré immédiatement après hydrolyse du complexe organométallique.

†Le magnésien du chloro-1 méthyl-2 butane a été préparé à partir du dérivé chloré lui-même obtenu à partir de l'alcool correspondant (5).

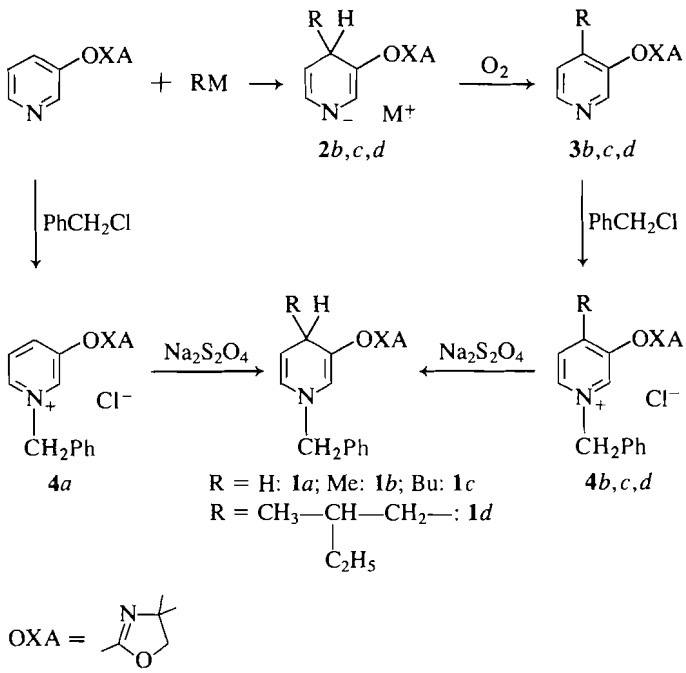


SCHÉMA 1

1. Addition d'un organométallique sur la (diméthyl-4,4 oxazolyl-2)-3 pyridine

L'addition régiosélective des organométalliques sur la (diméthyl-4,4 oxazolyl-2)-3 pyridine ou oxazolyl-3 pyridine a été étudiée par Hauck et Giam (3) et par Meyers et coll. (4). Ces auteurs ont montré que les facteurs déterminant la régiosélectivité de l'attaque sur le cycle pyridinique étaient la température, la durée de réaction, la nature du solvant.

Pour notre part, nous avons obtenu les résultats résumés dans le tableau 1.

Nos résultats sont en général très proches de ceux observés par Meyers et Gabel dans des conditions voisines (comparer entrées 2, 6 et réf. 4*a*). Par contre, on peut noter des différences dans la régiosélectivité de l'attaque de l'organométallique sur l'oxazoline pyridinique entre nos résultats et ceux obtenus par Hauck et Giam (comparer entrées 1 et 2 et réf. 3*a*). Nous n'avons pas observé pour notre part d'attaque notable sur le sommet 2.

Par ailleurs, les résultats décrits dans les entrées 4, 5 et 7 sont originaux. On peut remarquer que les rendements globaux sont toujours excellents, même s'il faut augmenter nettement le temps de la réaction avec des groupements R encombrants (entrées 6 et 7), et que la température joue un rôle prépondérant sur cette régiosélectivité (entrées 2 et 3).

2. Alkylation et passage aux structure dihydropyridiniques

L'alkylation directe des intermédiaires de type **2** par le chlorure de benzyle conduit à des mélanges difficiles à exploiter probablement à cause des divers sites nucléophiles apparaissant sur les composés **2** par suite de la délocalisation de la charge négative.

Nous avons choisi d'oxyder directement les composés **2** par l'oxygène sec (6). Les produits **3** sont ainsi obtenus avec d'excellents rendements variant de 85 à 90% en produit brut.

Le passage aux dihydropyridines a été réalisé par deux méthodes différentes :

(*i*) préparation des sels de pyridinium **4** puis réduction en dérivés dihydro-1,4 pyridiniques par le dithionite de sodium selon la méthode classique (7).

(*ii*) préparation des sels de pyridinium **4** par l'intermédiaire d'une réaction de Zincke (8) suivie d'une réduction par le dithionite de sodium.

Cette seconde méthode donne des rendements comparables à ceux obtenus par la première, mais elle est plus délicate à mettre en oeuvre; en particulier, il est nécessaire d'opérer avec un sel de Zincke de très bonne pureté.

On peut remarquer que dans les deux méthodes la quaternari-

For personal use only.

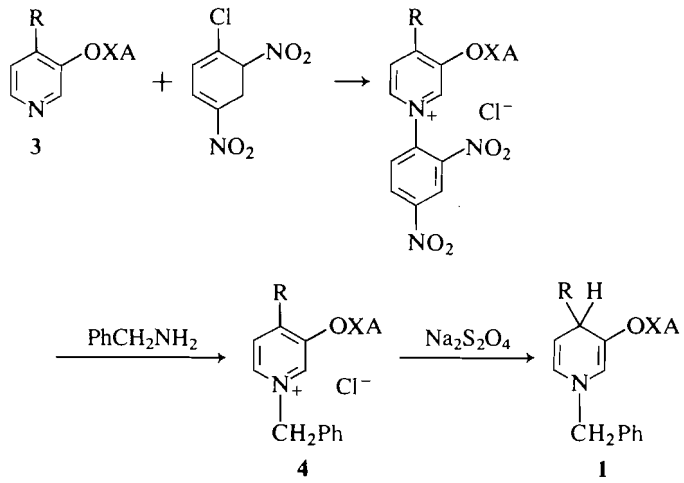

SCHÉMA 2

sation affecte l'atome d'azote du cycle pyridinique plutôt que celui du cycle oxazolinique. Le fort déblindage des protons en 2 et 6 des composés de type **4** par rapport aux déplacements chimiques des protons correspondants dans les composés du type **3** prouve sans ambiguité que l'on a préparé des sels de pyridinium.

Un calcul de chimie quantique nous a permis de confirmer la réactivité nettement plus élevée de l'azote pyridinique. En effet, la quaternarisation est une substitution nucléophile qui a lieu sous contrôle orbitalaire. Le calcul effectué par la méthode CNDO IV nous a fourni les résultats suivants concernant les coefficients orbitalaires des atomes d'azote pyridinique ou oxazolinique dans les orbitales σ occupées de plus haute énergie qui sont celles qui interviennent dans la réaction.

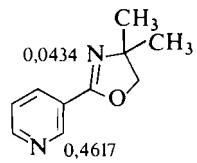

FIG. 1. Coefficients orbitalaires des atomes d'azote de la (diméthyl-4,4 oxazolyl-2)-3 pyridine.

II. Réactivité des modèles

1. Réactivité : réduction du p*-nitrobenzaldéhyde*

La réduction peut être schématisée ainsi avec le modèle **1***a* que nous avons étudié en premier (schéma 3).

Le choix du paranitrobenzaldéhyde (pNBA) est guidé par le

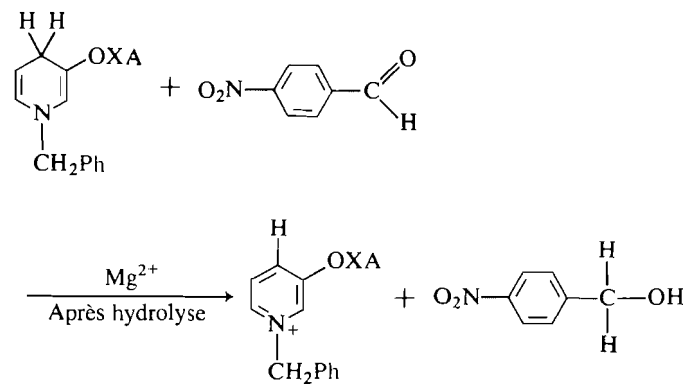

SCHÉMA 3

fait qu'il est facilement réduit par les modèles du type BNAH et que l'analyse rmn ^1H du mélange brut réactionnel est facile.

En travaillant dans des rapport 1:1:1, modèle:substrat:Mg^{2+}, nous avons obtenu avec les produits **1***a*, *b*, *c*, les résultats suivants (tableau 2) :

TABLEAU 2. Réduction du pNBA par divers modèles OPH*

Entrée	Réducteur	Durée (h)	Rapport réducteur/substrat	Rendement en alcool (%)
1	BNAH	18	1	100
2	BOPH **1***a*	18	1	33
3	BOPH **1***a*	25	1	56
4	BOPH **1***a*	43	1	61
5	BOPH **1***a*	68	1	61
6	BOPH **1***a*		2,5	100
7	Me4 BOPH **1***b*	18	1	27
8	Me4 BOPH **1***b*	43	1	59
9	Me4 BOPH **1***b*	68	1	60
10	Me4 BOPH **1***b*		2,5	100
11	Bu4 BOPH **1***c*	36	1	41
12	Bu4 BOPH **1***c*	68	1	41
13	Bu4 BOPH **1***c*	240	2,5	100

*pNBA : paranitrobenzaldéhyde. OPH : oxazolines pyridiniques hydrogénées.

On peut observer que le groupe oxazolyle rend le cycle dihydropyridinique moins réactif qu'il ne l'est avec un groupe carbamoyle dans les mêmes conditions (entrées 1 et 2). Ce résultat sera discuté plus loin.

Les composés **1***a* et **1***b* ont des réactivités assez proches (entrées 2, 4, 5 et 7, 8, 9) alors que dans le cas de **1***c* l'encombrement stérique du groupement butyle est sans doute responsable de la nette baisse de réactivité observée (entrées 11 et 12).

Nous avons alors décidé d'opérer avec un excès de modèle. En utilisant 2,5 équivalents de composé **1** pour 1 équivalent d'aldéhyde, la réduction est quantitative quel que soit le substituant en 4 (entrée 6, 10 et 13). Nous avons travaillé systématiquement en excès de réducteur par la suite.

2. Réduction avec des modèles chiraux

Au départ du sel de pyridinium **4***d* nous espérions que la présence d'une chiralité dans le groupement R induirait une asymétrie en 4 lors de la réduction par $Na_2S_2O_4$. Malheureusement cela n'a pas été le cas : les deux diastéréoisomères **1′***d* et **1″***d* sont obtenus en quantités sensiblement équivalentes (détermination par hplc). La réduction du benzoylformiate de méthyle par ce mélange nous a fourni l'alcool correspondant avec un rendement chimique de 100% et comme attendu, un rendement optique pratiquement nul.

Malgré la présence d'un carbone asymétrique sur la chaine latérale portée par le sommet 4 on constate que cette chiralité n'induit pas une réduction asymétrique du benzoylformiate. Ce résultat confirme le rôle prépondérant joué par la présence d'une chiralité sur le sommet à partir duquel s'effectue le transfert d'hydrogène (9).

Dans le but de tenter d'induire une asymétrie au niveau de ce carbone lors de la réduction par le dithionite de sodium, nous avons alors préparé des modèles portant un substituant chiral sur l'atome d'azote du cycle pyridinique.

SCHÉMA 4

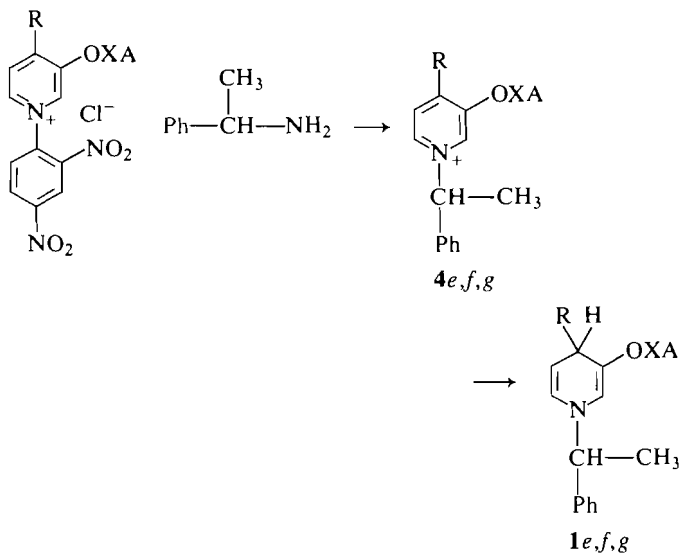

SCHÉMA 5

La réduction de PhCOCOOMe avec ces modèles a donné les résultats indiquées dans le tableau 3.

On observe cette fois une faible induction asymétrique lors de la réduction du benzoylformiate de méthyle par les modèles **1***e*, **1***f* et **1***g*. Avec **1***e* l'induction observée lors de la réduction est due à la chiralité portée par le substituant de l'azote pyridinique. Cette chiralité étant éloignée du site réactif du réducteur il n'est pas étonnant que le rendement optique soit faible.

Cependant la présence de cette chiralité dans le sel de pyridinium **4***f* permet d'obtenir majoritairement l'un des diastéréoisomères de structure **1***f* puisque la réduction du benzoylformiate de méthyle fournit un excès de l'alcool de configuration *S* inverse de celui obtenu avec **1***e*. Ce résultat est incontestablement dû à une induction issue de l'asymétrie présente sur le carbone en 4 de **1***f*.

Dans le cas de **1***g* on peut penser que le changement de configuration sur le substituant de l'azote pyridinique annule et contrarie l'induction exercée par la chiralité en 4 et justifie que l'on obtienne un faible excès enantiomérique de l'alcool *R*.

3. Étude de la réactivité du modèle **1** a

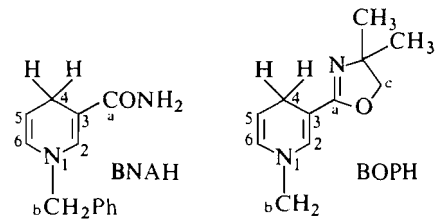
La réduction du paranitrobenzaldéhyde par le BNAH ou par le BOPH **1***a* en présence de Mg^{2+} s'est révélée plus facile avec le BNAH (entrées 1 et 2, tableau 2).

TABLEAU 3. Réduction de PhCOCOOMe par des OPH chirales

Modèle	R (configuration)	R′ (configuration)	Alcool e.e.* (configuration)
1*e*	H	—CH—CH_3 (*R*) Ph	2,4% (*R*)
1*f*	CH_2—CH—C_2H_5 CH_3 (*S*)	—CH—CH_3 (*R*) Ph	8,9% (*S*)
1*g*	CH_2—CH—C_2H_5 CH_3 (*S*)	—CH—CH_3 (*S*) Ph	1,6% (*R*)

*L'excès enantiomérique (e.e.) est calculé à partir de la valeur mesurée du pouvoir rotatoire du mandélate de méthyle comparée à celle du mandélate enantiomériquement pur (12).

TABLEAU 4. Spectres de résonance magnétique nucléaire (*a*) de ^1H et (*b*) de ^{13}C : déplacements chimiques pour le BNAH et le BOPH en solution dans CD_3CN



1*a*

(a)

	H(2)	H(4)	H(5)	H(6)	H_b	H_c
BNAH	6,96	3,05	4,70	5,84	4,29	—
BOPH **1***a*	6,76	3,03	4,70	5,90	4,29	3,83

(b)

	C(2)	C(4)	C(5)	C(6)	C_a	C_b	C_c
BNAH	138,4	22,2	102,5	127,3	169,0	56,4	—
BOPH **1***a*	136,4	22,7	102,0	127,4	162,0*	56,4	77,9

* Valeur sujette à caution.

Nous avons mesuré le potentiel de demi-vague du BNAH et du BOPH[2] et obtenu la même valeur de 0,4 V. Cela signifie que le cycle dihydropyridinique est aussi facile à oxyder dans les deux cas.

Nous avons ensuite enregistré les spectres de rmn du BNAH et du BOPH **1***a* en présence de Mg^{2+}. Cette méthode a permis d'obtenir des informations sur la complexation exercée par le métal divalent sur le BNAH (10).

On constate que les déplacements chimiques des protons portés par le carbone 4 ou de ce carbone 4 lui-même sont proches les uns des autres. D'une manière générale il n'existe pas de différences notables entres les atomes correspondants de l'un ou l'autre modèle.

2. Valeur mesurée sur électrode de graphite dans le milieu CH_3CH + 0,1 mol L^{-1} de Bu_4NBF_4 au laboratoire du Professeur M. Devaud à l'INSA.

*Rendement en produit pur calculé par rapport à la (diméthyl-4,4 oxazolyl-2)-3 pyridine.

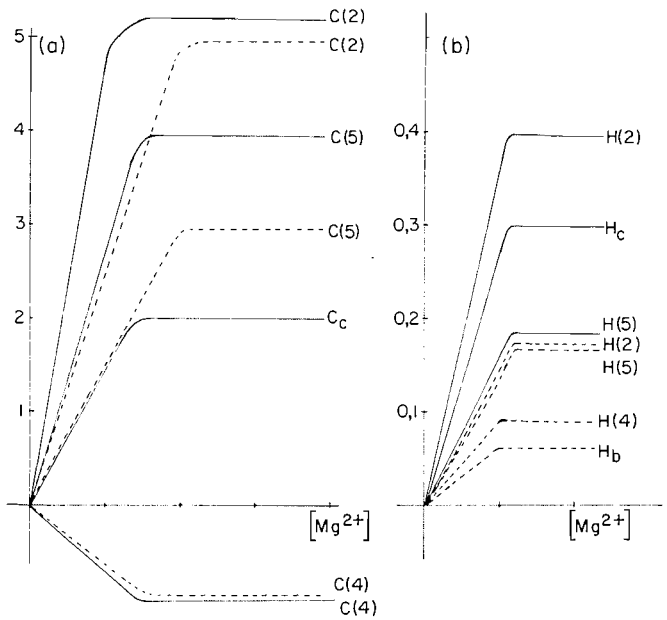

FIG. 2. Δδ en rmn (*a*) de ^{13}C et (*b*) de ^1H en présence de Mg^{2+} (en trait plein, BOPH; en trait pointillé, BNAH).

Si l'on examine maintenant les différences de déplacement chimique engendrées par addition de Mg^{2+} aux deux modèles, on obtient les résultats résumés dans la courbe ci-dessus (fig. 2).

On observe en rmn de ^1H et de ^{13}C que les protons et carbones 2, 5, 6 et c du modèle **1***a* sont déblindés alors que les protons ou carbone en 4 sont blindés par addition de $Mg(ClO_4)_2$.

On peut remarquer en particulier que le carbone méthylènique (C_c) du cycle oxazolinique subit un déblindage important en présence de Mg^{2+}. Ceci indique que la complexation affecte essentiellement le groupe oxazolinique et justifie les variations importantes de déplacements chimiques observées pour les atomes en 2, 4 et 5 situés au voisinage du site de complexation.

On peut noter que les déplacements chimiques des atomes liés au sommet 6 sont peu affectés par addition de Mg^{2+}, ce qui semble exclure une participation de l'atome d'azote du cycle dihydropyridinique dans la complexation.

On observe une différence importante dans les variations de déplacement chimique des carbones 2 et 5 de **1***a* et du BNAH en présence de Mg^{2+}. Les déblindages subis par les carbones de **1***a* sont supérieurs d'environ 1 ppm. On peut penser que la complexation par Mg^{2+} a pour effet de diminuer plus la densité électronique dans le cas du BOPH par rapport à la situation dans le BNAH : le groupement oxazolyle complexé exerce un effet attracteur plus fort sur le cycle dihydropyridinique que ne le fait le groupement carbamoyle complexé dans le BNAH. Ce phénomène ne facilite pas le départ d'un ion hydrure en polarisant la liaison C(4)—H un peu plus vers le carbone comme le montre le blindage un peu plus important pour le C(4) observé dans **1***a* par rapport au BNAH.

Lors de la réduction d'un composé carbonylé le magnésium permet d'établir un complexe ternaire : substrat/Mg^{2+}/modèle dihydropyridinique (BNAH ou BOPH). Si le magnésium est fortement complexé par le modèle dihydropyridinique il est alors moins disponible pour se lier au substrat et assurer son activation.

Ces hypothèses justifient que lors de la réduction du para-nitrobenzaldéhyde le BOPH soit moins réactif que le BNAH.

Partie expérimentale

Les points de fusion ont été déterminés sur un banc de Kofler et n'ont pas été corrigés.

Les spectres ir ont été enregistrés soit avec un spectrographe Perkin–Elmer 237 soit avec un spectrographe Beckman IR 4350; les solides sont dispersés dans du KBr sous forme de pastilles et les liquides sont insérés dans des fenêtres de NaCl sous forme de film.

Les spectres de rmn de ^1H ont été enregistrés sur un appareil Varian A60 ou Varian T60, les spectres de rmn de ^{13}C sur un appareil Brucker WH 90 D.

Les microanalyses ont été effectuées sur un appareil Carlo Erba 1106. Dans les tableaux récapitulatifs les produits pour lesquels la formule brute est donnée ont fourni des résultats corrects à l'analyse.

Les pouvoirs rotatoires ont été mesurés sur un micropolarimètre Perkin–Elmer type 241.

*Le sel de pyridinium a été préparé par la méthode au chlorure de benzyle (a) ou la méthode de Zincke (b).
†Le pouvoir rotatoire a été déterminé lorsque la solution chloroformique du sel de pyridinium possède une transparence suffisante.
‡Les déplacements chimiques sont donnés avec un seul chiffre après le virgule car ils varient avec la concentration dans $CDCl_3$.
§Ces produits n'ont pu être obtenus analytiquement purs. Il ont cependant fournis, dans l'étape suivante, les produits **1***f* et **1***g* purs.

A. Synthèse des modèles dihydropyridiniques

1. Addition d'un organométallique sur la (diméthyl-4,4 oxazolyl-2)-3 pyridine

La (diméthyl-4,4 oxazolyl-2)-3 pyridine est obtenue par action de l'amino-2 méthyl-2 propanol sur le chorure de nicotinoyle (11).

Dans un ballon d'un litre balayé par un courant d'argon, muni d'une agitation mécanique, d'un réfrigérant protégé de l'humidité atmosphérique par une garde à chlorure de calcium et d'un septum, on introduit 52,8 g (0,3 mol) de l'oxazoline ci-dessus et 400 mL de tetrahydrofuranne sec. On refroidit à −78°C puis on siphonne goutte à goutte 0,3 mol du dérivé organométallique en solution dans l'éther ou le THF. L'addition dure en générale 20 min. On maintient ensuite à basse température, puis on laisse remonter à température ambiante avant de procéder à l'oxydation.

*2. Oxidation : obtention des alkyl-4 (diméthyl-4,4 oxazolyl-2)-3 pyridines **3** (tableau 5)*

L'intermédiaire organométallique en solution dans l'éther ou le THF obtenu à l'étape précédente est oxydé par barbottage d'oxygène sec pendant 15 min. On concentre en éliminant la majeure partie du solvant à l'évaporateur rotatif. Le résidu est hydrolysé avec précautions, puis extrait à l'éther. La phase éthérée est séchée sur $MgSO_4$, évaporée sous vide et purifiée aussitôt par distillation sous vide. (Le produit brut se dégrade rapidement au cours du temps.)

3. Quaternarisation : passage aux chlorures de N*-benzyl alkyl-4 (diméthyl-4,4 oxazolyl-2)-3 pyridiniums : **4**a, b, c, d, e, f, g*

(a) Méthode au chlorure de benzyle. Dans un ballon muni d'un réfrigérant à reflux, on dissout 0,05 mol de composé **3** et 9,5 g (0,075 mol) de chlorure de benzyle fraîchement distillé dans 50 mL d'acétonitrile. On porte à reflux pendant trois jours, puis concentre sous vide. Le résidu est dissous dans le minimum d'éthanol chaud. On verse dans un large excès d'éther. Le sel de pyridinium se sépare généralement sous forme d'huile. Sa pureté est suffisante pour passer à l'étape suivante.

(b) Méthode par le sel de Zincke. Cette méthode a été utilisée au départ des alkyl-4 (diméthyl-4,4 oxazolyl-2)-3 pyridines **3***a* et **3***d*.

Dans un ballon muni d'un réfrigérant à reflux on introduit 0,05 mol de composé **3***a* ou **3***d* et 50 g (0,25 mol) de chloro-1 dinitro-2,4 benzène. On chauffe le mélange progressivement de 20 à 90°C en 30 min. On maintient à cette température pendant 2 h. On laisse refroidir, puis reprend le mélange dans un minimum de méthanol et verse ensuite dans un large excès d'éther. Le sel de Zincke précipite. Il est purifié par dissolution dans l'eau à ébullition en présence de noir animal. La solution est filtrée à chaud, puis évaporée. Le solide obtenu est recristallisé dans le méthanol. Rendement 80%.

Le sel de Zincke (4,5 g soit environ 0,01 mol) et 1,1 g (0,01 mol) de benzylamine ou 1,2 g (0,01 mol) d'α-méthylbenzylamine (*R* ou *S*) sont dissous dans le méthanol. On porte à reflux pendant 24 h. Le sel

de pyridinium est précipité dans un large excès d'éther et isolé par filtration. Les caractéristiques des produits préparés sont décrites dans le tableau 6.

NOTA : Le mélange brut obtenu après le reflux peut être repris dans l'eau. Dans ces conditions la dinitro-2,4 aniline précipite et la solution résiduelle peut être utilisée directement pour effectuer la réduction en dihydro-1,4 pyridine.

4. Réduction : obtention des N*-benzyl alkyl-4 dihydro-1,4 (diméthyl-4,4 oxazolyl-2)-3 pyridines :* **1** a, b, c, d, e, f, g

Dans un ballon muni d'une agitation et maintenu sous atmosphère d'argon, on dissout 3 g (environ 0,01 mol) de sel de pyridinium **4**) dans 10 mL d'eau (préalablement désoxygénée par bullage d'argon). On porte à 40°C et on ajoute sous agitation un mélange fraîchement préparé de 5 g de dithionite de sodium et de 5 g de $CO_3Na_{2,10}H_2O$ (ce qui correspond à un large excès). Après 30 min d'agitation, on extrait l'huile en suspension par 4 × 30 mL de chloroforme. Le solvant est éliminé, puis le résidu est purifié par flash chromatographie sur silice en éluant au chloroforme.

Les produits obtenus qui se présentent tous sous forme d'huile sont décrits dans le tableau 7.

B. Réduction de substrats

1. Réduction du paranitrobenzaldéhyde (pNBA)

La réactivité des modèles de type **1** vis-à-vis du pNBA a été étudiée en suivant l'évolution de la réaction par rmn de ^1H. Dans un tube de rmn sec on introduit le modèle, le perchlorate de magnésium et le pNBA dans les proportions décrites dans la partie théorique. On dissout dans l'acétonitrile deutérié. On maintient à 60°C et on enregistre le spectre rmn du mélange à intervalles réguliers.

Nous décrivons, par ailleurs, le mode opératoire suivi pour réaliser la réduction dans des conditions préparatives : dans un tube sec, purgé à l'argon, on introduit 0,151 g (0,001 mol) de pNBA, 0,001 mol ou 0,0025 mole de modèle **1***a*, **1***b* ou **1***c* et 0,446 g (0,002 mol) de perchlorate de magnésium anhydre, le mélange est mis en solution dans 2 mL d'acétonitrile parfaitement anhydre. Le tube est scellé et on maintient à 60°C (durée : voir partie théorique). Après refroidissement, on ouvre le tube, hydrolyse avec 2 mL d'eau et extrait à l'éther. Après séchage on évapore le solvant et récupère l'alcool *p*-nitrobenzylique par avec un rendement quasi quantitatif.

2. Réduction du benzoylformiate de méthyle

Dans un ballon sec, muni d'un septum, on mélange 0,0025 mol de modèle **1** fraîchement préparé, 0,446 g (0,002 mol) de perchlorate de magnésium et 0,164 g (0,001 mol) de benzoylformiate de méthyle. On purge à l'argon et on introduit, par le septum, 10 mL d'acétonitrile parfaitement anhydre.

La solution est agitée et chauffée au bain d'huile pendant trois jours. Chaque essai est hydrolysé en traitant le milieu réactionnel par un mélange de 2 mL d'eau et 100 mL de chloroforme. La phase organique est séparée. La phase aqueuse est extraite par 2 × 50 mL de chloroforme. Les extraits sont rassemblés, séchés sur $MgSO_4$, évaporés sous vide. On reprend le résidu par 1 mL d'éthanol absolu, puis on dilue par 100 mL d'éther. On sépare le sel de pyridinium qui a précipité et le filtrat est recueilli dans un ballon préalablement taré. On évapore à sec et on pèse le résidu.

On connait ainsi le rendement de la réduction qui est généralement quasi quantitatif. Le résidu est ensuite purifié par chromatographie sur silice en éluant par un mélange éther–hexane (1:2). Les fractions contenant le mandélate de méthyle pur (vérifié en ccm) sont évaporées à sec. Le mandélate cristallisé est mis à sécher pour mesurer ensuite son pouvoir rotatoire (mandélate de méthyle *d* ou *l* : $[\alpha]_D^{25}$ = 167° dans le chloroforme (12)).

The potassium permanganate oxidation of steroidal homoannular dienes

ZBIGNIEW BOŃCZA-TOMASZEWSKI
Department of Chemistry, Warsaw University, 02-093 Warszawa, ul. Pasteura 1, Poland

Received June 19, 1986

ZBIGNIEW BOŃCZA-TOMASZEWSKI. Can. J. Chem. **65**, 656 (1987).

The oxidation of 3β-acetoxycholesta-5,7-diene (**1**) with potassium permanganate – sodium periodate reagent gave epoxy-diol **2** with almost quantitative yield. Similar oxidation of cholesta-2,4-diene (**3**) afforded, as well as epoxy-diols **5** and **6**, products of cleavage of the double bonds. These results show that formation of epoxy-diols predominates in the case of hindered steroidal dienes (e.g., diene **1**), whereas oxidation of unhindered steroidal dienes (e.g., diene **2**) gives, in addition to epoxy-diols, products of cleavage of the double bonds.

ZBIGNIEW BOŃCZA-TOMASZEWSKI. Can. J. Chem. **65**, 656 (1987).

L'oxydation de l'acétoxy-3β cholestadiène-5,7 (**1**) par le couple permanganate de potassium – periodate de sodium conduit à l'époxy-diol **2** avec un rendement pratiquement quantitatif. Une oxydation semblable du cholestadiène-2,4 (**3**) conduit, en plus des époxy-diols **5** et **6**, aux produits de rupture des doubles liaisons. Ces résultats démontrent que la formation des époxy-diols est la réaction prédominante dans les cas des dienes stéroïdaux empêchés (comme le diène **1**) alors que l'oxydation des dienes stéroïdaux non-empêchés (comme le diène **2**) conduit, en plus des époxy-diols, à des produits provenant de la scission des doubles liaisons.

[Traduit par la revue]

A few years ago we undertook some studies on extensive degradation of steroids as a possible route for the preparation of intermediates required for the synthesis of heterocyclic steroids. The oxidative cleavage of double bonds in steroidal homoannular dienes should lead to γ-dicarbonyl compounds, which could be very useful in the synthesis of diazasteroids. Recently we described the utilization of ruthenium tetroxide for oxidation of steroidal conjugated dienes (1). In continuing the search for better oxidative methods we turned our attention to potassium permanganate – sodium periodate mixture (2). This reagent has been used especially for cleavage of double bonds and in many cases was found to be superior to ozonolysis.

We observed that hindered homoannular dienes (e.g. 3β-acetoxycholesta-5,7-diene (**1**)) were resistant to degradation with potassium permanganate – sodium periodate mixture. Instead of cleavage of conjugated double bonds we found that less hindered C(5)—C(6) double bonds underwent hydroxylation, whereas more hindered C(7)—C(8) bonds underwent epoxidation, and epoxy-diol **2** was obtained (3, 4).[1]

These results prompted us to establish whether oxidation of homoannular dienes with potassium permanganate – sodium periodate mixture had general character or if it was limited to hindered ring B in the steroid system. Therefore we investigated a reaction of cholesta-2,4-diene (**3**) with potassium permanganate.

When diene **3** was treated with neutral or alkaline potassium permanganate four products were isolated from the neutral fraction: the known lactol **4***a* (5)[2] (12% yield), epoxy-diol **5** (31% yield), epoxy-diol **6** (2.5% yield), and epoxy-lactol **7***a*[2] (1.5% yield). From the acidic fraction, after methylation with diazomethane, acetal ester **8***b* (2% yield) and hydroxy-lactone ester **9***b* (21% yield) were isolated (Scheme 1).

Structures of compounds **6**, **7**, and **8***b* followed from their analytical and spectral data (cf. Experimental). However, no definitive stereochemical assignment of epoxy-diol **5** and hydroxy-lactone ester **9***b* could be made on the basis of nmr evidence alone. In the case of epoxy-diol **5** it was not possible to establish unequivocally the configuration of the 2,3-epoxide ring and C-4 and C-5 hydroxyl groups. The only signal of 19-H (at δ 0.93 ppm) suggested their α configuration. In the case of β substituents at C-2, C-3, C-4, and C-5, these protons would be strongly deshielded (6). In the ^{13}C nmr spectrum of epoxy-diol **5** the observed shieldings were in good agreement with those calculated for an α configuration of the 2,3-epoxide and the C-4 and C-5 hydroxyl groups. The calculation was made by the addition of substituent effects listed by Blunt and Stothers for certain steroids (7) (see Table 1). Further evidence for an α configuration of 4-OH, 5-OH, and the 2,3-epoxide ring was obtained by reduction of epoxy-diol **5** with lithium aluminum hydride and lithium aluminum deuteride to triols **10***a* and **10***b*, respectively. The ^1H nmr spectrum of **10***a* showed (after shaking with D_2O) a narrow one-proton multiplet at δ 3.97 ppm ($W/2$ = 10.5 Hz) and a one-proton doublet at δ 3.49 ppm (J_{ae} = 3.5 Hz) corresponding to a β-equatorial proton at C-3 and a β-axial proton at C-4, respectively. The comparison of the ^1H nmr spectra of **10***a* and **10***b* exhibited one difference: instead of a multiplet at 3.97 ppm, a triplet was observed ($J_{ae} = J_{ee}$ = 3.5 Hz). It indicated that coupling constant $J_{2a,3e}$ = 3.5 Hz disappeared. The ^{13}C nmr spectrum of **10***a* strongly supported an α configuration of the 3-OH, 4-OH, and 5-OH hydroxyl groups. The observed shieldings were in good agreement with those calculated by the addition of substituent effects (7) (see Table 1). Hence triols **10***a* and **10***b* must arise by diaxial opening of the 2,3-α-epoxide ring during nucleophilic attack of hydride (or deuteride) ion from the β-side of the molecule (8). It showed that the 2,3-epoxide ring and C-4, C-5 hydroxyl groups had an α configuration.

Most of the assignments for hydroxy-lactone ester **9***b* followed from their analytical and spectral data (cf. Experimental). However, no definitive assignment of the lactone and ring B junction and the configuration at C-4 could be made. Evidence for five-membered lactone and B-ring *trans* fusion was obtained from a comparison of ^1H nmr of **9***b* (free OH group at C-4) and **9***c* (with an acetoxy group at C-4). In the ^1H nmr spectrum of **9***a* the magnitude of shielding of 19-H protons (at δ 1.20 ppm) was almost the same as in the spectrum of **9***c* (at δ 1.18 ppm). It

[1]In communication 3 compound **2** was erroneously described as tetrol. The correct structure was established after reinvestigation (cf. ref. 4).

[2]The lactols **4***a* and **7***a* are tautomers of seco-keto-acids **4***b* and **7***b*, respectively.

[b]The reference steroid here is 2α,3-epoxy-5α-androstan, the shieldings for which were obtained by subtracting the effects for the 17β-OAc group from the shieldings for 2α,3-epoxy-5α-androstan-17β-yl acetate.
[c]Assigned by off-resonance decoupling.

suggested that the substituent at C-5 occupied the opposite (α) position to 19-CH_3, hence fusion of five-membered lactone and B-ring should be *trans*. "*S*" configuration at C-4 in hydroxy-lactone ester **9***b* followed from the mechanism of its formation.

To gain further information about the oxidation reaction, diene **3** was subjected to potassium permanganate – sodium periodate mixture oxidation. We observed that the yield of hydroxy-lactone ester **9***b* was slightly increased (to 25%) and the yield of epoxy-diol **6** was decreased (to 1.5%). From these results it appears that sodium periodate is not necessary for degradation of diene **3** and the permanganate is effecting both hydroxylation (or epoxydation) and cleavage of conjugated double bonds.

To obtain evidence for the formation of compounds **8***a* and **9***a*, independent syntheses of acetal ester **8***b* and hydroxy-lactone ester **9***b* were carried out. When epoxy-diol **5** was oxidized with potassium permanganate – sodium periodate mixture for three days, after methylation with diazomethane, acetal ester **8***b* was obtained with a poor yield (3.75%). Epoxy-diol **6** was subjected to the same reaction conditions. In this instance the hydroxy-lactone ester **9***b* was formed in 6% yield (after methylation with diazomethane). It indicated that the epoxy-acid **7***b* and epoxy-diacid **11** could be intermediates in the formation of acetal **8***a* and hydroxy-lactone acid **9***a*, respectively (Scheme 2).

The simplest mechanism that explains this rearrangement is a nucleophilic attack by the carbonyl group at C-5 in epoxy-acid **7***b* concerted with epoxide bond rupture, leading to an acetal bridged structure **8***a*. Similarly, epoxide cleavage concerted with a nucleophilic attack by oxygen from the carbonyl group in epoxy-diacid **11** leads to hydroxy-lactone acid **9***a* (Scheme 2).

On the basis of data presented in this paper it was possible to draw the following conclusions: (a) the oxidation of homo-annular steroidal dienes with potassium permanganate – sodium periodate reagent gives epoxy-diols resistant to further oxidation, instead of cleavage products.[3] Small amounts of degraded and cyclized products are formed in the case of unhindered

[3]Certain vicinal glycols, for example, those having one or two tertiary hydroxyls, are known to be somewhat resistant to C—C bond cleavage with periodate. This is ascribed to difficulties in the formation of the cyclic transition state encompassing the two hydroxyls and periodic ion (9).

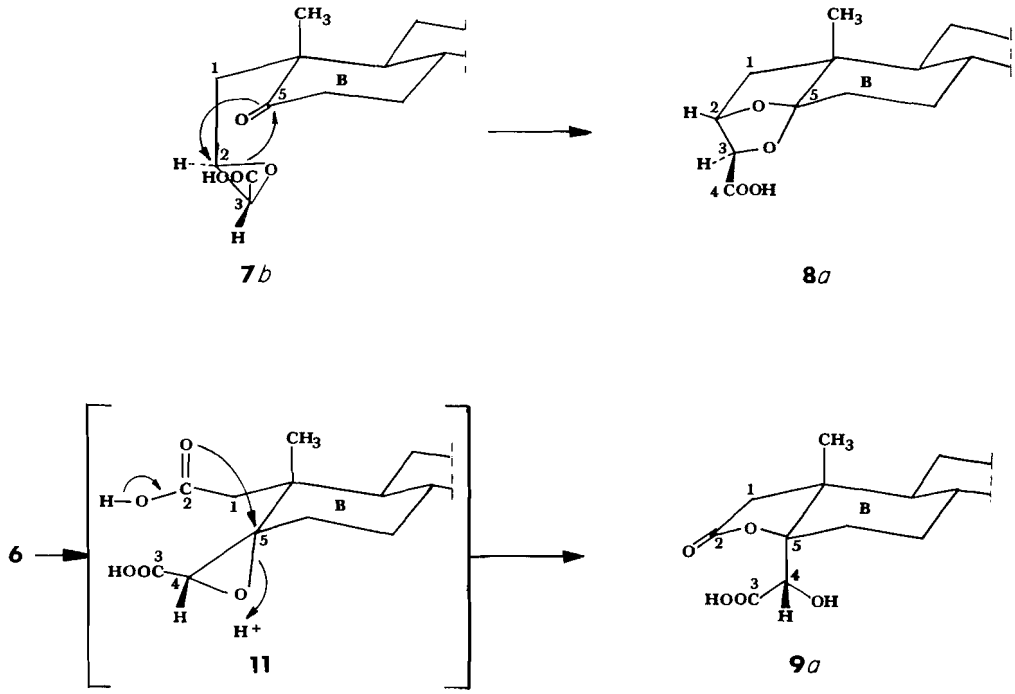
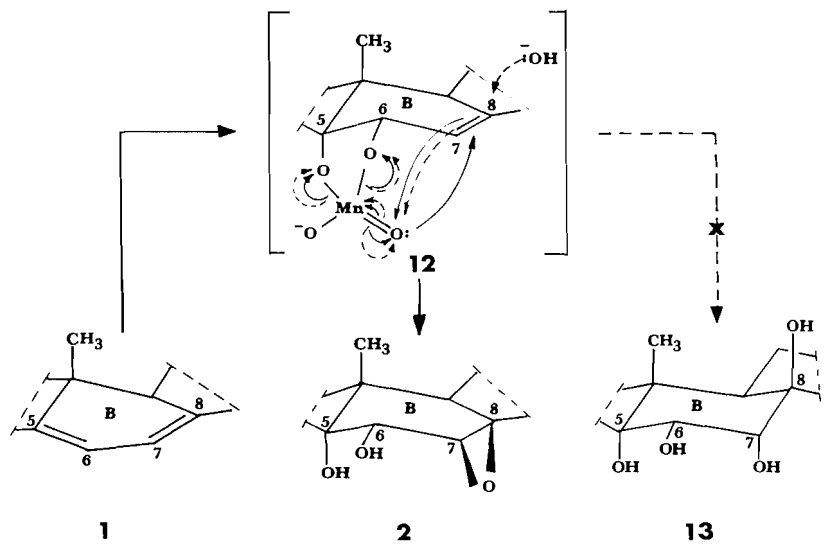


SCHEME 2



SCHEME 3

dienes (e.g., diene **3**); (b) the unhindered double bonds (Δ^5 in the diene **1** and Δ^6 in the diene **3**) undergo hydroxylation, whereas relatively hindered double bonds (Δ^7 in the diene **1** and Δ^3 in the diene **3**) are epoxydized; (c) the formation of epoxy-diol **2** occurs by a mechanism proposed by Sable *et al.* (10), with only one difference: the reactive intermediate **12** is converted only to epoxy-diol **2**, not to tetrol **13**, as indicated in Scheme 3. It is evident that the mechanism of oxidation of the diene **3** to epoxy-diols **5** and **6** should be the same.

Experimental

The melting points were determined on a Boetius micro melting apparatus and were uncorrected. Analyses were by Dr. J. Wasiak and Associates, Microanalytical Laboratories, Department of Chemistry, Warsaw University. Thin-layer chromatography (tlc) was carried out with DC-Alufolien plates (Merck) coated with Kieselgel 60. The plates were eluted with various solvent systems and visualized with 50% sulfuric acid after heating. The flash column chromatography was performed on silica gel (Kieselgel 60, 230–400 mesh Merck), packed in benzene, and the samples were put on the column in benzene. The infrared spectra were recorded on a UR-20 (Jena) spectrophotometer. The ^{1}H nmr spectra were taken with a 100-MHz Brucker WP-100 SY spectrophotometer, and the ^{13}C nmr spectra with a 22.5-MHz JEOL FX 90 Q spectrophotometer in deuterochloroform with TMS as an internal standard. Optical rotations were measured on a Perkin–Elmer 241 polarimeter in $CHCl_3$ (*c* 1.000). All solvents were dried and freshly distilled prior to use. The known cholesta-2,4-diene (**3**) was prepared according to the procedures described in ref. 11.

Oxidation of cholesta-2,4-diene (3) with potassium permanganate

To a solution of 5.00 g (13.6 mmol) of cholesta-2,4-diene (**3**) in 250 mL of *tert*-butanol was added 5.60 g of potassium permanganate in 100 mL of water and the resulting mixture was stirred for 3 h at room

temperature under nitrogen. The reaction was terminated with 20 mL of 40% sodium bisulfite solution, then extracted thoroughly with ether. The extract was washed with water, 50% bicarbonate solution, again with water, and dried (Na_2SO_4). Ether was evaporated to give 2.75 g of solid neutral fraction. The sodium bicarbonate wash was acidified with hydrochloric acid and extracted with ether. The extract was washed with water, dried (Na_2SO_4), and evaporated to give 1.58 g of a mixture of acids that was methylated with diazomethane.

The neutral fraction was chromatographed on silica, and elution with 9:1 benzene–ether gave 0.088 g (1.5%) of epoxy-lactol **7***a* and 0.635 g (12%) of lactol **4***a*. Elution with 4:1 benzene–ether gave 1.790 g (31%) of epoxy-diol **5** and 0.142 g (2.5%) of epoxy-diol **6**.

The acid fraction was chromatographed on silica, and elution with 9:1 benzene–ether gave 0.123 g (2%) of acetal ester **8***b* and 1.320 g (21%) of hydroxy-lactone ester **9***b*.

Similar results were obtained when potassium permanganate (5.60 g) and magnesium sulfate (5.00 g of $MgSO_4 \cdot 7H_2O$) mixture was used.

The samples were recrystallized twice for analysis. Spectral and analytical data are as follows.

Lactol **4**a: mp 165–166°C; $[\alpha]_D^{24}$ +29.8° (lit. (5) mp 165–166°C, $[\alpha]_D^{24}$ +28.8°); ir ν_{max}(KBr): 3355, 1770, 1250, 1145 cm^{-1}; ^1H nmr δ (100 MHz): 0.69 (s, 3H, 18-H), 1.12 (s, 3H, 19-H), 4.65 (s, 1H, 5ξ-O*H*, disappears on the addition of D_2O). *Anal.* calcd. for $C_{25}H_{42}O_3$: C 76.87, H 10.84; found: C 76.89, H 10.84.

Epoxy-lactol **7**a: mp 182–183°C (hexane – methylene chloride); $[\alpha]_D^{25}$ +40.9°; ir ν_{max}(KBr): 3525, 1725 cm^{-1}; ^1H nmr δ (100 MHz): 0.63 (s, 3H, 18-H), 0.90 (s, 3H, 19-H), 3.38 (d, 1H, 3β-H, J = 3.2 Hz), 3.59 (t, 1H, 2β-H, $J_1 = J_2$ = 3.2 Hz); ^{13}C nmr δ (22.5 MHz): 56.2 (C-2), 57.5 (C-3), 203.9 (C-4), 79.5 (C-5). *Anal.* calcd. for $C_{27}H_{44}O_4$: C 74.95, H 10.25; found: C 74.92, H 10.30.

Acetal ester **8**a: oil; $[\alpha]_D^{24}$ +42.1°; ir ν_{max}(KBr): 1735, 1085, 1010, 980 cm^{-1}; ^1H nmr δ (100 MHz): 0.68 (s, 3H, 18-H), 1.04 (s, 3H, 19-H), 3.76 (s, 3H, CH_3OOC), 3.85 (s, 1H, 3α-H), 3.65 (q, 1H, 2β-H, J = 2.5 Hz, J = 6 Hz); ^{13}C nmr δ (22.5 MHz): 175.65 (C-4), 107.55 (C-5), 74.12 (C-3), 72.06 (C-2). *Anal.* calcd. for $C_{28}H_{48}O_4$: C 74.95, H 10.78; found: C 74.89, H 10.70.

Hydroxy-lactone ester **9**b: mp 173–175°C (hexane – methylene chloride); $[\alpha]_D^{24}$ +38.7°; ir ν_{max}(KBr): 3560, 3472, 1785, 1735, 1085 cm^{-1}; ^1H nmr δ (100 MHz): 0.68 (s, 3H, 18-H), 1.20 (s, 3H, 19-H), 2.31 (d, 1H, 1α-H, J = 17.5 Hz), 3.28 (d, 1H, 4-O*H*, J = 7.5 Hz, disappears on the addition of D_2O), 3.84 (s, 3H, CH_3OOC-), 4.29 (d, 1H, J = 7.5 Hz); ^{13}C nmr δ (22.5 MHz): 177.2 (C-2), 172.3 (C-3), 88.6 (C-4), 76.7 (C-5). *Anal.* calcd. for $C_{28}H_{46}O_5$: C 72.69, H 10.02; found: C 72.72, H 10.08.

Acetoxy-lactone ester **9**c

Hydroxy-lactone ester **9***b* (30 mg) was acetylated with acetic acid anhydride (1 mL) in pyridine (3 mL) at room temperature for 24 h. Then 2 mL of methanol was added. The usual work-up gave 32 mg (95%) of a product, which upon crystallization from ether–hexane afforded 28 mg of acetoxy-lactone ester **9***c*, mp 238–240°C; $[\alpha]_D^{25}$ +40.2°; ir ν_{max}(KBr): 1785, 1735, 1725, 1085 cm^{-1}; ^1H nmr δ (100 MHz): 0.68 (s, 3H, 18-H), 1.16 (s, 3H, 19-H), 2.17 (s, 3H, 4-CH_3COO), 2.38 (d, 1H, 1α-H, J = 7.5 Hz), 2.75 (d, 1H, 1β-H, J = 7.5 Hz), 3.76 (s, 3H, CH_3OOC-), 4.93 (s, 1H, 4-H). *Anal.* calcd. for $C_{30}H_{48}O_6$: C 71.39, H 9.59; found: C 71.45, H 9.63.

*Oxidation of cholesta-2,4-diene (***3***) with potassium permanganate – sodium periodate reagent*

To a solution of 5.000 g (13.6 mmol) of cholesta-2,4-diene (**3**) in 250 mL of *tert*-butanol was added 5.60 g of potassium permanganate in 100 mL of water, followed by 18 g sodium periodate in 50 mL of water. The reaction mixture was stirred at room temperature under nitrogen for 3 h and worked up as in the previous oxidation to give 2.78 g of neutral material and 1.82 g of acidic material. Chromatography of the neutral fraction as before gave lactol **4***a* (0.740 g, 14% yield), epoxy-lactol **7***a* (0.110 g, 1.7% yield), epoxy-diol **5** (1.55 g, 25.2% yield), and epoxy-diol **6** (0.085 g, 1.5% yield). Chromatography of the acid fraction gave acetal ester **8***b* (0.123 g, 2% yield) and hydroxy-lactone ester **9***b* (1.567 g, 25% yield).

Acetal ester **8**b *by direct oxidation of epoxy-triol* **5**

To a solution of 0.300 g (0.72 mmol) of epoxy-diol **5** in 60 mL of *tert*-butanol was added 0.300 g of potassium permanganate in 50 mL of water, followed by 1.000 g of sodium periodate in 15 mL of water. The reaction mixture was stirred at room temperature under nitrogen for 3 days. After the usual work-up, 0.220 g of neutral material and 0.020 g of acidic material were obtained. The neutral fraction was chromatographed on silica and elution with 9:1 benzene–ether gave 0.080 g (25.5% yield) of epoxy-lactol **7***a*, identified in the usual fashion by comparison with an authentic sample. Elution with 4:1 benzene–ether gave 0.120 g of starting material. The acidic fraction, after methylation with diazomethane, was chromatographed on silica and elution with 9:1 benzene–ether gave 0.012 g (3.74% yield) of acetal ester **8***b*. The product was found identical in all respects with that described in the previous experiment.

Hydroxy-lactone ester **9**b *by direct oxidation of epoxy-diol* **6**

To a solution of 0.300 g (0.72 mmol) of epoxy-diol **6** in 50 mL of *tert*-butanol was added 0.28 g of potassium permanganate in 20 mL of water, followed by 0.90 g of sodium periodate in 10 mL of water. The reaction mixture was stirred at room temperature under nitrogen for 3 days. Work-up in the usual manner gave 0.250 g of neutral fraction and 0.070 g of acidic material. The neutral fraction was chromatographed on silica and elution with 4:1 benzene–ether gave 0.098 g of starting material and 0.080 g (28.6% yield) of lactol **4***a*. The acidic fraction, after methylation with diazomethane, was chromatographed on silica and elution with 9:1 benzene–ether gave 0.020 g (6%) of hydroxy-lactone ester **9***b*, identical in all respects with that obtained in the previous experiment.

Triol **10**a

To a suspension of 0.050 g of $LiAlH_4$ in 100 mL of dry tetrahydrofuran was added 0.200 g (0.48 mmol) of epoxy-diol **5** in 100 mL of dry tetrahydrofuran. After stirring at room temperature for 15 min and heating under reflux for 2 h, water was added and the precipitate was filtered through Celite and was thoroughly washed with tetrahydrofuran. Evaporation of the solvent gave crude triol **10***a* (0.185 g, 92.5%), mp 210–215°C. The analytical sample was obtained by two recrystallizations from ether – methylene chloride, mp 216–218°C; $[\alpha]_D^{25}$ +20.2° (*c* 1.000, dioxane); ir ν_{max}(KBr): 3360 cm^{-1}; ^1H nmr δ (100 MHz): 0.65 (s, 3H, 18-H), 0.95 (s, 3H, 19-H), 3.16 (m, 2H, O*H*, disappears on the addition of D_2O), 3.49 (d, 1H, 4β-H, J = 3.5 Hz), 3.97 (m, 1H, 3β-H, $W/2$ = 10.5 Hz). *Anal.* calcd. for $C_{27}H_{48}O_3$: C 77.07, H 11.32; found: C 77.00, H 11.55.

Deuteration of the 2β-position by reduction of epoxy-diol **5** *with lithium aluminum deuteride*

A solution of epoxy-diol **5** (0.200 g, 0.48 mmol) in anhydrous tetrahydrofuran (100 mL) was treated with lithium aluminum deuteride (0.059 g) and the resulting mixture was heated under reflux for 3 h. Then work-up as in the previous reduction gave 0.170 g (85% yield) of 2β-d_1-triol **10***b*; ir ν_{max}(KBr): 3360, 2185 cm^{-1} (C-D); ^1H nmr δ: 0.65 (s, 3H, 18-H), 0.95 (s, 3H, 19-H), 3.18 (m, 2H, O*H*, disappears on the addition of D_2O), 3.49 (d, 1H, 4β-H, J = 3.5 Hz), 3.97 (t, 1H, 3β-H, $J_{2e,3e} = J_{3e,4a}$ = 3.5 Hz).

Acknowledgments

Sincere thanks are extended to Dr. M. Kabat for some experiments. The author is grateful to Professor W. J. Rodewald, Dr. R. Siciński, and Dr. J. Morzycki for their helpful comments

and for fruitful discussion. This work was supported by the Polish Academy of Sciences.

Protonation of a conjugated Schiff base by weak to strong acids: a ^{13}C and ^{15}N nuclear magnetic resonance study

DANIEL COSSETTE AND DANIEL VOCELLE[1]

Département de chimie, Université du Québec à Montréal, C.P. 8888 Succ. A, Montréal (Qué.), Canada H3C 3P8

Received July 24, 1986

DANIEL COSSETTE and DANIEL VOCELLE. Can. J. Chem. **65**, 661 (1987).

The interactions (mostly protonation) between several carboxylic and mineral acids and *trans,trans*-2,4-heptadienylidene *tert*-butylamine (HBA) were determined by ^{13}C and ^{15}N nuclear magnetic resonance spectroscopies. Results indicate that protonation is only partial with weak acids in both polar and nonpolar solvents. No interaction between polar groups located on the acids and the polyenic chain of HBA seems to occur. The chemical shifts of all carbon atoms and also of the Schiff base nitrogen are linearly correlated with the acidity strength of the carboxylic acids.

DANIEL COSSETTE et DANIEL VOCELLE. Can. J. Chem. **65**, 661 (1987).

Les interactions (surtout la protonation) entre plusieurs acides carboxyliques et minéraux avec la *trans,trans*-heptadiényli-dène-2,4 *tert*-butylamine (HBA) ont été déterminées par la résonance magnétique nucléaire du ^{13}C et du ^{15}N. Les résultats indiquent que la protonation est partielle pour les acides faibles aussi bien pour les solvants polaires que non-polaires. Aucune interaction entre les groupes polaires des acides et la chaîne polyénique de HBA n'a pu être décelée. Les déplacements chimiques de tous les atomes de carbone et aussi de l'azote de la base de Schiff sont linéairement corrélés avec la force de l'acidité des acides carboxyliques.

Introduction

High-resolution nuclear magnetic resonance is a technique that has been widely used in the examination of structural and dynamic properties of molecules in solution and in the solid state. In particular, ^{13}C and ^{15}N nmr spectra have yielded important information in biological systems. Among these, two membrane proteins, rhodopsin (1) and bacteriorhodopsin (2–6), have been studied with a certain amount of success, using both nuclei as a probe for measuring the interactions of the chromophore with the proteins. However, to be able to study pigments by nmr, they need first to be isolated from the biological milieu by using different techniques, and the end results usually consist of a purified protein dispersed in a detergent or lyophilized to a thin film. Whatever the method used, the pigment has been perturbed to some degree and the nmr data obtained on these proteins must reflect this new situation. This being the case, the true state of the chromophore in rhodopsin and bacteriorhodopsin in intact membranes cannot be determined with complete accuracy. A rapid survey of recent literature on this subject indicates that different spectra are obtained depending on the state of the sample examined (5, 7). Because of this fact and since conjugated Schiff bases have not been fully studied by ^{13}C and ^{15}N nmr spectroscopies, we have devised a model system where spectra of both conjugated imines and their interactions with carboxylic acids could be evaluated. This model consists of a Schiff base, *trans,trans*-2,4-heptadienylidene *tert*-butylamine (HBA) (**1**), and different halogenated carboxylic acids in chloroform or methanol solutions. It represents the first ^{13}C and ^{15}N nmr study of a model of rhodopsin where carboxylic acids having pK_as similar to, or in the same region as, glutamic and aspartic acids are interacting with a conjugated Schiff base resembling the retinal chromophore. In particular, the extent of protonation of the Schiff base in the presence of weak to strong acids in a nonpolar ($CHCl_3$) or a more polar solvent (CH_3OH) will be investigated, since this question is still controversial, especially with visual pigments (8). Our system has already been studied using uv (9) and ^1H nmr spectroscopies (10).

Experimental

For our study we used equimolar concentrations of HBA and of one of the halogenated carboxylic acids of Table 1 in $CDCl_3$ or CD_3OD solution. Solutions were of the order of 0.07 *M* for the ^{13}C experiments and between 0.6 and 1.0 *M* for the ^{15}N spectra. The acids used are listed in Table 1 and numerotation of the carbon atoms of HBA is shown in Fig. 1. Spectra were obtained on a WH-400 pulse Fourier transform instrument (Bruker Co.) at frequencies of 100.0 MHz for ^{13}C and 40.4 MHz for ^{15}N. Typically, the ^{13}C proton noise-decoupled spectra were taken with rf pulses of 5 μs with a pulse angle of 45° and at intervals of 3.2 s; usually 400–600 scans were collected. Assignation of the different peaks with the proper carbon atoms was done using two well-known methods: selective proton decoupling centered at H5 using the same parameters as before, and 2D proton–carbon correlation. The chemical shifts were determined using TMS as an internal standard. The ^{15}N nmr spectra were determined using two different techniques. For the unprotonated Schiff base, proton noise-decoupled spectra in the gated decoupled mode, for nOe (nuclear Overhauser effect) suppression, were obtained using rf pulses of 12 μs with an angle of 90° and a pulse delay of 1.6 s; the acquisition time was 0.4 s and 2000–5000 scans were necessary. For the protonated Schiff base, the sequence called INEPT (11) was used and only 200–400 scans were then necessary. The chemical shifts reported in this paper are calculated from formamide. *trans,trans*-2,4-Heptadienylidene *tert*-butylamine was synthesized by using *trans,trans*-2,4-heptadienal and *tert*-butylamine according to a procedure that has already been described elsewhere (9).

Results and discussion

^{13}C nuclear magnetic resonance results

Table 1 shows the chemical shifts of C3, C4, C5, C6, and C7 of HBA in deuterated chloroform solution (first line) and when in equimolar concentrations with different carboxylic acids (all subsequent lines). It shows also the deshielding (or shielding) experienced by these carbon atoms and these values (in parentheses in Table 1) are calculated by subtracting the chemical shifts of unprotonated HBA from the chemical shifts of HBA in the presence of the acids. Deshielding is indicated by a positive value while shielding is expressed by a negative value. Table 2 gives the results obtained in deuterated methanol.

In $CDCl_3$, as expected, the most deshielded carbon atom is C7. Its chemical shift varies from 157.17 ppm for the pure imine to a value of 165.05 ppm in the presence of the strong acid HI.

TABLE 1. Chemical shifts of HBA in presence of acids in deuterated chloroform at 25°C

FIG. 1. Interaction between HBA and some substituted carboxylic acids.

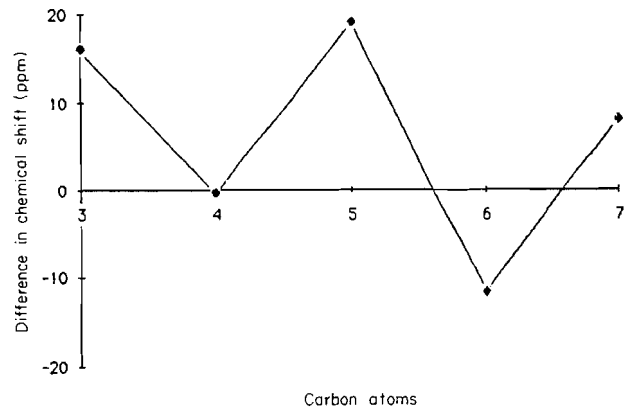

FIG. 2. Zigzag pattern of the differences in chemical shifts for C3–C7.

Table 1 also reports the pK_as, in water, of the acids. It would have been more appropriate to use pK_a values measured in chloroform since it is in that solvent that the nmr spectra were taken; however, in the absence of these values, it is still relevant to use the pK_as measured in water since Rumeau (12) has shown that in chloroform the ordering of all carboxylic acids of Table 1 is the same as in water. There exists a good linear correlation (with values exceeding 0.95) between the pK_as of all carboxylic acids and the differences in chemical shifts of C7, C6, C5, C3; it signifies that the polar groups located on the acids (such as Cl, Br, I, NO_2, CN, etc.) do not interact directly with the polyene chain except by increasing the acidity of the acids. The mineral acids behave differently: their acidity strengths are linearly correlated to C7 only, while affording a poor relationship with C6 and C5. This fact can be explained by the size of the counterions (Cl^-, Br^-, I^-), which varies considerably, while with the carboxylate anions the size remains constant. This also occurred in the ^1H nmr spectra of these systems, as for example between the pK_a of the acids and H6 (10*a*).

From Table 1, it is important to note a zigzag pattern: Fig. 2 shows an example of this using HBA and HI. This pattern is obtained for all acids used and in both solvents ($CDCl_3$ and CD_3OD). It has already been noted by Harbison *et al.* (5*b*), Inoue *et al.* (13), and by Pattaroni and Lauterwein (14), who report a similar behavior for all-*trans*-retinylidene *n*-butylamine (NRBA) and strong acids. It can be rationalized by the fact that all odd-numbered carbon atoms have a partial positive charge while those that are even numbered are in a nonresonance position. The first are deshielded while the others are shielded. The deshieldings are more important at carbon 5, then decrease slowly along the chain. Normally, because C7 is adjacent to the nitrogen of the azomethine function, it should be highly deshielded (it is in a resonance position), but the weak deshielding as shown in Tables 1 and 2 can be explained by the same argument already given by Sharma and Roels (15) for the weak deshielding value of the aldimine proton of NRBA. effect of being in a resonance position just beside nitrogen (high deshielding) is counterbalanced by the fact that resonance decreases the double bond character of the azomethine function, which in turn decreases the anisotropy of such a bond thus causing a shielding effect. Combination of both effects means that deshielding for carbon 7 is less important. The case of C6 is also rather interesting. Proton nmr indicates that H6 is highly deshielded (9, 10) while this work shows that C6 is quite shielded (the system and conditions being identical). Again it must be pointed out that H6, being close to the carboxylate anion, should feel strongly the anisotropy of the counterion, while C6 is less affected since it lies further away. In fact, the effects on H6 and C6 of the electric field generated by the counterion can be easily calculated using the following relation: the field on C6 is proportional to $1/R^2 \cos \phi$ where ϕ is the angle between the chain axis and the anion; R is the distance between the carbon atom C6 (or H6) and the anion (16). Using a distance of 3 Å between the anion and the Schiff base nitrogen, simple trigonometry indicates that R is 3.7 Å for C6 and 2.9 Å for H6. The field then encountered by C6 is approximately half the one felt by H6.

To summarize briefly, in deuterated chloroform the chemical shifts of HBA are related to the acidity strength of the carboxylic acids, and no secondary interactions between the polar function (X in Fig. 1) of the acids and HBA could be found.

The results obtained in deuterated methanol appear in Table 2. The first thing to note is that the chemical shifts are more deshielded, by around 3 ppm, in CD_3OD than in $CDCl_3$. Also, Table 2 shows the shielding effect of a *tert*-butyl group since there is a shielding of around 4.5 ppm for C7 on passing from an *n*-butyl to a *tert*-butyl group. Models of rhodopsin usually consist of an *n*-butyl group since lysine is the anchor by which the chromophore is attached to the protein. In our studies, we prefer a *tert*-butyl group since it affords a more stable compound than its counterpart and because the presence of the *syn* isomer is held at a minimum (less than 5%). The effect resides mostly in C7 since C3–C6 chemical shifts are roughly the same for both Schiff bases. The same zigzag patterns discussed previously are also obtained in deuterated methanol. From Table 2 it can readily be seen that strong acids (from TCA to HI) are able to perturb HBA in the same way, giving almost identical chemical shift differences. This is not surprising since methanol is known as a levelling solvent (17). The weaker acids act somewhat the same way as in deuterated chloroform except that deshielding (and shielding) is more important. Linear correlation curves between the pK_as of the weaker acids and the chemical shift differences show good linear correlations for C7, C6, C5, and C3, again indicating that there is no secondary interaction between the polar function and the polyenic chain of HBA.

Degrees of protonation of the Schiff base

As we have stated before, it is important to investigate the degree of protonation of a conjugated Schiff base when the protonating agent is a weak acid. Data given in Tables 1 and 2 allow the calculation of the degrees of protonation. However, it appears important to define some terms before discussing the protonating ability of the weak acids. Protonation is defined by the following equation:

[1] $R—CH=N—R' + HX \rightleftharpoons [R—CH=N^+H—R']X^-$

There is no doubt that the very strong mineral acids like HCl, HBr, and HI protonate HBA completely, so that in the above equation the equilibrium lies entirely to the right. That this is the case has been shown by several groups (principally by Blatz and Mohler (17)) and the subject has recently been reviewed by us (8). In a previous paper (10*b*), we have shown by ^1H nmr that HBA was 100% protonated by the strong mineral acids. Complete protonation was proven since alkylidene iminium hydrochlorides, in chloroform solution, show a doublet of doublets for the aldimine proton, while for the unprotonated Schiff base, as expected, only a doublet is present. Protonation

was also proven by ir spectroscopy. In three recent papers (18), Sandorfy and our group used FTIR to investigate the protonation of different Schiff bases. By using the same systems as the one described here, infrared spectra indicated 100% protonation when mineral acids were used: for *trans,trans*-2,4-heptadienylidene isopropylamine the pertinent bands were located at 2530 (N^+–H stretching), 1668 (ν(C=N^+), 1625 (ν(C=C), and 1069 cm^{-1} (N^+–H out-of-plane bending). In the same paper (18*b*), the degree of protonation of the Schiff base was also measured for weak carboxylic acids: propionic acid gave about 10% protonation, chloroacetic acid around 65%, and trichloroacetic acid 95–100%. These percentages were only estimated since overlap between the carboxylate band and the ν(CV=N^+) precluded a more precise treatment. Reversibility of the system was also shown to be occurring since varying amounts of carboxylic acids were able to shift the equilibrium (10).

The degree of protonation was calculated as follows. In methanol all strong acids affect HBA in the same fashion. Table 2 shows that with trichloro (TCA) and trifluoro acetic acids (TFA), HCl, HBr, and HI, the data are all very similar. This is due to a levelling effect caused by the solvent (17). Since the chemical shifts of HBA are linearly correlated with the pK_as of the acids, it can be safely presumed that deshielding (or shielding) values are indicative of the degrees of protonation. Considering, from Table 2, that strong acids cause a deshielding on C5 of some 16.2 ppm, then the extent of protonation can be easily calculated for the weaker acids. The protonation percentages are as follows: for propionic acid, 26%; benzoic acid, 49%; 3-nitropropanoic acid, 57%; iodoacetic acid, 82%; and chloroacetic acid, 93%. Protonation in chloroform solutions is somewhat more difficult to assess. Table 1 shows that the chemical shifts are all different since, in that solvent, there is no levelling effect. However, the chemical shifts are linearly correlated with the pK_as only for the carboxylic acids, while for the hydrohalides it is the size of the counterion that regulates the deshielding of HBA (14, 17). Since it has been demonstrated by ir (18*b*) and by nmr (10, 14) that TFA was protonating HBA completely (100%), the same procedure as described before can be used. Table 1 shows that for TFA, C5 is deshielded by some 16.5 ppm. Then, the degrees of protonation for the other acids are, for propionic acid, 19%; 3-nitropropanoic acid, 35%; iodo and bromoacetic acids, 58%; chloroacetic acid 70%; cyanoacetic acid, 77%; propiolic acid, 78%; and TCA, 93%. These last results compare very well with those obtained by ir (18*b*). Furthermore, it is important to note that protonation of HBA by weak acids is more favored in methanol than in chloroform. One would then expect from these data that an environment more polar than methanol is required in order to have 100% protonation by acids with pK_as of 4.

^{15}N nuclear magnetic resonance results

Roberts and co-workers (19) have studied Schiff bases, protonated and unprotonated, and have reported considerable chemical shift differences between the two. Thus ^{15}N nmr is a technique well suited to study the interaction between a conjugated Schiff base and carboxylic acids at the nitrogen site. Data from our study are reported in Table 3 for both $CDCl_3$ and CD_3OD. From this table it is readily seen that the chemical shifts vary by more than 160 ppm in deuterated chloroform and 130 ppm in deuterated methanol between protonated and unprotonated HBA. In $CDCl_3$, there exists a good linear correlation between the chemical shifts of the nitrogen of HBA and the acidity strength of the carboxylic acids (correlation coefficient of 0.932). The effect of the counterion can be best judged by considering the systems HBA–HCl and HBA–HI. The Cl^- anion induces a chemical shift of 96.89 ppm while I^- gives 75.28 ppm. The difference is more than 20 ppm while the pK_as vary by only 2.2. Passing from TCA to HCl, there is a small chemical shift difference of some 3 ppm for a large pK_a change of 7.5. In deuterated chloroform then, only the carboxylic acids correlate well with the pK_as, while for the mineral acids the size of the counterion is the prime factor that influences the chemical shifts. In CD_3OD, the situation is again quite different, as noted previously by ^1H and ^{13}C nmr. All strong acids give somewhat the same chemical shifts. For the weaker acids (propionic to chloroacetic acids), the chemical shifts vary according to the pK_as of the acids (correlation coefficient of 0.97) and, judging by the values obtained, protonation is far more extensive. As an example, propionic acid, the weakest acid used in our model system, shields HBA by some 29 ppm in $CDCl_3$ while CD_3OD shielding reaches roughly 90 ppm. The fact that acids shield the Schiff base nitrogen atom has been explained by Roberts and co-workers (19) on the basis of paramagnetic effects due to perturbations of the lone pair of nitrogen electrons by protonation. Table 3 reports also the chemical shifts obtained in a mixed solvent composed of 90% CH_3OH and 10% CD_3OD. This experiment was done to measure the impact on protonation by using CD_3OD instead of CH_3OH. Using deuterated methanol as solvent (for the purpose of obtaining a good lock) implies that HBA is protonated by a deuteron rather than a proton since there is a rapid exchange between the solvent and the acid. Table 3 shows that the chemical shifts did not vary significantly. The interaction between the polyenic chain and the polar functions of the substituted acetic acids was also investigated by measuring the chemical shifts of the nitrogen of the cyano group of cyanoacetic acid. If there exists a strong interaction between the two, the chemical shift of the cyano group should be particularly affected. Table 3 shows that the nitrogen of the cyano function has a chemical shift of 131.5 ppm in deuterated chloroform for cyanoacetic acid and 125.08 ppm for its carboxylate salt. With HBA, the cyano group has a value of 129 ppm, a value

TABLE 3. ^{15}N Chemical shifts of HBA in presence of acids in deuterated chloroform and deuterated methanol at 25°C

System studied	pK_a	Chloroform	Methanol
HBA		237.10	222.03

intermediate between the protonated and unprotonated form of cyanoacetic acid. This value does not rule out completely some form of interaction between the polyenic chain and the acid but it seems to indicate that if such an interaction is present, it has a weak effect on the chemical shift of the cyano group. Again we tried to calculate the percentage of protonation in CD_3OD. Since strong acids induce a chemical shift of approximately 92 ppm, HBA was considered 100% protonated. Simple calculations give 28% protonation for propionic acid, 78% for 3-nitropropanoic acid, 88% for iodoacetic acid, and more than 98% for chloroacetic acid. These protonation percentages compare well with those calculated previously by ^{13}C nmr. If we follow the same reasoning as before for the data obtained in deuterated chloroform and accept that a chemical shift of some 100 ppm (which means a shielding of some 137 ppm) does indicate 100% protonation, then we have the following protonation percentages: propionic acid, 21%; 3-nitropropanoic acid, 38%; iodoacetic acid, 58%; chloro and bromoacetic acids, 70%; cyanoacetic acid, 92%; and propiolic acid, 95%. These percentages again compare quite well with those obtained by ^{13}C nmr.

Finally, some mention must be made of the fact that we use a *tert*-butyl group instead of the customary *n*-butyl function. Mateescu and co-workers (1) found a value of 83 ppm (adjusted to formamide) for all-*trans*-2,4-hexadienylidene *n*-butylamine hydrochloride. Since we used all-*trans*-2,4-heptadienylidene *tert*-butylamine hydrochloride and found a value of 97 ppm (both salts in deuterated chloroform), we can say that a *tert*-butyl group creates a deshielding of some 14 ppm. For the unprotonated imine, Mateescu found 219 ppm (adjusted to formamide) while we found 237 ppm, a difference of 18 ppm. Again it must be said that a difference of a few ppm is not very important since full protonation gives shielding of more than 100 ppm. The greater stability of a *tert*-butyl Schiff base compared to an *n*-butyl group is reason enough to use it.

In conclusion, we can safely say that weak carboxylic acids in both polar and nonpolar solvents can only partially protonate HBA and that polar groups such as those used here (Cl, Br, I, NO_2, CN) do not seem to interact with the polyenic chain. Also, it is important to note that when the protonating agent is a weak acid, the chemical shifts of most carbon atoms of HBA as well as for the Schiff base nitrogen differ markedly from a nonpolar solvent to a more polar one and that these differences could possibly be used in the visual pigment field as an indicator of the polarity of the milieu surrounding the chromophore.

An improved route to pregna-5,20-dien-3β-ol (muricin aglycone): Carbon and proton nuclear magnetic resonance assignments for the aglycone and a number of related pregnene derivatives[1]

R. D. DAWE AND J. L. C. WRIGHT[2]

National Research Council of Canada, Atlantic Research Laboratory, 1411 Oxford Street, Halifax, N.S., Canada B3H 3Z1

Received August 11, 1986

R. D. DAWE and J. L. C. WRIGHT. Can. J. Chem. **65**, 666 (1987).

Carbon and proton assignments for muricin aglycone (**5**) and a number of related pregnenes, carried out with the aid of two-dimensional homo- and heteronuclear chemical shift correlation experiments, have resulted in previously reported carbon assignments for the aglycone being revised. An improved route to muricin aglycone is also reported.

R. D. DAWE et J. L. C. WRIGHT. Can. J. Chem. **65**, 666 (1987).

Sur la base de l'attribution des carbones et des protons de l'aglycone muricine (**5**) et d'un certain nombre de pregnènes apparentés, qui a été effectuée en faisant appel à des expériences de corrélation de déplacements chimiques homo- et hétéronucléaires bidimensionnelles, on a été amené à reviser des attributions faites antérieurement pour un certain nombre de carbones de l'aglycone. On rapporte aussi une méthode améliorée d'obtenir l'aglycone muricine.

Introduction

Several pregnene derivatives have been isolated from marine invertebrates. The pregnene derivative **1** was identified as aglycone from a complex saponin mixture from 3 species of starfish (1–3). The free pregnene derivatives **2**–**4** were isolated from the sponge *Haliclona rubens* (4), two others (**5** and **6**), were extracted from the soft coral *Gersemia rubiformis* (5), and steroid **6** together with **7** and **8** were isolated from an unidentified Pacific soft coral (6). More recently the vinyl steroid **5** was identified as the aglycone of muricin (**9**) as well as several other galactosamine saponins, from the Pacific gorgonian *Muricea fruticosa* (7), which displayed antifungal activity. With the exception of the latter compounds no ^{13}C nmr data have been reported for these steroids. Before the synthesis of muricin and other related saponins containing the C_{21} pregnene nucleus was attempted, it was necessary to develop a more efficient preparation of the aglycone **5** and at the same time obtain unambiguous proton and carbon data for these C_{21} steroids.

Results and discussion

Two syntheses of the C_{21} vinyl steroid **5** have been reported. In the original synthesis (8), the vinyl side chain was generated by Hofmann degradation of the appropriate C-21 amine in 3 steps and approximately 53% overall yield starting from the cholenic acid derivative **10**. More recently (5), a two-step synthesis from **2** in overall yield ca. 31% was accomplished by desulphurization of the C-20 thioacetal over deactivated Raney nickel. The synthesis reported here uses the commercially available keto-acetate **11**, which is converted to **5** in three steps and an overall yield of ca. 83%. In this short route, borohydride reduction of **11** gave **13**, which, after conversion to the mesylate **15**, was smoothly converted to **5** with potassium *tert*-butoxide.

The many reports concerning the assignment of ^{13}C resonances of steroids have been thoroughly reviewed (9), but only a few have been studied using modern pulse sequences. To establish a reliable set of data at the start of this short synthetic sequence, nmr assignments of **11** were secured as follows. The easily identified resonances for H-3 and H-6 are well separated from the methylene envelope and were used to assign signals for neighbouring protons (H-2, H-3, H-4 and H-6, H-7, H-8) by homonuclear 2-D chemical shift correlation experiments. These assignments were then used to identify the signals for carbons bonded to these protons by heteronuclear 2-D chemical shift correlation studies. Generally speaking, most resonances of the sterol nucleus are unaffected by variations in the side chain, and the converse is also true (10). Consequently the remaining

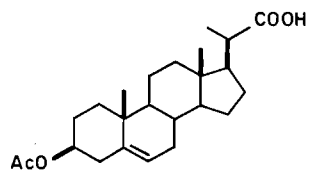
*These values for progesterone were reported in ref. 9.

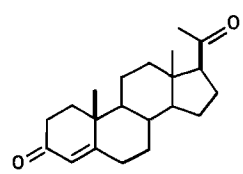
unidentified carbon resonances were assigned from their multiplicities and by comparison with published data (9, 11–13). It should be noted that acetylation of the 3β-hydroxy group results in shielding (ca. 4 ppm) of C-2 and C-4, whereas C-3 is deshielded by about 2 ppm (9) (Table 1). Furthermore the chemical shifts for C-15 and C-16 in steroids containing a 17β-acetyl group such as **12** have been unequivocally assigned by two groups (9, 14) using ^2H isotope effects. These experiments also confirmed the assignments for C-17 through C-21 and by comparison were used to assist in the assignment of these resonances in **2** and **11**. (For convenience, the published ^{13}C nmr data for **12** are reproduced in Table 1.)

Stereospecific reduction of the ketone **11** to the 20*R* alcohol **13** using borohydride resulted in predictable chemical shift changes: compared with **11**, the ring D carbons C-13 through C-15 of **13** were essentially unaffected, the resonance for C-16 was somewhat deshielded (+2.89 ppm), but the C-17 resonance was considerably shifted upfield (−5.14 ppm) upon reduction of the α-keto function. The new resonances at δ_C 70.24 and 23.70 were consistent with a methyl carbinol side chain and were assigned by comparison with 3-methyl-2-butanol (15). The remaining resonances displayed chemical shifts consistent with a 3β-acetoxy Δ^5 steroid nucleus and once again several of these assignments (C-1 through C-8 and C-17 through C-21) were confirmed by COSY and heteronuclear correlation experiments in the manner already described for **11**.

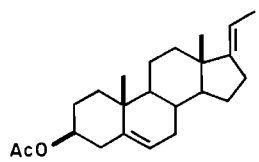
Acetylation of the methyl carbinol to yield the diacetate **14** resulted in the usual deshielding (ca. 2.5 ppm) of C-20 and shielding (ca. 3–4 ppm) of the adjacent carbons C-17 and C-21. Using the diacetate, the stereochemistry of C-17 and C-20 was confirmed by comparison with an authentic sample. In the mesylate **15**, the downfield shift of C-20, observed upon formation of the acetate, is more marked (ca. 11 ppm). However, the differences are less marked at the adjacent positions where C-17 is shielded by approximately the same amount as in the acetate, but C-21 is only shielded by about half. The resonance for C-18 is a little more shielded (ca. 0.5 ppm)



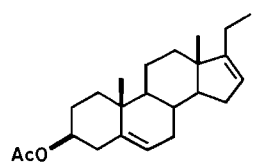
10



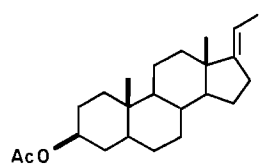
12



17



18



19

in the mesylate than the acetate, but the remaining resonances, which are removed from the side chain, are essentially unchanged.

Gas chromatographic analysis of the mesylate **15** resulted in decomposition and showed a mixture of three components with retention times 0.67, 0.68, 0.69 (relative to cholesterol) in the ratio 1:2.5:1.5. This mixture was obtained, in approximately the same ratio, upon elimination of methanesulphonic acid from **15** in refluxing pyridine. The olefinic region of the ^{13}C nmr spectrum of this mixture contained signals attributable to the vinyl sterol **16** (δ_C 114.51(t) and 139.7(d)) as well as two other

sets of signals ascribed to the sterols **17** (δ_C 113.55(d) and 150.12(s)) and **18** (δ_C 110.33(d) and 152.51(s)), as determined by comparison with an authentic sample of **18** and the pregnene derivative **19** (Table 1).

Elimination of methanesulphonic acid with potassium *tert*-butoxide simultaneously removed the acetate group and yielded the naturally occurring steroid **5** as the sole product. The ^{13}C nmr spectrum of this material contained an olefinic methylene resonance at δ_C 114.56 assigned to C-21, and another new resonance at δ_C 139.75 assigned to the olefinic methine at C-20. The two remaining olefinic resonances were consistent with Δ^5 substitution. Only two resonances in the sterol nucleus were significantly perturbed upon conversion of the mesylate **15** to the vinyl steroid **5** (Table 1): the resonances for C-13 and C-16 are shifted downfield (by 1.25 ppm and 1.84 ppm respectively), and the slight chemical shift differences for C-2, C-3, and C-4 are entirely consistent with hydrolysis of the acetate grouping (9). The assignments for C-1 through C-8 were confirmed by performing homonuclear and heteronuclear two-dimensional correlation experiments. Furthermore, the readily characterized resonances for H-20 (δ_H 5.74) and H-21 (δ_H 4.96) of the vinyl side chain were used to identify the ^1H–^1H connectivities H-21, H-20, H-17, and thus establish the assignment of C-17. Finally, the heteronuclear correlation data that yielded the ^1H resonance assignments in Table 2 were used to cross-check the assignment of the remaining ^{13}C resonances. The data listed in Table 1 show several discrepancies in the previously published ^{13}C nmr data (7) for **5**. In particular, the resonance at δ_C 37.3, assigned to C-4, is too low for a 3β-hydroxy sterol; the resonance is more appropriate for C-12. The resonance at δ_C 32.0 assigned to C-12 should be assigned to C-2. The resonance at δ_C 29.7 assigned to C-2 is incorrect, and is probably due to an impurity.

The muricins are an interesting group of metabolites that may account for the antifouling properties of the gorgonian *M. fruticosa*. The short high-yield synthesis of the aglycone **5** allows ready access to muricin and details of this, as well as the syntheses of other related saponins, will be reported later.

Experimental

The following steroids were purchased from Steraloids Inc., Wilton, NH: 5-pregnene-3β-ol-20-one 3-acetate (**11**) (Catalogue No. Q5501); pregna-5,16-diene-3β-ol (P1420) (**18**); 5α-pregn-17(20)-ene (**19**) (Q6790).

Optical rotations were measured using a Perkin–Elmer polarimeter, and infrared spectra were recorded with a Perkin–Elmer 283B spectrophotometer. Nuclear magnetic resonance spectra were obtained with a Bruker MSL-300 spectrometer using 5-mm tubes and ^2H lock as follows: ^1H spectra at 300 MHz, spectral width 4.5 kHz, data size 16 K zero-filled to 32 K (0.26 Hz/pt), 45 deg pulses (6 μs), repetition rate 6.8 s, temperature 20°C, sample amount in the 10–25 mg range in 0.7 mL $CDCl_3$: ^{13}C spectra (variables in same order): 75.4 MHz, 16.7 kHz, 16 K, 32 K (1.0 Hz/pt), 30 deg (2 μs), 1 s, 23°C, broadband [^1H]-decoupling; ^1H *J*-correlated "COSY" spectra (16); spectral width 1859 Hz, 512 × 128 word data table zero-filled in both dimensions giving data resolution 7.3 Hz/pt, data multiplication by squared sine-bell in both dimensions; $^{13}C/^1H$ heteronuclear *J*-correlated spectra (17); ^{13}C dimension 11 628 Hz, 1 K zero-filled, 11.4 Hz/pt, line broadening 10 Hz; ^1H dimension 2491 Hz, 128 words zero-filled, 9.7 Hz/pt, squared sine-bell. Mass spectra were obtained with a VG Analytical ZAB-EQ spectrometer operating in the EI mode (8 kV accelerating voltage, 70 eV ionizing energy). Gas–liquid chromatographic analyses were performed using a Varian 3400 chromatograph and a Varian series 600 chromatography data system. Operating conditions were as follows: fused silica capillary column (30 m × 0.25 mm) coated with DB5, injector port 310°C, detector 310°C, oven programmed from 150 to 270°C at 5°/min, helium carrier gas, flow 3 mL/min.

Pregn-5-ene-3β, 20R-diol, 3-acetate

The crystalline ketoacetate (**11**, 5.40 g, 15.1 mmol) was dissolved in methanol (150 mL), cooled to 0°C, and sodium borohydride was added slowly with stirring. After complete reduction (followed by tlc) excess borohydride was destroyed with acetic acid and the mixture was extracted twice with dichloromethane. The combined organic extracts were washed with saturated sodium bicarbonate, brine, and evaporated to yield the alcohol **13** as a white solid (5.40 g, 99%). Material that crystallized from methanol had the following characteristics: mp 152–155°C; $[\alpha]_D^{20}$ −76.4° (*c* 0.432, $CHCl_3$); ir (CCl_4): 3600 and 1720 cm^{-1}; ^1H nmr (300 MHz), δ_H: 0.77 (s, 3H), 1.03 (s, 3H), 1.14

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12

(d, J = 6.1 Hz, 3H), 2.04 (s, 3H), 3.73 (m, 1H), 4.62 (m, 1H), 5.37 (bd, J = 4.86 Hz, 1H).

The alcohol **13** (25 mg, 0.069 mmol) was acetylated in the usual manner to yield the diacetate **14** (25 mg, 89%), which had the same physical characteristics as authentic pregn-5-ene-3β,20β-diacetate (Steraloids), mp 126–128°C; $[\alpha]_D^{20}$ −36° (*c* 2.78, $CHCl_3$).

*Pregn-5-ene-3β, 20*R*-diol, 3-acetate, 20-methanesulphonate*

The secondary alcohol (**13**, 5.40 g, 15.0 mmol) was dissolved in dichloromethane (100 mL) and pyridine (15 mL) and treated with methanesulphonyl chloride (10 mL). When the reaction was complete (18 h), saturated aqueous sodium bicarbonate (100 mL) was added, the mixture was extracted with dichloromethane (200 mL), washed with water and brine, dried, and evaporated to yield a yellow solid (5.7 g). This solid was filtered through a short pad of Florosil using ethyl acetate/hexane (1:1) as eluant. Evaporation of the solvent yielded the mesylate **15** as an off-white solid (5.6 g, 85%), mp 125–127°C; $[\alpha]_D^{23}$ −37.5 (*c* 1.02, $CHCl_3$); ir (CCl_4): 1725 and 1330 cm^{-1}; ^1H nmr (80 MHz), δ_H: 0.79 (s, 3H), 1.01 (s, 3H), 1.40 (d, J = 6.0 Hz, 3H), 2.01 (s, 3H), 3.0 (s, 3H), 4.6 (bm, 2H (H-3, H-20)), 5.40 (bd, J = 4 Hz, 1H).

Pregna-5,20-diene-3β-ol

The mesylate **15** (0.5 g, 1.14 mmol), in dry toluene (6 mL) with potassium *tert*-butoxide (0.3 g, 2.7 mmol) added, was refluxed under nitrogen for 1.5 h. After cooling to room temperature the mixture was extracted twice with dichloromethane. The combined organic extracts were washed with water and brine, dried, and evaporated to yield the diene **5** as a white solid (0.35 g, 99%) that was homogeneous by tlc, ^1H and ^{13}C nmr spectral analysis. The material crystallized from methanol as needles, mp 136.5–138°C (lit. (8) mp 138–139°C); $[\alpha]_D^{23}$ −83.6° (*c* 0.616, $CHCl_3$) (lit. (8) $[\alpha]_D^{23}$ −85° (*c* 0.91, $CHCl_3$)); ir (CCl_4): 3450 and 1600 cm^{-1}; ^1H nmr (360 MHz), δ_H: 0.61 (s, 3H), 1.02 (s, 3H), 3.53 (m, 1H), 4.96 (dd, 2H), 5.36 (m, 1H), 5.76 (ddd, J = 8, 16, and 11 Hz, 1H); m/z (rel. intensity): 300.2557 (75) (M^+ calcd. for $C_{21}H_{32}O$: 300.2567), 285 (25) [M − 15], 282 (25) [M − 18], 267 (100) [M − (15 + 18)], 213 (50) [M − (33 + 54)].

*Treatment of mesylate **15** with refluxing pyridine*

The mesylate (50 mg, 0.11 mmol) was refluxed in dry pyridine (3 mL) for 3 h, after which time analysis of the mixture by tlc showed complete conversion to a new less polar spot. After extraction, analysis of the product by ^{13}C nmr (20 MHz) showed it to be a 2.5:1.5:1 mixture of the dienes **18**, **16**, and **17**. The olefinic resonances were δ_C 152.39(s), 150.12(s), 139.75(s), 139.75(d), 122.52(d), 114.56(t), 113.55(d), and 110.37(d).

Synthesis of functionalized bicyclo[3.2.1]octa-2,6-dienes by thermal rearrangement of substituted 6-*exo*-(1-alkenyl)bicyclo[3.1.0]hex-2-ene systems

EDWARD PIERS, GRACE L. JUNG, AND EDWARD H. RUEDIGER

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received September 2, 1986

EDWARD PIERS, GRACE L. JUNG, and EDWARD H. RUEDIGER. Can. J. Chem. **65**, 670 (1987).

Thermolysis of each of the enol silyl ethers **31**–**35** affords, cleanly and efficiently, the bicyclo[3.2.1]octadienes **36**–**40**, respectively. Similarly, thermal rearrangement of the enol silyl ether **50** provides the diene **51**. Hydrolysis of **36**, **37**, and **39**, and decarbomethoxylation of the resultant keto esters **41**, **42**, and **44**, gives the ketones **46**–**48**, respectively. The ketone **46** is also obtained by acid hydrolysis of **51**. Conversion of 6-methyl-1-hepten-4-yn-3-ol (**56**) into the enol ether **63** is described. Thermolysis of **63** gives **64**, which, upon acid hydrolysis, affords **65**. Thermolysis of the enones **68** and **69** produces the bicyclic dienones **70** and **71**, respectively. On the other hand, thermolysis of **73** and **74**, derived from the enone **69**, provides the C-8 *exo* substituted bicyclo[3.2.1]octa-2,6-dienes **75** and **76**, which are transformed smoothly, by acid hydrolysis, into the ketones **77** and **78**, respectively.

EDWARD PIERS, GRACE L. JUNG et EDWARD H. RUEDIGER. Can. J. Chem. **65**, 670 (1987).

Les thermolyses de chacun des éther énoliques silylés **31**–**35** conduisent respectivement, d'une manière propre et efficace, aux bicyclo[3.2.1]octadiènes **36**–**40**. De la même manière, la transposition thermique de l'éther énolique silylé **50** conduit au diène **51**. L'hydrolyse des composés **36**, **37** et **39** et la decarbométhoxylation des céto-esters **41**, **42** et **44** qui en résultent conduisent respectivement aux cétones **46**–**48**. On a aussi obtenu la cétone **46** par hydrolyse acide du composé **51**. On décrit la transformation du méthyl-6 heptène-1 yne-4 ol-3 (**56**) en son éther énolique **63**. La thermolyse du composé **63** conduit au produit **64** qui, par hydrolyse, conduit au composé **65**. La thermolyse des énones **68** et **69** conduit respectivement aux diénones bicycliques **70** et **71**. Par ailleurs, la thermolyse des composés **73** et **74**, qui proviennent du composé **69**, conduit aux bicyclo[3.2.1]octadiènes-2,4 (**75** et **76**) portant des substituants dans la positions C-8 *exo* qui se transforment respectivement, par hydrolyse acide, en cétones **77** et **78**.

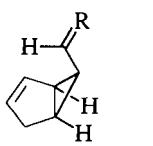
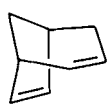
Introduction

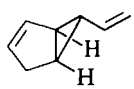
More than twenty years ago, Cupas, Watts, and Schleyer (1) reported that reaction of the bicyclic aldehyde **1** with methylenetriphenylphosphorane in refluxing tetrahydrofuran (THF) gives directly bicyclo[3.2.1]octa-2,6-diene (**3**). Thus, under these conditions, the initially formed 6-*endo*-vinylbicyclo[3.1.0]hex-2-ene (**2**) undergoes a facile [3,3]-sigmatropic (Cope) rearrangement to provide **3**. Subsequently, Brown (2) was able to isolate **2** and to show that this substance has a half-life of approximately one day at 25°C. In contrast, 6-*exo*-vinylbicyclo[3.1.0]hex-2-ene (**4**), like other *trans*-1,2-divinylcyclopropane systems,[1] is stable at ambient temperatures. However, **4** rearranges smoothly at 195°C to afford the bicyclic diene **3**. In



1 R = O
2 R = CH_2



3



4

an elegant study (6), the latter transformation was shown to proceed via a one-center epimerization at C-6. Presumably, this epimerization occurs via a diradical intermediate (5*a*) to produce the *endo* vinyl isomer **2**, which then undergoes rapid bond reorganization to yield **3** (5*b*).

Interestingly, the rearrangement of 6-(1-alkenyl)bicyclo-[3.1.0]hex-2-enes has received relatively little attention from a synthetic point of view (7–11). Since many natural products, particularly members of the terpenoid family, possess structures that incorporate the bicyclo[3.2.1]octane carbon skeleton, we have carried out a study aimed at the synthesis of functionalized bicyclo[3.2.1]octanes via Cope rearrangement of *trans*-divinylcyclopropane systems derived from 6-*exo*-(1-alkenyl)bicyclo[3.1.0]hexan-2-enes. We report herein the details of some of our work in this area.[2]

Results and discussion

(a) Preparation of the diene bromides 15–17

Of the diene bromides **14**–**17** (see Chart 1) required for this study, the "parent" (*E*)-5-bromo-1,3-pentadiene **14** was a known substance (14). The others, **15**–**17**, were prepared via relatively straightforward chemistry. Treatment of 2-methylpropanal with (carboethoxymethylene)triphenylphosphorane in

dichloromethane provided, highly stereoselectively, the enoate **5**. Reduction (diisobutylaluminum hydride) of **5**, followed by oxidation (pyridinium chlorochromate on alumina (15)) of the resultant alcohol **6**, gave the aldehyde **7**. The latter substance was transformed into the diene alcohol **9** via a two-step sequence very similar to that used for the conversion of 2-methylpropanal into **6**. Treatment of **9** with phosphorus tribromide in ether containing a small amount of pyridine (16) produced the bromide **15**.

Reaction of propenal and (*E*)-2-butenal with (carboethoxyethylidene)triphenylphosphorane in dichloromethane afforded the dienoates **10** and **12**, respectively. Reduction of the latter materials with lithium ethoxyaluminohydride (17) gave the alcohols **11** and **13**, which were converted into the corresponding bromides **16** and **17** by reaction with triphenylphosphine dibromide in acetonitrile containing one equivalent of triethylamine (18).

The allylic bromides **15**–**17** were rather unstable and tended to darken on standing. They were generally stored under argon at low temperatures (−20°C) and were distilled just prior to use.

*(b) Preparation of the 2-(*tert*-butyldimethylsiloxy)-6-*exo*-(1-alkenyl)bicyclo[3.1.0]hex-2-enes **31**–**35***

The β-keto esters **18**–**21** (see Chart 2) were prepared conveniently by use of the method developed by Huckin and Weiler (19). Successive treatment of methyl acetoacetate with 1.1 equivalents of each of sodium hydride and *n*-butyllithium, followed by alkylation of the resultant dianion with the bromide **15**, provided the β-keto ester **19** in 53% yield. In similar fashion, compounds **18**, **20**, and **21** were obtained by alkylation of $Li_2(CH_2COCHCO_2Me)$[3] with the bromides **14**, **16**, and **17**, respectively. The best yields for the latter alkylations were obtained when the reactions were carried out at 0°C for short periods of time (~5 min). Longer reaction times increased significantly the formation of undesired by-products.

Treatment of each of the β-keto esters **18**–**21** with *p*-toluenesulfonyl azide in acetonitrile containing one equivalent of triethylamine (20) afforded, in essentially quantitative yields, the corresponding diazo compounds **22**–**25**, respectively. The latter substances exhibited, in their infrared spectra, an absorption band in the region 2120–2125 cm^{-1}, typical of the diazo function.

Carbenoid ring closure (21) of the diazo dienes **22**–**25** was effected by treatment of these substances with copper(II) acetylacetonate (**22**–**24**) or copper-bronze (**25**) in refluxing benzene (**23**) or toluene (**22**, **24**, **25**). The yields of the bicyclic products **26**–**29** varied from 50 to 78%. Since it is well known (21) that carbenoid cyclizations of this type are stereospecific with respect to the stereochemistry of the double bond involved, only the expected 6-*exo*-alkenyl isomers were formed. Methylation (LDA, THF; MeI, THF–hexamethylphosphoramide) of the keto ester **26** provided the alkylated material **30**.

Treatment of each of the ketones **26**–**30** with 1.1 equivalents of LDA (THF, −78°C), followed by trapping of the resultant enolate anion with *tert*-butyldimethylsilyl chloride (THF–hexamethylphosphoramide, −78°C to room temperature), produced cleanly and efficiently the corresponding enol silyl ethers **31**–**35**, respectively. The stage was thus set for an investigation

[3]This species was prepared by reaction of methyl acetoacetate with 2.1 equivalents of lithium diisopropylamide (LDA) (19) or lithium 2,2,6,6-tetramethylpiperidide. In general, the yields of alkylations involving the bromides **14**–**17** were higher with $Li_2(CH_2COCHCO_2Me)$ than with $LiNa(CH_2COCHCO_2Me)$.

CHART 2

of the thermal rearrangement of these functionalized 6-*exo*-alkenylbicyclo[3.1.0]hex-2-enes.

*(c) Thermal rearrangement of the 6-*exo*-(1-alkenyl)bicyclo[3.1.0]hex-2-enes **31**–**35** and **50***

When a solution of the divinylcyclopropane **31** in dry xylene was refluxed for 2.5 h, the bicyclo[3.2.1]octa-2,6-diene **36** (see Chart 3) was obtained in nearly quantitative yield. In similar fashion, thermolysis of the more highly substituted substrates **32** (benzene, sealed tube, 200°C, 2 h), **33** (refluxing xylene, 6 h), **34** (refluxing mesitylene, 4 h), and **35** (refluxing mesitylene, 1 h) provided the Cope rearrangement products **37**–**40**, respectively, in high yields (>90%). In each case, the reaction was clean and the progress of the rearrangement process could be followed conveniently by gas–liquid chromatography (glc).

Presumably, the rearrangement of compounds **31**–**35** takes place via a mechanism outlined in general terms in Scheme 1 (3–6). Thus, one-center epimerization (6) of the substrates **31**–**35** to the corresponding *endo* isomers **B** by way of the diradical intermediate **A** (5*a*), followed by [3,3]-sigmatropic rearrangement of **B** via boat-like transition states **C** (3–5), would afford the bicyclic products **36**–**40**. Implicit in this mechanistic scheme is the prediction that substrates **32** and **34**, which possess a *trans*-1-alkenyl group at C-6, would produce bicyclo[3.2.1]octa-2,6-diene products (**37**, **39**, respectively) in which the R group at C-4 would have an *endo* (pseudoequatorial) orientation. Indeed, thermolysis of **32** and **34** provided exclusively the products **37** and **39**, respectively. Evidence in

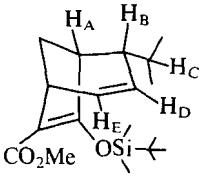
31–35 A B

36–40 C

SCHEME 1

support of the expectation that **37** possesses an *endo* oriented isopropyl group was obtained from an examination of the ^{1}H nmr spectrum of this material. Appropriate decoupling experiments showed that the coupling constant J_{AB} associated with the signals due to H_A and H_B is about 5 Hz. For example, irradiation at δ 5.44 (signal due to H_D) caused partial collapse of the resonance (δ 2.06) due to H_B, which changed from an "octet" (overlapped dddd, J_{BC} = 8.5 Hz, J_{AB} = 5 Hz, J_{BD} = J_{BE} = 2.5 Hz) to a "heptet" (overlapped ddd) with J_{BC} = 8.5 Hz, J_{AB} = 5 Hz, and J_{BE} = 2.5 Hz. Had the isopropyl group possessed an *exo* orientation, the dihedral angle between H_A and H_B would have been close to 90°C and a much smaller coupling constant would have been anticipated. This expectation was confirmed later in this study when a bicyclo[3.2.1]octa-2,6-diene bearing an *exo* isopropyl group at C-4 was prepared (*vide infra*).



37

The mechanism shown in Scheme 1 would also lead one to predict that the thermal rearrangement of **31–35** would be assisted by the angular carbomethoxy group. Normally, the rate-determining step of the Cope rearrangement of *trans*-divinylcyclopropane systems (e.g. **31–35**) is the epimerization of the *trans* compound to the corresponding *cis*-divinylcyclopropane (e.g. **B**) (3–5).[4] Presumably, the CO_2Me group would assist in stabilizing the diradical **A** (and, in turn, the transition state leading to this intermediate) and would thus be instrumental in facilitating the rate of the overall rearrangement of substrates **31–35** to the products **36–40**. This conclusion is qualitatively supported by comparison of the thermal rearrangements of the structurally similar substrates **31** and **50**[5] (Chart 3). When a solution of compound **31** in xylene (bp 138°C) was

refluxed, rearrangement to **36** was complete within a period of 2 h. On the other hand, complete transformation of **50** into **51** required a temperature of ~200°C (neat, sealed tube) for the same length of time. Nevertheless, the latter conversion was very clean and efficient (97% yield).

The rearrangement products **36–40** could be converted readily into the corresponding β-keto esters **41–45**, respectively. For example, treatment of **36** and **39** with potassium fluoride in methanol (0°C, 1 h) and **37** with tetra-*n*-butylammonium fluoride in dry THF (room temperature, 1 h) afforded, efficiently, the β-keto esters **41**, **44**, and **42**, respectively. In each case, the product consisted of a mixture of

[4]Exceptions to this generalization are known (see, for example, refs. 22 and 23).

[5]This substance is readily prepared (LDA, THF; *t*-BuMe$_2$SiCl, THF–hexamethylphosphoramide) from 6-*exo*-vinylbicyclo[3.1.0]hexan-2-one (24).

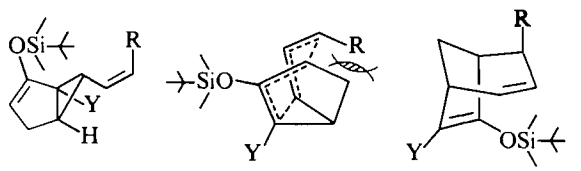
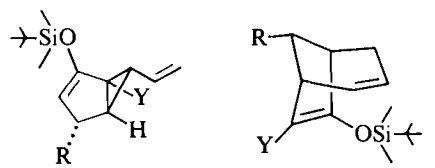
epimers associated with the carbomethoxy-bearing carbon. Acid hydrolysis – decarboxylation of **41** and **42** provided the bicyclic ketones **46** and **47**, respectively, while base hydrolysis of **44** gave **48**. Bicyclo[3.2.1]oct-2-en-6-one (**46**), which could also be obtained by treatment of the enol silyl ether **51** with dilute hydrochloric acid in THF, was shown to be identical (glc retention times, ^{1}H nmr spectrum) with a sample of the same substance obtained by preparative glc from an independently prepared mixture of the two isomeric keto alkenes **46** and **49** (25, 26).[6] Thus, the fact that the rearrangement products **36** and **51** possessed the bicyclo[3.2.1]octa-2,6-diene carbon skeleton was conclusively established.

The work summarized above demonstrated the utility of the Cope rearrangement of functionalized 6-*exo*-(1-alkenyl)bicyclo[3.1.0]hex-2-enes (e.g. **31**–**35**, **50**) for the preparation of substances possessing the bicyclo[3.2.1]octane carbon skeleton. The reactions employed for the preparation of the substrates **31**–**35** and **50** were relatively straightforward and the thermal rearrangement reactions were clean and efficient. The latter processes led to the preparation of bicyclo[3.2.1]octa-2,6-dienes with alkyl substituents at either bridgehead position (see **38**, **40**) and on C-4 with an *endo* orientation (see **37**, **39**). Furthermore, the rearrangement products contain on the 3-carbon and 2-carbon bridges functional groups (carbon–carbon double bond, "hidden" β-keto ester, enol silyl ether) suitable for further synthetic manipulations.

From a synthetic point of view, particularly as related to the possible use of the above-described methods in natural product synthesis, two additional goals remained. First, it was of considerable interest to test the viability of the Cope rearrangement of compounds of general structure **52**. Mechanistic considerations (see Scheme 1) would lead to the prediction that successful Cope rearrangement in these cases would afford bicyclo[3.2.1]octa-2,6-diene products **53** that possess at C-4 an *exo*, pseudoaxially oriented R group. However, if the R group is quite bulky (e.g. isopropyl), the presumed transition state for the Cope rearrangement would be destabilized considerably by steric and, perhaps, torsional strain involving the R group and the C-3 methylene group on the five-membered ring (see **D**). Therefore, it would not be unreasonable to conjecture that thermolysis of **52**, particularly if R is bulky, could result in bond reorganization processes different from the desired Cope rearrangement.



52 **D** **53**



54 **55**

A second extension to the work described thus far was related to our desire to prepare bicyclo[3.2.1]octadienes that contain functional groups on the 1-carbon bridge (C-8). Specifically, we wished to prepare substrates of general structure **54**. It is evident that successful Cope rearrangements of **54**, which would produce products of general structure **55**, would significantly enhance the synthetic utility of the method under investigation.

The results of our studies as related to the preparation and thermolysis of substances of general structure **52** and **54** are summarized in the next two sections of this paper.

(d) Preparation and thermolysis of 2-(tert-*butyldimethylsiloxy)*-6-exo-*[(Z)-3-methyl-1-butenyl]bicyclo[3.1.0]hex-2-ene (63)*

Treatment of a THF solution of 1-lithio-3-methyl-1-butyne with propenal provided (86%) the alcohol **56** (see Chart 4). Subjection of the latter substance to an orthoester-based Claisen rearrangement (27) afforded, in 66% yield, the ester **57**. The expectation (27) that the newly formed double bond would possess a *trans* configuration was verified by the ^{1}H nmr spectrum of **57**, which showed that the mutual coupling constant associated with the two olefinic protons is 15.5 Hz. Conversion of the ester **57** into the diazoketone **60**, via the acid **58** and the acid chloride **59**, was accomplished by means of standard reactions. Copper(II) acetylacetonate-catalyzed carbenoid ring closure of **60** in refluxing benzene provided the bicyclic ketone **61** (49% from the ester **57**). Hydrogenation of the alkyne **61** in the presence of Lindlar's catalyst gave, in 94% yield, the corresponding *cis* alkene **62**. The ^{1}H nmr spectrum of **62** revealed that the olefinic protons are mutually coupled with a coupling constant of 10.5 Hz. The latter value is typical of *cis* disubstituted alkenes.

It was gratifying to find that thermolysis (240°C, benzene, sealed tube, 4.5 h) of the enol silyl ether **63** (derived from the ketone **62**) provided, in 93% yield, a single product that proved to be the bicyclic diene **64**. The presumption that **64** would possess an *exo*, pseudoaxially oriented isopropyl group was substantiated by its ^{1}H nmr spectrum. An appropriate

CHART 4

[6]We are grateful to Professor Stephen Monti for a sample of a mixture of the two ethylene ketals corresponding to the ketones **46** and **49** (25). The ^{1}H nmr spectrum of **49** (26) is significantly different from that of **46**.

For personal use only.

decoupling experiment showed that J_{AB} (see **64**) is ≤ 1 Hz. Thus, irradiation of the broad doublet at δ 2.38 (H_A) did not alter the width-at-half-height associated with the multiplet at δ 1.88–1.94 (H_B), although the latter resonance did change to a clean 6-line signal (overlapped ddd, $J_{BC} = 7$ Hz, $J_{BD} \approx 3$ Hz, $J_{BE} \approx 2$ Hz). Molecular models indicate that the dihedral angle between H_A and H_B in **64** is close to 90°, and thus a small coupling constant would be expected. Furthermore, acid-promoted hydrolysis of the enol ether function in **64** furnished the ketone **65**, which, on the basis of spectral data, is clearly epimeric with the previously prepared ketone **47** (*vide supra*). In particular, suitable decoupling experiments similar to those described previously for the enol silyl ethers **64** and **37** (*vide supra*) showed that, in the ^{1}H nmr spectra of **65** and **47**, J_{AB} is ≤ 1 Hz and 5 Hz, respectively (see Chart 4). These observed coupling constants fully support the stereochemical assignments.

It is evident from the successful, efficient conversion of **63** into **64** that Cope rearrangements of 6-*exo*-(1-alkenyl)bicyclo[3.1.0]hex-2-enes possessing relatively bulky, *cis*-oriented alkyl groups on the 6-*exo*-(1-alkenyl) side chain are, in fact, viable processes. Thus, our initial misgivings concerning the viability of this type of transformation were unfounded. As implied previously, the success of the transformation of **63** into **64** is of importance for the possible application of this method to the synthesis of natural products.

(e) Preparation and thermolysis of compounds 68, 69, 73, and 74. Synthesis of bicyclo[3.2.1]octa-2,6-dienes functionalized at C-8

Conversion of the keto ester **26** into the enone **68** (see Chart 5) was effected by means of a selenenylation-selenoxide elimination method (28). Thus, reaction of the lithium enolate of **26** with phenylselenenyl chloride gave the α-phenylseleno ketones **66** (mixture of epimers). Oxidation of **66** with hydrogen peroxide provided the enone **68**, although the overall yield of this material from **26** was low (32%). Transformation of 6-*exo*-vinylbicyclo[3.1.0]hexan-2-one (24) into the corresponding enone **69** was accomplished more efficiently (88%) by use of a one-pot procedure (28, 29) in which the intermediate α-phenylseleno ketones **67** were not isolated.

It is evident from an examination of the structures of the enones **68** and **69** that these substances contain a *trans* divinylcyclopropane system in which one of the "vinyl" groups consists of the enone carbon–carbon double bond. Thus, although the functional group pattern in **68** and **69** is somewhat different from that present in the substrates (**31–35**, **50**, **63**) studied earlier, it might be expected that thermolysis of **68** and **69** would also lead to successful Cope rearrangement.

When a solution of compound **68** in xylene was refluxed for 18 h, the bicyclic keto ester **70** was obtained in 73% yield. Similarly, thermolysis (160°C, benzene, sealed tube, 4 h) of **69** provided bicyclo[3.2.1]octa-2,6-dien-8-one (**71**) in 68% yield. These interesting rearrangement reactions reveal that one solution to the problem of producing C-8 functionalized bicyclo[3.2.1]octadienes involves the preparation and thermolysis of 6-*exo*-(1-alkenyl)bicyclo[3.1.0]hex-3-en-2-ones (e.g. **68**, **69**). Presumably, suitable functional group manipulations of the C-8 carbonyl group in the resultant products (e.g. **70**, **71**) would produce substances with a variety of substituents on the 1-carbon bridge of the bicyclo[3.2.1]octadiene system.

Copper(I)-catalyzed conjugate addition of vinylmagnesium bromide to the enone **69** gave, in 80% yield, a single product[7]

[7]Treatment of the enone **68** with cuprate reagents gave complex mixtures of products.

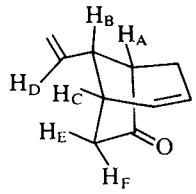
CHART 5

that, on the basis of steric considerations (approach of the vinylcopper(I) reagent from the less hindered side of the enone), was expected to possess the stereochemistry depicted in **72**. This expectation was verified by the ^{1}H nmr spectrum of the reaction product. Molecular models show that the dihedral angles between H_A and H_B and between H_B and H_D (see **72**) are close to 90° and therefore J_{AB} and J_{BD} would be expected to be small. Indeed, in a decoupling experiment, irradiation at δ 3.02 (overlapped dd, $J = 8, 8$ Hz, H_B) led to no change in the signals at δ 1.87–1.94 (which included H_D) and 2.04 (H_A, overlapped dd, $J = 5, 4$ Hz), while the anticipated simplifications occurred at δ 2.36 (H_E, dd, $J_{DE} = 18.5$ Hz, $J_{BE} = 8$ Hz to d, $J_{DE} = 18.5$ Hz) and δ 5.84 (H_C, ddd, $J = 17.5, 10, 8$ Hz to dd, $J = 17.5, 10$ Hz).

Transformation of the ketone **72** into the enol silyl ether **73** was accomplished by means of standard reactions. Interestingly, in the ^{1}H nmr spectrum of **73**, the coupling constant J_{AB} was found to be ~2.5 Hz. Thus, in a decoupling experiment, irradiation at δ 4.31 (H_C, br s) caused the signal at δ 3.13 (H_B, br unresolved d) to sharpen to a dd, with coupling constants 7.5 and 2.5 Hz (J_{AB}).

In an attempt to prepare a 2-(*tert*-butyldimethylsiloxy)-6-*exo*-vinylbicyclo[3.1.0]hex-2-ene containing a functionalized C-4 *exo* substituent different from a vinyl group, the reaction of the enone **69** with 1-(*tert*-butyldimethylsiloxy)-1-ethoxyethene (30) in warm acetonitrile (31) was investigated. Although this process was quite sluggish, it produced cleanly, after a reaction time of 12 h, a 33% yield (>95% based on consumed **69**) of the enol silyl ether **74**. A decoupling experiment similar to that described above for compound **73** showed that, in the ^{1}H nmr spectrum of **74**, $J_{AB} = 2.5$ Hz. Therefore, it is evident that substances **73** and **74** possess the same relative stereochemistry.

It was pleasing to find that thermal rearrangement (200°C, benzene, sealed tube) of compounds **73** and **74** proceeded smoothly to produce, in each case, a single product (**75**, **76**, respectively) in high yield. Acid hydrolysis of **75** and **76** under mild conditions provided the corresponding bicyclic ketones **77**



77

(97%) and **78** (94%), respectively. The expectation that the vinyl and carboethoxymethyl groups of **77** and **78**, respectively, would possess an *exo* orientation was corroborated by the ^{1}H nmr spectra of these substances. For example, in a decoupling experiment, irradiation of the signal due to H_D (δ 5.90) in the ^{1}H nmr spectrum of **77** caused the resonance at δ 2.91 (H_B) to sharpen to a broad s, ($w_{1/2}$ = 5 Hz). This experiment showed that H_B is only weakly coupled to the two bridgehead protons H_A and H_C. Furthermore, irradiation at δ 2.91 (H_B) changed the signal due to H_F (δ 2.22) from a dd (J_{EF} = 17.5 Hz, J_{BF} = 2 Hz) to a clean d (J_{EF} = 17.5 Hz). Thus, as expected, J_{CF} is very small (the dihedral angle between H_C and H_F is ~90°). However, there is long range coupling between H_B and H_F, indicating that these two protons, along with the two intermediate carbon–carbon single bonds, have a W-configuration (32). These spectral data show clearly that the vinyl group in **77** is in an *exo* orientation. In similar fashion, it was shown that the C-8 proton in the bicyclic ketone **78** couples only weakly to the two adjacent bridgehead protons. Therefore, the CH_2CO_2Et group in **78** also has an *exo* stereochemistry.

It is evident from the work summarized above that bicyclo[3.2.1]octa-2,6-dienes possessing a C-8 functional group (e.g. **70**, **71**) or containing a C-8 *exo* substituent (e.g. **75**, **76**) can be obtained readily by thermolysis of the requisite 6-*exo*-vinylbicyclo[3.1.0]hex-3-en-2-ones (e.g. **68**, **69**) or the C-4 *exo* substituted 6-*exo*-vinylbicyclo[3.1.0]hex-2-enes (e.g. **73**, **74**), respectively. These results demonstrate further the utility and versatility of the methods that formed the subject of the present study.

Experimental

General information

Melting points, boiling points, and air-bath temperatures (short-path Kugelrohr distillations) are uncorrected. Infrared (ir) spectra were recorded on a Perkin–Elmer model 710B spectrophotometer and were calibrated using the 1601 cm^{-1} band of polystyrene film. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded on deuteriochloroform solutions using tetramethylsilane as the internal standard. In cases of compounds with *tert*-butyldimethylsilyl groups, the resonance positions were determined relative to the chloroform signal (δ 7.25). Microanalyses were carried out in the Microanalytical Laboratory, University of British Columbia. Analytical gas–liquid chromatography (glc) was performed with a Hewlett–Packard model 5832A gas chromatograph (columns: 6 ft × 0.125 in., 5% OV-17 on 80–100 mesh Chromosorb W(HP), 6 ft × 0.125 in., 5% OV-210 on 80–100 mesh on Chromosorb W(HP), or 10 ft × 0.125 in., 10% SE-30 on 80–100 mesh Chromosorb W(HP)) or with a Hewlett–Packard model 5880 gas chromatograph (column: 25 m × 0.21 mm fused silica column coated with cross-linked SE-54). Thin-layer chromatography (tlc) was accomplished with commercial aluminum-backed silica gel plates (E. Merck, Type 5539). Preparative tlc was carried out on 20 × 20 cm glass plates coated with 0.9 mm of silica gel (E. Merck, Silica Gel 60). Conventional column chromatography was performed using 70–230 mesh silica gel (E. Merck), while flash column chromatography was done using 230–400 mesh silica gel (E. Merck).

Note. All reactions requiring dry conditions were done using glassware that had been flame-dried under an argon flow. Unless otherwise stated, all reactions were done under an atmosphere of argon.

Note. In experiments producing volatile products, the extraction and (or) chromatography solvent(s) were removed from the desired product by careful (fractional) distillation at atmospheric pressure.

Note. All compounds for which exact masses (high resolution mass spectrometry) are reported gave clean ^{1}H nmr spectra and exhibited essentially one peak by glc and one spot by tlc analyses.

*Ethyl (*E*)-4-methyl-2-pentenoate (**5**)*

To a stirred solution of (carboethoxymethylene)triphenylphosphorane (40 g, 114.9 mmol) in dry dichloromethane (100 mL) was added dropwise 10.4 mL (114.9 mmol) of 2-methylpropanal, and the resultant mixture was refluxed for 4 h. Removal of most of the solvent by distillation (atmospheric pressure) left a white residue that was triturated with pentane. The mixture was filtered through a short column of silica gel and the column was washed with pentane. Removal of the solvent from the eluate and distillation (air-bath temperature 45–50°C/0.1 Torr; 1 Torr = 133.3 Pa) of the residual yellow oil gave 15.0 g (92%) of the ester **5**, which exhibited ir (film): 1715, 1648 cm^{-1}; ^{1}H nmr (80 MHz), δ: 1.06 (d, 6H, J = 7 Hz), 1.30 (t, 3H, J = 7 Hz), 2.46 (overlapped dd septet, 1H, J = 7, 1, 7 Hz), 4.20 (q, 2H, J = 7 Hz), 5.76 (dd, 1H, J = 16, 1 Hz), 6.95 (dd, 1H, J = 16, 7 Hz). *Exact Mass* calcd. for $C_8H_{14}O_2$: 142.0994; found: 142.0991.

*(*E*)-4-Methyl-2-penten-1-ol (**6**)*

To a cold (−78°C), stirred solution of the ester **5** (1.0 g, 7.04 mmol) in dry pentane (15 mL) was added dropwise a hexane solution of diisobutylaluminum hydride (17.6 mmol). The mixture was stirred at −78°C for 1 h and at 0°C for 1 h. Saturated aqueous ammonium chloride (1 mL) was added and the mixture was poured into 5% hydrochloric acid. The organic phase was washed with 5% hydrochloric acid, brine, and saturated aqueous sodium bicarbonate and then was dried ($MgSO_4$). Removal of the solvent (distillation at atmospheric pressure) gave the allylic alcohol **6** (0.668 g, 95%) as a colorless oil; ir (film): 3300, 1660 cm^{-1}; ^{1}H nmr (80 MHz), δ: 1.00 (d, 6H, J = 7 Hz), 1.47 (br s, 1H), 2.10–2.60 (m, 1H), 4.04–4.17 (m, 2H), 5.38–5.87 (m, 2H). *Exact Mass* calcd. for $C_6H_{12}O$: 100.0888; found: 100.0887.

*(*E*)-4-Methyl-2-pentenal (**7**)*

To a stirred solution of the alcohol **6** (200 mg, 2.0 mmol) in dry dichloromethane (10 mL) was added pyridinium chlorochromate (3.2 mmol) supported on alumina (15). The mixture was stirred at room temperature for 3 h and then was filtered through a short column of silica gel (70–230 mesh). The column was eluted with dry ether. Removal of the solvent from the eluate (distillation at atmospheric pressure) gave a brown oil. Subjection of this material to flash distillation (air-bath temperature ~30°C/0.1 Torr, receiver cooled to −78°C) afforded the aldehyde **7** (194 mg, 99%) as a colorless oil; ir (film): 1675, 1622 cm^{-1}; ^{1}H nmr (80 MHz), δ: 1.13 (d, 6H, J = 7 Hz), 2.37–2.85 (m, 1H), 6.10 (ddd, 1H, J = 16, 8, 1 Hz), 6.86 (dd, 1H, J = 16, 7 Hz), 9.55 (d, 1H, J = 8 Hz). *Exact Mass* calcd. for $C_6H_{10}O$: 98.0732; found: 98.0732.

*Ethyl (2*E*,4*E*)-6-methyl-2,4-heptadienoate (**8**)*

This compound was prepared by reaction of the aldehyde **7** (1.78 g, 18.1 mmol) with (carboethoxymethylene)triphenylphosphorane (6.32 g, 18.1 mmol) in refluxing (5 h) dichloromethane (19 mL) via a procedure very similar to that described above for the preparation of the ester **5**. Distillation (air-bath temperature 68–75°C/0.1 Torr) of the crude yellow oil produced 1.34 g (44%) of the diene ester **8**, which exhibited ir (film): 1700, 1635, 1612 cm^{-1}; ^{1}H nmr (400 MHz), δ: 1.05 (d, 6H, J = 7 Hz), 1.30 (t, 3H, J = 7 Hz), 2.43 (overlapped d septet, 1H, J = 6, 7 Hz), 4.22 (q, 2H, J = 7 Hz), 5.80 (d, 1H, J = 14 Hz), 6.09 (dd, 1H, J = 15, 6 Hz), 6.13 (dd, 1H, J = 15, 9 Hz), 7.26 (dd, 1H, J = 14, 9 Hz). *Exact Mass* calcd. for $C_{10}H_{16}O_2$: 168.1150; found: 168.1151.

*(2*E*,4*E*)-6-Methyl-2,4-heptadien-1-ol (**9**)*

Reduction of the ester **8** (386 mg, 2.3 mmol) with diisobutylaluminum hydride (5.0 mmol) in dry pentane (7 mL) (−78°C, 1 h; 0°C, 3 h) was carried out via a procedure very similar to that employed for the preparation of the alcohol **6** (*vide supra*). Distillation (air-bath

For personal use only.

temperature 60–65°C/0.1 Torr) of the crude product afforded 280 mg (96%) of the alcohol **9**; ir (film): 3300, 1650 cm^{-1}; ^1H nmr (270 MHz), δ: 1.00 (d, 6H, J = 7 Hz), 1.57 (br s, 1H), 2.34 (overlapped d septet, 1H, J = 7, 7 Hz), 4.15 (d, 2H, J = 6 Hz), 5.68 (dd, 1H, J = 15, 7 Hz), 5.74 (dt, 1H, J = 15, 6 Hz), 6.02 (dd, 1H, J = 15, 10 Hz), 6.22 (dd, 1H, J = 15, 10 Hz). *Exact Mass* calcd. for $C_8H_{14}O$: 126.1045; found: 126.1043.

(2E,4E)-1-Bromo-6-methyl-2,4-heptadiene (15)

To a cold (0°C), stirred solution of the alcohol **9** (1.0 g, 7.93 mmol) and pyridine (32 μL, 0.4 mmol) in dry ether (2 mL) was added dropwise a solution of phosphorus tribromide (0.23 mL, 3.2 mmol) in ether (1 mL). The mixture was stirred at 0°C for 4 h and then was poured into ice-water. The organic phase was washed successively with brine, 5% aqueous sodium bicarbonate, and brine and then was dried ($MgSO_4$). Careful removal of the solvent under reduced pressure, followed by flash distillation (air-bath temperature ~30°C/0.1 Torr, receiver cooled to −78°C) of the residual oil, yielded 1.17 g (78%) of the diene bromide **15**. This material, a pale yellow oil, darkened on standing at room temperature. It was stored under argon at low temperatures and was distilled immediately prior to use. Compound **15** exhibited ir (film): 1643, 990 cm^{-1}; ^1H nmr (80 MHz), δ: 1.00 (d, 6H, J = 7 Hz), 2.10–2.60 (m, 1H), 4.04 (d, 2H, J = 8 Hz), 5.55–6.50 (m, 4H). *Exact Mass* calcd. for $C_8H_{13}{}^{79}Br$: 188.0200; found: 188.0200.

Ethyl (E)-2-methyl-2,4-pentadienoate (10)

To a stirred solution of (carboethoxyethylidene)triphenylphosphorane (40 g, 0.11 mmol) in dry dichloromethane (150 mL) was added dropwise propenal (6.2 g, 0.11 mol). An exothermic reaction ensued and the mixture was heated to maintain gentle reflux for an additional 2 h. Most of the solvent was removed under reduced pressure, the residue was diluted with pentane to precipitate triphenylphosphine oxide, and the mixture was filtered. The collected material was washed with pentane. Removal of the solvent from the combined filtrate, followed by flash distillation (air-bath temperature ~50°C/0.1 Torr, receiver cooled to −78°C) of the residual oil, provided the ester **10** (12.3 g, 80%) as a colorless liquid that exhibited ir (film): 1715, 1635, 1600 cm^{-1}; ^1H nmr (100 MHz), δ: 1.32 (t, 3H, J = 7 Hz), 1.97 (d, 3H, J = 2 Hz), 4.24 (q, 2H, J = 7 Hz), 5.46 (dd, 1H, J = 10, 2 Hz), 5.58 (dd, 1H, J = 17, 2 Hz), 6.68 (ddd, 1H, J = 17, 12, 10 Hz), 7.19 (dq, 1H, J = 12, 2 Hz). *Exact Mass* calcd. for $C_8H_{12}O_2$: 140.0837; found: 140.0841.

(E)-2-Methyl-2,4-pentadien-1-ol (11)

To a stirred solution–suspension of lithium aluminum hydride (2.55 g, 67 mmol) in 200 mL of dry ether at 0°C was added dropwise a solution of anhydrous ethanol (3.9 mL, 67 mmol). After the mixture had been stirred for 15 min, a solution of the ester **10** (12.3 g, 89 mmol) in 30 mL of dry ether was added and stirring was continued at 0°C for 1 h. Solid $Na_2SO_4 \cdot 10H_2O$ was added and stirring was maintained until a white granular precipitate formed. The mixture was filtered and the collected material was washed thoroughly with ether. Concentration of the combined filtrate and distillation (air-bath temperature ~60°C/0.1 Torr, receiving bath cooled to −78°C) gave 8.6 g (99%) of the alcohol **11**, a colorless liquid that exhibited ir (film): 3300, 1660, 1600 cm^{-1}; ^1H nmr (100 MHz), δ: 1.68 (s, 1H), 1.80 (s, 3H), 4.08 (s, 2H), 5.08–6.31 (m, 2H), 6.09 (br d, 1H, J = 10 Hz), 6.63 (ddd, 1H, J = 16, 10, 10 Hz). *Exact Mass* calcd. for $C_6H_{10}O$: 98.0731; found: 98.0730.

(E)-5-Bromo-4-methyl-1,3-pentadiene (16)

To a mixture of triphenylphosphine (23.6 g, 90 mmol) in 100 mL of dry acetonitrile at 0°C was added bromine (4.6 mL, 90 mmol) and the solution was stirred until triphenylphosphine dibromide precipitated as a flocculent white solid. To this suspension was added successively triethylamine (12.5 mL, 90 mmol) and a solution of the alcohol **11** (8.0 g, 81 mmol) in 15 mL of dry acetonitrile. The mixture was stirred at room temperature for 30 min and then was filtered. The collected material was washed thoroughly with petroleum ether and then filtered again. Removal of the solvent from the filtrate, followed by flash distillation (air-bath temperature ~40°C/0.1 Torr, receiver cooled to −78°C) of the residual oil gave 10 g (71%) of the bromide **16** as a pale yellow liquid; ir (film): 1645, 1600, 1210, 995, 920 cm^{-1}; ^1H nmr (80 MHz), δ: 1.92 (s, 3H), 4.05 (s, 2H), 5.15–5.43 (m, 2H), 6.13–6.68 (m, 2H). *Exact Mass* calcd. for $C_6H_9{}^{79}Br$: 159.9888; found: 159.9890.

Ethyl (2E,4E)-2-methyl-2,4-hexadienoate (12)

To a solution of (carboethoxyethylidene)triphenylphosphorane (10.86 g, 30 mmol) in 30 mL of dry dichloromethane was added dropwise 2.1 g (30 mmol) of freshly distilled (*E*)-2-butenal. The solution was refluxed for 20 h. Approximately 20 mL of solvent was removed under reduced pressure, the residual mixture was diluted with pentane, and the resultant mixture was filtered. The collected material was washed with pentane. Removal of the solvent from the combined filtrate and distillation (air-bath temperature 40°C/0.1 Torr, receiver cooled to −78°C) afforded 3.94 g (85%) of the ester **12**, which exhibited ir (film): 1710, 1640, 1615 cm^{-1}; ^1H nmr (100 MHz), δ: 1.31 (t, 3H, J = 8 Hz), 1.89 (d, 3H, J = 6 Hz), 1.94 (br s, 3H), 4.22 (q, 2H, J = 8 Hz), 6.10 (dq, 1H, J = 15, 6 Hz), 6.40 (dd, 1H, J = 15, 10 Hz), 7.21 (br d, 1H, J = 10 Hz). *Exact Mass* calcd. for $C_9H_{14}O_2$: 154.0994; found: 154.0992.

(2E,4E)-2-Methyl-2,4-hexadien-1-ol (13)

This alcohol was obtained by reduction of the ester **12** via a procedure very similar to that described for the preparation of **11** (see above). From 3.64 g (23.6 mmol) of the ester **12** there was obtained 2.6 g (98%) of the alcohol **13**; distillation temperature ~50°C/0.1 Torr (receiver cooled to −78°C); ir (film): 3325 cm^{-1}; ^1H nmr (80 MHz), δ: 1.58 (s, 1H), 1.80 (s, 3H), 1.83 (d, 3H, J = 7 Hz), 4.05 (s, 2H), 5.70 (dq, 1H, J = 15, 7 Hz), 6.00 (br d, 1H, J = 10 Hz), 6.30 (br dd, 1H, J = 15, 10 Hz). *Exact Mass* calcd. for $C_7H_{12}O$: 112.0888; found: 112.0892.

(2E,4E)-1-Bromo-2-methyl-2,4-hexadiene (17)

This substance was obtained from the alcohol **13** via a procedure similar to that outlined above for the preparation of the bromide **16**, except that the reaction time was 1 h rather than 30 min. Flash distillation (air-bath temperature 40–45°C/0.1 Torr, receiver cooled to −78°C) of the crude product provided 1.67 g (71%) of the bromide **17** as a pale yellow oil that darkened even when stored at −20°C in the dark. This material, which was routinely distilled immediately prior to being used, exhibited ir (film): 1650, 1610, 1445, 1215, 960 cm^{-1}; ^1H nmr (100 MHz), δ: 1.80 (d, 3H, J = 6 Hz), 1.87 (s, 3H), 4.05 (s, 2H), 5.70–6.42 (m, 3H). *Exact Mass* calcd. for $C_7H_{11}{}^{79}Br$: 174.0044; found: 174.0040.

Methyl (6E,8E)-10-methyl-3-oxo-6,8-undecadienoate (19)

To a cold (−78°C), stirred suspension of sodium hydride (0.15 g, 6.8 mmol) in dry THF (30 mL) was added a solution of methyl acetoacetate (0.719 g, 6.19 mmol) in dry THF (2 mL) and the mixture was stirred at 0°C for 10 min. A solution of *n*-butyllithium (6.81 mmol) was added and stirring was maintained at 0°C for an additional 15 min. A solution of the allylic bromide **15** (1.17 g, 6.19 mmol) in dry THF (3 mL) was added and the mixture was stirred at room temperature for 2 h. The mixture was diluted with ether and then was acidified with 5% hydrochloric acid. The layers were separated, the aqueous phase was washed with ether, and the combined organic extract was washed three times with brine and then dried ($MgSO_4$). Removal of the solvent and flash column chromatography (100 g of silica gel, elution with 5:1 petroleum ether – ethyl acetate) of the residual material afforded the β-keto ester **19** (0.743 g, 53%) as a colorless oil; ir (film): 1740, 1710, 1650, 1620, 993 cm^{-1}; ^1H nmr (400 MHz), δ: 1.00 (d, 6H, J = 7 Hz), 2.31 (overlapped d septet, 1H, J = 7, 7 Hz), 2.37 (overlapped dt, 2H, J = 7, 7 Hz), 2.65 (t, 2H, J = 7 Hz), 3.46 (s, 2H), 3.76 (s, 3H), 5.57 (overlapped dt, 1H, J = 14.5, 7 Hz), 5.61 (dd, 1H, J = 15, 7 Hz), 5.98 (dd, 1H, J = 15, 10 Hz), 6.06 (dd, 1H, J = 14.5, 10 Hz). *Exact Mass* calcd. for $C_{13}H_{20}O_3$: 224.1412; found: 224.1411.

Methyl (E)-3-oxo-6,8-nonadienoate (18)

To a solution of lithium diisopropylamide (LDA) (10.5 mmol) in 25 mL of dry THF at −5°C was added methyl acetoacetate (539 μL, 5.0 mmol), and the resulting yellow solution was stirred at 0°C for 20 min. The bromide **14** (735 mg, 5.0 mmol) was added and stirring

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

was continued at 0°C for 5 min. The reaction mixture was poured into a mixture of 1 *N* hydrochloric acid and ether. The layers were separated and the aqueous phase was extracted with ether. The combined organic extract was washed once with 1 *N* hydrochloric acid and three times with brine and then was dried ($MgSO_4$). Removal of the solvent, followed by distillation (air-bath temperature 81–85°C/0.1 Torr) of the residual oil, gave the desired product **18** (766 mg, 84%); ir (film): 1755, 1715, 1650, 1630, 1600 cm^{-1}; ^1H nmr (100 MHz), δ: 2.28–2.74 (m, 4H), 3.46 (s, 2H), 3.74 (s, 3H), 4.92–5.20 (m, 2H), 5.52–5.80 (m, 1H), 5.90–6.60 (m, 2H). *Exact Mass* calcd. for $C_{10}H_{14}O_3$: 182.0943; found: 182.0948.

*Methyl (*E*)-6-methyl-3-oxo-6,8-nonadienoate (**20**)*

This substance was prepared via a procedure very similar to that described above (preparation of **18**). From 712 μL (6.6 mmol) of methyl acetoacetate and 1.06 g (6.6 mmol) of the bromide **16** there was obtained a crude product that was subjected to flash column chromatography (silica gel, elution with 1:4 ether – petroleum ether). Distillation (air-bath temperature 88–92°C/0.1 Torr) of the oil thus obtained provided the keto ester **20** (920 mg, 71%); ir (film): 1750, 1720, 1655 cm^{-1}; ^1H nmr (100 MHz), δ: 1.78 (s, 3H), 2.34 (t, 2H, J = 8 Hz), 2.62–2.80 (m, 2H), 3.47 (s, 2H), 3.75 (s, 3H), 4.90–5.22 (m, 2H), 5.86 (br d, 1H, J = 10 Hz), 6.57 (overlapped ddd, 1H, J = 17, 10, 10 Hz). *Exact Mass* calcd. for $C_{11}H_{16}O_3$: 196.1099; found: 196.1102.

*Methyl (6*E*,8*E*)-6-methyl-3-oxo-6,8-decadienoate (**21**)*

This material was obtained from methyl acetoacetate (2.46 mL, 22.8 mmol) and the bromide **17** (4.0 g, 22.8 mmol) via a procedure very similar to that described for the preparation of **18** (see above). Purification of the crude product by flash column chromatography (silica gel, 3:1 pentane–ether) and distillation (air-bath temperature 103–108°C/0.1 Torr) afforded 2.87 g (60%) of the β-keto ester **21**; ir (film): 1750, 1720, 1650, 1630 cm^{-1}; ^1H nmr (80 MHz), δ: 1.73 (s, 3H), 1.76 (s, 3H), 2.20–2.80 (m, 4H), 3.48 (s, 2H), 3.75 (s, 3H), 5.58 (dq, 1H, J = 15, 6 Hz), 5.80 (d, 1H, J = 10 Hz), 6.25 (dd, 1H, J = 15, 10 Hz). *Exact Mass* calcd. for $C_{12}H_{18}O_3$: 210.1256; found: 210.1256.

*1-Carbomethoxy-6-*exo*-[(*E*)-3-methyl-1-butenyl]bicyclo[3.1.0]hexan-2-one (**27**)*

To a stirred solution of the β-keto ester **19** (200 mg, 0.89 mmol) and *p*-toluenesulfonyl azide (176 mg, 0.89 mmol) in dry acetonitrile (4 mL) was added triethylamine (0.89 mmol) and the mixture was stirred at room temperature for 24 h. Removal of the solvent under reduced pressure furnished a yellow residue, which was dissolved in a minimum amount of ether. Dilution of this solution with pentane precipitated *p*-toluenesulfonamide. The mixture was filtered through a layer of Celite. Removal of the solvent from the filtrate gave a yellow oil. The latter material was treated with pentane and the resultant mixture was refiltered to remove any residual insoluble material. Solvent removal (reduced pressure) provided 216 mg (97%) of the diazo compound **23** (ir (film): 2120, 1715, 1650 cm^{-1}), which showed a single spot on tlc analysis and was used without further purification.

To a stirred suspension of copper(II) acetylacetonate [$Cu(acac)_2$] (26 mg, 0.1 mmol) in dry, refluxing benzene (16 mL) was added dropwise a solution of the diazo keto ester **23** (180 mg, 0.72 mmol) in dry benzene (3 mL). The mixture was refluxed for 6 h, cooled to room temperature, and filtered through a layer of Celite. Removal of the solvent from the filtrate (reduced pressure) gave a dark yellow oil, which was subjected to preparative tlc (5:1 petroleum ether – ethyl acetate). Distillation (air-bath temperature 90–95°C/0.1 Torr) of the material thus obtained provided 125 mg (78%) of the desired compound **27**; ir (film): 1750, 1720 cm^{-1}; ^1H nmr (400 MHz), δ: 0.95, 0.96 (d, d, 3H each, J = 7 Hz), 2.00–2.34 (m, 6H), 2.67 (overlapped dd, 1H, J = 5.5, 5.5 Hz), 3.76 (s, 3H), 5.21 (ddd, 1H, J = 15.5, 8.5, 1 Hz), 5.71 (dd, 1H, J = 15.5, 7 Hz). *Exact Mass* calcd. for $C_{13}H_{18}O_3$: 222.1256; found: 222.1251.

*1-Carbomethoxy-6-*exo*-vinylbicyclo[3.1.0]hexan-2-one (**26**)*

Conversion of 3.03 g (16.6 mmol) of the β-keto ester **18** into 3.42 g (99%) of the corresponding diazo compound **22** (ir (film): 2125, 1720, 1655 cm^{-1}) was carried out as described above (preparation of **27**). Cyclization of **22** was accomplished as described above, except that the reaction medium was refluxing toluene instead of benzene, and the reaction time was 3 h. From 1.01 g (48.5 mmol) of **22** there was obtained, after purification of the crude product by flash column chromatography (4:1 petroleum ether – ethyl acetate) and distillation (air-bath temperature 100–110°C/0.1 Torr), 557 mg (64%) of the bicyclic keto ester **26**; ir (film): 1730 (br), 1635 cm^{-1}; ^1H nmr (100 MHz), δ: 2.0–2.4 (m, 5H), 2.64–2.77 (m, 1H), 3.78 (s, 3H), 5.12–5.86 (m, 3H). *Exact Mass* calcd. for $C_{10}H_{12}O_3$: 180.0787; found: 180.0787.

*1-Carbomethoxy-5-methyl-6-*exo*-vinylbicyclo[3.1.0]hexan-2-one (**28**)*

Treatment of 3.32 g (17 mmol) of the β-keto ester **20** with *p*-toluenesulfonyl azide (3.33 g, 17 mmol), as described above, provided 3.68 g (97%) of the diazo compound **24** (ir (film): 2125, 1720, 1665 cm^{-1}). Cyclization of the latter substance (3.68 g, 16.6 mmol) with $Cu(acac)_2$ in refluxing toluene (2 h) (see above), followed by purification of the crude product by flash column chromatography (4:1 petroleum ether – ethyl acetate) and distillation (air-bath temperature 83–88°C/0.1 Torr), afforded 1.84 g (57%) of the keto ester **28**. This material solidified on standing and exhibited mp 38–40°C; ir ($CHCl_3$): 1750, 1720, 1635 cm^{-1}; ^1H nmr (100 MHz), δ: 1.48 (s, 3H), 1.94–2.40 (m, 5H), 3.78 (s, 3H), 5.25 (dd, 1H, J = 10, 2 Hz), 5.32 (dd, 1H, J = 17, 2 Hz), 5.91 (overlapped ddd, 1H, J = 17, 10, 10 Hz). *Exact Mass* calcd. for $C_{11}H_{14}O_3$: 194.0943; found: 194.0949.

*1-Carbomethoxy-5-methyl-6-*exo*-[(*E*)-1-propenyl]bicyclo[3.1.0]-hexan-2-one (**29**)*

Conversion of the β-keto ester **21** (530 mg, 2.52 mmol) into the diazo compound **25** (595 mg, 100%; ir (film): 2125, 1720, 1655 cm^{-1}) was accomplished as described above (preparation of **27**). Copper-bronze (200 mg) catalyzed cyclization of **25** (595 mg) in refluxing toluene (25 mL, 2.5 h), followed by work-up as described above, gave a dark yellow oil. Purification of this material by preparative tlc (3:1 pentane–ether) and distillation (air-bath temperature 105–112°C/0.1 Torr) gave 259 mg (50%) of **29** as a colorless oil that solidified on standing. Recrystallization from pentane gave colorless crystals, mp 84–86°C; ir ($CHCl_3$): 1720 (br), 970 cm^{-1}; ^1H nmr (80 MHz), δ: 1.48 (s, 3H), 1.75 (d, 3H, J = 5 Hz), 1.9–2.6 (m, 5H), 3.79 (s, 3H), 5.3–6.1 (m, 2H). *Exact Mass* calcd. for $C_{12}H_{16}O_3$: 208.1100; found: 208.1105.

*1-Carbomethoxy-3-methyl-6-*exo*-vinylbicyclo[3.1.0]hexan-2-one (**30**)*

To a cold (−78°C), stirred solution of LDA (1.04 mmol) in 10 mL of dry THF was added a solution of the bicyclic keto ester **26** (156 mg, 0.87 mmol) in 2 mL of dry THF. The solution was stirred for 30 min. After addition of a mixture of iodomethane (108 μL, 1.74 mmol) and hexamethylphosphoramide (302 μL, 1.74 mmol), the reaction mixture was allowed to warm to room temperature and then was stirred for an additional 1 h. The solution was poured into brine and the resultant mixture was extracted thoroughly with pentane. The combined organic extract was washed with brine and dried ($MgSO_4$). Removal of the solvent, followed by distillation (air-bath temperature 110–115°C/0.1 Torr) of the residual yellow oil, gave 121 mg (72%) of compound **30**; ir (film): 1750, 1725, 1640 cm^{-1}; ^1H nmr (80 MHz), δ: 1.10 (d, 3H, J = 6 Hz), 1.68–2.60 (m, 5H), 3.80 (s, 3H), 5.08–5.85 (m, 3H). *Exact Mass* calcd. for $C_{11}H_{14}O_3$: 194.0943; found: 194.0946.

*2-(*tert*-Butyldimethylsiloxy)-1-carbomethoxy-6-*exo*-[(*E*)-3-methyl-1-butenyl]bicyclo[3.1.0]hex-2-ene (**32**)*

To a cold (−78°C), stirred solution of LDA (0.5 mmol) in dry THF (3 mL) was added a solution of the ketone **27** (100 mg, 0.45 mmol) in dry THF (1 mL) and the mixture was stirred for 30 min. After addition of a solution of freshly sublimed *tert*-butyldimethylsilyl chloride (98 mg, 0.65 mmol) and hexamethylphosphoramide (0.9 mmol) in dry THF (1 mL), the reaction mixture was stirred at −78°C for 30 min and at room temperature for 2 h. The solution was poured into saturated aqueous sodium bicarbonate and the layers were separated. The aqueous phase was extracted with ether. The combined extract was

For personal use only.

washed three times with brine and dried ($MgSO_4$). Removal of the solvent under reduced pressure gave a yellow oil that, upon purification by column chromatography on neutral alumina (80–100 mesh, petroleum ether) and distillation (air-bath temperature 149–152°C/0.1 Torr), afforded 131 mg (87%) of the enol silyl ether **32**; ir (film): 1720, 1620 cm^{-1}; ^1H nmr (400 MHz), δ: 0.16 (s, 6H), 0.95 (s, 9H), 0.97, 0.98 (d, d, 3H each, J = 7 Hz), 1.73 (dd, 1H, J = 9, 5 Hz), 2.11 (dd, 1H, J = 7, 5 Hz), 2.23 (dd, 1H, J = 16, 3 Hz), 2.24–2.34 (m, 1H), 2.58 (ddd, 1H, J = 16, 7, 2 Hz), 3.69 (s, 3H), 4.38 (br s, 1H), 5.48 (dd, 1H, J = 15, 9 Hz), 5.59 (dd, 1H, J = 15, 6 Hz). *Exact Mass* calcd. for $C_{19}H_{32}O_3Si$: 366.2121; found: 366.2122.

*2-(*tert*-Butyldimethylsiloxy)-6-*exo*-vinylbicyclo[3.1.0]hex-2-ene (**50**)*

Conversion of 6-*exo*-vinylbicyclo[3.1.0]hexan-2-one (24) (122 mg, 1.0 mmol) into the enol silyl ether **50** (224 mg, 95%; distillation temperature 50–54°C/0.2 Torr) was carried out via a procedure identical with that described above (preparation of **32**). Compound **50** exhibited ir (film): 1627, 1250, 1210, 840 cm^{-1}; ^1H nmr (400 MHz), δ: 0.15 (s, 6H), 0.93 (s, 9H), 1.14 (overlapped ddd, 1H, J = 9, 2, 2 Hz), 1.57–1.63 (m, 1H), 1.67–1.72 (m, 1H), 2.29 (overlapped ddd, 1H, J = 17, 3, 3 Hz), 2.52 (ddd, 1H, J = 17, 8, 2 Hz), 4.30 (br s, 1H), 4.86 (dd, 1H, J = 10, 2 Hz), 5.01 (dd, 1H, J = 16, 2 Hz), 5.41 (ddd, 1H, J = 16, 10, 9 Hz). *Exact Mass* calcd. for $C_{14}H_{24}OSi$: 236.1596; found: 236.1592.

*2-(*tert*-Butyldimethylsiloxy)-1-carbomethoxy-6-*exo*-vinylbicyclo-[3.1.0]hex-2-ene (**31**)*

To a solution of LDA (1.87 mmol) in 20 mL of dry THF at −78°C was added a solution of the ketone **26** (300 mg, 1.7 mmol) in 2 mL of dry THF and the solution was stirred for 20 min. Solid, freshly sublimed *tert*-butyldimethylsilyl chloride (385 mg, 2.55 mmol) and dry hexamethylphosphoramide (3.4 mmol) were added successively and the reaction mixture was stirred at −78°C for 30 min and at room temperature for 1 h. The solvent was removed under reduced pressure and the residual material was triturated several times with pentane. The combined pentane solution was washed with a small amount of brine and then was passed through a short column of Florisil (elution with 2:1 pentane–ether). Removal of the solvent from the eluate, followed by distillation (air-bath temperature 115–120°C/0.1 Torr) of the residual oil, gave 476 mg (97%) of the desired product **31**; ir (film): 1720, 860, 840, 780 cm^{-1}; ^1H nmr (100 MHz), δ: 0.08 (s, 6H), 0.88 (s, 9H), 1.72 (dd, 1H, J = 10, 6 Hz), 2.05–2.26 (m, 2H), 2.55 (ddd, 1H, J = 17, 6.5, 2.5 Hz), 3.64 (s, 3H), 4.33 (dd, J = 4.5, 2.5 Hz), 4.99 (dd, 1H, J = 10, 2.5 Hz), 5.12 (dd, J = 17, 2.5 Hz), 5.88 (overlapped ddd, 1H, J = 17, 10, 10 Hz). *Exact Mass* calcd. for $C_{16}H_{26}O_3Si$: 294.1652; found: 294.1657.

*2-(*tert*-Butyldimethylsiloxy)-1-carbomethoxy-5-methyl-6-*exo*-vinylbicyclo[3.1.0]hex-2-ene (**33**)*

Conversion of the ketone **28** (594 mg, 3.06 mmol) into the silyl enol ether **33** (888 mg, 94%; distillation temperature 94–98°C/0.1 Torr) was accomplished via a procedure very similar to that described above (preparation of **31**). Compound **33** exhibited ir (film): 1730, 1640, 840, 790 cm^{-1}; ^1H nmr (80 MHz), δ: 0.15 (s, 6H), 0.89 (s, 9H), 1.33 (s, 3H), 1.81 (d, 1H, J = 10 Hz), 2.43 (d, 2H, J = 2.5 Hz), 3.72 (s, 3H), 4.43 (t, 1H, J = 2.5 Hz), 5.13 (dd, 1H, J = 10, 2.5 Hz), 5.23 (dd, 1H, J = 17, 2.5 Hz), 6.25 (overlapped ddd, 1H, J = 17, 10, 10 Hz). *Exact Mass* calcd. for $C_{17}H_{28}O_3Si$: 308.1808; found: 308.1826.

*2-(*tert*-Butyldimethylsiloxy)-1-carbomethoxy-5-methyl-6-*exo*-[(*E*)-1-propenyl]bicyclo[3.1.0]hex-2-ene (**34**)*

This substance was prepared from the ketone **29** by the procedure described above (preparation of **31**). From 500 mg (2.4 mmol) of **29** there was obtained 717 mg (93%) of **34**; ir (film): 1730, 1640, 845 cm^{-1}; ^1H nmr (80 MHz), δ: 0.08 (s, 6H), 0.84 (s, 9H), 1.23 (s, 3H), 1.5–1.8 (m, 1H), 1.68 (d, 3H, J = 5 Hz), 2.33 (d, 2H, J = 2 Hz), 3.63 (s, 3H), 4.33 (t, 1H, J = 2 Hz), 5.40–5.97 (m, 2H). *Exact Mass* calcd. for $C_{18}H_{30}O_3Si$: 322.1964; found: 322.1985.

*2-(*tert*-Butyldimethylsiloxy)-1-carbomethoxy-3-methyl-6-*exo*-vinylbicyclo[3.1.0]hex-2-ene (**35**)*

Conversion of the ketone **30** (98 mg, 0.51 mmol) into the enol silyl ether **35** (102 mg, 65%; distillation temperature 105–110°C/0.1 Torr) was accomplished as described above (preparation of **31**). Compound **35** exhibited ir (film): 1725, 1675, 1635, 845, 785 cm^{-1}; ^1H nmr (100 MHz), δ: 0.04–0.07 (s, s, 3H each), 0.92 (s, 9H), 1.47 (br s, 3H), 1.4–2.8 (m, 4H), 3.66 (s, 3H), 4.90–6.05 (m, 3H). *Exact Mass* calcd. for $C_{17}H_{28}O_3Si$: 308.1808; found: 308.1802.

*6-(*tert*-Butyldimethylsiloxy)-7-carbomethoxy-4-*endo*-isopropylbicyclo[3.2.1]octa-2,6-diene (**37**)*

A solution of the enol silyl ether **32** (123 mg; 0.37 mmol) in dry benzene (2.5 mL) was placed in a pyrolysis tube[8] and was then degassed. The tube was cooled with liquid nitrogen, sealed under vacuum (0.1 Torr), and then was heated (200°C, 2 h) in a steel container (packed with sand). The tube was cooled to room temperature and unsealed. Removal of the solvent and distillation (air-bath temperature 131–136°C/0.1 Torr) of the remaining oil afforded 117 mg (95%) of the desired product **37**; ir (film): 1700, 1610, 1215, 850 cm^{-1}; ^1H nmr (400 MHz), δ: 0.19, 0.21 (s, s, 3H each), 0.91, 1.00 (d, d, 3H each, J = 7 Hz), 0.97 (s, 9H), 1.64 (d septet, 1H, J = 8.5, 7 Hz), 1.78 (d, 1H, J = 9.5 Hz), 2.06 (overlapped dddd, 1H, J = 8.5, 5, 2.5, 2.5 Hz), 2.20 (overlapped dddd, 1H, J = 9.5, 5, 4, 1 Hz), 2.73 (overlapped dd, 1H, J = 5, 4 Hz), 2.92 (overlapped dd, 1H, J = 6, 5 Hz), 3.66 (s, 3H), 5.44 (br d, J = 9.5 Hz), 6.30 (overlapped dddd, 1H, J = 9.5, 6, 2.5, 1 Hz). *Exact Mass* calcd. for $C_{19}H_{32}O_3Si$: 336.2121; found: 336.2128.

*6-(*tert*-Butyldimethylsiloxy)bicyclo[3.2.1]octa-2,6-diene (**51**)*

Thermolysis (200°C, 2 h) of compound **50** (112 mg, 0.47 mmol) was carried out via a procedure identical with that described above (preparation of **37**) except that no solvent was used. Distillation (air-bath temperature 79–82°C/0.1 Torr) of the thermolysate furnished 109 mg (97%) of the bicyclic diene **51** as a colorless oil; ir (film): 1615, 1245, 880 cm^{-1}; ^1H nmr (400 MHz), δ: 0.14, 0.16 (s, s, 3H each), 0.93 (s, 9H), 1.77 (d, 1H, J = 9.5 Hz), 2.06–2.23 (m, 3H), 2.46–2.54 (m, 2H), 5.11 (d, 1H, J = 2.5 Hz), 5.27–5.32 (m, 1H), 6.16–6.22 (m, 1H). *Exact Mass* calcd. for $C_{14}H_{24}OSi$: 236.1596; found: 236.1595.

*6-(*tert*-Butyldimethylsiloxy)-7-carbomethoxybicyclo[3.2.1]octa-2,6-diene (**36**)*

A solution of the silyl enol ether **31** (300 mg, 1.02 mmol) in 20 mL of dry, degassed xylene was heated to reflux for 2.5 h. The solution was cooled to room temperature and the solvent was removed under reduced pressure. The remaining oil was dissolved in pentane and the solution was passed through a short column of Florisil. The column was eluted with 5:1 pentane–ether. Removal of the solvent from the eluate provided 296 mg (99%) of compound **36**; ir (film): 1710, 1615, 840, 790 cm^{-1}; ^1H nmr (100 MHz), δ: 0.16 (s, 6H), 0.91 (s, 9H), 1.5–1.75 (m, 1H), 1.9–2.3 (m, 3H), 2.5–2.7 (m, 1H), 2.89 (br t, 1H, J = 5 Hz), 3.62 (s, 3H), 5.27 (m, 1H), 6.27 (m, 1H). *Exact Mass* calcd. for $C_{15}H_{23}O_3Si$ (M − CH_3): 279.1417; found: 279.1424.

*6-(*tert*-Butyldimethylsiloxy)-7-carbomethoxy-1-methylbicyclo[3.2.1]-octa-2,6-diene (**38**)*

Thermal rearrangement of **33** (440 mg, 1.43 mmol) in 50 mL of dry, refluxing xylene (6 h), followed by work-up as described above and distillation (air-bath temperature 100–105°C/0.1 Torr) of the oil thus obtained, afforded 410 mg (93%) of the product **38**; ir (film): 1700, 1600, 850, 790 cm^{-1}; ^1H nmr (80 MHz), δ: 0.21 (s, 6H), 0.98 (s, 9H), 1.30 (s, 3H), 1.55–2.80 (m, 5H), 3.69 (s, 3H), 5.29 (ddt, 1H, J = 10, 4, 2 Hz), 6.13 (br d, 1H, J = 10 Hz). *Exact Mass* calcd. for $C_{17}H_{28}O_3Si$: 308.1808; found: 308.1801.

*6-(*tert*-Butyldimethylsiloxy)-7-carbomethoxy-1,4(*endo*)-dimethylbicyclo[3.2.1]octa-2,6-diene (**39**)*

Thermolysis (4 h) of the enol silyl ether **34** (715 mg, 2.22 mmol) in

[8]The pyrolysis tubes (2-mm wall thickness) used in this study were treated as follows: (*a*) washed with detergent and water; (*b*) soaked (15 min) in 1% aqueous KOH; (*c*) washed with dry methanol and then with dry toluene; (*d*) soaked (15 min) in a 5% solution of *N*,*N*-bis(trimethylsilyl)acetamide in dry toluene; (*e*) rinsed with dry methanol, oven-dried, cooled, and stored in a desiccator.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

75 mL of dry, refluxing mesitylene, followed by work-up as described above (preparation of **36**), furnished 700 mg (98%) of the bicyclic diene **39**; ir (film): 1700, 1600, 840, 785 cm^{-1}; ^1H nmr (100 MHz), δ: 0.11, 0.14 (s, s, 3H each), 0.88 (s, 9H), 0.92 (d, 3H, J = 6 Hz), 1.20 (s, 3H), 1.50–2.58 (m, 4H), 3.60 (s, 3H), 5.07 (ddd, 1H, J = 10, 3, 2 Hz), 6.01 (br d, 1H, J = 10 Hz). *Exact Mass* calcd. for $C_{17}H_{27}O_3Si$ ($M - CH_3$): 307.1729; found: 307.1713.

*6-(*tert*-Butyldimethylsiloxy)-7-carbomethoxy-5-methylbicyclo[3.2.1]-octa-2,6-diene (40)*

A solution of 79 mg (0.26 mmol) of compound **35** in 10 mL of dry mesitylene was refluxed for 1 h. Work-up as described previously (preparation of **36**) gave 77 mg (97%) of the diene **40**; ir (film): 1700, 1600, 840, 790 cm^{-1}; ^1H nmr (100 MHz), δ: 0.06, 0.24 (s, s, 3H each), 0.88 (s, 9H), 1.07 (s, 3H), 1.5–2.8 (m, 4H), 2.88 (br t, 1H, J = 5 Hz), 3.60 (s, 3H), 5.33 (dt, 1H, J = 10, 3 Hz), 6.26 (m, 1H). *Exact Mass* calcd. for $C_{16}H_{25}O_3Si$ ($M - CH_3$): 293.1573; found: 293.1555.

*4-*endo*-Isopropylbicyclo[3.2.1]oct-2-en-6-one (47)*

To a stirred solution of the silyl enol ether **37** (150 mg, 0.45 mmol) in dry THF (5 mL) was added a THF solution of tetra-*n*-butylammonium fluoride (1.34 mmol) and the resulting mixture was stirred at room temperature for 1 h. The mixture was diluted with 1:1 ether – petroleum ether and then was poured into saturated aqueous ammonium chloride. The aqueous layer was extracted with ether and the combined extract was washed with brine and dried ($MgSO_4$). Removal of the solvent gave 100 mg of the β-keto ester **42** (mixture of epimers) as a pale yellow oil. A solution of this material in THF (7 mL) was treated with 5% hydrochloric acid (11 mL), the mixture was refluxed for 23 h, cooled to 0°C, and poured into saturated aqueous sodium bicarbonate. The aqueous phase was extracted with ether and the combined extract was washed with brine and dried ($MgSO_4$). Removal of the solvent and purification of the residual oil by flash column chromatography (18 g silica gel, 1:12 ether – petroleum ether) gave 37 mg (50%) of the bicyclic ketone **47**; ir (film): 1730 cm^{-1}; ^1H nmr (400 MHz), δ: 0.95, 1.06 (d, d, 3H each, J = 7 Hz), 1.43 (d septet, 1H, J = 10, 7 Hz), 2.00 (dd, 1H, J = 11.5, 3 Hz), 2.09 (dddd, 1H, J = 11.5, 5.5, 4, 1.5 Hz), 2.12 (overlapped dddd, 1H, J = 10, 5, 2.5, 2.5 Hz), 2.22 (dd, 1H, J = 17.5, 3 Hz), 2.28 (dd, 1H, J = 17.5, 5.5 Hz), 2.69–2.77 (m, 2H), 5.63 (ddd, 1H, J = 10, 2.5, 1.5 Hz), 6.05 (dddd, 1H, J = 10, 6, 2.5, 1.5 Hz). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1197.

Bicyclo[3.2.1]oct-2-en-6-one (46)

(a) From the enol silyl ether 36

To a cold (0°C) solution of the enol silyl ether **36** (111 mg, 0.38 mmol) in 7 mL of spectrograde methanol was added 66 mg (1.14 mmol) of anhydrous potassium fluoride and stirring was continued for 1 h at 0°C. Most of the solvent was removed (reduced pressure), the residue was treated with saturated aqueous ammonium chloride, and the resultant mixture was extracted with petroleum ether. The combined extract was washed with 1 *N* hydrochloric acid and twice with brine, and dried (Na_2SO_4). Removal of the solvent and distillation (air-bath temperature 85–88°C/0.1 Torr) of the residual oil gave 56 mg (82%) of the β-keto ester **41**, the ^1H nmr spectrum of which showed that this material consisted of a mixture of epimers (ratio ≈ 3:1). This material was dissolved in a mixture of THF (2 mL) and 1 *N* hydrochloric acid (5 mL) and the solution was refluxed for 4 h. The reaction mixture was poured into brine and the resultant mixture was extracted with pentane. The combined extract was washed with brine and dried ($MgSO_4$). Removal of the solvent, followed by distillation (air-bath temperature 40–45°C/0.1 Torr, receiver cooled to −78°C) of the remaining oil, gave 33 mg (88%) of the bicyclic ketone **46**; ir (film): 1730, 1640, 735 cm^{-1}; ^1H nmr (400 MHz), δ: 2.03 (d, 1H, J = 11 Hz), 2.08 (overlapped ddd, 1H, J = 11, 4.5, 4.5 Hz), 2.20 (br d, 1H, J = 18 Hz), 2.29 (dd, 1H, J = 17.5, 5 Hz), 2.34 (overlapped ddd, 1H, J = 17.5, 3, 1.5 Hz), 2.43 (overlapped dddd, 1H, J = 18, 5, 2.5, 2.5 Hz), 2.57–2.62 (m, 1H), 2.73–2.80 (m, 1H), 5.47 (overlapped ddd, 1H, J = 9.5, 3, 3 Hz), 6.01–6.09 (m, 1H). *Exact Mass* calcd. for $C_8H_{10}O$: 122.0732; found: 122.0732.

(b) From the enol silyl ether 51

A mixture of compound **51** (179 mg, 0.76 mmol), 5% hydrochloric acid (3 mL), and THF (3 mL) was stirred at room temperature for 6 h. The mixture was diluted with ether and poured slowly into saturated aqueous sodium bicarbonate. The layers were separated, the aqueous phase was extracted twice with ether, and the combined extract was washed with brine and dried. Removal of the solvent and distillation of the remaining oil gave 81 mg (88%) of the ketone **46**.

*1,4(*endo*)-Dimethylbicyclo[3.2.1]oct-2-en-6-one (48)*

The conversion of the enol silyl ether **39** into the β-keto ester **44** was accomplished via a procedure identical with that described above for the transformation of **36** into **41**. From 652 mg (2.0 mmol) of **39** there was obtained 347 mg (83%) of **44** (distillation temperature 92–96°C/0.1 Torr), which, on the basis of its ^1H nmr spectrum, consisted of a mixture of epimers in a ratio of about 1:1.

A solution of this material in methanol (20 mL) and 2 *N* aqueous potassium hydroxide (10 mL) was refluxed for 5 h. The solution was poured into aqueous ammonium chloride and the mixture was extracted thoroughly with 1:1 ether–pentane. The combined extract was washed with brine and dried ($MgSO_4$). Removal of the solvent and distillation (air-bath temperature 40–50°C/0.1 Torr, receiver cooled to −78°C) of the residual oil afforded 122 mg (50%) of the bicyclic ketone **48**; ir (film): 1730, 745, 700 cm^{-1}; ^1H nmr (100 MHz), δ: 1.01 (d, 3H, J = 7 Hz), 1.24 (s, 3H), 1.92–1.98 (m, 2H), 2.10–2.25 (m, 2H), 2.37–2.82 (diffuse m, 2H), 5.39 (overlapped ddd, 1H, J = 10, 2, 2 Hz), 5.77 (dd, 1H, J = 10, 2 Hz). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1045; found: 150.1044.

6-Methyl-1-hepten-4-yn-3-ol (56)

To a cold (−78°C), stirred solution of 3-methyl-1-butyne (1.5 mL, 14.7 mmol) in dry THF (25 mL) was added a hexane solution of *n*-butyllithium (16.1 mmol). The mixture was stirred at −30°C for 1 h and then a solution of propenal (1.08 mL, 16.1 mmol) in 5 mL of dry THF was added dropwise. After the reaction mixture had been allowed to warm to room temperature over a period of 1 h, it was diluted with ether and then was poured into saturated aqueous ammonium chloride. The organic phase was separated, washed (saturated aqueous sodium bicarbonate, brine), and dried ($MgSO_4$). Removal of the solvent, followed by distillation (air-bath temperature 65–68°C/0.1 Torr) of the residual oil, gave 1.57 g (86%) of the alcohol **56** as a colorless oil that exhibited ir (film): 3350 (br), 3050, 2215, 1630, 992, 930 cm^{-1}; ^1H nmr (80 MHz), δ: 1.18 (d, 6H, J = 7 Hz), 1.95 (br s, 1H, exchanges with D_2O), 2.62 (septet, 1H, J = 7 Hz), 4.87 (br s, 1H $w_{1/2}$ = 6 Hz), 5.20 (overlapped ddd, 1H, J = 10, 1.5, 1.5 Hz), 5.43 (overlapped ddd, 1H, J = 17, 1.5, 1.5 Hz), 6.00 (ddd, 1H, J = 17, 10, 5 Hz). *Exact Mass* calcd. for $C_8H_{12}O$: 124.0888; found: 124.0881.

*Ethyl (*E*)-8-methyl-4-nonen-6-ynoate (57)*

A stirred mixture of the alcohol **56** (1.82 g, 14.7 mmol), propanoic acid (0.066 mL, 0.88 mmol), and triethyl orthoacetate (13.4 mL) was heated at 130–135°C for 40.5 h. Most of the triethyl orthoacetate was removed by fractional distillation of the mixture at atmospheric pressure and the residual oil was subjected to flash chromatography (125 g of silica gel, 1:9 ether – petroleum ether). Distillation (air-bath temperature 91–104°C/0.1 Torr) of the oil obtained from the appropriate fractions provided 1.88 g (66%) of the ester **57** as an odoriferous, colorless oil that exhibited ir (film): 3000, 2190, 1730, 960 cm^{-1}; ^1H nmr (400 MHz), δ: 1.17 (d, 6H, J = 7 Hz), 1.25 (t, 3H, J = 7 Hz), 2.35–2.44 (m, 4H), 2.64 (septet, 1H, J = 7 Hz), 4.12 (q, 2H, J = 7 Hz), 5.49 (br d, 1H, J = 15.5 Hz), 5.95–6.04 (m, 1H). *Exact Mass* calcd. for $C_{12}H_{18}O_2$: 194.1307; found: 194.1316.

*(*E*)-8-Methyl-4-nonen-6-ynoic acid (58)*

A stirred mixture of methanol (20 mL), water (0.5 mL), potassium hydroxide (0.4 g, 7.1 mmol), and the ester **57** (1.15 g, 5.94 mmol) was refluxed for 3.5 h. The cooled solution was washed with petroleum ether and then was acidified (at 0°C) with 10% hydrochloric acid. The resulting mixture was extracted with ether and the combined extract was washed with brine and dried ($MgSO_4$). Removal of the solvent and distillation (air-bath temperature 139–143°C/0.1 Torr) of the residual material gave 0.77 g (78%) of the acid **58** as a colorless oil that solidified on standing. Recrystallization from heptane provided an analytical sample that exhibited mp 65.5–67.5°C; ir ($CHCl_3$): 3200–

For personal use only.

2500, 1701, 960 cm^{-1}; ^1H nmr (80 MHz), δ: 1.17 (d, 3H, J = 7 Hz), 2.32–2.52 (m, 4H), 2.65 (septet, 1H, J = 7 Hz), 5.53 (br d, 1H, J = 15.5 Hz), 5.85–6.30 (m, 1H). *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.25, H 8.49; found: C 72.09, H 8.40. *Exact Mass* calcd.: 166.0994; found: 166.0988.

*6-exo-(3-Methyl-1-butynyl)bicyclo[3.1.0]hexan-2-one (**61**)*

A stirred solution of the acid **58** (0.648 g, 3.9 mmol) and oxalyl chloride (1.02 mL, 11.7 mmol) in dry hexane (17 mL) was refluxed for 1 h. Removal of solvent and excess oxalyl chloride under reduced pressure, followed by distillation (air-bath temperature 70–75°C/0.1 Torr) of the residual oil, gave 0.60 g (83%) of the acid chloride **59** as a pungent, colorless oil. This material, which exhibited ir (film): 3000, 2190, 1790, 960 cm^{-1}, was dissolved in dry ether (4 mL) and the resultant solution was added, dropwise, to a cold (0°C), stirred solution of diazomethane (0.81 g, 19.3 mmol) in dry ether (30 mL). The solution was stirred at 0°C for 30 min and then was warmed to room temperature over a period of 1 h. Excess diazomethane was removed by passing argon, via a flame-polished pipette, through the solution for 30 min. Removal of the solvent afforded 0.60 g (97%) of the diazoketone **60**, a viscous yellow oil (ir (film): 3070, 2085, 1634, 960 cm^{-1}) that was used immediately for the next reaction.

To a stirred, refluxing suspension of copper(II) acetylacetonate (0.064 g) in dry benzene (16 mL) was added a solution of the diazoketone **60** (0.60 g) in 8 mL of dry benzene. The mixture was refluxed for 1 h and then was cooled to room temperature. Careful removal of the solvent under reduced pressure gave an oil that was subjected to flash chromatography (70 g of silica gel, 1:5 ether – petroleum ether). Distillation (air-bath temperature 74–80°C/0.1 Torr) of the oil thus obtained yielded 0.40 g (63% from the acid **58**) of the bicyclic ketone **61** as a colorless oil. This material exhibited ir (film): 3030, 1725, 1180, 882 cm^{-1}; ^1H nmr (400 MHz), δ: 1.12 (d, 6H, J = 6.5 Hz), 1.70–1.75 (m, 1H), 1.94–2.18 (m, 5H), 2.24 (dd, 1H, J = 10.5, 4.5 Hz), 2.49 (d septet, 1H, J = 6.5, 1.5 Hz). *Exact Mass* calcd. for $C_{11}H_{14}O$: 162.1045; found: 162.1044.

*6-exo-[(Z)-3-Methyl-1-butenyl]bicyclo[3.1.0]hexan-2-one (**62**)*

To a stirred, prehydrogenated suspension of Lindlar's catalyst (5% Pd on $CaCO_3$, 10 mg) in dry pentane (15 mL) containing 4 μL of quinoline was added a solution of the keto alkyne **61** (0.20 g, 1.23 mmol) in pentane (2 mL) and the mixture was stirred under hydrogen (1 atmosphere (101.3 kPa)) at room temperature. Reaction progress was monitored by glc, which indicated the absence of starting material after 2.5 h. The reaction mixture was filtered through Celite. Removal of the solvent from the filtrate gave a pale yellow oil that was shown (glc) to consist of the desired product **62** (>95%), along with a small amount of corresponding *trans* isomer. Subjection of this mixture to column chromatography (20 g of silica gel impregnated with 5 g of silver nitrate, 1:12 ether – petroleum ether), followed by distillation (air-bath temperature 75–80°C/0.1 Torr) of the oil thus obtained, furnished 190 mg (94%) of the keto alkene **62** as a colorless oil. This material exhibited ir (film): 3000, 1722 cm^{-1}; ^1H nmr (400 MHz), δ: 0.99, 1.01 (d, d, 3H each, J = 6.5, 6.5 Hz), 1.75 (dd, 1H, J = 5, 2.5 Hz), 2.00–2.21 (m, 6H), 2.70 (dd, septet, 1H, J = 9, 1, 6.5 Hz), 4.65 (overlapped ddd, 1H, J = 10.5, 9.5, 1 Hz), 5.24 (overlapped ddd, 1H, J = 10.5, 9.0, <1 Hz). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1203.

*2-(tert-Butyldimethylsiloxy)-6-exo-[(Z)-3-methyl-1-butenyl]bicyclo-[3.1.0]hex-2-ene (**63**)*

Conversion of the ketone **62** (160 mg, 0.98 mmol) into the enol silyl ether **63** (266 mg, 98%; distillation temperature 110–115°C/0.1 Torr) was carried out via a procedure identical with that described previously for the preparation of **32**. Compound **63**, a colorless oil, exhibited ir (film): 3030, 1625, 1255, 960, 787 cm^{-1}; ^1H nmr (400 MHz), δ: 0.17, 0.18 (s, s, 3H each), 0.94 (s, 9H), 0.99 (d, 6H, J = 6.5 Hz), 1.28 (br d, 1H, J = 10 Hz), 1.50–1.55 (m, 1H), 1.59–1.64 (m, 1H), 2.30 (overlapped ddd, 1H, J = 16.5, 3, 3 Hz), 2.52 (ddd, 1H, J = 16.5, 7, 2 Hz), 2.73 (dd septet, 1H, J = 9.5, <1, 6.5 Hz), 4.31 (br s, 1H, $w_{1/2}$ = 5.5 Hz), 4.64 (overlapped dd, 1H, J = 10.5, 10 Hz), 5.14 (overlapped dd, 1H, J = 10.5, 9.5 Hz). *Exact Mass* calcd. for $C_{17}H_{30}OSi$: 278.2066; found: 278.2073.

*6-(tert-Butyldimethylsiloxy)-4-exo-isopropylbicyclo[3.2.1]octa-2,6-diene (**64**)*

Thermal rearrangement (240°C, 4.5 h) of compound **63** (100 mg, 0.36 mmol) in dry benzene (2.5 mL) was carried out via a procedure similar to that described previously for the thermolysis of **32** (preparation of **37**). Distillation (air-bath temperature 89–93°C/0.1 Torr) of the crude product afforded 93 mg (93%) of the bicyclic diene **64** as a colorless oil that exhibited ir (film): 3050, 3010, 1620, 841, 785 cm^{-1}; ^1H nmr (400 MHz), δ: 0.13, 0.15 (s, s, 3H each), 0.92 (s, 9H), 0.96, 0.99 (d, d, 3H each, J = 7, 7 Hz), 1.68 (d septet, 1H, J = 7, 7 Hz), 1.75 (d, 1H, J = 9.5 Hz), 1.88–1.94 (m, 1H), 1.97 (overlapped dddd, 1H, J = 9.5, 5, 3, 1 Hz), 2.38 (br d, 1H, J = 5 Hz), 2.52–2.57 (m, 1H), 5.11 (d, 1H, J = 3 Hz), 5.33 (overlapped ddd, 1H, J = 9.5, 3, 2 Hz), 6.21 (overlapped dddd, 1H, J = 9.5, 6, 2, 1 Hz). *Exact Mass* calcd. for $C_{17}H_{30}OSi$: 278.2066; found: 278.2067.

*4-exo-Isopropylbicyclo[3.2.1]oct-2-en-6-one (**65**)*

A mixture of the enol silyl ether **64** (158 mg, 0.57 mmol), 5% hydrochloric acid (14 mL), and THF (6 mL) was stirred at room temperature for 3 h. The reaction mixture was cooled, diluted with ether, and then was poured into saturated aqueous sodium bicarbonate. The layers were separated and the aqueous phase was extracted thoroughly with ether. The combined ether extract was dried ($MgSO_4$) and concentrated to afford a pale yellow oil that was subjected to flash chromatography on silica gel (18 g; 1:9 ether – petroleum ether). Distillation (air-bath temperature 98–101°C/0.1 Torr) of the oil thus obtained gave 53 mg (57%) of the ketone **65** as a colorless oil; ir (film): 3013, 1735, 741 cm^{-1}; ^1H nmr (400 MHz), δ: 0.97, 0.98, (d, d, 3H each, J = 6.5, 6.5 Hz), 1.68 (d septet, 1H, J = 8, 6.5 Hz), 1.85–1.93 (m, 2H), 2.06 (br d, 1H, J = 11.5 Hz), 2.23 (dd, 1H, J = 16.5, 5 Hz), 2.28 (overlapped ddd, 1H, J = 16.5, 2.5, 1.5 Hz), 2.59 (br d, 1H, J = 5.5 Hz), 2.73–2.79 (m, 1H), 5.55 (ddd, 1H, J = 9.5, 3.5, 1.5 Hz), 6.07 (overlapped dddd, 1H, J = 9.5, 6.5, 2, 1.5 Hz). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1205.

*1-Carbomethoxy-6-exo-vinylbicyclo[3.1.0]hex-3-en-2-one (**68**)*

To a cold (−78°C), stirred solution of LDA (1.2 mmol) in 10 mL of dry THF was added a solution of the keto ester **26** (180 mg, 1 mmol) in 2 mL of dry THF, and the solution was stirred at −78°C for 30 min. A solution of phenylselenenyl chloride (230 mg, 1.2 mmol) and hexamethylphosphoramide (348 μL, 2.0 mmol) in 2 mL of dry THF was added, stirring was continued for 5 min, and the cold reaction mixture was poured into a mixture of 1 *N* hydrochloric acid and pentane–ether (1:1). The layers were separated and the aqueous phase was extracted with 1:1 pentane–ether. The combined organic extract was washed (saturated aqueous sodium bicarbonate), dried (Na_2SO_4), and concentrated. The remaining yellow oil was purified by preparative tlc (silica gel, chloroform) to afford 230 mg (69%) of the α-phenylseleno ketones **66** as a viscous yellow oil (ir (film): 1720, 745 cm^{-1}).

To a cold (0°C), stirred solution of the α-phenylseleno ketones **66** (428 mg, 1.28 mmol) in 25 mL of dichloromethane was added a solution of 30% hydrogen peroxide (0.35 mL) in 2 mL of water and the resulting two-phase system was stirred vigorously at room temperature for 30 min. The layers were separated and the aqueous phase was extracted with dichloromethane. The combined organic extract was washed twice with brine, dried ($MgSO_4$), and concentrated. Distillation (air-bath temperature 98–102°C/0.1 Torr) of the remaining yellow oil afforded 106 mg (47%) of the enone **68**, a colorless oil that exhibited ir (film): 1740, 1705, 1575 cm^{-1}; ^1H nmr (100 MHz), δ: 2.51 (dd, 1H, J = 10, 4 Hz), 3.12 (dd, 1H, J = 4, 3 Hz), 3.83 (s, 3H), 5.22 (dd, 1H, J = 10, 2 Hz), 5.32 (dd, 1H, J = 18, 2 Hz), 5.81 (d, 1H, J = 6 Hz), 5.86 (overlapped ddd, 1H, J = 18, 10, 10 Hz), 7.66 (dd, 1H, J = 6, 3 Hz). *Exact Mass* calcd. for $C_{10}H_{10}O_3$: 178.0629; found: 178.0629.

*6-exo-Vinylbicyclo[3.1.0]hex-3-en-2-one (**69**)*

To a cold (−78°C), stirred solution of LDA (4.9 mmol) in 10 mL of dry THF was added a solution of 6-*exo*-vinylbicyclo[3.1.0]hexan-2-one (500 mg, 4.1 mmol) in 7 mL of dry THF, and the resultant solution was stirred at −78°C for 30 min. A solution of phenylselenenyl chloride (940 mg, 4.9 mmol) in 6 mL of dry THF was added dropwise (syringe). After the mixture had been stirred at 0°C for 30 min, a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

solution of acetic acid (0.47 mL, 8.2 mmol) in water (0.5 mL) was added. Subsequently, 30% hydrogen peroxide (2.3 g, 20.5 mmol) was added dropwise and the mixture was stirred at 0°C for 1 h. The mixture was diluted with 1:1 ether – petroleum ether and then was poured into saturated aqueous sodium bicarbonate. The layers were separated, the aqueous phase was extracted with ether, and the combined organic extract was washed with brine and dried ($MgSO_4$). Removal of the solvent, followed by distillation (air-bath temperature 78–83°C/0.1 Torr) of the remaining oil, provided 430 mg (88%) of the enone **69** as a colorless oil; ir (film): 3070, 3050, 1690, 1640 cm^{-1}; ^1H nmr (400 MHz), δ: 2.17 (overlapped ddd, 1H, J = 9, 2.5, 2.5 Hz), 2.27–2.32 (m, 1H), 2.59 (overlapped ddd, 1H, J = 4, 3, 2.5 Hz), 5.06 (dd, 1H, J = 10, 1 Hz), 5.20 (dd, 1H, J = 17, 1 Hz), 5.45 (ddd, 1H, J = 17, 10, 9 Hz), 5.70 (d, 1H, J = 5.5 Hz), 7.64 (ddd, 1H, J = 5.5, 2.5, 1 Hz). *Exact Mass* calcd. for C_8H_8O: 120.0575; found: 120.0574.

*1-Carbomethoxybicyclo[3.2.1]octa-2,6-dien-8-one (**70**)*

A stirred solution of the enone **68** (15 mg, 0.08 mmol) in 5 mL of dry xylene was refluxed for 18 h. The solution was cooled and the solvent was removed under reduced pressure. Bulb-to-bulb distillation (air-bath temperature 76–80°C/0.1 Torr) of the residual oil afforded 11 mg (73%) of the bicyclic ketone **70**, a colorless oil that exhibited ir (film): 1770, 1730 cm^{-1}; ^1H nmr (100 MHz), δ: 2.35–3.05 (m, 2H), 2.9–3.0 (m, 1H), 3.82 (s, 3H), 5.58 (br dt, 1H, J = 10, 3 Hz), 6.28 (dd, 1H, J = 7, 3 Hz), 6.30 (m, 1H), 6.70 (d, 1H, J = 7 Hz). *Exact Mass* calcd. for $C_{10}H_{10}O_3$: 178.0629; found: 178.0629.

*Bicyclo[3.2.1]octa-2,6-dien-8-one (**71**)*

Thermolysis (160°C, 4 h) of the enone **69** (40 mg, 0.33 mmol) in dry benzene (3 mL) was accomplished via a procedure similar to that employed for the thermolysis of **32** (*vide supra*, preparation of **37**). Distillation (air-bath temperature 47–51°C/0.1 Torr) of the crude product gave 27 mg (68%) of the ketone **71** as a colorless oil that exhibited ir (film): 3050, 1755, 1622, 680 cm^{-1}; ^1H nmr (400 MHz), δ: 2.45–2.53 (m, 1H), 2.73–2.82 (m, 3H), 5.46–5.53 (m, 1H), 6.04 (overlapped dddd, 1H, J = 9, 7, 3, 2 Hz), 6.21 (dd, 1H, J = 7, 3 Hz), 6.69 (dd, 1H, J = 7, 3 Hz). *Exact Mass* calcd. for C_8H_8O: 120.0575; found: 120.0563.

*4-exo-6-exo-Divinylbicyclo[3.1.0]hexan-2-one (**72**)*

To a cold (−30°C), stirred solution of vinylmagnesium bromide (1.4 mmol) in 3 mL of dry THF was added copper(I) bromide – dimethyl sulfide complex (3.0 mg, 0.013 mmol) and the mixture was stirred at −30°C for 10 min. A solution of the enone **69** (95 mg, 0.79 mmol) in dry THF (3 mL) was added dropwise over a period of 10 min. After the reaction mixture had been allowed to warm to 0°C over a period of 40 min, it was diluted with ether and then poured into saturated aqueous ammonium chloride. The aqueous phase was extracted with ether and the combined organic extract was washed (once with saturated aqueous sodium bicarbonate, twice with brine), dried ($MgSO_4$), and concentrated. Distillation (air-bath temperature 80–85°C/0.1 Torr) of the residual oil furnished 93 mg (80%) of the ketone **72** as a colorless oil that exhibited ir (film): 3050, 1718, 1635, 990, 915 cm^{-1}; ^1H nmr (400 MHz), δ: 1.87–1.94 (m, 2H), 1.97 (overlapped ddd, 1H, J = 8.5, 4, 4 Hz), 2.04 (overlapped dd, 1H, J = 5, 4 Hz), 2.36 (dd, 1H, J = 18.5, 8 Hz), 3.02 (overlapped dd, 1H, J = 8, 8 Hz), 5.01 (dd, 1H, J = 10.5, 1 Hz), 5.04 (overlapped ddd, 1H, J = 10, 1, 1 Hz), 5.12 (overlapped ddd, 1H, J = 17.5, 1, 1 Hz), 5.15 (ddd, 1H, J = 17, 1, <1 Hz), 5.36 (ddd, 1H, J = 17, 10.5, 8.5 Hz), 5.84 (ddd, 1H, J = 17.5, 10, 8 Hz). *Exact Mass* calcd. for $C_{10}H_{12}O$: 148.0888; found: 148.0886.

*2-(tert-Butyldimethylsiloxy)-4-exo-6-exo-divinylbicyclo[3.1.0]hex-2-ene (**73**)*

Conversion of the ketone **72** (140 mg, 0.94 mmol) into the enol silyl ether **73** (240 mg, 97%; distillation temperature 130–135°C/0.1 Torr) was accomplished via a procedure identical with that employed for the transformation of **27** into **32** (*vide supra*). Compound **73**, a colorless oil, exhibited ir (film): 3060, 3015, 1618 cm^{-1}; ^1H nmr (400 MHz), δ: 0.18 (s, 6H), 0.95 (s, 9H), 1.23 (overlapped ddd, 1H, J = 8.5, 3.5, 2.5 Hz), 1.51 (ddd, 1H, J = 6.5, 3.5, 1.5 Hz), 1.75 (overlapped ddd, 1H, J = 6.5, 2.5, 2.5 Hz), 3.13 (br d, 1H, J = 7.5 Hz), 4.31 (br s, 1H, $w_{1/2}$ = 5 Hz), 4.88 (dd, 1H, J = 10.5, 1.5 Hz), 4.94 (ddd, 1H, J = 10, 2, 1 Hz), 5.03 (dd, 1H, J = 17, 1.5 Hz), 5.05 (ddd, 1H, J = 17, 2, 1 Hz), 5.41 (ddd, 1H, J = 17, 10.5, 8.5 Hz), 5.75 (ddd, 1H, J = 17, 10, 7.5 Hz). *Exact Mass* calcd. for $C_{16}H_{26}OSi$: 262.1753; found: 262.1759.

*2-(tert-Butyldimethylsiloxy)-4-exo-carboethoxymethyl-6-exo-vinylbicyclo[3.1.0]hex-2-ene (**74**)*

A stirred mixture of the enone **69** (157 mg, 1.3 mmol), 1-*tert*-butyldimethylsiloxy-1-ethoxyethene (397 mg, 1.96 mmol), and dry acetonitrile (3 mL) was heated at 55°C for 12 h. The solvent was removed and the residual oil was distilled. The colorless oil (140 mg, 33%) with distillation temperature 103–106°C/0.1 Torr proved to be the enol silyl ether **74**, which exhibited ir (film): 3050, 1730, 1620, 1255, 787 cm^{-1}; ^1H nmr (400 MHz), δ: 0.16 (s, 6H), 0.94 (s, 9H), 1.21 (overlapped ddd, 1H, J = 9, 3.5, 2.5 Hz), 1.26 (t, 3H, J = 7.5 Hz), 1.49 (overlapped ddd, 1H, J = 6.5, 3.5, 1.5 Hz), 1.73 (overlapped ddd, 1H, J = 6.5, 2.5, 2.5 Hz), 2.29 (dd, 1H, J = 15, 8 Hz), 2.34 (dd, 1H, J = 15, 7 Hz), 2.88–2.94 (m, 1H), 4.14 (q, 2H, J = 7 Hz), 4.35 (br s, 1H, $w_{1/2}$ = 5 Hz), 4.87 (dd, 1H, J = 10, 1.5 Hz), 5.20 (dd, 1H, J = 17, 1.5 Hz), 5.40 (ddd, 1H, J = 17, 10, 9 Hz). *Exact Mass* calcd. for $C_{18}H_{30}O_3Si$: 322.1964; found: 322.1957.

*6-(tert-Butyldimethylsiloxy)-8-exo-vinylbicyclo[3.2.1]octa-2,6-diene (**75**)*

Thermolysis (200°C, 5 h) of the divinylcyclopropane **73** (118 mg, 0.45 mmol) in dry benzene (2.5 mL) was carried out via a procedure similar to that used for the conversion of **32** into **37** (*vide supra*). Distillation (air-bath temperature 80–85°C/0.1 Torr) of the crude product gave 105 mg (89%) of the bicyclic compound **75**, a colorless oil that exhibited ir (film): 3050, 3010, 1624, 1245, 790 cm^{-1}; ^1H nmr (400 MHz), δ: 0.14, 0.15 (s, s, 3H each), 0.92 (s, 9H), 2.14–2.28 (m, 2H), 2.31–2.35 (m, 1H), 2.38 (dd, 1H, J = 6, 2.5 Hz), 2.65 (d, 1H, J = 7.5 Hz), 4.95–5.01 (m, 2H), 5.08 (ddd, 1H, J = 17.5, 2, 1 Hz), 5.33 (br d, 1H, J = 9.5 Hz), 6.03 (ddd, 1H, J = 17.5, 10, 7.5 Hz), 6.25 (dddd, 1H, J = 9.5, 6, 2, 2 Hz). *Exact Mass* calcd. for $C_{16}H_{26}OSi$: 262.1753; found: 262.1752.

*6-(tert-Butyldimethylsiloxy)-8-exo-(carboethoxymethyl)bicyclo-[3.2.1]octa-2,6-diene (**76**)*

Thermolysis (200°C, 2.5 h) of compound **74** (68 mg, 0.21 mmol) in dry benzene (3 mL) was accomplished via a procedure similar to that employed for the rearrangement of **32** to **37** (*vide supra*). Distillation (air-bath temperature 131–135°C/0.1 Torr) of the crude product afforded 65 mg (95%) of compound **76** as a colorless oil; ir (film): 3050, 3010, 1725, 1620, 790 cm^{-1}; ^1H nmr (400 MHz), δ: 0.14, 0.16 (s, s, 3H each), 0.92 (s, 9H), 1.26 (t, 3H, J = 7 Hz), 2.15 (br dd, 1H, J = 5.5, 2.5 Hz), 2.43–2.52 (m, 3H), 4.13 (q, 2H, J = 7 Hz), 4.97 (d, 1H, J = 2.5 Hz), 5.28–5.33 (br d, 1H, J = 10 Hz), 6.20–6.26 (m, 1H). *Exact Mass* calcd. for $C_{18}H_{30}O_3Si$: 322.1964; found: 322.1963.

*8-exo-Vinylbicyclo[3.2.1]oct-2-en-6-one (**77**)*

A mixture of the enol silyl ether **75** (96 mg, 0.37 mmol), 5% hydrochloric acid (9 mL), and THF (5 mL) was stirred at room temperature for 5.5 h, was diluted with 1:1 ether – petroleum ether, and then was poured slowly into saturated aqueous sodium bicarbonate. The layers were separated and the aqueous phase was extracted with ether. The combined organic extract was washed with brine, dried ($MgSO_4$), and concentrated. Distillation of the residual oil provided 50 mg (93%) of the ketone **77** as a colorless oil that exhibited ir (film): 3052, 3010, 1730, 1630, 998, 920, 730 cm^{-1}; ^1H nmr (400 MHz), δ: 2.20 (dd, 1H, J = 17.5, 2 Hz), 2.30 (overlapped dddd, 1H, J = 18, 3.5, 2, 2 Hz), 2.43 (dd, 1H, J = 17.5, 6 Hz), 2.52 (overlapped dddd, 1H, J = 18, 5.5, 2, 2 Hz), 2.59–2.63 (m, 1H), 2.66 (overlapped dd, 1H, J = 6.5, 6 Hz), 2.91 (br d, 1H, J = 5.5, 2 Hz), 5.08 (overlapped ddd, 1H, J = 17.5, 1.5, 1 Hz), 5.14 (overlapped ddd, 1H, J = 10.5, 1.5, 1.5 Hz), 5.53 (overlapped ddd, 1H, J = 9.5, 3.5, 2 Hz), 5.90 (ddd, 1H, J = 17.5, 10.5, 5.5 Hz), 6.14 (dddd, 1H, J = 9.5, 6.5, 2, 2 Hz). *Exact Mass* calcd. for $C_{10}H_{12}O$: 148.0888; found: 148.0887.

*8-exo-(Carboethoxymethyl)bicyclo[3.2.1]oct-2-en-6-one (**78**)*

Hydrolysis of the enol silyl ether **76** (54 mg, 0.168 mmol) with 5%

hydrochloric acid (2 mL) in THF (2 mL) was carried out via a procedure very similar to that described above (**75** → **77**). The keto ester **78** (33 mg, 94%), a colorless oil, exhibited ir (film): 3000, 1740, 1730, 1625 cm^{-1}; ^1H nmr (400 MHz), δ: 1.27 (t, 3H, J = 7 Hz), 2.22–2.45 (m, 6H), 2.54 (overlapped dddd, 1H, J = 18, 5.5, 2.5, 2 Hz), 2.60 (overlapped ddd, 1H, J = 7, 6, 1 Hz), 2.70 (overlapped dd, 1H, J = 8, 7.5 Hz), 4.15 (q, 2H, J = 7 Hz), 5.51 (overlapped ddd, 1H, J = 9.5, 3.5, 2.5 Hz), 6.11 (overlapped dddd, 1H, J = 9.5, 7, 2, 2 Hz). *Exact Mass* calcd. for $C_{12}H_{16}O_3$: 208.1099; found: 208.1096.

The He(I) photoelectron spectra of the propenoyl halides

DIETER KLAPSTEIN[1] AND ROBERT T. O'BRIEN
Department of Chemistry, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received September 5, 1986

DIETER KLAPSTEIN and ROBERT T. O'BRIEN. Can. J. Chem. **65**, 683 (1987).

The He(I) photoelectron spectra of propenal and the propenoyl halides, CH_2=CHCOX, X = H, F, Cl, Br, were measured and interpreted with the aid of semi-empirical MO calculations, comparison with results for structurally related species, and a sum-rule for the out-of-plane orbital energies. Information concerning the identities and relative energies of the higher occupied molecular orbitals of the neutral molecules could be deduced from the spectra.

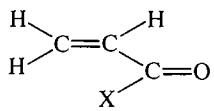
DIETER KLAPSTEIN et ROBERT T. O'BRIEN. Can. J. Chem. **65**, 683 (1987).

On a mesuré les spectres photoélectroniques He(I) du proènal et des halogénures de propènoyles, CH_2=CHCOX dans lesquels X = H, F, Cl et Br, et on les interprète à l'aide de calculs d'OM semi-empiriques, de comparaisons avec des résultats obtenus avec des espèces qui leur sont apparentées par la structure et d'une règle des sommes pour les énergies des orbitales hors-plan. L'information relative aux identités et aux énergies relatives des orbitales moléculaires hautes occupées des molécules neutres peut être déduite des spectres.

[Traduit par la revue]

Introduction

Valence-shell photoelectron spectroscopy is a powerful tool for studying the electronic structure of molecules through the approximation of Koopmans' Theorem (1), which equates an MO eigenvalue with the experimentally observed (vertical) ionization energy, $IE_v(i) = -\epsilon(i)$. Each band in a spectrum corresponds to ionization from a specific MO, and the IE is directly related to the MO energy. This paper reports the He(I) photoelectron spectra of a series of α,β-unsaturated carbonyl compounds of the general structure:



The specific members are propenal (acrolein), X = H, and the propenoyl halides, X = F, Cl, and Br. The spectra were interpreted by comparison with the spectra of structurally related molecules and by the use of semi-empirical molecular orbital calculations. The PE spectrum of propenal has been presented and interpreted elsewhere (2), but is included here to aid in the interpretation of the spectra of the propenoyl halides, reported here for the first time.

The primary goal of this study was to determine the identities and relative energies of some of the least-bound, occupied, MOs and their energy variation with the carbonyl substituent X. These MOs are expected to be the oxygen lone-pair, the ethenyl π-, and the carbonyl π-orbitals. Also, the degree of interaction between the out-of-plane π-orbitals, and the out-of-plane "lone-pair" orbital of the halogens, is of interest. We have previously studied similar trends and interactions in a similar series of ethynyl carbonyl compounds (3).

Experimental

The spectra were obtained with a photoelectron spectrometer incorporating a helium high voltage dc discharge lamp and a 127° cylindrical electron energy analyzer (32 mm mean radius) operated with a constant bandpass. The signals were gathered with a Nicolet 1170 Signal Averager and Apple IIe microcomputer data acquisition system. The working resolution of the full spectra scans was 30 meV, and was increased to 20 meV for scans of bands displaying fine structure. The ionization energy scale was calibrated with argon, nitrogen, and iodomethane. The band positions have an uncertainty of ±0.02 eV.

Commercial samples of propenal and propenoyl chloride (Aldrich) were used following vacuum distillation. Propenoyl fluoride was prepared by refluxing propenoyl chloride with potassium hydrogen fluoride, the acid fluoride being distilled off as it was formed, and purified by vacuum distillation. Propenoyl bromide was prepared by refluxing a mixture of propenoic (acrylic) acid and phosphorus tribromide, the acid bromide being distilled off as it was formed, and purified by vacuum distillation. The bromide was found to be quite sensitive to light. The purities of all samples were checked by gas-phase infrared and uv absorption spectroscopies, and for the bromide by ^{13}C nmr spectroscopy.

Semi-empirical molecular orbital calculations were carried out using CNDO/2 (4) and HAM/3 (5) programs adapted for use on a VAX 11/780 computer. The HAM/3 program was not parameterized for chlorine and neither program could handle bromine. The CNDO/2 eigenvalues have been divided by 1.35 to give better agreement with the observed IEs. The structural parameters used in the calculations were those assumed in the analyses of the microwave spectra (6).

Results and discussion

The molecules of this ethenyl carbonyl series may exist as rotational isomers by rotation about the ethenyl–carbonyl σ-bond. While propenal exists almost exclusively as the s-*trans* form in the gas-phase (at 25°C), the propenoyl halides exist as mixtures of two isomers, s-*trans* and s-*cis*. By studying the temperature-dependent ir (7, 8) and nmr (9) spectra, it has been concluded that the major form is s-*trans*. Of the two SCF-MO programs available to us, CNDO/2 and HAM/3, the latter predicts ionization energies in better agreement with experiment. The HAM/3 program was applied to propenoyl fluoride which has the highest percentage of s-*cis*, 40% at 25°C (7), to see how the individual ionization energies behaved in converting from one isomeric form to another. The energy differences were predicted to be quite small, on the PES energy scale, so that the analyses of the spectra were carried out using the dominant s-*trans* configuration for all species.

In the planar molecular geometry, the ethenyl carbonyls of this study have the symmetry classification C_s. As a consequence, the molecular orbitals may be described as a' (in-plane) or a'' (out-of-plane). The π-type orbitals associated with the ethenyl (π''_{CC}) and carbonyl (π''_{CO}) groups belong to the latter group. For the carbonyl halogen substituents there is another

orbital of a'' symmetry: the out-of-plane "lone-pair" orbital of the halogen atom (n''_X).

Figure 1 shows the He(I) photoelectron spectra. The band ionization energies, vibrational structure, MO eigenvalues, and band assignments for each of the species are given in Tables 1 to 4. It can be seen from Fig. 1 that the higher IE region of the spectra contain many overlapping bands due to the accessible σ-type MOs. Although many of the σ-bonding MOs are delocalized over most of the structures, the MO calculations predict some to have appreciable densities in specific internuclear regions, as noted in the tables.

A very useful aid for identifying the PE bands arising from the out-of-plane orbitals of planar molecules is the sum-rule of Kimura (10). The completely localized orbital energies are obtained from the PE spectra of simple molecules (for example, an orbital energy of -14.38 eV for π''_{CO} from the spectrum of formaldehyde (11)). The sum of the orbital energies of the completely localized orbitals should remain constant even after interaction of the orbitals takes place. This method has been successfully applied to many types of planar species, where the

out-of-plane orbitals form a small subset and are all usually accessible with He(I) radiation. It is particularly useful for identifying the higher IE out-of-plane orbital bands since they usually overlap with σ-type bands. Table 5 presents the calculated orbital energy sum, using the parameters given, and the sum taken from the band assignments and measured IEs of Tables 1 to 4. The agreement is satisfactory.

The following outlines of the band assignments focus on the low IE region where the bands due to ionization from the chemically interesting orbitals, n'_O (in-plane oxygen lone pair), n'_X, n''_X, π''_{CC}, and π''_{CO}, are expected. These band assignments are more conclusive because the bands are better resolved and

Cl	−37.67	−38.43
Br	−36.71	−36.5

[a]Using the localized orbital energies (in eV): π''_{CC} = −10.51 from ethene (11), π''_{CO} = −14.38 from formaldehyde (11), n''_F = −17.41 eV from F_2 (21) and F (22), n''_{Cl} = −12.78 from HCl (17), and n''_{Br} = −11.82 from HBr (17).

comparisons with photoelectron bands arising from similarly localized orbitals in structurally related molecules are straightforward.

Propenal

The measured ionization energies, observed vibrational fine-structure, and band assignments for propenal are gathered in Table 1. The values agree with those of previous studies on this species (2), as do the band assignments, which are also consistent with the other members of this series.

Of importance to this study are the two sharp bands in the low IE region. The intensity of the adiabatic component of the transition between the neutral ground state and the cationic states imply that electrons have been removed from MOs which are weakly- or nonbonding in nature. The 10.11 eV band is assigned to the $(n'_O)^{-1}$ ionization process, and corresponds to the bands of acetaldehyde (12) and propynal (3) appearing at IEs of 10.24 and 10.70 eV, respectively. The relative inductive effects of the aldehyde substituents are ethynyl > ethenyl > methyl. The second band of the spectrum, IE_v = 10.93 eV, corresponds to ionization from the π''_{CC} MO ($2a''$). The π-orbital of ethene itself has an IE of 10.51 eV (11). Thus, the major effect on the energy of the π''_{CC} orbital on adding the carbonyl group is a stabilization due to the inductive effect of the carbonyl group. On the other hand, conjugation between π''_{CC} and π''_{CO}, with a higher IE, would result in a destabilization of π''_{CC} relative to its energy in ethene. The $(\pi''_{CO})^{-1}$ band is one of the two overlapping bands at 14.03 eV. The corresponding bands of formaldehyde (11) and propynal (3) appear at 14.38 and 14.37 eV, respectively.

Propenoyl fluoride

Figure 1 shows that the low IE region of the spectrum contains only one distinct band. This must be assigned to overlap of the n'_O and π''_{CC} bands. Closer examination of the region, Fig. 2, shows what appears to be a fairly sharp band, adiabatic IE = 11.09 eV and vertical IE = 11.42 eV, with vibrational intervals of about 1120 cm^{-1}, overlapping with a broader band estimated to lie at 11.7 eV. Both MO calculations predict π''_{CC} to have a lower ionization energy than n'_O. Consideration of the energy shifts of the n'_O band of acetyl fluoride compared to acetaldehyde, +1.56 eV (12), and of propynoyl fluoride compared to propynal, +1.11 eV (3), leads to the prediction of the corresponding band of propenoyl fluoride to lie in the region 11.2–11.7 eV. The 11.42 and 11.7 eV bands (Fig. 2) are thus assigned as $(\pi''_{CC})^{-1}$ and $(n'_O)^{-1}$, respectively. The shifts to higher ionization energies, relative to propenal, reflect the strong inductive effect of the fluorine substituent. However, the energy of π''_{CC} is not stabilized as much as that of n'_O since the former may interact

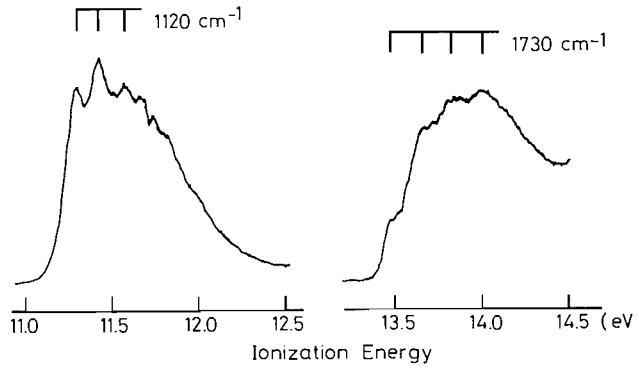

FIG. 2. Details of the first two bands in the spectrum of propenoyl fluoride.

with the other out-of-plane orbitals, π''_{CO} and n''_F, lying at higher IEs, which destabilizes it. Of the two opposing effects, inductive and resonance, the former is slightly more important since the π''_{CC} band is at a slightly higher IE compared to its position for propenal.

The 1120 cm^{-1} interval on the $(\pi_{CC})^{-1}$ band cannot be unambiguously assigned. This frequency is likely too low for the cationic ν(C=C) stretching mode (1636 cm^{-1} for the neutral (13)). For the $(\pi''_{CC})^{-1}$ bands of related species the following reductions from the ν(C=C) values of the neutrals are observed: 330 cm^{-1} for ethene (14), 310 cm^{-1} for propene (15), and 165 cm^{-1} for propenal. The 1120 cm^{-1} structure could be excitation of the ν(C—C) stretching mode (1002 cm^{-1} for the neutral (13)). The MO calculations, and the positions of the $(\pi''_{CO})^{-1}$ and $(n''_F)^{-1}$ bands (see below), suggest a substantial resonance interaction between the three out-of-plane orbitals with a node in the C—C internuclear region. Removal of an electron from the $3a''$ MO, which is antibonding in the C—C region, results in a slightly increased C—C bond strength and vibrational frequency.

The broad profile of the $(n'_O)^{-1}$ band is consistent with the observations for acetyl fluoride (12) and propynoyl fluoride (3), and is probably the result of some delocalization of this in-plane orbital over the entire —COF group. The MO calculations also predict this.

It is difficult to assign the other a'' bands, $(\pi''_{CO})^{-1}$ and $(n''_F)^{-1}$, since they lie in the congested part of the spectrum. They are assigned to the bands at 14.03 and 16.93 eV, respectively, by analogy with the spectra of propenal, propynoyl fluoride (3), and formyl fluoride (16). These assignments are also consistent with the sum-rule for the out-of-plane orbital energies. A broad vibrational progression of 1730 cm^{-1}, which could be the cationic ν(C=O) mode, is observed on the 14.03 eV band (Fig. 2). It should be noted that the energy separation of the $(n''_F)^{-1}$ and $(n'_F)^{-1}$ bands is quite large, about 2 eV, due to the substantial interaction of the out-of-plane lone-pair orbital with π''_{CO}.

Propenoyl chloride

In addition to the n'_O and π''_{CC} bands, the low IE region of the propenoyl chloride spectrum is expected to exhibit bands due to ionization from the in- and out-of-plane chlorine lone-pair orbitals (for example, these orbitals give rise to a band centered at 12.78 eV for HCl (17)). Only three bands are observed in the spectrum (Fig. 1). The intense band at 11.95 eV is due to the chlorine lone-pair electrons, the energy difference between the n'_{Cl} and n''_{Cl} orbitals being small, by analogy with formyl chloride (18) and acetyl chloride (12). Note that the CNDO/2

For personal use only.

MO calculation (Table 3) predicts the chlorine orbitals to have much lower IEs; this seems to be a result of the parameterization of the program. The lowest IE band in the spectrum, 10.90 eV, is assigned as $(n'_O)^{-1}$, the position being intermediate to the corresponding bands of the aldehyde and acid fluoride. Ionization from the π''_{CC} orbital gives rise to the band at 11.23 eV. The π''_{CO} band is located at 14.85 eV and can only be identified by comparison with the spectra of formyl chloride (18) and propynoyl chloride (3), and use of the sum-rule.

Propenoyl bromide

Figure 1 shows that the spectrum of the bromide is very similar to that of the chloride, with a general shift to lower IEs due to the decreased inductive effect of bromine. For example, both the n'_O and π''_{CC} bands are shifted by 0.4 eV. It is at first glance surprising, in view of the results for the chloride, that the bromine lone-pair orbitals gave rise to distinct bands at 11.16 and 11.49 eV. This energy difference is equal to the spin–orbit splitting of the doubly-degenerate bromine lone-pair orbital band in HBr (17). It has been demonstrated that this magnitude of splitting also occurs in alkyl bromides of C_s symmetry and is insensitive to the degree of conjugation of n''_{Br} with other a'' orbitals (19). This behaviour has been explained with the use of a simple orbital model which showed that two opposing trends, increased splitting with increased conjugation of n''_{Br} and increased spin–orbit splitting with increased localization on the halogen atom, compensated each other (20). A similar situation is believed to hold in the case of propenoyl bromide. The lower IE band is assigned as $(n''_{Br})^{-1}$ as this orbital should be destabilized by any interaction with the higher IE π''_{CO} orbital. Conversely, n'_{Br} would be stabilized by interaction with n'_O.

Summary

The photoelectron spectra of the propenoyl halides were interpreted by comparison with propenal and other related compounds. Semi-empirical MO calculations were carried out for some species and, where applicable, the HAM/3 method gave better agreement with measured ionization energies than the CNDO/2 method. The HOMO for the chloride and bromide was found to be n'_O while the penultimate occupied MO is π''_{CC}. For the fluoride this ordering must be reversed. Extensive delocalization of the out-of-plane orbitals was found only for the fluoride, and is due to the favourable π-type overlap of n''_F with the other π-orbitals. No specific features of the spectra could be assigned to the two rotational isomers of the acid halides owing to the overlap of the bands and the small orbital energy differences predicted by the HAM/3 MO calculation. At best, rotational isomerism gives rise to the broadness of the bands.

Received August 18, 1985[1]

ENRIQUE GALVEZ, ISABEL IRIEPA, ANTONIO LORENTE, JOSE MIGUEL MOHEDANO, FELICIANA FLORENCIO, and SEVERINO GARCIA-BLANCO. Can. J. Chem. **65**, 687 (1987).

Reaction of 8-aminoquinoline with pyridine-2-carboxaldehyde (**2**), pyridine-3-carboxaldehyde (**3**), pyridine-4-carboxaldehyde (**4**), and benzaldehyde (**5**) yields the corresponding aminals or Schiff's bases according to reaction conditions; analogous results are obtained from the reaction of 1-amino-naphtalene with pyridine-2-carboxaldehyde (**6**). On the other hand, reaction of 8-aminoquinoline with thiophene-2-carboxaldehyde or pyrrole-2-carboxaldehyde yields neither the aminal nor the Schiff's base. Crystals of **4** ($C_{24}H_{19}N_5$) belong to the triclinic space group $P\bar{1}$. Cell dimensions are a = 11.547(3), b = 11.759(2), c = 15.687(5) Å, α = 98.50(2)°, β = 101.61(2)°, γ = 107.28(2)°, V = 1942.6(9) Å^3. Final R = 0.077 and R_w = 0.064; 3160 reflections were observed. The ir, ^{1}H nmr of **2–6**, the mass spectra of **4** and **5** and the X-ray analysis of **4** are described and discussed. Preparative features, ir, ^{1}H nmr, analyses and crystal structure indicate that the formation of **2–6** are governed mainly by the nucleophilicity at the aldehyde carbon atom and the existence of the hydrogen bonds in the aminal.

ENRIQUE GALVEZ, ISABEL IRIEPA, ANTONIO LORENTE, JOSE MIGUEL MOHEDANO, FELICIANA FLORENCIO et SEVERINO GARCIA-BLANCO. Can. J. Chem. **65**, 687 (1987).

La réaction de l'amino-8 quinoléine avec le benzaldéhyde (**5**) ou avec les pyridinecarboxaldéhydes-2, -3 ou -4 (**2**, **3** ou **4**) conduit, suivant les conditions réactionnelles, soit aux aminals correspondants ou aux bases de Schiff; on obtient des résultats analogues lors de la réaction de l'amino-1 naphtalène avec le pyridinecarboxaldéhyde (**2**). Par ailleurs, lors de la réaction de l'amino-8 quinoléine avec le thiophènecarboxaldéhyde-2 ou avec le pyrrolecarboxaldéhyde-2, on n'obtient ni l'aminal ni la base de Schiff. Les cristaux du composé **4** ($C_{24}H_{19}N_5$) appartiennent au groupe d'espace $P\bar{1}$ et les dimensions de la maille sont: a = 11,547(3), b = 11,759(2) et c = 15,687(5) Å, avec α = 98,50(2), β = 101,61(2) et γ = 107,28(2)° et V = 1942,6(9) Å^3. La structure a été affinée jusqu'à des valeurs finales de R = 0,077 et R_w = 0,064 pour 3160 réflexions observées. On rapporte et on discute des spectres ir et rmn du ^{1}H des composés **2–6**, des spectres de masse des composés **4** et **5** et de la diffraction par les rayons-X du composé **4**. Les caractéristiques de la préparation, les spectres ir et rmn du ^{1}H, les analyses et les structures cristallines indiquent que la formation des composés **2–6** est gouvernée principalement par le caractère nucléophile de l'atome de carbone de l'aldéhyde par l'existence de liaisons hydrogènes dans l'aminal.

[Traduit par la revue]

Introduction

In a previous paper (1) we reported the preparation and spectroscopic features of 6M-PQUAM (**1**) and PQUAM (**2**). In the same line, and because of the chelating properties shown by these aminals for transition metals (1), we report in this paper the synthesis and structural studies, by several methods, of the aminals formed by condensation of 8-aminoquinoline with pyridine-3-carboxaldehyde (**3**), pyridine-4-carboxaldehyde (**4**), benzaldehyde (**5**), and the aminal obtained by condensation of 1-aminonaphtalene with pyridine-2-carboxaldehyde (**6**). Our objective is to establish the main structural stabilizing requirements for these compounds.

Applying the procedure for **1** and **2** (1) to **3–6** yielded neither the aminals nor the Schiff's bases. By condensing 8-aminoquinoline with the appropriate aldehyde and by removing water through azeotropic distillation with benzene, we were able to synthesize the aminals in good yields (Table 1). By addition to the reaction mixture of *p*-toluene – sulfonic acid, only the Schiff's base was isolated. Finally, it is interesting to remark that, in the reaction of 8-aminoquinoline with thiophene-2-carboxaldehyde or pyrrole-2-carboxaldehyde, neither the aminal nor the Schiff's base was isolated. These facts and the yields obtained for **2–6** (Table 1) show that the nucleo-

[b]This product is very unstable and cannot be purified by recrystallization.

philicity at the carbonyl carbon is the main factor affecting the condensation.

Experimental

Synthesis

General procedure for compounds 2–6

The appropriate aldehyde (2.08 mmol) was added to a solution of 8-aminoquinoline (or 1-aminonaphtalene) (1.04 mmol) in benzene (10 mL). The reaction mixture was warmed at reflux for 5 h, and water was removed by azeotropic distillation in a Dean-Stark apparatus. After cooling to room temperature, the reaction mixture was concentrated up to dryness under reduced pressure, and the oil obtained was treated with ether. The resulting solid was recrystallized. Melting points and elemental analyses are given in Table 1.

Methods

All melting points were measured in open capillary tubes in a Büchi SMP-20 apparatus and are uncorrected.

Infrared spectra were recorded on a Perkin Elmer 599 spectrophotometer. All compounds were compressed into KBr pellets.

^{1}H nmr spectra were obtained in DMSO-d_6 at 80 MHz with a Varian FT-80 spectrometer using TMS as internal standard.

The mass spectra were measured at 70 eV on a Varian MAT 711 or on a Hitachi-Perkin Elmer RMU-6M spectrometers.

The elemental analyses were performed in a Carlo Erba analyzer.

Crystallography

Preliminary cell dimensions and the possible space group of the compound 4-pyridyl-*N*,*N*-di((8-quinolyl)amino)methane (**4**) were determined from Weissenberg and precession photographs. Accurate cell parameters were determined by least-squares methods from the setting angles of 25 reflections measured on an automatic Nonius CAD4 four circle diffractometer on the range of $8 < \theta < 20°$ with graphite-monochromated MoKα radiation. Crystal data are as follows: $C_{24}H_{19}N_5$ mw = 377.447
Space group $P\bar{1}$, a = 11.547(3), b = 11.759(2), c = 15.687(5) Å, α = 98.50(2), β = 101.61(2), γ = 107.28(2)°, V = 1942.6(9) Å^3, d_0 = 1.3, d_x = 1.291(2) g cm^{-3}, Z = 4, λ(MoKα) = 0.71069 Å, $F(000)$ = 729, μ(MoKα) = 0.0074 mm^{-1}.

Experimental density was measured by flotation method using an aqueous KBr solution. There are two independent molecules, **A** and **B** in a unit cell.

Intensities were measured from a crystal of 0.18 × 0.20 × 0.40 mm on the same automatic Nonius CAD4 four circle diffractometer, for $2 < \theta < 28.5°$. The ω–2θ scan technique was used. $\Delta\omega = (1 + 0.3 \tan\theta)°$. Two reflections were used as standard and remeasured after every 100 reflections, with a variation <12%, due to the presence of some unstableness in the crystal, of the 6700 independent reflections measured on the range $\bar{15} < h < 15$, $\bar{15} < k < 15$, $0 < l < 21$, 3160 were considered observed with $I > 2\sigma(I)$, σ being determined from counting statistics. R_{int} = 0.01. Lorentz and polarization corrections were applied, but no correction was made for absorption.

The phase problem was solved by direct methods with MULTAN-80 programs (2). An E map generated from the phase set of 466 reflections with the highest combined figure of merit, located one of the two independent molecules and a fragment of the other one; the remaining atoms were found from difference Fourier syntheses.

Further least-squares refinements with isotropic and anisotropic temperature factors reduced R to 0.09. A difference Fourier map revealed the positions of all H atoms which were included with isotropic temperature factors. The process of refining was stopped when the averaged Δ/σ = 0.10, the maximum Δ/σ = 0.27 and the maximum residual peak = 0.20 e Å^{-3}. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$ with $w = k/\sigma_1^2\sigma_2^2$, $\sigma_1 = a_1 + b_1(F_o)$, $\sigma_2 = a_2 + b_2(\sin\theta/\lambda)$, and k = 0.543 (3).

The final R values are $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.077$ and $R_w = [\Sigma w\Delta^2/\Sigma w|F_o|^2]^{1/2} = 0.064$. $S = \Sigma[w\Delta F^2/(m - n)]^{1/2} = 1.15$.

The scattering factors were taken from the International tables for X-ray crystallography (4). The computations were made with programs of the X-RAY 70 system (5), PARST (6), and PESOS (3) on a VAX 11/750 computer.

The coordinates are listed in Table 2.[2]

[2]Tables of coordinates of H atoms, anisotropic temperature parameters, deviations of atoms from the mean plane and the structure factors may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

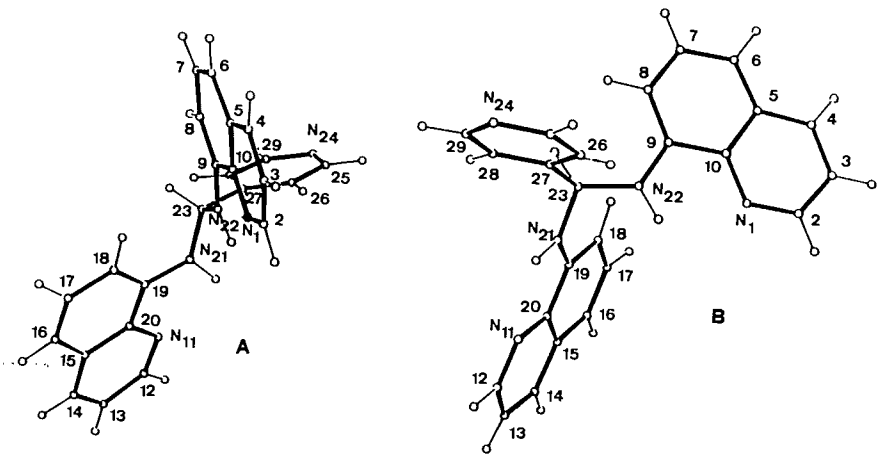

FIG. 1. A view of two independent molecules.

Results and discussion

Description of the structure of 4

Figure 1 shows a view of two independent molecules with the atomic labelling and Fig. 2 displays a projection along the *b* axis, with the intermolecular H bonds represented by dashed lines. Bonds lengths and bond angles with their esd's are given in Table 3. These values are very similar for the two independent molecules and are also in good agreement with that of **2** (7).

In molecule **A**, average torsion angles for the two 8-aminoquinolyl groups are 1.3(5)° and 1.5(6)°, and that for the pyridine ring is 1.2(6)°. In molecule B, the corresponding values are 1.7(6)°, 1.4(5)°, and 1.0(6)° respectively. That is to say, both 8-aminoquinolyl groups and pyridine rings are planar.

The dihedral angle between the two 8-aminoquinolyl planes are 75.6(2)° and 64.3(2)° in molecules **A** and **B**. The dihedral angles between the 8-aminoquinolyl planes and the pyridine ring are 92.7(1)° and 119.7(3)° in molecule **A**, and 64.3(2)° and 117.9(2)° in molecule **B**. These values are quite different and also different from those found for **2** (7) as a result of different molecular packing. In the former case intra- and interhydrogen bonds and short contacts are possible.

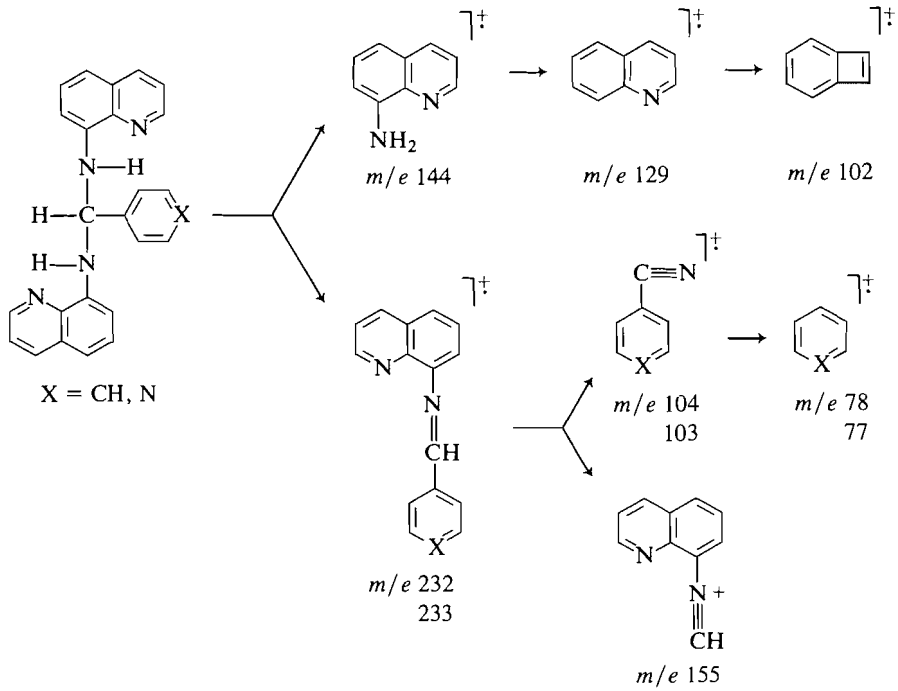

SCHEME 1

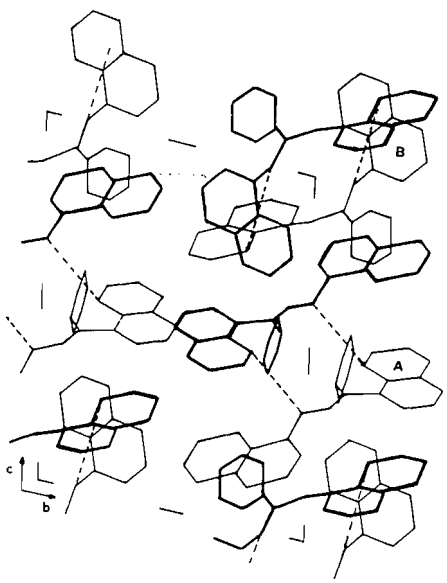

FIG. 2. A view of the relative positions of the two independent molecules, with the intermolecular H-bonds represented by dashed lines.

There is a short intramolecular N21...N22 contact and two intramolecular H-bonds in N22—H...N1 and N21—H...N11 for each **A** and **B** molecules.

There are also clear intermolecular interactions between each pair of molecules related by an inversion center, although the N...N distances are rather large. The corresponding distances and angles are shown in Table 4.

By comparing these distances with that of the compound **2**, it can be deduced that in compounds **2** and **4** the N amine is bonded to N quinoline through an intramolecular H-bond and the N amine...N amine is a short intramolecular contact. In compound **2**, there are two intramolecular H-bonds N amine—H...N pyridine and as this kind of H-bond can not be found in compound **4**, an intermolecular interaction, N amine—H...N quinoline, takes place between each two symmetrical molecules.

Infrared spectra

In compounds **2** and **4**, the bands at 3405 cm^{-1} and 3400 cm^{-1} are assigned respectively to the ν(N—H...N) single intramolecular hydrogen bonds, whereas the bands at 3370 cm^{-1} and 3355 cm^{-1} are assigned to the ν(N—H:::$^{N}_{N}$) bifurcated hydrogen bonds. These structural facts are in good

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

agreement with the results obtained by X-ray diffraction. For the ν(N—H) bands of compounds **3**, **5**, and **6**, the corresponding bands appear at 3410, 3410, —cm^{-1} and 3368, 3378, 3378 cm^{-1}, respectively, the conclusions seem to be similar to those deduced for compounds **2** and **4**.

Nuclear magnetic resonance spectra

The triplets at $\delta \simeq 6.5$ ppm which convert into singlets on deuteration are assigned to the methine protons coupled to the amine protons, as previously described for **2** (1).

The sequence δH_α (**2**) (6.57 ppm) $\simeq \delta H_\alpha$ (**3**) (6.59 ppm) > δH_α (**4**) (6.52 ppm) > δH_α (**5**) (6.33 ppm) is consistent with the increased electron-withdrawing effect exerted by the pyridine nitrogen atom. Finally, it is interesting to remark, that on dissolution of **1**–**6** in DMSO-d_6 a N—H free signal appears at $\delta \simeq 5.9$ ppm; and, as a consequence of deuteration, compounds **1**–**6** begin to hydrolyze, giving an aldehyde proton signal at $\delta \simeq 10$ ppm.

Mass spectra

The proposed fragmentation pathways of **4** and **5** are given in Scheme 1.

The cleavage of the C—N linkage in M^+ gives rise to the peaks at *m/e* 144, 233, and 232. From the aminoquinolinium ion, the peaks at *m/e* 129 (base peak) and *m/e* 102 are obtained. The fragmentation of the ions at *m/e* 233 and 232 originated the ions at *m/e* 104, 103, and 155. These fragmentation patterns are similar to those described for **2** and **3** (1).

Conclusions

From the preparative features, ir, and ^{1}H nmr data of **2**–**6** and the crystal structure of **2** and **4**, it was inferred that the syntheses of **1**–**6** are governed mainly by (*a*) the nucleophilicity at the carbonyl carbon of the appropriate aldehyde; and (*b*) the presence of intra- and intermolecular hydrogen bonds, which stabilize the aminal.

Received July 29, 1986

DENNIS M. WHITFIELD, CAROLINE J. RUZICKA, JEREMY P. CARVER, and JIRI J. KREPINSKY. Can. J. Chem. **65**, 693 (1987).

The title trisaccharide, **13***c*, was synthesized, as well as its two component disaccharides, **10***c* and **11***c*. Four disaccharides, **3***c*, **4***c*, **5***c*, and **7***c*, were also prepared to serve as model compounds for the investigation of the 3-dimensional structure of more complex oligosaccharides. The β-1,3 linkage was formed in 75% yield by coupling 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl bromide (**9**) with trideuteriomethyl 2-*O*-benzoyl-4,6-benzylidene-β-D-galactopyranoside (**2***a*), using silver trifluoromethanesulphonate as a promoter in the presence of the base 2,6-di-*tert*-butyl-4-methylpyridine. Using a silver zeolite as a promoter under a variety of conditions, both α-1,3 and β-1,3 linkages were formed. The β-1,6 linkages were prepared in high yield using **9** and silver zeolite with either trideuteriomethyl 2,3-di-*O*-benzoyl-β-D-galactopyranoside (**8***b*) or trideuteriomethyl 2-*O*-benzoyl-3-*O*-(3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl)-β-D-galactopyranoside (**11***b*). 2,3,4-Tri-*O*-benzyl-α-L-fucopyranosyl bromide (**1***b*) was used in the halide ion catalyzed fucosylation of **2***a* or its 3-*O*-benzoyl isomer **2***b*. The glycosylations of 3,6-di-*O*-acetyl-4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl bromide (**6***b*) and 4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2,3,6-tri-*O*-acetyl-α-D-glucopyranosyl bromide (**5***a*) by heptadeuterioisopropanol used silver zeolite as promoter.

DENNIS M. WHITFIELD, CAROLINE J. RUZICKA, JEREMY P. CARVER et JIRI J. KREPINSKY. Can. J. Chem. **65**, 693 (1987).

On a synthétisé le trisaccharide mentionné dans le titre (**13***c*) ainsi que les deux disaccharides qui le forment (**10***c* et **11***c*). On a aussi préparé les quatre disaccharides **3***c*, **4***c*, **5***c* et **7***c* comme composés modèles pour l'étude de la structure tridimensionnelle d'oligosaccharides plus complexes. On a formé la liaison β-1,3 avec un rendement de 75% en procédant au couplage du bromure de tri-*O*-acétyl-3,4,6 déoxy-2 phtalimido-2 β-D-glycopyrannosyle (**9**) avec le *O*-benzoyl-2 benzylidène-4,6 β-D-galactopyrannoside de trideutérométhyle (**2***a*), sous l'influence du trifluorométhanesulfonate d'argent comme promoteur de la réaction et en présence de di-*tert*-butyl-2,6 méthyl-4 pyridine comme base. Si on utilise le zéolite d'argent comme promoteur, sous diverses conditions, il y a formation des liaisons α-1,3 ainsi que β-1,3. On a préparé les liaisons β-1,6 avec de bons rendements en faisant réagir le composé **9**, en présence de zéolite d'argent comme promoteur, avec soit le di-*O*-benzoyl-2,3 β-D-galactopyrranoside de trideutérométhyle (**8***b*) soit le *O*-benzoyl-2 *O*-(tri-*O*-acétyl-3,4,6 déoxy-2 phtalimido-2 β-D-glucopyrannosyl)-3 β-D-galactopyrannoside de trideutérométhyle (**11***b*). On a utilisé le bromure de tri-*O*-benzyl-2,3,4 α-L-fucopyrannosyle (**1***b*) pour la fucosylation, catalysée par les ions halogénures, du composé **2***a* ou de son isomère *O*-benzoyle-3 (**2***b*). Les glycosylations des bromures de di-*O*-acétyl-3,6 *O*-(tétra-*O*-acétyl-2,3,4,6 β-D-galactopyrannosyl)-4 déoxy-2 phtalimido-2 β-D-glucopyrannosyle (**6***b*) et de *O*-(tétra-*O*-acétyl-2,3,4,6 β-D-galactopyrannosyl)-4 tri-*O*-acétyl-2,3,6 α-D-glucopyrannosyle (**5***a*) par l'heptadeutéro-isopropanol se font sous l'influence du zéolite d'argent comme promoteur.

[Traduit par la revue]

As part of our program of studies of complex oligosaccharides, in particular those structures related to neoplasia (1), we have synthesized trisaccharide **13***c* and several related disaccharides **3***c*, **4***c*, **5***c*, **7***c*, and **10***c* as their β-glycosides. These anomerically pure oligosaccharides are suitable for the elucidation of their 3-dimensional structures by nmr spectroscopic techniques (2).

It is our premise that to understand the biological functions of cell surface oligosaccharides it is necessary to have detailed knowledge of their 3-dimensional structures. For example, the origin of the specificities of antibodies directed against tumour associated carbohydrate antigens (1) probably resides in the antigen's shape. Furthermore, it has been suggested that the conformations of N-linked oligosaccharides, glycoproteins with carbohydrates linked to the amidic nitrogen of asparagine residues, regulate the processing pathways for their biosynthesis. The conformational analyses of N-linked oligosaccharides has relied extensively on chemically synthesized component oligosaccharides, which have allowed for the examination of each component linkage separately (3). Of particular interest are branch points, since these are points of potential flexibility and interchain interactions.

In O-linked oligosaccharides, trisaccharide **13***c* represents the branch point of "I antigen" structures, GlcNAc-β-1,3-[GlcNAc-β-1,6-]-Gal-β-. Branching resulting from the glyco-

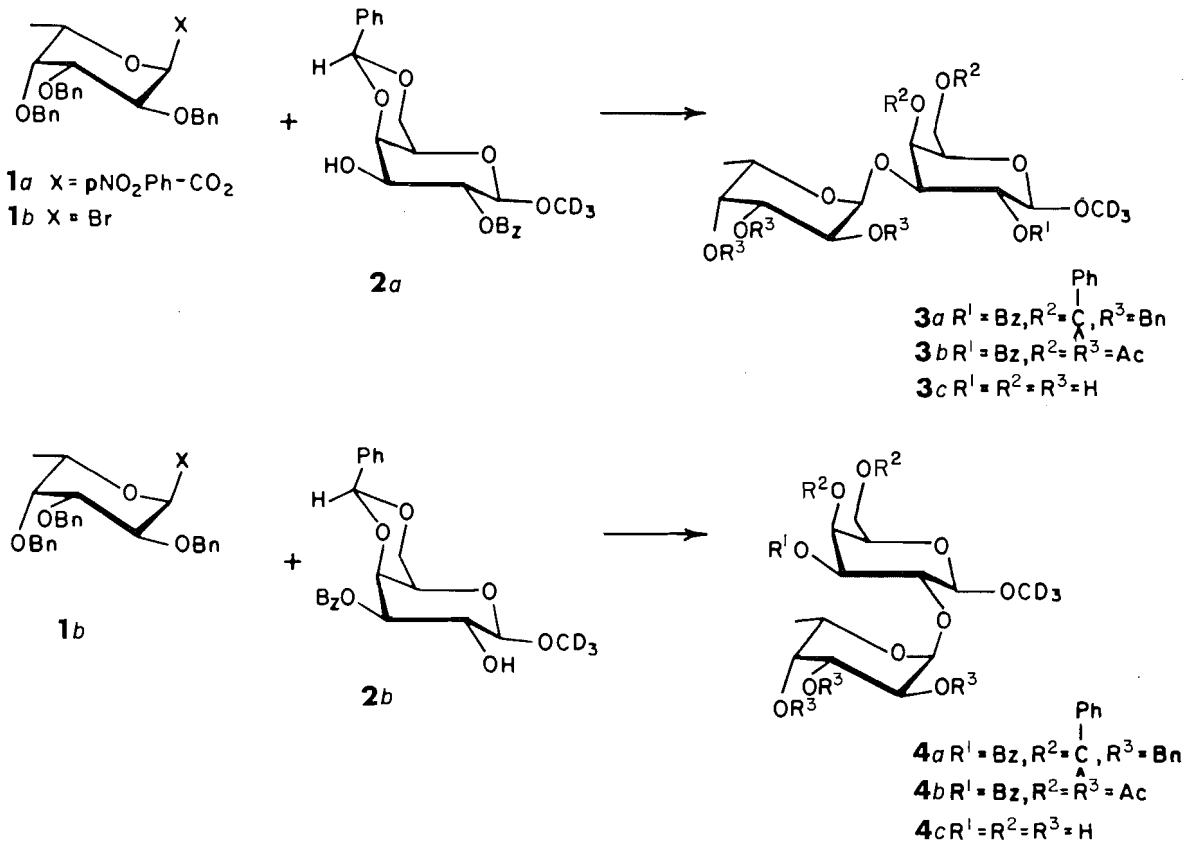

SCHEME 1. Syntheses of fucose disaccharides.

sylation of O-6 of the galactose residue of an "i" disaccharide fragment by another GlcNAc residue is responsible for the oncofetal differentiation from "i to I" structures. In fact, the previously prepared disaccharide **11***c* (4), GlcNAc-β-1,3-Gal-β-OCD_3, is an excellent acceptor for the GlcNAc transferase associated with this transformation (5, 6). A synthesis of the reducing trisaccharide related to **13** has been previously reported by Veyrières and co-workers (7) using a different synthetic design. The procedure described in this communication represents a simplification resulting in a better yield (75 vs. 40%) (4) of the β-1,3-linked β-disaccharide, **11***a*, and its subsequent elaboration into the β-trisaccharide **13***c*. This methodology applied to a galactose derivative, **8***a* (4), afforded the disaccharide **10***c*, GlcNAc-β-1,6-Gal-β-OCD_3.

Fucose containing disaccharides **3***c*, Fuc-α-1,3-Gal-β-OCD_3, and **4***c*, Fuc-α-1,2-Gal-β-OCD_3, are usually found at the non-reducing termini of oligosaccharides; for example the blood group H is associated with the structure Fuc-α-1,2-Gal-β-1,4-GlcNAc-β- and the grouping Fuc-α-1,3-Gal-β-1,4-Glc- has been found among the milk oligosaccharides (8). Syntheses of closely related derivatives of **4***c* have been reported by several groups (9, 10) and the 3-dimensional structure of this linkage has been elucidated by Lemieux and co-workers (11, 12).

The lactose disaccharides **5***c*, Gal-β-1,4-Glc-β-OC_3D_7, and **7***c*, Gal-β-1,4-GlcNAc-β-OC_3D_7, were prepared to investigate their conformations. They are ubiquitous structural elements of oligosaccharides found in glycoproteins and glycolipids. Syntheses of similar derivatives have been reported previously (13, 14). The solution conformations of the Gal-β-1,4-GlcNAc linkage have been studied (15–17) with reported values of ϕ (H1—C1—O—C4′) ranging from 40° to 55° and ψ (C1—O—C4′—H4′) from 0° to 20° in qualitative agreement with each other. The related Gal-β-1,4-Glc linkage has also been studied in solution (18, 19) with similar results. The reported solid state (20) conformation for β-lactose as determined by X-ray diffraction studies is $\phi \cong 50°$ and $\psi = 10°$, in qualitative agreement with the solution studies. However, the solid state conformation for β-lactosamine is $\phi \cong 30°$ and $\psi = -20°$, significantly different from the solution studies (21). Furthermore, Kochetkov and co-workers, studying related β-1,4 linkages, have presented evidence that a model considering a single predominant conformer (22), as in the studies above, is not sufficient to account for the experimental data and so the conformational preference(s) of these β-1,4 linkages still requires further investigations.

Synthesis of fucose disaccharides

The fucose containing β-disaccharides **3***c* and **4***c* were prepared by glycosylation of the galactose derivatives **2***a* and **2***b* (4) at O3 and O2 respectively (see Scheme 1) with bromide **1***b*, using the halide ion catalyzed method (8), to yield fully protected β-disaccharides **3***a* and **4***a*. The ^1H nmr spectra for these and all subsequent protected oligosaccharides are summarized in Table 1. It is interesting to note that the resonances of the benzoate group were very useful in assessing both the outcome and the purity of individual synthetic transformations.

The benzyl and the benzylidene groups were removed by hydrogenation in glacial acetic acid employing palladium black as catalyst (4).[6] Subsequent acetylation afforded the fully acylated derivatives **3***b* and **4***b*, which were purified by silica gel

[6]It should be noted that the benzoate groups at O2 (**3***b*) or O3 (**4***b*) were not removed during hydrogenolysis, cf. ref. 4.

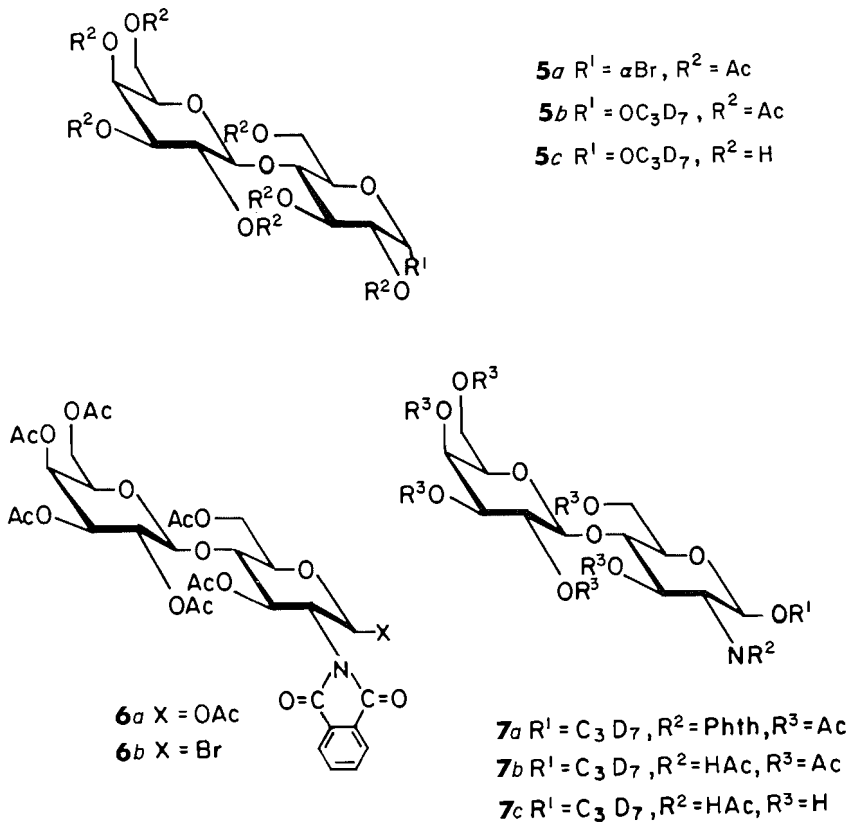

SCHEME 2. Syntheses of lactose derivatives.

column chromatography (23), and then deprotected to **3***c* and **4***c* by Zemplen transesterification in 28 and 40% overall isolated yields from **2***a* and **2***b* respectively. The physical data for **4***c* agree well with the reported values (see Experimental) (9). The ^{13}C and ^{1}H nmr spectra are summarized in Tables 2 and 3.

Syntheses of lactose derivatives

The disaccharide Gal-β-1,4-Glc-β-OC_3D_7, **5***c*, was prepared from peracetylated bromide **5***a*, silver zeolite, and a slight excess of heptadeuterioisopropanol (24, 25) (see Scheme 2). Peracetylated glycoside **5***b* was purified by silica gel chromatography and subsequently deprotected under Zemplen conditions to give **5***c*. The β-disaccharide **7***a* was prepared in an analogous manner from the bromide **6***b* (26) generated from the accessible acetate **6***a*. The peracetate **7***b* was obtained by treatment with hydrazine hydrate at 70°C for 30 min, followed by complete acetylation. Zemplen transesterification gave **7***c* in 57% overall isolated yield from **6***a*.

Synthesis of I antigen branch point trisaccharide

The β-1,6-linked β-disaccharide **10***c* was prepared from the trideuteriomethyl 2,3-di-*O*-benzoyl-β-D-galactopyranoside (**8***b*) accessible from the 4,6-benzylidene derivative **8***a* (4) by hydrogenation on palladium black in acetic acid. The primary 6-OH was sufficiently more reactive than the 4-OH that it reacted regiospecifically with 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl bromide (**9**), using silver zeolite, to give the required β-1,6-linked β-disaccharide in 79% yield (see Scheme 3). The deprotected β-disaccharide **10***c* was obtained in 78% yield from **10***a* by the hydrazine hydrate, acetylation, and Zemplen transesterification sequence. The nmr spectral data summarized in Tables 2 and 3 agree with the data reported for this linkage in other small oligosaccharides (27, 28).

The formation of the β-1,3 linkage in β-disaccharide **11***a* using silver zeolite (40% yield) as promoter from alcohol **2***a* and bromide **9** was previously reported (4). A subsequent attempt to increase the yield, by adding more bromide **9** and continuing the room temperature stirring for up to a week, did result in an apparent increase in yield (about 60%). The reaction product consisted of an approximately 2:3 α:β mixture of **11***a* and undesired **12***a* as determined from ^{1}H nmr analysis of the crude reaction product (see Scheme 4). This mixture could be completely separated by preparative hplc. The ^{1}H and ^{13}C nmr data clearly show the compound **12***a* to be the α-1,3-linked isomer of **11***a* (e.g. H1 GlcNPhth: δ = 5.225, J_{1-2} = 3.6 Hz; and C1 GlcNPhth: δ = 93.7, J_{C1-H1} = 172 Hz). This result was surprising since reports using bromide **9** or the similar bromide **6***b* describe the exclusive formation of β linkages (29, 30). Systematic variations of reaction conditions using freshly prepared aglycon **2***a*, bromide **9**, or silver zeolite led to similar mixtures. Further experiments, using 2 equivalents of bromide **9** and either overnight ultrasonic agitation or heating at 55–60°C, always resulted in similar mixtures with a reproducible crude yield (90%) of 1:2 α:β using ultrasonic agitation or (80%) of 4:3 α:β without ultrasound agitation. The heating experiment was performed as a control since the propylene glycol used in the ultrasonic bath reached 55–60°C. We originally thought that acid was produced under these conditions, which would then lead to a Fischer-like equilibrium. This explanation was ruled out by the following observations: an addition of the soluble bases 2,4,6-trimethylpyridine (*s*-collidine) or tetramethylurea led to almost complete suppression of product formation (about

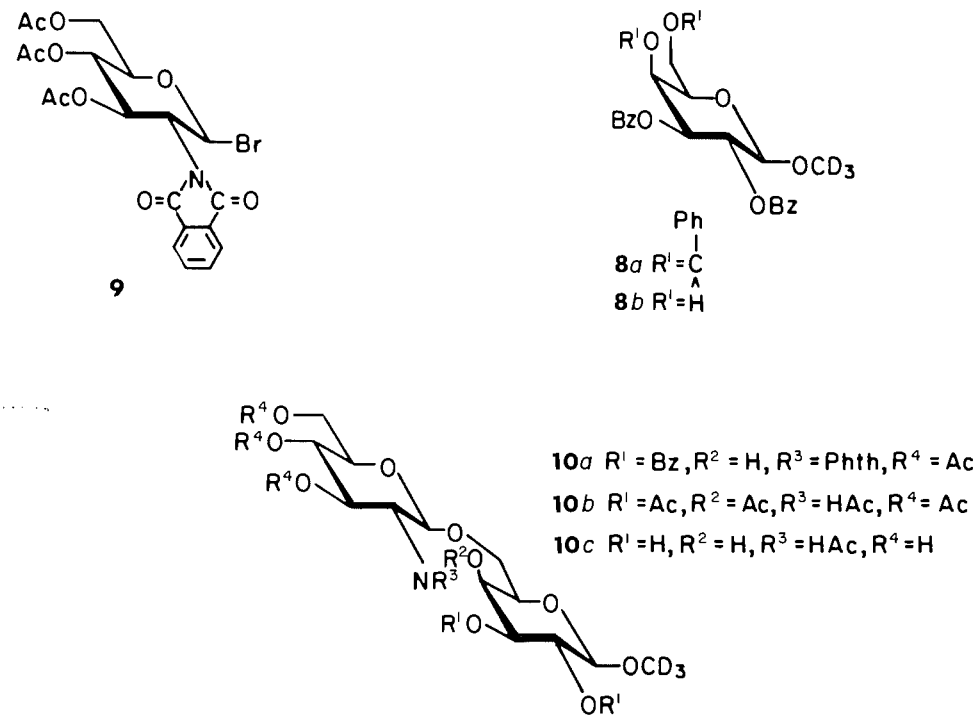

SCHEME 3. Synthesis of GlcNAc-β-1,6 disaccharide.

5% after 7 days of heating), while an addition of the insoluble silver carbonate and subsequent heating or ultrasonic agitation led to a similar α:β mixture, and an addition of the non-nucleophilic base 2,6-di-*tert*-butyl-4-methylpyridine (31) led to a high yield of a similar mixture. The desired β-disaccharide **11***a* was finally obtained using the last mentioned base and silver triflate in a 75% isolated yield. These results strongly support Paulsen's proposals that the glycosylation mechanism(s) using insoluble catalysts like silver zeolite or silver silicate are fundamentally different from soluble promoters

[a]Methyl of fucose with (J_{H5-CH_3}).
[b](2),(5)–(7) and (9)–(12) Resonances overlapped with resonances marked with the same superscript number.
[c]These resonances (Glc H2, H3, H4, and H5) are not a first-order spin system and Glc H2 shows at least 8 lines due to the overlap of H3 and H4.
[d]This resonance shows virtual coupling due to overlap of GlcNAc H2, H3 and H4.
[e]These resonances form a non-first-order spin system. The assignments were made by simulations.
[f]These resonances form a non-first-order spin system. The assignments were made by simulations.

(32). It has been suggested (24) that some type of solid surface carbonium ion pair is the reactive species, with the aglycon approaching from the opposite face leading in some cases to the thermodynamically unfavorable isomer (20).

This easy access to compound **11***a* made it a good starting material for the synthesis of trisaccharide **13***c* by the following sequence of reactions. The benzylidene group of **11***a* was cleaved (4) by hydrogenolysis using palladium black in acetic acid and the resulting diol **11***b* was treated with bromide **9** using silver zeolite as promoter to give protected trisaccharide **13***a* in 63% yield after purification. The deprotected trisaccharide **13***c* was obtained by a hydrazine hydrate, acetylation, and Zemplen transesterification sequence as described above in 67% yield from **13***a*. The nmr spectral data summarized in Tables 2 and 3 agree well with the values for β-disaccharides **10***c* and **11***c*. The analysis of the nmr data in our study of the 3-dimensional structure of these compounds will be published in a separate communication.

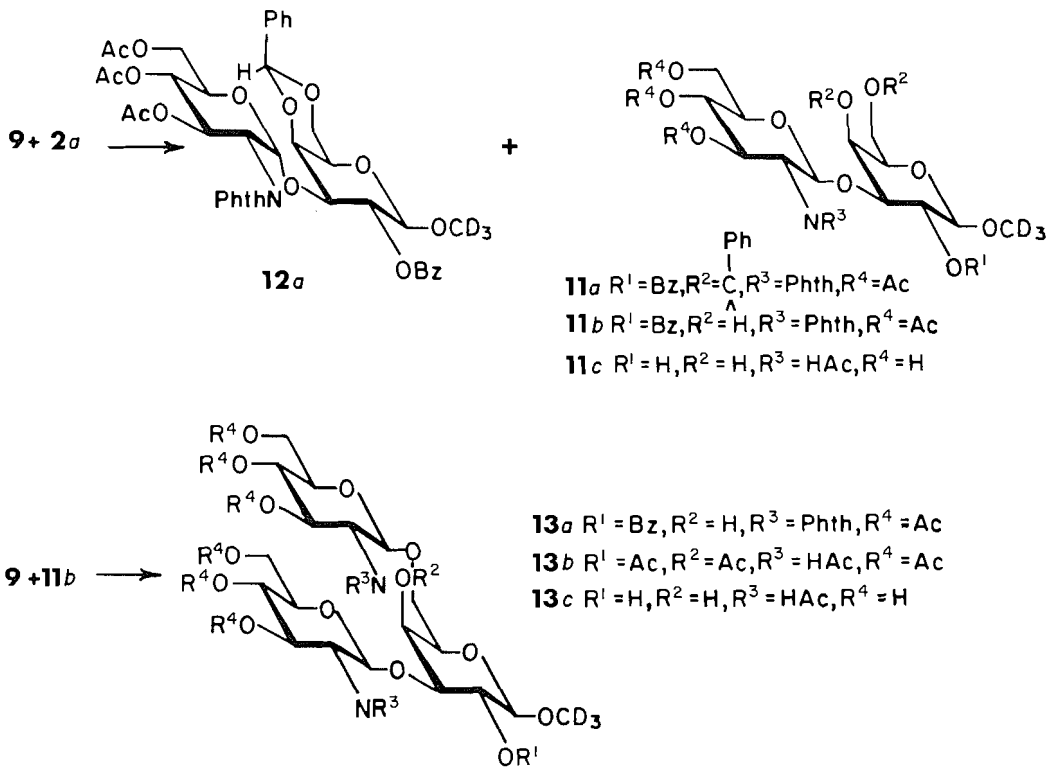

SCHEME 4. Synthesis of I antigen branchpoint trisaccharide.

Experimental

General methods

Melting points were determined on a Reichert Thermovar melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer polarimeter (Model 243 B) at 26 ± 1°C. Microanalyses were performed by the Microanalytical Laboratory Ltd., Markham, Ontario. The ^{1}H nmr spectra were recorded at 360.06 MHz with a Nicolet spectrometer at the NMR Spectroscopy laboratory of the Centre for the Determination of Carbohydrate Structures, University of Toronto. The ^{13}C nmr spectra were recorded at 100.566 MHz with a Varian XL-400 spectrometer at the Chemistry Department, University of Toronto. Spectra were obtained at 19 ± 2°C either in $CDCl_3$ containing a trace of TMS (0 ppm, ^{1}H and ^{13}C) as the internal standard or in D_2O (99.996%, Aldrich) containing a trace of acetone (2.225 ppm relative to internal DSS, ^{1}H) as the internal standard. The ^{13}C spectra in D_2O were referenced to external dioxane (67.4 ppm relative to TMS). Chemical shifts are cited in δ (ppm) scale and coupling constants are in Hz. Samples for nmr analyses in D_2O were passed through a Chelex 100 (Bio-Rad) ion-exchange resin in doubly distilled H_2O to remove paramagnetic impurities, lyophilized, and then lyophilized three times with D_2O. The ir spectra were recorded on a Perkin–Elmer (Model 1430) spectrometer using thin film on NaCl plates. Fast Atom Bombardment mass spectra (FAB-MS) were recorded with a VG Analytical ZAB HF reverse geometry instrument (for general conditions cf. ref. 33) at the Institute of Physiological Chemistry, University of Bonn, through the courtesy of Dr. H. Egge.

Thin-layer chromatography (tlc) was performed on silica gel $60F_{254}$ (Merck) plastic plates and visualized by spraying with 50% sulfuric acid and (or) 1% orcinol acidic ferric chloride (34) and heating at 200°C. Silica gel (230–400 mesh; Toronto Research Chemicals) was used for flash chromatography. All starting materials were dried overnight under vacuum (10^{-3} Torr; 1 Torr = 133.3 Pa) prior to use and the solvents were distilled from appropriate drying agents. Solutions were concentrated at water aspirator pressure.

*Trideuteriomethyl 2-O-benzoyl-4,6-O-benzylidene-3-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-galactopyranoside (**3**a)*

Activated molecular sieves 3A (5 g), tetraethylammonium bromide (7.5 g; 35 mmol), alcohol **2***a* (1.5 g; 3.85 mmol), and dichloromethane (50 mL) were mixed and stirred for 1 h. Then tribenzyl fucosyl bromide (35) **1***b* prepared from *p*-nitrobenzoate **1***a* (3.5 g; 6.2 mmol) in dichloromethane (50 mL) was added and the resulting mixture was left to stir for 6 days in the dark under an argon atmosphere. The mixture was diluted with dichloromethane (50 mL), filtered through Celite, rinsed with dichloromethane (50 mL), washed with cold water (2 × 200 mL), dried over Na_2SO_4, filtered, and evaporated to dryness. The disaccharide **3***a* was purified by flash chromatography (silica gel, hexane:ethyl acetate 60:40) as eluant to yield 1.4 g (45%); mp 68–70°C; $[\alpha]_D$ +47.0° (*c* 0.99, chloroform); ir (neat): 1720 (CO) cm^{-1}; ^{13}C nmr ($CDCl_3$) δ: 165.3 (CO), 101.72 ($PhCHO_2$[(1)],[7] $^2J_{C-H}$ 158), 101.3 (C1-Gal[(1)], $^2J_{C-H}$ 161), 100.5 (C1-Fuc, $^2J_{C-H}$ 166). *Anal.* calcd. for $C_{48}H_{47}D_3O_{11}$ (805.89): C 71.54, H 5.88; found: C 71.33, H 5.68.

*Trideuteriomethyl 4,6-di-O-acetyl-2-O-benzoyl-3-O-(2,3,4-tri-O-acetyl-α-L-fucopyranosyl)-β-D-galactopyranoside (**3**b)*

Hydrogenolysis of the disaccharide **3***a* (1.0 g; 1.24 mmol) in glacial acetic acid (30 mL) on Pd black (350 mg; Strem) at room temperature overnight gave, after removal of the solids by filtration through Celite, rinsing with ethyl acetate (50 mL) and toluene (50 mL), and evaporation, a syrupy residue. The residue was dissolved in toluene (2 × 50 mL) and the solvent was evaporated. To this residue was added pyridine (12 mL) and acetic anhydride (6 mL) and the mixture was stirred under argon overnight. Toluene (25 mL) was added and the mixture evaporated. The residue was taken up in dichloromethane (50 mL) and washed with water (3 × 50 mL), dried over Na_2SO_4, filtered, and the solvents evaporated. This yielded, after purification by flash chromatography (silica gel, ethyl acetate:hexane 50:50), disaccharide **3***b* (540 mg; 66%); mp 102–104°C; $[\alpha]_D$ −46.5° (*c* 1.84, chloroform); ir (neat): 1750 and 1720 sh (CO) cm^{-1}. *Anal.* calcd. for $C_{30}H_{35}D_3O_{16}$ (657.60): C 54.79, H 5.36; found: C 54.83, H 5.43.

*Trideuteriomethyl 3-O-α-L-fucopyranosyl-β-D-galactopyranoside (**3**c)*

Protected disaccharide **3***b* (125 mg; 0.19 mmol) was dissolved in methanol (20 mL), 1 *M* methanolic NaOMe (0.4 mL) was added, and

[7]Assignments may be interchanged with resonances marked with the same superscript number, e.g. (1).

the solution was stirred under argon for 14 h. After neutralization with Dowex 80W-8X H^+ ion exchange resin, filtration, and evaporation of the solvent, the residue was crystallized from methanol/benzene/hexane to yield **3***c* (61 mg; 94%); mp 218–221°C; $[\alpha]_D$ −123.1° (*c* 0.67, $CH_3OH:H_2O$, 9:1); ir (neat): 3300 (br, OH) cm^{-1}. *Anal.* calcd. for $C_{13}H_{21}D_3O_{10}$ (343.31): C 45.40, H 6.16; found: C 45.53, H 6.36.

*Trideuteriomethyl 3-O-benzoyl-4,6-O-benzylidene-2-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-galactopyranoside (**4**a)*

Compound **4***a* was prepared as for compound **3***a* using tetraethylammonium bromide (15 g; 71 mmol), alcohol **2***b* (3.0 g; 7.7 mmol), molecular sieves 3A (10 g), and tribenzyl fucosyl bromide **1***b* (12.4 mmol). The disaccharide **4***a* was purified by flash chromatography (silica gel, hexane:ethyl acetate 65:35) to yield 4.1 g (66%); mp 149–152°C; $[\alpha]_D$ +2.3° (*c* 0.64, $CHCl_3$); ir (neat): 1730 (CO) cm^{-1}; ^{13}C nmr ($CDCl_3$) δ: 165.9 (CO), 102.6 ($PhCHO_2$[(2)],[8] $^3J_{C-H}$ 158), 100.7 (C1–Gal[(2)],[8] $^2J_{C-H}$ 161), 97.2 (C1-Fuc, $^2J_{C-H}$ 170). *Anal.* calcd. for $C_{48}H_{47}D_3O_{11}$ (805.89): C 70.51, H 5.88; found: C 71.38, H 5.76.

*Trideuteriomethyl 4,6-di-O-acetyl-3-O-benzoyl-2-O-(2,3,4-tri-O-acetyl-α-Lfucopyranosyl)-β-D-galactopyranoside (**4**b)*

Compound **4***a* (3.5 g; 4.34 mmol) was hydrogenated using the same conditions as for compound **3***a* and subsequently acetylated in the same manner. The disaccharide **4***b* was purified by flash chromatography (silica gel, ethyl acetate:hexane 50:50) to yield 2.2 g (66%); mp 71–73°C; $[\alpha]_D$ −48.7° (*c* 1.02, $CHCl_3$); ir (neat): 1750 and 1720 sh (CO) cm^{-1}; ^{13}C nmr δ ($CDCl_3$): 169.4–170.4 (4 × CH_3CO), 165.0 (Ph*C*O), 102.2 (C1-Gal, $^2J_{C-H}$ 161), 96.9 (C1-Fuc, $^2J_{C-H}$ 174). *Anal.* calcd. for $C_{30}H_{35}D_3O_{16}$ (657.60): C 54.79, H 5.36; found: C 55.16, H 5.34.

*Trideuteriomethyl 2-O-α-L-fucopyranosyl-β-D-galactopyranoside (**4**c)*

The ester protecting groups were removed from **4***b* (200 mg; 0.3 mmol) under Zemplen conditions as described for compound **3***b*. The residue was crystallized from methanol/benzene/hexane to yield **4***c* (95 mg; 91%); mp 123–126°C; $[\alpha]_D$ −102.1° (*c* 1.24, $CH_3OH:H_2O$ 3:1); ir (neat): 3300 (br, OH) cm^{-1}. *Anal.* calcd. for $C_{13}H_{21}D_3O_{10}$ (343.31): C 45.40, H 6.16; found: C 45.54, H 6.19.

*Heptadeuterioisopropyl 4-O-β-D-galactopyranosyl-β-D-glucopyranoside (**5**c)*

The crude bromide **5***a* (prepared from lactose peracetate (15 g; 22 mmol)) in dry dichloromethane (50 mL) was added to a stirred suspension of silver zeolite 13X (25 g), dichloromethane (25 mL), and heptadeuterioisopropanol (2.0 mL; 25 mmol) under an argon atmosphere. The stirring was continued for 16 h at room temperature. The solids were removed by filtration, washed twice with dichloromethane, and the combined washings and filtrates were evaporated to dryness. The residue was purified by flash chromatography on silica gel (hexane:ethyl acetate 50:50) to yield peracetylated glycoside **5***b*. This product (6.3 g; 1.5 mmol) was dissolved in dry methanol (200 mL), 1 *M* methanolic NaOMe (2 mL) was added, and the mixture stirred for 4 h. After neutralization with Dowex mixed bed resin Ag-501-X8 and Dowex 80W-8X H^+ (3:1), the combined filtrates and washings were evaporated to dryness and the residue purified by flash chromatography on silica gel (isopropanol:water 95:5) to yield **5***c* (1.9 g; 22%), mp 189–191°C; $[\alpha]_D$ −15.0° (*c* 0.66, CH_3OH); ir (neat): 3350 (br, OH) cm^{-1}. *Anal.* calcd. for $C_{15}H_{21}D_7O_{11}$ (391.33): C 46.04, H 5.41; found: C 45.83, H 5.82.

*Heptadeuterioisopropyl 3,6-di-O-acetyl-2-deoxy-2-phthalimido-4-O-(2,3,4,6-tetra-O-acetyl-β-D-galactopyranosyl)-β-D-glucopyranoside (**7**a)*

The crude bromide **6***b* (from acetate **6***a*, 0.87 g; 1.14 mmol; cf. ref. 25) in dry dichloromethane (5 mL) was added to a stirred suspension of silver zeolite 13X (4 g), dry dichloromethane (10 mL), and heptadeuterioisopropanol (0.25 mL; 2.9 mmol) under argon, and the stirring was continued for 16 h at room temperature. The solids were removed by filtration, washed twice with dichloromethane, and the combined washings and filtrates were evaporated to dryness. The residue was purified by flash chromatography on silica gel (hexane:ethyl acetate 6:4) to give **7***a* (604 mg; 68%); mp 253–255°C; $[\alpha]_D$ +3.9° (*c* 0.96, $CHCl_3$); ir (neat): 1780 sh, 1750, 1720 (CO) cm^{-1}; ^{13}C nmr ($CDCl_3$) δ: 169.0–170.4 (6 × CH_3CO), 167.9, 167.6 (*CONCO*), 101.0 (C1-Gal, $^2J_{C-H}$ 161), 99.6 (C1-Glc, $^2J_{C-H}$ 163). *Anal.* calcd. for $C_{35}H_{36}D_7NO_{18}$ (722.67): C 54.41, H 4.70, N 1.81; found: C 54.36, H 4.82, N 1.72.

*Heptadeuterioisopropyl 2-acetamido-2-deoxy-3,6-di-O-acetyl-4-O-(2,3,4,6-tetra-O-acetyl-β-D-galactopyranosyl)-β-D-glucopyranoside (**7**b)*

Compound **7***a* (350 mg; 0.76 mmol) was dissolved in ethanol (8 mL) and hydrazine hydrate (85%, 4 mL) and heated at 70°C for 30 min. After concentration of the reaction mixture *in vacuo*, toluene was added (2 × 50 mL) and the solvent evaporated. The resulting residue was stirred in acetic anhydride (4 mL) and pyridine (8 mL) for 16 h under argon. Crude peracetylated disaccharide **7***b* was obtained after distilling off the reagents at reduced pressure, last traces being removed by codistillation with toluene (3 × 50 mL). The residue yielded, after flash chromatography (silica gel, dichloromethane:methanol 25:1), crystalline **7***b* (454 mg; 87%); mp 155–160°C; $[\alpha]_D$ −17.6° (*c* 0.64, $CHCl_3$:CH_3OH 10:1); ir (neat): 3360, 3300, 3080 (NH), 1750 (COO), 1670, 1550 (CON) cm^{-1}; ^{13}C nmr ($CDCl_3$) δ: 169.9–170.6 (7 × CH_3CO), 101.0 (C1-Gal, $^2J_{C-H}$ 160), 99.5 (C1-Glc, $^2J_{C-H}$ 159). *Anal.* calcd. for $C_{29}H_{36}D_7NO_{17}$ (684.60): C 50.88, H 5.30, N 2.05; found: C 50.92, H 5.41, N 2.08.

*Heptadeuterioisopropyl 2-acetamido-2-deoxy-4-O-(β-D-galactopyranosyl)-β-D-glucopyranoside (**7**c)*

Peracetylated disaccharide **7***b* (454 mg; 0.66 mmol) was dissolved in dry methanol (10 mL), 1 *M* methanolic NaOMe (0.1 mL) was added, and the resulting reaction mixture was stirred under argon for 16 h. After neutralization with a mixture of Dowex mixed bed resin Ag-501-X8 and Dowex 80W-8X H^+ (3:1), the resin was removed by filtration, washed with methanol (35 mL), and the combined filtrates evaporated to dryness. The residue was taken up in methanol (10 mL), toluene (30 mL) was added, and the mixture concentrated to about 5 mL and then precipitated with hexane to yield **7***c* (279 mg; 97%); mp 189–191°C; $[\alpha]_D$ −15.0° (*c* 0.66, CH_3OH); ir (neat): 3300 (br, OH, NH), 1650, 1550 (CON) cm^{-1}; ms *m/e*: 455 (MNa^+), 366 (MH − HOCD $(CD_3)_2^+$). *Anal.* calcd. for $C_{17}H_{24}D_7NO_{11}$ (432.38): C 47.22, H 5.59, N 3.24; found: C 47.02, H 5.32, N 3.34.

*Trideuteriomethyl 2,3-di-O-benzoyl-β-D-galactopyranoside (**8**b)*

Compound **8***a* (1.2 g; 2.43 mmol) prepared according to ref. 4, was hydrogenated in glacial acetic acid (25 mL) over Pd black (300 mg; Strem). The solids were filtered off through a Celite bed, washed with ethyl acetate (50 mL) and toluene (50 mL), and the combined filtrates evaporated to dryness. Toluene (2 × 50 mL) was added and evaporated to remove the residual acetic acid. The residue was purified by flash chromatography (silica gel, chloroform:acetone 5:1) to yield **8***b* (0.81 g; 82%); mp 70–72°C; $[\alpha]_D$ +98.2° (*c* 0.85, $CHCl_3$); ir (neat): 3350 (OH), 1720 (COO) cm^{-1}. *Anal.* calcd. for $C_{21}H_{19}D_3O_8$ (405.38): C 62.22, H 4.72; found: C 61.95, H 4.65.

*Trideuteriomethyl 2,3-di-O-benzoyl-6-O-(3,4,6-tri-O-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl)-β-D-galactopyranoside (**10**a)*

A solution of the diol **8***b* (213 mg; 0.53 mmol) in dry dichloromethane (5 mL) was added to silver zeolite 13X (2 g), which was cooled in an ice bath, and the suspension was stirred under an argon atmosphere for 30 min. A solution of bromide **9** (Toronto Research Chemicals; 0.275 mg; 0.55 mmol) in dichloromethane (5 mL) was added and the stirring was continued for 16 h. The solids were removed by filtration, washed with dichloromethane (25 mL), and the combined filtrates were evaporated to dryness. The residue was purified by flash chromatography (silica gel, dichloromethane:isopropanol 25:1) to yield **10***a* (343 mg; 79%); mp 122–126°C; $[\alpha]_D$ +58.0° (*c* 1.84, $CHCl_3$); ir (neat): 3500 (OH), 1780 sh, 1750, 1720 (CO) cm^{-1}; ^{13}C nmr ($CDCl_3$) δ: 169.4–170.7 (3 × CH_3CO), 167.5 (br, *CONCO*), 165.6, 165.3 (Ph*C*O), 101.7 (C1-Gal, $^2J_{C-H}$ 159), 98.1 (C1-Glc,

For personal use only.

$^2J_{C-H}$ 161). *Anal.* calcd. for $C_{41}H_{38}D_3NO_{17}$ (822.75): C 59.85, H 4.66, N 1.70; found: C 59.63, H 4.71, N 1.62.

*Trideuteriomethyl 2,3,4-tri-*O*-acetyl-6-*O*-(2-acetamido-2-deoxy-3,4,6-tri-*O*-acetyl-β-*D*-glucopyranosyl)-β-*D*-galactopyranoside (**10**b)*

Disaccharide **10***a* (343 mg; 0.41 mmol) was converted into the peracetate as described for compound **7***a*. Purification by flash chromatography (silica gel, dichloromethane:isopropanol 20:1) yielded pure **10***b* (221 mg; 83%); mp 216–222°C; $[\alpha]_D$ −17.1° (*c* 0.99, $CHCl_3$); ir (neat): 3290, 3070 (NH), 1750 (COO), 1660, 1550 (CON) cm^{-1}; ^{13}C nmr ($CDCl_3$) δ: 169.4–171.0 (7 × CH_3CO), 101.7 (C1-Gal, $^2J_{C-H}$ 160), 99.7 (C1-Glc, $^2J_{C-H}$ 163); ms *m/e*: 675 (MNa^+), 330 (PerAcGlcNAc − H^+). *Anal.* calcd. for $C_{27}H_{35}D_3NO_{17}$ (651.63): C 61.04, H 4.75, N 1.74; found: C 60.92, H 4.68, N 1.79.

*Trideuteriomethyl 6-*O*-(2-acetamido-2-deoxy-β-*D*-glucopyranosyl)-β-*D*-galactopyranoside (**10**c)*

Zemplen transesterification of **10***b* (105 mg; 0.61 mmol) using the same procedure as for compound **7***b* gave **10***c* (60 mg; 94%); mp 230–246°C; $[\alpha]_D$ −20.83° (*c* 0.85, $CH_3OH:H_2O$ 3:1); ir (neat): 3300 (br, OH, NH), 1650, 1550 (CON) cm^{-1}; ms *m/e*: 423 (MNa^+), 204 (GlcNAc − H^+). *Anal.* calcd. for $C_{15}H_{24}D_3NO_{11}$ (400.35): C 45.00, H 6.04, N 3.50; found: C 44.72, H 5.82, N 3.34.

*Trideuteriomethyl 2-*O*-benzoyl-4,6-*O*-benzylidene-3-*O*-(3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-*D*-glucopyranosyl)-β-*D*-galactopyranoside (**11**a)*

The bromide **9** (10 g; 20 mmol) in dry dichloromethane (25 mL) was added to a stirred mixture of alcohol **2***a* (3.63 g; 9.3 mmol), silver trifluoromethanesulphonate (5.2 g; 20 mmol), 2,6-di-*tert*-butyl-4-methylpyridine (4.1 g; 20 mmol), molecular sieves 3A (5 g), and dry dichloromethane (100 mL) at 0–5°C under an atmosphere of argon. The stirring was continued for 3 h and then the temperature was allowed to rise to room temperature. The solids were removed by filtration through a Celite bed, washed with dichloromethane, and the combined filtrates evaporated to dryness. The residue was purified by flash chromatography on silica gel (chloroform:acetone 98:2) to yield pure **11***a* (5.6 g; 75%); ^{13}C nmr ($CDCl_3$) δ: 169.3–170.5 (3 × CH_3CO), 167.5 (br, *C*O*N*C*O*), 164.5 (Ph*C*O), 101.7 (C1-Gal[3],[9] $^2J_{C-H}$ 158), 100.8 (PhCO_2[3], $^2J_{C-H}$ 159), 99.3 (C1-Glc[3], $^2J_{C-H}$ 162).

*Trideuteriomethyl 2-*O*-benzoyl-4,6-*O*-benzylidene-3-*O*-(3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-α-*D*-glucopyranosyl)-β-*D*-galactopyranoside (**12**a)*

Prepared as described for the β-isomer **11***a* (cf. ref. 4) except that a total of 4 equivalents of bromide **9** were added in 3 portions and the stirring continued for 5 days. The total disaccharide fractions accounted for about 80% of starting alcohol **2***a* and contained approximately a 2:1 α:β mixture of isomers. Pure α-disaccharide **12***a* was obtained by preparative hplc (μPorasil, hexane:ethyl acetate 1:1); mp 253–258°C; $[\alpha]_D$ +186.5° (*c* 1.15, $CHCl_3$); ir (neat): 1780 sh, 1750, 1720 (CO) cm^{-1}; ^{13}C nmr ($CDCl_3$) δ: 168.8–170.3 (3 × CH_3CO), 167.5 (br, *C*O*N*C*O*), 164.6 (Ph*C*O), 101.5 (C1-Gal, $^2J_{C-H}$ 162), 99.9 (PhCO_2, $^2J_{C-H}$ 156), 93.7 (C1-Glc, $^2J_{C-H}$ 172). *Anal.* calcd. for $C_{41}H_{38}D_3NO_{16}$ (806.75): C 61.04, H 4.75, N 1.74; found: C 60.92, H 4.68, N 1.79.

*Preparation of **12**a using ultrasound or heating*

The procedure described above was used except that 1,2-dichloroethane was used as solvent, 2 equivalents of bromide **9** to 1 equivalent of **2***a* (typically using 0.5 mmol), and 2 equivalents of added bases (2,4,6-trimethylpyridine or tetramethylurea or silver carbonate or 2,6-di-*tert*-butyl-4-methylpyridine (26)) were added and ultrasonic agitation, using a Bransonic 220 with propylene glycol as the bathing solution or heating to 55–60°C with an oil bath, was provided. The progress of the reactions was monitored by tlc (ethyl acetate:hexane 50:50) and the crude reaction mixtures were analyzed by ^1H nmr.

*Trideuteriomethyl 2-*O*-benzoyl-3,6-di-*O*-(3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-*D*-glucopyranosyl)-β-*D*-galactopyranoside (**13**a)*

Compound **13***a* was prepared as described for disaccharide **10***a* except that diol **11***b* (235 mg; 0.33 mmol) prepared as for diol **8***b* (cf. ref. 4) was used as aglycon. The trisaccharide **13***a* was ultimately purified by flash chromatography (silica gel, dichloromethane:isopropanol 25:1) to yield pure **13***a* (236 mg; 63%); mp 153–156°C; $[\alpha]_D$ +48.4° (*c* 1.01, $CHCl_3$); ir (neat): 3400 (OH), 1780 sh, 1750, 1720 (CO) cm^{-1}; ^{13}C nmr ($CDCl_3$) δ: 169.9–170.7 (6 × CH_3CO), 167.5 (br, *C*O*N*C*O*), 164.3 (Ph*C*O), 101.3 (C1-Gal, $^2J_{C-H}$ 160), 98.4 (C1, 3-Glc[4],[10] $^2J_{C-H}$ 160), 98.0 (C1, 6-Glc[4], $^2J_{C-H}$ 163). *Anal.* calcd. for $C_{54}H_{53}D_3N_2O_{25}$ (1136.15): C 57.09, H 4.70, N 2.47; found: C 57.52, H 4.62, N 2.32.

*Trideuteriomethyl 2,4-di-*O*-acetyl-3,6-di-*O*-(3,4,6-tri-*O*-acetyl-2-deoxy-2-acetamido-β-*D*-glucopyranosyl)-β-*D*-galactopyranoside (**13**b)*

Trisaccharide **13***a* (171 mg; 0.16 mmol) was converted into the peracetate **13***b* by exactly the procedure described for disaccharide **7***a*. The product was purified by flash chromatography (silica gel, chloroform:methanol 20:1) to yield pure **13***b* (124 mg; 85%); mp 252–255°C; $[\alpha]_D$ +1.7° (*c* 0.88, $CHCl_3$); ir (neat): 3285, 3090 (NH), 1750 (COO), 1650, 1540 (CON) cm^{-1}. *Anal.* calcd. for $C_{39}H_{53}D_3N_2O_{24}$ (939.85): C 49.84, H 5.68, N 2.98; found: C 50.22, H 5.42, N 3.03.

*Trideuteriomethyl 3,6-di-*O*-(2-acetamido-2-deoxy-β-*D*-glucopyranosyl)-β-*D*-galactopyranoside (**13**c)*

The acetates of **13***b* (85 mg; 0.09 mmol) were transesterified following the procedure used for compound **7***a* to yield pure trisaccharide **13***c* (43 mg; 79%); mp 263–273°C; $[\alpha]_D$ −4.6° (*c* 0.98, $CH_3OH:H_2O$ 3:1); ir (neat): 3300 (br, OH, NH), 1650, 1550 (CON) cm^{-1}. *Anal.* calcd. for $C_{19}H_{17}D_3N_2O_{16}$ (603.54): C 45.77, H 6.18, N 4.64; found: C 45.62, H 6.25, N 4.53.

Enzymes in organic synthesis. 36.[1]
Synthesis of optically active civet constituent from an enzyme-generated chiral synthon

J. Bryan Jones and R. Scott Hinks
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received September 11, 1986

J. Bryan Jones and R. Scott Hinks. Can. J. Chem. **65**, 704 (1987).

A synthesis of the civet constituent, (+)-(*S*,*S*)-(*cis*-6-methyltetrahydropyran-2-yl)acetic acid, is described, in which the key stereochemistry of the chiral starting material is set by an enantiotopically selective, porcine pancreatic lipase-catalyzed, hydrolysis of a *meso* diester.

J. Bryan Jones et R. Scott Hinks. Can. J. Chem. **65**, 704 (1987).

On décrit une synthèse du constituant du civet, l'acide (+)-(méthyl-6-*cis* tétrahydropyrannyl-2) acétique-(*S*,*S*), dans laquelle la stéréochimie clé du produit de départ chiral est obtenue par une hydrolyse énantiosélective d'un diester *méso* qui est effectuée par la catalyse d'une lipase pancréatique du porc.

For personal use only.

The broad spectrum of new asymmetric synthetic opportunities opened up by the exploration of the chiral catalytic properties of enzymes is now well documented (1). Stereospecific transformations on symmetrical substrates are particularly attractive in this regard, with the commercially available porcine pancreatic lipase (PPL) being one of the most widely applied of the enzymes in current use for this purpose (2). In this paper we report a new synthesis of the optically active civet constituent **8** from a PPL-generated chiron.

(+)-(*S*,*S*)-(*cis*-6-methyltetrahydropyran-2-yl)acetic acid (**8**) is a constituent of a glandular secretion of the civet cat (3), whose synthesis, both of the optically active (4) and racemic (5) forms, has attracted considerable attention. Of these syntheses, only the latest one of Keinan *et al.* (4*d*), which exploits alcohol dehydrogenase stereospecificity, has been based on an enzymically generated chiron. Our current PPL-based approach is outlined in Scheme 1.

The *meso* diester **1** starting material was readily prepared from 4*H*-pyran-2,6-dicarboxylic acid (**9**) (6) in 69% overall yield by the method summarized in Scheme 2.

The key stereochemistry of the starting chiron for the synthesis was set by stereoselective PPL-catalyzed hydrolysis of **1** to give the alcohol-ester (−)-**2** of 55% e.e. (enantiomeric excess) in 77% isolated yield. Oxidation of **2** → **3** proceeded smoothly in 94% yield. Homologation of **3** was effected in 41% yield by the Arndt–Eistert procedure, a reaction that is known to proceed with retention of configuration at the α-position of the carboxyl function (7). The remaining steps of transesterification (**4** → **5**), tosylation (**5** → **6**), reduction (**6** → **7**), and oxidation (**7** → **8**) were achieved in quantitative, 88%, 68%, and 76% yields respectively. The overall yield of the civet constituent **8** from **2** was 18%, with the target product having the same e.e. as the starting chiron **2**. The enantiomeric excesses of **2** and **8** were determined directly. The alcohol-ester **2** was oxidatively converted to its corresponding lactone, and hence to the (*R*,*R*)-butane-2,3-diol orthoester, for e.e. measurement by the standard glc method (8). The e.e. of **8** was established by its conversion to the methyl ester with diazomethane, followed by ^{1}H nmr examination of the methoxyl protons in the presence of Eu(hfc)$_3$ (9).

Since the stereoisomeric integrity of the enzymically generated chiron **2** is retained throughout the synthesis, it is evident that enantiomerically pure **8** would result from optically pure **2** as the starting material. For hydrolytic enzymes such as pig liver esterase and PPL, the stereospecificities of hydrolyses of *meso* diester and related substrates can be dramatically improved by manipulation of the reaction conditions (10, 11). This aspect is being pursued further and protocols for improving the stereospecificities of PPL-catalyzed hydrolyses will be reported shortly.

[1]For Part 35, see ref. 10.

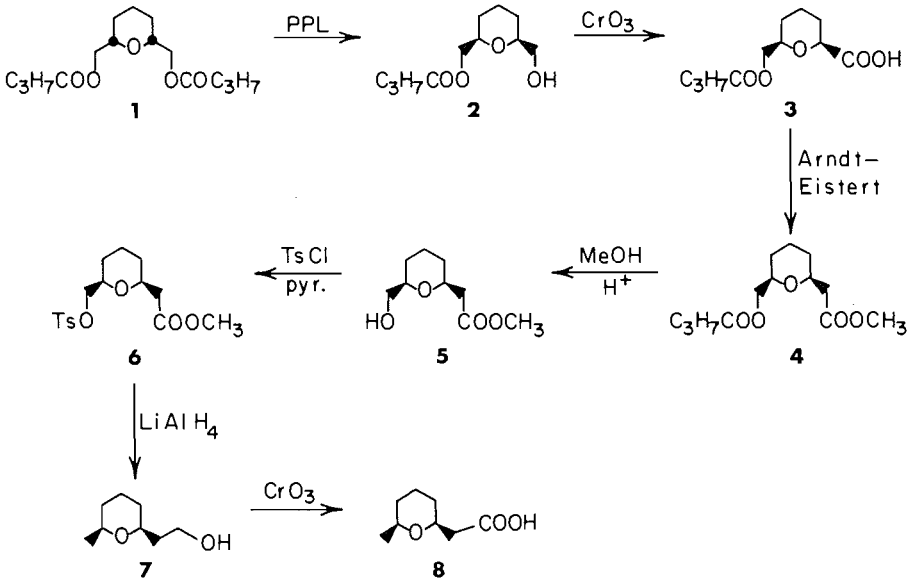
Experimental

Porcine pancreatic lipase (PPL, EC 3.1.1.3, Type II, Sigma L-3126, Lot # 82F-0636) was obtained from Sigma Chemical Co. All enzymic reactions were monitored using a Radiometer RTS 822 pH-stat. The ^{1}H nmr spectra were recorded on Varian T60 or XL 200 instruments and ^{13}C nmr spectra on a Varian CFT-20 spectrometer, both in $CDCl_3$ unless noted otherwise. The ir spectra were recorded on a Nicolet 5DX FT-IR system, optical rotations on a Perkin–Elmer 141 polarimeter, and glc analyses on a Hewlett–Packard HP 57/019 chromatograph. Melting points were determined on an Electrothermal capillary apparatus and are uncorrected. Chromatotron separations were performed with a Harrison Research model 7924 using Merck 7749 silica gel on 8-inch rotors with 4 mm thickness of adsorbent.

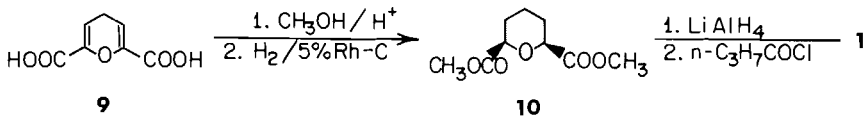
Preparation of substrate: cis-*2,6-bis(butanoxymethyl)tetrahydropyran (**1**)*

The 4*H*-pyran-2,6-dicarboxylic acid (**9**) starting material was prepared from diethyl oxaloacetate in 22% yield, mp >360°C (lit. (6) mp >300°C). The diacid **9** (39.2 g, 0.23 mol) and trimethylorthoformate (50.5 mL, 48.9 g, 0.46 mol) in dry MeOH (200 mL) containing concentrated H_2SO_4 (1 mL) was heated under reflux for 3 h. The dark mixture was then cooled and kept at 20°C for 2 days. The crystalline product was filtered and the mother liquors concentrated to give a second crop. The combined crystalline products were washed with cold (0°C) MeOH (3 × 50 mL) and then sublimed at 85°C/0.1 Torr (1 Torr = 133.3 Pa). Recrystallization from MeOH yielded 2,5-dicarbomethoxy-4*H*-pyran (38.6 g, 84%), mp 122–123°C; ir (KBr) ν: 1750, 1721, 1702, 1687, 1642 cm^{-1}; ^{1}H nmr δ: 3.09 (t, 2H, J = 4 Hz), 3.86 (s, 6H), and 6.10 (t, 2H, J = 4 Hz) ppm; ^{13}C nmr δ: 21.31, 52.11, 109.53, 141.61, and 161.16 ppm. *Anal.* calcd. for $C_9H_{10}O_5$: C 54.55, H 5.09; found: C 54.78, H 5.00%.

This unsaturated diester (36.8 g, 0.186 mol) in MeOH (250 mL) containing 5% Rh–C (0.4 g) was hydrogenated in a Parr apparatus at 50 psi (1 psi = 6.9 kPa) for 4 h. The mixture was then filtered through Celite and rotoevaporated. The crude product (37.8 g, 100%) was recrystallized from diethyl ether (20 mL) to give *cis*-2,6-dicarbomethoxytetrahydropyran (**10**, 30.8 g, 82%), mp 52–54°C (lit. (12) mp 54°C); ir (molten film) ν: 1749 cm^{-1}; ^{1}H nmr δ: 1.30–2.20 (m, 6H), 3.81 (s, 6H), and 3.90–4.25 (m, 2H) pm; ^{13}C nmr δ: 22.07, 27.20, 51.32, 75.89, and 170.04 ppm.



SCHEME 1



SCHEME 2

The dimethyl ester **10** (15.0 g, 74.3 mmol) in dry THF (100 mL) was added dropwise with stirring during 30 min to a suspension of $LiAlH_4$ (8.5 g, 220 mmol) in dry THF (200 mL) at 25°C. The mixture was then heated under reflux for 30 min, cooled, and then quenched with saturated aqueous sodium potassium tartrate. Rotoevaporation of the dried ($MgSO_4$) THF solution followed by Kugelrohr distillation and then recrystallization from diethyl ether afforded *cis*-2,6-dihydroxymethyltetrahydropyran (9.26 g, 85%), bp 90°C/0.1 Torr, mp 44–46°C (lit. (6) mp 45.7–46.4°C); ir (molten film) ν: 3350 (br) cm^{-1}; ^1H nmr δ: 1.20–2.00 (m, 6H), 2.90–3.70 (m, 8H) ppm; ^{13}C nmr δ: 22.38, 26.71, 65.80, and 78.08 ppm.

To the above diol (3.01 g, 20.6 mmol) in dry THF (50 mL) and dry pyridine (8.3 mL, 103 mmol) at 20°C was added, with stirring and via a syringe, butanoyl chloride (3.4 mL, 41.2 mmol) during 2 min. After stirring for a further hour, the mixture was rotoevaporated and the residue dissolved in water (50 mL) and acidified with concentrated HCl to pH 1. This solution was extracted with diethyl ether (2 × 50 mL) and the ether solution washed with saturated aqueous $NaHCO_3$ (2 × 10 mL) and then with brine (10 mL). The ether solution was then decolorized with Norit (1 g), dried ($MgSO_4$), and rotoevaporated. Kugelrohr distillation of the residue yielded *cis*-2,6-dibutanoyloxymethyltetrahydropyran (**1**, 5.7 g, 96%), bp 105°C/0.15 Torr; ir (film) ν: 1738 cm^{-1}; ^1H nmr δ: 0.95 (t, 6H, J = 6 Hz), 1.18–2.03 (m, 10H), 2.23 (t, 2H, J = 7 Hz), 3.40–3.83 (br m, 2H), and 4.08 (apparent d, 4H, J(app) = 5 Hz) ppm; ^{13}C nmr δ: 13.43, 18.25, 22.45, 27.32, 35.94, 66.69, 75.34, and 173.25 ppm. *Anal.* calcd. for $C_{15}H_{26}O_5$: C 62.91, H 9.15; found: C 62.96, H 9.06%.

Preparation of hydroxyester 2 via PPL-catalyzed hydrolysis of 1

The diester **1** (3.30 g, 11.5 mmol) was suspended at 25°C in buffer solution (30 mL) of pH 7.0 consisting of 0.01 *M* KH_2PO_4, 0.1 *M* NaCl, and 0.0025 *M* $CaCl_2$. PPL (104 mg, 12 U/mg) was then added and the reaction maintained at 25°C, and at pH 7.0 by pH-stat controlled titration of the liberated acid with 0.5 *M* NaOH. After 9 h, when one equivalent of base had been taken up, the mixture was filtered through Celite and extracted with diethyl ether (3 × 70 mL). The combined ether extracts were washed with saturated aqueous $NaHCO_3$, then with brine, and finally dried ($MgSO_4$) and rotoevaporated. The mixture obtained was purified by Chromatotron separation (pentane:diethyl ether gradient = 1:1 (150 mL), 0:1 (250 mL)). The central fractions were Kugelrohr distilled to give (−)-(2*R*,6*S*)-2-butanoyloxymethyl-6-hydroxymethyltetrahydropyran (**2**, 2.09 g, 84%, 55% e.e.), bp 80°C/0.05 Torr; $[\alpha]_D^{25}$ −4.3° (*c* 4.4, $CHCl_3$); ir (film) ν: 3460 (br), 1738 cm^{-1}; ^1H nmr δ: 0.96 (t, 3H, J = 6 Hz), 1.13–2.15 (m, 8H), 2.26 (br s, 1H), 2.32 (t, 2H, J = 6 Hz), 3.26–3.86 (m, 4H), and 4.10 (d, 2H, J = 5 Hz) ppm; ^{13}C nmr δ: 13.28, 18.10, 22.29, 26.66, 27.37, 35.75, 65.64, 66.16, 75.16, 77.97, and 173.17 ppm. *Anal.* calcd. for $C_{11}H_{20}O_4$: C 61.09, H 9.32; found: C 60.84, H 9.22%.

The enantiomeric excess determination for (−)-**2** was performed via its oxidation (50-mg scale) with CrO_3 (see below) followed by esterification with CH_2N_2 to the corresponding methyl ester. This was then heated under reflux with (*R*,*R*)-butane-2,3-diol (2 equiv.) in benzene (25 mL) containing *p*-TsOH (10 mg). Following an initial lactonization to (−)-(1*S*,5*R*)-3,9-dioxabicyclo[3.3.1]nonan-2-one, the orthoester formed in the usual (8) way and was analyzed by glc (8) using the orthoester from (±)-**2** as reference standard. With a Supelcowax capillary column, 6 psi (41.4 kPa), 140°C, the diastereomeric peak retention times were 12.98 min (22.5%) and 13.81 min (77.5%), for an e.e. of 55 ± 3%.

Synthesis of the civet constituent (+)-(2S,6S)-8

To the PPL-derived alcohol-butyrate (−)-(2*R*,6*S*)-**2** (1.83 g, 8.46 mmol, 55% e.e.) in acetone (100 mL) at 20°C was added Jones reagent until a yellow colour persisted. At this point, a 50% excess of Jones reagent was added and the mixture stirred at 20°C for 15 min. The reaction was then quenched by the dropwise addition of 2-propanol, then filtered, and the residue was washed with acetone (3 × 20 mL). The combined acetone solutions were rotoevaporated and the residual oil dissolved in 0.5 *M* hydrochloric acid (25 mL) and extracted with diethyl ether (3 × 50 mL). Rotoevaporation of the dried ($MgSO_4$) extract followed by Kugelrohr distillation gave (−)-(2*S*,6*R*)-*cis*-butanoyloxymethyltetrahydropyran-2-carboxylic acid (**3**, 1.84 g, 94%), bp 110°C/0.05 Torr; $[\alpha]_D^{25}$ −21.3° (*c* 3.7, $CHCl_3$); ir (film) ν: 3400–2500, 1735, and 1718 cm^{-1}; ^1H nmr δ: 0.95 (t, 3H, J = 6 Hz),

1.20–2.20 (m, 8H), 2.33 (t, 2H, J = 7 Hz), 3.51–4.28 (m, 4H), and 9.41 (s, 1H) ppm; ^{13}C nmr δ: 13.44, 18.25, 22.51, 26.70, 27.96, 35.91, 66.26, 75.54, 75.96, 173.59, and 173.82 ppm. *Anal.* calcd. for $C_{11}H_{18}O_5$: C 57.38, H 7.88; found: C 56.93, H 7.90%.

The acid-butyrate (−)-**3** (689 mg, 3.03 mmol) in benzene (30 mL) was dried by distillation of part (10 mL) of the benzene under N_2. After cooling the remaining solution to 20°C, oxalyl chloride (5 mL) was added and the mixture stirred for 2 h at 20°C. The solvent and excess oxalyl chloride were distilled off at 14 Torr and dry diethyl ether added to the residual oil. The ether solution was cooled to −78°C and, via cannula, a Na-dried solution of CH_2N_2 (1 g, 24 mmol) in diethyl ether (75 mL) containing Et_3N (2 mL, distilled from $LiAlH_4$) was added slowly. The mixture was warmed to 20°C during 30 min and then stirred at this temperature for 1 h. The reaction solution was then washed successively with water (30 mL), 10% aqueous acetic acid (50 mL), water (30 mL), saturated aqueous $NaHCO_3$ (20 mL), and brine (20 mL). The dried (Na_2SO_4, **not** $MgSO_4$) ether solution was rotoevaporated, with final solvent traces removed at 20°C/0.05 Torr, to afford (2*S*,6*R*)-*cis*-6-butanoyloxymethyl-2-diazoketotetrahydropyran (758 mg, 98%); ir (film) ν: 3132, 2109, 1737, and 1644 cm^{-1}; ^{1}H nmr δ: 0.96 (t, 3H, J = 7 Hz), 1.13–2.25 (m, 11H), and 3.50–4.20 (m, 2H) ppm; ^{13}C nmr δ: 13.62, 18.46, 22.60, 27.05, 28.37, 36.10, 52.37, 66.44, 75.73, 80.97, 173.55, and 181.02 ppm.

The above diazoketone (732 mg, 2.88 mmol) in dry MeOH (10 mL) was brought to reflux under N_2 and 1 mL of catalyst (prepared from silver benzoate (1 g) in dry Et_3N (10 mL)) was added. N_2 was evolved immediately and the reaction was completed by refluxing for a further 45 min, with two further additions of 1-mL aliquots of catalyst during this period after 5 and 15 min respectively. The mixture was then cooled to 20°C, filtered through Celite, and rotoevaporated. The residue was dissolved in diethyl ether (50 mL), washed with 1 *M* hydrochloric acid, then with saturated aqueous $NaHCO_3$ (20 mL), and finally with brine (20 mL). The dried ($MgSO_4$) ether solution was rotoevaporated and the residue purified by flash chromatography on silica (30 g, pentane:diethyl ether:MeOH 79:20:1 (200 mL) elution). Kugelrohr distillation then yielded (−)-methyl (2*S*,6*R*)-*cis*-(6-butanoyloxymethyltetrahydropyran-2-yl)acetate (**4**, 287 mg, 42%), bp 85°C/0.025 Torr; $[\alpha]_D^{25}$ −2.8° (*c* 8.5, $CHCl_3$); ir (film) ν: 1739 and 1733 cm^{-1}; ^{1}H nmr δ: 0.96 (t, 3H, J = 7 Hz), 1.13–2.16 (m, 8H), 2.16–2.63 (m, 4H), 3.69 (s, 3H), and 3.50–4.20 (m, 4H) ppm; ^{13}C nmr δ: 13.31, 18.12, 22.60, 27.06, 30.62, 35.79, 41.01, 51.13, 66.51, 73.99, 75.36, 171.19, and 173.00 ppm. *Anal.* calcd. for $C_{13}H_{22}O_5$: C 60.45, H 8.58; found: C 60.34, H 8.39%.

The methyl-butanoate diester **4** (226 mg, 0.89 mmol) in MeOH (50 mL) containing *p*-TsOH (20 mg) was heated under reflux for 24 h, when conversion to the hydroxyester **5** was shown by tlc to be complete. The solution was then rotoevaporated, with the final traces of solvent being removed at 25°C/0.05 Torr. Dry pyridine (10 mL) was then added and the solution cooled to 0°C. *p*-Toluenesulfonyl chloride (340 mg, 1.78 mmol) was added and the mixture kept for 20 h at 0–5°C. Ice-water was then added and, after 20 min, the mixture was extracted at 0°C with diethyl ether (75 mL). The cold ether extract was washed at 0°C with cold 1 *M* hydrochloric acid (2 × 40 mL) and then with ice-water (20 mL). The ether layer was dried ($MgSO_4$) and rotoevaporated to yield methyl (2*S*,6*R*)-(*cis*-6-tosyloxymethyltetrahydropyran-2-yl)acetate (**6**, 268 mg, 88%) as a pale yellow oil; ir (film) ν: 1738 cm^{-1}; ^{1}H nmr δ: 1.10–2.00 (m, 6H), 2.20–2.56 (m, 2H), 2.46 (s, 3H), 3.35–4.12 (m, 4H), 3.68 (s, 3H), 7.36 (d, 2H, J = 8 Hz), and 7.79 (d, 2H, J = 8 Hz) ppm.

$LiAlH_4$ (600 mg, 15 mmol) was added with stirring to the tosylate **6** (265 mg, 0.78 mmol) in dry THF (50 mL) at 0°C. After stirring for 10 min at 0°C, the mixture was stirred for 10 min at 20°C and finally refluxed for 1 h. The cooled (20°C) reaction mixture was then quenched with saturated aqueous sodium potassium tartrate and the THF solution rotoevaporated. The residue was dissolved in diethyl ether, dried ($MgSO_4$), rotoevaporated, and finally Kugelrohr distilled to give (+)-(*S*,*S*)-cis-2-(2′-hydroxyethyl)-6-methyltetrahydropyran (**7**, 77 mg, 68%), bp 30°C/0.05 Torr (lit. (5*c*) (±-**7**) bp 45–47°C/12 Torr); $[\alpha]_D^{25}$ +15.3° (*c* 5, $CHCl_3$) (lit. (4*b*) $[\alpha]_D^{25}$ +24.6° ($CHCl_3$)); ir (film) ν: 3400 (br) cm^{-1}; ^{1}H nmr δ: 1.16 (d, 3H, J = 6 Hz), 1.10–1.93 (m, 8H), 2.78 (br s, 1H), 3.25–3.66 (m, 2H), and 3.78 (t, 2H, J = 5.5 Hz) ppm; ^{13}C nmr δ: 22.06, 23.36, 31.17, 32.96, 61.51, 73.95, and 78.41 ppm.

Jones reagent was added dropwise with stirring at 20°C to the above alcohol **7** (46 mg, 0.32 mmol) in acetone (25 mL) until the yellow color persisted, then 50% excess of Jones reagent was added and the mixture stirred for 30 min at 20°C. The reaction was then quenched by the dropwise addition of 2-propanol until colorless, and the mixture rotoevaporated. The residue was then dissolved in water (25 mL), the solution brought to pH 1 with 12 *M* hydrochloric acid, and then extracted with diethyl ether (6 × 50 mL). The dried ($MgSO_4$) ether extracts were rotoevaporated to yield the civet constituent (+)-(*S*,*S*)-(*cis*-6-methyltetrahydropyran-2-yl)acetic acid (**8**, 39 mg, 76%, 58% e.e.); $[\alpha]_D^{25}$ +24.5° (*c* 3.3, C_6H_6) (lit. (4*a*) $[\alpha]_D^{22}$ +32.86° (*c* 1.05, C_6H_6); (4*b*) $[\alpha]_D^{25}$ +46.8° (C_6H_6); (4*d*) $[\alpha]_D^{22}$ +43.85° (*c* 2.52, C_6H_6); ir (film) ν: 2500–3500 cm^{-1}; ^{1}H nmr δ: 1.08 (d, 3H, J = 6 Hz), 1.05–2.00 (m, 6H), 2.55 (d, 2H, J = 6.5 Hz), 3.30–4.00 (m, 2H), 9.46 (br s, 1H) ppm; ^{13}C nmr δ: 21.93, 23.18, 30.76, 32.75, 41.30, 73.96, 74.43, and 175.50 ppm.

The e.e. of (+)-**8** was determined via its esterification with diazomethane, followed by 200-MHz ^{1}H nmr examination of the methoxyl protons (ΔΔδ 0.014 ppm in the presence of Eu(hfc)$_3$ (0.4 equiv.) (9). An e.e. value of 58 ± 3% was measured.

Received July 14, 1986

HELMUT GÖRNER, JOSEPH POULIQUEN, and JEAN KOSSANYI. Can. J. Chem. **65**, 708 (1987).

The relaxation pathways of excited *trans-N,N'*-diacylindigo dyes (*trans*-**1**–*trans*-**4**) and of the rigid *trans* (**5**) and *cis* (**6**) indigo analogues have been studied by nanosecond flash photolysis and steady state measurements. In fluid solution the *trans* to *cis* photoisomerization of **1**–**4** occurs via a singlet excited state mechanism on direct excitation, and the triplet state appears to be reached only by sensitized reaction. The lower quantum yield for *trans* → *cis* isomerization of **2**–**4** at room temperature, as compared to **1**, is due to a thermally activated internal conversion step leading to the *trans* ground state. This pathway competes with fluorescence and twisting of the molecule around the central double bond in the excited singlet state. Increasing the viscosity of the medium decreases the twisting of the flexible molecules and, as a consequence, increases the population of the lowest triplet state. A triplet transient, the intensity of which increases with the viscosity of the medium, could be characterized at low temperature under direct excitation. A transient species, which can be assigned to a triplet state on the basis of quenching experiments and on the fact that the same transient could be found under sensitized conditions, also has been observed at room temperature for the rigid **5** and **6** molecules. Quenching measurements of triplet sensitizers by **5**, *trans*-**1**, and *trans*-**2** enables the localization of the triplet energy at around 40 kcal/mol.

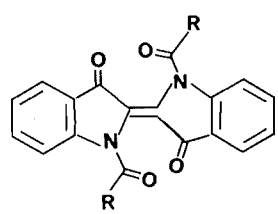
HELMUT GÖRNER, JOSEPH POULIQUEN et JEAN KOSSANYI. Can. J. Chem. **65**, 708 (1987).

Les différentes voies de désactivation des états excités du *trans N,N'*-diacétylindigo (*trans*-**1**) et des *N,N'*-dibenzoylindigos substitués (*trans*-**2**–*trans*-**4**), ainsi que leurs analogues rigides *trans* (**5**) et *cis* (**6**), ont été étudiés par photolyse laser nanoseconde et par irradiation continue. En solution fluide, la photoisomérisation *trans* → *cis* obtenue par irradiation directe se produit à partir du seul état excité singulet, l'état triplet n'étant atteint que par sensibilisation. La plus faible valeur du rendement quantique d'isomérisation *trans* → *cis* observée pour **2**–**4** à la température ambiante, est attribuable à une étape activée de la conversion interne qui mène à l'état fondamental *trans*. Cette voie est en compétition avec la fluorescence et la rotation autour de la double liaison centrale dans l'état excité singulet. L'augmentation de la viscosité du milieu permet d'accéder à l'état triplet *trans* avec une efficacité croissante, et un transitoire triplet, dont l'intensité augmente précisemment avec la viscosité de ce milieu, a pu être caractérisé pour les indigos flexibles **1**–**4**. Pour les composés **5** et **6**, à la température ambiante, un transitoire analogue est obtenu qui a été attribué à l'état triplet à l'aide d'expériences de sensibilisation et d'inhibition (par l'azulène, le ferrocène et l'oxygène). L'inhibition de l'état triplet d'une série de sensibilisateurs par le composé bloqué **5** permet de localiser son énergie de triplet autour de 40 kcal/mol.

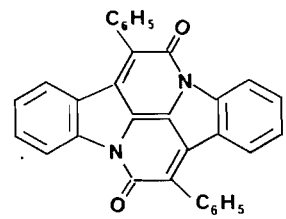
Introduction

Thioindigo and substituted indigo dyes in *cis* ⇄ *trans* isomerization (1–4) show interesting photochemical behaviour, which has been proposed for solar energy conversion and storage (5). A triplet mechanism, postulated by Wyman and co-workers (1, 6), is now generally accepted for the *trans* → *cis* photoisomerization of thioindigo and its derivatives (7–12), while the *cis* → *trans* pathway is still under debate (9, 12). *N,N'*-Diacetyl indigo **1** and *N,N'*-dibenzoyl substituted indigo dyes **2**–**4** undergo *trans* → *cis* photoisomerization from the singlet excited state and no evidence for participation of a triplet excited state (13) could be put forward. In any case, since a transient could be characterized as a triplet state for *trans*-**1** (8),[2] an isomerization that would involve this triplet can still be questioned. On the other hand, unsubstituted indigo itself does not isomerize due to an efficient intramolecular hydrogen transfer from the nitrogen atom to the carbonyl group (14).

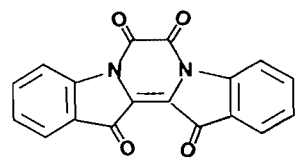
The purpose of the present work is to describe the photophysical and photochemical properties of trans-**1** and of three



1-4



5



6

trans-**1** R = CH_3
trans-**2** R = C_6H_5
trans-**3** R = *p*-ClC_6H_4
trans-**4** R = *p*-$MeOC_6H_4$

N,N'-disubstituted indigo dyes (**2**–**4**). In addition, two rigid analogues (**5** and **6**) were studied. Due to their longer lifetime, the excited states of the latter two should be more readily accessible by nanosecond laser flash photolysis than those of the flexible dyes, since rotation around the central C=C double bond is for them impossible. Evidence for a singlet pathway for direct *trans* → *cis* photoisomerization is further established.

Experimental

Laser excitation was carried out with a neodymium laser (λ_{exc} = 353 and 530 nm, pulse width ~ 15 ns) (8, 15). If not otherwise indicated, 530-nm light was used and the samples were purged with argon. Concentrations of (0.3–1) × 10^{-4} *M* for **5** and (0.5–3) × 10^{-4} *M* for *trans*-**1**–*trans*-**4** were used for experiments under direct excitation while higher concentrations were generally used for sensitized excitation (λ_{exc} = 353 nm). Low temperature measurements were carried out in a 1 × 1 or 0.6 × 0.6 cm^2 rectangular cell placed in a cooled Dewar for steady state and pulsed measurements, respectively.

Fluorescence spectra at +25 and −196°C were recorded on a Spex–Fluorolog (corrected spectra), and at various temperatures on Perkin–Elmer MPF44-B or LS-5 spectrofluorimeters. Since ϕ_f is only slightly quenched by oxygen for **1**–**4** at +25°C (<10% in air- versus argon-saturated dichloromethane solution), the fluorescence spectra of the flexible dyes were recorded in air-saturated solutions. The concentrations were kept small, corresponding to an absorption of 0.1–0.4 in 1-cm cells at λ_{exc} = 530 nm. Values for ϕ_f were determined by using 9,10-diphenylanthracene (from EGA) as reference (cf. ref. 16). Singlet lifetimes were measured by excitation at 354 nm with an Applied Photophysics SP-1 single-photon counting fluorimeter, which was connected to an Ortec multichannel analyzer and a VAX 11/780 computer system.

Steady state irradiation measurements were carried out with a 1000-W xenon–mercury lamp combined with a monochromator (12-nm bandwidth, λ_{irr} = 546 nm unless otherwise indicated). For the direct excitation measurements in argon-saturated solutions, indigo concentrations of (4–6) × 10^{-5} *M* were used. Low temperature measurements were performed by irradiating the sample in a Dewar. Values for $\phi_{t\rightarrow c}$ were obtained by analysis of the visible absorption spectra (Perkin–Elmer 554) using as reference the absolute values in chloroform (13).

The *trans* isomers were prepared according to the procedure of Ross and Blanc (3*b*) for **1** and by Posner's method for **2**–**4** (17); the *cis* isomers of **1**–**3** were the same as described previously (13). The rigid molecule **5** was prepared using a procedure adapted from the one described by Engi (18). Oxalylindigo **6** was obtained according to the procedure of Heller (19). The compounds were purified by repetitive recrystallization in benzene (**1**–**5**) or in chloroform (**6**).

Ferrocene (Merck) was recrystallized from methanol while azulene (Aldrich) was used as received. The sensitizers were purified by recrystallization except for benzophenone, which was zone-refined. The solvents (Merck) were of p.A. quality (toluene, dichloromethane, glycerol triacetate (GT), acetone, *N*,*N*-dimethylformamide, and ethanol), Uvasol (acetonitrile), gold label (benzene, Aldrich); 2-methyltetrahydrofuran (MTHF, free of peroxides), ethyl iodide, and butyronitrile were purified by distillation.

The poly(methyl methacrylate) (PMMA) samples were prepared by dissolving 0.05–0.1% (by weight of the monomer) of the dye in 18 mL of methyl methacrylate at room temperature. Quantities of 5–6 mL of the solution were placed in a 16 mm diameter Pyrex tube with 0.075% by weight (based on methyl methacrylate) of 2,2-azobis(2-methyl propionitrile). The contents of the tubes were frozen by means of Dry Ice; the tubes were flushed with argon for several minutes and then sealed. The sealed tubes were placed in a sand bath, the temperature of which was gradually raised from 40 to 60°C, and subsequently were held at this temperature for 24 h. The polymerization was completed by heating further for 2 h at 120°C. The solidified samples were then cut and polished to make rectangular blocks (ca. 10 × 10 × 25 mm^3).

Results

A. *Transients at room temperature*

Rigid trans *compound 5*

On excitation (λ_{exc} = 530 nm) of compound **5** in ethyl iodide at 25°C, a transient absorption spectrum with two maxima (λ_{max} = 415 and 590 nm) and a bleaching zone in the range of the main ground state absorption band (maxima: λ_b = 510, 550 nm) were observed (Fig. 1*a*). The recovery at λ_b and the

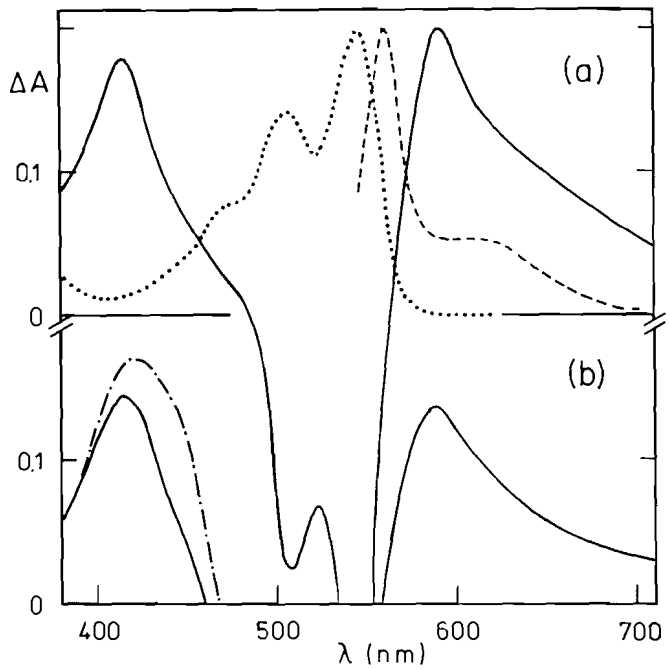

FIG. 1. Transient absorption spectra of compound **5** at 25°C; (*a*) in ethyl iodide (full line) 200 ns after the laser pulse; ground state absorption (dotted line) and fluorescence spectra (dashed lines); (*b*) in PMMA at the pulse end (broken line) and after 200 ns (full line).

decay at λ_{max} show the same time dependence; the main component of the transient (Tr_3) decays at both λ_{max} by first-order kinetics with a rate constant $k_{obs} = \tau^{-1} < 2 \times 10^5\ s^{-1}$. Similar absorption spectra and lifetimes in the μs range were recorded for the transient in dichloromethane solution and in a PMMA matrix (Fig. 1*b* and Table 1). In addition to Tr_3, a short-lived transient (Tr_1) was found in PMMA around 430 nm with a lifetime shorter than 50 ns; due to the strong fluorescence of **5** during the laser pulse, Tr_1 would escape our observation at $\lambda > 550$ nm. The transient absorbance (ΔA) at λ_{max}, as a measure of the relative yield of Tr_3, is about three times larger in ethyl iodide than in dichloromethane.

The lifetime of Tr_3 of **5** is reduced by addition of oxygen whereas ΔA (at the end of the laser pulse) remains constant. From linear plots of k_{obs} versus the concentration of oxygen (argon-, air-, oxygen-saturated solutions), rate constants for quenching by oxygen of $k_{ox} = 1.3 \times 10^9$ and $1.8 \times 10^9\ M^{-1}\ s^{-1}$ in dichloromethane and ethyl iodide, respectively, were obtained, using a solubility of $[O_2] = 8 \times 10^{-3}\ M$ for saturation. Tr_3 is also quenched by ferrocene and azulene but not by perylene (rate constant $< 10^7\ M^{-1}\ s^{-1}$). The rate constant for quenching by ferrocene in dichloromethane and by azulene in ethyl iodide (λ_{exc} = 353 nm in the latter case) is about 0.8 × 10^9 and 0.4 × $10^9\ M^{-1}\ s^{-1}$, respectively. No attempt was made to evaluate other effects on k_{obs} (e.g. concentrations of ground and (or) excited states). On the basis of these results, the short-lived transient Tr_1 has been attributed to the singlet excited state and the long-lived Tr_3 to the triplet excited state.

Rigid cis *compound 6*

With compound **6**, the following results were found on excitation at 353 nm: the transient absorption spectrum (Fig. 2*a*) shows maxima around 350, 500–600, and 700 nm and a bleaching zone around 420 nm, with the same rate constant for recovery as the k_{obs} observed for the decay of the transient absorption at longer wavelengths. The triplet lifetime τ_T is in the

PMMA: poly(methyl methacrylate). GT: glycerol triacetate. MTHF–DCM: 2-methyltetrahydrofuran/dichloromethane (1:1, vol.).

[a]In argon-saturated solutions, λ_{exc} = 530 nm, unless indicated otherwise.

[b]The lifetime is probably reduced by oxygen.

[c]Benzophenone sensitized, λ_{exc} = 353 nm.

[d]λ_{exc} = 353 nm.

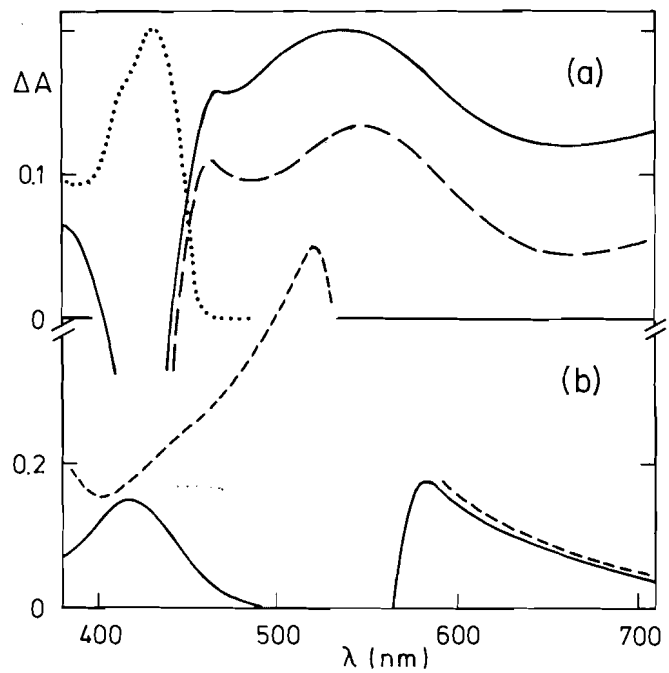

FIG. 2. Transient absorption spectra at 25°C using laser excitation at 353 nm of (*a*) **6** in acetonitrile solution (——) at the end of the pulse and (---) in the presence of benzophenone 0.5 μs after the pulse; (····) ground state absorption; (*b*) **5** in benzene solution with benzophenone sensitization (---) 20 ns after the laser pulse and (——) 1 μs after the pulse.

μs range when taken in fluid solution but much higher, in the ms range, when **6** is inserted in a PMMA matrix (Table 1). The rate constants for quenching of Tr_3 by oxygen (ferrocene) are about 2×10^9 (8×10^9) M^{-1} s^{-1} in benzene solution and 2×10^9 (10×10^9) M^{-1} s^{-1} in acetonitrile solution, but 5×10^9 M^{-1} s^{-1} for quenching by azulene in dichloromethane solution.

Flexible molecules ***1–4***

Two transients, a short-lived one Tr_1 ($\tau < 30$ ns, λ_{max} = 430 nm) and a longer-lived one Tr_3 with two maxima (λ_{max} around 380 and 570 nm), were recorded for *trans*-**1** in a PMMA matrix at 25°C. Analogous spectra were recorded for *trans*-**2** and *trans*-**3** (Table 1); here, Tr_3 has three maxima. However, the singlet transient Tr_1 could be detected with low absorbance only in some specific cases, e.g. for *trans*-**1** in benzene (6, 8) or dichloromethane solutions (with λ_{max} around 450 nm). At room temperature and in the solvents used here, no triplet transient that would have a lifetime longer than 20 ns could be observed for *trans*-**1**–*trans*-**4**.

B. Transients at low temperatures

Similar to the results in PMMA matrix, a short-lived transient (Tr_1, λ_{max} around 440 nm and $\tau < 50$ ns) was found at low temperature in some cases (Fig. 3*b*). Tr_1 is assigned to the lowest excited *trans* singlet state $^1t^*$ as already proposed for *trans*-**1** (6, 8), on the basis of its short lifetime even in rigid matrices. An $S_1 \rightarrow S_n$ absorption transition also has been reported for *trans* thioindigo (12). It is noteworthy that the singlet lifetime (τ_S) deduced from the fluorescence decay is around 5 ns for *trans*-**1**–*trans*-**3** in PMMA at 20°C and around 12 ns in MTHF glass at −196°C (13). For **5** in dichloromethane at 25°C, τ_S was found to be around 6 ns.

In contrast to measurements in fluid solution at ambient temperature, a long-lived transient (Tr_3) was observed for *trans*-**1**–*trans*-**4** in several viscous media at lower temperatures. Examples are shown for *trans*-**1** in GT at −70°C (Fig. 3*a*) and for *trans*-**3** in a 1:1 mixture of 2-methyltetrahydrofuran and dichloromethane (MTHF–DCM) at −170°C (Fig. 3*b*). In both glassy solvents, *trans*-**2**–*trans*-**4** show triplet transient absorption ($Tr_3 = {}^3t^*$) with λ_{max} at about 370, 500, and 620 nm, and λ_b around 580 nm (Table 1).

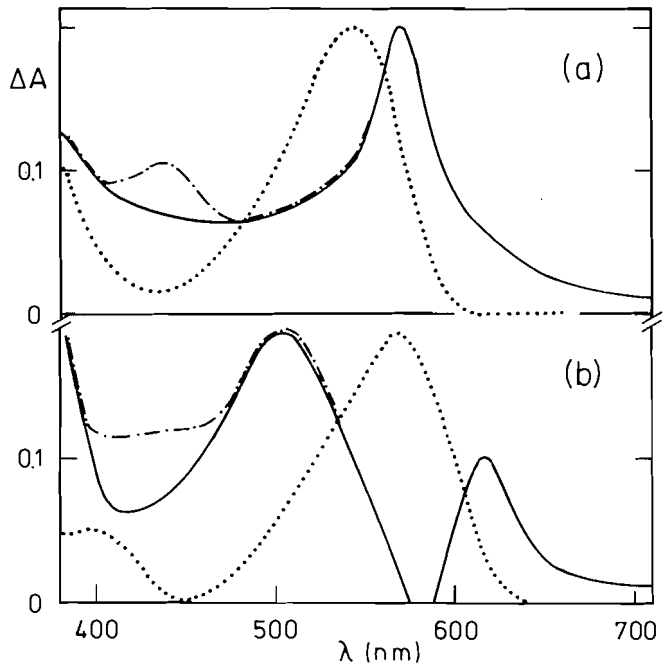

FIG. 3. Transient absorption spectra in rigid media: (*a*) of *trans*-**1** in GT at −70°C (·····) at the end of the pulse and (—) after 200 ns; (*b*) of *trans*-**3** in MTHF–DCM at −170°C (·····) at the pulse end and (—) after 200 ns; (····) ground state absorption at 25°C.

The temperature dependence of the transient absorption at 570 nm, ΔA_{570}, is shown for *trans*-**1** in MTHF–DCM and GT (Figs. 4 and 5). The following general trend was found for *trans* indigos: on going from 25°C to lower temperatures, $^3t^*$ was first observed (around λ_{max}) at the temperature t_m; on decreasing the temperature further, ΔA_{570} increases and reaches a maximum value at about −70°C in GT and at about −180°C in MTHF–DCM. The ratio of ΔA_{570} values (*trans*-**1**) and ΔA_{550} (**5**) in GT at −70°C is ≧3 under identical excitation conditions.

In the accessible temperature range (Table 2), the absorption of the triplet $^3t^*$ of *trans*-**1** decays at its maximum λ_{max} by first-order kinetics. As shown in Figs. 4 and 5, k_{obs} decreases from about $\tau^{-1} = 1 \times 10^7\ s^{-1}$ (at $t_m = -30$°C in GT and −135°C in MTHF–DCM) to values smaller than $10^5\ s^{-1}$ below a certain temperature t_0 (−70°C in GT and −175°C in MTHF–DCM). Below t_0, k_{obs} is virtually constant, with small variations when observed at around 400 and 600 nm.

For *trans*-**2**–*trans*-**4** in GT, plots of k_{obs} versus T^{-1} are similar to that of *trans*-**1** but, in MTHF–DCM and in a certain temperature range between t_m and t_0, the decay is no longer first order. Due to small ΔA values no kinetic analysis was performed.

C. Quenching of sensitizers by the trans *isomers*

To obtain some information about the triplet energy (E_T) of the *N,N'*-disubstituted indigo dyes, the effect of triplet quenching of several aromatic compounds (sensitizer: Sens) by *trans*-**1**, *trans*-**2**, and **5** was studied in dichloromethane solution at room temperature using $\lambda_{exc} = 353$ nm. On increasing the indigo concentration, the rate constant for decay of a given aromatic triplet (k_{obs}^{Sens}) increases linearly (up to a limit of $5 \times 10^6\ s^{-1}$ corresponding to a lifetime of 200 ns). The rate constant for triplet quenching (k_q), obtained from the slope of this dependence, is around $3 \times 10^9\ M^{-1}\ s^{-1}$ for several high energy triplet donors ($E_T > 42$ kcal/mol) and decreases on going to lower E_T values (Table 3).

TABLE 2. Lifetime of the triplet transient Tr_3 at low temperature[a]

Indigo	Solvent	t_m[b] (°C)	τ_T^{min} (μs)	t_0 (°C)	τ_T^{max} (μs)
trans-**1**	MTHF–DCM	−135	0.1	−165	~13 (20)
	GT	−30	0.1	−65	~12 (18)
trans-**2**	MTHF–DCM	−90	0.2	−150	≧4
	GT	−15	0.1	−50	~5

	GT	−7	0.1	−45	≧5
trans-**4**	MTHF–DCM	−100	0.6	−160	≧3
	GT	0	0.1	−60	~6

[a]Observed in the 400–430 nm and (or) 580 nm range; values in parentheses refer to $\lambda_{max} = 580$ nm; for **2**–**4** no wavelength dependence (400 vs. 580 nm) of k_{obs} is found.
[b]t_m is the highest temperature at which the triplet transient could be observed.

When benzophenone is used as triplet sensitizer of **5** in benzene solution, it is observed that the remaining spectrum after decay of ^{3}Sens* is very similar to that obtained for Tr_3 on direct excitation (compare Figs. 2*b* and 1). This confirms the triplet nature of Tr_3. Using $\varepsilon_{TT} = 7.6 \times 10^3\ M^{-1}\ cm^{-1}$ for benzophenone in benzene solution (20) and assuming 100% energy transfer, the absorption coefficient of Tr_3 of **5** (at 580 nm) is $5 \times 10^3\ M^{-1}\ cm^{-1}$. Under the same conditions, the rigid *cis* molecule **6** shows also a triplet transient for which ε_{TT} was estimated to be $\leqq 2 \times 10^3\ M^{-1}\ cm^{-1}$ at its maximum (530 nm). Similar experiments at room temperature with the *trans* isomers showed a permanent (>1 ms) increase in ΔA in the range between the isosbestic points (e.g. 410 nm and 516 nm for **1**, where the ground state of the *cis* isomer absorbs and where the triplet is expected to absorb as well) and a permanent decrease in ΔA above 516 nm, where mainly the ground state of the *trans* isomers absorbs. Such a result is typical for *cis* ⇄ *trans* isomerization (7, 9). However, no transient was found after 200 ns that could be assigned to an indigo triplet state.

At high indigo concentrations, corresponding to $k_{obs}^{Sens} > 5 \times 10^6\ s^{-1}$, the yield of ^{3}Sens* is markedly reduced due to the increasing absorption of the *trans* isomer at 353 nm and (or) (benzophenone excepted) to fluorescence quenching of the sensitizer by the indigo dye. Dynamic fluorescence quenching of Sens should be of minor importance since under the conditions used here (indigo concentration $< 2 \times 10^{-3}\ M$) only a few per cent of ^{1}Sens* ($\tau_S < 10$ ns) can react with a quencher even under diffusion-controlled conditions.

D. Fluorescence quantum yield and singlet lifetime

While **6** shows virtually no emission throughout in fluid media at ambient temperature, compound **5** exhibits fluorescence with maxima at 515 and 525 nm in dichloromethane and ethyl iodide solutions, respectively (Fig. 1*a*). Its quantum yield of fluorescence (ϕ_f) in several solvents at room temperature is close to unity and is significantly smaller only in the heavy atom solvent ethyl iodide (Table 4). On the other hand, changing the temperature (e.g. in GT from 25 to −75°C) has virtually no effect on ϕ_f.

For *trans*-**1**–*trans*-**4** the substituent R, the temperature, and the nature of the solvent have remarkable effects on ϕ_f (Table 4). While the fluorescence maximum is only little affected by the solvent (610 nm in MTHF–DCM and butyronitrile, 620 nm

in ethanol for **1**, and 620 nm for **4** in MTHF–DCM), in a given solvent, ϕ_f decreases in the order **1**–**4**. For **2**–**4**, ϕ_f depends only slightly on solvent properties while for **1** it decreases when the solvent polarity increases. At low temperatures and corresponding high viscosities, ϕ_f is strongly enhanced but the values remain well below unity.

The temperature dependence of ϕ_f is shown for the flexible *trans* isomers in GT and MTHF–DCM (Figs. 4–6). ϕ_f increases monotonously on lowering the temperature. From the linear parts of log ϕ_f versus T^{-1} (at higher temperatures) activation energies (E_a) of about 1 kcal/mol (**2** in MTHF–DCM) to 5 kcal/mol (**4** in GT) were determined (Table 5). An exception is *trans*-**1** in MTHF–DCM, where ϕ_f changes only slightly at the beginning when going down to −130°C but exhibits a steep increase in the −130 to −150°C temperature range where the viscosity increases strongly (Fig. 4). This viscosity-induced increase is also indicated for **1** (Fig. 4) in butyronitrile and for **2** in MTHF–DCM (Fig. 6).

Data reported in the previous work (13) already indicate that the singlet lifetime τ_s of the flexible *trans* molecules increases to a smaller extent than the corresponding fluorescence quantum yields when going from 25 to −196°C. To verify this important observation τ_S was now determined in the same solvent at these temperatures. For the flexible *trans* isomers, values of τ_s are

typically 2–5 ns at 25°C and show no pronounced dependence on the substituent R or on the solvent properties (Table 6). Moreover, in rigid media τ_S is only prolonged by a factor of less than 10. This is in striking constrast to the behaviour of the ϕ_f values (Table 4).

For the rigid compound **5** in MTHF solution τ_S changes only little between +25 and −196°C, but it decreases at room temperature (Table 6) in a similar manner to ϕ_f (Table 4) when changing MTHF to ethyl iodide as solvent.

E. Steady-state irradiation measurements

Depending on λ_{irr}, a photostationary state is formed from both isomers. In a given solvent and at ambient temperature, the quantum yield of *trans* → *cis* photoisomerization ($\phi_{t\to c}$), which is larger for **1** than for **2** and **3** (Table 7), shows a trend to decrease with increasing solvent polarity (as it already has been observed for *N,N'*-dimyristoylindigo; see ref. 4*c*). The photostationary state depends on λ_{irr} and is shifted towards the *trans* side in the order **1**, **2**, **3** for λ_{irr} = 546 nm.

[a]In argon-saturated solution at 25°C.
[b]Taken from ref. 13.
[c]Thermal *cis* → *trans* isomerization during the irradiation time (10 min).

$\phi_{t\rightarrow c}$ decreases also with temperature: for **1** and **2** in MTHF–DCM, it changes only little above −100°C and decreases on going to lower temperatures (Figs. 4 and 6). A similar dependence was observed for **1** in GT with a marked change below −30°C (Fig. 5). Measurements at higher temperatures were unsuccessful because of the occurrence of thermal *cis* → *trans* isomerization (13, 21).

Discussion

A. Triplet state

For the rigid *trans* analogue **5**, Tr_3 is assigned to a triplet state due to the following. First, the kinetics are independent of the wavelength, indicating the formation of a single species. Second, Tr_3 is efficiently quenched by azulene (E_T = 39 kcal/mol), ferrocene (E_T = 39.5 kcal/mol (22)), and by oxygen. Third, the triplet yield is enhanced in a heavy atom solvent. Fourth, energy transfer measurements from the triplet state of aromatic compounds (^{3}Sens*), with $E_T > 41$ kcal/mol, to **5** show that ^{3}Sens* is quenched in solution at room temperature with a rate constant k_q (Table 3) that is a factor of 3–7 below the diffusion-controlled limit (10^{10} M^{-1} s^{-1} for benzene and 1.5×10^{10} M^{-1} s^{-1} for dichloromethane). Finally, the spectrum of the remaining transient under sensitized excitation conditions is similar to that of Tr_3 (compare Figs. 1 and 2*b*). On the basis of energy transfer and quenching measurements the triplet energy of **5** is placed at about 40 kcal/mol. A similar value is estimated for *trans*-**1** and *trans*-**2** (Table 3). The rigid *cis* analogue **6** also shows a long-lived transient (Table 1) after excitation with the 353-nm laser beam. Quenching of this transient by ferrocene and azulene occurs with a rate constant close to the diffusion controlled limit; in addition, **6** quenches the triplet state of aromatic compounds (^{3}Sens*). These results are in agreement with the assignment of the transient to a triplet species the energy of which, E_T, would be slightly higher than that of **5** or of the *trans* isomers.

For the flexible indigo dyes, Tr_3 is assigned to a triplet state with *trans* configuration ($^3t^*$) on the following basis. First, the transient absorption spectra of a *trans* isomer in PMMA at 25°C and in glassy media at low temperatures are more or less similar (Table 1). This confirms the identity of the transient. Second, Tr_3 was observed for *trans*-**1**–*trans*-**4** only in viscous media (Fig. 3 and Table 1), i.e., under conditions where the *trans* to *cis* photoisomerization is strongly reduced. Third, the increase of the transient absorption at 570 nm (ΔA_{570}) as the temperature is decreased (Figs. 4 and 5) is in line with the proposal that the triplet is populated by intersystem crossing at the *trans* side (8). Analogous temperature and viscosity dependences were also found for *trans*-stilbenes (16, 23) and other dyes that can twist around a C=C double bond, e.g. azobenzenes (15).

That the donor triplet with $E_T > 40$ kcal/mol could be quenched to a rate constant limit of about 5×10^6 s^{-1} and that the triplet state of the *trans* isomers, in contrast to that of **5**, was not spectroscopically observed at ambient temperature, places the triplet lifetime of the flexible dyes at a value smaller than 200 ns. An estimate of ≦100 ns would be expected from the temperature dependences under direct excitation (Figs. 4 and 5). The maximum yield for triplet formation ϕ_{isc}^{max} is probably smaller than $(1 - \phi_f)$ since, even at −196°C, ϕ_f remains significantly smaller than 0.5 (Table 4); consequently, the triplet yield would remain smaller than 0.5. This agrees with estimates based on the relative values of the transient absorption ΔA_{570} obtained for *trans*-**1** and **5** in GT at −70°C assuming $\phi_{isc} = 1 - \phi_f \leqq 0.1$ for **5**.

B. Excited trans *singlet state*

The emission of compounds **1**–**5** is attributed to fluorescence from the lowest excited *trans* singlet state ($^1t^*$) on the basis of the short lifetime. This is in agreement with the previous conclusion that the *cis* isomers of **1**–**4** exhibit no fluorescence even in rigid media and that both isomers show no phosphorescence (13). Only recently has the very weak fluorescence emission ($\phi_f < 10^{-5}$) for matrix isolated *cis* thioindigo been reported (24). For **5** in MTHF–DCM (as an example of a solvent without heavy atom effect), ϕ_f is close to unity (Table 4). This shows that fluorescence is the major deactivation step of excited **5** in fluid and rigid media. A minor step is intersystem crossing (≦0.1).

For the *trans* isomers of **1**–**4**, the temperature dependence of ϕ_f (Figs. 4–6) indicates that a temperature induced activated step ($A \times \exp(-E_a/RT)$) competes with the radiative decay (k_f). Assuming that k_f is independent of temperature, at least one radiationless, nonactivated step should be involved since ϕ_f is markedly smaller than unity even if the activated step is frozen out (Table 4). One possibility for this nonactivated step is intersystem crossing (k_{isc}) at the *trans* configuration. Indeed, a transient was observed (Fig. 3) that can be assigned to a triplet state. However, the maximum yield for triplet formation (ϕ_{isc}^{max}) is small, as indicated above. Therefore, we propose the involvement of internal conversion at the *trans* form (k_{ic}) as a second nonactivated, radiationless step.

According to this minimum number of decay channels of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

trans singlet excited state $^1t^*$, the effect of temperature on ϕ_f may be described by eq. [1] (in a simplified manner, e.g. assuming that k_f and k_{isc} are independent of the temperature):

$$[1] \quad \phi_f = \frac{k_f}{k_f + k_{ic} + k_{isc} + A \times \exp(-E_a/RT)}$$

Although **1**–**4** show similar temperature dependence in both GT and butyronitrile solution, a net difference is observed in MTHF–DCM solution: an activated step is found for *trans*-**2**–*trans*-**4** (Fig. 6), while two activated steps (a temperature- and a viscosity-induced one) seem to occur for *trans*-**1** (Fig. 4). Twisting around the central double bond seems to depend on the viscosity of the medium, as demonstrated by the absence of isomerization in GT at −70°C or in th PMMA matrix at room temperature. The temperature activated step is less simple and will be discussed with the photoisomerization mechanism in the next section. In any case, distinction between the two activation steps is difficult and the Arrhenius expression in eq. [1] includes both of them. At high temperature

$$[2] \quad [1 + (k_{ic} + k_{isc})/k_f] \ll (A/k_f) \exp(-E_a/RT)$$

and consequently one can write

$$[3] \quad \log \phi_f = \log k_f - \log A + E_a/2.3RT$$

showing that $\log \phi_f$ is proportional to T^{-1}. The E_a values obtained from the slope are generally larger in GT than in MTHF–DCM and increase in the order **1** < **2** < **3** < **4**. The use of known k_f values (13) yields A factors in the order of 10^9–10^{10} s^{-1} in MTHF–DCM (Table 5). The lower ϕ_f values for **2**–**4**, as compared to **1**, are due to the differences in k_f, A, and E_a. Solvent properties may have further influence on ϕ_f, as claimed for *N,N'*-dimyristoylindigo (4*d*) and as observed here for **1** (Table 4). Nevertheless, the properties of the excited *trans* singlet state are still not fully understood and need further study. For example, the ratio ϕ_f/τ_S seems not to be independent of temperature and increases significantly on going from fluid to rigid media (Tables 4 and 6).

C. Mechanism of trans *to* cis *photoisomerization*

For *trans*-**2**–*trans*-**4**, as compared to *trans*-**1**, the following differences were found: first, $\phi_{t\rightarrow c}$ is significantly larger (~0.25) for *trans*-**1** than for the benzoylindigos (Table 7). Second, ϕ_f also is markedly larger for *trans*-**1** than for *trans*-**2**–*trans*-**4** at room temperature (Table 4). Third, a step with a pronounced activation energy (E_a) competes for **2**–**4** with fluorescence between −20 and −130°C in MTHF–DCM solution (Table 5). Finally, the temperature t_m at which $^3t^*$ is first observed is lower for *trans*-**1** than for *trans*-**2**–*trans*-**4** (Table 2). The origin of these differences will be discussed tentatively as follows.

(a) N,N'-*Diacetylindigo* ***1***

At room temperature an important pathway for *N,N'*-diacetylindigo is *trans* to *cis* photoisomerization since ϕ_f is small (Table 4) and $\phi_{t\rightarrow c}$ is substantial (Table 7). Twisting in the excited singlet state to the twisted configuration ($^1p^*$) rather than in the triplet state is suggested since the triplet state is observed only at high viscosities (Table 2). The main reason for the lack of *T–T* absorption at room temperature in fluid solution is probably the small ϕ_{isc} (cf. ref. 8) rather than a too short triplet lifetime. Furthermore, the temperature dependence of the triplet transient absorption $\Delta A(Tr_3)$ and of ϕ_f show no evident correlation below t_m (Figs. 4 and 5).

A *trans* → *cis* photoisomerization could occur via an upper excited triplet state, not involving an activation barrier at the *trans* side, and such an upper excited triplet pathway has been already suggested for *trans*-4-bromostilbene (16, 23). However, if such an upper excited triplet pathway were the only one involved, then ϕ_f would remain constant even in the high viscosity media. Since ϕ_f still increases in MTHF–DCM between −130 and −160°C (Fig. 4), this disagrees with a nonactivated pathway at the *trans* side and with an increase of the triplet transient absorption as the temperature is reduced. Obviously, $^3t^*$ is populated only in the high viscosity range, i.e., in the range where the molecule can no longer rotate around the C=C double bond in the excited state. The singlet decay can be interpreted by two processes: intersystem crossing at only the *trans* configuration below the temperature t_0 for which the rate constant k_0 for recovery of the transient is virtually constant, and twisting, which is important above t_0 (8).

We suggest that the step $^1t^* \rightarrow {}^1p^*$ has to overcome only a small activation barrier in fluid solution. This, together with a small ϕ_f value and a certain contribution of internal conversion at the *trans* side, leads to moderate $\phi_{t\rightarrow c}$ values unless a high viscosity of the medium hinders the twisting process; then $\phi_{t\rightarrow c}$ decreases while both ϕ_f and ϕ_{isc} increase. The high temperature (> −20°C) dependence of ϕ_f in MTHF–DCM (Fig. 4) indicates another activated step. Whether or not this step leads to the *cis* form is as yet unknown. If a second *trans* to *cis* pathway were operating, $\phi_{t\rightarrow c}$ should increase at higher temperatures. Unfortunately, these measurements failed due to the occurrence of thermal *cis* → *trans* isomerization above room temperature (13, 21).

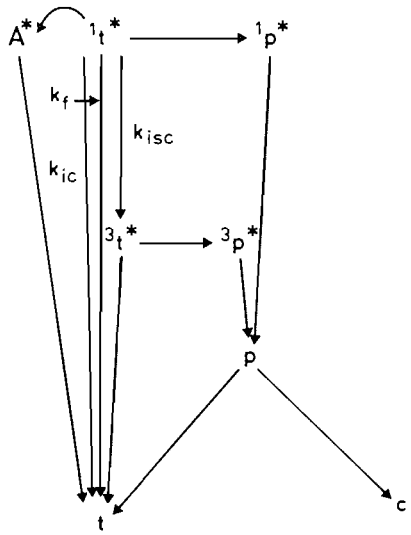
(b) Substituted N,N'-*dibenzoylindigos* ***2–4***

A triplet route for *trans* to *cis* photoisomerization of the benzoylindigos is also excluded on the basis of the arguments presented above. In addition, the photostationary state obtained from direct excitation is different (Table 7). The lower values for ϕ_f and $\phi_{t\rightarrow c}$ (for instance, 0.012 and 0.05 respectively for **2** in benzene solution as compared to 0.10 and 0.25 for **1** in the same solvent) are at least partly due to an activated step competing with fluorescence. In the simplest cases this activated step could lead to a twisted excited configuration (p^*) and finally to the *cis* and *trans* forms in the ratios α and $(1 - \alpha)$, respectively. This would imply that α is ca. 0.05 since the activated step is the main process for deactivation of $^1t^*$ at room temperature and since $\phi_{t\rightarrow c}$ is 0.05 in benzene and 0.06 in chloroform (Table 7). On the other hand, $\phi_{c\rightarrow t}$ is also small (0.12 and 0.09 for **2** and **3**, respectively) (13). Thus, α should be of the order of 0.88 if the *cis* → *trans* photoisomerization also occurs via the same intermediate p^*. This is inconsistent with the small value obtained above for α.

A more likely possibility is that the $^1t^*$ state decays on the one hand via $^1p^*$ to *trans* and *cis* ground states ($^1t + {}^1c$) as a minor route and, on the other hand, to the *trans* ground state through an activated step, which leads to an A^* excited state with essentially transoid configuration (Scheme 1). Such a scheme has already been suggested in the case of the *trans* to *cis* photoisomerization of 4-nitro-4'-dimethylaminostilbene in toluene solution (25).

Formation of A^* may involve an intrinsic as well as a viscosity-induced activation barrier. The effect of viscosity is indicated by a comparison of the temperature dependence of ϕ_f in MTHF–DCM and GT (Fig. 6). Thus, at the same temperature between +25 and −50°C, ϕ_f is ca. ten times higher in the more viscous solvent GT than in MTHF–DCM. The nature of A^* may

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.



SCHEME 1. Pathways for deactivation of $^1t^*$ for **1** (essentially not involving A^*) and for **2–4** (mainly via A^*).

be related to the process of rotation of the benzoyl groups around the N—C single bond (thermally activated free rotor effect). Differences in τ_S, for the compounds inserted in PMMA matrices at room temperature as compared to fluid solution, have already been ascribed to this rotation (13).

The fast atom bombardment mass spectra of selected 1,2-dihydro-1,3-disubstituted-2-oxo-pyrimidinium salts are presented. Loss of N-substituents from the solute cation is the principal fragmentation observed in the positive ion spectra. Several concentration dependent features of the spectra are identified; these are thought to result from the interaction of the solute cation with bombardment-induced matrix fragments. Cluster ions are observed in both positive and negative ion spectra. In a mixed solute system cluster ions resulting from extensive cation and anion mixing are observed; the concentration dependence of these mixed cluster ion peaks can be approximately described in terms of conventional solution equilibria.

CLEMENT W. KAZAKOFF, ROBIN T. B. RYE et OSWALD S. TEE. Can. J. Chem. **65**, 718 (1987).

On rapporte les spectres de masse par bombardement avec des atomes rapides (FAB) de sels de dihydro-1,2 oxo-2 pyrimidinium disubstitués dans les positions 1 et 3. Dans le spectre des ions positifs, la principale fragmentation observée correspond à la perte des substituants du cation dissous. On a identifié plusieurs caractéristiques qui dépendent de la concentration; on croit que ces variations proviennent de l'interaction du cation dissous avec les fragments de matrice induits par le bombardement. On a observé des agrégats d'ions tant dans les spectres des ions positifs que ceux des ions négatifs. Dans un système de solutés mixtes, on observe des agrégats d'ions provenant d'un important échange des anions et des cations; pour décrire la relation qui existe entre la concentration et les pics de ces agrégats mixtes d'ions, on peut faire appel aux équilibres conventionnels en solution.

Introduction

Since the 1981 publication of the work of Barber *et al.* (1) fast atom bombardment (FAB) has become a widely-used ionization method, with particular application to the mass spectrometric study of thermally fragile and nonvolatile compounds. Several recent reviews have surveyed the development of the technique and the increasingly wide range of its applications (2).

As part of a continuing study of the mass spectra of 2-pyrimidinones and related compounds (3), we have examined the FAB mass spectra of selected pyrimidinium salts (Table 1). Preliminary measurements showed that the FAB spectra of many of these compounds exhibited cluster ion peaks of significant intensity. These observations suggested that the FAB technique might be used for the study of ion pairing in solutions of the pyrimidinium salts. Ion pairing in solutions of *N*-alkylpyridinium salts has received considerable attention (4).

Experimental

The 1,2-dihydro-1,3-disubstituted-2-oxo-pyrimidinium salts used in this work were stable samples remaining from earlier solution studies (5). Fast atom bombardment mass spectra were taken on a VG-7070E instrument, with 9-keV xenon atoms as bombarding particles at a beam current of 1.5 mA. The accelerating voltage was 6 kV. Data were acquired using the VG DEC PDP8A data system except for the B/E linked scans, in which spectra were taken on a Visicorder. Samples for quantitative measurement were prepared by weight, using glycerol as the liquid matrix. The long term stability of the solutions was confirmed by the excellent reproducibility of the spectra over a period of several months.

Results and discussion

Single solute

The positive ion FAB spectra of the quaternary salts **1**–**7** are given in Table 2. The effect of solute concentration on the spectra was investigated for **1** and **3**. With **1** at a solute concentration of 25 mg/mL (0.11 *M*) the protonated glycerol dimer gave the base peak in the spectrum at *m/z* 185. The solute cation peak (*m/z* 125) was clearly observable at this concentration, and at concentrations as low as 4 mg/mL (0.02 *M*). At concentrations greater than ca. 0.15 *M* the base peak in the spectrum of **1** was due to the solute cation. At the higher solute concentrations cluster ions C_nA_{n-1} (C = cation, A = anion) of low (<5%) relative intensities are observed. The intensities of these cluster ion peaks, particularly for $n > 3$, were found to depend markedly on the N substituents. For **1**–**3**, clusters up to $n = 5$ could be observed under appropriate conditions, whereas for **4**–**7** the $n = 2$ cluster was barely detectable. The unimolecular fragmentation of the $n = 2$ cluster from **1** was examined by B/E linked scan. Losses of $A - 1$, A, $A + 1$, and $CA + 1$ were observed. There was some evidence for very minor losses of methyl radical and water from the cluster ion, but identification of these processes is only tentative because of the poor S/N ratio at the high gain used.

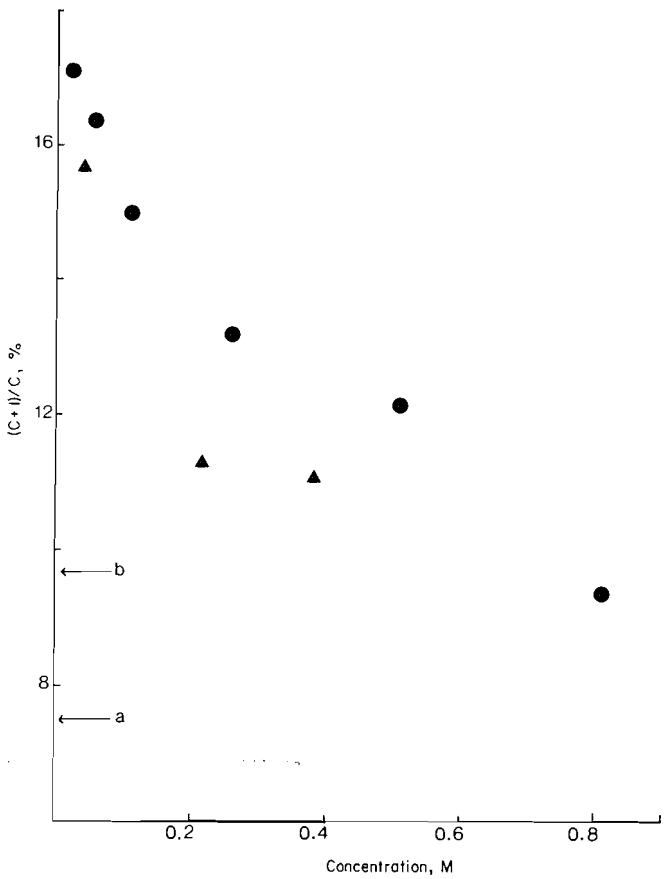

FIG. 1. Variation of $(C + 1)C$ ratio for **1** (●) and **3** (▲). Calculated values (based on natural isotopic abundances) indicated by horizontal lines as *a* (**1**, 7.5%) and *b* (**3**, 9.7%).

Concentration effects related to reactions of the solute cation with bombardment-induced matrix fragments are also observed. The variation of the $(C + 1)/C$ peak intensity ratio with concentration, as shown in Fig. 1, has obvious analytical implications. Similar enhancement effects in the FAB spectra of dyestuffs have been explained in terms of oxidation–reduction reactions in the matrix (6), but the mechanism of such reactions has not been established. While the enhancement of the $C + 1$ peak intensity in our case is small compared to that reported for organic dyestuffs (6), it is sufficiently large to preclude

use of natural isotopic abundance ratios as a means of solute characterization. Adduct ions of nominal masses $C + 14$ and $C + 32$ daltons were also observed in all the positive ion spectra. The abundance of these ions, relative to that of the solute cation, decreased as solute concentration increased. Thus, for **1**, the $C + 14/C$ ratio dropped from ca. 0.4 to ca. 0.08 as the solute concentration was increased from 0.06 M to 0.81 M. The effect of solute concentration on the fragmentation pattern is discussed below.

Compounds **1**, **2**, and **4–6** constitute a convenient series for examination of substituent effects in the fragmentation of the solute cations. In agreement with the even-electron rule (7) the fragment ion $C_5H_7N_2O$ (m/z 111) is observed in all the spectra. For **2** and **5** this peak can be rationalized in terms of hydrogen transfer from the N(1) substituent to the pyrimidine ring followed by loss of the substituent as the unsaturated neutral molecule. For **1** and **4**, however, this pathway would be energetically unfavourable compared to loss of the N(1) substituent as the neutral radical from the $C + 1$ ion. In the case of **1** this alternative mechanism is given support by the observation that the relative abundance of m/z 111 shows a variation with concentration similar to that observed for the $C + 1$ peak. Because of the particular stability of the tropyl cation, **6** fragments almost exclusively by inductive cleavage to give m/z 91 as the base peak in the spectrum. This mode of fragmentation is observed to only a limited extent in **4** (m/z 77, relative intensity = 7%) and **5** (m/z 83, rel. int. = 7%); for **1** and **2** the poor S/N ratio in the appropriate regions of the spectra precluded reliable measurements. Limited fragmentation of the pyrimidinium ring was observed for **1**; in the B/E linked scan of the m/z 125 peak minor losses of 28, 29, 41, and 42 daltons were noted. Unambiguous identification of the corresponding peaks in the conventional spectrum was complicated by matrix interference below m/z 100.

The negative ion spectra are characteristically simple and relatively free from background interference. The solute anion

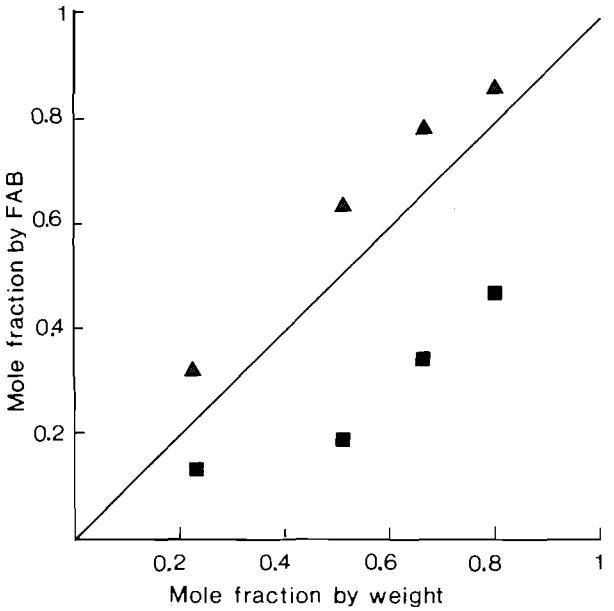

FIG. 2. Actual vs. experimental mole fraction of **1** in mixtures of **1** and **3**; positive (■) and negative (▲) ion FAB.

gave the base peak in all cases. Peaks of moderate intensity corresponding to A + glycerol were observed (**1**, m/z 189, rel. int. = 7%; **3**, m/z 219, rel. int. = 7%), but peaks for more highly solvated anions were of negligible intensity. As described above for the positive ion FAB, cluster ion peaks of significant intensity were observed. In the spectrum of **1** peaks at m/z 195 (rel. int. = 16%) and m/z 319 (rel. int. = 6%) were assigned to AHA and ACA, respectively. At higher gain A_nC_{n-1} cluster ions were observable up to $n = 4$ (m/z 763), with peak intensity decreasing rapidly with increasing n. The AHA peak (m/z 255) was not observed in the spectrum of **3**, but peaks corresponding to $n = 2$ (m/z 407) and $n = 3$ (m/z 687) were seen. Analogous results were obtained for the other salts.

Mixed solutes

Several reports have emphasized the application of FAB mass spectrometry to the study of solution equilibria. Caprioli (8) showed that the pK_a of weak acids in glycerol–water mixtures could be determined by FAB, and concluded that the FAB spectra accurately reflect the ionic equilibria in the matrix. The SIMS spectra of mixed organic salts in an ammonium chloride matrix showed cluster ions with all possible combinations of cation and anion (9); these authors also cite unpublished FAB experiments that gave similar results.

In the present work solutions of **1** and **3**, containing from 0.2 to 0.8 mole fraction of **1**, were examined in both positive and negative ion mode. As a simple test of the degree to which the FAB spectra reflected solution composition, the mole fraction of **1** in each of the mixtures was calculated from the negative ion spectra, using the m/z 97 (HSO_4^-) and m/z 127 (I^-) absolute peak area (Table 3). Analogous calculations were done from the positive ion data, using absolute peak areas for the cations (**1**, m/z 125; **3**, m/z 153). The results are shown in Fig. 2. Agreement between theoretical and experimental mole fractions was as expected, but it is not clear why the negative ion results were superior to those based on the cation spectra, particularly in view of the similarity of the two cations **1** and **3**. Inspection of the $n = 2$ cluster ion regions of both the positive and negative ion spectra (Fig. 3) reveals extensive cation and anion mixing

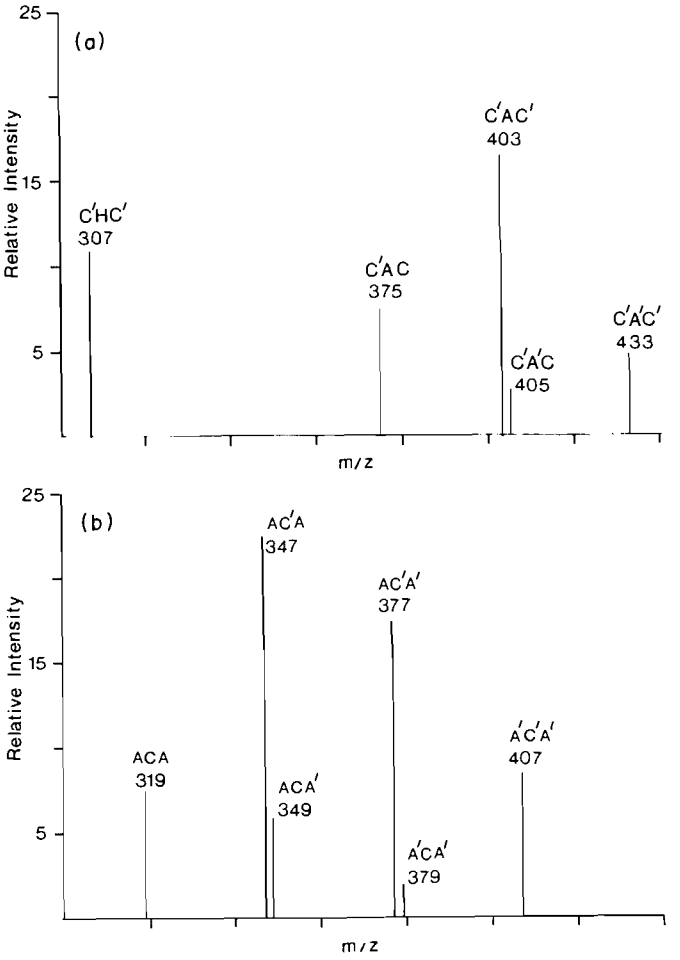

FIG. 3. Expanded (×10) cluster ion region of the FAB spectrum of a mixture of **1** and **3** containing 0.5 mole fraction of **1**. (*a*) Positive ion; (*b*) negative ion. Anion and cation of **1** and **3** denoted by A, C and A′C′, respectively.

in this system. The spectra in Fig. 3 were obtained from an approximately equimolar mixture (mole fraction of **1** = 0.504). It is evident from the negative ion spectra (Fig. 3*b*) that the cation of **3** confers greater stability to the cluster ions (peaks at m/z 347, 377, and 407) than does the cation of **1** (peaks at m/z 319, 349, and 379). Selectivity in favour of HSO_4^- as the cluster anion is also indicated by a decrease in relative abundance with an increase in I^- content, regardless of the cation involved. In an attempt to quantify the interactions involved in these effects, the peaks at m/z 319, 349, 377, and 407 in the negative ion spectrum were taken as convenient probes of ionic equilibria. Denoting the anion and cation of **1** as A and C, and of **3** as A′ and C′, respectively, these cluster ions can be identified as ACA (m/z 319), ACA′ (m/z 349), A′C′A (m/z 377), and A′C′A′ (m/z 407). A detailed analysis of this multiequilibrium system is not feasible, but rough calculations have shown that the concentration dependence of these cluster ion peaks can be approximately described in terms of conventional solution equilibria. While concentrations of neutral or cationic species cannot be estimated from the negative ion FAB spectra, ratios of dissociation constants can be estimated from the ion peak intensity data. Thus, for the equilibria

$$\begin{aligned} \text{ACA} &\rightleftharpoons \text{AC} + \text{A} & K_1 \\ \text{A'C'A'} &\rightleftharpoons \text{A'C'} + \text{A'} & K_2 \\ \text{A'C'A} &\rightleftharpoons \text{A'C'} + \text{A} & K_3 \end{aligned}$$

we estimate $K_3/K_2 < 1$ and, setting [AC]/[A′C′] = [**1**]/[**3**]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

for the equimolar mixture, $K_1/K_2 > 1$. The value of K_3/K_2 reflects the fact that the interaction between A′C′ and HSO_4^- is stronger than the interaction between the ion pair and I^-.

The predominant effect of the cation in determining cluster ion stability is reflected in the comparison of the dissociation constants for ACA and A′C′A′, with $K_1 > K_2$. Given the many approximations made in these calculations, the ratios are, at best, rough estimates. The results are consistent with the observed spectra, and indicate the potential of this approach for the study of ion pairing in this type of system.

Dissociation constants of 2,4,6-trinitrophenol (picric acid) in 2-methoxyethanol and 1,2-ethanediol were measured by a conductance method at temperatures ranging from −10 to 80°C. The determined constants in the two solvents are discussed and are compared on the basis of the physical properties of the solvents, which have been measured at the various temperatures. The dissociation constants show different behaviour with the temperature in the investigated range and they are fitted by equations of the type $\ln K = A+BT+C/T+D \ln T$. Furthermore, the thermodynamic functions have been evaluated and discussed.

GIANCARLO FRANCHINI, ELENA ORI, CARLO PRETI, LORENZO TASSI et GIUSEPPE TOSI. Can. J. Chem. **65**, 722 (1987).

Opérant à des températures allant de −10 à 80°C et faisant appel à la conductimétrie, on a mesuré les constantes de dissociation du trinitro-2,4,6 phénol (acide picrique) dans le méthoxy-2 éthanol et dans l'éthanediol-1,2. On discute des constantes déterminées dans ces deux solvants et on les compare entre elles en fonction des propriétés physiques de ces solvants qui ont été mesurées aux diverses températures. Dans la fourchette des températures examinées, les constantes de dissociation présentent des comportements différents que l'on peut toutefois représenter par des équations du type $\ln K = A + BT + C/T + D \ln T$. De plus, on a évalué et on discute des fonctions thermodynamiques.

[Traduit par la revue]

Introduction

This work is to study the effect of solvent on dissociation constants of weak acids and the influence of temperature.

Although alcohols have received much attention as solvents for acid–base determinations (1, 2) there are not many studies on the use of 2-methoxyethanol (hereafter abbreviated Gliem) and 1,2-ethanediol (Gliet) as solvents in acid–base titrations and on the determination of dissociation constants of weak acids. Our previous works (3–6) have reported on the feasibility of conductometric titrations of monoprotic and diprotic acids, phenols and aromatic nitroderivatives in the above solvents using *N*,*N*′-diphenylguanidine as titrant. The results indicated the possibility of also performing differential titrations of acid mixtures in cases where such determinations are impossible in aqueous solutions.

Preliminary studies have shown that temperature plays an important role in the shape of the conductometric titrations curves and that the effect is different for different solvents.

Continuing our conductometric studies, the dissociation constants of picric acid in Gliet and Gliem have been determined at different temperatures and the data obtained are discussed. The reaction under study in the two solvents is

[1] $HA + Solv \rightleftarrows (SolvH^+A^-) \rightleftarrows SolvH^+ + A^-$

In addition, in view of the importance of the solvents employed in this study, dipolar and amphiprotic in nature, it would also be desirable to have more data on ionization enthalpies and entropies. These thermodynamic data can contribute to an understanding of solute–solvent interactions as well as problems specifically involving acidity in solvents or solvents mixtures other than water.

The conductometric rather than the potentiometric method is chosen because there are limitations in using hydrogen or glass electrodes in nonaqueous solvents, i.e. (*i*) if the emf of the hydrogen electrode is taken to be zero in all the solvent systems, quite a large number of unrelated pH or emf scales will be generated (7), and it is difficult to correlate the values of dissociation constants; (*ii*) liquid junction potentials and responses of the glass electrodes change with solvent system composition (8).

Results and discussion

The experimental data of conductance measurements, performed at nineteen temperatures in the −10 to 80°C range for six different concentrations in the two solvents, are reported in the Tables 1 and 2. All data were corrected at each temperature with the specific conductances of the solvents. The corrected values were analyzed by means of the method of Fuoss and Shedlovsky (9). The equation

$$\frac{1}{\Lambda S} = \frac{1}{\Lambda_0} + \frac{c\Lambda Sf^2}{K\Lambda_0^2}$$

was used, where the symbols have the usual significance. If $1/\Lambda S$ is plotted vs. $c\Lambda Sf^2$, the intercept is $1/\Lambda_0$ and the slope is $1/K\Lambda_0^2$. In practice an initial value of Λ_0 is estimated from a plot of Λ vs. $c^{1/2}$ and then an iterative method allows us to calculate K and Λ_0; usually only a few iterations are necessary.

The values of Λ_0 and K at different temperatures are reported in Tables 3 and 4 for picric acid in 1,2-ethanediol and 2-methoxyethanol, respectively.

For the purpose of calculating the thermodynamic functions, the experimental data for K at the various temperatures were fitted to an equation of the type

[2] $\ln K = A + BT + C/T + D \ln T$

by the method of least-squares to yield, using standard equations, the thermodynamic data, also reported in Tables 3 and 4.

By examining the behaviour of the K values with temperature in the two solvents, we may note that although the same equation fits the data, the trend in the temperature range investigated is different. Figure 1 shows this behaviour: the curves are plotted using eq. [2] ($A = 317.2531$, $B = 0.04648$, $C = -11683.34$, $D = -52.2908$ for Gliet; $A = -2148.1026$, $B = -0.6903$, $C = 54518.42$, $D = 379.1845$ for Gliem). While in the case of Gliet the dissociation constant of picric acid shows a maximum, estimated by setting the derivative of eq.

[2] equal to zero, ($K_{max} = 2.49 \times 10^{-3}$) in the investigated temperature range at 34.4°C, in the case of Gliem a continuous decrease of the K value is observed.

The value for K_{max} calculated to best fit eq. [2] is quite in good agreement both with the results obtained by a method suggested by Harned (10) ($K_{max} = 2.46 \times 10^{-3}$ at $t = 38.4$°C) and with those evaluated by a correlation of pK vs. $1/\epsilon$. In fact, knowing the relationship between ϵ and t, the above correlation provides two straight lines (one of negative slope, $r = 0.923$, and the other of positive slope, $r = 0.980$) intersecting in a point whose ordinate and abscissa give pK_{max} and the temperature of K_{max}, respectively ($K_{max} = 2.61 \times 10^{-3}$, $t = 34.3$°C).

A further difference in the behaviour of experimental data in the two solvents comes by examining the relation between Λ_0 and viscosity. We observe (Tables 3 and 4) that in the case of Gliem the Walden rule $\Lambda_0\eta$ = constant is substantially obeyed, while for Gliet $\Lambda_0\eta$ decreases as the temperature increases. Such behaviour, observed by Fuoss (11), has been attributed to a decrease in dielectric constant. On the contrary, for Gliet our results are better reproduced by a modified Walden product as

suggested by Stokes (12) for high density aqueous solutions: $\Lambda_0\eta^{0.7}$ = constant; the better fitting of this empirical relation suggests that this unusual behaviour is probably a consequence of the high viscosity of the medium.

Tables 3 and 4 report the thermodynamic data calculated by the usual equations from the best fitting equation [2]. Many difficulties and uncertainties are associated with these calculations which derive from the inevitable experimental errors in K values and partly from the calculator's choice of the function which represents the dependance on the temperature. However, $\Delta H°$, and especially $\Delta S°$ values, have proved useful in yielding structural information about solute species and solute–solvent interactions.

When considering the entropy of dissociation in detail, we are concerned with entropy changes due to differences "within" the acid and its anion and also with entropy changes due to differences in solute–solvent interactions. As a consequence, by using the same solute in two different solvents in this work, our thermodynamic data, in particular the $\Delta S°$ values, could be useful in investigating the properties of the media.

The factors that define $\Delta S°$ values in the two solvents are many and sometimes opposite. The entropies of ionization here reported (Tables 3 and 4) indicate that the solute species orienting neighbouring molecules are more effective in Gliem than in Gliet.

Bearing in mind that dielectric constant decreases as temperature increases, an increase in temperature should play an important role in stabilizing ion pairs of reaction [1], particu-

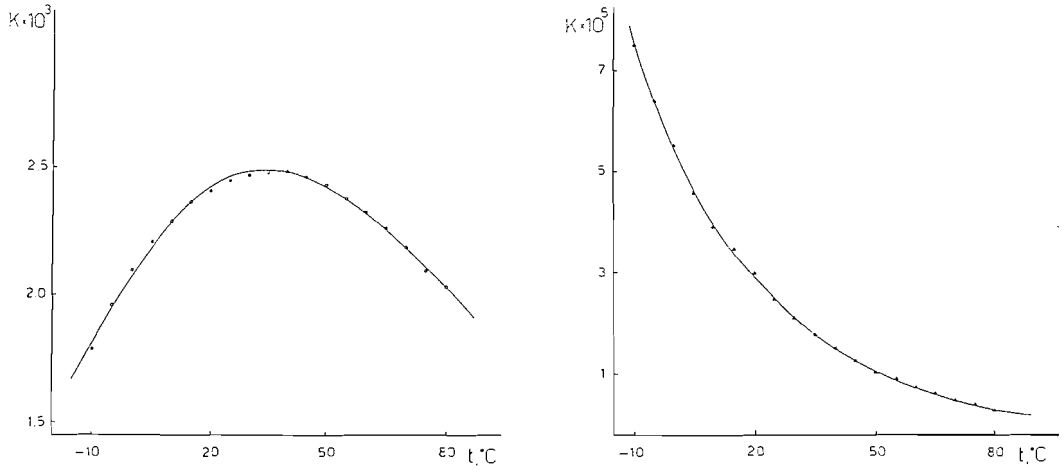

FIG. 1. The dissociation constant of picric acid in Gliet (left) and Gliet (right) as a function of the temperature.

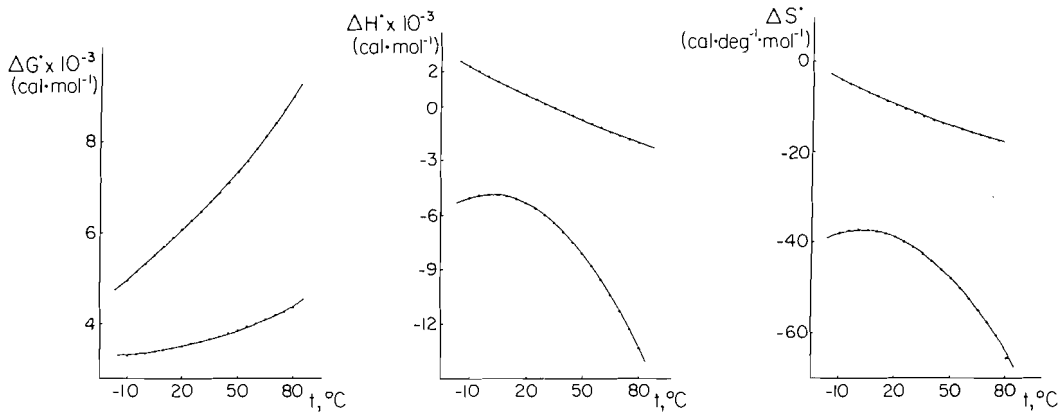

FIG. 2. The dependance on the temperature of $\Delta G°$, $\Delta H°$, and $\Delta S°$ of dissociation for picric acid in Gliet (●) and Gliem (▲).

larly in the case of Gliem. In fact we may think that the species ($SolvH^+A^-$) can orient solvent molecules in its immediate neighbourhood with increasing ease as the dielectric constant decreases. Consequently, $\Delta S°$ values are always more negative for Gliem ($\epsilon_{25°C}$ = 16.94) than for Gliet ($\epsilon_{25°C}$ = 41.06) (but other factors may play a role, see below) and the $\Delta S°$ vs. t curves show a negative temperature coefficient, except for Gliem in the temperature range between −10 and 0°C (Fig. 2).

In the case of the solvent Gliet we need further considerations in addition to the ones above mentioned. We must consider the viscosity effect; in fact the greater value of η suggests a highly polymerized structure of this solvent especially at the lower temperatures. This structure is quickly depolymerized as the temperature increases and this fact is supported by the sudden decrease of η (from 97.12 cP at −10°C to 3.04 cP at 80°C). Thus we may think of a positive contribution to the entropy of the system; a more positive contribution would be expected also by considering the increase in the K values of our solute in Gliet up to 34.4°C. The actual negative $\Delta S°$ values for the Gliet system indicate that probably the importance of these two last contributions is small if compared to the importance of the opposite effect produced by the charged species (ions or ion pairs) on the neighbour solvent molecules.

Experimental

Materials

2,4,6-Trinitrophenol (picric acid), supplied by Fluka (reagent grade), was used without further purification. The solvents 1,2-ethanediol and 2-methoxyethanol (containing less than 0.10 and 0.05% water, respectively, found by Karl Fischer titration) were supplied by Carlo Erba in high purity grade.

Apparatus

Conductances of the solutions were measured with an Amel Mod. 123 conductivity bridge and platinized platinum electrodes (cell constant equal to 0.98 cm), operating in the 0.1 μS to 0.3 S f.s.; the instrument, for the conductance range studied, has a sensitivity of ±1.0%.

The temperature control was provided by a Lauda K2R thermostatic bath maintained to ±0.02°C.

Viscosity measurements were performed by a AVS 400 viscosity measuring system Schott-Geräte, equipped with a series of Ubbelhode viscometers.

Densities at the different temperatures were determined with calibrated Hg densimeters (sensitivity ±0.0005 g cm^{-3}).

The dielectric constants were measured using a WTW-DM01 Dipolmeter equipped with two stainless-steel cylindrical cells: MFL2 ($7 < \epsilon < 21$) was calibrated with dichloromethane (ϵ = 9.08 at 20°C), pyridine (ϵ = 12.30 at 25°C), 1-butanol (ϵ = 17.80 at 20°C), and acetone (ϵ = 20.70 at 25°C) (13); MFL3 ($21 < \epsilon < 90$) was calibrated with ethanol (ϵ = 24.30 at 25°C), methanol (ϵ = 32.63 at 25°C), glycerol (ϵ = 42.50 at 25°C), and water (ϵ = 80.37 at 20°C) (13).

Karl Fischer titrations were performed with an automatic titration system Crison Mod. KF431 equipped with a digital burette Crison Mod. 738.

Procedure

The solutions of picric acid at different concentrations were obtained by successive dilution of stock solutions, freshly prepared by weight

For personal use only.

corrected to the vacuum values; concentration in volume was then calculated from weight concentration and density. Conductance readings were recorded when they became invariant with time; this took about 30 min for each measurement. Solvent conductance corrections were applied to all data at different temperatures.

Received September 18, 1986

JAHANGIR, DAVID B. MACLEAN, and HERBERT L. HOLLAND. 1987. Can. J. Chem. **65**, 727 (1987).

Methyllithium reacted with oxyberberine, affording on alkaline work-up a compound with an exomethylene group at C-8 that was transformed in acidic media into an 8-methylberberinium salt. The iminium salt was reduced to a mixture of racemic α- and β-8-methylcanadine. 5,6-Dihydro-8*H*-isoquino[2,1-*b*][2,7]naphthyridin-8-ones were similarly transformed into 8-exomethylene and 8-methyl derivatives, which were subjected to further reduction. These reactions have been employed in a synthesis of the *Alangium* alkaloid, (±)-alamaridine.

JAHANGIR, DAVID B. MACLEAN et HERBERT L. HOLLAND. 1987. Can. J. Chem. **65**, 727 (1987).

La réaction du méthyl-lithium avec l'oxyberbérine conduit, après récupération en milieu alcalin, à un composé contenant un groupement exométhylène en position C-8 qui se transforme, en milieu acide, en un sel de méthyl-8 berbérinium. On a réduit le sel d'iminium en un mélange racémique des méthyl-8α (ainsi que 8β) canadines. De la même manière, on a transformé les dihydro-5,6 8*H*-isoquino [2,1-*b*][2,7] naphtyridinones-8 en dérivés exométhylène-8 et méthyl-8 que l'on a soumis à des réductions subséquentes. On a utilisé ces réactions pour synthétiser la (±)-alamaridine, un alcaloïde de l'*Alangium*.

Alamaridine **1** was isolated a few years ago as a minor constituent of *Alangium lamarckii* Thw. (1) and the synthesis of the racemic base and its relative stereochemistry has since been reported (2). We have recently described general methods (3, 4) for the synthesis of the ring system found in alamaridine and related *Alangium* alkaloids (5) that provide ready access to compounds of type **2** and **3**. The conversion of these lactams into 8-methyl derivatives, of which **1** is an example, and the related conversion of 8-oxyberberine (**4**) (6) into 8-methylberberines is described here.

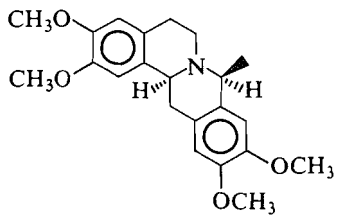
9



10

8-Oxyberberine, because of its availability, was used as a model substance to investigate the reaction of methyllithium with a lactam function at C-8 as a means of introducing a methyl group at C-8 of a berberine system. As outlined in Scheme 1, treatment of **4** with MeLi at −40°C followed by work-up of the reaction mixture under alkaline conditions afforded the exomethylene compound **5**. The presence of two singlets in the ^{1}H nmr spectrum of **5** at δ 4.20 and δ 5.35 was indicative of the presence of the $>C=CH_2$ group. Compound **5** was transformed as expected in acidic media into the iminium salt **6**, which showed a signal (3H) at 3.60 in the region expected of a methyl group α to a quaternary nitrogen atom in an iminium system (7). Reduction of **6** with sodium borohydride in ethanol afforded a separable mixture of (8*R**,13a*S**)- and (8*S**,13a*S**)-8-methylcanadine, **7** and **8**, respectively, in a ratio of ca. 1:3. The ratio is similar to that observed in the borohydride reduction of 8-methylberberinium salts that have oxygen substituents at C-10 and C-11 (8). Oxyberberine could also be converted into a mixture of **7** and **8**, without isolation of intermediates, in a "one-pot" process.

The assignment of the relative stereochemistry of **7** and **8** is based upon spectroscopic examination of the two isomers and a comparison of their ir and nmr spectra with those of *O*-methylcorytenchirine **9** and coralydine **10** (8, 9) whose relative stereochemistry has been established by X-ray analysis (10). The ir spectrum of **8**, like that of coralydine, displays Bohlmann bands but these are absent in the spectra of **7** and *O*-methylcorytenchirine. Thus **8**, like coralydine, has a *trans* quinolizidine ring fusion, and **7**, like *O*-methylcorytenchirine, a *cis* fusion at the N-13a bond.[2]

The reaction of **2** (3) (Scheme 2) with methyllithium proceeded analogously to that of **4**. The methylene compound (**11**), isolated on alkaline work-up, was readily converted in acidic media into iminium salt **12**. Reduction of **12** with sodium borohydride in ethanol afforded a separable 1:3 mixture of the (8*R**,13a*S**)- and (8*S**,13a*S**)-8-methyl compounds **13** and

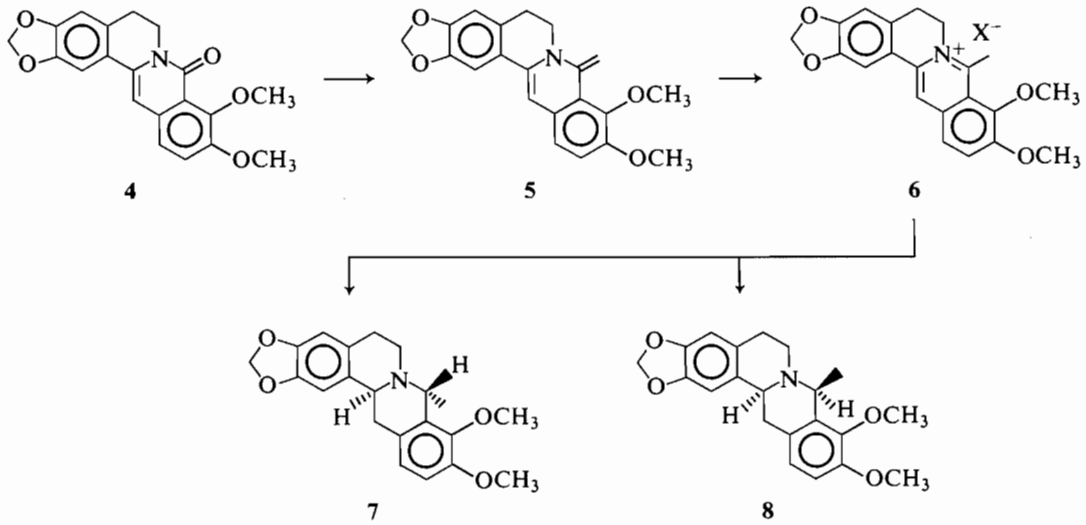
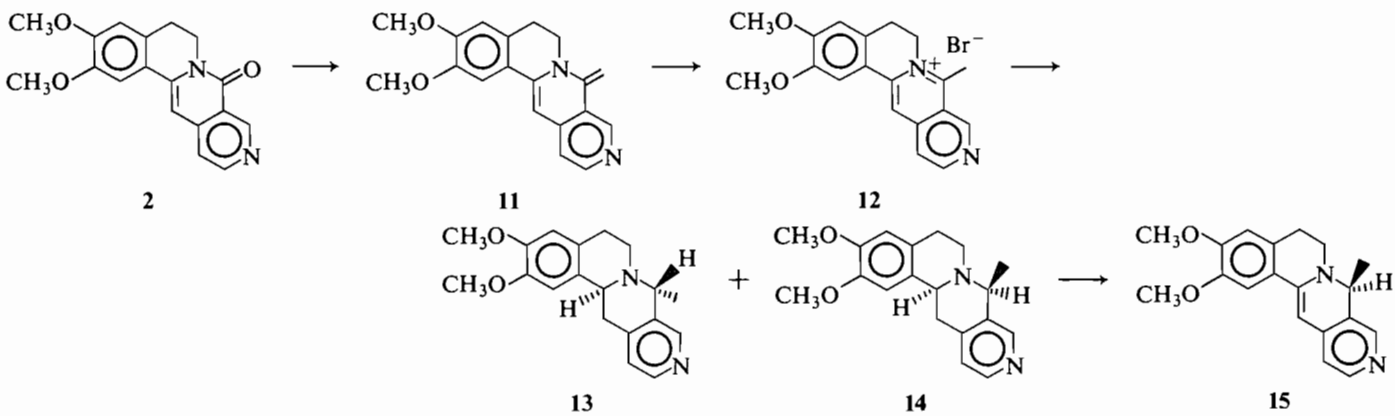
[2]Nuclear magnetic resonance data in support of these assignments is discussed below.



SCHEME 1



SCHEME 2

14, respectively, the former corresponding in structure to (±)-*O*-methylalamaridine. The assignment of relative stereochemistry to **13** and **14** is based on their spectroscopic properties. Of special importance is the fact that **14** shows Bohlmann bands in its ir spectrum but **13** does not. Compounds **13** and **14** may also be prepared without isolation of the intermediates in a "one-pot" reaction.

The tetrahydro compounds **13** and **14** were highly susceptible to aerial oxidation, which was a complicating factor in their isolation and purification. The product of aerial oxidation, **15**, was a 13,13a didehydro compound that was strongly fluorescent. A related oxidation of tetrahydro-2,7-naphthyridines has been reported (11). It should be noted that (±)-alamaridine (*vide infra*) does not undergo a similar facile oxidation.

The treatment of **15** with sodium borohydride in ethanol afforded, as expected, the same ratio of products as that obtained in the reduction of **12**.

The *O*-benzyl analogue of **2**, compound **16** (3), was converted without isolation of intermediates into a mixture of **17** and **18** in a ratio of 1:3 (Scheme 3) but only **18** was isolated in pure form. The mixture of **17** and **18**, like the mixture of compounds **13** and **14**, was highly susceptible to aerial oxidation. As a result, the separation and purification of the isomers was only partially successful. Debenzylation of the mixture of **17** and **18** was effected by hydrogenolysis, affording a separable mixture of (±)-8-epialamaridine (**19**) and (±)-alamaridine (**1**). The ir and ^{1}H nmr spectra of **1** in solution correspond with the spectra of natural (1) and synthetic alamaridine (2), which were kindly sent to us by Dr. S. C. Pakrashi. The ^{1}H nmr spectra of Pakrashi were recorded in $CDCl_3$ at 100 MHz and ours in the same solvent at 500 MHz. Our measured chemical shifts for the aromatic signals, the *O*-methyl signal, and the *C*-methyl signal agree with those of Pakrashi within experimental error. The aliphatic protons of the ring, which occur as complex multiplets, are much better resolved at 500 MHz but are situated in each spectrum within the same range of δ values. The ir spectrum of **19** had Bohlmann bands typical of a *trans* quinolizidine system but these bands were absent in the spectrum of (±)−**1**.

We also examined the reaction of **3** with methyllithium, and the subsequent treatment of the addition product with borohydride and hydrogen to determine the ratio (8α to 8β) of reduction products (Scheme 4). Compound **3** was prepared in two steps by treatment of 3,4-dihydro-6,7-dimethoxyisoquinoline (**20**) with the lithium salt of 3-cyano-4-methylpyridine (**21**) at −40°C in THF in the manner already described (4). The initial product, amidine (**22**), was hydrolysed in aqueous base to **3**. Treatment of **3** with MeLi afforded a product on alkaline work-up, presumably **23**, that was hydrogenated over a Pd catalyst. The reaction product, which was homogeneous by tlc,

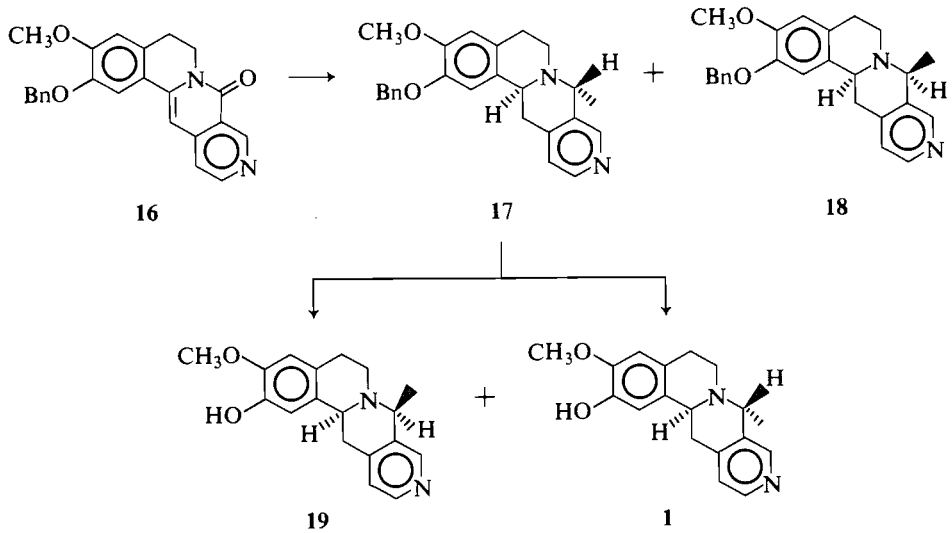
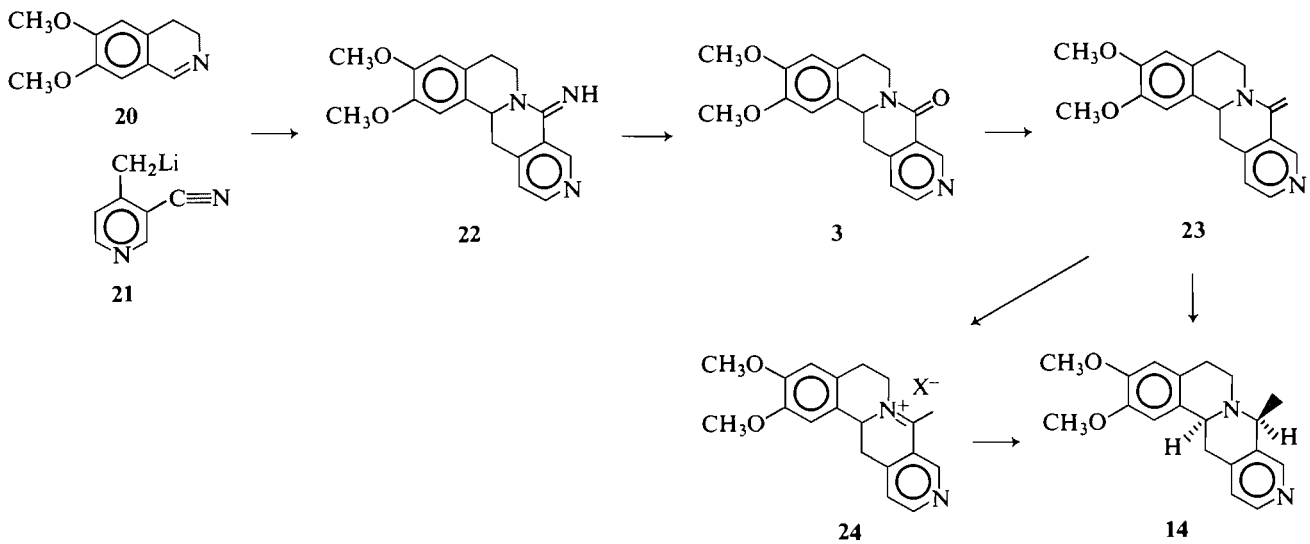


SCHEME 3



SCHEME 4

was identical with **14**. In another experiment the crude reaction product from the methyllithium reaction was taken up in glacial acetic acid, in which **23** would be expected to be converted into **24**, and then treated with sodium cyanoborohydride. Again, only **14** was isolated. In the cyanoborohydride reduction of **24** the iminium bond undergoing reduction is the N—C-8 double bond. In the other cases examined that involved reduction of berberinium salts, and in the case of **15**, the last bond to be reduced would be an iminium bond between C-13a and N. It is apparent that the reductions of the two bonds are subject to different steric constraints. The stereospecific reduction of an N—C-8 bond has also been observed in a recently reported asymmetric synthesis of coralydine (7).

Tourwé *et al.* (9) have reported that nmr spectroscopy may be used effectively to ascertain the conformation of dibenzo[*a*,*g*]-quinolizidines. In an examination of the spectra of coralydine (**10**) and *O*-methylcorytenchirine (**9**) they have noted along with other observations that the chemical shift of the protons of C-8 H, C-8 CH_3, and C-13a H and the coupling constant between C-8 H and C-8 CH_3 are diagnostic of the conformation and configuration of the molecules. In the *trans* quinolizidine, coralydine (**10**), the methyl group at C-8 is deshielded and the protons at C-8 and C-13a are shielded relative to the corresponding signals in *O*-methylcorytenchirine (**9**), which has been assigned a *cis* quinolizidine conformation and which is a diastereomer of coralydine. The coupling constant between C-8 H and C-8 CH_3 also differs in the two systems, as shown in Table 1. In the same table the relevant data for the isomeric pairs of 8-methyl compounds prepared in this investigation are collated. It is evident that there is an excellent correlation between the conformation (as ascertained by ir examination) and the ^1H nmr of the signals examined. It may be inferred therefore that the conclusions drawn by Tourwé *et al.* (9) regarding the use of ^1H nmr spectroscopy in assigning the conformation of the quinolizine ring in 8-methylberberines substituted at C-10 and C-11 are generally valid for berberines and apply equally well to the related systems prepared in this investigation.

An examination of the ^{13}C spectra of the 8-methylberberines has revealed a correlation between the chemical shifts of selected carbon atoms and the stereochemistry. These data, collated in Table 2, show that the signals at C-8, C-8 CH_3, and C-13a are diagnostic of the stereochemistry. Signals at C-6 and C-13, which have been used in assigning conformation in other

TABLE 2. Correlation between stereochemistry and ^{13}C nmr signals of 8-methylberberines and 8-methylazaberberines

Compound	Signal C-8	C-13a	C-8 CH_3	Compound	Signal C-8	C-13a	C-8 CH_3
Coralydine (**10**)[a]	58.9	58.6	21.3	*O*-Methylcorytenchirine (**9**)[a]	58.8	50.0	17.7
8β-Methylcanadine (**8**)[b]	57.3	59.1	23.0	8α-Methylcanadine (**7**)[b]	50.7	55.6	15.9
8-*epi*-*O*-Methylalamaridine (**14**)	57.6	58.3	21.2	*O*-Methylalamaridine (**13**)	49.9	56.7	17.7
(±)-*epi*-Alamaridine (**19**)	57.8	58.4	21.4	(±)-Alamaridine (**1**)	49.7	57.0	17.3

[a]Data from ref. 8.
[b]The assignment of signals to C-8 and C-13a in **7** and **8** was made on the basis of a hetero-COSY experiment. The assignment of signals to these two centres in **9** was made prior to the development of 2D techniques and probably should be reversed in view of our results.

protoberberine systems (12), are not appreciably different in the isomeric pairs examined in this investigation and the signals have not been tabulated. Tourwé and Van Binst (12) have noted that differences between the ^{13}C spectra of **9** and **10** may not be a reliable criterion for the assignment of conformation to the two systems. However, there is no doubt that ^{13}C nmr may be used to differentiate between diastereomers. Nevertheless, ir and ^1H nmr appear to be more reliable measures of conformation.

In summary, it has been shown that 8-oxoberberines react readily with methyllithium. The products isolated on alkaline work-up are enamines with an 8-exomethylene group. The enamines are transformed to iminium salts in acidic media and the latter undergo facile reduction to 8-methylberberines. (±)-Almaridine has been synthesized from the readily available lactam (**2**) using these procedures.

Experimental

Apparatus, materials, and methods

The continuous wave ^1H nmr spectra were recorded on a Varian EM 390 spectrometer and the Fourier transform spectra on either a Bruker WP 80 (80 MHz), WM 250 (250 MHz), or WM 500 (500 MHz) spectrometer. Unless otherwise specified, the samples were dissolved in chloroform-*d* using tetramethylsilane (TMS) as internal standard. Chemical shifts, quoted as δ values, were measured in relation to TMS. The symbols s, singlet, d, doublet, t, triplet, q, quartet, br, broad, and m, multiplet are used in reporting spectra. The ^{13}C nmr spectra were recorded at 62.9 MHz on a Bruker WM 250 FT or at 125.76 MHz on a WM 500 FT spectrometer at ambient temperature.

EI mass spectra were recorded at 70 eV with a source temperature of ca. 200°C either on a VG Micromass 7070 F mass spectrometer equipped with a data system comprised of a PDP 8A with VG 2000 software or a VG analytical ZAB E mass spectrometer equipped with a VG 11-250 data system. High resolution mass spectra (hrms) were recorded on either of the above instruments. CI mass spectra were recorded on a VG Micromass 7070 F mass spectrometer using NH_3 at ca. 1 Torr (133.3 Pa) as reagent gas and DCI mass spectra were recorded under similar conditions on a VG analytical ZAB E mass spectrometer. Infrared spectra were run on a Perkin–Elmer 283 spectrometer in $CHCl_3$ solution or $CHCl_3$ film. Melting points were determined using a Gallenkamp apparatus and are uncorrected. The microanalyses were performed by the Guelph Chemical Laboratories Ltd., Guelph, Ontario.

Thin-layer chromatography (tlc) was performed using Polygram Sil G/UV_{254} and Polygram Alox N/UV_{254} plates. For flash column chromatography (13) Kieselgel 60 (230–400 mesh) was used.

All reactions involving lithiation steps were carried out in flame-dried apparatus under a blanket of argon, using septa and syringes for transfer of reagents. Diisopropylamine and 1,1,1,3,3,3,-hexamethyldisilazane were heated under reflux over calcium hydride and distilled onto activated molecular sieves (4A) for storage. THF was dried by distillation from Na/benzophenone under a nitrogen atmosphere just prior to use.

5,6-Dihydro-9,10-dimethoxy-2,3-methylenedioxy-8H-dibenzo[a,g]-quinolizin-8-one (oxyberberine) **4**

Oxyberberine **4** was prepared by the procedure of Perkin (6) from berberine chloride by refluxing with 30% NaOH solution (aqueous) for 3 h; mp 204°C (EtOAc) (lit. (15) mp 200°C, lit. (16) mp 192–195°C); ^1H nmr (90 MHz), δ: 2.85 (2H, t, J=6.0 Hz, C-5 H's), 3.95 (3H, s, $-OCH_3$), 4.00 (3H, s, $-OCH_3$), 4.25 (2H, t, J=6.0 Hz, C-6 H's), 5.97 (2H, s, $-OCH_2O-$), 6.70 (2H, s, C-1 and C-4 H's), 7.20 (1H, apparent s, C-13 H), 7.30 (2H, apparent s, C-11 and C-12 H's); ms (EI), *m/z* (%): 351 (100)$M^{+\cdot}$, 336 (84), 321 (33), 308 (28), 291 (25), and 83 (14).

(8α)- and (8β)-8-methylcanadine, 7 and 8, respectively, from 4

(a) Without isolation of intermediates

To a stirred solution of oxyberberine (**4**) (0.526 g, 1.5 mmol) in dry THF (100 mL) at −40°C was added a solution of MeLi (5 mL, 1.5 *M* in hexane, 7.5 mmol) under an argon atmosphere. The reaction mixture was stirred at −40°C for 3 h and then the temperature was raised slowly to ca. 20°C and stirring was continued for a further 2–3 h. The excess of MeLi was destroyed by adding water (1 mL) at 0°C and a few drops of concentrated HCl solution (aqueous). The reaction mixture was then stirred for another 15 min at room temperature. Sodium borohydride (0.57 g, 15 mmol) was added in portions to the above stirred reaction mixture and stirring continued for 1 h. At this point the solution became clear and the solvent was evaporated *in vacuo*. The excess $NaBH_4$ was cautiously destroyed with glacial acetic acid; the resulting reaction mixture was basified with concentrated NH_3 solution (aq.) to pH 10 and

For personal use only.

then thoroughly extracted with $CHCl_3$. The combined $CHCl_3$ extracts were washed with brine, dried over Na_2SO_4 (anhydrous), and evaporated *in vacuo*, affording in nearly quantitative yield a mixture of isomeric 8-methylcanadines in a ratio (8α:8β = 1:3) as estimated by nmr. The crude product on crystallization from EtOH (95%) gave the 8β isomer **8** (0.2 g). The ethanolic mother liquor was evaporated and the residue subjected to flash chromatography on silica gel (eluting with cyclohexane and EtOH in a ratio of 10:3), affording an additional 0.163 g of the 8β isomer (8*S**,13a*S**) and the 8α isomer (8*R**,13a*S**) **7** (0.13 g).

8β *Isomer* (**8**): 0.363 g (69%); R_f 0.70 (silica; EtOAc–cyclohexane (1:1)); mp 166–167°C (EtOH); ir ($CHCl_3$), ν_{max}: 2820–2740 cm^{-1} (Bohlmann bands); ^1H nmr (500 MHz), δ: 1.50 (3H, d, J=6.1 Hz, C-8 CH_3), 2.52 (1H, m, C-6 H_{ax}), 2.65 (1H, apparent d, J=16.0 Hz, C-5 H_{ax}), 2.80 (1H, m, C-13 H_{ax}), 3.10 (2H, m, C-5 H_{eq} and C-13 H_{aq}), 3.30 (1H, m, C-6 H_{eq}), 3.53 (1H, d, J=10.8 Hz, C-13a H), 3.81 (1H, q, J=6.1 Hz, partially overlapped by OCH_3 signals, C-8 H), 3.85 (3H, s, -OCH_3), 3.86 (3H, s, -OCH_3), 5.88 (2H, m, OCH_2O), 6.58 (1H, s, C-4 H), 6.75 (1H, s, C-1 H), 6.78 (1H, A part of AB, J=8.3 Hz, C-11 H), 6.86 (1H, B part of AB, J=8.3 Hz, C-12 H); ^{13}C nmr (125.76 MHz), δ: 23.0 (q, C-8 CH_3), 30.8 (t, C-5), 37.8 (t, C-13), 49.3 (t, C-6), 56.0 (q, OCH_3), 57.3 (d, C-8), 59.1 (d, C-13a), 60.4 (q, OCH_3), 100.8 (t, OCH_2O) 105.8 (d, C-4), 108.6 (d, C-1), 110.8 (d, C-12), 123.6 (d, C-11), 128.5, 129.1, 131.6, 134.0, 146.0, 146.1 146.2, 151.1 (s's, Ar C's); ms(EI), *m/z* (%): 353 (10)$M^{+\cdot}$, 338 (100), 336 (20), 178 (45), and 163 (18). *Exact Mass* (hrms) calcd. for $C_{21}H_{23}NO_4$: 353.163; found: 353.163.

8α *Isomer* (**7**): 0.13 g (25%); R_f 0.52 (silica; EtOAc–cyclohexane (1:1)); mp 138°C (EtOAc–hexane); ir ($CHCl_3$), ν_{max}: no Bohlmann bands; ^1H nmr (500 MHz), δ: 1.37 (3H, d, J=6.7 Hz, C-8 CH_3), 2.71–3.10 (6H, complex m, C-5, C-6, and C-13 H's), 3.83 (3H, s, OCH_3), 3.85 (3H, s, OCH_3), 4.19 (1H, dd, J=11.3 and 4.2 Hz, C-13a H), 4.30 (1H, q, J=6.7 Hz, C-8 H), 5.88 (2H, s, OCH_2O), 6.57 (1H, s, C-4 H), 6.67 (1H, s, C-1 H), 6.76 (1H, A part of AB, J=8.4 Hz, C-11 H), 6.80 (1H, B part of AB, J=8.4 Hz, C-12 H); ^{13}C nmr (125.76 MHz), δ: 15.9 (q, C-8 CH_3), 30.0 (t, C-5), 35.2 (t, C-13), 47.2 (t, C-6), 50.7 (d, C-8), 55.6 (d, C-13a), 55.9 (q, OCH_3), 60.6 (q, OCH_3), 100.8 (t, OCH_2O), 106.3 (d, C-1), 108.7 (d, C-4), 111.3 (d, C-11), 124.1 (d, C-12), 126.6, 127.6, 132.2, 133.7, 145.4, 146.0, 146.1, and 150.5 (s's, Ar C's); ms (EI), *m/z* (%): 353 (12)$M^{+\cdot}$, 338 (100), 178 (72), 163 (26), and 135 (10). *Exact mass* (hrms) calcd. for $C_{21}H_{23}NO_4$: 353.163; found: 353.160.

(b) With isolation of intermediates

8-Methylene-5,6-dihydro-9,10-dimethoxy-2,3-methylenedioxy-8H-dibenzo[a,g]quinolizine (**5**): The reaction was carried out using oxyberberine **4** (1.5 mmol) as described previously. After an appropriate reaction time, the excess MeLi was destroyed by adding a saturated solution of Na_2SO_4 (2 mL aq.). The reaction mixture was diluted with $CHCl_3$ (100 mL), dried over Na_2SO_4 (anhyd.), and filtered. The residue was washed several times with $CHCl_3$ and the combined $CHCl_3$ filtrates were evaporated *in vacuo* to give the exomethylene compound as an oil in almost quantitative yield; ^1H nmr (90 MHz), δ: 2.87 (2H, t, J=6.0 Hz, C-5 H's), 3.48 (2H, q, J=6.0 Hz, C-6 H's), 3.80 (3H, s, OCH_3), 3.86 (3H, s, OCH_3), 4.20 and 5.35 (1H each, s's, methylene protons), 5.90 (2H, s, OCH_2O), 6.00 (1H, s, C-13 H), 6.63 (1H, s, C-4 H), 6.87 (2H, s, C-11 and C-12 H's), 7.10 (1H, s, C-1H).

5,6-Dihydro-9,10-dimethoxy-2,3-methylenedioxydibenzo[a,g]quinolizinium bromide (**6**)

To a methanolic solution of the crude exomethylene compound was added 48% HBr solution (1 mL, aq.). The reaction mixture was stirred for 5 min at room temperature and then evaporated to dryness *in vacuo* to give the quaternary bromide (0.6 g), which was crystallized from MeOH (0.405 g, 63%), mp 220–223°C (dec.); ^1H nmr (90 MHz, TFA), δ: 3.25 (2H, t, J=6.0 Hz, C-5 H's), 3.60 (3H, s, C-8 CH_3), 4.20 (6H, s, 2×OCH_3), 4.88 (2H, t, J=6.0 Hz, C-6 H's), 6.12 (2H, s, OCH_2O), 6.95 (1H, s, C-4 H), 7.48 (1H, s, C-1 H), 8.04 (2H, s, C-11 and C-12 H's), 8.37 (1H, s, C-13 H); ms (EI), *m/z* (%): 350 (19) (M^+), 349 (35), 334 (100), 318 (25), 290 (34), 167 (24), 148 (36), and 135 (32).

Sodium borohydride reduction of the iminium salt (**6**)

To a stirred solution of the salt **6** (0.3 g) in EtOH (50 mL) was added $NaBH_4$ (0.3 g) in small portions with cooling and the reaction mixture was stirred for 1 h at room temperature. The excess $NaBH_4$ was carefully destroyed with glacial acetic acid at 0°C, the solution was made basic with concentrated NH_3 solution (aq.), and then the product was thoroughly extracted into $CHCl_3$. The combined $CHCl_3$ extracts were washed with brine and evaporated *in vacuo*. The crude product, containing an isomeric mixture of 8-methylcanadines **7** and **8**, was subjected to flash chromatography on silica gel, eluting with EtOAc–cyclohexane (3:10) to give the 8β isomer (0.17 g, 73%) and the 8α isomer (0.056 g, 23%), identical with the samples described above (mp, tlc, ^1H nmr, and mass spectra).

(8S,13aS*)-5,6-13,13a-Tetrahydro-2,3-dimethoxy-8-methyl-8H-isoquino[2,1-b][2,7]naphthyridine* (**14**) *and its epimer at C-8* (**13**)

(a) Without isolation of intermediates

To a solution of the lactam (**2**) (0.39 g, 1.27 mmol) in dry THF (25 mL) was added a solution of MeLi (6 mL, 1.5 *M* in hexane) dropwise at −78°C and the mixture was then stirred for ca. 3 h. The excess MeLi was destroyed with saturated Na_2SO_4 solution (2 mL), a few drops of 48% HBr (aq.) were added, and the solution was stirred for 10 min. Excess $NaBH_4$ (0.4 g) was added to the reaction mixture, which was stirred for a further 3 h, and then the solvent was removed *in vacuo*. The excess $NaBH_4$ was destroyed with glacial acetic acid, the resulting solution basified with concentrated NH_3 (aq.), and the solution thoroughly extracted with $CHCl_3$. The combined $CHCl_3$ extracts were washed successively with water and brine, and then dried over Na_2SO_4 (anhyd.). Evaporation of the solvent *in vacuo* gave the crude product (0.378 g), which was approximately a 3:1 mixture of **14** and **13** as estimated by ^1H nmr of the crude product. The reduced product undergoes rapid aerial oxidation, giving a highly fluorescent green-coloured solution, and therefore it must be immediately chromatographed after work-up. Flash chromatography on silica gel using 1–5% MeOH in $CHCl_3$ enabled the two isomers to be separated.

8β *Isomer* (**14**): 213 mg (54%); mp 158–159°C (EtOAc); R_f 0.30 (alumina; EtOAc–hexane (1:1)); ir ($CHCl_3$ film), ν_{max}: 2820–2740 cm^{-1} (Bohlmann bands); ^1H nmr (500 MHz), δ: 1.60 (3H, d, J=6.4 Hz, C-8 CH_3), 2.48 (1H, d of t, J=11.2 and 3.5 Hz, C-6 H_{ax}), 2.73 (1H, br d, J=16.0 Hz, C-5 H_{eq}), 2.91 (1H, dd, J=16.5 and 11.2 Hz, C-13 H_{ax}), 3.06 (1H, m, C-5 H_{ax}), 3.18 (1H, dd, J=16.5 and 3.1 Hz, C-13 H_{eq}), 3.39 (1H, complex m, C-6 H_{eq}), 3.75 (1H, apparent d, J=10.0 Hz, C-13a H), 3.83 (1H, q, J=6.4 Hz, C-8 H), 3.87 (3H, s, OCH_3), 3.89 (3H, s, OCH_3), 6.63 (1H, s, C-4 H), 6.71 (1H, s, C-1 H), 7.07 (1H, d, J=5.0 Hz, C-12 H), 8.35 (1H, d, J=5.0 Hz, C-11 H), 8.49 (1H, s, C-9 H); ^{13}C nmr (125.76 MHz), δ: 21.2 (C-8 CH_3), 29.6 (C-5), 36.6 (C-13), 46.5 (C-6), 55.9 (OCH_3), 56.2 (OCH_3), 57.6 and 58.3 (C-8 and C-13a), 109.0, 111.5, 123.0 and 127.1, 129.7, 135.6, 143.6, 146.7, 147.6, 147.8, and 148.4 (Ar C's); ms (EI), *m/z* (%): 310 (41)$M^{+\cdot}$, 309 (43), 295 (100), 191 (25), 190 (39), 176 (17), and 118 (11). *Exact Mass* (hrms) calcd. for $C_{19}H_{22}N_2O_2$: 310.168; found: 310.168.

8α *Isomer* (**13**): 97 mg (25%); glassy solid; R_f 0.23 (alumina; EtOAc–hexane, (1:1)); ir ($CHCl_3$), ν_{max}: no Bohlmann bands; ^1H nmr (500 MHz), δ: 1.42 (3H, d, J=6.9 Hz, C-8 CH_3), 2.90–3.10 (5H, complex m, C-5 H, C-6 H and C-13 H_{ax}), 3.13 (1H, dd, J=17.2 and 4.2 Hz, C-13 H_{eq}), 3.87 (3H, s, OCH_3), 3.89 (3H, s, OCH_3), 4.23–4.27 (2H, m, C-8 and C-13a H's), 6.63 (1H, s, C-4 H), 6.69 (1H, s, C-1 H), 7.03 (1H, d, J=5.0 Hz, C-12 H), 8.33 (1H, d, J=5.0 Hz, C-11 H), and 8.35 (1H, s, C-9 H); ^{13}C nmr (125.76 MHz), δ: 17.7 (C-8 CH_3), 29.7 (C-5), 35.9 (C-13), 47.5 (C-6), 49.9 (C-8), 56.1 (C-13a), 56.3 (OCH_3), 57.2 (OCH_3), 109.4, 111.8, 123.8, 126.9, 130.2, 136.4, 143.1, 147.1, 147.7, 147.8, and 148.9 (Ar C's); ms (EI), *m/z* (%): 310 (45)$M^{+\cdot}$, 309 (40), 295 (100), 192 (13), 191 (35), 190 (49), 176 (20), 120 (8), 119 (9), and 118 (12). *Exact Mass* (hrms) calcd. for $C_{19}H_{22}N_2O_2$: 310.168; found: 310.167.

(*b*) *With isolation of intermediates*

(*i*) *8-Methylene-5,6-dihydro-2,3-dimethoxy-8*H*-isoquino[2,1-*b*][2,7]naphthyridine* (***11***): To a solution of lactam (**2**) (0.2 g) in dry THF (12 mL) was added a solution of MeLi (5 mL, 1.5 *M* in hexane) dropwise at −78°C as described previously. The reaction mixture was stirred under argon at −78°C for 3–4 h (reaction monitored by tlc). The excess MeLi was destroyed with saturated Na_2SO_4 (2 mL, aq.). The reaction mixture was diluted with $CHCl_3$, filtered through a pad of Na_2SO_4 (anhyd.), and the residue washed several times with $CHCl_3$. Evaporation of the $CHCl_3$ filtrate *in vacuo* afforded an oil (0.187 g, 94%); ^{1}H nmr (90 MHz), δ: 2.90 (2H, t, *J*=6.0 Hz, C-5 H's), 3.45 (2H, t, *J*=6.0 Hz, C-6 H's), 3.90 (3H, s, OCH_3), 3.93 (3H, s, OCH_3), 4.65 and 5.95 (1H each, s's, methylene protons), 6.68 (1H, s, C-4 H), 6.93 (1H, d, *J*=5.5 Hz, C-12 H), 7.00 (1H, s, C-1 H), 7.17 (1H, s, C-13 H), 8.35 (1H, d, *J*=5.5 Hz, C-11 H), and 8.83 (1H, s, C-9 H).

*(ii) 5,6-Dihydro-2,3-dimethoxy-8-methylisoquino[2,1-*b*][2,7]naphthyridinium bromide* (***12***): The crude product **11** obtained above was taken into EtOH (5 mL), 48% HBr solution (1 mL, aq.) added, and the reaction mixture was stirred for 15 min. The solvent was evaporated *in vacuo* and the last traces of water were removed by codistillation with benzene. The crude product **12** was crystallized from EtOH–EtOAc (0.12 g, 51%), mp 190–198°C (dec.); ^{1}H nmr (90 MHz), δ: 2.95 (2H, t, *J*=6.0 Hz, C-5 H's), 3.95 (6H, s, OCH_3 and NCH_3), 4.00 (3H, s, OCH_3), 4.34 (2H, t, *J*=6.0 Hz, C-6 H's), 6.76 (2H, s, C-1 and C-4 H's), 7.30 (1H, s, C-13 H), 7.39 (1H, d, *J*=5.4 Hz, C-12 H), 8.68 (1H, d, *J*=5.4 Hz, C-11 H), 9.61 (1H, s, C-9 H); ms (EI), *m/z* (%): 307 (23)M^+, 306 (100), 305 (75), 291 (68), 289 (30).

(±)-*5,6-Dihydro-2,3-dimethoxy-8-methyl-8*H*-isoquino[2,1-*b*][2,7]-naphthyridine* (***15***)

A chloroform solution of a mixture of **13** and **14** undergoes rapid aerial oxidation, producing a highly fluorescent green solution. A sample of the mixture, when left open to air for ca. 48 h at room temperature, was found completely oxidized to **15**. The crude product was purified on neutral alumina (EtOAc), yielding a glassy solid; ^{1}H nmr (90 MHz), δ: 1.28 (3H, d, *J*=6.5 Hz, C-8 CH_3), 2.80–3.05 (2H, m, C-5 H's), 3.30–3.63 (2H, m, C-6 H's), 3.90 (3H, s, OCH_3), 3.95 (3H, s, OCH_3), 4.65 (1H, q, *J*=6.5 Hz, C-8 H), 5.76 (1H, s, C-13 H), 6.76 (1H, s, C-4 H), 6.88 (1H, d, *J*=5.2 Hz, C-12 H), 7.25 (1H, s, C-1 H), 8.18 (1H, s, C-9 H), 8.30 (1H, *J*=5.2 Hz, C-11 H); ms (EI), *m/z* (%): 308 (14)$M^{+\cdot}$, 293 (100), and 277 (20). This compound was reduced with $NaBH_4$ to give an isomeric mixture of **13** and **14** in a ratio of ca. 1:3.

(8S,13aS*)-2-Benzyloxy-5,6,13,13a-tetrahydro-3-methoxy-8-methyl-8*H*-isoquino[2,1-*b*][2,7]naphthyridine* (***18***)

To a solution of lactam **16** (0.3 g, 0.78 mmol) in dry THF (20 mL) (3) was added dropwise a solution of MeLi (4 mL, 1.5 *M* in hexane) and the resulting solution was stirred for 3.5 h at −78°C. The excess MeLi was then decomposed with a saturated Na_2SO_4 solution (2 mL aq.). The resulting mixture was treated with an excess of $NaBH_4$ (0.4 g) and stirred for ca. 3 h at room temperature. After removal of the solvent *in vacuo*, the excess $NaBH_4$ was carefully destroyed with glacial acetic acid. The mixture was basified with concentrated NH_3 solution and thoroughly extracted with $CHCl_3$. The $CHCl_3$ extract was washed with brine, dried over Na_2SO_4 (anhyd.), and the solvent recovered *in vacuo*, affording a crude product (0.293 g, 97%) that was a mixture of (8*S**,13a*S**) isomer **18** and (8*R**,13a*S**) isomer **17** as shown by ^{1}H nmr of the crude product.

The reduced product in solution oxidizes rapidly in air, forming a highly fluorescent green-coloured mixture, and must be chromatographed immediately.

The reduced product was separated into two fractions by flash chromatography on silica gel ($CHCl_3$-EtOAc, 8:1) but only the (8*S**,13a*S**) isomer **18** was obtained in pure form (167 mg, 55%); mp 137–141°C (EtOAc–hexane); R_f 0.65 (silica; $CHCl_3$–EtOAc (2:1)); ir ($CHCl_3$), ν_{max}: 2840–2740 cm^{-1} (Bohlmann bands); ^{1}H nmr (500 MHz), δ: 1.59 (3H, d, *J*=6.4 Hz, C-8 CH_3), 2.47 (1H, d of t, *J*=11.0 and 3.6 Hz, C-6 H_{ax}), 2.71–3.01 (3H, complex m, C-5 and C-13 H_{ax} H's), 3.05 (1H, dd, *J*=17.3 and 3.1 Hz, C-13 H_{eq}), 3.31 (1H, complex m, C-6 H_{eq}), 3.71 (1H, m, C-13a H), 3.79 (1H, q, *J*=6.4 Hz, C-8 H), 3.88 (3H, s, OCH_3), 5.13 (2H, m, OCH_2Ar), 6.66 and 6.67 (1H each, s's, C-1 and C-4 H's), 7.18 (1H, d, *J*=5.8 Hz, C-12 H), 7.32–7.44 (5H, complex m, Ar H's), 8.31 (1H, d, *J*=5.8 Hz, C-11 H), and 8.44 (1H, s, C-9 H); ms (EI), *m/z* (%): 386 (53)$M^{+\cdot}$, 385 (38), 371 (95), 295 (33), 280 (21), 279 (27), 267 (14), 266 (25), 120 (21), 119 (12), 118 (16), and 91 (100). *Exact Mass* (hrms) calcd. for $C_{25}H_{26}N_2O_2$: 386.199; found: 386.199.

(±)-*8*-epi-*Alamaridine* (***19***) *and* (±)-*alamaridine* (***1***)

The crude mixture of **17** and **18**, obtained from the reaction of 300 mg of lactam **16** and excess MeLi under conditions described above, was dissolved in MeOH (15 mL) and glacial acetic acid (1 mL), 10% Pd–C (0.1 g) was added, and the reaction mixture was treated with H_2 for ca. 12 h at 30 psi (1 psi = 6.9 kPa). The catalyst was removed by filtration through Celite and the residue washed with $CHCl_3$. The filtrate was diluted with water (25 mL), basified with 20% Na_2CO_3 (aq.), and thoroughly extracted with $CHCl_3$. The combined $CHCl_3$ extracts were washed with brine, dried over Na_2SO_4 (anhyd.), and evaporated *in vacuo* to give a mixture (0.167 g, 72%) containing **1** and **19**, which was subjected to flash chromatography (silica gel; eluting with 5–10% MeOH in $CHCl_3$), yielding two components.

(*a*) (±)-*8*-epi-*Alamaridine* (**19**): 93 mg (40%); mp 197-200°C (dec.) (EtOAc–hexane); R_f, 0.26 (silica; $CHCl_3$–MeOH (10.1)); ir ($CHCl_3$), ν_{max}: 3550 cm^{-1}, 2820–2740 cm (Bohlmann bands); ^{1}H nmr (500 MHz), δ: 1.60 (3H, d, *J*=6.4 Hz, C-8, CH_3), 2.46 (1H, d of t, *J*=11.3 and 3.5 Hz, C-6 H_{ax}), 2.71 (1H, apparent d, *J*=15.8 Hz, C-5 H_{ax}), 2.89 (1H, dd, *J*=16.5 and 11.2 Hz, C-13 H_{ax}), 3.05 (1H, m, C-5 H_{eq}), 3.13 (1H, dd, *J*=16.5 and 2.8 Hz, C-13 H_{eq}), 3.39 (1H, m, C-6 H_{eq}), 3.71 (1H, d, *J*=10.9 Hz, C-13a H), 3.79 (1H, q, *J*=6.4 Hz, C-8 H), 3.87 (3H, s, OCH_3), 5.55 (1H, br s, phenolic -OH), 6.61 (1H, s, C-4 H), 6.80 (1H, s, C-1 H), 7.05 (1H, d, *J*=4.9 Hz, C-12 H), 8.34 (1H, d, *J*=4.9 Hz, C-11 H), and 8.48 (1H, s, C-9 H); ^{13}C nmr (125.76 MHz), δ: 21.4 (C-8, CH_3), 29.8 (C-5), 36.7 (C-13), 47.0 (C-6), 56.1 (OCH_3), 57.8 (C-8), 58.4 (C-13a), 110.8 (C-1), 111.7 (C-4), 123.4, 126.4, 130.6, 135.8, 144.0, 144.2, 145.5, 146.8, and 148.4 (Ar C's); ms (EI), *m/z* (%): 296 (33)$M^{+\cdot}$, 295 (36), 281 (100), 279 (25), 178 (18), 177 (20), 176 (32), 162 (13), 120 (18), 119 (11), and 118 (12). *Exact Mass* (hrms) calcd. for $C_{18}H_{20}N_2O_2$: 296.152; found: 296.152.

(*b*)(±)-Alamaridine (***1***): 46 mg (20%); mp 178–182°C; R_f 0.20 (silica; $CHCl_3$–MeOH (10:1)); ^{1}H nmr (500 MHz), δ: 1.41 (3H, d, *J*=6.9 Hz, C-8, CH_3), 2.76–3.14 (5H, complex m, C-5, C-6, and C-13 H_{ax} H's), 3.12 (1H, dd, *J*=17.5 and 4.5 Hz, C-13 H_{eq}), 3.88 (3H, s, OCH_3), 4.21 (1H, dd, *J*=11.0 and 4.5 Hz, C-13a H, partially overlapped with q of C-8 H), 4.24 (1H, q, *J*=6.9 Hz, C-8 H), 5.20 (1H, br s, phenolic OH), 6.60 (1H, s, C-4 H), 6.77 (1H, s, C-1 H), 7.02 (1H, d, *J*=4.9 Hz, C-12 H), 8.32 (1H, d, *J*=4.9 Hz, C-11 H), and 8.37 (1H, s, C-9 H); ^{13}C nmr (125.76 MHz), δ: 17.3 (C-8 CH_3), 29.7 (C-5), 35.8 (C-13), 47.4 (C-6), 49.7 (C-8), 56.0 (OCH_3), 57.0 (C-13a), 110.9 (C-1), 111.9 (C-4), 123.7, 126.0, 130.9, 136.2, 143.0, 144.1, 145.2, 146.9, and 148.6 (Ar C's); ms (EI), *m/z* (%): 296 (36)$M^{+\cdot}$, 295 (29), 281 (100), 237 (4), 178 (38), 177 (19), 176 (29), 163 (11), 162 (16), 120 (18), 119 (11), and 118 (5). *Exact Mass* (hrms) calcd. for $C_{18}H_{20}N_2O_2$: 296.153; found: 296.150. The ir spectrum of the synthetic sample was identical with that of natural alamaridine. The ^{1}H nmr (500 MHz) spectrum of our synthetic sample and the ^{1}H nmr (100 MHz, $CDCl_3$) spectra of natural alamaridine (1) and synthetic alamaridine (2) of Pakrashi had chemical shifts for C-methyl, O-methyl, and aromatic protons that agreed within experimental error. Other signals that appeared as multiplets fell within the same range of δ values.

(±)-*5,6,13,13a-Tetrahydro-2,3-dimethoxy-8*H*-isoquino[2,1-*b*]-[2,7]naphthyridine-8-imine* (***22***)

A solution of imine **20** (0.6 g, 3.15 mmol) in dry THF (4 mL) was treated dropwise with trimethylsilyl triflate (0.75 mL, 3.83 mmol) at −78°C under an argon atmosphere. The resulting cloudy suspension was stirred first at −78°C for 1 h, then at 0°C for an additional 1 h. Meanwhile a solution of *n*-BuLi (2.33 mL, 1.55 *M* in hexane, 3.6 mmol) was added dropwise to a stirred solution of 1,1,1,3,3,3-hexa-

For personal use only.

methyldisilazane (0.76 mL, 3.6 mmol) in dry THF (3 mL) at −78°C. The lithium bistrimethylsilylamide (LHS) solution so generated was stirred for an additional 10 min at −20°C and then cooled to −78°C. A solution of 3-cyano-4-methylpyridine **21** (0.354 g, 3 mmol) in dry THF (2 mL) was added dropwise to the above LHS solution at −78°C and the golden anion solution generated was stirred for a further 15 min at −78°C. The anion solution was then added dropwise to the imine – TMS triflate complex at −78°C and, when the addition was complete, the mixture was stirred for a further 4 h at −40°C. The reaction mixture was allowed to warm slowly to room temperature and stirred for ca. 12 h. The mixture was quenched with saturated NH_4Cl solution (1 mL, aq.) and the resulting mixture was evaporated to dryness, water added, and the contents extracted with $CHCl_3$. The $CHCl_3$ extract was dried over Na_2SO_4 (anhyd.) and the solvent evaporated *in vacuo*. The crude product was filtered through a short neutral alumina column, eluting first with $CHCl_3$ and then with $CHCl_3$–MeOH (3:1), affording the amidine **22** (0.904 g, 97.5%); mp 160–163°C (EtOAc); ir ($CHCl_3$ film), ν_{max}: 1615 cm^{-1}; ^1H nmr (500 MHz), δ: 2.79–2.82 (1H, m, C-6 H_{ax}), 2.92–3.05 (3H, complex m, C-5 and C-13 H_{ax} H's), 3.16 (1H, dd, J=16.0 and 2.6 Hz, C-13 H_{eq}), 3.90 (6H, s, 2×OCH_3), 4.63 (1H, dd, J=12.4 and 2.6 Hz, C-13a H), 4.85 (1H, m, C-6 H_{eq}), 6.68 (1H, s, C-4 H), 6.71 (1H, s, C-1 H), 7.20 (1H, d, J=4.9 Hz, C-12 H), 8.60 (1H, d, J=4.9 Hz, C-11 H), and 9.13 (1H, s, C-9 H); ^{13}C nmr (125.76 MHz), δ: 29.2 (C-5), 38.3 (C-13), 39.9 (C-6), 54.4 (C-13a), 56.1 (OCH_3), 56.4 (OCH_3), 109.1, 111.6, 122.5, 147.8, and 150.8 (15 × Ar CH's), 125.5, 144.9, 148.2, 148.3, and 150.8 (Ar C's),[3] and 159.6 (>C=NH); ms (EI), m/z (%): 309 (100)$M^{+\cdot}$, 294 (58), 255 (18), 192 (40), 190 (24), 176 (59), 149 (40), and 118 (47). *Exact Mass* (hrms) calcd. for $C_{18}H_{19}N_2O_3$: 309.148; found: 309.146.

*(±)-5,6,13,13a-Tetrahydro-2,3-dimethoxy-8*H*-isoquino[2,1-*b*]-[2,7]naphthyridin-8-one (**3**)*

Amidine **22** (250 mg) was dissolved in a mixture of dioxane (15 mL) and 20% KOH solution (10 mL, aq.) and the mixture was gently heated under reflux for 2 days. The solution was then evaporated to dryness *in vacuo*, acidified with concentrated HCl (aq.), and heated under reflux for an additional 30 min. Evaporation of the acidified solution was followed by basification with saturated Na_2CO_3 solution (aq.) and extraction with $CHCl_3$. The combined $CHCl_3$ extracts were washed with brine and dried over $MgSO_4$ (anhyd.). Removal of the solvent *in vacuo* and crystallization from EtOAc gave lactam **3** (231 mg, 92%); mp 173–175°C (EtOAc); R_f 0.34 (alumina; EtOAc); ir ($CHCl_3$ film), ν_{max}: 1655 cm^{-1}; ^1H nmr (500 MHz), δ: 2.78–2.80 (1H, C-6 H_{ax}), 2.93–3.00 (3H, complex m, C-5 and C-13 H_{ax} H's), 3.24 (1H, dd, J=16.2 and 3.3 Hz, C-13 H_{eq}), 3.90 (3H, s, OCH_3), 3.91 (3H, s, OCH_3), 4.85 (1H, dd, J=13.3 and 3.3 Hz, C-13a H), 4.98–5.00 (1H, m, C-6 H_{eq}), 6.70 and 6.72 (1H each, s's, C-1 and C-4 H's), 7.21 (1H, d, J=4.7 Hz, C-12 H), 8.66 (1H, d, J=4.7 Hz, C-11 H), and 9.27 (1H, s, C-9 H); ^{13}C nmr (125.76 MHz), δ: 29.1 (C-5), 37.4 (C-13), 38.8 (C-6), 54.5 (C-13a), 56.1 (OCH_3), 56.4 (OCH_3), 108.9, 111.8, 121.7, 150.3 and 152.3 (5 × Ar CH's), 124.9, 126.9, 127.4, 145.8, 148.4 and 148.4 (6 × Ar C's), and 163.3 (>C=O); ms (EI), m/z (%): 310 (100)$M^{+\cdot}$, 295 (46), 279 (42), 190 (48), 176 (20), 149 (21), and 119 (51). *Exact Mass* (hrms) calcd. for $C_{18}H_{18}N_2O_3$: 310.132; found: 310.130.

*Reaction of lactam **3** with MeLi followed by reduction with $NaCNBH_3$ in glacial acetic acid*

To a solution of lactam **3** (0.1 g, 0.323 mmol) in dry THF (10 mL) was added dropwise with stirring a solution of MeLi (1.5 mL, 1.5 *M* in hexane, 2.26 mmol) at −78°C under an argon atmosphere. The stirring was continued for ca. 4 h after which the excess MeLi was decomposed at −78°C with saturated Na_2CO_3 solution (1 mL, aq.). The reaction mixture was diluted with $CHCl_3$ (50 mL), filtered, and the residue washed several times with $CHCl_3$. The combined $CHCl_3$ extracts were washed with brine and then dried over Na_2SO_4 (anhyd). Removal of the solvent *in vacuo* provided a crude product, which was a mixture of 8-exomethylene compound **23** and iminium salt **24** (by ^1H nmr).

The crude material obtained above was dissolved in glacial acetic acid (3 mL), an excess of $NaCNBH_3$ was added, and the reaction mixture was stirred for ca. 30 min at 5–10°C. The mixture was then evaporated to dryness *in vacuo*, basified with concentrated NH_3 solution (aq.), and thoroughly extracted with $CHCl_3$. The $CHCl_3$ extracts were washed with brine, dried over Na_2SO_4 (anhyd.), and evaporated to dryness, yielding 85 mg of product homogeneous on tlc. It proved to be identical with the (8*S**,13a*S**) isomer **14** (tlc, ^1H nmr, and mass spectra).

*Reaction of lactam **3** with MeLi followed by catalytic reduction of the 8-exomethylene compound (**23**)*

Lactam **3** (100 mg) was heated with excess of MeLi in the manner already described. The reaction mixture was treated with a saturated Na_2CO_3 solution (1 mL) at −78°C, and extracted with $CHCl_3$ as in the previous experiment. The crude exomethylene compound so obtained was dissolved in EtOH (10 mL) and a few drops of concentrated NH_3 solution. It was then treated with H_2 over 10% Pd–C (50 mg) at room temperature for ca. 12 h. The catalyst was removed by filtration and the residue was washed with $CHCl_3$. Evaporation of the combined filtrate *in vacuo* gave a compound (88 mg, 88%) homogeneous by tlc that proved to be identical with the (8*S**,13a*S**) isomer **14** (tlc, ^1H nmr, and mass spectra).

[3]Five signals were observed for the six aromatic quaternary C atoms.

Facile calculations of select eigenvalues and the characteristic polynomial of small molecular graphs containing heteroatoms

JERRY RAY DIAS
Department of Chemistry, University of Missouri, Kansas City, MO 64110, U.S.A.

Received September 17, 1986

JERRY RAY DIAS. 1987. Can. J. Chem. **65**, 734 (1987).

Determination of common eigenvalues by embedding smaller subgraphs onto larger ones is illustrated. A nearly universal expression of the sixth coefficient of the characteristic polynomial valid for all conjugated hydrocarbon polyenes is presented. Its use in a graph theoretical determination of the Hückel MO characteristic polynomial of molecular graphs possessing heteroatoms is detailed.

JERRY RAY DIAS. 1987. Can. J. Chem. **65**, 734 (1987).

On illustre comment on peut déterminer les valeurs propres communes en incorporant des petits graphiques dans des plus grands. On présente une expression qui est pratiquement universelle pour la détermination du sixième coefficient du polynome caractéristique qui est valide pour tous les hydrocarbures polyéniques conjugés. On présente les détails de son utilisation dans la détermination, dans la théorie des graphs, du polynôme caractéristique des OM de Hückel des graphiques moléculaires possédant des hétéroatomes.

Introduction

Previously the author derived less comprehensive versions of the following general equations for the fourth and sixth coefficients of the characteristic polynomial

$$[1]\quad a_4 = (1/2)(q^2 - 9q + 6N_c) - 2r_4 - d_1 - d_4 - 3d_5 - 6d_6 - \ldots$$

$$[2]\quad a_6 = -(1/6)(q^3 - 27q^2 + 116q) - N_c(3q - 16) - e(3,3) - 2r_6 + (q - 6)e(2,1) + (q - 5)e(3,1) + 2(q - 4 - \alpha_4)r_4 + r_3$$

where q = number of C—C σ bonds, N_c = number of carbon vertices, r_n = number of rings of size n, d_i = number of carbon vertices of degree i, $e(i, j)$ = number of edges (C—C σ bonds) with end points of degree i and degree j, and α_4 = number of attachments or branches on the tetragonal ring (1). Equation [1] is valid for all graphs and eq. [2] now, for the first time, presented in a more universal form is valid for all graphs having vertices of degree 1 to 3 and having no more than one trigonal or/and one tetragonal ring. With eq. [1] and eq. [2] the characteristic polynomial of small molecules can be quickly generated by inspection.

The following equation for the characteristic polynomial is valid for all conjugated polyenes having no more than one trigonal ring

$$P(G;X) = X^N - qX^{N-2} - 2r_3X^{N-3} + a_4X^{N-4} - [2r_5 - 2(q - 3 - \alpha_3)r_3]X^{N-5} + a_6X^{N-6} + \ldots$$

where a_4 is given by eq. [1], a_6 is given by eq. [2], α_3 is the number of attachments or branches on the trigonal ring, and $X = (E - \alpha)/\beta$. With this equation one can compute by inspection the characteristic polynomial of polyene molecules with seven or less carbon vertices. Polyene molecules with 8, 9, or 10 carbon vertices can be determined also if one or more eigenvalues are known via embedding or by its alternant or symmetry characteristics (2, 3). The method presented in this paper expands the scope of those previously published (4–6).

All the eigenvalues of a graph are collectively called the spectrum of the graph. If the eigenvalues of a smaller graph are contained among the eigenvalues of a larger graph, then the smaller graph is said to be subspectral to the larger one (3). This paper will show how to identify subspectral components by a process called embedding. Embedding along with the above equations allows one to quickly determine the Hückel MO energy levels of many molecules without the aid of a computer.

Throughout this paper only the σ-bond graph will be drawn where the carbon and hydrogen atoms and the C—H and p π bonds are omitted (1). A graph edge (line) and σ bond are synonymous, and a vertex (point) is equivalent to a carbon atom (carbon vertex). A primary carbon has a degree of one, a secondary carbon has a degree of two, and a tertiary carbon has a degree of three. Both benzene and cyclohexane have the same σ-bond molecular graph which is a hexagon that consists of only second degree vertices joined by $e(2,2)$-type edges. In this paper a 3(2)-valent polycyclic graph, denoted as a 3(2)-polycyclic graph, is a polycyclic molecular σ-bond graph consisting of only degree-2 and degree-3 carbon vertices with no internal second degree vertices, i.e., a polycyclic graph containing third degree vertices with some second degree vertices on its outer boundary that can be contracted to give a simple 3-polycyclic graph which is 3-connected and 3-valent.

Results and discussion

Identifying select eigenvalues in alternant hydrocarbons through embedding

In a series of papers, Hall provided the basis for recognition of the HMO eigenvalues of $\epsilon = \pm 1.0$ and $\pm 2.0\beta$ by inspection of the molecular topology of alternant hydrocarbons (7). His rules derive immediately from the eigenvector equations themselves and were translated into descriptive form called embedding that will now be reviewed (8). To repetitively embed a fragment into a molecule the following rules must be followed: (1) all atoms connected directly to the fragment must be nodes; (2) on the other side of each of these nodes will be the repetition of the fragment with the opposite sign; and (3) other branches at these nodes will also be nodes since at all nodes the sum of nearest neighbor fragments must be zero in regard to their signs (8). Ethene, allyl, butadiene, and benzene are the most common fragments embedded in benzenoid hydrocarbons. All nodes are designated in the figures by open circles.

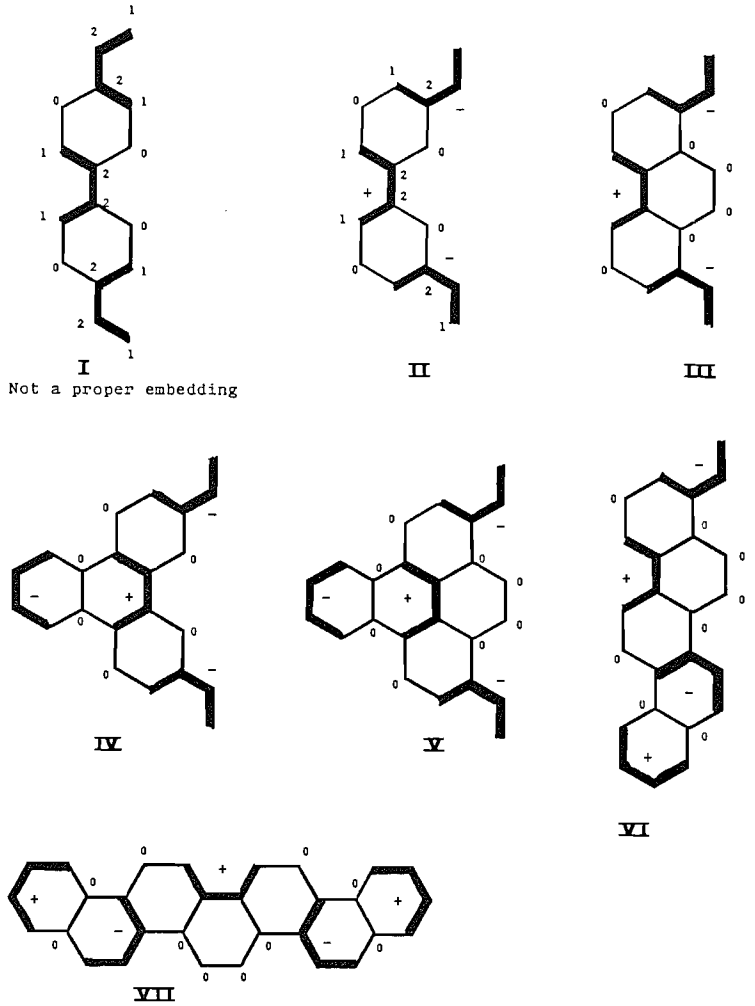

FIG. 1. 1,3-Butadiene embedding of 3,3′-divinylbiphenyl and related structures.

A number of aspects associated with embedding are illustrated by the structures presented in Fig. 1. Structure **I** illustrates an improper embedding of 1,3-butadiene fragments where corresponding fragment positions through the node positions do not match whereas those in structure **II** do. Since structures **II** to **VII** are embeddable by butadiene fragments, they all have eigenvalues of $\epsilon = \pm(\sqrt{5} + 1)/2$ and $\pm(\sqrt{5} - 1)/2$; butadiene is subspectral to **II** to **VII**. Molecule **II**, 3,3′-divinylylbiphenyl, is the principal structure from which the others can be derived. Placement of a heteroatom or polyene substituent at a node position in **II** does not change the butadiene embedding in the molecule thus obtained. Therefore **III** has the same butadiene embedding as **II**, and **V** has the same embedding pattern as **IV**. Structure **IV** was constructed from **II** by connecting a butadiene fragment through nodes onto nonnode positions of **II**. Similarly, **V** and **VI** were constructed from **III**, and **VII** was constructed from **VI** by this same process. In these constructions, the butadiene fragments were added on in such a manner as to always have corresponding butadiene positions match up through the new node positions.

Figure 2 presents a number of structures embedded by allyl that can be constructed from styrene or *m*-quinodimethane, and Fig. 3 illustrates benzene embedding of pentaphene-related structures produced by a similar construction. Mixed embedding with more than one type of substructure without common eigenvalues is not allowed. Embedding is a sufficient but not a necessary requirement for the presence of a set of eigenvalues. For example, 1,2-diethenylcyclobutadiene has $\epsilon = \pm 1.0\beta$ but cannot be embedded by ethene. The embedding of fragments other than methyl, ethene, or benzene must be done so as to always have corresponding fragment positions align through each node position. This requirement makes mixed embedding less *a priori* predictable and embedding of more complicated fragments increasingly more difficult. The construction process shown in Figs. 1 to 3 has features making it similar to Dixon's construction method which appears to be equivalent to retro-embedding (9). Since both benzene and trivinylmethyl radical have the same eigenvalues of $\epsilon = \pm 1, \pm 1$, and $\pm 2\beta$, Dixon showed that the following structure could be constructed from one benzene, two methyl, and two trivinylmethyl fragments where the methyl fragments become node positions (9, 10).

$\epsilon = \pm 1, \pm 1$, and $\pm 2\beta$

Since benzene can be embedded by ethene and naphthalene by butadiene, it should be noted that every benzenoid in Fig. 3 can be embedded by ethene and in Fig. 4 by butadiene. These observations suggest that whenever a benzenoid can be embed-

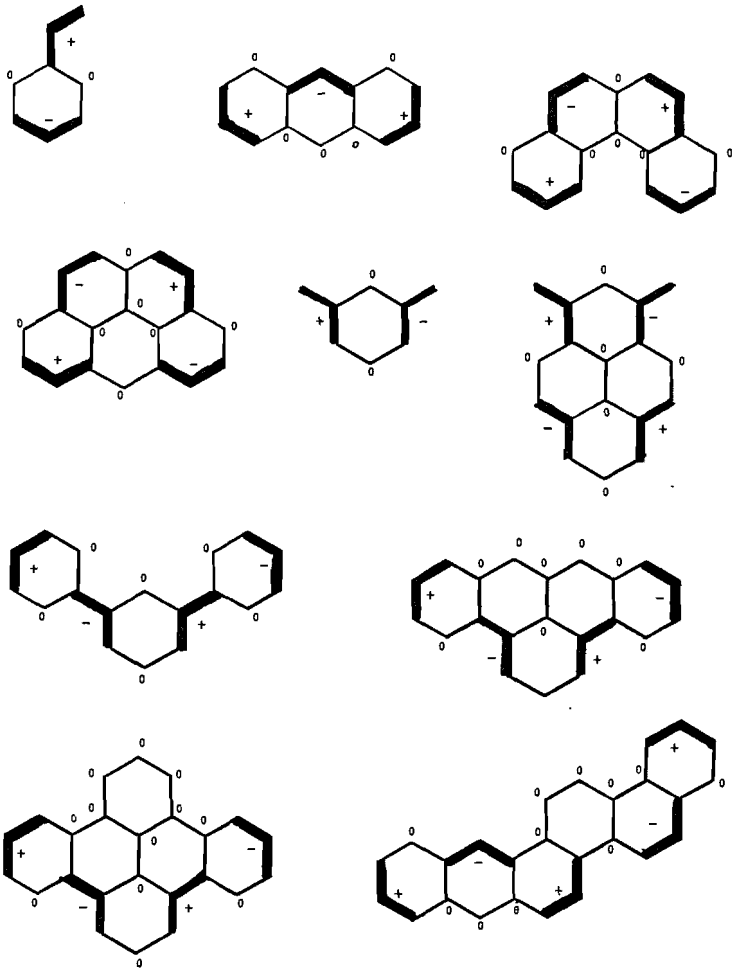

FIG. 2. Representative allyl embedding where all the above structures have eigenvalues of $\pm \sqrt{2}\beta$.

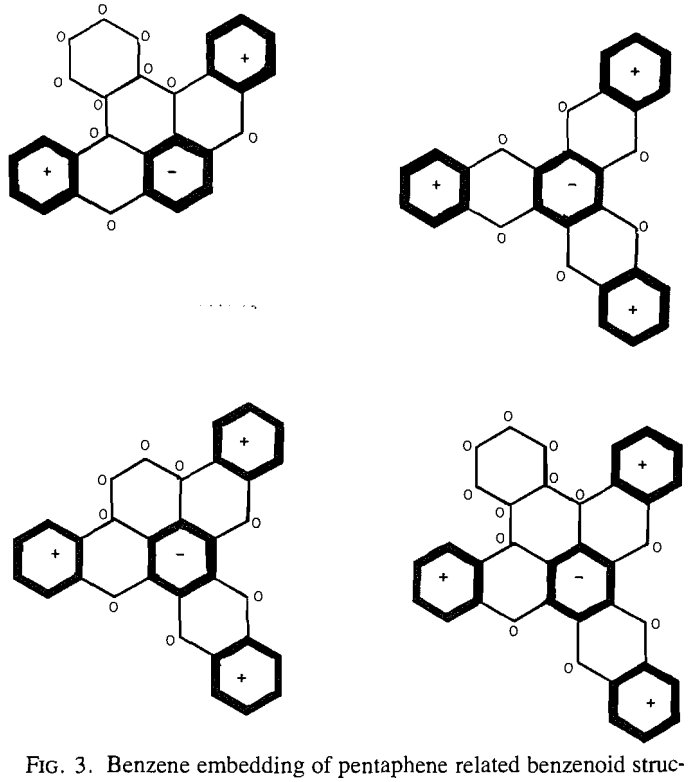

FIG. 3. Benzene embedding of pentaphene related benzenoid structures which have eigenvalues of ± 1, ± 1, and $\pm 2\beta$.

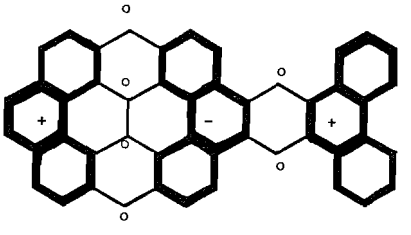
ded by ethene or butadiene, one should check to see if it can be embedded by the larger benzene or naphthalene substructures, respectively.

Examples of naphthalene embedding are presented in Fig. 4. Both ovalene and tetrabenzo[*a*,*c*,*h*,*j*]anthracene can be embedded by phenanthrene, and both these molecules have phenanthrene as a mirror plane fragment. The following benzenoid hydrocarbon has no mirror plane benzenoid fragments but can be embedded by phenanthrene as shown and therefore has the eigenvalues of phenanthrene in its spectrum.



Characteristic polynomials of small molecular graphs with one heteroatom

If one wishes to compute the characteristic polynomial of a small molecular graph possessing one heteroatom utilizing eq. [1] and eq. [2], the following relationship presented here for the first time will be needed

$$[3]\quad P(G_x; X) = XP(G_x - \nu_x; X) - hP(G_x - \nu_x; X) - k^2[XP(G_x - \nu_x; X) - P(G; X)]$$

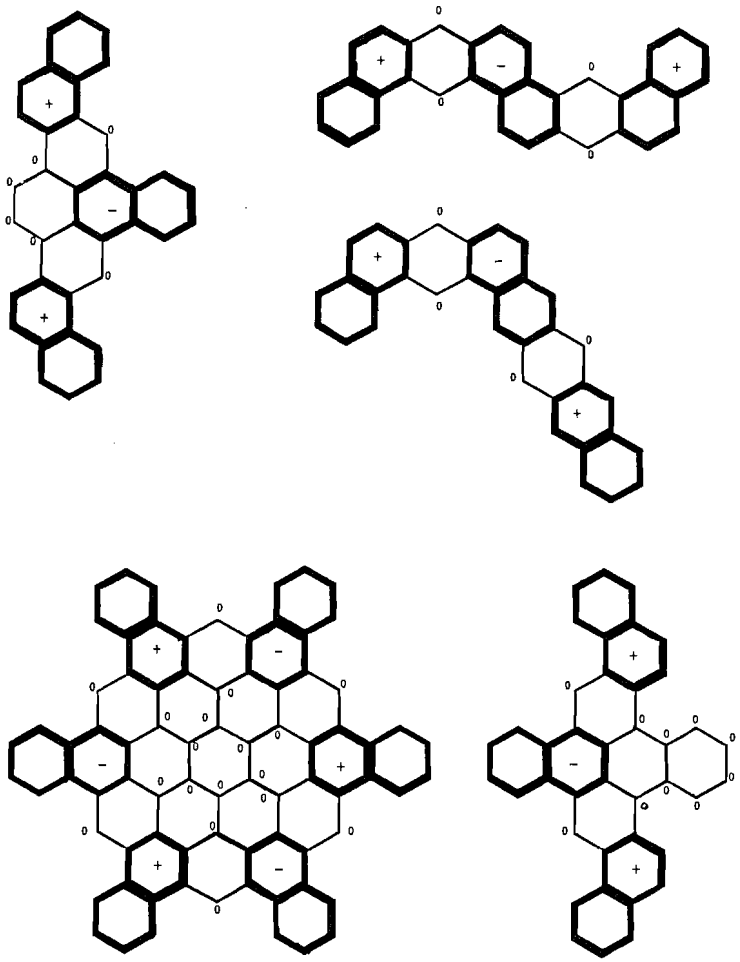


FIG. 4. Benzenoid hydrocarbons that have naphthalene eigenvalues.

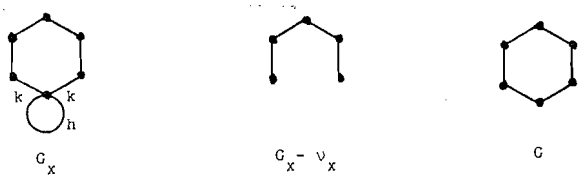
where G_x is the graph containing the heteroatom, G is its isoconjugate graph, $G_x - \nu_x$ is the graph obtained upon deletion of the heteroatom vertex with its adjacent edges, h comes from $\alpha_x = \alpha_c + h\beta$, k comes from $\beta_{cx} = k\beta_{cc}$, and $X = (E - \alpha)/\beta$. Equation [3] is valid for both the acyclic and characteristic polynomials. The application of eq. [3] will be illustrated with the molecular graphs in Fig. 5. Computation of the HMO characteristic polynomial for the pyridine-like structure **3** is equivalent to the graph theoretical determination of the charcteristic polynomial of the following edge/vertex weighted molecular graph.



The characteristic polynomial of both $G_x - \nu_x$ and G can be easily computed using eq. [1] and eq. [2] giving

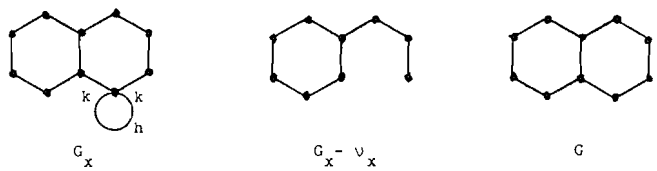
$$P(G_x - \nu_x; X) = X^5 - 4X^3 + 3X$$

$$P(G; X) = X^6 - 6X^4 + 9X^2 - 4$$

which when combined according to eq. [3] gives

$$P(G_x; X) = (X^6 - 4X^4 + 3X^2) - h(X^5 - 4X^3 + 3X) - k^2(2X^4 - 6X^2 + 4)$$

Note that if $h = 0$ and $k = 1$, this latter equation gives $P(C_6H_6;X) = X_6 - 6X^4 + 9X^2 - 4$ which is the characteristic polynomial for benzene. Computation of the characteristic polynomial of the quinoline-like structure **4** is achieved as follows.



From eq. [1] and eq. [2] and ethene embedding of $G_x - \nu_x$ and G, it is determined that

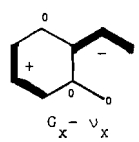
$$P(G_x - \nu_x; X) = X^9 - 9X^7 + 26X^5 - 29X^3 + 11X$$

$$P(G; X) = X^{10} - 11X^8 + 41X^6 - 65X^4 + 43X^2 - 9$$

where when combined per eq. [3] gives

$$P(G_x; X) = (X^{10} - 9X^8 + 26X^6 - 29X^4 + 11X^2) - h(X^9 - 9X^7 + 26X^5 - 29X^3 + 11X) - k^2(2X^8 - 15X^6 + 36X^4 - 32X^2 + 9).$$

The $G_x - \nu_x$ subgraph of the isoquinoline-like structure **5** can be embedded by allyl fragments as shown by the following.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

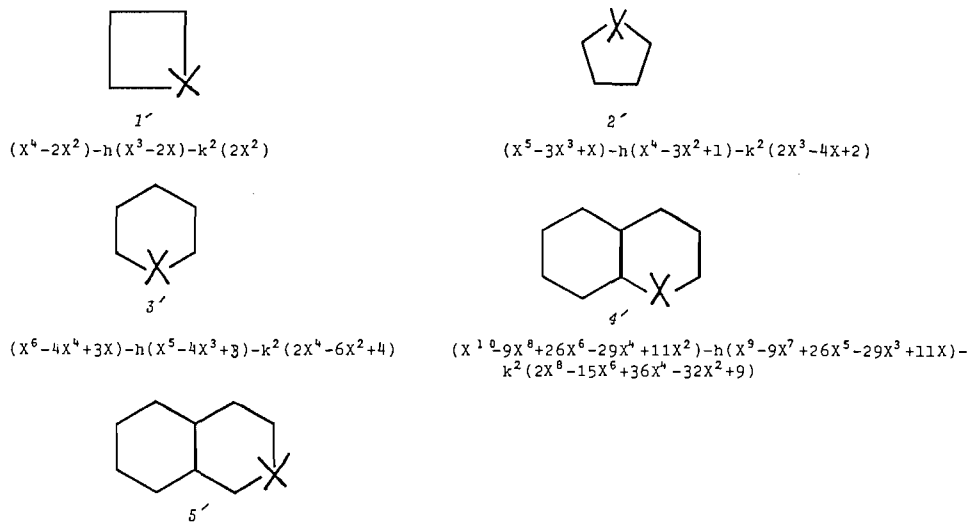


FIG. 5. The HMO characteristic polynomials for several heterocyclic molecular graphs where $\alpha_x = \alpha_c + h\beta$, $\beta_{cx} = k\beta_{cc}$, and $X = (E - \alpha)/\beta$.

Thus from eq. [1] and eq. [2], we get

$$P(G_x - \nu_x; X) = X^9 - 9X^7 + 25X^5 - 26X^3 + 8X$$

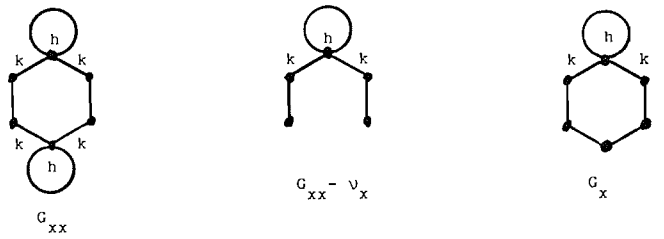
which, when combined with eq. [3], gives

$$P(G_x; X) = (X^{10} - 9X^8 + 25X^6 - 26X^4 + 8X^2) - h(X^9 - 9X^7 + 25X^5 - 26X^3 + 8X) - k^2(2X^8 - 16X^6 + 39X^4 - 35X^2 + 9)$$

From these examples, it is evident that a weighted graph vertex makes no contribution to the even terms of a characteristic polynomial. Since in a set of Sach's graphs a weighted vertex (h) in G_x excludes a K_2 component from the same two edge sites as excluded when the number of non-edge-weighted K_2 and C_n combinations are counted in $G_x - \nu_x$, then the combinatorial possibilities for both cases become identical and, therefore, the two associated polynomial parts will have the same set of coefficients. This observation is key to the formulation of eq. [3] which represents a distinct improvement over the recursive pair of equations used by Trinajstić where the latter are valid only for acyclic polynomial computations (11).

Characteristic polynomials of small molecular graphs with multiple heteroatoms

Successive use of eq. [3] on molecular graphs possessing multiple heteroatoms will be illustrated. Consider the pyrazine-like structure G_{xx} and its subgraphs.



To compute $P(G_{xx}; X)$ using eq. [3], one needs to know $P(G_{xx} - \nu_x; X)$ and $P(G_x; X)$ which are obtained per the method outlined above for molecular graphs containing a single heteroatom. Thus,

$$P(G_{xx} - \nu_x; X) = (X^5 - 2X^3 + X) - h(X^4 - 2X^2 + 1) - k^2(2X^3 - 2X)$$

$$P(G_x; X) = (X^6 - 4X^4 + 3X^2) - h(X^5 - 4X^3 + 3X) - k^2(2X^4 - 6X^2 + 4)$$

Incorporation of these latter quanties into eq. [3] leads to

$$P(G_{xx}; X) = [(X^6 - 2X^4 + X^2) - h(X^5 - 2X^3 + X) - k^2(2X^4 - 2X^2)] - h[(X^5 - 2X^3 + X) - h(X^4 - 2X^2 + 1) - k^2(2X^3 - 2X)] - k^2[(2X^4 - 2X^2) - h(2X^3 - 2X) - k^2(4X^2 - 4)]$$

For $h = 1$ and $k = 1$, this latter equation becomes

$$P(G_{xx}; X) = X^6 - 2X^5 - 5X^4 + 8X^3 + 7X^2 - 6X - 3$$

having eigenvalues of $\epsilon = \pm\sqrt{3}, \pm 1, 1 - \sqrt{2}$ and $1 + \sqrt{2}\beta$. Although the weighted vertices in this example both had the same values of h and k, this method is still valid for molecular graphs having multiple heteroatoms with different values for h and k. Successive use of eq. [3] per this procedure will yield the characteristic polynomial of molecular graphs having multiple heteroatoms of different kinds.

These results lead us to the conclusion that if embedding of a fragment can be accomplished on a molecular graph such that all the heteroatoms are located at node positions, then the eigenvalues of the fragment will also be eigenvalues of the heteroatom containing molecular graph. Consider anthracene which can be embedded by allyl, benzene, and ethene substructures giving it eigenvalues of $\epsilon = \pm 1, \pm 1, \pm\sqrt{2}$, and $\pm 2\beta$; if a carbon atom is substituted by a heteroatom at position 9, then these eigenvalues remain unchanged while the others change (Fig. 6). If a carbon atom at position 1 in anthracene is substituted by a heteroatom, then the resulting stucture can be embedded only by allyl and ethene substructures where the heteroatom is located at a node position giving eigenvalues of $\epsilon = \pm 1$ and $\pm\sqrt{2}\beta$. If a heteroatom is located at position 2 in the anthracene skeleton, then the resulting structure can only be embedded by ethene where the heteroatom is located at a node position giving $\epsilon = \pm 1\beta$.

From eq. [3] it is apparent that the two kinds of roots exist for vertex-edge weighted graphs. The roots of the first kind are those that remain unchanged regardless of the values of h and k, whereas roots of the second kind depend on the values of h and k. The greatest common divisor of polynomials $P(G_x - \nu_x; X)$ and $P(G; X)$ is a polynomial, $R_f(X)$, composed of all the roots of the first kind. This latter polynomial is the last nonzero

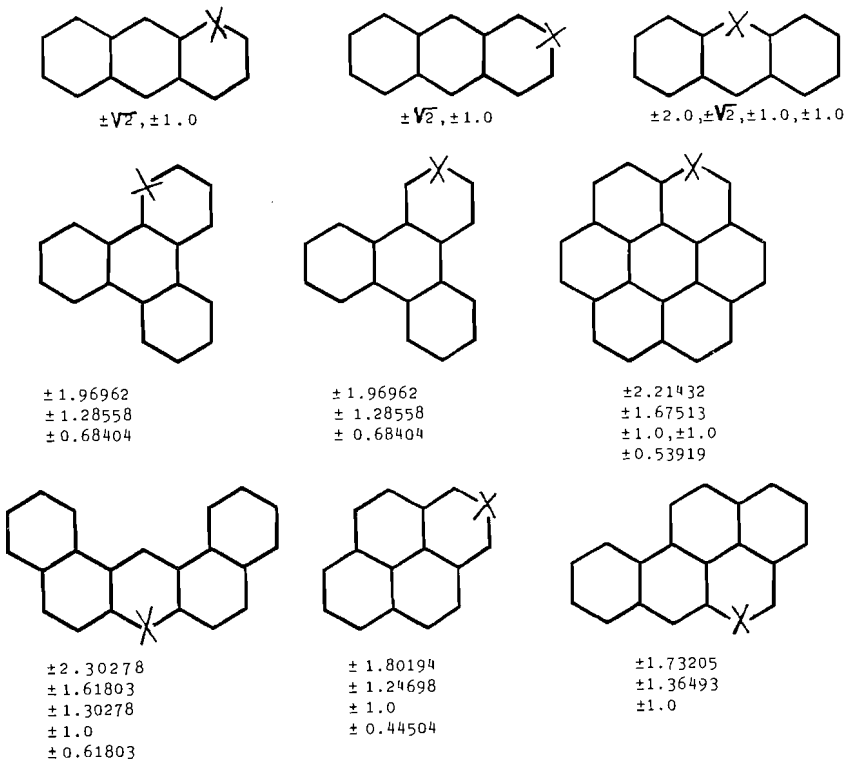

FIG. 6. Eigenvalues for representative heterocyclic molecular graphs.

remainder $R_l(X)$ obtained after l iterations of the Euclidean division algorithm. Figure 6 presents some representative molecular graphs with a single heteroatom along with their roots of the first kind; many of these roots can be obtained via embedding. Coronene has 1,4-diethenylbenzene as a mirror plane fragment and is doubly degenerate in the eigenvalues of this fragment because of its three-fold summetry. Taking the appropriate linear combination of these molecular orbitals one can obtain a node at position 1 in coronene, and thus the vertex–edge weighted graph shown in Fig. 6 will have the eigenvalues of 1,4-diethenylbenzene regardless of the values assigned to the parameters of h and k in eq. [3].

Conclusion

The nearly universal expression for a_6 derives quite naturally from our a_6 (PAH6) expression previously published (1). Since 2-dimensional 3(2)-polyhexagonal structures represent a fundamental type of structure of nature that results in minimization of energy, the ramification of our topological studies of this structural class should find applicability beyond benzenoid hydrocarbons.

Embedding is possible on molecules with a high to low degree of symmetry. Placement of heteroatoms or polyene substituents at node positions of an embedded molecular graph does not alter its associated eigenvalues. Use of the equations presented in this paper allows one to determine the characteristic polynomial of many small molecules without having to solve a secular determinant.

The study of molecular topology in-itself and by-itself is a worthwhile endeavor. In this study we have found that the ultimate graphical invariants of q, N_c, r, $e(i,j)$, and d_i can be interrelated to transmit information regarding other properties such as a_4 and a_6. Embedding is shown to be invariant with the node positions possessing special properties. Determination of select eigenvalues by embedding is applicable to both Hückel and extended Hückel molecular orbital models. Symmetrical polyene molecules having a mirror plane bisecting only vertices can be embedded by the mirror fragment where the vertices on the mirror plane become nodes. Less symmetrical alternant polyene molecules can frequently be embedded by smaller fragments. Embedding combined with equations for a_4 and a_6 provides a powerful method for computing the characteristic polynomial of many small polyene molecules. These calculations are easily performed by a novice without a computer.

Acknowledgement

The author wishes to thank Professor Ivan Gutman for bringing to his attention ref. 12 which deals with the relationship of $P(G_x; X) = P(G; X) - hP(G_x - \nu_x; X)$ that is a less comprehensive form of eq. [3].

The direct electrochemical synthesis of some transition metal carboxylates

N. KUMAR, DENNIS G. TUCK, AND KATHERINE D. WATSON
Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received July 14, 1986

N. KUMAR, DENNIS G. TUCK, and KATHERINE D. WATSON. Can. J. Chem. **65**, 740 (1987).

The transition metal carboxylates $M(O_2CR)_n$ (M = Cr, R = C_2H_5, C_6H_5, n = 3; M = Mn, Fe, Ni, R = CH_3, C_2H_5, C_6H_5, n-C_7H_{15}, n = 2, not all combinations) have been prepared by oxidising suitable metal anodes electrochemically in solutions of RCOOH in acetonitrile. With Co and Cu, a wide range of carboxylic acids (R = C_2H_5, c-C_3H_5, c-C_5H_9, C_6H_5, n-C_4H_9, n-C_7H_{15}, 2-ethylhexanoic, oleic, linoleic) has been used successfully to give $M(O_2CR)_2$. The advantages of the method are discussed. The preparation of $Cu(O_2CR)_2$ involves the prior formation of CuO_2CR at the anode, followed by oxidation by the solvent.

N. KUMAR, DENNIS G. TUCK et KATHERINE D. WATSON. Can. J. Chem. **65**, 740 (1987).

On a préparé les carboxylates des métaux de transition $M(O_2CR)_n$ (M = Cr, R = C_2H_5, C_6H_5, n = 3; M = Mn, Fe, Ni, R = CH_3, C_2H_5, C_6H_5, n-C_7H_{15}, n = 2; toutefois, toutes les combinaisons n'ont pas été préparées) en oxydant électrochimiquement des anodes métalliques appropriées dans des solutions de RCOOH dans l'acétonitrile. Avec le Co et le Cu, on a utilisé avec succès un grand nombre d'acides carboxyliques (R = C_2H_5, c-C_3H_5, c-C_5H_9, C_6H_5, n-C_4H_9, n-C_7H_{15}, éthyl-2 hexanoïque, oléique et linoléique) pour préparer des dérivés $M(O_2CR)_2$. On discute des avantages de la méthode. La préparation des composés $Cu(O_2CR)_2$ implique la formation préalable de CuO_2CR à l'anode qui est suivie d'une oxydation par le solvant.

[Traduit par la revue]

Introduction

Previous papers from this laboratory have described the synthesis of metallic derivatives of weak acids by the oxidation of a sacrificial anode in a non-aqueous solution of the acid. Typical examples include neutral and anionic derivatives of alkyl and aryl thiolates (1–3), thiocyanates (4), phenylacetylene (5), and β-diketonates (6, 7). An obvious extension of these studies to include derivatives of carboxylic acids has now been carried out, and we show below that a variety of transition metal salts are easily prepared from the parent element. We have also used two metals, cobalt and copper, in studies of the synthesis of salts of acids with both cyclic and long chain groups. As emphasized below, the electrochemical method offers distinct advantages in the latter systems in particular, since conventional methods do not easily yield clean products.

Experimental

General

Acetone was dried by refluxing over anhydrous magnesium sulphate, and was stored over this reagent. Acetonitrile was refluxed over calcium hydride and stored over molecular sieves. Carboxylic acids were used as supplied (Aldrich). All metals were used as foils, usually 0.1–1.0 mm thick.

Products were characterised by metal analysis (atomic absorption spectrophotometry), by infrared spectroscopy, and in some cases by molecular weight, determined by mass spectrometry using a Varian MAT CH-5DF instrument operating in the field desorption mode. Elemental analysis (C, H) on selected compounds was by Guelph Chemical Co. Ltd.

Electrochemical

The electrochemical preparation followed essentially the same procedure in each case, with the metal forming the anode of a simple cell

$$Pt_{(-)}/CH_3CN + RCOOH/M_{(+)}$$

Acetone replaced acetonitrile in a number of cases. The solution composition and electrochemical conditions are shown in Table 1.

Product isolation

(*i*) Propionates. The propionates of all the metals used were soluble in the electrolyte solution, and the mixture was therefore filtered at the end of the experiment to remove the metallic particles which occasionally broke away from the anode, and the solvent removed at 60°C *in vacuo*. This procedure yielded solids which were collected, washed with diethyl ether, and dried at 110°C. These products, as others produced in this work, were characterised by metal analysis, and by infrared spectroscopy which confirmed the presence of the RCOO ligand. Results are given in Table 2.

In the case of cobalt and chromium propionates, removal of solvent precipitated an oil which was collected and triturated with acetone to give solid $Co(O_2CEt)_2 \cdot H_2O$ (**1**) and $Cr(O_2CEt)_3 \cdot 2H_2O$ (**2**), respectively (*Anal.* calcd. for **1**: Co 26.4, C 32.3, H 5.4; found: Co 25.6, C 32.5, H 5.3. *Anal.* calcd. for **2**: Cr 16.9, C 34.3, H 6.2; found: Cr 17.2, C 35.2, H 6.6). The cobalt compound lost H_2O on heating (80°C, 15 h, 15 mm pressure) to give $Co(O_2CEt)_2$, changing color from red–violet to deep violet in the process. Extended heating of **2** did not remove water, and the solid was therefore dissolved in benzene and reprecipitated by the addition of petroleum ether (35–60°C) to give $Cr(O_2CEt)_3$ as a green solid, which was washed with petroleum ether and dried *in vacuo*.

(*ii*) Benzoates. Chromium(III) and cobalt(II) benzoates precipitated in the cell and were collected, washed, and dried in the manner just described.

(*iii*) Octanoates. All but one of the metal derivatives of $C_8H_{17}COOH$ precipitated during the electrolysis and were subsequently collected, washed with acetonitrile, and dried *in vacuo* for 3–4 h at room temperature. The copper(II) derivative is soluble in the reaction mixture, but was thrown down as a blue solid when the volume of the solution was reduced by 50% *in vacuo*.

(*iv*) Cobalt(II) salts. Most of the cobalt(II) carboxylates precipitated directly during the electrochemical oxidation in either acetone or acetonitrile media (see Table 1*b*). The exceptions were the *o*-toluate, where the addition of acetonitrile was needed to precipitate the salt, and 2-ethylhexanoate, for which the addition of diethyl ether, or removal of solvent *in vacuo*, lead to the formation of solid. The cobalt compounds are all pink–red, free-flowing powders, and are generally air-stable, although the benzoate and 2-ethylhexanoate compounds are slightly hygroscopic.

(*v*) Copper(II) salts. The electrochemical oxidation of copper was carried out in acetone solutions of carboxylic acids (see Table 1*c*) producing in each case a blue solution. The solution was removed from the cell, and solvent partially evaporated *in vacuo*; with cyclopropanoic or oleic acids the blue copper(II) salt precipitated at this stage. For the remainder, evaporation was taken to dryness, and the copper salt dissolved in diethyl ether, leaving behind Et_4NClO_4. The ether extract was itself taken to dryness, and the salt recrystallised from solvents

such as ethanol (R = C_6H_5), diethyl ether + acetone (2-ethylhexanoic, linoleic), diethyl ether + petroleum ether (c-C_5H_9), or diethyl ether + CH_3CN + petroleum ether (n-C_4H_9). The products were all air-stable, light blue powders. The results of studies of the mechanism of the formation of copper(II) salts are discussed below.

The electrochemical synthesis of copper(II) carboxylates can also be carried out in acetonitrile, but the significant deposition of copper metal on the cathode is a major problem.

Hydrogen formation

The production of H_2 (g) at the cathode was monitored directly by mounting a gas burette, total volume 10 mm, directly above the platinum cathode, which in these experiments was fused through the bottom of the cell. Visual observation confirmed that all the gas formed at the cathode was collected by virtue of the widened mouth of the burette. The results of these measurements are discussed below.

Results and discussion

General

The preparative studies show that the technique of direct electrochemical oxidation is a convenient and simple route to a variety of transition metal carboxylates. The results include the salts of both short- and long-chain carboxylic acids and of benzoic acid for the range chromium–copper, and an extended series of acids for cobalt and copper, including the C_{17}-chain oleic and linoleic acid. In view of the range of compounds prepared under a wide variety of conditions, it seems reasonable to suggest that the method is a general one for the synthesis of metal carboxylates.

The methods generally recommended for preparing metal carboxylates of (say) copper are based on dissolving the metal hydroxide or carbonate in an aqueous solution of the appropriate carboxylic acid. Crystallisation may yield either anhydrous or hydrated materials (8). For the higher molecular weight acids, which are relatively insoluble in water, mixing alcoholic solutions of the acetate and RCOOH leads to precipitation of $Cu(O_2CR)_2$. For the high molecular weight metal carboxylates which find use as driers in the paint industry, or as co-catalysts in polymerisation, reactions involving aqueous solutions of $Na^+ \cdot RCOO^-$ and a soluble metal mineral salt give a better commercial product that is obtained by fusing a metal salt with the parent carboxylic acid (9). The present method appears to offer substantial advantages, both in simplicity of experiment and in purity of product, over the techniques otherwise available, and we have shown that the electrochemical method is readily adapted to continuous production if so desired.

Electrochemical efficiency

Following our standard procedure, we have measured the electrochemical efficiency, defined as the number of moles of metal dissolved per Faraday of electricity, using cells with a constant current of 20 mA and weighed anodes. For reactions leading to the M^{II} derivatives of Mn, Fe, and Ni, $E_F = 0.51 \pm 0.03$ mol F^{-1} (10 systems), and for the ten Co^{II} compounds listed in Table 1*b*, $E_F = 0.49 \pm 0.01$ mol F^{-1}. The results for copper compounds are discussed below.

The evolution of H_2(g) was measured for a series of solvents, taking the Co/*o*-toluic acid system as a standard, and using $E_F = 0.5$ mol F^{-1} for anionic dissolution as an internal measure of total charge. With both *N*,*N*-dimethylformamide and acetone, the production of H_2, corrected for temperature, atmospheric pressure, and solvent vapor pressure, gave $E_F(H_2) = 0.5$ mol F^{-1} as expected. With acetonitrile, the initial (theoretical) value dropped with time of electrolysis, suggesting some reduction of CH_3CN (cf. ref. 10 for the aqueous phase reduction of CH_3CN). Gas production was much below theoretical with *N*-methyl pyrrolidinone, and was close to zero with nitromethane and propylene carbonate, all of which are readily reduced electrochemically.

The combination of these E_F determinations confirms the mechanism proposed for other weak acid systems in non-reducible solvents, namely

[1] cathode: $n\text{RCOOH} + ne \rightarrow \frac{n}{2}\text{H}_2(\text{g}) + n\text{RCOO}^-$

[2] anode: $n\text{RCOO}^- + \text{M} \rightarrow \text{M}(\text{O}_2\text{CR})_n + ne$

One preparative advantage which follows from these results is that a precise relationship exists between total current and quantity of product.

Copper carboxylates

The behaviour of Cu/RCOOH systems has been investigated in some detail because of two significant differences from those discussed so far. The most obvious factor is that although the final products were always $Cu(O_2CR)_2$, E_F was not 0.5 mol F^{-1}; in acetonitrile, $E_F = 1.02 \pm 0.02$ for eight different acids, while for the same acids in acetone the average value was 0.85 ± 0.08 F^{-1}, within a range of 0.72 (R = n-C_4H_9) and 0.93 (2-ethylhexanoic). In addition, we observed that the reaction developed a blue color as soon as current began to flow, that copper deposited as the cathode after about 15 min, and that small

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

quantities of a yellow solid precipitated on the anode and subsequently fell to the bottom of the cell. The only systems for which a copper(I) product was isolated were with *c*-C_3H_5COOH and *c*-C_5H_9COOH in acetone, where small quantities of white solid (approximately 40 mg) were recovered.

In the case of *o*-toluic acid in acetone, we showed that the yellow substance is Cu_2O (calcd.: Cu 88.8, found: 79.0) mixed with RCOOH (infrared spectroscopy). Bubbling oxygen gas through the solution inhibited the formation of this yellow substance, while the addition of 1 mL of water increased both the rate of formation and the quantity produced. These observations are consistent with the properties of Cu_2O, which is known to be formed by the hydrolysis of copper(I) carboxylates and is readily oxidised to copper(II) by oxygen. The presence of traces of H_2O in the acetone, which is notoriously difficult to dry completely, may be responsible for the formation of Cu_2O in the present experiments. When appropriate allowance is made for the production of Cu_2O, the electrochemical efficiency for the dissolution of copper is close to 1.0 mol F^{-1}.

It is clear that in both acetone and acetonitrile, the sequence of electrode reactions is

[3] cathode: $RCOOH + e \rightarrow RCOO^- + (1/2)H_2(g)$

[4] anode: $RCOO^- + Cu \rightarrow Cu(OOCR) + e$

but that eq. [4] must be followed by an electroless process to produce $Cu(O_2CR)_2$. Since hydrogen formation was not observed in the bulk solution phase, the process

[5] $Cu(O_2CR) + RCOOH \rightarrow Cu(O_2CR)_2 + (1/2)H_2$

or the equivalent sequence beginning with disproportionation

[6] $2\,Cu(O_2CR) \rightarrow Cu(O_2CR)_2 + Cu$

[7] $Cu + RCOOH \rightarrow Cu(O_2CR) + (1/2)H_2$

can be ruled out. We suggest that in acetone solution, the oxidation of CuO_2CR to $Cu(O_2CR)_2$ involves reaction of the former with solvent. This conclusion is based on the results of an extended (7 h) electrolysis of copper in an acetone solution of octanoic acid. The solvent phase was stripped from the final solution in a rotary evaporator, and acetone then removed by distillation to give about 0.5 mL of a pale yellow liquid. Gas–liquid chromatography (10% Carbowax) established the presence of acetone, *i*-propanol, and two minor components, one of which could not be clearly separated from acetone, and the other of which had $m/e = 204$ as the main peak in an EI mass spectrum, and is probably a derivative of octanoic acid and solvent. The presence of *i*-propanol implies that the oxidation of CuO_2CR involves the sequence

[8] $CuO_2CR + RCOOH + Me_2CO \rightarrow Cu(O_2CR)_2 + Me_2COH$

[9] $Me_2COH \xrightarrow{H} Me_2C(H)OH$

We have not attempted to establish the source of the hydrogen atom in eq. [9]. Pinacol, diacetone alcohol, and mesityl oxide were not detected in the glc spectrum. The overall reaction is apparently similar to the Meerwein–Pondorf–Verley reduction. A similar sequence can be written for the oxidation of CuO_2CR in acetonitrile via $CH_3C{=}NH$, but since the main thrust of the present work was the electrochemical synthesis of metal carboxylates, these mechanistic problems have not been investigated in any detail.

Mechanism of electroreduction of 9-anthraldehyde

ANDRZEJ LASIA AND ABDELHAQ RAMI

Department of Chemistry, University of Sherbrooke, Sherbrooke, Que., Canada J1K 2R1

Received July 15, 1986

ANDRZEJ LASIA and ABDELHAQ RAMI. 1987. Can. J. Chem. **65**, 744 (1987).

The electroreduction of 9-anthraldehyde (ANCHO) and 10-methyl-9-anthraldehyde (MeANCHO) has been studied in aprotic solvents. The anion free radicals of both compounds undergo subsequent dimerization reaction with $ANCHO^{\cdot}$ being more reactive than $MeANCHO^{\cdot}$. The rate constant of the dimerization reaction depends on the solvent and for $ANCHO^{\cdot}$ in HMPA is equal to $2 \times 10^4 M^{-1} s^{-1}$. Using spectroscopic measurements it has been shown that the dimerization takes place at position 10.

ANDRZEJ LASIA et ABDELHAQ RAMI. 1987. Can. J. Chem. **65**, 744 (1987).

L'électroréduction du 9-anthraldéhyde (ANCHO) et du 10-méthyl-9-anthraldéhyde (MeANCHO) a été étudiée dans les solvants aprotiques. Les anions radicaux de ces composés se dimérisent et $ANCHO^{\cdot}$ est beaucoup plus réactif que $MeANCHO^{\cdot}$. La constante de vitesse de dimérisation dépend du solvant et pour $ANCHO^{\cdot}$ dans le HMPA cette constante égale $2 \times 10^4 M^{-1} s^{-1}$. La structure de dimère a été étudiée par la spectroscopie rmn et on a trouvé que la dimérisation a lieu à la position 10.

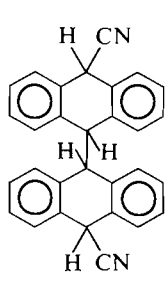
Introduction

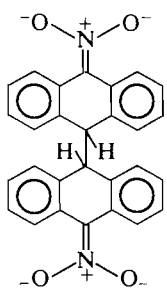
The electroreduction of aromatic aldehydes has been studied extensively (1, 2). In protic solvents they are reduced in two one-electron or one two-electron processes. In aprotic solvents aromatic aldehydes form two one-electron polarographic waves (1, 3). The most detailed studies have been carried out for benzaldehyde (4–8) and it was found that the product of the one-electron reduction of aldehydes is a radical ion which is not stable and undergoes subsequent dimerization (9–12). The reactivity of the ion radicals in aprotic solvents is influenced by the ion-pair formation with the supporting electrolyte cations and the rate of the dimerization reaction increases with the decrease in the radius of the cation (9). The reactivity of the radical anions of the aromatic aldehydes depends strongly on the structure of the aldehydes and increases in the order: 1-naphthaldehyde ≤ 2-naphthaldehyde ≤ 3-benzaldehyde ≤ 9-anthraldehyde (9).

The structure of the dimer was studied in detail in the case of benzaldehyde which, upon one-electron reduction, forms hydrobenzoin (4, 5). The structure of a dimer formed by 9-anthraldehyde (ANCHO) has not been studied chemically but it has been suggested (without proof) that it does not form a glycol but instead forms a dimer by coupling in position 10 (10, 11). The mechanism of the electroreduction of similar compounds: 9-cyano and 9-nitroanthracene has also been studied (10–16). In the case of 9-cyanoanthracene it was found that the dimerization process is reversible and two mechanisms have been proposed: formation of a non-bonded dimer followed by a C—C bond formation (14) and a reversible formation of the C—C dimer (16).

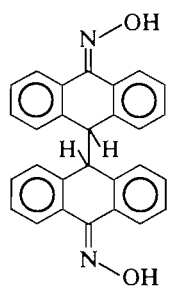
The structure of the dimers has been studied by chemical and spectroscopic techniques. It was established that 9-cyanoanthracene forms dimer **I** (16) and that 9-nitroanthracene forms initially compound **II** which, upon reaction with methyl iodide, forms bianthronyldioxime **III** (11) (isolated product). We have undertaken studies of the electrodimerization of 9-anthraldehyde (ANCHO) and 10-methyl-9-anthraldehyde (MeANCHO) in order to explain the mechanism of the reaction and a structure of the dimer.



I



II



III

Experimental

Chemicals

9-anthraldehyde (Aldrich) was purified by column chromatography using silica gel (60–200 mesh, J. T. Barker) and an eluting mixture of 1:1 hexane–dichloromethane. The purity of the product was verified using thin layer chromatography. 10-Methyl-9-anthraldehyde (Aldrich) was used as received.

Dimethylsulfoxide (DMSO) (Anachema) and dimethylfornamide (DMF) (Fisher) were dried by calcium hydride, stored over activated molecular sieves type 4A (Fisher), and distilled at reduced pressure under nitrogen. Hexamethylphosphoramide (HMPA) (Aldrich) was dried over molecular sieves 4A and distilled under reduced pressure before use. DMSO-d_6 (99.9% MSD isotopes) was dried using molecular sieves.

Tetraethylammonium perchlorate (TEAP) was prepared from tetraethylammonium bromide and perchloric acid, recrystallized three times from water, and then dried *in vacuo* over P_2O_5 at 60°C.

Lithium perchlorate (BDH) was dried *in vacuo* over P_2O_5 at 140°C.

All products were stored in a controlled atmosphere chamber (Vacuum Atmospheres) before use.

Apparatus

The apparatus for electrochemical measurement consisted of a PAR Model 173 potentiostat, PAR Model 175 wave form generator, and IBM PC microcomputer equipped with a data translation DT 2801-A interface. Positive feedback compensation was used with the fast scan rate.

The working electrode was a dropping mercury electrode with a drop time 1–5 s in dc polarography and 20 s for fast cyclic voltammetric measurements. In slow voltammetric measurements the working electrode was a mercury drop attached to a platinum disk (9). The reference electrode was a silver wire in 0.05 *M* $AgNO_3$ + 0.05 *M* TEAP in a given solvent but in the fast voltammetric experiments a tungsten wire was used as a pseudoreference electrode (9). Electrochemical measurements were carried out in a dry box (Vacuum Atmospheres). Marcoelectrolyses were performed in the H-type cell (volume ~ 70 mL) and electrolyses in deutered DMSO in a smaller cell (volume ~ 4 mL) on a mercury pool electrode. The concentration of the depolariser used for the electrolyses in DMSO-d_6 was ~ 4 mg/mL.

Infrared spectra were recorded using a Perkin-Elmer 621 instrument and nmr spectra were obtained using Brucker WM 250 MHz instrument.

Results and discussion

ANCHO in non-aqueous solvents forms two one-electron

polarographic waves. In DMF the half-wave potentials obtained in the presence of 0.1 *M* TEAP are −1.646 and −2.229 V vs. Ag/Ag^+ reference electrode and in DMSO −1.433 and −1.974 V, respectively. The logarithmic analysis of the first polarographic wave in DMF gives a slope of 49 mv. However, the analysis according to an equation describing a reversible process with the fast subsequent irreversible dimerization (19)

$$E = E^\circ_{\frac{1}{2}} + \frac{RT}{3nF}\ln\frac{\pi k_d C^*_{Ox} t}{7} + \frac{RT}{nF}\ln\frac{2^{\frac{1}{3}}(i_l - i)}{i^{\frac{2}{3}} i_l^{\frac{1}{3}}}$$

gives a slope of 59 mV, which is in agreement with the theoretical value expected for that mechanism. The half-wave potential of MeANCHO is more negative (−1.522 V in DMSO) which reflects an inductive effect of the methyl group at position 10.

Radical anions of ANCHO are not stable in solution. In DMF values of k_d of $10^5 M^{-1}$ s^{-1} (0.1 *M* TEAP) (9) and $3.1 \times 10^5 M^{-1}$ s^{-1} (0.1 *M* Bu_4NBF_4) (11) are reported in the literature. We have found no anodic peak in cyclic voltammetry at slow sweep rates which means that the dimerization reaction is not reversible, contrary to 9-cyanoanthracene (14, 16). However, voltammetric measurements of MeANCHO show that at sweep rates of 0.02–0.1 V s^{-1} the anodic peak is well formed and the radical anion is stable. The methyl substituent in position 10 makes the dimerization process less favored.

If the supporting electrolyte is changed from 0.1 *M* TEAP to 0.1 *M* $LiClO_4$ a shift of ~16 mV towards a positive direction is observed for the half-wave potential of the first wave which may be explained by ion-pair formation and a consequent increase in rate of the dimerization process.

The cyclic voltammetric measurements performed in HMPA in the presence of 0.1 *M* $LiClO_4$ indicate that the dimerization reaction is slower than in DMF or DMSO. Using sweep rates between 10 and 20 *V* s^{-1} the kinetics of dimerization was determined by measuring the ratio of the absolute values of the anodic $(i_{ap})_o$ to cathodic i_{cp} peak currents according to data presented in ref. 17. The second order rate constant obtained equals to $2 \times 10^4 M^{-1} s^{-1}$ in 2×10^{-3} *M* ANCHO solution. The decrease in rate of dimerization in HMPA may be explained by the stronger solvating power of that solvent towards cations (donor number of HMPA: 38.8, DMF: 26.6) (18). In HMPA cations are very well solvated and the probability of the formation of the contact ion pairs is negligible which means that the measured rate constant is that of dimerization of the free anion radicals.

We have also carried out macroelectrolyses in order to study the structure of the dimer. Figure 1 shows polarograms of ANCHO in 0.1 *M* TEAP in DMF before (*A*), during (*B*), and after electroreduction (*C*) at the potentials of the plateau of the first polarographic wave. During electrolysis the wave height of the first and the second polarographic wave decreases while the anodic wave at −1.21 V is formed. At the beginning of the anodic wave a large maximum is formed. The addition of a proton donor (acetic acid) to the dimer after electrolysis causes shift of the anodic wave to more positive potentials (of ~0.49 V), making the electrooxidation process more difficult and causing the maximum to disappear. During electrolysis one electron per molecule is consumed. Electrochemical oxidation of the dimer at potentials at the plateau of the anodic wave gives the initial product ANCHO. The electroreduction of MeANCHO proceeds in a similar way, that is, dimer is also formed but the kinetics of the dimerization is much slower than ANCHO (it can be observed only during macroelectrolysis, not during cyclic voltammetric experiments).

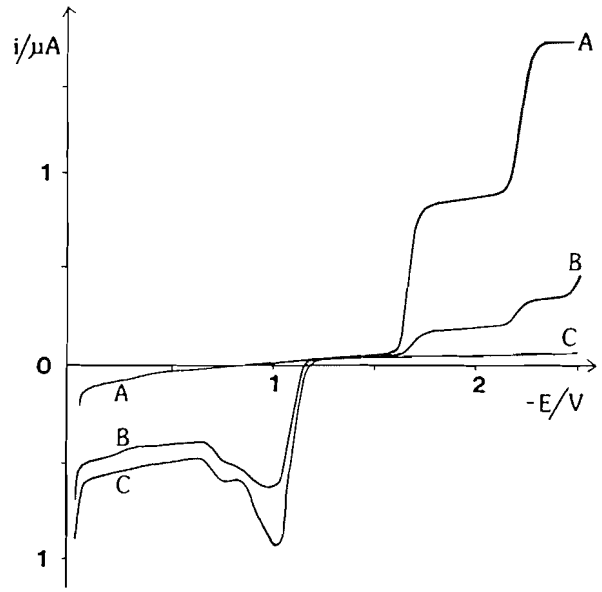


FIG. 1. Direct current polarograms of $6 \times 10^{-4} M$ ANCHO in 0.1 *M* TEAP in DMF; *A*, before, *B*, during, and *C* after electrolysis at −1.8 V.

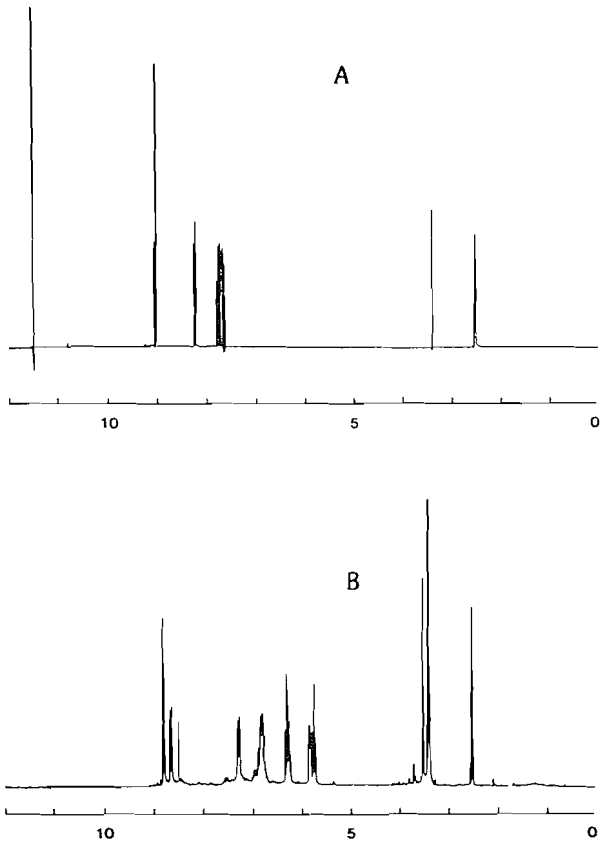

FIG. 2. ^1H nmr spectra of ANCHO (*A*) and dimer (*B*) in DMSO-d_6. Peaks at 2.5 ppm and 3.4 ppm are caused by DMSO and HDO, respectively.

We have tried to isolate the dimer of ANCHO but it was immediately oxidized by the air. Because of that we have used spectroscopic techniques to determine the structure of the dimer formed in solution. Infrared measurements show that during electrolysis in DMSO, the C—O band of ANCHO at 1645 cm^{-1} disappears which means that the carboxyl group is reduced.

Nuclear magnetic resonance measurements after electrore-

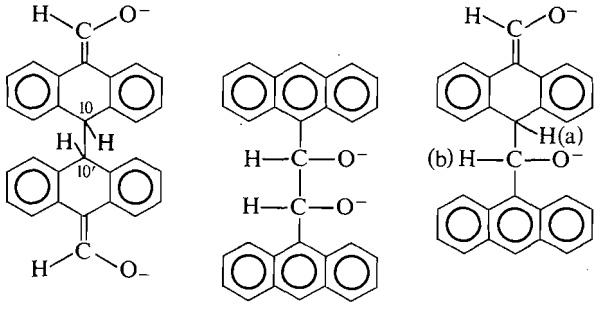
duction in DMSO-d_6 in the presence of $LiClO_4$ (to avoid interferences of protons of tetraalkylammonium salts) were performed (see Figs. 2 and 3). ^1H nmr of ANCHO shows the carbonyl proton at 11.47 ppm and aromatic signals between 7.6 and 9 ppm. ^{13}C nmr shows the carbonyl group at 193.8 ppm with the aromatic protons between 123.3 and 143.9 ppm. The nmr spectrum of the product of electrolysis is more complex. The ^1H spectrum shows that the signal of the carbonyl proton disappears. There are seven groups of protons with ratio 1:2:2:2:1:1:1 at 3.49 ppm (d), 5.70–5.83 ppm (m), 6.21–6.33 ppm (m), 6.74–6.86 ppm (m), 7.24–7.28 ppm (m), 8.61–8.65 ppm (d), and 8.76–8.79 (d). The ^{13}C *J*-modulated spectrum of the dimer shows C–H carbons with negative phase at 51.70–51.52 ppm (d), 118.03–118.97 ppm (m), 123.84 ppm (s), 124.28–124.45 ppm (m), 127.90 ppm (s), 128.57–128.71 ppm (d), and 163.11–163.26 ppm (d). The quaternary carbons appear between 102.4–140.7 ppm with positive phase. The ^1H–^{13}C correlation spectrum shows that the carbon ^{13}C 51.6 ppm is linked with ^1H 3.49 ppm, ^{13}C 163.2 ppm with ^1H 8.78 ppm, and ^{13}C 128.6 ppm with ^1H 8.63 ppm.

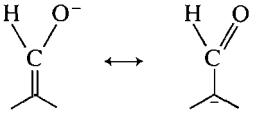
From the point of view of the reactivity of the radical three structures of the dimer are probable:



IV **V** **VI**

In structure **VI** two types of aliphatic protons, (*a*) and (*b*), exist and should give two different signals in the aliphatic region, each having an intensity 1/20 the total intensity of all protons. Since only one aliphatic proton is observed, this structure must be eliminated. For compound **V** one signal of two carbons of the glycol group should be observed in the aliphatic region and all the other carbons of the anthryl groups should be similar to those found in ANCHO. That structure cannot explain the appearance of the carbon signal at 163.2 ppm.

On the other hand, structure **IV** is in agreement with the obtained spectra. The carbons 10 and 10′ having configuration sp^3 appear at 51.6 ppm and the corresponding protons at 3.49 ppm, both in the aliphatic region. The hydrogen and the carbon of the —CHO^- group appear at 8.78 ppm and 163.2 ppm, respectively. The shift of the carbon signal to lower fields (higher ppm values) may be connected with the negative charge on oxygen atom and the possibility of existence of the mesomeric structures:



The anions are probably stabilized by the ion-pair formation with lithium cations. All other C—H carbons of anthryl groups appear between 118.0–128.7 ppm and are shifted to higher field as compared with ANCHO. It should be noted in passing that the ^1H resonance at 3.49 ppm is a doublet with a very small splitting which might suggest that the product is a 1:1 mixture of isomers.

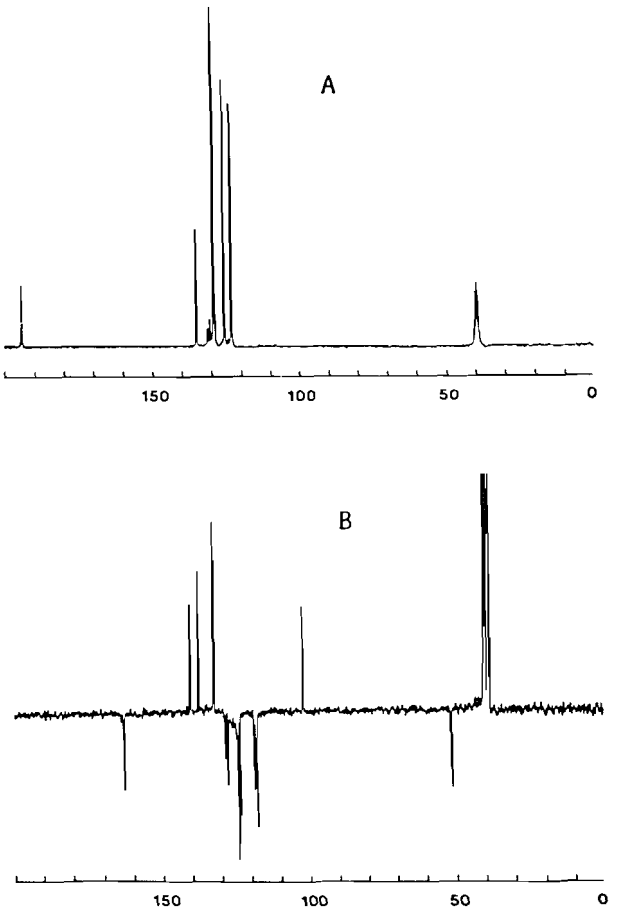


FIG. 3. ^{13}C nmr spectra of ANCHO (*A*) and dimer (*B*) in DMSO-d_6. *J*-modulated spectrum *B* shows C—H carbons with negative and quaternary carbons with positive phase. Peaks at 38.5–40.5 ppm are caused by DMSO.

We have also carried out semiempirical quantum-chemical calculations of the anion radical of ANCHO using an open shell restricted Longuet–Higgins–Pople method in π-approximation (PPP-like method) (20). We have found that the highest spin density in the radical is on carbon 10, $\rho_{10} = 0.2257$ and the spin density on the carbonyl carbon atom is 0.0863. This observation is in agreement with our supposition that the dimerization reaction takes place at position 10. Our previous calculations using simple HMO technique (9) gave $\rho_{10} = 0.3833$ which seems to be too high.

The study of MeANCHO shows that the initially formed dimer is not stable and undergoes subsequent reactions, probably polymerization.

Conclusions

The study of the electroreduction of 9-anthraldehyde shows that the radical ion formed undergoes subsequent dimerization reaction. Dimer is stable in the absence of oxygen but may be electrochemically oxidized to ANCHO. The kinetics of the dimerization reaction depend on the solvent and in HMPA in the presence of 0.1 *M* $LiClO_4$ the second order rate constant is $2 \times 10^4 M^{-1}\ s^{-1}$.

From spectroscopic studies, the dimer has been shown to be that of structure **IV** (and does not form glycols). The proposed structure is supported by the quantum-chemical calculations

which show the highest spin density in the radical at position 10. It is also in agreement with the structure found for the dimers of 9-cyano and 9-nitroanthracenes but is different from the structure of the dimers of benzaldehyde. Also the comparison of the reactivity of the radical of ANCHO and its 10-Me derivative shows that, the MeANCHO radical anion is much more stable in solution, the methyl substituent at position 10 sterically hindering dimerization.

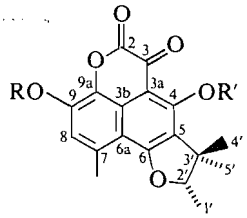
Scleroderolide, a yellow pigment produced by the Scleroderris canker fungus *Gremmeniella abietina* (Lagerb.) Morelet, is shown to possess structure **1**. The structure was determined by an X-ray crystallographic study of the racemic monoacetate **1***a*. The crystal of **1***a* belongs to the triclinic system space group, $P\bar{1}$, the *R*-factor converged to 0.047 for the 1957 observed reflections. Scleroderolide occurs mainly as the levorotatory enantiomer (*S* configuration at C-2′) although on one occasion it was obtained in partially racemic form. The absolute stereochemistry of the levorotatory form was determined by transformation of (−)-sclerodione (**5**) of known absolute configuration into (−)-scleroderolide. The absolute configuration of (−)-sclerodione was established by correlation with (−)-sclerodin (**3**). The diacetyl derivative of scleroderolide (**1***b*) shows interesting temperature dependent nuclear magnetic resonance spectral properties due to restricted rotation of the C-4 O-acetyl group. Oxidation of the red pigment sclerodione (**5**) with *m*-chloroperbenzoic acid provides both sclerodin (**3**) and scleroderolide (**1**). Scleroderolide (**1**) is the first natural product to be reported that contains a phenylglyoxylate lactone functionality.

WILLIAM A. AYER, YUMIKO HOYANO, M. SOLEDADE PEDRAS, JON CLARDY et EDWARD ARNOLD. Can. J. Chem. **65**, 748 (1987).

On démontre que le sclérodérolide, un pigment jaune qui est produit par le champignon nécrosant Scleroderris *Gremmeniella abietina* (Lagerb.) Morelet, possède la structure **1**. On a déterminé la structure grâce à une étude cristallographique à l'aide de rayons-X effectuée sur le monoacétate **1***a*, à l'état racémique. Le cristal de **1***a* appartient au groupe d'espace triclinique $P\bar{1}$ et le facteur *R* converge vers une valeur de 0,047 pour les 1957 réflexions observées. On retrouve le sclérodérolide principalement sous la forme de l'énantiomère lévogyre (configuration *S* au niveau du C-2′) même si, à une occasion, on l'a obtenu sous une forme partiellement racémique. On a déterminé la stéréochimie absolue de la forme lévogyre en se basant sur une transformation de la (−)-sclérodione (**5**) de configuration absolue connue en (−)-sclérodérolide. On a établi la configuration absolue de la (−)-sclérodione par une corrélation avec la (−)-sclérodine (**3**). Les propriétés spectrales rmn du dérivé diacétylé (**1***b*) du sclérodérolide varient d'une façon intéressante avec la température à cause d'une rotation empêchée du groupement O-acétyle attaché en position C-4. L'oxydation du pigment rouge sclérodione (**5**) par l'acide *m*-chloroperbenzoïque conduit à la sclérodine (**3**) ainsi qu'au sclérodérolide (**1**). Le sclérodérolide (**1**) est le premier produit naturel pour lequel on rapporte la présence d'une fonctionnalité phénylglyoxylate lactone.

[Traduit par la revue]

In Part 1 of this series (1) we have reported on the isolation of several colored metabolites produced by the Scleroderris canker causing fungus *Gremmeniella abietina*. In addition to the compounds already reported, one strain of *G. abietina* (C699) produces a bright yellow metabolite that possesses the biogenetically novel internal phenylglyoxylate lactone structure, **1**.



1 R = R′ = H
1*a* R = Ac R′ = H
1*b* R = R′ = Ac

In this article we describe the isolation, structure determination, and some of the chemical properties of this unusual compound.

Gremmeniella abietina (strain C-699) was grown in still culture, at 16–17°C on a medium of 10% V-8 juice containing 1% added glucose (2). Chromatographic separation of the crude mycelium extract gave Scleroderris blue (**2**), sclerodin (**3**), *ent*-atrovenetinone (**4**), sclerodione (**5**), and the yellow metabolite (**1**), for which we propose the name scleroderolide.

Scleroderolide (mp 239–240°C) is isomeric with sclerodin (**3**, $C_{18}H_{16}O_6$) and initially we suspected it to be the isomeric ether **6**. The ^{1}H nmr spectrum of scleroderolide is similar to that of **3** except for the OH hydrogens (δ 6.65 and 13.73 vs. δ 11.43 and 11.64). Scleroderolide readily forms a monoacetate on treatment with acetic anhydride – pyridine, whereas **3** forms the

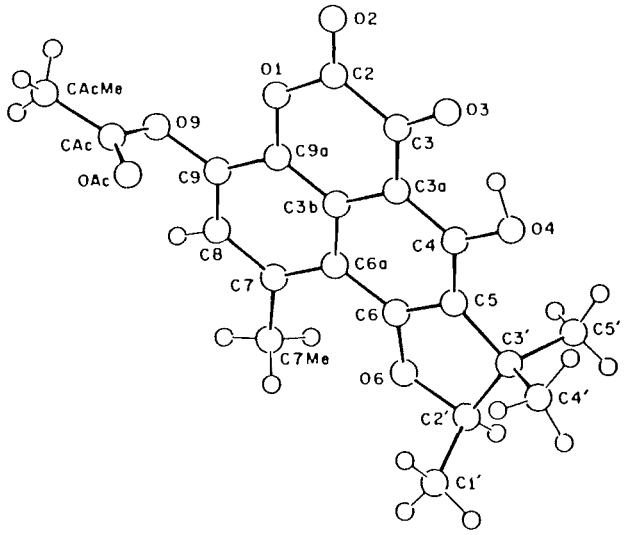

FIG. 1. A perspective drawing of the structure of scleroderolide monoacetate.

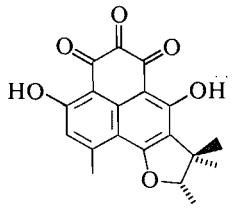
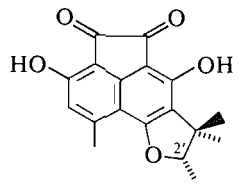
diacetate **3***c* (1). This is consistent with structure **6**, since an OH group at carbon 6 would be expected to be sterically hindered. However, the ^{13}C nmr spectrum of **1** shows carbonyl absorption at δ 170.1 and 155.7, which is not in good agreement with the anhydride structure (δ 165.4 and 164.9 in **3**). Also the ir spectrum shows carbonyl absorption at 1750 cm^{-1} while that of the anhydride **3** appears at 1705 cm^{-1}.

The monoacetate of scleroderolide crystallizes from dichloromethane – petroleum ether in the form of beautiful red-orange crystals, well suited for an X-ray cyrstallographic study. Figure 1 shows a computer generated perspective drawing of the X-ray model of scleroderolide monoacetate, which reveals that it possesses structure **1***a*.

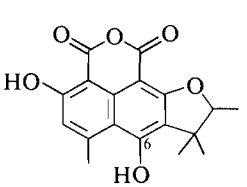
To our surprise, the sample used for X-ray analysis proved to be racemic, though the parent compound (**1**) had an optical rotation of −22.3°. Several hypotheses may be entertained to explain these unusual results: 1, scleroderolide was not optically pure (i.e., both enantiomers are produced by *G. abietina*); 2, scleroderolide was racemized during isolation; 3, scleroderolide was racemized during acetylation. Hypothesis 1 was tested in two ways: using a chiral shift reagent (3, 4); using an optically active acylating agent.



4



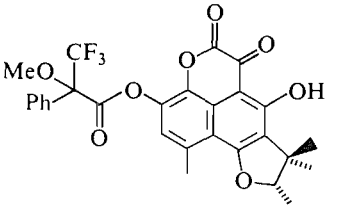
5



6

In the first instance, tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]europium(III) ($Eu(tfc)_3$) was added to scleroderolide in $CDCl_3$ in successively increasing amounts (up to 1 equiv.) and the ^1H nmr spectra were obtained; however, no significant shifts were observed although there was a considerable amount of broadening of the spectral lines. This result is probably due to the lack of effective complexation of the shift reagent with scleroderolide.

We then acylated **1** with the Mosher reagent (−)-α-methoxy-α-trifluoromethyl-α-phenylacetic acid (5); the ^{19}F nmr spectrum of the resulting monoester **7** (no diester was formed) showed a single peak at δ −72.17 (internal standard $CFCl_3$). Although we did not observe two ^{19}F signals (indicating two diastereomeric products), this result may be due to the large distance (approximately 9.9 Å) between the two asymmetric centers in **7**.



7

Sclerodin (**3**) and sclerodione (**5**) were used to test hypothesis 2.[1] Sclerodione was dissolved in chloroform – trifluoroacetic acid (several ratios) at room temperature (up to 15 days) and at 60°C (1 h); the optical rotation ($[\alpha]_D$ −115.3°) of the recovered material was unchanged. In the case of sclerodin (**3**) we used deuterated solvents (C_6D_6–CF_3CO_2D) at 80°C (sealed tube) and monitored the reaction by ^1H nmr spectroscopy. After 24 h the aromatic hydrogen was exchanged for deuterium. Prolonged treatment (7 days) led to no further changes. The optical rotation ($[\alpha]_D$ −72.6°) of the recovered compound was unchanged. Thus racemization is not likely to have occurred during the isolation of these metabolites.

To test hypothesis 3 scleroderolide was isolated from a fresh culture of *G. abietina*. Surprisingly, this sample of scleroderolide (mp 232–233°C) had a much higher optical rotation ($[\alpha]_D$ −116°) than the previous sample. The monoacetate from this new preparation showed the same optical rotation ($[\alpha]_D$ −69°)[2] regardless of its method of formation (acetic anhydride, and either pyridine or 4-*N*,*N*-dimethylaminopyridine or sulfuric acid as catalyst). These results were not due to the selective crystallization of one enantiomer, as demonstrated in the following manner: acylation of the combined mother liquors from recrystallization of scleroderolide (**1**) gave a monoacetate with the same optical rotation as obtained previously. The optical rotation was unchanged after crystallization. These results seem to indicate that *G. abietina* (strain C-699) produces scleroderolide in high optical purity and that scleroderolide is not racemized during acylation.

Scleroderolide is closely related to atrovenetin, a metabolite of *Penicillium atrovenetum* (6) and *P. herquei* (7). The structure of atrovenetin (**8**) was established by X-ray crystallographic analysis (8) and the configuration (*R*) at C-2′ was determined by chemical correlation with (*S*)-ethyl lactate (9). Interestingly, atrovenetin isolated from *P. herquei* has a lower optical rotation ($[\alpha]_D$ +54.6°) than atrovenetin isolated from *P. atrovenetum* ($[\alpha]_D$ +100.6°) (10). Thus in the case of
