induced rats (8) and using up to 25 μg/plate nitrofurazone, the initial precipitate dissolved and a substantial increase in revertants was observed.

Since the azine has two nitrofuryl groups, it could conceivably act as a bifunctional agent and cross-link DNA. This possibility was tested by isolating DNA from *E. coli* B/r and WPS *uvr A* exposed to 1 or 5 μg or azine per mL for 60 min, heating the DNA above its melting point and rapidly cooling the preparation. In a typical experiment, all of the DNA from the azine-treated cells remains denatured while 22% (B/r) and 45% (WP2 *uvr A*) of the DNA of bacteria treated with 1 μg/mL of mitomycin (a known cross-linking agent used as a positive control) renatured. These results show that the azine at concentrations up to 5 μg/mL did not induce detectable stable DNA cross-links in either of these strains.

Discussion

Our results provide dramatic confirmation of the photolability of nitrofuran derivatives and emphasize that experiments using these agents should be conducted in the dark or under yellow light. Interference from *anti/syn* isomerization due to accidental exposure to light can also be minimized by keeping

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

samples dissolved in aqueous solvents, since the thermal conversion of *syn* to *anti* is facilitated. A high column temperature and aqueous acetonitrile as a mobile phase can also be used to avoid the HPLC resolution of the isomer pair, although slightly different extinction coefficients would lead to slight quantitative errors.

The rapid conversion of *anti-* to *syn*-nitrofurazone and the corresponding isomerization of nitrofurantoin and furazolidone have not been reported previously. However, it has been suggested that the *anti/syn* isomerization might account for the lack of fluorescence or phosphorescence when nitrofurans are irradiated with ultraviolet light by providing a nonradiative path for reversion of excited molecules to the ground state (12). The photochemistry of the carbon-nitrogen double bond and the *anti/syn* isomerization of such compounds is, of course, a well known phenomenon (13). The photodecomposition of some nitrofurans in UV light has been investigated previously (14–17), but the only photoproducts reported were the corresponding aldehydes formed by hydrolysis of the azomethine bond. We did not observe any 5-nitro-2-furaldehyde, **4**, in our experiments.

Given the relatively small amount of the azine that is formed and the relatively weak mutagenicity of this compound, it seems unlikely that the reported actions of nitrofurazone can be due to azine generated by photolysis. Some commercial preparations contain appreciable concentrations of azine as a synthetic byproduct and quite lengthy analytical assays have been used in the past (4). The reverse phase hplc method reported here allows a very rapid and precise measurement of azine levels.

At this point we are unable to provide a plausible mechanism for the photochemical conversion of nitrofurazone to the azine. It appears that the hydrazone, **5**, is not intermediate in this process since we did not observe the hydrazone (it elutes just before compound **2**) and added hydrazone did not increase the amount of azine formed in either the light or the dark.

Nafion-coated mercury-coated glassy carbon electrodes for metals analysis and speciation

ROBERT D. GUY[1] AND SARATH NAMARATNE

Trace Analysis Research Centre, Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J1

Received November 5, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

ROBERT D. GUY and SARATH NAMARATNE. Can. J. Chem. **65**, 1133 (1987).

The properties of mercury-coated glassy carbon electrodes coated with a thin membrane of Nafion 117 were studied to evaluate the potential analytical applications in metal ion analysis. The Nafion membrane was found to contain two types of binding sites — a strong site that bound metal ions in a nonelectroactive form and cation exchange sites that were useful for preconcentrations prior to differential pulse voltammetry. The exchange constants for the weak sites ranged from 0.413 for copper to 12.5 for methyl viologen. The differential pulse currents were increased by a factor of 75 to 100 and a linear calibration curve was observed from about 25 n*M* to 1000 n*M* for copper, lead, cadmium, and zinc. The ion exchange reaction is very sensitive to ionic strength and significant enrichments occur only in solutions of ionic strength below 0.10. The Nafion-coated glassy carbon electrode in a flow cell can be used to determine the free copper ion concentration in samples by a combination of ion exchange and differential pulse voltammetry. The flow-through system required about 15 mL of sample solution and an analysis time of about 10 min. The ion exchange measurement gave a linear calibration from 40 n*M* to 10 μ*M* for free copper.

ROBERT D. GUY et SARATH NAMARATNE. Can. J. Chem. **65**, 1133 (1987).

Dans le but d'évaluer leurs applications analytiques potentielles dans l'analyse des ions métalliques, on a étudié les propriétés d'électrodes de charbon vitreux, recouvertes de mercure et recouvertes d'une fine membrane de Nafion 117. On a trouvé que la membrane de Nafion contient deux types de sites de liaison — un site fort qui lie les ions métalliques par une forme qui n'est pas électroactive et des sites d'échanges cationiques qui sont utiles pour les préconcentrations réalisées avant la voltamétrie différentielle pulsée. Les constantes d'échange des sites faibles varient de 0,413 pour le cuivre à 12,5 pour le viologène de méthyle. Les courants différentiels pulsés ont été augmentés par un facteur de 75 à 100 et on a observé une courbe de calibration linéaire d'environ 25 n*M* à 1000 n*M* pour le cuivre, le plomb, le cadmium et le zinc. La réaction d'échange ionique est très sensible à la force ionique et il ne se produit des enrichissements importants que dans des solutions de force ionique inférieure à 0,10. Si on fait appel à une combinaison de l'échange ionique et de la voltamétrie différentielle pulsée, on peut utiliser l'électrode de charbon vitreux recouverte de Nafion dans une cellule à flux pour déterminer la concentration d'ions cuivres libres. Le système à écoulement nécessite environ 15 mL de solution de l'échantillon et un temps d'analyse d'environ 10 min. Pour le cuivre libre, les mesures d'échanges ioniques donnent une calibration linéaire d'environ 40 n*M* à 10 μ*M*.

[Traduit par la revue]

Introduction

Voltammetric techniques provide a sensitive method for the detection and quantification of inorganic and organic species in aqueous and organic solutions. The modification of electrodes has recently provided methods to improve both the selectivity and sensitivity of voltammetric methods. Wang and co-workers (1, 2) have coated a mercury-coated glassy carbon electrode (MCGCE) or glassy carbon electrode with a cellulose acetate membrane. The membrane was hydrolyzed with base to form a porous structure. The membrane acts like a miniature dialysis membrane and reduced the adsorption interferences from organic substances. A second approach to altering the selectivity of voltammetric methods is to form a species that adsorbs onto the mercury surface. Wang and Mahmoud (3) have used adsorptive preconcentration to determine titanium in natural waters. A third approach is to form a permanent membrane on the electrode surface that chemically reacts with metal ions in solution. Polymer-coated electrodes with attached chelating groups have been shown (4) to selectively preconcentrate iron and copper.

A non-selective approach to sensitivity enhancement is to coat the electrode surface with a cation exchange membrane. A commonly used membrane is the Nafion series of polymers produced by Dupont. The membrane is perfluorinated hydrocarbon with sulphonate exchange sites and can be obtained commercially dissolved in low molecular weight alcohols. This solution can be easily used to coat glassy carbon or mercury-coated glassy carbon electrodes. Szentirmay and Martin (5) have studied the electrochemistry of methyl viologen and ruthenium complexes at the Nafion-coated glassy carbon electrode. They measured exchange constants on the order of 10^4 for the hydrophobic cations. These can be compared with values less than 10 for most inorganic cations (6). This paper describes two applications of the Nafion-coated electrode — preconcentration of copper, lead, cadmium, and zinc prior to differential pulse or anodic stripping voltammetry and a rapid ion exchange speciation procedure combined with electrochemical detection.

Experimental

Chemicals

A 5% Nafion 117 solution in aliphatic alcohols was obtained from Aldrich. Nafion 117 has an equivalent weight of 1100 g and the solution has the polymer in the hydrogen form. Citric acid, acetate buffers, and sodium nitrate solutions were prepared from reagent grade chemicals and the stock solutions were passed through a short column of Chelex 100 in the sodium form to remove trace metal impurities. Methyl viologen was obtained from Aldrich and standardized by ion exchange (7).

Electrochemical measurements were made using a Princeton Applied Research Model 174A Polarographic Analyzer equipped with a Model 303 SMDE and a glassy carbon electrode was used for batch studies. A Bioanalytical Services Model TL-5 glassy carbon detector block was used for flow studies. All potential measurements are against a BAS Model RE-1 Ag/AgCl reference electrode. A Masterflex pump was used for the flow studies. Ion selective electrode measurements were made using an Orion Model 94-29A copper ion selective electrode and

a Fisher Accumet 144 pH meter. The copper ion selective electrode was calibrated using triethylenetetramine/copper metal ion buffers.

The glassy carbon electrodes were polished with alumina before use. A mercury film was formed on glassy carbon by plating a 1.0×10^{-4} *M* mercuric nitrate solution in 0.01 *M* acetate buffer at pH 4 at −1.00 V for 15 min. The potential was changed to +0.10 V for 30 s to remove trace metal impurities. The electrode was removed from the SMDE assembly, washed with distilled water and acetone, and dried with a stream of nitrogen. The dry electrode was coated with 5 μL of a 3% Nafion solution (prepared by dilution of the stock with 50% methanol) and dried for 15 min. After visual inspection to ensure uniform coating the electrode was immersed in 0.01 *M* acetate buffer (pH 5.0) overnight to allow the polymer to swell and convert the polymer to the sodium form.

The membrane exchange constants were determined by placing 300 μL of the 5% Nafion solution on clean, dry microscope slides and allowing the solvent to evaporate. The glass slides were placed in 25 mL of 10 μ*M* metal ion solution and 0.010 *M* sodium nitrate. The membrane and solution were allowed to equilibrate for 12 h and the equilibrium metal ion concentrations in solution were determined by flame atomic absorption. Methyl viologen measurements were done using differential pulse polarography. Preliminary studies indicated that the differential pulse voltammetry (DPV) calibration curves for the ions were linear over the range of 10 n*M* to 100 n*M*. A second set of exchange constants were determined at 0.10 μ*M* metal ion by comparing the DPV currents of solutions equilibrated twice with fresh membranes on the MCGCE — the second current measurement gave the equilibrium concentration of the ion remaining in solution from the first equilibration. The amount bound to the membrane was determined by difference.

Metal ion preconcentration experiments were done using the PAR glassy carbon electrode coated with mercury and a Nafion membrane. The electrochemical cell was filled with 15 mL of test solution, placed in contact with the Nafion-coated MCGCE, deoxygenated with nitrogen for 4 min, and stirred for an additional 1 min with a magnetic stirrer bar. The preconcentrations in differential pulse polarography were done open circuit. Differential pulse voltammograms were recorded using a negatively going scan at a rate of 5 mV/s, a pulse of 100 mV, and measurement time of 0.5 s. The DPASV measurements were done using 15 mL of test sample adjusted to pH 5 with 0.01 *M* acetic acid buffer. The sample was placed in contact with the Nafion-coated MCGCE, deoxygenated for 4 min with nitrogen, stirred for 1 min. The DPASV voltammograms were recorded using a 5 min plating time at −1.40 V and stripping at a rate of 5 mV/s, a pulse of 100 mV, and measurement time of 0.5 s.

The simple metal ion speciation studies were done using the BAS flow cell and the Masterflex pump. The glassy carbon (without a mercury film) was coated with 10 μL of the 5% Nafion solution. After drying, a visual inspection showed that the Nafion film covered the glassy carbon electrode and some of the surrounding polyethylene block. The cell was used with a second glassy carbon electrode as the counter electrode and was connected to the Masterflex pump using 0.8 mm id Teflon tubing. A 0.10 *M* sodium nitrate solution adjusted to pH 5.0 with acetic acid buffers was passed through the cell for 2 h to convert the membrane to the sodium form. The speciation solutions were made up in 0.10 *M* sodium nitrate solutions and the pH adjusted to 5.0 with 0.01 *M* acetic acid buffers. The differential pulse current of the detector cell was continuously monitored at the copper peak potential. The sample solutions were passed through the cell at 2 to 3 mL/min until the current attained a plateau.

Results and discussion

The measured exchange constants for calcium, copper, cadmium, lead, zinc, and methyl viologen are given in Table 1 for the reaction:

[1] $2NaR + M^{2+} = MR_2 + 2Na^+$

$$K = \frac{X_M a_{Na}^2}{X_{Na}^2 a_M}$$

TABLE 1. Exchange constants for Nafion 117*

Cation	K^M_{2Na} (10 μ*M*)	K^M_{2Na} (0.10 μ*M*)
Copper	0.413	430
Lead	0.745	657
Cadmium	0.516	37
Zinc	0.589	105
Calcium	3.68	nd
Methyl viologen	12.5	139

*Values are the average of three measurements. Typical uncertainties were ±0.005 at 10 μ*M* and ±5 at 0.10 μ*M*; nd = not detected.

where *a* represents the activity of the ions in the solution and *X* represents the equivalent ionic fractions of the metal ions in the membrane. The measured concentrations were converted to activities using the single ion activity coefficients given by Kielland (8). The values for the metal cations compare favorably with values reported by Steck and Yeager (6) for a Nafion 120 membrane. The value for methyl viologen, however, is three orders of magnitude lower than the value reported by Szentirmay and Martin (5) for Nafion films on glassy carbon electrodes. The methyl viologen work on the Nafion/glassy carbon electrode system was done at concentrations two to three orders of magnitude lower than those reported in this work. A possible reason for some of the discrepancy between this work and the earlier report is that at low cation concentrations a small percentage of strong adsorption sites may dominate the exchange reaction between the membrane and solution. Blaedel and Niemann (9) attributed some nonlinearities in the exchange reaction for Nafion XR-170 (at low metal concentrations) to carboxylate or olefinic impurities. A study of Nafion 811X in our laboratory showed that at pCu values above 7 that the adsorption isotherm changed slope and a strong site dominated the adsorption reaction. A comparison of exchange constants measured at cation concentrations of 0.10 and 10 μ*M* are shown in Table 1 and tend to support the hypothesis of strong and weak sites on the membrane. At low metal concentrations the exchange constant tends to increase by two orders of magnitude. This dependence of exchange constant on cation concentration means that the analytical usefulness of the Nafion-coated electrodes may be limited to linear calibrations over narrow concentration ranges.

Exchange constants of 0.4 to 3 may still provide useful preconcentrations for the metal cations. The Nafion coatings on the MCGCE used in these studies corresponded to 0.437 mg Nafion or 3.97×10^{-7} mol of sites (assuming an equivalent weight of 1100). Equilibrium calculations using 1.0×10^{-7} *M* copper, an ionic strength of 0.010, and an exchange constant of 0.413 indicate that X_{Cu} would be about 0.0004 which corresponds to 5% of the copper removed from 10 mL of solution. The density of the swelled sodium form of Nafion is 1.58 g/cm^3 so the "volume" of the membrane on the Nafion-coated electrode would be about 2.8×10^{-7} L. The copper concentration in the membrane would correspond to 0.29 m*M* or an enrichment factor of about 3000. One could expect, therefore, that currents should be enhanced significantly at the Nafion-covered mercury coated glassy carbon electrode. Figure 1 shows the differential pulse voltammogram for 50 n*M* copper, lead, cadmium, and zinc ions in 0.01 *M* sodium acetate buffer at pH 5.5. The voltammogram was obtained using a membrane formed from 5 μL of a 1% Nafion solution and a

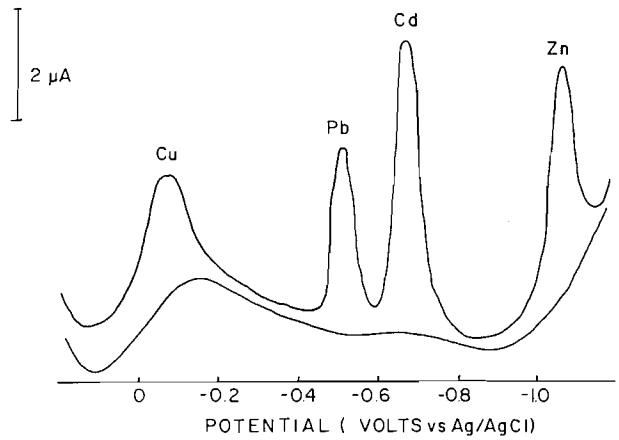

FIG. 1. Differential pulse voltammogram of copper, lead, cadmium, and zinc in 0.01 *M* acetic acid buffer at pH 5.5. A 10 min equilibration and a membrane formed from 5 μL of 1% Nafion were used in this experiment. The second curve is a blank equilibration with electrolyte.

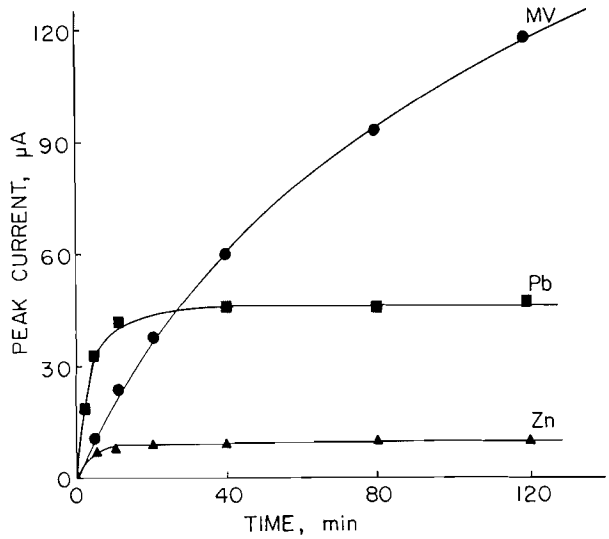

FIG. 2. Time study of the ion exchange equilibration for a membrane formed from 5 μL of a 3% Nafion solution.

10 min equilibration. The current enhancements observed for the four ions ranged from about 50 to 100 — considerably lower than the 3000 calculated above. The lower than expected current enhancement can be explained by considering the effects of diffusion and strong sites on the observed currents.

The usefulness of the Nafion-coated mercury coated glassy carbon electrode will depend on the kinetics of exchange, sensitivity of the exchange reaction to secondary ions and ionic strength, and the linearity of the calibration curve. The kinetics of equilibration for lead, methyl viologen, and zinc onto a Nafion membrane formed by adding 5 μL of the 3% stock solution to the mercury-coated electrode is given in Fig. 2. The lead and zinc equilibrate rapidly and attain the maximum response at 20 min but methyl viologen required greater than 120 min to attain equilibrium. The slow equilibration of methyl viologen was also noted by other workers (5) and was attributed to slow diffusion of the cation in the Nafion film. Diffusion coefficients in Nafion membranes have been reported (5) to range from $\sim 10^{-10}$ cm^2/s (for methyl viologen) to 9.44 × 10^{-7} cm^2/s for sodium. These diffusion constants are considerably smaller than diffusion constants noted for ions in solution.

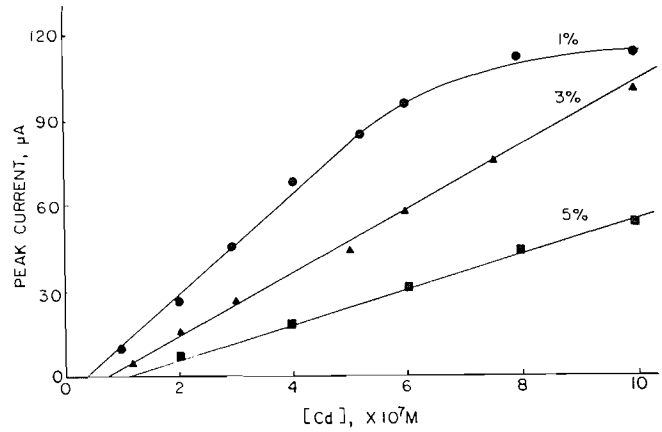

FIG. 3. Effect of membrane thickness on the calibration curves for cadmium. The membranes were formed by adding 5 μL of 1, 3, or 5% Nafion solutions and preconcentrations were done in 0.01 *M* acetic acid buffer at pH 5.5.

The slow diffusion of the ions in the Nafion membrane will affect the analysis of metal cations in two ways: the slow diffusion will increase the time necessary for equilibration of the membrane with the sample solution and the slow diffusion will affect the reduction currents at the mercury-coated glassy carbon electrode.

The effect of film thickness on the analytical response is given in Fig. 3. These calibration curves were obtained using a 5 min equilibration period. The decrease in slopes as one goes from a 1% membrane to a 5% membrane reflects the longer time necessary to reach equilibrium as one increases the thickness of the membrane. A longer time is required for the ions to diffuse through the thick membrane. Each of the calibration curves do not pass through the origin and it appears that one titrates a site before one obtains a measureable current. As one increases the thickness by using 1, 3, and 5% Nafion solutions the intercept changes from 2.5 to 7.5 to 10 × 10^{-8} *M*. This supports the earlier argument that the Nafion contains at least two types of sites: the first site binds metal ions strongly and the bound metal is not electroactive and a second, more numerous type of site that binds the metal in an electroactive form. A rough calculation suggests that about 1% of the exchange capacity is present in the strong sites. The presence of the strong sites will limit the analytical applications of the membrane to metal ion concentrations above about 20 to 50 n*M* if one uses the 3% membrane.

The ion exchange reaction given in eq. [1] indicates that the response will be very sensitive to the ionic strength of the solutions. Figures 4 and 5 illustrate the effect of sodium and calcium on the analytical response for several ions. The data in Fig. 4 indicate that the membrane will only give significant enhancements at ionic strengths below 0.10 but Fig. 5 indicates that at calcium levels typical of natural waters one can determine the four metal ions. The two diagrams do suggest that analytical measurements can be best done using a standard addition procedure to compensate for variations in ionic compositions of unknown solutions. It should be noted that over the concentration ranges of interest (50 n*M* to 1 μ*M*) there were no interferences between copper, zinc, cadmium, and lead and each calibration was linear. It should also be noted that the current enhancements will depend on the pH of the sample solution. At pH values lower than 2 the proton will start to compete for sites on the membrane and at pH values greater than

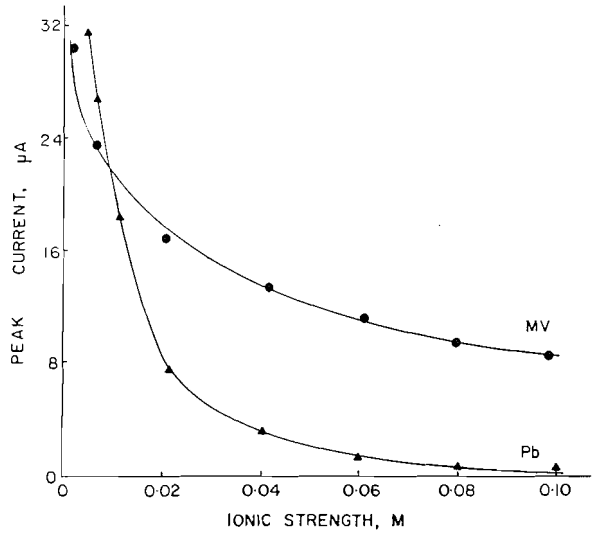

FIG. 4. Effect of sodium nitrate concentration on the differential pulse voltammetry current after a 10 min equilibration. The membrane was formed from 5 μL of a 3% Nafion solution.

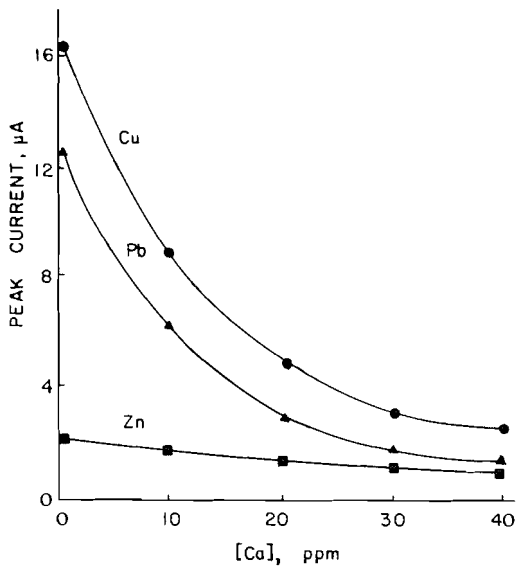

FIG. 5. The effect of calcium on the differential pulse voltammetry currents for a 5 μL of 3% Nafion membrane.

five formation of hydroxy species will lower the activity of the free ion.

The analytical usefulness of the Nafion-coated electrode is limited by the sensitivity of the ion exchange reaction to ionic strength variations and the presence of strong, non-electroactive sites on the membrane. One advantage of the membrane is that it may isolate the mercury surface from surfactants and organics in the sample solution. Wang and Hutchins-Kumar (1) have shown that a cellulose acetate membrane decreases adsorption effects at the mercury-coated glassy carbon electrode. Figure 6 shows that a Nafion-coated electrode, like the cellulose-acetate-coated electrode, also removes the interference of gelatin on the DPASV of copper. The slight decrease in stripping current as the concentration of gelatin increases is probably due to the binding of copper to sites on the gelatin. A similar decrease in copper currents was noted for DPASV at the cellulose-acetate-coated electrode. The removal of organic interferences and

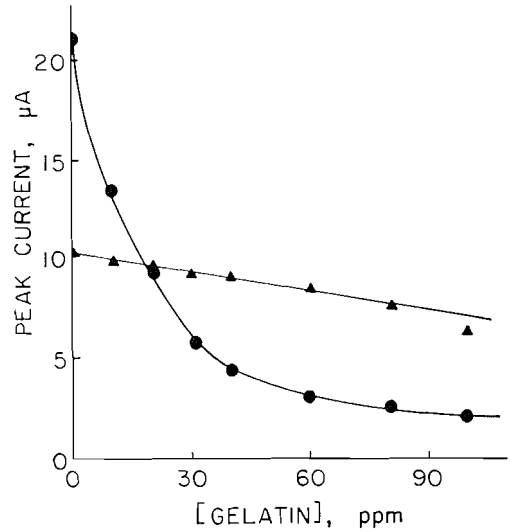

FIG. 6. The effect of gelatin on the DPASV of copper: ● MCGCE and ▲ Nafion-coated MCGCE (5 μL of 3% solution).

TABLE 2. Metal ion concentrations in water samples*

Ion	Concentration in Mineral water	Rain water	Lake water
Cu	2.6	7.8	nd
Pb	0.7	3.4	1.9
Cd	nd	nd	0.9
Zn	2.0	1.7	16.7

*All values are in ppb, the mean of 4 measurements made using pH 5.5 buffer, and using standard additions. The relative standard deviations for the values are 10%; nd = not detected.

slight current enhancements does permit the application of DPASV at the Nafion-coated glassy carbon electrode for the analysis of some simple solutions. The results for several types of water samples are given in Table 2. These measurements were done by adding acetate buffers to adjust the pH to 5.5 and the ionic strength to 0.01. The metals were quantified by a standard additions procedure. The lake water sample gives no copper and this is probably a result of the pH adjustment — the copper may be bound to organic colloids in water and not sufficiently labile to be detected in this experiment.

The Nafion-coated MCGCE improves the sensitivity of differential pulse polarography by a factor of about 75 but the sensitivity does not compare favorably with conventional differential pulse anodic stripping voltammetry. The Nafion-coated MCGCE effects the preconcentration by an ion exchange reaction and the membrane system is sensitive to ionic strength and pH variations in the samples. Conventional DPASV, however, is relatively insensitive to sample ionic strength and, for cadmium, copper, and lead, can be done at low pH values. A second limitation of the Nafion-coated MCGCE is the non-zero intercepts in the calibration curves noted for batch equilibrations. This limits the practical usefulness of the membranes to metal ion concentrations above 50 n*M* for DPV. The analytical usefulness of the ion exchange perconcentration may be more fully realized for cations that do not deposit electrolytically, for example, iron. Preliminary results suggest that iron preconcentrates on the membrane and is electrochemically active and this is under further investigation.

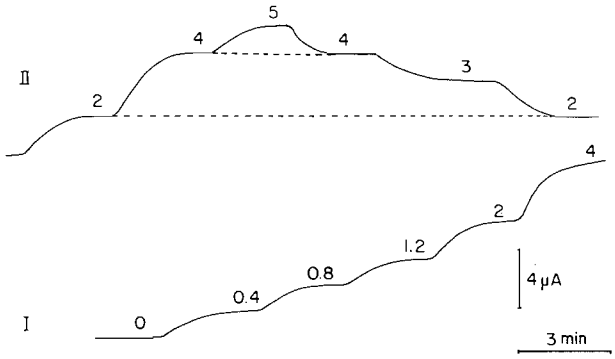

FIG. 7. Current traces for the ion exchange measurement of free copper in 0.10 *M* sodium nitrate at pH 5 (adjusted with 0.01 *M* acetate buffer). Trace I represents the calibration curve and Trace II is an extension that shows that the exchange process is reversible. The numbers written on the curves are the copper concentrations in μ*M* units. Measurements taken using the BAS flow cell.

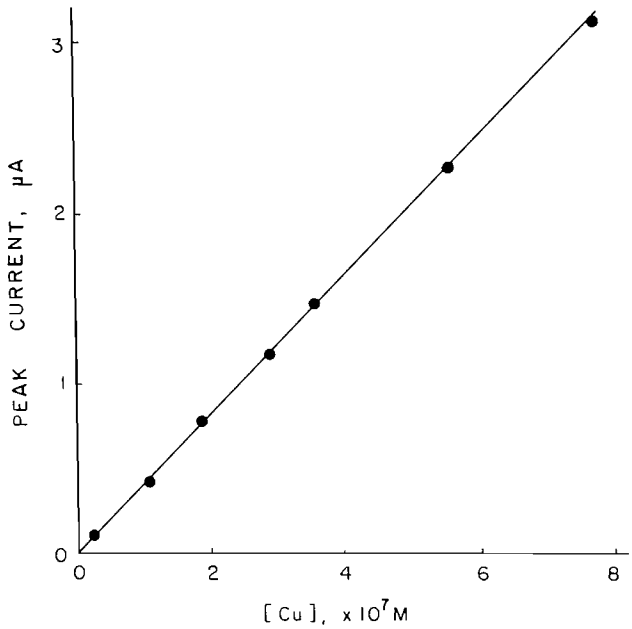

FIG. 8. Calibration curve for copper in citric acid metal ion buffers. The metal ion buffers were calibrated using a copper ion selective electrode calibrated with TRIEN metal ion buffers.

The Nafion-coated electrode can be used to measure the activity of the free metal ion by using an ion exchange reaction. Cantwell *et al.* (10, 11) have shown that short ion exchange columns can be used with atomic absorption analysis to determine the free copper and nickel ions in water samples. Zorkin *et al.* (12) have also shown that the ion exchange method gives a limited agreement with bioassay results. A glassy carbon electrode was coated with Nafion and placed in the BAS flow cell to permit a flow through equilibration of the membrane with the sample solution. The copper currents were monitored as a function of time and the results are given in Fig. 7 for copper ions in 0.10 *M* sodium nitrate. The lower curve in Fig. 7 shows the data used to obtain a calibration curve — it is evident that the equilibration is rapid and about 15 mL of solution are necessary to attain the plateau. The upper curve in Fig. 7 shows that the exchange membrane is reversible — it is possible to use the membrane continuously without washing the membranes between samples (note that these solutions were not metal ion buffers). Citric acid metal ion buffers were used to calibrate a membrane over an extended pCu range and the calibration from 40 n*M* to 800 n*M* is shown in Fig. 8. The calibration gives a linear response between free copper and current and, though not shown in Fig. 8, the linear range extended up to 10 μ*M* free copper. A second point that should be noted in the calibration curve is the zero intercept. The difference between the calibrations of Figs. 3 and 8 is that in the flow cell configuration the membrane equilibrates with fresh metal ion solution — in the flow cell the strong and weak sites can both equilibrate fully with the metal ion solution. A separate study using cadmium in 0.01 *M* sodium nitrate and the flow cell also showed a linear calibration with zero intercept. This suggests that the flow cell configuration may also be used in the preconcentration mode with zero intercepts and no interference from the strong membrane sites.

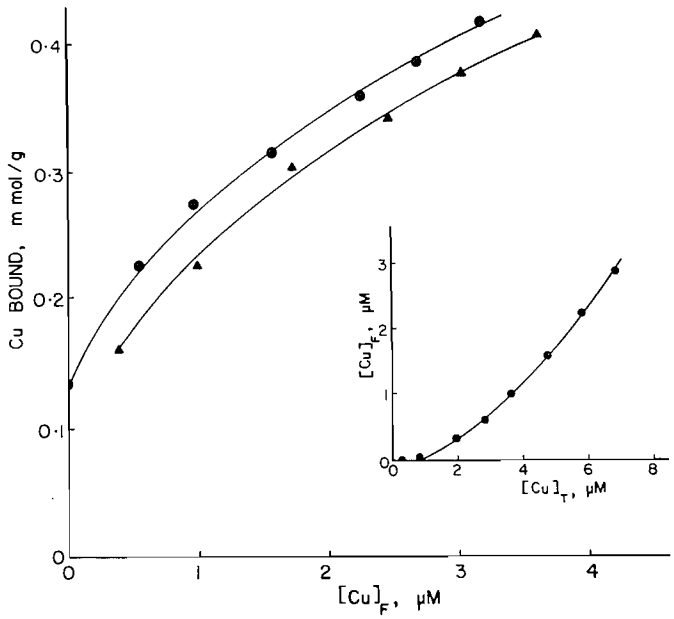

FIG. 9. Ion exchange measurements of free copper in a 10 ppm humic acid solution at pH 5.0. The inset shows the titration curve and the main figure shows the binding isotherm for copper onto humic acid. ▲, Potentiometric determination of free copper; ●, ion exchange determination of free copper.

One application of the metal speciation is to study the binding capacity of water samples and the binding of metal ions to soil organic matter. A preliminary study using a copper ion selective electrode and the Nafion membrane system indicated good agreement for EDTA solutions at the micromolar level. Figure 9 shows the copper titration and binding isotherm for a humic acid solution in 0.10 *M* sodium nitrate at pH 5.0. The isotherm obtained by potentiometric measurements with the copper ion selective electrode is also given in Fig. 9. The ion exchange method and the ion selective electrode do not give the same isotherm and the ion exchange method gives a lower measured free copper than the ion selective electrode (hence more copper binding). A similar result has been noted in our laboratory using the ion exchange column method described by Cantwell *et al.* (10). The ion selective electrode results may be in error because the electrode is sensitive to organic substances (13) and it has been reported in the literature that the presence of humic materials can interfere with the copper ion selective electrode (14).

The Nafion-coated glassy carbon electrode can be used for

current enhancements in analysis under well-defined sample conditions of fixed ionic strength, pH, and using a standard additions method. The more important application would be in measurement of pCu in complexing solutions of interest in bioassays.

Received October 22, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

JAMAL ELWERFALLI, JOHN A. PAGE, and GARY W. VANLOON. Can. J. Chem. **65**, 1139 (1987).

Trace U(VI) in seawater has been determined by voltammetry after preconcentration by adsorption of the U(VI)/Br—PADAP complex (Br—PADAP = 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol).

The reagent and the metal complex are adsorbed at a Hg drop electrode polarized at −0.40 V vs. a Ag/AgCl reference from a seawater electrolyte containing 3×10^{-7} *M* added Br—PADAP and buffered at pH 7.8 by the addition of triethanolamine/$HClO_4$. The adsorption is at a mass transfer controlled rate. Voltammetry of the adsorbed electroactive material gave two peaks, one at −0.56 V for reduction of adsorbed Br—PADAP and one at −0.65 V for reduction of adsorbed U(VI)—PADAP complex. The height of the second peak was a sensitive measure of the concentration of U(VI) in the electrolyte. Analysis is carried out with preconcentration restricted to a low fractional electrode coverage with calibration by the method of standard additions. The method is subject to interference from organic surfactants but not from common metal ions. Interferences were minimized by the use of short adsorption times in the preconcentration step.

For a 60 s adsorption time, a scan rate of 0.050 V s^{-1} and peak current measurement, the sensitivity was 8.2 nA/($\mu g\ L^{-1}$ U(VI)). Values of 3.44 and 3.21 $\mu g\ L^{-1}$ U(VI) were determined for NASS-1 and CASS seawater reference standards.

JAMAL ELWERFALLI, JOHN A. PAGE et GARY W. VANLOON. Can. J. Chem. **65**, 1139 (1987).

Appliquant la voltamétrie à des échantillons préconcentrés par adsorption du complexe U(VI)/Br—PADAP (Br—PADAP = (bromo-5 pyridyl-2 azo)-2 diéthylamino-5 phénol), on a déterminé des traces de U(VI) dans de l'eau de mer.

Pour un électrolyte d'eau de mer contenant 3×10^{-7} *M* de Br—PADAP et tamponné à un pH de 7,8 par l'addition de triéthanolamine/$HClO_4$, le réactif et le complexe métallique sont adsorbés sur une électrode de goutte de mercure polarisée à −0,40 V par rapport à une référence Ag/AgCl. L'adsorption se produit à une vitesse qui est contrôlée par le transfert de masse. La voltamétrie du matériel électroactif adsorbé donne deux maxima, l'un à −0,56 V pour la réduction du Br—PADAP adsorbé et un à −0,65 V pour la réduction du complexe U(VI)—PADAP adsorbé. La hauteur de la deuxième vague est une mesure sensible de la concentration de U(VI) dans l'électrolyte. On a effectué l'analyse en procédant à une préconcentration restreinte impliquant une couverture fractionaire faible de l'électrode et une calibration par la méthode des additions standards. La méthode est sujette à des interférences de la part des agents de surface organiques; toutefois, il n'y a pas d'interférences de la part des ions des métaux usuels. On peut minimiser les interférences en n'utilisant que des temps d'adsorption courts dans l'étape de la préconcentration.

Pour un temps d'adsorption de 60 s, un taux de balayage de 0,050 V s^{-1} et une mesure au maximum du courant, la sensibilité de la méthode est 8,2 nA/($\mu g\ L^{-1}$ U(VI). On a pu déterminer des valeurs de 3,44 et 3,21 $\mu g\ L^{-1}$ U(VI) dans les échantillons de référence standards NASS-1 et CASS.

[Traduit par la revue]

Introduction

Uranium is normally present in seawater at the trace level as a U(VI) species. In aqueous non-complexing systems, U(VI) exists as a uranyl UO_2^{2+} species but U(VI) forms moderately stable complexes with chloride and very stable complexes with carbonate and these would be expected to dominate in natural sea water. A number of different techniques have been used to measure the concentration of the element and recent reports have given values of 2.6 $\mu g\ L^{-1}$ U in a coastal seawater by isotope dilution mass spectrometry after Chelex-100 preconcentration (1), 3.08 $\mu g\ L^{-1}$ U in a similar seawater by neutron activation analysis after preconcentration by adsorbing colloid flotation (2) and a value of 3.16 $\mu g\ L^{-1}$ U in Sea of Japan water by a spectrophotometric method using Arsenazo III reagent (3). The values reported presumably represent U(VI), but the specificity of these methods for the particular oxidation state of uranium is uncertain.

Electrochemical analysis is attractive but most methods are not sufficiently sensitive for the determination of uranium in sea water. Milner *et al.* (4) used a pulsed polarographic method but a complex separation and preconcentration step was required. Whitnack (5) attempted a direct polarographic analysis but was unable to detect uranium in seawater. A sensitive "catalytic" polarographic measurement involving nitrate ion is known but interferences prevent its use in seawater analysis (6). Attempts to determine uranium by anodic stripping voltammetry have failed because of the difficulty in depositing the element and the poor form of the stripping peaks (7).

A sensitive electrochemical method would appear dependent upon other forms of preconcentration of the uranium species from the electrolyte. It has been reported that U(VI) can be adsorbed on a mercury drop electrode and then determined voltammetrically by reduction of the adsorbed U(VI) (8). Preconcentration has also been achieved by the reaction of U(VI) with organophosphorus compounds adsorbed on a graphite electrode surface. Tripropyl- and tributyl-phosphate have been employed with the adsorbed U(VI) again determined by a voltammetry (9). Graphite electrodes modified by a surface coat of trioctylphosphine oxide have also been employed (10, 11). The U(VI) is effectively adsorbed from a chloride electrolyte at 0 V vs. a Ag/AgCl reference and determined by voltammetry. The method has been used to determine uranium in seawater, with the only pretreatment being removal of carbonate by boiling of an acidified sample before adjustment to pH 4 (3). A value of 3.14 $\mu g\ L^{-1}$ U(VI) was reported for Sea of Japan water, and this compared well with a value of 3.16 $\mu g\ L^{-1}$ U determined by a spectrophotometric procedure.

Catechol has also been employed for adsorptive accumula-

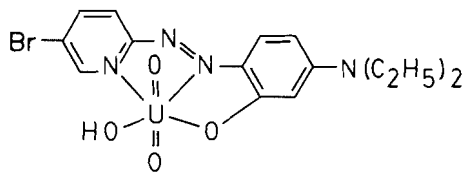

FIG. 1. Structure of the U(VI)/Br—PADAP complex with OH^- as auxiliary ligand.

tion of uranium. Lam *et al.* (12) adsorbed the U(VI) complex from a pH 4.7 electrolyte onto a mercury drop electrode at −0.10 V vs. a Ag/AgCl reference. The adsorbed species gave a reduction peak at −0.35 V. The direct determination of uranium in seawater was not possible but after preconcentration and ion exchange separation steps a value of 1.48 μg L^{-1} U, presumably U(VI), was reported for Atlantic seawater. Other techniques gave a value of 1.70 μg L^{-1} U for the sample. Van den Berg and Huang (13) also used the reagent for direct analysis of seawater buffered to pH 7. The U(VI) catechol complex was adsorbed at −0.40 V vs. a Ag/AgCl reference with a reduction peak for the electroactive material at −0.55 V. Values of 3.14 μg L^{-1} U(VI) in an Irish Sea sample and 3.21 μg L^{-1} U(VI) in an Atlantic seawater were reported. However, catechol is not a selective reagent and interferences were noted. It is known that adsorption processes involving catechol can enhance the voltammetric response of a number of ions including those of Cd(II), Cu(II), Fe(III), Pb(II), and Sn(IV) (14, 15) and these and other ions are potential interferences in the method.

While there are no specific guidelines for choosing reagents for such adsorptive preconcentration, candidates can be found in the analytical literature. A possibility exists with 2-(5-bromo-2-pyridylazo)-5-diethyl aminophenol (Br—PADAP) which has been recommended by Johnson and Florence as the most suitable spectrophotometric reagent for uranium (16). The reaction of the reagent with U(VI) is highly specific and it forms a stable 1:1 complex over the pH range 4.0–8.4. Incorporation of an auxiliary ligand such as OH^- gives a neutral chelate as shown in Fig. 1. For the complex, $\log \beta_1 = 5.1$ with OH^- as auxiliary ligand, while the incorporation of F^- is said to result in a more stable complex than with OH^-. The complex absorbs strongly with $\lambda_{max} = 578$ nm and $\epsilon = 74\,000\ cm^{-1}/(mol\ L^{-1})$.

The reagent itself is electroactive and can be reduced at a mercury electrode. Such aromatic azo dyes have been extensively studied by polarography and when present in excess with a metal exhibit two discreet polarographic reduction processes, one due to free reagent, the other due to the metal ligand complex. Under most conditions the reduction involves 4 Faradays per mole of ligand, leading to scission and formation of amine groups. Under some circumstances there can be a 2 Faraday per mole reduction leading to a dihydroazo compound (17).

The reagent and its metal complexes would also appear to be adsorbable species. The related pyridylazo-5-diethylamino-phenol reagent (PADAP) can be readily adsorbed on C-18 bonded glass beads and the immobilized reagent has been used for the concentration of trace metal ions such as Cd(II), Cu(II), Pb(II), and Zn(II). The metals can then be stripped from the substrate for determination by conventional anodic stripping voltammetry (18).

Experimental

The inverse voltammetric measurements were made using an E G and G Princeton Applied Research Corporation (PARC) Model 384 Analyzer. A PARC Model 303 Static Mercury Drop Electrode assembly was used with a Model 350 Stirrer Drive operating at 500 Hz. The three electrode system consisted of a Hg drop ("M" 0.017 cm^2), a Pt auxiliary electrode and a Ag/AgCl reference electrode. With the seawater electrolyte the reference had a potential of −0.010 V vs. a conventional SCE electrode at 25°C. The electrode capillaries were silanized according to the PARC instructions. A 15 mL quartz glass cell was used with a 1.0 cm diameter Teflon "SpinFin" for stirring. The voltammograms were stored in a digital form and subsequently plotted using a Houston Instruments HiPlot Plotter. For the polarographic and triangular wave experiments a PARC Model 174A Analyzer was used with the cell assembly but without electrolyte stirring. Voltammograms were recorded using a Hewlett Packard Model 7005 X–Y Recorder.

The N_2 gas used to deareate and blanket the electrolyte solutions was CANOX "oxygen-free" grade purified by passage over hot BASF catalyst. The sample and cell manipulations were carried out in a Canadian Cabinets Model HB-97-T laminar flow clean hood equipped with a high efficiency air filter. All glass and plastic ware was cleaned and conditioned by soaking in 3 *M* aq. nitric acid and thoroughly rinsed with good quality distilled water before use. While contamination of the cell and electrolyte was evident in some cases, it could be removed by rinsing and filling the cell with fresh sample electrolyte and continuing the process until satisfactory results were obtained.

The nitric acid used in this work was purified by sub-boiling distillation in a quartz still. The triethanolamine (TEA) buffer solution was prepared from 97% "BDH Assured" TEA and Analar Grade 70% "Aristar" perchloric acid supplied by BDH Chemicals. The stock buffer solution was 1.0 *M* in TEA and 0.5 *M* in added $HClO_4$ and had a pH of 8.0. Normally 500 μL of the stock buffer solution was added to each 0.010 L seawater sample to give a pH of 7.8. For experiments in which pH was a variable, additions of 1.0 *M* TEA or 0.5 *M* $HClO_4$ were made, as required, to the buffered system. The Br—PADAP reagent was of reagent grade quality supplied by the Aldrich Chemical Company, Inc. It was used without further purification. Dilute stock solutions, approximately 1×10^{-4} *M* in dissolved Br—PADAP, were accurately prepared by dissolving weighed amounts of reagent in a 1:1 H_2O/methanol solvent. The methanol was HPLC Grade supplied by the J. T. Baker Chemical Company. While the stock solution was evidently stable for periods exceeding 30 days, fresh solutions were prepared at 7 days intervals.

The stock U(VI) solution was prepared by dissolving 0.0214 g of uranyl acetate dihydrate in water, acidifying with 2.0 mL of nitric acid and making up to a volume of exactly 1 L. The uranyl acetate was an "Analar" reagent supplied by BDH Chemicals. The stock solution had a concentration of 12.1 μg mL^{-1} U(VI) and was diluted as needed for standard addition calibrations. The concentration was verified by a Zn(Hg) reduction of the U(VI), air oxidation to U(IV), and titration with an aq. $KMnO_4$ oxidant (19).

Direct voltammetry

Sampled current polarography gave a single well-defined but drawn out reduction wave with $E_{1/2}$ of −0.65 V for Br—PADAP in the buffered seawater electrolyte. The ratio of the limiting current to that for the reduction of an equal concentration of Cd(II) was 1.07:1, indicating a two electron mass transfer controlled reduction process for the Br—PADAP. The inequality in the limiting currents may be due to differences in the diffusion coefficients of the species involved, or there may be a small contribution from a four electron process for the reduction of the Br—PADAP. Triangular wave voltammograms are shown in Fig. 2. A fresh Hg drop was used for each voltammogram but the results were dependent upon the time of contact of the drop with the electrolyte. The Br—PADAP gave a cathodic peak at −0.58 V and an anodic peak at a corresponding potential on the reverse scan. The peak was nearly symmetrical in keeping with reduction of an adsorbed species and did not tail as might be expected for a mass transfer controlled contribution to the reduction process. The appearance

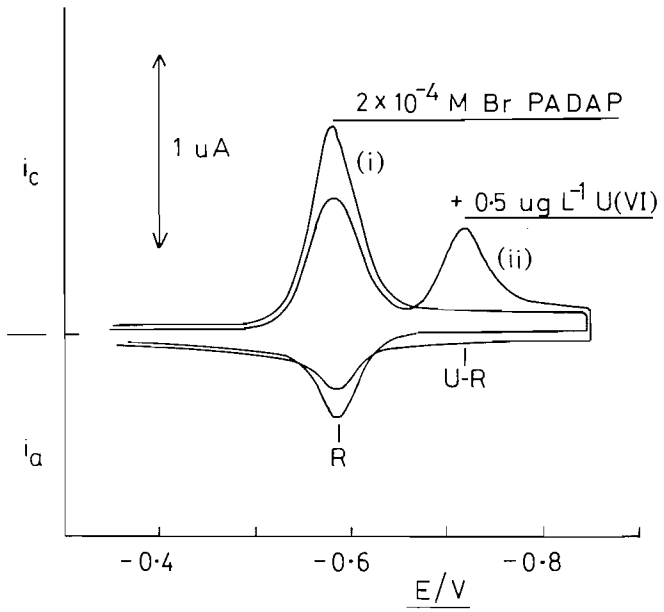

FIG. 2. Triangular wave voltammetry: seawater electrolyte, pH 7.8, 2×10^{-4} *M* Br—PADAP, scan rate 0.10 V s^{-1}; (*i*) no added U(VI), (*ii*) 0.5×10^{-6} g mL^{-1} added U(VI).

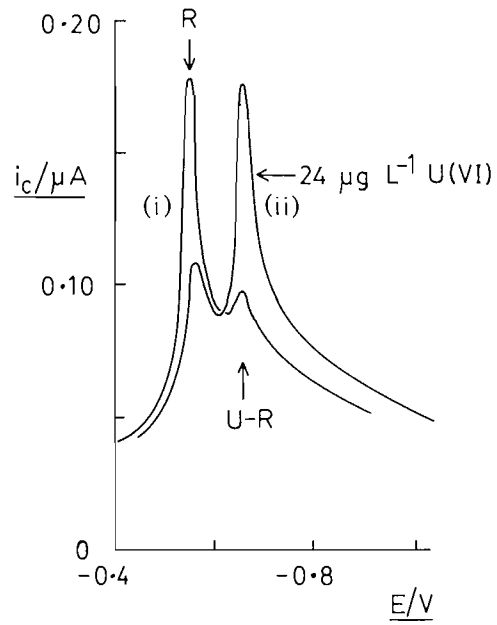

FIG. 3. Reduction of adsorbed reagent and U-complex species: seawater electrolyte, pH 7.8, 3×10^{-7} *M* Br—PADAP; 120 s adsorption at −0.40 V, scan rate 0.05 V s^{-1}; (*i*) no added U(VI); (*ii*) 24×10^{-6} g L^{-1} added U(VI).

of a symmetrical oxidation peak at the same potential on the reverse scan indicates that the reduction product was adsorbed on the electrode. Addition of trace substoichiometric amounts of U(VI) to the system produced a second symmetrical reduction peak at −0.72 V with no corresponding anodic peak. This would indicate a reduction step involving metal complex adsorbed on the electrode. The reduction is irreversible or desorption and loss of the reduced species from the electrode surface occurs. The height of the second peak was dependent upon the concentration of added U(VI).

Inverse voltammetry

(1) Adsorption/reduction

Inverse voltammograms obtained after adsorption of the electroactive species from the seawater electrolyte are shown in Fig. 3. Two cathodic current peaks are evident, at −0.55 V, corresponding to reduction of adsorbed Br—PADAP and at −0.66 V corresponding to reduction of adsorbed complex. The seawater shows a large peak for Br—PADAP and a small peak evident of trace U(VI). The sample with added U(VI) shows a small peak for uncomplexed reagent and a large peak for the metal complex. The peaks are relatively sharp, with a half-maximum width of 0.038 V, in keeping with reduction of a surface layer of electroactive material. The peak current for reduction of the complex was a linear function of scan rate over the range examined from 0.02–0.08 V s^{-1}.

Integration of the Br—PADAP peak (in the absence of added U(VI)) to a tangent baseline gave 4.4×10^{-8} C for reduction of the reagent. An equivalent Cd amalgam prepared by deposition at −0.90 V from a seawater electrolyte with 3×10^{-7} *M* added Cd(II) required 5.4×10^{-8} C for stripping. The near equality of the quantities of electricity indicates that equivalent amounts Br—PADAP and Cd are collected at the Hg drop electrode under comparable conditions. Adsorption of Br—PADAP, like deposition of Cd, appears to be a mass transfer controlled process.

Figure 4 shows the effects of added U(VI) on the voltammetric behaviour. Reproducible voltammograms were obtained within 10 min after addition of the metal, indicating a rapid

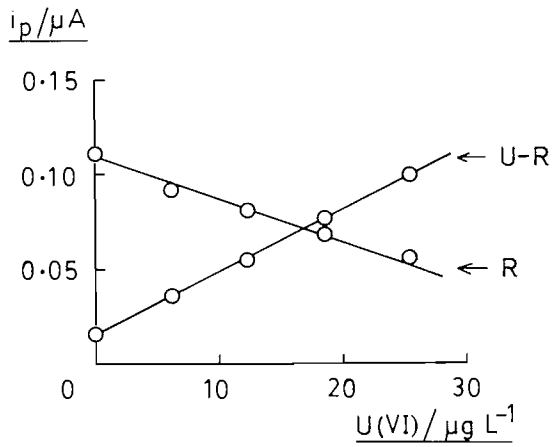

FIG. 4. Effect of added U(VI) on voltammetric response: seawater electrolyte, pH 7.8, 3×10^{-7} *M* Br—PADAP; 120 s adsorption at −0.40 V, scan rate 0.05 V s^{-1}.

reaction between the U(VI) and the Br—PADAP. The height of the peak at −0.65 V grew in a linear fashion with added U(VI), while that at −0.56 V decreased. The slopes of the plots were for Br—PADAP, −2.2 and for the U-complex, +3.2 nA/(μg mL^{-1} U(VI)). The larger sensitivity for the metal complex may indicate a coreduction of the ligand and the metal of the adsorbed complex or the diffusion coefficient of the complex may be significantly greater than that of the free ligand. Only one peak for reduction of adsorbed metal complex was apparent in the voltammograms.

If the height of the peak at −0.56 V is assumed proportional to the concentration of free Br—PADAP in the electrolyte, then the ratio: (amount Br—PADAP removed)/(amount added U(VI)) = 1.3. The result differs from the unit value expected for a 1:1 metal–ligand complex, but could be explained by errors in the estimation of the concentration of free Br—PADAP.

(2) Surface saturation

The effect of increased adsorption time on the response is

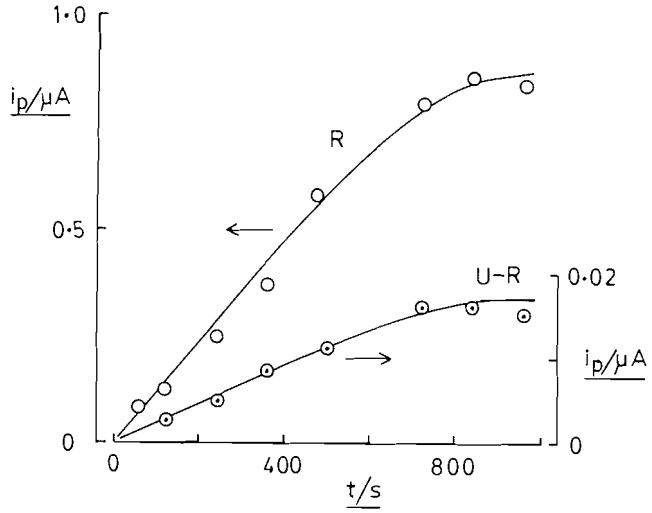

FIG. 5. Effect of adsorption time on voltammetric response: seawater electrolyte, pH 7.8, 3×10^{-7} *M* Br—PADAP; Adsorption at -0.40 V, scan rate 0.05 V s^{-1}.

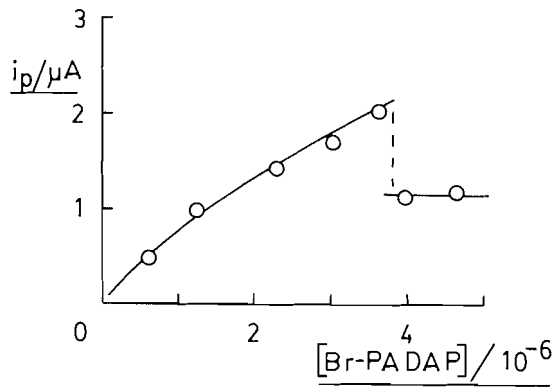

FIG. 6. Effect of Br—PADAP concentration on voltammetric response: seawater electrolyte, pH 7.8, 60 s adsorption at -0.40 V, scan rate 0.05 V s^{-1}.

shown in Fig. 5. Both the Br—PADAP and the metal complex peaks grew to a limiting value corresponding to saturation of the Hg drop surface with electroactive material. The reduction peak for the Br—PADAP broadened at high electrode coverage and shifted to more negative potentials. At low fractional coverage, the complex peak grew linearly with time despite the simultaneous adsorption of Br—PADAP. The adsorption of both the reagent and the complex would appear to be mass transfer controlled at low fractional electrode coverage. Integration of the peak for reduction of the Br—PADAP at saturation gave a cathodic process of 1.3×10^{-6} C. If the reduction is a two electron process, then a Faraday Law calculation gives 6.7×10^{-12} mol adsorbed reagent on a 0.017 cm^2 electrode corresponding to an area of $(0.65\ nm)^2$ per molecule. This value in keeping with dimensions previously reported for adsorbed molecules (13, 20). Figure 6 shows the effect of increased concentration of Br—PADAP on the response at a fixed adsorption time. The results are again in keeping with a saturation of the electrode surface with a degree of surface supersaturation evident at intermediate Br—PADAP concentrations.

(3) pH

The response was dependent upon the pH of the electrolyte. A reduction peak for adsorbed metal complex was apparent only above pH 7.4 but the response remained constant up to pH 8.8. The lack of a response at low pH may be due to an insignificant degree of formation of the complex or a low activity of OH^- as the auxiliary ligand required for an uncharged metal complex. The peak for reduction of adsorbed Br—PADAP was apparent over the whole range of pH examined. The reagent has two N atoms as protonation sites and one phenolic proton. For H_3L^{2+}, $pK_{a1} = 0.1$, $pK_{a2} = 2.02$, and $pK_{a3} = 11.30$ so that the reagent exists in an uncharged form over the pH range 3–10 (21). No significant shift in peak potential for either the reagent or the complex was observed over the range of pH examined.

(4) Adsorption potential

The response was sensitive to the adsorption potential. The metal complex was adsorbed over a range of potential from -0.20 to -0.50 V but the sensitivity was maximum at -0.40 V. Over this range, the Br—PADAP sensitivity decreased with increasingly negative values of potential, probably due to simultaneous adsorption and reduction of the reagent species. The metal complex peak remained well defined over the range of potentials.

Analysis

(1) Procedure

The analysis procedure was based on the optimal values of the experimental parameters. The adsorption time was kept short, despite a decreased sensitivity, to minimize electrode coverage and the adsorption of interfering species. The concentration of added Br—PADAP was chosen to give a minimum excess relative to the concentration of U(VI).

The normal procedure involved a 0.010 L sample of seawater, with addition of 500 μL of TEA stock buffer reagent and 50 μL of stock Br—PADAP reagent. The samples as provided were normally acidified to pH 1.8 with HNO_3 and the buffered system had a pH of 7.8. The precise volume of sample was determined from electrolyte weight at the end of an analysis/calibration sequence. For analysis, adsorptive preconcentration was carried out at -0.40 V for 60 s with stirring. The stirring was then shut down and after an additional 20 s at the initial potential the electrode potential was scanned at 0.05 V s^{-1} to more negative potentials to reduce the adsorbed electroactive material. The peak current for the reduction of adsorbed uranium complex at -0.66 V was measured relative to an estimated baseline. For the standard addition calibration, aliquots of a standard U(VI) solution were added to the electrolyte. A fresh Hg drop was used for each preconcentration/analysis step. Allowing for a two fold excess of Br—PADAP limits the U(VI) concentrations measurable to 60 μg L^{-1}.

(2) Interferences

The Br—PADAP is not completely specific for U(VI) and can form complexes with other metal species. A series of metal ions that would constitute possible interferences in the analysis were added to the buffered seawater electrolyte at concentrations of 50 μg L^{-1} in separate experiments. No response or interference was observed with added Al(III), Cd(II), Co(II), Cr(III), Cu(II), Mo(V), Ni(II), Pb(II), Zn(II), and V(V). A reduction peak was obtained with added Fe(III) evidently resulting from the reduction of an adsorbed Fe(III) complex. The peak appeared at -0.80 V and was well removed from the peak for reduction of the adsorbed U(VI) complex.

Non-electroactive surface active substances also constitute a potential interference in the analysis by preferential adsorption

	Sensitivity: 7.7 ± 0.3 nA/(μg L^{-1})

and blocking of the electrode surface. Triton X-100 was used as a model non-ionic surfactant and the effect of added surfactant on the metal complex peak is shown in Fig. 7. The added surfactant resulted in a decrease in sensitivity of the measurement but the effect was only significant at surfactant concentrations at the ppm level, rather greater than those normally present in seawater. Surfactants constitutes a serious potential interference in the method, and adsorption times should be kept short to minimize the effect. A compensation for the interference is provided by the standard addition calibration of the method.

(3) Calibration and analysis

NASS-1 and CASS-1 Reference Seawater Samples provided by the Marine Analytical Chemistry Standards Program of The National Research Council of Canada (22) were analyzed by the standard procedure with results from standard addition calibration as given in Table 1. While there are no certificate values for the element available for comparison purposes, the results obtained were in agreement with values of 2.6 μg L^{-1} (1) and 3.08 μg L^{-1} (2) recently reported for coastal seawaters. The method was found to be convenient to apply and required a minimum of handling and pretreatment of a sample. While other sorts of aqueous samples have yet to be examined, the procedure should be applicable, although experience has indicated that the presence of organic surfactants can constitute a serious interference in methods involving preconcentration by adsorption at an electrode.

^{1}H nuclear magnetic resonance studies on D-galactopyranoses with chirally deuterated hydroxymethyl groups revealed that the preferred rotamer about the C_5—C_6 bond of the D-galactopyranoses was not *tg* but *gt*. Studies on the stereochemistry of dehydrogenation of D-galactose oxidase from *Dactylium dendroides* with chirally pure deuterated methyl β-D-galactopyranosides showed that there were two mechanisms for the enzymatic reaction: an efficient *pro-S* hydrogen atom specific oxidation and a far less efficient non-specific or *pro-R* specific oxidation.

HIROSHI OHRUI, YOSHIHIRO NISHIDA, HIROKO HIGUCHI, HIROSHI HORI et HIROSHI MEGURO. Can. J. Chem. **65**, 1145 (1987).

Des études de résonance magnétique nucléaire du ^{1}H sur des D-galactopyrannoses portant des groupements hydroxyméthyles deutérés d'une façon chirale révèlent que le rotamère privilégié autour de la liaison C_5—C_6 des D-galactopyrannoses n'est pas *tg* mais plutôt *gt*. Des études sur la stéréochimie de la déshydrogénation, par l'oxydase du D-galactose provenant du *Dactylium dendroides*, de β-D-galactopyrannosides de méthyles deutérés et purs d'un point de vue chiral ont démontré qu'il existe deux mécanismes pour la réaction enzymatique; une oxydation spécifique de l'atome d'hydrogène *pro-S* qui est efficace et un oxydation non-spécifique ou spécifique *pro-R* qui est beaucoup moins efficace.

Introduction

A complete understanding of the interaction between carbohydrates and proteins (enzymes, antibiotics, and lectins) is to a large extent dependent on the information available about the preferred conformation of the carbohydrate molecule in solution (1, 2). For example, the current stereochemical concept that D-galactose residues favor the *tg* rotamer as shown in Fig. 1 (3) in the binding sites of D-galactosyl binding proteins (1) has been based mainly on the conformational analyses of methyl β-D-galactopyranoside by Lemieux and co-workers (1, 4) and of acetylated D-galactoses by Hall *et al.* (5) and Perlin and co-workers (6). The assignment of the preferred rotamer about the C_5—C_6 bond of D-galactose and its derivatives has been a controversial problem. For example, Yamana (7), by a chiroptical method, reported that the preferred rotamer was *gg*. Hall, by an ^{1}H nmr study on D-galactopyranose peracetate (5), reported it to be *tg*. On the other hand, De Bruyn suggested it to be *tg* (8) and Lemieux first assigned it to be *gt*, based on both ^{1}H nmr and chiroptical studies (9), and later corrected it to be *tg*, based on a detailed ^{1}H nmr study on methyl β-D-galactopyranoside (4). Recently Lew and Nakanishi assigned the preferred rotamer of methyl D-galactopyranoside perbenzoates to be *tg* on the basis of their "dibenzoate chirality rule" (10). Therefore *tg* has been accepted as the preferred rotamer of both acylated and OH-free D-galactopyranoses. The difficulty in the conformational analysis of the C_5—C_6 bond of D-galactopyranose by ^{1}H nmr has been ascribed to the difficulty of differentiating unequivocally the two protons, H6*proR* and H6*proS*, and of obtaining the precise coupling constants, $J_{H5,H6proR}$ and $J_{H5,H6proS}$, which is the key information needed for the study. Our recent development of syntheses of sugars with chirally deuterated hydroxymethyl groups has enabled us to differentiate the two protons and obtain the coupling constants (11–14).[4] In this paper, we would like to describe the results of our conformational analyses and the stereochemistry of oxidation by D-galactose oxidase from *Dactylium dendroides* using the chirally deuterated D-galactopyranoses as substrates.

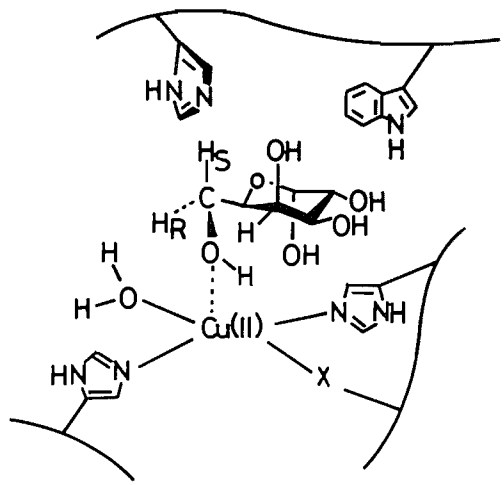

FIG. 1. The current concept of the active site of D-galactose oxidase.

Results and discussion

Previously we reported the synthesis of (6*R*)- and (6*S*)-(6-$^2H_1$)-D-galactoses through photobromination (15) of 1,6-anhydro-2,3,4-tri-*O*-benzoyl-D-galactopyranose **1** followed by

[1]Part of this study has been already reported in ref. 13.

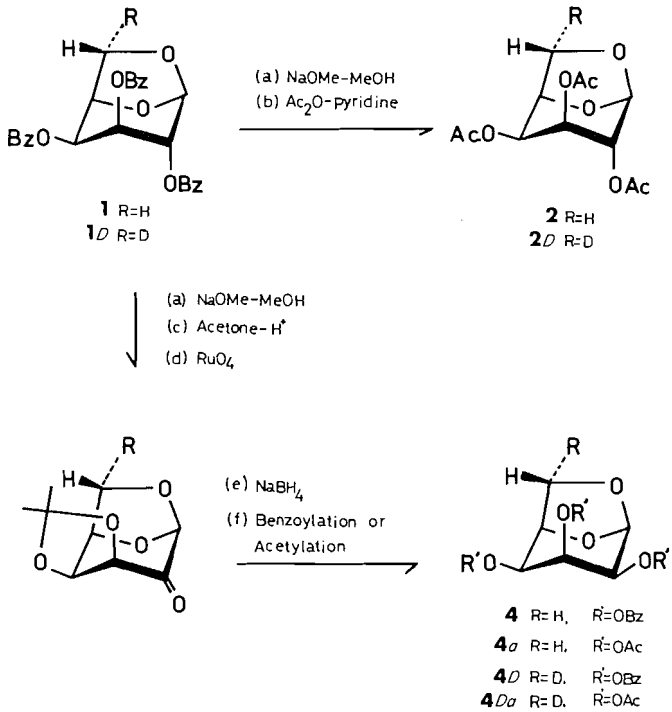
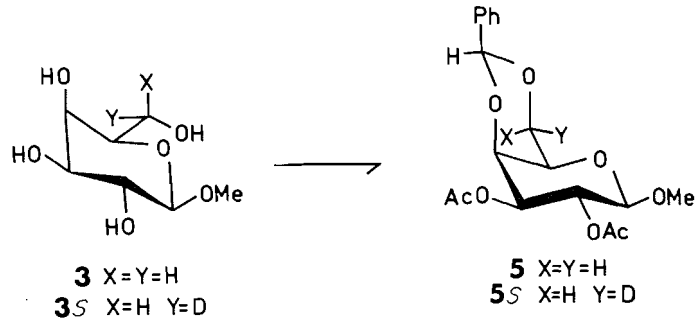
[3]Revision received October 15, 1986.

[4]The authors are very grateful to a referee for pointing out the errors in assigning the ^{1}H nmr spectrum of 1,6-anhydro-D-glucopyranose (11). The correction will be reported in another manuscript (see footnote 5).



SCHEME 1



SCHEME 2

tri-*n*-butyltindeuteride reduction of the resulting *exo*-bromide (12). Our assignments of absolute configuration of the specifically deuterated galactose derivatives have been based on the "assumption" that protons at C-6 of 1,6-anhydrohexopyranose 2,3,4-tri-*O*-benzoates, which resonate at higher field and have larger coupling constants with H-5 than the other proton at C-6, could be assigned to H-6*exo* (12), because the same findings have been reported for 1,6-anhydro-D-hexopyranoses and for their 2,3,4-tri-*O*-acetate (16, 17).

In the present paper, several other pieces of evidence that confirm the correctness of our previous assignments are presented.

Compound **1***D*, which we had assigned to (6*S*) (12), was converted to the acetate **2***D* by a conventional method (sodium methoxide in MeOH and then acetylation) (Scheme 1). In the ^{1}H nmr spectra of **2***D* the signal at 3.72 ppm, which had been assigned to H-6*exo* of nondeuterated **2** by Černý (17), disappeared completely and the doublet at 4.347 ppm, which had been assigned to H-6*endo* (17), appeared at 4.326 ppm (0.021-ppm upfield shift by deuterium isotope effect (18, 19)) as a singlet. The result supports the correctness of our previous assignments.

Next, our methyl (6*R*)-(6-^{2}H$_1$)-β-D-galactopyranoside **3***R* and methyl (6*S*)-(6-^{2}H$_1$)-β-D-galactopyranoside **3***S* were converted to the corresponding acetates **3***Ra* and **3***Sa*, respectively. The partial ^{1}H nmr spectra of **3***Ra* and **3***Sa* and nondeuterated **3***a* are shown in Fig. 2. The assignments of H6*proR* and H6*proS* are consistent with those reported by Perlin and co-workers (6). This result also supports the validity of our previous assignments. The ^{1}H nmr spectra of both **3***Ra* and **3***Sa* show the presence of a very small amount of **3***a*. This amount depends on the quality of tin deuteride used. As is observed clearly in Fig. 2, deuteration causes a 0.015-ppm upfield shift of H6*proR*, a 0.017-ppm upfield shift of H*proS*, and a 0.004-ppm upfield shift of H-5; however, *deuteration has little effect on the coupling constants*. Similar deuterium isotope-induced chemical shifts of protons have been reported by Hall and Wong (18).

Another method of assignment of H-6*exo* in 1,6-anhydrohexopyranoses is measurement of the "W" arranged long-range coupling between H-6*exo* and H-4, since only H-6*exo* can enjoy the "W" type long-range coupling (17, 20). Irradiation at 5.74 ppm of **1** sharpened the quartet of broad signals at 3.85 ppm, which we assigned to H-6*exo* (12), indicating the presence of long-range coupling in the signal of H-6*exo*. However, the result does not give us an unequivocal assignment of H-6*exo* because the chemical shifts of H-1 and H-4 are almost the same at 5.74 ppm, and long-range coupling between H-1 and H-6*exo* has been reported (16).

Therefore, compound **1** was transformed to 1,6-anhydrotalopyranose-2,3,4-tri-*O*-benzoate **4** (mp 178°C, $[\alpha]_D^{21}$ −58° (*c* 0.1, $CHCl_3$)) and tri-*O*-acetate **4***a* by the established method (20) (Scheme 1). The "W" arranged long-range coupling between H-6*exo* and H-4 of **4***a* has already been reported by Horton and Jewell (20) and a "W" arranged long-range coupling is observed between H-6 (quartet of a small doublet at 3.993 ppm) and H-4 (triplet of small doublets at 5.608 ppm) of **4**. Therefore the H-6 signal at 3.993 ppm, which has a larger coupling with H-5 than the other H-6 signal at 4.78 ppm, is assigned to H-6*exo*. Compound **1***D* was also converted to **4***D* and **4***Da*. The ^{1}H nmr spectra of **4***D* and **4***Da* showed complete disappearance of the signals for H-6*exo* protons. Therefore **4***D* and **4***Da* are unequivocally assigned to be the (6*S*)-(6-^{2}H$_1$) derivatives of **4** and **4***a*, respectively. Since all reactions used for transformations proceed with retention of configuration at C-6, **1***D* is definitively assigned to be the (6*S*)-(6-^{2}H$_1$) derivative of **1**.

To confirm further the assignment of absolute configuration of these C-6 chirally deuterated galactoses, **3** and **3***S* were converted into methyl 2,3-di-*O*-acetyl-4,6-*O*-benzylidene-β-D-galactopyranosides **5** and **5***S*, respectively, with the *gg* fixed conformation (Scheme 2).

In the ^{1}H nmr spectrum of **5**, it is reasonable to assign the more deshielded H-6 proton to H6*proS* and the more shielded one to H6*proR* because H6*proS* and H6*proR* are in equatorial and axial dispositions, respectively, with respect to the 4,6-*O*-benzylidene ring structure. Thus, in the ^{1}H nmr spectrum of **5**, the H-6 proton signals at 4.34 ppm (dd, 1.7 and 12.4 Hz) and 4.07 ppm (dd, 1.7 and 12.4 Hz) are assigned to H6*proS* and H6*proR*, respectively. In the spectrum of **5***S*, the lower field signal in that of **5** disappeared and the other appeared as a doublet at 4.06 ppm (1.7 Hz). These results also confirm our previous assignments.

All these pieces of evidence strongly confirm the assignments

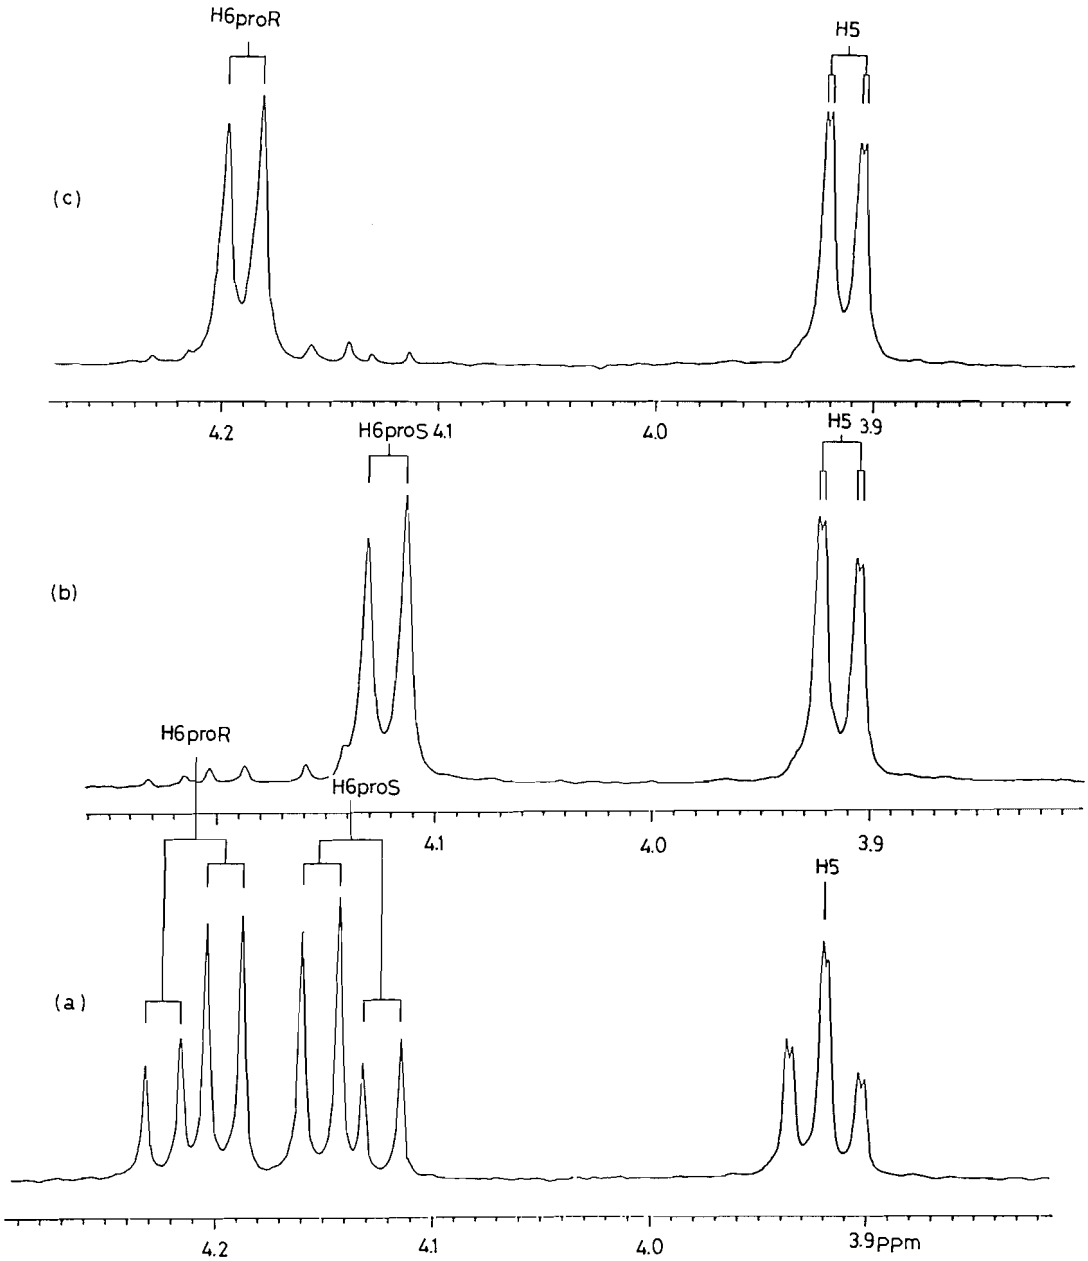

FIG. 2. The ^{1}H nmr spectra of (*a*) methyl tetra-*O*-acetyl-β-D-galactopyranoside **3***a*, (*b*) methyl (6*R*)-(6-$^2H_1$)-tetra-*O*-acetyl-β-D-galactopyranoside **3***Ra*, and (*c*) methyl (6*S*)-(6-$^2H_1$)-tetra-*O*-acetyl-β-D-galactopyranoside **3***Sa* at 400 MHz in $CDCl_3$.

of absolute configuration of the two specifically 6-deuterated galactoses made by us.[5]

The ^{1}H nmr spectra of methyl β-D-galactopyranoside **3**, methyl (6*R*)-(6-$^2H_1$)-β-D-galactopyranoside **3***R*, and methyl (6*S*)-(6-$^2H_1$)-β-D-galactopyranoside **3***S* are shown in Fig. 3 to demonstrate how the chirally deuterated sugars are useful for the study. The complex signals of H-5, H-6*proR*, H-6*proS* of **3** are dramatically simplified in the spectra of deuterated **3***R* and **3***S*. Therefore it is very easy to assign the signals and to measure $J_{H5,H6proR}$ and $J_{H5,H6proS}$. Deuterium-isotope induced upfield chemical shifts (18, 19) are also observed in these spectra. Therefore the chemical shifts of H6*proR* and H6*proS* of nondeuterated **3** should be about 0.015–0.02 ppm lower than those obtained with deuterated derivatives **3***R* and **3***S*.

So far as the data obtained by us is concerned, *a deuterium isotope effect on the coupling constants has not been observed*; therefore the coupling constants obtained with deuterated derivatives can be considered those of normal compounds.

The ^{1}H nmr parameters of **3**, **3***R*, **3***S* and their acetates **3***a*, **3***Ra*, **3***Sa*, together with those of **3** reported by Bock and Thøgersen (21) and De Bruyn (8), are listed in Table 1. Differences between our chemical shifts and theirs arise from differences in the conditions of measurement, for example the different internal standards. We used 3-(trimethylsilyl)propane-

[5]We are now very confident that the assignments of H-6 protons of 1,6-anhydrohexopyranoses can be made by the rule that the *exo* protons resonate at higher field and have larger coupling with H-5 than do the *endo* protons. This is discussed in a paper that has been submitted to the Journal of Carbohydrate Chemistry.

sulfonic acid sodium salt as 0.00 ppm and Bock and Thøgersen used acetone as 2.12 ppm.

The chemical shifts and the coupling constants by first-order analysis[6] of the stereospecifically deuterated D-galactose derivatives and those reported in the literature (6, 21), together with rough proportions of the populations of rotamers about the C_5—C_6 bond calculated by equations A devised by Rabczenko and co-workers (22), and B and C by Altona and co-workers (23, 24) are listed in Table 2. Although the two H-6 protons in the literature (21) have not been specifically assigned to H6*proR* and H6*proS*, they can be assigned unequivocally to H6*proR* and H6*proS*, respectively, by comparing their chemical shifts and coupling constants with those of the stereospecifically deuterated derivatives. Here, our value of $J_{H5,H6proS}$ of methyl β-D-galactopyranoside is revised from 6.0 (13) to 4.4 Hz, because the former value was obtained by comparing the first-order analysis of the two H-5 signals of nondeuterated compound **3** and of (6*S*)-(6-$^2H_1$) derivative **3***S* and the latter value was obtained directly from the (6*R*)-(6-$^2H_1$) derivative **3***R*.

The finding that $J_{H5,H6proS} > J_{H5,H6proR}$ in acylated derivatives and $J_{H5,HproR} > J_{H5,H6proS}$ in OH-free derivatives indicates (4, 8) that the preferred rotamer of acylated galactoses is *tg*, which is consistent with the reported results (5, 6, 10); however, the preferred rotamer of OH-free galactoses is not the previously predicted *tg* (1, 4, 6, 8), but *gt*. The same results were obtained by all three calculations except for the reported data of α-D-galactopyranose (4, 21). Although the populations of "unfavored" *gg* rotamers might be overestimated in our calculations, the not negligible contributions of *gg* will be partially rationalized in terms of the "*gauche* effect" (25).

As has been assumed (1, 2), if the conformation of the substrates in the binding sites of protein is the preferred conformation in solution, our results suggest that the *gt* rotamer should be the most plausible candidate for the galactosyl-binding protein.

The discrepancy between our result and the result previously suggested (4, 8), concerning the preferred rotamer of OH-free galactoses and chirally deuterated galactoses of high purity (99% deuterium content and no trace of diastereomer), prompted us to investigate the stereochemistry of the D-galactose oxidase reaction.

D-Galactose oxidase catalyzes the reaction:

[1] D-Galactose + O_2 → DL-galactohexodialdose + H_2O_2

The stereochemistry of D-galactose oxidase from *Polyporus circinatus* has been shown by Perlin and co-workers (6) to be a specific *pro-S* 6-hydrogen atom removal.

Methyl β-D-galactopyranoside **3**, methyl (6*R*)-(6-$^2H_1$)-β-D-galactopyranoside **3***R* (99% pure, 1% of **3**), methyl (6*S*)-(6-$^2H_1$)-β-D-galactopyranoside **3***S* (99% pure, containing 1% of **3**), and methyl (6,6-$^2H_2$)-β-D-galactopyranoside **3***DD* (99% pure, containing 1% of **3**) were used as the substrates of D-galactose oxidase (Fig. 4).

The galactose oxidase reactions were carried out under conditions similar to those reported by Perlin and co-workers (6). Acetylation and chromatographic purification (6) of the 6-aldehyde product of **3** gave three isolable products. One of

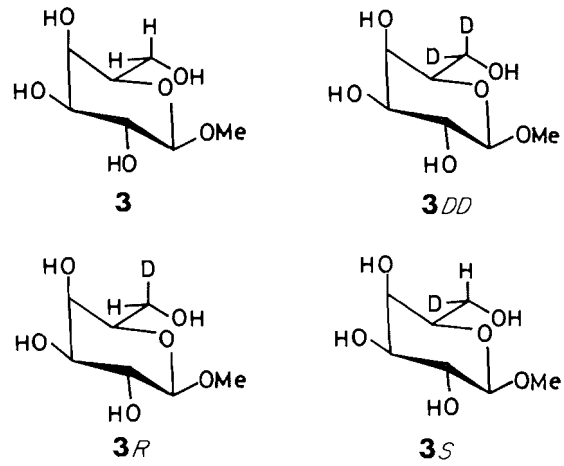

FIG. 4. Structures of substrates.

these was characterized as the known methyl 2,3-di-*O*-acetyl-L-*threo*-4-deoxyhex-4-eno-dialdopyranoside **6** (6, 26), and the others were acetylated dimers **7***a* and **7***b* of the 6-aldehyde (Fig. 5) on the basis of their ^1H nmr spectra (Table 3) and elemental analyses. The main dimer **7***a* was identified as the hexaacetate of dimeric methyl β-D-galactohexo-dialdo-1,5-pyranoside reported by Maradufu and Perlin (26).

The elemental analysis of the minor product **7***b* gave the same compositions of C, H, O as that of **7***a*. The ^1H nmr spectrum of **7***b* indicated that **7***b* had six acetyl groups and five signals that were almost the same as those of the ring protons (H_1', H_2', H_3', H_4', H_5') of the methyl D-galactopyranoside residue (ring B) of **7***a*. In **7***b*, H-4 resonates at 4.21 ppm, which is 0.19 ppm more shielded than H-4 of **7***a*; H-6′ resonates at 4.80 ppm, which is 0.21 ppm more shielded than H-6′ of **7***a* and, further, H-6 resonates at 5.91 ppm, which is 0.39 ppm more shielded than H-6 (6.22 ppm) of **7***a*. The chemical shifts of other protons of **7***b* showed little difference from those of **7***a* (in the order of −0.02 to 0.07 ppm).

All these results suggested that **7***b* has the same fundamental structure as that of **7***a*. The upfield shifts of H-4, H-6′, and H-6 indicate the change of configuration of the 6-OAc group from axial (6*R*) to equatorial (6*S*), since the change loses the 1,3-diaxial relationships between H-4, H-6′, and 6-OAc and converts H-6 from equatorial to axial configuration.

The chemical shift of H-5 of **7***b* is 3.66 ppm, which is 0.29 ppm more deshielded than that of **7***a*. Similar differences in the chemical shifts of the H-2 protons between α- and β-D-mannopyranose acetates are usually observed and reported for L-rhamnopyranose tetraacetate (27). Compound **7***a* is more dextrorotatory than **7***b*. The predominant formation of **7***a* may be rationalized in terms of the anomeric effect (26, 28). Therefore the structures of **7***a* and **7***b*, including the absolute configurations at C-6 and C-6′, are elucidated to be methyl (6*R*)-6-acetoxy-2,3-di-*O*-acetyl-4,6-*O*-[(6′*R*)-methyl-2′,3′,4′-tri-*O*-acetyl-6′-deoxy-β-D-galactopyranosid-6′-ylidene]-β-D-galactopyranoside and its (6*S*) isomer, respectively.

The ratio of the yields of **6** and **7** was a function of the enzymic reaction time, and prolonged reaction time caused the preponderant formation of the dimer **7**.

Since the structures of all isolable products were elucidated, and the H-6 signals of these products in their ^1H nmr spectra turned out to be diagnostically useful for our study, the galactose oxidase reaction with deuterated substrates was investigated.

[6]It is recognized that our coupling constants, obtained by first-order analysis, given in Table 2, and hence the rotamer populations in Table 2, are only approximately correct. The true coupling constants can only be obtained by full analysis including all spins involved.

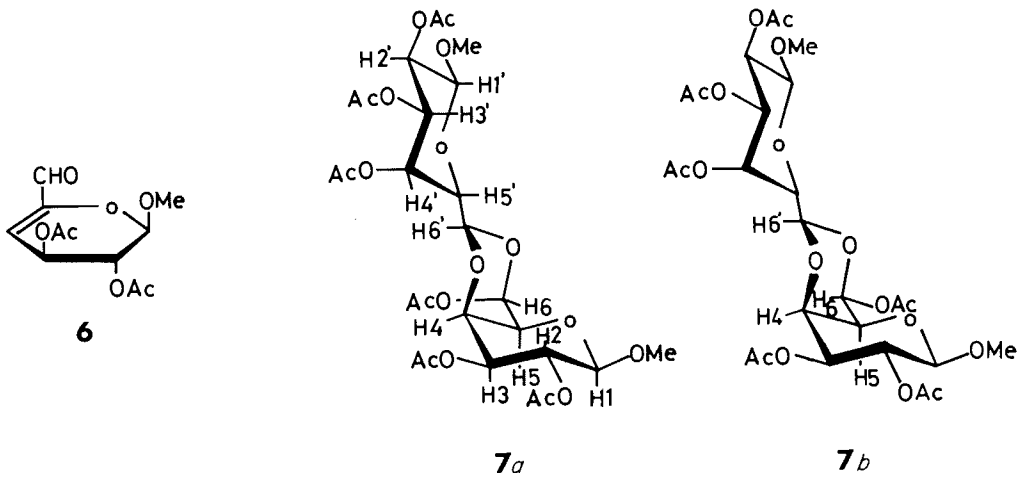

FIG. 5. Structures of the products.

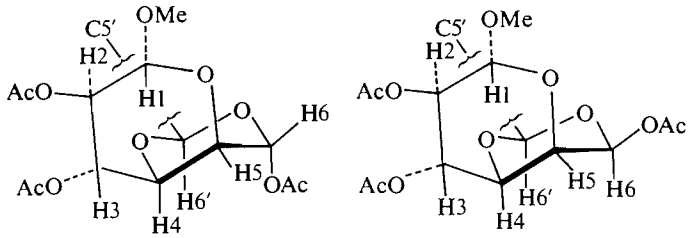
TABLE 3. Proton chemical shifts of **7***a* and **7***b*



Proton	Shift (ppm)[a] 7*a*	7*b*	Δ 7*b* − 7*a*
H1	(4.39)[b]	4.36–4.37	−0.02 to −0.03
H2	5.05–5.25 (5.18)[b]	5.05–5.25	±0
H3	4.77	4.75	−0.02
H4	(4.40)[b]	4.21	−0.19
H5	3.37 (3.39)[b]	3.66	+0.29
H6	6.22 (6.22)[b]	5.91	−0.31
H1′	(4.37)[b]	4.37	±0
H2′	5.27	5.25	−0.02
H3′	5.05–5.25 (5.08)[b]	5.05–5.25	±0
H4′	5.54 (5.55)[b]	5.54	−0.01
H5′	3.78 (3.81)[b]	3.85	+0.07 to +0.04
H6′	5.03	4.80	−0.21
OAc	1.9–2.2 (six OAc)	1.9–2.2 (six OAc)	±0

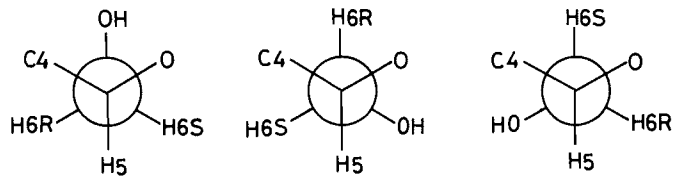
[a]Measured at 100 MHz in $CDCl_3$ at 296 K relative to internal TMS (0.000 ppm).
[b]Values quoted from ref. 26.

The relative rates of oxidation of these four substrates were first examined. Although the detailed kinetics (6) were not examined, under the same conditions it took 1.5 h for **3***R*, 3.0 h for **3**, 4.5 h for **3***S*, and more than 30 h for **3***DD* to be completely oxidized, judged by the disappearance of the starting material on tlc. Here it is interesting to note that the most favorable substrate for the enzyme is not the normal galactoside **3** but the (6*R*)-(6-$^2H_1$)-galactoside **3***R*.

The products from (6,6-$^2H_2$)-galactoside **3***DD* completely retained a deuterium atom at C-6, which indicated no exchange of hydrogen atom with the reaction medium during the reactions. The products **6**, **7***a*, and **7***b* from **3***R* contained 1% of proton at C-6, judged by both ^1H nmr and mass spectra. The results indicated the complete stereospecific removal of the *pro-S* hydrogen atom from the substrate. The products from (6*S*)-(6-$^2H_1$)-galactoside **3***S* (99% pure) retained about 80% of one proton at C-6 (loss of about 20% proton). The result indicated that the *pro-S* stereospecificity of the enzyme was substantially retained for the substrate but some of the *pro-R* hydrogen atoms were removed.

The above results can be rationalized as follows: There are two mechanisms by which the enzyme can oxidize the substrate; one is a very efficient *pro-S* hydrogen specific removal mechanism and the second is a far less efficient non-specific or *pro-R* hydrogen specific removal mechanism, which does not work detectably for the *pro-R* deuterium because of its inefficiency (see isotope effect (6) and the reaction rates (*vide supra*)).

The difference between the stereospecificity of the galactose oxidase oxidations of Perlin (6) and ourselves might be attributed to the difference in the origins of the enzymes.



Here, the plausible conformation of D-galactose residues in the binding site of D-galactose oxidase should be discussed based on the above results. Although Fig. 1 explains the selective removal of the *pro-S* 6-hydrogen atom, the *tg* conformation is somewhat questionable because of the following: (1) The preferred rotamer of D-galactose is not *tg* but *gt*. (2) In the *tg* conformation, the more acidic hydrogen atom of 4-OH is accessible to the imidazole group, resulting in the deactivation of the imidazole group (Fig. 6). (3) Since the assignments of H6*proR* and H6*proS* have been mistaken (4, 8), the proton that has been assigned as axial by ^{13}C and ^{19}F nmr relaxation experiments (3) would not be H6*proS* but H6*proR*. If this is the case, these nmr experiments indicate also that the preferred rotamer of D-galactose is *gt*.

It has been known that 4-deoxy-D-galactose (4-deoxy-D-glucose) is a fairly good substrate for the enzyme, indicating

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

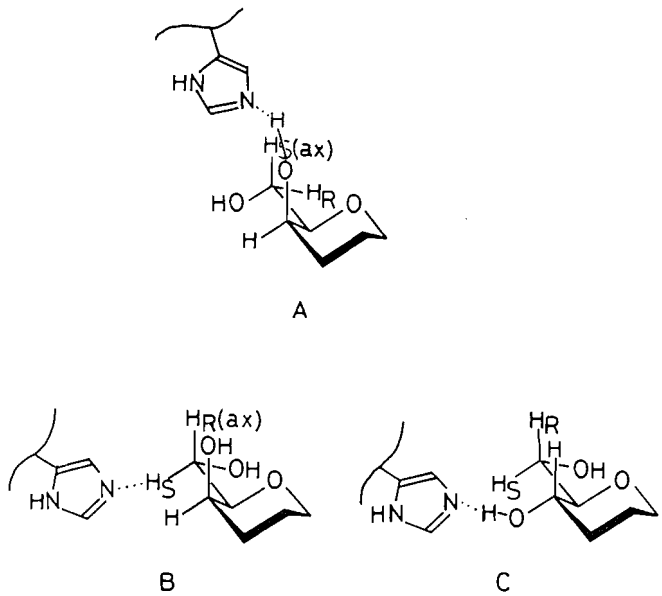


FIG. 6. Possible conformation of hexopyranose residues in the binding site of D-galactose oxidase; A, *tg* rotamer of D-galactose; B, *gt* rotamer of D-galactose; and C, *gt* rotamer of D-glucose.

that the 4-OH of D-galactose is not an important factor in the sugar being a substrate, but D-glucose is not a substrate at all, indicating that the 4-OH of D-glucose (equatorial 4-OH) should not be present if the sugar is to be the substrate of the enzyme (3). If the hydroxymethyl groups of the hexopyranoses are oxidized in the *gt* conformation as shown in Fig. 6, the above problems are solved, and the fact that D-glucose is not the substrate will be rationalized as follows (of course other steric factors have to be taken into account): In the *gt* conformation the more acidic hydrogen atom of the 4-OH of D-glucose, which is in 1,3-*syn*-diaxial relation with the *pro-S* 6-hydrogen, is accessible to the imidazole and reacts much faster than the *pro-S* 6-hydrogen, resulting in no oxidation of the hydroxymethyl group. Therefore, the *gt* conformation is recommended as a more plausible rotamer of D-galactose than *tg* in the binding sites of the enzyme.

Our results show that chirally pure deuterated sugars are very useful for both ^{1}H nmr studies of carbohydrates and stereochemical studies of enzymatic reactions. Studies along this line are being undertaken in our laboratory.

Experimental

Melting points were taken with a Yanako Model P hotplate apparatus and were uncorrected. The ^{1}H nmr spectra were recorded on JEOL JNM-FX 100 or JEOL FX 400 instruments with TMS as an internal standard in $CDCl_3$, or with 3-(trimethylsilyl)propanesulfonic acid sodium salt as an internal standard in D_2O. Direct mass spectra were recorded on a Hitachi M-52 spectrometer with the ionizing potential at 70 eV. Specific rotations were measured on a Jasco ORD/UV at 589 nm. Merck silica gel 60 (Art. 7734) was used for column chromatography and Merck silica gel 60 F_{254} (Art. 5548) was used for both preparative and analytical thin-layer chromatographies (tlc).

Materials

The substrates **3***R* and **3***S* were prepared from the corresponding (6*R*)-(6-$^2H_1$)- and (6*S*)-(6-$^2H_1$)-D-galactoses (12, 13), respectively, according to conventional methods (6). D-Galactose oxidase (EC 1.1.3.9.) Type V from *Dactylium dendroides* and catalase from bovine liver were purchased from Sigma Chemical Company.

*1,6-Anhydro-2,3,4-tri-O-benzoyl-D-talopyranose (**4**)*

To a solution of 1,6-anhydrotalopyranose (20) (1.7 g) in dry pyridine (50 mL) was added benzoyl chloride (10 g). After the mixture had been stirred for 12 h at room temperature, water (50 mL) was added to the reaction mixture and it was stirred for 2 h. The mixture was extracted with $CHCl_3$ (25 mL × 3) and the $CHCl_3$ layer was successively washed with water, saturated $NaHCO_3$, and water and then dried over $MgSO_4$. Evaporation of the solvent gave a syrup, which was crystallized from ethyl ether – hexane to give **4** (4.5 g, 90%); mp 178°C; $[\alpha]_D^{21}$ −58° (*c* 0.1, $CHCl_3$).

*Methyl 2,3-O-acetyl-4,6-O-benzylidene-β-D-galactopyranoside (**5**) and its (6S)-(6-$^2H_1$) derivative (**5S**)*

A solution of **3** (500 mg, 2.6 mmol), benzaldehyde dimethyl acetal (1 g, 6.6 mmol), and *p*-toluenesulfonic acid (5 mg) in *N*,*N*-dimethylformamide (20 mL) was stirred for 1 h at 55–60°C under reduced pressure (water pump) to remove methanol from the reaction mixture. To the stirred solution was added anhydrous sodium acetate (100 mg), pyridine (20 mL), and acetic anhydride (5 mL), and the suspension was stirred overnight at room temperature. The tlc analysis of the reaction mixture indicated the formation of two products (R_f 7.4, minor, and R_f 6.8, main; benzene/ethyl acetate 8:1, v/v). The mixture was evaporated *in vacuo* and the residue was chromatographed on a silica gel column with a mixture of benzene and ethyl acetate (50:1, v/v) to give methyl 2,3-di-*O*-acetyl-4,6-*O*-benzylidene-β-D-galactopyranoside **5** (480 mg, 50%), mp 148–150°C; $[\alpha]_D^{23}$ +65.2° (*c* 1.1, $CHCl_3$). ^{1}H nmr (δ(ppm, $CDCl_3$)): 4.44 (1H, d, 8.0 Hz, H-1), 5.39 (1H, dd, 8.0 and 10.4 Hz, H-2), 4.96 (1H, dd, 3.6 and 10.4 Hz, H-3), 4.38 (1H, br d, ≅3.6 Hz, H-4), 3.5 (1H, br s, H-5), 4.07 (1H, dd, 1.7 and 12.4 Hz, H6*proR*), 4.34 (1H, dd, 1.7 and 12.4 Hz, H6*proS*), 3.52 (3H, s, OMe), 5.51 (1H, s, Ph-CH), 2.07 (6H, s, OAc). *Anal.* calcd. for $C_{18}H_{23}O_8$: C 58.84, H 6.31; found: C 58.71, H 6.13. Also obtained was methyl 2,6-di-*O*-acetyl-3,4-*O*-benzylidene-β-D-galactopyranoside (70 mg, 7%), mp 132–143°C; $[\alpha]_D^{23}$ +16.8° (*c* 0.8, $CHCl_3$). ^{1}H nmr (δ(ppm, $CDCl_3$)): 4.35 (1H, d, 7.7 Hz, H-1), 5.11 (1H, dd, 5.5 and 7.7 Hz, H-2), 4.51 (1H, dd, 5.5 and 6.5 Hz, H-3), 4.22 (1H, dd, 2.0 and 6.5 Hz, H-4), 3.98 (1H, q, 2.0, 5.6 and 7.7 Hz, H-5), ≅4.4 (2H, H-6,6′). *Anal.* calcd. for $C_{18}H_{23}O_8$: C 58.84, H 6.31; found: C 59.10, H 6.22.

The (6*S*)-(6-$^2H_1$) derivative (**5***S*) of **5** was obtained by the same procedures as described for **5**. The physical data of **5***S* are essentially the same as those of **5** except for the chemical shifts of H6*proR* (δ 4.06) and H5 (δ 3.49).

Oxidation of methyl β-D-galactopyranosides with D-galactose oxidase

In a typical experiment, the substrate (40 mg) was dissolved in phosphate buffer (4 mL:0.1 *M*, pH 6.0) and incubated with D-galactose oxidase (5 mg, 350 units) and catalase (5 mg) at 28°C. The reaction was monitored by tlc (*n*-propanol:acetic acid:water 6:1:2, v/v). The reaction was stopped when the tlc showed the complete disappearance of the substrate (R_f 0.58) and the formation of main product (R_f 0.69) (it took 1.5 h for **3***R*, 3.0 h for **3**, 4.5 h for **3***S*, and more than 30 h, i.e., usually did not complete, for **3***DD*). A mixture of Amerlite IR-120 (H^+) and Dowex-1 (bicarbonate) was added to the digest with stirring, and it then was lyophilized. The product (40 mg) was treated with pyridine (1 mL) and acetic anhydride (0.5 mL) at room temperature overnight, the reaction mixture was concentrated, and the syrupy residue was chromatographed on a column of silica gel (5 g). Elution with a mixture of benzene and ethyl acetate (10:1, v/v) afforded methyl 2,3-di-*O*-acetyl-α-L-*threo*-4-deoxyhex-4-eno-dialdopyranoside **6** as a syrup (4 mg) (R_f 0.75, benzene:ethyl acetate 10:1, v/v). The subsequent elution with a mixture of benzene and ethyl acetate (3:1, v/v) afforded a mixture of **7***a* and **7***b* (18 mg). The mixture was separated by preparative tlc using a mixture of $CHCl_3$ and MeOH (70:1, v/v, three developments) to give a crystalline **7***a* (9 mg), mp 204–205°C, $[\alpha]_D^{22}$ +38.4° (*c* 0.07, EtOH) (lit. (26) mp 206–208°C; $[\alpha]_D^{22}$ +41.6° (*c* 2.1, $CHCl_3$)). *Anal.* calcd. for $C_{26}H_{36}O_8$: C 49.00, H 5.70; found: C 49.08, H 5.95; and **7***b* (3 mg), mp 130–131°C; $[\alpha]_D^{22}$ ±0° (*c* 0.04, EtOH). *Anal.* calcd. for $C_{26}H_{36}O_{18}$: C 49.00, H 5.70; found: C 49.25, H 6.00.

The (6,6′-$^2H_2$) derivative of **7***a*, obtained by oxidation of **3***DD*, had

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

mp 208–210°C; $[\alpha]_D^{22}$ +45.5° (*c* 0.05, EtOH) (lit. (26) mp 210–211°C; $[\alpha]_D^{22}$ +47° (*c* 0.4, $CHCl_3$)).

Oxidation of **3** R *and* **3** S

Oxidation of **3***R* gave the same products as with **3***DD*. Oxidation of **3***S* gave mixtures of **6** and the (6-$^2H_1$) derivative of **6**, and of **7***a* and the (6,6′-$^2H_2$) derivative of **7***a* in ratios ca. 80:20 judged by both ^{1}H nmr and mass spectroscopies.

Acknowledgements

The authors are most grateful to Dr. J. Uzawa of the Institute of Physical and Chemical Research for the 400-MHz ^{1}H nmr and to Mrs. Chieko Suzuki for the 100-MHz ^{1}H nmr spectra. Structure of 5,5-dimethyl-2-phenylimino-Δ^3-1,3,4-thiadiazoline from oxidative cyclization of a thiosemicarbazone

R. FAGGIANI, M. KAMINSKI, C. J. L. LOCK,[1] AND J. WARKENTIN[1]

Department of Chemistry and Institute for Materials Research, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 7, 1986[2]

R. FAGGIANI, M. KAMINSKI, C. J. L. LOCK, and J. WARKENTIN. Can. J. Chem. **65**, 1154 (1987).

The X-ray crystal structure of 5,5-dimethyl-2-phenylimino-Δ^3-1,3,4-thiadiazoline, $C_{10}H_{11}N_3S$, has been determined. The compound is monoclinic, $P2_1/c$ (No. 14), with $a = 13.200(5)$, $b = 6.340(4)$, and $c = 13.823(4)$ Å, $\beta = 113.50(4)°$, and $Z = 4$. The structure was determined by direct methods and refined to $R = 0.061$, $R_w = 0.067$ for 1277 unique reflections. The molecule has the *Z* configuration. The thiadiazoline ring is planar. C—N and N=N bond lengths are within the normal range. The C—S bond lengths are similar to those we have observed previously in thiazolidines. Angles differ markedly from an expected average 108°. The small C—S—C angle (90.6(2)°) is accompanied by larger C—N=N angles (114.9(3), 117.8(3)°). The phenyl ring is not coplanar with the thiadiazoline ring (dihedral angle 38.6(4)°) because of repulsive interaction of the phenyl *o*-hydrogen atom with the sulphur atom.

R. FAGGIANI, M. KAMINSKI, C. J. L. LOCK et J. WARKENTIN. Can. J. Chem. **65**, 1154 (1987).

On a déterminé la structure cristalline de la diméthyl-5,5 phénylimino-2 Δ^3-thiadiazoline-1,3,4, $C_{10}H_{11}N_3S$, par diffraction des rayons-X. Le composé est monoclinique, $P2_1/c$ (N° 14), avec $a = 13,200(5)$, $b = 6,340(4)$ et $c = 13,823(4)$ Å, $\beta = 113,50(4)°$ et $Z = 4$. On a déterminé la structure par des méthodes directes et on l'a affinée jusqu'à des valeurs de $R = 0,061$ et $R_w = 0,067$ pour 1277 réflexions indépendantes. La molécule possède une configuration *Z*. Le noyau thiadiazoline est plan et les longueurs des liaisons C—N et N=N sont dans les limites normales. Les longueurs des liaisons C—S sont semblables à celles qui ont été observées antérieurement dans les thiazolidines. Les angles divergent toutefois considérablement de la valeur moyenne prévue de 108°. L'angle C—S—C qui est petit (90,6(2)°) est accompagné d'angles C—N=N qui sont plus grands (114,9(3) et 117,8(3)°). Le noyau phényle n'est pas coplanaire avec le cycle thiaziazoline (angle dièdre de 38,6(4)°) à cause de l'interaction répulsive de l'atome d'hydrogène en *ortho* du phényle avec l'atome de soufre.

[Traduit par la revue]

Introduction

Oxidation of semicarbazones (1–3),[3] thiosemicarbazones (3, 4), guanylhydrazones (5), carbohydrazones (6), and thiocarbohydrazones (6) of ketones (**1**) affords heterocycles **2** and (or) **3**, eq. [1], depending on the reaction conditions. The structures of the products were inferred from analytical and spectroscopic data and, for the cases of **2***b* (Y = *p*-C_6H_4Br, $R^1 = R^2 = CH_3$), **2***h* (3), **3***b* (Y = C_6H_5, $R^1 = R^2 = CH_3$) (3), and **3***c* (Y = C_6H_5, $R^1 = R^2 = CH_3$) (3), these were confirmed by X-ray crystallography. Crystal structures are particularly important for elucidating the complete structures of **2**, which can have either the *E* or the *Z* configuration at the exocyclic nitrogen. In both cases (**2***b*, **2***h* above) the material obtained from oxidation of the appropriate semicarbazone with lead tetraacetate had the *Z* configuration (3, 7). For other members of the family **2**, namely, iminothiadiazolines **2***c*, **2***g* and iminotriazolines **2***e*, the configurations were still uncertain although the *Z* configurations might appear to be the more likely, assuming that similar mechanisms are involved in the oxidative cyclizations. However, for the iminothiadiazolines, the mechanistic analogy is weak because they are prepared (4) by oxidation on manganese dioxide, whereas the others are prepared by oxidation in homogeneous solution with lead tetraacetate.

We now report the crystal structure for one of the type **2***c* (Y = C_6H_5, $R^1 = R^2 = CH_3$), which we designate **A** and which not only confirms the *Z* configuration but also permits extension of the comparisons of **2** and **3**, particularly of the bond lengths and angles at C(2) of the ring, begun by Katritzky *et al.* (3). Moreover, the complete structure of **A** provides a basis for reducing the number of likely geometric isomers for some of Landquist's thiadiazolines (4*a*) from four to two.

Experimental

The compound 5,5-dimethyl-2-phenylimino-Δ^3-1,3,4-thiadiazoline, **A**, was prepared by the method of Landquist (4). Crystals

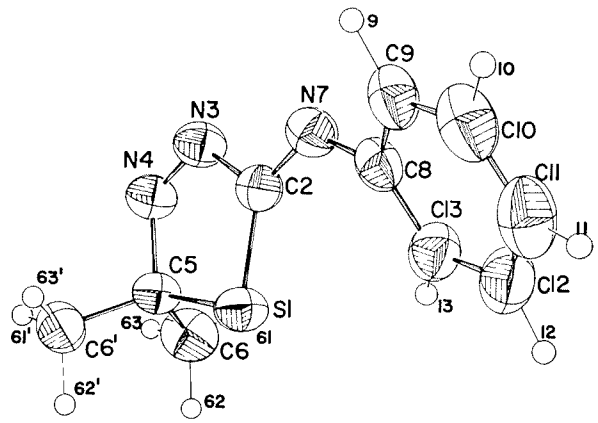

FIG. 1. The molecule of **A**, showing the atom numbering. Hydrogen atoms are shown by affixes only, in smaller numbers.

were prepared by crystallization from petroleum ether (60–80°). The crystals were pale yellow needles. Precession photographs of one, mounted along the long axis, revealed the monoclinic symmetry, and unit cell parameters were obtained from the least-squares fit of χ, φ, and 2θ for 15 reflections in the range 19° < 2θ < 30°, measured on a Nicolet P3 diffractometer with graphite monochromatized MoKα$_1$ radiation (λ = 0.70926 Å). Crystal data and other numbers related to data collection are summarized in Table 1. The density was obtained by flotation in aqueous zinc bromide solution. Intensities were also measured on the P3 diffractometer with use of a coupled θ(crystal) – 2θ(counter) scan. The methods of selection of scan rates and initial data treatment have been described (8, 9). Corrections were made for Lorentz and polarization effects but not for absorption. This will introduce a maximum error in F_o of <1.5%.

The phases were determined by direct methods with use of 50 reflections with $|E| > 1.255$ and 12 sets of starting phases. All non-hydrogen atoms were found in the subsequent E map. Subsequent refinement and electron density difference syntheses revealed the hydrogen atoms. At this stage, the temperature factors for all non-hydrogen atoms were made anisotropic. Further refinement with full-matrix least squares, which minimized $\Sigma w(|F_o| - |F_c|)^2$, was continued with four cycles varying all parameters except the hydrogen atom temperature factors, and was terminated after another two cycles in which only parameters for non-hydrogen atoms were varied and when the maximum shift/error had fallen below 0.03. Corrections were made for secondary extinction by the method of SHELX.[4] Scattering curves were taken from ref. 10, and anomalous dispersion

[4]All calculations were carried out on a CYBER 170-815 computer. Programs for initial data treatment were from the XRAY 76 package (ref. 22). The structure was solved with SHELX (ref. 23). Planes, and dihedral and torsional angles were calculated by using NRC-22 (ref. 24). Diagrams were prepared with ORTEP II (ref. 25).

TABLE 3. Selected interatomic distances and angles

Atoms	Distance (Å)	Atoms	Distance (Å)	Atoms	Distance (Å)
S1—C2	1.745(5)	C2—N3	1.465(4)	N3—N4	1.236(5)

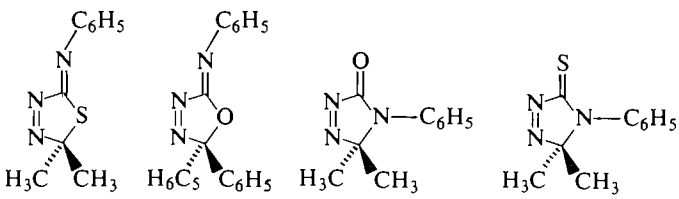
corrections from ref. 11 were applied to the curve for sulphur. The atom parameters are listed in Table 2.[5]

Discussion

The molecule is shown in Fig. 1 and bond lengths and angles are given in Table 3. The molecule has the *Z* configuration. In this configuration, H13 on the phenyl ring interacts repulsively with S1 (S1...H13 = 2.73(5) Å vs. van der Waals distance of 3.0 Å (12)) and the strain is relieved by rotating the plane of the phenyl ring with respect to the plane of the thiadiazoline ring (dihedral angle 38.6(4)°), by the large S1—C2—N7 angle (133.2(3)°), and by increasing the N7—C8—C13 angle (124.9(3)°) at the expense of the N7—C8—C9 angle (115.7(3)°) from the ideal 120°. A similar effect is found in 5,5-diphenyl-2-phenylimino-Δ^3-1,3,4-oxadiazoline, **B** (or **2***h*) (3). Katritzky *et al.* (3) have also examined the structures of similar compounds 3,3-dimethyl-4-phenyl-Δ^1-1,2,4-triazoline-5-one, **C**, and 3,3-dimethyl-4-phenyl-Δ^1-1,2,4-triazoline-5-thione, **D**.



A **B** **C** **D**

The thiazolidine ring is planar, within the errors, although exocyclic N7 is significantly out of the plane of the ring (0.062(4) Å). C2—N3, C5—N4, and N3—N4 are within the normal range for C—N single and N=N double bonds (13). C2—S1 (1.745(5) Å) is significantly shorter than C5—S1 (1.827(4) Å), and the former distance lies outside the range we have observed in thiazolidine rings (1.784(5)–1.869(6) Å) (14, 15). The difference is in the expected direction since an sp^2 carbon atom is smaller than an sp^3 carbon atom (0.743 vs. 0.763 Å) (16). The difference is greater than expected, however, and the distances are respectively shorter and longer than the distances calculated from covalent radii (1.783, 1.803 Å) (13, 16). There may be some delocalization of the S1 nonbonding electrons into the C2—N7 bond and consequent further shortening of the S1—C2 bond. C2—N7 and N7—C8 are in the normal range (13), as are bond lengths or angles involving methyl or phenyl groups attached to the tetrahedral ring carbon in **A**–**D**. The deviation of the internal ring angles at this carbon atom (range 101.1(2)°–106.2(3)°) from the tetrahedral angle is compensated for by the larger C(exocyclic)—C(ring)—C(exocyclic) angle (range 112.0(4)°–116.8(6)°) for the exocyclic methyl or phenyl groups. The internal ring angle at sulphur in **A** (C2—S1—C5, 90.6(2)°) is much smaller than that observed at oxygen in **B** (107.3(5)°) or at nitrogen in **C** and **D** (110.6(2)°, 110.7(2)°). It is also marginally smaller than C—S—C angles we have observed in thiazolidine rings (range 92.4(2)°–95.4(3)°) (14, 15). Nevertheless, it lies well within the range of C—S—C angles observed in five-membered rings since the earliest X-ray studies (range 83°–95° (17–21). The small C—S—C angle is accompanied by an increase in the ring

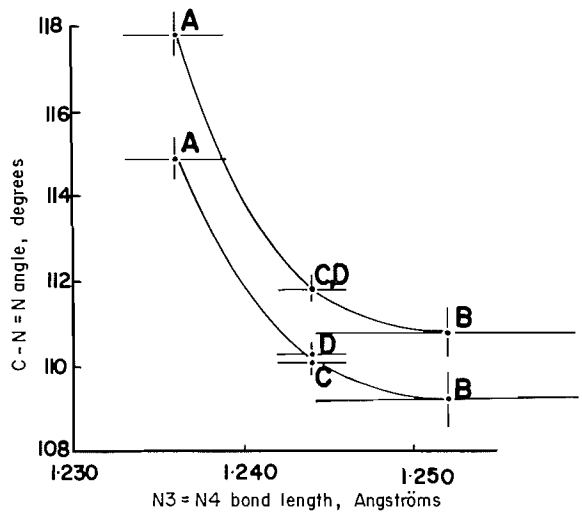


FIG. 2. The relationship between the N3=N4 bond and the C—N=N angles. The upper set represents the C5—N4=N3 angles and the lower set the C2—N3=N4 angles. The error bars are one e.s.d. Points **A**–**D** are for the molecules shown as **A**–**D** in the text.

[5]Lists of anisotropic temperature factors, hydrogen atom positional parameters, bond lengths and angles involving hydrogen atoms, best planes, dihedral and torsional angles, and a listing of the moduli of the observed and calculated structure factors may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont. Canada K1A 0S2.

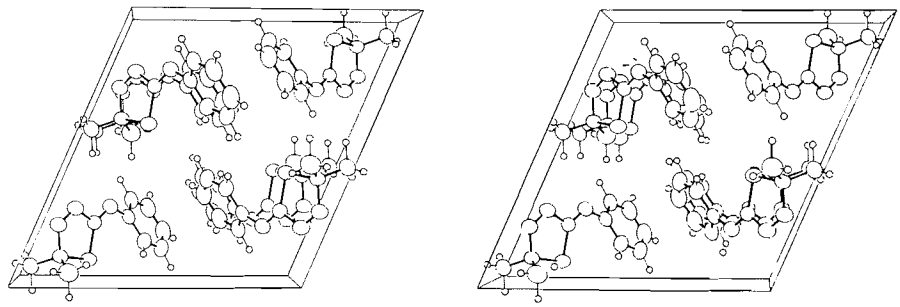

FIG. 3. The packing of **A** within the unit cell. **a** and **c*** are parallel to the bottom and sides of the page and the view is down **b**.

angles at the azo nitrogen atoms rather than at the carbon atoms (Δ = **A** minus **B**); (N3, $\Delta = +4.8°$, N4, $\Delta = +7.0°$) (C2, $\Delta = +0.5°$, C5, $\Delta = +3.5°$). In **C** and **D** the changes at carbon and nitrogen atoms are comparable. We postulate that the angular change occurs at the nitrogen atoms rather than at the carbon atoms because the strain in **B** is greater at these points. The relaxation of this strain in **A** causes a change which brings the C—N=N angles much closer to the expected 120°. One might expect that a relaxation of the angular strain at the nitrogen atoms will cause the N3—N4 bond to strengthen. This distance differs from **A** to **B** by 1.70σ ($\sigma = (\sigma_1^2 + \sigma_2^2)^{1/2}$), which is significant only at the 90% confidence level. Nevertheless, a plot of ring angles at the nitrogen atoms vs. N—N bond length suggests that such a relationship exists (Fig. 2).

The packing of the molecules in the unit cell is shown in Fig. 3. Surprisingly, there is no evidence of any $\pi-\pi$ interactions between the phenyl rings or the phenyl rings and the N=C—N=N system. The packing does not allow this and all interactions are van der Waals.

The *Z* configuration of **A**, expected on the basis of analogy to the oxadiazoline analogue, but not previously established, nicely explains Landquist's finding (4*a*) that only two isomeric 1,3,4-thiadiazolines are obtained by cyclization of 4-substituted thiosemicarbazones of ketones such as 2-methylcyclohexanone. Presumably those isomers are different in configuration at C5 of the thiadiazoline ring, as assumed by Landquist, and not *E*,*Z*-isomers at the exocyclic nitrogen.

An improved synthesis of 1,3-dihydro-1-methyl-5-phenyl-2*H*-pyrido[3,4-*e*]-1,4-diazepin-2-one via *ortho*-directed lithiation of 3-*tert*-butyl and 3-*tert*-butoxycarbonylaminopyridine

CHARLES Y. FIAKPUI AND EDWARD E. KNAUS[1]

Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alta., Canada T6G 2N8

Received July 8, 1986

CHARLES Y. FIAKPUI and EDWARD E. KNAUS. Can. J. Chem. **65**, 1158 (1987).

The *ortho*-directed lithiation of 3-*tert*-butyl- or 3-*tert*-butoxycarbonylaminopyridines (**3**) with alkyllithiums and reaction with *N*,*N*-diethylbenzamide followed by acid hydrolysis gave 3-amino-4-benzoylpyridine (**6**) in good yield. Reaction of BTBO with the glycine derivatives **7***a*, *b* and then reaction with **6** afforded 3-alkoxycarbonylaminomethylcarbonylamino-4-benzoylpyridines **8***a*, *b*. Acid-catalyzed hydrolysis and cyclization of **8***a*, *b* yielded **9**, which on methylation gave 1,3-dihydro-1-methyl-5-phenyl-2*H*-pyrido[3,4-*e*]-1,4-diazepin-2-one (**10**) in 36% overall yield from **3***a*.

CHARLES Y. FIAKPUI et EDWARD E. KNAUS. Can. J. Chem. **65**, 1158 (1987).

La lithiation en position *ortho* des *tert*-butyl- ou *tert*-butoxycarbonylamino-3 pyridines (**3**) par les alkyllithiens ou leur réaction avec du *N*,*N*-diéthylbenzamide, suivie d'une hydrolyse acide, conduisent à l'amino-3 benzoyl-4 pyridine (**6**) avec de bons rendements. La réaction du BTBO avec les dérivés **7***a*, *b* de la glycine, suivie d'une réaction avec le composé **6**, conduit aux alkoxycarbonylaminométhylcarbonylamino-3 benzoyl-4 pyridines (**8***a*, *b*). L'hydrolyse acido-catalysée des composés **8***a*, *b*, suivie d'une cyclisation, conduit au composé **9** qui, par méthylation, fournit la dihydro-1,3 méthyl-1 phényl-5 2*H*-pyrido[3,4-*e*] diazépine-1,4 one-2 (**10**), avec un rendement global de 36% à partir du composé **3***a*.

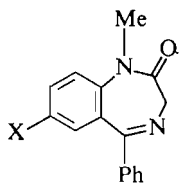
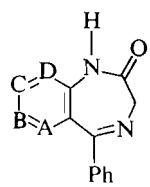
Introduction

The 1,4-benzodiazepin-2-ones **1** are a clinically useful class of compounds that exhibit a wide spectrum of powerful effects on the central nervous system, including anxiolytic, sedative, hypnotic, anticonvulsant, and muscle relaxant properties (1). Although it is known that an electronegative X substituent at C-7 of **1** is required for high potency (1), very few electronically analogous pyrido-1,4-diazepin-2-ones **2** have been investigated. Methods for the synthesis of **2** are often laborious, of narrow applicability, require the relatively inaccessible aminopyridinecarboxylic acid precursors, and provide low overall yields (2). Although **2***c* has been reported, no experimental details were provided (2). An efficient synthesis of **2***c*



1



2

a, A = N; B, C, D = CH
b, B = N; A, C, D = CH
c, C = N; A, B, D = CH
d, D = N; A, B, C = CH

and the 4-benzoyl-3-aminopyridine derivatives **4**–**6** and **8** was required for the synthesis of bicyclic and monocyclic reduced pyridyl analogues for other studies in our drug design program. The regioselective *ortho*-directed metallation of 3-substituted pyridines possessing pivaloylamino (3), dialkylaminocarbonyl (4), O-carbamate (5), 4,4-dimethyl-2-oxazolinyl (6), and halogeno (7) substituents is a versatile method for the synthesis of 3,4-disubstituted pyridines. *Ortho*-lithiation of 2- and 4-*tert*-butoxycarbonylaminopyridine has been utilized for the synthesis of 3-substituted-2-aminopyridines (8) and 3-substituted-4-aminopyridines (9), respectively. We now report an improved synthesis of 1,3-dihydro-1-methyl-5-phenyl-2*H*-pyrido[3,4-*e*]-1,4-diazepin-2-one (**10**) using *ortho*-directed lithiation of 3-*tert*-butyl- or 3-*tert*-butoxycarbonylaminopyridine (**3**).

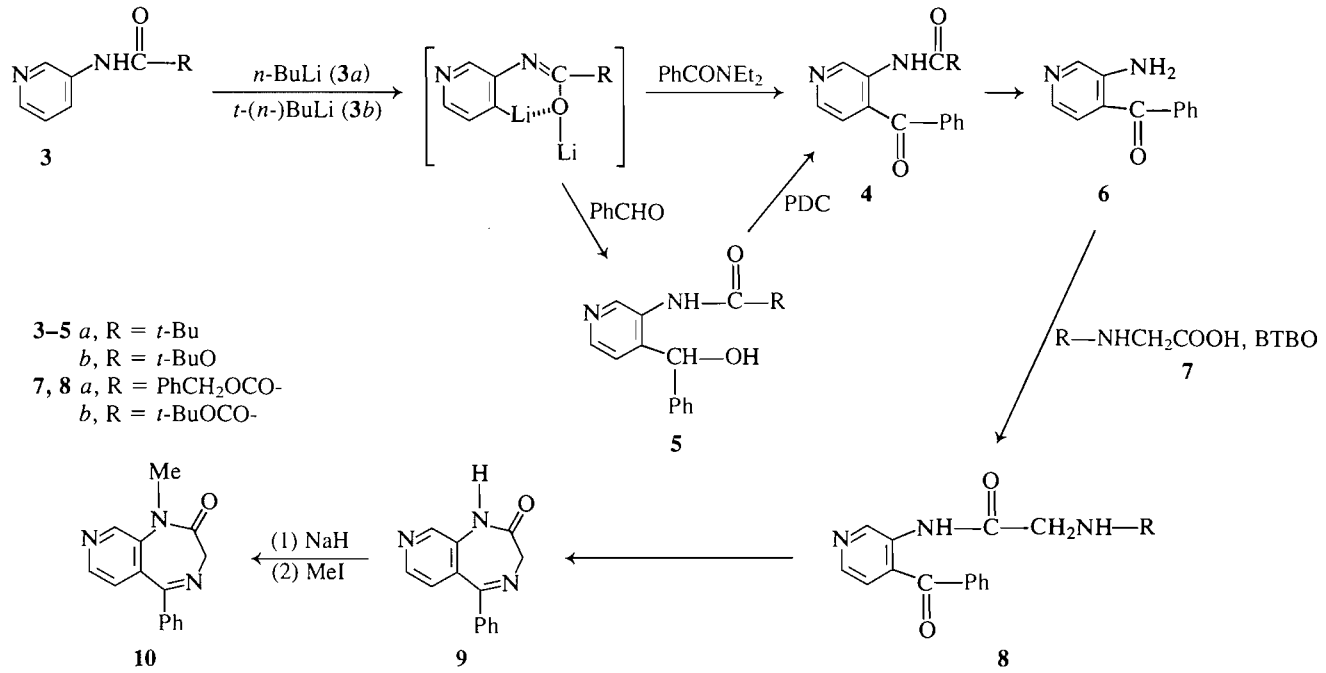
Results and discussion

Lithiation of 3-*tert*-butylcarbonylaminopyridine (**3***a*) in THF using *n*-butyllithium and reaction with *N*,*N*-diethylbenzamide yielded 3-*tert*-butylcarbonylamino-4-benzoylpyridine (**4***a*, 70% yield, Scheme 1). Recent reports have suggested that clean metallation of **3***a* is not possible with *n*-butyllithium in THF (3*b*, 10), that specific conditions (THF, Et_2O, TMEDA, 20°C) are required for optimum yields of 50–60% (3*b*), or that C-4 metallation was competitive with nucleophilic attack by the metallation reagent at C-4 (3*a*). Other metallating agents such as lithium diisopropylamide and methyllithium lead neither to *ortho*-lithiation nor nucleophilic addition to the nucleus (3*b*). Alternatively, **4***a* was prepared less efficiently by a multiple step reaction sequence, involving *ortho*-lithiation of **3***a* with *n*-butyllithium, reaction with benzaldehyde, and oxidation of **5***a* with pyridinium dichromate.[2] A similar *ortho*-lithiation of 3-*tert*-butoxycarbonylaminopyridine (**3***b*),[3] using *tert*-butyllithium or *n*-butyllithium, in THF followed by reaction with *N*,*N*-diethylbenzamide as described previously, afforded **4***b* in 65 and 63% yield, respectively. There was no evidence of metallation at any position other than C-4 nor of any nucleophilic addition of the metallating agent to the pyridine ring. The 3-*tert*-butoxycarbonylamino substituent of **3***b* is therefore an example of a single electron-donating substituent that is capable of inducing *ortho*-lithiation of **3***b* by a "coordination-only" mechanism (3*a*). In contrast, reaction of pyridines possessing such electron-attracting substituents as cyano, diethylaminocarbonyl, and oxazolinyl at C-3, with nucleophilic alkyllithium reagents, yielded 1,2-, 1,4-, and (or) 1,6-dihydropyridine products where proton abstraction was superseded by nucleophilic addition to the pyridine ring (6, 12).

[1]Author to whom correspondence may be addressed.

[2]The synthesis of **5***a* has been reported using different reagents and (or) reaction conditions (3*a*, *b*).

[3]1,2,2,2-Tetrachloroethyl *tert*-butyl carbonate has also been reported to be a simple and efficient reagent for the *tert*-butoxycarbonylation of amines and aminoacids, see ref. 11.



SCHEME 1

The reaction of **3***b* with *tert*-butyllithium or *n*-butyllithium, condensation with benzaldehyde to yield **5***b* (68 and 62% yield respectively), and oxidation of **5***b* with pyridinium dichromate also yielded **4***b* (89% yield). Hydrolysis of the 3-*tert*-butylcarbonylamino analog **4***a* using ethanol – hydrochloric acid at reflux afforded 3-amino-4-benzoylpyridine (**6**) in 94% yield, whereas hydrolysis of the 3-*tert*-butoxycarbonylamino derivative **4***b* with trifluoroacetic acid in 1,2-dichloroethane at 25°C yielded **6** in 97% yield. Although the overall yields of **6** prepared from **3***a* and **3***b* are quantitatively similar (**3***a* → **4***a* → **6**, 66% yield, and **3***b* → **4***b* → **6**, 63% yield), the *tert*-butoxycarbonylamino *ortho*-directing substituent may be advantageous for compounds possessing labile substituents or ring systems, due to its more facile conversion to a free amino group.[4]

Activation of *N*-benzyloxycarbonylglycine (**7***a*) with 1,1′-bis-[6-(trifluoromethyl)benzotriazolyl] oxalate (BTBO) (14), followed by condensation with **6**, afforded crystalline **8***a* in 90% yield. A similar reaction of BTBO with *tert*-butoxycarbonylglycine (**7***b*) followed by reaction with **6** yielded crystalline **8***b* in 83% yield.[5] Acid hydrolysis of **8***a* (HBr–CH_3COOH) and **8***b* (CF_3COOH) at 25°C gave the pyridodiazepinone **9** in 82 and 89% yield, respectively. Methylation of **9** using sodium hydride and iodomethane afforded the title compound 1,3-dihydro-1-methyl-5-phenyl-2*H*-pyrido[3,4-*e*]-1,4-diazepin-2-one (**10**) in 73% yield.

The synthesis of 3-amino-4-benzoylpyridine, using *ortho*-lithiation methodology, has provided a shorter, simpler, and more efficient method for the synthesis of the pyridodiazepinone **10**. This methodology will be applicable to the construction of structurally related bicyclic nitrogen heterocycles.

Experimental

Melting points were determined with a Büchi capillary apparatus and are uncorrected. Nuclear magnetic resonance spectra were determined for solutions of deuteriochloroform or deuteriodimethyl sulfoxide with a Bruker AM-300 spectrometer. Infrared spectra were recorded on a Nicolet 5DX FT spectrometer. Mass spectra were measured on a Hewlett Packard 5995A gas chromatograph – mass spectrometer using the direct insertion probe method. Kieselgel silica gel DSF-5 (Camag) was used for preparative thin-layer chromatography (tlc). Silica gel (Baker, 70–200 mesh) was used for column chromatography. Tetrahydrofuran and ether were distilled from sodium-benzophenone immediately before use. *n*-Butyllithium (2.6 *M* solution in hexanes) and *tert*-butyllithium (2.0 *M* solution in pentane) were obtained from the Aldrich Chemical Co. Elemental analyses were performed by the Microanalytical Laboratory, Department of Chemistry, University of Alberta. 3-*tert*-Butylcarbonylaminopyridine (**3***a*) was prepared by the literature procedures (**3***a*, *b*).

*3-*tert*-Butylcarbonylamino-4-benzoylpyridine (**4**a)*

Method 1

A solution of *n*-butyllithium (27 mL, 70 mmol) was added dropwise to a solution of **3***a* (5.12 g, 29 mmol) in 100 mL THF at −78°C with stirring under a nitrogen atmosphere. The temperature was maintained at −78°C for a further 15 min, and then at 0°C for 3 h. The reaction mixture was cooled to −78°C, a solution of *N*,*N*-diethylbenzamide (9.92 g, 52 mmol) in 20 mL THF was added dropwise, and the reaction mixture was allowed to stir at 25°C overnight. The reaction mixture was poured into a mixture of ice (100 g) and 5 *N* HCl (20 mL); this mixture was stirred for 10 min and neutralized with aqueous potassium carbonate prior to extraction with ethyl acetate. The organic extract was washed with brine, dried ($MgSO_4$), and the solvent removed *in vacuo*. Recrystallization from ethyl acetate – hexane (2:1 v/v) afforded **4***a* (5.71 g, 70%): mp 125–126°C; ir (KBr): 3337, 2968, 1688, 1680, 1647 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 10.5 (br s, 1H, NH, exchanges with deuterium oxide), 9.98 (s, 1H, H-2), 8.52 (d, J = 5.8 Hz, 1H, H-6), 7.54–7.88 (m, 5H, phenyl hydrogens), 7.43 (d, J = 5.8 Hz, 1H, H-5), 1.35 (s, 9H, *tert*-butyl); ms, m/z: 282 (M^+). *Anal.*

[4]The *ortho*-functionalization of *N*-(*tert*-butoxycarbonyl)aniline and near quantitative hydrolysis of the *tert*-butoxycarbonylamino group to a free amino group has been reported (13).

[5]BTBO is a superior coupling reagent to dicyclohexylcarbodiimide (DCC) since reactions employing DCC yielded **8** as oils due to the difficulty in removing dicyclohexylurea and *N*-acylurea side products. Compound **8** has been reported as an oil (2*b*).

calcd. for $C_{17}H_{18}N_2O_2$: C 72.32, H 6.43, N 9.92; found: C 72.30, H 6.41, N 10.04.

Method 2

A solution of benzaldehyde (22.3 g, 210 mmol) in THF (35 mL) was added dropwise to a solution of 4-lithio-3-*tert*-butylcarbonylaminopyridine, prepared from reaction of **3***a* (25.1 g, 140 mmol) in 350 mL THF and *n*-butyllithium (135 mL, 351 mmol) as described under Method 1 at −78°C, and the reaction mixture was allowed to stir at 25°C overnight. The reaction mixture was poured into water (200 mL) and the THF fraction was separated. Removal of the solvent *in vacuo* gave a residue that was dissolved in chloroform and washed with water. The chloroform fraction was dried ($MgSO_4$), the solvent was removed *in vacuo*, and the residue was triturated with hexane to yield **5***a*, which was recrystallized from ethyl acetate – hexane (24.1 g, 60%): mp 208–209°C (lit. (3*b*) mp 200–202°C; lit. (3*a*) mp 206–209°C).

A solution of **5***a* (6.79 g, 24 mmol) in 40 mL DMF and pyridinium dichromate (12 g, 32 mmol) was stirred at 25°C for 2 h prior to pouring into water (300 mL). Extraction with ethyl acetate, drying ($MgSO_4$), and removal of the solvent *in vacuo* yielded the product **4***a*, which was purified by silica gel column chromatography using hexane – ethyl acetate (1:1 v/v) as eluant. The product **4***a* (5.6 g, 83%) was identical (mp, ^{1}H nmr) to that of **4***a* described under Method 1.

*3-*tert*-Butoxycarbonylaminopyridine (**3**b)*

A mixture of di-*tert*-butyldicarbonate (41 g, 188 mmol), 3-aminopyridine (17.3 g, 184 mmol), and *tert*-butyl alcohol (200 mL) was heated at 80°C for 2 h. The solvent was removed *in vacuo*, and the residue was dissolved in ethyl acetate and washed with 0.5 *M* citric acid (30 mL) and water. The ethyl acetate fraction was dried (Na_2SO_4) and the solvent removed *in vacuo*. The product was purified by silica gel column chromatography, using ethyl acetate – hexane (2:1 v/v) as eluate, and subsequent recrystallization from ethyl acetate – hexane (2:1 v/v) to yield **3***b* (27.1 g, 74%): mp 115–116°C; ir (KBr): 3238, 2976, 1729, 1598, 1548 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 8.56 (d, J = 2.5 Hz, 1H, H-2), 8.35 (dd, J = 1.5 Hz, J = 5 Hz, 1H, H-6), 8.14 (dd, J = 8 Hz, J = 2.5 Hz, 1H, H-4), 7.75 (br s, 1H, NH, exchanges with deuterium oxide), 7.3 (dd, J = 8 Hz, J = 2.5 Hz, 1H, H-5), 1.55 (s, 9H, *tert*-butyl); ms, m/z: 194 (M^+). *Anal.* calcd. for $C_{10}H_{14}N_2O_2$: C 61.84, H 7.26, N 14.42; found: C 61.53, H 7.32, N 14.38.

*3-*tert*-Butoxycarbonylamino-4-benzoylpyridine (**4**b)*

Method 1

A solution of *tert*-butyllithium (24.6 mL, 40 mmol) was added dropwise, with stirring, to a solution of **3***b* (3.3 g, 17 mmol) in THF (30 mL) at −78°C under a nitrogen atmosphere. The temperature was maintained at −78°C for a further 15 min and then at −20°C for 3 h. The reaction mixture was cooled to −78°C and a solution of *N*,*N*-diethylbenzamide (5.79 g, 32.7 mmol) in THF (10 mL) was added dropwise. The reaction mixture was allowed to warm to 25°C, poured into a mixture of ice (100 g) and 5 *N* HCl (20 mL), stirred for 10 min, and neutralized with aqueous potassium carbonate. The THF layer was separated and the aqueous fraction was extracted with ethyl acetate. The combined organic fractions were washed with brine, dried (Na_2SO_4), and the solvent was removed *in vacuo*. The product was purified by silica gel column chromatography with hexane – ethyl acetate (1:1 v/v) as eluant prior to recrystallization from the same solvent mixture to yield **4***b* (3.3 g, 65%): mp 123–124°C; ir (KBr): 3353, 2984, 1729, 1655 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 9.75 (s, 1H, H-2), 9.22 (br s, 1H, NH, exchanges with deuterium oxide), 8.44 (d, J = 5.8 Hz, 1H, H-6), 7.52–7.88 (m, 5H, phenyl hydrogens), 7.35 (d, J = 5.8 Hz, 1H, H-5), 1.56 (s, 9H, *tert*-butyl); ms, m/z: 298 (M^+). *Anal.* calcd. for $C_{17}H_{18}N_2O_3$: C 68.44, H 6.08, N 9.39; found: C 68.55, H 6.03, N 9.74.

Use of *n*-butyllithium, rather than *tert*-butyllithium as described above, afforded **4***b* in 63% yield.

Method 2

A solution of benzaldehyde (4.15 g, 39 mmol) in THF (10 mL) was added dropwise to a solution of 4-lithio-3-*tert*-butoxycarbonylaminopyridine, prepared from reaction of **3***b* (5.0 g, 26 mmol) in 40 mL THF and *tert*-butyllithium (38 mL, 75 mmol), as described above, at −78°C. The reaction mixture was allowed to warm to 25°C and water (25 mL) was added. Extraction with ethyl acetate, drying (Na_2SO_4), removal of the solvent *in vacuo*, and recrystallization from hexane – ethyl acetate yielded **5***b* (5.26 g, 68%): mp 134–135°C; ir (KBr): 3337 (br), 2976, 1606 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 8.99 (s, 1H, H-2), 8.09 (br s, 1H, NH, exchanges with deuterium oxide), 8.0 (d, J = 5.8 Hz, 1H, H-6), 7.38 (m, 5H, phenyl hydrogens), 7.0 (d, J = 5.8 Hz, 1H, H-5), 6.3 (br s, 1H, OH, exchanges with deuterium oxide), 5.89 (s, 1H, -*CH*—OH), 1.57 (s, 9H, *tert*-butyl); ms, m/z: 300 (M^+). *Anal.* calcd. for $C_{17}H_{20}N_2O_3$: C 67.98, H 6.71, N 9.33; found: C 68.13, H 6.70, N 9.36.

Use of *n*-butyllithium, rather than *tert*-butyllithium as described above, afforded **5***b* in 62% yield.

A solution of **5***b* (2.3 g, 7.7 mmol) in DMF (15 mL) and pyridinium dichromate (3.6 g, 9.6 mmol) was stirred at 25°C for 2 h before pouring into water (150 mL). Isolation and purification of the product, as described for **4***a* under Method 2, afforded **4***b* in 89% yield.

*3-Amino-4-benzoylpyridine (**6**)*

Method 1

A solution of 95% ethyl alcohol (10 mL) and 5 *N* HCl (30 mL) was added to **4***a* (1.0 g, 3.5 mmol) and the mixture was heated at reflux for 6 h. After cooling to 0°C the reaction mixture was neutralized with aqueous ammonium hydroxide to yield **6** as yellow crystals (0.6 g, 94%): mp 127–129°C (lit. (2*a*) mp 126–128°C).

Method 2

A solution of trifluoroacetic acid-1,2-dichloroethane (1:12 v/v) (50 mL) was added to **4***b* (1.0 g, 3.4 mmol) and the mixture was stirred at 25°C for 3.5 h. The mixture was neutralized with aqueous potassium carbonate at 0°C, extracted with chloroform, washed with water, dried ($MgSO_4$), and the solvent removed *in vacuo*. Recrystallization from *n*-heptane–chloroform yielded **6** (0.645 g, 97%): mp 126–128°C.

*3-Benzyloxycarbonylaminomethylcarbonylamino-4-benzoylpyridine (**8**a)*

A suspension of BTBO (14) (1.03 g, 2.2 mmol) in acetonitrile (20 mL) was added to a mixture of **7***a* (0.455 g, 2.2 mmol) and pyridine (0.174 g, 2.2 mmol) in acetonitrile (20 mL) at 25°C. The reaction mixture became clear in a few seconds. The mixture was stirred for a further 2 h at 25°C, **6** (0.4 g, 2 mmol) in THF (20 mL) and triethylamine (0.215 g, 2 mmol) were added, and the mixture was allowed to stir at 25°C for an additional 6 h. Removal of the solvent *in vacuo*, dissolution in ethyl acetate (30 mL), and washing with 10% aqueous sodium carbonate and then brine were performed consecutively. The ethyl acetate fraction was dried (Na_2SO_4) and most of the solvent was removed *in vacuo*, at which time hexane was added to afford **8***a* (0.694 g, 90%): mp 88–90°C; ir (KBr): 3385, 3017, 2286, 1704, 1655, 1401 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 10.56 (s, 1H, *NH*CO, exchanges with deuterium oxide), 9.86 (s, 1H, H-2), 8.62 (d, J = 5.8 Hz, 1H, H-6), 7.3–7.84 (m, 11H, phenyl hydrogens, H-5), 5.68 (br t, 1H, *NH*CH_2, exchanges with deuterium oxide), 5.17 (s, 2H, *CH_2*-Ph), 4.06 (d, J = 6.5 Hz, *CH_2*NH); ms, m/z: 389 (M^+). *Anal.* calcd. for $C_{22}H_{19}N_3O_4$: C 67.86, H 4.92, N 10.79; found: C 67.70, H 4.92, N 10.73.

*tert-Butoxycarbonylglycine (**7**b)*

Di-*tert*-butyldicarbonate (6.4 g, 29.3 mmol) in DMF (15 mL) was added to a mixture of glycine (2.03 g, 27 mmol) and triethylamine (4.04 g, 39.9 mmol) in water (15 mL) and the reaction was allowed to proceed with stirring at 25°C overnight. Water (200 mL) was added, the mixture was cooled to 0°C, and the pH of the solution was adjusted to 2 with 5 *N* HCl. Extraction with ethyl acetate, washing with brine, drying (Na_2SO_4), and removal of the solvent *in vacuo* gave the product **7***b*. Recrystallization from petroleum ether (bp 30–60°C) – ethyl acetate yielded **7***b* (4.05 g, 87%): mp 88–90°C (lit. (15) mp 87–90°C).[6]

*3-*tert*-Butoxycarbonylaminomethylcarbonylamino-4-benzoylpyridine (**8**b)*

Reaction of BTBO (28.52 g, 62 mmol) in acetonitrile (200 mL) with

[6]This synthesis of **7***b* provides a simple alternative to the preparation from *tert*-butyl *S*-4,6-dimethylpyrimidin-2-ylthiocarbonate and glycine reported in ref. 15.

7*b* (10.9 g, 62 mmol) and pyridine (4.9 g, 62 mmol) in acetonitrile (300 mL) followed by addition of **6** (12.3 g, 62 mmol) and triethylamine (6.27 g, 62 mmol) in THF (200 mL), and completion of the reaction as described for the synthesis of **8***a*, afforded **8***b* (18.4 g, 83%): mp 144–145°C; ir (KBr): 3353, 2976, 2935, 2853, 1704, 1655, 1598, 1565, 1516, 1401 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 10.5 (s, 1H, *NH*CO, exchanges with deuterium oxide), 9.84 (s, 1H, H-2), 8.48 (d, J = 5.8 Hz, 1H, H-6), 7.34–7.84 (m, 6H, phenyl hydrogens, H-5), 5.38 (br t, 1H, *NH*CH_2, exchanges with deuterium oxide), 3.98 (d, J = 6 Hz, 2H, *CH_2*NH), 1.44 (s, 9H, *tert*-butyl); ms, m/z: 355 (M^+). *Anal.* calcd. for $C_{19}H_{21}N_3O_4$: C 64.21, H 5.96, N 11.82; found: C 64.01, H 5.88, N 11.83.

*1,3-Dihydro-5-phenyl-2*H*-pyrido[3,4-*e*]-1,4-diazepin-2-one (**9**)*

Method 1

A saturated solution of hydrogen bromide in acetic acid (40 mL) was added to **8***a* (2.15 g, 5.5 mmol) and the mixture was stirred at 25°C for 2 h. Ether (50 mL) and then 10% aqueous methanol (100 mL) were added. Neutralization with aqueous ammonium hydroxide at 0°C, extraction with chloroform, drying the chloroform extract (Na_2SO_4), and removal of the solvent *in vacuo* afforded a residue, which was heated at reflux in toluene (200 mL) and pyridine (2 mL) for 7 h. Removal of the solvent *in vacuo* and addition of hexane yielded **9** (1.31 g, 82%), which was recrystallized from benzene–methanol: mp 258–260°C (lit. (2*a*) mp 258–260°C).

Method 2

A 1 *N* solution of trifluoracetic acid in 1,2-dichloroethane (50 mL) was added to **8***b* (0.227 g, 0.64 mmol) and the resulting solution was stirred at 25°C for 6 h. The solvent was removed *in vacuo*, and the residue was dissolved in ethyl acetate (30 mL) and neutralized with aqueous potassium carbonate. The ethyl acetate fraction was washed with brine, dried (Na_2SO_4), and the solvent removed *in vacuo*. Toluene (20 mL) and pyridine (0.5 mL) were added to the residue and the solution was heated at reflux for 7 h. Removal of the solvent *in vacuo* and purification of the residue by preparative tlc, using plates 1.0 mm in thickness, with chloroform–ether–methanol (7:2:1 v/v/v) as development solvent afforded **9**, R_f 0.4 (0.135 g, 89%): mp 258–260°C.

*1,3-Dihydro-1-methyl-5-phenyl-2*H*-pyrido[3,4-*e*]-1,4-diazepin-2-one (**10**)*

Sodium hydride (50% dispersion in oil, 0.64 g, 13.2 mmol) was added in aliquots to a solution of **9** (2.95 g, 12.4 mmol) in DMF (20 mL) with stirring at 0°C. Stirring was continued for 25 min, at which time iodomethane (1.76 g, 12.4 mmol) in ether (1 mL) was added. The reaction mixture was stirred for an additional 30 min at 0°C. Addition of water (200 mL), extraction with ethyl acetate, drying ($MgSO_4$), and removal of the solvent *in vacuo* gave a residue. Purification by preparative tlc, using plates 1.0 mm in thickness, with dichloromethane–methanol (11:1 v/v) as development solvent gave **10** (2.28 g, 73%). Recrystallization from ethyl acetate – hexane afforded **10** as white needles: mp 126–127°C; ir (KBr): 3058, 3000, 2992, 1688, 1614 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 8.84 (s, 1H, H-9), 8.52 (d, J = 5.8 Hz, 1H, H-7), 7.45–7.69 (m, 5H, phenyl hydrogens), 7.27 (d, J = 5.8 Hz, 1H, H-6), 4.97 (d, J_{gem} = 12 Hz, 1H, NCH′CO), 3.82 (d, J_{gem} = 12 Hz, 1H, NCH″CO), 3.52 (s, 3H, N-CH_3); ms, m/z: 251 (M^+). *Anal.* calcd. for $C_{15}H_{13}N_3O$: C 71.70, H 5.21, N 16.72; found: C 71.53, H 5.20, N 16.71.

Acknowledgments

We are grateful to the Medical Research Council of Canada (Grant MT-4888) for financial support of this work and to the Alberta Heritage Foundation for Medical Research for a fellowship awarded to one of us (C.Y.F.). The grant from the Alberta Heritage Foundation to purchase the Bruker AM-300 spectrometer is also gratefully acknowledged.

Received July 25, 1986

TAIN-JEN YU, RONALD G. SUTHERLAND, and RONALD E. VERRALL. Can. J. Chem. **65**, 1162 (1987).

Sonolysis of cytosine has been studied at 630 kHz in the presence of air and nitrogen. The degradation products were identified by gas chromatographic – mass spectral analysis. Under aerated conditions the following products were found: urea, formyl urea, parabanic acid, isobarbituric acid, oxaluric acid, alloxan monohydrate, alloxantin, dialuric acid, and uracil glycols. Under nitrogen the degradation products were isobarbituric acid, alloxan monohydrate, and uracil glycols. The observed products have been used to develop a possible mechanism for the sonolytic degradation. There appears to be some similarity with the products reported from radiolysis studies of this compound. Sonolysis of thymine in the presence of air was reinvestigated and the gc–ms analysis shows that a previously reported, unidentified, product may be 5-hydroxy-5-methylbarbituric acid.

TAIN-JEN YU, RONALD G. SUTHERLAND et RONALD E. VERRALL. Can. J. Chem. **65**, 1162 (1987).

Opérant en présence d'air et d'azote, on a étudié la sonolyse de la cytosine à 630 kHz. On a identifié les produits de dégradation en faisant appel à la sm/cpg. Dans les produits obtenus par des réactions effectuées en présence d'air, on a retrouvé de l'urée, de la formyl-urée, de l'acide parabanique, de l'acide isobarbiturique, de l'acide oxalurique, du monohydrate d'alloxane, de l'alloxantine, de l'acide dialurique et des glycols d'uracile. Les produits obtenus au cours des réactions effectuées dans un atmosphère d'azote comprennent l'acide isobarbiturique, le monohydrate d'alloxane et des glycols d'uracile. On a utilisé les produits observés pour développer un mécanisme plausible pour la dégradation par sonolyse. Il semble qu'il existe une certaine similarité avec la nature des produits observés lors des études de radiolyse effectuées sur ce composé. La sonolyse de la thymine, en présence d'air, a été réétudiée; la sm/cpg démontre qu'un produit qui avait été observé antérieurement et qui n'avait pas été identifié, est l'acide hydroxy-5 méthyl-5 barbiturique.

[Traduit par la revue]

Introduction

Ultrasonically induced chemical reactions of biologically important molecules related to RNA and DNA have been reported previously (1–4).[2] In this paper we report the results of the sonolytic degradation of the pyrimidine bases cytosine and thymine. Results of such studies on thymine have been reported earlier (2); however, analyses of products were carried out using tlc techniques. This study reports an attempt to determine whether gc–ms techniques could reveal any additional compounds not observed in the previous work (2), and allows a direct comparison with the results obtained with cytosine.

The radiolysis of cytosine has been investigated in aerated aqueous solutions (5–9). Since the primary reactions in the sonolysis of aqueous solutions (10–14) are now known to be essentially similar to those produced in radiolytic reactions, the sonolysis and radiolysis are compared and contrasted.

Experimental

Ultrasonic irradiation and general analysis procedures

The ultrasound generator and power output, gc–ms equipment, and all other instruments and methods used in the experiment are as previously reported (3). The calculation of per cent degradation of a compound is based on the change in absorbance at λ_{max} of the sample before and after sonolysis. Cytosine absorbance was measured at 267 nm. Aqueous solutions of cytosine and thymine were saturated with the appropriate gas for at least 30 min prior to and during sonolysis. A Beckman Expandomatic SS-2 pH meter was used to measure pH values.

The sonolytic degradation products were identified using both CI and EI mass spectra. Whenever possible, final confirmation was made by comparison with authentic samples.

Materials

Cytosine, thymine (Aldrich Chemical Co.), and all authentic samples were used without further purification. The procedures and materials for converting degradation products to their trimethylsilyl derivatives for gc–ms analysis were as reported previously (3).

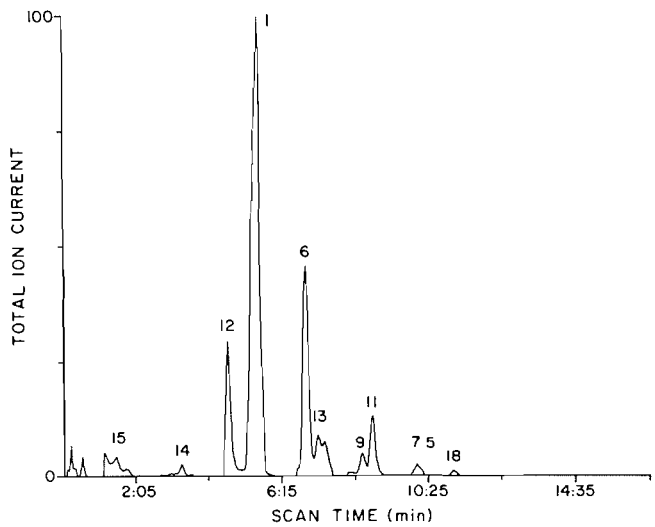

FIG. 1. Mass spectral reconstructed ion chromatogram of a 2 m*M* aqueous solution of cytosine insonated at 630 kHz in the presence of air.

Results and discussion

Figure 1 shows the gc spectrum of a 2 m*M* aqueous solution of cytosine sonicated at 630 kHz for 2 h in the presence of air. Absorbance measurements showed that the upper limit of the cytosine degradation was 67%. A pH decrease from 6.2 to 4.2 was observed during insonation. Ten compounds, including unreacted cytosine, are identified. They are urea (**15**), formyl urea (**14**), parabanic acid (**12**), cytosine (**1**), isobarbituric acid (**6**), oxaluric acid (**13**), alloxan monohydrate (**9**), alloxantin (**11**), dialuric acid (**7**), and uracil glycols (**5**).

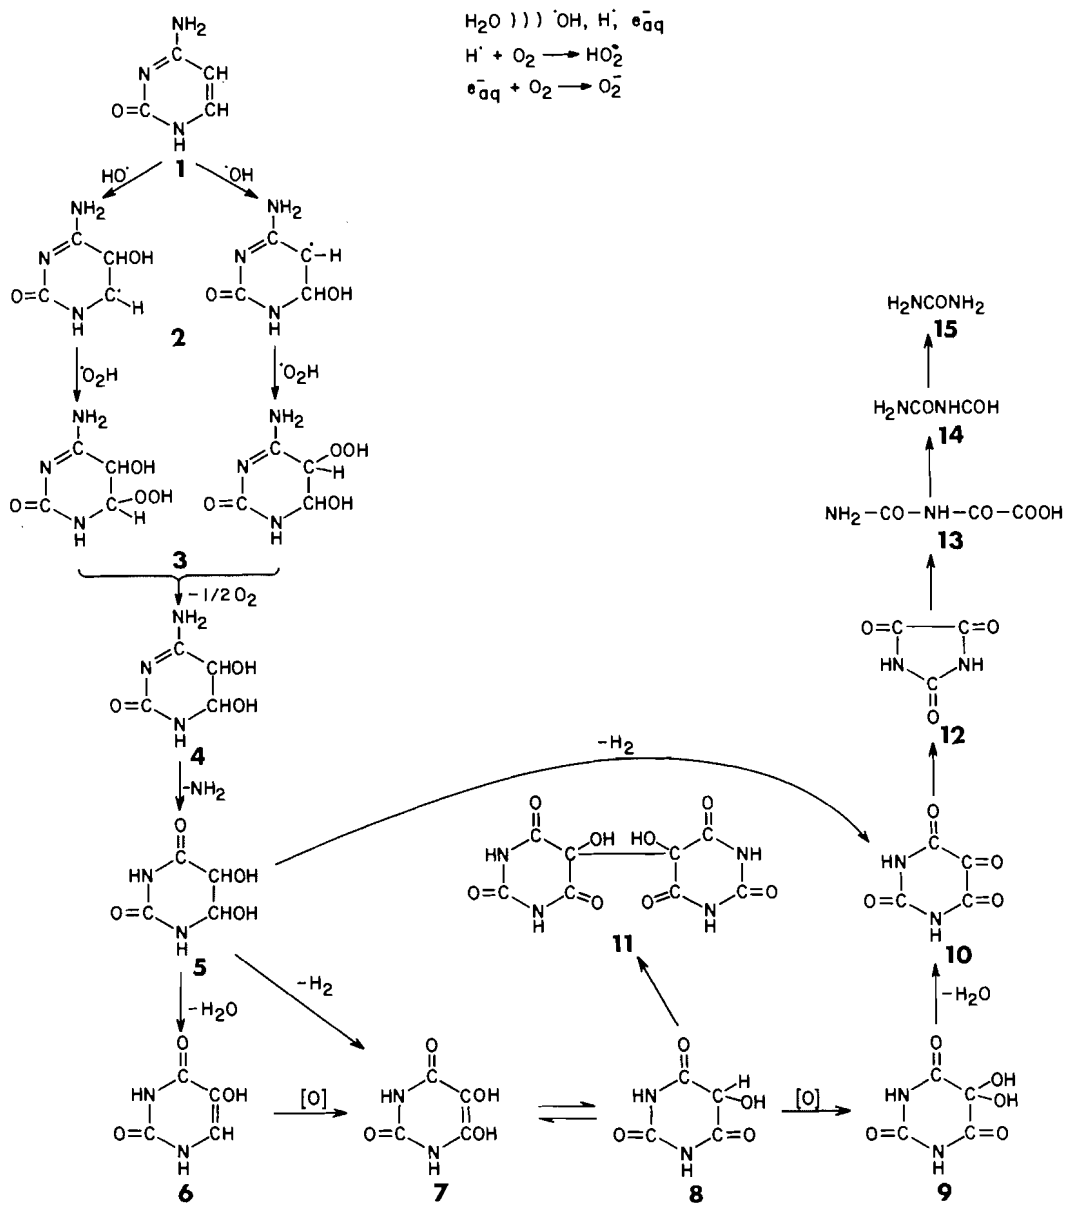

FIG. 2. Proposed sonolytic mechanism of degradation of aqueous cytosine solutions in aerated state.

sonicated at 630 kHz for 2 h in the presence of nitrogen revealed only three compounds in addition to cytosine. They are isobarbituric acid (**6**), alloxan monohydrate (**9**), and uracil glycols (**5**). The percent degradation of cytosine under these conditions decreased to 18% and the acidity of the solution remained constant at pH 6 during the sonication.

A mechanism for the sonolytic degradation of cytosine in the presence of air is summarized in Fig. 2 and is described briefly as follows. In the presence of air, $OH^{\bullet}$, $HO_2^{\bullet}$, and O_2^{-} are the primary species produced during the cavitation process induced by the high intensity ultrasonic waves (2, 3). Cytosine hydroxyhydroperoxides (**3**) may arise from the successive attacks of $OH^{\bullet}$ and $HO_2^{\bullet}$ across the 5,6 double bond of cytosine. Cytosine glycols (**4**) can arise from the peroxides through loss of oxygen (**2**) and can give rise to uracil glycols (**5**) by means of a deamination pathway. Isobarbituric acid (**6**) could be formed from uracil *cis*-glycol through loss of a water molecule. Dialuric acid (**7**) may be derived both by the dehydrogenation of uracil glycols (**5**) or by the oxidation of isobarbituric acid (**6**). Alloxan monohydrate (**9**) could be oxidized from isodialuric acid (**8**), the tautomer of dialuric acid (**7**). Alloxantin (**11**) may arise from isodialuric acid (**8**) and (or) from alloxan (**10**), the dehydrated product of alloxan monohydrate (**9**). Alloxan (**10**) can be produced also from uracil glycols (**5**) by dehydrogenation.

Parabanic acid (**12**) may be derived from the ring opening and rearrangement of alloxan (**10**). Further hydrolysis of parabanic acid would lead to open chain products like oxaluric acid (**13**), formyl urea (**14**), and urea (**15**).

Most of these degradation products have been observed in the sonolysis of uracil (3) and are similar to those observed in radiolysis studies of cytosine (6, 8) that give radiation products belonging to the deamination pathway. However, non-deamination pathway products such as 4-amino-isobarbituric acid, 1-carbamoyl-5-hydroxyhydrantoin, and 1-carbamyl-imidazolidone-4,5-diols also have been identified in radiolysis work (5, 7, 9). We did not detect any sonolysis products arising from ring cleavage.

Since oxygen is absent in the case of sonolysis under nitrogen

atmosphere, then hydroxyl radicals, hydrogen atoms, as well as the possibility of hydrated electrons must be considered (3) as the primary reactive species. In a manner similar to that proposed for the sonolysis of uracil, OH• attack of the 5,6 double bond of cytosine occurs, producing adducts. These adducts may undergo disproportionation reaction to produce cytosine and cytosine glycols. The uracil glycols (**5**) can be formed by the deamination of cytosine glycols (**4**). The remaining products may occur as follows: isobarbituric acid (**6**) derives from uracil *cis*-glycol by loss of a water molecule; alloxan monohydrate (**9**) may result from hydration of alloxan (**10**), which is derived from uracil glycols (**5**) by loss of H_2.

No degradation products have been identified that can be related to attack of hydrogen atoms or hydrated electrons. However, three gc peaks were observed in which the molecular weights of the trimethylsilyl derivatives were determined by mass spectral methods to be 371, 406, and 477 atomic mass units. The peak having a mass of 371 is found also in the sonolysis work in the presence of air and is labelled as compound **18**. Attempts to identify these compounds have not been successful and we report them simply for information.

Previous results of the sonolysis of of thymine (2) were analyzed using tlc methods and the following compounds were positively identified: *cis*- and *trans*-5,6-dihydroxy-5,6-dihydrothymine (thymine glycols), 5-hydroxymethyluracil, urea, and *N*-pyruvyl-*N'*-formyl urea. The concentration of organic peroxides was estimated indirectly (2).

In this work insonation at 630 kHz of an aqueous 2 m*M* solution of thymine in the presence of air for 2 h produced five products in addition to the unreacted thymine. These include *N*-pyruvyl-*N'*-formyl urea, 6-hydroxymethyluracil, *cis*- and *trans*-5,6-dihydroxydihydrothymine, and 5-hydroxy-5-methylbarbituric acid. It is to be noted that the last compound was not observed in previous sonolysis studies (2), although it is known to be a product arising from radiolysis work on thymine (15, 16). We could not identify urea in this study. However, since authentic samples of urea come off the column packing (8% SE-30 on AW-DMCS Chromosorb W, 80–100 mesh) very quickly, small amounts of urea may not be detectable using this separation technique. Previous work (2) has shown that a very small amount of urea is formed and that the amount produced decreases with increasing sonication time.

Organic peroxides observed in radiolysis studies on thymine (15, 16) were not detected in our analysis, although we cannot rule out that the derivatization procedure may be sufficiently harsh to induce their thermal decomposition.

In previous work one unidentified product was isolated using tlc methods. It would appear that 5-hydroxy-5-methylbarbituric acid could be this compound.

Finally, the energy output in previous work at 450 kHz (2) was not measured on the same quantitative basis as reported here and in other work (3). Consequently, it is still uncertain as to whether there is any ultrasonic frequency dependence of the product distribution. On balance, it would appear that the majority of products are the same and the gc–ms analysis procedure is more efficient in identifying products.

$Ba(OH)_2$ as the catalyst in organic reactions. Part XIV. Mechanism of Claisen–Schmidt condensation in solid–liquid conditions

A. AGUILERA, A. R. ALCANTARA, J. M. MARINAS, AND J. V. SINISTERRA[1]

Department of Organic Chemistry, Faculty of Sciences, Córdoba, Spain

Received August 15, 1986

A. AGUILERA, A. R. ALCANTARA, J. M. MARINAS, and J. V. SINISTERRA. Can. J. Chem. **65**, 1165 (1987).

The mechanism of the Claisen–Schmidt condensation, catalyzed by a series of activated barium hydroxide catalysts, is discussed. Two kinds of ketones are studied: R—CO—CH_3 (R = Me, Et, Pr^i, Bu^t) and acetophenone (R = Ph). The influence of the chemical and textural properties of the catalysts, as well as the nature of the solvent, are studied. The process is an interfacial solid–liquid reaction between the adsorbed carbanion and the benzaldehyde. The different structures of the adsorbed carbanion produced from Ph—CO—CH_3 and R—CO—CH_3 are analyzed by infrared spectroscopy, and could explain the different reactivities observed in the process. The kinetic runs are discussed.

A. AGUILERA, A. R. ALCANTARA, J. M. MARINAS et J. V. SINISTERRA. Can. J. Chem. **65**, 1165 (1987).

On discute du mécanisme de la condensation de Claisen–Schmidt, catalysée par une série de catalyseurs d'hydroxydes de baryum activés. On a étudié deux sortes de cétones : R—CO—CH_3 (R = Me, Et, i-Pr et *t*-Bu) et l'acétophénone (R = Ph). On a étudié l'influence des propriétés chimiques et texturales des catalyseurs ainsi que la nature du solvant. Le processus est une réaction interfaciale solide–liquide entre le carbanion qui est adsorbé et le benzaldéhyde. Faisant appel à la spectroscopie infrarouge, on a analysé les différentes structures des carbanions formés à partir des cétones Ph—CO—CH_3 et R—CO—CH_3. Ces structures peuvent expliquer les diverses réactivités observées dans ce processus. On discute des données cinétiques.

[Traduit par la revue]

Introduction

Aldol condensation type reactions catalyzed in the homogeneous phase have been studied extensively from a mechanistic point of view. In heterogeneous conditions, catalyzed by solids (1, 2), the mechanism is not well known, due to the presence of acidic as well as basic sites on the catalyst surface. Claisen–Schmidt condensation (3) is a process, related to aldol condensation, that leads to styril ketones and chalcones, very useful compounds in pharmaceutics (4). The mechanism of the process has been studied in the homogeneous phase (5, 6), but we cannot say the same about the processes in the heterogeneous phase (7). In this case, the reaction seems to be first order in benzaldehyde, with a Langmuir–Hinshelwood type kinetic equation, when the reaction is carried out using Al_2O_3 (7). The ketone is adsorbed on basic sites and reacts with the aldehyde (7, 8).

$$\underset{\mathbf{1}}{\text{Ph—CHO}} + \underset{\mathbf{2}}{\text{R—CO—CH}_3} \xrightarrow{\text{base}} \underset{\mathbf{3}}{\text{Ph—CH=CH—CO—R}} + \text{H}_2\text{O}$$

R = Me, Et, Pr^i, Bu^t, Ph

Earlier we described some new barium hydroxide catalysts (9), and studied their catalytic activity in interfacial solid–liquid processes, in some organic reactions, e.g., aldol condensation (10), Michael addition (11), Wittig–Horner reaction (12), and Claisen–Schmidt condensation (13), from a synthetic point of view. These catalysts are more active and selective than the commercial ones: K_2CO_3, KOH, etc., in similar experimental conditions (interfacial solid–liquid processes) (12, 13). In the present paper we discuss the mechanism of the process and the influence of the chemical and textural properties of the catalysts on the condensation mechanism.

Experimental

Catalysts

The activated barium hydroxide catalysts C-200 and C-300 were obtained by dehydration of commercial $Ba(OH)_2 \cdot 8H_2O$ Probus S.A. (C-0). The preparation of these catalysts has been previously described (10).

The surface area of the catalysts was determined by a Sortomatic Carlo–Erba. The values obtained were C-0, (1.4 ∓ 0.1) $m^2\ g^{-1}$; C-200, (1.9 ∓ 0.1) $m^2\ g^{-1}$; C-300, (1.4 ∓ 0.1) $m^2\ g^{-1}$.

The titration of basic sites was carried out by a spectrophotometric method previously described (14). Benzoic acid (BA) was used to titrate the total amount of basic sites. The values obtained were C-0, (0.68 ∓ 0.07) × 10^{-3} equiv./g catalyst; C-200, (0.91 ∓ 0.09) × 10^{-3} equiv./g catalyst; C-300, (0.85 ∓ 0.09) × 10^{-3} equiv./g catalyst.

TABLE 1. Ultraviolet spectrometric characteristics of the enones (Ph—CH=CH—CO—R)

R	λ_{max} (nm)[a]	ϵ ($cm^{-1}\ mol^{-1}\ L$) × 10^{-4}[b]
Me	310 ± 2	(1.86 ± 0.03)
Et	288 ± 2	(1.65 ± 0.02)
iPr	305 ± 2	(1.18 ± 0.02)
*t*Bu	310 ± 2	(2.10 ± 0.09)
Ph	314 ± 2	(2.31 ± 0.03)

[a] b = 1 cm.
[b] Solvent, EtOH (96%).

Claisen–Schmidt condensation

The kinetic runs of the condensation were carried out with 20 mL of ethanolic Ph—CHO and ketone solutions. The initial concentration was 0.1 *M* in both compounds. The conversion was determined by ultraviolet–visible measurements at λ_{max} of the enone (R—CH=CH—CO—Ph), using an ultraviolet–visible Varian model Cary 219 spectrometer.

Reactions with the supported polymeric reagent Ⓟ-CHO

The supported polymeric reagent Ⓟ-CHO was obtained according to a previously described method (15), using Merrifield's peptide resin (1% cross-linked; 200–400 mesh; 1 mequiv. Cl/g; Aldrich).

Fourteen grams of resin were mixed with 300 mL of DMSO and 19 g of $NaHCO_3$, and refluxed for 6 h. Afterwards the resin was filtered and washed with (2:1 v/v) 1,4-dioxane–water mixture and with acetone, and dried at 110°C. A 1695 cm^{-1} C=O band was detected in the ir spectrum of the polymer.

The reaction with the polymeric reagent (Ⓟ-CHO) was carried out

[1] Author to whom correspondence may be addressed.

For personal use only.

with 0.0196 mol of R—CO—Me, 0.1 g of polymeric reagent Ⓟ-CHO (equivalent to 0.001 equiv. of —CHO/g polymer), and 10 mL of EtOH (96%).

The mixture was refluxed for 6 h. Then 1 *M* HCl was added to destroy the barium hydroxide catalyst (C-200). The resin was filtered and washed with EtOH, and dried to get the ir spectrum.

Adsorption experiments

The adsorption experiments with ketones (R—CO—Me; R = Ph, Me, Et, Pr^i, and Bu^t Merck p.a.) and benzaldehyde (Panreac S.A.) were carried out using 0.2 mL of carbonylic compound, 0.1 g of catalyst, and 10 mL of EtOH (96%). The mixture was refluxed for 15 min, and filtered. The ir spectra of the solid and liquid were obtained on an ir spectrometer (Perkin–Elmer model 599B) with a Perkin–Elmer Data Station model 2000. The PECDS program was used for accumulation and manipulation of the spectra of the adsorbed species.

Results and discussion

1. Catalysts

In a previous paper (14) we discussed the nature and number of active sites of our catalysts. We showed that acidic and oxidizing sites were not present in the catalysts, due to the nature of Ba(II). Only reducing sites versus 1,3-dinitrobenzene and basic sites versus benzoic aicd (BA) were detected (14). In the experimental part of this work, the total number of basic sites versus benzoic acid is shown. We can observe that the number of basic sites is very similar in the three catalysts:

$$\text{C-200} \gtrsim \text{C-300} > \text{C-0}$$

On the other hand, the surface area is similar and very small in all cases (1.9, 1.4, and 1.4 m^2/g respectively), and this fact is due to the microcrystalline structure of the solids. An X-ray study was carried out to learn more about that point. The results were

C-0

$Ba(OH)_2 \cdot 8H_2O$

Cell lattice: a_0 = 9.35 Å; b_0 = 9.38 Å; c_0 = 11.87 Å; $\alpha = \gamma = 90°$; $\beta = 99°$

C-200

Empirical formula from TGA (16) = $Ba(OH)_2 \cdot 0.8H_2O$; main compound: $Ba(OH)_2 \cdot H_2O$

Cell lattice: a_0 = 6.366 Å; b_0 = 6.955 Å; c_0 = 3.895 Å; $\alpha = \beta = \gamma = 90°$

Secondary product: $\beta\,Ba(OH)_2$

Cell lattice: a_0 = 9.40 Å; b_0 = 6.79 Å; c_0 = 3.95 Å; $\alpha = \gamma = 90°$; $\beta = 97.6°$

C-300

Empirical formula from TGA (16) = $Ba(OH)_2 \cdot 0.39H_2O$; main compound: $\alpha\,BA(OH)_2$

Cell lattice: a_0 = 11.03 Å; b_0 = 12.56 Å; c_0 = 7.11 Å ($\alpha = \beta = \gamma = 90°$)

Secondary product: $Ba(OH)_2 \cdot H_2O$

A more detailed study (17) of the equilibria between α and β barium hydroxide and the monohydrate leads us to deduce that the C-200 catalyst contains β $Ba(OH)_2$ in the bulk of the solid, and $Ba(OH)_2 \cdot H_2O$ on the surface. The monohydrate is produced from the original β $Ba(OH)_2$ by the adsorption of water during storage in the presence of anhydrous NaOH.

The equilibrium between β $Ba(OH)_2$ and the $Ba(OH)_2 \cdot H_2O$ is reached in 24 h of storage, and the product obtained presents an empirical formula of $Ba(OH)_2 \cdot 0.8H_2O$. This rehydration is very easy, because the cell lattice dimensions of both barium hydroxides are very similar. These structures are very similar to those described for the isotypic structures of $Sr(OH)_2 \cdot H_2O$ (18) and $Sr(OH)_2$ (18, 19). Thus we can postulate the structure pictured in Fig. 1 for the C-200 catalyst. The β $Ba(OH)_2$ stands inside the bulk and the $Ba(OH)_2 \cdot H_2O$ is on the surface.

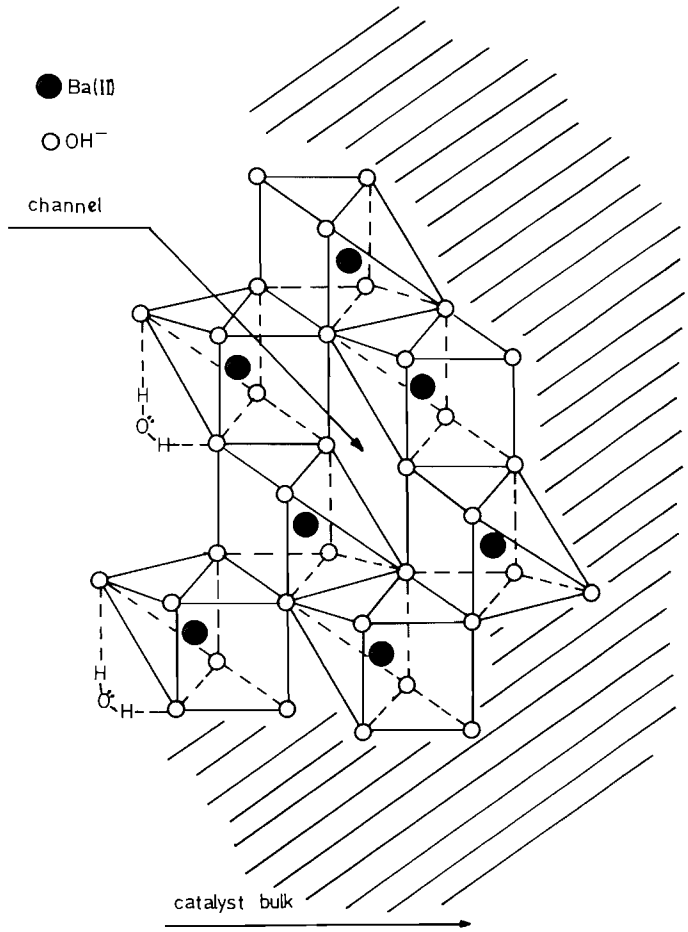

FIG. 1. Proposed structure for C-200 catalyst; average Ba(II)—OH^- = 2.6 Å; average OH^-—OH^- or OH^-—H_2O = 3.5 Å.

When the C—O is calcinated at 300°C, α $Ba(OH)_2$ (stable form at $T > 250°C$) (20) is produced. This solid is stored in a bottle in the presence of anhydrous NaOH. As in the case of C-200, the α $Ba(OH)_2$ is partially rehydrated to get the C-300 catalyst.

From X-ray analysis (17), we could deduce that the C-300 is a mixture of α $Ba(OH)_2$ and $Ba(OH)_2 \cdot H_2O$, with an empirical formula of $(Ba(OH)_2 \cdot 0.3H_2O)$. Rehydration is slower in this case, because of the quite different cell lattice dimensions of both compounds. Therefore we can say that C-300 consists of α $Ba(OH)_2$ in bulk and of $Ba(OH)_2 \cdot H_2O$ on the surface.

The structure of commercial barium hydroxide C-0 ($Ba(OH)_2 \cdot 8H_2O$) has been described in the literature (21) as an antiprism around the Ba(II) with an average distance Ba—OH^- = 3.63 Å.

2. Influence of the chemical and textural properties of the catalysts on the yield

The influence of the nature of the catalyst upon the yield of the process, with different ketones, was analyzed. The results are shown in Table 2.

From these results we can observe that the steric hindrance of the alkyl group in the ketone (R) diminishes the yield of **3** in all cases. This group will hinder the adsorption and generation of

[b]Error ±5%.

the carbanion from the ketone (see Sect. 4) so that the yield will be lower.

The high yields obtained with Ph—CO—CH_3 can be related to the different nature of adsorbed carbanion compared to that obtained from R—CO—CH_3 (see Sect. 4).

The catalytic activity of the three catalysts is similar with the same ketone. Therefore we can say that the reaction seems to be insensitive to the structure of the catalyst for this kind of ketone. This behaviour has only been observed in the hydrolysis of the salicylic esters (22). It can be related to a similar structure of the adsorbed carbanion produced from the R—CO—CH_3 ketones (see Sect. 4).

Nevertheless, in the case of Ph—CO—CH_3, the process actually seems to be sensitive to the structure of the catalyst:

$$C—O \approx C\text{-}200 > C\text{-}300$$

The structures of C-0 and the main component of C-200 ($Ba(OH)_2 \cdot H_2O$) present very similar distances Ba—OH^- (3.63 Å) and OH^-—H_2O (3.66 Å) (17, 21). These distances allow the unconjugated carbanion (Sect. 4) to be placed where the OH^- was in the lattice, and the aromatic ring will interact with the Ba(II) by means of a charge transfer complex, which will stabilize the intermediate.

In the case of C-300, the amount of $Ba(OH)_2 \cdot H_2O$ is lower than in C-200. Therefore the number of active sites is not as high as in the C-200 catalyst (14, 17), and the yield diminishes.

TABLE 3. Yields obtained in Ph—CH=CH—CO—R (% molar)[a]

% (v/v)	ε (mixture)	Yield[b] Ph	Me	Et	iPr	*t*Bu

[b]Error ±5%.

3. Influence of the dielectric constant of the solvents

To learn more about the influence of the solvent in the process, we chose two low dielectric constant solvents, cyclohexane (ϵ = 1.89) and 1,4-dioxane (ϵ = 2.2). The latter could chelate the Ba(II), due to the pair of oxygen atoms, and could lead to an homogeneous catalysis by means of ionic pairs, as in the Michael addition (16). The mixtures chosen were cyclohexane/EtOH (96%) and 1,4-dioxane/EtOH (96%), and the ϵ of these mixtures was calculated as follows:

$$[1] \quad \epsilon = \Sigma_i x_i \epsilon_i$$

where: x_i = molar fraction of component "i" in the mixture of solvents and ϵ_i = dielectric constant of component "i." The experimental results are shown in Table 3.

From the results in Table 3, we can deduce that the process needs a high value of dielectric constant. This could be explained if we postulate an homogeneous catalytic process by ionic pairs (R—CO—CH_2^-) (Ba(II), OH^-), but we must reject this idea because those species have not been observed in solution (using ir or uv–visible spectroscopy) for these reaction

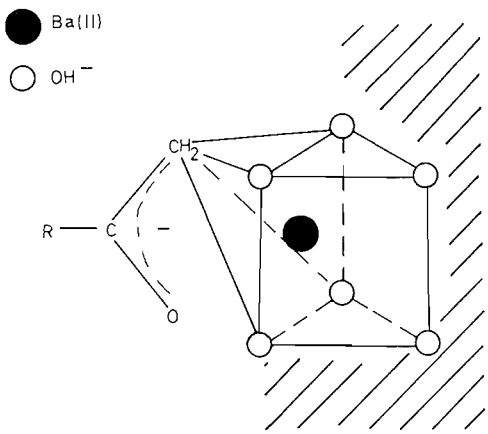

FIG. 3. Adsorbed carbanion from R—CO—CH_3 (R = Me, Et, iPr, and *t*Bu) on C-200 catalyst.

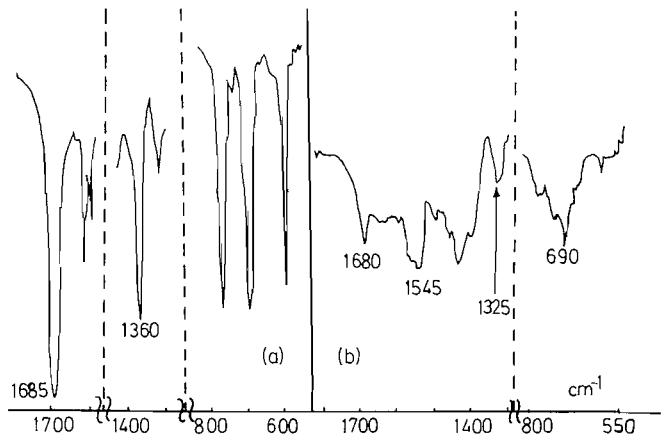
conditions (see Sect. 4). Another reason for rejecting the ionic pair process is that these pairs have not been trapped by the polymeric reagent (Ⓟ-CHO). Thus we can say that a high value of dielectric constant is necessary to relax the catalyst lattice, giving a more active OH^- on the catalytic surface.

On the other hand, the chelating power of 1,4-dioxane over the Ba(II) is not important in this process, because similar yields are obtained with the same amount of 1,4-dioxane and cyclohexane. Comparable results were obtained in the Michael addition (16).

The increase in the percentage of water (related to the percentage of commercial EtOH (96%) in the mixture) does not seem to affect the catalytic activity of C-200, because this basic solid may act in aqueous media (e.g., hydrolysis of esters (22)). This property makes this catalyst interesting from the synthetic point of view, because many basic catalysts are only active in anhydrous media.

4. Study of the reaction intermediates

The ir spectra of adsorbed species over the catalytic surface on the C-200 were carried out in open air (see Experimental).



(a) acetophenone
(b) adsorbed species

FIG. 4. Infrared spectra: (*a*) acetophenone; (*b*) adsorbed species from acetophenone on C-200 catalyst.

Thus, an absorption at 1545 cm^{-1}, related to the adsorbed CO_2, was detected in all cases (20). The main bands of adsorbed species produced from CH_3—CO—R (R = Me, Et, Pr^i, and Bu^t) are shown in Table 4.

From the results in Table 4 we can deduce that the C=O bond is not present in the adsorbed species produced from ketones of type R—CO—CH_3 (there is no band at 1715–1730 cm^{-1}). The absorptions at 1590 and 1320 cm^{-1} can be related to the presence of C=O and C=C, according to the literature (23, 24), and to the ir spectra of sulfur ylids adsorbed on C-200 (25). Therefore we can postulate the generation of a carbanion (Fig. 3) from the ketone. Due to the low pK_a of the ketones, these species should be produced on the strong basic sites of the catalyst, titrated with BA as has been described in the Michael addition (26), and in the Corey–Chaykowsky reaction (25), because they are not trapped by the polymeric supported reagent Ⓟ-CHO. The ir bands of enone Ⓟ-CH=CH—CO—R were not detected in the resin after the reaction.

When the adsorption of acetophenone was carried out, a different ir spectrum (Fig. 4) was obtained.

The 1680 cm^{-1} band (quite close to the conjugated C=O of the acetophenone) was present in the spectrum. There is a clear band at 1325 cm^{-1}, besides the CO_2 adsorbed band (1545 cm^{-1}). The former can be related to the presence of a C=C bond in a $(O=C=CH_2)^-$ carbanion. On the other hand, there is no band at 1360 cm^{-1} related to CH_3—CO, and the aromatic zone is very altered (see Fig. 3). So we could postulate adsorbed species like **4** (Fig. 2), where the negative charge is practically unconjugated with C=O, and there is a π interaction between the aromatic ring and the $5d^0$ orbital of Ba(II).

The negative charge is thus greater in the "CH_2" of the carbanion from Ph—CO—CH_3 than in the case of R—CO—CH_3. Therefore the yield obtained with acetophenone will be greater than those with R—CO—CH_3, as has been observed (see Table 2). This could be explained by the different structure of the intermediate in each case: in the methyl alkyl ketones, a conjugated carbanion is produced (as has been proved by the ir spectrum); in the aromatic ketone, the intermediate could be pictured as **4**, because in this case the C=O band at 1680 cm^{-1} is present. The difference in behaviour could be explained by the geometry of the catalytic crystal, where the distance between C and O (2.5 Å) is smaller than 3.6 Å (in the lattice).

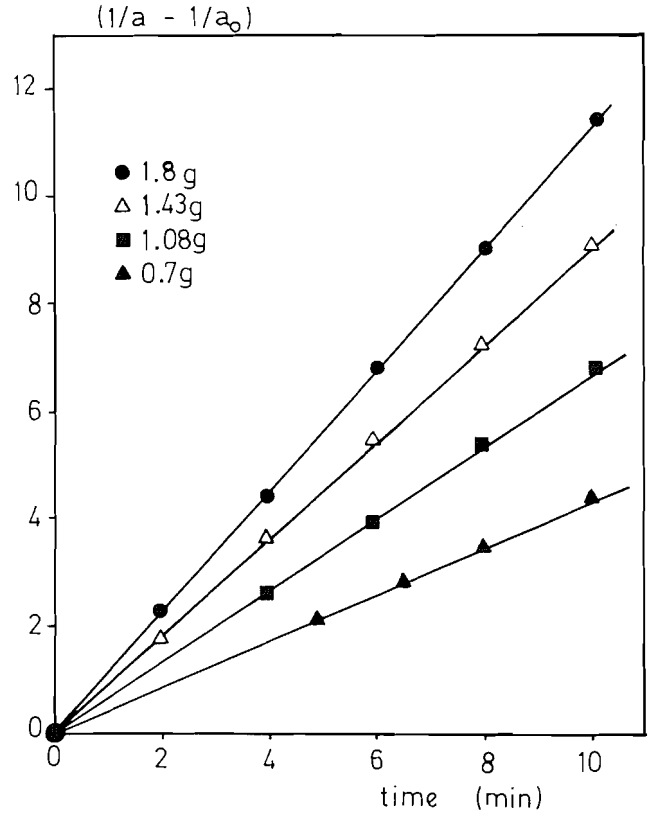

FIG. 5. Second-order kinetic plots: Ph—CH=CH—CO—Ph synthesis with C-200 catalyst.

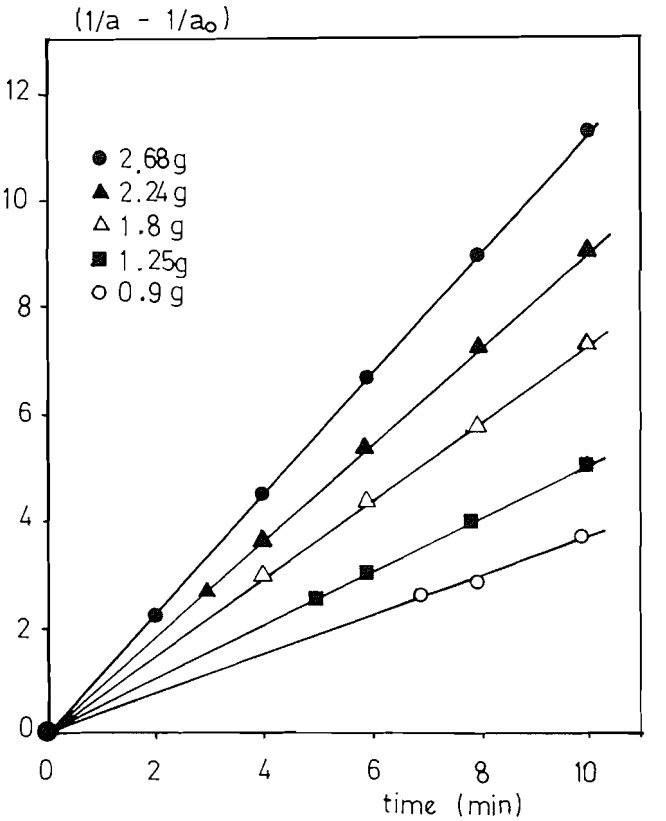

FIG. 6. Second-order kinetic plots: Ph—CH=CH—CO—Et synthesis with C-200 catalyst.

In the case of aliphatic ketones, the only possible adsorption state is that produced by the enolate, because the R group cannot interact with the Ba(II).

When the adsorption of benzaldehyde was carried out, no C=O band (1695 cm^{-1}) was observed, and there was a band at 1590 cm^{-1}. This band could be related to a $\pi^2_{C=O} \rightarrow 5d^0$ Ba(II) interaction, as has been shown in several substituted benzaldehydes (27).

On the other hand, ionic pairs such as ($R—CO—CH_2^-$, $Ba(OH)^+$) have not been detected by ir or uv–visible spectroscopy. This observation is consistent with the fact that these species were not trapped by the polymeric supported reagent Ⓟ-CHO.

Therefore we can say that the Claisen–Schmidt condensation catalyzed by C-200 is an interfacial solid–liquid process. The reaction takes place between an adsorbed carbanion (generated by reaction between the ketone and the basic site), and an adsorbed aldehyde molecule on a barium ion of the surface.

5. Kinetic runs

The kinetic runs of the Claisen–Schmidt reaction were carried out with Et—CO—CH_3 and Ph—CO—CH_3. These compounds were taken as models for the two kinds of adsorbed carbanions.

The kinetic runs were fitted to a second-order kinetic equation using [R—CO—Me] = [Ph—CHO] = 0.1 *M*. The experimental results obtained by several amounts of C-200 catalyst are shown in Figs. 5 and 6.

The van't Hoff plot gave a partial kinetic order in basicity (basicity = [(wt. cat. (g) · ((mequiv./g)/20 mL)] equal to one.

$$R = Ph;\ \ln r_0 = -2.041 + 1.02 \ln (\text{mequiv. base/L})$$

$$R = Et;\ \ln r_0 = -2.45 + 1.03 \ln (\text{mequiv. base/L})$$

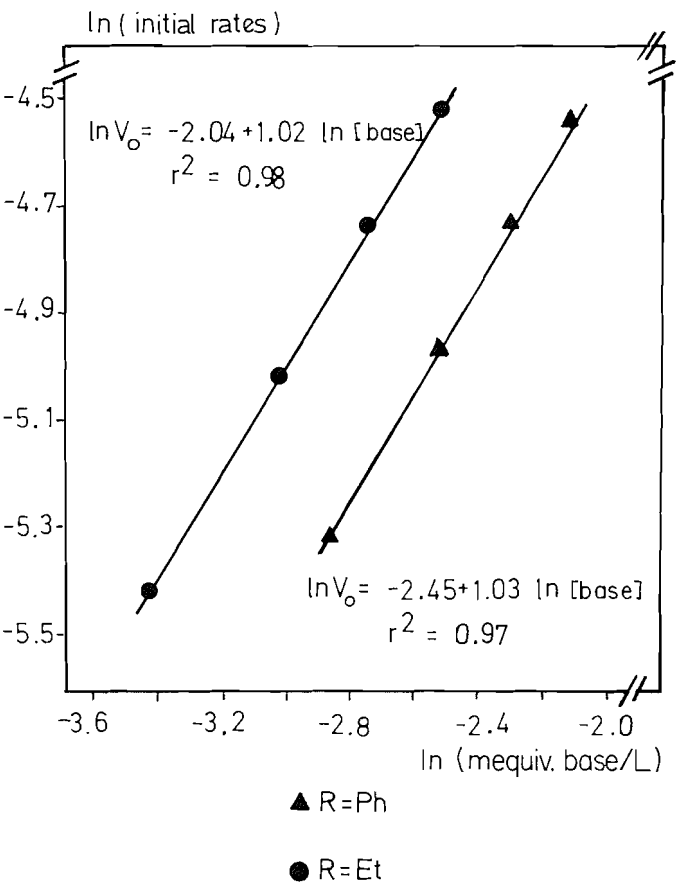

FIG. 7. van't Hoff plot for the catalyst kinetic order.

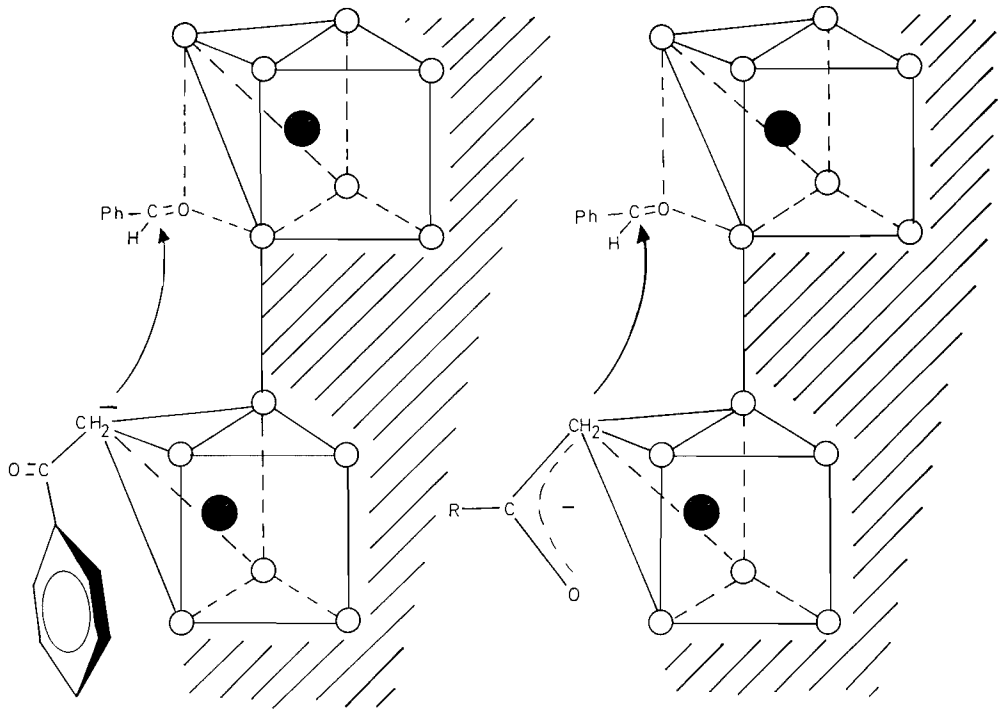

FIG. 8. Transition state for the Claisen–Schmidt condensation.

So we can say that the Claisen–Schmidt reaction catalyzed by C-200 has a rate governed by a rate law, eq. [2]

[2] $r = k$[R—CO—CH_3][Ph—CHO][equiv. base/L]

for both kinds of ketones, as in the homogeneous phase (28, 29).

This equation shows that only one active site of the catalyst acts in the rate controlling step. It agrees with a process in which the carbanion (produced from the reaction of ketone and the basic site) reacts with the adsorbed aldehyde, which is on a Ba(II) crystal. This structure can be pictured as in Fig. 8.

This interaction increases the electrophilicity of the carbon of the C=O bond, favouring the process.

If we represent the apparent kinetic constant of the second-order equation,

$$k_{ap} = k[\text{equiv. base/L}]$$

we obtain the straight line that appears in Fig. 9.

The slopes of these lines give us the true kinetic constant:

Ph—CO—CH_3 (50°C)

$$k = (13.8 \mp 0.2)\ \text{L}^2\ \text{equiv.}^{-2}\ \text{min}^{-1}$$

Et—CO—CH_3 (50°C)

$$k = (8.9 \mp 0.1)\ \text{L}^2\ \text{equiv.}^{-2}\ \text{min}^{-1}$$

The Arrhenius plot gives us the apparent activation energy:

Ph—CO—CH_3 $E_{ap} = (9 \mp 1)$ kcal/mol

$$PZ = (6.9 \mp 0.8)\ \text{L}^2\ \text{equiv.}^{-2}\ \text{min}^{-1}$$

Et—CO—CH_3 $E_{ap} = (12 \mp 1)$ kcal/mol

$$PZ = (8.3 \mp 0.8)\ \text{L}^2\ \text{equiv.}^{-2}\ \text{min}^{-1}$$

The higher value of k for Ph—CO—CH_3 than for Et—CO—CH_3, and the lower value of the apparent activation energy for Ph—CO—CH_3 than for Et—CO—CH_3 an be explained by the different nature of the adsorbed carbanion.

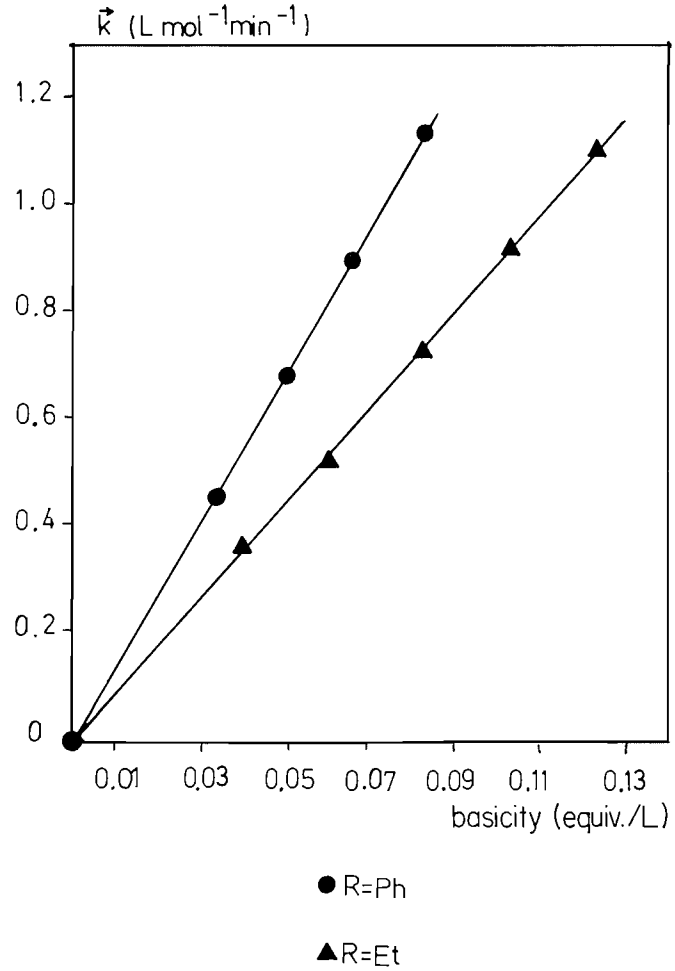

FIG. 9. Real kinetic constants in the synthesis of Ph—CH=CH—CO—R catalyzed by C-200.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

In the case of Ph—CO—CH_3, we think there is a practically unconjugated carbanion (Ph—CO—CH_2^-), because the C=O band of the adsorbed species (1680 cm^{-1}) is very close to the C=O band of the original ketone (1685 cm^{-1}). In the case of the R—CO—CH_3 ketones, the carbanion is actually conjugated with the C=O bond (absorption at 1590 cm^{-1}, from a C=O bond). The more active carbanion of acetophenone reacts more quickly, and with lower activation energy, than the conjugated carbanion from Et—CO—CH_3. This assumption agrees with the experimental results.

Therefore, although the kinetic equation is the same for the two kinds of ketones, the mechanism is different, due to the nature of the adsorbed carbanions. This fact shows us the importance of the study of the adsorbed species in verifying the true mechanism of the interfacial solid–liquid reaction.

The rates and products of addition of 4-chlorobenzenesulfenyl chloride to a series of trisubstituted alkenes

GEORGE H. SCHMID,[1] DENNIS G. GARRATT, AND COLEEN L. DEAN
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received August 22, 1986

GEORGE H. SCHMID, DENNIS G. GARRATT, and COLEEN L. DEAN. Can. J. Chem. **65**, 1172 (1987).

The rates and products of addition of 4-chlorobenzenesulfenyl chloride to *E*- and *Z*-3-methyl-2-pentene, *E*- and *Z*-3,4-dimethyl-2-pentene, *E*- and *Z*-3,4,4-trimethyl-2-pentene, and 2,4,4-trimethyl-2-pentene were studied to determine if the mechanism involved a tertiary β arylthio carbocation. It was found that the rates of addition are not as fast as one would predict based on the polar effects of the substituents on the rate of addition to mono- and disubstituted alkenes. The products are formed by *anti*-stereospecific addition as in the case of addition to 1,2-disubstituted alkenes. As a result it is concluded that the reaction occurs by means of the usual mechanism involving a bridged thiiranium ion.

GEORGE H. SCHMID, DENNIS G. GARRATT et COLEEN L. DEAN. Can. J. Chem. **65**, 1172 (1987).

Dans le but de déterminer si le mécanisme de la réaction implique un carbocation β-arylthio tertiaire, on a déterminé les vitesses de réaction ainsi que la nature des produits obtenus lors de l'addition du chlorure de chloro-4 benzènesulfènyle sur les méthyl-3 pentènes-2 (*E* ou *Z*), sur les diméthyl-3,4 pentènes-2 (*E* ou *Z*), sur les triméthyl-3,4,4 pentènes-2 (*E* ou *Z*) et sur le triméthyl-2,4,4 pentène. On a trouvé que les vitesses d'addition ne sont pas aussi rapides que celles que l'on pourrait prévoir en se basant sur les effets polaires des substituants sur les vitesses d'addition sur des alcènes mono- ou disubstitués. Les produits se forment par une addition stéréospécifique *anti*, comme dans les cas des additions sur des alcènes disubstitués en positions 1,2. Sur la base de ces résultats, on en conclut que la réaction se produit par le biais du mécanisme usuel impliquant un ion thiiranium ponté.

[Traduit par la revue]

The systematic study of the addition of arenesulfenyl chlorides to alkenes carried out in this laboratory has established many of the mechanistic features of this reaction (1). It is possible to conclude that in this addition reaction the rate-determining transition state is bridged and there is little charge on either carbon or sulfur (2). Furthermore, in the product-determining step, attack by chloride ion occurs at the least hindered carbon of the thiiranium ion (3). These results are in contrast to the reactions of stable thiiranium ions, which undergo reactions with nucleophiles at the most hindered carbon atom (4). A possible explanation (5) for this difference in product regiochemistry is that the addition reaction, carried out in relatively nonpolar solvents, occurs by means of a contact ion pair. The reaction of stable thiiranium ions, carried out in highly polar solvents, occurs by means of a dissociated ion.

The importance of ion pairs in the mechanism of many reactions in solution is well documented (6). Electrophilic additions are no exception. A number of people have proposed that the mechanism of an electrophilic addition reaction could involve ion-pair intermediates (7). Subsequent work by Rolston and Yates (8) and Garnier and Dubois (9) established the importance of ion pairs in the bromination of alkenes. In 1972, we provided evidence that the mechanism of the electrophilic addition of arenesulfenyl chlorides to alkenes and the mechanism of neighboring sulfur participation in the reaction of β-chloroalkyl aryl sulfides both involve the same series of thiiranium ions (10). The mechanism that we proposed is shown in Scheme 1 (ref. 1, p. 838).

The upper sequence of reactions in the scheme involving ion pairs **3** and **4** is the general solvolysis scheme proposed by Winstein (for a summary and complete references see ref. 13) and applied to the reactions of β-chloroalkyl aryl sulfides. Evidence for ion pairs **3** and **4** and ion **5** is provided by the fact that a special salt effect, common ion rate depression and radioactive chloride ion exchange, is observed in the solvolysis of 2-chlorocyclohexyl 4-chlorophenyl sulfide (10). The lower sequence of reactions is similar to that proposed by Poutsma and Kartch (7*c*). The increase in rearranged, solvent incorporated, and perchlorate products caused by added $LiClO_4$ in the addition of arenesulfenyl chlorides to alkenes has been cited as evidence for ion pairs **1** and **2** (12). Not included in the scheme are an episulfurane (**1***a*) and a charge transfer complex, because there is no evidence for either of these species. Ion pairs **1** and **3** are contact ion pairs and **2** and **4** are solvent-separated ion pairs that differ only in the location of the counterion. Our contribution to the mechanism was to link these two paths either directly between ion pairs **1**–**3** and **2**–**4** or by means of the dissociated ion **5**. We propose in the scheme that electrophilic addition of arenesulfenyl chlorides to alkenes, isomerization of the Markownikoff–*anti*-Markownikoff adducts, and solvolysis of β-chloroalkyl aryl sulfides all occur by means of a common mechanism (14).

There is an additional difference between the reactions of stable thiiranium ions and the ion formed in the addition reaction that is not explained by our original proposal. This difference can be illustrated by the following example. The addition of 4-chlorobenzenesulfenyl chloride to *Z*-1-phenylpropene in methylene chloride forms products by *anti*-stereospecific but nonregiospecific addition (15). Such a reaction involves a thiiranium ion as an intermediate. This same thiiranium ion, prepared by the addition of 4-chlorophenyl(bis-4-chlorophenyl)sulfonium hexachloroantimonate to *Z*-1-phenylpropene in methylene chloride at −70°C according to the method of Modena and co-workers (16), reacts with chloride ion to form products whose stereochemistry varies with time (17). Thus at short reaction times, the product is formed via a thiiranium ion, while at longer reaction times the thiiranium ion forms an open β arylthio carbocation, which is the precursor to the reaction products. Therefore this thiiranium ion, formed under stable conditions, has a pathway to products not available to the thiiranium ion formed in the addition of 4-chlorobenzenesulfenyl chloride to *Z*-1-phenylpropene. We have added this new path to form an open ion **6** in the scheme. The possibility of

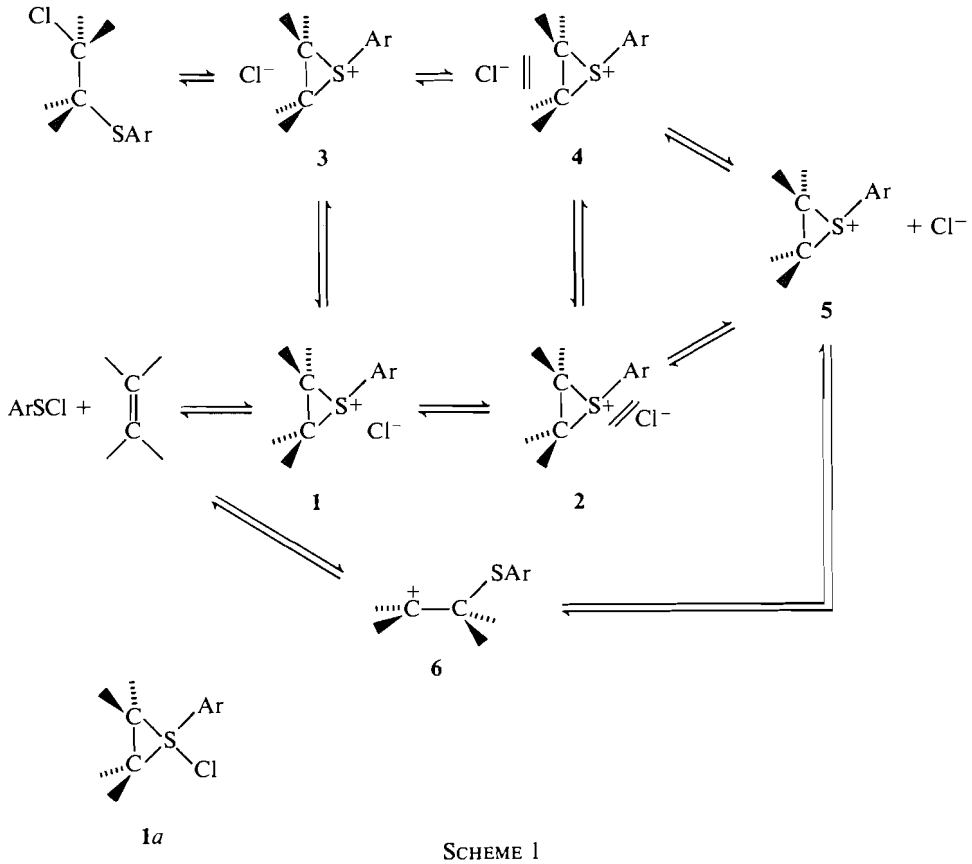
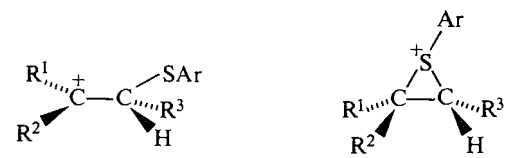


SCHEME 1

the intervention of open ions in the reactions of stable thiiranium has not previously been seriously considered.

These results suggest that in certain systems the energy difference may not be very great between an open β arylthio carbocation and a thiiranium ion. In the case of addition to *Z*-1-phenylpropene, the path leading to a thiiranium ion is still of lower energy than the one leading to an open ion. However, nonstereospecific addition of 2,4-dinitrobenzenesulfenyl chloride to *Z*-1-(4′-methoxyphenyl)propene is known (18). Thus an open ion is lower in energy in this system. It seems from all available data that addition of arenesulfenyl chlorides to styrene is close to the borderline between a bridged mechanism and one involving an open ion. This suggests that an alkene that would form an open β arylthio carbocation, which is slightly more stable than the analogous benzylic ion, might add arenesulfenyl chlorides in a nonstereospecific manner. Likely candidates include trisubstituted alkenes that can form a tertiary open β arylthio carbocation. Thus the open ion **7** may be of comparable energy to the thiiranium ion **8** particularly if the groups R^1, R^2, and R^3 are bulky, causing an increase in the intramolecular interactions in the transition state for the addition reaction.[2]

Surprisingly few studies of electrophilic additions to trisubstituted alkenes have been carried out. We have extended our structure–reactivity studies of arenesulfenyl chloride additions



7 **8**

to trisubstituted alkenes to investigate whether it is possible that the mechanism of this reaction involves an open ion. For this purpose we have measured the rates and products of addition of 4-chlorobenzenesulfenyl chloride (**9**) to a series of *E*- and *Z*-trisubstituted alkenes. The data and the mechanistic conclusions reached from these data are reported in this paper.

Results

The rates of addition of **9** to the trisubstituted alkenes **10–16** were measured in 1,1,2,2-tetrachloroethane at 25°C by means of the stopped-flow technique using a Durrum–Gibson stopped-flow spectrophotometer.

to follow a normal second-order rate law, first order in both alkene and sulfenyl chloride to 80% completion of the reaction. The rate data are presented in Table 1.

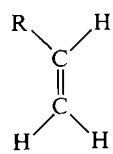
The product compositions were determined by ^{1}Hmr spectroscopy. Additions to the *E*- and *Z*-isomeric alkenes formed the four possible regio- and stereo-isomers. Isomerization of the Markownikoff to the *anti*-Markownikoff isomer served to identify the peaks associated with each regioisomer. Their identification could be made based on the fact that the chemical shifts of protons α or β to chlorine are further downfield than the corresponding protons α or β to sulfur (20). The ^{1}Hmr data are given in Table 2. The product compositions, determined by integration of nonoverlapping ^{1}Hmr peaks, are given in Table 3.

Discussion

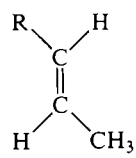
It is known that the first step in the addition of arenesulfenyl chlorides to alkenes is the rate-determining step (ref. 1, p. 836; ref. 21) and the reaction of the thiiranium ion intermediate is product determining. The data in Tables 1 and 3 allow us to compare the effect of substituents on the reactivity of alkenes **10–16** with the effect of the same substituents on the reactivity of mono- and disubstituted alkenes. First consider their effect on the rate-determining step.

The rate of addition of **9** to the alkenes **10–16** is not as fast as one would predict based on the polar effects of the substituents on the rate of addition to mono- and disubstituted alkenes. This rate-retarding effect can best be seen by comparing the effect of an alkyl group R on the reactivity of the trisubstituted alkenes to that of the same group R in the corresponding mono- and disubstituted alkenes. The reactivity ratio $I = k_2(R)/k_2(CH_3)$ has been proposed (22) and can be applied to the following series of compounds.

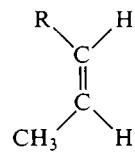
Series 1



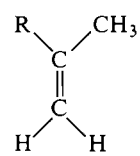
Series 2



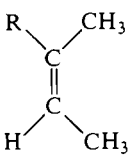
Series 3



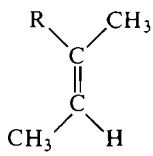
Series 4



Series 5



Series 6



The specific compounds, their rates of addition, and the reactivity ratios are given in Table 4.

A consistent pattern emerges in the reactivity ratio for Series 1–4. Substituting a methyl group by an ethyl group causes a modest increase in the reactivity ratio while substituting an isopropyl group causes a decrease. Replacing the methyl group by a tertiary butyl group causes a further decrease in the ratio. In contrast, replacing one methyl group by any of the three substituents causes a decrease in the ratio in Series 5 and 6. From this we can conclude that the rate enhancement expected by increasing the number of substituents

[c]Value taken from ref. 11.

on the double bond is substantially lower than that expected from polar substituent effects estimated in less-substituted alkenes. Thus the effect on the rate of increasing the number of alkyl substituents on the double bond is noncumulative. Consequently the accumulation of alkyl substituents on the double bond results in an increasingly important contribution from steric effects on the reaction rate.

Similar substituent effects are found in the addition of bromine to trisubstituted alkenes (22). In bromination, substituting a methyl group by an ethyl group causes an increase in the reactivity ratio for all the series while, as before, substituting an isopropyl group causes a decrease. Such behavior is consistent with previous observations (1), from which it has been concluded that the rate-determining transition state for the addition of arenesulfenyl chlorides is more congested than that for bromination.

It is clear from the data in Table 2 that the addition of **9** to the trisubstituted alkenes **10**–**16** forms products in a stereospecific manner. The question is whether these adducts are formed by *syn* or *anti* addition. The large majority of products of the reaction of arenesulfenyl chlorides and alkenes are formed by *anti* stereospecific addition (1). Very few cases of nonstereospecific addition have been reported (18), while products of *syn* addition have never been observed. Therefore the only reasonable conclusion is that the addition of **9** to **10**–**16** is *anti* stereospecific. Further support for this conclusion is provided by the isomerization of the adducts. Both Markownikoff and *anti*-Markownikoff regioisomers are formed in the addition reaction to five of the seven alkenes. Such isomerization between Markownikoff and *anti*-Markownikoff regioisomers is known to occur stereospecifically by means of a thiiranium ion (1). Thus both addition and isomerization involve a thiiranium ion.

There is a difference in the relative proportions of Markownikoff to *anti*-Markownikoff regioisomers in Series 5 and 6 when compared to Series 1–4. The initially observed product composition is richer in the Markownikoff isomer than in the kinetically controlled product compositions found in the addition to mono- and disubstituted alkenes (3). But in the reactions studied here, the Markownikoff to *anti*-Markownikoff

2,4,4-Trimethyl-2-pentene (**16**)	57.73	57.78	6.92	7.01	11.01	11.10

rearrangement occurs very rapidly. The rearrangement is complete within 15 minutes of adding **9** to the alkenes. Consequently the initially observed product composition is not the kinetically controlled product composition. Unfortunately, this means that we cannot determine which carbon atom of the thiiranium ion is attacked preferentially by the chloride ion in the product-determining step.

All of the data presented here are consistent with the addition of **9** to the trisubstituted alkenes occurring by means of the normal mechanism involving a thiiranium ion. Therefore we conclude that the path leading to a thiiranium ion is lower in energy than the one leading to an open ion in the addition of arenesulfenyl chlorides to trisubstituted alkenes in nonpolar solvents.

Experimental

Proton nmr spectra were obtained on a Varian T-60, HA-100, or HX-400 spectrometer. All spectra are referenced to tetramethylsilane as an internal standard.

Microanalyses were carried out by A. B. Gygli Microanalysis Laboratory, Toronto.

The alkenes were obtained commercially and their purity was verified by glc.

4-Chlorobenzenesulfenyl chloride was prepared as previously described (23). 1,1,2,2-Tetrachloroethane was purified as previously described (23).

Kinetics, product composition, and analytical samples were carried out or prepared as previously described (23). The elemental analyses for the adducts are given in Table 5.

Reactions of diazoalkanes with isocyanates. Synthesis of imidazolidine-2,4-diones, oxindoles, and oxazolidinones

JANET B. FULTON AND JOHN WARKENTIN[1]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 15, 1986

JANET B. FULTON and JOHN WARKENTIN. Can. J. Chem. **65**, 1177 (1987).

Thermolysis of a 5,5-dialkyl-Δ^3-1,3,4-oxadiazolin-2-one in nitrobenzene containing an aryl isocyanate at 150°C affords a 1,3-diaryl-5,5-dialkyl imidazolidine-2,4-dione, an *N*-arylcarbamoyl-3,3-dialkyloxindole, and a 3-aryl-2-arylimino-5,5-dialkyl-1,3-oxazolidin-4-one. Those products arise from attack of a diazoalkane, generated *in situ* from the oxadiazolinone by thermal cycloreversion, on the isocyanate function. Two imidazolidine diones, three oxazolidinones, and 14 oxindoles were prepared.

JANET B. FULTON et JOHN WARKENTIN. Can. J. Chem. **65**, 1177 (1987).

La thermolyse d'une dialkyl-5,5 Δ^3-oxadiazoline-1,3,4 one-2, à 150°C et dans du nitrobenzène contenant un isocyanate d'aryle, conduit à une diaryl-1,3 dialkyl-5,5 imidazolidinedione-2,4, un *N*-arylcarbamoyl dialkyl-3,3 oxindole et une aryl-3 arylimino-2 dialkyl-5,5 oxazolidine-1,3 one-4. Ces produits proviennent d'une attaque d'un diazoalkane, généré *in situ* par une cycloréversion thermique de l'oxadiazolinone, sur la fonction isocyanate. Deux imidazolidinediones, trois oxazolidinones et 14 oxindoles ont été préparés.

Introduction

Reactions of diazoalkanes with heterocumulenes have been known since Staudinger *et al.* first prepared a Δ^3-1,3,4-oxadiazoline by that approach (1), eq. [1]. Lipp and Köster (2)

[1] $Ph_2C{=}C{=}O + R^1R^2C{=}\overset{+}{N}{=}\overset{-}{N} \rightarrow Ph_2C$ (1,3,4-oxadiazoline ring: N=N, O, R^1, R^2)

obtained cyclobutanone (isolated as the semicarbazone derivative) from the 2:1 reaction of diazomethane with ketene (eq. [2])

[2] $2CH_2{=}\overset{+}{N}{=}\overset{-}{N} + CH_2{=}C{=}O \rightarrow$ (cyclobutanone, O) $+ 2N_2$

and Roberts and co-workers (3) demonstrated that cyclopropanone is a likely intermediate in that reaction. Hammond and Turro (4) isolated cyclopropanones by treating diazoalkanes with ketenes at low temperatures, and they postulated a dipolar intermediate as the precursor of a cyclopropanone, eq. [3].

[3] $RR'C{=}\overset{+}{N}{=}\overset{-}{N} + CH_2{=}C{=}O \rightarrow$

$CH_2{=}\overset{O^-}{\overset{|}{C}}{-}C(RR')\overset{+}{N}{\equiv}N \rightarrow$ (cyclopropanone, O, R, R^1) $+ N_2$

von Pechmann (5) and, later, Sheehan and Izzo (6), treated phenyl isocyanate with diazomethane to obtain a β-lactam, eq. [4]. Benzoyl isocyanate gave a 1:1 adduct, eq. [5]. Those

[4] $CH_2{=}\overset{+}{N}{=}\overset{-}{N} + PhN{=}C{=}O \rightarrow$

$[Ph{-}N{=}\overset{O^-}{\overset{|}{C}}{-}CH_2\overset{+}{N}_2] \xrightarrow{CH_2N_2}$ (β-lactam, Ph, N, O)

[5] $PhC(=O){-}N{=}C{=}O + CH_2{=}\overset{+}{N}{=}\overset{-}{N} \rightarrow$

$\left[Ph{-}C(O^-){=}N{-}C(CH_2\overset{+}{N}_2){=}O\right] \rightarrow$ (oxazolinone, Ph, O, N, O)

results were rationalized in terms of the dipolar intermediates written in the equations. A dipolar intermediate was postulated also in the process by which 3-oxo-1,2-diazetidinium hydroxide inner salts are formed from reaction of *N*-isocyanatoimines with diazoalkanes (7), eq. [6].

[6] $Ph_2C{=}N{-}N{=}C{=}O + Me_2CN_2 \xrightarrow{-N_2}$

$\left[Ph_2C{=}N{-}N{=}\overset{-O}{\overset{|}{C}}{-}\overset{+}{C}Me_2\right] \rightarrow$ ($Ph_2C{=}\overset{+}{N}{-}\overset{-}{N}$, Me, Me, O)

There are no publications, to the best of our knowledge, of reactions of dialkyl diazomethanes with aryl isocyanates. We now report the results of a study of such reactions.

Methods, results, and discussion

The thermal cycloreversion of a Δ^3-1,3,4-oxadiazolin-2-one (**1**) (eq. [7]) was used to generate a diazoalkane *in situ* (8) in the presence of an isocyanate. That fragmentation pathway has been shown to predominate over the competing fragmentation

[7] (oxadiazolinone, O, N, O, N, R^1, R^2) $\xrightarrow{a}$ $R^1R^2C{=}\overset{+}{N}{=}\overset{-}{N} + CO_2$

$\xrightarrow{b}$ $R^1R^2CO + N_2 + CO$

to R^1R^2CO, N_2, and CO in polar solvents (8). In neat aryl isocyanates the ratio of the fragmentation pathways (eq. [7]) was about a/b = 2. Although oxadiazolinones (8) are not very efficient as sources of diazoalkanes because of the competition between two fragmentation pathways, they are convenient alternatives to diazoalkanes prepared by oxidation of ketone hydrazones, partly because such hydrazones are generally contaminated with the corresponding azines unless special procedures are used (9) and also because diazoalkanes decompose readily (10), making their storage difficult.[2] Oxadiazolinones, on the other hand, are stable for many months in a freezer. Moreover, the alternative fragmentation (path b, eq. [7]) of

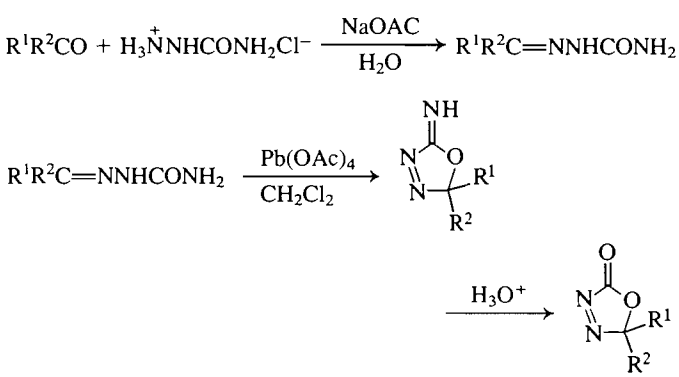
[a]CCl_4 solvent. The band near 1540 cm^{-1} is attributed tentatively to N=N stretching while that near 1835 cm^{-1} is attributed to C=O stretching.
[b]$CDCl_3$ solvent. The spectra were obtained at either 60 or 90 MHz.



SCHEME 1. Synthesis of oxadiazolinones

oxadiazolinones, although undesirable because of inefficient production of diazoalkanes, leads to products that are innocuous and, in general, easily separated from desired final products. Finally, oxadiazolinones are relatively easy to prepare by the sequence of reactions in Scheme 1.

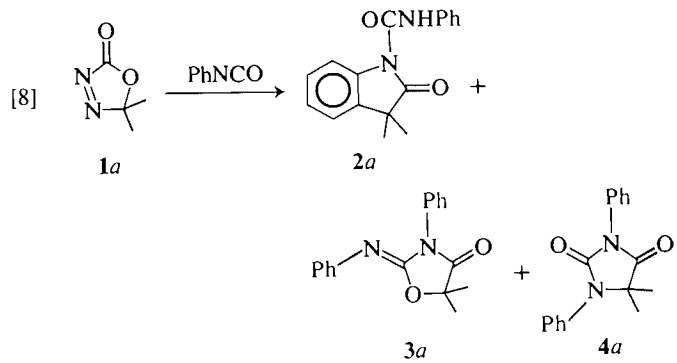
The oxadiazolinones prepared in connection with this study, and their diagnostic ir and ^1H nmr spectra, are listed in Table 1. Yields of recrystallized semicarbazones were generally near 70%. Their oxidation and hydrolysis (Scheme 1) afforded crude oxadiazolinones, in 55–65% yields, and pure oxadiazolinones, either by sublimination or bulb-to-bulb distillation at 40°C and 10^{-2} Torr (1 Torr = 133.3 Pa), in ca. 40% yields.

Thermolyses of oxadiazolinones were carried out in nitrobenzene solution of isocyanates at 150°C. Nitrobenzene was chosen for its high boiling point, its inertness toward isocyanates, and its polarity.

Characterization of reaction products

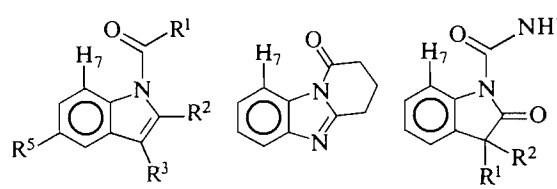
The major product from thermolysis of **1***a* in nitrobenzene containing phenylisocyanate (eq. [8]) was identified as 1-phenylcarbamoyl-3,3-dimethyloxindole (**2***a*) on the basis of microanalytical, spectroscopic, and chemical evidence. That evidence, applicable to other oxindoles of the family **2**, is summarized in Table 2 and is discussed below.

Both microanalyses and mass spectrometry indicated a 2:1 adduct of aryl isocyanate and diazoalkane, less N_2. The infrared spectra of compounds **2** showed a broad, intense band between 1700 and 1730 cm^{-1} that was partly resolved into two bands, suggesting two carbonyl groups. *N*-Methyl oxindoles exhibit a single intense ir absorption in the range 1700–1710 cm^{-1} (11). A weak to medium intensity band near 3240 cm^{-1} in the ir spectra of compounds **2** can be assigned to NH stretching.



The ^1H nmr spectra of compounds **2** contained an interesting feature in the low field region. One aryl proton was significantly deshielded (δ ca. 8.2) compared to the rest. In spectra of products from *p*-substituted phenyl isocyanates, that low field signal was a doublet with ca. 8 Hz splitting. That unique 1-proton signal was assigned to H-7, on the basis of the spectra of the model compounds below (12).

The ^{13}C nmr spectra of the *N*-arylcarbamoyl oxindoles **2**



H-7, δ 8.4 H-7, δ 8.2 **2**(H-7, δ = 8.2)

(Table 3) were consistent with the assigned structure. In particular, the signal at δ 184.0 ± 1.0 could be assigned to the carbonyl carbon of the 5-membered ring and the signal at δ 149.5 ± 0.2 could be assigned to the second carbonyl carbon, modelled with *N*,*N*′-diphenylurea (δ 152.6). Signals from the

[c]Not determined.
[d]The isomers **2***m* and **2***n* were obtained in 1:1 ratio. The yield, estimated before separation of the isomers from each other and from minor impurities, was 44%.

ring atoms were assigned on the basis of empirical substituent shielding parameters (13). Agreement between calculated and observed chemical shifts was poor in cases where large *ortho* interactions (13) might be expected. Ultraviolet spectra of representative 1-arylcarbamoyl-3,3-dialkyloxindoles (250 nm, inflection, log ε 4.58; 244 nm, log ε = 4.45 for **2***a*) were similar to those of oxindole (11), 249 nm (log ε 3.97), 277 nm (inflection, log ε 3.26), and *N*-methyloxindole (14).

Finally, basic hydrolysis of **2***a* afforded the known 3,3-dimethyloxindole. Moreover, 3,3-dimethyloxindole reacted with phenyl isocyanate in nitrobenzene at 150°C to form **2***a*.

The minor products from the reaction (eq. [8]) were identified as 5,5-dimethyl-3-phenyl-2-phenylimino-4-oxazolidinone (**3***a*) and 5,5-dimethyl-1,3-diphenyl imidazolidine-2,4-dione (**4***a*) as described below.

Mass spectrometry showed that both minor products were isomers of **1***a*. Both gave a fragment ion (m/z = 161) suggestive of the loss of phenyl isocyanate from the parent ion. One of them also gave an intense signal (m/z = 194) attributable to *N*,*N*′-diphenyl carbodimide, and that isomer was therefore assigned structure **3***a*. The infrared spectrum of isomer **3***a* included a broad intense band between 1685 and 1710 cm^{-1}, which was partially resolved into two bands with maxima at 1690 and 1705 cm^{-1}. In addition, there was a sharp band of medium intensity at 1745 cm^{-1}. The broad, partially resolved band was attributed to stretching of both the carbonyl group and the exocyclic imine group. The model compounds below were used to support the assignment of structures **3** (14).

The infrared spectrum of **4***a* had bands at 1775 and 1710 cm^{-1},

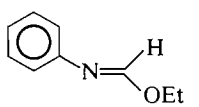
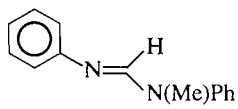
in good agreement with the infrared spectrum of 1,3-diphenyl imidazolidine-2,4-dione (1780 and 1720 cm^{-1}) (15). Those bands are attributed to the symmetric and antisymmetric coupled stretching vibrations of the carbonyl groups of **4***a*.

^1H nuclear magnetic resonance spectroscopy supported the structural assignments in the following way. Isomer **3***a*, with phenyl groups in quite different environments, gave aryl proton signals spread over a width of 45 Hz at 60 MHz, whereas **4***a* gave more collimated aryl proton signals. The high field signals, on the other hand, were not useful for differentiating between **3***a* and **4***a*.





The ^{13}C nmr spectra, although not definitive, were consistent with the assignments of the isomeric minor products, **3***a* and **4***a*. Thus, the imino-carbon signal of **3***a* at δ 147.0 is similar to that of imino ethers (δ 154.2) and of aryl amidines (δ 149.8), the compounds that are illustrated below (16). Moreover, the ^{13}C-signal of **4***a* (δ 153.5), assigned to the ureide carbon, is very close to those of 1,3-diphenyl imidazolidine-2,4-dione (δ 153.1) and *N,N′*-diphenylurea (δ 152.6). Thus, all the evidence, taken together, leaves no room for doubt about the assignments of structures **3***a* and **4***a*. The fact that only one ^{13}C signal was observed near δ 147 in the spectrum of **3***a* indicates that only one of the two possible configurations about the imino group was represented. Although it was not possible to make a choice on the basis of the spectroscopic evidence, the *Z*-configuration (eq. [8]) is the more likely from considerations of steric interactions.

The structures of other members of the families **3** and **4** were assigned on the basis of analogy (Table 4).

Mechanism

A concerted 1,3-cycloaddition between a diazoalkane and phenyl isocyanate, to form cycloadduct **5** (Scheme 2), is a potential first step. An alternative first step is nucleophilic addition of the diazoalkane to the isocyanate carbonyl carbon to form dipolar intermediate **6**. Theory suggests that the reactivity and regioselectivity of dipolarophile–dipole reactions are controlled by the interaction between the dipole's HOMO and the dipolarophile's LOMO (17). Isocyanates have a low-lying in-plane LUMO and a vacant π MO only slightly above it in energy (18). The latter interacts well with an aryl substituent, affording stabilization for a dipolar intermediate. That feature, together with the fact that out-of-plane approach to the isocyanate carbon cannot be accompanied by the $[\pi^2s + \pi^2a]$ interaction (18), has led to the prediction that only nonconcerted cycloadditions to aryl isocyanates are to be expected. We assume, therefore, that the initial species formed from attack of a diazoalkane on phenyl isocyanate is **6**. The subsequent steps must account for the apparent difference between diazomethane (which leads to β-lactams, see Introduction) and disubstituted diazomethanes, which afford **2**, **3**, and **4** but not β-lactams. We propose that the intermediate **6**, which may be in equilibrium with **5** at high temperature, loses N_2 to form **7** and (or) **8** and **9**, in steps reminiscent of the Favorskii reaction. Ring closure to **8** or **9** would be most likely to occur directly from **6** in the case of the diazomethane-derived intermediate ($R^1 = R^2 = H$), but via **7** in cases where R^1 and R^2 are alkyl groups. From thermochemical considerations, the α-lactam intermediate **9** is more likely than the imino oxirane **8**. We postulate that the point of diversion, between the chemistry of diazomethane and its dialkyl derivatives, comes at the α-lactam stage. In the case where $R^1 = R^2 = H$, **8** and **9** are relatively long lived and **9** (the major isomer) reacts with diazomethane in a ring-expansion sense (eq. [9]) reminiscent of the ring expansion of cyclic

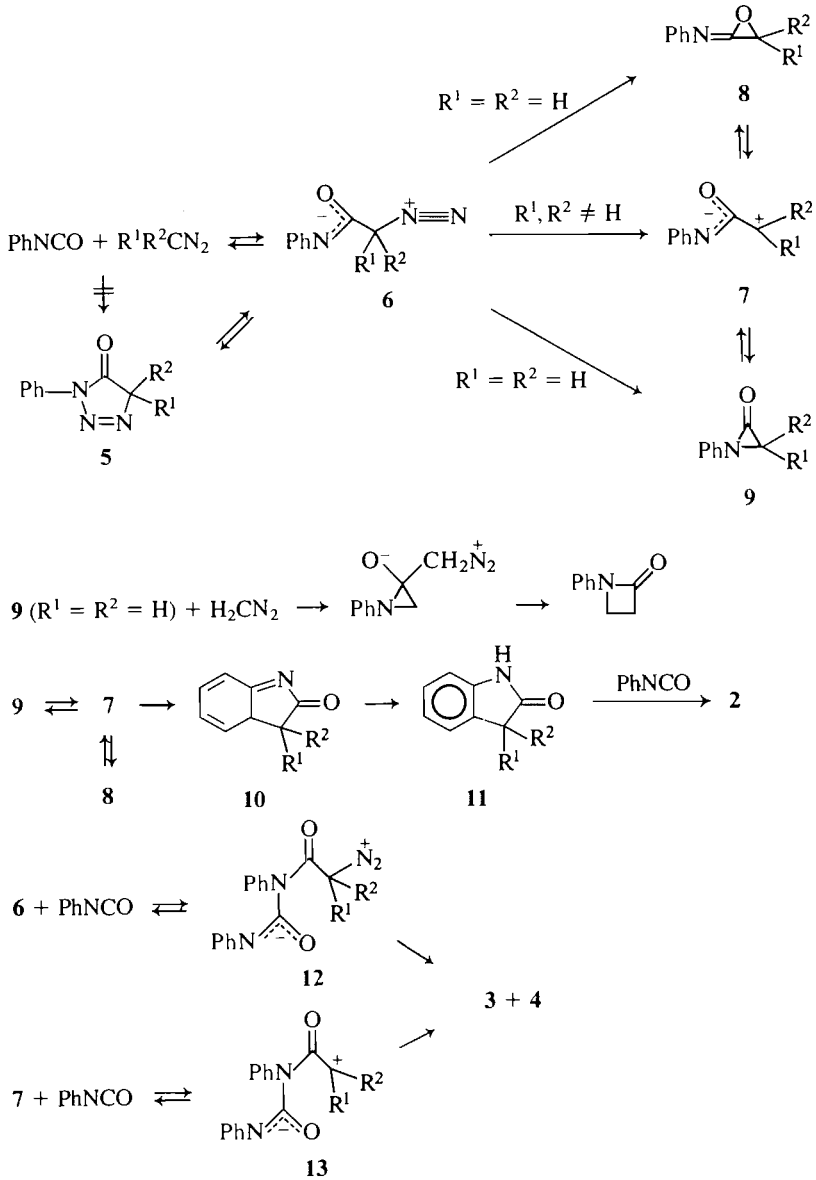

SCHEME 2

[9] $PhN{-}CH_2 + CH_2N_2 \rightarrow PhN{-}CH_2 \rightarrow PhN{-} + N_2$

ketones with diazomethane. In cases where $R^1 = R^2$ = alkyl and where the steady state concentration of $R^1R^2CN_2$ is low (as in the present experiments), the reaction of **9** with diazoalkane is very slow and **7**, in equilibrium with **8** and **9**, is consumed by intramolecular electrocyclic ring closure to **10** (Scheme 2). That closure can be viewed as the first step of an electrophilic aromatic substitution on a highly activated phenoxide-like aromatic system. Tautomerization of **10** to **11**, followed by its attack on excess aryl isocyanate, affords **2**. Intermediates **6** and **7** can also be intercepted by aryl isocyanate to form new dipolar intermediates (**12** and **13**), which undergo ring closure through both O and N of the anionic moiety to form **3** and **4**, respectively. The above steps, illustrated in Scheme 2 for the case of phenyl isocyanate, form a mechanistic hypothesis for the formation of **2**, **3**, and **4**. It is based in part on analogy (see Introduction) and in part on the evidence discussed below.

2-Diazopropane, prepared by oxidation of acetone hydrazone with mercuric oxide, was obtained as an ethereal solution containing water and ethanol (10). A portion of that solution, upon treatment with excess phenylisocyanate at room temperature, afforded α-hydroxy isobutyranilide and α-ethoxy isobutyranilide (as well as *N,N'*-diphenylurea) but not **2***a*, **3***a*, or **4***a*. Another portion of the diazopropane solution, dried before treatment with phenyl isocyanate, gave mostly α-ethoxy isobutyranilide and a trace of the hydroxy compound. Since **5**, from a concerted cycloaddition, is expected to be kinetically stable at room temperature (**14** and **15** are very stable) (19) the

14 **15**

above observations point to an acyclic intermediate (e.g., **6** or **7**, $R^1 = R^2 = CH_3$) formed from phenyl isocyanate and diazopropane, which can be intercepted efficiently by water and

TABLE 4. Effects of concentration and temperature on the product distribution from **1***a* and PhNCO[a]

		Relative yields[c]

[a]These experiments were conducted under conditions that might be used by synthetic chemists. They are not strictly comparable because of differences in the way in which the reactant concentrations and the medium were changed. See Experimental.

[b]Calculated final concentration, excluding isocyanate consumed.

[c]Determined by ^{1}H nmr spectrometry of the mixture of products and subject to errors of ca. 10%.

by ethanol. Similarly, the fact that the relative yields of **3** and **4** rose with increasing concentration of phenyl isocyanate, while that of **2** fell, requires a competition such as that between unimolecular cyclization of **7** and its bimolecular reaction with PhNCO.

Although **6** is included in Scheme 2 as a species that can react with PhNCO, we have not included **6** as a direct source of **10**. The preferred route for forming **10**, from **7** instead of from **6**, is based on the assumption that steric hindrance to direct closure of **6** to **10** would be excessive, at least in the reactions leading to **2***f* and **2***i*. The fact that *m*-tolyl isocyanate afforded oxindoles **2***m* and **2***n* in 1:1 ratio is also more easily accommodated in terms of cyclization of a species like **7** rather than **6**.

The effects of isocyanate concentration and of the reaction temperature on the distribution are predictable from Scheme 2. The yield of a given **2** should fall, and the sum of the yields of the corresponding **3** and **4** should rise, with increasing isocyanate concentration. At a given isocyanate concentration, the yield of **2** should fall with increasing temperature while the sum of the yields **3** and **4** should rise because bimolecular reactions normally have more negative entropies of activation than unimolecular reactions. Those expectations were borne out for the case of **2***a*, **3***a*, and **4***a*, from **1** and phenyl isocyanate (Table 5) and they can probably be extrapolated with confidence to the other members to design favourable conditions for a given synthetic objective. We have not attempted to optimize conditions for the formation of a given product in this work, although our conditions were chosen, in general, to favour oxindoles. For that reason, and also because the separation of **2**, **3**, and **4** from mixtures containing all three was difficult in some cases, only a few members of the families **3** and **4** were characterized.

Experimental

Synthesis of ketone semicarbazones

Ketone semicarbazones were prepared by the method described by Vogel (20). They are listed below in the format: starting ketone, % yield of purified semicarbazone, mp, mp (lit.), ^{1}H nmr spectrum ($CDCl_3$, 90 MHz). Propanone, 75%, 187–188°C, 190°C (21), δ: 1.90 (s, 3H), 1.98 (s, 3H), 5.62 (s, br, 2H), 8.09 (s, br, 1H); 2-butanone, 65%, 143–144°C, 146°C (21), δ: 1.08 (t, 3H), 1.83 (s, 3H), 2.28 (q, 2H), 5.83 (s, br, 2H), 8.56 (s, br, 1H); 2-pentanone, 60%, 107–108°C, 106°C (21), δ: 0.94 (t, 3H), 1.52 (m, 2H), 1.83 (s, 3H), 2.22 (m, 2H), 5.99 (s, br, 2H), 8.82 (s, br, 1H); 3-methyl-2-butanone, 45%, 113–114°C, 113°C (21), δ: 1.06 (d, 6H), 1.77 (s, 3H), 2.46 (sept, 1H), 6.03 (s, br, 2H), 8.78 (s, br, 1H); 4-methyl-2-pentanone, 75%, 129–131°C, 132°C (21), δ: 0.94 (m, 7H), 1.81 (s, 3H), 2.10 (m, 2H), 5.79 (s, br, 2H), 8.48 (s, br, 1H); 3,3-dimethyl-2-butanone, 60%, 156.5–157°C, 155°C (22), δ: 1.12 (s, 9H), 1.83 (s, 3H), 6.07 (s, br, 2H), 8.85 (s, br, 1H); cyclohexanone, 70%, 165–166°C, 166°C (21), δ: 1.37–2.52 (m, 10H), 5.89 (s, br, 2H), 9.71 (s, br, 1H); 1-phenyl-2-propanone, 70%, 196–198°C, 198°C (20), δ (DMSO-d_6): 1.40 (s, 3H), 3.17 (s, 2H), 5.95 (s, br, 2H), 6.98 (s, 5H), 8.78 (s, br, 1H); 2,4-dimethyl-3-pentanone, 60%, 161°C, 160°C (21), δ: 1.09 (d, 12H), 2.74 (sept, 2H), 6.03 (s, br, 2H), 8.69 (s, br, 1H).

*5,5-Disubstituted-Δ^3-1,3,4-oxadiazolin-2-ones (**1**)*

To the semicarbazone (0.030 mol) in well-stirred, ice-cooled methylene chloride (200 mL) under dry N_2 was added lead tetraacetate (0.035 mol). After the initially pale yellow colour was discharged (ca. 30 min), ice water (100 mL) was added followed by hydrochloric acid (2.4 *M*, 20 mL). The reaction mixture, still cooled with ice, was stirred for 30 min more before it was filtered through a bed of Celite to remove insoluble inorganic material. The separated organic layer was washed in succession with ice water (200 mL), saturated sodium bicarbonate solution (200 mL), and ice water (200 mL) before it was dried over anhydrous magnesium sulfate. Filtration and evaporation of the solvent with a rotary evaporator afforded the crude product as an oil or as a solid. Oils were purified by bulb-to-bulb distillation at 10^{-2} Torr, with the pot at 40°C and the receiver at −78°C. Solids were sublimed at ambient temperature and 10^{-2} Torr. Yields of crude oxadiazolinones ranged from 65 to 55% and yields of purified compounds were ca. 40%. The infrared spectra of the oxadiazolinones showed a strong band between 1835 and 1840 cm^{-1} characteristic of carbonyl group stretching for that ring system (23). Proton nmr spectra for compounds **1** are included in Table 1.

Thermolysis of an oxadiazolinone in the presence of an aryl isocyanate

The following is a typical procedure for the preparation and separation of products **2**, **3**, and **4**. A solution of the oxadiazolinone (4.0 mmol) in nitrobenzene (25 mL, fractionally distilled after ordinary distillation from P_2O_5) was added dropwise, with stirring during one hour, to a solution of freshly distilled phenyl isocyanate (80 mmol) in nitrobenzene (10 mL), at 150°C and under nitrogen (L-grade). After addition was complete, the solution was kept at 150°C for 2 hours before the solvent and the excess phenyl isocyanate were largely removed by vacuum distillation. The crude residue was taken up in a small volume of chloroform for column chromatography on neutral alumina (100 g, Brockman activity II, 80–200 mesh), using a solution of light petroleum ether (bp 30–45°C, 5 parts) and ether (2 parts) for elution. Separated fractions were either recrystallized or rechromatographed on preparative tlc plates (20 × 20 cm, neutral alumina with fluorescent indicator, uv-254) using ether in light petroleum ether, in ratios between 1:15 and 1:5, for plate development. Some liquid fractions had to be chromatographed four times on tlc plates before a product of satisfactory purity could be obtained.

Concentration and temperature dependence of product ratios

A typical run in which the isocyanate concentration changed from an initial value of ca. 4.6 *M* to a final value of 2.2 *M* is described first.

A solution of **1***a* (0.52 g, 4.5 mmol) in nitrobenzene (20 mL) was added dropwise during 1 hour, with stirring and under N_2, to a solution of phenyl isocyanate (9 mL, 0.083 mol) in nitrobenzene (9 mL) at 150°C. Heating and stirring were continued for 2 hours after addition was complete. Removal of nitrobenzene and excess phenyl isocyanate under reduced pressure left a residue that was analyzed qualitatively by tlc and quantitatively by ^{1}H nmr spectroscopy. The average of the ratios **2***a*:**3***a*:**4***a* from three separate runs was 4.8:1.0:1.0.

A typical run in which the isocyanate concentration changed from an initial value of ca. 9.2 *M* (neat phenyl isocyanate) to a final concentration near 6.3 *M* follows.

A solution of **1***a* (0.49 g, 4.3 mmol) in nitrobenzene (10 mL) was added as described above to phenyl isocyanate (22 mL, 0.20 mol).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

Quantitative analysis of the product ratio, as described above, gave **2***a*:**3***a*:**4***a* = 2.4:1.0:1.0.

Thermolyses at lower temperatures followed procedures already described for the appropriate final isocyanate concentration, with the following exception. For the 65°C and 68°C runs (Table 5) the oxadiazolinone solution was added all at once and the heating period was extended to 48 h.

Reaction of 2-diazopropane with phenylisocyanate

2-Diazopropane, prepared by the method of Whiting and co-workers (10) was obtained as a pink ethereal solution containing unknown quantities of ethanol and water. The initial solution was redistilled quickly and dried briefly over sodium sulfate.

The partially dried ethereal solution, containing ca. 0.11 mol of 2-diazopropane, was dropped during 1 hour into a stirring solution of phenyl isocyanate (13.1 g, 0.11 mol) in ether (50 mL) at room temperature. Two hours after addition was complete, the pink colour had disappeared and the solution was concentrated with a rotary evaporator. Addition of petroleum ether to the crude residue resulted in precipitation of α-hydroxyisobutyranilide, which was recrystallized from a chloroform – petroleum ether solvent: mp 133–134°C (lit. (24) mp 135°C); ir: 3400 and 1695 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 1.54 (s, 6H), 2.95 (s, br, 1H), 7.29 (m, 5H), 9.00 (s, br, 1H); ms (low resolution) *m/z*: 179.

The mother liquor from the precipitation was concentrated and the residue was chromatographed on a column (Florisil, 60–100 mesh, 200 g) using light petroleum for elution. α-Ethoxyisobutyranilide was obtained as a colourless liquid: ir: 3395, 1730, and 1690 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 1.32 (t, 3H), 1.52 (s, 6H), 3.43 (q, 2H), 7.26 (m, 5H), 8.43 (s, br, 1H); ms (low resolution) *m/z*: 206.

A similar reaction, in which the ethereal diazopropane solution was first dried briefly over KOH pellets, gave largely α-ethoxyisobutyranilide.

Hydrolysis of 1-phenylcarbamoyl-3,3-dimethyloxindole

1-Phenylcarbamoyl-3,3-dimethyloxindole (0.25 g, 0.89 mmol) in a solution made from 10% KOH (15 mL) and methanol (15 mL) was refluxed for 1 h. The resulting solution was neutralized with aqueous HCl and extracted with ether (3 × 50 mL). The ether extract was washed with saturated sodium bicarbonate solution, dried, and concentrated. Crystallization of the residue from methanol afforded 3,3-dimethyl oxindole (0.11 g, 79%) as colourless prisms: mp 152–154°C (lit. (25) mp 150°C); ir: 3450 and 1720 cm^{-1}; ^1H nmr, δ: 1.40 (s, 6H), 7.06 (m, 4H), 9.37 (s, br, 1H); ms (low resolution) *m/z*: 161.

Reaction of 3,3-dimethyloxindole with phenyl isocyanate

3,3-Dimethyloxindole (0.15 g, 0.93 mmol), dissolved in a solution made from phenyl isocyanate (1 mL) and nitrobenzene (8 mL), was heated at 150°C for 2 h. Concentration of the resulting solution by vacuum distillation afforded a residual viscous oil, which crystallized from aqueous ethanol to afford colourless needles (0.20 g, 80%) of 1-phenylcarbamoyl-3,3-dimethyloxindole, mp 73–75°C, with spectra matching those of **2***a* obtained from oxadiazolinone **1***a* and phenyl isocyanate.

The stretched polymer film technique combined with γ-irradiation has been employed to measure the polarized absorption (linear dichroism) spectra of radical anions of quinoline, isoquinoline, quinoxaline, phthalazine, phenylpyridine, 4,4′-bipyridyl, and 2,2′-bipyridyl. Profiles of polarized absorption spectra of all the radical anions are similar to those of the parent naphthalene or biphenyl radical anions. Those of radical cations of isoquinoline and 2,2′-bipyridyl are also similar to those of radical cations of their parent molecules. Quinoxaline radical cations, however, show quite a different spectrum from that of naphthalene radical cations; a long vibrational structure with ca. 550 cm^{-1} intervals was observed and peaks of these vibrational bands were polarized parallel to the molecular short-axis or normal to the molecular plane.

HIROSHI HIRATSUKA, KEN'ICHI SEKIGUCHI, YOSHIHIKO HATANO, YOSHIE TANIZAKI et YUJI MORI. Can. J. Chem. **65**, 1185 (1987).

On a utilisé la technique du film de polymère étiré, combinée avec l'irradiation-γ, pour mesurer les spectres d'absorption polarisée (dichroïsme linéaire) des anions radicaux de la quinoléine, de l'isoquinoléine, de la quinoxaline, de la phtalazine, de la phénylpyridine, des bipyridyles-4,4′ et 2,2′. Tous les spectres d'absorption polarisée de ces anions radicaux sont semblables à ceux des anions radicaux du naphtalène ou du biphényle parent. Les spectres des anions radicaux de l'isoquinoléine et du bipyridyle-2,2′ sont aussi semblables à ceux des cations radicaux de leurs molécules parentes. Toutefois, le spectre des cations radicaux de la quinoxaline est très différent de celui des cations radicaux du naphtalène; on a observé une longue structure vibrationnelle ayant des intervalles d'environ 550 cm^{-1} et les maxima de ces bandes de vibration sont polarisés d'une manière parallèle à l'axe court de la molécule ou normale au plan de la molécule.

[Traduit par la revue]

Introduction

Extensive studies have been carried out on absorption spectra of aromatic radical ions which are one of the important intermediates in electrochemical, photochemical, and radiation chemical reactions. Polarization measurements on electronic spectra were carried out by Hoytink *et al.* for radical anions of aromatic hydrocarbon molecules (1). Absorption spectra of radical ions of aza-aromatic molecules were also extensively studied (2–7) but, to the best of our knowledge, there has been no report on polarization measurements of electronic spectra for these aza-aromatic radicals.

In previous papers we have shown that the stretched polymer film technique combined with γ-irradiation is available for polarization measurements (linear dichroism) on radicals and radical ions, such as aromatic hydrocarbons and their derivatives (8, 9). We have also measured the polarization spectra of radical ions of acridine and phenazine (aza-anthracenes) prepared in polyethylene or poly(vinyl chloride) films (10). In this paper we present the results of polarization measurements on the radical ions of some derivatives of aza-naphthalene and -biphenyl in comparison with those of the parent hydrocarbon radical ions.

Experimental

Ultra pure grade naphthalene and biphenyl, guaranteed grade quinoline, quinoxaline, 4,4′-bipyridyl, and 2,2′-bipyridyl, extra pure grade isoquinoline (Tokyo Kasei Co.), and phthalazine and 4-phenylpyridine (Aldrich Chem. Co. Inc.) were used as received. Poly(fluorinated ethylene-propylene) (PFEP) films, ca. 0.2 mm thick, were obtained from Mitsui Fluorochemical Co. Freon 113 (1,1,2-trichloro-1,2,2-trifluoroethane), *s*-butylamine, and *s*-butylchloride (Tokyo Kasei Co.) were used without further purification.

In the same way as before (10), radical anions were prepared at 77 K by γ-irradiation of the polyethylene (PE) films containing the sample and solvent *s*-butylamine. Radical cations were prepared by use of poly(vinyl chloride) (PVC) films containing the sample and *s*-butylchloride. To prepare radical cations of quinoxaline, PEEP films and solvent Freon 113 were used. Films containing sample molecules were stretched to three times their original length and then irradiated by ^{60}Co γ-rays for 5 h at 77 K with a dose rate of 1.0×10^6 rads/h. Polarized absorption spectra were measured in the range from 300 to 850 nm on a JASCO SS-50 spectrophotometer equipped with a Rochon polarizer. Absorption base lines for sample films were recorded before γ-irradiation and then absorption spectra of irradiated films were recorded. The spectra observed are shown in Figs. 1 and 3–6 in the region where the absorption band due to the parent molecule does not overlap with that of radical ions or is negligibly small. In the case of PFEP films, photobleaching of the film was carried out for 10 min after γ-irradiation, using a high pressure mercury lamp combined with a uv light cut-off filter in order to remove the absorption due to the positive holes and/or charge-transferred species (5). The difference in absorbance before and after irradiation was ascribed to the absorption of the produced species. Dichroic ratio, R_d, is defined as the absorbance ratio $A_\parallel / A_\perp$, where $A_\parallel$ and $A_\perp$ denote the absorbances when the electric vectors of the incident light are parallel and perpendicular to the stretching direction of the film, respectively. Error in R_d value is less than 5%. In order to analyze polarized absorption spectra qualitatively, this R_d value is employed in reference to the results of MO calculations in a π-electron approximation (10*a*).

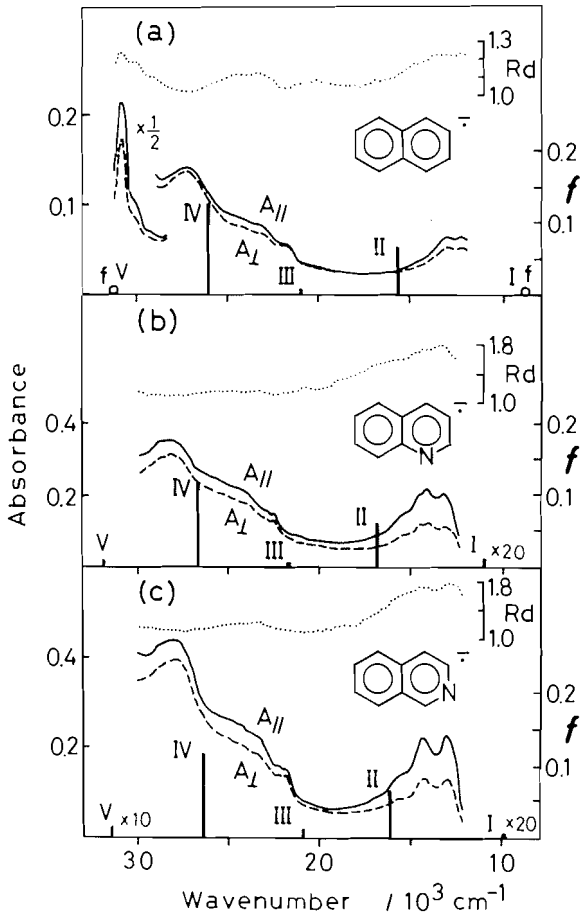

FIG. 1. Polarized absorption spectra of radical anions of naphthalene (*a*) in the γ-irradiated PVA film, quinoline (*b*), and isoquinoline (*c*) in the γ-irradiated PE films. $A_{\parallel}$ and $A_{\perp}$ are the absorbances when the electric vectors of the incident light are parallel and perpendicular, respectively, to the stretching direction of the films. R_d is $A_{\parallel}/A_{\perp}$. Calculated results are shown as the vertical lines and open circles. Roman figures represent the transition number and f (open circle) is the forbidden transition.

When polarization directions of electronic transitions of radical ions are limited to the directions parallel to the molecular long- and short-axis, a quantitative analysis can be easily carried out by use of R_d values; "polarization" resolved spectra can be determined by reducing the absorption spectrum (A) according to eqs. [1] and [2] given below as shown in previous papers (8, 9).

$$[1]\quad A_l = \frac{R_d - R_d^s}{R_d^l - R_d^s}\frac{R_d^l + 2}{R_d + 2}A$$

$$[2]\quad A_s = \frac{R_d^l - R_d}{R_d^l - R_d^s}\frac{R_d^s + 2}{R_d + 2}A$$

where A_l and A_s are absorption components whose transition moments are polarized parallel to the molecular long- and short-axis, respectively. R_d^l and R_d^s are extreme R_d values of the "purely" long- and short-axis polarized bands. These equations are identical with those derived by Margulies and Yogev (11). This analysis was applied to the aromatic radicals of hydrocarbon molecules and their derivatives which belong to C_{2v} symmetry or higher (8, 9, 10*b*).

Results and discussion

Absorption spectra of the γ-irradiated non-stretched films containing sample molecules are similar to those reported previously for the corresponding radical ions of aza-naphthalenes and -biphenyls (2–5, 7). Polarized absorption spectra observed for aza-naphthalenes and -biphenyls in γ-irradiated stretched films are shown in Figs. 1 and 3–6. Results of MO calculations for the corresponding radical ions are also shown in the figures by vertical lines.

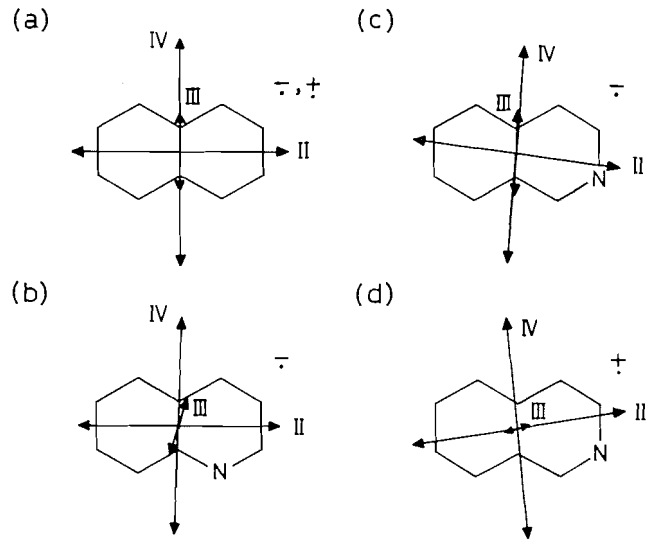

FIG. 2. Direction of transition moments of some electronic transitions of *N*-aza-substituted naphthalene radical ions.

Polarized absorption spectra can be analyzed qualitatively by examining the R_d curve based on the assumption that the molecular long-axis inclines preferentially along the stretched direction of films. The validity of this assumption has been confirmed for some radical ions (8–10). If the molecular long-axis inclines along the stretched direction of the film, an electronic transition polarized parallel to the molecular long-axis should give greater R_d values than those of the other transitions, while a transition parallel to the short-axis a smaller R_d value than the others. Therefore we can qualitatively determine the polarization direction of absorption bands by analyzing the profile of the R_d curve.

Figure 1*a* shows the polarized absorption spectra of radical anions of naphthalene in a poly(vinyl alcohol) film. For the radical anions of naphthalene resolved spectra were determined and reported elsewhere (8), but here we show the results as an example for a qualitative analysis of R_d profile. R_d values are greater in the region below 15×10^3 cm^{-1} and in the intense band of $(30–31) \times 10^3$ cm^{-1} than those of the others, while R_d values are relatively small at the absorption bands of $(21–28) \times 10^3$ cm^{-1}. These results indicate that transition moments of the absorption bands appearing below 15×10^3 cm^{-1} and in the $(30–31) \times 10^3$ cm^{-1} region are polarized parallel to the molecular long-axis, and the bands in the region $(21–28) \times 10^3$ cm^{-1} are to the short axis. The long-axis polarized absorption bands are respectively assigned to the second (below 15×10^3 cm^{-1}) and the seventh ($(30–31) \times 10^3$ cm^{-1} band) transitions, where the seventh transition is calculated to appear at 40.03×10^3 cm^{-1} with an oscillator strength 0.412 (8) but it is not shown in this figure. The short-axis polarized ones in the region of $(21–28) \times 10^3$ cm^{-1} are attributed to the third and fourth electronic transitions.

Figures 1*b* and *c* show the polarized absorption spectra of radical anions of quinoline and isoquinoline, respectively. These spectra are similar to those of naphthalene radical anions. R_d profile is also similar to that of naphthalene radical anions,

For personal use only.

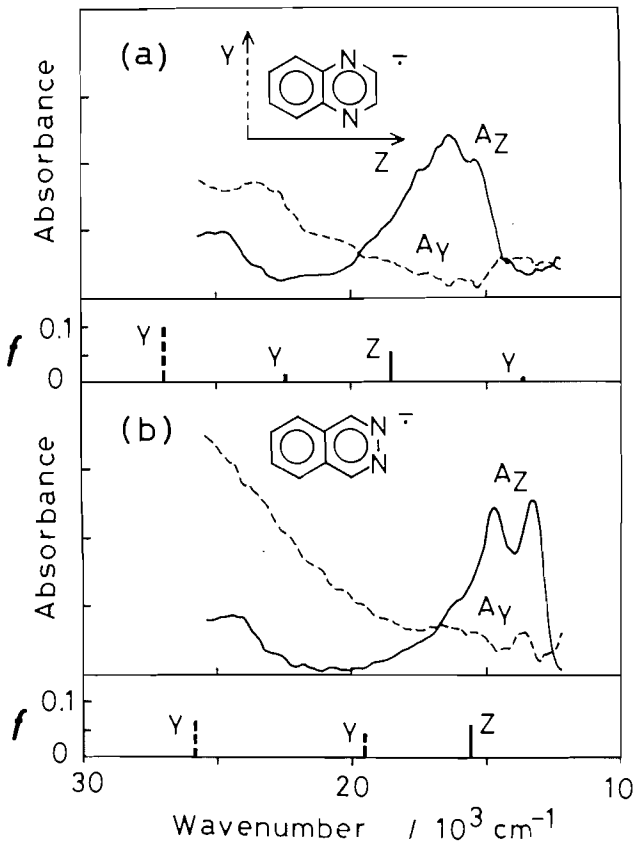

FIG. 3. Resolved spectra of the radical anions of quinoxaline (*a*) and phthalazine (*b*). Extreme R_d values used are as follows; $R_d^l = 1.60$ and $R_d^s = 0.99$ for quinoxaline and $R_d^l = 1.40$ and $R_d^s = 0.98$ for phthalazine. Calculated results for these radicals are also shown in the bottom. *Z* and *Y* mean that the transition moments are polarized parallel to the molecular long- and short-axis, respectively.

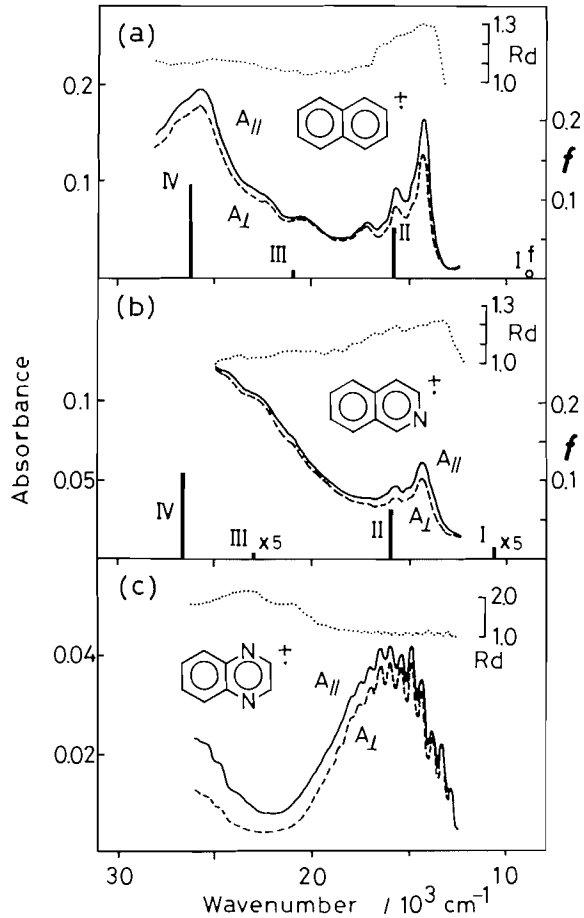

FIG. 4. Polarized absorption spectra of radical cations of naphthalene (*a*), isoquinoline (*b*) in the γ-irradiated PVC films and quinoxaline (*c*) in the γ-irradiated PFEP film. See the footnotes of Fig. 1.

R_d values in the region below 16 × 10^3 cm^{-1} are greater than those of other regions. This indicates that the polarization direction of absorption bands in (12–16) × 10^3 cm^{-1} is rather close to the molecular long-axis compared to those of the other bands. As shown in Fig. 2, directions of transition moments of the second, third, and fourth transition are not varied so much by *N*-aza-substitution in the naphthalene radical anion. Thus, as in the case of naphthalene, it is reasonable to assign the absorption band at (12–16) × 10^3 cm^{-1} to the second transition, while the weak band at (21–26) × 10^3 cm^{-1} and the intense one at (26–29) × 10^3 cm^{-1} can be assigned to the third and fourth transitions, respectively.

Figures 3*a* and *b* show the "polarization"-resolved spectra of radical anions of quinoxaline and phthalazine. These spectra have been obtained by resolving the absorption spectra by use of eqs. [1] and [2]. Extreme R_d values (R_d^l and R_d^s) used are shown in the figure caption. The long-axis polarized band (A_z absorption) appears at low wavenumbers of the spectrum and is assigned to the second transition. As shown in Figs. 1*b* and *c*, only a very small shift is observed for this long-axis polarized band between isoquinoline and quinoline, while a rather large blue shift (ca. 2 × 10^3 cm^{-1}) is observed from phthalazine to quinoxaline as can be seen in Fig. 3, in agreement with MO calculations.

Figure 4 shows the polarized absorption spectra of isoquinoline, and quinoxaline radical cations. For comparison those of naphthalene radical cations are also shown in Fig. 4. Naphthalene (Fig. 4*a*) and isoquinoline radical cations (Fig. 4*b*) were prepared in PVC films by γ-irradiation, while the absorption spectra of quinoxaline radical cations (Fig. 4*c*) was observed in PFEP films. The absorption spectrum of quinoxaline cation radicals was not observed in γ-irradiated PVC films containing quinoxaline. This difference in the radical cation formation between isoquinoline and quinoxaline in PVC films can be attributed to the difference in ionization potentials of isoquinoline (8.5 eV) and quinoline (9.0 eV) (12).

Profiles of R_d curves in Figs. 4*a* and *b* are similar to each other; the absorption band around 15 × 10^3 cm^{-1} shows relatively greater R_d values than those of the other bands. This indicates that the directions of transition moments of the second and the fourth electronic transitions are not affected so much by *N*-aza-substitution at the β-position in naphthalene radical cation. This is rationalized by the results of MO calculations on these radicals as shown in Figs. 2*a* and *d*.

The absorption spectra of quinoxaline radical cations, however, are quite different from those of naphthalene radical cations. A long vibrational structure extends from 13 × 10^3 cm^{-1} to 18 × 10^3 cm^{-1} with approximately constant intervals of 550 cm^{-1} and with the maximum around 15 × 10^3 cm^{-1}. This long progression can be related to the a_1 vibration (526 cm^{-1}) observed for the n–π* absorption band of quinoxaline in durene (13). The R_d curve shows minima at each absorption peak of the vibrational structure. This indicates that the transition moment is polarized parallel to the molecular

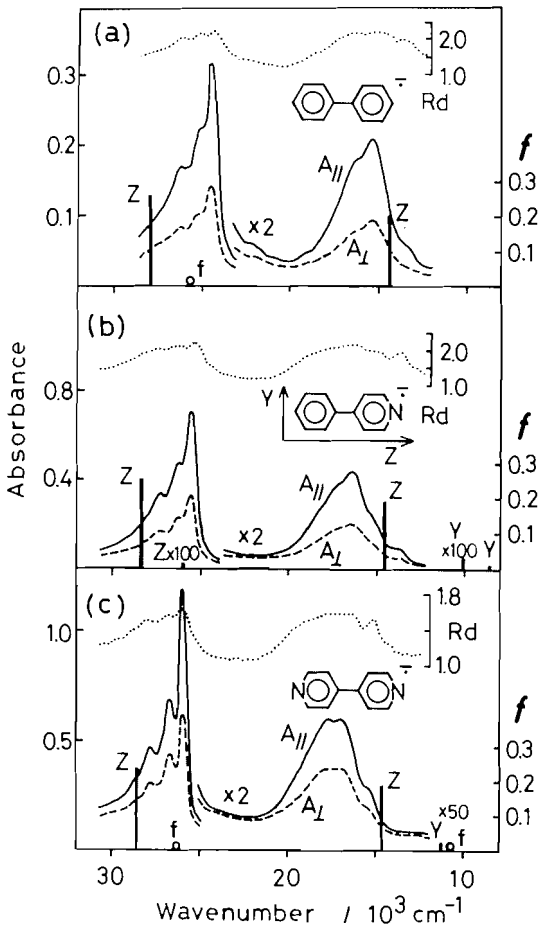

FIG. 5. Polarized absorption spectra of radical anions of biphenyl (*a*), phenylpyridine (*b*), and 4,4′-bipyridyl in the γ-irradiated PE films. See the footnotes in Figs. 1 and 3.

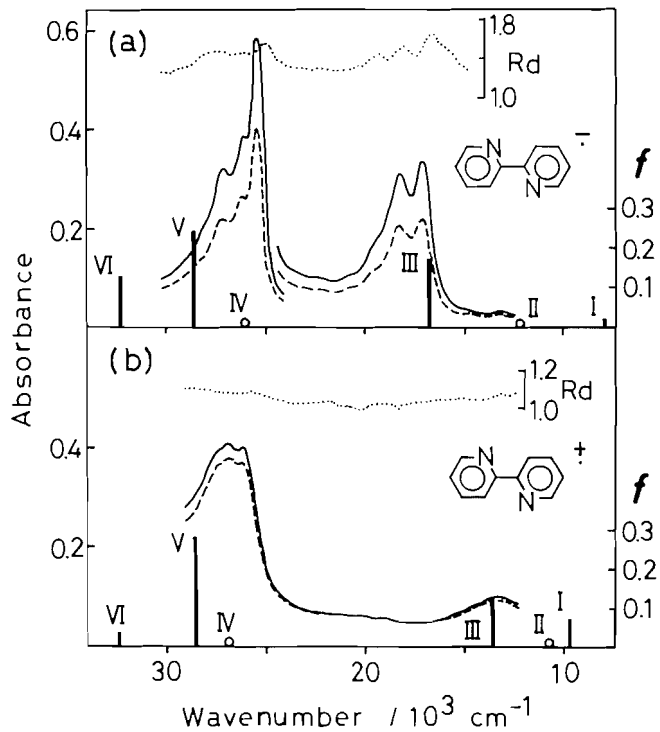

FIG. 6. Polarized absorption spectra of 2,2′-bipyridyl radical anions (*a*), in the γ-irradiated PE film and cations (*b*) in PVC films. See the footnotes of Fig. 1.

short axis or normal to the molecular plane. Therefore the absorption band can be attributed to a $\pi-n_+$ or $n_+-\pi^*$ transition with the polarization normal to the molecular plane, or an n_+-n_- transition with the short-axis polarization, where $n_+ = (n_1 + n_2)/\sqrt{2}$ and $n_- = (n_1 - n_2)/\sqrt{2}$, and n_1 and n_2 are the two non-bonding orbitals of nitrogen atoms.

Katoh and Shida observed the absorption spectrum of quinoxaline radical cations in a Freon mixture at 77 K (5). They studied esr and optical absorption spectra, and concluded that the cation is an "n cation"; the spin density is localized mostly on the in-plane lone-pair orbitals on nitrogen atoms. In comparison with the photoelectron spectrum of quinoxaline, the singly occupied lone-pair orbital has been assigned to the n_+ orbital. They assigned this band to the transition between n_+ and n_- orbitals by taking into account the spectral resemblance in esr and optical absorption spectra to those of pyrazine radical cations. Our results of polarization measurement on quinoxaline cation radicals are consistent with their assignment. However, the possibility that this structured absorption band is due to $n_+-\pi^*$ or $\pi-n_+$ transition is still not excluded because a long progression is also observed for the $n-\pi^*$ band of parent quinoxaline in durene (13).

Figure 5 shows the polarized absorption spectra of biphenyl (Fig. 5*a*), phenylpyridine (Fig. 5*b*), and 4,4′-bipyridyl (Fig. 5*c*) in PE films at 77 K. These spectra are similar in profile to each other but slight blue shifts are observed for the intense absorption bands by *N*-aza-substitution. R_d curves for these absorption spectra are also similar to each other in profile. R_d values around the intense bands are great, indicating these bands are polarized parallel to the molecular long-axis. No distinct short-axis polarized band is observed (8). These characteristics in absorption spectra are consistent with the calculated results.

Figure 6 shows the polarized absorption spectra of the 2,2′-bipyridyl radical anion in a PE film (*a*) and the radical cation in a PVC film (*b*). The spectra in Fig. 6*a* are similar to those of Fig. 5 but the visible absorption band and the R_d curve of 2,2′-bipyridyl radical anion show more resolved structure than those of biphenyl. The wavenumbers at the R_d curve maxima do not coincide with those of the absorption peaks but are slightly shifted to red. Maximum R_d values in the intense bands in the visible region are almost equal to those in the near-uv region for biphenyl, phenylpyridine, and 4,4′-bipyridyl radical anions, while the maximum R_d value in the visible region of 2,2′-bipyridyl is clearly greater than that of the near-uv region. These observations seem to indicate that 2,2′-bipyridyl radical anions in PE film do not have C_{2v} symmetry; the absorption spectra in Fig. 6*a* cannot be attributed to the *cis*-form.

The absorption spectra shown in Fig. 6*b* are similar to those of the biphenyl radical cation and explained by MO calculations (vertical lines). The R_d value is nearly constant but relatively great R_d values are obtained in the vicinity of the intense absorption band.

Concluding remarks

Polarized absorption (linear dichroism) spectra of the radical anions of quinoline, isoquinoline, quinoxaline, phthalazine, phenylpyridine, 4,4′-bipyridyl, and 2,2′-bipyridyl have been measured in stretched polymer films and analyzed for the first

time. Those of the radical cations of isoquinoline, quinoxaline, and 2,2′-bipyridyl were also measured and discussed.

Acknowledgments

We are greatly indebted to Professor Shida of Kyoto University and Dr. Das of the University of Notre Dame for their valuable suggestions on this work. Received August 27, 1986

ALAN SHAVER and JUDY HARTGERINK. Can. J. Chem. **65**, 1190 (1987).

The polysulfano complexes $(\eta^5\text{-}C_5H_5)W(CO)_3Q$, where Q = SSR, SSSR, SS(O)R, and R = $CH_2C_6H_5$ and $p\text{-}C_6H_4CH_3$ have been prepared via treatment of $(\eta^5\text{-}C_5H_5)W(CO)_3SH$ with RSphth, RSSphth, and RS(O)phth, respectively, at −20°C, where phth = *N*-phthalimido. The complexes where Q = SSR and SSSR lost sulfur spontaneously in solution to give the thiolato complexes $(\eta^5\text{-}C_5H_5)W(CO)_3SR$ and the disulfano complexes, respectively. The presence of PPh_3 accelerated this reaction for Q = SSR. Treatment of $(\eta^5\text{-}C_5H_5)W(CO)_3SSR$ with *m*-chloroperbenzoic acid gave a mixture of complexes for which Q = SR, SO_2R, SS(O)R, and higher oxidized sulfur ligands. $As(C_6H_5)_4[W(CO)_5SH]$ reacted with $p\text{-}CH_3C_6H_4Sphth$ to give an unstable first product, tentatively identified as $As(C_6H_5)_4[W(CO)_5SS\text{-}p\text{-}C_6H_4CH_3]$, the isolated product being $As(C_6H_5)_4[W(CO)_5S\text{-}p\text{-}C_6H_4CH_3]$.

ALAN SHAVER et JUDY HARTGERINK. Can. J. Chem. **65**, 1190 (1987).

On a préparé les complexes polysulfurés $(\eta^5\text{-}C_5H_5)W(CO)_3Q$, dans lesquels Q = SSR, SSSR et SS(O)R et R = $CH_2C_6H_5$ et $p\text{-}C_6H_4CH_3$, en faisant réagir respectivement les composés RSphth, RSSphth et RS(O)phth avec le $(\eta\text{-}C_5H_5)W(CO)_3SH$, à −20°C. En solution, les complexes dans lesquels Q = SSR et SSSR perdent spontanément du soufre pour donner respectivement les complexes thiolato $(\eta^5\text{-}C_5H_5)W(CO)_3SR$ et disulfano. La présence de PPh_3 accélère cette réaction lorsque Q = SSR. La réaction du $(\eta^5\text{-}C_5H_5)W(CO)_3SSR$ avec l'acide *m*-chloroperbenzoïque conduit à un mélange de complexes contenant des groupements Q = SR, SO_2R, SS(O)R et d'autres ligands sulfurés plus oxydés. Le composé $As(C_6H_5)_4[W(CO)_5SH]$ réagit avec le $p\text{-}CH_3C_6H_4Sphth$ pour donner un produit préliminaire instable, temporairement identifié comme étant le $As(C_6H_5)_4[W(CO)_5\text{-}SS\text{-}p\text{-}C_6H_4CH_3]$; le produit isolé est le $As(C_6H_5)_4[W(CO)_5S\text{-}p\text{-}C_6H_4CH_3]$.

Catenated polycarbon systems are the basis for σ and π type ligands in organometallic chemistry. Sulfur, an excellent catenator (1), might also be expected to form similar classes of ligands. However, while metal thiolates (MSR) form a very large and important class of molecules (2), metal disulfanes (MSSR) and trisulfanes (MSSSR) are quite rare (3). In view of the importance of metal–sulfur chemistry in biology and industry, it seems appropriate to investigate the chemistry of simple catenated polysulfano ligands.

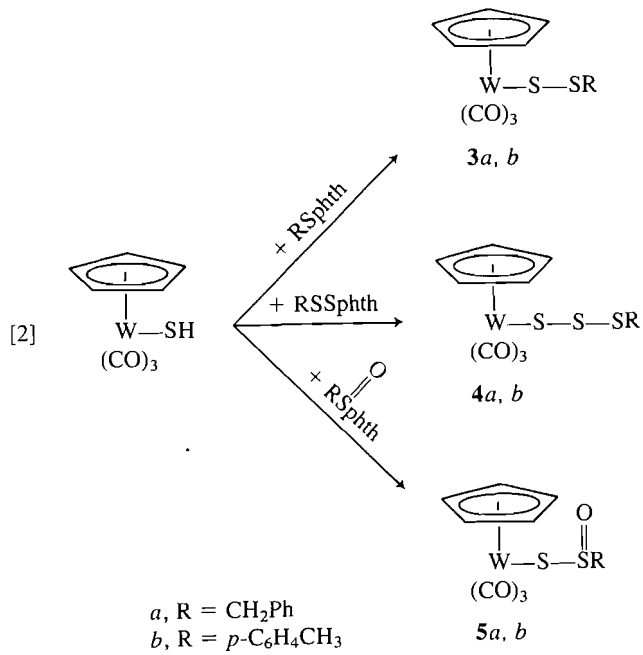
The preparation of unsymmetrical organic di- and trisulfanes can be accomplished (4) via the application of sulfur-transfer reagents of the type RS_xphth, where phth = *N*-phthalimido and $x = 1, 2$ (5). Treatment of such reagents with a thiol gives the desired products (reaction [1]).

[1] $RS_x\text{phth} + R'SH \rightarrow RS_xSR' + \text{Hphth}$

Accordingly, the metal thiolo complexes $AsPh_4[W(CO)_5SH]$ (6) and $CpW(CO)_3SH$ (7), where Cp = $(\eta^5\text{-}C_5H_5)$, were chosen for treatment with the sulfur-transfer reagents. The results of these reactions, which give novel polysulfanotungsten species, are reported below. Some of this work has appeared as part of a preliminary communication (8).

Results and discussion

The preparation of $CpW(CO)_3SH$, **1**, from $CpW(CO)_3I$ and NaSH is a viable alternative to that reported (*7a*) which was unsuccessful in our hands. **1** decomposes upon heating but reacts smoothly with sulfur transfer reagents (reaction [2]).



a, R = CH_2Ph
b, R = $p\text{-}C_6H_4CH_3$

At room temperature, the mono-sulfur transfer reagents, RSphth, gave a mixture of the thiolates, $CpW(CO)_3SR$, **2**, and the disulfanes, $CpW(CO)_3SSR$, **3**, in the ratio 1:4, where R = CH_2Ph (**2***a*, **3***a*) and $p\text{-}C_6H_4CH_3$ (**2***b*, **3***b*). The presence of **2** was determined by comparison of the nmr spectra of the crude products to that of authentic samples. Lowering the reaction temperature to −20°C reduced the contamination by **2** to 5%. The disulfanes could not be isolated by chromatography since

[1]The IUPAC convention for linear polysulfur compounds is that they be named polysulfanes (33).

[a]In cyclohexane solvent.

they desulfurize to the thiolates on the column. Recrystallization at −40°C gave good yields (70%) of **3***a*,*b*. Treatment of **1** with the disulfur transfer reagents, RSSphth, at −20°C, gave a mixture of two complexes also in the ratio 1:4 as determined by the relative heights of the peaks due to the Cp groups in the nmr spectra. The minor products were identified as **3***a*,*b* on the basis of their nmr spectra. The major products were assigned to be the trisulfane complexes $CpW(CO)_3SSSR$, (**4***a*,*b*), on the basis of their infrared and nmr spectra in solution since pure samples could not be isolated due to contamination by **3** and **2**. Treatment of **1** with the sulfinyl phthalimides, RS(O)phth at −20°C gave the novel oxodisulfanes $CpW(CO)_3SS(O)R$ (**5***a*,*b*) as the only products.

Elemental analyses consistent with their formulation were obtained for all of the above complexes, except **4***a*,*b*. The X-ray structure of **3***b* has been determined (8) and confirms the disulfane linkage.

The infrared spectra in the metal carbonyl stretching region and the nmr spectra of the complexes are summarized in Tables 1 and 2, respectively. The carbonyl stretching frequencies are fairly insensitive to the length of the sulfur chain. The spectra of crude **4** were superimposable on those of pure **3**. The bands observed for **5** exhibit a 5–10 cm^{-1} shift to higher wave numbers consistent with a slight reduction of electron density at the metal due to the presence of the SS(O) functionality. The latter complexes also gave bands (1073(m), 1049(m) cm^{-1}, **5***a*; and 1075(m), 1052(m) cm^{-1}, **5***b*) which do not appear in the spectra of **3**. These are assigned to S=O stretching modes (9); the presence of two bands possibly indicating conformational isomerism in **5** (10).

The ^{1}H nmr spectra of **2**–**5** are qualitatively very similar, as expected. Comparing **2***a*, **3***a*, and **4***a*, the peaks are shifted to lower field as the sulfur chain increases. This is consistent with the nmr spectra of organic polysulfides (11). A similar shift is observed for **2***b*, **3***b*, and **4***b* except that the band due to the Cp protons in **3***b* is upfield of that of **2***b*. The spectra of **5** are shifted slightly downfield from those **2**, **3**, and **4**, again consistent with the chemical shift observed (12) for organic thiosulfinates relative to organic disulfides. The resonance for the methylene protons of **5***a* is a doublet due to the presence of the oxygen on the sulfur atom which makes the latter chiral, thus rendering the methylene protons of **5***a* diastereotopic. Similar splitting is observed by this moiety in $PhCH_2S(O)$phth (13).

Complexes **3** and **4** spontaneously desulfurized in solution at room temperature to give **2** as the final products. The process was more rapid in benzene than in acetone. Thiolate formation from **3** was generally detected after 3 to 4 h in solution. For example, **3***b* showed 15% conversion after 5 h in deuteroacetone as shown by monitoring the nmr spectrum. The trisulfanes desulfurized more rapidly in solution than **3**. Complex **4***a* desulfurized to **3***a* upon attempted crystallization from CH_2Cl_2/hexanes; whereas **3***a* was isolated as a crystalline product under similar conditions. The nmr spectra of fresh crude **4** always indicated the presence of significant amounts of **3** but minimal formation of the final thiolates. The preparations of **3** and **4** were performed in THF which should be similar in its solvent effects to acetone. However, in the room temperature preparation of **3**, 20% of the thiolate was detected in the crude product after a reaction time of only 30 min. Thus desulfurization occurs to a greater extent during the preparation of the disulfanes than would be expected. This implies that thiolate formation during the preparation does not arise solely from desulfurization of the disulfane products. The observation of a significant amount of disulfane, but very little thiolate, in the crude product mixture of the trisulfanes is further indication that loss of sulfur may occur during the reactions.

Triphenylphosphine greatly enhanced the rate of desulfurization of **3** in C_6D_6. In the absence of PPh_3, 25% conversion to **2** had occurred after 4 h as shown by nmr while in the presence of PPh_3 conversion was complete. Desulfurization is a characteristic reaction of organic polysulfanes both thermally (14) and induced by trivalent phosphorus compounds (15). Normally, however, thermal desulfurization is slow at room temperature for organic trisulfanes and very slow for disulfanes; in addition, PPh_3 will not desulfurize most disulfanes. Thus, these metal polysulfanes are much more prone to desulfurization than their organic analogues. However, the greater lability of **4** compared to **3** is consistent with the relative ease of desulfurization of organic trisulfanes and disulfanes. Complexes **5** seemed to decompose more readily than the disulfanes **4** to give intractable mixtures. This behaviour is consistent with the behaviour of organic thiolsulfinates, RSS(O)R′, which are very unstable and disproportionate readily to disulfanes and thiolsulfonate esters, $RS(O)_2SR$, under mild conditions (16). However, the presence of an organometallic substituent appears to inhibit decomposition somewhat.

Oxidation of **3** with metachloroperbenzoic acid, under conditions similar to those used in the oxidation of organic sulfur compounds (13), led to the detection of several compounds in the ^{1}H-nmr spectra of the crude products. The cyclopentadienyl peaks were particularly diagnostic of the number of products formed (Table 3). In addition to **3**, significant amounts of **2**, and the oxodisulfanes, **5**, were identified in the ^{1}H-nmr spectra of the product mixtures. The cyclopentadienyl resonance of the known sulfinate complex $CpW(CO)_3SO_2CH_2Ph$, **6***a*, appears at 5.75 ppm (17) which corresponds to a peak in the spectrum of oxidized **3***a*. Peroxidation of **2***b* under similar condition gives a product, **6***b*, whose cyclopentadienyl resonance appears at 5.91 which corresponds to one of the products of oxidized **3***b*. The infrared spectra of the mixtures obtained upon oxidation of **3** displayed bands consistent with the presence of —S(O)— and $—SO_2—$ moieties (1050–1100 cm^{-1}, S=O stretch (9); 1100–1200 cm^{-1}, SO^2 asymmetric stretch (17)).

The peracid oxidation of unsymmetrical organic disulfanes (18) initially results in the preferential formation of a specific thiosulfinate, RS(O)SR′ or RSS(O)R′, depending on the nature of R and R′. Further oxidation occurs at the sulfur atom already oxidized to give a $—SO_2—$ moiety. However, due to the instability of organic thiosulfinates, complex mixtures are

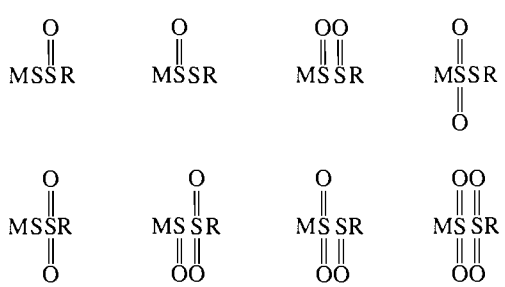
[b]Not observed.

isolated. At least eight products can be envisioned from the oxidation of **3** and the detection of **2** indicates that their oxidized forms must be considered.



The disappearance of certain cyclopentadienyl peaks upon addition of excess peracid implies the further oxidation of products such as **5**. The appearance of the new Cp peaks to low field of those of **3** and **5** is also consistent with increased oxygenation of the ligands. The —SO_2SO_2— linkage has been observed in $[CpFe(CO)_2]_2S_2O_4$ (19) and $[Cp^*M(CO)_3]_2S_2O_4$, where Cp* = C_5Me_5 and M = Mo and W (20).

The tungsten thiol $AsPh_4[W(CO)_5SH]$, **7**, reacts with $CH_3C_6H_4Sphth$ to give, after recrystallization, the thiolate $AsPh_4[W(CO)_5S$-*p*-$C_6H_4CH_3]$, **8**. The nmr spectrum of fresh crude product from this reaction (Table 2) indicated that the first product was not **8** but another species tentatively assigned as the disulfane $AsPh_4[W(CO)_5SS$-*p*-$C_6H_4CH_3]$, **9**. After 24 h the spectrum indicated the presence of **8** at the expense of **9**. The results are consistent with formation of the disulfane during the reaction and its subsequent desulfurization upon work up.

The tendency of **3**, **4**, and **8** to lose sulfur easily contrasts with the complexes *cis*-$(PPh_3)_2Pt(phth)SSR$ which are quite stable (8, 21) and with complexes containing the biscyclopentadienyltitanium moiety which tend to incorporate sulfur into long chains (3*c*, 22). The factors which determine the length of the sulfur chain in a catenated polysulfano ligand are not well understood; however, an inverse correlation between the electron density at the metal center and sulfur chain length has been proposed (22). Thus, the lability observed for these tungsten systems is consistent with the relatively high electron density at the metal, particularly in the case of **8**.

Experimental

Apparatus and general procedures

All reactions and manipulations were carried out under nitrogen atmosphere, using the appropriate-sized three-necked round bottom flask, one neck of which was always equipped with a gas inlet. Standard inert atmosphere techniques were used (23). Chromatography was performed on activated alumina (Anachemia) (80–200 mesh). Irradiations were performed in a water-cooled Pyrex apparatus using an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

immersion lamp (Hanovia, Hg vapour, 100 W). Infrared spectra were obtained on a Perkin–Elmer 297 spectrophotometer using 0.1 mm pathlength sodium chloride solution cells or pressed potassium bromide pellets containing the sample. The instrument was calibrated with the 1601.4 cm^{-1} band of polystyrene. ^{1}H-nmr spectra were measured on a Varian XL-200 spectrometer and all data are reported in ppm relative to an internal standard, TMS. Mass spectra were measured on an LKB 9000 mass spectrometer at the McGill University Mass Spectrometry Unit, with ionizing potentials of 15 or 70 eV. All mass ions are reported only for the lowest isotope (24) of tungsten (i.e. 182) as this simplified interpretation of overlapping fragmentation patterns. Elemental analyses were carried out by Midwest Microlab Ltd., Indianapolis, IN, and Guelph Chemical Laboratories Ltd., Guelph, Ont. Melting points were measured with a Thomas Hoover capillary melting point apparatus, and are uncorrected.

Tetrahydrofuran (THF), toluene, and dimethoxyethane were refluxed over sodium metal and benzophenone and collected by distillation under nitrogen. Spectrograde chloroform was passed through activated alumina and collected under nitrogen. Ethanol was refluxed over calcium hydride and distilled under nitrogen. The solvents used for recrystallizations and chromatography were spectrograde quality and, with the exception of ethanol and acetone, were stored over type 3A molecular sieves and purged with nitrogen prior to use. The following reagents were prepared as reported: *N*-(phenylmethyl)thiophthalimide, ($PhCH_2$Sphth) (25), *N*-(phenylmethyl)bisthiophthalimide ($PhCH_2$SSphth) (26), *N*-(phenylmethyl)sulfinylphthalimide ($PhCH_2$S(O)phth) (13), *N*-(4-methylbenzene)thiosuccinimide (*p*-$CH_3C_6H_4$Ssucc) (25), *N*-(4-methylbenzene)thiophthalimide (*p*-$CH_3C_6H_4$Sphth) (27), *N*-(4-methylbenzene)bisthiophthalimide (*p*-$CH_3C_6H_4$SSphth) (26), *N*-(4-methylbenzene)sulfinylphthalimide (*p*-$CH_3C_6H_4$S(O)phth) (13), sodium hydrogen sulfide (28), $AsPh_4$[W(CO)$_5$SH] (6*b*,*c*). The thiolato complexes $AsPh_4$[W(CO)$_5$S-*p*-$C_6H_4CH_3$] and $AsPh_4$[W(CO)$_5$)$_2$S-*p*-$C_6H_4CH_3$] (29) were prepared by an analogous route (6*b*,*c*) from W(CO)$_5$THF (30) and sodium 4-methylbenzenethiolate, both prepared *in situ*, in the appropriate ratio (1:4 and 1:1, respectively). Cp$_3$W(CO)$_3$I was prepared by the method reported (31) for the analogous molybdenum complex (^{1}H-nmr ($CDCl_3$): 5.65 ppm; infrared (cyclohexane) ν(CO): 2030 (w), 1961 (m), 1948 (m) cm^{-1}. This complex was treated with the appropriate sodium thiolate to give Cp$_3$W(CO)$_3$SCH_2Ph and Cp$_3$W(CO)$_3$S-*p*-$C_6H_4CH_3$ (32).

*Cyclopentadienyltricarbonylthiolotungsten(II), Cp$_3$W(CO)$_3$SH, **1***

A solution of (C_5H_5)W(CO)$_3$I (3.33 g, 7.29 mmol) in 100 mL of tetrahydrofuran was added dropwise over 0.5 h to a solution of NaSH (22 mmol, 3 equiv.) prepared *in situ* in 40 mL of ethanol. The resultant mixture was stirred for 12 h at room temperature, followed by removal of the solvent under reduced pressure (water aspirator). Sublimation of the crude material, under vacuum at 70°C, gave 0.99 g (39%) of the title compound as orange needles (mp 105°C, lit. (7) 106°C; infrared (cyclohexane) ν(CO): 2028 (w), 1961 (sh), 1949 (s) cm^{-1}. Mass spectrum: *m*/*e* 364 (M^+), 336 (M^+ − CO), 308 (M^+ − 2CO), 303 (M^+ − CO − SH), 280 (M^+ − 3CO), 275 (M^+ − 2CO − SH), 247 (M^+ − 3CO − SH), 252–259 (unassigned peaks). *Anal.* calcd. for $C_8H_6O_3SW$: C 26.2, H 1.64, S 8.75; found: C 26.3, H 1.71, S 8.82.

*Cyclopentadienyltricarbonylphenylmethyldisulfanotungsten(II), Cp$_3$W(CO)$_3$SSCH_2Ph, **3**a*

This preparation is typical of the general methods employed and is described in detail. A solution of $PhCH_2$Sphth (0.221 g, 0.82 mmol), in 20 mL of THF was added dropwise over 15 min to Cp$_3$W(CO)$_3$SH (0.300 g, 0.82 mmol) in 300 mL of THF, at −20°C. The resulting red solution was stirred, at −20°C, for an additional 15 min, and reduced to dryness under vacuum at 0°C. The residue was extracted twice with carbon disulfide (25 mL total). The combined extracts were filtered through celite and evaporated to dryness under vacuum. The crude product was dissolved in a minimum of methylene chloride (5–10 mL) and 20–40 mL of hexane was added so as to form a layer on top of this solution. Cooling at −40°C overnight gave the complex as red crystals. The mother liquors were removed with a syringe and the crystals were washed with pentane and dried *in vacuo* for 6 h (0.28 g, 70%, mp 89°C). Infrared (cyclohexane) ν(CO): 2022 (w), 1947 (sh), 1942 (m) cm^{-1}. Mass spectrum *m*/*e*$^+$ 458 (M^+ − CO), 426 (M^+ − CO − S), 402 (M^+ − 3CO), 398 (M^+ − S − 2CO), 370 (M^+ − S − 3CO), 367 (M^+ − CO − $CH_2C_6H_5$), 338 (M^+ − 3CO − 2S), 335 (M^+ − CO − S$CH_2C_6H_5$), 307 (M^+ − 2CO − S$CH_2C_6H_5$), 279 ((C_5H_5)WS$^+$), 275 ((C_5H_5)W(CO)$^+$), 247 ((C_5H_5)W$^+$). *Anal.* calcd. for $C_{15}H_{12}O_3S_2W$: C 36.9, H 2.46, S 13.1; found: C 36.8, H 2.57, S 12.8.

*Cyclopentadienyltricarbonyl-4-methylbenzenedisulfanotungsten(II), Cp$_3$W(CO)$_3$SS-p-$C_6H_4CH_3$, **3**b*

As above, *p*-$CH_3C_6H_4$Sphth (0.081 g, 0.30 mmol) in THF (20 mL) was stirred, at −20°C, with Cp$_3$W(CO)$_3$SH (0.110 g, 0.30 mmol) in THF (20 mL) for 0.5 h. Recrystallization gave orange crystals (0.125 g, 70%, mp 89°C). Infrared (cyclohexane) ν(CO): 2028 (w), 1956 (m), 1943 (m) cm^{-1}. Mass spectrum: *m*/*e*$^+$ 458 (M^+ − CO), 454 (M^+ − S), 430 (M^+ − 2CO), 426 (M^+ − CO − S), 402 (M^+ − 3CO), 398 (M^+ − S − 2CO), 370 (M^+ − S − 3CO), 367 (M^+ − CO − $C_6H_4CH_3$), 335 (M^+ − CO − S$C_6H_4CH_3$), 307 (M^+ − 2CO − S$C_6H_4CH_3$), 279 ((C_5H_5)WS$^+$), 279 ((C_5H_5)WS$^+$), 247 ((C_5H_5)W$^+$). *Anal.* calcd. for $C_{15}H_{12}O_3S_2W$: C 36.9, H 2.46, S 13.1; found: C 37.3, H 2.50, S 13.0.

*Cyclopentadienyltricarbonylphenylmethyltrisulfanotungsten(II), Cp$_3$W(CO)$_3$SSSCH_2Ph, **4**a*

Cp$_3$W(CO)$_3$SH (0.096 g, 0.26 mmol) in THF (10 mL) was stirred for 30 min with $PhCH_2$SSphth (0.080 g, 0.27 mmol) in THF (10 mL) at −20°C. The ^{1}H-nmr spectrum ($CDCl_3$) showed that the crude product was contaminated by Cp$_3$W(CO)$_3$SSCH_2Ph present in about 25% with respect to the title complex. Attempts to isolate the trisulfano complex were unsuccessful leading instead to the production of more of the disulfano contaminant or to decomposition. The infrared spectrum of the crude product in cyclohexane gave three bands in the carbonyl region, at 2028 (w), 1959 (m), and 1944 (m) cm^{-1}.

*Cyclopentadienyltricarbonyl-4-methylbenzenetrisulfanotungsten(II), Cp$_3$W(CO)$_3$SSS-p-$C_6H_4CH_3$, **4**b*

Cp$_3$W(CO)$_3$SH (0.046 g, 0.126 mmol) in THF (10 mL) was stirred for 30 min with $CH_3C_6H_4$SSphth (0.038 g, 0.126 mmol) in THF (10 mL) at −20°C. The ^{1}H-nmr spectrum ($CDCl_3$) showed that the crude product contained Cp$_3$W(CO)$_3$SS$C_6H_4CH_3$ present in about 25% with respect to the title complex. Repeated recrystallizations from methylene chloride/hexane gave solids which exhibited spectra identical to the crude material. The infrared spectrum in cyclohexane gave bands at 2026 (w), 1956 (m), and 1945 (m) cm^{-1}.

*Cyclopentadienyltricarbonylphenylmethyl-2-oxodisulfanotungsten(II), Cp$_3$W(CO)$_3$SS(O)CH_2Ph, **5**a*

$PhCH_2$S(O)phth (0.075 g, 0.27 mmol) in THF (10 mL) was added to Cp$_3$W(CO)$_3$SH (0.088 g, 0.25 mmol) in THF (10 mL) at −20°C and stirred for 30 min. The product was obtained as orange–red microcrystals (0.075 g, 61%, mp 97°C). Infrared (cyclohexane) ν(CO): 2036 (w), 1960 (m), 1950 (m). Mass spectrum: *m*/*e*$^+$ 458 (M^+ − CO − O), 430 (M^+ − 2CO − O), 418 (M^+ − 3CO), 402 (M^+ − 3CO − O), 370 (M^+ − 3CO − S − O), 335 (M^+ − CO − S(O)$CH_2C_6H_5$), 307 (M^+ − 2CO − S(O)$CH_2C_6H_5$), 247 ((C_5H_5)W$^+$). *Anal.* calcd. for $C_{15}H_{12}O_4S_2W$: C 35.7, H 2.38, S 12.7; found: C 35.6, H 2.46, S 12.9.

*Cyclopentadienyltricarbonyl-4-methybenzene-2-oxodisulfanotungsten(II), Cp$_3$W(CO)$_3$SS(O)-p-$C_6H_4CH_3$, **5**b*

p-$CH_3C_6H_4$S(O)phth (0.114 g, 0.40 mmol) in THF (15 mL) was added, at 0°C, to Cp$_3$W(CO)$_3$SH (0.146 g, 0.40 mmol) in THF (15 mL) and the solution stirred for 30 min. The complex is orange–red in colour (0.086 g, 41%, mp 96°C). Infrared (cyclohexane) ν(CO): 2034 (w), 1958 (m), 1949 (m) cm^{-1}. Mass spectrum: *m*/*e*$^+$ 430 (M^+ − 2CO − O), 418 (M^+ − 3CO), 402 (M^+ − 3CO − O), 370 (M^+ − 3CO − S(O)), 366 (M^+ − 2CO − SS(O)), 279 ((C_5H_5)WS$^+$), 247 ((C_5H_5)W$^+$). *Anal.* calcd. for $C_{15}H_{12}O_4S_2W$: C 35.7, H 2.38, S 12.7; found: C 35.4, H 2.53, S 12.7.

Desulfurization of $CpW(CO)_3SSCH_2Ph$ and $CpW(CO)_3SS$-p-$C_6H_4CH_3$

Two nmr samples in C_6D_6 were prepared for each complex: one, A, contained only the complex while the other, B, contained equimolar amounts of complex and triphenylphosphine. The peaks due to the starting complexes gradually decreased in intensity while those due to the thiolates concommitantly appeared and increased in intensity in all samples. For **3***a*, the ratio of starting complex to thiolate after 5 h was 5:2 in sample A while in sample B signals due to starting complex were not detected. For **3***b*, the corresponding ratio after 4 h was 4:1 in sample A and no signal was observed for the disulfano complex in sample B. The dried residue from the B samples exhibited ir bands characteristic of triphenylphosphinesulfide superimposed on those due to the thiolate complexes.

Oxidation of $CpW(CO)_3SSCH_2Ph$ and $CpW(CO)_3SS$-p-$C_6H_4CH_3$ with m-chloroperbenzoic acid

Each complex was treated with a stoichiometric amount of oxidant and, in a second reaction, with 2.5 equiv. *m*-Chloroperbenzoic acid in $CHCl_3$ (10 mL) was added dropwise over 15 min to the complex in $CHCl_3$ (10 mL) at 0°C. After stirring for an additional 15 min, the solution was rapidly transferred to a separatory funnel and washed with 5% aqueous sodium bicarbonate (3 × 15 mL) and with 15 mL of distilled water, purging the chloroform layer with nitrogen after each washing. The solution was dried (under nitrogen) with anhydrous sodium sulfate and filtered. The solvent was vacuum evaporated and the residue dried under vacuum for 12 h. These residues were characterized by their ^{1}H-nmr spectra in $CDCl_3$ (Table 3).

*Attempted synthesis of tetraphenylarsonium pentacarbonyl-4-methylbenzenedisulfanotungstate(0), $AsPH_4[W(CO)_5SS$-p-$C_6H_4CH_3]$, **9***

p-$CH_3C_6H_4S$succinimido (0.111 g, 0.50 mmol) in THF (15 mL) was added dropwise to $AsPh_4[W(CO)_5SH]$ (0.346 g, 0.49 mmol) in THF (50 mL) and the mixture was stirred for 90 min. Then it was filtered and evaporated under vacuum to a yellow oil. This was dissolved in a minimum of 1:1 ethanol/methanol and treated with 2 volumes of hexane. Cooling at −40°C gave a yellow crystalline solid in low yield, identified as $AsPh_4[W(CO)_5S$-*p*-$C_6H_4CH_3]$, **8**, on the basis of its ^{1}H-nmr and ir spectra and elemental analysis. Repeating the preparation using *p*-$CH_3C_6H_4$Sphth gave the same result. However, in one experiment the latter reaction was conducted at −20°C for 15 min and rapidly vacuum dried at 0°C. The ^{1}H-nmr spectrum of the residue in acetone-d_6 gave peaks at 7.21 (q, 4H, C_6H_4, J(H—H) = 8 Hz) and 2.23 (s, 3H, CH_3) in addition to peaks due to *p*-$CH_3C_6H_4$Sphth and phthalimide. After 24 h peaks due to **8** had appeared at the expense of those originally observed.

Preparation, properties, and characterization of methanesulfonato complexes of arsenic(III), antimony(III), and bismuth(III)

RAMESH KAPOOR, POONAM WADHAWAN, AND PRATIBHA KAPOOR
Department of Chemistry, Panjab University, Chandigarh-160014, India

Received July 25, 1986[1]

RAMESH KAPOOR, POONAM WADHAWAN, and PRATIBHA KAPOOR. Can. J. Chem. **65**, 1195 (1987).

Arsenic(III), antimony(III), and bismuth(III) oxides, sodium arsenite and bismuthate react with methanesulfonic anhydride, $(CH_3)_2S_2O_5$, to yield $M(SO_3CH_3)_3$ (M = As(III), Sb(III), and Bi(III)), $Na[AsO(SO_3CH_3)_2]$, and $Na[Bi(SO_3CH_3)_4]$, respectively, in quantitative yield. Reaction of arsenic(III) oxide with pure methanesulfonic acid yields oxo(methanesulfonato)arsenic(III), $AsO(SO_3CH_3)$, which behaves as a non-electrolyte in 100% methanesulfonic acid. The compounds have been characterized by elemental analysis, conductance, infrared, ^1H nmr and thermal measurements. Their properties have been studied by ligand substitution and complex formation reactions. The $M(SO_3CH_3)_3$ (M = As(III), Sb(III), and Bi(III)) compounds are capable of functioning both as Lewis acids and bases. These compounds exhibit basic behaviour in 100% methanesulfonic acid. The synthesis of complex mathanesulfonates $Cs[M(SO_3CH_3)_4]$ (M = As(III), Sb(III), and Bi(III)) is also described.

RAMESH KAPOOR, POONAM WADHAWAN et PRATIBHA KAPOOR. Can. J. Chem. **65**, 1195 (1987).

Les oxydes d'arsenic(III), d'antimoine(III) et de bismuth(III) ainsi que l'arsénite et le bismuthate de sodium réagissent avec l'anhydride de l'acide méthanesulfonique, $(CH_3)_2S_2O_5$, pour conduire respectivement et quantitativement aux sels $M(SO_3CH_3)_3$ (M = As(III), Sb(III) et Bi(III)), $Na[AsO(SO_3CH_3)_2]$ et $Na[Bi(SO_3CH_3)_4]$. La réaction de l'oxyde d'arsenic(III) avec l'acide méthanesulfonique pur conduit à l'oxo(méthanesulfonato)arsenic(III), $As(O(SO_3CH_3)$, qui se comporte comme un non-électrolyte dans l'acide méthanesulfonique à 100%. On a caractérisé les composés en se basant sur les analyses élémentaires, sur les conductivités, sur les spectres infrarouges et rmn du ^1H ainsi que sur des mesures thermiques. On a étudié les propriétés chimiques en procédant à des réactions de substitution de ligands et de formation de complexes. Les composés $M(SO_3CH_3)_3$ (M = As(III), Sb(III) et Bi(III)) peuvent aussi bien fonctionner comme acides que comme bases de Lewis. Dans l'acide méthanesulfonique à 100%, ces composés agissent comme bases. On décrit aussi la synthèse des méthanesulfonates complexes $Cs[M(SO_3CH_3)_4]$ (M = As(III), Sb(III) et Bi(III)).

[Traduit par la revue]

Introduction

Methanesulfonates of only a few elements have been prepared in the past mainly using solvolytic reactions in methanesulfonic acid (1–12). This paper describes the synthesis and characterization of compounds $M(SO_3CH_3)_3$ (M = As(III), Sb(III), and Bi(III)), $[NaAsO(SO_3CH_3)_2]$, and $Na[Bi(SO_3CH_3)_4]$ by reaction of methanesulfonic anhydride with suitable oxides or oxosalts. The corresponding $M(SO_3X)_3$ salts (M = Sb(III) and Bi(III), and X = F and CF_3) have been reported in the literature (13–15) and are compared here with the methanesulfonates.

Experimental

All reagents (As_2O_3, Sb_2O_3, Bi_2O_3, As_2O_5, Sb_2O_5, $NaAsO_2$, $NaBiO_3$, $(CH_3)_4N^+Br^-$, NH_4SCN) were dried by heating them under vacuum at about 110°C for several hours. Methanesulfonic acid (BDH, 98%) was made anhydrous by equilibrating it with methanesulfonic anhydride for about 4 to 6 h at ≅70°C and then distilling it under reduced pressure (bp 165°C at 2 mm Hg). Acid having a minimum conductivity of ca. 4.8×10^{-4} ohm^{-1} cm^{-1} was used (5). Methanesulfonic anhydride was prepared by mixing methanesulfonic acid (60 g) and P_4O_{10} (20 g) and heating the mixture to ≅100°C for about 2 h to complete the dehydration of the acid. The equilibrated mixture was then distilled under reduced pressure and methanesulfonic anhydride was obtained as a white crystalline solid, mp 68–70°C. 1,2-Dimethyoxyethane was refluxed over sodium metal for 8 h and then distilled. The distilled product was kept over sodium wire. Dimethylformamide was dried over molecular sieves and distilled at reduced pressure. Pyridine was distilled after keeping it over KOH pellets for 24 h. Acetonitrile was distilled over P_4O_{10} and kept over molecular sieves. Cesium methanesulfonate was prepared by dissolving cesium carbonate in aqueous methanesulfonic acid and evaporating to dryness. It was recrystallized from water and dried for several hours at 110°C.

[1]Revision received December 29, 1986.

Instrumentation

Conductance measurements were performed with a Toshniwal C1 01/01 type conductivity bridge at 25°C using conductivity cell having a cell constant of 51.98 cm^{-1}. Infrared spectra were recorded on a Perkin-Elmer 621 double beam grating spectrophotometer as Nujol and hexachlorobutadiene mulls between NaCl and polyethylene plates. Potassium bromide plates could not be used as the compounds react with them to liberate bromine. Thermal analysis was carried out on MOM Budapest Derivatograph, type Paulik, Paulik, Erdey. ^1H nmr spectra were recorded in formamide solutions on Varian EM 390 with reference to TMS as internal standard. Mass spectra were recorded on VG Micromass mm 70/70.

Synthesis

All the compounds discussed here are air-sensitive and required handling in dry nitrogen atmosphere, dry box, or *in vacuo*.

Tris(methanesulfonates) of arsenic, antimony, and bismuth, M-$(SO_3CH_3)_3$: These comounds were prepared by heating metal oxide (10 mmol) and methanesulfonic anhydride (40 mmol) to approximately 140°C for 24 h. The time taken for completion of the reaction decreased with increasing basicity of the oxide, i.e., reaction of Bi_2O_3 with $(CH_3)_2S_2O_5$ was over only in 2 to 3 h. The contents were then stirred with 40–50 mL of freshly distilled diethylether. The white-to-grey solid products were removed by vacuum filtration and then washed with several portions of diethylether. The final products were obtained by drying them under vacuum for several hours.

Ammonium methanesulfonatotris(isothiocyanato)arsenate(III)/antimonate(III)/bismuthate(III), $NH_4[M(SO_3CH_3)(NCS)_3]$ (M = As, Sb or Bi): To a solution of 0.20 g (0.5 mmol) of $As(SO_3CH_3)_3$ in 1,2-dimethyloxyethane (15 mL) was added a clear solution of 0.16 g (2.1 mmol) of NH_4CNS in 20 mL of the same solvent. A white precipitate immediately appeared which was stirred for about an hour. The product was filtered and dried under vacuum. The compound is highly air-sensitive. To 0.34 g (0.8 mmol) of $Sb(SO_3CH_3)_3$ was added a solution of 0.26 g (3.4 mmol) NH_4CNS in 30 mL of dimethoxyethane. The suspension immediately gave a white precipitate which

was filtered and dried *in vacuo*. The procedure used for bismuth complex was identical with that for the antimony complex. However, the product was a pale-yellow compound which was quite stable to moist air.

Tetramethylammonium tetrabromoantimonate(III)/bismuthate(III), $[(CH_3)_4N]^+[MBr_4]^-$ (M = Sb and Bi): To about 0.4–0.5 g (≅1 mmol) of $Sb(SO_3CH_3)_3$ or $Bi(SO_3CH_3)_3$ was added a solution of about 0.9 to 1.0 g (≅6 mmol) of $(CH_3)_4NBr$ in 20 mL of anhydrous methanol. The resulting suspension immediately turned into a thick creamy white precipitate. It was stirred for 4 to 6 h and then filtered. The precipitates were washed with methanol and dried *in vacuo*. The products are air-stable. Reaction of $As(SO_3CH_3)_3$ with $(CH_3)_4NBr$ did not yield any precipitate. On addition of diethylether to the solution, the original compound $As(SO_3CH_3)_3$ separated out.

Pyridine and dimethylformamide complexes: All the complexes were prepared in the same general manner. In a typical experiment, excess amount of pyridine or DMF was added to the suspension of metal(III) methanesulfonate (4:1) in light petroleum ether at about −10°C. The contents were stirred for about 4 to 6 h. The products were vacuum filtered, washed several times with fresh samples of light petroleum ether, and finally dried *in vacuo*.

Boron tribromide complexes, $M(SO_3CH_3)_3 \cdot BBr_3$ (M = As, Sb, or Bi): In a typical experiment, $As(SO_3CH_3)_3$ (0.47 g, 1.3 mmol) was taken in $CHCl_3$ (10 mL) and a solution of BBr_3 (0.33 g, 1.3 mmol) in $CHCl_3$ (5 mL) was added. An exothermic reaction occurred immediately and the mixture was allowed to stir for 2 h at −10°C. The contents were vacuum filtered and dried under vacuum. Complexes of BBr_3 with $Sb(SO_3CH_3)_3$ and $Bi(SO_3CH_3)_3$ were prepared in a similar fashion. The pale-yellow adducts were unstable and highly sensitive to moist air.

Cesium tetrakis(methanesulfonato)arsenate(III)/antimonate(III)/bismuthate(III), $Cs[M(SO_3CH_3)_4]$ (M = As, Sb or Bi): Equimolar solutions of cesium methanesulfonate and tris(methanesulfonate) arsenic(III)/antimony(III)/bismuth(III) in pure methanesulfonic acid were heated for about 12 h around 140°C. The complexes were recovered as greyish-white precipitates by adding a large excess of dry diethylether to the solution. The complexes were vacuum filtered and dried *in vacuo*.

Sodium oxobis(methanesulfonato)arsenate(III), $Na[AsO(SO_3CH_3)_2]$: Sodium arsenite, $NaAsO_2$ (1.3 g, 10 mmol), was stirred with methanesulfonic anhydride (3.8 g, 22 mmol) in diethylether at room temperature for 2–4 h. The fluffy white precipitate was vacuum filtered, washed with several lots of freshly distiled diethylether, and dried *in vacuo*.

Sodium tetrakis(methanesulfonato)bismuthate(III), $Na[Bi(SO_3CH_3)_4]$: Sodium bismuthate, $NaBiO_3$ (1.4 g, 5 mmol), was stirred with methanesulfonic anhydride (2.6 g, 15 mmol) in diethylether for about 4 h at room temperature. The rest of the procedure was the same as followed above.

Oxo(methanesulfonato)arsenic(III), $AsO(SO_3CH_3)$: Saturated solution of As_2O_3 in pure methanesulfonic acid at room temperature gave a white precipitate which was filtered, washed with diethylether, and dried *in vacuo*. Its adduct with pyridine was obtained by stirring $AsO(SO_3CH_3)$ with excess of pyridine in light petroleum ether at room temperature for 6 to 8 h. The product was filtered, washed with light petroleum ether, and dried *in vacuo*.

Arsenic and antimony in these compounds were estimated volumetrically by titrating with standard potassium iodate. Bismuth was estimated gravimetrically as oxyiodide, BiOI. Sulfur and bromine were estimated gravimetrically as $BaSO_4$ and AgBr, respectively. Carbon, hydrogen, and nitrogen were estimated microanalytically. Table 1 summarizes the analytical data of the complexes prepared above.[2]

Results and discussion

Arsenic(III), antimony(III), and bismuth(III) methanesulfonates have been prepared in quantitative yield by the reaction of methanesulfonic anhydride with the respective metal oxides.

$$M_2O_3 + 3(CH_3)_2S_2O_5 \rightarrow 2M(SO_3CH_3)_3$$

M = As(III), Sb(III), and Bi(III)

This reaction is a very convenient preparative route to the synthesis of methanesulfonate derivatives. Reactions of methane and trifluoromethanesulfonic acids with metal halides/acetates or oxides even at elevated temperatures often do not yield desired products in pure form due to contamination with side products.

These compounds are highly sensitive to moisture. They do not melt up to 240°C. They are insoluble in common organic solvents such as $C_6H_5NO_2$, CH_3NO_2, and CH_3CN. They are, however, soluble in basic organic solvents such as MeOH, DMF, NMF, DMSO. Λ_M values of their millimolar solutions in DMF (81 to 98 ohm^{-1} cm^2 mol^{-1}) and DMSO (66 to 73 ohm^{-1} cm^2 mol^{-1}) suggest that the compounds behave as 1:1 electrolytes (16):

$$[1] \quad M(SO_3CH_3)_3 \xrightarrow{DMF} [M(SO_3CH_3)_2(DMF)_2]^+ + CH_3SO_3^-$$

Possibly, the basic solvent molecules (DMF or DMSO) displace the weakly coordinating $CH_3SO_3^-$ group.

Methanesulfonate anion, $CH_3SO_3^-$, has the potential to bond to metal ions as bidentate or tridentate bridging ligand with the consequent formation of highly polymeric materials. In view of this it is essential to visualize the changes in the vibrational spectrum of the CH_3SO_3 group in different stereochemical environments. (*i*) The symmetry of an isolated CH_3SO_3 group (CSO_3 moiety) is C_{3v} which is responsible for six fundamentals, three *E* ($\nu_{as}(SO_3)$, $\delta_{as}(SO_3)$, and $\rho_r(SO_3)$) and three *A* ($\nu_s(SO_3)$, ν(S—CH_3), and $\delta_s(SO_3)$) modes of ir-active vibrations. (*ii*) A tridentate methanesulfonate group has C_{3v} symmetry which suggests that it will have the vibrational spectrum quite similar to that of the free ion. This mode of coordination has been observed in some bivalent transition metal methanesulfonates (10). (*iii*) If CH_3SO_3 group enters into monodentate type of coordination, its symmetry is lowered from C_{3v} to C_s. With this lowering of symmetry the three *E* modes are split to give a total of six bands (7), and a total of nine ir-active bands are expected.

The ir spectra of $M(SO_3CH_3)_3$ (M = As, Sb, and Bi) were recorded in the region 4000–200 cm^{-1} (Table 2). Similarities in their infrared spectra suggest structural similarities in these compounds. Band assignments have been made by comparison with the spectra of ionic $K^+CH_3SO_3^-$ (17) and trivalent metal methanesulfonates (10, 12). The doubly degenerate SO_3 asymmetric stretching, and SO_3 asymmetric bending modes, show very significant splitting which suggests reduction of the CSO_3 symmetry below C_{3v}. This is consistent with six coordinate arsenic(III), antimony(III), and bismuth(III) since the stoichiometry requires that for MO_6 chromophores each methanesulfonate ion must utilize only two of its oxygen atoms for bonding. The ^1H nmr spectra of $M(SO_3CH_3)_3$ (M = As, Sb, and Bi) in formamide at 90 MHz show only a single peak at 2.80 to 2.85 ppm. The methyl protons are deshielded relative to those in methanesulfonic anhydride which exhibit a single peak at 2.45 ppm.

TG/DTG studies of $M(SO_3CH_3)_3$ (M = As, Sb, and Bi) compounds show that they all begin to decompose when heated above 45–50°C. These compounds decompose to their oxo-salts with the loss of methanesulfonic anhydride. The thermal decomposition schemes for these compounds are given below:

[1] $As(SO_3CH_3)_3 \xrightarrow{A} AsO(SO_3CH_3) \xrightarrow{B}$ No residue

[II] $Sb(SO_3CH_3)_3 \xrightarrow{A} SbO(SO_3CH_3) \xrightarrow{B} \underbrace{\tfrac{1}{3}[Sb + Sb_2(SO_4)_3]}_{C}$

$\tfrac{1}{6}Sb_2O_4 \xleftarrow{D} \tfrac{1}{6}Sb_2O_3$

[III] $Bi(SO_3CH_3)_3 \xrightarrow{A} BiO(SO_3CH_3) \xrightarrow{B} \underbrace{\tfrac{1}{3}[Bi + Bi_2(SO_4)_3]}_{C}$

$\tfrac{1}{6}Bi_2O_3$

The observed weight loss (or gain) values for the different steps agree closely with the theoretically required values (Table 3). In reaction [1], no residue was obtained in the ceramic crucible. Possibly, As_2O_3 which may have been formed on heating above 350°C sublimes at this temperature (18) and the crucible was completely empty by the time the temperature had reached 600°C when the run was stopped. The residue in [II] and [III] was qualitatively checked for the presence of SO_4^{2-} ions. Methanesulfonic anhydride was distilled when each of these compounds was heated separately under vacuum in the line.

TABLE 3. Thermal analysis data of tris(methanesulfonates) of arsenic, antimony, and bismuth

Compound	Step	Temperature range (°C)	Wt. loss (or gain) (−) (+) % found (calcd.)
$As(SO_3CH_3)_3$	*A*	45–350	−47.4 (48.3)

	B	370–430	−47.2 (46.5)
	C	430–500	+2.0 (2.0)
	D	500–620	+2.6 (2.6)
$Bi(SO_3CH_3)_3$	*A*	70–360	−35.4 (35.2)
	B	360–420	−39.4 (38.3)
	C	420–540	+1.7 (1.6)

Solutions in 100% methanesulfonic acid: These compounds should also be suitable solutes for solution studies in CH_3SO_3H and simple ionization should lead to solvated $[M(SO_3CH_3)_2]^+$ cations. Solubility of $M(SO_3CH_3)_3$ (M = As, Sb, and Bi) compounds decreases in going from arsenic to the bismuth compound. The specific conductivities of $As(SO_3CH_3)_3$ and $Sb(SO_3CH_3)_3$ in 100% methanesulfonic acid are shown in Fig. 1. Tris(methanesulfonato)bismuth(III) is only very sparingly soluble in methanesulfonic acid and it was not possible to study the conductivity of its solutions. The specific conductivities of $As(SO_3CH_3)_3$ and $Sb(SO_3CH_3)_3$ are compared with solutions of pyridine in CH_3SO_3H in which it is known to behave as a fully ionized base (19). Both $As(SO_3CH_3)_3$ and $Sb(SO_3CH_3)_3$ behave as weak electrolytes. In order to ascertain whether $As(SO_3CH_3)_3$ ionized as an acid or a base, the conductivities of solutions obtained by adding small amounts of pyridine to $As(SO_3CH_3)_3$ solutions were measured. The conductivity increased immediately and no minimum conductivity was observed even at very low pyridine concentrations, suggesting that $As(SO_3CH_3)_3$ behaves as a base:

[2] $As(SO_3CH_3)_3 \overset{CH_3SO_3H}{\rightleftharpoons} [As(SO_3CH_3)_2]^+_{solv.} + CH_3SO_3^-$

This mode of ionization of $As(SO_3CH_3)_3$ was also confirmed when a decrease in conductivity of its solution was observed on addition of small amounts of antimony(V) chloride; the latter has been shown to behave as a strong acid in methanesulfonic acid (20). Surprisingly, this behaviour of $As(SO_3CH_3)_3$ in methanesulfonic acid is different from that observed for $As(HSO_4)_3$ which ionizes as an acid in 100% sulfuric acid (21).

[3] $As(HSO_4)_3 + 2H_2SO_4 \rightleftharpoons H_3SO_4^+ + As(HSO_4)_4^-$

Tris(methanesulfonato)antimonate(III) which behaves as a very weak electrolyte in 100% CH_3SO_3H was also shown to behave as a base.

Thiocyanato complexes from $M(SO_3CH_3)_3$ (M = As, Sb, and Bi): Ammonium thiocyanate reacts rapidly with tris(methanesulfonates) of arsenic, antimony, and bismuth to form mixed-ligand complexes of the general formula, $NH_4[M(SO_3CH_3)(NCS)_3]$. The infrared spectra of these complexes indicate N bonding for the thiocyanate ligands. The presence of bands at about 2080 (C—N stretch), 790 (C—S stretch), and 470 cm^{-1} (N—C—S bending mode) are consistent with some known complexes having N-bonded thiocyanate ligand (22). The methanesulfonate group may be considered to be very weakly coordinated. The S—O asymmetric and symmetric stretching vibrations are observed at 1246 and 1050 cm^{-1}, respectively, as would be

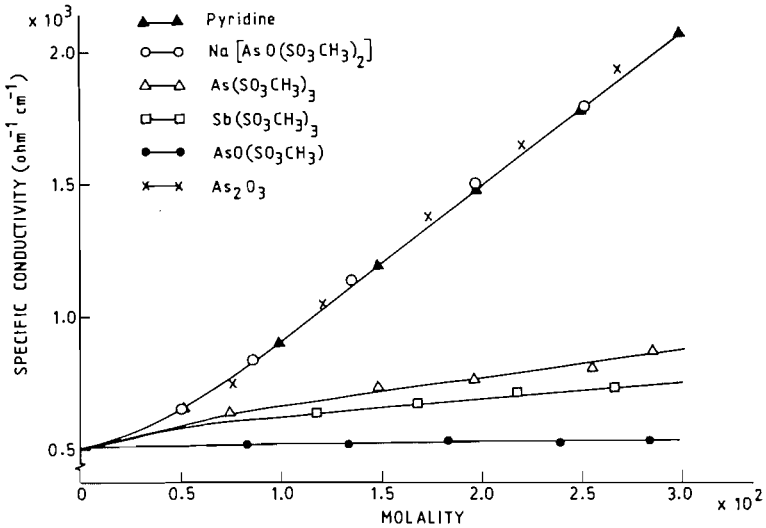

FIG. 1. Plot of specific conductivities in methanesulfonic acid at 25°C.

expected on coordination of the CH_3SO_3 group. However, the other two asymmetric modes observed at about 540 and 330 cm^{-1} are not split.

Bromide complexes from $M(SO_3CH_3)_3$ (M = Sb and Bi): Tetramethylammonium bromide reacts instantly with tris(methanesulfonates) of antimony and bismuth to form complexes of the formula, $(CH_3)_4N^+[MBr_4]^-$ in which all the three methanesulfonate groups have been replaced. Their ir spectra are quite similar above 400 cm^{-1} and contain no bands due to the $CH_3SO_3^-$ group.

Complexes of $M(SO_3CH_3)_3$ with DMF and pyridine (M = As, Sb, and Bi): The Lewis acid character of MCl_3 (M = As, Sb, and Bi) compounds is well known (23). It is also possible that two monodentate ligands could displace a methanesulfonate ligand. In order to distinguish between these two possibilities, we have investigated the reactions of $M(SO_3CH_3)_3$ compounds with DMF and pyridine (Table 1). As would be expected the adducts are considerably less moisture-sensitive than the parent compounds. Comparison of their infrared spectra with those of the original compounds suggest the following: (*1*) Bands due to S—O stretching modes are observed in these compounds. Their frequencies are very close to those observed in the parent compounds. Some additional bands assignable to ionic methanesulfonate S—O stretches (1190, 1050, 780, 550, 530, and 350 cm^{-1}) are also observed in their spectra. (*2*) The amide I band observed in DMF at 1680 cm^{-1} is shifted to a lower value around 1630–1640 cm^{-1} in these compounds which is suggestive of coordination via the carbonyl oxygen (24). (*3*) The C—C and C—N stretching modes which are usually observed between 1450 and 1615 cm^{-1} show definite positive shift indicating coordination through nitrogen (25).

Two bidentate methanesulfonate ligands, two monodentate ligands, and an ionic methanesulfonate group suggest the formulation $[M(SO_3CH_3)_2L_2]^+CH_3SO_3^-$ for these compounds.

Complexes of $M(SO_3CH_3)_3$ (M = As, Sb, and Bi) with BBr_3: Like MCl_3 compounds which are known to function as Lewis acids and Lewis bases (23), $M(SO_3CH_3)_3$ (M = As, Sb, and Bi) compounds also appear capable of functioning in both these capacities. It was not possible to characterize these adducts by infrared largely because of their instability at room temperature and extreme moisture sensitivity.

Complexes of $M(SO_3CH_3)_3$ (M = As, Sb, and Bi) with $CsSO_3CH_3$: An investigation was made of the ability of the methanesulfonato derivatives to form complexes with further methanesulfonate ions. It was found that cesium methanesulfonate gave cesium tetrakis(methanesulfonato)arsenate(III)/antimonate(III)/bismuthate(III) by reaction with the appropriate trismethanesulfonate. These compounds are highly sensitive to moisture. They are not soluble in $C_6H_5NO_2$, CH_3NO_2, and CH_3CN but dissolve in basic organic solvents like formamide and DMF. As expected Λ_M of $Cs[Bi(SO_3CH_3)_4]$ in DMF (200 $ohm^{-1}\,cm^2\,mol^{-1}$) corresponds to 2:2 electrolyte (16).

$$[4]\quad Cs[Bi(SO_3CH_3)_4] \overset{DMF}{\rightleftharpoons} Cs^+ + [Bi(SO_3CH_3)_2(DMF)_2]^+ + 2CH_3SO_3^-$$

Sodium oxobis(methanesulfonato)arsenate(III) and sodium tetrakis(methanesulfonato)bismuthate(III): Sodium arsenite, $NaAsO_2$, and sodium bismuthate, $NaBiO_3$, react with methanesulfonic anhydride at room temperature to yield $Na[AsO(SO_3CH_3)_2]$ and $Na[Bi(SO_3CH_3)_4]$, respectively. Both these compounds are insoluble in common organic solvents. Conductometric studies on $Na[AsO(SO_3CH_3)_2]$ in 100% CH_3SO_3H (Fig. 1) show that it ionizes as follows:

$$[5]\quad Na[AsO(SO_3CH_3)_2] \overset{CH_3SO_3H}{\rightleftharpoons} Na^+ + AsO(SO_3CH_3) + CH_3SO_3^-$$

The conductivity of the solution corresponds to the formation of only one mole of conducting $CH_3SO_3^-$ ions per mole of the solute, thereby suggesting that $AsO(SO_3CH_3)$ was behaving as a non-electrolyte. The bismuth double salt was insoluble in pure methanesulfonic acid. Infrared spectra (Table 2) show that the S—O region is quite complex and may be interpreted in terms of the presence of bridging bidentate methanesulfonato groups. The *E* modes ($\nu_{as}(SO_3)$ and $\delta_{as}(SO_3)$) show wide splitting while the lower *E* mode $\rho_r(SO_3)$ does not exhibit any splitting. This observation suggests the presence of bridging CH_3SO_3 groups in these compounds (26).

Solutions of M_2O_3 (M = As, Sb, and Bi) in 100% CH_3SO_3H: Cryoscopic and conductometric studies in 100% sulfuric acid have shown that As_2O_3 in 100% sulfuric acid forms arsonyl(III) hydrogensulfate, $AsO\cdot HSO_4$ which is partly ionized to give the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

AsO^+ cation (21). The present investigations are concerned with the possible formation of AsO^+ species in methanesulfonic acid. The conductometric behaviour of solutions of As_2O_3 in 100% methanesulfonic acid is shown in Fig. 1. As As_2O_3 is only slightly soluble in methanesulfonic acid it was not possible to study solutions more concentrated than 0.04 m. The number of moles of methanesulfonate ions, $CH_3SO_3^-$, formed by the ionization of 1 mol of As_2O_3 was found by the comparison of the concentrations of As_2O_3 and of C_5H_5N having the same specific conductance. Possible modes of ionization including some which are not consistent with the experimental results, are given below:

[6] $As_2O_3 + 3CH_3SO_3H = 2AsO^+ + H_3O^+ + 3CH_3SO_3^-$

[7] $As_2O_3 + 3CH_3SO_3H = 2AsO(SO_3CH_3) + H_3O^+ + CH_3SO_3^-$

[8] $As_2O_3 + 6CH_3SO_3H = 2As(SO_3CH_3)_3 + 3H_3O^+ + 3CH_3SO_3^-$

[9] $As_2O_2 + 9CH_3SO_3H = 2As(SO_3CH_3)_4^- + 3H_3O^+ + CH_3SO_3^-$

[10] $As_2O_3 + 6CH_3SO_3H = [As(SO_3CH_3)_2]_2O + 2H_3O^+ + 2CH_3SO_3^-$

The observed results (number of $CH_3SO_3^-$ ions = 1) easily rule out reactions [6], [8], and [10]. Reaction [9] can be ruled out as it has been shown earlier (reaction [2]) that the conductivity of $As(SO_3CH_3)_3$ in methanesulfonic acid is due to its basic ionization. The experimental results are consistent with reaction [7] in which it is assumed that $AsO(SO_3CH_3)$ is unionized in pure methanesulfonic acid. This observation gets further support from the isolation of a white precipitate formed slowly in the more concentrated solutions of As_2O_3 in methanesulfonic acid. Analysis of the precipitate showed that it had a composition corresponding to $AsO(SO_3CH_3)$ (Table 1). It behaves as a non-electrolyte in nitrobenzene ($\Lambda_M = 2.0$ ohm^{-1} cm^2 mol^{-1}) (16) and in pure CH_3SO_3H. Its infrared spectrum (Table 2) showed bands which may be attributed to the presence of bridging bidentate methanesulfonato group. The sulfur–oxygen stretching modes are split beyond what is anticipated for reduced C_s symmetry upon coordination of CH_3SO_3 group. The additional bands may be attributed to the splitting of S—O modes by the local crystal symmetry or to the binding of the free oxygen atom of one complex to the arsenic atom of the adjacent complex. Its mass spectrum shows the molecular ion with highest intensity (100%, 70 eV) at m/e 372 $[As_2O_2(SO_3CH_3)_2]^+$. The spectrum shows prominent fragments at 292 $[M - SO_3]^+$ (54%), 182 $[M - SO(CH_3)_2]^+$ (4%), and 91 $[M - AsO(SO_3CH_3)_2]^+$ (35%). Oxo(methanesulfonato)arsenic(III) reacts with pyridine to give 1:1 adduct, $AsO(SO_3CH_3)\cdot NC_5H_5$ (Table 1).

Antimony(III) and bismuth(III) oxides have very limited solubility in 100% CH_3SO_3H and therefore conductivity data on their solutions in the pure acid could not be obtained. These oxides, on stirring for a few hours, yield white precipitates which on analyses were found to be the fully solvolysed products, $Sb(SO_3CH_3)_3$ and $Bi(SO_3CH_3)_3$. Because of the increasing basicity of the oxides in going from arsenic to bismuth, we observe this change in the nature of the reaction products.

Attempted reactions of As_2O_5 and Sb_2O_5 with $(CH_3)_2S_2O_5$: Reaction between As_2O_5 and Sb_2O_5 with methanesulfonic anhydride do not yield methanesulfonate derivatives and the oxides are recovered unchanged even when the contents are refluxed at $\simeq$ 160°C for several days. This lack of reactivity of the pentoxides may be attributed to their increased acidity vis-à-vis the trioxides.

Reactions of 4-*tert*-butyl-5-methylene-3,3-dimethyl-Δ^1-1,2,4-triazoline with dimethyl acetylenedicarboxylate[1]

FOR ERRATA SEE 66(5) 1988 P.1342

ADRIAN L. SCHWAN AND JOHN WARKENTIN[2]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 12, 1986

ADRIAN L. SCHWAN and JOHN WARKENTIN. Can. J. Chem. **65**, 1200 (1987).

4-*tert*-Butyl-5-methylene-3,3-dimethyl-Δ^1-1,2,4-triazoline (**1**) reacts rapidly with dimethyl acetylenedicarboxylate (**2**) to afford dienamines **3** and **4** from Michael addition and enamine **5** by extensive skeletal rearrangement. Assignments of their structures and probable mechanisms of their formation are discussed.

ADRIAN L. SCHWAN et JOHN WARKENTIN. Can. J. Chem. **65**, 1200 (1987).

La *tert*-butyl-4 méthylène-5 diméthyl-3,3 Δ^1-triazoline-1,2,4 (**1**) réagit rapidement avec l'acétylènedicarboxylate de diméthyle (**2**) pour conduire aux dièmamines **3** et **4**, par addition de Michael, et à l'ènamine **5**, par une transposition importante du squelette. On discute des attributions de structure et des mécanismes qui sont probablement impliqués dans la formation de ces composés.

[Traduit par la revue]

Introduction

The literature concerning reactions of nitrogen compounds with dimethyl acetylenedicarboxylate (**2**, EC≡CE, E = CO_2CH_3) and with other substituted acetylenes is very extensive (1–4). Principal nitrogenous nucleophiles that react with **2** (or with analogues of **2**) are amines (5–8), pyridines (9, 10), and enamines (11–21). Typical reactions are illustrated with eqs. [1] (6), [2] (7), and [3] (12), in which E = CO_2CH_3.

[1] $\rangle NH + \mathbf{2} \longrightarrow \rangle NC(E)=CHE$ (both isomers)

[2] $PhCOCH_2NHPh + \mathbf{2} \longrightarrow$ (*Z*)-$PhCOCH_2N(Ph)C(E)=CH(E)$

[3] 
In many cases where more than one product is obtained, the product ratio is sensitive to the reaction temperature and to the polarity of the solvent.

The potential for interesting chemical reactions between **1** and **2** seemed to us to be particularly high because of the presence of the azo functional group. That feature held promise for formation of an azomethine ylide following quaternization of C-5 of **1** by overall cycloaddition of **2**, eq. [4]. Moreover, there was the interesting possibility for cyclization of dipolar intermediate **6**, if it were on the reaction coordinate, not only in the 4-*exo* sense, to form **7**, but also in the 5-*exo* sense to form **9** and **10**, eq. [5].

[5] 
9 **10**

We now report our findings concerning the reactions of **1** with **2**.

Results and discussion

Synthesis of 1

Triazoline **1** was prepared by the sequence of reactions below (22), Scheme 1.

$$CH_3CN + (CH_3)_3CCl \xrightarrow{FeCl_3} CH_3C{\equiv}\overset{+}{N}C(CH_3)_3FeCl_4^-$$

$$\xrightarrow{(CH_3)_2C=NNHLi} CH_3C(=NC(CH_3)_3)NHN=C(CH_3)_2$$

$$\xrightarrow[C_6H_6,\ K_2CO_3]{Pb(OAc)_4} \mathbf{1}$$

SCHEME 1

Identification of products

Compounds **3** (*Z*,*E*) and **4** (*Z*,*Z*) were identified as geometric isomers from Michael addition of **1** to **2** on the basis of their ^1H nmr, ^{13}C nmr, uv, ir, and mass spectra (Table 1). The *Z* configuration about the double bond exocyclic to the triazoline ring was assigned for each on the basis of nuclear Overhauser effect (nOe) enhancement of the intensity of the vinyl proton signal as a result of irradiating at the absorption frequency of the *tert*-butyl group (Table 1). The *Z* configurations about that double bond are not surprising, in view of the larger steric interactions that would exist in the *E* isomers. Configurations about the double bonds bearing carbomethoxy groups were assigned on the basis of the following observations. The isomer assigned structure **4** eluted more slowly than **3** from a silica-packed hplc column and it had the smaller R_f value on alumina-coated tlc plates (Experimental). Those differences between maleates and fumarates, in chromatographic retention

times, are normally observed and are a consequence of the larger dipole moments of maleates compared with those of fumarates (23, 5). The faster eluting isomer (**3**) had λ_{max} = 420 nm (log ε = 4.13) in the uv spectrum compared to λ_{max} = 414 nm (log ε = 3.55) for the isomer that was eluted more slowly (**4**). These observations too are characteristic of simpler fumarates and maleates, the higher transition energy and the lower transition probability of the maleates being ascribed to out-of-plane twisting of the Z-ester functions because of nonbonded interactions between them (24). Finally, nOe measurements (irradiation at the frequency of the *tert*-butyl signal) showed a significant enhancement (ca. 9%) of the intensity of the terminal vinyl proton signal of **4** and no enhancement of the corresponding signal of **3**. Thus, all of the evidence from physical properties and from spectroscopy is consistent with the *Z,E* configuration for **3** and the *Z,Z* configuration for **4**. Structure **5** was determined by single crystal X-ray crystallography.[3] The ^1H and ^{13}C nmr spectra of **5** are included in Table 1.

Mechanisms

The dependence of product yields on the solvent is given in Table 2. In methanol solvent the isomeric Michael adducts (**3** and **4**) predominate, but in dichloromethane the azabicycloheptene (**5**) is the major product. Those results can be rationalized in terms of the mechanisms of Scheme 2. Formation of zwitterionic intermediate **11** is postulated as the first step, in accord with some precedents from the literature (25, 26). Reinhoudt *et al.*, however, have proposed recently that cycloadditions between enamines and **2** to form aminocyclobutenes are concerted and that a dipolar species, analogous to **11**, can

[3]We thank Professor C. J. L. Lock and Mr. R. Faggiani for determining the crystal structure of **5**. The crystallographic data will be published elsewhere.

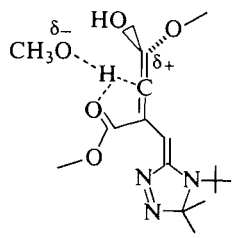
TABLE 2. Solvent dependence of yields (25°C)

Solvent	Yields (%) 3	4	5
CH_3OH	72	4	19
CH_2Cl_2	17	5	56

be formed by ring opening of first-formed aminocyclobutenes, analogous to **13**, in polar solvents (14). We postulate a stepwise mechanism[4] for formation of **13**, primarily because **3** and **4** are obtained from reactions carried out in CH_2Cl_2, albeit in lower yields than in CH_3OH. It seems unlikely to us that **13** would undergo ring opening to **11** in CH_2Cl_2 at room temperature although that reaction may occur to a limited extent in CH_3OH.

Protonation of **11** is probably faster at oxygen than at carbon, by analogy to the protonation of enolates, forming **12** initially, and **12** can give rise to **3** and **4** by a series of proton transfers. Deprotonation from the methylene group followed by protonation at the allenic carbon and deprotonation from oxygen would lead to **3** and **4**. The large preference for formation of **3** in CH_3OH may be the result of internal hydrogen bonding at the transition state for protonation at carbon, as illustrated with **19**.



19

Proton transfers involving CH_3OH were confirmed by showing that **3** and **4**, isolated from a reaction carried out in CH_3OD, were fully deuterated at the terminal vinyl position.

Mechanisms by which **3** and **4** could be formed in CH_2Cl_2 include proton transfers between **11** (or **12**) and **1**, or between **12** and the conjugate base of **11**, for example. Adventitious impurities, including moisture as well as reaction products not shown in Scheme 2, may also be involved.

A 1,3-sigmatropic rearrangement of **11** to **3** and (or) **4** in the absence of protic solvent molecules need not be considered seriously because it would have to be antarafacial (27) and therefore very slow.

Equilibration or partial equilibration of **3** and **4** after their formation could be ruled out when it was found that **4** was not isomerized to **3** and **3** was not isomerized to **4** in CH_3OH containing either **1** or **2**.

No isomers of **3** and **4**, with the *E* configuration about the exocyclic double bond, could be detected among the products obtained in either solvent. Although the *Z* configurations are undoubtedly the preferred ones, because of steric congestion in the *E* isomers, the possibility that there is equilibration of a kinetically formed mixture of those isomers cannot be ruled out at this stage.

[4]Since our aminocyclobutene intermediates are spiro compounds, whereas those of Reinhoudt *et al.* are not, and because the substituents are different, it is possible that the mechanisms by which they are formed are different also.

Cyclobutenes analogous to **13** have been isolated in a few cases (12, 14, 28) but, in general, they undergo electrocyclic ring opening rapidly, in the sense **13** → **14** (11, 13, 26, 29). We were unable to isolate any **14**. Ring opening of **13** to **14** is presumably suppressed because loss of N_2 from **13**, to generate **15**, is faster. Azomethine ylide **15** isomerizes to **16** by H-atom transfers analogous to those that convert some carbonyl ylides to enol ethers (30). In CH_2Cl_2 those transfers may be intramolecular but in CH_3OH there is a stepwise process, probably involving protonation at the cyclobutyl carbon followed by deprotonation from the isopropylidene function. That mechanism was indicated by the finding that **5**, generated in CH_3OD, was deuterium labelled at the vinyl position. Incorporation of the label during the steps by which **15** is converted to **16** is in keeping with the known high reactivity of ylides toward alcohols (31).

Conrotatory electrocyclic ring opening of aminocyclobutene **16**, already mentioned above in connection with the minor process **13** → **14**, would generate trienamine **17** and its geometric isomer (not shown in Scheme 2), with the alternative configuration about the nonterminal enamine double bond. Those isomers must be interconvertible, because the yield of **5** in CH_2Cl_2 could not be as high as 56% if more than half of the **17** formed were unable to close to **18**. Cyclization of **17** to **18** is a conrotatory electrocyclic reaction analogous to that of octatetraenes (32), and conversion of **18** to **5** presumably occurs by disrotatory electrocyclic ring closure. As precedent for the steps that lead from **16** to **5** (Scheme 2) we site the example reported by Acheson and Procter (33), eq. [6].

[6] 
Although the various steps of Scheme 2 are based largely on precedents and on deuterium incorporation from methanol-OD, there is direct evidence for the formation of unstable intermediates. Monitoring of the progress of the reaction by ^1H nmr spectroscopy revealed the growth and decay, with time, of several vinyl signals not present in either the reactants or the final products. However, the spectra were too complex to permit assignments of those signals to likely intermediates (**16**, **17**, **18**) or to permit a kinetic description of the reactions of **1** with **2**.

Experimental

General

Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected. Proton nuclear magnetic resonance (^1H nmr) spectra were recorded on a Bruker WM-250 or a Varian EM-390 spectrometer using either TMS or the residual $CHCl_3$ in $CDCl_3$ as the internal standard. Carbon-13 nuclear magnetic resonance (^{13}C nmr) spectra were obtained with a Bruker WM-250 or a Bruker WP-80/90 machine. Infrared (ir) spectra, obtained with a Perkin–Elmer model 283 instrument, are reported in wavenumbers calibrated against the 1601.4 cm^{-1} band of polystyrene. Ultraviolet (uv) spectra were obtained with a Hewlett–Packard model 8451A

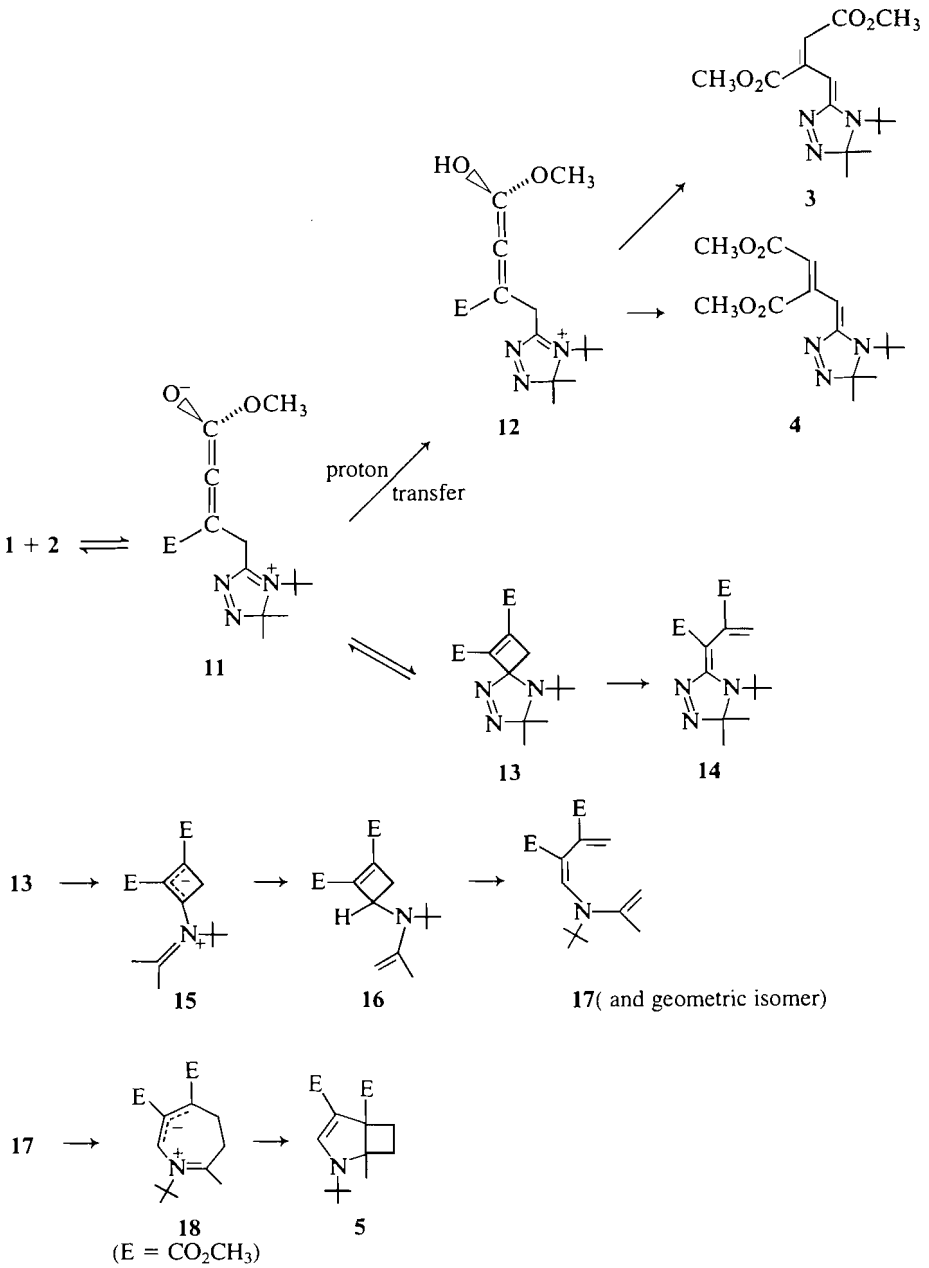

SCHEME 2

diode array spectrometer. Mass spectra (ms) were recorded on a VG 70-70F double focussing spectrometer.

Analyses by high performance liquid chromatography (hplc) were carried out with a Varian 5000 instrument equipped with a Varian Vista 402 processor and with a uv detector set at 310 nm. A Varian SI-5 silica column (4 × 150 mm) was used with the following elution program: 0–10 min (10% CH_2Cl_2 in hexane changing to 9% CH_2Cl_2, 1% isopropyl alcohol in hexane); 10–35 min (no change); 35–40 min (return to initial composition). With that program and a pumping rate of 1 mL min^{-1}, the retention times were 19 min (**3**), 23 min (**5**), and 27 min (**4**).

Dimethyl acetylenedicarboxylate, from Aldrich Chemical Co., was distilled under vacuum before use. Dichloromethane (Caledon) was dried over molecular sieves (4Å) before use. Methanol (Baker Analyzed) and methanol-OD (Aldrich) were used as received.

Nuclear Overhauser enhancement (nOe) measurements

The substrate (10–20 mg) in ca. 0.4 mL of $CDCl_3$ containing a trace of CH_2Cl_2 was sealed into a medium-walled nmr tube after three cycles of freeze–pump–thaw degassing at 0.03 Torr (1 Torr = 133.3 Pa). Eight normal scans on the WH-250 spectrometer were followed by eight scans taken during irradiation at the frequency of the substrate's *tert*-butyl signal. Each spectrum was integrated against the signal from internal CH_2Cl_2. No correction was made for enhancement, if any, of the reference signal during double irradiation.

N^1-*Isopropylidene*-N^3-tert-*butylacetamidrazone* (*$((CH_3)_2C{=}NNHC(CH_3){=}NC(CH_3)_3$*, ***19***)

The procedure for preparation of **19** is based on that of Fuks (34). A two-necked flask, fitted with an efficient mechanical stirrer and a pressure equalizing dropping funnel, was charged with anhydrous ferric chloride (30 g, 0.18 mol). During constant stirring and cooling with ice were added, dropwise and in succession, anhydrous ether (40 mL), anhydrous acetonitrile (7.6 g, 0.19 mol) in ether (10 mL), and *tert*-butyl chloride (17.1 g, 0.18 mol) in 20 mL of dry ether. The mixture was stirred for 30 min at ice temperature, during which time an orange-red suspension was formed. The suspension was added quickly, at −78°C, to a solution of the lithium salt of acetone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

hydrazone, prepared as follows. Methyllithium in hexane (0.31 mol of MeLi) was added to 400 mL of ether at −78°C. Acetone hydrazone (20.4 g, 0.28 mol) in ether (80 mL) was then added, dropwise with stirring, to the cold solution.

When addition of the suspension was complete the resulting mixture was allowed to reach 0°C, approximately, during 1 h of stirring, after which aqueous sodium hydroxide solution (0.64 mol of NaOH in 50 mL) was added. The subsequent work-up according to the procedure of Fuks (34) gave crude amidrazone, which was distilled. After an initial fraction of acetone azine, **19** and *N-tert*-butyl acetamide distilled together at 80–85°C (1.5 Torr). That fraction was chromatographed on Al_2O_3(II) to afford **19** (14.2 g, 47% based on acetonitrile) as a low-melting solid. A sample of **19** collected by preparative gc had mp 49–50.5°C.

4-tert-Butyl-3,3-dimethyl-5-methylene-Δ^1-1,2,4-triazoline, 1 (22)

In a typical oxidation, amidrazone **19** (1.0 g, 5.9 mmol) in 10 mL of benzene was added all at once to lead tetraacetate (2.9 g, 6.5 mmol) in 30 mL of benzene over 16 g of anhydrous potassium carbonate. The reaction mixture was stirred and cooled with ice-water during the addition and for 45 min after. Aqueous sodium bicarbonate solution (5%) was then added, the mixture was filtered through Celite, and the organic phase was separated. It was washed with brine and dried over magnesium sulfate. The dried benzene solution was concentrated and the residue was chromatographed on Al_2O_3(II) using ether (10%) in light petroleum for elution. After pure **1** had been collected, the solvent was changed to 50% ether in petroleum to elute unreacted **19**. Addition of solid NaOH to the aqueous phase (above), extraction with dichloromethane, washing the organic phase with brine, drying over $MgSO_4$, and evaporation of the dichloromethane afforded additional **19** (25–35% total recovery) of the same quality, after distillation, as that initially used for oxidation. The yield of **1**, based on **19** consumed, was 45%. It is an oil at room temperature but it freezes during storage at ca. −20°C. The spectral data are in Table 1.

Reaction of 1 with 2

A solution of **1** (200 mg, 1.2 mmol) and **2** (200 mg, 1.4 mmol) in 20 mL of solvent (methanol or dichloromethane, see text) was stirred at room temperature for 12 h. The solution was concentrated with a rotary evaporator and the residue was chromatographed on Al_2O_3(II). The column was developed initially with 10% ether in light petroleum and the polarity was increased gradually after each component was eluted. The component to be eluted first was **3** (R_f 0.65 on 0.20-mm alumina tlc plates, ether), which was recrystallized from petroleum to mp 115–116°C. Compound **5** (R_f 0.50) was obtained second, mp 90–91°C (from petroleum) and **4** (R_f 0.36) was eluted last. Spectral data are in Table 1.

New positive mixed alkali and mixed anion effects on fast Na^+ ion conductivity in Na_2SO_4[1,2]

U. M. GUNDUSHARMA AND E. A. SECCO[3]

Chemistry Department, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1CO

Received September 2, 1986

U. M. GUNDUSHARMA and E. A. SECCO. Can. J. Chem. **65**, 1205 (1987).

The ac conductivity data for the binary alkali sulfate Rb^+:Na_2SO_4 reveal a new positive mixed alkali effect in contrast to the so-called mixed alkali effect observed in β-aluminas. The binary alkali sulfate Rb^+:Li_2SO_4 exhibits conductivity behavior intermediate between the two mixed alkali effects. A new positive mixed anion effect is also reported for the MoO_4^{2-}:Na_2SO_4 system. The higher Na^+ conductivity in the Rb^+:Na_2SO_4 and MoO_4^{2-}:Na_2SO_4 solid solutions is attributed to lattice expansion in a hexagonal structure effected by the larger radius isovalent guest ion and is interpreted in terms of a percolation type of transport mechanism.

U. M. GUNDUSHARMA et E. A. SECCO. Can. J. Chem. **65**, 1205 (1987).

Des données relatives à la conductivité c.a. du sulfate alcalin binaire Rb^+:Na_2SO_4 révèle la présence d'un nouvel effet positif des métaux alcalins mixtes; ces données sont en opposition avec l'effet des métaux alcalins mixtes observé dans les β-alumines. Le comportement de la conductivité du sulfate alcalin binaire Rb^+:Li_2SO_4 est intermédiaire entre celui des deux effets alcalins mixtes. On rapporte aussi un nouvel effet positif de l'anion mixte dans le système MoO_4^{2-}:Na_2SO_4. On attribue la conductivité plus élevée du Na^+ dans les solutions solides de Rb^+:Na_2SO_4 et de MoO_4^{2-}:Na_2SO_4 à une expansion du réseau vers une structure hexagonale qui est affectée par un rayon plus grand de l'ion hôte isovalent et on l'interprète en fonction d'un mécanisme de transport du type percolation.

[Traduit par la revue]

Introduction

Solid state fast ion conductors are characterized by very high ionic conductivity, either anionic or cationic relative to the ionic conductivity of most crystalline solids. This relatively small group of solids, also known as solid electrolytes, has a specific ion which is not confined to specific lattice sites but is essentially free to move throughout the three-dimensional structure.

Recent attention has been focused on Na_2SO_4 which exhibited a sharp jump by a factor of 10 in electrical conductivity (1) as it transforms from Na_2SO_4(III) → Na_2SO_4(I) accompanied by a volume expansion of 4%. The structure of Na_2SO_4(I) is hexagonal, space group $P6_3/mmc$, characterized by orientational disorder of the SO_4 tetrahedra in the SO_4 sublattice (2). The ionic conductivity in Na_2SO_4(I) is increased appreciably by the presence of low concentrations of isovalent cations or anions (3–5). The consistent result of higher Na^+ conductivity in Na_2SO_4 when a larger radius isovalent guest ion is present in minor concentration supports the dominant role of "free" or "unoccupied" volume in facilitating intersite mobility within structural limits. Furthermore, the higher conductivity with 10 mol% Rb^+ in Na_2SO_4 suggested that the Na^+ mobility might attain higher values at higher concentrations of Rb^+ in Na_2SO_4. This result runs contrary to the so-called mixed alkali effect observed for Li/Na and Li/Rb disilicate glasses of composition $0.33A_2O{:}0.67SiO_2$ where A_2O is the alkali oxide component (6, 7) and for Na/K β-aluminas and Na/K gallate (8). This paper presents ac electrical conductivity results of a study designed to test the hypothesis that higher conductivity will result over the complete composition range in mixed alkali, Li/Rb and Na/Rb, sulfate and mixed anion, Na_2SO_4–MoO_4, compositions where the guest ions are of larger ionic radius.

Experimental procedure

All chemicals used were the Alfa Products with the specified grade cited: $Li_2SO_4 \cdot H_2O$ and Na_2SO_4 ultrapure, Rb_2SO_4 99.9%, $Na_2MoO_4 \cdot 2H_2O$ 99.5%. All studied samples were prepared by fusing in air the requisite composition mixture of the respective dehydrated compounds, previously well ground manually, at 50–75 K above its melting point (11, 12) in a platinum crucible. There was no discernible weight loss after fusion. The fused product in each case was a solid solution as evidenced by its DTA peak temperature which was within ±5 K of temperatures reported in the phase diagrams (11, 12) and the effect of temperature lowering associated with solid solution formation.

Electrical conductivity measurements were made on compressed, a force of 1.2×10^4 kg, polycrystalline specimen in a stainless steel conductivity cell. The experimental procedure for these measurements as described earlier (9), maintained the sample by a spring-loaded support between stainless steel leads using two polished Pt discs as electrodes. The two surfaces of the sample were touched with graphite (DAG #54 Acheson) to ensure proper contact. Each sample was installed and allowed to stand in the cell ca. 15 h at ~150°C under reduced pressure (~10^{-3} Torr) prior to measurement. The conductivity was measured under reduced pressure at 0.1 kHz, 1 kHz, and 10 kHz as a function of temperature using a GR 1608-A impedance bridge; the heating rate was 60 deg h^{-1}. The specific conductivity σ values were within experimental limits for 0.1–1 kHz frequencies with higher values at 10 kHz; this behavior is consistent with the reported impedance dependence on frequency in Na_2SO_4 (10). Most samples were discs of ~1 mm thickness and 100 mm^2 surface area; other samples were ~1 mm thick and ~70 mm^2 surface area which was the crack-free portion recovered from the compressed disc. Temperature was monitored within ±1 K by standardized chromel–alumel thermocouples with a Keithley digital multimeter.

Results and discussion

The ionic conductivity σ in a condensed phase is a composite quantity $\sigma = nqu$ where n is the number of carriers of charge, q per unit volume, and u is the mobility of these charged carriers. The dependence of the ionic conductivity on temperature usually follows an Arrhenius-type expression.

$$[1] \quad \sigma T = \sigma_0 \exp(-Q_c/RT) = n^2q^2\lambda^2\nu/k \exp(-Q_c/RT)$$

the result of combining the Nernst–Einstein relation $\sigma/D =$

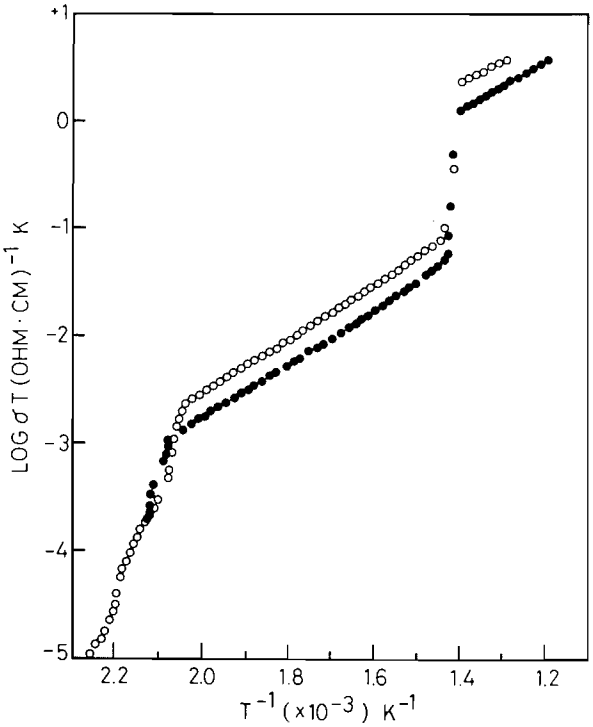

FIG. 1. Plots of log σT versus $T(\mathrm{K})^{-1}$ of Na_2SO_4–Rb_2SO_4 in mole ratios 1:2 (●) and 2:1 (○).

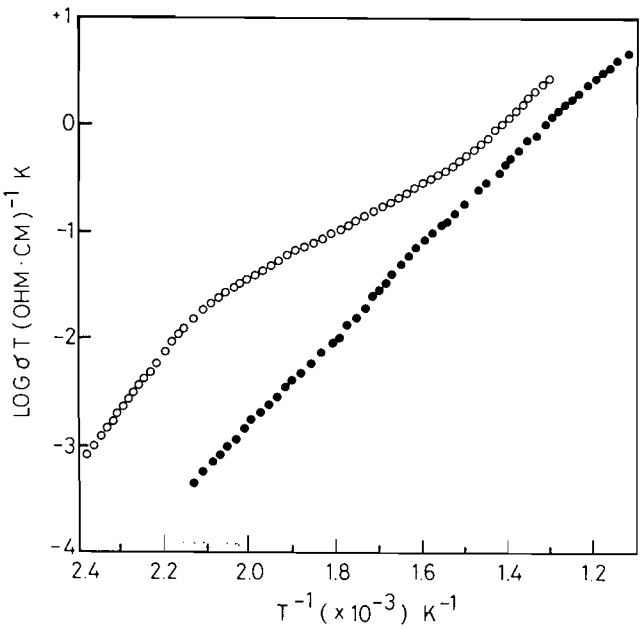

FIG. 2. Plots of log σT versus $T(\mathrm{K})^{-1}$ of Na_2SO_4–Na_2MoO_4 in mole ratios 1:1 (●) and 4:1 (○).

nq^2/kT and the diffusion equation $D = D_0 \exp(-Q_c/RT)$. In this equation ν is the vibration frequency, λ the inter-atomic distance, and Q_c the apparent activation energy for mobility of the specific ion, k and R are fundamental constants.

On the basis of eq. [1] for temperature dependence of ionic conductivity typical cool mode plots of log σT at 1 kHz versus $T(\mathrm{K})^{-1}$ are given in Fig. 1 for Rb^+:Na_2SO_4 compositions and in Fig. 2 for MoO_4^{2-}:Na_2SO_4 compositions. The solid–solid phase transition temperatures observed in the conductivity measurements are within ±5 K of the peak temperatures

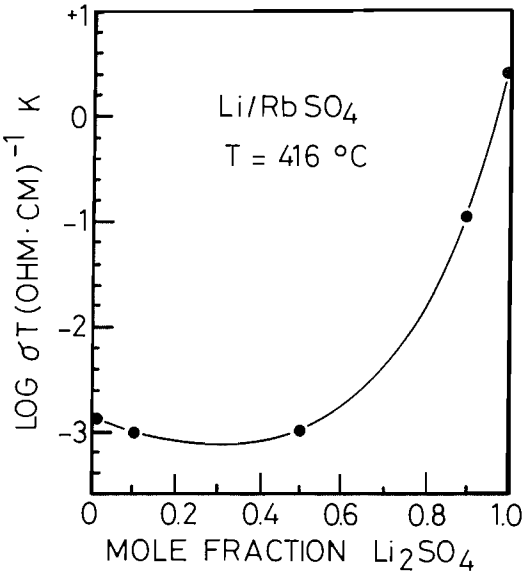

FIG. 3. Plot of log σT versus mole fraction Li_2SO_4 of binary alkali sulfate system Li_2SO_4–Rb_2SO_4 at T = 416°C (reproduced by permission of North Holland Physics Publishing).

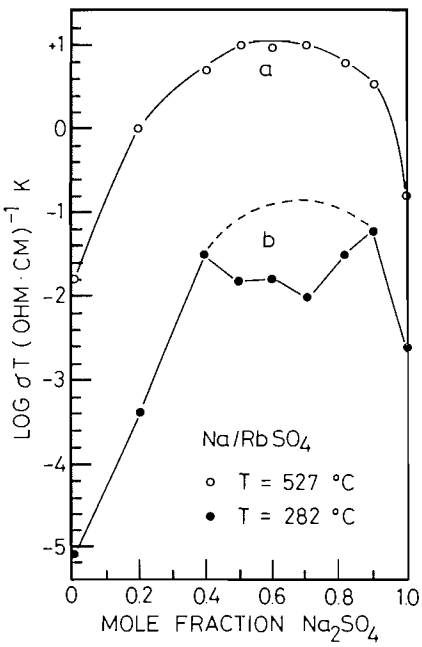

FIG. 4. Plots of log σT versus mole fraction Na_2SO_4 of binary alkali sulfate system Na_2SO_4–Rb_2SO_4 at T = 527°C (a) and T = 282°C (b); --- in (b) represents the expected behavior paralleling (a). The points are linked for guidance.

obtained in our DTA and DSC traces for these transitions. Similar plots of log σT versus $T(\mathrm{K})^{-1}$ for $Li/RbSO_4$ compositions, not shown, exhibit a monotonic behavior with no evidence of phase transition in the temperature interval 200–500°C.

The log σT (1 kHz) values at a constant temperature as a function of alkali composition are plotted in Figs. 3 and 4 for Rb^+:Li_2SO_4 and Rb^+:Na_2SO_4 systems, respectively, and for the MoO_4^{2-}:Na_2SO_4 system in Fig. 5. The temperature 416°C was chosen for the Rb^+:Li_2SO_4 system because no phase transition is evident over the complete Rb^+:Li_2SO_4 composition according to its phase diagram (11) and our DTA traces. Above 518°C a phase transition occurs on the Li_2SO_4-rich side of the

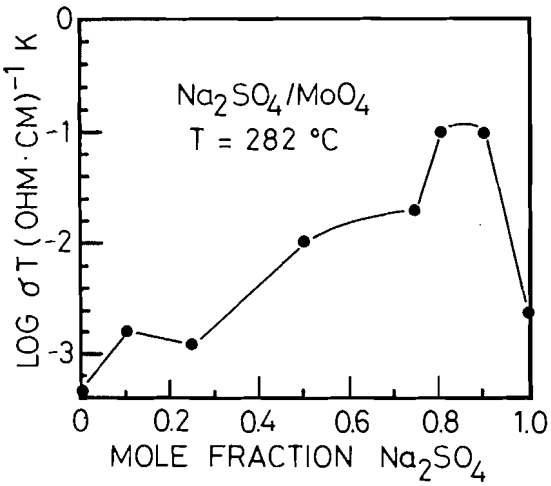

FIG. 5. Plot of log σT versus mole fraction Na_2SO_4 of binary system Na_2SO_4–Na_2MoO_4 at T = 282°C. The points are linked for guidance.

1:1 compound identified with $RbLi_5(SO_4)_3$. The temperatures 282°C and 527°C were chosen for the Rb^+:Na_2SO_4 system because these represented in each case a stable state of the system over the complete Rb^+:Na_2SO_4 composition range according to its phase diagram (12) and our DTA traces. The state of the Rb^+:Na_2SO_4 system at 282°C is taken as hexagonal Na_2SO_4(I) phase incorporating Rb_2SO_4 whereas at 527°C a solid solution exists with structures or phases dominated by the high temperature hexagonal phase of Rb_2SO_4 and identified as α, β, γ. Again the state of the MoO_4^{2-}:Na_2SO_4 system at 282°C is taken to be the hexagonal Na_2SO_4(I) phase incorporating Na_2MoO_4.

Tables 1 and 2 give the activation energy values for the Rb^+:Na_2SO_4 and MoO_4^{2-}:Na_2SO_4 systems, respectively, for the two phases. The Q_c values for the Na_2SO_4-rich compositions remain essentially constant for the Na_2SO_4(I) phase at 282°C in both Rb^+:Na_2SO_4 and MoO_4^{2-}:Na_2SO_4 systems.

The conductivity–alkali composition behavior for the Rb^+:Li_2SO_4 system shown in Fig. 3 is to be expected to a first approximation where a decrease in the fraction of highly mobile carrier Li^+ ion, with all other factors remaining constant, effects a decrease in the overall conductivity. The structure of Li_2SO_4 is monoclinic and that of Rb_2SO_4 is orthorhombic below 580°C. Such an interpretation suggests that the number of mobile Li^+ ions depends on the number of Li^+ ions per unit volume which is not unexpected. The hypothesis that the large Rb^+ ions provide more "free" volume to enhance the mobility of the smaller Li^+ is not confirmed. Since Li_2SO_4 and Rb_2SO_4 structures differ significantly this result suggests that the hypothesis of large guest ion-free volume contribution is only valid for isomorphous structure systems.

The positive conductivity–alkali composition effect for the Rb^+:Na_2SO_4 system in two structural states is obvious in Fig. 4. Only solid solutions are present and no compound formation is evident in this system. Since one can assume that the fraction of mobile charge carriers Na^+ decreases with mole fraction of Na_2SO_4 in the binary alkali sulfate then it would appear that the compositional structure is conducive to higher mobility of the Na^+ ions. That is, the decrease in the number of carriers is more than compensated by the facility of Na^+ mobility provided by the structural factor, especially over the Na_2SO_4 mole fraction inverval 0.4–0.9.

TABLE 1. Ionic conductivity activation energy Q_c for Na/$RbSO_4$ mixed alkali effect

Additive Rb_2SO_4 (mol%)	Q_c (kJ/mol) 282°C	Q_c (kJ/mol) 527°C
0	55±5	55±5
10	44±3	57±5
18.5	48±3	67±5
30	46±4	72±4
40	50±3	36±3
50	46±4	52±5
60	46±4	90±6(?)
67	50±3	42±3
75	70±4	65±4
100	150±8	120±5

TABLE 2. Ionic conductivity activation energy Q_c for Na_2SO_4/MoO_4 mixed anion effect

Additive Na_2MoO_4 (mol %)	Q_c (kJ/mol) 282°C
0	55±5
10	44±3
20	44±3
25	52±4
50	72±5
75	86±6
90	86±6

Again the positive conductivity–anion composition effect for the MoO_4^{2-}:Na_2SO_4 system is evident in Fig. 5. Since the mole fraction of Na^+ remains constant one can assume that the fraction of mobile Na^+ also remains effectively constant. The fact that Na_2MoO_4 is isomorphous with Na_2SO_4(I), $P6_3/mmc$, in this temperature range suggests ease of substitution in their respective anion sublattices. The presence of MoO_4^{2-} in the SO_4^{2-} sublattice would effect lattice expansion, $R_{Mo—O}$ = 1.77 Å versus $R_{S—O}$ = 1.44 Å (13), providing more "free" volume to allow greater facility for Na^+ mobility leading to higher conductivity.

The conductivity results presented herein are in strong contrast to the mixed alkali effect observed in disilicate glasses (6, 7), β-aluminas and β-gallate (8), where a dramatic decrease in conductivity occurs when one alkali ion is in the presence of another alkali ion. It is obvious that the weak electrolyte model or the "quasiliquid" conduction model proposed to interpret the mixed alkali effect cannot be used in the case of mixed alkali sulfate and sodium mixed anion systems.

The central questions in the theory of conductivity in fast ion conductors revolve on n and Q_c in eq. [1]. The activation energy for ionic conductivity Q_c involving defects is a composite quantity consisting mainly of two terms (*i*) the enthalpy of defect formation h_s and (*ii*) the enthalpy of migration Δh_c (14). At low temperatures ~200°C, Q_c is identified with Δh_c where the fractional molar concentration of mobile Na^+ in the Na_2SO_4-rich compositions can be taken as effectively constant at 1×10^{-3} as calculated earlier (5). The minimum Q_c values correlate with the maximum σT values excepting the 90 kJ/mol at 527°C for 60 mol% Rb^+, for mixed alkali and mixed anion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

effects. The same σT values, within experimental limits, for the same Rb^+ and MoO_4^{2-} concentrations strongly support the straightforward physical or lattice expansion basis for the enhanced ionic conductivity. Recent results from the experimental test for the anion-rotatory motion or paddle-wheel mechanism which showed convincingly that the anion-rotation mechanism does not contribute to the enhanced cationic conductivity in Na_2SO_4 (4) is further confirmed by the MoO_4^{2-} results. A contribution to ionic conductivity and Q_c can originate with the lower vibrational amplitude of the heavier guest ion (Rb^+, MoO_4^{2-}) giving a more rigid cation or anion sublattice network which would reduce the scattering of the mobile Na^+ ions.

Our cationic conductivity data for the Li_2SO_4–Rb_2SO_4, Na_2SO_4–Rb_2SO_4, and Na_2SO_4–Na_2MoO_4 systems can be explained in terms of a percolation type of transport mechanism in a lattice structure with an increased degree of "free" volume or openness (15). We visualize the existence of percolation paths through a network of interconnected, irregularly positioned sites with Li^+ or Na^+ occupancy. In pure Li_2SO_4 or Na_2SO_4 a minimum of interconnected sites, that is, a restricted number of complete pathways, exist in the low temperature ordered phase. But in the transformation to the high temperature disordered phase, the lattice expands (3% increase in molar volume in Li_2SO_4, 4% increase in molar volume in Na_2SO_4) so the number of accessible interconnected sites involving lower Q_c increases resulting in higher ionic conductivity. In the Li_2SO_4–Rb_2SO_4 system the results are for the low temperature ordered structure prior to any phase transition, monoclinic for Li_2SO_4 and orthorhombic for Rb_2SO_4, with no volume increase and no change in the accessibility of interconnected sites. On the other hand, the Rb^+:Na_2SO_4 system transforms from the ordered phase to the disordered hexagonal phase of Na_2SO_4(I) above 200°C as does the MoO_4^{2-}:Na_2SO_4 system. The Rb^+:Na_2SO_4 system undergoes a further phase transition to a more open or larger "free" volume structure characteristic of Rb^+:Na_2SO_4 solid solution above 460°C. The solid solution phase above 460°C dominated by the high temperature phase of Rb_2SO_4 is speculated to be hexagonal, paralleling the orthorhombic–hexagonal transition of its analogs, e.g. Rb_2WO_4 (16). The higher conductivity in the Rb^+:Na_2SO_4 and MoO_4:Na_2SO_4 systems is attributed to lattice expansion in a hexagonal structure effected by the presence of the larger radius guest ions, Rb^+ and MoO_4^{2-}. However, the conductivity versus composition profiles of Figs. 4 and 5 prompt some fundamental questions relating to (*i*) the effectiveness of guest ion in the cation sublattice versus the guest ion in the anion sublattice, (*ii*) the effect of cation–cation interaction versus the mixed anion pair presence, and (*iii*) the effect of the reduced vibrational amplitude of heavier guest ion on the reduced scattering of mobile ions. These questions will be explored in our laboratory in the future.

A theoretical study of the structures and stabilities of $C_2H_3S^+$ ions

CHRISTOPHER F. RODRIQUEZ AND ALAN C. HOPKINSON
Department of Chemistry, York University, Downsview, Ont., Canada M3J 1P3

Received August 12, 1986

CHRISTOPHER F. RODRIQUEZ and ALAN C. HOPKINSON. Can. J. Chem. **65**, 1209 (1987).

Ab initio molecular orbital calculations at the 6-31G* level have been used to locate eight minima and five saddle points on the $C_2H_3S^+$ hypersurface. The thioacetyl ion, H_3CCS^+ (**1**), is the global minimum and the 1-thiovinyl cation (**4**), 106 kJ mol^{-1} higher, is the next lowest. Interconversion of **1** and **4** has the highest barrier calculated for this surface (250 kJ mol^{-1} above **4**) but all transition structures to intramolecular rearrangement are lower than the energies of the dissociation products. These results are consistent with the experimental observation that there is only one dissociation channel for ions $C_2H_3S^+$, regardless of the structure of organosulphur compound from which $C_2H_3S^+$ was produced. Comparisons are made with the $C_2H_3O^+$ hypersurface.

CHRISTOPHER F. RODRIQUEZ et ALAN C. HOPKINSON. Can. J. Chem. **65**, 1209 (1987).

On a utilisé des calculs d'orbitales moléculaires au niveau 6-31G* pour déterminer la position de huit minima et de cinq cols sur l'hypersurface du $C_2H_3S^+$. L'ion thioacétyl, H_3CCS^+ (**1**), correspond au minimum global et le cation thio-1 vinyle (**4**), dont l'énergie est 106 kJ mol^{-1} plus élevée, est le minimum suivant. La barrière à l'interconversion des ions **1** et **4** est la plus élevée de cette surface (250 kJ mol^{-1} au-dessus de **4**); toutefois, toutes les structures de transition de la transposition intramoléculaire possèdent des énergies qui sont plus basses que celles des produits de dissociation. Ces résultats sont en accord avec les données expérimentales selon lesquelles, quelle que soit la structure du composé organosulfuré à partir duquel l'ion $C_2H_3S^+$ est produit, il n'existe qu'une seule voie de dissociation pour la dissociation de ces ions. On fait des comparaisons avec l'hypersurface de l'ion $C_2H_3O^+$.

For personal use only.

The relative energies and structures of gaseous ions $C_2H_3O^+$ have been examined in considerable detail both by *ab initio* molecular orbital theory (1–3) and by experiment (4–10). Two isomers, the acetyl and 1-hydroxyvinyl cations, have been identified as long-lived species in the gas phase (5, 8) and the existence of a third isomer, the oxiranyl cation, has been indicated by collisional activation studies (9). High level *ab initio* molecular orbital calculations (3) have shown these three ions to be at minima on the $C_2H_3O^+$ hypersurface and two other structures, $H_3C—O^+{=}C$: and $HC{\equiv}C—OH_2^+$, have low energies and high barriers to rearrangement, making them potentially detectable in the gas phase.

For $C_2H_3S^+$ the hypersurface is less well understood. $C_2H_3S^+$ is produced in the mass spectrum of organosulphur compounds of widely differing structure but collisionally activated decomposition mass-analysed kinetic energy spectroscopy of these $C_2H_3S^+$ ions shows almost identical fragmentation patterns regardless of the structure of the precursor organosulphur compound (11). These results have been interpreted as evidence for a single common ion and the question arises as to what structure any such ion might have. By analogy with the $C_2H_3O^+$ surface the common ion is expected to be the thioacetyl ion (structure **1**, Fig. 1), but decomposition of the observed $C_2H_3S^+$ ion produces very little CH_3^+ and this has been taken as evidence that the common ion does not have structure **1**.

We have been studying carbenium ions containing heteroatoms from the second and third rows (12, 13) of the periodic table and, in an attempt to resolve the problem posed by the experimental results, we now present our molecular orbital results on isomers on the $C_2H_3S^+$ hypersurface. The eight structures, all minima, which we have examined are labelled **1** → **8** and are given in Fig. 1. *Ab initio* molecular orbital calculations, at lower levels of theory, have been previously reported for four of these structures (**2**, **3**, **4**, and **5**) (14, 15).

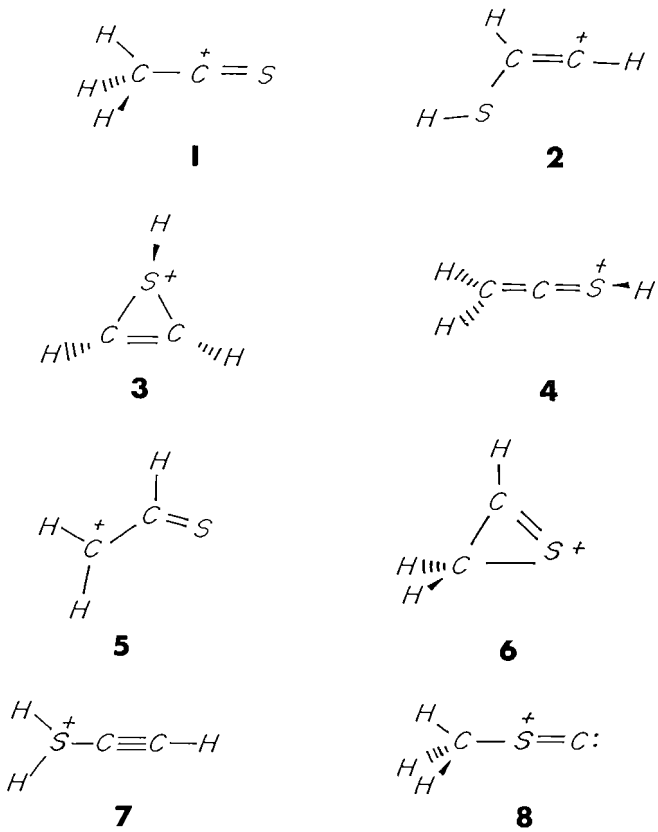

FIG. 1. Possible structures for ion $C_2H_3S^+$.

Method

Standard closed shell *ab initio* molecular orbital calculations were carried out using the Monstergauss program (16). Minima were located using the optimally conditioned (OC) method (17) and transition structures using the VA05AD technique (18). All structures were optimised initially at the STO-3G level (19) and then subsequently at the 6-31G* level (20).

Results and discussion

1. Structures and energies

The structures for the ions, as optimised at the 6-31G* level,

are given in Fig. 2 and the energies at both the STO-3G and 6-31G* levels are given in Table 1.

(a) Thioacetyl cation (1)

Ion **1** has the lowest energy on the hypersurface. The C—S bond length of **1** (1.468 Å) is shorter than that of CS (1.520 Å at 6-31G*) and the sulphur atom carries the majority of the positive charge (+0.521) indicating that valence bond structure **1***b* is an important contributor. The methyl group functions

$$H_3C—\overset{+}{C}=S \longleftrightarrow H_3C—C\equiv S^+$$

1*a* **1***b*

as a donor, mainly through hyperconjugation (charge on CH_3 is +0.318) and the carbon–carbon bond is intermediate between a single and a double bond. Curiously the geometry of the H_3C—C fragment is identical to that calculated for H_3CCO^+ at the 4-31G level (3).

(b) 2-Thiovinyl cation (2)

The *anti* conformer of the 2-thiovinyl cation (shown in Fig. 1) is lower in energy than the *syn* conformer by only 2 kJ mol^{-1} at the STO-3G level and by 1 kJ mol^{-1} at the 6-31G* level. By comparison for the 2-hydroxyvinly cation at the 4-31G level the *anti* conformer is lower than the *syn* by 11 kJ mol^{-1}. On the $C_2H_3S^+$ surface both conformers are higher in energy than the thiirenium ion, **3***b*, and are relatively unimportant as the barriers to collapse into **3***b* are very low. Extension of the calculations beyond the Hartree–Fock level is expected to improve the cyclic ion relative to the open (3) and it is questionable whether **2** will be at a minimum when correlation energy is included.

(c) Thiirenium ion (3)

The thiirenium ion has carbon–sulphur bonds which are slightly longer than a normal single bond and the carbon–carbon distance is intermediate between a double and a triple bond and is almost identical to that in the oxiranyl cation (3). The bonds within the ring are a little shorter than those calculated for thiirene at the 6-311G* level (21), consistent with a tightening of bonds resulting from the positive charge on the ring.

The SH bond is 77.9° out of the plane defined by the heavy atoms and the inversion barrier, calculated as the difference between the planar (**3***a*) and pyramidal (**3***b*) thiirenium ions, is 369 kJ mol^{-1}. This high barrier has been attributed to σ interactions with a relatively small contribution from four-electron – two-orbital interaction in the π system of the planar ion (14).

(d) 1-Thiovinyl cation (4)

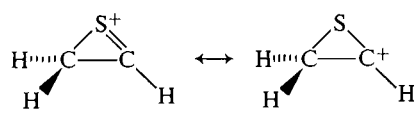
The 1-thiovinyl cation is isoelectronic with allene (neglecting inner shells) and adopts the same twisted conformation for the terminal groups. The ∠CCS is 174.9° (ethynylthiol has ∠CCS of 176.7° (21) and the two hydrogens of the methylene group are very slightly bent away from the sulphur atom. The bond lengths between heavy atoms are both a bit shorter than double bonds. This structure has the second lowest energy on the hypersurface.

(e) Thioformylmethyl cation (5)

The carbon–carbon bond length is shorter than a single bond and the carbon–sulphur is longer than a double bond, indicating considerable donation to the cationic carbon from C=S. The π density on C^+ is 0.338 e and on S is 0.630 e. Sulphur also acts as a σ donor and has a net charge of +0.476. Isomer **5** is of little physical significance as rotation about the carbon–carbon bond has a low barrier and results in formation of the thiiranyl cation, **6**.

(f) Thiiranyl cation (6)

The HC—S bond length in **6** is shorter than a carbon–sulphur double bond and the calculated net charge on S is +0.505, indicating that resonance structure **6***a*, where most of the positive charge is located on sulphur rather than on carbon, is the best description. The π populations of the carbon of CH and of sulphur are 0.572 e and 1.406 e, respectively (excluding the inner shell electrons of π symmetry on sulphur). Hence structure **6***b* is not insignificant.



6*a* **6***b*

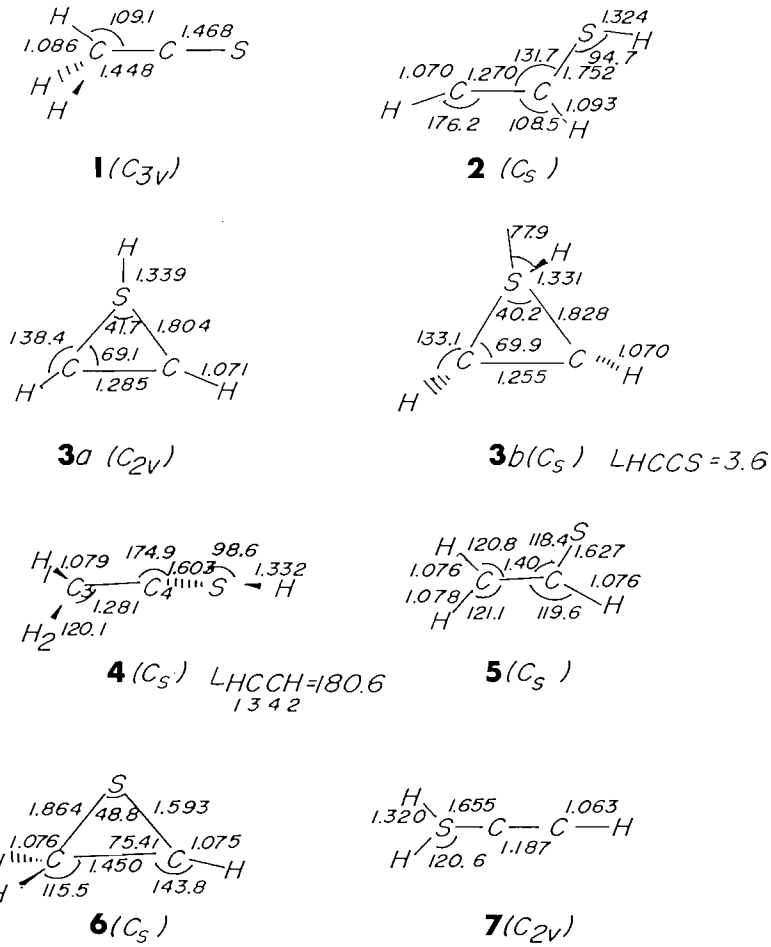

FIG. 2. Structural parameters for $C_2H_3S^+$ as obtained from optimisation at 6-31G* level. Bond lengths in Å and bond angles in deg.

(g) Structures 7 and 8

Isomer **7** is formed by protonation of ethynylthiol on sulphur and both the C—S and C—C bonds are shorter than those in the base. This structure has considerably higher energy than isomers **1** → **6** and consequently was not considered as a likely candidate for the common ion observed in mass spectrometry. Structure **4**, which is generated by protonation of ethynylthiol at the carbon, has much lower energy and it is interesting to note that for ethynylthiol the relative proton affinities are β-carbon > α-carbon > sulphur.

Structure **8**, by analogy with the $C_2H_3O^+$ surface, was expected to be low in energy, but in preliminary calculations at the STO-3G level it had higher energy than the other isomers and we did not consider this structure at the 6-31G* level.

2. Interconversion of open and cyclic ions

Sulphur is a large polarisable atom and in ions where the sulphur is in the β position relative to the carbon formally carrying the positive charge then bridging by sulphur is likely. We therefore examined the profiles for formation of cyclic ions from structures **2** and **5**.

(a) 2-Thiovinyl cation (2) → thiirenium ion (3b)

Ions **3***b* and **2** are models for the intermediates formed in the initial slow step in the electrophilic addition of arene and alkanesulphenyl halides to alkynes (for a review, see ref. 22). The structures of **3***b* and **2** and the profile to their interconversion have been previously studied by *ab initio* molecular orbital calculations in a comprehensive study of electrophilic addition to acetylene (refs. 14, 15, for a review, see ref. 23).

The transition structures for conversion of the *anti* conformer (**2**) and the *syn* conformer into **3***b* have activation energies of 5 kJ mol^{-1} and 11 kJ mol^{-1}, respectively, above the 2-thiovinyl cations. These energies are slightly smaller than the barrier to rotation previously calculated for conversion of the *syn* isomer into the *anti* (13.8 kJ mol^{-1} (14)) and both would collapse into the cyclic isomer in preference to interconverting.

The transition structure (**9**) for conversion of the *anti* conformer into **3***b* has similar geometric parameters to **2** with the major changes being a decrease in ∠SCC (to 118.7° from 131.7°), an increase in C—S (to 1.789 Å from 1.752 Å) and rotation about the C—S bond (by 28°). A small distortion of **2** then leads to transition structure **9** and the low energy barrier to formation of **3***b* seems to make observation of **2** by experiment to be very unlikely. We were unable to locate a transition structure for conversion of **3***b* into **6**, and conversion of **3***b* into other lower energy isomers appears to require formation of **2** as an intermediate. The direct observation of the stable trimethylthiirenium ion (24) supports this conclusion (Fig. 3).

(b) Thioformylmethyl cation (5) → thiiranyl cation (6)

The thiiranyl cation is lower in energy than the thioformylmethyl cation at both the STO-3G and 6-31G* levels and inclusion of correlation energy is expected to further favour the thiiranyl cation. Transition structure **10** for the collapse

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12

of **5** into **6** is only 6 kJ mol^{-1} at the 6-31G* level and under experimental conditions **5** will not be observable. Transition structure **10** is similar in geometry to **5** with rotation of the methylene group and bending of ∠CCS being the major changes.

3. Intramolecular rearrangements leading to formation of 1 and 4

Ions **1** and **4** have the lowest energies on the $C_2H_3S^+$ hypersurface and if there is one common ion in the gas phase then it is likely to have one of these structures. Accordingly we have calculated transition structures for the formation of **1** and **4** from the other ions.

(a) Thioformylmethyl cation (5) → thioacetyl cation (1)

The thioformylmethyl cation is converted into the thioacetyl cation by a 1,2-shift of a hydrogen. The transition structure, **11**, for this rearrangement is 81 kJ mol^{-1} above **5**. **11** essentially has C_s symmetry and the major differences from structure **5** are increases in ∠CCS and the C_1—H distance, and decreases in $\angle C_1C_2H_3$ and the C—S distance. All these parameters are intermediate between the values for **5** and **1**.

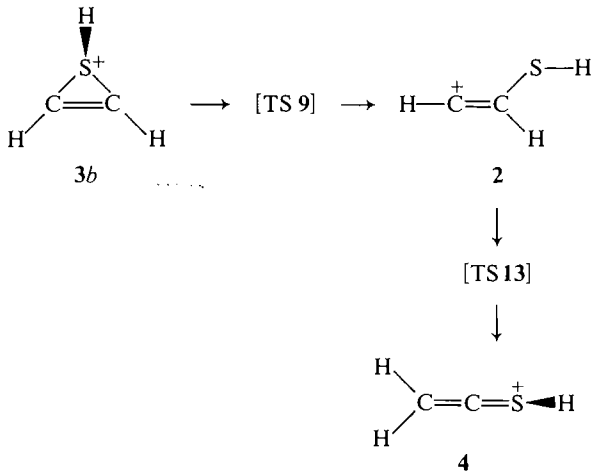
As discussed earlier, structure **5** collapses into **6** with a very small barrier and at the 6-31G* level then conversion of **6** into **1** can be considered to pass through **5** as an intermediate and the activation energy for the reaction **6** → **1** by this mechanism has a barrier 143 kJ mol^{-1} above **6**.

(b) Thioformylmethyl cation (5) → 1-thiovinyl cation (4)

A 1,2-shift of a hydrogen from carbon to sulphur converts **5** into **4** via transition structure **12**. This is a high energy process although the calculated activation energy of 177 kJ mol^{-1} above **5** is probably an overestimate. Inclusion of correlation energy generally results in a lowering of barrier heights and for the analogous reaction on the $C_2H_3O^+$ energy hypersurface (3) the barrier at the HF/6-31G** level is 247 kJ mol^{-1} while at the MP2/6-31G** level it is reduced to 113 kJ mol^{-1}.

(c) Thiirenium ion (3b) → 1-thiovinyl cation (4)

Attempts at finding transition structures for the conversion of thiirenyl cation **3***b* into **4** by a 1,2-shift accompanied by ring opening was unsuccessful. One possible route for this reaction to occur is via **2** as an intermediate. Structure **9** is only 5 kJ mol^{-1} above **2** and for the second step the transition



structure **13** is 18 kJ mol^{-1} above **2**. For the overall process **3***b* → **4** by this pathway the activation energy is 96 kJ mol^{-1} above **3***b*.

(d) 1-Thiovinyl cation (4) → thioacylium ion (1)

In general 1,3-hydrogen shifts along a linear molecule have high barriers (25, 26) and we have been unable to locate a transition structure for the 1,3-shift of a hydrogen required to convert **4** into **1**. Similar difficulties were encountered for the analogous isomers on the $C_2H_3O^+$ hypersurface (3).

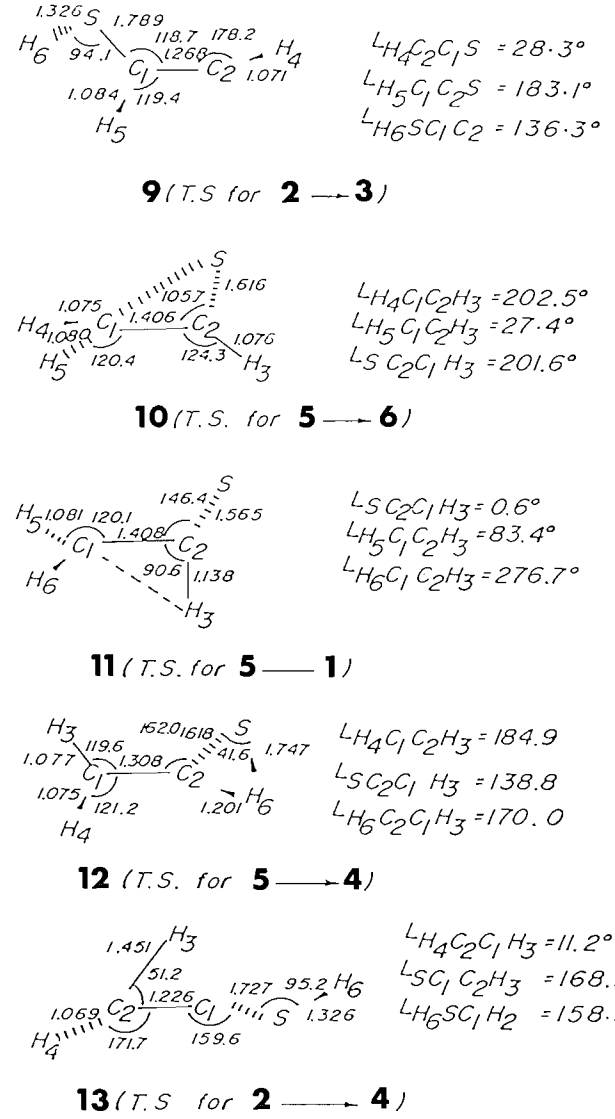


FIG. 3. Transition structures from optimisation at 6-31G* level. Bond lengths in Å and bond angles in deg.

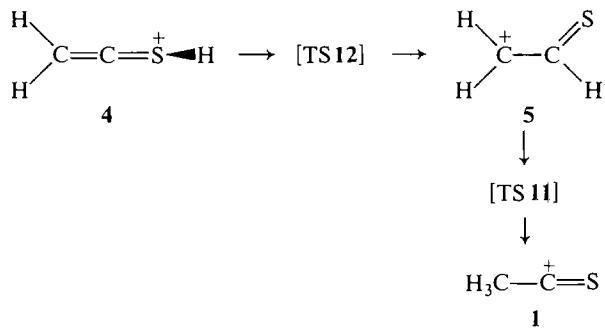
One mechanism for achieving the 1,3-shift is to have a sequence of 1,2-shifts involving **4** → **5** → **1**.



For this pathway transition structure **12** has the highest energy and conversion of **4** into **1** then has a barrier of 251 kJ mol^{-1} above **4**.

4. Protonation of thioketene

The experimental proton affinity of $H_2C{=}C{=}O$ is 842 kJ

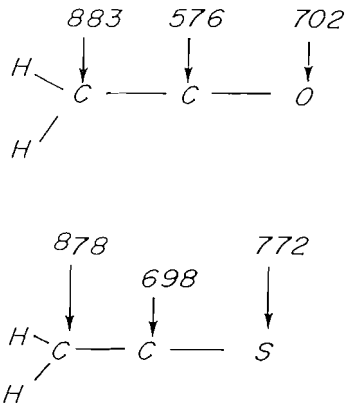


FIG. 4. $-\Delta E$ (kJ mol^{-1}) for protonation at each heavy atom in ketene (at 6-31G**) and in thioketene (at 6-31G* level).

mol^{-1} and Nobes *et al.* (3) have calculated values ranging from 848–883 kJ mol^{-1} at various levels of theory, with their highest level calculation giving 849 kJ mol^{-1}. At the 6-31G** SCF level the calculated proton affinity for ketene is 883 kJ mol^{-1}; this is almost identical to our 6-31G* level proton affinity for thioketene (878 kJ mol^{-1}). Clearly then the methylene carbon has almost the same basicity regardless of the heteroatom.

Protonation on the sulphur of thioketene occurs more easily than on the oxygen of ketene (Fig. 4). Protonation on the central carbon atom has the highest energy for both molecules but thioketene has the higher basicity.

5. Comparison of the $C_2H_3O^+$ and $C_2H_3S^+$ hypersurfaces

The relative energies of the isomers at 6-31G*//6-31G* is **1** < **4** < **6** < **3***b* < **5** < **2** < **7** and this order is also followed at the STO-3G level with **3***b* and **5** being interchanged. Structure H_3CS^+=C:, **8**, which, by analogy with the $C_2H_3O^+$ surface, was expected to be of low energy, had the highest energy of all species studied at the STO-3G level and was not considered at the higher level. There are, however, many similarities between the $C_2H_3O^+$ and $C_2H_3S^+$ surfaces. On the oxygen surface at the 6-31G** level, the order of the isomers is **1** < **8** < **4** < **6** < **5** < **2** < **7** < **3***b* and the energy differences are one and a half to two times larger than on the $C_2H_3S^+$ surface. The only major difference other than the low energy of **8** is that on the $C_2H_3O^+$ surface at the SCF level, protonated oxirene is high in energy and is the transition state for the 1,2-shift of a hydroxyl group in the degenerate hydroxyl shift in the 2-hydroxyvinyl cation. On the $C_2H_3S^+$ surface the bridging ability of sulphur results in **3***b* being at a minimum and the transition state for conversion of **2** into **3***b* is sufficiently low (5.5 kJ/mol) that **2** will not be observable under experimental gas phase conditions.

Conclusions

The thioacetyl ion (**1**) has the lowest energy of all $C_2H_3S^+$ isomers and if there is one common ion in the gas phase it is expected to have this structure. Ion **4** has the second lowest energy and conversion of this ion into **1** via the intermediate **5** has a high barrier, 250 kJ mol^{-1} above **4**. For the other ions considered here at the HF/6-31G* level relatively little energy is required to convert **5** and **6** into **1**, and to convert **2** and **3** into **4** and inclusion of correlation energy should further decrease these barriers. The high barrier for reaction **4** → **1** (via **5**) then determines whether all the ions interconvert. The transition structure for this reaction, **12**, is lower in energy (by 49 kJ mol^{-1}) than the dissociation products of lowest energy (CH_3^+ plus CS). Clearly then ions from all precursors will isomerise prior to dissociation and the existence of a common dissociation pathway is not surprising.

Of the possible dissociation products listed in Table 1 the combination of CH_3^+ and CS has the lowest energy and by comparison with the $C_2H_3O^+$ hypersurface it is probable that there is zero reverse activation energy for dissociation of H_3CCS^+. One of the observed major products, HCS^+, if accompanied by singlet methylene, requires 138 kJ mol^{-1} more energy to form and we are therefore at a loss to explain why dissociation into CH_3^+ and CS does not occur.

Received July 16, 1986

DAVID W. BOYKIN, ALFONS L. BAUMSTARK, MARGARET M. KAYSER, and CHANTAL M. SOUCY. Can. J. Chem. **65**, 1214 (1987).

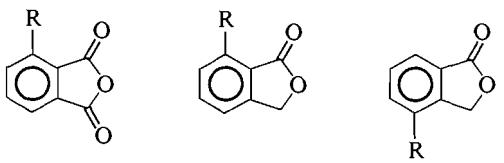
^{17}O chemical shift data (natural abundance) for 3-substituted phthalic anhydrides and 4- and 7-substituted phthalides in acetonitrile at 75°C are reported. Steric interactions of substituents *ortho* to the carbonyl groups result in deshielding effects (9–22 ppm) relative to parent compounds regardless of the electronic character of the substituents. Factors contributing to the deshielding effects are discussed. The relationship between ^{17}O chemical shifts and regiochemistry of the phthalic anhydrides is discussed.

DAVID W. BOYKIN, ALFONS L. BAUMSTARK, MARGARET M. KAYSER, et CHANTAL M. SOUCY. Can. J. Chem. **65**, 1214 (1987).

Les rmn ^{17}O (abondance naturelle) pour une serie d'anhydrides phtaliques substitués en position-3 et de phtalides isomères correspondants ont été étudiés dans une solution d'acétonitrile à 75°C. Les interactions stériques, entre le groupement carbonyle et les substituants de la position *ortho*, provoquent un déblindage de 9 à 22 ppm par rapport aux composés non-substitués. Le déblindage est indépendant du caractère électronique des substituants. Les effets contribuants au déblindage sont évalués. La relation entre le déplacement chimique ^{17}O et la régiochimie des anhydrides phtaliques est discutée.

Introduction

The differential reactivity of the two carbonyl groups of unsymmetrically substituted phthalic anhydrides has been extensively studied (1–9); however, clear understanding of the factors that control the selectivity has yet to be achieved. The utility of ^{17}O nmr spectroscopy has been rapidly increasing (10–12), and it has been successfully used to estimate electronic characteristics (13–15) and local environment changes arising from steric interactions for a number of functional groups (16–21), including carbonyl groups (18–21). For example, it has been recently demonstrated that large bulky groups (e.g., *tert*-butyl) cause considerable in-plane distortion of the molecular structure of phthalic anhydride when placed at the 3 position (22). The steric interactions were reflected in the ^{17}O chemical shift data of these compounds. In an effort to gain insight into the influence of substituents of varying electronic character on the properties and reactivities of the two carbonyl functions of 3-substituted phthalic anhydrides, we have studied the ^{17}O chemical shifts of a series of phthalic anhydrides (**1**) and related phthalides (**2** and **3**).



1 **2** **3**

Results and discussion

^{17}O chemical shift data for the 3-substituted phthalic anhydrides (**1**), 7-substituted phthalides (**2**), and 4-substituted phthalides (**3**) in acetonitrile at 75°C, measured at natural abundance, are given in Tables 1 and 2. The substituted anhydrides show two carbonyl signals in the 370–395 ppm region and one signal near 265 ppm (Fig. 1). The single bonded oxygen signal for all 3-substituted anhydrides is insensitive to substituents, with all chemical shift values at 263 ± 1 ppm with the exception of the value for 4-nitrophthalic anhydride. The carbonyl group *meta* to the substituent is relatively insensitive to the 3-substituent, ranging in value from 367 to 377 ppm. The chemical shift of the carbonyl *ortho* to the substituent for the 3-methoxy compound **1***b* is deshielded relative to the parent **1***e* by 9 ppm, and the shift data for the 3-nitro compound **1** is deshielded by 22 ppm relative to the parent. The carbonyl group *ortho* to the 3-substituent is deshielded relative to the parent compound by all substituents regardless of their electronic character.

The chemical shift data for the carbonyl group of the 7-substituted phthalides (**2**) are all deshielded by 10–26 ppm compared to that of the parent molecule **2***d*, which exhibits a carbonyl signal at 320 ppm. In series **2**, electron donating or electron withdrawing substituents result in deshielding, an effect also observed in series **1**. The resonances for the anhydride (dicoordinate) oxygens of **2** are essentially invariant, all appearing at 170 ± 2 ppm. The chemical shift values for the carbonyl oxygen for **3** are only slightly affected by the substituent, appearing at 323 ± 4 ppm, as are those of the single bonded oxygen, which appear at 171 ± 3 ppm.

The assignment of the two carbonyl signals for the anhydrides **1** is made possible by using the results from the corresponding phthalides **2** and **3** (Table 2). It is clear from the data for the phthalides **2** and **3** that the effect of a substituent *ortho* to the planar carbonyl is deshielding, regardless of the electronic character of the substituent. Consequently, the assignments for the two carbonyl signals of the anhydrides shown in Table 1 are made by analogy with the corresponding phthalides. With the exception of the 3-*tert*-butyl and the 3-nitro compounds in series

1, the effect of substituents is a uniform deshielding value of 9 ± 1 ppm. This, in part, is presumably a result of repulsive van der Waals interactions (23). It is of interest to note that there is no appreciable difference in the data for the compounds **1***f*–**1***i* even though the substituents (halogen) are quite different sterically. Molecular mechanics calculations (MM2) were carried out on this series (**1***f*–**1***i*). In-plane distortions were found to be similar to that calculated for **1***c* (22). Apparently the increase in halogen size is offset by the lengthening halogen–carbon bond distance, resulting in the effective steric interactions remaining roughly constant. A possible explanation for the relatively invariant deshielding effects noted for ^{17}O chemical shifts for the anhydrides is that the repulsive van der Waals interactions between substituents and the *ortho* carbonyl group are roughly constant. The two substituents that lead to large downfield shifts, 3-*tert*-butyl **1***d* (22 ppm) and 3-nitro **1***j* (21 ppm), exhibit opposite electronic effects, the former a moderate electron donor, the latter strongly electron withdrawing. In the case of **1***d* the large effective size causes larger in-plane distortions and presumably gives rise to increased repulsive van der Waals interactions (22). The large downfield shift for **1***j* is a composite of the electronic deshielding effect of the nitro group as well as the influence of repulsive van der Waals forces.

Due to steric congestion, the nitro group of 3-nitrophthalic anhydride **1***j* is forced to rotate from the plane and a reciprocal effect from this interaction is noted on the nitro group ^{17}O signal. This is in contrast to the steric effect on the carbonyls which are only in-plane distortions. On comparing the ^{17}O shift of the nitro signal for 3- and 4-nitrophthalic anhydride, some information regarding torsion angle rotation for the 3-nitro group can be deduced. Note that the nitro groups of both isomers are electronically equivalent; the 3-nitro isomer has one carbonyl *ortho* and the other *meta* to it whereas the 4-nitro isomer has one carbonyl *para* and the other *meta* to it. Therefore, it is reasonable to assume that the difference in chemical shifts (NO_2 group) for the two isomers (27 ppm) can be attributed to torsion angle rotation, which minimizes the lone pair repulsion of the carbonyl oxygen and the oxygens of the nitro group. Using the slope (0.76 δ/° angle) of the line for the nitro group ^{17}O chemical shift – torsion angle relationship previously reported (17, 20), it is estimated that the 3-nitro group is rotated 35° from the plane of the aromatic ring. It is of interest that this torsion angle rotation is roughly equivalent to that of placing a methyl group *ortho* to a nitro group (17).

The effect of substituents on the ^{17}O chemical shifts for the 3-substituted phthalic anhydrides **1** and 7-substituted phthalides **2** is similar, both experiencing a comparable magnitude of deshielding in relation to the respective parent molecules. The magnitude of the deshielding effect is surprisingly constant for all the groups except the large *tert*-butyl group and, to a lesser extent, the nitro group. The relative consistency in chemical shift for the substituents of varying size and electronic effects is explained in terms of competition between simple electronic effects and van der Waals interactions (in-plane). Series **3** has a *meta* relationship between the carbonyl group and the substituent. The small ^{17}O chemical shift differences can be explained by normal electronic effects. An interesting conclusion to be made from the results for all the 3-substituted compounds listed in Table 1 is that the ^{17}O chemical shift values suggest that reactivity difference 1–9 for the two carbonyl groups of these compounds cannot be explained by simple electronic effects alone.

Experimental

The phthalic anhydrides were either commercially available or prepared by literature methods (24). The phthalides were prepared by a variety of reductive methods from the corresponding anhydrides (24). The isomeric lactones were purified by chromatographic and physical methods (24). The ^{17}O spectra were obtained on a JEOL GX-270 spectrometer equipped with a 10-mm broad-band probe operating at 36.5 MHz. The spectra were acquired at natural abundance on 0.5 *M* solutions in acetonitrile (anhydrous, packed under nitrogen, Aldrich) at 75°C. Chemical shift data were referenced to external water at 75°C (1.0% butan-2-one added as internal standard, 558 ± 1 ppm). The instrument settings were 25 kHz spectral width, 2 K data points, 90° pulse angle (28 μs pulse width), 0.3 ms acquisition delay, and

Enthalpy of solution of tris(2,4-pentanedionato)cobalt(III) in aqueous mixed solvents of 1,4-dioxane and 2-methyl-2-propanol

YASUKI YOSHIMURA

Laboratory of Chemistry, College of Humanities and Social Sciences, Iwate University, Ueda, Morioka, 020 Japan

Received October 9, 1986

YASUKI YOSHIMURA. Can. J. Chem. **65**, 1218 (1987).

The solubilities X_s of tris(2,4-pentanedionato)cobalt(III) ($Co(acac)_3$) in water – 1,4-dioxane (D) and water – 2-methyl-2-propanol (TBA) mixtures were determined over the temperature range of 15–60°C and 20–43°C, respectively. These data were fitted to $\ln X_s = A(1/T) + B\sqrt{T} + C$ and the enthalpy of solution $\Delta\bar{H}_s$ of $Co(acac)_3$ was estimated by differentiating the equation. For the water–D system, a linear correlation was found between the excess enthalpy of solution $\delta\Delta\bar{H}_s$ of $Co(acac)_3$ and the excess internal pressure δP_i of the mixtures. $\Delta\bar{H}_s$ of $Co(acac)_3$ in the water–TBA mixtures showed complicated composition dependence due to microheterogeneity in the mixtures. The enthalpy of hydrophobic hydration $\Delta\bar{H}_h$ of $Co(acac)_3$ in the water–D mixtures was also estimated from the solubility curves and it was found that $\Delta\bar{H}_h$ decreased exponentially with decreasing mole fraction of water.

YASUKI YOSHIMURA. Can. J. Chem. **65**, 1218 (1987).

On a déterminé les solubilités X_s du tris(pentanedione-2,4 ato) cobalt(III) ($Co(acac)_3$) dans des mélanges eau/dioxanne-1,4 (D) et eau/méthyl-2 propanol-2 (ATB) à des intervalles de températures respectifs de 15 à 60°C et de 20 à 43°C. On a ajusté ces données à l'équation $\ln X_s = A(1/T) + B\sqrt{T} + C$ et on a évalué l'enthalpie de solution $\Delta\bar{H}_s$ du $Co(acac)_3$ en procédant à la différenciation de l'équation. Pour le système eau/D, on a trouvé une corrélation linéaire entre l'excès d'enthalpie de solution, $\delta\Delta\bar{H}_s$ du $Co(acac)_3$ et l'excès de pression interne δP_i des mélanges. On a démontré que le $\Delta\bar{H}_s$ du $Co(acac)_3$, dans les mélanges eau/ATB, présente une relation compliquée avec la composition qui est due à une microhétérogénéité des mélanges. On a aussi déterminé l'enthalpie d'hydratation hydrophobe $\Delta\bar{H}_h$ du $Co(acac)_3$ dans les mélanges eau/D à partir des courbes de solubilité et on a trouvé que le $\Delta\bar{H}_h$ diminue d'une façon exponentielle avec une diminution de la fraction molaire de l'eau dans les mélanges.

[Traduit par la revue]

Introduction

In analysis of metal ions in aqueous solutions, the technique of solvent extraction of metal chelates has been extensively applied. In the previous investigation, as an approach to clarify a behavior of metal chelates in aqueous solutions, the enthalpy of solution $\Delta\bar{H}_s$ of tris(2,4-pentanedionato)cobalt(III) ($Co(acac)_3$) in the mixtures of water and dimethyl sulfoxide (DMSO) has been examined and it has been found that the composition dependence of $\Delta\bar{H}_s$ can be satisfactorily related to the composition dependence of the internal pressure P_i of the water–DMSO mixtures (1).

Various properties of many aqueous organic mixtures have been very widely examined in connection with the effect of these organic solvents on the structure of water (2). Among these solvents, 1,4-dioxane (D) and 2-methyl-2-propanol (TBA) seem to be interesting from the following aspects: (*i*) in highly dilute aqueous solutions, TBA exhibits remarkable structure-making effect (3–6), while different explanations have been given to the effect of D on the structure of water, that is, structure-making (7–11) or structure-breaking effect (3, 12–16); (*ii*) microheterogeneity or pseudophase separation is brought about in the water-rich regions of the water–TBA mixtures (17–19) but not in the water–D mixtures (18, 19).

It would be of interest to determine whether the previous conclusion for $\Delta\bar{H}_s$ of $Co(acac)_3$ in the water–DMSO mixtures is valid for other aqueous organic mixtures or not. Furthermore, it would also be of interest to examine the behavior of dissolution of a third solute in the microheterogeneous water–TBA mixtures. The behavior may be characterized by comparison with that in the water–D mixtures.

Thus, in this study, the temperature dependence of the solubilities of $Co(acac)_3$ in both the water–D mixtures and the water–TBA mixtures is determined. From these data $\Delta\bar{H}_s$ of $Co(acac)_3$ is estimated and its composition dependence is discussed. The enthalpy of hydrophobic hydration $\Delta\bar{H}_h$ of $Co(acac)_3$ in the dilute aqueous D solution is also estimated.

Experimental

The purification of $Co(acac)_3$ was described previously (1). Commercial D (spectrophotometric grade reagent, Dojin Chemical Laboratories Ltd.) was passed through a column of activated alumina, refluxed over calcium hydride for a day under an atmosphere of nitrogen gas dried by passing through concentrated sulfuric acid and a column of sodium hydroxide, and then distilled. TBA (reagent grade, Wako Chemical Industries Ltd.) was refluxed over calcium hydride for a day and distilled. The water contents in the purified D and TBA, measured by Karl Fischer titration, were less than 0.02% and 0.04% by weight, respectively. These purified solvents were stored over molecular sieves (type 4A) in a dry box. The mixed solvents were prepared by the same method as described previously (1).

In order to minimize the influence of the evaporation of volatile TBA during the solubility measurement, the apparatus used for saturating the desired sample solutions with $Co(acac)_3$ was modified as shown in Fig. 1. The main modification was to reduce the volume of the apparatus. By this modification, the deviations of 95% confidence levels from the mean values of the solubilities in the water–TBA mixtures could be reduced to about half of those found by the use of the apparatus described previously (1). The procedure used for the solubility measurement was identical with that described previously (1), except that the saturated solution was passed through a cotton filter by injecting dry nitrogen gas.

Results

Solubility of $Co(acac)_3$ in water–D and water–TBA mixtures

The solubilities of $Co(acac)_3$ in molality (mol kg^{-1}), S_m in the water–D and water–TBA mixtures are listed in Tables 1 and 2, respectively. For the water–TBA mixtures, the solubilities were determined in the narrow temperature region 20–43°C because of the high melting point (about 25°C) and low boiling point (about 82°C) of TBA. The deviations of the 95% confidence levels from the mean values were less than 2% for the water–D system and less than 4% for the water–TBA system. It has been confirmed in the previous work that $Co(acac)_3$ is not decomposed in the course of the equilibration (1). The solubility data at 25°C were reproducible within

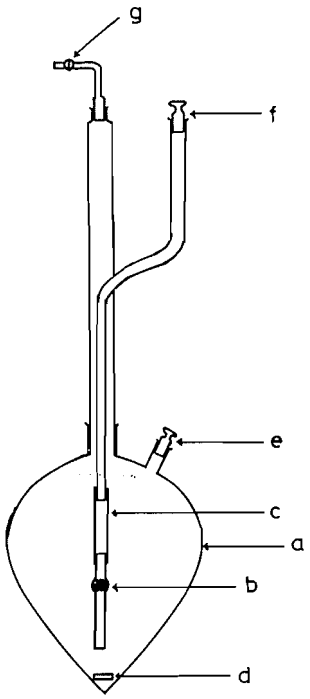

FIG. 1. Apparatus for solubility measurement: *a*, flask with a volume of 100 cm^3; *b*, filter filled with absorbent cotton; *c*, teflon tube; *d*, magnetic stirring bar; *e*, stopper for transferring water–D or water–TBA mixture and $Co(acac)_3$ to the flask; *f*, stopper for pipetting off saturated solution; *g*, stop-cock for injecting dry nitrogen gas.

experimental error when the solutions at the end of experiment at the highest temperature were allowed to attain equilibrium at 25°C. This finding shows that the evaporation of components during the equilibration produces no detectable effect.

The S_m values were converted to solubilities in mole fraction X_s and $\ln X_s$ was plotted against $1/T$. Typical plots are shown for the water–D and water–TBA mixtures in Figs. 2 and 3, respectively. The solubility curve in water passed through a minimum at about 55°C (1). The minima of the solubility curves in the aqueous D and TBA mixtures were shifted to lower temperatures with increases in the mole fraction of D or TBA, X_D or X_{TBA} (45°C for $X_D = 0.0153$, 35°C for $X_D = 0.0237$, about 45°C for $X_{TBA} = 0.0143$, 30°C for $X_{TBA} = 0.0234$). In the mixtures with a composition $X_D \geq 0.0570$ or $X_{TBA} \geq 0.0401$, the minimum was no longer distinct over the temperature range studied.

$\Delta\bar{H}_s$ of $Co(acac)_3$ in water–D and water–TBA mixtures

For representing the solubility curves, the experimental values were fitted to

$$[1] \quad \ln X_s = A(1/T) + B\sqrt{T} + C$$

where A, B, and C are fitting parameters.[1] Equation [1] could reproduce the X_s values within the errors of ±1.5% for the water–D mixtures and of ±1.8% for the water–TBA mixtures.

The $\Delta\bar{H}_s$ values at 25°C in the water–D and water–TBA

[1]In a previous work, experimental values were fitted to $\ln X_s = A(1/T) + B \ln T + C$. When the present values were fitted to this equation, standard deviations of fit were slightly higher than those obtained by using [1]. For the water–D system the values of $\Delta\bar{H}_s$ estimated by using the above equation were identical with those estimated from [1], while for the water–TBA system the two methods gave slightly different $\Delta\bar{H}_s$ values probably because of the narrow temperature range of the solubility measurement. Therefore, in the present work eq. [1] was adopted since it provided a better fit to the data.

mixtures were estimated by

[2] $\Delta\bar{H}_s = R(-A + B/2 \times T^{3/2})$

where R is the gas constant 8.314×10^{-3} kJ mol^{-1} K^{-1} and are listed in Tables 3[2] and 4, respectively. The errors in these Tables were estimated from the 95% confidence levels of the parameters in [1]. The errors in the water–TBA system became large as indicated by the large 95% confidence levels of the parameters which were caused by the narrow temperature range of the solubility measurement.

Discussion

Composition dependence of $\Delta\bar{H}_s$ of $Co(acac)_3$ in water–D and water–TBA mixtures

The composition profile of $\Delta\bar{H}_s$ of $Co(acac)_3$ in the water–D and water–TBA mixtures is shown in Fig. 4. $\Delta\bar{H}_s$ in the water–D mixtures increased rapidly up to $X_D = 0.2$, passed through a small maximum at $X_D = 0.3$, and then decreased nearly linearly to $\Delta\bar{H}_s$ in pure D. A similar maximum or minimum has been found for various properties in the water–D mixtures such as the enthalpy (10, 20–22) and volume (21, 23) of mixing, ultrasonic absorption (9, 24), and compression (14, 25). $\Delta\bar{H}_s$ in the water–TBA mixtures showed a complicated composition profile with three maxima at $X_{TBA} = 0.1$, 0.4–0.5, and 0.95. It has been extensively reported that several properties in the water–TBA mixtures exhibit a maximum or a minimum at a lower concentration than $X_{TBA} = 0.1$ (3–6, 17, 18). Nakanishi and Ozasa have found a sharp maximum at $X_{TBA} = 0.05$ and broad one at about $X_{TBA} = 0.6$ in the composition profile of diffusion of iodine in the water–TBA mixtures (26). To the author's knowledge there are no literature references to a maximum or a minimum in the TBA-rich region of $X_{TBA} = 0.95$.

In the previous work (1), it has been found that the excess enthalpy of solution $\delta\Delta\bar{H}_s$ of $Co(acac)_3$ in the water–DMSO mixtures can be explained in terms of the excess enthalpy of cavity formation $\delta\bar{H}_c$ by

[3] $\delta\Delta\bar{H}_s = \delta\bar{H}_c = (\bar{V}_c - a^3N\pi/6)(R/82.05)\delta P_i$

where $\bar{V}_c$, a, and N are the partial molar volume of cavity formation, the hard-sphere diameter of the solute, and Avogadro's number, respectively. $\delta\Delta\bar{H}_s$ and δP_i are defined by

[4] $\delta Y = Y - \{(1 - X_W)Y(0) + X_W Y(W)\}$

where the symbol Y stands for $\Delta\bar{H}_s$ or P_i, X_W is the mole fraction of water, and $Y(0)$ and $Y(W)$ are the values of Y in pure D or TBA and in water, respectively.

In Fig. 5, $\delta\Delta\bar{H}_s$ of $Co(acac)_3$ is plotted against δP_i for the water–D and water–TBA systems. Values of δP_i were calculated from values found in the literature of P_i in the water–D (27) and water–TBA mixtures (28). For the water–D system, the plot showed the linear relationship expected from [3] between $\delta\Delta\bar{H}_s$ and δP_i similar to the finding in the water–DMSO system (1). On the other hand, for the water–TBA

[2] $\Delta\bar{H}'_s$ and $\Delta\bar{H}_h$ in Table 3 will be discussed in the last section.

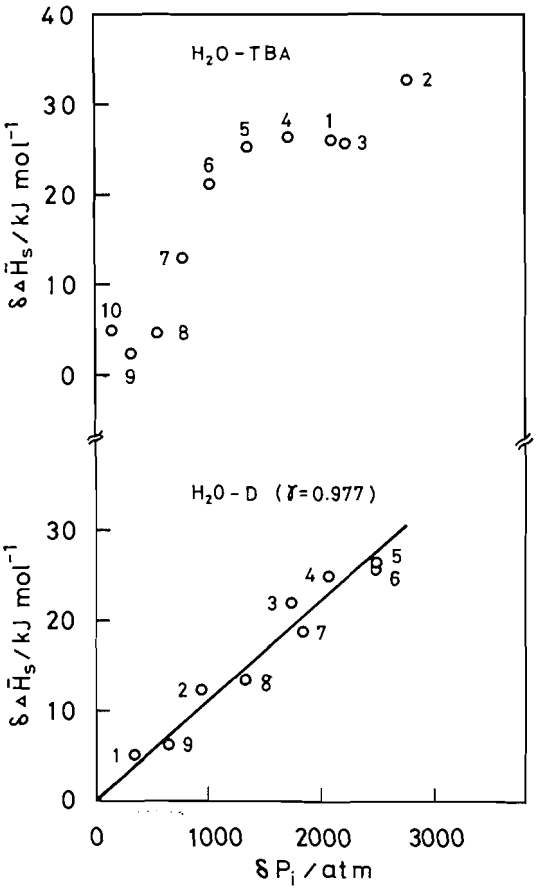

FIG. 5. Correlation between excess enthalpy of solution $\delta\Delta\bar{H}_s$ of $Co(acac)_3$ and excess internal pressure δP_i for water–D and water–TBA systems. For water–D system X_D is as follows: *1*, 0.0122; *2*, 0.0345; *3*, 0.0780; *4*, 0.1039; *5*, 0.1650; *6*, 0.2787; *7*, 0.4787; *8*, 0.6125; *9*, 0.8097. For water–TBA system X_{TBA} is as follows: *1*, 0.05; *2*, 0.1; *3*, 0.2; *4*, 0.3; *5*, 0.4; *6*, 0.5; *7*, 0.6; *8*, 0.7; *9*, 0.8; *10*, 0.9. Value of γ is correlation coefficient.

(6, 17–19). In studies of the heat capacities of such microheterogeneous mixtures, it has been found that composition profiles of the apparent molar heat capacities or the partial molar heat capacities of organic components show maxima (5, 8, 17, 29–31).

In order to make clearer the unique behavior of the dissolution

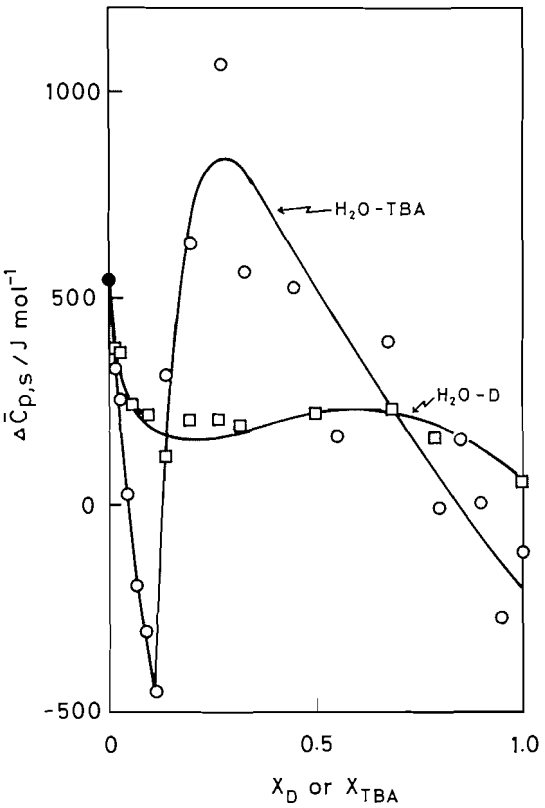

FIG. 6. Composition dependence of heat capacity of solution $\Delta\bar{C}_{p,s}$ of $Co(acac)_3$ in water–D and water–TBA mixtures: □, water–D mixtures; ○, water–TBA mixtures.

of $Co(acac)_3$ in the water–TBA mixtures, the heat capacities of solution $\Delta\bar{C}_{p,s}$ of $Co(acac)_3$ at 25°C in the water–D and water–TBA mixtures were estimated by [5] obtained by differentiating eq. [2]

$$[5]\quad \Delta\bar{C}_{p,s} = (3/4)BR\sqrt{T}$$

and are plotted against X_D or X_{TBA} in Fig. 6. In the water–D mixtures which are not microheterogeneous (18, 19), $\Delta\bar{C}_{p,s}$ decreased slightly up to $X_D = 0.14$ and then was nearly constant. When $\Delta\bar{C}_{p,s}$ estimated from the previous data in the water–DMSO mixtures (1) was plotted, a similar trend was found. In the water–TBA mixtures, $\Delta\bar{C}_{p,s}$ decreased markedly up to $X_{TBA} = 0.1$, increased discontinuously in the X_{TBA} region 0.1–0.25, and then decreased to $\Delta\bar{C}_{p,s}$ in pure TBA.

Though the values of $\Delta\bar{C}_{p,s}$ derived from the second derivative of [1] lack accuracy, a feature characteristic of the dissolution of $Co(acac)_3$ in the water–TBA mixtures can be recognized satisfactorily in Fig. 6.

The present results suggest that, in general, the composition dependence of $\Delta\bar{H}_s$ of a nonelectrolyte in aqueous organic mixtures except for microheterogeneous mixtures depends primarily on the enthalpy of cavity formation. The finding that $\delta\Delta\bar{H}_s$ can be linearly correlated to δP_i is practical from the viewpoint that the composition dependence of $\Delta\bar{H}_s$ can be explained in terms of P_i which is measurable.

Enthalpy of hydrophobic hydration of $Co(acac)_3$

In the previous study, a method to estimate approximate values of $\Delta\bar{H}_h$ of $Co(acac)_3$ in the water–DMSO mixtures was presented (1). The method is based on the assumption that the curvature of the solubility curves in Figs. 2 and 3 results from the hydrophobic hydration of $Co(acac)_3$ and a disappearance

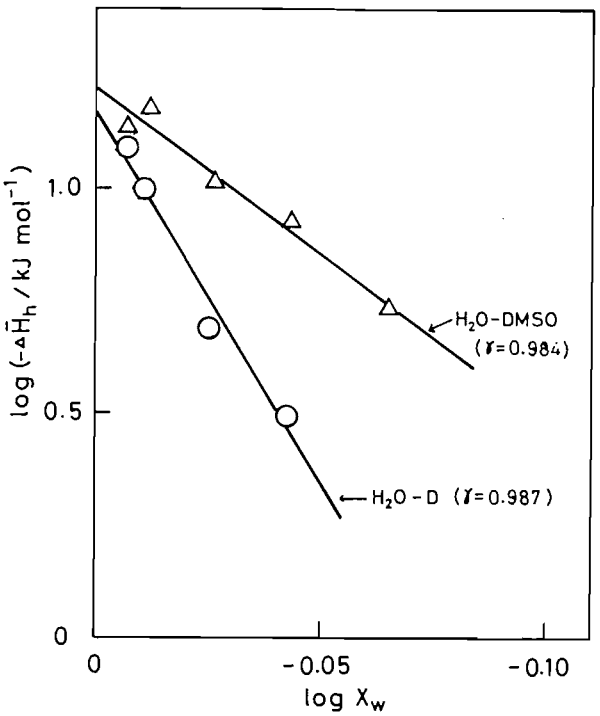

FIG. 7. Correlation between log $(-\Delta\bar{H}_h)$ for $Co(acac)_3$ and log X_w in water–D and water–DMSO mixtures. The values of log $(-\Delta\bar{H}_h)$ in water–DMSO mixtures were taken from ref. 1. Values of γ are correlation coefficients.

of the hydrophobic hydration results in straightening of the solubility curves (32).

For the water–D system, the solubility data in the temperature regions given in the parentheses in Table 3 were also fitted to

[6] $$\ln X_s = a(1/T) + b$$

and the enthalpy of solution without the hydrophobic hydration $\Delta\bar{H}_s'$ for $Co(acac)_3$ was calculated from the slope of [6].

Table 3 shows that in the concentration region $X_D \geq 0.14$, $\Delta\bar{H}_s$ and $\Delta\bar{H}_s'$ agree with each other within the experimental errors and suggests that the hydrophobic hydration disappears practically in the concentration region. As significant differences between $\Delta\bar{H}_s$ and $\Delta\bar{H}_s'$ were found in the concentration region $X_D \leq 0.094$, the values of $\Delta\bar{H}_h$ were obtained by subtracting $\Delta\bar{H}_s'$ from $\Delta\bar{H}_s$.

When log $(-\Delta\bar{H}_h)$ was plotted against log X_W, satisfactory linear relationship was recognized as shown in Fig. 7. This result shows that the following empirical equation settled in the previous work (1) is also valid for the water–D system.

[7] $$\Delta\bar{H}_h = \Delta\bar{H}_h(W)X_W^n$$

Thus, the enthalpy of hydrophobic hydration of $Co(acac)_3$ in water $\Delta\bar{H}_h(W)$ may be estimated to be -14.7 ± 1.6 kJ mol^{-1} from the intercept of the straight line for the water–D system in Fig. 7. This value agrees fairly well with the value of -16.7 ± 1.2 kJ mol^{-1} obtained in the water–DMSO system (1).

The estimation of $\Delta\bar{H}_h(W)$ is strictly tentative since validity of the above assumption to estimate $\Delta\bar{H}_h$ in these mixtures has not been established. The author intends to examine an experiment to establish this assumption.

FRANCIS M. F. CHEN and N. LEO BENOITON. Can. J. Chem. **65**, 1224 (1987).

Acylation of amino acids using benzoyl chloride in aqueous alkali leads to benzoylamino acids containing one percent of benzoyldipeptide. Use of diisopropylethylamine instead of sodium hydroxide as base eliminates the side reaction responsible for the contaminant. Ethoxycarbonylamino acids are advantageously prepared in the same manner using ethyl chloroformate or diethyl dicarbonate. The latter gives rise to some *N*-substituted dipeptide when used in aqueous alkali. The method is unsatisfactory for the benzyloxycarbonylation of amino acids. Use of 9-fluorenylmethyl chloroformate and diisopropylethylamine gives the pure derivative of leucine in moderate yield.

FRANCIS M. F. CHEN et N. LEO BENOITON. Can. J. Chem. **65**, 1224 (1987).

L'acylation des acides aminés par le chlorure de benzoyle en solution aqueuse alcaline conduit à des acides benzoylaminés qui contiennent un pourcent de benzoyldipeptide. L'utilisation de la diisopropyléthylamine à la place de l'hydroxyde de sodium permet d'éliminer la réaction secondaire qui est responsable du contaminant. Faisant appel à la même méthode, on peut préparer avantageusement les acides éthoxycarbonylaminés en utilisant le chloroformate d'éthyle ou le dicarbonate de diéthyle. Lorsqu'on utilise des solutions aqueuses alcalines, ce dernier composé donne lieu à la formation de dipeptides *N*-substitués. La méthode n'est pas satisfaisante pour la benzyloxycarbonylation d'acides aminés. L'utilisation du chloroformate de fluorènyl-9 méthyle et de la diisopropyléthylamine conduit, avec un rendement raisonnable, à un dérivé de la leucine qui est pur.

It is now recognized that a small amount of *N*-substituted dipeptide **5***a* is formed as side product when 9-fluorenylmethyl chloroformate (**1***b*) (1–5) or benzyl chloroformate (**1***c*) (4, 5) is used as reagent for the acylation of amino acids in aqueous alkali. It is also generally agreed that the source of peptide **5***a* is aminolysis of mixed anhydride **4***a*, which is generated during acylation by reaction of *N*-alkoxycarbonylamino acid anion product **3***a* with reagent **1***a* (1–6). The corresponding side product **5***d* has also been detected in some cases when the acylating agent was di-*tert*-butyl dicarbonate (**6***d*) (4, 5). Use of alternative reagents that disallow formation of anhydride **4***a* has been recommended, 9-fluorenylmethyl succinimidyl carbonate first suggested by Paquet (6) being the most favoured for the synthesis of Fmc-amino acids[1] (**3***b*) (2, 3).

In the course of studies on the side reaction of urethane formation associated with the use of anhydrides **4***a* for the synthesis of peptides (7), it was found that the amount of urethane produced depended significantly on the nature of the tertiary amine used to generate the anhydride from **1***a* and **3***a*. In fact, when DIEA was used as base in a mixed anhydride coupling of Boc-Ile with Lys(Z)-OMe in dichloromethane, no peptide at all was formed.[2] The product isolated was the urethane, ROCO-Lys(Z)-OMe, in 90% yield. The conclusion was that the mixed anhydride had not been generated, and that the amino acid ester had reacted with the unconsumed chloroformate. That the mixed anhydride is generated much more slowly when DIEA instead of *N*-methylmorpholine or *N*-methylpiperidine is used as base was established by isolating the anhydrides from reaction mixtures at various times (8). The reluctance of mixed anhydrides to form in the presence of DIEA suggested to us that if the mixed anhydride indeed were responsible for the dimerization side reaction, eqs. [2] and [3], the use of DIEA instead of NaOH for acylation reactions, eq. [1], might eliminate the side reaction. Our studies on the use of DIEA to try to eliminate the dimerization side reaction associated with the acylation of amino acids are the subject of this communication. The study includes the acylation of amino acids with benzoyl chloride (**1***f*) since it is in the preparation of these derivatives **3***f* that the dimerization reaction was first encountered many years ago (9, 10).

[1]Abbreviations: Bz, benzoyl; Boc, *tert*-butoxycarbonyl; Eoc, ethoxycarbonyl; Fmc, 9-fluorenylmethoxycarbonyl; Moc, methoxycarbonyl; Z, benzyloxycarbonyl; DIEA, diisopropylethylamine; DMF, dimethylformamide; hplc, high-performance liquid chromatography. The amino acid symbols have no configurational implication. For convenience, derivatives of acids are indicated without the terminal OH; e.g. Bz-Ala instead of Bz-Ala-OH.

[2]Couplings of Boc-Ile, Boc-Leu, and Boc-Pro with Lys(Z)-OMe using EtOCOCl in the presence of DIEA in tetrahydrofuran also gave no peptide (unpublished).

Results and discussion

A method by which a reference mixture of the two pertinent products **3***a* and **5***a* (acid form) is prepared and analyzed was devised and has been published (5). It involves reaction of the symmetrical anhydride **7***a* (11, 12) of the protected amino acid **3***a* with the corresponding amino acid anion **2** in aqueous DMF. The proportions of the two compounds in the mixture are determined by ^{1}H nmr spectroscopy. The components are separated and the relative absorbances of the two are established by reversed-phase hplc on a C_{18} column with uv absorbance monitoring. The same analytical method was used for determining the benzoylation products **3***f* and **5***f* (acid form). However, the reference mixtures could not be prepared in the same manner since the symmetrical anhydride **7***f* of an acylamino acid, in contrast to that of the alkoxycarbonylamino acid, does not exist (13). The reference benzoyldipeptides **5***f* were nevertheless prepared in an analogous manner by reaction of the 2-alkyl-5(4*H*)-oxazolone **8***f* (14) with the amino acid anion **2** in aqueous DMF, except for the lysyl derivative. This acylation reaction with oxazolone **8**, R^1 = alkyl, in partially aqueous solutions is novel and will be discussed further in detail elsewhere.

Amino acids were benzoylated in aqueous solution according to the conventional procedure using NaOH as base (15), and with DIEA instead of NaOH. It was found that some amino acids remained insoluble in the presence of DIEA. Therefore

the procedure adopted in all cases was to dissolve the amino acid by the addition of 1 equiv. of NaOH, and the DIEA was used only to neutralize the acid generated during the acylation. Acidic products were isolated by extraction of the mixture at acidic pH with ethyl acetate. Contaminating benzoic acid was removed by extracting solid product mixtures with hot carbon tetrachloride (15). It was noticeable with leucine in particular that the product, Bz-L-Leu, mp 105–106°C, obtained using DIEA, crystallized readily, while that with mp 103–105°C, obtained using NaOH, crystallized with difficulty. The results of the analyses of the products appear in Table 1. It is seen that the four benzoylamino acids **3***f* prepared using DIEA contained no *N*-acyl dimer **5***f*, while the three products with $R^1 \neq H$ prepared using NaOH contained about 1% of **5***f*. Only in the case of the side-chain substituted derivative H-L-Lys(Z)-OH, which is notoriously insoluble in water, was the dimerization side reaction not completely eliminated but only suppressed, the amount of contaminant being reduced by two-thirds. The yields obtained by the two methods were comparable. Thus, the acylation of amino acids with benzoyl chloride in the presence of NaOH invariably leads to the production of a significant amount of benzoyldipeptide. The contaminant is not readily removed by crystallization of the benzoylamino acid. Use of DIEA instead of NaOH eliminates the formation of the side product during the benzoylation of amino acids. The method may find application in the acylation of amino acids, also with ring-substituted benzoyl chlorides. The results substantiate the proposition that the mixed anhydride **4***f* is not generated when the counterion to the benzoylamino acid anion is $DIEAH^+$. The phenomenon which obtains for *N*-benzoylamino acids in aqueous solution is thus the same as that which obtains

for *N*-alkoxycarbonylamino acids in dichloromethane (7). The validity of the original hypothesis also substantiates the notion that generation of mixed anhydride **4** is responsible for the formation of *N*-substituted dipeptide **5**. Generation of anhydride **4** by reaction of **3***a* with benzoyl chloride was the basis for the development of the mixed anhydride method of coupling in peptide synthesis (10).

Alkoxycarbonylation of amino acids in the presence of DIEA proved to be less straightforward than benzoylation. Varying success was achieved depending on the nature of R. Representative results appear in Table 1. Fmc-Leu was obtained free of Fmc-dipeptide when the solvent was aqueous DMF, but not when it was aqueous tetrahydrofuran. Fmc-Gly contained much less contaminant than when prepared by the conventional procedure (3), but still a significant amount. No general pattern could be discerned for the benzyloxycarbonylation reaction, other than that the yields were poor. *Z*-Asp was obtained purer using DIEA, but in other cases the organic base increased the amount of dimer. A similar situation obtained in the synthesis of Boc-amino acids using di-*tert*-butyl dicarbonate (**6***d*) for acylation, except that the yields were high. The amount of dimer was increased by DIEA for Boc-Val but reduced for Boc-Phe(Cl). However, the use of DIEA proved satisfactory for the preparation of Eoc- and Moc-amino acids. Dimer was completely absent in Eoc-Val and Eoc-Phe (16), and Moc-Val, Moc-Leu, and Moc-Phe (17, 18) prepared on frequent occasions, and the products were enantiomerically pure. Eoc-L-Val was obtained in crystalline form for the first time by this procedure. With respect to generation of dimer **5***e*, an unexpected observation is that in the presence of NaOH much more was generated when diethyl dicarbonate (**6***e*) was the acylating agent than when it was EtOCOCl. This is surprising but not inconsistent with the observation that **6***e* reacted more readily than **6***d* with anion **3***a* in dichloromethane (8). No dimer was generated when **6***e* was used in the presence of DIEA.

The present study emerged from the observation that no anhydride was formed from **1***a* and **3***a* in dichloromethane in the presence of DIEA (7). It was uncertain if the same phenomenon would obtain in other solvents. The results indicate that the course of events depends both on the nature of the acylating agent and the side chain of the amino acid in question. The initial observation seems to hold in aqueous solution for the reagents benzoyl chloride and ethyl chloroformate. Attempts to get consistent behaviour from Z-Cl by effecting the reactions in aqueous DMF or tetrahydrofuran proved unsuccessful. In addition, the yields of product **3***c* were poor, we suspect, because of destruction of the Z-Cl by the tertiary amine. Z-Cl is quickly decomposed in pyridine (personal observation). Fmc-Cl may undergo the same fate, but at a slower rate. Despite the moderate yield of Fmc-Leu obtained, its successful synthesis using Fmc-Cl with DIEA indicates that the method might be a viable alternative to the use of 9-fluorenyl succinimidyl carbonate (2, 3, 6) in some cases.

Experimental

Reference mixtures of **3***a* and **5***a* were prepared by reaction of **7***a* (11, 12) with **2** in aqueous DMF (5). Separation and quantitation were done by hplc (C_{18}-μBondapak column, isocratic elution, uv absorbance monitoring at 208 nm, or 215 nm for aromatics) as previously described (5). Analyses of products **3***f* and **5***f* were carried out in identical manner using hplc. Reference compounds **5***f* (50–70% yields) were prepared by reaction of **8***f* (14) with **2** in aqueous DMF, with the same work-up as described (5). Bz-Lys(Z)-Lys(Z)-OH could not be obtained this way because of the slight solubility of H-L-Lys(Z)-OH. It was obtained by saponification of Bz-Lys(Z)-Lys(Z)-OMe, which had been prepared by reaction of the oxazolone with H-Lys(Z)-OMe in dichloromethane. All products **5***f* (solids) were epimeric mixtures resulting from the use of racemic **8***f* or racemization of **8***f* during aminolysis. As example of purity, Bz-Leu-Leu contained 0.8% of Bz-Leu. The hplc data not appearing in ref. 5 are as follows (solvent; k' = capacity factor = $(t - t_0)/t_0$; R_s = resolution = $2(t_2 - t_1)/(w_1 + w_2)$): 11% CH_3CN, Bz-Gly 1.40, Bz-Gly-Gly 0.99, R_s 1.06; 17% CH_3CN, Bz-Ala 1.57, Bz-Ala-Ala 1.39, R_s 0.85; 50% CH_3CN, Bz-Leu 0.82, Bz-Leu-Leu 1.39, R_s 1.52; 50% CH_3CN, Bz-Phe 0.77, Bz-Phe-Phe 1.47, R_s 1.79; 50% CH_3CN, Bz-Lys(*Z*) 1.16, Bz-Lys(*Z*)-Lys(*Z*) 2.76; R_s 4.58; 40% CH_3OH, Eoc-Val 1.81, Eoc-Val-Val 2.83, R_s 3.07; 50% CH_3OH, Eoc-Phe 2.62, Eoc-Phe-Phe 6.20, R_s 7.0. Emergence from the column of **5***f* before **3***f*, for glycine and alanine, is consistent with the chromatographic behaviour of **5***a* and **3***a* (5).

N-Benzoyl- and N-ethoxycarbonyl-amino acids

To a vigorously stirred solution containing amino acid (10 mmol) and NaOH (10 mmol) in 30 mL of water at 0°C was added alternately in small portions during 30 min benzoyl chloride or ethyl chloroformate (11 mmol) and DIEA or 1 *N* NaOH (11 mmol). The cooling bath was removed, the mixture was stirred an additional 30 min, then cooled again and acidified to Congo red with 6 *N* HCl. The oil that separated was extracted into ethyl acetate, the extract was washed with 1 *N* HCl, dried ($MgSO_4$), and the solvent was removed with a rotary evaporator. For Bz-amino acids, the residue was triturated in boiling carbon tetrachloride (20 mL), the mixture was cooled to 23°C, and the Bz-amino acid was collected by filtration. Products were analyzed for dimer **5** content before any recrystallization. Eoc-amino acids were then recrystallized from ethyl acetate – light petroleum. Eoc-DL-Phe, mp 78–79°C; Eoc-L-Phe, mp 86–87°C, $[\alpha]_D^{22}$ +23.4° (*c* 2.0, ethanol); Eoc-L-Val, mp 37°C, $[\alpha]_D^{22}$ +1.8° (*c* 2.0, ethanol), lit. (12) oil.

Fmc- and Boc-amino acids

These were prepared as described above except that the inorganic base was Na_2CO_3, the solvent was 20 mL of tetrahydrofuran–water (1:1), or DMF–water (1:1), the acylating reagent was dissolved in 10 mL of the organic solvent, the mixture was stirred 1 h after removal of the ice bath, and 10% aqueous citric acid was used to acidify solutions of Boc-amino acids.

N,N-Dialkoxycarbonylamino acid formation from a mixed anhydride through intramolecular urethane acylation

FRANCIS M. F. CHEN AND N. LEO BENOITON

Department of Biochemistry, University of Ottawa, Ottawa, Ont., Canada K1H 8M5

Received August 22, 1986

FRANCIS M. F. CHEN and N. LEO BENOITON. Can. J. Chem. **65**, 1228 (1987).

Methoxycarbonylation at the urethane nitrogen of *N*-benzyloxycarbonyl- and *N*-methoxycarbonylvaline has been identified as a side reaction accompanying the aminolysis of the mixed anhydride formed from the acid and methyl chloroformate when the anhydride is coupled in aqueous dimethylformamide and the nucleophile is an amino acid anion. The side reaction occurs to a lesser but still significant extent when the activated residue is leucyl.

FRANCIS M. F. CHEN et N. LEO BENOITON. Can. J. Chem. **65**, 1228 (1987).

On a identifié la méthoxycarbonylation de l'azote de l'uréthane de la *N*-benzyloxycarbonyl- et de la *N*-méthoxycarbonylvaline comme une réaction secondaire accompagnant l'aminolyse de l'anhydride mixte qui se forme à partir de l'acide et du chloroformate de méthyle lorsqu'on effectue un couplage dans le diméthylformamide aqueux et que le nucléophile est un anion d'acide aminé. La réaction secondaire se produit aussi à des degrés qui ne sont pas négligeables, même si son importance est moindre, lorsque le résidu activé est la leucine.

Previous papers have reported the use of symmetrical anhydrides of *N*-alkoxycarbonyl amino acids **1** as reagents for preparing reference mixtures of monomer **1** and the *N*-alkoxycarbonyldipeptide (1) and for converting amino acid enantiomers into epimeric *N*-substituted dipeptides for the analysis of enantiomeric mixtures (2). The products are generated by reaction of the anhydride with the amino acid anion in aqueous dimethylformamide. Accompanying this peptide bond forming reaction, however, is a side reaction involving rearrangement of the symmetrical anhydride to give the *N,N'*-bisalkoxycarbonyldipeptide (3, 4). Our interest in mixed carboxylic acid – carbonic acid anhydrides **3** (5, 6) and their availability in pure form (7) prompted us to examine the reaction of **3** with the same nucleophile under identical conditions. To simplify the interpretation of nmr spectra, anhydride **3***a* with R^1 and R^2 = methyl was used at the start of the investigation. The identify of the side product emanating from the symmetrical anhydride was not known to us at the time. A completely novel rearrangement of the mixed anhydride was identified, and this reaction forms the subject of the present communication. The different but related side reaction of urethane acylation accompanying mixed anhydride couplings of *N*-protected glycine derivatives has been described (8–11).

Results and discussion

Moc-Val-O-COOMe[1] (**3***a*), prepared by the standard procedure in dichloromethane from Moc-Val-OH (**1***a*) and MeOCOCl (**2***a*) followed by aqueous washes (7), was left at room temperature in aqueous DMF containing $NaHCO_3$. Acidification of the mixture followed by extraction with ethyl acetate and removal of solvent gave a mixture of starting material **1***a* and a second product that was stable to aqueous acid and $NaHCO_3$. Removal of **1***a* by its crystallization led to a mixture containing only a small amount of **1***a*. The nmr curve of the mixture showed a major methoxy singlet peak at δ = 3.80 ppm compared with 3.69 ppm for the singlet of **1***a*. The ratio of methyl to isopropyl groups was close to 2. Mass spectrometric analysis indicated a molecular ion of 233 corresponding to the molecular weight of *N,N*-dimethoxycarbonylvaline (**4***a*). The amount isolated corresponded to a yield of 20%. It was apparent that the mixed anhydride underwent the same initial deprotonation of the urethane nitrogen as the symmetrical anhydride (4) followed by nucleophilic attack at the carbon atom of the carbonate moiety, i.e. **3** → **4**. Confirmatory evidence for this was obtained by using Z-Val-O-COOMe (**3***b*) as the starting anhydride. Catalytic hydrogenation of the acid fraction isolated after acidification of the reaction mixture gave a 13% yield of crystalline Moc-Val-OH. There is one report in the literature on the existence of *N,N*-dialkoxycarbonylamino acids, namely $(Boc)_2$-Gly-OCH_2Ph obtained by the reaction of Boc-Gly-OCH_2Ph with $(Boc)_2O$ in the presence of 4-dimethylaminopyridine (14).

The proton nmr spectrum of **4***a* is characterized by a sharp α-proton doublet indicating the absence of the N-H proton, and two well-separated doublets of the isopropyl methyl groups indicating a rigid molecule. The pattern is similar to that seen in the nmr curves of the 2-alkyl and 2-alkoxy-4-isopropyl-5(4*H*)-oxazolones derived from derivatives of valine (7, 12, 13), except that the integration of the peak corresponding to the 2-substituent is twice that of the peaks of the 4-substituent.

[1]Abbreviations: Boc, *tert*-butoxycarbonyl; Moc, methoxycarbonyl; Z, benzyloxycarbonyl. The symbols for the amino acid residues represent the L isomers.

The methoxy protons appeared as a singlet with a chemical shift (δ = 3.80 ppm) close to that observed for the protons of the methoxy group of —CO—N(OCOCH$_3$)—CHR— of *N*,*N*′-bismethoxycarbonylvalylvaline (3), both compounds being *N*,*N*-diacylamines. The same chemical shift was observed for the methoxy protons in *N*-Z,*N*-Moc-Val-OH (**4***b*) (not obtained pure), the PhCH$_2$O protons at δ = 5.22 ppm showing a similar downfield displacement compared with those at 5.08 ppm in Z-Val-OH (**1***b*).

Initial attempts to gain further insight into the reaction involved studies on the reaction of Z-Val-O-COOMe and Boc-Val-O-COOMe (**3***c*) with the sodium salt of valine under various conditions. Deprotection of the products led to unusually high yields (15–20%) of Moc-Val-OH, but it was realized that aminolysis at the carbonate moiety of the anhydride (7) could account for some of the product. Meaningful results were then obtained using a different nucleophile. Z-Val-O-COOMe was reacted at 23°C with an equivalent of phenylalanine in DMF–H$_2$O (3:1) containing an equivalent of NaHCO$_3$. Hydrogenolysis of the acidic fraction gave a mixture of Moc-Val-OH (6%) originating from rearrangement of the anhydride, and Moc-Phe-OH (12%) originating from aminolysis at the carbonate moiety of the anhydride. The same experiment in tetrahydrofuran gave no Moc-Val-OH and 18% of Moc-Phe-OH, while an experiment using Na$_2$CO$_3$ instead of NaHCO$_3$ gave 2% of Moc-Val-OH and 22% of Moc-Phe-OH. A similar experiment with Z-Leu-O-COOMe in DMF (NaHCO$_3$) gave 0.5% of Moc-Leu-OH and 6% of Moc-Phe-OH. Experiments with Boc-Val-O-COOMe, Z-Val-O-COOEt, and Z-Val-O-COOiBu with appropriate deprotection of the products yielded only traces of the corresponding R^{1}OCO-Val-OH derivatives with R^1 = Me, Et, iBu respectively. Reaction of Z-Val-O-COOMe with H-Phe-OCH$_2$Ph in DMF at 23°C followed by acidification and hydrogenation of the ethyl acetate-soluble fraction gave no Moc-Val-OH (<0.5%) and 5% of Moc-Phe-OH. Finally, coupling of Z-Val-OH with H-Phe-OCH$_2$Ph by the conventional mixed-anhydride procedure, using MeOCOCl and *N*-methylpiperidine in tetrahydrofuran at −5°C followed by the same work-up, gave no detectable amount of Moc-Val-OH. We conclude that the side reaction of rearrangement of anhydride **3** to *N*,*N*-dialkoxycarbonylamino acid **4** occurs only in aqueous DMF when R^2 is methyl and R^1 is benzyl or methyl (R^1 = ethyl was not examined), and furthermore only when the nucleophile is the amino acid anion. The reaction does not occur when R^1 = *tert*-butyl and R^2 = ethyl or isobutyl. Ten times as much side product is formed when R = isopropyl (of valine) than when R = isobutyl (of leucine). On this basis, amongst the other amino acids, only when R = *sec*-butyl (of isoleucine) is a significant amount of the side product to be expected.

With respect to the formation of side product by aminolysis at the carbonate moiety of a mixed anhydride, it is possible to conclude that the amounts are greater when the reation is carried out in aqueous solvents with the amino acid anion as the nucleophile (12% of Moc-Phe-OH from **3***a* and H-Phe-O$^-$) than when the reaction is carried out in anhydrous solvents with the amino acid ester as the nucleophile (5% of Moc-Phe-OH from **3***a* and H-Phe-OCH$_2$Ph).

Experimental

The source of reagents and the general methods of operation were as previously described (7). Proton nmr spectra were determined in deuterochloroform using a Varian EM-360 60-MHz instrument. Chemical shifts are given in ppm relative to Me$_4$Si as internal standard. Mixed anhydrides **3** were obtained as described (7), and used immediately. Moc-Val-OH, mp 109–110°C, $[\alpha]_D^{22}$ +0.6° (*c* 2.0, ethanol), was prepared by a modified Schotten–Baumann procedure using MeOCOCl and diisopropylethylamine (15).

*Preparation of (Moc)$_2$-Val-OH (**4**a)*

A solution of Moc-Val-O-COOMe (309 mg; 1 mmol) in 6 mL of DMF was added to 2 mL of water containing NaHCO$_3$ (1 mmol) and the mixture was stirred at 23°C for 30 min. The solution was acidified with 1 *N* HCl and extracted with ethyl acetate (10 mL × 2), the extract was dried (MgSO$_4$), and the solvent was removed with a rotary evaporator. The residue contained (nmr) **4***a* and Moc-Val-OH (**1***a*) in ratio of 1:3. The mixture was dissolved in ethyl acetate to which was added light petroleum. The crystals of Moc-Val-OH were removed by filtration, and the crystallization was repeated three times. The residue (oil) remaining after removal of the solvent contained **4***a* contaminated with 5% of **1***a*; nmr of **4***a* (δ, ppm): 0.87 (3H, d, *J* = 7 Hz), 1.17 (3H, d, *J* = 7 Hz), 2.50 (1H, m), 3.80 (6H, s), 4.63 (1H, d, *J* = 9 Hz); ms *m*/*e*: 233 (M$^+$).

Aminolysis reactions

Z-Val-O-COOMe (**3***b*) (1 mmol) in 9 mL of DMF was added to a solution containing phenylalanine (1 mmol) and NaHCO$_3$ (1 mmol) in 3 mL of water and the mixture was stirred at 23°C for 1 h. The solution was acidified and extracted with ethyl acetate (10 mL × 2), the extract was dried, and the solvent was removed by evaporation. The residue was dissolved in 15 mL of 95% ethanol containing 1 mL of acetic acid and the mixture was hydrogenated over 10% palladium-on-charcoal for 16 h. The mixture was filtered, the filtrate was concentrated to a small volume, dichloromethane (20 mL) was added, and the solution was extracted with 10 mL of 1 *N* HCl. The organic layer was dried, the solvent was removed, and the residue was weighed and examined by nmr spectroscopy to determine the ratio of Moc-Val-OH to Moc-Phe-OH.

Introduction

There is now a great deal of interest in the field of low coordinated species of groups 13, 14, and 15 (1). Some doubly-bonded molecules of silicon, germanium, and tin have been recently prepared, but many more doubly-bonded phosphorus compounds are known. Among doubly-bonded boron compounds are those with nitrogen (2), carbon (3), and oxygen (4), though the last ones have been identified only by trapping reactions.

Simultaneous with us, Cowley's group has characterized by mass spectroscopy the phosphaborene **1** formed by thermolysis of diphosphadiboretane **3** at 250°C (5).

We present here a chemical characterization of phosphaborene **1** by trapping reactions on lithio compounds.

Experimental

Syntheses were performed under an atmosphere of dry nitrogen using standard Schlenk and high-vacuum line techniques. Solvents were dried by distillation from sodium benzophenone ketyl immediately prior to use. ^{1}H nmr spectra (reference TMS) were recorded on a Varian EM 360 A at 60 MHz. ^{11}B (reference $BF_3 \cdot OEt_2$) and ^{31}P (reference 85% H_3PO_4) nmr spectra were recorded on a Bruker WH 90, respectively, at 28.88 and 36.44 MHz. Nuclear magnetic resonance spectra were measured on samples in C_6D_6 solution. Infrared spectra were recorded on a Perkin Elmer 457 grating spectrometer. Mass spectra were measured on a Varian MAT 311 A spectrometer (EI). Experimental molecular peak patterns were assigned after comparison with theoretical peak patterns calculated on a Tektronics 4051. Melting points were determined on a Reichert apparatus and are uncorrected. Elemental analyses were done by the "Service de Microanalyse de l'ENSCT" Toulouse.

Synthesis of chloroborylphosphine 2

Equimolar quantities of dichloro-2,2,6,6-tetramethylpiperidinoborane $RBCl_2$ (5.20 g, 0.023 mol) and 2,4,6-tri-*tert*-butylphenyllithiophosphide ArP(H)Li (prepared from 6.39 g (0.023 mol) of $ArPH_2$ and 14.4 mL (0.023 mol) of a solution of *n*-butyllithium in hexane (1.6 *N*)), were allowed to react in Et_2O (50 mL) at 0°C for half an hour before warming to 25°C. After the mixture was stirred for an hour at room temperature, solvents were removed *in vacuo* and crude **2** was recrystallized from pentane as white crystals (7.67 g, yield: 72%, mp 155–156°C). nmr: ^{1}H: 1.25 (s, 12H, CH_3(R)), 1.50–1.60 (m, 6H, CH_2), 1.66 (s, 9H, *p*-*t*Bu), 1.83 (s, 18H, *o*-*t*Bu), 4.23 (d, $^1J_{P-H}$ = 229 Hz, 1H, PH), 7.70 (d, $^4J_{P-H}$ = 2.0 Hz, 2H, arom H). ^{11}B: +47.6, ^{31}P: −98.7, $^1J_{P-H}$ = 229 Hz. Mass spectrometry (EI) *m/e*: 463 (M^+).

Addition of tert-*butyllithium to 2 (reaction* a*)*

To a solution of **2** (5.09 g, 0.011 mol) in THF (30 mL) cooled at −78°C was slowly added via syringe a solution of *tert*-butyllithium in pentane (1.7 *N*, 12.9 mL, 0.022 mol). A red coloration appeared immediately. The reaction mixture was allowed to warm to room temperature; ^{31}P nmr analysis showed the formation of **3** and **4** in the ratio 30/70. After elimination of solvents *in vacuo*, a selective recrystallization from pentane afforded 0.99 g (yield: 21%) of yellow–green crystals of **3** (mp: 164–165°C) ^{31}P nmr −92.8. Mass spectrometry (EI) *m/e*: 854 (M^+, 5%); 740 ($(M - 2tBu)^+$, 15%); 427 ($M^+/2$, 70%); 370 ($(M/2 - tBu)^+$, 100%). *Anal.* calcd. for $C_{54}H_{94}B_2N_2P_2$: C 75.86, H 11.08, N 3.28; found: C 75.80, H 10.81, N 3.54.

Addition of 2 to tert-*butyllithium (reaction* a′*)*

To a solution of *tert*-butyllithium in pentane (1.7 *N*, 6.5 mL, 0.011 mol) and THF (30 mL) at −78°C was added a solution of **2** (2.54 g, 0.0055 mol) in THF (20 mL). ^{31}P nmr analysis (see Results and discussion) after warming to room temperature showed the nearly quantitative formation of **4**.

Synthesis of 5 and 6 from 4

In a typical experiment, to a solution of **4** (0.005 mol) prepared according to reaction *a′*, was added a solution of equimolar quantities of methanol, methyl iodide, or trimethylchlorosilane, respectively, in THF at room temperature. After removal of lithio salts and solvents **5**, **6***a*, and **6***b* were crystallized from pentane.

5: yellow–green crystals, mp 102–103°C, 2.06 g, yield: 85%; nmr: ^{1}H: 0.83 (broad s, 9H, *t*BuB), 1.33 (s, 9H, *p*-*t*Bu), 1.37–1.57 (m, 18H, CH_3(R), and CH_2), 1.67 (s, 18H, *o*-*t*Bu), 5.37 (d, $^1J_{P-H}$: 320 Hz, 1H, PH), 7.50 (d, $^4J_{P-H}$: 2.2 Hz, 2H, arom H). ^{11}B: +46.2,

^{31}P: −51.1 ($^{1}J_{PH}$ = 320 Hz), ir (KBr disc) ν(PH): 2407 cm^{-1}. Mass spectrometry (EI) m/e: 485 (M^+). *Anal.* calcd. for $C_{31}H_{57}BNP$: C 76.67, H 11.83, N 2.88; found: C 76.16, H 11.46, N 3.05.

6*a*: yellow–green crystals, mp 147–148°C, 2.02 g, yield: 81%; nmr: ^{1}H: 0.83 (d, $^{4}J_{P-H}$ = 1.2 Hz, 9H, *t*BuB), 1.33 (s, 9H, *p*-*t*Bu), 1.13–1.53 (m, 6H, CH_2), 1.47 (s, 12H, CH_3(R)), 1.67 (s, 18H, *o*-*t*Bu), 2.17 (d, $^{2}J_{P-H}$ = 12.0 Hz, 3H, CH_3—P), 7.57 (d, $^{4}J_{P-H}$ = 2.3 Hz, 2H, arom, H). ^{11}B: +58; ^{31}P: −14.6; mass spectrometry (EI) m/e: 499 (M^+). *Anal.* calcd. for $C_{32}H_{59}BNP$: C 76.92, H 11.90, N 2.80; found: C 76.68, H 12.01, N 3.04.

6*b*: yellow–green crystals, mp 152–153°C, 2.17 g, yield: 78%; nmr: ^{1}H: 0.53 (d, $^{3}J_{P-H}$ = 6.0 Hz, 9H, CH_3Si), 1.10 (d, $^{4}J_{P-H}$: 1.0 Hz, 9H, *t*BuB), 1.33 (s, 9H, *p*-*t*Bu), 1.20–1.66 (m, 6H, CH_2), 1.53 (s, 6H, CH_3(R)), 1.60 (s, 6H, CH_3(R)), 1.83 (s, 18H, *o*-*t*Bu), 7.67 (d, $^{4}J_{P-H}$ = 2.6 Hz, 2H, arom H). ^{11}B: +62; ^{31}P: −23.9; mass spectrometry (EI) m/e: 557 (M^+). *Anal.* calcd. for $C_{34}H_{65}BNPSi$: C 73.21, H 11.75, N 2.51; found: C 72.98, H 11.60, N 2.67.

Results and discussion

Chloroborylphosphine **2**,[1] the precursor of **1**, was synthesized (reaction [1]) by the reaction of dichloro-2,2,6,6-tetramethylpiperidinoborane with 2,4,6-tri-*tert*-butylphenyllithiophosphide in pentane or diethylether:

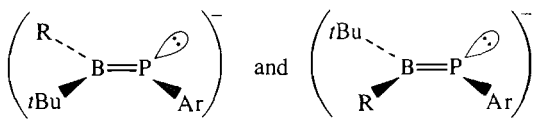
[1] $RBCl_2 + ArP(H)Li \xrightarrow[-LiCl]{} R—B(Cl)—P(H)—Ar$ **2**

R = 
Ar = 
Addition of *tert*-butyllithium[2] to **2** at −78°C in THF (reaction [2], path *a*) resulted in an immediate red coloration; room temperature ^{31}P nmr measurements showed the formation of **3** and **4** in the ratio 30/70. The last two products probably result from the phosphaborene intermediate **1** which either dimerizes to give **3**, or reacts with *tert*-butyllithium to afford **4**. The formation of phosphaborene **1** seems to be confirmed by the "reverse" reaction *a'* in which **2** is added to an excess of *tert*-butyllithium, this producing compound **4** exclusively. Here **1** is quantitatively trapped by *tert*-butyllithium prior to dimerization:

[2] 
The formation of **4** could also be explained by an alkylation of **5** (route *b*). However, the complete absence of **5** in reaction *a* and of **3** in the "reverse" reaction *a'* (**3** does not react with *t*BuLi) support route *a*. It should be noted that Cowley's group has reacted **2** with *t*BuLi in Et_2O at 25°C but obtained exclusively **4**. In this case, due to the absence of **3**, the intermediate formation of **1** was not evidenced in this reaction.

In mass spectral measurements of **3** at 200°C, we also observed an intense peak at 427, attributable to the phosphaborene **1**. Heterocycles such as 2,4-diphospha-1,3-diboretane **3**, are rare (6).

Compound **4** is extremely air-sensitive and is characterized by ^{31}P nmr and its chemical reactivity. The ^{31}P spectrum immediately after the reaction generates two signals at +84 (90%) and +82 ppm (10%), indicating deshielded phosphorus atoms. Chemical shifts of lithiophosphides are generally at high field, e.g. at −109 ppm for ArP(H)Li and at −151 ppm for $ArP(SiMe_3)Li$ in THF (7) and so we postulate that one electron pair on phosphorus is involved in multiple bonding to boron in **4**. From our data, further support for this is the presence of two ^{31}P signals, that result probably from the existence of the two geometric isomers:



At about the same time as we did our experiments, Power's group obtained, from the reaction between *tert*-butyllithium and $Mes_2BP(H)R$ (R = Ph, C_6H_{11}, mesityl) in Et_2O, the derivatives $Mes_2BP(R)Li(Et_2O)_2$ (8); as demonstrated by X-ray studies of these compounds, bond distances are consistent with a high degree of BP double bond character.

Compound **4** reacts very easily with protic reagents such as water, and methanol, to afford **5**,[3] and with alkyl halides such as methyl iodide or trimethylchlorosilane to give quantitatively **6**:

[1]Compound **2** has been prepared by Cowley's group but only ^{31}P nmr and mass spectroscopy data are given (5).

[2]An attempt to remove HCl from **2** with other basic reagents such as Et_3N failed.

[3]Compound **5** was mentioned in the recent communication from Cowley's group but the physico-chemical data were not presented (5).

ipso Nitration. XXIX.[1] Nitration of substituted 4-methylanisoles and phenols

ALFRED FISCHER,[2] GEORGE N. HENDERSON, AND SUMIT RAYMAHASAY
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received November 11, 1986

ALFRED FISCHER, GEORGE N. HENDERSON, and SUMIT RAYMAHASAY. Can. J. Chem. **65**, 1233 (1987).

Nitration of 2-chloro-4-methylanisole (**1***a*) in acetic anhydride gives (*Z*)-4-chloro-3-methoxy-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**2***a*), 2-chloro-4-methyl-4-nitrocyclohexa-2,5-dienone (**3***a*), and 2-chloro-4-methyl-6-nitroanisole (**4***a*). Similarly 2-bromo-4-methylanisole (**1***b*) gives (*Z*)-4-bromo-3-methoxy-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**2***b*), 2-bromo-4-methyl-4-nitrocyclohexa-2,5-dienone (**3***b*), and 2-bromo-4-methyl-6-nitroanisole (**4***b*), whereas 4-methyl-2-nitroanisole (**1***c*) gives (*Z*)-3-methoxy-6-methyl-4,6-dinitrocyclohexa-2,4-dienyl acetate (**2***c*), (*Z*)-3-methoxy-6-methyl-2,6-dinitrocyclohexa-2,4-dienyl acetate (**7**), and 4-methyl-2,6-dinitroanisole (**4***c*). Nitration of 3-chloro-4-methylanisole (**9***a*) gives 3-chloro-4-methyl-4-nitrocyclohexa-2,5-dienone (**10***a*), 3-chloro-4-methyl-2-nitro anisole (**11***a*), and 5-chloro-4-methyl-2-nitroanisole (**12***a*), and 4-methyl-3-nitroanisole (**9***c*) gives (*Z*)-3-methoxy-6-methyl-5,6-dinitrocyclohexa-2,4-dienyl acetate (**13**), 4-methyl-2,3-dinitroanisole (**11***c*), and 4-methyl-2,5-dinitroanisole (**12***c*). Nitration of 2-chloro-4-methylphenol (**14**) in chloroform gives **3***a* and 2-chloro-4-methyl-6-nitrophenol (**5***a*), and 3-chloro-4-methylphenol (**15**) gives dienone **10***a*, 3-chloro-4-methyl-2-nitrophenol (**16**), and 5-chloro-4-methyl-2-nitrophenol (**17**).

ALFRED FISCHER, GEORGE N. HENDERSON et SUMIT RAYMAHASAY. Can. J. Chem. **65**, 1233 (1987).

La nitration du chloro-2 méthyl-4 anisole (**1***a*), dans l'anhydride acétique, conduit à l'acétate du chloro-4 méthoxy-3 méthyl-6 nitro-6 cyclohexadiène-2,4 yle-(*Z*) (**2***a*), à la chloro-2 méthyl-4 nitro-4 cyclohexadiène-2,5 one (**3***a*) et au chloro-2 méthyl-4 nitro-6 anisole (**4***a*). De la même manière, le bromo-2 méthyl-4 anisole (**1***b*) conduit à l'acétate du bromo-4 méthoxy-3 méthyl-6 nitro-6 cyclohexadiène-2,4 yle-(*Z*) (**2***b*), à la bromo-2 méthyl-4 nitro-4 cyclohexadiène-2,5 one (**3***b*) et au bromo-2 méthyl-4 nitro-6 anisole (**4***b*) alors que le méthyl-4 nitro-2 anisole (**1***c*) conduit à l'acétate du méthoxy-3 méthyl-6 dinitro-4,6 cyclohexadiène-2,4 yle-(*Z*) (**2***c*), à l'acétate du méthoxy-3 méthyl-6 dinitro-2,6 cyclohexadiène-2,4 yle-(*Z*) (**7**) et au méthyl-4 dinitro-2,6 anisole (**4***c*). La nitration du chloro-3 méthyl-4 anisole (**9***a*) fournit la chloro-3 méthyl-4 nitro-4 cyclohexadiène-2,5 one (**10***a*), le chloro-3 méthyl-4 nitro-2 anisole (**11***a*) et le chloro-5 méthyl-4 nitro-2 anisole (**12***a*) et celle du méthyl-4 nitro-3 anisole (**9***c*) fournit l'acétate du méthoxy-3 méthyl-6 dinitro-5,6 cyclohexadiène-2,4 yle-(*Z*) (**13**), le méthyl-4 dinitro-2,3 anisole (**11***c*) et le méthyl-4 dinitro-2,5 anisole (**12***c*). La nitration du chloro-2 méthyl-4 phénol (**14**), dans le chloroforme, conduit au composé **3***a* accompagné de chloro-2 méthyl-4 nitro-6 phénol (**5***a*) alors que celle du chloro-3 méthyl-4 phénol (**15**) conduit à la dienone **10***a* accompagnée de chloro-3 méthyl-4 nitro-2 phénol (**16**) et de chloro-5 méthyl-4 nitro-2 phénol (**17**).

The nitration of 4-acetamido-, 4-bromo-, 4-chloro-, and 4-methoxy-toluene in acetic anhydride gives in each case, in addition to the nitro substitution product(s), a *cis* 1,2 nitronium acetate adduct (1, 2). Nitration of 4-fluorotoluene and of 4-*tert*-butyltoluene gives, in both cases, a pair of diastereomeric 1,4 nitronium acetate adducts and the *cis* 1,2 adduct (1, 3), whereas the nitration of other 4-alkyltoluenes gives, in addition to the nitro substitution products, only the diastereoisomeric 1,4 adducts (4–6). The extent of *ipso* nitration is explicable in terms of the relative activation of *ipso* and unsubstituted positions towards the electrophile (7). The factors that determine the addition of acetate to the *ortho* versus the *para* position of the *ipso*-nitrocyclohexadienyl cation are yet to be elucidated. The present study of nitration of substituted 4-methoxytoluenes represents an attempt to determine how the additional substituent affects the preferred position of addition of acetic acid to the *ipso* cation. We have also investigated the nitration of some related substituted 4-hydroxytoluenes.

Results and discussion

For each substrate, conditions were employed which led to the optimum yield(s) of adduct(s) and which were determined by carrying out preliminary reactions on a 0.5-mmol scale and following the reactions by nuclear magnetic resonance spectroscopy (^{1}H nmr). Products and their yields are shown in Scheme 1. Generally, the products consisted of dienes and (or) dienones formed by addition of nitronium ion *ipso* to the methyl group together with the nitro substitution derivative(s) of the substrates. Some secondary products were obtained in the course of work-up of the reaction mixtures and these are described below.

2-Chloro-4-methylanisole (**1***a*) was nitrated at −40°C. The ^{1}H nmr spectrum of the reaction mixture indicated the presence of (*Z*)-4-chloro-3-methoxy-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**2***a*), 2-chloro-4-methyl-4-nitrocyclohexa-2,5-dienone (**3***a*), and 2-chloro-4-methyl-6-nitroanisole (**4***a*). After low temperature work-up, diene **2***a* separated out as a solid during evaporation of the solvent. The ^{1}H nmr spectrum of the remaining mixture indicated that dienone **3***a* had disappeared and that 2-chloro-4-methyl-6-nitrophenol (**5***a*) and 2-chloro-4-methyl-4-nitrocyclohexa-2,5-dienone dimethyl ketal (**6***a*) had been formed.

A mixture of (*Z*)-4-bromo-3-methoxy-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**2***b*), 2-bromo-4-methyl-4-nitrocyclohexa-2,5-dienone (**3***b*), and 2-bromo-4-methyl-6-nitroanisole (**4***b*) was obtained on nitration of 2-bromo-4-methylanisole (**1***b*) at −40°C. The dienone rearranged during the low temperature work-up with ammonium hydroxide and the 2-bromo-4-methyl-6-nitrophenol (**5***b*) thus formed was partially removed in the basic solution. Pure diene **2***b* was obtained by crystallization.

(*Z*)-3-Methoxy-6-methyl-4,6-dinitrocyclohexa-2,4-dienyl acetate (**2***c*), (*Z*)-3-methoxy-6-methyl-2,6-dinitrocyclohexa-2,4-dienyl acetate (**7**), and 4-methyl-2,6-dinitroanisole (**4***c*) were formed on nitration of 4-methyl-2-nitroanisole (**1***c*) in acetic anhydride at 0°C. Diene **7** was precipitated by pouring the reaction mixture into ether at −78°C. After neutralization of the filtrate with ammonium hydroxide, diene **2***c* crystallized from the ethereal solution. When the nitration was carried out in mixtures of acetic anhydride and trifluoroacetic anhydride,

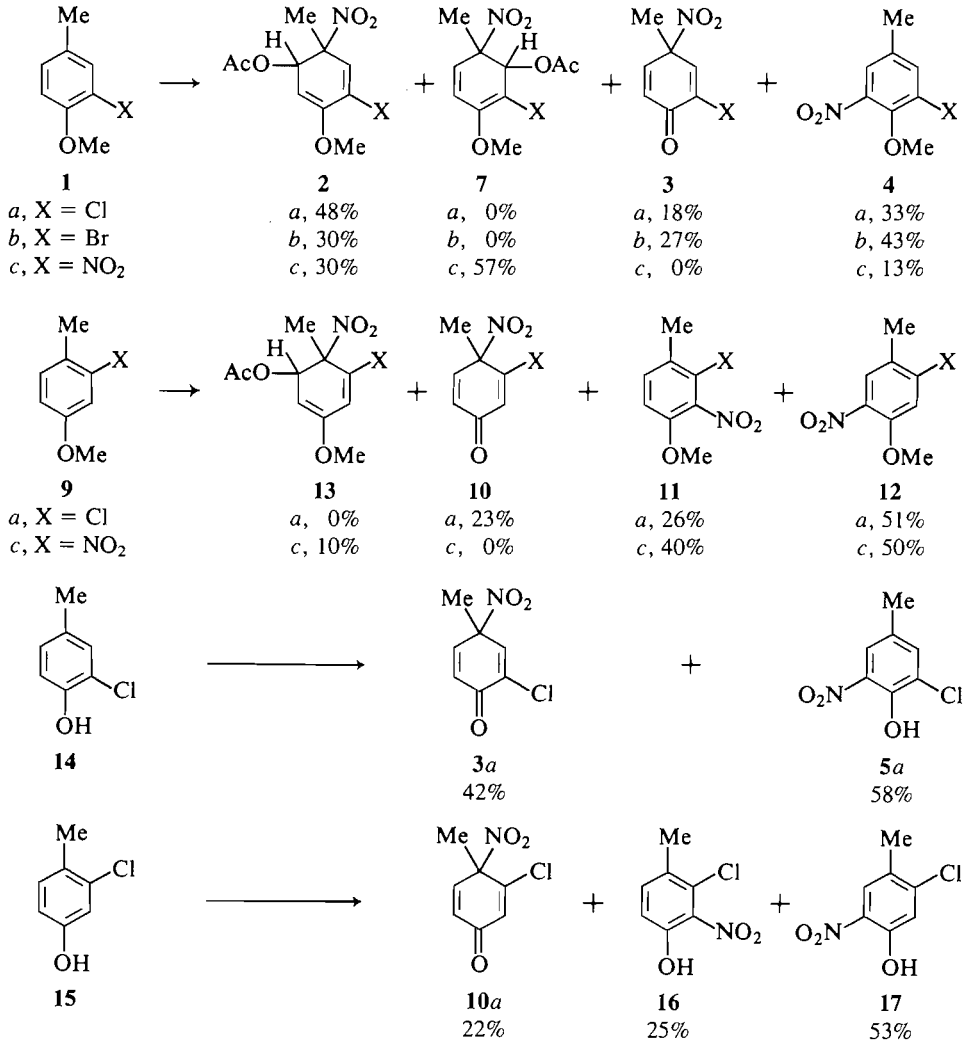

SCHEME 1

minor amounts of (*E*)-3-methoxy-6-methyl-2,6-dinitrocyclohexa-2,4-dienyl acetate ((*E*)-**7**) and 1-methoxy-4-methyl-2,4,6-trinitrocyclohex-2-enyl-1,5-diacetate (**8**) were formed in addition to the other products, and were isolated. 4-Methyl-2,4-dinitrocyclohexa-2,5-dienone dimethyl ketal (**6***c*), which was not present in the original mixture, was also obtained after chromatography.

8

Nitration of 3-chloro-4-methylanisole (**9***a*) at temperatures ranging from −60 to −40°C, with varying molar proportions of nitric acid and acetic anhydride, gave mixtures containing 3-chloro-4-methyl-4-nitrocyclohexa-2,5-dienone(**10***a*),3-chloro-4-methyl-2-nitroanisole (**11***a*), and 5-chloro-4-methyl-2-nitroanisole (**12***a*). Formation of diene was not detected.

Heterogeneous mixtures were invariably obtained on addition of 4-methyl-3-nitroanisole (**9***c*) to nitrating solutions and it was difficult to obtain homogeneous solutions for ^{1}H nmr, even after further dilution with acetic anhydride. (*Z*)-3-Methoxy-6-methyl-5,6-dinitrocyclohexa-2,4-dienyl acetate (**13**), 4-methyl-2,3-dinitroanisole (**11***c*), and 4-methyl-2,5-dinitroanisole (**12***c*) were present in the reaction mixture, although diene **13** could not be detected after low temperature work-up with ammonium hydroxide. Diene **13** evidently decomposed to 3,4-dinitro-4-methylcyclohexa-2,5-dienone (**10***c*) since some of this compound could be detected by ^{1}H nmr after work-up.

Nitration of 2-chloro-4-methylphenol (**14**) in acetic anhydride at −45°C gave dienone **3***a* and nitrocresol **5***a*. On work-up with ammonium hydroxide, followed by filtration of the ether solution of the product through basic alumina at −78°C, and removal of the solvent at −50°C, pure **3***a* was obtained. A solution of **3***a* in chloroform rearranged to **5***a*, with a half-life of 20 min at 0°C and 5 min at ambient temperature.

Nitration of 3-chloro-4-methylphenol (**15**) in chloroform at −60°C gave dienone **10***a*, 3-chloro-4-methyl-2-nitrophenol (**16**), and 5-chloro-4-methyl-2-nitrophenol (**17**). Pure **10***a* was separated by chromatography on alumina at −78°C. In chloroform-*d*, at 0°C, dienone **10***a* rearranged to an equimolar mixture of **16** and **17**, with a half-life of 10 min.

Structure and spectra of the adducts

The infrared spectrum of diene **2***a* exhibits characteristic peaks of nitro (1540 cm^{-1}) and acetate (1735 cm^{-1}) groups. The elemental analysis corresponds to the empirical formula of

[a]From ref. 1.

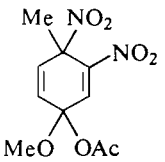
the adduct of **1***a* and acetyl nitrate. The close similarity between the nmr spectra, both ^{1}H (Table 1) and ^{13}C (Table 2), of (*Z*)-3-methoxy-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**2***d*) and **2***a*, with the expected differences resulting from the presence of the 4-chloro substituent in **2***a*, allows the assignment of the structure of the latter. In particular, the 71.2-ppm peak in the ^{13}C nmr spectrum characteristic of the sp^3 carbon $CMeNO_2$ is within 0.5 ppm of the similar peak in **2***d*. The high field vinyl carbon (91.1 ppm) has an attached hydrogen and must be adjacent to the methoxyl-substituted carbon (152.4 ppm). The chlorine substituent must be attached to the carbon at 127.6 ppm, since this carbon shows no strong coupling to hydrogen in the gated spectrum. In the proton spectrum the methine hydrogen is at 5.6 ppm, as in **2***d*. The hydrogen vinylic to the methoxy substituent is at the expected high field (5.12 ppm in **2***a*, cf. 4.97 ppm in **2***d*) and shows the appropriate 6.5-Hz splitting with the methine proton. The chlorine must be attached to the 4,5 double bond since the 10-Hz splitting present in **2***d* is absent in **2***a*. The 1.85-Hz splitting of the methine proton must reflect a 1,5 coupling and this confirms that chlorine is at the 4 position. Parallel arguments can be made to assign the 4-bromo-3-methoxy-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate structure (**2***b*) to the diene obtained on nitration of **1***b*.

The empirical formula of the two major dienes, **2***c* and **7**, and the minor diene, obtained from anisole **1***c*, is, in each case, $C_{10}H_{12}N_2O_7$, accounted for by the addition of one acetyl nitrate molecule. The ir spectra of these dienes confirmed the presence of acetate and nitro groups. The ^{1}H and ^{13}C nmr spectra of **2***c* are closely similar to those of dienes **2***a* and **2***b* with an essentially identical splitting pattern. In the assigned structure the 4-halo substituent of **2***a* and **2***b* is replaced by nitro, explaining the spectral similarity. The largest difference between the ^{13}C spectra of **2***a* and **2***c* is the 18-ppm downfield shift of C-4 in the latter. This is accounted for by the greater substituent shift effect of the nitro (attached to C-4) than that of chlorine (8). In the ^{1}H nmr spectra the 5-H is 0.6 ppm further downfield in **2***c* than in **2***a* and this is explained by the β-substituent effect of the nitro group attached at the other end of the 4,5 double bond. The general similarity of the ^{13}C nmr spectra of **2***c* and its isomers suggests that the structures are closely related. The most striking difference between the spectra is that the very high field vinyl carbon absorption, which appears close to 90 ppm in **2***d* and its 4-chloro, 4-bromo, and 4-nitro derivatives **2***a*, **2***b*, and **2***c*, respectively, and which is assigned to C-2, is absent in the isomers, for which the highest field sp^2 carbon (in the major isomer) is at 117 ppm. This implies that the nitro group in **7** is at C-2 and this is confirmed by the ^{1}H spectra, which show the 10-Hz splitting of adjacent vinyl protons (4-H and 5-H), also present in **2***d* but not present in the 4-substituted derivatives. Thus, there are no substituents on C-4 and C-5 in **7**, consistent with the location of the nitro group at C-2. Further confirmation is provided by the downfield shift of the adjacent methine proton (1-H). In the series of compounds in which C-2 is not substituted, this proton is consistently close to 5.6 ppm. Hence **7** has the 3-methoxy-6-methyl-2,6-dinitrocyclohexa-2,4-dienyl acetate structure. The ring protons of **7** are readily assigned since the 10-Hz coupling identifies the 4,5-vinylic pair and the 2-Hz splitting present in 1-H is also present in 5-H. In the ^{13}C nmr spectrum of the major isomer, C-1 (70.4 ppm), C-3 (155.9 ppm), and C-6 (88.9 ppm) have the chemical shifts and presence or absence of proton coupling appropriate for their substitution patterns. The C-2 signal (123.7 ppm) is readily identified as the remaining substituted vinyl carbon. The signals of the unsubstituted vinyl carbons C-4 (117.2 ppm) and C-5 (138.3 ppm) are assigned on the basis that the C-5 carbon is downfield, as in **2***d*. The nitro group conjugated with the diene system results in an additional downfield shift (9 ppm) of C-5,

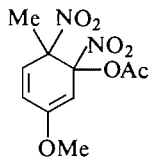
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

whereas C-4 is moved upfield (5 ppm). The minor isomer has ^1H and ^{13}C nmr spectra that are closely similar to those of the major isomer: they are diastereomers. *Syn* 1,2 addition of acetyl nitrate appears to be preferred over *anti* addition (1,2) and thus the major isomer (the only isomer obtained in acetic anhydride) is assigned as the (*Z*) isomer and the minor isomer is (*E*)-**7**. The dienes **2***a*, **2***b*, and **2***c*, of which only one diastereoisomer was obtained, are assigned the (*Z*) configuration.

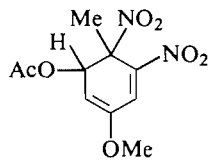
Diene **13** was characterized on the basis of its ^1H nmr spectrum. The cyclohexadienyl cation formed by attack by nitronium ion *ipso* to the methyl group can lead to three possible regioisomeric adducts **13***x*, **13***y*, and **13***z*. Structures 13*x* and



13*x*



13*y*



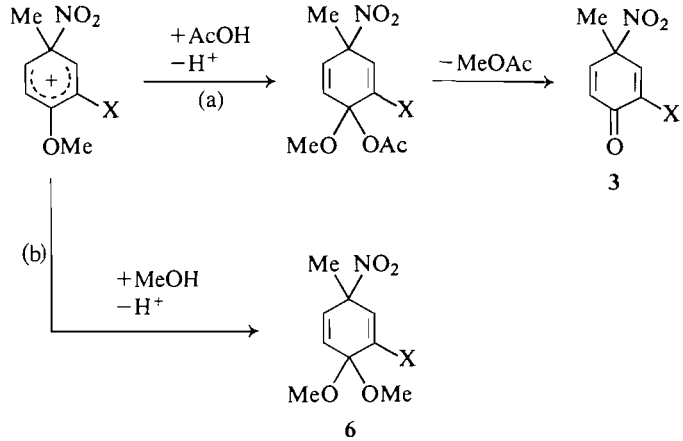
13*z*

13*y* have adjacent vinylic protons and their ^1H spectrum would exhibit a 10-Hz coupling that is not present in the spectrum of **13**. Thus **13** has the structure **13***z*. The 6.5-Hz coupling between protons at 5.32 and 5.58 ppm indicates that these are protons 2 and 1 with the 5.32-ppm assignment being confirmed as 2-H by the 1.5-Hz 2,4-coupling. The 1-H signal is at the 5.6-ppm position, characteristic of the 1-protons in dienes **2***a*, **2***b*, **2***c*, and **2***d*, which have the identical substitution pattern at each of C-2, C-3, and C-6. The 4-H is shifted downfield, as compared with the 4-H proton of **2***d*, by the vinylic nitro substituent.

Dienone **3***a* was characterized by its ^1H nmr and ^{13}C nmr spectra. The spectra of 4-methyl-4-nitrocyclohexa-2,5-dienone are known (9, 10) and the changes in the spectra of **3***a* are those that would be predicted from the introduction of the 2-chloro substituent. In the ^1H nmr spectrum there are three well-separated signals in the low field vinylic region, two below 7 ppm and one at 6.5 ppm. The lowest field signal (d, J = 2.8 Hz) is assigned to 3-H and the multiplicity can be explained by a four-bond coupling with 5-H at 7.20 ppm. The latter proton is a doublet of a doublet (J = 10.1 and 2.8 Hz) and the larger coupling constant is due to coupling with 6-H at 6.52 ppm. Similarly, in the ^{13}C spectrum, there are two unsubstituted vinyl carbons at ~140 ppm and one at ~130 ppm. Dienone **3***b*, observed by ^1H nmr in the reaction mixture obtained on the nitration of **1***b*, is evidently the bromo analog of **3***a*, as confirmed by its ^1H nmr spectrum.

The nmr spectra of dienone **10***a* exhibit the differences from those of **3***a* appropriate to **10***a* being the 3-chloro derivative of 4-methyl-4-nitrocyclohexa-2,5-dienone. In the ^1H nmr there is just one proton at ~7 ppm and two at ~6.5 ppm (all with the appropriate couplings) and in the ^{13}C nmr there is one unsubstituted carbon at 140 ppm and two at 130 ppm.

It is evident from the empirical formula ($C_{12}H_{15}N_3O_{11}$) of compound **8**, obtained from nitration of **1***c* in the trifluoroacetic anhydride mixtures, that it was formed by the addition of two acetyl nitrate molecules to the substituted anisole. In the ir spectrum there are two strong absorptions (1790 and 1755 cm^{-1}) due to acetate groups. The ^1H and ^{13}C nmr spectra also indicate the presence of the two acetate groups. The peaks at 68.0 and 87.3 ppm in the ^{13}C spectrum have the shifts and proton couplings appropriate to the ring carbons of the CHOAc and $CMeNO_2$ groups, respectively, and are so assigned. These must be the 1- and 6-carbon atoms (following the enumeration of **2***d*).



SCHEME 2

The single double bond is substituted at one end. It cannot terminate at C-3 because that carbon has a methoxyl substituent that would send the adjacent unsubstituted vinylic carbon to very high field (90 ppm), whereas the vinylic carbon is at 130 ppm. Thus the double bond must be between C-4 and C-5 and must have the original nitro substituent at C-4, and the second molecule of acetyl nitrate must have been added across the C-2, C-3 positions. The chemical shift of C-2 (87.6 ppm), as well as the directing effect of methoxyl on the addition of nitronium ion, indicates that the C-2 substituent is nitro and the second C-3 substituent is acetate. Thus the compound **8** has the structure 3-acetoxy-3-methoxy-6-methyl-2,4,6-trinitrocyclohexa-4,5-dienyl acetate. The ^1H nmr (experimental section) is readily assigned. The 11.8-Hz coupling identifies the methine protons, and the highest field signal of these is assigned to the proton attached to the same carbon as the nitro group.

Substituent effects

As described above, nitration of **1***a* and **1***b* gave the 1,2 adduct and dienone as well as the nitro substitution product. In the case of **9***a* only dienone and nitro substitution products were obtained. The formation of the dienone likely involves the addition of acetate (as acetic acid) to the 4-position of the *ipso* cation followed by loss of elements of methyl acetate, as shown in path (a) of Scheme 2. Thus the amount of the dienone is indicative of the extent of reaction of the *ipso* cation at the 4 position in competition with reaction at the 2 (or 6) position leading to the 1,2 adduct. Dienone formation also occurred in the course of work-up of some of the reaction mixtures. In such cases this secondary formation of dienone likely involves the re-formation of the *ipso* cation from adduct by protonation at acetate and loss of acetic acid, followed by capture of acetic acid or water at the 4 position. Nitrodienones are labile and readily rearrange to the corresponding *o*-nitrophenols (11), as was explicitly demonstrated in the cases of dienones **3***a* and **10***a*. This reaction accounts for the presence of nitrophenol, after work-up, in several of the product mixtures. The dimethyl ketal of the dienone was also observed in reaction mixtures after work-up. The formation of dimethyl ketal (e.g. **6***a*) presumably involves the capture of *ipso* cation by methanol, as shown in path (b), Scheme 2. The methanol would have been liberated on the formation of the dienone.

Moodie, Schofield, and co-workers have studied the nitration of **1***a* in aqueous sulphuric acid solutions (12). They obtained **4***a* and **5***a*, and detected dienone **3***a* as an intermediate, but did not observe the adduct analogous to **2***a*. Adduct formation may well

1*b*	3-Br	57	0	—	43	0	46	0	—	54	0
1*c*	3-NO_2	87	0	—	13	0	46	0	—	54	0
9*a*	2-Cl	23	—	26	51	0	13	—	15	72	0
9*c*	2-NO_2	10	—	40	50	0	34	—	40	26	0

[a]Calculated product distributions are based on isomer distributions for nitration of 4-methoxytoluene and the relevant monosubstituted benzenes.[3]

have occurred but, in the strongly acidic solutions, the adduct would rapidly re-form the *ipso* cation and eventually the dienone.

The effect of the third substituent on the position of attack of the nitronium ion on the substituted 4-methoxytoluene is shown by the data listed in Table 3. In 4-methoxytoluene the directing effect of the methoxyl substituent is dominant and substitution occurs only *ortho* and *para* (*ipso* to methyl) to methoxyl. Introduction of a third substituent at the 3 position (enumeration here and in the following discussion is as for toluene) should have no differential electronic effect at the 1 and 5 positions since both of these are *meta* to the 3 position. It is evident from the observation that no attack occurs at the 2 and 6 positions and, in accord with expectation, that the directing effect of the 3-halo substituents is overwhelmed by that of methoxyl. The directing effect of the 3-nitro substituent reinforces that of the methoxyl group. Since the introduction of a 3 substituent should not change the ratio of attack of nitronium ion at the 1 and 5 positions, it follows that this ratio should be the same as in 4-methoxytoluene. In fact, the ratio is increased from 46:54 (4-methoxytoluene) to 57:43 (**1***b*), or 67:33 (**1***a*), or 87:13 (**1***c*). Clearly, factor(s) other than additive electronic effects are involved, such as additional steric hindrance to substitution at the 5 position caused by the buttressing effect of the 3 substituent on the methoxyl group.

In the cases of the substrates that contain the 2-chloro or 2-nitro substituents (**9***a* and **9***c*), the chloro substituent reinforces the directing effect of the methoxyl and, while the directing effect of the nitro is in opposition to that of the methoxyl, it does not result in any attack at the 6 position, *meta* to methoxyl. Calculated and observed ratios of attack by nitronium ion are shown in Table 3.[3] As predicted, the chloro substituent reduces the extent of *ipso* attack, although not to the extent calculated. However, the nitro substituent, which should slightly increase the extent of *ipso* attack, actually leads to a significant reduction. Here again a steric effect may be involved, with steric hindrance at the substituted position being greater than at the unsubstituted 3 position. Directive effects in the substitutions of the chlorocresols **14** and **15** are completely dominated by the hydroxyl group, with attack by nitronium ion limited to positions *ortho* and *para* to hydroxyl. In the hydroxy-substituted *ipso* cation, addition of a nucleophile cannot compete with the facile deprotonation to dienone and no adduct is therefore obtained.

[3]The calculations involve the application of the relative partial rate factors for halo (13) and nitro (14) substituents to the observed ratios of attack in 4-methoxytoluene (1).

TABLE 4. Addition of acetate to X-4-methoxy-1-methyl-1-nitrocyclohexadienyl cations: amount of cation/mol% which undergoes addition of acetate at the indicated position

			Distribution of addition

1*c*	3-NO_2	87	66	0	34
9*a*	2-Cl	23	—	100	0
9*c*	2-NO_2	10	—	0	100

[a]Yield of X-4-methoxy-1-methyl-1-nitrocyclohexadienyl cation = yield of products from this cation.

In the earlier study of the nitration of **1***a*, yields of nitrocresol **5***a* (indicative of the extent of *ipso* attack) approaching 80% were obtained (12). This is somewhat larger than the extent of *ipso* attack observed in acetic anhydride (Table 3). The difference, in so far as it is significant, might arise from a greater selectivity of the nitronium ion for the *ipso* position in the aqueous acid, or from greater trapping efficiency of the carbocation by water than by acetic acid.

Table 4 shows the relative amount of capture of the relevant 4-methoxy *ipso* cation at the 2, 4, and 6 positions. In the cases of the 3 substituted cations (from **1***a*, **1***b*, and **1***c*), capture at the 2 or 6 position dominates over capture at the 4 position. In the parent cation (from 4-methoxytoluene), no capture occurs at the 4 position. No capture occurs at the 4 position in the 3-nitro cation and here again it appears that the extent of 2/6 versus 4 capture is not related in any simple way to the electronic effects of the substituent groups. A striking feature of the results is that selectivity between the 2 and 6 positions as to capture is completely in favour of 6 for the 3-halo substituted cations whereas it is largely in favour of 2 for the 3-nitro cation. Addition of acetic acid at the 2 position would be hindered by the adjacent 3 substituent. This would account for the observations in the cases of the 3-halo derivatives. In the case of the 3-nitro derivative, addition of the acetic acid to the 2 position would lead to a product and a prior transition state in which there is a strongly stabilizing resonance interaction between the methoxy and nitro groups through the 3,4 double bond. This interaction is absent when addition occurs at the 6 position and this factor may be sufficient to override the steric effect.

The minor amount of (*E*)-**7**, which was formed when nitration of **1***c* was carried out in the presence of trifluoroacetic anhydride, presumably arose from epimerization of (*Z*)-**7** by protonation at acetate and reversible dissociation of acetic acid in these, more acidic, conditions. Adduct **8** was likely formed from **2***c* by addition of nitronium acetate across the 3,4 double bond (diene enumeration). The addition of nitronium ion to the 4 position would occur readily since the bond is activated by the methoxyl group at 3.

Experimental

General experimental methods have been described previously (1, 2).

2-Bromo-4-methylphenol, 4-methyl-2-nitrophenol, and 4-methyl-3-nitrophenol were from Aldrich. 2-Chloro-4-methylphenol was prepared by chlorination of *p*-cresol with sulphuryl chloride. 3-Chloro-4-

methylphenol was prepared by the rearrangement of 4-chloro-4-methylcyclohexa-2,5-dienone in trifluoromethanesulphonic acid (15). 2-Bromo-4-methyl-6-nitrophenol (**5***b*) was prepared by nitrating 2-bromo-4-methylphenol with nitric acid in methylene chloride and had mp 69°C (lit. (16) mp 69°C); ^{1}H nmr (250 MHz, $CDCl_3$) δ: 2.35 (d, 3, J = 0.78 Hz, CH_3), 7.70 (d, 1, J = 1.00 Hz, 3-*H*), 7.89 (dd, 1, J = 1.00 and 0.78 Hz, 5-*H*), 10.97 (br s, 1, O*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 20.0 (*C*H_3), 112.8 (*C*-2), 124.0 (*C*-5), 130.6 (*C*-4), 133.8 (*C*-6), 141.7 (*C*-3), 150.0 (*C*-1) ppm.

Substituted anisoles were prepared by heating under reflux, for 3 h, an aqueous sodium hydroxide solution of the corresponding phenol with dimethyl sulphate. The crude product was purified by distillation. 2-Chloro-4-methylanisole (**1***a*) was obtained in 94% yield and had bp 214–218°C (lit. (17*a*) bp 215–218°C); ir (film): 1255 and 1062 (ArOCH_3) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$) δ: 2.20 (s, 3, CH_3), 3.79 (s, 3, OCH_3), 6.74 (d, 1, J = 8.40 Hz, 6-*H*), 6.95 (dd, 1, J = 8.40 and 2.30 Hz, 5-*H*), 7.11 (d, 1, J = 2.30 Hz, 3-*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 20.3 (*C*H_3), 56.3 (O*C*H_3), 112.3 (*C*-6), 122.2 (*C*-2), 128.3 (*C*-5), 130.9 (*C*-3), 131.1 (*C*-4), 153.1 (*C*-1) ppm.

3-Chloro-4-methylanisole (**9***a*) was obtained in 95% yield and had bp 210–213°C (lit. (17*a*) bp 212°C); ir (film): 1240 and 1045 (ArOCH_3) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$) δ: 2.29 (s, 3, CH_3), 3.76 (s, 3, OCH_3), 6.70 (dd, 1, J = 2.50 and 8.40 Hz, 6-*H*), 6.90 (d, 1, J = 2.50 Hz, 2-*H*), 7.99 (d, 1, J = 8.40 Hz, 5-*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 18.9 (*C*H_3), 55.5 (O*C*H_3), 112.8 (*C*-6), 114.6 (*C*-2), 127.9 (*C*-4), 131.2 (*C*-5), 134.3 (*C*-3), 158.4 (*C*-1) ppm.

2-Bromo-4-methylanisole (**1***b*) was obtained in 85% yield and had bp 125–126°C, 3 kPa (lit. (18) bp 126–127°C, 3 kPa); ir (film): 1255 and 1050 (ArOCH_3) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$) δ: 2.20 (s, 3, CH_3), 3.79 (s, 3, OCH_3), 6.72 (d, 1, J = 8.30 Hz, 6-*H*), 6.98 (dd, 1, J = 8.30 and 1.50 Hz, 5-*H*), 7.29 (d, 1, J = 1.50 Hz, 3-*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 19.9 (*C*H_3), 56.1 (O*C*H_3), 111.1 (*C*-2), 111.7 (*C*-6), 128.7 (*C*-5), 131.2 (*C*-4), 133.5 (*C*-3), 153.6 (*C*-1) ppm.

4-Methyl-2-nitro anisole (**1***c*) was obtained in 76% yield and had bp 272–274°C (lit. (17*b*) bp 274°C); ir (film): 1530 and 1350 (NO_2), 1260 and 1020 (ArOCH_3) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$) δ: 2.33 (s, 3, CH_3), 3.92 (s, 3, OCH_3), 6.98 (d, 1, J = 8.55 Hz, 6-*H*), 7.34 (dd, 1, J = 8.55 and 2.10 Hz, 5-*H*), 7.64 (d, 1, J = 2.10 Hz, 3-*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 19.8 (*C*H_3), 56.3 (O*C*H_3), 113.3 (*C*-6), 125.4 (*C*-3), 129.9 (*C*-4), 134.6 (*C*-5), 139.0 (*C*-2), 150.7 (*C*-1) ppm.

4-Methyl-3-nitroanisole (**9***c*) was obtained in 76% yield and had bp 263–269°C (lit. (17*b*) bp 266–267°C); ir (film): 1527 and 1345 (NO_2), 1250 and 1035 (ArOCH_3) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$) δ: 2.21 (s, 3, CH_3), 3.79 (s, 3, OCH_3), 6.72 (d, 1, J = 8.35 Hz, 5-*H*), 6.98 (dd, J = 8.35 and 1.40 Hz, 6-*H*), 7.30 (d, 1, J = 1.40 Hz, 2-*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 19.3 (*C*H_3), 55.5 (O*C*H_3), 108.9 (*C*-2), 119.6 (*C*-6), 125.2 (*C*-4), 133.2 (*C*-5), 149.2 (*C*-3), 157.9 (*C*-1) ppm.

2-Bromo-4-methyl-6-nitroanisole (**4***b*) was obtained in 87% yield and had mp 45°C; ^{1}H nmr (250 MHz, $CDCl_3$) δ: 2.37 (d, 3, J = 0.54 Hz, CH_3), 3.98 (s, 3, OCH_3), 7.52 (dd, 1, J = 0.55 and 2.05 Hz, 3-*H*, or 5-*H*), 7.60 (d, 1, J = 2.05 Hz, 5-*H* or 3-*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 20.3 (*C*H_3), 62.5 (O*C*H_3), 119.2 (*C*-2), 124.5 (*C*-5), 135.6 (*C*-4), 138.1 (*C*-3), 144.9 (*C*-6), 148.5 (*C*-1) ppm.

*Nitration of 2-chloro-4-methylanisole (1*a*)*

Anisole **1***a* (7.8 g, 0.05 mol) was added, over 2 min, to a nitrating mixture prepared from nitric acid (6.3 g, 0.1 mol) and acetic anhydride (25.5 g, 0.25 mol) at −40°C. The nitrating solution had been mixed at −78°C and warmed to 0°C before being brought to −40°C. After stirring the reaction mixture for 1 h at −40°C it was cooled to −78°C. At this stage the ^{1}H nmr spectrum showed that the composition was diene **2***a* (49%), dienone **3***a* (18%), and 2-chloro-4-methyl-6-nitroanisole (**4***a*) (33%). The mixture was poured into ether (500 cm^3) at −78°C. Ammonium hydroxide (75 cm^3, 1.1 mol) was slowly added to this mixture and stirring was continued for 1 h. The ether layer was separated and the residue was dissolved in water (200 cm^3) and extracted with ether (2 × 100 cm^3). The combined ether solution was washed with water (4 × 150 cm^3), dried, and concentrated on the rotovapor at 15°C to yield a heterogeneous mixture. Crude **2***a* (5.2 g) was obtained on filtration. Removal of ether from the filtrate gave a yellow oil (6 g). The ^{1}H nmr spectrum of this oil indicated the presence of unreacted **1***a* (10.5%), **2***a* (4%), **4***a* (56.5%), 2-chloro-4-methyl-6-nitrophenol (**5***a*) (22.5%), and 2-chloro-4-methyl-6-nitrocyclohexadienone dimethyl ketal (**6***a*) (5.5%). Pure diene **2***a* was obtained as white crystals after recrystallization from ether – petroleum ether mixture at −20°C. It had mp 82°C; ir (KBr): 1735 and 1230 (O$COCH_3$), 1540 and 1360 (NO_2), 1235 (OCH_3), 665 (C-Cl) cm^{-1}; uv (CH_2Cl_2): 275.6 nm (ε = 124 m^2 mol^{-1}); ^{1}H nmr (250 MHz, $CDCl_3$): Table 1; ^{13}C nmr ($CDCl_3$, 62.9 MHz): Table 2. *Anal.* calcd. for $C_{10}H_{12}NO_5Cl$: C 45.90, H 4.62, N 5.35; found: C 45.70, H 4.55, N 5.22. The nitroanisole **4***a* and nitrocresol **5***a* were isolated from further reactions of diene **2***a* (19) and had ^{1}H nmr identical with literature values (12). Ketal **6***a* was also isolated from further reactions of **2***a* and characterized (19).

*Nitration of 2-bromo-4-methylanisole (1*b*)*

Anisole **1***b* (8 g, 0.05 mol) was added over 2 min to a nitrating mixture prepared from nitric acid (7.56 g, 0.12 mol) and acetic anhydride (20.4 g, 0.2 mol) at −40°C. The ^{1}H nmr spectrum of the reaction mixture indicated the presence of diene **2***b* (30%), dienone **3***b* (27%), and **4***b* (43%). The mixture was stirred for 40 min, cooled to −78°C, and poured into ether (450 cm^3) at −78°C. The ^{1}H nmr spectrum of the crude mixture (8.6 g) after low temperature work-up with NH_4OH showed **2***b* (38%), **4***b* (46%), and 2-bromo-4-methyl-6-nitrophenol (**5***b*) (16%). Crystallization of the mixture from ether – petroleum ether mixture yielded pure **2***b* (1.05 g) as pale yellow crystals, mp 85°C; ir (KBr): 1749 (O$COCH_3$), 1550 and 1320 (NO_2) cm^{-1}; uv (CH_2Cl_2): 280.5 nm (ε = 232 m^2 mol^{-1}), 235.6 nm (ε = 288 m^2 mol^{-1}); ^{1}H nmr (250 MHz, $CDCl_3$): Table 1; ^{13}C nmr ($CDCl_3$, 62.9 MHz): Table 2. *Anal.* calcd. for $C_{10}H_{12}NO_5Br$: C 39.23, H 3.95, N 4.57; found: C 39.20, H 3.70, N 4.69. Dienone **3***b* was not isolated but it was readily identified by comparison of its ^{1}H nmr spectrum with that of **3***a*, its chloro analog. The identities of **4***b* and **5***b* were confirmed by comparison of their ^{1}H nmr spectra with the spectra of the authentic compounds (above).

*Nitration of 4-methyl-2-nitroanisole (1*c*)*

Anisole **1***c* (8.35 g, 0.05 mol) was added dropwise over 2 min to a nitrating mixture prepared from nitric acid (9.45 g, 0.15 mol) and acetic anhydride (51 g, 0.5 mol), at −40°C. The reaction mixture was warmed to 0°C in an ice bath and stirred for 1 h. After this time the reaction was complete and **2***c* (30%), **7** (57%), and **4***c* (13%) had been formed. The mixture was poured into cold ether (500 cm^3) at −78°C and the precipitate that formed was filtered off in a jacketed filtering funnel (−78°C). The residue was dissolved in CH_2Cl_2 (500 cm^3) and washed with 10% aqueous $NaHCO_3$ (3 × 150 cm^3). This solution was dried and evaporated to dryness. The residue, on crystallization from ether – petroleum ether mixture at −20°C, yielded pure diene **7** (3.5 g), mp 112–114°C; uv (CH_2Cl_2): 335.6 nm (ε = 812 m^2 mol^{-1}), 238.9 nm (ε = 239 m^2 mol^{-1}); ir (KBr): 1755 (O$COCH_3$), 1586 and 1565 (NO_2), 1210 (OCH_3) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$): Table 1; ^{13}C nmr ($CDCl_3$, 62.9 MHz): Table 2. *Anal.* calcd. for $C_{10}H_{12}N_2O_7$: C 44.12, H 4.44, N 10.29; found: C 44.11, H 4.10, N 10.02.

The original filtrate was placed in a 2-dm^3 three-necked round bottom flask, fitted with a mechanical stirrer and cooled to −78°C. Ammonium hydroxide (200 cm^3, 3 mol) was slowly added and the mixture was stirred for 2 h. The organic layer was decanted, washed with water (3 × 250 cm^3), dried, and evaporated to dryness to yield a yellow residue (2.05 g). The ^{1}H nmr spectrum of this mixture indicated the presence of diene **2***c* (75%) and anisole **4***c* (25%). Crystallization from ether – petroleum ether mixture gave pure **2***c* (550 mg), mp 99–100°C; uv (CH_2Cl_2): 248.9 nm (ε = 204 m^2 mol^{-1}); ir (KBr): 1745 and 1010 (O$COCH_3$), 1545 and 1360 (NO_2), 1060 (OCH_3) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$): Table 1; ^{13}C nmr ($CDCl_3$, 62.9 MHz): Table 2. *Anal.* calcd. for $C_{10}H_{12}N_2O_7$: C 44.12, H 4.44, N 10.29; found: C 44.02, H 4.29, N 10.18.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

The ammonia solution, after separation of the organic layer, was diluted with water (250 cm^3) and extracted with ether (2 × 250 cm^3). The ether layer was washed with saturated brine (2 × 200 cm^3), dried, and evaporated to dryness to yield a brown residue (3 g). The ^1H nmr spectrum of this mixture showed **4***c* (75%) and **2***c* (25%). Anisole **4***c* was obtained after chromatography on silica and recrystallization, mp 122°C (lit. (17*c*) mp 122°C); ^1H nmr (250 MHz, $CDCl_3$) δ: 2.48 (s, 3, CH_3), 4.04 (s, 3, OCH_3), 7.85 (s, 2, 3-*H* and 5-*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 20.3 (CH_3), 64.5 (OCH_3), 129.2 (*C*-3 and *C*-5), 134.9 (*C*-4), 144.8 (*C*-2 and *C*-6), 145.1 (*C*-1) ppm.

Nitration of **1***c* was also carried out in the presence of trifluoroacetic anhydride. A mixture of **1***c* (4.4 g, 0.026 mol) and acetic anhydride (7 g, 0.068 mol) was added to a nitrating mixture prepared from nitric acid (8.8 g, 0.14 mol), acetic anhydride (35 g, 0.34 mol), and trifluoroacetic anhydride (5.88 g, 0.028 mol), at −20°C. The mixture was stirred for 30 min, cooled to −78°C, and poured into a mixture of aqueous sodium bicarbonate (160 g, 2 mol, in 750 cm^3) and ether (1 dm^3). The mixture was stirred for 2 h and the ether layer was separated. The aqueous layer was extracted with ether (2 × 500 cm^3). The combined ether solution was washed with saturated brine (4 × 500 cm^3), dried, and then evaporated to dryness on the rotovapor, at ambient temperature. The ^1H nmr of the yellow residue (5.5 g) was closely similar to that of the reaction mixture prior to work-up and indicated the formation of **2***c* (25%), (*Z*)-**7** (53%), (*E*)-**7** (5%), 1-methoxy-4-methyl-2,4,6-trinitrocyclohex-2-enyl-1,5-diacetate (**8**) (5%), and **4***c* (12%). The residue was triturated with ether (250 cm^3) and the residue (1.1 g) then obtained on filtration contained (*Z*)-**7** (80%) and (*E*)-**7** (20%). Fractional crystallization from CH_2Cl_2 at −20°C gave (*E*)-**7** (88 mg) as the first crop, a mixture of (*E*)-**7** and (*Z*)-**7** (18:82, respectively) in the second crop (200 mg), and pure (*Z*)-**7** (200 mg) in the third crop.

Crystallization from the filtrate of the trituration gave pure (*Z*)-**7** (500 mg). On further crystallization from the mother liquor only mixtures were obtained, and the residue after the separation of (*Z*)-**7** was therefore chromatographed on a silica gel column (125 g) at −40°C, using ether – petroleum ether mixtures as eluents. 1-Methoxy-4-methyl-2,4,6-trinitrocyclohex-2-enyl-1,5-diacetate (**8**) was obtained in the 10% ether fraction, **4***c* was obtained in the 20 and 25% ether fractions, and **2***c* was obtained in the 30% ether fractions. Later fractions contained mainly mixtures of **4***c* and 4-methyl-2,4-dinitrocyclohexa-2,5-dienone dimethyl ketal (**6***c*), which could not be separated.

All dienes were purified by recrystallization from ether – petroleum ether mixtures at −20°C. Diene (*E*)-**7** had mp 138°C; ir (KBr): 1755 ($OCOCH_3$), 1586 and 1565 (NO_2), 1210 (OCH_3) cm^{-1}; uv (CH_2Cl_2): 336.4 nm (ε = 800 m^2 mol^{-1}); ^1H nmr (250 MHz, $CDCl_3$): Table 1; ^{13}C nmr ($CDCl_3$, 62.9 MHz): Table 2. *Anal.* calcd. for $C_{10}H_{12}N_2O_7$: C 44.12, H 4.44, N 10.29; found: C 43.93, H 4.23, N 10.09. Compound **8** had mp 134°C; uv (CH_2Cl_2): 244.3 nm (ε = 257 m^2 mol^{-1}); ir (KBr): 1790 and 1755 ($OCOCH_3$), 1545 and 1560 (NO_2), 1190 (OCH_3) cm^{-1}; ^1H nmr (250 MHz, $CDCl_3$) δ: 1.88 (s, 3, CH_3), 2.07 (s, 3, 5-$OCOCH_3$), 2.21 (s, 3, 1-$OCOCH_3$), 3.66 (s, 3, OCH_3), 5.72 (d, 1, *J* = 11.8 Hz, 6-*H*), 6.33 (d, 1, *J* = 11.8 Hz, 5-*H*), 6.96 (s, 1, 3-*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 20.1 ($OCOCH_3$), 20.9 ($OCOCH_3$), 22.2 (CH_3), 53.4 (OCH_3), 68.0 (*C*-5), 87.3 (*C*-4), 87.6 (*C*-6), 95.1 (*C*-1), 130.1 (*C*-3), 148.5 (*C*-2), 168.1 ($OCOCH_3$), 168.7 ($OCOCH_3$) ppm. *Anal.* calcd. for $C_{12}H_{15}N_3O_{11}$: C 38.20, H 4.00, N 11.10; found: C 37.95, H 3.87, N 10.70.

*Nitration of 3-chloro-4-methylanisole (**9**a)*

Anisole **9***a* (78 mg, 0.5 mmol) was added to a nitrating mixture prepared from nitric acid (63 mg, 1 mmol) and acetic anhydride (510 mg, 5 mmol), at −45°C. After 3 min at −45°C an ^1H nmr sample was withdrawn and the reaction was followed by ^1H nmr while the sample remained in the probe at −40°C. After 35 min the reaction was complete and there was present **10***a* (23%), **11***a* (δ: 6.96 (d, *J* = 9 Hz) and 7.30 (d, *J* = 9 Hz) ppm) (26%), and **12***a* (δ: 7.14 (s) and 7.68 (s) ppm) (51%). Similar product mixtures were obtained from other nitrating solutions prepared from (*a*) a 1.5 mol proportion of nitric acid and a 10 mol proportion of acetic anhydride at −40°C and (*b*) a 2 mol proportion of nitric acid, a 10 mol proportion of acetic anhydride, together with a 1 mol proportion of trifluoroacetic anhydride at −60°C.

*Nitration of 4-methyl-3-nitroanisole (**9**c)*

Anisole **9***c* (1.17 g, 7 mmol) was added to a nitrating mixture prepared from nitric acid (2.21 g, 35 mmol), acetic anhydride (7 g, 70 mmol), and trifluoroacetic anhydride (2.94 g, 14 mmol), at −40°C. The resulting slurry was stirred for 30 min at −40°C and then poured into ether at −78°C. The ^1H nmr spectrum of the red solid residue (1.38 g) obtained after work-up with aqueous ammonia showed the presence of **11***c* (71%) and **12***c* (29%). Crystallization of the residue from ether – petroleum ether gave **11***c* (300 mg), which on recrystallization had mp 132°C (lit. (20) mp 132–133°C); ^1H nmr (250 MHz, $CDCl_3$) δ: 2.40 (s, 3, CH_3), 3.97 (s, 3, OCH_3), 7.18 (d, 1, *J* = 8.8 Hz, 6-*H*), 7.43 (d, 1, *J* = 8.8 Hz, 5-*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 17.2 (CH_3), 57.1 (OCH_3), 115.9 (*C*-6), 122.6 (*C*-4), 134.5 (*C*-5 and *C*-2), 143.3 (*C*-3), 150.0 (*C*-1) ppm.

The remaining residue was separated by chromatography on silica. Anisole **11***c* was eluted with 10% ether – 90% petroleum ether, and **12***c* with 60% ether – 40% petroleum ether. After crystallization **12***c* was obtained as pale yellow flakes, mp 122°C (lit. (20) mp 123–124°C); ^1H nmr (250 MHz, $CDCl_3$) δ: 2.58 (s, 3, CH_3), 4.03 (s, 3, OCH_3), 7.68 (s, 1, 6-*H*), 7.79 (s, 1, 3-*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 19.4 (CH_3), 57.3 (OCH_3), 110.2 (*C*-6), 125.8 (*C*-4), 129.3 (*C*-3), 141.7 (*C*-2), 151.2 (*C*-1), 161.3 (*C*-5) ppm.

Attempts were made to isolate the small amount of 3-methoxy-6-methyl-5,6-dinitrocyclohexa-2,4-dienyl acetate (**13**), which was also formed on nitration of **9***c*, in addition to **11***c* and **12***c*, and which could be detected by nmr in the reaction mixture before work-up. When the reaction mixture was poured into cold 50% ether – petroleum ether and the precipitated product filtered at −78°C the ^1H nmr spectrum of the precipitate indicated the presence of aromatic products only. The ^1H nmr spectrum of the residue, obtained after removing the solvent from the filtrate at −40°C, showed that it was a mixture of **11***c* and **12***c*, together with **13** (10%) and some 4-methyl-3,4-dinitrocyclohexa-2,5-dienone (**10***c*). The peaks corresponding to the **13** and **10***c* disappeared on raising the temperature of the probe to −30°C. Several attempts to isolate the diene after low temperature work-up of the filtrate with aqueous ammonia were not successful.

Diene **13** had ^1H nmr (90 MHz, Ac_2O, lock 2.15 ppm, −45°C) δ: 5.32 (dd, 1, 2-*H*), 5.58 (d, 1, 1-*H*), 7.13 (d, 1, 4-*H*) ppm, $J_{1,2}$ = 6 Hz, $J_{2,4}$ = 1.5 Hz. Dienone **10***c* had nmr (90 MHz, Ac_2O, lock 2.15 ppm, −45°C) δ: 6.50 (dd, 1, 6-*H*), 7.07 (d, 1, 5-*H*), 7.42 (d, 1, 2-*H*) ppm, $J_{2,6}$ = 2 Hz, $J_{5,6}$ = 10 Hz.

*Nitration of 2-chloro-4-methylphenol (**14**)*

Cresol **14** (1.42 g, 0.01 mol) was added to a nitrating mixture prepared from nitric acid (1.89 g, 0.03 mol) and acetic anhydride, at −45°C. The solution was stirred for 10 min, then cooled to −78°C. The ^1H nmr spectrum at this stage indicated the presence of **3***a* (42%) and **5***a* (δ: 7.50 (d, *J* = 2 Hz) and 7.76 (d, *J* = 2 Hz) ppm) (58%). The solution was poured into ether (200 cm^3) at −78°C and neutralized with excess aqueous ammonia (35 cm^3, 0.5 mol). After stirring the mixture for 1 h at −78°C, the ether layer was separated and the residue was diluted with water (100 cm^3) and extracted with cold ether (2 × 50 cm^3). The combined ether solution was washed with water (4 × 75 cm^3), dried, and filtered through a jacketed filtering funnel cooled to −78°C. The ether was removed from the filtrate at −40°C. The ^1H nmr spectrum of the remaining residue indicated the presence of **3***a* (88%) and **5***a* (12%). The mixture was dissolved in 80% ether – petroleum ether (30:60) (250 cm^3) and filtered through basic alumina (150 g) contained in a jacketed filtering funnel cooled to −78°C. The alumina was washed with 80% ether – petroleum ether (250 cm^3) and then with ether (250 cm^3). After evaporation of the solvent at −50°C from the filtrate and the washings, pure **3***a* was obtained. It had ^1H nmr (250 MHz, $CDCl_3$, −40°C) δ: 2.04 (s, 3, CH_3), 6.52 (d, 1, *J* = 10.12 Hz, 6-*H*), 7.20 (dd, 1, *J* = 10.12 and 2.80 Hz, 5-*H*), 7.34 (d, 1, *J* = 2.80 Hz, 3-*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$, −40°C) δ_C:

25.1 (CH_3), 84.6 (C-4), 128.4 (C-6), 137.5 (C-3), 142.0 (C-5), 142.2 (C-2), 198.5 (C-1) ppm.

*Nitration of 3-chloro-4-methylphenol (**15**)*

Cresol **15** (490 mg, 3.4 mmol) was added dropwise over a period of 5 min to a mixture of nitric acid (270 mg, 4.28 mmol) and $CHCl_3$ (4 cm^3) at −60°C. The mixture was stirred for 30 min, during which time the temperature was allowed to rise to −40°C. The ^1H nmr spectrum of the mixture at this stage indicated the composition as **10***a* (22%), **16** (25%), and **17** (53%). The solution was cooled to −78°C and transferred onto a column of basic alumina (30 g), cooled to −78°C, and kept under argon. The column was eluted with ether (50 cm^3) followed by CH_2Cl_2 (200 cm^3). The eluents were collected in a receiving flask cooled to −78°C, and evaporated at −50°C to yield pure **10***a* (70 mg) as a colourless liquid; ^1H nmr (250 MHz, $CDCl_3$, −50°C) δ: 2.01 (s, 1, CH_3), 6.50 (dd, 1, J = 9.95 and 1.47 Hz, 6-*H*), 6.69 (d, 1, J = 1.47 Hz, 2-*H*), 6.95 (d, 1, J = 9.95 Hz, 5-*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$, −50°C) δ_C: 22.3 (CH_3), 87.4 (C-4), 129.1 (C-2), 130.0 (C-6), 141.4 (C-5), 148.0 (C-3), 181.7 (C-1) ppm. The dienone decomposed to an equimolar mixture of cresols **16** and **17** at 0°C, over a period of 10 min. The alumina, after isolation of the dienone, was stirred with concentrated HCl in methanol (1:9 v/v, 200 cm^3). The filtrate was evaporated to dryness to yield a mixture of **15**, **16**, and **17**. The mixture was separated by chromatography on silica (80 g) using ether – petroleum ether mixtures as eluents. The fractions eluted with 5–10% ether solutions contained pure **17**. Mixtures of **17** and **15** were obtained on elution with 20% ether solutions. Pure **15** was eluted in the later 20% ether fractions. Elution with 40–80% ether solutions gave pure **16**. Cresol **17** crystallized from ether – petroleum ether mixtures as yellow flakes, mp 69–70°C; ir (KBr): 3500 (OH), 1569 and 1320 (NO_2) cm^{-1}; uv (CH_2Cl_2): 361 nm (ε = 580 m^2 mol^{-1}), 291 nm (ε = 1167 m^2 mol^{-1}); ^1H (250 MHz, $CDCl_3$) δ: 2.35 (s, 3, CH_3), 7.18 (s, 1, 6-*H*), 7.97 (s, 1, 3-*H*), 10.43 (s, 1, exchanges with D_2O, O*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 19.1 (CH_3), 120.1 (C-6), 120.4 (C-4), 126.0 (C-3), 128.8 (C-2), 144.2 (C-5), 153.4 (C-1) ppm; ms (70 eV, EI), *m/e* (relative intensity): 189 (16), 187.003 (48, $M_r(C_7H_6NO_3Cl)$ = 187.003), 157 (20), 129 (23), 90 (16), 77 (100). Cresol **16** was obtained as brown crystals, mp 68.5°C; ir (KBr): 3360 (OH), 1530 and 1390 (NO_2); uv (CH_2Cl_2): 365 nm (ε = 219 m^2 mol^{-1}), 286 nm (ε = 403 m^2 mol^{-1}); ^1H nmr (250 MHz, $CDCl_3$) δ: 2.37 (s, 3, CH_3), 6.97 (d, 1, J = 8.70 Hz, 6-*H*), 7.33 (d, 1, J = 8.70 Hz, 5-*H*), 8.80 (bs 1, O*H*) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_C: 18.9 (CH_3), 116.1 (C-6), 126.7 (C-3), 129.5 (C-4), 134.7 (C-2 and C-5), 151.0 (C-1) ppm; ms (70 eV), *m/e* (relative intensity): 189 (14), 187.003 (41, $M_r(C_7H_6NO_3Cl)$ = 187.003), 157 (17), 105 (13), 93 (10), 77 (100). The composition of the reaction mixture prior to chromatography was determined from a separate reaction using cresol **15** (71 mg, 0.5 mmol) and nitric acid (47.5 mg, 0.75 mmol) in $CDCl_3$ (0.5 cm^3). The ^1H nmr spectrum of the reaction mixture indicated the presence of dienone **10***a* (39%), cresol **16** (32%), and cresol **17** (29%).

Chelated compounds and derivative of β-alkoxycarbonylalkyltin chlorides — 5-arylazo-8-quinolinolates, alizarinates, and thiocyanate: preparation and spectroscopic studies

BARUN KANTI DEB AND AMIYA KANTI GHOSH[1]

Department of Chemistry, University of North Bengal, Darjeeling – 734 430, India

Received August 29, 1986

BARUN KANTI DEB and AMIYA KANTI GHOSH. Can. J. Chem. **65**, 1241 (1987).

Complex formation with chelating ligands like 5-phenylazo-8-quinolinol, 5-(2[I]-carboxyphenylazo)-8-quinolinol, 1,2-dihydroxyanthraquinone (i.e., alizarin), and 1-nitroso-2-naphthol is due to nucleophilic attack on tin of the β-alkoxycarbonylalkyltin chlorides (a unique class of PVC stabilizer intermediates) with the subsequent elimination of hydrogen chloride. A number of complexes of the types R_2SnL_2, $RSnL_2Cl$, R_2SnLCl, $R_2Sn(L^IH^I)_2$, R_2SnL^{II}, and $RSnL^{II}Cl$ (where R = $CH_3OCOCH_2CH_2$—, $C_4H_9OCOCH_2CH_2$—, and $CH_3OCOCH(CH_3)CH_2$—; LH = 5-phenylazo-8-quinolinol, 1-nitroso-2-naphthol; L^IHH^I = 5-(2[I]-carboxyphenylazo)-8-quinolinol; and $L^{II}H_2$ = 1,2-dihydroxyanthraquinone) and a thiocyanate derivative viz. $(CH_3OCOCH_2CH_2)_2Sn(SCN)_2$ have been prepared. 5-Arylazo-8-quinolinols exhibit azo–hydrazone tautomeric equilibria but their complexes exist only in the azo form. β-Alkoxycarbonylethyltin alizarinates are somewhat different from other complexes. In these complexes two hydroxyl groups of alizarin have been utilised in complex formation, moreover, one of the two carbonyl groups of alizarin also remains involved in coordination to tin. In $(CH_3OCOCH_2CH_2)_2Sn(SCN)_2$, the thiocyanate group is possibly linked to tin atom through nitrogen. All the complexes and the thiocyanate derivative have been characterised by elemental analyses, electronic, ir, and ^1H nmr spectra. Possible structural features of the compounds are discussed.

BARUN KANTI DEB et AMIYA KANTI GHOSH. Can. J. Chem. **65**, 1241 (1987).

Les chlorures d'alkoxy-3 alkyl étain (une classe unique d'intermédiaires dans la préparation de stabilisants du PVC) forment des complexes avec les ligands chélatants comme le phénylazo-5 quinolinol-8, le (carboxy-2[I] phénylazo)-5 quinolinol-8, la dihydroxy-1,2 anthraquinone (c'est à dire l'alizarine) et le nitroso-1 naphtol-2; cette réaction implique une attaque nucléophile sur l'étain qui est suivie d'une élimination de chlorure d'hydrogène. On a préparé un certain nombre de complexes des types R_2SnL_2, $RSnL_2Cl$, R_2SnLCl, $R_2Sn(L^IH^I)_2$, R_2SnL^{II} et $RSnL^{II}Cl$ (dans lesquels R = $CH_3OCOCH_2CH_2$—, $C_4H_9OCOCH_2CH_2$— et $CH_3OCOCH(CH_3)CH_2$—; LH = phénylazo-5 quinolinol-8, nitroso-1 naphtol-2; L^IHH^I = (carboxy-2[I] phénylazo)-5 quinolinol et $L^{II}H_2$ = dihydroxy-1,2 anthraquinone) ainsi qu'un dérivé thiocyanate, soit le $(CH_3OCOCH_2CH_2)_2Sn(SCN)_2$. Alors que les arylazo-5 quinolinols-8 sont sujets à l'équilibre tautomère azo/hydrazone, leurs complexes n'existent que sous la forme azo. Les alizarinates d'alkoxycarbonyl-3 éthyl étains diffèrent un peu des autres complexes. Dans ces complexes, les deux groupements hydroxyles de l'alizarine sont utilisés dans la formation du complexe; de plus, l'un des deux groupements carbonyles de l'alizarine demeure impliqué dans la coordination avec l'étain. Dans le $(CH_3OCOCH_2CH_2)_2Sn(SCN)_2$, il est possible que le groupement thiocyanate soit lié à l'atome d'étain par le biais de l'azote. On a caractérisé tous les complexes ainsi que le dérivé thiocyanate par les analyses élémentaires, les spectres électroniques, ir et rmn ^1H. On discute des diverses caractéristiques possibles de ces composés.

[Traduit par la revue]

Introduction

β-Alkoxycarbonylalkyltin chlorides, a class of excellent PVC stabilizer intermediates (1), have aroused considerable interest because of their simple and relatively inexpensive methods of preparations (2–4). The existence of intramolecular carbonyl coordination to tin through their carbonyl functions (2, 5, 6) and the Lewis acidity of these compounds (7–11) have also been reported. Moreover, it has also been established that the reduction of Lewis acidity of the organotin chloride improves the efficiency of a stabilizer viz., the ketopentyl tin compounds, where the keto groups would be free, are more effective in stabilization than the corresponding dialkyl tin derivatives (12).

Although known for a long time as analytical reagents (13–15), literature contains very few reports of isolation and characterisation of organometallic complexes of 5-arylazo-8-quinolinols. Studies on this group of compounds deal with the azo–hydrazone tautomeric equilibria (16–18) and bacteriocidal properties (19, 20). Some of these compounds, especially 5-(2[I]-carboxyphenylazo)-8-quinolinol, are very suitable ligands for the preparation of some unique types of complexes in which the available coordination sites may be bonded to two different ions or groups. Moreover, organotin-5-(2[I]-carboxyphenylazo)-8-quinolinolates can be made water soluble through conversion to their sodium salts by reaction with $NaHCO_3$.

All the above findings have encouraged us to pursue the preparation and characterization of β-alkoxycarbonylalkyltin chelates with 5-phenylazo-8-quinolinol, 5-(2[I]-carboxyphenylazo)-8-quinolinol, 1,2-dihydroxyanthraquinone (i.e., alizarin) or 1-nitroso-2-naphthol as ligands. This paper describes the results of preliminary investigations in this area.

Experimental

All chemicals were of reagent grade and were used without further purification. Solvents used were dried by reflux over appropriate reagents and were distilled before use.

1. Preparation of β-alkoxycarbonylalkyltin chlorides

The compounds used were of the types R_2SnCl_2 and $RSnCl_3$, where R = $CH_3OCOCH_2CH_2$—, $C_4H_9OCOCH_2CH_2$—, and $CH_3OCOCH(CH_3)CH_2$. All these compounds were prepared by reported methods (2–4).

2. Preparation of 5-phenylazo-8-quinolinol (LH) and 5-(2[I]-carboxyphenylazo)-8-quinolinol (LHH^I; where H and H^I refer to the hydroxyl and carboxyl protons, respectively)

The ligands LH and LHH^I were synthesized by literature methods (14).

3. General method of preparation of complexes

All complexes, except the thiocyanate derivative, were prepared

by reacting stoichiometric quantities of β-alkoxycarbonylalkyltin chlorides and the ligands in appropriate molar ratios. The hydrochloric acid liberated was neutralised with ammonia solution (17 *N*) and the precipitated ammonium chloride was removed by filtration. The filtrate was refluxed, concentrated, and the resulting complexes were isolated and purified by fractional crystallisation (21).

4. Some typical preparations of complexes

(a) $(CH_3OCOCH_2CH_2)_2SnL_2$ (where LH = 5-phenylazo-8-quinolinol)

A mixture of $(CH_3OCOCH_2CH_2)_2SnCl_2$ (1.09 g, 2.99 mmol) and 5-phenylazo-8-quinolinol (1.50 g, 6.02 mmol) in benzene (200 mL) was heated on a water bath for 10 min. A few drops of ammonia solution were added and a sharp change in colour was observed. The resulting ammonium chloride was then filtered. The filtrate was refluxed for 2 h, concentrated, cooled, and petroleum ether (bp 60–80°C) added. The orange solid separated was recrystallised from benzene/petroleum ether (bp 60–80°C) mixture.

(b) $(CH_3OCOCH_2CH_2)_2Sn(L^IH^I)_2$ (where LHH^I = 5-(2^I-carboxyphenylazo)-8-quinolinol)

5-(2^I-Carboxyphenylazo)-8-quinolinol (1.17 g, 3.99 mmol) was soxhlet-extracted in tetrahydrofuran (THF) and then a hot solution of $(CH_3OCOCH_2CH_2)_2SnCl_2$ (0.73 g, 2.01 mmol) in THF and a few drops of ammonia solution were added. The resulting mixture was refluxed for 1 h, filtered, and the filtrate was evaporated to dryness. The residue was then extracted with hot benzene and the benzene extract was concentrated, cooled, and petroleum ether was added. A bright orange solid appeared and was recrystallised from benzene/petroleum ether.

(c) $(CH_3OCOCH_2CH_2)_2SnL^{II}$ (where $L^{II}H_2$ = alizarin)

A solution of alizarin (0.75 g, 3.00 mmol) in hot methanol was added to a stirred solution of $(CH_3OCOCH_2CH_2)_2SnCl_2$ (1.09 g, 2.99 mmol) in hot methanol. The resulting mixture was heated on a water bath, a few drops of ammonia solution were added and then filtered. The filtrate was refluxed for 1 h, concentrated, and cooled. Greenish black fluorescent crystals appeared and were recrystallised from chloroform/methanol.

(d) $(CH_3OCOCH_2CH_2)_2Sn(SCN)_2$

A suspension of potassium thiocyanate (0.60 g, 6.20 mmol) in hot ethanol was added slowly to a stirred solution of $(CH_3OCOCH_2CH_2)_2SnCl_2$ (1.09 g, 2.99 mmol) in hot ethanol. The resulting suspension was stirred for 1 h, filtered, and the filtrate was evaporated to dryness. The resulting white residue was extracted with chloroform and the chloroform extract was concentrated to a minimum volume. The white solid that crystallized overnight was filtered and dried *in vacuo*. The product was recrystallized from methanol.

5. Preparation of Ph_2ShL^{II} (where Ph = C_6H_5, $L^{II}H_2$ = alizarin)

A mixture of triphenyltin hydroxide (prepared from triphenyltin chloride and NaOH in ether/water mixture; 3.53 g, 9.61 mmol) and alizarin (2.35 g, 9.79 mmol) in 400 mL methanol was refluxed for 6 h, cooled, and the resulting solid was filtered off. The solid was treated with hot benzene and the benzene soluble fraction yielded tetraphenyltin (mp 224°C). The filtrate was evaporated to dryness and the residue was extracted with benzene. The benzene extract was concentrated and cooled. The red needles separated were recrystallised from benzene.

6. Reaction of triphenyltin hydroxide and quinalizarin (1,2,5,8-tetrahydroxy anthraquinone)

A solution of triphenyltin hydroxide (3.00 g, 8.17 mmol) and quinalizarin (2.25 g, 8.27 mmol) in 400 mL methanol was refluxed for 6 h and then reduced to dryness under vacuum. The solid obtained was dried *in vacuo* and found to weigh less (4.48 g) than the total weight of the reactants indicating the formation of volatile product due to reaction. The volatile product was identified as benzene by spectrophotometric technique. The solid was washed thoroughly with benzene and the benzene insoluble fraction was crystallized several times with THF/petroleum ether mixture to yield a violet compound which appeared to be polymeric in nature and was infusible up to 360°C. Dearylation of this compound with mercuric chloride showed that it contained two phenyl groups per molecule. Thus the compound yielded stepwise two equivalents of phenylmercuric chloride when refluxed first with one equivalent and then with excess of mercuric chloride. Analytical data of this compound (Table 1) support the composition to be $C_{54}H_{25}O_{18}Sn_2$.

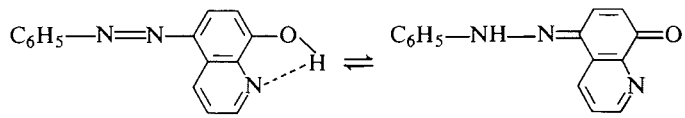
The electronic spectra were recorded on a Beckman DU-2 or a Pye-Unicam SP-300 spectrophotometer using methanol (Uvasol – E. Merck) as the solvent. The ir spectra (KBr pellets) were recorded as Nujol mulls on a Beckman IR-20 spectrophotometer. The ^{1}H nmr spectra were recorded as solutions in $CDCl_3$ on a Varian EM-390 or a Zeol-Japan FT NMR or a Varian A-60 spectrophotometer.

Results and discussion

The analytical and physical data of the complexes are listed in Table 1. The electronic/ir and ^{1}H nmr spectral data are shown in Tables 2 and 3, respectively.

Electronic spectra

In azobenzene and related compounds the band at the longest wavelength is ascribed to an n–π* transition and the other bands are ascribed to π–π* transitions. Substituents like —OH, —COOH, —NH_2, —NMe_2 etc. may produce large bathochromic shift of the π–π* transitions (by extending conjugation) to such an extent that the characteristic n–π* absorption is masked by this strong absorption (22). In the electronic spectrum of 5-phenylazo-8-quinolinol (Table 2), an absorption band at 380 nm and an inflexion at 450 nm indicate the azo–hydrazone tautomerism well known is such systems (23, 24) and also the existence of intramolecular hydrogen bonding in the azo form (structure **I***a*). The band at 380 nm is due to the π–π* transition of the azo form and the inflexion at 450 nm is due to the hydrazone from (structure **I***b*). In the



I*a* **I***b*

electronic spectra of all the β-alkoxycarbonylalkyltin 5-phenylazo-8-quinolinolates (Table 2) the 450 nm band of the free ligand is completely absent since the hydrazone form is not relevant for chelate formation. The 380 nm band of the free ligand suffers a red shift to ~400–430 nm in the complexes and is assigned to the π–π* transition of the azo form. Therefore, all the 5-phenylazo-8-quinolinol complexes exist only in the azo form. In these compounds the oxygen atom is expected to have a large negative charge because of the high polarity of the tin–oxygen bonds ($Sn^{\delta+}$ — $O^{\delta-}$) and the π–π* transition energy is expected to be further lowered (25). The bathochromic shift of the free ligand band from 380 nm to ~400–430 nm in all the compounds therefore results due to the chelation of the ligand (7, 8). The band at ~320–340 nm in these complexes is possibly associated with the ligand band as also observed in other metal oxinates or substituted oxinates (7). β-Alkoxycarbonylalkyltin 5-phenylazo-8-quinolinolates are thus structurally quite similar (structure **II**) to other organotin oxinates (7, 8, 26–29).

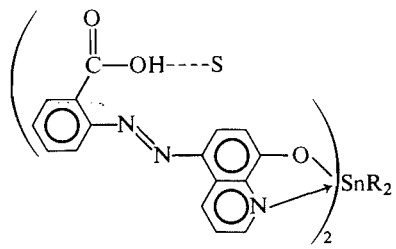
*Multiplicity (S = Singlet, d = doublet, t = triplet, Q = quartet, c = complex pattern, and N = not resolved properly) and proton count in parentheses. R^I = $CH_3OCOCH_2CH_2$—, R^{II} = $C_4H_9OCOCH_2CH_2$—, and R^{III} = $CH_3OCOCH(CH_3)CH_2$—. LH = 5-phenylazo-8-quinolinol, L^IHH^I = 5-(2^ICarboxyphenylazo)-8-quinolinol, where H and H^I refer to hydroxyl and carboxyl protons respectively, $L^{II}H_2$ = alizarin, and $L^{III}H$ = 1-nitroso-2-naphthol. Chemical shifts (δ ppm) of (*i*) $R^I_2SnCl_2$ at 1.92 (H_α), 2.93 (H_β), and 3.82 (H_c), (*ii*) R^ISnCl_3 at 2.27 (H_α), 2.99 (H_β), and 3.97 (H_c), (*iii*) $R^{II}_2SnCl_2$ at 1.90 (H_α), 2.92 (H_β), and 4.24 (H_c), (*iv*) $R^{II}SnCl_3$ at 2.24 (H_α), 2.98 (H_β), 4.37 (H_c), 1.08 (—CH_3), and 1.11–2.02 (—CH_2—CH_2), and (*v*) $R^{III}SnCl_3$ at 2.25 (H_α), 3.30 (H_β i.e., —CH), 4.41 (H_c), and 1.56 (—CH_3).

The compound $(CH_3OCOCH_2CH_2)_2Sn(L^IH^I)_2$ absorbs predominantly at 420 nm in the donor solvent methanol (Table 2). Since, only donor solvents (capable of forming strong hydrogen bonds) give rise to a blue shift, the structure **III** may be



(S = donor solvent, R = $CH_3OCOCH_2CH_2$—)

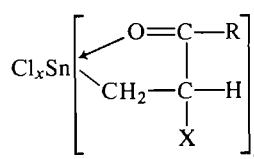
III

suggested for this complex. Moreover, any interaction with azo-nitrogen atoms through intramolecular hydrogen bonding, as in 5-(2^I-carboxyphenylazo)-8-quinolinol, is expected to lead to a bathochromic shift. Since the hydrogen atom is not directly involved in the π-system (as shown in structure **III**), such systems will have little influence on the π–π* transition and consequently the absorption spectrum of this complex closely resembles those of the corresponding 5-phenylazo-8-quinolinol complexes.

In all the alizarin complexes (Table 2), the bands in the region ~460–480 nm, and in $(CH_3OCOCH_2CH_2)_2SnL^{III}Cl$ (where $L^{III}H$ = 1-nitroso-2-naphthol) the band at 580 nm, are also due to the bathochromic shift of the ligand band which indicates strong chelation.

Infrared spectra

In β-alkoxycarbonylethyltin chlorides the carbonyl coordinations to tin are intramolecular in origin (structure **IV**) and ν_{CO} appears in the region ~1640–1680 cm^{-1} (2, 3, 30).



(R = OCH_3, OC_4H_9, CH_3; X = H or CH_3; n = 1 or 2; x = 4 − n)

IV

The ir spectra of β-alkoxycarbonylethyltin 5-phenylazo-8-quinolinolates (Table 2) show that the ν_{CO} appear at higher wave numbers (~1715–1725 cm^{-1}) and the intramolecular carbonyl coordinations (structure **V**) are thus cleaved (structure **VI**) on complex formation (7, 8).

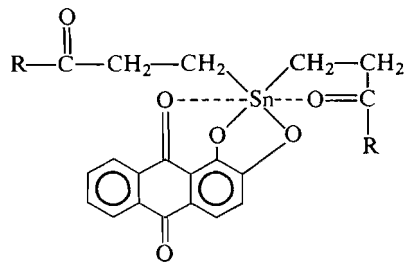
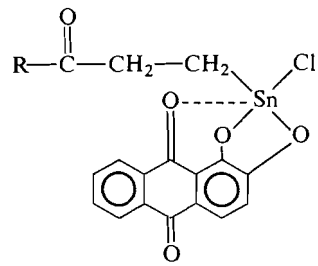
+ 2HCl

(R = OCH_3, OC_4H_9, CH_3; X = H or CH_3; L = ligand;
Y = $ROCH(X)CH_2$— or Cl; n = 1 or 2; $x = 4 - n$)



(R = OCH_3, OC_4H_9)

VII



(R = OCH_3, OC_4H_9)

VIII

The ν_{OH} of 5-phenylazo-8-quinolinol disappeared in the complexes. Moreover, in these complexes the Sn—O stretch at ~510–520 cm^{-1} (9, 31, 32), the characteristic C—O stretching of =C—O—Sn site at ~1100 cm^{-1} (33) and the C=N stretching frequency (somewhat coupled with the pyridine ring vibration) at 1580 cm^{-1} (34) clearly indicate the chelating nature of the ligand. The upward shift of $\nu_{C_{(aryl)}—O}$ (i.e., C_8—O stretch of quinoline ring) in the complexes is expected, because the large polarity of —O—Sn= bond (35) increases the conjugative interaction of oxygen atoms with the π-ring resulting in an increase of the C—O bond order. The $\nu_{(N=N)}$ in the complexes is likely to be very weak (36).

In the ir spectrum of $(CH_3OCOCH_2CH_2)_2Sn(L^IH^I)_2$, hydrogen bonded ν_{OH} (phenolic) of the ligand at ~3360 cm^{-1} (shoulder) is absent whereas the bands at ~3460 cm^{-1} (broad) and 1650 cm^{-1} are due to the ν_{OH} (hydrogen bonded) and ν_{as} (OCO) of the carboxyl group respectively. Other characteristic ir bands (Table 2) of this complex are similar to those of the 5-phenylazo-8-quinolinol complexes. The bands at 1725 cm^{-1} and 1690 cm^{-1} in this complex may indicate that one of the two intramolecular coordinations by the estercarbonyl groups is cleaved while the other is still dominating.

The complete absence of ν_{OH} in the ir spectra of β-alkoxycarbonylethyltin alizarinates signifies that both the hydroxyl groups of alizarin are involved in complex formation. Moreover, in $(CH_3OCOCH_2CH_2)_2SnL^{II}$ the appearance of ν_{CO} at 1730 and 1675 cm^{-1} indicates that on complex formation one of the two intramolecular carbonyl coordinations in $(CH_3OCOCH_2CH_2)_2SnCl_2$ (at 1677 cm^{-1}) is cleaved while the other is still dominating. This is also observed in the case of $(C_4H_9OCOCH_2CH_2)_2SnL^{II}$. However, in $CH_3OCOCH_2CH_2$-$SnL^{II}Cl$ and $C_4H_9OCOCH_2CH_2SnL^{II}Cl$ the lone intramolecular carbonyl coordinations of the alkyl tin chlorides are cleaved and thus shifted to longer wave lengths (~1705–1710 cm^{-1}). In all the alizarinate complexes the carbonyl frequencies of alizarin appear at ~1610–1650 cm^{-1} along with a new band at ~1510–1520 cm^{-1} which is due to the coordination of one of the two carbonyl groups of alizarin to tin. Although it requires further detailed studies, on the basis of ir and ^1H nmr spectra, two types of bonding as shown in **VII** and **VIII** may be suggested which indicate that bis(β-alkoxycarbonylethyl)tin alizarinates are hexacoordinated whereas β-alkoxycarbonylethylchlorotin alizarinates are pentacoordinated around tin. The ir spectrum of diphenyltin alizarinate also shows similar behaviour. In the organotin quinalizarinate complex (product of reaction *6*) the complete absence of ν_{OH} and the appearance of ν_{CO} only at 1530 cm^{-1} indicate that all the hydroxyl and carbonyl groups of quinalizarin have participated in bonding.

In the nitrosonaphthol complex the shift of the N=O group frequency of the ligand (at 1610 cm^{-1}) (37) to lower wave number at ~1510–1565 cm^{-1} (somewhat coupled with the ring breathing mode), the appearance of ν_{CO} of estercarbonyl at higher wave number, and the absence of any ν_{OH}, also suggest chelation.

The appearance of two new bands at 2060 cm^{-1} and 860 cm^{-1} in $(CH_3OCOCH_2CH_2)_2Sn(SCN)_2$ are assigned to $\nu_{C\equiv N}$ and $\nu_{C—S}$ vibrations. Therefore, in this compound the SCN group is linked to tin through nitrogen (38). ν_{NCS} could not be assigned because the parent organotin chloride also exhibits a band at ~490 cm^{-1}. The shift of ν_{CO} in this compound to lower wave number is consistent with the more electronegative character of SCN group in comparison to chloride.

^1H nmr spectra

In the ^1H nmr spectra of all complexes the ratios of different protons are found to be consistent with their compositions. All types of protons in β-alkoxycarbonylethyl groups, with H_α, H_β, and H_c defined as:

$CH_3OCOCH_2CH_2$—; (H_c) (H_β)(H_α)

$CH_3CH_2CH_2CH_2OCOCH_2CH_2$—; ($H_c$) ($H_\beta$)($H_\alpha$)

$CH_3OCOCH(CH_3)CH_2$— (H_c) (H_β) (H_α)

on tin in 5-phenylazo-8-quinolinol and 5-(2^I-carboxyphenylazo)-8-quinolinol complexes (Table 3) exhibit shielding and thereby resonate at higher magnetic field which is in agreement with the increased electron density on the tin via ligand donation. From the chemical shift values it can be seen that both the β-methylenic and methyl protons in the complexes revert to positions characteristic of the free ester group which is again in support of the fact that the intramolecular estercarbonyl coordinations in β-alkoxycarbonylethyltin chlorides are cleaved in the complexes. In all these complexes the α-methylenic proton is shielded most, except in $R^{III}SnL_2Cl$ (Table 3) where the methyl proton is shielded most like its similar oxinate and dibromooxinate complexes (7). The aromatic protons at 2- and 4-positions in all the 5-phenylazo-8-quinolinolates are affected most and appear downfield as in oxine and substituted oxine complexes. The spectrum of $(CH_3OCOCH_2CH_2)_2Sn(L^IH^I)_2$ possibly indicates the presence of mixture of isomers.

In $(CH_3OCOCH_2CH_2)_2SnL^{II}$ and $(C_4H_9OCOCH_2CH_2)_2SnL^{II}$ also, the H_α, H_β, and H_c protons are shielded and the H_α proton is shielded most. In the nitrosonaphthol compound,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

complex formation is indicated by the appearance of alkyl protons upfield where the H_α proton is shielded most.

The ^1H nmr spectrum of $(CH_3OCOCH_2CH_2)_2Sn(SCN)_2$ also indicates the existence of mixture of geometrical isomers and it requires further studies for confirmation. However, in this compound the alkyl protons appear upfield compared to those in $(CH_3OCOCH_2CH_2)_2SnCl_2$ which is quite consistent with the less electronegative character of the thiocyanate group.

Acknowledgements

The reaction of 2,1-benzisothiazoline-3-thiones with acetylenic reagents

DAVID M. MCKINNON, ANTHONY S. SECCO, AND K. ANN DUNCAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received October 8, 1986

DAVID M. MCKINNON, ANTHONY S. SECCO, and K. ANN DUNCAN. Can. J. Chem. **65**, 1247 (1987).

N-Methyl-2,1-benzisothiazoline-3-thione reacts with acetylene esters to form *o*-iminobenzoquinone methides which either form diazocines **2** by head-to-tail dimerisation, or react further with the acetylenic ester forming diadducts. With phenylacetylene a 1,2-dithiolo[2,3-*b*]2,1-benzisothiazole structure is obtained by rearrangement of an initial adduct. Related thiones and acetylenes react similarly but in poorer yields. The crystal and molecular structures of the diazocine were determined by single crystal X-ray diffractometry techniques. The compound crystallizes in space group $P\bar{1}$ with unit cell dimensions a = 7.9465(10), b = 13.6421(14), c = 13.9183(18) Å, α = 82.38(1), β = 83.67(1), γ = 85.77(1) deg, and Z = 2. The structure was solved by direct methods and refined to an R value of 0.056 for 3037 observed reflections. The structure consists of molecules of **2***a* which have an approximate C_2 axis passing through the center of the eight-membered ring. Deviations from true symmetry result from internal ring strain, lone pair–lone pair repulsions, and packing effects.

DAVID M. MCKINNON, ANTHONY S. SECCO et K. ANN DUNCAN. Can. J. Chem. **65**, 1247 (1987).

La *N*-méthyl 2,1-benzisothiazolinethione-3 réagit avec les esters acétyléniques pour former des méthylures d'*o*-imino-benzoquinones qui conduisent soit à des diazocines **2**, par une dimérisation tête à queue, soit à des diadduits provenant d'une réaction subséquente avec l'ester acétylénique. Avec le phénylacétylène, on obtient une structure dithiolo-1,2[2,3-*b*] 2,1-benziothiazole qui provient d'une transposition de l'adduit initial. Des thiones et des acétylènes apparentés réagissent d'une façon semblable; les rendements sont toutefois moins bons. On a déterminé les structures cristalline et moléculaire de la diazocine en faisant appel à la diffraction des rayons-X sur un cristal unique. Le composé cristallise dans le groupe d'espace $P\bar{1}$, avec a = 7,9465(10), b = 13,6421(14) et c = 13,9183(18) Å, α = 82,38(1), β = 83,67 et γ = 85,77(1)° et Z = 2. On a résolu la structure par des méthodes directes et on l'a affinée jusqu'à une valeur de R de 0,056 pour 3037 réflexions observées. La structure comporte des molécules de **2***a* qui possèdent un axe approximativement C_2 qui traverse le centre du cycle à huit chaînons. Les déviations par rapport à la vraie symétrie proviennent d'une tension interne de cycle, de répulsions entre des paires libres et d'effets de remplissage.

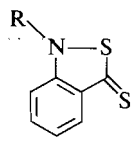
Introduction

While the reactions of monocyclic isothiazoline-3- and 5-thiones with various acetylenic reagents to form mono- and diadducts have been studied (1), surprisingly no data are reported on the reactions of their benzo- derivatives. It was of interest then to investigate these reactions to determine to what extent they paralleled the reactions of the monocyclic systems, or the structurally related benzo-1,2-dithiole-3-thiones which are reported to give diadducts (2).

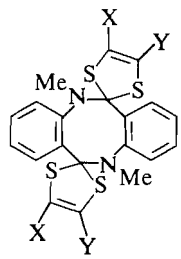
Results and discussion

N-Methyl-2,1-benzisothiazoline-3-thione (**1***a*) treated with 1 equiv. of dimethyl acetylenedicarboxylate in benzene gave an immediate deep violet colour, which faded to yellow after several hours at room temperature or more quickly on heating.



1
a, R = Me
b, R = Ph

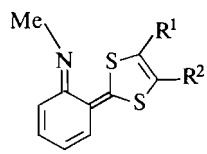
When the reaction was performed in a more polar solvent, e.g. dioxane or tetrahydrofuran, the violet colour faded in a few minutes. Work-up of the yellow solution gave pale yellow prisms, whose nmr and mass spectral properties were consistent with a 1:1 adduct. However, an X-ray crystallographic structure determination indicated that this was in fact the dimer (**2***a*) of a 1:1 adduct (**3***a*) formed by a head-to-tail coupling. This molecule has a folded conformation, with the planes of the two aromatic rings at approximately 120° to each other.



2
a, X = Y = CO_2Me
b, X = H, Y = CO_2Me

The two methoxycarbonyl groups on the spiro-1,3-dithiole rings thereby become non-equivalent, and indeed the nmr spectrum of **2***a* showed two types of O-methyl protons. Surprisingly, the nmr spectrum showed virtually no change on heating (by 30°), indicating some steric resistance to inversion of the diazocine ring, and an examination of a space filling model of **2***a* demonstrated great steric crowding and resistance to inversion. Other less substituted dibenzodiazocines have inversion energy barriers of approximately 20 kcal mol[1] (3).

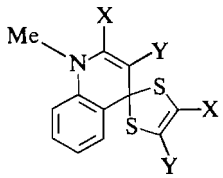
The nature of the initially formed violet material is not known. It may be a charge transfer complex between the reactants,



3
a, R_1 = R_2 = CO_2Me
b, R_2 = H, R_1 = CO_2Et
c, R_2 = CO_2Et, R_1 = H

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

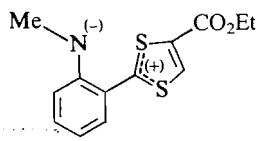
or possibly the initially formed *o*-quinonoid 1:1 adduct (**3***a*). In this reaction the thione **1***a* parallels the reaction of benzo-1,2-dithiole-3-thione with dimethyl acetylenedicarboxylate (2), but there the monoadduct rapidly reacted with more acetylenic ester to form a diadduct. No such monoadduct dimers are reported from the reaction of the structurally related benzo- or naphtho-1,2-dithiole-3-thiones with acetylenic reagents, but the photo-reaction with alkenes produces adducts which are in equilibrium with dimers (4, 5). It is also reported that *o*-xylylenes may undergo dimerisation (6) but a more closely related imino-*o*-quinomethide only shows a [2 + 4] type addition (7). Polar factors induced by the 1,3-dithiole ring in **3***a* may be significant in this dimerisation. Since an adduct of type **3***a* should also react with more dimethyl acetylenedicarboxylate to give a diadduct, the thione was allowed to react with 2 mol of the ester. However, only the monoadduct dimer was isolated. In fact, only when the thione was warmed with a large excess of the ester was the diadduct **4***a* obtained.



4

a, X = Y = CO_2Me
b, X = H, Y = CO_2Me
c, X = CO_2Et, Y = H

The reaction of the thione **1***a* with ethyl propiolate was complex. An initially produced dark red color faded after one hour and subsequent chromatography revealed a slow running yellow band, and faster running red and colorless bands. The red band could not be purified and indeed may have been converting into the colorless band. Isolation of the yellow band gave pale yellow needles, which were the only product when the thione was treated with excess ethyl propiolate. The properties of these were consistent with the diadduct **4***b*. This structure rather than the isomeric **4***c* is favored as the initial adduct **3***b* would be expected to have contributions from a polar structure **5**. If this has a bias towards addition in a conjugate fashion to the acetylenic ester, the adduct **4***b* should be obtained.



5

The colorless band on work-up gave a pale yellow oil which could not be crystallized. Its ^1H and ^{13}C nmr spectra indicated the presence of four different *N*-methyl and ester functions. We consider these to represent the signals of the three geometrical isomers of the monoadduct dimer **2***b* (plus enantiomers). As with the diazocine **2***a*, **2***b* should also resist inversion and therefore a dimerisation of an initially formed mono adduct by an "*exo*" approach, which has a similar transition state, should be unlikely. The most favoured approach is therefore "*endo*". The initial adduct of **1***a* and ethyl propiolate could exist as two geometrical isomers **3***b* or **3***c*, with **3***b* being favored if polar factors are significant in the reaction. The combination of two molecules of **3***b* would give the dimer **2***bi* (Fig. 1), i.e. with the ester functions in an "up–up" arrangement. Likewise

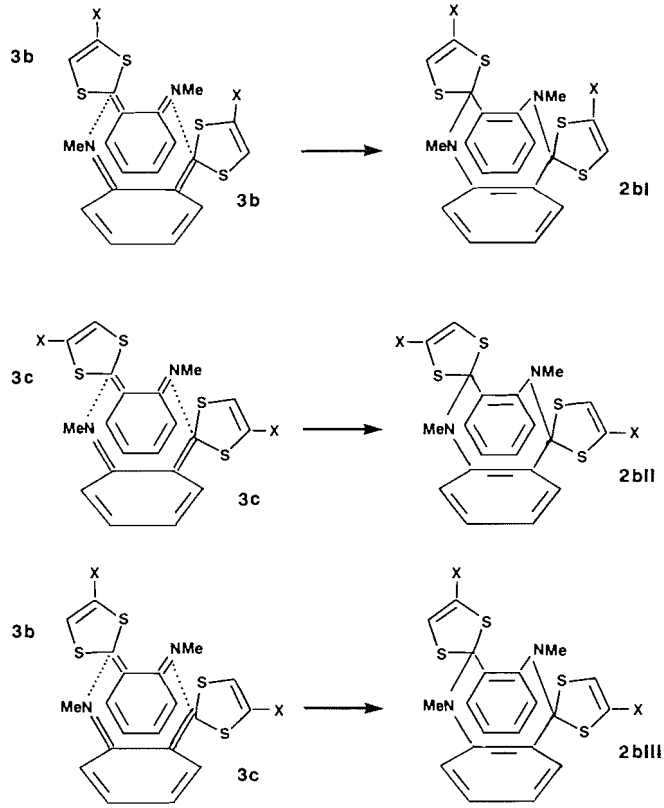


FIG. 1. Dimerisations of **3***b*, **3***c*.

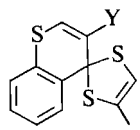
dimerisation of **3***c* would give a "down–down" arrangement, i.e. **2***bii* and a **3***b*–**3***c* combination would give the compound **2***biii* with an "up–down" arrangement. Both **2***bi* and **2***bii* have axes of symmetry, therefore each possesses only one type of *N*-methyl group and one type of ester function, whereas **2***biii* lacks such an axis and possesses two *N*-methyl groups and two ester functions. Thus the nmr spectra are consistent with a **2***bi*–*iii* mixture.

To try to obtain another compound of related type, benzo-1,2-dithiole-3-thione was treated with ethyl propiolate. Since only a diadduct **6** was isolated these results are consistent with earlier studies (2).



6

Y = CO_2Me

Reaction of the thione **1***a* with dibenzoylacetylene was also complex. An initial dark red color faded after 3 h at reflux in toluene and examination by chromatography showed many ill-defined bands. However, two products isolated in low yields had mass spectra corresponding to a 1:1 adduct and a 1:1 adduct less one atom of sulfur. The former then may have a structure analogous to compounds **2**.

Reaction of **1***a* with phenylacetylene was much slower than for the esters and no deep color was initially formed. Continued reflux gave a dark red solution which on work-up gave a dark red crystalline product, identical to the hypervalent sulfur system **7***a* prepared earlier by another method (8). This reaction is therefore related to the formation of 1,6,6*a*λ^4-trithiapentalenes from 1,2-dithiole-3-thiones by reaction with acetylenes (9–11).

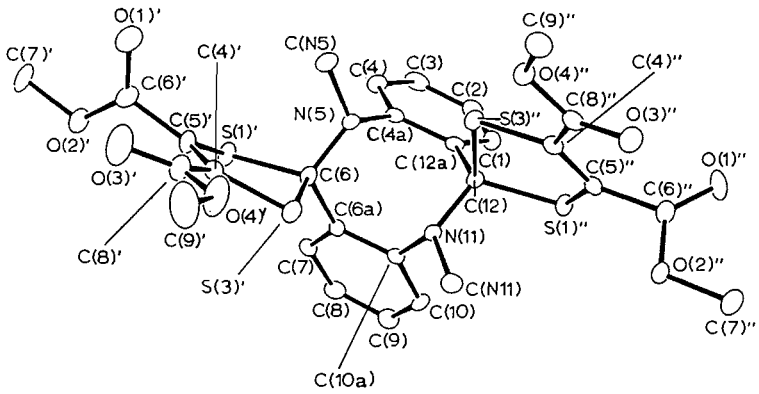


FIG. 2. ORTEP plot of the diazocine derivative, **2***a*, with boundary ellipses for atoms displayed at the 50% probability level.

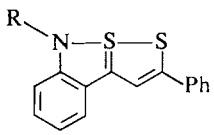
N-Benzyl-2,1-benzisothiazoline-3-thione **1***c* reacted similarly to form **7***b*.

No products of type **2** or **4** were observed hence if any monoadduct of type **2** is formed it must be rearranging entirely to the system **7**, possibly by a reaction catalysed by sulfur

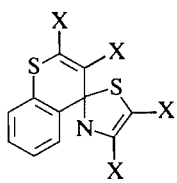


7

similar to that proposed or perhaps the compound **7** is formed from the reaction of the thione with an α-thiocarbene (12).

N-Phenyl-2,1-benzisothiazoline-3-thione **1***b* reacted rapidly with dimethyl acetylenedicarboxylate. A complex deep-colored mixture was obtained from which no definite product could be isolated, and *N*-benzyl-2,1-benzisothiazoline-3-thione **1***c* also gave a mixture of products which could not be purified satisfactorily, but on the basis of the nmr spectrum appears to contain a diadduct, possibly of type **4***a*.

With one example of an isomeric system, i.e. *N*-methyl-1,2-benzisothiazoline-3-thione, dimethyl acetylenedicarboxylate gave a yellow material, whose properties were consistent with the diadduct **8**.



8

X = CO_2Me

With the exception of the ester moieties branching from C(5)′ and C(5)″, molecules of the *bis*-dithiolotetrahydrodibenzodiazocine, (**2***a*), (Fig. 2) have an approximate C_2 axis passing through the center of the eight-membered ring. The twofold molecular symmetry is preserved in all bond lengths (Table 1) and angles (Table 2) within experimental error. However, the deviation from true C_2 symmetry is manifested in the torsion angles involving the non-hydrogen atoms with differences averaging 5.7°. While the major deviations occur between torsion angles along the bonds joining esters to the dithiole rings at C(3)′ and C(3)″, smaller but significant differences exist between torsion angles involving bonds within the dithiole rings themselves.

The tetrahydrodibenzodiazocine ring system, including methyls

TABLE 1. Bond lengths (Å) with estimated standard deviations in parentheses

Bond	Length (Å)	Bond	Length (Å)
S(1)′—C(6)	1.886(5)	N(11)—C(12)	1.417(7)

O(4)′—C(8)′	1.274(8)	C(4)—C(4a)	1.392(7)
O(4)′—C(9)′	1.455(9)	C(6)—C(6a)	1.520(7)
O(1)″—C(6)″	1.181(6)	C(6a)—C(7)	1.399(8)
O(2)″—C(6)″	1.318(7)	C(6a)—C(10a)	1.403(7)
O(2)″—C(7)″	1.454(7)	C(7)—C(8)	1.356(9)
O(3)″—C(8)″	1.202(6)	C(8)—C(9)	1.367(9)
O(4)″—C(8)″	1.320(6)	C(9)—C(10)	1.372(9)
O(4)″—C(9)″	1.446(7)	C(10)—C(10a)	1.390(8)
N(5)—C(4a)	1.435(7)	C(12a)—C(1)	1.384(7)
N(5)—C(6)	1.429(7)	C(12a)—C(4a)	1.383(7)
N(5)—C(N5)	1.459(7)	C(12)—C(12a)	1.541(7)

C(N5) and C(N11), shows perfect C_2 symmetry with the eight-membered ring adopting a slightly twisted boat conformation. The extent of the twist, given by the angle formed by projecting bond N(5)—C(6) onto bond C(12)—N(11), is 11.4(3)°. Whereas the twist in the boat conformation in the tetrahydrodiazocine ring is probably due to intramolecular steric effects and internal ring strain (*vide infra*), distortion from a symmetrical disposition of the dithioles and their extended ester substituents is a result of packing considerations. This is evident from the intermolecular steric crowding which would result between ester substituents on adjacent molecules translated on *b* if either of the ester groups attached to C(5)′ and C(5)″ were rotated approximately 180° about the C(5)′–C(6)′ or C(5)″—C(6)″ bonds, respectively (Fig. 3). Furthermore, the fact that the torsion angle S(3)″—C(4)″—C(8)″—O(3)″ (176.6(4)°) shows the largest deviation from its approximately twofold related counterpart S(3)′—C(4)′—C(8)′—O(3)′ (−171.4(6)°) is consistent with the relatively short contact distance of 3.035(8) Å between O(3)″ and C(N11) (2 − *x*, 1 − *y*, 2 − *z*). Normal

van der Waals intermolecular contacts are observed in the remainder of the structure.

Many crystal structures containing dithiole rings have been reported in the literature, invariably as a tetrathiafulvalene (TTF) derivative or addition complex. However, the present study appears to be the first crystal structure of a compound containing dithiole rings with the apical carbons being sp^3-hybridized. The rings are characterized by bends at the sulfurs giving two planar moieties, S(1)′, C(6)′, S(3)′ and S(1)′, C(4)′, C(5)′, S(3)′ in one ring, and S(1)″, C(6)″, S(3)″ and S(1)″, C(4)″, C(5)″, S(3)″ in the other with dihedral angles of 23.1° and 28.1°, respectively. These differ markedly from dithioles with sp^2-hybridized carbons at the apex, such as TTF (13) where the bend is only 2.1°. Molecular models show no intramolecular factors contributing to the large interplanar angles observed in the present structure. This suggests that packing forces accommodating the ester groups on carbons 4 and 5 of the dithioles dictate the pronounced ring bend.

The twist from the boat conformation in the tetrahydrodiazocine ring does not appear to be due to packing effects, but more likely originates from intramolecular effects such as internal ring strain. Hendrickson's tabulation of strain energies of various cycloalkanes (14) indicates that the boat conformation (the highest energy conformer) in cyclooctane is 10.3 kcal/mol greater in internal strain energy than the lowest energy conformer, the boat–chair suggesting that any degree of twist away from the boat conformation would be favored. In the present structure an additional tendency to twist from the boat conformation stems from a lone pair–lone pair repulsion between S(3)′...S(3)″. A pure boat conformation would place these lone pairs in close proximity to each other directly over the tetrahydrodiazocine ring, whereas a boat–boat conformation which maximizes the distance between the sulfur lone pairs would have the nitrogen-bound methyls overlapping. Hence, the twist from the pure boat conformation in the present structure represents a compromise between these two limiting interactions.

Bond angles around the nitrogens tend toward values of 120° indicating some degree of conjugation with the aromatic rings. However, the nitrogens cannot be considered pure sp^2-hybridized as they remain significantly distant (0.2 Å) from the planes defined by their three adjoining atoms. All other bond

angles and lengths appear to have typical values with the exception of the dithiole rings for which there are no apparent crystallographic data with which to compare.

Experimental

The ^1H nmr and ^{13}C spectra were obtained in deuterochloroform solution using tetramethylsilane as an internal standard on Varian model EM360 and Bruker WH90 spectrometers, respectively. Mass spectra were obtained on a Finnigan model 1015 spectrometer, and thick-layer chromatography was performed on "Merck" silica gel type Kieselgel PF-254. Acetylenic reagents were distilled before use.

Reaction of N-*methyl-2,1-benzisothiazoline-3-thione (**1**a) with dimethyl acetylenedicarboxylate*

(*a*) Using equimolar proportions. The thione (**1***a*, 0.181 g, 1 mmol) and the ester (0.142 g, 1 mmol) were mixed in benzene (10 mL). An immediate purple color faded on standing or evaporation. The pale yellow oil from evaporation crystallized on trituration with ethanol and was recrystallized from a toluene/hexane 1:1 mixture or ethanol giving **2***a* as pale yellow prisms mp 195–196°C (93%).

(*b*) Using a 2:1 ratio of ester to thione. This gave substantially the same results as above.

(*c*) Using excess ester. To the thione (**1***a*, 0.181 g, 0.1 mmol) was added the ester (1 g, 0.704 mmol) and warmed gently until the purple color disappeared. The excess ester was removed *in vacuo* at 100°C and the residue chromatographed on silica gel with a benzene/chloroform 3:1 mixture. Two main bands were obtained. The faster running was the monoadduct dimer **2***a*, and the slower was the spiro diadduct **4***a*. The latter was eluted to give a pale yellow oil that crystallized from ethanol as pale yellow prisms mp 164–165°C (41%).

The nmr spectrum of **2***a*, δ, 3.23 (two 3H, s, N—CH_3); 3.82, 3.87 (four 3H, s, O—CH_3); 6.96–7.61 (two 5H bands, the aromatic protons). At 29 and 59°C the nmr spectra were identical. The mass spectrum, parent ion 323. $M^+/2 = 323$. *Anal.* calcd. for $C_{28}H_{26}N_2O_8S_4$: C 52.01, H 4.02, N 4.33, S 19.81; found: C 52.35, H 4.01, N 4.26, S 19.97.

The nmr spectrum of **4***a*, δ, 3.28 (3H, s, N—CH_3), 3.83 (two 3H, s, O—CH_3 on dithiole ring); 3.87, 3.90 (two 3H, s, O—CH_3 on the quinoline ring). *Anal.* calcd. for $C_{20}H_{19}NS_2O_8$: C 51.61, H 4.09, N 3.01, S 13.76; found: C 51.49, H 4.11, N 3.25, S 13.62.

Reaction of N-*methyl-2,1-benzisothiazoline-3-thione (**1**a) with ethyl propiolate*

(*a*) Using equimolar proportions. The thione (**1***a*, 0.362 g, 2 mmol) and ethyl propiolate (0.196 g, 2 mmol) in tetrahydrofuran (10 mL) were refluxed 1 h. The mixture became dark immediately but after 1 h was reddish. Evaporation gave a red oil which was chromatographed using a benzene:chloroform 3:1 mixture. A faster running colorless band overlaid by a red band and a slower running yellow band were evident. Removal of the faster band gave a reddish oil which on rechromatography could not be separated. However, the red material was labile and eventually a pale yellow oil was obtained. This was the monoadduct dimer **2***b* (65%). Removal of the slower running yellow band gave **4***b* as a crystalline solid which was recrystallized from ethanol as pale yellow needles mp 181–183°C (22%).

(*b*) Using 2 equiv. of ethyl propiolate. The thione (**1***a*, 0.085 g, 0.5 mmol) and ethyl propiolate (0.098 g, 1.00 mmol) in benzene (5 mL) were warmed gently. The solution rapidly became dark, then pale yellow. The solvent was removed under reduced pressure and the residue, a pale yellow semicrystalline material, was triturated with ethanol. The solid was collected and recrystallization from ethanol gave **4***b* as pale yellow needles (81%). The mother liquor on examination by tlc showed a complex mixture.

The mass spectrum of **2***b*, parent ion 279, $M^+/2 = 279$. The nmr spectrum, complex bands δ, 1.3, 4.3 (CH_3—CH_2—O—) 3.1–3.2 (N—CH_3), 6.9–7.6 (aromatic and vinyl). The ^{13}C spectrum likewise showed a mixture but at δ 160.8–161.2 (four carbonyl peaks) and 38.0–38.3 (four N—CH_3). *Anal.* calcd. for $C_{26}H_{26}N_2O_4S_4$: C 55.90, H 4.66, N 5.02, S 22.94; found: C 56.04, H 4.55, N 5.19, S 22.81.

The mass spectrum of **4***b*, 377, M^+ calcd. 377. The nmr spectrum. δ, 1.28 (two 3H, t, the ethyl CH_3), 4.15, 4.27 (two 2H, q, the CH_2—), 3.38 (3H, s, the N—CH_3), 6.97, 7.37 (two 1H, s, the vinyl protons); 6.65–8.50 (4H bands, the aromatic protons). *Anal.* calcd. for $C_{18}H_{19}NS_2O_4$: C 57.29, H 5.04, N 3.71, S 16.98; found: C 57.46, H 5.35, N 3.65, S 16.76.

Reaction of N-*methyl-2,1-benzisothiazoline-3-thione (**1**a) with dibenzoylacetylene*

The thione (**1***a*, 0.362 g, 2.0 mmol) and dibenzoylacetylene (0.468 g, 2.0 mmol) were mixed in toluene (10 mL). An immediate dark red color was produced. The solution was refluxed 3 h and evaporated. The dark red tar was examined by tlc, using 1% methanol in chloroform as an eluent. Four main bands were evident: yellow, orange, red, and orange in order of elution. The two middle bands were collected and evaporated to give oils which slowly deposited crystals under toluene. The red band gave small red crystals, mp 270–290°C, and the orange band gave orange prisms, mp 265–267°C. The mass spectrum of the red material, M 415, M^+ calcd. for a 1:1 adduct was 415. The mass spectrum of the orange prisms, M 383, M^+ calcd. for a 1:1 adduct − S, 383. Owing to the small quantities these were not examined further.

Reaction of N-*methyl-2,1-benzisothiazoline-3-thione (**1**a) with phenylacetylene to form* 7a

The thione (**1***a*, 0.362 g, 2.0 mmol) and phenyl acetylene (1 mL) were refluxed in toluene (10 mL) for 24 h. The mixture was separated by tlc and the intense red band collected. Evaporation and crystallization from a petroleum ether/benzene 1:1 mixture gave **7***a* as dark red needles mp 155°C lit (8) 155°C mixture mp 155°C (45%).

Reaction of N-*benzyl-2,1-benzisothiazoline-3-thione (**1**a) with phenylacetylene to form* 7b

The thione (**1***a*, 0.257 g, 1.0 mmol) and phenylacetylene (0.5 mL) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

toluene (10 mL) were refluxed for 24 h. The mixture was examined by tlc and many colored bands were evident, but the main dark red band contained most material. Extraction gave a dark red oil which crystallized partly under cyclohexane. The dark red material was collected. Recrystallization from cyclohexane gave **7***b* as dark red prisms mp 150–152°C (16%). The mother liquor contained another material but it could not be satisfactorily purified.

The nmr spectrum of **7***b* δ, 5.16 (2H, s, the benzylic protons), 7.02–8.24 (14H, bands, the aromatic protons), 8.57 (1H, s, the heterocyclic proton). The mass spectrum 359, M^+ calcd. 359. *Anal.* calcd. for $C_{22}H_{17}NH_2$: C 73.54, H 4.74, N 3.90, S 17.83; found: C 73.61, H 4.05, N 3.83, S 18.01.

Reaction of N*-methyl-1,2-benzisothiazoline-3-thione with dimethyl acetylenedicarboxylate to form* **4**d

The thione (0.181 g, 1.0 mmol) and dimethyl acetylenedicarboxylate (0.142 g, 1.0 mmol) in benzene (10 mL) were refluxed 24 h. Evaporation gave a yellow oil which on examination by tlc gave two main yellow bands. The first contained starting thione and the second on elution gave a yellow oil which crystallized under ethanol. Recrystallization from methanol gave **4***d* as yellow needles mp 126–127°C (42%).

When the reaction was performed with a 1:2 molar ratio of reactant, the yield was 63%.

The nmr spectrum of **4***d*, δ, 2.97 (3H, s, N—CH_3), 3.66, 3.85, 3.92, 3.96 (four 3H, s, O—CH_3), 7.22–7.93 (4H, bands, the aromatic protons). The mass spectrum, 465 M^+ calcd. 465. *Anal.* calcd. for $C_{20}H_{19}NS_2O_8$: C 51.61, H 4.09, N 3.01, S 13.76; found: C 51.47, H 4.21, N 3.16, S 13.85.

Reaction of N*-phenyl-2,1-benzisothiazoline-3-thione (***1***b) with dimethyl acetylenedicarboxylate*

Equimolar quantities of the two materials were allowed to react in benzene. A dark violet color was produced immediately. The solution was refluxed 1 h and examination by tlc showed a complex mixture which could not be separated.

Reaction of N*-benzyl-2,1-benzisothiazoline-3-thione (***1***c) with dimethyl acetylenedicarboxylate*

The thione (**1***c*, 0.257 g, 1.0 mmol) and the ester (0.142 g, 1.0 mmol) in benzene (10 mL) were refluxed 1 h. Work-up gave a yellow oil which was complex. This was chromatographed (benzene/chloroform, 1:1) and a strongly adsorbed yellow band removed. A yellow oil was obtained which was still a mixture, but appeared to be substantially a 1:2 adduct. This was not further examined.

Reaction of benzo-1,2-dithiole-3-thione with ethyl propiolate

The thione (0.92 g, 5 mmol) and the ester (0.49 g, 5 mmol) in benzene (10 mL) were heated 1 h at reflux. The red solution rapidly became dark yellow, then lightened somewhat. Evaporation gave an oil which was separated by chromatography (benzene/chloroform, 1:1) into starting thione and a yellow oil which crystallized on standing under methanol. This was crystallized from methanol giving **6** as yellow prisms mp 72°C (86%, based on the amount of ester). When the reaction was performed with a 2:1 molar ratio of ester to thione, only the compound **6** was isolated.

The nmr spectrum of **6**, δ, 1.13–1.43 (two superimposed 3H, t, C—CH_3), 4.03–4.53 (two superimposed 2H, q, —CH_2—), 6.97, 7.65 (two 1H, s, vinyl protons), 6.95–8.50 (4H bands, aromatic protons). The mass spectrum 380 M^+ calcd. 380. *Anal.* calcd. for $C_{17}H_{16}S_3O_4$: C 53.68, H 4.21, S 25.26; found: C 53.81, H 4.22, S 25.51.

Crystallographic analysis of **2**a

Crystals of **2***a* were grown from an ethanol solution at room temperature. The well-defined faces made the crystals readily indentifiable as belonging to the pinacoidal class. The one chosen for data collection measured 0.18 mm × 0.26 mm × 0.40 mm and was mounted in a general orientation on a Nicolet *R3m* diffractometer. The unit cell and an orientation matrix were derived from the setting angles of 25 centered reflections with $31° < 2\theta < 44°$. Data were collected with graphite-monochromatized MoKα radiation. An ω–2θ scan type was employed with scan widths determined by $2.00 + (2\theta_{K\alpha_2} - 2\theta_{K\alpha_1})°$. During each scan, peak and peak backgrounds were counted for equal times. Virtually no decrease in intensity of any of the three standard reflections was observed throughout the exposure period of 39.7 h. Data processing, which included corrections for Lorentz and polarization effects, indicated that 78% of the 3910 measured reflections with $3° \leq 2\theta \leq 45°$ were considered observed with $I \geq 1.5\sigma(I)$, where $\sigma(I) = R[S + B_L + B_R]^{1/2}$; R is the scan rate; S, the total scan count; and B_L, B_R, the left and right background counts, respectively.

The structure was solved by direct methods using the MULTAN system of programs (15) which indicated the positions of 39 out of a total of 42 non-hydrogen atoms in the asymmetric unit. Subsequent cycles of full-matrix least-squares refinement and difference Fourier

†U_{eq} is equal to one third the trace of the diagonalized anisotropic temperature-factor matrix.

maps[1] revealed the remaining non-hydrogen atoms, as well as 17 of the 26 hydrogens; the other 9 hydrogen atoms were placed at calculated positions and not refined. In the final cycles of refinement, all non-H atoms were assigned anisotropic temperature factors while the thermal motion of H atoms was assumed to be isotropic. The refinement of 448 parameters converged for the 3037 observed data at $R = 0.056$, $R_w = 0.075$ and $S = 1.209$ where $R = \Sigma||F_o| - k|F_c||/\Sigma|F_o|$ and $R_w = [\Sigma w(|F_o| - k|F_c|)^2/\Sigma w|F_o|^2]^{1/2}$. For all data $R = 0.076$ and $R_w = 0.075$. The function $\Sigma w\Delta^2$, where Δ^2 is $(|F_o| - k|F_c|)^2$ was minimized throughout the refinement with the weights, w, for observed reflections derived from the expression $w = [1 + ((|F_o| - a)/b)^2]^{-1}$. For this structure, $a = 11.6$ and $b = 20.0$ were found to be suitable constants in the above expression. Data classified as unobserved were assigned zero weights during refinement. Δ/σ (max) in the final cycle was 0.910 and the final difference map showed random fluctuations in the range -0.315–0.477 e Å^{-3}. X-ray atomic scattering factors were taken from Cromer and Mann (16) for non-H atoms, and from Stewart, Davidson, and Simpson (17) for H atoms. Final atomic positional parameters for non-H atoms are listed in Table 3.[2]

Crystal data are as follows:

$C_{28}H_{26}S_4O_8N_2$ fw = 646.784

Triclinic, $P\bar{1}$, $a = 7.9465(10)$, $b = 13.6421(14)$, $c = 13.9183(18)$ Å, $\alpha = 82.38(1)$, $\beta = 83.67(1)$, $\gamma = 85.77(1)$ deg, $F(000) = 672$, $V = 1483.8$ Å^3, $Z = 2$, $\rho_c = 1.448$, $\rho_o = 1.436$ g cm^{-3}, $\mu = 3.57$ cm^{-1} (21°C; MoKα, $\lambda = 0.71073$ Å).

Étude du comportement d'un alliage Cu–Ni 70:30 dans une solution de NaCl à 3% par la détermination de sa résistance de polarisation

YVAN MASSIANI, SYLVIE PETETIN, GUY NGO NGOC ET JEAN-PIERRE CROUSIER[1]

Laboratoire de chime des matériaux—corrosion, Université de Provence, 13331 Marseille CEDEX 3 France

Reçu le 19 septembre 1986

YVAN MASSIANI, SYLVIE PETETIN, GUY NGO NGOC et JEAN-PIERRE CROUSIER. Can. J. Chem. **65**, 1254 (1987).

L'utilisation d'une méthode galvanostatique permet de suivre l'évolution de la résistance de polarisation d'un alliage cuivre–nickel 70:30, en fonction du temps, malgré la présence d'une couche de produits de corrosion formée à la surface de l'échantillon au bout de plusieurs jours d'immersion. La résistance de polarisation de l'alliage qui est, au début de l'immersion, comparable à celle du cuivre, se rapproche, aprés plusieurs jours de celle du nickel pur.

YVAN MASSIANI, SYLVIE PETETIN, GUY NGO NGOC, and JEAN-PIERRE CROUSIER. Can. J. Chem. **65**, 1254 (1987).

A galvanostatic method can be used to measure the evolution of the polarization resistance of a 70:30 copper–nickel alloy with time, in spite of the presence of a layer of corrosion products formed on the surface of the sample after a few days of immersion. At the beginning, the polarization resistance of the alloy is similar to that of copper; after many days, it evolves toward that of pure nickel.

Introduction

Malgré un grand nombre de travaux, le mécanisme de dissolution des alliages Cu–Ni 70:30 n'est pas totalement élucidé. Si la plupart des auteurs concluent, comme dans le cas des alliages Cu–Zn, Cu–Mn, à la dissolution de l'élément allié au cuivre (1–3), d'autres envisagent la possibilité d'une décuprisation (4–6). Dans le cas des laitons, la dézincification est visible au microscope sur une coupe transversale (1). Dans le cas des alliages Cu–Ni, la dénickélisation ou la décuprisation n'a pas la même profondeur et ne peut être mise en évidence par observation au microscope. Les méthodes électrochimiques, qui concernent les atomes en surface, permettent d'observer des variations de composition superficielle.

Certains auteurs (2, 7–10) ont montré que la dissolution d'un alliage est différente en corrosion libre et sous polarisation anodique ou même cathodique. Selon le potentiel, l'alliage passe de la dissolution sélective de l'un des éléments à la dissolution simultanée de chacun d'eux.

Pour détecter une éventuelle modification de la composition à la surface de l'alliage, il faut suivre l'évolution du courant de corrosion en fonction de la durée de l'immersion. Cela est possible en utilisant une méthode qui permet d'effectuer des mesures à différents intervalles de temps, sans interrompre l'immersion de l'échantillon, tout en évitant de fortes surtensions éloignant trop l'électrode de l'équilibre.

Les mesures de résistance de polarisation R_p répondent à ces exigences. Elles présentent plusieurs avantages : (*i*) elles sont effectuées *in situ*; (*ii*) elles sont non destructives, permettant ainsi des études ultérieures du même échantillon; (*iii*) elles sont en général très rapides à effectuer; (*iv*) dans le cas d'expériences comparatives, elles constituent un test d'évolution du comportement du matériau.

Si on utilise l'approximation de l'équation de Butler–Volmer appliquable, pour une faible surtension, autour de E_{cor} ($\eta = \mp 10$ mV), i est une fonction linéaire du potentiel d'électrode.

Dans ces conditions, R_p et i_{cor} sont reliées par la relation de Stern et Geary :

$$R_p = \frac{1}{2{,}3\, i_{cor}} \cdot \frac{\beta_a \cdot \beta_c}{\beta_a + \beta_c}$$

avec

$$\left[\frac{d\eta}{di}\right]_{\eta \to 0} = R_p$$

η étant la surtension.

Puisque la résistance de polarisation est inversement proportionnelle à l'intensité du courant de corrosion, son évolution au cours du temps permet de suivre l'évolution du courant de corrosion, si on admet que β_a et β_c sont constantes.

Mais cette hypothèse est mise en défaut si, au cours du même temps il y a recouvrement de la surface comme dans le cas de la formation d'une couche de produit de corrosion. C'est la situation que nous avons rencontrée au cours de l'étude du comportement des alliages Cu–Ni dans des solutions de NaCl à 3%.

Dans ce cas, d'une part la pente anodique β_a varie et augmente avec le temps d'immersion, d'autre part la partie cathodique de la courbe de polarisation ne permet pas de tracer une droite de Tafel à cause de la «bosse cathodique» déjà signalée sur le cuivre pur (11). Il est donc difficile de passer de R_p à i_{cor}. Néanmoins une étude de l'évolution de la R_p en fonction du temps d'immersion peut donner des indications sur une modification de la composition en surface. Efird (12) a étudié aussi les alliages Cu–Ni 70:30 et 90:10 et montré que si dans les premières minutes leur résistance de polarisation est différente, celle du 90:10 étant la plus faible, après quelques heures d'immersion leur valeur est la même. Ce résultat peut s'expliquer par un enrichissement en nickel de la surface.

Nous avons repris cette méthode sur l'alliage Cu–Ni 70:30 mais aussi sur le cuivre et le nickel purs dont la modification en surface n'est pas le résultat d'une dissolution sélective comme dans le cas d'un alliage.

Mesures des résistances de polarisation

Très souvent, la méthode par balayage de potentiels autour du potentiel de corrosion est utilisée. C'est un test très rapide. Cependant, on n'est pas sûr avec un tel protocole d'être dans un état quasi stationnaire; de plus avec les méthodes à potentiel contrôlé, dans le cas où E_{cor} varie avec le temps, la tension appliquée peut ne plus correspondre à la zone de linéarité entre E et i.

Par contre, si on impose le courant, quelle que soit l'évolution

1. Auteur à qui adresser toute correspondance.

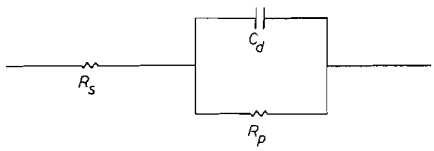

FIG. 1. Schéma équivalent de l'interface électrode–solution.

de E_{cor}, en choisissant convenablement l'échelon d'intensité, on peut ne perturber que très faiblement le système. C'est ce qui nous conduit à utiliser une méthode à intensité contrôlée. Plusieurs méthodes galvaniques sont utilisées :

Certains auteurs (13) appliquent un courant constant dont l'intensité crée une surtension très inférieure à 10 mV. Puis des incréments d'intensité sont ajoutés successivement, jusqu'à obtention d'une surtension de l'ordre de 10–15 mV. Le temps d'application du courant est le même, quelle que soit l'intensité choisie.

On obtient ainsi des couples de points (E,i) pendant la polarisation galvanostatique, dont le graphe est une droite de pente $\Delta E/\Delta i = R(\Omega)$. Si i est exprimé en A cm^{-2} et E en volts, on obtient R_p (Ω cm^2).

Cependant, cette technique est peu adaptée dans deux cas : (i) quand la résistance de l'électrolyte, R_s, est grande : on introduit alors un facteur IR_s qui est très important et qui conduit à une erreur importante sur la mesure des potentiels; et (ii) quand il y a modification des conditions à la surface, par exemple par formation d'une couche de produits de corrosion.

Utilisation d'une méthode galvanostatique alternative

Récemment, une méthode galvanostatique a été utilisée pour déterminer des résistances de polarisation dans des sols (9). Il s'agit d'appliquer un signal rectangulaire alternatif, d'intensité constante en valeur absolue, choisi pour provoquer une surtension de l'éléctrode de travail qui n'excède pas les limites de linéarité de E–i, c'est-à-dire $\eta = \mp 10$ mV.

Dans ces conditions, certains inconvénients des différentes autres méthodes sont supprimés : le potentiel obtenu par application du courant suit les éventuelles fluctuations du potentiel de repos, l'état quasi stationnaire est atteint rapidement, et la présence d'une couche de produit de corrosion n'est pas un obstacle à la mesure.

Cette méthode a été adaptée pour déterminer la résistance de polarisation du cuivre, nickel et du Cu–Ni 70:30.

Principe de la méthode

Lorsqu'on applique un échelon de courant I à un système représenté par le schéma équivalent (Fig. 1), la surtension $\eta = E - E_{cor}$ de l'électrode de travail peut s'exprimer par :

$$I = C_d \frac{d\eta}{dt} + I_{cor}\left[\exp\left(\frac{2{,}3\eta}{\beta_a}\right) - \exp\left(\frac{-2{,}3\eta}{\beta_c}\right)\right]$$

Si η est petit ($\eta = \pm 20$ mV), cette équation se réduit à :

$$I = C_d \cdot \frac{d\eta}{dt} + \frac{\eta}{R_p}$$

avec C_d la capacité de double couche (cf. équation de Stern et Geary).

Si l'impulsion de courant est alternative, carrée et appliquée à la fréquence f, l'équation précédente devient (14) :

$$E(f) = IR_s + IR_p \tanh\left(\frac{1}{4R_pC_d} \cdot \frac{1}{f}\right)$$

Quand la fréquence f est infiniment grande, cette équation

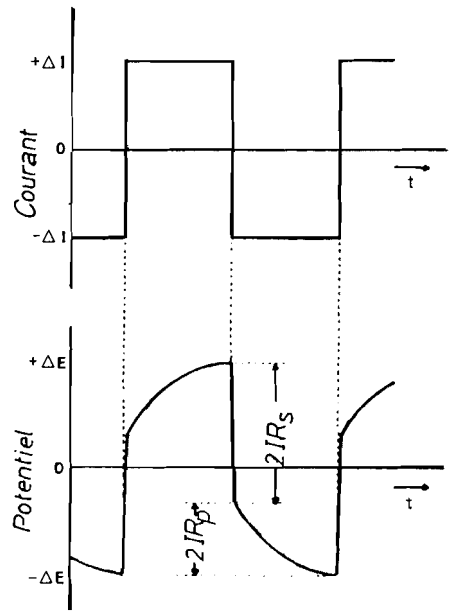

FIG. 2. Schéma du signal appliqué et du signal recueilli sur l'échantillon.

tend vers une valeur limite telle que :

$$E(f) = IR_s$$

mais quand $f \to 0$, $E(f) = IR_s + IR_p$. Par différence, on trouve donc la valeur de R_p.

Schématiquement, la figure 2 représente le signal appliqué, et la forme du signal réponse.

On peut par suite tracer le graphe R en fonction de la fréquence de balayage des impulsions galvanostatiques (fig. 3). Sur celui-ci, on repère directement les paliers permettant d'atteindre la valeur de R_s, et de $R_s + R_p$ donc de R_p.

Partie expérimentale

Les mesures ont été réalisées avec des échantillons de 1 cm^2 de surface préparés à partir d'un alliage Niclal 30 préparé par le Comptoir Lyon Alemand Louyot (Paris). Ces échantillons étaient polis sur papier abrasif 600 sous courant d'eau puis rincés plusieurs fois dans un bac à ultra-sons.

Tous les essais sont effectués dans une solution de NaCl à 3% en aération naturelle et non agitée. Ils nécessitent : un générateur de courant; un générateur de signaux rapides Tacussel type GSTP 3, celui-ci permet de choisir la forme du signal et sa fréquence entre 4×10^{-5} et 5000 Hz; un millivoltmètre à forte impédance d'entrée pour suivre la différence de potentiel entre l'éléctrode de travail et l'électrode de référence; une table traçante JJ Instruments PL3; un oscilloscope à deux voies permettant de visualiser le signal obtenu par application de courant à haute fréquence, en même temps que le signal appliqué. L'oscilloscope utilisé est un Hameg type HM 705; et un amplificateur différentiel assurant un double fonction : l'amplification (jusqu'à 1000 fois) du signal choisi, et un rôle de filtre, éliminant les phénomènes de «retour» jusqu'à l'oscilloscope. La limite d'amplification est de l'ordre de 10 V.

Le montage ainsi réalisé permet d'appliquer un courant de 0,5 μA. Ce courant de très faible intensité ne provoque qu'une faible surtension qu'il faut considérablement amplifier pour pouvoir la mesurer. C'est cette très faible surtension qui nous permet de toujours nous placer dans la zone où la relation entre E et i est linéaire.

Dans le cas du cupronickel 70:30, dans une solution de NaCl à 3%, le potentiel de corrosion est égal à -210 mV/ecs; lorsque l'on applique un courant alternatif carré de 0,5 μA, la surtension de l'électrode est très faible et la réponse en tension est apparemment identique à celle

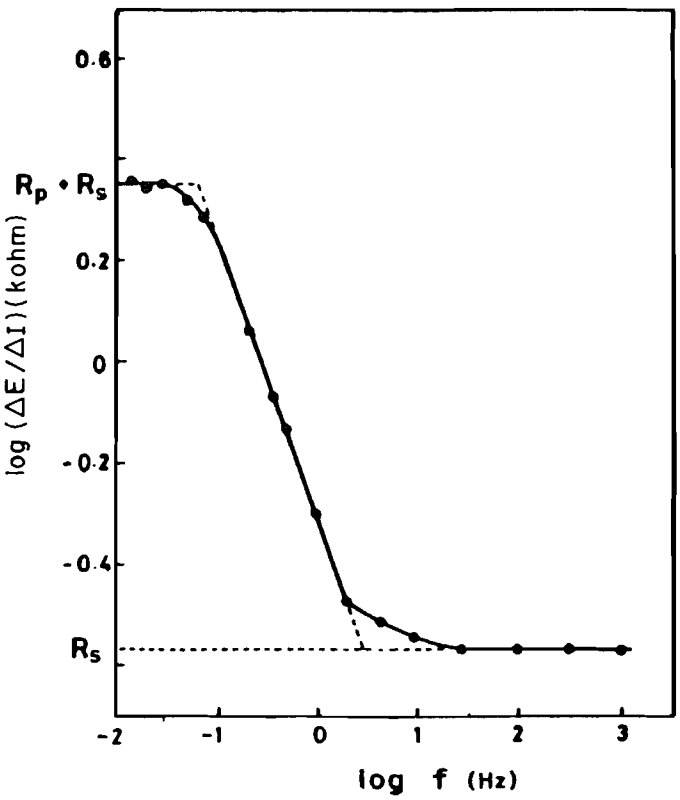

FIG. 3. Résistance de l'interface en fonction de la fréquence du signal appliqué (9).

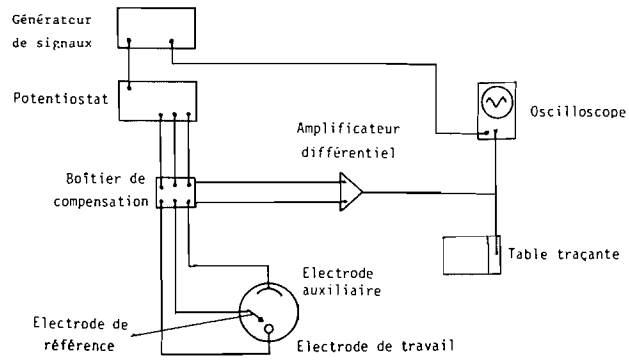

FIG. 4. Montage expérimental. La résistance extérieure, permettant de transformer la rampe de tension en rampe d'intensité, a été intégrée au boitier de compensation.

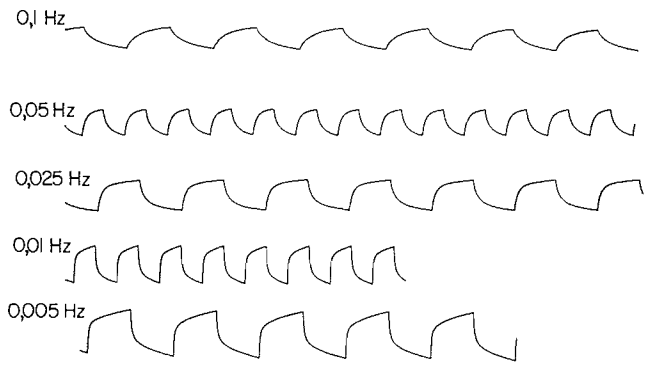

FIG. 5. Signal $E = f(t)$ sur Cu–Ni après 64 jours d'immersion.

obtenue sans surimposer de signal carré, c'est-à-dire identique à la tension délivrée par l'électrode au repos. Il faut donc amplifier ce signal. C'est le rôle de l'amplificateur différentiel. Mais ce dernier amplifie tout le signal : la tension de l'électrode au repos plus la surtension due au courant appliqué. On est, de ce fait, très vite limité dans l'amplification, par le maximum de l'appareil fixé à 10 V, soit environ 50 fois notre signal. Nous avons dû décaler le signal de la valeur du potentiel de corrosion, afin de n'amplifier que le signal provoqué par l'application du courant. Un système de compensation propre à notre montage a été mis au point.

Deux potentiomètres permettent d'opérer soit un réglage grossier, soit un réglage fin de la ligne de base. Pour un gain maximum de l'amplificateur différentiel et une bonne sensibilité de l'oscilloscope, celle-ci doit être centrée sur le zéro de l'écran.

Le montage définitif est représenté sur la figure 4.

Par cette technique nous avons mesuré la résistance de polarisation du cuivre, du nickel, du cupronickel 70:30 sans immersion préalable, et du cupronickel 70:30 après un temps d'immersion allant de quelques heures à 73 jours.

Une fois le potentiel de corrosion stabilise (pour les mesures faites après 15 min d'immersion), celui-ci est repéré sur l'oscilloscope. On branche alors le système de compensation, et par combinaison de celui-ci et de l'amplificateur différentiel, on décale la ligne de base sur le zéro de l'écran, jusqu'à obtention du gain optimum. Ce réglage effectué, on applique le courant alternatif carré d'intensité égale à 0,5 μA, en commençant par les fréquences élevées. En effet, celles-ci ne risquent pas d'endommager l'interface des échantillons. Nous reviendrons ultérieurement sur ce dernier point. On effectue un balayage en fréquence entre 5 kHz et 10^{-3} Hz, parfois 10^{-4} Hz. Pour chaque fréquence, on relève l'amplitude crête à crête du signal du potentiel de corrosion de l'électrode de travail. Grâce à la rémanence de son écran, l'oscilloscope permet de mesurer des signaux d'assez basse fréquence : 2,5–3 Hz. En deçà, les signaux sont enregistrés sur une table traçante.

Résultats

Chacun des échantillons de cuivre, nickel et cupronickel 70:30 a fait l'objet d'une étude de la résistance de polarisation en fonction de la fréquence du courant alternatif appliqué. L'allure générale des enregistrements sur table traçante ne diffère pas avec la nature de l'échantillon. Nous donnons l'exemple d'enregistrement pour Cu/Ni 70:30 (fig. 5). Les valeurs des résistances ainsi mesurées sont ensuite reportées sur un graphe $R = f(\log f)$ (fig. 6).

Le palier obtenu à basse fréquence représente la somme de la résistance de la solution, R_s, et de la résistance de polarisation, R_p. Le palier obtenu à haute fréquence donne la résistance de l'électrolyte R_s seule.

Nous avons obtenu après 15 min d'immersion des résistances de polarisation pour le cuivre et le nickel purs, égales à :

$$R_p(\text{Cu}) = 9\,000\,\Omega\ \text{cm}^2$$

$$R_p(\text{Ni}) = 115\,000\,\Omega\ \text{cm}^2$$

Ces mesures ont été effectuées un grand nombre de fois, donnant des valeurs très reproductibles pour le cuivre et pour le nickel.

Les valeurs de R_p et R_s obtenues pour le cupronickel 70:30 après différents temps d'immersion sont reportés dans le tableau 1.

La valeur trop grande de R_s pour des solutions aussi conductrice que NaCl 3% pourrait provenir de la limitation, avec notre appareillage, du balayage aux fréquences très élevées.

La valeur de la résistance de polarisation du cupronickel 70:30 après 15 min d'immersion est elle aussi très reproduc-

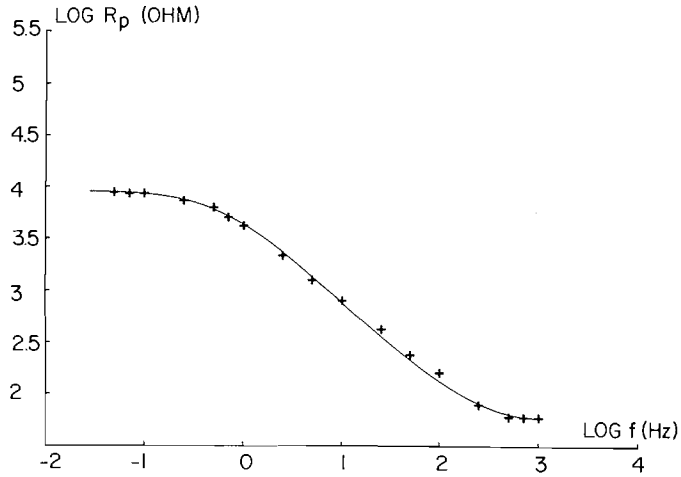

FIG. 6. Résistance de l'interface d'un Cu–Ni en fonction de la fréquence du signal.

TABLEAU 1. Evolution de la résistance de polarisation de l'alliage cuivre–nickel 70:30 en fonction du temps d'immersion

Temps d'immersion	R_p (Ω cm^2)	R_s(Ω)
15 min	8 950	50
5 h	11 040	60
1,5 d	37 000	40
2 d	31 600	40
4 d	43 300	40
5 d	41 000	40
68 d	59 220	30
71 d	95 000	90
73 d	100 000	120

tible, elle est pratiquement égale à celle du cuivre pur et vaut 8950 Ω cm^2.

Après environ 48 h, une couche de produits de corrosion se forme à la surface du cupronickel. Cette couche ne gêne en rien la mesure de résistance (fig. 5), alors qu'elle la perturbait grandement dans les méthodes classiques.

Conclusion

Cette méthode a permis de suivre l'évolution de la résistance de polarisation d'un alliage Cu–Ni 70:30 en fonction du temps d'immersion dans une solution de NaCl, malgré la formation d'une couche de produit de corrosion. Sa valeur, qui est proche de celle du cuivre pur au début de l'immersion, se rapproche, après plusieurs jours, de celle du nickel pur. Ceci indique une diminution de la vitesse de corrosion de l'alliage lorsque le temps d'immersion augmente; la vitesse de dissolution ne change pas avec le temps d'immersion dans le cas du cuivre ou du nickel pur et elle peut donc être reliée à une décuprisation de la surface de l'échantillon.

Relationship between gas-phase proton affinities of conjugate bases B's and free energies of hydration of conjugate acid ions BH^+'s for B = alkyl-substituted H_2O and NH_3

KENZO HIRAOKA
Faculty of Engineering, Yamanashi University, Takeda-4, Kofu 400, Japan

Received July 16, 1986[1]

KENZO HIRAOKA. Can. J. Chem. **65**, 1258 (1987).

An approximate linear relationship between the proton affinities of conjugate bases (B's) and the free energies of hydration of conjugate acid ions (BH^+'s) is found for B = alkyl-substituted H_2O and NH_3. With increase in proton affinities, the free energies of hydration increase linearly with a slope of about 1 for analogous compounds. The charge delocalization in the protonated bases and the structure-making effect induced by the hydrophobic groups in the alkyl-substituted H_3O^+ and NH_4^+ are crucial factors in the determination of the free energies of hydration.

KENZO HIRAOKA. Can. J. Chem. **65**, 1258 (1987).

Dans les cas des produits où B = du H_2O ou du NH_3 substitué par des groupements alkyles, on a trouvé qu'il existe une relation approximativement linéaire entre les affinités protoniques des bases conjuguées (B) et les énergies libres d'hydratation des ions de l'acide conjugué (BH^+). Lorsque les affinités protoniques augmentent, les énergies libres d'hydratation augmentent d'une façon linéaire; la pente est d'environ 1 pour les composés d'une même série d'analogues. La délocalisation de la charge dans les bases protonées et l'effet d'établissement de structure induit par les groupements hydrophobes des H_3O^+ et NH_4^+ substitués par des groupements alkyles sont des facteurs cruciaux dans la détermination des énergies libres d'hydratation.

[Traduit par la revue]

Introduction

The present work is part of a continuing effort from our laboratory to provide additional insights in ion solvation by means of intrinsic molecular properties such as basicities, acidities, and binding energies between ions and molecules measured in the gas phase (1, 2).

The study of ion/molecule reactions in the gas phase has led in recent years to precise determinations of intrinsic protic acid–base behavior. The proton affinity of a molecule B is defined as the negative enthalpy change of reaction [1]:

[1] $B + H^+ \rightarrow BH^+$

The determination of proton affinities is based on the measurements of the equilibrium constants of gas-phase proton transfer reactions:

[2] $BH^+ + A \rightleftarrows AH^+ + B$

where

[3] $-RT \ln K_{eq} = \Delta G = \Delta H^0 - T\Delta S^0$

and the equilibrium constants for reaction [2] is obtained from a mass spectrometric observation of the relative abundances of equilibrated ions, BH^+ and AH^+ in a mixture of known composition of compounds A and B. Recently, Lias *et al.* (3) have compiled a complete and internally-consistent set of proton affinities based mainly on the vast body of data generated by equilibrium constant measurements.

The hydrogen-bonded dimer cations BH^+---A have been investigated in the gas phase. A general trend relating ionic hydrogen bond strength of BH^+---A to the proton affinity difference $\Delta PA = PA(B) - PA(A)$ was observed by Kebarle (4–7). The dissociation energy of the ionic hydrogen bond decreases with the proton affinity difference, ΔPA. A qualitative interpretation of this trend is given by viewing the formation of the BH^+---A bond as partial proton transfer from BH^+ to A in the complex. The trend was further demonstrated in a series of ammonium ion hydrates (8), and also in hydrates of pyridinium ions $X_{py}H^+ \cdot OH_2$ and substituted anilinium ions $XC_6H_4NH_3^+ \cdot OH_2$ (7, 9). More recently, Meot-Ner and co-workers found a linear correlation between the bond dissociation energy of BH^+---A and the difference between the proton affinities for proton donor B and that for proton acceptor A (10–12). We found a similar trend for symmetric proton-held dimer cations $H^+(B)_2$ that the bond energies of the complexes decrease as the proton affinity of base B increases (13). It was indicated that the positive charge on the protic hydrogen atom in the protonated molecule BH^+ plays a most important role for the determination of the bond energies of $H^+(B)_2$.

Arnett and Taft have examined the gas and aqueous basicities of a majority of bases (14, 15). By means of Born-type cycles involving the gas phase and the aqueous proton transfer reactions as well as associated thermochemical data, these authors were able to obtain the relative hydration energies of protonated bases BH^+'s (14). The substituent and solvent effects on proton transfer equilibria were fully discussed (15). They found that when the alkyl-substituted amines have higher gas-phase basicities, their conjugate acid ions have smaller free energies of hydration (14). In our previous paper (2), we also found similar trends for H_2O and alcohols. This indicates that there is some correlation between gas-phase basicities and free energies of hydration. In the present work, the relationship between proton affinities of conjugate bases B's and free energies of hydration of conjugate acid ions BH^+'s for B = alkyl-substituted H_2O and NH_3 is studied in detail.

Discussion

Figure 1 shows the reproduced thermodynamic data for the dissolution of hydrocarbons in H_2O (17). As the number of carbon atoms in *n*-alkanes increases, both ΔH^0 and $T\Delta S^0$ decrease. However, the variation in ΔG^0 with solute size is very small compared to that in ΔH^0 and $T\Delta S^0$. The first detailed explanation for such an effect was provided by Frank and Evans and was based on the unique hydrogen-bonding properties of liquid water (16). The solvent H_2O molecules in the vicinity of hydrophobic groups were assumed to organize cooperatively, forming microscopic "ice-like patches". This causes reductions in both enthalpy and entropy. Since the changes in ΔH^0 and $-T\Delta S^0$ compensate each other, the ΔG^0 values stay almost

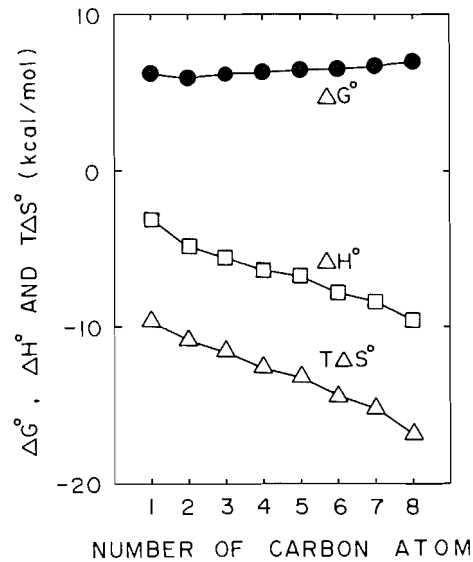

FIG. 1. Thermodynamic properties for the dissolution of aliphatic hydrocarbons (nC_1–nC_8) in water. ●: Standard free energy of hydration $\Delta G(G \rightarrow S)$. □: Standard enthalpy of hydration $\Delta H^0(G \rightarrow S)$. △: Standard entropy of hydration $T\Delta S^0(G \rightarrow S)$.

constant as shown in Fig. 1. When the solutes are ions, the following effects should also be taken into account (18): (*1*) The remnant of the central electric field, beyond the shielding caused by the first coordination sphere, still has an orienting influence on the outer molecules around it. The water molecules in the first coordination sphere exert their own orienting effect on the outer water molecules (1, 18). (2) The tetrahedral structure of bulk water will tend to orient the water molecules in conformity with the geometry favorable for the three dimensional hydrogen-bonded network (16). This effect will extend as close to the ion as the competition with other effects permits. If the ion contains nonpolar hydrophobic parts, these may shield the region near the ion from disruption of the tetrahedral structure by the thermal motion of free water molecules.

These two effects compete with each other in the orientation of water molecules beyond the first hydration shell. The incompatibility of the structures generated by these effects will cause a certain region around the ion to consist of disoriented water molecules, a thawed region (1, 2, 18).

1. Relationship between gas-phase proton affinities and enthalpies of hydration

Figure 2 shows the relationship between the gas-phase proton affinities (PA's) of the conjugate bases B and the enthalpies of hydration (ΔH_s^0's) of conjugate acid ions BH^+ for B = alkyl-substituted H_2O and NH_3. With an increase of PA, a general increase in the values of ΔH_s^0 is observed. The PA values increase with the increase in number and size of the hydrophobic groups, as shown in Fig. 2. With an increase of PA, the positive charge in the protonated base BH^+ gets more dispersed. This will lead to a decrease in the exothermicity for the hydration of protic hydrogens of BH^+ due to the smaller positive charges on the protic hydrogens of BH^+. On the contrary, the increase in the number and size of the hydrophobic groups promote the formation of ice-like patches around them, leading to a more exothermic contribution on the values of ΔH_s^0 (see Fig. 1). The observed rapid increase of ΔH_s^0 values with PA in Fig. 2 indicates that the former effect is much more prominent than the latter. It may thus be concluded that the proton affinity of the base B is the crucial factor in the determination of the enthalpy of hydration of the conjugate acid ion BH^+.

As shown in Fig. 2, the increases in ΔH_s^0 values for ammonia → primary amines → secondary amines → tertiary amines are large, while those for the compounds of the same analogues are small with increasing PA. It is well known (7, 14, 15) that the decrease in positive charge density on the ammonium group is rapid when direct substitution occurs, e.g. $MeNH_3^+$, $Me_2NH_2^+$, Me_3NH^+, compared with that for $MeNH_3$, $EtNH_3^+$, n-$PrNH_3^+$, n-$BuNH_3^+$, etc. Thus, both decrease in H-bonding hydrogens and decrease in positive charge density in the first series occurs and lead to less effective hydration of the onium ions. A similar trend is also observed for alkyl-substituted H_2O, that is, the increase of ΔH_s^0 (MeOH → EtOH) is less than that for ΔH_s^0 (MeOH → Me_2O).

It was found that (14, 19–22) the heats of hydration of amines become increasingly exothermic, as the carbon content is increased, and are apparently much more dependent on hydrophobic structure-making effect than on hydrogen bonding to or from the amino group. As shown in Fig. 2, the ΔH_s^0 values are about the same for primary amines, $MeNH_2$, $EtNH_2$, n-$PrNH_2$, and n-$BuNH_2$. The ΔH_s^0 value for n-$BuNH_2$ is even smaller than that for n-$PrNH_2$. This may be due to the fact that the aliphatic chain in aqueous solution acts as a structure maker and this leads to the negative contribution to the value of ΔH_s^0. This effect attenuates the increase of the values ΔH_s^0's to some extent with an increase of PA.

2. Relationship between the proton affinities and free energies of hydration

In Fig. 2 is also shown the relationship between the gas-phase proton affinities of bases B's and free energies of hydration (ΔG_s^0's) of conjugate acid ions BH^+'s. As shown in Fig. 2, it appears that there are approximate linear relationships between ΔG_s^0 and PA with a slope of about 1 for compounds of the same analogues:

$$[4] \quad \Delta G_s^0 = PA + \text{constant}$$

It is rather surprising that there is such a simple relationship between the PA value which represents the intrinsic molecular property and the ΔG_s^0 value which is determined by so many factors such as size and shape of the ion, charge and its density of the ion, size and structure of the hydrophobic group in the ion, number of protic hydrogen atoms in the ion, structure of the solvation shells, and so on. In any case, such a simple relationship would be very useful since the free energies of transfer of conjugate acid ions from the gas phase to the dilute aqueous solutions can be readily estimated from the available gas-phase proton affinities of conjugate bases (3).

While an approximately linear relationship is observed between ΔG_s^0 and PA, there is the scatter in the line, i.e., the ΔG_s^0 for the series of NH_4^+ → $MeNH_3^+$ → $Me_2NH_2^+$ → Me_3NH^+ increases faster than linearly. In fact, this faster increase is very important and leads to the famous "amine anomaly" of aqueous basicities with methyl substitution (NH_3 < $MeNH_2$ < Me_2NH > Me_3N). The relative aqueous basicities may be described as (14) $\delta\Delta G_i^0(w) = \delta\Delta G_i^0(g) + \delta\Delta G_s^0(B) - \delta\Delta G_s^0(BH^+)$ where $\Delta G_i^0(w)$ is the free energy of ionization $BH^+ = B + H^+$ in aqueous solution (i.e. the scale of basicity in solution), $\Delta G_i^0(g)$ is the free energy of ionization $BH^+ = B + H^+$ in the gas phase, $\Delta G_s^0(B)$ is the free energy of hydration of B, and $\Delta G_s^0(BH^+)$ is the free energy of hydration of BH^+. The $\Delta G_s^0(B)$ values for $MeNH_2$, Me_2NH, and Me_3N relative to

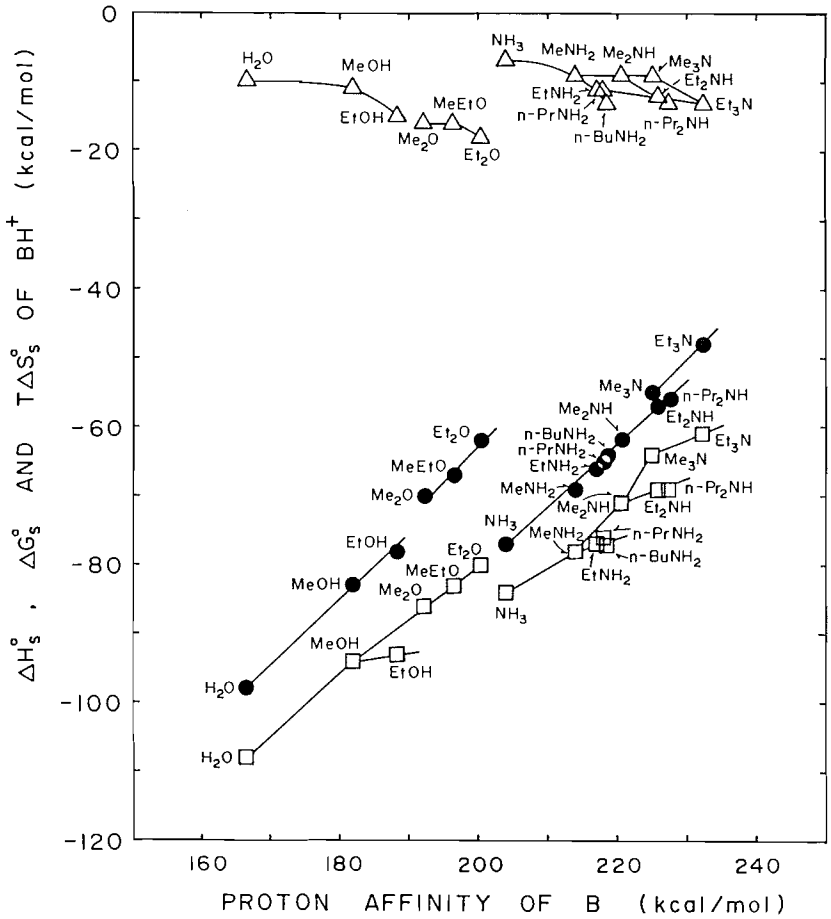

FIG. 2. □: The relationship between the proton affinity (PA) of the conjugate base measured in the gas phase and the enthalpy of hydration (ΔH_s^0) for the conjugate acid ion. ●: The relationship between the proton affinity (PA) of the conjugate base and the free energy of hydration (ΔG_s^0) for conjugate acid ion. △: The relationship between the gas-phase proton affinity of the conjugate base B and the entropy of hydration ($T\Delta S_s^0$) of conjugate acid ion BH^+. The $T\Delta S_s^0$ values are calculated from the ΔG_s^0 and ΔH_s^0 values reported by Taft (ref. 4).

NH_3 are small ($\lesssim$1 kcal/mol) (14) due to the compensation of enthalpy and entropy of hydration of B's (19, 20). Thus, relative basicities in aqueous solution $\delta\Delta G_i^0(w)$ are mainly determined by the values $\delta\Delta G_i^0(g) - \delta\Delta G_s^0(BH^+)$. Since $\delta\Delta G_i^0(g)$ are about the same with δPA (3), the approximate expression $\delta\Delta G_i^0(w) \approx \delta PA - \delta\Delta G_s^0(BH^+)$ may be derived. This relationship implies that the relative aqueous basicities $\delta\Delta G_i^0(w)$ may be roughly predicted by inspection of the inclination of the line in Fig. 2. For example, when the slope is unity, the aqueous basicities of BH^+'s falling on the line are predicted to be about the same. In Fig. 2, two straight lines with a slope of about 1 can be drawn on which NH_3 and Me_3N, and $MeNH_2$ and Me_2NH locate, respectively. This suggests that $\delta\Delta G_i^0(w)_{NH_3} \approx \delta\Delta G_i^0(w)_{Me_3N}$ and $\delta\Delta G_i^0(w)_{MeNH_2} \approx \delta\Delta G_i^0(w)_{Me_2NH}$, and the basicities for NH_3 and Me_3N are weaker than those for $MeNH_2$ and Me_2NH. This qualitatively predicts the quantitatively determined (14) $\delta\Delta G_i^0(w) = 0.00$, 1.92, 2.09, and 0.75 for NH_3, $MeNH_2$, Me_2NH, and Me_3N relative to NH_3. The most effective factors which determine the aqueous basicities are gas-phase basicities (PA) of B's and free energies of hydration of BH^+'s.

Close inspection of Fig. 2 indicates that the slopes of the linear relationships between ΔG_s^0 vs. PA are steeper than those between ΔH_s^0 vs PA for the analogous compounds, e.g., MeOH → EtOH, Me_2O → MeEtO → Et_2O, $MeNH_2$ → $EtNH_2$ → *n*-$PrNH_2$ → *n*-$BuNH_2$, Me_2NH → Et_2NH → *n*-Pr_2NH, and Me_3N → Et_3N. This is likely to be due to the more positive entropic contribution to the ΔG_s^0 values with an increase in the number and size of the structure-making hydrophobic groups (see Fig. 1).

The increase in the number and size of the aliphatic chains of alkyl-substituted H_3O^+ and NH_4^+ leads to an increase in PA due to the delocalization of positive charges in BH^+. The hydration energy of the protic hydrogens of BH^+ will decrease with an increase in PA. This may result in an *increase* in the entropy of hydration due to the formation of less tight hydration shells around the protic hydrogens. On the other hand, the ice-patch formation around the hydrophobic groups will be promoted with an increase in the number and size of the structure-making hydrophobic groups and this will *decrease* the entropy of hydration with an increase of PA. Figure 2 also shows the relationship between the gas-phase proton affinities of bases B's and entropies of hydration ($T\Delta S_s^0$) of conjugate acid ions BH^+'s which are calculated from the ΔH_s^0 and ΔG_s^0 values reported by Taft (15). Generally, the entropy of hydration $T\Delta S_s^0$ decreases with an increase of PA. This suggests that the contribution of the negative entropy change due to the hydration of hydrophobic groups is greater than that of the positive entropy change due to the hydration of protic hydrogen atoms of BH^+.

In Fig. 2, the change of $T\Delta S_s^0$'s values for NH_3 → $MeNH_2$ → Me_2NH → Me_3N is rather small. On the contrary, rapid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

decreases in $T\Delta S_s^0$'s are observed for $MeNH_2 \rightarrow EtNH_2$(*n*-$PrNH_2$) $\rightarrow$ *n*-$BuNH_2$. As already pointed out, direct methyl substitution of NH_3 decreases the exothermicity of hydration of the conjugate acid ions and this reduces structure of the hydrates directly solvating the onium ends, i.e. an increase in ΔS_s^0. This compensates for the ΔS_s^0 decrease due to hydrophobic water structure-making for these alkyl groups. The same compensation is not available for the *n*-alkyl NH_2 because the gas-phase basicity changes for these compounds are small, i.e. the ΔS_s^0's due to onium ion hydration are approximately constant.

Concluding remarks

The relationships between ΔH_s^0, ΔG_s^0, $T\Delta S_s^0$ and the gas-phase PA are studied. Generally, the $T\Delta S_s^0$ and ΔH_s^0 values decrease and increase, respectively, with an increase in PA. The values of ΔG_s^0 ($= \Delta H_s^0 - T\Delta S_s^0$) are found to increase almost linearly with a slope of about 1 with an increase of PA for analogous compounds. Such a simple relationship would be very useful for the estimating free energies of transfer of protonated acid ions from the gas phase to the dilute aqueous solution using the available gas-phase PA.

The $-\Delta G_s^0$ values correspond to the energies required for the extraction of hydrated ions in aqueous solutions to the gas phase. The evaporation of ions from the condensed phases to the gas phase is a very important process in many fields such as the thermospray technique for the liquid chromatograph – mass spectrometer interface (23), electrohydrodynamic ionization (electrostatic spray) (24), field ionization, field-induced ion evaporation from liquid surface (25), etc. From the results presented here, one may draw a zeroth order principle that the protic acid ions whose conjugate bases have higher proton affinities are easier to be extracted from the aqueous solution to the gas phase.

Diels–Alder reactions of 4,4-dimethyl-2-cyclohexenones. A direct route to the 4,4-dimethyl-1-decalones[1]

HSING-JANG LIU AND ERIC N. C. BROWNE[2]
Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 2, 1986

HSING-JANG LIU and ERIC N. C. BROWNE. Can. J. Chem. **65**, 1262 (1987).

Diels–Alder additions to enones **1** and **2**, synthetic equivalents of the synthon **3**, were studied using a variety of hydrocarbon dienes. The two enones have been shown to be effective and synthetically useful dienophiles. Spectroscopic (especially ^1H and ^{13}C magnetic resonance) and chemical techniques were used to define unambiguously the full structures of the adducts. The structures of the various reaction products were used to draw qualitative conclusions about the nature of the transition states involved and the various electronic and steric effects that play a role in the mechanistic course of the Diels–Alder reaction.

HSING-JANG LIU et ERIC N. C. BROWNE. Can. J. Chem. **65**, 1262 (1987).

Utilisant une grande variété d'hydrocarbures diéniques, on a étudié les réactions d'additions de Diels–Alder sur les cétones **1** et **2**, les équivalents de synthèse du synthon **3**. On a démontré que les énones sont des diénophiles efficaces et utiles d'un point de vue de synthèse. On a utilisé la spectroscopie (principalement la résonance magnétique nucléaire du ^1H et du ^{13}C) ainsi que des techniques chimiques pour définir sans ambiguïtés les structures complètes des adduits. On a utilisé les structures des divers produits réactionnels pour tirer des conclusions qualitatives sur la nature des états de transition impliqués et sur les divers effets électroniques et stériques qui jouent un rôle dans l'orientation des réactions de Diels–Alder.

Introduction

Since the cycloaddition of dienes with olefins to give cyclohexenes was correctly formulated and seen to be a general process by Diels and Alder (1), it has proven to be one of the most versatile and powerful synthetic tools available to the organic chemist.[3] At the same time, mechanistic studies of the process have only lately begun to account successfully for the various effects upon the course of the reaction (3, 4). The early development of a series of empirical rules for predicting the structural outcome of the reaction facilitated its use in organic synthesis. The *cis* principle predicts that addition to the diene in the required cisoid conformation occurs from the same side at each end of the diene moiety and also that attack at both ends of the dienophilic double bond occurs from the same face of the dienophile. It further predicts that the relative configurations of the substituents in the transition state are preserved in the products. The *endo* rule, originally formulated (3, 5) for additions of cyclic dienes and dienophiles, has been explained (6) by a stabilization of the transition state in which secondary orbital overlap (6) can occur between the π system of the diene and a π system in conjugation with the dienophilic double bond. Using this requirement, it is evident that even in acyclic cases the term "*endo*" is correctly used when the addition proceeds by a transition state in which secondary orbital overlap occurs, while "*exo*" refers to additions via transition states in which no secondary orbital overlap occurs.

A group of orientation rules that predict the regiochemistry of additions between unsymmetrical dienes and dienophiles has also been developed. The *ortho* rule predicts that a substituent at C-1 of the diene promotes addition to give an adduct in which the substituent from the diene component is adjacent (*ortho*) to the substituent from the dienophile. In the case of 2-substituted dienes the *para* rule predicts formation of a product having the two substituents in a *para* relationship. More recently, using frontier orbital theory, Houk and Strozier predicted (7, 8) that, where substituents of both diene and dienophile are electron donating, the favoured product should be that with the *meta* orientation of the substituents.[4] This "*meta* rule" has since been observed experimentally by Fleming *et al.* (10).

Empirically determined priorities have been used to determine which of many possible substituent types and rule systems take precedence over others in any combination of experimental situations. The empirical rules can be broadened to a model of the controlling features of the reaction through the visualization of the reaction as an essentially electronically governed process, as highlighted by the rules of Woodward and Hoffmann (6) and by the many and various frontier orbital treatments that have been applied since that time (4, 6–8, 11). However, any model is necessarily a simplification of the actual process that occurs during a chemical reaction. Variation of actual results from those predicted by the model serves only to illustrate that the model lacks sufficient detail to cover all eventualities.

In theory the application of the Diels–Alder reaction (12, 13) to the synthesis of *cis*-1-octalones requires only a straightforward addition of a cyclohexenone to an appropriately substituted diene. The method has the potential for rapid assembly of the decalin skeleton of a number of natural products such as those of the eudesmane, drimane, and cadinane classes. As well, the unique stereo- and regioselectivity of the reaction promises that the required adducts could be obtained efficiently. Unfortunately, the thermal cycloaddition of dienes to cyclohexenone and its substituted analogs has been the least successful of the simple applications of the reaction. Early reports (14–16) of low yields and drastic conditions for the addition to cyclohexenones appear to have discouraged continued investigation on the direct generation of their adducts.

The observation that Lewis acid catalysis produces very large increases in the rates of the Diels–Alder additions of α,β-unsaturated carbonyl compounds (17–19) has made available

[1]Taken in part from the Ph.D. thesis of E.N.C. Browne, The University of Alberta, 1980.

[2]Present address: DeVoe–Holbein Canada Inc., 175 Bouchard Blvd., Dorval, Que., Canada H9S 1A9.

[3]The comments of Wenkert and co-workers (2) serve to highlight some of the very few limitations to this statement.

[4]This is also predicted by the heterolytic mechanism, which, however, incorrectly predicts the same outcome when both substituents are electron withdrawing (9).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12

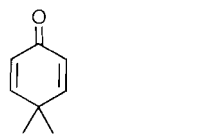
many adducts that had previously been obtained only with difficulty. Furthermore, it has been observed that such catalysis also has a marked effect on the regio- and stereoselectivity of the reaction so that the *ortho* (20) and *para* selectivity (21, 22) of the addition as well as the *endo* selectivity (23) are markedly increased. The application of Lewis acid catalysis to acyclic α,β-unsaturated carbonyl containing dienophiles has received fairly rapid recognition but it was not until recently that investigations (2, 24–32) have shown that the practice is equally applicable to cyclohexenones.

In connection with synthetic studies on himachalenes (33) and other terpenoids, we investigated the Diels–Alder reaction of 4,4-dimethylcyclohexenones as a direct route to the 4,4-dimethyl-1-decalone ring system common to a wide variety of natural products (34). We have previously reported (33, 35, 36) briefly on the dienophilic character of the two enones **1** and **2** and we wish now to elaborate on the full scope of our work in this area and to comment on the mechanistic and spectroscopic aspects of the results.

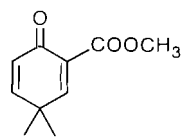
Results and discussion

I. Diels–Alder reactions of 4,4-dimethyl-2-cyclohexenone (3)

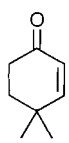
The Diels–Alder reaction of the parent enone **3** (37) with isoprene and 1,3-butadiene[5] was first studied using boron trifluoride etherate or aluminum chloride as a catalyst[6] in a variety of solvents and at a wide range of temperatures (20–110°C). In virtually all cases, the dimeric compounds **4** and **5** were obtained as the major products and in no instance



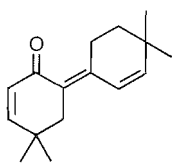
1



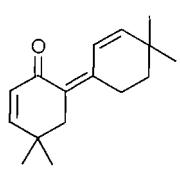
2



3



4



5

was a Diels–Alder adduct produced in a significant quantity (<14% yield). The Diels–Alder reactions were also examined under thermal conditions. The results were, however, equally disappointing; whereas enone **3** remained unchanged at lower temperatures, reaction with isoprene at 250°C in mesitylene in a sealed tube gave a complex mixture from which the desired adduct was absent. These findings indicated to us that enone **3** is a rather poor dienophile. Although Wenkert and co-workers have subsequently achieved cycloaddition of **3** in synthetically useful yield (2) by aluminum chloride catalysis, it was more promising in our context to investigate addition of dienes to a modified dienophile system.

II. Diels–Alder reactions of 4,4-dimethyl-2,5-cyclohexadienone (1)

Effective addition of the enone **3** synthon to dienes appears to require both increased dienophilicity and protection of the molecule against side reactions such as aldol condensation. The introduction of a second double bond into the ring of enone **3** offers the dual advantage of preventing the troublesome aldol condensation experienced with **3** as well as enhancing the desired reactivity of the molecule both by increasing the number of dienophilic double bonds and by increasing the planarity of the molecule. With this in mind we examined the Diels–Alder reactivity of dienone **1** (38, 39).

It was found that in ether solution at room temperature with boron trifluoride etherate as the catalyst and using a large excess of diene, adducts were obtained in moderate yield over rather extended reaction times. The results of this study are summarized in Table 1. The adducts were found to be those predicted on the basis of the normal rules governing the orientation and the stereochemistry of Diels–Alder addition (12), with one exception. The addition of isoprene to **1** (Entry 1) proceeded exclusively to give the adduct **6** formed in violation of the *para* rule.[7]

TABLE 1. Diels–Alder additions to dienone **1**

Entry	Diene (equiv.)	Time (days)	Yield (%)	Adduct
1	(40)	22	61[a]	 (36) **6**

[b]See ref. 36.

[c]The corresponding 3-methoxy ketone (**22**, **23**, or **24**) arising from conjugate addition of methanol was also obtained in ~20% yield.

Structural assignments

Several aspects of the structural assignments of adducts **6–10** should be discussed. The regiochemistry of the Diels–Alder additions of unsymmetrical dienes (Table 1, Entries 1 and 3–5) was conclusively demonstrated by conversion of the enones to aryl-ketone derivatives by treatment with *N*-bromosuccinimide (36, 41) in refluxing carbon tetrachloride, as summarized in Table 2. The structures of the resulting ketones were unambiguously established by their ^{1}Hmr spectra, which showed, in each case, the absence of a *peri* proton and a profound *peri* effect (42) of the carbonyl on the substituent at C-8, which is held in the deshielding zone of the carbonyl group, causing the signal of that substituent to be shifted downfield significantly. For example, the ^{1}Hmr spectrum of **14** displayed an aryl methyl group as a singlet at δ 2.70 and three aromatic protons at δ 7.30 (2H) and 7.05. The absence of any signals at lower field[8] as well as the appearance of an aryl methyl group at a field considerably lower than normal (~δ 2.3) were in agreement only with the assigned structure.

The ring junction stereochemistry of all the adducts could be readily assigned on the basis of the *cis* principle (12), for which no violations have been observed. This was confirmed by conversion of each adduct with sodium hydroxide in aqueous methanol at room temperature to the thermodynamically more stable *trans* isomers **18–21**, as summarized in Table 2.

The relative stereochemistries of B-ring substituents in **8–10** were assigned as indicated on the basis of their ^{1}Hmr spectra presented and discussed below.

Nuclear magnetic resonance assignments

Nuclear magnetic resonance spectral data for adducts of **1** and their epimerization products are summarized in Tables 3 and 4. Spectra were readily assigned, based on first-order analysis. The chemical shifts of several protons and carbons on enones of this series are significantly different in the *cis*- and *trans*-enones and these nmr signals were used routinely in assigning the stereochemistry of the substituted enones obtained in this work. For instance, the readily distinguishable C-3 proton invariably appears at ~0.3–0.4 ppm higher field in the *cis* isomers than in

[8]In the ^{1}Hmr spectrum of the known ketone **17** (43), the *peri* proton appeared as a doublet with a coupling constant of 7 Hz at δ 8.25. Similarly, the ^{1}Hmr spectrum of ketone **13** (36) showed a narrowly split multiplet (<1 Hz) at δ 7.90, assigned to the *peri* proton.

the corresponding *trans* isomers. Likewise the sharp singlets due to the *gem*-dimethyl group are consistently separated by ~0.1 ppm in the *trans* isomers and by ~0.2 ppm in the *cis* isomers. In the ^{13}Cmr spectrum, shifts for C-3 routinely differ by 5 ppm between *cis* and *trans* isomers, with the former at higher field, while the geminal methyl carbons differ from each other by less than 1 ppm for *cis* versus more than 5 ppm for *trans* isomers.

A detailed discussion of the ^{1}Hmr spectrum of **7** is warranted in order to introduce several features that apply to other adducts in this series. The ^{1}Hmr spectrum of **7** showed that the two protons at C-8 had quite different chemical shifts. The assignment of the signal at δ 2.83 to the α proton and the signal at δ 1.94 to the β proton was made after selection of conformation **7***a* as the more stable conformation of the molecule. In this conformation, the α proton is held in the deshielding zone of the carbonyl group and thus the signal appears at considerably lower field (δ 2.83) than a normal allylic proton (δ 2.0) (42). The β proton is out of the plane of the carbonyl and further from it than the α proton and so experiences virtually no deshielding by the carbonyl. This argument was demonstrated conclusively by proton decoupling experiments on adduct **6**. Successful extrapolation of these arguments to analysis of the other C-8 substituted *cis*-hexalones summarized in Table 4 clearly reflects the utility of this effect and its action on C-8 protons and substituents on the α face of the molecule. The epimeric products **39** and **40** as well as **43** and **44** obtained later by alternative routes (see Table 6) exhibited the spectral characteristics expected on the basis of the preceding arguments.

Most of the *cis* isomers also exhibited a particularly distinct coupling arrangement, which confirms the ring junction stereochemistry and preferred conformation. For instance, in the case of adduct **8**, a long range W-type coupling of 1.5 Hz was observed in the signal at δ 6.15, which was attributed to coupling of the proton at C-3 with the proton at C-4a. A W configuration of these two protons is possible only in the *cis*-enone **8** in which the proton at C-4a could assume a quasi-equatorial position relative to ring A in the preferred conformation **8***a*. Such a configuration cannot be achieved in the *trans* isomer.

[a]Compare to shifts reported by Wenkert and co-workers (44).
[b]The signals for these protons were particularly useful for distinguishing the *cis* from the *trans* enones.
[c]This signal showed a long range W-type coupling to the proton at C-4a.
[d]The signal for this proton(s) was not clearly defined in the spectrum.

In confirming the stereochemistry at C-8[9] of adduct **10**, the only two ^{1}Hmr signals that might be attributable to the deshielded C-8 proton of the alternative epimer **25** were easily assignable to other protons. However, the α proton on the methylene carbon attached to C-8 lies in the deshielding zone of the carbonyl group and would be expected to be shifted downfield from its normal region (45) of δ 1.4. The predicted couplings for this proton fit well with the observed couplings of the signal at δ 2.50. No other proton in enone **10** would be expected to exhibit such a shift and coupling pattern, nor would any proton in structure **25**. This and the absence of any other signal in the region δ 2.5–5.0 would appear to rule out structure **25** and confirm structure **10** as the identity of the adduct.

Mechanistic discussion

The preceding results show that dienone **1** is a useful though moderately weak dienophile. Addition to simple hydrocarbon dienes proceeds smoothly to give acceptable yields of adducts. The most important item of note is the total violation of the *para* rule in the case of addition to isoprene. The normal addition of 1-substituted dienes leads to the conclusion that the cause of the abnormal addition of isoprene is a steric one; in the normal addition leading to the expected adduct **26**, the substituent at C-2 of the diene interacts with a substituent at C-4 of the dienophile as shown in the transition state **26A**.[10] If the steric effect were sufficiently strong, the electronically favoured *para* addition would be excluded and the otherwise less favourable *anti-para*[11] addition would predominate.

Comparison of the various dienes is interesting in this context. *trans*-Piperylene would not be expected to encounter any steric barrier to normal *ortho* addition and the *ortho*-addition product **8** is the only one observed. Similarly, only the expected product **10** is obtained from 1-vinylcyclohexene.

The addition of *trans*-2-methyl-1,3-pentadiene, however, raises an important point since the steric effect would act in opposition to the combined directing influence of the *ortho* and *para* rules. This offers the opportunity to determine the influence of the steric effect relative to the combined electronic effects. Total steric control would produce only enone **27** whereas electronic control would result only in formation of **9**. As we have seen, enone **9** is the only Diels–Alder addition product, indicating that a stronger electronic directing effect might be used to counteract the steric effect.

Clearly, this effect is tied to the influence of secondary orbital overlap (*endo*-rule addition) in the course of the reaction. The results of 2-substituted diene addition indicate that the influence of *endo* addition holds a higher level priority in this type of system than the steric effect and that indeed the *endo-anti-para* transition state **6A** is preferred to the extent of virtually complete exclusion over *endo-para* transition state **26A** and *exo-para* transition state **26B**.

One possible method to increase the influence of the electronic directing effect of **1** might be the use of a stronger, and therefore more electron-withdrawing, Lewis acid as the catalyst. The larger induced polarization of the dienophilic double bond should act to promote *para* addition. But the use of boron tribromide (benzene, room temperature, 11 days) did not

[9]The numbering scheme used in this discussion for phenanthrene ring systems and illustrated for structure **25** is applied only to be consistent with other compounds in this series.

[10]A similar explanation has been offered to account for the relatively poor dienophilicity of cyclohexenones (46).

produce any detectable trace of adducts of **1** with isoprene. Two other catalysts were also examined. Stannic chloride (ether, room temperature, 11 days) gave no detectable trace of Diels–Alder adduct, and ferric chloride (ether, room temperature, 7 days) produced an adduct in 3% yield, which ^{1}Hmr analysis showed to be almost exclusively enone **6**.[12] And, subsequently, Wenkert's work (44) using aluminum chloride provided only *anti-para* product **6** (and its *trans* isomer **11**).

III. Diels–Alder reactions of 2-carbomethoxy-4,4-dimethyl-2,5-cyclohexadienone (2)

Although Diels–Alder additions of dienone **1** produce acceptable yields of useful adducts, the long reaction times might tend to lessen its general utility. Furthermore, in the case of *para*-rule directed additions, the total violation of the electronic directing effect renders such *para*-substituted adducts inaccessible. On the basis of the Alder rule,[13] one method of increasing the reaction rate would be to place an additional electron-withdrawing substituent on the dienophilic double bond, increasing the polarization of that bond and the strength of the electronic *para*-directing effect on 2-substituted dienes, as well as the reaction rate. Appropriate choice of substituent could overcome the steric effect that promotes the observed *anti-para* addition.

In an effort to test these assumptions the dienone ester **2** was examined. The choice of a carbomethoxyl group as an activating substituent offers several advantages. It can be easily removed from the resulting β-keto-esters by decarboxylation, and it offered a level of functionalization that might be used effectively in synthetic schemes (for example see refs. 33 and 47).

On the basis of the Alder rule, the unsubstituted enone system of **2** is expected to be relatively less reactive and addition to the trisubstituted double bond would be preferred. In cases where the *endo* rule comes into effect, addition could occur with secondary orbital overlap either with the ketone or ester carbonyl system (transition states of type **A** or **B**). The factor determining which system would dominate the reaction pathway is expected to be a function of the stabilization of the transition state by secondary orbital overlap with the diene. However, in the case of addition of 2-substituted butadienes, it is apparent that preferential interaction with the ester carbonyl would totally eliminate the steric effect between the substituent and the methyl groups of the dienophile that might be experienced by overlap with the ketone carbonyl. This could contribute to the production of the electronically favoured product in the addition of 2-substituted dienes.

Dienone ester **2** was easily prepared from enone **3** by procedures published previously (33, 35). It was found to add rapidly to dienes in ether solution and, under boron trifluoride etherate catalysis, to give 1:1 adducts in good yield, as summarized in Table 5.

The adducts produced were, in general, consistent with those forecast by the usual rules. Addition occurred almost exclusively at the more highly activated site and orientational rules were maintained. *Endo*-rule addition by secondary orbital overlap with the ketone carbonyl predominated in simple cases where this could be observed (Entries 3, 4, and 7) uncomplicated by other factors. Again the notable exception to predicted behavior was the addition of isoprene (Entry 6), which proceeded under boron trifluoride etherate catalysis to give a 70:30 mixture of the *anti-para* and *para* addition products **34** and **35**.[14]

Structural assignments

The structural assignments of the various adducts deserve some explanation. In general, the keto-ester adducts were converted by decarboxylation with lithium iodide dihydrate in refluxing 2,4,6-collidine (48) to the corresponding hexalones, as summarized by the specific examples in Table 6. Those hexalones were identified by comparison with similar or identical compounds obtained directly from Diels–Alder additions to **1** (Table 2) on the basis of their ^{1}Hmr and ^{13}Cmr spectral (Tables 3 and 4) methods described previously (*vide supra*). As was the case with adducts of **1**, the regiochemistry of addition was conclusively demonstrated by aromatization of the decarboxylation products by treatment with *N*-bromosuccinimide (36, 41) and observation of the "*peri*" deshielding effect (42) of the carbonyl double bond on the C-8 substituent. The *cis* stereochemistry of the ring junction of the adducts of **2** was assigned based on the ^{1}Hmr evidence exemplified as follows for the case of adduct **28**. Firstly, it should be noted that *no exceptions* to the *cis* principle are known (46). Secondly, the ^{1}Hmr spectrum of the adduct (Table 7) showed a doublet of doublets (J = 6 Hz, J = 4 Hz) at δ 2.75. This signal showed no evidence of a geminal coupling and therefore was assigned to the methine proton at C-4a. The normal chemical shift of a proton β to a ketone is δ 1.95 (45). It was possible that the

[12]This was confirmed by comparison (gc, ^{1}Hmr) with authentic enones **6** (36) and **26** (33).

[13]The Alder rule predicts that substitution of an electron-withdrawing substituent on the dienophilic double bond increases the reactivity of that bond and that substitution of electron-donating substituents on the diene increases the reactivity of the diene (3).

[14]The structural identification of **34** and **35** and certain limited aspects of the effect of different catalysts on the product ratio have been discussed in connection with the application of this reaction to the synthesis of himachalenes (33).

[a]A small amount (~7% yield) of keto-ester **32** was observed in the unrecrystallized product.
[b]A small amount (<5% yield) of compound **33** was also obtained.
[c]An unambiguous confirmation of the structural assignment of this compound was made by X-ray analysis (J. Scheffer, personal communication).
[d]Ferric chloride was used as the catalyst.
[e]The formation of a pair of epimeric adducts **31** and **33** from addition of *cis*-piperylene probably stems from the presence of *trans*-piperylene (~3%) as an impurity in the commercial *cis*-piperylene used. *trans*-Piperylene is a much more reactive diene than the *cis* isomer and could compete effectively for the dienophile. The tenfold molar excess of diene used would provide sufficient *trans*-piperylene for conversion of up to 30% of the dienophile to **31**.

[d]Pure **9** was aromatized.

proton at C-4a was strongly deshielded by the ester carbonyl group and this was taken as evidence that the ester and the C-4a proton were on the same face of the molecule. Although this evidence for a *cis*-ring fusion is not absolutely conclusive in this particular case, several examples of this series (Entries 3, 4, and 8) give additional ^{1}Hmr evidence. These adducts show a long range W-coupling between the C-3 and C-4a protons in the ^{1}Hmr, which has been described previously for adducts of **1** and which can only be achieved by the *cis* isomer. We believe that, when coupled with the generality of the *cis* principle, the evidence is sufficient to warrant extrapolation of the stereochemical assignment to the whole series.

The relative stereochemistry of the B-ring substituents in **31**, **33**, **36**, **37**, and **38** was assigned as indicated on the basis of the ^{1}Hmr and ^{13}Cmr spectra (Tables 7 and 8) and also on the basis of identity of decarboxylation products with those obtained directly from addition to **1**.

Nuclear magnetic resonance spectral assignments

The nmr spectra for adducts of **2** are summarized in Tables 7 and 8, while nmr spectra of their decarboxylated derivatives are shown in Tables 3 and 4. Several points are noteworthy. Firstly, the previously mentioned downfield shift of the C-4a proton in the ^{1}Hmr spectrum from a normal value of δ 1.95 (45) to a range of δ 2.49–2.75, which is considered diagnostic for the *cis*-ring junction, is clearly evident. Secondly, the deshielding effect of the ketone carbonyl double bond on the C-8 α proton, which is diagnostic in the case of the adducts of **1**, must be treated more carefully in the case of adducts of **2**. While the effect is as predicted in the case of C-8 unsubstituted adducts, the C-8 substituted adducts generated in this sequence show an unexpected reversal. The signal due to the C-8 β proton of **31**, **36**, and **37** is deshielded by ~0.5 ppm relative to the corresponding proton in adducts of **1** (due to the ring junction carboxylate group), while the signals due to the C-8 α proton of **33** and **38**, rather than being unchanged relative to those in **39** and **43**, are in fact shielded by ~0.5 ppm.

In the ^{13}Cmr spectra, signals for C-3, C-4, C-4a, C-8, and the *gem*-dimethyl groups are all shifted significantly in the C-8 α-substituted group (**31** and **37**) relative to the C-8 β-substituted group (**33** and **38**).

The ^{1}Hmr spectrum was essential in assigning the bridge stereochemistry of **30**. In **30**, the conformation is a "sandwich-like" structure **30*a*** in which the isolated double bond is held above the carbon–carbon double bond of the enone system. As a result, the proton of C-2 would be shielded by the isolated double bond and the proton at C-6 would be shielded by the enone double bond. On the other hand, in **45** one of the C-9 protons would be shielded by the enone double bond.

On close examination of the ^{1}Hmr spectrum of the adduct, it was evident that neither of the C-9 protons (δ 1.60 and 1.41) was particularly shielded relative to the bridge protons of the model compound norbornene (δ 1.32 and 1.07 (42)). Comparison of the chemical shift of the proton at C-2 (δ 5.60) with other compounds in this series (δ 5.69–5.87) showed that it was experiencing a shielding effect. Furthermore, one of the olefinic protons (δ 5.75) was shifted upfield from the normal value of δ 5.95 for norbornene (42). These data supported the assignment of structure **30**.

In view of the unexpected shifts described previously for the C-8 substituted adducts of **2**, their C-8 stereochemistries are most reliably determined by ^{1}Hmr analysis of their decarboxylation products, the rationalization of whose spectra has been presented in the earlier discussion of Table 4. For example, conclusive evidence of the C-8 stereochemistry of keto-ester **38** was determined by analysis of the ^{1}Hmr spectrum of its decarboxylation products **43** and **44**. As was predicted in the discussion of Entry 4, Table 1, the C-8 proton of *cis*-enone **43** was deshielded by the ketone carbonyl and appeared at δ 2.97 while the C-8 methyl substituent appeared at the normal shift of δ 0.97. Such an effect is only possible if the C-8 stereochemistry is as depicted in **43**.

Mechanistic discussion

From the preceding results it can be seen that dienone ester **2** is a much more reactive dienophile than dienone **1** and reacts even with relatively unreactive dienes (Table 5, Entry 2) to give adducts in good yields. Furthermore, the dienophilicity (with one minor exception, Entry 4) is entirely restricted to the more substituted double bond. As expected, the *ortho* rule is followed when applicable (Entries 4, 5, 7, and 8). However, the anticipated promotion of *para* addition of 2-substituted dienes under boron trifluoride ethereate catalysis was disappointingly small (Entry 6). The *endo* selectivity of additions to dienone ester **2** appears to be with a dominant preference for secondary overlap (6) with the ketone carbonyl group (transition states of type **A**) rather than with the ester group (transition states of type **B**) (Entries 3–5 and 7). However, the formation of the two C-8 epimeric adducts **37** and **38** by addition of *trans*-2-methyl-1,3-pentadiene (Entry 8) clearly results from addition via two quite different transition states. Keto-ester **37** would be the result of addition via transition state **37A**, whereas keto-ester **38** would be the result of addition via transition state **38B**. The

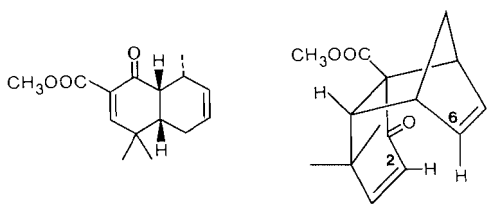
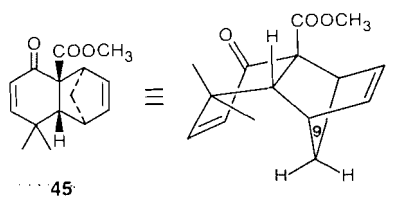
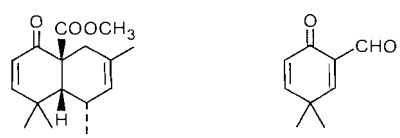
competition of these two transition states is attributed to the now familiar destabilization of transition state **37A** by steric interaction between the C-2 methyl group of the diene and a C-4 methyl group of the dienophile in a manner analogous to that encountered in the addition of isoprene to dienone **1** (Table 1, Entry 1). The combined *ortho*- and *para*-directing electronic effects are sufficient to counteract the steric destabilization of transition state **37A** and no abnormal addition product **46** is observed. However, the steric destabilization in transition state **37A** can be alleviated without violation of the *ortho* and *para* rules in this case by addition via transition state **38B**. The experimental results confirm that reaction through this transition state does in fact compete effectively with **37A**.



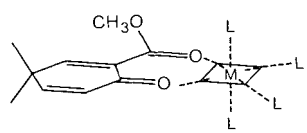
32 **30a**



45



46 **47**



L=ligand : Cl^-, R_2CO and/or R_2O

48 M=Sn
49 M=Fe

The competition of the two different transition states **37A** and **38B** for addition of *trans*-2-methyl-1,3-pentadiene suggests that a similar effect might operate for addition of isoprene. A portion of the material would proceed via the *para*-rule guided transition state **35B**, in which there is no steric interaction between the methyl groups, to give only keto-ester **35**. The remainder would proceed via transition state **34A/35A** through which the ratio of products **34** and **35** would be governed by the relative strengths of the steric and electronic directing effects, and the ratio of the two competing pathways would thus be reflected in the product ratio.

Catalyst studies

In view of the preceding discussion, two possible methods are available for further enhancement of the *para* selectivity of addition of isoprene to dienophiles of this type. Increasing the polarization of the dienophilic double bond should lead to increased *para* selectivity regardless of which transition state type (**A** or **B**) is in effect. And secondly, any change in the reaction conditions that would favour a transition state of type **B** relative to one of type **A** should also increase the *para* selectivity, since only *para* addition of isoprene is expected via transition states of type **B**. The former requirement might be achieved either by the use of a stronger (and therefore more electron-withdrawing) Lewis acid catalyst or by substitution of the carbomethoxy group of **2** with a more electron-withdrawing substituent. Thus the ratio of *para:anti-para* addition products could well be a function of the relative Lewis acidity of the catalyst. However, both the addition of other activating groups and change of catalyst could have a less clearly defined influence on the course of the reaction.[15] *Endo* selectivity is

[15]Liotta *et al.* (49) have subsequently examined the Diels–Alder reaction of formyl substituted dienone **47** with piperylene and observed preference for a transition state of type **A**.

[a]Reaction was not run to completion.

increased under the influence of Lewis acid catalysis (8, 23). Thus one might predict that appropriate choice of a Lewis acid that would, in the ideal case, complex *only* with the ester carbonyl would promote preferential secondary overlap with the ester group (as in type **B**) rather than with the ketone carbonyl (as in type **A**).

To study these possibilities, we examined a variety of Lewis acids as catalysts for the addition of isoprene to dienone ester **2** in ether solution and also briefly examined the reaction under thermal conditions. The results are summarized in Table 9. The table shows that the increase in the proportion of *para*-addition product obtained by varying the catalyst does not strictly parallel the general order of Lewis acidity (51): $BX_3 > AlX_3 > FeX_3 > SbX_5 > SnX_4 > ZnX_2$. It appears that the results are complicated by other factors, most probably the effect of the relative hardness or softness (52) of the Lewis acids and the effect of the Lewis acid on the relative stabilities of type **A** and type **B** transition states mentioned previously.

Several examples are particularly noteworthy. Firstly, the catalytic effect of boron trifluoride actually acts to decrease the *para* selectivity of the reaction relative to the thermal cases. This would appear to be due to the effect of preferential coordination of the relatively hard Lewis acid boron trifluoride with the ketone carbonyl group. The result is promotion of a type **A** transition state in which the electron-withdrawing effect on the dienophilic double bond promoting *para*-rule guided addition is insufficient to counteract the steric directing effect which promotes *anti-para* addition. Thus the predominant product is **34** rather than **35**.

In the case of stannic chloride, the Lewis acid is capable of forming 1:2 complexes with certain Lewis bases such as aldehydes, ketones, esters, and ethers (53). This could result in the formation of a complex such as **48** between the Lewis acid and the bidentate ligand dienone ester **2**. The electron-withdrawing effect of the Lewis acid exerted on the dienophilic double bond through the two carbonyl groups at once, together with the expected increase in contribution to the reaction from transition state **35B**,[16] could account for the surprisingly high **35**:**34** product ratio. Regardless of the reason for this effect, the ability to select the predominant product of addition (**34** or **35**) solely by the choice of the Lewis acid catalyst (boron trifluoride etherate or stannic chloride) constitutes a prime example[17] of the concept of "guidance by catalysis," which has been conceived and demonstrated by Valenta and co-workers (55, 56). The realization of this capability for product selection constitutes a powerful tool in the design of synthetic schemes.

The case of ferric chloride is also noteworthy. The remarkable increase in reaction rate brought about by this catalyst has made possible the addition to **2** of the relatively unreactive diene *cis*-piperylene (Table 5, Entry 5) to give keto-ester **33**, and has also allowed the rapid generation of adduct **36** in good yield with efficient use of the rather costly diene.[18]

The reasons for this effect could stem from the ability of Fe(III) to form hexacoordinate complexes (58) with β-dicarbonyl compounds, so that the bidentate ligand keto-ester **2** could form a complex such as **49**, as was suggested for stannic chloride. The electron-withdrawing effect of the Lewis acid acting through both carbonyls could lead to a particularly strong polarization of the double bond. Since ferric chloride is expected (51) to be a stronger Lewis acid than stannic chloride, the slower rate for stannic chloride is not considered unusual. Clearly the differing ligand field energies and bond lengths and angles introduced by the different size and electronic character of the two transition metals in these complexes also play a definitive role in this effect that is not yet clearly definable.

[16]This increase is expected for two reasons. Firstly, Lewis acid complexation of the ester carbonyl to any extent would be expected to promote secondary overlap with the ester group (8, 23) at the expense of secondary overlap with the ketone. And secondly, since the experimental evidence suggests that the hard Lewis acid boron trifluoride complexes preferentially with the ketone carbonyl, it is possible that the very soft Lewis acid stannic chloride might exhibit a preference for closer association with the ester carbonyl in complex **48**. This would further promote secondary overlap with the ester relative to the ketone and lead to an increased contribution to the reaction from **35B**.

[17]For another example, see ref. 54.

[18]Yield of 72% after 45 min using 2 equiv. of 1-vinylcyclohexene (57).

Conclusions

Demonstration of the scope of dienone **1** and dienone ester **2** as dienophiles makes available two useful new intermediates for the synthetic chemist. In particular, dienone ester **2** offers a reactive dienophile that can add efficiently even to relatively unreactive dienes. Furthermore, the activating substituent (carbomethoxyl) of **2** can either be removed or used as reactive site for further elaboration of the adducts.

Experimental

General

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Elemental analyses were performed by the microanalytical laboratory of this department. Infrared (ir) spectra were recorded on a Perkin–Elmer model 457 or Nicolet 7-199 FT-IR spectrophotometer and, except where otherwise stated, were obtained on solutions in chloroform. The ^{1}Hmr spectra were recorded on a Varian HA-100, HA-100/Digilab, or Bruker WH-200 spectrometer and, except where otherwise stated, were obtained on solutions in carbon tetrachloride with tetramethylsilane as internal reference. The ^{13}Cmr spectra were recorded on a Bruker WP-60/Nicolet BNC-12 system or a Bruker HFX-90/Nicolet 1085 system and were obtained on solutions in deuteriochloroform using tetramethylsilane as internal reference. Mass spectra (ms) were recorded using A.E.I. model MS9, MS12, or MS50 mass spectrometers. Gas chromatography (gc) was performed on a Hewlett Packard 5750 research chromatograph using stainless steel columns (8 ft × 1/8 in.) packed with either 10% diethylene glycol succinate (Column A) or 15% SE-30 (Column B) on 80–100 mesh Chromosorb W, acid washed and treated with dimethylchlorosilane. Unless stated otherwise, anhydrous magnesium sulfate was used for drying organic solutions.

Materials

Benzene was distilled over lithium aluminum hydride or sodium wire. Pyridine was distilled over barium oxide and stored over potassium hydroxide pellets. 2,4,6-Collidine was distilled over potassium hydroxide pellets. Isoprene was distilled prior to use. Boron trifluoride etherate was distilled over calcium hydride according to the procedure of Brown (59, 60). Nitrogen was passed through a purification train of Fieser's solution (60), saturated aqueous lead acetate, concentrated sulfuric acid, and potassium hydroxide pellets. 4,4-Dimethyl-2,5-cyclohexadienone (**1**) was prepared from 4,4-dimethyl-2-cyclohexenone (**3**) by the method of Zimmerman *et al.* (39). 4,4-Dimethyl-2-cyclohexenone was prepared from methyl vinyl ketone and *N*-(1-isobutenyl)-piperidine by the method of Djerassi and co-workers (37). *N*-(1-Isobutenyl)-piperidine was prepared by the method of Benzing (61). 1-Vinylcyclohexene was prepared according to the established procedure (62) or by a more efficient method described herein. Cyclopentadiene was prepared by thermal cracking of dicyclopentadiene and was stored at −30°C prior to use. *cis*-Piperylene (≥97% *cis*) was obtained from Fluka A.G.

*4,4-Dimethyl-4aβ,5,8,8aβ-tetrahydro-1(4*H*)-naphthalenone (7)*[19]

Dienone **1** (306 mg, 2.51 mmol) was dissolved in ether (20 mL) under an atmosphere of nitrogen. Boron trifluoride etherate (179 mg, 1.26 mmol) was added to the stirred solution and after 15 min dry butadiene gas[20] (passed through a drying tube of anhydrous calcium chloride) was bubbled into the solution. Additional butadiene gas was introduced for 15 min each day for 22 days. Then saturated aqueous

[19]The stereochemical designations used in this section denote *relative* stereochemistry. All compounds employed and obtained were racemic.

[20]A more convenient method of introducing butadiene to a reaction at atmospheric pressure and room temperature is to introduce a saturated solution of butadiene in benzene (~20% v/v in butadiene) to the ethereal solution of the dienophile (63).

sodium bicarbonate (3 mL) was added and the reaction mixture was extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 2% ether in petroleum ether, gave enone **7** (78 mg, 26% yield based on consumed starting material), which crystallized on standing. Further elution with 10% ether in petroleum ether gave recovered dienone **1** (99 mg, 31% recovery). Molecular distillation of chromatographically pure enone **7** in a Kugelrohr apparatus gave pure crystals of enone **7**; mp 69.5–70.5°C; ir (CCl_4): 1675 (C=O), 1383, and 1371 (CH_3) cm^{-1}; ^{1}Hmr δ: 6.31 (dd, 1H, J = 10, J' = 2 Hz, -C*H*=CH—CO-), 5.72 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 5.55 (m, 2H, -CH=CH-), 2.92 (m, 1H, —CH—CO—), 2.83 (dm, 1H, J = 18 Hz, C-8α H), 1.99 (m, 3H, C-4a H and C-5 -CH_2-), 1.94 (dm, 1H, J = 18 Hz, C-8β H), 1.31 (s, 3H, CH_3), and 1.10 (s, 3H, CH_3); ms M^+: 176.1202 (calcd. for $C_{12}H_{16}O$: 176.1202). *Anal.* calcd. for $C_{12}H_{16}O$: C 81.77, H 9.15; found: C 81.83, H 9.29.

*4,4,6,8β-Tetramethyl-4aβ,5,8,8aβ-tetrahydro-1(4*H*)-naphthalenone (**9**) and 2-(1,4-dimethyl-3-butenyl)-4,5-dimethylphenol (**12**)*

Dienone **1** (292 mg, 2.32 mmol) was dissolved in anhydrous ether (10 mL) and boron trifluoride etherate (104 mg, 1.16 mmol) was added followed by *trans*-2-methyl-1,3-pentadiene (1.90 g, 23.1 mmol). After stirring for 7 days, saturated aqueous sodium bicarbonate (1 mL) was added and the resulting mixture was extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 2–5% ether in petroleum ether, gave a mixture (236 mg) of enone **9** and phenol **12**. Further elution with 10–50% ether in petroleum ether gave recovered dienone **1** (33 mg, 12% recovery). Flash chromatography (64) of the mixture of enone **9** and phenol **12** on silica gel, eluting with 5% ethyl acetate in petroleum ether, gave pure enone **9** (84 mg, 20% yield based on consumed starting material); ir: 1687 (C=O), 1396, 1374, 1365 (CH_3), and 815 (C=CH) cm^{-1}; ^{1}Hmr δ: 6.13 (dd, 1H, J = 10, J' = 2 Hz, -C*H*=CH—CO-), 5.53 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 5.19 (br s, 1H, =CH—), 2.77 (dd, 1H, J = 4, J' = 3 Hz, C-8a H), 2.24 (m, 1H, —C*H*—CH_3), 1.57 (s, 3H, =C—CH_3), 1.33 (d, 3H, J = 7 Hz, —CH—CH_3), 1.31 (s, 3H, CH_3), and 1.09 (s, 3H, CH_3); ms M^+: 204.1510 (calcd. for $C_{14}H_{20}O$: 204.1514). Continued elution gave a mixture (20 mg) of ketone **9** and phenol **12** (~50:50 by ^{1}Hmr integration). Final elution gave pure phenol **12** (53 mg, 13% yield based on consumed starting dienone **1**); ir: 3438 (OH), 1668 (C=C), 1619, 1510 (aromatic C=C), and 1376 (CH_3) cm^{-1}; ^{1}Hmr δ: 6.73 (s, 1H, C-3 Ar-H), 6.38 (s, 1H, C-6 Ar-H), 5.18 (dm, 1H, J = 9, J' = 1 Hz, =CH—), 4.91 (br s, 1H, -OH), 3.70 (dq, 1H, J = 9, J' = 7 Hz, —C*H*—CH_3), 2.14 (s, 6H, 2 × Ar-CH_3), 1.70, 1.66 (both d, 6H total, each J = 1 Hz, =C(CH_3)$_2$), and 1.24 (d, 3H, J = 7 Hz, —CH—CH_3); ms M^+: 204.1508 (calcd. for $C_{14}H_{20}O$: 204.1514).

1-Vinylcyclohexanol

A 1.40 *N* solution of vinyllithium in tetrahydrofuran (300 mL, 0.42 mol of vinyllithium) was added to anhydrous ether (700 mL) by forced siphon (65) at 0°C under an atmosphere of nitrogen. A solution of cyclohexanone (39.3 g, 0.40 mol) in anhydrous ether (300 mL) was added to the stirred solution dropwise over 90 min. After stirring for 30 min the reaction mixture was poured into ice-cold saturated aqueous ammonium chloride with vigorous stirring. The resulting mixture was extracted with ether and the extracts were washed with water, dried (sodium sulfate), filtered, and concentrated. Distillation of the residue gave the pure alcohol (44.35 g, 78% yield) as a colourless oil: bp 67–69°C/16 Torr (1 Torr = 133.3 Pa); ir (neat): 3600 (OH, free), 3390 (OH, H-bonded), 3080 (-CH=CH_2), 1640 (C=C), 995 and 970 (-CH=CH_2) cm^{-1}; ^{1}Hmr δ: 5.87 (dd, 1H, J = 18, J' = 11 Hz, -C*H*=CH_2), 5.14 (dd, 1H, J = 18, J' = 2 Hz, -CH=CH—*H* (*Z*)), 4.90 (d, 1H, J = 11, J' = 2 Hz, -CH=CH—*H* (*E*)), 1.64 (s, 1H, -OH), and 1.47 (br s, 10H, 5 × -CH_2-).

1-(p-Toluenesulfonylcarbamoyl)-1-vinylcyclohexane

1-Vinylcyclohexanol (1.22 g, 9.71 mmol) was dissolved in benzene (10 mL) and a solution of *p*-toluenesulfonylisocyanate (2.11 g, 10.6 mmol) in benzene (5.0 mL) was added with stirring. After 1 h, a small amount of water (~100 μL) was added to destroy excess isocyanate and the solution was diluted with ether (~5 mL), dried, filtered, and concentrated under vacuum at room temperature. The crude carbamate (3.95 g, 126% yield) thus obtained as powdery crystals[21] was contaminated with *p*-toluenesulfonamide. Column chromatography of a portion (495 mg) of this crude product on silica gel, eluting with 25–50% ether in petroleum ether, gave the pure carbamate (230 mg, 59% yield from 1-vinylcyclohexanol) as a colourless viscous oil; ir (neat): 1780 (C=O), 1588, 1483 (C=C, aromatic), 1335 (-SO_2—N—), and 1145 (-SO_2-) cm^{-1}; ^{1}Hmr δ: 8.30 (s, 1H, -NH-), 7.83 (d, 2H, J = 8 Hz, 2 × -SO_2—C=CH-), 7.24 (d, 2H, J = 8 Hz, 2 × CH_3—C=C*H*—), 5.83 (dd, 1H, J = 18, J' = 11 Hz, -C*H*=CH_2), 4.96 (d, 1H, J = 11 Hz, -CH=CH—*H* (*E*)), 4.91 (d, 1H, J = 18 Hz, -CH=CH—*H* (*Z*)), 2.43 (s, 3H, -CH_3), 2.10 (br s, 2H, 2 × -O—C—CH—*H*), and 1.50 (br s, 8H, 3 × -CH_2- and 2 × -O—C—CH—*H*); ms (NH_3 chemical ionization) parent peak: 341 (M + NH_4^+). *Anal.* calcd. for $C_{16}H_{21}NO_4S$: C 59.42, H 6.54, N 4.33, S 9.91; found: C 59.21, H 6.83, N 3.96, S 9.55.

1-Vinylcyclohexene[22]

The crude carbamate (3.38 g, ~10.4 mmol) obtained from the preceding experiment was heated in a Kugelrohr apparatus to ~150°C and the distillate was collected in a water-cooled outer trap for 1 h. The distillate was found to be pure 1-vinylcyclohexene (790 mg, 87% from 1-vinylcyclohexanol) as a colourless liquid; ir (neat): 3090 (-CH=CH_2), 3030 (-CH=CH_2), 1645 (C=C), 995 and 905 cm^{-1} (-CH=CH_2); ^{1}Hmr δ: 6.21 (dd, 1H, J = 18, J' = 10 Hz, -C*H*=CH_2), 5.65 (br s, 1H, -C=CH—), 4.93 (d, 1H, J = 18 Hz, -CH=CH—*H* (*Z*)), 4.80 (d, 1H, J = 10 Hz, -CH=CH—*H* (*E*)), 2.02 (m, 4H, -CH_2—C=CH—CH_2-), and 1.64 (m, 4H, -CH_2—CH_2-).

*4,4-Dimethyl-4aβ,5,7,8,9,10,10aβ,10bβ-*octahydro-1(4H)*-phenanthrenone (**10**)*

Dienone **1** (160 mg, 1.31 mmol) was dissolved in anhydrous ether (10 mL). Boron trifluoride etherate (93 mg, 0.66 mmol) was added with stirring followed by 1-vinylcyclohexene (450 mg, 2.50 mmol). After 3 days, a solution of 1-vinylcyclohexene (450 mg, 2.50 mmol) in ether (2.0 mL) was added. The mixture was stirred for an additional 2 days and then saturated aqueous sodium bicarbonate (1 mL) was added. The mixture was extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with

[21] One crystallization of the crude carbamate (900 mg) from ether gave colourless crystals (mp 48–59°C, 350 mg), which were identified as the mono-etherate complex of the carbamate by their ^{1}Hmr spectrum. In addition to signals due to the carbamate, two signals due to diethyl ether were observed at δ 3.35 (q, 4H, J = 7 Hz, 2 × -OCH_2-), and δ 1.12 (t, 6H, J = 7 Hz, 2 × -CH_3).

[22] This approach to 1-vinylcyclohexene was suggested to us by Dr. Z. Valenta as a reliable procedure which uses the 1-vinylcyclohexanol precursor more efficiently.

3–5% ether in petroleum ether, gave pure enone **10** (201 mg, 67% yield), which crystallized on standing; mp 43–47°C; ir: 1686 (C=O), 1392, 1373, and 1362 (CH_3) cm^{-1}; ^{1}Hmr δ: 6.12 (d, 1H, J = 10 Hz, -C*H*=CH—CO-), 5.57 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 5.08 (br s, 1H, =CH—), 2.86 (m, 1H, -CO—C*H*—), 2.50 (dddd, 1H, $J = J' = J'' = 12$, $J''' = 4$ Hz, C-10α H), 1.28 (s, 3H, CH_3), and 1.04 (s, 3H, CH_3); ^{1}Hmr (200 MHz, $CDCl_3$) δ: 6.23 (d, 1H, J = 10 Hz, -C*H*=CH—CO—), 5.71 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 5.21 (s, 1H, =CH—), 3.00 (dddd, 1H, $J = J' = J'' = 12$, $J''' = 4$ Hz, C-10α H), 1.28 (s, 3H, CH_3), and 1.04 (s, 3H, CH_3); ms M^+: 230.1666 (calcd. for $C_{16}H_{22}O$: 230.1670). *Anal.* calcd. for $C_{16}H_{22}O$: C 83.43, H 9.63; found: C 83.38, H 9.62.

*4,4,6,8-Tetramethyl-1(4*H*)-naphthalenone (**15**)*

Enone **9** (35 mg, 0.172 mmol) was dissolved in carbon tetrachloride (5 mL) and *N*-bromosuccinimide (61 mg, 0.343 mmol) was added, followed by benzoyl peroxide (3 mg, 0.012 mmol). The mixture was heated at reflux with vigorous stirring for 1 h, then cooled to room temperature, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 1% ether in petroleum ether, gave pure aryl-ketone **15** (6 mg, 17% yield); ir: 1665 (C=O), 1604 (aromatic C=C), 1395, 1375, and 1363 (CH_3) cm^{-1}; ^{1}Hmr δ: 7.06 (br s, 1H, C-7 Ar-H), 6.86 (br s, 1H, C-5 Ar-H), 6.59 (d, 1H, J = 10 Hz, -C*H*=CH—CO-), 6.09 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 2.64 (s, 3H, C-8 Ar-CH_3), 2.34 (s, 3H, C-6 Ar-CH_3), and 1.43 (s, 6H, 2 × -CH_3); ms M^+: 200.1199 (calcd. for $C_{14}H_{16}O$: 200.1201).

*4,4-Dimethyl-7,8,9,10-tetrahydro-1(4*H*)-phenanthrenone (**16**)*

trans-Enone **21** (77 mg, 0.33 mmol) was dissolved in carbon tetrachloride (10 mL), and *N*-bromosuccinimide (119 mg, 0.67 mmol) and benzoyl peroxide (5 mg, 0.021 mmol) were added. The mixture was heated at reflux with stirring for 1 h, then cooled to room temperature, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 2–3% ether in petroleum ether, gave aryl-ketone **16** (26 mg, 30% yield), which crystallized on standing. One recrystallization from petroleum ether gave yellowish crystals of aryl-ketone **16**; mp 102–110°C; ir: 1657 (C=O), 1631 (C=C), 1597 (aromatic C=C), 1375 and 1360 (CH_3) cm^{-1}; ^{1}Hmr δ: 7.17 (d, 1H, J = 4 Hz, C-6 H), 7.13 (d, 1H, J = 4 Hz, C-5 H), 6.59 (d, 1H, J = 10 Hz, -C*H*=CH—CO-), 6.12 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 3.24 (m, 2H, C-10 -CH_2-), 2.76 (m, 2H, C-7 -CH_2-), 1.76 (m, 4H, C-8 and C-9 -CH_2-), and 1.42 (s, 6H, 2 × -CH_3); ms M^+: 226.1358 (calcd. for $C_{16}H_{18}O$: 226.1358).

*Equilibrium of 4,4-dimethyl-4aβ,5,8,8aβ-tetrahydro-1(4*H*)-naphthalenone (**7**) and 4,4-dimethyl-4aβ,5,8,8aα-tetrahydro-1(4*H*)-naphthalenone (**18**)*

A mixture of *cis*- and *trans*-enones **7** and **18**[23] (43:57 by ^{1}Hmr integration, 202 mg, 1.15 mmol) was dissolved in methanol (10 mL) and 1 *N* aqueous sodium hydroxide (10 mL) was added. After stirring for 26 h, the mixture was extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 2% ether in petroleum ether, gave a mixture of *cis*- and *trans*-enones **7** and **18** (145 mg, 72% yield) in a 33:67 ratio as determined by gc analysis (Column B). The ^{1}Hmr analysis of this mixture showed two distinct sets of signals. The minor set was identical with the spectrum of pure *cis*-enone **7** while the major set was attributable to *trans*-enone **18**; ^{1}Hmr δ: 6.58 (d, 1H, J = 10 Hz, -C*H*=CH—CO-), 5.82 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 5.62 (m, 2H, -CH=CH-), 1.13 (s, 3H, CH_3), and 1.04 (s, 3H, CH_3). The following data were recorded for the mixture: ir (neat): 1680 (C=O), 1381, 1369 (CH_3), 670 (HC=CH, *cis*) cm^{-1}; ms M^+: 176.1202 (calcd. for $C_{12}H_{16}O$: 176.1201).

[23]This mixture was obtained in 78% yield by decarboxylation of keto-ester **28** under conditions similar to those used for decarboxylation of keto-esters **31** through **38** (*vide infra*).

*4,4,8α-Trimethyl-4aβ,5,8,8aα-tetrahydro-1(4*H*)-naphthalenone (**19**) and 3β-methoxy-4,4,8-trimethyl-3,4,4aβ,5,8,8aα-hexahydro-1(2*H*)-naphthalenone (**22**)*

Enone **8** (36) (108 mg, 0.57 mmol) was dissolved in methanol (5 mL) and an aqueous 1 *N* solution of sodium hydroxide (1 mL) was added with stirring. After 20 h, the reaction mixture was extracted with methylene chloride and the extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel eluting with 2–3% ether in petroleum ether gave pure *trans*-enone **19** (69 mg, 64% yield) as an oil; ir: 1677 (C=O), 1660 (C=C), 1374, 1360 (CH_3), and 690 (*cis* CH=CH) cm^{-1}; ^{1}Hmr δ: 6.49 (d, 1H, J = 10 Hz, -C*H*=CH—CO-), 5.72 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 5.58, 5.41 (each dm, total 2H, each J = 12 Hz, -CH=CH-), 2.44 (m, 1H, —CC*H*—CH_3), 1.19 (d, 3H, J = 6 Hz, —CH—CH_3), 1.14 (s, 3H, CH_3), and 1.06 (s, 3H, CH_3); ms M^+: 190.1360 (calcd. for $C_{13}H_{18}O$: 190.1358). *Anal.* calcd. for $C_{13}H_{18}O$: C 82.06, H 9.54; found: C 82.16, H 9.78. Further elution with 2–3% ether in petroleum ether gave methoxy ketone **22** (32 mg, 26% yield); ir: 1714 (C=O), 1383, 1360 (CH_3), and 683 (HC=CH) cm^{-1}; ^{1}Hmr δ: 5.51, 5.33 (each dm, total 2H, each J = 10 Hz, -HC=CH-), 3.26 (s, 3H, -OCH_3), 3.18 (dd, 1H, $J = J'$ = 3 Hz, —C*H*—OCH_3), 2.55 (d, 2H, J = 3 Hz, -CH_2—CO-), 1.07 (s, 3H, CH_3), 1.03 (s, 3H, CH_3), and 0.97 (d, 3H, J = 6 Hz, —CH—CH_3); ms M^+: 222.

*4,4,6,8α-Tetramethyl-4aβ,5,8,8aα-tetrahydro-1(4*H*)-naphthalenone (**20**) and 3β-methoxy-4,4,6,8α-hexahydro-1(2*H*)-naphthalenone (**23**)*

Enone **9** (18 mg, 0.088 mmol) was dissolved in methanol (5 mL) and aqueous 1 *N* sodium hydroxide (1 mL) was added. The mixture was stirred for 20 h, then extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 1% ether in petroleum ether, gave *trans*-enone **20** (8 mg, 44% yield); ir (neat): 1673 (C=O), 1379, and 1366 (CH_3) cm^{-1}; ^{1}Hmr δ: 6.45 (d, 1H, J = 10 Hz, -C*H*=CH—CO-), 5.60 (d, 1H, J = 10 Hz, -CH=C*H*—CO), 5.13 (br s, 1H, =CH-), 2.38 (m, 1H, —C*H*—CH_3), 1.66 (br s, 3H, =C—CH_3), and 1.07 (s, 3H, -CH_3); ms M^+: 204.1505 (calcd. for $C_{14}H_{20}O$: 204.1514). Further elution with 1–2% ether gave a mixture of enone **20** and methoxy-ketone **23** (5 mg, 75:25 by ^{1}Hmr integration). Final elution with 2% ether in petroleum ether gave pure methoxy-ketone **23** (5 mg, 24% yield); ir: 1713 (C=O), 1390, 1377, 1367 (CH_3), and 799 (C=CH) cm^{-1}; ^{1}Hmr δ: 5.05 (br s, 1H, =CH—), 3.22 (s, 3H, -OCH_3), 3.16 (dd, 1H, $J = J'$ = 3 Hz, —CH—O—), 2.53 (d, 2H, J = 3 Hz, —CH_2—CO—), 1.61 (s, 3H, =C—CH_3), 1.08 (s, 3H, -CH_3), 1.04 (s, 3H, -CH_3), and 0.93 (d, 3H, J = 7 Hz, —CH—CH_3).

*4,4-Dimethyl-4aβ,5,7,8,9,10,10aβ,10bα-octahydro-1(4*H*)-phenanthrenone (**21**) and 3β-methoxy-4,4-dimethyl-3,4,4aβ,5,7,8,9,-10,10aβ,10bα-*tetrahydro-1(2*H*)-phenanthrenone (**24**)*

Enone **10** (194 mg, 0.843 mmol) was dissolved in methanol (10 mL) and a 1 *N* aqueous solution of sodium hydroxide (2 mL) was added. The mixture was stirred for 24 h and then extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 3% ether in petroleum ether, gave enone **21** (92 mg, 49% yield), which crystallized on standing. One recrystallization from petroleum ether gave white crystals of *trans*-enone **21**; mp 36–45°C, ir: 1673 (C=O), 1395, 1377, 1365 (CH_3), and 799 (C=CH) cm^{-1}; ^{1}Hmr δ: 6.45 (d, 1H, J = 10 Hz, -C*H*=CH—CO-), 5.68 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 5.28 (br s, 1H, =CH—), 1.11 (s, 3H,

$-CH_3$), and 1.02 (s, 3H, $-CH_3$); ms M^+: 230.1667 (calcd. for $C_{16}H_{22}O$: 230.1670). *Anal.* calcd. for $C_{16}H_{22}O$: C 83.43, H 9.63; found: C 83.70, H 9.44. Continued elution gave a mixture (14 mg) of enone **21** and methoxy-ketone **24**. Further elution with 3–5% ether in petroleum ether gave pure methoxy-ketone **24** (20 mg, 9% yield); ir: 1712 (C=O), 1389, 1367 (CH_3) and 807 (C=CH) cm^{-1}; ^{1}Hmr δ: 5.28 (br s, 1H, =CH—), 3.27 (s, 3H, $-OCH_3$), 3.18 (dd, 1H, $J = J' =$ 3 Hz, —O—CH—), 2.55 (d, 2H, $J = 3$ Hz, $-CH_2$—CO-), 1.05 (s, 3H, $-CH_3$), and 1.02 (s, 3H, $-CH_3$); ms M^+: 262.

*8aβ-Carbomethoxy-4,4-dimethyl-4aβ,5,8,8a-tetrahydro-1(4H)-naphthalenone (**28**)*

Dienone ester **2** (311 mg, 1.73 mmol) was dissolved in ether (20 mL) under an atmosphere of nitrogen. Boron trifluoride etherate (106 μL, 122 mg, 0.86 mmol) was added and, after stirring for 15 min, dry butadiene gas (passed through calcium sulfate) was bubbled into the solution. After 6 h, saturated aqueous sodium bicarbonate (2 mL) was added and the resulting mixture was extracted with chloroform. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 10% ether in Skelly B, gave pure keto-ester **28** (286 mg, 70% yield); ir (KBr disk): 1730 (ester C=O), 1663 (enone C=O), 1619 (C=C), 1384, 1373, and 1361 (CH_3) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 6.57 (d, 1H, $J =$ 10 Hz, -C*H*=CH—CO-), 5.87 (d, 1H, $J = 10$ Hz, -CH=C*H*—CO-), 5.66 (m, 2H, -CH=CH-), 3.70 (s, 3H, -O—CH_3), 2.75 (dd, 1H, $J =$ 6, $J' = 4$ Hz, C-4a H), 2.70 (dm, 1H, $J = 18$ Hz, C-8α H), 2.25 (dm, 1H, $J = 18$ Hz, C-8β H), 2.11 (m, 2H, C-5 $-CH_2$-), 1.18 (s, 3H, $-CH_3$), and 1.07 (s, 3H, $-CH_3$); ms M^+: 234.1258 (calcd. for $C_{14}H_{18}O_3$: 234.1256). *Anal.* calcd. for $C_{14}H_{18}O_3$: C 71.77, H 7.74; found: C 72.01, H 7.80.

*8aβ-Carbomethoxy-4,4,6,7-tetramethyl-4aβ,5,8,8a-tetrahydro-1(4H)-naphthalenone (**29**)*

Dienone ester **2** (343 mg, 1.91 mmol) was dissolved in ether (20 mL) under an atmosphere of nitrogen. Boron trifluoride etherate (118 μL, 136 mg, 0.96 mmol) was added and, after 15 min, 2,3-dimethyl-1,3-butadiene (4.34 mL, 3.15 g, 38.2 mmol) was added. After stirring for 4 days, saturated aqueous sodium bicarbonate (3 mL) was added and the resulting mixture was extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 10% ether in Skelly B, gave pure keto-ester **29** (316 mg, 63% yield). An analytical sample was prepared by molecular distillation in a Kugelrohr apparatus (60°C at 1 Torr) and this sample crystallized on standing; mp 77.5–78.5°C; ir (neat): 1746 (ester C=O), 1676 (enone C=O), 1383 and 1370 (CH_3) cm^{-1}; ^{1}Hmr δ: 6.46 (d, 1H, $J = 10$ Hz, -C*H*=CH—CO-), 5.75 (d, 1H, $J = 10$ Hz, -CH=C*H*—CO-), 3.61 (s, 3H, -O—CH_3), 2.63 (dd, 1H, $J = 6$, $J' = 4$ Hz, C-4a H), 2.47 (d, 1H, $J = 18$ Hz, C-8α H), 2.09 (d, 1H, $J = 18$ Hz, C-8β H), 1.92 (br s, 2H, C-5 $-CH_2$-), 1.58 (s, 6H, 2 × =C-CH_3), 1.13 (s, 3H, $-CH_3$), and 0.94 (s, 3H, $-CH_3$); ms M^+: 262.1568 (calcd. for $C_{16}H_{22}O_3$: 262.1569). *Anal.* calcd. for $C_{16}H_{22}O_3$: C 73.25, H 8.45; found: C 73.06, H 8.51.

*8aβ-Carbomethoxy-4,4-dimethyl-5,8β-methano-4aβ,5,8,8a-tetrahydro-1(4H)-naphthalenone (**30**)*

Dienone ester **2** (297 mg, 1.65 mmol) was dissolved in ether (20 mL) under an atmosphere of nitrogen. Boron trifluoride etherate (100 μL, 116 mg, 0.82 mmol) was added and, after stirring for 20 min, a solution of cyclopentadiene (2.71 mL, 2.17 g, 33 mmol) in dry ether (5 mL) was added. After stirring for 3 h, saturated aqueous sodium bicarbonate (2 mL) was added and the resulting mixture was extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 10% ether in Skelly B, gave pure keto-ester **30** (284 mg, 70% yield), which crystallized on standing. An analytical sample was prepared by molecular distillation in a Kugelrohr apparatus (60°C at 10 Torr); mp 57–59°C; ir (neat): 1738 (ester C=O), 1662 (enone C=O), 1379, 1366 (CH_3), and 720 (C=CH) cm^{-1}; ^{1}Hmr δ: 6.31 (dd, 1H, $J = 10$, $J' = 1.5$ Hz, -C*H*=CH—CO-), 6.05, 5.75 (each dd, each 1H, each $J = 6$, $J' = 2.5$ Hz, -CH=CH-), 5.60 (d, 1H, $J = 10$ Hz, -CH=C*H*—CO-), 3.65 (s, 3H, -O—CH_3), 3.45 (m, 1H, C-8 H), 3.00 (m, 1H, C-5 H), 2.49 (dd, 1H, $J = 2.5$, $J' = 1.5$ Hz, C-4a H), 1.60 (d, 1H, $J = 9$ Hz, bridge -CH*H*-), 1.41 (ddd, 1H, $J = 9$, $J' = J'' = 2$ Hz, bridge -CH*H*-), 1.27 (s, 3H, $-CH_3$), and 1.17 (s, 3H, $-CH_3$); ms M^+: 246.1253 (calcd. for $C_{15}H_{18}O_3$: 246.1256). *Anal.* calcd. for $C_{15}H_{18}O_3$: C 73.15, H 7.37; found: C 72.88, H 7.42.

*8aβ-Carbomethoxy-4,4,8α-trimethyl-4aβ,5,8,8a-tetrahydro-1(4H)-naphthalenone (**31**) and 2-carbomethoxy-4,4,8α-trimethyl-4aβ,5,8,8aβ-tetrahydro-1(4H)-naphthalenone (**32**)*

Dienone ester **2** (287 mg, 1.59 mmol) was dissolved in ether (20 mL) under an atmosphere of nitrogen. Boron trifluoride etherate (98 μL, 114 mg, 0.80 mmol) was added and, after 15 min, *trans*-piperylene (1.59 mL, 15.9 mmol) was added. After stirring for 43 h, saturated aqueous sodium bicarbonate (2 mL) was added and the resulting mixture was extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 7–8% ether in petroleum ether, gave keto-ester **31** (329 mg, 83% yield), which crystallized on standing. One recrystallization from ether gave white crystals of pure keto ester **31**; mp 66–68°C; ir (neat): 3010 (HC=CH), 1725 (ester C=O), 1685 (enone C=O), and 1375 (CH_3) cm^{-1}; ^{1}Hmr δ: 6.11 (dd, 1H, $J = 10$, $J' = 2$ Hz, -C*H*=CH—CO-), 5.72 (d, 1H, $J = 10$ Hz, -CH=C*H*—CO-), 5.50, 5.35 (each dm, 2H, each $J = 12$ Hz, -CH=CH-), 3.67 (s, 3H, -O—CH_3), 2.70 (m, 1H, —C*H*—CH_3), 2.56 (ddd, 1H, $J = 11$, $J' = 6$, $J'' = 6$, $J'' = 2$ Hz, C-4a H), 2.10 (m, 2H, C-4 $-CH_2$-), 1.20 (d, 3H, $J = 8$ Hz, —CH—C*H*$_3$), 1.14 (s, 3H, $-CH_3$), and 1.10 (s, 3H, $-CH_3$); ms M^+: 248.1413 (calcd. for $C_{15}H_{20}O$: 248.1414). *Anal.* calcd. for $C_{15}H_{20}O$: C 72.55, H 8.12; found: C 72.52, H 8.13. Further elution with 8–20% ether in petroleum ether gave keto-ester **32** (22 mg, 6% yield); ^{1}Hmr δ: 6.78 (d, 1H, $J = 2$ Hz, -CH=C—CO-), 5.45 (complex, 2H, -HC=CH-), 3.73 (s, 3H, -O—CH_3), 2.96 (dd, 1H, $J = J' = 4$ Hz, -CO—CH—), 2.33 (m, 1H, —C*H*—CH_3), 1.39 (s, 3H, $-CH_3$), 1.36 (d, 3H, $J = 8$ Hz, —CH—CH_3), and 1.18 (s, 3H, $-CH_3$); ms M^+: 248.

Lithium iodide dihydrate/collidine reagent

Finely divided anhydrous lithium iodide (514 mg, 3.84 mmol) was suspended in 2,4,6-collidine (3.05 mL) with vigorous stirring. Water (138 μL, 138 mg, 7.68 mmol) was added and the suspension rapidly dissolved. The resulting pale yellow solution had a calculated concentration of 1.28 *N* in lithium iodide dihydrate.

*4,4,8α-Trimethyl-4aβ,5,8α,8aβ-tetrahydro-1(4H)-naphthalenone (**8**) from keto-ester (**31**)*

Keto-ester **31** (315 mg, 1.27 mmol) was dissolved in lithium iodide hydrate/collidine reagent (2.04 mL, 2.61 mmol) and heated at reflux with stirring. After 1 h, the mixture was cooled to room temperature, poured into cold 5% aqueous hydrochloric acid, and extracted with ether. The extracts were washed with 5% aqueous hydrochloric acid and water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 2% ether in petroleum ether, gave pure *cis*-enone **8** (104 mg, 45% yield based on consumed starting material), which was identical in its ^{1}Hmr and ir spectra with *cis*-enone **8** previously reported (36). Further elution with 4–10% ether in petroleum ether gave keto-ester **31** (86 mg, 27% recovery).

*8aβ-Carbomethoxy-4,4,8α-trimethyl-4aβ,5,8,8a-tetrahydro-1(4H)-naphthalenone (**31**) and 8aβ-carbomethoxy-4,4,8β-trimethyl-4aβ,5,8,8a-tetrahydro-1(4H)-naphthalenone (**33**)*

Dienone ester **2** (360 mg, 2.0 mmol) was dissolved in anhydrous ether (10 mL) and ferric chloride (162 mg, 1.0 mmol) was added, followed quickly by *cis*-piperylene (1.97 mL, 1.36 g, 20 mmol). After

For personal use only.

stirring for 90 min, saturated aqueous sodium bicarbonate (2 mL) was added and the resulting mixture was extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 10–20% ether in petroleum ether, gave a mixture of keto-esters **31** and **33** (223 mg, 45% yield, 74% based on consumption of 61% of the starting dienone ester **2**, 50:50 mixture by ^{1}Hmr integration). One recrystallization from ether gave white crystals of keto-ester **33** (58 mg); mp 110–112°C; ir: 1741 (ester C=O), 1668 (enone C=O), 1382, 1376 (CH_3), and 702 (HC=CH) cm^{-1}; ^{1}Hmr δ: 6.40 (d, 1H, J = 10 Hz, -C*H*=CH—CO-), 5.74 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 5.48 (s, 2H, -CH=CH-), 3.60 (s, 3H, -O—CH_3), 2.63 (dd, 1H, $J = J'$ = 5 Hz, C-4a H), 2.52 (dq, 1H, J = 7, J' = 4 Hz, —C*H*—CH_3), 2.02 (m, 2H, C-5 -CH_2-), 1.18 (s, 3H, -CH_3), 1.10 (d, 3H, J = 7 Hz, —CH—C*H*$_3$), and 1.06 (s, 3H, -CH_3); ms M$^+$: 248.1414 (calcd. for $C_{15}H_{20}O_3$: 248.1412). *Anal.* calcd. for $C_{15}H_{20}O_3$: C 72.55, H 8.21; found: C 72.65, H 8.02. One recrystallization of the mother liquor gave additional colourless crystals of keto-ester **33** (37 mg). Further elution with ether gave dienone ester **2** (142 mg, 39% recovery).

*4,4,8β-Trimethyl-4aβ,5,8,8aβ-tetrahydro-1(4*H*)-naphthalenone (**39**) and 4,4,8β-trimethyl-4aβ,5,8,8aα-tetrahydro-1(4*H*)-naphthalenone (**40**)*

Keto-ester **33**[24] (67 mg, 0.27 mmol) was dissolved in 2,4,6-collidine (2 mL) under an argon atmosphere. Anhydrous lithium iodide (224 mg, 1.67 mmol) was added, followed by water (58 μL, 58 mg, 3.24 mmol). The mixture was heated at reflux with vigorous stirring for 90 min, then cooled to room temperature, poured into cold aqueous 5% hydrochloric acid, and extracted with ether. The extracts were washed with aqueous 5% hydrochloric acid and water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 3–5% ether in petroleum ether, gave a 32:68 mixture of *cis*- and *trans*-enones **39** and **40** (33 mg, 64% yield). The ^{1}Hmr spectrum showed two sets of signals; one assignable to *cis*-ketone **39**, δ: 6.27 (dd, 1/3H, J = 10, J' = 2 Hz, -C*H*=CH—CO-), 5.70 (d, 1/3H, J = 10 Hz, -CH=*CH*—CO-), 5.70–5.40 (complex, 2 × 1/3H, -HC=CH-), 3.06[25] (m, 1/3H, —C*H*—CH_3), 2.55 (m, 1/3H, —C—H—CO-), 1.30 (s, 3 × 1/3H, -CH_3), 1.12 (s, 3 × 1/3H, -CH_3), and 1.04 (d, 3 × 1/3H, J = 7 Hz, —CH—C*H*$_3$); the other assignable to the *trans*-enone **40**, δ: 6.60 (d, 2/3H, J = 10 Hz, -C*H*=CH—CO-), 5.77 (d, 2/3H, J = 10 Hz, -CH=C*H*—CO-), 5.70–5.40 (complex, 2 × 2/3H, -HC=CH-), 2.83 (ddq, 2/3H, J = 7, $J' = J''$ = 5 Hz, —C*H*—CH_3), 1.17 (s, 3 × 2/3H, CH_3), and 1.04 (s, 3 × 2/3H, CH_3). The following data were recorded on the mixture of **39** and **40**: ir: 1671 (C=O), 1655 (C=C), 1396, 1378, 1367 (CH_3), and 714 (HC=CH) cm^{-1}; ms M$^+$: 190.1356 (calcd. for $C_{13}H_{18}O$: 190.1357).

*4,4,8-Trimethyl-1(4*H*)-naphthalenone (**14**) from enones **39** and **40***

A mixture of *cis*- and *trans*-enones **39** and **40** (32:68, 24 mg, 0.13 mmol) was dissolved in carbon tetrachloride (5 mL), and *N*-bromosuccinimide (45 mg, 0.25 mmol) and benzoyl peroxide (2 mg, 0.008 mmol) were added. The mixture was heated at reflux for 1 h, then cooled to room temperature, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 0.5% ether in petroleum ether, gave aryl-ketone **14** (9 mg, 38% yield) identical with an authentic sample prepared from **8** (36).

*10bβ-Carbomethoxy-4,4-dimethyl-4aβ,5,7,8,9,10,10aβ,10b-octahydro-1(4*H*)-phenanthrenone (**36**)*

Dienone ester **2** (360 mg, 2.0 mmol) was dissolved in anhydrous ether (20 mL) under an atmosphere of nitrogen. Boron trifluoride etherate (126 μL, 142 mg, 1.0 mmol) was added and, after 15 min, a solution of 1-vinylcyclohexene (2.53 mL, 2.16 g, 20 mmol) in anhydrous ether (20 mL) was also added. After stirring for 60 h, saturated aqueous sodium bicarbonate (10 mL) was added and the resulting mixture was extracted with ether. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 10–12% ether in petroleum ether, gave keto-ester **36** (501 mg, 87% yield), which crystallized on standing. One recrystallization from ether – petroleum ether gave white crystals of pure keto ester **36**; mp 75.5–77°C; ir: 1728 (ester C=O), 1689 (enone C=O), 1370 (CH_3), and 835 (C=CH) cm^{-1}; ^{1}Hmr δ: 6.20 (d, 1H, J = 10 Hz, -C*H*=CH—CO-), 5.76 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 5.16 (br s, 1H, =CH—), 3.66 (s, 3H, -O—CH_3), 2.70 (m, 1H, C-10a H), 2.56 (dd, 1H, $J = J'$ = 6 Hz, C-4a H), 2.28 (dm, 1H, J = 14 Hz, C-7α H), 2.03 (br s, 3H, C-5 -CH_2- and C-7β H), 1.30 (m, 4H, C-8 and C-9 -CH_2-), 1.16 (s, 3H, -CH_3), and 1.10 (s, 3H, -CH_3); ms M$^+$: 288.1725 (calcd. for $C_{18}H_{24}O_3$: 288.1725). *Anal.* calcd. for $C_{18}H_{24}O_3$: C 74.97, H 8.39; found: C 74.79, H 8.32.

*4,4-Dimethyl-4aβ-5,7,8,9,10,10aβ,10bβ-octahydro-1(4*H*)-phenanthrenone (**10**) and 4,4-dimethyl-4aβ,5,7,8,9,10,10aβ,10bα-octahydro-1(4*H*)-phenanthrenone (**21**) from keto-ester **36***

Keto-ester **36** (170 mg, 0.59 mmol) was dissolved in lithium iodide dihydrate/collidine reagent (1.26 mL, 1.62 mmol). The mixture was heated at reflux with stirring for 1 h, then cooled to room temperature, poured into cold aqueous 5% hydrochloric acid, and extracted with ether. The extracts were washed with cold 5% aqueous hydrochloric acid and water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 2% ether in petroleum ether, gave a mixture of *cis*- and *trans*-enones **10** and **21** (47:53 by ^{1}Hmr integration, 83 mg, 61% yield). The ^{1}Hmr spectrum of this mixture showed two sets of signals identical with those already reported for *cis*-enone **10** and *trans*-enone **21** (*vide supra*).

*4,4-Dimethyl-7,8,9,10-tetrahydro-1(4*H*)-phenanthrenone (**16**) from keto-ester **36***

A mixture of *cis*- and *trans*-enones **10** and **21** (47:53 by ^{1}Hmr integration, 81 mg, 0.35 mmol) obtained by decarboxylation of keto-ester **36** was dissolved in carbon tetrachloride (10 mL), and *N*-bromosuccinimide (125 mg, 0.70 mmol) was added. The mixture was heated at reflux with stirring for 1 h, then cooled to room temperature, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 1.5% ether in petroleum ether, gave aryl-ketone **16** (16 mg, 20% yield), which showed an ^{1}Hmr spectrum identical with that already reported for aryl-ketone **16** (*vide supra*).

*8aβ-Carbomethoxy-4,4,6,8α-tetramethyl-4aβ,5,8,8a-tetrahydro-1(4*H*)-naphthalenone (**37**) and 8aβ-carbomethoxy-4,4,6,8β-tetramethyl-4aβ,5,8,8a-tetrahydro-1(4*H*)-naphthalenone (**38**)*

Dienone ester **2** (329 mg, 1.83 mmol) was dissolved in anhydrous ether (10 mL) and boron trifluoride etherate (112 μL, 130 mg, 0.95 mmol) was added. After stirring for 10 min, *trans*-2-methyl-1,3-pentadiene (2.08 mL, 1.50 g, 18.3 mmol) was added. The mixture was stirred for 2 h and saturated aqueous sodium bicarbonate (2 mL) was added. The resulting mixture was extracted with methylene chloride and the extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 5–20% ether in petroleum ether, gave a mixture of keto-esters **37** and **38** (396 mg, 83% yield, 50:50 by ^{1}Hmr integration). One recrystallization from ether gave white crystals of keto-ester **38** (72 mg); mp 112–116°C; ir: 1739 (ester C=O), 1672 (enone C=O), 1382, 1377, and 1369 (CH_3) cm^{-1}; ^{1}Hmr δ: 6.40 (d, 1H, J = 10 Hz, -C*H*=CH—CO-), 5.73 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 5.20 (br s, 1H, =CH—), 3.60 (s, 3H, -O—CH_3), 2.63 (dd, 1H, J = 6,

[24]It should be noted that the mixtures **8** + **19** and **39** + **40** are chromatographically separable from each other so that the separation of the precursors **31** and **33** by fractional crystallization is unnecessary for preparative purposes.

[25]This assignment was confirmed by the observation of significant sharpening of the signal upon irradiation of the protons of the adjacent methyl group (δ 1.04).

J' = 4 Hz, C-4a H), 2.52 (m, 1H, —C*H*—CH_3), 1.89 (br s, 2H, C-5 -CH_2-), 1.65 (s, 3H, =C—CH_3), 1.16 (s, 3H, -CH_3), 1.07 (d, 3H, J = 8 Hz, —CH—C*H*$_3$), and 1.02 (s, 3H, -CH_3); ms M^+: 262.1574 (calcd. for $C_{16}H_{22}O_3$: 262.1569). *Anal.* calcd. for $C_{16}H_{22}O_3$: C 73.25, H 8.45; found: C 73.21, H 8.38. One recrystallization from the mother liquor gave white crystals of keto-ester **37** (28 mg); mp 97–104°C; ir: 1728 (ester C=O), 1689 (enone C=O), 1374 (CH_3), and 729 (C=CH) cm^{-1}; ^{1}Hmr δ: 6.09 (dd, 1H, J = 10, J' = 2 Hz, -C*H*=CH—CO-), 5.69 (d, 1H, J = 10 Hz, -CH=C*H*—CO-), 5.17 (m, 1H, =CH—), 3.64 (s, 3H, -O—CH_3), 2.65 (m, 1H, —C*H*—CH_3), 2.53 (ddd, 1H, J = 10, J' = 6, J'' = 2 Hz, C-4a H), 1.57 (br s, 3H, =C—CH_3), 1.13 (d, 3H, J = 7 Hz, —CH—C*H*$_3$), and 1.10 (s, 6H, 2 × -CH_3); ms M^+: 262.1567 (calcd. for $C_{16}H_{22}O_3$: 262.1569). *Anal.* calcd. for $C_{16}H_{22}O_3$: C 73.25, H 8.45; found: C 72.91, H 8.61.

*4,4,6,8α-Tetramethyl-4aβ,5,8,8aβ-tetrahydro-1(4*H*)-naphthalenone (**9**) and 4,4,6,8a-tetramethyl-4aβ,5,8,8aα-tetrahydro-1(4*H*)-naphthalenone (**20**) from keto-ester **37***

Keto-ester **37**[26] (62 mg, 0.24 mmol) was dissolved in 2,4,6-collidine (2 mL) under an atmosphere of argon. Anhydrous lithium iodide (192 mg, 1.43 mmol) and water (51 μL, 51 mg, 2.85 mmol) were added and the mixture was heated at reflux for 90 min. The reaction mixture was then cooled to room temperature, poured into cold aqueous 5% hydrochloric acid, and extracted with ether. The extracts were washed with aqueous 5% hydrochloric acid and water, dried, filtered, and concentrated. Column chromatography on silica gel, eluting with 2–5% ether in petroleum ether, gave a 65:35 mixture of *cis*- and *trans*-enones **9** and **20** (16 mg, 35% yield).

*4,4,6,8β-Tetramethyl-4aβ,5,8,8aβ-tetrahydro-1(4*H*)-naphthalenone (**43**) and 4,4,6,8β-tetramethyl-4aβ,5,8,8aα-tetrahydro-1(4*H*)-naphthalenone (**44**)*

Keto-ester **38**[26] (112 mg, 0.43 mmol) was dissolved in 2,4,6-collidine (2 mL) under an atmosphere of argon. Anhydrous lithium iodide (343 mg, 2.56 mmol) and water (92 μL, 92 mg, 5.12 mmol) were added and the mixture was heated at reflux with vigorous stirring. After 2 h, the mixture was cooled to room temperature, poured into cold aqueous 5% hydrochloric acid, and extracted with ether. The extracts were washed with aqueous 5% hydrochloric acid and water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 2–5% ether in petroleum ether, gave a 55:45 mixture of *cis*- and *trans*-enones **43** and **44** (73 mg, 83% yield). The ^{1}Hmr spectrum showed two sets of signals; one assignable to *cis*-enone **43**, δ: 6.25 (dd, ~1/2H, J = 10, J' = 2 Hz, -C*H*=CH—CO-), 5.67 (d, ~1/2H, J = 10 Hz, -CH=C*H*—CO-), 5.38 (d, ~1/2H, J = 5 Hz, =CH—), 2.97[27] (qm, ~1/2H, J = 7 Hz, —C*H*—CH_3), 2.46 (d, ~1/2H, J = 4 Hz, —CH—CO-), 1.56 (br s, 3 × ~1/2H, =C—CH_3), 1.28 (s, 3 × ~1/2H, -CH_3), 1.11 (s, 3 × ~1/2H, -CH_3), and 0.97 (d, 3 × ~1/2H, J = 7 Hz, —CH—C*H*$_3$); the other assignable to the *trans*-enone **44**, δ: 6.57 (d, ~1/2H, J = 10 Hz, -C*H*=CH—CO-), 5.73 (d, ~1/2H, J = 10 Hz, -CH=C*H*—CO-), 5.23 (m, ~1/2H, =CH—), 2.77 (qm, ~1/2H, J = 7 Hz, —C*H*—CH_3), 1.64 (br s, 3 × ~1/2H, =C—CH_3), 1.16 (s, 3 × ~1/2H, -CH_3), 1.02 (s, 3 × ~1/2H, -CH_3), and 0.75 (d, 3 × ~1/2H, J = 7 Hz, —CH—C*H*$_3$). The following data were recorded on the mixture of **43** and **44**: ir: 1681, 1670 (C=O), 1395, 1377, 1366 (CH_3), and 840 (C=CH) cm^{-1}; ms M^+: 204.1518 (calcd. for $C_{14}H_{20}O$: 204.1514).

[26]It should be noted that the mixtures **9** + **20** and **43** + **44** are chromatographically separable from each other so that the separation of **37** and **38** by fractional crystallization is unnecessary for preparative purposes.

[27]This assignment was confirmed by a decoupling experiment irradiating the methyl doublet at δ 0.97.

*4,4,6,8-Tetramethyl-1(4*H*)-naphthalenone (**15**) from keto-ester **38***

A 55:45 mixture of *cis*- and *trans*-enones **43** and **44** (72 mg, 0.35 mmol) was dissolved in carbon tetrachloride (10 mL), and *N*-bromosuccinimide (125 mg, 0.71 mmol) and benzoyl peroxide (5 mg, 0.02 mmol) were added. The mixture was heated at reflux for 1 h, then cooled to room temperature, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 0.5% ether in petroleum ether, gave aryl-ketone **15** (22 mg, 31% yield).

*General conditions for Lewis acid catalyzed reaction of dienone ester **2** with isoprene*

Dienone ester **2** (95 mg, 0.52 mmol) was dissolved in anhydrous ether (5 mL). The Lewis acid catalyst (0.26 mmol) was added and, after 5–10 min, isoprene (1.04 mL, 10.4 mmol) was added. The progress of the reaction was followed by tlc and gc (Column A). After completion of the reaction, saturated aqueous sodium bicarbonate (~2 mL) was added and the mixture extracted with ether. The extracts were washed with water, dried, filtered, and concentrated. In several cases (see Table 9), the residue was purified by column chromatography on silica gel, eluting with 8–20% ether in petroleum ether. The crude residues or purified products were analyzed by gc (Column A) and the product ratios (**34**:**35**, Table 9) were determined by integration of the gc peaks. In the case of the boron trifluoride etherate and stannic chloride catalyzed reactions, the principal products (**34** and **35** respectively) were easily obtained pure by fractional crystallization from the product mixtures.

Associations of ajmaline and homatropine with bromocresol green and bromophenol blue in dichloromethane: thermodynamic and kinetic parameters

ALBERTO HERNÁNDEZ GAÍNZA

Departamento de Química Física, Facultad de Farmacia, Universidad de Granada, 18001 Granada, España

Received September 3, 1986

ALBERTO HERNÁNDEZ GAÍNZA. Can. J. Chem. **65**, 1279 (1987).

Ajmaline (AJ) and homatropine (HM) react with bromocresol green (BCG) and bromophenol blue (BPB) in dichloromethane forming 1:1 and 1:2 ion pairs clearly in a chemical equilibrium. Thermodynamic parameters ΔG^0, ΔH^0, and ΔS^0 are calculated using the Van't Hoff equation. In a large excess of HM a product P is formed from the 1:2 ion pair in a pseudo-first order kinetic process which fits Arrhenius' equation. The P product has been identified as a type of charge transfer complex. The thermodynamic parameters corresponding to the formation of the ion pairs BPB—$(AJ)_2$, BCG—$(AJ)_2$, BPB—$(HM)_2$, and BCG—$(HM)_2$ are, respectively: ΔG^0 at 294 K, −26, −21, −26, and −19 kJ/mol; ΔH^0, −63, −39, −63, and −61 kJ/mol; ΔS^0, −125, −62, −125, and −138 J/K mol (ΔH^0 and ΔS^0 determined in a 288 to 313 K range). The values of the activation energy, E_a, for the reaction of HM (in large excess) with BCG and BPB are 58 and 91 kJ/mol.

ALBERTO HERNÁNDEZ GAÍNZA. Can. J. Chem. **65**, 1279 (1987).

L'ajmaline (AJ) et l'homotropine (HM) réactionnent avec le vert de bromocresol et le bleu de bromophenol dans le chlorure de méthylène en formant des paires d'ions de stéchiométrie 1:1 et 1:2 (colorant:amine). On a démontré l'existence d'un équilibre chimique entre les complexes 1:1 et 1:2 et on a calculé les paramètres thermodynamiques, ΔG^0, ΔH^0 et ΔS^0 de la réaction. Pour des concentrations élevées de HM on met en évidence la formation d'un produit après un processus de pseudopremière ordre et on a demontré que les constantes de vitesse vérifient la relation d'Arrhenius. Le produit, P, est un complexe de transfert de charge. Les paramètres thermodynamiques correspondants à la formation des paires d'ions BPB—$(AJ)_2$, BCG—$(AJ)_2$, BPB—$(HM)_2$ et BCG—$(HM)_2$ sont respectivement : ΔG^0 à 294 K, −26, −21, −26 et −19 kJ/mol; ΔH^0, −63, −39, −63 et −61 kJ/mol; ΔS^0, −125, −62, −125 et −138 J/K mol (ΔH^0 et ΔS^0 determinés dans un intervale de 288–313 K). Les valeurs de l'énergie d'activation, E_a, pour la réaction des concentrations élevées d'HM avec BCG et BPB sont 58 et 91 kJ/mol.

Introduction

The two phase photometric titration of amines with sulphonphthaleinic dyes is an important method for the analysis of pharmacologically active substances.

The most widely proposed dye is bromothymol blue (BTB) because of its high hydrophobicity and exclusive extraction as 1:1 associates in the complete pH range (1–6).

The reaction, however, is unspecific. This is a disadvantage and a number of studies have been dedicated to this aspect (7, 8). More recently, Sakai (9, 10) has proposed a method of selective extraction for a number of quaternary ammonium ions using the 1:2 associates of bromocresol green (BCG) and bromophenol blue (BPB) and quinine as a favourable substance for quantitative extraction of the complex. The stoichiometry assigned to the complex is 1:1:1 (quinine:dye:ammonium ion) and it is the quinine which is responsible for the specificity of the extraction of the quaternary ammonium ion. The dye is extracted as divalent anion, X^{2-}, associated at the same time with protonated quinine, QH^+, and the quaternary ammonium compound, B^+.

In this study the formation of ion pairs of the divalent anion, X^{2-}, of BCG and BPB with the alkaloids ajmaline (AJ) and homatropine (HM) is investigated. The changes in the visible–ultraviolet absorption spectra of mixed solutions of BCG and BPB with variable quantities of AJ and HM in dichloromethane are elucidated. The formation of 1:1 and 1:2 ion pairs in a clear chemical equilibrium is established and the variations in the thermodynamic variables, ΔG^0, ΔH^0, and ΔS^0 are calculated from the spectrophotometric measurements.

With a large excess of HM there appear new changes in the visible absorption spectrum of BCG and BPB; changes which cannot be attributed to the formation of ion pairs. The formation of a third product, P, in a pseudo-first order kinetic process is established, and the kinetic parameters are calculated from the spectrophotometric measurements.

This study also provides conductivity measurements in the dichloromethane solutions of the dye:amine associates to complement the spectrophotometric interpretation.

Experimental procedure and results

Apparatus

Perkin Elmer Lambda 5 Spectrophotometer with a B. Braun Melsungen AG model Frigomix 1.495 and thermomix 1.441 (±0.2°C) thermostation system; quartz cells of 1 cm path length; Hewlett-Packard 9825A microcomputer; Model CDM 83 radiometer; conductometer.

Chemicals and reagents

The analytical grade amines supplied by Boerhinger–Ingelheim S.A. were used without prior purification and were kept in a desiccator with phosphorus pentoxide and under low pressure. The amines used were as follows:

α-Hydroxybenzeneacetic acid, 8-methyl-8-azabiciclo[3,2,1]oct-3-yl ester (homatropine base); ajmalan-17, -21 (diol) (Ajmaline base).

Analytical grade dyes from Merck were used without prior purification. The dyes used were bromocresol green and bromophenol blue. Carlo Erba analytical grade dichloromethane was used without prior purification.

Visible–ultraviolet spectrophotometry of dye–amine associates in dichloromethane

Bromocresol green (BCG) and bromophenol blue (BPB) in dichloromethane solution do not show any absorption in the visible spectrum range. On the other hand, upon mixing either of the dyes with ajmaline (AJ) or homatropine base (HM) in dichloromethane, intense absorption bands are seen in the visible spectrum range. The absorption spectra of BCG, BPB, AJ, and HM in dichloromethane and their corresponding mixtures BCG—AJ, BCG—HM, BPB—AJ and BPB—HM when the molar ratio is 1:1 (dye:amine) are shown in Fig. 1. In all cases the mixed solutions show a new band with a maximum at 410 nm. The absorption values at 410 nm of solutions with variable concentrations of each amine and an excess of BCG or BPB are presented at Table 1. As an example in Fig. 2, absorption spectra which correspond to mixed solutions of BCG—HM with variable concentrations of amine and

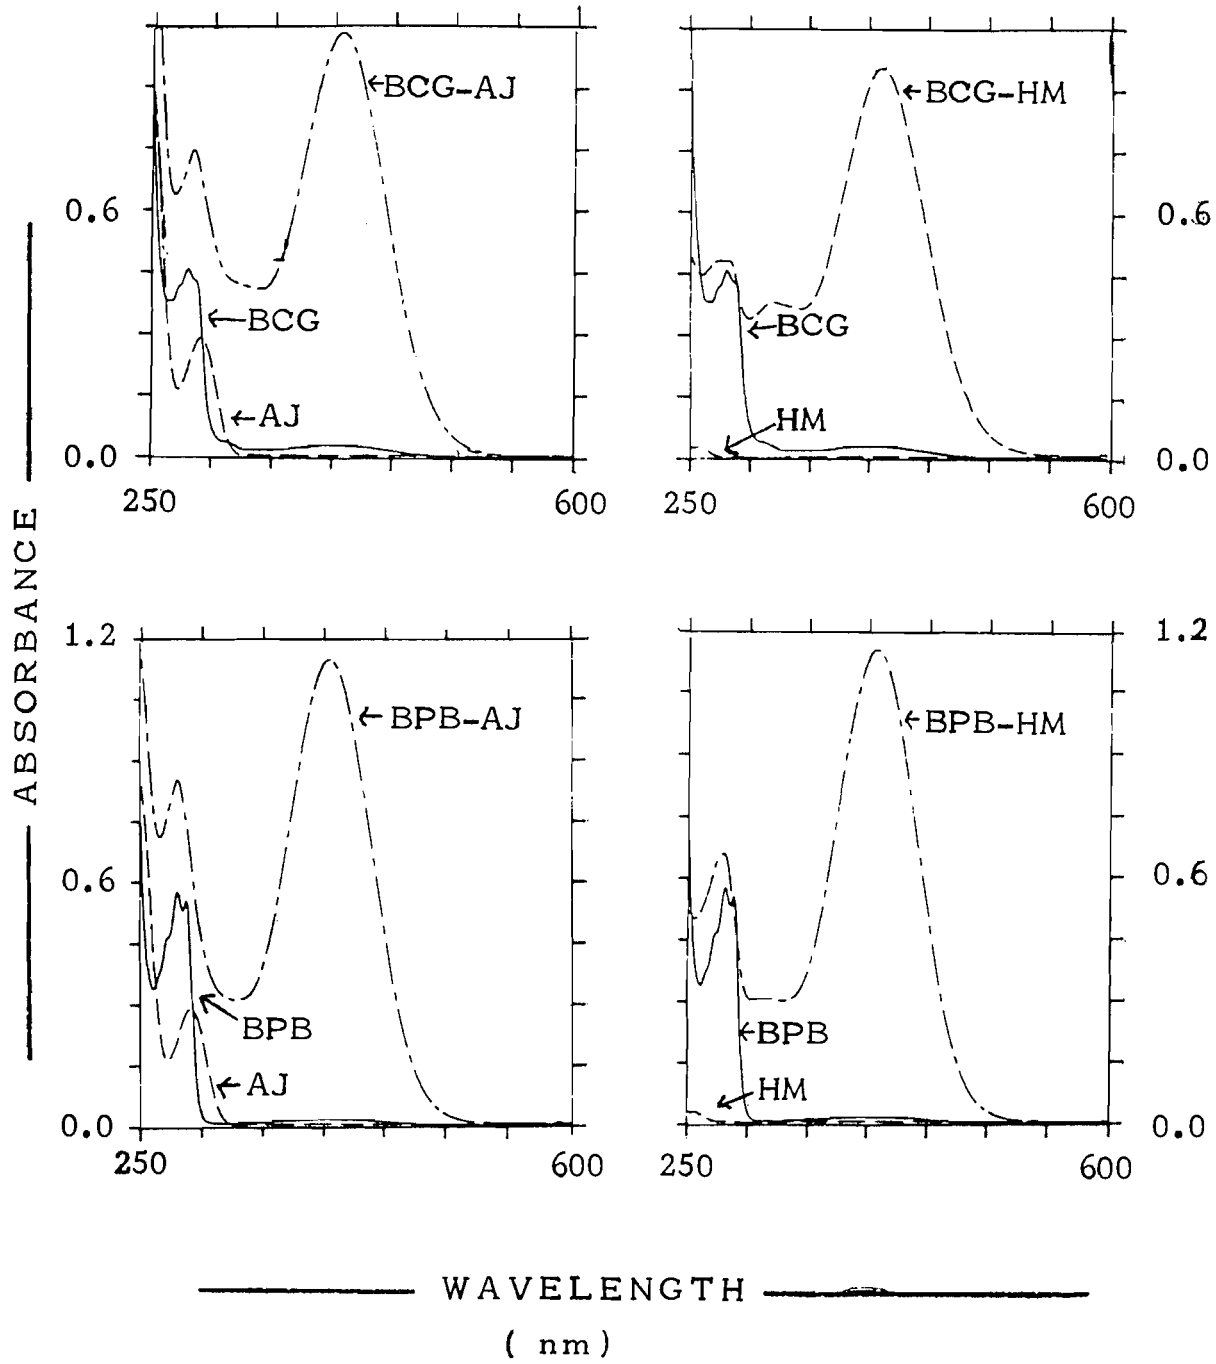

FIG. 1. Visible–ultraviolet spectra of solutions of dye 10^{-4} *M*, amine 10^{-4} *M*, and of dye–amine mixture 5×10^{-5} *M* in dichloromethane; $T = 293.16$ K.

excess of dye have been presented over the whole visible spectrum range.

When the dye–amine mixture is carried out with a slight excess of amine a second absorption band appears in the 560–580 nm region of the spectrum, the exact location of the maximum depending upon the dye:amine system being considered. This new absorption zone determines an isosbestic point which is seen beginning from an equimolar solution of dye–amine mixture and later addition of amine base in increasing concentrations. As an example of the obtained isosbestic points for BPB—AJ and BCG—HM mixtures in dichloromethane the v–uv spectra are presented in the upper part of Fig. 3.

In the lower part of Fig. 3 the v–uv spectra corresponding to the two mixtures BPB—AJ and BCG—HM with a slight excess of amine at different temperatures between 283.16 and 333.16 K are presented. Also from the spectra isosbestic points analogous to those seen in the upper part of Fig. 3 can be determined.

When BCG or BPB reacts with highly concentrated HM (if the HM dichloromethane solution is freshly prepared), a third new absorption zone is seen in the visible spectrum range with a maximum of 630 nm for BCG—HM and 600 nm for BPB—HM. The intensity increases with time until it reaches a maximum according to the temperature of the experiment. As an example the spectra of a solution of BCG in large excess of HM are presented in Fig. 4.

Mixtures of BCG—HM and BPB—HM in a large excess of HM and variable concentrations of BCG and BPB were also prepared, and their absorption spectra after 48 h recorded. Maximum absorption values (630 nm for BCG—HM and 600 nm for BPB—HM) were measured to see if BCG or BPB follows (lack of reagent) Beer's law. These

5.0	4.16	0.970	1.004

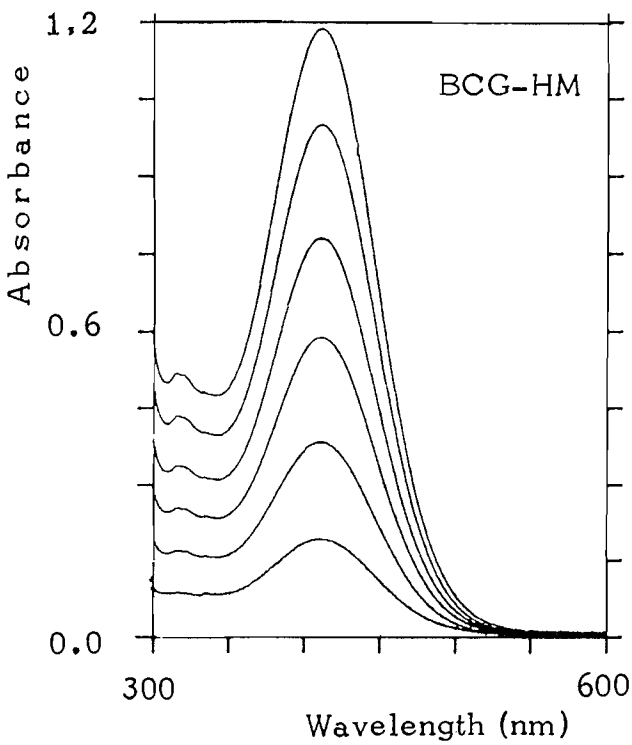

FIG. 2. Visible–ultraviolet spectra of solutions of BCG, 5×10^{-4} M and HM, 0.98, 1.97, 3.03, 3.94, 5.05, and 5.98×10^{-5} M in dichloromethane; $T = 293.16$ K.

experiments were carried out at 293.16 K. The absorption values for BCG—HM and BPB—HM mixtures at 630 and 600 nm, respectively, in a large excess of amine at longer times (48 h) are presented in Table 2. If the solution of HM in dichloromethane is prepared 36 h before being mixed with another solution of dye then the v–uv absorption spectrum immediately shows the bands of maximum intensity at 630 and 600 nm, respectively, and no variation is shown in the v–uv spectrum with the transition of time.

Analogous experiments were carried out in a large excess of AJ (including finally saturation of dichloromethane with ajmaline base) and for both BCG and BPB and no difference was observed in the spectrum compared to that seen using a slight excess of AJ. Thus with AJ the new third absorption band was not observed.

All absorption measurements and graphic recordings were carried out against pure dichloromethane.

Stoichiometry of the dye:amine compounds

The calculation of the stoichiometry of the reaction corresponding to each new absorption band was done using Job's (11) method of continuous variations. Dye–amine solutions of different molar ratios between 1:5 and 5:1 were prepared and their absorptions were measured at 410 nm and 560 nm for BCG—AJ, 564 nm for BPB—AJ, 577 nm for BCG—HM, and 573 nm for BPB—HM mixtures. Dichloromethane was used as the blank. The absorption values for each mixture are shown in Table 3. An example of Job's representation is drawn in Fig. 5.

The influence of temperature and time on the reactions

The absorption spectra of the mixtures of BCG and BPB with AJ and HM remain constant for at least 48 h, except if the reaction is carried out with a large excess of HM and, only if this latter solution is recently prepared.

The temperature does not significantly affect the spectrum of the amine–dye mixtures if they are equimolar, have an excess of dye, or a large excess of HM after reaching the maximum intensity of the third absorption range (after a longer time). The small variations in the spectra in these cases is attributed to the dilatation of the solvent.

On the other hand, in the dye:amine mixtures with a slight excess of amine, the absorption spectrum changes with the temperature owing to the presence of a chemical equilibrium, as can be seen in the lower part of Fig. 3.

It can also be seen that for dye–HM mixtures with a large excess of HM in freshly prepared solutions, intensification of the third absorption range changes markedly with the increase in temperature.

Determination of the number of absorbance species using Coleman's method

The study of the reactions using the changes in the absorption spectra is facilitated by applying Coleman's matrix procedure (12) for the assignment of species that cause the absorption. Coleman's method is the first step in a systematic spectrophotometric study and allows for the rigorous determination of the number of absorption species beginning from the absorbance values of a group of solutions at different wavelengths. This group of data is represented by the matrix $||A_{ij}||$ where A_{ij} is the absorbance of a particular solution, j, at wavelength i. Given that the observed changes in the v–uv absorption spectrum of dye–amine mixtures basically affect the visible spectrum range, the Coleman test is generally restricted to this range.

Firstly in order to apply Coleman's method, A_{ij} matrix corresponding to Figs. 2, 3, and 4 has been formed by spectrophotometric measurement of the absorption values at different wavelengths. From the A_{ij} matrix the matrices, $||A_{ij}/A_{nj}||$ and $||A_{ij} - A_{ij'}||$, have been formed. The graphic resolution of these three matrices gives rise to three Coleman tests for one, two, and two absorbance species whose sum of concentrations is always constant. The matrices obtained from Figs. 2, 3, and 4, together with other details about the application of Coleman's method, have been deposited.[1]

The graphic resolution of the matrix corresponding to Fig. 2 is shown in Fig. 6 for the BCG—HM system. In Fig. 6 it is suggested that the range of $||A_{ij}||$ is one, and, thus, in an excess of dye there only exists one absorbing species in the visible spectrum range. The selection of row A_{420j} for abcissa values is because they are the maximum values of the A_{ij} matrix elements. The same reasoning has been followed for all the dye–amine mixtures in an excess of dye. The matrices' range corresponding to Fig. 3*B*, which belongs to the BCG—HM reaction with a constant concentration of BCG and a slight and variable excess of HM, is deduced from the observation in Fig. 7 (upper graphics). In the upper part of Fig. 7 the Coleman tests are shown for two species (left hand side graphs) and two species whose sum of concentrations is

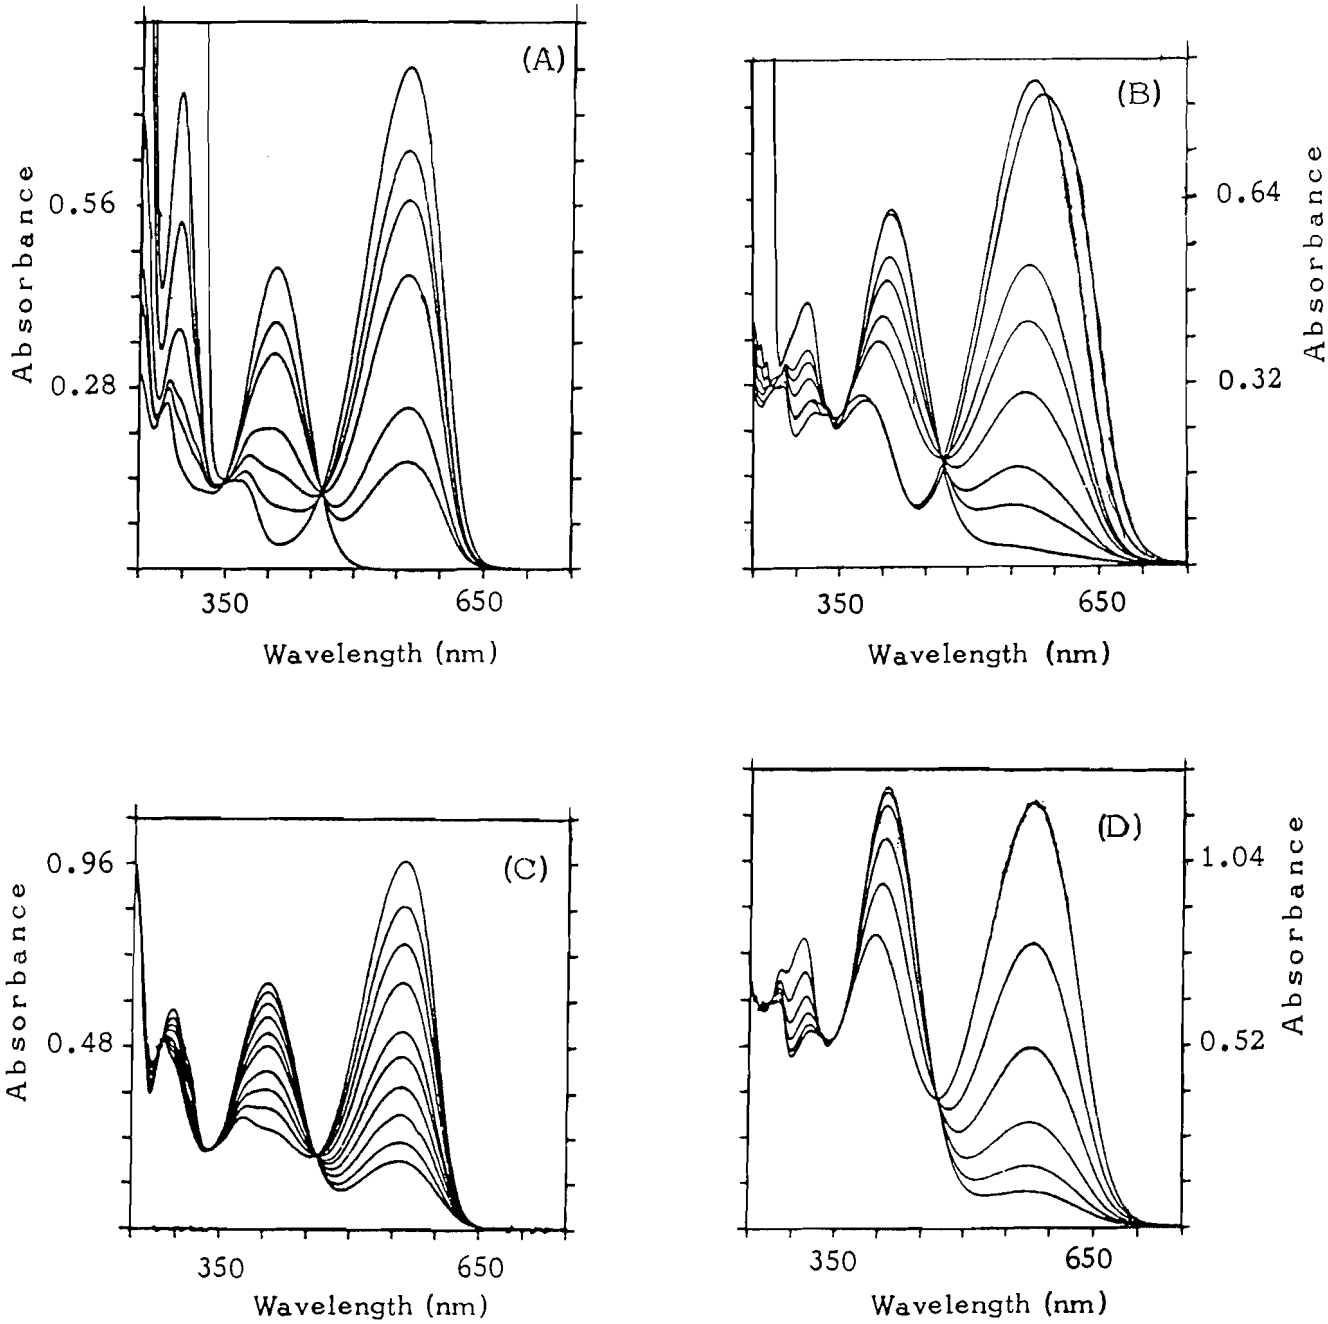

FIG. 3. (*A*) Visible–ultraviolet spectra of solutions of BPB 2×10^{-5} *M* and AJ, 2.0, 2.9, 3.5, 5.6, 8.2, 10.9, and 37.5×10^{-5} *M* in dichloromethane; $T = 293.16$ K. (*B*) Visible–ultraviolet spectra of solutions of BCG 3.2×10^{-5} *M* and HM 4.2, 6.9, 9.6, 16.1, 22.5, 34.6, 722.4, and 9000×10^{-5} *M* in dichloromethane; $T = 293.16$ K. (*C*) Visible–ultraviolet spectra of BPB 3.4×10^{-5} *M* and AJ 4.7×10^{-5} *M* at 283.16, 288.16, 293.16, 298.16, 303.16, 308.16, 313.16, 318.16, 323.16, and 328.16 K in dichloromethane. (*D*) Visible–ultraviolet spectra of BCG 6.3×10^{-5} *M* and HM 10.3×10^{-5} *M* at 283.16, 293.16, 303.16, 313.16, 323.16, and 333.16 K in dichloromethane.

constant (right hand side graphs) and which are positive for the visible spectrum range. In these tests 570 nm has been selected as corresponding to the maximum absorption of the BCG—HM mixture and a wavelength of 490 nm as an arbitrary but fixed wavelength. This result has been repeated for all the dye–amine mixtures with constant concentrations of dye and variable concentrations of amine (in slight excess), for the visible spectrum range. The test at Fig. 7 (lower left) corresponding to the BPB—AJ mixtures from Fig. 3*A* indicates two absorption species whose sum of concentration is a constant. On the other hand, the broken curves indicate that in the ultraviolet spectrum there are no two absorption species, this also being a general result given the overall character of the experimental conditions and of each dye–amine system tested in this study (three species exist because in the uv range the excess amine is absorbent). With a large excess of HM, in systems of BCG or BPB, the new changes in the absorption spectrum (Fig. 4) are also interpreted with the help of Coleman's method. Coleman's graphic resolution for the A_{ij} values in Fig. 4 for the BCG—HM system, with a large excess of HM, indicates two absorption species whose sum of concentrations is constant over time. An identical result has been demonstrated for the BPB—HM mixture under the same conditions.

However, when applying Coleman's test to BCG—HM or BPB—HM absorption spectra at longer times (48 h), just one absorption species is shown.[1]

Determination of the formation constants and molar extinction coefficients for 1:2 (dye:amine) ion pairs

The isosbestic points in Fig. 3 and the Coleman tests of Fig. 7 indicate a chemical equilibrium when a dye solution is mixed with another which contains a slight excess of amine. For this reason a series of experiments was carried out to determine the equilibrium constants, *K*, the molar extinction coefficients, ϵ, and the thermodynamic parameters of the reaction.

A series of solutions which contained dye–amine mixtures of different concentrations, always with a slight excess of the amine, were prepared in dichloromethane. In all the experiments the molar ratio of dye:amine was held constant to facilitate the experimental method and later treatment of the data using a computer program. The photometric measurement of the solutions was made at different temperatures between 287.16 and 313.16 K using pure dichloromethane as blank.

The dye–amine solutions, under these experimental conditions (slight excess of amine), presented two absorption maxima, the first at 410 nm (corresponding to a 1:1 ion pair) and the second in the 560–580 nm region (corresponding to a 1:2 ion pair), the exact location

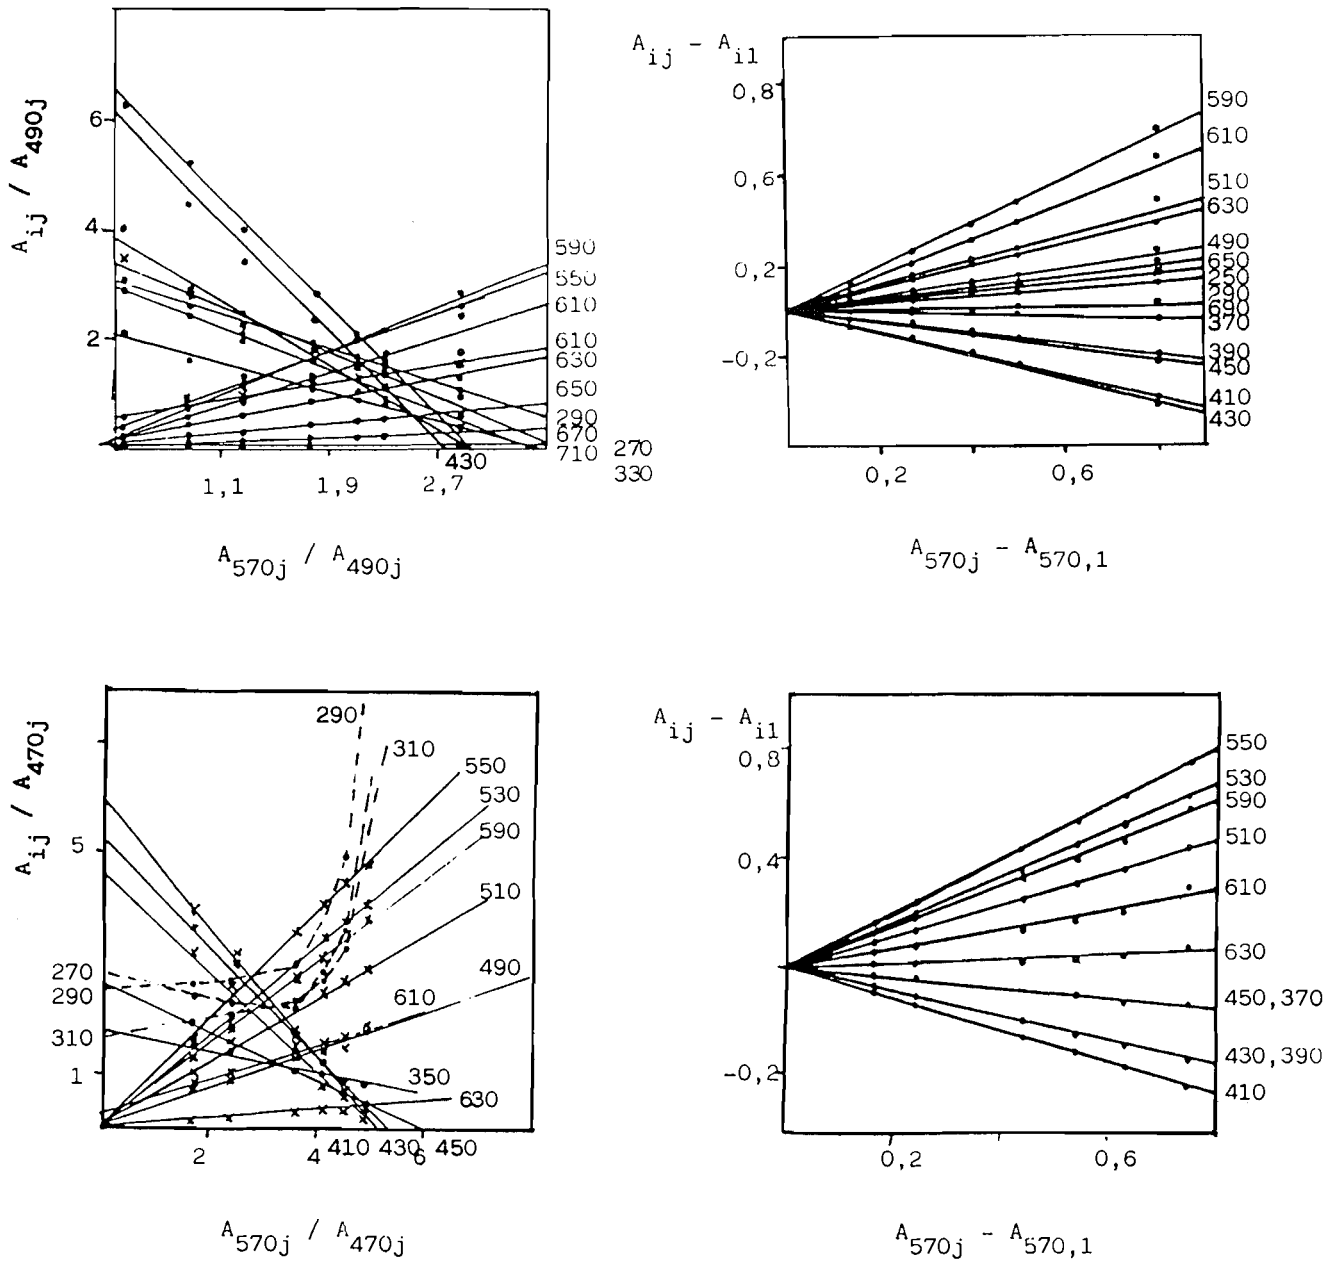

FIG. 7. Coleman's method for two species and for two species whose sum of concentrations is constant — (left and right upper figures) corresponding to the BCG—HM system taken from the data in Fig. 3*B*. The same tests in the lower zone for the BPB—AJ system taken from Fig. 3*A*. The numbers correspond to the wavelength, *i*, of the row of matrix which has been resolved graphically according to Coleman (see footnote 1).

of the maximum being dependent on the dye–amine system under consideration. The experimental absorption measures were carried out at the absorption maximum in the 560–580 nm region, corresponding to a 1:2 ion pair, since at this wavelength the 1:1 ion pair shows no absorption. The experimental data and other details are available from the Depository of Unpublished Data.[1]

Determination of the reaction constants

The v–uv absorption spectrum changes of the BCG and BPB dyes in dichloromethane on being mixed with solutions of HM in large excess suggest a kinetic process.

To determine the order of the reaction and the rate constants, a solution of dye–homatropine was prepared with a large excess of HM and the absorption of the mixture was measured at different times, against pure dichloromethane. The wavelengths for measurement were 630 nm for BCG—HM and 600 nm for BPB—HM. The experiments were done at different temperatures to see if Arrhenius' equation was followed. The homatropine solution was used immediately after its preparation. The experimental absorption measurements were carried out up to a maximum of 48 h, time enough for the reaction to complete. The experimental data and other details are available from the Depository of Unpublished Data.

Conductivity measures of the dye–amine solutions in dichloromethane

The specific conductivity, χ, of solutions of dye, amine, and a mixture of both in dichloromethane was measured. The amines HM and AJ, and the dyes BCG and BPB, show a specific conductivity close to zero, while on the other hand the dye–amine mixture shows a small but appreciable specific conductivity. The conductivity measurements were made at 293.16 K and are shown in Tables 4 to 7.

Discussion

Interpretation and assignment of the absorption bands

The new absorption bands that are shown by the solutions of dye–amine mixture are attributed to the formation of new compounds in the solution. In an excess of dye there is always a new band in the visible region with a maximum of 410 nm, as can be seen in Table 1 and in Figs. 1 and 2.

TABLE 7. Specific conductivity values, χ (μS cm^{-1}), for different concentrations of BPB and HM in dichloromethane are shown: concentrations of the BPB—HM ionic pair, $C_{1:1}$, and BPB—$(HM)_2$, $C_{1:2}$, at $T = 293.16$ K

BPB—HM	24280 ± 1897	0.009	0.998

This absorption complies with Beer's law for each amine, as is shown in Table 8 and indicates that the absorption corresponds to only one new compound, a result confirmed by the application of Coleman's (12) matrix method for the whole visible spectrum, and may be deduced from observations in Fig. 6.

In an excess of amine two new bands appear, one at 410 nm and the other at 580–600 nm. These are cut by an experimental isosbestic point as can be seen in Fig. 3. The isosbestic point allows us to suggest the existence of two new compounds in equilibrium, a conclusion which is again reinforced by Coleman's method. In this case the two absorption species satisfy the condition that the sum of their concentrations is constant. Figure 7 confirms this result, meaning the two new compounds which absorb in the visible spectrum range are in equilibrium.

In a large excess of homatropine (Fig. 4) the absorption in the region of 575 nm increases in intensity with the passage of time, and the maximum wavelength is displaced from 577 to 630 nm for BCG and from 573 nm to 600 nm for BPB. The elucidation of the two species assigned to this new change is also resolved by Coleman's method. The application of the test to the data of Fig. 4 for BCG—HM indicates two absorption species whose sum of concentration is constant,[1] one, already described, having a maximum at 577 nm and a new one at 630 nm. As the absorption intensity increases with the passage of time, different solutions with a large excess of HM and variable concentrations of BCG (always much less) were prepared and measured after 48 h at 293.16 K.[1] The application of Coleman's method again suggests only one absorption species at longer time,[1] which satisfies Beer's law as indicated in Table 16. Thus, at shorter times there are two species and at longer times there is only one, a finding to suggest that the new spectral change is a kinetic process.

The prior discussion indicates three new absorption species in the visible spectrum region as a result of the changes in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

absorption spectrum. The identification of these species can be facilitated by comparison with the absorption spectra of BCG and BPB in an aqueous medium at different pH values (13, 14). In effect, at pH 1 both dyes in water show a maximum at approximately 430 nm and at higher pH from 3 to 7, a second maximum appears in the region of 590 nm, both being cut by an isosbestic point. Both types of ions exist in an aqueous medium, namely, the monovalent anion, XH^-, and the divalent X^{2-} of the dye. By analogy with the dissociation in aqueous medium it is possible to assign it to a similar effect in an organic medium in which the amine in the form of a base neutralizes the protons of the dye. Given the low dielectric constant of the organic solvent, the stabilization of the dye with the amines is produced by formation of 1:1 and 1:2 ion pairs, that is to say $\{XH^-, BH^+\}$ and $\{X^{2-},(BH^+)_2\}$. The reactions in a non-polar medium could be the following:

$$[1] \quad XH_2 + B \rightarrow \{XH^-, BH^+\}$$

$$[2] \quad \{XH^-, BH^+\} + B \rightleftharpoons \{X^{2-}, (BH^+)_2\}$$

where XH_2 is the free dye, B, the amine in base state, $\{XH^-, BH^-\}$, the 1:1 ion pair, and $\{X^{2-}, (BH^+)_2\}$, the 1:2 ion pair. The formation of $\{XH^-, BH^+\}$ is quantitative from the spectrophotometric point of view while that of the 1:2 ion pair is clearly a chemical equilibrium which is displaced towards the formation of this last compound with an increase in the concentration of the alkaloid base or a decrease in temperature.

The first reaction is produced with excess or with equal concentrations of dye and the second in an excess of amine. This stoichiometry is confirmed by the application of Job's method, as indicated in Fig. 5 and suggests stoichiometry 1:1 for the maximum at 410 nm and stoichiometry 1:2 for that at 560–580 nm. From the absorption values in Table 2 it can be concluded that in an excess of dye or at equal concentrations of dye and amine (experiments with molar ratio 1:1, 2:1, and 5:1) the reaction is totally displaced to the right. Its formation constant is so high that it cannot be evaluated from the data using Job's method, unlike the reaction of bromothymol blue in which the formation constant can be found using Job's method (15, 16). Reaction [2] is clearly a chemical equilibrium whose formation constant is dependent on the temperature (Fig. 3). The fact that reaction [1] is quantitative and reaction [2] is an chemical equilibrium correlates with the fact that the first proton of the sulphonphthaleins is extremely acidic and the second proton is much less acidic.

The spectral change originating from a large excess of homatropine can be attributed, according to the points already discussed, to the formation of a third product originating from the 1:2 complex when it reacts again with HM.

This third interaction does not constitute a chemical equilibrium since at longer times, as previously discussed, there is only one absorption species. Apparently the 1:2 ion pair in a large excess of HM is transformed into another compound by a pseudo-first order kinetic process, as we will see subsequently. For small differences in amine–dye concentrations the changes in the absorption spectrum of BCG and BPB have been attributed to the formation of ion pairs but with a large excess of homatropine the displacement to higher wavelengths and the intensification of the bands cannot be interpreted in this way. The saturation of the central carbon of sulphonphthaleine is not possible since the colour then disappears and thus the visible absorption. The saturation of the central carbon has been described in the case of a strongly alkaline aqueous medium giving rise to carbinol which is colourless (17, 18).

The interaction with a large excess of homatropine can be written as

$$[3] \quad \{X^{2+},(HMH^+)_2\} + HM \rightarrow P$$

where P is the obtained product. The nature of P will be discussed subsequently. It is important to note that when bromhydrate of homatropine (analytical grade) is used none of the described associated reactions are produced whereas they are produced with homatropine in base state. It is therefore deduced that the nitrogen is the reactive element in amine, in agreement with the previous interpretation, since it is the nitrogen which contributes to the basic character of the amine. Obviously the bromhydrate of homatropine forms a more stable ion pair than those corresponding BCG—HM or BPB—HM associates.

Formation constants and thermodynamic parameters corresponding to the 1:2 ion pair

The formation constants, K, of the 1:2 ion pair are given by the following expression

$$[4] \quad K = \frac{[\{X^{2-},(BH^+)_2\}]}{[\{XH^-, BH^+\}][B]}$$

where B is the concentration of free amine.

The formation constants, K, have been determined from the spectrophotometric data using methods of specific calculation, since the molar extinction coefficient, ϵ, for the 1:2 ion pair is unknown and cannot be found directly. This is due to the fact that the equilibrium of reaction [2] cannot be displaced to the right to give a complete reaction, because of the weak character of the 1:2 associate. Moreover, with a large excess of homatropine the product, P, would be formed (reaction [3]).

The general equation that combines the concentrations of the chemical equilibrium of the reaction, e.g. [2], K, and ϵ is

$$[5] \quad \frac{C^0_{XH_2}(C^0_B - C^0_{XH_2})}{A} = -\frac{A}{\epsilon^2} + \frac{1}{K\epsilon} + \frac{C^0_{XH_2} + (C^0_B - C^0_{XH_2})}{\epsilon} + E$$

where A is the measured experimental absorption value at the absorption maximum for the 1:2 ion pair and E is a correction factor for experimental error. Equation [5] is the Rose–Drago expression (19, 20) applied to reaction [2]; seeing that $C^0_{XH_2} = C^0_{\{XH^-,BH^+\}}$ and the initial concentration of amine in reaction [2] is $C^0_B - C^0_{XH_2}$, as a result of the quantitative nature of reaction [1].

Spectrophotometric methods are known for the simultaneous calculation of K and ϵ (21–27). It is more frequent to solve eq. [5] using approximations disregarding the error, E, and it is perhaps the Benesi–Hildebrand (28, 29) treatment which is most known although it has the disadvantage of requiring a large excess of one of the reagents. Another approach is the linear approximation, which underestimates $1/\epsilon^2$ in eq. [5] but leads to error if K is large (30). Another proposed approximation is the modified Rose–Drago method (25) based on a linear approximation. This poses no restriction in the required concentration ranges but carries with it the Benesi–Hildebrand (B–H) approximation.

Both methods of approximation give a value of the linear determination coefficient, r^2, obtained by the least squares method and is an indication of the validity of the equations applied. The modified Rose–Drago method (MRD) has been used in this study as an approximation for the simultaneous

calculation of K and ϵ in the reactions of BCG—HM and BPB—HM because with a large excess of HM, P is produced. For reactions of BCG—AJ and BPB—AJ, both approximation methods (the MRD and B–H) are possible as P is not produced at high concentrations of AJ. Both methods have been used, the MRD for the BPB—AJ reaction and the B–H method for the BCG—AJ reaction, since in the latter the concentration of AJ was 10 times higher than that of BCG.[1] The Benesi–Hildebrand and, likewise, the Modified Rose–Drago methods yield a value of K and ϵ and a linear determination coefficient, r^2, obtained from the least squares method.

As a means of calculation the Rosseinsky (31) iterative method is proposed. This method requires a first-approximate value for K and ϵ, obtained from the MRD and B–H approximations and has the advantage of estimating other indices of great experimental and statistical importance, such as the root-mean-squared deviation of the experimental absorption measures, r.m.s.d., and an estimation of the objective errors of K and ϵ.

Both methods (of approximation and calculation) imply (*a*) the addition reaction is 1:1, (*b*) the reagents do not absorb at the maximum absorption of the addition compound, and (*c*) the addition compound follows Beer's law.

Reaction [2] satisfies these prerequisites as will be shown.

The parameters selected for the Rosseinsky method were K^{-1}, $\alpha_{K^{-1}}$, ϵ, and α_ϵ, defined as the inverse of the formation constant, K, with the estimation of its standard deviation, $\alpha_{K^{-1}}$ and ϵ with its standard deviation, α_ϵ, respectively. In order to obtain K and ϵ, and their respective confidence intervals the Tchebicheff (32) inequalities have been used. The results are shown in Tables 9–12. The parameters selected for Rosseinsky's iterative procedure were obtained when in two consecutive iterations $\Delta\epsilon < 10^{-3}$ and $\Delta K^{-1} < 10^{-8}$, respectively. The root-mean-squared deviation (r.m.s.d.) values in Tables 9–12 indicate that the error in the absorption measures is of the order of 0.01, a result which is sufficiently precise to allow the acceptance of the validity, from a quantitative point of view, of the supposed equilibrium in eq. [2]. The values of r^2, which appear in Tables 9–12, are those which correspond to the last iteration of the modified Rose–Drago approximation, ($\Delta\epsilon < 10^{-3}$ is required) or the Benesi–Hildebrand approximation, which is an indication of the validity of the assumed equilibrium in reaction [2] and likewise of all other assumptions. Another important result in these tables is that the values of ϵ have the same degree of constancy at different temperatures for the 1:2 complex of homatropine or ajmaline.

Gupta (15) has suggested that the moderately high values for the formation constants can mean a complex character for the 1:1 addition products of bromothymol blue (but not one of salts) although the reaction has an acid–base character. By analogy the magnitude of the obtained constants reveals a complex character for the 1:2 compound given that the value of K is not high and oscillates in a wide range with temperature. However, the reaction is apparently an acid–base process in which the order of magnitude of the equilibrium constants depends as much on the basic properties of the amine as on the dye employed.

The calculation of the variation in the thermodynamic magnitudes ΔG^0, ΔH^0, and ΔS^0 was carried out using the expressions (34)

$$[6] \quad \ln K = \frac{\Delta S^0}{R} - \frac{\Delta H^0}{RT}$$

$$[7] \quad \Delta G^0 = -RT \ln K$$

The calculated constants justify, within their respective confidence intervals, the linear regression of eq. [6] as can be seen in Fig. 8. In Table 13 values of ΔG^0, ΔH^0, and ΔS^0 and their confidence intervals are given for each one of the dye–amine complexes following the Student "t"-test (33) for 95% proba-

For personal use only.

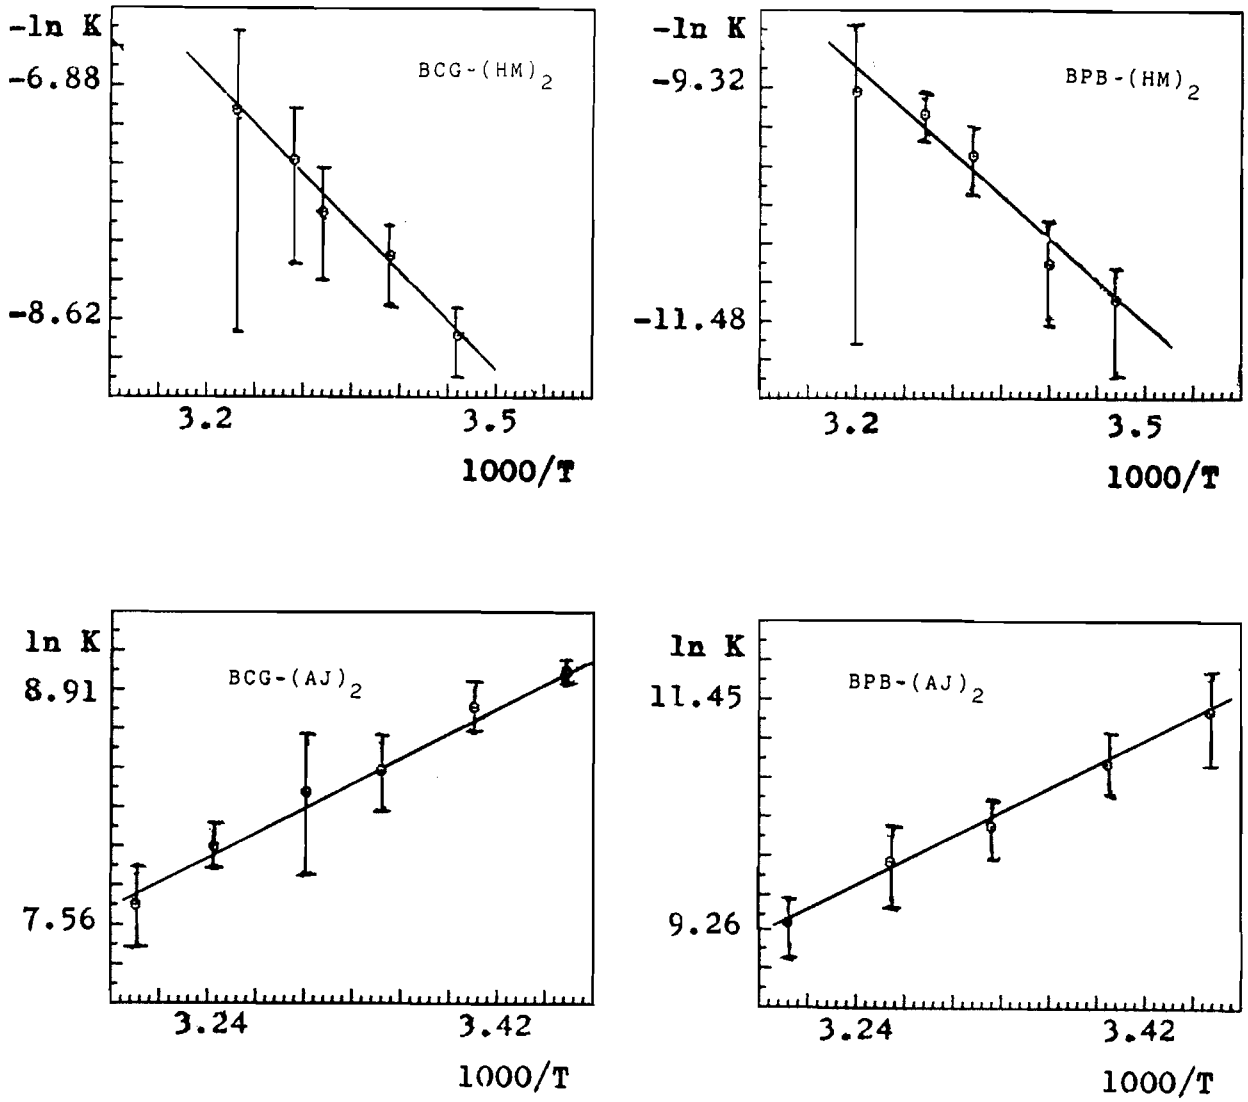

FIG. 8. The Van't Hoff representation for each dye–amine compound. The formation constants, K, or those of dissociation, K^{-1}, appear with their confidence intervals.

bility. The values of the determination coefficients obtained by least squares are 0.995 for BPB—$(AJ)_2$, 0.984 for BCG—$(AJ)_2$, 0.952 for BPB—$(HM)_2$, and 0.990 for BCG—$(HM)_2$ which indicates in general an acceptable fit of Van't Hoff's equation in the temperature ranges studied. The value of ΔG^0 is obtained from eq. [7] and its confidence interval from that of K.

The values of ΔH^0 are negative, indicating that the formation of the 1:2 ion pair is an exothermic process. The variation of entropy ΔS^0 is negative which suggests a greater ordering of the 1:2 complex and ΔG^0 is negative because of the spontaneous process.

Rate constants and kinetic parameters

As has been previously discussed, with a large excess of homatropine the absorption spectrum for the dye:(homatropine)$_2$ ion pair is displaced towards higher wavelengths and intensified by the transition of time, if the homatropine solution is recently prepared.

The experimental absorption values have been adjusted by the equation

$$[8] \quad \ln (A_\infty - A_t) = \ln (A_\infty - A_0) - k't$$

where ln is the Naperian logarithm, A_∞, the absorption at longer time, A_t the absorption at time t, in minutes, and k' the apparent constant of velocity for the pseudo-first order reaction. The rate constant of the process, k, is obtained from the quotient $k'/[HM]$ where HM is the homatropine which is always in excess. In Fig. 9*A* the absorption values at different times can be seen, and they suggest a first order process with respect to the dye. Quantitatively all the experimental results are adjusted by eq. [8] as can be seen in Fig. 9*B*. The values of the ordinate at the origin, ln $(A_\infty - A_0)$, the rate constant, k, and the determination coefficients, r^2, obtained by the least squares method for the reactions of HM with BCG and BPB are shown in Table 14.

The high value of r^2 suggests an exact fit of eq. [8] for all the experimental data at the temperatures studied. The rate constants are presented in Table 14 with a confidence interval for a 95% probability obtained by the Student "t"-test method (33).

The calculated rate constants also satisfy Arrhenius' equation

$$[9] \quad \ln k = \ln A - \frac{E_a}{RT}$$

	323.16	−0.596	2.271 ± 0.076	0.999

TABLE 15. Activation energy, E_a, frequency factor, $\ln A$, confidence intervals to a probability of 0.95 and determination coefficients, r^2, obtained by least squares method

Dye	E_a (kJ mol^{-1})	$\ln A$ (min^{-1})	r^2
BCG	58.859 ± 12.883	21.6 ± 5.1	0.988
BPB	91.337 ± 18.848	34.8 ± 7.4	0.995

where A is the frequency factor and E_a the activation energy. In Figs. 9*C* and *D* the straight lines obtained for the homatropine–bromocresol green, and homatropine – bromophenol blue reactions are drawn and in Table 15 the ordinate values at the origin, $\ln A$, the activation energy, E_a, and the determination coefficients, r^2, for the corresponding lines are presented.

The confidence intervals for $\ln A$ and E_a were obtained by the Student's "t"-test (33) for a probability of 0.95. The values of r^2 in Table 15 are very close to unity indicating that the described kinetic reactions satisfy the Arrhenius equation in the temperature ranges studied.

The reaction of homatropine with BCG or BPB can be shown schematically:

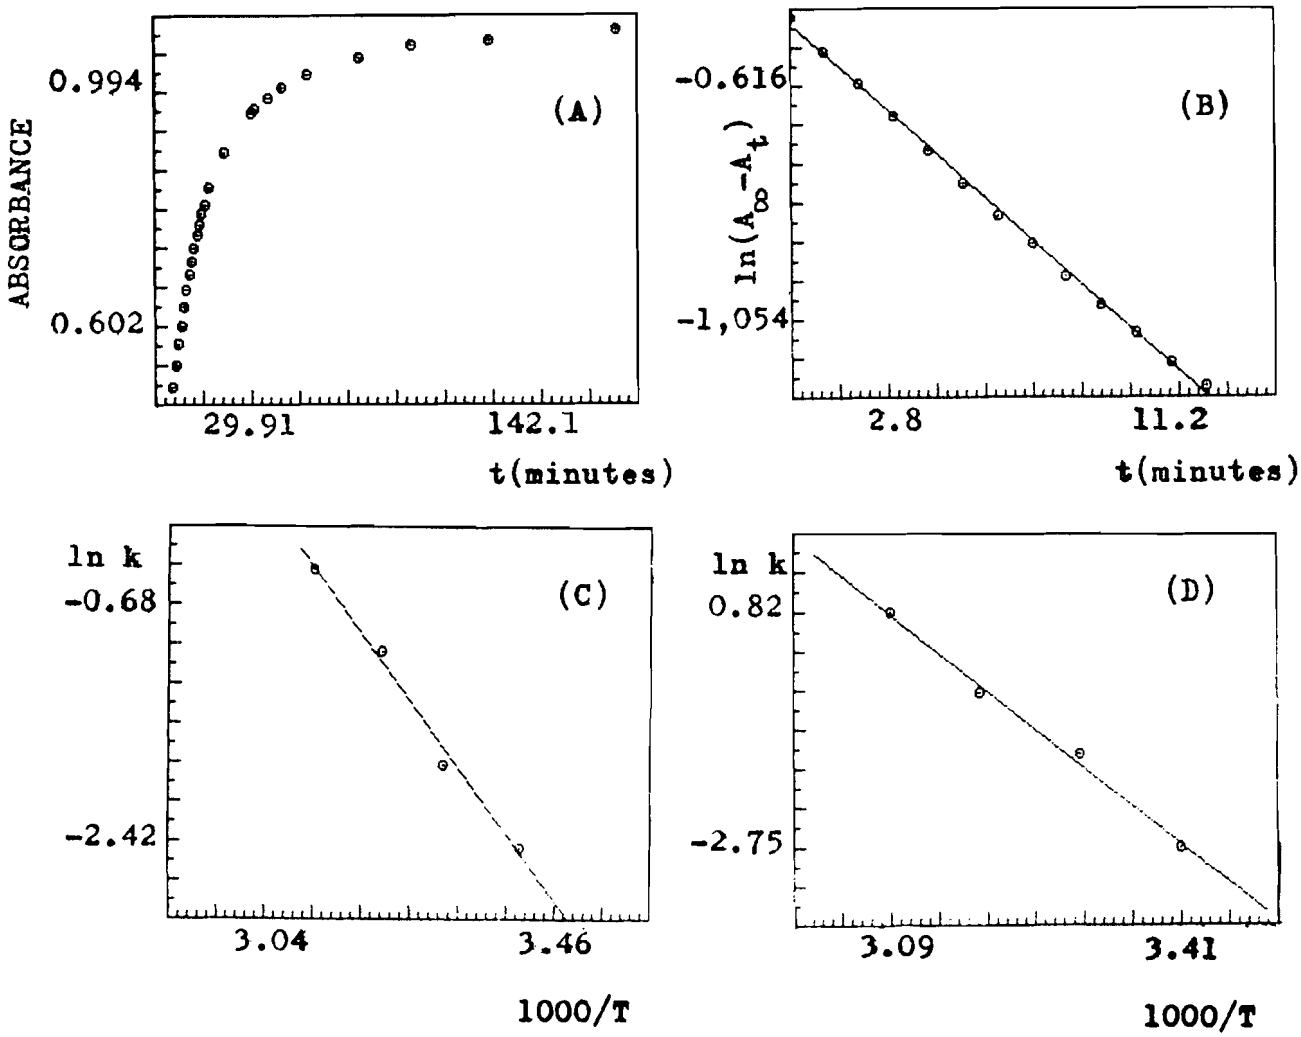

FIG. 9. (*A*) Representation of the absorption at 630 nm of a solution of BCG 1.82×10^{-5} *M* and of HM 0.091 *M* for different times (in minutes); $T = 321.16$ K. (*B*) Representation of ln $(A_\infty - A_t)$ against time, *t*, of a solution of BCG 1.82×10^{-5} *M* and of HM 0.091 *M*; $T = 321.16$ K. (*C*) Arrhenius' representation for the product, P, corresponding to the reaction BCG—HM. (*D*) Arrhenius' representation for the product, P, corresponding to the reaction BPB—HM.

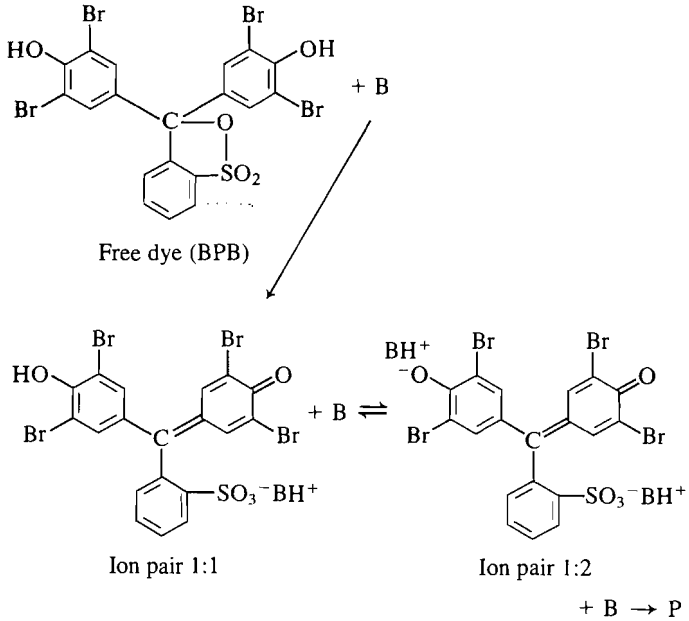

In the first two reactions B can be either HM or AJ but the formation of the product P is only possible with HM. The binding sites of the amine with sulphonphthaleine are not necessarily those shown in the diagram, since the dye (BCG or BPB) is an extensively conjugated molecule (14) and can show resonance.

Each P product obtained in the two reactions studied satisfies Beer's law. The intercept values, *b*, the slope, ϵ_P, and the linear determination coefficient, r^2, obtained by least squares are presented in Table 16. The confidence intervals for ϵ_P were obtained by the Student's "*t*"-test (33) for a probability of 0.95.

The calculated extinction coefficients are of the order of 10^5 L/mol cm, practically double that calculated for the molar extinction coefficients of the 1:2 ion pair (dye:homatropine).

The molar extinction coefficients of the 1:1 and 1:2 ion pairs and P are approximately in the order $\epsilon_{1:1} = \epsilon_{1:2}/2 = \epsilon_P/4$. The fact that $\epsilon_{1:2}$ is double $\epsilon_{1:1}$ could be due to the presence of two alternative quinonoid rings for the 1:2 ion pair. The intensification of the band with a maximum at 600 nm does not allow acceptance of the saturation of the central carbon which would break the chromophore group (17, 18).

The kinetic aspect of reaction [3] is only seen if the dye–amine mixture is carried out with a recently prepared solution of homatropine. If the solution of the tropane compound was prepared 36 h before mixing the P product is immediately formed. From this it is interpreted that the tropane alkaloid reacts slowly with the solvent in the first phase and later with the dye.

TABLE 16. Molar absorptivity of P product, ϵ_P, intercepts, b, and determination coefficients, r^2, obtained by least squares method; confidence intervals to a probability of 0.95 from Student "t" Test, $T = 293.16$ K

Compound	ϵ_P (L/mol cm)	b	r^2
BCG—HM	63600 ± 10007	0.014	0.994
BPB—HM	107750 ± 18679	−0.030	0.991

The data in Table 14 suggest that the order of magnitude of the calculated rate constants is the same as that of the acid strength of the dye used (BCG or BPB). In a previous paper (35) evidence has been presented that the rate constants of the reaction of the tropane derivative with bromophenol blue increase with the basicity of the tropane alkaloid considered (hyoscyamine and tropine base pK_a = 9.99 and 10.73, respectively).

The preceding discussion indicates that reaction [3] is a complex process in which the solvent plays an important role. Dichloromethane has a capacity to form hydrogen bridges with the tropane alkaloid at high concentrations. Probably in an excess of homatropine an electron is transfered to the 1:2 ion pair across such a bridge. As a result, P is probably a charge transfer complex type of compound. The fact that ajmaline does not form the P product, although its basic character is similar to homatropine (see the respective values of K), could be due to steric factors which make the transition of the electron from the ajmaline to the 1:2 ion pair dye—(ajmaline)$_2$ difficult.

Conductivity of dye–amine solutions in dichloromethane

The data in Tables 4–7 indicate that neither the amines nor the dyes conduct electric current in dichloromethane. On the other hand, mixtures of both do conduct electricity in dichloromethane. This result suggests an ionic nature for the associate species. The weak values of specific conductivity corroborate the conclusion that the associate species are ionic pairs, a conclusion which agrees with the spectrophotometric interpretation. In Tables 4–7 the specific conductivity values are given for the different concentrations of dye–amine ion pair obtained from the equilibrium constants, K, by spectrophotometric methods (Tables 9–12). The specific conductivity increases with an increase in the concentration of the ion pair, be it 1:1 or 1:2, probably because of the presence of a larger number of free ions. However, in the case of the BCG—AJ and BPB—AJ mixtures, after a certain excess concentration of AJ (the limiting AJ concentration is given in Tables 4 and 5) the specific conductivity does not have a stable value, decreasing as time passes. On the other hand, for the BCG—HM and BPB—HM mixtures, if the HM concentration increases sharply, the specific conductivity increases with time.

The interpretation of the spectrophotometric data is in agreement with the conductometric results since in a large excess of AJ the reaction is complete, making the ionization of the ion pair more difficult. On the other hand, in a large excess of HM the formation of product P may make its ionization easier. However, even after waiting 18 h, the specific conductivity did not exceed 2 μs/cm. Thus, the ionization in the solvent is practically negligible and it seems justified not to take it into account in the spectrophotometric study.

Conclusions

Ajmaline and homatropine react in dichloromethane with sulphonphthaleins in acid–base reactions, forming ion pairs of stoichiometry 1:1 and 1:2 in proportion with the increase in the amount of alkaloid base. The formation of the 1:1 ion pair is quantitative and shows evidence of a clear chemical equilibrium between 1:1 and 1:2 ion pairs. The thermodynamic parameters indicate that the formation of the 1:2 ion pair is spontaneous and exothermic, giving rise to a greater ordering. With a large excess of homatropine a new associate, P, is formed in a pseudo-first order kinetic process when the alkaloid base reacts once again with the 1:2 ion pair (dye:homatropine). The P product has been identified as being a kind of charge-transfer complex.

Nuclear magnetic resonance measurements of metallic nuclei (δ ^{207}Pb, δ ^{95}Mo, and ^1J(W–Pb)) have been carried out on dimetallic $Cp(CO)_3MPbR_3$ (M = Mo, W; R = Me, Et, Ph) and trimetallic $[Cp(CO)_3M]_2PbPh_2$ (M = Mo, W) complexes. ^{207}Pb chemical shifts increase in the sequence $PbEt_3 < PbMe_3 < PbPh_3$ and are observed at higher fields in the tungsten compounds than in the molybdenum ones. It is suggested that both paramagnetic and diamagnetic contributions determine the overall shielding of lead, and that the higher field resonances of ^{207}Pb in the case of W–Pb compounds are due to an efficacious operation of the Z/r dependent diamagnetic term (higher atomic number Z of tungsten and roughly the same Mo–Pb and W–Pb distances resulting from the $4f$ level induced lanthanide contraction). ^{95}Mo chemical shifts (−1838 to −2007 ppm) lie in the region typical of the molybdenum – main group metal bonded complexes but at lower fields than in the corresponding Mo–Sn compounds. It is concluded from this observation that the Z/r dependent diamagnetic contribution does not operate efficaciously for ^{95}Mo shieldings, which are hence primarily dominated by the paramagnetic term. The nature of metal–metal interactions is discussed.

MAREK M. KUBICKI, JEAN-YVES LE GALL, RENÉ KERGOAT et LUIZ C. GOMES DE LIMA. Can. J. Chem. **65**, 1292 (1987).

Des mesures de résonance magnétique nucléaire de noyaux métalliques (δ ^{207}Pb, δ ^{95}Mo et ^1J(W–Pb)) ont été réalisées sur des complexes dimétalliques $Cp(CO)_3MPbR_3$ (M = Mo, W; R = Me, Et, Ph) et trimétalliques $[Cp(CO)_3M]_2PbPh_2$ (M = Mo, W). Les déplacements chimiques δ ^{207}Pb augmentent selon $PbEt_3 < PbMe_3 < PbPh_3$ et se situent à des champs plus élevés dans les composés du tungstène que dans ceux du molybdène. On suggère qu'à la fois les contributions paramagnétique et diamagnétique déterminent le blindage global du noyau ^{207}Pb, et que les résonances du noyau ^{207}Pb à champs plus forts dans le cas des composés à liaison W–Pb sont dues à une intervention efficace du terme diamagnétique dépendant de Z/r (nombre atomique Z plus grand pour le tungstène et à peu près les mêmes distances Mo–Pb et W–Pb résultant de la contraction lanthanidique induite par la présence de la couche $4f$). Les déplacements chimiques δ ^{95}Mo (−1838 à −2007 ppm) se situent dans la région typique des complexes à liaison molybdène–métal (autre qu'un métal de transition) mais à des champs plus faibles que dans des composés correspondants à liaison Mo–Sn. On en conclue que la contribution diamagnétique dépendant de Z/r n'opère pas de manière efficace pour le blindage du molybdène ^{95}Mo dans lequel le terme paramagnétique entre de manière prépondérante. La nature des interactions métal–métal est discutée.

Introduction

For some years we have been interested in the scope of nmr studies of metallic nuclei and especially of ^{95}Mo in cyclopentadienyl (Cp) complexes. Our object consists of studies on the utility of this technique for chemical applications related to the nature of the transition metal – main group metal bonds.

Heteronuclear metal$^{(a)}$–metal$^{(b)}$ bonds in cyclopentadienyl complexes involving metal$^{(a)}$ of the chromium triad have been known for several years. However, very little has been done on the measurements of metallic nmr parameters of these complexes although they are of interest in light of the continuing discussion of the factors influencing variations in metal shieldings and the nature of metal–metal bonds. To our knowledge there are only three reports on this subject concerning monocyclopentadienyl complexes of the type $Cp(CO)_3M^a$–$[M^b]$ (containing formally M^a(II)), including the resonances of M^b = ^{119}Sn (1), ^{199}Hg (2), and our earlier paper on both M^a = ^{95}Mo and M^b = ^{199}Hg resonances (3). In the class of biscyclopentadienyl complexes of the type $Cp_2M^aX[M^b]$ or $Cp_2M^a[M^b]_2$ (containing formally M^a(IV)), the chemical shifts of ^{119}Sn (1) and of ^{199}Hg (4) have been measured. Our attempts to record the ^{95}Mo spectra in $Cp_2Mo\diagup$ compounds failed, except for that of Cp_2MoH_2 (δ ^{95}Mo = −2497 ± 30 ppm) (4). Recently, Grieves and Mason (5) published the ^{95}Mo data for Cp_2MoH_2 and $(Cp_2MoH_3)Cl$. The molybdenum is formally Mo(VI) in the cation of the latter. A compilation of ^{95}Mo studies covering all fields of molybdenum chemistry has recently been published (6). The overall range of the ^{95}Mo resonances in its monocyclopentadienyl complexes covers about 2000 ppm, but is restricted to about 300 ppm (in the high field part of the overall range) for the compounds with molybdenum – main group metal (Hg, Sn) bonds.

In our continuing interest in the application of nmr studies of metallic nuclei to the problem of chemical bonding, we recorded the ^{207}Pb resonances in monocyclopentadienyl complexes $Cp(CO)_3MPbR_3$ (M = Mo and W) together with the ^{95}Mo resonances for M = Mo, as well as in some trimetallic compounds $[Cp(CO)_3M]_2PbR_2$. The choice of lead derivatives was suggested by the fact that contrary to the complexes with $[M^a]$–Sn bonds, which were extensively studied, only a few publications report on the compounds with $[M^a]$–Pb bonds. These are the nmr studies of M^a = ^{59}Co (7), ^{55}Mn (8), ^{93}Nb (9), and ^{51}V (10). Both metallic nuclei (M^a and ^{207}Pb) were studied only in platinum–lead bonded compounds (11, 12).

Experimental

The complexes were synthesized as previously described (13, 14). Samples for nmr measurements were prepared under a nitrogen atmosphere by using dried and degassed CH_2Cl_2 and C_6D_6 as internal lock. Solutions close to saturation were sealed in 10-mm tubes.

The nmr spectra were recorded on a JEOL FX 100 spectrometer at ambient temperature. A 10-mm multinuclear probe model NM 3980 operating at 20.80 MHz for ^{207}Pb and at 6.44 MHz for ^{95}Mo measurements was used. The 90° pulse was found to be 40 μs for ^{207}Pb and 80 μs for ^{95}Mo. The routine acquisition parameters used in this

[1]Part VI of this series: ref. 35.

TABLE 1. δ ^{207}Pb and δ ^{95}Mo chemical shifts and ^1J(W–Pb) coupling constants for $[Cp(CO)_3M]_nPbR_{4-n}$ complexes

Complex	δ ^{207}Pb (ppm)	$\Delta\nu_{1/2}$ (Hz)	δ ^{95}Mo (ppm)	$\Delta\nu_{1/2}$ (Hz)	^1J(W–Pb) (Hz)
$Cp(CO)_3MoPbEt_3$	+301	8	−2007	120

[a]This complex has not been synthesized; its formulation has been attributed for an extra peak observed during the recording of the ^{207}Pb resonance for $Cp(CO)_3WPbEt_3$; see text.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

study were as follows: pulse width 40 μs (^{95}Mo) and 10 μs (^{207}Pb); acquisition time 5×10^{-2} s with the repetition time of $7–9 \times 10^{-2}$ s for ^{95}Mo and 0.4 s and 1 s, respectively, for ^{207}Pb (acquisition times for ^{95}Mo are shorter than for ^{207}Pb because of its quadrupole moment); spectral width 20 kHz; data points 2K (^{95}Mo) and 16K (^{207}Pb); number of scans $5 \times 10^4 – 6 \times 10^5$ (^{95}Mo) and $10^3–10^5$ (^{207}Pb) depending on the solubility of compounds. Na_2MoO_4 (2 *M*) at pH 11 (^{95}Mo) and neat $PbMe_4$ (^{207}Pb) were used as external references.

The ^{207}Pb and ^{95}Mo chemical shifts together with the line widths at half-height and the coupling constants W–Pb are given in Table 1.

Results and discussion

Before a discussion of the ^{95}Mo and ^{207}Pb nmr data, we indulge in a brief recall of the parameters determining the nuclear screening. These are usually discussed in the terminology developed by Ramsey (15), introducing the "diamagnetic" (σ_d) and "paramagnetic" (σ_p) components of the overall shielding (σ) (eq. [1]),

$$[1] \quad \sigma = \sigma_d + \sigma_p$$

where σ_d involves the free rotation of the electrons about the nucleus in question and σ_p describes the hindrance to this rotation caused by other electrons and nuclei in the molecule. The σ_d term for a nucleus A can be expressed by eq. [2].

$$[2] \quad \sigma_d^A = \text{const} \sum_\mu P_{\mu\mu} \langle \mu | r_{A\mu}^{-1} | \mu \rangle$$

where $P_{\mu\mu}$ is the charge density of the atomic orbital μ, which is at an average distance of $r_{A\mu}$ from nucleus A. An approximation to the paramagnetic term σ_p can be given by eq. [3] of Jameson and Gutowsky (16),

$$[3] \quad \sigma_p = -\text{const}\, \overline{\Delta E^{-1}} (\langle r_{np}^{-3} \rangle Q_p + \langle r_{nd}^{-3} \rangle Q_d)$$

where $\overline{\Delta E}$ is the mean energy of electronic excitation from the ground state to excited states, which can be mixed in by the magnetic field and interpreted often as HOMO–LUMO separation, $\langle r_{np} \rangle$ and $\langle r_{nd} \rangle$ are the radial expansion terms for the valence *p* and *d* electrons, and Q_p and Q_d represent the degree of ground-state electron imbalance in the bonds associated with the *p* and *d* components of the hydridized orbitals.

In another approach, the MO theory developed by Pople (17) within the framework of an independent electron model expresses the nuclear screening as the sum of local, non-local, and interatomic diamagnetic and paramagnetic contributions (eq. [4]),

$$[4] \quad \sigma = \sigma_d^{loc} + \sigma_d^{non\text{-}loc} + \sigma_d^{inter} + \sigma_p^{loc} + \sigma_p^{non\text{-}loc} + \sigma_p^{inter}$$

where the various σ_d and σ_p terms are not directly comparable with the expressions bearing these names in Ramsey's equations. In Pople's approach the local terms arise from electronic currents localized on the atom containing the nucleus of interest, both non-local contributions are derived from currents on neighboring atoms, and the interatomic contributions are due to the currents not localized on any atom in the molecule, e.g. ring currents. The interatomic contributions in eq. [4] are small, so the overall shielding may be considered as depending on the local and non-local σ_p and σ_d terms.

A chemist is particularly interested in the electronic structure of atoms forming the different kinds of bonds and therefore in the nature of their valence shell, which depends on the structure of their own electrons, local symmetry, and on the nature and symmetry of the orbitals associated with the neighboring atoms. The Ramsey paramagnetic term approximated by eq. [3] seems to respond well to the above chemical problems because the parameters determining the nature of the bonds are included therein. As the influence of the neighbors is thus involved, eq. [3] results from both local and non-local contributions.

Flygare and Goodisman (18) have proposed an atom–dipole model for estimating the diamagnetic contribution, in which the electronic eigenfunctions are not explicitly involved as in the case of eq. [2] (eq. [5]),

$$[5] \quad \sigma_d^A = \sigma_d^A \text{ (free atom)} + \frac{\mu_0 e^2}{12\pi m} \sum_{B \neq A} \frac{Z_B}{r_{AB}}$$

where Z_B is the atomic number of the atoms other than A present in the molecule and r_{AB} is the separation between nucleus A and its neighbors B. The values calculated by Dickinson may be taken as σ_d^A (free atom) (19). In this light, eq. [5] gives a σ_d^A contribution related to that defined by Ramsey. Using eq. [5] with the summation over only the atom in question and those bonded directly to it, Mason obtained the σ_d^{loc} values useful for interpretation of nitrogen (20) and carbon (21) chemical shifts. The increment in σ_d^A arises from the final, non-local, term in eq. [5] and thus, perhaps not wholly accurately from the theoretical point of view, the diamagnetic term may be separated into the local and non-local contributions as in Pople's approach. Such an artificial division is attractive for a chemist, especially when the chemical shifts are compared for the series of structurally similar compounds. Thus in this paper we shall use the term "local" for the nucleus studies and "non-local" for the influence of its neighbors (eq. [6]),

$$[6] \quad \sigma = \sigma_p + \sigma_d^{loc} + \sigma_d^{non\text{-}loc}$$

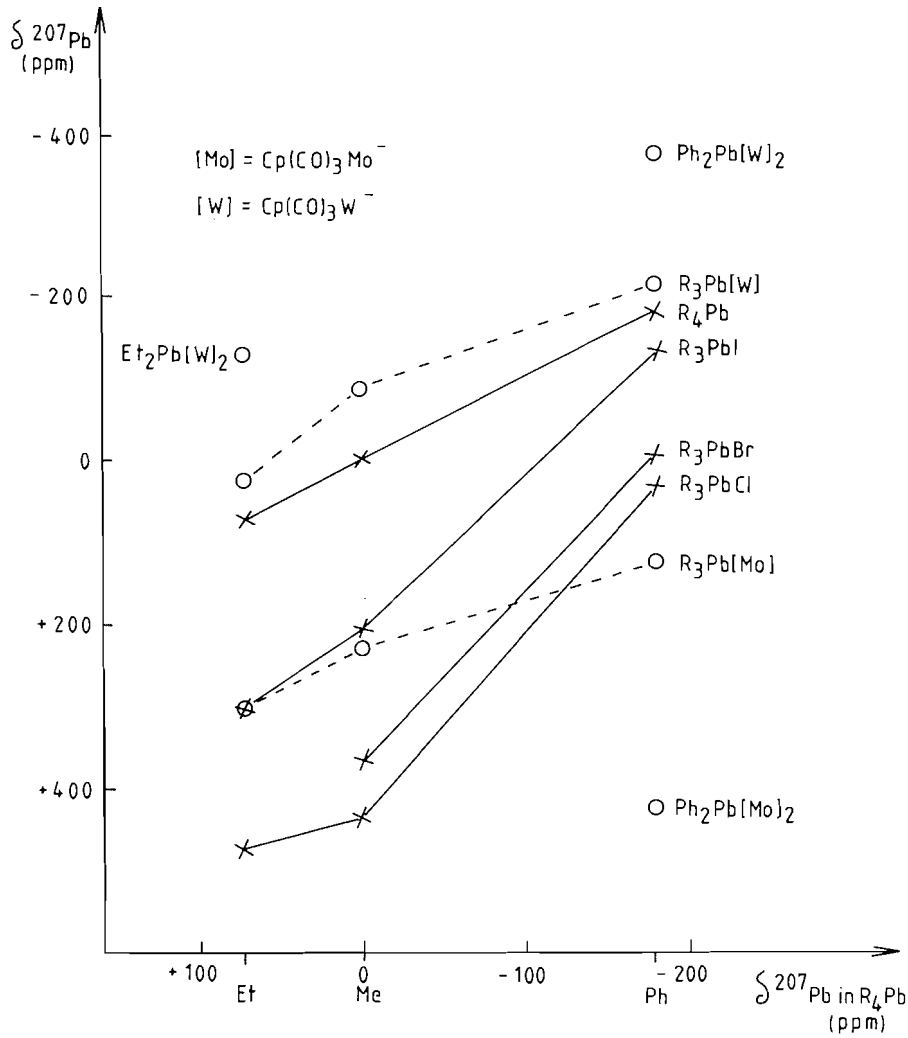

FIG. 1. ^{207}Pb chemical shifts in R_3PbY (×: Y = Cl, Br, I and R; ○: Y = $Cp(CO)_3Mo$ and $Cp(CO)_3W$) and $R_2Pb[M(CO)_3Cp]_2$ complexes as a function of δ (^{207}Pb) in R_4Pb.

^{207}Pb chemical shifts and coupling constants

Inspection of Table 1 shows that the shielding of the lead nucleus in $Cp(CO)_3MPbR_3$ complexes increases in the sequence $PbEt_3 < PbMe_3 < PbPh_3$, and is the same as that observed in triorgano- (R_3PbX, R = Et, Me, Ph; X = Cl, Br, I) and tetraorgano-lead (R_4Pb) compounds (22). In the analogous tin derivatives R_3SnCl and R_4Sn, the corresponding sequence of ^{119}Sn shieldings is inverted for R = Me and Et, although there exists a general linear relationship between the chemical shifts of ^{119}Sn and ^{207}Pb (23, 24). However, the differences of shielding in M^bMe_3 and M^bEt_3 are small compared to the much higher shieldings of tin and lead in phenyl derivatives. Thus it is possible that these weak differences (Me vs. Et), which have no chemical consequences, are due to a higher polarizability of lead, thus modifying the electron movements responsible for the shieldings of M^b.

Shielding variations of ^{207}Pb nuclei in the compounds $YPbR_3$, where Y is a halide (X), R, or $Cp(CO)_3M^a$, are graphically presented in Fig. 1 as a function of chemical shifts of ^{207}Pb measured for R_4Pb. One observes an important increase of shielding from R = Me and Et to R = Ph in the compounds R_3PbX but a moderate one in dimetallic complexes R_3Pb–$[M^a]$. This suggests clearly a different nature of R_3Pb—X and R_3Pb—M^a bonds with repercussions on, or as the consequence of, the Pb–Ph magnetic interactions.

Magnetic anisotropy of the phenyl ring, which generally leads to higher field resonances of neighboring nuclei, may operate more easily in Ph_3PbX than in Ph_3PbM^a compounds. In these latter complexes the higher covalency of Pb—M^a bonds and the presence or participation of metal (M^a) *d* orbitals in bonding can modify the nature of the valence electrons on lead. The differences (Δ) of the chemical shifts of ^{207}Pb in the compounds Me_3PbY and Ph_3PbY are given in Table 2. These data show a clear distinction between the halides (Y = X), R, and [M^a]. Because there is no doubt that, among the compounds involved, the Pb—Cl bond has the most pronounced ionic nature, the values of Δ reflect the covalency of Pb—Y bonds. Thus the Pb—M^a bonds are highly covalent and the covalency of the Pb—Mo bonds seems to be higher than that of the Pb—W bonds. This last statement may be confused with the problem of d_π–d_π interactions, which appear to be less important for heavier transition metals (25).

With the exception of tungsten complexes, the ^{207}Pb resonances in the compounds R_3PbY are observed, for a given R, at lower fields than in the corresponding tetraorganoleads (Fig. 1). This can be easily deduced from the paramagnetic contribution to the overall shielding (eq. [3]). For four-coordinate lead compounds, the *d*-electron term may be ignored if there is no π-bonding. In R_4Pb compounds Q_p is equal to 0, but the 6*p* electron imbalance increases in the compounds R_3PbY. More-

over, a change of symmetry from idealized T_d to C_{3v} decreases the $\overline{\Delta E}$ value. Both these parameters increase the value of the paramagnetic term σ_p and consequently decrease the overall shielding of ^{207}Pb.

The chemical shifts of lead in tungsten complexes are observed at higher fields than in R_4Pb, apparently in contradiction to the above symmetry related discussion of the paramagnetic term σ_p. However, the same phenomenon has been observed in group-VII transition metal complexes of tin: δ ^{119}Sn in $(CO)_5ReSnMe_3$ is −89 ppm (ref. $SnMe_4$), but the expected shielding (+63 ppm) appears in $(CO)_5MnSnMe_3$ (1). It has been suggested that the diamagnetic contribution due to the nearest neighbors (eq. [5]) may explain the high field resonances when heavier atoms are present in the coordination sphere of the nucleus studied (1) ($\sigma_d^{\text{non-loc}}$ term in eq. [6]). Similar trends in δ ^{119}Sn were observed in the complexes of Ru vs. Os and Rh vs. Ir (26). Such an influence of heavier nuclei on the nucleus studied is known as the "heavy atom effect" or "Z dependence" but its cause has not yet been satisfactorily stated. It appears that such a dependence should mainly affect the diamagnetic contribution (eq. [5]), but the strain reasoning fails when examples of "inverse halogen dependence" are encountered (6, 27, 28). Similar "anomalies" are also found when considering the influence of metallic nuclei. If Z dependence is apparently exhibited by the δ ^{119}Sn values in complexes of the type $Cp(CO)_3MSnMe_3$: M = Cr + 161, Mo + 121, W + 42 ppm (1), and by ^{199}Hg values in $Cp(CO)_3MHgCl$: M = Cr − 542, Mo − 617, W − 997 ppm (ref. $HgMe_2$) (2), it fails in trimetallic organomercurials $[Cp(CO)_3M]_2Hg$: M = Cr − 80, Mo + 115, W − 348 ppm (2). Other examples may be found with other nuclei, e.g. ^{1}H in the anions $HM(CN)_5^{3-}$: M = Co − 47.2, Rh − 45.4, Ir − 49.0 ppm (ref. bare proton) (29) or ^{13}C in $M(Me)_4$: M = Sn − 202.1, Pb − 196.2 ppm (ref. CS_2) and $M(Me)_2$: M = Zn − 197.0, Cd − 191.8, Hg − 169.3 (ref. CS_2) (30). Some cases involving transition metal [M[a]] resonances bonded to tin and lead will be cited below in the discussion of ^{95}Mo data. One can conclude from the examples cited above that, in the case of the influence of *transition metals*, the chemical shifts of the nucleus studied may or may not obey the Z dependence (eqs. [5] and [6]) if the metal belongs to the 3*d* or 4*d* blocks, but that in the presence of 5*d*-block metals the highest shieldings are observed. Thus it seems clear that the presence of the 4*f* level in 5*d* transition metals, leading to the well-known lanthanide contraction, may explain the high shieldings of the nuclei bonded to them. The σ_d term should vary more widely than does the σ_p term. The parameters determining the extent of σ_d domination should therefore be, aside from the atomic number Z, the covalent or ionic radii of the atoms and, hence, the interatomic distances r_{AB}. These increase on going down from 3*d* to 4*d* metals, but they are the same or even smaller for 5*d* than for 4*d* metals. It can be assumed that when "inverse Z dependence" for 3*d* vs. 4*d* metals in a similar structural environment is observed, the interatomic distances increase rapidly and the changes in paramagnetic contribution σ_p may overlap the increase in σ_d. The σ_p term is much more sensitive to variations in expansion of the orbitals involved (r^{-3} dependent, eq. [3], which depends on the bond distances) than is the σ_d term (r_{AB}^{-1}) dependent, eqs. [2] and [5]).

In trimetallic complexes $[Cp(CO)_3M]_2PbR_2$, the lead resonances are observed at higher fields for M = W (R = Et and Ph) but at lower field for M = Mo (R = Ph) than in the corresponding dimetallic complexes $Cp(CO)_3MPbR_3$ (Table 1, Fig. 1). The case of molybdenum may have been expected on the grounds of the increased value of the σ_p term. Replacement of a single R group in PbR_4 by a second-row transition metal entity gives a shift to low field, and multiple substitution does nothing to reverse the trend as it was still observed for ^{119}Sn resonances in the carbonyl complexes of the first-row transition metals $[(CO)_xM]_nSnMe_{4-n}$ (M = Co, x = 4; M = Mn, x = 5) (1). It is possible that d_π–d_π interactions in the trimetallic Mo complexes are stronger than in the dimetallic complexes and that this leads to an increased σ_p contribution as a consequence of electron delocalization reducing the $\overline{\Delta E}$ parameter in eq. [2]. An earlier study of $[\{(CO)_4Co\}_nSnMe_{4-n}]$ by ^{59}Co nuclear quadrupole resonance indicated such an increase in d_π–d_π Co–Sn interactions with increasing value of n (31). In complexes of tungsten the non-local diamagnetic contribution of two third-row transition metal nuclei and the lower extent (or absence) of d_π–d_π interactions (higher $\overline{\Delta E}$, lower σ_p) may be responsible for the high field resonances observed. A similar dependence of ^{119}Sn chemical shifts on multiple substitution has been observed in manganese and rhenium complexes (1). This is graphically shown in Fig. 2.

In Table 1 we reported the values of ^1J(W–Pb) coupling constants. These values increase with the increasing field of ^{207}Pb resonances in dimetallic complexes $Cp(CO)_3WPbR_3$, which agrees with the assumption that the coupling constants are primarily dominated by the Fermi contact term (32):

$$[7]\quad {}^1K(M^a\text{–}M^b) = \text{const.}\ \overline{\Delta E}\,\psi^2_{M^a}(0)\,\psi^2_{M^b}(0)\,\alpha^2_{M^a}\alpha^2_{M^b}$$

This term is related to the paramagnetic contribution σ_p to the overall shielding because its magnitude depends on the mean electron excitation energy ($\overline{\Delta E}$). Other parameters influencing this term are the valence-electron density (ψ^2) and the s character of the hybridized orbital of bonded nuclei. This correlation (higher δ ^{207}Pb, higher ^1J(W–Pb)) is less clear for trimetallic complexes $[Cp(CO)_3W]_2PbR_2$. Here the relation is verified by δ and J values for both complexes, R = Et and Ph (Table 1). However, for a given R, the W–Pb coupling constant is greater in the trimetallic complex $[Cp(CO)_3W]_2PbEt_2$ than in the dimetallic one $Cp(CO)_3WPbEt_3$, as expected from the δ ^{207}Pb values, but the tendency is inverted in the case of phenyl derivatives (higher δ, lower J).

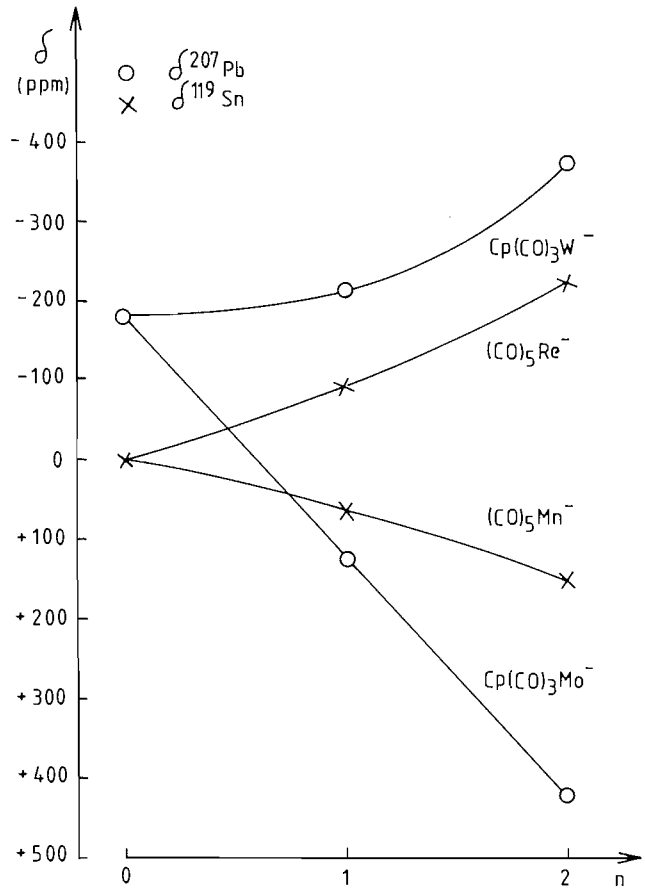

FIG. 2. δ (^{207}Pb) in $[Cp(CO)_3M]_nPbPh_{4-n}$ (ref. $PbMe_4$) and δ (^{119}Sn) in $[(CO)_5M]_nSnMe_{4-n}$ as a function of n.

^{95}Mo chemical shifts

Chemical shift values of ^{95}Mo (Table 1) lie well within the region observed for other compounds with molybdenum – heavy metal bonds: −1795 to −1939 ppm for $Cp(CO)_3MoHgX$(3) and −2072 ppm for $Cp(CO)_3MoSnMe_3$ (33). It is of interest to note that the ^{95}Mo resonances in the Mo–Pb complexes studied here are observed at lower fields than in the corresponding Mo–Sn derivatives (δ ^{95}Mo in [Mo] − $PbMe_3$ = −1989 ppm). The same trends have been observed for the chemical shifts of other transition metals, e.g. ^{55}Mn(8), ^{93}Nb(9), and ^{51}V(10), which were found at lower fields for M^a–PbR_3 than for M^a–SnR_3 compounds. However, one would expect that the shielding of transition metals bonded to lead should be higher than in the analogous tin complexes because of the influence of the $\sigma_d^{non\text{-}loc}$ (eq. [6]) term and the presence of the 4*f* level in the lead atom[2] (*vide supra*, discussion of the ^{207}Pb shielding). However, the lead is not a transition metal, so the lanthanide contraction does not operate effectively therein. It is evidenced by, for example, the ionic radii, Sn(IV) 0.69 and Pb(IV) 0.78 Å (34). Thus the diamagnetic contribution and especially the *Z* dependence become less efficacious as a consequence of longer M^a–Pb bonds, as compared with the M^a–Sn bonds. In this light, the higher shielding of ^{207}Pb nuclei in the tungsten than in the molybdenum compounds may be understood, because the W—Pb and Mo—Pb bond lengths are roughly the same in the structurally analogous complexes.

The above discussion indicates clearly that the non-local diamagnetic contribution (terminology of eq. [6]) to the overall shielding of transition metals bonded to tin and lead is overlapped by the paramagnetic term. With the statement that σ_p determines the overall shielding of ^{95}Mo, one can further ask which is the most important component of this contribution (eq. [3]). In the paramagnetic term, there are two main effects governing its value; (*i*) influences via ΔE, i.e., increase in σ_p and decrease in σ with decreasing ligand strength, and (*ii*) influences via $\langle r^{-3} \rangle Q$ factor that represents nephelauxetic and covalency effects and should give rise to a decrease in σ_p and an increase in σ as the polarizability of the ligating function increases and its electronegativity decreases. Because the ligand strength decreases and the polarizability increases down to a given group of the periodic table, it appears that ΔE is the most important factor determining the shieldings when the group 14 (lead and tin) atoms are present as ligands.

Inspection of Table 1 shows that in the bimetallic complexes $Cp(CO)_3MoPbR_3$, shielding of the lead nuclei is accompanied by deshielding of the molybdenum nuclei. A similar trend has been observed in complexes with a molybdenum–mercury bond (3) and one can suppose that the chemical shifts of ^{95}Mo and ^{207}Pb together reflect the polarization of electron density over the Mo—Pb bonds. Thus it seems that no d_π–d_π interaction is necessary to explain the trends of the shielding in dimetallic complexes. However, in the trimetallic complex $[Cp(CO)_3Mo]_2PbPh_2$, both ^{95}Mo and ^{207}Pb resonances are observed at lower fields than in the dimetallic $Cp(CO)_3MoPbPh_3$. In this case, the presence of d_π–d_π interactions, leading to a decrease of ΔE in eq. [2], as well as an involved electron imbalance increase the σ_p term and decrease the overall shielding σ.

As a final remark, we note that during the recording of the ^{207}Pb resonances for $Cp(CO)_3MoPbEt_3$ and $Cp(CO)_3WPbEt_3$ low intensity secondary peaks appeared on the spectra. In the case of the molybdenum complex a ghost peak centered at +73 ppm was identified as $PbEt_4$, resulting from degradation of the starting product. The extra peak detected for the tungsten compound was centered at −140 ppm with ^1J(W–Pb) equal to 135 Hz. A reasonable explanation of its appearance is the transformation of the parent dimetallic complex into the trimetallic one. Such a thermal transformation has been observed for Pannell and Kapoor (14).

A simple and direct method of cyclization for the synthesis of 10-membered rings

PIERRE DESLONGCHAMPS, SERGE LAMOTHE,[1] AND HO-SHEN LIN

Laboratoire de synthèse organique, Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received December 4, 1986

PIERRE DESLONGCHAMPS, SERGE LAMOTHE, and HO-SHEN LIN. Can. J. Chem. **65**, 1298 (1987).

Ten-membered rings containing two unsaturations are produced without the use of high dilution techniques by the intramolecular malonate anion displacement of an allylic chloride.

PIERRE DESLONGCHAMPS, SERGE LAMOTHE et HO-SHEN LIN. Can. J. Chem. **65**, 1298 (1987).

La synthèse de cycles à 10 membres contenant deux insaturations est réalisée sans utiliser les techniques de haute dilution par déplacement intramoléculaire d'un chlorure allylique par l'anion malonate.

[Traduit par la revue]

The last decade has seen organic chemists gain interest in the synthesis of medium and large rings (1–8). The growing activity in this area was triggered by the sophistication of already existing techniques along with discovery of new ones for structure determination of organic molecules. Many naturally occurring compounds contain medium and large rings but few reliable methods for the preparation of such systems by direct cyclization involving carbon–carbon bond formation are known to this day (1–8). Moreover, most published methods require the use of high dilution techniques (either high dilution or slow additions of the substrate) to avoid polymerization. The 10-membered ring is known to be one of the most difficult rings to prepare; it combines strong enthalpy effects (Baeyer, Pitzer, and transannular strains) with a disfavorable entropy effect that keeps terminal carbon atoms from approaching within reacting distance (9).

An efficient way to overcome the problems associated with medium ring closure is to replace sp^3 carbon atoms in the chain by sp^2 or *sp* carbons. This has the effect of lowering the number of degrees of freedom of the molecule, thereby statistically favoring encounters between the ends of the chain (10). Moreover, the proper disposition of those unsaturated carbon atoms can substantially reduce transannular interactions.

With this in mind, we chose to prepare precursors **1***a* in all possible combinations (A–A, C–A, T–A, T–C, T–T, C–C) (Scheme 1) in order to obtain monomers **2***a* and cyclic dimers **3***a* (C = *cis* olefin, T = *trans* olefin, and A = acetylene).

The preparation of the different precursors **1***a* is described in Scheme 2. We chose commercial diol **4** as our starting material since it could readily be converted into all precursors but one **1***a*. Mono protection (11) followed by formation of the allylic chloride using Meyers's procedure (12) afforded olefin **6**. Three sequential alkylations were then carried out starting with dimethyl malonate to give **7**, which was coupled with 1,4-dichloro-2-butyne. The resulting chloride **8** was reacted with another equivalent of dimethyl malonate affording tetraester **9**. Simple deprotection (13) and chlorination of the resulting allylic alcohol **10** afforded precursor **1***a* [C–A].

Alkylation of **6** with tetraester **11** (obtained in 2 steps from 1,4-dibromo-2-butyne) afforded precursor **1***a* [C–C] after the usual deprotection and chlorination sequence.

For the *trans* series we needed to prepare chloride **16**, which was easily obtained by reduction and chlorination (14) of the known aldehyde **14** (previously prepared by Corey and Suggs (15)). Again, coupling with tetraester **11** gave **17**, which was readily transformed into precursor **1***a* [T–C] through alcohol **18**.

Introduction of a malonate moiety on chloride **16** gave **19**, which could be alkylated by either *trans*-1,4-dichloro-2-butene, affording precursor **1***a* [T–T], by the usual sequence or by 1,4-dichloro-2-butyne to give **23**, which was then converted to precursor **1***a* [T–A].

The last possible precursor was the one containing two triple bonds. 2-Butyne-1,4-diol was chosen as the starting material and afforded, after monochlorination (16) and alcohol protection, acetylene **28**. Three subsequent alkylations transformed **28** into tetraester **31**, which was readily converted to precursor **1***a* [A–A].[2]

The cyclization runs were carried out in a mixture of *N*,*N*-dimethylformamide and tetrahydrofuran with excess potassium carbonate at either 2×10^{-2} or 2×10^{-3} molar concentrations and without the use of high dilution techniques. The results are listed in Table 1. Monomer yields vary from 10 to 84% depending on the nature and geometry of the unsaturations, and the effect of concentration is important in most cases. Interestingly, yields as high as 42% were observed in the formation of cyclic dimers, showing that 20-membered ring cyclization is an important secondary process that can be even more important than polymerization, in some cases.

Molecular model examination of the cyclization process shows that one of the carbomethoxy groups in the middle of the chain must take an orientation (e.g. pseudo-axial in the case of [A–A]) generating unfavorable steric interactions that could be stronger than the favorable *gem*-dimethyl effect (17).[3] This could be demonstrated by comparing cyclization results for decarbomethoxylated precursors **1***b* (Scheme 1) with those obtained for tetraesters **1***a*.

The preparation of precursors **1***b* is detailed in Scheme 3. The previously prepared malonate **29** was alkylated with chloride **33** affording **34**, which after selective deprotection was decarbomethoxylated using Krapcho's procedure (18) at a relatively low temperature. The resulting propargylic alcohol **36** was readily converted to **1***b* [A–A] following the usual sequence.

Decarbomethoxylation prior to alkylation of malonate **7** provided a shorter route to precursors **1***b*. 1,4-Dibromo-2-

[1]NSERCC and FCAR predoctoral fellowships, 1983–1987.

[2]For preparation of a similar compound see ref. 7.

[3]Although the *gem*-dimethyl effect is known (17) to be small in saturated 10-membered ring formation, we believed that it could be stronger in the case of unsaturated substrates because of a larger degree of conformational restriction.

SCHEME 1

butyne was used to alkylate monoester **40** affording bromide **41**, which was converted in 3 steps to precursor **1***b* [C–A].

The same sequence using *trans* malonate **19** afforded *trans*-acetylene precursor **1***b* [T–A]. Alkylation of monoester **44** with *trans*-1,4-dibromo-2-butene afforded allylic bromide **50**, which was readily transformed into precursor **1***b* [T–T]. Finally, partial hydrogenation of intermediate **46** with Lindlar catalyst provided direct access to precursor **1***b* [T–C].

Triesters **1***b* were submitted to the same reaction conditions as tetraesters **1***a* (Table 2). The results clearly indicate that within experimental error most cyclization processes are not influenced by the removal of one carbomethoxy group. Two isolated cases (entries 2 and 10) give respectively much more monomer and dimer than the corresponding tetraesters but we found no consistent explanation to rationalize these facts. However, detailed molecular model studies could perhaps provide an explanation.

The 10-membered ring is one of the most difficult to synthesize by way of direct cyclization (9, 17). The above results show that suitably functionalized precursors can provide respectable yields of cyclic monomers even without the use of high dilution techniques. It has already been proven in our laboratory that this method can be extended to the preparation of large rings (1*a*,*b*). Progress is now being made in the synthesis of polycyclic molecules from macrocyclic precursors available by the above cyclization method.

**Cis–trans* mixture.

Experimental

All reactions were carried out under an argon atmosphere. The infrared spectra (ir) were taken on a Perkin–Elmer 681 spectrophotometer. Proton nmr spectra were recorded on a Varian EM-360, Bruker WP-60, Bruker WP-80 SY, or Bruker WP-250 instrument. Carbon nmr spectra were recorded on a Bruker WP-80SY instrument. Mass spectral assays (ms *m*/*e*) and peak matching were obtained using a VG Micromass ZAB-1F spectrometer. Chromatographic separations were made using Merck Kieselgel 60 (230–400 mesh ASTM). Chemical shifts are reported in δ values relative to tetramethylsilane. Abbreviations used are m: multiplet, s: singlet, t: triplet, d: doublet, dt: double triplets, app: apparent, br: broad, qc: quaternary carbon. No attempts were made to optimize the yields of most reactions.

Mono-protected diol **5**

To an ice-cooled solution of diol **4** (9.9 g; 114 mmol) and dihydropyran (9.6 g, 114 mmol) in 100 mL of methylene chloride and 250 mL of tetrahydrofuran was added *p*-toluenesulfonic acid (1.5 g) with vigorous stirring. After 90 min the mixture was allowed to warm up to room temperature and stirred an additional 90 min. Aqueous sodium bicarbonate (50 mL) was added to the mixture, and the water layer was separated and extracted with ether (2 × 75 mL). The combined organic layers were dried over sodium sulfate, filtered, and concentrated to give an oily residue that was purified by column chromatography (3% acetone in dichloromethane) to afford mono-protected diol **5** (10.4 g, 53%); ir (neat): 3400, 2945, 1120, 1030 cm^{-1}; nmr ($CDCl_3$) δ: 6.20–5.50 (2H, m, —CH=CH—), 4.90–4.60 (1H, m, O—CH—O), 4.60–3.30 (6H, m, —CH_2—CH_2—O and =C—CH_2—O), 2.75 (1H, s, -OH), 2.10–1.10 (6H, m, —$(CH_2)_3$—CH_2O); ms *m*/*e* (CI, CH_4): 173 (M^+ + 1).

Chloride **6** (Procedure A)

A stirred mixture of alcohol **5** (6.88 g, 40 mmol), *syn*-collidine (5.33 g, 44 mmol), and lithium chloride (1.70 g, 40 mmol) was dissolved in 60 mL of *N*,*N*-dimethylformamide. On cooling to 0°C, a suspension was formed, which was treated dropwise with methanesulfonyl chloride (3.41 mL, 44 mmol). Stirring was continued at 0°C for 15 min, then at room temperature for 1 h. The yellow reaction mixture was poured over ice-water (300 mL) and extracted with

SCHEME 3

ether–*n*-hexane (1:1, 2 × 300 mL). The combined extracts were washed successively with saturated aqueous copper nitrate solution to remove excess collidine, then with brine, and finally dried over sodium sulfate. Concentration followed by vacuum distillation (105–108°C/1 Torr; 1 Torr = 133.3 Pa) afforded chloride **6** (6.35 g, 83%) as a colorless oil; ir (neat): 2940, 1134, 1120, 1070, and 1030 cm^{-1}; nmr ($CDCl_3$) δ: 6.30–5.70 (2H, m, —CH=CH—), 5.10–4.65 (1H, m, O—CH—O), 4.65–3.30 (6H, m, CH_2—CH_2—O, =C—CH_2O, and =C—CH_2—Cl), 2.20–1.20 (6H, m, —$(CH_2)_3$—CH_2O); ms *m/e* (CI, CH_4): 191 (M^+(^{35}Cl) + 1), 193 (M^+(^{37}Cl) + 1), relative intensity 3:1.

Malonate 7 (Procedure B)

To a stirred solution of chloride **6** (3.36 g, 17.7 mmol) and dimethylmalonate (11.7 g, 88.2 mmol) in 60 mL of a 1:1 mixture of *N,N*-dimethylformamide and tetrahydrofuran was added dry potassium carbonate (12.2 g, 88.2 mmol). The resulting mixture was heated to reflux (oil bath temperature ≈90°C) for 13 h. The cooled reaction mixture was filtered through a short pad of Celite and the filtrate was concentrated at room temperature to ≈2 mL of volume. The residue was dissolved in 50 mL of dichloromethane, washed with water, and dried over sodium sulfate, giving, after concentration, a crude oil that was purified by column chromatography (2% acetone in dichloromethane) to afford malonate **7** (4.51 g, 89%); ir (neat): 2955, 1757, 1740, 1275–1120, 1028 cm^{-1}; nmr ($CDCl_3$) δ: 5.99–5.15 (2H, m, —CH=CH—), 4.40–4.80 (1H, m, —OCHO—), 4.17 (2H, app t, *J* = 4.5 Hz, =C—CH_2—O), 3.71 (6H, s, -CO_2Me), 4.02–3.24 (3H, m, -CH($CO_2Me)_2$ and CH_2—CH_2—O), 2.68 (2H, app t, *J* = 7.2 Hz, —CH_2—C($CO_2Me)_2$), 1.95–1.26 (6H, m, —$(CH_2)_3$—CH_2O); ms *m/e* (70 eV): 286 (M^+).

Chloride 8

Using procedure B, malonate **7** (2.86 g, 10 mmol) afforded, after column chromatography (1% acetone in dichloromethane), chloride **8** (2.05 g, 70%, based on 22% starting material recovered); ir (neat): 2955, 1740, 1440, 1210, 1028 cm^{-1}; nmr ($CDCl_3$) δ: 6.06–4.91 (2H,

m, —CH=CH—), 4.73–4.44 (1H, m, O—CH—O), 4.09 (2H, t, J = 2.3 Hz, —CH_2—Cl), 3.74 (6H, s, -CO_2Me), 4.44–3.31 (4H, m, CH_2—CH_2—O and =C—CH_2—O), 2.84 (2H, t, J = 2.3 Hz, ≡C—CH_2—), 2.97–2.59 (2H, m, =C—CH_2—C), 2.08–1.19 (6H, m, —$(CH_2)_3$—CH_2O); ms m/e (CI, CH_4): 373 (M^+(^{35}Cl) + 1), 375 (M^+)^{37}Cl) + 1), ratio 3:1.

Tetraester ***9***

Using procedure B, chloride **8** (1.94 g, 5.2 mmol) afforded, after column chromatography (2% acetone in dichloromethane), tetraester **9** (2.08 g, 85%); ir (neat): 2950, 1760–1730, 1440, 1205, 1028 cm^{-1}; nmr ($CDCl_3$) δ: 6.07–5.04 (2H, m, —CH=CH—), 4.75–4.45 (1H, m, O—CH—O), 4.21 (2H, app dt, J = 4.0 and 1.1 Hz, =C—CH_2—O), 3.76 (6H, s, $R_2C(CO_2Me)_2$), 3.72 (6H, s, -$CH(CO_2Me)_2$), 3.53 (1H, t, J = 7.0 Hz, -$CH(CO_2Me)_2$), 4.04–3.24 (2H, m, =C—CH_2—O), 3.04–2.48 (6H, m, =C—CH_2— and —CH_2—C≡C—CH_2—), 1.99–1.17 (6H, m, —$(CH_2)_3$—CH_2O); ms m/e (70 eV): 468 (M^+).

Alcohol ***10*** (Procedure C)

To a stirred solution of tetraester **9** (1.90 g, 4.1 mmol) in 75 mL of methanol was added pyridinium tosylate (102 mg, 0.41 mmol). The resulting mixture was stirred at room temperature for 24 h and then concentrated. The residue was subjected to column chromatography (2–10% acetone in dichloromethane) to afford alcohol **10** (1.43 g, 91%); ir (neat): 3500, 2960, 1760–1730, 1440, 1210, 1025 cm^{-1}; nmr ($CDCl_3$) δ: 6.18–4.91 (2H, m, —CH=CH—), 4.21 (2H, t, J = 6.0 Hz, —CH_2—OH), 3.77 (6H, s, $R_2C(CO_2Me)_2$), 3.73 (6H, s, -$CH(CO_2Me)_2$), 3.54 (1H, t, J = 7.0 Hz, -$CH(CO_2Me)_2$), 3.07–2.60 (6H, m, =C—CH_2—C and —CH_2—C≡$CH(CO_2Me)_2$), 1.82 (1H, t, J = 6.0 Hz, -OH); ms m/e (20 eV): 385 (M^+ + 1), 384 (M^+), 383 (M^+ − 1).

Precursor ***1****a* [C–A]

Following procedure A, alcohol **10** (1.40 g, 3.6 mmol) gave, after column chromatography (1% acetone in dichloromethane), pure chloride ***1a*** [C–A] (1.39 g, 95%); ir (neat): 2955, 1763–1730, 1440, 755 cm^{-1}; nmr ($CDCl_3$) δ: 6.05–5.10 (2H, m, —CH=CH—), 4.12 (2H, d, J = 7.4 Hz, —CH_2—Cl), 3.76 (6H, s, $R_2C(CO_2Me)_2$), 3.73 (6H, s, -$CH(CO_2Me)_2$), 3.52 (1H, t, J = 6.9 Hz, -$CH(CO_2Me)_2$), 2.95–2.34 (6H, m, =C—CH_2—C and —CH_2—C≡C—CH_2—); ms m/e (CI, CH_4): 403 (M^+(^{35}Cl) + 1), 405 (M^+(^{37}Cl) + 1) ratio 3:1.

Tetraester ***11***

1,1,6,6-Tetracarbomethoxy-3-hexyne, prepared following Johnson's method (16*a*) (2.75 g, 8.8 mmol), was dissolved in 20 mL of benzene. Quinoline (0.2 mL) and 5% Pd/$BaSO_4$ (550 mg) were added and the reaction mixture was stirred under hydrogen atmosphere until about 200 mL of hydrogen had been consumed. The reaction mixture was filtered on a short pad of Celite and concentrated to give tetraester **11** (2.75 g, 99%); ir (neat): 2955, 1750, 1730, 1440, 1240, 1160, 1030 cm^{-1}; nmr ($CDCl_3$) δ: 5.80–5.20 (2H, m, —CH=CH—), 3.80 (12H, s, -CO_2Me), 3.45 (2H, t, J = 7.5 Hz, -$CH(CO_2Me)_2$), 3.10–2.35 (4H, m, —CH_2—); ms m/e (70 eV): 316 (M^+).

Tetraester ***12*** (Procedure D)

To a stirred solution of sodium *tert*-amylate (5.0 mg, 5.4 mmol) in 5 mL of benzene was added tetraester **11** (1.27 g, 4.0 mmol) in 10 mL of benzene, followed by chloride **6** (768 mg, 4.0 mmol) in 10 mL of benzene. The resulting mixture was heated to reflux for 4.5 h. On cooling down, 20 mL of ether and 10 mL of a saturated aqueous NH_4Cl solution were poured into the reaction mixture. The organic layer was washed with brine, dried over sodium sulfate, and evaporated to give an oily residue that was purified by column chromatography (1% acetone in dichloromethane) to give tetraester **12** (588 mg, 31%); ir (neat): 2950, 1750, 1740, 1730, 1440, 1290–1120, 1030 cm^{-1}; nmr ($CDCl_3$) δ: 6.10–5.00 (4H, m, —CH=CH—), 4.84–4.54 (1H, m, O—CH—O), 3.80 (12H, s, -CO_2Me), 4.40–3.14 (5H, m, CH_2—CH_2—O, =C—CH_2—O, and -$CH(CO_2Me)_2$), 3.14–2.27 (6H, m, =C—CH_2—C), 2.07–1.10 (6H, m, —$(CH_2)_3$—CH_2O); ms m/e (CI, CH_4): 470 (M^+ + 1).

Alcohol ***13***

Following procedure C, tetraester **12** (550 mg, 1.2 mmol) gave, after column chromatography, alcohol **13** (433 mg, 96%); ir (neat): 3540, 1735, 1440, 1290–1208–1160 cm^{-1}; nmr ($CDCl_3$) δ: 6.10–4.90 (4H, m, —CH=CH—), 4.20 (2H, d, J = 6.0 Hz, —CH_2—OH), 3.80 (12H, s, -CO_2Me), 3.45 (1H, t, J = 7.0 Hz, -$CH(CO_2Me)_2$), 2.90–2.20 (7H, m, =C—CH_2—C and -OH); ms m/e (70 eV): 386 (M^+).

Precursor ***1****a* [C–C]

Following procedure A, alcohol **13** (386 mg, 1.0 mmol) afforded, after column chromatography (2% acetone in dichloromethane), pure ***1a*** [C–C] (403 mg, 100%); ir (neat): 2950, 1760–1720, 1440, 1300–1150, 750 cm^{-1}; nmr ($CDCl_3$) δ: 6.20–5.20 (4H, m, —CH=CH—), 4.20 (2H, d, J = 7.0 Hz, —CH_2—Cl), 3.82 (12H, s, -CO_2Me), 3.50 (1H, t, J = 7.5 Hz, -$CH(CO_2Me)_2$), 3.03–2.45 (6H, m, =C—CH_2—C); ms m/e (CI, CH_4): 405 (M^+(^{35}Cl) + 1), 407 (M^+(^{37}Cl) + 1), ratio 3:1.

Alcohol ***15***

Aldehyde **14** (1.1 g, 6.5 mmol), prepared according to Corey's procedure (15), was dissolved in 15 mL of methylene chloride at −78°C. DIBAH (7.1 mmol, 1 *M* in cyclohexane) was added dropwise and the mixture was stirred for 40 min after which it was quenched with 5 mL of aqueous saturated NH_4Cl solution, allowed to warm up to room temperature, and stirred for 40 min. After diluting with 50 mL of ether, the mixture was filtered through Celite and the water layer was extracted with ether (2 × 20 mL). The combined organic layers were washed with brine, dried over sodium sulfate, and concentrated to give an oily residue that was passed through a short column of silica gel (10% acetone in dichloromethane) to afford alcohol **15** (994 mg, 89%); ir (neat): 3610, 3440, 3010, 2950, 2870, 1020 cm^{-1}; nmr ($CDCl_3$) δ: 6.1–5.6 (2H, m, —CH=CH—), 5.0–3.0 (7H, m, CH_2—CH_2—O, —CH_2—OH, —CH_2—OTHP, and —OCHO—), 2.55 (1H, s, -OH), 2.70–0.70 (6H, m, —$(CH_2)_3$—CH_2O).

Chloride ***16***

Using procedure A, alcohol **15** (1.79 g, 10.4 mmol) gave, after column chromatography (1% acetone in dichloromethane), chloride **16** (1.98 g, 100%); ir (neat): 2940, 1135, 1125, 1078, 1040, 1025, 965 cm^{-1}; nmr ($CDCl_3$) δ: 6.40–5.60 (2H, m, —CH=CH—), 4.95–4.60 (1H, m, O—CH—O), 4.60–3.30 (6H, m, CH_2—CH_2—O, =C—CH_2—O, and —CH_2—Cl), 2.45–0.80 (6H, m, —$(CH_2)_3$—CH_2O); ms m/e (CI, CH_4): 191 (M^+(^{35}Cl) + 1), 193 (M^+(^{37}Cl) + 1), ratio 3:1.

Tetraester ***17***

Following procedure D, tetraester **11** (2.25 g, 7.1 mmol) and chloride **16** (686 mg, 3.6 mmol) afforded, after column chromatography (2% acetone in dichloromethane), tetraester **17** (638 mg, 38%); ir (neat): 2950, 1740, 1440, 1290–1205–1120, 1040, 1028 cm^{-1}; nmr ($CDCl_3$) δ: 6.00–5.30 (4H, m, —CH=CH—), 4.95–4.55 (1H, m, O—CH—O), 3.85 (6H, s, $R_2C(CO_2Me)_2$), 3.82 (6H, s, -$CH(CO_2Me)_2$), 3.48 (1H, t, J = 7.0 Hz, -$CH(CO_2Me)_2$), 4.55–3.20 (4H, m, CH_2—CH_2—O and =C—CH_2—O), 3.00–2.45 (6H, m, =C—CH_2—C), 2.05–1.10 (6H, m, —$(CH_2)_3$—CH_2O); ms m/e (CI, CH_4): 471 (M^+ + 1).

Alcohol ***18***

Following procedure C, tetraester **17** (630 mg, 1.3 mmol) gave, after chromatographic separation (10% acetone in dichloromethane), pure alcohol **18** (490 mg, 95%); ir (neat): 3500, 2955, 1735, 1440, 1340, 1280–1210–1180, 975 cm^{-1}; nmr ($CDCl_3$) δ: 6.00–5.28 (4H, m, —(CH=CH—), 4.20 (2H, d, J = 4.0 Hz, —CH_2—OH), 3.83 (12H, s, -CO_2Me), 3.50 (1H, t, J = 7.0 Hz, -$CH(CO_2Me)_2$), 3.10–2.48 (6H, m, =C—CH_2—C), 2.02 (1H, s, -OH); ms m/e (CI, CH_4): 387 (M^+ + 1), 386 (M^+), 385 (M^+ − 1).

Precursor ***1****a* [T–C]

Using procedure A, alcohol **18** (480 mg, 1.2 mmol) afforded, after column chromatography (1% acetone in dichloromethane), pure chloride ***1a*** [T–C] (450 mg, 90%); ir (neat): 2960, 1760–1730, 1440, 1345, 1285–1210–1160, 974 cm^{-1}; nmr ($CDCl_3$) δ: 6.10–5.30 (4H, m, —CH=CH—), 4.13 (2H, d, J = 5.5 Hz, —CH_2—Cl), 3.85 (12H, s, -CO_2Me), 3.52 (1H, t, J = 8.0 Hz, -$CH(CO_2Me)_2$),

3.10–2.38 (6H, m, =C—CH_2—C); ms *m/e* (CI, CH_4): 405 ($M^+(^{35}Cl)$ + 1), 407 ($M^+(^{37}Cl)$ + 1), ratio 3:1.

Malonate ***19***

Using procedure B, chloride **16** (800 mg, 4.2 mmol) and dimethyl malonate (2.77 g, 21.0 mmol) afforded, after column chromatography (2% acetone in dichloromethane), malonate **19** (1.08 g, 90%); ir (neat): 2950, 1755, 1740, 1440, 1155, 1025 cm^{-1}; nmr ($CDCl_3$) δ: 6.00–5.66 (2H, m, —CH=CH—), 4.93–4.56 (1H, m, O—CH—O), 3.83 (6H, s, -CO_2Me), 3.58 (1H, t, *J* = 7.5 Hz, -CH($CO_2Me)_2$), 4.56–3.33 (4H, m, CH_2—CH_2—O and =C—CH_2—O), 2.93–2.53 (2H, m, —CH_2—$C(CO_2Me)_2$), 2.03–1.23 (6H, m, —$(CH_2)_3$—CH_2O): ms *m/e* (CI, CH_4): 287 (M^+ + 1).

Chloride ***20***

Malonate **19** (4.0 g, 14.0 mmol) and *trans*-1,4-dichlorobut-2-ene (98% *trans*, 5.25 g, 42.0 mmol) were treated according to procedure B, yielding, after column chromatography (2% acetone in dichloromethane), chloride **20** (2.50 g, 45%) along with 50% recovered malonate **19**; ir (neat): 2950, 1740, 1732, 1440, 1205, 1025 cm^{-1}; nmr ($CDCl_3$) δ: 6.25–5.35 (4H, m, —CH=CH—), 4.90–4.55 (1H, m, O—CH—O), 3.82 (6H, s, -CO_2Me), 4.55–3.30 (6H, m, CH_2—CH_2—O, —CH_2—Cl, and —CH_2—OTHP), 2.90–2.50 (4H, m, —CH_2—$C(CO_2Me)_2$), 2.00–1.30 (6H, m, —$(CH_2)_3$—CH_2O); ms *m/e* (CI, CH_4): 375 ($M^+(^{35}Cl)$ + 1), 377 ($M^+(^{37}Cl)$ + 1), ratio 3:1.

Alcohol ***22***

Following procedure B, chloride **20** (1.80 g, 4.8 mmol) and dimethyl malonate (2.64 g, 20.0 mmol) gave, after work-up, crude malonate **21** (2.1 g), which was treated according to procedure C to afford, after column chromatography (5–20% acetone in dichloromethane), alcohol **22** (1.5 g, 81% overall); ir (neat): 3500, 2955, 1755–1725, 1440, 1280–1160, 975 cm^{-1}; nmr ($CDCl_3$) δ: 5.82–5.27 (4H, m, —CH=CH—), 4.07 (2H, t, *J* = 4.7 Hz, —CH_2—OH), 3.74 (6H, s, $R_2C(CO_2Me)_2$), 3.71 (6H, s, -CH($CO_2Me)_2$), 3.40 (1H, t, *J* = 7.2 Hz, -CH($CO_2Me)_2$), 2.80–2.40 (6H, m, =CH_2—C), 1.72–1.16 (1H, br s, -OH); ms *m/e* (70 eV): 386 (M^+).

Precursor ***1***a [T–T]

Following procedure A, alcohol **22** (1.0 g, 2.6 mmol) afforded, after column chromatography (1% acetone in dichloromethane), precursor **1***a* [T–T] (1.0 g, 94%); ir (neat): 2950, 1755–1727, 1438, 1340, 1275–1160, 972 cm^{-1}; nmr ($CDCl_3$) δ: 5.99–5.16 (4H, m, —CH=CH—), 3.98 (2H, app d, *J* = 6.1 Hz, —CH_2—Cl), 3.74 (6H, s, $R_2C(CO_2Me)_2$), 3.72 (6H, s, -CH($CO_2Me)_2$), 3.39 (1H, t, *J* = 7.5 Hz, -CH($CO_2Me)_2$), 3.03–2.21 (6H, m, =C—CH_2—C): ms *m/e* (20 eV): 405 ($M^+(^{35}Cl)$ + 1), 407 ($M^+(^{37}Cl)$ + 1), ratio 3:1.

Chloride ***23***

Using procedure B, malonate **19** (970 mg, 3.4 mmol) and 1,4-dichloro-2-butyne (2.1 g, 17.0 mmol) gave, after column chromatography (2% acetone in dichloromethane), chloride **23** (927 mg, 73%); ir (neat): 1740, 1210, 1200, 1023 cm^{-1}; nmr ($CDCl_3$) δ: 6.00–5.20 (2H, m, —CH=CH—), 4.84–4.45 (1H, m, O—CH—O), 4.09 (2H, t, *J* = 2.3 Hz, —CH_2—Cl), 3.75 (6H, s, -CO_2Me), 4.39–3.41 (4H, m, CH_2—CH_2—O and =C—CH_2—O—), 3.12–2.57 (4H, m, —CH_2—$C(CO_2Me)_2$), 2.20–1.20 (6H, m, —$(CH_2)_3$—CH_2O); ms *m/e* (70 eV): 373 ($M^+(^{35}Cl)$ + 1), 375 ($M^+(^{37}Cl)$ + 1), ratio 3:1.

Malonate ***24***

Chloride **23** (896 mg, 2.4 mmol) was treated according to procedure B, affording, after column chromatography (2% acetone in dichloromethane), malonate **24** (1.1 g, 94%); ir (neat): 2955, 1760–1730, 1438, 1280–1116, 1038, 1032, 1024 cm^{-1}; nmr ($CDCl_3$) δ: 5.94–5.14 (2H, m, —CH=CH—), 4.91–4.41 (1H, m, O—CH—O), 3.99 (2H, t, *J* = 5.2 Hz, —CH_2—Cl), 3.73 (6H, s, $R_2C(CO_2Me)_2$), 3.68 (6H, s, -CH($CO_2Me)_2$), 4.36–3.22 (5H, m, CH_2—CH_2—O, -CH($CO_2Me)_2$), and —CH_2—OTHP), 3.07–2.32 (6H, m, —CH_2—$C(CO_2Me)_2$)—CH_2— and —CH_2—CH), 2.04–0.81 (6H, m, —$(CH_2)_3$—CH_2O); ms *m/e* (70 eV): 468 (M^+).

Alcohol ***25***

Following procedure C, malonate **24** (1.02 g, 2.2 mmol) gave, after column chromatography (5–10% acetone in dichloromethane), alcohol **25** (783 mg, 94%); ir (neat): 3500, 1758–1730, 1440, 1338, 1280–1150 cm^{-1}; nmr ($CDCl_3$) δ: 6.03–5.18 (2H, m, —CH=CH—), 4.34–3.92 (2H, m, —CH_2—OH), 3.76 (6H, s, $R_2C(CO_2Me)_2$), 3.71 (6H, s, -CH($CO_2Me)_2$), 3.51 (1H, t, *J* = 7.2 Hz, -CH($CO_2Me)_2$), 2.99–2.41 (6H, m, C—CH_2—C), 2.09–1.39 (1H, br s, -OH); ms *m/e* (70 eV): 384 (M^+).

Precursor ***1***a [T–A]

Treatment of alcohol **25** (780 mg, 2.0 mmol) according to procedure A afforded, after column chromatography (2% acetone in dichloromethane), precursor **1***a* [T–A] (780 mg, 95%); ir (neat): 2960, 1760–1732, 1440, 1343, 1287–1152 cm^{-1}; nmr ($CDCl_3$) δ: 6.04–5.29 (2H, m, —CH=CH—), 3.99 (2H, d, *J* = 5.7 Hz, —CH_2—Cl), 3.77 (6H, s, $R_2C(CO_2Me)_2$), 3.72 (6H, s, -CH($CO_2Me)_2$), 3.53 (1H, t, *J* = 7.3 Hz, -CH($CO_2Me)_2$), 2.88–2.54 (6H, m, C—CH_2—C); ms *m/e* (CI, CH_4): 403 ($M^+(^{35}Cl)$ + 1) and 405 ($M^+(^{37}Cl)$ + 1), ratio 3:1.

Chloride ***28***

Known alcohol **27** (16*b*) (18.3 g, 175 mmol) and dihydropyran (16.2 g, 192 mmol) were dissolved in 400 mL of dichloromethane at 0°C. Trifluoroacetic acid (200 μL) was added to the mixture, which was stirred overnight at room temperature and concentrated to afford chloride **28** (31.6 g, 95%); ir (neat): 2943, 1264, 1120, 1025 cm^{-1}; nmr ($CDCl_3$) δ: 4.77 (1H, br s, O—CH—O), 4.29 (2H, t, *J* = 2.0 Hz, —CH_2—OTHP), 4.17 (2H, t, *J* = 2.0 Hz, —CH_2—Cl), 4.08–3.26 (2H, m, CH_2—CH_2—O), 2.68–0.69 (6H, m, —$(CH_2)_3$—CH_2O); ms *m/e* (70 eV): 187 ($M^+(^{35}Cl)$ − 1) 189 ($M^+(^{37}Cl)$ − 1), ratio 3:1.

Malonate ***29***

Crude chloride **28** (3.05 g, 16.2 mmol) and dimethyl malonate (10.69 g, 81.0 mmol) were treated according to procedure B to afford, after column chromatography (1–2% acetone in dichloromethane), malonate **29** (4.18 g, 91%); ir (neat): 2955, 1757, 1748, 1740, 1440, 1024 cm^{-1}; nmr ($CDCl_3$) δ: 4.71 (1H, br s, O—CH—O), 4.15 (2H, t, *J* = 2.1 Hz, —CH_2—OTHP), 3.71 (6H, s, $(CO_2Me)_2$), 3.92–3.24 (3H, m, -CH($CO_2Me)_2$ and CH_2—CH_2—O), 2.76 (2H, dt, *J* = 7.8 and 2.1 Hz, -CH_2—$CH(CO_2Me)_2$), 1.93–1.29 (6H, m, —$(CH_2)_3$—CH_2O); ms *m/e* (70 eV): 285 (M^+ + 1), 284 (M^+), 283 (M^+ − 1).

Chloride ***30***

Reaction of malonate **29** (3.0 g, 10.6 mmol) and 1,4-dichloro-2-butyne (6.50 g, 52.8 mmol) using procedure B gave, after column chromatography (1% acetone in dichloromethane), chloride **30** (2.33 g, 60%); ir (neat): 2950, 1742, 1435, 1205, 1024 cm^{-1}; nmr ($CDCl_3$) δ: 4.77 (1H, br s, O—CH—O), 4.21 (2H, t, *J* = 2.2 Hz, —CH_2—OTHP), 4.08 (2H, t, *J* = 2.2 Hz, —CH_2—Cl), 3.76 (6H, s, —$(CO_2Me)_2$), 4.04–3.39 (2H, m, CH_2—CH_2—O), 3.22–2.87 (4H, m, —CH_2—$C(CO_2Me)_2$—CH_2—), 2.04–1.27 (6H, m, —$(CH_2)_3$—CH_2O); ms *m/e* (10 eV): 371 ($M^+(^{35}Cl)$ + 1), 373 ($M^+(^{37}Cl)$ + 1), ratio 3:1.

Tetraester ***31***

Following procedure B, chloride **30** (2.10 g, 5.7 mmol) and dimethyl malonate (3.74 g, 28.4 mmol) afforded, after column chromatography (1% acetone in dichloromethane), tetraester **31** (2.45 g, 93%); ir (neat): 2953, 1762, 1733, 1438, 1021 cm^{-1}; nmr ($CDCl_3$) δ: 4.75 (1H, br s, O—CH—O), 4.20 (2H, t, *J* = 2.2 Hz, —CH_2—OTHP), 3.77 (6H, s, $R_2C(CO_2Me)_2$), 3.74 (6H, s, -CH($CO_2Me)_2$), 3.91–3.20 (3H, m, -CH($CO_2Me)_2$ and CH_2—CH_2—O), 3.06–2.53 (6H, m, ≡C—CH_2—C), 1.94–1.19 (6H, m, —$(CH_2)_3$—CH_2O); ms *m/e* (70 eV): 466 (M^+), 465 (M^+ − 1).

Alcohol ***32***

Using procedure C, tetraester **31** (2.36 g, 5.1 mmol) gave, after column chromatography (2–5% acetone in dichloromethane), alcohol **32** (1.83 g, 94%); ir (neat): 3500, 1745, 1440, 1345–1150 cm^{-1}; nmr ($CDCl_3$) δ: 4.20 (2H, dt, *J* = 6.1 and 2.1 Hz, -CH_2—OH), 3.77 and 3.74 (12H, both s, -CO_2Me), 3.53 (1H, t, *J* = 7.5 Hz, -CH($CO_2Me)_2$), 3.10–2.60 (6H, m, ≡C—CH_2—C), 1.92 (1H, t, *J* = 6.1 Hz, -OH); ms *m/e* (70 eV): 382 (M^+), 381 (M^+ − 1).

Precursor ***1***a *[A–A]*

Treatment of alcohol **32** (1.80 g, 4.7 mmol) according to procedure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

A afforded, after column chromatography (1% acetone in dichloromethane), precursor **1***a* [A–A] (1.74 g, 92%); ir (neat): 2960, 1740, 1440, 1210 cm^{-1}; nmr ($CDCl_3$) δ: 4.06 (2H, t, J = 2.2 Hz, —CH_2—Cl), 3.75 and 3.73 (12H, both s, -CO_2Me), 3.51 (1H, t, J = 7.4 Hz, -$CH(CO_2Me)_2$), 3.23–2.44 (6H, m≡C—CH_2—C); ms m/e (70 eV): 401 (M^+(^{35}Cl) + 1) and 403 (M^+(^{37}Cl) + 1), ratio 3:1.

Chloride 33

To a stirred solution of alcohol **27** (16.4 g, 155 mmol) and triethylamine (17.2 g, 170 mmol) in 500 mL of dichloromethane at 0°C was added chloro-*tert*-butyl dimethylsilane (26.3 g, 170 mmol). The mixture was warmed to room temperature and stirred for 24 h. Water (600 mL) and ether (800 mL) were added and, after separation, the water layer was washed with 2 × 600 cm^3 ether. The combined organic layers were dried over sodium sulfate and concentrated to give an oily residue that was subjected to column chromatography (1% acetone in dichloromethane) to afford chloride **33** (23.2 g, 84%); ir ($CHCl_3$): 2960, 2930, 2860, 1260, 1145, 1080, 835 cm^{-1}; nmr ($CDCl_3$) δ: 4.4 and 4.0 (4H, both t, J = 2.0 Hz, —CH_2—), 0.91 (9H, s, *t*-Bu), 0.12 (6H, s, -CH_3).

Alcohol 35

Following procedure B, malonate **29** (18.2 g, 63 mmol) and chloride **33** (13.3 g, 69.7 mmol) gave, after work-up, crude adduct **34**, which was dissolved in tetrahydrofuran (500 mL) at 0°C. To that solution was added tetra-*n*-butylammonium fluoride (60 mmol) and the resulting mixture was stirred at room temperature for 2 h. Evaporation of the solvent gave a crude oil, which was purified by column chromatography (10% acetone in dichloromethane) to afford alcohol **35** (11 g, 58% overall); ir (neat): 3610, 3700–3100, 1740 cm^{-1}; nmr ($CDCl_3$) δ: 4.78 (1H, m, O—CH—O), 4.21 (4H, app t, J = 2 Hz, —CH_2—O), 3.76 (6H, s, -CO_2Me), 3.90–3.25 (2H, m, CH_2—CH_2—O), 3.00 (4H, t, J = 2 Hz, ≡C—CH_2—C), 1.90–1.25 (6H, m, —$(CH_2)_3$—CH_2O).

Chloride 37

A solution containing diester **35** (3.12 g, 8.9 mmol) and sodium cyanide (830 mg, 17.7 mmol) in 100 mL of dimethylsulfoxide was stirred at 100°C for 1.75 h. The cooled reaction mixture was then diluted with 400 mL of water and extracted with a mixture of ether, hexane, and methylene chloride 4:4:1 (4 × 200 cm^3). The combined organic layers were washed with water (2 × 50 cm^3) and dried over sodium sulfate. The residue was purified by column chromatography (10% acetone in dichloromethane) to afford ester **36** (58%), which was treated according to procedure A, giving, after column chromatography (1% acetone in dichloromethane), chloride **37** (1.42 g, 84%); ir (neat): 2950, 1740, 1025 cm^{-1}; nmr ($CDCl_3$) δ: 4.79 (1H, m, O—CH—O), 4.23 (2H, m, —CH_2—OTHP), 4.11 (2H, m, —CH_2—Cl), 3.73 (3H, s, -CO_2Me), 3.80–3.25 (2H, m, CH_2—CH_2—O), 3.00–2.25 (5H, m, —CH_2—$CH(CO_2Me)$—CH_2—), 1.90–1.25 (6H, m, —$(CH_2)_3$—CH_2O).

Alcohol 39

Using procedure B, chloride **37** (1.40 g, 4.5 mmol) and dimethyl malonate (2.96 g, 22.4 mmol) afforded, after work-up, crude malonate **38** (1.75 g), which was treated according to procedure C to give, after column chromatography (4–10% acetone in dichloromethane), alcohol **39** (1.16 g, 82% overall); ir (neat): 3520, 2960, 1735, 1435, 1030 cm^{-1}; nmr ($CDCl_3$) δ: 4.20 (2H, app d, J = 6.0 Hz, —CH_2—OH), 3.78 (6H, s, -$(CO_2Me)_2$), 3.72 (3H, s, -CO_2Me), 3.54 (1H, m, -$CH(CO_2Me)_2$), 2.90–2.25 (7H, m, —CH_2—$CH(CO_2Me)$—CH_2— and —CH_2—$C(CO_2Me)_2$), 1.90 (1H, app t, J = 6.0 Hz, -OH).

*Precursor 1*b [A–A]

Following procedure A, alcohol **39** (524 mg, 1.6 mmol) afforded, after column chromatography (2% acetone in dichloromethane), precursor **1***b* [A–A] (524 mg, 95%); ir (neat): 2960, 1740, 1440, 1030 cm^{-1}; nmr ($CDCl_3$) δ: 4.11 (2H, m, —CH_2—Cl), 3.77 (6H, s, -$(CO_2Me)_2$), 3.72 (3H, s, -$CH(CO_2Me)_2$), 3.55 (1H, t, J = 7.4 Hz, -$CH(CO_2Me)_2$), 2.90–2.50 (7H, m, —CH_2—$CH(CO_2Me)$—CH_2 and —CH_2—$C(CO_2Me)_2$).

Ester 40 (Procedure E)

To a solution containing malonate **7** (5.0 g, 17.5 mmol) in 35 mL of dimethyl sulfoxide was added sodium cyanide (1.7 g, 35 mmol) and water (315 mg, 17.5 mmol). The mixture was then stirred at 140–145°C for 5 h, poured over 500 mL of water, and extracted with ether–hexane (1:1) (3 × 200 mL). The combined organic layers were washed with water (2 × 75 mL) and saturated aqueous bicarbonate solution (1 × 75 mL), and dried over sodium sulfate. Column chromatography purification of the residue (2% acetone in dichloromethane) afforded ester **40** (2.1 g, 53%); ir ($CHCl_3$): 2950, 1740, 1025 cm^{-1}; nmr ($CDCl_3$) δ: 5.60 (2H, m, —CH=CH—), 4.62 (1H, m, O—CH—O), 4.18 (2H, m, —CH_2—OTHP), 3.67 (3H, s, -CO_2Me), 4.00–3.20 (2H, m, CH_2—CH_2—O), 2.40 (4H, m, —CH_2—CH_2—CO_2Me), 1.75–1.00 (6H, m, —$(CH_2)_3$—CH_2O).

Bromide 41 (Procedure F)

To a stirred solution of diisopropylamine (107 mg, 1.1 mmol) in 0.8 mL of tetrahydrofuran at 0°C was added *n*-butyllithium (1.0 mmol). After 30 min, the temperature was lowered to −78°C, ester **40** (200 mg, 0.9 mmol) was added, and the mixture was allowed to react for 20 min after which 1,4-dibromo-2-butyne (373 mg, 1.8 mmol) was added rapidly. The resulting mixture was stirred at −78°C for 1.5 h and quenched with saturated aqueous ammonium chloride. Water was added and the mixture was extracted with ether (3 × 20 mL). The combined organic layers were washed with bicarbonate (10 mL) and water (10 mL), dried over magnesium sulfate, and concentrated to give a crude oil that was subjected to column chromatography (1–2% acetone in dichloromethane) to afford bromide **41** (180 mg, 57%); ir ($CHCl_3$): 3005, 2945, 1735, 1020 cm^{-1}; nmr ($CDCl_3$) δ: 5.9–5.4 (2H, m, —CH=CH—), 4.61 (1H, m, O—CH—O), 3.70 (3H, s, -CO_2Me), 4.30–3.20 (6H, m, —CH_2—OTHP, CH_2—CH_2—O and —CH_2—Br), 2.80–2.30 (5H, m, —CH_2—$CH(CO_2Me)$—CH_2—), 1.60 (6H, m, —$(CH_2)_3$—CH_2O).

Malonate 42

Bromide **41** (1.40 g, 3.9 mmol) and dimethyl malonate (1.90 g, 4.4 mmol) were treated according to procedure B (except for temperature, which was kept at 35°C) affording, after column chromatography (2% acetone in dichloromethane), malonate **42** (1.50 g, 94%); ir ($CHCl_3$): 3020, 2950, 1740, 1440, 1025 cm^{-1}; nmr ($CDCl_3$) δ: 5.90–5.40 (2H, m, —CH=CH—), 4.60 (1H, m, O—CH—O), 3.75 (6H, s, -$(CO_2Me)_2$), 3.69 (3H, s, CO_2Me), 4.30–3.35 (5H, m, —CH_2—OTHP, CH_2—CH_2—O, and -$CH(CO_2Me)_2$), 2.90–2.25 (7H, m, —CH_2—$CH(CO_2Me)$—CH_2— and —CH_2—$C(CO_2Me)_2$), 1.60 (6H, m, —$(CH_2)_3$—CH_2O).

Alcohol 43

Using procedure C, malonate **42** (1.50 g, 3.7 mmol) afforded, after column chromatography (4–10% acetone in dichloromethane), alcohol **43** (1.03 g, 87%); ir ($CHCl_3$): 3620, 3530, 3020, 2960, 1735 cm^{-1}; nmr ($CDCl_3$) δ: 6.00–5.30 (2H, m, —CH=CH—), 4.30–4.00 (2H, m, —CH_2—OH), 3.75 (6H, s, -$(CO_2Me)_2$), 3.68 (3H, s, -CO_2Me), 3.54 (1H, app t, J = 7 Hz, -$CH(CO_2Me)_2$), 2.90–2.20 (7H, m, —CH_2—$CH(CO_2Me)$—CH_2— and —CH_2—$C(CO_2Me)_2$), 1.90–1.60 (1H, m, -OH).

*Precursor 1*b [C–A]

Following procedure A, alcohol **43** (1.0 g, 3.1 mmol) afforded, after column chromatography (1% acetone in dichloromethane), chloride **1***b* [C–A] (956 mg, 90%); ir ($CHCl_3$): 3030, 2960, 1740, 1440 cm^{-1}; nmr ($CDCl_3$) δ: 5.80–5.40 (2H, m, —CH=CH—), 4.10 (2H, m, —CH_2—Cl), 3.75 (6H, s, -$(CO_2Me)_2$), 3.68 (3H, s, -CO_2Me), 3.54 (1H, t, J = 7.7 Hz, -$CH(CO_2Me)_2$), 2.74 (2H, dt, J = 7.7 and 2.3 Hz, ≡C—CH_2—$C(CO_2Me)_2$), 2.65–2.30 (5H, m, —CH_2—$CH(CO_2Me)$—CH_2—).

Ester 44

Malonate **19** (12 g, 42 mmol) was treated according to procedure E to afford ester **44** (4.6 g, 48%); ir (neat): 2940, 1740, 1025 cm^{-1}; nmr ($CDCl_3$) δ: 5.90–5.50 (2H, m, —CH=CH—), 4.60 (1H, m, O—CH—O), 3.66 (3H, s, -CO_2Me), 4.30–3.20 (4H, m,

For personal use only.

—CH_2—OTHP and CH_2—CH_2—O), 2.40 (4H, br s, —CH_2—CH_2—CO_2Me), 1.60 (6H, m, —$(CH_2)_3$—CH_2O).

Bromide ***45***

Following procedure F, ester **44** (2.0 g, 8.8 mmol) and 1,4-dibromo-2-butyne (3.7 g, 17.5 mmol) gave, after column chromatography (1% acetone in dichloromethane), bromide **45** (2.7 g, 86%) as a diastereoisomeric mixture; ir ($CHCl_3$): 3000, 2950, 1735 cm^{-1}; nmr ($CDCl_3$) δ: 5.64 (2H, m, —CH=CH—), 4.60 (1H, m, O—CH—O), 3.69 (3H, s, -CO_2Me), 4.35–3.30 (6H, m, —CH_2—OTHP, CH_2—CH_2—O, and -CH_2Br), 2.80–2.20 (5H, m, —CH_2—$CH(CO_2Me)$—CH_2—), 1.60 (6H, m, —$(CH_2)_3$—CH_2O).

Malonate ***46***

Treatment of bromide **45** (2.30 g, 6.5 mmol) and dimethyl malonate (2.90 g, 22.3 mmol) according to procedure B afforded, after column chromatography (2% acetone in dichloromethane), malonate **46** (2.30 g, 88%) as a diastereoisomeric mixture; ir (neat): 2950, 1740 cm^{-1}; nmr ($CDCl_3$) δ: 5.62 (2H, m, -CH=CH-), 4.60 (1H, m, O—CH—O), 3.75 (6H, s, -$(CO_2Me)_2$), 3.68 (3H, s, -CO_2Me), 4.30–3.20 (5H, m, —CH_2—OTHP, CH_2—CH_2—O, and -$CH(CO_2Me)_2$), 2.90–2.10 (7H, m, —CH_2—$CH(CO_2Me)$—CH_2— and —CH_2—$C(CO_2Me)_2$), 1.62 (6H, m, —$(CH_2)_3$—CH_2O).

Alcohol ***47***

Following procedure C, malonate **46** (800 mg, 1.9 mmol) afforded, after column chromatography (10% acetone in dichloromethane), alcohol **47** (584 mg, 92%); ir (neat): 3700–3100 (br), 2950, 1740 (br) cm^{-1}; nmr ($CDCl_3$) δ: 5.66 (2H, m, —CH=CH—), 4.06 (2H, m, —CH_2—OH), 3.74 (6H, s, -$(CO_2Me)_2$), 3.68 (3H, s, -CO_2Me), 3.54 (1H, app t, J = 7.5 Hz, -$CH(CO_2Me)_2$), 2.90–2.20 (7H, m, —CH_2—$CH(CO_2Me)$—CH_2— and —CH_2—$C(CO_2Me)_2$, 1.53 (1H, m, -OH).

Precursor ***1****b* [T–A]

Alcohol **47** (600 mg, 1.8 mmol) was treated according to procedure A to give, after column chromatography (25% AcOEt in hexane), chloride ***1b*** [T–A] (587 mg, 92%); ir (neat): 2950, 1740 cm^{-1}; nmr ($CDCl_3$) δ: 5.68 (2H, m, —CH=CH—), 4.00 (2H, m, —CH_2—Cl), 3.75 (6H, s, -$(CO_2Me)_2$), 3.69 (3H, s, -CO_2Me), 3.54 (1H, t, J = 7.7 Hz, -$CH(CO_2Me)_2$), 2.74 (2H, dt, J = 7.7 and 2.3 Hz, —CH_2—$C(CO_2Me)_2$), 2.65–2.25 (5H, m, —CH_2—$CH(CO_2Me)$—CH_2—); ms *m/e* (CI, CH_4): 347 (M^+ + 1). *Exact Mass* calcd.: 347.1261 (M^+ + 1); found: 347.1266 (M^+ + 1).

Alcohol ***49***

To a suspension of Lindlar catalyst (250 mg) in 20 mL of cyclohexane was added acetylene **46** (1.1 g, 2.7 mmol) dissolved in 5 mL of ethyl acetate and 5 mL of cyclohexane. The mixture was mechanically stirred under a hydrogen atmosphere for 5 h at room temperature. The catalyst was filtered off and the solvent evaporated to give an oil that was submitted to the conditions of procedure C to afford, after column chromatography (50% AcOEt in hexane), alcohol **49** (624 mg, 70% overall); ir (neat): 3650–3200 (br), 3000, 2950, 1740 (br) cm^{-1}; nmr ($CDCl_3$) δ: 5.68 (2H, m, —$\overset{H}{C}$=$\underset{H}{C}$—), 5.40 (2H, m, —$\overset{H}{C}$=$\overset{H}{C}$—), 4.10 (2H, m, —CH_2—OH), 3.73 (6H, s, -$(CO_2Me)_2$), 3.67 (3H, s, -CO_2Me), 3.39 (1H, app t, J = 7.5 Hz, -$CH(CO_2Me)_2$), 2.80–2.00 (7H, m, —CH_2—$CH(CO_2Me)$—CH_2— and —CH_2—$C(CO_2Me)_2$), 1.50–1.20 (1H, m, -OH).

Precursor ***1****b* [T–C]

Using procedure A, alcohol **49** (410 mg, 1.2 mmol) gave, after column chromatography (1% acetone in dichloromethane), precursor ***1b*** [T–C] (403 mg, 93%); ir (neat): 3000–2950, 1740 (br) cm^{-1}; nmr ($CDCl_3$) δ: 5.68 (2H, m, —CH=CH—CH_2Cl), 5.40 (2H, m, —CH=CH—CH_2—$C(CO_2Me)_2$), 4.00 (2H, m, —CH_2—Cl), 3.73 (6H, s, -$(CO_2Me)_2$), 3.66 (3H, s, -CO_2Me), 3.39 (1H, t, J = 7.6 Hz, —$CH(CO_2Me)_2$), 2.70–2.20 (7H, m, —CH_2—$CH(CO_2Me)$—CH_2— and —CH_2—$C(CO_2Me)_2$); ms *m/e* (70 eV): 347 (M^+ + 1), 315 (M − OMe), 311 (M − Cl). *Exact Mass* calcd.: 347.1261 (M^+ + 1); found: 347.1253 (M^+ + 1).

Bromide ***50***

Following procedure F, ester **44** (1.1 g, 4.8 mmol) and *trans*-1,4-dibromo-but-2-ene (1.5 g, 7.0 mmol) afforded, after column chromatography (1% acetone in dichloromethane), bromide **50** (1.1 g, 62%) as a diastereoisomeric mixture along with 8% starting material recovered; ir ($CHCl_3$): 3010, 2950, 1735 cm^{-1}; nmr ($CDCl_3$) δ: 5.80–5.50 (4H, m, —CH=CH—), 4.61 (1H, m, O—CH—O), 3.68 (3H, s, -CO_2Me), 4.20–3.30 (6H, m, —CH_2—OTHP, CH_2—CH_2—O, and —CH_2—Br), 2.60–2.10 (5H, m, —CH_2—$CH(CO_2Me)$—CH_2—), 1.63 (6H, m, —$(CH_2)_3$—CH_2O).

Malonate ***51***

Using procedure B, bromide **50** (1.05 g, 2.9 mmol) and dimethyl malonate (1.54 g, 11.7 mmol) afforded, after column chromatography (1–2% acetone in dichloromethane), malonate **51** (1.05 g, 88%) as a diastereoisomeric mixture; ir ($CHCl_3$): 3010, 2950, 1735 (br) cm^{-1}; nmr ($CDCl_3$) δ: 5.63 and 5.43 (4H, both m, —CH=CH—), 4.60 (1H, m, O—CH—O), 4.25–3.35 (4H, m, —CH_2—OTHP and CH_2—CH_2—O—), 3.72 (6H, s, -$(CO_2Me)_2$), 3.64 (3H, s, -CO_2Me), 3.39 (1H, t, J = 7.6 Hz, -$CH(CO_2Me)_2$), 2.57 (2H, app dd, J = 5.4 and 7.6 Hz, =C—CH_2—$C(CO_2Me)_2$), 2.55–2.10 (5H, m, —CH_2—$CH(CO_2Me)$—CH_2—), 1.90–1.45 (6H, m, —$(CH_2)_3$—CH_2O).

Alcohol ***52***

Treatment of malonate **51** (997 mg, 2.4 mmol) according to procedure C gave, after column chromatography (10% acetone in dichloromethane), alcohol **52** (741 mg, 96%); ir ($CHCl_3$): 3620, 3020, 2950, 1730 (br) cm^{-1}; nmr ($CDCl_3$) δ: 5.75–5.35 (4H, m, —CH=CH—), 4.08 (2H, app t, J = 5.2 Hz, =C—CH_2—OH), 3.73 (6H, s, -$(CO_2Me)_2$), 3.66 (3H, s, -CO_2Me), 3.40 (1H, t, J = 7.6 Hz, -$CH(CO_2Me)_2$), 2.58 (2H, m, —CH_2—$C(CO_2Me)_2$), 2.50–2.10 (5H, m, —CH_2—$CH(CO_2Me)$—CH_2—), 1.32 (1H, app t, J = 5 Hz, -OH).

Precursor ***1****b* [T–T]

Following procedure A, alcohol **52** (400 mg, 1.2 mmol) afforded, after column chromatography (1% acetone in dichloromethane), chloride ***1b*** [T–T] (418 mg, 99%); ir ($CHCl_3$): 3020, 2950, 1750–1720 (br) cm^{-1}; nmr ($CDCl_3$) δ: 5.65 and 5.42 (4H, both m, —CH=CH—), 3.99 (2H, m, —CH_2—Cl), 3.72 (6H, s, -$(CO_2Me)_2$), 3.65 (3H, s, -CO_2Me), 3.39 (1H, t, J = 7.5 Hz, -$CH(CO_2Me)_2$), 2.57 (2H, m, —CH_2—$C(CO_2Me)_2$), 2.50–2.10 (5H, m, —CH_2—$CH(CO_2Me)$—CH_2—); ms *m/e* (70 eV): 347 (M^+ + 1(^{35}Cl)), 349 (M^+ + 1(^{37}Cl)), ratio 3:1; ^{13}C nmr ($CDCl_3$) δ: 174.6 and 169.0 (CO_2Me), 131.9, 129.7, 128.3 and 128.1 (—CH=CH—), 52.2, 51.5, 51.2, 44.6, 44.5, 34.1, 33.5, and 31.5.

Monomer ***2****a* [C–C]

To a stirred solution of chloride ***1a*** [C–C] (84 mg, 0.21 mmol) in 5 mL of dry acetone was added dry potassium carbonate (287 mg, 2.1 mmol). The resulting mixture was refluxed with vigorous stirring for 4 days and neutralized with 30 mL of 0.1 *N* HCl solution. Crystalline cyclized product was filtered, washed with 15 mL of a 3:1 water–acetone mixture, and dried under vacuum to afford monomer ***2a*** [C–C] (64 mg, 84%); mp 221.5–222°C; ir ($CHCl_3$): 3030, 3020, 2955, 1735, 1285 cm^{-1}; nmr ($CDCl_3$) δ: 5.33–5.15 (4H, m, —CH=CH—), 3.75 (12H, s, -CO_2Me), 2.86–2.61 and 2.50–2.39 (8H, both m, —CH_2—); ms *m/e* (70 eV): 368 (M^+). *Exact Mass* calcd.: 368.1471; found: 368.1471; ^{13}C nmr ($CDCl_3$) δ: 171.2 (CO_2Me), 127.7 (C=C), 56.7 (qc), 52.7 (O—CH_3), 30.0 (CH_2).

Monomer ***2****a* [C–T] *and dimer* ***3****a* [C–T] (Procedure G)

To a stirred solution of precursor ***1a*** [C–T] (237 mg, 0.58 mmol) in 30 mL of dry DMF–THF (1:1) was added dry potassium carbonate (798 mg, 5.8 mmol). The resulting mixture was heated to reflux (oil bath temperature ≃90°C) for 32 h. The mixture was then filtered through a short pad of Celite at room temperature and the filtrate was concentrated under reduced pressure at room temperature to ≃2 mL of volume. The residue was dissolved in 50 mL of dichloromethane, washed with water, dried, filtered, and concentrated to afford a residue

For personal use only.

that was purified by column chromatography (2% acetone in dichloromethane) yielding monomer **2***a* [C–T] (92.8 mg, 44%; crystallized from hexane–ether); mp 119–121°C; ir ($CHCl_3$): 3030, 2960, 1735, 1440, 1270–1200 (br), 1180 cm^{-1}; nmr ($CDCl_3$) δ: 5.57–5.07 (4H, m, —CH=CH—), 3.76, 3.75, 3.73 and 3.72 (12H, all s, -CO_2Me), 3.15–2.05 (8H, m including app d (3.10), J = 12.0 Hz and app t (2.14), J = 12.0 Hz, —CH_2—); ^{13}C nmr ($CDCl_3$) δ: 172.4, 171.7 and 170.8 (CO_2Me), 132.9, 128.9, 125.0 and 124.1 (C=C), 56.7, 56.9 (qc), 52.7, 52.4 (-OCH_3), 40.1, 36.3, 32.0 and 30.7 (-CH_2-); ms *m/e* (70 eV): 368 (M^+). *Exact Mass* calcd.: 368.1471; found: 368.1471; and dimer **3***a* [C–T] (52.8 mg, 25%) (crystallized from hexane–ether); mp: 155–156°C; ir ($CHCl_3$): 3030, 2960, 1733, 1200, 1180 cm^{-1}; nmr ($CDCl_3$) δ: 5.39–5.18 (8H, m, —CH=CH—), 3.72 (24H, s, -CO_2Me), 2.73–2.48 (16H, m, —CH_2—); ^{13}C nmr ($CDCl_3$) δ: 171.1 (CO_2Me), 128.7 and 126.5 (C=C), 57.1 (qc), 52.5 (-OCH_3), 29.9 and 35.5 (—CH_2—); ms *m/e* (70 eV): 736 (M^+). *Exact Mass* calcd.: 736.2942; found: 736.2929.

Monomer **2**a [C–A] *and dimer* **3**a [C–A]

Following procedure G, chloride **1***a* [C–A] (297 mg, 0.74 mmol) afforded, after column chromatography (2% acetone in dichloromethane), monomer **2***a* [C–A] (162 mg, 60%) (recrystallized from hexane–ether); mp 98.5–99.5°C; ir ($CHCl_3$): 3030, 2960, 1735, 1440, 1285–1220–1182, 1068, 1053 cm^{-1}; nmr ($CDCl_3$) δ: 5.55–5.35 (2H, m, —CH=CH—), 3.73 (12H, s, -CO_2Me), 3.25–2.40 (8H, m, —CH_2—); ^{13}C nmr ($CDCl_3$) δ: 170.7 (CO_2Me), 127.7 (C=C), 79.8 (C≡C), 55.1 (qc), 52.6 (-OCH_3), 31.4 (CH_2—C=), 24.5 (CH_2—C≡); ms *m/e* (CI, CH_4): 367 (M^+ + 1). *Exact Mass* calcd.: 366.1315; found: 366.1315; along with dimer **3***a* [C–A] (46.7 mg, 17%) (recrystallized from hexane–ether); mp 163.5–165.0°C; ir ($CHCl_3$): 3040, 2960, 1735, 1440, 1295, 1202 cm^{-1}; nmr ($CDCl_3$) δ: 5.52–5.21 (4H, m, —CH=CH—), 3.74 (24H, s, -CO_2Me), 2.78 (8H, s, —CH_2—C≡), 2.97–2.77 (8H, m, —CH_2—C=), ^{13}C nmr ($CDCl_3$) δ: 170.3 (CO_2Me), 127.7 (C=C), 78.1 (C≡C), 57.1 (qc), 52.7 (-OCH_3), 30.5 (CH_2—C=), 23.5 (CH_2—C≡); ms *m/e* (70 eV): 732 (M^+). *Exact Mass* calcd.: 732.2629; found: 732.2629.

Monomer **2**a [T–T] *and dimer* **3**a [T–T]

Using procedure G, chloride **1***a* [T–T] (400 mg, 0.99 mmol) afforded, after column chromatography (2% acetone in dichloromethane), monomer **2***a* [T–T] (37 mg, 10%) contaminated with a small amount (less 10%: gc) of **2***a* [C–T]; ir ($CHCl_3$): 3020, 2960, 1735, 1440, 1230, 1175 cm^{-1}; nmr ($CDCl_3$) δ: 5.26 (4H, m, —CH=CH—), 3.79 and 3.70 (12H, both s, -CO_2Me), 3.05 and 2.75 (8H, app d, J = 13.2 Hz and m, —CH_2—); ^{13}C nmr ($CDCl_3$) δ: 172.1 and 170.9 (CO_2Me), 132.3 (C=C), 54.0 (qc), 52.8 and 52.5 (-OCH_3), 39.5 (—CH_2—); ms *m/e* (70 eV): 368 (M^+). *Exact Mass* calcd.: 368.1471; found: 368.1471; along with dimer **3***a* ([T–T] (154 mg, 42%); ir ($CHCl_3$): 3030, 2960, 1735, 1440, 1200, 1170 cm^{-1}; nmr ($CDCl_3$) δ: 5.42–5.20 (8H, app t, J = 4.2 Hz, —CH=CH—), 3.69 (24H, s, -CO_2Me), 2.67–2.49 (16H, app d, J = 5.6 Hz, —CH_2—); ^{13}C nmr ($CDCl_3$) δ: 170.9 (CO_2Me), 128.3 (C=C), 57.1 (qc), 52.3 (-OCH_3), 35.0 (—CH_2—); ms *m/e* (70 eV): 736 (M^+). *Exact mass* calcd.: 736.2942; found: 736.2937.

Monomer **2**a [T–A] *and dimer* **3**a [T–A]

Precursor **1***a* [T–A] (376 mg, 0.934 mmol) was treated according to procedure G giving, after column chromatography (2% acetone in dichloromethane), monomer **2***a* [T–A] (59.2 mg, 17%) (recrystallized from hexane–ether); mp 101–102°C; ir ($CHCl_3$): 3035, 3025, 2960, 1732, 1440, 1250 cm^{-1}; nmr ($CDCl_3$) δ: 5.89–5.72 (2H, m, —CH=CH—), 3.79 and 3.69 (12H, both s, -CO_2Me), 2.98 (2H, app d, J = 12.7 Hz, —CH_2—), 2.88–2.66 (4H, m, —CH_2—), 2.59–2.45 (2H, m, —CH_2—); ^{13}C nmr ($CDCl_3$) δ: 171.3 and 169.8 (-CO_2Me), 130.1 (C=C), 84.1 (C=C), 55.1 (qc), 52.9 and 52.6 (OCH_3), 39.2 (CH_2—C=), 25.2 (CH_2—C≡); ms *m/e* (70 eV): 366 (M^+). *Exact Mass* calcd.: 366.1315; found: 366.1315; along with dimer **3***a* [T–A] (120 mg, 35%) (recrystallized hexane–ether–dichloromethane); mp 196.5–197.0°C; ir ($CHCl_3$): 3030, 2960, 1735, 1200 cm^{-1}; nmr ($CDCl_3$) δ: 5.55–5.35 (4H, m, —CH=CH—), 3.71 (24H, s, -CO_2Me), 2.80–2.64 (16H, m, —CH_2—); ^{13}C nmr ($CDCl_3$) δ: 170.2 (CO_2Me), 128.7 (—C=C—), 78.0 (C≡C), 56.7 (qc), 52.6 (OCH_3), 35.7 (CH_2—C=), 22.7 (CH_2—C≡); ms *m/e* (70 eV): 732 (M^+). *Exact Mass* calcd.: 732.2629; found: 732.2634.

Monomer **2**a [A–A] *and dimer* **3**a [A–A]

Following procedure G, chloride **1***a* [A–A] (383 mg, 0.96 mmol) afforded, after column chromatography (1% acetone in dichloromethane), monomer **2***a* [A–A] (89 mg, 26%) (recrystallized from benzene–hexane); mp 144.5–145.5°C); ir ($CHCl_3$): 3040, 3020, 2960, 1740, 1440, 1255 cm^{-1}; nmr ($CDCl_3$) δ: 3.77 (12H, s, -CO_2Me), 2.81 (8H, s, —CH_2—); ^{13}C nmr ($CDCl_3$) δ: 169.5 (CO_2Me), 80.4 (C≡C), 54.8 (qc), 53.0 (OCH_3), 25.6 (—CH_2—); ms *m/e* (70 eV): 364 (M^+). *Exact Mass* calcd.: 364.1158; found: 364.1158; along with dimer **3***a* [A–A] (138 mg, 40%) (recrystallized from benzene–hexane); mp 244.5–246.0°C; ir ($CHCl_3$): 3030, 2960, 1740, 1440, 1291 cm^{-1}; nmr ($CDCl_3$) δ: 3.72 (24H, s, -CO_2Me), 2.99 (16H, s, —CH_2—); ^{13}C nmr ($CDCl_3$) δ: 169.6 (CO_2Me), 78.0 (C≡C), 56.0 (qc), 52.9 (OCH_3), 23.3 (—CH_2—); ms *m/e* (70 eV): 728 (M^+). *Exact Mass* calcd.: 728.2316; found: 728.2326.

Monomer **2** b [A–A] *and dimer* **3** b [A–A]

Reaction of precursor **1***b* [A–A] (159 mg, 0.46 mmol) in the conditions of procedure G afforded, after column chromatography (4% acetone in dichloromethane), monomer **2***b* [A–A] (38 mg, 27%) (recrystallized from ether–hexane); mp 102.0–102.5°C; ir ($CHCl_3$): 3030, 3010, 2955, 1735, 1440, 1255 cm^{-1}; nmr ($CDCl_3$) δ: 3.78, 3.77, and 3.71 (9H, all s, -CO_2CH_3), 2.95–2.60 (5H, m, —CH_2—$C(CO_2Me)_2$—CH_2 and —CH—), 2.60–2.50 (4H, m, —CH_2—$C(CO_2Me)$—CH_2—); ^{13}C nmr ($CDCl_3$) δ: 173.1, 169.7, and 169.4 (CO_2Me), 82.0, 79.7 (C≡C), 54.6 (qc), 52.8, 52.9 (OCH_3), 40.8 (CH), 25.5, 22.1 (—CH_2—); ms *m/e* (70 eV): 306 (M^+). *Exact Mass* calcd.: 306.1103; found: 306.1103; along with an unseparable mixture of *cis* and *trans* dimers (54 mg, 38%) (recrystallized from ether–hexane); mp 143–148°C; ir ($CHCl_3$): 3020, 2955, 1735, 1438, 1200 cm^{-1}; nmr ($CDCl_3$) δ: 3.72 (12H, s, $(CO_2Me)_2$), 3.69 and 3.68 (6H, both s, -CO_2Me), 2.98 (4H, br s, —CH_2—), 2.63 (5H, br s, —CH_2— and —CH—); ^{13}C nmr ($CDCl_3$) δ: 1734, 169.8 (CO_2Me), 80.1, 76.8 (C≡C), 56.3 (qc), 53.0, 52.1 (OCH_3), 42.8, 42.6 (—CH—), 23.4, 20.2 (—CH_2—); ms *m/e* (70 eV): 612 (M^+). *Exact Mass* calcd.: 612.2207; found: 612.2216.

Monomer **2** b [C–A] *and dimer* **3** b [C–A]

Precursor **1***b* [C–A] (148 mg, 0.43 mmol) was treated under the conditions of procedure G to give, after column chromatography (2% acetone in dichloromethane), monomer **2***b* [C–A] (recrystallized from ether–pentane); mp 62–63°C; ir ($CHCl_3$): 3020, 2955, 1733, 1440 cm^{-1}; nmr ($CDCl_3$) δ: 5.70–5.30 (2H, m, —CH=CH—), 3.76 and 3.75 (6H, both s, -$(CO_2Me)_2$), 3.69 (3H, s, -CO_2Me), 3.25–3.05 and 2.85–2.35 (9H, both m, —CH_2— and —CH—); ^{13}C nmr ($CDCl_3$) δ: 174.8, 171.1 (-CO_2Me), 132.6, 124.3 (C=C), 81.7, 79.6 (C≡C), 55.6 (qc), 52.8, 51.9 (OCH_3), 42.1 (—CH—), 31.0, 29.7, 23.6, 22.0 (—CH_2—); ms *m/e* (70 eV): 309 (M^+ + 1). *Exact Mass* calcd.: 309.1337 (M^+ + 1); found: 309.1330 (M^+ + 1); along with dimer **3***b* [C–A] (35 mg, 27%) as an unseparable *cis–trans* mixture; ir ($CHCl_3$): 3030, 3015, 1733, 1438, 1200 cm^{-1}; nmr ($CDCl_3$) δ: 5.55–5.35 and 5.26–5.10 (4H, both m, —CH=CH—), 3.74, 3.72, 3.71, 3.70 (18H, all s, -CO_2Me), 3.00–2.35 (18H, m, —CH_2— and —CH—); ^{13}C nmr ($CDCl_3$) δ: 174.1, 170.4 (CO_2Me), 130.7, 130.5, 125.6, 125.5 (C=C), 80.0, 79.9 (C≡C), 57.0 (qc), 52.7, 51.8 (OCH_3), 44.1, 43.7 (-CH-), 30.2, 88.6, 28.1, 23.1, 23.0, 21.0, 20.7 (-CH_2-); ms *m/e* (70 eV): (M^+ + 1). *Exact Mass* calcd.: 616.2520; found: 616.2520.

Monomer **2** b [T–A] *and dimer* **3** b [T–A]

Using procedure G, chloride **1***b* [T–A] (159 mg, 0.46 mmol) gave, after column chromatography (2% acetone in dichloromethane), monomer **2***b* [T–A] (41 mg, 29%) assumed to be a mixture of conformers (4:1); ir ($CHCl_3$): 3020, 2955, 1735, 1140 cm^{-1}; nmr ($CDCl_3$) δ: 5.90–5.60 (2H, m, —CH=CH— minor conf.), 5.75–5.65 (2H, m, —CH=CH— major conf.), 3.80, 3.73, 3.70 (9H, all s,

$-CO_2Me$ minor conf.), 3.81, 3.70, 3.65 (9H, all s, $-CO_2Me$ major conf.), 3.05–2.20 (9H, m, $—CH_2—$ and —CH— both conf.); ^{13}C nmr ($CDCl_3$) δ: 174.8, 171.5, 169.9 ($-CO_2Me$), 132.9, 131.3 (C=C), 85.7, 83.4 (C≡C), 55.0 (qc), 52.9, 52.7, 51.9 ($-OCH_3$), 41.4, 39.2, 37.4, 25.3, 22.2 ($—CH_2—$ and —CH—); ms *m/e* (70 eV): 308 (M^+). *Exact Mass* calcd.: 308.1260; found: 308.1260; along with dimer **3***b* [T–A] (68 mg, 48%) as a *cis–trans* mixture; ir ($CHCl_3$): 3030, 2950, 1735, 1440 cm^{-1}; nmr ($CDCl_3$) δ: 5.65–5.25 (4H, m, —CH=CH—), 3.71 (12H, s, $-(CO_2Me)_2$), 3.67 (6H, s, $-CO_2Me$), 2.77 and 2.74 (4H, both br s, $CH_2—C≡$), 2.60–2.30 (5H, m, $—CH_2—CH—CH_2—$); ^{13}C nmr ($CDCl_3$) δ: 174.1, 170.4 (CO_2Me), 131.6, 131.4, 126.6, 126.4 (C=C), 80.4, 76.7 (C≡C), 65.8, 56.9, 56.8, 52.6, 51.7, 43.9, 43.6, 35.5, 33.4, 33.2, 22.7, 20.2, 19.9, 15.2; ms *m/e* (70 eV): 617 ($M^+ + 1$).

Monomer **2** b [T–C] *and dimer* **3** b [T–C]

Following procedure G, precursor **1***b* [T–C] (151 mg, 0.43 mmol) afforded, after column chromatography (2% acetone in dichloromethane), monomer **2***b* [T–C] (39.7 mg, 29%) assumed to exist as a mixture of conformers: ir ($CHCl_3$): 3030, 2955, 1730, 1440 cm^{-1}; nmr ($CDCl_3$) δ: (major conf.) 5.55–5.05 (4H, m, —CH=CH—), 3.76, 3.74 and 3.69 (9H, all s, $-CO_2Me$), 3.05–2.05 (9H, m, $—CH_2—$ and —CH—); ms *m/e* (70 eV): 310 (M^+). *Exact Mass* calcd.: 310.1416; found: 310.1424; along with dimer **3***b* [T–C] (56 mg, 42%) as a *cis–trans* mixture; nmr ($CDCl_3$) δ: 5.55–5.10 (8H, m, —CH=CH—), 3.71, 3.69 and 3.67 (18H, all s, $-CO_2Me$), 2.75–2.15 (18H, m, $—CH_2—$ and —CH—); ms *m/e* (70 eV): 620 (M^+). *Exact Mass* calcd.: 620.2832; found: 620.2828.

Monomer **2** b [T–T] *and dimer* **3** b [T–T]

Treatment of precursor **1***b* [T–T] (150 mg, 0.43 mmol) according to procedure G gave, after column chromatography (2% acetone in dichloromethane), monomer **2***b* [T–T] (13 mg, 10%) as a mixture of conformers (6:1 (nmr)); ir ($CHCl_3$): 3020, 2950, 1730, 1435, 1180 cm^{-1}; nmr ($CDCl_3$) δ: 5.40–5.10 (4H, m, —CH=CH—), 3.80, 3.72, 3.67 (9H, all s, $-CO_2Me$ (major conf.)), 3.79, 3.73, 3.71 (9H, all s, $-CO_2Me$ (minor conf.)), 3.15–3.00 and 2.90–2.40 (9H, both m, $—CH_2—$ and —CH—); ^{13}C nmr ($CDCl_3$) δ (major conf.): 175.7, 172.3 (CO_2Me), 135.0, 130.7 (C=C), 54.2 (qc), 52.8, 52.5, 51.8 ($-OCH_3$), 40.9 (—CH—), 29.6, 37.2 ($—CH_2—$); ms *m/e* (70 eV): 310 (M^+). *Exact Mass* calcd.: 310.1416; found: 310.1422; along with dimer **3***b* [T–T] (56 mg, 42%) as a *cis–trans* mixture; ir ($CHCl_3$): 3020, 2950, 1730, 1195 cm^{-1}; nmr ($CDCl_3$) δ: 5.55–5.38 and 5.35–5.18 (8H, both m, —CH=CH—), 3.71, 3.67 (18H, s, $-CO_2Me$), 2.60 (8H, app d, J = 7.2 Hz, $-CH_2C(CO_2Me)_2—CH_2—$), 2.50–2.15 (10H, m, $—CH_2—CH(CO_2Me)—CH_2—$); ms *m/e* (70 eV): 620 (M^+). *Exact Mass* calcd.: 620.2833; found: 620.2833.

Reçu le 28 juillet 1986

ANDRÉ G. MICHEL, GUY EVRARD et B. NORBERG. Can. J. Chem. **65**, 1308 (1987).

La synthèse des composés indiqués dans le titre a été décrite récemment. Le mode de synthèse laissait croire à l'obtention de diastéréoisomères. Cependant, un seul isomère fut obtenu. Par le présent travail, nous montrons comment les propriétés conformationnelles justifient ces observations. La détermination de structure, par diffraction des rayons-X, du composé (*p*-hydroxybenzyl)-3*R* carbéthoxy-6 oxo-2 pipérazine montre que la molécule adopte une conformation repliée et que la configuration absolue au niveau du carbone C6 est [*R*]. L'étude en solution par la résonance magnétique nucléaire du ^{1}H montre l'existence de trois conformères et on discute des populations relatives. Ces travaux apportent également certains éléments quant à l'activité de tels composés au niveau du récepteur opiacé.

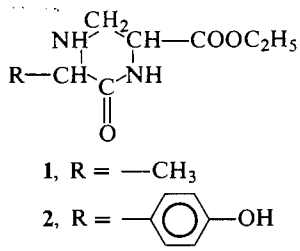
ANDRÉ G. MICHEL, GUY EVRARD, and B. NORBERG. Can. J. Chem. **65**, 1308 (1987).

The synthesis of the title compounds has been described recently. It was anticipated that the product would be a diastereomeric mixture. Surprisingly, only one isomer was obtained. The present work is an attempt to find the conformationnal properties accounting for those observations. X-ray structure determination of 3*R*-[*p*-hydroxybenzyl]-6-carbethoxy-2-oxopiperazine shows that the molecule adopts a folded conformation and that the absolute configuration at C6 is [*R*]. Investigation in solution using ^{1}H nuclear magnetic resonance shows the existence of three conformers and discusses the relative populations. Those findings are also relevant in terms of the activity of such compounds at the opiate receptor level.

Introduction

L'étude conformationnelle des cétopipérazines s'inscrit dans le cadre de nos recherches sur les propriétés géométriques des peptides andogènes et de leurs analogues. Les composés dont cette étude fait l'objet, sont à la base de la synthèse d'analogues rigidifiés de l'enképhaline (1). L'objectif final est de rechercher la conformation que ces dérivés doivent adopter au moment de l'association avec le site actif du récepteur opiacé. La présente étude a pour but de décrire les propriétés conformationnelles caractéristiques des composés indiqués dans le titre. Elle vise à mettre en évidence le comportement conformationnel du cycle phénolique, faisant partie du groupe tyramine, dont le rôle en tant que pharmacophore est essentiel dans l'activité morphinomimétique de tels dérivés (1).

Les dérivés faisant l'objet de cette étude sont présentés ci-dessous.



1, R = $-CH_3$

2, R =

Formule chimique

Les composés **I** et **II** ont fait l'objet d'une étude conformationnelle en solution grâce à la résonance magnétique nucléaire du proton à différentes températures.

Une étude cristallographique du composé **II** a permis de déterminer la chiralité du carbone C6. Cette détermination est basée sur la connaissance de la chiralité du carbone C3, correspondant à la chiralité «*S*» du produit de départ, la L-tyrosine, utilisée dans la synthèse. Il n'était donc pas nécessaire de l'établir expérimentalement.

La conformation de ces composés est alors comparée à celles qu'on observe pour les dioxopipérazines (8, 9).

Partie expérimentale

*Structure cristalline du composé **II***

Des cristaux incolores, de forme prismatique du composé **II** ont été obtenus par évaporation lente d'un mélange eau–méthanol dans un rapport 1:1. La solution a été maintenue dans un bain réfrigérant et conservé à 5°C jusqu'à obtention des cristaux. Les dimensions de la maille et les intensités ont été mesurées sur un diffractomètre Enraf–Nonius CAD-4. Les principales données concernant le cristal sont données au tableau 1. Aucune correction d'absorption n'a été appliquée, tenant de la faible valeur de ce terme. Le tableau 2 donne les conditions expérimentales de prise des données. La mesure de l'intensité de la réflexion standard a été réalisée après chaque groupe de 50 réflexions. Seule la correction de polarisation Lorentz a été effectuée au cours de la réduction des données. Les facteurs de diffusion atomiques ont été utilisés tels que générés dans le système SHELX (3); ceux-ci sont décrits à la référence 11.

La structure a été déterminée par méthodes directes, en utilisant le programme MULTAN (2), et affinée par la technique des moindres carrés (3). Tous les atomes, hydrogènes exceptés, ont été localisés dans la carte de Fourier calculée à partir des 180 valeurs les plus élevées des facteurs de structures normalisés. Les atomes d'hydrogène ont été tous positionnés grâce à une série de différence de Fourier.

En assignant des facteurs thermiques anisotropes à tous les atomes sauf les hydrogènes et des facteurs isotropes fixes pour ceux-ci, le dernier cycle d'affinement a donné un indice $R = 0.035$ pour toutes les réflexions observées. Le tableau 1 contient les données particulières à l'affinement. Les coordonnées finales sont données au tableau 3.

Étude en solution par rmn H des composés I et II

Les spectres rmn H ont été enregistrés sur un spectromètre Varian XL 200 à des concentration de 0,05 *M* dans D_2O. Les systèmes de spin étudiés sont présentés à la figure 2.

Ces systèmes ont été examinés simultanément afin d'élucider la conformation en solution : (*i*) le premier est constitué par les 3 protons, α, β^r, β^s du groupe *p*-hydroxybenzyl (composé **II**); (*ii*) le second est constitué par les 3 protons, α′, β'_1, β'_2 du cycle oxopiperazine (composés **I** et **II**).

Nous les avons considérés l'un et l'autre comme des systèmes de type ABX. Les paramètres rmn, déterminés à partir des mesures effectuées à différentes températures, sont repris dans le tableau 4.

Résultats et discussion

De l'étude par diffraction des rayons-X, il ressort que la caractéristique la plus surprenante est la forme repliée qu'adopte la molécule. La figure 3 illustre la conformation moléculaire. En effet, les groupes hydroxybenzyl et carbéthoxy sont tous les deux en position pseudo-axiale. Le quasi parallélisme entre les

plans moyens du phényl (C9—C10—C11—C12—C14—C15) et du groupe carboxylique (C6—C16—O17—O18—O19) (angle dièdre entre les deux plans : 20°) et les courtes distances entre les atomes de ces deux plans (entre 3,6 et 4,4 Å) conduisent à penser à une interaction stabilisant cette conformation. La nature de cette interaction est cependant difficile à caractériser. Elle a été également observée dans le cas des dipeptides cycliques en phase solide, pour des composés semblables, où une chaîne latérale aromatique fait face à un cycle dioxopipérazine (9).

À l'exception de l'atome C5, tous les atomes du cycle oxopipérazine sont coplanaires. La stéréochimie de la molécule est fixée sans ambiguïté. On sait en effet, que la configuration

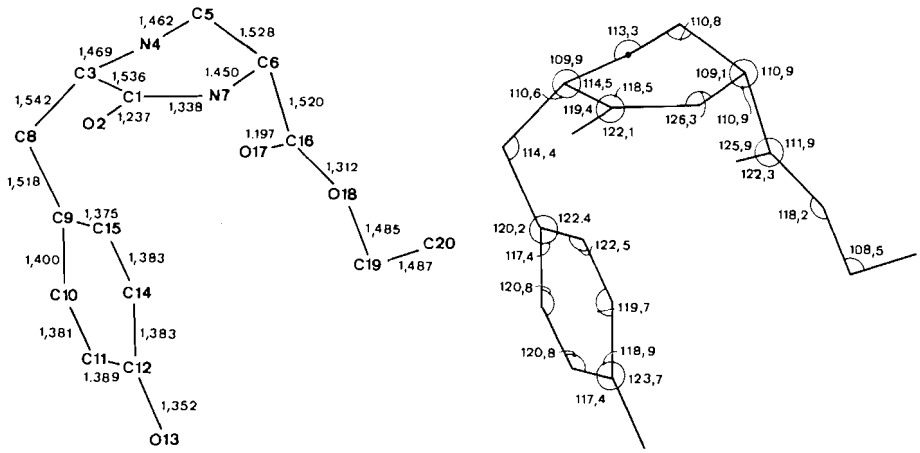

FIG. 1. Numérotation des atomes, longueurs des liaisons (Å) et angles (°), pour le composé **II**. Les déviations standards sont inférieures à 0,014 Å et 0,6° respectivement.

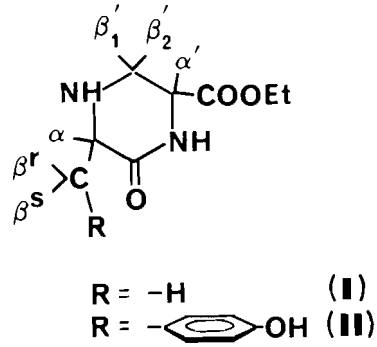

FIG. 2. Systèmes de spin utilisés pour interpréter les spectres en rmn H.

absolue du carbone C3 de la L-tyrosine utilisée dans la synthèse est «*S*»; l'atome de carbone C6 est donc de configuration «*R*».

L'empilement moléculaire à l'intérieur du cristal est présenté à la figure 4. Une première liaison hydrogène intermoléculaire (A) présente une longueur de 2.694 Å; elle est allongée selon *b* et formée entre le groupe —OH (*p*-hydroxybenzyl) et le groupe C=O (oxopipérazine). La deuxième liaison hydrogène assure la cohésion suivant l'axe *c*; elle relie les atomes d'azote N7 et N4 (N7—H...N4), l'un étant d'hybridation sp^2 et l'autre sp^3.

En ce qui concerne l'étude en solution par résonance magnétique nucléaire, nous avons examiné les déplacements chimiques et les constantes de couplage du système ABX formé des protons $\alpha'\beta'_1\beta'_2$, afin de déterminer l'orientation préférentielle du groupe carbéthoxy par rapport au cycle oxopipérazine. Les composés **I** et **II** présentent des signaux assez semblables et le système de spin ne se modifie pas dans le domaine de température étudié. L'examen des déplacements chimiques montre un effet de glissement simultané vers les fréquences plus basses ($-0,1$ ppm pour β'_1 et $-0,15$ ppm pour α' et β'_2) pour les protons et en fonction de la température. On peut corréler cet effet à une modification de l'orientation du groupe *p*-hydroxybenzyl du composé **II**; en effet ce phénomène n'est plus observé pour le composé **I**.

Les valeurs des constantes de couplage entre les protons $\alpha'\beta'_1$ et $\alpha'\beta'_2$ ont été utilisées pour estimer l'orientation préférentielle du groupe carbéthoxy. Les valeurs des angles de torsions obtenues en utilisant la relation de Karplus (4) sont données au tableau 4. On voit que le proton α' est dans une orientation bissectrice de l'angle β', β'_2, c'est-à-dire qu'il adopte une position pseudo-équatoriale par rapport au cycle oxopipérazine. En conséquence, le groupe carbéthoxy s'oriente de manière pseudo-axiale par rapport à l'hétérocycle.

Grâce au système ABX constitué par les protons $\alpha\beta^r\beta^s$, nous avons ensuite déterminé les populations relatives des différents rotamères du groupe *p*-hydroxybenzyl selon la méthode de Pachler (5). Les résultats sont indiqués au tableau 5.

Les conformations décrites correspondent à celles qui ont été observées pour les dipeptides cycliques contenant un acide aminé aromatique, tels que Deslauriers *et al.* (6) et Anteunis (7) le décrivent. Il est important d'observer que l'orientation pseudo-axiale du groupement carbéthoxy en position 6 n'empêche pas le rotamère *c* d'avoir un temps de résidence relativement important. Dans le cas plus particulier des dipeptides, il semble que le conformère *c* soit également prédominant.

En vue de comprendre quelles sont les forces intramoléculaires stabilisant ce conformère replié, des calculs d'énergie conformationnelle par méthode semi-empirique MO CNDO/2 ont été entrepris (9), sans cependant pouvoir reproduire les résultats expérimentaux que nous présentons. Ceux-ci sont cependant confirmés dans le cas des dipeptides cycliques (7). Kopple et Marr (10), qui les premiers avaient mis en évidence ce phénomène dans le cas de dioxopipérazines, proposent une stabilisation préférentielle de 15 kJ/mol en faveur du composé replié, ce qui rejoint assez bien nos résultats obtenus pour les dicétopipérazines.

Ils proposèrent alors une stabilisation par interaction dipole–dipole induit (μ–μ'), particulièrement dans le cas de solutions polaires, telles que nous les avons utilisées, tant pour l'étude rmn que pour la cristallisation. Cependant, Anteunis, quant à lui (7) considérait plutôt l'intervention prédominante de forces de dispersion. Revenant au problème posé au départ, la structure repliée fournit l'explication quant à la stéréospécificité observée au cours de la synthèse. La conformation adoptée (fig. 1) provoque un encombrement stérique important pour une des faces du cycle oxopipérazine et oriente ainsi l'attaque de l'agent catalyseur ou donneur ionique. Il en résulte une réduction stéréospécifique de la double liaison initiale C5=C6. Cette conformation justifie qu'au cours de la synthèse de ces composés (1) un seul des diastéréoisomères ait été obtenu, correspondant à la configuration «*R*» pour l'atome de carbone C6.

Microanalytical determination of calcium, phosphate, and arsenate including kinetics of formation of molybdenum blue from reduction of molybdoarsenic acid by ferrous ammonium sulphate

U. S. RAI AND T. S. B. NARASARAJU[1]

Department of Chemistry, Banaras Hindu University, Varanasi-221 005, India

Received October 27, 1986

U. S. RAI and T. S. B. NARASARAJU. Can. J. Chem. **65**, 1313 (1987).

A method for the microdetermination of calcium, phosphate, and arsenate in mixtures of the three has been developed. In an aliquot of the mixture calcium was determined complexometrically using EDTA. Phosphate and arsenate were determined in second and third aliquots, respectively, using spectrophotometric methods. The interference of arsenate in the determination of phosphate was avoided by masking arsenate with thiosulphate. The kinetics of formation of molybdenum blue from molybdoarsenic acid by reduction with ferrous ammonium sulphate was also studied. The rate-determining step was found to be the reduction of molybdoarsenic acid with iron(II); the reaction was first order in iron(II) and arsenate over the concentration ranges studied. Values found for the enthalpy, entropy, and free energy of activation were 22, 0.05, and 7.5 kcal, respectively.

U. S. RAI et T. S. B. NARASARAJU. Can. J. Chem. **65**, 1313 (1987).

On a mis au point une méthode pour la microdétermination du calcium, du phosphate et de l'arsenate dans des mélanges de ces trois ions. Faisant appel à la complexométrie à l'aide de l'EDTA, on peut déterminer le calcium sur un aliquot du mélange. Utilisant des méthodes spectrophotométriques, on peut déterminer le phosphate et l'arsenate sur deux autres aliquots. On a éliminé le problème de l'interférence de l'arsenate dans la détermination du phosphate en masquant l'arsenate par du thiosulfate. On a aussi étudié la cinétique de la formation du bleu de molybdène à partir de l'acide moblydoarsenique par réduction avec du sulfate d'ammonium ferreux. On a trouvé que l'étape déterminante est la réduction de l'acide molybdoarsenique par le fer(II); pour toutes les concentrations étudiées, la réaction est du premier ordre en fer(II) ainsi qu'en arsenate. Les valeurs de l'enthalpie, de l'entropie et de l'énergie libre d'activation sont respectivement 22, 0,05 et 7,5 kcal.

Introduction

A microanalytical determination of calcium, phosphate, and arsenate was needed in the course of some physicochemical investigations on the synthetic solid solutions of calcium hydroxylapatite, $Ca_{10}(PO_4)_6(OH)_2$, the principal inorganic constituent (1) of human bones and teeth, and the isomorph containing arsenic. Quantitative separation of the pairs: calcium, phosphate; calcium, arsenate; and phosphate, arsenate have been reported earlier (2–4). However, complications arise when all three ions are present simultaneously in microquantities. While microanalytical determinations of calcium and phosphate have been discussed earlier (5–8), that of arsenate needs further investigation. The estimation of microquantities of arsenate is based (7) on the reduction of molybdoarsenic acid by ferrous ammonium sulphate and subsequent spectrophotometric determination of the molybdenum blue formed. These investigations necessitated a study of the kinetics of formation of molybdenum blue from molybdoarsenic acid by reduction with ferrous ammonium sulphate. The present investigations into the microdetermination of calcium, phosphate, and arsenate were undertaken with a view to studying the solubility (9) of solid solutions of hydroxylapatites containing phosphorus and arsenic.

In the procedure developed here calcium in an aliquot of a solution containing calcium, phosphate, and arsenate was determined complexometrically (2, 6). Next, phosphate was determined spectrophotometrically in a second aliquot in the presence of calcium and arsenate. Calcium does not interfere, but arsenate does. The interference of arsenate was avoided by masking (10) with thiosulphate. In a third aliquot molybdenum blue was formed in the usual way. From knowledge of the contribution of phosphorus to this absorbance, obtained separately from a calibration curve relating the amount of phosphorus to absorbance under identical conditions, the contribution of arsenic was calculated. The kinetics of formation of molybdenum blue was studied spectrophotometrically at different temperatures, and a mechanism is suggested in light of the effect of change of concentrations of Fe^{2+} ion, acid, and arsenate ion on the reduction kinetics.

Experimental

Stock solutions were prepared by dissolving 0.25 g $CaCO_3$; 0.4393 g KH_2PO_4, and 0.4163 g $Na_2HAsO_4.7H_2O$, each in 1 L distilled water so that the resulting solutions contained 100 μg each of calcium, phosphorus, or arsenic per mL. A calibration curve representing the relationship between the amount of phosphorus and the absorbance was obtained by preparing ten solutions (Set No. 1) within the concentration range 25 to 200 μg per 100 mL. For each solution, an appropriate volume of the stock solution of phosphate was treated successively with 10 mL of 7.5 *N* sulphuric acid, 20 mL of 0.001 *N* sodium thiosulphate, and 10 mL each of 6.6% ammonium molybdate and 15% ferrous ammonium sulphate, and the resulting solution made up to 100 mL. The absorbance was recorded against a blank at 750 nm using a Beckman DB Spectrophotometer, the quartz cell width being 1.0 cm. A calibration curve representing the relationship between the amount of arsenic and the absorbance was obtained by preparing a set of solutions (Set No. 2) identical with Set No. 1, but without thiosulphate solution, which masks the arsenic. Each of these solutions was transferred to a 250-mL polyethylene beaker, heated on a water bath for about 15 min, cooled, transferred to a standard 100-mL volumetric flask, and made up to the mark. The absorbance was measured as for the phosphorus. To know the contribution of phosphorus to the absorbance after subjecting the solutions to heating, solutions of Set No. 1 were prepared once again (Set No. 3); the absorbance this time was measured by bringing about the colour reaction at 100°C as in the case of the arsenic system. A calibration curve was plotted of amount of phosphorus against absorbance after heating the solutions for about 15 min.

Having obtained these calibration curves, known and convenient volumes of calcium, phosphate, and arsenate solutions were mixed and

12	37	200	6.6	0.75	25	0.064

the resulting solution was made up to a known volume. Calcium was first estimated in an aliquot by titrating it against EDTA solution using Eriochrome black-T as an indicator (2). In a second aliquot, the amount of phosphorus was determined from the calibration curve obtained for Set No. 1. In a third aliquot, colour was produced without sodium thiosulphate as in Set No. 1 and the absorbance was measured against a blank. This absorbance is the sum of the absorbances due to phosphate and arsenate ions after heating. From knowledge of the amount of phosphate in the second aliquot, its corresponding absorbance after heating was calculated using the third calibration curve, and upon subtraction of this value from the absorbance obtained in the third aliquot, the contribution of arsenic to the absorbance could be determined. The amount of arsenic was determined from the second calibration curve.

Kinetic studies were carried out with a standard solution of sodium arsenate containing 100 μg arsenic per mL. Standard solutions of ammonium molybdate (66 g per L), 7.5 *N* sulphuric acid and ferrous ammonium sulphate (150 g per L) were prepared. All chemicals were of AR (BDH) or E Merck grade. To avoid possible interference of silica from glassware, all solutions were preserved in polyethylene containers and the experiments were carried out in polyethylene beakers. A convenient amount of arsenate solution was taken in a 100-mL volumetric flask and treated with 10 mL of 6.6% ammonium molybdate and 7.5 *N* sulphuric acid. Ferrous ammonium sulphate solution (10 mL) was then added and when the pipette was half empty the stop watch was started. The resulting solution was made up to 100 mL and transferred to a polyethylene beaker. About 3 mL of this solution was transferred to a spectrophotometer cell and the absorbance measured immediately, providing a zero time reading. At a convenient time interval, a fresh solution was placed in the cell and the absorbance was noted. To find the infinity reading, a separate system was prepared as above and the reaction was carried to completion by heating the solution in boiling water for about 15 min and measuring the final absorbance. The absorbance taken at different time intervals, when subtracted from the infinity reading, corresponds to the unreacted arsenic in the system. These data were found to obey the first order rate equation. To determine the slow step, a system was prepared as above without ferrous ammonium sulphate. The solutions were heated for about 15 min in a boiling water bath to complete the reaction, cooled, treated with the reducing agent, and the absorbance was measured as before. The results were found to obey the first order rate equation. To determine the effect of arsenic concentration, experiments were carried out at different concentrations of arsenate. The effect of temperature was studied by carrying out the experiment over the temperature range 34 to 45°C using a Colora thermostat. The dependence of the rate of the reaction on ferrous ammonium sulphate concentration was studied over a concentration range of 10 to 25%. To study the effect of acid concentrations on the reaction kinetics, experiments were carried out over the acid concentration range of 0.1 to 1.0 *N*. In the concentration range 0.1 to 0.6 *N* an instantaneous blue colour was obtained. The kinetics were not affected in the concentration range 0.7 to 1.0 *N* of sulphuric acid. The reaction was also carried out separately in the presence of 0.165 *N* NaCl and 0.01 *M* $CaCl_2$ and was found to be independent of their presence.

Results and discussion

Results of the kinetics of formation of molybdenum blue through reduction of molybdoarsenic acid by ferrous ammonium sulphate are given in Table 1. Rate constants, obtained by substituting the experimental data in the first order rate equation, are given in column 7 of the table. It is evident from the table that as temperature increases the rate constant also increases. A graph of log k vs. $1/T$ yields a straight line, from which the energy of activation is calculated to be 23 kcal. The enthalpy of activation, entropy of activation, and free energy of activation, were also calculated (11) and were found to be 22, 0.05, and 7.5 kcal, respectively. The increase in rate constant as a function of temperature is in accordance with the well known Arrhenius equation. When experiments were carried out with different concentrations of arsenic the rate constant was found to be unchanged, while the rate of the reaction was found to increase with the arsenic content of the reaction mixture, in agreement with theoretical considerations. It was also observed from Table 1 that the rate constant increases with increasing concentration of ferrous ammonium sulphate solution. This indicates that ferrous ammonium sulphate takes an active part in the reaction and its concentration alters as a result of the chemical change. The concentration of ferrous ammonium sulphate is very high and does not alter the order of the reaction, indicating a pseudo monomolecular reaction in the present investigation. It was observed that the rate of reaction increases with the concentration of ferrous ammonium sulphate; at a concentration of 25% the reaction is complete within 5 min. It is well known (12) that the formation of molybdenum blue from arsenate is a two-step reaction. Molybdoarsenic acid forms in the first step and is subsequently reduced in the second step. To determine the

rate-determining step, the first step of the reaction was allowed to proceed to completion, the reducing agent was added, and the kinetics were again studied. The reaction was found to follow the same reaction kinetics, indicating that the second step is the rate-determining step. In light of these results the following reaction scheme may be proposed:

[1] Arsenate + ammonium molybdate $\xrightarrow[\text{fast}]{k_1\ (\text{acid})}$ molybdoarsenic acid (MA)

[2] $\text{MA} + \text{Fe}^{2+} \xrightarrow[k_2]{\text{slow}} \text{molybdenum blue (MB)} + \text{Fe}^{3+}$

The velocity (v) of the overall reaction is given by

$$[3] \quad v = \frac{\text{d(MB)}}{\text{d}t} = k_2[\text{MA}][\text{Fe}^{2+}]$$

Since eq. [1] is instantaneous, the MA formed will be dependent on the amount of arsenate taken to start the reaction. Thus,

[4] [MA] = [arsenate]

The quantities given in square brackets represent molar concentrations. From eqs. [3] and [4],

$$[5] \quad v = \frac{\text{d(MB)}}{\text{d}t} = k_2[\text{arsenate}][\text{Fe}^{2+}]$$

The rate of reaction will depend on the concentration of arsenate as well as Fe^{2+}. Thus, Fe^{2+} takes an active part in the reaction and its concentration changes, even though it is present in excess and does not affect the order of the reaction. The intense blue colour obtained for acid concentrations below 0.6 N may be because of formation of molybdenum blue from molybdic acid. At higher acid concentrations molybdoarsenic acid reduction is independent of acid concentration. To obtain rapid quantitative conversion of arsenate into molybdoarsenic acid a very high concentration of ammonium molybdate was chosen in all the reactions. The intensity of the molybdenum blue obtained for the infinity reading was found to be independent of time for at least 50 h, indicating that the reaction is complete after heating for 15 min.

In light of the fact that both phosphorus and arsenic undergo an identical set of chemical reactions in the presence of molybdic acid and a reducing agent, the determination of the individual amounts of the two elements in a mixture is complicated. An expeditious formation of molybdenum blue in the presence of arsenate occurs only at about 100°C (9) while ordinary temperatures are suitable for the reaction in the case of phosphate (7). In addition, the occurrence of the reaction with arsenate can be prevented by the presence of $S_2O_3^{2-}$ ions (10); thiosulphate does not affect the reaction with phosphate. Based on these considerations a procedure has been developed for the determination of microquantities of phosphorus and arsenic in a mixture of the two.

The accuracy and precision of the method employed for the individual determination of calcium, phosphate, and arsenate when present together was assessed by applying it to sample solutions containing known amounts of these ions. The results, given in Table 2, suggest the maximum percent error to be of the order of ±2.5. The method is rapid and simple once the required calibration curves have been acquired.

Carbon-13 nuclear magnetic resonance chemical shifts are reported for a series of 4-substituted phenols and 2-nitrophenols in dimethyl sulfoxide solution. For chemical shift correlations, it was found by factor analysis and iterative multiple linear regression that the *para* chemical shifts require two substituent factors whereas the *ipso*, *ortho*, and *meta* chemical shifts require three factors. Regression analyses were performed using the field and resonance parameters (σ_F, σ_R^0) and the appropriate *ipso*, *ortho*, and *meta* parameters (**I**, **O**, **M**) determined by Reynolds. Good correlations were obtained except for the three *meta* carbon analyses, where the correlation coefficients range from 0.877 to 0.963.

HAROLD M. HUTTON, KENNETH R. KUNZ, JOHN D. BOZEK et BARRY J. BLACKBURN. Can. J. Chem. **65**, 1316 (1987).

On a déterminé les déplacements chimiques, en rmn ^{13}C, d'une série de phénols substitués en position 4 ainsi que de nitro-2 phénols en solution dans le diméthylsulfoxyde. Pour les corrélations des déplacements chimiques, on a trouvé par des analyses factorielles et par des régressions linéaires multiples itératives que les déplacements chimiques des positions *para* requièrent deux facteurs de substituants alors que les déplacements chimiques des positions *ipso*, *ortho* et *méta* requièrent trois facteurs. On a effectué des analyses de régression en utilisant les paramètres de champ et de résonance (σ_F, σ_R^0) ainsi que les paramètres *ipso*, *ortho* et *méta* appropriés (**I**, **O** et **M**) déterminés par Reynolds. On a obtenu de bonnes corrélations, excepté pour trois analyses de carbones *méta* pour lesquelles on a obtenu des coefficients de corrélation allant de 0,877 à 0,963.

[Traduit par la revue]

Introduction

There has been considerable interest in the determination of electronic properties of aromatic compounds from the correlation of ^{13}C chemical shifts with various substituent parameters (1). A number of different procedures have been attempted, including the Swain–Lupton approach (2) and the Hammett analysis (3) using either a single substituent parameter (SSP) or dual substituent parameter (DSP) procedure (4, 5). The relative merits of the SSP and DSP scales have been discussed in detail (6–9). The DSP method, using the correlation of δ with the field/inductive and resonance substituent constants σ_F and σ_R^0, has been found to be effective in the determination of the relative contribution from the field and resonance effects (10–13). Since Reynolds has recently shown that the inductive parameter, I, is more accurately described as a field parameter, F (13), this convention will be used throughout this paper. For 1,4-disubstituted benzenes with one fixed substituent, Bromilow and co-workers (14, 15) have shown that the effect of substituents on *para* carbon chemical shifts is dependent on the electron demand exerted by the common group and can be analyzed with a dual substituent parameter nonlinear resonance effect (DSP–NLR) equation. The lack of statistical support (for example an F-test of the variance (14)) when applying a particular linear free-energy relationship has caused some concern (16, 17).

The use of factor analysis and principal component analysis has only recently been used to explore the effect of substituents on ^{13}C chemical shifts (17–21). Reynolds *et al.* (22) have used factor analysis on their extensive 3- and 4-substituted styrene data to show that the DSP procedure is necessary to fit the *para* chemical shifts, and that a third parameter is required for each of the *ortho*, *meta*, and *ipso* carbons in the styrene derivatives.

The purpose of this paper is to report the analysis of the substituent effects on the ^{13}C chemical shifts for a series of 4-substituted phenols and 2-nitrophenols and to determine if Reynolds parameters (22) apply to these aromatic systems.

Prior to this work there has not been a comprehensive study of the ^{13}C chemical shifts of phenols or 2-nitrophenols using a minimum substituent set. Lauterbur (23) has studied the ^{13}C chemical shifts of methylphenols, and Ilczyszyn *et al.* (24) reported the influence of substituents on the ^{13}C chemical shifts for a series of chloro and nitro substituted phenols. Smith and Proulx (25) examined the dependence of the ^{13}C chemical shifts of 2-substituted phenols with the Swain and Lupton parameters and the semiempirical factor Q (26).

The association that occurs in phenols has been well established. In nonpolar solvents, phenol (27) and many phenol derivatives (28) generally exist as a monomer–trimer equilibrium. In dimethyl sulfoxide (DMSO) solution, Ouellette has shown from ^1H nmr studies that these aggregates are eliminated as the phenolic hydrogen preferentially interacts with solvent molecules (29).

2-Nitrophenol is one of the exceptions where no association is found (28), due to the strong intramolecular hydrogen bond between the OH and NO_2 substituents. Evidence for the existence of this hydrogen bond has been provided by uv spectroscopy (30), ^1H nmr (31, 32), and the torsional frequency of the hydroxyl group (33). Although the energy of this hydrogen bond has not been measured directly, it has been estimated by Schaefer (34) to be about 6.6 kcal mol^{-1}. In 2,4-dinitrophenol de Kowalewski and co-workers (35) have shown that, even under conditions of fast exchange with the solvent, the OH group maintains its preferential *cis* conformation with the NO_2 group.

Experimental

Compounds

Phenol, the 4-substituted phenols, 2-nitrophenol, and some of the 4-substituted 2-nitrophenols, namely, the amino, chloro, nitro, and methyl derivatives, were obtained commercially and used with-

out further purification. The following 4-substituted 2-nitrophenols were synthesized: 4-acetamido- (36*a*), 4-acetyl- (36*b*), 4-benzoyl- (36*c*), 4-bromo- (36*d*), 4-*tert*-butyl- (36*e*), 4-carbomethoxy- (36*f*), 4-carboxy- (36*g*), 4-cyano- (36*h*, *i*), 4-formyl- (36*j*), 4-fluoro- (36*k*), 4-iodo- (36*g*), 4-methoxy- (36*l*), and 4-phenyl-2-nitrophenol (36*m*). All compounds used were free of extraneous peaks in their ^{13}C nmr spectra.

Nuclear magnetic resonance

The carbon-13 nmr spectra were recorded on a Varian CFT-20 spectrometer at a temperature of 30°C. The compounds were run as 1.0 *M* solution in DMSO, using a coaxial tube with D_2O as external lock; chemical shifts were referenced to TMS by setting the DMSO resonance at 40.5 ppm (37).

Calculations

Factor analyses with the program FACTANAL (38) and the multiple linear regression analyses were performed on the Amdahl 470 computer at the University of Manitoba.

Results and discussion

Spectral assignment

The assignments for the 4-substituted phenols in Table 1 were primarily based on substituent-induced chemical shifts (SCS) (39), with C-2, C-6 usually to high field of C-3, C-5 and, similarly, C-4 to high field of C-1. The chemical shift difference between these pairs of resonances is sufficiently large to allow an unambiguous assignment, except for the amino and possibly the methoxy derivatives. With the substituted 2-nitrophenols in Table 1 the assignments were more straightforward since coupled spectra can be used to distinguish all carbon resonances except C-3 and C-5. However, the large chemical shift difference of these permits easy assignment on the basis of the *ortho* SCS values, with C-3 always to high field of C-5 as in 2-nitrophenol.

Factor analysis of the chemical shifts

The relationship between chemical shift data and substituent constants can either be expressed directly

$$[1] \quad \delta_x = \delta_0 + \Sigma\rho_n\sigma_n$$

or with the SCS relative to the parent compound

$$[2] \quad \Delta\delta_x = \Sigma\rho_n\sigma_n$$

The factor analysis of the data using eq. [1] should give one additional factor, the intercept, but the same number of substituent factors obtained by eq. [2], as has been shown by Reynolds *et al.* (22*a*). To determine the number of factors required to fit the data within the experimental accuracy, a number of tests can be applied (40). We have used the same indicators as Reynolds *et al.* (22*a*). In our analyses we estimate the overall average error to be 0.15 ppm for the chemical shifts and 0.2 ppm for the SCS values. To obtain the correct number of factors, (*a*) the residual standard deviation (RSD) for the data matrix should be approximately equal to the experimental uncertainty, (*b*) no individual value should have a deviation that is more than three times the experimental uncertainty (3σ), and (*c*) the empirical indicator function IND, where IND = RSD/($x - n$), should reach a minimum. In the definition of IND, x is the number of rows or columns (whichever is the lesser) in the data matrix and n is the number of factors.

The data used in the factor analysis of the substituted phenols and 2-nitrophenols is represented by a 18 × 10 matrix but the number of columns is reduced to the number of chemical shifts for a particular analysis. For example, there are only three different *ortho* chemical shifts in the two systems and thus 3 columns. Since there is some uncertainty in determining the correct number of factors with a limited data set, both the chemical shifts and the SCS were analyzed to serve as a check on the number of substituent factors. The results are given in Table 2. Four sets of analyses were used to determine the number of factors required for the short-range substituent effects. Using both compounds as one series, each of the *ortho* (C-3, C-5), *meta* (C-2, C-6), and *ipso* (C-4) chemical shifts was analyzed in combination with the long-range *para* (C-1) values.

Factor analysis could not be applied to the individual *ortho*, *meta*, *para* values because of the limited data set. For the same reason, the C-1, C-4 combination could only be determined with SCS values.

For the factor analysis of each of the *meta* and *ipso* chemical shifts with that of C-4, the RSD and 3σ tests indicate that three substituent parameters are required to fit the data; the RSD drops to about the value of the experimental uncertainty and the number of points with a deviation larger than 3σ drops to zero at the same time. However, IND does not give consistent results, possibly because of the limited data available. The results in Table 2 indicate an ambiguity with the factor analysis of the *ortho* chemical shifts. The analysis of δ values suggests three substituent factors (plus an intercept), whereas using $\Delta\delta$ values there is still 3.5% (3 points) of the data outside the 3σ limit with three factors. The *ortho*, *meta*, and *ipso* results are confirmed with the analysis of all ring carbons simultaneously since both the δ and $\Delta\delta$ results indicate that five substituent factors are required. As has been found by Reynolds *et al.* for substituted styrenes (22), the factor analysis shows that correlations should be possible with substituent parameters such as σ_F, σ_R^0, plus one additional factor for each of the *ortho*, *meta*, and *ipso* carbons.

Multiple linear regression of chemical shifts

(i) Long-range substituent effects

The values of the coefficients ρ_F and ρ_R determined from the multiple linear regression of the ^{13}C chemical shifts of the phenols and 2-nitrophenols using eq. [3] are given in Table 3.

$$[3] \quad \delta = \delta_0 + \rho_F\rho_F + \rho_R\rho_R^0$$

The data were analyzed using the σ_F (previously labelled as σ_I), σ_R^0 substituent constants given by Taft and co-workers (5). For the *para* carbon C-1, the substituent constants recently published by Reynolds (22) were also used in the analysis and the results given in Table 3. However, the number of data points is decreased since only 13 substituents (H, NH_2, OCH_3, CH_3, F, Cl, Br, I, $COCH_3$, CN, CO_2CH_3, NO_2, $C(CH_3)_3$) are common to those available from Reynolds (22). If Taft's values of σ_F, σ_R^0 are used, and the analyses restricted to these 13 substituents, the substituent coefficients do not differ significantly from those given in Table 3 using Reynolds' data; for phenol the correlation coefficient and F-test of the variance are 0.9974 and 949, respectively, while for the 2-nitrophenol they are 0.9978 and 1131. There is some improvement of the regression analysis for the phenol system, but for the 2-nitrophenols the results are virtually identical.

The values of the correlation coefficient and the F-test in Table 3 indicate an excellent correlation for the long-range substituent effects at C-1 for both the phenols and 2-nitrophenols. The goodness of the fit appears to be similar for both series, indicating that the nitro group does not significantly affect the chemical shift correlation.

The field and resonance contributions for C-1 can be examined in terms of λ, defined as ρ_R/ρ_F, the ratio of the resonance and field effects. From the results in Table 3 (Taft values) for C-1, λ is 4.42 for phenol and 5.05 for the 2-nitrophenol derivatives, in the range expected for these systems in DMSO. For monosubstituted benzenes in DMSO Bromilow *et al.* (11) found $\rho_F = 5.48$ and $\rho_R = 22.21$, with $\lambda = 4.05$. Comparing these results with the values given in

TABLE 3. Results of multiple linear regression analysis of substituent effects using eq. [3][a] with σ_F and σ_R^0

[a] σ_F, σ_R^0 values taken from ref. 5, except as noted.
[b] Chemical shift of parent compound.
[c] Calculated values given with standard error.
[d] Multiple correlation coefficient.
[e] F-test of the variance, with the degrees of freedom due to regression, error indicated.
[f] Standard deviation.
[g] σ_F, σ_R^0 values taken from ref. 22*b*, with analysis restricted to 13 substituents (see text).

Table 3, the resonance effect at C-1 decreases with the common OH substituent, and a further decrease is obtained with the inclusion of the NO_2 substituent. The field effect decreases in the same manner but to a larger extent.

The influence of the 2-nitro group on the C-1 chemical shift of the phenol derivatives can be shown from the plots of the shifts of the phenol and 2-nitrophenol with respect to the shift of the corresponding benzene derivative (11). In Fig. 1, the chemical shift plot of phenol versus benzene derivatives in DMSO shows an approximately bilinear relationship. For the π-acceptor substituents the slope is 0.97 and for the π acceptors it is 0.76. For the common OH group, which is a π donor, these results are consistent with donor–acceptor conjugation for the π acceptors and π-repulsive saturation interactions (15, 41) for the π donors. The plot for the 2-nitrophenol and benzene shifts in Fig. 1 is a roughly linear relationship (the slopes are 0.69 for the π donors and 0.72 for the π acceptors, which is the same within the experimental uncertainty). This indicates that with the nitro group there is no longer any π saturation interaction. It is possible that the NO_2 group acts as an electron sink, by virtue of its $-R$ effect, to reduce the π-donor ability of the OH group, and that this is further enhanced by the stabilization that occurs with the O—H--O_2N hydrogen bond.

Both the linear regression analysis and the chemical shift plots indicate that the common groups are only weakly interacting with the substituents. For a strongly interacting common substituent, a nonlinear resonance effect equation (14, 15) would have been required to allow for the electron demand of the common group.

(ii) Short-range substituent effects

DSP correlations were also attempted with the ^{13}C chemical shifts for the *ortho*, *meta*, and *ipso* carbons in phenol and 2-nitrophenol. The results given in Table 3 indicate a rather poor set of correlations, as would be expected from the factor analysis data. Reynolds *et al.* (22*b*) have recently derived a set of short-range factors, which can be used with σ_F, σ_R^0:

$$[4] \quad \delta = \delta_0 + \rho_F\sigma_F + \rho_R\sigma_R^0 + \rho_X{}^X$$

In eq. [4] X represents the appropriate short-range factor and ρ_X is its weighting constant. These factors are **O**, **M**, and **I**, the *ortho*, *meta*, and *ipso* parameters, respectively. Using his extensive styrene chemical shift data, Reynolds has determined values of these short-range substituent constants. He has shown that it is reasonable to assume that these parameters represent an orthogonal nonelectronic component of the substituent effect and that σ_F and σ_R^0 still give reasonable field and resonance contributions after the nonelectronic effects are

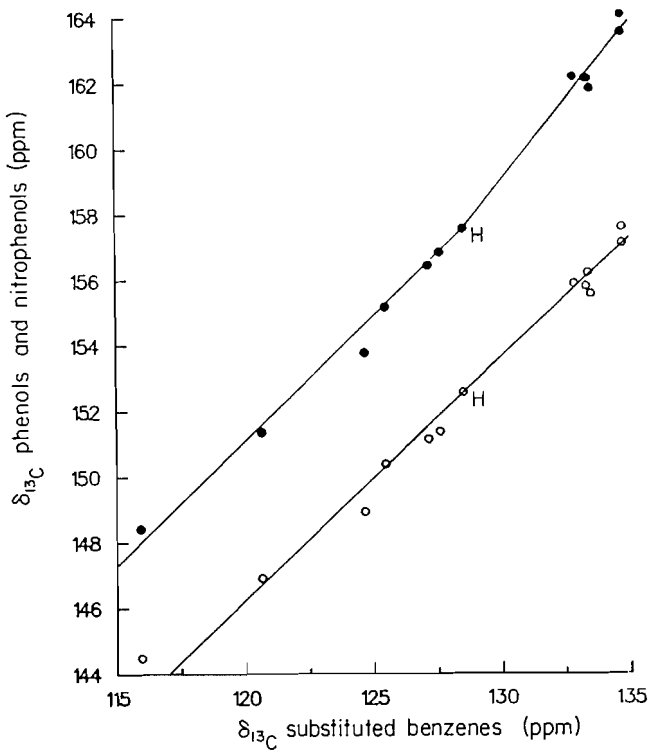

FIG. 1. A plot of the ^{13}C chemical shift for C-1 of 4-substituted phenols (●) and 4-substituted 2-nitrophenols (○) with respect to the corresponding chemical shift for substituted benzenes. The positions for the compounds with the hydrogen substituent are indicated on the plot.

[a] σ_F, σ_R^0, and short-range parameter X taken from ref. 22*b*.
[b] Chemical shift of parent compound.
[c] Calculated values given with standard error.
[d] Multiple correlation coefficient.
[e] *F*-test of the variance, with the degrees of freedom due to the regression, error indicated.
[f] Standard deviation.

factored out (22*b*). There is some question about the reliability of the *ipso* factor **I**. These *ipso* values were derived from cyclohexane α ^{13}C chemical shifts as the initial target testing input vector. The *ipso* factor and σ_F (and possibly σ_R^0) are partially related to substituent group electronegativity, but since this partially related component is factored out in deriving **I**, it would appear in the values of ρ_F and ρ_R in a σ_F, σ_R^0, **I** correlation (12, 22*b*). Thus the field and resonance components would not be reliable, as Reynolds has suggested (22*b*).

The results of the regression analysis using eq. [4] are given in Table 4. Reynolds' values of σ_F and σ_R^0 and the short-range parameters (22*b*) were used for these analyses. Similar results were obtained with the σ_F and σ_R^0 values published by Taft (5) and the short-range parameters. The use of the *ortho* factor, **O** and the *ipso* factor, **I**, significantly improves the correlations. However, the inclusion of **M** improves the correlation, but not to the same extent; the least improvement is at C-2 for the 2-nitrophenol series, although C-2 for the phenol derivatives is not much better. When these *meta* correlations were examined further, it was found that the π-donor substituents gave very good correlations for both series of compounds (correlation coefficient for C-2 and C-6 carbons varied from 0.993 to 0.999) while poor correlations were observed for the π acceptors (correlation coefficient varied from 0.733 to 0.908). These results again emphasize the requirement of a well-balanced set of substituents (5) ranging from electron withdrawing to electron releasing for any correlation analysis.

The standard deviation is given for each correlation in Tables 3 and 4. The results confirm that the two-parameter linear regression fits the data within the experimental uncertainty for the *para* carbon chemical shifts and that the three-parameter analysis is required for each of the *meta*, *ortho*, and *ipso* carbons. With the inclusion of the *meta* factor the standard deviation is reduced to the estimated error in the data, and thus it is possible that the values obtained for the correlation coefficient and *F*-test of the variance could result from the small range of *meta* chemical shifts. The standard deviation of the *ipso* carbon analysis is still about three times the error in chemical shifts, a further indication of the difficulties associated with an *ipso* factor.

In the derivation of the short-range substituent parameters the coefficient ρ_X (eq. [4]) was defined to be unity (22*b*). For the substituted phenols and 2-nitrophenols it is uncertain why the ρ_X coefficients for the *ortho* and *ipso* carbon analyses are close to unity whereas those for the *meta* are larger. Since there is a slight solvent dependence in σ_F values (5), the additional *meta* factor may also be attempting to correct for the uncertainties in σ_F, in addition to any *meta* effect. More systems would have to be analyzed using Reynolds' approach to determine if this is to be expected.

Received September 23, 1986

HONG WANG, RICHARD J. BARTON, BEVERLY E. ROBERTSON, JOHN A. WEIL, and KEITH C. BROWN. Can. J. Chem. **65**, 1322 (1987).

The crystal structure of 9-(2,4,6-trinitroanilino)-carbazole, $C_{18}H_{11}N_5O_6$, has been determined by X-ray diffraction. Crystals are monoclinic, space group $P2_1/c$, a = 14.686(11), b = 24.601(12), c = 10.047(5) Å, β = 107.76(5)° at 292 K, with Z = 8. The two nitrogen atoms in the central fragment have a staggered conformation with an N—N distance of 1.381(4) Å, which is considerably shorter than N—N distances in related *N*-picrylhydrazine molecules. The picryl moiety has a geometry similar to that of related *N*-picrylhydrazine molecules. The title compound contains an N—H···O intramolecular bond to one of the *ortho* nitro groups on the picryl ring. The carbazole plane of one molecule and the picryl plane of a neighboring molecule overlap to form an infinite linear chain of the form...DhA:DhA...where D represents the carbazole donor, h the linear chain linkage within the molecule, and A represents the picryl acceptor of one molecule. The two interplanar distances between D of one molecule and A of an adjacent molecule are 3.28(13) and 3.34(13) Å, indicating a strong π-molecular interaction.

HONG WANG, RICHARD J. BARTON, BEVERLY E. ROBERTSON, JOHN A. WEIL et KEITH C. BROWN. Can. J. Chem. **65**, 1322 (1987).

On a déterminé la structure cristalline du (trinitro-2,4,6 anilino)-9 carbazole, $C_{18}H_{11}N_5O_6$, par diffraction des rayons-X. Les cristaux sont monocliniques, groupe d'espace $P2_1/c$, a = 14,686(4), b = 24,601(12) et c = 10,047(5) Å, β = 107,76(6)° à 292 K et Z = 8. Les deux atomes d'azote du fragment central sont dans une conformation décalée et la distance N—N de 1,381(4) Å est beaucoup plus courte que les distances N—N observées dans les molécules de *N*-picrylhydrazines apparentées. La portion picryle possède une géométrie qui est semblable à celle des molécules de *N*-picrylhydrazines apparentées. Le composé mentionné dans le titre possède une liaison N—H...O intramoléculaireimpliquant un des groupements nitro en position ortho du cycle picryle. Le plan du carbazole d'une molécule et le plan du picryle d'une molécule voisine se recouvrent pour former une chaîne linéaire de la forme...DhA:DhA...dans laquelle D représente le donneur carbazole, h représente la liaison linéaire de la chaîne à l'intérieur de la molécule et A représente l'accepteur picryle d'une molécule. Les deux distances entre les plans du D d'une molécule et du A de la molécule adjacente sont de 3,28(13) et 3,34(13) Å; ceci indique qu'il existe une interaction moléculaire π qui est forte.

[Traduit par la revue]

Introduction

2,2-Diaryl-1-picrylhydrazine compounds and related hydrazyl and hydrazinate compounds have been studied extensively because of the importance of the stable free radicals as standards in epr spectroscopy and as chemical reagents. 2,2-Diphenyl-1-picrylhydrazyl itself adopts a variety of polymorphic forms, often involving co-crystallized solvent (1). The hydrazine and related hydrazinate compounds have been studied by ^{1}H nmr (2, 3). The free radicals have been studied by various epr techniques (4, 5). The present analysis is one of a series of studies of the structures of these compounds. The structure of a hydrazinate has also been reported (6).

Experimental

$C_{18}H_{11}N_5O_6$ mw = 393.31

Monoclinic, space group $P2_1/c$, a = 14.686(11), b = 24.601(12), c = 10.047(5) Å, β = 107.76(5)°, T = 292 K, V = 3457 Å^3, Z = 8, D_x = 1.511 g cm^{-3}, μ(Mo Kα) = 1.26 cm^{-1}, λ = 0.71069 Å, F(000) = 1616.

9-Nitrosocarbazole was prepared by reacting carbazole with sodium nitrite in a mixture of acetic acid and water below 10°C. 9-Aminocarbazole was prepared by reducing the 9-nitrosocarbazole with lithium aluminum hydride. Picryl chloride was prepared by reacting picric acid with pyridine in ethanol followed by treatment of the precipitate with phosphorus oxychloride in refluxing benzene. The 9-aminocarbazole was fused with the picryl chloride in chloroform at 62°C. 9-(2,4,6-Trinitroanilino)-carbazole was recrystallized from ethanol and then from benzene.

An orange crystal with dimensions 0.60 × 0.10 × 0.16 mm was selected for X-ray study. The space group was determined to be $P2_1/c$ from precession photographs. The lattice constants were obtained by least-squares refinement using 30 reflections with 36° < 2θ < 45°. Data collection was carried out on a modified Picker four-circle diffractometer with graphite-monochromated Mo Kα radiation. Three reflections were measured as reference reflections after every 47 reflections. A total of 5559 reflections were collected with 3° ≤ 2θ ≤ 48°, 3140 of which were considered to be observed with $I \geq 2\sigma(I)$ ($\sigma(I)$ is the standard deviation of the intensity derived both from the counting statistics of the individual reflection, and the machine instability factor).

Intensity data were corrected for Lorentz-polarization effects. No corrections were made for absorption, dispersion, or extinction effects. Direct methods were used to solve the structure. A total of 2001 Σ_2 relations were generated using 641 reflections with $E > 1.75$. The coordinates of 42 non-hydrogen atoms in the two molecules were determined from the best E-map. The positions of all remaining non-hydrogen atoms were identified in the electron density Fourier map. After initial refinement, all hydrogen atoms were assigned positions 1.0 Å from their attached atoms. The final structure was refined by full-matrix least-squares with anisotropic temperature factors for non-hydrogen atoms and isotropic temperature factors for hydrogen atoms using 3140 observed reflections. The number of least-squares variables was 611. The weights used in the least-squares refinement were $w = (\sigma_c^2 + \sigma_m^2)^{-1}$ where σ_c is derived from $\sigma(I)$ and σ_m is chosen to make the average value of $w\Delta^2(F)$ independent of $|F_o|$ and sin θ/λ (7). The final agreement factors were R = 0.048,

*Atoms numbered greater than 20 belong to molecule **II** and are chemically equivalent to atoms in molecule **I** numbered less by 20.

$\omega R = 0.030$. XTAL crystallographic system of programs (8) was used for all calculations.

Discussion

Molecular structure

The atomic parameters, with standard deviations in parentheses, for the two independent molecules, labeled molecule **I** and molecule **II**, are listed in Table 1.[2] The atom numbering and a view of one of the two independent molecules are given in Fig. 1. Selected bond lengths and bong angles are given in Table 2.

As indicated earlier, this structure was refined with modified weights. The procedure used differs from the normal practice of adding a term proportional to $|F^2|$ or $\sin\theta/\lambda$ to $\sigma^2(F)$ in the numerator of the expression for the weights only in that it is more precise. Based on a comparison of refinement procedures, we have concluded that structures refined with modified weights tend to be more accurate than those refined with purely $\sigma^2(F)$ weights, but that the estimated standard deviations should be treated as estimates of the lower limit of the true standard deviation (7). A comparison of the differences between equivalent bond lengths in Table 2 suggests that the true esd's are no greater than two times those given by the data analysis. There is no significant difference in the geometry of the two molecules. In what follows the first and second quantities refer to molecule **I** and molecule **II**, respectively.

The C(1)—N(4) and C(21)—N(24) bond lengths, 1.355(4) and 1.361(4) Å, are shorter than a C—N single bond length (1.479 Å) and very close to the C—N partial double bond length (1.352 Å), which suggests that the lone-pair electrons of N(4) and N(24) are delocalized over the picryl rings. The Newman projection along the N(4)—N(5) and N(24)—N(25) linkages are shown in Fig. 2. The arrangement of atoms around the N atoms shows an approximately staggered conformation, caused by the spatial repulsion between the carbazole plane and picryl plane. Both N atoms of a molecule are sp^2 hybridized and one of them is conjugated to the aromatic system of the picryl moiety and the other to the carbazole moiety. The N(4)—N(5) and N(24)—N(25) bond lengths, 1.381(3) and 1.380(4) Å, suggest that they are single bonds with some limited double bond character. This is consistent with the observation that the staggered conformation is only approximated, i.e., the angles in Fig. 3 are not exactly 90°.

The H atoms on N(4) and N(24) form an intramolecular hydrogen bond to O(1) and O(21), respectively. The N(4)···O(1) and N(24)···O(21) distances are 2.596(4) and 2.608(4) Å which indicates a strong hydrogen bond, consistent with the ^{1}H nmr findings (9).

The conformation of the picryl moiety in 9-(2,4,6-trinitroanilino)-carbazole is quite different from that of related picryl hydrazyl and hydrazinate compounds. Due to the intramolecular hydrogen-bonding in 9-(2,4,6-trinitroanilino)-carbazole, the *ortho* nitro group involved in the hydrogen bond is coplanar with the picryl ring. The other *ortho* nitro group is twisted from the phenyl plane with dihedral angles of 59.4(1) and 64.2(2)°, because of steric repulsion from the carbazole moiety. The *para* nitro group is approximately coplanar with the phenyl plane. Selected dihedral angles are listed in Table 3.

[2]Lists of structure factor amplitudes, anisotropic thermal parameters, H-atom coordinates. Least-squares planes, and bond distances and angles may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

6—7	3.3(1)	2.2(1)

*See Fig. 3.

Bearing in mind the aforementioned qualifications concerning the interpretation of the estimated standard deviations of the bond lengths and angles, the structure of the carbazole moiety is not significantly different from that of the carbazole molecule (10).

Molecular packing

The molecular packing diagram for a complete unit cell is shown in Fig. 4. The carbazole planes of one molecule overlap with the picryl planes of an adjacent molecule forming infinite chains. The two modes of overlap of one molecule with an adjacent molecule are shown in Fig. 5. The distance between the carbazole plane and the picryl plane is 3.28(13) Å in mode 1 and 3.34(13) Å in mode 2. The standard deviations in the interplanar spacings are $[\Sigma_i(l_i - \bar{l})^2/n - 1]^{1/2}$ where $\bar{l} = \Sigma_i l_i/n$ and l_i is the distance of the ith atom of the carbazole moiety from the plane of the six carbon atoms in the neighboring picryl moiety. This is similar to equivalent distances in related donor–acceptor (D:A) species of aromatic π-electron systems. In the D:A complex between carbazole and trinitrobenzene, the two independent interplanar distances are 3.37 and 3.38 Å (11).

This suggests that there is a strong π-molecular interaction between the picryl plane (A) of one molecule and carbazole plane (D) of an adjacent molecule. Therefore, 9-(2,4,6-trinitroanilino)-carbazole forms crystals containing single component donor–acceptor chains of the form ···DhA:DhA:DhA···, where

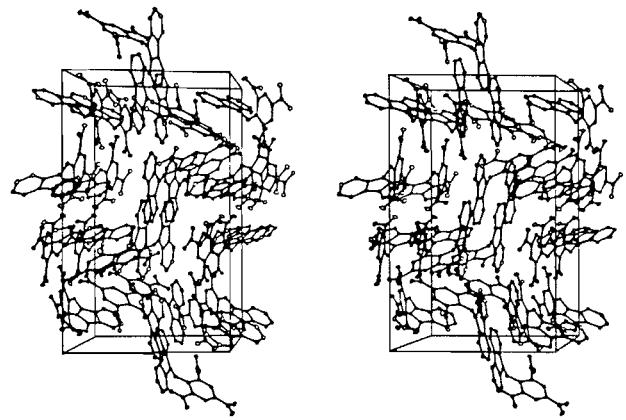

FIG. 4. ORTEP stereoscopic view of the unit cell, viewed along the *c* axis.

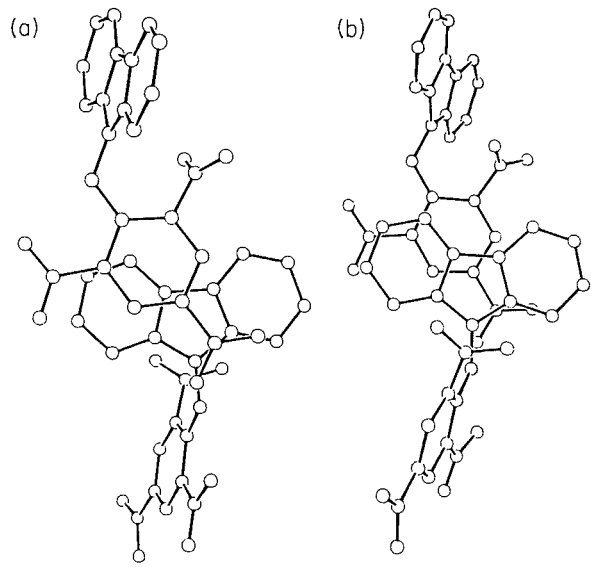

FIG. 5. The molecular overlap diagrams looking normal to the plane (*a*) mode 1; (*b*) mode 2.

the symbol h denotes the chain linkage between the donor and acceptor moieties within one molecule, which involves the hydrazine moiety. The internal degrees of freedom of one molecule do not permit the carbazole and picryl moieties to be coplanar. Therefore it is difficult to form an infinite linear chain with one independent molecule in the unit cell. The angles between the chain axis, [101], and the normals to the planes of the two picryl rings are 124.56(8)° and 58.40(4)°.

It has been suggested by Aviram and Ratner (12) that DσA molecules (σ representing a σ bond in the linkage between the donor and acceptor) might form a molecular crystal with the properties of a molecular rectifier. It would be necessary for the molecules to pack in the crystal with the donor and acceptor parts of one molecule in the same chain, and for the chains to all be of the same polarity. The structure reported here fulfils the first requirement but not the second. The lowest order bonds joining the donor and acceptor moieties of the molecule (N(4)—N(5) and N(24)—N(25)) are clearly not pure σ bonds, but they approximate σ bonds. It may be possible to modify 9-(2,4,6-trinitroanilino)-carbazole to force a more appropriate packing mode.

The unusual packing in this structure obviously owes its

For personal use only.

existence to the C(12)—C(13) and C(32)—C(33) bonds, which force the two phenyl rings to be nearly co-planar, creating a flat three-ring aromatic donor moiety suitable for π-molecular donor–acceptor interaction with the picryl acceptor moiety.

Notes on the directed aldol synthesis and reduction of some compounds related to cycloheximide

DAVID M. PIATAK[1] AND PUI-FUN LOUISA TANG
Department of Chemistry, Northern Illinois University, DeKalb, IL 60115, U.S.A.

Received September 25, 1986

DAVID M. PIATAK and PUI-FUN LOUISA TANG. Can. J. Chem. **65**, 1327 (1987).

Several *N*-phenylcycloheximide analogues were prepared by $TiCl_4$-promoted aldol condensation between trimethylsilyl enol ethers of cyclic ketones and (*N*-phenylglutarimide)-β-acetaldehyde. Favored stereoisomers were isolated in several instances and identified from nuclear magnetic resonance data. Only for the analogue from 4-*tert*-butylcyclohexanone was it possible to obtain both *erythro* and *threo* isomers. Catalytic reduction of the β-hydroxyketone system over PtO_2 gave dihydrocycloheximide analogues possessing an axial ring hydroxyl group. Reduction in glacial HOAc was noted as promoting fission of the glutarimide ring with formation of lactone amides and, in several instances, concomitant reduction of the phenyl ring to a cyclohexyl group.

DAVID M. PIATAK et PUI-FUN LOUISA TANG. Can. J. Chem. **65**, 1327 (1987).

On a préparé plusieurs analogues de la *N*-phénylcycloheximide en procédant à la condensation aldolique, catalysée par le $TiCl_4$, d'éthers énoliques triméthylsilyles de cétones cycliques et de (*N*-phénylglutarimide)-β-acétaldéhyde. Dans plusieurs cas, on a isolé les stéréoisomères les plus favorisés et on les a caractérisés par la résonance magnétique nucléaire. L'analogue de la *tert*-butyl-4 cyclohexanone est le seul cas où l'on a pu isoler les isomères tant *érythro* que *thréo*. La réduction catalytique du système β-hydroxycétonique, à l'aide de PtO_2, conduit aux analogues dihydrocycloheximides possédant un groupement hydroxyle axial. On a noté que la réduction dans l'acide acétique glacial favorise une fission du noyau glutarimide qui conduit à la formation d'amides lactoniques et, dans plusieurs cas, à une réduction concomitante du noyau phényle en groupement cyclohexyle.

[Traduit par la revue]

Our prior work (1) with analogues of the antibiotic and DNA biosynthetic inhibitor cycloheximide **1***a* indicated that these compounds held some promise as potential anticonvulsants. A general synthetic procedure leading regio- and stereospecifically to the requisite β-hydroxyketone functionality was sought, since the previous methods we used were not as simple and direct as we had hoped. We began by examining the $TiCl_4$-promoted directed aldol condensation procedure, initially described by T. Mukaiyama *et al.* (2), to develop an efficient strategy for the synthesis of additional analogues whereby the cyclohexane ring substituents and (or) the imide ring portion of the molecule could be varied before introducing the β-hydroxyketone system. Recently, S. Kudo *et al.* (3, 4) used titanium and tin halide mediated methods to prepare optically active *trans*-cycloheximide isomers and chiral *cis*-cycloheximide isomers for antimicrobial activity studies. Thus, the method offered promise.

Our initial experience with the Mukaiyama procedure using the glutarimide-β-acetaldehyde (5) was unsatisfactory as we were unable to effect adequate protection of the imide group with benzyl chloride. Direct reaction of the imidealdehyde and 6-methyl-1-trimethylsiloxycyclohexene employing 2 equiv. of $TiCl_4$ to overcome its deactivation gave only a 3.3% yield of product **1***b*, isolated as the acetate.[2] The product was readily identified by its spectral data and contained an isomeric mixture as indicated by ^1H nmr doublets at δ 1.0 (J = 6.35) and 1.16 (J = 7.2) for the C-2 methyl group.

Studies were then continued with *N*-phenylglutarimide-β-acetaldehyde since the *N*-phenyl substituent should provide the necessary imide protection needed for the aldol condensation process. At the same time, this group should afford products containing a substituent that has been a feature of some biologically interesting glutarimides (6, 7). *N*-Phenylglutarimide-β-acetaldehyde was readily synthesized by starting with methanetriacetic acid (8) and one equivalent of aniline, converting the imideacid to the acid chloride, and then reducing the corresponding acid chloride by the Rosenmund procedure. The silylated enol ethers were available from the corresponding cyclohexanones and cyclopentanone by standard procedures (9), and their purity was established from nmr data.

The $TiCl_4$-promoted aldol condensation proceeded smoothly with the cyclohexanone enol ethers and the *N*-phenylglutarimide aldehyde at −78°C as described by Mukaiyama (2). The reaction mixtures crystallized upon standing and the products were recrystallized to afford purified materials (see Table 1). Although the quantity of recovered crystalline product was not high, overall yields averaged 60–70%, as tlc of the mother liquors often indicated only a single material with an R_f value identical to the recrystallized material. The products were generally characterized by three distinct ir carbonyl absorptions at about 1725, 1700, and 1680 cm^{-1} for the ketone and cyclic imide moieties as well as bands at 3555–3510 cm^{-1} for the hydroxy group. Also, two nmr multiplets at δ 7.1 and 7.4, equal to two and three protons in area, respectively, represented the aromatic ring protons as influenced by the proximity of the imide carbonyl groups. Further analysis of the nmr spectra of the crude products in many cases indicated the presence of isomers, as evidenced by two signals (about δ 4.2 and 3.85) for the carbinol proton and by more than one methyl doublet, for products originating from methylcyclohexanones. Attempts to effect a separation and isolation of individual isomers were not successful although recrystallization did result in the isolation of a single racemic isomer in some instances and in two separate *tert*-butyl analogue isomers **2***a*,*b*. The latter isomers nevertheless had tlc R_f values identical with one another and with the crude reaction product. This latter reaction also led to a small amount of an anhydro product **3**, which might be expected from dehydration of the aldol product.

The lack of high stereoselectivity was not surprising since

[2]During this project we became aware of the work by S. Kudo *et al.* (refs. 3 and 4), in which they used the unprotected imidealdehyde with the *trans* and *cis* forms of 4,6-dimethyl-1-trimethylsiloxycyclohexene to achieve condensation yields of 18.3 and 10.8%, respectively.

[a]No attempt was made to effect complete recovery of all isomers owing to similar tlc properties.
[b]From CH_2Cl_2–ether.
[c]Isolated only after extensive chromatography of the acetylated crude reaction mixture.
[d]From CH_2Cl_2.
[e]From acetone.

Mukaiyama *et al.* (2) and Heathcock *et al.* (10) have reported Lewis acid catalyzed aldol condensations to give poor diastereoselectivity. Nonetheless, the preferential formation of some isomers might ensue (2) when steric hindrance is encountered between the trimethylsiloxy group of the cyclohexene and a substituent at position 6. Kudo *et al.* (3, 4), for example, found a favored isomer to prevail in their work on 4,6-dimethyl-1-trimethylsiloxycyclohexenes.

Stereochemical identification of the isolated compounds was established through ^1H nmr data for the carbinol proton and for the cyclohexane ring methyl groups. For 1-methyl **2***c*, 4-methyl **2***d*, and 3,5-dimethyl **2***e* aldol products a multiplet at ca. δ 3.9 established a *threo* relationship between the glutarimide side chain attachment and the alcohol. Because of its bulk, the side chain was assumed to orient itself in the equatorial conformation on the cyclohexanone ring. Analysis of the methyl group signals for **2***c* revealed equatorial and axial epimers from two doublets at δ 1.03 and 1.19. Acetylation of crude product from the C-2 methyl reaction permitted the isolation of a *threo* product **2***f* with an equatorial methyl, albeit in poor yield. The C-4 methyl product **2***d* exhibited only one methyl doublet at δ 1.19 (J = 6.7) indicative of an axial configuration (the axial C-4 methyl of cycloheximide is found at δ 1.25 with J = 6.9), and, as expected, the 3,5-dimethyl analogue **2***e* had two separate doublets at δ 1.04 and 1.12 for various combinations of methyl group orientations.

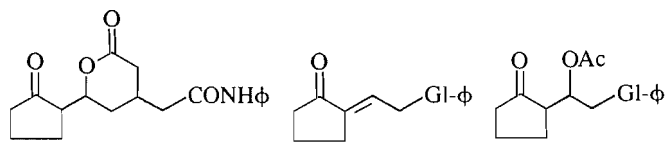
[a]This product was recrystallized from acetone, while EtOAc was used for all others.

Proton nmr data for the 2,4-dimethyl analogue **2***g* fit best with a *cis* dimethyl configuration (δ 1.0 and 1.08) for the cyclohexane ring methyls (4) and with an unassigned hydroxyl group orientation owing to a broad signal at δ 4.0. Without a methyl group on the cyclohexane ring to influence the course of the reaction as in the normethyl product **2***h*, stereospecificity should be lost and an equimolar mixture of isomers would be expected. The crystalline product, however, was a mixture of *threo* and *erythro* isomers in a 1:3 ratio, as determined from integration of the nmr multiplet at δ 3.85 for the *threo* isomer and the doublet at δ 4.2 for the *erythro* form.

In the case of the two separate *tert*-butyl analogue isomers, the *erythro* form **2***a* was readily ascertained by observation of a doublet at δ 4.25 for the proton on the carbinol carbon and the *threo* product **2***b* by a multiplet centered at δ 3.82. These assignments were supported by ^{13}C nmr spectra in which the hydroxyl carbon was at δ 66.77 for **2***a* and at δ 69.23 for **2***b*. Cycloheximide with its *erythro* configuration has this carbon atom absorption (11) at δ 66.5. In addition, ^1H nmr spectra of the corresponding acetates recorded first in $CDCl_3$, then C_6D_6, revealed an upfield shift from δ 5.35 to 5.29 for the *erythro* **2***a* acetate similar to the shift for cycloheximide acetate (δ 5.34 to 5.30), while a downfield shift from δ 5.39 to 5.41 was observed for the *threo* **2***b* acetate.

Use of cyclopentanone, the only non-cyclohexane type ketone employed, gave a crude product with a significant nmr signal at δ 6.5 indicative of a vinylic proton. Acetylation and tlc separation of the mixture led to three distinct compounds. The least mobile was identified as lactone amide **4**, primarily from ir bands at 3350 cm^{-1} for the NH, at 1680 and 1540 cm^{-1} for the amide I and II absorptions, and at 1725 cm^{-1} for the lactone carbonyl. Lactones of this type have been reported (12) to arise from glutarimide antibiotics under strongly acidic or basic conditions, and we encountered the same in our prior



4 **5** **6**

work (1). The second compound was the unsaturated ketone **5**, characterized by ir peaks at 1730, 1710, 1689, and 1645 cm^{-1}, a uv maximum at 242 nm, and an nmr signal at δ 6.5 (m, 1H) for the vinylic proton. The most mobile compound on tlc was the anticipated product **6**. Major ir absorptions were evident at 1735, 1705, 1670, and 1250 cm^{-1} while nmr signals were seen at δ 5.96 (t, 1H) and 2.04 (s, 3H), supporting this assignment. The acetoxy moiety was found to eliminate readily, making isolation difficult.

To provide dihydrocycloheximide analogues, the aldol condensation products were reduced catalytically, essentially as before (1), except 5–10% HOAc–EtOAc was substituted for the glacial HOAc solvent to avoid appreciable glutarimide ring fission. The diols normally crystallized from the reaction mixture in an average yield of 60% and were characterized by their differences in the hydroxyl group region of the infrared, and by nmr signals at δ 4.0–4.3 for the proton on the ring hydroxyl carbon and at δ 3.4–3.8 for the proton on the side chain hydroxyl carbon (see Table 2). From the former nmr absorptions the ring hydroxyl group is considered to be axial, in agreement with previous stereochemical studies (13) on the reduction of cycloheximide and with our observations (1) on the reduction of dehydrocycloheximide compounds.

Analysis of the nmr signals for the methyl groups indicated that the 2-methyl diol **7***a* had an equatorial methyl, a result different from the parent compound in which both equatorial and axial methyl signals were observed. This orientation is

9

probably a consequence of equilibration by an α-alkyl ketone in an acidic medium during a rather slow reduction. For the other diols the methyl group stereochemistry, as indicated by nmr, remained as observed in the aldol products, i.e., axial in the C-4 methyl diol **7***b*, a combination of both orientations in the 3,5-dimethyl analogue **7***c*, and diequatorial (*cis*) in the dihydrocycloheximide type compound **7***d*. For the *tert*-butyl analogues the reduction went smoothly and in good yield to afford the axial-*erythro* **7***f* and the axial-*threo* **7***g* diols with appropriate spectral characteristics.

Some unusual products, however, were obtained when the catalytic reductions were performed in glacial HOAc on material contained in the mother liquors, which were identical to crystalline material by tlc. These experiments prompted employment of a less acidic solvent for later reduction work. For example, the 2,4-methyl aldol product **2***g* mother liquors yielded the expected diol **7***d* but also hydroxy lactone **8***a* and keto lactone **8***b*. The acetoxy lactone **8***c*, characterized from the absence of aromatic proton signals in an nmr spectrum and correct C, H, N data, was not expected, however, since these hydrogenation conditions are not normally associated with reduction of an aromatic ring.

Hydrogenation of material from the 2-methyl aldol product **2***g* mother liquors under identical conditions, followed by acetylation to facilitate separation, also afforded similar aromatic ring reduced lactones **8***d* and **8***e*. Both were characterized from the absence of aromatic peaks in ir and nmr spectra and the presence of typical hydroxy, acetoxy, lactone, and amide ir bands, from analytical data, and from nmr proton integration. The acetoxy imide **9** was also isolated and was characterized from analytical and spectral data. This latter compound undoubtedly results from reduction of the α,β-unsaturated ketone (similar to **3**), which can be produced by acidic or basic dehydration of an aldol condensation product.

Experimental

Melting points were taken on a Fisher–Johns apparatus and are uncorrected. Infrared (ir) spectra were obtained with a Sargent–Welch 3-200 infrared spectrophotometer on solids incorporated into KBr wafers or on neat liquid samples. The nmr spectra were obtained on an IBM-NR 80 spectrometer on samples dissolved in $CDCl_3$ containing TMS as internal standard, unless otherwise noted. Ultraviolet spectra were recorded with a Varian 2290 spectrophotometer.

Precoated thin-layer chromatography (tlc) sheets of silica gel 60 F_{254} from EM Reagents were used for qualitative tlc, while preparative tlc was performed on 0.5-mm plates of silica gel PF_{254}.

N-*Phenyl-4-carboxymethyl-2,6-piperidinedione*

A solution of methanetriacetic acid (8) (8.87 g; 4.56 mmol), water (2 mL), and aniline (4.46 mL; 1 equiv.; distilled from zinc) was slowly heated to 180–200°C, then maintained at that tempeature for 1 h. The liquid materials were removed at 170°C/0.3 Torr (1 Torr = 133.3 Pa) and the residue was taken up in EtOAc and filtered. Concentration of the filtrate gave crystals, which were recrystallized to afford 8.54 g (81%); mp 200–201.5°C; ir: 3500–2600, 1730, 1670, 1600, 1490 cm^{-1}; nmr δ: 7.4 (m, 3H), 7.2 (m, 2H). *Anal.* calcd. for $C_{13}H_{13}NO_4$: C 63.15, H 5.30, N 5.66; found: C 63.24, H 5.31, N 5.82.

N-*Phenyl-4-carbonylmethyl-2,6-piperidinedione*

The *N*-phenylimidyl acid (5.92 g) and $SOCl_2$ (59 mL) were heated at reflux for 0.5 h until the solids dissolved, then the excess $SOCl_2$ was removed *in vacuo*. The resultant crystals were washed with dry benzene to afford 5.53 g (86.9%) of intermediate acid chloride; mp 115–117°C; ir: 1810, 1730, 1675 cm^{-1}.

The acid chloride, dry toluene (280 mL), and 5% $Pd/BaSO_4$ (2.24 g) were placed into a flask, hydrogen was introduced into the solution through a gas diffusion tube, and the mixture was heated to reflux. The excess H_2 and other gases were passed through a standardized NaOH solution until the evolution of HCl essentially stopped (5 h; 82.5% of theoretical). Removal of the catalyst and concentration of the filtrate yielded 4.01 g (83.2%) of crystals. Recrystallization from $CHCl_3$ gave colorless crystals (3.64 g; 75.7%) of the desired *N*-phenylimidyl aldehyde; mp 113–115°C; ir: 2850, 2745, 1730, 1710 cm^{-1}; nmr δ: 9.8 (s, 1H), 7.4 (m, 3H), 7.01 (m, 2H), 3.1–2.5 (7H). *Anal.* calcd. for $C_{13}H_{13}NO_3$: C 67.52, H 5.67, N 6.05; found: C 67.80, H 5.84, N 5.95.

Preparation of N-*phenylcycloheximide analogues*

In a typical experiment, a solution of the *N*-phenylimidyl aldehyde (1 g, 4.32 mmol) in CH_2Cl_2 (20 mL) at −78°C was treated with $TiCl_4$ (0.48 mL; 1 equiv.). The trimethylsilyl enol ether of 4-*tert*-butylcyclohexanone (1 equiv.) was added slowly, and the reaction was stirred at −78°C for 3 h, then at ambient temperature for 3 h. An ice–water mixture was used to quench the reaction, and the product was isolated by extraction with ether. Fractional recrystallization of the ether residue from acetone yielded first the *erythro tert*-butyl analogue **2***a* (310 mg; 18.7%); mp 184.5–187°C; ir: 3555, 1732, 1700, 1678, 1590, 1490 cm^{-1}; nmr δ: 7.4 (m, 3H), 7.1 (m, 2H), 4.25 (d, 1H, J = 10.9), 3.2–1.4 (16H), 0.95 (s, 9H); ^{13}C nmr δ: 66.77 (*C*HOH). *Anal.* calcd. for $C_{23}H_{31}NO_4$: C 71.66, H 8.11, N 3.63; found: C 71.52, H 8.15, N 3.85.

The *threo* analogue **2***b* was then isolated as colorless crystals (174 mg; 10.5%); mp 178–180.5°C; ir: 3540, 1730, 1700, 1680, 1590, 1490 cm^{-1}; ^1H nmr δ: 7.4 (m, 3H), 7.1 (m, 2H), 3.82 (br m, 1H), 3.2–1.3 (16H), 0.95 (s, 3H); ^{13}C nmr δ: 69.23 (*C*HOH). *Anal.* found: C 71.84, H 8.28, N 3.91.

Chromatography of the mother liquors by preparative tlc (50% EtOAc–hexane) gave 100 mg (6.0%) of anhydro compound **3**; mp 144–146°C; uv_{max}: 243 (ε 7680), sh 280–286 nm; ir: 1734, 1700, 1680, 1600 cm^{-1}; ^1H nmr δ: 7.4 (m, 3H), 7.1 (m, 2H), 6.58 (t, 1H),

3.1–1.25 (14H), 0.96 (s, 9H). *Anal.* calcd. for $C_{23}H_{29}NO_4$: C 75.17, H 7.95, N 3.81; found: C 74.86, H 8.11, N 3.78.

Each of the isomers was acetylated by acetic anhydride – pyridine to afford the corresponding acetate, which was recrystallized from EtOAc.

Erythro **2***a* acetate: mp 142.5–144°C; ir: 1740, 1710, 1678, 1240 cm^{-1}; ^1H nmr δ: 7.4 (m, 3H), 7.15 (m, 2H), 5.35 (m, 1H), 2.08 (s, 3H), 0.93 (s, 9H); ^1H nmr (C_6D_6) δ: 5.29 (m, 1H), 1.83 (s, 3H), 0.79 (s). *Anal.* calcd. for $C_{25}H_{33}NO_5$: N 3.28; found: N 2.95.

Threo **2***b* acetate: mp 131–132.5°C; ir: 1735, 1710, 1680, 1235 cm^{-1}; ^1H nmr δ: 7.4 (m, 3H), 7.1 (m, 2H), 5.39 (m, 1H), 2.09 (s, 3H), 0.95 (s, 9H); ^1H nmr (C_6D_6) δ: 5.41 (m, 1H), 1.8 (s, 3H), 0.78 (s). *Anal.* found: N 3.61.

Data for other aldol condensation products are in Table 1.

Directed aldol condensation with cyclopentanone enol ether

The *N*-phenylglutarimidyl aldehyde (0.76 g; 3.3 mmol) in CH_2Cl_2 (20 mL) at −78°C was treated with $TiCl_4$ (0.36 mL; 1 equiv.), then with 1-trimethylsilyloxycyclopentene (0.54 g; 1 equiv.). After the reaction mixture was stirred for 3 h, it was stirred at room temperature for another 3 h. Extraction with ether following ice–water quenching gave a crude oil (0.61 g), which was acetylated by acetic anhydride – pyridine and separated by preparative tlc (5% MeOH–$CHCl_3$) into three fractions.

The least mobile fraction (R_f 0.11) was determined to be amide lactone **4** (0.1 g); ir: 3350, 1725, 1715, 1680, 1545 cm^{-1}; nmr δ: 7.4, 7.1, 6.5, 5.3.

The next fraction (R_f 0.23) was recrystallized from ether–CH_2Cl_2 to yield pure unsaturated ketone **5** (0.12 g); mp 138–139°C; uv_{max}: 242 (ε 13 200), sh 275 nm; ir: 1730, 1710, 1689, 1645 cm^{-1}; nmr δ: 7.47 (m, 3H), 7.02 (m, 2H), 6.5 (m, 1H). *Anal.* calcd. for $C_{18}H_{19}NO_3$: C 72.71, H 6.44, N 4.71; found: C 72.58, H 6.44, N 4.99.

The most mobile material (R_f 0.38) was the acetylated aldol product **6**, which crystallized from ether to give 0.02 g; mp 108–109.5°C; ir: 1735, 1705, 1670, 1250 cm^{-1}; nmr δ: 7.4 (m, 3H), 7.1 (m, 2H), 5.96 (m, 1H), 2.04 (s, 3H). *Anal.* calcd. for $C_{20}H_{23}NO_5$: N 3.92; found: N 4.35. The product lost the acetate moiety readily.

Reduction of aldol condensation products

In a typical experiment a mixture of the 2,4-dimethyl analogue **2***g* (40 mg), PtO_2 (50 mg), and 10% HOAc–EtOAc (20 mL) was shaken under 50 psi (1 psi = 6.9 kPa) of H_2 for 26 h. Fresh catalyst was added (50 mg) and shaking was continued for 16 h. The catalyst was collected on Celite, and the filtrate was washed with dilute $NaHCO_3$, then with water, and dried. Removal of the EtOAc gave an oil (42 mg) that crystallized upon standing. Recrystallization from EtOAc yielded 19.1 mg (47.5%) of diol **7***d*; mp 130–135°C; ir: 3500, 3380, 1725, 1675 cm^{-1}; nmr δ: 7.4 (m, 3H), 7.1 (m, 2H), 4.18 (br m, 1H), 3.48 (br, 1H), 1.01 (d, 3H, J = 6.35), 0.84 (d, 3H, J = 6.4). *Anal.* calcd. for $C_{21}H_{29}NO_4$: C 70.17, H 8.13, N 3.90; found: C 69.81, H 8.47, N 3.73.

Data for other diols are given in Table 2.

Reduction of N*-phenyl-2,4-dimethyl analogue* **2***g mother liquors in HOAc*

A mixture of the mother liquor (0.41 g), (identical to crystalline material by tlc) from the condensation reaction leading to **2***g*, PtO_2 (55 mg), and glacial HOAc (15 mL) was stirred under H_2 (44 psi) for 22 h. The catalyst was removed and the filtrate was diluted with EtOAc, then washed with dilute $NaHCO_3$ and water. The crude product (0.42 g) was purified by flash chromatography into three fractions. The least polar fraction (9 mg) was determined to be diol **7***d* by comparative spectral data.

The second fraction was separated into two lactones by preparative tlc (40% EtOAc–hexane; two dips). The more polar fraction gave hydroxy lactone **8***a* as colorless crystals from $CHCl_3$ (13.7 mg); mp 165–167°C; ir: 3500, 3320, 1720, 1662, 1525 cm^{-1}; nmr δ: 7.4 (m, 3H), 7.1 (m, 2H), 4.37 (br, 1H), 3.73 (m, 1H), 0.96 (d, 3H, J = 2.8), 0.92 (d, 3H, J = 3.4). *Anal.* calcd. for $C_{21}H_{29}NO_4$: C 70.17, H 8.13, N 3.90; found: C 69.95, H 8.46, N 3.95.

The less polar lactone was keto lactone **8***b* (13.2 mg); mp 164–170°C; ir: 3300, 1720, 1700, 1655, 1535 cm^{-1}; nmr δ: 7.5 (m, 3H), 7.3 (m, 2H), 4.7 (br m, 1H), 3.35 (d, 1H), 3–1.4 (14H), 1.0 (d, 6H, J = 6.35). *Anal.* calcd. for $C_{21}H_{27}NO_4$: C 70.56, H 7.62, N 3.92; found: C 70.61, H 7.52, N 4.05.

A third column fraction furnished acetoxy lactone **8***c* (10 mg); mp 160.5–163°C; ir: 3280, 1730, 1710, 1675, 1630 cm^{-1}; nmr δ: 5.5 (br, 1H), 4.6 (br, 1H), 3.75 (br, 1H), 2.01 (s, 3H), 2.8–1.2 (28H), 1.0 (d, 6H, J = 4.1). *Anal.* calcd. for $C_{23}H_{37}NO_5$: C 67.78, H 9.15, N 3.44; found: C 67.55, H 9.45, N 3.95.

Reduction of 2-methyl analogue **2***c mother liquors in HOAc*

Mother liquors from preparation of 2-methylcycloheximide analogue **2***c* (0.67 g), which were identical by tlc to crystalline material, were reduced over PtO_2 (100 mg) in glacial HOAc (20 mL) as above. The crude product was acetylated by Ac_2O–pyridine as usual and then separated by preparative tlc (3% MeOH–$CHCl_3$; two dips) into five fractions. Three fractions crystallized and were identified.

The least mobile fraction gave hydroxy lactone **8***d* (11 mg); mp 167–169.5°C; ir: 3460, 3330, 1715, 1655, 1530 cm^{-1}; nmr δ: 5.4 (br, 1H, lost with D_2O), 4.45 (br, 1H), 3.74 (m, 1H), 2.8–1.2 (27H), 0.96 (d, 3H, J = 5.7). *Anal.* calcd. for $C_{20}H_{33}NO_4$: C 68.34, H 9.45, N 3.98; found: C 68.55, H 9.54, N 4.18.

The second fraction was identified as acetoxy lactone **8***e* (10 mg); mp 175–176°C; ir: 3330, 1725, 1645, 1530, 1245 cm^{-1}; nmr δ: 5.4 (m, 1H), 4.2 (m, 1H), 3.7 (m, 1H), 2.07 (s, 3H), 2.7–1.0 (29H), 0.85 (d, 3H, J = 6.1). *Anal.* calcd. for $C_{22}H_{35}NO_5$: C 67.14, H 8.97, N 3.56; found: C 67.08, H 9.11, N 3.56.

The most mobile fraction (82 mg) gave 12 mg of acetoxy imide **9** from EtOAc; mp 149–150°C; ir: 1725, 1680, 1250 cm^{-1}; nmr δ: 7.4 (m, 3H), 7.2 (m, 2H), 5.13 (m, 1H), 2.09 (s, 3H), 3.1–1.1 (17H), 0.85 (d, 3H, J = 5.4). *Anal.* calcd. for $C_{22}H_{29}NO_4$: C 71.13, H 7.87, N 3.77; found: C 71.16, H 8.18, N 3.88.

The ^{59}Co nuclear magnetic resonance spectra of polycrystalline complexes

DONALD R. EATON,[1] RICHARD J. BUIST, AND BRIAN G. SAYER
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 3, 1986

DONALD R. EATON, RICHARD J. BUIST, and BRIAN G. SAYER. Can. J. Chem. **65**, 1332 (1987).

The solid state ^{59}Co nmr spectra of a number of octahedral complexes are reported. In the case of sodium hexanitrocobaltate(III) the spectra have been obtained at several different field strengths and the results are analysed to give a quadrupole coupling constant of 9.4 MHz, an asymmetry parameter of zero and an axial chemical shift tensor with an anisotropy of 180 ppm. Several other complexes have been examined at high field (11.8T) to minimize the effects of quadrupole coupling and maximize the influence of chemical shift anisotropy. The results are, where possible, compared with single crystal X-ray and low field nmr data. It is concluded that high fields are necessary to obtain reliable chemical shift anisotropy values. The conditions necessary for obtaining reasonable quality spectra from polycrystalline samples containing quadrupolar nuclei are discussed.

DONALD R. EATON, RICHARD J. BUIST et BRIAN G. SAYER. Can. J. Chem. **65**, 1332 (1987).

On rapporte les spectres rmn ^{59}Co, à l'état solide, d'un certain nombre de complexes octaédraux. Dans le cas de l'hexanitrocobaltate(III) de sodium, on a déterminé les spectres à plusieurs forces de champs et on a analysé les résultats pour déterminer la constante de couplage quadrupolaire qui est égale à 9,4 MHz, le paramètre d'asymétrie qui égal à zéro et un tenseur de déplacement chimique axial comportant une anisotropie de 180 ppm. On a examiné les spectres de plusieurs autres complexes à champ élevé (11,8T) pour minimiser les effets des couplages quadrupolaires et pour maximiser l'influence de l'anisotropie du déplacement chimique. Lorsque cela est possible, on compare les résultats avec ceux obtenus par diffraction des rayons-x sur un cristal unique ainsi que par rmn à bas champs. On en conclut que les hauts champs sont nécessaires pour obtenir des valeurs fiables pour l'anisotropie du déplacement chimique. On discute des conditions nécessaires pour obtenir des spectres de qualité raisonnable à partir d'échantillons polycristallins contenant des noyaux quadrupolaires.

Introduction

The introduction of cross polarization and magic angle spinning techniques (CPMAS) has lead to a large increase in interest in the nmr spectra of solid samples. The majority of these studies have been concerned with nuclei with $I = 1/2$ and particularly with ^{13}C. For nuclei with $I > 1/2$ there is the additional complication of quadrupole coupling and the CPMAS technique is no longer simply applicable. Modifications involving variable angle spinning (VASS) have been described (1–3) and have been applied to ^{17}O nmr spectroscopy. Some line narrowing results but the effects of chemical shift anisotropy cannot be completely eliminated.

The ^{59}Co nucleus has $I = 7/2$ and a rather large quadrupole moment. Compounds containing this nucleus have been extensively studied in solution but very little has been reported on their solid state ^{59}Co spectra. There are three possible motivations for obtaining such spectra:

(*a*) A comparison of the isotropic chemical shift in the solid state with that in solution may be informative. ^{59}Co chemical shifts are very sensitive to second sphere coordination effects and have been used to study this subject. The nature of the second coordination sphere in solution is always a topic for speculation whereas that in the solid is known if the crystal structure has been determined. Solid state spectra are therefore a logical starting point for second coordination sphere studies.

(*b*) In principle the chemical shift anisotropy, which is averaged out by molecular tumbling in solution, can be determined from solid state spectra. This is useful information since it can be easily and directly related to the kind of crystal field parameters obtained from optical and magnetic measurements.

(*c*) Quadrupole coupling constants can also be obtained from nmr powder spectra. However these parameters are not easy to interpret and for most cobalt complexes are more conveniently measured by nuclear quadrupole resonance.

Since ^{59}Co has $I = 7/2$ the selection rule $\delta m_i = +1$ predicts seven transitions in the nmr spectrum. Of these the central line, corresponding to the $+1/2$ to $-1/2$ transition, is only affected by the quadrupolar splitting to second order. If the quadrupole coupling is large, as it is for Co, this is likely to be the only transition observed in the nmr spectrum. The second order quadrupole interaction splits the line into a doublet. The splitting is proportional to the square of the quadrupole coupling constant and inversely proportional to the Zeeman term as measured by the spectrometer frequency. The effect of chemical shift anisotropy on the line shape is directly proportional to spectrometer frequency. It is anticipated therefore that at high magnetic fields chemical shift anisotropy effects will dominate and at low fields quadrupolar effects will be most important.

The calculation of the powder lineshape in the presence of quadrupolar and chemical shift anisotropy interactions has been considered by a number of authors (4–8). The problem becomes progressively more complex when both types of interaction are considered and when the molecule has non-axial symmetry. The most complete treatment is due to Baugher *et al.* (8) who give explicit formulae for the positions of the shoulders and singularities in terms of quadrupolar and chemical shift parameters. This treatment will be used to analyse the present data.

The amount of experimental data reported for Co complexes is quite small. All of the experiments have been carried out at low fields where quadrupolar effects dominate. Most studies have made use of single crystals. This leads to a more direct analysis of the data but, since rather large crystals are required, it is a time-consuming process which is impractical for an extended series of compounds. If the measurements are carried out at low field, as those reported in the literature have been, the effects of chemical shift anisotropy are small and the parameters correspondingly difficult to measure accurately. Saraswati and Vijayaraghavan (9) some years ago reported the ^{59}Co spectra of several polycrystalline complexes obtained at low field on a broad line instrument. The signal-to-noise ratio of the spectra

[1]Author to whom correspondence should be addressed.

obtained using this instrument was poor. This study did not provide chemical shift anisotropy information and subsequent single crystal studies did not in all cases agree with the quadrupole coupling constants reported.

In the present paper we report the ^{59}Co nmr spectra of several cobalt complexes in polycrystalline form. Our major interest is in the chemical shift tensor. Since the magnetic fields available at present are approximately one order of magnitude greater than those used by Saraswati and Vijayaraghaven the chances for obtaining useful chemical shift data are correspondingly enhanced. The increased sensitivity of high field instruments also results in much better quality spectra. One complex, the hexanitrocobaltate(III) (this ion is often called cobaltinitrite), has been examined at a number of different fields to check the feasibility of analysis using the formulae of Baugher *et al.* (8). The results for the remainder are reported at a single field which was the highest available since the quality of the spectra deteriorates rapidly at lower fields. The complexes chosen all have high molecular symmetry and most of their crystal structures have been reported, thus optimizing the chances for obtaining useful information. The quality of the spectra obtained with these compounds provides a basis for estimating the likely success of experiments with complexes of lower symmetry and with other quadrupolar metal nuclei.

Experimental

Samples of the cobalt complexes were purchased from Baker and were of analytical quality. They were used without further purification. Nuclear magnetic resonance spectra were obtained on Bruker WH90, CXP200, WM250, AM300, WM400, and AM500 instruments. Chemical shifts were measured relative to solutions of the corresponding complexes and were obtained by direct frequency calibration. The solvent used was water except in the case of the acetylacetonate which was dissolved in chloroform for reference purposes.

Results

Figure 1 shows the ^{59}Co nmr spectra of a polycrystalline sample of sodium cobaltinitrite obtained at several different field strengths. At low fields the appearance is that expected for a quadrupolar broadened resonance — a broad doublet. The spectra have been plotted on a uniform frequency scale and the inverse relationship between the doublet separation and field strength is readily apparent. At a field of 9.5T the quadrupolar splitting has been lost and at the highest field of 11.8T the pattern is typical of that expected from a molecule with axial chemical shift anisotropy. The observed isotropic chemical shifts and the measured peak separations at the lower fields are given in Table 1. Figure 1*B* shows a spectrum obtained at 4.7T but with MASS at 3.85 kHz. The peak separation has been reduced by a factor of 3.5. This reduction is in good agreement with the theoretical treatment of Ganapathy *et al.* (2). However, the quadrupolar splitting is not eliminated and the reduction is accompanied by the appearance of undesirable sidebands. There would seem to be no great advantage to magic angle spinning for samples such as these.

Figure 2 shows powder spectra obtained for five other Co(III) complexes. They were all obtained at 119.57 MHz using a Bruker AM500 spectrometer. Several types of behaviour are apparent. The trisethylene diamine complex gives a spectrum similar to that of the cobaltinitrite at the same spectrometer frequency. The effects of chemical shift anisotropy are dominant and the chemical shift tensor has axial symmetry. In this case though $\sigma_\perp$ is greater than $\sigma_\parallel$ rather than vice versa. The spectrum of the hexacyanocobaltate(III) ion also appears to

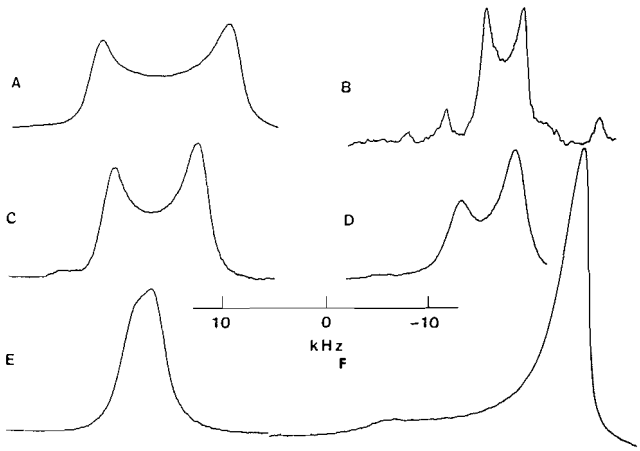

FIG. 1. ^{59}Co nmr spectra of polycrystalline sodium hexanitrocobaltate(III): (*A*) $B_0 = 4.7$T; (*B*) $B_0 = 4.7$T with MASS at 3.85 kHz; (*C*) $B_0 = 5.9$T; (*D*) $B_0 = 7.1$T; (*E*) $B_0 = 9.5$T; (*F*) $B_0 = 11.8$T.

$Co(en)_3^{3+}$	−25	−255
$Co(NH_3)_6^{3+}$	~+250	—

[a]Positive chemical shifts are to low field.

be determined by chemical shift anisotropy effects but several chemically distinct sites are present. On the other hand, the appearance of the spectra obtained with the trisacetylacetonato and trisoxalato complexes are characteristic of quadrupolar splitting, or more probably a mixture of quadrupolar and chemical shift anisotropy effects, and are considerably broader than those in the two previous cases. Finally the spectrum of the hexammine complex is quite complicated and analysis has not been attempted. Chemical shift data are gathered together in Table 2.

Discussion

Baugher *et al.* (8) have calculated the powder nmr line shape for the $m = 1/2$ to $m = -1/2$ transition as a function of Zeeman frequency for the general case where both the quadrupole coupling tensor and the chemical shift tensor lack axial symmetry. They identified six locations for shoulders or singularities in the patterns and give explicit formulae for the frequencies of each of these positions. At low fields the prominent features of the spectrum are two maxima, the separation of which is primarily determined by the quadrupolar coupling. This is illustrated by the spectra in Fig. 1. If the effects of chemical shift anisotropy are neglected the separation of these maxima is inversely proportional to spectrometer frequency. If chemical shift anisotropy is included the separation is given by

$$[1] \quad \Delta\nu = A/\nu_0 + B\nu_0 + C\nu_0^3$$

where the constants A, B, and C represent the expressions

$$A = R/144(\eta^2 - 19\eta + 25)$$

$$B = \{\sigma_2 - [(5 - \eta)\sigma_3 + 2(2 - \eta)\sigma_1]\}$$

and

$$C = 4(\sigma_3 - \sigma_1)^2$$

where

$$R = \nu_Q^2[I(I + 1) - 3/4]$$

$$\nu_Q = 3e^2qQ/[2I(I + 1)h]$$

C depends upon the square of the chemical shift anisotropy and this term can be neglected if the field is not too high and if $\delta\sigma$ is no more than a few hundred parts per million as it is in the present case. A plot of $\nu_0\, d\nu$ versus ν_0^2 should therefore be linear. Such a plot is shown for the hexanitrocobaltate(III) data in Fig. 3. There are four unknows involved: two chemical shift parameters (the third chemical shift unknown is provided by the isotropic shift) and the quadrupole coupling constant and asymmetry parameter. In the present case the chemical shift information can be obtained directly from the high field spectra so that the slope and intercept of the line in Fig. 3 suffice to determine the quadrupole coupling constant and asymmetry. The high field spectra clearly show that the chemical shift tensor is axially symmetric and give an estimate of $\delta\sigma$. Fitting of the data to the formula of eq. [1] gives a best value of the quadrupole coupling constant of 9.4 MHz and of the asymmetry parameter of zero. The calculated splittings in Table 1 were obtained using these values together with a chemical shift anisotropy of 180 ppm. An asymmetry parameter as high as 0.1 is not ruled out but since the chemical shift tensor is axially symmetric it seems plausible that the quadrupole tensor will have similar symmetry although this is not mathematically required. This value is in reasonable agreement with the quadrupole coupling constant of 8.4 MHz reported by Saraswati and Vijayaraghavan (9) who were unable to obtain the assymmetry parameter independently but assumed it was zero.

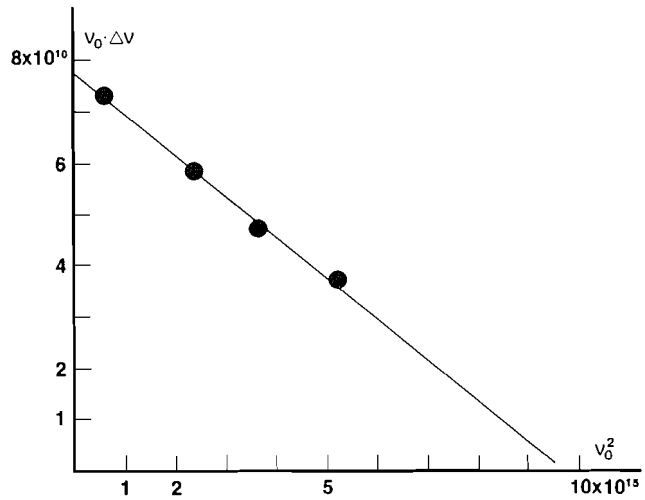

FIG. 3. Plot of $\nu_0\Delta\nu$ versus ν_0^2 for the sodium hexanitrocobaltate(III) data.

A crystal structure has been reported for the compound $K_2Na[Co(NO_2)_6]$ (10) but that of the simple sodium salt does not appear to have been determined. The structure reported shows cubic site symmetry for the Co atom so that neither quadrupole coupling nor chemical shift anisotropy would be anticipated. The observed axial symmetry implies either that the structure of the simple sodium salt is different or that effects beyond the second coordination sphere must be considered.

More relevant crystal structure data are available for the remaining compounds in Table 2. Thus Co(III) trisethylene diamine chloride shows only a single type of Co site with axially distorted octahedral symmetry (11). There is hydrogen bonding between the chloride anions and the ethylene diamine protons situated perpendicular to the three-fold axis. The nmr results are consistent with this structure. The trisacetylacetonato complex is structurally similar except that there are no strong hydrogen bonding possibilities. The nmr spectrum is consistent with a single type of Co site as expected from the reported crystal structure (12). The ^{59}Co nmr of a single crystal of this complex has been reported by Reynhardt (13). He measured a quadrupole coupling constant of 9.26 MHz, an asymmetry parameter of 0.9 and principal values of the chemical shift tensor of −510, −210, and +720 ppm. If these values are used to calculate the positions of the shoulders and singularities in the powder spectrum using the formulae of Baugher *et al.* (8) the calculated spectrum is broader than the observed spectrum by more than an order of magnitude.

The results for potassium cobalticyanide can also be compared with literature data (14–16). The single crystal nmr spectrum (16) of this compound shows three different chemically shifted types of cobalt which were associated with different polytypes resulting from the disordered stacking found in the X-ray crystallographic structure determination (17, 18). The quadrupole coupling constant measured by Lourens and Reynhardt (15) differed by a factor of more than two from that found by Saraswati *et al.* (9) from powder measurements. Three different principal chemical shift values were reported with separations of 155 and 178 ppm. These data may be used to calculate the powder spectrum at 119.5 MHz in the manner described above. In this case the observed spectrum is consistent with the three sites reported and the overall width is approximately correct (if only chemical shift anisotropy is included) but the line shape cannot be reconciled with the non-axially symmetric chemical shift tensor reported by Lourens and Reynhardt (16). There are also literature data on the X-ray structure and single crystal nmr spectrum of the hexammine complex (19, 20). This is a much more complicated case with four crystallographically distinct cobalt sites each with greatly differing quadrupole coupling constants and asymmetry parameters. The high field powder spectrum is clearly appropriately complex but we have not attempted any calculations leading to a quantitative comparison. There appears to be no relevant literature data on the oxalato complex.

Calculations have also been carried out on two less symmetric cobalt complexes for which Spiess *et al.* (21) have reported single crystal nmr studies. For the case of *trans*-$Co(en)_2(NO_2)_2$ (en = ethylene diamine) they report a quadrupole coupling constant of 13.217 MHz, an asymmetry parameter of 0.7272 and $\delta\sigma$'s of 300 and 400 ppm. These values lead to an overall width of the spectrum of some 600 ppm at 119.5 MHz which would probably be observable. On the other hand, calculations for the complex $Co(NH_3)_4CO_3^+$ which has a similar quadrupole coupling constant but a larger chemical shift anisotropy predict a width of some 1700 ppm which would make the spectrum difficult to observe.

From the above discussion it is apparent that although the expressions of Baugher *et al.* (8) will produce a good fit for the cobaltinitrite data at different fields, when these expressions are used to calculate high field powder spectra using low field single crystal data as input there are large discrepancies. We suspect that these discrepancies arise from two causes. At low fields the effects of chemical shift anisotropy are small compared with those due to quadrupolar coupling and the derived chemical shift anisotropy parameters are probably not accurate. Thus it seems very difficult to reconcile the high field powder spectrum of cobalticyanide with the non-axial chemical shift tensor reported. We also suspect that the theory breaks down when the chemical shift anisotropy is relatively large and the quadrupole coupling relatively small. In these circumstances at high fields the cross term involving both quadrupolar and chemical shift anisotropy, which is proportional to ν_0^3, becomes very large which does not seem plausible. It should also be noted that the second term in eq. [1] can be either positive or negative depending on the sign of the chemical shift anisotropy and that this is an important consideration in determining whether the spectrum will be reasonably narrow at high field. It seems likely therefore that high field powder nmr spectra of ^{59}Co and similar quadrupolar nuclei will prove useful in providing chemical shift anisotropy data for a fair number of complexes although complete line shape fitting by computer will probably be necessary to obtain reliable parameters. This information is of potential value to the understanding of both first and second sphere bonding in metal complexes.

The direct electrochemical synthesis of thiolato complexes of copper, silver, and gold; the molecular structure of $[Cu(SC_6H_4CH_3\text{-}o)(1,10\text{-phenanthroline})]_2.CH_3CN$

RAJ K. CHADHA, RAJESH KUMAR, AND DENNIS G. TUCK

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ontario N9B 3P4

Received October 3, 1986

RAJ K. CHADHA, RAJESH KUMAR, and DENNIS G. TUCK. Can. J. Chem. **65**, 1336 (1987).

The electrochemical oxidation of anodic copper or silver (= M) into non-aqueous solutions of RSH (R = alkyl, axyl) gives M^ISR as insoluble materials in high yield. In the presence of 1,10-phenanthroline (= L), the products are $M^ISR.phen$ for M = Cu, but not Ag. Gold resists oxidation under such conditions, and Au^ISR (R = n-C_4H_9, C_6H_5) was obtained in only poor yield. The crystal structure of the solvated dimeric adduct $[Cu(SC_6H_4CH_3\text{-}o).phen]_2.CH_3CN$ is triclinic, with a = 10.682(3) Å, b = 11.729(4) Å, c = 15.608(5) Å, α = 76.87(2)°, β = 76.35(2)°, γ = 68.07(2)°, V = 1742(1) Å^3, Z = 2 and space group $P\bar{1}$. The structure is based on a folded Cu_2S_2 ring with an unusually short Cu—Cu distance of 2.613(3) Å. Each copper atom has CuS_2N_2 pseudo-tetrahedral stereochemistry, with Cu—S = 2.337 Å(av) and Cu—N = 2.10 Å(av).

RAJ K. CHADHA, RAJESH KUMAR et DENNIS G. TUCK. Can. J. Chem. **65**, 1336 (1987).

L'oxydation électrochimique de l'argent ou du cuivre anodique (= M), dans des solutions non-aqueuses de RSH (R = alkyle, axyle), fournit, avec des rendements élevés, des M^ISR qui sont des produits insolubles. En présence de phénanthroline-1,10 (= L) et lorsque M = Cu, on obtient des composés du type $M^ISR.L$; ce n'est toutefois pas le cas lorsque M = Ag. Dans ces conditions, l'or ne s'oxyde que difficilement et les composés Au^ISR (R = n-C_4H_3 et C_6H_5) ne sont obtenus qu'avec de mauvais rendements. L'adduit dimère solvaté $[Cu(SC_4H_4CH_3\text{-}o).L]_2CH_3CN$ est triclinique et il cristallise dans le groupe d'espace $P\bar{1}$ avec a = 10,682(3), b = 11,729(4) et c = 15,608(5) Å, α = 76,87(2), β = 76,35(2) et γ = 68,07(2)°, V = 1742(1) Å^3 et Z = 2. La structure est basée sur un cycle Cu_2S_2 replié comportant une distance Cu—Cu qui est inhabituellement courte (2,613(3) Å). Chaque atome de cuivre possède une stéréochimie pseudo-tétraédrique CuS_2N_2 dans laquelle les distances moyennes Cu—S = 2,377 Å et Cu—N = 2,10 Å.

[Traduit par la revue]

Introduction

Previous papers from this laboratory have reported the direct electrochemical synthesis of metal thiolato complexes by the oxidation of a sacrificial anode in a non-aqueous solution of a thiol (RSH) or disulfide (R_2S_2). The metals successfully used in such experiments include zinc (1, 2), cadmium (1, 2), mercury (2), tin (3), lead (3), gallium (4), indium (4), thallium (4), nickel (4), and cobalt (4), to produce the neutral $M(SR)_n$ compounds, their adducts, or anionic complexes. We now report the use of these simple experimental techniques in the synthesis of thiolato derivatives of copper(I), silver(I), and gold(I), and a number of neutral adducts with the bidentate ligand 1,10-phenanthroline.

The structure of molecules containing copper–sulfur bonds has been the focus of considerable interest (see below), and the investigations therefore included the X-ray structural determination of the acetonitrile solvate of the dimeric adduct formed by *o*-tolylthiolatocopper(I) and 1,10-phenanthroline, $[Cu(SC_6H_4CH_3\text{-}o).C_{12}H_8N_2]_2.CH_3CN$, which involves a Cu_2S_2 ring and CuS_2N_2 coordination.

Experimental section

General techniques

Solvents were distilled from calcium hydride and stored over molecular sieves. Copper, silver, and gold foils were washed with concentrated aqueous nitric acid and then distilled water and dried immediately before use. Thiols, and 1,10-phenanthroline(phen), were used as supplied.

Copper analysis was by atomic absorption spectrophotometry; silver was determined gravimetrically. Microanalysis was performed by Guelph Chemical Laboratories Ltd. Infrared spectra were recorded on Perkin-Elmer PE 180 or Nicolet 5DX instruments; ^1H nmr spectra were obtained with Bruker WP-80 or Perkin-Elmer 20 spectrometers.

Electrochemical procedures

The electrochemical syntheses were carried out by the methods described in previous papers (e.g. refs. 5, 6). The anode was suspended in a solution of the appropriate composition (see Table 1) in a 100-mL tall-form beaker, with cells of the general form

$$Pt_{(-)}/CH_3CN + RSH\ (+ L)/M_{(+)}\ (M = Cu, Ag, Au)$$

The oxidations were carried out under an atmosphere of dry nitrogen which was bubbled through the solution and so also served to mix the contents of the cell. Details of isolation procedures are given below. Yields were generally better than 90%, based on the quantity of metal dissolved from the anode. Products were characterized by analysis (Table 2) and by infrared and ^1H nmr spectroscopy.

(i) Copper(I) thiolates. The electrolysis was carried out at room temperature (ca. 20°C). The product precipitated as the oxidation proceeded and was collected at the end of the reaction, washed with acetonitrile and then petroleum ether (30–65°C), and dried *in vacuo*. Diethyl ether could be substituted for petroleum ether without affecting the product. The compounds are amorphous powders, which are insoluble in hydrocarbon solvents, acetone, acetonitrile, and carbon disulfide, except that $CuSC(CH_3)_2CH_2CH_3$ and $CuSC_6HF_4$ are soluble in hot acetonitrile, and the former is soluble in CS_2. This compound is also photosensitive, changing color from yellow to orange on long exposure to light. Benzenethiolatocopper(I) could also be synthesized by oxidizing the metal in a solution of diphenyldisulfide in acetonitrile (see Table 1).

The electrochemical efficiency, defined as the quantity of metal (moles) dissolved per Faraday of charge, was found to be 1.0 ± 0.05 mol F^{-1} in all Cu/RSH systems studied, and the same value was found for Cu/Ph_2S_2.

(ii) 1,10-Phenanthroline adducts of copper(I) thiolates. Addition of 1,10-phenanthroline to the solution phase prior to electrolysis resulted in the direct electrochemical synthesis of CuSR.phen compounds. The color of the solution changed from light red–brown to deep red–brown as the electrolysis proceeded; no precipitation occurred, but slow cooling, or removing solvent slowly by bubbling nitrogen through the solution, lead to the formation of red–brown crystals which were collected, washed with acetonitrile and then diethyl ether, and finally dried *in vacuo*. In the case of $CuSC_6H_5$.phen, the same compound was obtained when either C_6H_5SH or $(C_6H_5)_2S_2$ was the source of the thiolate anion. No adduct was obtained from a solution containing

[a]In 50 mL acetonitrile, plus ca. 25 mg Et_4NClO_4.
[b]Voltage required to produce an initial current of 20 mA.
[c]$C_5H_{11}SH$ = 2-methylbutane-2-thiol.
[d]Initial current 30 mA.

n-C_4H_9SH and phen, with $CuSC_4H_9$-n precipitating as the anode was consumed. The electrochemical efficiency for dissolution of copper remained at 1.0 ± 0.05 mol F^{-1} when phen was present in the cell, although this value fell if product adhered to the anode surface.

The phen adducts are soluble in acetonitrile, dimethylsulfoxide, and chlorinated hydrocarbons. The red solution formed on dissolving $CuSC_6H_5$.phen (0.3 g) in chloroform (30 mL) shows evidence of reaction, with a red–yellow solid precipitating at room temperature with stirring over 30–45 min. Chloride analysis of this solid gave Cl = 11.7% (cf. CuCl.phen, Cl calcd. 12.7). When stirring was continued for 3–4 h, a green precipitate was obtained (calcd. for $CuCl_2$.phen; Cl 22.5; found: Cl 20.3).

(iii) Silver(I) thiolates. A creamy white precipitate formed at the electrode within 5 min of beginning the electrolysis in each system studied. After 1 h, the solid which had accumulated in the bottom of the cell was collected, washed with acetonitrile and then n-pentane, and dried *in vacuo*. No adducts were obtained when phen was added to the cell; with C_6H_5SH + phen, the product was identified as $AgSC_6H_5$. The electrochemical efficiency for the dissolution of silver was found to be 1.00 ± 0.05 mol F^{-1}.

(iv) Gold(I) thiolates. When electrolysis was carried out with solutions of n-C_4H_9SH or C_6H_5SH in acetonitrile, the gold anode rapidly became covered with a heavy adherent deposit which effectively prevented any further reaction, and the current fell to almost zero. With solutions of the corresponding disulfide, a slow reaction occurred with AuSR precipitating as the reaction proceeded. The electrochemical efficiency for these systems was low for $(C_6H_5)_2S_2$ ($E_F \approx 0.6$), and very low for $(C_4H_9)_2S_2$ ($E_F \approx 0.05$ mol F^{-1}).

(v) Miscellaneous. Attempts to prepare pyridine or dimethylsulfoxide adducts of $CuSC_6H_5$ by electrolysis with an acetonitrile or acetone solution of these ligands were unsuccessful. We also found that acetone solutions of C_6H_5SH, or C_6H_5SH + phen, were unsatisfactory media for the electrochemical oxidation of copper; in each case, only 20–40 mg of metal dissolved over a period of 2–3 h, which implies an efficiency some 5–10 times lower than when acetonitrile was used.

Crystallographic analysis

Plate-like red–brown crystals of the acetonitrile solvate of $[Cu(SC_6H_4CH_3$-$o)(phen)]_2$, **1**, were obtained by electrochemical oxidation as described. The density was measured by flotation in CCl_4/benzene. A crystal was mounted along the largest dimension on a Syntex $P2_1$ diffractometer for X-ray data collection. Details on the data collection procedures have been given previously (7). Although the positions of the copper and sulphur atoms were obtained from MULTAN using 268 reflections with $|E_{min}| \geq 1.2$ and 2448 phase relationships, the quality of this data set was too poor to refine the structure using SHELX, because of one dimension being much smaller than the other two. Another crystal with maximum possible thickness was therefore chosen and the data were recollected (see Table 3 for dimensions and other relevant information). The intensity of three monitor reflections

Radiation	MoKα, $\lambda = 0.71069$ Å
Monochromator	Highly oriented graphite
Temperature (°C)	21
2θ angle (°)	3.5–45
Scan type	Coupled θ (crystal)/2θ (counter)
Scan width	$K_{\alpha_1} - 1°$ to $K_{\alpha_2} + 1°$
Scan speed (deg min^{-1})	Variable, 2.02–4.88
Background time/scan time	0.5
Total reflections measured	4718 ($+h, \pm k, \pm l$) ($R = 0.0$)
Unique data used	3000 [$I > 3\sigma(I)$]
No. of parameters (NP)	341, blocked, see text
$R = (\Sigma\|\|F_o\| - \|F_c\|\|/\Sigma\|F_o\|)$	0.0967
$R_w = [\Sigma w(\|F_o\| - \|F_c\|)^2/\Sigma_w\|F_o\|^2]^{1/2}$	0.1029
$\Delta\rho_{max}$ (e Å^{-3})	0.3
Shift:error (max)	0.05

did not change significantly during data collection. The data were corrected for Lorentz and polarization effects and analytical absorption corrections were applied. Cell parameters were obtained from 15 strong reflections ($15 < 2\theta < 35°$). The space group $P\bar{1}$ was used and later assumed to be correct because of the successful refinement.

In the least-squares analysis, all atoms except the carbon atoms of one tolyl and one phenanthroline groups were refined anisotropically in blocks as follows: Cu(1) and Cu(2) every cycle; S(1), S(2), N(1)—N(4), C(1)—C(17) in alternate cycles with C(21)—C(62). The hydrogen atoms were fixed in ideal geometry (r(C—H) = 0.95 Å), and assigned thermal parameters whose values exceeded those for the appropriate carbon atoms by 0.01 U (Å^2). The anisotropic thermal parameters of a few atoms were too small along the x axis, the thinnest side of the crystal, due to the plate-like shape of the crystal. The refinement minimizing the function $\Sigma w(|F_o| - |F_c|)^2$ converged to $R = 0.0967$ and $R_w = 0.1029$. A weighting scheme of the form $w = 1/[\Sigma\sigma^2(F) + pF^2]$ was employed with a final p value of 0.0001. No evidence of secondary extinction correction was found. The final difference map showed no features of chemical significance. These high R values are a result of the difficulties encountered in choosing a suitable crystal, and of the relative dimensions of the crystal (see above). Computer programs, and sources of scattering factors, were those reported previously (3, 7). Positional and thermal parameters are given in Table 4 and interatomic distances and bond angles in Table 5. The molecular structure is shown in Fig. 1, and a view of the unit cell in Fig. 2. There are no intermolecular contacts of significance.

Tables of anisotropic thermal parameters, positional coordinates and thermal parameters for hydrogen atoms, and observed and calculated structure factors, are available as supplementary data.[1]

Results and discussion

Preparative

As with other electrochemical syntheses, the techniques described above provide an efficient one-step route to the M(SR) compounds of copper and silver and to adducts of copper thiolates with a typical bidentate nitrogen donor. As with other earlier work, the E_F values of 1.0 ± 0.05 mol F^{-1} for Cu and Ag correspond to the reactions

$$\text{Cathode: } RSH + e \rightarrow RS^- + (1/2)H_2(g)$$

$$\text{Anode: } RS^- + M \rightarrow MSR + e$$

for RSH, and

$$\text{Cathode: } R_2S_2 + 2e \rightarrow 2RS^-$$

$$\text{Anode: } 2RS^- + 2M \rightarrow 2MSR + 2e$$

for R_2S_2 systems.

The only experimental difficulty calling for comment is that gold resists attack, leading to low E_F values, and this is no doubt related to the chemical inertness of this metal. A more difficult point is that with RS^- generated from R_2S_2, the reaction with gold proceeds, albeit with low efficiency, whereas with the apparently identical anions from RSH a deposit forms on the cathode and inhibits further reaction. One possible explanation is that the AuSR which forms at the anode surface reacts with RSH to give an insoluble metal sulfide which is adherent, but that no such reaction occurs with R_2S_2, or that the product of such a reaction is soluble.

The spectroscopic properties of CuSR compounds (see below) suggest that these solids are sulfur bridged homo-polymers, as proposed for other d^{10}-metal thiolates (1, 8). Adduct formation then depends in part on the ligand–metal interaction being strong enough to overcome this metal–sulfur bridging, and the present evidence indicates that the typical bidentate donor phen satisfies this condition whereas monodentate donors do not for copper, except that with R = n-C_4H_9 the bridging prevails against the attempted formation of a phen adduct. Similar results have been recorded with alkylthiolate derivatives of

cadmium(II) and explained in terms of a strong polarized M—S bond (8). The experiments described did not yield adducts of silver, which may again be due to the increased strength of the polarized Ag—S bond, given that silver is a more electropositive element than gold.

The insolubility of the copper, silver, and gold thiolates prevented any study of the nmr spectra of these compounds. The phen adducts of CuSR are slightly soluble in d_6-*DMSO*, so that spectra could be recorded, but it was not possible to get reliable integration. The *p*-tolyl and triphenylmethyl thiolato compounds are insoluble in this solvent, but for the remainder multiplets in the 6.5–9.0 ppm region were assigned to phen, and to the aromatic thiolato ligand; the aliphatic protons of $n\text{-}C_5H_{11}S$ (0.43–1.55, m) were also observed.

Structure of $[Cu(SC_6H_4CH_3\text{-}o)phen]_2.CH_3CN$ (**1**)

Our X-ray studies establish that **1** is a dimeric molecule, with a molecule of acetonitrile present in the lattice but playing no role in the coordination of the metal. Each copper atom has quasi-tetrahedral stereochemistry (sum of all angles at Cu(1) = 652.9°, at Cu(2) = 655.3°), and is the centre of a CuS_2N_2 kernel. There is an unusually large number of reports of structures involving copper(I) derivatives and thiolate ligands, against which the present results can be compared. Two of these reports refer to the $Cu(SPh)_3^-$ anion (9, 10), in which the copper has approximately trigonal symmetry in the CuS_3 kernel, with Cu—S bond lengths 2.274(4)–2.335(4) Å in the Ph_4P^+ salt (9), and 2.239(2)–2.258(2) Å when the cation (10) is Et_4N^+. These values serve to establish the Cu—S bond distance in the absence of major ligand–ligand or bridging interactions, as well as the S—C(phenyl) distance of 1.75–1.76 Å.

Several of the structures are concerned with cages or clusters in which bridging by thiolate ligands plays an important role. Molecules containing three, four, five, and eight copper atoms have been structurally characterized, and the results up to 1980 have been reviewed elsewhere (9); more recent papers by Dance *et al.* have discussed the structural relationship involved (11, 12). The formation of six-membered rings in the boat conformation is apparently a common feature of such structures (cf. ref. 13), as is the extensive bridging by μ-SPh and

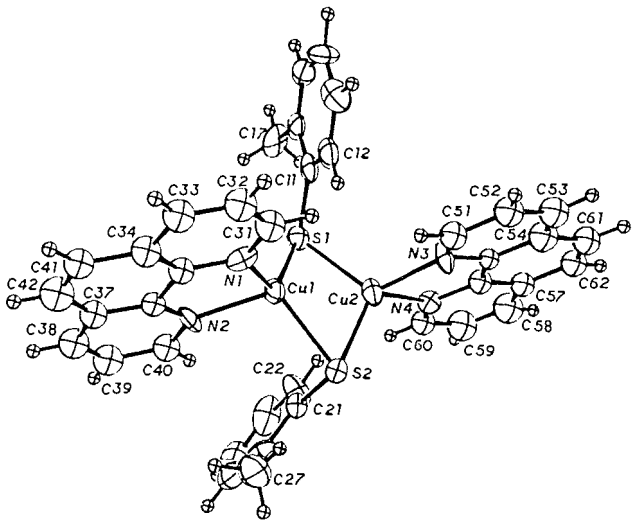

FIG. 1. Ortep diagram of $[Cu(SC_6H_4CH_3\text{-}o)(C_{12}H_8N_2)]_2.CH_3CN$; 50% probability for all atoms other than hydrogen.

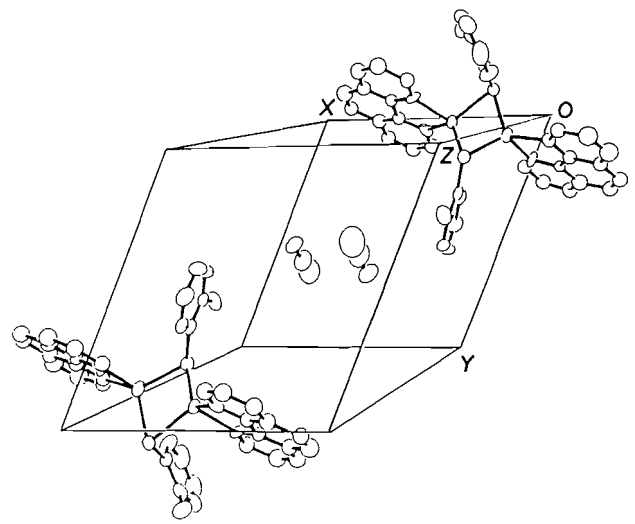

FIG. 2. Packing diagram.

μ_3-SPh groups. An examination of the bond distances and angles in these molecules serves to emphasize the effect of atomic environment on these parameters, especially in terms of the number of atoms being bridged, and of the other atoms bonded to copper, so that comparisons must be made with caution.

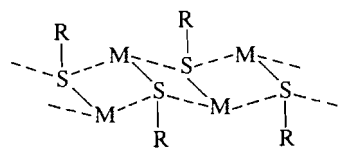
Two structures appear especially relevant to the present results. One is the dimeric $(CuSPh.2PPh_3)_2$ (14), or $(Ph_3P)_2Cu(\mu\text{-}SPh)_2Cu(Ph_3P)_2$ (**2**), and the other is $(CuSPh.PPh_3)_4$ (12), or $(\mu_3\text{-}SPh)_2(\mu\text{-}SPh)_2Cu_4.(PPh_3)_4$ (**3**). Both **1** and **2** are dimeric species, but with different neutral donor ligands supported on Cu_2S_2 rings. A striking feature of **2** is the planarity of this ring, with axially directed SPh ligands and approximately planar ligand stereochemistry at the sulfur atom. The steric interaction between the phenyl group of the thiolate and those of Ph_3P plays a major role in stabilizing this structure (14), but such factors are absent in **1**, so that arguably the shape observed in the present work is that which the $(RSCu)_2$ adopts in the absence of exterior constraints.

The relationship between **1** and **3** is also interesting, since the latter is a centrosymmetric molecule which can be described as two folded Cu_2S_2 units joined by Cu—S bonds which themselves produce a planar Cu_2S_2 rhombus. The folded units in **1** and **3** are rather similar, with $Cu_{tet\text{-}\mu_2\text{-}S}$ = 2.337 Å(av) in **1** and 2.327 Å in **3**, and Cu—μ-S—Cu angles of 68.0°(av) and 74.3°, respectively. Given the difference in the neutral donor ligands (see above), the different angles at Cu are not surprising (μ-S—Cu—μ-S = 106.3°(av) in **1**, μ-S—Cu_{tet}—μ_3-S = 99.2(1)°, 110.6(1)° in **3**). The fold angle, taken as the dihedral angle at the μ-S—μ-S diagonal, is 149.9° in **1** and 142.3° in **3**. The most significant difference lies in the Cu—Cu distance which is 2.782(1) Å in **3**, but significantly shorter at 2.613(3) in the present case, which represents a closeness of approach of these atoms comparable to that in copper metal (2.551 Å) (15). Similar close contacts have been reported for the dimeric copper(I) derivative of diazoaminobenzene (16) where the Cu—Cu distance is 2.45 Å, and for $[Cu(S_2CNEt_2)]_4$ (r(Cu—Cu) = 2.71 Å(av)) (17). Copper–copper bonding has been postulated for a number of dimeric copper(II) compounds, but the analogous copper(I) systems have not been investigated in detail, although Coucouvanis *et al.* (9) have discussed such effects in $Cu_8L_{12}^{4-}$ and $Cu_4L_6^{2-}$ structures, and Mehrotra and Hofmann (18) have analyzed the possible Cu—Cu bonding interactions in copper(I) cluster compounds. Since the present structure is one in which ligand–ligand steric interactions are apparently absent, in that there are no interligand distances below 2.3 Å, the folded Cu_2S_2 ring may be evidence for a significant Cu—Cu interaction in this system.

The remaining features of the stereochemistry call for little comment. The μ-S—C_{phenyl} distances (1.77 Å(av)) are close to those in the compounds discussed above, and the stereochemical features of the 1,10-phenanthroline ligand are also in agreement with previous results, as is the bite angle of 79.3°(av) at the copper atom.

Vibrational spectra

The infrared spectra of all the compounds prepared were routinely recorded over the range 4000–100 cm^{-1}, and these spectra served in part to demonstrate the presence of the appropriate alkyl or aryl thiolate, and of the neutral donor ligand. Results in the far infrared region should identify ν(M—S) modes, and there has been considerable discussion of the frequency range in which these are to be found in the case of copper, zinc, cadmium, and mercury thiolates (19–22). A major problem, and one which proved difficult in the present work, is that vibrations of the alkyl or aryl group, and of the neutral ligand, obscure much of the region of interest. Infrared absorptions in the region 323–74 cm^{-1} have been assigned as ν(S—M) modes in $(CH_3SCu)_n$ and $[Cu_2(SMe)_3]^-$, and we find bands at 304s and 238m in n-C_4H_9SCu, at 300s and 216m in n-C_4H_9SAg, and 280w, br cm^{-1} in n-C_4H_9SAu. These values are compatible with a polymeric structure (cf. ref. 21) with



only a slight dependence of frequency on the metal. With 1,1-dimethylpropane-1-thiolates, the only vibrations which could be unambiguously identified were those at 195 and 130 (Cu) and 107 cm^{-1} (Ag). The dominant features in the spectra of derivatives of aryl thiols are due to vibrations of the phenyl group, and we cannot assign any ν(M—S) modes with

For personal use only.

certainty, although metal-dependent absorptions were seen at 174 (Cu), 163 (Ag), and 110 cm^{-1} (Au).

N-Allyloxycarbonyl derivatives of D-glucosamine as promotors of 1,2-*trans*-glucosylation in Koenigs–Knorr reactions and in Lewis acid catalyzed condensations

PAUL BOULLANGER,[1] JOSEPH BANOUB,[2] AND GÉRARD DESCOTES

Université Lyon I, École supérieure de chimie industrielle de Lyon, Unité associée 463, Centre national de la recherche scientifique, 43 Bd. du 11 Novembre 1918, 69622-Villeubranne CEDEX, France

Received November 7, 1986

PAUL BOULLANGER, JOSEPH BANOUB, and GÉRARD DESCOTES. Can. J. Chem. **65**, 1343 (1987).

The use of suitably blocked D-glucosamine derivatives possessing the *N*-allyloxycarbonyl protective group of the amino function represents potential new routes to 1,2-*trans*-glucosylations. Both 3,4,6-tri-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-α-D-glucopyranosyl bromide (**2**) and 1,3,4,6-tetra-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-β-D-glucopyranose (**3**) could be used in Koenigs–Knorr reactions or Lewis acid catalyzed condensations, respectively. Glucosides of simple alcohols and disaccharides were synthesized in good to excellent yields. The *N*-allyloxycarbonyl protective group was, moreover, easy to remove with Pd(0) complexes, thus affording, after acetylation, the corresponding *N*-acetyl-β-D-glucosamine glucosides under very smooth conditions.

PAUL BOULLANGER, JOSEPH BANOUB et GÉRARD DESCOTES. Can. J. Chem. **65**, 1343 (1987).

L'utilisation de dérivés de la D-glucosamine protégés sur la fonction amine par un groupement *N*-allyloxycarbonyle constitue une nouvelle voie d'accès potentielle aux glucosides 1,2-*trans*. Le bromure de tri-*O*-acétyl-3,4,6 *N*-allyloxycarbonyl-2-amino-2 désoxy-2 α-D-glucopyrannosyle (**2**) et le tétra-*O*-acétyl-1,3,4,6 *N*-allyloxycarbonyl-2 amino-2 désoxy-2 β-D-glucopyrannose (**3**) peuvent être utilisés respectivement dans les réactions de type Koenigs–Knorr ou dans les condensations catalysées par les acides de Lewis. Les glucosides d'alcools simples et les disaccharides ont été préparés avec des rendements de bons à excellents. Le groupe protecteur *N*-allyloxycarbonyle est, de plus, facile à cliver avec les complexes du Pd(0) et conduit, après acétylation, aux glucosides de la *N*-acétyl β-D-glucosamine dans des conditions très douces.

Introduction

The β-D-glucosides of *N*-acetyl glucosamine are widely distributed in living organisms where they constitute important building blocks of peptidoglycans, mucopolysaccharides (hyaluronic acids, keratan sulfate), glycoproteins (inner and outer core regions), oligosaccharides of human milk, and blood group determinants (1). They are also often encountered in bacterial antigens where they constitute part of the antigenic determinant (2). The teichoic acids of *Staphylococcus aureus* (3), for example, contain a β-D-GlcNAc-(1→4)-D-ribitol repeating unit, the synthesis of which was realized recently in our laboratory (4, 5).

The usual procedures for the 1,2-*trans*-glucosylation of D-glucosamine are mainly the so-called oxazoline method (6) and the phthalimido procedure (7). Despite their synthetic usefulness, these methods suffer some disadvantages. In the first method, the 2-methyl-(3,4,6-tri-*O*-acetyl-1,2-dideoxy-D-glucopyrano)[2,1-*d*]-2-oxazoline (6) or a synthetic precursor (8) is reacted with the alcohol (usually in refluxing nitromethane–toluene) in acidic medium. Yields are generally good with primary alcohols and still satisfactory with reactive secondary alcohols (9), affording the β-D-glucosides of *N*-acetylated glucosamine directly. Nevertheless, the rather drastic conditions do not allow the use of acid-sensitive protective groups in the glycosylating agent or the aglycon.

In the phthalimido method, the alcohol is reacted with 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-D-glucopyranosyl bromide (usually at low temperature) in the presence of the silver triflate – collidine complex. The yields are generally excellent, even with weakly reactive alcohols, and this method is the most widely used for the preparation of complex oligosaccharides. The major disadvantage of the method is the need of further steps for deprotection and reacetylation of the amino function, requested for the synthesis of natural oligosaccharides. Despite some recent improvements (10), the phthalimido cleavage still remains a rather drastic procedure, which causes the removal of most alkaline-sensitive protective groups and which also often results in an important decrease of the overall yield.

The results described recently in the literature dealing with the versatile uses of the allyloxycarbonyl protective group (11, 12) prompted us to study its participating properties in 1,2-*trans*-glucosylation reactions. In a continuation of our studies on the glucosylation reactions (4, 5), we now report two different efficient methods for 1,2-*trans*-glucosylation of D-glucosamine. Both Koenigs–Knorr type reactions and condensations catalyzed by Lewis acids are depicted and compared.

Results and discussion

The carbamate approach for the synthesis of 1,2-*trans*-glucosides of D-glucosamine has already been mentioned in the literature. Using a benzyl carbamate derivative, K. Heyns *et al.* (13) did not succeed in obtaining the expected β-D-glucoside whereas J. Lessard *et al.* (14) were able to prepare such β-D-glucosides in moderate yields using reactive alcohols only. Most recently, S. Kusumoto *et al.* (15) described the synthesis of a disaccharide from a trichloroethyl carbamate derivative of D-glucosamine.

These rather divergent results induced us to undertake a systematic study on the glucosylation reactions of the *N*-allyloxycarbonyl derivatives of D-glucosamine.

As previously reported (16), the reaction of 3,4,6-tri-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-α-D-glucopyranosyl bromide (**2**) with alcohols promoted by mercury[II] or silver[I] salts afforded the expected β-D-glucosides (**4**), together with various amounts of oxazolidinone (**5**) as a by-product. This reaction has been extended to 1,2-*trans*-glucosylations promoted by Lewis acids (17) and both methods were compared with regard to the stability of the protective groups and the reactivity of the aglycons (Scheme 1).

SCHEME 1

The glycosyl bromide (**2**) could be prepared with a 74% overall yield from D-glucosamine hydrochloride, via the intermediate 1,3,4,6-tetra-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-α-D-glucopyranose (**1**), as a stable crystalline material, contrary to its *N*-acetylated analog. This glucoside precursor was synthesized by a very classical pathway and could, in turn, be converted into another precursor, namely the corresponding β-acetate (**3**), by means of mercury[II] acetate in acetic acid, with an excellent yield. The preparation of compound **3** could be realized by shorter pathways, but the method described herein was the only one not requiring a chromatographic separation of α and β anomeric acetates at the final step of the synthesis.

The reaction of the glycosyl bromide (**2**) with one equivalent of alcohol and one equivalent of mercury[II] cyanide in dichloromethane at room temperature resulted in the complete consumption of the starting material in less than 24 h, depending on the aglycon. With reactive alcohols, the expected β-D-glucosides (**4***a–c* and **4***e–g*) were obtained in good yields, whereas with unreactive aglycons, such as 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose, the glucoside (**4***d*) was accompanied by important amounts of the oxazolidinone (**5**), the formation of which was already reported by K. Heyns *et al.* (13).

The formation of both products (**4***a–g* and **5**) could be explained by the participation of the *N*-allyloxycarbonyl group giving rise to a strongly delocalized carbocationic species (Scheme 1). This intermediate could react following pathway (a) (leading to the β-D-glucosides **4**) or pathway (b) (forming the oxazolidinone **5**) but the possible pathway (c) resulting from an attack on the C-2 carbon atom of the oxazolidinium ion, was never observed. Pathway (a) was very preponderant with reactive alcohols (with regard to steric hindrance and (or) nucleophilicity) while pathway (b) gained in importance with less reactive alcohols (see entry **d** in Table 1). It was, moreover, observed that the oxazolidinone (**5**) was not reactive itself toward the alcohol under the experimental conditions, and therefore cannot constitute an intermediate in the formation of β-D-glucosides (**4**).

[a]Reactions performed with one equivalent of alcohol and one equivalent of mercury[II] cyanide with respect to **2**, at room temperature in dichloromethane.

[b]Reactions performed with one equivalent of alcohol and one equivalent of trimethylsilyl triflate with respect to **3**, at −35°C in dichloromethane.

[c](1→6)-β-D-glucoside resulting from a rearrangement of the isopropylidene protective group.

[d]The poor yield could be attributed to the cleavage of the tertiobutyldimethylsilyl protective group during the reaction and (or) extraction and purification of the disaccharide.

Several experimental observations allowed us to conclude that, contrary to Heyns' results, the nucleophile (Nu^-) involved in pathway (b) was not the alcohol but, probably, the bromide ion formed in the first step of the reaction, since no allylated alcohol (resulting from pathway (b) with Nu^- = ROH) was detected in any condensations and since the addition of one equivalent of tetraethylammonium bromide to the reaction medium resulted in an increase of oxazolidinone formation. The results obtained with this Koenigs–Knorr type reaction are summarized in Table 1.

The reaction of the β-D-acetate (**3**) with alcohols, on the other hand, could be conducted with various Lewis acids. Amongst those tested, the trimethylsilyl triflate gave the best results with regard to the yields of glucosides, ease of use, and lower amount of by-products. The reactions were conducted with one equivalent of the alcohol and one equivalent of the Lewis acid, with respect to the starting β-D-acetate at −35°C in dichloromethane. The β-D-glucosides were obtained in good yields, even with the unreactive aglycon previously mentioned, and the oxazolidinone resulting from pathway (b) (Scheme 1) was not observed in that case. The results obtained with the Lewis acid promoted glucosylations are reported in Table 1.

It should be noticed that the low yield of β-glucoside (**4***e*) obtained by both methods could be attributed to undesired cleavage of the tertiobutyldimethylsilyl protective group during the reaction and (or) the purification of the product, rather than to an important formation of oxazolidinone (**5**).

As already reported in the literature (18), the Koenigs–Knorr reaction carried out on 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose resulted in an acetal migration from the 5,6 to the 3,5 position of the aglycon and therefore afforded a 1→6 glycoside (**4***d*) as attested mainly by ^{13}C nmr (the chemical shifts of the quaternary carbons of the acetal protective groups, 112.53 ppm and 101.36 ppm, correspond to those of dioxolane and dioxane rings, respectively). The isopropylidene migration had been observed in a glycosylation promoted by trimethylsilyl triflate (19).

The yields of glucosylations described in this paper can be compared favourably with those reported in the literature. The isopropyl glucoside, for example, was obtained in 85% yield only by the oxazoline method, using a 2–10 molar excess of the alcohol (20). The glucosides of 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose (**c**) were obtained, under the best conditions, in 81% yield by the oxazoline method (21) and in 86% yield by both phthalimido (22) and *N*-allyloxycarbonyl procedures (Table 1). On the other hand, the glucosylations of the ribitol derivatives (**f** and **g**) were realized, in our laboratory, respectively in 71 (5) and 50% yields by the oxazoline method, in 79 and 71% yields by the phthalimido procedure, and in 83 and 85% yields by the *N*-allyloxycarbonyl procedure (Table 1).

As can be seen from Table 1, the yields are slightly better starting from the bromide **2** than from the β-acetate **3** with primary alcohols but lower with secondary and hindered alcohols. These two methods are quite complementary since the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

lower reactivity of the bromide (**2**) is accompanied by a better selectivity towards primary alcohols and a better preservation of the acid-sensitive protective groups. The β-D-acetate (**3**), on the other hand, seems to be much more reactive; these two properties will be explored in the near future in the field of complex carbohydrate synthesis involving selectivity and (or) reactivity towards various alcohols.

The deprotection of the *N*-allyloxycarbonyl group could be realized by using the numerous methods reported in the literature; the reductive cleavage (23) and the deprotection promoted by nickel tetracarbonyl (24) have now been substituted by newer methods based on homogeneous palladium catalysis. These methods are promoted by Pd(0) complexes, usually tetrakis(triphenylphosphine) palladium, together with an allyl acceptor. Amongst these acceptors, the most widely used are dimedone (25), 2-ethylhexanoic acid (26), or tributyltin hydride (27); these acceptors give rise to by-products of low volatility, creating the need of further chromatographic purification to recover the free amine after deprotection. The Pd(0) catalyzed deprotection can also be realized by hydrogenolytic cleavage with formic acid (28) to afford the amine as a quaternary salt, requiring an ion exchange to remove the free amine. The results of these different techniques have been recently reviewed in the field of nucleotide synthesis (12).

To take advantage, in the field of carbohydrates, of the remarkable selectivity of Pd(0) complexes, and to avoid the above-mentioned inconveniences, we have used dimethyl malonate as allyl acceptor to obtain volatile by-products after allylation. After complete deprotection, the amino-free glycoside could be reacetylated to prepare natural oligosaccharide analogs (Scheme 1) or esterified with a fatty acid to obtain analogs of glycolipids (15).

This new strategy for the synthesis of β-D-glucosides of glucosamine should, in our opinion, complete the panel of well-known and classical methods of 1,2-*trans*-glucosylations. The *N*-allyloxycarbonyl approach is easy to use; the glucosylation conditions are very smooth, and compatible with most hydroxyl protective groups stable in slightly acidic medium. The choice between a glycosyl bromide and an anomeric β-D-acetate as glucosylation precursor will permit selective reactivities towards alcohols. The *N*-allyloxycarbonyl function is quite stable in most of the conditions encountered in saccharide chemistry and can survive the deprotection of many other groups; its cleavage is, moreover, perfectly selective and compatible with most *O*- and *N*-protective groups, which represents a real advantage over the classical methods used in that field.

Experimental

Melting points were determined on a Büchi apparatus and were uncorrected. Optical rotations were measured using a Perkin Elmer 241 polarimeter in 1-dm cells. The ^{1}H nmr spectra were recorded on Varian EM-360, Brucker W.P. 80 CW, or Brucker A.C. 200 instruments. The ^{13}C nmr spectra were recorded on a Varian XL-100A (25.3 MHz) spectrometer operating in the Fourier transform mode. Chemical shifts are relative to internal Me_4Si. In ^{13}C nmr spectra of the disaccharides, the primed carbon atom resonance signals are attributed to the carbohydrate moiety bound to β-D-glucosamine. The ^{13}C nmr spectra always contain additional signals corresponding to acetates and aromatics in the case of benzylated ribitol derivatives. Microanalyses were carried out by the Laboratoire Central d'Analyse du CNRS (Solaise, France) and acceptable values are reported to a ±0.4% tolerance. Chromatographic separations were performed on Merck silica gel (230–400 mesh). Dichloromethane was washed with water and dried on $CaCl_2$ before distillation over P_2O_5. Oxolane was treated with basic aluminium oxide (Alumina Woelm B) before distillation over $LiAlH_4$ and exhaustively flushed with argon just prior to use.

*1,3,4,6-Tetra-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-α-D-glucopyranose (**1**)*

D-Glucosamine hydrochloride (21.6 g, 0.1 mol) was added to a sodium methylate solution, obtained by reaction of methanol (100 mL) with sodium (2.3 g, 0.1 mol), and then shaken at room temperature for 10 min. After filtration, triethylamine (14 mL, 0.1 mol) and allyl-chloroformate (12.0 g, 0.104 mol) were added to the filtrate at a temperature maintained below 30°C. The reaction was completed after 3 h at room temperature and the solvent was evaporated to dryness, followed by acetylation overnight (acetic anhydride: 100 mL, pyridine: 200 mL). After the usual extraction procedure, the title compound (**1**) was recovered as a pink foamy material that could be used directly in the next step or recrystallized from ether (38.5 g, 89%): mp 119–121°C; $[\alpha]_D^{23}$ +27.6 (*c* 2.36, $CHCl_3$); 200-MHz ^{1}H nmr ($CDCl_3$) δ: 6.20 (d, 1H, *J* = 3.6 Hz, H-1), 5.96–5.70 (m, 1H, vinyl proton), 5.32–5.11 (m, 4H), 4.97 (d, 1H, *J* = 9.4 Hz, N*H*) 4.58–3.98 (m, 5H), 2.19, 2.12, 2.09, 2.04 (4s, 12H, 4OAc); ^{13}C nmr (CD_3COCD_3) δ: 156.37 (*C*O: allyloxycarbonyl), 133.87 (*C*H=CH_2), 117.11 (CH=*C*H_2), 90.96 (C-1), 71.33, 70.25 (C-5, C-3), 68.90 (C-4), 65.73 (*C*H_2—CH=CH_2), 62.24 (C-6), 53.48 (C-2). *Anal.* calcd. for $C_{18}H_{25}O_{11}N$ (Mol. Wt. 431.39): C 50.11, H 5.84, N 3.25; found: C 49.97, H 5.90, N 3.11.

*3,4,6-Tri-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-α-D-glucopyranosyl bromide (**2**)*

The above-mentioned derivative (**1**) (30 g, 0.07 mol) dissolved in dry dichloromethane (200 mL) was treated at 0°C with 33% hydrobromic acid in acetic acid (50 mL) for 0.5 h. The mixture was then poured into cold water and the aqueous layer extracted with chloroform. The mixed organic extracts were then neutralized with an aqueous solution of sodium carbonate, washed once with cold water, and dried over calcium chloride. After evaporation to dryness, compound **2** was recovered as a dark yellow foam. The pure derivative was recovered after two recrystallizations from ether (26 g, 82%): mp 93–94°C; $[\alpha]_D^{24}$ +147 (*c* 1.9, $CHCl_3$); 80-MHz ^{1}H nmr ($CDCl_3$) δ: 6.55 (d, 1H, *J* = 3.6 Hz, H-1); ^{13}C nmr (CD_3COCD_3) δ: 155.95 (*C*O: allyloxycarbonyl), 133.63 (*C*H=CH_2), 117.28 (CH=*C*H_2), 93.55 (C-1), 73.43, 71.17 (C-5, C-3), 68.10 (C-4), 65.96 (*C*H_2—CH=CH_2), 61.77 (C-6), 55.85 (C-2). *Anal.* calcd. for $C_{16}H_{22}O_9NBr$ (Mol. Wt. 452.25): C 42.49, H 4.90, N 3.10, Br 17.67; found: C 42.64, H 5.09, N 2.92, Br 17.48.

*1,3,4,6-Tetra-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-β-D-glucopyranose (**3**)*

The glycosyl bromide **2** (20 g, 0.044 mol) dissolved in acetic acid (100 mL), was treated for 45 min with mercury[II] acetate (16 g, 0.050 mol) at room temperature. After filtration on a bed of Celite, the filter cake was washed three times with chloroform and the mixed chloroformic extracts poured into cold water. After washing and neutralization with an aqueous solution of sodium carbonate, the organic extracts were dried over calcium chloride and evaporated, to leave crude compound **3** as a yellowish crystalline material. Recrystallization from ether afforded the pure derivative (16.5 g, 87%): mp 109–110°C; $[\alpha]_D^{23}$ +25.9 (*c* 2.14, $CHCl_3$); 200-MHz ^{1}H nmr ($CDCl_3$) δ: 5.87–5.76 (m, 1H, vinyl proton), 5.37–5.12 (m, 4H), 4.95 (m, 1H, N*H*), 4.58–3.81 (m, 6H), 2.15, 2.09, 2.08, 2.05 (4s, 12H, 4OAc); ^{13}C nmr (CD_3COCD_3) δ: 156.21 (*C*O: allyloxycarbonyl), 133.99 (*C*H=CH_2), 116.83 (CH=*C*H_2), 92.88 (C-1), 73.13, 72.98 (C-5, C-3), 69.08 (C-4), 65.54 (*C*H_2—CH=CH_2), 62.37 (C-6), 55.50 (C-2). *Anal.* calcd. for $C_{18}H_{25}O_{11}N$ (Mol. Wt. 431.39): C 50.11, H 5.84, N 3.25; found: C 50.35, H 5.91, N 3.20.

*General procedure for the Koenigs–Knorr glycosidations starting from compound **2***

The glycosyl bromide **2** (1.00 g, 2.21 mmol), the alcohol to be glucosylated (2.21 mmol), and dry mercury[II] cyanide (0.558 g, 2.21 mmol) were dissolved simultaneously in dry, alcohol-free dichloromethane (20 mL). The reaction, stirred at room tempeature, was monitored by tlc and stopped 1 h after completion (reaction times

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

in Table 1). The reaction mixture was filtered on Celite, the filter cake washed twice with chloroform, and the mixed chloroformic extracts washed once with water. After drying over calcium chloride and evaporation, the product was purified by column chromatography (eluent: ethyl acetate/hexane from 1:2 to 2:1 depending on the aglycon); yields are given in Table 1.

General procedure for the Lewis acid promoted glucosylations starting from compound **3**

The β-acetate **3** (1.00 g, 2.32 mmol), the alcohol to be glucosylated (2.32 mmol), and powered 5 Å molecular sieves (0.5 g) were added simultaneously in dry alcohol-free dichloromethane (50 mL). The reaction mixture was then flushed with argon while cooling to −35°C. Trimethylsilyl triflate (0.516 g, 2.32 mmol) was then introduced through a syringe and the argon flush maintained for 0.5 h; the external temperature was kept near −35 ± 5°C all during the processing. The reaction times indicated in Table 1 are purely indicative, since the reactions were not monitored to avoid hydrolysis during the withdrawal of aliquots. The reaction was stopped by addition of triethylamine (0.5 g, 4.94 mmol) at −35°C; the mixture was then allowed to reach 0°C, filtered on Celite, and the filtrate was collected into a cold, dilute aqueous solution of sodium carbonate. The same work-up and purification procedures as previously mentioned were then applied; yields are indicated in Table 1.

*Methyl 3,4,6-tri-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-β-*D*-glucopyranoside (***4***a)*

White crystalline material: mp 111–112°C (ether); $[\alpha]_D^{24}$ +10.2 (*c* 1.9, $CHCl_3$); 200-MHz ^{1}H nmr ($CDCl_3$) δ: 5.89 (m, 1H, vinyl C*H*), 5.33–5.15 (m, 3H, vinyl CH_2, H-3), 5.07 (t, 1H, *J* = 9.5 Hz, H-4), 4.92 (m, 1H, N*H*), 4.63–4.47 (m, 3H, allyl CH_2, H-1), 4.22 (m, 2H, $J_{6,6'}$ = 12.3 Hz, $J_{5,6}$ = 4.7 Hz, $J_{5,6'}$ = 2.4 Hz, H-6, H-6′), 3.70 (m, 1H, H-5), 3.60 (m, 1H, H-2), 3.52 (s, 3H, OCH_3), 2.09, 2.04, 2.03 (3s, 9H, 3OAc); ^{13}C nmr (CD_3COCD_3) δ: 156.19 (*C*O: allyloxycarbonyl), 133.84 (*C*H=CH$_2$), 116.74 (CH=*C*H$_2$), 102.30 (C-1), 73.40, 71.98 (C-5, C-3), 69.55 (C-4), 65.36 (*C*H$_2$—CH=CH$_2$), 62.60 (C-6), 56.68 (O*C*H$_3$), 56.33 (C-2). *Anal.* calcd. for $C_{17}H_{25}O_{10}N$ (Mol. Wt. 403.38): C 50.62, H 6.25, N 3.47; found: C 50.58, H 6.36, N 3.44.

*1-Methylethyl 3,4,6-tri-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-β-*D*-glucopyranoside (***4***b)*

White crystalline material: mp 148–149°C (ether); $[\alpha]_D^{24}$ +4.2 (*c* 1.0, $CHCl_3$); ^{13}C nmr (CD_3COCD_3) δ: 156.27 (*C*O: allyloxycarbonyl), 134.12 (*C*H=CH$_2$), 116.66 (CH=*C*H$_2$), 100.29 (C-1), 73.45, 72.53, 71.96 (C-5, C-3, *C*H: isopropyl), 69.84 (C-4), 65.27 (*C*H$_2$—CH=CH$_2$), 62.85 (C-6), 56.81 (C-2), 23.59, 22.17 (*C*H$_3$: isopropyl). *Anal.* calcd. for $C_{19}H_{29}O_{10}N$ (Mol. Wt. 431.44): C 52.89, H 6.78, N 3.25; found: C 52.85, H 6.75, N 3.21.

*6-O-(3,4,6-Tri-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-β-*D*-glucopyranosyl)-1,2:3,4-di-*O*-(1-methylethylidene)-α-*D*-galactopyranose (***4***c)*

The aglycon was prepared according to ref. 29. Compound **4***c* was obtained as a white crystalline material: mp 135–136°C (ether); $[\alpha]_D^{24}$ −41.3 (*c* 1.4, $CHCl_3$); 200-MHz ^{1}H nmr ($CDCl_3$) δ: 5.89 (m, 1H, vinyl C*H*), 5.52 (d, 1H, *J* = 5.2 Hz, H-1: galactose moiety), 5.53–5.18 (m, 3H, vinyl CH_2, H-3), 5.07 (t, 1H, *J* = 9.7 Hz, H-4), 4.92 (m, 1H, N*H*), 2.09, 2.02, 2.01 (3s, 9H, 3OAc), 1.51, 1.44, 1.32 (3s, 12H, 2 isopropylidene); ^{13}C nmr (CD_3COCD_3) δ: 156.19 (*C*O: allyloxycarbonyl), 134.20 (*C*H=CH$_2$), 116.74 (CH=*C*H$_2$), 109.29, 108.78 (quaternary *C*: isopropylidene), 102.15 (C-1), 96.79 (C′-1), 73.40, 72.18 (C-5, C-3), 71.56, 71.26, 71.11 (C′-2, C′-3, C′-5), 69.70 (C-4), 69.06 (C′-6), 67.70 (C′-4), 65.45 (*C*H$_2$—CH=CH$_2$), 62.94 (C-6), 56.88 (C-2), 26.30, 25.17, 24.53 (*C*H$_3$: isopropylidene). *Anal.* calcd. for $C_{28}H_{41}O_{15}N$ (Mol. Wt. 631.63): C 53.24, H 6.54, N 2.25; found: C 53.29, H 6.56, N 2.16.

*6-O-(3,4,6-Tri-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-β-*D*-glucopyranosyl)-1,2:3,5-di-*O*-(1-methylethylidene)-α-*D*-glucofuranose (***4***d)*

The aglycon was prepared according to ref. 29. Compound **4***d* was obtained as a white crystalline material: mp 109–111°C (ether/petroleum ether); $[\alpha]_D^{22}$ +15.5 (*c* 2.3, $CHCl_3$); ^{13}C nmr (CD_3COCD_3) δ: 156.56 (*C*O: allyloxycarbonyl), 134.54 (*C*H=CH$_2$), 117.03 (CH=*C*H$_2$), 112.53 (quaternary *C*: 1,2-isopropylidene), 106.90 (C′-1), 102.60 (C-1), 101.36 (quaternary *C*: 3,5-isopropylidene), 84.87 (C′-2), 79.73 (C′-4), 75.85 (C′-3), 73.76, 72.54, 72.45 (C-5, C-3, C′-5), 71.03 (C′-6), 70.04 (C-4), 65.62 (*C*H$_2$—CH=CH$_2$), 63.05 (C-6), 56.91 (C-2), 27.46, 26.83, 24.33 (*C*H$_3$: isopropylidene). *Anal.* calcd. for $C_{28}H_{41}O_{15}N$ (Mol. Wt. 631.63): C 53.24, H 6.54, N 2.22; found: C 53.29, H 6.75, N 2.21.

*2,3,5-Tri-*O*-benzyl-1-*O*-tertiobutyldimethylsilyl-*D*-ribitol (***e***)*

2,3,5-Tri-*O*-benzyl-D-ribitol (30) (2.55 g, 6.04 mmol), dissolved in dry DMF (20 mL), was treated for 36 h at room temperature with imidazole (1.0 g, 14.7 mmol) and tertiobutyldimethylsilyl chloride (1.21 g, 7.93 mmol). After concentration to 5 mL, the mixture was diluted with chloroform (20 mL) and washed with cold water. After drying ($CaCl_2$) and evaporation, a clear syrup was obtained (3.17 g, 98%). This compound (**e**), homogeneous in tlc, was purified by column chromatography for analytical purposes, but could be used directly for further steps: syrup; $[\alpha]_D^{23}$ +22.8 (*c* 7.0, $CHCl_3$); ^{13}C nmr (CD_3COCD_3) δ: 80.95, 80.04 (C-2, C-3), 73.75, 73.12, 72.55, 72.18 (C-5, 3CH_2: benzyl), 70.82 (C-4), 63.33 (C-1), 26.06 (*C*H$_3$: *tert*-butyl), 18.40 (quaternary *C*: *tert*-butyl), −5.27 (*C*H$_3$-Si). *Anal.* calcd. for $C_{32}H_{44}O_5Si$ (Mol. Wt. 536.79): C 71.60, H 8.26, Si 5.23; found: C 71.20, H 8.18, Si 5.27.

*4-O-(3,4,6-Tri-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-β-*D*-glucopyranosyl)-2,3,5-tri-*O*-benzyl-1-tertiobutyldimethylsilyl-*D*-ribitol (***4***e)*

Waxy material: $[\alpha]_D^{21}$ −3.3 (*c* 3.4, $CHCl_3$); ^{13}C nmr (CD_3COCD_3) δ: 156.43 (*C*O: allyloxycarbonyl), 134.23 (*C*H=CH$_2$), 116.97 (CH=*C*H$_2$), 101.54 (C-1), 80.76, 80.12 (C′-2, C′-3), 79.38 (C′-4), 74.40, 73.65, 72.98 (3CH_2: benzyl), 73.65, 72.32 (C-5, C-3), 71.23 (C′-5), 69.99 (C-4), 65.58 (*C*H$_2$—CH=CH$_2$), 63.87, 62.99 (C′-1, C-6), 57.26 (C-2), 26.46 (*C*H$_3$: *tert*-butyl), 18.89 (quaternary *C*: *tert*-butyl), −5.01 (*C*H$_3$-Si). *Anal.* calcd. for $C_{48}H_{65}O_{14}NSi$ (Mol. Wt. 908.13): C 63.49, H 7.21, N 1.54, Si 3.09; found: C 63.31, H 7.22, N 1.51, Si 3.13.

*4-O-(3,4,6-Tri-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-β-*D*-glucopyranosyl)-1-*O*-allyl-2,3,5-tri-*O*-benzyl-*D*-ribitol (***4***f)*

The aglycon was prepared according to ref. 5. Syrup; $[\alpha]_D^{24}$ −2.3 (*c* 2.8, $CHCl_3$); ^{13}C nmr (CD_3COCD_3) δ: 156.27 (*C*O: allyloxycarbonyl), 135.96 (*C*H=CH$_2$: allyl), 134.03 (*C*H=CH$_2$: allyloxycarbonyl), 116.76 (CH=*C*H$_2$: allyloxycarbonyl), 116.01 (CH=*C*H$_2$: allyl), 101.23 (C-1), 80.02, 79.03, 78.98 (C′-2, C′-3, C′-4), 74.18, 73.49, 72.56 (3CH_2: benzyl), 73.49, 72.29 (C-5, C-3), 72.10 (*C*H$_2$—CH=CH$_2$: allyl), 70.93, 70.72 (C′-1, C′-5), 69.76 (C-4), 65.39 (*C*H$_2$—CH=CH$_2$: allyloxycarbonyl), 62.81 (C-6), 57.03 (C-2). *Anal.* calcd. for $C_{45}H_{55}O_{14}N$ (Mol. Wt. 833.93): C 64.81, H 6.65, N 1.68; found: C 64.92, H 6.65, N 1.68.

*4-O-(3,4,6-Tri-*O*-acetyl-2-*N*-allyloxycarbonyl-2-amino-2-deoxy-β-*D*-glucopyranosyl)-1-*O*-allyloxycarbonyl-2,3,5-tri-*O*-benzyl-*D*-ribitol (***4***g)*

The aglycon was prepared according to ref. 31. Syrup; $[\alpha]_D^{22}$ −8.4 (*c* 4.4, $CHCl_3$); ^{13}C nmr (CD_3COCD_3) δ: 156.35 (*C*O, *N*-allyloxycarbonyl), 155.54 (*C*O: *O*-allyloxycarbonyl), 134.15 (*C*H=CH$_2$: *N*-allyloxycarbonyl), 132.95 (*C*H=CH$_2$: *O*-allyloxycarbonyl), 118.43 (CH=*C*H$_2$: *O*-allyloxycarbonyl), 116.94 (CH=*C*H$_2$: *N*-allyloxycarbonyl), 101.15 (C-1), 79.14, 78.39, 77.97 (C′-4, C′-3, C′-2), 74.39, 73.78, 72.64 (3CH_2: benzyl), 73.49, 72.26 (C-5, C-3), 70.77 (C′-5), 69.82 (C-4), 68.64 (C′-1), 67.52 (*C*H$_2$—CH=CH$_2$: *O*-allyloxycarbonyl), 65.55 (*C*H$_2$—CH=CH$_2$: *N*-allyloxycarbonyl), 62.94 (C-6), 57.08 (C-2). *Anal.* calcd. for $C_{45}H_{53}O_{16}N$ (Mol. Wt. 863.91): C 62.56, H 6.18, N 1.62; found: C 62.20, H 6.35, N 1.59.

General procedure for the cleavage of the N*-allyloxycarbonyl protective group*

Palladium bis(dibenzylidene acetone) (20 mg, 0.035 mmol) was reacted with triphenylphosphine (50 mg, 0.191 mmol) in dry, oxygen-

free oxolane (3.5 mL) at room temperature for 10 min. The *N*-allyloxycarbonyl-β-D-glucosaminide (**4***a–f*) (1.00 mmol) dissolved in oxygen-free oxolane (5 mL) and dimethyl malonate (0.6 mL, 7.0 mmol) was then added to the above solution and the mixture was stirred for 24 h at room temperature. After concentration to 1 mL, the mixture was applied at the top of a small silica gel column and eluted first with ethyl acetate, to remove the triphenylphosphine by-products, and then with methanol, to recover the expected amino-free derivative in almost quantitative yield.

Synthesis and structural characterization of glycinatodimethylgallium, $(C_2H_4NO_2)Ga(CH_3)_2$

STEVEN J. RETTIG, ALAN STORR,[1] AND JAMES TROTTER[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received July 17, 1986

STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **65**, 1349 (1987).

Details of the preparation and crystal structure of the title compound are given. Crystals of glycinatodimethylgallium are monoclinic, $a = 12.502(1)$, $b = 12.023(1)$, $c = 10.732(1)$ Å, $\beta = 110.05(1)°$, $Z = 8$, space group $P2_1/c$. The structure was solved by conventional heavy atom methods and was refined by full-matrix least-squares procedures to $R = 0.033$ and $R_w = 0.039$ for 1172 reflections with $I \geq 3\sigma(I)$. The structure consists of monomeric $(C_2H_4NO_2)GaMe_2$ molecules which are linked together by an extensive network of N—H···O hydrogen bonds. The Ga atoms have tetrahedral coordination geometry with bond lengths averaged over the two crystallographically independent molecules: Ga—O = 1.958(18), Ga—N = 2.031(5), and Ga—C = 1.937(7) Å.

STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **65**, 1349 (1987).

On décrit les détails de la préparation et de la structure cristalline du composé mentionné dans le titre. Les cristaux du glycinatodiméthylgallium sont monocliniques et ils cristallisent dans le groupe d'espace $P2_1/c$, avec $a = 12{,}502(1)$, $b = 12{,}023(1)$ et $c = 10{,}732(1)$ Å, $\beta = 110{,}05(1)°$ et $Z = 8$. On a résolu la structure par les méthodes conventionnelles aux atomes lourds et on l'a affinée par la méthode de moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0{,}033$ et $R_w = 0{,}039$ pour 1172 réflexions avec $I \geq 3\sigma(I)$. La structure comporte des molécules monomères de $(C_2H_4NO_2)GaMe_2$ qui sont liées par un réseau important de liaisons hydrogènes N—H···O. Les atomes de Ga possèdent une géométrie de coordination tétraédrique et les longueurs des liaisons, déterminées en établissant une moyenne sur deux molécules qui sont indépendantes d'un point de vue cristallographique, sont les suivantes : Ga—O = 1,958(18), Ga—N = 2,031(5) et Ga—C = 1,937(7) Å.

[Traduit par la revue]

Introduction

The importance of α-amino acids as the principal constituents of protein and living matter is unquestionable. One such protein, transferrin (a glycoprotein of molecular weight ~ 80 000), is responsible for iron transport in mammalian systems and has been implicated in the transport of gallium in vivo (1, 2). Recently we have been interested in the area of gallium citrate chemistry (3), primarily since gallium citrate complexes are important clinical agents in medicinal chemistry (1) and definitive structural data on such complexes was entirely lacking. Our attention has also focussed on the coordination chemistry of gallium species with simple α-amino acids with a view to elucidating the binding of gallium by such compounds. The present paper details the preparation and structural characterization of the glycinatodimethylgallium complex.

Experimental

Air-sensitive materials were handled under oxygen-free dry nitrogen or on a high-vacuum line. Benzene was dried by refluxing over molten potassium followed by distillation under an atmosphere of nitrogen.

Starting materials

Trimethylgallium was synthesized from gallium metal and dimethylmercury as described previously (4). Glycine (Eastman Organic Chemicals) was used as supplied.

Synthesis of glycinatodimethylgallium

Me_3Ga (1.325 g, 11.55 mmol) was condensed onto glycine (0.866 g, 11.55 mmol) at −196°C. Alternate warming and cooling resulted in a vigorous reaction well below room temperature, with evolution of methane:

$$Me_3Ga + H_2NCH_2CO_2H \rightarrow H_2NCH_2CO_2GaMe_2 + CH_4$$

After cessation of methane evolution the product mixture was extracted with benzene and the mixture filtered. The resultant filtrate yielded crystals of the desired product on slow evaporation of the solvent. Yield 70%. *Anal.* calcd. for $(C_2H_4NO_2)GaMe_2$: C 27.60, H 5.76, N 8.06; found: C 27.69, H 5.83, N 7.93.

Mass spectrum

The mass spectrum displayed as its highest m/e signal one due to the monomer − Me^+ ion. In addition signals from ions arising from the expected fragmentation of the monomer species were also observed.

X-ray crystallographic analysis

Crystals were sealed under dry nitrogen in glass capillaries. A crystal bounded by the eight faces (followed by the distances in mm between parallel faces): {1 0 0}, 0.08, {1 1 0}, 0.18, {−1 0 1}, 0.31 was mounted in a general orientation. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections (2θ = 30–36°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1) = 0.70930$, $\lambda(K\alpha_2) = 0.71359$ Å). Crystal data at 22°C are:

$C_4H_{10}GaNO_2$ fw = 173.85

Monoclinic, $a = 12.502(1)$, $b = 12.023(1)$, $c = 10.732(1)$ Å, $\beta = 110.05(1)°$, $V = 1515.4(5)$ Å^3, $Z = 8$, $\rho_c = 1.524$ Mg m^{-3}, $F(000) = 704$, μ(Mo-$K\alpha$) = 35.5 cm^{-1}. Absent reflections: $h0l$, l odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.18–10.06° min^{-1} over a range of (0.75 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 50°. The intensities of three check reflections, measured every 3600 s throughout the data collection, decreased uniformly by 18.5%, the data being scaled accordingly. After data reduction,[2] an absorption correction was applied using the Gaussian integration method (5, 6). Transmission factors ranged from 0.474 to 0.782 for 180 integration points. Of the 2664 independent reflections measured, 1172 (44.0%) had intensities greater than or equal to $3\sigma(I)$ above background where $\sigma^2(I) =$

$S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by conventional heavy atom methods, the coordinates of the two crystallographically independent Ga atoms being determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. The non-hydrogen atoms were refined with anisotropic thermal parameters. In the final stages of refinement the hydrogen atoms were included as fixed contributors in idealized positions (N—H = 0.91, C—H = 0.98 Å, based on observed positions for methyl groups), recalculated after each least-squares cycle. The scattering factors of ref. 7 were used for non-hydrogen atoms and those of ref. 8 for hydrogen atoms. Anomalous scattering factors from ref. 9 were used for the Ga atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix refinement of 145 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at $R = 0.033$ and $R_w = 0.039$ for 1172 reflections with $I \geq 3\sigma(I)$. For all 2664 reflections $R = 0.123$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.01 and 0.13σ, respectively. The mean error in an observation of unit weight was 1.492. A final difference map showed maximum fluctuations of −0.88 to +0.57 e A^{-3} near Ga and was featureless elsewhere. The final positional and thermal parameters appear in Tables 1 and 7,[3] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3] Bond lengths, bond angles, intra-annular torsion angles, and details of the hydrogen bonding are given in Tables 2–5, respectively. Calculated hydrogen atom parameters (Table 6) and a complete listing of torsion angles (Table 8) are included as supplementary material.[3]

Results and discussion

The title compound, glycinatodimethylgallium, represents the second example of a simple α-amino acid coordinating a gallium atom. A previous study (10) reported the polymeric five-coordinate structure of (L-prolinato)dimethylgallium and more recently a structure with a Ga(III) ion octahedrally coordinated to the hexadentate ligand derived from the complex ethylenebis[(*o*-hydroxyphenyl)glycine] (EHPG) has been reported (11). The present structure consists of tetrahedrally coordinated Ga atoms in monomeric units (Fig. 1) which are linked together via extensive N—H···O hydrogen bonding (Fig. 2 and Table 5). The monomer units show no tendency to associate via formation of a $(Ga—O)_2$ four-membered ring system as was found previously in the solid-state structures of numerous five-coordinate gallium complexes (3, 12), or to form a polymeric chain via weak Ga—O bonding to the "uncoordi-

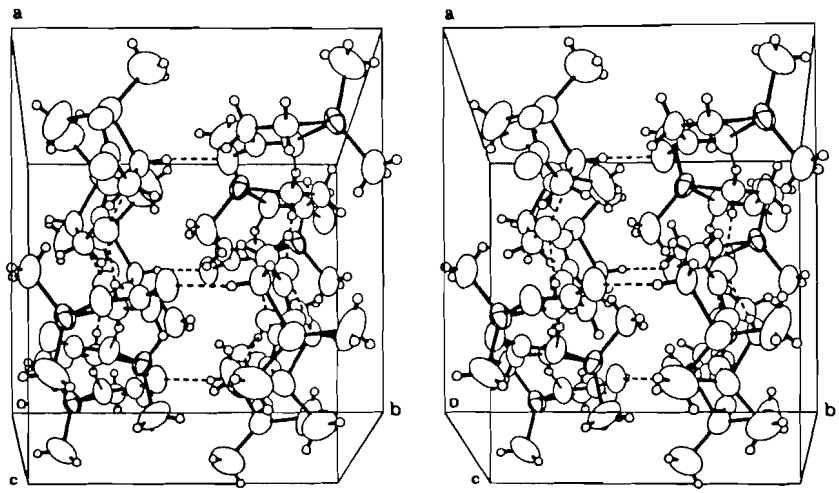

FIG. 2. Stereoscopic view of the packing arrangement of glycinatodimethylgallium; broken lines indicate hydrogen bonds.

nated" carboxylate oxygen atoms as in (L-prolinato)dimethylgallium (10). In this regard the complex is similar to the ethanolamine dimethylgallium complex, $H_2NCH_2CH_2O.GaMe_2$, which also exists in the solid state as discrete monomers linked by an extensive network of N—H···O hydrogen bonds (13). The five-coordinate dimeric structures of the methylated analogs $[Me_2NCH_2CH_2O.GaR_2]_2$ (R = Me, H) (14) support the contention that extensive hydrogen bonding involving ligand atoms in compounds of this type is energetically more favorable than the formation of oligomers involving weak Ga—O interactions.

The two crystallographically independent molecules of glycinatodimethylgallium are essentially identical, the most notable difference between the two being the shorter Ga—O bond in the molecule containing Ga(2) which probably results from differences in hydrogen bonding (see Table 5). The five-membered chelate rings in both molecules are non-planar, having conformations best described as *N*-envelopes. The mean Ga—O bond length of 1.958(18) Å is (as expected) shorter than the corresponding axial bond of 2.036(3) Å in the trigonal bipyramidal proline complex (10) and also shorter than the mean distance of 2.006(4) Å in octahedral $[Ga(EHPG)]^-$ (11). The mean Ga—N distance of 2.031(5) Å is similar to the equatorial bond of 2.027(3) Å in the proline complex and shorter than the mean of 2.090(12) Å in the EHPG complex. In the tetrahedral ethanolamine complex (13) a stronger Ga—O bond, mean 1.917(5) Å, is balanced by relatively weaker

Acidity level in concentrated mineral acid mixtures. Iso-acidic media

C. LOUIS, A. BEBBA, AND J. BESSIERE

Laboratoire de Chimie et Electrochimie Analytique, Faculté des Sciences. Université de Nancy 1, B.P. 239, 54506 Vandoeuvre Les Nancy Cedex, France

Received November 26, 1986

C. LOUIS, A. BEBBA, and J. BESSIERE. Can. J. Chem. **65**, 1353 (1987).

Assuming the relationship between the R_0(H) acidity function and the water activity in mineral acid concentrated solutions, iso-acidic solutions are prepared by mixing in all proportion two or three of the acids: H_3PO_4, HCl, $HClO_4$, H_2SO_4, H_2SiF_6. These solutions are characterized by an equal R_0(H) acidity level and different redox and complexing properties. Their R_0(H) acidity level is determined from potential measurements involving *o*-chloranil as an H^+ indicating system and ferricinium/ferrocene as a comparison system.

C. LOUIS, A. BEBBA et J. BESSIERE. Can. J. Chem. **65**, 1353 (1987).

En se basant sur la relation qui a été établie entre la fonction d'acidité R_0(H) et l'activité de l'eau dans des solutions concentrées d'acides minéraux, on a préparé des solutions iso-acides en procédant au mélange, dans toutes les proportions, de deux ou trois des acides suivants : H_3PO_4, HCl, $HClO_4$, H_2SO_4 et H_2SiF_6. Ces solutions sont caractérisées par le fait qu'elles ont des niveaux d'acidité R_0(H) qui sont égaux et par des propriétés redox et de complexation qui sont différentes. On a déterminé leurs niveaux d'acidité en se basant sur des mesures de potentiels impliquant l'*o*-chloranil comme système indicateur de H^+ et le couple ferricinium/ferrocène comme système de référence.

Introduction

Concentrated mineral acid mixtures are very often used in surface processing: metal pickling, chemical polishing of crystal. The acidic treatment of phosphate ore with sulfuric, nitric, hydrochloric, or fluosilicic acids produces phosphoric acid concentrated solutions still containing a large proportion of the acid uses in the process (1). Any improvement of attack or solubilization processes requires a correct understanding of complexation and protonation phenomena in highly concentrated media.

From a fundamental point of view, the solvation properties of ionic or molecular species in concentrated acid solutions with various complexing or redox properties are significant: they allow one to foresee changes in solubilization and partition reactions when the nature of the acid changes or its concentration is modified (2, 3). The modification of the complexing properties of a concentrated acidic solution without any change of its acidity level is difficult to realize since most complexing compounds have basic properties.

We present in this paper means to prepare what we call "iso-acidic" solutions, that is solutions with the same R_0(H) acidity level and different complexing properties in the case of mixtures containing phosphoric acid and sulfuric, hydrochloric, or perchloric acids. Mixtures containing fluosilicic acid are also considered although its R_0(H) acidity function is not yet known.

Results and discussion

Bascombe and Bell (4) and Wyatt (5) brought evidence that the concentrated aqueous solutions of strong acids are characterized by the same H_0 acidity function value when they have the same water acidity value. This property has been experimentally verified in the case of HCl, $HClO_4$, H_2SO_4, and HNO_3 but not in the case of H_3PO_4 and HF which are not completely dissociated in concentrated media (5).

Recently, it has been shown by Louis and Bessiere (6) that the R_0(H) acidity function (Strehlow (7)) is the same for every acid solution having the same water activity. This relationship is also valid in the case of H_3PO_4 and HF. Owing to these two important results, the iso-acidity notion has been introduced in order to characterize acid mixtures. An iso-acidic solution is defined as the mixture in all proportion of two or several concentrated acid solutions, each of them having the same R_0(H) value. We assume that the mixture is characterized by a water activity value equal to those of each constituting solution. This assumption is related to those by Zdanovskii (8, 9) according to which mixtures of several strong electrolyte binary solutions, each of them with an equal water activity value, are characterized by the same water activity value provided that there is no chemical interaction between electrolyte species in the final mixture. Nevertheless, the solutions we are considering are not always completely dissociated and possibly contain molecular species.

The R_0(H) values are calculated from potential measurements involving an appropriate quinone/hydroquinone redox system (Q_s/QH_{2s}) by reference to the ferricinium/ferrocene (Fc^+/Fc) system in the various acidic media.

R_0(H) acidity function values have been experimentally determined in the case of iso-acidic solutions prepared in mixing 5.5 *M* or 11.5 *M* phosphoric acid solutions and the appropriate solutions of sulfuric, perchloric, or hydrochloric acids (Table 1).[1] They confirm that it is possible to prepare media with the same acidity level and different redox or complexing properties. For example, a 5.5 *M* phosphoric acid solution can be mixed in all proportion with a 3.25 *M* sulfuric acid solution, or a 3.4 *M*

[1] In all tables, the same abbreviations are used. Q_s/QH_{2s} represents the acidity indicating system: *o*-chloranil (3,4,5,6-tetrachloro-1,2-benzoquinone); $E^{w}_{Q} - E_0{}^{w}_{Fc} = +492$ mV represents the Q_s/QH_{2s} potential referred to the Fc^+/Fc normal potential at pH = 0 (phosphoric acid solution). E^{a}_{Q} represents the Q_s/QH_{2s} potential in the acidic mixture; $E_0{}^{a}_{Fc}$ represents the Fc^+/Fc normal potential in the acidic mixture. These potentials are referred to sce in 0.1 *M* H_3PO_4 separate compartment.

In Tables 1 and 4, the R_0(H) acidity function is calculated according to the relation:

$$R_0(H) = [(E^{w}_{Q} - E_0{}^{w}_{Fc}) - (E^{a}_{Q} - E_0{}^{a}_{Fc})]/0.058$$

In Tables 2 and 3, the R_0(H) acidity function is evaluated from the relation $R_0(H) = f(\log a_{H_2O})$.

perchloric acid solution, or a 3.85 *M* hydrochloric acid solution giving binary mixtures characterized all by the same R_0(H) acidity function value: −1.9.

Binary or ternary mixtures containing H_2SiF_6 and iso-acidic of the 5.5 *M* phosphoric acid solution can be prepared only if the concentration for which its R_0(H) acidity level is the same as those of the phosphoric solution (that is −1.9) is known. It has been determined using the H_0 acidity function in sulfuric acid solutions as an intermediary. From the relations $H_0 = f$(acid concentration) for H_2SiF_6 solutions (Table 2) and H_2SO_4 solutions (10–12), the concentrations of solutions which have the same H_0 acidity level can be known. For example, 2.8 *M*

TABLE 4. R_0(H) function in 5.5 M H_3PO_4 iso-acidic solutions (ternary mixtures): H_3PO_4–H_2SO_4–H_2SiF_6 mixtures

x% (vol) 5.5 M H_3PO_4 + y% (vol) 3.25 M H_2SO_4 + z% (vol) 2.25 M H_2SiF_6

x–y–z % (vol)	E^a_{Fc} (mV)	E^a_Q (mV)	R_0(H)
50–40–10	−48	550	−1.8
60–20–20	−48	544	−1.7
50–10–40	−48	549	−1.8

H_2SiF_6 and 4.5 M H_2SO_4 are characterized by the same H_0 value: −2.01. The fact that it is also true for any mixture of the two acid solutions (Table 3) is in favour of the complete dissociation of H_2SiF_6 then an equal value of the term water activity in these solutions. From the relation $R_0(H) = f(\log a_{H_2O})$ it is then possible to determine that 2.25 M H_2SiF_6 and 5.5 M H_3PO_4 solutions are iso-acidic (Table 3).

It has also been shown (Table 4) that, whatever the ratio, ternary mixtures of 5.5 M H_3PO_4, 2.25 M H_2SiF_6, and 3.25 M H_2SO_4 solutions are characterized by the same R_0(H) acidity level.

Conclusion

Assuming the notion of iso-acidity, it is possible to modify in a continuous way the solvation, complexation, and oxidation –reduction properties of a concentrated acidic medium with no change of its acidity level. At the present time, these results are applied to the analysis of mineral species solution reactions in mixtures of mineral acids.

RAPHAËL E. PASTOR, JOËLLE FABRON, AIMÉ CAMBON et YOU-CHUAN HU. Can. J. Chem. **65**, 1356 (1987).

Nous avons analysé les spectres de résonance magnétique nucléaire du ^{13}C de six F-méthyl-4 coumarines. La présence de ce substituant F-alkyle en 4 n'affecte que très peu les déplacements chimiques des divers atomes de carbone. Seuls les carbones C-10, C-4 et C-5 sont véritablement perturbés et apparaissent à champs plus forts. L'importance de ces effets a été évaluée et comparée avec ceux provoqués par un méthyle en 4. Le phénomène le plus important est l'apparition d'un couplage $^4J_{CF}$ (et $^5J_{CF}$ pour **6**). Nous montrons que ce couplage se transmet manifestement à travers l'espace et qu'il nécessite pour sa transmission la présence d'un troisième noyau intermédiaire couplé aux deux précédents.

RAPHAËL E. PASTOR, JOËLLE FABRON, AIMÉ CAMBON, and YOU-CHUAN HU. Can. J. Chem. **65**, 1356 (1987).

Analysis of ^{13}C nuclear magnetic resonance spectra of six 4-F-methyl coumarins are reported. This 4-F-alkyl substituent has a very slight effect on the chemical shifts of different carbon atoms. Only the C-10, C-4, and C-5 atoms are really affected and are shifted towards higher fields. The size of these effects was evaluated and compared with the corresponding effects of a 4-methyl substituent. The most important fact is the appearance of a $^4J_{CF}$ (and $^5J_{CF}$ for **6**) coupling constant. We have shown that this effect is a through-space coupling.

I. Introduction

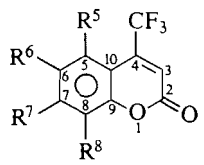
Dans un travail précédent (1), nous présentions la synthèse de F-alkyl-4 coumarines.[2] L'étude rmn, proton et fluor, de ces composés nous a permis de mettre en évidence un couplage longue distance entre l'hydrogène en 5 et les fluors α de la chaine F-alkyle en 4.

Le squelette coumarine qui forme la structure de base de nombreux produits naturels a fait l'objet de nombreuses études tant en rmn du proton que du carbone 13 (2); l'influence de la substitution a été particulièrement étudiée afin d'établir des régles d'incrémentation permettant la prévision des déplacements chimiques des divers carbones cycliques et l'identification d'isomères de position.

À notre connaissance, aucun de ces travaux ne faisait mention de composé fluoré; aussi nous a-t-il paru intéressant d'étudier l'influence d'un substituant F-méthyle sur ce type de composés.

Dans ce travail, nous présentons l'étude rmn ^{13}C de six F-méthyl-4 coumarines : F-méthyl-4 ombelliférone (**1**), F-méthyl-4 daphnétine (**2**), F-méthyl-4 esculétine (**3**), F-méthyl-4 méthyl-8 ombelliférone (**4**), F-méthyl-4 nor-limettine (**5**) et F-méthyl-4 diméthyl-5,7 coumarine (**6**).

Composés étudiés



Composé	R^5	R^6	R^7	R^8
1	H	H	OH	H
2	H	H	OH	OH
3	H	OH	OH	H
4	H	H	OH	Me
5	OH	H	OH	H
6	Me	H	Me	H

II. Partie expérimentale

Les spectres rmn du ^{13}C ont été enregistrés à l'aide d'un appareil Bruker WH-90 à transformée de Fourier, opérant à la fréquence 22,63 MHz. Une fenêtre spectrale de 4000 Hz et une mémoire de 8 K ont été utilisées ce qui permet une résolution spectrale d'environ 0,5 Hz et une précision de 0,03 ppm. Une impulsion de 4 μs ($\alpha 90° = 11$ μs) et un délai de 0,3 s entre les acquisitions ont été les conditions de tous les enregistrements standards. L'irradiation des fluors a été réalisée à l'aide d'un découpleur Brucker de type BSV 3; leur fréquence a été déterminée à partir des spectres ^{19}F préalablement enregistrés.

Les solutions d'environ 0,4 mol L^{-1} étaient préparées en plaçant 0,3 g de composé dans 3 mL de $CDCl_3$ et en rajoutant si nécessaire une faible quantité (de quelques gouttes à 0,5 mL) de CD_3OD afin d'assurer une solubilisation totale. Dans ces conditions, de 50 000 à 100 000 acquisitions (une nuit) étaient nécessaires pour obtenir des spectres exploitables.

Les déplacements chimiques sont mesurés en ppm par rapport au TMS utilisé en référence interne.

Les diverses coumarines étudiées ont été préparées suivant les modes opératoires décrits précédemment (1).

III. Attribution des différents signaux et déplacements chimiques correspondants

A. Attribution des signaux

L'étude détaillée des spectres des composés les plus solubles (F-méthyl-4 ombelliférone (**1**) et F-méthyl-4 diméthyl-5,7 coumarine (**6**)) a constitué la base de toutes nos attributions. Pour ces deux composés, les multiplicités observées dans les spectres réalisés avec ou sans découplage, tant du fluor que du proton, et la comparaison des données de la littérature, concernant les déplacements chimiques (2–7), les couplages (2–7, 8–10) dans des composés homologues, nous ont permis d'effectuer les attributions sans ambiguïté (cf. tableau 1).

Par rapport à l'ombelliférone et à la méthyl-4 ombelliférone, la détermination des effets induits par un F-méthyle en 4 nous a permis d'établir une régle d'incrémentation qui complétée par les résultats de la littérature (2), nous a permis d'établir les attributions ultérieures de tous les composés. Celles-ci sont rassemblées dans le tableau 2.

B. Effets du substituant F-méthyle

Nous avons rassemblé dans le tableau 3 les différences

1. Révision reçue le 9 février 1987.

2. Nous conserverons le terme coumarine pour désigner le squelette 2,4-benzopyran-1 one-2 et le terme F-méthyle ou F-alkyle pour désigner un substituant perfluoré (Cf. réf. 19).

des déplacements chimiques entre les hydroxycoumarines de référence et leurs homologues F-méthyl-4 substitués.

Malgré une certaine variation pouvant être attribuée à une non additivité déjà signalée dans le cas de dérivés di et tri substitués (2, 4), nous pouvons remarquer une certaine constance des effets du substituant F-méthyle sur les carbones voisins.

Effet α

Cet effet se manifeste sur le carbone C-4.

Notons qu'il est tout à fait inversé par rapport à ce que l'on pourrait attendre des données de la littérature. En effet, en série benzénique un substituant F-méthyle induit un déplacement vers les champs faibles d'environ +2,5 ppm (9, 11), alors que nous observons un déplacement vers les champs forts variant de −2 à −2,8 ppm.

Par contre, en série aliphatique, le remplacement d'un méthyle par un groupement F-méthyle ou F-alkyle provoque un déplacement vers les champs forts de −7 à −10 ppm (12). C'est bien ce que l'on observe en comparant avec les dérivés méthylés en 4.

Effets β

Deux carbones C-3 et C-10 sont à considérer. Ils subissent tous deux un déplacement vers les champs forts, voisin de −1 ppm pour le C-3 et de −6 ppm pour le C-10. Cet effet est bien en accord avec celui relevé en série benzénique (9, 11).[3]

Mais, c'est cette fois par rapport à la série coumarinique que l'on trouve une anomalie. En régle générale, dans le cas d'une substitution en 4 (méthyle, hydroxy), les signaux des carbones α sont déplacés vers les champs forts, mais le déplacement de carbone méthine (C-3) est toujours supérieur à ce qui est observé pour les carbones quaternaires C-10 (ou C-9).

Dans le cas d'un substituant F-méthyle, nous observons le phénomène inverse : le carbone C-10 est toujours le plus déplacé vers les champs forts.

Effets γ

Ils se manifestent sur les carbones C-2, C-9 et C-5.

Leurs valeurs relativement faibles sont de l'ordre de celles pouvant être produites par les variations de solvants et de concentration, mais ces effets sont tout de même significatifs (au moins pour les carbones C-2 et C-5).

Ces effets γ provoquent un déplacement vers les champs forts : ce déplacement est faible pour le C-2,[4] relativement important pour le C-5.

Cet effet *péri* en C-5 (−2,9 à −3,9 ppm) traduit un effet stérique diamagnétique bien connu, tout à fait comparable à ceux produits en série coumarinique par des substituants divers (méthyle, hydroxy ou méthoxy) qui vont de −3,2 à −5,3 ppm (2) et très voisins de celui observé (−3,4 ppm) dans le F-méthyl-1 naphtalène (11).

Effets longue distance

Nous ne discuterons pas des effets à plus longue distance qui nous paraissent vraiment négligeables.

Il eut par contre été beaucoup plus intéressant de discuter des effets provoqués par la proximité en *péri* des substituants hydroxy ou méthyle dans le cas des composés **5** et **6**. Malheureusement l'absence de tout élément de comparaison nous ôte cette possibilité. Malgré tout, nous pouvons noter qu'il n'y a aucune variation significative dans le déplacement chimique des CF_3 que le composé soit *péri* substitué ou non.

IV. Couplages fluor–carbone

Pour tous les composés étudiés, les différents couplages carbone–fluor sont bien distincts et aisément mesurables sur les

3. Il est probable qu'une erreur d'attribution entre carbones quaternaires C-9 et C-10 soit intervenue dans l'article de Doddrell *et al.* (11). La correction ainsi effectuée inverserait les déplacements chimiques de ces carbones et rendrait homogène les effets des CF_3.

4. L'effet sur le C-2 dans le composé **1** nous parait disproportionné et doit être ramené à une plus juste valeur en ajustant le déplacement chimique du C-2 de l'ombelliférone à 161 ppm, valeur moyenne de la littérature (2, 4, 6, 7).

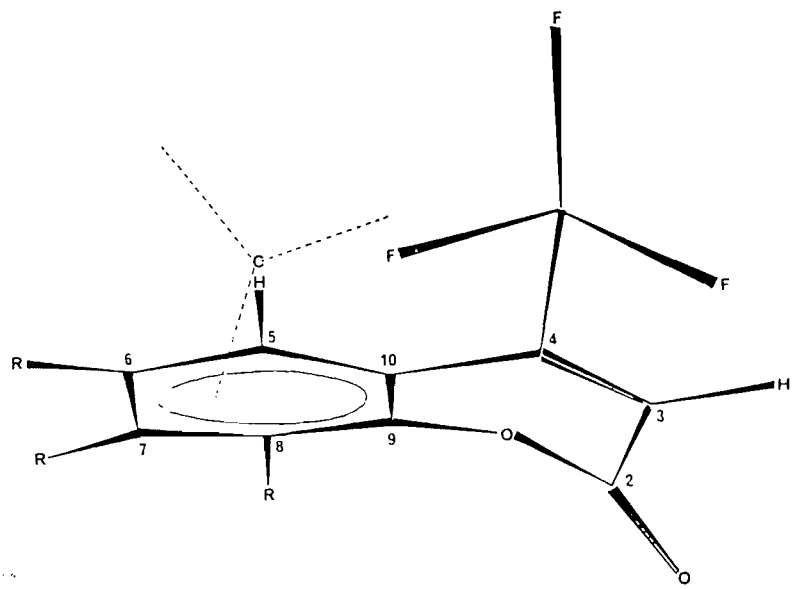

FIG. 1. Représentation perspective des F-méthyl-4 coumarines.

spectres : ils suivent l'ordre décroissant bien connu en série benzylique : $^2J_{CF} > {}^3J_{CF} > {}^5J_{CF} > {}^4J_{CF}$ (8–10).

Ce fait constitue d'ailleurs un critère d'attribution.

Un même type de couplage parait constant pour un même type de composé; c'est ainsi que l'on mesure $^1J_{CF}$ = 275 Hz, $^2J_{CF}$ = 32,4 et 33,8 Hz, $^3J_{CF}$ = 5,9 et 8,3 Hz, $^4J_{CF}$ = 2,9 Hz.

Plusieurs remarques s'imposent :

Si l'on peut mesurer un $^3J_{CF}$ de 5,9 ou 8,3 Hz sur les carbones C-3, les carbones C-10 similairement à 3 liaisons de distance des fluors ne manifestent aucun couplage.

Les carbones C-2 et C-9 ne présentent aucun couplage avec les atomes de fluor. Si ce fait n'est nullement surprenant (un $^4J_{CF}$ étant toujours très faible et souvent non observable), ce sont dés lors les couplages $^4J_{CF}$ apparaissant sur le C-5 qui deviennent exceptionnels par leur importance.

Enfin, dés que le composé est substitué en 5 (composés **5** et **6**), ce couplage $^4J_{CF}$ disparaît totalement. On peut alors observer un $^5J_{CF}$ particulièrement important (8,3 Hz) sur le méthyle en 5 du composé **6**. Or, dans notre travail précédent (1), nous faisions état d'un couplage proton–fluor longue distance entre les fluors α de la chaine F-alkyle et le proton en 5 (ou avec les protons méthyliques pour **6**). Nous avions attribué ces couplages exceptionnels à une transmission spatiale et à un phénomène de contact entre les deux noyaux couplés.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

Toutes ces observations nous conduisent à formuler l'interprétation suivante concernant ces couplages $^4J_{C5-F}$ et $^5J_{C-Me-F}$.

Ces deux couplages procédent vraisemblablement du même processus :

—la transmission du couplage ne s'effectue pas à travers les liaisons du système carboné cyclique (absence de $^3J_{CF}$ en C-10, absence de $^4J_{CF}$ en C-5 pour **5** et **6**).

—la transmission du couplage s'effectue à travers l'espace, non par un phénomène de contact direct (absence de $^4J_{CF}$ en C-5 pour **5** et **6**), mais elle nécessite la présence d'un noyau intermédiaire lui-même couplé avec les fluors (hydrogènes en 5 ou hydrogènes du méthyle en 5). L'importance de ce couplage dés lors croît aussi corrélativement avec l'importance du couplage proton–fluor qui lui-même dépend de la distance entre les noyaux couplés.[5]

Nous relions ainsi les deux types de couplages carbone–fluor et fluor–hydrogène et donnons ainsi une explication globale à toutes les observations tant en rmn du proton et du fluor qu'en ^{13}C.

Les carbones C-10, C-2 et C-9 ne peuvent être couplés avec les fluors car ils ne peuvent prétendre à un tel processus.

La proximité entre les substituants en *péri*, n'a pas pour seul effet le couplage $^5J_{CF}$ avec le méthyle. Elle provoque aussi une variation du couplage $^3J_{C3-F}$ qui atteint ainsi 8,3 Hz (composés **5** et **6**).

Cette augmentation a probablement pour cause un rapprochement du site C-3 (hydrogène et carbone) soit par déformation de la géométrie du système, soit en privilégiant certaines conformations (17, 18) (cf. fig. 1). C'est le seul effet «*péri*» décelable.

Par contre, aucun effet direct ne se manisfeste sur la constante $^1J_{CF}$. Elle semble insensible à toute variation dépendant d'un effet *péri*.

5. Un tel phénomène était déjà signalé par Jerome et Servis (13) dans le cas du méthyl-4 fluoro-5 phénanthrène et a été dernièrement évoqué dans le cas de l'halogénure de fluoro-8 méthyl-1 quinolinium (14) et dans plusieurs travaux récents (15, 16).

Remerciements

Nous remercions Mr. Bernard Septe, Ingénieur C.N.R.S., pour la part active qu'il a apportée à la réalisation de ce travail, tant dans la partie technique que dans les interprétations.

Ternary charge transfer complexes. V.[1] Complexes with thiazyl salts[2]

SYDNEY BROWNSTEIN[3] AND BRENDA LOUIE
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received September 15, 1986

SYDNEY BROWNSTEIN and BRENDA LOUIE. Can. J. Chem. **65**, 1361 (1987).

Charge transfer complexes $NS^+MFn^-\cdot$arene, where M = B, n = 4; M = P, As, or Sb, n = 6; and arene is hexamethylbenzene, mesitylene, napthalene, or 9,10-dimethylanthracene, have been prepared and characterized. The reaction of $NS^+MF_6^-$ (M = As or Sb) with highly oriented pyrolytic graphite results in graphite intercalated only with the metal fluoride anions.

SYDNEY BROWNSTEIN and BRENDA LOUIE. Can. J. Chem. **65**, 1361 (1987).

On a préparé et caractérisé les complexes de transfert de charge $MS^+MFn^-\cdot$arène dans lesquels M = B, n = 4; M = P, As ou Sb, n = 6 et arène = hexaméthylbenzène, mésitylène, naphtalène ou diméthyl-9,10 anthracène. La réaction des composés $MS^+MF_6^-$ (M = As ou Sb) avec du graphite pyrolytique hautement orienté conduit à des graphites qui sont uniquement intercalés par des anions de fluorures métalliques.

[Traduit par la revue]

Introduction

Numerous charge transfer (CT) complexes of type $NO^-MXn^-\cdot$ arene have been previously reported, where M may be B, Al, Ga, Tl, P, As, Sb, Nb, Ta, Mo, W, U, or Fe; X may be F or Cl; n may be 4, 6, or 7; and arene may be benzene or a methyl substituted benzene (1–3). Some of these complexes exhibit appreciable conductivity in the solid state and have been structurally characterized. We have now prepared several analogs of this type of CT system incorporating the thiazyl cation, NS^+.

It has previously been reported that nitronium salts such as $NO_2^+SbF_6^-$ react with graphite to form highly conducting intercalation compounds. In CH_3NO_2 as solvent the simultaneous intercalation of solvent molecules and SbF_6^- occurs (4), and in one study a small amount of $NO_2^+SbF_6^-$ itself has been suggested as an additional intercalated species (5). In a related U.S. patent there is brief mention of intercalating numerous stable anions into graphite by exposing the carbon to a saturated solution of the nitrosyl salt of the anion (6). These reactions are related to the intercalation of AsF_6^- into graphite by the use of $O_2^+AsF_6^-$ (7). The cation of the salt is reduced to a neutral gas while the anion becomes the primary intercalated species in the oxidized graphite. Unlike NO, the isoelectronic NS does not exist as a stable entity. Therefore it was of interest to examine how thiazyl salts such as $NS^+SbF_6^-$ would behave when in contact with graphite.

Experimental

$F_2S{=}NCOF$ (8) was prepared by a literature method from $Si(OCN)_4$ (9) and SF_4. NSF was prepared by the decomposition of $F_2S{=}NCOF$ over CsF with the following modifications of the previously described method (10). $F_2S{=}NCOF$ (6 mmol) was heated with 2 g of dried CsF in a 20-mL Monel cylinder for 3 h at 126°C and then the reactor contents were fractionated through a series of U-tubes at −45, −78, and −196°C respectively. A small amount of $F_2S{=}NCOF$ was found in the −45°C U-tube, NSF was isolated from the −78°C U-tube, while the −196°C trap contained primarily COF_2. NSF was prepared only as needed since it polymerizes readily at room temperature.

For the reactions involving graphite, rectangular flakes (4 × 2 × 0.5 mm) of highly oriented pyrolytic graphite (HOPG) were heated to 280°C *in vacuo* for 8–10 h before use.

$(NSCl)_3$ was prepared by a standard method (7). Methylene chloride and 1,2-dichloroethane were purified (8), distilled from P_2O_5, and stored under vacuum. All other starting materials were used as purchased or purified as previously described (11–13).

$NS^+AsF_6^-\cdot$HMB (HMB = hexamethylbenzene)

HMB (0.4 mmol) was weighed accurately into a glass reactor equipped with a Teflon high vacuum stopcock and an nmr tube as a side arm. Approximately 2 mL of either CH_2Cl_2 or SO_2 was condensed into the reactor and the reactor reweighed. One equivalent each of AsF_5 and NSF were then condensed onto the reaction mixture, yielding an intense red-brown solution immediately upon thawing and mixing. The solution was mixed gently at room temperature for a few minutes and then all volatile materials were removed *in vacuo*. The resulting dark red-brown solid was dried *in vacuo* for a minimum of 2 h. *Anal.* calcd. for $C_{12}H_{18}NSF_6As$: C 36.28, H 4.57, N 3.53, S 8.07, As 18.86%; found: C 37.06, H 4.75, N 4.03, S 11.3, As 15.8%.

$NS^+AsF_6^-\cdot$HMB was also prepared by first isolating $NS^+AsF_6^-$ by the method of Mews (13), and subsequently adding one equivalent of HMB to the salt, followed by 2 mL of CH_2Cl_2 or SO_2. Evacuation of the solvent after gentle mixing for several minutes resulted in the same dark red-brown solid product. The complexes $NS^+MF_n^-\cdot$arene (M = B, n = 4; M = P, As, or Sb, n = 6; arene = HMB, mesitylene (mes), naphthalene (npth), or 9,10-dimethylanthracene (DMA)) were similarly prepared by the methods described above. *Anal.* calcd. for $C_{12}H_{18}NSF_6Sb$: C 32.46, H 4.09, N 3.15, S 7.22%; found: C 38.16, H 4.45, N 3.45, S 8.25%.

$NS^+MF_6^-$ (M = As or Sb) and HOPG

The graphite reactions were conducted in a glass U-tube closed on either end with a Teflon high vacuum stopcock. One side of the U-tube had an additional side arm, which could be isolated from the U-tube via another Teflon high vacuum stopcock. Graphite flakes were heated *in vacuo* in the side arm and then isolated from the U-tube. $NS^+SbF_6^-$ (13) was prepared by first condensing SbF_5 directly from the manufacturer's cylinder into the U-tube using a Dry Ice/acetone bath and a dynamic vacuum. SO_2 and NSF were subsequently introduced into the U-tube. The graphite flakes were tipped into this solution, containing an excess of $NS^+SbF_6^-$. After 8 days at room temperature the solution was tipped into the sidearm and the graphite was washed several times with recondensed SO_2. The graphite surfaces were steel blue in colour and the flakes had swollen to approximately 3 times their original thickness. The graphite was pumped *in vacuo* for several minutes to remove any residual SO_2. Infrared and ^{19}F resonance spectra of the graphite showed only the presence of intercalated SbF_6^- (14) and no evidence for intercalated NS^+. A similar procedure with AsF_5 showed only the hexafluoroarsenate anion, identified by its characteristic infrared and ^{19}F resonance spectra (15), intercalated in the HOPG.

Ultravilet–visible, infrared, and nmr spectra were obtained as previously described (13). Conductance measurements were performed on a pressed disc having a diameter and thickness of 19 and 0.2 mm respectively. In a nitrogen atmosphere the disc was mounted in a three-terminal, circular, parallel-plate, brass capacitor cell of an Andonion Associates, Inc. variable temperature cryogenic system (0–25/7M series). Conductance at a frequency of 10 kHz was measured with a Hewlett–Packard 4275A multi-frequency LCR meter and verified with a General Radio 1615-A capacitance bridge.

Results and discussion

$NS^+MF_n^-$·arene complexes have been prepared from NSF, MF_{n-1}, and the aromatic compound in CH_2Cl_2 or SO_2 as solvent. These intensely colored CT complexes have been identified by the physical properties listed in Table 1. All of these compounds are thermally unstable in solution at room temperature. Thus nmr spectra were recorded at −40°C, as solutions allowed to warm to ambient temperatures displayed decomposition via fluorination of the aromatic. All of the thiazyl complexes decompose fairly rapidly in air but can be stored in glass containers at room temperature in an inert atmosphere. As an added precaution the samples were routinely stored in the dark. Among the various hydrocarbons, the HMB adducts tend to be the most stable.

The N—S stretching vibration of the thiazyl cation, NS^+ (1437 cm^{-1}), is at a significantly higher frequency than that of NSF (1361 cm^{-1}) (16). We have found that the effect of an aromatic hydrocarbon on $NS^+MF_n^-$ salts is to consistently lower the N—S stretching frequency by about 40 cm^{-1}. A similar but much larger effect was observed for the NO^+ congeners (2), indicating that in these systems NO^+ is more effective in acquiring electron density from the arene than NS^+. The weaker charge transfer interaction present in the thiazyl compounds is manifested in the decreased stability of these species in solution or in the air as compared to their NO^+ analogs. As expected, the presence of the aromatic hydrocarbon has little effect on the frequencies observed for the M—F vibrations. This is consistent with π-electron donation from the arene into the π^* antibonding orbitals of the thiazyl cation. The close proximity of the cationic portion of the salt to the aromatic ring has been observed in the crystal structures of some of the NO^+ congeners (2, 3).

The ^1H and ^{13}C nmr spectra of the CT compounds further reflect the deshielding of the aromatic hydrocarbon by exhibiting resonances displaced downfield from those of the uncomplexed arene. In the ^{19}F nmr spectra the observed chemical shifts are those expected for BF_4^- or MF_6^- (M = P, As, Sb) anions.

The uv–visible spectra of the thiazyl CT compounds, where arene is HMB, mes, npth, display strong absorptions due to the aromatic hydrocarbon in the region of 250–300 nm. The CT band is present as a weaker absorption at slightly longer wavelength. In general the CT interaction broadens all of the peaks in the spectrum so that the CT band itself is not well defined, usually being partially obscured by the poorly resolved aromatic bands. For the HMB adducts the CT absorption shifts to longer wavelength as M is changed from B to P to As to Sb, a trend not previously observed for the NO^+ congeners (1, 2). For $NS^+MF_6^-$·HMB (M = As or Sb) the CT absorptions are sufficiently separated from the aromatic portion of the spectrum so that a definite band maximum can be observed. The spectra of HMB and $NS^+MF_n^-$·HMB (M = B, n = 4; M = As, n = 6) are shown in Fig. 1 as illustrative examples of typical uv spectra that were obtained. The CT peaks for the DMA derivatives were obscured by broadened bands due to the DMA and thus the positions of the maxima for the charge transfer peaks could not be measured. It is the long tail of these broad bands extending into the visible which causes the intense colour found for these solutions.

Any CT complexes initially formed between NO^+ salts and

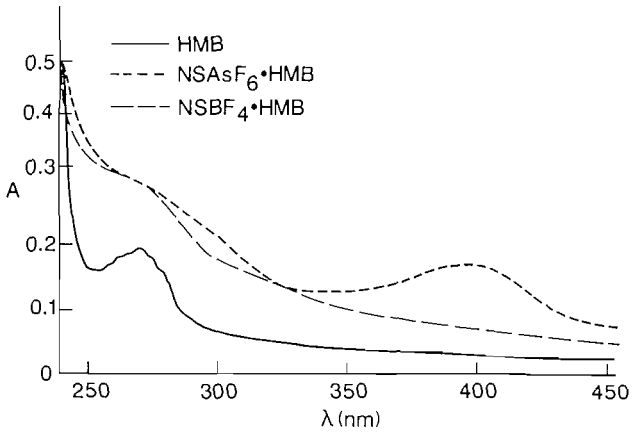

FIG. 1. The optical spectra of HMB, $NSAsF_6 \cdot HMB$, and $NSBF_4 \cdot HMB$.

npth or DMA underwent rapid oxygenation or halogenation of the aromatic portion (2). In contrast, the NS^+ CT complexes of these hydrocarbons can be isolated as solids although they are partially dissociated in solution. The increased dissociation of the polycyclic hydrocarbons relative to hexamethylbenzene has been reported for the tetracyanoethylene adducts (17). It was not possible to obtain meaningful magnetic resonance spectra of these complexes because of this dissociation.

From the limited crystal data previously reported for CT species containing the nitrosyl cation it appears that high conductivity ($>10^{-13}$ ohm^{-1} cm^{-1}) requires a long N—O bond (2, 3). We have so far been unable to obtain crystals of the NS^+ complexes suitable for X-ray diffraction. Routine conductance measurements on the thiazyl complexes presented difficulties due both to the quantity of material required to press an adequate pellet and the air sensitivity of the compounds. Nevertheless the conductivity of $NS^+AsF_6^- \cdot HMB$ at room temperature was measured to be 3.3×10^{-11} ohm^{-1} cm^{-1} at an operating frequency of 10 kHz. This is significantly smaller than the conductivity of 1.4×10^{-7} ohm^{-1} cm^{-1} reported for $NO^+AsF^- \cdot HMB$ (2) and may reflect the lesser extent of charge transfer in the NS^+ system.

We have observed that the thiazyl salts of AsF_6^- and SbF_6^- react with HOPG to yield a product in which the metal fluoride anions alone are intercalated into the graphite. This is a circuitous route to these materials, however, as the metal fluorides themselves lead to the same end products. With the thiazyl salts the cation NS^+ oxidizes the graphite, but does not itself intercalate.

The rather poor agreement of the elemental analyses with the theoretical values illustrates the difficulties in obtaining pure materials with these very reactive and thermally labile compounds.

The reaction of $(NSCl)_3$ and HMB with $AlCl_3$ or $FeCl_3$ in 1,2-dichloroethane yielded clear solutions with the dark red-brown colour characteristic of CT complex formation. However, removal of the solvent resulted only in tacky dark brown residues that would not solidify after prolonged pumping *in vacuo*. These residues were too unstable to obtain meaningful ir spectra, both samples being extremely hygroscopic. Because of their sensitivity to moisture these systems were not studied further.

Acknowledgements

We would like to thank Dr. A. Moore (Union Carbide) for the gift of HOPG and Dr. M. Desando for assistance with the electrical conductivity measurements.

The reduction of specific disulfides with titanium(III) chloride

HUGH A. AKERS, MENG C. VANG,[1] AND TRACIE D. UPDIKE[2]
Department of Chemistry, Lamar University, Beaumont, TX 77710, U.S.A.

Received October 3, 1986

HUGH A. AKERS, MENG C. VANG, and TRACIE D. UPDIKE. Can. J. Chem. **65**, 1364 (1987).

The reaction between titanium(III) chloride and disulfides was investigated. Aryl and alkyl disulfides did not react while heterocyclic aromatic disulfides with a nitrogen α to the sulfur were reduced to the corresponding thiols. Products were identified and characterized by nuclear magnetic resonance and infrared spectra, and melting point comparisons with authentic compounds. The reductions occurred only in the presence of citrate and were found to require 2 moles of titanium(III) per mole of disulfide.

HUGH A. AKERS, MENG C. VANG et TRACIE D. UPDIKE. Can. J. Chem. **65**, 1364 (1987).

On a étudié la réaction du chlorure de titane (III) avec les disulfures. Les disulfures d'aryles ou d'alkyles ne réagissent pas alors que les disulfures d'hétérocycles aromatiques portant un azote en α du soufre sont réduits en thiols correspondants. On a identifié et caractérisé les produits grâce à des comparaisons de leurs spectres de résonance magnétique nucléaire et infra-rouge ainsi que de leurs points de fusion avec ceux de produits authentiques. Les réductions ne se produisent qu'en présence de citrate et on a trouvé qu'il faut deux moles de titane (III) par mole de disulfure.

[Traduit par la revue]

Interconversions between thiols and disulfide are important in a variety of chemical and biochemical situations. Numerous procedures have been presented for the oxidation of thiols or reduction of disulfides (1). Titanium(III) chloride has been reported as a mild reducing agent, most frequently for the reduction of nitrogen–oxygen bonds (2). A single often cited publication implicates titanium(III) in the reduction of disulfides (3); however, in this laboratory's continuing studies on the use of titanium(III) chloride for the reduction of substances of biochemical interest, it was observed that cystine (a disulfide) was not reduced. To resolve this problem, several model disulfides were exposed to titanium(III) chloride and the products of this exposure identified. In addition, the amounts of titanium(III) consumed during the exposure to these model disulfides were determined.

Experimental

Titanium(III) chloride as a 20% aqueous solution was from J. T. Baker Chemical Company or as a solid from Aldrich Chemical Company. The disulfides were obtained from Aldrich Chemical Co., Pfaltz and Bauer, Inc., Sigma Chemical Co., or were prepared by oxidation of the corresponding thiols with iodine (4). Thiols were purchased from the above suppliers or were prepared by reduction of the disulfide with zinc dust in acetic acid (5). 2-Thio-5-aminopyridine was prepared from 2,2′-dithio-bis(5-nitropyridine) by reduction with zinc dust and acetic acid (5). The free base of 2-thio-4(6)-methylpyrimidine was prepared (6) from the hydrochloride salt (Aldrich Chemical Co.).

Phenyl 2-pyridyl disulfide was synthesized from benzenesulfenyl chloride and the sodium salt of 2-thiopyridine (7). The resulting product gave an mp of 48–49°C (lit. (7) mp 49°C), a picrate salt with an mp of 127°C (lit. (7) mp 127°C), and upon gc/ms produced an M^+ ion of 219 m/e ($C_{11}H_9S_2N$ has a mol. wt. of 219).

All ir spectra (4000–600 cm^{-1}) were recorded on a Perkin–Elmer 710B infrared spectrophotometer. Samples were run on NaCl plates as mulls in Nujol or as the neat liquids. Melting points were determined with a Thomas Hoover Unimelt apparatus and were uncorrected. A Varian EM-390 nuclear magnetic resonance spectrometer was utilized to record 90-MHz proton spectra of the compounds and a Hewlett–Packard 5970B gc/ms was used for the analysis of phenyl 2-pyridyl disulfide. Chemical shifts were measured relative to an internal standard of tetramethylsilane for samples run in deuterochloroform and deuterated dimethylsulfoxide.

For exposure of disulfides to titanium(III) chloride, 0.11–2.0 g of disulfide was dissolved in 10–100 mL of acetic acid (8.7 or 17.4 *M*) and (or) ethanol, combined with 5–40 mL of 1.4 *M* aqueous sodium citrate, and aqueous titanium(III) chloride was added slowly until a faint purple color persisted. The solutions during reduction usually had a pH between 4.5 and 6.0. After a 3–24 h wait to allow any excess titanium(III) to oxidize with air to titanium(IV), the mixture was extracted with ether (often continuous) or $CHCl_3$. Solid products were usually crystallized by concentrating the extracting solvent, while liquids were recovered from the extraction solvent by distillation. Prior to extraction of 2-thio-5-aminopyridine the mixture was made alkaline (about pH 11) with NaOH.

Stoichiometric determinations were carried out by dissolving between 0.001 and 0.005 mol of the disulfide in 25 mL of ethanol, water, or acetic acid. Standard titanium(III) chloride (20 mL) and 10 mL of 1.7 *M* sodium citrate were added. After a measured period of time (usually 30 min), the excess titanium(III) chloride was titrated against standard ferric ammonium sulfate, using sodium thiocyanate as indicator (3, 8, 9). The titanium(III)/disulfide consumptive ratio was then calculated after applying a correction factor obtained from titration of a disulfide-free sample in the appropriate solvent. The values reported represent the average of at least 3 separate stoichiometric determinations.

Results

The effect of titanium(III) chloride on disulfides is presented in Table 1. Also recorded are the yield, melting (boiling) point, and mixture melting point of the product recovered. The ir and nmr were also determined (not shown) for each reactant and product. Products from exposure to titanium(III) chloride gave mp, nmr, and ir spectra that were identical to the original disulfides for substances **1** through **8** and to the corresponding thiol for substances **9**–**17**. Spectral comparisons were made with spectra from authentic compounds or published information (16). All disulfides failed to oxidize titanium(III) chloride in the absence of sodium citrate (data not shown). All products were found to burn without leaving an ash, and if soluble in water or ethanol did not produce a precipitate upon the addition of NaOH.

In addition to the substances listed in Table 1, the following

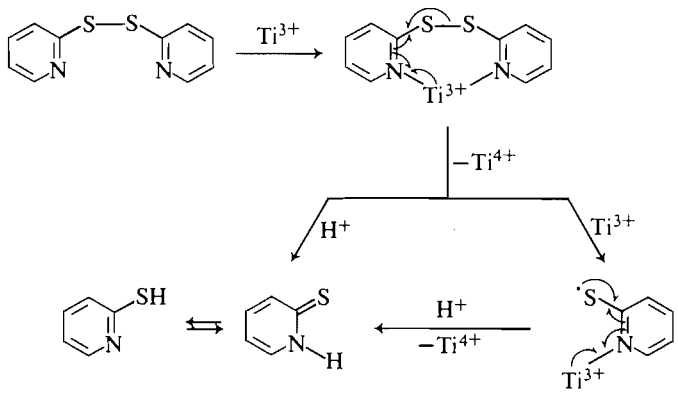
disulfides did not oxidize titanium(III) chloride in the presence or absence of sodium citrate: DL-6,8-thioctic acid (lipoic acid); DL-6,8-thioctic acid amide; *trans*-4,5-dithiane-4,5-diol; cystamine; oxidized glutathione (free acid); L-cystine dimethylester; and DL-homocystine. The original disulfides were not recovered following exposure to titanium(III) chloride; therefore the substances were not included in Table 1.

Discussion

The product of the exposure of disulfides to titanium(III) chloride in the presence of citrate is clearly the original disulfide for compounds **1** through **8** and the corresponding thiol for compounds **9** through **17**. From nmr observations it was determined that the carbon–hydrogen skeleton of the compounds was not altered by exposure to titanium(III). The determination of the thiol or disulfide nature of the product was determined primarily by ir (1). All thiols in Table 1 were found to have C=N stretching frequencies of 1600–1630 cm^{-1} while that of the disulfides was located at 1565–1585 cm^{-1}. The thione tautomer of all the thiols produced readily identifiable bands at 1100–1800 cm^{-1} (C=S stretching), 3110–3200 cm^{-1} (N—H stretching), and 1500–1590 cm^{-1} (N—H bending), which were absent in all spectra of the disulfides. Because all products burned without an ash and gave mps and ir spectra identical to titanium-free authentic compounds or reference spectra, the products were judged to be free of titanium.

The disulfides in Table 1 that were reduced by titanium(III) were observed to require 1.9 moles of titanium(III) per mole of disulfide, which is in agreement with the theoretical quantity of 2 moles of titanium(III) required per mole of disulfide. Substance **9** requires 6 moles of titanium(III) because the N-oxide portions are also reduced (requiring 2 moles of titanium(III) each). Each nitro group is reduced to an amino group with 6 moles of titanium(III); therefore, substance **11** required 14 moles of titanium(III). The stoichiometry observed for **16** suggests there may have been reduction in addition to the disulfide bond, possibly of the benzoxazole ring; however, no product in addition to the thiol was observed. Little systematic literature information exists on the reduction potentials of disulfides and titanium(III). However, diaryl disulfides and diheterocyclic disulfides (e.g., disulfide of 2-thiohistidine) are more readily reduced than dialkyl disulfides (17, 18). Titanium(IV) to titanium(III) is usually listed in handbooks with a reduction potential of −0.05 to −0.10 volts but the potential is quite pH dependent (19). In the presence of ligands or chelators, titanium(III) is known to be a stronger reducing agent (20) and has altered reactivities (2, 21).

The failure of disulfides **1** through **8** to be reduced by titan-



SCHEME 1. The proposed mechanism of reduction of heterocyclic aromatic disulfides by titanium(III) chloride.

ium(III) chloride suggests a reaction mechanism (Scheme 1) involving chelation of titanium(III) to both heteroaromatic nitrogens of **9** through **17**. The titanium(III) relinquishes an electron, the disulfide bond cleaves homolytically, titanium(IV) is released, and, following proton abstraction from the solvent, the thione tautomer of the thioamide and a free radical are produced. A second titanium(III) reduces the free radical to produce a second molecule of the thione (which then tautomerizes to the thiol). Support for this mechanism also comes from the fact that **10** is known to form seven-membered ring complexes with transition metal ions (22, 23). Also, because the disulfide bond of **10** is lengthened and the geometry was slightly altered by complex formation (23), it should become more susceptible to reduction.

The type of disulfide shown here to be reduced by titanium(III) is not the most common in nature; however, it could occur with such substances as 2-thiolhistidine (an ergot fungal product component) and the thiol tautomer of 4-thiouridine (a common tRNA component). Substances examined in Table 1 that were reduced include a common topical antifungal and antibacterial agent (substance **10**) and a compound used in the production of rubber (substance **13**). Compound **10** is also used extensively in thiol identification and quantification (24), and recently 3-(2-pyridyldithio)propanoyl derivatives have been used extensively by biochemists as covalent coupling tools (25). Because of the color change associated with the oxidation of titanium(III), this reaction makes a convenient spot test for the determination of the type of disulfide present in an unknown substance.

Synthesis and characterization of transition metal complexes containing novel, unsymmetric tridentate organogallate ligands

EMMANUEL C. ONYIRIUKA AND ALAN STORR

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received August 18, 1986

EMMANUEL C. ONYIRIUKA and ALAN STORR. Can. J. Chem. **65**, 1367 (1987).

Two novel unsymmetric tridentate anionic organogallate ligands have been synthesized and their coordinating properties toward a number of transition metal carbonyl species, and toward the "NINO" moiety, have been investigated. The ligand $[Me_2Ga(N_2C_3H_3)\cdot O(C_5H_3N)CH_2NMe_2]^-$, L_a, has shown unusual behaviour in that it produces both the *fac* and *mer* octahedral isomers, $L_aM(CO)_3$, (M = Mn or Re), on reaction with $Mn(CO)_5Br$ and $[Re(CO)_4Cl]_2$, respectively. In addition, this ligand gives a stable Rh(III) addition product, $L_aRh(Me)(I)CO$, on reaction of $L_aRh(CO)$ with MeI. The second ligand, $[Me_2Ga(N_2C_3H_3)\cdot O(C_9H_6N)]^-$, L_q, containing a quinolyl moiety in addition to a pyrazolyl group attached to dimethylgallium, displays more predictable behaviour in its coordinating properties.

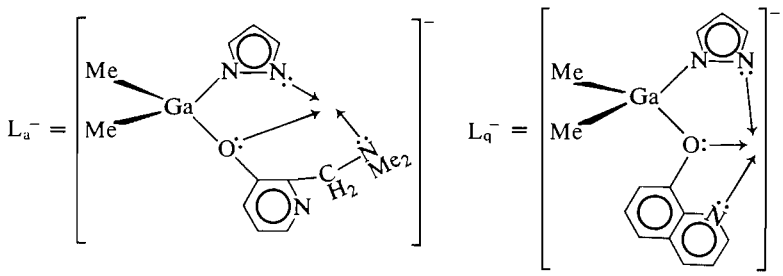
EMMANUEL C. ONYIRIUKA et ALAN STORR. Can. J. Chem. **65**, 1367 (1987).

On a synthétisé deux nouveaux ligands organogallates anioniques, tridentates et qui ne sont pas symétriques et on a examiné leurs propriétés de coordination par rapport à un certain nombre d'espèces de métaux de transition carbonylés. Le ligand $[Me_2Ga(N_2C_3H_3)\cdot O(C_5H_3N)CH_2NMe_2]^-$, L_a, a un comportement inhabituel; par réaction respectivement avec le $Mn(CO)_5Br$ et le $[Re(CO)_4Cl]_2$, il conduit aux deux isomères octaédriques *fac* et *mer*. De plus, la réaction du produit $L_aRh(CO)$ avec le MeI conduit à un produit d'addition stable du Rh(III), soit le $L_aRh(Me)(I)CO$. Les propriétés de coordination du second ligand, $[Me_2Ga(N_2C_3H_3)\cdot O(C_9H_6N)]^-$, L_q, qui contient une portion quinoléyle en plus du groupement pyrazolyle attaché au diméthylgallium, sont plus prévisibles.

[Traduit par la revue]

Introduction

The first of a new class of unsymmetric tridentate chelating organogallate ligands was introduced some time ago (1). These ligand systems, containing a pyrazolyl group, together with a bifunctional donor moiety, both attached to a dimethylgallium unit, have been shown to coordinate facially in a variety of octahedral transition metal carbonyl compounds (2–4). In addition both the *fac* and *mer* isomers have been structurally characterized for the coordination compound $[Me_2Gapz(OCH_2CH_2NH_2)]_2Ni$ (pz = pyrazolyl, $N_2C_3H_3$) (5). The many novel aspects displayed by compounds incorporating this class of ligand prompted further investigation into the general area of unsymmetrical uninegative organogallate ligands to include the more sterically bulky amino-pyridyl moiety as well as a fused quinolyl "aromatic" unit in the ligand system to give L_a and L_q, respectively:



The present account details the reactivity of the above ligands toward a variety of transition metal halide species.

Experimental

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen, in a nitrogen-blanketed apparatus, or on a high-vacuum line. Tetrahydrofuran (THF) was dried by refluxing over Na/benzophenone and was used immediately following distillation. Benzene, CH_2Cl_2, and hexane were dried by refluxing over potassium, calcium hydride, and calcium sulphate respectively, followed by distillation. Sodium pyrazolide was prepared by reacting sodium hydride (Alfa) with pyrazole (K and K Laboratories) in THF. Trimethylgallium (6), Ni(NO)I (7), $Mn(CO)_5Br$ (8), $[Re(CO)_4Cl]_2$ (9), and $(MeCN)_2Mo(\eta^3\text{-}C_3H_5)(CO)_2Br$ (10) were prepared according to literature methods. $[Rh(CO)_2Cl]_2$ (Strem Chemicals), 2-(dimethylaminomethyl)-3-hydroxy pyridine (Aldrich), and 8-quinolinol (Eastman organic chemicals) were used as supplied.

Preparation of the ligands L_a^- and L_q^-

$$Me_3Ga + Na^+(N_2C_3H_3)^- \rightarrow Na^+[Me_3Ga(N_2C_3H_3)]^-$$

$$Na^+[Me_3Ga(N_2C_3H_3)]^- + HO(C_5H_3N)CH_2NMe_2 \rightarrow Na^+L_a^- + CH_4$$

Trimethylgallium (6.20 g, 54.0 mmol) in ~50 mL THF was added to sodium pyrazolide (4.86 g, 54.0 mmol) dissolved in ~50 mL THF. The reaction mixture was stirred for ~4 h. The solution was then diluted with THF to 500 mL in a volumetric flask. An 12.96 mmol aliquot of this standard $Na^+[Me_3Ga(N_2C_3H_3)]^-$ ligand solution was added to a stirred solution of 2-(dimethylaminomethyl)-3-hydroxy-

pyridine (1.973 g, 12.96 mmol) in the same solvent. The reaction mixture was refluxed under N_2 until the evolution of methane gas had ceased completely (~2 days). The cooled solution was then diluted with THF to 250 mL in a volumetric flask. Aliquots of this standard $Na^+L_a^-$ ligand solution were used in subsequent reactions with transition metal halide species.

The ligand $Na^+L_q^-$ was prepared by an identical procedure to that described above, using 8-quinolinol, $HO(C_9H_6N)$, as the starting material. Aliquots of the resulting $Na^+L_q^-$ standard solution were used in subsequent reactions.

Preparation of $L_aM(CO)_3$ (M = Re, Mn)

A 40.0 mL aliquot of the ligand solution $Na^+L_a^-$ (0.64 mmol) was added slowly to $[Re(CO)_4Cl]_2$ (0.216 g, 0.324 mmol) dissolved in 30 mL THF. The reaction mixture turned cloudy almost immediately. The reaction mixture was refluxed for ~24 h during which time the cloudiness increased and the yellow coloration intensified. The solution was cooled to room temperature and the solvent removed under vacuum. The resulting residue was extracted with benzene and filtered. Evaporation of the benzene solvent containing the extracts afforded pale yellow crystalline needles of the product $L_aRe(CO)_3$ in approximately 80% yield.

The $L_aMn(CO)_3$ complex was prepared similarly using $Mn(CO)_5Br$ as the starting material. The orange solid product was collected in ~75% yield. Physical data for both complexes are compiled in Tables 1 and 2.

Preparation of $L_aNi(NO)$

To a stirred solution of Ni(NO)I (0.33 g, 1.5 mmol) in ~50 mL THF was added an equimolar amount of the $Na^+L_a^-$ (1.5 mmol) ligand solution in the same solvent. The resulting dark blue solution was stirred overnight and the solvent then removed under vacuum. The dark blue residue was extracted with benzene. The benzene filtrate was concentrated, and upon evaporation of the solvent, blue crystals of the product were recovered in ~60% yield. Analytical and spectroscopic data for the complex are collected in Tables 1 and 2.

Preparation of $L_aRh(CO)$

Two molar equivalents of the ligand $Na^+L_a^-$ were added to $[Rh(CO)_2Cl]_2$ (0.30 g, 0.77 mmol) dissolved in ~40 mL THF. The reaction mixture was refluxed under nitrogen until the disappearance of the $[Rh(CO)_2Cl]_2$ dimer (ν_{CO}: 2068, 1989 cm^{-1} THF) was indicated by ir measurements. At this juncture, three new brands had appeared in the ν_{CO} region of the spectrum at 2085, 2025, and 1970 cm^{-1}, respectively. The reaction mixture was cooled, and the solvent removed *in vacuo*. The residue was washed with hexane followed by extraction with benzene. Evaporation of the benzene solvent from the filtrate containing the extracts afforded orange crystals of the product in ~60% yield. The solid is moderately stable but its solutions decompose with time. Physical data for the complex are summarized in Tables 1 and 2.

Preparation of $L_qM(CO)_3$ (M = Re, Mn)

Two molar equivalents of $Na^+L_q^-$ ligand solution in THF were added to $[Re(CO)_4Cl]_2$ (0.18 g, 0.27 mmol) dissolved in 30 mL THF. The reaction mixture was refluxed overnight. The solvent was then removed under vacuum. The residue was extracted in benzene. Evaporation of the benzene from the filtrate resulted in a yellow cake. Recrystallization of the yellow cake from CH_2Cl_2/hexane (1:1) afforded yellow crystals of the $L_qRe(CO)_3$ product in ~80% yield.

The $L_qMn(CO)_3$ complex was prepared by an identical procedure using $Mn(CO)_5Br$ as starting material, and benzene as the crystallization solvent. The orange crystals of the product were collected in ~80% yield. Analytical, ir, and ^1H nmr data for both complexes are listed in Tables 1 and 2.

Preparation of $L_qMo(CO)_2(\eta^3\text{-}C_3H_5)$

Stoichiometric amounts of the $Na^+L_q^-$ ligand solution and $(MeCN)_2Mo(\eta^3\text{-}C_3H_5)(CO)_2Br$ were reacted in THF. After stirring the reaction mixture overnight, the solvent was removed *in vacuo*. The resulting residue was extracted with hexane and filtered. Evaporation of the hexane from the filtrate afforded red–orange crystals of the product in ~70% yield. Analytical, ir, and ^1H nmr data for this product are given in Tables 1 and 2.

Preparation of $L_qRh(CO)$

Preparation of the compound L_qRhCO was accomplished by a similar procedure to the one described above for $L_aRh(CO)$. New ν_{CO} bands at 2080, 2020, and 1965 cm^{-1} in THF were indicated by ir sampling of the reaction mixture prior to solvent removal *in vacuo*. After work-up, yellow orange crystals of the product were isolated in ~65% yield. Analytical, ir, and ^1H nmr data for the compound are collected in Tables 1 and 2.

Reaction of $L_aRh(CO)$ with MeI

$$L_aRhCO + MeI \rightarrow L_aRh(Me)(I)CO$$

A slight excess of methyl iodide in CH_2Cl_2 was added dropwise to a stirred solution of L_aRhCO (0.40 g, 0.70 mmol) in the same solvent. After stirring the reaction mixture at room temperature for about 18 h,

the initial orange solution had turned deep red–orange. The ir spectrum of the solution at this stage revealed the presence of a new ν_{CO} band at ~2060 cm^{-1} and the complete disappearance of the ν_{CO} band at 1970 cm^{-1}, attributable to the L_aRhCO starting material. Removal of the solvent *in vacuo*, extraction of the residue in benzene, followed by recrystallization from CH_2Cl_2, afforded red crystals of the product in almost quantitative yield. This compound contained a trace of benzene solvate which remained after several days of pumping under vacuum.

Anal. calcd. for $[Me_2Gapz{\cdot}O(C_5H_3N)CH_2NMe_2]Rh(Me)(I)CO$ $0.5C_6H_6$: C 34.31, H 4.13, N 8.89; found: C 33.93, H 4.06, N 8.55. Infrared (CH_2Cl_2) ν_{CO}: 2060 cm^{-1}; ir (Nujol) ν_{CO}: 2055 cm^{-1}. ^{1}H nmr (270 MHz, $CDCl_3$) $\tau CHCl_3$ = 2.73 ppm, 10.34s, 10.12s (—$GaMe_2$); 8.85s, 7.63s (—NMe_2); 6.15s, (—CH_2); 3.71t (pz-H^4); 2.43d (pz-H^3); 2.98d (pz-H^5); 9.25s (Rh-Me) (J_{HCCH} = ~2 Hz for pz protons). Positive ion fast atom bombardment mass spectrometry (FABMS) in thioglycerol matrix: $[P + H]^+$, $[P - H]^+$, and $[P - Me]^+$ (P^+ = parent ion) ion signals were observed at 591, 589, and 575 mass units, respectively.

Reaction of L_qRh(CO) with MeI

$$L_qRhCO + MeI \rightarrow L_qRh(COMe)I$$

To a solution of L_qRhCO (0.40 g, 0.91 mmol) in ~35 mL CH_2Cl_2 was added one molar equivalent of MeI in the same solvent. The mixture was stirred for about 1½ h, at which stage ir evidence indicated the presence of two new bands in the ν_{CO} region of the spectrum at ~2070 and 1700 cm^{-1}, respectively; with no trace of the ν_{CO} band due to the L_qRhCO starting material. The solvent was then allowed to evaporate from the solution. The dark orange solid obtained was washed in hexane followed by benzene to give small dark orange crystals in low yield (~35%).

Anal. calcd. for $[Me_2GapzO(C_9H_6N)]Rh(COMe)I$: C 32.90, H 3.08, N 7.20; found: C 33.00, H 3.04, N 6.90, ir (CH_2Cl_2) ν_{CO}; 2070, 1700 cm^{-1}. Infrared (Nujol) ν_{CO}; 1710 cm^{-1}. ^{1}H nmr (270 MHz, $CDCl_3$) $\tau CHCl_3$ = 2.73 ppm, 10.08s, 9.89s (—$GaMe_2$); 7.58s (—CO*Me*); 3.71t (pz-H^4); 2.29d (pz-H^3); pz-H^5 obscured by the quinolyl ring proton resonances. Mass spectrum: P^+, $P - Me^+$, $P - Me - CO^+$, $P - Me - I^+$, and $P - 2Me - I^+$ (P^+ = parent ion) ion signals were observed.

Reaction of LRh(CO) (L = L_a; L_q) with I_2

$$LRhCO + I_2 \rightarrow LRh(I)_2(CO)$$

To a CH_2Cl_2 solution of LRhCO was added a slight excess of the dihalogen, I_2, in the same solvent. An immediate color change from orange to red was observed on mixing the reagents. After stirring the mixture for a few hours, an ir spectrum of the reaction solution indicated complete disappearance of the ν_{CO} band of the rhodium(I) monocarbonyl starting material, and the appearance of a new ν_{CO} band at ~2090 cm^{-1} (L = L_a), and ~2085 cm^{-1} (L = L_q). The single ν_{CO} band persisted in solution after stirring the reaction mixture overnight. Although the ir spectra of the reaction mixtures suggested the presence of six-coordinate Rh(III) monocarbonyl species in solution, analytically pure compounds of the expected diiodides, $LRh(I)_2(CO)$ could not be isolated from the black solid material obtained after removal of solvent.

Results and discussion

Metal derivatives of multi-dentate ligand systems incorporating both the pyrazolyl and pyridyl functional groups have been the subject of recent publications (4, 11, 12). It has been inferred that although pyrazole has stronger σ-donor properties than pyridine (1), the former has weaker π-acceptor capability (13). The present study extends our investigations in the area

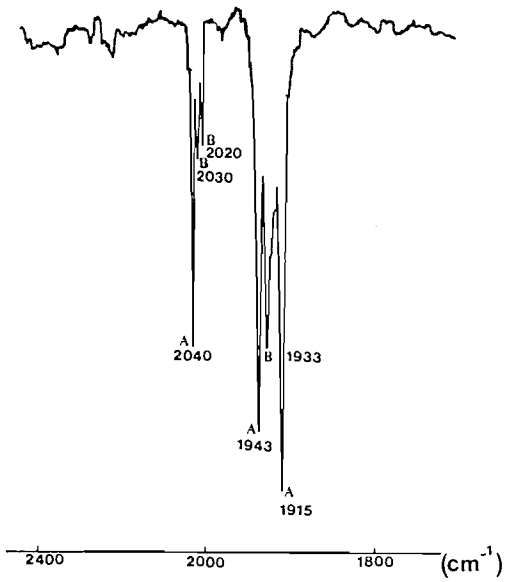

FIG. 1. Infrared spectrum of $[Me_2Gapz{\cdot}O(C_5H_3N)CH_2NMe_2]$-$Mn(CO)_3$ in C_6H_{12} solution: **A** *fac* isomer; **B** *mer* isomer.

of unsymmetrical tridentate organogallate ligands to include ligand systems incorporating both a pyrazolyl and (*i*) an amino pyridyl donor group and (*ii*) a quinolyl donor moiety. A variety of transition metal derivatives incorporating these ligands have been isolated and characterized by elemental analysis and ir, nmr, and mass spectral methods.

The first of this class of unsymmetrical tridentate ligands $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NR_2)]^-$ (R = H or Me), has been shown to be capable of either facial or meridional coordination in transition metal complexes (5). However, in all octahedral transition metal carbonyl compounds studied thus far, coordination of the unsymmetric tridentate organogallate ligand has been found to be exclusively facial (4, 14). The present manganese and rhenium tricarbonyl compounds incorporating the ligand $[Me_2Ga(N_2C_3H_3){\cdot}O(C_5H_3N)CH_2NMe_2]^-$ (L_a^-), therefore, represent the first and the only examples of such complexes featuring both the *fac* and *mer* isomers in solution. Evidence for the co-existence of both isomers in solution is provided by ir and ^1H nmr results. Infrared measurements in cyclohexane showed six bands (four strong, two weak) in the ν_{CO} region of the spectrum. A typical example of the spectra obtained for the $L_aM(CO)_3$ (M = Re, Mn) complexes is shown in Fig. 1 for the Mn compound. Three strong bands were assigned to the *fac* isomer, while one strong and two weak bands were assigned to the *mer* isomer. Thus, for octahedral transition metal tricarbonyl complexes, a *fac* arrangement of the unsymmetric tridentate ligand would give three strong ν_{CO} bands while for a *mer* arrangement one strong and two weak ν_{CO} bands would be observed (15, 16).

Additional evidence for the proposed *fac* and *mer* isomers in solution is provided by the room temperature ^1H nmr spectra of the $L_aM(CO)_3$ complexes. As a representative example, the room temperature ^1H nmr spectrum of the rhenium complex in C_6D_6 solution is shown in Fig. 2. In the spectrum, two sets of signals were displayed. In one set, the —Ga*Me*$_2$, —N*Me*$_2$, and the —CH_2 methylene group signals appeared as sharp singlets, consistent with a *mer* structure (**B**) (Fig. 3). The second set consists of two singlets each for the —$GaMe_2$ and NMe_2 moieties suggesting inequivalence of the methyl groups on gallium and the amino nitrogen as expected for a facially coordinated ligand (structure **A**, Fig. 3). The pyrazolyl proton resonances appeared as two sets again providing additional supporting evidence for the presence of both isomers in solution. The ir and ^1H nmr results discussed here, together with results for related compounds (4, 14), strongly support the presence of both *fac* and *mer* isomers in solution for the $L_aM(CO)_3$ complexes.

The room temperature ^1H nmr spectrum of the $L_aNi(CO)$ complex in $CDCl_3$ is interesting in that it displays sharp singlets for the —$GaMe_2$, —NMe_2, and —CH_2 groupings. This is suggestive of a square planar arrangement about the Ni center with a meridionally coordinated organogallate ligand. The "linear" NO group suggested by the ir result (ν_{CO} 1775 cm^{-1}), in conjunction with results from previous studies which have shown that square planar $\{MNO\}^{10}$ complexes should have an M—N—O bond angle of 120° (17–19), led us to suspect that a fluxional process must be occurring in solution at room temperature, in order to explain the observed ^1H nmr result. The closely related $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]NiNO$ has been shown to be stereochemically non-rigid at room temperature in solution and to possess a tetrahedral conformation about the Ni center in the solid state (20). Variable temperature ^1H nmr spectra in both d_6-acetone and toluene-d_8 did indeed reveal a fluxional process to be operative in solution for the present complex, $L_aNi(NO)$. In the experiment, the sharp —Ga*Me*$_2$ signal was monitored. As the solution was cooled, marked broadening of the —$GaMe_2$ signal was observed. At −85°C (the lowest temperature attainable), it was still not possible to collapse the original signal and observe new signals in this region. However, it is evident that at these lower temperatures, the fluxional process responsible for the average square-planar arrangement in solution at room temperature is beginning to slow down. Unfortunately, instrumental limitations precluded the attainment of temperatures low enough to observe splitting of the monitored signals. These results together with results for related compounds (4, 20), led us to the conclusion that the Ni atom in the L_aNiNO is probably facially coordinated by the L_a ligand, with the coordination geometry about Ni being tetrahedral. Possible mechanisms for the proposed fluxional process in solution at room temperature are shown in Fig. 4. Two possibilities may be envisaged. A trigonal planar intermediate (**A**) formed by breaking the Ni—N (amino) bond, followed by inversion at the pyramidal oxygen and reformation of the Ni—N (amino) bond; or a square planar intermediate (**B**) with inversion at the Ni center through the plane.

The ir spectral data for the octahedral $L_qM(CO)_3$ (M = Re, Mn) complexes compiled in Table 1, are consistent with a *fac* tridentate organogallate ligand in the two compounds. Thus, three strong ν_{CO} bands were observed for each complex, indicative of a facial arrangement of the tridentate ligand in the complexes (15, 16). The molybdenum dicarbonyl "allyl" complex $L_qMo(CO)_2(\eta^3\text{-}C_3H_5)$ showed two strong bands in the ν_{CO} region at the ir spectrum, indicative of a *cis* arrangement of the CO ligands.

Further confirmation of a facial tridentate organogallate ligand in the complexes incorporating the L_q ligand is provided by the ^1H nmr results. Of significance in the spectra of the $L_qM(CO)_3$ (M = Mn or Re) complexes is the gallium alkyl region (9–11τ), where two sharp singlets were observed for the "$GaMe_2$" moiety as expected for inequivalent methyl groups on gallium in a facial arrangement of the ligand. A meridionally

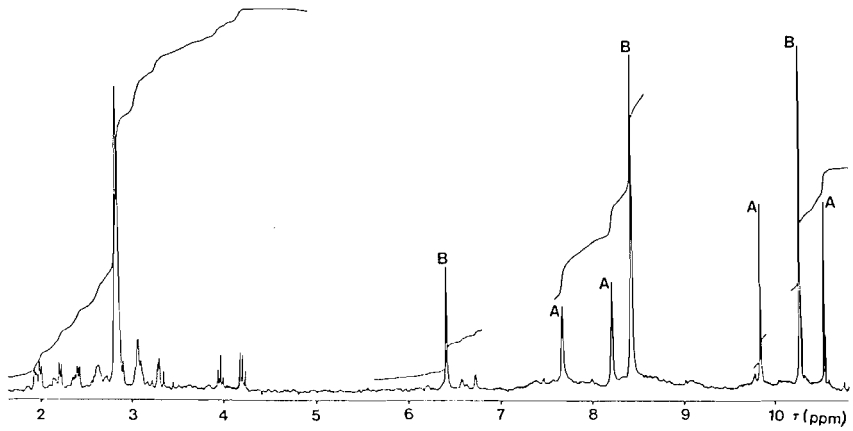

FIG. 2. Room temperature 80 MHz ^{1}H nmr spectrum of $[Me_2Gapz{\cdot}O(C_5H_3N)CH_2NMe_2]Re(CO)_3$ in C_6D_6 solution: **A** *fac* isomer; **B** *mer* isomer.

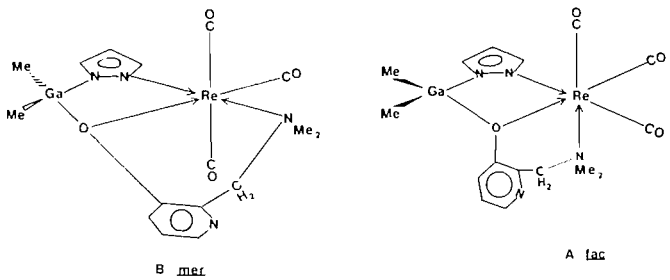

FIG. 3. *Fac* and *mer* isomers of $[Me_2Gapz{\cdot}O(C_5H_3N)CH_2NMe_2]$-$Re(CO)_3$.

coordinated ligand on the other hand, would lead to equivalent Ga–*Me* groups and therefore a singlet in this region of the spectrum.

The solution ^{1}H nmr spectrum of $L_qMo(CO)_2(\eta^2\text{-}C_3H_5)$ complex shown in Fig. 5 is again consistent with a facially coordinated ligand in the complex. Positional isomerism cannot be ruled out in this molybdenum allyl complex since interchange of the CO groups and the allyl group could potentially occur. It is clear, however, from the ^{1}H nmr spectrum, that only one positional isomer is produced in the reaction. Substitution of the allyl group in more than one position would lead to more than one set of Ga–*Me* signals in the spectrum, a feature which was not observed. Molecular models indicate that substitution opposite the "pyrazolyl" moiety is most favored sterically, a position confirmed by X-ray structural determination for the related complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2$-$(\eta^3\text{-}C_4H_7)$ (21). It is noteworthy, however, that in the related $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2(\eta^3\text{-}C_7H_7)$ (22) and $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt)]Mo(CO)_2(\eta^3\text{-}C_7H_7)$ (23), the η^3-C_7H_7 moiety occupies a position opposite the amino nitrogen and the alkyl sulfur donor atoms, respectively. This positional preference of the η^3-C_7H_7 and η^3-allyl ligands was rationalized using structural *trans* effect arguments. In addition molecular models show that an η^3-C_7H_7 group occupying a position *trans* to the pyrazolyl nitrogen would result in close contacts with the amino group or alkyl sulfido group in the latter complexes.

Mass spectral data obtained for the $L_aM(CO)_3$ and $L_qM(CO)_3$ (M = Re, Mn) compounds revealed some interesting differences dependent on the metal involved. For example, while the Re species displayed signals corresponding to the parent, P^+, and $P - Me^+$ ions prior to loss of the CO ligands, the highest mass fragment observed for the Mn species is attributable to the $P - 3CO^+$ ion. The reluctance to lose CO exhibited by the Re species reflects the comparatively stronger "M – CO" bonds in the Re complex than in the valence-isoelectronic Mn compound. This rationale is further supported by a comparison of the ν_{CO} values for the compounds. The ν_{CO} values for the Re compounds are consistently lower than those for the Mn compounds, indicating that the Re donates more electron density to the CO ligands. The increased M—CO back bonding in the Re compounds, as attested to by the lower ν_{CO} values, implies a stronger "M—CO" bond in the Re complexes (24).

The reaction of the sterically bulky L_a^- and L_q^- ligands with the $[Rh(CO)_2Cl]_2$ dimeric species afforded orange to dark orange crystals of Rh(I) monocarbonyl compounds via transient dicarbonyl species $LRh(CO)_2$, as evident from ir monitoring of the reaction mixture during the course of the reactions. It is interesting to compare similar Rh(I) carbonyl species. The cyclopentadienyl ligand, $C_5H_5^-$, and the comparable six-electron uninegative donor ligand $HB(3,5\text{-}Me_2pz)_3^-$ are known to react with $[Rh(CO)_2Cl]_2$ to give the $(\eta\text{-}C_5H_5)Rh(CO)_2$ (25) and $[HB(3,5\text{-}Me_2pz)_3]Rh(CO)_2$ (26, 27) dicarbonyl complexes, respectively. However, the introduction of the similar $HBpz_3^-$ and $MeGapz_3^-$ ligand systems led to the dinuclear rhodium species $[HBpz_3]_2Rh_2(\mu\text{-}CO)_3$ (28) and $[MeGapz_3]_2Rh_2(\mu\text{-}CO)_3$ (29). Recently, attempts at isolating rhodium dicarbonyl complexes incorporating the uninegative, unsymmetrical, tridentate $[Me_2Gapz(OCH_2CH_2NR_2)]^-$ (R = H, Me), and the $[Me_2GapzOCH_2(C_5H_4N)]^-$ ligand systems resulted in the isolation of stable, four-coordinate, square-planar Rh(I) monocarbonyl complexes. In the complexes, structurally characterized by X-ray crystallography as $[Me_2Gapz(OCH_2CH_2NH_2)]RhCO$ (30), and $[Me_2GapzOCH_2(C_5H_4N)]RhCO$ (31), the coordination mode of the tridentate organogallate ligands about the Rh(I) center was unequivocally demonstrated to be meridional. The ν_{CO} values obtained for the present complexes compare quite well with those reported for related Rh(I) monocarbonyl complexes (Table 3).

The ^{1}H nmr spectrum of the L_qRhCO complex in C_6D_6 solution clearly established the presence of a square planar Rh(I) species in solution for this complex. The sharp singlet observed for the —$GaMe_2$ group is consistent with a meridionally coordinated organogallate ligand in the complex. Similarly, with the L_aRhCO compound, sharp singlets were displayed for the "—$GaMe_2$," "—NMe_2," and "—CH_2—" moieties in conformity with a *mer* configuration of the ligand in this square-planar Rh(I) monocarbonyl compound.

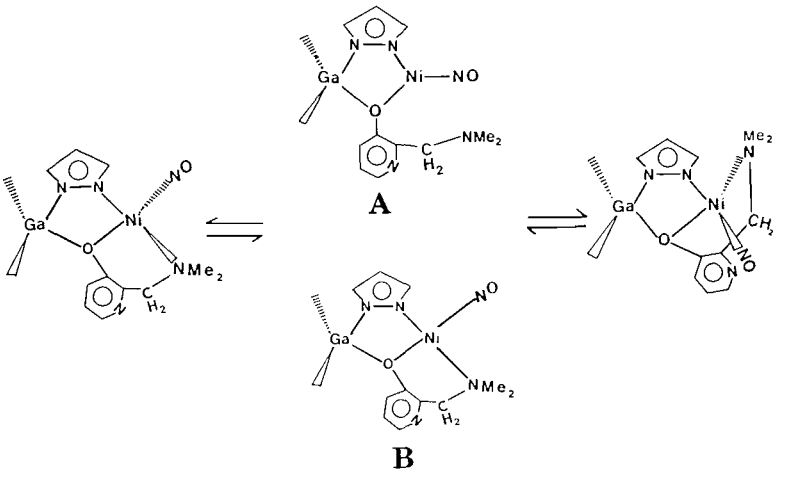

FIG. 4. Proposed mechanism for the fluxional process observed for $[Me_2Gapz{\cdot}O(C_5H_3N)CH_2NMe_2]Ni(NO)$ in d_8-toluene solution.

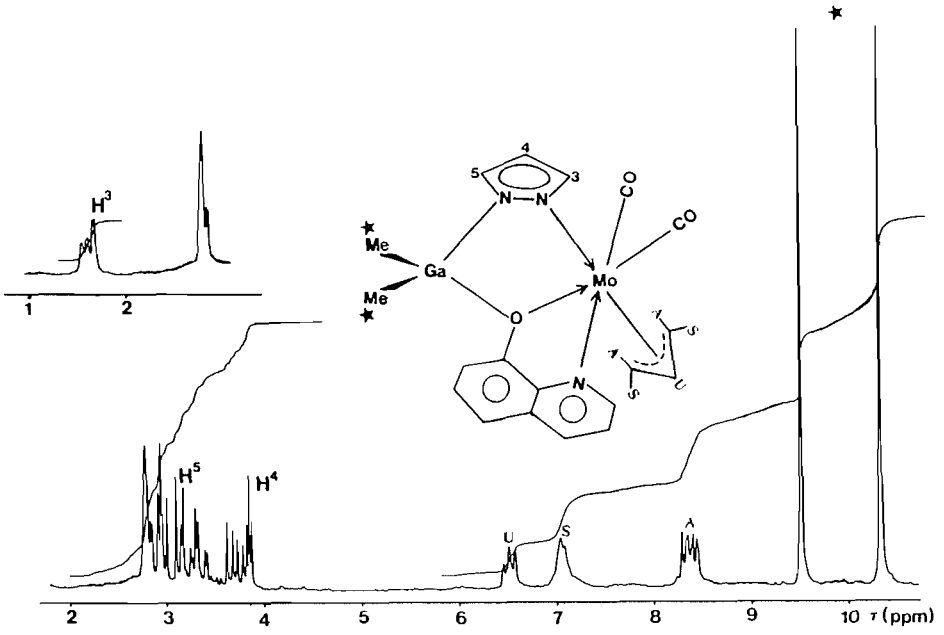

FIG. 5. Room temperature 80 MHz ^1H nmr spectrum of $[Me_2Gapz{\cdot}O(C_9H_6N)]Mo(CO)_2(\eta^3\text{-}C_3H_5)$ in C_6D_6 solution.

The mass spectrum of the L_aRhCO species showed trace signals (<0.5%) attributable to the $P - 3Me^+$ and $P - 2Me - CO^+$ ions. The parent (P^+) ion was not observed and the most intense signal in the spectrum was assigned to the $C_5H_4N^+$ ion fragments. In contrast, the mass spectrum of the L_qRhCO species displayed prominent signals due to the parent (P^+) ion, in addition to signals corresponding to the $P - Me^+$, $P - CO^+$, and $P - Me - CO^+$ ions, the latter being the most intense signal in the spectrum.

The reaction of L_qRhCO with methyl iodide, resulted in the isolation of a five-coordinate Rh(III) acetyl complex [MeGapz-$O(C_9H_6N)$]Rh(COMe)I, presumably via a six-coordinate Rh(III) oxidative–addition intermediate. Thus, the ν_{CO} band of the Rh(I) monocarbonyl starting material at 1968 cm^{-1} slowly disappeared upon addition of MeI, and was gradually replaced by two new bands at 2070 and 1700 cm^{-1} which intensified with time. Attempts at isolating the species responsible for the ν_{CO} band at 2070 cm^{-1} failed, and instead crystals of the Rh(III) acetyl complex, $L_qRh(COMe)I$, (ν_{CO}: 1710 cm^{-1}, Nujol mull) were obtained. A proposed reaction sequence for the formation of the Rh(III) acetyl species is shown in Fig. 6. It is postulated that the ν_{CO} band at 2070 cm^{-1}, observed in solution during the reaction, is probably due to the presence of a labile six-coordinate Rh(III) *trans*-addition product. Thus, alkyl halides are generally known to oxidatively add to square-planar d^8 Rh(I) and Ir(I) centers via this addition mode (32, 33). This six-coordinate Rh(III) intermediate subsequently undergoes a methyl migration or migratory insertion of CO to form the five-coordinate Rh(III) complex $L_qRh(COMe)I$, containing a terminal acetyl group. The solution ir spectrum of the Rh(III) acetyl product isolated is interesting in that it shows two bands at ~2070 cm^{-1} and 1700 cm^{-1} in CH_2Cl_2 but in Nujol mull, only one strong ν_{CO} band was observed at ~1710 cm^{-1}. This observation is suggestive of the presence of both the six-coordinate Rh(III) methyl carbonyl iodide species, and the five-coordinate Rh(III) acetyl iodide species in solution. A similar observation has been reported for the compound $[Ru(\eta^2\text{-}COMe)I(CO)(PMe_3)_2]$, an η^2-acyl complex which exists in equilibrium with

its carbonyl σ-alkyl isomer, $[Ru(CO)_2(Me)I(PMe_3)_2]$, in solution (34).

The ^1H nmr spectrum of the $L_qRh(COMe)I$ complex in $CDCl_3$ solution is consistent with a square pyramidal arrangement about the Rh center, since such a non-planar arrangement would render the methyl groups on gallium inequivalent and lead to two sharp singlets in the $GaMe_2$ region of the spectrum as observed. The position of the CO*Me* signal (7.58τ, $CDCl_3$), compares nicely with those reported for similar rhodium acetyl compounds (30, 31, 35) and the square pyramidal arrangement proposed for the present complex has been established by X-ray crystallography for the closely related $[Me_2Gapz(OCH_2CH_2NMe_2)]Rh(COMe)I$ (30) complex.

The mass spectrum of the $[Me_2GapzO(C_9H_6N)]Rh(COMe)I$ complex displayed signals corresponding to the parent, P^+, $P - Me^+$, $P - Me - I^+$, $P - 2Me - I^+$, and $P - Me - CO^+$ ions, but no $P - CO^+$ signals were observed. Signals arising from the latter ion are usually characteristic of transition metal carbonyl compounds containing terminally bound CO groups.

In contrast to the mode of reactivity discussed above for the L_qRhCO complex, the reaction of the L_aRhCO monocarbonyl complex with MeI proceeds directly to the formation of what is thought to be a six-coordinate Rh(III) oxidative *trans*-addition product $L_aRh(Me)(I)CO$. Quite interestingly, such six-coordinate addition products containing σ-bonded methyl groups have not been observed either as intermediates or as the net reaction products in the analogous reaction of the related cyclopentadienyl rhodium carbonyl compounds with MeI. For example, reaction of $(\eta\text{-}C_5Me_5)Rh(CO)_2$ with MeI proceeds directly to the $(\eta\text{-}C_5Me_5)Rh(CO)(COMe)I$ (36) acetyl complex at 50°C. Thus, the diagnostic ν_{CO} band at 2060 cm^{-1}, indicative of a terminal M—CO linkage, observed during the reaction of L_aRhCO with MeI provided strong evidence for the presence of a six-coordinate Rh(III) species in solution. The absence of a ν_{CO} band between 1600–1750 cm^{-1}, meanwhile, suggests that an acetyl derivative is not formed in this reaction.

The only crystalline product isolated from the reaction displayed a ν_{CO} band at 2060 cm^{-1} (CH_2Cl_2) and 2055 cm^{-1} (Nujol) which is consistent with the isolation of the six-coordinate Rh(III) species, $L_aRh(Me)(I)(CO)$. Such a formulation is consistent with the room temperature ^1H nmr data for the complex, which suggest a facial coordination mode for the tridentate ligand. Thus, two sharp singlets were observed for each of the —$GaMe_2$ and —NMe_2 groupings and a sharp singlet was observed for the Rh—Me resonance at ~9.3τ. It is noteworthy that no signal was seen in the —COMe region of the spectrum.

It is difficult to rationalize the difference in reactivity towards MeI observed for the L_aRhCO and L_qRhCO complexes. It is probable, however, that the Rh—Me bond is stronger in the $L_aRh(Me)(I)CO$ species compared to the $L_qRh(Me)(I)CO$ compound and hence methyl migration is discouraged in the former compound. Unfortunately, numerous attempts to grow crystals suitable for a definitive X-ray structural studies on the $L_aRh(Me)(I)CO$ complex have been unsuccessful.

Addition of molecular iodine to a CH_2Cl_2 solution of LRhCO (L = L_a, L_q), resulted in the immediate disappearance of the ν_{CO} band attributable to the appropriate Rh(I) monocarbonyl starting material with concomitant appearance of a new ν_{CO} band at 2090 cm^{-1} (L = L_a), or 2085 cm^{-1} (L = L_q). The new band suggests weakly-bound CO ligands in the products. Oxidation of the rhodium center (Rh(I)(d^8), Rh(III)(d^6)), would lead to a weaker backbonding contribution from the metal, a strengthening of the C—O bond and consequently an increased ν_{CO} value. Based on this observation, it does appear that six-coordinate Rh(III) diiodide species $LRhI_2(CO)$ had formed in solution, although analytically pure samples of the products could not be isolated. The ν_{CO} values of the present $LRhI_2(CO)$ species are in good agreement with those reported for some related Rh(III) diiodides (see Table 4).

It is interesting, however, that the ν_{CO} values for the pyrazolylgallate or borate-containing species are consistently higher than the values reported for the analogous cyclopentadienyl-containing rhodium diiodide species. This is rather unusual since these observations oppose the trend previously estab-

For personal use only.

lished for complexes incorporating these ligands (39, 40). That is, pyrazolylgallate tridentate ligands, and the related isoelectronic tridentate pyrazolylborate ligands are generally stronger net electron donors compared to the tridentate cyclopentadienyl ligands and give rise to lower ν_{CO} values in analogous transition metal carbonyl complexes.

4-Demethoxy-10-nordaunomycinone (**4**) is synthesized starting with 4,7-dimethoxy-1-indanone (**8**). Nucleophilic addition of ethynyl magnesium bromide to **8** followed by mercuric acetate oxidation and iron pentacarbonyl – tri-*n*-butyltin hydride reduction gave 4,7-dimethoxy-1-acetylindane (**16**). Condensation of **16** with phthalic anhydride followed by methylation with dimethylsulfate and oxidation gave **22**, which was epimerized to **24** by 2,2-dimethoxypropane and trifluoroacetic acid. Demethylation of **24** with aluminum chloride gave the 4-demethoxy-10-nordaunomycinone (**4**).

C. M. WONG, P. M. GORDON, A. G. CHEN et H. Y. P. LAM. Can. J. Chem. **65**, 1375 (1987).

On a synthétisé la déméthoxy-4 nor-10 daunomycinone (**4**) à partir de la diméthoxy-4,7 indanone-1 (**8**). L'addition nucléophile du bromure d'éthynylmagnésium à la cétone **8**, suivie d'une oxydation par l'acétate mercurique et d'une réduction par l'hydrure de tri-*n*-butylétain/pentacarbonyle de fer, conduit au diméthoxy-4,7 acétyl-1 indane (**16**). La condensation de **16** avec l'anhydride phtalique, suivie d'une méthylation par le sulfate de méthyle et d'une oxydation, conduit au composé **22** que l'on a épimérisé en **24** par le diméthoxy-2,2 propane et l'acide trifluoroacétique. La déméthylation de **24** par le chlorure d'aluminium fournit la déméthoxy-4 nor-10 daunomycinone (**4**).

Discovery of the antitumor properties of anthracyclines daunomycin (**1**) and adriamycin (**2**) and their subsequent successful clinical application raised interest in anthracycline research internationally (1–3). The study of the nature of their cardiotoxicity (4) and structure–activity relationship remains one of the most active areas of research into cancer chemotherapy. The challenge can be met, at least partially, by a new molecular structure, which exhibits stronger activity against a broader neoplastic syndrome and is much less toxic than daunomycin or adriamycin. Structure modification through partial or total synthesis or by mutant microorganism transformation has afforded a large number of new anthracycline derivatives, several of which have shown very encouraging results in terms of activity and toxicity (5–9). Of these numerous new anthracycline derivatives, no practical or biologically active example involving modification of the basic aglycone skeleton has been reported (3, 10), except the heteroanthracyclines, their aglycones (11–14), and the two recently reported syntheses of 4-demethoxy-8-nordaunomycinone (**4***a*) (16) and its dimethyl ether derivative. However, these elegantly designed syntheses were more laborious and meandering than anticipated and the juxtaposition of the C-7 and C-8 substitutions would eventually hinder the ensuing glycosidation process. All other syntheses involved functional group modification or substitution derivatives of daunomycin, adriamycin, aclacinomycins, and rhodomycins (3, 10, 15). In light of these considerations and of the fact that 4-demethoxydaunomycin is several times more potent than daunomycin and adriamycin (5), we would like to report the total synthesis of (±)-4-demethoxy-10-nordaunomycinone (**4**) and its C-7 epimer **25**.

Results and discussion

A logical approach to the tetracyclic skeleton would be the Friedel–Crafts condensation of 4,7-dimethoxy-1-hydroxy-1-acetylindane (**5**) with phthalic anhydride, analogous to our early synthesis of 7-*O*-methyl-4-demethoxydaunomycinone (17). However, it was observed that **5** was not stable under acidic conditions. The compound decomposed in the presence of strong Lewis acids. Polymeric unidentifiable amorphous foam was the major product recovered from all reactions involving strong acids. Attempts to condense the corresponding acetoxy compound 4,7-dimethoxy-1-acetoxy-1-acetylindane (**6**) with phthalic anhydride were equally futile. The precursor, 4,7-dimethoxy-1-hydroxy-1-ethynyl-indane (**7**), was also very

unstable in the presence of strong acids or bases. It regenerated the starting indanone **8**, which was inactive toward all Friedel–Crafts reactions. However, **9**, prepared by reduction of **8** by triethylsilane in trifluoroacetic acid solution, underwent the condensation with phthalic anhydride smoothly, forming the tetracyclic quinone **10** whose methyl ether **11** can be oxidized in good yield to **12** by chromium trioxide – acetic anhydride and converted to the fragile hydroxy acetylene **13** by excess lithium acetylide. Following the lithium acetylide nucleophilic addition process, it was observed that the quinone chromophore disappeared initially, and the D-ring carbonyl group remained practically unaffected until most of the quinone chromophore disappeared. Further reaction with excess lithium acetylide led to an unstable crude product, which displayed only very weak quinone absorption in the infrared spectrum and could not be characterized. But on standing, the quinone carbonyl group was regenerated at a rate faster than the regeneration of the D-ring carbonyl group. This allowed the isolation of **13**, albeit in poor yield. The acetylene group was converted to the acetyl group by mercuric acetate in aqueous acetic acid solution to form the stable intermediate **14**. The low yield of the acetylide addition necessitated a modification of our approach to this compound.

The disparate properties of **5** and its homologue **15** (17) very likely stemmed from the benzylic hydroxyl function, and its removal may facilitate the acylation process with phthalic anhydride. Dehydroxylation, however, proved to be more difficult than anticipated. The yield of **16** from either **5** or **6** under various conditions for dehydroxylation or deacetoxylation of α-hydroxy and α-acetoxyketones or benzylic alcohols was poor, and when reactions were carried out in acidic medium the product contained an unidentifiable polymeric solid as the major component. The small amount of **16** so accumulated did give excellent yield of **17** when it was allowed to react with phthalic anhydride in the presence of aluminium chloride. Thus allylic reduction by a free radical process in nonacidic medium is essential. Eventually, **16** was obtained in good yield when **6** was allowed to react with iron pentacarbonyl and tributylin hydride in xylene solution.

Attempts to methylate **17** by iodomethane under various basic conditions invariably gave **19** as the only methylated product. A 3H singlet at δ 1.55 showed unequivocally the presence of a methyl group, and oxidation of **19** by molecular oxygen in *tert*-butyl alcohol, potassium *tert*-butoxide, and dimethylformamide solution gave a mixture of two compounds whose ^{1}H nmr spectrum revealed the presence of two methyl singlets at δ 1.55 and 1.65 ppm, and four methoxy singlets at δ 3.87, 3.96, 4.05, and 4.08 ppm. Together with a molecular ion M^+ = 380 in the mass spectrum, it is very likely that the oxidation of **19** gave the two isomers **20** and **21**. This result ascertained that a one-step conversion of **18** to **22** and **4** is feasible.

Selective methylation of the phenolic groups of **17** was achieved following the HSAB principal. Thus, methylation of **17** in basic solution by dimethyl sulfate, whose conjugate anion and the phenolic anion were hard bases, gave exclusively the desired product **18**. Oxidation of **18** by molecular oxygen as before gave the *trans*-diol **22**. This convenient bishydroxlation process, reported independently by Swenton and co-workers (18*a*, *b*) and Wong *et al.* (18*c*), provided an easy route to the fully functionalized D-ring of the hetero- and noranthracyclinones. The monohydroxy compound **14** could be isolated as the major product if the reaction was quenched within 0.5 h by dilute acid.

The *trans*-diol **22** exhibits none of the general properties of daunomycinone and heteroanthracyclinone analogues, which gave a mixture of *cis*- and *trans*-diols under similar oxidation conditions, the *trans* isomers isomerizing to the *cis* isomers upon heating in trifluoroacetic acid; furthermore, the *trans* isomers exist in an equilibrium involving the C7-OH and the C9-acetyl groups (11–13) to form hemiacetals. The *trans*-diol **22** was recovered completely after being heated in trifluoroacetic acid for 72 h. Attempts to crystallize it also failed. The corresponding *trans*-diols in the heteroanthracyclinone and anthracyclinone series are also adverse to crystallization. The ^{1}H nmr spectrum of **22** (Fig. 1) shows no sign of an equilibrium between **22** and the hemiacetal **23**. It was thus easily mistaken for the *cis* isomer **24**. The epimerization to **24** was successfully carried out when **22** was heated in an acetone

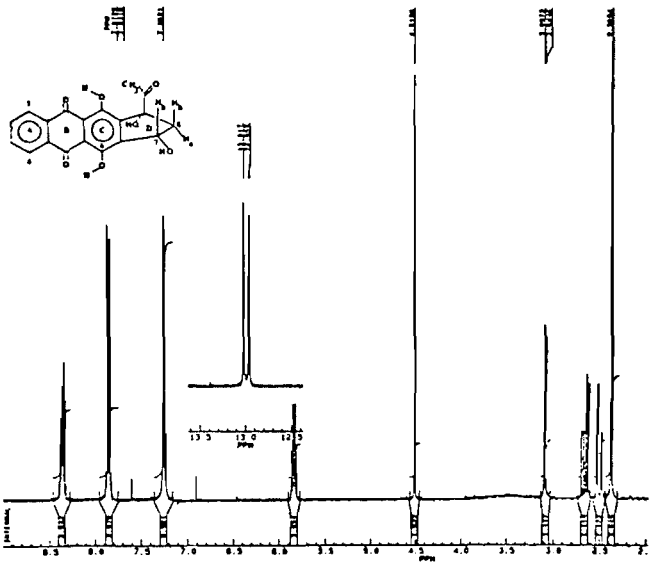

FIG. 4. The ^{1}H nmr spectrum of **4**.

solution of 2,2-dimethoxypropane and trifluoroacetic acid. The ^{1}H nmr spectra of **22** (Fig. 1) and **24** (Fig. 2) detail the structural features of these two isomers. Comparison of these two spectra reveals that the major differences are the chemical shifts and coupling constants of the C7-H_a, C7-H_b, and C8-H_a, H_b. For the *trans*-diol **22**, the free rotation of both C7-OH and C9-$COCH_3$ groups is impeded by the hydrogen bonding between these two groups, freezing the D-ring conformation to the extent that the acetyl methyl group experiences the diamagnetic anisotropic effect of the C-ring and thus appears at δ 2.163 ppm instead of δ 2.285 ppm for that of the *cis*-diol **24**. This conformation of the D-ring also places the C8-H_b of **22** at the fringe of the diamagnetic shielding zone of the acetyl carbonyl function, shifting it to a higher field of δ 2.174 ppm as compared to the C8-H_b of **24** at δ 2.428 ppm. The **22** value J_{7a8b} = 1.7 Hz versus the **24** J_{7b8a} = 5.1 Hz also reflects that the H8b—C8—H7a dihedral angle of **22** is close to 90° instead of 120° for the H7b—C7—C8—H8a dihedral angle of **24**. The H7b of **22** at δ 5.517 ppm, appearing as a broad doublet instead of an eight-line pattern of the X part of a ABMX spin system, is due to the small coupling of $J_{7a,8b}$ = 1.7 Hz and the spin–spin interaction with the fast exchanging C7-OH proton. Also in agreement with the structure is the H7b of **24** at δ 5.875 ppm appearing as a doublet of a doublet with J_{7b8b} = 7.2 Hz and J_{7b8a} = 5.1 Hz.

The demethylation of **22** and **24** to **25** and **4** by aluminum chloride was very easily achieved. Having observed the averseness of **22** to epimerize to **24**, it is surprising to note that **22** gave exclusively **25** and **24** gave exclusively **4**. No epimerization of **4** to **25** or vice versa was observed. The ^{1}H nmr spectra of **25** (Fig. 3) and **4** (Fig. 4) reveal explicitly the structural features of both **25** and **4** and are compatible with those of **22** (Fig. 1) and **24** (Fig. 2). Coupling of **4** to several amino sugars and their cytotoxic activities will be reported separately, together with the biological data of heteroanthracyclines.

Experimental

The ^{1}H nmr spectra were recorded on Bruker WH-90 or Bruker AM-300 spectrometers. Chemical shift is quoted in δ ppm downfield

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

from TMS using $CDCl_3$ as solvent, unless otherwise specified. The ir spectra were recorded on a Perkin–Elmer 710 Infracord or a Nicolet MX-1 FT spectrometer using CH_2Cl_2 as solvent, and transmittance is quoted in wave numbers (cm^{-1}). Mass spectra were recorded on a Finnigan 1015 spectrometer and high resolution mass spectra were recorded on a V.G. 7070 E HF spectrometer. Melting points were determined on a Fisher–Johns apparatus and are uncorrected.

Preparation of 4,7-dimethoxy-1-ethynyl-1-indanol (7)

To a 3-necked flask (2 L), equipped with a pressure equalized dropping funnel, condenser with drying tube, and a gas dispersion tube, and containing anhydrous tetrahydrufuran (750 mL) saturated with anhydrous acetylene, was added ethyl magnesium bromide in tetrahydrofuran solution (200 mL, 2 *M* solution) dropwise through the dropping funnel at room temperature. Acetylene was introduced continuously. The addition of the ethyl magnesium bromide – tetrahydrofuran solution was controlled at the rate of about 2 mL/min. The solution was then stirred for an additional 20 min and 4,7-dimethoxy-1-indanone (**8**) (30 g) (19) was added. Acetylene was introduced continuously for an additional 0.5 h. The solution was stirred for 2 h at room temperature under anhydrous conditions, poured into ice-cooled saturated ammonium chloride solution (100 mL) to decompose the excess ethynyl magnesium bromide, and then extracted by methylene chloride (3 × 700 mL), washed with water, dried over anhydrous $MgSO_4$, and evaporated to dryness to give the crude product (**7**) (26 g), a portion (1 g) of which was purified by fast chromatography over silica and recrystallized from ether–hexane; mp 77–79°C; ir: 3560 (OH), 3300 (C≡C—H), 1610 (aromatic); ^{1}H nmr: 2.38 (q, 1H, C2-H), 2.60 (s, 1H, —C≡C—H), 2.70 (dq, 1H, C2-H), 2.86 (q, 1H, C3-H), 2.97 (dq, 1H, C3-H), 3.74 (s, 1H, —OH), 3.79 (s, 3H, —OCH_3), 3.88 (s, 3H, —OCH_3), 6.72 (s, 2H, aromatic); ms: 218 (M^+), 203 ($M^+ - CH_3$), 201 ($M^+ - OH$), 185 ($M^+ - H_2O - CH_3$).

Preparation of 4,7-dimethoxy-1-acetoxy-1-acetylidane (6)

The crude indanol (**7**) from the previous preparation was dissolved in ethyl acetate (1.5 L) to which was added mercuric acetate (99.5 g) and the mixture was stirred for a period of 24 h at room temperature. Hydrogen sulfide was introduced into the solution until the formation of black precipitate ceased. The precipitate was removed by filtration and the solution was evaporated to dryness under reduced pressure giving the crude crystalline product (**6**) (52 g), which was further purified by recrystallization from methylene chloride – petroleum ether; mp 98–100°C; ir: 1730 (—O—$COCH_3$), 1715 (—$COCH_3$), 1605 (aromatic); ^{1}H nmr: 2.13 (s, 3H, —O—$COCH_3$), 2.25 (s, 3H, —$COCH_3$), 2.30–2.80 (m, 1H, C2-H), 2.85–3.20 (m, 3H, C2-H and C3-H), 3.78 (s, 3H, OCH_3), 4.0 (s, 3H, OCH_3), 6.72 (q, 2H, aromatic); ms: 278 (M^+), 235 ($M - COCH_3$), 192 ($M - 2 \times COCH_3$). *Exact Mass* (high resolution ms) calcd. for $C_{15}H_{18}O_5$: 278.1154; found: 278.1158. *Anal.* calcd.: C 64.72, H 6.52; found: C 64.8, H 6.57.

Preparation of 4,7-dimethoxy-1-acetylindane (16)

An *o*-xylene solution (250 mL) of iron pentacarbonyl (40 mL), tri-*n*-butyltin hydride (2 mL), and **6** (4.6 g) was heated in a 130°C oil bath under N_2 for 72 h. The solution was allowed to cool to room temperature and cupric chloride in acetone solution was added slowly until fizzing or carbon monoxide evolution ceased. The mixture was diluted with water and extracted with chloroform. The chloroform extract was washed with aqueous cupric chloride solution, dried, and evaporated to dryness, giving the crude product (**16**) (3.2 g), which was readily purified by column chromatography over silica and recrystallization from ether – petroleum ether; mp 56–58°C; ir: 1705 ($COCH_3$), 1610 (aromatic); ms: 220 (M^+), 177 ($M - COCH_3$); ^{1}H nmr: 2.144 (s, 3H, $COCH_3$), 2.223 (m, 1H, C2-H), 2.338 (m, 1H, C2-H), 2.78 and 3.03 (2 sym. m, 2H, C3-H3), 3.754 (s, 3H, OCH_3), 3.787 (s, 3H, OCH_3), 4.122 (dd, 1H, C1-H, J = 9 Hz, J = 5.4 Hz), 6.659 (1, 2H, aromatic, J = 9 Hz).

Preparation of 17

Pulverized phthalic anhydride (2.3 g), 4,7-dimethoxy-1-acetylindane (**16**) (2.2 g), NaCl (4 g), and pulverized freshly sublimed aluminum chloride (22 g) was mixed mechanically and heated in a 180°C oil bath for 10 min. The dark red syrupy mixture was allowed to cool, taken up in saturated oxalic acid solution, and stirred overnight at room temperature. The solution with red solid suspension was extracted exhaustively with chloroform and the chloroform extract was washed with saturated oxalic acid solution and water, dried, and evaporated to dryness. The red solid residue (2.7 g) was recrystallized from chloroform–ether; mp 188–192°C; ir: 3500–2700 (chelated OH), 1720 ($COCH_3$), 1625 (chelated quinone), 1595 (aromatic); ^{1}H nmr: 2.37 (s, 3H, $COCH_3$), 2.44 (m, 2H, C8-H2), 3.16 (m, 2H, C7-H2), 4.36 (dd, 1H, C9-H, J = 9 Hz, J = 5 Hz), 7.82 (m, 2H, C2-H, C3-H), 8.33 (m, 2H. C1-H, C4-H), 1304 (s, 1H, chelated OH), 13.15 (s, 1H, chelated OH); ms: 322 (M^+, 40%), 279 ($M - COCH_3$, 100%). *Exact Mass* (high resolution ms) calcd. for $C_{19}H_{14}O_5$: 322.0842; found: 322.0844. *Anal.* calcd.: C 70.78, H 4.38; found: C 70.81, H 4.42.

Preparation of 18 and 19

An acetone solution (100 mL) of dimethyl sulfate (5 mL), potassium carbonate (15 g), and **17** (1 g) was heated under reflux for 24 h. The acetone solution was cooled, filtered, and concentrated. The residue was taken up in methylene chloride, filtered, and evaporated to dryness under reduced pressure. The residue crystallized on standing and was recrystallized from methylene chloride – ether (910 mg); mp 135–137°C; ir: 1715 ($COCH_3$), 1675 (quinone), 1600–1585 (aromatic); ^{1}H nmr: 2.99 (s, 3H, $COCH_3$), 2.30 (m, 1H, C8-H), 2.43 (m, 1H, C8-H), 3.11 (m, 1H, C7-H), 3.25 (m, 1H, C7-H), 3.856 (s, 3H, OCH_3), 3.935 (s, 3H, OCH_3), 4.343 (dd, 1H, C9-H, J = 9.1 Hz, J = 5.7 Hz), 7.75 (m, 2H, C2-H, C3-H), 8.37 (m, 2H, C1-H, C4-H); ms: 350 (M^+, 90%), 307 ($M - COCH_3$, 100%). *Anal.* calcd. for $C_{21}H_{18}O_5$: C 72.0, H 5.14; found: C 72.1, H 5.1.

When dimethylsulfate was replaced by methyl iodide, **19** was isolated as the only product, mp 104–106°C; ir: 1710 ($COCH_3$), 1675 (quinone), 1600–1580 (aromatic); ^{1}H nmr: 1.55 (s, 3H, C9—CH_3), 2.01 (m, 1H, C8-H), 2.44 (m, 1H, C8-H), 3.18 (m, 2H, C7-H2), 3.86 (s, 3H, OCH_3), 3.97 (s, 3H, OCH_3), 7.75 (m, 2H, C2-H, C3-H), 8.19 (m, 2H, C1-H, C4-H); ms: 364 (M^+, 10%), 321 ($M - COCH_3$, 100%).

Preparation of 6,10-di-O-methyl-4-demethoxy-7-epi-10-nordaunomycinone (22) and 6,10-di-O-methyl-4-demethoxy-7-deoxy-10-nordaunomycinone (23)

To a solution of dry *N,N*-dimethylformamide (50 mL), *tert*-butyl alcohol (10 mL), and potassium *tert*-butoxide (2.2 g) was added **18** (700 mg). The solution was then cooled in a −30°C bath and dry O_2 was introduced for a period of 4 h. Trimethylphosphite (1 mL) was added, the solution was adjusted to pH 8–9 by dilute hydrochloric acid, stirred for 2 h, diluted with water, and extracted exhaustively with chloroform. The residue, obtained after routine work-up of the chloroform solution, was subjected to column chromatography on silica. Elution of the column by chloroform gave **23** (170 mg), recrystallized from methylene chloride – ether; mp 182–184°C; ir: 3450 (C9-OH), 1715 ($COCH_3$), 1675 (quinone), 1595, 1580 (aromatic); ^{1}H nmr: 2.21 (s, 3H, $COCH_3$), 2.22 (ddd, 1H, C8-H_b, J_{8b8a} = 14 Hz, J_{8b7b} = 8.2 Hz, J_{8b7a} = 3 Hz), 2.49 (ddd, 1H, C8-H_a, J_{8a8b} = 14 Hz, J_{8a7a} = 8.4 Hz, J_{8a7b} = 8.0 Hz), 3.23 (ddd, 1H, C7-H_a, J_{7a7b} = 17.5 Hz, J_{7a8a} = 8.5 Hz, J_{7a8b} = 3 Hz), 3.44 (ddd, 1H, C7-H_b, J_{7b7a} = 17.5 Hz, J_{7b8b} = 8.2 Hz, J_{7b8a} = 8.1 Hz), 3.88 (s, 3H, OCH_3), 4.01 (s, 3H, OCH_3), 4.75 (s, 1H, OH), 7.72–7.78 (m, 2H, C2-H, C3-H), 8.17–8.23 (m, 2H, C1-H, C4-H); ms: 366 (M^+, 1%), 323 ($M - COCH_3$, 100%). In a separate batch where **18** (70 mg) was oxidized under similar conditions for 0.5 h, only **23** (62 mg) was isolated. Further elution of the column by chloroform–acetone (10%) gave the product **22** (280 mg), which defied all attempts to induce crystallization; ir: 3550, (C7-OH), 3440 (C9-OH), 1715 ($COCH_3$), 1670 (quinone), 1600–1580 (aromatic); ^{1}H nmr: 2.163 (s, 3H, $COCH_3$), 2.173 (dd, 1H, C8-H_b, J_{8b8a} = 14.5 Hz, J_{8b7a} = 1.7 Hz), 2.730 (dd, 1H, C8-H_a, J_{8a8b} = 14.5 Hz, J_{8a7a} = 6.5 Hz), 2.920 (s, 1H, C7-OH), 3.877 (s, 3H, OCH_3), 4.113 (s, 3H, OCH_3), 4.80 (s, 1H, C9-OH), 5.517 (bd, 1H, C7-H, $J_{7,8a}$ = 5.9 Hz); ms: 382 (M^+, 1%), 339 ($M - COCH_3$, 100%).

Preparation of 6,11-di-O-methyl-4-demethoxy-10-nordaunomycinone (24)

An acetone solution (20 mL) of 2,2-dimethoxypropane (5 mL), trifluoroacetic acid (1/3 mL), and **22** (80 mg) was heated under reflux in a dry nitrogen atmosphere. The solution was concentrated under reduced pressure, diluted with CH_2Cl_2 (100 mL), and washed with water and sodium bicarbonate solution, then dried and evaporated to dryness. The residue, after separation by tlc on silica, afforded starting material **22** (12 mg) and the product **24** (42 mg), which was recrystallized from CH_2Cl_2–ether; mp 148–151°C; ir: 3560 (C7-OH), 3450 (C9-OH), 1715 ($COCH_3$), 1670 (quinone), 1600, 1580 (aromatic); ^{1}H nmr: 2.285 (s, 3H, $COCH_3$), 2.428 (dd, ^{1}H, C8-H_a, J = 14.4 Hz, J_{8a7b} = 5.1 Hz), 2.602 (dd, 1H, C8-H_b, J_{8b8a} = 14.4 Hz, J_{8b7b} = 7.2 Hz), 3.187 (s, H, C-OH), 3.889 (s, 3H, OCH_3), 4.093 (s, 3H, OCH_3) 4.718 (s, 1H, C9-OH), 5.874 (dd, 1H, C7-H_b, J_{7b8b} = 7.2 Hz, J_{7b8a} = 5.1 Hz), 7.785 (m, 2H, C2-H, C3-H), 8.178 (m, 2H, C1-H, C4-H).

Demethylation of 22 and 24

The *trans*-diol **22** (90 mg) was allowed to react with $AlCl_3$ (500 mg) in anhydrous chloroform solution (20 mL) for a period of 3 h at room temperature. Saturated oxalic acid solution (15 mL) was added and the solution was stirred for $1\frac{3}{4}$ h at room temperature. The aqueous phase was separated and extracted by chloroform, and the combined chloroform solutions, dried with anhydrous sodium sulfate and evaporated to dryness under reduced pressure, gave a red solid residue (50 mg), which was purified by precipitation from methylene chloride – ether; mp 225–228°C; ir: 3560 (C7-OH), 3450 (C9-OH), 3600–2600 (chelated phenols), 1720 ($COCH_3$), 1630 (chelated quinone), 1590 (aromatic); ^{1}H nmr: 2.222 (s, 3H, $COCH_3$), 2.307 (dd, 1H, C8-H_b, J_{8b8a} = 14.7 Hz, J_{8b7a} = 3.9 Hz), 2.881 (d, 1H, C7-OH, $J_{OH,7a}$ = 4.6 Hz), 2.943 (dd, 1H, C8-H_a, J_{8a8b} = 14 ***Hz,*** J_{8a7a} = 7.3 Hz), 4.561 (s, 1H, C9-OH), 5.583 (ddd, 1H, $J_{OH,7a}$ = 4.5 Hz, J_{7a8b} = 4.0 Hz, J_{7a8a} = 7.3 Hz), 7.849–7.878 (m, 2H, C2-H, C3-H), 8.235–8.370 (m, 2H, C1-H, C4-H), 12.994 (s, 1H, C6-OH), 13.081 (s, 1H, C10-OH); ms: 354 (M^+, 1%), 311 (M − $COCH_3$, 100%), 293 (M − $COCH_3$ − H_2O, 70%).

Demethylation of **24** to 4-demethoxy-10-nordaunomycinone (**4**) was carried out under identical condition with similar yield, and the crude product showed in tlc that **4** was the only demethylated product; mp 230–232°C; ir: 3560 (weak) (OH), 3430 (OH), 3560–2700 (chelated OH), 1715 ($COCH_3$), 1630 (chelated quinone), 1590 (aromatic); ^{1}H nmr (Fig. 4): 2.369 (s, 3H, $COCH_3$), 2.50 (dd, 1H, C8-H_a, J_{8a8b} = 10.75 Hz, J_{8a7b} = 3.96 Hz), 2.659 (dd, 1H, C8-H_b, J_{8b8a} = 10.74 Hz, J_{8a7b} = 7.4 Hz), 3.091 (d, 1H, C7-OH, $J_{OH,7b}$ = 3.8 Hz), 4.5 (s, 1H, C9-OH), 5.839 (ddd, 1H, C7-H_b, $J_{OH,7b}$ = 3.8 Hz, J_{7b8b} = 7.3 Hz, J_{7b8a} = 4.0 Hz), 7.842 (m, 2H, C2-H, C3-H), 7.872 (m, 2H, C1-H, C4-H), 12.956 (s, 1H, C6-OH), 13.017 (s, 1H, C10-OH).

Target factor analysis of bond dissociation energies

DARRYL G. HOWERY[1] AND MATTHEW RUBENSTEIN
Department of Chemistry, The City University of New York, Brooklyn College, Brooklyn, NY 11210 U.S.A.

Received August 7, 1986

DARRYL G. HOWERY and MATTHEW RUBENSTEIN. Can. J. Chem. **65**, 1380 (1987).

Six data matrices of bond dissociation energies ranging from a 6 × 6 matrix involving only hydrocarbon radicals to a 14 × 14 matrix involving several types of radicals are target factor analyzed. The number of factors to reproduce the data near experimental error range from two to four for the six matrices. The hydrogen and fluorine radicals are shown to be the most unique radicals. Combination sets of vectors from the data matrices reproduce the data within experimental error, with the hydrogen, fluorine, and hydroxyl radicals being the most important ones. Using target testing, a few of the properties of the radicals are identified as basic factors.

DARRYL G. HOWERY et MATTHEW RUBENSTEIN. Can. J. Chem. **65**, 1380 (1987).

On a effectué une analyse par vecteurs spécifiques de six matrices de données d'énergies de dissociation de liaison qui vont d'une matrice 6 × 6 n'impliquant que des radicaux hydrocarbonés à une matrice 14 × 14 impliquant plusieurs types de radicaux. Pour les six matrices, il faut de deux à quatre facteurs pour reproduire lés données expérimentales en dedans des erreurs expérimentales. On démontre que les radicaux hydrogène et fluor sont les radicaux les plus typiques. Une combinaison d'ensembles de vecteurs des matrices de données permet de reproduire les données expérimentales en dedans des erreurs expérimentales; les radicaux hydrogène, fluor et hydroxyle sont les plus importants. Utilisant la méthode de la vérification des vecteurs spécifiques, on a identifié les propriétés des radicaux qui sont des facteurs de base.

Introduction

The development of theoretical and empirical models for bond dissociation energies (BDE) is one of the most important objectives in modern chemistry (1). Though many correlations and theories for BDE have been proposed, general models which can account for observed BDE involving a diversity of radical types are not yet available. Factor analysis (FA) (2), a multivariate method for analyzing matrices of data, is particularly suited for correlating and modeling multifactor data such as BDE. A discussion of the methodology and applications of factor analysis in chemistry is given in Malinowski and Howery's monograph (2). Factor analysis can be applied to many kinds of chemical problems. For example, spectra of multicomponent solutions (3), properties of solvents (4), retention indices in gas–liquid chromatography (5), and solid-state nmr spectra (6) have been fruitfully studied using FA.

Factor analysis is particularly suited to studies of BDE. With FA, a bond dissociation energy can be characterized in terms of the properties of the two radicals resulting from the dissociation of the molecule. Specifically, a data matrix of BDE, [E], can be modeled via FA according to the equation:

$$[1] \quad [E] = [R_r][R_c]$$

where $[R_r]$ and $[R_c]$ are matrices involving the properties of the radicals associated with the rows and with the columns, respectively, of the data matrix. Abstract matrices which obey eq. [1] are calculated using principal-component analysis. Then, the number of fundamental factors responsible for the data can be determined by several methods. In addition, the abstract principal factors can be utilized to correlate the data by identifying groups of radicals which have similar behavior as well as individual radicals which have unique behavior. Finally, parameters of the radicals which represent the underlying factors influencing the BDE can be identified by a least-squares procedure called target testing. This last step of a factor analysis allows physical models for the BDE to be developed.

We report here some results from a factor analysis of bond dissociation energies involving 14 radicals of diverse properties. Using the various techniques of FA, we are able to correlate the data in several ways and to identify a few properties of the radicals which influence BDE.

Experimental section

Critically evaluated bond dissociation energies were furnished by Zavitsas.[2] A copy of the data matrix is available upon request. The values for the BDE which we used are in agreement with those reported by Egger and Cocks (7) usually within 1 kcal/mol, with our values generally being lower. Bonds involving all possible pairs of the 14 radicals listed in Table 1 were utilized to form a symmetrical 14 × 14 data matrix of BDE. In order to study the effects of the various groups of radicals, five symmetrical submatrices formed from the parent 14 × 14 matrix were also studied. The six problems studied with estimated experimental errors for each matrix are spelled out in the lower portion of Table 1.

A computer program in FORTRAN IV (8) was used to perform the factor analyses. All computations were conducted on an I.B.M. model 370/165 digital computer. The methodology employed is explained in detail in ref. 2, where particular emphasis is given to the techniques of an extended form of FA called target factor analysis.

Results and discussion

Number of factors

The number of factors to reproduce a data matrix near experimental error is a useful measure of the overall complexity of a problem. In the reproduction step of factor analysis, the complete set of least-squares principal-component factors is calculated and then, stepwise, reproduction is carried out using the first, most important, factor; the first and second factors together; the first three factors jointly; and so forth. For the correct, physically significant number of factors, the root-mean-square (rms) error for reproduction (calculated from a comparison of the original data with the FA reproduced data) is reasonably similar to the estimated experimental error.

Results for the six data matrices described in Table 1 are given in Table 2. The rms error for reproduction, the percentage of data points reproduced with errors exceeding the experi-

TABLE 1. Radicals studied and description of problems

(*a*) Radicals

Symbol	Name	Symbol	Name
H	Hydrogen	F	Fluorine
Me	Methyl	Cl	Chlorine
Et	Ethyl	Br	Bromine
*i*Pr	Isopropyl	OH	Hydroxyl
*t*Bu	*tert*-Butyl	MeO	Methoxyl
Ph	Phenyl	MeCO	Acetyl
Bz	Benzyl	NH_2	Amine

(*b*) Problems

Designation[a]	Radicals involved	Estimated error (kcal/mol)
6 × 6	Me—Bz	2
7 × 7	H—Bz	2
9 × 9	Me—Br	2
10 × 10	H—Br	2
13 × 13	Me—NH_2	3
14 × 14	H—NH_2	3

[a]Indicates the dimensions of the data matrix.

mental error (listed in Table 1), and the magnitude of the largest error are all taken into account to arrive at the number of factors stated in the second column of Table 2. As the chemical complexity of a problem increases, the number of factors estimated from FA also increases. For example, the data for the 6 × 6 problem (hydrocarbon radicals only) reproduced well with only two factors, whereas the complete 14 × 14 matrix requires four factors. Adding a vector for the hydrogen radical to a matrix increases the rms error significantly, as seen, for example, by comparing the results for the 9 × 9 and the 10 × 10 problems. The group of four polar radicals, based on a comparison of results for the 10 × 10 and the 14 × 14 problems, also seem responsible for a major effect.

An approach based on a theory of error for abstract FA by Malinowski (9) can also be used to determine the number of factors. Malinowski found that a quantity called the factor indicator function usually has its minimum value at the correct number of factors. Further, for that number of factors, an estimate of the experimental error, called the real error, is predicted from the theory. In five of the six BDE problems, the indicator function exhibits a minimum value. The number of factors for which the indicator function has minimum values and the associated value for the real errors are given in the last two columns of Table 2. The number of factors indicated from the reproduction approach and from the theoretical approach are equivalent except for the 13 × 13 problem. In addition, the real errors from theory are reasonably close to the estimated experimental errors.

Combination of typical factors

A procedure called target combination is used to compress the information content of a data matrix into a much smaller matrix (3, 5). In the combination procedure, vectors from the data matrix, called typical vectors or typical factors, are tested in combination to determine which subsets of data columns best model the complete data matrix. The best model, which gives the smallest rms error in combination reproduction, is called the key combination set. For each of the six problems, all combinations of typical vectors, taken *n* at a time (where *n* for each problem is given in the second column of Table 2), were run to find the best model.

A summary of the results from the target combination procedure is shown in Table 3, in which are listed the rms errors and the radicals represented in each of the key sets. For each problem, the best model using typical factors has an rms error only slightly greater than the rms error calculated from reproduction using abstract, principal factors (column three of Table 2). The key combination sets are excellent models for the data. For instance, the rms error for the 14 × 14 problem using typical vectors is 1.41 kcal/mol, well within the estimated experimental error of 3 (from Table 1), and for practical purposes equivalent to the rms error of 1.33 (from Table 2) using the abstract factors. The methyl radical is incorporated in all but one of the five key combination sets, indicating that this radical best represents the group of hydrocarbon radicals in the overall model. Fluorine radical is the most important of the halogen radicals and the hydroxyl radical is the key radical in the group of four polar radicals, based on representations in the best combination models. Hydrogen radical is quite important in the 7 × 7 and 10 × 10 problems, being present in each of the five best combination sets for both problems. Fluorine radical occurs in nearly all of the five best models for the 9 × 9 through 14 × 14 problems. Finally, the key combination sets of typical factors for the 13 × 13 and 14 × 14 problems are chemically reasonable, consisting of a representative from each of the four types of radicals.

Target testing

Knowing the proper number of factors, we wish to transform the abstract, principal factors to factors having physical significance, called basic factors. A least-squares method called target testing is used to identify basic factors, one at a time. Parameters of the radicals are tested mathematically for possible identification with the fundamental influences on the BDE. A test vector representing the idea to be target tested is input and a predicted vector having the best least-squares fit to the target test vector is calculated. If the point-by-point agreement between the test vector and the predicted vector is satisfactory using chemical criteria, then the tested parameter is said to be a basic factor.

The uniqueness test is a simple, yet informative, target test designed to ascertain which radicals exhibit the most atypical behavior. A uniqueness test vector contains a "1" for the radical being tested for uniqueness and "0"'s for the remaining radicals on that test vector. A uniqueness test is run for each radical in each of the six problems. The radicals having the largest predicted uniqueness values are listed in Table 4. Predicted uniqueness values greater than say 0.75 are taken to indicate unique radicals. Thus, the fluorine radical, having by far the largest uniqueness value in the 14 × 14 problem, is a particularly important radical due to some property of a unique nature. Hydrogen radical in the 7 × 7 and 10 × 10 problems and the *t*-butyl radical in the 6 × 6 problem also exhibit unique behavior. Information from the uniqueness tests is reinforced by results from the target combination procedure. Invariably, the radicals which test as unique in Table 4 are identified as key radicals in Table 3.

Using target testing, the basic factors which control bond dissociation energies can be expressed in terms of the properties of the radicals forming the molecules. Nearly 50 candidates for basic factors, as well as the square, reciprocal and logarithm transforms of each test vector, were target tested one

[b]Radicals represented in best target-combination models.

TABLE 4. Summary of uniqueness tests

Problem[a]	Unique radicals (predicted uniqueness values)[a,b]
6 × 6	*t*Bu (0.76), Ph (0.44)
7 × 7	H (0.92)
9 × 9	F (0.77)
10 × 10	H (0.83), F (0.83)
13 × 13	F (0.90), OH (0.46)
14 × 14	F (0.87), OH (0.44)

[a]See Table 1 for designations.
[b]Only values greater than 0.40 are listed.

TABLE 5. Summary of selected target tests from the 14 × 14 problem using four factors

Property[a]	Example values[b] *i*Pr	Example values[b] MeCO	Points[c]	Fit[d]
Mass (R)	43	43	14	p
Group electronegativity (R)	2.39	1.93	14	f
Ionization potential (R)	7.90	8.08	14	g
Electron affinity (R)	1.0	ff	10	f
Unity	1.0	1.0	14	g
Carbon number (R)	3.0	2.0	14	p
Halogen uniqueness	0	0	14	p
Fluorine uniqueness	0	0	14	g
Number of electrons (A)[e]	13	14	12	f
Bond dissociation energy (RR)	77.7	67.2	14	f
Free energy of formation (RH)	−5.6	−32.0	14	p

[a]R = radical, A = atom of radical having unpaired electron, RR = molecule formed with same radical, RH = molecule formed with hydrogen radical. References 10 and 11 were particularly useful sources for physical-property data.
[b]Example values given for the two radicals: isopropyl (*i*Pr) and acetyl (MeCO). Missing value denoted by "ff" was free floated on the electron affinity vector for MeCO.
[c]Number of test values input on the test vector.
[d]Qualitative evaluation of the results of the target test: g = good agreement between the test and the predicted vectors, f = fair agreement (overall pattern predicted but a few points predicted poorly), p = poor agreement.
[e]Number of electrons on the atoms bonded to the atom having an unpaired electron.

at a time for the 13 × 13 and 14 × 14 problems. Parameters of the radicals which target test with fair or better fits between the test and predicted vectors are identified as basic factors. Some of the parameters tested are properties of the radicals, others are properties of the molecules formed from the radicals and a hydrogen radical (e.g., H_2 and CH_4), and still others are properties of the bonding atoms in the radicals (e.g., the oxygen atom in the hydroxyl radical).

Results for representative target tests from the 14 × 14 problem are summarized in Table 5. Shown for each parameter are the test values input on each test vector for the isopropyl and acetyl radicals, the number of points input on the test vector and a qualitative evaluation of the fit of the predicted vector with the test vector. Comparisons of the patterns and of the magnitudes for the test and predicted vectors led to the evaluation of fit given in the table. For example, a vector is considered to have a fair fit if the overall patterns in the test and predicted vectors are similar but one or a few test points are predicted with fairly large errors. Essentially all of the parameters which yielded good or fair fits are listed in the table. Since such a small number of the tested parameters appear to be basic factors, the detailed modeling of bond dissociation energies is indeed a difficult problem.

Details for four target tests from the 13 × 13 problem are shown in Table 6. The first and second tests, for ionization potential and group electronegativity to the 3/2 power, give acceptable fits between the test and predicted vectors. The two parameters of the radicals are basic factors. The power utilized for the group electronegativity vector was suggested by Zavitsas from empirical correlations.[2] Results for these two tests also illustrate that test vectors do not have to be complete. Some of the test points on a test vector can be left blank on the test vector, a procedure called free floating. For example, three test points (known values given in parentheses on the test vector) were deliberately free floated on both the ionization potential and the group electronegativity test in the table. Since the free floated points are predicted fairly accurately, the success of the two target tests is further validated. The third and

fourth tests in the table, for the mass of the radical and for halogen-group uniqueness, do not show adequate agreement between the test and predicted vectors. These two parameters according to factor analysis are not basic factors.

Any property associated with the row-designee radicals in the data matrix (or with the column designees if the matrix were unsymmetrical) can be target tested. However, a vector involving a difference of properties, such as the difference of group electronegativities, cannot always be legitimately target tested. On the one hand, a test vector such as ($GE - GE_H$), which expresses the group electronegativity (GE) of the row-designee radicals relative to the constant value GE_H for the hydrogen radical, can be validly target tested. On the other hand, since factor analysis isolates the factors of the row designees from the factors of the column designees, any vector based on the difference between a property of the row designees and a property of a column designee cannot be validly tested. For example, a difference vector of the form ($GE_i - GE_j$) involving the ith row radical and the jth column radical of the data matrix, in which both GE's are varying along the test vector, should not be target tested.

Received December 10, 1986

JOHN A. FINDLAY, MAHESH JASEJA, D. JEAN BURNELL, and JEAN-ROBERT BRISSON. Can. J. Chem. **65**, 1384 (1987).

The structures of the two major saponins isolated from the starfish *Asterias forbesi* have been deduced totally by nuclear magnetic resonance methods applied to the undegraded molecules. The structure of forbeside A, 6α-*O*-{β-D-galactopyranosyl-(1→3)-β-D-fucopyranosyl-(1→2)-β-D-galactopyranosyl-(1→4)-[β-D-quinovopyranosyl-(1→2)]-β-D-xylopyranosyl-(1→3)-β-D-quinovopyranosyl}-20-hydroxy-23-oxo-5α-cholest-9(11)-en-3β-yl sodium sulfate, was deduced principally from ^{1}H 2D-COSY, *J*-resolved, nuclear Overhauser enhancement and selected decoupling experiments. The structure of forbeside B, 6α-*O*-{β-D-quinovopyranosyl-(1→2)-β-D-galactopyranosyl-(1→4)-[β-D-quinovopyranosyl-(1→2)]-β-D-xylopyranosyl-(1→3)-β-D-quinovopyranosyl}-20-hydroxy-23-oxo-5α-cholest-9(11)-en-3β-yl sodium sulfate, was deduced principally from 2D-COSY, HCORR, RECSY, and NOESY experiments.

JOHN A. FINDLAY, MAHESH JASEJA, D. JEAN BURNELL et JEAN-ROBERT BRISSON. Can. J. Chem. **65**, 1384 (1987).

Faisant appel à des méthodes de résonance magnétique nucléaire appliquées à des molécules qui n'ont pas été dégradées, on a déterminé d'une façon complète les structures des deux saponines principales qui ont été isolées de l'étoile de mer *Asterias forbesi*. Pour la résolution de la structure de la forbeside A, le sulfate de sodium du *O*-{β-D-galactopyrannosyl-(1→3)-β-D-fucopyrannosyl-(1→2)-β-D-galactopyrannosyl-(1→4)-[β-D-quinovopyrannosyl-(1→2)]-β-D-xylopyrannosyl-(1→3)-β-D-quinovopyrannosyl}-6α hydroxy-20 oxo-23 5α-cholestène-9(11) yle-3β, on a principalement fait appel à des expériences de ^{1}H 2D-COSY, résolues pour *J*, d'effets Overhauser nucléaire et de découplages sélectifs. Pour déduire la structure de la forbeside B, le sulfate de sodium du *O*-{β-D-quinovopyrannosyl-(1→2)-β-D-galactopyrannosyl-(1→4)-[β-D-quinovopyrannosyl-(1→2)]-β-D-xylopyrannosyl-(1→3)-β-D-quinovopyrannosyl}-6α hydroxy-20 oxo-23 5α-cholestène-9(11) yle-3β, on a principalement fait appel à des expériences de 2D-COSY, HCORR, RECSY et de NOESY.

[Traduit par la revue]

In view of the widespread interest (1) in the biological functions, toxicity, and pharmacology of starfish saponins (asterosaponins), we recently embarked on structural studies on the asterosaponins of *Asterias forbesi*. This is a common species on the Atlantic seaboard and, in particular, in the Bay of Fundy.

Shimizu (2) reported antiviral activity in three glycosidic substances (probably asterosaponins) from *A. forbesi*, and Goldsmith and Carlson (3) demonstrated that analgesic, hypotensive, and anti-inflammatory properties were associated with asterosaponins from this species. An antimitotic substance from the ovaries of *A. forbesi* reported by Heilbrunn *et al.* (4) in 1954 was possibly an asterosaponin.

Previous chemical studies on *A. forbesi* have been limited to the structures of the steroidal products of hydrolysis of its asterosaponin mixture. Shimizu (5) isolated 3β,6α-dihydroxy-5α-pregn-9(11)-en-20-one (asterone) from the hydrolysate, and ApSimon *et al.* (6) reported asterone and the corresponding triol (asterogenol) from hydrolysed asterosaponin from the same organism.

A methanol extract of specimens collected in Passamaquoddy Bay (August 1984) was chromatographed on an Amberlite XAD2 column to yield a crude saponin-containing fraction, the chloroform/methanol (6:4) soluble portion of which was subjected to preparative layer chromatography (plc) on silica gel to provide three fractions, which, after further purification on reversed phase plc and high performance liquid chromatography (hplc), yielded four pure saponins that were designated forbesides A, B, C, and D (~2:3:1:1). This paper deals with the structures of A and B, which were deduced entirely by nuclear magnetic resonance methods.

One-dimensional nuclear magnetic resonance (nmr) methods have yielded limited information for the determination of complete structure and stereochemistry of complex saponins. No systematic method for complete structural analysis has resulted, largely because of the severe resolution problems encountered, since most oligosaccharide proton signals fall within a 2-ppm chemical shift range and substantial overlap of multiplets occurs.

In view of this, it has generally been necessary to resort to permethylation and hydrolysis experiments to determine the sugar sequence and the sites of interglycosidic linkage (7–11). The whole process is somewhat tedious and also consumes saponin, which is often very difficult to separate and purify and may be better employed in biological evaluation experiments.

These difficulties can be overcome by the use of modern high field 2D nmr experiments. The critical requirement is the unambiguous assignment of ^{1}H resonances, especially in the oligosaccharide portion. We have used two-dimensional (2D) nuclear proton correlation (COSY) (12), relayed correlation spectroscopy (RECSY) (13), *J*-resolved (12), nuclear Overhauser enhancement (NOESY) (14), and one-dimensional nuclear Overhauser enhancement experiments to determine the complete sugar sequence and the sites of interglycosidic linkage, thus obviating the need for hydrolysis reactions. In one case (forbeside B), we have utilized a hydrogen–carbon correlation (HCORR) (15) experiment to arrive at unambiguous assign-

ment of ^{13}C chemical shifts. In the past the ^{13}C chemical shift assignments in the oligosaccharide moiety of saponins have been made mainly by comparisons with reference substances (10, 16).

2D nuclear magnetic resonance has enjoyed much success in the structural elucidation of a variety of natural products (16–20). In this paper we illustrate the utility of 2D techniques for the complete structural elucidation of marine saponins.

The 500-MHz ^{1}H nmr spectrum (pyridine-d_5/D_2O, 5:1) of forbeside A shows six anomeric proton doublets (see Table 1), while multiplets due to oligosaccharide ring protons appear in the region δ 3.5–4.6 ppm. In the upfield region are methyl doublets at δ 1.391 (6.3 Hz), 1.594 (6.1 Hz), and 1.831 (6.2 Hz) indicative of the presence of three 6-deoxy sugars, in addition to signals characteristic of the 18, 19, 21, 25, and 27 thornasterol A methyl groups (21).

Using 2D-COSY, *J*-resolved, nOe, and selected decoupling experiments, it has been possible to establish the connectivity of all proton resonances in the aglycone and the oligosaccharide side chain. A complete inventory of proton chemical shift assignments has thus been generated for the first time for this aglycone and is contained in Table 2. Table 1 shows the assignments for the oligosaccharide moiety. Thus the nature of the aglycone, the sugar units, their stereochemistry, and sequence have been deduced solely from ^{1}H nmr data. As an illustration, Fig. 1 shows the 2D-COSY spectrum from δ 3.30–5.30 ppm for forbeside A. The anomeric proton Q′1 at δ 4.826 is coupled to Q′2H at δ 3.983, which in turn is coupled

to Q′3H at δ 3.885. The latter is coupled to Q′4H at δ 3.358, which is coupled to Q′5 at δ 3.714, which in turn is coupled to a methyl doublet at δ 1.594. From the coupling constant data (Table 1), it is evident that these signals must emanate from a quinovose (Q′) (6-deoxyglucose) moiety. That this unit is linked via a β-anomeric oxygen to C6 of the aglycone is revealed by nOe experiments. Figure 2 shows the δ 3.4–5.2 portion of the nOe difference spectra resulting from irradiation at the anomeric protons. Thus, upon irradiation of Q′1H (some irradiation at F1H is also occurring), substantial enhancement is noted for protons at Q′3 and Q′5 and lesser amounts at Q′2H, Q′4H, and Q′6H corroborating the stereochemistry deduced from coupling constant data. In addition, one notes the largest nOe is to a signal at δ 3.81 corresponding to 6βH of the aglycone while lesser but significant enhancements occur at signals for protons due to 4α, 4β, 5α, 7α, 7β, and 8β. Irradiation of the signal at δ 5.067, due to the xylose unit anomeric proton X1H, in addition to causing the anticipated enhancement at X2H, X3H, X4H, X5α, and X5β, gave a large enhancement (22%) of the signal for Q′3H and lesser enhancements for Q′2H, Q′4H, and Q′5H. Thus it is abundantly clear that the xylose unit X is connected via a β anomeric linkage to the Q′3 carbon. In like manner the nature and sequencing of the remaining sugars was determined, and their stereochemistry corroborated by nOe experiments. The structure **1**, 6α-*O*-{β-D-galactopyranosyl-(1→3)-β-D-fucopyranosyl-(1→2)-β-

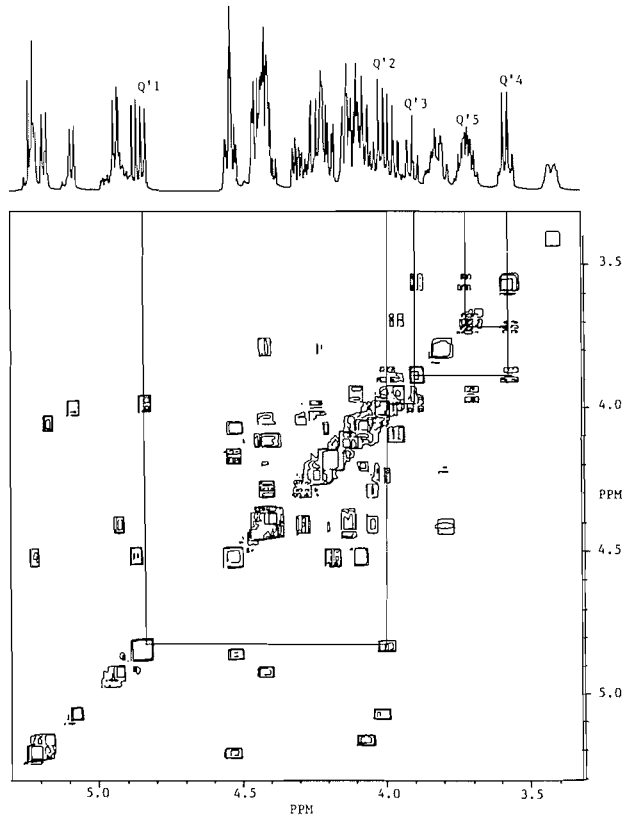

FIG. 1. 2D Nuclear proton correlation (COSY) spectrum (δ 3.30, 5.30 ppm) of forbeside A.

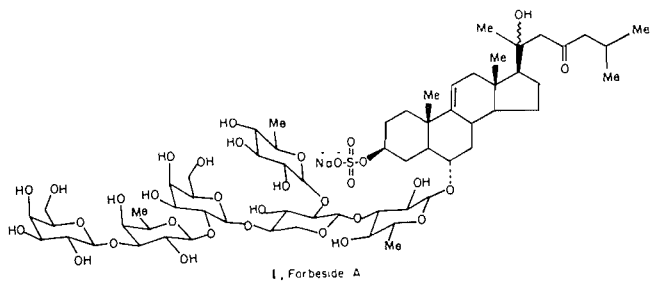
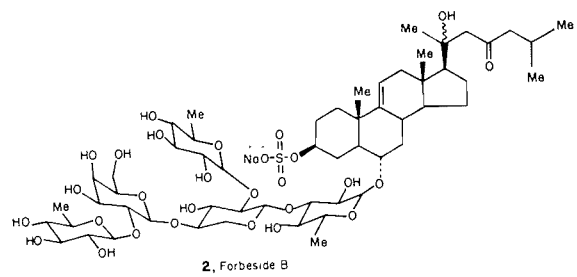
D-galactopyranosyl-(1→4)-[β-D-quinovopyranosyl-(1→2)]-β-D-xylopyranosyl-(1→3)-β-D-quinovopyranosy}-20-hydroxy-23-oxo-5α-cholest-9(11)en-3β-yl sodium sulfate, is assigned to forbeside A.





This structure is identical with that reported by Itakura *et al.* (10) for the saponin versicoside A isolated from *Asterias amurensis* and deduced chiefly from ^{13}C nmr, mass spectrometric data, and enzymatic hydrolyses experiments. Our ^{13}C nmr and FAB mass spectral data for forbeside A are in excellent agreement with those reported for versicoside A. The positive ion FAB mass spectrum of forbeside A shows pseudomolecular ion peaks at m/z 1429.4 (M + H) and 1451.6 (M + Na), which,

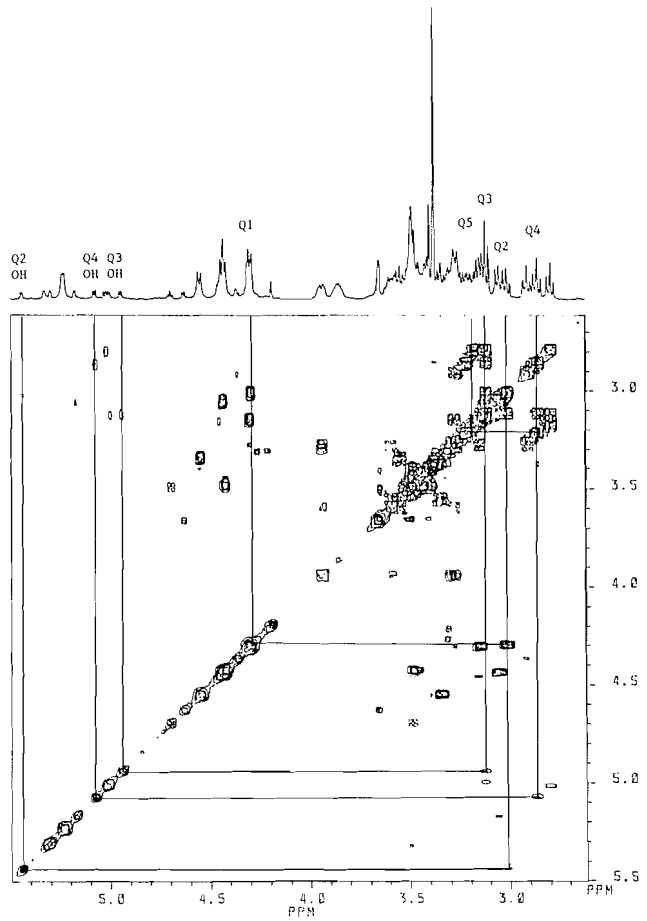

FIG. 3. 2D-COSY spectrum of forbeside B showing connectivity of protons in quinovose (Q''') unit.

in conjunction with ^{13}C data, confirm the molecular formula $C_{62}H_{101}O_{33}SNa$.

The structure of forbeside B, the second major saponin from *A. forbesi*, has been deduced also by nmr methods, employing 2D-COSY, HCORR, RECSY, and NOESY experiments.

Since forbeside B appeared to be sensitive to pyridine, prior to achieving final purification, most of the spectra were recorded in dimethyl sulfoxide-d_6. Table 2 contains a summary of chemical shift assignments for all carbon atoms and protons belonging to the aglycone of forbeside B derived from ^1H, ^{13}C, distortionless enhancement by polarization transfer (DEPT) analysis, and HCORR experiments. The virtually identical carbon chemical shifts for the aglycone moieties of forbesides A and B show they possess the same thornasterol A aglycone.

Table 3 contains the carbon and proton chemical shift assignments for the oligosaccharide moiety of forbeside B. The proton assignments for each sugar moiety were deduced from the 2D COSY experiment as in the case of forbeside A. For example, Fig. 3 shows the 2D COSY spectrum from δ 2.2 to 5.5 ppm. Starting from the anomeric proton signal Q'''1 at δ 4.29, one can trace out the complete *J* connectivity pathway to methyl signal Q'''6 establishing the chemical shifts of each proton in the sugar unit Q'''. The coupling constant values (Table 3), obtained from a 2D-*J* resolved experiment, show the deoxy hexose unit Q''' to be a quinovose unit.

The proton chemical shift assignments for the oligosaccharide chain were further corroborated by RECSY experiment. This assisted in establishing connectivities between remote nuclei belonging to the same ring spin system and thus provided an unambiguous chemical shift assignment of protons belonging to each saccharide unit. The contour plot shown in Fig. 4 illustrates the utility of this method. In it one can see peaks directly connecting resonances due to X1H, X2H, X3H, X4H, and X3H, X4H, X5Hα, X5Hβ, thus completing the connectivity pathway of protons in the xylose ring system.

From Table 4, which summarizes significant nOe effects as determined from a 2D-NOESY experiment, it is evident that sugar Q' is linked to the aglycone at C6 and that Q'3H and Q'5H are *cis* to Q'1H, while Q'2H and Q'4H are *trans* to Q'1H. Thus, in view of the coupling constant values (Table 3), it is evident that the first sugar directly attached to the aglycone is a quinovose unit. The nOe correlation between Q'3H and X1H shows sugar X is attached to the quinovose unit Q' at Q'3 position via an interglycosidic linkage. The stereochemistry and sequencing of the remaining sugars follow from a similar analysis of the remaining data.

To improve the quality of the nmr spectra of forbeside B, the sample was exchanged several times with D_2O prior to dissolution in DMSO-d_6. This resulted in an array of 12 partially exchanged hydroxyl doublets in the downfield region (δ 4.3–5.3 ppm), which from COSY and RECSY spectra could each be assigned without ambiguity to their respective secondary proton coupling partners (see Table 3) and provided an independent corroboration of the substitution pattern of the sugar units

Major significant ions from positive ion spectrum.

FIG. 5. FAB Mass spectral fragmentation of forbeside B.

and confirmed the sites of glycosidic linkages established by NOESY experiments.

We thus conclude that forbeside B possesses structure **2**, 6α-*O*-{β-D-quinovopyranosyl-(1→2)-β-D-galactopyranosyl-(1→4)-[β-D-quinovopyranosyl-(1→2)]-β-D-xylopyranosyl-(1→3)-β-D-quinovopyranosyl}-20-hydroxy-23-oxo-5α-cholest-9(11)en-3β-yl sodium sulfate. This is the same structure that has been assigned to glycoside B_2 from *A. amurensis* by Ikegami *et al.* (11) principally on the basis of hydrolysis products following permethylation experiments. No spectral data for the intact glycoside B_2 have appeared in the literature.

The FAB mass spectra of forbeside B provide corroboration for a number of its features in addition to its elemental composition $C_{56}H_{91}O_{28}SNa$ (Mol. Wt. 1266), which was revealed by the base peak at *m/z* 1289 (M + Na) in the +ve ion spectrum and by peaks at 1265 (M − H) and 1243 (M − Na) in the −ve ion spectrum. Significant ions at *m/z* 1023, 877, and 861 in the +ve ion spectrum (Fig. 5) are consistent with the presence of two terminal quinovose units, one of which is attached to a galactose moiety. The fragmentation patterns M + Na → 773 → 627, M + Na → 771 → 625 → 479, and M + Na → 755 → 609 → 463 are in full agreement with the sugar sequence deduced from nmr data. Other significant fragments correspond to dealdolization of the sidechain, loss of $NaSO_4H$, quinovose, and quinovose-galactose from the base peak. We have not noted distinctive fragments corresponding to these latter in the FAB mass spectrum of forbeside A, which is very similar to that published for versicoside A (10). Nor are they featured in the FAB mass spectral data reported for thornasteroside A (10). The latter differs from forbeside B only by the presence of a fucose (6-deoxygalactose) unit in place of Q‴ in structure **1**.

[c]Interresidual coupling via glycosidic bond.

It is apparent from the foregoing that the complete structure and relative stereochemistry of starfish saponins can be obtained by appropriate combinations of 1D and 2D nmr experiments. It should be emphasized that this procedure is viable even when limited amounts of material are available; in the case of forbe-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

side A only 13 mg of pure material was used for all nmr experiments. The minor saponins, forbesides C and D, are currently under investigation.

Experimental

Isolation of saponins

The starfish, *Asterias forbesi*, were collected on the shores of Passamaquoddy Bay, Bay of Fundy, in August 1984 and frozen prior to extraction. Frozen animals (20 kg wet wt) were defrosted, chopped into small pieces, and placed in vats containing methanol. After 24 h the solvent was decanted and replaced with fresh methanol. This was repeated three times and the total aqueous methanolic extract (8 L) was filtered and concentrated on a rotary evaporator at 30°C until all methanol was removed. The aqueous extract thus obtained was introduced onto an XAD-2 Amberlite resin (1 kg, mesh 30–50) column. After elution with water until halide ion was no longer detected, the column was eluted with a methanol/water gradient. The combined 80–100% methanol/water fractions contained saponins and were evaporated to dryness at 30°C on a rotary evaporator. The crude saponin residue was stirred for 1 h with chloroform/methanol (1 L, 3:2) and filtered. The filtrate was evaporated to dryness at 30°C and then dissolved in the minimum amount of water and lyophilized, giving the saponin mixture (8.1 g) as a yellow/beige powder.

A portion (3 g) of the saponin mixture thus obtained was chromatographed on precoated preparative tlc silica gel (F-254, 1 mm) plates (~90 mg/plate) using chloroform/methanol/water (66:44:5) as solvent. The following fractions were obtained:

Fraction (mg)	R_f
1 (200)	0.41–0.50
2 (175)	0.31–0.40
3 (186)	0.21–0.30
4 (126)	0.16–0.20

Fraction 1 proved to be an intractable mixture, while fractions 2 and 3 each had one major component, and fraction 4 displayed two major bands by tlc scrutiny. Fractions 2 and 3 were rechromatographed on precoated reverse phase (KC18F, 0.2 mm) plates (25–30 mg/plate) using methanol/water (62:38) to provide from each a pure saponin. Fraction 2 provided forbeside C (35 mg), while fraction 3 yielded forbeside B (76 mg).

Fraction 4 was rechromatographed on precoated reverse phase (KC18F, 0.2 mm) plates (~25 mg/plate) using methanol/aqueous NaCl 0.002 *M* (64:36) and provided forbeside D (18 mg) and forbeside A (52 mg).

The saponins were further purified by hplc using a semipreparative reverse phase column as below:

Saponin (mg)	Elution time (min)
Forbeside A (48)	11–12
B (70)	12.5–13.5
C (30)	12–13
D (15)	12–13

The hplc column (Whatman Partisil IUCCS/C8) was operated at 1800–2000 psi (1 psi = 6.9 kPa) using methanol/water (64:36) at a flow rate of 7.5 mL/min and a refractive index detector.

Forbeside A, a glassy foam, showed mp 200–203°C and $[\alpha]_D^{28}$ −1.5 (*c* 0.0067, H_2O).

Forbeside B, a glassy foam, showed mp 206–208°C and $[\alpha]_D^{28}$ −2.8 (*c* 0.009, H_2O).

Nuclear magnetic resonance experiments

^{13}C and ^1H nmr spectra were recorded on a Bruker AM-500 spectrometer at ambient temperature. Tetramethylsilane was used as the internal reference. Forbeside A was run in 0.4 mL of pyridine-d_5/D_2O (5:1) at a concentration of 13 mg/mL. Forbeside B was run in 0.4 mL of DMSO-d_6/D_2O (5:1) at a concentration of 30 mg/mL.

All one-dimensional and two-dimensional nmr experiments were performed using the standard pulse sequences provided by Bruker (DISNMRO).

The nOe difference experiments were performed as previously described (22). However, instead of irradiation at a single frequency of the whole multiplet, each line in the multiplet was sequentially irradiated for 100 ms for a total of 1 s/multiplet.

The proton homonuclear shift correlated 2-D nmr experiment on forbeside A was performed using the standard $90°-t_1-90°$ pulse sequence. Quadrature detection in both dimensions was used. The initial (t_1, t_2) matrix of 256 × 2048 data points over a sweep width of 10 ppm in both dimensions was zero-filled to 2048 × 4096 data points. Unshifted sine square bell functions were used for resolution enhancement. Magnitude calculations and symmetrization about the diagonal were used to represent the data.

Mass spectra

Low resolution FAB mass spectra were obtained on VG7070E and VGZAB-SE mass spectrometers employing xenon as an ionizing gas, accelerating voltages of 5 and 10 kV, respectively, and the DT's (a mixture of dithioerythritol, "magic bullet") (23) as a matrix.

Acknowledgements

The authors are grateful to Professor K. L. Rinehart, University of Illinois at Urbana–Champaign, for providing FAB mass spectra and to Larry Calhoun, Department of Chemistry, University of New Brunswick, for helpful discussions. Thanks are due to John R. Foster, Huntsman Marine Laboratory, St. Andrews, New Brunswick, for assistance in collecting material. This study was funded by grants from the Natural Sciences and Engineering Research Council of Canada.

Synthesis and chemiluminescence of new derivatives of isoluminol

ALAIN BÉLANGER, PAUL BRASSARD, SYLVIE LAQUERRE, AND YVES MÉRAND

Department of Molecular Endocrinology, Le Centre Hospitalier de l'Université Laval, Ste-Foy, P.Q., Canada G1V 4G2 and Department of Chemistry, Université Laval, Ste-Foy, P.Q., Canada G1V 4G2

Received May 29, 1986[1]

ALAIN BÉLANGER, PAUL BRASSARD, SYLVIE LAQUERRE, and YVES MÉRAND. Can. J. Chem. **65**, 1392 (1987).

In an attempt to improve the sensitivity of luminescent immunoassays, we have prepared some new isoluminol, 7-(*N*,*N*-dialkylamino)-5-methyl-2,3-dihydrophthalazine-1,4-diones by means of a novel procedure involving the cycloaddition of dienamines to maleic acid derivatives. These compounds are characterized by the presence of a methyl group at C-5 and give quantum yields three to five times greater than those of the most efficient isoluminols in use at present.

ALAIN BÉLANGER, PAUL BRASSARD, SYLVIE LAQUERRE et YVES MÉRAND. Can. J. Chem. **65**, 1392 (1987).

Afin d'améliorer la sensibilité des dosages luminoimmunoétalonnages, nous avons préparé de nouveaux isoluminols: des *N*,*N*-dialkylamino-7 methyl-5 dihydro-2,3 phtalazinedione-1,4 par une synthèse originale qui implique la cycloaddition d'une diénamine à des dérivés de l'acide maléique. Ces produits caractérisés par un groupe methyle en position C-5 ont un rendement quantique de trois à cinq fois supérieur à celui du meilleur isoluminol actuellement utilisé.

Introduction

The chemiluminescence of cyclic hydrazides was first demonstrated by Albrecht in 1928 (1); since then the efficiency and mechanism of the process continue to raise wide interest. A considerable body of synthetic work has been carried out with the object of isolating the various factors that control light production (2–4). Several of these were early identified by Drew as substituent effects: thus, the unimpeded resonance of electron-donating groups with the system generally exerts a favorable influence as does mild steric hindrance of other substituents with adjacent carbonyls at C-1 and C-4. However, substitution of the heterocyclic moiety completely inhibits the process.

A major application of chemiluminescence to clinical analysis consists in using luminescent molecules as alternatives for radioactive and enzymatic labels in immunoassays. Indeed, luminescent immunoassay (LIA) procedures have recently been described for steroids (5–7), proteins (8, 9), and other biological compounds (10). In this respect, two factors play a major role in the sensitivity of the immunoassay: the affinity of antibodies for the tracer and the specific activity of the latter. In chemiluminescence, the quantum yield is the specific activity of the tracer and probably is the most important parameter affecting the sensitivity of LIA.

Although luminol provides a greater light yield than isoluminol, derivatives of the latter that can be coupled to proteins or steroids have been used extensively since by virtue of the foregoing rules they are more efficient than substituted luminols. Schroeder *et al.* (11) prepared several luminescent compounds and found that aminobutyl ethyl isoluminol in particular showed high efficiency. The use of such a derivative in the LIA of steroids has resulted in a procedure with a sensitivity comparable to that of radioimmunoassays (RIA) (5–7). In an attempt to further improve the sensitivity of LIA, we have prepared and characterized a series of new chemiluminescent derivatives of isoluminol. This novel synthesis involves the cycloaddition of dienamines to maleic acid derivatives and was designed to give compounds with a methyl group at the C-5 position, a feature expected to enhance the quantum efficiency.

Experimental

A. Synthesis (Fig.1)

All melting points were taken for samples in capillary tubes with a Thomas–Hoover Apparatus and are not corrected. The uv spectra were determined on a Hewlett-Packard 8450A spectrophotometer and the ir spectra on a Beckman Model IR 4250. Nuclear magnetic resonance spectra were recorded with Varian EM360 A and XL-200 spectrophotometers using tetramethylsilane as internal standard. Mass spectra were obtained with a Hewlett-Packard 5995 A spectrophotometer. Merck silica gel $60F_{254}$ for dry column chromatography and Woelm neutral aluminium oxide activity II were used throughout. Elementary analyses were carried out by Galbraith Laboratories Inc., Knoxville, TN. Exact masses were provided by the Laboratoire de spectrométrie de masse, Université de Sherbrooke, Sherbrooke, Canada.

*2-Alkylsiloxy-4-*N*-pyrrolidyl-2,4-pentadiene (**2**a or **2**a′)*

To a solution of lithium diisopropylamine (LDA) prepared in the usual way with *n*-butyllithium (*n*-BuLi) (10 mmol, 2.7 *M* in hexane), diisopropylamine (11 mmol) and tetramethylethylenediamine (TMEDA) (12) (10 mmol) in dry tetrahydrofuran (THF) (10 mL) at 0°C under nitrogen and cooled at −78°C, were added 4-*N*-pyrrolidyl-3-penten-2-one (**1***a*) (13) (10 mmol) in dry THF (15 mL) in 15 min, and then after 2 h, a solution of chlorotrimethylsilane (TMSCl) or *t*-butylchlorodimethylsilane (TBDMSCl) (11 mmol), in the same solvent (8 mL; 45 min). The reaction mixture was allowed to warm and kept for 90 min at room temperature, evaporated, diluted with dry petroleum ether (bp 30–60°C, 70 mL), filtered under nitrogen, and evaporated. These operations were repeated and finally the residue was stirred for 3 h under vacuum (0.2 Torr). The unstable dienamine **2***a* or **2***a′* was used without further purification.

2-Trimethylsiloxy-4-*N*-pyrrolidyl-2,4-pentadiene (**2***a*); nmr ($CDCl_3$) δ 5.00 (1H, s), 3.97 (1H, s), 3.57 (1H, s) 3.00 (4H, m), 1.78 (7H, m), and 0.13 (9H, s).

2-*t*-Butyldimethylsiloxy-4-*N*-pyrrolidyl-2,4-pentadiene (**2***a′*); nmr ($CDCl_3$) δ 5.06 (1H, s), 3.86 (1H, s), 3.6 (1H, s), 3.06 (4H, m), 1.86 (7H, m), 0.99 (9H, s), and 0.16 (6H, m).

*3-Methyl-5-*N*-pyrrolidylphthalic anhydride (**4**a)*

To a solution of bromomaleic anhydride (849 mg, 4.8 mmol) in dry benzene (20 mL) was added under nitrogen freshly prepared crude dienamine **2***a* (1.3 g, 5.8 mmol) in the same solvent (20 mL) in 30 min at 5–7°C. The dark reaction mixture was allowed to warm to room temperature and after 2 h, the solvent evaporated, the crude product dissolved in $CHCl_3$, and separated by chromatography on silica gel (50 g). Elution with $CHCl_3$ gives phthalic anhydride **4***a*, yellow needles (218 mg, 19.5%) mp 222–222.5°C; ir ν_{max} (KBr) 1823, 1753, 1620, 1578, and 865 cm^{-1}; uv λ_{max} (C_2H_5OH) 212, 267, 321, and 386 nm (log ε 4.23, 4.19, 4.05, and 3.89); nmr ($CDCl_3$) δ 6.83 (1H, d, J = 2.2 Hz), 6.55 (1H, d, J = 2.2 Hz) (this doublet is not well defined: coupling with the 3-methyl), 3.42 (4H, m) (s, with irradiation at δ 2.10), 2.59 (3H, s) and 2.10 (4H, m) (s, with irradiation at δ 3.42); mass spectrum: m/e 231 (M^+). *Anal.* calcd. for $C_{13}H_{13}O_3N$: C 67.52, H 5.66, N 6.06; found: C 67.65, H 5.62, N 6.02.

[1]Revision received February 11, 1987.

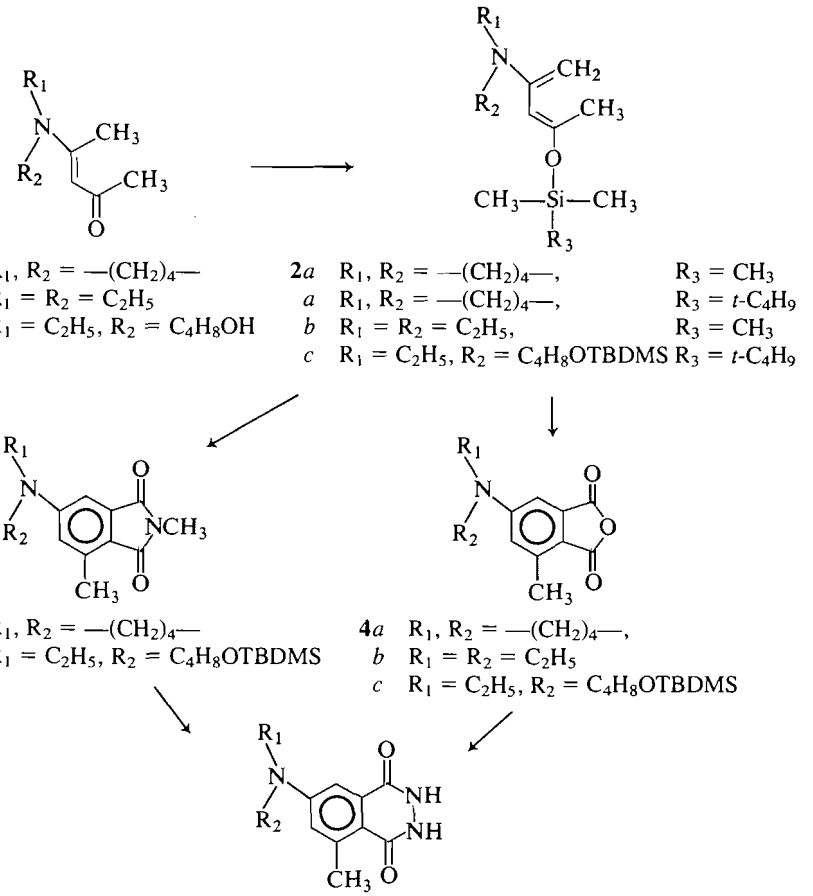

FIG. 1. Synthesis of chemiluminescent compounds.

*3-Methyl-5-*N*-pyrrolidyl-*N*-methylphthalimide (**3**a)*

To a solution of *N*-methylmaleimide (488 mg, 4.4 mmol) in dry benzene (10 mL) was added under nitrogen freshly prepared crude dienamine **2***a*′ (1.07 g, 4 mmol) in the same solvent (10 mL) in 30 min at 5–7°C. The reaction mixture was kept overnight at room temperature and then refluxed for 1 h. Palladium (10%) on activated charcoal (100 mg) was then added and refluxing continued for 3.5 h. After cooling, the catalyst was removed by filtration and the product isolated by chromatography on silica gel (100 g). Elution with CH_2Cl_2 gave methylphthalimide **3***a* (230 mg, 23.5%), yellow needles, mp 159.5–159.8°C (CH_2Cl_2, $(C_2H_5)_2O$); ir ν_{max} (KBr) 1748, 1685, 1610, 1575, and 855 cm^{-1}, uv λ_{max} (C_2H_5OH) 212, 268, 323, and 402 nm (log ϵ 4.46, 4.50, 3.93, and 3.92); nmr ($CDCl_3$) δ 6.83 (1H, d, J = 2.4 Hz), 6.38 (1H, d, J = 2.4 Hz) (this doublet is not well defined: coupling with 3-methyl), 3.39 (4H, m) (s with irradiation at δ 2.06), 3.10 (3H, s), 2.59 (3H, s), and 2.06 (4H, m) (s with irradiation at δ 3.39); $C_{14}H_{16}O_2N_2$ requires 244.1212; found 244.1206. *Anal.* calcd.: C 68.83, H 6.60, N 11.47; found: C 69.19, H 6.56, N 11.70.

*3-Methyl-5-*N,N*-dimethylaminophthalic anhydride (**4**b)*

In a similar reaction, 4-(*N*-dimethylamino)-3-penten-2-one (**1***b*) (13) (750 mg, 5 mmol) gave anhydride **4***b* (143 mg, 0.613 mmol, 12.3%), yellow needles, mp 128–128.5°C ($(C_2H_5)_2O$, petroleum ether); ir ν_{max} (KBr) 1823, 1750, 1615, 1570, and 840 cm^{-1}; uv λ_{max} (C_2H_5OH) 214, 268, 321, and 385 nm (log ϵ, 4.33, 4.31, 4.16 and 4.00); nmr ($CDCl_3$) δ 6.94 (1H, d, J = 2.2 Hz), 6.65 (1H, d of q, J = 2.2 and 0.6 Hz), 3.47 (4H, q, J = 7.3 Hz), 2.60 (3H, s), 1.24 (6H, t, J = 7.3 Hz); mass spectrum m/e 233 (M^+). *Anal.* calcd. for $C_{13}H_{15}O_3N$: C 66.93, H 6.48, N 6.00; found: C 66.89, H 6.21, N 5.91.

*7-(*N,N*-Dialkylamino)-5-methyl-2,3-dihydrophthalazine-1,4-dione (**5**a or **5**b)*

A solution of phthalic anhydride **4***a* or **4***b* (0.43 mmol) in acetic acid (4 mL) was refluxed with hydrazine hydrate (14) (85%) for 1 h under nitrogen and then poured, after cooling, into ice water. The resulting precipitate was filtered and dried: 5-methyl-7-*N*-pyrrolidyl-2,3-dihydrophthalazine-1,4-dione (**5***a*) (82 mg, 0.33 mmol, 77%), white crystals, mp 330–335°C dec. (CH_3OH, NH_4OH 10% in H_2O); ir ν_{max} (KBr) 1640, 1595, 1545, and 845 cm^{-1}, uv λ_{max} (0.1 *M* K_2CO_3) 226, 287, and 326 nm (log ϵ 4.34, 4.45, and 4.13); nmr [$(CD_3)_2SO$] δ 6.77 (1H, s), 6.75 (1H, s), 3.35 (4H, m) (under H_2O peak visible by addition of D_2O) (s with irradiation at δ 1.98), 2.72 (3H, s), 1.98 (4H, m) (s with irradiation at δ 3.35); mass spectrum m/e 245 (M^+). *Anal.* calcd. for $C_{13}H_{15}O_2N_3$: C 63.65, H 6.16, N 17.13, found: C 63.78, H 6.26, N 16.99.

This product (65 mg, 0.26 mmol, 63.4%) was also prepared under the same conditions (reflux time, 12 h) from *N*-methylphthalimide **3***a* (100 mg, 0.41 mmol).

5-Methyl-7-(*N*,*N*-dimethylamino)-2,3-dihydrophthalazine-1,4-dione (**5***b*) (93 mg, 0.37 mmol, 86%), white crystals, mp 290–292°C dec. (CH_3OH, NH_4OH 10% in H_2O); ir ν_{max} (KBr) 1635, 1595, 1540 and 845 cm^{-1}; uv λ_{max} (0.1 *M* K_2CO_3) 227, 288, and 326 nm (log ϵ 4.17, 4.43, and 4.11); nmr [$(CD_3)_2SO$] δ 6.89 (2H, s), 3.44 (4H, 1, J = 7.0 Hz), 2.72 (3H, s), 1.14 (6H, t, J = 7.0 Hz); mass spectrum m/e 247 (M^+). *Anal.* calcd. for $C_{13}H_{17}O_2N_3$: C 63.13, H 6.93, N 16.99; found: C 62.97, H 7.20, N 16.83.

*4-(*N*-ethyl-*N*-4′-hydroxybutylamino)-3-penten-2-one (**1**c)*

To 2,4-pentadione (20 g, 0.2 mol) in $CHCl_3$ (50 mL) was added

rapidly, redistilled oxalyl chloride (63 g, 0.5 mol) according to the procedure of Clark and Heathcock (15). The mixture was refluxed (45 min), evaporated, and upon distillation, the residue yielded 4-chloro-3-pentadien-2-one (15.8 g, 66%, bp 34°C/8 Torr, lit. (16) 44–45°C/23 Torr). This product (2.38 g, 20 mmol) in dry THF (10 mL) was added (5 min) to a solution of 4-(ethylamino)butanol (17, 18) (2.38 g, 20 mmol) and triethylamine (2.78 mL, 20 mmol) in the same solvent (10 mL). After 2 h at 50–55°C, an additional amount of this substance (1.19 g, 10 mmol) and triethylamine (1.4 mL) was added and the solution heated at 60°C for 1 h. After cooling, the precipitate was filtered, the solvent evaporated, and the oily residue purified by chromatography on aluminium oxide (150 g). Elution with CH_2Cl_2 and $CH_3CO_2C_2H_5$ yielded hydroxyenaminone **1***c* (2.4 g, 78%), white crystals, mp 41–41.5°C; ir ν_{max} (KBr) 3300, 1605, 1525, and 1043 cm^{-1}; uv λ_{max} (C_2H_5OH) 312 nm (log ϵ 4.38); nmr ($CDCl_3$) δ 5.09 (1H, s), 3.70 (2H, t, J = 6.0 Hz), 3.29 (5H, m), 2.52 (3H, s), 2.07 (3H, s), 1.7–1.5 (4H, m), and 1.17 (3H, t, J = 7 Hz); mass spectrum m/e 199 (M^+). *Anal.* calcd. for $C_{11}H_{21}O_2N$: C 66.29, H 10.62, N 7.03; found: C 66.02, H 10.85, N 6.93.

*2-(*t*-Butyldimethylsiloxy)-4-[*N*-4′-(*t*-butyldimethylsiloxy)butyl-*N*-ethylamino-2,4]-pentadiene (**2**c)*

To a solution of LDA prepared in the usual way from *n*-BuLi (8.8 mmol, 2.7 *M* in hexane), diisopropylamine (8.8 mmol), and TMEDA (12) (4.4 mmol) in dry THF (9 mL) at 0°C under nitrogen and then cooled to −78°C was added hydroxy enaminone **1***c* (800 mg, 4 mmol) in the same solvent (25 mL) during a period of 30 min. After 2 h, a solution of TBDMSCl (1.47 g, 9.6 mmol) in the same solvent (5 mL) was added over a period of 30 min. The reaction mixture was allowed to warm and kept for 90 min at room temperature, evaporated, diluted with dry petroleum ether (bp 30–60°C) (50 mL), filtered under nitrogen and evaporated. These operations were repeated and finally the residue was stirred for 3 h under vacuum (0.2 Torr). An nmr spectrum of the crude dienamine **2***c* (1.26 g, 2.9 mmol, 72%) was recorded, ($CDCl_3$, N_2) δ 1.9 (3H, m), 0.90 (18H, m) and 0.1 (12H, m); showing the disappearance of two singlets at δ 2.52 and 2.07. This very unstable dienamine **2***c* was used without further purification.

*5-N-4′-[t-Butyldimethylsiloxy)butyl-N-ethylamino]-3-methylphthalic anhydride (**4**c)*

To a solution of bromomaleic anhydride (684 mg, 3.87 mmol) in dry benzene (20 mL) was added in 30 min at 5–7°C under nitrogen freshly prepared crude dienamine **2***c* (700 mg, 1.6 mmol) from the preceding reaction in the same solvent (20 mL). The dark reaction mixture was allowed to warm to room temperature and after 15 h, the solvent was evaporated, the crude product dissolved in CH_2Cl_2, filtered, and separated by chromatography on silica gel (50 mg). Elution with CH_2Cl_2 gave phthalic anhydride **4***c*, yellow oil (28 mg, 0.072 mmol, 4.5%); ir ν_{max} (film) 1827, 1765, 1617, 1580, 1250, 1090, and 830 cm^{-1}; uv λ_{max} (C_2H_5OH) 214, 268, 322, and 387 nm (log ϵ 3.98, 3.97, 3.83, and 3.49); nmr ($CDCl_3$) δ 6.94 (1H, d, J = 1.9 Hz), 6.65 (1H, d, J = 1.9 Hz), (this doublet is not well defined: coupling with the 3-methyl), 3.67 (2H, t, J = 5.9 Hz), 3.46 (4H, m) (3.49, s and 3.42, m with irradiation at δ 1.23), 2.59 (3H, s) 1.8–1.5 (4H, m), 1.23 (3H, t, J = 7.2 Hz), 0.89 (9H, s), 0.06 (6H, s); $C_{21}H_{33}O_4NSi$ requires 391.2179; found 391.2181. *Anal.* calcd: C 64.41, H 8.49, N 3.57; found: C 64.98, H 8.56, N 3.34).

*5-[N-4′-(t-Butyldimethylsiloxy)butyl-N-ethylamino]-3-methyl-N-methylphthaleimide (**3**c)*

To a solution of *N*-methylmaleimide (286 mg, 2.58 mmol) in dry benzene (10 mL) was added in 30 min at 5–7°C under nitrogen freshly prepared crude dienamine **2***c* (1.1 g, 2.57 mmol) in the same solvent (10 mL). After 48 h at room temperature, the solvent was evaporated and palladium (10%) on activated charcoal (100 mg) with xylenes (10 mL) was added. The reaction mixture was refluxed (6 h), cooled, filtered, and then purified by chromatography on silica gel (100 g). Elution (CH_2Cl_2, $CH_3CO_2H_5$; 99:1) gave methylphthaleimide **3***c*, yellow oil (174 mg, 0.45 mmol, 17.5%), ir ν_{max} (film) 1755, 1695, 1612, 1585, 1245, 1090, and 830 cm^{-1}; uv λ_{max} (C_2H_5OH) 211, 270, 324, and 402 (log ϵ 4.06, 4.09, 3.51, and 3.51); nmr ($CDCl_3$) δ 6.88 (1H, d, J = 1.9 Hz), 6.44 (1H, d, J = 1.9 Hz) (this doublet is not well defined: coupling with the 3-methyl), 3.63 (2H, t, J = 5.8 Hz), 3.42 (2H, q, J = 7.1 Hz), 3.35 (2H, t, J = 7.6 Hz), 3.07 (3H, s), 2.55 (3H, s), 1.65–1.44 (4H, m), 1.17 (3H, t, J = 5.8 Hz), 0.86 (9H, s), 0.03 (6H, s); $C_{22}H_{36}O_3N_2Si$ requires 404.2495; found 404.2484.

*7-[N-4′-(t-Butyldimethylsiloxy)butyl-N-ethyl amino]-5-methyl-2,3-dihydrophthalazine-1,4-dione (**5**c)*

A solution of methylphthalimide **3***c* (47 mg, 0.12 mmol) in acetic acid (1 mL) was refluxed with hydrazine hydrate (14, 19) (85%) (2 mL) under nitrogen for 4 h. After cooling, precipitated dihydrophthalazinedione **5***c* (32 mg, 0.079 mmol, 66%) was isolated by filtration (this product (16 mg, 0.039 mmol, 64%) was also prepared from phthalic anhydride **4***c* (24 mg, 0.061 mmol)), white crystals, mp 107–108.5°C (CH_3COCH_3, hexanes); ir ν_{max} (KBr) 1650, 1592, 1250, 1100, and 830 cm^{-1}; uvλ_{max} (0.1 *M* K_2CO_3, C_2H_5OH 4:1) 224, 289, and 327 nm (log ϵ 4.24, 4.47, and 4.15); nmr ($CDCl_3$) δ 7.25 (1H, m), 6.86 (1H, m), 3.75 (2H, t, J = 6.0 Hz), 3.52–3.40 (4H, m), 2.87 (3H, s), 1.8–1.5 (4H, m), 1.24 (3H, t, J = 6.0 Hz), 0.9 (9H, s) and 0.065 (6H, s); $C_{21}H_{35}O_3N_3Si$ requires 405.2448; found 405.2444. *Anal.* calcd.: C 62.18, H 8.49, N 10.35; found: C 62.18, H 8.69, N 10.36.

*7-[N-Ethyl-N-4′-hydroxybutylamino]-5-methyl-2,3-dihydrophthalazine-1,4-dione (**5**d)*

Methylphthalimide **3***c* (56 mg, 0.144 mmol) was refluxed with hydrazine hydrate (19, 20) (85%, 1 mL) under nitrogen for 1 h. The solvent was evaporated, the product dried overnight under vacuum (0.2 Torr) over P_2O_5 and then dissolved in a dry THF (5 mL) solution of tetrabutylammonium fluoride (21) (0.432 mmol, 1 *M* in THF). The reaction mixture was stirred at room temperature (3 h), then evaporated; H_2O (10 mL) added and alcohol **5***d* isolated by filtration (17 mg, 0.058 mmol, 40.6%), light yellow crystals, mp 221–222°C (CH_3OH, CH_3COCH_3); ir ν_{max} (KBr) 3260, 1640, 1592, 1020, and 840 cm^{-1}; uv λ_{max} (0.1 *M* K_2CO_3) 227, 288, and 326 nm (log ϵ 4.18, 4.44, and 4.12); nmr [$(CD_3)_2SO$] δ 6.86 (2H, s), 4.45 (1H, broad, exchange with D_2O), 3.40 (6H, m) (under H_2O, visible by addition of D_2O), 2.69 (3H, s), 1.63–1.4 (4H, m) and 1.10 (3H, t, J = 6.7 Hz). *Anal.* calcd. for $C_{15}H_{21}O_3N_3$: C 61.83, H 7.27, N 14.42; found: C 61.82, H 7.38, N 14.42.

B. Chemiluminescence

Measurements of luminescence were made on a LKB-Wallac 1251 luminometer using the automatic mode for injection and reading of the decay portion of light from the 3rd second to the 12th. Aliquots of the luminescent compound in 100 μL of phosphate buffer (0.01 *M* phosphate-buffered saline, pH 7.4) were introduced into the cuvettes (Clinicon, polystyrene 2174-086) and volumes were completed with 200 μL of NaOH (0.03 *N* to 2.0 *N*) according to the desired pH. Fixed amounts of microperoxidase (MP-11) (42 μL, 0.4 n*M*) and hydrogen peroxide (33 μL, 0.6%) were then automatically injected and light emitted was recorded.

Results and discussion

A. Synthesis

Early work on cyclic hydrazides involved mainly the search for structure-efficiency relationships while more recent studies have concentrated on the mechanism of the luminescence reaction (2, 22, 23) and on applications of these molecules as potential tracers for biochemical analysis (5–10). Synthesis of luminescent compounds has been carried out starting with nitrophthalic acid derivatives (2, 3, 19, 20) but substituted luminols or isoluminols have only been obtained by tedious step-wise processes (10, 11). In the present approach, 5-alkyl isoluminols are formed by a simple and general procedure in which all substituents are introduced in a single step, the Diels–Alder addition of a 2-amino-4-siloxydiene to bromomaleic anhydride. The required diene **2** has been prepared from the corresponding tertiary enaminone **1** using the observation that silylation of enaminones though (24) easy in the case of primary ones, is more difficult with secondary and quite un-

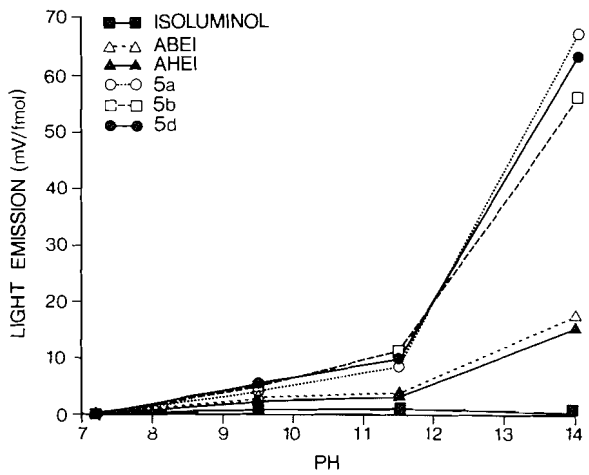

FIG. 2. Effect of pH on the decay portion (3rd to 12th second) light emission produced by isoluminol and its derivatives (ABEI, aminobutylethylisoluminol; AHEI, aminohexylethylisoluminol; **5***a*, **5***b*, and **5***c*, see Experimental).

known for tertiary examples. It was found (25) that strong base (LDA) was necessary for the regiospecific (and probably kinetic) removal of the hydrogen in the γ-position of enaminone **1** while the resulting enolate could readily be trapped as the enol silyl ether in the usual way (**1***a* and **1***b* are well described compounds; **1***c* can be prepared conveniently from 4-ethylaminobutanol (15, 17) and 4-chloro-3-pentene-2-one).

All of the dienes obtained are very labile particularly those containing a trimethylsilyl group; indeed hydroxyenaminone **1***c* does not give a detectable amount of the trimethylsiloxydiene. The crude dienol ethers were immediately added to bromomaleic anhydride or to *N*-methylmaleimide in benzene at 5–10°C. The corresponding 3-methylphthalic anhydrides were then obtained by rapid aromatization of the crude product on a column of silica gel. Use of the less reactive dienophiles *N*-methylmaleimide affords good yields of 3-methyl-*N*-methylphthaleimides **3** (especially in the case of the siloxy compound **3***c* where the yield improves by about 4-fold). In this approach, aromatization of the adduct requires an extra step involving dehydrogenation with 10% palladized charcoal and is followed by chromatography on silica gel. The pyridazine ring is formed by the well-documented action of hydrazine hydrate on anhydride **4** or *N*-methylimide **3**. In the instance of siloxyphthalazinedione **5***c* the *tert*-butyldimethylsiloxy group is best removed by fluoride ion at room temperature rather than by treatment with a refluxing mixture of acetic acid and water.

B. Chemiluminescence

With chemiluminescent substances of this type, it is a well-established fact that the pH of the medium plays an important role on the detection limit (5). Hence, we have first studied the effect of this parameter on the decay portion of the light produced by our new derivatives of isoluminol and have compared the results with those obtained for well known analogues. As in previous cases (5), the new derivatives show a clear dependency of light yield on pH (Fig. 1). This figure also indicates that the introduction of a methyl group at the C-5 position in derivatives **5***a*, **5***b*, and **5***d* also brings about a 3- to 5-fold increase on the efficiency of the chemiluminescent process.

These data extend and amplify previous observations by Brundrett *et al.* (2, 3) who had earlier shown that the presence of a methyl group at the C-5 position of luminol increases the efficiency of light production. Since the methyl groups show a weakly electron-donating character, the enhanced luminescence observed is probably accounted for by the *ortho* effect between it and the adjacent carbonyl (2, 3). Furthermore, the presence of terminal hydroxyl or amine groups seems to provide little or no influence on chemiluminescence since the three new derivatives all show approximately the same high yields.

TABLE 1. Luminescence reaction kinetics of isoluminol and its derivatives at pH 14

Compounds*	Percentage of light emitted between 0–2 s	3–12 s	13–60 s
Isoluminol	26	55	19
ABEI	21	55	24
AHEI	22	56	22
5*a*	25	60	15
5*b*	25	57	18
5*d*	22	56	22

*ABEI, aminobutylethylisoluminol; AHEI, aminohexylethylisoluminol.

Table 1 indicates the pattern of light emission of isoluminol and its derivatives. It can be seen that the increase of luminescence obtained with the new derivatives is not due to a change in the kinetics of the oxidation reaction since, as observed for the previous compounds, approximately 55% of light occurs between 3rd and 12th second at pH 14. These data confirm the high efficiency achieved when a methyl group is added.

Aminobutyl isoluminol, which shows a high level of light emission, has been extensively used in immunoassays using a luminescent tracer. The present report describes new derivatives of isoluminol which exhibit particularly high luminescent efficiency and, moreover, possess functional groups that permit ready coupling with steroids and proteins, for example with human chorionic gonadotropin; particulars will be communicated later. Hence, these compounds present an excellent potential for use as tracers in immunoassays.

Adsorption de l'azote sur l'amiante chrysotile phosphaté et lixivié

JALEH KHORAMI, LUC NOEL ET HUGUES MÉNARD
Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received October 23, 1986

JALEH KHORAMI, LUC NOEL, and HUGUES MÉNARD. Can. J. Chem. **65**, 1397 (1987).

Le tracé des isothermes d'adsorption et de désorption de l'azote par la méthode volumétrique (B.E.T.), nous a permis de déterminer la surface spécifique et la porosité d'une série de fibres de l'amiante chrysotile avant et après des traitements chimiques. Nous avons démontré que les composés phosphatés formés durant la réaction entre le $POCl_3$ et l'amiante chrysotile encapsulent la surface des fibrilles et obstruent les pores entre les fibrilles. Ces modifications chimiques diminuent d'une façon significative la surface spécifique et la porosité des fibres. Les résultats de lessivage des fibres avec HCl 0,1 *M* montrent l'accroissement de la surface spécifique et de la porosité. La solvatation des impuretés et la lixiviation de la surface brucitique des fibres en fonction du temps sont responsables de cette augmentation.

JALEH KHORAMI, LUC NOEL et HUGUES MÉNARD. Can. J. Chem. **65**, 1397 (1987).

Adsorption and desorption isotherms of nitrogen, obtained by the volumetric (B.E.T.) method, have been used to determine the specific surface and the porosity of a series of chrysotile asbestos fibers, before and after chemical treatments. It was shown that the phosphorus compounds that are formed by the reaction of $POCl_3$ and chrysotile asbestos seal the surface of the fibrils and block the pores between the fibrils. These chemical modifications result in an important diminution of the specific surface and of the porosity of the fibers. Washing the fibers with 0.1 *M* HCl results in an increase of the specific surface and of the porosity. Solvation of the impurities and leaching of the brucitic surface of the fibers are responsible for this increase.

Introduction

L'amiante chrysotile, $Mg_3Si_2O_5(OH)_4$, est souvent associé à des impuretés que l'on retrouve entre les fibrilles ou à l'intérieur de celles-ci (1). Ses principaux minerais sont la brucite $Mg(OH)_2$, la magnésite $MgCO_3$, la dolomite $MgCO_3 \cdot CaCO_3$, la calcite $CaCO_3$, le talc $Mg_3Si_4O_{10}(OH)_2$ et la magnétite Fe_3O_4.

Nauman et Dresher (2) ont déterminé la surface spécifique et la porosité de quelques grades de fibres chrysotile d'origine canadienne. Ils ont observé que les fibres soumises aux traitements thermiques (100–200 et 400°C) et mécaniques par les voies humide et sèche, possèdent une surface spécifique plus grande.

La surface spécifique apparente des fibres traitées à plus haute température est plus élevée à cause de l'élimination totale de l'eau capillaire. L'augmentation de la surface des fibres qui ont subi des traitements mécaniques est attribuée à la défibrillation et libération des fibrilles individuelles. Une défibrillation complète est constatée pour les fibres traitées par la voie humide. Ces fibres possèdent alors la plus grande surface spécifique dûe aux surfaces externes des fibrilles accessibles pour l'adsorption des gaz. Nauman et Drescher (2) ont aussi étudié les isothermes d'adsorption de l'azote des fibres de chrysotile Cassiar avant et après la défibrillation. Le procédé d'adsorption et de désorption s'effectue réversiblement dans le cas des matériaux non-poreux. Avec les solides poreux, dans un intervalle précis de pression relative (P/P_0[1]), les deux tracés des isothermes d'adsorption et désorption se déplacent pour former une boucle qu'on appelle hysteresis.

Parmi les deux échantillons de fibres non traitées et défibrillées, nous constatons que ceux-ci possèdent des isothermes caractéristique des matériaux poreux. De ceci, nous pouvons conclure que les pores sont associés à la surface des fibrilles et à leurs dispositions spatiales et non pas à l'intérieur des fibrilles. De cette façon l'amiante chrysotile défibrillé a une surface plus élevée que les mêmes fibres non traitées.

Les études sur la porosité de l'amiante chrysotile avaient été poursuivies par Gorski et Steller (3, 4). Ces auteurs ont étudié les isothermes d'adsorption et de désorption de molécules telles que l'eau et le benzène.

Nos travaux sont orientés vers les fibres modifiées avec le $POCl_3$, suivant le procédé Lalancette et Dunnigan (5), les propriétés physico-chimiques de ces fibres ayant été étudiées auparavant par Kimmerle *et al.* (6).

Huber (7) a démontré que les fibres d'amiante chrysotile traitées à l'acide subissaient une augmentation de porosité proportionnelle au temps de traitement.

Nous avons entrepris ces travaux en lixiviant les fibres originales d'une part et les fibres modifiées au $POCl_3$ d'autre part. Les résultats obtenus démontrent que pour les fibres traitées au $POCl_3$ nous avons une diminution de la surface spécifique et de la porosité. Pour les fibres lixiviées nous notons une augmentation de la porosité proportionnelle au temps de traitement.

Partie expérimentale

Un appareil Quantsorb (modèle No QS-10) de Quantachrome Corp. est utilisé dans ces travaux. Les analyses sont effectuées selon la méthode décrite (8) et suivant les instructions données par Gregg et Sing (9).

Les mélanges des gaz d'azote et d'hélium de qualité pure sont fournis par « Liquid Carbonic Canada Ltd ».

Tous les échantillons sont conditionnés et dégazés pendant 16 h à 110°C sous atmosphère d'hélium. La pesée exacte des échantillons est nécessaire avant et après les analyses. Nous avons utilisé un intégrateur modèle 3390A de Hewlett Packard Co. pour les mesures de la surface des pics. Une valeur de 16,2 Å^2 comme surface de projection de l'azote a été utilisé lors de la détermination de la surface spécifique des matériaux. Les isothermes de désorption sont tracés avec 25 points en utilisant 25 mélanges de différents pourcentages d'azote dans l'hélium. Un appareil de Technicon Auto-Analyzer II est utilisé pour le dosage de phosphore.

Les fibres utilisées sont de la compagnie Johns Manville 4T-30. Les fibres courtes sont isolées selon le procédé Jolicœur *et al.* (10). Toutes les fibres ont été chauffées à 300°C pendant 150 min avant les traitements chimiques.

Partie théorique

De l'équation de Kelvin, telle que démontrée par Gregg et Sing (9) lorsque p_0 est la pression de saturation de la vapeur à

1. P = pression partielle; P_0 = pression de saturation à une température donnée.

TABLEAU 1. Identification des fibres

Nature des fibres	Surface spécifique ($m^2 g^{-1}$)	Pourcentage de phosphore
Fibres courtes	31	—
Fibres courtes modifiées avec $POCl_3$	24	2,7
Fibres longues chauffées à 300°C	18,5	—
Fibres longues modifiées avec $POCl_3$	5,4	1,6
Fibres longues modifiées avec $POCl_3$ et lixiviées 5 h	31,4	0,4
Fibres longues lixiviées 5 h	43,7	—
Fibres longues lixiviées 72 h	110	—

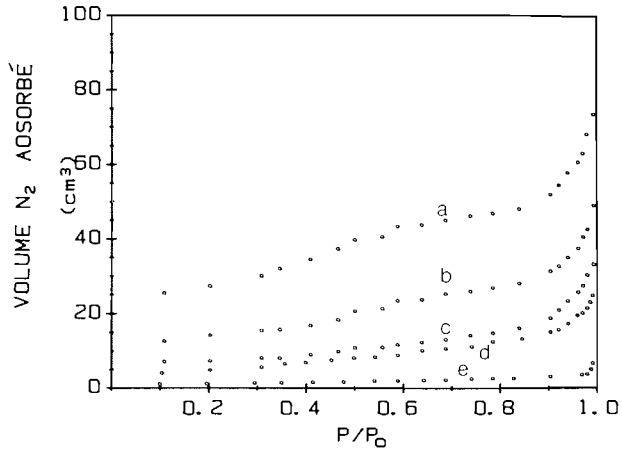

FIG. 1. Isothermes d'adsorption de l'azote sur des fibres longues : (*a*) longues lixiviées 72 h, (*b*) longues lixiviées 5 h, (*c*) phosphatées et lixiviées 5 h, (*d*) originales, (*e*) longues phosphatées.

la température T (K), V le volume molaire de l'adsorbat sous la forme liquide (azote = 89,2 $cm^3 mol^{-1}$), γ la tension interfaciale (azote = 28,9 dyne cm^{-1}), R la constante des gaz parfaits

$$[1] \quad \ln p/p_0 = \frac{-2\gamma V}{rRT} \cos \phi$$

($R = 8{,}31 \times 10^7$ erg $mol^{-1} K^{-1}$), ϕ l'angle de mouillage que fait l'azote liquide avec la surface qui, dans bien des cas, est dite $\phi = 0$, ce qui donne un $\cos \phi = 1$, et r représente le rayon d'un capillaire cylindrique très souvent appelé rayon de Kelvin.

Cependant, de la théorie il découle que dépendamment de la forme du pore il y a une certaine épaisseur, t, d'azote liquide qui reste sur les parois d'où la détermination du rayon r peut être biaisée.

Le rayon des pores sera donc :

$$[2] \quad r_p = r_K + t$$

lorsque cette épaisseur t d'azote sur la parois s'exprime

$$[3] \quad t = \sigma_N \left[\frac{5}{2.303 \log_{10}(p_0/p)} \right]^{1/3}$$

lorsque σ_N est l'épaisseur d'une monocouche d'azote (σ_N = 3.54 Å).

Au fur et à mesure que les pores se vident, le volume d'azote libéré par un même pore variera, car en réalité, comme la pression partielle (p/p_0) diminue, cette épaisseur d'azote liquide va elle aussi diminuer. Ceci aura donc pour effet de donner un volume de pore qui augmentera avec cette diminution de la pression partielle. Pour tenir compte de cette variation, de l'équation [4] nous aurons

$$[4] \quad \Delta V_p = \left[\frac{\bar{r}_p}{r_K} \right]^2 (V_{liq} - \Delta t \Sigma A)$$

lorsque A représente l'aire obtenue pour chaque pression partielle. Cette aire, A, se calcule de la façon suivante, soit :

$$[5] \quad A = \frac{2V_p}{r_p}$$

et la variation du volume azote liquide selon l'équation [6]

$$[6] \quad \Delta V_{liq} = \frac{\Delta V_{gaz} P}{T}$$

lorsque P et T représentent la pression atmosphérique et la température lors de l'expérience.

En construisant un graphique de $\Delta V_p/\Delta r_p$ en fonction de $\bar{r}_p$ nous aurons la distribution des pores en fonction de leur grosseur.

Résultats et discussion

La surface spécifique des fibres

Le tableau 1 illustre les mesures de la surface spécifique ainsi que le pourcentage de phosphore des fibres. On peut constater que la surface spécifique des fibres courtes et longues modifiées avec le $POCl_3$ a diminuée. La diminution est plus remarquable pour les fibres longues. D'autre part la lixiviation des fibres en fonction du temps augmente la surface spécifique des fibres. Cependant, la comparaison des résultats des fibres lixiviées pendant 5 h et les fibres modifiées avec le $POCl_3$ et lixiviées pendant 5 h montrent que la surface spécifique des fibres modifiées–lixiviées est moins grande que celle des fibres uniquement lixiviées.

L'augmentation de la surface spécifique des fibres lixiviées est due à la solvatation des impuretés types carbonate et brucite qui sont associées entre les fibrilles. La solvatation de ces impuretés aboutit à la libération des fibrilles. Cette attaque acide partielle à court terme, peut se compléter en fonction du temps avec la solvatation totale des impuretés et puis la lixiviation des couches brucitiques de l'amiante. Johan *et al.* (11) montrent que la lixiviation du chrysotile conduit à un changement considérable des propriétés physico-chimiques de ce minéral. L'augmentation de la surface spécifique des fibres est particulièrement frappante, allant de 46 $m^2 g^{-1}$ à 450 $m^2 g^{-1}$ environ pour le chrysotile lessivé à 95%.

En ce qui concerne les fibres modifiées avec le $POCl_3$, les études précédentes (6) montrent un changement des caractéristiques physico-chimiques qui est dû à la formation des composés phosphatés et en grande partie des polyphosphates. La réaction de phosphorylation se produit préférentiellement avec les couches brucitiques de l'amiante et la probabilité d'une réaction entre le $POCl_3$ et les impuretés ($Mg(OH)_2$, les carbonates, etc.) n'est pas écartée.

D'après ces résultats, la surface des fibrilles de l'aminante chrysotile modifié avec le $POCl_3$ est encapsulée par les composés phosphatés et les produits formés durant la réaction peuvent obstruer les pores existant entre les fibrilles. La diminution de la surface spécifique des fibres ainsi modifiées illus-

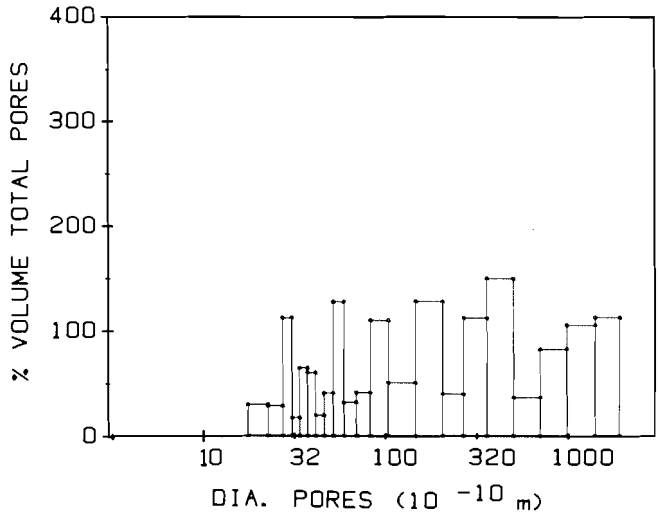

FIG. 2. Histogrammes représentant le pourcentage de volume total des pores en fonction du diamètre des fibres longues originales.

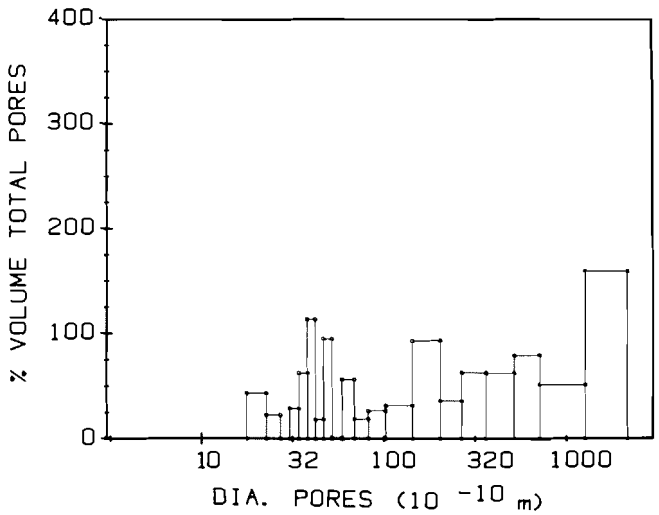

FIG. 3. Histogrammes représentant le pourcentage de volume total des pores en fonction du diamètre des fibres longues lixiviées 5 h.

tre bien les effets de l'encapsulation de la surface et l'obstruction des pores entre les fibrilles.

Sur le tableau 1, on peut constater que le pourcentage de phosphore sur les fibres courtes (2,7% de phosphore) est plus élevé comparativement aux fibres longues 1,65%. Cependant, la diminution de la surface spécifique est plus remarquable pour les fibres longues phosphatées. Il faut noter que les fibres courtes utilisées sont en grande partie sous forme de fibrilles individuelles dont leur surface brucitique est plus disponible et la réaction de la phosphatation est plustôt effectuée sur la surface des fibrilles pour encapsuler ces dernières. Dans le cas des fibres longues il faut signaler les deux effets: d'une part l'encapsulation de la surface brucitique (moins disponible) et d'autre part l'obstruction des pores.

Isotherme d'adsorption de l'azote et volume des pores

La figure 1 montre l'isotherme d'adsorption de l'azote pour les fibres longues originales (courbe *d*) en comparaison avec les mêmes fibres lixiviées (courbes *a* et *b*) et modifiées avec le $POCl_3$ (courbe *e*) ainsi que les fibres modifiées et lixiviées pendant 5 h (courbe *c*). Les figures 2–6 montrent les histogrammes représentant le pourcentage de volume total des pores

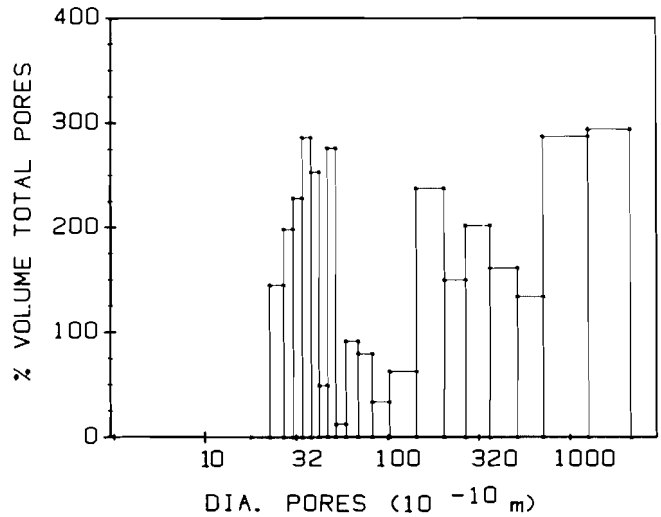

FIG. 4. Histogrammes représentant le pourcentage de volume total des pores en fonction du diamètre des fibres longues lixiviées 72 h.

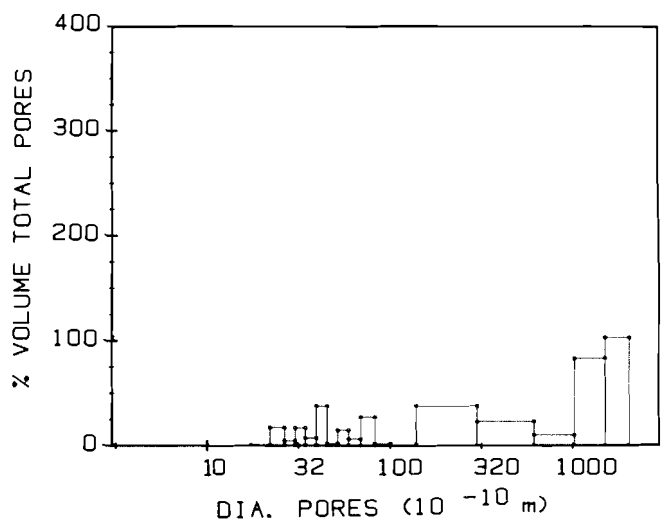

FIG. 5. Histogrammes représentant le pourcentage de volume total des pores en fonction du diamètre des fibres longues phosphatées.

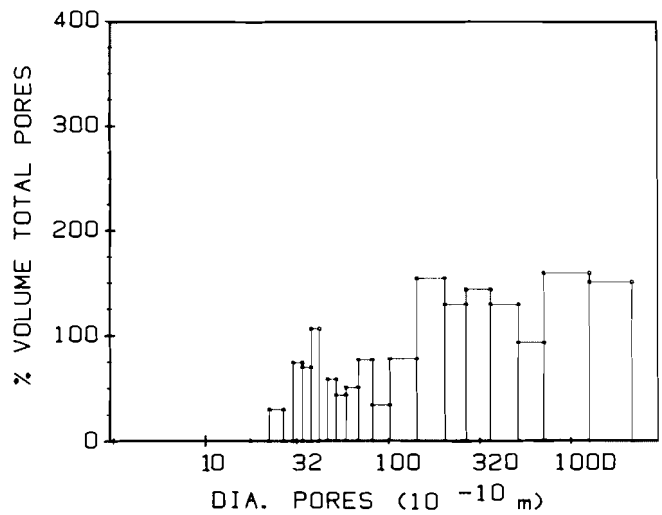

FIG. 6. Histogrammes représentant le pourcentage de volume total des pores en fonction du diamètre des fibres longues phosphatées et lixiviées.

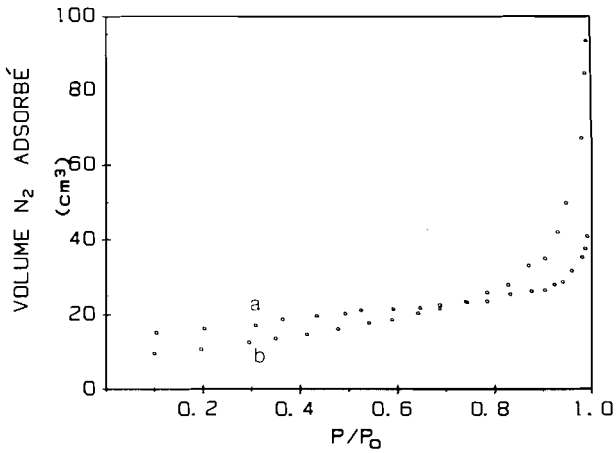

FIG. 7. Isothermes d'adsorption de l'azote des fibres (*a*) courtes originales, (*b*) courtes phosphatées.

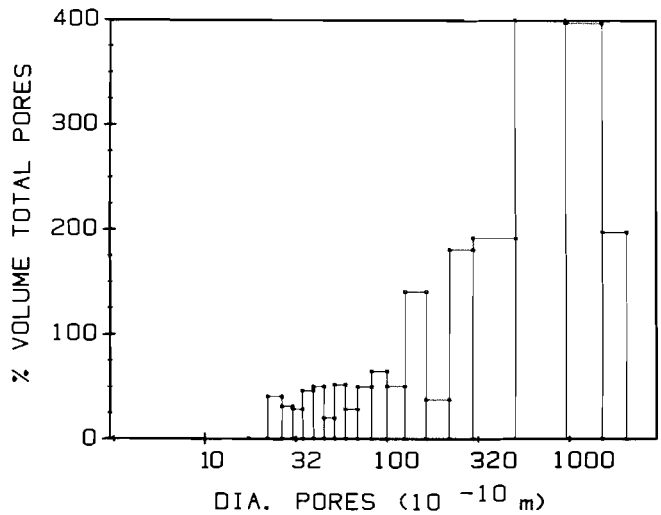

FIG. 8. Histogrammes représentant le pourcentage de volume total des pores en fonction du diamètre des fibres courtes originales.

en fonction du diamètre pour les fibres longues originales (fig. 2), lixiviées (fig. 3 et 4), phosphatées (fig. 5) et phosphatées et lixiviées (fig. 6).

Si on se base sur la description donnée par Gregg et sing (9), on peut classifier les courbes des isothermes d'adsorption. À la figure 1, les courbes *a* et *b* des fibres lixiviées montrent un point d'inflection vers $P/P_0 = 0{,}5$ correspondant aux matériaux poreux. D'après Brunauer *et al.* (12, 13), ces courbes peuvent être classées comme type IV. Les deux courbes des isothermes d'adsorption *c* et *d* présentées sont plutôt à la limite du type IV et II d'après la classification de Brunauer *et al.* La courbe *e* est plutôt typique de la classification type II.

La comparaison des histogrammes des fibres originales et des fibres lixiviées montre une nette augmentation de volume de pore sur toute l'échelle de diamètre présentée. Cependant, pour les fibres lixiviées 72 h, cette augmentation est plus considérable entre 20 et 50 Å de diamètre, ce qui explique l'augmentation appréciable de la surface spécifique de ces fibres.

Si nous comparons les deux histogrammes des fibres originales (fig. 2) et phosphatées (fig. 5), nous pouvons constater une diminution remarquable de volume de pore sur toute l'échelle de diamètre et même la disparition des pores sur l'histogramme illustré. Les résultats obtenus pour les fibres phosphorylées et

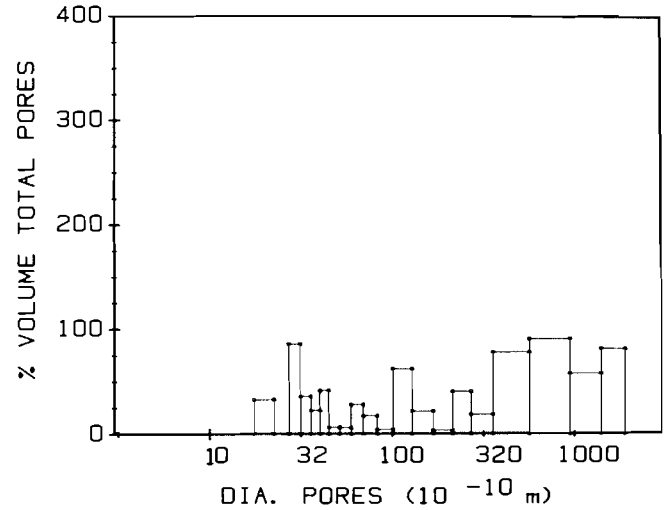

FIG. 9. Histogrammes représentant le pourcentage de volume total des pores en fonction du diamètre des fibres courtes phosphatées.

lixiviées montrent une certaine similarité entre ces fibres et les fibres originales.

La figure 7 ainsi que les figures 8 et 9 représentent les isothermes d'adsorption de l'azote et les histogrammes pour les fibres courtes et les fibres courtes phosphatées. On peut remarquer sur la figure 7 que les fibres courtes phosphatées (*b*) adsorbent une quantité plus élevée d'azote en comparaison avec les fibres courtes non traitées (*a*). Sur les histogrammes nous observons une diminution de volume global des pores.

Les résultats obtenus par les isothermes d'adsorption et le volume de pore des fibres étudiées confirment les interprétations mentionnées dans la partie précédente de nos études.

La lixiviation en fonction du temps des fibres longues originales aboutit à la création des nouveaux pores et surtout des mésopores.

De plus la phosphatation des fibres longues a comme effet d'encapsuler les fibrilles et de créer l'obturation des pores. Donc, les résultats des isothermes d'adsorption de l'azote et l'histogramme présenté pour ces fibres démontrent d'une façon plus claire les effets mentionnés.

Les résultats pour les fibres phosphatées et lixiviées montrent que les fibres phosphatées subissent l'attaque acide plus difficilement que les fibres originales qui sont plus poreuses (tableau 2). On peut constater que le pourcentage de surface par unité de surface n'est que de 97% pour les fibres longues modifiées avec $POCl_3$ et lixiviées 5 h en comparaison à 180% pour les fibres longues lixiviées 5 h. Le pourcentage de pore par unité de volume est de 121% pour ces fibres traitées au $POCl_3$ et lixiviées 5 h tandis que pour les fibres lixiviées 5 h nous obtenons 175%. Cet écart entre les fibres longues lixiviées 5 h et 72 h est considérablement augmenté, passant de 180 à 280% et de 175 à 236% pour les fibres lixiviées 5 h et 72 h respectivement.

Dans le cas des fibres courtes, comme on a déjà mentionné dans la partie précédente, ces fibres sont en grande partie sous forme de fibrilles et l'effet d'encapsulation est plus probable pour ces fibres. Cependant, les études précédentes effectuées par la microscopie électronique en transmission (14) montrent une aggrégation des fibres courtes après la phosphatation. Ce phénomène explique une légère augmentation de volume d'azote adsorbé sur ces fibres et l'apparition de certains pores.

TABLEAU 2. Comparaison de la surface et du volume des pores

Nature des fibres	Surface des pores ($m^2 g^{-1}$)	Volume de pore ($cm^3 g^{-1}$)	Pourcentage de surface par unité de surface	Pourcentage de pore par unité de volume
Fibres courtes	33	0,127	100	100
Fibres courtes modifiées avec $POCl_3$	22,9	0,044	72	35
Fibres longues chauffées	17,8	0,036	100	100
Fibres longues modifiées avec $POCl_3$	3,3	0,0089	18,7	25
Fibres longues modifiées avec $POCl_3$ et lixiviées 5 h	17,2	0,043	97	121
Fibres longues lixiviées 5 h	32	0,062	180	175
Fibres longues lixiviées 72 h	49,7	0,084	280	236

Conclusion

Les mesures de la surface spécifique ainsi que les études effectuées sur la porosité des fibres de l'amiante chrysotile modifié avec le $POCl_3$ montrent l'encapsulation des fibrilles et l'obturation des pores disponibles entre les fibrilles par les composés phosphatés formés durant la réaction. Ces modifications ont comme effet la diminution de la porosité et la surface spécifique des fibres.

Les résultats de l'attaque d'acide HCl 0,1 *M* montrent la solvatation des impuretés et la lixiviation de la surface brucitique des fibres en fonction du temps. L'augmentation de la surface spécifique et la porosité des fibres ainsi lessivées est frappante. La lixiviation du chrysotile augmente plutôt la quantité des mésopores situés entre 20 et 50 Å de diamètre. Nous avons aussi démontré que les fibres modifiées avec le $POCl_3$ sont plus résistantes à l'attaque d'acide.

Heat capacities and isentropic compressibilities of electrolytes in propylene carbonate at 25°C[1]

GÉRALD PERRON, GUYLAINE TRUDEAU, AND JACQUES E. DESNOYERS[2]

Department of Chemistry, Université de Sherbrooke, Sherbrooke, P.Q., Canada J1K 2R1 and INRS-Energie, 1650 Montée Ste-Julie, Varennes, P.Q., Canada J0L 2P0

Received October 24, 1986

GÉRALD PERRON, GUYLAINE TRUDEAU, and JACQUES E. DESNOYERS. Can. J. Chem. **65**, 1402 (1987).

The heat capacities per unit volume and sound velocities of many solutions of 1:1 electrolytes in propylene carbonate (PC) were measured at 25°C. Combining these data with previously published densities, apparent molar heat capacities and isentropic compressibilities were calculated. By extrapolation to infinite dilution, the corresponding standard partial molar quantities were obtained. The heat capacities and compressibilities of water in PC were also calculated. Through ionic additivity, it was possible to calculate these functions for all alkali and tetraalkylammonium halides. The magnitude and trends with ionic size of the heat capacities of electrolytes in PC are similar to those in other aprotic solvents such as acetonitrile (ACN) and dimethylformamide (DMF) and significantly different from those in water. On the other hand, with compressibilities, the magnitudes are the same in PC and in water for alkali halides but significantly different for tetraalkylammonium halides. The trends with ionic size are similar to those in ACN. These effects can be interpreted through ion–solvent interactions. The separation of these thermodynamic functions into their ionic contributions is also discussed.

GÉRALD PERRON, GUYLAINE TRUDEAU et JACQUES E. DESNOYERS. Can. J. Chem. **65**, 1402 (1987).

Les capacités calorifiques volumiques et les vitesses ultrasonores de plusieurs solutions d'électrolytes 1:1 dans le propylene carbonate (PC) ont été mesurés à 25°C. En combinant ces données avec les densités déjà publiées, les capacités calorifiques et compressibilités isentropiques apparentes molaires ont été obtenues. Les capacités calorifiques et compressibilités de l'eau dans le PC ont aussi été mesurées. Les quantités molaires partielles standard ont aussi été obtenues par extrapolation à dilution infinie. Grâce au principe d'additivité ionique, ces fonctions ont été calculées pour les halogénures alcalins et de tetraalkylammonium. L'ordre de grandeur et la dépendance sur la taille des ions des capacités calorifiques dans la PC sont semblables à celles dans d'autres solvants aprotiques tels que l'acétonitrile (ACN) et le diméthylformamide (DMF) mais différentes des valeurs dans l'eau. Par contre, pour les compressibilités, l'ordre de grandeur est le même dans le PC et dans l'eau pour les halogénures alkalins mais pas pour les sel quaternaires d'ammonium. La dépendance sur le taille des ions est la même que dans l'ACN. Ces résultats peuvent être interprétés au moyen d'interactions soluté–solvant. La séparation des données thermodynamiques standard en valeurs ioniques est aussi discutée.

Introduction

Propylene carbonate (PC) is a very interesting solvent for electrolytes, in view of its high dielectric constant (64.9), wide liquid range, good solubilizing power for many electrolytes, and its inertness towards metals as reactive as lithium (1). As such, it is a useful solvent, alone or in combination with other aprotic solvents, for high energy batteries (2). It is also often suggested as a reference solvent for the study of solvation of ions (3).

Thermodynamic data are very useful for the prediction of the temperature and pressure dependences of equilibrium properties, e.g. the emf of cells, and for the understanding of solvation effects. Good data exist in the literature for free energies and enthalpies of solvation (3) and for apparent molar volumes (4) of electrolytes in PC. In the present work, we will extend these systematic studies to apparent molar heat capacities and isentropic compressibilities. Since these properties have been well studied for electrolytes in water (5, 6), methanol (MeOH) (7, 8), acetonitrile (ACN) (9, 10), and dimethylformamide (DMF) (11). The present study should be a good complement for a study of the solvating power of various solvents.

Experimental

The PC for the heat capacity measurements is the same as that used previously for density measurements (4). Moreover, the heat capacities per unit volume were measured with the same solutions and at the same time as the density measurements. The PC was redistilled for sound velocity measurements.

Most electrolytes, and their purification, are the same as those used in previous studies (4, 9, 10). $LiClO_4$ (ALFA INORGANIC VENTRON) was recrystallized in ACN, Et_4NCl in a mixture of ethanol and ether, and Et_4NI was prepared from Et_4NOH and HI and recrystallized from water. The water content of the electrolyte solutions and pure PC was analyzed by the Karl Fischer technique (Aqua-test II by Photovolt). The PC used for heat capacity measurements had 0.002% of water and for sound velocities 0.014% of water.

The relative change in heat capacities per unit volume were measured with a Picker flow microcalorimeter as described previously (12) and converted to specific heat capacities with the known densities (4). The induced change in temperature was 1.50 K for a flow rate of 0.45 mL per min. The specific heat capacity of the reference PC was determined in two ways. Against pure water, c_p^* was found to be $1.6220\ J\ g^{-1}\ K^{-1}$. If heptane and benzene were used as reference, as described previously (13), c_p^* was $1.6192\ J\ g^{-1}\ K^{-1}$. As it will be shown elsewhere (14), a small heat loss can occur with some commercial flow calorimeter, and this loss is a function of the flow rate. This source of error can account for the difference in the two above values. The literature value is $1.642\ J\ g^{-1}\ K^{-1}$ (1). For the calculation of apparent molar heat capacities, the value 1.6192 was used, and for densities, $1.19965\ g\ cm^{-3}$.

The procedure followed for the measurement of compressibilities was the same as the one for electrolytes in ACN (10). Sound velocities were measured with the "sing around" method using a Nusonic Model

6105 solution monitor (Mapco Inc). With the exception of RbI, CsI, $KClO_4$, and sodium tetraphenylboride ($NaB\phi_4$), the electrolytes were sufficiently soluble to proceed by addition of a stock solution to the pure solvent. Otherwise, the measurements were made by successive dilutions of the stock solution. The temperature of the measurements was 25.00°C and monitored with a thermistor placed directly in the cell.

The probe of the velocimeter was calibrated with water using the data of Del Grosso (15) and Millero (6). The drift in the sound velocities over a one day period was about 0.03 m s^{-1}. The isentropic compressibility of pure PC was obtained as $40.14 \pm 0.01 \times 10^{-6}$ bar^{-1}, which is in reasonably good agreement with the value of Hoiland (16), 40.08×10^{-6} bar^{-1}. However, this value did change from run to run, and it was found that better apparent molar compressibilities could be obtained if the sound velocity or isentropic compressibility of the pure solvent was obtained by extrapolation of the data to infinite dilution in each set of experiments.

Results

The apparent molar heat capacities and isentropic compressibilities were calculated from the heat capacities at constant volume σ and the isentropic compressibilities β_s using the following relations:

$$[1] \quad C_{p,2,\phi} = Mc_p + (1000(c_p - c_p^*))/m$$

$$[2] \quad c_p = c_p^*(1 + \Delta\sigma/\sigma^*)d^*/d$$

$$[3] \quad K_{s,2,\phi} = V_{2,\phi}\beta_s + (1000(\beta_s - \beta_s^*))/md^*$$

$$[4] \quad \beta_s = 100/du^2$$

where M is the solute molecular mass, c_p the specific heat capacity, d the density, $V_{2,\phi}$ the apparent molar volume of the solute, $K_{s,2,\phi}$ the apparent isentropic compressibility and u the sound velocity. The superscript * refers to the pure solvent. The densities required for the calculation of the apparent molar values were all taken from our previous work (4).

TABLE 2. Partial molar heat capacities $C_{p,2}^0$ of ions in propylene carbonate at 25°C based on the assumption $C_{p,Br^-}^0 = 45$ J K^{-1} mol^{-1}

Ion	$C_{p,2}^0$	Ion	$C_{p,2}^0$
Li^+	26	ϕ_4P^+	496
Na^+	56	ϕ_4As^+	512
K^+	38	ϕ_4B^-	498
Rb^+	35	Cl^-	45
Cs^+	35	Br^-	45
Me_4N^+	159	I^-	42
Et_4N^+	267	ClO_4^-	104
Pr_4N^+	383		
Bu_4N^+	496		
Pen_4N^+	610		
i-Pen_4N^+	599		

The original data and derived $C_{p,2,\phi}$ and $K_{s,2,\phi}$ are given in Tables 1 and 2.[3] The Debye–Hückel limiting slopes for electrolytes in PC are not available since sufficiently precise dielectric constant data as a function of temperature and pressure are not available. The standard partial molar quantities Y_2^0 were therefore obtained by extrapolation to infinite dilution using the Masson equation

$$[5] \quad Y_{2,\phi} = Y_2^0 + A_Y m^{1/2}$$

The conductivity results (17) which were reinterpreted by Zana *et al.* (4), show that 1:1 electrolytes are largely dissociated in PC, and under such conditions extrapolation with the Masson equation is valid.

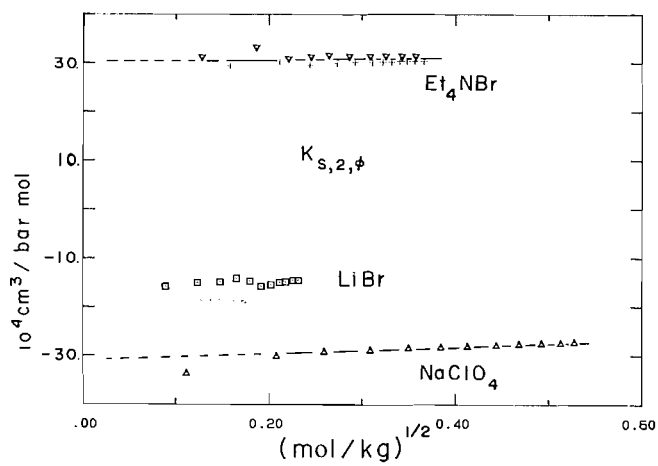

FIG. 2. Some typical plots of $K_{s,2,\phi}$ against the square root of the molality in PC at 25°C. Two sets of measurements were made with Et_4NBr and the presence of water in the LiBr solution affects the extrapolation.

Some examples of heat capacity data are shown in Fig. 1. These data were analyzed by least-squares and the derived parameters are given in Table 3. It should be noted that in the case of fully dissociated electrolytes the slopes A_c are on the average close to 6 $J\,K^{-1}\,mol^{-3/2}\,kg$, which is significantly smaller than in ACN.

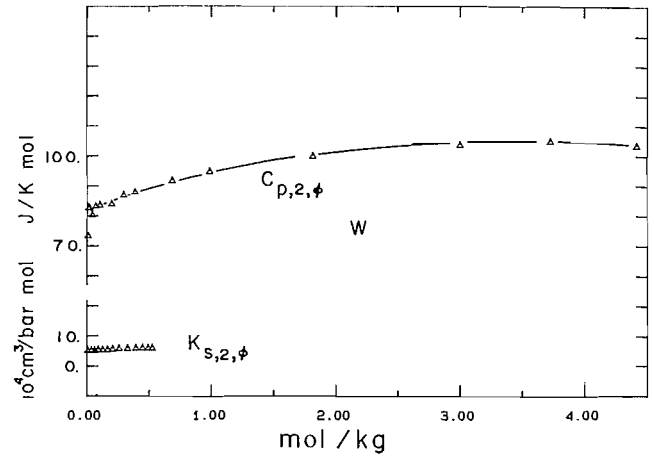

FIG. 3. The concentration dependence of $K_{s,2,\phi}$ and $C_{p,2,\phi}$ of water in PC at 25°C.

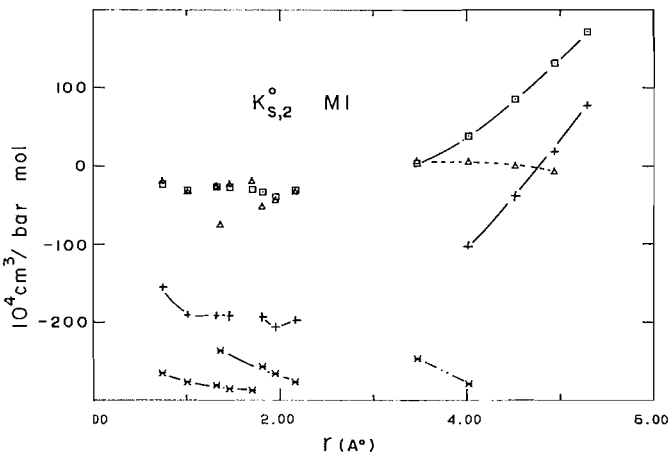

FIG. 4. The dependence of $K_{s,2}^0$ of alkali and tetraalkylammonium iodides on the cation ionic size: △ in water; + in ACN; □ in PC; * in MeOH.

Since very few reliable data exist in the literature on these systems, the only way of estimating the accuracy of the present data is through an ionic additivity scheme. The couples that could be used to check the additivity indicate a maximum error on heat capacities of 4 $J\,K^{-1}\,mol^{-1}$. The uncertainty on the data for LiBr seem somewhat larger than this value, probably because of the presence of water in the solid electrolyte. Also, the $K_{s,2}^0$ of Et_4NBr seems to be 5 to 10 × $10^{-4}\,cm^3\,bar^{-1}\,mol^{-1}$ too low when $K_{s,2}^0$ is plotted against the cations molecular weight.

Some difficulties were observed in some cases as a result of high viscosities, namely with $LiClO_4$ above 0.17 mol kg^{-1}, NaI and Pr_4NCl over the whole concentration range. Some LiBr seems to precipitate out above 0.10 mol kg^{-1} after standing for about 12 h. Also the solutions of Et_4NCl, below 0.3 mol kg^{-1} were slightly cloudy.

Some examples of plots of $K_{s,2,\phi}$ are shown in Fig. 2, and the derived parameters are given in Table 3. By the repetition of experiments and the additivity rule, the uncertainty on $K_{s,2}^0$ can be fixed at about 5 × $10^{-4}\,cm^3\,bar^{-1}\,mol^{-1}$. As in ACN (10), the data for LiBr are very sensitive to the presence of water, and $K_{s,2,\phi}$ seems to go through a maximum at low concentration. The infinite dilution value was therefore taken from the additivity rule. Other salts, such as Pr_4NCl and ϕ_4AsCl are also less reliable due to the presence of some water in the salts. As in the

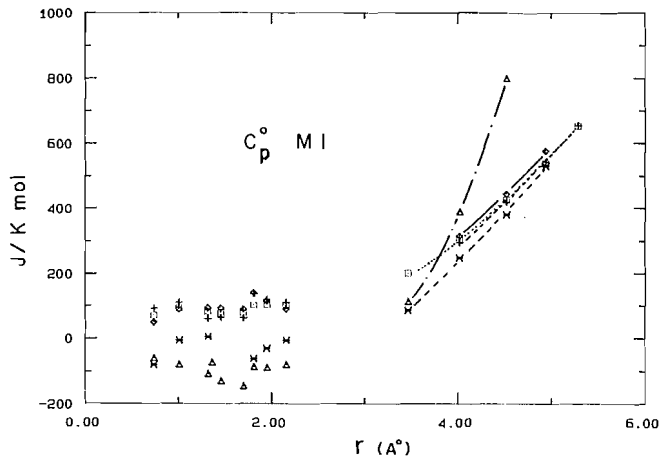

FIG. 5. The dependence of $C_{p,2}^0$ of alkali and tetraalkylammonium iodides on the cation ionic size: △ in water; + in ACN; □ in PC; * in MeOH; ◇ in DMF.

case of heat capacities, the parameters A_K are much smaller in PC than they were in ACN.

The heat capacities and compressibilities of water were also measured in PC and are shown in Fig. 3. As it was observed in other non-aqueous solvents (4, 18), $C_{p,2,\phi}$ has the same magnitude as the molar heat capacity of pure water and increases with increasing water concentration. The values of $K_{s,2,\phi}$, on the other hand remain fairly constant with water concentration in opposition to the corresponding values in lower alcohols (19).

Discussion

Thermodynamic properties can be quite informative on solute–solvent interactions. For this, it is important to examine the effect of solvent and different properties for the same electrolytes and, for each system, examine the effect of ionic size and compare anions with cations (20). It is with these objectives in mind that the present results will be examined.

Effect of ionic size

Through the additivity principle it is possible to obtain $K_{s,2}^0$ of most 1:1 electrolytes using the present results. For a common I^-, the effect of varying the cationic size on compressibilities is shown in Fig. 4 for the electrolytes in PC and compared with those in other typical solvents: water, ACN, and MeOH. Two main observations can be made on the PC data. Firstly, the data for alkali halides are very nearly the same in water and in PC but diverge significantly with tetraalkylammonium halides. Secondly, the trends with ionic size are similar for tetraalkylammonium halides in ACN and PC. The data in MeOH are much lower.

Criss and co-workers (8) have shown that with small ions there is a simple relationship between $K_{s,2}^0$ and β_s^* of the solvent and that, with the exception of lithium salts, $K_{s,2}^0$ increases slightly with ionic size in solvents of low compressibility. The present results on alkali halides are consistent with this. Since the compressibility of PC is similar to that of water, the similarity between $K_{s,2}^0$ of alkali halides in PC and in water is not unexpected and suggests that the particular structural effects that are characteristic of aqueous solutions are either not too sensitive to compressibilities or that they are largely accounted for in the compressibility of the pure solvent. With large organic ions like the tetraalkylammonium ions the increase with ionic size is, as in the case of other nonaqueous solvents, much more pronounced. These organic ions have a large intrinsic compressibility which is due primarily to the presence of compressible free space between the molecules. In this respect, the compressibility of these organic ions are not too different from those of a corresponding organic liquid. The observed difference between the $K_{s,2}^0$ of tetraalkylammonium iodides in PC and in ACN would then largely be due to I^-. In the case of aqueous solutions, the situation is quite different. Compressibilities are sensitive to hydrophobic hydration, and this hydration contribution largely cancels the intrinsic compressibility of the ions.

Through the additivity principle, the values of $C_{p,2}^0$ of most 1:1 electrolytes were also calculated and are plotted for the iodides against the cationic size in Fig. 5. The data in PC are now very similar to those in ACN and in DMF. The data in water are more negative with alkali halides and more positive with the tetraalkylammonium iodides. The data in MeOH fall somewhere in between water and the aprotic solvents.

The trends in Figs. 4 and 5 show that compressibilities and heat capacities are not sensitive to the same type of solvation effects. On the one hand, it appears that heat capacities are relatively insensitive to coulombic-type of ion–solvent interactions but very sensitive to structural hydration effects (structure-breaking and hydrophobic hydration) (20). The values of $C_{p,2}^0$ in non-aqueous solvents primarily reflect the intrinsic heat capacity and the Born polarization. This Born polarization (negative contribution) is much larger in MeOH than in aprotic solvents. In water, at low temperatures, the structure-breaking effect is at the origin of the negative $C_{p,2}^0$ of alkali ions and the hydrophobic effect predominates with R_4N^+. On the other hand, compressibilities are sensitive both to coulombic solvation and to structural effects. With alkali halides, the electrostatic interactions prevail in all solvents, while with R_4N^+ the hydrophobic hydration takes over in water.

Ionic contributions

Contrary to partial molar volumes (21), there are no direct methods of separating heat capacities and compressibilities into ionic contributions. As in the case of electrolytes in other non-aqueous solvents (4, 7–10), various approximate techniques can be used. For example, for heat capacities; (*1*) the method based on $C_{p,2}^0(\phi_4P^+) = C_{p,2}^0(\phi_4B^-)$ gives a value of $43\,J\,K^{-1}\,mol^{-1}$ for Br^-; (*2*) the extrapolation method of $C_{p,2}^0$ (R_4NBr) to zero cationic molecular weight gives a value for Br^- of $47\,J\,K^{-1}\,mol^{-1}$. (*3*) a comparison of $C_{p,2}^0$ (ϕ_4P^+) with $(4/3)C_{p,2}^0$ (ϕ_3CH) should also give an approximate value for Br^- in PC if the large ions and molecules are not solvated. The value obtained is $45\,J\,K^{-1}\,mol^{-1}$. All these approximate methods suggest that cations and anions of the same size have similar heat capacities in PC. Using the mean value $45\,J\,K^{-1}\,mol^{-1}$ for Br^-, ionic heat capacities in PC are given in Table 2. It should be stressed that this absolute scale is only approximate. For example, French and Criss (22) have presented evidence to show that the heat capacity of ϕ_4P^+ and ϕ_4B^- should actually differ by some $18\,J\,K^{-1}\,mol^{-1}$. These values are thus essentially conventional values which at the same time give the magnitude of the absolute values.

Essentially the same procedures used for heat capacities can be extended to compressibilities, if it can be assumed that large organic ions are unsolvated in PC: (*1*) the technique based on $K_{s,2}^0(\phi_4P^+) = K_{s,2}^0(\phi_4B^-)$ gives a value of $-5.6 \times 10^{-4}\,cm^3\,bar^{-1}\,mol^{-1}$ for Br^-; (*2*) the extrapolation method of $K_{s,2}^0$ (R_4NBr) gives $-58 \times 10^4\,cm^3\,bar^{-1}\,mol^{-1}$ for Br^-; (*3*) the comparison of $K_{s,2}^0(\phi_4P^+)$ with $(4/3)K_{s,2}^0(\phi_3CH)$ gives $-48 \times 10^{-4}\,cm^3\,bar^{-1}\,mol^{-1}$ for Br^-.

The agreement between the various techniques is far less

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

satisfactory with compressibilities than it was with heat capacities. This is a consequence of the larger dependence of compressibilities on solvation. Therefore, only conventional ionic values can be given. Since the compressibilities of dissociated acids in PC are not known the usual convention of taking the value for H^+ as zero is not possible and we have chosen the first procedure above to prepare Table 3.

Properties of water in non-aqueous solvents

The high heat capacity of liquid water is associated with the fluctuating structure of the liquid. Since no such structure exists in dilute solutions of water in non-aqueous solvent, a much lower value for $C_{p,2}^0$ of water in non-aqueous solvents is expected. As it is generally observed, the heat capacity of water remains comparable to that of the pure liquid down to very low concentrations. A possible explanation could be in terms of dimers or trimers of water in these systems. As the temperature is changed the concentration of dimers changes and this causes a relaxational contribution to $C_{p,2}$. Another approach is that of Berti *et al.* (23), who have investigated the volumes of water in a large number of solvents and have shown that V_w^0 are lower than the molar volume of water in polar solvents where the interactions are primarily with the polar group. In non-polar solvents the interactions are primarily with the hydrophobic part of the molecule and V_w^0 becomes larger than the molar volume. Such an approach can probably be extended to heat capacities and compressibilities but, unfortunately, most data in the literature has been extrapolated to infinite dilution from rather high water concentrations and no systematic trends can be observed with the polarity of the solvent. Further work along these lines is certainly desirable.

The structures of some sulphur-stabilized carbanions and stereoelectronic requirements for the formation of α-sulphonyl carbanions[1]

J. Stuart Grossert,[2] Jeffrey Hoyle,[3] T. Stanley Cameron,[2] Stephen P. Roe, and Beverly R. Vincent

Received October 29, 1986

This paper is dedicated to Professor Douglas E. Ryan in honour of his 65th birthday

J. Stuart Grossert, Jeffrey Hoyle, T. Stanley Cameron, Stephen P. Roe, and Beverly R. Vincent. Can. J. Chem. **65**, 1407 (1987).

Relatively few structure determinations of α-sulphonyl stabilized carbanions have been reported. The salient features of these are summarized and discussed in the light of the X-ray crystal structures of the potassium salt from bis(methylsulfonyl)-3-(2,6-dimethoxypyridyl)sulfonylmethane (**5**), the carbon acid bis(methylsulphonyl-4-(1,3-dimethoxyphenyl)sulphonylmethane (**6**), the triethylammonium salt of 2-methylsulphonyl-2-phenylthio-1-(3-pyridyl)-1-ethanone (**7**), the carbon acid 2-methylsulphonyl-2-phenylthio-1-phenylethanone (**8**), and its triethylammonium salt (**9**). Results of these structure determinations show that the α-sulphonyl carbanion has a significantly shorter $^{-}C—SO_2$ bond distance than the free sulphone, but that the S—O bond distances are essentially unchanged. The coordination about the carbanionic carbon atoms is planar; these atoms can be described as interacting with the sulphur atoms in an ylid-like manner, with a barrier to rotation about the $^{-}C—SO_2$ bond. The sulphonyl oxygen atoms do interact to a significant degree with the counterion, but there is no close contact between the counterion and the carbanionic carbon atom. A comparison of the structures of **6** and **5**, or of **8** and **9**, permits an assessment to be made concerning the stereoelectronics of deprotonation reactions on carbon atoms adjacent to sulphones.

J. Stuart Grossert, Jeffrey Hoyle, T. Stanley Cameron, Stephen P. Roe et Beverly R. Vincent. Can. J. Chem. **65**, 1407 (1987).

Il y a relativement peu de structures de carbanions stabilisés par un groupement sulfonyle en α qui ont été déterminées. On résume leurs caractéristiques principales et on en discute en fonction des structures, déterminées par diffraction des rayons-X, du sel de potassium du bis(méthylsulfonyl) (diméthoxy-2,6 pyridyl)-3 sulfonylméthane (**5**), de l'acide carboné bis(méthylsulfonyl) (diméthoxy-1,3 phényl)-4 sulfonylméthane (**6**), du sel de triéthylammonium de la méthylsulfonyl-2 phénylthio-2 (pyridyl-3)-1 éthanone-1 (**7**), de l'acide carboné méthylsulfonyl-2 phénylthio-2 phényl-1 éthanone (**8**) et de son sel de triéthylammonium (**9**). Les résultats obtenus lors de ces déterminations de structure démontrent que la distance $^{-}C—SO_2$ est beaucoup plus courte dans l'anion que dans la sulfone libre; toutefois, les distances S—O sont essentiellement inchangées. La coordination autour des atomes de carbones carbanioniques est plane; on peut imaginer que ces atomes interagissent avec les atomes de soufre d'une manière qui ressemble à celle qui existe dans les ylides et il en résulte une barrière à la rotation autour de la liaison $^{-}C—SO_2$. Les atomes d'oxygène du sulfonyle interagissent beaucoup avec le contre-ion; toutefois, il n'y a pas de contact direct entre le contre-ion et l'atome de carbone carbanionique. Une comparaison des structures des composés **5** et **6** ou **8** et **9** permet de faire une évaluation relative aux facteurs stéréoélectroniques influencant les réactions de déprotonations qui se produisent sur des atomes de carbones adjacents à des sulfones.

Introduction

The stabilization of carbanions by adjacent sulphur-containing moieties has been the subject of numerous studies (1–18). Calculations are at present limited to addressing the problem in the gas phase (10–14), and it would be useful to compare the results from calculations with data from the actual structures of anions in the solid state. It is, however, not a simple matter to gain insight into the actual structures of these carbanions (15, 17) and a limited number of solid-state structural studies have been reported (19–24). Since the reactions of sulphur-stabilized carbanions continue to attract the interest of synthetic chemists (8), further work on their structural features is merited. This paper reports on structural evidence obtained for two types of sulphur-stabilized carbanions, in one case involving only sulphonyl groups and, in the other, a combination of sulphenyl and sulphonyl groups. A brief summary of the structures of anions stabilized by these groups follows.

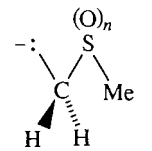
Sulphenyl-stabilized carbanions

Recent theoretical calculations (10, 13) suggest that the optimum geometry of a sulphenyl-stabilized carbanion has a pyramidal structure at the carbanion, with the adjacent S—C bond being oriented in an *anti* conformation, **1***a*. This is



1*a* : $n = 0$
1*b* : $n = 2$

reminiscent of molecules that show an anomeric effect (hyperconjugative interaction). When the carbanion is formed, the anionic $^{-}C—S$ bond is shortened, while the adjacent S—C bond is lengthened. Experiment shows that dithiane rings are preferentially deprotonated and alkylated in an equatorial orientation (15, 16), but it is difficult to obtain detailed structural evidence since sulphenyl-stabilized carbanions are highly reactive species that are invariably formed by the use of strong organolithium bases. This results in the formation of complexed lithiated anions, for which calculations have not, so far as we are aware, been published. A crystal structure determination has been made on a lithiated dithiane derivative (23). It shows that the bonding about the lithiated carbon forms a distorted tetra-

hedron, and that the lithium atom interacts equally with the carbanionic carbon atom and a sulphur atom.

Carbanions stabilized by one sulphonyl group

The structures of sulphonyl-stabilized carbanions in solution have also been the subject of extensive experimental work (2, 6), but much of the recent chemical literature on these carbanions has emphasized their use as synthetic intermediates (4, 7, 8), after which the sulphur atom is discarded. Some recent papers (11, 13, 14, 17) have sought to shed further light on the structural problems, but these are not as yet completely solved. The experimental work comes from a group who have reported extensive spectroscopic studies (17) on the nature of carbanions (and associated counterions) adjacent to sulphinyl and sulphonyl groups. For the latter group of anions, the data provided reflect a lengthening of the S—O bond length with concomitant shortening of the C—S bond length. Chassaing *et al.* (17) interpreted these data as being due to delocalization of negative charge between the carbon and sulphonyl oxygen atoms, and suggested that these atoms are involved in a tridentate complex with a lithium cation, with the bonding about the carbanionic carbon showing tetrahedral character.

Two recent notes from Wolfe's laboratory address the structure of both free and lithiated carbanions stabilized by a sulphonyl group (11). The calculations suggested a shortening of the $^{-}$C—S bond of the free carbanion, **1***b*, as compared to the calculated C—S bond length in dimethyl sulphone.

Very recently, Bors and Streitwieser (14) have published their calculations on Me_2SO_2, on its monoanion (**1***b*), on $LiCH_2SO_2Me$ (**1***c*), and on the dilithio salts of the 1,1- and 1,3-dianions. The conclusion of these calculations is that *two* potential energy minima exist in **1***c*, one similar to the structure described by Wolfe *et al.* (11), and a second in which the lithium cation is complexed to both sulphone oxygen atoms, but not to the carbanionic carbon atom. In **1***c*, the structure of C_s symmetry with the lithium cation complexed to both sulphonyl oxygen atoms has an LiC—S bond that is 8.6% shorter, an S—Me bond that is 1.0% longer, and S—O bonds that are 4.4% longer than the corresponding bonds calculated for Me_2SO_2 (14).

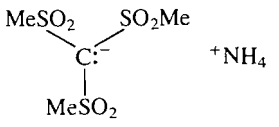
Two recent communications (19, 20) report on determinations of the crystal structures of carbanions stabilized by only a single sulphonyl group; such species are unstable and are difficult to isolate as crystalline solids suitable for X-ray work. It is also of interest to note that the crystal structures of three lithium ester enolates (25), of two phenyl-stabilized free carbanions (26), and of several ketone enolates, with a range of metal counterions (27), have been published recently.

The lithium cations of $[TMEDA–Li]^+[Ph^-CHSO_2Ph]$ (**1***d*) (19),[4] a dimer complex, are coordinated by the two TMEDA nitrogen atoms and by both sulfonyl oxygen atoms; there is no bonding to be observed between the carbanionic carbon and the Li cation (cf. ref. 14). The $^{-}$C—S bond length is only 1.1% longer than the C=S bond in thioformaldehyde (19) and the S—O bond length "is only a little larger than that in sulphones," which is in accord with both spectroscopic results (17) and calculations (11, 14). In addition, coordination about the anionic carbon is planar.

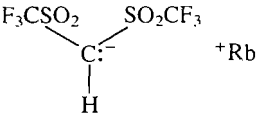
The second structure to be reported on (20) is $[TMEDA–Li]^+[^-CH_2SO_2Ph]$ (**1***e*),[4] which likewise exists in the solid state as a dimer. The authors of this communication did succeed in finding both the hydrogen atoms on the anionic carbon atom, these three atoms being located in a plane that is orthogonal to the plane described by the anionic carbon and the Ph—S bond, in agreement with calculations (11, 14). Likewise, **1***e* has a short $^{-}$C—S bond[4] that is 12.2% shorter than the corresponding bond in its conjugate acid and is essentially identical with the length of a C=S bond (20). No increase in length of the S—O or S—Ph bonds could be detected when compared to those in $MeSO_2Ph$. As with **1***d*, the lithium cation is complexed only by the TMEDA and by the sulphonyl oxygen atoms.

Carbanions stabilized by several sulphonyl groups

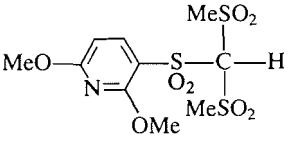
There are three earlier reports of structures (21, 22, 24) having been determined for anions stabilized by multiple sulphonyl groups. The first of these, due to Hoogsteen (21), is not readily accessible, but reports carefully determined atomic parameters for the salt, $^{+}NH_4\ ^{-}C(SO_2Me)_3$, **2**.[4] The environ-



2



3



4

ment of the carbanionic carbon atom exhibits C_1 symmetry. The $^{-}$C—S bonds have lengths that can be compared with 1.83(1) Å for the HC—S bonds in the disordered structure of $(MeSO_2)_3CH$ (28), or with 1.834(4) Å for the equivalent C—S bond in $(EtSO_2)_3CH$ (29). These data suggest an approximate shortening of the C—S bond of 7% when the anion, **2**, is formed, which is about 2/3 of the bond shortening that occurs when only a single sulphone stabilizes the negative charge. The six S—O bonds are quite similar in length to the mean value of 1.434 Å quoted in ref. 19.[4] The three S—Me bonds in **2** may be compared to the S—Me bond length of 1.73(2) Å in its conjugate acid (28) or with 1.757(2) Å in $(MeSO_2CH_2)_2$ (30); this small increase when the anion is formed may be significant and is in accord with calculations (11, 14). Hoogsteen found that four of the sulphonyl oxygen atoms are located within a range of 2.85–2.93 Å from the ammonium ion, evidence of an $^{+}$N—H···O hydrogen bonding network in the crystal (31).

The second reported structure determination was carried out on the salt, $Rb^+\ ^{-}CH(SO_2CF_3)_2$, **3**, (22).[4] In this molecule, the rubidium cations are coordinated by the sulphonyl oxygen atoms, but not to the anionic carbon atoms. The third report is a preliminary communication from this laboratory (24) in which the preparation of bis(methylsulfonyl)-3-(2,6-dimethoxypyridyl)-sulfonylmethane (**4**) and the X-ray crystal structure determination of its potassium salt (**5**) were reported. We now present full details of this structure, plus the structures of bis(methylsulphonyl-4-(1,3-dimethoxyphenyl)sulphonylmethane (**6**), the triethylammonium salt of 2-methylsulphonyl-2-phenylthio-1-(3-pyridyl)-1-ethanone (**7**), the carbon acid 2-methylsulphonyl-2-

[4]Selected structural features are collected in Table 1. See footnote 6.

phenylthio-1-phenylethanone (**8**), and its triethylammonium salt (**9**).

Experimental

The compound **8** was prepared using a previously published procedure (32) and **9** was prepared by the treatment of **8** with triethylamine followed by recrystallization from aqueous ethanol. Compounds **4–7** were prepared by published methods (24, 33). Full details are available (34).[5] A Nonius CAD-4 four-circle diffractometer with an ω/2θ scan was used for all crystals to establish unit-cell dimensions and in the intensity data collections. Reflection data were reduced by routine procedures described previously (35). Lorentz and polarization factors were applied, but not absorption or extinction corrections. Partial structures were determined by the MULTAN-80 program (36), in which the E-maps having the highest figure-of-merit were chosen, and the maxima corresponding with nearly all non-hydrogen atoms were located. Other atoms were found on subsequent difference-Fourier maps. Scattering factors were taken from ref. 37. Full matrix least-squares refinements ($w\Delta F^2$ = min) were preformed with anisotropic temperature factors on the non-hydrogen atoms and isotropic temperature factors on the hydrogens. The converged refinements were based on reflections with $I > 3\sigma(I)$, where σ is the individual reflection e.s.d. derived from the counting statistics and the weighting schemes used are defined in Table 2. The SHELX-76 system (38) was used for the structure refinement calculations for compounds **5–7**. The CRYSTALS system (Issue V) (39) was used for the structure refinement calculations for compounds **8** and **9**.

Results and discussion

Crystal data for the five compounds investigated in this study are recorded in Table 2, selected bond lengths are given in Table 3, selected bond angles are in Table 4, while selected torsion angles are provided in Tables 5 and 6.[6] Figures 1–5 contain stereoscopic drawings to show the geometries of compounds **5–9**.[7] Examination of the structures of the five molecules reveals a number of interesting features. Foremost amongst these is the acidic central carbon atom in the carbon acid, **8**. This atom is bonded to electron-withdrawing groups and has an approximately tetrahedral bonding geometry. When the proton on this carbon atom is removed, the geometry about the resulting carbanionic carbon atom in **9** becomes approximately planar. Similar geometries, as appropriate, pertain to the anions **5** and **7**, and in the carbon acid **6**. Unfortunately, the structure of the carbon acid **4** could not be determined and the conjugate acid of **7** could not be isolated, thus preventing some direct comparisons. The planar environment of the carbanion carbon atom is consistent with theory (11, 13, 14), with the structure of Hoogsteen's salt (21), and with the structure of other stabilized carbanions (19, 20). The carbon acid, **6**, crystallized with two different molecules in each unit. These were quite similar, but some bond lengths are significantly different; these have been noted in Table 3, which provides values of selected bond lengths

[5]Complete details of the preparation, spectral characterization, and reactions of these compounds remain to be reported: J. S. Grossert, J. Hoyle, and P. K. Dubey, to be published.

[6]Selected bond lengths and angles as reported for compounds **1***d* (19), **1***e* (20), **2** (21), and **3** (22) have been collected and deposited (Table 1); sets of the positional parameters and isotropic thermal parameters (Tables 7–11), of the complete anisotropic thermal parameters (Tables 12–16), of the structure factor tables (Tables 17–21), plus full details of distances, bond angles, and torsion angles (Tables 22–26) for each molecule are available and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[7]The stereoscopic drawings were produced by the SNOOPI program, a part of the CHEMGRAF system (Chemical Designs, Oxford, U.K.).

in the molecules. Different aspects of the structures are detailed below.

Bond lengths

The S—Me bond lengths in $(MeSO_2CH_2)_2$ and $MeSO_2CH_2CH_2SO_2Ph$ are 1.757(2) Å (30) and 1.759(3) Å (40), respectively. These values are very similar to the S—Me bond lengths in a series of four substituted sulfones studied previously (33, 41), which average 1.759 Å. Examination of the seven S—Me bond lengths in **5–9** shows lengths that range from 1.732(6) to 1.769(4) Å (mean = 1.758 Å). The reason for one apparently short S—Me bond is not obvious.

In general, S—O bond lengths in sulphones are remarkably constant at a value of 1.439(14) Å (42), while a recent analysis of 53 bond lengths from the Cambridge Crystallographic Data Base gives a mean value of 1.434 Å (19). The nine S—O bond lengths in $(MeSO_2CH_2)_2$ (30), $MeSO_2CH_2CH_2SO_2Ph$ (40), $(EtSO_2)_3CH$ (29), and Me_2SO_2 (43) range from 1.439(3) to 1.452(2) Å with a mean of 1.445 Å. The mean of the six S—O bond lengths in the anion **5** was 1.436 Å, but that of the six S—O bond lengths in the carbon acid **6** was 1.425 Å. Both the *t*-test and analysis of variance show that these lengths are statistically different at the 0.5% confidence level. A similar set of tests on the S—O bonds in **7**, **8**, and **9** revealed that these bond lengths could not be distinguished with confidence as being different. Calculations (11, 14) suggest a lengthening of

*Negative rotation is anticlockwise in A4—A3—A2—A1 when viewed down A2—A3.

the S—O bonds on the formation of an α-sulphonyl carbanion and this was possibly observed in the case of anion **1***d* (19), but not in the case of **1***e* (20). In addition, the spectroscopic results of Chassaing *et al.* (17, *vide supra*) must be considered; these offer carefully documented experimental evidence for the lengthening of the S—O bonds in α-lithio sulphones.

The salts **5**, **7**, and **9** offer an interesting series of compounds with which to compare the interaction of the cationic and anionic moieties. In the case of **5**, the potassium cation is separated from five of the sulphonyl oxygen atoms by distances varying between 2.695(5) and 3.125(5) Å. Water of crystallization coordinates to the potassium cation from two different sites, with the H_2O–K^+ distances being 2.860(5) and 2.780(5) Å respectively. There is no bonding between the potassium ion and the anionic carbon atom; in fact, the potassium ion is closer to two sulphur atoms and a second potassium cation (distances about 3.5 Å) than it is to any of the carbon atoms. The $^-$O–K^+ distances in the potassium enolate of pinacolone range from 2.568(2) to 2.661(3) Å (27), which are significantly shorter than those in **5**. This presumably, at least partly, reflects the high electron density on the oxygen atom of an enolate anion. Hydrogen-bonded interactions are apparent in the triethylammonium salts, **7** and **9**. Compound **7** exhibits an N(1)—H···O(3) distance of 1.972(4) Å and associated N—H—O angle of 165.3°, while **9** exhibits an N(1)—H···O(3) distance of 1.848(4) Å and associated N—H—O angle of 169.7°; these data are comparable to hydrogen bonds in other species between other trialkylammonium cations and oxygen atoms in various types of acceptor groups (31). Thus there is interaction between the triethylammonium ion and the enolate anion, but not to the sulphonyl oxygen atoms.

The shortening of the anionic carbon–sulphur bond vis-à-vis the C—S bond in sulphones became apparent even in the earlier crystal structure determinations of Hoogsteen (21) and Davøy *et al.* (22) despite relatively large uncertainties in the atomic positions. The mean of the $^-$C—SO_2Me bond lengths in Hoogsteen's salt (**2**) (1.701 Å) is not significantly different from the two $^-$C—SO_2Me bond lengths in structure **5**. Comparison of these bonds with the equivalent bond lengths in the carbon acid **6** shows an averaged decrease of 6.6% in the $^-$C—SO_2Me bond length on the formation of the anion (stabilized by three sulphonyl groups). This decrease can be compared to the corresponding decrease of 7% between $(MeSO_2)_3CH$ and Hoogsteen's salt (**2**), and the decrease of 12.2% between $MeSO_2Ph$ and **1***e* (*vide supra*). Calculations (11, 14) suggest a decrease of about 7.5% for the $^-$C—S bond length in an anion stabilized by a single sulphonyl group.

The anions **7** and **9** are more complex than the anion **5** in which the negative charge is only stabilized by sulphonyl groups. The $^-$C—SO_2Me bonds in the anions **7** and **9** average to a length of 1.743 Å, which is 3.6% shorter than the length of the equivalent C—S bond in the carbon acid **8**. In **7** and **9** the charge is also delocalized into the carbonyl, as is manifested by the 9.1% decrease in the C(2)—C(3) bond length, when compared to that in **8**. This may be compared with a shortening of about 11% in the corresponding C—C bond when ester lithium enolates are formed (25); given other sites for delocalization of charge in **7** and **9**, it is quite likely that this C—C bond shortening should be less than in an ester enolate. Of more interest is the fact that the phenylsulphenyl group also contributes to the charge stabilization since the mean of the $^-$C—SPh bond lengths in **7** and **9** is 3.7% shorter than the corresponding bond in **8**. The fact that phenylsulphenyl groups can stabilize negative charge has been discussed previously by Bordwell *et*

al. (44). Wolfe's calculations (10) on Me_2S suggest a 4.7% shortening of the C—S bond when the anion is formed, but this is for a pyramidal anion, whereas the anionic carbon atoms in **7** and **9** are almost planar. We did not find any evidence for a lengthening of the S—Ph bond when comparing **7** and **9** with **8**. A 3.4% increase was found by Wolfe *et al.* (10) when comparing Me_2S and **1***a*, but this small increase could be diffused by more complex interactions with the phenyl ring. Finally, the mean of the carbonyl C=O bond lengths in **7** and **9** is 8.0% longer than the C=O bond in **8**. This may be compared to a 10% increase in the lengths of the corresponding bonds in ester lithium enolates (25) or an approximately 8% increase in the case of pinacolone enolates (27).[8]

Bond angles

Selected bond angles are summarized in Table 4.[6] The

[8]The length of the C=O bond in these enolates is dependent on the nature of the cation.

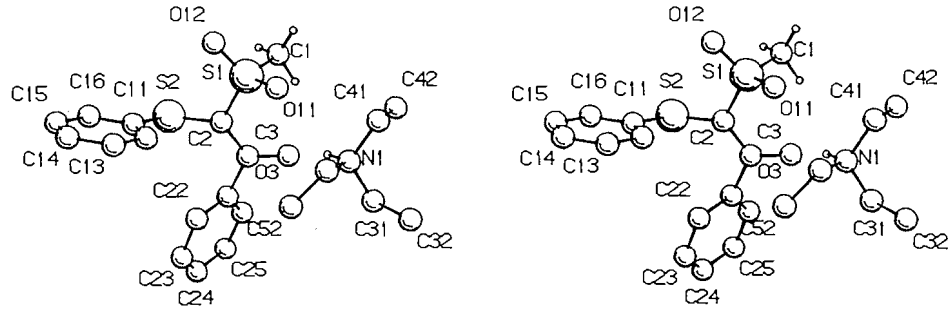

FIG. 5. The crystal structure of the triethylammonium salt of 2-methylsulphonyl-2-phenylthio-1-phenylethanone, **9**, as seen in a stereoscopic view.

S—C—S angles about the central anionic carbon atom in **5** total 359.5°, which is indicative of the fact that the bonding geometry about this atom is planar. Similar results obtain for the corresponding carbon atom in **7** and **9**, but in these cases the anion is much less symmetrical. The corresponding angles in Hoogsteen's anion, **2**, total 359.7° (21). All other angles are as expected, based on past precedent.

Torsion angles

A study of the dihedral angles in these five compounds (Tables 5 and 6) provides some interesting information,[6] especially when the projections outwards from C(2) along the three non-hydrogen bonds in structures **5**–**9** are compared. It is useful also to examine the orientations of the various aromatic rings with respect to their bonding to the remainder of the molecules. In a previous paper (33), we have commented on the considerable number of structures in which a polar group bound to one of the α carbon atoms is found to be *gauche* only to one of the oxygen atoms in a sulphone. This fact must reflect the strongly polar nature of the sulphonyl S—O bonds, although this is not the only factor that influences the orientation of groups in a structure, as not all sulphones exhibit this phenomenon (42, 45).[9]

Nonetheless, neither Hoogsteen's anion, **2** (21), nor **5** exhibit C_3 symmetry for the sulphonyl groups around the central carbon atom, but rather have the sulphonyl groups oriented so that one OSCS dihedral angle is essentially in an eclipsed conformation; no sulphur atom lies on the bisector of the OSO angle of any of the sulphonyl groups. However, in both the conjugate acid of **2**, and in **6**, at least one sulphur atom is *gauche* to any oxygen atom on an adjacent sulphonyl group. Importantly, the acidic proton is *gauche* to both oxygen atoms with respect to one sulphonyl group. It is noteworthy that there are three sulphonyl groups in **6**, yet H(21) is *gauche* to both oxygen atoms *only in the case of the C(2)—S(3) bond.* In **8**, H(21) is *gauche* to both oxygen atoms along the C(2)—S(1) bond. This orientation of a proton with respect to sulphonyl oxygen atoms is suggested to lead to greater kinetic acidity, both by calculation (11) and by experiment (1).

One of the C(2)—S bonds is almost eclipsed with an S(1)—O bond in the anions **5**, **7**, and **9**, the dihedral angles ranging from 7° to 16°, which is in contrast to the more symmetrical orientation for α-sulphonyl carbanions found by calculations (11, 14). Furthermore, the other two sulphonyl groups in **5** are arranged with S—C(2)—S—O dihedral angles of 1° and 17°, which

[9]J. S. Grossert, S. Sotheeswaran, and T. S. Cameron, to be published.

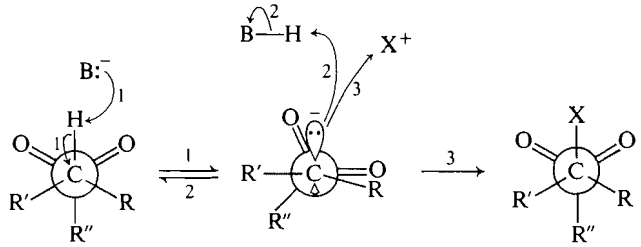

FIG. 6. Stereoelectronic requirements in the formation and reactions of α-sulphonyl carbanions from the species $RR'CHSO_2R''$ ($R \neq R'$), as viewed by means of Newman projections.

suggest some generality to the phenomenon. The anion of benzyl phenyl sulphone, **1***d*, shows the same asymmetry in the environment about the carbanionic center (19), whereas $^-CH_2SO_2Ph$, **1***e*, (20) is much more symmetrically oriented. As commented on by Boche *et al.* (19), this local chirality in unsymmetrically substituted, α-sulphonyl carbanions is undoubtedly the key factor in the retention of configuration in their formation, followed by subsequent protonation or alkylation reactions. These structures therefore provide good evidence for the stereoelectronic requirements of these reactions, as is illustrated in Fig. 6.

Finally, it should be noted that the carbanions represented by **7** and **9** indeed contain enolate anions, since atoms S(1)—C(2)—S(2) are coplanar with atoms C(21)—C(3)—O(3). However, *the aryl rings are twisted out of conjugation at angles of 40°–50° to the enolate anion system*, whereas the phenyl ring in **8** is almost coplanar with the carbonyl group, as expected for a benzoyl group. The aryl groups in both **5** and **6** are similarly arranged with respect to their adjacent sulphonyl groups, viz., essentially eclipsed with one of the S—O bonds; this is not so in the case of **1***e* (20).

Conclusions

It is interesting to recognize how earlier experimental results, which could be interpreted in terms of a planar, chiral structure for α-sulphonyl carbanions (1, 6), can now be understood from the series of structural studies reviewed and discussed in this paper. The general trends established by calculations (10–14), experiments (15, 17, 18), and crystal structure determinations (19–24) are in agreement. Results from calculations are increasingly becoming closer to experimental results, and will no doubt improve further when it is possible to do calculations on cations with a complete set of coordinating ligands.

The most acidic proton α to a sulphonyl group is that which lies in the bisector of the OSO angle; removal of such a proton is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

both kinetically and thermodynamically favoured. On removal of this proton, it is necessary for one of the ^{-}C—R bonds to be able to become approximately coplanar with one of the S—O bonds (see Fig. 6), and the inability to achieve this is the likely cause of a recently announced cleavage reaction in the attempted formation, in a five-membered ring, of an anion between two sulphonyl groups (46). It is apparently possible to remove protons in other conformations with respect to the sulphonyl oxygen atoms, but such a reaction must be less facile.

Once formed in its preferred conformation, the anion is configurationally stable under normal conditions due to a kinetic barrier to rotation about the $^{-}C—SO_2$ bond. The anions are chiral if the carbanionic carbon is disubstituted with different ligands, the carbanionic carbon atom being stabilized by a polar interaction between the sulphur and carbon atoms. The concept that the anion is ylid-like, with greater electron density on the carbon atom (4), is a good working model for the structure of these species. Reaction of the anion with an electrophile would normally take place along the same trajectory as that along which the proton was removed, as shown in Fig. 6.

Finally, the interactions between the sulphonyl oxygen atoms and the cation must be considered. The Li^{+}—O distances in the sulphur-stabilized anions **1***d* and **1***e* (19, 20) are very similar to the corresponding distance in lithium enolates (25, 27), which suggests a significant concentration of electron density on the oxygen atoms in α-sulphonyl carbanions. However, the oxygen atoms in neutral sulphones are very weakly basic (7), and nucleophilic interactions with electrophiles are also very weak (7, 47), except in special circumstances (48).

The results presented in this work show quite clearly that the formation of an α-sulphonyl carbanion does not produce a significant change in the electron density *between* the sulphur and the oxygen atoms. The carbanionic carbon atom is electron rich and, if this atom is substituted with two different ligands, has a chiral environment. These are the facts that distinguish α-sulphonyl carbanions from enolate anions.

Two dimensional fluorescent sensors: the different dependences of the fluorescence band position and the fluorescence quantum yield of 1,5-diphenyl-3-vinyl-Δ^2-pyrazoline upon solvent dipolarity and hydrogen bond acidity

MERINNAGE DAYAL PREMAKUMARA DE COSTA, AMILRA PRASANNA DE SILVA,[1] AND SURAM THERESE PATHIRANA

Chemistry Department, Queen's University, Belfast BT9 5AG, Northern Ireland and Chemistry Department, University of Colombo, P.O. Box 1490, Colombo 3, Sri Lanka

Received November 4, 1986

MERINNAGE DAYAL PREMAKUMARA DE COSTA, AMILRA PRASANNA DE SILVA, and SURAM THERESE PATHIRANA. Can. J. Chem. **65**, 1416 (1987).

1,5-Diphenyl-3-vinyl-Δ^2-pyrazoline (**1**) has a fluorescence quantum yield (ϕ_F) which is strongly controlled by the hydrogen bond acidity of the solvent (α) and to a minor extent by the dipolarity of the solvent (π^*) according to the equation:

$$\log [(\phi_{F\text{aprotic}}/\phi_F) - 1] = 0.44(\pi^* + 6.1\alpha) - 2.03$$

The wavenumber of the fluorescence band maximum ($\bar{\nu}_F$) is controlled nearly equally by π^* and α according to the equation:

$$\bar{\nu}_F = -1.9(\pi^* + 1.1\alpha) + 23.7$$

Thus the fluorescence spectrum of **1** delivers two distinct and independent parameters of its microenvironment while its electronic absorption spectrum is essentially solvent invariant.

MERINNAGE DAYAL PREMAKUMARA DE COSTA, AMILRA PRASANNA DE SILVA et SURAM THERESE PATHIRANA. Can. J. Chem. **65**, 1416 (1987).

Le rendement quantique de la fluorescence (ϕ_F) de la diphényl-1,5 vinyl-3 Δ^2-pyrazoline (**1**) est fortement assujetti au contrôle de l'acidité de la liaison hydrogène du solvant (α) et, à un degré moindre, à celui du caractère dipolaire du solvant (π^*); ces facteurs sont reliés par l'équation suivante:

$$\log [(\phi_{F\text{aprotique}}/\phi_F) - 1] = 0{,}44(\pi^* + 6{,}1\alpha) - 2{,}03$$

Le nombre d'onde du maximum de la bande de fluorescence ($\bar{\nu}_F$) est assujetti à un contrôle à peu près égal de la part de π^* et de α: ces divers facteurs sont reliés entre eux par l'équation suivante:

$$\bar{\nu}_F = -1{,}9(\pi^* + 1{,}1\alpha) + 23{,}7$$

Ainsi, le spectre de fluorescence du composé **1** fournit deux paramètres distincts et indépendants de son microenvironnement: par ailleurs, son spectre d'absorption électronique ne varie pratiquement pas avec le solvant.

[Traduit par la revue]

Introduction

Fluorescent molecular sensors possess several advantageous features which are well suited to the study of dynamic microheterogeneous systems (1), examples of which are common in many areas of chemistry and biology. The features are (*a*) high spatial resolution (nanometer), (*b*) high temporal resolution (nanosecond), (*c*) extreme sensitivity (single molecule detection is now possible (2)), (*d*) good selectivity of detection, and (*e*) non-destructive and virtually non-invasive nature (mainly in the biological, rather than chemical context).

A fluorescent sensor molecule delivers information about its immediate microenvironment to a remote controller/observer. However, in general the exact location of the sensor is unknown (except for highly qualitative hydrophilicity/hydrophobicity arguments) and so the information remains uninterpretable. Thus (*a*) the lack of methods to determine the location of the sensor, or (*b*) the lack of specific targeting/anchoring strategies for sensors hamper the widespread rational use of fluorescent sensors. The latter problem can be tackled in specific instances by covalently binding the sensor to a chemically reactive location or by building the sensor into a specific point in a building block of the microheterogeneous system by organic synthesis (as in functionalized micelles (3)). The former problem remains unsolved in general.

A corollary of these general problems can be appreciated when we recognize that many fluorescent (and other) sensors deliver only one microenvironmental property per sensor. Two microenvironmental properties determined by two sensors bear no relation to one another because they concern two different locations. One solution to this is to employ a sensor molecule which can be operated on by two spectroscopic methods, several such sensors being available (4). However, to be useful the two spectroscopic methods must deliver two different kinds of microenvironmental information and that has not been always appreciated. We now improve this approach by demonstrating that a single sensor molecule operated in a single spectroscopic (fluorescence emission) mode can be made to simultaneously deliver information about two distinct and independent microenvironmental properties, i.e. fluorescent sensing in two dimensions. These two microenvironmental properties will show a one-to-one correspondence since both refer to the same location. A steady state fluorescence emission spectrum is a data file from which at least three quasi-independent spectral parameters (position of band maximum, maximum band height (or quantum yield) and band width)) can be extracted. In judiciously chosen cases each one of these can be made to be sensitive to a specific microenvironmental property or a combination of several. The utility of this concept of multidimensional fluorescent sensors can be further enhanced with the availability of time as an additional spectral parameter.

Results and discussion

Perusal of Table 1 indicates the essential invariance of the fluorescence quantum yield (ϕ_F) of 1,5-diphenyl-3-vinyl-Δ^2-

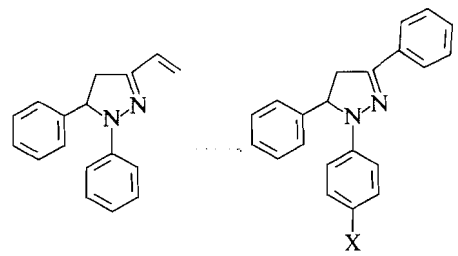
pyrazoline (**1**) in aprotic solvents whereas the protic solvents possessing O—H or N—H bonds cause significant quenching. In particular, we note that ϕ_F in all of the aprotic solvents (entries 1–6 in Table 1) obeys the relation [1]

[1] $\phi_F = 0.64$
SD = 0.048, $n = 6$

$\phi_{Faprotic}$ is obtained by averaging the ϕ_F values in all of the aprotic solvents. The scatter of ϕ_F values within this group of solvents appears random (see the aprotic solvent region in Fig. 1) and is in accord with the model given below. The scatter is attributed to the experimental error of 10% in the determination of quantum yields due to the spectral correction procedure. The constancy of ϕ_F values of 1-phenyl-Δ^2-pyrazolines in aprotic solvents is supported by the data in Table 2 for **2**, X = H.



1 **2**

In order to quantitatively interpret the variation of ϕ_F in protic solvents and the variation of $\bar{\nu}_F$ in all solvents we make use of the following reasonable model. 1,3-Diaryl-Δ^2-pyrazolines show a significant degree of internal charge transfer in their lowest excited singlet state (refs. 5*a–d*, internal charge transfer states are discussed in ref. 5*e*). In particular, the charge separation is such that a substantial negative charge builds up on the N(2) and C(3) centres, which in turn should lead to an enhanced availability of the lone electron pair on N(2) towards a hydrogen bond donor solvent. Thus, excitation of **1** leads to the strengthening of the hydrogen bond between N(2) and the protic solvent, which results in the radiationless

TABLE 2. Electronic spectral data of **2**, X = H[a]

Solvent	$\bar{\nu}_{abs}$ (10^3 cm^{-1})	$\bar{\nu}_F$ (10^3 cm^{-1})	ϕ_F

Dichloromethane	27.9	21.8	0.66
Dimethylformamide	27.6	21.5	0.68

[a] All conditions as for Table 1, except for excitation wavelength = 358 nm.

deactivation of the singlet state of **1**. Radiationless deactivations involving hydrogen bonding are known (6). The ϕ_F values of **1** are expected to remain uniformly high in aprotic solvents where such powerful hydrogen bonding effects are absent. Equation [2] therefore applies to protic solvents whereas eq. [3] is valid for aprotic solvents where k_H is absent (Scheme 1).

[2] $\phi_F = k_F/(k_F + k_d + k_H)$

[3] $\phi_{Faprotic} = k_F/(k_F + k_d)$

k_F, k_H, and k_d are the rate constants for excited state decay via fluorescence, solvent hydrogen bonding and other radiationless channels respectively. It is assumed that k_F and k_d are solvent independent to a first approximation (in spite of eq. [10]). Fluorescence lifetime (τ_F) data, if available, would obviate the need for this assumption by evaluation of eqs. [2]–[5].

[4] $\tau_F = (k_F + k_d + k_H)^{-1}$

[5] $\tau_{Faprotic} = (k_F + k_d)^{-1}$

The above model is justified by the observation of a solvent kinetic (deuterium) isotope effect of 2.0 on k_H (entries 11 and 12 in Table 1) which clearly shows the stretching of the O—H bond of the solvent by interaction with the lowest excited singlet state of **1**.

From Scheme 1 we see that k_H will be controlled largely by

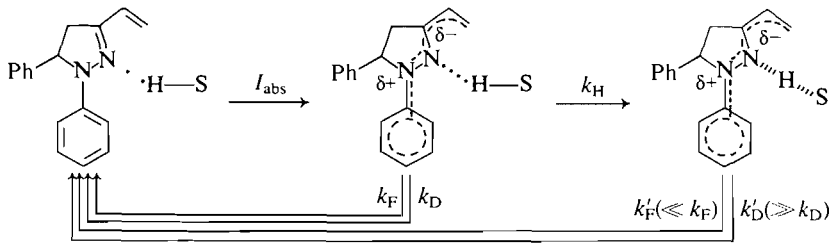

SCHEME 1

the solvent hydrogen bond acidity, α (7), though a minor dependence on the solvent dipolarity, π^* (7) is also to be expected in view of the orientation of the solvent molecule by dipole–dipole interaction which would maximize the hydrogen bonding. Casting this statement into the form of a linear free energy relationship gives eq. [6].

$$[6] \quad \log k_H = A(\pi^* + k\alpha) + B'$$

where A, k, and B' are adjustable parameters. The combination of eqs. [2], [3], and [6] gives eq. [7].

$$[7] \quad \log [(\phi_{Faprotic}/\phi_F) - 1] = A(\pi^* + k\alpha) + B$$

where $B = B' - \log (k_F + k_d)$. We have evaluated the three-parameter eq. [7] in a preliminary manner by the use of the four protic solvents (entries 7–10 in Table 1) which yields eq. [8] (with the aid of eq. [1]).

$$[8] \quad \log [(\phi_{Faprotic}/\phi_F) - 1] = 0.44(\pi^* + 6.1\alpha) - 2.03$$

$$SD = 0.058, \quad r = 0.994, \quad n = 4$$

It is important to note that eq. [7] can be tested with reasonable accuracy only for those solvents which give ϕ_F values which clearly deviate from $\phi_{Faprotic}$ and zero. The logarithmic term cannot be evaluated with confidence as these two limits are approached. Figure 1 combines equations [1] and [8] and clearly shows the difference between protic and aprotic solvent classes. Further work is planned with more solvents as well as with other fluors with instrumentation which will allow the determination of ϕ_F with lower error limits, which should reduce the scatter in $\phi_{Faprotic}$.

Among the Δ^2-pyrazolines (8, 9), **1** shows this hydrogen bonding-induced fluorescence quenching to an extreme extent because of the limited delocalization afforded by the 3-vinyl group which leaves much of the negative charge concentrated on N(2) in the excited state of **1**. **1** shows nearly complete switching ("on–off") behaviour when compared in hexane and methanol (a switching factor of 9 in ϕ_F — entries 1 and 10 in Table 1). Many other Δ^2-pyrazolines give lower switching factors (8, 9) though there are several exceptions in **2**, X = $NHCOCH_3$, NH_2, and OCH_3 (9). However, these have not received close scrutiny.

As seen from Scheme 1, the fluorescent state of **1**, in contrast to ground state (**1**), has substantial charge separation which leads to considerable stabilization by the dipole–dipole interactions with the solvent. Thus the energy gap between these two states, as measured by $\bar{\nu}_F$ (see ref. 10 for the difference in behaviour of $\bar{\nu}_{abs}$) is expected to be controlled by the solvent dipolarity, π^*. A degree of control by α is also to be expected since the fluorescent state of **1** may also be stabilized by weak hydrogen bonding to N(2). The corresponding linear free energy relationship is eq. [9].

$$[9] \quad \bar{\nu}_F = C(\pi^* + k'\alpha) + D$$

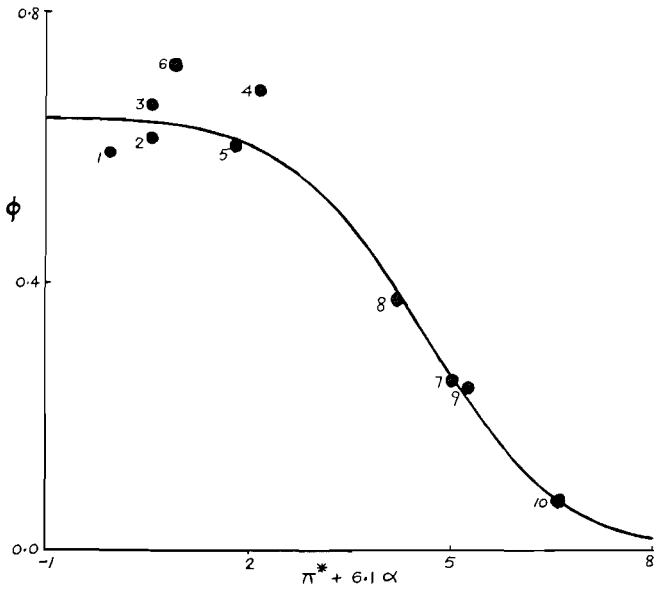

FIG. 1. Variation of the fluorescence quantum yield of **1** with the solvent polarity function ($\pi^* + 6.1\alpha$). Full line calculated from eqs. [1] and [8]. The numbers correspond to the entries in Table 1.

where C, k', and D are adjustable parameters. Equation [9] has been evaluated with data from all the solvents (entries 1–10 in Table 1) which gives eq. [10].

$$[10] \quad \bar{\nu}_F = -1.90(\pi^* + 1.1\alpha) + 23.7$$

$$SD = 0.283, \quad r = 0.968, \quad n = 10$$

Solvent-dependent fluorescence band positions of many 1,3-diaryl-Δ^2-pyrazolines have been previously analyzed via Lippert–Mataga type equations and yield excited state dipole moments (5, 11). The universal interaction function used therein (11) is quite closely related to solvent dipolarity (7). In particular, the Koppel–Palm treatment of solvent effects (12) employs a variant of the universal interaction function as the counterpart of solvent dipolarity of the Kamlet–Taft treatment used here (7). For our purposes it is more profitable to use the present correlation of $\bar{\nu}_F$ with π^* and α (eq. [10]) rather than the Lippert–Mataga equation since the present correlation allows a direct comparison with the ϕ_F correlation (eq. [8]). It is essential to consider α for a successful correlation of ϕ_F.

Many fluors with twisted internal charge transfer states (13) such as anilino naphthalene sulphonates (14) and dialkylamino phenyl triazines (15) as well as exciplexes (16) show solvent dependent $\bar{\nu}_F$ and ϕ_F. However, these two quantities show a large degree of correlation, i.e. the microenvironmental properties sensed via $\bar{\nu}_F$ and ϕ_F cannot be easily dissected into independent parameters as can be done for **1**. The Δ^2-pyrazolines in general and **1** in particular differ from the twisted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

internal charge transfer systems in that the twisting of the donor (N(1)) and acceptor (N(2) and C(3)) moieties is prevented by the pyrazoline ring. The suitability of **1** as a two dimensional fluorescent sensor is enhanced by the fact that its electronic absorption spectral parameters are essentially solvent independent (Table 1), i.e. the variations in emission properties are not trivially caused by variations in excitation properties.

Entry 13 in Table 1 illustrates the utility of **1** in microenvironmental studies. **1** senses a hydrogen bond acidity of 0.82 and a dipolarity of 0.52 as deduced from the ϕ_F and $\bar{\nu}_F$ data in sodium lauryl sulphate micelles with the aid of eqs. [8] and [10]. These values of α and π^* lie in between those of ethanol and 2-propanol (7). **1** therefore resides at a location which is accessible to hydroxyl groups, i.e. water (1, 3, 17) though the moderate α value indicates the moderate concentration of water molecules at this location. The intermediate π^* value suggests that **1** is located in the region between the micellar core and the surface region which is exposed to non-electrostricted water. The conclusion therefore is that there is substantial penetration of water into the interior of the micelle.

Experimental

1 was prepared according to a known procedure (18). The following instruments were used in this work: Varian DMS90 ultraviolet–visible spectrophotometer, Aminco-Bowman SPF spectrophotofluorimeter, and Data General eclipse minicomputer. The fluorescence spectral data in Table 1 were determined as follows. The wavelength response function of the emission monochromator – photomultiplier tube combination of the spectrofluorimeter was determined over the range 340–590 nm by the well-known procedure of Lippert *et al.* (19) and Argauer and White (20). In particular, we employed 2-naphthol in acetate buffer (pH = 4.5), quinine sulphate in 0.1 *M* H_2SO_4, and 3-nitrophenyl dimethylamine in hexane:toluene (7:3 v/v) as the fluorescence emission spectral standards. The wavelength response function (which showed a maximum at 411 nm) was employed to correct the raw fluorescence emission spectra of **1** in various solvents. The excitation wavelength was maintained at 342 nm for all these cases since the ultraviolet absorption spectra were essentially solvent invariant. Even though the excitation spectra were not corrected, the band maxima in excitation and in absorption were nearly identical in all cases at 342 ± 3 nm. The optical densities of all these solutions of **1** at 342 nm were adjusted to 0.20 before the raw emission spectra were obtained. The corrected fluorescence intensity (at arbitrary but constant gain) versus wavenumber plots directly gave the wavenumber of maximum fluorescence emission $\bar{\nu}_F$ and their areas are directly proportional to the corresponding fluorescence quantum yields (ϕ_F). Such relative ϕ_F values were converted to absolute ϕ_F values by comparison with the area of a corrected fluorescence emission spectrum 1,3,5-triphenyl-Δ^2-pyrazoline, **2**, X = H, in aerated methanol obtained under identical conditions. This has $\phi_F = 0.37$ (8), obtained by comparison with the primary standard 9,10-diphenylanthracene which has $\phi_F = 0.95$ (21). Refractive index corrections were not applied since the refractive indices of various solvents at the required wavelengths are not accessible. Anyway, these corrections are expected to be small (8) and are of the order of the limits of experimental error in ϕ_F which are about 10%.

The three-parameter equations [8] and [10] were obtained by optimizing the blend of π^* and α with a linear least squares computer program which maximized the coefficient of correlation (r) between $\log [(\phi_{Faprotic}/\phi_F) - 1]$ or $\bar{\nu}_F$ and $(\pi^* + k\alpha)$ where k was adjusted by increments of 0.1.

Photoacoustic infrared spectra (250–10 000 cm^{-1}) of partially deuterated kaolinite #9

K. H. MICHAELIAN, K. BUKKA, AND D. N. S. PERMANN

Energy, Mines and Resources Canada, CANMET, Coal Research Laboratory, P.O. Bag 1280, Devon, Alta., Canada T0C 1E0

Received September 26, 1986

K. H. MICHAELIAN, K. BUKKA, and D. N. S. PERMANN. Can. J. Chem. **65**, 1420 (1987).

Partial deuteration of kaolinite #9 was accomplished by grinding lumps to a size of 9 μm and refluxing a D_2O suspension for periods ranging from 8 to 146 h. Photoacoustic infrared spectra were obtained and compared with previously published infrared and Raman spectra of undeuterated kaolinite and with infrared spectra of deuterated kaolinite. Data from this investigation indicate an extent of deuteration of about 20%; with the exception of the OD stretching bands near 2700 cm^{-1}, most of the bands observed are attributable to undeuterated kaolinite. The infrared band at 2718 cm^{-1}, which was previously assigned to uncoupled inner surface OD stretching, is the analogue of the 3684 cm^{-1} band observed in Raman and photoacoustic infrared spectra of undeuterated kaolinite. The results support assignment of the 3684 cm^{-1} band to uncoupled inner surface hydroxyl stretching vibrations.

K. H. MICHAELIAN, K. BUKKA et D. N. S. PERMANN. Can. J. Chem. **65**, 1420 (1987).

On a réalisé une deutération partielle de la kaolinite #9 en broyant des morceaux pour les réduire en poudre de 9 μm et en portant ensuite cette poudre en suspension dans le D_2O au reflux pour des périodes allant de 8 à 146 h. On a déterminé les spectres infrarouges photoacoustiques et on les a comparé avec les spectres rapportés antérieurement tant pour les régions infrarouges et Raman de la kaolinite non-deutérée que pour la région infrarouge de la kaolinite deutérée. Les résultats de cette comparaison indiquent que le niveau de deutération atteint est d'environ 20%; à l'exception des bandes d'élongation OD que l'on retrouve près de 2700 cm^{-1}, la plupart des bandes observées peuvent être attribuées à la kaolinite qui n'est pas deutérée. La bande infrarouge que l'on retrouve à 2718 cm^{-1} avait été attribuée antérieurement à la bande d'élongation du OD non-couplé de la surface interne; elle est analogue à la bande à 3684 cm^{-1} qui est observée dans les spectres Raman et infrarouge photoacoustique de la kaolinite non-deutérée. Les résultats suggèrent que l'on doit attribuer la bande à 3684 cm^{-1} aux vibrations de l'élongation de l'hydroxyle non-couplé de la surface interne.

Introduction

Infrared spectra of kaolinite, a common dioctahedral layer silicate of composition $Al_2Si_2O_5(OH)_4$, and its deuterated analogue have been reported by a number of authors (1–9). For well-crystallized samples, there is a general consensus (4–7, 9) that the four OH stretching bands at 3620, 3651, 3669, and 3695 cm^{-1} are shifted to 2675, 2698, 2710, and 2725 cm^{-1} respectively upon deuteration. These frequencies yield an average value of 1.354 for the ratio $\nu(OH)/\nu(OD)$. Deuteration experiments have also played an important role in the assignment of the hydroxyl stretching frequencies to particular OH groups in kaolinite; the comparative ease with which the three high frequency bands are shifted led to their assignment to inner surface hydroxyls, whereas the 3620 cm^{-1} band was attributed to the less readily exchanged inner hydroxyl groups (5). (A description and illustration of the different types of hydroxyl groups in kaolinite is given in ref. 4.)

Despite the common belief that kaolinite possesses four hydroxyl stretching bands, it is now known that a fifth band exists. Raman spectra of kaolinite #9 obtained in our laboratory (10) and elsewhere (11), Georgia kaolinite (11), and Keokuk kaolinite (12), all contain a band at approximately 3684 cm^{-1} in addition to four bands at frequencies corresponding to those in the infrared. Moreover, we have recently shown (13)[1] that the 3684 cm^{-1} band is active in the photoacoustic infrared spectrum of kaolinite. Thus it is firmly established that undeuterated kaolinite (kaolinite-H) has OH stretching bands at 3620, 3651, 3669, 3684, and 3695 cm^{-1}. Possible origins of the 3684 cm^{-1} band have been discussed previously (10), and it is of interest to observe the corresponding frequency for deuterated kaolinite (kaolinite-D) using infrared and (or) Raman spectroscopy so as to establish the correct assignment of this band.

[1]J. C. Zwinkels, J. C. Donini, and K. H. Michaelian. Paper in preparation.

In the present study, photoacoustic (PA) infrared spectra of partially deuterated kaolinite #9 have been obtained in the infrared spectral region between approximately 250 and 10 000 cm^{-1}. Because the samples studied were only partially deuterated, the spectra are generally quite similar to that of kaolinite-H. Nevertheless, the region near 2700 cm^{-1} does contain several OD stretching bands, which arise from deuterated kaolinite: in particular, bands at 2675 cm^{-1} and 2718 cm^{-1} are well defined in spectra of samples that were subjected to the exchange reaction for a prolonged time. As is discussed below, observation of the 2718 cm^{-1} band is consistent with its previous assignment (9) to uncoupled inner-surface hydroxyl vibrations.

Experimental

D_2O was purchased from MSD Isotopes, and had a reported isotopic purity of 99.8 at.% deuterium. Kaolinite #9, from Mesa Alta, New Mexico, U.S.A., was obtained from Ward's Natural Science Establishment, Inc.; the purity of this clay was described previously (10). The large lumps provided were reduced to an average size of ~9 μm with a ball grinder.

The exchange reaction was carried out by refluxing a ~4% suspension of kaolinite in D_2O for extended periods of time. The reaction mixture was contained in a round bottom flask isolated from atmospheric moisture by means of a drying tube filled with Drierite. Portions of kaolinite were withdrawn from the flask at 8, 24, 50, 74, 100, and 146-h intervals. These deuterated samples were dried several hours before their spectra were recorded.

Photoacoustic (PA) infrared spectra were obtained using an evacuable Bruker 113V Fourier transform infrared spectrometer and a Princeton Applied Research Corporation photoacoustic cell and preamplifier. The use of this equipment in the mid-infrared (15) and near-infrared (16) regions has been discussed previously. Far-infrared spectra were obtained using the same procedure as that for the mid-infrared, except that a 3.5-μm Mylar beamsplitter was used instead of the standard Ge/KBr beamsplitter. A CsI window was used on the PA cell for all spectral regions. Typical 4 cm^{-1} resolution spectra were obtained by coadding 500 interferograms. To improve the signal-

For personal use only.

to-noise ratio in the mid-infrared region, a number of spectra were recorded at a specific interferometer mirror velocity and subsequently averaged; results for several velocities were then averaged to produce the final spectrum.

Results and discussion

OH/OD stretching region

Spectra of two partially deuterated samples of kaolinite #9 have been chosen to illustrate typical results. Figure 1 shows the OD stretching region of spectra obtained for samples exchanged for 8 and 100 h, while Fig. 2 displays the OH stretching bands in the same spectra. Band positions are summarized in Table 1.

Spectral characteristics of the isotopic exchange

Two observations indicate the relatively slow progress of the exchange reaction. First, comparison of the intensities in the OD region (Fig. 1) or in the OH region (Fig. 2) reveals little difference between the two samples; secondly, the amount of exchange estimated from the relative intensities of the OD and OH bands and the assumption that the absorption coefficient per OH group is approximately twice that per OD group (9) shows a slight increase from 18% at 8 h to 22% after 100 h. It can be noted here that most previous deuteration studies included intercalation (expansion) of the kaolinite, which makes the inner surface hydroxyls more accessible, or hydrothermal treatment of synthetic kaolinite. These procedures appear to effect exchange more readily than the method used in the present work, and can lead to a much higher proportion of deuterated kaolinite.

As deuteration proceeds, definition of the individual bands near 2700 cm^{-1} becomes progressively more complete. Initially one observes a weak, rather broad, featureless band centred at ~2700 cm^{-1}. After several hours a significant amount of exchange has occurred, particularly for the inner surface hydroxyl groups. Thus the lower curve in Fig. 1, obtained for a sample refluxed 8 h, shows a broad band centred near 2700 cm^{-1} with several barely identifiable features superimposed. After approximately two days, the exchange has apparently proceeded almost as far as is possible by this method, and one obtains a spectrum similar to the upper curve in Fig. 1. It can be seen that the features are more well developed, although the individual bands still overlap more than in the OH stretching region. This lack of definition appears to be characteristic of the OD stretching region in spectra of deuterated natural kaolinites (4–7, 9).

The 2675 cm^{-1} band in Fig. 1 is intensified relative to the other bands after prolonged deuteration. The counterpart of this band in the spectrum of kaolinite-H falls at 3620 cm^{-1} (Table 1). Thus, our results are consistent with the conclusion of Ledoux and White (5) that the 3620 cm^{-1} band arises from hydroxyls that are less readily exchanged, i.e., inner hydroxyl groups.

Comparison of Fig. 1 with previously published (4–7) infrared spectra of deuterated kaolinite reveals a significant difference with regard to the selectivities of the exchange reactions. When kaolinite is intercalated prior to deuteration, the inner surface hydroxyl groups become much more accessible to the D_2O molecules; it is for this reason that these OH groups are first replaced by OD groups. In contrast, the inner hydroxyls are situated in such a way (Fig. 1, ref. 4) that they may not be readily approached, even by small molecules. Because of this situation, deuteration of intercalated kaolinite readily shifts the inner surface hydroxyl bands at 3651, 3669, and 3695 cm^{-1} to 2691, 2706, and 2725 cm^{-1} respectively (cf. Table 1). On the other hand, the reflux exchange reaction used in the current investigation affects the hydroxyl groups approximately equally, with only a slight preference for exchange of inner surface hydroxyls (Fig. 1).

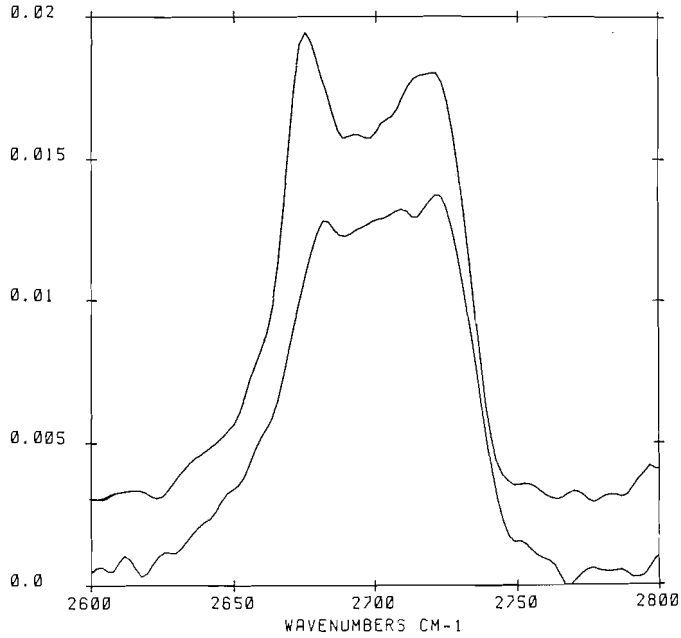

FIG. 1. OD stretching region of PA spectra of partially deuterated kaolinite #9; spectra have been baseline-linearized and smoothed. Lower curve: coaddition of 11 500-scan files; exchange reaction time 8 h. Upper curve: average of 3 coadditions (each corresponding to a different mirror velocity) of 10 500-scan files; reaction time 100 h. Spectra are displaced vertically for clarity.

Assignment of the OH/OD stretching bands

Following the convention of Miller and Oulton (17), the

TABLE 1. Effect of deuteration on the OH stretching bands of kaolinite

Band	ν/cm^{-1} Kaolinite-H[a,b]	ν/cm^{-1} Kaolinite-D[a]	$\nu(OH)/\nu(OD)$
D	3620	2675	1.353
C	3651	2691	1.357
B	3669	2706	1.356
A′	3684	2718	1.355
A	3695	2725	1.356

[a]Infrared data (this work).
[b]Raman data (ref. 10).

four principal maxima in Fig. 2 are designated D, C, B, and A (Table 1); in agreement with our previous practice (10), the 3684 cm^{-1} band will be referred to as band A′ in the following discussion.

We have previously noted (16) that the PA spectrum of kaolinite has an intensity distribution somewhat different than that in transmission or diffuse reflectance spectra. These differences will be discussed in more detail elsewhere (19); the important point that should be mentioned here is that band A′ is weakly active in the PA spectrum, giving rise to a shoulder in Fig. 1*a* of ref. 16 and a less prominent change of slope in Fig. 2 in this paper. (Band A′ is clearly visible after deconvolution of PA spectra of kaolinite (13).) Different kaolinite samples were employed in these investigations; the relative intensity of band A′ in the PA spectrum thus appears to be sample dependent. Nevertheless, its PA activity facilitates its observation in spectra of weakly deuterated kaolinite.

The OD stretching region of the PA infrared spectrum of partially deuterated kaolinite #9 contains well-defined bands at 2675 and 2718 cm^{-1} (Fig. 1, upper curve). In addition, three weak, barely identifiable features were observed at approximately 2691, 2706, and 2725 cm^{-1} for several samples exchanged for longer periods. These band positions and their correlation to kaolinite-H frequencies (4, 5) are given in Table 1. As mentioned above, identification of the bands at 2675, 2691, 2706, and 2725 cm^{-1} as bands D, C, B, and A, respectively, is generally accepted. On the other hand, assignment of the 2718 cm^{-1} band requires further analysis.

As shown in Table 1, the 2718 cm^{-1} band in the PA spectrum of kaolinite-D corresponds to the 3684 cm^{-1} frequency (band A′) for kaolinite-H. These frequencies yield a $\nu(OH)/\nu(OD)$ ratio of 1.355, in close agreement with the values calculated for the other four bands.

The only previous observation of band A′ in spectra of kaolinite-D was reported by Rouxhet *et al.* (9) for both synthetic and natural kaolinites. Spectra of synthetic samples, in which the degree of deuteration ranged from a few per cent up to 73%, showed a band at 2714 cm^{-1} for isotopically dilute kaolinite-D, which is replaced by bands at 2708 and 2723 cm^{-1} when the deuteration is more complete. This led to the reasonable conclusion that the 2714 cm^{-1} band arises from uncoupled inner surface OD stretching vibrations; when these vibrations are coupled at higher concentrations, the antisymmetric and symmetric vibrations at 2708 and 2723 cm^{-1} are observed instead. In other words, band A′ is due to the uncoupled vibration, whereas bands A and B originate from the coupled vibrations.

The results of the present deuteration study support the conclusions of Rouxhet *et al.* (9), so far as the existence of

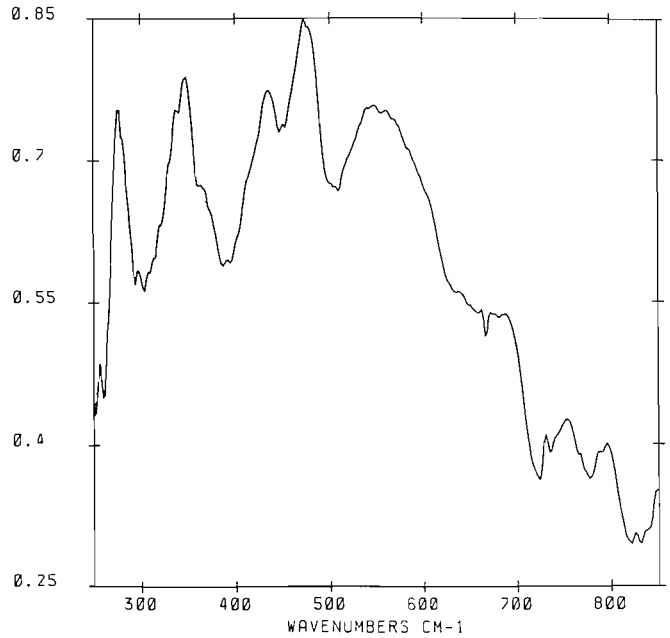

FIG. 3. Far infrared PA spectrum of partially deuterated kaolinite #9 merged from two 1000-scan spectra, each obtained at a different mirror velocity. Exchange reaction time 100 h.

band A′ has been confirmed in spectra of weakly deuterated kaolinite. As mentioned above, the extent of exchange realized in the present investigation is not very high; therefore, we have no data that verify that band A′ is *replaced* by bands A and B when the degree of deuteration is high. It is to be expected that spectra of highly deuterated kaolinite #9, or other kaolinites, would confirm the earlier observations (9) for synthetic kaolinite. Results of both the current study and previous investigations suggest, however, that it may be difficult to achieve a sufficient degree of deuteration for a natural kaolinite to verify this conclusion.

The activity of band A′ in Raman spectra of undeuterated kaolinite (10–12), which suggests that uncoupled inner surface hydroxyl vibrations occur even in the absence of isotopically dilute species, points to the need for a Raman investigation of kaolinite-D. Several Raman spectra of partially deuterated kaolinite were recorded in our laboratory in conjunction with the present infrared study; although the OH stretching bands were readily visible in the Raman spectra, the OD bands were too weak to be detected. Successful observation of the Raman bands near 2700 cm^{-1}, the need for which has been mentioned previously (11), is anticipated to provide further evidence confirming the conclusions of Rouxhet *et al.* (9).

Lattice vibration region

The kaolinite bands below 2000 cm^{-1} arise primarily from vibrations involving the heavier atoms (Si, O, and Al) in the lattice. Nevertheless, some participation of the lighter atoms in several vibrations is implied by earlier deuteration studies (2, 8). For simplicity, the region from 250 to 2000 cm^{-1} will be referred to as the lattice vibration region in the present discussion.

Results for the far-infrared region are shown in Fig. 3 and summarized in Table 2. Ten bands have been identified in the low frequency (~250–800 cm^{-1}) region of the PA spectrum of partially deuterated kaolinite; comparison of these frequencies with those from our earlier diffuse reflectance study of undeuterated kaolinite (18) shows that the two sets of frequencies are

substantially the same in the common region up to 700 cm^{-1}. (The weaker bands in the diffuse reflectance spectrum have been omitted from Table 2 because they are not identifiable in the slightly noisier PA spectrum in Fig. 3.) This similarity arises because of the relatively small percentage of deuteration, as well as the fact that many of the bands (e.g. those at ~434, 472, 545, 701, and 797 cm^{-1} (2)) are shifted by only a few cm^{-1}, even when the degree of deuteration is high.

In the remainder of the lattice vibration region, bands of medium to strong intensity were observed at 918, 939, 1016, 1042, and 1117 cm^{-1}. These frequencies agree within a few cm^{-1} with those in transmission spectra of kaolinite-H, again presumably because of the relatively small degree of deuteration. According to familiar assignments of the spectrum of undeuterated kaolinite (14), the first two bands are due to AlOH bending vibrations, while the latter three arise from SiO stretching. In addition to these five bands, three weak bands at approximately 1637, 1823, and 1933 cm^{-1} were observed. The first band may indicate the presence of a small amount of H_2O, while the latter two can be assigned to combination transitions involving the strong bands at lower frequencies.

Near-infrared region

Near-infrared (nir) spectra of layer silicates typically display only a few bands. For kaolinite, these bands are due to combination transitions involving various OH stretching vibrations and an AlOH bending mode, or to overtones of the OH stretches. Thus one expects substantial changes in this region when kaolinite-H is converted to kaolinite-D.

The nir spectra of partially deuterated samples of kaolinite #9 obtained in this investigation display all of the bands observed previously (16) for international kaolinite; in addition one new band, presumably attributable to the isotopic exchange, is present. The bands reported in our earlier work are situated at 4526, 4620, 7065, and 7160 cm^{-1}. The first two arise from combination of bands D and A with the 915 cm^{-1} AlOH bending vibration, while the latter two frequencies are assigned to overtones of D and A, respectively. The overtone frequencies suggest (16) anharmonicities of ~100 cm^{-1} for the OH stretching vibrations. Using this value and the observed fundamental OD stretching frequencies (Table 1), one predicts that the overtones of the OD stretching vibrations will occur near 5200 cm^{-1}: this is, in fact, the approximate frequency of the weak new band in the nir spectrum of partially deuterated kaolinite. Therefore it is logical to conclude that this broad band is due to overtones of several of the OD stretching vibrations in kaolinite-D.

Conclusions

Partial conversion of kaolinite #9 to its deuterated form by refluxing the coarsely ground clay in D_2O for several days is described in this paper. Photoacoustic infrared spectra of samples exchanged for up to 146 h indicate that the degree of deuteration is of the order of 20%; consequently, the spectra resemble those of undeuterated kaolinite rather closely, except that several OD stretching bands near 2700 cm^{-1} are identifiable.

In the OD stretching region, a band at 2718 cm^{-1} was observed, in agreement with previously published data for partially deuterated synthetic and natural kaolinites. This band is the analogue of the 3684 cm^{-1} band recently observed in Raman and photoacoustic infrared spectra of undeuterated kaolinite. The most straightforward interpretation of both current and published data is that the 3684 cm^{-1} band arises from an uncoupled inner surface hydroxyl stretching vibration, whereas the bands at 3669 and 3695 cm^{-1} (2706 and 2725 cm^{-1} for deuterated kaolinite) are, respectively, due to the corresponding antisymmetric and symmetric coupled vibrations.

Electroionization study of ethane: ionization and appearance energies, ion-pair formations and negative ions

PIERRE PLESSIS AND PAUL MARMET

Herzberg Institute of Astrophysics, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received October 9, 1986

PIERRE PLESSIS and PAUL MARMET. Can. J. Chem. **65**, 1424 (1987).

Threshold region ionization efficiency curves of ethane, of all singly charged fragments consisting of at least one carbon atom, and of $C_2H_5^{2+}$ and $C_2H_3^{2+}$ are presented and analysed. An energy filtered monoenergetic electron beam apparatus capable of producing very high signal-to-noise ratio data was used to study these ions. The C_2H_6 ionization energy is evaluated to be 11.57 ± 0.02 eV and structures due to competition with $C_2H_4^+$ fragment production are observed at higher energy in the $C_2H_6^+$ curve. As a result of the high apparatus sensitivity several of the measured appearance energies are lower (some by several eV) than previously reported. $C_2H_3^+ + H^-$, $CH_3^+ + CH_3^-$, and $C_2H_5^{2+} + H^-$ ion pair formations are observed. The $C_2H_5^+ + H^-$ ion pair formation, previously reported by several studies, is shown to be obscured by the isotopic $C_2H_4^+$ fragment signal.

PIERRE PLESSIS et PAUL MARMET. Can. J. Chem. **65**, 1424 (1987).

Les régions du seuil des courbes d'efficacité d'ionisation d'éthane, de tous les fragments simplement ionisés composés d'au moins un atome de carbone, et du $C_2H_5^{2+}$ et $C_2H_3^{2+}$, sont présentées et analysées. Ces ions, produits par bombardement avec un faisceau d'électrons monoénergétiques, sont étudiés avec un montage qui permet d'accumuler des données de très grand rapport signal sur bruit. L'énergie d'ionisation du C_2H_6 estimé à 11,57 ± 0,02 eV et des structures, causées par un mécanisme de compétition avec la production du $C_2H_4^+$, sont observées à plus haute énergie dans la courbe du $C_2H_6^+$. La haute sensibilité de l'appareil a permis de mesurer des seuils d'apparition à des énergies inférieures, quelques uns par plusieurs eV, aux valeurs des études antérieures. Les formations de paires d'ions $C_2H_3^+ + H^-$, $CH_3^+ + CH_3^-$ et $C_2H_5^{2+} + H^-$ sont observées. Il est démontré que la formation de paires d'ions $C_2H_5^+ + H^-$, rapportée par des travaux précédents, est masquée par l'isotope du fragment $C_2H_4^+$.

1. Introduction

In this paper the onset region electroionization efficiency (EIE) curves for ethane and all fragments composed of at least one carbon atom are presented and analysed. These curves have very high signal-to-noise ratio and have been obtained using an energy filtered monoenergetic electron beam. Ethane's ground state configuration is generally accepted as being $(1a_{1g})^2(1a_{2u})^2(2a_{1g})^2(2a_{2u})^2(1e_u)^4(3a_{1g})^2(1e_g)^4$, $^1A_{1g}$ for the staggered D_{3d} symmetry (1). The ionization and appearance curves of this molecule and its fragments have been studied considerably by photon and electron impact techniques (2, 3), but until now only Suzuki and Maeda (4) have studied this gas by a monoenergetic electron beam method. The present work shows a great improvement in the electron impact data for the ethane ions. Previous studies of CH_4 (5), C_2H_2 (6), C_2H_4 (7), and other atoms and molecules have clearly shown that our instrument is capable of producing high resolution data having very high signal-to-noise ratio, which yield more accurate threshold energies and the observation of new structures. This article deals with the initial threshold region of each curve. New features have been observed in the region up to 10 eV above threshold in each curve and these will be the subject of another paper (manuscript in preparation).

2. Apparatus and method

The apparatus is described in greater detail elsewhere (5). The ions are produced by intersecting electron and molecular beams. A large quadrupole mass filter provides the mass discrimination. The transmitted ions are detected by a dynode electron multiplier and counted individually as a function of the electron beam energy. Data acquisition is computer controlled and fully automated. The electron beam is produced by two 127° cylindrical selectors in series capable of giving a current of 10^{-8} A for an energy distribution of 30 meV full width at half maximum (FWHM). The high transmission characteristics of the mass filter combined with an efficient detection system allows for high counting rates (>10^6/s). Therefore, with integration times ranging from 100 to 200 h, electroionization efficiency curves of very high signal-to-noise ratio (>10^4) can be obtained. Energy calibration of each curve was done periodically (typically every 24 h) using the intense narrow threshold structure of argon (15.760 eV). The energy drift of the apparatus, after an initial stabilizing period of 2 days, was usually less than 10 meV per 24 h. At energies above 19 eV photon and (or) metastable neutral particle signal could be detected. This was done by taking data with the quadrupole mass filter adjusted so that no ions are transmitted. The stated purity of the ethane gas used was 99.96%. The gas pressure just outside the ion source region was generally maintained near 10^{-6} Torr. The pressure inside the ion source where the gas is introduced is approximately one to two orders of magnitude higher. Non-linear effects as a function of pressure, attributed to ion–molecule reactions, were seen in the threshold region curves of some fragment ions by comparing data taken at different pressures.

Structures in some of the threshold region curves were made more evident by taking the first derivative or by filtering the data with a specialized Fourier filtering technique (8–10) whose transmission factor for the mth frequency component is given by

$$[1] \quad T_{m,S} = 1 - \left(\cos\frac{\pi m}{N}\right)^{2S}$$

S is a parameter controlling the amount of low frequency component that is eliminated and N is the number of channels used. For the special case of $S = 1$ and eq. [1] multiplied by -1, the result is identical to the second derivative. It has been shown qualitatively that for small values of S ($S \leq 100$) the result is similar to the second derivative but contains a larger amount of low frequency components (11). In order to have direct resemblance with the second derivative, the vertically inverted filtered curves are presented in this paper.

2.1. *Factors affecting the shape of thresholds*

Ionization and appearance thresholds of ethane or of any other molecules are not as sharp as one would like. This can be attributed to various factors:

(*1*) The energy spread of the electron beam produces of course some broadening of the threshold structure. In the present work this is not the main cause since this contribution is only about 30 meV.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

(2) There is also a doppler broadening due to the velocity distribution of the molecules, i.e. translational energy of the molecules. This effect makes a noticeable contribution (as much as 50 meV) in the case of low energy electron beams colliding with light molecules such as hydrogen, but is negligible when the mass of the particle is greater than about 20.

(3) Another cause of broadening of ionization or appearance thresholds results from the electron impact on thermally excited molecules. If the target molecules are previously vibrationally or rotationally excited, such vibrational or rotational quanta can be added to the electron energy so that the total energy reaches the threshold energy even if the electron energy alone is still slightly below the ionization or appearance threshold. In such a case, ions appear below the true threshold. This is easily observed experimentally in that the ionization thresholds of atoms (having no vibrational or rotational quanta) are sharper than those of molecules.

(4) It is also quite generally observed that the ionization thresholds of molecules show a longer and longer tail below the threshold as the number of atoms in the molecules increases. The importance of the thermal effect at a given temperature thus seems to be proportional to the number of atoms in the molecule. This is easily explained by the fact that larger molecules have a greater number of degrees of freedom and consequently possess a larger amount of internal energy which can contribute to ionization or to dissociative ionization.

(5) There is finally another very important factor which can lead to the absence of a clear threshold and this is the molecular structure of the molecule itself. Let us consider the case of a molecule for which the ionization mechanism is related to multiple structures existing just above the ionization threshold. This can be, for example, a series of vibrational states that are not quite resolved due to thermal effects as explained above. If, for the first five states, the relative ionization cross section increases by a factor of ten when one passes from one to the next, the four first states will not be clearly visible in the data and might be undistinguishable from pure thermal broadening effects. In such a case the ionization threshold will appear as a vertical ionization potential and not the adiabatic. However, when one has some knowledge of the structure of the molecule being studied, this information can be taken into acount in order to provide some guidance on the location or the shape of the ionization threshold.

3. Results and discussion

The ionization and appearance energies measured in this work are listed in Table 1 with those of other studies. The errors associated with our values are estimated by taking into account the error in calibration (±0.01 eV) and the estimated precision with which a threshold energy can be evaluated. This depends on the sharpness of the threshold structure and the statistical fluctuation in that region. The expression "threshold" in this paper refers to the true threshold of a reaction in which all products are in their ground state and possess no kinetic energy.

Activation energy may exist in some cases. Quantum mechanically, the probability for a process to occur at threshold can be many orders of magnitude smaller than when activation energy is present. Our instrument can detect cross sections as much as 10^{10} times smaller than some other cross sections, therefore it is possible to measure processes which are less probable by as much as ten orders of magnitude than those that are easily observed. It is this extreme sensitivity that allows us to measure such very low probability thresholds. This is illustrated by the fact that for most of our data it is possible to observe the formation of fragment ions at an electron energy which is so low that energy conservation according to thermochemistry does not allow the existence of any appreciable kinetic or internal (electronic, rotational, or vibrational) energy of the fragments. There is of course some curvature at threshold

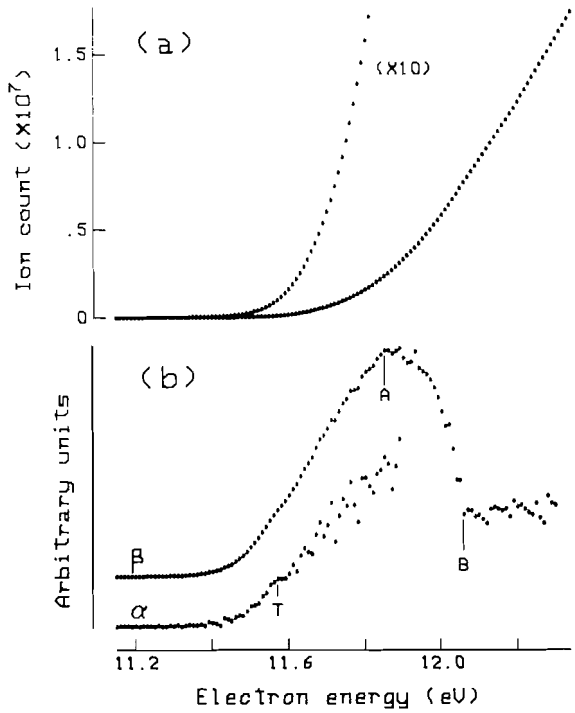

FIG. 1. (*a*) $C_2H_6^+$ EIE threshold region curve (10 meV/point). Resolution ≈ 30 meV FWHM. (*b*) Above curve high pass filtered with $S = 5$ (curve α) and $S = 50$ (curve β).

which is caused by the various phenomena described in section 2.1 and this has been taken into account in determ ining the position of the thresholds.

One must also recall that before a collision, one has an electron which is independent of the target molecule. Later, during the interaction of the electron with the target, there can be only quantum transitions in which the number of charges is conserved. Therefore only negative ion states are involved where these correspond to discrete states (Feshbach resonances), shape resonances, or continua. When a transition occurs, a new state of the negative ion complex is formed. This state may be repulsive leading to autoionization, dissociation, or photon emission. After autoionization or dissociation has occurred, which takes a relatively long time since slow particles are involved, one may again deal with independent neutrals and (or) ions. Finally, it must be realized that the number of charges of the negative complex is not the same as the number of charges of the initial neutral molecule, and therefore the states differ in these two cases. Consequently, by electron impact, the states involved are not the states of the neutral molecule as in photoionization. For this reason the negative ion complex $C_2H_6^{-*}$ is included in the reactions given below.

3.1. $C_2H_6^+$

The raw EIE threshold curve of ethane, presented in Fig. 1(*a*), shows fairly uniform curvature in the onset region making it difficult to accurately determine the ionization energy. The absence of any clear break at the ionization threshold can be attributed to two main factors: thermally excited vibrational states of ethane (hot bands) which produce ions below the true adiabatic threshold (such hot bands have been observed in C_2H_2 (6) and C_2H_4 (7)), and a low probability for going from the ethane ground state to the ion ground state (1). However, filtering the above curve with a high pass filter does reveal some interesting features. Previous studies have shown that an

TABLE 1 (*concluded*)

$C_2H_6 \rightarrow$	Present study	Others	
		Method[a]	Results
$C_2H_5^{2+} + H^-$	31.60±0.15		
$C_2H_5^{2+} + H$	32.3 ±0.2	EI	32.0±1.5 (14), 31.4 (15)
$C_2H_3^{2+} + H_2 + H$	35.5 ±0.3	EI	34.5 (15)

[a]Method: EDD, energy distribution difference; EI, electron impact (non-monoenergetic); EM, electron monochromator; PES, photoelectron spectroscopy; PIMS, photoionization mass spectrometry; RPD, retarding potential difference; RPI, resonance photoionization; TC, thermochemically. Data used to determine TC values are given in Table 4.

[b]Upper limit for this appearance energy.

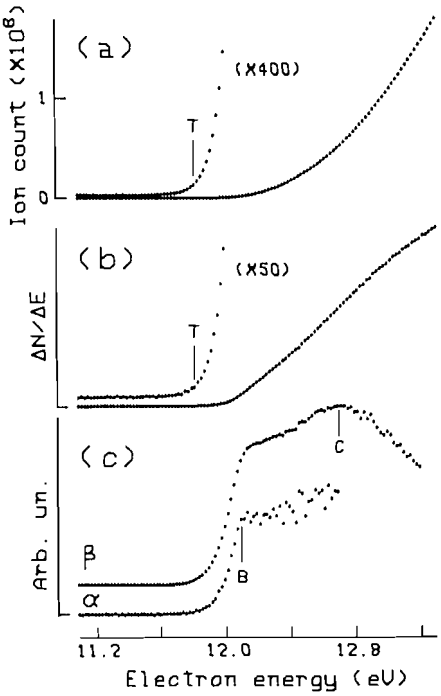

FIG. 2. (*a*) $C_2H_4^+$ appearance curve (20 meV/point). (*b*) First derivative of curve (*a*). (*c*) Curve (*a*) high pass filtered with $S = 2$ (curve α) and $S = 30$ (curve β).

TABLE 2. Structures observed in the $C_2H_6^+$ and $C_2H_4^+$ curves

Ion	Structure	Energy (eV)	Interpretation
$C_2H_6^+$	**T**	11.57	Ionization energy $(1e_g)^{-1}$
	A	11.85	Competition with $C_2H_4^+$(**T**) + H_2
	B	12.06	Competition with $C_2H_4^+$(**B**) + H_2
$C_2H_4^+$	**T**	11.81	Appearance energy ($C_2H_4^+ + H_2$)
	B	12.09	
	C	12.70	

ionization threshold often manifests itself by an initial maximum in the filtered curve (5–7). The weak but statistically valid local maximum at 11.57 ± 0.02 eV (structure **T**) of curve α of Fig. 1(*b*) corresponds very likely to the ionization energy of ethane and is in excellent agreement with the values reported by most photoelectron spectroscopy works (see Table 1). No other feature is observed below 11.57 eV in our filtered curves.

Curve β ($S = 50$) of Fig. 1(*b*), which contains a larger amount of low frequency components than curve α ($S = 5$),

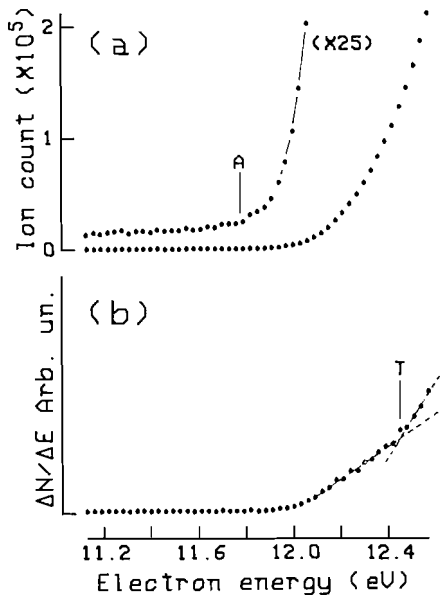

FIG. 3. (*a*) $C_2H_5^+$ appearance curve (30 meV/point). (*b*) First derivative of above curve.

increases gradually with energy up to 11.85 eV (structure **A**). The amplitude then diminishes at an increasing rate, stopping suddenly at 12.06 eV (structure **B**) where a distinct break is observed. The shape of curve β can be understood by comparing with the $C_2H_4^+$ fragment curves of Fig. 2. The initial $C_2H_4^+$ onset occurs at 11.81 ± 0.05 eV (structure **T**). The filtered $C_2H_4^+$ curve (α) shows that the rate of increase of the $C_2H_4^+$ signal rapidly reaches a maximum at 12.09 eV (structure **B**). The energies of structures **T** and **B** of the $C_2H_4^+$ curve correspond reasonably well with those of structures **A** and **B** of the $C_2H_6^+$ curve, respectively. These values are recorded in Table 2. Also, the shape of these two curves in the region between the indicated structures resembles the inverse of the other. This comparison indicates the presence of a competitive mechanism between the $C_2H_6^+$ and the $C_2H_4^+$ production channels. Structures **A** and **B** of the $C_2H_6^+$ curve are therefore attributed to the onset of the $C_2H_4^+$ fragment production. This fragmentation channel is highly probable. It is observed that the $C_2H_4^+$ peak height intensity is more than twice that of the $C_2H_6^+$ peak for 35 eV electrons.

3.2. $C_2H_5^+$

The $C_2H_5^+$ appearance curve of Fig. 3 shows an initial onset structure, **A**, at 11.76 eV with evidence of another structure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

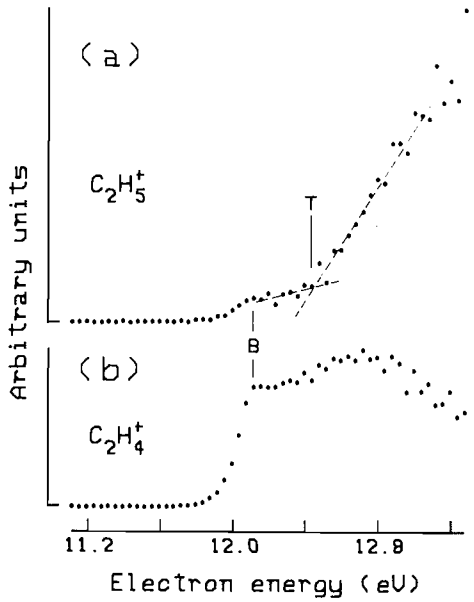

FIG. 4. (*a*) $C_2H_5^+$ appearance curve filtered using $S = 1$ (second derivative). (*b*) $C_2H_4^+$ appearance curve filtered using $S = 1$ (40 meV/point).

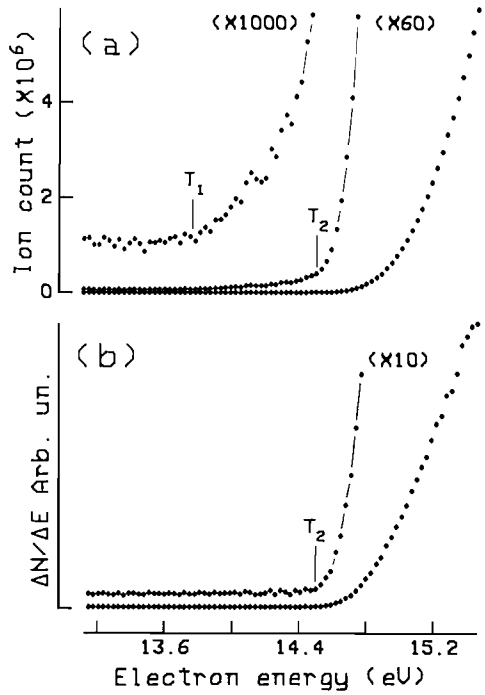

FIG. 5. (*a*) $C_2H_3^+$ appearance curve (30 meV/point). Ion pair formation is observed. (*b*) First derivative of above curve.

near 11.85 eV. This curve was taken at a reduced pressure (6×10^{-7} Torr) in order to minimize the effects of ion–molecule reactions which were relatively important at higher pressures. The energy of structure **A** coincides fairly well with the reaction energy of 11.69 ± 0.07 eV for the ion-pair formation

[2] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow C_2H_5^+ + H^- + e^-$

Values of 12.0 eV or greater are reported for this process (see Table 1) which are inconsistent with the above values.

In spite of the good agreement between our value of structure **A** and the above stated thermochemical value, it is uncertain that structure **A** corresponds to the onset of reaction [2]. The second derivative $C_2H_5^+$ curve, shown in Fig. 4(*a*), reveals a step-like feature near 12.09 eV (structure **B**). From thermochemistry the appearance energy for the ion–neutral process

[3] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow C_2H_5^+ + H + 2e^-$

is estimated to be 12.45 ± 0.07 eV (see Table 1). Feature **B** does not concur with the values of either reaction [2] or [3]. However, structure **T** at 12.45 ± 0.08 eV, seen in both the first and second derivative curves of $C_2H_5^+$ (Figs. 3(*b*) and 4(*a*), respectively), is in excellent agreement with the thermochemical value of process [3], indicating that this feature corresponds to the appearance threshold of the ion–neutral formation. This value is lower than most measurements for the onset of this reaction (Table 1).

No precise mechanism is known which can produce a distinct structure (**B**) between the thresholds of processes [2] and [3]. Figure 4 compares the $C_2H_5^+$ and $C_2H_4^+$ second derivative curves. It is observed that, in the range up to 12.45 eV, the two curves are similar except for the amplitudes. For the same source conditions the ratio of the $C_2H_5^+$ signal to the $C_2H_4^+$ signal at 12.1 eV is 0.02, which is precisely the isotopic concentration of $^{13}C^{12}CH_4^+$. It therefore appears evident that most if not all the signal below 12.45 eV is due to the mass 29 isotope of $C_2H_4^+$. If there is ion-pair production in this region it is much weaker than the $C_2H_4^+$ isotopic signal. It is probably this latter signal that the previous works measured near 12.0 eV.

3.3. $C_2H_4^+$

This fragment is by far the most abundant of the ethane ions at 35 eV (a table of the relative intensities will be published in another paper). The raw data $C_2H_4^+$ EIE curve is presented in Fig. 2(*a*). A weak slope has been subtracted to compensate for the ethylene impurity (0.03%) signal. An onset (**T**) is observed at 11.81 ± 0.05 eV. The same structure is more apparent in the first derivative curve (Fig. 2(*b*)). The high pass filtered curves of Fig. 2(*c*) reveal a clear break, **B**, at 12.09 eV and a broad maxima, **C**, at 12.70 eV. The energy of structure **T** agrees well with the energy of formation (11.846 ± 0.011 eV) of process

[4] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow C_2H_4^+ + H_2 + 2e$

and corresponds to the appearance energy of the $C_2H_4^+$ fragment. This interpretation is supported by the aforementioned comparison between the $C_2H_6^+$ and $C_2H_4^+$ curves where structures due to competition with $C_2H_4^+$ production are seen in the $C_2H_6^+$ curve starting from 11.85 eV (see Table 2). The previously reported values for this appearance energy, listed in Table 1, are all near 12.1 eV, coinciding very well with the energy of the steo like feature **B** of our filtered curve. It is probable that these studies lacked sufficient sensitivity to measure the $C_2H_4^+$ signal below 12.1 eV. The $C_2H_4^+$ fragment cross section increases significantly from 12.09 eV on. It is presently unclear what processes are associated with structures **B** and **C**.

3.4. $C_2H_3^+$

The $C_2H_3^+$ fragment appearance curve, presented in Fig. 5, shows evidences of two processes. A weak slope caused by ion–molecule reactions has been subtracted from the curve. The onset of the first process occurs at 13.76 ± 0.08 eV (structure T_1) and corresponds to the threshold of the ion pair formation

[5] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow C_2H_3^+ + H^- + H_2 + e$

This is in good agreement with the heat of reaction of 13.72 ±

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

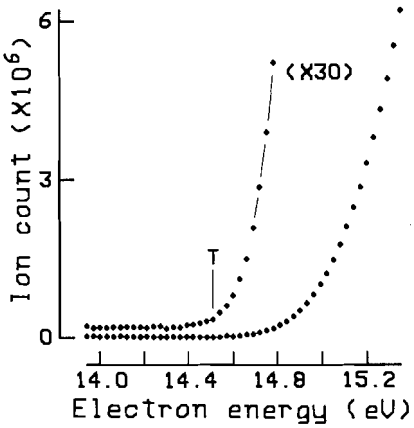

FIG. 6. $C_2H_2^+$ appearance curve (30 meV/point).

0.18 eV for this process. No other study reports observing this ion pair formation. The onset of the second process, indicated by $\mathbf{T}_2$, appears at 14.50 ± 0.04 eV. The first derivative curve (Fig. 5(*b*)) also clearly displays this feature which corresponds to the threshold of the ion–neutral process

[6] $C_2H_6 + e^- \rightarrow C_2H_6^{-}* \rightarrow C_2H_3^+ + H + H_2 + 2e^-$

Our value is in excellent agreement with the thermochemical value of 14.48 ± 0.18 eV for this process and compares well with Suzuki and Maeda's (4) value of 14.6 ± 0.1 eV and Chatham *et al.*'s (12) value of 14.5 ± 0.4 eV, but not with Selim's (13) value of 15.02 ± 0.02 eV. The 0.74 eV difference between $\mathbf{T}_1$ and $\mathbf{T}_2$ coincides very well with the hydrogen electron affinity (0.754 eV) and this supports the above interpretations of these two structures. The weak feature observed near 14.2 eV is probably due to statistical fluctuations.

3.5. $C_2H_2^+$

The $C_2H_2^+$ fragment EIE curve is shown in Fig. 6. A very weak slope, caused mainly by the $C_2H_2^+$ fragment signal of the ethylene impurity and by acetylene residual gas, was subtracted to render the baseline horizontal. The indicated structure **T**, at 14.5 ± 0.04 eV, corresponds very likely to the threshold of reaction

[7] $C_2H_6 + e^- \rightarrow C_2H_6^{-}* \rightarrow C_2H_2^+ + 2H_2 + e^-$

By comparing the values given in Table 1 it is seen that the above value concurs with the energy of formation of process [7] but is significantly lower than other measured values except for that of Chatham *et al.* (12) which has a large error. This discrepancy is indicative of the lack of sensitivity of these previous works.

3.6. C_2H^+

The appearance curve of this fragment (abundance: 0.63% of the $C_2H_4^+$ peak at 35 eV) presented in Fig. 7 shows a break at 22.4 ± 0.3 eV (structure **T**). The weak but long tail below this feature is attributed principally to the ethylene impurity and to the acetylene residual gas. Photon emission or metastable excited neutral particles also contribute to the signal with increasing intensity starting from about 19.7 eV. Structure **T** is associated with reaction

[8] $C_2H_6 + e^- \rightarrow C_2H_6^{-}* \rightarrow C_2H^+ + H + 2H_2 + 2e^-$

but because of the large discrepancy between the energy of this structure and the calculated heat of reaction for this purpose (19.4 ± 0.8 eV), it is doubtful that feature **T** corresponds to the

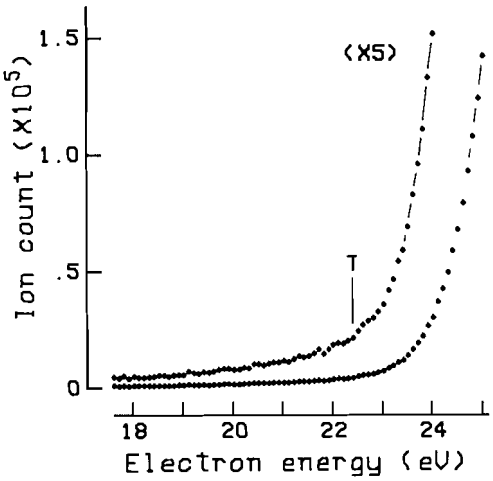

FIG. 7. C_2H^+ appearance curve (100 meV/point).

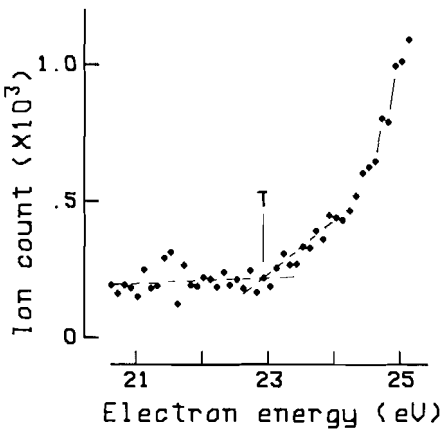

FIG. 8. C_2^+ appearance curve (100 meV/point).

minimum energy required to produce the C_2H^+ fragment. The genuine C_2H^+ signal may extend below 22.4 eV but is obscured by the signal produced by impurities. It is clear that if this is the case the C_2H^+ cross section below 22.4 eV is very small. At 22.4 eV it is likely that the products of reaction [8] possess excitation and (or) kinetic energy. Structure **T** is considered to be an upper limit for the C_2H^+ appearance energy. Previous results (Table 1) are several eV higher in energy.

3.7. C_2^+

Figure 8 presents the C_2^+ fragment appearance curve. A weak slope has been subtracted, caused by the factors given above for C_2H^+. Structure **T**, at 22.9 ± 0.3 eV, is associated with process

[9] $C_2H_6 + e^- \rightarrow C_2H_6^{-}* \rightarrow C_2^+ + 3H_2 + 2e^-$

and, for the same reasons that are given for C_2H^+, is considered to be an upper limit for the C_2^+ appearance energy. The value of 31.5 eV reported by Suzuki and Maeda (4) and Hipple (14) for this threshold is 8.6 eV higher than our value, indicating a severe limitation in the sensitivity of these measurements. There appears to be an increase in the C_2^+ cross section near 24.3 eV.

3.8. CH_4^+

An attempt was made to measure the appearance energy of the CH_4^+ fragment but, because of residual gases and gas impurities, no clear onset for this fragment could be observed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

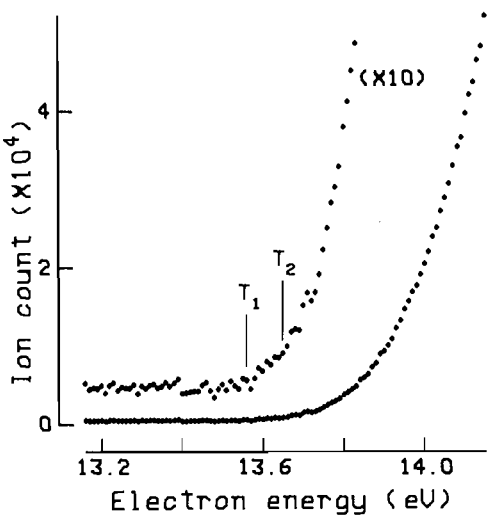

FIG. 9. CH_3^+ appearance curve (10 meV/point). Ion pair formation is observed.

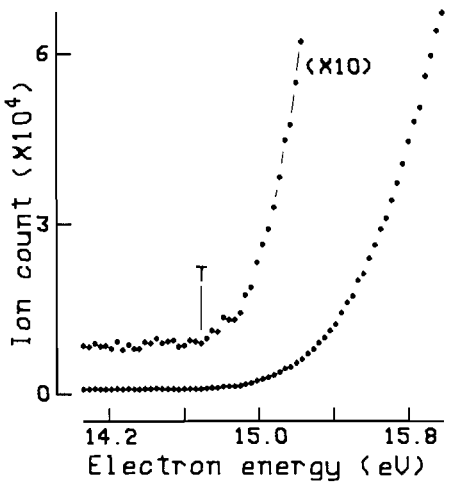

FIG. 10. CH_2^+ appearance curve (30 meV/point).

Suzuki and Maeda (4) report a value of 20.4 ± 0.3 eV for this threshold. No significant feature was seen at this energy in our curve and given that an ethane gas of higher purity was used in this work (99.96% as opposed to 99.7%), we suspect that impurities contributed significantly to their signal.

3.9. CH_3^+

The onset region of the CH_3^+ appearance curve presented in Fig. 9 has an initial break at 13.56 ± 0.04 eV and a second break at 13.65 ± 0.04 eV (structures $\mathbf{T}_1$ and $\mathbf{T}_2$, respectively). The energy difference between these two features is 0.09 eV which agrees very well with the CH_3 electron affinity of 0.08 ± 0.03 eV (see Table 4). Therefore it is probable that structures $\mathbf{T}_1$ and $\mathbf{T}_2$ correspond to the thresholds of reactions

[10] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow CH_3^+ + CH_3^- + e^-$

and

[11] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow CH_3^+ + CH_3 + 2e^-$

respectively. The respective energies of formation are 13.59 ± 0.05 and 13.67 ± 0.02 eV, in good agreement with our measured values. The electron affinity of 0.08 eV claimed by Suzuki and Maeda (4) for CH_3 is evidently much too large

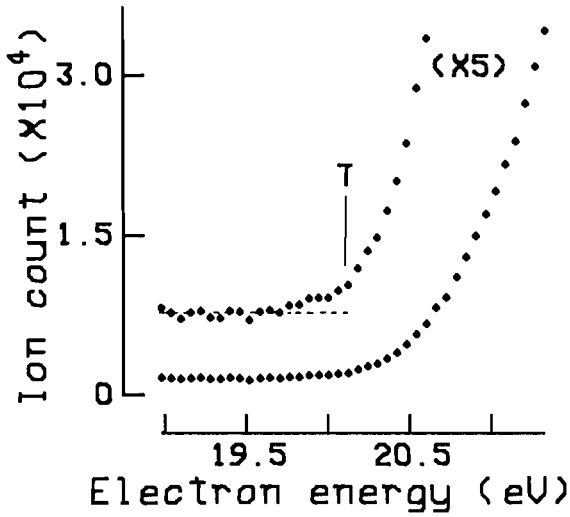

FIG. 11. CH^+ appearance curve (60 meV/point).

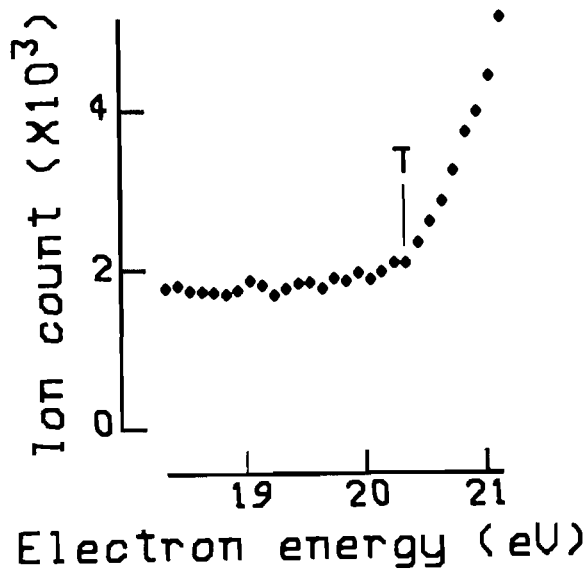

FIG. 12. C^+ appearance curve (100 meV/point).

(Table 1). The irregularities observed just above $\mathbf{T}_2$ are probably due to statistical scatter.

3.10. CH_2^+

The EIE curve of this fragment shown in Fig. 10 has a distinct onset at 14.69 ± 0.05 (structure **T**) which likely corresponds to the threshold of process

[12] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow CH_2^+ + CH_4 + 2e^-$

The calculated energy of formation for this reaction is somewhat lower (14.41 ± 0.05 eV) while the values of previous works listed in Table 1 are all more than 1.5 eV higher in energy. The CH_2^+ curve shows an increase in cross section near 14.9 eV.

3.11. CH^+

The CH^+ appearance curve of Fig. 11 has an onset energy of 20.10 ± 0.08 eV (structure **T**). The weak tail below this energy, starting from 19.7 eV, is due to photon emission and (or) to metastable excited neutral molecules or atoms. Structure **T** is associated with processes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

TABLE 3. Deduced double ionization energies (in eV)

Molecule	Ionization energy	
	Present study	Others
C_2H_3	30.0±0.4	29.6±0.3 (7), 29.1±0.5 (16), 29.9±0.3 (17)
C_2H_5	28.3±0.2	27.5±0.5 (16), 28.6±0.3 (17)

[13] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow CH^+ + CH_4 + H + 2e^-$

and

[14] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow CH^+ + CH_3 + H_2 + 2e^-$

which have energies of formation of 19.02 ± 0.02 and 19.03 ± 0.02 eV, respectively. Reaction [14] is the more probable process as it requires less hydrogen rearrangement. The discrepancy between these values and that of structure **T** leads us to consider 20.10 ± 0.08 eV to be an upper limit for the CH^+ appearance energy. Much higher values have been reported for this threshold (Table 1).

3.12. C^+

The C^+ EIE curve (Fig. 12) shows a relatively clear onset at 20.3 ± 0.2 eV. The weak tail below structure **T** is again due to the photon/metastable signal. Process

[15] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow C^+ + CH_4 + H_2 + 2e^-$

is the only one that can be associated with this feature even though its energy of formation is 18.645 ± 0.011 eV. The C^+ fragment intensity is very weak (abundance: 0.02% of the $C_2H_4^+$ peak at 35 eV) and the value of structure **T** is considered as an upper limit for this appearance energy. Previously reported values for this threshold are higher by more than 9 eV (Table 1) indicating the very limited sensitivity of these measurements.

3.13. Doubly charged ions

Electroionization efficiency curves of the $C_2H_5^{2+}$ and the $C_2H_3^{2+}$ fragments (respective abundances: 0.33% and 0.015% of the $C_2H_4^+$ peak at 50 eV) were obtained and these are shown in Figs. 13 and 14, respectively. A slope caused by the photon/metastable signal has been subtracted from each curve. The $C_2H_5^{2+}$ onset region shows evidence for two processes. Structures $\mathbf{T}_1$ and $\mathbf{T}_2$ at 31.60 ± 0.15 eV and 32.3 ± 0.2 eV, respectively, correspond to the threshold of the following respective reactions:

[16] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow C_2H_5^{2+} + H^- + 2e^-$

and

[17] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow C_2H_5^{2+} + H + 3e^-$

The ion pair process is measured here for the first time. The 0.7 eV difference between $\mathbf{T}_1$ and $\mathbf{T}_2$ is in good agreement with the hydrogen electron affinity (0.754 eV). Our value for the ion neutral process is in good agreement with that of Hipple (14) (32.0 ± 1.5 eV) but higher than the value reported by Jones *et al.* (15) (31.4 eV). Given that the ion pair formation is observed, it is unlikely that the $C_2H_5^{2+}$ threshold occurs at lower energy. Our value of 31.60 ± 0.15 eV for the threshold of reaction [16] yields a value of 28.3 ± 0.2 eV for the C_2H_5 double ionization energy. By comparison, Rabrenovic and Beynon's (16) and Cooks *et al.*'s (17) values of 19.1 ± 0.5 and 20.3 ± 0.3 eV, respectively, for the $C_2H_5^+$ to $C_2H_5^{2+}$

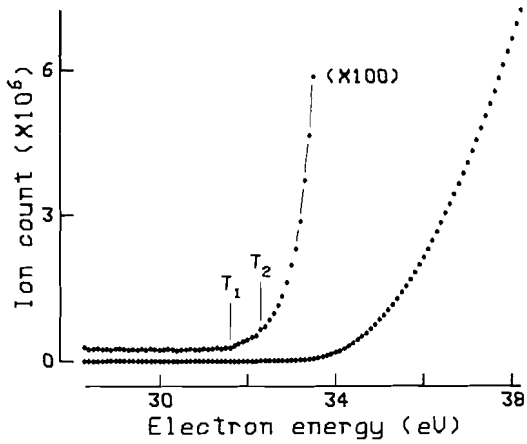

FIG. 13. $C_2H_5^{2+}$ appearance curve (100 meV/point). Ion pair formation is observed.

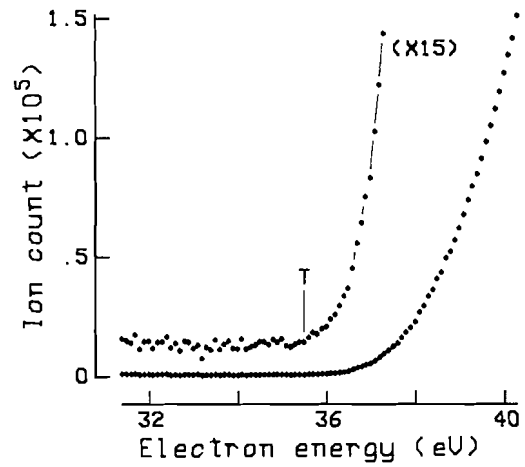

FIG. 14. $C_2H_3^{2+}$ appearance curve (100 meV/point).

ionization energy, combined with the ionization energy of C_2H_5 (8.39 ± 0.02, Table 4), give 27.5 ± 0.5 and 28.6 ± 0.3 eV, respectively, for the C_2H_5 double ionization energy. The above values are listed in Table 3.

The $C_2H_3^{2+}$ appearance energy is evaluated at 35.5 ± 0.3 eV, corresponding to the threshold of process

[18] $C_2H_6 + e^- \rightarrow C_2H_6^{-*} \rightarrow C_2H_3^{2+} + H + H_2 + 3e^-$

Jones *et al.* (15) reports a value of 34.5 eV for this threshold. A value of 30.0 ± 0.4 eV is deduced for the C_2H_3 double ionization potential which is in good agreement with the value of 29.6 ± 0.3 deduced from the work on ethylene (7) and also with the deduced values of Rabrenovic and Beynon (16) and Cooks *et al.* (17) (see Table 3).

Received August 20, 1986

GEORGE R. PETTIT, GORDON M. CRAGG, JUDITH POLONSKY, DELBERT L. HERALD, ANIMESH GOSWAMI, CECIL R. SMITH, CHRISTIAN MORETTI, JEAN M. SCHMIDT, and DAVID WEISLEDER. Can. J. Chem. **65**, 1433 (1987).

Rollinia mucosa (Annonaceae), known in primitive medical practices of Indonesia and the West Indies as a treatment for tumors, has been investigated employing the seeds from a South American variety and the murine P388 lymphocytic leukemia (PS) for bioassay. The principal antineoplastic constituent (PS, 28% life extension, at 0.25 mg/kg and ED_{50} 4.5×10^{-5} μg/mL) was found to be a new *bis*-tetrahydrofuran designated rolliniastatin 1. Structural elucidation of rolliniastatin 1 was accomplished by a combination of high resolution nuclear magnetic resonance (300 MHz), mass spectral, and X-ray crystal structure techniques.

GEORGE R. PETTIT, GORDON M. CRAGG, JUDITH POLONSKY, DELBERT L. HERALD, ANIMESH GOSWAMI, CECIL R. SMITH, CHRISTIAN MORETTI, JEAN M. SCHMIDT et DAVID WEISLEDER. Can. J. Chem. **65**, 1433 (1987).

Utilisant les graines d'une variété sud-américaine de la plante et la murine P388 de leucémie lymphocitaire (PS) pour des bioessais, on a étudié les propriétés de la *Rollinia mucosa* (Annonaceae), qui est connue dans les pratiques médicales primitives de l'Indonésie et des Antilles pour le traitement des tumeurs. On a trouvé que le principal constituant actif (PS, augmentation de vie de 28%, à 0,25 mg/kg et ED_{50} de $4,5 \times 10^{-5}$ μg/mL) est un nouveau bis-tétrahydrofuranne que l'on a appelé rolliniastatine 1. On a déterminé la structure de la rolliniastatine 1 en combinant les techniques de la résonance magnétique nucléaire à haute résolution (300 MHz), du spectre de masse et de la diffraction des rayons-X par des cristaux uniques.

[Traduit par la revue]

The Annonaceae (ca. 2,100 species) is composed of shrubs and trees found mainly in tropical regions. The genus *Rollinia* generally occurs in Central and South America, and *R. mucosa* (Jacq.) Vaill, also known as *Annona mucosa* (Jacq.), has been used for the primitive medical treatment of tumors in the West Indies and in Indonesia (2). To assess the potential of this plant in respect to potentially useful antineoplastic components, seeds of *Rollinia mucosa* were collected in French Guiana in 1979. The lipophilic extract of these seeds showed activity in the P388 lymphocytic leukemia system, and fractionation of this extract was guided by bioassay using the murine P388 system in vitro.

Extraction of *Rollinia mucosa* seed (600 g) with hexane afforded 136 g of oily extract from which rolliniastatin 1 was isolated by a series of chromatographic steps. Steric exclusion chromatography was followed by gradient elution chromatography on silica gel with hexane – ethyl acetate. Rolliniastatin 1 (1.75 g, 0.29% yield) was isolated as a wax, mp 81–83°C from acetone: $[\alpha]_{589}$ +25.2°, $[\alpha]_{578}$ +26.2°, $[\alpha]_{546}$ +30.1°, $[\alpha]_{436}$ +48.5°, $[\alpha]_{365}$ +76.70° (t = 28°C, c 1.03, CH_2Cl_2); uv λ_{max} (CH_3OH): 224 nm (log ε, 3.93) (α,β-unsaturated carbonyl; ir ν_{max} ($CHCl_3$): 3580, 3460 (OH), 2928, 2855, (C—H), and 1748 cm^{-1}; SO-SIMS (3), m/z 645 $[M + Na]^+$, 730 $[M + Ag]^+$; and SP-SIHRMS, m/z 623.4917 (calcd. for $C_{37}H_{66}O_7$ + H: 623.4887). In deuterioglycerol SP-SIMS (3) gave m/z 627 $[M + D]^+$, indicating three exchangeable protons.

Spectral characteristics suggested that rolliniastatin 1 was a member of a new class of bioactive *bis*-tetrahydrofurans ("acetogenins"), which include uvaricin (4*a*), rollinicin (4*c*), isorollicin (4*b*), rollinone (4*b*), desacetyluvaricin (4*d*), cherimoline (4*e*), dihydrocherimoline (4*e*), 14-hydroxy-25-desoxyrollinicin (4*f*), and, most recently, asimicin (4*g*). These compounds characteristically contain 37 carbons, and have a γ-lactone moiety (usually α,β-unsaturated) and two tetrahydrofuran rings with a long hydrocarbon chain attached.

The ^{13}C and ^1H nmr spectra (Tables 1 and 2), elaborated by COSY and heteronuclear correlation experiments, established the α,β-unsaturated γ-lactone moiety of rolliniastatin 1. The following features were documented by ^{13}C shifts: the carbonyl group at C-1 (δ 174.5, singlet), the double bond between C-2 (δ 131.1, singlet) and C-35 (δ 151.7, doublet), a δ 77.9 doublet for C-36, and a δ 19.1 quartet for the C-37 methyl group. A heteronuclear correlation experiment connected C-35 with a downfield proton at δ 7.16, and C-36 with another at δ 5.02. Chemical shifts reminiscent of fatty acids were observed: ^1H and ^{13}C signals (Tables 1 and 2) for C-32, C-33, and C-34, and for a number of nearly equivalent methylene groups.

A DEPT nmr experiment revealed eight ^{13}C doublets associated with oxygenated carbons (δ 69.9, 71.8, 74.0, 77.9, and four more δ 81.0–83.0). One of these is in the lactone ring, and three others bear hydroxy groups that account for the three exchangeable protons. The presence of three secondary hydroxyl groups was confirmed by observing spectral changes induced by acetylation. The remaining four oxygen-bearing carbons were assigned to the tetrahydrofuran rings. Methine proton resonances complementing each of the doublet ^{13}C shifts occurred in the region δ 3.38–3.85, except for the C-36 proton signal at δ 5.02.

A high resolution mass spectrum of rolliniastatin 1 yielded a fragmentation pattern (Fig. 1) strikingly parallel to that of rol-

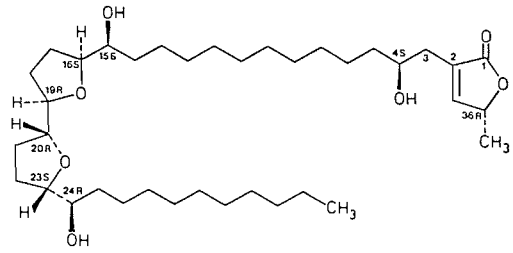
[a]Chemical shifts in ppm (δ) at 300 MHz are reported relative to tetramethylsilane using a deuteriochloroform solution.

linone (4*b*), an isomeric *bis*-tetrahydrofuran that has a 14-oxo group and a saturated lactone moiety. Furthermore, the mass spectral fragmentation pattern allowed location of the presumptive *bis*-tetrahydrofuran system with its two α-hydroxyl groups between C-15 and C-24. Corroborative evidence for the α-hydroxy tetrahydrofuran system was provided by ^{1}H nmr. COSY experiments established couplings between the following sets of protons: H-14–H-15 (δ 1.45 → 3.38), H-15–H-16 (δ 3.38 → 3.85). The relationships between H-23, H-24, and H-25 were discerned by the same method. The following C-13/H-1 connections were delineated by heteronuclear connectivity experiments: C-14–H-14a + 14b (δ 34.1 → 1.45), C-15–H-15 (δ 74.0 → 3.38), C-16–H-16 (δ 83.0 → 3.85), and C-19–H-19 (δ 81.0 → 3.85). Corresponding connections were noted among protons and carbons from C-20 through C-25.

The plausible assumption that rolliniastatin 1, like rollinone, has an oxygen function at C-14 proved erroneous despite their similar mass spectra. Surprisingly, mass spectral results gave no hint of the third hydroxyl group location. By means of nmr experiments (including COSY, heteronuclear correlation, and simulation by PANIC) the third hydroxyl was located in relation to the lactone ring and placed at C-4. Allylic couplings (J = 1.5, 1.2 Hz) between the two nonequivalent protons, 3a and 3b (δ 2.50 and 2.36), and H-35 (δ 7.16) supported this assignment. In addition, protons 3a and 3b exhibited long range couplings (J = 1.6, 1.4 Hz) with H-36 (δ 5.02). Protons 3a and 3b were also found coupled (J = 3.4, 8.1 Hz) to H-4 (δ 3.85). In turn H-4 was found connected to a carbon appearing as a doublet at δ 69.9. Thus, the ^{13}C and ^{1}H shifts both indicated that C-4 was bonded to oxygen. Also established were appropriate connections between carbons and protons at C-3 (δ 2.36 + 2.50 → 33.2) and C-5 (δ 1.45 → 37.4).

TABLE 2. ^{13}C nuclear magnetic resonance chemical shifts of asimicin and rolliniastatin 1[a]



Carbon no.	Rolliniastatin	Asimicin

[a]Both spectra were determined in deuteriochloroform solution and chemical shifts are expressed in ppm (δ) from tetramethylsilane.
[b,c]These shifts may be interchanged.

The structure herein assigned rolliniastatin 1 was confirmed and stereochemical details were elucidated by an X-ray crystal structure (Fig. 2) determination of rolliniastatin 1 15-*O*-*p*-bromophenylurethane: needles from ethyl acetate melting at 91–92°C; $[\alpha]_D^{28}$ +38.3° (*c* 0.9, $CHCl_3$): ir ν_{max} (KBr): 3531, 3444, 1737, 1716 cm^{-1}; HREIMS, *m/z*, [M$^+$] 819.4223 (calcd. for $C_{44}H_{70}{}^{79}BrNO_8$: 819.4285). The X-ray structure determination (ρ(density) 1.067 g/cm^3 and *V* (cell volume) 4311.65 Å^3; $P2_12_12_1$; crystal dimension 0.13 × 0.37 × 0.08 mm; 4007 reflections; 2117 reflections observed (3σ cutoff); and R = 9.40, Rw = 7.92) of rolliniastatin 1 15-*O*-*p*-bromophenylurethane provided the following relative stereochemistry (Fig. 2) for the eight chiral centers: 4*S**, 15*S**, 16*S**, 19*R**, 20*R**, 23*S**, 24*R**, 36*R**. The absolute configuration was not unequivocally established on the basis of present X-ray data and is presently being investigated.

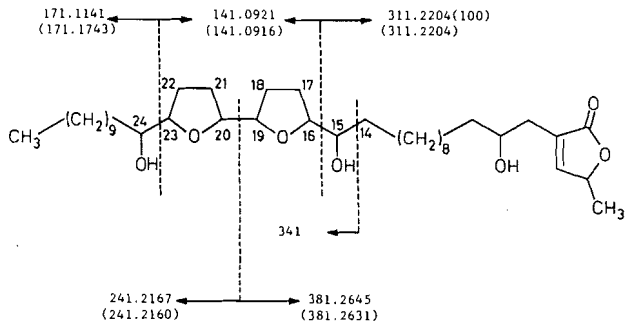

FIG. 1. HREIMS fragmentation of rolliniastatin 1 with calculated values in parentheses.

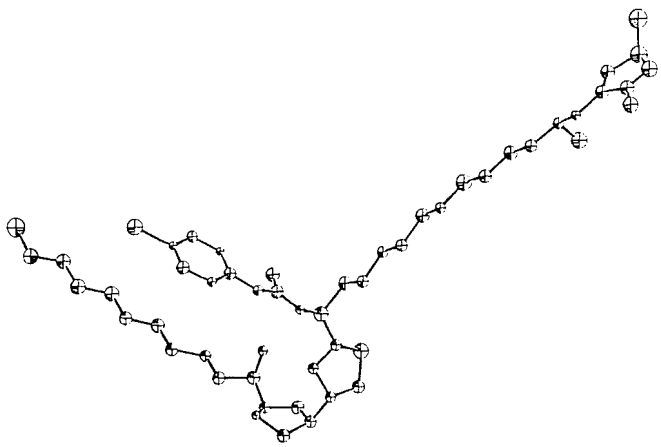

FIG. 2. The 15-*O*-*p*-Bromophenylurethane derivative of rolliniastatin 1, as depicted by ORTEP II (62% probability thermal ellipsoids) and viewed down the *X*-axis.

The rolliniastatin 1 spectral data suggest that asimicin[5,6] (4*g*) is a diastereomer of this bis-tetrahydrofuran. The ^{13}C nmr shifts for rolliniastatin 1 and asimicin (Table 2) are almost identical except those for C-14, C-24, and C-25 (alternatively, C-14, C-15, and C-25). The carbon nmr data indicate that the two compounds are diastereomers differing in configuration at a chiral center(s) in or near the bis-tetrahydrofuran systems. Asimicin's ^{13}C shifts for carbons 14–19 are virtually identical with those for carbons 20–25, suggesting that asimicin is pseudosymmetrical about the midpoint of the bond connecting C-19 and C-20. In contrast, rolliniastatin 1 is not symmetrical in this respect. These observations, and results herein of the first crystal structure determination for a member of this relatively new class of natural products, indicate that the rolliniastatin 1 isomer asimicin reported (4*g*) as this manuscript was being prepared receives further structural support. But a few of the other six known compounds (4) of this class may require some additional structural refinements. Presently we are investigating a series of *Rollinia mucosa* constituents related to rolliniastatin 1.

Biological evaluation (5) of rolliniastatin 1 (PS, 28% life extension, and ED_{50} 4.5×10^{-5} μg/mL) from *Rollinia mucosa* is continuing and includes an assessment of insecticidal activity well known for tropical American plants of this family, such as *Annona muricata* L. and *A. reticulata* L (6), and just noted for asimicin (4*g*).

[5]We thank Dr. J. L. McLaughlin, Purdue University, for a reference sample of asimicin.

[6]When compared by tlc, rolliniastatin 1 and asimicin initially were barely resolved, but were convincingly separated (when minimal amounts of sample were applied) on a silica plate using triple development with methylene chloride – methanol (95:5) as mobile phase. In this system the R_f for rolliniastatin 1 is slightly higher than that for asimicin.

Acknowledgments

High-yield regioselective synthesis of 9-glycosyl guanine nucleosides and analogues via coupling with 2-*N*-acetyl-6-*O*-diphenylcarbamoylguanine[1]

RUIMING ZOU AND MORRIS J. ROBINS
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received January 6, 1987

RUIMING ZOU and MORRIS J. ROBINS. Can. J. Chem. **65**, 1436 (1987).

Treatment of 2-*N*,9-diacetylguanine with diphenylcarbamoyl chloride followed by heating with aqueous ethanol gave 2-*N*-acetyl-6-*O*-diphenylcarbamoylguanine (2-acetamido-6-diphenylcarbamoyloxypurine). Bis-trimethylsilylation of this product followed by coupling with glycosyl acetates (trimethylsilyl triflate catalysis) or α-haloethers in *anhydrous toluene* gave 9-substituted guanine compounds in high yields with no 7-isomers detected.

RUIMING ZOU et MORRIS J. ROBINS. Can. J. Chem. **65**, 1436 (1987).

La réaction de la diacétyl-2-*N*,-9 guanine avec le chlorure de diphénylcarbamoyle, suivie d'un chauffage avec de l'éthanol aqueux, conduit à la *N*-acétyl-2 *O*-diphénylcarbamoyl-6 guanine (acétamido-2 diphénylcarbamoyloxy-6 purine). La bis-triméthylsilylation de ce produit, suivie d'un couplage avec soit les acétates de glycosyle (catalyse par le triflate de triméthylsilyle) ou les α-haloéthers dans le *toluène anhydre*, conduit aux composés de la guanine substitués en position 9; les rendements sont élevés et on ne détecte pas la présence d'isomères 7.

Of the five heterocyclic bases commonly found in DNA and RNA, guanine (**1**) causes markedly enhanced experimental problems. Guanosine and its analogues are amphoteric ($pK_a1 \sim 1.7$, $pK_a2 \sim 9.2$) polyfunctional compounds that are sparingly soluble in water and polar aprotic solvents, and effectively insoluble in all other common solvents. They often self-associate in solution to form viscous gels and hydrate tenaciously in the crystalline state. Direct coupling with guanine-type bases produces N7/N9 isomeric mixtures (*1*) that are frequently difficult to separate for the above reasons. Changes in experimental variables affect the isomer ratios, but do not eliminate contamination of the desired thermodynamic N9 product by significant quantities of the kinetic N7 isomer (2).

Discovery (3) of the potent activity against herpes simplex type 1 and 2 viruses and low mammalian toxicity of 9-[(2-hydroxyethoxy)methyl]guanine (acyclovir) triggered a massive worldwide effort to synthesize and test guanine nucleosides and "acyclic nucleoside" analogues. Very recent syntheses of acyclovir analogues have employed 2-amino-6-alkoxypurines (4, 5) to enhance selectivity for N9 coupling.

Reese and Ubasawa (6) and Hata and co-workers (7) had observed O6 functionalization of guanine during phosphate activation for oligonucleotide synthesis, and Hata and co-workers have exploited O6 diphenylcarbamoylation of guanosine derivatives as a protection strategy (8). We now report regioselective coupling of bis-trimethylsilylated 2-*N*-acetyl-6-*O*-diphenylcarbamoylguanine (**2**) with acetylated pentofuranoses and α-haloethers as a convenient new route to guanine N9 products.

A suspension of 30.22 g (0.2 mol) of guanine (**1**) in 250 mL of dry DMAc and 50 mL of Ac_2O was stirred at 160°C for 7 h. The brown solution was cooled and crystalline 2-*N*,9-diacetylguanine[2,3] (9) was filtered and washed with EtOH. A second crop raised the yield to 42.53 g (90%). A stirred suspension of 5.88 g (25 mmol) of 2-*N*,9-diacetylguanine in 8.7 mL of $EtN(i\text{-}Pr)_2$ and 120 mL of dry C_5H_5N was treated with 6.37 g (27.5 mmol) of Ph_2NCOCl for 1 h at ambient temperature. H_2O (10 mL) was added and stirring continued for 10 min. Evaporation *in vacuo* and coevaporation (3 × 20 mL of $PhCH_3$) was followed by heating (steam bath) the residue with 300 mL of 50% $EtOH/H_2O$ for 1.5 h. Cooling, filtration, washing (EtOH), and drying gave 8.93 g (92%) of **2**.[3,4]

N,*O*-Bis(trimethylsilyl)acetamide (0.5 mL) was added to a suspension of 388 mg (1 mmol) of **2** in 10 mL of dry 1,2-dichloroethane. Stirring at 80°C for 15 min gave a clear solution that was evaporated *in vacuo*. The residue was dissolved in 5 mL of dry $PhCH_3$ and 0.25 mL of $CF_3SO_3SiMe_3$, and 382 mg (1.2 mmol) of 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose in 5 mL of dry $PhCH_3$ was added. The solution was stirred at 80°C for 1 h and cooled, 50 mL of EtOAc was added, and the solution was worked up in the usual manner. The crude product was chromatographed (25 g silica, 2 × 15 cm; Et_2O/Me_2CO 8:2) to give 589 mg (91%) of **3**: ms (FAB) m/z 647 ($M + 1$); ^1H and ^{13}C nmr spectra were compatible with structure **3**.

Trace quantities (<3%) of a more rapidly migrating bis-ribosylated product (2-N,9 by nmr) were separated from **3** by the column chromatography. Deprotection of **3** with NH_3/H_2O/MeOH gave 75% (68% from **2**) of guanosine (**4**) hemihydrate[3] after recrystallization from water.

Analogous coupling reactions with $\mathbf{2}(SiMe_3)_2$ and tetra-*O*-acetyl-D-furanosyl derivatives of arabinose and xylose gave good yields of the corresponding 9-α- and 9-β-guanine nucleosides, respectively. Coupling of $\mathbf{2}(SiMe_3)_2$ and (2-acetoxyethoxy)methyl bromide (10) in toluene proceeded readily at ambient temperature without catalyst. The resulting acyclovir derivative was obtained in 63% yield after column chromatography and crystallization. X-ray crystallographic analysis of this intermediate confirmed the 6-diphenylcarbamoyloxy structure.[5] Deprotection gave acyclovir hemihydrate[3] (10) in 91% yield after recrystallization (H_2O).

Vorbrüggen *et al.* (11) had reported coupling of tris-trimethylsilylated 2-*N*-acetylguanine and 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose in 1,2-dichloroethane at reflux with trimethylsilyl triflate as catalyst. The crude product was deprotected to give "pure guanosine" in 66% yield after recrystallization from water. Careful repetition of this sequence gave 66% of crystalline product that comigrated (tlc) with guanosine as described (11). However, the 400-MHz ^1H nmr spectrum of this material in Me_2SO-d_6 revealed a mixture of **4** and its N7 isomer. The nmr analysis of the crude coupling product showed a N9/N7 ratio of ~3:1.

Analysis (400-MHz ^1H and 100-MHz ^{13}C nmr) of our crude coupling product and the recrystallized deprotected nucleoside showed only **3** (plus trace amounts of the bis-ribosyl by-product) and **4**, respectively, with no detected N7 contaminant. Therefore, coupling of glycosyl acetate (and chloride) derivatives and α-haloethers with the readily accessible **2**$(SiMe_3)_2$ under *anhydrous* conditions in *toluene* as described herein represents a new and experimentally convenient route to 9-glycosyl guanine derivatives and analogues. These can be purified and manipulated readily and deprotected under mild conditions. It represents the method of choice among presently published alternatives for the preparation of guanine N9 nucleosides.[6] Further investigations on selective syntheses of N7 products and kinetic/thermodynamic isomer studies will be reported in detail.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada, the National Cancer Institute of Canada, and the University of Alberta for generous support. We thank the Alberta Heritage Foundation for Medical Research for a Graduate Studentship to R.Z. 1982–1985.

[6]Alkylation of **2**$(SiMe_3)_2$ did not proceed satisfactorily under comparable conditions with "unactivated" alkyl halides. The use of salts of 2-amino-6-alkoxypurines (4, 5) appears to be favorable for preparation of 9-alkylguanines.

Total synthesis of leukotriene B_4 analogues: 3-thia-LTB_4 and 3-thia-20,20,20-trifluoro-LTB_4

YVAN GUINDON AND DANIEL DELORME[1]

Merck Frosst Canada Inc., P.O. Box 1005, Pointe Claire – Dorval, P.Q., Canada H9R 4P8

Received December 11, 1986

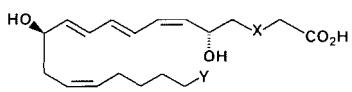
YVAN GUINDON and DANIEL DELORME. Can. J. Chem. **65**, 1438 (1987).

Using *C*-furanosides as chiral precursors of (*Z*,*E*) 1,3-dienes has permitted the synthesis of two leukotriene B_4 analogues: 3-thia-LTB_4 and 3-thia-20,20,20-trifluoro-LTB_4.

YVAN GUINDON et DANIEL DELORME. Can. J. Chem. **65**, 1438 (1987).

L'utilisation de *C*-furanosides comme précurseurs chiraux de diènes-1,3 de stéréochimie (*Z*,*E*) a permis de synthétiser divers analogues du leucotriène B_4, en particulier le thia-3 LTB_4 et le thia-3 trifluoro-20,20,20 LTB_4.

LTB_4 **1** (Scheme 1) is an oxygenated metabolite of arachidonic acid that has been recently isolated (1), characterized, and synthesized by us and others (2, 3). Putative important roles in allergic, inflammatory (4), and immunological reactions (5) have been attributed to LTB_4. This local hormone is rapidly and extensively metabolized in vivo first by hydroxylation at C-20 to give **2** (ω-oxidation), followed by oxidation to the diacid **3** and subsequent β-oxidation of the two acidic chains (6). Metabolically stable analogues (7) of LTB_4 would lead to a better comprehension of the biological effects of this important mediator. This would also permit the elaboration of in vivo assays suitable for the evaluation of chemical entities as potential therapeutic agents. We would like to report herein on the total synthesis of two such analogues, 3-thia-LTB_4 **4** and 3-thia-20,20,20-trifluoro-LTB_4 **5**.

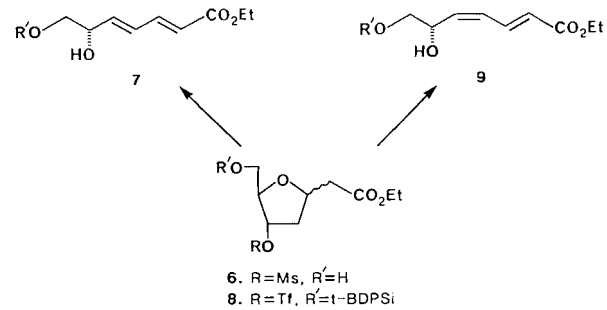


1. X = CH_2, Y = CH_3 : LTB_4
2. X = CH_2, Y = CH_2OH : 20-OH-LTB_4
3. X = CH_2, Y = CO_2H : 20-CO_2H-LTB_4
4. X = S, Y = CH_3 : 3-thia-LTB_4
5. X = S, Y = CF_3 : 3-thia-20-CF_3-LTB_4

SCHEME 1

Our approach to the synthesis of LTB_4 analogues is based on the utilization of properly substituted tetrahydrofurans as masked dienic functionalities. Recently, we described the transformation of *C*-furanosides (e.g. **6**) (Scheme 2) to chiral (*E*,*E*)-dienic precursors (e.g. **7**) in the synthesis of LTB_4 (2*a*). Our initial success was based on consecutive retro-Michael reaction followed by elimination of an activated oxygen in one chemical step. In this paper we present another alternative, which consists of using structurally similar tetrahydrofuran derivatives (e.g. **8**) as precursors of the (*Z*,*E*)-dienic functionality **9**. In this case the elimination of the leaving group is accomplished first, using the tetrahydrofuran ring as a template for the formation of the *cis* double bond (e.g. **13**). Our synthesis is summarized in Scheme 3.

The *C*-furanosides **12** were prepared from a known synthetic sequence using 2-deoxy-D-ribose **10** (8). The intracyclic olefin **13** was obtained, in 78% yield, through the formation of a secondary triflate ester **8** (9) followed by treatment, in the same



6. R=Ms, R′=H
8. R=Tf, R′=t-BDPSi

SCHEME 2

reaction mixture, with DBU. We were pleased to note that the efficient opening of **13** by LDA in THF (for LDA induced retro-Michael reactions see refs. 8, 10) led cleanly and exclusively to the optically active (*Z*,*E*)-diene ester **14**, $[\alpha]_D$ + 73.9° (*c* 1.33, $CHCl_3$), in very high yield.[2] It should be noted that the same *C*-furanosides may be expediently transformed to the optically active (*E*,*E*)-diene **7** by simply adding sodium ethoxide directly to the triflate ester reaction mixture. This latter transformation underscores the versatility of this approach and confirms the synthetic utility of tetrahydrofurans as masked 1,3-dienes.[3]

The allylic alcohol in **14** was to become the hydroxyl group at C-5 of our LTB_4 analogues, so that an inversion of configuration at this centre was necessary. This was achieved using a well-known procedure (DEAD, triphenylphosphine, benzoic acid, ref. 12) to give the benzoate **16**[4] in 89% yield,

[2]^{1}H nuclear magnetic resonance (250 MHz, $CDCl_3$) δ 1.09 (s, 9H, $(CH_3)_3$), 1.34 (t, 3H, *J* = 7.5 Hz, CH_2CH_3), 2.68 (m, 1H, OH), 3.63 (ddd, 2H, *J* = 11 Hz, *J* = 8.0 Hz, *J* = 4.2 Hz, $SiOCH_2$), 4.22 (q, 2H, *J* = 7.5 Hz, CH_2CH_3), 4.78* (m, 1H, C*H*—OH), 5.73 (dd, 1H, *J* = 11 Hz, *J* = 8 Hz, H-5), 5.90 (d, 1H, *J* = 15 Hz, H-2), 6.20 (t, 1H, *J* = 11 Hz, H-4), 7.55 (dd, 1H, *J* = 12 Hz, *J* = 15 Hz, H-3), 7.35–7.71 (m, 10H, 2Ph).

*Decoupling experiment: 5.73 (d, 1H, *J* = 11 Hz, H-5); *Z* olefin; ir (neat); 3440, 2930, 2860, 1700, 1640, 1610 cm^{-1}. High resolution mass spectrum, *m*/*z* calcd. for $C_{25}H_{30}O_3Si$ (M^+ H_2O) 406.1964; found: 406.1986.

[3]A procedure for obtaining chiral (*Z*,*E*)-diene using a Wittig reaction on pseudoglucal was recently reported (11).

[4]The extent of the inversion of the allylic alcohol has been verified in the following way. In trityl series the benzoate **17** was treated sequentially with sodium ethoxide and LDA to give the corresponding alcohol with $[\alpha]_D$ −77.2° (*c* 1.55, $CHCl_3$) as opposed to $[\alpha]_D$ +79.4° (*c* 1.11, $CHCl_3$) for **15** (Scheme 3). Mosher esters (13) of both alcohols were, as well, made and ^{1}H nmr indicated that **17** was obtained with >97% inversion.

SCHEME 4

$[\alpha]_D$ +74.8° (*c* 1.01, $CHCl_3$). DIBAH reduction (14) of both esters led to the dienediol **18**, $[\alpha]_D$ −42.0° (*c* 1.24, $CHCl_3$). The resulting primary alcohol was then tritylated, followed by desilylation using nBu_4 N^+F^- in THF, affording **19** in 61% yield from **16**. Selective primary sulfonylation of **19** with triisopropylbenzenesulfonyl chloride (15) in the presence of triethylamine was then followed by protection of the secondary alcohol as *tert*-butyldiphenylsilyl ether (16) to give **20**. Successive displacement of the sulfonate **20** with sodium iodide in hot 2-butanone, followed by sodium thiolate of methylthioglycolate in THF at 50°C for 4 h, led to C-1—C-10 unit **21** in 79% yield.

Completion of the synthesis of 3-thia-LTB_4 was then performed in the following way. Regeneration of the primary hydroxyl group from **21** was achieved with 20% aqueous trifluoroacetic acid (17) in CH_2Cl_2. The resulting primary alcohol was converted to the corresponding bromide and treated with triphenylphosphine in acetonitrile to give the phosphonium salt **22**. The Wittig coupling between **22** and the aldehyde **23** (2*b*) was then achieved through ylide formation at −78°C (THF) using LiHMDS, followed by the addition of aldehyde **23** and warming of the reaction mixture to 0°C. Trienes **24***a* and **24***b* were thus obtained in a 1:1 ratio. Removal of both silyl ethers using nBu_4 N^+F^- in the presence of acetic acid, followed by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

separation of the isomers using hplc,[5] led to the 3-thia-LTB_4 methyl ester. Subsequent saponification gave the 3-thia-LTB_4, **4**.

The introduction of a metabolically stable group such as trifluoromethyl (CF_3) at C-20 of 3-thia-LTB_4 **4** was then achieved as follows. Treatment of 6-bromohexanoic acid **25** with sulfur tetrafluoride (18) gave the trifluoro derivative **26** (Scheme 4). The corresponding phosphonium salt **27** was treated with butyllithium in dry THF followed by addition of aldehyde **28** (19) to afford the *Z*-olefin **29**. Selective removal of the acetonide and cleavage of the resulting diol in the presence of potassium carbonate gave the aldehyde **30**, $[\alpha]_D$ −14.7° (*c* 1.02, $CHCl_3$), in 79% isolated yield from **29**.

The aldehyde **30** was then coupled with the phosphonium bromide **22** (the C-1—C-10 unit) as described previously (Scheme 3). Removal of silyl ethers followed by separation of the resulting trienes and saponification gave 3-thia-20,20,20-trifluoro-LTB_4 **5**.[6] Both analogs **4** and **5** were shown to be biologically active in a PMN aggregation assay (20), with similar potency to LTB_4 itself. Functional effects and in vivo activities will be reported elsewhere.

In conclusion, the potential usefulness of optically active tetrahydrofurans as masked stable precursors of stereochemically well-defined 1,3-dienes has been illustrated in the synthesis of 3-thia-LTB_4 and 3-thia-20,20,20-trifluoro-LTB_4.

HANS H. BAER, ISAMU ARAI, BRUNO RADATUS, JUNE RODWELL, and NGUYEN CHINH. Can. J. Chem. **65**, 1443 (1987).

A new synthesis of 2-deoxystreptamine (**21**), a component of numerous antibiotics, was developed. Starting from D-mannose, it proceeds through chiral intermediates and is designed to furnish starting points for the preparation of stereospecifically modified derivatives of the *meso* compound **21**. 1,2-Dideoxy-1-nitro-D-*manno*-heptitol (**2**), obtainable from mannose by the nitromethane method, was protected as the 4,5:6,7-di-*O*-isopropylidene derivative **4**, which was mesylated or triflated in position 3. From the sulfonic esters (**5** and **6**) two different routes involving displacement by azide, partial deacetonation at O-6,7, periodate oxidation, and cyclization of the resulting nitroaldohexose derivatives converged to give 1L-(1,3/2,4,6)-6-azido-1,2-*O*-isopropylidene-4-nitro-1,2,3-cyclohexanetriol (**19**) as a key intermediate. Catalytic hydrogenation then afforded optically active 4,5-*O*-isopropylidene-2-deoxystreptamine (**23**), isolated as its *N,N'*-diacetyl derivative **24**. Deacetonation of **19** gave the azidonitrotriol **15**, which was reduced to **21**. The potential utility of the chiral intermediates for stereospecific syntheses of deoxystreptamine-containing aminoglycosides is discussed.

HANS H. BAER, ISAMU ARAI, BRUNO RADATUS, JUNE RODWELL et NGUYEN CHINH. Can. J. Chem. **65**, 1443 (1987).

On a mis au point une nouvelle synthèse de la désoxy-2 streptamine (**21**), un composant de plusieurs antibiotiques. Utilisant le D-mannose comme produit de départ, cette synthèse procède par le biais d'intermédiaires chiraux et il est prévu qu'elle pourra fournir des points de départ pour la préparation de dérivés modifiés d'une façon stéréospécifique du composé *méso* **21**. Le didésoxy-1,2 nitro-1 D-*manno*-heptitol (**2**), que l'on peut obtenir à partir du mannose en faisant appel à la méthode au nitrométhane, a été protégé sous la forme du dérivé di-*O*-isopropylidène-4,5:6,7 (**4**) et l'on a ensuite transformé en dérivé mésylé ou triflé en position 3. À partir des esters sulfoniques (**5** et **6**), deux voies différentes impliquant une substitution par un ion azoture, une déacétonation partielle en O-6,7, une oxydation periodique et une cyclisation des dérivés nitroaldohexoses qui en résultent convergent pour donner l'azido-6 *O*-isopropylidène-1,2 nitro-4 cyclohexanetriol-1,2,3 1L(1,3/2,4,6) (**19**), un intermédiaire clé. L'hydrogénation catalytique fournit ensuite la *O*-isopropylidène-4,5 désoxy-2 streptamine optiquement active (**23**) qui a été isolée sous la forme de son dérivé *N,N'*-diacétylé (**24**). La déacétonation du composé **19** fournit l'azidonitrotriol **15** qui est réduit en **21**. On discute de l'utilité potentielle d'intermédiaires chiraux dans les synthèses stéréospécifiques d'aminoglycosides contenant la désoxystreptamine.

Introduction

2-Deoxystreptamine (**21**) is a pivotal component of numerous important aminoglycoside antibiotics, several of which are in clinical use (1). Early syntheses in the laboratories of Nakajima *et al.* (2) and Suami *et al.* (3) embodied elegant concepts in certain stages but, being predicated on the use of achiral starting materials such as "benzeneglycols" (cyclohexadienediols) and *myo*-inositol, they did not lend themselves to, nor were they intended for, the synthesis of stereospecifically substituted, chiral derivatives of **21**. The same was true for an approach departing from 4,6-dinitropyrogallol (4) and for the more recent and convenient, high-yielding synthesis from 4,5-epoxycyclohexene reported by Prinzbach *et al.* (5). By contast, any approach based on the conversion of a sugar into an aminocyclitol inherently offers the possibility of generating asymmetrically structured derivatives. This is a desirable feature, for although **21** itself is achiral, as a constituent of antibiotics it invariably bears a substituent (i.e., a glycosyl residue) at one or other of its chemically equivalent but enantiotopic positions 4 and 6, or unequal substituents at both. Similarly, either one of the amino groups may occur alkylated, rendering the compound chiral. For example, the *N*-methyl-2-deoxystreptamine (hyosamine) present in destomycin A is levorotatory, whereas hygromycin B contains the dextrorotatory enantiomer (1). With their classical streptamine synthesis, Wolfrom *et al.* (6) have paved the way from *N*-acetyl-D-glucosamine into the diaminocyclitol series, utilizing the nitroalkane cyclization methodology (7), and by further elaboration of this approach Suami and Rinehart and co-workers (8) did in fact avail themselves of the chirality present in this amino sugar to synthesize optically active inosadiamines including (−)-hyosamine, the 1*S*-amino-3*R*-methylamino analog of **21**. Géro and co-workers (9) used carbohydrate-related D-(−)-quinic acid as an alternative resource for chiral aminocyclitol syntheses.

We report here a chiral synthesis of **21**, which departs from commercial D-mannose and proceeds through a number of intermediates that are potentially suitable for the stereospecific preparation of both *O*- and *N*-substituted derivatives.

Results and discussion

Known 1-deoxy-1-nitro-D-*glycero*-D-*galacto*-heptitol hexaacetate (**1**) was prepared from D-mannose by the nitromethane method (10). Although **1** can be dehydroacetoxylated (with sodium bicarbonate), and the resulting 1-nitroalkene then hydrogenated to give 1,2-dideoxy-1-nitro-D-*manno*-heptitol pentaacetate (**2**) (10, 11), we chose to perform this transformation in one step by reductive elimination with sodium borohydride in acetonitrile solution. Subsequent *O*-deacetylation (Zemplén) gave the pentaol **3**, which was acetonated to furnish

[1]This project was initiated by I.A. during a postdoctoral sojourn (1978), and preliminary results were communicated at the 62nd Canadian Chemical Conference, Vancouver, June 1979 (Abstract OR-91). Completion of the work was reported by H.H.B. and B.R. at the 191st ACS National Meeting, New York City, April 1986 (Abstract CARB-45).

[2]Revision received February 9, 1987.

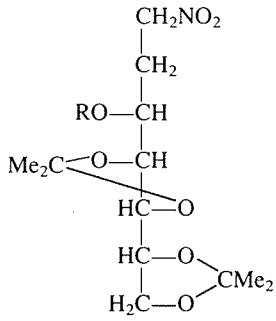
3 R = H



4 R = H
5 R = SO_2Me
6 R = SO_2CF_3

the 4,5;6,7-di-*O*-isopropylidene derivative **4**.[3] Mesylation and triflation of **4** afforded, respectively, the sulfonates **5** and **6**. In the 300-MHz ^1H nmr spectrum of **5**, the proton signal that occurred at lowest field and was, therefore, attributable to the hydrogen atom at the sulfonylated position was determined to be coupled to the two methylene protons H-2 and -2′, which resonated at high field, both on account of the mutual splitting patterns and by homonuclear shift correlation. This established C-3 as the site of sulfonylation. Overall yields of **5** and **6** from D-mannose were in the range of 20–25%. Two alternative routes toward the synthetic goal were elaborated from here, differing in the order by which the carbocycle was generated and the second nitrogen function introduced.

For route A (see Scheme 1), the mesylate **5** was selectively deacetonated at the 6,7 position by trifluoroacetic acid in toluene, and the resulting 4,5-mono-*O*-isopropylidene derivative **7** was cleaved with sodium metaperiodate to afford 5,6-dideoxy-2,3-*O*-isopropylidene-4-*O*-methylsulfonyl-6-nitro-*al*-D-*arabino*-hexose (**8**). Nitroalkane cyclization of this sugar, effected by sodium methoxide in methanolic solution, led to a mixture of epimeric cyclitols that could be isolated crystalline upon chromatographic separation. The structures **9** (for the less-mobile, higher-melting, and slightly preponderant epimer) and **10** (for the other component) followed from clearly resolved and readily interpretable ^1H nmr spectra. At first glance, one might have expected the axial-OH epimer **10** to exceed the equatorial-OH epimer **9** by approximately 0.9 kcal/mol in conformational energy, and since the reaction conditions employed for the cyclization probably favored thermodynamic control,[4] one should have anticipated an equilibrium of 85:15 (at 25°C) in favor of **9**, the desired epimer. Such a selectivity was not obtained, and inspection of Dreiding models suggests a possible explanation. It can be seen that, because of the considerable distortion imposed, in both compounds, on the cyclohexane chair by the *trans*-fused dioxolane ring, the axial OH group in **10** recedes in an outward direction from the opposing, coaxial hydrogen atoms. This may diminish nonbonding interaction and, consequently, the energy difference to the equatorially substituted counterpart **9**. Fortunately, it proved possible to isolate **9** directly from the mixture by fractional crystallization, thanks to its lower solubility, and, by doing so under epimerizing conditions (in the presence of a catalytic amount of base), part of **10** could be converted into **9**, which was thus obtained in 70% yield without resort to chromatography.

The *trans*-fused cyclic ketal groups in **9** and **10** were very acid labile, as was to be expected. When, in an early experiment, the alkaline mixture from the cyclization was processed with a sulfonic acid-type resin for deionization, loss of acetone occurred. Similarly, partial deacetonation was observed after prolonged exposure of the crystalline compounds to the laboratory atmosphere. Although not required for the present synthesis, a sample of **10** was deliberately methanolyzed under acid catalysis, and the highly crystalline triol **11** so obtained was characterized further through its triacetate **12**. Similar deacetonation of **9** gave the (amorphous) triol **13**, characterized likewise as its crystalline triacetate **14**. Unambiguous ^1H nmr data obtained for **12** and **14** reaffirmed the structures of the epimers.

With the nitrocyclitol **9** and its progeny **13** in hand, we proceeded to introduce the second nitrogen function. Both mesylates underwent displacement by azide ion, **13** with lithium azide in *N*,*N*-dimethylformamide (3 h at 100°C), and **9** also in this fashion or, more cleanly, under phase transfer conditions in benzene–water (3 days at 80°C) that entailed less decomposition. Unfortunately, the vicinal hydroxy-nitro groupings in **9** and **13** lost their stereochemical integrity in these displacement reactions; partial epimerization occurred at the carbinol positions, which vitiated the epimer separation previously performed. Thus, **13** gave a mixture from which the desired azidonitrotriol **15** was isolated crystalline by chromatography. This product was identical with **15** prepared from **19** (see later on). A second product, although not isolated pure, was judged to be the 3-epimer since it showed a similar infrared spectrum and was partly converted into **15** by base-catalyzed epimerization. Similarly, **9** furnished a mixture of the corresponding 1,2-*O*-isopropylidene derivatives **19** and[5] **20**. The products **15**, **19**, and **20** constitute a junction with the synthetic route B that is now to be delineated, and it will be seen in that context that separation of **19** and **20**, although somewhat laborious, is not a serious problem.

For route B, the mesylate **5** was first converted into the 3-azido-3-deoxy-D-*gluco*-heptitol derivative **16**. As reported by us elsewhere (12), treatment of **5** with tetrabutylammonium azide in boiling toluene had provided **16**, but only in 46% yield owing to interference of a competing reaction. This side reaction, which led to nitrocyclopropane derivatives, was of much interest in its own right (12); however, for the present purpose it was desirable to suppress it as far as possible to improve the yield of **16**. After considerable experimentation, displacement under phase transfer conditions using sodium azide and tetrabutylammonium hydrogen sulfate in benzene–water at 56°C was found to give a 76% yield and to minimize the

[3]Care should be exercised in the deionization of the alkaline reaction mixture obtained from **2**, which contains the nitronate of **3**, to avoid Nef reaction (10). In one large-scale experiment, in which the precaution of cooling was not observed and the crude product acetonated directly, the yield of **4** was diminished and a by-product, isolated in 7% yield, arose, which on spectroscopic evidence was judged to be methyl 2-deoxy-3,4:6,7-di-*O*-isopropylidene-α,β-D-*manno*-heptopyranoside.

[4]Prolongation of the reaction time did not seem to change the product ratio significantly.

[5]In the hope of forestalling such epimerization, we examined a mesylate displacement by azide in the 3-(trimethylsilyl) ether that was readily prepared from **9**. The attempt failed completely, giving a mixture of unidentified, chromatographically slow-moving products and no trace of the expected, fast-moving trimethylsilyl ether of **19**. The latter had been prepared for comparison from pure **19** (see route B), and when subjected to the same reaction conditions it, too, suffered similar degradation. A mixture of **19** and **20** can probably be prepared more rationally from crude **9** + **10** without their prior separation.

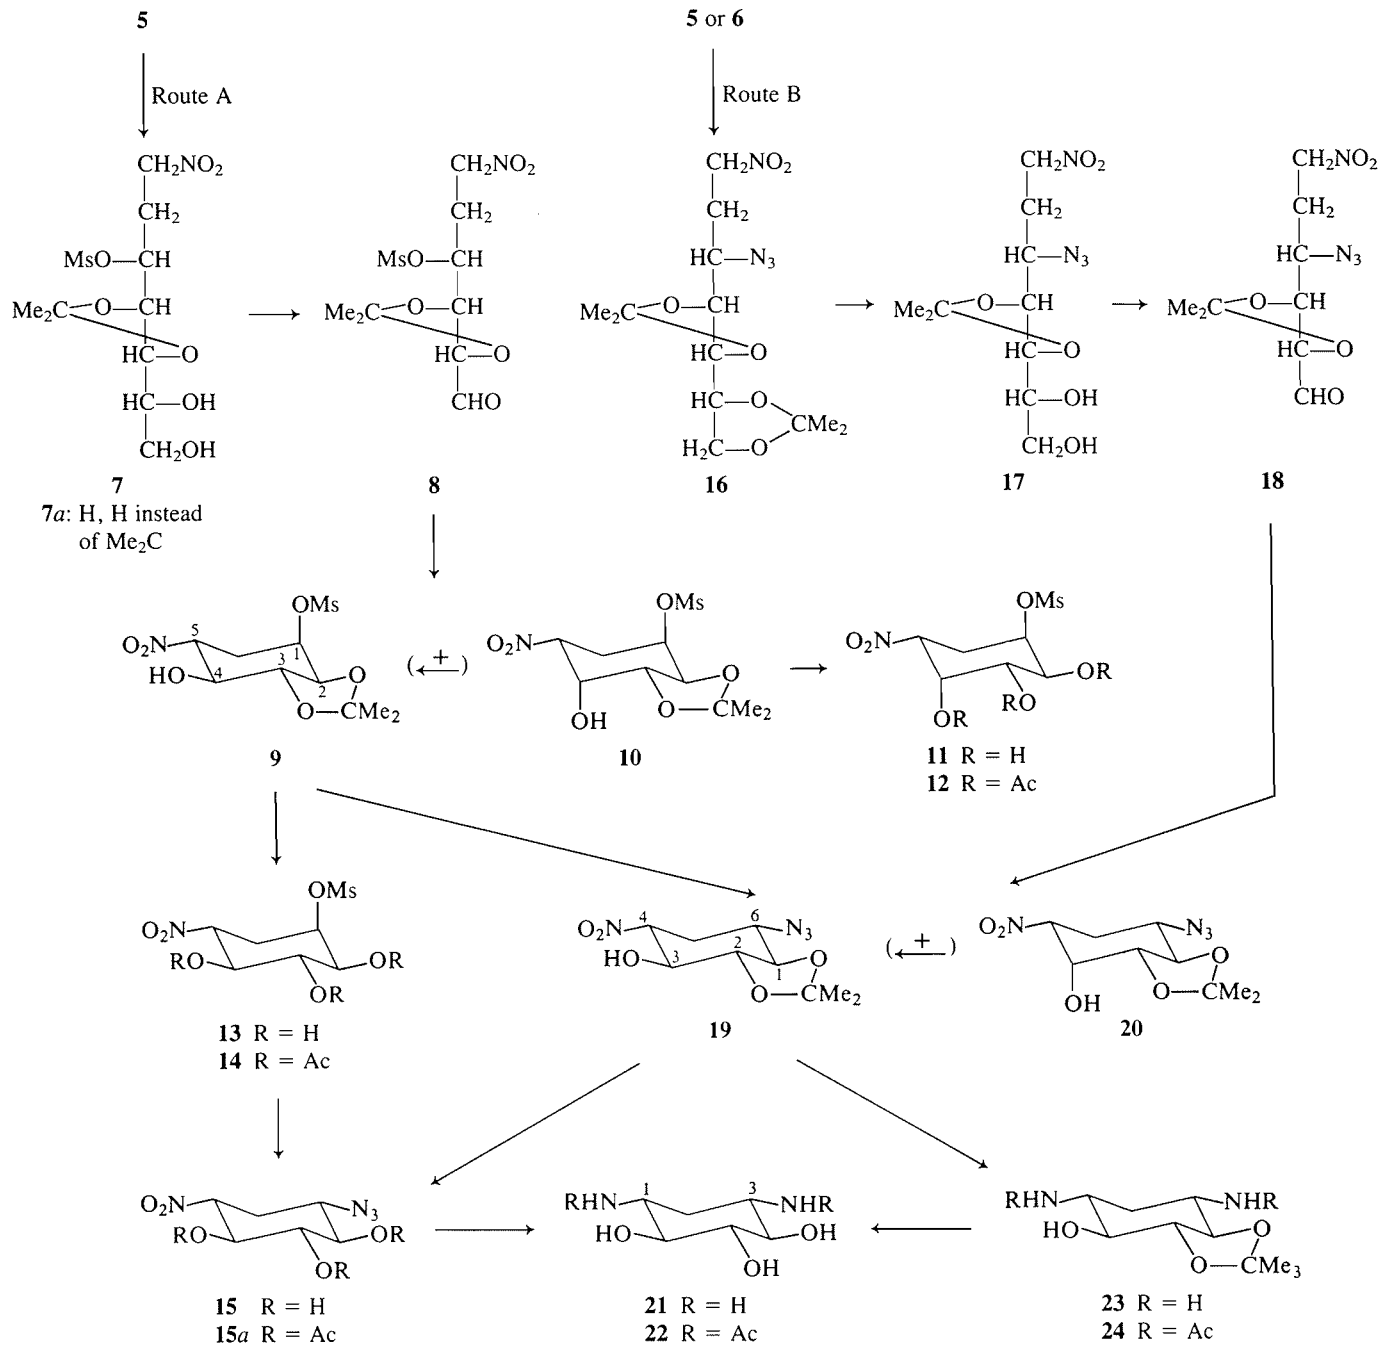

SCHEME 1

proportions of by-products, but the conversion was very slow, requiring 6 days for completion. Its performance at 80 or 100°C led to larger proportions of the unwanted products. A great improvement resulted from use of the triflate **6**, which, under similar phase transfer conditions but applied at room temperature for a few hours only, gave **16** in yields of 84% or better, and no cyclopropano by-products were detected. Compound **16** was then selectively 6,7-deacetonated with trifluoroacetic acid in toluene; a certain amount of full deacetonation occurred in the process, but the resulting tetraol could be reacetonated for recycling, and the 4,5-mono-*O*-isopropylidene derivative **17** was thus obtained in 88% yield. Subsequent periodate oxidation produced the aldehydo sugar **18** as an unstable intermediate that was not characterized but immediately subjected to methoxide-catalyzed ring closure, which furnished a mixture of **19** and its epimer **20**, similar in composition to that obtained from **9** by route A. The more stable isomer **19** was isolated from the mixture in 69% yield by direct crystallization, performed under conditions that allowed part of **20** to epimerize. The well-resolved ^{1}H nmr spectrum of **19** unambiguously indicated the all-equatorial substituent orientation in the compound. The epimer **20** that remained in the mother liquor was not isolated pure on a preparative scale, but a small sample was procured by column chromatography for nmr analysis, which ascertained its structure and configuration. Deacetonation of **19** quantitatively afforded crystalline **15**.

Hydrogenation over Adams catalyst converted **15** into 2-deoxystreptamine (**21**), and **19** into the latter's optically active, 4,5-*O*-isopropylidene derivative **23** that was isolated as a crystalline *N*,*N*′-diacetyl compound (**24**), which had previously

been obtained (13) in racemic form.[6] *N*-Acetylation of **21** and deacetonation of **24** yielded identical *N,N'*-diacetyl-2-deoxystreptamine (**22**).

Conclusion

With the preparation of 2-deoxystreptamine the ultimate success of our synthetic design has been demonstrated. It is to be stressed, however, that chemical synthesis of such chiral intermediates as **15**, **19**, **23**, and **24** was the primary goal of the enterprise.[7] These intermediates or conventionally prepared analogs such as the *N,N'*-diethoxycarbonyl or -dibenzyloxycarbonyl derivatives of **23**, which are known in racemic form only (16), are expected to open new avenues to stereospecific, total syntheses of deoxystreptamine-containing aminoglycosides where glycosylations specifically at O-4 or O-6 are required. Syntheses in that area have previously been accomplished (1) by use of racemic synthons of type **24**, but the necessary separation of diastereomers was generally troublesome and yields were often modest, as may be gleaned from several examples (16–18). Furthermore, it is to be expected that the unequal nitrogen functions present in **15** or **19** can be reduced to the amine stage in a stepwise fashion, which should allow mono-*N*-alkylation or -acylation to be effected stereospecifically. Such a protocol should prove valuable for synthetic designs in the area of destomycin A, hygromycin B, and the butirosins. Studies to exploit this chemistry along the lines indicated are in progress in our laboratory.

Experimental

Melting points were determined in capillaries with a Gallenkamp apparatus and are uncorrected. Optical rotations were measured at ~25°C in a Perkin–Elmer 241 polarimeter. Infrared (ir) data were recorded with a Perkin–Elmer 783 instrument from Nujol mulls for solid samples, and from neat films for syrups. Proton magnetic resonance (^{1}H nmr) spectra were taken at 300 MHz with a Varian XL 300 spectrometer from solutions in deuteriochloroform ($CHCl_3$ lock signal at δ 7.23), unless noted otherwise. Signal patterns are given as s = singlet, d = doublet, q = quartet, t = triplet, quin = quintet, sx = sextet, or m = multiplet, occasionally modified by prefixes b = broad, c = complex, or n = narrow. The ^{13}C nmr data were recorded with the same instrument, at 75.43 MHz. Column chromatography was performed with silica gel Merck 9385 (particle size, 20–45 μm), and analytical thin-layer chromatography (tlc) with precoated plates Si250F of J. T. Baker Chemical Co. The following solvent combinations (v/v) were used for chromatography, unless otherwise specified: A, methanol–$CHCl_3$ 1:2; B, the same, but 1:3; C, ether–hexane 1:1; D, EtOAc–hexane 1:1; E, the same, but 1:1.5; F, the same, but 1:2; G, the same, but 1:3; H, the same, but 1:4; and I, the same, but 1:19.

*1,2-Dideoxy-1-nitro-*D*-*manno*-heptitol pentaacetate (**2**)*

Crystalline 1-deoxy-1-nitro-D-*glycero*-D-*galacto*-heptitol hexaacetate (**1**) (10) (7.00 g) was dissolved in CH_3CN (70 mL, dried over molecular sieve), and to the chilled (0°C) solution was added $NaBH_4$ (0.56 g) followed by a few drops of ethanol. Gradual replacement of **1** by slightly less-mobile **2** was seen in tlc (Et_2O). The mixture was processed after 1 h by stirring it with Amberlite IR-120(H^+) resin until H_2 evolution ceased, decolorizing the filtrate with activated charcoal, and evaporating it with several sequential additions of methanol. The dry residue was dissolved in 5 mL of warm ethanol from which **2** crystallized on refrigeration. The mother liquor was evaporated, and the residue similarly crystallized from ethanol, to give a second crop of **2**, for a total of 5.241 g (85%), mp 91–93°C (lit. (11) mp 98–99°C); ν_{max}: 1740 (OAc) and 1555 (NO_2) cm^{-1}; no OH band. The product was sufficiently pure for further use, although a trace contaminant was present (tlc).

*1,2-Dideoxy-1-nitro-*D*-*manno*-heptitol (**3**)*

To a chilled (0°C) solution of **2** (14.2 g) in absolute methanol (650 mL) was added solid $NaOCH_3$ (10.34 g), and the mixture was stirred for 3 h at 0°C, after which tlc (solvent A) indicated complete replacement of **2** (R_f 0.95) by product ($R_f \sim 0.6$, with tailing due to the presence of base). The continuously chilled mixture was deionized with Dowex 50-X8(H^+) resin, and the clear, yellowish solution evaporated to dryness *in vacuo*, with portionwise addition of fresh methanol towards the end. The crude, dry product weighed 5.555 g (76%); in several runs performed on a 1–2 g scale, yields of 80–85% were obtained. Crude **3** was usable for the next step. An analytical sample, crystallized and recrystallized from ethanol, showed mp 116–118°C (lit. (11) mp 116–117°C); $[\alpha]_D$ +15° (*c* 3.2, water); ν_{max}: 3300 (bd, OH) and 1550 (NO_2) cm^{-1}; no ester CO band.

*1,2-Dideoxy-4,5;6,7-di-*O*-*isopropylidene-1-nitro-*D*-*manno*-heptitol (**4**)*

To a suspension of **3** (5.612 g) in reagent-grade acetone (280 mL) containing 2,2-dimethoxypropane (15 mL) was added freshly dried, anhydrous $CuSO_4$ (20 g). The mixture was stirred under ice cooling, and when it had reached +4°C, concentrated H_2SO_4 (2.0 mL) was added dropwise. Stirring was then continued at room temperature for 18–20 h. The formation of **4** ($R_f \sim 0.4$) was indicated by tlc (solvent G; R_f 0 for **3**). After neutralization of the mixture by stirring it with solid $NaHCO_3$, the supernatant was filtered through sintered glass with the aid of Celite, and evaporated to give a brownish oil. This was chromatographed on a column (4 × 10 cm) of silica gel, with solvent H as the eluant. The yield of chromatographically homogeneous, oily **4** (dried in high vacuum) was 6.16 g (81%); $[\alpha]_D$ +18° (*c* 1, $CHCl_3$); ν_{max}: 3450 (sharp, OH), 1545 (NO_2), 1430, 1370, 1250–1200, 1150, 1065, and 840 cm^{-1}; δ ($CDCl_3$): 4.56 (cm, 2H, AB part of ABMX system, H-1,1'), 4.19 (octet, H-6), 4.00 and 3.65 (m, 2 and 3H, H-3,4,5,7,7'), 3.75 (~s, exchangeable, OH), 2.48 (dtd, *W* 34 Hz, H-2), and 2.12 (dtd, *W* 36 Hz, H-2'); 1.42, 1.34, 1.335, 1.33 (s, 4 × 3H, $2Me_2C$). *Anal.* calcd. for $C_{13}H_{23}NO_7$ (305.3): C 51.14, H 7.59, N 4.59; found: C 51.21, H 7.65, N 4.40.

In several experiments using **3** of variable purity, the early chromatographic fractions of **4** contained a slightly more mobile by-product (see footnote 3), which was removed by rechromatography with solvent C.

*1,2-Dideoxy-4,5;6,7-di-*O*-*isopropylidene-3-*O*-*methylsulfonyl-1-nitro-*D*-*manno*-heptitol (**5**)*

Methanesulfonyl chloride (8 mL) in dry pyridine (26 mL) was added dropwise to a solution of **4** (6.16 g) in dry pyridine (50 mL), stirred at 0°C. After 1.5 h the reaction was complete (tlc, solvent D). The mixture was stirred for 10 min with some added water, poured onto crushed ice, and extracted with chloroform (2 × 120 mL). The extract was washed twice with $NaHCO_3$ solution, dried with Na_2SO_4, and evaporated with several added portions of toluene. The crude, oily **5** so obtained was chromatographed on silica gel (200 g) with solvent H. The fractions containing the product gave an oil (6.60 g, vacuum dried; 85%) that crystallized partially on storage in a desiccator overnight. Recrystallization from a minimum aount of EtOAc – petroleum ether gave pure **5** (5.874 g, 76%) as large, colorless plates, mp 74–75°C; $[\alpha]_D$ +24.3° (*c* 1.3, $CHCl_3$); ν_{max}($CHCl_3$): 1554 (NO_2), ~1370 (several bands, including NO_2 and OMs), and 1178 (OMs) cm^{-1}; OH band absent; ^{1}H nmr data (assignments confirmed by HOMCOR method), δ: 5.00 (septet, $J_{3,4}$ = 2.7, $J_{2,3}$ = 4.35; $J_{2',3}$ = 8.0 Hz, H-3), 4.58 (cm, 2H, H-1,1'), 4.22 (dd, $J_{3,4}$ = 2.7, $J_{4,5}$ = 7.2 Hz, H-4), 4.15

[6]According to regular organic nomenclature, **24** is 1L-(1,3/2,4,6)-4,6-diacetamido-1,2-*O*-isopropylidene-1,2,3-cyclohexanetriol; its enantiomer would receive the prefix 1D. In terms of the nomenclature (14) usually employed in the field of aminoglycoside antibiotics, **24** is 1,3-di-*N*-acetyl-4,5-*O*-isopropylidene-2-deoxystreptamine, and its enantiomer would be the corresponding 5,6-*O*-isopropylidene derivative.

[7]An analogous chiral compound, the 5,6-*O*-cyclohexylidene derivative of **21**, has been prepared semisynthetically from natural neamine (15).

(dd, $J_{6,7}$ = 6.1, J_{gem} = 8.55 Hz, H-7), 4.03 (dt, $J_{5,6}$ = 8.6, $J_{6,7}$ = 6.1, $J_{6,7'}$ = 5.2 Hz, H-6), 3.93 (dd, J = 5.2 and 8.5 Hz, H-7′), 3.78 (dd, J = 7.2 and 8.55 Hz, H-5), 3.08 (s, 3H, OSO_2Me), 2.45 (cm, 2H, H-2,2′), and 1.40s, 1.36s, 1.31s (6, 3, and 3H, $2Me_2C$). *Anal.* calcd. for $C_{14}H_{25}NO_9S$ (383.4): C 43.85, H 6.57, S 8.36; found: C 43.67, H 6.51, S 8.19.

*1,2-Dideoxy-4,5;6,7-di-*O*-isopropylidene-1-nitro-3-*O*-(trifluoromethylsulfonyl)-*D*-*manno*-heptitol (**6**)*

A solution of trifluoromethanesulfonic anhydride (5.7 mL) in dry CH_2Cl_2 (20 mL) was added dropwise, over a period of 45 min, to a solution of **4** (8.70 g) in dry CH_2Cl_2 (60 mL) and pyridine (10 mL), stirred at 0°C. After an additional 15 min, tlc (solvent: CH_2Cl_2) indicated complete conversion of **4** (R_f 0.15) into **6** (R_f 0.40). The mixture was poured into, and shaken with, ice water; after phase separation, the aqueous phase was extracted once with CH_2Cl_2, and the combined organic phase was washed with 2% H_2SO_4 followed by ice-cold $NaHCO_3$ solution and water, dried (Na_2SO_4), and evaporated at room temperature to give a syrup which, upon trituration with 5 mL of methanol, afforded a crystalline material. Isolated after short refrigeration, washed with methanol, and dried *in vacuo*, this first crop of **6** (7.385 g, 59%) melted at 77–79°C with decomposition (prior darkening from 68°C); $[\alpha]_D$ +23.9° (*c* 1, $CHCl_3$). Processing of the mother liquor furnished a second crop of crystalline **6** (1.05 g, 8.4%). The mother liquor therefrom, processed as before, left a syrup (~2 g) still rich in **6** (tlc); it could also be used in a subsequent operation (see preparation of **16**).

Compound **6** is rather unstable and tends to decompose rapidly at room temperature. It may be stored for some weeks at −20°C but is best utilized immediately. The ^{1}H nmr data, δ: 5.30 (m, $J_{3,4}$ = 2.3, $J_{2,3}$ ~ 4, $J_{2',3}$ ~ 8 Hz, H-3), 4.56 (cm, 2H, H-1,1′), 4.28 (dd, $J_{3,4}$ = 2.3, $J_{4,5}$ = 7.5 Hz, H-4), 4.17 (dd, $J_{6,7}$ = 6.1, J_{gem} = 8.6 Hz, H-7), 4.03 (~dt, $J_{5,6}$ =8.8 Hz, H-6), 3.92 (dd, $J_{6,7'}$ = 5.2, J_{gem} = 8.6 Hz, H-7′), 3.70 (dd, $J_{4,5}$ = 7.5, $J_{5,6}$ = 8.7 Hz, H-5), 2.57 (cm, 2H, H-2,2′), and 1.42s, 1.39s, 1.37s, 1.32s (4 × 3H, $2Me_2C$).

*1,2-Dideoxy-4,5-*O*-isopropylidene-3-*O*-methylsulfonyl-1-nitro-*D*-manno-heptitol (**7**)*

A solution of **5** (1.24 g) in toluene (9 mL) was cooled to −20°C, and 90% CF_3CO_2H (0.7 mL) was added. Oily **7** began to separate within a few minutes. The mixture was stirred magnetically for 30 min, then made homogeneous by the addition of a small amount of EtOAc, and immediately neutralized by agitation with solid sodium carbonate. The filtered solution was evaporated to give an oil that, according to tlc (solvent D), was a 3:1 mixture of **7** (R_f 0.25) and unreacted **5** (R_f 0.7). Chromatography of the material on a column (25 × 2 cm) of silica gel with solvent D as the eluant produced **5** (0.355 g), and subsequent elution with EtOAc furnished **7**. The recovered **5** was subjected to an identical hydrolysis (but on one-quarter scale), which gave an additional crop of **7** for a combined yield of 1.012 g (92%); $[\alpha]_D$ +9° (*c* 2.3, water), +25° (*c* 0.5, EtOAc); ir data, ν_{max}: 3400 (bd, OH), 1550 (NO_2), 1380–1330, 1250, 1175 (OMs), 1060, 925, 875, and 800 cm^{-1}; ^{1}H nmr ($CDCl_3$), δ: 5.02 (dt, $J_{2,3}$ = 3.4, $J_{3,4}$ = 3.5, $J_{2,3'}$ = 8.4 Hz, H-3), 4.58 (m, 2H, H-1,1′), 4.30 (dd, $J_{3,4}$ = 3.5, $J_{4,5}$ = 7.2 Hz, H-4), 3.9–3.6 (m, 4H, H-5,6,7,7′), 3.09 (s, 3H, CH_3SO_3), 3.02 (bs, 2H, OH), 2.47 (cm, 2H, H-2,2′), 1.40 and 1.37 (s, 3H each, Me_2C). *Anal.* calcd. for $C_{11}H_{21}NO_9S$ (343.4): C 38.47, H 6.16, N 4.08; found: C 38.70, H 5.91, N 3.86.

When a sample of **7** that had been stored at +4°C for 2 months was triturated with EtOAc it failed to dissolve fully, and part of the material crystallized, mp 97–98°C. Recrystallized from hot methanol, the fine needles showed mp 98°C; $[\alpha]_D$ +12° (*c* 1.2, water); ν_{max}: 3540 (sharp) and 3400–3250 (bd, OH), 1540 (NO_2), and multiple sharp bands in the 1200–800 cm^{-1} region. An ^{1}H nmr spectrum (D_2O) indicated retention of the mesyl function but absence of isopropylidene methyl groups. It was concluded that slow deacetonation, perhaps catalyzed by traces of acid left in the sample of **7**, had generated the tetraol **7***a*. *Anal.* calcd. for $C_8H_{17}NO_9S$ (303.3): C 31.68, H 5.65, S 10.58; found: C 31.95, H 5.79, S 10.44.

*5,6-Dideoxy-3,4-*O*-isopropylidene-4-*O*-methylsulfonyl-6-nitro-*al*-*D*-arabino-hexose (**8**)*

Sodium metaperiodate (0.60 g) was dissolved in an ice-cooled solution of **7** (1.012 g) in water (50 mL). The oxidation of **7** to give more mobile **8** (tlc, solvent D) was complete within 15 min. After addition of ethylene glycol (5 drops) the solution was concentrated by evaporation, with several sequential additions of ethanol, whereby solid $NaIO_3$ was deposited. The latter was removed by filtration and washed with ethanol, and the filtrate evaporated to give a colorless syrup. The syrup was taken up in $CHCl_3$ and the filtered solution was washed with a small amount of water, dried ($MgSO_4$), and evaporated. The resulting, chromatographically homogeneous syrup (0.95 g) showed broad ir absorption at 3400 cm^{-1} (presumably due to aldehyde hydrate); other prominent peaks were at 1555 (NO_2), ~1350, 1180, 1170, and 930 cm^{-1}. An ^{1}H nmr spectrum ($CDCl_3$) showed an aldehydic proton signal, δ 9.51, integrating to only 0.3 H. However, an analytical sample dried in high vacuum at 56°C for 18 h gave C,H values in agreement with the free-aldehyde structure **8**. *Anal.* calcd. for $C_{10}H_{17}NO_8S$ (311.3): C 38.58, H 5.50; found: C 38.60, H 5.53.

*1L-(1,2,4/3,5)-2,3-*O*-Isopropylidene-1-O-(methylsulfonyl)-5-nitro-1,2,3,4-cyclohexanetetrol (**9**) and 1L-(1,2/3,4,5)-2,3-*O*-isopropylidene-1-*O*-(methylsulfonyl)-5-nitro-1,2,3,4-cyclohexanetetrol (**10**)*

A solution of aldehyde **8** (2.33 g) in dry methanol (100 mL) containing $NaOCH_3$ (1 g) was allowed to stand at 25°C for 30 min, during which period **8** (R_f ~ 0.2, elongated spot) was consumed and two products having R_f 0.50 and 0.55 were formed, with the less mobile one (**9**) predominating slightly over the other (**10**) (tlc, solvent D). The solution was neutralized by stirring it with a *carboxylic acid*-type cation exchange resin (Amberlite IRC-50, H^+, or equivalent), which after filtration was washed exhaustively with methanol. The filtrate was evaporated and the resulting syrup dried in a high vacuum to give a mixture of **9** and **10** as a fluffy foam (2.193 g, 94%). Although for the preparation of **9** this mixture was processed as described in a subsequent paragraph, a mixture obtained in a similar experiment was partially separated by column chromatography on silica gel with solvents G and F, to characterize **9** and **10**. Pure and almost-pure fractions of either epimer were obtained.

The fractions of **9** (R_f 0.50) gave crystalline product, mp 147–148°C (dec.), after recrystallization from 99% ethanol; $[\alpha]_D$ −20.7° (*c* 1.4, $CHCl_3$); δ ($CDCl_3$): 5.25 (nm, H-1), 4.69 (ddd, $J_{5,6e}$ = 5, $J_{4,5}$ = 9.5, $J_{5,6a}$ = 12.5 Hz, H-5), 4.42 (td, $J_{4,OH}$ = 4, $J_{3,4}$ = $J_{4,5}$ = 9.5 Hz, H-4), 3.88 (t, $J_{2,3}$ = 10, $J_{3,4}$ = 9.5 Hz, H-3), 3.62 (dd, $J_{1,2}$ = 2, $J_{2,3}$ = 10 Hz, H-2), 3.09 (s, 3H, CH_3SO_3), 2.78 (d, J = 4 Hz, OH-4, superposed on ddd, which is clearly revealed after D_2O exchange, $J_{1,6e}$ = 3, $J_{5,6e}$ = 5, $J_{6a,6e}$ = 14.5 Hz, H-6e), 2.25 (quin, $J_{1,6a}$ = 3, $J_{5,6a}$ = 12.5, $J_{6a,6e}$ = 14.5 Hz, H-6a), 1.46 and 1.445 (s, 3H each, Me_2C). *Anal.* calcd. for $C_{10}H_{17}NO_8S$ (311.3): C 38.58, H 5.50, S 10.30; found: C 38.34, H 5.65, S 10.29.

Fractions of pure **10** (R_f 0.55) gave crystals from CH_2Cl_2–hexane, mp 130°C, and 130–131°C after recrystallization; $[\alpha]_D$ +6° (*c* 0.8, $CHCl_3$); δ ($CDCl_3$): 5.26 (nm, H-1), 5.09 (nm, H-4), 4.69 (ddd, $J_{4,5}$ = 2.5, $J_{5,6e}$ = 5.5, $J_{5,6a}$ = 12 Hz, H-5), 4.11 (dd, $J_{3,4}$ = 2.7, $J_{2,3}$ = 9.9 Hz, H-3), 3.86 (dd, $J_{1,2}$ = 2.2, $J_{2,3}$ = 9.8 Hz, H-2), 3.07 (s, 3H, CH_3SO_3), 2.65 (cm, 2H, H-6a,6e), 2.43 (d, $J_{4,OH}$ = 3 Hz, OH), 1.44 and 1.425 (s, 3H each, Me_2C). *Anal.* calcd. as for **9**; found: C 38.42, H 5.43, S 10.37.

Preparative isolation of **9** in good yield was achieved by fractional crystallization, coupled with base-catalyzed epimerization of the epimer **10**. Thus, the aforementioned amorphous mixture of **9** and **10** (2.19 g) was dissolved in 99% ethanol (2.5 mL), and seeded with **9**. Crystallization was allowed to proceed, undisturbed, at room temperature for 2 h. The mixture was diluted with ethanol (15 mL), the supernatant decanted, and the first crop of **9** (209 mg) washed with ethanol and collected. The combined supernatant and washings were evaporated with addition of CH_2Cl_2 to give a syrupy residue, which was dissolved in 2.5 mL of ethanol containing 10 mg of $NaOCH_3$. Seeding with **9** and storage of the mixture at room temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

overnight produced a second crop of **9** (1.147 g), isolated after dilution with ethanol as described before. Three repetitions of the procedure, using progressively smaller volumes of solvent, gave additional crops (191, 125, and 43 mg), for a total of 1.715 g of **9** (78.3% of the original mixture). The crops melted in the range 136–143°C (dec.) and were contaminated by small amounts of **10**. For further purification, the material was dissolved in CH_2Cl_2 and the solution washed twice with water, dried (Na_2SO_4), and evaporated. One or two recrystallizations from ethanol of the recovered material gave chromatographically pure **9**, mp 147–148°C (dec.). All mother liquors were combined and reprocessed with $NaOCH_3$ as described, and a total of 1.54 g (70%) of pure **9** was eventually obtained.

It was observed that both **9** and **10** slowly underwent partial deacetonation when exposed to the laboratory air for prolonged periods. Such samples became incompletely soluble in $CHCl_3$ and showed a new, immobile spot in tlc (solvent D).

*1L-(1,2/3,4,5)-1-O-(Methylsulfonyl)-5-nitro-1,2,3,4-cyclohexanetetrol (**11**) and its 2,3,4-triacetate **12***

A solution of **10** (100 mg) in methanol (3 mL) was acidified with 3 drops of 1 *M* HCl and left overnight at room temperature, then heated briefly (2 min) to 60°C for a completion of the hydrolysis, which was monitored by tlc (solvent D). Evaporation with several added portions of methanol followed by 95% ethanol quantitatively gave crystalline **11**, which was recrystallized from hot methanol; mp 173°C (dec.), $[\alpha]_D$ −32.7° (*c* 1.4, 1:1 MeOH–DMF); ν_{max}: 3470 and 3410 (OH), 1335 (NO_2), 1170 (MsO), 1090–1070, 1030, 1000, 980, 900, and 870 cm^{-1}. *Anal.* calcd. for $C_7H_{13}NO_8S$ (271.2): C 30.99, H 4.83, N 5.16, S 11.82; found: C 31.19, H 4.85, N 4.92, S 11.89.

To a suspension of **11** (20 mg) in acetic anhydride (1 mL) was added BF_3–Et_2O (5 drops), with initial ice-cooling. All of **11** dissolved rapidly. The solution was kept at ambient temperature for 1 h and then brought to dryness. Trituration of the residue with a small amount of 95% ethanol gave **12** as fine needles, mp 191–192°C; $[\alpha]_D$ −71° (*c* 0.4, $CHCl_3$); ν_{max}: 1750 (ester CO) and 1553 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$; assignments confirmed by HOMCOR method), δ: 6.19 (nm, H-4), 5.31 (nm, H-1), 5.26 (dd, $J_{1,2}$ = 2.8, $J_{2,3}$ = 10.9 Hz, H-2), 5.15 (dd, $J_{3,4}$ = 3.0, $J_{2,3}$ = 10.9 Hz, H-3), 4.85 (ddd, $J_{4,5}$ = 2.7, $J_{5,6e}$ = 5, $J_{5,6a}$ = 12.5 Hz, H-5), 3.08 (s, 3H, CH_3SO_3), 2.77 (dtd, $J_{4,6e}$ = −1.2, $J_{5,6e}$ = 5, $J_{1,6e}$ = 4, $J_{6a,6e}$ = 15 Hz, H-6e), 2.64 (quin, $J_{1,6a}$ = 2.3, $J_{5,6a}$ = 12.5, $J_{6a,6e}$ = 15 Hz, H-6a), and 2.08, 2.07, 2.00 (s, 3H each, OAc). *Anal.* calcd. for $C_{13}H_{19}NO_{11}S$ (397.4): C 39.29, H 4.82, S 8.07; found: C 39.50, H 4.83, S 7.97.

*1L-(1,2,4/3,5)-1-O-(Methylsulfonyl)-5-nitro-1,2,3,4-cyclohexanetetrol (**13**) and its 2,3,4-triacetate **14***

A suspension of the acetonide **9** (300 mg) in ether (15 mL) containing 90% CF_3CO_2H (0.3 mL) was boiled under reflux. Deacetonation monitored by tlc (solvent D), to give nearly immobile **13**, was slow under these conditions but was accelerated upon addition of several drops of methanol to render the medium homogeneous, and it was complete after 3 h. Solvent removal and evaporation of several added portions of ether–methanol, followed by pure ether, from the material gave **13** (262 mg, quantitative) as a white, low-melting (50–60°C), amorphous powder after drying *in vacuo* over KOH; $[\alpha]_D$ −30° (*c* 1.2, methanol); ν_{max}: 3500–3200 (OH), 1550 (NO_2), 1170 (MsO), 1120–1070, 1000 (weak), 975, 900, 860–820, 780, and 720 cm^{-1}. *Anal.* calcd. for $C_7H_{13}NO_8S$ (271.2): C 30.99, H 4.83; found: C 30.91, H 4.82.

A sample of **13** (20 mg) was treated with acetic anhydride (1 mL) and BF_3–Et_2O (2 drops). The reaction mixture was allowed to dry in the air, leaving **14** as a crust of beautiful crystals that were washed with a small amount of cold methanol; mp 197–198°C, unchanged on recrystallization from methanol; $[\alpha]_D$ −61.9° (*c* 0.8, $CHCl_3$); ν_{max}: 1740 (ester CO) and 1563, 1543 cm^{-1} (a doublet for NO_2; compare the single band in **12**). The fingerprint region was clearly distinct from that of **12**. The ^1H nmr ($CDCl_3$; assignments confirmed by HOMCOR method), δ: 5.61 (~t, $J_{3,4}$ = 9.5, $J_{4,5}$ = 10 Hz, H-4), 5.40 (~t, $J_{2,3}$ = 10.5, $J_{3,4}$ = 9.5 Hz, H-3), 5.27 (nm, H-1), 5.00 (dd, $J_{1,2}$ = 3, $J_{2,3}$ = 10.5 Hz, H-2), 4.94 (ddd, $J_{5,6e}$ = 4.5, $J_{4,5}$ = 10, $J_{5,6a}$ = 13 Hz, H-5), 3.13 (s, 3H, CH_3SO_3), 2.76 (dt, $J_{1,6e}$ = $J_{5,6e}$ = 4.5, $J_{6a,6e}$ = 14.5 Hz, H-6e), 2.35 (quin, $J_{1,6a}$ = 2.2, $J_{5,6a}$ = 13, $J_{6a,6e}$ = 14.5 Hz, H-6a), and 2.06, 2.01, 2.00 (s, 3H each, OAc). *Anal.* calcd. for $C_{13}H_{19}NO_{11}S$ (397.4): C 39.29, H 4.82, S 8.07; found: C 39.37, H 4.65, S 8.21.

*6-Azido-4-nitro-1,2,3-cyclohexanetriol (**15**)*

*(a) From **13***

Compound **13** (200 mg) and LiN_3 (100 mg) were heated in dry *N,N*-dimethylformamide (2 mL) at 100°C for 3 h, under exclusion of atmospheric moisture. Thin-layer chromatography with solvent B indicated conversion of **13** (R_f 0.55) into products giving a strong spot (R_f 0.65) for **15** and a weaker spot (R_f ~ 0.57) attributed to the 3-epimer, differentiated from **13** by its color shade (5% H_2SO_4 spray, heat). The solvent was removed *in vacuo* at 50°C and by several coevaporations with added toluene. The brown syrup obtained was mixed with a few drops of water and triturated with $CHCl_3$ containing a small amount of methanol. The organic solution was washed with water, dried ($MgSO_4$), concentrated, and applied to a column of silica gel (6 g) for chromatography with solvent B. Colorless crystalline material was obtained from several fractions, totalling 115 mg (72%). Chromatographically homogeneous **15** (R_f 0.65) showed mp 163–166°C (dec.); $[\alpha]_D$ −21.0° (*c* 2.5, methanol); ν_{max}: 3400 (OH), 2110 (N_3), and 1550 (NO_2) cm^{-1}. Fractions in which the less abundant product (R_f 0.57) was enriched were dissolved in a small volume of methanol containing a catalytic amount of $NaOCH_3$, seeded with **15**, and allowed to dry slowly in an open vessel placed over KOH in an unevacuated desiccator. The dry residue then indicated (tlc) preponderance of **15**. *Anal.* calcd. for $C_6H_{10}N_4O_5$ (218.2): C 33.03, H 4.62, N 25.68; found: C 33.11, H 4.66, N 25.68.

*(b) From **19***

Slow evaporation (overnight) of a solution of **19** (100 mg) in methanol (2 mL) containing 5 drops of 1 *M* HCl, in a lightly covered Petri dish, gave a dry crust of stout crystals of **15** (84 mg after washing with small amounts of ether, EtOAc, and ether again); mp 169–170°C with decomposition from 165°C; $[\alpha]_D$ −20° (*c* 1.1, methanol). The ir spectrum was identical with that of **15** obtained from **13**.

*(c) Triacetate **15**a*

An analytical sample of **15** was treated on a watchglass with a few drops of acetic anhydride and a droplet of BF_3–Et_2O. Slow evaporation of the reagent in the air left **15***a* as a dry residue of long needles that were washed with ether–hexane; mp 140°C; ν_{max}: 2100 (N_3), 1750 (ester CO), and 1560 (NO_2) cm^{-1}; δ ($CDCl_3$): 5.59 (t, $J_{2,3}$ = $J_{3,4}$ = 10 Hz, H-3), 5.10 (septet, 2H, H-1,2), 4.66 (ddd, $J_{4,5e}$ = 4.5, $J_{3,4}$ = 10.7, $J_{4,5a}$ = 13.1 Hz, H-4), 3.63 (ddd, $J_{5e,6}$ = 4.5, $J_{1,6}$ = 9.5, $J_{5a,6}$ = 12.8 Hz, H-6), 2.63 (dt, $J_{4,5e}$ = $J_{5,6e}$ = 4.5, $J_{5a,5e}$ = 13.1 Hz, H-5e), 2.10 (q, line separation ~ 13 Hz, H-5a), 2.08, 2.00, and 1.99 (s, 3H each, OAc), and 1.55 (bs, H_2O). The presence of water of crystallization, not removed after drying the substance *in vacuo* at 80°C, was surprising, but was confirmed also by a broad ir band at 3200 cm^{-1} and by the combustion data. *Anal.* calcd. for $C_{12}H_{16}N_4O_8 \cdot 1.5\ H_2O$ (371.3): C 38.81, H 5.16, N 15.09; found: C 38.89, H 4.97, N 14.97.

*3-Azido-1,2,3-trideoxy-4,5;6,7-di-O-isopropylidene-1-nitro-D-glucoheptitol (**16**)*

*(a) From mesylate **5** by an improved procedure*

A mixture of mesylate **5** (9.59 g), NaN_3 (14 g), $Bu_4N^+HSO_4^-$ (8 g), water (50 mL), and benzene (250 mL) was efficiently stirred in a jacketed reaction vessel, the outer chamber of which contained boiling acetone. Monitored by tlc (solvent H), the reaction was estimated to be about 50% complete after 3 days. Additional NaN_3 (6 g) and $Bu_4N^+HSO_4^-$ (4 g) was introduced, and after a further 3 days only traces of **5** (R_f 0.12) were visible. The main product **16** (R_f 0.42) was accompanied by small proportions of by-products having R_f 0.49 and 0.29. The benzene layer was washed 4 times with water, dried (Na_2SO_4), and evaporated. The amber syrup so obtained (9.08 g) was chromatographed on a column of silica gel (83 × 2.5 cm) with solvent I. Mixture fractions were rechromatographed on a similar column. The combined fractions of **16**, homogeneous in tlc with solvent H, nevertheless contained a slow-moving impurity (R_f 0.03) as revealed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

by tlc with CH_2Cl_2. This impurity was removed by passage of the product through a column (20 × 2.8 cm) by means of CH_2Cl_2. The evaporated eluate was decolorized with activated charcoal in ethanol, and final evaporation gave **16** as a syrup (6.281 g, vacuum dried; 76%), $[\alpha]_D$ +15° (*c* 0.7, $CHCl_3$), indistinguishable by ir and nmr spectra from the preparation previously described (12).

The by-products having R_f 0.49 and 0.29 were isolated in amounts of 501 and 47 mg, respectively. Both lacked N_3 absorption in the ir and were identical with the cyclopropano derivatives previously encountered (12), according to their ^1H nmr spectra.

(b) From triflate 6

To a solution of NaN_3 (15 g) and $Bu_4N^+HSO_4^-$ (8 g) in water (30 mL) was added crystalline **6** (8.374 g) followed by benzene (60 mL). The mixture was efficiently stirred at room temperature. Monitoring of the reaction by tlc was difficult because of similar mobilities of **6** and **16**; however, with CH_2Cl_2 as the solvent, **16** was seen to migrate marginally more slowly. (It also charred to a darker spot than **6**, after spraying the plate with dilute sulfuric acid and heating it on a hot-plate.) Although the reaction was close to completion after 1 h, stirring was continued overnight. The phases were then separated, the aqueous phase was extracted with benzene, and the combined benzene phases were washed 5 times with water, dried (Na_2SO_4), and evaporated, to give crude **16** (6.79 g), $[\alpha]_D$ +13.1° (*c* 0.8, $CHCl_3$). The colored syrup was purified by passage through silica gel (25 g) with CH_2Cl_2 as the solvent. The eluate gave on evaporation pure **16** (5.308 g, 84.1%) as a colorless syrup, $[\alpha]_D$ +14.6° (*c* 0.9, $CHCl_3$). The ^1H nmr data were the same as those for the product obtained under (*a*).

The mother liquor that had remained in the preparation of the crystalline batch of **6** (*vide supra*) here utilized was subjected to azide displacement in the same way, furnishing an additional 434 mg of **16**. Based on alcohol **4**, the yield was therefore 61%. In a similar operation (but on one-half scale), a two-step yield of 71% was achieved. Finally, a 93% yield from **4** was obtained when the alcohol was triflated as described but isolation of crystalline **6** was dispensed with and the entire, crude triflate syrup was used for azide displacement. The product was less pure (tlc; $[\alpha]_D$ +13.4°), but could be used for the preparation of **19**.

*3-Azido-1,2,3-trideoxy-4,5-*O*-isopropylidene-1-nitro-*D*-*gluco*-heptitol (17)*

Pure **16** (8.55 g) in toluene (80 mL) was treated at −30°C with 90% CF_3CO_2H (5 mL). After 15 min, tlc (solvent E) showed **17** (R_f 0.2) and a considerable amount of remnant **16** (R_f 0.75). Further acid (5 mL) was added, and after another 15 min the formation of immobile product was observed, even though some **16** was still present. The reaction was quenched by stirring the mixture for 0.5 h with solid $NaHCO_3$ (25 g), then shaking it with added water (40 mL) and ethyl acetate (10 mL). The phases were separated, and the organic phase was washed exhaustively with water. The organic phase contained unreacted **16**, which was isolated and subjected to an identical acid treatment (with appropriately adjusted volumes). All aqueous extracts were combined; they contained **17** as well as tetraol resulting from over-hydrolysis. Neutralization of excess $NaHCO_3$ with acetic acid followed by exhaustive extraction of the aqueous phase with ethyl acetate gave an extract that, after concentration to a volume of 100 mL, washing once with water at that stage, drying, and complete solvent removal, furnished the main crop of **17** as a syrup (6.38 g). The remaining aqueous phase was evaporated to dryness, to give a residue of salts containing tetraol. By acetonation of this material (compare the preparation of **4** from **3**), 580 mg of regenerated **16** was obtained, which yielded another 250 mg of **17** upon partial hydrolysis as just described. The total yield of **17** was therefore 6.63 g (88%); $[\alpha]_D$ +18.8° (*c* 0.9, EtOAc); ν_{max}: 3500–3200 (OH), 2110 (N_3), and 1550 (NO_2) cm^{-1}; δ ($CDCl_3$): 4.55 (dd, 2H, J = 6.4 and 7.1 Hz, H-1,1′), 4.08 (dd, $J_{3,4}$ = 3, $J_{4,5}$ = 7.2 Hz, H-4), 3.98 (~t, $J_{4,5}$ = 7.2, $J_{5,6}$ = 7.3 Hz, H-5), 3.85 (m, H-6), ~3.70 (two partially overlapping dd, $J_{6,7}$ and $J_{6,7'}$ = 5.1–5.2 Hz, H-7,7′), 3.49 (ddd, W = 17 Hz, H-3), ~2.40 (cm, 2H, H-2,2′), 1.9 (broad band, 2H, exchangeable with D_2O, 2OH), 1.44 and 1.36 (s, 3H each, Me_2C). *Anal.* calcd. for $C_{10}H_{18}N_4O_6$ (290.3): C 41.38, H 6.25, N 19.30; found: C 41.23, H 6.41, N 19.09.

*1L-(1,3/2,4,6)-6-Azido-1,2-*O*-isopropylidene-4-nitro-1,2,3-cyclohexanetriol (19)*

(a) From 17 via 18

A solution of diol **17** (6.63 g) in water (100 mL) was mixed with a solution of $NaIO_4$ (5.35 g) in water (50 mL), at 25°C. Oxidation was complete within a few minutes (tlc with EtOAc: R_f 0.7 → R_f 0.85). Ethylene glycol (0.3 g) was added after 10 min, and the solution was then extracted with EtOAc (4 × 100 mL), concentrated to a small volume, and extracted twice more with EtOAc. The dried extracts were evaporated to give syrupy aldehyde **18** (5.58 g, 95%, dried under oil-pump vacuum).

The entire syrup (**18**) was immediately dissolved in reagent-grade methanol (100 mL), and $NaOCH_3$ (0.5 g) in methanol (50 mL) was added with swirling. Thin-layer chromatography with solvent H indicated that the inhomogeneous starting material (R_f 0.0–0.25), which may have contained aldehyde hydrate or hemialdal, or already some cyclization product, was converted after 1 h into product(s) giving a single spot (R_f 0.25). The reaction mixture was concentrated to a small volume and then distributed between water and EtOAc. Repeated extractions of the water phase, and washing (H_2O), drying (Na_2SO_4), and evaporation of the EtOAc extracts gave syrupy product (5.0 g). Concentration of the combined water phases to a small volume, addition of 0.2 mL of glacial acetic acid, and several further extractions performed alternately with benzene and with EtOAc gave an additional crop of syrup (570 mg). Excess CH_2Cl_2 was added to, and evaporated from, the combined syrupy material, which was then taken up in 5 mL of 95% ethanol. After brief heating to dispel remnant CH_2Cl_2 the solution was stored overnight at ambient temperature for crystallization. A first crop of white crystals (1.181 g) of slightly impure **19**, mp 162–167°C, was collected and washed with 95% ethanol. The mother liquor was evaporated to a syrup, which was briefly heated (5 min; steam bath) with 2-propanol (3 mL) containing 10 mg of $NaOCH_3$. On subsequent seeding and standing (20 h) a second crop of crystals (0.834 g) was formed. The process was repeated several times, using 2-propanol or 95% ethanol as the solvent, until 4.11 g of crystalline product was eventually accumulated (73.6% from **18**, or 69.7% from **17**). The various fractions melted in the range of 147–167°C and contained small proportions of the epimer **20** as evidenced by nmr spectra. (In tlc with solvent E the epimers had similar R_f values of 0.55–0.60, but mixtures tended to give a double spot, with **19** migrating marginally faster.) For further purification, the material was dissolved in 4:1 benzene–CH_2Cl_2 and the solution was washed once with water, dried, and evaporated. The recovered crystalline product was then recrystallized once more from 95% ethanol, to give 3.60 g of pure **19**, mp 171°C; $[\alpha]_D$ −12.7° (*c* 0.8, $CHCl_3$). Processing of the mother liquor with $NaOCH_3$ as described above, and recrystallization of the crystals obtained, gave another 250 mg of pure **19**, for a total yield of 3.85 g (65% from **17**); ir, ν_{max}: 3500 (OH), 2100 (N_3), and 1550 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$), δ: 4.46 (ddd, $J_{4,5e}$ = 5, $J_{3,4}$ = 9, $J_{4,5a}$ = 12.5 Hz, H-4), 4.39 (dt; t after D_2O exchange; $J_{3,OH}$ = 3,3 $J_{2,3}$ = $J_{3,4}$ = 9.2 Hz, H-3), 3.72 (ddd, $J_{5e,6}$ = 4.8, $J_{1,6}$ = 9.6, $J_{5a,6}$ = 11.5 Hz, H-6), 3.50 (~t, $J_{1,2}$ = 9.3, $J_{1,6}$ = 9.6 Hz, H-1), 3.41 (t, $J_{1,2} \approx J_{2,3}$ = 9.35, H-2), 2.92 (d, exchangeable, J = 3.3 Hz, OH), 2.65 (dt, $J_{4,5e} \approx J_{5e,6}$ = 4.85, $J_{5a,5e}$ = 13.4 Hz, H-5e), 1.95 (ddd, $J_{5a,6}$ = 11.5, $J_{4,5a}$ = 12.6, $J_{5a,5e}$ = 13.4 Hz, H-5a), 1.47 and 1.46 (s, 3H each Me_2C). *Anal.* calcd. for $C_9H_{14}N_4O_5$ (258.3): C 41.85, H 5.46, N 21.70; found: C 41.61, H 5.77, N 21.52.

For additional characterization, a 50-mg sample of **19** was converted quantitatively into its *3-(trimethylsilyl) ether* by treatment for 2 h with hexamethyldisilazane (0.3 mL) in refluxing EtOAc (3 mL), in the presence of 3 mg of powdered $(NH_4)_2SO_4$. The ether was isolated by evaporation of the solution with added, excess EtOAc followed by toluene, washing with water, and drying of the colorless syrup obtained, *in vacuo*, whereupon it readily and completely crystallized on scratching. The ether had mp 76°C; R_f 0.85 (tlc, solvent F); ν_{max}:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

2100 (N_3), 1550 (NO_2), and 1250, 850 (Si-C) cm^{-1}; ^1H nmr ($CDCl_3$), δ: 4.44 (ddd, $J_{4,5e}$ = 5, $J_{3,4}$ = 8.9, $J_{4,5a}$ = 12.9 Hz, H-4), 4.26 (~t, width 18.7 Hz, H-3), 3.66 (ddd, $J_{5e,6}$ = 4.8, $J_{1,6}$ = 10.1, $J_{5a,6}$ = 11.4 Hz, H-6), 3.46 (dd, $J_{1,2}$ = 9, $J_{1,6}$ = 10.1 Hz, H-1), 3.31 (dd, $J_{1,2}$ = 9.1, $J_{2,3}$ = 9.7 Hz, H-2), 2.52 (dt, $J_{4,5e} \approx J_{5e,6}$ = 4.9 Hz, $J_{5a,5e}$ = 13.3 Hz, H-5e), 1.98 (~sx, J = 11.5, 12.8, and 13.3 Hz, H-5a), 1.44 and 1.42 (s, 3H each, Me_2C), and 0.08 (s, 9H, Me_3Si).

Mother liquors remaining after the aforedescribed procedures of isolation and recrystallization of **19** contained **19** together with comparable amounts of its 3-epimer **20**, as was clearly revealed by ^1H nmr spectra that showed good separation of signals for the two components, except for overlapping H-4 signals. Epimerism at C-3 was indicated for **20** by a downfield shift and small splittings for the signal of equatorial H-3, and by deshielding of the H-1 and H-5a signals caused by an axial OH-3 group. Although attempted preparative separation of the epimers by column chromatography was inefficient, a small fraction containing virtually pure **20** could so be secured for spectral analysis; δ: 4.99 (nm, H-3), 4.44 (ddd, $J_{3,4}$ = 2.85, $J_{4,5e}$ = 4.9, $J_{4,5a}$ = 12.7 Hz, H-4), 3.99 (~t, $J_{1,2} \approx J_{1,6} \approx$ 9.8 Hz, H-1), 3.60 (ddd, $J_{5e,6}$ = 4.7, $J_{1,6}$ = 10.1, $J_{5a,6}$ = 11.7 Hz, H-6), 3.38 (dd, $J_{2,3}$ = 1.9, $J_{1,2}$ = 9.4 Hz, H-2), 2.49 (dt, H-5e), 2.33 (~sx, J = 11.7 and 12.7, and $J_{5a,5e}$ = 13.5 Hz, H-5a), ~1.5 (broad, exchangeable; OH), 1.46 and 1.445 (s, 3H each, Me_2C).

It was found that crystalline samples of **19** sometimes gave a weak spot (R_f ~ 0.33) in addition to the main spot (R_f 0.6) in tlc with solvent E. The intensity of the former, though always low, seemed to vary with the solvent of application and with the time span of the sample's exposure to silica gel. The phenomenon was probably due to reversal of the cyclization occurring to a minor extent under certain conditions. A substance (presumably **18**) that had the same R_f value accumulated in mother liquors of **19** and was found to be reconvertible into the mixture of epimeric cyclitols by treatment with $NaOCH_3$ in methanol.

(b) From **9**

To a solution of **9** (100 mg) in warm benzene (8 mL) was added NaN_3 (200 mg), $Bu_4N^+HSO_4^-$ (135 mg), and water (2 mL). The vigorously stirred mixture was boiled under reflux for 3 days. The mixture was then diluted with water and benzene, and the benzene phase was washed several times with water, dried ($MgSO_4$), treated with activated charcoal, and evaporated to give a colorless syrup; R_f 0.6 (strong) and 0.35–0.45 (traces; tlc with solvent E). The slow-moving contaminants were removed by passage of the material through a small column of silica gel (6 g) by means of solvent F. The purified syrup (60 mg, 72%) crystallized on trituration with a few drops of 95% ethanol and seeding with **19**. The ir spectrum matched that of pure **19** in all of its features, but additional peaks present in the fingerprint region were attributable to accompanying **20** (by comparison with the spectrum of isolated **20**). The ^1H nmr spectrum was a superposition of those of **19** and **20**, suggesting a ratio of roughly 4:1 for these components.

*2-Deoxystreptamine (**21**) and N,N'-diacetyl-2-deoxystreptamine (**22**)*

Azidonitrotriol **15** (125 mg) in water (20 mL) containing 1 *M* HCl (1.5 mL) was hydrogenated overnight, at ordinary temperature and pressure, with prehydrogenated Adams catalyst (from 90 mg of PtO_2). Evaporation of the optically inactive filtrate, followed by trituration of the residue with 95% ethanol, gave **21** as the crystalline dihydrochloride (136 mg, 100%); it partially sublimed above 300°C and decomposed at about 325°C (lit. (19) mp 325°C (dec.)). The ir spectrum was identical in every detail with that of an authentic sample kindly provided by Bristol Laboratories, Syracuse, N.Y.

A sample of the dihydrochloride was converted into the *N,N'*-diacetyl derivative **22** by treatment with acetic anhydride and triethylamine in methanol–water. Washed with methanol–ether, the crystalline **22** melted with decomposition at 297–300°C, with prior darkening from 290°C (lit. (20) mp 292°C (dec.)). The ir spectrum was identical with that of **22** prepared from an authentic sample of **21**, as well as with that of **22** obtained from the acetonide **24** in the following way. Compound **24** (144 mg) was dissolved in methanol (0.6 mL) with the aid of sonication, and 1:4 concentrated HCl – methanol (5 drops) was then added. After 5 min the reaction appeared to be largely finished (tlc with 1:4 methanol–EtOAc), and **22** began to crystallize. Collected after 2 days and washed with methanol, the crystals (109 mg, 88%) showed mp 299–301°C (dec., with darkening from ~292°C); ^{13}C nmr data (D_2O, dioxane reference signal at 67.4 ppm), δ: 174.8 (CO), 76.7 (C-5), 75.1 (C-4,6), 50.5 (C-1,3), 33.3 (C-2), and 22.9 (Me), in excellent agreement with reported (21) data; [α] 0.0° in the spectral region 365–589 nm (*c* 1.4, water).

*1L-(1,3/2,4,6)-4,6-Diacetamido-1,2-O-isopropylidene-1,2,3-cyclohexanetriol (N,N'-diacetyl-4,5-O-isopropylidene-2-deoxystreptamine, **24**)*

Platinum dioxide (775 mg) suspended in ethanol (12 mL) was prehydrogenated. Glacial acetic acid (1.08 g, 18 mmol) was then added to the suspension, followed by a solution of **19** (775 mg, 3 mmol) in warm ethanol (8 mL). The mixture was vigorously shaken under hydrogen at ordinary temperature and pressure for 5 h. Progress of the reaction was monitored by tlc (1:4 methanol–EtOAc), which indicated gradual disappearance of **19** (R_f 0.9) and formation of nearly immobile diamine **23**, with several intermediary products of intermediate mobilities being visible. The catalyst was filtered off and washed exhaustively with ethanol, and acetic anhydride (1.3 mL) was added to the filtrate. After 30 min the solution was evaporated *in vacuo* (bath temperature 30°C), and several portions of added ethanol were evaporated from the residue until the acidic smell had vanished. Crystallization of the syrup from about 2 mL of ethanol to which 4 drops of saturated, methanolic ammonia had been added gave a first crop (392 mg) of **24**. Processing of the mother liquor by use of ethanol, ethanol–acetone, and acetone as solvents gave several additional crops for a total of 608 mg (70.8%). The crops melted with decomposition in the range of 250–260°C, dependent on the rate of heating. Recrystallized from ethanol, **24** had mp 253–255°C (lit. (13) mp 193–195°C for racemic compound); ν_{max}: 3350 and 3280 (OH, NH), 1660, 1630 and 1560, 1530 (amide I and II) cm^{-1}; δ ($CDCl_3$): 5.57 and 5.49 (bd, 1H each, J = 7–8 Hz, exchangeable, NH), 3.98, 3.85, and 3.75 (bm, 1H each, H-1,3,6), 3.47 (cm, 2H, H-4,5), 2.52 (dt, $J_{1,2e} = J_{2e,3}$ = 4.8, $J_{2a,2e}$ = 12.9 Hz, H-2e), 2.00 and 1.96 (s, 3H each, Ac), and 1.43 (s, 6H, Me_2C). The optical rotation in methanol (*c* = 6.8, and in parentheses, *c* = 1.36) was noticeably concentration dependent: $[\alpha]_{365}$ −12.7° (−10.3°), $[\alpha]_{436}$ −3.8° (−2.4°), $[\alpha]_{546}$ −0.25° (+0.40°), $[\alpha]_{578}$ +0.1° (+0.65°), $[\alpha]_D$ +0.15° (+0.80°). *Anal.* calcd. for $C_{13}H_{22}N_2O_5 \cdot 0.5\,H_2O$ (295.3): C 52.87, H 7.85, N 9.48; found: C 52.65, H 7.78, N 9.30.

A sample of **24** was *O*-acetylated (acetic anhydride – pyridine); the *acetate* (R_f 0.45, tlc with 1:4 methanol–EtOAc) showed $[\alpha]_{365}$ +53.9°, $[\alpha]_{436}$ +38.6°, $[\alpha]_{546}$ +24.4°, $[\alpha]_{578}$ +21.9°, $[\alpha]_D$ +21.3° (*c* 1.5, $CHCl_3$).

The synthesis and structure of $Fe[\eta^5\text{-}C_5H_3(CHMeNMe_2)\overline{SiCl_2\text{-}1,2}][\overline{C_5H_4}\text{-}\eta^5]$

IAN R. BUTLER, WILLIAM R. CULLEN,[1] AND STEVEN J. RETTIG[2]

Chemistry Department, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received September 4, 1986

IAN R. BUTLER, WILLIAM R. CULLEN, and STEVEN J. RETTIG. Can. J. Chem. **65**, 1452 (1987).

The novel ferroceneophane $Fe[C_5H_3(CHMeNMe_2)\overline{SiCl_2\text{-}1,2}][\overline{C_5H_4}]$, **1***c*, is the product of the reaction of silicon tetrachloride with the dilithio derivative of *N,N*-dimethyl-α-ferrocenylethylamine. Crystals of **1***c* are monoclinic, space group $C2/c$, $a = 15.275(2)$, $b = 9.0869(4)$, $c = 22.363(2)$ Å, $\beta = 95.814(5)°$, $Z = 8$, $R = 0.037$ for 2274 reflections. The tilt angle between the cyclopentadieneyl rings is 19.0(2)° and the bridge-head angle at silicon is 100.7(1)°. Other angles at silicon indicate some repulsive interaction with the $CHMeNMe_2$ group. Silica rapidly reacts with **1***c* to give materials which have essentially the same Mössbauer spectra as the starting material. **1***c* reacts with methanol to give $Fe(C_5H_3(CHMeNMe_2)Si(OMe)_3\text{-}1,2)(C_5H_5)$ and other products.

IAN R. BUTLER, WILLIAM R. CULLEN et STEVEN J. RETTIG. Can. J. Chem. **65**, 1452 (1987).

Le nouveau ferrocènephane $Fe[C_5H_3(CHMeNMe_2)\overline{SiCl_2\text{-}1,2}][\overline{C_5H_4}]$, **1***c*, est produit par la réaction du chlorure de silicium avec le dérivé dilithié de la *N,N*-diméthyl α-ferrocènyléthylamine. Les cristaux de **1***c* sont monocliniques, groupe d'espace $C2/c$, avec $a = 15,275(2)$, $b = 9,0869(4)$ et $c = 22,363(2)$ Å, $\beta = 95,814(5)°$, $Z = 8$ et $R = 0,037$ pour 2274 réflexions. L'angle de déviation entre les noyaux cyclopentadiènеyles est de 19,0(2)° et l'angle à la tête de pont du silicium est de 100,7(1)°. Les autres angles au niveau du silicium indiquent qu'il existe des interactions répulsives avec le groupement $CHMeNMe_2$. La silice réagit rapidement avec le composé **1***c* pour conduire à des produits qui ont essentiellement les mêmes spectres de Mossbauer que le produit de départ. Le composé **1***c* réagit avec le méthanol pour donner du $Fe[C_5H_3(CHMeNMe_2)Si(OMe)_3\text{-}1,2][C_5H_5]$ ainsi que d'autres produits.

[Traduit par la revue]

The reaction of ferrocenophanes such as **1***a* with an electrode surface is a useful means of attaching a ferrocenyl group (1–4). In the case of **1***a* and **1***b* one Si—C bond is believed to be cleaved during attachment so that the final product, **2***a* = **3***a*, is as shown in reaction [1].

We are interested in preparing polymers functionalized with chiral ferrocene groups for use as "heterogenized" catalysts (5, 6). We also have an interest in exploring the electrochemistry of chiral surfaces (7, 8). For these reasons the synthesis of **1***c*, which contains both a chiral center and planar chirality, and its binding to silica, was an attractive target since, if necessary, it could readily be prepared as an optically pure enantiomer (9, 10).

We now report the successful synthesis of **1***c*, its binding to silica, and its solid state structure. Unfortunately, model studies indicate that a ring cleavage reaction would not be stereospecific so that both **2***c* and **3***c* could be expected from a reaction such as described by reaction [1].

Experimental section

General procedures

Unless otherwise stated all air- or moisture-sensitive materials were manipulated under a nitrogen atmosphere using standard Schlenk techniques. Mössbauer spectra were recorded and processed as described previously (11). Isomer shifts are listed relative to iron foil. Nuclear magnetic reosnance spectra were run on Bruker WP-80 and WH-400 instruments. Microanalyses were performed by Mr. Peter Borda of this Department.

*(1) Reaction of 2,1'-dilithio-*N,N*-dimethyl-α-ferrocenylethylamine with silicon tetrachloride. Preparation of the ferrocenophane* **1***c*

The dilithio derivative of *N,N*-dimethyl-α-ferrocenylethylamine (3.0 g, 7.8 mmol), prepared and isolated as the TMED adduct according to the literature procedure (12), was suspended in diethyl ether (20 mL) and added slowly to a chilled (−70°C) solution of silicon tetrachloride (5 g, 29.4 mmol) in diethyl ether (50 mL).

The reaction mixture was allowed to warm slowly to room temperature (~1 h) and was further stirred for 3 h. The solvent and excess $SiCl_4$ were removed by vacuum transfer to leave a yellow/brown powder. The powder was extracted with a 1:1 mixture of dry diethyl ether and dichloromethane (50 mL) and filtered through a *thin* layer of grade 1 activity, neutral alumina to give a clear yellow/orange solution. The solvent volume was reduced under vacuum until an oil began to form. Diethyl ether (10 mL) was then added carefully. The solution was chilled for 3–4 days at −20°C and large yellow crystals of the ferrocenophane **1***c* were obtained (yield ~ 40%, not optimised). These crystals were washed with dry hexane and vacuum dried. *Anal.* calcd. for $C_{14}H_{17}Cl_2FeNSi$: C 47.48, H 4.84, N 3.95; found: C 47.29, H 4.90, N 3.99. Mass spectrum, *m/e* (relative intensity) 357 (1.48), 355 (7.30), 353 (10.83)M^+; 342, 340, 338 (P − Me)$^+$, 314, 312, 310 (P − NMe_2 + H)$^+$. ^1H nmr ($CDCl_3$, 80 MHz) δ 1.50 (d, 3, J = 7 Hz), 2.25 (bs, 6), 3.92 (m, 1), 4.25 (m, 2), 4.70 (2m, 4). Mössbauer δ 0.52, Δ 2.38.

(2) Attachment of **1c** *to silica gel*

To 1.0 g of Kieselgel 60 (Fisher), which had been heated under vacuum at 110°C (oil bath) for 2 h then cooled, was added a stirred solution of **1c** (0.5 g, 1.4 mmol) in dry $CHCl_3$ (20 mL). The solution colour was rapidly discharged (~1 min). The coated silica was filtered off, and washed with chloroform (2 × 10 mL), and vacuum dried. *Anal.* C 6.77, H 1.10, N 0.49. Subsequent experiments showed that loadings of up to 1 g of **1c** per g of silica could be achieved.

Similarly, Aerosil 200 (Degussa), after drying at 180°C under vacuum, was added to a solution of **1c** in dry $CHCl_3$. The color was slowly discharged. Mössbauer δ 0.53; Δ 2.36.

(3) Reaction of **1c** *with MeOD*

A solution of **1c** (1.0 g, ~28 mmol) in CH_2Cl_2 was added to a mixture of MeOD (10.0 mL) in CH_2Cl_2 (10 mL). The solvent volume was reduced to a few mL and a top layer of diethyl ether was added. A yellow oil was obtained by this procedure. The oil was extracted with chloroform and the extracts were concentrated under vacuum. Addition of hexene resulted in the formation of pale yellow diamond shaped crystals. Mass spectrum, m/e (relative intensity) 378 (82.55) P, 363 (68.35) P − Me, 334 (100.00) P − NMe_2; 302 (80.95), 270, 121, 91, 72. ^{1}H nmr ($CDCl_3$, 400 MHz) δ 1.85 (bm), 1.97 (d, CH*Me*), 2.3–2.9 (bm), 3.49 (s, Si(O*Me*)$_3$), 3.71 (s, Si(O*Me*)$_3$), 4.1–4.6 (series of multiplets including 4.23 (s, C_5H_5 or C_5H_4D)).

(4) X-ray crystallographic analysis of **1c**

Crystallographic data are presented in Table 1. The final unit-cell parameters were obtained by least squares on 2 sin θ/λ values of 25 reflections (with 2θ = 35–41°) measured with MoKα_1 radiation. The intensities of three check reflections, measured each hour of X-ray exposure time throughout the data collection, showed only small random variations. The data were corrected for absorption using the Gaussian integration method (13, 14) the range of transmission factors being given in Table 1.[3]

The centrosymmetric space group $C2/c$ was suggested by the E-statistics and by the Patterson function from which the coordinates of the Fe, Cl, and Si atoms were determined. All remaining atoms, including hydrogen, were positioned from subsequent difference maps. In the final stages of refinement the non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. Neutral atom scattering factors and anomalous scattering corrections for Fe, Cl, and Si were taken from ref. 15.

Final atomic coordinates and equivalent isotropic (U_{eq} = (1/3) trace diagonalized U) or isotropic thermal parameters are given in Table 2.

[3]The computer programs used include locally written programs for data processing and locally modified versions of the following: ORFLS, full matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier Syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

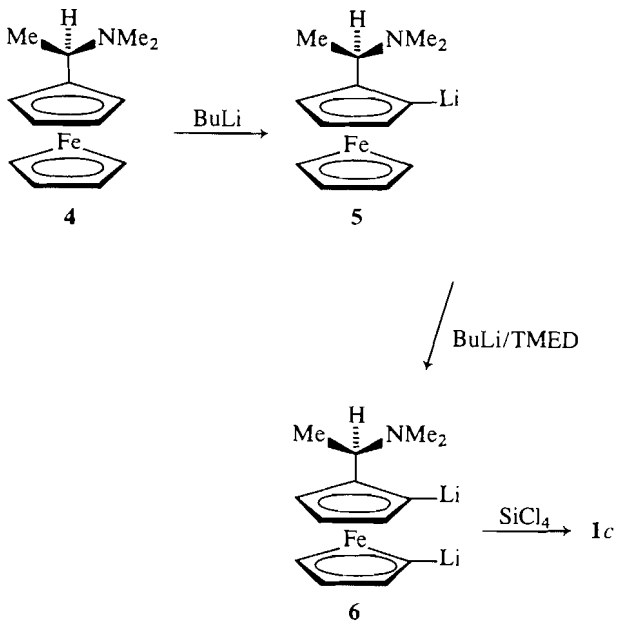
N—C(11)	1.478(4)		

Bond lengths and angles involving non-hydrogen atoms appear in Tables 3 and 4, respectively.[4]

Results and discussion

The ferrocenophane **1***c* was prepared as outlined in reaction [2]:



The amine **4** is easily resolved into its enantiomers and the initial lithiation to give **5** is essentially stereospecific (16, 17) and introduces a new chiral center because of planar chirality. For the synthesis of **1***c* a second lithiation of **4** affords a dilithio derivative **6** which easily reacts with $SiCl_4$ to give the ferrocenophane **1***c*, reaction [2]. This procedure in principal, allows the synthesis of chiral **1***c* from chiral **4**. The simpler ferrocenophane **1***a* was prepared by an analogous route from dilithioferrocene (3). The formulation of **1***c* is established by the microanalytical data and the spectroscopic properties, and confirmed by an X-ray structure determination. A view of the molecule is shown in Fig. 1.

Only one diastereomer is produced because of the directing effect of the NMe_2 group on the initial lithiation, reaction [2] (17). That the "correct" isomer is obtained is seen by rotating the $CHMeNMe_2$ group about the C(11)—C(2) bond. This brings the NMe_2 group in proximity to C(2) when the methyl group of C(12) is in the "less hindered" position outside the two η^5-rings (18). Recent studies indicate that this is a rather simplistic rationalization of the experimental observations (19).

Both the cyclopentadienyl rings are planar within experimental error, and, as has been previously established (20), ring bonds to substituted atoms (1.435(5)–1.461(2), mean 1.447(10) Å) are longer than those between unsubstituted atoms (1.405(5)–1.417(5) Å, mean 1.410(5) Å).

The crystal structure of a related [**1**]ferrocenophane **1***d* has been determined (21). The general features of the two structures are very similar and are tabulated in Table 5. The strain in the compounds is mainly reflected in the large value of $\overline{\beta}$. Other [**1**]ferrocenophanes containing Group V bridging atoms have smaller β values but their rings are tilted more and the α values range from 22.9–26.7° (12).

Strain in **1***c* does not seem to cause a shortening of the Si—C_5H_X bonds where the two values are not significantly different at 1.852(3) and 1.847(3) Å. The same distance in **1***d* is 1.881(11) Å (20). In a similar molecule where a $SiMe_2$ group (essentially tetrahedral) bridges two Cp rings which are separated by *two* Fe atoms (and bridging carbonyl groups) the Si—Cp distances seem to be longer at 1.876(7) Å (21), although they are still within the normal Si—C range. For example, in the compound $Fe(C_5H_3(CHMeNMe_2)(SiMe_3)_2$-1,2,3)$(C_5H_4SiMe_3)$ the bond lengths are 1.846(6), 1.862(5), and 1.880(5) Å (22). The angles at Si in **1***c* and **1***d* show departure from idealized tetrahedral geometry. In **1***d* the smallest angle at Si is 99.1(3)° (θ) whilst the largest is 114.4(4)° for the Ph—Si—Ph angle; one is probably the consequence of the other. In **1***c*, however, although θ is relatively unchanged at 100.70(14)° the Cl—Si—Cl angle is also small (107.26(6)°). The C—Si—Cl angles involving Cl(1) and Cl(2) are significantly different with average values of 110.0° (to Cl(1)) and 114.4° (to Cl(2)). Since Cl(2) is on the same side of the molecule as the $CHMeNMe_2$ substituent it is probably a repulsive interaction which opens up the angles. Certainly the H(11)---Cl(2) and H(14b)---Cl(2) distances at 2.99(3) and 2.90(5) Å are less than van der Waals contacts.

As mentioned in the Introduction, it was of interest to study the reaction of **1***c* with a surface.

Silica (two different brands) easily reacts with **1***c* at room temperature, and high loadings can be achieved. It was hoped to establish if a reaction such as described in reaction [*1*] had occurred by measuring the ^{57}Fe Mössbauer spectrum of the bound material. The basis for this expectation being the work of Clemance *et al.* (23) who report that the ring tilt of certain ferrocenophanes such as **1***d* correlates with the quadrupole splitting value, Δ. Thus for **1***d* this value is 1.97 mm s^{-1} whereas that for ferrocene is 2.40. The present results show that this is not a general phenomenon since the Mössbauer parameters for **1***c*, δ 0.52 and Δ 2.38 are in the range found for ferrocene derivatives with parallel rings. Moreover, the parameters are only slightly changed (δ 0.53 and Δ 2.36) after binding to silica has taken place. These results give little information about the occurrence of a reaction such as expected from reaction [1].

[4]Tables and anisotropic thermal parameters, bond lengths involving hydrogen, bond angles involving hydrogen, torsion angles, and measured and calculated structure factor amplitudes (Tables 5–9) (21 pages) have been deposited and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

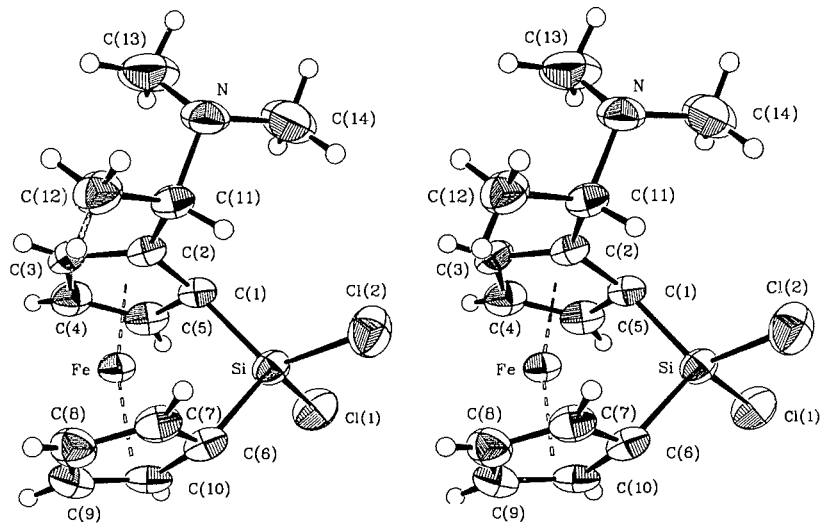

FIG. 1. Stereoscopic view of the structure of **1***c* (50% probability thermal ellipsoids are shown for non-hydrogen atoms).

In order to probe the stability of **1***c* further, it was treated with MeOD at 25°C. The initial product is an oil from which a yellow solid can be extracted. A ferrocenophane cleavage reaction would be expected to proceed according to reaction [3]. The isolated product has a mass spectrum with a parent peak of *m/e* 378 and fragmentation pattern expected for both **7** and **8**. (The pattern is similar to that of **1***c*.) The nmr spectrum of the yellow product is complicated and shows the presence of more than one compound. The principal features of the spectrum can be assigned to **7** or better its DCl derivative since the —NMe_2 resonances are very broad whereas the rest of the spectrum is sharp. If **8** is present, its amount is approximately 25% that of **7** as judged by the ratio of the *two* compounds present with $Si(OMe)_3$ groups. However, there is a problem in that only one compound with a —CH*Me*NMe_2 appear to be present, i.e. **7**. The very complicated set of resonances in the cyclopentadienyl region confirm that **7** is present in addition to other compounds which are *in higher concentration*.

Some samples of the yellow solid also show mass spectra with peaks of *m/e* 710, 696, 665, 651, 622--- corresponding to a siloxane such as **9**.

In conclusion, it seems that any cleavage reaction of **1***c* which might take place on binding to a surface (reaction [1]), is likely to result in more than one product. This is not a desirable property and calls into question the potential use of ferrocenophanes such as **1***c* for the preparation of chiral surfaces of known composition.

Received September 4, 1986

W. KLIEGEL, U. LAUTERBACH, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **65**, 1457 (1987).

Crystals of 8-methyl-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-6,7-dihydro-5*H*-benzocycloheptene are triclinic, a = 12.917(1), b = 13.285(1), c = 10.567(1) Å, α = 94.183(8), β = 90.094(5), γ = 72.176(6)°, Z = 4, space group $P\bar{1}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.045 and R_w = 0.042 for 2914 reflections with $I \geq 2\sigma(I)$. The envelope-like conformation adopted by the seven-membered chelate ring places one *B*-phenyl group above the plane of the fused-ring system facilitating a thermally-induced 1,4-migration of a *B*-phenyl group to the nitrone carbon atom. Mean bond lengths (corrected for libration) are (N)O—B = 1.559(6), (C)O—B = 1.496(3), C—B = 1.610(4) Å.

W. KLIEGEL, U. LAUTERBACH, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **65**, 1457 (1987).

Les cristaux du méthyl-8 diphényl-6,6 dioxa-5,7 azonia-8 borata-6 dihydro-6,7 5*H*-benzocycloheptène sont tricliniques, a = 12,917(1), b = 13,285(1) et c = 10,567(1) Å, α = 94,183(8), β = 90,094(5) et γ = 72,176(6)°, Z = 4 et groupe d'espace $P\bar{1}$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,045 et R_w = 0,042 pour 2914 réflexions avec $I \geq 2\sigma(I)$. La conformation en forme d'enveloppe qu'adopte le cycle chélaté à sept chaînons conduit à placer un groupement *B*-phényle au-dessus du plan du système de cycles condensés et ainsi à faciliter la migration-1,4, induite thermiquement, d'un groupement *B*-phényle vers l'atome de carbone de la nitrone. Les longueurs moyennes des liaisons (corrigées pour la libration) sont : (N)O—B = 1,559(6), (C)O—B = 1,496(3) et C—B = 1,610(4) Å.

[Traduit par la revue]

Introduction

The diphenylboron chelate of *N*-methylsalicylaldonitrone (8-methyl-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-6,7-dihydro-5*H*-benzocycloheptene, **1**) reacts with phenylboronic acid upon heating, eliminating water to give the tricyclic compound **4**. The phenylboronate structure of **4** has been established by an earlier X-ray crystallographic analysis (1). The mechanism of this reaction involves an inter- or intramolecular shift of one phenyl group which results in the oxidation of the diphenylborinate group to a phenylboronate group and an associated reduction of the nitrone moiety to a hydroxylamine function. A combined theoretical and experimental approach to the question of the reaction mechanism (2) suggests an intramolecular 1,4-shift of one *B*-phenyl group occurs. The same type of phenyl group shift has also been observed in the thermal rearrangement of open-chain triphenylborane-adducts of nitrones (1, 3). Such a 1,4-migration of a phenyl group in **1** would require a conformation of the seven-membered ring which would bring one of the phenyl groups close enough to the nitrone group to allow a transition state such as **2**. This would favor the reaction via the intermediate **3** which has not as yet been isolated but rather reacts immediately with phenylboronic acid (or its anhydride) to give **4**. In order to determine the conformation of the seven-membered ring in **1** and, more importantly, the orientation of the *B*-phenyl groups, an X-ray crystallographic analysis was undertaken.

Experimental

8-Methyl-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-6,7-dihydro-5H-benzocycloheptene, 1

Compound **1** was prepared as described previously (4). Crystals suitable for X-ray analysis were obtained as described below. Dichloromethane was added to a suspension of the newly synthesized and purified substance in ethanol until complete dissolution was achieved at room temperature. The solution was slowly evaporated at room temperature until crystallization began after 2 weeks. The compound decomposes at 160–161°C (4).

X-ray crystallographic analysis

A crystal ca. 0.2 × 0.3 × 0.4 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 56–81°) measured on a diffractometer with Cu-$K\alpha$ radiation ($\lambda(K\alpha_1) = 1.540562$, $\lambda(K\alpha_2) = 1.544390$ Å). Crystal data at 22°C are:

$C_{20}H_{18}BNO_2$ fw = 315.2

Triclinic, $a = 12.917(1)$, $b = 13.285(1)$, $c = 10.567(1)$ Å, $\alpha = 94.183(8)$, $\beta = 90.094(5)$, $\gamma = 72.176(6)°$ (cell with $c < a < b$ and two obtuse angles conforms to the conventions of ref. 5; the Buerger reduced cell is the same cell reoriented: $00\bar{1}/100/010$), $V = 1721.2(3)$ Å^3, $Z = 4$, $\rho_c = 1.216$ Mg m^{-3}, $F(000) = 664$, μ(Cu-$K\alpha$) = 5.8 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ from structure analysis.

Intensities were measured with nickel-filtered Cu-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.06–10.06° min^{-1} over a range of (0.65 + 0.14 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 150°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 4%. After data reduction,[2] no absorption correction was made due to irregularity of the crystal surface. Of the 7071 independent reflections measured, 2914 (41.2%) had intensities greater than or equal to $2\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, all non-hydrogen atoms of each of the two crystallographically independent molecules being positioned from an E-map and hydrogen atoms from subsequent difference maps. In the final stages of refinement the non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. The scattering factors of ref. 6 were used for non-hydrogen atoms and those of ref. 7 for hydrogen atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 577 variables. Reflections with $I < 2\sigma(I)$ were not included in the refinement. Convergence was reached at $R = 0.045$ and $R_w = 0.042$ for 2914 reflections with $I \geq 2\sigma(I)$. For all 7071 reflections $R = 0.155$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.02 and 0.47σ, respectively. The mean error in an observation of unit weight was 1.463. A final difference map showed maximum fluctuations of −0.32 to +0.21 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 5,[3] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

least-squares analysis) is 0.0028 Å^2. The subunits PhB and "methylbenzocycloheptene" of each of the two independent molecules were analysed separately (rms ΔU_{ij} = 0.0025–0.0065 Å^2). The appropriate bond distances have been corrected for libration (8, 9), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; corrected bond angles do not differ by more than 1 σ from the uncorrected values given in Table 3. Intra-annular torsion angles defining the conformations of the seven-membered chelate rings are listed in Table 4. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 6–8) are included as supplementary material.

Results and discussion

The crystal structure of 8-methyl-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-6,7-dihydro-5*H*-benzocycloheptene, **1**, consists of discrete molecules separated by normal van der Waals distances. The shortest intermolecular contact between non-hydrogen atoms is C···C = 3.336(5) Å. The two crystallographically independent molecules in the asymmetric unit are virtually identical (Fig. 1, Tables 2–4) and are related to one another in the crystal lattice by a pseudo-glide plane. The coordinates of the primed molecule are related to those of the unprimed molecule by the approximate operation: $-1/2 + x, y, 1.45 - z$.

The X-ray analysis confirms the seven-membered chelate structure of **1**. Only a few stable seven-membered chelate rings involving bidentate ligands have been reported in the literature (4). This is the first crystallographic example of a boron chelate with such a ring system although the structures of compounds with seven-membered rings containing 4-coordinate (10) and 3-coordinate (11, 12) boron have been reported. A similar

structure, **5**, was suggested by Balaban *et al.* (13) for the catecholatoborate complex of salicylaldoxime but has been ruled out by the X-ray analysis of the diphenylboron chelate of salicylaldoxime, **6** (14), and by chemical findings (15). The seven-membered ring in **1** has an "envelope-like" conformation in which the boron atom is displaced (by 0.751(4), 0.740(4) Å) from the mean plane formed by the remaining ring atoms (maximum deviations from these six-atom mean planes are 0.091(3) and 0.123(3) Å for the two molecules). The O—C—C—C—N—O portion of the seven-membered ring actually consists of a pair of planar 4-atom groups, O(1)—C(1)—C(2)—C(7) and C(2)—C(7)—N—O(2), which are rotated about the C(2)—C(7) bond with respect to one another (by 11.8(6) and 15.8(6)°). The ring conformation places one *B*-phenyl group distinctly above the mean plane of the fused-ring system, the mean[4] distance between the boron-bound phenyl carbon atom C(16) and the nitrone carbon atom C(7) being 3.190(4) Å. This distance, which corresponds to a van der Waals contact, is probably sufficiently short to facilitate the 1,4-migration of the phenyl group via a transition state **2**. The aromatic rings in **1** are all planar to within experimental error, their geometry being consistent with normal substituent effects (16).

The C=N and N—O bond distances in the nitrone group of **1** (mean values of 1.290(2) and 1.364(1) Å, respectively) are comparable to those reported for the boron chelate **7** containing a nitrone ligand[5] (1.286(6) and 1.355(5) Å) (17). In both cases the relatively short C=N and the long N—O bond distances indicate an increased iminium salt character of the nitrone moiety within a *B*,*N*-betaine complex. The C=N bond lengths in free (uncomplexed) nitrones are somewhat longer in most cases while the N—O bonds are generally shorter (17–22).

As in other diphenylboron chelates with an *N*-oxide ligand (18, 23–25), the O—B bond between the nitrone oxygen atom and boron in **1** (mean 1.559(6) Å) is longer than the O—B bond to the phenolate (mean 1.496(3) Å) or, in other examples, alcoholate ligand. The sum of bond lengths involving the boron

[4]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

[5]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion of the geometry of the boron atom and are compared with similarly treated (8) distances unless otherwise stated.

atom in *O,O*-chelates of diphenylboron is essentially constant for a given chelate ring size: 6.328(7) and 6.28(1) Å for five-and six-membered rings, respectively (26, and references therein). In **1**, with a seven-membered chelate ring, the corresponding sum is 6.276 Å. The average O—B and C—B bond lengths in **1** (1.528 and 1.610 Å), when compared with those in similar compounds having six-membered chelate rings, indicate relatively strong overall binding of the *O,O*-chelate to the Ph_2B moiety (26). Compound **1** may be regarded formally as a ring-enlarged analog (by *o*-phenyl insertion) of the *N*-methylacethydroximate **8** which shows comparable bond distances in the ring system and in the diphenylboron moiety (27).

Azides. Part VIII. Thermolysis of ethyl azidoformate in acetic and propionic anhydrides: facilitation of intramolecular cyclization of the resultant carbethoxynitrene to 2-oxazolidinone[1]

N. R. AYYANGAR, K. C. BRAHME, AND K. V. SRINIVASAN
National Chemical Laboratory, Poona 411008, India

Received March 19, 1986[2]

N. R. AYYANGAR, K. C. BRAHME, and K. V. SRINIVASAN. Can. J. Chem. **65**, 1463 (1987).

The thermolysis of ethyl azidoformate in acetic and propionic anhydrides as solvents yielded the corresponding *N*-acyl-2-oxazolidinones (**2***a*,*b*) in relatively significant yields. The other major products isolated were *N*-carboxyethyl-*N*,*O*-diacyl hydroxylamine (**1***a*,*b*) and *N*,*N*,*O*-triacetyl hydroxylamine (**3**). The intramolecular cyclization is facilitated by the solvent.

N. R. AYYANGAR, K. C. BRAHME et K. V. SRINIVASAN. Can. J. Chem. **65**, 1463 (1987).

La thermolyse de l'azidoformate d'éthyle, dans les anhydrides acétique ou propionique comme solvants, conduit aux *N*-acyl oxazolidinones-2 correspondantes (**2***a*,*b*), avec des rendements relativement importants. Les autres produits majeurs qui ont pu être isolés sont les *N*-carboxyéthyl *N*,*O*-diacyl hydroxylamines (**1***a*,*b*) et la *N*,*N*,*O*-triacétyl hydroxylamine (**3**). La cyclisation intramoléculaire est facilitée par le solvant.

[Traduit par la revue]

Introduction

The facile synthesis of 2,5-dicarbomethoxy-*N*,*p*-toluenesulphonyl-1*H*-azepine in high yield (60%) by the thermal reaction of *p*-toluenesulphonylazide with dimethyl terephthalate (DMT) in refluxing propionic anhydride was reported earlier by our group (1). Likewise, the thermolysis of ethyl azidoformate with DMT in refluxing acetic anhydride yielding *N*-carbethoxy-2,5-dicarbomethoxy-1*H*-azepine and a new diazabicyclooctadiene derivative in 1 and 2.2% yields respectively has been reported in a recent communication (2). Although considerably lower yields of the products in the latter reaction may be attributed in part to the loss of singlet nitrene through triplet pathways, we thought that the parallel reaction of the nitrene with acetic anhydride itself is worth a closer scrutiny. The study of the thermolytic reaction of ethyl azidoformate with acetic anhydride is discussed in this communication.

Intramolecular cyclizations involving nitrenes as intermediate species have resulted in the synthesis of interesting heterocyclic systems and natural products (3–6). Azidoformates containing a C—H bond at a sterically favourable position relative to the azido group cyclize upon thermolysis or photolysis to yield 2-oxazolidinones (3). The photolysis of *tert*-butyl azidoformate in *tert*-butanol yielded 5,5-dimethyl-2-oxazolidinone in 60–75% yields (7). In this case, the shielding of the nitrene generated by the *tert*-butyl group and the close proximity of the methyl group promoted the cyclization. In this communication, we wish to report the formation of *N*-acyl-2-oxazolidinones in significant yields when ethyl azidoformate is thermolysed in acetic and propionic anhydrides as solvents. The only other instance involving the intramolecular cyclization of carbethoxy nitrene in an organic solvent is the thermolysis of ethyl azidoformate in methyl cyanoacetate and ethyl cyanoformate to yield 2-oxazolidinone and *N*-ethoxycarbonyl-2-oxazolidinone in 2 and 14% yields respectively (8).

Results and discussion

The thermolysis of ethyl azidoformate was carried out in an excess of acetic and propionic anhydrides as solvents. The decomposition of the azido group to the nitrene was complete in 0.5 h as revealed by the ir spectrum of an aliquot of the reaction mixture, which showed absence of the absorption frequency at 2128–2135 cm^{-1} due to the azido group. The reaction was continued for a further 11 h and the concentration profile of the reaction products was plotted (Fig. 1) by careful glc analysis of aliquots of the reaction mixture at regular intervals of time. The *N*-carboxyethyl-*N*,*O*-diacyl hydroxylamine (**1***a*,*b*) was obtained as a major product along with significant amounts of the *N*-acyl-2-oxazolidinone (**2***a*,*b*) (Scheme 1). Thermolysis in acetic anhydride also resulted in the formation of the *N*,*N*,*O*-triacetyl hydroxylamine (**3**). Although this product could not be isolated from the reaction mixture, its presence was detected by gc–ms and was characterized by comparison with the superposable mass spectra and identical glc retention times of an authentic sample synthesized by the acetylation of hydroxylamine. The thermolysis of ethyl azidoformate was also carried out in the corresponding carboxylic acids, viz. acetic and propionic acids. The products were isolated by column chromatography and characterized by spectral and elemental analysis.

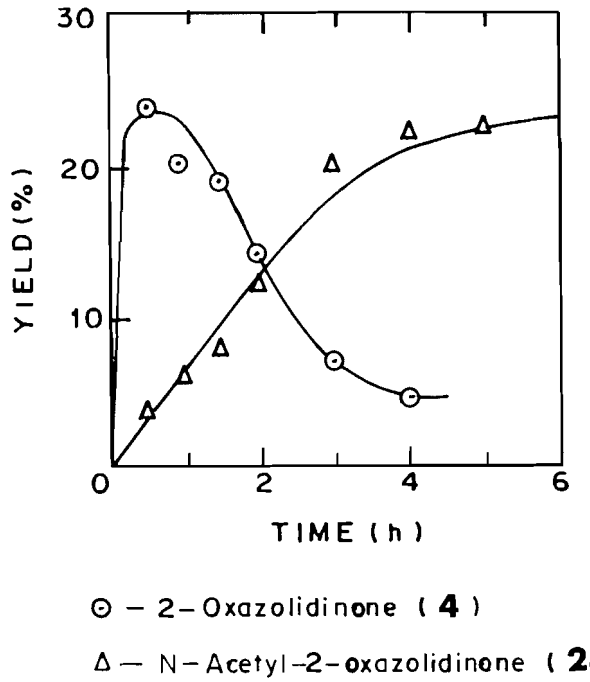

FIG. 2. A plot of % yields of **4** and **2***a* versus time.

The yields of the products are summarized in Table 1. Reaction products of the thermolysis of ethyl azidoformate in acetic acid did not contain 2-oxazolidinone (**4**) as indicated by careful glc analysis. In this reaction the major component was the hydroxylamine derivative (**5**), which was isolated in 75.2% yield. In the case of the thermolysis in propionic acid, however, *N*-acyl-2-oxazolidinone (**2***b*) was isolated in minor amounts (4.6%) (Table 1). The employment of an organic base such as triethylamine as catalyst for the thermolysis reactions in the anhydrides resulted in the lowering of yields of both the compounds **1***a*,*b* and **2***a*,*b*, and the formation of substantial amounts of polymeric material. Similar results were obtained when the thermolysis in propionic anhydride was carried out at the higher reflux temperature (165°C). Thus, the reaction temperature appears to be a critical parameter for maximizing the yields of **1***a*,*b* and **2***a*,*b*.

The photolysis of ethyl azidoformate in acetic anhydride resulted in the formation of **1***a* as a major product with no trace of the oxazolidinone **2***a*. In another experiment, the photolysis of the ethyl azidoformate in acetic anhydride was carried out for 6 h until the azide completely decomposed to the carbethoxy nitrene as indicated by the ir spectra. The photolysed reaction mixture was then refluxed (140°C) for 11 h and the products analysed by glc. The product analysis (Table 1) indicated formation of **2***a* to an extent of 2%. This indicates that thermal energy is required for activating the carbethoxy nitrene for intramolecular cyclization to the 2-oxazolidinone **2***a*. The low yields of **2***a* could be due to formation of **1***a* as the major product during the photolysis process itself. A major proportion of the remaining singlet nitrene might have been lost by triplet pathways. A careful examination of the products of thermolysis of ethyl azidoformate in *o*-dichlorobenzene, an inert solvent providing only the necessary temperature, did not reveal any oxazolidinone formation. The products of the reaction were not characterized. This observation highlights the role of anhydrides in favouring intramolecular cyclization to the oxazolidinones.

The concentration profiles of the reaction products with respect to time are shown in Figs. 1 and 2. To detect and estimate 2-oxazolidinone **4**, initially formed in the reaction (Fig. 2), a set of several experiments were performed for a period of 0.5, 1.0, 1.5, 2.0, 3.0, 4.0, and 5.0 h respectively under identical thermolysis conditions. The solvent was removed at 40°C under reduced pressure (2 Torr; 1 Torr = 133.3 Pa) in each case. The residue was made up to the required minimum volume (2 mL) and analysed by glc. This elaborate procedure became necessary to avoid the possible acetylation of 2-oxazo-

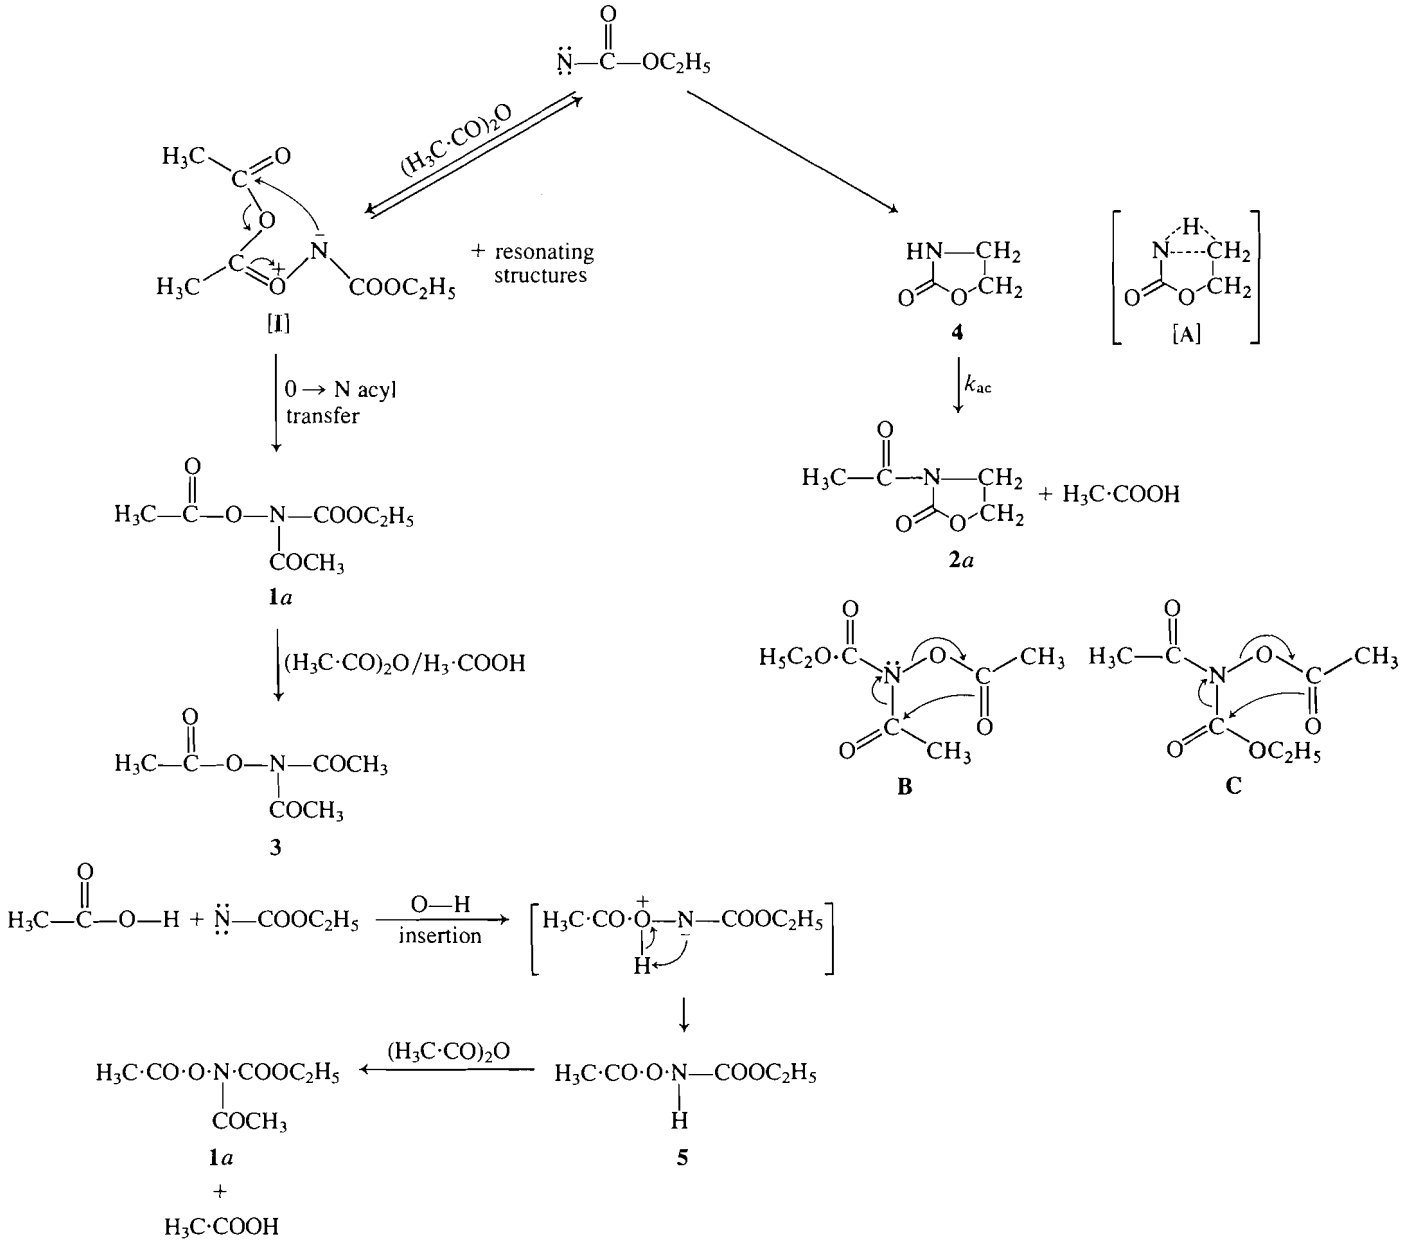

SCHEME 2

lidinone by acetic anhydride at the injection port temperature conditions of the glc instrument and due to the poor response of the compound during the glc analysis. It can be seen from Fig. 2 that the formation of **4** has reached a maximum value of 24.5% at 0.5 h and falls off subsequently as the process of acetylation starts taking place at a significant rate. Together with 4.5% of *N*-acetyl 2-oxazolidinone **2***a*, it is quite apparent that almost the entire intramolecular cyclization is complete within 0.5 h. The yield of **1***a* rapidly reaches a maximum value of 45.6% (in ca. 1 h) after the decomposition of all the azide at 140°C. The reduction in the yield of **1***a* to 12% after 11 h is accounted for by the subsequent formation of the triacetyl derivative **3** (29%). The compound **3** is formed by the *N*-acetylation of **1***a*, accompanied by the acid-catalysed elimination of carbethoxy substituent. This has been established by separate experiments in which **1***a* was refluxed with acetic anhydride in the presence and absence of acetic acid respectively. It was found that the yield of **3** increased by 15% when acetic acid was added to acetic anhydride. As can be seen (Scheme 2), there is a continuous formation of acetic acid in the reaction catalysing the decarboxylation of **1***a* to **3**. It was initially thought that an intermediate such as **1***a*, a truly covalently bonded species having stability at 140°C, could slowly give singlet nitrene on heating via the cyclic transition states such as **B** and **C** (Scheme 2), which may provide low-energy pathways to the singlet nitrenes. However, this hypothesis has been ruled out by the fact that under similar conditions there was no formation of 2-oxazolidinone from **1***a* as starting material (see Experimental).

Thermolysis of ethyl azidoformate in acetic anhydride at 140°C was found to follow first-order kinetics (Fig. 3). The rate constant k_t was evaluated as 0.111 ± 0.001 min^{-1}. The rate of acetylation of 2-oxazolidinone (**4**) was also followed kinetically at 140°C and was found to be first order (Fig. 4). The rate constant k_{ac} was evaluated as 0.081 ± 0.0005 min^{-1}. The azide decomposition is completed in approximately 0.5 h. Likewise, the acetylation of 2-oxazolidinone to **2***a* is completed in approximately 50 min.

In separate experiments, ethyl azidoformate was thermolysed

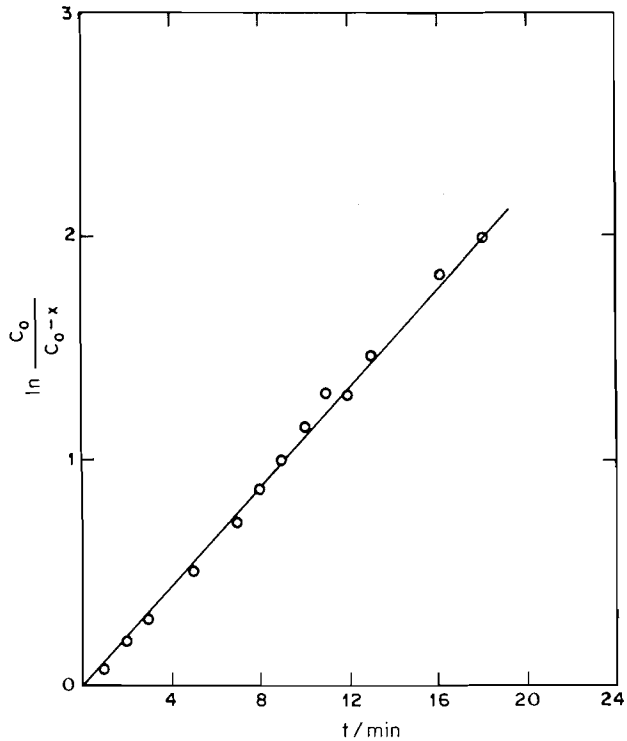

FIG. 3. First-order plot for the decomposition of ethyl azidoformate in acetic anhydride at 140°C.

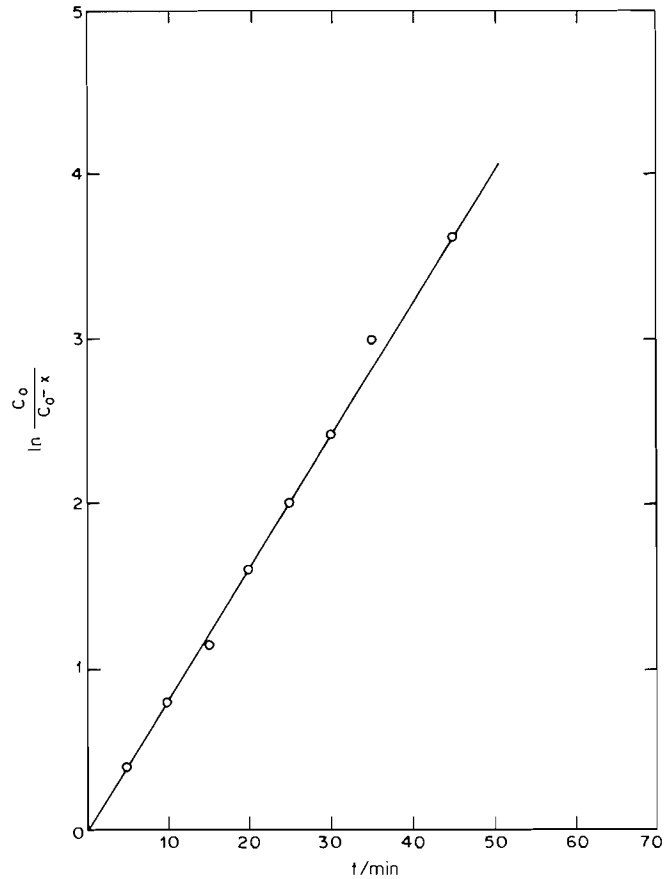

FIG. 4. First-order plot for the acetylation of 2-oxazolidinone at 140°C.

at 140°C with 0.4 and 1 molar equivalents of acetic acid, respectively, in excess of acetic anhydride under similar reaction conditions. The concentration profiles of products **1***a* and **2***a* are shown in Figs. 5 and 6. The above reactions have resulted in significantly lowering the yield of **2***a* to approximately 12% in both cases.

Based on the above observations, a probable pathway for the thermolysis of ethyl azidoformate in acetic anhydride is shown in Scheme 2. The nucleophilic carbonyl oxygen of acetic anhydride forms an ylidic bond with the electrophilic nitrene in a reversible equilibrium to form the reosnance stabilized intermediate [$\mathbf{I}_1$]. However, in the case of carboxylic acids such as acetic acid, the nitrene is trapped by an irreversible O—H insertion process, which by the sequence of reactions generates the hydroxylamine derivative **1***a* (Scheme 2). This explains the nonformation or insignificant formation of the 2-oxazolidinone derivative when the thermolysis was carried out in acetic and propionic acids, respectively, as well as the reduction in the yields of **2***a* in Figs. 5 and 6. The product **1***a* is formed by an O to N acetyl transfer from the initial ylide adduct [$\mathbf{I}_1$]. The compound **1***a*, by a process of acetylation accompanied by decarboxylation, yields **3**. The carbethoxy nitrene, whose intersystem crossing from a singlet to triplet state is probably retarded by acetic anhydride, undergoes intramolecular cyclization by a C—H insertion via [**A**] (9) to give rise to 2-oxazolidinone (**4**) (Fig. 2). The 2-oxazolidinone, on acetylation, yields *N*-acetyl-2-oxazolidinone (**2***a*).

Further confirmation for the mechanism is obtained from the kinetic data (Figs. 1–4), which indicate first-order decomposition of the azide to the nitrene, followed by rapid cyclization to 2-oxazolidinone (**4**), then pseudo first-order acetylation to give **2***a*. The rate of acetylation is slower than that of azide decomposition and cannot occur at a significant rate until the

concentration of 2-oxazolidinone builds up. The observed plots for **2***a* and **4** in Figs. 1 and 2 are quite consistent with these mechanistic considerations.

Experimental

Melting points were recorded in capillary tubes. Infrared spectra were recorded on a Perkin–Elmer 221 spectrophotometer, and proton nmr spectra on Varian FT-80 and Varian T-60 spectrometers using TMS as internal standard; mass spectra were recorded on a Finnigan MAT 1020 Automated GC/MS, gc–ms on an AEI MS 3074 gc–ms spectrometer, and glc analysis was carried out on a Hewlett Packard 700 laboratory chromatograph with Hewlett Packard 3380A integrator.

General procedure for the thermolysis

Ethyl azidoformate (43 mmol) was added dropwise to an excess of the anhydride (500 mmol) at 140°C over a period of 0.5 h with good stirring. The decomposition of the azide to the nitrene was complete (evident from the ir spectra showing the absence of frequency at 2128 cm^{-1} due to the azido group) after stirring for 0.5 h at 140°C. The reaction was continued further for 11 h at 140°C. At the end, the solvent was removed by distillation at 2 Torr pressure. The residue was dissolved in acetone, adsorbed on silica gel, and chromatographed through a column of silica gel. Elution with benzene:petroleum ether (1:1) initially yielded the hydroxylamine derivative (**1***a*,*b*) followed by *N*-acyl-2-oxazolidinone (**2***a*,*b*).

The thermolyses in other solvents were carried out in the same manner as described above. After removal of the solvent, the residue was refluxed with an excess of the anhydride for 3 h. The anhydride was removed by distillation under reduced pressure (2 Torr). The residue was dissolved in acetone and the products analysed by gas chromatography. The yield data are recorded in Table 1.

N-*Carboxyethyl*-N,O-*diacetyl hydroxylamine* (**1**a): bp 83°C/6 Torr: ir (Nujol): 1820, 1765, 1740, 1485, 1445, 1388, 1310, 1250, 1195, 1130, and 1095 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.2 (t, 3H, CH_3), 2.2 (s, 3H, $NCOCH_3$), 3.0 (s, 3H, $OCOCH_3$), and 4.3 (q, 2H, $-CH_2$); ms, *m/e*: 189 (M^+) (73.6%), 163 (62%), 148 (76%), 147 (100%, base), 144 (69%), 118 (36%), 117 (86%), 105 (77%), 103 (77%), 78 (77%), 76 (71%), 70 (43%), 61 (42%), and 44 (99%). *Anal.* calcd. for $C_7H_{11}NO_5$: C 44.5, H 5.8, N 7.4; found: C 44.9, H 6.0, N 7.3%.

Photolysis of ethyl azidoformate in acetic anhydride

Ethyl azidoformate (86 mmol) was dissolved in acetic anhydride (2000 mmol) and the solution was transferred to a quartz tube. It was irradiated in an atmosphere of nitrogen by a 450-W high pressure mercury lamp at 28°C for a period of 11 h. The reaction was followed by ir spectroscopy. The reaction mixture was worked up as per the general procedure described above. The product analysis was carried out by glc. The yield data is given in Table 1.

Ethyl azidoformate (87 mmol) was dissolved in acetic anhydride (1863 mmol) and subjected to photolysis in the usual manner until the ir spectra indicated complete decomposition of the azido group to the nitrene (6 h). The reaction mixture was then transferred to a round-bottomed flask and refluxed further at 140°C for 11 h. The reaction products were analysed by glc. The yield data are recorded in Table 1.

Gas–liquid chromatographic (glc) analysis

The glc analysis was carried out on a column consisting of OV-17 as the stationary phase on Chromosorb WAW-DMCS (60–80 mesh) with a loading of 5% w/w. The following operating parameters were employed: column temperature 150°C, injection temperature 190°C, detector (FID) temperature 300°C, and carrier gas (Nitrogen) flow rate 40 mL min^{-1}. The composition of the products in the reaction mixture was then determined using the external standard quantitation method with the aid of the data processor unit present in the instrument. The eluted components with their retention times in parentheses are as follows: *N*-carboxyethyl-*N*,*O*-diacetyl hydroxylamine (**1***a*) (2.54 min); *N*-carboxyethyl-*N*,*O*-dipropionyl hydroxylamine (**1***b*) (7.67 min); *N*-acetyl-2-oxazolidinone (**2***a*) (3.59 min); *N*-propionyl-2-oxazolidinone (**2***b*) (12.15 min); *N*,*N*,*O*-triacetyl hydroxylamine (**3**) (1.57 min); 2-oxazolidinone (**4**) (10.96 min).

Attempts at conversion of **1**a *to* **2**a

(*i*) The hydroxylamine derivative (**1***a*) (5.3 mmol) was refluxed in acetic anhydride (49 mmol) for 11 h. (*ii*) The compound **1***a* (5.3 mmol) was refluxed in acetic anhydride (49 mmol) in the presence of acetic acid (5 mmol) for 11 h. In both the experiments, the solvents were distilled off under reduced pressure (2 Torr).

For personal use only.

A careful glc analysis of the products did not reveal any trace of oxazolidinone **2***a*. The triacetyl compound **3** was formed to an extent of 2 and 17% yield, respectively, in the two experiments (as determined by glc analysis).

Attempts at conversion of ***3*** *to* ***2***a

N,N,O-Triacetyl hydroxylamine **3** (25 mmol) was dissolved in acetic anhydride (392 mmol) and refluxed for 11 h. On work-up as described above, the unreacted **3** was completely recovered and a careful glc analysis also did not reveal any trace of the oxazolidinone **2***a*.

2-Oxazolidinone: The compound was synthesized by the reaction of monoethanolamine with diethyl carbonate by a reported procedure (7).

Kinetic measurements

(i) Thermolysis of ethyl azidoformate in acetic anhydride at 140°C

(*a*) Ethyl azidoformate (130 mmol) was added quickly to refluxing acetic anhydride (1470 mmol) at 140°C with good stirring. Aliquots of the reaction mixture were withdrawn at regular time intervals and rapidly cooled externally to ambient temperatures. The samples were analysed by glc for the quantitative estimation of *N*-carbethoxy-*N,O*-diacetyl hydroxylamine (**1***a*), *N*-acetyl-2-oxazolidinone **2***a*, and *N,N,O*-triacetyl hydroxylamine **3**. A plot of their yields versus time is shown in Fig. 1.

(*b*) Ethyl azidoformate (10.87 mmol) was added quickly to refluxing acetic anhydride (123 mmol) at 140°C with good stirring. The reaction mixture was stirred for 0.5 h at 140°C and rapidly cooled externally to room temperature. Acetic anhydride was distilled off at 40°C under reduced pressure (2 Torr). The residue was diluted to 2 mL with acetone and the solution was analysed by glc for the quantitative estimation of 2-oxazolidinone (**4**) and *N*-acetyl-2-oxazolidinone (**2***a*).

The reactions were performed under exactly similar conditions over a period of 1.0, 1.5, 2.0, 3.0, 4.0, and 5.0 h respectively. The reaction mixtures were worked up as described above. The samples were analysed by glc for the quantitative estimation of **4** and **2***a*. The plot of % yields of **4** and **2***a* versus time in the above experiments is shown in Fig. 2.

(ii) Thermolysis of ethyl azidoformate

Ethyl azidoformate (27.4 mmol) was added quickly to refluxing acetic anhydride (304 mmol). The rate of decomposition of azide was determined by measurement of the volume of nitrogen evolved as a function of time (Fig. 3).

(iii) Acetylation of 2-oxazolidinone

2-Oxazolidinone (23 mmol) was added in one lot to refluxing acetic anhydride (196 mmol). Aliquots of samples were taken out at 5-min intervals, the reaction quenched by external cooling, and then were analysed by glc. The plot of percentage yield of **2***a* versus time is given in Fig. 4.

(iv) Thermolysis of ethyl azidoformate in the presence of 0.4 and 1.0 molar equivalent of acetic acid respectively in acetic anhydride at 140°C

Ethyl azidoformate (41 mmol) was added quickly with stirring to a mixture of 16.4 mmol or 41 mmol of acetic acid, as the case may be, and acetic anhydride (465 mmol) at 140°C. The reaction mixture was stirred at 140°C for 11 h. Aliquots of the reaction mixture were withdrawn at regular time intervals. The samples were cooled rapidly by external means to room temperature. They were subjected to glc analysis for the quantitative estimation of **1***a* and **2***a*. Plots of their % yields versus time are shown in Figs. 5 and 6.

Deuterium isotope effects on the ^{119}Sn shielding constants and spin–spin coupling constants in stannane and the stannonium cation

KEVIN L. LEIGHTON AND RODERICK E. WASYLISHEN[1]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received December 5, 1986

KEVIN L. LEIGHTON and RODERICK E. WASYLISHEN. Can. J. Chem. **65**, 1469 (1987).

Deuterium induced isotope effects on the ^{119}Sn chemical shielding constants have been measured for stannane and the stannonium cation; they are found to be approximately -0.403 ppm/D and -0.05 ppm/D respectively. The ^{119}Sn shifts in the series SnD_nH_{4-n} ($n \leq 4$) deviate from additivity as predicted by Jameson and Osten. The primary and secondary isotope effects on Sn–H spin–spin coupling for stannane were obtained and are -2.8 Hz and -1.7 Hz respectively. The primary isotope effect for Sn–H spin–spin coupling for the stannonium cation was found to be -11.6 ± 7 Hz; an accurate value for the secondary isotope effect on the spin–spin coupling could not be obtained. The derivative of the ^{119}Sn shielding constant and J (Sn,H) with respect to extensions in the equilibrium bond length have been calculated for stannane.

KEVIN L. LEIGHTON et RODERICK E. WASYLISHEN. Can. J. Chem. **65**, 1469 (1987).

Pour le stannane et le cation stannonium, on a mesuré les effets isotopiques induits par le deutérium sur les constantes de blindage chimique du ^{119}Sn; on a trouvé qu'ils sont respectivement d'environ $-0{,}403$ ppm/D et de $-0{,}05$ ppm/D. Les déplacements du ^{119}Sn, dans la série des composés SnD_nH_{4-n} ($n \leq 4$), dévient de l'additivité comme prédité par Jameson et Osten. Pour le stannane, on a déterminé les effets isotopiques primaire et secondaire sur le couplage spin–spin Sn–H et ces valeurs sont respectivement de $-2{,}8$ Hz et $-1{,}7$ Hz. On a trouvé que l'effet isotopique primaire, pour le couplage spin–spin Sn–H du cation stannonium est de $-11{,}6 \pm 7$ Hz; on n'a pas pu obtenir de valeur précise pour l'effet isotopique secondaire sur le couplage spin–spin. Dans le cas du stannane, on a calculé la dérivée de la constante de blindage du ^{119}Sn et du J (Sn,H) par rapport aux extensions dans la longueur de la liaison en équilibre.

[Traduit par la revue]

Introduction

Isotope effects on chemical shifts have been known for many years and have been the subject of several reviews (1–4). For an observed nucleus, A, substitution of the directly bonded nucleus, ^{m}X, with a heavier isotope, $^{m'}$X, causes a shortening of the A—X bond that leads to a greater shielding in the heavier isotopomer. If the one-bond isotope shift is defined as

$$[1] \quad {}^1\Delta A(^{m'/m}X) = \sigma^A(A^{m}X\ldots) - \sigma^A(A^{m'}X\ldots) \qquad (m' > m)$$
$$= \sigma - \sigma'$$

where the prime indicates the heavier isotopomer, the one-bond isotope shift is normally negative (4). In this study we have measured isotope effects on the ^{119}Sn shielding constants in stannane, SnD_nH_{4-n} ($n \leq 4$) and the stannonium cation, $SnD_nH_{3-n}^+$ ($n \leq 3$). Also, we have obtained experimental values of ^1J (Sn,H) and ^1J (Sn,D) for each isotopomer of these two compounds.

Jameson and Osten have recently made significant contributions to the interpretation of isotope effects on both shielding constants (4–8) and spin–spin coupling constants (9). Our experimental results are discussed in terms of the theoretical models developed by these authors and we briefly outline their results as they pertain to stannane.

Chemical shielding

For a symmetric molecule of the type AX_n, where mean bond angle deformations have a negligible effect on the isotope shift, the one-bond isotope shift may be written as

$$[2] \quad {}^1\Delta A(^{m'/m}X) = (\partial\sigma^A/\partial\Delta r)_e \sum_n [\langle\Delta r_n\rangle - \langle\Delta r_n\rangle'] + \ldots$$

where $\langle\Delta r_n\rangle$ is the mean bond length displacement of bond n (5). If secondary isotope effects on $\langle\Delta r\rangle$ of other bonds caused by isotopic substitution of the A—X bond are neglected, then the one-bond isotope shift may be approximated (6) as

$$[3] \quad {}^1\Delta A(^{m'/m}X) = (\partial\sigma^A/\partial\Delta r_{AX})_e[\langle\Delta r_{Am}\rangle - \langle\Delta r_{Am'}\rangle]$$

where $\langle\Delta r_{Am}\rangle$ and $\langle\Delta r_{Am'}\rangle$ are the mean bond displacements of the A—^{m}X and A—$^{m'}$X bonds, respectively. Jameson and Osten (7) have shown that the difference in mean bond displacements can be expressed as a product of $\langle\Delta r_{Am}\rangle$ and a ratio of masses; thus eq. [3] becomes

$$[4] \quad {}^1\Delta A(^{m'/m}X) = (\partial\sigma^A/\partial\Delta r_{AX})_e\langle\Delta r_{Am}\rangle[(m' - m)/m'] \times (1/2)[m_A/(m_A + m)]$$

The mass term in this equation indicates that the $^{2/1}$H substitution of SnH_4 should provide a good case for the observation of an isotope shift on σ (^{119}Sn), since the fractional change in mass on isotopic substitution is large; $(m' - m)/m'$ is 0.5 and $m_A/(m_A + m)$ is $\simeq 1$. Also the magnitude of the electronic factor, $(\partial\sigma^A/\partial\Delta r_{AX})_e$, has been found to be related to the chemical shift range of A. Since tin has a relatively large chemical shift range, ~2700 ppm (10), $^1\Delta$Sn($^{2/1}$H) is expected to be relatively large.

For a symmetric molecule, such as CH_4 (11) or NH_4^+ (12), the isotope shift has been found to be proportional to the number of isotopically substituted atoms in equivalent positions; several examples are given in ref. 7. Deviations from strict additivity have been noticed in a few cases (4, 12); however, in general the experimental error associated with measuring isotope shifts is larger than any deviation from additivity. If secondary isotope effects on mean bond displacement are not neglected, deviations from additivity may be predicted. For a tetrahedral species AD_nH_{4-n} ($n \leq 4$) Jameson and Osten have predicted deviations from additivity to be in the ratio 0:3:4:3:0 (4, 7, 12). In the case of $ND_nH_{4-n}^+$ ($n \leq 4$) the ratio was observed to be 0:2.8:4:2.8:0. Here we present another case, SnD_nH_{4-n} ($n \leq 4$), where the deviations from additivity are much greater than the experimental error.

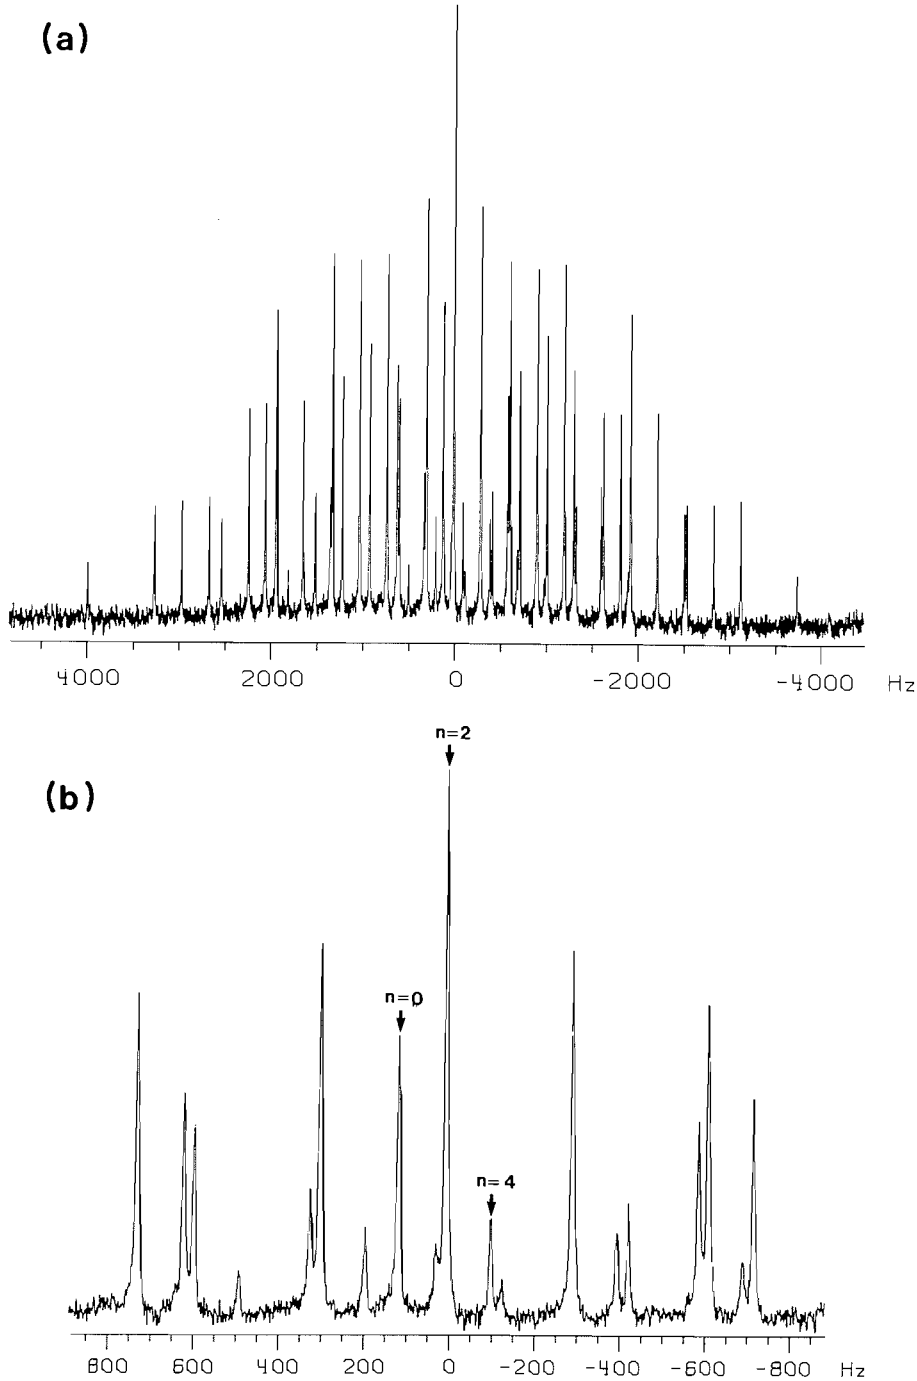

FIG. 1. (*a*) Tin-119 nmr spectrum of stannane, SnD_nH_{4-n} ($n \leq 4$) at 134.5735 MHz and −50°C. (*b*) Expansion of the central region of the spectrum in Fig. 1*a*. The arrows indicate the relative chemical shifts of each isotopomer.

Spin–spin coupling constants

Recently Jameson and Osten have summarized isotope effects on spin–spin coupling (9), of which there have been relatively few reports. In many cases the observed effects are comparable to the experimental error. The primary isotope effect on spin–spin coupling involving H is defined (9) as follows:

$$[5] \quad \Delta_p{}^nJ(A,{}^{2/1}H) \equiv |{}^nJ(A,D)|(\gamma_H/\gamma_D) - |{}^nJ(A,H)|$$

This is the change in coupling constant between two nuclei caused by isotopic substitution of one of the nuclei; n indicates the number of bonds separating the two coupled nuclei. The largest primary isotope effect on ^1J has been observed in phosphine (13) where $\Delta_p{}^1J(^{31}P,^{2/1}H)$ is +12 Hz, approximately 6% of the coupling constant. In general, the primary isotope effect is much smaller; for example in methane the primary isotope effect on $^1J(^{13}C,^{2/1}H)$ is approximately −0.3 Hz, or less than 0.5% of the carbon–proton coupling constant (11). In molecules where neither of the coupled nuclei have a lone pair, the primary isotope effect on the reduced coupling constant, $^1K(A,X)$, appears to be negative (9). Here the reduced coupling constant is independent of the magnetogyric ratios of the two coupled nuclei, γ_A and γ_X, and is defined by eq. [6].

$$[6] \quad K(A,X) = 4\pi^2J(A,X)/h\gamma_A\gamma_X$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

The rovibrational model of Jameson and Osten (9) predicts the $^{2/1}H$ isotope effect on $^1K(A,^{2/1}H)$ to depend on both an electronic factor (independent of mass) and a dynamic factor, eq. [7],

$$[7]\quad \Delta_p{}^1K(A^{2/1}H) = (\partial K/\partial \Delta r_{AH})_e[\langle \Delta r_{AD}\rangle - \langle \Delta r_{AH}\rangle] + 1/2(\partial^2 K/\partial \Delta r_{AH}{}^2)_e[\langle (\Delta r_{AD})^2\rangle - \langle (\Delta r_{AH})^2\rangle] \ldots$$

The terms of eq. [7] that involve the difference in mean bond length and the mean square amplitudes are generally negative (9). For one-bond carbon–proton spin–spin coupling constants both the partial derivatives in eq. [7] are positive (9); thus, as observed, a negative isotope effect is predicted. By analogy, a negative value for $\Delta_p{}^1K(Sn,^{2/1}H)$ in stannane is predicted.

Secondary isotope effects on spin–spin coupling constants are often smaller than primary effects and can be of either sign (9). The secondary isotope effect is defined as the change in observed coupling between two nuclei, A and B, caused by isotopic substitution of a neighbour X. The largest secondary isotope effect reported is in hydrogen selenide where $^1J(^{77}Se,H)$ in H_2Se is 0.9 Hz larger than the value observed for this same coupling in HDSe (14). The theoretical interpretation of secondary isotope effects on J is more difficult (9) and will not be discussed further here.

Stannane and the stannonium cation have been chosen for this study because the value of $^1J(^{119}Sn,^1H)$ is large for each, approximately −1930 Hz and −2910 Hz, respectively (15); with such large coupling constants, these two compounds represent a unique opportunity to investigate 1° and 2° isotope effects on spin–spin coupling constants and not be restricted by large experimental error.

Experimental

SnD_nH_{4-n} ($n \leq 4$) was prepared (16) from anhydrous $SnCl_4$ (BDH Chemicals, 98%) by reduction with a mixture of $LiAlH_4$ (Aldrich, 95%) and $LiAlD_4$ (MSD Isotopes, 99%). The mole ratio, hydrogen:deuterium, employed was 3:2; 0.006 mol of SnD_nH_{4-n} were condensed into a 10-mm od thick-walled nmr tube containing 5 mL of degassed CS_2 (BDH Chemicals, Spec. Grade) at −196°C; then the tube was sealed under vacuum. The sample tube was stored at liquid nitrogen temperature.

$SnD_nH_{3-n}{}^+$ ($n \leq 3$) was prepared (15, 17) by the reaction of 0.01 mol of SnD_nH_{4-n} (H:D mole ratio = 2:3) and 4 mL of HSO_3F (Aldrich), which had been distilled under nitrogen, in a 10-mm o.d. thick-walled nmr tube. The hydrogen evolved was pumped off periodically. After 2.5 h at −78°C, no further hydrogen was produced and the tube was sealed under vacuum. To avoid decomposition the sample was never warmed above −78°C.

The ^{119}Sn nmr spectra were recorded on a Nicolet 360 NB spectrometer (B_0 = 8.48 T) using a broad band variable temperature 10-mm probe. The spectrum of stannane was recorded at −50°C, and that of the stannonium ion at −80°C. The temperature was maintained at ±1.0°C by a nitrogen gas flow.

Results and discussion

Isotope effects on σ

(a) Stannane

The ^{119}Sn nmr spectrum of SnD_nH_{4-n} ($n \leq 4$) is shown in Fig. 1*a*; in Fig. 1*b*, the central region of the spectrum has been expanded and the chemical shifts of each isotopomer have been indicated. Replacement of each ^1H by ^2H in stannane results in an isotope shift of approximately −0.4 ppm/deuterium; however, as indicated in Table 1 the isotope shifts are not strictly additive. The deviations from additivity are 0.0:3.0:4.0:2.9:0.0, in excellent agreement with the predictions of Jameson and Osten (4, 7).

TABLE 1. ^{119}Sn chemical shifts (in ppm) and deviations from additivity for SnD_nH_{4-n} ($n \leq 4$)

	Experimental value	Perfect additivity	Difference	Ratio
SnH_4	0.0000	0.0000	0.0000	0.00
SnH_3D	−0.4266	−0.4026	0.0240	3.03
SnH_2D_2	−0.8369	−0.8052	0.0317	4.00
$SnHD_3$	−1.2306	−1.2077	0.0229	2.89
SnD_4	−1.6103	−1.6103	0.0000	0.00

Using the model of Jameson and Osten (4–6) one can estimate the partial derivative $(\partial\sigma^{Sn}/\partial\Delta r_{SnH})_e$. To obtain this derivative one must first obtain an estimate of $\Delta r_{Sn,H}$; see eq. [4]. For symmetrical AX_n molecules where isotopic substitution takes place at the terminal position (i.e., X) Jameson and Osten (4, 6) have suggested that to a first approximation one can associate $\langle \Delta r_{A,H}\rangle$ with $\langle \Delta r_{A,H}\rangle_{vib}$ where the latter term can be estimated using eq. [8].

$$[8]\quad \langle \Delta r\rangle_{vib} \simeq 22 \times 10^{-3}\, \mu^{-1/2}\, 10^{-D}$$

Here μ is the reduced mass in atomic units and D is given by eq. [9] where r_e

$$[9]\quad D \equiv (r_e - a_3)/b_3 - 3(r_e - a_2)/2b_2$$

is the equilibrium bond length and a_2, a_3, b_2, and b_3 are the Herschbach–Laurie parameters, which are tabulated in refs. 4 and 18. An accurate value of r_e in stannane is available from a recent microwave study of three different deuterated stannanes (19).

Using this procedure we find that $\langle \Delta r_{Sn-H}\rangle \simeq 17.65 \times 10^{-3}$ Å and substitution into eq. 4 gives $(\partial\sigma^{Sn}/\partial\Delta r_{SnH})_e = -92$ ppm/Å. This is to be compared with a value of −38 ppm/Å derived for $(\partial\sigma^C/\partial\Delta r_{CH})_e$ in methane (4, 8).

The magnitude of $(\partial\sigma^{Sn}/\partial\Delta r_{SnH})_e$ calculated here for stannane is smaller than the value one might intuitively expect. Previously, values of $(\partial\sigma^A/\partial\Delta r_{AH})_e$ for the first-row hydrides, AH_n, have been found to be proportional to $\langle a_0{}^3/r^3\rangle_A$ of the p orbitals (4, 5). Applying this argument to Group IV hydrides one estimates

$$[10]\quad (\partial\sigma^{Sn}/\partial\Delta r_{Sn-H})_e \simeq \frac{\langle a_0{}^3/r^3\rangle_{Sn}}{\langle a_0{}^3/r^3\rangle_C}(\partial\sigma^C/\partial\Delta r_{C-H})$$

Using values of $\langle a_0{}^3/r^3\rangle$ given by Barnes and Smith (20) one would predict the shielding derivative for Sn in SnH_4 to be approximately 9 times that for C in CH_4. Using the above arguments one predicts $^1\Delta Sn(^{2/1}H) = -1.6$ ppm/D in stannane, approximately four times the observed value. Thus the results here suggest that in the case of Sn factors other than $\langle a_0{}^3/r^3\rangle$ must play a significant role in accounting for variations in the electronic factor.

Recent theoretical calculations and shielding derivatives for the first- and second-row hydrides by Chesnut and Foley (21) indicate that the relative polarity of the heavy atom with respect to hydrogen plays an important role in determining the behaviour of the heavy atom shielding derivative. If the heavy atom is highly positive, e.g., NaH, the derivative is positive; however, if the central nucleus is highly negative, e.g., HCl, the derivative is large and negative (21). The derivative observed in this study for stannane appears to be consistent with the systematic change of derivatives reported in ref. 21.

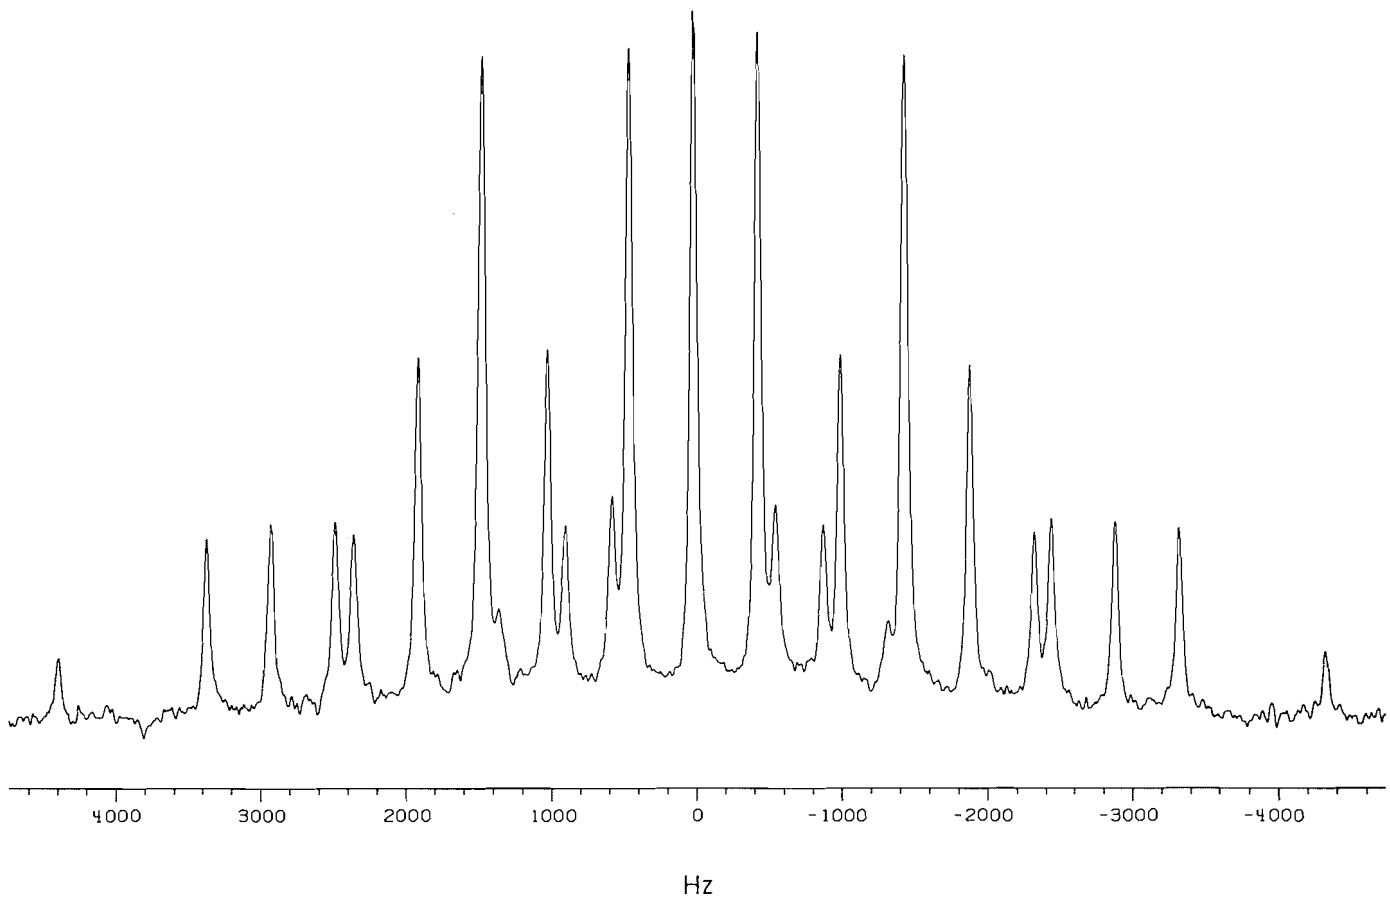

FIG. 2. Tin-119 nmr spectrum of the stannonium cation, $SnD_nH_{3-n}^+$ ($n \leq 3$) at 134.613 MHz and −80°C.

TABLE 2. Primary isotope effect on ^1J(Hz) in stannane

	$^1J(^{119}Sn,H)$	$^1J(^{119}Sn,D)$	$^1J(^{119}Sn,H)$*	$\Delta_p{}^1J(^{119}Sn,^{2/1}H)$
SnH_4	−1933.3 ± 0.1	—	—	—
SnH_3D	−1931.6 ± 0.1	−296.1 ± 0.1	−1928.9 ± 0.6	−2.7 ± 0.6
SnH_2D_2	−1929.9 ± 0.1	−295.8 ± 0.1	−1926.9 ± 0.6	−3.0 ± 0.6
$SnHD_3$	−1928.3 ± 0.2	−295.6 ± 0.1	−1925.6 ± 0.6	−2.7 ± 0.6
SnD_4	—	−295.2 ± 0.2	−1923.0 ± 1	—

*The value of $^1J(^{119}Sn,D)$ has been multiplied by the ratio, γ_H/γ_D, 6.51440.

Previously a $^{2/1}H$ induced isotope shift of −1.62 ppm had been reported for the tin chemical shift of Bu_3SnH (22).

(b) The stannonium cation

The ^{119}Sn nmr spectrum of $SnD_nH_{3-n}^+$ ($n \leq 3$) is much more symmetrical than that of stannane and is shown in Fig. 2. This indicates that the isotope shift is much smaller; $^1\Delta^{119}Sn(^{2/1}H)$ was found to be −0.05 ± 0.03 ppm/D, compared with −0.403 ± 0.001 ppm/D obtained for stannane. The ^{119}Sn nmr linewidths were 25 Hz, and not all of the lines of the spectrum could be resolved; thus the errors associated with this experiment were much larger than those for stannane. It is not possible to decide if the isotope shifts deviate from additivity because of the uncertainties in the experimental data.

It is possible to obtain a crude estimate of the shielding derivative for SnH_3^+; since the bond length is not known we must assume that it is about 1.7 Å. A value of −10 ppm/Å is obtained, which indicates the relative insensitivity of the ^{119}Sn nuclear shielding to Sn—H bond extension in the stannonium ion.

TABLE 3. Secondary isotope effect on ^1J(Hz) in stannane

Compounds	$\Delta_s{}^1J(^{119}Sn,H)[^1H]$	$\Delta_s{}^1J(^{119}Sn,D)[^2H]$
SnH_4–SnH_3D	−1.7 ± 0.1	—
SnH_3D–SnH_2D_2	−1.7 ± 0.1	−0.3 ± 0.1
SnH_2D_2–$SnHD_3$	−1.6 ± 0.2	−0.2 ± 0.1
$SnHD_3$–SnD_4	—	−0.4 ± 0.2

The small isotope shift and shielding derivative observed for the stannonium cation can be explained in terms of the charge argument mentioned above. Consideration of BH_3, BH_4^- and AlH_3, AlH_4^- indicates derivatives of +3.5, −27.0 and +84.2, +11.6 ppm/Å, respectively; thus in going from SnH_3^+ to SnH_4 one expects the derivative to decrease algebraically as observed.

Isotope effects on spin–spin coupling

(a) Stannane

Table 2 lists the observed coupling constants and values of

TABLE 4. Primary isotope effects on ^1J in the stannonium ion (Hz)

	$^1J(^{119}Sn,H)$	$^1J(^{119}Sn,D)$	$^1J(^{119}Sn,H)$*	$\Delta_p{}^1J(^{119}Sn,^{2/1}H)$
SnH_3^+	-2906.8 ± 5	—	—	
SnH_2D^+	-2907.2 ± 1	-444.5 ± 1	-2895.6 ± 6.5	-11.6 ± 7
$SnHD_2^+$	-2906.8 ± 1.5	-444.5 ± 1.5	-2895.6 ± 9.8	-11.2 ± 10
SnD_3^+	—	-443.6 ± 2	-2889.8 ± 24	—

*The value of $^1J(^{119}Sn,D)$ has been multiplied by the ratio γ_H/γ_D, 6.51440.

the primary isotope effect on spin–spin coupling in stannane. $^1J(^{119}SnH)$ for SnH_4 was found to be -1933.3 ± 0.1 Hz, in very good agreement with the value of -1933 Hz that has been reported (15). $\Delta_p{}^1J(^{119}Sn^{2/1}H)$ was found to be between -2.7 and -3.0 Hz, the average value being -2.8 ± 0.7 Hz, which is approximately 0.15% of the total coupling constant. Assuming that the first term of eq. [7] is much larger than the second, one can obtain an estimate of $(\partial J/\partial \Delta r_{SnH})_e$. The value we obtain is -640 Hz/Å, compared with $+190$ Hz/Å, the value calculated for $^1J(C,H)$ in methane using semiempirical molecular orbital calculations (9, 23). To compare these two values it is necessary to use the reduced coupling constant, K, since this eliminates the nuclear γ factor. The partial derivative of the reduced coupling constant in stannane is found to be 1.43×10^{21} kg m^{-2} s^{-2} A^{-2}/Å compared to a value of 3.5×10^{21} kg m^{-2} s^{-2} A^{-2}/Å in methane, an indication that the C–H coupling in methane is more sensitive to bond extension than is the Sn–H coupling in stannane.

The secondary isotope effect on $^1J(^{119}Sn,H)$ is -1.7 ± 0.2 Hz (see Table 3), about 0.09% of the total coupling constant. Unfortunately there is not enough information to reliably calculate the unknown derivative in eq. [14] of ref. 9. As expected, the secondary isotope effect on $^1J(^{119}Sn,D)$ is -0.3 ± 0.2 Hz, approximately 1/6.514 of the isotope effect on $^1J(^{119}Sn,H)$.

(b) The stannonium cation

The primary isotope effect on the spin–spin coupling for the stannonium ion is -11.7 ± 7 Hz (see Table 4). From this we obtain an estimate for the coupling derivative, $(\partial J/\partial \Delta r_{SnH})_e$, of -2680 Hz/Å, significantly larger than the value obtained for stannane, an indication that the coupling constant is more sensitive to bond extension. The secondary isotope is smaller than the experimental error and so an estimate of its magnitude would be meaningless.

Since the value of $\Delta_p{}^1J(^{31}P^{2/1}H)$ is positive in phosphine (13), a positive value of $\Delta_p{}^1J(^{119}Sn^{2/1}H)$ is anticipated for the isoelectronic SnH_3^- ion.

Enthalpies and heat capacities of solution for *tert*-butyl chloride and bromide in alcohols. Application of SPT, SRMR, and MS

R. M. C. GONÇALVES AND A. M. N. SIMÕES

CECUL, Instituto Bento da Rocha Cabral, Cd. Bento da Rocha Cabral, 14, 1200 Lisboa, Portugal

Received October 30, 1986

R. M. C. GONÇALVES and A. M. N. SIMÕES. Can. J. Chem. **65**, 1474 (1987).

Enthalpies and heat capacities of solution at infinite dilution for *tert*-butyl chloride and bromide in several alcohols are reported at 30, 35, and 40°C.

The Scaled Particle Theory (SPT), the Sinanoglu, Reiss, and Moura Ramos (SRMR) and the Model Solute (MS) methods were applied to the enthalpies of solvation. Significant differences in the results calculated from these theories were analysed and data discussed in terms of solute–solvent–solvent interactions.

R. M. C. GONÇALVES et A. M. N. SIMÕES. Can. J. Chem. **65**, 1474 (1987).

Les valeurs des enthalpies et capacités calorifiques de solution sont présentées pour les chlorure et bromure de tertiobutyle dans plusieurs alcools étudiés à 30, 35 et 40°C.

On a appliqué la "Scaled Particle Theory" (SPT) et les méthodes "Sinanoglu, Reiss et Moura Ramos" (SRMR) et "Model Solute" (MS). Les désaccords entre les valeurs obtenues par les différentes approches sont analysés dans cette article. On discute les resultáts en tenant compte des interactions solvant–solvant–soluté.

Introduction

Information about solute–solvent–solvent interactions occurring in the initial state of *tert*-butyl halides (*t*-BuX) solvolysis was first achieved by Arnett *et al.* (1) who reported thermodynamic quantities of solution in water–ethanol mixtures for *t*-BuCl.

Recently, Abraham (2) and Gonçalves and Simões (3) reported enthalpies of solution for *tert*-butyl chloride and bromide in several alcohols at 25°C. However, while kinetic studies of these reactions have been made at other temperatures, corresponding values for the enthalpies of solution do not appear to be available.

The first objective of this paper is to extend this study to other temperatures. Enthalpies of solution at infinite dilution, $\Delta_s H^\infty$, are now given for those substrats in *n*-alcohols (methanol to pentanol) and isopropanol and *tert*-butanol, at 30, 35, and 40°C. Together with previously reported values (3) heat capacities of solution were estimated, $\Delta_s C_p^\infty$.

The effect of hydroxylic solvents on the solvolysis of *t*-BuCl has been interpreted earlier, based on determinations of Gibbs' energy (4). The Scaled Particle Theory (SPT), the Sinanoglu, Reiss, and Moura Ramos (SRMR) and the Model Solute (MS) methods were used to calculate the terms due to the formation of cavities into the solvent and to decompose the transfer Gibbs' energy in a non-electrostatic and an electrostatic term.

Some large differences in the results from SPT and SRMR were noted although not leading to contradictory interpretations. A parallel development for the enthalpy has not yet been made.

The second purpose of this paper is to examine the results of the application of SPT, SRMR, and MS methods to the enthalpies of solvation $\Delta_{solv} H^\infty$, of *t*-BuCl and *t*-BuBr in water and in straight-chain and branched mono-alcohols.

Experimental

All enthalpies of solution were measured in a calorimeter previously described (3). The calorimetric technique, tests, calibration, and calculations were performed as earlier (3). Heats of empty ampoule breaking were negligible and corrections for condensation of solute vapour were performed in all cases. $\Delta_s H^\infty$ are the averages of the results from at least five measurements.

Numerical results

The solution enthalpies of *t*-BuCl and *t*-BuBr in several straight-chain and branched mono-alcohols, at 30, 35, and 40°C, are shown in Tables 1 and 2, except for the system *t*-BuBr in methanol at the higher temperatures, since the following solvolytic reaction path was found to significantly influence the solution process. Previous results for the same systems at 25°C from two different sources of data (2, 3), both obtained by a calorimetric technique, were also included as well as the solution enthalpy of *t*-BuCl in water, extrapolated from Arnett's values (1). $\Delta_s H^\infty$ are given along with twice the standard deviation of the mean. The solvation enthalpies at 25°C are also listed in Tables 1 and 2 and were obtained by subtracting the enthalpies of vaporization (Table 3) from the solution enthalpies.

The values $\Delta_s C_p^\infty$ in Table 4 were estimated as the slope of the linear regression analysis performed on the ($\Delta_s H^\infty$, T) pairs of points. $\sigma(\Delta_s C_p^\infty)$ is the standard deviation obtained directly from the least-squares method. Although it should be possible to fit a polynomial of higher order to our results, the coefficients would have questionable significance.

Application of SPT, SRMR, and MS

Before we discuss the application of SPT, SRMR, and MS methods to the solvation enthalpies of *t*-BuX in water and alcohols, we would like to emphasize that this study will be restricted to the temperature of 25°C due to the lack of fundamental properties and molecular values to perform this kind of analysis at other temperatures.

Application of SPT

According to the SPT (8), the enthalpy of creating a spherical cavity in a hard-sphere fluid is

$$[1]\quad H_c = y\alpha RT^2(1-y)^{-3}[(1-y)^2 + 3(1-y)r + 3(1+2y)r^2] + y(Rp/\rho\kappa)r^3 \qquad (r = \sigma_2/\sigma_1;\ \rho = N/V_1;\ y = \pi\rho\sigma_1^3/6)$$

where σ_1 and σ_2 are the diameter of the solvent and solute, respectively, and ρ is the number density of the solvent. For pressures around 1 atm the contribution of the pressure term was found to be negligible (8). Tables 3 and 5 give the values of the several parameters used in the calculations of H_c. The cavity formation term together with the interaction term, H_i, obtained from eq. [2],

$$[2]\quad \Delta_{solv} H^\infty = H_c + H_i + RT(\alpha T - 1)$$

where α is the coefficient of thermal expansion of the solvent, are listed in Table 6. The enthalpies of transfer to methanol, ∂H_i, are summarized in Table 7.

Application of SRMR

According to the SRMR method (15),

$$[3]\quad H_c/\text{J mol}^{-1} = 40.840KV_2^{2/3}\gamma\left[1 - \left(\frac{T}{\gamma}\frac{\partial\gamma}{\partial T} + \frac{2T}{3}\alpha\right)\right]$$

where γ is the surface tension of the solvent (dyne cm^{-1}) and K is a correction term due to the microscopic curvature of the cavity surface.

K may be calculated through eq. [4] proposed by Halicioglu and Sinanoglu (16):

$$[4]\quad K = 1 + (V_1/V_2)^{2/3}[K(1) - 1]$$

V_1 and V_2 are the molar volumes of the solvent and the solute, respectively. $K = K(1)$ when the cavity has the solvent molecule dimensions.

Following Eyring (17), the enthalpy associated with the formation of such a cavity is given by the vaporization enthalpy of the solvent. $\Delta_{vap}H$ and $K(1)$ as well as γ and $\partial\gamma/\partial T$ for the different alcohols and water are shown in Table 5. H_c and the corresponding H_i values, obtained from eq. [2], are given in Table 6. For transfer to methanol, values of ∂H_i were calculated (Table 7).

Application of MS

Another approach to the study of solvent effects involves the decomposition of the transfer solvation enthalpy from one solvent to another in two terms, one concerned with the electrostatic contribution ∂H_e, and the other with the non-electrostatic contribution, ∂H_{ne} (6):

$$[5] \quad \partial\Delta_{solv}H^\infty = \partial H_e + \partial H_{ne}$$

This method makes use of reference molecules in order to evaluate ∂H_{ne}. ∂H_{ne} is assumed to be equal to $\partial\Delta_{solv}H^\infty$ of a model solute, rare gases or alkanes of identical molar volume. The hydrocarbons 2-methylpropane (2-mp) and 2,2-dimethylpropane (2,2-dmp) seem to be suitable model solutes for *tert*-butyl halides. Calorimetric enthalpy values for these two alkanes in water were reported by Dec and Gill (18). Unfortunately, solvation enthalpies in other solvents are only available from low precision gas-solubility measurements (19). The enthalpies of solvation of 2-mp and 2,2-dmp are given in Table 8. Table 7 shows ∂H_c values for *t*-BuCl, using 2-mp as model solute.

Discussion

The enthalpy term associated with the cavity formation in the solvents is a function of the cohesive properties of the solvents and the molar volumes of the solutes. The cohesive energy of the solvent may be characterized by its internal pressure, cohesive energy density, or surface tension. The two first cases lead to the cavity term to be proportional to the cavity volume, as it happens in the Scaled Particle Theory (8), while, in the last

case, H_i is proportional to the cavity surface, as stated by the Sinanoglu, Reiss, and Moura Ramos method (15).

The comparison of the two sets of H_c and H_i results in Table 6 and of ∂H_i in Table 7 show that values calculated from SPT and SRMR differ quite considerably. In spite of the numerical discrepancies, the sign and the order of magnitude of the transfer Gibbs' functions calculated for t-BuCl in some hydroxylic solvents, using both SPT and SRMR models, led to a common interpretation of solvent effects (2). Unfortunately, this is not true for our ∂H_c and ∂H_i values. The theories may even lead to opposite interpretations and this is particularly relevant in water. As Desrosiers and Morel (20) pointed out recently, SPT and SRMR should not be expected to give the same H_c values, since SPT is based on statistical mechanics and uses molecular parameters, while SRMR is a macroscopic theory, relating the bulk surface tension to the energy of formation of a molecular sized cavity. In their opinion, SPT terms are probably the best we can get at present and SRMR can just be used to get gross approximations of the cavity terms. It is true that SPT calculations are very much dependent on the uncertainty of the molecular diameters. However, if a coherent choise of σ_1 and σ_2 is made, the comparison of thermodynamic data relative to the formation of cavities and, consequently, to the solute–solvent–solvent interactions is still valid. It is also true that according to the hypothesis of the SPT (8), the theory could not be used, in principle, for polar liquids. Tests of the validity of SPT, even when applied to solvents involving strong interactions such as alcohols and water, however, show that, provided the studied molecule is of small size and as hard sphere as possible, SPT can be used to calculate H_c whatever the solvent (20). We wish to emphasize that the solute molecules used in this work satisfy these conditions.

From now on we shall only analyse values calculated through SPT. Data in Table 6 show that there are positive and large solute–solvent–solvent interactions. As expected, a parallel behaviour is observed for both solutes in several media. Two exothermic contributions to H_i should be considered: one, due to the interaction of hydrophilic centers of the solute with solvent molecules and the other, due to the enhancement of hydrogen bonding of water or alcohol near the non–polar groups of the substrats. However, less hydrogen bond disruption and subsequent less strong solvent reorganization should take place in alcohols rather than in water, attending to the structural differences of these solvents. H_i and ∂H_i for water compared with values for other solvents are in accordance with this explanation (Tables 6 and 7).

The variation in the solvation of a certain compound in different solvents is reflected directly by the enthalpies of transfer from a chosen reference solvent.

The results in Table 7, using MeOH as reference solvent, show that, for normal alcohols, the larger the solvent molecule becomes the more exothermic is the solute–solvent–solvent interaction. A solute molecule dissolved in an alkanol with a short alkyl chain will probably disturb easily the hydrogen bonding in the solvent. On the other hand, in alkanols with large molecules a solute which is approximately of the same volume may fit into the solvent structure without substantial disruption of hydrogen bonding. ∂H_i for branched alcohols do not follow the same tendency (Table 7). At the moment we have no satisfactory explanation for this. ∂H_e and ∂H_i values in Table 7 differ considerably, which is not surprising bearing in mind that ∂H_i includes not only electrostatic effects covered by ∂H_e but also dispersive interactions (2). The same kind of variation seems to be observed for ∂H_i values calculated through SPT and ∂H_e from MS in alcohols. The few data available in the literature do not allow further interpretations.

Although this study has only been performed at 25°C, we don't see any reason to consider a different explanation at other temperatures. $\Delta_s C_p^{\infty}$ is always positive and the order of magnitude seems to be reasonable for this kind of compounds. As we could expect, based on the charge density of both substrate and consequent solute–solvent interactions, the selectivity towards the solvent is higher for t-BuCl, which is mainly revealed on the higher $\Delta_s C_p^{\infty}$ values for this compound.

In conclusion, from the application of SPT and SRMR to the solvation enthalpies of t-BuX (X = Cl, Br) in water and alcohols, we found that, though SPT may lead to some uncertainty in the results, if a coherent choise of the molecular diameters of the involved species is made, this theory seems to be a useful approach to compare the thermodynamic data relative to the formation of cavities and, consequently, to the solute–solvent–solvent interactions.

These results are consistent with similar conclusions based on recent applications of SPT to polar systems (21, 22). It should

be of main interest to obtain more calorimetric data for model hydrocarbons, specially gaseous ones, in a larger variety of solvents and at different temperatures (18, 23).

Reçu le 24 septembre 1986

RAOUL M'BOUNGOU, MICHELLE PETIT-RAMEL, GERMAINE THOMAS-DAVID, GÉRARD PERICHET et BERNARD POUYET. Can. J. Chem. **65**, 1479 (1987).

Les constantes de protonation du monomère (TM) et du dimère (TD) de la thymine, du monomère (OM) et du dimère (OD) de l'acide orotique et de la thymidine (TY) ont été calculées à 25 et à 37°C et à force ionique $\mu = 0,1(NaNO_3)$. Dans les mêmes conditions, les constantes de stabilité des complexes formés avec le Cu(II), le Hg(II) et le Pt(II) ont été déterminées par protométrie. Les résultats sont discutés en termes de sites de liaison : azote N3 pour la thymine monomère et dimère et la thymidine; anion carboxylate en C6 et azote adjacent N1 pour l'acide orotique monomère et dimère.

RAOUL M'BOUNGOU, MICHELLE PETIT-RAMEL, GERMAINE THOMAS-DAVID, GÉRARD PERICHET, and BERNARD POUYET. Can. J. Chem. **65**, 1479 (1987).

The protonation constants of monomeric (TM) and dimeric (TD) forms of thymine and monomeric (OM) and dimeric (OD) forms of orotic acid and thymidine (TY) have been calculated at 25 and 37°C and at ionic strength $\mu = 0.1(NaNO_3)$. Under the same conditions the stability constants of their Cu(II), Hg(II), and Pt(II) complexes have been determined by protometric methods. The results have been discussed and a comparison has been established in terms of binding sites: nitrogen N3 for monomeric and dimeric forms of thymine and thymidine; carboxylate anion at C6 and adjacent ring nitrogen N1 for monomeric and dimeric forms of orotic acid.

Introduction

Sous l'action d'une irradiation monochromatique, la thymine (une des quatre bases azotées de l'ADN) peut se dimériser (fig. 1*a*) et donner lieu à une réaction autodéfensive de l'organisme qui utilise alors des enzymes de photoréactivation pour monomériser le dimère de la thymine. Des articles précédents (1, 2) ont montré, à titre d'exemple, une analogie de mécanisme réactionnel lorsque l'enzyme est remplacé par les ions Hg^{2+}.

Dans ce mémoire, nous étendrons cette première approche à l'acide orotique et à son espèce dimérisée (fig. 1*b*), qui, transformée par voie métabolique en nucléotide, entre dans la biosynthèse des bases pyrimidiques, classe à laquelle appartient la thymine (3). De plus, la substitution des ions Hg^{2+} par les ions Cu^{2+} et par les ions Pt^{2+}, issus du *cis*-platine, conduit à des complexes qui présentent non seulement les caractéristiques souhaitées en photochimie, mais sont susceptibles de plusieurs applications dans le domaine des traitements antitumoraux (4).

Outre l'intérêt évident de ces complexes dans de nombreux processus physiologiques, le choix de ces deux dérivés de la pyrimidine pose, lors de la formation des complexes métalliques monomères et dimères, un problème au niveau de la liaison métal–coordinat, notamment en ce qui concerne l'atome d'azote donneur d'électrons.

Dans la même ligne, nous aborderons l'étude des interactions du Cu(II) et du Hg(II) avec la thymidine, nucléoside correspondant à la thymine (fig. 1*c*), qui a la propriété de s'incorporer à l'ADN sans subir de modification (3).

La démarche suivie pour la mise en évidence des espèces protonées, puis des espèces complexes $M_pH_qA_r$, ainsi que le calcul de leurs constantes de stabilité β_{pqr} découle directement du protocole développé dans un précédent mémoire (1) : (*i*) examen des courbes de formation $\bar{n} = f(pL)$ où $\bar{n}$ représente le nombre moyen de ligands L déprotonés; (*ii*) affinement

par minimisation d'écart-type sur les points expérimentaux et calculés des transformées des courbes de titration, $\bar{q} = f(\text{pH})$, rendues linéaires, où $\bar{q}$ est le nombre moyen de protons neutralisables par mole de ligand.

Résultats

Les bases puriques et pyrimidiques monomères composant des acides nucléiques sont susceptibles de complexer de nombreux cations tels que Hg^{2+}, Pt^{2+}, Cu^{2+}, Ni^{2+}, Zn^{2+}, Co^{2+}, Mg^{2+}, Ca^{2+} et Pb^{2+} bien que les constantes de stabilité correspondantes ne soient pas calculées (1, 2, 5–8). Excepté les travaux que notre laboratoire a publiés nous n'avons repertorié aucune donnée bibliographique relative à la déprotonation et aux stabilités thermodynamiques de ces mêmes bases sous forme dimérisée.

1. Thymine monomère et dimère

Bien qu'il y ait dans chaque molécule de thymine (5-méthyl-2,4 (1*H*, 3*H*) pyrimidinedione) monomère deux possibilités d'échange relatives aux hydrogènes portés par les fonctions amines N1 et N3, seule la déprotonation N3 est observable dans le domaine de pH envisagé. Par voie de conséquence la molécule de dimère subira deux déprotonations en N3 et N3′ (1).

(a) Interactions avec le cuivre

Thymine monomère, H(TM). En ce qui concerne la complexation du cuivre, seul le complexe $[Cu(TM)]^+$ est mentionné (8, 9). Pour notre part, nous observons que la variation systématique dans les limites de solubilité, de la concentration en ions cuivriques met en évidence d'autres espèces complexes. Les interactions thymine–cuivre se situent dans le domaine $6 < \text{pH} < 9$ et pour les deux rapports coordinat–métal considérés, l'examen des courbes de formation $\bar{n} = f(\text{p[TM]})$ conduit à deux remarques :

L'ensemble des courbes de formation tend vers $\bar{n} = 2$, ce qui implique la formation d'espèces faisant intervenir une, puis deux molécules de ligand par métal.

Le déplacement de ces courbes $\Delta(\text{p[TM]})$ avec l'accroissement de la concentration en métal, Δm, indique de plus, la formation d'espèces polynucléaires M_2L_2 et M_2L_4 (10, 11).

$$2Cu^{2+} + 2H(TM) \rightleftarrows [Cu_2(TM)_2]^{2+} + 2H^+$$

$$2Cu^{2+} + 4H(TM) \rightleftarrows [Cu_2(TM)_4] + 4H^+$$

La bonne convergence du processus d'affinement permet de vérifier les hypothèses émises. Les valeurs définitives des constantes affinées par la méthode de «pit-mapping», ainsi que les données bibliographiques sont rassemblées dans le tableau 1.

Thymine dimère, H_2(TD). La faible solubilité de la thymine dimère impose rapidement une limite supérieure à la concentration en coordinat ($\sim 10^{-4}$ *M*). Pour ce système il est possible de mettre en évidence (tableau 1) une espèce protonée $[CuH(TD)]^+$ due au départ du premier proton neutralisable en N3, puis une espèce complexe simple [Cu(TD)] répondant aux équilibres :

$$Cu^{2+} + H_2(TD) \rightleftarrows [CuH(TD)]^+ + H^+$$

$$Cu^{2+} + H_2(TD) \rightleftarrows [Cu(TD)] + 2H^+$$

(b) Interactions avec le platine

Thymine monomère. Si de nombreuses publications (1, 2, 13–17) détaillent la préparation de complexes de Pt(II) avec la presque totalité des bases constitutives de l'ADN, il faut noter que certains auteurs (18, 19) précisent que le *cis*-$[PtCl_2(NH_3)_2]$ n'a aucune réactivité directe vis-à-vis de la thymine ou de la thymidine même à 37°C. De plus dans chaque cas l'ion hydraté

TABLEAU 2. Constantes de stabilité des complexes de l'acide orotique (monomère et dimère); $t = 25°C$, $\mu = 0,1$ ($NaNO_3$)

Espèce	*pqr*	log β_{pqr}	Domaine de formation	Référence 23	Référence 24	Référence 25
H(OM)	011	9,33(0,01)*		9,45		9,45
H_2(OM)	021	11,77(0,3)		12,25		12,52
[Cu(OM)]	101	8,39(0,02)	pH 4–8		9,48	
[Hg(OM)]	101	8,6 (0,1)	pH 3–7			
$[Hg_2(OM)_3]^{2-}$	203	20,03(0,1)	pH 4,5–6,5			
cis-$[Pt(OM)(NH_3)_2]$	101	6,61(0,003)	pH 3,5–9			
cis-$[Pt(OM)_2(NH_3)]^{2-}$	102	11,59(0,003)	pH 5–9			
H(OD)	011	10,56(0,03)				
H_2(OD)	021	19,4 (0,04)				
H_3(OD)	031	23,8				
H_4(OD)	041	26,6				
$[Cu(OD)]^{2-}$	101	12,27(0,2)	pH 4,5–11			
$[Hg(OD)]^{2-}$	101	13,2 (0,6)	pH 4–10			
cis-$[Pt(OD)(NH_3)_2]^{2-}$	101	11,8 (0,4)	pH 4,5–10			

*Écarts-types correspondants aux constantes.

cis-$[Pt(H_2O)_2(NH_3)_2]^{2+}$ est beaucoup plus réactif que le composé chloré *cis*-$[PtCl_2(NH_3)_2]$.

Cette anomalie nous a semblé d'autant plus intéressante à étudier que quelques travaux récents (4, 20, 21) font état d'interactions *cis*-$[PtCl_2(NH_3)_2]$ avec l'ADN à 25°C. Et pour mieux cerner l'influence des ligands chlorés, nous avons procédé en deux temps en suivant par des mesures protométriques à 25 et à 37°C :

les interactions *cis*-$[PtCl_2(NH_3)_2]$ – thymine monomère

les interactions *cis*-$[Pt(H_2O)_2(NH_3)_2]^{2+}$ – thymine monomère

La constante de déprotonation de la thymine monomère a été recalculée à 37°C. Nous avons vérifié que le *cis*-$[PtCl_2(NH_3)_2]$ se complexait très difficilement avec la thymine monomère quelle que soit la température. Par contre l'ion substitué *cis*-$[Pt(H_2O)_2(NH_3)_2]^{2+}$ conduit à des mesures expérimentales fiables et reproductibles permettant le calcul précis des constantes de stabilité pour deux complexes successifs mixtes, uniquement identifiés par Lippert (22).

$$cis\text{-}[Pt(H_2O)_2(NH_3)_2]^{2+} + H(TM) \rightleftarrows cis\text{-}[Pt(TM)(NH_3)_2]^{+} + H^+ + 2H_2O$$

$$cis\text{-}[Pt(H_2O)_2(NH_3)_2]^{2+} + 2H(TM) \rightleftarrows cis\text{-}[Pt(TM)_2(NH_3)_2] + 2H^+ + H_2O$$

Thymine dimère. En ce qui concerne la thymine dimère, l'addition de *cis*-$[Pt(H_2O)_2(NH_3)_2]^{2+}$ n'a pas d'incidence sur les déplacements protométriques : il n'y a donc pas de formation d'espèce complexe dans nos conditions expérimentales. En outre, les modèles de Dreiding qui permettent une bonne visualisation des composés moléculaires montrent aisément l'impossibilité d'insertion «sandwich» de l'ion métallique entre les deux plans de la molécule dimère.

2. Acide orotique monomère et dimère

L'acide orotique (acide 6-uracilcarboxylique) n'est pas une base de l'ADN, et bien que possédant un groupement carboxylique en C6 il s'intègre dans l'ensemble des dérivés pyrimidiques dont nous avons souligné l'importance physiologique.

La première dissociation protonique concerne l'hydrogène du groupement carboxylique en C6. De plus il existe dans chaque molécule de monomère deux possibilités d'échange relatives aux hydrogènes portés par les fonctions amines en N1 et N3 (fig. 1*b*).

(a) Interactions avec le cuivre

Acide orotique monomère, H_2(OM). Nous avons calculé dans un premier temps, les constantes de stabilité protonique β_{011} et β_{021} de l'acide orotique monomère à 25°C (tableau 2). Bien qu'il y ait dans chaque molécule de monomère, deux possibilités d'échange protonique relatives aux hydrogènes portés par les fonctions amines N1 et N3 (fig. 1*b*), les mesures protométriques se révélant inopérantes pour une telle différenciation, nous pouvons supposer que le fort effet inductif du groupement carboxylique porté par C6 active préférentiellement l'hydrogène porté par N1 en position α, la seconde déprotonation de l'hydrogène porté par N3 se situant vers pH 13 (23).

Dans le domaine de pH où l'hydrolyse des métaux est négligeable, l'acide orotique monomère complexe les ions Ni^{2+} et Cu^{2+} en formant les chélates du type [Ni(OM)] et [Cu(OM)]. Pour chacun de ces chélates la liaison coordinat–métal passe par l'intermédiaire du groupement carboxylique et l'atome d'azote N1 (24–26).

En accord avec ces données, la complexation des ions Cu^{2+} par le monomère et pour deux rapports coordinat–métal se traduit par la formation d'une seule espèce complexe répondant à l'équilibre :

$$Cu^{2+} + H_2(OM) \rightleftarrows [Cu(OM)] + 2H^+$$

Dans ce cas, il y a formation d'un chélate par liaison coordinante entre le groupement carboxylique et l'azote adjacent N1 (27–30).

Acide orotique dimère, H_4(OD). Nous ne disposons d'aucune donnée bibliographique chiffrant les stabilités protoniques et les stabilités des complexes et nous avons suivi le même protocole d'étude que pour le monomère. La transformée des courbes de neutralisation $\bar{q} = f(pH)$ correspond bien à la présence de quatre protons neutralisables H_4(OD) relatifs aux constantes β_{011}, β_{021}, β_{031}, β_{041} du tableau 2.

Le traitement des données potentiométriques relatives au système Cu^{2+} – acide orotique dimère fait apparaître la formation d'une seule espèce complexe de type $[Cu(OD)]^{2-}$ qui répond à l'équilibre :

$$Cu^{2+} + H_4(OD) \rightleftarrows [Cu(OD)]^{2-} + 4H^+$$

For personal use only.

(b) Interactions avec le mercure

Acide orotique monomère. En présence des ions Hg^{2+}, l'acide orotique monomère conduit à la formation simultanée du complexe simple [Hg(OM)] et de l'espèce complexe polynucléaire $[Hg_2(OM)_3]^{2-}$ dont les équilibres correspondants sont :

$$Hg^{2+} + H_2(OM) \rightleftarrows [Hg(OM)] + 2H^+$$

$$2Hg^{2+} + 3H_2(OM) \rightleftarrows [Hg_2(OM)_3]^{2-} + 6H^+$$

Les phénomènes secondaires qui accompagnent généralement la complexation des ions Hg^{2+} (hydrolyse et dismutation (1, 31, 32)) en présence d'un excès de métal, n'ont pas été pris en compte lors de l'affinement des constantes. L'introduction, dans le cycle d'affinement de la constante β_{1-10}, relative à la formation d'espèce hydroxylée soluble $[Hg\ H_{-1}]$ n'améliore pas sensiblement la convergence.

Acide orotique dimère. La solubilité importante de l'acide orotique dimère ne favorise pas l'hydrolyse des ions mercuriques que nous considérons comme négligeable. Les interactions de l'acide orotique dimère avec les ions Hg^{2+} se traduisent par la formation d'une seule espèce complexe de type $[Hg(OD)]^{2-}$ dont l'équilibre est :

$$Hg^{2+} + H_4(OD) \rightleftarrows [Hg(OD)]^{2-} + 4H^+$$

(c) Interactions avec le platine

Acide orotique monomère. Le platine complexé sous forme d'ions *cis*-$[Pt(H_2O)_2(NH_3)_2]^{2+}$ conduit à la formation de deux espèces chélates mixtes successives :

$$cis\text{-}[Pt(H_2O)_2(NH_3)_2]^{2+} + H_2(OM) \rightleftarrows cis\text{-}[Pt(OM)(NH_3)_2] + 2H^+ + 2H_2O$$

$$cis\text{-}[Pt(H_2O)_2(NH_3)_2]^{2+} + 2H_2(OM) \rightleftarrows cis\text{-}[Pt(OM)_2(NH_3)_2]^{2-} + 4H^+ + 2H_2O$$

Acide orotique dimère. Contrairement à la thymine dimère, la présence du groupement carboxylate en C6 favorise la formation d'un chélate externe impliquant l'azote N1 adjacent :

$$cis\text{-}[Pt(H_2O)_2(NH_3)_2]^{2+} + H_4(OD) \rightleftarrows cis\text{-}[Pt(OD)(NH_3)_2]^{2-} + 4H^+ + 2H_2O$$

3. Thymidine H(TY)

De nombreux travaux mentionnent les interactions de la thymidine avec les ions métalliques tels que Hg^{2+}, Cu^{2+}, Co^{2+}, Cd^{2+} et Mn^{2+} (12, 14, 18, 31, 33–35), mais fort peu se rapportent aux calculs des stabilités thermodynamiques permettant de chiffrer les équilibres de complexation.

Si l'introduction du groupe sucre sur l'azote N1 confère à la thymidine une plus grande solubilité que celle de la thymine, elle n'a pratiquement pas d'incidence sur la stabilité protonique de l'hydrogène porté par N3. La constante calculée (tableau 3) concorde avec les rares données bibliographiques que nous possédons (14, 31).

(a) Interactions avec le cuivre

Comme dans le cas de la thymine, l'obtention d'espèces polynucléaires se confirme rapidement selon les équilibres :

$$2Cu^{2+} + 2H(TY) \rightleftarrows [Cu_2(TY)_2]^{2+} + 2H^+$$

$$2Cu^{2+} + 4H(TY) \rightleftarrows [Cu_2(TY)_4] + 4H^+$$

(b) Interactions avec le mercure

Ferreira *et al.* (31) font état d'un complexe stable $[Hg(TY)_2]$ engageant deux molécules de ligands.

Dans nos conditions expérimentales (excès de ligand) nous avons détecté dès pH 3 la présence de la première espèce successive $[Hg(TY)]^+$. L'introduction de la constante correspondante à cette dernière améliore sensiblement la convergence de l'affinement relatif aux points expérimentaux de deux rapports coordinat:métal.

$$Hg^{2+} + H(TY) \rightleftarrows [Hg(TY)]^+ + H^+$$

$$Hg^{2+} + 2H(TY) \rightleftarrows [Hg(TY)_2]^{2+} + 2H^+$$

TABLEAU 3. Constantes de formation des complexes de la thymidine; $t = 25°C$, $\mu = 0{,}1$ ($NaClO_4$)

Espèce	*pqr*	log β_{pqr}	Domaine de formation	Référence 14	Référence 31
H(TY)	011	9,78		9,6	9,6
$[Cu_2(TY)_2]^{2+}$	202	12,78	pH 5,5–8,5		
$[Cu_2(TY)_4]$	204	23,1	pH 6–8,5		
$[Hg(TY)]^+$	101	7,88	pH 2–4		
$[Hg(TY)_2]$	102	14,94	pH 2–10		21,2

Conclusion

L'examen comparé des complexes du cuivre, du mercure et du platine, que nous venons d'explorer appelle plusieurs remarques en ce qui concerne les coordinats.

En outre, les constantes de formation consignées dans le tableau 1 donnent accès aux concentrations de toutes les espèces en solution et la figure 2, un exemple de leur répartition et précisent très exactement les conditions expérimentales de concentration et de pH nécessaires au bon déroulement de la transformation photochimique.

1. Thymine et thymidine

Thymine monomère, thymidine

La thymine monomère et la thymidine, coordinats monodentates, donnent préférentiellement des complexes polynucléaires avec le cuivre et le mercure, l'interaction unique en N3 favorisant l'apparition de liaisons métal–métal, notamment avec le cuivre tétracoordinant. Dans le cas du platine, les espèces mixtes mononucléaires obtenues par substitution successives des molécules d'eau satisfont totalement la tétracoordinence du métal. Ces espèces apparaissent dans un domaine de pH essentiellement plus alcalin que celui du milieu biologique et par là même indécelables dans les expérimentations «in vivo» rapportées par J. L. Butour (4) qui signale que seule la guanine est susceptible de complexer l'ion *cis*-platine.

Thymine dimère

La géométrie de la molécule favorise l'inclusion de l'atome métallique (cuivre ou mercure) entre les deux cycles adjacents. Par contre, aucun complexe n'a été détecté avec le platine, ce qui semble confirmé à l'aide des modèles de Dreiding par l'impossibilité stérique d'immiscer l'ion *cis*-$[Pt(H_2O)_2(NH_3)_2]^{2+}$ substitué entre les cycles uracile parallèles.

2. Acide orotique

Acide orotique monomère

Quel que soit le métal, les espèces mononucléaires sont les plus fréquentes avec le coordinat bidentate, chélatant par l'azote N1 et le groupement carboxylate porté par C6.

La comparaison des constantes de stabilité des complexes du cuivre et du mercure avec celles des complexes correspondants obtenus avec l'acide picolinique déjà étudiées dans notre laboratoire (respectivement $\beta_{101} = 7{,}76$, $\beta_{102} = 14{,}70$ (36) et $\beta_{101} = 7{,}70$, $\beta_{102} = 15{,}4$ (37)), corrobore les observations de Tucci *et al.* (25). Bien que dans le cas de l'acide picolinique, les sites de fixation soient identiques, l'azote adjacent en N1 n'étant

pas chargé induit la formation d'un chélate moins stable que le complexe correspondant de l'acide orotique.

Acide orotique dimère

La chélation du cuivre, du mercure et du platine ne présente aucune difficulté dans un rapport coordinat:métal 1:1. Il faut noter que la chélation du platine (sous forme d'ion *cis*-$[Pt(H_2O)_2(NH_3)_2])^{2+}$, non observable avec la thymine dimère reste un phénomène externe à la «cage» formée par les deux cycles adjacents.

En ce qui concerne la transposition à une réaction photochimique reversible entre les complexes mercuriques dimère et monomère, nous avons précédemment montré l'intérêt (2) du complexe dimère [HgTD] de la thymine dont l'irradiation à 280–300 nm entraîne la formation des espèces monomères $[HgTM]^+$ ou $[Hg(TM)_2]$. La présence d'espèces hydroxylées $[HgH_{-1}TD]^-$ et $[HgH_{-2}TD]^{2-}$ observées dans ce cas, et susceptibles de gêner le processus de monomérisation, est écartée par l'utilisation de l'acide orotique dimère, qui, plus soluble, favorise beaucoup moins l'hydrolyse de l'ion Hg^{2+}.

Partie expérimentale

Nous disposons d'une chaîne de mesure étalonnée avec précision :

électrode en verre | solution thermostatée | NaCl saturé | électrode au calomel

Le jeu d'électrodes est relié à un potentiomètre ISIS 20000 Tacussel et les mesures sont effectuées que des solutions aqueuses thermostatées à 25 ± 0,1°C et sous atmosphère d'azote. La force ionique de chaque solution est maintenue constante à l'aide d'une solution de $NaNO_3$ 0,1 *M*.

Sels métalliques

Les sels de cuivre et de mercure sont préparés par dissolution de $Cu(NO_3)_2 \cdot 3H_2O$ et $Hg(NO_3)_2 \cdot H_2O$ Prolabo et dosés par complexométrie à l'EDTA notamment à l'aide d'une électrode reversible aux ions Hg^{2+} couplée à une électrode de référence au sulfate mercureux pour le mercure.

La solution de *cis*-$[Pt(H_2O)_2(NH_3)_2](NO_3)_2$ est préparée à partir de *cis*-$[PtCl_2(NH_3)_2]$ R. Bellon par substitution stoechiométrique des ions Cl^- effectuée à l'aide d'une solution titrée de nitrate d'argent (38–41). Une triple centrifugation du chlorure d'argent permet de garantir la reproductibilité de l'échange qui n'affecte en rien la liaison Pt—N (41).

Coordinats

La thymine monomère, l'acide orotique monomère et la thymidine proviennent respectivement des laboratoires Merck, Sigma Chemical Company et Boehringer Mannheim GMBH.

La thymine dimère est préparée par irradiation de solutions de monomère dans l'eau (10^{-3} *M*) gelée à −10°C. L'irradiation est effectuée à l'aide d'une lampe à vapeur de mercure haute pression et les solutions sont évaporées à sec. Le résidu est ensuite dissous dans l'eau bouillante puis filtré. Le filtrat est concentré et les cristaux de thymine dimère cristallisent avant ceux du monomère (1).

En ce qui concerne la préparation de l'acide orotique dimère, le processus général reste le même, les irradiations ayant lieu à 20°C, sur des solutions amenées à pH 1 sous barbotage d'azote pour éliminer l'oxygène. Dans chaque cas, deux rapports de concentration ligand:ion métallique (~2 et ~5) ont été considérés pour chaque système, soit environ 100 points expérimentaux.

Remerciements

Nous remercions vivement les laboratoires Roger Bellon, 159 avenue du Roule, 92200 Neuilly sur Seine de nous avoir fourni gracieusement le *cis*-$[PtCl_2(NH_3)_2]$.

M. N. BAKOLA-CHRISTIANOPOULOU, P. D. AKRIVOS, and M. BAUMGARTEN. Can. J. Chem. **65**, 1485 (1987).

Homobinuclear metal chelate complexes having 1,4-dihydroxy-9,10-anthracenedione (quinizarin) as a bridging unit have been prepared with four bivalent first row transition elements, namely cobalt, nickel, copper, and zinc. The coordination spheres of the metal ions consist of two nearly equivalent six-membered rings with oxygen donor atoms derived from the quinizarin and the terminal ligands which are either β-diketones or salicylic aldehyde. TG, spectroscopic (ir, uv–vis, epr), and magnetic measurements have been applied to an investigation of the geometry adopted by the MO_4 chromophores. The results are consistent with varying degrees of distortion from the ideal square planar toward a tetrahedral arrangement around the metal ions, closely related to the specific metal center involved.

M. N. BAKOLA-CHRISTIANOPOULOU, P. D. AKRIVOS et M. BAUMGARTEN. Can. J. Chem. **65**, 1485 (1987).

On a préparé les complexes homobinucléaires métal/chélate de quatre éléments bivalents de la première rangée des éléments de transition (soit le cobalt, le nickel, le cuivre et le zinc) couplés à de la dihydroxy-1,4 anthracènedione-9,10 (quinizarine) agissant comme unité de pont. Les sphères de coordination des ions métalliques comportent deux cycles à six chaînons qui sont pratiquement équivalents et dans lesquels les atomes d'oxygène donneurs proviennent de la quinizarine alors que les ligands terminaux sont soit des β-dicétones ou de l'aldéhyde salicylique. On a utilisé des mesures de TG, de spectroscopie (ir, uv–visible et rpe) et de magnétisme pour étudier la géométrie adoptée par les chromophores MO_4. D'après ces résultats, l'arrangement autour des ions métalliques implique divers degrés de distorsion du plan carré idéal vers un arrangement tétraédrique; cet arrangement autour des ions métalliques ressemble beaucoup à celui qui existe autour du centre métallique spécifique impliqué.
[Traduit par la revue]

Introduction

Quinones, hydroxyquinones, and their substituted derivatives form an extended class of compounds that has attracted the interest of chemists and has been studied thoroughly. The investigations reported cover practically every topic of synthetic and experimental chemistry, including isolation from natural products (1), total synthesis (2), testing of antimicrobial activity (3), and preparation and identification of metal chelates and polymers (4). Metal chelates of hydroxyquinones with both first row transition metal elements and Pt(II) have been the main part of our research in recent years, both theoretical (5) and spectroscopic methods (6, 7) having been applied in our effort to gain insight into the chelating ability of hydroxyquinones and their subsequent modifications following coordination to different metal ion spheres. The formation of coordination compounds has attracted much more interest since the observation that many of the commercially used antibiotics possess active hydroxyquinonic sites (8), and the suspicion that this local structure might be responsible for the detected biological activity. As our contribution in this line of research, we have reported both the preparation and chemical (9) as well as biological (10) justification of such an activity of naphthazarinato bridged binuclear Pt(II) complexes. In the present paper we report on the synthesis and characterization of a series of mixed ligand neutral homobinuclear complexes of first row transition elements with the dianion 1,4-dihydroxy-9,10-anthracenedione (quinizarin) as the bridging unit, β-diketonates as terminal ligands (acetylacetone, benzoylacetone, and salicylic aldehyde), and the bivalent metal ions Co(II), Ni(II), Cu(II), and Zn(II) (Fig. 1).

Experimental

Materials and instruments

Quinizarin obtained from Bayer was recrystallized from hot benzene prior to its use in the preparation while no purification was performed on the diketones used (Aldrich). All the solvents used were of reagent grade. The ir spectra were recorded in the region 4000–250 cm^{-1} on a Perkin–Elmer 467 spectrophotometer, using KBr discs (1:100 in KBr) while the electronic spectra were obtained (900–250 nm) on a Perkin–Elmer–Hitachi 200 spectrophotometer. Magnetic measurements were carried out with a Faraday-type magnetometer equipped with a Cahn RG-HV electrobalance and the complex $Hg[Co(SCN)_4]$ as standard. Electron paramagnetic resonance spectra were recorded on a Bruker 200D X-band spectrometer equipped with a 100 kHz field modulator and a variable temperature control unit (120–400 K). Calibration of the magnetic field was done using a Bruker NMR Gaussmeter (BNM 12) or an nmr probe (Bruker) coupled to an AEG rf-oscillator. The frozen solution spectra were recorded at 130 K with a typical modulation depth of 4 Gpp.

Elemental analyses for C and H were carried out on a Perkin–Elmer 240 Elemental Analyzer. Results are given in Table 1.

TG measurements were carried out on a Dupont Instruments Series 99 Thermal Analyzer and DTG on the same instrument connected to

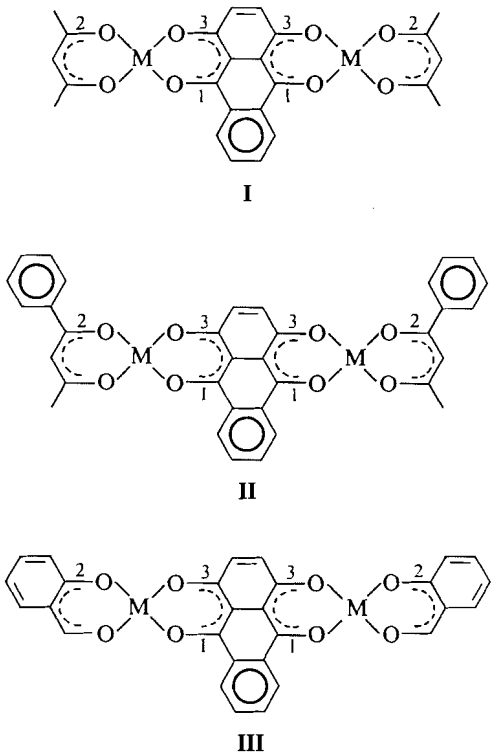

FIG. 1. The three classes of compounds prepared: **I**, acetylacetonates; **II**, benzoylacetonates; and **III**, salicylates. M:a for Zn(II); b for Cu(II); c for Ni(II), and d for Co(II).

a Dupont Instruments Series 951 thermogravimetric analyzer. The measurements were performed in a dynamic nitrogen atmosphere at a flow rate of 60 mL/min, up to 900°C, using a chromel/alumel thermocouple to measure the temperature. The heating rate was 10 deg/min and the sample weights about 10 mg.

Preparative

First, digestion of the β-diketone was performed with the stoichiometric amount of NaOH under moderate heating, in order to prepare the corresponding sodium salt. The process did not last for more than 15 min (for benzoylacetone). The filtered solution of the β-diketonate salt (2 mmol in 20 mL EtOH) was then added to a stirred solution of 2 mmol of the appropriate metal perchlorate in ethanol. To the resulting dark coloured mixture, an ethanolic solution containing 1 mmol of 1,4-dihydroxy-9,10-anthracenedione disodium salt was added over 5 min under vigorous stirring and moderate heating. The reaction mixture was allowed to stir for a further 15 min, filtered after cooling and the microcrystalline products were washed successively with water, ethanol, and diethylether, and finally dried in a vacuum desiccator over P_2O_5.

Results and discussion

The complexes were obtained in yields of 60–75%. They are microcrystalline substances of deep colour, stable in air, and insoluble in water and most of the common organic solvents. They are only slightly soluble in hot DMF and $CHCl_3$, a fact that does not allow molecular weight determination or ^1H nmr to be carried out. TG results presently discussed reveal the low temperature dissociation occurring within the β-diketonato groups, which precludes study of the mass spectra of the complexes. A number of recordings did not show the molecular ion peak but only indicated the presence of the organic ligands and their fragmentation patterns (11, 12).

TG measurements carried out on the Zn, Cu, and Co members of the series clearly showed that the thermal decomposition

of the complexes is a rather complicated phenomenon, taking place in several steps and is affected by the central metal ion (Figs. 2–4). The temperature ranges, percent mass losses (observed and theoretically predicted) are presented in Table 2. Only in two cases did the final residue at 900°C correspond to purely metallic substance (i.e. **I***b* and **I***d*), while in the rest it must be ascribed to the metal plus a portion of the hydroxyquinone bridging unit. In all three classes of compounds investigated, the first stage of decomposition is clearly a cleavage occurring in the β-diketonato group and corresponds to a $CH_3C{=}O$ fragment in classes **I** and **II** and $HC{=}O$ for class **III**. The remaining part of the diketone then undergoes further fragmentation, which is completed in several steps in the region 400–700°C. In the case of cobalt complexes, apart from the observation of the maximum rate of decomposition at

*The fragment notation holds for all the equivalent fragments in a molecule (e.g. C_6H_5 means both phenyl groups of a benzoylacetonate). M(quin) is used in the case of dissociation of the metal–quinizarin polymer. A smoothly descending curve is obtained and therefore no maximum rate decomposition temperature is reached and no theoretical mass loss may be calculated (it would correspond to the total mass of quinizarin).

slightly lower temperatures, quinizarin fragments appear also in this region of temperatures (e.g. **II***d*).

The bonding scheme expressed by both the bridging and the terminal ligands is revealed to an extent by the ir spectra (Table 3). The main bands of interest are those connected to the C=O stretching modes, which are coded as $\nu(C\cdots O)_1$ and $\nu(C\cdots O)_3$ for quinizarin and $\nu(C\cdots O)_2$ for the β-diketones (13), respectively. More information is gained by considering the shifts of these bands relative to the corresponding ones in the free ligands. The absence of detectable bands higher than 1600 cm^{-1} is evidence for a bidentate chelation of the anthraquinonic unit (14). The shift of this band to lower frequencies is accompanied by an analogous shift to higher ones of the $\nu(C\cdots O)_3$ band which further confirms the above-mentioned bidentate coordination. The regular band of the coordinated acetylacetone carbonyl group can be clearly seen in group **I** members (15), while those of benzoylacetone and salicylic aldehyde are often hard to distinguish from the other constituents of the envelope present at 1595–1565 cm^{-1}. In accordance with the elemental analyses and the molecular conductivity measurements, no perchlorate anion band is present in the region 1050–1130 cm^{-1} (16). Therefore no coordination or semicoordination may occur through this anion, a fact enabling us to focus only on coordination number four arrangements coordination number four arrangements around the metal ions. Thus the possible local geometries are limited to tetrahedral, square planar, or any intermediate which is more likely to be adopted.

Unfortunately the solution electronic spectra do not offer sufficient evidence for either of the aforesaid coordination schemes. This is a consequence of both the low solubility of the complexes and the widespread $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions of the extended aromatic rings of the organic substituents. Therefore the $d \rightarrow d$ absorptions can not offer their valuable information as they are masked by the more intense and broad intraligand or CT bands. The lowest energy CT bands should appear around 575 nm as this is the lowest energy band observed for the zinc members of the series. The shoulders therefore detected for a number of Co(II) and Ni(II) complexes in the region 600–630 nm (Table 3) may be assigned to $d \rightarrow d$ transitions and would be consistent with a distorted tetrahedral environment around the metal ions, though no unambiguous assignment or detailed analysis is possible.

The magnetic measurements become therefore more essential for our study as they offer stronger evidence in account with the ligand orientation around the metal ions.

Of course the most interesting are the μ_{eff} of cobalt and nickel complexes, since it has been firmly established that relatively small structural changes affect in a dramatic way their *d*-orbital splitting and occupation, giving rise to detectable changes in

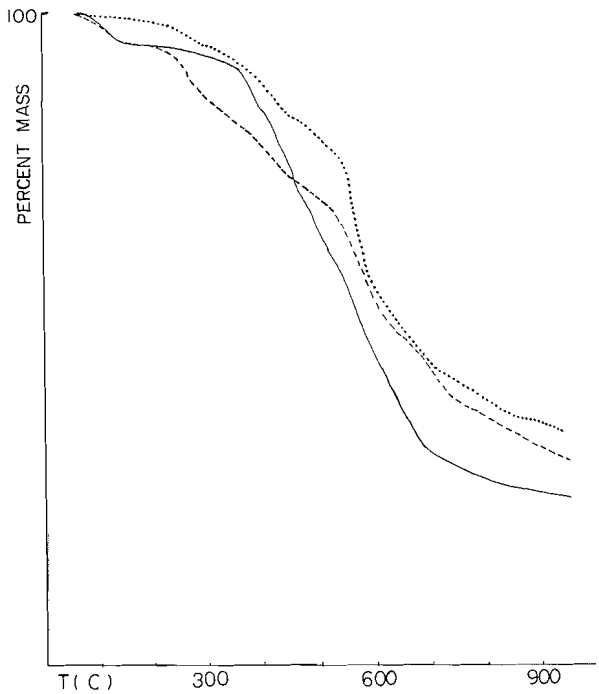

FIG. 4. TG curves for the three Co(II) complexes. Notation as in Fig. 2.

the values of the recorded μ_{eff}. For cobalt, the μ_{eff} values are indicative of an approximately tetrahedral Co^{2+} coordination sphere, since all the known planar Co^{2+} complexes are of low spin, their μ_{eff} values being less than half (16) of those observed (Table 3). Quite similar arguments may be applied in the case of Ni^{2+} compounds, where the measured μ_{eff} are in agreement with the general observation that small changes in the ligand field strength or chromophore geometry tend to decrease the spin-only value of 4.2 BM. The lower values obtained may be attributed to the compressed tetrahedral environment present in the complexes. In such a ligand field, the $d_{x^2-y^2}$ and d_{z^2} atomic orbitals lie close in energy, allowing spin singlet, triplet, and quintet states to be thermally populated at room temperature.

Low temperature magnetic measurements were not performed because it has been verified through a number of investigations that this and analogous bridging units (naphthazarin, anthrarufin) do not allow magnetic exchange phenomena to be propagated through their extended π systems (17).

Electron paramagnetic resonance spectroscopy has been applied to determine the local environment of the Cu^{2+} lone electron. The epr spectra were recorded in pyridine and exhibit the characteristic features of tetragonally distorted complexes ($g_{\parallel} \gg g_{\perp} > g_e$) with a $d_{x^2-y^2}$ ground state (18) (Figs. 5–8). This is not surprising in view of the well established fact that pyridine readily forms adducts through the heterocyclic nitrogen lone pair. It must therefore be assumed that two pyridine molecules occupy the axial positions in the coordination sphere of Cu^{2+} thus forcing the two chelate rings to adopt a coplanar orientation.

TABLE 4. Electron paramagnetic resonance parameters obtained by fitting procedure*

Compound	$g_\parallel$	$g_\perp$	$A_\parallel$	$A_\perp$	α^2	k	ΔE	
I*b*	2.302	2.058	486	36	0.827	0.314	18.28	25.04
II*b*	2.303	2.058	489	36	0.826	0.314	18.31	25.05
III*b*	2.284	2.062	515	40	0.832	0.323	19.56	23.08

*The hyperfine tensor components are listed in units ($\times 10^{-4}$ cm^{-1}) while ΔE is measured in kK and its two values represent the $xy \rightarrow x^2 - y^2$ and $xz,yz \rightarrow x^2 - y^2$ transitions respectively.

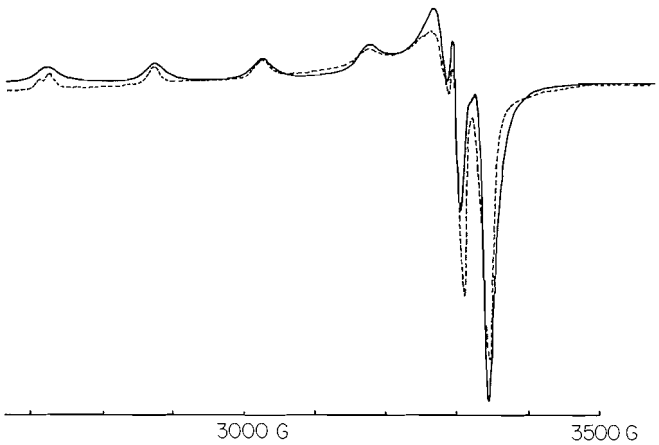

FIG. 5. The experimental (dashed line) and computer simulated (solid line) epr spectrum of **I***b* in pyridine.

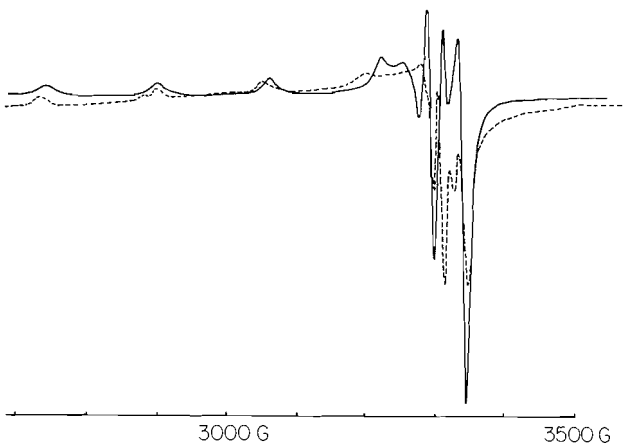

FIG. 6. The experimental and computer simulated epr spectrum of **II***b* in pyridine.

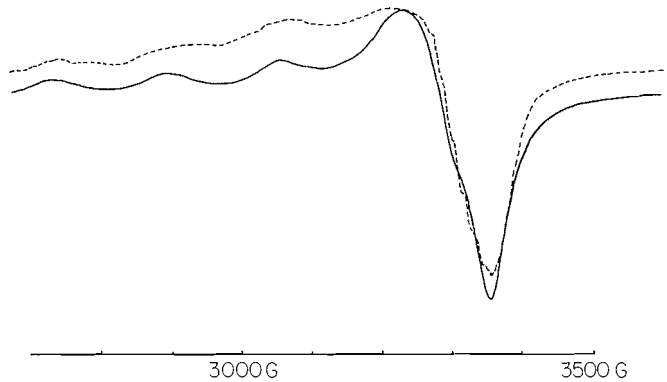

FIG. 7. The experimental and computer simulated epr spectrum of **III***b* in pyridine.

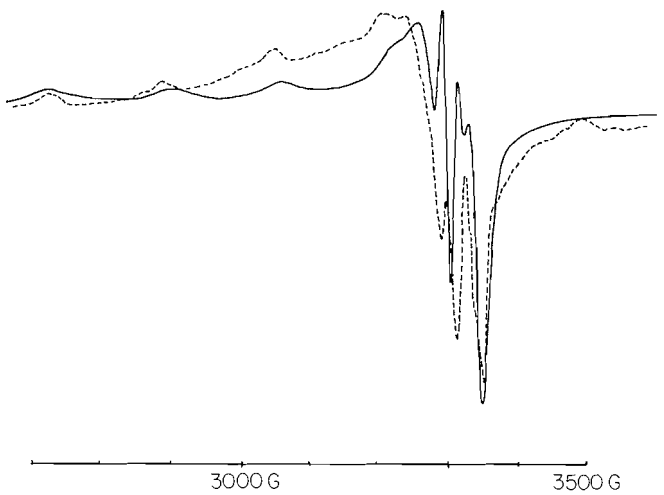

FIG. 8. The experimental and computer simulated epr spectrum of **II***b* in $CHCl_3$.

The parallel region of the spectra (lowfield) clearly shows the resolved Cu–hyperfine interaction while the perpendicular (highfield) is less resolved or even unresolved as in **III***b*. Furthermore, this region often renders additional difficulties in its analysis, as a result of the occurrence of extra splitting (19) or to a lesser extent from the nuclear quadruple splitting of the copper ion and the forbidden transitions ($\Delta M = \pm 1, \pm 2$) (20).

Regarding the terminal ligands, there seems to be no detectable change in the nature and parameters of the acac and bzac complexes, a fact readily understood since they both possess identical binding sites, the perturbation provoked by the aromatic ring in bzac being negligible. The case for sal is different though, owing to the strong π-withdrawing ability of the ligand. The consequence is a more electron deficient copper center, thus being more available for pyridine coordination and thus approaching a more regular elongated octahedral environment (Table 4).

More evidence is offered by the calculated $\Delta E(xy \rightarrow x^2 - y^2)$ and $\Delta E(xz,yz \rightarrow x^2 - y^2)$ transition energies where the effect of narrowing the gap between the d_{xy} and $d_{xz,yz}$ levels is quite clear. These data emerged via an analysis of the recorded spectra based on the expressions proposed by Vänngard (21) and McGarvey (22) for the $d_{x^2-y^2}$ ground state. The formulae used in the fitting procedure are:

$$g_\parallel = g_e - 8\lambda\alpha^2/\Delta E(xy \rightarrow x^2 - y^2)$$

$$g_\perp = g_e - 2\lambda\alpha^2/\Delta E(xz,yz \rightarrow x^2 - y^2)$$

$$A_\parallel = P|-K - 4\alpha^2/7 + \Delta g_\parallel + 3\Delta g_\perp/7|$$

$$A_\perp = P|-K + 2\alpha^2/7 + 11\Delta g_\perp/14|$$

During this procedure, λ and P were kept fixed at -828 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

350×10^{-4} cm^{-1}, respectively, while both α^2 and E were allowed to vary.

Frozen solution spectra in chloroform have also been recorded for the sake of comparison. The general characteristics of the spectra remain the same as those already discussed but now all three complexes were nearly identical (for **I***b*: $g_\parallel$ 2.279, $g_\perp$ 2.064, $A_\parallel$ 512, $A_\perp$ 47, and α^2 0.814, ΔE 19.49 and 21.85 respectively). This is a consequence of the weak coordinating ability of chloroform relative to that of pyridine, which allows the complexes to retain their originally distorted structures. The distortion, a common one in copper acetylacetonates, namely the stepped type distortion in which the chromophore remains essentially planar through the two heterocyclic rings form a dihedral angle that ranges from a few degrees to a few decades degrees (23).

The above assumption is further verified through the calculated E values which are less separated than those calculated from the spectra in pyridine (Table 4). Such a depression in energy separation of the d_{xy} and d_{xz} atomic levels is apparently the result of a small structural distortion away from the planar arrangement of the chromophore.

Conclusions

Quinizarin has proved to form readily homobinuclear mixed ligand complexes with first row transition elements. These complexes, neutral in character (uncharged) are characterized by two nearly identical six-membered heteroatomic chelate rings both with terminal oxygen atoms originating from the coordination of both the bridging and the peripheral ligands which are β-diketones or salicylic aldehyde. The two planes defined by quinizarin and the β-diketone, respectively, adopt an orientation intermediate between planar and tetrahedral relative to one another, the dihedral angle between them tending to lower in value on going from cobalt to copper as it can be deduced from the magnetic measurements and the epr spectral data presented.

Mécanisme de réaction de mélanges méthane–chlore à haute température et faible taux de chlore

MARC CHAMBON, PAUL-MARIE MARQUAIRE ET GUY-MARIE CÔME[1]

Département de chimie physique des réactions, Centre national de la recherche scientifique (Unité associée 328), Institut national polytechnique de Lorraine (École nationale supérieure des industries chimiques) et Université de Nancy I, 1, rue Grandville, 54000 Nancy, France

Reçu le 11 août 1986

MARC CHAMBON, PAUL-MARIE MARQUAIRE et GUY-MARIE CÔME. Can. J. Chem. **65**, 1491 (1987).

Un brevet déposé par S. W. Benson en 1980 indique qu'une flamme chlore–méthane produit de l'éthane et de l'éthylène. Suite à ce brevet, nous avons effectué une étude fondamentale de la réaction à l'aide d'un réacteur continu agité isotherme, à des températures comprises entre 800 et 1000°C, à pression subatmosphérique, à faible taux de chlore (1% environ en volume) et à des temps de passage de l'ordre de 1 s. Dans ces conditions, la réaction conduit aux produits carbonés CH_3Cl, C_2H_4, C_2H_6 et C_3H_6 essentiellement. Le pourcentage du méthane converti transformé en hydrocarbures non chlorés croît avec la température et atteint 77% à 1000°C. Un mécanisme radicalaire qui rend compte des présentes observations est proposé et analysé.

MARC CHAMBON, PAUL-MARIE MARQUAIRE, and GUY-MARIE CÔME. Can. J. Chem. **65**, 1491 (1987).

A patent of Benson (1980) states that a methane/chlorine flame produces some ethane and some ethylene. A fundamental study of the reaction has been carried out using an isothermal, continuous, stirred reactor operated at temperatures varying from 800 to 1000°C, at subatmospheric pressures, at low concentrations of chlorine (about 1% by volume), and with reaction times of about 1 s. Under these conditions, the reaction leads mainly to the formation of the following carbon compounds: CH_3Cl, C_2H_4, C_2H_6, and C_3H_6. The percentage of methane that is transformed into non-chlorinated hydrocarbons rises with the temperature and reaches a level of 77% at 1000°C. A radical mechanism which takes into account all the data is proposed and analysed.

[Journal translation]

Introduction

La valorisation chimique du méthane, compte-tenu notamment des disponibilités en gaz naturel, suscite actuellement un vif intérêt et des recherches dans de nombreuses directions (cf. par exemple, réfs. 1 et 2).

En particulier, un procédé, suggéré par Benson en 1980 (3), consiste à faire une flamme de méthane et de chlore dans des rapports molaires compris entre 1:1 et 10:1, dont la température adiabatique est comprise entre 700 et 1710°C, la pression voisine de 1 atmosphère (101,3 kPa), et la durée de réaction de quelques millisecondes; la réaction conduite dans ces conditions est réputée conduire essentiellement à de l'*ethane* et à de l'*éthylène* d'une part, et à de l'*hydrogène* et de l'*acide chlorhydrique* d'autre part. Comme il est d'usage dans les brevets, aucune explication théorique n'est avancée pour rendre compte des revendications.

Dans une publication (4) postérieure au brevet, Weissmann et Benson présentent les résultats d'une étude de la *pyrolyse du chlorure de méthyle* effectuée de 924 à 1127°C en réacteur continu avec des temps de passage de 0,03 à 0,3 s. Les produits principaux de la réaction sont HCl, CH_4, C_2H_2 et C_2H_4, des produits mineurs étant C_6H_6, C_3H_6, C_2H_5Cl, $C_2H_4Cl_2$, etc.; du charbon, de la suie sont observés. Weissmann et Benson (4) proposent un mécanisme réactionnel détaillé pour rendre compte de leurs observations expérimentales relatives à la pyrolyse de CH_3Cl. À la suite de cette analyse, ils estiment que la réaction décrite dans le brevet (3) a lieu en *deux phases consécutives, la chloration du méthane en chlorure de méthyle, suivie de la pyrolyse de ce dernier*; l'argument essentiel avancé est que la formation de CH_3Cl à partir de chlore et de méthane s'effectue par une réaction en chaînes très rapide. Cette conclusion constitue évidemment une justification de leur étude.

En 1983, lorsque nous avons entrepris nos travaux sur la réaction de mélanges Cl_2/CH_4 à «haute» température, il n'existait alors aucune tentative d'élucidation dans ces conditions du mécanisme de la réaction, et ce fait persiste dans une large mesure. L'importance pratique potentielle du procédé (2) incitait, et incite toujours, à une meilleure compréhension des phénomènes.

Protocole expérimental

L'élucidation d'un mécanisme réactionnel nécessite de bien maîtriser les variables d'état du système. Ceci explique que nous ayons fait choix du réacteur continu agité, fonctionnant en régime permanent, à température et à pression constantes, et mis en oeuvre selon une technique maintenant classique au laboratoire (6).

La réaction des mélanges méthane–chlore a été étudiée à des températures comprises entre 1081 et 1273 K, des pressions de 170 et 577 Torr (1 Torr = 133,3 Pa), des temps de passage compris entre 0,8 et 1,6 s et des taux de chlore $[Cl_2]_0/[CH_4]_0$ compris entre 0,42 et 1,2%, c'est-à-dire dans des conditions très différentes à certains égards du brevet (3).

À titre de référence, la pyrolyse de méthane pur a été étudiée à 1181 K, 570 Torr et des temps de passage compris entre 0,8 et 2 s.

Les réactifs chlore et méthane ont été fournis par la Société «L'Air Liquide» et contiennent des teneurs très faibles en impuretés.

L'analyse des produits de réaction a été effectuée par chromatographie en phase gazeuse.

Résultats expérimentaux

Les produits suivants, par ordre d'importance décroissante, ont été mis en évidence : CH_3Cl, C_2H_4, C_2H_6, C_3H_6, C_2H_2, des traces de $CH_3—C{\equiv}CH$ et d'un composé qui pourrait être $CH_3—CH_2—CH_2—CH_3$ ou $CH_3—CH_2—CH{=}CH_2$. Du «charbon» se forme en quantités variables selon les conditions opératoires.

On ne peut pas conclure si $CH_2{=}C{=}CH_2$ est formé ou non, car il n'est pas séparé de CH_3Cl en chromatographie. On n'a pas recherché de produits ayant plus de 4 atomes de carbone. HCl, Cl_2 et H_2 n'ont pas été analysés quantitativement jusqu'à présent.

Les produits suivants n'ont pas été décelés, au moins

TABLEAU 1. Influence de la température et du taux de chlore sur les concentrations des produits carbonés de la réaction en sortie du réacteur, pour un temps de passage de 1 seconde

P(Torr)	T(K)	x(%)	$[CH_3Cl]$	$[C_2H_6]$	$[C_2H_4]$	$[C_2H_2]$	$[C_3H_6]$
300	1023	0,4	$1,5\times10^{-5}$	$7,5\times10^{-8}$	$3,7\times10^{-8}$	0	0
	1181		$1,1\times10^{-5}$	$1,3\times10^{-6}$	$2,1\times10^{-6}$	$4,9\times10^{-8}$	$1,3\times10^{-7}$
577	1181	0	0	$2,4\times10^{-7}$	0	0	0
		0,4	$2,0\times10^{-5}$	$3,7\times10^{-6}$	$4,6\times10^{-6}$	$1,9\times10^{-7}$	$3,4\times10^{-7}$
		0,8	$3,7\times10^{-5}$	$5,0\times10^{-6}$	$1,1\times10^{-5}$	$3,8\times10^{-7}$	$8,1\times10^{-7}$

NOTA : P, pression totale dans le réacteur; T, température de réaction; x, pourcentage molaire de chlore à l'entrée du réacteur, $x = [Cl_2]_0/([CH_4]_0 + [Cl_2]_0)$. Les concentrations sont exprimées en mol L^{-1}.

dans quelques expériences : CH_3—CH_2Cl, CH_2Cl—CH_2Cl, CH_2=$CHCl$, CH_2Cl_2, $CHCl_3$, CCl_4, C_3H_8.

La pyrolyse du méthane «pur» (sans chlore ajouté), dans des conditions similaires, conduit uniquement à de l'éthane.

Des résultats typiques, mettant en évidence l'influence de la température et du taux de chlore sur la réaction sont présentés dans le tableau 1.

Toutes choses égales par ailleurs, on constate que la quantité de méthane chloré décroît avec la température, tandis que les quantités de méthane transformées en hydrocarbures non chlorés croissent fortement, ainsi que la proportion d'hydrocarbures insaturés parmi ces derniers.

Toutes choses égales par ailleurs, l'accroissement du pourcentage de chlore à l'entrée du réacteur entraîne un accroissement important du taux de transformation du méthane. C'est ainsi qu'à 577 Torr, 1181 K, l'addition de 0,4% de chlore au méthane entraîne une multiplication par un facteur de l'ordre de 50 de la quantité de méthane transformée. Par ailleurs, le chlore a pour effet d'augmenter les quantités de méthane chloré ou transformées en hydrocarbures non chlorés et spécialement parmi ceux-ci les hydrocarbures insaturés.

Mécanisme réactionnel

Le mécanisme de pyrolyse du méthane pur paraît bien établi (cf. par exemple, réf. 7), de même que celui de chloration du méthane à «basse» température (cf. par exemple, réf. 5). D'une manière plus générale, les mécanismes de chloration d'hydrocarbures ou de pyrolyse d'hydrocarbures chlorés paraissent compris dans leurs grandes lignes, même si de nombreux points restent ouverts à la discussion (4, 5, 8–10).

Il paraît raisonnable, dans un premier temps, de chercher à rendre compte de nos résultats par un mécanisme radicalaire homogène. Nous discuterons tout d'abord le mécanisme primaire.

1. Mécanisme primaire

Il comporte les processus suivants :

Amorçages

[1] $CH_4 \rightarrow CH_3\cdot + H\cdot$

[2] $Cl_2 + M \rightarrow 2Cl\cdot + M$

Transferts

[3] $H\cdot + CH_4 \rightarrow H_2 + CH_3\cdot$

[4] $H\cdot + Cl_2 \rightarrow HCl + Cl\cdot$

Propagations

[5] $CH_3\cdot + Cl_2 \rightarrow CH_3Cl + Cl\cdot$

[6] $Cl\cdot + CH_4 \rightarrow HCl + CH_3\cdot$

Terminaison

[7] $2\,CH_3\cdot \rightarrow C_2H_6$

Les processus de terminaison consistent en principe en la recombinaison 2 à 2 des radicaux libres H·, Cl· et CH_3·. Mais, d'une part, les combinaisons d'atomes libres nécessitent des triples chocs et peuvent donc être négligées par rapport aux autres processus de terminaison. Il ne reste donc en compétition que les processus

[7′] $CH_3\cdot + Cl\cdot \rightarrow CH_3Cl$

et

[7″] $CH_3\cdot + H\cdot \rightarrow CH_4$

et le processus [7]. Les réactivités des radicaux libres Cl·, H· et CH_3· sont du même ordre de grandeur, mais la concentration de méthane étant très supérieure à celle du chlore, il s'ensuit que Cl· et H· sont beaucoup moins concentrés que CH_3·. La terminaison prépondérante s'effectue donc par le processus [7].

En appliquant l'approximation de l'état quasi stationnaire aux atomes et radicaux libres, on obtient les expressions suivantes des vitesses de formation des deux produits carbonés :

$$r_{C_2H_6} = k_1[CH_4] + k_2[Cl_2][M]$$

$$r_{CH_3Cl} = \frac{k_5}{k_7^{1/2}}(k_1[CH_4] + k_2[Cl_2][M])^{1/2}[Cl_2]$$

d'où l'on déduit :

$$\lambda = \frac{r_{CH_3Cl}}{r_{C_2H_6}} = \frac{k_5[Cl_2]}{k_7^{1/2}(k_1[CH_4] + k_2[Cl_2][M])^{1/2}}$$

C'est essentiellement à la discussion des variations du rapport λ avec la température que nous allons nous attacher, $[Cl_2]$, $[CH_4]$ et [M] étant supposés constants. Les valeurs des énergies d'activation E_5, E_7, E_1 et E_2 étant de l'ordre de 2, 0, 108 et 49 kcal mol^{-1} respectivement (7–10), il est clair que l'énergie d'activation «apparente» E_λ du terme λ est fortement négative, et ceci quelles que soient les importances respectives des vitesses d'amorçage par les processus [1] et [2]. On peut donc tirer les conclusions suivantes :

À basse température, le produit primaire principal carboné est CH_3Cl et la réaction a lieu en *chaînes longues*, comme il est bien connu, ce qui conduit à la stoechiométrie principale :

$$CH_4 + Cl_2 = CH_3Cl + HCl$$

Au fur et à mesure que la température augmente, le rapport λ diminue et, à haute température, le produit primaire principal carboné de la réaction devient C_2H_6, la *réaction par stades*

d'équation stoechiométrique

$$2CH_4 + Cl_2 = C_2H_6 + 2HCl$$

étant alors prépondérante, ce qui signifie que la vitesse du processus [5] est négligeable par rapport à celle du processus [7].

2. Mécanisme secondaire

Les deux produits primaires carbonés sont CH_3Cl et C_2H_6, ils interviennent donc comme réactifs dans le mécanisme secondaire, il s'ensuit que les radicaux libres secondaires sont $CH_2Cl\cdot$ et $C_2H_5\cdot$. Ces radicaux sont impliqués dans les processus de propagation suivants, où RH désigne n'importe quelle molécule possédant un atome d'hydrogène labile :

[8] et [-8] $CH_2Cl\cdot + RH \rightleftarrows CH_3Cl + R\cdot$

[9] $CH_2Cl\cdot + Cl_2 \rightarrow CH_2Cl_2 + Cl\cdot$

[10] $C_2H_5\cdot \rightarrow C_2H_4 + H\cdot$

[11] et [-11] $C_2H_5\cdot + RH \rightleftarrows C_2H_6 + R\cdot$

[12] $C_2H_5\cdot + Cl_2 \rightarrow C_2H_5Cl + Cl\cdot$

Parmi les produits secondaires nouveaux issus de processus de propagation, nous avons observé uniquement la formation de C_2H_4, mais ni celle de CH_2Cl_2, ni celle de C_2H_5Cl. Nous sommes donc amenés à conclure que, dans nos conditions, les processus [9] et [12] sont négligeables, et que le processus [10] est au minimum compétitif par rapport au processus [11].

L'explication de ces faits réside pour une part importante dans le caractère β ou μ (11) des radicaux libres, caractère susceptible du reste d'évoluer selon les conditions expérimentales (12). C'est ainsi que le radical $CH_2Cl\cdot$ est de caractère β, c'est-à-dire qu'il ne peut réagir que dans des processus bimoléculaires, alors que le radical $C_2H_5\cdot$ possède également un caractère μ, c'est-à-dire qu'il peut se décomposer monomoléculairement en donnant naissance à une molécule insaturée. Toutes choses égales par ailleurs, et notamment les concentrations des réactifs moléculaires impliqués dans les métathèses, le caractère μ du radical $C_2H_5\cdot$ l'emporte de plus en plus sur son caractère β lorsque la température augmente. Ceci permet de comprendre que, la température étant assez élevée et la concentration de chlore assez faible dans nos conditions, le processus [10] conduisant à l'éthylène soit prépondérant par rapport au processus [12] qui conduit au chlorure d'éthyle.

Le caractère essentiellement μ du radical $C_2H_5\cdot$ *dans nos conditions* comporte également des conséquences importantes au niveau des processus de terminaison qui ne peuvent faire intervenir que des radicaux de type β. Ceci conduit notamment à l'exclusion des recombinaisons des radicaux éthyles donnant du *n*-butane ou des radicaux éthyle et méthyle conduisant au propane, conclusion compatible avec nos résultats expérimentaux. Il reste donc uniquement à considérer les combinaisons des radicaux $CH_3\cdot$ et $CH_2Cl\cdot$, soit :

[13] $CH_3\cdot + CH_2Cl\cdot \rightarrow C_2H_5Cl$

[14] $2\,CH_2Cl\cdot \rightarrow CH_2Cl{-}CH_2Cl$

Or nous n'observons ni la formation de C_2H_5Cl ni celle de $CH_2Cl{-}CH_2Cl$, ce qui revient à dire que les processus de terminaison [13] et [14] sont négligeables par rapport au processus de terminaison [7], ou, ce qui revient au même, que *la concentration du radical $CH_2Cl\cdot$ est négligeable par rapport à celle de $CH_3\cdot$*. Cette conclusion est confortée par l'absence de formation de CH_2Cl_2 par le processus [9], à comparer avec la formation importante de CH_3Cl par le processus [5].

Pour les raisons déjà évoquées lors de l'analyse du mécanisme primaire, il n'y a pas lieu de tenir compte des terminaisons impliquant les atomes libres $Cl\cdot$ et $H\cdot$.

Nous examinerons en dernier lieu les réactions de HCl et H_2, produits primaires non carbonés. Ils peuvent intervenir par les processus de métathèse :

$$R\cdot + HCl \rightarrow RH + Cl\cdot$$

$$R\cdot + H_2 \rightarrow RH + H\cdot$$

ce qui n'introduit ni produits, ni radicaux libres nouveaux, mais peut éventuellement modifier la répartition entre ces derniers. Il en sera de même dans les mécanismes tertiaire et quaternaire. En outre, dans nos conditions, les concentrations de HCl et H_2 sont faibles, par rapport à CH_4 tout au moins, ce qui devrait limiter leurs effets. Par ailleurs, HCl est réputé avoir peu ou pas d'effet sur les pyrolyses de CH_3Cl (4) et de C_2H_6 (13).

3. Mécanisme tertiaire

L'analyse faite ci-dessus montre que, dans nos conditions, le seul produit secondaire nouveau est l'éthylène. Ce corps peut donner lieu, non seulement à des réactions de métathèse, mais également à des réactions d'additions ce qui n'était pas le cas des hydrocarbures saturés impliqués dans les mécanismes primaires et secondaires.

Les processus d'addition ne font intervenir que les radicaux libres prépondérants du milieu réactionnel, c'est-à-dire essentiellement $CH_3\cdot$ et, dans une certaine mesure, $C_2H_5\cdot$, soit :

[15] et [-15] $CH_3\cdot + C_2H_4 \rightleftarrows CH_3{-}CH_2{-}CH_2\cdot$

[16] et [-16] $C_2H_5\cdot + C_2H_4 \rightarrow CH_3{-}CH_2{-}CH_2{-}CH_2\cdot$

Les radicaux formés étant de type μ vont se décomposer monomoléculairement :

[17] $CH_3{-}CH_2{-}CH_2\cdot \rightarrow CH_3{-}CH{=}CH_2 + H\cdot$

[18] $CH_3{-}CH_2{-}CH_2{-}CH_2\cdot \rightarrow CH_3{-}CH_2{-}CH{=}CH_2 + H\cdot$

On observe bien la formation de propène, mais seulement celle de traces d'un composé susceptible d'être le butène-1. Ces résultats confirment à nouveau le caractère μ du radical $C_2H_5\cdot$ dans nos conditions, et le fait que l'on peut négliger le processus [16] et par conséquent [18].

REMARQUE : L'addition de l'atome de chlore sur l'éthylène suivie de la décomposition monomoléculaire du radical libre formé par perte d'un atome d'hydrogène aboutit à la formation de chlorure de vinyle, non détecté dans nos conditions. Ceci confirme l'hypothèse faite lors de l'élaboration du mécanisme primaire, à savoir que l'atome de chlore est en concentration négligeable par rapport aux radicaux libres méthyles.

L'éthylène peut également réagir par métathèse :

[19] $R\cdot + C_2H_4 \rightarrow RH + C_2H_3\cdot$

[20] $C_2H_3\cdot \rightarrow C_2H_2 + H\cdot$

On observe bien effectivement la formation d'acétylène.

REMARQUE : Il est logique que $CHCl_3$ ne soit pas formé, dans la mesure où son précurseur «secondaire» CH_2Cl_2 ne l'est pas.

4. Mécanisme quaternaire

Il y aurait lieu de considérer ici systématiquement les réactions d'addition et de métathèse impliquant le propène et l'acétylène et les décompositions monomoléculaires subséquentes de radicaux libres, comme il a été fait pour l'éthylène, mais nous nous limiterons aux quelques processus conduisant à des produits observés ou potentiellement formés.

Additions

[21] et [-21] $CH_3\cdot + C_2H_2 \rightleftarrows CH_3—CH{=}CH\cdot$

Métathèses

[22] $R\cdot + CH_3—CH{=}CH_2 \rightarrow RH + \cdot CH_2—CH{=}CH_2$

[23] $R\cdot + C_2H_2 \rightarrow RH + CH{\equiv}C\cdot$

Décompositions

[24] $CH_3—CH{=}CH\cdot \rightarrow CH_3—C{\equiv}CH + H\cdot$

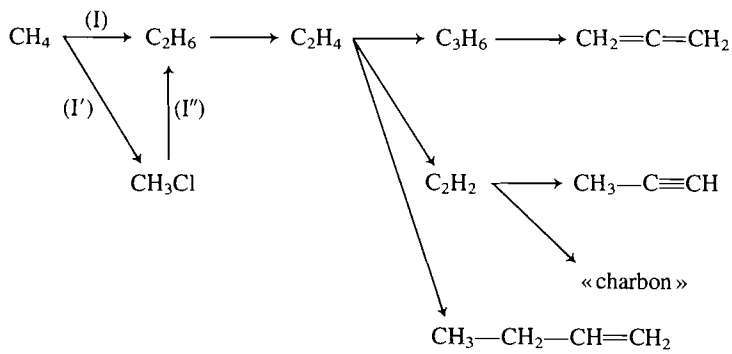
[25] $CH{\equiv}C\cdot \rightarrow$ «charbon» + $H\cdot$

[26] $\cdot CH_2—CH{=}CH_2 \rightarrow CH_2{=}C{=}CH_2 + H\cdot$

REMARQUE : Le processus [25] décrit la formation de «charbon» de manière très formelle, bien qu'il soit clair que l'acétylène soit le précurseur habituel des suies, etc. (cf. par exemple ref. 14).

5. Discussion du mécanisme global

Le mécanisme radicalaire construit ci-dessus, selon les principes généraux de la cinétique des réactions en phase gazeuse, conduit au *schéma réactionnel* suivant indiquant la «filiation» des différents produits carbonés de réaction observés dans nos conditions :



Le mécanisme, et le schéma qui en est déduit, rendent compte de façon remarquable des caractéristiques que nous avons observées, au minimum d'un point de vue qualitatif; ils permettent notamment de comprendre l'influence de la température sur la sélectivité de la réaction.

En effet, le premier fait important, dans la réaction thermique de mélanges méthane–chlore, consiste dans la *diminution de la longueur de chaînes primaire avec la température*, qui se traduit par une production primaire croissante de C_2H_6 (voie I) au détriment de CH_3Cl (voie I'). Cette évolution est du reste «aggravée» par le fait que CH_3Cl donne également potentiellement naissance, dans nos conditions du moins, à C_2H_6 (voie I''), par les processus suivants :

$$CH_3Cl \rightarrow CH_3\cdot + Cl\cdot$$

$$Cl\cdot + CH_4 \rightarrow HCl + CH_3\cdot$$

$$2CH_3\cdot \rightarrow C_2H_6$$

Par ailleurs, le schéma réactionnel ci-dessus montre que tous les hydrocarbures non-chlorés proviennent du précurseur C_2H_6.

À partir de ces deux faits, il est immédiat de déduire que le pourcentage de méthane converti transformé en hydrocarbures non-chlorés croît avec la température, toutes autres choses égales par ailleurs, en accord avec nos constatations expérimentales.

Le mécanisme réactionnel explique la formation des diverses molécules insaturées par des réactions de métathèse et d'addition radicalaires suivies d'une décomposition unimoléculaire des radicaux libres ainsi formés. Ceci est dû à un deuxième fait important, très caractéristique des réactions radicalaires, et qui est le *caractère μ prédominant des radicaux libres alcoyles* (à l'exclusion des radicaux méthyle) *à température suffisamment élevée*. Il n'est donc pas étonnant que le pourcentage de molécules insaturées parmi les hydrocarbures non-chlorés formés croisse avec la température.

Enfin, on peut observer que le processus d'amorçage [2] et les processus de propagation impliquant Cl_2 et $Cl\cdot$ permettent de comprendre aisément l'effet fortement accélérateur de Cl_2 sur le taux de transformation de CH_4.

Conclusion

Le mécanisme réactionnel radicalaire proposé ici permet de rendre compte, de façon qualitative au moins, des observations que nous avons effectuées sur la réaction chlore–méthane vers 900°C et à faible taux de chlore. Il n'est pas possible d'appliquer tel quel ce mécanisme, compte-tenu des nombreuses simplifications résultant des conditions opératoires particulières pour lesquelles il a été établi, à des domaines expérimentaux différents : la flamme chlore–méthane (3), la pyrolyse du chlorure du méthyle (4), bien qu'il soit évident que de nombreuses conclusions soient déjà aisément transposables, telles que nature des produits formés, influence de la température sur les sélectivités. Il sera nécessaire de procéder à l'écriture d'un mécanisme beaucoup plus complet et à une identification quantitative du modèle ainsi créé, appuyée éventuellement sur des résultats expérimentaux ad hoc. Ce mécanisme, généralisant celui présenté dans cet article, permettra de répondre à la question évoquée en la référence 4 de l'importance relative des voies [I] et [I', I''] dans la formation de l'éthane, selon les niveaux de température et de taux de chlore. La simulation à partir d'un tel modèle permettrait également de prévoir l'exis-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

tence de conditions opératoires, probablement très restrictives, où les produits formés seraient différents; on peut citer ici le chlorure de vinyle, et on comprend alors aisément l'importance d'une telle approche mécanistique.

Remerciements

The structure and internal rotational barrier of 3-phenyl-1-propyne by molecular orbital calculations and the *J* method

TED SCHAEFER AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 7, 1987

TED SCHAEFER and GLENN H. PENNER. Can. J. Chem. **65**, 1496 (1987).

The ^1H nuclear magnetic resonance spectral parameters are reported for 3-phenyl-1-propyne dissolved in CCl_4, C_6D_6, and in acetone-d_6. The long-range spin–spin coupling constants imply very small and perhaps vanishing barriers to internal rotation about the C_{sp^2}—C_{sp^3} bond in all three solutions, in contrast to benzyl cyanide in which there exist significant solvent perturbations of the internal barrier. STO 3G MO computations, utilizing geometry optimization procedures, imply an internal rotational potential of $V/\text{kJ mol}^{-1} = -2.8 \sin^2\psi - 0.6 \sin^2 2\psi$; the angle ψ is 90° when the C≡C bond lies in a plane perpendicular to the benzene plane. 6-31G MO energies imply $V/\text{kJ mol}^{-1} = -0.3 \sin^2\psi - 0.4 \sin^2 2\psi$, the fourfold component being larger than the twofold. A flat minimum occurs near $\psi = 50°$.

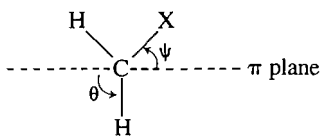
TED SCHAEFER et GLENN H. PENNER. Can. J. Chem. **65**, 1496 (1987).

On a déterminé les paramètres spectraux, en résonance magnétique nucléaire du ^1H, du phényl-3 propyne-1 dissous dans le CCl_4, le C_6D_6 ou dans l'acétone-d_6. Les constantes de couplage spin–spin à longue distance impliquent que, dans le trois solutions, les barrières à la rotation interne autoure de la liaison C_{sp^2}—C_{sp^3} sont très faibles ou inexistantes; ces résultats contrastent avec ceux obtenus avec le cyanure de benzyle, dans lequel les solvants perturbent fortement la barrière interne. Des calculs d'OM STO 3G, faisant appel à des procédés d'optimisation de la géométrie, impliquent que le potentiel à la rotation interne $V/\text{kJ mol}^{-1} = -2{,}8 \sin^2\psi - 0{,}6 \sin^2 2\psi$; l'angle ψ est égal à 90° lorsque la liaison C≡C se trouve dans un plan qui est perpendiculaire au plan du benzène. Les énergies évaluées à l'aide de calculs d'OM 6-31G impliquent que $V/\text{kJ mol}^{-1} = -0{,}3 \sin^2\psi - 0{,}4 \sin^2 2\psi$; la composante quaternaire est plus importante que la composante binaire. On retrouve un minimum aplati autour de $\psi = 50°$.

[Traduit par la revue]

Introduction

The internal barriers to rotation about the C_{sp^2}—C_{sp^3} bond in a number of benzyl X compounds (e.g. X = F, Cl, CN) have been measured in solution by means of the *J* method (1–3). For $^1H,^1H$ couplings the latter depends on the relationship, $^6J(H,CH_2) = {}^6J_{90}\langle\sin^2\theta\rangle$, where $^6J(H,CH_2)$ is the long-range spin–spin coupling constant over six bonds between the *para* and methylene protons (4, 5).



1

The angle θ is the angle by which the α C—H bond twists out of the benzene plane, as in **1**, and $^6J_{90}$ is the value of $^6J(H,CH_2)$ when $\theta = 90°$. The expectation value of $\langle\sin^2\theta\rangle$ can be related to the internal barrier by a hindered rotor model (5) or by a classical averaging procedure.

For X = F, Cl, CN the internal barrier depends on the polarity of the solvent (1–3). Although the twofold barriers for X = F, Cl are quite different in magnitude, being about 1 kJ/mol for benzyl fluoride and about 9 kJ/mol for benzyl chloride in CS_2 solution, the conformations with $\psi = 90°$ are both stabilized by about 2 kJ/mol in passing from CS_2 to the polar acetone-d_6 solutions. Presumably these phenomena are a consequence of electrostatic stabilization of the more polar perpendicular conformer, that with $\psi = 90°$ (6). In benzyl cyanide the internal barrier is rather small in CS_2 solution, in the vicinity of 1 kJ/mol, and contains an appreciable fourfold component (3). Again, polar solvents increase the stability of the perpendicular conformer.

Some molecular orbital computations (1–3) agree rather well with the barriers deduced in solution for X = F, Cl, CN. Furthermore, for hydrocarbons such as styrene, quantitative agreement exists between experiment and results at the 6-31 G level of *ab initio* molecular orbital theory (7). While benzyl cyanide is rather polar, its dipole moment being about 3.5 D (8), that of 3-phenyl-1-propyne must be rather smaller, while retaining a triple bond in the X substituent. This paper reports molecular orbital computations of the structure and internal rotational barrier in the latter molecule. In addition, the ^1H nmr spectra in CCl_4, C_6D_6, and acetone-d_6 are analyzed. The spectral parameters indicate a very small barrier, essentially independent of solvent, and in agreement with the molecular orbital results.

Results and discussion

Molecular orbital calculations

Energies for optimized geometries, but holding the carbon framework as a planar hexagon, were computed at 15° intervals of ψ (seven values) at the STO 3G level of *ab initio* molecular orbital theory (409 m of cpu time). The minimum energy of −341.197 092 au occurred at $\psi = 90°$. The relative energies are represented by eq. [1]. The errors in the twofold and fourfold

$$[1] \quad V/\text{kJ mol}^{-1} = -2.78(4) \sin^2\psi - 0.64(4) \sin^2 2\psi$$

components are given at the 95% confidence level. At 300 K a classical averaging procedure then yields $\langle\sin^2\psi\rangle$ as 0.626, $\langle\sin^2\theta\rangle$ as 0.437, and $\langle\psi\rangle$ as 54.1°.

It is known that 6-31G computations may be more reliable for hydrocarbons than are those with minimal basis sets, as for styrene, for example (7, 9). They are also much more expensive. Hence the 6-31G calculations were performed with geometry optimization only at $\psi = 0$, 45, and 90° (total cpu time of 32 h). The three energies yield eq. [2]

$$[2] \quad V(\psi)/\text{kJ mol}^{-1} = -0.27 \sin^2\psi - 0.43 \sin^2 2\psi$$

implying $\langle\sin^2\psi\rangle$ as 0.513, $\langle\sin^2\theta\rangle$ as 0.494, and $\langle\theta\rangle$ as 47.6° at

[a]Solution is 5.0 mol% in CCl_4, containing 10 mol% of C_6D_{12} and 0.5 mol% of tetramethylsilane (TMS).
[b]Solution is 5.0 mol% in benzene-d_6 with 0.5 mol% of TMS.
[c]Solution is 5.0 mol% in acetone-d_6 with 0.5 mol% of TMS.
[d]To high frequency of internal TMS at 300.135 MHz (carrier frequency), numbers in parentheses being standard deviations in the last significant figure.
[e]No evidence was observed for coupling interactions between the methine and ring protons.
[f]No significant correlations were observed between the spectral parameters.

300 K. In other words, the internal rotation is very nearly free[1] (the total energy at $\psi = 45°$ was computed as −345.287 029 au).

The experimental barriers

For benzyl cyanide, INDO MO FPT calculations yield a $^6J_{90}$ insignificantly different from that in toluene, so that it was taken as −1.20 Hz, as discussed previously (3). For 3-phenyl-1-propyne, such calculations with a standard geometry, as also used for toluene (4), give $^6J_{90}$ as −1.24 Hz, as compared to −1.22 Hz for toluene. For the latter, $^6J_{90}$ is actually −1.20 Hz (10). Accordingly, the assumption that $^6J_{90}$ is -1.21 ± 0.01 Hz for the propyne derivative implies $\langle \sin^2 \theta \rangle$ values of (Table 1) 0.497(4), 0.490(4), and 0.488(4) in CCl_4, C_6D_6, and acetone-d_6 solutions, respectively. The hindered rotor model (5) then indicates *apparent* twofold barriers as large as 0.4 ± 0.2 kJ/mol in the acetone solution, dropping essentially to zero in CCl_4 solution (a vanishing barrier corresponds to a $\langle \sin^2 \theta \rangle$ of 0.5). Of course, the small 6-31G barrier, which has a larger fourfold than a twofold component, implies $\langle \sin^2 \theta \rangle$ as 0.494. It is probably sensible to conclude that the internal barrier in 3-phenyl-1-propyne is indeed very small and that it is largely independent of solvent. In the polar benzyl cyanide, by way of contrast, the internal rotational barrier is also small but is significantly solvent dependent (3). In an *n*-propyl benzene derivative the barrier about the C_{sp^2}—C_{sp^3} bond in the *anti* form of the molecule is apparently greater than 5 kJ/mol (11) with θ as 30° for the conformation of lowest energy ($\psi = 90°$).

^{4}J(H,CH_2) and ^{5}J(H,CH_2)

In toluene ^5J(H,CH_3) is 0.329(1) Hz(10). It has been written as $0.366 \langle \sin^2 \theta \rangle + 0.322 \langle \sin^2 (\theta/2) \rangle$, where the first term is the σ–π contribution, and the second term is the σ electron component of ^5J(H,CH_3) and is absent in ^6J(H,CH_3). Because $^6J_{90}^{\pi}$ in toluene and the present compound are almost identical and because $\langle \sin^2 \theta \rangle$ in the latter is very nearly 0.5, as in toluene, ^5J(H,CH_2) should be just a little smaller in the propyne. It is, by about 0.01 Hz (Table 1).

On the other hand, ^4J(H,CH_2) is −0.782(1) Hz in CCl_4 solution, rather larger in magnitude than the −0.702(1) Hz in toluene (10). ^4J(H,CH_3) in the latter was taken (12) as $-1.08 \langle \sin^2 \theta \rangle - 0.32 \langle \cos^2 \theta \rangle$. For toluene this sum becomes −0.70 Hz. The second term is considered (12) to be a σ electron contribution to ^4J. The 10% increase in the magnitude of ^4J in the phenylpropyne is not understood.

The computed structure of 3-phenyl-1-propyne

Figure 1 displays the 6-31G structure of 3-phenyl-1-propyne for the conformation in which the acetylenic group lies in the benzene plane. Steric crowding is indicated by the large exocyclic bond angles of 123.3° and 115.6°. The internal *ipso* angle of 118.7° is similar to that observed, 118.1°, for a methyl substituent (13). In methyl acetylene, the triple bond length is 1.206 Å, according to microwave spectroscopy (14), and presumably refers to the ground vibrational state.

Experimental

3-Phenyl-1-propyne was prepared from 1-phenyl-1-propyne, exactly as described in the literature (15). Solutions, 5.0 mol% in CCl_4, benzene-d_6, and acetone-d_6, containing 0.5 mol% tetramethylsilane and an additional 10 mol% of cyclohexane-d_{12} in the CCl_4 mixture, were prepared and transferred to 5-mm od nmr tubes. These solutions were degassed by the freeze–pump–thaw technique and the sample tubes were then flame-sealed. The ^{1}H nmr spectra were obtained on a Bruker AM300 spectrometer at a probe temperature of 300 K. The procedure was identical to that recently described in detail for toluene (10). The ^{1}H nmr spectra were analyzed with the computer program NUMARIT (16), as modified by R. Sebastian. Figure 2 displays the

[1]For benzyl cyanide V_2 and V_4 are −1.1 and −0.29 kJ/mol for 6-31G level calculations (3).

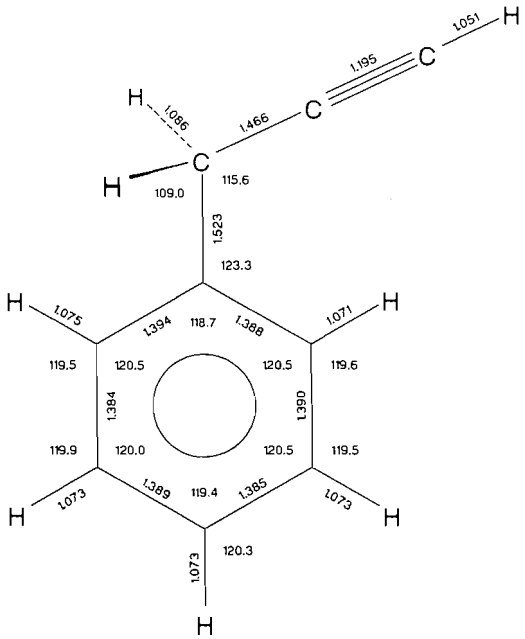

FIG. 1. The geometry-optimized structure of 3-phenyl-1-propyne at the 6-31G level of molecular orbital theory is shown for the conformation in which the acetylenic group lies in the benzene plane ($\psi = 0°$ for **1** in the text). The total energy is −345.286 817 au and is not the minimum energy, which occurs near $\psi = 50°$ (see text). Bond lengths are given in angstroms and bond angles in degrees. The phenyl group was constrained to planarity during the optimization procedure. Although the exocyclic bond angles imply significant crowding for this structure, it is only 0.5$_6$ kJ/mol less stable than that at $\psi = 50°$C.

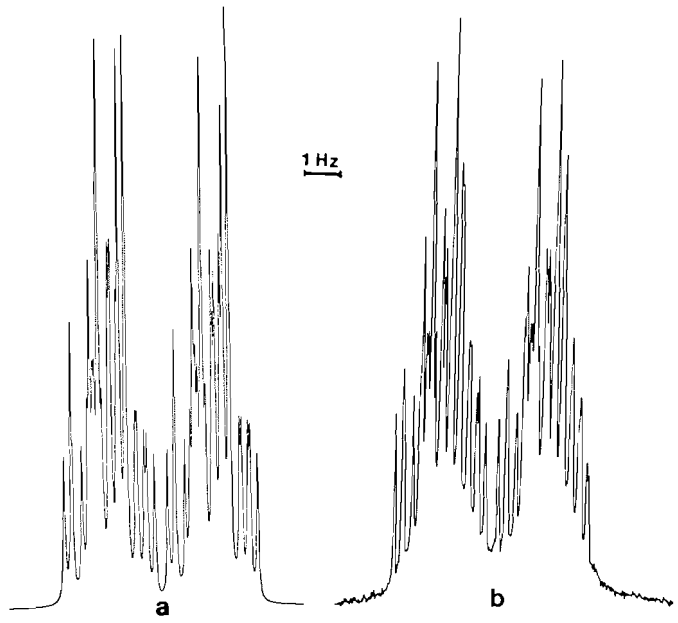

FIG. 2. The calculated (*a*) and observed (*b*) ^{1}H nmr spectrum of the methylene protons of 3-phenyl-1-propyne as a 5 mol% solution in acetone-d_6 at 300 K and 300 MHz. The linewidths at half-height are approximately 0.08 Hz. The intensity differences between some peaks in the two spectra have their origin in the presence of many transitions lying within, say, 0.01 Hz of each other in a given observed peak, but which cannot be distinguished in an assignment. Of course, the long-range coupling constants also appear in the ring proton spectrum, so that, in fact, they can be extracted precisely from an 8-spin analysis.

observed and computed ^{1}H nmr spectra of the methylene protons in acetone-d_6 solution. Table 1 presents the spectral parameters for 3-phenyl-1-propyne in the three solutions.

STO 3G MO computations utilized the program MONSTERGAUSS (17) and the 6-31G calculations employed GAUSSIAN 82 (18), both on an Amdahl 470 system. INDO MO FPT computations (19) of $^6J(H,CH_2)$ on 3-phenyl-1-propyne were also done. The dipole moments at $\psi = 0°$ and 90° (see **1**) were 0.37 and 0.47 D at the 6-31G level of MO theory, so that electrostatic interactions with the solvent (7) differ very little for the two forms.

A new procedure for the *in situ* generation of methylene ketenes

ANDREW P. MASTERS, TED S. SORENSEN,[1] AND PHU MANH TRAN
The Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received October 21, 1986

ANDREW P. MASTERS, TED S. SORENSEN, and PHU MAHN TRAN. Can. J. Chem. **65**, 1499 (1987).

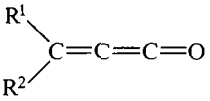
The reaction of pentacarbonylmanganate anion **3** and 2-bromopropenoyl chlorides **2** leads to 2,4-alkylidenecyclobutane-1,3-diones **5**. The latter are formed from dimerization of the corresponding methylene ketenes **1** so that the reaction of **2** and **3** constitutes a new synthetic procedure for the *in situ* generation of these very reactive intermediates. Acid chlorides **2** are readily available from α,β-unsaturated acids via bromination–dehydrobromination – thionyl chloride sequences.

ANDREW P. MASTERS, TED S. SORENSEN et PHU MAHN TRAN. Can. J. Chem. **65**, 1499 (1987).

La réaction de l'anion pentacarbonylmanganate (**3**) et des chlorures de bromo-2 propènoyles (**2**) conduit aux dialkylidène-2,4 cyclobutanediones-1,3 (**5**). Ces derniers composés se forment par dimérisation des méthylène cétènes correspondants (**1**); il en résulte que la réaction des composés **2** et **3** constitue une nouvelle voie de synthèse pour la préparation *in situ* de ces intermédiaires très réactifs. Les chlorures d'acides **2** sont facilement disponibles à partir des acides α,β-insaturés, par le biais de la série de réaction de bromation/d'élimination de HBr/chlorure de thionyle.

[Traduit par la revue]

Methylene ketenes **1** are extremely reactive and short-lived compounds, nevertheless some knowledge of their chemistry has developed in the past fifteen years (1). Present procedures for preparing **1** generally involve either photochemistry (2)



1

or high-temperature pyrolysis (most often of Meldrum's acid derivatives) (3). Neither method is particularly well suited for preparative chemistry (although clearly useful for directly observing **1**) and in this paper we present a new synthetic procedure capable of the convenient *in situ* generation of **1** at subambient temperatures.

Results

The overall stoichiometry for this methylene ketene synthesis is shown in eq. [1]. A closely related reaction has recently been

[1] 
2*a* $R^1 = R^2 = CH_3$
2*b* $R^1 = R^2 = \phi$
2*c* $R^1 = R^2$ = 2-adamantylidene
2*d* $R^1 = H$, $R^2 = CH_3$

used for the preparation of ketenes and vinyl ketenes, where the bromine atom in these cases is located on an sp^3 centre (4). Surprisingly, 2-bromopropenoyl chlorides **2** (sp^2-bromine) are, if anything, even more reactive towards **3**, the eq. [1] reaction appearing to proceed at temperatures as low as −80°C in some cases. The pentacarbonylmanganate **3** has been used in this work as the sodium salt in tetrahydrofuran solvent or as the partially air-stable bistriphenylphosphineiminium (PPN^+) salt (5) in chloroform or methylene chloride solvent. The latter method is somewhat more convenient but can involve work-up problems in some cases.

[1]Author to whom correspondence may be addressed.

To detect the *in situ* formation of **1**, one must have a trapping procedure that unequivocally indicates that **1** was indeed formed. Because of the acid chloride functionality in **2**, as well as the triviality of the trapping product, we have steered clear of trapping agents such as alcohols, amines, etc. and have looked for suitable $\pi^2 + \pi^2$ or $\pi^4 + \pi^2$ trapping reactions. Unfortunately, only the $\pi^2 + \pi^2$ self-dimerization has so far been successful, and this only in cases where R^1 and R^2 are alkyl or aryl. Three representative examples are described, involving $R^1 = R^2 = CH_3$, $R^1 = R^2$ = phenyl, and the cyclic 2-adamantyl case. In the latter case, we had hoped to also observe directly the monomer species. The reactions are shown in eq. [2].

[2] 
1*a* $R^1 = R^2 = CH_3$
1*b* $R^1 = R^2 = \phi$
1*c* $R^1 = R^2$ = 2-adamantylidene

5*a–c*

Both **5***a* and **5***b* have previously been reported as the sole dimerization products of the corresponding methylene ketenes (3), so that the *in situ* generation of **1***a–c* cannot really be in doubt in our examples. In each case, dimer **5** is initially formed in high yield (ir measurements), but only **5***b* and **5***c* have been isolated in good yield. Compound **5***a* decomposes extensively on silica gel flash chromatography and the pure solid has consequently been isolated in only about 40% yield.

The acid chloride **2***d* reacts rapidly at subambient temperatures with **3** to give $Mn(CO)_5Br$ (characteristic ir bands), but the also characteristic ir stretching frequencies expected for **5***d* ($R^1 = H$, $R^2 = CH_3$) are completely absent (the assumption here is that **5***d* would have very similar frequencies to **5***a* and **5***c*). The ^1H nmr spectrum of the crude reaction mixture is broad (paramagnetic Mn species) and uninformative (insoluble material precipitates out with time). This failure to observe **5***d* is not entirely unexpected since previous pyrolysis work, intended to give methylene ketene **1***d* ($R^1 = H$, $R^2 = CH_3$), gave no **5***d* (3) on warming the pyrolysate.

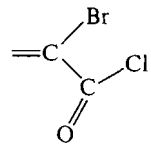
Since **1***d* could not be trapped as an observable self-dimer, attempts were made to trap this ketene with cyclopentene, acrolein, 2,3-dimethylbutadiene, ethyl vinyl ether, and dihydropyran. In the first four cases, part of the tetrahydrofuran solvent volume was replaced with the potential trapping agent (corresponding to about an 80-fold molar excess compared to **2***d*) and the reactions were then performed in the normal way (sodium salt procedure). In the case of dihydropyran and ethyl vinyl ether, the reaction was also carried out under dilute addition conditions using a syringe pump to add **2***d* to the solution of **3**. However, in all cases, the crude reaction mixture, on glc analysis, failed to show the presence of any 1:1 adduct (or indeed of any volatile material). Significantly, when the acid chloride **2***a* is reacted with **3** in tetrahydrofuran – ethyl vinyl ether solvent mixtures, one also obtains no 1:1 adduct with the ether (but one gets the usual ir spectrum of **5***a* in good yield). Previous workers in this area (1) have also failed to trap methylene ketenes with a range of alkenes and dienes, although ketenes and methylene ketenes have been coreacted, and we plan to conduct experiments in this area since both ketenes and methylene ketenes can be prepared using the same synthetic procedure, i.e. with **3** and mixed bromoacyl chlorides.

Discussion

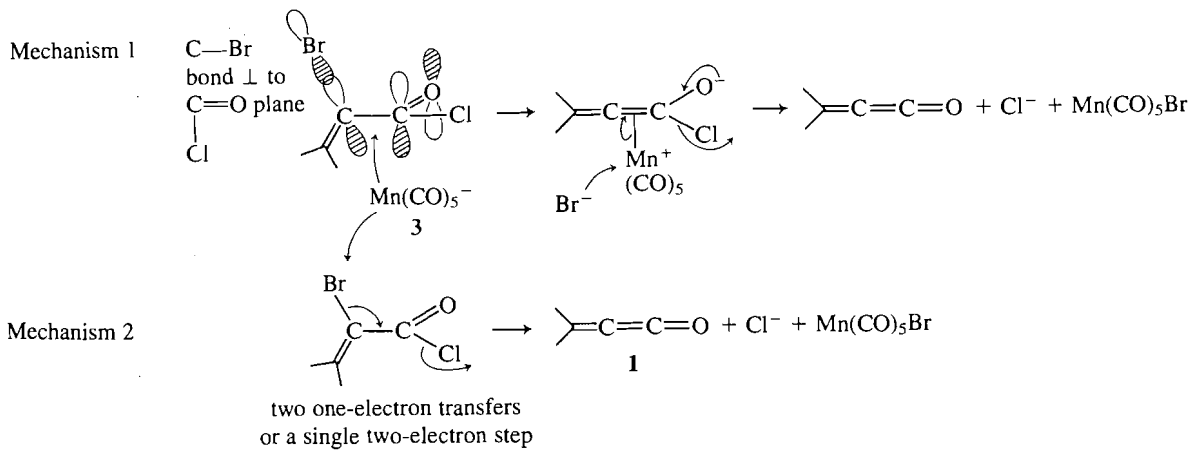
The 2-adamantylidene ketene **1***c* is, from molecular models, reasonably hindered, but even this appears (ir) to dimerize faster than it is formed from the acid chloride **2***c*, i.e. typical *in situ* generation conditions. However, such conditions are often ideally suited for trapping experiments (cf. numerous studies of vinyl ketene cycloadditions where the ketene is generated *in situ* in the presence of the trapping agent) (for two recent examples see ref. 6). Hopefully, the experimental ease of the present methylene ketene synthesis will enable a testing of a much wider range of potential trapping species, including cases with internal "built-in" trapping functionality.

The mechanism of the methylene ketene formation is quite obviously related to the more general reaction of **3** with all α-bromoacyl chlorides, i.e., the crucial functionality is the partial structure **6**, and it does not matter whether the remaining

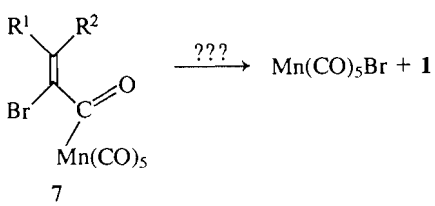


6

structure is part of a double bond (sp^2) or is directly bonded to R or H substituents (sp^3). As before (4), one can formulate the reaction as a HOMO–LUMO interaction between **3** and **2**, the LUMO on **2** having a significant C—Br σ* component. Interaction of **3** with the C1—C2 pseudo π-bond could lead to an intermediate π-complex and eventually to a methylene ketene (mechanism 1). Alternatively, and perhaps more likely, is a direct interaction of **3** with the α-bromine. This could



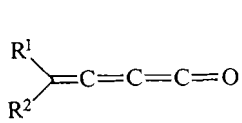
involve either two one-electron steps or a single two-electron process (mechanism 2). We have previously ruled out the initial formation of an acyl manganese intermediate, e.g. **7**, in the simple sp^3-Br cases and believe that such an intermediate is even less likely in the present case.



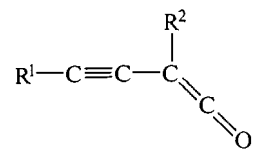
7

Future prospects

The reaction used to prepare **1** can possibly be extended to the formation of two virtually unknown types of ketenes, butatrienones **8** (7) and acetylenic ketenes **9**, the former from α-bromobutadienoyl chlorides, the latter from the γ-bromo



8



9

isomer (cf. vinyl ketene formation from γ-bromocrotonyl chlorides (4)).

Experimental

All melting and boiling point values are uncorrected. Gas chromatography analyses were performed on 6 ft × 4 mm columns of OV-1 or OV-17. Mass spectrometric analyses were obtained on a Kratos MS80, infrared spectra on a Nicolet 5DX FT instrument, and ^1H and ^{13}C nmr spectra on a Varian XL-200 spectrometer.

2-Bromo-3-methyl-2-butenoyl chloride **2**a, bp 72–73°C/12 Torr (1 Torr = 133.3 Pa); ^1H nmr, δ: 2.07 and 2.09 (3H each), was prepared by the standard thionyl chloride procedure (8).

For personal use only.

2-Bromo-2-butenoyl chloride **2**d was prepared from the *E*-acid and was obtained as a 1:2 *E–Z* mixture (by ^{1}H nmr) of acid chlorides, bp 65°C/10 Torr (9).

Tricyclo[3.3.1.1^{3,7}]decylideneacetic acid

The title compound was prepared by a variant of the literature routes (10), involving the direct condensation (11) of 2-adamantanone and ethyl acetate, in near quantitative yield. The hydroxy ester so formed (15 g) was both hydrolyzed and dehydrated by dissolving it in 75 mL of methylene chloride and adding this to 75 mL of stirred 96% sulfuric acid (ice bath). After 3 h at 20°C, the sulfuric acid layer was slowly added to a large excess of ice. The resulting solid acid was filtered (extraction of the filtrate with methylene chloride provides a small additional amount) and dried. Recrystallization from hexane–CCl_4 provided the title acid in high overall yield.

2-Bromo-2-tricyclo[3.3.1.1^{3,7}]decylideneacetic acid

The preceding acid was quantitatively brominated in CCl_4 solution at 0°C (left overnight in the refrigerator). A sample recrystallized from CCl_4 had mp 153–154°C; ^{1}H nmr, δ: 5.66, H—C(Br)(COOH)—. The crude dibromide (2.00 g, 5.68 mmol) was added in portions to 15 mL of 10% KOH – 95% ethanol cooled to 0°C in ice. After 3 h at 20°C, the solid was filtered and the filtrate acidified with 5% HCl. This heterogeneous aqueous phase was extracted (3 × 25 mL) with methylene chloride, which was dried and concentrated until the title acid began to crystallize out. Two crops were collected, 0.83 g (54%), mp 201–203°C; ^{1}H nmr $(CD_3)_2CO$, δ: 3.55 and 3.23 (1H, each, nonequivalent allylic), 1.7–2.0 (remaining hydrogens); ^{13}C nmr, $(CD_3)_2CO$, δ: 28.3 (d × 2), 36.9 (t), 37.1 (d), 38.9 (t × 2), 39.0 (d), 39.6 (t × 2), 102.7 (?, q), 135.6 (q), 159.5 (q). *Exact Mass* calcd. for $C_{12}H_{15}O_2{}^{79}Br$: 270.0277; found: 270.0254.

2-Bromo-2-tricyclo[3.3.1.1^{3,7}]decylideneacetyl chloride **2**c

The above acid, 4.00 g, 14.7 mmol, was refluxed for several hours with an excess of thionyl chloride (6 mL). After the excess thionyl chloride was distilled off, the acid chloride was distilled, bp 174–177°C/9 Torr, 3.61 g (85%). It solidifies in the refrigerator; ^{1}H nmr $(CD_3)_2CO$, δ: 3.23 and 3.18 (1H each, allylic), 1.8–2.05 (remaining H); ^{13}C nmr ($CDCl_3$), δ: 27.9 (d × 2), 36.8 (t), 37.6 (d), 39.1 (t × 2), 39.6 (t × 2), 105.8 (q), 162.1 (q). *Exact Mass* calcd. for $C_{12}H_{12}{}^{35}Cl^{79}BrO$: 287.9916; found: 287.9900.

3,3-Diphenyl-2-bromopropenoyl chloride **2**b

The bromoacid (12) (3.00 g; 9.90 mmol), 5 mL of thionyl chloride, and two drops of dimethylformamide were stirred at ca. 20°C for 1 h. A few millilitres of methylene chloride were added and the excess thionyl chloride and solvent removed on the Rotovap. This procedure was repeated twice with the fresh addition of solvent each time. Addition of carbon tetrachloride and crystallization gave two crops of **2***b*, 2.35 g (74%). A sample was recrystallized from the same solvent, mp 86–88°C. Application of the ordinary thionyl chloride procedure to prepare **2***b* yielded a mixture of the acid chloride and a red compound with an ir C=O stretch at 1721 cm^{-1}, which likely corresponds to 3-phenyl-2-bromoindenone formed by intramolecular acylation. Acid chloride **2***b* has a C=O stretch at 1764 cm^{-1} (CH_2Cl_2); ^{13}C nmr ($CDCl_3$), δ: 112.5 (q), 128.2 (d × 2), 128.6 (d × 2), 129.3 (d × 3), 129.5 (d × 2), 129.6 (d), 138.95 (q), 139.2 (q), 150.6 (q), 165.2 (l). *Exact Mass* calcd. for $C_{15}H_{10}O^{79}Br^{35}Cl$: 319.9604; found: 319.9605.

2,4-Bis(tricyclo[3.3.1.1^{3,7}]decylidene)-cyclobutane-1,3-dione **5**c

Under an argon atmosphere, a solution of $Na^+Mn(CO)_5^-$ was prepared by stirring 0.15 g (0.77 mmol) of $Mn_2(CO)_{10}$ in 7 mL of tetrahydrofuran (distilled from benzophenone ketyl) over 1.5 mL of 1% sodium amalgam for 20 min. The solution was then transferred under argon via a hollow needle to a filter tube containing Celite. After filtering, the tube was washed with 2 mL of tetrahydrofuran. The pale yellow anion solution contained in a round bottom flask was removed from the filter tube and quickly fitted with a serum cap. This solution was cooled to −78°C and 0.2167 g (0.749 mmol) of the adamantyl acid chloride **2***c* in 2 mL of tetrahydrofuran was added dropwise via syringe, with stirring, over 3 min. The solution was then allowed to warm to 20°C, a precipitate forming. The solution was filtered through Celite, and extraction of the Celite with hot methylene chloride and the removal of solvent yielded 57.5 mg of pure **5***c*. From the filtrate, an additional 21.2 mg of dimer **5***c* was eventually obtained by concentrating the volume, total 78.7 mg (60% recovery). Eventually $Mn(CO)_5Br$ cocrystallizes with **5***c*. A recrystallized sample (yellow plates) had mp ca. 330°C (dec.); ir: characteristic peaks at 1683 and 1615 cm^{-1}; ^{1}H nmr ($CDCl_3$), δ: 3.63 (allylic), 1.90–2.10 (remaining protons); ^{13}C nmr ($CDCl_3$), δ: 27.7 (d × 4), 36.7 (t × 2), 40.7 (d × 8), 144.1 (q × 2), 176.4 (q × 2), 192.0 (q × 2). In the off-resonance spectrum, the quaternary carbon at 176.5 is broader than the one at 144.1 and is probably the carbon at the 2-position of the adamantane ring. *Anal.* calcd. for $C_{24}H_{28}O_2$: C 82.72, H 8.10; found: C 82.99, H 8.13.

2,4-Bis(diphenylmethylene)-cyclobutane-1,3-dione **5**b

To a stirred, −78°C, solution of $PPN^+Mn(CO)_5^-$ (2.521 g; 3.44 mmol), in 25 mL of methylene chloride, contained in a 100-mL round bottom flask and protected by a rubber septum, was added dropwise from a syringe over a 5-min period a solution of acid chloride **2***b* in 10 mL of methylene chloride. Even at −78°C, the solution appears to darken and become somewhat murky. After a few minutes at −78°C, the solution was gradually allowed to warm to room temperature (ca. 0.5 h). The infrared spectrum of the dark red solution taken immediately on warming showed characteristic peaks for $Mn(CO)_5Br$ and the dimer **5***b*. About one-half of the methylene chloride was removed on the Rotovap and the solution was stored overnight in a refrigerator. This treatment converts most of the $Mn(CO)_5Br$ to a polar species with lower frequency infrared peaks, probably $PPN^+Mn(CO)_4ClBr^-$. Most of the remaining methylene chloride was removed and the residue subjected to flash chromatography on silica gel using hexane – methylene chloride elution. A small first fraction of $Mn(CO)_5Br$ is followed by essentially pure **5***b*, 0.454 g (71%), as dark red crystals; mp ca. 307°C (dec.) (lit. (3) mp 315°C (dec.)); ir (CH_2Cl_2): 1684 and 1541 cm^{-1} (lit. (3) ir (Nujol) 1694 and 1537 cm^{-1}); ^{13}C nmr ($CDCl_3$), δ: 127.9 (d × 8), 131.7 (d × 4), 132.3 (d × 8), 136.1 (q × 4), 152.4 (q × 2), 156.0 (q × 2), 186.6 (q × 2); ms, *m/e* (% base): 412 (36, M^+), 178 (100) (lit. (3) ms *m/e* 412 (50, M^+), 178 (100)).

2,4-Di(1'-methyl-1'-ethylidene)cyclobutane-1,3-dione **5**a

Using acid chloride **2***a*, the methylene ketene dimer **5***a* could be prepared using either the sodium salt method (see above for **5***c*) or the PPN^+ salt procedure used for **5***b*. The infrared spectra in each case, taken immediately on warming the reaction solutions, showed a carbonyl region containing only peaks for $Mn(CO)_5Br$ (2005, 2047, and 2136 cm^{-1}) and the dimer **5***a* (see below). Weighed samples of pure **5***a* and $Mn(CO)_5Br$ were prepared as mixtures for infrared calibration, indicating that the ketene dimer **5***a* yield is about 90% based on $Mn(CO)_5Br$. Using the sodium salt procedure, $Mn(CO)_5Br$ and **5***a* could be cosublimed (0.01 Torr, 20 → 60°C) from the crude reaction mixture and the combined weight was close to that expected for 100% $Mn(CO)_5Br$ and ca. 90% **5***a*. Attempts to sublime the crude PPN^+ salt mixture gave no **5***a*, an indication that the latter reacts rapidly with PPN^+Cl^- under these conditions. Using the sodium salt procedure (1.00-mmol scale), the crude products after filtration could be flash chromatographed on silica gel (methylene chloride solvent), whereby one obtains about 40% overall recovery of pure, crystalline **5***a* as orange-yellow needles (this **5***a* fraction is preceded by a very small $Mn_2(CO)_{10}$ fraction and then $Mn(CO)_5Br$ in 83% yield). Streaking on the chromatography column or tlc plates indicated that decomposition to a more polar compound was occurring on the column. Alternative attempts at an aqueous work-up procedure resulted in the immediate loss of **5***a*. Dimer **5***a* is characterized by a pair of strong infrared peaks at (THF) 1694 and 1632 cm^{-1} (lit. (3) ir (Nujol) 1680 and 1621 cm^{-1}); mp 150–151°C (lit. (3) mp 135°C; lit (13) mp 143°C); ^{1}H nmr: δ 2.26 (s) (lit. (3) δ 2.25); ms, *m/e* (% base peak): 164 (61, M^+), 136 (55), 93 (70), 83 (64), 67 (100) (lit. (3) ms *m/e*: 164 (36, M^+), 67 (100)). Attempted trapping reactions were carried out using the sodium salt

procedure. In all cases the infrared spectrum of the crude reaction solution indicated that **5***a* was formed in about 90% yield.

Reaction of acid chloride **2** d *with* $Na^+Mn(CO)_5^-$

This reaction was carried out as described for the preparation of **5***c*. Immediately on warming, an infrared spectrum was taken, showing peaks for $Mn(CO)_5Br$, no peaks for $Mn(CO)_5^-$, and only broad low intensity "bumps" in the rest of the carbonyl region. The reaction was repeated with five different potential trapping agents (see Results), giving similar results. The latter reactions were also analyzed by glc, showing $\leq 1\%$ of any volatile 1:1 trapping products.

The synthesis of 3-carboxymethyleneazetidinones

WERNER HINZ AND GEORGE JUST[1]
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received September 30, 1986

WERNER HINZ and GEORGE JUST. Can. J. Chem. **65**, 1503 (1987).

A series of novel azetidinones bearing the methoxycarbonylmethylene, thioethoxycarbonylmethylene, and alkylaminocarbonylmethylene side chain in their three position have been synthesized from the reaction of the potassium salt of 4,4′-bis(thioethoxy)-3-butenoic acid with a number of Schiff bases.

WERNER HINZ et GEORGE JUST. Can. J. Chem. **65**, 1503 (1987).

Faisant appel à la réaction du sel de potassium de l'acide bis(thioéthoxy)-4,4′ butène-3 oïque avec un certain nombre de bases de Schiff, on a synthétisé une série de nouvelles azétidinones portant les chaînes latérales méthoxycarbonylméthylène, thioéthoxycarbonylméthylène et alkylaminocarbonylméthylène en position 3.

[Traduit par la revue]

Introduction

The mechanism of β-lactam action on bacterial cell wall enzymes has been at the centre of much interest over many years (1). Recently, Keith *et al.* (2) put forward the oxazolone structure **2** for the reactive intermediate directly preceding acylation of the penicillin-sensitive enzyme and this report prompted us to explore possible syntheses of azetidinones of type **3**. Their mode of action in biological systems should, by analogy, involve the intermediate **4**, and comparing the biological activities of β-lactam compounds of types **1** and **3** could provide evidence either in support of or against the suggested mechanism of β-lactam activity. We here wish to describe a short and efficient synthesis of these novel 3-substituted azetidinones.

Results and discussion

Several years ago, the reaction of crotonyl chloride with various Schiff bases was developed in this laboratory to yield 3-vinylazetidinones in good yield (3). Based on this approach, we investigated the use of appropriately substituted crotonic acid derivatives, which, employed in cyclization reactions with corresponding imines, should lead to precursors for 3-carboxymethyleneazetidinones.

To obtain the desired oxidation state (carboxylic acid) at the β-carbon of the azetidinone (C-3) side chain, it was evident that the methyl group (C-4) of our starting crotonic acid had to be converted into an aldehyde functionality and suitably protected.

Aldehyde **5** was readily available, although only in moderate yield, both via the selenium dioxide oxidation of methyl crotonate (4) and via ozonolysis of methyl sorbate (5). The dimethyl acetal **6** (5, 6) and the protected cyanohydrin derivatives **8** and **9** (7–9) were readily prepared following standard procedures; however, neither **6** nor **8** and **9** underwent cyclization reactions with **12***a* under a number of reaction conditions. We observed either no reaction (with **6**) or facile decomposition of the substrate (with **8** and **9**).

As a third approach, the reaction of **5** with ethanethiol and zinc chloride gave **7** in near quantitative yield. The thioacetal functionality proved to be the protecting group of choice, and the possible use of **8** or **9** was not further explored in detail.

During the hydrolysis of the methyl ester of **7** to give the free carboxylic acid **10**, the double bond migrated to form the thioketeneacetal functionality. This migration was most easily followed by ^{1}H nmr spectroscopy showing the disappearance of the alkene proton resonances of **7** and the appearance of a triplet resonance (1H) at 6.17 ppm and of a doublet resonance (2H) at 3.51 ppm. Since this shift had not been observed when the ester grouping of **6** was hydrolysed, it was evident that the acidity of the C-4 proton in **7** was considerably higher than the acidity of the corresponding proton in **6**, and we were confident that the reaction of **10** with Schiff bases **12** to give azetidinones **13** should proceed well.

Reaction of potassium salt **11** with imine **12***a*, obtained from cinnamaldehyde and *p*-anisidine (10), in the presence of cyanuric chloride and triethylamine, gave **13***a* in 50% yield. Only the *cis* isomer was isolated, the configuration being confirmed by the coupling constant between the azetidinone ring protons, which was $^3J_{H3-H4} = 6$ Hz. In an analogous fashion, **13***b* was obtained as its *cis* isomer from the reaction of **11** with Schiff base **12***b*. However, the reaction of **12***c* (11) and of **12***d* (12), prepared from benzaldehyde and 2-naphthaldehyde, with **11** gave considerably lower yields of azetidinones **13***c* and **13***d* under identical reaction conditions (ca. 7%); both *cis* and *trans* isomers were present in the product mixture in an approximately 1:1 ratio (*trans*:$^3J_{H3-H4} = 2$ Hz, *cis*:$^3J_{H3-H4} = 6$ Hz), and **13***c* and **13***d* as well as **15***c* and **15***d* were found to be rather unstable compounds.

Key intermediates **13***a*–**13***d* required chemical transformations at three sites: conversion of the thioketeneacetal grouping into the amide functionality; transformation of the styryl side chain into the methyl substituent common in many biologically active monobactams (13); reduction of the styryl and the phenylpropargyl side chains, and removal of the N-protecting group with subsequent sulfonation.

Treatment of **13***a* with boron trifluoride etherate and methanol yielded the methyl ester **14***a*. Alternatively, the considerably more reactive thioesters **15** were obtained from the hydrolysis of **13** with trifluoroacetic acid and aqueous ethanol.

h: R = CH_2CH_2Ph *i*: R = *cis*-styryl

This reaction provided surprisingly good yields, even with our rather sensitive substrates, when the reaction was carried out under gentle conditions over a period of several days.

Transformation of the styryl side chain of **15***a* into the C-4 methyl substituent of **15***g* was carried out at the thioester stage since the attempted ozonolysis of **13***a* had led to a multitude of products. Ozonolysis of **15***a* gave a reasonably clean aldehyde, which was reduced without purification with sodium borohydride, followed by mesylation, to give **15***e*. The mesylate **15***e* was readily converted into the iodomethylene derivative **15***f* using tetra-*n*-pentylammonium iodide – potassium iodide. In the ^{13}C nmr spectrum, an upfield shift of the methylene resonance of 65 ppm accompanied this substitution reaction, with the iodomethylene resonance observed distinctly at −0.02 ppm. Tributyltin hydride reduction of **15***f* gave **15***g* in good yield.

Similarly, removal of the N-protecting group was not possible in the presence of the thioketeneacetal functionality of **13***a*. However, it was a rapid and clean reaction once the hydrolysis to the thioester group of **15** had been carried out. Oxidation with ceric ammonium nitrate in acetonitrile and water yielded the N-unsubstituted β-lactams **16**.

Simply warming a mixture of the deprotected thioesters **16** and an excess of the appropriate alkylamine (benzylamine, 2-thiophenemethylamine, piperidine) in the absence of any solvent to 70°C yielded the azetidinones **17**, **18**, and **19** with the desired "reversed amide" side chain. The reactions employing the primary amines appeared cleaner than those with the secondary amine.

At this point of the synthetic scheme, two new C-4 side chains were introduced. The *trans*-styryl group of **17***a* was reduced to the phenylethyl substituent of **17***h* via hydrogenation using platinum as the catalyst. Only a small degree of debenzylation was observed. Similarly, hydrogenation of the triple bond of **17***b* using nickel boride as a catalyst (14) led to the formation of the *cis*-styryl derivative **17***i*. The ^1H nmr spectrum showed three-bond coupling constants of 11 Hz across the double bond, as compared to $^3J_{H,H}$ = 17 Hz, observed for the *trans*-styryl substituent.

Sulfonation using the pyridine – sulfur trioxide complex was followed by treatment with tetrabutylammonium hydrogen sulfate and passing of the intermediate ammonium salt through a short column of Dowex 50X8-200 ion exchange resin. The resulting potassium salts **20–22** were identified by their FAB (fast atom bombardment) low and high resolution mass spectra in which $M + 1$ and $M + 39$ peaks were always prominent.

All sulfonium salts **20–22** were tested for their activity against strains of Gram-positive and Gram-negative bacteria. Some promising initial results unfortunately were not confirmed when a larger number of compounds were submitted to the testing process. The lack of biological activity of course implies that support for the "Keith mechanism" was not produced, although these negative testing results do not necessarily disprove the proposed mechanism.

Compounds were tested by the standard agar dilution method of Mueller Hinton. Plates were inoculated with $1–5 \times 10^4$ CFU using the STERS replicator and incubated 18 h at 35°C. The lowest concentration for inhibition of growth is the MIC (minimum inhibitory concentration). Although styrylmonobactam **17** initially showed activity against various strains of *Staphylococcus aureus* and *Streptococcus faecalis* at a MIC of 0.12–4 mg/mL, inducing us to prepare the other analogues, these biological results were not reproducible.

Experimental

Melting points were determined on a Gallenkamp melting point apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer infrared spectrometer, model 297, or a Nicolet 7000 FT-IR spectrometer as thin films in bromoform between potassium bromide plates. Nuclear magnetic resonance spectra were measured on Varian XL-200 or Varian XL-300 FT-NMR spectrometers using deuterated chloroform or dimethylsulfoxide-d_6 as the solvent. All chemical shift values are quoted in ppm (δ) downfield from tetramethylsilane, which was used as an internal standard. Mass spectra were recorded on a Hewlett Packard mass spectrometer, model 5984A, with the chemical ionization mode (isobutane, source pressure 1 Torr (1 Torr = 133.3 Pa)) or the FAB mode (matrix: glycerol, atom energy 8 kV, 1 mA) being used as indicated. Column chromatography was carried out on silica gel 60 (230–400 mesh, Merck No. 9485).

Methyl 4,4'-bis(thioethoxy)but-2-enoate 7

Aldehyde **5** (2.28 g, 20 mmol), ethanethiol (5 mL), and zinc chloride (400 mg) were stirred at −15°C for 1 h. Hydrochloric acid (0.5 *N*, 5 mL) was added and stirring was continued at room temperature for 15 min. Excess ethanethiol was removed and the residue dissolved in water and dichloromethane. The organic layer was washed with aqueous sodium hydrogen carbonate (5%), dried ($MgSO_4$), and the solvent removed. Column chromatography (dichloromethane:hexanes 2:1) or distillation gave **7** as a yellow oil, bp 90–100°C/0.1 Torr

For personal use only.

(3.4 g, 77%); ir: 1730, 1645 cm^{-1}; ^1H nmr ($CDCl_3$): 1.26 (t, 6H), 2.61 (m, 4H), 3.77 (s, 3H), 4.41 (d, 1H, J = 9 Hz), 5.92 (d, 1H, J = 16 Hz), 6.87 (dd, 1H, J = 16 Hz, J = 9 Hz); ^{13}C nmr ($CDCl_3$): 14.27 (q), 24.98 (t), 44.80 (d), 51.63 (q), 120.55 (d), 144.72 (d), 166.24 (s); ms (ei): 220 (M^+).

4,4'-Bis(thioethoxy)-3-butenoic acid ***10***

The ester **7** (22 g, 0.1 mol), potassium hydroxide (6.72 g, 0.12 mol), water (100 mL), and ethanol (100 mL) were heated under reflux for 3 h. The mixture was concentrated, and water (100 mL) was added and extracted with dichloromethane (50 mL). It was then acidified with hydrochloric acid and extracted with dichloromethane (3 × 50 mL). The combined organic layers were dried ($MgSO_4$) and the solvent removed to yield the acid **10** as an oil (19.2 g, 93%); ir: 3700–2500, 1690 cm^{-1}; ^1H nmr ($CDCl_3$): 1.21 (t, 6H), 2.72 (q, 4H), 3.47 (d, 2H, J = 7 Hz), 6.12 (t, 1H, J = 7 Hz), 11.25 (bs, 1H); ^{13}C nmr ($CDCl_3$): 14.05 (q), 14.35 (q), 26.98 (t), 27.32 (t), 35.73 (t), 127.65 (d), 134.47 (s), 177.50 (s). *Exact Mass* calcd.: 207.0514; found: 207.0513.

The acid **10** (6.76 g, 32.8 mmol), potassium hydroxide (1.84 g, 32.8 mmol), and water (50 mL) were left at room temperature for 30 min. Removal of the solvent gave the potassium salt **11** (8 g, 100%), which was used without further purification.

Schiff base ***12***b

Phenylprogargylaldehyde (2.8 g, 21.5 mmol) and dichloromethane (50 mL) were added dropwise to anisidine (2.65 g, 21.5 mmol), magnesium sulfate (5 g), and dichloromethane (100 mL) at 0°C. After 24 h at the same temperature, the mixture was filtered and the solvent removed. Recrystallization from ethyl acetate and hexanes gave the Schiff base ***12b*** as a yellow solid (4.3 g, 85%); mp 107–109°C; ir: 2160, 1590 cm^{-1}; ^1H nmr ($CDCl_3$): 3.82 (s, 3H), 6.90 (d, 2H), 7.23 (d, 2H), 7.34–7.39 (m, 3H), 7.56–7.61 (m, 2H), 7.94 (s, 1H). *Exact Mass* calcd.: 236.1076; found: 236.1075.

3-[2,2-Bis(thioethoxy)ethenyl]azetidinones ***13***a–d*: General procedure*

Cyanuric chloride (368 mg, 2 mmol) and dichloromethane (10 mL) were added to the potassium salt **11** (488 mg, 2 mmol), triethylamine (0.3 mL, 2 mmol), dichloromethane (80 mL), and the corresponding imine (2 mmol) at −40°C. This temperature was maintained for 4 h and the mixture was allowed to warm to −18°C overnight. The solution was washed with water and brine, dried ($MgSO_4$), and the solvent was removed. Column chromatography (dichloromethane:hexanes 2:1) gave the azetidinone.

Hydrogenation of 4-styryl substituent: azetidinone ***17***h

Azetidinone **17***a* (32 mg, 0.1 mmol), platinum (catalyst), and ethanol (5 mL) were hydrogenated at normal pressure for 30 min. The mixture was filtered and the solvent removed. Column chromatography (dichloromethane:ethyl acetate 3:2) yielded **17***h* (18 mg, 56%); mp 149°C; ir: 1750 cm^{-1}; ^1H nmr ($CDCl_3$): 1.73 (m, 1H), 1.97 (m, 1H), 2.49 (dd, 1H), 2.60–2.77 (m, 3H), 3.61 (m, 1H), 3.81 (m, 1H), 4.44 (d, 2H), 5.78 (bs, 1H), 7.15–7.39 (m, 10H). *Exact Mass* calcd.: 323.1760; found: 323.1744.

Hydrogenation of 4-alkynyl substituent: ***17***i

Azetidinone **17***b* (32 mg, 0.1 mmol), nickel(II) acetate (50 mg, 0.2 mmol), sodium borohydride (7.6 mg, 0.2 mmol), ethylene diamine (0.3 mL), and ethanol (2 mL) were hydrogenated at normal pressure for 6 h. The mixture was filtered and the solvent removed. Column chromatography (dichloromethane:ethyl acetate 1:1) yielded the *cis*-styryl derivative **17***i* (7 mg, 20%); mp 170°C; ir: 1755 cm^{-1}; ^1H nmr ($CDCl_3$): 2.53 (dd, 1H), 2.78 (dd, 1H), 3.89 (m, 1H), 4.43 (d, 2H), 4.78 (dd, 1H, J = 9 Hz, J = 6 Hz), 5.62 (dd, 1H, J = 11 Hz, J = 9 Hz), 5.95 (bs, 1H), 6.77 (d, 1H, J = 11 Hz), 7.16–7.41 (m, 5H). *Exact Mass* calcd.: 321.1581; found: 321.1571.

N-sulfonation of azetidinones to give ***20–22****: General procedure*

The N-deprotected azetidinone **17–19** (0.1 mmol), pyridine sulfur trioxide complex (48 mg, 0.3 mmol), and pyridine (0.5 mL) were heated to 80°C for 2 h. Buffer solution (sodium hydrogen phosphate, 0.5 *N*, 5 mL) was added, the mixture extracted with dichloromethane (3 × 10 mL), and the combined organic layers reextracted with buffer solution (3 × 10 mL). Tetrabutylammonium hydrogen sulfate (0.1 mmol) was added to the combined aqueous layers and these were then extracted with dichloromethane (3 × 20 mL). The combined organic layers were dried ($MgSO_4$) and the solvent removed to yield the tetrabutylammonium salt as an oil that was dried under high vacuum. The crude salt was passed through Dowex 50X8-200 ion exchange resin (6 mL, potassium form) to yield, after lyophylization, **20–22** as colourless solids.

A proton nuclear magnetic resonance relaxation study of the glycine, alanine, and lactate complexes of gadolinium(III) in aqueous solution

R. Stephen Reid and Benjamin Podányi

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received October 17, 1986

R. Stephen Reid and Benjamin Podányi. Can. J. Chem. **65**, 1508 (1987).

The ^{1}H nuclear magnetic resonance spin-lattice and spin–spin relaxation rate enhancements induced by the gadolinium(III) ion were measured in solutions of glycine, alanine, and sodium lactate containing different amounts of Gd(III). The proton relaxation rates in the Gd(III) complexes were calculated from these data, and were used to calculate metal–hydrogen atom distances. Comparison of these data with corresponding distances calculated from literature X-ray crystallographic data for model compounds shows that in the two amino acid complexes the Gd(III) ion is coordinated in a four-membered ring through the two oxygen atoms of the carboxylate group. By contrast, in the lactate complex coordination is via a five-membered ring involving one oxygen atom of the carboxylate group and the α-hydroxyl oxygen.

R. Stephen Reid et Benjamin Podányi. Can. J. Chem. **65**, 1508 (1987).

Opérant dans des solutions de glycine, d'alanine et de lactate de sodium contenant diverses quantités de Gd(III), on a mesuré les rehaussements que provoquent les ions gadolinium(III) sur les vitesses de relaxation spin–spin et spin–réseau, en résonance magnétique nucléaire du ^{1}H. En se basant sur ces données, on a calculé les vitesses de relaxation des protons dans ces complexes de Gd(III) et on a utilisé ces vitesses pour calculer les distances entre le métal et l'hydrogène. Une comparaison de ces données avec les distances correspondantes calculées à partir des données de diffraction des rayons-X de composés modèles démontre que, dans les deux complexes d'acides aminés, l'ion Gd(III) est impliqué dans un cycle de coordination à quatre membres par le biais des deux atomes d'oxygène du carboxylate. Par ailleurs, dans le complexe du lactate, la coordination se fait par le biais d'un cycle à cinq chaînons impliquant un atome d'oxygène du groupement carboxylate et l'oxygène de l'hydroxyle en α.

[Traduit par la revue]

Introduction

The gadolinium(III) ion has the longest electronic relaxation time amongst the lanthanide(III) cations, and is therefore well suited to use as a paramagnetic relaxation agent (1). Gd(III) complexes are now widely used as "contrast agents" in magnetic resonance imaging (2). Because Gd(III) has a similar ionic radius to Ca(II), the aquo Gd(III) ion has also been used as an nmr probe in the structural investigation of Ca(II) complexes in solution (3). For these reasons, a detailed understanding of the behaviour of Gd(III) complexes with biologically relevant small molecules is of some interest. Such understanding necessitates investigation of the stability and structure of such complexes in aqueous solution.

X-ray crystallographic studies have shown that in the Gd(III) complexes of simple carboxylic acids coordination is through both oxygen atoms of the carboxylic acid group (4). Solution studies using ^{13}C nmr relaxation rate enhancement reached the same conclusion. By contrast, the α-hydroxy acid complexes in solution involve coordination via the hydroxy group and one carboxylic acid group oxygen atom (5).

Some controversy has surrounded the structure of lanthanide(III) – amino acid complexes. Early results from cd (circular dichroism) studies suggested involvement of the amino group (6); however, this was questioned by later workers (7). Proton and ^{13}C chemical shift changes induced by lanthanide ions suggested that for the alanine complexes of light lanthanides coordination was via only one oxygen, but for heavier lanthanides via two (8). Another nmr study reported the opposite trend (9). Later studies by Elgavish and Reuben on the sarcosine complexes show that this entire series is isostructural, coordinating through both oxygens (10, 11). A similar conclusion was reached in another ^{13}C relaxation rate study of the conformation of leucine, lysine, and methionine (12).

Because of the lack of proton relaxation rate data in the literature, it was decided to investigate the complexation of Gd(III) by glycine, alanine, and lactic acid using this technique. All three of these molecules can be readily observed by nmr in biological systems such as the erythrocyte (13); lactic acid was one of the first compounds to be detected using in vivo proton nmr (14).

The relaxation rate enhancement induced by a paramagnetic ion is described by the Solomon–Bloembergen equation (15, 16). In the present study the metal ion and the protons are separated by 4 or 5 bonds, so contact contributions may be neglected. Equations [1] and [2] describe the spin-lattice (R_{1c}) and the spin–spin (R_{2c}) relaxation rates in the complex:

$$[1] \quad R_{1c} = \frac{5.17 \times 10^{-43}}{r^6}\left(\frac{3\tau_c}{1 + \omega_I^2\tau_c^2} + \frac{7\tau_c}{1 + \omega_S^2\tau_c^2}\right)$$

$$[2] \quad R_{2c} = \frac{2.58 \times 10^{-43}}{r^6}\left(4\tau_c + \frac{3\tau_c}{1 + \omega_I^2\tau_c^2} + \frac{13\tau_c}{1 + \omega_S^2\tau_c^2}\right)$$

where r is the distance between the paramagnetic ion and the proton under observation and ω_I and ω_S are the proton and the electron Larmor precession frequencies, 1.88×10^9 Hz and 1.24×10^{12} Hz respectively, at an applied magnetic field of 7 T. τ_c is the correlation time of the dipole–dipole interaction between the paramagnetic electron spin and the proton nuclear spin, which is expected to be in the 10^{-9}–10^{-11} s time range.

Since $\omega_S^2\tau_c^2 \gg 1 \simeq \omega_I^2\tau_c^2$ in the whole correlation time range, the terms containing the electronic Larmor precession frequency can be neglected. τ_c can be described by eq. [3]:

$$[3] \quad \frac{1}{\tau_c} = \frac{1}{\tau_S} + \frac{1}{\tau_b} + \frac{1}{\tau_d}$$

where τ_S is the electron-spin relaxation time, τ_b is the lifetime of the coordinated ligand, and τ_d is the rotational correlation time of the complex.

The lower limit of τ_S of the Gd(III) ion can be estimated to be 2×10^{-7} s at 5 T or higher magnetic fields (17), based on esr data (18). τ_b can be estimated by Lenkinski's method to be in the range of 10^{-5}–10^{-7} s for the ligands under investigation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 72.64.146.136 on 09/07/12
For personal use only.

(17). The observed correlation time τ_c is therefore ultimately dominated by the rotational correlation time of the complex (τ_d), so in our case the relaxation rates in the complex can be described by eqs. [4] and [5]:

$$[4] \quad R_{1c} = \frac{1.55 \times 10^{-42} \cdot \tau_d}{r_6 \cdot (1 + 3.55 \times 10^{18} \cdot \tau_d^2)}$$

$$[5] \quad R_{2c} = \frac{2.58 \times 10^{-43}}{r^6} \cdot \left(4\tau_d + \frac{3\tau_d}{1 + 3.55 \times 10^{18} \cdot \tau_d^2}\right)$$

Dividing [4] by [5] gives:

$$[6] \quad \frac{R_{1c}}{R_{2c}} = \frac{6.01}{3 + 4(1 + 3.55 \times 10^{18} \cdot \tau_d^2)}$$

from which the correlation time may be calculated.

The relationship between the observed relaxation rates (R_{io}) and those in the complex (R_{ic}) in a chemically exchanging ligand system was first described by Luz and Meiboom (19) and Swift and Connick (20); the problem of the two-site exchanging system was later solved without restrictions by Leigh (21). Leigh also derived an approximate solution (eq. [7]) assuming no contribution of the outer sphere relaxation, dilute solution of the paramagnetic spins, and that the shift caused by the complexation is much less then the reciprocal of the lifetime of the coordinated ligand ($\Delta\omega \ll 1/\tau_b$):

$$[7] \quad R_{io} = R_{if} + \frac{N_f}{N_b(T_{ic} + \tau_b)} \qquad (i = 1, 2)$$

where T_{ic} is $1/R_{ic}$, R_{if} is the relaxation rate of the free ligand and N_f/N_b is the mole fraction of the ligand in the free and in the coordinated state.

All the above assumptions apply in our case, where small amounts of Gd(III) ions have been added to dilute solutions of small ligands, which are in fast exchange between the free and the coordinated state. Equation [7] can be further simplified, because $T_{ic} \gg \tau_b$, so the effect of the lifetime of the coordinated ligand can be neglected, and because $N_f \simeq N_L$ (the total amount of ligands in solution). Rearrangement of the equation then gives

$$[8] \quad R_{ic} = \frac{R_{io} - R_{if}}{q \cdot p} \qquad (i = 1, 2)$$

where q is the average coordination number of the metal ion (i.e., $N_b = N_M \times q$) and p is the molar ratio of the metal ion to ligand in the solution (i.e., $p = N_M/N_L$). The determination of these quantities and of τ_d, and the calculation of Gd(III)–proton distances for the three complexes, is described below.

Experimental

Chemicals

Glycine, *l*-alanine (US Biochemical Corporation), sodium-*l*-lactate (Fluka AG), and gadolinium nitrate (Alfa Products) were used as received.

Preparation of solutions

A. For measurements at variable p: Stock solutions (0.013–0.020 *M*) were prepared in D_2O. pH* was adjusted to 4.5 by adding DCl to the solution. The pH* was measured using a Beckman SS-2 pH meter equipped with a glass combination electrode and calibrated in the usual manner. Samples (0.4 mL) were taken for the nmr measurements. Different Gd(III) concentrations were obtained by the successive addition of small volumes (3–6 μL) of a stock solution of 0.001 *M* $Gd(NO_3)_3$ in D_2O to the ligand solutions. The exact amount of Gd(III) solution added was determined by weight.

B. For measurements at constant p: The pH* of a stock solution 0.1 *M* in alanine and 0.002 *M* in Gd(III) was adjusted to 4.5. Samples were obtained by dilution of this solution and readjustment of pH* to 4.5.

^{1}H nuclear magnetic resonance measurements

The 300-MHz ^{1}H nmr spectra were obtained on a Bruker AM300 spectrometer, and 400-MHz data on a Bruker WH400 instrument. All data were collected at a proble temperature of 30 ± 1°C. Spin-lattice relaxation time measurements were made by the standard inversion–recovery method, with 10–12 different delay values. Relaxation times were calculated by the standard Bruker routine, and checked by a linearized plot and a weighted linear least-squares analysis. The standard deviation of the T_1 values yielded by the latter program was less than ±3% in all cases. Spin–spin relaxation time measurements on the glycine solutions were performed using the standard CPMG technique, and the relaxation times calculated using the Bruker routine. The spin–spin relaxation times of the sodium lactate solutions were estimated from the measured line-broadening caused by the Gd(III) ions. Experimental spectra were compared to simulations calculated by the Bruker routine PANIC, adjusting parameters in the latter to achieve the closest agreement. To correct for variations in field homogeneity, a small amount of TMS was added to the solutions, and the linewidth of the TMS signal was subtracted from the linewidth of the lactate signals in each case.

Calculations

The relaxation rates in the glycine and lactate complexes were calculated by linear least-squares regression from the observed relaxation rate measurements at 4 different p values. The relaxation rates in the complex of alanine, as well as the formation constants K_1 and K_2, were calculated by the MINPACK nonlinear least-squares regression program (36). The seven measurements with different p values and (or) alanine concentrations gave 14 experimental points, from which the 4 parameters were calculated. Different starting values gave identical solutions. The standard deviation of the parameters was estimated from the diagonal elements of the covariance matrix of the regression.

The gadolinium–hydrogen distances in the model compounds were calculated by the BONDLA program, which is a part of the XTAL83 program system (37). The crystal coordinates and the appropriate symmetry operations were loaded in, and the distances of all atoms within 1 nm of the metal ion were returned. Molecular connectivities were checked from the bond-distance list. The conformations in the solid state were investigated by calculating the torsion angles around all the important bonds using the program.

Results

Lactate

The proton relaxation rate enhancements for sodium lactate were measured at various Gd(III) concentrations. Figure 1 shows the results as a function of p. The response appears linear. From literature formation constants (22) the effective coordination number q was calculated to be 1.87 at the 0.02 *M* lactate concentration used. The resultant R_{1c} and R_{2c} values are shown in Table 1, together with the values of τ_d calculated from eq. [6]. The close agreement between the two τ_d values supports the assumption that a single correlation time can be used. The calculated distances between the Gd(III) ion and the protons, based upon the mean of the measured correlation times, are also given in Table 1.

Glycine

Relaxation rate data are shown in Fig. 1. Using literature formation constants (23), q was calculated to be 0.066 at the 0.013 *M* glycine concentration used. Because of the short correlation time of the small glycine molecule, both the R_{1c}/R_{2c} ratio and the ratio of R_{1c} measured at 7.0 and 9.4 T are close to

unity. The upper limits of the correlation time gained from these measurements are 2.0×10^{-10} and 1.4×10^{-10} s respectively. On the basis of the difference in size of the glycine and alanine molecules, a difference in correlation times in excess of 30% would not be expected. The latter upper limit was used therefore in the calculation of Gd–hydrogen distance (Table 1).

Alanine

The R_{1o} data, collected at different Gd(III) and alanine concentrations, are given in Table 2. No reliable formation constant data are available in the literature, but known stepwise formation constants of the complexes of alanine with other lanthanide ions (11) suggest that, at most, only the first and second stepwise complexation processes are of importance in the concentration range used in our investigations. In this case, eq. [8] becomes:

$$[9] \quad R_{1c} = \frac{(R_{1o} - R_{1f})}{p} \cdot \frac{(1 + K_1[L] + K_1K_2[L]^2)}{(K_1[L] + 2K_1K_2[L]^2)}$$

where K_1 and K_2 are the first and second stepwise formation constants respectively, and [L] is the equilibrium ligand concentration. The experimental data were fitted to eq. [9] using nonlinear least-squares analysis. Both K_1 and K_2 were approximately 3 M^{-1}, although these values are imprecise due to the relatively small number of data points, and the strong interaction between these parameters in the fitting process. The resultant R_{1c} values (shown in Table 1) are, however, fairly precise. Agreement between experimental R_{1c} values and those calculated from the fit parameters is good (see Table 2). Attempts to fit to a model involving only K_1 failed. This means that under the experimental conditions used here both 1:1 and 1:2 complexes are formed between Gd(III) and alanine. The correlation time of the complex was calculated from the field strength dependence of R_{1c}. The ratios of R_{1c} measured at 7.0 T and at 9.4 T were 0.90 ± 0.03 and 0.88 ± 0.07 for the CH_3 and the CH protons respectively. The close agreement between these again supports the assumption of a single correlation time. The calculated correlation time together with calculated Gd(III)–proton distances are given in Table 1.

Discussion

To use the distance data calculated above to determine the mode of coordination in these complexes, corresponding data must be predicted for the various possibilities illustrated in Fig. 2. These could be determined using X-ray crystallographic data. According to a search of the Cambridge Crystallographic Data Bank, there are only 43 Gd(III) complex structures in the literature, only one (the glycolic acid complex (24)) being relevant to the present study. However, comparison of ion–oxygen distances in the Gd(III) complexes of acetate (4), propionate (25), and EDTA (26) with those in the Ca(II) complexes (27–29) shows that corresponding distances are very similar. This similarity in size has already been exploited in solution nmr work, as mentioned above (3). It is therefore possible to use appropriate Ca(II) compounds, for which an extensive crystallographic literature exists (30), as models for the Gd(III) analogues.

The crystal structure of Ca(II)–*l*-glutamate includes two modes of coordination: via both oxygens of the carboxylate group next to the amino group (Mode I in Fig. 2), and via one

oxygen of this carboxylate group and the amino group (31) (Mode II). The latter mode is also shown in the crystal structure of the Ca(II)–di-*dl*-glycerate complex (32). Selection of a model for coordination through one oxygen only (Mode III) requires care. In the amino-acid complexes, the positively charged amino group and the metal ion will be as far as possible from each other, so a suitable model structure requires an antiperiplanar arrangement of the coordinating oxygen atom and the α-substituent. A suitable compound is a mixed calcium – cobalt aspartic acid complex (33).

The Gd(III)–proton distances predicted using these models have been calculated. A quick evaluation can also be performed using the ratios $R_{1c}(CH_3)/R_{1c}(CH)$. The average distance of the three methyl hydrogens was calculated according to eq. [10].

$$[10] \quad \frac{3}{r_{av}^6} = \frac{1}{r_1^6} + \frac{1}{r_2^6} + \frac{1}{r_3^6}$$

The experimental distances were generally shorter than those calculated from the crystal structures. It has been previously observed that the experimental relaxation rates of gadolinium complexes of amino acids (12) and of dipeptides (34) are described satisfactorily by the Solomon–Bloembergen equation only if the coordinating Gd—O bond length is set to be somewhat longer than it is expected to be from crystallographic data. In the present case, if the coordinating bond lengths are increased by 15% and the metal ion is placed onto the axis of the C1—C2 bond in Mode I, then good agreement is obtained with experimental values, as shown in Table 3. It is clear that the amino acid complexes involve coordination through both oxygens of the carboxylate group, and the lactate complex coordination through one oxygen of the carboxylate group and the hydroxyl group.

In the lactate case, the possible conformational equilibrium of the chelate ring makes the situation more complex. In a five-membered ring, with planarity of the carboxylate group, there are four possible envelope conformations and two half-chairs. The latter were not observed in any of the X-ray structures. The four possible envelope conformations are shown in Fig. 3. The metal–proton distances calculated for the di-*dl*-glycerate and glutamic acid complexes correspond to conformations A and C respectively. In terms of metal–proton distances these represent the extremes, conformations B and D being intermediate. The experimentally determined distances are also intermediate, indicating a probable equilibrium between two or more of these forms. However, the possibility of contributions from other forms not suggested by X-ray studies cannot be excluded. The rate of interchange, as expected (35), is fast, since no line-broadening not ascribable to paramagnetic relaxation was observed.

This paper is dedicated to Professor Zdenek Valenta on the occasion of his 60th birthday

J. DESROCHES, H. DUGAS, M. BOUCHARD, T. M. FYLES, and G. D. ROBERTSON. Can. J. Chem. **65**, 1513 (1987).

A series of monopiperidine, **1**, dipiperidine **2**, **3** (*syn* and *anti*), as well as the corresponding oxazoline and oxazolidine crown ethers have been prepared and their ionophoric properties evaluated. The *syn*-dipiperidine **2***c* turned out to be a particularly efficient Ca^{2+} ligand (log $K = 9.7$). ^{13}C and ^{23}Na nuclear magnetic resonance spectroscopy was used to evaluate the nature of the complex between the monopiperidine **1***c*, the *syn*-dipiperidine **2***c*, and Ca^{2+} and Na^+ ions. In methanol–water solution, the dimeric salt $(\mathbf{2}c)_2Ca$ exhibits both a tight or asymmetric and a symmetric or loose ion pair between the cation and the carboxylate groups. Sodium-23 chemical shifts and line-width variation both support a 1:1 complex with **1***c* and **2***c*. The structural results correlate with observations from ion transport experiments.

J. DESROCHES, H. DUGAS, M. BOUCHARD, T. M. FYLES et G. D. ROBERTSON. Can. J. Chem. **65**, 1513 (1987).

On a préparé une série de monopipéridines (**1**), de dipipéridines (**2** et **3**) (*syn* et *anti*) ainsi que les éthers couronnes oxazolines et oxazolidines correspondantes et on a évalué leurs propriétés ionophoriques. La dipipéridine *syn* (**2***c*) est un ligand particulièrement efficace pour le Ca^{2+} (log $K = 9{,}7$). On a utilisé la spectroscopie de résonance magnétique nucléaire du ^{13}C et du ^{23}Na pour évaluer la nature du complexe qui se forme entre la monopipéridine **1***c*, la dipipéridine-*syn* (**2***c*) et les ions Ca^{2+} et Na^+. Dans une solution méthanol–eau, le sel dimère $(\mathbf{2}c)_2Ca$ se présente à la fois sous la forme d'une paire intime (ou asymétrique) d'ions et d'une paire symétrique (ou lâche) d'ions entre le cation et les groupements carboxylates. Les déplacements chimiques du ^{23}Na ainsi que les variations de la largeur des raies sont tous les deux en accord avec l'existence d'un complexe 1:1 avec **1***c* et **2***c*. Les résultats structuraux permettent d'établir une corrélation avec les expériences de transport d'ions.

[Traduit par la revue]

Introduction

A number of research groups have devoted some effort to the synthesis of nitroxide crown ethers in recent years (1–4). We have also been involved in this endeavor, particularly the preparation of dinitroxide (spin label) crown ethers **2***a*,*b* and **3***a*,*b* (5). The *syn* compound **2***a* turned out to be a good epr monitor of K^+ ion binding in the cavity because of the observable spin–spin exchange interaction between the two nitroxide groups. As the presence of a nitroxide function on these systems makes any nmr study rather tedious, we have decided to prepare the piperidine analogues **1***c*,*d*, **2***c*,*d*, and **3***c*,*d*. Furthermore, the corresponding oxazolines **1***f*, **2***f* and oxazolidines **1***g*, **2***g* have been prepared. The syntheses of these compounds were undertaken in view of their potential as new ion carriers and consequently their rates of transport of Na^+, K^+, and Ca^{2+} ions have been evaluated. This work is complemented by a ^{13}C nmr study of **1***c* and **2***c* in the presence of Ca^{2+} ion and a ^{23}Na nmr study in the presence of Na^+ ion. Data such as those provided by nmr experiments are useful and complementary to earlier epr results (5) to confirm the pH dependency of the solution conformation of *syn* **2***a*.

These compounds were studied to have a better understanding of the role played by one or two carboxylic groups near an ion complexing cavity such as a crown ether. Factors such as charge-to-size ratio and the concept of hole-size selectivity in macrocyclic chemistry will be examined.

Results and discussion

Syntheses

The syntheses and purification of **1***c*, **2***c*, and **3***c* involved the condensation of 2,2,6,6-tetramethyl-4-aminopiperidine with the corresponding mono- or dianhydride [18]-crown-6-*R*,*R*-tartaric acid following known procedures (6, 7). For instance, the addition of 2 equivalents of 2,2,6,6-tetramethyl-4-aminopiperidine to the [18]-crown-6 monoanhydride in CH_2Cl_2 gave, after stirring for 2 h at room temperature, the monoacid **1***c* in 90% yield. The *syn* adduct **2***c* was prepared similarly in the presence of an excess of triethylamine. In the absence of triethylamine, 4 equiv. of the aminopiperidine were needed and a 2:8 mixture of *syn*-**2***c* and *anti*-**3***c* diacids was obtained. The assignment of the configuration of the *syn* and *anti* isomers was based on the polarity and mobility on tlc, spectral data, and comparison with previous work (6). The corresponding methyl esters **1***d*, **2***d*, and **3***d* were made by treatment with a large excess of ethereal CH_2N_2.

In parallel with this study, the corresponding crown ether anilide mono- and diacids were prepared as before (6) and treated with CH_2N_2 to obtain **1***e* in 80% yield and **2***e* in 78% yield. The monooxazoline **1***f* was synthesized in 80% yield by refluxing 2 equiv. of 2-amino-2-methyl-1-propanol with the methyl ester **1***e* in xylene (8, 9). The dioxazoline **2***f* was prepared similarly using 4 equiv. of the amino alcohol. The corresponding oxazolidines **1***g* and **2***g* were obtained in 50% yield by reduction of **1***f* and **2***f* with 1.0 equiv. of $NaBH_4$ at −30°C, pH 7, for 2 h (10).

Ion transport rates

In all cases, the transport of cations across a chloroformic liquid membrane was studied using a U-shaped cell, where typically a 10^{-3} *M* solution of a crown ether carrier and a 10^{-2} *M* solution of metal picrate produce transport behavior that can be described as zero order (linear increase in picrate

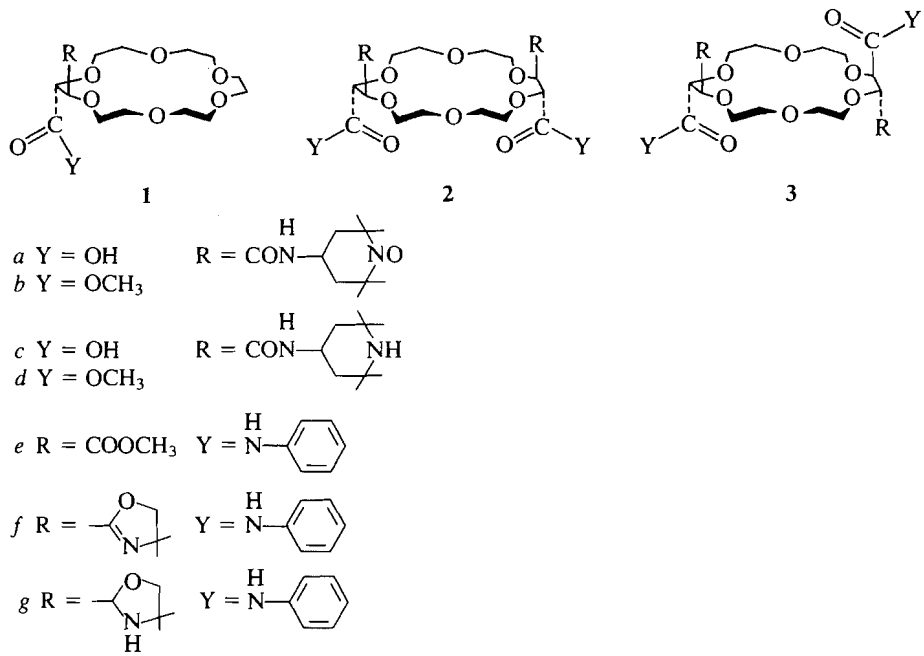
For personal use only.



concentration in the receiving phase) (11). In such a situation, the transfer of the metal salt is considered to be a carrier-facilitated process whereby the species are moved down a concentration gradient across the organic liquid phase by the organic carrier molecule that resides in this artificial membrane. Without a carrier, no transfer of ions is observed in this system. Under these conditions, a diffusion mechanism of the [metal–carrier] complex can safely be regarded as the rate limiting step, the organic layer being magnetically stirred at a rate of 400 rpm. However, at this stirring rate a related system is kinetically limited by adsorption/desorption processes at the interface (12). A similar phenomenon may be applicable to some of the new carboxylic acid carriers prepared here, but for neutral macrocycles a diffusion-limited treatment is more appropriate in the sense that, to date, all related cases known are diffusion limited (13, 14). We therefore discuss our results in terms of a diffusion mechanism.

The transport rates of Na^+, K^+ and Ca^{2+} ions for the various crown ether carriers are presented in Table 1, and the corresponding nitroxide crown ethers were also evaluated for comparison. From these results, the following general observations can be made. Firstly, values obtained for the transport rates are quite comparable to those obtained for similar crown ethers with aliphatic chains (17). Secondly, very little selectivity is observed for Ca^{2+} ions and most compounds exhibit a marked preference for K^+ over the other cations. Thirdly, a comparison between the oxazoline and oxazolidine series indicates that neither seems to favor any ion selectivity. Lastly, an appreciable change in relative rate of transport is detected for the *syn*/*anti* pair and K^+ transport only in the case of the *anti*-dipiperidine ester **3***d*. The larger values in rate of transport for the *syn*-dinitroxide ester **2***b* over the *syn*-dipiperidine ester **2***d* are also noteworthy.

One might expect that relative rates in ion transport can be explained simply in terms of the selectivity of complexation, which is determined from stability constants (discussed in the next section). Basically, as the overall extraction constant gets bigger (in parallel with the stability constant) the rate goes up. This means that the systems lie on the low side of the optimal extraction constant (13); in this case, selectivity and relative rate will come out the same in a competitive experiment, but this has yet to be done. Furthermore, the selectivity of a crown ether for a given ion has often been intuitively attributed to a matching of the cavity size and the metal ion diameter. However, more recent investigations (15) have revealed that such a single "cavity-size" selectivity concept is not always applicable.

In the present paper, the general trend found in Table 1

TABLE 1. Transport rates for the various carriers at 10^{-3} *M*

Crown ether carrier	Metal ion* (rate, μmol/h)

*As picrate salts using the procedure of refs. 18 and 19. The experiments were conducted in a U-tube cell (diam. 1.7 cm) with $CHCl_3$ as the organic liquid membrane and 0.05 *M* diethanolamine·HCl, pH 9.7, for the receiving aqueous phase at 20°C. The initial concentration of picrate salts was 10^{-2} *M*. The mono- and diacid crown ethers **1***c*, **2***c*, and **3***c* were much too soluble in water and insoluble in $CHCl_3$ to perform an experiment under such conditions. Error estimates ± 10%.

†Determined at pH 7.0 (water, unbuffered) rather than 9.7 because of the solubility of the crown ethers in basic solution.

‡Even after repeated chromatography, it was not possible to obtain the *anti* isomer completely devoid (20%) of *syn* isomer **2***d*.

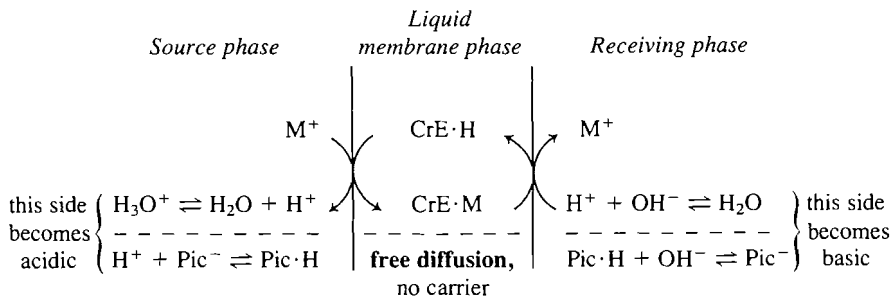
indicates that for the series of [18]-crown-6 mono derivative, the anticipated preference for K^+ ion is observed. In the [18]-crown-6 di-derivatives series, a similar behavior is maintained except for compounds **2***a* and **2***d*, where little selectivity is shown.

It is worthwhile to point out that the presence of carboxylate groups close to the crown ether cavity could have a profound effect on the stability of the corresponding ion complex as well as on the ionophoric properties of such macrocyclic compounds. Indeed, other carboxylic acid crown ethers have been described (16) and found to form substantially more stable complexes, when deprotonated. One might thus expect that the replacement of the ionic carboxylic function in **2***a* by a neutral methyl ester, **2***b*, should modify the stability constant and eventually lead to a difference in the ion transport rate. Comparing compounds **2***a* and **2***b* (Table 1) exemplified such expectation. In the case of **2***a*, the low transport rate and the lack of transport selectivity can be rationalized primarily in terms of electrostatic interaction with a favorable stabilizing effect of the carboxylate groups on the complexation. However, in **2***b*, a pole–dipole interaction of the cation with the crown ether is the main stabilizing factor, leading to a less tightly bound ion, but with a greater hole-size selectivity.

Another point to be considered is how the carboxylate crowns actually do the transport. For the neutral crowns it is just a simple example of cotransport of a pair of ions (M^+ and picrate$^-$). For the acids it is not so clear. We assume that there is a *countertransport* of cations and protons, forming some picric acid on the source side of the membrane, which diffuses to the receiving side without intervention of the carrier. The pH of the source phase changes from 6.9 to 6.6 over 19 h of experiment. Similarly, the receiving phase varies from pH 6.8 to 7.0 because of the countertransport of picric acid, which forms picrate ion (Pic^-). The net result is the same as with the neutral crowns: a cotransport of M^+ and Pic^-. Therefore, in the biochemical sense the acid crown behaves as an electrically neutral transporter while the picric acid becomes an uncoupler of the proton gradient. The following diagram summarizes the observations:



Finally, the introduction of oxazoline (**1***f*, **2***f*) or oxazolidine (**1***g*, **2***g*) groups as potentially active ion ligands seems to decrease appreciably the ion transport rate of the corresponding crown ether carriers. Although the stability constants have not been determined, this behavior might be attributed to the participation of the oxygen or the nitrogen atom of the heterocycle in the ion complexation.

Ionization and association constants

The values obtained by potentiometric titration (7, 21) for the pK_a and association constants with K^+, Na^+, or Ca^{2+} and mono-, *syn*-di-, and *anti*-dinitroxide crown ethers **1***a*, **2***a*, **3***a* are summarized in Table 2, and compared to values for mono- and *syn*-dipiperidines **1***c* and **2***c*. Noteworthy is the observation that for the *anti* series, ΔpK_a has a value close to one log unit. The *syn* series, however, has a ΔpK_a value larger than 2 log units. This general trend has previously been noticed in similar dialiphatic chain [18]-crown-6 diacids (18). Among the various compounds synthesized, the *syn* arrangement is unique in the sense that the two carboxylate groups are attached on the same side of the macrocyclic ring and converge to provide two identical sites by which binding information can be passed on. The presence of two acidic groups oriented *syn* and facing one another thus increases considerably the pK_a of the second carboxylic function. There could very well be a water molecule trapped between the two carboxylic groups to ensure proper proton transfer. This is reminiscent of the differences in pK_a values found for fumaric acid ($pK_1 = 3.02$, $pK_2 = 4.39$, $\Delta pK = 1.37$) and maleic aicd ($pK_1 = 1.92$, $pK_2 = 6.22$, $\Delta pK = 4.30$). The *syn* orientation of the two carboxylic groups in **2***c* directly affected their reactivity, since diazomethane esterification never resulted in high yield of **2***d*. Such behavior was also noticed in other systems where two carboxylic functions facing each other are separated by a rigid naphthyl moiety (20).

Stability constants for complexation with Na^+ and K^+ ions were in the 10^4–10^6 M^{-1} range for all three crown compounds examined. For the **2***c*·Ca^{2+} complex, however, much higher

TABLE 2. Ionization and association constants*

Crown ether ligand (L)	pK_a	log *K*		
		K^+	Na^+	Ca^{2+}
1*a*	6.18	3.8 (L^-)		
1*c*	6.28		4.3 (LH)	5.0 (LH)
	8.68 (NH)	5.0 (L^-)	4.4 (L^-)	5.1 (L^-)
2*a*	5.67	4.4 (LH^-)		
	8.05	5.4 (L^{2-})		
	$\Delta pK_a = 2.38$			
2*c*	4.20			
	6.17	4.2 (LH_2)	4.5 (LH_2)	7.8 (LH_2)
	8.15	4.3 (LH^-)	4.7 (LH^-)	8.3 (LH^-)
	10.61 (NH)	5.4 (L^{2-})	5.6 (L^{2-})	9.7 (L^{2-})
	$\Delta pK_a = 1.98$			
3*a*	6.09	5.1 (LH^-)		
	7.02	6.8 (L^{2-})		
	$\Delta pK_a = 0.93$			

*Measured in $MeOH/H_2O$ (9:1), 0.05 *M* Me_4NCl, 25°C. Error in pK_a, ±0.1; in log *K*, ±0.2. L stands for fully deprotonated crown ether ligand. The equilibria involved are $LH \rightleftharpoons L^-$ for **1***a* and **1***c*, and $LH_3^+ \rightleftharpoons LH_2 \rightleftharpoons LH^- \rightleftharpoons L^{2-}$ for **2***a*, **2***c*, and **3***a*. The species implicated with the corresponding log *K* are indicated in the parentheses.

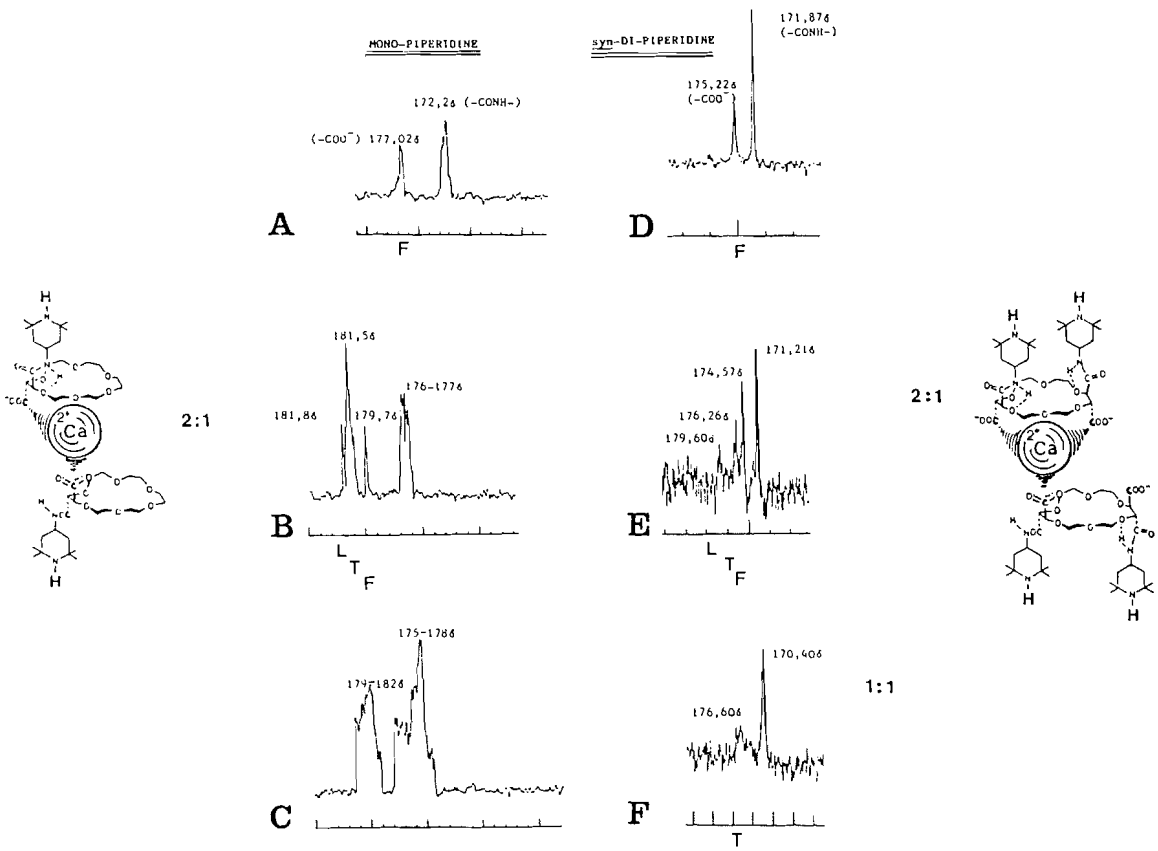

FIG. 1. Carbonyl region of the ^{13}C nmr spectra of monopiperidine **1***c* and *syn*-dipiperidine **2***c* in CD_3OD/D_2O (90:10 v/v), Me_4NOH, pH 11.6. A and D, free form (mono- and dicarboxylate); B and E, in the presence of Ca^{2+} [$Ca(SCN)_2$] ion at a 2:1 ratio of crown ether:metal ion, C and F, at a 1:1 ratio of crown ether:metal ion. The letters F, L, and T under the spectra mean *free*, *loose*, and *tight* bound ions respectively (see text).

values were obtained (from 10^7 to almost 10^{10}) depending on the degree of ionization of the carboxylic groups. Therefore, *syn* crown ether diacids are particularly good Ca^{2+} ligands (17). This observation reflects the correlation in the electrostatic attraction to be made between the charge of the crown ether carrier (dicarboxylate vs. monocarboxylate) and the nature and charge of the ion involved in the complexation (16). As noted above, there is no simple relationship between stability and extraction constants. The slow Ca^{2+} transport rate could be due to a high value of extraction constant (complex too stable) or might be related to the slow diffusion of the picric acid uncoupler down its concentration gradient.

Finally, in the dicarboxylic crown molecule **2***c*, the complexation selectivity could be controlled by the charge-to-size (Q/r) ratio. For Ca^{2+}, this ratio is larger than for Na^+ or K^+ and the complexation constant is consequently much larger.

These findings generally agree with earlier considerations (7) that binding selectivity does not directly result in transport selectivity of the same magnitude, although overall complex stability and selectivity both play a role in the transport process (17).
